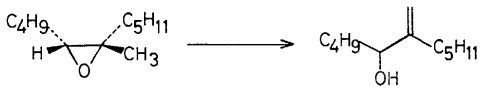
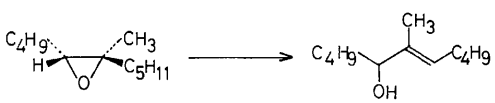
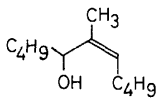
With the demonstration of the facility and effectiveness of this reagent, attention was directed toward the orientational selectivity in the reaction of unsymmetrical trisubstituted oxiranes. Remarkably, DATMP did react with oxiranes **10** and **12** under sharp discrimination of the configuration of oxiranes. Thus, the reaction of DATMP with oxirane **10** in benzene at 0 °C for 30 min gave the disubstituted allylic alcohol **11** in 96% yield. In marked contrast, the diastereomeric oxirane **12**[16] gave under the same conditions the trisubstituted (*E*)-allylic alcohol **13** predominantly in 83% yield. The structure of the product was unambiguously confirmed by the alternative synthesis of **13** and **14** by means of the β-oxido ylide technique.[17]



10 11



12 13



14

Aluminum amides preferentially abstract α-proton of the alkyl group located on the same side as hydrogen of oxirane to give the corresponding allylic alcohols (see Fig. 1). This is attributed to the attack of the aluminum reagent from the less hindered side of the oxirane group ("steric approach control"). This is supported by the

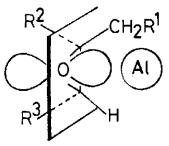


Fig. 1.

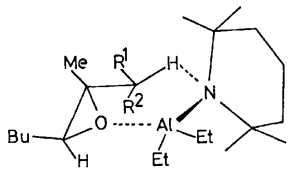
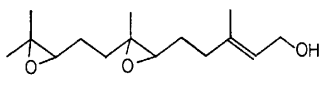


Conformer A (R^1=Bu, R^2=H)
B (R^1=H, R^2=Bu)

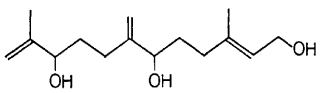
Fig. 2.

above finding that only sluggishly *cis*-2,3-disubstituted oxiranes **3** reacted with DATMP. In addition, the resulting allylic double bond prefers the (*E*)-configuration. Such significantly high stereoselectivity observed with DATMP is rationalized by presuming intermediary stage illustrated in Fig. 2 with respect to the reaction of the oxirane **12** with DATMP. Of the possible conformers, the chair ones should suffer from substantial steric interference because of the bulk of the extremely large TMP group. Moreover, of the two boat conformers (A and B), obviously the conformer A has the least steric crowdedness and the subsequent collapse would certainly furnish trisubstituted (*E*)-allylic alcohol **13**. The conformer B has severe crowdedness below the six-membered plane and this explains the minor amount of (*Z*)-allylic alcohol **14**.

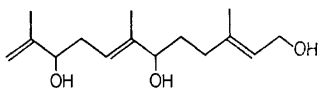
Such a remarkable selectivity inherent in DATMP is further demonstrated by the following example. Bisoxirane **15** gives triol **16** upon exposure to lithium diethylamide,[18] while treatment of **15** with DATMP has converted it to the isomeric triol **17**[19,20] in 41% yield.



15



16



17

The selection rules of the DATMP isomerization of oxiranes into allylic alcohols are therefore:

(1) The sole product is a secondary allylic alcohol.

(2) The required proton is supplied by the alkyl group located on the same side as hydrogen of oxirane C(3).

(3) The resulting double bond prefers the (*E*) configuration.

Experimental

The infrared spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L mass machine; the GLPC analyses on a Yanagimoto GCG-550F; and NMR spectra on a JNM-PMX 60 or Varian EM-360 spectrometer. The chemical shifts are given in δ in ppm with TMS as the internal standard. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were carried out by the staffs at the Elemental Analyses Center of Kyoto University. All experiments were carried out under an atmosphere of dry argon. In experiments requiring dry solvents, tetrahydrofuran was distilled from sodium-benzophenone. Ether, benzene, and hexane were dried over sodium metal. During workup, drying of the organic solution was performed over anhydrous sodium sulfate. Thin layer or preparative thick layer plates were made of E. Merck PF-254, and preparative column chromatography on silica gel E. Merck Art. 7734.

Preparation of Dialkylaluminum N,N-*Dialkylamides. From Diethylaluminum Chloride and Lithium Amides*:[9] A benzene solution of diethylaluminum chloride (1 equiv) was added at 0 °C dropwise to a solution of lithium *N,N*-dialkylamide (1 equiv) in benzene. The resulting slurry was stirred at the same temperature for 30 min and used immediately. The following aluminum amides were prepared by this method: diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP); diethylaluminum diisopropylamide; diethylaluminum diethylamide.

From Diisobutylaluminum Hydride and Amines:[11] Diisobutylaluminum hydride (1 equiv) dissolved in benzene was added drop by drop to a solution of amine (1 equiv) in benzene at 0 °C. The resulting solution was gently heated until theoretical volume of hydrogen gas was evolved. The reaction mixture was allowed to cool to 0 °C and then used immediately. The following aluminum amides were prepared by this method: diisobutylaluminum diphenylamide; diisobutylaluminum *N*-methylanilide; diisobutylaluminum diisopropylamide.

Preparation of Oxiranes. 1-Oxaspiro[2,11]tetradecane (**4**): To a mixture of methylenecyclododecane[21] (540 mg, 3.0 mmol) and dichloromethane (15 ml) *m*-chloroperbenzoic acid (712 mg, 3.3 mmol) was added at 0 °C in small portions. The whole mixture was stirred at the same temperature for 1.5 h. After dilution with ether, the mixture was poured into ice-cold saturated sodium sulfite. The separated organic phase was washed with saturated sodium sulfite and saturated sodium bicarbonate, dried, and concentrated *in vacuo*. The residue was submitted to column chromatography using 10: 1 hexane–ether as an eluent to give 534 mg (91% yield) of pure **4** as a clear oil: bp 90 °C (bath temp, 1 Torr); TLC, R_f 0.28 (5: 1 hexane–ether); IR (neat), 2940 (s), 1470 (s), 1445 (m), and 1150 cm^{-1} (w); NMR (CCl_4), 2.39 (2H, s, CH_2–O); MS (*m/e*), 196 (13), 178 (12), 153 (25), 125 (70), and 111 (100).

Found: C, 79.3; H, 12.3%. Calcd for $C_{13}H_{24}O$: C, 79.5; H, 12.3%.

c-*3-Butyl-2-methyl*-r-*2-pentyloxirane* (**10**). A solution of (*Z*)-6-methyl-5-undecene[16] (250 mg, 1.50 mmol) in dichloromethane (8 ml) was treated with *m*-chloroperbenzoic acid (354 mg, 1.65 mmol) as described above to furnish **10** (250 mg, 90 % yield) as a colorless liquid: bp 64 °C (1 Torr); TLC, R_f 0.65 (1: 1 hexane–ether); IR (neat), 1470 (s), 1370 (s), and 1115 cm^{-1} (m); NMR (CCl_4), 1.19 (3H, s, CH_3–CO), and 2.48 (1H, bt, CH–O); MS (*m/e*), 184 (13), 155 (4), 141 (38), 127 (12), and 71 (100).

Found: C, 78.2; H, 13.4%. Calcd for $C_{12}H_{24}O$: C, 78.2; H, 13.1%.

Reaction of Oxiranes with Aluminum Amides. A General Procedure: To a stirred mixture of aluminum amide (4.0 mmol) and benzene (10 ml) a solution of oxirane (1.0 mmol) in benzene (3 ml) was added at 0 °C drop by drop over a period of 5 min. The whole mixture was stirred at the same temperature until oxirane could not be detected by TLC analysis. The reaction was quenched by the addition of ice-cold 1 M hydrochloric acid and the resulting organic phase was separated. The aqueous layer was extracted with ether. The organic solutions were combined, washed with saturated brine, dried, and concentrated *in vacuo*. The residue was submitted to preparative TLC to give the desired allylic alcohol.

(E)-*2-Cyclododecen-1-ol* (**2**):[6] TLC, R_f 0.22 (2: 1 hexane–ether); IR (neat), 3330—3370 (s), 1465 (s), 1450 (m), and 970 cm^{-1} (s); NMR (CCl_4), 3.73—4.20 (1H, m, CH–OH), and 4.97—5.82 (2H, m, CH=); MS (*m/e*), 182 (16), 164 (13), 139 (32), 125 (46), and 98 (100).

1-Cyclododecenylmethanol (**5**): This is an (*E,Z*)-mixture, bp 110 °C (bath temp, 1 Torr); TLC, R_f 0.40 (1: 1 hexane–ether); IR (neat), 3300—3360 (s), 1665 (w), 1470 (s), 1000—1010 (s), and 800 cm^{-1} (w); NMR (CCl_4), 3.96 and 4.10 (2H, s, CH_2–O), and 5.15—5.71 (1H, m, CH–); MS (*m/e*), 196 (19), 178 (6), 149 (8), 109 (35), and 83 (100).

Found: C, 79.3; H, 12.5%. Calcd for $C_{13}H_{24}O$: C, 79.5; H, 12.3%.

A small aliquot of **5** was acetylated by stirring with acetic anhydride in pyridine. GLPC analysis (10 % Apiezon, 230 °C, 1.3 kg/cm^2) showed a 69: 31 mixture of (*E*) and (*Z*)-allylic acetates.

(E)-*3,7-Dimethyl-2,7-octadiene-1,6-diol* (**7**):[22] The title compound was prepared according to the general procedure, except the use of 5 equiv. of DATMP; TLC, R_f 0.28 (ether); IR (neat), 3340—3400 (s), 1650 (m), 1440 (m), 1000 (s), and 890 cm^{-1} (s); NMR ($CDCl_3$), 1.67 (3H, s, CH_4–C= on C-3), 1.73 (3H, s, CH_3–C= on C-7), 3.87—4.23 (3H, d and t, CH–O and CH_2–O), 4.90 (2H, bd, CH_2=), and 5.43 (1H, bt, CH=); MS (*m/e*), 152 (2), 134 (10), 119 (30), 84 (95), and 67 (100).

(E,E,E,E)-*2,6,10,15,19,23-Hexamethyltricosa-1,6,10,14,18,22-hexaen-3-ol* (**9**): Bp 195 °C (bath temp, 0.5 Torr); TLC, R_f 0.45 (1: 1 hexane–ether); IR (neat), 3400—3480 (m), 1710 (m), 1450 (s), 1380 (s), and 895 cm^{-1} (m); NMR (CCl_4), 3.92 (1H, bt, CH–O), and 4.60—5.33 (7H, m, CH= and CH_2=).

Found: C, 84.6; H, 11.7 %. Calcd for $C_{30}H_{50}O$: C, 84.4; H, 11.8 %.

2-Pentyl-1-hepten-3-ol (**11**): Bp 105 °C (bath temp, 1 Torr); TLC, R_f 0.64 (30: 1 benzene–ethyl acetate, 3 developments); IR (neat), 3310—3400 (s), 1650 (m), 1465 (s), 1015 (s), and 895 cm^{-1} (s); NMR (CCl_4), 3.97 (1H, m, CH–O), 4.80 and 4.96 (2H, s, CH_2=); MS (*m/e*), 184 (2), 155 (3), 127 (15), 113 (25), and 71 (100).

Found: C, 78.1; H, 13.0%. Calcd for $C_{12}H_{24}O$: C, 78.2; H, 13.1%.

(E)-*6-Methyl-6-undecen-5-ol* (**13**). A sample free from **11** was produced by preparative TLC purification (30: 1 benzene–ethyl acetate, 3 developments): bp 105 °C (bath temp, 1 Torr); TLC, R_f 0.55 (30: 1 benzene–ethyl acetate, 3 developments); IR (neat), 3310—3400 (s), 1470 (s), 1010 (s), and 850 cm^{-1} (w); NMR (CCl_4), 1.60 (3H, s, CH_3–C=), 3.90 (1H, bt, CH–O), and 5.33 (1H, t, CH=); MS (*m/e*), 184 (4), 155 (8), 127 (66), 109 (30), and 71 (100).

Found: C, 78.0; H, 13.1%. Calcd for $C_{12}H_{24}O$: C, 78.2; H, 13.1%.

A small aliquot was acetylated with Ac_2O–pyridine. GLPC analysis (10% Apiezon, 210 °C, 1.0 kg/cm^2) showed that the product was $>$96 % pure.

Alternative Synthesis of a Mixture of ***13*** *and* ***14****.*[17] To a slurry of ethyltriphenylphosphonium bromide (2.32 g, 6.0 mmol) in THF (10 ml) was added dropwise butyllithium (4.6 ml of a 1.3 M hexane solution, 6.0 mmol) at 0 °C. After stirring at 0 °C for 30 min, the resulting red ylide solution was cooled to −78 °C and treated with pentanal (516 mg, 6.0 mmol) dissolved in THF (5 ml). Butyllithium (4.6 ml of a 1.3 M hexane solution, 6.0 mmol) was added dropwise at this temperature to effect immediate red coloring. To this solution was added pentanal (516 mg, 6.0 mmol) dissolved in THF (5 ml), and the solution was brought to room temperature and stirred for 2 h. The reaction mixture was poured into ice-cold water, and the product was extracted with ether. The ethereal solution was dried and freed of the solvent to leave a crude oil, which was purified by preparative TLC (4: 1 hexane–ether) to furnish a mixture of **13** and **14** (820 mg, 74% yield). GLPC analysis as described above showed the ratio of **13**: **14** 84: 16.

*(E,E)-3,7,11-Trimethyldodeca-2,7,11-triene-1,6,10-triol (****17****)*: The title compound was prepared from **15** by the reaction of 10 equiv. of DATMP in benzene at 0 °C for 3 h: TLC, R_f 0.25 (ether); IR (neat), 3260—3400 (s), 1650 (m), 1450 (s), 1000 (s), and 900 cm^{-1} (m); NMR ($CDCl_3$), 1.64—1.80 (9H, bs, CH_3–C=), 3.83—4.69 (4H, m, CH_2–O and CH–O), 4.80—5.12 (2H, d, CH_2=), and 5.20—5.77 (2H, m, CH=).

The microanalysis was performed after trimethylsilylation of both hydroxyl groups.

Found: C, 61.5; H, 10.5%. Calcd for $C_{21}H_{50}O_3Si_3$: C, 61.3; H, 10.6%.

Syntheses of Capreomycin Analogs in Relation to Their Antibacterial Activities[1)]

Shinya NOMOTO and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 11, 1978)

Six analogs of an antituberculous antibiotic capreomycin were synthesized in order to clarify the structure-activity relationship, especially with regard to the significance of the β-amino group in α,β-diaminopropionic acid residue as well as the position of linkage of the branch residue, β-lysine, to the cyclic peptide moiety. All the synthetic products were found to have the same conformations in solution as those of the natural antibiotics in terms of NMR spectra. It was found from their antibacterial activities that an amino group located at β-position of the α,β-diaminopropionic acid residue adjacent to ureidodehydroalanine residue remarkably strengthens the biological activity, and that the position of a branch does not significantly influence the antibacterial potency.

Peptide antibiotics such as, capreomycin,[2)] viomycin,[3)] and tuberactinomycin,[4)] show comparable antituberculous activities. From a structural point of view, these antibiotics constitute one group of branched cyclic pentapeptides with analogous amino acid sequence (Figs. 1 and 2). However, capreomycin, whose chemical structure was established,[5)] is structurally unique. The Ser[4] residue[6)] in all tuberactinomycins including viomycin (tuberactinomycin B) is replaced by A_2pr[7)] residue in capreomycins. This antibiotic contains one more amino group in its molecule than in tuberactinomycin. Capreomycin differs from tuberactinomycin in the position of linkage of the branch part, *i.e.*, β-Lys or γ-Hy-β-Lys,[7)] to the cyclic pentapeptide moieties, which is of interest in connection with the structure-activity relationship as well as biosynthesis of capreomycin.

Little is known about structural requirements for the antimicrobial activity of capreomycin so far. Syntheses of several capreomycin analogs have been carried out in the present study in order to clarify how the above-mentioned structural differences between capreomycin and tuberactinomycin are reflected on the antibacterial activity.

Fig. 3. Structures of capreomycin analogs synthesized.

Capreomycin analogs and related compounds synthesized are summarized in Fig. 3. Capreomycin IIA and IIB lacking β-Lys residue in capreomycin IA and IB molecules, respectively, were obtained from natural sources as minor components of the antibiotics.[8)] Capreomycin IIA and IIB have comparable antibacterial activities to those of IA and IB,[9)] whereas a similar cyclic moiety of tuberactinomycin, *i.e.*, tuberactinamine N shows less activity than tuberactinomycin itself.[10)] It was suggested that the β-amino group of A_2pr[4] residue[6)] in capreomycin II might act to enhance the antibacterial activity. For the sake of confirmation, we compared not only the antimicrobial spectra of tuberactinamine N and capreomycin IIA and IIB synthesized here, under the same conditions, but also those of tuberactinomycin O and so-called pseudocapreomycin IB whose branch part is linked to the second amino acid (A_2pr) residue in a similar way to that of the former. [Orn[4]]-Capreomycin IIB[6)] and reversecapreomycin IIB, in which the positions of Ala[3] and A_2pr[4] residue in capreomycin IIB are exchanged, were also synthesized for the purpose of observing the effects of the length of the side chain in the basic amino acid residue and its sequential position.

In order to prepare a more potent analog of this antibiotic than natural capreomycin or tuberactinomycin, and taking into account the fact that the addition of β-lysine branch to the cyclic peptide moiety virtually increases the biological activity in the case of tuberactinomycin, introduction of β-Lys to the free α-amino group of A_2pr^2 residue[6] in capreomycin IB, *viz.*, the preparation of di-β-Lys-capreomycin IIB, was undertaken.

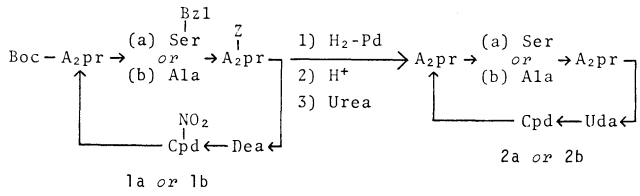

Fig. 4. Synthetic scheme for capreomycin IIA(**2a**) and IIB(**2b**).

Syntheses of Capreomycin IIA and IIB. The protected cyclopentapeptides **1a** and **1b** (Fig. 4), whose syntheses were reported in the total syntheses of capreomycin IA and IB,[5] were deprotected by catalytic reduction followed by acid treatment. The products were immediately treated with excess urea in order to convert the aldehyde group liberated from Dea[7] into Uda[7] residue, affording capreomycin IIA and IIB (**2a** and **2b**).

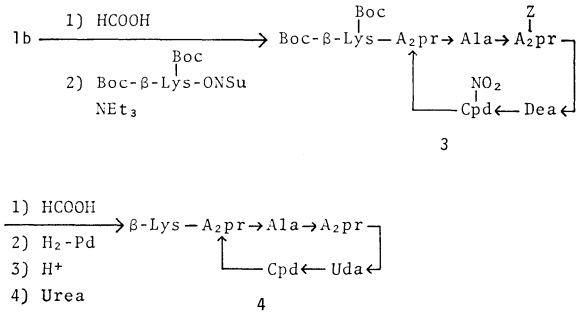

Fig. 5. Synthetic scheme for pseudocapreomycin IB(**4**).

Synthesis of Pseudocapreomycin IB. After cleavage of the Boc[7] group in **1b** (Fig. 5) with 99 % formic acid, Boc-β-Lys(Boc) residue was introduced to the α-amino group of the A_2pr^2 residue by the ONSu[7] active ester method. The product **3** was subsequently converted into pseudocapreomycin IB (**4**) through successive removal of Boc, Z, and nitro groups followed by the transformation of Dea into Uda residue.

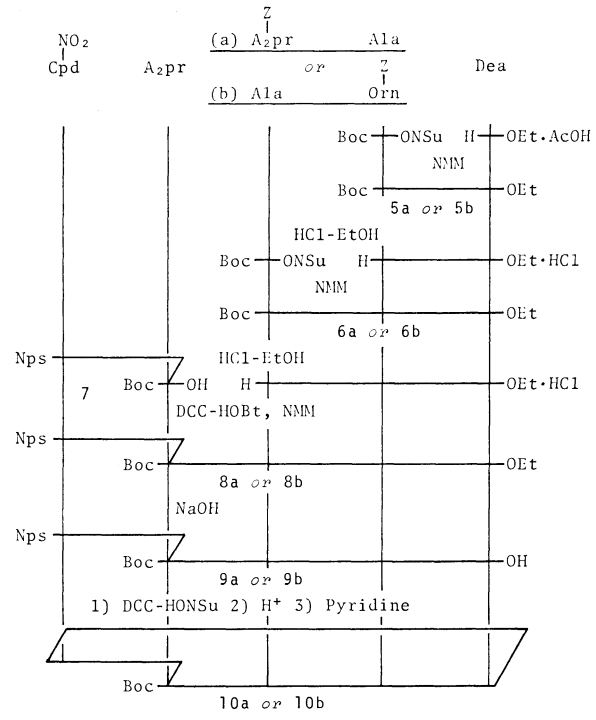

Fig. 6. Synthetic scheme for protected cyclopentapeptides **10a** and **10b**.

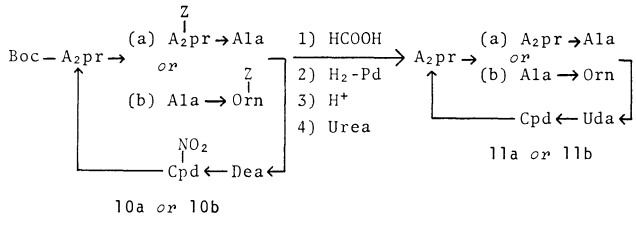

Fig. 7. Synthetic scheme for reversecapreomycin IIB (**11a**) and [Orn[4]]-capreomycin IIB(**11b**).

Syntheses of Reversecapreomycin IIB and [Orn[4]]-Capreomycin IIB. The synthetic schemes for these compounds

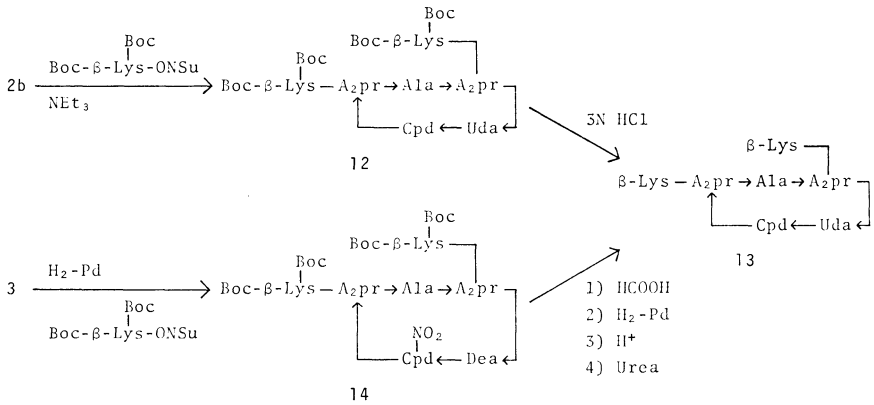

Fig. 8. Synthetic scheme for di-β-Lys-capreomycin IIB (**13**).

are given in Figs. 6 and 7. The C-terminal tripeptides (**6a**) and (**6b**) were prepared by the stepwise elongation method from the C-terminal utilizing ONSu active esters. Cleavage of Boc groups in dipeptides (**5a**) and (**5b**) was carried out in ethanol, otherwise severe decomposition occurred at diethyl acetal group of Dea residue.

The N-terminal dipeptide **7**[12] was condensed with deprotected C-terminal tripeptides (**6a**) and (**6b**) by means of DCC-HOBt[7] to afford linear pentapeptides (**8a**) and (**8b**), which were then cyclized by the ONSu active ester method. Conversion of the protected cyclic pentapeptides (**10a**) and (**10b**) thus obtained into the final products (**11a**) and (**11b**) were carried out as in the preparation of capreomycin IIA (**2a**) or IIB (**2b**).

Synthesis of Di-β-Lys-capreomycin IIB. This analog was prepared in the following two ways. Route A (Fig.

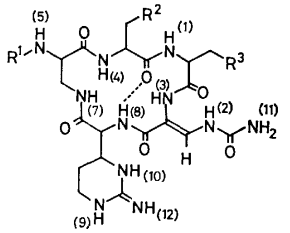
a) Abbreviation: Cpm, capreomycin. b) The chemical shifts of protons 6 and 7 are exchangeable.



(6)
R^3: β-Lys-NH- in Cpm IA, IB and di-β-Lys-Cpm IIB

8): Boc-β-Lys(Boc) residue was introduced simultaneously to both the α-amino group of A_2pr^2 and β-amino group of A_2pr^4 in capreomycin IIB (**2b**). Subsequently, four Boc groups in the product **12** were removed to afford di-β-Lys-capreomycin IIB (**13**). Route B (Fig. 8): when the protected hexapeptide (**3**, Fig. 5) was hydrogenated in the presence of Boc-β-Lys(Boc)-ONSu, a heptapeptide **14** was directly obtained in a good yield without cleavage of the nitro group as well as *N*,*N*-acyl migration at the A_2pr^4 residue.[5] The hexapeptide **14** was then subjected to deprotection followed by conversion of Dea into Uda residue.

The advantage of route B over route A lies in its applicability to a possible need in which analogs possessing different kinds of amino acid residues at two branch positions are required.

NMR Analysis. The NMR spectral data of capreomycin analogs prepared in this study are summarized in Tables 1 and 2, together with those of natural antibiotics for comparison. Assignment of each signal was performed by means of decoupling technique and a comparison with the spectra of natural antibiotics.[11,12]

The cyclic peptide moieties of tuberactinomycin and capreomycin as well as tuberactinomycin analogs have a stable and rigid conformation with an intramolecular hydrogen bond in commom as shown in Figs. 1 and 2.[11a] This is shown in particular by constant chemical shifts of each α-NH and α-CH signal in all the cyclic moieties. The fact that all capreomycin analogs show similar NMR spectral patterns to those of the natural ones, especially with respect to signals of α-NH and α-CH, indicates the conformational similarity of the analogs to the natural antibiotics.

Antibacterial Activities. The minimum inhibitory concentrations of capreomycin analogs were determined by a serial agar dilution method (Table 3). Both capreomycin IIA and IIB showed apparently greater activities than the corresponding tuberactinamine N,

TABLE 3. MINIMUM INHIBITORY CONCENTRATIONS (mcg/ml) OF CAPREOMYCIN ANALOGS

a) Abbreviations: Cpm, capreomycin; Tum tuberactinomycin; Tua, tuberactinamine.

being comparable to Tum O, whereas activities of both reversecapreomycin IIB and [Orn^4]-capreomycin IIB proved to be weaker than that of capreomycin IIB, being comparable to that of tuberactinamine N. On the other hand, pseudocapreomycin IB and di-β-Lys-capreomycin IIB showed even slightly greater activities than those of capreomycin IB or tuberactinomycin O.

Structure-activity Relationship. Both capreomycin IIA and IIB lacking the β-Lys branch showed stronger activities than tuberactinamine N which is also a cyclic peptide having no branch part. It is suggested that the β-amino group of A_2pr^4 residue promotes biological potency, although no such effect could be recognized for the same β-amino group of A_2pr^4 residue in pseudocapreomycin IB as compared with tuberactinomycin O. A possible explanation is as follows: the antibacterial potency of tuberactinomycin or capreomycin I might reach the upper limit in this sort of peptide antibiotics, since no synthetic analog has been found remarkably more active than the natural antibiotics so far.

Weaker activities of both [Orn^4]- and reversecapreomycin IIB apparently indicate the significance of the location of β-amino group of A_2pr^4 residue for its function as an activity-enhancing group.

A comparable activity of pseudocapreomycin IB to natural capreomycin IA or IB may imply that the effectiveness of β-Lys residue does not differ so much at either position of A_2pr residues for the enhancement of antibacterial activity. However, even if two β-Lys residues were attached to both amino groups, no significant increase of the activity was observed as seen in the case of di-β-Lys-capreomycin IIB.

Experimental

All the melting points are uncorrected. NMR spectra were recorded with a Varian XL-100-15 spectrometer using sodium dimethylsilapentanesulfonate as an internal standard. Specific rotations were measured with a Perkin-Elmer 141 Polarimeter. Molecular weights were determined with a Knauer vapor pressure osmometer using DMF as a solvent.

*Capreomycin IIA (**2a**).* A protected cyclopentapeptide **1a**[5] (170 mg, 0.180 mmol) was treated with 99 % formic acid (5 ml) at room temperature for 1 h. After removal of formic acid by evaporation, the product was hydrogenated with palladium black in methanol. The filtrate from catalyst was concentrated *in vacuo*. The residue was dissolved in 1 M hydrochloric acid–acetone (1: 1) (5 ml) and heated under reflux for 10 min. To the cooled solution was added urea (500 mg, 8.33 mmol) and the mixture was stirred at room temperature overnight. After evaporation of the solvent *in vacuo*, ethanol was added to the residue to form a white precipitate, which was reprecipitated from water–methanol–ethanol, yield 99 mg (84.6 %), mp 250 °C (dec), $[\alpha]_D^{23}$ +9.3° (*c* 2.8, H_2O). Found: C, 34.77; H, 5.60; N, 25.13; Cl, 15.35 %. Calcd for $C_{19}H_{35}N_{12}O_7Cl_3 \cdot 1/2H_2O \cdot 1/2CH_3OH$: C, 34.70; H, 5.67; N, 24.90; Cl, 15.76 %.

*Capreomycin IIB (**2b**).* The compound was prepared from a protected cyclopentapeptide **1b**[5] (150 mg, 0.179 mmol) in a similar manner to that for **2a**, yield 93 mg (81.6 %), mp 252 °C (dec), $[\alpha]_D^{23}$ −24.9° (*c* 0.57, H_2O). Found: C, 31.99; H, 6.15; N, 23.82; Cl, 15.24 %. Calcd for $C_{19}H_{35}N_{12}O_6Cl_3 \cdot 4H_2O$: C, 32.32; H, 6.14; N, 23.81; Cl, 15.07 %.

*Cyclo[Boc-β-Lys(Boc)-A_2pr-Ala-A_2pr(Z)-Dea-Cpd(NO_2)] (**3**).* Compound **1b**[5] (300 mg, 0.359 mmol) was treated with 99 % formic acid at room temperature for 2 h. Formic acid was removed *in vacuo* and the residue was dried over sodium hydroxide under reduced pressure. The white powder thus obtained was then coupled with Boc-β-Lys(Boc)-ONSu[10] (191 mg, 0.431 mmol) in DMF (2 ml) in the presence of triethylamine (54 mg, 0.538 mmol) at room temperature for 40 h. To the reaction mixture was added chloroform to form a gelatinous precipitate (335 mg, 87.7 %). The product was reprecipitated from DMF–ether for elemental analysis, mp 240 °C (dec), $[\alpha]_D^{23}$ −43.7° (*c* 0.90, DMF). Found: C, 50.36; H, 6.81; N, 17.13 %. Calcd for $C_{46}H_{73}N_{13}O_{16} \cdot 3/2H_2O$: C, 50.63; H, 7.02; N, 16.69 %.

*Pseudocapreomycin IB (**4**).* Deprotection of **3** (110 mg, 0.132 mmol) and conversion of Dea into Uda residue were carried out as in the preparation of **2a**, yield 62 mg (74 %), mp 245 °C (dec), $[\alpha]_D^{23}$ −30.7° (*c* 0.61, H_2O). Found: C, 37.44; H, 6.09; N, 24.27 %. Calcd for $C_{25}H_{48}N_{14}O_7Cl_4$: C, 37.60; H, 6.06; N, 24.56 %.

*Boc-Orn(Z)-Dea-OEt (**5b**).* Z-Dea-OEt[5b] (12.4 g, 36.6 mmol) was hydrogenated with palladium black catalyst in ethanol (100 ml) in the presence of acetic acid (4.40 g, 73.2 mmol) to give an oil of H-Dea-OEt·AcOH. This was then dissolved in ethyl acetate (30 ml) and added dropwise to an ice-cooled solution of Boc-Orn(Z)-ONSu (17.0 g, 36.6 mmol) in ethyl acetate (30 ml) with stirring. Subsequently, *N*-methylmorpholine (4.44 g, 43.9 mmol) was added dropwise and the mixture was stirred at 0 °C for 2 h and at room temperature for 16 h. The solution was washed with 10 % aqueous citric acid, saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo* to afford a white solid (17.1 g, 84.7 %). It was recrystallized from ethyl acetate–hexane, mp 62—63 °C, $[\alpha]_D^{23}$ −5.9° (*c* 2.4, DMF). Found: C, 57.91; H, 7.96; N, 7.27 %. Calcd for $C_{27}H_{43}N_3O_9 \cdot 1/2H_2O$: C, 57.67; H, 7.89; N, 7.47 %.

*Boc-A_2pr(Z)-Ala-Dea-OEt (**6a**),* A protected tripeptide **6a** was obtained from Boc-A_2pr(Z)-ONSu[12] (10.0 g, 22.9 mmol) and Z-Ala-Dea-OEt (**5a**)[12] (9.40 g, 22.9 mmol) in a similar way to that in the preparation of **5b**, yield 11.7 g (85.3 %), mp 94—96 °C, $[\alpha]_D^{23}$ −10.7° (*c* 2.4, DMF). Found: C, 56.69; H, 7.48; N, 9.45%. Calcd for $C_{28}H_{44}N_4O_{10}$: C, 56.36; H, 7.43; N, 9.39 %.

*Boc-Ala-Orn(Z)-Dea-OEt (**6b**).* Compound **5b** (6.00 g, 10.8 mmol) was treated with 28 ml of 5.8 M hydrogen chloride in ethanol at room temperature for 90 min. Benzene (300 ml) was added to the solution, which was then lyophilized. After the same procedure had been repeated twice, the resulting white powder was dried over sodium hydroxide under reduced pressure. To a solution of the deprotected dipeptide thus obtained and Boc-Ala-ONSu (3.10 g, 10.8 mmol) in ethyl acetate (70 ml) was added *N*-methylmorpholine (1.32 g, 13.0 mmol) dropwise at 0 °C with stirring. After being stirred at 0 °C for 2 h and then at room temperature for 16 h, the solution was washed with 10 % aqueous citric acid, saturated aqueous sodium hydrogencarbonate and brine successively, and dried over anhydrous magnesium sulfate. When ethyl acetate was removed *in vacuo*, a white solid (6.06 g, 89.5 %) was obtained. For elemental analysis, the product was recrystallized from ethylacetate–hexane, mp 70—75 °C, $[\alpha]_D^{23}$ −4.3° (*c* 2.3, DMF). Found: C, 57.49; H, 7.68; N, 8.96%. Calcd for $C_{30}H_{48}N_4O_{10}$: C, 57.68; H, 7.74; N, 8.97 %.

*Boc-A_2pr(Nps-Cpd(NO_2))-A_2pr(Z)-Ala-Dea-OEt (**8a**).* Removal of Boc group in **6a** (2.36 g, 3.95 mmol) was carried out as in the preparation of **6b**. The deprotected tripeptide obtained above was dissolved in DMF (15 ml) together with dipeptide **7**[12] (2.00 g, 3.59 mmol), HOBt (680 mg, 5.03 mmol),

N-methylmorpholine (436 mg, 4.31 mmol), and DCC (815 mg, 3.95 mmol) at 0 °C with stirring. Stirring was continued at 0 °C for 2 h and at room temperature for 16 h. The solution was filtered and concentrated *in vacuo*. The resulting oily residue was dissolved in ethyl acetate, washed with 10 % aqueous citric acid, saturated aqueous sodium hydrogencarbonate and brine successively and dried over anhydrous magnesium sulfate. The solution was concentrated *in vacuo* to give a yellow solid (3.30 g, 88.7 %). For elemental analysis, it was reprecipitated from THF–ether, mp 136—140 °C (dec), $[\alpha]_D^{23}$ +32.9° (*c* 2.0, DMF). Found: C, 49.19; H, 6.08; N, 15.78; S, 2.96 %. Calcd for $C_{43}H_{62}N_{12}O_{16}S \cdot H_2O$: C, 49.04; H, 6.13; N, 15.96; S, 3.04 %.

*Boc–A_2pr(Nps–Cpd(NO_2))–Ala–Orn(Z)–Dea–OEt (**8b**).* The compound was obtained from **6b** (3.37, 5.39 mmol) and **7**[12] (3.00 g, 5.39 mmol) as a yellow solid according to the method used for **8a**, yield 4.89 g (85.3 %), mp 155—160 °C (dec), $[\alpha]_D^{23}$ +38.0° (*c* 1.8, DMF). Found: C, 50.70; H, 6.33; N, 15.40; S, 3.03 %. Calcd for $C_{45}H_{66}N_{12}O_{16}S$: C, 50.84; H, 6.26; N, 15.81; S, 3.02 %.

*Boc–A_2pr(Nps–Cpd(NO_2))–A_2pr(Z)–Ala–Dea–OH (**9a**).* To a suspension of **8a** (3.00 g, 2.90 mmol) in ethanol (5 ml) was added 2.2 ml of 2 M aqueous sodium hydroxide. After being stirred at room temperature for 30 min, the solution was diluted with water (50 ml), and acidified with 10 % aqueous citric acid. The precipitated oil was extracted with ethyl acetate. The organic layer was washed with brine and dried over anhydrous magnesium sulfate. When the solvent was removed *in vacuo*, a yellow solid (2.45 g, 83.9 %) was obtained. It was reprecipitated from THF–ether for elemental analysis, mp 134—137 °C (dec), $[\alpha]_D^{23}$ +42.5° (*c* 1.7, DMF). Found: C, 48.64; H, 6.05; N, 15.98; S, 3.07 %. Calcd for $C_{41}H_{58}N_{12}O_{16}S \cdot 1/2H_2O \cdot 1/2C_4H_8O$: C, 49.09; H, 6.04; N, 15.98; S, 3.05 %.

*Boc–A_2pr(Nps–Cpd(NO_2))–Ala–Orn(Z)–Dea–OH (**9b**).* This peptide was obtained as a yellow solid from **8b** (4.44 g, 4.18 mmol) according to the method used in the preparation of **9a**: yield 3.91 g (90.5 %), mp 125—130 °C (dec), $[\alpha]_D^{23}$ +34.0° (*c* 1.9, DMF). Found: C, 49.94; H, 6.27; N, 15.18; S, 2.79 %. Calcd for $C_{43}H_{62}N_{12}O_{16}S \cdot 1/2H_2O \cdot 1/2C_4H_8O$: C, 50.04; H, 6.25; N, 15.56; S, 2.97 %.

*Cyclo[Boc–A_2pr–A_2pr(Z)–Ala–Dea–Cpd(NO_2)] (**10a**).* To a solution of **9a** (2.20 g, 2.19 mmol) and HONSu (276 mg, 2.40 mmol) in THF (10 ml), was added DCC (496 mg, 2.40 mmol) with stirring room temperature. After being stirred for 5 h, the solution was filtered and concentrated *in vacuo*. The residual yellow oil was triturated with hexane to give a yellow powder of the ONSu ester of **9a**, yield 2.51 g. Only an oil was obtained in spite of efforts to crystallize the product.

To a solution of the active ester obtained above in THF (3 ml) was added 1.85 ml of 2.7 M hydrogen chloride in THF dropwise with stirring at 0 °C, stirring being continued for 30 min. Ether was added to the solution to obtain a pale yellow powder (1.94 g).

The deprotected peptide active ester thus prepared was then dissolved in DMF (200 ml) and added slowly to pyridine (2 l) with vigorous stirring for 40 h, stirring being continued for 20 h. The solution was then concentrated *in vacuo*. The desired cyclic pentapeptide **10a** was isolated by silica gel column chromatography using a mixture of chloroform and methanol (19: 1) as an eluting solvent. The product was recrystallized from hot methanol to give fine needles (441 mg, 26.5 % based on **9a**), mp >250 °C, $[\alpha]_D^{23}$ −38.1° (*c* 1.2, DMF). Found: C, 49.42; H, 6.32; N, 18.21 %; molecular weight, 781. Calcd for $C_{35}H_{53}N_{11}O_{13} \cdot H_2O$: C, 49.23; H, 6.49; N, 18.04 %; molecular weight, 854.

*Cyclo[Boc–A_2pr–Ala–Orn(Z)–Dea–Cpd(NO_2)] (**10b**).* The cyclopentapeptide was obtained from **9b** (3.70 g, 3.57 mmol) according to the method used for **10a** as fine needles (561 mg, 20.1 %), mp 250 °C, $[\alpha]_D^{23}$ −44.7° (*c* 1.6, DMF). Found: C, 51.04; H, 6.64; N, 17.66 %; molecular weight, 743. Calcd for $C_{37}H_{57}N_{11}O_{13} \cdot 1/2H_2O$: C, 50.91; H, 6.70; N, 17.65 %; molecular weight, 873.

*Reversecapreomycin IIB (**11a**).* This analog was synthesized from **10a** (150 mg, 0.179 mmol) as in the preparation of capreomycin IIA, yield 101 mg (88.6 %), mp >250 °C, $[\alpha]_D^{23}$ +29.2° (*c* 0.26, H_2O). Found: C, 31.15; H, 5.99; N, 22.80; Cl, 14.55 %. Calcd for $C_{19}H_{35}N_{12}O_6Cl_3 \cdot 5.5H_2O$: C, 31.13; H, 6.33; N, 22.93; Cl, 14.51 %.

*[Orn[4]]-Capreomycin IIB (**11b**).* This analog was obtained from **10b** (150 mg, 0.174 mmol) in a similar way to that for the preparation of capreomycin IIA, yield 107 mg (93.0 %), mp 245—248 °C (dec), $[\alpha]_D^{23}$ −51.5° (*c* 1.5, H_2O). Found: C, 33.02; H, 6.24; N, 22.07; Cl, 14.14 %. Calcd for $C_{21}H_{39}N_{12}O_6Cl_3 \cdot 5.5H_2O$: C, 33.14; H, 6.62; N, 22.09; Cl, 13.98 %.

*Di-β-Lys-capreomycin IIB (**13**). Route A*: To a suspension of capreomycin IIB·3HCl (**2b**) (45 mg, 0.071 mmol) in DMF (2 ml) were added Boc-β-Lys(Boc)–ONSu[10] (79 mg, 0.18 mmol) and triethylamine (18 mg, 0.18 mmol) with stirring at room temperature. After being stirred for 48 h, the solution was concentrated *in vacuo*. To the residual oil was added 3 M hydrochloric acid (5 ml). The mixture was stirred at room temperature for 1 h and then neutralized with 4 M aqueous sodium hydroxide. The solution was applied to a column (2.5×80 cm) of Sephadex G10. The desired product **13** was eluted with water, yield 51 mg (75 %). For elemental analysis the product was reprecipitated from water–methanol–ethanol, mp 245 °C (dec), $[\alpha]_D^{23}$ −50.5° (*c* 1.3, H_2O). Found: C, 35.01; H, 6.89; N, 20.23; Cl, 16.44 %. Calcd for $C_{31}H_{61}N_{16}O_8Cl_5 \cdot 6H_2O \cdot CH_3OH$: C, 34.83; H, 7.03; N, 20.31; Cl, 16.07 %.

Route B: The hexapeptide **3** (150 mg, 0.141 mmol) was hydrogenated with palladium black catalyst in DMF (15 ml) in the presence of Boc–β-Lys(Boc)–ONSu[10] (94 mg, 0.21 mmol) for 40 h. To the filtrate from catalyst was added ethyl acetate (50 ml) to form a gelatinous precipitate of **14**, which was collected by centrifugation, yield 147 mg (83.1 %). It was reprecipitated from DMF–chloroform–ether for elemental analysis, mp >250 °C, $[\alpha]_D^{23}$ −43.1° (*c* 0.42, DMF). Found: C, 50.07; H, 7.52; N, 16.61 %. Calcd for $C_{54}H_{95}N_{15}O_{19} \cdot 2H_2O$: C, 50.10; H, 7.71; N, 16.23 %.

Deprotection and conversion of Dea to Uda residue in compound **14** (66 mg, 0.052 mmol) were carried out by a similar procedure to that in the preparation of **2a**, yield 39 mg (78 %). The product thus obtained was identical with the product in route A in thin-layer chromatography (silica gel; phenol–water–concd aqueons ammonia 30: 10: 1; R_f 0.22).

The authors are indebted to The Research Laboratories, Toyo Jozo Co., Ltd. for measurements of antibacterial activities, and to Dr. Kenji Okawa and his coworkers for use of the vapor pressure osmometer.

(Received December 13, 1978)

Active methylene compounds are selectively monoalkylated with alkyl halides in benzene using 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as a base. Selectivity of monoalkylation decreases when the reaction is carried out in a polar solvent. Ethyl acetoacetate is O-acylated with acyl halides in the presence of DBU in acetonitrile to give the (*E*)-enol esters stereoselectively.

Alkylation and acylation of active methylene compounds are important reactions in organic chemistry and have been studied extensively.[2)] Most reactions have been carried out in hydroxylic or dipolar aprotic solvents, for the anion species of active methylene compounds are not soluble in less polar solvents. Recent development of phase transfer method[3)] or the method of ion pair extraction[4)] has enabled this reaction to be carried out in a nonpolar solvent. The merits of the reaction in a nonpolar solvent are found in the simple work-up better yields and better selectivity.[3-4)] In a previous paper it has been shown that carboxylic acids are esterified with alkyl halides in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in benzene.[5)] In this paper we wish to report that active methylene compounds are alkylated or acylated with alkyl halides or acyl halides, respectively, in the presence of DBU. The new procedure is noteworthy for affording the selectively monoalkylated products in alkylation of active methylene compounds and the (*E*)-enol esters stereoselectively in acylation of ethyl acetoacetate.

Results and Discussion

Alkylation of active methylene compounds (Ia—f) was carried out as follows. A mixture of Ia—f, DBU, and alkyl halides (RX) in benzene was stirred at room temperature for an appropriate period, after which the DBU-hydrogen halide (DBU·HX) was either filtered off or washed out with water from the reaction mixture. The products were purified by distillation, recrystallization or column chromatography. The products of the reaction of Ia—c were also analyzed by GLPC to

$$\underset{\text{Ia—f}}{CH_2(Y)(Z)} + RX \xrightarrow[\text{benzene}]{\text{DBU}} \underset{\text{IIa—f}}{RCH(Y)(Z)} + \underset{\text{IIIa—f}}{RRC(Y)(Z)} + DBU\cdot HX \quad (1)$$

Ia: Y=CN, Z=$COOC_2H_5$
Ib: Y=CCH_3 (=O), Z=CCH_3 (=O)
Ic: Y=CCH_3 (=O), Z=$COOCH_3$
Id: Y=$COOCH_3$, Z=$SO_2C_6H_4$-CH_3-(*p*)
Ie: Y=CC_6H_5 (=O), Z=SO_2CH_3
If: Y=CCH_3 (=O), Z=$SO_2C_6H_5$

determine the exact ratio of monoalkylation to dialkylation (II/III). Results are summarized in Table 1. The O-alkylated products are also formed in alkylation of Ib or Ic, but the yields of them are poor, so discussion of O-alkylation is omitted in this paper.

The monoalkylated products (IIa—f) are important intermediates in organic synthesis, for example, they are readily coverted to the corresponding nitriles, ketones or esters by dealkoxycarbonylation or desulfonylation, and IIa, IIc, or IId can be the starting materials for the preparation of α,β-unsaturated nitriles,[6)] α,β-unsaturated ketones,[7)] or α,β-unsaturated esters,[8)] respectively.

Alkylation of Ia—f has been done by various method, but the present procedure has some advantages over the conventional methods. First, the reaction proceeds in benzene, making the work-up very simple. Secondly, as seen in Table 1, the new procedure gives the monoalkylated products exclusively. In general, the selective monoalkylation of relative stable carbanions involves difficulties such as concurrent dialkylation.[9)] This problem becomes paticularly serious in alkylation of ethyl cyanoacetate (Ia). Alkylation of Ia with ethyl iodide was carried out under various conditions to search for the best monoalkylation method. Results are summarized in Table 2. As can be seen from Table 2, the method using DBU in benzene gives monoalkylated products more selectively than the other methods and is far more superior to the ion pair extractive method of Bröndstrom[4)] which has been the best monoalkylation method known to date.[10)] The use of a nonpolar solvent such as benzene is important for this selective monoalkylation, since the ratio of mono to dialkylation decreases when the reaction is carried out in a polar solvent. The ratio of monoalkylation increases when alkylation of Ia is carried out in a nonpolar solvent, but such a tendency is not observed in alkylation of the sodium salt of Ia(Table 2). Bröndstrom and Junggern also point out that polarity of the solvent causes no appreciable effect on the ratio of mono to dialkylation in alkylation of the tetrabutylammonium salt of Ia.

The concurrent occurrence of mono and dialkylation can occur if the proton transfer equilibrium between the unreacted anion (I^-) and the monoalkylated product (II) is established at a rate comparable with that of the alkylation process.[11)] The small ratio of dialkylation in the reaction using DBU in benzene can be explained by assuming that this conditions suppress proton transfer relative to alkylation. However, it is difficult to discuss

this matter further at the present stage, for we do not have the precise information about the structures of the reactive species in such solvents.[12]

Recently, it has been reported that DBU is effective as a base for dialkylation of active methylene compounds in *N*,*N*-dimethylformamide (DMF).[13] This and the results in Table 2 tell us that the use of DBU in a polar solvent is preferable when dialkylation or second alkylation in stepwise alkylation of I is the desired reaction. In fact, alkylation of Ia successively with butyl iodide in benzene and with ethyl iodide in DMF gave ethyl 2-cyano-2-ethylhexanoate in a good overall yield (60 %). The second step could also be carried out in benzene, but the reaction proceeded more slowly in benzene than in DMF.

$$\text{Ia} + n\text{-}C_4H_9I \xrightarrow[\text{benzene}]{\text{DBU}} n\text{-}C_4H_9\text{-}\underset{\displaystyle CN}{\overset{\displaystyle COOC_2H_5}{\underset{|}{\overset{|}{CH}}}} \quad (77\%) \qquad (2)$$

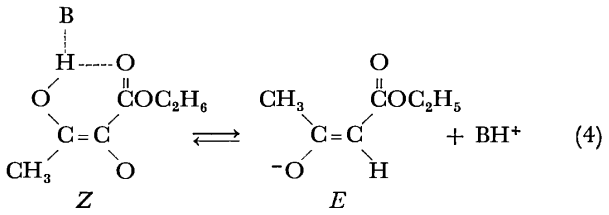
Acylation of ethyl acetoacetate with acyl chlorides was carried out in the presence of DBU. Various bases such as sodium hydride, triethylamine, or pyridine have so far been used for this reaction. In general, the reaction using sodium hydride gives the C-acylated products and the reaction using triethylamine or pyridine gives the O-acylated products consisted of the mixture of the *E* and *Z* enol esters.[14] The composition of these mixtures depends on the initial concentration of the enolate, for acyl chlorides are much more reactive than most alkylating reagents. The DBU salt of ethyl acetoacetate upon treatment with acyl chlorides gave the *E* enol esters stereoselectively, the selectivity became poor when acylation was carried out in benzene. The results of acylation are summarized in Table 3. Selectivity of the formation of the *E* isomers is poor in acylation induced by triethylamine. These results suggest that the reactive forms of the enolate consist of the mixture of the *E* and *Z* form and the ratio of them depends on the nature of solvent and bases. The ^1H NMR and carbon spectra indicate that the triethylamine salt of β-dicarbonyl compounds in a nonpolar solvent is best described as one in which the chelated enol form of β-dicarbonyl compounds is hydrogen bonded to triethylamine.[15] From the analogy of the triethylamine salt, the DBU salt is also considered as the similar hydrogen bonded complex in a nonpolar solvent. In a polar solvent, these complexes become the solvent separated ions, where the *E* conformation would be preferred since the oxygen atoms bearing negative charge are maximally separated. The DBU salt is more easily solvated than the triethylamine salt, for the DBU salt has a larger and more delocalized cation than the triethylamine salt.



Consequently, acylation of ethyl acetoacetate with acyl chlorides using DBU in acetonitrile gives the *E* enol esters stereoselectively. For synthetic purposes, the *E* enol esters are very important, for the reaction of them with dialkyl cuprates gives the *E* isomers of β-dialkyl-α, β-unsaturated esters in good yields with high stereospecificity, which are important intermediates in the synthesis of natural products.[14]

Table 3. The reaction of ethyl acetoacetate with acyl chloride in the presence of DBU

C_6H_5CCl ‖ O	CH_3CN[b]	75	84	16

a) Yield of isolated products. b) Triethylamine was used as a base.

In summary, DBU can be used as a base for alkylation of various active methylene compounds and acylation of ethyl acetoacetate, and the reaction proceeds both in a polar and in a nonpolar solvent. The merit of the use of DBU can be found in that the reaction course is easily controlled by polarity of the solvent.

Experimental

Solvents, DBU, and other commercially obtained materials were purified by distillation. The IR spectra were recorded with a Hitachi 215 spectrophotometer. The ^1H NMR spectra were recorded using a JEOL PS-100 spectrometer with TMS as an internal standard. GLPC analyses were performed with a Varian Aerograph 920 using a column containing Silicone-DC-550 (20%). Most of the starting materials and products were prepared by the literature methods. Sulfonyl ester (Id) was prepared by the reaction of methyl chloroacetate with sodium *p*-toluenesulfinate in DMF.[16] Keto sulfone (Ie) was prepared by the reaction of ethyl benzoate with the anion of dimethyl sulfone.[17] Keto sulfone (If) was prepared by the reaction of chloroacetone with sodium benzenesulfinate in DMF.[16]

Alkylation of Ia—c. A solution of alkyl halides (0.01 mol) in benzene (10 ml) was added to a stirred solution containing Ia—c (0.01 mol) and DBU (0.01 mol) in 50 ml of benzene. The reaction mixture was stirred at room temperature for the period indicated in Table 1, then washed with water, and the organic layer was dried over anhydrous magnesium sulfate. After removal of the solvent the residue was analyzed by GLPC. The results are given in Table 1. Some typical procedure to isolate the pure products is given below. Physical and spectral properties of the products are in good agreement with the literature value.

Ethyl 2-Cyanohexanoate (IIa, R=n-C_4H_9) from Butyl Bromide. A solution of butyl bromide (13.7 g, 0.1 mol) in 50 ml of benzene was added to a solution of ethyl cyanoacetate (11.3 g, 0.1 mol) and DBU (15.2 g, 0.1 mol) in 100 ml of benzene and the mixture was stirred at room temperature for 15 h. The reaction mixture was then washed with water, the organic layer was dried over anhydrous magnesium sulfate, and distilled. Ethyl 2-cyanohexanoate; bp 130°C/22 mmHg (lit,[18] 108 °C/8 mmHg), 11.0 g (65% yield). NMR (CCl_4) δ=0.95 (3H, t, J=4.8 Hz), 1.2—1.4 (7H, m), 1.9 (2H, m), 3.5 (1H, t, J=5.6 Hz), 4.25 (2H, q, J=7.2 Hz); IR (neat) 2250 cm^{-1} (CN), 1740 cm^{-1} (C=O).

Ethyl 2-Cyanohexanoate from Butyl Iodide. A mixture of ethyl cyanoacetate (6.7 g, 0.05 mol), DBU (7.6 g, 0.05 mol), and butyl iodide (9.2 g, 0.05 mol) in 150 ml of benzene was stirred at room temperature for 5 h, and was worked up as above to give ethyl 2-cyanohexanoate (6.5 g, 77% yield). The purity of the product was more than 95 %.

Ethyl 2-Cyano-2-ethylhexanoate. A mixture of ethyl 2-cyanohexanoate (3.4 g, 0.02 mol), DBU (3.1 g, 0.02 mol), and ethyl iodide (3.2 g, 0.02 mol) in 50 ml of DMF was stirred at room temperature for 5 h. The reaction mixture was worked up as above. Ethyl 2-cyano-2-ethylhexanoate; bp 141 °C/22 mmHg, 3.1 g (78% yield). NMR (CCl_4) δ=0.9 (6H, t, J=4.8 Hz), 1.25 (3H, t, J=7.2 Hz), 1.3 (4H, m), 1.8 (4H, m), 4.2 (2H, q, J=7.2 Hz); IR (neat) 2250 cm^{-1} (CN), 1740 cm^{-1} (C=O).

Ethyl 2-Cyanobutanoate (IIa, R=C_2H_5). A mixture of ethyl cyanoacetate (10.4 g, 0.1 mol), DBU (15.2 g, 0.1 mol), and ethy iodide (15.6 g, 0.1 mol) in 200 ml of benzene was stirred at room temperature for 3 h. The reaction mixture was then worked up as above to give 2-cyanobutanoate (11 g, 80% yield, bp 109 °C/29 mmHg) which contains ethyl cyanoacetate (about 5%) and dialkylated product (about 5%). They could not be separated by simple distillation.

Alkylation of Id. Methyl 2-(p-Tolylsulfonyl)hexanoate (IId, R=n-C_4H_9). A mixture of Id(11.0 g, 0.05 mol), DBU (7.6 g, 0.05 mol), and butyl bromide (6.9 g, 0.05 mol) in benzene (150 ml) and DMF (5 ml) was stirred at room temperature for 15 h. The reaction mixture was then washed with water and the organic layer was dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was chromatographed on silica gel with benzene as an eluent to give methyl 2-(*p*-tolylsulfonyl) hexanoate (13.6 g, 93% yield). Mp 54—55 °C; NMR ($CDCl_3$) δ=0.9 (3H, t, J=4.8 Hz), 1.28 (4H, m), 1.90 (2H, m), 2.48 (3H, s), 3.60 (3H, s), 3.70 (1H, t, J=5.6 Hz), 7.3 (2H, d, J=8.0 Hz), 7.6 (2H, d, J=8.0 Hz); IR (Nujol) 1740 cm^{-1} (C=O), 1320, 1140 cm^{-1} (SO_2).

Methyl 2-(p-Tolylsulfonyl)decanoate (IId, R=n-C_8H_{17}). A mixture of Id (2.3 g, 0.01 mol), DBU (1.52 g, 0.01 mol), and octyl bromide (1.94 g, 0.01 mol) in benzene (20 ml) and DMF (5 ml) was stirred at room temperature for 15 h. The reaction mixture was worked up as above, and the crude product was chromatographed on silica gel with benzene as an eluent to give methyl 2-(*p*-tolylsulfonyl)decanoate as a colorless oil in 81 % yield (2.7 g). NMR ($CDCl_3$) δ=0.88 (3H, t, J=4.8 Hz), 1.22 (12H, m), 1.82 (2H, m), 2.42 (3H, s), 3.60 (3H, s), 3.70 (1H, s, J=5.6 Hz), 7.30 (2H, d, J=8.0 Hz), 7.60 (2H, d, J=8.0 Hz); IR (neat) 1740 cm^{-1} (C=O), 1320, 1140 cm^{-1} (SO_2).

Methyl 2-(p-Tolylsulfonyl)-4-pentenoate (IId, R=CH_2–CH=CH_2). A mixture of Id (4.56 g, 0.02 mol), DBU (3.04 g, 0.02 mol),

and allyl bromide (2.44 g, 0.02 mol) in benzene (100 ml) and DMF (5 ml) was stirred at room temperature for 5 h. The reaction mixture was worked up as above to give methyl 2-(*p*-tolylsulfonyl)-4-pentenoate (5.1 g, 96% yield) as a colorless oil. NMR ($CDCl_3$) δ=2.40 (3H, s), 2.60 (2H, m), 3.60 (3H, s), 3.80 (3H, s), 5.00 (2H, m), 5.58 (1H, m), 7.25 (2H, d, J=8.0 Hz), 7.60 (2H, d, J=8.0 Hz); IR (neat) 1740 cm^{-1} (C=O), 1600 cm^{-1} (C=C), 1320, 1140 cm^{-1} (SO_2).

Alkylation of Ie. α-Methylsulfonylpropiophenone (IIe, R=CH_3). A mixture of Ie (1.0 g, 0.005 mol), DBU (0.76 g, 0.005 mol), and methyl iodide (0.71 g, 0.005 mol) in benzene (10 ml) and DMF (2 ml) was stirred at room temperature for 1 h. The reaction mixture was then washed with water and the organic layer was dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was recrystallized from ethanol to give colorless needles (0.85 g, 80% yield), mp 55 °C (lit,[16] 56—57 °C). NMR ($CDCl_3$) δ=1.80 (3H, d, J=7.8 Hz), 2.98(3H, s), 4.98 (1H, q, J=7.8 Hz), 7.7—8.2 (5H, m).

α-Methylsulfonylbutyrophenone (IIe, R=C_2H_5). A mixture of Ie (1.0 g, 0.005 mol), DBU (0.76 g, 0.005 mol), and ethyl iodide (0.8 g, 0.005 mol) in benzene (10 ml) and DMF (2 ml) was stirred at room temperature for 5 h. The reaction mixture was worked up as above, and the crude product was recrystallized from ethanol to give the product (0.86 g, 76 % yield) as colorless needles, mp 110 °C (lit,[19] 113 °C). NMR ($CDCl_3$) δ=1.0 (3H, t, J=7.8 Hz), 2.3 (2H, q, J=7.8 Hz), 1.98 (3H, s), 4.80 (1H, t, J=7.8 Hz), 7.5—7.8 (5H, m).

Alkylation of If. 3-Phenylsulfonylhex-5-en-2-one (IIf, R=CH_2–CH=CH_2). A mixture of If (1.93 g, 0.01 mol), DBU (1.52 g, 0.01 mol), and allyl bromide (1.27 g, 0.01 mol) in 50 ml of benzene was stirred at room temperature for 5 h. The reaction mixture was worked up as above, and the crude product was chromatographed on silica gel with benzene as an eluent to give the product (1.8 g, 80% yield) as a colorless oil. NMR (CCl_4) δ=2.30 (3H, s), 2.50 (2H, m), 4.15 (1H, t, J=7.2 Hz), 5.00 (2H, m), 5.51 (1H, m), 7.6 (5H, m); IR (neat) 1725 cm^{-1} (C=O), 1310, 1140 cm^{-1} (SO_2).

3-Phenylsulfonyl-3-hexanone (IIf, R=n-C_3H_7). A mixture of IIf (1.93 g, 0.01 mol), DBU (1.52 g, 0.01 mol), and propyl iodide (1.7 g, 0.01 mol) in 50 ml of benzene was stirred at room temperature for 15 h. The reaction mixture was worked up as above and the crude product was chromatographed on silica gel with benzene as an eluent give the product (1.7g, 72 % yield as a colorless oil. NMR (CCl_4) δ=0.85 (3H, t, J=4.8 Hz), 1.20 (2H, m), 1.78 (2H, m), 2.38 (3H, s), 4.16 (1H, t, J=5.6 Hz), 7.6—7.9 (5H, m); IR (neat) 1725 cm^{-1} (C=O), 1310, 1140 cm^{-1} (SO_2).

General Procedure of Acylation of Ethyl Acetoacetate. A solution of an acyl chloride (0.012 mol) in 10 ml of acetonitrile was added dropwise over 30 minutes to a stirred solution of ethyl acetoacetate (1.3 g, 0.01 mol) and DBU (1.8 g, 0.012 mol) in 10 ml of acetonitrile maintained below 5 °C by an ice bath. The reaction mixture was then stirred at room temperature for 3 h and was worked up by addition of water and ether, separation, and extaction of water layer with ether. The combined ethereal layers were washed with water, dried over anhydrous magnesium sulfate, and distilled to give the O-acylated product (enol ester), and the *E*/*Z* ratio of the product was determined by GLPC. The yield and the *E*/*Z* ratio of the product are given in Table 3. The following enol esters were prepared by this procedure.

Ethyl (E)-3-Benzoyloxy-2-butenoate: Bp 112 °C/0.4 mmHg (lit,[14a] 111 °C/0.4 mmHg); NMR (CCl_4) δ=1.30 (3H, t, J=7.2 Hz), 2.45 (3H, s), 4.20 (2H, q, J=7.2 Hz), 5.82 (1H, s), 7.2—8.2 (5H, m); IR (neat) 1750, 1725 cm^{-1} (C=O).

Ethyl (E)-3-Acetoxy-2-butenoate: Bp 110 °C/19 mmHg (lit,[14c] 78 °C/5 mmHg); NMR (CCl_4) δ=1.25 (3H, t, J=7.2 Hz), 2.10 (3H, s), 2.30 (3H, s), 4.05 (2H, q, J=7.2 Hz), 5.50 (1H, s); IR (neat) 1755, 1730 cm^{-1} (C=O).

Ethyl (E)-3-Pivaloyloxy-2-butenoate: Bp 103 °C/3 mmHg (lit,[20] 100 °C/2.5 mmHg); NMR (CCl_4) δ=1.26 (9H, s), 1.35 (3H, t, J=7.2 Hz), 2.32 (3H, s), 4.12 (2H, q, J=7.2 Hz), 5.55 (1H, s); IR (neat) 1755, 1730 cm^{-1} (C=O).

The authors are grateful to the Sanyo Chemical Co., Ltd. (Kyoto) for the supply of DBU.

Synthesis of *D*:*A*-Friedo-18β-lupane Derivatives[1]

Yasushi YOKOYAMA, Takahiko TSUYUKI, Yoshihiko MORIYAMA, Tatsushi MURAE, Hirokazu TOYOSHIMA, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 19, 1978)

D: *A*-Friedo-18β-lup-19-ene and *D*: *A*-friedo-18β-lup-19-en-3-one with a new migrated lupane framework were synthesized and the former compound was converted into known methyl trinorshionanoate.

There have been reported a number of migrated triterpene compounds with *D*-, *D*: *C*-, *D*: *B*-, and *D*: *A*-friedo-type frameworks. Among them, a series of migrated oleanane derivatives, taraxerol, multiflorenol, walsurenol, alnusenone (=glutinone), and friedelin (**1**) are well known.[2] In a series of migrated lupane derivatives, however, only guimarenol (**2**) has been isolated from *Ceropegia dichotoma* as a migrated lupane derivative, which has been shown to possess a *D*: *B*-friedolupane framework.[3] Neither isolation nor synthesis of a triterpene with a *D*: *C*- or *D*: *A*-friedolupane framework has yet been reported. We wish to describe a synthesis of *D*: *A*-friedo-18β-lup-19-ene (**3**) and *D*: *A*-friedo-18β-lup-19-en-3-one (**4**) from friedelin (**1**) and also conversion of **3** into known methyl trinorshionanoate (**5**)[4] *via* a trinor ketone (**6**).

Friedelan-19α-ol (**7**),[5] prepared from friedelin (**1**) *via* friedel-18-ene (**8**), was treated with phosphorus pentachloride in toluene at 0 °C to give an olefin mixture. The mixture was separated by column chromatography on silica gel impregnated with silver nitrate into an olefin (**3**; yield 61%) and friedel-18-ene (**8**; yield 4%). The olefin (**3**) has a molecular formula $C_{30}H_{50}$ determined by elemental analysis and mass spectrum, and shows a signal at δ 1.64 characteristic of an isopropylidene group together with signals at δ 0.78—0.90 due to six methyl groups in the ^{1}H NMR spectrum. These observations indicate the occurrence of *E*-ring contraction during the dehydration reaction and, therefore the structure of **3** could be inferred to be *D*: *A*-friedo-18β-lup-19-ene. The structure **3** was further confirmed by the following transformation.

	R^1	R^2
1	O	H_2
7	H_2	β-H, α-OH
11	O	O
13	β-H, α-OH	α-H, β-OH
14	-O(CH$_2$)$_2$O-	O
15	-O(CH$_2$)$_2$O-	β-H, α-OH
16	O	β-H, α-OH

Oxidation of the olefin (**3**) with ruthenium tetraoxide[6] in carbon tetrachloride at room temperature gave a ketone (**6**), $C_{27}H_{44}O$. The presence of α-monosubstituted five-membered ketone was demonstrated for **6** by IR ($\nu_{C=O}$ 1725 cm^{-1}) and NMR (δ 2.18, 2H, m and δ 2.20, 1H, s) spectra. CD measurement showed a positive Cotton effect. Godtfredsen *et al.*[7] reported that 3α,11α-diacetoxy-13β-fusidan-17-one showed a positive Cotton effect, while its 13α-isomer a strong negative maximum. Therefore the *D*/*E* ring juncture in **6** could be determined to be *cis*, leading to 18βH configuration.

The trinor ketone (**6**) in methanol was irradiated using a high pressure mercury lamp to afford methyl trinorshionanoate (**5**), which was identical with a specimen obtained from shionone (**9**).[5] The framework of **6** was thus confirmed and the structure of the olefin (**3**) was shown to be *D*: *A*-friedo-18β-lup-19-ene.

Since a C$_{(3)}$-functionalized *D*: *A*-friedolupane derivative is considered to be one of the important key compounds for preparation of migrated lupane derivatives with *D*: *B*- and *D*: *C*-friedo-type frameworks, *D*: *A*-friedo-18β-lup-19-en-3-one (**4**) was prepared as follows.

Friedel-18-en-3-one (**10**)[8] was converted into friedelane-3,19-dione (**11**)[9] *via* 18β,19β-epoxyfriedelan-3-one (**12**)[9] and friedelane-3α,19β-diol (**13**).[10] The diketone

(**11**) was stable to an alkaline treatment. This suggests an 18βH configuration (ring juncture *C/D/E*: *trans*-anti-*cis*) for **11**. The 18αH isomer (*trans*-syn-*trans*) is considered to be much less stable than the 18βH isomer.[5,11]

Treatment of the diketone (**11**) with ethylene glycol in the presence of *p*-toluenesulfonic acid in benzene gave a mono-ethylene acetal (**14**). The absorption band at 1685 cm^{-1} in the IR spectrum of **14** indicated that the carbonyl group at C-19 was left unchanged and that the ethylene acetalization occurred on the carbonyl group at C-3. Reduction of **14** with lithium aluminium hydride in tetrahydrofuran gave 19α-hydroxyfriedelan-3-one 3-ethylene acetal (**15**), which, on treatment with *p*-toluenesulfonic acid in acetone, afforded 19α-hydroxyfriedelan-3-one (**16**; ν_{OH} 3450 and 3620 and $\nu_{C=O}$ 1705 cm^{-1}) in about 76% yield from **11**. The NMR spectrum of **16** showed a multiplet at δ 2.1—2.5 due to three protons α and α′ to the carbonyl group and a doublet at δ 3.79 (J=5.5 Hz)[5] due to a proton on C-19β. The 19α-hydroxy configuration for **15** and **16** received support from the fact that the reduction of friedelan-19-one with lithium aluminium hydride gave friedelan-19α-ol (**7**) as a sole product.[5]

The dehydration reaction of the hydroxy ketone (**16**) with phosphorus pentachloride was examined under various conditions and it was found that the best results were obtained under the following reaction conditions. The hydroxy ketone (**16**; 0.012 mmol) in toluene (5 ml) was treated with phosphorus pentachloride (*ca.* 10 mg) at −10 °C for 20 h to give an olefin (**4**) as a single reaction product in 90% yield. Reaction under reflux conditions resulted in the formation of undesired friedel-18-en-3-one (**10**), and reaction with a larger amount of phosphorus pentachloride gave an unidentified olefin in considerable amounts (see Experimental).

The olefin (**4**), mp 276—278 °C, gave a molecular formula $C_{30}H_{48}O$ (by elemental analysis and mass spectrometry) and showed the presence of a carbonyl group ($\nu_{C=O}$ 1710 cm^{-1}) and an isopropylidene group (δ 1.65, br s, 6H) in the IR and NMR spectra, indicating that the olefin (**4**) corresponds to an *E*-ring contraction product. On Huang-Minlon reduction, the olefin (**4**) gave *D*: *A*-friedo-18β-lup-19-ene (**3**) identical with a specimen obtained from **7** (*vide supra*). Therefore, the structure of the olefin (**4**) was shown to be *D*: *A*-friedo-18β-lup-19-en-3-one.

Experimental

General Procedures. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and were uncorrected. IR spectra were measured in Nujol mull using a Hitachi EPI-G2 spectrometer. CD measurement was carried out on a JASCO Model J-20 spectrometer. Optical rotations were measured on a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer at 70 eV with a direct inlet system. The relative intensity was expressed in the parenthesis. ^1H NMR spectra were measured using a Hitachi R-20 spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard and coupling constants in Hz. GLC analyses were made using a Shimadzu Gas Chromatograph GC-6A equipped with a hydrogen flame ionization detector (column: Dexsil 300GC, temperature 290 °C). HPLC analyses were carried out on a Waters Liquid Chromatograph ALC/GPS 202/401 at room temperature with an RI detector (column: μ-Porasil 1/8 (inch) × 1 (foot); solvent system: 5% ether–hexane; flow rate: 0.5 ml/min; pressure: *ca.* 250 psi). TLC was carried out on Kieselgel G (E. Merck) coated in 0.25 mm thickness. Wakogel C-200 (Wako) was used for column chromatography.

Dehydration of Friedelan-19α-ol (7). To a solution of friedelan-19α-ol[5] (**7**; 407 mg) in toluene (100 ml) kept at 0 °C, phosphorus pentachloride (*ca.* 660 mg) dissolved in toluene (25 ml) was added and the reaction mixture was stirred for 1.5 h at 0 °C. After addition of 15% sodium carbonate solution (70 ml), the reaction product was treated in usual way and subjected to separation by column chromatography on silica gel (40 g) impregnated with 20% silver nitrate. Elution with petroleum ether (320 ml) gave an isopropylidene derivative (**3**; 236 mg) and further elution with benzene (160 ml) and then with ether (80 ml) gave friedel-18-ene (**8**; 15 mg). The isopropylidene derivative (**3**) was recrystallized from acetone to afford *D*: *A*-friedo-18β-lup-19-ene (**3**; 218 mg), mp 181.5—182.5 °C; NMR ($CDCl_3$) δ 0.78—0.90 (6×CH_3), 1.64 (6H, s; $(CH_3)_2C{=}C\langle$), and the absence of signals due to olefinic proton; MS *m/e* (%) 410 (M^+; 14), 395 (12), 259 (39), and 121 (100); Found: C, 87.86; H, 12.43%. Calcd for $C_{30}H_{50}$: C, 87.73; H, 12.27%.

Oxidation of D: A-*Friedo-18β-lup-19-ene (3).* A ruthenium tetraoxide solution was prepared according to Nakata's procedure[6c] as follows. To ruthenium dioxide (83.6 mg) dissolved in carbon tetrachloride (10 ml), a solution of sodium periodate (361.4 mg) in water (10 ml) was added and the mixture was stirred for 19 h initially at 0 °C then at room temperature.

A solution of *D*: *A*-friedo-18β-lup-19-ene (**3**; 33.4 mg) in carbon tetrachloride (3 ml) was covered with water (2 ml) and stirred. The carbon tetrachloride solution (5 ml) of ruthenium tetraoxide was added dropwise and the stirring was continued for 21 h at room temperature. An excess of the oxidizing reagent was destroyed by addition of 2-propanol (2 ml). The reaction product was treated as usual and purified by column chromatography on silica gel (5 g). The unchanged hydrocarbon (6.2 mg) was eluted with petroleum ether (20 ml) and subsequent elution with petroleum ether–benzene (1: 1, 100 ml) gave a trinor ketone (**6**; 17.0 mg), mp 217—218 °C (crystallized from acetone); IR 1725 cm^{-1}; CD (*c* 0.0014, dioxane, at 26 °C) $[\theta]_{302}$ +7570, $[\theta]_{313}$ +7710, and $[\theta]_{325}$ +4190; NMR ($CDCl_3$) δ 0.77—1.00 (6×CH_3), 2.18 (2H, m; $-CH_2-CO-$), and 2.20 (1H, s; $-\dot{C}H-CO-$); MS *m/e* (%) 384 (M^+; 32), 369 (37), 259 (39), 257 (41), 245 (29), 190 (41), 149 (82), and 109 (100); Found: C, 84.19; H, 11.73%. Calcd for $C_{27}H_{44}O$: C, 84.31; H, 11.53%.

Photoirradiation of Trinor Ketone (6). A solution of trinor ketone (**6**; 27.2 mg) in methanol (35 ml) in a quartz vessel was irradiated using a high pressure mercury lamp (100 W) for 2.5 h under a nitrogen atmosphere at room temperature. Column chromatographic separation on silica gel (6 g) gave methyl trinorshionanoate (**5**; 14.4 mg) together with unidentified hydrocarbons and the unchanged starting material (4 mg). The photo-produced methyl trinorshionanoate (**5**) was identical (mp, IR, NMR, MS, and TLC) with an authentic specimen prepared from shionone (**9**).[5]

Treatment of Friedelane-3,19-dione (11) with Alkali. Friedelane-3,19-dione[9] (**11**; 14.6 mg) in methanol (15 ml) was heated under reflux with sodium methoxide (*ca.* 55 mg) for 2 h. The residue, after removal of the solvent, was extracted with ether. The ethereal extract was worked up as usual and the examination on TLC showed only one spot identical with that of the starting diketone (**11**).

*Ethylene Acetalization of Friedelane-3,19-dione (**11**).* A mixture of friedelane-3,19-dione (**11**; 2.9 g), ethylene glycol (5 ml), *p*-toluenesulfonic acid (*ca.* 100 mg), and benzene (600 ml) was heated under reflux using Dean-Stark apparatus for 2.5 h. The reaction mixture was worked up as usual, and crystallization from dichloromethane–ether gave friedelane-3, 19-dione 3-ethylene acetal (**14**; 2.7 g), mp 271—272 °C) crystallized from chloroform–acetone); IR 1685 cm^{-1}; NMR ($CDCl_3$) δ 0.77 (3H, d, J=7 Hz; *s*-CH_3), 0.89 (9H, s; 3× *t*-CH_3), 1.01, 1.18 (each 3H, s; *t*-CH_3), 1.11 (6H, s; 2×*t*-CH_3), 2.19 (1H, s; 18β-H), and 3.8—4.0 (4H, m; –O–CH_2–CH_2–O–); MS *m/e* (%) 484 (M^+; 5), 469 (4), 317 (7), 139 (35), and 99 (100); Found: C, 79.22; H, 10.62%. Calcd for $C_{32}H_{52}O_3$: C, 79.28; H, 10.81%.

*Reduction of Friedelane-3,19-dione 3-Ethylene Acetal (**14**).* The ethylene acetal (**14**; 2.7 g) dissolved in tetrahydrofuran (500 ml) was treated with lithium aluminium hydride (300 mg) at reflux temperature for 6.5 h and the reaction mixture was worked up as usual to give 19α-hydroxyfriedelan-3-one 3-ethylene acetal (**15**; 2.6 g), mp 287—289 °C (crystallized from chloroform–acetone); IR 3500 cm^{-1}; NMR ($CDCl_3$) δ 0.78 (3H, d, J=7 Hz; *s*-CH_3), 0.88, 1.08 (each 6H, s; 2× *t*-CH_3), 0.90, 1.01, 1.25 (each 3H, s; *t*-CH_3), and 3.7—4.0 (5H, m; 19β-H and –O–CH_2–CH_2–O–); MS *m/e* (%) 486 (M^+; 6), 471 (4), 468 (4), 317 (14), and 99 (100).

*Deacetalization of Hydroxy Ethylene Acetal (**15**).* A solution of the hydroxy ethylene acetal (**15**; 160 mg) in acetone (160 ml) was heated with a catalytic amount of *p*-toluenesulfonic acid. The reaction product was purified by column chromatography on silica gel (20 g) to give 19α-hydroxyfriedelan-3-one (**16**; 139 mg), mp 261—265 °C; IR 3620, 3450, and 1705 cm^{-1}; $[\alpha]_D^{24}$ −9.9° (*c* 0.25, $CHCl_3$); NMR ($CDCl_3$) δ 0.74, 0.90, 1.02 (each 3H, s; *t*-CH_3), 0.88 (3H, d, J=7 Hz; *s*-CH_3), 1.09, 1.26 (each 6H, s; 2×*t*-CH_3), 2.1—2.5 (3H, m; –CH_2–CO–CH–), and 3.79 (1H, d, J=5.5 Hz; 19β-H); MS *m/e* (%) 442 (M^+; 3), 424 (13), 409 (13), 273 (43), 186 (31), and 123 (100); Found: C, 81.29; H, 11.32%. Calcd for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38%.

*Dehydration of 19α-Hydroxyfriedelan-3-one (**16**).* Five portions of 19α-hydroxyfriedelan-3-one (**16**; each *ca.* 2 mg) dissolved in toluene (each 3 ml) were treated with phosphorus pentachloride (each *ca.* 10 mg) at reflux temperature, 60 °C, 40 °C, room temperature, and at −10 °C, respectively, and the reaction product was examined by GLC. A single product was obtained at reflux temperature and was shown to be friedel-18-en-3-one (**10**). A mixture of *D*: *A*-friedo-18β-lup-19-en-3-one (**4**) and an unidentified dehydration product was obtained in a ratio of 3: 4 and 1: 2 in the reactions at 60 °C and 40 °C, respectively. This mixture was inseparable by HPLC, silica gel chromatography, and by recrystallization. Reactions at room temperature and at −10 °C gave the same mixtures as above in a ratio of 3: 1 and 8: 1, respectively.

A solution of **16** (5.6 mg) in toluene (5 ml) was treated with phosphorus pentachloride (*ca.* 63 mg) at −10 °C for 20 h, and the reaction product was examined by GLC. Only the unidentified dehydration product was detected. A solution of **16** (5.4 mg) in toluene (5 ml) was treated with phosphorus pentachloride (*ca.* 10 mg) under the same conditions to yield a reaction product (4.6 mg), which was shown to be the desired isopropylidene derivative (**4**), mp 276—278 °C (crystallized from chloroform–acetone); IR 1710 cm^{-1}; $[\alpha]_D^{24}$ −24° (*c* 0.22, $CHCl_3$); NMR ($CDCl_3$) δ 0.73, 0.83 (each 3H, s; *t*-CH_3), 0.78 (3H, d, J=6 Hz; *s*-CH_3), 0.93 (9H, s; 3×*t*-CH_3), 1.65 (6H, br s; $(CH_3)_2C$=C<), and 2.0—2.5 (6H, m; –CH_2–CO–CH– and  ; MS *m/e* (%) 424 (M^+; 13), 409 (4), 273 (33), and 121 (100); Found: C, 85.02; H, 11.48%. Calcd for $C_{30}H_{48}O$: C, 84.84; H, 11.39%.

Huang-Minlon Reduction of D: A-*Friedo-18β-lup-19-en-3-one(**4**).* A mixture of *D*: *A*-friedo-18β-lup-19-en-3-one (**4**; 23 mg), hydrazine hydrate (100 %, 0.3 ml), potassium hydroxide (200 mg), and diethylene glycol (2 ml) was heated under reflux for 1 h. An excess of hydrazine was distilled off and the distillation was continued until the vapor temperature reached to about 220 °C. Then the reaction mixture was heated under reflux for 4 h. Usual work up gave a residue, which was subjected to separation by column chromatography on silica gel (3 g) impregnated with 20% silver nitrate. Elution with hexane (20 ml) gave a hydrocarbon (11 mg), which was completely identical with *D*: *A*-friedo-18β-lup-19-ene (**3**) prepared from **7**.

Synthesis and Reactions of Perylenecarboxylic Acid Derivatives. VI. Sulfonation of 3,4-Perylenedicarboximide

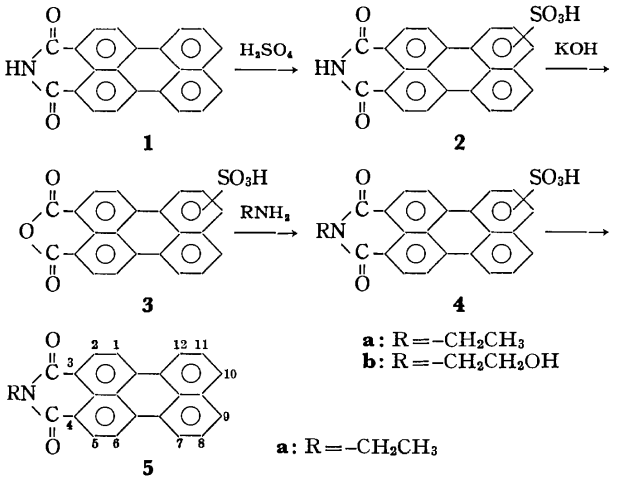
Yukinori NAGAO* and Takahisa MISONO

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda-shi, Chiba 278

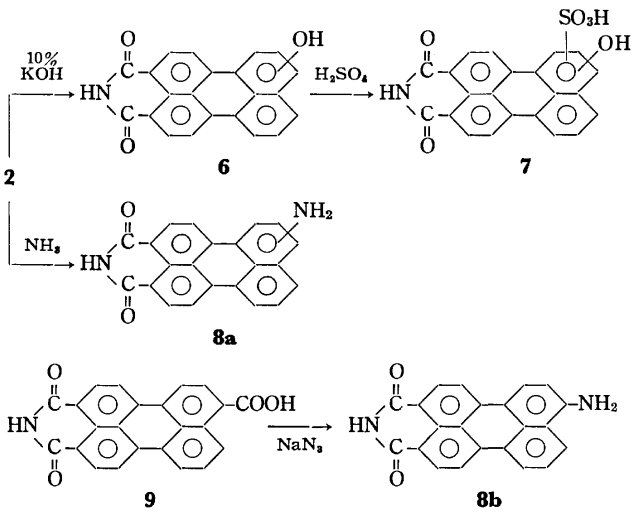
(Received July 3, 1978)

The sulfonation of 3,4-perylenedicarboximide (**1**) with sulfuric acid has been studied. The position of the sulfo group in the monosulfonated product (**2**) obtained at 100 °C has been discussed on the basis of the NMR and IR spectra of **2** and the related compounds, and has been confirmed to be the 9-sulfoperylene-3,4-dicarboximide. The localized treatment of **1** by Hückel and Pople MO calculations confirmed substitution at the 9-position. Paper chromatographic analysis indicated that the reaction product was only **2** in the temperature range 60—120 °C, and the reaction rate was determined spectroscopically. The maximum formation of **2** was approximatedly 97% at 100 °C. The rate of reaction was found to be a pseudo first order process and the activation energy found to be 19.5 kcal/mol.

In a previous publication the 3,4-perylenedicarboximide (PDCI) (**1**) was sulfonated at 100 °C, and the *N*-substituted-perylene-3,4-dicarboximide (*N*-R-PDCI) (**5**) prepared from the sulfonic acid (PDCI-SO_3H) (**2**) *via* **3** and the *N*-substituted-sulfoperylene-3,4-dicarboximide (*N*-R-PDCI-SO_3H) (**4**), as presented below.[1]



The substituted position of the sulfo group in **2**, however, remains. The position of substitution has been discussed on the basis of the NMR and IR spectra data of **2** and related compounds; **4a**, **4b**, **5a**, **7**, **8a**, perylene, perylenedisulfonic acids, and **8b**. The kinetics of the sulfonation of **1** have also been determined.



Experimental

Materials. PDCI (**1**), the potassium salt of PDCI-SO_3H (PDCI-SO_3K), the potassium salt of *N*-(2-hydroxyethyl)-PDCI-SO_3H (**4b**), the potassium salt of *N*-ethyl-PDCI-SO_3H (**4a**), and *N*-ethyl-PDCI (**5a**) were prepared and purified by previous methods.[1] The free sulfonic acid was prepared by adding hydrochloric acid to the solution of the potassium salt. PDCI-SO_3H was confirmed to be a free sulfonic acid by titration with potassium hydroxide solution and in the TG analysis the water of hydration was lost at 100 °C. PDCI-SO_3H dried at 100 °C was used as the standard reagent for spectroscopical determination.

Perylene was prepared from 3,4,9,10-perylenetetracarboxylic dianhydride by the method of Goto *et al.*[2] Perylenedisulfonic acid was prepared by the methods of Marschalk.[3]

Measurements and Molecular Orbital Calculations. The NMR spectra were obtained using a JNM-4H-100 spectrometer (Japan Electron Optics Laboratory Co.) at 100 MHz. All spectra were measured in DMSO-d_6 using TMS as an internal standard and samples for measurement at 150 °C were contained in sealed tubes. Mass spectra were obtained using a Hitachi RMU-7M mass spectrometer. Visible spectra were measured using a Hitachi 124 spectrometer for solutions in concd sulfuric acid and IR spectra on a Nippon Bunko IR-E spectrophotometer. The developing solvent used in paper chromatography was a 1-butanol–pyridine–28 % ammonia–water mixture (1 : 1 : 1 : 1). The molecular orbitals were calculated using an IBM 370 computer with a modification of the program of Wiberg.[4]

Sulfonation of Hydroxyperylene-3,4-dicarboximide. Hydroxyperylene-3,4-dicarboximide (6): In an autoclave was added PDCI-SO_3K 0.60 g and 10% KOH 50 ml. The autoclave was heated at 200 °C for 10 h with stirring. The reaction mixture was filtered, the precipitate washed with water, and poured into water. The suspension was acidified with hydrochloric acid and filtered and the precipitate washed with water, and dried, **6** 0.50 g: λ_{max} (H_2SO_4) 620 nm; R_f 0.78 (violet); MS (70 eV), *m/e* 337 (M^+). After sublimation at 400 °C/3—5 mmHg, an analytical sample was given.

Found: C, 77.53; H, 3.05; N, 4.08%. Calcd for $C_{22}H_{11}O_3N$: C, 78.33; H, 3.29; N, 4.15%.

Sulfonation of Hydroxyperylene-3,4-dicarboximide: Into a three

necked flask fitted with a stirrer was added concentrated sulfuric acid 20 ml and **6** 0.10 g. The mixture was warmed at 50 °C for 2 h with stirring, and the cooled mixture poured into ice water 100 ml. The mixture was filtered and the solid dissolved in refluxing ethanol, and filtered to remove the unreacted **6**. The solution was concentrated in an evaporator, and concentrated hydrochloric acid added until the material solidified. The solid was filtered and dried, giving the sulfonic acid **7** 0.08 g: λ_{max} (H_2SO_4) 623 nm; R_f 0.62 (violet).

Aminoperylene-3,4-dicarboximide. Preparation from PDCI-SO_3K: In an autoclave was added PDCI-SO_3K 0.50 g and 28% ammonia 50 ml, followed by ammonia gas until a pressure of 10 kg/cm² was attained. The autoclave was heated at 200 °C for 10 h. The reaction mixture was filtered, and the precipitate washed with hot 1% potassium hydroxide to remove the unreacted PDCI-SO_3K. The precipitate was washed with water and dried, giving the amine **8a** 0.32 g: λ_{max} (H_2SO_4) 609 nm; R_f 0.88 (blue); MS (70 eV), *m/e* 336 (M^+). After sublimation at 400 °C/1 mmHg, an analytical sample was given.

Found: C, 78.23; H, 3.31; N, 7.72%. Calcd for $C_{22}H_{12}N_2O_2$: C, 78.56; H, 3.60; N, 8.33%.

Preparation from 9-Carboxy-3,4-perylenedicarboximide (9): **9** 0.50 g was dissolved in concentrated sulfuric acid 25 ml and to the solution was slowly added sodium azide 0.10 g. The solution was maintained at 50 °C for 4 h and then the reaction mixture was poured into water and filtered. The precipitate was washed with hot 1% potassium hydroxide, water, ethanol, and dried, giving the amine **8b** 0.22 g: λ_{max} (H_2SO_4) 609 nm; R_f 0.88 (blue); MS (70 eV), *m/e* 336 (M^+). The DMSO solution gave an analytical sample by acidification with hydrochloric acid.

Found: C, 71.08; H, 3.23; N, 6.59 %. Calcd for $C_{22}H_{12}N_2O_2$+HCl: C, 70.88; H, 3.51; N, 7.51%.

Sulfonation of PDCI. In order to study the rate of sulfonation, concentrated sulfuric acid 25 ml was added into a three neeked flask, and the temperature of the flask adjusted to the temperature of the rate measured. To the flask was added PDCI 0.50 g and the flask maintained at the same temperature with stirring. An aliquot of the reaction mixture was withdrawn periodically and analyzed by paper chromatography and spectroscopy.

Paper Chromatography: The reaction mixture was poured into water and the precipitated reaction mixture separated by centrifuging. The precipitate was dissolved in 1% potassium hydroxide, placed on the paper and developed by the solvent.

Determination by Spectroscopy: The reaction mixture were diluted with concentrated sulfuric acid, and the absorbance at two wavelength (570 and 585 nm) measured. The mole ratio of PDCI and PDCI-SO_3H to the mixture was calculated from the following relationship:

$$A_{570} = 0.743 \times (\text{PDCI}) + 0.583 \times (\text{PDCI-SO}_3\text{H})$$

$$A_{585} = 0.714 \times (\text{PDCI}) + 0.726 \times (\text{PDCI-SO}_3\text{H})$$

A_{570} and A_{585}; Absorbances of the reaction mixture at 570 and 585 nm. (PDCI) and (PDCI-SO_3H) are the concentrations of PDCI and PDCI-SO_3H (mg/ml), respectively.

Results and Discussion

NMR Spectra of Sulfonic Acids. The sulfonic acid **2** was confirmed to be a mono-sulfonic acid by the potassium analysis of the potassium salt of **2**.[1] The position of the sulfo group in **2** has been evaluated by comparing the NMR spectra of the related compounds, the spectra data being shown in Table 1. Assignment of the proton positions has been assumed on the basis of the perylene spectrum (in CCl_4).[5,6] The differences between the spectra in DMSO-d_6 and CCl_4 were significantly small.

Table 1. NMR spectra of perylene derivatives

Compound	Chemical shift δ/ppm	Position
2[a]	11.5—11.6 (1H, singlet)	N
	8.8—9.1 (1H, doublet)	10
	8.0—8.5 (7H, multiplet)	1, 2, 3, 6, 7, 8, 12
	7.5—7.8 (1H, triplet)	11
4a[a]	8.8—9.1 (1H, doublet)	10
	8.0—8.5 (7H, multiplet)	1, 2, 3, 6, 7, 8, 12
	7.5—7.8 (1H, triplet)	11
4a[b]	9.0—9.2 (1H, doublet)	10
	8.4—8.6 (6H, multiplet)	1, 2, 3, 6, 7, 12
	8.1—8.2 (1H, doublet)	8
	7.5—7.8 (1H, triplet)	11
4b[a]	8.8—9.1 (1H, doublet)	10
	8.0—8.5 (7H, multiplet)	1, 2, 3, 6, 7, 8, 12
	7.5—7.8 (1H, triplet)	11
10[a]	8.3—8.5 (4H, doublet)	X
	7.8—7.9 (4H, doublet)	B
	7.4—7.7 (4H, triplet)	A
11[a]	8.7—8.9 (2H, doublet)	4, 10
	8.3—8.5 (4H, triplet)	1, 6, 7, 12
	7.9—8.1 (2H, doublet)	2, 8
	7.4—7.7 (2H, triplet)	5, 11
5a[b]	8.2—8.6 (6H, multiplet)	1, 2, 5, 6, 7, 12
	7.7—8.0 (2H, doublet)	9, 10
	7.5—7.7 (2H, triplet)	8, 11
7[a]	11.4—11.6 (singlet)	N
	8.0—8.5 (multiplet)	
	7.4—7.9 (triplet)	

a) Measured at 25 °C. b) Measured at 150 °C.

Both **4a** and **4b** exhibited similar peaks to **2** except the peak δ 11.5—11.6 — the addition of D_2O to the solution of **2**, caused the peak at 11.5—11.6 to diminish. The potassium salt showed a similar relation. Thus in the spectrum of **2**, the δ 11.5—11.6 peak has been assigned to the proton of the imide group, and δ 8.8—9.1 and 7.5—7.8 to the single proton in the perylene ring.

The structures of the perylenedisulfonic acids have not been confirmed as 3,9- or 3,10-disulfonic acids, and it is expected that there will be no significant differences in the spectra due to the symmetrical structures. Consequently the structure of the 3,9-derivative (**11**) has been tentatively assigned on the following basis (Table 1): the δ 8.3—8.5 triplet signals appear to overlap the two doublet signals, and the δ 8.7—8.9 signal has been attributed to the 4 and 10 positions, since the steric effect of the sulfo group is larger than that of the others.

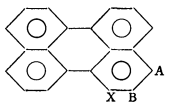
The NMR spectrum of **5a**† shows that the imide group does not influence the protons at the 8, 9, 10, and 11 positions.

† In order to examine the influence of the imide group the NMR spectrum of **5a** was taken at 150 °C—**5a** has the greatest solubility among the other *N*-substituted PDCI.

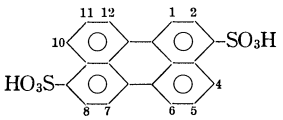
Table 2. Electron densities and the chemical shifts of **5a**

Position	Electron densities		Chemical shifts (ppm)	
	Hückel	Pople	**5a**	Perylene
1, 6	1.007	1.297	8.2—8.6	8.3—8.5
2, 5	0.895	0.596	8.2—8.6	7.4—7.7
7, 12	0.914	0.785	8.2—8.6	8.3—8.5
8, 11	1.001	1.124	7.5—7.7	7.4—7.7
9, 10	0.918	0.826	7.7—8.0	7.8—7.9

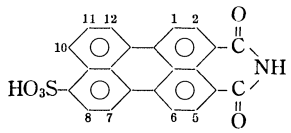
The ring proton shift has been found to be approximately proportional to the calculated charge densities on the attached ring-carbon sites.[7] In the polycyclic molecules however, the resonance shifts of a particular ring proton need be corrected for the ring current of the neighbouring rings.[8] There have been several theoretical studies of NMR chemical shifts in polycyclic aromatic hydrocarbons on the basis of the ring current theory.[5,6,9,10] For a complex molecule such as **5a** both the charge densities and ring currents must be considered. The electron densities of **5a** (see later) and the chemical shifts of the protons are shown together with the chemical shifts of perylene in Table 2. The lowest density position showed the largest proton shift to lower field for perylene.



10



11



2a

The NMR spectra of **4a** at 150 °C gave sharper peaks than at room temperature. The peaks at δ 9.0—9.2, 8.1—8.2, and 7.5—7.8 almost coincide with the peaks at 8.7—8.9, 7.9—8.1, and 7.4—7.7 of perylenedisulfonic acids. Therefore on the basis of the NMR spectra of the related compounds, **2** has been estimated as the 9-sulfonic acid (**2a**), and the position of the proton assigned as in the Table. Substitution of the sulfo group confirmed that the peak near δ 9.1 was not observed, as shown in the spectrum of **7**.

Preparation of the Amine from the Sulfonic Acid. By the reaction of the sulfonic acid **2** with NH_3, the corresponding amine **8a** has been prepared and compared with the amine **8b**, prepared by the Schmidt reaction from 9-carboxy-3,4-perylenedicarboximide (**9**). These compounds were very difficult to purify due to poor properties of sublimation and solubility in the solvent. Subsequent analysis gave rather low N analysis (%) but the effect of impurities on the spectra as shown in Fig. 1 is negligible since paper chromatography gave only one spot. Both the IR (Fig. 1) and mass spectra of **8a** and **8b** showed the same spectra.

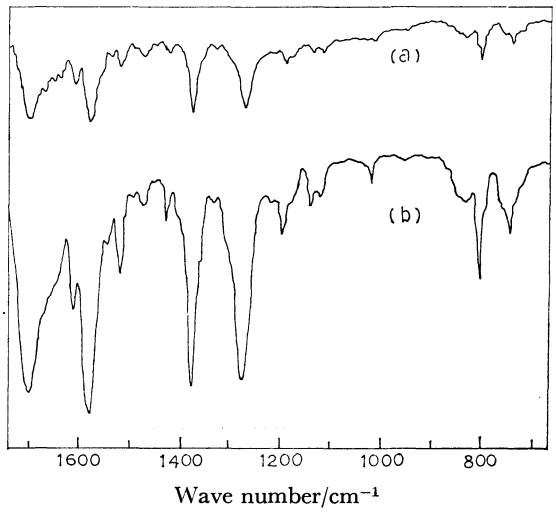


Fig. 1. IR spectra of aminoperylene-3,4-dicarboximide; (a) **8b**, (b) **8a**.

Localized Treatment of the Hückel and Pople Method. The total energies of the calculated models (Fig. 2) for perylene and PDCI by the methods of Hückel[11,14] and Pople[12,13] have been calculated for the localized treatment of electrophilic aromatic substitution.[15,16] The parameters used are shown in Table 3 and the calculated total energies are shown in Table 4. The results show that 9-substitution for PDCI and 3-substitution for perylene have the lowest energy and thus the quantum chemical calculations support the conclusions.

Sulfonation of PDCI. Yields of Sulfonation: From paper chromatography, the reaction products were

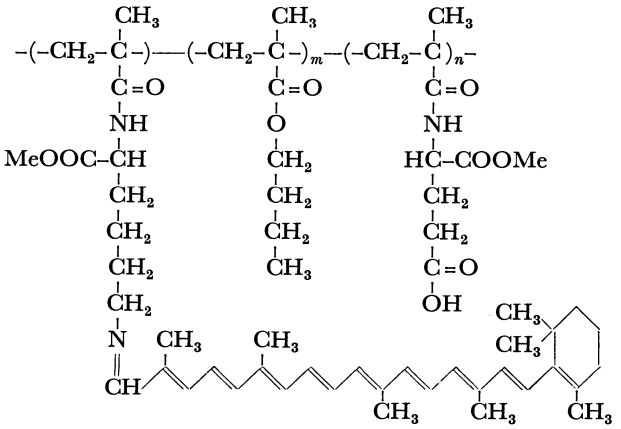
Preparation of Model Polymers for Visual Pigment and Spectral Changes

Masato NANASAWA* and Hiroyoshi KAMOGAWA
Faculty of Engineering, Yamanashi University, Takeda, Kofu 400
(Received July 11, 1978)

N-(8′-Apocarotene-8′-ylidene)butylamine (Bu-SB) has been protonated with amino acid derivatives in aqueous solution and the absorption maxima of the protonated products observed at 500 nm. Copolymers (from N^{α}-methacryloyl-L-lysine methyl ester and α-methyl *N*-methacryloyl-L-glutamate) bearing long conjugated double bonds as a side chain have been synthesized for the simulation of rhodopsin. The absorption spectra shifted to longer wavelengths, and the absorbances amounted to 4—8%, based on the maximum peaks.

The literature is extensive concerning the photochromic process in visual pigments and a number of interesting observations and results have been reported.[1] Nevertheless the mechanism remains unclarified. Absorption maxima (λ_{max}) of pigments bonded to opsin by Schiff base (SB) linkages are observed at approximately 500 nm, although the 11-*cis*-retinylidene analogue in solution absorbs in the ultraviolet. The bathochromic shift was thought due to the protonation of the SB linkage,[2] this hypothesis being qualitatively supported by indirect methods and theory.

The absorption spectra of long pendant conjugated chains attached to peptide backbones was reported to shift approximately 120 nm to longer wavelengths by the addition of acceptors with strong electron affinities and small molecular sizes.[3] It is difficult to produce an experimental model identical with rhodopsin in which the absorption peak shifts reversibly to the red region, but the following models have been prepared with the intention of simulating a visual pigment and examining spectral changes: amino acid derivatives have been employed as protonating agents for low molecular SB, since the acid components reported to date were mineral acids[4] and organic acids possessing a strong proton transfer constant such as trichloroacetic acid;[5] other models have been vinyl polymers bearing N^{ε}-(8′-apocarotene-8′-ylidene)-L-lysine methyl esters and α-methyl L-glutamates as side chains. The spectral changes of the amino acid derivatives have been investigated.



m: 0—4, *n*: 0—2.

The methacryloyl chain has been employed as the polymer backbone in place of peptides, since poly(amino acid)s are insoluble in organic solvents by denaturation during cleavage of the protecting groups and subsequent purification, bringing about low yields

of SB and difficulties in measurement of the shift magnitude in a heterogeneous system. N^{α}-Methacryloyl-N^{ε}-benzyloxycarbonyl-L-lysine methyl ester [Vinyl-Z-Ly(OMe)] has been prepared by the esterification of Z-Ly with thionyl chloride–methanol,[6] followed by amidation with methacryloyl chloride. Attempts to esterify γ-benzyl L-glutamate by conventional means were unsuccessful due to ready hydrolysis and ester exchange. Consequently γ-benzyl α-methyl N-methacryloyl-L-glutamate [Vinyl-Glu-OBzl(OMe)] has been prepared by the amidation of Glu-OBzl in cold alkaline solution with methacryloyl chloride, followed by the esterification with ethereal diazomethane solution. In order to examine the effect of neighboring groups and increase in solubility of the polymers, the vinyl amino acid derivatives have been copolymerized with butyl methacrylate (BMA) in dioxane by conventional free radical polymerization. The protecting groups at the amino acid ω-position have been cleaved with hydrogen bromide.

Table 1 gives the polymers and the SB linkages synthesized. The ω-group contents are seen to be slightly lower than the calculated values due to the preferential polymerization of BMA and the presence of protecting groups. The copolymer of Vinyl-Glu (OMe) and Vinyl-Ly(OMe) which consisted of 1:1 or 2:1 molar ratios did not bond with 8′-apocarotene-8′-al presumably due to salt formation of the amino groups with neighboring carboxyl groups in the polymer molecule. It was reported that only 11-*cis*- and 9-*cis*-retinal combine with opsin to form pigments and that only the 11-*cis* pigment has an absorption spectrum identical with that of rhodopsin.[7] In this study, however, the effect of the isomers of carotenal was not examined and 8′-apocarotene-8′-al, which was readily obtained by the potassium permanganate oxidation of β-carotene[8] and put up resistance to oxidation, was used as a pigment.

The absorption maxima (λ_{max}) of Poly-SB shifted to shorter wavelengths compared with Bu-SB (Table 1). This tendency increased after isolation and drying for Poly-SB (*e.g.* Poly-Ly-1: λ_{max}, 427 nm; $E_{1\%}$, 118), which may indicate that the delocalization of the π-electrons involved in the long pendant conjugated chain is affected by steric hindrance. The absorptivities were lower than the calculated values based on the amino group content in the polymer and the $E_{1\%}$ of Bu-SB, especially that of Copoly-SB being below 10. The measurements were conducted in the concentration range satisfying Lambert's Law, so that the low absorptivities indicate that SB formation is affected by the polymer backbones and the amount of amino group available for SB formation is decreased by salt formation in the polymer.

The spectrum of Bu-SB protonated with hydrochloric acid shifted 95 nm to longer wavelengths as previously reported.[9] For amino acid derivatives with low acidic dissociation constants (pK_a), Bu-SB remained unprotonated in non aqueous solvents but protonated in strong organic acids such as p-toluenesulfonic acid. In aqueous solvents, however, the spectrum of Bu-SB shifted to the red on mixing with amino acid derivatives,

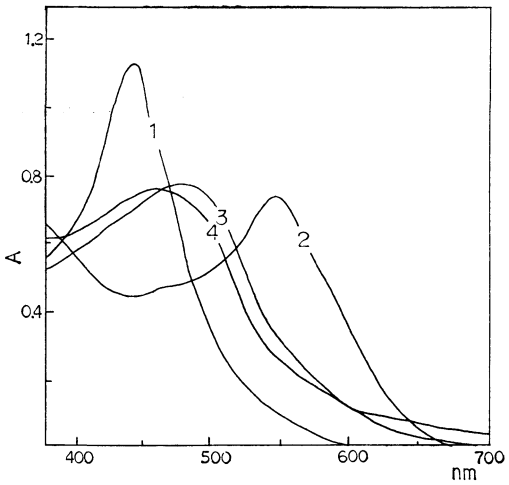

Fig. 1. Absorption spectra of Bu-SB with amino acids. 1; Bu-SB, 2; Bu-SB with HCl, 3; Bu-SB with Z-Glu, 4: Bu-SB with Poly-Glu(OMe). Solvent: 80% DMF.

although new peaks were observed at shorter wavelengths than that with hydrochloric acid (Fig. 1). The cause of this may be the difference in electrostatic energies of the counter ions.[10] The region of the maximum peaks are not clear with α- and γ-carboxy groups of amino acids. The absorptivity of Bu-SB protonated with poly(α-methyl N-methacryloyl-L-glutamate) [Poly-Glu(OMe)] was approximately half the value with low molecular amino acids, probably due to limited protonation by steric hindrance.

The spectra of Poly-Ly-SB protonated with amino acids were similar to those of Bu-SB, but the shifts were smaller. The amino acids as proton donors were in a large excess to the amino residue of Poly-Ly, and consequently neutralization was negligible. The positive charge on the nitrogen of the protonated lysine delocalized throughout the π-electron system is presumably interfered with the torsion of the conjugated chains and a small amount of acid components may be brought in

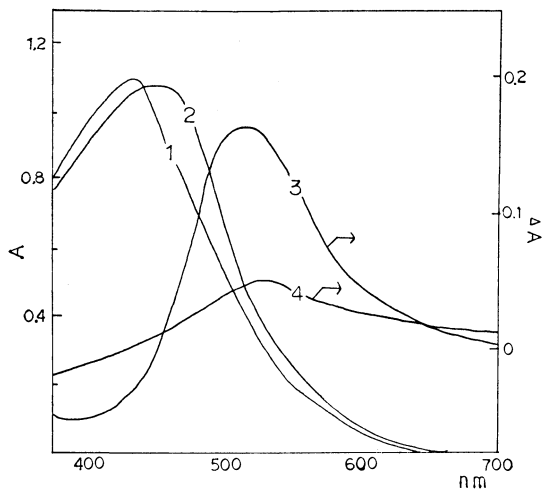

Fig. 2. Absorption spectra of Poly-SB and Copoly-SB 1: Poly-Ly-SB, 2: Poly-Ly-SB with Poly-Glu(OMe), 3: ΔA for Poly-Ly-SB with Z-Glu, 4: ΔA for Copoly-SB. Solvent: 80% DMF.

the proximity of the C=N bond due to steric hindrance of the polymer backbone or the long side chains. The low absorbance of Poly-Ly-SB with acids possessing large molecular sizes are analogous to those of Bu-SB and may be interpreted in terms of the steric hindrance discussed above. The bathochromic shift decreased in the order Z-Glu and Poly-Glu(OMe) (72, 47 nm respectively), indicating that the poorly dissociated carboxylic acid is incompletely bonded to the nitrogen in the hydrophobic region of the polymer matrix, thereby bringing about the poor delocalization of the positive charge throughout the conjugated double bonds.

The spectrum of Copoly-SB, which possesses an environment analogous to rhodopsin slightly shifted towards a longer wavelength by the addition of water. In order to obtain more obvious magnitude of the shift, the difference in absorbance (ΔA) plotted against the wavelength of Copoly-SB and Bu-SB in aqueous solution, the ΔA at the maximum peak being 4% of that for the λ_{max} of Copoly-SB (Fig. 2). This low absorbance appears to be due to there being fewer opportunities for collision between the SB linkage and the carboxylic acids fixed as side chains in the copolymer, since the addition of a lower molecular acid instead of an acid component as the side chain increases the absorbance (9%). The ΔA_{max} of Copoly-SB and with the addition of low molecular acids in aqueous solution was located at a slightly longer wavelength (5—10 nm) compared with Poly-SB and Bu-SB with the addition of amino acids. This suggests that the pendant polar groups such as the carboxylate anions and the salts in the vicinity of the chromophore pull the positive charge into the conjugate chain,[11] thus increasing the contribution to the resonance structure.

It is experimentally impossible to produce a highly selective and restrictive model which forms a SB in the aqueous phase and protonates quantitatively. It has been possible, however, to synthesize a simple polymer model simulating rhodopsin, in which the absorption spectrum shifted towards the longer wavelength *via* intramolecular protonation without the addition of external acid components. The magnitude of the shift, however, was small.

Experimental

The infrared, visible, ^{1}H-NMR and mass spectra were obtained using a Hitachi 215, a Hitachi 200-10, a JEOL-PXM60 and a Hitachi RMU-6MG spectrometer respectively. Elemental analyses were conducted using a Perkin-Elmer 250 instrument. 8′-Apocarotene-8′-al was prepared by the $KMnO_4$-oxidation of β-carotene and purified by aluminum oxide chromatography (Woelem-neutral), followed by partition separation.

Preparation of Vinyl-Z-Ly(OMe): Z-Ly(OMe) was prepared with Z-Ly and methanol–thionyl chloride.[6] To Z-Ly(OMe) HCl (10 g, 30.3 mM) in DMF–THF (2: 5, 70 ml) was added triethylamine (8.9 ml, 60 mM) and the Et_3N–HCl precipitated was filtered off. Methacryloyl chloride (3.5 ml) was added to the filtrate maintained below 5 °C. Stirring was maintained overnight in an ice bath, after which the mixture was filtered and washed with benzene. The filtrate, washed with dil.HCl, 10 % $NaHCO_3$ and water, was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The oily residue was purified by precipitation with a mixture of carbon tetrachloride and hexane. Yield 11.0 g. Found: C, 62.23; H, 7.08; N, 7.13%. Calcd for $C_{19}H_{26}N_2O_5$: C, 62.64; H, 7.14; N, 7.69%. IR (CCl_4): 3400 (NH), 1730 (ester C=O), 1700 (carbamate C=O), 1670 (amide C=O), 945 (C=C) cm^{-1}. ^{1}H-NMR (CCl_4), δ: 1.4—1.7 (m, 6H, lysine CH_2), 1.9 (s, 3H, methacryl CH_3), 3.1 (d, 2H, lysine δ-CH_2), 3.6 (s, 3H, ester CH_3), 4.3 (s, 1H, lysine α-CH), 5.1 (s, 2H, benzyl CH_2), 5.3, 5.6 (s, 2H, CH_2–C), 7.3 (s, 5H, phenyl) ppm. Mass (*m/e*): 364 (M^+, 5 % to CH_2=C–CH_3^+).

Preparation of Vinyl-Glu-OBzl(OMe): A finely powdered Glu–OBzl (7.13 g, 30 mM) was vigorously stirred for one minute with Et_3N (5 ml) in H_2O (50 ml) in an ice bath, followed by the immediate addition of methacryloyl chloride (3 ml) below 5 °C. The mixture was vigorously stirred for 15 min, after which the reaction mixture was extracted with two portions of chloroform (100 ml). The extract, washed with dil.HCl and water was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The Vinyl-Glu-OBzl thus obtained was esterified with an ethereal diazomethane solution and the solution washed with 10 % $NaHCO_3$ and water, dried over anhydrous sodium sulfate and concentrated *in vacuo*. The reaction product was purified by precipitation with a mixture of carbon tetrachloride and hexane. Yield 4.7 g. Found: C, 63.34; H, 6.36; N, 5.23%. Calcd for $C_{17}H_{21}NO_5$: C, 63.95; H, 6.58; N, 4.39%. IR (CCl_4); 3400 (NH), 1740 (ester C=O), 1675 (amide C=O), 920 (C=C) cm^{-1}. ^{1}H-NMR (CCl_4), δ: 1.9 (s, 3H, methacryl CH_3), 2.2—2.4 (m, 4H, glutamate CH_2), 3.8 (s, 3H, ester CH_3), 4.6 (t, 1H, α-CH), 5.1 (s, 2H, benzyl CH_2), 5.3, 5.8 (s, 2H, CH_2=C), 7.4 (s, 5H, phenyl) ppm. Mass (*m/e*): 319 (M^+, 15 % to benzyl ion).

Preparation of Poly-SB: A portion of the monomer (5 g), the composition of which is listed in Table 1, the α,α'-azobisisobutyronitrile (50 mg) and dioxane (10 ml) were placed in a Pyrex glass ampoule which had been previously flushed with nitrogen, sealed, and heated at 75 °C for 48 h. The polymer thus obtained was precipitated by ether, washed with ether, and dried *in vacuo*. The polymer (1 g) was dissolved in trifluoroacetic acid (3 ml). Cleavage of the protecting groups was conducted with a 30 % solution of hydrobromic acid in acetic acid (3 ml) at 50 °C for 1 h. The polymer thus obtained was tranformed into the free state of the ω-position by the following procedure: Poly-Ly HBr in H_2O (10 ml) was basified with Et_3N, precipitated into acetone, and freeze-dried from H_2O; Poly-Glu(OMe) was dissolved in 5% Na_2CO_3 solution and acidified with dil.HCl to pH 2, the polymer thus precipitated was washed with water and dried *in vacuo*; the copolymer dissolved in a mixture of THF and H_2O was neutralized with 0.1 M NaOH to the isoelectric point[12] and stirred at this point for 10 h. The polymer thus precipitated was washed with water and freeze-dried from dioxane. IR (KBr) and ^{1}H-NMR (DMSO-d_6) indicated no absorption peak at 695 cm^{-1} and 7—8 ppm.

Poly-SB was prepared as follows: 0.5 mM of polymer (based on lysine residue) and 1 mM of 8′-apocarotene-8′-al were stirred in DMF (10 ml) with a molecular sieve (3A) under nitrogen and allowed to stand in the dark for several days. The reaction mixture was poured into ether, dissolved in DMF without drying, and the DMF solution extracted with petroleum ether using a Soxhlet liquid extractor to attain a sufficient removal of remaining 8′-apocarotene-8′-al. The spectra were measured in a 1 mm cell approximately 5 min after 10^{-3} M/l of SB (1 ml) and 10^{-3} M/l of amino acid derivatives (10 ml) in DMF were mixed.

The Ullmann Condensation Reaction of Haloanthraquinone Derivatives with Amines in Aprotic Solvents. IV. Kinetic Studies of the Condensation with Ethylenediamine

Sadao ARAI, Akira TANAKA, Mitsuhiko HIDA,* and Takamichi YAMAGISHI

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received September 8, 1978)

In the Ullmann condensation of bromoanthraquinones (AQBr) with ethylenediamine using copper(I) bromide as a catalyst, the reaction rate decreased with time which has been interpreted in terms of the formation of the ineffective copper(II) species. The kinetic investigation showed the reaction rate to be first order both for the copper(I) species and AQBr. After prolonged reaction the copper(I) species was quantitatively converted to the copper(II) species, the copper(II) species appearing to have little catalytic activity due to strong coordination with ethylenediamine. The reactivities of the haloanthraquinones were dependent on the ease of coordination with Cu(I) and the rate of Cu(II) formation. The mechanism, including the reaction between Cu^{I}(AQBr) and ethylenediamine, has been proposed and discussed.

Aryl halides readily undergo nucleophilic replacement of the halogen atom by moieties such as OR and NH_2, with the aid of a copper catalyst. The reaction mechanism, has however, been the subject of little research and the catalytic action of the copper species remains obscure.

The authors have reported the mechanism of the Ullmann condensation reaction for haloanthraquinones with amines using copper salts as the catalyst in protic and aprotic solvents.[1-4] In aprotic solvents, the effective copper(I) species oxidizes to the ineffective copper(II) species during the course of reaction and the formation of the copper(II) species has been shown to have an important role in the reaction.[2,3] Thus, in the condensation with 2-aminoethanol, the resulting copper(II) species increased the catalytic activity of the copper(I) species. The pseudo-first order rate constant may be expressed as follows:

$$k = k_1[Cu^{I}] + k_2[Cu^{I}][Cu^{II}].^{4)}$$

In this paper the reaction of haloanthraquinones with ethylenediamine, will be reported which is more reactive than 2-aminoethanol, by copper(I) catalyst in aprotic media.

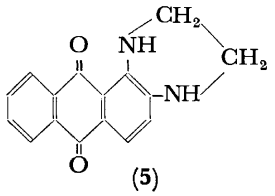
4: R=NH_2

Experimental

General. 1-Bromoanthraquinone (**1**), 1-amino-4-bromoanthraquinone (**2**), and copper(I) bromide were prepared by the methods described in a previous paper.[2] Commercially available ethylenediamine was dried over sodium, distilled, and stored under nitrogen. The solvents used were dried by standard procedures, distilled, and stored under nitrogen. The details of the kinetic measurements have been described in Part I of this series.[2] The anthraquinone and 1-aminoanthraquinone formed in the course of reaction were analyzed by high speed liquid chromatography in a manner similar to that described in a preceding paper[4]: column, Zorbax ODS 25 cm; mobile phase, methanol–water 67: 33; temperature, 40 °C; detector, UV-254 nm. ESR spectra were measured as described in preceding papers.[3,4] IR and UV and visible spectra were recorded with JASCO IRA-1 and Shimadzu UV-200 spectrophotometers respectively. NMR spectra were obtained on a Hitachi R-24 spectrometer for solutions in dimethyl-d_6 sulfoxide with tetramethylsilane as an internal reference. Mass spectra were taken on a JEOL JMS-D 100 mass spectrometer by direct insertion.

Condensation Products. The condensation product, 1-(2-aminoethylamino)anthraquinone (**3**), was very liable, cyclizing thermally to give compound (**5**).[5] The condensation reaction of **1** and **2** with ethylenediamine in 1,2-dimethoxyethane–methyl cellosolve (4: 1) solution were conducted at temperatures below 100 °C in order to avoid possible side reactions, *e.g.*, cyclization of the condensation products.



(**5**)

The condensation products were obtained from the reaction mixture in a following manner: The solvents were removed under reduced pressure and the reaction mixture poured into water. After filtration, the products were washed with water and dried and the precipitate chromatographed on a silica gel column with benzene–methanol (4: 1, v/v) as the eluent. No formation of ring closed compounds were observed.

1-(2-Aminoethylamino)anthraquinone (3): λ_{max}(C_2H_5OH) 501 nm (ε 6460); IR (KBr) 1660 cm^{-1} (C=O); NMR δ=2.37 (2H, disappearing on deuteration, NH_2), 2.85 (2H, $-CH_2-$), 3.25 (2H, $-CH_2-$), 6.95—8.35 (7H, quinone ring), 9.80 (1H, NH); MS, *m/e*=266 (M^+).

1-Amino-4-(2-aminoethylamino)anthraquinone (4): λ_{max}(C_2H_5-OH) 501 nm (ε 15700), 571 nm (ε 14100); NMR δ=2.85 (2H, $-CH_2-$), 3.44 (2H, $-CH_2-$), 7.10—8.40 (6H, quinone

ring), 10.91 (1H, disappearing on deuteration, NH); MS, m/e=281 (M^+).

Results and Discussion

The reactivities of the haloanthraquinones in the presence or absence of copper(I) catalyst have been compared in Fig. 1 and indicate the following observations:

(i) The copper(I) catalyst greatly enhanced the reactivities of the haloanthraquinones.

(ii) 1-Bromoanthraquinone (**1**) was more reactive than 1-amino-4-bromoanthraquinone (**2**), both in the absence and presence of catalyst. The relative initial rates have been calculated as follows: **1** (without catalyst): **2** (without catalyst): **1** (with catalyst): **2** (with catalyst)=20: 1: 5900: 5500.

(iii) The catalytic activity decreased as the reaction proceeded, a tendency more marked in reaction **2** than in **1**.

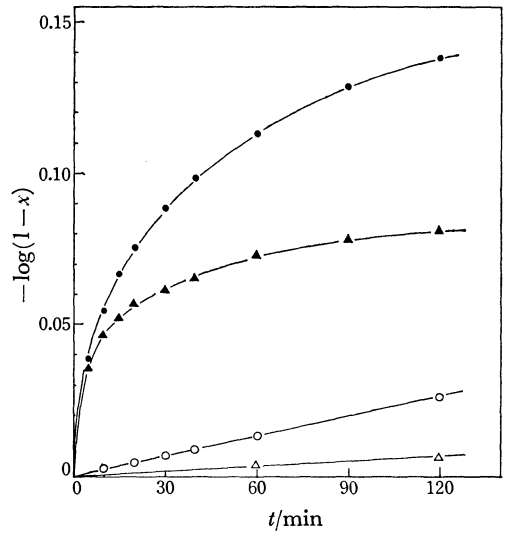


Fig. 1. Pseudo-first order plots of the reaction between bromoanthraquinones and ethylenediamine. $[AQBr]_0 = 5\times10^{-3}$ mol/l, $[EN]_0$=0.5 mol/l, $[CuBr]_0 = 1\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4: 1.
●: 1-BrAQ(**1**)–EN–CuBr, ▲: 1-NH_2-4-BrAQ(**2**)–EN–CuBr, ○: 1-BrAQ–EN, △: 1-NH_2-4-BrAQ–EN.

The above results may be explained in terms of the change in catalyst from copper(I) to copper(II). The following kinetic studies of the reaction between the haloanthraquinones and ethylenediamine reasonably support this reasoning.

Kinetics of Catalyst-free Reactions. Figure 1 shows that both the reactions of **1** and **2** in the absence of copper(I) bromide catalyst can be interpreted in terms of pseudo-first order kinetics. Since ethylenediamine (EN) was in a large excess, the second order rate constants were obtained by dividing the pseudo-first order rate constants by the concentration of amine. The second order rate constants of **1** and **2** (k_I and k_{II}) are expressed by Eqs. 1 and 2:

$$k_I\ (l\cdot mol^{-1}\cdot min^{-1}) = (3.2[EN]+7.0)\times10^{-4}, \quad (1)$$

$$k_{II}\ (l\cdot mol^{-1}\cdot min^{-1}) = (7.16\pm1.22)\times10^{-5}. \quad (2)$$

Bunnett *et al.* reported that the nucleophilic substitution reactions of halonitrobenzenes with amines were accelerated, strongly or mildly with an increase in the concentration of amine or by the addition of bases.[6] Under these conditions the second order rate constant largely conform to Eq. 1. This observation has been interpreted by the following scheme:

$$ArX + RNH_2 \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} \left[\begin{matrix} & X \\ Ar & \\ & NH_2R \\ & + \end{matrix}\right] \underset{k_c[RNH_2]}{\overset{k_b}{\circlearrowright}} ArNHR. \quad (3)$$

Application of steady state hypothesis to this mechanism gives a second order rate constant (k') expressed by

$$k' = \frac{k_a k_b}{k_{-a}+k_b+k_c[RNH_2]} + \frac{k_a k_c[RNH_2]}{k_{-a}+k_b+k_c[RNH_2]}. \quad (4)$$

Assuming k_{-a} is much larger than $(k_b+k_c[RNH_2])$ in the reaction of **1**, k_I may be expressed as follows:

$$k_I = \frac{k_a k_b}{k_{-a}} + \frac{k_a k_c[RNH_2]}{k_{-a}}. \quad (5)$$

By comparing Eq. 5 with Eq. 1, $k_a k_b/k_{-a}$ and $k_a k_c/k_{-a}$ have been evaluated as 7.0×10^{-4} $l\cdot mol^{-1}\cdot min^{-1}$ and 3.2×10^{-4} $min^{-1}\cdot l^2\cdot mol^{-2}$, respectively. Thus, the ratio of k_c to k_b has been calculated as 0.46 $mol^{-1}\cdot l$ indicating that the reaction of **1** with ethylenediamine is mildly accelerated. Assuming k_{-a} is much less than $(k_b+k_c[RNH_2])$, Eq. 4 simplifies to $k'=k_a$ and the reaction is not base catalyzed. The reaction of **2** may correspond to this instance.

Kinetics of Copper(I) Catalyzed Reactions. The pseudo-first order plots for the reaction using copper(I) bromide as a catalyst were not linear (Fig. 1) presumably indicating that the reaction rate decreased with the formation of the ineffective copper(II) species. The rate equation has been interpreted as first order in concentration of bromoanthraquinones (AQBr) and copper(I) species. Thus,

$$-\frac{d[AQBr]}{dt} = (k_0+k_1[CuBr])[AQBr], \quad (6)$$

where k_0 denotes the pseudo-first order rate constant ($k_1[EN]$ or $k_{II}[EN]$) of the catalyst-free reactions.

ESR measurements suggested that the copper(I) species was oxidized to the copper(II) species exponentially increased during the course of reaction. Then, the concentration of CuBr may be mathematically expressed by Eq. 7:

$$[CuBr] = a\cdot\exp(-\gamma t) + b. \quad (7)$$

The initial concentration of CuBr is given by

$$[CuBr]_0 = a + b, \quad (8)$$

and the concentration of CuBr approaches b after prolonged reaction.

Combining Eq. 6 with Eq. 7 and integrating gives Eq. 9.

$$-\ln(1-x) = \frac{k_1 a}{\gamma}(1-e^{-\gamma t}) + (k_1 b+k_0)t \quad (9)$$

This may be rewritten:

$$-\frac{\ln(1-x)}{t} = A\cdot\frac{(1-e^{-\gamma t})}{t} + B, \quad (10)$$

where x denotes the yield of the condensation product, and $A=k_1a/\gamma$ and $B=k_1b+k_0$. By assuming a value of γ, A and B were determined by means of linear regression analysis. The values of the parameters (A, B, and γ), which gave the maximum correlation coefficient, were taken to be the most suitable parameters. The agreement between calculated and observed data was very good, since the correlation coefficients were greater than 99% in all cases.

The rate constant k_1 can be obtained from Eq. 11,

$$k_1 = \frac{\gamma A+B-k_0}{[\mathrm{CuBr}]_0} \tag{11}$$

and the values of k_1 and γ are summarized in Tables 1

Table 1. Rate constant k_1, γ, and the value of $b/(a+b)$ for the reaction of 1-bromoanthraquinone (**1**) with ethylenediamine (EN)

and 2. Tables 1 and 2 show that the rate constant k_1 is approximately independent of the initial concentration of CuBr. The plot of γA against the initial concentration of CuBr gives a straight line supporting the assumption that the condensation with ethylenediamine is first order with respect to copper(I) bromide. The values of the ratio $b/(a+b)$ are given by Eq. 12:

$$\frac{b}{a+b} = \frac{B-k_0}{\gamma A+B-k_0}. \tag{12}$$

As shown in Tables 1 and 2, the value of $b/(a+b)$ was less than about 4% in most cases indicating that the copper(I) species is almost perfectly oxidized to the copper(II) species after prolonged reaction.[7] Under these condensation conditions debrominated products were also produced suggesting that the copper(II) species was formed by an electron transfer from copper(I) to bromoanthraquinone (AQBr+Cu(I)⟶AQBr$^{\cdot}$ +Cu(II)) in a similar manner to the condensation with 2-aminoethanol and that part of the resulting bromoanthraquinone anion radical may be debrominated.[4]

The catalytic activity of copper(I) species in the reaction with ethylenediamine was insensitive to the resulting copper(II) species. This is presumably because ethylenediamine strongly coordinates to the copper(II) species and thereby prevents cooperation between the copper(I) and copper(II) species. It has been reported that copper(II) forms stable chelate complex with ethylenediamine ($[Cu(EN)]^{2+}$ and $[Cu(EN)_2]^{2+}$).[8]

The catalytic activity of the copper(I) species in the reaction with ethylenediamine was 20 times greater than that with 2-aminoethanol. After a statistical correction of 2 was applied, ethylenediamine was more reactive than 2-aminoethanol by a factor of 10. This has been attributed to the fact that electrons are more delocalized in the copper(I) species with a bidentate amine such as ethylenediamine.

Reaction Mechanism. As indicated in Tables 1 and 2, the rate constant k_1 increased with increasing concentration of amine, the plot of $1/k_1$ against 1/[EN] giving a linear relationship (Fig. 2). On the other hand, the rate constant k_1 decreased with increasing concentration of bromoanthraquinone ([AQBr]), the plot of $1/k_1$ against [AQBr] giving a straight line (Fig. 3).

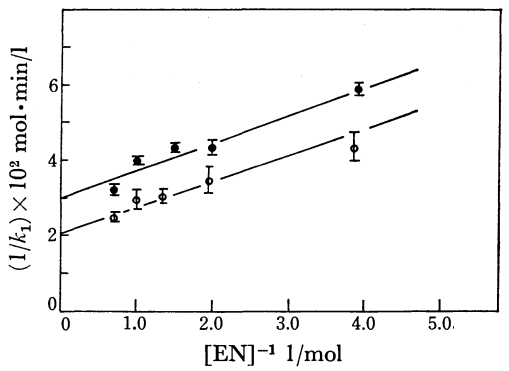

Fig. 2. Plots of $1/k_1$ against 1/[EN]. Temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4: 1.
●: 1-BrAQ–EN–CuBr, ○: 1-NH_2-4-BrAQ–EN–CuBr.

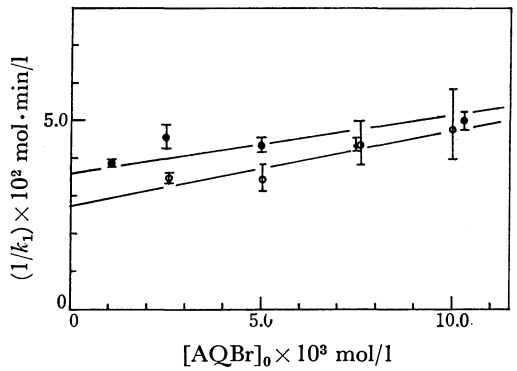

Fig. 3. Plots of $1/k_1$ against [AQBr]. Temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4: 1. ●: 1-BrAQ–EN–CuBr ○: 1-NH_2-4-BrAQ–EN–CuBr.

All results can be interpreted by assuming the following reaction scheme (Eq. 13):

$$\begin{aligned} &Cu^I + EN \overset{K_1}{\rightleftharpoons} Cu^I(EN) \\ &Cu^I + AQBr \overset{K_2}{\rightleftharpoons} Cu^I(AQBr) \xrightarrow[k_r]{EN} \text{product.} \end{aligned} \tag{13}$$

On the basis of this (Eq. 13), the rate constant k_1 is expressed by

$$k_1 = \frac{k_r K_2[EN]}{1+K_1[EN]+K_2[AQBr]}. \tag{14}$$

The concentration of AQBr under smal conversion is approximately equal to the initial concentration ($[AQBr]_0$). Thus equation 14 may be rewritten:

$$k_1^{-1} = \frac{k_1}{k_r K_2} + \frac{1+K_2[AQBr]_0}{k_r K_2} \cdot \frac{1}{[EN]}, \tag{15}$$

$$k_1^{-1} = \frac{1+K_1[EN]}{k_r K_2[EN]} + \frac{K_2}{k_r K_2[EN]} \cdot [AQBr]_0. \tag{16}$$

The values k_r, K_1, and K_2 can be evaluated from the slope and the intercept of Figs. 2 and 3, and the concentrations of AQBr and EN, the values of which are shown in Table 3. Since the equilibrium between Cu^I and EN does not include haloanthraquinone, there should not be any difference in the magnitude of K_1 between **1** and **2**. Table 3 shows that K_1 in the reaction of **1** is approximately equal to that in the reaction of **2**, which supports the above mechanism.

The parameter γ corresponds to the decreasing rate of copper(I) species. As shown in Tables 1 and 2, the magnitude changes with the initial concentrations of haloanthraquinone and copper(I) bromide, but it is little affected by the concentration of amine. The kinetics of the formation of the copper(II) species, however, is not yet clearly understood.

Table 3. Rate parameters

Rate parameter	1-BrAQ (**1**)	1-NH_2-4-BrAQ (**2**)
k_r ($mol^{-1}\cdot l\cdot min^{-1}$)	1.24	0.98
K_1 ($l\cdot mol^{-1}$)	8.9	10.0
K_2 ($l\cdot mol^{-1}$)	243	500

Temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4: 1, $[AQBr]_0=5\times 10^{-3}$ $mol\cdot l^{-1}$, $[EN]_0=5\times 10^{-1}$ $mol\cdot l^{-1}$.

As previously reported, in the presence of copper(I) catalyst, **1** is more reactive than **2** and this may be reasonably explained as follows: The rate constant k_r of **2** is smaller than that of **1**, while the equilibrium constant between Cu(I) and **2** has a greater value than that between Cu(I) and **1**. Thus, **2** has an initial rate similar to that of **1**. The reaction rate of **2**, however, diminishes more rapidly than that of **1** with time, an observation caused possibly by the concentration of copper(I) species decreasing more rapidly in the reaction of **2** than in the reaction of **1**, since the magnitude of the parameter γ of **2** is greater than that of **1**.

The authors wish to thank Dr. Kinji Anda and Mr. Masao Usui of the Tokyo Metropolitan Industrial Technical Institute for assistance with the mass spectral measurements.

The Regioselective Amino-exchange Reaction of β-Amino Conjugated Enones

Choji KASHIMA* and Yasuhiro YAMAMOTO

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received September 21, 1978)

By heating with various amines, the amino-exchange reaction of β-amino conjugated enones was regioselectively accomplished on β-carbon to give the corresponding β-amino conjugated enones. The resulting β-dialkylamino conjugated enones could then be used for the synthesis of β,β-disubstituted conjugated enones by treatment with Grignard reagents.

Previously, it has been reported that *cis*-1-substituted-4-amino-3-penten-2-ones were regioselectively prepared from 2,4-pentanedione through 5-substituted 3-methylisoxazoles by catalytic hydrogenation.[1] Benary described[2] how β-dialkylamino conjugated enones reacted with Grignard reagents to afford β,β-disubstituted conjugated enones. However, *N*-unsubstituted and *N*-monosubstituted β-amino conjugated enones are inert toward Grignard reagents, even under forced conditions. Therefore, the conversion from *N*-unsubstituted β-amino conjugated enones to *N*,*N*-disubstituted analogues seems to be the key step in the regioselective synthesis of β,β-disubstituted conjugated enones.

The reactions of β-amino conjugated enones with hydroxylamine[3] and ureas[4] have already been reported. In both cases, nucleophiles attack first the β-carbon of β-amino conjugated enones as a Michael-type addition, and then eliminate the amine or ammonia to afford the corresponding heterocycles. By analogy, we expected the amino-exchange reaction of β-amino conjugated enones upon the treatment with a primary or secondary amine to afford *N*-monosubstituted or *N*,*N*-disubstituted β-amino conjugated enones. (Scheme 1).

When *cis*-4-amino-3-penten-2-one (**1**) was treated with dimethylamine, *trans*-4-dimethylamino-3-penten-2-one (**2a**) was formed in a quantitative yield. In this reaction, the β-amino conjugated enone has two reaction sites, on the β-carbon and on the carbonyl carbon atoms. In the case of the reaction of *cis*-2-amino-2-hepten-4-one (**3**) with dimethylamine, four reaction products, *trans*-2-dimethylamino-2-hepten-4-one (**4a**), *trans*-4-dimethylamino-3-hepten-2-one, and their *cis* isomers, could be expected. When **3** was treated with dimethylamine under the same conditions, however, only one product was obtained. This product was independently prepared from **3** by direct methylation on nitrogen in the presence of sodium hydride. This result showed that the amino-exchange reaction occurred regioselectively on β-carbon to afford 2-dimethylamino-2-hepten-4-one. For determining the configuration, the NMR spectrum of this product was compared with those of **1**, **2a**, **2d**, **2e**, **2f**, and **2h**, which configurations had already been confirmed by means of the IR, UV, and olefinic proton NMR spectra.[5] The allyl methyl proton signal appeared at δ 2.49 ppm, and the molarinduced shift (Δδ) by Eu(fod)$_3$ was larger than that of the olefinic proton signal. This was similar not to the cases of **1** and **2h**, but to those of **2a**, **2d**, **2e**, and **2f** (*cf.* Table 2). These results indicated that *trans*-2-dimethylamino-2-hepten-4-one (**4a**) was more favorable for the reaction product from **3** and dimethylamine.

Similarly, **1** and **3** were treated with various secondary amines to give the corresponding β-amino conjugated enones, **2** and **4**, with *trans* configurations, as are listed in Table 1. On the contrary, the reaction products from primary amines with **3** and **5** were found to be the corresponding *cis*-β-(*N*-monosubstituted)-amino conjugated enones, **4h**, **4i**, and **6j**, which showed allyl methyl protons and the chelated NH signals at about δ 1.9 and 10.5 ppm in NMR respectively. These results suggested that the configurations of the resulting β-amino conjugated enones were easily changed to the thermodynamically stable form under an amino-exchange reaction or on alkylation reaction. In the cases of piperidine, morpholine, diethylamine, diisopropylamine, aniline, *N*-methylaniline, acetamide, and *N*-methylacetamide, the reaction did not occur, even at high temperatures, because of their bulkiness and/or the lack of nucleophilicity.

As applications of this amino-exchange reaction, the syntheses of several terpens, such as ar-turmerone (**9**)[6] and targetone (**12**),[7] were demonstrated. The synthesis of **11** was carried out from *cis*-2-amino-6-*p*-tolyl-2-

hepten-4-one (**7**) through *trans*-2-(1-pyrrolidinyl)-6-*p*-tolyl-2-hepten-4-one (**8d**). Similarly, **12** was synthesized by the reaction of *cis*-2-amino-6-methyl-2-hepten-4-one (**10**) and pyrrolidine, followed by the reaction with vinylmagnesium bromide. The total yields of **9** and **12** were 22 and 9%, based on the corresponding *N*-unsubstituted β-amino conjugated enones respectively.

In conclusion, the treatment of *N*-unsubstituted β-amino conjugated enones with various amines afforded *N*-substituted β-amino conjugated enones by the regioselective amino-exchange reaction. The resulting β-dialkylamino conjugated enones should be very useful intermediates for the synthesis of β,β-disubstituted conjugated enones in combination with the Grignard reaction.

Experimental

The Preparation of N-*Unsubstituted β-Amino Conjugated Enones.* *cis*-4-Amino-3-penten-2-one (**1**) was prepared from 2,4-pentanedione by treatment with anhydrous ammonia in anhydrous ethanol.[8] By hydrogenation on platinum, *cis*-2-amino-2-hepten-4-one (**3**) was prepared from 3-methyl-5-propylisoxazole, which had itself been obtained by the action of ethyl bromide on 3,5-dimethylisoxazole in the presence of sodium amide in liquid ammonia.[1] The configurations of all the β-amino conjugated enones were confirmed by the chemical shifts of the allyl methyl and the chelated NH proton signals, and the

shifts of the allyl methyl and olefinic proton signals induced by Eu(fod)$_3$, on NMR in chloroform-d_1, as are listed in Table 2.

cis-*2-Amino-6-*p*-tolyl-2-hepten-4-one (7).* According to the alkylation method,[1] 3,5-dimethylisoxazole was treated with 1-bromo-1-*p*-tolyl-ethane to afford 3-methyl-5-[1-methyl-2-(*p*-tolyl)ethyl]isoxazole; yield, 37 %. Bp 110 °C/3 mmHg. IR (liquid film): 2950, 1610, 1530, 1450, 1420, 1120, and 815 cm^{-1}. Found: C, 78.09; H, 7.93; N, 6.13%. Calcd for $C_{14}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51 %. This isoxazole derivative was then hydrogenated to Compound **7**, which was purified by distillation *in vacuo*; yield, 95%. Bp 137 °C/4 mmHg. IR (liquid film): 3350, 3200, 2950, 1615, 1530, 1410, 1020, and 815 cm^{-1}.

cis-*2-Amino-6-methyl-2-hepten-4-one (10).* By the hydrogenation of 3-methyl-5-isobutylisoxazole, **10** was obtained and purified by recrystallization from hexane; yield, 57%. Mp 56—57 °C, bp 102—105 °C/5 mmHg. Found: C, 67.82; H, 10.57; N, 9.82%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.82%.

General Procedure of Amino-exchange Reaction. A solution of β-amino conjugated enone (5 mmol) and primary or secondary amine (6 mmol) in 2 ml of benzene was heated in a sealed tube. The mixture was then cooled to room temperature and concentrated. The crude *N*-substituted β-amino conjugated enone was purified by fractional distillation and/or recrystallization. The product was identified with an authentic sample by means of VPC and the spectral data.

trans-*2-Dimethylamino-2-hepten-4-one (4a).* Compound **4a** was prepared from **3** and dimethylamine. The NMR peaks were shifted by Eu(fod)$_3$ (*cf.* Table 2). Bp 100—110 °C/3 mmHg. Mass (*m/e*): 155 (M), 140 (M−15), 138, 127 (M−28), 112 (M−43), 98, 85, 84, 70, 69, 56, and 44. Found: C, 68.80; H, 11.07; N, 8.82%. Calcd for $C_9H_{17}NO$: C, 69.63; H, 11.03; N, 9.02%.

trans-*2-(1-Pyrrolidinyl)-2-hepten-4-one (4d).* Compound **4d** was prepared from **3** and pyrrolidine. Bp 112—114 °C/5 mmHg. IR (liquid film): 2950, 2910, 1630, 1530, 1340, and 1020 cm^{-1}. Found: C, 72.44; H, 10.40; N, 7.88%. Calcd for $C_{11}H_{19}NO$: C, 72.88; H, 10.57; N, 7.73%.

cis-*2-Methylamino-2-hepten-4-one (4h).* Compound **4h** was prepared from **3** and methylamine. Bp 53—55 °C/5 mmHg. Found: C, 68.33; H, 10.46; N, 9.90%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%.

cis-*2-Butylamino-2-hepten-4-one (4i).* Compound **4i** was prepared from **3** and butylamine. Bp 105 °C/3 mmHg. IR (liquid film): 2950, 2915, 1605, 1580, 1300, and 735 cm^{-1}. Found: C, 72.19; H, 11.21; N, 7.65%. Calcd for $C_{11}H_{21}NO$: C, 72.08; H, 11.55; N, 7.64%.

trans-*2-(1-Pyrrolidinyl)-6-*p*-tolyl-2-hepten-4-one (8d).* Compound **8d** was obtained from **7** and pyrrolidine, and subsequently purified by distillation. Bp 130 °C/5 mmHg. IR (liquid film): 2950, 1630, 1340, 1020, 815, and 730 cm^{-1}.

trans-*2-(1-Pyrrolidinyl)-6-methyl-4-hepten-2-one (11d).* Compound **11d** was obtained by the amino-exchange reaction from **10** and pyrrolidine, and subsequently purified by recrystallization from hexane. Mp 67—68.5 °C. Found: C, 73.26; H, 10.57; N, 7.15%. Calcd for $C_{10}H_{21}NO$: C, 73.79; H, 10.84; N, 7.17%.

The Direct Methylation of 3. Sodium hydride in Bayol was washed with dry ether 2 times. To the suspension of sodium hydride in dry ether, **3** (5 mmol) was then added, drop by drop, at 0 °C to precipitate a pasty mass. Then methyl tosylate (12 mmol) in dry ether was added slowly to the mixture. After the reaction mixture had been stirred at room temperature for 5 h, the reaction mixture was washed with aqueous sodium chloride and dried over anhydrous magnesium sulfate. The ether was evaporated off, and the residue was distilled *in vacuo* to afford **4a**, which was identified with amino-exchange reaction product by means of VPC and the spectral data; yield, 34%.

ar-Turmerone (9). The title compound was obtained from **8d** and methylmagnesium iodide, and the product was identified with authentic sample by means of its spectral data;[6] yield, 28 %.

ar-Dihydroturmerone (14). By the treatment of **11d** with *p*-tolylmagnesium bromide, 2-*p*-tolyl-6-methyl-2-hepten-4-one (**13**) was prepared; yield, 24 %. Bp 70—75 °C/2 mmHg. NMR ($CDCl_3$): 0.92 (d, 6H, J=7.0 Hz), 2.0 (m, 1H), 2.3 (m, 2H), 2.34 (s, 3H), 2.47 (s, 3H), 6.35 (broad s, 1H), 7.04 (d, 2H, J=10.0 Hz), and 7.30 ppm (d, 2H, J=10.0 Hz). IR (liquid film): 2950, 1680, 1600, 1195, 1060, and 810 cm^{-1}. Found: C, 82.23; H, 9.20%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.32%. Compound **13** was hydrogenated on platinum in ethanol to afford Compound **14**; yield, 36 %. Bp 111—114 °C/6 mmHg. NMR (CCl_4): 0.90 (d, 6H, J=7.0 Hz), 1.16 (d, 3H, J=7.5 Hz), 2.06 (m, 3H), 2.27 (s, 3H), 2.48 (m, 2H), 3.21 (m, 1H), and 7.0 ppm (s, 4H). Found: C, 82.95; H, 10.25%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

The title compound was also obtained by the hydrogenation of **9** on platinum in ethanol; the two products were identical in their spectral data.

Targetone (12). The title compound was prepared from **11d** and vinylmagnesium bromide, and subsequently purified by distillation. The product was identified with an authentic sample by means of its spectral data.[8]

The Hydrogen-transfer Reaction of a Diazo Compound Catalyzed by a Cobalt Complex

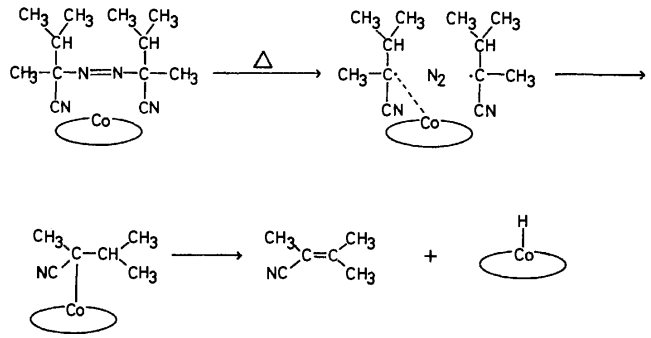
Kenji YOSHINO, Yasukazu OHKATSU, and Teiji TSURUTA*

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 27, 1978)

Acetophenone α-methylbenzylhydrazone was produced by the thermolysis of 1,1′-diphenylazoethane in the presence of a cobalt complex in benzene. In this reaction, the cobalt complex seemed to stabilize the radicals formed from the azo compound by the elimination of α-hydrogen. The stabilized radicals underwent 1,3-rearrangement to form acetophenone α-methylbenzylhydrazone. The driving force of this rearrangement is considered to be the nature of the cobalt atom, which prefers a bond formation with a more electronegative nitrogen atom to a carbon atom.

In our previous study,[1] it was found that scarcely no inner olefin  was produced by the thermolysis of 2,2′,3,3′-tetramethyl-2,2′-azodibutyronitrile in benzene, but the substance was produced in quantity in the presence of a cobalt complex such as Co(II)TPP. The mechanism for the formation of the inner olefin was explained by the following scheme:



Scheme 1.

where the participation of Co(II)TPP was assumed in a certain hydrogen-transfer reaction.

A typical example of a hydrogen-transfer reaction catalyzed by a metal complex is a reaction in the co-enzyme vitamin B_{12}. Particularly, 1,2-hydrogen transfer processes from glycol to aldehyde catalyzed by diol dehydrase were studied; the co-enzyme B_{12} was established as playing an important role in the hydrogen-transfer reaction.[2]

The present paper reports that acetophenone α-methylbenzylhydrazone is produced from 1,1′-diphenylazoethane by thermolysis in the presence of a cobalt complex as a result of a hydrogen-transfer reaction (1,3-rearrangement). This reaction provides not only evidence for a possible interaction between a transition-metal complex and a free radical, but also a model for the rearrangement reaction of vitamin B_{12}.

Experimental

Syntheses of Azo Compounds. (*S*)-(−)-α-Methylbenzylamine and (*R*)-(+)-α-methylbenzylamine were obtained using the resolution method of Theilacker.[3]

The levorotatory amine: $\alpha_D^{23}=-38.2°$(neat) ($\alpha_D^{22}=-38.3°$).[3]

The dextrorotatory amine: $\alpha_D^{23}=+38.3°$(neat) ($\alpha_D^{22}=+37.16°$).[3]

(*S,S*)-(−)-1,1′-Diphenylazoethane (*SS*-Azo compound) was prepared according to the method of Green *et al.*[4]

$[\alpha]_D^{18}=-284.2°$ (453.8 mg/5 ml CCl_4) ($[\alpha]_D^{25}=-304.9°$ (35.8 mg/2 ml CCl_4)).[4]

 *SS*-Azo compound

(*R,R*)-(+)-1,1′-Diphenylazoethane (*RR*-Azo compound) was prepared by means of the procedure used in the case of the *SS*-Azo compound except for the use of (*R*)-(+)-α-methylbenzylamine in place of (*S*)-(−)-α-methylbenzylamine.

$[\alpha]_D^{18}=+288.8°$(156.8 mg/5 ml CCl_4)

 *RR*-Azo compound

meso-1,1′-Diphenylazoethane (*RS*-Azo compound) was prepared starting with racemic α-methylbenzylamine according to the procedure described above; when the reaction products (mixtures of *SS*, *RR*, and the *RS*-Azo compound) were allowed to stand in a refrigerator, crystals of the *RS*-Azo compound were formed. The crystals were recrystallized twice from ethanol; white prism crystals; mp 72.5—73.5 °C (72—73 °C).[4]

 *RS*-Azo compound

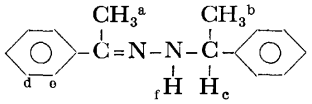
Preparation of Metal Complexes. Tetraphenylporphyrin (H_2TPP) was prepared according to the method of Falk.[5] Cobalt(II) tetraphenylporphyrin [Co(II)TPP] was prepared according to the method of Rothemund and Menotti.[6] Ni(II)-TPP, Mn(II)TPP, and Cu(II)TPP were prepared using nickel(II) acetate, manganese(II) acetate, and copper(II) acetate, respectively, in place of cobalt(II) acetate.

(1*R*,2*R*)-*N*,*N*′-Disalicylidene-1,2-cyclohexanediaminatocobalt(II) [Co(II)(sal)$_2$(*R*-CHXDA)] was prepared according to the method of Aoi *et al.*[7] Ni(II)(sal)$_2$(*R*-CHXDA), Mn(II)-(sal)$_2$(*R*-CHXDA), and Cu(II)(sal)$_2$(*R*-CHXDA) were prepared using nickel(II) acetate, manganese(II) acetate, and copper(II) acetate, respectively, in place of cobalt(II) acetate.

Preparation of Acetophenone α-Methylbenzylhydrazone. A mixture of 1-bromo-1-phenylethane (50 g, 0.27 mol), 100 % hydrazine hydrate (103 g, 2.06 mol), triethylamine (50 ml), and benzene (100 ml) was refluxed for 6 h. The contents were then poured into an aqueous solution of sodium hydroxide

and extracted five times with 400 ml of diethyl ether. After drying over Na_2CO_3 and removing the ether, the resulting α-methylbenzylhydrazine was purified by distillation (64.5—66.0 °C/1.6 mmHg); yield, 31.2 g (78 %); IR: 3280 cm^{-1} (N–H); and PMR: 1.24 ppm (methyl), 3.16 ppm (N–H), 3.66 ppm (methine), and 7.25 ppm (phenyl).

A mixture of α-methylbenzylhydrazine (31.2 g, 0.211 mol), acetophenone (25.3 g, 0.211 mol), acetic acid (40 mg), and anhydrous ethanol (50 ml) was purged with nitrogen and then refluxed for 12 h. After the solvent had been removed, a pale yellow viscous liquid was obtained; yield, 50 g (94 %); IR: 3275 cm^{-1} (N–H) and 1597 cm^{-1} (C=N); PMR: 2.02 ppm (a), 1.56 ppm (b), 4.55 ppm (c), 7.25 ppm (d), 7.55 ppm (e), and 4.87 ppm (f); and GC-MS: *m/e* (rel intensity), 238 (parent peak, 0.6), 237 (2.9), 222 (3.8), 133 (2.3), 118 (2.9), 105 (100), 104 (2.4), and 92 (2.3).



Decomposition of Azo Compound. A benzene solution of an Azo compound with or without a metal complex was charged into an ampoule and degassed twice by a freeze-thaw method to remove the oxygen; the ampoule was then sealed *in vacuo*. After standing at 104 °C in a light-shielded oil bath for 2 days, the contents of the ampoule were subjected to analysis.

Analysis of Decomposition Products. 2,3-Diphenylbutane was isolated from the decomposition products by using column chromatography (silica gel–hexane). It was identified by PMR: 1.01 ppm (methyl), 2.78 ppm (methine), and 7.20 ppm (phenyl); and GC-MS: *m/e* (rel intensity), 210 (parent peak, 1.1), 106 (9.5), 105 (100), 104 (25), 79 (4.4), and 77 (1.9).

It was not easy to isolate acetophenone α-methylbenzylhydrazone from the decomposition products because of the oxygen-sensitive nature of the hydrazone. Therefore, a reaction mixture was freeze-dried for six hours, and the remaining oily residue (C) was subjected to elemental analysis and PMR, GC-MS, and IR analyses. The oily residue (C) was found to be almost pure acetophenone α-methylbenzylhydrazone (purity 98 %, by GLC determination) when the thermolysis was carried out with the *RS*-Azo compound (512.1 mg) and Co(II)TPP (15.6 mg) in benzene (50 ml) at 104 °C. The PMR, GC-MS, and IR spectra of (C) agreed well with those of acetophenone α-methylbenzylhydrazone synthesized separately. Found: C, 80.76; H, 7.57; N, 11.09%. Calcd:** C, 80.57; H, 7.51; N, 11.65%.

Quantitative analyses of the products were carried out by means of GLC techniques using a column packed with Silicone DC-550. The column temperatures were 120 °C for ethylbenzene and styrene, 200 °C for 2,3-diphenylbutane, and 250 °C for acetophenone α-methylbenzylhydrazone. Benzene, the solvent, was used as the internal standard.

Measurement of Decomposition Rates. The decomposition rates of the azo compounds were measured in benzene using a differential pressure gauge at 70 °C. After the calculation of the rates, the vapor pressure of the benzene used as the solvent was corrected. AIBN: 3.7×10^{-5} mol l^{-1} s^{-1}, *SS*-Azo compound: 1.1×10^{-6} mol l^{-1} s^{-1}.

Measurement of ESR. The ESR of a benzene solution of the reaction mixture was measured under nitrogen at room temperature or at −196 °C. A benzene solution of Co(II)TPP and a mixture of Co(II)TPP and acetophenone α-methylbenzylhydrazone synthesized separately were measured in the manner described above.

Measurement of the Specific Rotation of the Hydrogen-transfer Product. The *SS*-Azo compound (3.67×10^{-2} M) was decomposed in the presence of Co(II)TPP (6.3×10^{-5}—1.56×10^{-4} M) in benzene at 104 °C. An optical rotation of the benzene solution containing decomposition products was measured using a 100 mm quartz cell at 20 °C. The optical rotation was reduced to optically active products, especially the hydrogen-transfer product, based on a quantitative analysis of the products by means of GLC.

Results and Discussion

General Aspects of Decomposition. The yield distribution of the thermolysis products from 1,1′-diphenylazoethane (Azo compound) with or without a metal complex are summarized in Table 1. The products from the Azo compound by thermolysis in the presence of a metal complex are identified as ethylbenzene, styrene, 2,3-diphenylbutane, and acetophenone α-methylbenzylhydrazone (called hereafter the hydrogen-transfer product).

The hydrogen-transfer product is resistant to heat (unchanged at 104 °C for 10 days) or light (unchanged for 60 min under UV light), but it is very sensitive to oxygen and turns to acetophenone and 1-phenylethanol when placed in contact with oxygen.[8] Table 1 shows that the hydrogen-transfer product is formed in the presence of a metal complex such as Co(II)TPP or Co(II)(sal)$_2$(*R*-CHXDA) (Scheme 2(b)), and that the yield is increased with an increase in the concentration of the metal complex. The Azo compound was changed into the hydrogen-transfer product almost quantitatively with 1 mol % of Co(II)TPP for the Azo compound. No hydrogen-transfer product is produced in the absence of the metal complex.

The mode of the decomposition of the Azo compound without a metal complex, on the other hand, is shown in Scheme 2(a).[9] The decomposition products are styrene, ethylbenzene, and 2,3-diphenylbutane derived from the 1-phenylethyl radical.

Co*: Co(II)$(sal)_2$(*R*-CHXDA). Reaction Conditions: 104 °C, 2 days, in benzene (50 ml).

Stabilization of the Radical by Metal Complexes. The formation of the hydrogen-transfer product is not observed at room temperature, regardless of the presence of a metal complex in the reaction system. A comparison of the yield of the hydrogen-transfer product from the *SS*-Azo compound with Co(II)TPP in the presence and in the absence of AIBN at 70 °C is shown in Fig. 1. The rates of the decomposition reaction at 70 °C were found to be 3.7×10^{-5} M s^{-1} for AIBN and 1.1×10^{-6} M s^{-1} for the *SS*-Azo compound, AIBN being decomposed 34 times more rapidly than the *SS*-Azo compound. The radical concentration in the reaction system with AIBN should be much higher than that in the system without AIBN. As may be seen in Fig. 1, the rate of the formation of the hydrogen-transfer product is very high in the reaction system containing AIBN (A). This shows that a radical formation is necessary for the formation of the hydrogen-transfer product.

Table 2 shows the influence of the central metal and its ligand on the yield of the hydrogen-transfer product. The yields of the hydrogen-transfer product decreased in this order; Co>Ni>Mn>Cu, and TPP>$(sal)_2$(*R*-

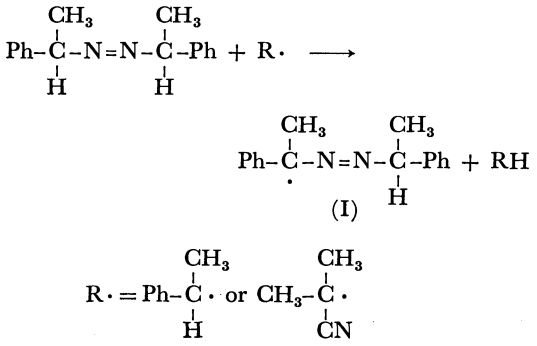
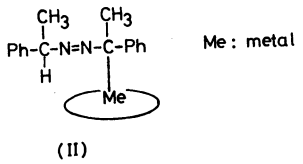
CHXDA). This order is in good agreement with that of the ability of metal complexes to stabilize 1-cyano-1,2-dimethylpropyl radical ($CH_3\dot{C}(CN)CH(CH_3)_2$), Co(II)-TPP>Ni(II)TPP>Mn(II)TPP>Cu(II)TPP.[1] It may be supposed that the α-hydrogen of the Azo compound is easily abstracted by a radical. By the elimination of the α-hydrogen, Ph–$\dot{C}(CH_3)$–N=N–$CH(CH_3)$–Ph (I) is produced as is shown below:

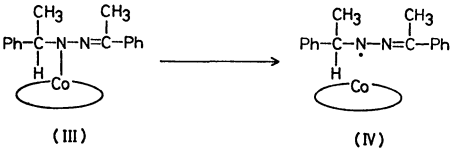


It is considered that the dependence of the yield of the hydrogen-transfer product on kinds of metal complex is attributable to degree of interaction between radical(I) and the metal complex, that is, the stability of the intermediate(II) formed in the reaction system.



(II)

The ESR spectra of a reaction mixture which contains decomposition products from the *SS*-Azo compound in the presence of Co(II)TPP are shown in Fig. 2. A peak of Co^{II} was observed when the reaction mixture was measured at room temperature (a). At −196 °C, on the other hand, a characteristic octet of Co^{II} was observed, and each peak was split into a triplet, indicating the N–Co^{II} bond (b). Furthermore, a very small peak ($g=2.001_2$) was observed at −196 °C; the intensity of this peak increased upon irradiation with UV light (c). It is considered that the peaks in Figs. 2(a) and 2(b) are attributable to an intermediate(III) which has a cobalt nitrogen bond, while the peak in Fig. 2(c) is attributable to a radical(IV) formed possibly by the cleavage of the cobalt-nitrogen bond of the intermediate(III), as is shown below:



(III) (IV)

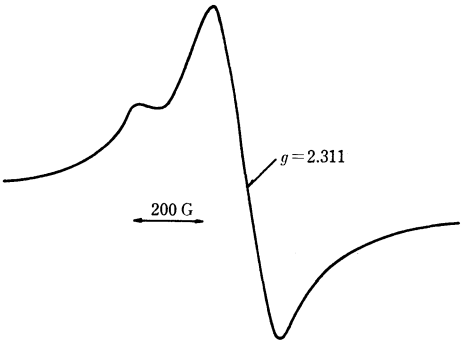


Fig. 2(a). ESR spectrum of reaction mixture of *SS*-Azo compound in the presence of Co(II)TPP at room temperature.

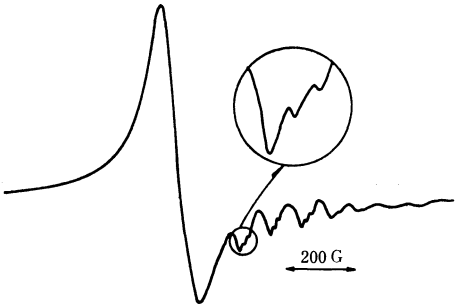

Fig. 2(b). ESR spectrum of reaction mixture of *SS*-Azo compound in the presence of Co(II)TPP at −196 °C.

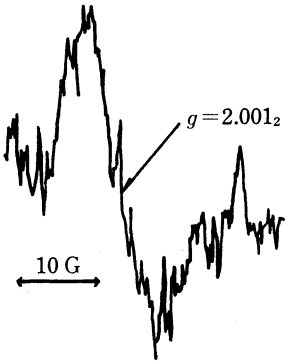

Fig. 2(c). ESR spectrum of reaction mixture of *SS*-Azo compound in the presence of Co(II)TPP at −196 °C.

In this connection, it should be noted that carbon-cobalt bond of alkyl cobalamine or vitamine B_{12} is cleaved by UV light.[10]

No peaks were observed, at room temperature, for either the benzene solution of Co(II)TPP only, or the benzene solution of Co(II)TPP and the hydrogen-transfer product synthesized separately. This means that the peaks in Fig. 2 can not result from an interaction of Co(II)TPP and the hydrogen-transfer product.

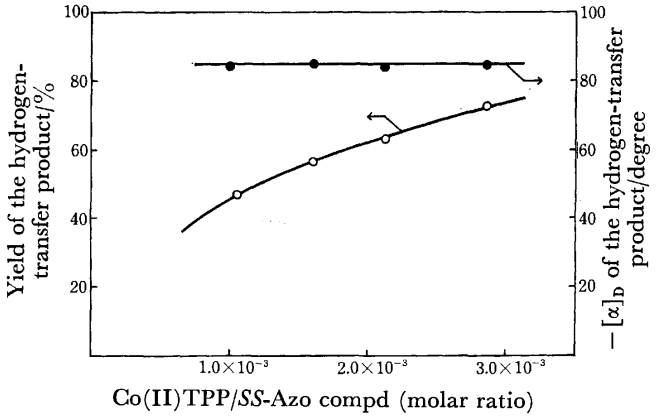

Fig. 3. Yield and specific rotation of the hydrogen-transfer product obtained from *SS*-Azo compound in the presence of Co(II)TPP in benzene at 104 °C for 2 days.

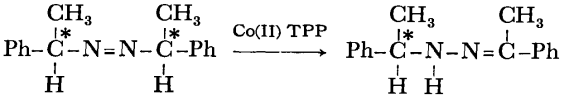
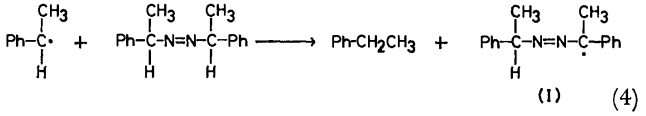
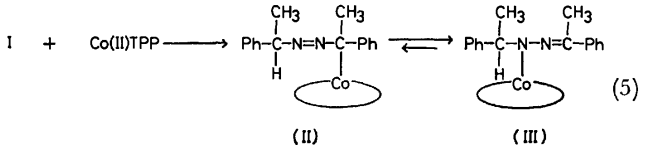
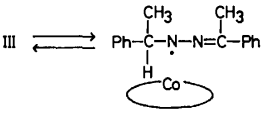
Stereochemistry of Acetophenone α-Methylbenzylhydrazone. The specific rotation of the hydrogen-transfer product, which was obtained from the *SS*-Azo compound by thermolysis in the presence of Co(II)TPP, was almost constant ($[\alpha]_D=-88°$), regardless of its yield (Fig. 3). This means that the configuration of one of the two asymmetric carbons of the original *SS*-Azo compound is probably retained in the hydrogen-transfer product.

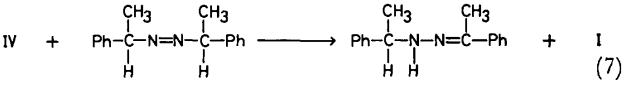


A Possible Mechanism:









Scheme 3 is a step in which radicals are released by thermolysis. In the beginning, the concentration of the radical is very low; therefore, scarcely no coupling and disproportionation reactions of the diffusion radicals occurs, and the diffusion radical formed abstracts the α-hydrogen of the Azo compound (Scheme 4). The radical(I) thus formed is immediately stabilized by a cobalt complex (Scheme 5) or abstracts the α-hydrogen from another Azo compound to form the radical(I) again. However, the latter mechanism is not probable in the light of the results shown in Fig. 3. The intermediate(II) undergoes a rearrangement reaction to the intermediate(III), in which a nitrogen-cobalt bond is newly formed. The intermediates(II) and (III) are presumably equilibrated with each other (Scheme 5). The existence of the intermediate(III) is suggested by the results of the ESR spectra, shown in Fig. 2. The series of steps from Scheme 4 to Scheme 7 is a chain reaction.

The authors would like to express their thanks to Professor Shohei Inoue for giving useful advice.

Temperature Effects on the Stereochemistry of the Solvolysis of *trans*-2,3-Diphenyloxirane†

Masashi INOUE, Yoshio TAGUCHI, Toshio SUGITA, and Katsuhiko ICHIKAWA*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received November 8, 1978)

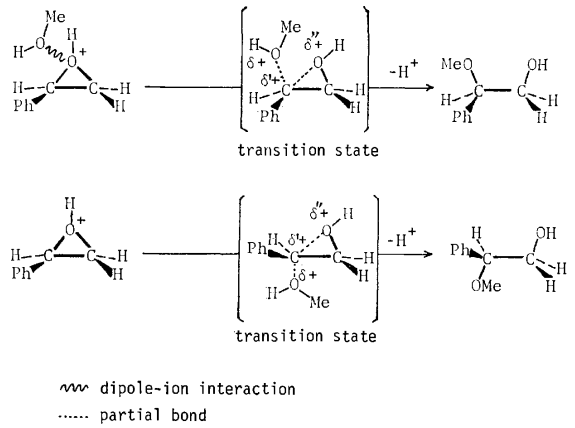
The temperature effects on the stereochemistry of the acid-catalyzed ethanolysis of *trans*-2,3-diphenyloxirane were examined. The stereochemistry of the reaction became more retentive as the reaction temperature was raised. The reaction mechanisms are discussed, and it is concluded that concurrent reactions take place in the ethanolysis, one of them giving an inverted product, and the other, a retained one, and that the former reaction is caused by a nucleophilic attack of ethanol on the carbon of the conjugate acid of the epoxide, while the latter proceeds *via* an intermediate which has a carbonium-ion character.

Nucleophlic ring-opening reactions of epoxide have been widely studied.[1] It is now generally accepted that epoxides react by means of an S_N2 mechanism under basic conditions. The mechanism of the ring opening of epoxides in acidic media is, however, quite a complex matter. The initial protonation to the epoxide oxygen atom is recognized as a fast, reversible step.[2] In the limiting form, two mechanisms are possible for the ring opening and the attack of the nucleophile, *i.e.*, *A*1 and *A*2 mechanisms. As the attacking nucleophile is the solvent in the solvolyses, though, both mechanisms lead to the same rate expression. Thus, alternative criteria have been used. They have been carefully discussed by Chapman and his coworkers.[3] Long *et al.*,[4] following a suggestion by Taft and his coworkers,[5] proposed the use of ΔS^* as a criterion for the mechanism of a hydrolytic reaction. The entropies of activation for the acid-catalyzed hydrolysis of simple epoxides are between -6.1 and -3.9 cal mol^{-1} K^{-1},[6] much lower than those of the reactions of the established *A*1 mechanism and yet greater than those of the established *A*2 mechanism; these values can be explained in terms of a borderline *A*2 mechanism.[1a,7]

A nucleophilic attack by an *A*2 mechanism involves complete inversion of configuration, whereas an *A*1 mechanism involves racemization in the limiting form. It is generally recognized that simple aliphatic epoxides give inverted products in acid-catalyzed ring opening.[1a] The only exception is the reaction of *cis*- and *trans*-2,3-dimethyloxirane with aluminum chloride in nitromethane, which yields more than 85% retained 3-chloro-2-butanol.[8]

In aryl- or carbonyl-substituted epoxides, reactions are known in which epoxides ring-open with retention of configuration at the position attacked. In a few epoxides, ring openings give rise to both stereoisomeric products. Parker and Isaacs concluded that concurrent S_Ni and S_N2 mechanisms take place in reactions of this type.[1a]

Recently Chapman and his coworkers have studied the acid-catalyzed ethanolysis of 2-phenyloxirane both kinetically and stereochemically.[3,9] The reaction yielded a mixture of 89% inverted and 11% retained products at 23 °C. They explained their observation by only a borderline *A*2 mechanism involving the transition states depicted in Scheme 1. Obviously, the two transition states, which have different situations around



Scheme 1.

the carbon atom attacked by ethanol, are different in energy. Therefore, the reaction parameters, activation enthalpy and activation entropy, are different for the two reactions, one of which yields a retained product, while the other gives an inverted one. As the two reactions have different activation parameters, it is ridiculous to discuss the two reactions in terms of a single pair of ΔH^* and ΔS^*. The stereochemical outcome must also be altered by the variation in the reaction temperatures. They did not, however, explore the temperature effects on stereochemistry.

Although a number of papers, including those of Chapman *et al.*, have discussed the temperature effects on reaction kinetics, *i.e.*, activation parameters, only a few papers have dealt with the effects on stereochemistry. Even so, two contrasting results have appeared in the literature. Fisher and Koch reported the acid-catalyzed hydrolysis of *trans*- and *cis*-2-methyl-3-phenyloxiranes in aqueous dioxane.[10] The reaction afforded 67% inverted and 33% retained glycols from the trans epoxide and 76% inverted and 24% retained ones from the cis isomer, and the stereochemistry of the reaction did not change in the temperature range of 20—45 °C. From these results, one can expect that the reaction has only one transition state, yielding both retained and inverted products.

On the other hand, Macchia *et al.* reported that the acid-catalyzed solvolysis of 1-aryl-1,2-epoxycyclohexane afforded larger amounts of the retained product at higher reaction temperatures.[11] From this observation,

† Taken from Ph D. thesis of M. I.

one can expect that concurrent reactions take place, one of which leads to a inverted product, and the other, to a retained one.

A previous paper has described the co-solvent effects on the stereochemistry of the ethanolysis of *trans*-2,3-diphenyloxirane (**1**). In that paper, we reported that the steric course of the reaction can be controlled from 85% retention–15% inversion (nitromethane: ethanol= 20: 2 by volume) to 10% retention–90% inversion (HMPA: ethanol=10: 12) by the choice of co-solvent.[12] This paper will report the temperature effects on the stereochemistry of the ethanolysis of **1** and will discuss the mechanism of the reaction.

Results and Discussion

In the study of the stereochemistry of the acid-catalyzed ethanolysis of **1** in the temperature range below the boiling point of ethanol, the same experimental conditions as in the previous paper were chosen. The results are summarized in Table 1. The reaction products were *threo*-2-ethoxy-1,2-diphenylethanol (*threo*-**2**, the retained product), the erythro isomer (*erythro*-**2**, the inverted product), 1,1-diethoxy-2,2-diphenylethane (**3**), and benzophenone (**4**, an oxidized product of diphenylacetaldehyde (**5**) in the course of the work-up); the identification and an outline of the sequence of the formation of these products have already been presented in the previous paper. As is shown in Table 1, the proportion of the retained product *threo*-**2** increased as the reaction temperature was raised. Similar temperature effects were observed in the experiments in binary solvent systems.

To examine the stereochemistry of the reaction at temperatures higher than the boiling point of ethanol, experiments were carried out in an autoclave. Unexpectedly, sulfuric acid, which was used as a catalyst in the experiments listed in Table 1 and in those of the previous paper, has no catalytic activity in the temperature range higher than 130 °C; only the starting material, **1**, accompanied by traces of 1,2-diphenylethanol (**6**) and 2,2-diphenylethanol (**7**), 1,2-diphenyl-2-hydroxyethanone (**8**), and/or diphenylethanedione (**9**), was detected on GLC analysis when an ethanolic solution of **1** containing sulfuric acid was allowed to stand at 200 °C for 4 h. This observation may be attributed to the facts that sulfuric acid acts as an oxidizing agent and that the reduced material of sulfuric

acid has no catalytic activity toward the ethanolysis. Therefore, hydrochloric acid was used as the catalyst for the experiments at higher reaction temperatures. Some typical results are given in Table 2. As is shown in Table 2, larger proportions of the retained product were observed at higher temperatures, and almost equal amounts of retained and inverted products were formed at 200 °C. Although it is interesting whether or not the proportion of the retained product increases monotonously at more higher temperatures, no clear-cut results could be obtained because of the formation of undesired products, *i.e.* rearranged products (**3**, **5**, 1,2-diphenyl-1-ethoxyethylene (**10**), and benzyl phenyl ketone (**11**)) and oxidation-reduction products (**6**, **7**, **8**, and **9**). It must be noted that the yield of **11** increased suddenly at higher than 160 °C; **11** has previously been reported not to be formed in the rearrangement by acid.[13]

Higher acid concentrations gave more inverted product; this forms a striking contrast to the results mentioned in the previous paper, in which we reported that the stereochemical outcome of the sulfuric acid-catalyzed ethanolysis of **1** at ordinary temperatures was not affected by the variation in the acid concentration. Four reasons for this can be considered: **a** the effects of a trace of water contaminating the acid solution; **b** the contamination of the non-acid-catalyzed reaction which yields the retained product; **c** the formation of chlorohydrin, or the subsequent ethanolysis of the chlorohydrin, and **d** the effects of the ion-pairing of the acid. To examine the effects of water, reactions were carried out with small amounts of water added. The results are shown in Fig. 1. As the proportion of the retained product increased with an increase in the amount of water added, the **a** reason can be excluded. The **b** reason can also be easily excluded because no reaction occurred without an acid catalyst. The **c** reason was recently proposed by Whalen *et al.* as the specific effects of chloride ion in the hydrolysis of phenanthrene 9,10-oxide;[14] it cannot be completely excluded in the present case, though no chlorohydrin was detected in the reaction products and the chloride-ion concentrations are a hundred times smaller than those of **1**. The **d** reason was proposed by Wylde and his coworkers;[15] it seems to be the most probable explanation in the present case. As the counter anion exists near the protonated oxygen in the ion pair of protonated epoxide and chloride, the probability of the existence of ethanol in the front side of the epoxide ring decreases as compared with that in free ion, and an inversion reaction is favored by the ion pair. As the dilution of the acid solution causes the ion pair to dissociate into free ions, the reaction becomes more retentive with a lowering in the acid concentration.

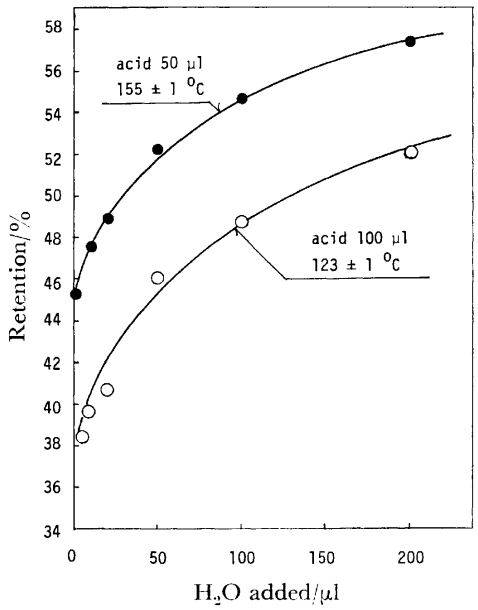

Fig. 1. Effects of water on ethanolysis of *trans*-2,3-diphenyloxirane.

As the stereochemistry of the ethanolysis is affected by the reaction temperatures, two reaction are expected to take place in the ethanolysis. If Parker-Isaacs' conclusion is true, the overall kinetical expression is as follows:

$$k_{obsd} = k'K[H^+] = (k_{ret}+k_{inv})K[H^+]$$

in which k_{ret} is a second-order rate constant for the reaction which gives the retained product, while k_{inv} is that for the inversion reaction. The pre-equilibrium constant between **1** and the oxonium ion is presented as K. Then, the reaction parameters for each of the reactions can be defined as[16]

$$k_{ret} = \gamma \exp\left(\frac{-\Delta G^{\ddagger}_{ret}}{RT}\right) = \exp\left(\frac{T\Delta S^{\ddagger}_{ret}-\Delta H^{\ddagger}_{ret}}{RT}\right)$$

$$k_{inv} = \gamma' \exp\left(\frac{-\Delta G^{\ddagger}_{inv}}{RT}\right) = \exp\left(\frac{T\Delta S^{\ddagger}_{inv}-\Delta H^{\ddagger}_{inv}}{RT}\right).$$

Therefore,

$$\frac{k_{ret}}{k_{inv}} = \frac{\gamma}{\gamma'} \exp\left(\frac{\Delta S^{\ddagger}_{ret}-\Delta S^{\ddagger}_{inv}}{R}\right) \exp\left(-\frac{\Delta H^{\ddagger}_{ret}-\Delta H^{\ddagger}_{inv}}{RT}\right)$$

Assuming that the activation parameters are constant in the temperature range of the experiments, the following equation can be deduced:

$$\ln\left(\frac{k_{ret}}{k_{inv}}\right) = -\frac{\Delta H^{\ddagger}_{ret}-\Delta H^{\ddagger}_{inv}}{RT} + \text{Const.}$$

If two reactions have the same reaction order, which was proved to be the case by the constancy of the stereochemical outcomes with the variation in the reaction times, the ratio of the two rate constants, k_{ret}/k_{inv}, can be substituted for the ratio of the two reaction products, *threo*-**2**/*erythro*-**2**. Therefore, a straight line should be obtained if $\ln$(*threo*-**2**/*erythro*-**2**) is plotted *vs.* $1/T$; the results are shown in Fig. 2. From the results, $\Delta H^{\ddagger}_{ret} > \Delta H^{\ddagger}_{inv}$ and $\Delta S^{\ddagger}_{ret} > \Delta S^{\ddagger}_{inv}$ are obtained. The enthalpic factor favors the formation of the inverted product, whereas the entropic factor favors the retention reaction.

Macchia *et al.* proposed the mechanism shown in Scheme 2 for the acid-catalyzed solvolysis of 1-aryl-1,2-epoxycyclohexanes.[11] However, we cannot agree with their mechanism in view of the following considerations: (1) the entropy of the transition state, **12**, is expected to be equal to, or smaller than, that of **13**, because **12** involves a molecule of ethanol and (2) the enthalpy of

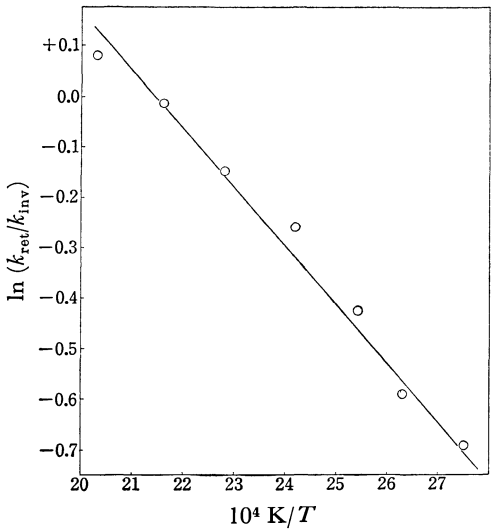

Fig. 2. Plot of $\ln(k_{ret}/k_{inv})$ *vs.* $1/T$ for the ethanolysis of *trans*-2,3-diphenyloxirane.

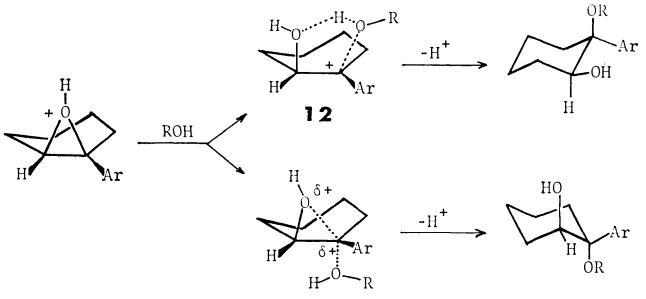
12 is expected to be smaller than that of **13**, because hydrogen bonding from the ethanol involved in the transition state to the oxygen of the epoxide supplies an additional stabilization energy to **12**. Both suppositions are contrary to the observations.

Bruice *et al.* examined the temperature effects on the product distribution of the hydrolysis of phenanthrene



Scheme 2.

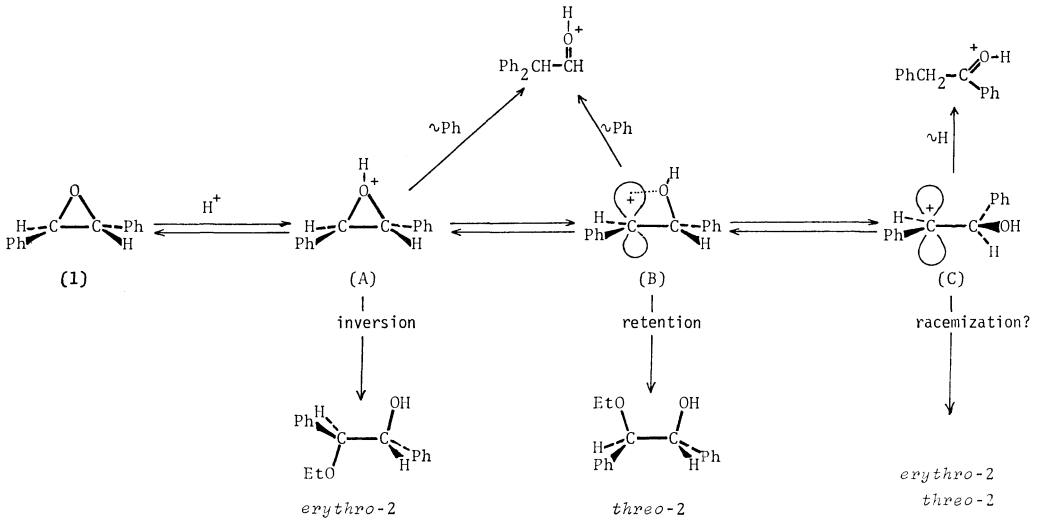
9,10-oxide[18] and reported those relative activation parameters: $\Delta H^{\neq}_{ret}-\Delta H^{\neq}_{inv}=2.05$ kcal mol^{-1} and $\Delta S^{\neq}_{ret}-\Delta S^{\neq}_{inv}=5.0$ cal deg^{-1} mol^{-1}. They explained their observations in terms of an S_N1 mechanism. The energy difference, 2.05 kcal mol^{-1}, however, seems to be rather large for the fast reaction step after the rate-determining formation of a carbonium ion.

A possible mechanism for the reaction is shown in Scheme 3, in which (A) is the conjugate acid of the epoxide and (C) is a completely developed carbonium ion. The intermediate (B) is considered to be in a circumstance in which *p*-obital of the carbon is solvated by the intramolecular hydroxyl group. As the broken C–O bond provides more freedom to the system, the reaction which yields the retained product should have a lower activation entropy than the reaction yielding the inverted product.

Finally, we shall discuss briefly the rearrangement of **1**. Blum *et al.* reported that $Rh_2(CO)_4Cl_2$ catalyzed rearrangement of **1** gave 8% of **11**, 25% of **5**, 11% of diphenylmethane, 12% of 1,2-diphenylethylene, and 18% of *cis*-2,3-diphenyloxirane after 2 h at 210 °C, while the same catalyst gave 25% of **5**, 5% of 1,2-diphenylethylene, and 65% of unchanged **1** without **11** after 5 h in boiling benzene.[18] These results, together with the results shown in Table 2, indicate that the predominant factor affecting the rearranged-product distribution is the reaction temperature, and that high reaction temperatures favor the formation of **11**. These observations may be explained by Pearson's HSAB principle.[19] At low temperatures C–O bond breaking is assisted by the more polarizable (softer than hydride) phenyl group, resulting in phenyl migration to give **5**. On the other hand, the fully developed carbonium ion formed at a high temperature is attacked by the more electronegative (harder) hydride ion, since the positive charge of the cation is easily neutralized by the electron density of the hydride ion.

Experimental

The materials and analytical methods have been described in a previous paper.[12]



Scheme 3.

Ethanolysis of **1** *in an Autoclave.* To a 1-ml portion of an ethanolic solution containing 10 mg of **1**, a definite volume of hydrochloric acid in ethanol (*ca.* 0.005 mol/l) was added. The reaction mixture was then shaken vigorously, set in an autoclave, and heated to the desired temperature. Ten minutes usually (and thirty minutes at the longest) were required to arrive at the reaction temperature. After an appropriate time interval at that temperature, the mixture was cooled and poured into sampling tube containing a small amount of potassium carbonate. The quenched sample was then kept at room temperature for a day and analyzed by GLC.

Isolation of the Product. To a mixture of 206.4 mg of **1** and 20 ml of ethanol, 0.5 ml of ethanolic hydrochloric acid (*ca.* 0.005 mol/l) was added. The reaction mixture was then shaken vigorously, set in an autoclave, and heated to 240 °C. Thirteen minutes were required to arrive at that temperature; the autoclave was then held at that temperature (237—260 °C) for 3 h. To the cooled reaction mixture, a portion of potassium carbonate was added. The filtered mixture was washed with water, and the aqueous layers were extracted with ether. After the removal of the solvent, the dried product was chromatographed on an $8\phi \times 720$ mmH silica-gel column under a 1-m head of elutant (hexane, hexane–benzene and benzene–diethyl ether successively, with concentration gradients). The products (in the order of elution) and the yields were as follows: **10** (0.4%), recovered **1** (4%), **5** (9%), **4** (8%), **9** (0.5%), **3** (2%), **8** (0.3%), **6** (3%), **2** (50%), and **7** (3%).

The authors wish to thank Professor Kunio Okamoto of this Department for his critical discussion.

Modified Preparation of Sodium Guaiazulenide and Reaction of the Reagent with 3-Formylguaiazulene

Shinji KUROKAWA

Department of Chemistry, Faculty of Education, Saga University, Honjo-machi, Saga 840

(Received November 10, 1978)

As a modification for facilitating small-scale reactions, sodium *N*-methylanilinide was prepared from sodium hydride and *N*-methylaniline instead of by the usual method from sodium, *N*-methylaniline, and naphthalene (as assistant). Sodium *N*-methylanilinide, made by this procedure, was successively converted to sodium guaiazulenide, the formation of which was checked by tracing known reactions. The reaction of the reagent with 3-formylguaiazulene was also studied, and found to yield 4-substituted 2-formyl-1,4-dihydroguaiazulene and 6-substituted 2-formyl-3,6-dihydroguaiazulene. In this case, nucleophilic addition of guaiazulenide anion occured not at the carbonyl group but at the 6- and 8-positions of the seven-membered ring of formylguaiazulene, accompanied by formyl group and hydrogen migrations.

In the previous paper we reported that 1-[2-(4-azulenyl)vinyl]azulene and 1-[2-(1-azulenyl)vinyl]-azulene derivatives were formed by thermolysis of 3-formylguaiazulene (**9**).[1] One of the skeletal hydrocarbons, 1-[2-(1-azulenyl)vinyl]azulene, has already been synthesized from azulenylmethylphosphonium salt and formylazulene.[2]

As a means of access to hitherto unknown 1-[2-(4-azulenyl)vinyl]azulene, the reaction of sodium guaiazulenide (**1**) with **9** was studied, since the reaction was thought, if followed by dehydration of the resulting alcohol, to be a possible route to 1-[2-(7-isopropyl-1-methyl-4-azulenyl)vinyl]guaiazulene.[3,4]

Sodium *N*-methylanilinide, used for preparation of **1**,[3] is usually made from sodium wire and *N*-methylaniline, using naphthalene as an assistant.[5] However, the procedure was not satisfactory for our purpose of small-scale experiments, due to the technical problem of how to make such fine wires as would allow a fairly smooth reaction with a millimol-order quantity of *N*-methylaniline. For this reason, the sodium hydride available as fine powder (as oil mull) was used instead of sodium metal, without the aid of the assistant, for the preparation of **1** in this paper.

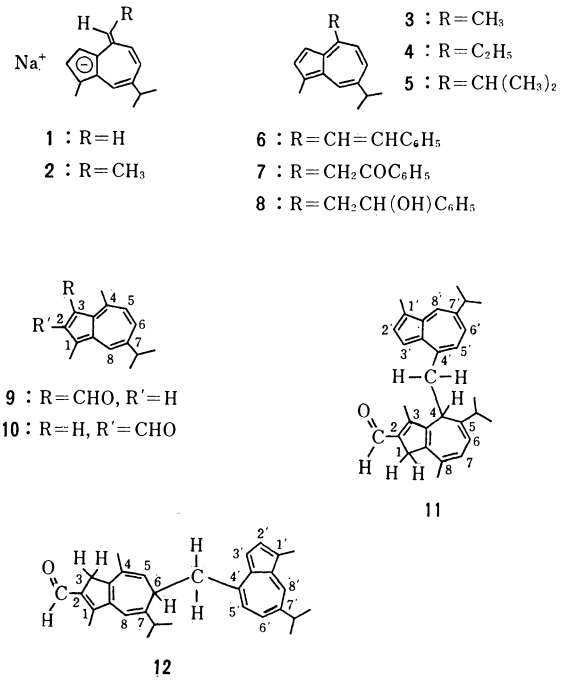

Fig. 1.

Results and Discussion

Sodium hydride and *N*-methylaniline reacted smoothly with evolution of hydrogen when a suspension in THF was heated, to form a pale yellow solution of sodium *N*-methylanilinide, which was subsequently changed into **1** by addition of **3**. The formation of **1** was apparent from the immediate color change of **3** from blue to brown, but was also proved by the reaction of **1** with methyl iodide to afford 4-ethyl-7-isopropyl-1-methylazulene (**4**),[3] though the yield (27.6%) was slightly lower than that (35%) in Ref. 3.

In this reaction, a by-product $C_{17}H_{22}$ (MS) was also found in a 3.4% yield. This compound is thought to be 4,7-diisopropyl-1-methylazulene (**5**) formed from **2**, because an alternative structure, 1,4-diethyl-7-isopropylazulene, is impossible owing to the lack of 1-ethyl-7-isopropyl-4-methylazulene in the reaction products.

For an additional proof of **1**, the reactivity toward formyl groups was examined by reaction of **1** with benzaldehyde.[4] The same products **6**, **7**, and **8** were isolated as in Ref. 4 and identified by UV, IR, NMR, and mass, but the yield of dehydration product **6** was prominent in our case (in THF) in contrast to the mere trace of **6** in Ref. 4 (in benzene).[7]

Reaction of **1** with **9** yielded two products: 1,4-dihydro-5-isopropyl-4-(7-isopropyl-1-methyl-4-azulenyl)-methyl-3,8-dimethyl-2-azulenecarbaldehyde (**11**) and 3,6-dihydro-7-isopropyl-6-(7-isopropyl-1-methyl-4-azulenyl)methyl-1,4-dimethyl-2-azulenecarbaldehyde (**12**), in 25.6 and 19.6% yields, respectively. Contrary to our expectation that addition of **1** would occur at carbonyl group, as in benzaldehyde, the nucleophilic addition of methylene carbanion of **1** took place at 6- and 8-positions of **9**, followed by migrations of the formyl group and hydrogen.

Rearrangement of the formyl group was shown by dehydrogenation of **11** and **12** with chloranil or *o*-chloranil, yielding 2-formylguaiazulene (**10**). The substitution mode of five-membered ring was also indicated by the NMR of **11** and **12**, in which the

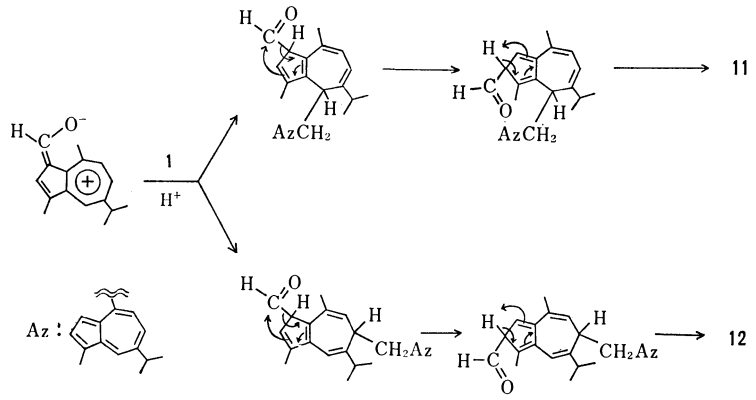

Fig. 2.

coupling constant 2.2 Hz (or 2.3 Hz) of 3-methyl and 1-methylene protons (or 1-methyl and 3-methylene protons) is in good agreement with 1.9 Hz of those of azulenium cations.[8,9]

In the NMR of **11**, moreover, 6-, 7-, and 4-hydrogens appeared as doublet (6.06), double quartet (6.44) (quartet is due to allyl coupling with 8-methyl protons), and double doublet signals (3.96 ppm), respectively, in accordance with the 4-substituted 1,4-dihydroguaiazulene structure. Also, the 6-substituted 3,6-dihydroguaiazulene structure of **12** was supported by the appearance of singlet (6.33), double quartet (5.34), and doublet signals (2.84) for 8- and 5-hydrogens and for the 6-methylene group, though splitting of 6-hydrogen signals were not clear owing to the overlapping with 3-methylene signals. Furthermore, all of these assignments were ascertained by double resonance spectra.

Addition of a nucleophilic strong base at 4- and 6-positions of the azulene nucleus was already observed by NMR spectroscopy.[10] In the present reaction, 4- (or 8-) and 6-positions of **9** would become reactive toward nucleophiles owing to the contribution of the mesomeric form of a tropylium cation type, in which the formyl group plays an important role. This may cause an exclusive addition of the methylene carbanion of **1** to the seven-membered ring and thus would explain the difference between this reaction and that with benzaldehyde. This conclusion is supported by the fact that the seven-membered ring of diethyl 1,3-azulenedicarboxylate and its derivatives is activated enough to react with Grignard reagents.[11]

On the other hand, conjugation of the formyl group with double bonds of dihydroguaiazulene is only attainable in **11** and **12** in a successive reaction course, and this might act as a driving-force of subsequent migrations of the formyl group and hydrogen.

Experimental

NMR spectra were taken in $CDCl_3$ with TMS as internal standard on a JEOL MH-100 spectrometer (100 MHz), or on a JEOL FX-90Q instrument (90 MHz) for spin-decoupling experiments. Mass spectra (MS) were obtained at 70 eV with a JEOL JMS-O1SG spectrometer, or at 24 eV with a JEOL-D300 instrument for GC-MS. UV spectra were recorded in cyclohexane on a Hitachi 624 digital spectrometer with a Hitachi 056 recorder, and IR spectra (liquids as films; solids as CCl_4 solutions) on a Hitachi 260-10 spectrometer. Mps are uncorrected. GLC was carried out on a Shimadzu GC-3AH instrument.

Preparation of Sodium Guaiazulenide (1). Under dry nitrogen 500 mg (10.4 mmol) of sodium hydride (50% dispersion in Bayol 85) was washed with hexane (10 cm^3), then with dry THF (10 $cm^3 \times 2$), and suspended in a solution of 3.62 g (33.8 mmol) of *N*-methylaniline in 20 cm^3 of THF. This suspension was heated to refluxing for 30 min, and the resulting pale yellow solution was refluxed for 30 more min to complete the reaction. To this solution, at room temperature, was added another solution of 1.98 g (10.0 mmol) of **3** in 10 cm^3 of THF over a period of 20 min. The color of **3** changed from blue to brown at each moment of addition, and finally yielded a brown solution of **1** in THF, which was used for successive reactions without further purification.

Reaction of 1 with Methyl Iodide. To a stirred solution of **1** in THF was added dropwise 2.20 g (15.5 mmol) of methyl iodide over a period of 5 min; stirring was continued for an additional 1 h. The reaction mixture, after evaporation of THF (reduced pressure), was taken up into 200 cm^3 of hexane and the insoluble sodium iodide was filtered off. The filtrate was washed with 7% hydrochloric acid (100 $cm^3 \times 3$), then with water, dried on sodium sulfate, and concentrated(reduced pressure) to give a blue oil. Successive hexane–silica gel elution chromatography afforded blue fractions containing **3**, **4**, **5**, and unknown minor components. From GLC analysis of these fractions, the yields of **3** (recovery), **4**, and **5** are calculated to be 47.4, 27.6, and 3.4%, respectively, based on **3**. Purification of each compound was not successful by means of elution chromatography, except that **4** was isolated as a mixture with **3** and **5**, and characterized by its NMR spectrum. **3**: GC-MS, *m/e* (rel intensity), 198 (66), 183 (100), 168 (17), 167 (18), 155 (17), 153 (26), and 128 (12). **4**: GC-MS, 212 (100), 197 (94), 169 (13), 167 (15), 154 (11), and 153 (12); NMR $\delta = 1.26$ (6H, d, $J = 7.0$ Hz, $CH(C\underline{H}_3)_2$), 1.34 (3H, t, $J = 7.5$ Hz, $CH_2C\underline{H}_3$), 2.64 (3H, s, 1-CH_3), 3.04 (2H, q, $J = 7.5$ Hz, $CH_2C\underline{H}_3$), 3.84 (1H, m, $J = 7.0$ Hz, $C\underline{H}(CH_3)_2$), 3.82 (1H, d, $J = 11.0$ Hz, 5-H), 7.23 (1H, dd, $J =$ 11.0 and 2.0 Hz, 6-H), 7.24 (1H, d, $J = 3.8$ Hz, 3-H), 7.58 (1H, d, $J = 3.8$ Hz, 2-H), and 8.16 (1H, d, $J = 2.0$ Hz, 8-H). **5**: GC-MS, 226 (100), 211 (76), 183 (39), 181 (17), 169 (17), and 155 (23).

Reaction of 1 with Benzaldehyde. To a stirred solution of **1** in THF (from 10 mmol of **3**) was added dropwise 2.5 g

(24 mmol) of benzaldehyde over a period of 20 min; stirring was continued for 4 h. The reaction mixture was worked up in the usual manner,[3,4] and **6**, **7**, and **8** were isolated in 64, 12, and 24% relative yields (**6**+**7**+**8**=100%).[7] **6**: NMR δ=1.32 (6H, d, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 2.64 (3H, s, 1-CH$_3$), 3.04 (1H, m, J=7.0 Hz, C$\underline{H}$(CH$_3$)$_2$), 7.08—7.60 (9H, m, 3-H, 5-H, 6-H, vinyl-H, and Ph), 7.60 (1H, d, J=4.0 Hz, 2-H), 7.94 (1H, d, J=17.0 Hz, vinyl-H (*trans*)), and 8.14 (1H, d, J=2.0 Hz, 8-H); MS, *m/e* (rel intensity), 286 (100), 285 (38), 284 (27), 271 (97), 243 (45), 241 (31), 239 (22), and 228 (26). **7**: NMR δ=1.32 (6H, d, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 2.64 (3H, s, 1-CH$_3$), 3.04 (1H, m, J=7.0 Hz, C$\underline{H}$(CH$_3$)$_2$), 4.76 (2H, s, CH$_2$), 6.99 (1H, d, J=10.0 Hz, 5-H), 7.16—7.72 (6H, m, 2-H, 3-H, 6-H, and B_2C part of A_2B_2C system of Ph), 8.00—8.20 (2H, m, A_2 part of A_2B_2C system of Ph), and 8.08 (1H, d, J=2.0 Hz, 8-H); MS, 302 (95), 105 (100), and 77 (28). **8**: NMR δ=1.38 (6H, d, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 2.70 (3H, s, 1-CH$_3$), 3.12 (1H, m, J=7.0 Hz, C$\underline{H}$(CH$_3$)$_2$), 3.56 (2H, d, J=8.0 Hz, CH$_2$), 5.20 (1H, m, C$\underline{H}$(OH)), 7.03 (1H, d, J=10.0 Hz, 5-H), 7.20—7.80 (8H, m, 2-H, 3-H, 6-H, and Ph), and 8.24 (1H, d, J=2.0 Hz, 8-H); MS, 304 (100), 198 (69), 185 (90), 184 (25), 183 (63), 167 (21), 165 (21), 155 (57), 149 (97), 143 (25), 107 (21), 105 (46), 84 (27), 79 (33), 78 (24), 77 (33), 43 (21), and 41 (26).

*Reaction of **1** with 3-Formylguaiazulene (**9**).* A solution of 1.13 g (5.00 mmol) of **9** in 15 cm^3 of THF was added to a solution of **1** in THF (from 10.0 mmol of **3** and 25 cm^3 of THF) drop by drop over a period of 40 min. The reaction mixture was stirred for an additional 4 h, diluted with water (20 cm^3), and extracted with benzene (100 cm^3×3); the extract was washed with 7% hydrochloric acid (100 cm^3×3), then with water, dried, and concentrated (reduced pressure) to give a green oil. The oil was subsequently submitted to silica gel chromatography with hexane–AcOEt (4: 1) as the eluant, and separated into 331 mg (16.7%) of unchanged **3**, 543 mg (25.6 %) of **11**, 417 mg (19.6%) of **12**, 89.6 mg of unknown mixture, and 336 mg (29.7%) of recovery of **9**.

Dimer **11** was obtained as a green oil, which solidified in a refrigerator to give green microprisms, mp 113—115 °C. TLC (hexane–AcOEt) R_f 0.30. UV_{max} 205 nm (log ε 4.50), 246 (4.44), 287 (4.61), 305 (sh 4.17), 341 (sh 4.09), 353 (4.17), 366 (sh 4.14), 543 (sh ε 269), 568 (sh 384), 592 (sh 469), 610 (543), 632 (493), 667 (485), 698 (sh 254), and 739 (192); IR 1650 (C=O), 2720 and 2825 cm^{-1} (formyl CH); NMR[12] δ= 1.10 (6H, q, J=6.8 Hz, 5-CH(C$\underline{H}_3$)$_2$), 1.30 (6H, d, J=6.8 Hz, 7′-CH(C$\underline{H}_3$)$_2$), 1.55 (3H, t, J=2.2 Hz, 3-CH$_3$), 2.26 (3H, broad s, 8-CH$_3$) (broadening is due to couplings with 6-H and 7-H), 2.47 (1H, m, J=6.8 Hz, 5-C$\underline{H}$(CH$_3$)$_2$), 2.62 (3H, s, 1′-CH$_3$), 2.93 (1H, m, J=6.8 Hz, 7′-C$\underline{H}$(CH$_3$)$_2$), 3.04 (2H, dd, J=8.8 and 6.6 Hz, 4-CH$_2$), 3.27 (2H, q, J=2.2 Hz, 1-H$_2$), 3.96 (1H, dd, J=8.8 and 6.6 Hz, 4-H) (double doublets look like a broad triplet due to allyl coupling with 6-H), 6.06 (1H, broad d, J=7.0 Hz, 6-H) (broadening is due to couplings with 4-H and 8-CH$_3$), 6.44 (1H, dq, J=7.0 and 1.3 Hz, 7-H), 6.52 (1H, d, J=10.6 Hz, 5′-H), 7.15 (1H, d, J=4.0 Hz, 3′-H), 7.21 (1H, dd, J=10.6 and 1.8 Hz, 6′-H), 7.59 (1H, d, J=4.0 Hz, 2′-H), 8.08 (1H, d, J=1.8 Hz, 8′-H), and 9.62 (1H, s, 2-CHO); MS, *m/e* (rel intensity), 424 (4), 227 (100), 226 (11), 199 (13), 183 (14), 157 (21), and 142 (14).

Found: C, 87.79; H, 8.35%. Calcd for $C_{31}H_{36}O$: C, 87.69; H, 8.55%.

Dimer **12** was obtainde as a blue oil, which also solidified in a refrigerator to give blue crystals, dec at *ca.* 70 °C. TLC (hexane–AcOEt) R_f 0.26. UV_{max} 202 nm (log ε 4.44), 249 (sh 4.51), 285 (4.62), 289 (sh 4.61), 303 (sh 4.18), 346 (sh 4.10), 352 (4.14), 368 (sh 4.03), 543 (sh ε 298), 565 (sh 402), 591 (sh 489), 609 (557), 632 (500), 666 (482), 699 (sh 238), and 738 (182); IR 1655 (C=O), 2720 and 2825 cm^{-1} (formyl CH); NMR[12] δ=1.02 (6H, d, J=6.8 Hz, 7-CH(C$\underline{H}_3$)$_2$), 1.35 (6H, d, J=7.0 Hz, 7′-CH(C$\underline{H}_3$)$_2$), 1.96 (3H, d, J=1.3 Hz, 4-CH$_3$), 2.40 (1H, m, J=6.8 Hz, 7-C$\underline{H}$(CH$_3$)$_2$), 2.48 (3H, t, J=2.3 Hz, 1-CH$_3$), 2.65 (3H, s, 1′-CH$_3$), 2.84 (2H, d, J=7.9 Hz, 6-CH$_2$), 3.06 (1H, m, J=7.0 Hz, 7-C$\underline{H}$(CH$_3$)$_2$), 3.50 (1H, broad m, J=9.0 and 7.9 Hz, 6-H) (broadening is due to allyl coupling with 8-H), 3.61 (2H, m, J=2.3 Hz, 3-H$_2$), 5.34 (1H, dq, J=9.0 and 1.3 Hz, 5-H), 6.33 (1H, broad s, 8-H) (broadening is due to allyl coupling with 6-H), 6.62 (1H, d, J=10.8 Hz, 5′-H), 7.06 (1H, d, J=3.7 Hz, 3′-H), 7.32 (1H, dd, J= 10.8 and 2.0 Hz, 6′-H), 7.60 (1H, d, J=3.7 Hz, 2′-H), 8.13 (1H, d, J=1.7 Hz, 8′-H), and 10.08 (1H, s, 2-CHO); MS, 424 (7), 227 (100), 157 (15), 149 (19), 142 (11), and 43 (11).

Found: C, 87.80; H, 8.35 %. Calcd for $C_{31}H_{33}O$: C, 87.69; H, 8.55 %.

*2-Formylguaiazulene (**10**). A. From **11**.* A solution of 10 mg (0.024 mmol) of **11** and 15 mg (0.061 mmol) of chloranil in 2 cm^3 of benzene was stirred for 12 h at room temperature. The reaction mixture was diluted with petroleum ether (20 cm^3), shaken with a 4% aqueous solution of potassium hydroxide (25 cm^3), washed with water, dried, and the resultng green precipitates, insoluble in most organic solvents, were filtered off. Evaporation of the solvent and subsequent benzene–silica gel elution chromatography yielded 0.33 mg (6.2%) of **10**, identical with the authentic specimen in TLC, IR, and MS.

*B. From **12**.* The procedure given in *A* afforded 0.71 mg (4.7%) of **10**, identical (TLC and IR) with that from *A*, from 28 mg (0.067 mmol) of **12** and 60 mg (0.24 mmol) of *o*-chloranil.

As a control experiment, **9** was treated with a mixture of chloranil and *o*-chloranil in the same manner as described in *A*. In this case, however, only unchanged **9** was observed and formation of **10** was not detected in TLC of the reaction mixture.

The author wishes to thank Miss Naoko Kitahara of Saga University for her assistance in the experimental work as a part of her graduation thesis of Saga University. Thanks are also due to Dr. Hajime Koga of Hisamitsu Pharmaceutical Co., Ltd., and Dr. Toru Hinomoto of JEOL, Ltd., for their kind measurements of mass spectra and double resonance spectra.

A Highly Stereospecific Procedure for the Transformation of Allylic Alcohols into 1,3-Dienes[1)]

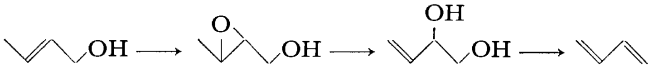
Arata YASUDA,*,† Shin TANAKA, Hisashi YAMAMOTO,†† and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University Yoshida, Kyoto 606

(Received December 6, 1978)

The title synthesis involves (1) epoxidation of allylic alcohols with *t*-butyl hydroperoxide in the presence of vanadium catalyst followed by trimethylsilylation, (2) specific oxirane ring opening by means of diethylaluminum 2,2,6,6-tetramethylpiperidide and subsequent desilylation producing 3-ene-1,2-diols, and (3) removal of both hydroxyl groups through bromination with a mixture of phosphorus tribromide and copper(I) bromide and the successive zinc debromination. The sequence of reactions has been extended with considerable success to the preparations of *β*-myrcene from nerol, *trans*-*β*-ocimene from geraniol in a specific way, and *α*- and *β*-farnesenes from their biological precursors. A C_{12} sex pheromone of red bollworm moth has been prepared efficiently by this method with cyclododecene as a starting material.

The high regio- and stereospecific isomerization of oxiranes into allylic alcohols has recently been accomplished by means of aluminum amides, especially diethylaluminum 2,2,6,6-tetramethylpiperidide(DATMP).[2)] To explore the applicability of this technique, we have undertaken an investigation of the reactions with a variety of oxirane derivatives.



Of particular interest among them should be the conversion of 2,3-epoxy alcohols to 3-ene-1,2-diols. The recent development of effective methods of catalytic epoxidation of allylic alcohols with *t*-butyl hydroperoxide has made 2,3-epoxy alcohol species readily available for synthetic purpose.[3)] Furthermore, it could be envisioned that such ene-diols would provide us with the chance of success in the stereocontrolled synthesis of 1,3-dienes.[4)]

Epoxidation of nerol (**1a**) with the Sharpless reagent ($VO(acac)_2$–*t*-BuOOH) furnished epoxy alcohol **2a** in quantitative yield. Although the direct transformation of **2a** into 3-ene-1,2-diol **4a** by means of DATMP did not proceed smoothly, the problem was easily solved by protection of the hydroxyl group with either trimethylsilyl ether or 1-ethoxyethyl group. Of the two protecting groups, the trimethylsilyl group was more favorable for our purpose for ease of both introduction and removal. Thus, the epoxy alcohol **2a** was converted *in situ* to the epoxy silyl ether **3a** by the successive addition of pyridine, hexamethyldisilazane, and chlorotrimethylsilane at 0 °C. The crude product was immediately subjected to the action of DATMP, followed by desilylation with potassium fluoride in aqueous methanol, to furnish **4a** in 79% overall yield from **1a**. A striking feature is that none of the vinyl silyl ether was detected in the crude reaction mixture before KF treatment. As anticipated from the previous results,[2)] geraniol (**5a**) gave the isomeric diol **8a** as a predominant product. The detailed product distribution in the reaction of **7a** with DATMP and diethylaluminum diisopropylamide

a) Aluminum amide reagents were prepared as previously reported.[2)] b) Isomer ratio was determined as follows. After KF treatment, the resulting crude 1,2-diols were converted to the corresponding aldehydes by the reaction with sodium periodate in ethanol. The chemical shifts ($CDCl_3$, TMS) of aldehyde protons appeared at *δ* 9.3 (the aldehyde derived from **8a**); 10.1 (the aldehyde derived from **9**); 9.5 (the aldehyde derived from **4a**). The ratio was determined by their intensities. c) Yields are based on material isolated by preparative TLC.

† Present Address: The Institute for Molecular Science, Myodaiji, Okazaki 444.

†† Present Address: Department of Chemistry, University of Hawaii at Manoa, Honolulu, Hawaii 96822.

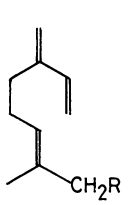
are listed in Table 1. In addition to the previous observation, Table 1 shows following points of interest:

(1) This transformation can be believed to involve initial complex formation where aluminum amides approach the oxirane so as to enable a greater orbital overlap. Then the presence of the bulky trimethylsiloxyl group should make the attack of aluminum amides even more selective so that the reagents attack the oxirane group exclusively on the less hindered side (on the same side as hydrogen of oxirane) to produce trisubstituted olefinic diol **8a** or the isomer **9**.

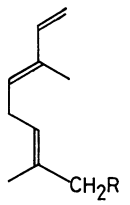
(2) Substitution of diisopropylamide for tetramethylpiperidide moiety results in the complete lack of the (*E*) preference, which supports that the bulk of the extremely large TMP group did play an even more significant role in determining the course of elimination. Thus, in the abstraction stage of hydrogen, the favored direction is to be strictly arranged so as to minimize the severe nonbonded interactions. It should be added that using *t*-butyldimethylsilyl protecting group[5] in place of trimethylsilyl moiety even more improved the selectivity (**4a**: **8a**: **9**=2: 96: 2).

A similar sequence was extended to transform (2*Z*,6*E*)-farnesol (**1b**) to ene-diol **4b** (71% yield) and the isomer **5b** to **8b** (70% yield), respectively.

Now the remaining step toward 1,3-dienes consists in selective transformation of 1,2-diol group into vinyl moiety. Attempted application of the Eastwood method[6] proved to be disappointing. Treatment of the diol **4a** with *N*,*N*-dimethylformamide dimethyl acetal and the subsequent heating of the resulting dioxolane derivative in acetic anhydride at 110 °C afforded myrcene (**10a**)[7] in less than 20% yield.[8] Reaction of the benzaldehyde acetal of the diol with butyllithium was also tested without any success.[9] We therefore developed the following alternative route. The diol **4a** was initially brominated with a mixture of copper(I) bromide (2.5 equiv) and phosphorus tribromide (1.2 equiv) at 0 °C for 1 h and then successively treated with excess zinc dust at room temperature for 2 h to furnish myrcene (**10a**) in 58% yield. Similarly, the following terpenes were prepared efficiently from the corresponding ene-diols: *trans*-β-ocimene (**11a**),[10] from diol **8a**; β-farnesene (**10b**),[11] from **4b**; *trans*-α-farnesene (**11b**),[12] from **8b**. The homogeneity of each product was attested by the NMR analysis. Although the role of excess copper(I) bromide in this process is still obscure, it



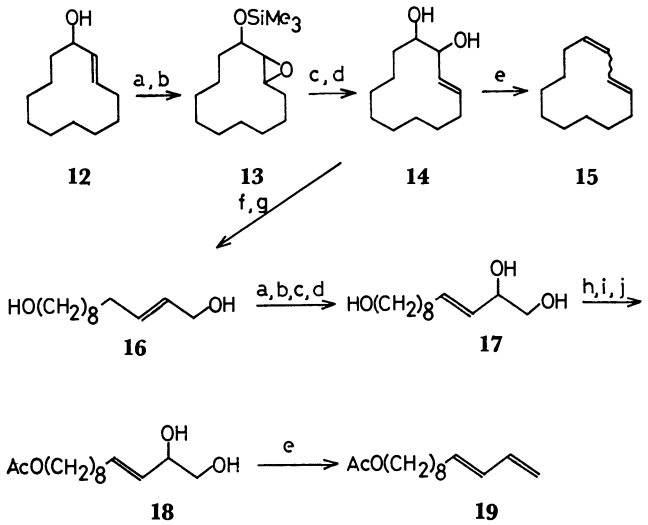
10a R=H
10b R=Me_2C=$CHCH_2$



11a R=H
11b R=Me_2C=$CHCH_2$

appears to facilitate both bromination and debromination and is essential for securing good yields. The synthesis of **10b** and **11b** should be monitored by TLC assay, since the longer reaction time causes cyclization induced by zinc bromide at the expense of the desired product.

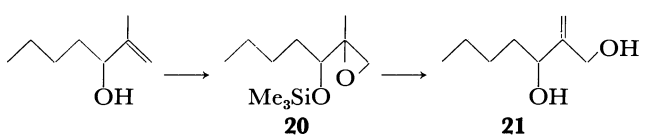
The present method permitted the facile synthesis of the following 1,3-diene compounds. 1,3-Cyclododecadiene (**15**) was prepared from (*E*)-2-cyclododecen-1-ol (**12**).[13] In addition, (*E*)-9,11-dodecadienyl acetate (**19**), which was known as the major sex pheromone of the red bollworm moth,[14] was prepared smoothly from the diol **14** as a starting material. Thus, **14** was converted to the open chain diol **16** by sodium periodate oxidation followed by sodium tetrahydroborate reduction. The same series of reactions transformed **16** into the triol **17**. The terminal alcohol (C-12) was converted to the



a, $VO(acac)_2$–*t*-BuOOH; b, Me_3SiCl–$(Me_3Si)_2NH$–C_5H_5N; c, DATMP; d, KF; e, PBr_3–Cu_2Br_2–Zn; f, $NaIO_4$; g, $NaBH_4$; h, $Me_2C(OMe)_2$–*p*-TsOH; i, Ac_2O–C_5H_5N; j, $(CH_2OH)_2$–*p*-TsOH.

acetate **18** as follows. Treatment of **17** with 2,2-dimethoxypropane with a catalytic amount of *p*-toluenesulfonic acid followed by acetylation (acetic anhydride-pyridine) afforded acetonide acetate, which was transformed to diol **18** using ethylene glycol and trace *p*-toluenesulfonic acid. The desired diene **19** was obtained by the similar treatment with PBr_3–Cu_2Br_2–Zn.

Finally a further extension of the sequence should be added. Reaction of an epoxy silyl ether **20** with DATMP and then KF gave 2-methylene-1,3-diol **21**. Although this class of compounds are potential intermediates for



20 **21**

the synthesis of substituted trimethylenemethane and other related compounds, there exist few synthetic routes available.[15]

Experimental

The infrared spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L mass machine; and NMR spectra on a JNM-PMX 60 or

Varian EM-360 spectrometer. The chemical shifts are given in δ in ppm with TMS as the internal standard. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were carried out by the staffs at the Elemental Analyses Center of Kyoto University. All experiments were carried out under an atmosphere of dry argon. In experiments requiring dry solvents, tetrahydrofuran was distilled from sodium-benzophenone. Ether and benzene were dried over sodium metal. During workup, drying of the organic solution was performed over anhydrous sodium sulfate. Thin layer or preparative thick layer plates were made of E. Merck PF-254, and preparative column chromatography on silica gel E. Merck Art. 7734.

*Synthesis of Myrcene (**10a**). 2-Methyl-r-2-(4-methyl-3-pentenyl)-c-3-trimethylsiloxymethyloxirane (**3a**).* The epoxy alcohol **2a** was prepared as previously reported.[3a] A solution of *t*-butyl hydroperoxide (300 mg, 3.0 mmol) in benzene (3 ml) was added at 0 °C dropwise to a mixture of nerol (**1a**) (308 mg, 2.0 mmol) and oxobis(2,4-pentanedionato-*O*,*O*')vanadium-(IV) (16 mg, 0.06 mmol) in benzene (10 ml). Stirring was continued at room temperature for 3 h (TLC analysis indicated the absence of starting material). The epoxy alcohol **2a** was converted *in situ* to the epoxy silyl ether **3a** by the successive addition of pyridine (4.0 ml), hexamethyldisilazane (0.8 ml), and chlorotrimethylsilane (0.4 ml) at 0 °C. The reaction was completed in 1 h at room temperature, then saturated sodium sulfite was added and the whole mixture was vigorously stirred at ambient temperature for 20 min. The separated organic phase was washed with saturated copper(II) sulfate and water, dried, and concentrated *in vacuo*. The crude product was immediately subjected to the next reaction.

A sample was purified by column chromatography on silica gel (20: 1 hexane–ether) followed by bulb-to-bulb distillation: bp 92—94 °C (bath temp, 1 Torr); TLC, R_f 0.49 (2: 1 hexane–ether); IR (neat), 1450 (m), 1245 (s), 1122 (s), 1080 (s), and 845 cm^{-1} (s); NMR (CCl_4), 0.11 (9H, s, CH_3–Si), 1.25 (3H, s, CH_3–CO), 1.59 (3H, s, CH_3–C=), 1.65 (3H, s, CH_3–C=), 2.63 (1H, t, J=6 Hz, CH–O), 3.54 (2H, dd, CH_2–O), and 5.00 (1H, bt, CH=); MS (*m/e*), 242 (1), 181 (8), 173 (10), 160 (100), and 145 (44).

Found: C, 64.4; H, 10.7 %. Calcd for $C_{13}H_{26}O_2Si$: C, 64.4; H, 10.8 %.

*7-Methyl-3-methylene-6-octene-1,2-diol (**4a**).* To a benzene solution (20 ml) of diethylaluminum 2,2,6,6-tetramethylpiperide (8.0 mmol) a solution of crude **3a** (*ca.* 2.0 mmol) in benzene (2 ml) was added at 0 °C dropwise and the mixture was stirred at the same temperature for 1 h. The reaction mixture was quenched with dil. hydrochloric acid at 0 °C and the resulting organic phase was separated. The aqueous layer was extracted with ether, and the combined organic solutions were washed with saturated brine, dried, and freed of the solvent. The residue was dissolved in 80 % aqueous methanol (5 ml) and potassium fluoride (1.2 g, 20.0 mmol) was added at 0 °C. After stirring at room temperature for 3 h, the volatile material was removed under reduced pressure. The residue was partitioned between saturated brine and ethyl acetate, and the aqueous phase was extracted several times with ethyl acetate. The combined organic phase was washed with saturated brine, dried, and concentrated *in vacuo*. The remaining liquid was submitted to preparative TLC (1: 1 hexane–ethyl acetate) to give pure **4a** (269 mg, 79% yield from **1a**) as a clear oil: bp 130 °C (bath temp, 1 Torr); TLC, R_f 0.41 (ether); IR (neat), 3350—3440 (s), 1440—1455 (m), 1065—1090 (s), and 905 cm^{-1}(m); NMR ($CDCl_3$), 1.61 (3H, s, CH_3–C=), 1.69 (3H, s, CH_3–C=), 4.00—4.33 (1H, m, CH–O), and 4.83—5.27 (3H, bd, CH= and CH_2–); MS (*m/e*), 170 (1), 152 (4), 127 (9), 109 (18), and 69 (100).

Microanalysis was performed after converting the 1,2-glycol group to isopropylidene acetal group by treating the glycol with 2,2-dimethoxypropane in dichloromethane in the presence of a catalytic amount of *p*-toluenesulfonic acid:

Found: C, 74.4; H, 10.7%. Calcd for $C_{13}H_{22}O_2$: C, 74.2; H, 10.5%.

*Myrcene (**10a**).*[7] To an ethereal solution (10 ml) of diol **4a** (200 mg, 1.2 mmol), copper(I) bromide (860 mg, 3.0 mmol) and phosphorus tribromide (0.09 ml, 0.5 mmol) were successively added at −78 °C, and the whole mixture was stirred at 0 °C for 1 h. Zinc dust (392 mg, 6.0 mmol) was added at 0 °C and stirring was continued at room temperature for 2 h. Dilution of the mixture with pentane, folowed by workup and short-path column chromatography (pentane as an eluent), furnished myrcene (**10a**) (98 mg, 58 % yield) as a colorless oil: TLC, R_f 0.80 (hexane); IR (neat), 1600 (s), 1435—1450 (m), 1365 (m), 990 (s), and 890 cm^{-1} (s); NMR (CCl_4), 1.53 (3H, s, CH_3–C=), 1.62 (3H, s, CH_3–C=), 2.20 (4H, d, CH_2–C=), 4.98 (2H, s, CH_2= on C-3), 4.81—5.46 (3H, m, CH_2= on C-1 and CH= on C-6), and 6.35 (1H, dd, J=18 and 10 Hz, CH= on C-2); MS (*m/e*), 136 (8), 121 (7), 107 (5), 93 (100), and 69 (99).

Synthesis of trans-*β-Ocimene (**11a**). 2-Methyl-r-2-(4-methyl-3-pentenyl)-t-3-trimethylsiloxymethyloxirane (**7a**).* The epoxy alcohol **6a**[3a] was converted to epoxy silyl ether **7a** as described above, and used for the next reaction without purification.

A small aliquot was purified by column chromatography (20: 1 hexane–ether) followed by evaporative distillation: bp 95 °C (bath temp, 1 Torr); TLC, R_f 0.50 (2: 1 hexane–ether); IR (neat), 1450 (m), 1240 (m), 1120 (s), 1065—1080 (s), and 840 cm^{-1} (s); NMR (CCl_4), 0.11 (9H, s, CH_3–Si), 1.19 (3H, s, CH_3–CO), 1.59 (3H, s, CH_3–C=), 1.65 (3H, s, CH_3–C=), 2.63 (1H, t, J=5 Hz, CH–O), 3.54 (2H, dd, CH_2–O), and 5.00 (1H, bt, CH=); MS (*m/e*), 242 (1), 181 (14), 160 (100), 145 (45), and 103 (76).

Found: C, 64.2; H, 10.7%. Calcd for $C_{13}H_{26}O_2Si$: C, 64.4; H, 10.8 %.

*(E)-3,7-Dimethyl-3,6-octadiene-1,2-diol (**8a**).* The title compound was prepared from the crude **7a** by treatment with DATMP (4 equiv) at 0 °C for 1.5 h in benzene and then with potassium fluoride (10 equiv) at room temperature for 3 h (59 % yield based on geraniol **5a**): bp 135 °C (bath temp, 1 Torr); TLC, R_f 0.37 (ether); IR (neat), 3250—3400 (s), 1430—1445 (s), 1035—1070 (s), and 880—890 cm^{-1} (m); NMR ($CDCl_3$), 1.64 (6H, s, CH_3–C=), 1.69 (3H, s, CH_3–C=), 2.52—2.94 (2H, t, J=8 Hz, CH_2–C=), 3.80—4.32 (1H, m, CH–O), 5.12 (1H, bt, CH= on C-6), and 5.46 (1H, bt, CH= on C-4); MS (*m/e*), 170 (6), 152 (11), 139 (36), 109 (60), and 81 (100).

Microanalysis was performed with the isopropylidene acetal derivative:

Found: C, 74.4; H, 10.5%. Calcd for $C_{13}H_{22}O_2$: C, 74.2; H, 10.5%.

trans-*β-Ocimene (**11a**).*[10] The title compound was prepared from sequential treatment of the diol **8a** with copper-(I) bromide, phosphorus tribromide, and zinc as described above. The desired triene **11a** (66 % yield) formed a clear oil: TLC, R_f 0.80 (hexane); IR (neat), 1650 (m), 1610 (s), 1380 (s), 990 (s), and 890 cm^{-1} (s); NMR (CCl_4), 1.65—1.72 (9H, m, CH_3–C=), 2.79 (2H, bt, CH_2–C=), 4.58—5.55 (4H, CH= on C-4 and C-6, CH_2=), and 6.26 (1H, dd, J=18 and 10 Hz, CH= on C-2); MS (*m/e*), 136 (13), 121 (24), 105 (18), 93 (100), and 79 (47).

*Synthesis of β-Farnesene (**10b**). r-2-[(3E)-4,8-Dimethyl-3,7-nonadienyl]-2-methyl-c-3-trimethylsiloxymethyloxirane (**3b**):* Bp 135 °C (bath temp, 1 Torr); TLC, R_f 0.48 (5: 1 hexane–ether); IR (neat), 1450 (m), 1245 (s), 1120 (s), 1080 (s), and 845 cm^{-1} (s); NMR (CCl_4), 0.09 (9H, s, CH_3–Si), 1.23 (3H, s,

CH_3–CO), 2.67 (1H, t, CH–O), 3.54 (2H, d, J=6 Hz, CH_2–O), and 4.82—5.23 (2H, m, CH=); MS (*m/e*), 310 (M^+).

Found: C, 69.7; H, 11.2 %. Calcd for $C_{18}H_{34}O_2Si$: C, 69.6; H, 11.0 %.

*(6E)-7,11-Dimethyl-3-methylene-6,10-dodecadiene-1,2-diol (**4b**).* The title compound (169 mg, 71 % yield) was prepared from **1b** employing a series of reactions as aforementioned: TLC, R_f 0.53 (ether); IR (neat), 3330—3420 (s), 1438—1454 (m), 1065—1090 (s), and 905 cm^{-1} (s); NMR ($CDCl_3$), 1.61 (6H, s, CH_3–C= on C-7 and C-11), 1.69 (3H, s, CH_3–C= on C-11), 3.39—3.91 (2H, m, CH_2–O), 4.00—4.36 (1H, m, CH–O), and 4.70—5.34 (4H, bd, CH_2= and CH=).

Microanalysis was performed with its isopropylidene acetal derivative:

Found: C, 77.9; H, 10.9 %. Calcd for $C_{18}H_{30}O_2$: C, 77.7; H, 10.8 %.

*β-Farnesene (**10b**).*[11] The preparation of the diene **10a** was repeated, except stirring was stopped in 1.5 h to suppress the formation of by-products. β-Farnesene (**10b**) (78 mg) was obtained from the diol **4b** (238 mg) in 38 % yield as a colorless liquid: TLC, R_f 0.80 (hexane); IR (neat), 1600 (s), 1440—1465 (s), 990 (s), 910 (sh), and 895 cm^{-1} (s); NMR (CCl_4), 1.60 (6H, s, CH_3–C=), 1.69 (3H, s, CH_3–C=), 4.82—5.41 (6H, m, CH_2= and CH= on C-6, C-10), and 6.32 (1H, dd, J=18 and 11 Hz, CH= on C-2); MS (*m/e*), 204 (8), 161 (10), 133 (20), 93 (59), and 69 (100).

Synthesis of trans-α-*Farnesene (**11b**).* r-2-[*(3E)-4,8-Dimethyl-3,7-nonadienyl*]-2-methyl-t-3-trimethylsiloxymethyloxirane (**7b**): Bp 135 °C (bath temp, 1 Torr); TLC, R_f 0.53 (5:1 hexane–ether); IR (neat), 1450 (m), 1250 (s), 1120 (s), 1060—1080 (s), and 835 cm^{-1} (s); NMR (CCl_4), 0.09 (9H, s, CH_3–Si), 1.19 (3H, s, CH_3–CO), 2.67 (1H, t, CH–O), 3.54 (2H, d, J=6 Hz, CH_2–O), and 4.82—5.23 (2H, m, CH=); MS (*m/e*), 310 (M^+).

Found: C, 69.6; H, 11.1 %. Calcd for $C_{18}H_{34}O_2Si$: C, 69.6; H, 11.0 %.

*(3E,6E)-3,7,11-Trimethyl-3,6,10-dodecatriene-1,2-diol (**8b**).* The same sequence as aforementioned furnished the diol **8b** (168 mg, 70 % yield) from (*E,E*)-farnesol (**5b**) (222 mg) as a clear oil: TLC, R_f 0.48 (ether); IR (neat), 3340—3420 (s), 1440—1455 (m), 1060—1080 (m), and 890 cm^{-1} (w); NMR ($CDCl_3$), 1.61 (6H, s, CH_3–C= on C-7 and C-11), 1.65 (3H, s, CH_3–C= on C-3), 1.69 (3H, s, CH_3–C= on C-11), 2.72 (2H, t, J=7 Hz, CH_2–C= on C-4), 3.92—4.31 (1H, m, CH–O), 5.12 (2H, bt, CH= on C-6 and C-10), and 5.46 (1H, bt, CH= on C-4).

Microanalysis was performed with its isopropylidene acetal derivative:

Found: C, 77.9; H, 11.1 %. Calcd for $C_{18}H_{30}O_2$: C, 77.7; H, 10.8 %.

trans-α-*Farnesene (**11b**).*[12] The title compound was obtained in 45 % yield from **8b**: TLC, R_f 0.80 (hexane); IR (neat), 1610 (m), 1440—1455 (s), 1380 (s), 990 (s), 910 (sh), and 895 cm^{-1} (s); NMR (CCl_4), 1.50—1.74 (12H, m, CH_3–C=), 2.80 (2H, bt, CH_2–C= on C-4), 4.60—5.66 (5H, m, CH_2= and CH= on C-4, C-6, and C-10), and 6.32 (1H, dd, J=18 and 11 Hz, CH= on C-2); MS (*m/e*), 204 (9), 135 (14), 119 (48), 107 (43), and 93 (100).

*Synthesis of 1,3-Cyclododecadiene (**15**).* trans-*1,2-Epoxy-3-trimethylsiloxycyclododecane (**13**)*: Bp 110—112 °C (bath temp, 1 Torr); TLC, R_f 0.59 (3:1 hexane–ether); IR (neat), 1240 (s), 1105 (m), 950 (w), 865 (m), and 840 cm^{-1} (s); NMR (CCl_4), 0.10 (9H, s, CH_3–Si), 2.42—2.90 (2H, m, CH–O on C-1 and C-2), and 3.83—4.16 (1H, m, CH–O on C-3); MS (*m/e*), 270 (1), 255 (48), 185 (6), 129 (100), and 95 (38).

Found: C, 66.9; H, 11.4 %. Calcd for $C_{15}H_{30}O_2Si$: C, 66.6; H, 11.2 %.

*(E)-3-Cyclododecene-1,2-diol (**14**).* This compound was prepared from **12** in 63 % yield: mp 89—91 °C (benzene–hexane); TLC, R_f 0.68 (ether); IR (Nujol), 3300—3410 (s), 1450 (s), 1030 (s), 980 (s), and 915 cm^{-1} (m); NMR ($CDCl_3$), 3.20—3.98 (2H, m, CH–O), and 5.39—5.83 (2H, m, CH=).

Found: C, 72.7; H, 11.3 %. Calcd for $C_{12}H_{22}O_2$: C, 72.7; H, 11.2 %.

*1,3-Cyclododecadiene (**15**).*[16] The diol **14** was transformed to the title compound in 70 % yield: TLC, R_f 0.80 (hexane); IR (neat), 1470—1485 (s), 1445 (m), 980 (s), and 950 cm^{-1} (m); NMR (CCl_4), 5.00—6.59 (4H, m, CH=); MS (*m/e*), 164 (37), 121 (25), 93 (37), 79 (100), and 67 (100).

*Synthesis of (E)-9,11-Dodecadienyl Acetate (**19**). (E)-2-Dodecene-1,12-diol (**16**).* Sodium periodate (3.08 g, 14.4 mmol) was added at 0 °C to a solution of diol **14** (1.42 g, 7.2 mmol) in 80 % aqueous ethanol (26 ml). After stirring at 0 °C for 1.5 h, the solid was filtered off and the filtrate was concentrated *in vacuo*. The residue was partitioned between saturated brine and ether, then the ethereal solution was washed with saturated brine, dried, and freed of the solvent to yield dialdehyde: TLC, R_f 0.60 (2:1 ether–hexane); IR (neat), 1720—1730 (s), 1690 (s), 1460—1470 (m), and 980 cm^{-1} (m); NMR (CCl_4), 6.00 (1H, dd, J=16 and 8 Hz, CH= on C-2), 6.80 (1H, dt, J=16 and 7 Hz, CH= on C-3), 9.43 (1H, d, J=7 Hz, CH=O on C-1), and 9.70 (1H, t, CH=O on C-12); MS (*m/e*), 196 (3), 98 (48), 83 (76), 70 (74), and 55 (100).

The crude product was treated with sodium tetrahydroborate (274 mg, 7.2 mmol) in methanol (10 ml) at room temperature for 1 h. Acetic acid was then added dropwise to hydrolyze the excess hydride and the volatile material was removed *in vacuo*. The residue was diluted with ethyl acetate and the organic phase was washed with saturated brine, dried, and concentrated *in vacuo*. Purification by column chromatography (1:1 benzene–ethyl acetate) furnished the diol **16** (1.05 g, 73 % yield from **14**) as a semi-solid: TLC, R_f 0.13 (1:2 hexane–ether); IR (neat), 3350—3450 (s), 1480 (m), 1470 (s), 1090 (s), and 970 cm^{-1} (s); NMR ($CDCl_3$), 3.60 (2H, t, CH_2–O on C-12), 4.05 (2H, d, CH_2–O on C-1), and 5.41—5.73 (2H, m, CH=).

Microanalysis was performed after trimethylsilylation of both hydroxyl groups:

Found: C, 63.0; H, 12.0 %. Calcd for $C_{18}H_{40}O_2Si_2$: C, 62.8; H, 11.7 %.

*(E)-9,11-Dodecadienyl Acetate (**19**).*[14] The sequence as described above converted the diol **16** to the triol **17** in 75 % yield: TLC, R_f 0.31 (ethyl acetate); IR (neat), 3300—3450 (s), 1450—1480 (m), 1050—1070 (s), and 970 cm^{-1} (s); NMR ($CDCl_3$), 3.20—4.05 (5H, m, CH_2–O and CH–O), and 5.51—5.73 (2H, m, CH=).

Before the synthesis of diene **19**, the terminal alcohol (C-12) was converted to the acetate as follows. To a mixture of triol **17** (80 mg, 0.37 mmol), 2,2-dimethoxypropane (0.07 ml, 0.55 mmol), and THF (3 ml) was added *p*-toluenesulfonic acid (4 mg, 0.02 mmol) at 0 °C, and the solution was stirred at room temperature for 4 h. A drop of pyridine was added and the mixture was diluted with ether. The organic solution was washed with saturated brine, dried, and freed of the solvent. The residue was treated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) at ambient temperature for 5 h. Aqueous workup in the usual manner, drying, and concentrating *in vacuo* gave acetonide acetate, which was treated with *p*-toluenesulfonic acid (4 mg, 0.02 mmol) in ethylene glycol (2 ml) at room temperature for 4 h to furnish diol **18** (89 % yield based on **17**) after purification by preparative TLC (2:1 ether–hexane): TLC, R_f 0.53 (2:1 ether–hexane); IR (neat), 3400—3450 (s), 1740 (s), 1370 (m), 1235—1255 (s), and 970 cm^{-1} (m); NMR ($CDCl_3$), 1.96 (3H, s, CH_3–CO), 3.59 (2H, t, CH_2–OAc), 3.87—4.38 (3H, m, CH–O and CH_2–O), and

5.18—6.09 (2H, m, CH=).

The diol **18** was converted to the desired diene **19** with the Cu_2Br_2–PBr_3–Zn system in 75 % yield: TLC, R_f 0.38 (5: 1 hexane–ether); IR (neat), 1740 (s), 1260 (s), 1005 (m), 960(w), and 900 cm^{-1} (m); NMR ($CDCl_3$, 100 MHz), 2.02 (3H, s, CH_3–CO), 1.95—2.21 (2H, m, CH_2–C=), 4.06 (2H, t, J=7 Hz, CH_2–O), and 4.85—6.50 (5H, m, CH= and CH_2=, 5.00, 5.15, 5.61, 5.69, 5.75, 5.82, 5.92, 6.03, 6.15, 6.24, 6.30, 6.40, and 6.50); MS (*m/e*), 224 (7), 164 (18), 135 (15), 121 (20), and 67 (100).

*2-Methyl-2-(1-trimethylsiloxypentyl)oxirane (**20**)*: Bp 60 °C (bath temp, 1 Torr); TLC, R_f 0.68 (1: 1 hexane–ether); IR (neat), 1450—1700 (w), 1245 (s), 1090 (s), 940 (m), 865 (sh), and 840 cm^{-1} (s); NMR (CCl_4), 0.53 (9H, s, CH_3–Si), 1.67 (3H, s, CH_3–CO), 2.68—3.16 (2H, dd, CH_2–O), and 3.50—3.90 (1H, bt, CH–O); MS (*m/e*), 216 (2), 201 (25), 160 (43), 131 (34), and 75 (100).

Found: C, 61.3; H, 11.3 %. Calcd for $C_{11}H_{24}O_2Si$: C, 61.1; H, 11.2 %.

*2-Methylene-1,3-heptanediol (**21**)*. Treatment of **20** (216 mg, 1.0 mmol) with DATMP (4.0 mmol) and then with KF furnished the diol **21** (108 mg) in 75 % yield: TLC, R_f 0.33 (ether); IR (neat), 3340—3400 (s), 1655 (w), 1010—1060 (s), and 905 cm^{-1} (m); NMR ($CDCl_3$), 3.84—4.48 (3H, m, CH–O and CH_2–O), and 5.09 (2H, s, CH_2=).

Found: C, 66.5; H, 11.5 %. Calcd for $C_8H_{16}O_2$: C, 66.6; H, 11.2 %.

The authors wish to thank the Ministry of Education, Japan, for a Grant-in-Aid (No. 011010, 110309, 203014, and 303023).

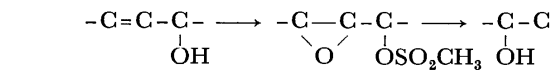
A Stereoselective 1,3-Transposition Reaction of Allylic Alcohols[1)]

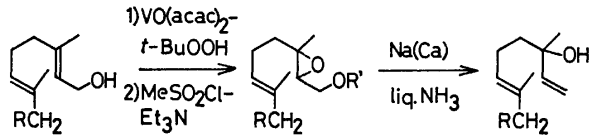
Arata YASUDA,*,† Hisashi YAMAMOTO,†† and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received December 6, 1978)

Reduction of glycidyl mesylate with dissolving metal produces allylic alcohol in fair to excellent yield. Combined with the highly stereoselective epoxidation of allylic alcohols with *t*-butyl hydroperoxide and oxobis(2,4-pentanedionato-*O*,*O*')vanadium(IV) as a catalyst, the sequence provides a new and efficient means for 1,3-transposition of allylic alcohols, by which geraniol is transformed into linalool, farnesol into nerolidol, and furthermore, (−)-*cis*-carveol into the (+) antipode and vice versa in a stereospecific way.

The recently discovered procedure for making 2,3-epoxy-1-alkanols by catalytic epoxidation of allylic alcohols[2)] has initiated an investigation into the possible utilization of the dissolving metal reduction of glycidyl mesylate (methanesulfonate) obtained therefrom as a possible way of 1,3-transposition of allylic alcohols.

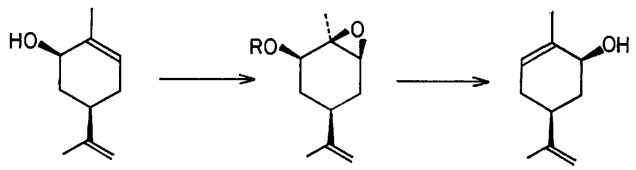


The epoxy alcohol **2** was treated with methanesulfonyl chloride and triethylamine in dichloromethane at −26 °C to give the mesylate **3**. Reduction of **3** with calcium metal in liquid ammonia-tetrahydrofuran furnished linalool (**4**) (88% yield). Some variations in the metal reagent have been studied: sodium, 87% yield; lithium, 50% yield. The use of methylamine, ethylamine, and hexamethylphosphoric triamide in place of liq. ammonia was tested without any success. Reduction with sodium-naphthalene in THF also effected the same transformation yielding linalool. This procedure gave the best result when a THF solution of the mesylate was added to a THF solution of the radical anion.[3,4)] Nerolidol (**8**)[5)] was similarly obtained by reaction of the mesylate **7** with sodium-metal in liq. ammonia-THF.



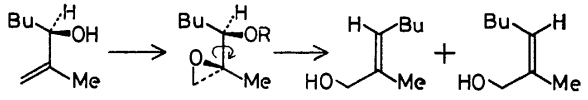
1 R=H **2** R=R'=H **4** R=H
3 R=H, R'=SO_2Me
5 R=Me_2C=$CHCH_2$ **6** R=Me_2C=$CHCH_2$, R'=H **8** R=Me_2C=$CHCH_2$
7 R=Me_2C=$CHCH_2$, R'=SO_2Me

Although the facility and directness of this procedure are appealing, even more important is the advantage that glycidols are prepared from allylic alcohols with high stereospecificity by the Sharpless reagent.[2)] For example, (−)-*cis*-carveol (**9**) was selectively oxidized to the *cis*-epoxy alcohol **10**. Treatment of the mesylate **11** with either Na–NH_3 or Na-naphthalene furnished (+)-*cis*-carveol (**12**) in good yield. The reverse transformation of **12** into **9** was smoothly carried out by employing the same sequence as described above. From the known specific rotation,[6)] each product was found to be no less than 90% optically pure.



9 **10** R=H, **11** R=Ms **12**

In order to examine the stereochemistry of the reduction of an open-chain glycidyl mesylate, (2*R**,3*S**)-glycidol **14**[2b)] was prepared and subjected to the transformation.



13 **14** R=H, **15** R=Ms **16**

Reduction of the mesylate **15** with dissolving calcium furnished an (*E*), (*Z*) mixture of allylic alcohols **16** in a ratio of ≈4: 1. Obviously, the oxirane ring opening is not in concert with the reductive cleavage of the mesylate moiety, but the indicated rotation around the C–C bond is allowed in the acyclic mesylate **15**.

Experimental

The optical rotations were measured using a Yanaco-OR-50 polarimeter. The infrared spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L mass machine; the glpc analyses on a Yanagimoto GCG-550F; and the NMR spectra on a JNM-PMX 60 or Varian EM-360 spectrometer. The chemical shifts are given in δ in ppm with TMS as the internal standard. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were carried out by the staffs at the Elemental Analyses Center of Kyoto University. All experiments were carried out under an atmosphere of dry argon. Tetrahydrofuran was dried by distillation from sodium-benzophenone. During workup, drying of the organic solutions was performed over anhydrous sodium sulfate. Thin layer or preparative thick layer plates were made of E. Merck PF-254, and preparative column chromatography on silica gel E. Merck Art. 7734.

Transformation of Geraniol (1) into Linalool (4). To a mixture of epoxy alcohol **2** (340 mg, 2.0 mmol) prepared from geraniol (**1**) according to the procedure of Sharpless,[2a] and triethylamine (0.3 ml, 2.2 mmol) dissolved in dichloromethane (3 ml) a solution of mesyl chloride (252 mg, 2.2 mmol) in dichloromethane (3 ml) was added drop by drop at −26 °C. After stirring at this temperature for 1 h, the reaction mixture was quenched in ice-cold water. The organic phase was removed and the aqueous layer was extracted with ether. The combined organic solutions were washed with saturated brine, dried, and concentrated *in vacuo* to leave a crude oil, which was purified by preparative TLC (1:1 hexane–ether) to furnish epoxy mesylate **3** (436 mg, 96 % yield): TLC, R_f 0.50 (1: 1 hexane–ether, 2 developments); IR (neat), 1450 (m), 1340—1360 (s), 1240 (w), 1170 (s), and 940—980 cm^{-1} (s); NMR ($CDCl_3$), 1.34 (3H, s, CH_3–CO), 1.64 (3H, s, CH_3–C=), 1.71 (3H, s, CH_3–C=), 2.89—3.24 (1H, m, CH–O), 3.03 (3H, s, CH_3–S), 4.13 and 4.41 (2H, dd, J=11 and 5 Hz, CH_2–OS), and 5.07 (1H, bt, CH=).

To a mixture of the mesylate **3** (248 mg, 1.0 mmol), THF (1 ml), and redistilled ammonia (10 ml) freshly polished calcium metal was added in small pieces at −35 to −37 °C (cooling bath temperature) with vigorous stirring and as rapidly as the metal dissolved, until the blue color persisted. After another 10 min, ammonium chloride (1.00 g) was added carefully to discharge the blue color. The cooling bath was removed and the mixture was poured into ice-cold water. The product was extracted with ether, dried, and freed of the solvent. The residue was submitted to preparative TLC (1: 1 hexane–ether) to give linalool (**4**) (136 mg, 88 % yield) as a clear oil which was homogeneous by TLC. IR and NMR spectra were superimposable on those of authentic specimen.

Linalool (**4**) was also prepared from **3** using the sodium-naphthalene reagent as follows. A green solution of sodium-naphthalene (3.0 mmol) in THF (10 ml) was prepared in the usual manner.[7] To this a solution of the mesylate **3** (124 mg, 0.5 mmol) in THF (1 ml) was added drop by drop over a period of 10 min at room temperature. Stirring was continued for 10 min and the reaction was terminated by the addition of ammonium chloride (1.00 g). The resulting mixture was partitioned between ether and ice-cold water and the organic layer was washed with saturated brine, dried, and concentrated *in vacuo*. Preparative TLC purification (1: 1 hexane–ether) of the residue gave linalool (**4**) (64 mg, 83 % yield). NMR analysis indicated that the product was almost free from impurities.

Transformation of Farnesol (5) into Nerolidol (8). The epoxy alcohol **6**[8] was converted to the mesylate **7** in 97 % yield as described above: TLC, R_f 0.23 (1: 1 hexane–ether); IR (neat), 1450 (s), 1350 (s), 1250 (m), 1160—1180 (s), and 950—980 cm^{-1} (s); NMR ($CDCl_3$), 1.33 (3H, s, CH_3–CO), 2.85—3.20 (1H, m, CH–O), 2.99 (3H, s, CH_3–S), 4.10—4.35 (2H, dd, CH_2–OS), and 4.82—5.23 (2H, m, CH=).

Freshly cut sodium was added in small pieces to a mixture of the mesylate **7** (316 mg, 1.0 mmol), THF (1 ml), and redistilled ammonia (10 ml) at −37 °C (cooling bath temperature) until the blue color persisted. After stirring for another 10 min, the reaction mixture was worked up according to the above mentioned procedure. After drying and concentrating *in vacuo*, the remaining liquid was submitted to preparative TLC (1: 1 hexane–ether) to furnish nerolidol (**8**)[5] (194 mg, 87 % yield) as a clear oil. This material was identical in all respects with the reported one.[5]

*Transformation of (−)-*cis*-Carveol (9) into the (+) Antipode (12).* According to the previously reported procedure,[9] (−)-*cis*-carveol (**9**) (18.24 g, 80 % yield, $[\alpha]_D^{25}$ −26.4 (c=5.6, C_2H_5OH)) was prepared from (−)-carvone (22.50 g, $[\alpha]_D^{25}$ −58 (neat)) by reduction with lithium aluminum hydride (226 mg) in THF (150 ml) and purified by column chromatography (5: 1 hexane–ether) followed by distillation (106—107 °C/10 Torr). From the known specific rotation,[6] the product was estimated to contain 98 % of (−)-*cis*-carveol (**9**) and 2 % of the *trans* isomer. GLPC analysis (10 % PEG 20 Mesh, 120 °C, 0.2 kg/cm^2) also showed the same isomer ratio.

A solution of *t*-butyl hydroperoxide (600 mg, 6.0 mmol) in benzene (8 ml) was added drop by drop to a mixture of (−)-*cis*-carveol (**9**) (608 mg, 4.0 mmol) and oxobis(2,4-pentanedionato-*O*,*O*′)vanadium(IV) (16 mg, 0.06 mmol) dissolved in benzene (8 ml) at 0 °C. After stirring at 50 °C for 4.5 h, the reaction mixture was cooled to room temperature and poured into saturated sodium sulfite. The product was extracted with ether, washed with water, dried, and freed of the solvent. The residue was submitted to column chromatography (5: 1 hexane–ether) to give epoxy alcohol **10** (420 mg, 64 % yield) as a pale yellow oil:[10] TLC, R_f 0.18 (1: 1 hexane–ether); IR (neat), 3400—3500 (s), 1370 (m), 1065 (m), 890 (s), and 860 cm^{-1} (m); NMR ($CDCl_3$), 1.25 (3H, s, CH_3–CO), 1.60 (3H, s, CH_3–C=), 3.10—3.25 (2H, m, CH–O), and 4.95 (2H, s, CH_2=). GLPC analysis (5 % PEG 20 Mesh, 140 °C, 0.2 kg/cm^2) showed that the product was >94 % chemically pure.

Treatment of **10** with mesyl chloride–triethylamine as described above afforded the epoxy mesylate **11** in 87 % yield: TLC, R_f 0.15 (1: 1 hexane–ether); IR (neat), 1450 (m), 1350 (s), 1170 (s), 960 (s), and 890 cm^{-1} (s); NMR ($CDCl_3$), 1.34 (3H, s, CH_3–CO), 1.60 (3H, s, CH_3–C=), 3.10 (3H, s, CH_3–S), 3.50—4.55 (2H, m, CH–O), and 4.98 (2H, s, CH_2=).

Dissolving sodium reaction with the epoxy mesylate **11** (246 mg, 1.0 mmol) furnished 57 % yield of (+)-*cis*-carveol (**12**)[11] (87 mg) as a clear oil: $[\alpha]_D^{25}$ +35.9 (c=4.3, C_2H_5OH), >92 % optically pure. IR, NMR, and mass spectra were identical with those of the authentic sample.

The sodium-naphthalene reagent also effected the same reductive cleavage to give **12** in 54 % yield.

*Transformation of (+)-*cis*-Carveol (12) into the (−) Antipode (9).* The same sequence described above afforded (−)-*cis*-carveol (**9**) $[\alpha]_D^{25}$ −23.0 (c=5.6, C_2H_5OH) (98 % optically pure) from **12** $[\alpha]_D^{25}$ +35.9 (c=5.6, C_2H_5OH) (95 % optically pure).

Preparation of (E)-2-Methyl-2-hepten-1-ol (16). The epoxy alcohol **14**[2b] was converted to the mesylate **15** in 95 % yield: bp 110 °C (bath temp, 1 Torr); TLC, R_f 0.28 (1: 1 hexane–ether); IR (neat), 1450 (s), 1360 (m), 1230—1240 (w), 1100 (m), and 970 cm^{-1} (s); NMR ($CDCl_3$), 1.21 (3H, s, CH_3–CO), 2.96 (2H, dd, CH_2–O), 3.03 (3H, s, CH_3–S), and 4.32 (1H, t, CH–O). Found: C, 48.8; H, 8.2 %. Calcd for $C_9H_{18}O_4S$: C, 48.6; H, 8.2 %.

The epoxy mesylate **15** (222 mg, 1.0 mmol) was treated with calcium metal in liq NH_3–THF as described above to give the alcohol **16** (74 mg, 58 % yield) as a clear oil: bp 120 °C (bath temp, 25 Torr); TLC, R_f 0.35 (1: 1 hexane–ether); IR (neat), 3300—3360 (s), 1470 (m), 1380 (m), and 1005 cm^{-1} (s); NMR (CCl_4), 1.75 (3H, s, CH_3–C=), 4.12 (2H, s, CH_2–O), and 5.29 (1H, bt, CH=); MS (m/e), 128 (M^+).

Found: C, 74.7; H, 12.7 %. Calcd for $C_8H_{16}O$: C, 74.9; H, 12.6 %.

GLPC analysis (20 % PEG 20 Mesh, 130 °C, 0.4 kg/cm^2) of the product showed two peaks in the ratio of 81: 19. The major peak, having the longer retention time, was ascribed to the (*E*) isomer by comparison with the previously reported results.[12]

The authors wish to thank the Ministry of Education, Japan, for Grant-in-Aid (No. 011010, 110309, 203014,

and 303023).

A Highly Stereoselective Synthesis of Trisubstituted Ethylenes from α-Trialkylsilyl Ketones[1,2]

Michio OBAYASHI, Kiitiro UTIMOTO,* and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received February 19, 1979)

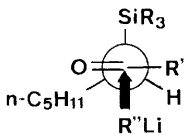
A novel procedure for preparing trisubstituted ethylenes stereoselectively is based on the reaction of α-trialkylsilyl-substituted ketones with alkyllithium reagents and on the following highly discriminative elimination of the silyl and oxido (or hydroxyl) groups from the resulting adducts. The *syn*-elimination of both groups is observed under basic conditions, while the reaction proceeds in *anti*-fashion on acid treatment. Furthermore α-trimethylsilylated ketones are shown to be readily obtained from 2-trimethylsilyl-2,3-dialkyloxiranes. The reaction sequence is applied to the stereoselective synthesis of tetrahomonerol which has been obtained from the codling moth.

Synthesis of trisubstituted ethylenes[3,4] has received considerable attention because of the widespread occurrence of these olefin units in many classes of naturally occurring compounds. Furthermore, recent progress in organic synthesis *via* silicon compounds[5] has disclosed novel methods for the synthesis of 1,2-disubstituted ethylenes with rigorous stereochemistry.[6] This paper describes a facile procedure for the stereoselective synthesis of trisubstituted ethylenes *via* reaction of α-trialkylsilyl ketones with alkyllithium reagents followed by *syn*-elimination under basic conditions or by *anti*-elimination on acid treatment.[7,8]

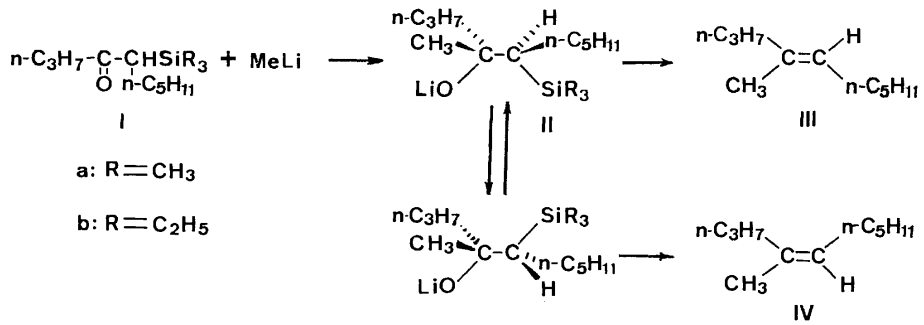
Reaction of 5-trimethylsilyl-4-decanone (Ia)[1] with MeLi in THF at −78 °C afforded a reaction mixture containing IIa.[9] Treatment of the reaction mixture directly with KO^{t}Bu (Run 1 in Table 1) afforded (*E*)-4-methyl-4-decene (III)[10] in 76% overall yield as shown in Scheme 1. When the reaction mixture was treated with glacial acetic acid saturated with sodium acetate (Run 5), the (*Z*)-isomer IV was obtained with *E*/*Z* ratio of 12/88.[11] On the contrary the elimination with concentrated sulfuric acid (Run 7) gave less the stereoselectivity. Similar results were obtained in the case of 5-triethylsilyl-4-decanone (Ib). These and other data are summarized in Table 1.[12,13]

Further information about the stereoselectivity of this olefin synthesis was obtained from the reaction of 3-trimethylsilyl-2-octanone with *n*-PrLi. Treatment of the reaction mixture with KO^{t}Bu gave IV in 21% yield (*E*/*Z*=4/96) *via* the diastereomer of II.[15]

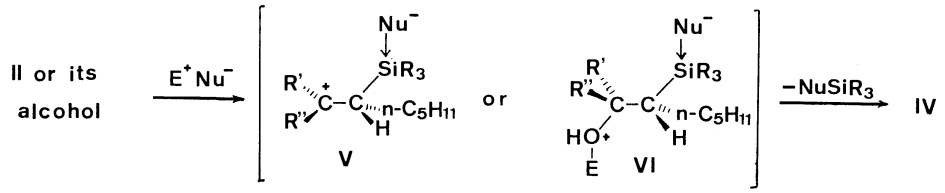
Clearly β-trialkylsilyl alcoholates II are produced from α-trialkylsilyl ketones and alkyllithium reagents with high stereoselectivity. Although it was unsuccessful to directly determine the diastereomeric composition of the alcoholate II or the respective alcohol, the composition was inferred from the *E*/*Z* ratios of the olefins obtained in the elimination reactions. The high selectivity of this carbonyl addition is explained formally by the Felkin model,[16] in which the separation between the trialkylsilyl group and the incoming alkyllithium is the greatest.



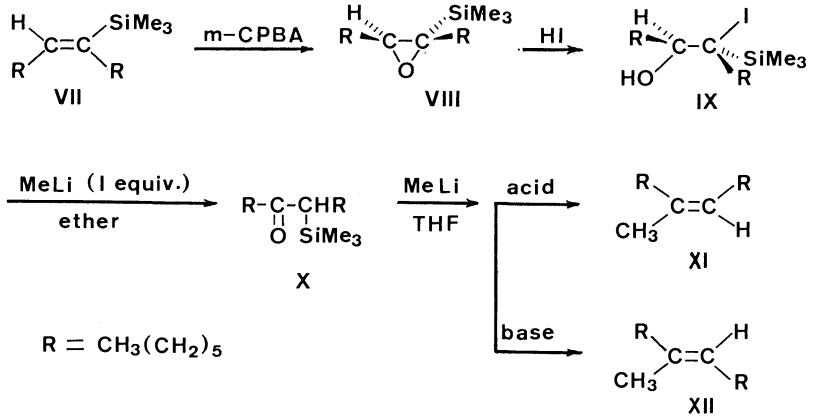
The lithium salt or the potassium salt of the alcohol produces a trisubstituted ethylene by *syn*-elimination of trialkylsilyl and oxido groups. Comparison of Runs 1 and 2, or Runs 3 and 4 as well, indicates that the *syn*-elimination from the lithium salt is slower than that from the potassium salt. On the other hand, acidic treatment of the alcoholates II directly or of the isolated alcohols induces *anti*-elimination of trialkylsilyl and hydroxyl groups as shown in Scheme 2.[6a-c] Poor stereoselectivity is observed when such nucleophiles having weak affinity to silicon as HSO_4^- or H_2O are present (Runs 7 and 8). Meanwhile, nucleophiles with strong affinity to silicon such as AcO^- and F^- give much improved selectivity data (Runs 5, 9—12). Probably in the absence of suitable nucleophiles, C–C bond rotation of the β-silyl carbocation V competes with the *anti*-elimination. The effective nucleophiles obviously favor the concerted *anti*-elimination of the intermediate VI without the loss of stereochemistry. Runs 11 and 12, indicate that the acid strength is an additional factor influencing the *E*/*Z* ratio.



Scheme 1.



Scheme 2.



Scheme 3.

Furthermore as shown in Scheme 3, both isomers (XI and XII) of a trisubstituted ethylene have been obtained from the silylated olefin (VII) *via* the trialkylsilyloxirane (VIII) and the iodohydrin (IX). Treatment of IX with 1 equivalent of MeLi in ether afforded α-trimethylsilyl ketone (X). The resulting mixture was further treated with MeLi (3 equiv.) at −78 °C affording (*Z*)-7-methyl-7-tetradecene (XI) after acidic work-up (Scheme 3 and Table 2). Reaction of IX with 4 equivalents of MeLi in ether at −78 °C gave the same result. The stereoselectivity of the olefin formation is rather low as compared with the previous reaction (for example, Run 5 in Table 1). Remarkably, the *E*/*Z* selectivity of olefin formation is much improved by the coexistence of THF in the MeLi-treatment of X.

An application of these stereoselective olefin formations has provided (2*Z*,6*Z*)-7-methyl-3-propyl-2,6-decadien-1-ol (XIX), which is known to be a tetrahomonerol obtained from the codling moth (Scheme 4).[17] Silyloxirane (XIV) prepared from XIII[6k] was converted to XVII by the following two ways. Isomerization of silyloxirane XIV[1b] in the presence of MgI_2 gave α-trimethylsilyl ketone (XVI). Further treatment

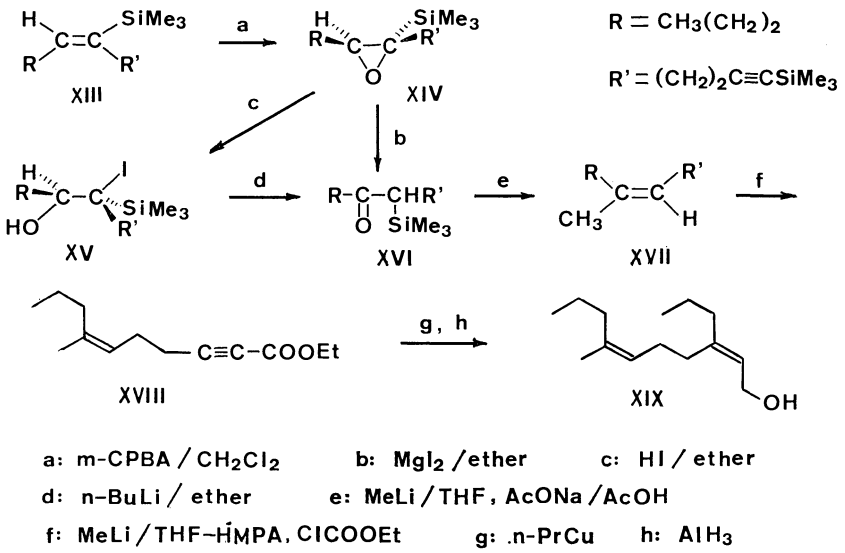
a) The amount of MeLi (ether) admixed initially. b) The amount of MeLi (ether) added (at −78 °C) to the isomerization mixture, which was diluted with THF in advance. c) Without dilution with THF, the reaction was carried out in ether. d) Overall yield from VIII. e) Determined by GLPC.



Scheme 4.

of XVI with MeLi, AcONa/AcOH afforded XVII. Secondly, iodohydrin (XV) obtained from XIV was treated with *n*-BuLi (1 equiv.) followed by MeLi giving XVII after acidic work-up. Direct ethoxycarbonylation of XVII to acetylenic ester XVIII was effected by treatment with MeLi/THF–HMPA[18] and then with ClCOOEt. The acetylenic ester was finally transformed into XIX by the reported procedure.[17]

Experimental

GLPC was performed on Shimadzu GC-4BPT with 3 m×3 mm glass column packed with 20 % polyethylene glycol and 20 % HVSG on Chromosorb W-AW (80—100 mesh). Mass spectra were obtained on Hitachi RMU-6L with 70 V chamber voltage. NMR were measured on Varian EM-360, JEOL JNM-PMX 60, and Varian EM-390 with Me_4Si as internal standard and CCl_4 as solvent. IR on Shimadzu IR-27G spectrometer. Elemental microanalyses were performed by Elemental Analyses Center of Kyoto University. All the reactions were carried out under an atmosphere of dry argon.

Reaction of α-Trialkylsilyl Ketones (I) with Alkyllithium Reagents. (E)-4-Methyl-4-decene (III, Run 1): To a solution of 5-trimethylsilyl-4-decanone (Ia, 0.23 g, 1 mmol) in 5 ml of THF was added MeLi (3 mmol, 3.5 ml of 0.87 M ethereal solution) at −78 °C. The mixture was stirred at a room-temperature for 1 h and treated with KO^{t}Bu (1.0 g, 9 mmol) at reflux for 1 h. The resulting mixture was poured into aq NH_4Cl overlaid with hexane, washed (aq NH_4Cl, sat. NaCl), and dried (Na_2SO_4). GLPC analysis indicated that III was formed in 76 % overall yield (E/Z=91/9). Bp 93—96 °C/21 mmHg; IR (neat) 1380 cm^{-1}; MS *m/e* (rel. %), 154 (M^+, 11), 111 (13), 97 (22), 84 (16), 69 (52), 55 (100); NMR (CCl_4) δ=0.60—1.03 (6H, m), 1.03—1.70 (8H, m), 1.55 (3H, br-s), 1.70—2.20 (4H, m), 5.03 (1H, t, J=7 Hz).

Found: C, 85.50; H, 14.45 %. Calcd for $C_{11}H_{22}$: C, 85.63; H, 14.37 %.

(Z)-4-Methyl-4-decene (IV, Run 5): The reaction mixture from Ia (1 mmol) and MeLi (3 mmol) was treated with 10 ml of glacial acetic acid saturated with sodium acetate under stirring at −20 °C for 30 min and at a room-temperature overnight. The resulting mixture was poured into sat. NaCl overlaid with hexane, washed (sat. $NaHCO_3$, sat. NaCl), and dried (Na_2SO_4). GLPC analysis indicated that IV was formed in 69 % overall yield (E/Z=12/88). Bp 90—95 °C/21 mmHg; IR (neat) 1380 cm^{-1}; MS *m/e* (rel. %), 154 (M^+, 15), 111 (15), 97 (23), 84 (19), 69 (57), 55 (100); NMR (CCl_4) δ=0.60—1.03 (6H, m), 1.03—1.70 (8H, m), 1.63 (3H, br-s), 1.70—2.15 (4H, m), 5.01 (1H, t, J=7 Hz).

Found: C, 85.77; H, 14.40 %. Calcd for $C_{11}H_{22}$: C, 85.63; H, 14.37 %.

4-Phenyl-4-decene: To a solution of Ia (0.23 g, 1 mmol) in 5 ml of THF was added PhLi (3 mmol, 3.5 ml of 0.87 M ethereal solution) at −78 °C. The mixture was stirred at a room-temperature for 1 h and poured into aq NH_4Cl overlaid with ether. The ether layer was washed (aq NH_4Cl, sat. NaCl) and dried (Na_2SO_4). The concentrate was dissolved in 5 ml of THF and treated with a few drops of concentrated H_2SO_4 at a room-temperature for 1 h. The reaction mixture was poured into sat. $NaHCO_3$ overlaid with hexane, washed (sat. $NaHCO_3$, sat. NaCl), and dried (Na_2SO_4). Chromatography of the concentrate on silica-gel column (hexane) afforded 0.11 g (52 %) of 4-phenyl-4-decene (E/Z=39/61). The mixture formed an oil; IR (neat) 1601, 1492, 1380, 705 cm^{-1}; NMR (CCl_4) δ=0.65—1.10 (6H, m), 1.10—1.67 (8H, m), 1.67—2.60 (4H, m), 6.90—7.70 (5H, m) and two olefinic signals at 5.35 (br-t, J=7 Hz, C=CH of (4*Z*)-isomer) and 5.58 (br-t, J=7 Hz, C=CH of (4*E*)-isomer). The sum of these olefinic signals was equal to 1H. GLPC gave each isomer in pure form.

(4E)-Isomer: MS *m/e* (rel. %), 216 (M^+, 19), 173 (31), 159 (16), 131 (20), 118 (33), 117 (100), 105 (14), 91 (49), 77 (7), 55 (5), 41 (12), 40 (48), 29 (32).

Found: C, 88.80; H, 11.44 %. Calcd for $C_{16}H_{24}$: C, 88.82; H, 11.18 %.

(4Z)-Isomer: The mass spectrum was very similar to that of (4*E*)-isomer.

Found: C, 88.55; H, 11.24 %. Calcd for $C_{16}H_{24}$: C, 88.82; H, 11.18 %.

Reaction of (7S,8S*)-8-Iodo-8-trimethylsilyl-7-tetradecanol (IX) with MeLi.* Iodohydrin (IX) was prepared according to the reported procedure from (2*S**,3*S**)-2-trimethylsilyl-2,3-dihexyloxirane (VIII).[1c]

(Z)-7-Methyl-7-tetradecene (XI): To a solution of IX (0.41

g, 0.98 mmol) in 5 ml of ether was added MeLi (0.98 mmol, 0.61 ml of 1.63 M ethereal solution) at −20 °C. The mixture was stirred at a room-temperature for 1 h and treated with 5 ml of THF and MeLi (3 mmol, 1.84 ml of 1.63 M ethereal solution) at −78 °C. The resulting mixture was stirred at a room-temperature for 1 h and treated with 5 ml of glacial acetic acid saturated with sodium acetate under stirring at −20 °C for 0.5 h and at a room-temperature overnight. The mixture was poured into sat. NaCl overlaid with hexane, washed (sat. $NaHCO_3$, sat. NaCl), and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (hexane) afforded 0.16 g of XI (yield, 74 % based on 1 mmol of VIII, E/Z=9/91). Bp 115—120 °C/4 mmHg; IR (neat) 1368 cm^{-1}; MS *m/e* (rel. %) 210 (M^+, 12), 181 (0.6), 140 (10), 125 (16), 112 (14), 111 (17), 97 (26), 84 (25), 83 (65), 71 (17), 70 (100), 43 (33), 41 (50), 29 (23); NMR (CCl_4) δ=0.88 (6H, t, J=6 Hz), 1.05—1.50 (16H, m), 1.62 (3H, s), 1.70—2.10 (4H, m).

Found: C, 85.22; H, 14.33 %. Calcd for $C_{15}H_{30}$: C, 85.63; H, 14.37 %.

(E)-7-Methyl-7-tetradecene (XII): The reaction mixture from IX (0.39 g, 0.94 mmol) and MeLi (0.94 mmol, 0.58 ml of 1.63 M ethereal solution) was treated with 5 ml of THF and MeLi (3 mmol) at −78 °C. The resulting mixture was stirred at a room-temperature for 1 h and poured into sat. $NaHCO_3$ overlaid with ether. The ether layer was washed (sat. $NaHCO_3$, sat. NaCl) and dried ($MgSO_4$). The concentrate was dissolved in 5 ml of THF and treated with KO^{t}Bu (1.0 g, 8 mmol) at a room-temperature for 1 h. The resulting mixture was poured into aq. NH_4Cl overlaid with hexane, washed (aq NH_4Cl, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (hexane) afforded 0.17 g of XI (yield, 79 % based on 1 mmol of VIII, E/Z=91/9). Bp 115—120 °C/4 mmHg; IR (neat) 1368 cm^{-1}; NMR (CCl_4) δ=0.88 (6H, t, J=6 Hz), 1.05—1.50 (16H, m), 1.53 (3H, s), 1.75—2.10 (4H, m). The mass spectrum was very similar to that of (7*Z*)-isomer.

Found: C, 86.27; H, 14.47 %. Calcd for $C_{15}H_{30}$: C, 85.63; H, 14.37 %.

(2Z,6Z)-7-Methyl-3-propyl-2,6-decadien-1-ol (XIX). (2S, 3S*)-2-Trimethylsilyl-2-(4-trimethylsilyl-3-butynyl)-3-propyloxirane (XIV)*: Treatment of (*E*)-1,5-bis(trimethylsilyl)-5-nonen-1-yne (XIII, 1.0 g, 3.9 mmol) with *m*-chloroperbenzoic acid (85 % purity, 1.0 g, 5 mmol) in CH_2Cl_2 at 0 °C overnight gave 1.1 g (quantitative yield) of XIV. IR (neat) 2200, 1245, 837, 758, 696, 640 cm^{-1}; MS *m/e* (rel. %), 282 (M^+, 0.2), 267 (0.2), 253 (2), 239 (3), 225 (8), 171 (9), 169 (5), 147 (15), 133 (5), 91 (5), 83 (4), 75 (13), 74 (9), 73 (100), 59 (8), 43 (5); NMR (CCl_4) δ=0.03 (9H, s), 0.10 (9H, s), 0.75—1.15 (3H, m), 1.15—2.50 (8H, m), 2.61 (1H, br-t, J=6 Hz).

Found: C, 63.82; H, 10.88 %. Calcd for $C_{15}H_{30}OSi$: C, 63.76; H, 10.70 %.

Conversion of XIV to (Z)-1-Trimethylsilyl-6-methyl-5-nonen-1-yne (XVII) Involving the Isomerization of XIV to 5,9-Bis(trimethylsilyl)-8-nonyn-4-one (XVI) in the Presence of MgI_2: To a solution of MgI_2 (10 mmol) in 10 ml of ether was added XIV (0.28 g, 1 mmol dissolved in 10 ml of ether). The resulting mixture was stirred at reflux for 2 h and then treated with 6 ml of 1,4-dioxane at 0 °C overnight. The solution was freed from solids by filtration. The solids were washed with hexane several times and the combined organic layer was washed (sat. $NaHCO_3$, sat. NaCl), dried ($MgSO_4$), and concentrated affording 0.28 g (98 %) of XVI. Oil; IR (neat) 2200, 1686, 1246, 840, 761, 700, 642 cm^{-1}; MS *m/e* (rel. %), 282 (M^+, 1), 267 (2) 253 (3), 239 (2), 225 (2), 209 (5), 172 (10), 171 (61), 147 (11), 143 (12), 130 (32), 115 (5), 75 (22), 74 (9), 73 (100), 59 (7), 45 (16), 43 (7). To a solution of XVI (0.28 g, 0.98 mmol) in 2 ml of THF was added MeLi (3 mmol, 2.9 ml of 1.04 M ethereal solution) at −78 °C. The mixture was stirred at 0 °C for 1 h and treated with 3 ml of glacial acetic acid saturated with sodium acetate under stirring at −20 °C for 30 min and at a room-temperature overnight. The resulting mixture was poured into sat. NaCl overlaid with hexane, washed (sat. $NaHCO_3$, sat. NaCl), and dried (Na_2SO_4). Chromatography of the concentrate on silica-gel column (hexane) afforded XVII (0.11 g, yield, 51 % based on XIV, E/Z=5/95). Bp 104—108 °C/17 mmHg; IR (neat) 2210, 1247, 844, 763, 701, 645 cm^{-1}; MS *m/e* (rel. %), 208 (M^+, 0.6), 193 (3), 179 (4), 165 (2), 149 (5), 144 (12), 119 (6), 105 (5), 97 (37), 96 (15), 83 (7), 81 (16), 75 (3), 74 (7), 73 (65), 69 (10), 59 (22), 55 (100), 43 (12); NMR (CCl_4) δ=0.10 (9H, s), 0.90 (3H, t, J=6 Hz), 1.10—1.65 (2H, m), 1.67 (3H, br-s), 1.80—2.40 (6H, m), 5.14 (1H, br-t, J=6 Hz).

Found: C, 75.05; H, 11.74 %. Calcd for $C_{13}H_{24}Si$: C, 74.92; H, 11.61 %.

Conversion of XIV to XVII via (4S,5S*)-5,9-Bis(trimethylsilyl)-5-iodo-8-nonyn-4-ol (XV)*: To a solution of XIV (0.37 g, 1.3 mmol) in 5 ml of ether was added 0.6 ml of 57 % HI at −20 °C. After 20 min the mixture was poured into sat. $NaHCO_3$ overlaid with ether. The ether layer was washed (10 % $Na_2S_2O_3$, sat. $NaHCO_3$, sat. NaCl), dried ($MgSO_4$), and concentrated, affording 0.50 g (29 %) of XV. To a solution of XV (0.50 g, 1.2 mmol) in 5 ml of ether was added *n*-BuLi (1.2 mmol, 1.5 ml of 0.82 M hexane solution) at −20 °C. The mixture was stirred at room temperature for 0.5 h and treated with 5 ml of THF and MeLi (3.7 mmol, 2.2 ml of 1.63 M ethereal solution) at −78 °C. Work-up gave XVII (0.16 g, yield, 57 % based on XIV, E/Z=5/95).

Transformation of XVII into (2Z,6Z)-7-Methyl-3-propyl-2,6-decadien-1-ol (XIX): To a solution of XVII (0.10 g, 0.48 mmol) in 2 ml of THF and 1 ml of HMPA was added MeLi (0.6 mmol, 0.58 ml of 1.04 M ethereal solution) at −78 °C. The mixture was stirred at −30 °C for 1 h and treated with ClCOOEt (0.06 ml, 0.6 mmol) at −78 °C. The resulting mixture was stirred at a room-temperature for 0.5 h and poured into sat. $NaHCO_3$ overlaid with ether. The ether layer was washed (sat. $NaHCO_3$, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (benzene) gave 70 mg (70 %) of ethyl (*Z*)-7-methyl-6-decen-2-ynoate (XVIII, E/Z=4/96). IR (neat) 2265, 1709, 1371, 1360, 1243, 1070, 757 cm^{-1}; MS *m/e* (rel. %), 208 (M^+, 0.5), 193 (1), 180 (16), 151 (7), 149 (5), 135 (8), 134 (7), 121 (7), 112 (15), 111 (7), 97 (26), 84 (16), 69 (11), 56 (8), 55 (100), 43 (8), 41 (13); NMR (CCl_4) δ=0.88 (3H, t, J=6 Hz), 1.25 (3H, t, J=7 Hz), 1.10—1.53 (2H, m), 1.65 (3H, br-s), 1.75—2.15 (2H, m), 2.15—2.40 (4H, m), 4.04 (2H, q, J=7 Hz), 4.80—5.25 (1H, m). The product XVIII was transformed into the tetrahomonerol XIX according to the reported procedure.[16] IR (neat) 3300, 1659, 1366, 1239, 1002, 833, 750 cm^{-1}; MS (as trimethylsilyl ether) *m/e* (rel. %), 282 (M^+, 10), 267 (3), 239 (12), 197 (13), 192 (10), 171 (11), 169 (15), 161 (25), 156 (15), 155 (11), 149 (48), 143 (10), 129 (12), 121 (24), 119 (25), 97 (38), 93 (18), 91 (20), 81 (20), 79 (22), 75 (59), 73 (81), 55 (100), 43 (23), 41 (22); NMR (CCl_4) δ=0.90 (6H, t, J=6 Hz), 1.10—1.77 (4H, m), 1.67 (3H, br-s), 1.77—2.40 (9H, m), 4.02 (2H, br-d, J=7 Hz), 5.10 (1H, m), 5.33 (1H, t, J=7 Hz).

The authors wish to thank the Ministry of Education, Science and Culture, Japan, for the Grant-in-Aid (911506, 011010, 110309, 203014, 303023).

A Theoretical Treatment of the Difference in the Fragmentation of Urea and Acetamide

Tsutomu TAKAGI* and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564

(Received June 21, 1978)

The difference in the hydrogen migration in urea and acetamide under electron impact has been discussed from the standpoint of the all-valence electron semi-empirical SCF-MO theory (CNDO/2). The features of the molecular ion in the ground state and the hydrogen-migration models for both compounds were estimated based on the variations in the total and the partitioned energies. The variation in the total energy with the hydrogen migration in urea was smaller than that in acetamide. Moreover, the bonding interaction between carbon and nitrogen becomes weak; the cleavage of the migrated molecular ion to NH_3 was predicted. On the other hand, the weak bonding interaction between carbon and carbon in acetamide does not change through the migration of hydrogen. It is predicted that the α-cleavage in the C–C bond will occur in preference to the migration of hydrogen. Finally, in acetamide, it was found that the possibility of the migration of hydrogen is lower than that in urea, judging from the variations in the total and the partitioned energies.

It is interesting to ascertain the hydrogen-migration process involved in fragmentation from the standpoint of the molecular orbital (MO) theory. The analyses, by MO theory, of the mass spectral data of the organic compounds have not been completely established because of the complexity of the driving factors governing the cleavage of the molecular ion ($M^{\ddagger}$) on electron-impact collision.

The mass spectra of urea[1] and acetamide[2] have been reported. In the mass spectrum of urea, a peak thought to be the ion formed by the migration of hydrogen has been observed. This shows that the NH_3 ion with *m/e* 17 is richly abundant, accompained by the migration of hydrogen from one nitrogen to another nitrogen. On the other hand, in acetamide the most important fragmentation arises from α-cleavage, resulting in the formation of an ion with a mass of 44. The migration of hydrogen from carbon to nitrogen does not appear as clearly as that of urea. This fragmentation of acetamide has, however, not been fully elucidated, but only speculated from the mass spectral data.

This paper will describe an attempt to analyze the hydrogen migration in urea and the possibility of the migration of hydrogen in acetamide by calculations based on the CNDO/2 method.

Method and Calculations

Interaction Energies. These discussions were supported by unrestricted open-shell SCF calculations with a CNDO/2 approximation. The total molecular energy, E, can be expressed by the sum of one- and two-center terms:[3]

$$E_{\text{total}} = \sum_{A} E_A + \sum_{A<B} E_{AB}$$

where

$$E_A = \sum_{r}^{A} p_{rr} U_{rr} + \frac{1}{2} \sum_{r}^{A} \sum_{s}^{A} \{p_{rr} P_{ss} - (p_{rs}^{\alpha})^2 - (p_{rs}^{\beta})^2\} \gamma_{AA}$$

$$E_{AB} = \sum_{r}^{A} \sum_{s}^{B} 2 p_{rs} \beta_{AB}^{\circ} S_{rs} - \sum_{r}^{A} \sum_{s}^{B} \{(p_{rs}^{\alpha})^2 + (p_{rs}^{\beta})^2\} \gamma_{AB} + (Z_A - P_{AA})(Z_B - P_{BB}) \gamma_{AB}$$

E_{AB} is the contribution to the total energy from all the two-center integrals involving A and B centers; it can be partitioned into covalent binding, core repulsion, and ionic terms. The total E_{AB} is used for discussing the nature of each bond with a hydrogen migration.

Table 1. Molecular geometries[c] for the $M^{\ddagger}$ ions

Geometry. It is difficult to determine absolutely the reaction coordinate in the hydrogen-migration process under electron impact.[4] Consequently, the parameters for the geometry of the $M^{\ddagger}$ ion employed here were decided as is shown in Table 1. These values of the bond lengths and the bond angles for the starting geometry, with the exception of the r_1, r_2, and r_3, were taken from the standard tables.[5]

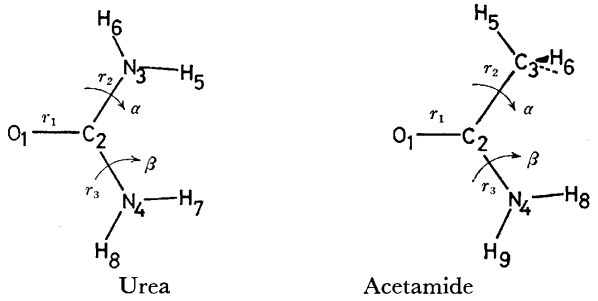

Fig. 1. Representation of the geometries of urea and acetamide.

The basic conformations in the $M^{\ddagger}$ ions of urea and acetamide are shown in Fig. 1. As the lengths of the N–H bonds in urea and acetamide we employed 1.000 Å, and as that of the C–H bonds in acetamide, 1.080 Å.

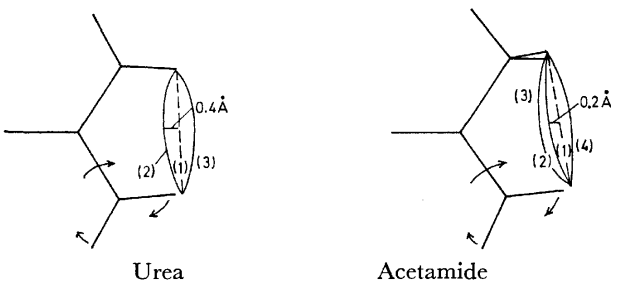
diagram[6] of the M^+ ion for the origin of the migration shows the deep energy minima at $\alpha=0°$ and $\beta=0°$ in both compounds, adopting the values in Table 1. The variation in the E_{AB} of the N_4H_5 by the rotation by β is shown in Table 2 for urea. The bonding interaction between N_4 and H_5 is strong at $\beta=90°$. These results suggest that the possibility of the migration of hydrogen to N_4 is large in this conformation. However, in this conformation the variation in the total energy with the hydrogen migration in the first stage was large. On the other hand, in acetamide the bonding interaction in the possible conformation of the hydrogen migration was weak, as is shown in Table 3. Consequently, as a model of the hydrogen migration, the planar geometries shown in Fig. 2 were employed, judging from the E_{AB} values and the total energies.

Models of both compounds, in which the migration of hydrogen was assumed to follow the curve path(2),



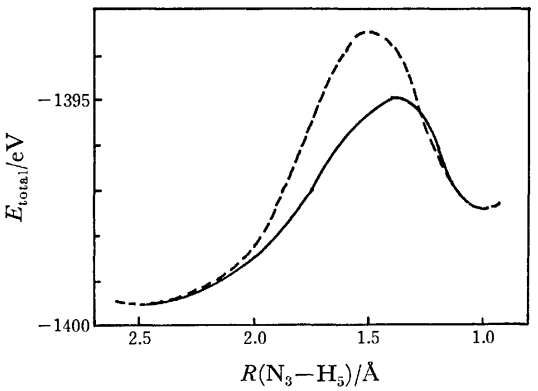
Urea Acetamide

Fig. 2. Migration model and paths.

show that the migrating hydrogen moves to N_4. The deviations from the least-motion path[7] at the transition state are at 0.4 Å in urea and 0.2 Å in acetamide. The variations in the total energies with the hydrogen migration in the models, caused by the least-motion path(1) and the other paths, were large in comparison with that caused by the curve path. The curve-path model was, therefore, chosen for the hydrogen migration in both compounds.

Results and Discussion

Urea. The results calculated by using the curve path are shown in Table 4 and Fig. 3. It is apparent from the shape of the curve that the total energy of the transition state, in which the N_3–H_5 distance is 1.306 Å, was low in the curve path. The potential energy was 4.736 eV. The total energy tends to decrease in the latter half of the migration of hydrogen. It is thought that a comparatively stable state results from the hydrogen migration. In this case, the variation in the total energy between the origin and the terminus of the migration was 2.105 eV.



Reaction coordinate for hydrogen migration

TABLE 4. VARIATIONS IN THE TOTAL ENERGY AND E_{AB}[a]

	Point	1	3	5
E_{total}		−1399.511	−1394.775	−1397.406
$R(N_4$–$H_5)$/Å		2.494	1.359	1.000
E_{AB}	O_1–C_2	−34.266	−33.787	−37.462
	C_2–N_3	−36.436	−37.299	−37.607
	C_2–N_4	−36.436	−30.561	−26.857
	N_3–H_5+N_4–H_5	−20.934	−18.056	−19.843

a) Energies in eV.

The increase in the total energy results from the increases in the E_{AB} value of the C_2–N_4 and the sum of the E_{AB} values of the two bonds (N_3–H_5 and N_4–H_5), as is shown in Table 4.

Although it is thought that the slight increase in the sum of the E_{AB} values of the two bonds hinders the migration of hydrogen, there is a tendency to decrease

near the terminus of the migration.

The tendency of the E_{AB} value of the C_2–N_4 bond to increase with the approach of H_5 to N_4 shows that the interaction between C_2 and N_4 is weakened; this results from the change in the bond length of this bond through the hydrogen migration. On the other hand, the variations in the E_{AB} values of the C_2–N_3 and the O_1–C_2 were small; this shows a slight tendency to decrease, after which these values were large and negative. This phenomenon may be related to the cleavage of the migrated M^+ ion to the fragment ion, *m/e* 17 or *m/e* 42.

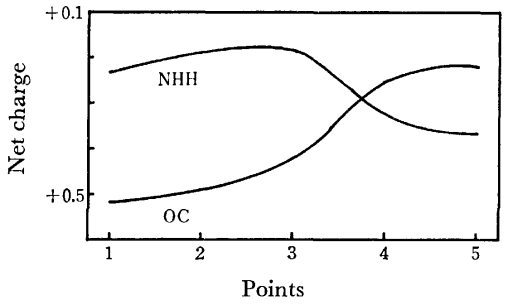

Fig. 4. Variation of the net electric charges.

Next, the variation in the net eleetric charge is shown in Fig. 4. The charge of the CO tends to be positively small with the hydrogen migration, while that of the N_4HH is large and positive. In the OCN_3H, after the migration of hydrogen, the density increases. These results may be reflected in the intense peak height of the NH_3 ion.

Acetamide. The most apparent fragmentation arises from cleavage, resulting in the formation of the ion with a mass of 44. If the migration of hydrogen as well as urea occurs, the hypothetical process for the migration of hydrogen can be expected to be energetically favored.

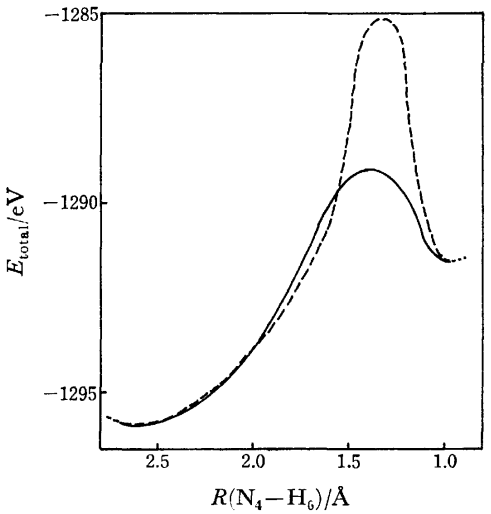

Fig. 5. Variation of the total energies in acetamide.
——: The curve path (1). – – –: The least-motion path (2).

The variation in the total energy in the model was larger than that in urea, as is shown in Fig. 5. This variation in the least-motion path was larger than that in the curve path. The potential energy in this curve-path process was 6.675 eV, which is larger by 2.0 eV than that in urea. Moreover, the variation in the total energy between the point of origin and the terminus of the migration was 4.075 eV, which is large. The variation in the total energy with the hydrogen migration at the conformation at $\alpha=180°$ and $\beta=0°$ was also large, similar to that at $\alpha=0°$ and $\beta=0°$, which was 11.284 eV.

Difference in Urea and Acetamide. The values of the E_{AB} of the N_4–H_6 in $\alpha=0°$ and of the N_4–H_5 in $\alpha=180°$ were −0.031 and 0.057 eV respectively, as is shown in Table 3. The values of the resonance interaction were positive (0.097 and 0.144 eV) in acetamide, while in urea this value of the N_4–H_5 was −0.168 eV. Therefore, the bonding interaction between hydrogen and nitrogen in urea is strong; this may be related to the ease of the migration of hydrogen. It may be predicted that the chance of the migration of hydrogen in urea is fairly strong.

Although the decrease in the E_{AB} values of the two bonds is not smooth, the variation in this energy in urea is smaller than that in acetamide. In acetamide, the increase (from −20.185 to −16.561 eV) shows the hindrance of the migration of hydrogen.

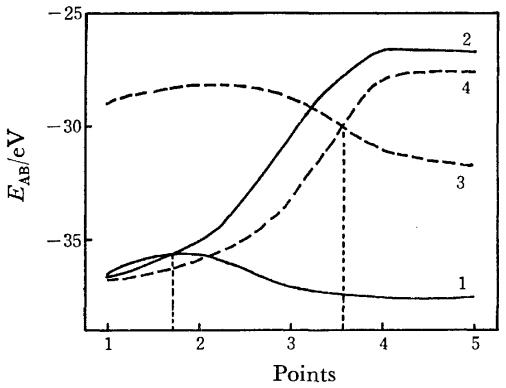

Fig. 6. Variation of the E_{AB} values of the skeletal bonds with the hydrogen migration.
——: Urea, 1: C_2–N_3, 2: C_2–N_4. – – –: Acetamide, 3: C_2–C_3, 4: C_2–N_4.

Fig. 6 shows the variations in the E_{AB} values of the C–C and C–N bonds. The E_{AB} value of the C_2–N_4 decreases smoothly. In acetamide, that of the C_2–C_3 is negatively small in comparision with the other bonds, including that of urea, in the origin of the migration. Moreover, the variation in this value is small, as in the case of the C_2–N_4 bond in urea.

It is found that the bonding interaction between C_2 and N_4 in acetamide is weaker than that of the C_2–C_3 bond after Point 3. However, the interaction in the first stage is strong. These features in acetamide show a great difference from urea. It may be thought that, even if the hydrogen migration occurs, the cleavage of the C_2–C_3 bond will occur preferentially to that of the C_2–N_4.

Conclusion

The estimation of the CNDO scheme provides fairly good information with respect to the fragmentation, including the migration of hydrogen in urea and acetamide. The treatment for the M^+ ion in the ground state shows a different profiles for the hydrogen migrations in the two compounds. As for the variation in the total energy in acetamide, the potential energy is large; therefore, there are large differences in the changes in E_{AB} values of the skeletal bonds. It is, therefore, found that the possibility of the migration of hydrogen is undoubtedly large in urea.

Finally, the quantitative discussion was unsatisfactory; the precise relation between the relative intensity of the rearranged ion and the estimation of the energy by the migration process has not been established. However, the possibility of the migration of hydrogen was qualitatively predicted by this treatment with respect to urea and acetamide, based on the partitioned energy and the migration model.

A Theoretical Approach to the Possible Hydrogen Migration in Butadiene under Electron Impact

Tsutomu TAKAGI* and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564

(Received July 13, 1978)

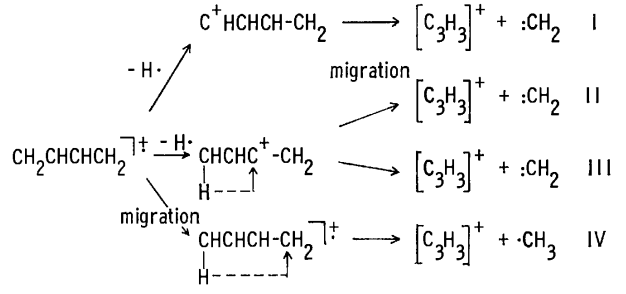
The hydrogen migration in butadiene under electron impact was studied by means of the calculated potential energy surfaces. The all-valence electron semi-empirical SCF-MO(MINDO/2-Unrestricted Hartree Fock) theory was employed. The possibility of the migration of hydrogen has been discussed. Moreover, the mechanisms (I—IV) including the hydrogen migration for the formation of the C_3H_3 ion have been discussed. The hydrogen-migration models are presented based on the variations in the total and the partitioned energies. It is very probable that the hydrogen on C_1 in the M^+ ion migrates to the other carbon, C_4, *via* Models 1 and 2 in Mechanism IV. It was predicted that the formation of the C_3H_3 ion occurs by means of the fragmentation of the migrated M^+ ion, although the other mechanisms can not always be ignored. Finally, for the hydrogen-migration models, the theoretical predictions were found to be in good agreement with the available experimental results.

The fragmentation in the unsaturated hydrocarbons is more complex than in the case of the saturated hydrocarbons. The hydrogen migration in the molecular ion(M^+) can be expected to be essentially prevalent if the M^+ ion possesses a large amount of excess vibrational energy. In this case, it is thought that the hydrogen migration proceeds *via* the four- or six-ring transition state.[1,2]

The possibility of the migration of hydrogen in butadiene can not always be neglected, judging from the mass number of the produced fragment ions. In butadiene, the C_3H_3, C_2H_3, and C_4H_5 ions are found in the mass spectrum in rich abundance. The precise mechanisms for the formation of these fragment ions, especially the C_3H_3 ion, have, however, not yet been elucidated, but only speculated from the mass spectral data.

By the way, the Woodward-Hoffmann rule is very useful in discussing the migration of hydrogen. However, with respect to the mechanism of the formation of the C_3H_3 ion including the hydrogen migration, the contribution of the hydrogen migration to the cleavage of the C–C bond can not be discussed in terms of the W-H rule. Therefore, it is necessary that the role of the M^+ ion for the hydrogen migration be discussed in terms of energy.

The mechanisms for the C_3H_3 ion with *m/e* 39 are thought to be as follows:



Mechanism I shows the formation of the C_3H_3 ion by the scission of the C–C bonds in the $[M-H]^+$ion. The mechanism with the hydrogen migration to the carbon atom loses a hydrogen atom as is shown in II. In Mechanism III, this process shows the simple fragmentation of the $[M-H]^+$ion. If the existence of the five-ring transition state in Mechanism IV is real, *i.e.*, if it is estimated that the hydrogen-migration process is energetically favorable, Mechanism IV should not be ignored. Mechanism IV shows the process with the migration of hydrogen.

The present paper is concerned with a discussion of the migration of hydrogen and with the treatment by the simple models for the formation of the C_3H_3 ion in order to gain a better understanding of the fragmentation in butadiene from the standpoint of the MO theory.

Method and Conformation

Computations. All the computations were carried out on a FACOM 230-48 computer at Kansai University. The wave functions were calculated by means of the MINDO method, with the original parameterization.[3] The MINDO calculation of the open shell-configuration was carried out using the method reported by Dewar.[3]

The total energy, E, can be partitioned into these chemically useful terms:[4,5]

$$E = \sum_A E_A + \sum_{A<B} E_{AB}$$

E_A is the energy due to the atom A. E_{AB} is the contribution to the total energy from all two-center integrals involving A and B centers, and can be partitioned into covalent binding, core repulsion, and ionic terms.[6]

Geometry. The starting geometry for the hydrogen-migration model requires a minimization of the total energy of the system with respect to all its independent internal coordinates, as has been discussed in a previous paper.[7] Moreover, it is difficult to determine absolutely the reaction coordinate passing through the equilibrium geometry. A full optimization of the

TABLE 1. MOLECULAR GEOMETRIES FOR THE M^+ ION

Parameter		Parameter	
r_1	1.37 Å	α	122°
r_2	1.47 Å	β	125°
r_3	1.06 Å	θ	119°

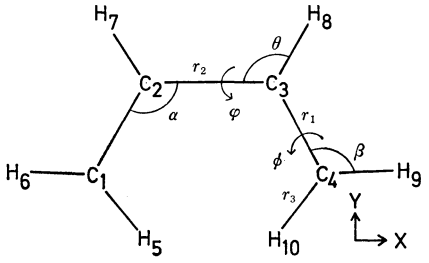


Fig. 1. Definition of the geometrical parameters for the M^+ ion.

geometries at each point in the migration process is thus quite impractical. Consequently, we employed the parameters[8] for the geometry of the M^+ ion as shown in Fig. 1 and Table 1.

The geometries were chosen by assuming the same valence angles for the hydrogen atoms on the CH_2 groups and by neglecting the changes in the C–C bond lengths in the migration process. The twisting of the carbon frame is expressed by φ, the dihedral angle between the $C_1C_2C_3$ and $C_4C_3C_2$ planes; $\varphi=0°$ for *cis*. The CH bond length was changed from 1.06 Å in the starting geometry to 1.09 Å in the terminus of the migration. At the terminus of the hydrogen migration, the angles of β and φ are 109.5° and 90° respectively.

Rotation. The variation in the total energy of the M^+ ion, as a function of the angle, φ, keeping the other internuclear distances and angles constant, is shown in Table 2.

The bond distance between C_4 and H_5 is 2.691 Å in *cis*($\varphi=0°$) and 2.812 Å in $\varphi=30°$, while the bond distance between C_4 and H_7 is 2.720 Å in *trans*($\varphi=180°$). Upon the rotation in φ from 0° to 180°, the chance of the migration of H_7 to C_4 becomes large. The resonance interaction (E^R) between C_4 and H_5 is slightly stronger at 30° than at 0°. Therefore, as a starting conformation, it seems reasonable to adopt that one at $\varphi=30°$ with respect to the migration of H_5 to C_4.

By the way, the net electric charge on C_4 is 0.2048, which is larger and more positive than that as C_3. If the migration of hydrogen is induced by the positive charge, it can be predicted that the migration of hydrogen to the end carbon atom is possible. One findings are, of course, as yet insufficient for us to discuss the possibility of the migration of hydrogen.

Energy Contour. In order to ascertain the migration path, a two-dimensional energy surface was generated by calculating the energy minimum as a function of the α angle, as well as of φ, assuming the other parameters in Table 1. The calculations were carried out with the φ angle increased from 0° to 90°, and at each value of φ, with α varying from 60° to 122°.

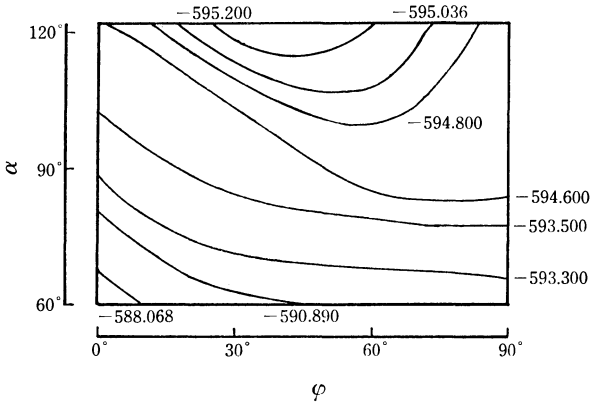

Fig. 2. Energy contours (in eV) of the M^+ ion of the origin of the migration of bent and twisted butadiene, as a function of the angles α and φ. Note that the contours are not separated by equal intervals of energy.

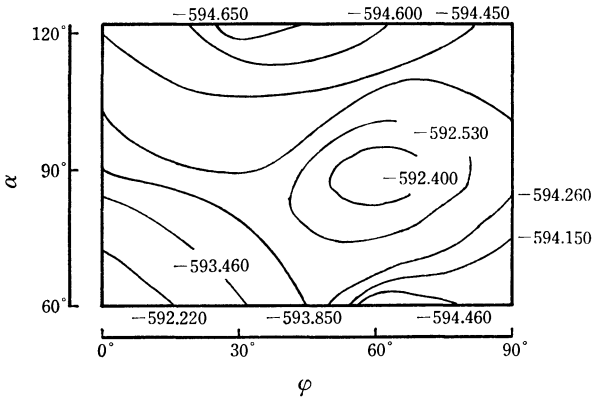

Fig. 3. Energy contours (in eV) of the M^+ ion of the terminus of the migration of bent and twisted butadiene, as a function of the angles α and φ. Note that the contours are not separated by equal intervals of energy.

The total energy-contour diagram for the origin of the migration is given in Fig. 2. The most obvious feature was the deep energy minimum at $\varphi=30°$ and $\alpha=122°$. It can be predicted that this feature results from the electron deficiency; the rotation of the C_2–C_3 bond is comparatively more favorable than a neutral molecule. On the other hand, the total energy-contour diagram calculated for the terminus of the migration is given in Fig. 3. The energy minimum was situated

at $\varphi=30°$ and $\alpha=122°$, while the local minimum energy was −594.662 eV at $\varphi=60°$ and $\alpha=60°$. If this local minimum-energy state is formed by the hydrogen migration, an interesting feature emerges: the formation of the C_3H_3 ion with a three-memberd ring will be accelerated by the fragmentation of the M^+ ion after the hydrogen migration.

Results and Discussion

Migration Models. Mechanism IV was also discussed assuming several models for the hydrogen migration. Model 1, in which the starting and final geometry are $\varphi=30°$ and $\alpha=122°$, is the migration process of H_5 to C_4. The C_4 carbon atom was then changed from sp^2 to sp^3 hybridization by means of the C_3–C_4 bond through the hydrogen migration, as is shown in the following figure. The other parameters were kept constant.

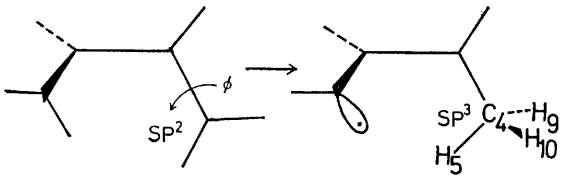

Table 3 shows the variation in the total and the partitioned energies. It is apparent from the variation in the total energy that the transition state lies at Point 3 along the coordinate representing the migration of hydrogen from C_1 to C_4. The potential energy in this process in Model 1 was 1.290 eV, smaller than the minimum energy required for the scission of the C–C bond. The total energy in the first stage shows a tendency to decrease. This results from the decrease in the sum of the two-center energies of the C–C bonds. The increase in the total energy from Point 2 to the transition state results from the increase in the sum of the E_{AB} values of the two bonds (C_1–H_5 and C_4–H_5).

The variation in the bonding interaction of each C–C bond is shown in Fig. 4. The variation in the E_{AB} value of the C_3–C_4 bond increases remarkably with the approach of H_5 to C_4; this shows that the interaction between C_3 and C_4 is weakened by the hydrogen migration, while the variations in the E_{AB} values of the C_1–C_2 and C_2–C_3 bonds are small, which shows a slight decreasing trend. These results may be related to the fragmentation of the migrated M^+ ion to the $[M-CH_3]^+$ ion.

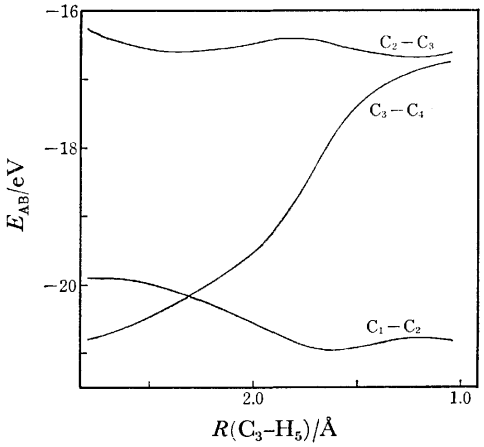

Fig. 4. Variation of E_{AB} of the C–C bonds due to the hydrogen migration in Model 1.

Table 4. Charge distribution of the M^+ ion

	Origin			Terminus	
	0°	30°	180°	0°	30°
C_1	0.2048	0.1699 (0.2465)[a]	0.2372	0.1791	0.1453
C_2	0.0506	0.1210 (0.1535)	0.0356	−0.0966	−0.0541
C_3	0.0506	0.0324 (0.0109)	0.0356	0.3551	0.3220
C_4	0.2048	0.1559 (0.2803)	0.2372	−0.0267	−0.0190

a) The values in parentheses correspond to the net electric charge on the p_z orbital.

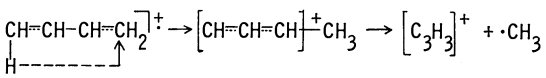
The sum of the E_{AB} values of the C_1–H_5 and C_4–H_5 bonds decreases in the latter half of the reaction. This implies that the bonding interaction between C_4 and H_5 becomes strong through the migration process.

The net electric charge of the C_4 atom is large and positive, as is summarized in Table 4. The net electric charge on the p_z orbital on C_4 at $\varphi=30°$ is very positively large. It seems, therefore, that the possibility of the migration of hydrogen to C_4 is certainly large. There is also an electron flow of the $C_1C_2C_3$ moiety, changing from +0.3233 to +0.4132 by the migration of hydrogen. Consequently, it is apparent that the charge on the migrated M^+ ion remains on the CH_3 moiety, suggesting the formation of the $[M-CH_3]^+$ ion with *m/e* 39. These features are shown in the following process:

TABLE 5. VARIATIONS IN THE TOTAL ENERGY AND E_{AB}[a] IN MODEL 2

	Points	1	2	3	4	5
$R(C_4-H_5)$/Å		2.691	1.948	1.716	1.322	1.090
E_{total}		−594.560	−594.824	−594.151	−594.382	−594.662
E_{AB}	C_1-C_2	−20.359	−19.619	−19.354	−19.154	−18.519
	C_2-C_3	−17.059	−16.971	−16.580	−15.479	−14.109
	C_3-C_4	−20.359	−20.928	−19.905	−16.143	−14.423
	$C_1-H_5+C_4-H_5$	−12.484	−11.426	−11.738	−11.660	−12.396

a) Energies in eV.



In the simple model employed here, these results indicate that the migration of H_5 to C_4 is very probable. Moreover, the hydrogen migration gives fairly good information with respect to the formation of the C_3H_3 ion.

In Model 2, the calculations were carried out with the $C_1C_2C_3$ chain bent at C_2 with the α values varying from 122° to 60° in 15.5° increments; then, at each value of α, the calculations were made by increasing φ from 0° to 60° in 15° increments. For the other parameters we adopted the same values as in Model 1.

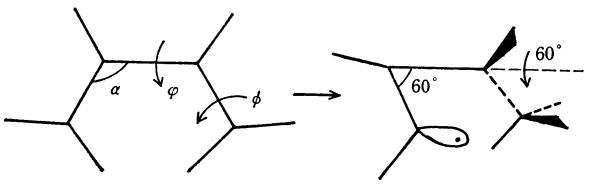


Table 5 shows the variations in the total and the partitioned energies in Model 2. The energy profile is depicted by the curve, as in Model 1. The total energy at the terminus of the migration is −594.662 eV, nearly equal to that in Model 2. The most remarkable difference from Model 2 is that the bonding interaction between C_1 and C_3 becomes strong. These results indicate that the hydrogen-migration process in Model 2 is energetically favorable, as in Model 1.

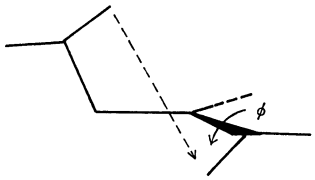
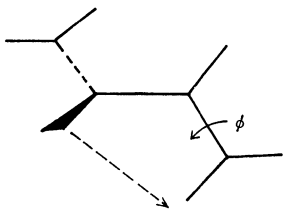
Next, the starting geometry at $\varphi=90°$ and $\alpha=122°$, in which H_5 migrates to C_4, is shown as Model 3. The migration path of H_5 was chosen as the least-motion path[9] from C_1 to C_4. This release of H_5 from C_1 requires more energy than in Models 1 and 2; the potential



energy in this process was 1.367 eV. This is related to the increase in the sum of the E_{AB} values of the C_1-H_5 and C_4-H_5 bonds; this remarkable increase shows that the migration of H_5 is prevented in this process. The bonding interaction between C_2 and C_3 was almost unchanged with the hydrogen migration. The value of the C_2-C_3 bond is larger than that of the C_3-C_4 bond; it may be thought, therefore, that the scission of the C_2-C_3 bond occurs in preference to that of the C_3-C_4 bond. As a result, judging from this variation, it may be predicted that the C_2H_3 ion is formed.



In Model 4, the variation in the total energy between the origin and terminus of the migration was 0.276 eV; the potential energy was, then, 1.448 eV. It is possible to form the resonance structure by the migration of H_7 as follows:

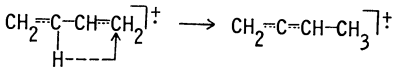


TABLE 6. VARIATIONS IN THE TOTAL ENERGY AND E_{AB}[a] IN MODELS 3 AND 4

	Points	1	2	3	4	5
				Model 3		
E_{total}		−594.702	−594.527	−593.335	−593.751	−594.435
E_{AB}	C_2-C_3	−16.852	−14.973	−14.812	−16.074	−16.233
	C_3-C_4	−20.536	−21.849	−20.733	−17.049	−17.392
	$C_1-H_5+C_4-H_5$	−12.621	−11.539	−5.804	−10.106	−12.476
				Model 4		
E_{total}		−595.301	−595.561	−593.853	−594.323	−595.025
E_{AB}	C_2-C_3	−17.273	−15.259	−15.080	−16.683	−16.993
	C_3-C_4	−21.016	−21.046	−20.021	−17.374	−17.174
	$C_1-H_7+C_4-H_7$	−12.657	−12.136	−9.734	−10.693	−12.434

a) Energies in eV.

The bonding interaction energy between C_2 and C_3 was larger than that between C_3 and C_4. This is the same as in Model 3. On the other hand, the variation in the sum of the E_{AB} values of the C_2–H_7 and C_4–H_7 bonds in Model 4 was similar to that in Model 1. Therefore, the possibility of the migration of H_7 to C_4 is larger than in Model 3.

Table 7. The total energies and the net electric charges in the $[M-H]^+$ ions

	$[M-H_5]^+$	$[M-H_6]^+$	$[M-H_8]^+$

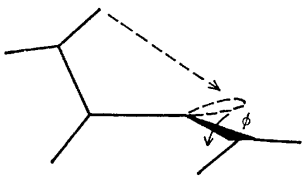
$[M-H]^+$ Ion. In order to discuss Mechanism II, the calculations for the $[M-H]^+$ ion were carried out using the same parameters as in Model 1. The stable structure of the $[M-H]^+$ ion was in a state which lost H_7 and H_8 in *trans*; this phenomenon is estimated to be more energetically favorable than in *cis*. Table 7 shows the total energies of the several structures for the $[M-H]^+$ ion and the net electric charges on the carbon atoms. The net electric charge of the C_3 which had lost H_8 was +0.3138, which is large and positive. If the driving force is this positive charge, as much as in the M^+ ion, in the $[M-H]^+$ ion it can be predicted that the possibility of the migration of hydrogen to C_3 is large. Therefore, as a model, the migration process of H_5 to C_3 was discussed.

The total energy in the $[M-H]^+$ ion upon the rotation of the C_2–C_3 bond was the energy minimum at 90°. Therefore, this starting geometry for the migration of H_5 from C_1 to C_3 at 90° was chosen:



The variation in the total energy in this process is shown in Table 8. The position of the H_5 atom at Point 3 was decided on the basis of the energy-minimum state; the position of H_5, in which the $C_1H_5C_3$ angle is 90°, was chosen.

The potential energy in this process was 3.251 eV, larger than those in the models of the M^+ ion. Moreover, the bonding interaction between C_2 and C_3 was weakened, contrary to the case of the C_2–C_3 bond in the M^+ ion. Therefore, it can be predicted that this bond is easy to cleave in the $[M-H]^+$ ion. The bonding interaction of this bond at 180° was also weakened from −17.257 to −15.210 eV by the loss of the hydrogen atom; in other $[M-H]^+$ ions this trend also appeared. Consequently, it seems that it is more difficult for the

migration of H_5 to occur in the $[M-H]^+$ ion than in the M^+ ion.

Fragmentation Pattern. Considering the variation in the total energies in the fragmentation process, the energy relations are shown in Fig. 5. It is apparent from the total energies that the variation for the hydrogen migration is smaller than that for the simple fragmentation. The variation for the C_3H_3 ion which is produced from the $[M-H]^+$ ion is larger than that for the C_2H_3 ion. The fragmentation of the M^+ ion to the C_3H_4 ion is energetically less favorable than the direct cleavage to the C_2H_3 ion; it may, then, be asserted that the formation of the C_3H_4 ion by the direct release of the CH_2 radical is energetically less favorable. This tendency causes the $[M-H]^+$ ion to appear. Moreover, by the fragmentation of the migrated $[M-H]^+$ ion, the scission of the C_2–C_3 bond occurs in preference to that of the C_3–C_4 bond.

Conclusion

Calculations have been presented in support of a discussion of the possibility of the hydrogen migration in butadiene, taking account of the variations in the total and the partitioned energies with respect to the migration of hydrogen in the M^+ ion.

This treatment is not absolutely essential, but it is a very convenient starting point.

The following features were postulated: (1) The net electric charges on the C_1 and C_4 atoms were large and positive in the M^+ ion. The positive charge on the carbon atom was one of the driving factors in the migration of hydrogen. (2) It is very probable that the hydrogen atom migrates *via* Models 1 and 2 in Mechanism IV, judging from the variation in the total energy. (3) The migration of hydrogen from C_1 to C_4 migrates in the M^+ ion, and then the C_3H_3 ion is produced by the hydrogen migration. (4) It was found that the positive charge remains in the $C_1C_2C_3$ moiety after the hydrogen migration. (5) It can be predicted that the formation of the C_3H_3 ion results from the fragmentation of the M^+ ion. (6) The fragmentation of the $[M-H]^+$ ion leads to the formation of the C_2H_3 ion. Finally, this treatment for the migration of hydrogen gives fairly good information as the mass spectrum of butadiene.

(Received August 22, 1978)

Rotating disk electrode voltammetry was applied to study the reduction mechanism of *p*-dimethylaminobenzaldehyde (**1**) in water–ethanol alkaline solutions by using a mercury-plated platinum rotating disk electrode. In the logarithmic analysis of the wave, the plots of log $[i^{2/3}/(i_d-i)]$ *vs.* E showed good linearity, and the shifts of the half-wave potential with an increase in the rotation speed of the electrode (ω) and in the initial concentration of **1** (C) were $\partial E_{1/2}/\partial \log \omega = -22 \pm 2$ mV and $\partial E_{1/2}/\partial \log C = 19 \pm 2$ mV, respectively. On the other hand, no appreciable change in $E_{1/2}$ was observed with varying alkalinities of the solutions. These results and the large shift of $E_{1/2}$ with an increase in the concentration of water ($\partial E_{1/2}/\partial \log[H_2O] = ca.$ 50 mV) are explained in terms of the following reactions:

$$R + e \rightleftarrows R^{\cdot} \text{ (solvated by water)}, \quad (1)$$

$$2R^{\cdot} \xrightarrow{k} D^{2-} \text{ (r.d.s.)}, \quad (2)$$

$$D^{2-} + 2H_2O \longrightarrow DH_2 + 2OH^-, \quad (3)$$

where R and $R^{\cdot}$ are the molecule and the radical of **1**, respectively, D^{2-} is the dimer of $R^{\cdot}$ and DH_2 is the hydrodimer (**2**) of R. The rate of the dimerization reaction (k in Eq. 2) was estimated to be 2.5×10^4 M^{-1} s^{-1} from the shift of $E_{1/2}$ with log ω for the 50% water–ethanol solution containing 1 M NaOH, and this rate constant decreased with decreasing water concentration.

Rotating disk electrode voltammetry (RDEV) is one of the most useful techniques for studying an electrode reaction. It is more advantageous than polarography using a dropping-mercury electrode because (i) the rotation speed of the electrode can be varied over a wide range, whereas the variation of the drop-time is limited, and (ii) even in a high concentration of a reactant the current-potential curve at an RDE can be obtained and the reaction mechanism may be examined under conditions similar to those for a macro-scale electrolytic synthesis. Furthermore, recently Saveant *et al.* have reported[1,2] the theoretical relationship between current and potential at a rotating disk electrode (RDE) and have given some diagnostic criteria for determining the correct mechanism among various types of hydrodimerization reactions coupled to an electron transfer.

On the other hand, Allen reported[3] that *p*-dimethylaminobenzaldehyde (**1**) was reduced to 1,2-bis(*p*-dimethylaminophenyl)-1,2-ethanediol (**2**) (the mixture of *dl* and *meso* types) in a water–alcohol solution of KOH with a mercury electrode at −1.9 V (*vs.* NCE) in 97% yield. However, no report has been published for the reduction mechanism. Thus, to clarify the reaction pathway, RDEV was applied for the reduction of **1** to **2** in alkaline solutions at a mercury-plated rotating disk electrode (MPRDE).

Experimental

The voltammograms were measured using a set of apparatuses for RDEV (Nikko Keisoku RRD-1, SC-2, NPS-2, and NPGS-1) and an X-Y recorder (Riken D-72BP). The electrolytic cell (NKC-1) and the platinum rotating disk electrode (PRDE) were also constructed by Nikko Keisoku. The MPRDE ($r = 0.302$ cm) was prepared for each set of runs as follows: The PRDE was first polarized cathodically at 5 mA and at the rotation speed of the electrode of 104.7 rad s^{-1} for 10 min in a copper sulfate solution used commonly for a copper coulometer, and then the copper-plated platinum electrode was dipped into a saturated $Hg(NO_3)_2$ solution for 30 s. The MPRDE thus prepared was set into the apparatus immediately after being washed with distilled water.

The test solution was a 1 M NaOH solution containing 50 % v/v ethanol, unless stated otherwise, and the solution was deaerated by bubbling with purified nitrogen. The measurements were carried out at 25±0.5 °C under continuous flow of nitrogen over the solution surface. The rate of potential sweep used was 16.7 mV s^{-1}. The reference electrode was a saturated calomel electrode (SCE); the potentials given in this paper are referred to this electrode without any correction the liquid junction potential. The value of the half-wave potential adopted is the average of values obtained by several experiments. The uncertainty is within ±3 mV. The kinematic viscosity (ν) of the solution (0.0331 cm^2 s^{-1} for a 1 M NaOH solution containing 50% v/v ethanol) was measured by using a viscometer (Shibata SF 7741). The diffusion coefficient (D) of **1** (3.09×10^{-6} cm^2 s^{-1}) was determined by using the Levich equation, and this value was also assumed to be valid for the diffusion coefficient of the anion radical of **1**.

The macro-scale electrolyses were carried out in 100 ml of 1 M NaOH water–ethanol solutions containing 1 g (67 mM) of **1** by controlling the cathode potential at −1.8 V *vs.* SCE. An H-type electrolytic cell, which is the same as that described elsewhere,[4] was used. The cathode was a mercury pool (20 cm^2) and the anode was a platinum plate (4 cm^2). During electrolysis, one electron/molecule of **1** was consumed. After reduction, the products were separated into *dl* and *meso* types of **2** by Allen's method,[3] and were weighed to determine the *dl*/*meso* ratio. After electrolysis, *meso*-**2** was always obtained from 50 % water–ethanol solution, by adding water when necessary. The total yield of the products was *ca.* 70%.

The diastereomers were identified by means of both their NMR spectra[5] (100 MHz at room temperature) and melting points.[3] The characteristics obtained are:
dl; mp 113 °C, NMR (DMSO-d_6) δ=5.0 (2H, s, hydroxylic),
meso; mp 178 °C, NMR (DMSO-d_6) δ=4.76 (2H, s, hydroxylic).

All reagents used were analytical GR grade without further purification. Throughout this paper 1 M=1 mol dm^{-3}.

Results

The voltammograms for the reduction of **1** at the MPRDE were measured in water–ethanol alkaline solutions by changing the rotation speed of the electrode (ω), the initial concentration of **1** (C), and the alkalinity of the solution. The results are shown in Figs. 1—4. In the logarithmic analysis of the wave (Fig. 1), the relationship between log $[i^{2/3}/(i_d-i)]$ and the cathode potential (E) shows good linearity, with the slope of the line being 57±3 mV (the plots of log $[i/(i_d-i)]$ *vs.* E are also shown for comparison in Fig. 1). The half-wave potential ($E_{1/2}$) shifted to more negative potentials with increasing ω ($\partial E_{1/2}/\partial \log \omega = -22\pm2$ mV, see Fig. 2) and to more positive potentials with increasing C ($\partial E_{1/2}/\partial \log C = 19\pm2$ mV, see Fig. 3). On the other hand, no appreciable change in $E_{1/2}$ was observed with alkalinity of the solution (Fig. 4), when we take into account the liquid junction potential (from the Henderson equation, the liquid junction potentials between the test solution and the saturated KCl solution are: 8.5 mV (1 M NaOH), 0.44 mV (0.1 M NaOH+0.9 M $NaClO_4$), and 0.01 mV (0.01 M NaOH+0.99 M $NaClO_4$)).

[**1**]=10 mM. The ionic strength and sodium ion concentration were maintained constant (1 M) by adding $NaClO_4$ crystals.

Discussion

Reduction Mechanism. The results shown in Fig. 1 indicate that the reduction of **1** is successfully explained

in terms of Eq. 13 in the appendix of the present paper, for $n=1$. This mechanism is also consistent with the facts that (i) the n-value (electrons consumed/molecule of **1**) obtained by coulometry was one, (ii) **2** was produced by controlled-potential electrolysis, and (iii) the dependences of $E_{1/2}$ on both ω and C were in good agreement with those estimated by Eq. 14 in the appendix. Thus, when we take into account the diagnostic criteria (see Tables 3 and 4 in Ref. 2), **1** was reduced by

$$R + e \rightleftarrows R^{\cdot}, \quad (1)$$

$$2R^{\cdot} \longrightarrow D^{2-} \text{ (r.d.s.)}, \quad (2)$$

$$D^{2-} + 2H_2O \longrightarrow DH_2 + 2OH^-, \quad (3)$$

where R and $R^{\cdot}$ are the molecule and the anion radical of **1**, respectively, D is the dimer of R, and thus DH_2 is the hydrodimer (**2**). It should be noted that, as is shown by Eq. 2, the dimerization reaction occurred between two anion radicals of **1**.

For dimerization reactions, (i) the coupling between two anion radicals (DIM I mechanism) has been excluded because of the coulombic repulsive force between the radicals, and the coupling between an anion radical and a neutral radical produced by a protonation to the anion radical (DIM II mechanism) has generally been considered to be the predominant reaction in aqueous alkaline solutions, and (ii) in a non-aqueous medium without proton-donating reagents, an ion-pair formation of an anion radical with the cation of a supporting electrolyte (DIM III mechanism) has been reported to be important for the coupling reaction. Both these considerations were examined. For the DIM II mechanism, $E_{1/2}$ must vary in 19.7 mV/pH (in fact, for the reduction of benzaldehyde, $E_{1/2}$ shifts in this manner[6]), but in the present experiment, since no appreciable change in $E_{1/2}$ was observed with alkalinity of the solution (see Fig. 4), the DIM II mechanism must be rejected. When the anion radical forms an ion-pair with the cation of a supporting electrolyte, $E_{1/2}$ is affected by the concentration and the kind of the cation. Thus the variation of $E_{1/2}$ was tested by changing the supporting electrolyte. No appreciable difference in $E_{1/2}$ was observed when either 0.1 M tetraethylammonium hydroxide or 0.1 M sodium hydroxide was used as a supporting electrolyte.

According to recent developments in the study of ion-pair formations,[7,8] not only does an anion radical form a contact ion-pair ($R^{\cdot}/M^+$, where M^+ is the cation of a supporting electrolyte), but an anion radical interacts with water molecules; thus solvation ($R^{\cdot}/H_2O$) and/or a separated ion-pair ($R^{\cdot}/H_2O/M^+$) formation are to be considered when water concentration is greater than 1 M. In both cases the electric repulsion between anion radicals diminishes. Recently, Lamy *et al.*[9] have concluded from the results obtained by linear sweep voltammetry that for the electrohydrodimerization of activated olefines, the coupling of two anion radicals solvated by water molecule was the most probable reaction in a low acidity media.

The effect of water concentration of $E_{1/2}$ was then examined. The $E_{1/2}$ shifted to a more negative potential with a decrease in the concentration of water (Fig. 5).

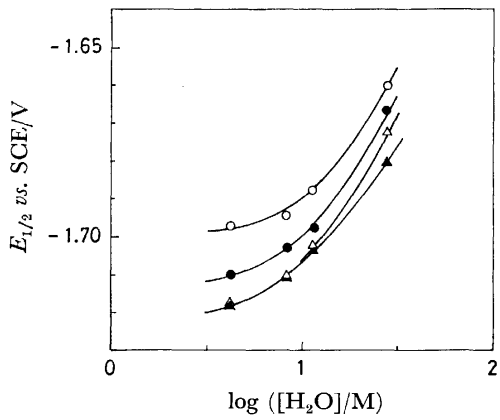

Fig. 5. Variations of half-wave potential as a function of water concentration in 1 M NaOH water–ethanol solutions containing 10 mM of **1** at various rotation speeds of the electrode; ○: 62.8 rad s^{-1}, ●: 104.7 rad s^{-1}, △: 209.4 rad s^{-1}, ▲: 314.2 rad s^{-1}.

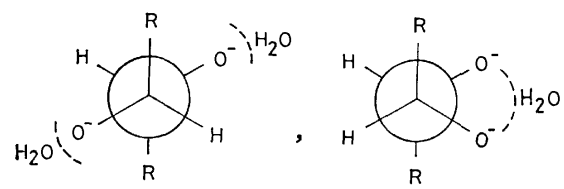
Though the shift of $E_{1/2}$ may include the variation of the liquid junction potential which results from the change of the composition of the test solution, the large shift of $E_{1/2}$ (*ca.* 50 mV/log [H_2O]) suggests strongly that an increase of the number of anion radicals solvated by water facilitates the rate of coupling between the anion radicals because of a decrease in the coulombic repulsive force between two anion radicals.

To examine whether or not the reactions (Eqs. 1—3) are applicable in the solution containing a low concentration (7.5%) of water, the voltammograms for the reduction of **1** were also measured by changing the experimental parameters. In the 7.5% water–ethanol solution, results similar to those obtained in the 50% water–ethanol solution were obtained. That is, the plots of log $[i^{2/3}/(i_d-i)]$ *vs.* E showed a straight line having a slope of 53 mV, and the dependences of $E_{1/2}$ on both ω and C, $\partial E_{1/2}/\partial \log \omega$ and $\partial E_{1/2}/\partial \log C$, were −25 and 20 mV, respectively. Thus, we concluded that no serious change in the mechanism occurred in the water concentration range tested.

The dl/meso *Ratio of the Products.* To give further experimental support for the formation of the solvated anion radical, the variation of isomer ratio (*dl*/*meso*) of **2** was examined. On steric grounds, when the water concentration is high enough to solvate all anion radicals, the most favorable conformation in the transition state of the dimerization reaction is I, whereas when a part of the radicals are solvated, structure II is more attractive than I because of the aid of inter-radical hydrogen bonding.



where R=$-C_6H_4N(CH_3)_2$.

TABLE 1. ISOMER RATIOS IN REDUCTION PRODUCTS OF **1**

Run	Solvent[a]	Amount of **1** g	(mM)	Charge passed mF	Yield of product (**2**) *meso* g	*dl* g	Ratio of *dl*/*meso*	Total yield of product %
1	50% H_2O + 50% EtOH	1.0045	(67.0)	6.57	0.38	0.32	0.84	70
2		1.0090	(67.3)	6.57	0.38	0.31	0.82	68
3		1.0011	(66.7)	6.57	0.38	0.30	0.79	68
							Av 0.82	
4	5% H_2O + 95% EtOH	1.0236	(69.4)	6.94	0.23	0.45	2.0	66
5		1.0116	(67.3)	8.66	0.28	0.44	1.6	71
6		1.0044	(67.0)	6.58	0.24	0.47	2.0	71
							Av 1.9	

a) The volume of all solutions was 100 ml.

Thus, the *dl*/*meso* ratio of the products must increase with a decrease in the concentration of water. According to the macroscale electrolysis data obtained (Table 1), the *dl*/*meso* ratio changed from 0.8 in the 50% water–ethanol solution to 1.9 in the 5% water–ethanol solution. In the latter case, the current decreased to less than one-tenth of the current in the former case at the same cathode potential, −1.8 V *vs.* SCE; this is because the rate of dimerization decreased with decreasing water concentration, as will be described later. The result of the *dl*/*meso* ratio is consistent with the above consideration about the formation of the solvated anion radical.

For some aromatic aldehydes, the DIM II mechanism which was rejected in the present experiment for **1** has been proposed in aqueous basic solutions. This unusual behavior for **1** is probably because the electron density on the oxygen atom of the carbonyl group is high, due to the extremely strong electron-donating effect of the *N*,*N*-dimethylamino group, and thus the hydrogen bonding with a water molecule is facilitated. To clarify the structure of the anion radical and the mechanism of the solvation, further experiments are required.

TABLE 2. RATE CONSTANT CALCULATED FROM Eq. 4

Concentration of Water[a] vol %	**1** mM	log ω_0	ω_0 rad s^{-1}	k[b] $M^{-1}\,s^{-1}$
50	1.19	2.70	501.2	2.21×10^4
50	0.406	2.34	218.8	2.38
				Av 2.5×10^4
15	9.31	2.38	239.9	1.4×10^3
7.5	10.0	2.25	177.8	9.6×10^3

a) Water–ethanol solution containing 1 M NaOH.
b) For the calculation, the diffusion coefficient (D) of **1** and the kinematic viscosity of the solution obtained for each solution were used.

Rate of the Dimerization. The rate constant of the dimerization (k) can be estimated from the variation of $E_{1/2}$ with log ω.[2] The value of ω at the intersection of the oblique linear part of the $E_{1/2}$—log ω plots with the horizontal part, ω_0, gives

$$(1/3)kC(\delta^2/D) = 1, \tag{4}$$

where $\delta = 1.61\,D^{1/3}\nu^{1/6}\omega_0^{-1/2}$.

As can be seen in Fig. 2, an intersection in the $E_{1/2}$—log ω plots is observed for the concentrations of **1** lower than 1.2 mM in 50% water–ethanol solutions containing 1 M NaOH. Thus the apparent rate constant for the dimerization is calculated to be 2.5×10^4 $M^{-1}\,s^{-1}$ by using Eq. 4 (Table 2), where the value of k obtained is the total value of the rate constants for the two reactions of $R^{\cdot}$ to both *dl* and *meso* types of **2**. When the water concentration decreased, the intersection in $E_{1/2}$—log ω plots was observed even in the solution containing 10 mM of **1** (Fig. 5); this is because the rate of dimerization decreased. For 7.5 and 15% water–ethanol solutions, the values of k thus obtained are listed in Table 2. The decrease in the k value at low concentrations of water indicates that an increase in the coulombic repulsive force between the anion radicals lowered the rate of the dimerization.

The authors wish to express their thanks to Associate Professor Tsutomu Nonaka of Tokyo Institute of Technology for his useful advice.

Appendix

Let us consider the following reactions:

$$A + ne \rightleftarrows B \text{ (reversible)}$$

$$2B \xrightarrow{k} B_2 \text{ (irreversible fast dimerization)}$$

At the steady state, the boundary value problem of the above reactions at an RDE can be formulated as follows, under the usual experimental conditions:

$$D_A\frac{d^2A}{dx^2} - V_x\frac{dA}{dx} = 0, \tag{1}$$

$$D_B\frac{d^2B}{dx^2} - V_x\frac{dB}{dx} - kB^2 = 0, \tag{2}$$

where $V_x = -0.51\,\omega^{3/2}\nu^{-1/2}x^2$, with the boundary conditions of

$$x = 0\text{: } A = A_0,\ B = B_0, \text{ and } D\frac{dA}{dx} = -D\frac{dB}{dx} = \frac{i}{nF}$$

$$(D_A = D_B = D \text{ is assumed}), \tag{3}$$

$$x \to \infty\text{: } A = A^*, \text{ and } B = 0, \tag{4}$$

where A^* is the bulk concentration of A, and A_0 and B_0 are, respectively, the concentrations of A and B at the surface of the RDE. The symbols used without definition have their ordinary meanings.[10]

The solution of Eq. 1 is

$$A = A_0 + (A^*-A_0)\frac{\int_0^x \exp\left(\int_0^x \frac{V_x}{D}dx\right)dx}{\int_0^\infty \exp\left(\int_0^\infty \frac{V_x}{D}dx\right)dx}, \quad (5)$$

and the concentration gradient of A at the electrode surface is

$$\left(\frac{dA}{dx}\right)_{x=0} = \frac{A^*-A_0}{\int_0^\infty \exp\left(\int_0^\infty \frac{V_x}{D}dx\right)dx}, \quad (6)$$

and thus the current density (i) is represented by

$$i = nFD\left(\frac{dA}{dx}\right)_{x=0} = nFD(A^*-A_0)/\delta \quad (7)$$

where $\delta = 1.61\ D^{1/3}\ \nu^{1/6}\ \omega^{-1/2}$.

By using the limiting current, i_d ($A_0=0$ in Eq. 7), we obtain

$$A_0 = \left(\frac{i_d-i}{nFD}\right)\delta. \quad (8)$$

On the other hand, Eq. 2 can not be solved analytically, but we may use the simplified model.[11] Here, let us neglect the second term in Eq. 2; thus we obtain

$$D\frac{d^2B}{dx^2} - kB^2 = 0. \quad (9)$$

After satisfying the boundary conditions, we obtain the solution of Eq. 9:

$$B = \frac{6D/k}{(\sqrt{6D/(kB_0)}+x)^2}, \quad (10)$$

Thus, the current is

$$i = -nFD\left(\frac{dB}{dx}\right)_{x=0} = (nFD)^{3/2}B_0^{3/2}/\varepsilon \quad (11)$$

where $\varepsilon = (3/2)^{1/3}\ (nF)^{1/3}\ D^{2/3}\ k^{-1/3}$,
and we obtain

$$B_0 = \left(\frac{i^{2/3}}{nFD}\right)\varepsilon. \quad (12)$$

Under the condition of the Nernst equation holding for the electron transfer reaction ($A+n\ e \rightleftarrows B$), we obtain

$$\begin{aligned} E &= E_0 - \frac{RT}{nF}\ln\frac{B_0}{A_0} \\ &= E_0 - \frac{RT}{nF}\ln\frac{i^{2/3}}{(i_d-i)}\frac{\varepsilon}{\delta} \\ &= E_0 - \frac{RT}{nF}\ln\frac{\varepsilon}{\delta} - \frac{RT}{nF}\ln\frac{i^{2/3}}{(i_d-i)}. \end{aligned} \quad (13)$$

By substituting $i=(1/2)i_d$ and $i_d = nFDA^*/\delta$ into Eq. 13, we get the half-wave potential:

$$\begin{aligned} E_{1/2} &= E_0 - \frac{RT}{nF}\ln\frac{2^{1/3}\varepsilon}{i_d^{1/3}\delta} \\ &= E_0 - \frac{RT}{nF}\ln\frac{3^{1/3}D^{1/3}k^{-1/3}A^{*-1/3}}{\delta^{2/3}} \\ &= E_0 - \frac{RT}{3nF}\ln\frac{3D}{kA^*\delta^2} \end{aligned} \quad (14\text{-}1)$$

or

$$= E_0 - \frac{RT}{3nF}\ln\frac{3D^{1/3}}{1.61^2\nu^{1/3}} + \frac{RT}{3nF}\ln\frac{kA^*}{\omega}. \quad (14\text{-}2)$$

Equations 13 and 14 obtained here are the same as those derived by other workers,[2,12] and were used in the present work.

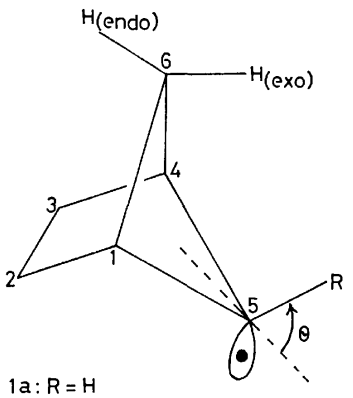
Electron Spin Resonance Study of the Pyramidal Geometry around the Tervalent Carbon Atom of the Bicyclo[2.1.1]hexan-5-yl Radical[1)]

Takashi KAWAMURA,* Shigeru HAYASHIDA, and Teijiro YONEZAWA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received September 11, 1978)

The bicyclo[2.1.1]hexan-5-yl and the 5-deuteriobicyclo[2.1.1]hexan-5-yl radicals have been examined using ESR. A comparison of the spectra confirmed that geometry around C_5 is pyramidal and showed highly stereoselective long-range spin-transfer from C_5 to the endo proton on C_6; $a(H_{6endo})=28.22$ and $a(H_{6exo})=0.49$ G. A potential curve for the out-of-plane bending motion of the C_5–H_5 bond, selected from the trial curves gave a reasonable simulation of the temperature dependence and isotope effects on $a(H_5)$ and $a(H_{6endo})$. The curve has two minima with a relatively low barrier to inversion; the geometry of the C_5–H_5 bond bent in the exo direciton has been estimated as approximately 0.9 kcal/mol more stable than that with the C_5–H_5 bond located in the endo direction.

Stereospecific intramolecular interactions in bicyclo[2.1.1]hexanes have been of theoretical and experimental interest for several years and large long-range nuclear spin couplings between the two endo protons on methano bridges of bicyclo[2.1.1]hexanes have been observed.[2)] A strong interaction has been revealed by the nonempirical molecular orbital calculation of bicyclo[2.1.1]hexane between the two endo C–H bonds on the methano bridges.[3)] Furthermore the *endo*-bicyclo[2.1.1]hexan-5-yl tosylate has been found to undergo faster solvolysis, by a factor of 10^8 than the exo isomer.[4)] All these results indicate a strong stereospecific intramolecular interaction operating between the two endo C–H bonds on the methano bridges.



1a: R = H
1b: R = D

The potential curves for the umbrella-mode vibrations around tervalent carbon atoms of several alkyl radicals have been correlated with the temperature dependence and the isotope shifts of hyperfine splitting constants (hfsc) of α carbon nuclei and/or α protons.[5)] In the bicyclo[2.1.1]hexan-5-yl radical (**1a**), the temperature dependences of $a(H_5)$ and $a(H_{6endo})$ and their shifts upon replacement of H_5 with a deuterium atom are closely correlated with the out-of-plane bending motion of the C_5–H_5 bond.[1b)] The potential curve for this motion will be estimated by simulating the temperature dependence and isotope effects with the aid of geometrical dependence of spin distribution calculated from INDO-UHF method.[6)]

Results and Discussion

ESR Spectra and Stable Geometry of ***1****.* The radical **1a** and the 5-deuteriobicyclo[2.1.1]hexan-5-yl radical, **1b**, have been generated in an ESR cavity by the photolysis of bis(bicyclo[2.1.1]hexane-5-carbonyl) peroxide and bis(5-deuteriobicyclo[2.1.1]hexane-5-carbonyl) peroxide in cyclopropane solvent, respectively. Typical ESR spectra for these radicals and the computer simulations have been published elsewhere.[1)] The spectrum of **1a** at −115 °C has been analyzed as three sets of doublets (28.22, 9.14, and 0.49 G), split further into three sets of 1 : 2 : 1 triplets (0.80, 0.49, and 0.25 G) with a g factor of 2.0027_6. At the same temperature the spectrum of **1b** consisted of two sets of doublets (28.80 and 0.50 G), three sets of 1 : 2 : 1 triplets (0.82, 0.36, and 0.11 G), and a 1 : 1 : 1 triplet of 1.34 G. The principal difference between the spectrum of **1a** and that of its deuterated analogue, **1b**, is the replacement of the large doublet of 9.14 G by the 1 : 1 : 1 triplet of 1.34 G. This result reconfirms the assignment[1a)] of $|a(H_5)|=9.14$ G for **1a** and previous estimations of the stable geometry of **1a**;[1a)] **1a** has a pyramidal radical center with C_5–H_5 bent in the exo direction (*i.e.*, $\theta>0$).

The remaining two sets of doublets of 28.22 and 0.49 G for **1a** should belong to H_{6endo} and H_{6exo}. The C_6–H_{6endo} bond is arranged in a double W-plan[7)] with respect to the odd electron orbital in the stable geometry of **1**, suggesting that $a(H_{6endo})$ is larger than $a(H_{6exo})$. This is consistent with the INDO-UHF calculations.[1a)] Thus the largest doublet of 28.22 G has been assigned to H_{6endo} and the smallest doublet of 0.49 G to H_{6exo}. It should be pointed out that the long-range spin-transfer from the tervalent carbon atom to the two hydrogen atoms on C_6 is highly stereoselective. The remaining three sets of triplets of 0.80, 0.49, and 0.25 G of **1a** are expected to arise from H_1, H_{2syn} and H_{2anti} and their equivalents, but the assignments remain uncertain. Table 1 summarizes the observed hfsc's of **1a** and **1b** together with the assignments.

Temperature Dependence and Isotope Shift of hfsc's. The replacement of H_5 with a deuterium atom shifted not only the splitting pattern attributed to H_5 but also the hfsc's of other protons; a typical example is the increase of the hfsc of H_{6endo} from 28.22 to 28.80 G

Table 1. Observed hfsc's of **1a** and **1b** at −115 °C

Radical	hfsc's (G)[a]					
1a	28.22 d	9.14 d	0.49 d	0.80 t	0.49 t	0.25 t
1b	28.80 d	1.34 t[b]	0.50 d	0.82 t	0.36 t	0.11 t
assignt.	H_{6endo}	H_5	H_{6exo}	(H_1	H_{2anti}	H_{2syn})[c]

a) d: doublet; t: triplet. b) Triplet due to a deuterium nucleus c) The hfsc's of the protons in the parentheses have not been assigned.

upon the deuteration.[1b] The ratio of the observed splitting of [$a(D_5)$ of **1b**]/[$a(H_5)$ of **1a**] at −115 °C is 0.147[1b] which is smaller than that of the magnetic moments of the nuclei (0.1535).

The temperature dependence of the hfsc's of **1a** are illustrated in Figs. 1 and 2. The hfsc's of H_5 and H_{6endo} depend on the temperature (T) as $d|a(H_5)|/dT=7.9$ mG deg^{-1} and $d|a(H_{6endo})|/dT=-33$ mG deg^{-1}, respectively.

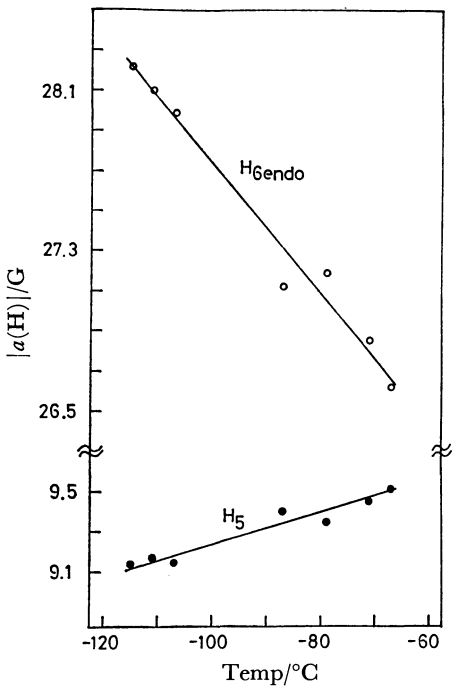


Fig. 1. Temperature dependence of $a(H_5)$ and $a(H_{6endo})$.

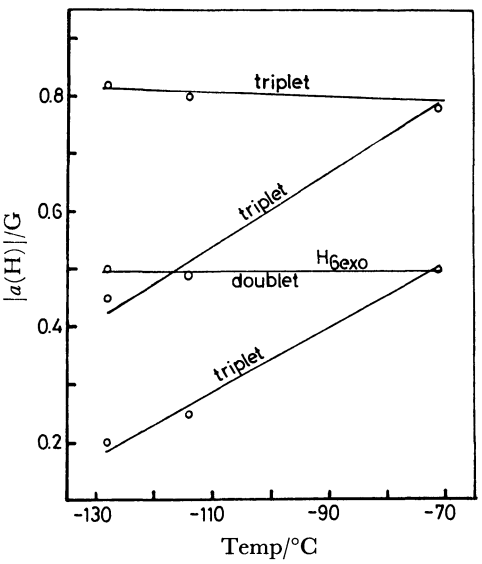

Fig. 2. Temperature dependence of the small hfsc's of **1a**.

The replacement of an α hydrogen atom with a deuterium atom has a similar effect as the lowering of the temperature for the out-of-plane bending mode vibration of the C_α–H_α (or C_α–D_α) bond; both effects decrease the average amplitude of the vibration. Therefore, the small ratio of $a(D_5)$ of **1b** to $a(H_5)$ of **1a** and the positive temperature dependence of $|a(H_5)|$ may be assumed to originate largely from the shift of the average amplitude of the out-of-plane bending vibration of the C_5–H_5 (or C_5–D_5) bond.

The temperature effect on $a(H_{6endo})$ of **1a** may result from the temperature dependence of the out-of-plane bending vibration of the C_5–H_5 bond or of some mode(s) of vibration(s) resulting in a shift of the time-averaged arrangement between the odd electron orbital on C_5 and the C_6–H_{6endo} bond. The observed increase of $a(H_{6endo})$ upon replacement of the H_5 with a deuterium atom was 28.80−28.22=0.58 G, which is similar to the observed increase of the hfsc upon lowering the temperature 15—20 °C. This indicates that the temperature and isotope effects result from the out-of-plane bending mode (and/or the in-plane bending and the stretching modes) vibration of the C_5–H_5 bond. Otherwise, the observed isotope effect on $a(H_{6endo})$ is unreasonably large, since the replacement of H_5 with a deuterium atom has only a small effect on the reduced masses of the other modes of vibrations.

The small triplets of 0.49 and 0.25 G of **1a** (at −115 °C) exhibit a relatively large temperature dependence (Fig. 2). The corresponding splitting of the deuterated analogue, **1b**, at −115 °C are 0.36 and 0.11 G, respectively, which are similar to those of **1a** at a 15 to 20 °C lower temperature. These results indicate that the temperature dependences and deuterium isotope shifts of the hfsc's of **1** may originate largely from the out-of-plane bending vibration of the C_5–H_5 bond.

Procedure for Estimation of the Potential Curve for the Out-of-plane Bending Motion of the C_5–H_5 Bond. The potential curve for the out-of-plane bending vibration of the C_5–H_5 bond may be estimated by reproducing the four experimental values (the temperature dependences and the isotope shifts of the hfsc's of H_5 and H_{6endo}) with trial potential functions.

For this procedure the geometrical dependences of the hfsc's of **1** are required. Calculations using the UHF-INDO method have been shown to give reliable geometrical dependences of the spin distribution. The valence s orbital spin densities on the hydrogen atoms of **1** were calculated at 7.5° intervals of θ, where θ is

defined as the angle between the C_5–H_5 bond and the $C_1C_5C_4$ plane. The remaining geometry of **1** is assumed to be the same as the parent hydrocarbon reported by Chiang.[8] The INDO spin densities, ρ, on H_5 and H_{6endo} have been fitted to fourth-order polynomials in θ in order to evaluate ρ at any value of θ desired, and multiplied by C, which converts the spin density into the hfsc:

$$a(\theta) = C(\rho_0+\rho_1\theta+\rho_2\theta^2+\rho_3\theta^3+\rho_4\theta^4). \quad (1)$$

Figure 3 illustrates the calculated geometrical dependence of the hfsc's of H_5 and H_{6endo}. The conversion factor C was set tentatively to 1100 G in Fig. 3.

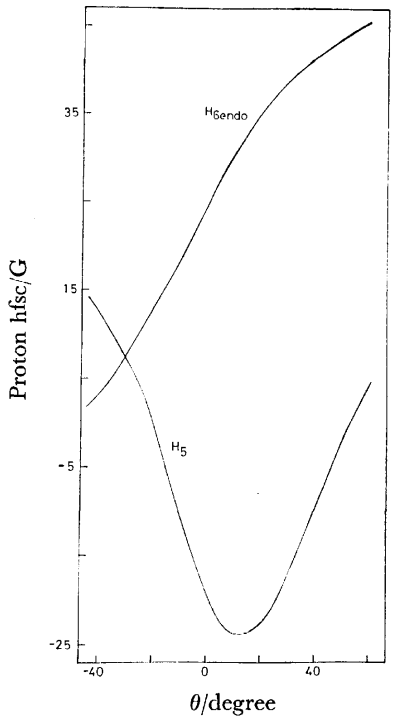

Fig. 3. Geometrical dependence of $a(H_5)$ and $a(H_{6endo})$.

The vibrations of the C_5–H_5 bond have been treated as motions of H_5 bonded to an infinite mass. The hamiltonian for the out-of-plane motion is expressed by the following equation:

$$\mathcal{H} = -\frac{\hbar^2}{2\cdot I}\frac{\partial^2}{\partial\theta^2} + V(\theta) \quad (2)$$

where I is the moment of inertia and $V(\theta)$ an arbitrary potential function which is expressed by an eighth-order polynomial in θ. The eigenfunctions, ψ_i, are calculated as linear combinations of the lowest twenty eigenfunctions of an appropriate harmonic oscillator that minimizes the difference between the square of the expectation value of the hamiltonian and the expectation value of the square of the hamiltonian in the lowest state,

$$|\langle\psi_0|\mathcal{H}|\psi_0\rangle^2-\langle\psi_0|\mathcal{H}^2|\psi_0\rangle|.$$

The expectation values, $a_i=\langle\psi_i|a(\theta)|\psi_i\rangle$, for each vibrational level i were then calculated using the wave functions obtained for the particular potential. The hfsc of a proton at a given temperature, $a(T)$, is expressed as an average of the expectation values weighted by Boltzmann populations:

$$a(T) = [\sum_i a_i\cdot\exp(-\varepsilon_i/kT)]/[\sum_i \exp(-\varepsilon_i/kT)]. \quad (3)$$

For convenience in the comparison between the experimental and calculated values, the isotope shift of the hfsc of H_5, $\Delta|a(H_5)|$, is defined as shown below from the hfsc's of **1a** and **1b** observed at -115 °C:

$$\Delta|a(H_5)| = [|a(D_5)| \text{ of } \mathbf{1b}]/0.1535-[|a(H_5)| \text{ of } \mathbf{1a}], \quad (4)$$

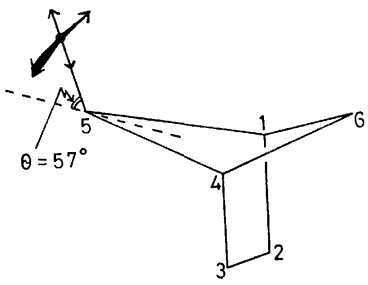
where 0.1535 is the ratio of the magnetic moments of the deuterium nucleus and proton. The isotope shift of the hfsc of H_{6endo} is simply given as the difference between the observed hfsc's of the H_{6endo} of **1a** and **1b** at -115 °C. The temperature coefficient, $d|a(T)|/dT=[|a(T_2)|-|a(T_1)|]/(T_2-T_1)$, and the isotope shift, $\Delta|a(H)|$, are divided by $|a(-115\ °C)|$ in order to get rid of the somewhat arbitrary multiplication factor, C, in Eq. 1:

$$\begin{aligned} d|A(H)|/dT &= [d|a(T)|/dT]/|a(-115\,°C)|, \\ \Delta|A(H)| &= \Delta|a(H)|/|a(-115\,°C)|. \end{aligned} \quad (5)$$

The experimental values are $d|A(H_5)|/dT=+0.86\times10^{-3}$ deg^{-1}, $\Delta|A(H_5)|=-4.5\times10^{-2}$, $d|A(H_{6endo})|/dT=-1.2\times10^{-3}$ deg^{-1}, and $\Delta|A(H_{6endo})|=+2.1\times10^{-2}$. From this point $d|A(H)|/dT$ and $\Delta|A(H)|$ are defined as the temperature dependence and isotope shift of the hfsc of a particular proton.

Effect of Vibrations of In-plane Bending and of Stretching Modes of the C_5–H_5 Bond. The wave numbers of the vibrations of the in-plane (or in-cone) bending mode and the stretching mode of the C_5–H_5 bond are expected to be around 1000 and 3000 cm^{-1}, respectively.[9] The energy gaps between these vibrational levels are too large for effective thermal excitation; these vibration modes can not effectively contribute to the temperature dependence of the hfsc's of H_5 and H_{6endo}. However, the replacement of H_5 with a deuterium atom changes the average amplitude of these modes of vibration, possibly resulting in isotope shifts of the hfsc's of H_5 and H_{6endo}.

The isotope shifts of the hfsc's of H_5 and H_{6endo} due to these two modes of vibration have been examined. The motions of the in-plane bending and the stretching vibrations taken into account are shown below:



The angle $\theta=57°$ is the estimated potential minimum for the out-of-plane bending of the C_5–H_5 bond (*vide infra*). The stretching and in-plane bending vibrations have been assumed harmonic with wave numbers in the range 2800—3100 and 800—1500 cm^{-1}, respectively. The geometrical dependence of the spin densities on H_5 and H_{6endo} for these modes of motions may be calculat-

ed using the UHF-INDO method and expressed in quadratic forms (*cf.* Eq. 1). The isotope shifts of the hfsc's of H_5 and H_{6endo} due to in-plane bending vibration of C_5–H_5 are then obtained[10] as $\Delta|A(H_5)|=(0.22—0.75)\times10^{-2}$ (−5——17% of the observed) and $\Delta|A(H_{6endo})|=(0.05—0.17)\times10^{-2}$ (2—8% of the observed). The calculated values of the isotope shifts resulting from the stretching vibration of the C_5–H_5 bond are $\Delta|A(H_5)|=(1.8—1.9)\times10^{-2}$ (−40——42% of the observed) and $\Delta|A(H_{6endo})|\approx-0.02\times10^{-2}$ (−1% of the observed). These modes of vibration have negligible effects on the isotope shift of the hfsc of H_{6endo}. These vibrations, however, have quite a large contribution to the isotope shift of the hfsc of H_5, and the estimated contribution of both vibrations are opposite to the experimental observation and also opposite to the contribution of the out-of-plane bending motion (*vide infra*).

The foregoing analyses show that the temperature dependence of the hfsc's of H_5 and H_{6endo} and the deuterium isotope shift of the hfsc of H_{6endo} arise largely from the out-of-plane bending vibration of the C_5–H_5 bond. The isotope shift of the hfsc of H_5 is, however, a result of the counteracting contributions from the out-of-plane bending motion and the stretching and in-plane bending vibrations. Therefore, the isotope shift of the hfsc of H_5 is not such a good indicator as the other three experimental values in the estimation of the potential curve for the out-of-plane bending motion of the C_5–H_5 bond. Calculations, taking only into account the out-of-plane bending vibration, may overestimate the isotope shift of the hfsc of H_5.

Estimation of the Potential Curve. The dependence of the hfsc of H_5 on the pyramidal deformation of C_5 in Fig. 3 reveals that the hfsc of H_5 should be negative, otherwise the radical center must have an unreasonably pyramidal geometry. Thus the hfsc of H_5 has been assumed negative. Based on this assumption the observed positive temperature dependence of the absolute value of the hfsc of H_5 indicates that the potential curve for the out-of-plane vibration of C_5–H_5 bond is anharmonic.[5a,5e] Several typical trial anharmonic potential functions, selected from more than thirty trials, are illustrated in Fig. 4. Table 2 summarizes the calculated temperature dependences and isotope shifts of the hfsc's of H_5 and H_{6endo}.

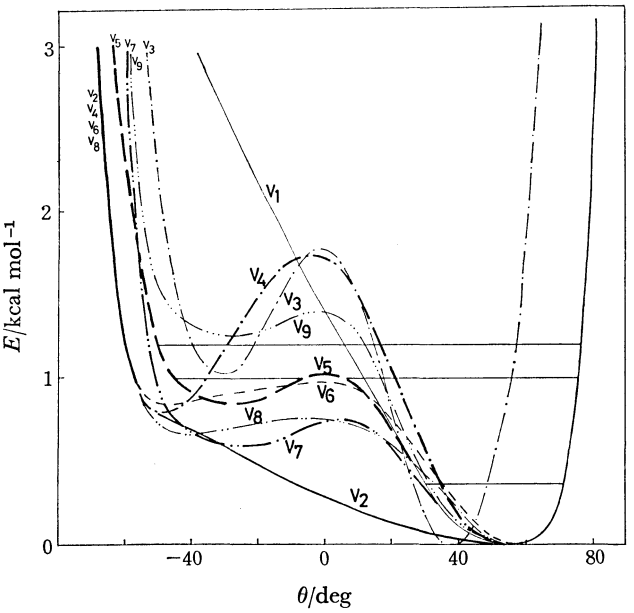


Fig. 4. Trial potential curves. Horizontal solid lines are vibrational levels calculated with curve V_5 for **1a**.

Simple single-minimum anharmonic potential curves (V_1, V_2) gave calculated values which were too small for the temperature dependence of the hfsc of H_{6endo}. The reason for this is that the expectation values of $a(H_{6endo})$ for the second and higher vibrational levels of **1a** are not sufficiently shifted from the lowest vibrational level to reproduce the observed large temperature dependence of $a(H_{6endo})$. In order to reproduce the experimentally observed large negative temperature dependence of the hfsc of H_{6endo}, the lowest vibrational level needs to be restricted in the positive range of θ, whereas in the second and higher excited vibrational levels, the extent of the vibration of C_5–H_5 bond needs to be extended to a very large negative value of θ. Such requirements can be satisfied by unsymmetrical double-minimum potential curves. ΔE (kcal/mol) is defined as the difference between the two minima and $\Delta\varepsilon$ (kcal/mol) as the barrier to inversion measured from the higher minimum. Double-minimum potential curves with relatively high barrier to inversion (V_3, V_4)

Table 2. Calculated temperature dependences and isotope shifts of hfsc's of H_5 and H_{6endo}

Curve	$d\|A(H_{6endo})\|/dT$ [a]	$d\|A(H_5)\|/dT$ [a]	$\Delta A(H_{6endo})$ [a]	$\Delta A(H_5)$ [a]	ΔE [b]	$\Delta\varepsilon$ [b]

obsd	-1.2×10^{-3}	0.86×10^{-3}	2.1×10^{-2}	-4.5×10^{-2}	—	—

a) Calculated values are given as a per cent of the experimental values. b) In kcal/mol.
c) Single-minimum. d) Not monotonous and very small.

predict a too small temperature dependence and a too small isotope shift of the hfsc of H_{6endo}.

The potential curves with a ΔE of around 0.9 kcal/mol and a relatively low barrier to inversion (V_5, V_6) give reasonable temperature dependences of the hfsc's of H_5 and H_{6endo} and an acceptable isotope shift for H_{6endo}. The isotope shifts of the hfsc of H_5 calculated with V_5 and V_6 are acceptable since the contributions of the in-plane and stretching vibrations to the isotope effects on $a(H_5)$ (*vide supra*) have been ignored. Potential curves with small values of ΔE gave an unacceptable small temperature dependence of $a(H_5)$ (V_7, V_8) and a curve with a large value of ΔE gave a too large temperature dependence of $a(H_5)$ (V_9).

Thus the potential curve for the out-of-plane vibration of C_5–H_5 bond is suggested as a double-minimum potential with a small barrier to inversion with an energy difference of around 0.9 kcal/mol between the two energy minima. The geometry with the C_5–H_5 bond tilting in the exo direction is about 0.9 kcal/mol more stable than that with the C_5–H_5 bond located on the endo side. The barrier to inversion, $\Delta\varepsilon$, is very small and there is no vibrational steady state in which the C_5–H_5 bond is localized in the endo side of the $C_1C_5C_4$ plane ($\theta<0$); even the zero-point vibrational level in the left well ($\theta<0$) is located above the barrier top and effectively mixed with the vibrational state(s) in the right well ($\theta>0$).

Estimation of the Potential Curve. The dependence of $a(H_{6endo})$ on the out-of-plane deformation angle, θ, is large and monotonic. This feature was helpful in estimating the potential curve of the out-of-plane vibration of C_5–H_5 bond. However, in the case of most alkyl radicals, the parameters available for estimation of the potential curve would be only the temperature dependence of the hfsc of α proton(s). In such cases, it would be impossible to estimate the potential curve only from the temperature dependence of the hfsc of the α proton(s). For example in the case of the present radical, the results in Table 2 show that at least three potential curves would give acceptable temperature dependence of the hfsc of H_5: a single-minimum curve lying between V_1 and V_2, a double-minimum curve with a relatively high barrier to inversion lying between V_3 and V_4, and a double-minimum potential with a low barrier to inversion similar to V_5 or V_6.

Experimental

ESR Measurements. The ESR spectra of **1a** and **1b** were obtained during photolysis of bis(bicyclo[2.1.1]hexane-5-carbonyl) peroxide and bis(5-deuteriobicyclo[2.1.1]hexane-5-carbonyl) peroxide, respectively. The solvent was deoxygenated liquid cyclopropane. Measurements were conducted on a JEOL PE-2X spectrometer modified with a JEOL ES-SCXA gunn diode X-band microwave unit equipped with a cylindrical mode cavity with slits for UV irradiation. The field sweep was monitored during each ESR measurement with ^1H NMR using a water sample, which was set just outside the ESR cavity. A tunable NMR radio frequency was supplied from a JEOL ES-FC3 oscillator and counted on a Takeda-Riken TR-5501 frequency counter. The magnetic field difference between the ESR and NMR sample position was calibrated daily with perylene cation in concentrated sulfuric acid. ($g=2.002583$).[11] Photolysis was performed with a Philips SP-500 super-high-pressure mercury lamp focused with two quartz lenses and filtered through a distilled water cell of 45 mm path length. Accumulations and simulations were performed using a JEOL JEC-6 minicomputer.

The g factor and hfsc's were corrected against the microwave frequency drift,[12] which may result from the heating of the cavity by radiation and/or the change of chemical constituents in the sample through photochemical reactions.

The ESR samples were cooled with a cold nitrogen gas flow controlled by a JEOL JES-VT-3A temperature controller. The heating of samples by radiation was calibrated by measuring the temperature of liquid cyclopropane in a sample tube during irradiation and the temperature of the cooling nitrogen gas.

For the measurements of the isotope shifts of the hfsc's, the spectrum of **1b** was measured immediately after observation of the spectrum of **1a** without any change in the setting of the temperature of the nitrogen gas flow cooling the sample.

Bicyclo[2.1.1]hexane-5-carbonyl Chloride. A mixture of bicyclo[2.1.1]hexane-5-carboxylic acid[13] (3.0 g, 24 mmol) and thionyl chloride (8.7 g, 73 mmol) in chloroform (14 ml) was refluxed for 4 h. The chloroform was removed by distillation under atmospheric pressure. Distillation of the residue gave a forerun of the excess thionyl chloride (52—54 °C/400 Torr) followed by bicyclo[2.1.1]hexane-5-carbonyl chloride (2.8 g 19 mmol) (bp 68—74 °C/21 Torr); yield 80 %.

Bis(bicyclo[2.1.1]hexane-5-carbonyl) Peroxide. To a suspension of sodium peroxide (290 mg, 3.7 mmol) in dry ether (12 ml) cooled in an ice bath was added a solution of bicyclo-[2.1.1]hexane-5-carbonyl chloride (1.0 g, 6.9 mmol) in dry ether (8 ml) and two drops of water. The mixture was stirred overnight in an ice bath and then at room temperature for several hours followed by the dropwise addition of cold water (20 ml) to dissolve the excess sodium peroxide and the generated sodium chloride. The ethereal layer was washed with a saturated sodium hydrogencarbonate aqueous solution and then with a sodium chloride aqueous solution and finally dried over anhydrous magnesium sulfate. The ether was evaporated to dryness by a flow of nitrogen gas; yield 50 %. The white crystalline peroxide was stored as a pentane solution (or suspension).

5-Deuteriobicyclo[2.1.1]hexane-5-carboxylic Acid. A solution of norbornane diazo ketone[13] (3.5 g, 0.026 mol) in a mixed solvent of 1,4-dioxane (70 ml) and D_2O (50 ml) was irradiated under nitrogen with a 200 W medium-pressure mercury lamp. The course of the reaction was monitored by the disappearance of the diazo band at 4.80 μm in the infrared absorption, and required about 1.5 h. Approximately 100 ml of the mixed solvent was removed by distillation through a 30-cm Vigreux column under reduced pressure (bp 43—44 °C/100 Torr). The residue was made alkaline with 1 M sodium hydroxide and extracted with three 50 ml portions of ether to remove the neutral materials. The aqueous solution was acidified with hydrochloric acid and extracted with four 50 ml portions of ether, and dried over anhydrous magnesium sulfate. The ether solvent was removed and distillation of the residue gave 0.88 g of 5-deuteriobicyclo[2.1.1]hexane-5-carboxylic acid, bp 106—109 °C at 7 Torr; yield 27 %.

Bis(5-deuteriobicyclo[2.1.1]hexane-5-carbonyl) Peroxide. The 5-deuteriobicyclo[2.1.1]hexane-5-carboxylic acid was converted to the acid chloride with thionyl chloride and treated with sodium peroxide to obtain the peroxide.

The authors would like to thank Dr. S. Kato (Institute of Molecular Science) for the computer program to solve the anharmonic oscillation. This work was partly

supported by a grant from the Ministry of Education. INDO-UHF calculations are performed with FACOM M190 computer at Data Processing Center of Kyoto University.

Note Added in Proof

The potential curve for the out-of-plane bending motion of the C_5–H_5 bond of **1** was calculated with *ab initio* UHF method. Basis functions were the STO-3G set[14] except those for the tervalent carbon atom, for which Dunning's 4s/2p basis set[15] was adopted. The calculated curve resembles the curve V_3 in Fig. 4. The extrema of the calculated curve are (θ deg, E kcal/mol): (−22, 1.2), (7, 2.1), and (42, 0.0). This result is consistent with the present conclusion.

We thank Dr. H. Nakatsuji and Mr. K. Ohta (Kyoto) for discussions and Gauss-70 program. *Ab initio* calculations were performed on HITAC M-180 computer at Institute of Molecular Science.

The Correlation of Basicity and Equilibrium Constants Evaluated from Lanthanoid-induced Shifts in the Eu(fod)$_3$-*p*-Substituted Aniline Systems

Masatoshi HIRAYAMA* and Masashiro OWADA

Department of Chemistry, Ibaraki University, 2-1-1 Bunkyo, Mito 310

(Received September 18, 1978)

An approximate linear correlation has been found between the basicity of substrate (pK_a) and the logarithm of the equilibrium constant K_1 for 1:1 adducts evaluated from the least squares analysis of lanthanoid-induced shifts (LIS) for the systems containing Eu(fod)$_3$ and a series of *p*-substituted anilines in $CDCl_3$. In contrast, both the observed *S*-values and intrinsic shifts have shown no simple correlation to pK_a's of substrates.

The equilibrium constants (K) and chemical stoichiometry for several systems containing shifts reagents (LSR) and substrates (S) in solution have quantitatively been investigated by several workers in terms of the least-squares analysis of lanthanoid-induced shifts (LIS).[1-9] The orders of magnitude of K have, though roughly, been estimated for several functional groups as a coordination site. The validity of these estimates of K values has been checked solely by the degree of fits of the LIS data to the equilibrium system and by the magnitude of the free energy change, ΔG. Indeed, it has generally been confirmed that such a fit to each envelope of proton data in a substrate molecule is satisfactory (measured in terms of the standard deviation, σ). However the variation in K-values with the position in a molecule is relatively large. It has not been investigated which of some possible origins of errors is directly related to this variation in K.

From the characteristics of LSR as a Lewis acid it is reasonable to expect that the K-values should be correlated to the basicity of the substrate, the degree of steric hindrance on complexation, and the nature of the solvent, *e.g.*, the dielectric constant. It has recently been found in our laboratory that there is a qualitative correspondence between K and the degree of steric hindrance on complexing to LSR for the Eu(fod)$_3$–alkylaniline system in CCl_4.[6]

This paper will report on the relation of K to the basicity of the substrate for a selected series of *p*-substituted anilines with similar steric effects and various pK_a's with Eu(fod)$_3$ in $CDCl_3$.

Experimental

Eu(fod)$_3$ dried over P_2O_5 in a vaccum desiccator was used immediately after sublimation. $CDCl_3$ as the solvent and liquid amine samples were dried over molecular sieves in the dark, the solid samples being recrystallized. The sample solutions were prepared by the so-called "S_0-incremental dilution method,"[11] with a constant concentration of substrate (S_0), 0.2 M. The maximum ratio, $[L_0]/[S_0]$ (ρ), was 2.4 to 3.4, where $[L_0]$ is the total concentration of Eu(fod)$_3$, the number of data points, 23 to 28. NMR spectra were recorded on a Hitachi R-20A at 60 MHz at 34 °C in the frequency-swept mode, using TMS as an internal standard. The program used for the fitting analysis was LISA[5] developed by Shapiro *et al.* and partially modified in this laboratory. All computations were made on HITAC 8800/8700 computers at The University of Tokyo.

Results and Discussion

The systems consisting of aniline and Ln(fod)$_3$ in $CDCl_3$ at room temperature fullfil "the condition of fast substrate exchange" for the measurement of NMR shifts,[6,11,12] as well as those studied in most literatures. It has been found for most substrates with Ln(fod)$_3$ that the highest complex present in solution is LS_2 for very small values of ρ.[1,3-9] Consequently, the equilibria to be considered are 1) $L+S \rightleftharpoons LS \cdots K_1$, 2) $LS+S \rightleftharpoons LS_2 \cdots K_2$, and 3) $L+2S \rightleftharpoons LS_2 \cdots K_3$. Eq. 3 may be neglected because its formation constant is expected to be much smaller than for the others. The formation of L_2 dimer ($L+L \rightleftharpoons L_2 \cdots K_L$ (4)) has been considered in the literature through vapor phase osmometric measurements.[13] The introduction of this effect to the fitting analysis of LIS gave poorer fits for several substrates in solution.[4,5] This suggests that K_L has a very small value, even if the dimerization reaction were considered. Thus, in the present analysis for each substrate, the attempts were made for fitting the LIS data to the four equilibrium systems; (a) only (1), (b) (1)+(4), (c) (1)+(2), and (d) (1)+(2)+(4). For the two step equilibrium (c), the appropriate ranges of K_1 and K_2 were first estimated on the basis of the K-values[6] already obtained for analogous substrates. The respective Q-values ($Q = \sum_i^N (\delta_{exp,i} - \delta_{calcd,i})^2$, where the δ-values represent the LIS's and N the number of data points) for *o*- and *m*-proton data, Q_o and Q_m, were calculated by the introduction of a set of K_1 and K_2 values common to the two data series. The Q_{av}-value was evaluated as the

a) The values of K_1, K_2, δ_1 and δ_2 are those corresponding to $Q_{av,min}$. The standard deviations given in parentheses were evaluated on the basis of each pair of parameters corresponding to $Q_{o,min}$ and $Q_{m,min}$. b) Measured in ppm. Negative signs designate shifts to lower field. c) See text for $Q_{av,min}$. σ is the standard deviation for the fitting analysis, $\sqrt{Q_{av,min}/N}$, where N is the number of date points. d) K_L-values. e) Two sets of parameters obtained by the fitting analyses to both the equilibrium systems are listed. See text.

average which was weighted for the respective δ_1-values corresponding to Q_o and Q_m, where δ_1 is the intrinsic shift for the 1 : 1 complex (LS). The minimum value of Q_{av}, $Q_{av,min}$, was found from the Q_{av}-map in the range of K_1 and K_2 selected above. In the equilibrium system (d), after the introduction of the appropriate value ($0.01 \leqq K_L \leqq 50$) into K_L, the above procedure was conducted. For the one step mechanisms, (a) and (b), the Q_{av}-map for K_1 and K_L was prepared, where K_L was assumed to be zero for (a).

For compounds **1** to **6**, the best results were obtained from the analysis using (c), satisfactorily small values being observed for $Q_{av,min}$. Thus, the set of K_1 and K_2 values which gives the $Q_{av,min}$ value, is a reasonable one, and the values are shown in Table 2 together with the $Q_{av,min}$ values. Simultaneously, the $Q_{o,min}$ and $Q_{m,min}$ for the *o*- and *m*-proton data were independently determined from the Q_o and Q_m maps, respectively. The values of Q_{min} were satisfactorily small except for the *o*-proton data of **5**. The standard deviations for each of the values of K_1 and K_2 decided above were evaluated from the respective K_1 and K_2 values corresponding to $Q_{o,min}$ and $Q_{m,min}$ (Table 2). Representative examples of the analysis and Q-map's are shown in Figs. 1 and 2 for the two step equilibrium, respectively. The values of K vary widely from the *o*- to the *m*-system, especially for the K_2-values as presumed. It is, however, difficult to determine the error responsible for this variation and some explanations will be given later.

The optimum values for the intrinsic shifts, δ_1 and δ_2, were obtained from the set of K_1 and K_2 values which gave $Q_{av,min}$, and each standard deviation was calculated on the basis of the δ_1 and δ_2 values corresponding to $Q_{o,min}$ and $Q_{m,min}$, as the case of K. As may be seen

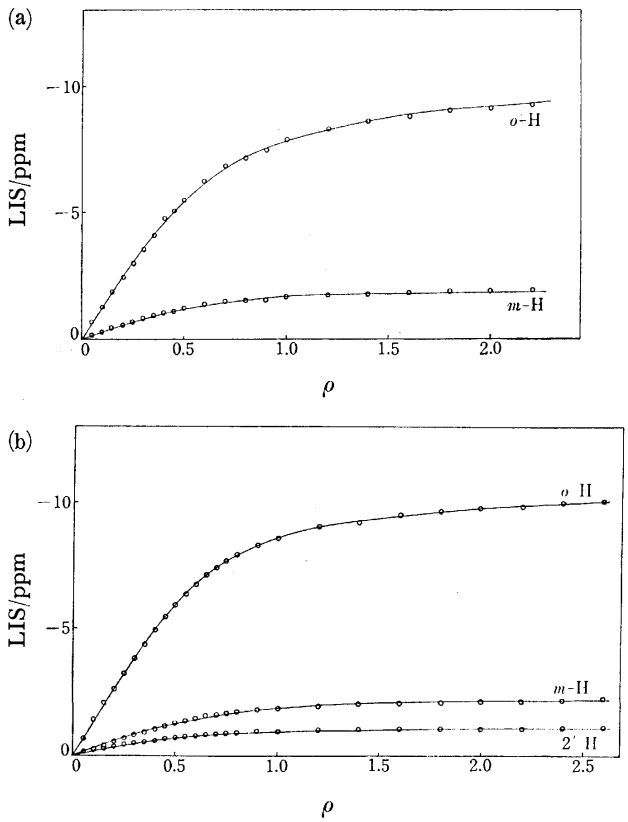

Fig. 1. Results of theoretical fits of the observed Eu(fod)$_3$-induced shifts to the two step mechanism for (a) *p*-chloroaniline and (b) 4-aminobiphenyl.
○: The observed data.

from Table 2, the values of the intrinsic shift do not vary so widely as the K-values, since they are not so

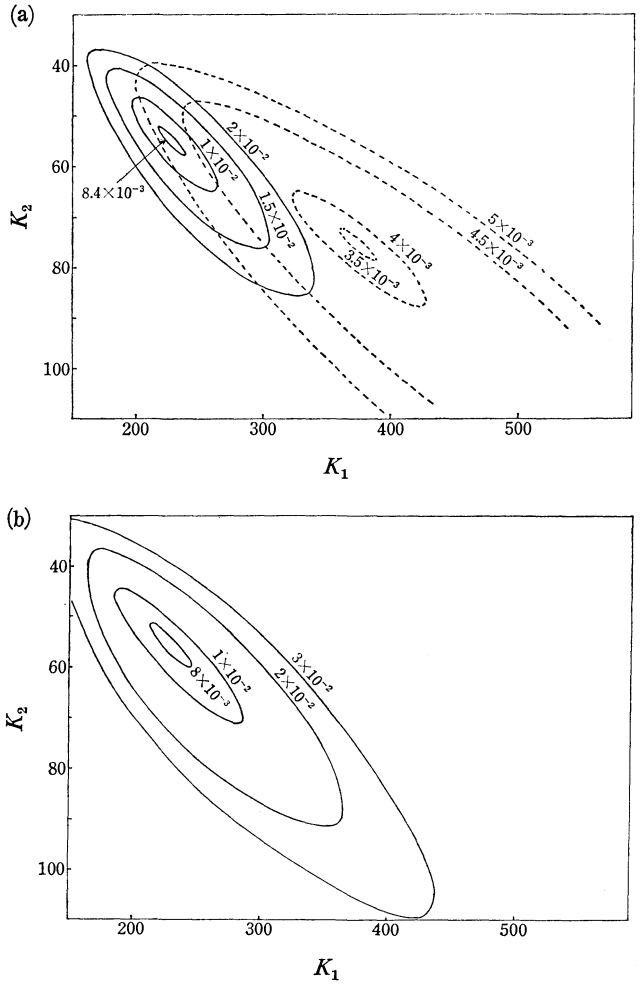

Fig. 2. Contour plots of Q calculated by fitting the LIS's to the equilibrium system, L+S⇄LS and LS+S⇄LS$_2$, for the *p*-fluoroaniline–Eu(fod)$_3$ system in $CDCl_3$ at 34 °C. a) The results calculated independently for *o*- and *m*-proton data. Solid and broken lines denote Q_o and Q_m, respectively. b) The average of Q_o and Q_m, Q_{av}.

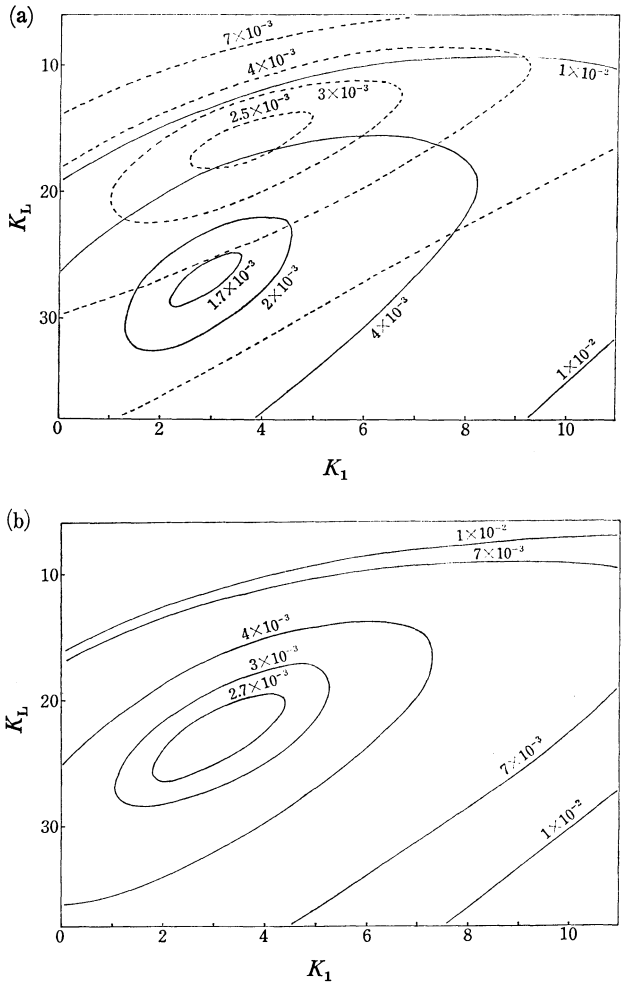

Fig. 3. Contour plots of Q calculated by fitting the LIS's to the equilibrium system, L+S⇄LS and L+L⇄L$_2$, for the *p*-nitroaniline–Eu(fod)$_3$ system in $CDCl_3$ at 34 °C. a) Solid and broken lines denote Q_o and Q_m, respectively. b) Q_{av}.

sensitive to small variations in Q near Q_{min} as the K-value.

For **8**, while the data did not fit well (c), the considerably small value of $Q_{av,min}$ was observed solely by the application of (b) to the analysis of data; the Q-map's are shown in Fig. 3. Attempts to fit the data for **7** to both (b) and (c) resulted in similar small magnitudes of $Q_{av,min}$, and further small variation in values of K, δ_1 and δ_2. It is difficult to select the equilibrium system for the determination of K_1, and however, (b) appears preferable to (c), from the view point of the linearity of log K_1 *vs.* pK_a (Fig. 4). The considerably small or zero values of K_2 obtained for compounds **7** and **8**, appear consistent with the fact that these pK_a values are smaller than for **1** to **6**. Furthermore, it is very plausible from the view point of the competing effect of coordination that only the data for the compound **8** having the smallest pK_a value can be well explained in terms of the addition of the effect of self-association of Eu(fod)$_3$ in solution. In Fig. 4, log K_1 is plotted *vs.* pK_a, where the approximately linear relationship is valid from the nature of the Lewis acid of Eu(fod)$_3$. This is supported by the larger shifts observed for methoxy protons than those expected from the adduct formed by coordination through the N-lone pair. For **10** and **11**, the fits of data to (a) were relatively good for the envelope of *m*-proton shifts ($Q\approx0.01$), but very poor for the *o*-proton shifts. These two substrates did not lead to a clear minimum of Q from the fitting analysis to any other equilibrium systems. This may be due also to the expected effect of coordination of the X-group to the Eu(fod)$_3$. For this type of bifunctional substrate, an additional coordination state, Eu···X-ϕ-NH_2 needs to be taken into account in the equilibrium system.[14] However, the number of parameters determined by least squares analysis becomes considerably greater. Even if more parameters could be evaluated, the results would have no physical significance.

The possible sources of scatter in data in Fig. 4 may be attributed to the following facts; (1) the steric accessibility of the substrate to Eu(fod)$_3$ may be affected by X, (2) the substrate molecule in the present system may be under somewhat different condition from that under which the pK_a-value was measured in Ref. 10, (3) the effect of the coordination effect of X to Eu(fod)$_3$

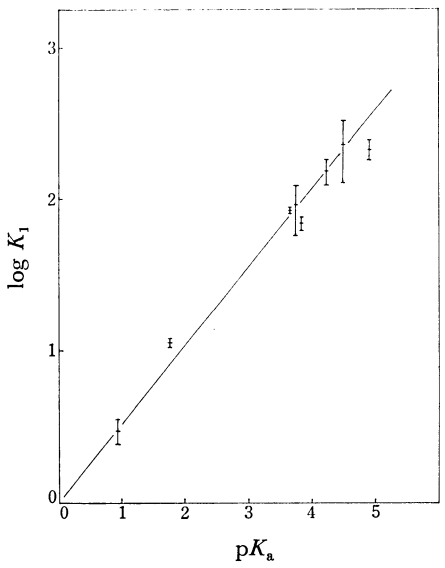

Fig. 4. The logarithms of the equilibrium constants for 1 : 1 adducts (K_1) formed between Eu(fod)$_3$ and *p*-substituted anilines in $CDCl_3$ at 34 °C, *vs.* pK_a-values. The range of each data point corresponds to its standard deviation.

on the observed shifts is not taken into account for all the groups, and (4) a small error may be inherent in the measurement of the concentration of substrate or shift reagent.

The weighting average of K_1, 667, obtained for aniline (pK_a=4.46) with Eu(fod)$_3$ in $CDCl_3$ is very large in the tendency of variation of K_1 in Fig. 4. It may be thought that aniline is not subject to the steric hindrance anticipated for *p*-substituted anilines.[16] However, such a large magnitude of K_1 may not be ascribed solely to this effect. From Table 2, no correlation may be seen between the K_2 and pK_a values for **1** to **6**. This seems acceptable from the possible expectation that the relative acidity and geometry of 1 : 1 adducts (LS) and the steric effect of LS on the accessibility of the second amine molecule may vary with X. On the other hand, the *S*-values and intrinsic shifts estimated in the present investigation also showed no correlation to the pK_a values, in contrast to the linear correlation of *S*-values to pK_a's for the same substrate with Eu(dpm)$_3$ obtained by Ernst *et al.*[11] There may be several explanations to account for such different results with the Eu-chelete, containing the observation of the larger *S*-values with Eu(dpm)$_3$ than with Eu(fod)$_3$.[17] It appears that the difference in contact shift contribution to LIS may dominate among the various explanations.

The authors would like to express their grateful appreciation to Professor B. L. Shapiro for the LISA program.

Studies of the Dissolved State of Sodium Tetradecyl Sulfate in Ethanol-Water Mixtures by Measurements of the Activity

Masakatsu KOSHINUMA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received September 25, 1978)

The details of electromotive-force measurement by means of a concentration cell consisting of sodium tetradecyl sulfate (NaTS) in ethanol–water mixtures and of anionic and cationic ion-exchange membranes as septams were described. The membranes used proved to be permeable exclusively to the surfactant (TS^-) and Na^+ ions respectively. The activities of the TS^- and Na^+ ions were measured separately, and then the mean activity was computed as a function of the ethanol content in the solvent. Below the CMC, the activities for TS^- and Na^+ ions and the mean activity increased with an increase in the NaTS concentration, but decreased with an increase in the ethanol concentration. Above the CMC, the activity of the TS^- ion decreased, whereas that of the Na^+ ion increased; the mean activity also slightly increased with an increase in the NaTS concentration. The values of CMC obtained were 1.5×10^{-3}, 1.7×10^{-3}, and 2.2×10^{-3} mol/dm^3 for 5, 10, and 15 vol % ethanol concentrations respectively. The mechanism of mixed micelle formation was also expressed by a charged phase-separation model in an ethanol–water mixture much as in the case of a simple aqueous solution. The degrees of counterion attachment were found to be 0.73, 0.68, and 0.62 for 5, 10, and 15 vol % ethanol respectively. The intermicellar concentrations of TS^-, (C_{TS}), and Na^+ ions, (C_{Na}), were calculated. With an increase in the NaTS concentration, C_{Na} monotonously increased, but C_{Na} decreased. At a given NaTS concentration, C_{Na} increased with an increase in the ethanol concentration, while C_{Na} was approximately constant.

It is well known that the addition of a nonelectrolyte to a surfactant solution greatly affects the nature of the solution. Many studies regarding the influence of nonelectrolytes on the CMC values have been performed with anionic[1–4] and cationic[1,5,6] surfactants. On the addition of alcohols, the decrease in the CMC was explained by the diluted surface-charge density and the enhanced hydrophobic interaction on a micelle.[7,8] The increase in the CMC was correlated by the hydrophobic nature of the additives and their micellar breaking-up power.[1] Though there have been investigations of the effects of the addition of nonelectrolytes, there have been relatively few studies of the adsorption from the solution,[9] the state of the solution[10] and the micellar state;[11] this has been due in part to the difficulty of activity measurement. In a previous report, the various properties of an aqueous sodium tetradecyl sulfate (NaTS) solution were investigated by measuring its activity.[12] In the present paper, the dissolved state of NaTS in an ethanol–water mixture was studied by measuring the electromotive force (EMF) of the concentration cell. Ethanol was used as a nonelectrolyte additive since it mixes with water in all proportions; also, it is a good solvent for the surfactant. From the activity measurements, the mechanism of micelle formation, the degree of counterion attachment to the micelle, and the intermicellar concentration will be discussed.

Experimental

Materials. The sodium tetradecyl sulfate used was synthesized and purified as in the previous paper.[12] Special-grade ethanol was dehydrated by calcium oxide and distilled before use. Deionized water was used for the EMF measurement.

Procedure. The construction of the concentration cell and the method of measurement were the same as in the previous paper.[12] For the EMF measurements, a solution of 4.0×10^{-3} mol/dm^3 NaTS was used as a reference for each composition of the ethanol–water mixture. The surface tension was measured by the Wilhelmy plate method.[13]

Results and Discussion

Calculation of Activities. The values of the EMF of the TS^- ion, E_{TS}, and of the Na^+ ion, E_{Na}, were obtained from the concentration cells. According to Nernst's equation, E_{TS} and E_{Na} in an ethanol–water mixture are given by

$$E_{TS} = (\lambda_{TS}-\lambda_{Na})(2.303RT/F)\log(a_{TS}/a_{OTS}) \quad (1)$$

$$E_{Na} = (\lambda'_{TS}-\lambda'_{Na})(2.303RT/F)\log(a_{Na}/a_{ONa}) \quad (2)$$

where λ_{TS}, and λ_{Na} are the transport numbers of the TS^- and Na^+ ions for an anionic exchange membrane, and λ'_{TS}, and λ'_{Na}, those for a cationic membrane; F, the Faraday constant; R, the gas constant, and T, the absolute temperature. The values of a_{TS} and a_{Na} are the activities of the TS^- and Na^+ ions in a given solution, and a_{OTS} and a_{ONa}, the corresponding values in a reference solution. If the following Eqs. 3 and 4, may be assumed:

$$\lambda_{TS} = 1, \quad \lambda_{Na} = 0, \quad (3)$$

$$\lambda'_{TS} = 0, \quad \lambda'_{Na} = 1. \quad (4)$$

Eqs. 5 and 6 are obtained:

$$E_{TS} = (2.303RT/F)\log(a_{TS}/a_{OTS}) \quad (5)$$

$$E_{Na} = -(2.303RT/F)\log(a_{Na}/a_{ONa}). \quad (6)$$

If the values of a_{OTS} and a_{ONa} are known, the activities of the given solutions can be computed from Eqs. 5 and 6 by the substitution of the E_{TS} and E_{Na} measured. Plotting the following extrapolation function,[14] a_{OTS} and a_{ONa} can be obtained:

$$E'_{TS} = (2.303RT/F)\log C - E_{TS}$$
$$= (2.303RT/F)(-\log f_{TS}+\log a_{OTS}) \quad (7)$$

$$E'_{Na} = (2.303RT/F)\log C + E_{Na}$$
$$= (2.303RT/F)(-\log f_{Na}+\log a_{ONa}). \quad (8)$$

* Present address: Laboratory of Chemistry, Faculty of Education, Chiba University, Chiba 260.

Here, C denotes the concentration of NaTS, and f_{TS} and f_{Na}, the activity coefficients of the TS^- and Na^+ ions at the C concentration respectively. If E'_{TS} and E'_{Na} are plotted against $C^{1/2}$ and the curves are extrapolated C to 0, a_{OTS} and a_{ONa} can be calculated by Eq. 9 from the extrapolated values of E'_{OTS} and E'_{ONa};

$$\left.\begin{aligned}\log a_{OTS} &= (F/2.303RT)E'_{OTS}\\ \log a_{ONa} &= (F/2.303RT)E'_{ONa}\end{aligned}\right\} \quad (9)$$

because f_{TS} and f_{Na} are unity at $C=0$ in Eqs. 7 and 8. The mean activity and also each activity are calculated by introducing Eq. 9 into Eqs. 5 and 6.

The assumption of Eqs. 3 and 4 of NaTS in an ethanol–water mixture must be confirmed by experiments; however, verification is difficult. The influences were examined, as the addition of ethanol might affect the nature of the ion-exchangers by swelling, dissociation of ion-exchange fixed groups, and transport of the solvent through them; (osmosis effect), depending on the ethanol concentration. It has been reported that swelling, which is closely related to the effective mean pore size of a membrane, its decrease interfering with the ion transport because of the steric disturbance, is little affected by the addition of a low concentration of a lower alcohol, and even in a 20% concentration is nearly equal to that in water.[15] Therefore, the other influences were investigated from the point of view of whether or not Eqs. 10 and 11 for the anionic and cationic exchange membranes hold, using NaCl, the activities of which have been established.

$$\lambda_{Cl} = 1, \quad \lambda_{Na} = 0 \quad (10)$$

$$\lambda'_{Cl} = 0, \quad \lambda'_{Na} = 1 \quad (11)$$

The EMF values of the Cl^- ion, E_{Cl}, and of the Na^+ ion, E_{Na}, resulting from the concentration cell with the reference solution containing the 4.0×10^{-3} mol/kg mixed solvent, were measured for NaCl in an ethanol–water mixture containing 20 wt % ethanol at 25 °C in a manner similar to that used for NaTS. The results obtained are shown in Fig. 1. The value of E_{Cl} increased, and that of E_{Na} decreased, linearly with an increase in the logarithmic concentration of NaCl in a way analogous

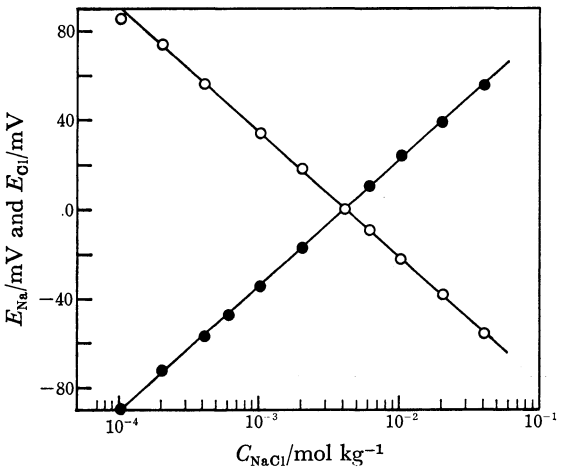

Fig. 1. Electromotive force of Na^+ and Cl^- ions against NaCl concentration.

to that in water. The activities were calculated from these results. The equations corresponding to those from 1 to 9 were also set up in the case of NaCl. The extrapolated E'_{OCl} and E'_{ONa} values were obtained as −144.3 and −144.5 mV respectively; then, a_{OCl} and a_{ONa} were calculated to be 3.64×10^{-3} and 3.61×10^{-3} mol/kg mixed solvent respectively. The activities of the Cl^- and Na^+ ions and the mean activity were calculated separately. The mean activities of NaCl in the ethanol–water mixture are shown by the circles in Fig. 2. A rule for the activity coefficients of NaCl in ethanol–water mixtures has been states as[16,17]

$$(f_{\pm NaCl})_{org} = (f_{\pm NaCl})_{water}[(f_{\pm HCl})_{org}/(f_{\pm HCl})_{water}]. \quad (12)$$

Here, $(f_{\pm NaCl})_{water}$ and $(f_{\pm HCl})_{water}$ are the activity coefficients of NaCl and HCl respectively, in water and $(f_{\pm NaCl})_{org}$ and $(f_{\pm HCl})_{org}$ are the activity coefficients of NaCl and HCl respectively in ethanol–water mixtures. In Eq. 12, $(f_{\pm NaCl})_{water}$ and $(f_{\pm HCl})_{water}$ were calculated using the Debye-Hückel equation, with the mean ionic radii of 4.0 Å for NaCl and of 4.3 Å for HCl. On the other hand, $(f_{\pm HCl})_{org}$ has been given by this empirical equation:[18]

$$\log (f_{\pm HCl})_{org} = -[0.6428C^{1/2}/(1+1.529C^{1/2})] + 0.1293 - \log(1+0.04104m) \quad (13)$$

where C and m denote the concentrations of NaCl in a mol/dm^3-mixture and in a mol/kg-mixture respectively. The computed mean activities of NaCl in an ethanol–water mixture containing 20 wt % ethanol are shown as a solid line in Fig. 2. The experimental mean activities were in good agreement with the values calculated by means of Eqs. 12 and 13; therefore, Eqs. 10 and 11 were verified. Even in an ethanol–water mixture containing below 20 wt % ethanol, no significant changes occur in the characteristics of anionic and cationic exchange membranes; that is they swell well, their ion-exchange fixed groups fully dissociate, and no solvent transport takes place, as in water. Eqs. 3 and 4 for NaTS can also be established as in water.[12]

The values of E_{TS} and E_{Na} measured for NaTS in ethanol–water mixtures containing 5, 10, and 15 vol %

ethanol are shown in Figs. 3 and 4. With an increase in the logarithmic concentration of NaTS, E_{TS} increased linearly to the CMC and then decreased, while E_{Na} decreased linearly to the CMC and through a plateau region decreased in all ethanol concentrations. In order to calculate the activities of the TS^- and Na^+ ions, the plots by the extrapolation functions, 7 and 8, are shown in Fig. 5 for 5 and 15 vol % ethanol concentrations. The extrapolated values of E'_{OTS} and E'_{ONa}, and also the activities of a_{OTS} and a_{ONa} as computed by Eq. 9,

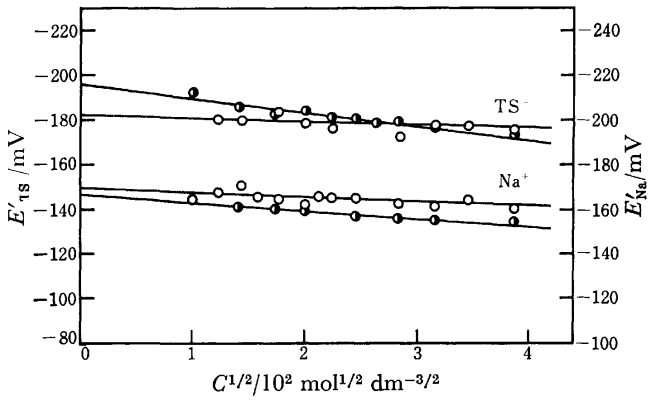

Fig. 5. Extrapolation of E'_{TS} and E'_{Na} against NaTS concentration.

are shown in Table 1. The activities of the TS^- and Na^+ ions, as calculated from Eqs. 5 and 6, are shown in Figs. 6 and 7. With an increase in the NaTS concentration, the activities of the TS^- and Na^+ ions increased, but above a breaking point concentration that of the TS^- ion decreased. The increase in the ethanol concentration caused a decrease in the activities of the TS^- and Na^+ ions. The breaking points agreed with the CMC's determined from the surface-tension measurements, which are shown in Fig. 8 for different ethanol concentrations. The CMC values were 1.5×10^{-3} for 5 vol%, 1.7×10^{-3} for 10 vol%, and 2.2×10^{-3} mol/dm^3 or 15 vol% ethanol. The mean activities, as calculated from the definition, are shown in Fig. 9. also, the tangents increased with an increase in the ethanol concentration. The mean activity coefficients of NaTS are given for different ethanol concentrations, both below the CMC down to 1.0×10^{-4} mol/dm^3 and above it up to 40.0×10^{-3} mol/dm^3, by

$$\log f_{\pm} = -(\alpha \log C + \beta), \tag{14}$$

where α and β are constants, the values of which are shown in Table 2.

Micelle Formation and Counterion Attachment. It has been reported that the micelle formation of NaTS in water can be explained by the charged phase-separation model[12] according to

$$p\mathrm{TS}^- + q\mathrm{Na}^+ \rightleftarrows \mathrm{TS}_p\mathrm{Na}_q^{-(p-q)}$$

where a micelle consists of pTS$^-$ ions and qNa$^+$ ions; therefore,

$$p \log a_{TS} + q \log a_{Na} = \text{constant}. \tag{15}$$

Since, in the ethanol–water mixture, the mixed micelles are considered to be formed by the penetration of ethanol, penetration is taken account of in the discussion of the micelle-formation mechanism. If the charged phase-separation model holds in the mixed micelles, the formation of a mixed micelle, which consists of pTS$^-$ ions, qNa$^+$ ions, and n ethanol molecules, can be expressed as follows:

$$p\mathrm{TS}^- + q\mathrm{Na}^+ + n\mathrm{EtOH} \rightleftarrows \mathrm{TS}_p\mathrm{Na}_q\mathrm{EtOH}_n^{-(p-q)}$$

and also: $(a_{TS})^p(a_{Na})^q(a_E)$=constant where EtOH denotes ethanol. Then, the following equation is given:

$$p \log a_{TS} + q \log a_{Na} + n \log a_E = \text{constant}. \tag{16}$$

In the present study, the activity of ethanol is considered to be constant in Eq. 16 because the experiments were performed with the concentration of ethanol kept constant when that of NaTS was varied. Moreover, the decrease in the ethanol activity due to the formation of the mixed micelle can be neglected because the concentration of ethanol was much larger than that of NaTS. The value of n can be regarded as constant, since the concentrations of NaTS were varied within a narrow range of NaTS concentrations above the CMC. Therefore, Eq. 16 can be simplified to

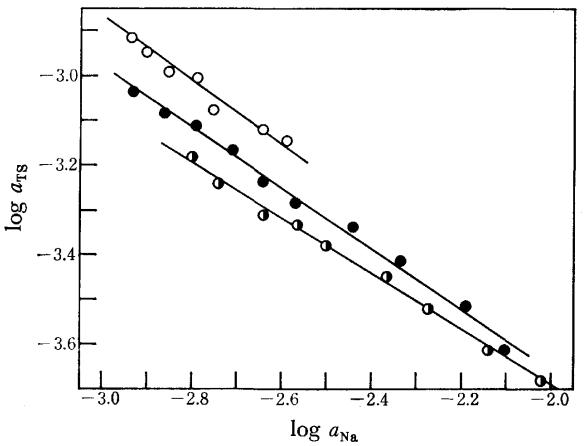

Fig. 10. Relation between log a_{TS} and log a_{Na} above the CMC. Ethanol concentrations for 5 vol %; ○, 10 vol %; ●, and 15 vol %; ◑.

$$p \log a_{TS} + q \log a_{Na} = \text{constant}, \quad (17)$$

which can then be reduced to the same form as Eq. 15. According to Eq. 17, the degree of counterion attachment can be estimated from the slope of the curves if a linear relation is obtained when log a_{TS} is plotted against log a_{Na}. We attempted to examine whether or not Eq. 17 holds. The relations between log a_{TS} and log a_{Na} are shown in Fig. 10, where the plots give good linear relationships for each ethanol concentration. Thus, the mixed-micelle formation in the ethanol–water mixtures can also be explained by the charged phase-separation model. Moreover, the value of n proves to be constant in each concentration range. The degree of counterion attachment, $r=-q/p$, was obtained as 0.73 for 5 vol %, 0.68 for 10 vol %, and 0.62 for 15 vol % ethanol. Figure 11 shows the degrees of counterion attachment and the CMC values obtained. The CMC values decrease, pass through a minimum near the 5 vol % ethanol concentration, and then increase, while the degree of counterion attachment gradually decreases with an increase in the ethanol concentration.

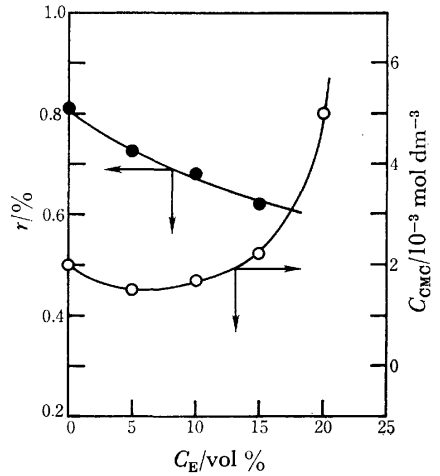

Fig. 11. Degree of counterion attachment and CMC value against ethanol concentration.
●; Degree of counterion attachment,
○; CMC value.

The decrease in the CMC value in the low ethanol-concentration range can be explained by the penetration of ethanol into the NaTS micelle forming the mixed micelle; this causes the decrease in the electrostatic energy on the micelle surface by the dilution of the charge density and the increase in the entropy of mixing.[7,8] The increase in the CMC value in the high ethanol-concentration range results from the increasing affinity of the hydrocarbon chain for ethanol; consequently, the ethanol-rich mixture is a good solvent for NaTS. The degree of counterion attachment gradually decreases; therefore, the charge density on the micelle surface decreases, the result mainly of the penetration of ethanol into the micelle and the decrease in the micelle size.[19]

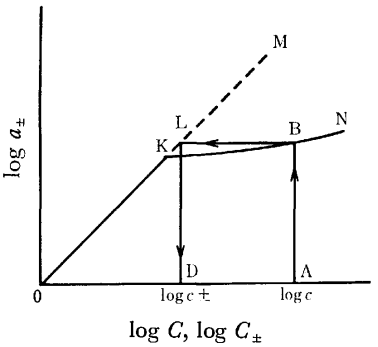

Fig. 12. Schematic representation of calculation of intermicellar concentration.
The broken line determined by the Eq. 14.

Calculation of Intermicellar Concentration. The principles of the calculation of the intermicellar concentration are shown schematically in Fig. 12, where the OKBN line represents the mean activity curve observed and where the K point is the CMC. If a relation between the mean activities and the concentrations of NaTS below the CMC is held similarly above the CMC, the broken line, KLM, which is obtained by the extension of the OK line to above the CMC indicates the relation between the mean activity and the intermicellar concentration. It can be considered that the micelles have no effects upon the relation between the mean activity above the CMC and the intermicellar concentration; that is the activity cofficient for the mean intermicellar concentration behaves the same as just below the CMC when the micelle concentration is very dilute. The mean concentration is defined by the same relation as that of below the CMC;

$$a_{\pm} = f_{\pm} \cdot C_{\pm} \quad (18)$$

where $f_{\pm}$ and $C_{\pm}$ denote the intermicellar activity coefficient and the intermicellar concentration respectively. The value of $f_{\pm}$ is assumed to be expressed by Eq. 14. On the other hand, the mean intermicellar concentration is given by

$$C_{\pm} = (C_{Na} \cdot C_{TS})^{1/2}. \quad (19)$$

Here, C_{TS} and C_{Na} express the intermicellar concentrations of the TS^- and Na^+ ions, since they are not necessarily equal to each other. Then, the intermicellar mean concentration corresponding to the total concen-

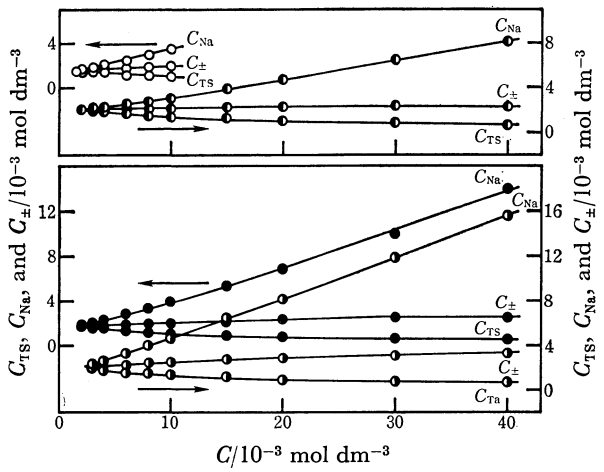

Fig. 13. Intermicellar concentrations of Na^+ and TS^- ions and intermicellar mean concentration.
C_{Na}, C_{TS}, and $C_{\pm}$ represent intermicellar concentrations of Na^+, TS^- ions and intermicellar mean concentration respectively. Ethanol concentrations for 0 vol %; ◐, 5 vol %; ○, 10 vol %; ●, and 15 vol %; ◑.

tration, C, of NaTS is obtained by the process of ABLD on the diagram shown in Fig. 12, while the intermicellar concentration of the TS^- and Na^+ ions for the solution with a total concentration of C are related to each other[20] thus:

$$C_{Na} = (C - C_{TS})(1-r) + C_{TS} \quad (20)$$

where r denotes the degree of counterion attachment. From Eqs. 18, 19, and 20, the intermicellar concentrations are given thus:

$$C_{TS} = -(1-r)(C/2r) + (1/2r)[(1-r)^2C^2 + 4rC_{\pm}^2]^{1/2},$$
$$C_{Na} = -(1-r)(C/2) - (1/2)[(1-r)^2C^2 + 4rC_{\pm}^2]^{1/2}. \quad (21)$$

The results calculated are shown in Fig. 13 for the four ethanol-water mixtures; in the calculation for the 0 vol% ethanol medium, the experimental data are quoted from the previous paper.[12] The intermicellar concentration of C_{Na} increased monotonously, while that of C_{TS} decreased and then asymptotically approached a constant value, with an increase in the NaTS concentration. It was noticed further that C_{TS} was approximately constant, independent of the ethanol concentration, while C_{Na} increased with an increase in the ethanol concentration. The intermicellar mean concentration also increased with increases in both the NaTS and ethanol concentrations. This increase indicates the effect of a good solvent for NaTS, as has been mentioned previously. Also, the difference in inclinations between the C_{TS} and C_{Na} curves in Fig. 13 is roughly proportional to $(1-r)$, which is the degree of dissociation of the Na^+ ion from the micelles.

It should be noted that such relations[21] as

$$C_{Na} = (C - C_{CMC})(1-r) + C_{CMC}$$

and

$$a_{Na} = f_{Na}(C - C_{CMC})(1-r) + C_{CMC}$$

are not correct because C_{CMC} varies with an increase in C, as is shown in Fig. 13. The problem, however, remains of to what extent the presence of micelles influences the activity of intermicellar ions.

The author wishes to express his hearty thanks to Professor Tsunetaka Sasaki of Tokai University for his encouragement and guidance throught the experiments.

The Similarity between the π,π^* Absorption Spectra of 1-Indenone and 1,2-Naphthoquinone

Akira KUBOYAMA* and Hitoshi MATSUMOTO†

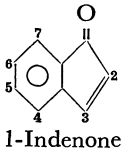
National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

†*School of Pharmacy, Tokushima University of Arts and Science, Yamashiro-cho, Tokushima 770*

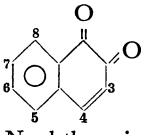
(Received October 6, 1978)

The π,π^* absorption spectrum and its solvent effect of 2-methyl-1-indenone have been found to be similar to those of 1,2-naphthoquinone. This fact is discussed on the basis of the results calculated using the P-P-P method. The similarity of the calculated π-electronic structures in the low-energy π,π^* singlet states between 1-indenone and 1,2-naphthoquinone is not so good as that between fluorenone and 9,10-phenanthrenequinone.

Recently, we have found a similarity between the π,π^* absorption spectra of fluorenone and 9,10-phenanthrenequinone.[1] This similarity is thought to be due to a similarity between the π-electronic systems of the two compounds, on the assumption that the carbonyl group of fluorenone and the α-dicarbonyl group of phenanthrenequinone are equivalent. According to this idea, the above similarity has been reasonably explained on the basis of the results calculated using the P-P-P method. Such a similarity may be expected to exist between 1-indenone and 1,2-naphthoquinone. Heretofore, scarcely nothing has been known about the π,π^* absorption spectra of 1-indenone and its alkyl derivatives.[2] In this work, we have obtained the π,π^* absorption spectra of relatively stable 2-methyl-1-indenone in solutions and have studied the similarity between the π,π^* absorption spectra of 2-methyl-1-indenone and 1,2-naphthoquinone.[3,4]



1-Indenone



1,2-Naphthoquinone

Experimental

Measurements. The absorption spectra of 2-methyl-1-indenone and 1,2-naphthoquinone were measured with a Hitachi 200-20 and a Cary 14 spectrophotometer respectively. Hexane, heptane, benzene, and methanol were used as the solvents.

Materials. According to an earlier article,[5] 2-methyl-1-indenone was synthesized from *trans*-α-methylcinnamic acid by UV inside irradiation (Hg 253.7 nm line) in the ethanol solution,[6,7] and then by a ring-closure reaction in sulfuric acid. The product thus obtained was purified by vacuum distillation and then by recrystallization from a diluted aqueous solution of ethanol (mp 46.5—47.0 °C). It began to decompose four days after its preparation. The 1,2-naphthoquinone was the same as that used in a previous work.[4] The solvents used were of a commercially available spectrograde.

Results. The absorption spectra obtained and the numerical data about them are shown in Fig. 1 and Table 1 respectively.

Calculations

Method. In the calculations using the P-P-P method for 1-indenone, the values of the core and electronic repulsion integrals were the same as those used for 1,2-naphthoquinone in the previous work.[4] As for the effect of alkyl-group substitution, the core Coulomb integral of the substituted carbon atoms was taken as −9.00 eV, considering only the inductive effect, as in the previous work. In the calculations, all the singly-excited configurations were included. The molecular dimensions[8] of 1-indenone assumed are shown in Fig. 2.

Results. The calculated results are shown in Tables 2 and 3 and in Fig. 3. In Table 2, the first column

a) ($i\rightarrow j$) denotes the electron configuration due to the one-electron promotion of i-MO→j-MO. Each configuration of 1-indenone in the table corresponds to that of 1,2-naphthoquinone directly below it.

denotes the numbering of the states in the order of increasing excitation energies (calculated).

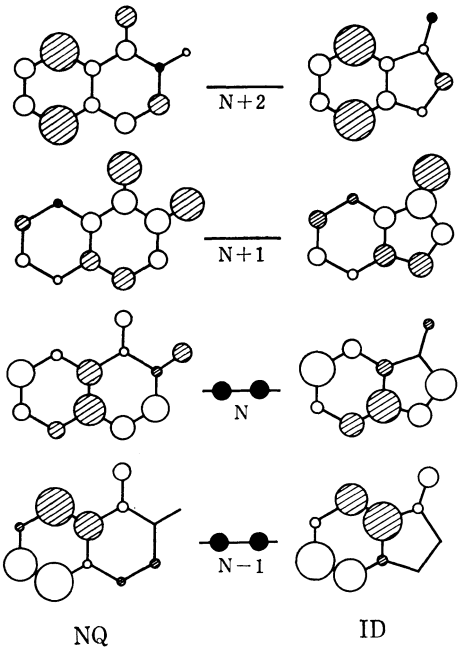

Fig. 3. π-Molecular orbitals of 1-indenone and 1,2-naphthoquinone. The N and N+1 MO energy levels denote the highest occupied and lowest vacant levels respectively. The figures on both sides denote the π-electron distributions and the signs of coefficients of the 2pπ AO's in the corresponding MO's.

Discussion

As may be seen in Fig. 2, both 2-methyl-1-indenone and 1,2-naphthoquinone have two weak π,π^* bands at the longer wavelengths and a strong π,π^* band at the shorter wavelengths. These π,π^* bands are denoted as Bands I—III, as is shown in Table 1. Bands I—III of 2-methyl-1-indenone[9] are located close to the corresponding bands of 1,2-naphthoquinone. In the hexane solution of 2-methyl-1-indenone, Band II has a far sharper structure than Band I. On the other hand, in the heptane solution of 1,2-naphthoquinone, while Band II has a structure, Band I has no structure at all. In the solvent effects of Bands I—III, the following two similarities are found between the two compounds. First, Band I in the methanol solutions, where the hydrogen bond may be formed between the solute and solvent molecules, lies at longer wavelengths than that in the cyclohexane solutions, while Bands II and III lie at almost the same position in both solutions. Second, the intensity ratio of Band I to Band II in the methanol solutions is similar than that in the cyclohexane solutions. The π,π^* absorption spectrum and its solvent effect of 1-indenone are thought to be similar to those of 2-methyl-1-indenone. Therefore, the above discussion may also equally hold good between the π,π^* absorption spectra of 1-indenone and 1,2-naphthoquinone.

On the other hand, in Table 2, the calculated results for the low-energy π,π^* singlet states of 1-indenone and 1,2-naphthoquinone are similar and Bands I—III are favorably assigned on the basis of them. The assignment of Band I of 1,2-naphthoquinone in Table 2 was sup-

ported by the consistency between the experimental and calculated results for the energy shift of Band I through alkyl-group substitutions in the previous work.[4] As may be seen in Fig. 3, the corresponding highest occupied and lowest vacant π-MO's of the two compounds are similar if we assume that the carbonyl group of 1-indenone and the α-dicarbonyl group of 1,2-naphthoquinone are equivalent, as in the case of the pair of fluorenone and 9,10-phenanthrenequinone. However, the similarity between the π-MO's of 1-indenone and 1,2-naphthoquinone is less than that between the above pair. This may be due to the poor molecular symmetry of 1-indenone and 1,2-naphthoquinone. In a previous work,[1] a close similarity of the configurational mixings in the low-energy π,π^* singlet states was found between fluorenone and 9,10-phenanthrenequinone. On the other hand, in Table 3, although the configurational mixings in 1-indenone and 1,2-naphthoquinone are similar in the No. 3 state, those in the Nos. 1 and 2 states are not so similar. Therefore, the similarity between the π,π^* absorption spectra of 1-indenone and 1,2-naphthoquinone can not be so clearly explained as that between fluorenone and 9,10-phenanthrenequinone. The above-mentioned dissimilarity between the configurational mixings in the two compounds is puzzling in view of the similarity between their π-MO's.

As for the change in the calculated excitation energy of the No. 1 state of 1-indenone through an alkyl-group substitution, it is found that the energy decrease ($\Delta E=-0.094$ eV) for the 2-position is the largest and that there is an energy increase ($\Delta E=0.014$ eV) for the 5-position. The 2- and 5-positions in 1-indenone are the positions α and para to the carbonyl group respectively. In 1,2-naphthoquinone, similar calculated results have been obtained in a previous work.[4] Therefore, these findings may support the assignment of Band I of 1-indenone to the transition, the No. 1 state←ground state, in Table 2. After all, it may be concluded that the similarity between the calculated π-electronic structures in the low-energy π,π^* singlet states of 1-indenone and 1,2-naphthoquinone is not so good as that between fluorenone and 9,10-phenanthrenequinone.

Recently, data about the π,π^* absorption spectrum of *p*-tropoquinone  have been obtained by Ito *et al.*[11] which are similar to those of *p*-benzoquinone.[12] This similarity can be clearly explained, on the basis of the calculated results, much as that between fluorenone and 9,10-phenanthrenequinone.

The authors are grateful to Drs. Hideaki Tanaka and Koichi Honda of this laboratory for their helpful advice about the photochemical *trans*→*cis* isomerization of α-methylcinnamic acid in the preparation of 2-methyl-1-indenone.

(Received October 27, 1978)

The extraction of water from a 1 mol dm^{-3} sodium perchlorate solution with trioctylphosphine oxide (TOPO) in four organic solvents and the co-extraction of water with hydrochloric, hydrobromic, hydroiodic, perchloric, nitric, and thiocyanic acids from 1 mol dm^{-3} of the acid solution by TOPO in hexane have been studied at 25 °C. The extraction constants of water in the absence of any of the acids, $K'_{H_2O}=[TOPO\cdot H_2O]_{org}[TOPO]_{org}^{-1}$, were determined to be $10^{0.40}$, $10^{0.00}$, $10^{-0.12}$, and $10^{-0.36}$ in benzene, hexane, carbon tetrachloride, and chloroform respectively. A discrepancy from the 1 : 1 molar ratio of TOPO and water in the extract was observed in the higher-TOPO-concentration region in the hexane system. The co-extraction of water with the acids disolvated by TOPO was greater in the order of $HCl \simeq HBr > HI > HClO_4$, and it was much poorer with the monosolvated acids, nitric and thiocyanic acid. The equilibria for these co-extractions of water with the acids are complicated.

The co-extraction of water with various acids by oxygen-containing solvents has been studied with ethers, ketones, alcohols, and tributyl phosphate.[1,2] The extraction of acids and the co-extraction of water with the acids into various organic diluents containing trioctylphosphine oxide (TOPO) have also been studied, and the equilibria have been considered from several standpoints.[3-8]

After a series on the extraction equilibria of several acids with TOPO,[9-14] the present authors have studied the co-extraction of water with some of these acids. The present paper will describe the experimental results and will discuss the equilibria of these co-extractions.

Experimental

All of the experiments were carried out in a thermostatted room at 25 °C in a manner essentially similar to that described previously.[9-14] A portion of a 1 mol dm^{-3} aqueous electrolyte solution and the same volume of an organic solution were placed in a stoppered glass tube, and the contents were vigorously agitated and centrifuged. The concentration of water in the organic phase was determined by the Karl Fischer method.

Statistical

In the present paper, HX and E denote an acid and TOPO, and the subscript "org" denotes chemical species in the organic phase.

In the absence of any acid, the extraction equilibrium of water with TOPO may be written by the following equations, on the basis of the results to be presented later:

$$E(org) + H_2O \rightleftarrows E\cdot H_2O(org) \quad (1)$$

$$K'_{H_2O} = [E\cdot H_2O]_{org}[E]_{org}^{-1} \quad (2)$$

The concentration of water in the organic phase is written as

$$[H_2O]_{org,total} = [H_2O]_{org,blank} + [H_2O]_{org,E} \quad (3)$$

where $[H_2O]_{org,blank}$ and $[H_2O]_{org,E}$ are the concentrations of free water in the diluent and of bound water with TOPO respectively.

In the presence of an acid, the concentration of water in the organic phase may be written as

$$[H_2O]_{org,total} = [H_2O]_{org,blank} + [H_2O]_{org,E} + [H_2O]_{org,HX} \quad (4)$$

where $[H_2O]_{org,HX}$ is the concentration of the water co-extracted with the acid. Since the extraction of the acids in the absence of TOPO is negligible, the concentration of the extractant may be written as

$$[E]_{org,total} - a[H^+]_{org} = [E]_{org} + [E\cdot H_2O]_{org} \quad (5)$$

where $[H^+]_{org}$ is the concentration of the acid in the organic phase and where a is the mole of TOPO combined with one mole of the acid. As has been described previously,[9,10,13] the value for this a is two for hydrochloric, hydrobromic, hydroiodic, and perchloric acid, while it is one for nitric and thiocyanic acid.

The concentration of the acid-free TOPO, that is, TOPO combined with no acid, can be calculated by means of Eq. 5, and the amount of water combined with the acid-free TOPO, $[H_2O]_{org,E}$, can be calculated from the calibration curves, $\log [H_2O]_{org,E}$ *vs.* $\log [E]_{org,total}$. Finally, the concentration of the water co-extracted with the acid can be calculated by introducing this calculated value of $[H_2O]_{org,E}$ and the experimentally obtained value of $[H_2O]_{org,blank}$ into Eq. 4.

Results

The concentrations of water in the organic solvents containing no TOPO and being equilibrated with an aqueous 1 mol dm^{-3} sodium perchlorate solution are listed in Table 1. The amounts of water in the organic phases containing TOPO and being equilibrated with this aqueous solution (thus, no extraction of any acid

Table 1. The values of the extraction constant in Eq. 2 and those of the water concentration dissolved by the diluent at equilibrium

	$\log [H_2O]_{org,blank}$	$\log K'_{H_2O}$
Benzene	−1.45	0.40
Hexane	−2.39	0.00
Carbon tetrachloride	−2.02	−0.12
Chloroform	−1.14	−0.36

Org. phase: diluent containing TOPO. Aq. phase: 1 mol dm^{-3} sodium perchlorate solution.

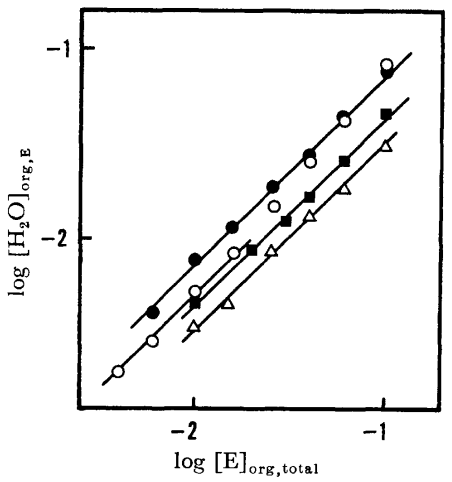

Fig. 1. Variation of water content of the organic phase with total TOPO concentration in benzene (●), hexane (○), carbon tetrachloride (■), or chloroform (△), after correction for the dissolved water by the diluent. The straight lines are slope of +1. The aqueous phase was 1 mol dm^{-3} sodium perchlorate solution.

was expected) were also determined; the $[H_2O]_{org,E}$ values were calculated by means of Eq. 3. Figure 1 shows these calculated values as a function of the total TOPO concentration in the organic phase. The values of $K'_{H,O}$ were calculated from these data by using Eq. 2; they are listed in Table 1. (For the calculation of the value in the hexane system, only those data which fitted with the straight line of a slope one were employed).

The co-extraction of water with mineral acids by TOPO was studied only when the diluent was hexane. The concentration of the co-extracted water with the acid by TOPO was calculated by means of Eq. 4.

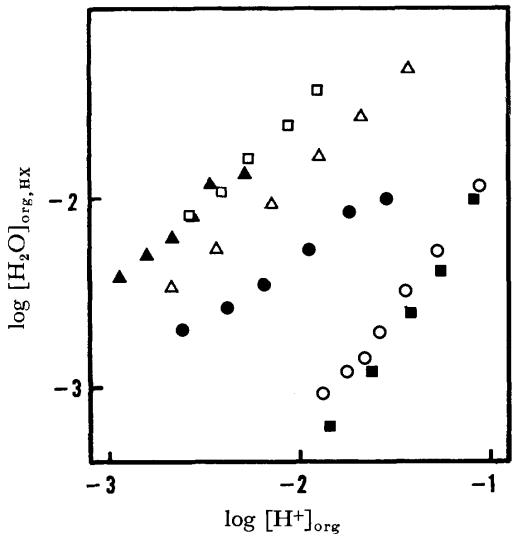

Fig. 2. Co-extracted water with hydrochloric (▲), hydrobromic (□), hydroiodic (△), perchloric (●), nitric (○), or thiocyanic (■) acid-TOPO complex in the hexane phase containing various amount of TOPO, where the aqueous phase for thiocyanic acid system was 0.9 mol dm^{-3} hydrochloric acid and 0.1 mol dm^{-3} sodium thiocyanate, and that for others was 1 mol dm^{-3} only the acid.

Figure 2 shows the values as a function of the concentration of the extracted acid in the organic phase. In these experiments, the aqueous phase was a solution of the acid at 1 mol dm^{-3} except in the thiocyanic acid system; in this case, the aqueous phase contained 0.9 mol dm^{-3} of hydrochloric acid and 0.1 mol dm^{-3} of sodium thiocyanate, and the calculation was made by assuming that the extraction of the hydrochloric acid was negligible compared to that of the thiocyanic acid (*cf.* Refs. 10 and 13).

It is anticipated that the error in the water co-extracted with hydrochloric acid is greater than that co-extracted with the other acids, because its extraction with TOPO was poor, and so much smaller amounts of co-extracted water had to be determined.

Another series of experiments on the co-extraction of water were also made by keeping the TOPO concentration at 0.04 mol dm^{-3}, while changing the hydrogen-ion concentration in the 1 mol dm^{-3} (H,Na)ClO_4 or 1 mol dm^{-3} (H,Na)NO_3 ionic media. The log $[H_2O]_{org,HX}$ *vs.* log $[H^+]_{org}$ plots obtained from these data were found to overlap approximately with those shown in Fig. 2.

Discussion

The above results may be summarized as follows.

i) TOPO in benzene, carbon tetrachloride, and chloroform, and that in hexane at its low concentrations (below 0.02 mol dm^{-3}), extract water from a 1 mol dm^{-3} sodium perchlorate solution as a 1:1 species, TOPO·H_2O. The mole fractions of the TOPO·H_2O species relative to the total TOPO are 0.72, 0.50, 0.43, and 0.30 in benzene, hexane, carbon tetrachloride, and chloroform respectively. Thus, the TOPO is not completely hydrated. In hexane, a discrepancy from the 1:1 mole ratio in the extract was observed when the TOPO concentration was higher.

ii) The amount of water co-extracted into hexane with the three hydrohalogenic acids was proportional to the amount of acid extracted. One mole of hydrochloric and hydrobromic acid in hexane which is combined with two moles of TOPO[10,13] co-extracted approximately three moles of water, but one mole of hydroiodic acid which is also combined with two moles of TOPO[13] co-extracted only approximately 1.3 moles of water.

iii) One mole of perchloric acid which is combined with two moles of TOPO in hexane[9] co-extracts less than one mole of water, and the amounts of water co-extracted per mole of the acid decrease with an increase in the acid concentration.

iv) The co-extractions of water with nitric and with thiocyanic acid, each of which is combined with one mole of TOPO in hexane,[9,13] are approximately the same as each other, and much less than with the other acids; only about one-tenth mole of water is co-extracted with one mole of each of the acids, but the mole ratio of water and acid slightly increases with an increase in the acid concentration.

The extraction of water in the absence of acid in the present work is similar to that in the previous reports;[3-5] moreover, the present results when the solvent is hexane

are similar to those when the solvent was cyclohexane or isooctane in the previous reports.

Attempts were made to find species other than $TOPO \cdot H_2O$ in the hexane system in the higher TOPO concentrations by statistical treatments of the data, but they were not successful. Thus, the present authors can not conclude whether the discrepancy from unity of the slope of the plot in Fig. 1 is due to the formation of higher aggregates such as $(TOPO)_b(H_2O)_c$ (where b/c is lower than unity) or is due to changes in the chemical activities of the solutes. The same kind of discrepancy found in the previous work was explained in terms of the formation of a species, $(TOPO)_3(H_2O)_4$.[15]

It is noticeable that, although a 1:1 species of TOPO and water is formed in the organic phase, still a certain fraction of TOPO, sometimes more than a half of the total TOPO, is in the unhydrous state. Although the salt in the aqueous phase may affect the extraction of water, this can not be explained by the decrease in the water activity because the water activity in a 1 mol dm^{-3} sodium perchlorate solution is about 0.96; thus, the change is not serious.[16]

As may be seen from Fig. 2, the co-extraction of water was proportional to the extraction of the acid when it was a hydrogen halogenide. However, the slope of the $\log [H_2O]_{org,HX}$ *vs.* $\log [H^+]_{org}$ plot was somewhat lower than unity when the acid was perchloric acid and higher than unity when the acid was nitric or thiocyanic acid (in the latter cases, the slopes were about 1.5). It is difficult to give an explanation of these values of the slope of the $\log [H_2O]_{org,HX}$ *vs.* $\log [H^+]_{org}$ plot or of the observation that the molar ratio of the extracted acid and the co-extracted water is quite different when the acid is different. Furthermore, these results can not explain why certain monoprotonic acids are extracted with two molecules of TOPO in the organic phase.

As was previously reported,[9,10,13] only perchloric and the three hydrohalogenic acids among the monoprotonic inorganic acids we have studied were disolvated with TOPO in hexane. One of the explanations for this disolvation to one proton may be that the proton in the extract is in the oxonium-ion form; two of the hydrogens are combined with the phosphoryl oxygen of TOPO, and the last hydrogen is combined with the anion. However, this does not explain the finding that the average composition of the extract was $(TOPO)_2(HClO_4)(H_2O)_d$, where d is a number decreased by an increase in the acid concentration in the organic phase and always lower than unity. Moreover, for the three extracted hydrohalogenic acid species, whose average compositions were $(TOPO)_2(HX)(H_2O)_e$, where e was about 1.3 for hydroiodic acid and about 3 for the other two acids, we should consider that a certain proportion of co-extracted water was in a form other than the oxonium-ion form.

Diamond and his coworkers studied the co-extraction of water with hydrochloric, hydrobromic, perchloric, perrhenic, and tetrachloroauric acid by TOPO in various solvents and reported a tendency similar to that shown by the present results.[3-6] Since less than one mole of water was co-extracted with one mole of the perchloric, perrhenic, and tetrachloroauric acid which were disolvated with TOPO, they concluded that the proton combined with the TOPO molecules was not a oxonium-ion, but was unhydrous, and that the anion which was assumed to combine with the proton as an ion pair was responsible for the co-extraction of water.

However, when the water is assumed to be co-extracted only by an "ion-paired" anion, the very poor co-extraction of water with nitric and thiocyanic acid can not be explained; a nitrate ion should interact with water molecules more strongly than a perchlorate ion.

It is noticeable that the two monoprotonic acids which co-extracted water only poorly were monosolvated by TOPO in the organic phase, while the other monoprotonic acids, which co-extracted greater amounts of water than nitric and thiocyanic acid, were disolvated. It is also marked that these monosolvated acids were weaker acids than the disolvated ones. These facts seem to lead us to other kinds of explanations. For example, none of the anions of the monosolvated acids are in the form of an ion pair in the organic phase; they all interact with the proton more strongly, and thus are less available for the water molecules than the ion-paired anion, and/or each of the two phosphoryl oxygens of TOPO in the disolvated acid species interact with the proton less strongly than that in the monosolvated acid species, thus becoming more available for hydration. However, since spectroscopic measurements have not been made, no final conclusion can be reached on the basis of only the results in the present study.

Molecular Weight Distribution and Kinetics of Low-temperature Propene Polymerization with Soluble Vanadium-based Ziegler Catalysts

Yoshiharu Doi,* Morio Takada, and Tominaga Keii

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 8, 1978)

A kinetic study has been carried out on the low-temperature polymerization of propene with the soluble catalyst system, VCl_4 and alkylaluminium ($AlEt_2Cl$, $AlEt_2Br$, or $AlEt_3$). The rate coefficients of the elementary reactions were evaluated at −78 °C. The molecular weight distribution function was derived on the basis of the polymerization mechanism. The theoretical distribution curves and experimental distribution curves obtained by use of a gel permeation chromatography agree, supporting the mechanism proposed for the coordination polymerization.

The molecular weight distribution (MWD) of polymers depends on the kinetic scheme of polymerization. Flory[1] and Bamford *et al.*[2] derived some distribution functions related to kinetic parameters for vinyl polymerization. Since the advent of gel permeation chromatography,[3] detailed kinetic investigations on the basis of the MWD data of polymers produced have been carried out for various models of polymerization, such as the radical polymerization of styrene with benzoyl peroxide as initiator[4] and the radiation-induced polymerization of styrene[5] and α-methylstyrene.[6] Agreement between the theoretical and experimental MWD curves can be regarded as evidence for the proposed kinetic scheme. However, this type of investigation does not seem to have been applied to the coordination polymerizaton of α-olefin with Ziegler-type catalysts.

In the present study, carrying out the polymerization of propene with the soluble catalyst mixture of VCl_4 with alkylaluminium [$AlEt_2Cl$, $AlEt_2Br$, or $AlEt_3$ ($Et=C_2H_5$)] at −78 °C, we compare the experimental MWD curves with a theoretical one derived from a proposed kinetic scheme. The catalyst system, VCl_4/$AlEt_2Cl$[8] or VCl_4/$AlEt_2Br$,[7] at −78 °C gives the syndiotactic form of polypropylene, whereas VCl_4/$AlEt_3$[10] gives the stereoirregular (atactic) form of polypropylene.

The kinetic scheme for polymerization is discussed, values being then determined for the rate coefficients of elementary reactions along the scheme.

Kinetic Scheme

The mechanism of syndiotactic polymerization of propene with the soluble catalyst system VCl_4/$AlEt_2Cl$ has been extensively investigated by Natta and coworkers.[8–11] Their kinetic data[9,10] on the polymerization and spectroscopic data[11] of the catalyst system suggest the following mechanistic features concerning the polymerization of propene. The catalytically active vanadium formed by the reaction of VCl_4 with $AlEt_2Cl$ is only a small fraction (less than 1%) of the total amount of vanadium[9] and a trivalent state.[11] The polymerization of propene takes place *via* two successive reactions, propene monomer coordination to the active vanadium and the subsequent insertion of the coordinated monomer into the growing chain attached to the metal.[10] The molecular weight of the growing chain is restricted either by the propene monomer coordinated or by the attack of alkylaluminium.[9,10] The chain transfer with monomer may be caused by a hydrogen transfer from the growing chain to the coordinated monomer with the subsequent formation of a new growing chain and a dead polymer. In the chain transfer with alkylaluminium, the growing chain attached to the vanadium may be replaced by the alkyl group on aluminium. In both cases the number of polymerization centers remains unchanged. For the purpose of calculation, the above reactions are written as follows.

Coordination to monomer

$$R_n + M \overset{K_m}{\rightleftharpoons} C_n \tag{1}$$

Propagation

$$C_n \xrightarrow{k_p} R_{n+1} \tag{2}$$

Chain transfer with monomer

$$C_n \xrightarrow{k_{tm}} R_1 + Y_n \tag{3}$$

Chain transfer with alkylaluminium

$$R_n + A \xrightarrow{k_{tal}} R_1 + Z_n \tag{4}$$

Here C_n and R_n represent the growing chain with n units attached to the active vanadium metal with and without the monomer coordinated, respectively. M, A, Y_n, and Z_n represent the propene monomer, alkylaluminium, polymer with n units and polymer molecule with n units attached to inactive aluminium metal, respectively.

The overall rates of propagation, R_p, and chain transfer, R_t, are given by

$$R_p = k_p\sum_1^\infty[C_n] = k_pK_m\sum_1^\infty[R_n][M]$$

$$= k_p\left(\frac{K_m[M]}{1+K_m[M]}\right)\sum_1^\infty([C_n]+[R_n]) \tag{5}$$

$$R_t = (k_{tm}K_m[M]+k_{tal}[A])\sum_1^\infty[R_n] \tag{6}$$

The number average degree of polymerization of the isolated polymers, $\bar{P}_n$, at a given time, t, is given by

$$\bar{P}_n = \frac{\int_0^t R_p dt}{\sum_1^\infty([C_n]+[R_n])+\int_0^t R_t dt} \tag{7}$$

If we assume the steady-state conditions under which R_p and R_t remain constant during the course of polymerization, the reciprocal of $\overline{P}_n$ can be expressed as

$$\frac{1}{\overline{P}_n} = \left(\frac{1+K_m[M]}{k_p K_m[M]}\right)\cdot\frac{1}{t} + \frac{R_t}{R_p} \quad (8)$$

Under the conditions that $t \gg 0$, Eq. 8 can be approximated as

$$\frac{1}{\overline{P}_n} \simeq \frac{R_t}{R_p} = \frac{k_{tm}}{k_p} + \frac{k_{tal}}{k_p K_m}\cdot\frac{[A]}{[M]} \quad (9)$$

We now derive the MWD function in this polymerization. The formation of the growing chain with n units is given by

$$\frac{d[R_n+C_n]}{dt} = k_p K_m[M]([R_{n-1}]-[R_n]) - (k_{tm}K_m[M]+K_{tal}[A])[R_n] \quad (10)$$

When the polymerization is stationary, *i.e.*, $[C_n]$ and $[R_n]$ remain constant during the course of polymerization, the right-hand side of Eq. 10 is zero. Thus we have

$$[R_n] = \beta[R_{n-1}] = \beta^{n-1}[R_1] \quad (11)$$

with

$$\beta = \frac{k_p K_m[M]}{k_p K_m[M]+k_{tm}K_m[M]+k_{tal}[A]} \quad (12)$$

The rate of formation of the polymer with n units is given by

$$\frac{d[Y_n+Z_n]}{dt} = (k_{tm}K_m[M]+k_{tal}[A])[R_n] \quad (13)$$

For a low conversion of monomer the concentration of polymer, $[Y_n+Z_n]$, may be expressed as a function of t.

$$[Y_n+Z_n] = (k_{tm}K_m[M]+k_{tal}[A])\beta^{n-1}[R_1]t \quad (14)$$

Thus, we have the mole fraction of polymer with n units, $X(n)$

$$X(n) = (1-\beta)\beta^{n-1} \quad (15)$$

which is the same as the MWD function derived by Flory.[1)]

Experimental

Reagents. Propene (Mistubishi Petrochemical Co. 99.7 % purity, the impurity being propane) was dried by passing through columns of NaOH and P_2O_5. Heptane (reagent grade) was dried by refluxing over sodium metal under nitrogen atmosphere after distillation. Alkylaluminiums (Japan Aluminium Alkyl Co.) and VCl_4 (Wako Pure Chemicals) were used without further purification.

Polymerization Procedure. A three-neeked glass flask with a magnetic stirrer was used as a reactor. Propene was condensed into heptane in the reactor kept at −78 °C with methanol–Dry Ice. The amount of heptane used was adjusted to be 100 ml as the total volume of solution. Prescribed amounts of alkylaluminium and VCl_4 were charged one after the other. Polymerization was timed from the addition of the VCl_4 component, and quenched at a given time by introducing 100 ml of an ethanol solution of hydrochloric acid cooled at −78 °C. The polymers obtained were washed several times with 200—300 ml ethanol and dried *in vacuo* at room temperature.

Gel-permeation Chromatography Analysis. Molecular weight distributions of polymers were measured by gel permeation chromatography (GPC) (Waters Associates, Model 200) with the use of five polystyrene gel columns (10^7, 10^6, 10^5, 10^4, and 10^3 Å pore sizes) and *o*-dichlorobenzene as a solvent at 135 °C. The solvent flow rate was maintained at 1.0 ml/min. A molecular weight calibration curve was obtained on the basis of the universal calibration,[12,13)] with 10 standard samples of monodisperse polystyrene of molecular weights 2100—2610000. From the GPC data, the number-average and weight-average molecular weights ($\overline{M}_n$, $\overline{M}_w$) were obtained by standard procedures by using the data at 1/2 count (2.5 ml elution volume).

Results and Discussion

The polymerization results obtained at −78 °C under various conditions are summarized in Tables 1, 2, and 3 for the $VCl_4/AlEt_2Cl$, $VCl_4/AlEt_2Br$, and $VCl_4/AlEt_3$ catalysts, respectively. Polymerization was carried out in the range of a low conversion of propene monomer up to several percents. The concentration of monomer may be regarded as constant during the course of polymerization. Kinetic analysis for the polymerization was made from the data given in the Tables.

Polymerization Rate. The time dependence of the yields of polymers produced in the course of polymerizations with different catalyst systems is shown in Fig. 1. The yield-time curves are almost linear with no induction periods. This shows that the formation of the polymerization centers is complete just after the start of polymerization and the number of the centers remains constant during the course of polymerization.

The polymer yields at a given polymerization time were of first-order, as anticipated, with respect to the amount of vanadium tetrachloride at a constant concentration of alkylaluminium. On the other hand, it was found that the relationship between polymerization rate and propene monomer concentration is not of simple first-order kinetics. The polymerization rate, R_p, increased to a constant value with increase in monomer

concentration, [M].[14] $1/R_p$ is plotted against 1/[M] for the respective catalyst system in Fig. 2. The linearity of the plots indicate that Eq .5 is applicable to the polymerization of propene with soluble vanadium-based catalysts. The values of the coordination equilibrium constant of monomer, K_m, were determined from the slopes and the intercepts of the straight lines. The results are given in Table 4.

−78 °C, $[AlEt_2Cl]=[AlEt_2Br]=0.05$ mol/l or $[AlEt_3]=0.025$ mol/l.

The effect of alkylaluminium concentration on the polymerization rate is complicated (Fig. 3). The polymerization rate rises to a maximum value followed by a gradual fall with increase in the concentration of alkylaluminium, *i.e.*, in the Al/V ratio. The polymerization rate is correlated with the following function of the concentration of alkylaluminium [A].

$$R_p \propto \frac{K_A[A]}{(1+K_A[A])^2} \tag{16}$$

Table 4. Rate coefficients of elementary reactions in the polymerization of propene with $VCl_4/AlEt_2X$ (X=Cl, Br, Et) catalyst systems at −78 °C

	$AlEt_2Cl$	$AlEt_2Br$	$AlEt_3$
K_m(l·mol^{-1})	0.26±0.03	0.02±0.01	0.04±0.01
K_A(l·mol^{-1})	6.8±0.3	31±3	46±2
k_p(h^{-1})	(4.3±1.0)×10^3	(2.5±1.2)×10^2	(5.3±0.6)×10^4
k_{tm}(h^{-1})	5.4±0.1	1.7±0.1	2.3±0.3
k_{tal}(l·mol^{-1}·h^{-1})	18±6.5	3.5±2.0	9.0±1.5

The value of the constant, K_A, decreases in the order: $AlEt_3$>$AlEt_2Br$>$AlEt_2Cl$ (Table 4). The order appears to correspond to the reducing powers of the alkylaluminium for VCl_4. Though we can not present a conclusive explanation for Eq. 16, alkylaluminium seems to take part in the deactivation of polymerization centers as well as in the formation of the centers through the alkylation and complexation of VCl_4. This is supported by the obervation of Lehr[15] that higher Al/V ratios result in some reduction of vanadium to its divalent state at −78 °C in the $VCl_4/Al(i\text{-}Bu)_3$ catalyst system. The influence of the alkylaluminium concentration on the polymerization rate is thus understandable as a result of the change in the number of polymerization centers, $\sum_1^\infty([C_n]+[R_n])$.

−78 °C, [M]=8.4 mol/l.

Average Molecular Weight. The number-average molecular weghts, $\overline{M}_n$, of polymers produced increase with the polymerization time, attaining constant values in a few hours for all the catalyst systems (Tables 1—3). The plots of $1/\overline{M}_n$ *vs.* $1/t$ are shown for different catalyst systems in Fig. 4. The linearity of plots indicates that the experimental results are satisfactorily correlated by Eq. 8, which is a linear form of Eq. 7. Using the values of K_m given in the preceding section, we can estimate the values of the propagation rate coefficient of monomer, k_p, from the slopes of the straight lines. The values of k_p for different catalyst systems are summarized in Table 4.

The values of $\overline{M}_n$ of the polymers produced at 3 h increase with increase in the concentration of propene monomer, [M]. The dependence of the value of $\overline{M}_n$ on [M] is given by Eq. 9. The relation between the value of $\overline{M}_n$ of the polymers produced and the concentration of alkylaluminiums, [A], also follows Eq. 9 (Figs. 5—7). The values of intercepts of both straight lines in the respective figure agree closely with each other. This suggests that the chain terminating steps other than the transfer with monomer and alkylaluminium is not significant in the polymerization. The values of the rate coefficients of the chain transfers, k_{tm} and

k_{tal}, may be obtained from the intercepts and slopes of the straight lines. The values of k_{tm} and k_{tal} are given in Table 4 with the experimental deviation for each catalyst system.

The rate coefficients of the elementary reactions are remarkably affected by the type of alkylaluminium used. The mole fraction of syndiotactic dyads of the polypropylene produced decreases as follows.[7]

$$AlEt_2Cl\ (86) > AlEt_2Br\ (65) > AlEt_3\ (50) \qquad (17)$$

The remarkable influence of the type of alkylaluminium on the elementary reaction rates and stereospecificity may be interpreted in terms of the bimetallic structure of the polymerization center, first proposed by Zambelli *et al.*,[11] in which the alkylaluminium complexed with alkylvanadium chloride regulates the catalytic capability.

Molecular Weight Distributions. Comparison has been made between the theoretical and experimental MWD curves of the polypropylene samples. Three

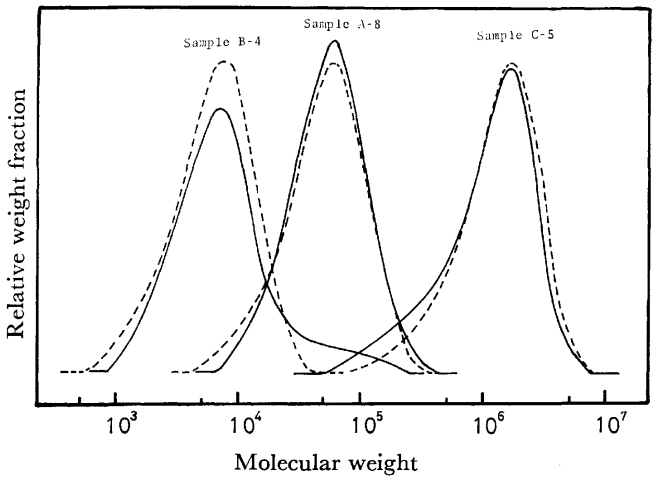

Fig. 8. Experimental and theoretical molecular weight distribution curves of polypropylenes prepared at −78 °C with different soluble vanadium-based catalysts.
(——): Experimental curves, (– – –) theoretical curves.

nomalized GPC curves of samples A-8, B-4 and C-5 are shown in Fig. 8 by solid lines. The polypropylene samples were prepared by the polymerization with different catalyst systems. The weight fraction of polymer is plotted against common logarithms of molecular weight. For the sake of comparison the theoretical MWD curves of the three samples were calculated from a plot of $42 \cdot n^2 \cdot [X(n)]$ *vs.* $\log (42 \cdot n)$, with $[X(n)]$ by means of Eq. 15 and the values of β (0.99865 for sample A-8, 0.98915 for sample B-4 and 0.99995 for sample C-5) were determined using the kinetic parameters (Table 4), taking the conditions for the preparation into consideration. The results are shown in Fig. 8 by dotted lines. The modes of curves and the values of maxima are in close agreement between theory and experiment, except sample B-4 prepared with $VCl_4/AlEt_2Br$ system. The shoulder at the higher molecular weights observed in the GPC curve of sample B-4 may be due to the coexistence of $AlEt_2Cl$ formed by the halogen interchange between VCl_4 and $AlEt_2Br$.

It may be concluded that the molecular weight distributions of polymers produced with soluble vanadium-based catalysts are expressed by the distribution function of Eq. 15 derived from the kinetic scheme proposed.

14) Further purification of monomer by bubbling in the heptane solution of $AlEt_3$ was made to remove the trace of O_2 prior to use in the VCl_4–$AlEt_2Cl$ catalyst system. However, no effect of purification was observed on the polymerization rates. It is concluded that the unusual dependence of monomer concentration on the polymerization rate can not be interpreted in terms of the inhibiting effect of O_2 trace in the monomer.

Temperature Effects on CD Spectra of β-Cyclodextrin Complexes with 2-Substituted Naphthalenes

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received November 13, 1978)

CD spectra of β-cyclodextrin complexes with 2-naphthol, 2-naphthyloxyacetic acid, potassium 2-naphthoate, and potassium 2-naphthylacetate were measured at various concentrations of β-cyclodextrin and at temperatures ranging from 10 to 70 °C. The temperature-dependent CD spectra of the 2-naphthyloxyacetic acid complex clearly show the 1 : 1 complex formation, but the other three complexes give CD intensity changes which are inexplicable in terms of the 1 : 1 stoichiometry. The molecular ellipticity and thermodynamic parameters were determined by the least-squares method. Enthalpy and entropy are in the ranges from −22.2 to −26.8 kJ·mol^{-1} and from −24 to −38 J·K^{-1}·mol^{-1}, respectively. They are strongly correlated to the volume of the substituent of the guest molecule, although the free energy is found in a quite narrow region (from −14.3 to −15.4 kJ·mol^{-1}). The correlation is explained on the basis of the β-cyclodextrin–guest interaction and the solvation around the guest molecule.

Cyclodextrins, which are α-1,4-linked cyclic oligosaccharides, form a number of inclusion complexes with a variety of guest molecules owing to the large cylindrical cavity in the center of the molecule.[1,2] Since cyclodextrins are asymmetric molecules, optical activity is induced when an optically inactive guest is included in the cavity.[3–7] For the cyclodextrin complexes with aromatic guests, the origin of induced optical activity was reasonably explained in terms of the Kirkwood-Tinoco coupled oscillator model.[5–7] Although CD spectra of many cyclodextrin complexes have already been reported, the molecular ellipticity of the complex has not been precisely determined. Since the induced CD is caused by cyclodextrin–guest interactions, CD spectra are expected to give information on the structure of the complex in solution. In the previous paper,[8] we reported the temperature dependence of CD spectra of α-cyclodextrin complexes with *m*- and *p*-nitrophenols. We present here the temperature effects on CD spectra of β-cyclodextrin complexes with 2-substituted naphthalenes and will discuss the structure and binding force of the complexes on the basis of the thermodynamic parameters determined by the least-squares method.

Experimental

Materials. β-Cyclodextrin (G. R., Tokyo Kasei Co.) was twice recrystallized from water and dried *in vacuo* over phosphorous pentaoxide. 2-Naphthol and 2-naphthyloxyacetic acid (G. R., Tokyo Kasei Co.) were recrystallized from ethanol. Potassium 2-naphthoate and potassium 2-naphthylacetate were prepared from 2-naphthoic acid and 2-naphthylacetic acid, which were treated by KOH-saturated ethanol, and were recrystallized from water.

CD Measurements. Solutions were prepared with deionized and distilled water. The CD spectra were recorded on a JASCO J-40A circular dichrograph with a J-DPZ data-processor. The recording of each spectrum was repeated four times, and the averaged spectra were obtained on the data-processor. The temperature was regulated by using a Tokyo Rico TC-100 thermo-controller with an accuracy of ±0.5 °C inside the cell.

Results

The CD spectra measured at 30 °C are shown in Fig. 1. The concentrations of β-cyclodextrin, 2-naphthol, 2-naphthyloxyacetic acid, potassium 2-naphthoate, and potassium 2-naphthylacetate are 5.0×10^{-3}, 1.89×10^{-4}, 2.12×10^{-4}, 1.90×10^{-4}, and 2.02×10^{-4} M, respectively. Each complex shows negative CD bands in the wavelength region longer than 250 nm. The CD bands found in the 250—300 nm region give a peak intensity higher than the intensity of the 300—350 nm bands. A large positive-signed CD band was found in the wavelength region from 200 to 250 nm. The temperature dependence of the CD intensity was measured by increasing the temperature from 10 to 70 °C. After the measurement at 70 °C, the temperature was again lowered to 10 °C. Then, the CD intensity returned to the initial value.

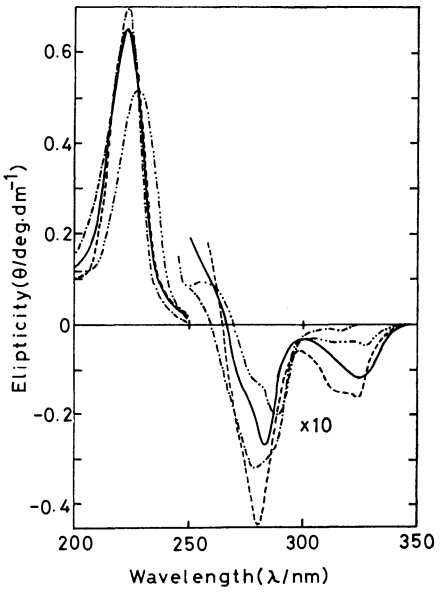

Fig. 1. CD spectra of β-cyclodextrin complexes with 2-naphthol (——), 2-naphthyloxyacetic acid (– – –), potassium 2-naphthylacetate (–·–·), and potassium 2-naphthoate (–··–) at 30 °C. The concentrations of β-cyclodextrin, 2-naphthol, 2-naphthyloxyacetic acid, potassium 2-naphthylacetate, and potassium 2-naphthoate are 5.0×10^{-3}, 1.89×10^{-4}, 2.12×10^{-4}, 2.02×10^{-4}, and 1.90×10^{-4} M, respectively.

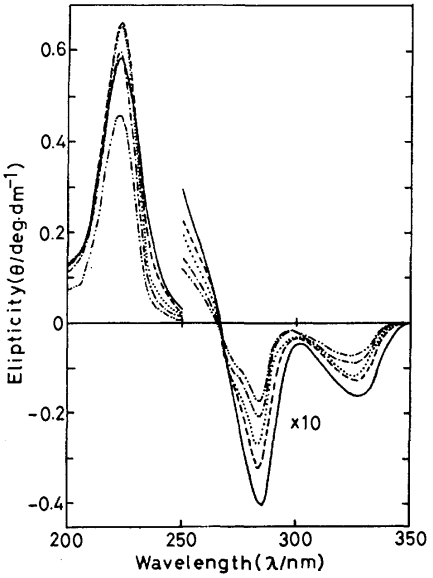

Fig. 2. CD spectra of β-cyclodextrin–2-naphthol complex measured at 10 °C (——), 20 °C (——), 30 °C (·····), 50 °C (-·-·), and 70 °C (-···-). The concentrations of β-cyclodextrin and 2-naphthol are 5.0×10^{-3} and 1.89×10^{-4} M, respectively.

β-Cyclodextrin–2-Naphthol Complex. The CD spectra measured at 10, 20, 30, 50, and 70 °C are shown in Fig. 2. With the increase of temperature, the negative CD bands lower their intensity. The intensity change in these bands is more rapid at lower temperature conditions. When the temperature is raised from 10 to 30 °C, the CD intensity of the 285 nm band decreases by 0.14 deg·dm^{-1}, which corresponds to 33% of the intensity measured at 10 °C. On the other hand, the intensity change is only 0.035 deg·dm^{-1} between the temperatures of 50 and 70 °C. The 285 nm band is slightly sharpened by increasing the temperature, and a shoulder appears at 274 nm. A similar sharpening is observed in the positive CD band centered at 222 nm. The intensity change in the 222 nm band is different from that of the negative-signed bands measured in the longer wavelength region. The CD intensity enhances when the temperature is raised up to 20 °C; after that, however, the intensity lowers with increasing temperature. Figure 4a gives the more detailed intensity change measured at 222 nm. In this case, the concentration of 2-naphthol is adjusted to 1.83×10^{-4} M, and the intensity was measured at β-cyclodextrin concentrations of 1.0×10^{-3}, 2.0×10^{-3}, and 9.0×10^{-3} M. At each β-cyclodextrin concentration, the highest CD intensity was not observed at 10 °C. The temperature which gives the maximum CD intensity becomes lower with the decrease of the β-cyclodextrin concentration. At 9.0×10^{-3} M β-cyclodextrin concentration, the CD intensity increases with the temperature up to 40 °C, and after that decreases gradually. The intensity maxima were also observed at 20 and 15 °C at the β-cyclodextrin concentrations of 2.0×10^{-3} and 1.0×10^{-3} M, respectively. The molecular ellipticity of the complex and thermodynamic parameters were determined by the least-squares method (see Appendix) on the basis of the assumption of the 1 : 1 stoichiometry. The intensity data measured at temperatures lower than 40 °C (9.0×10^{-3} M), 30 °C (2.0×10^{-3} M), and 25 °C (1.0×10^{-3} M) were not included in the calculation, since these values systematically deviated from the expected ones and can not be explained on the basis of the 1 : 1 stoichiometry. The calculated intensity is shown by the solid line in Fig. 4a. The 1 : 1 stoichiometry predicts the monotonous decrease of the CD intensity with the increase of the temperature. The molecular ellipticity of the complex is $5.7(1)\times10^{4}$ deg·cm^{2}·dmol^{-1}, and the dissociation constant at 25 °C is $2.0(2)\times10^{-3}$ mol. The free energy at 25 °C, enthalpy, and entropy for the complex formation are −15.4(3), −26.8(9) kJ·mol^{-1}, and −38(3) J·K^{-1}·mol^{-1}, respectively.

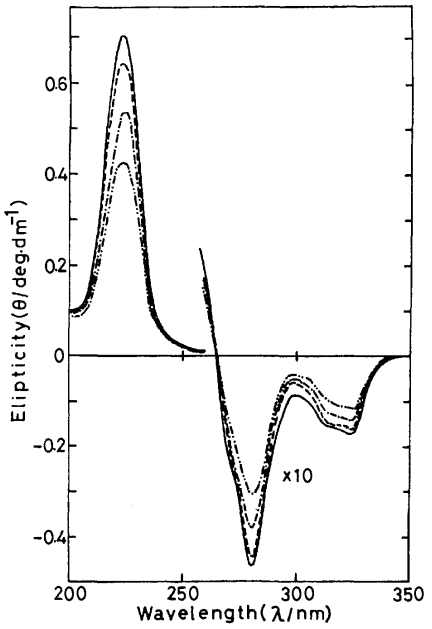

Fig. 3. CD spectra of β-cyclodextrin–2-naphthyloxyacetic acid complex measured at 10 °C (——), 30 °C (——), 50 °C (-·-·), and 70 °C (-···-). The concentrations of β-cyclodextrin and 2-naphthyloxyacetic acid are 5.0 $\times10^{-3}$ and 2.13×10^{-4} M, respectively.

β-Cyclodextrin–2-Naphthyloxyacetic Acid Complex. The CD spectra of the 2-naphthyloxyacetic acid complex measured at 10, 30, 50, and 70 °C are shown in Fig. 3. Unlike the 2-naphthol complex, the intensity change is slow in the temperature range from 10 to 30 °C. Two weak CD bands are centered at 313 and 326 nm, while the larger negative band found at 280 nm has a weak shoulder at 273 nm. The intensity of these CD bands becomes lower with the increase of the temperature, and the intensity change is more rapid at higher temperature. The intensity of the 280 nm peak reduces to *ca.* 65% of the intensity measured at 10 °C when the temperature is raised to 70 °C. The intensity of the positive CD band, which is centered at 224 nm, also decreases with increasing temperature. The intensity at 70 °C is about 60% of that measured at 10 °C. Figure 4b shows plots of the intensity change measured at 224 nm against the temperature. The concentration of

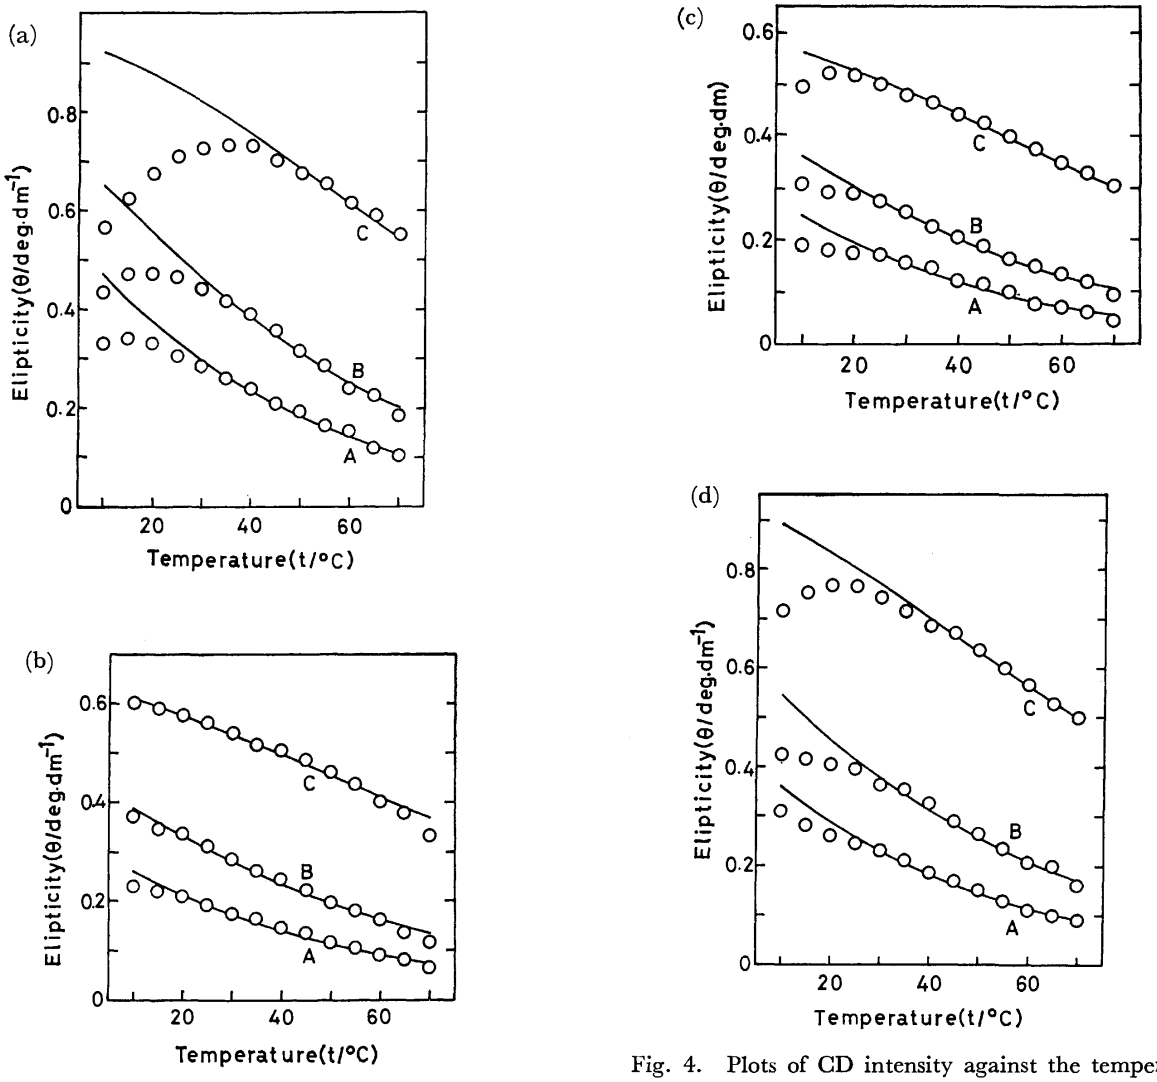

Fig. 4. Plots of CD intensity against the temperature; the intensity is measured at 222 nm for the 2-naphthol complex (a), 224 nm for the 2-naphthyloxyacetic acid complex (b), 230 nm for the potassium 2-naphthoate complex (c), and 224 nm for the potassium 2-naphthylacetate complex (d) with the concentrations of 1.83×10^{-4}, 1.73×10^{-4}, 1.71×10^{-4}, and 1.96×10^{-4} M, respectively. The concentration of β-cyclodextrin is 1.0×10^{-3} (A), 2.0×10^{-3} (B), and 9.0×10^{-3} M (C). Solid lines are calculated intensity by using molecular ellipticity and thermodynamic parameters which are determined by the least-squares method on the basis of a 1:1 complex.

2-naphthyloxyacetic acid is 1.73×10^{-4} M, and the measurement was carried out at the β-cyclodextrin concentrations of 1.0×10^{-3}, 2.0×10^{-3}, and 9.0×10^{-3} M. The least-squares calculation was done by using all the intensity data measured. The CD intensity decreases monotonously with the temperature increase, and the calculated values (shown by solid lines) fitted well with the observed ones. In this case, the molecular ellipticity is $4.20(4)\times10^{4}$ deg·cm²·dmol⁻¹, and the dissociation constant at 25 °C is $2.7(1)\times10^{-3}$ mol. The free energy at 25 °C, enthalpy, and entropy are −14.6(1), −22.5(5) kJ·mol⁻¹, and −24(2) J·K⁻¹·mol⁻¹, respectively.

β-Cyclodextrin–Potassium 2-Naphthoate Complex. This complex shows two weak peaks at 328 and 312 nm in the longer wavelength region, while in the 250—300 nm region there is found a negative CD peak at 289 nm and a shoulder at 281 nm. The positive CD band is observed at 230 nm. The intensity change measured at 230 nm is shown in Fig. 4c. The concentration of the guest is 1.71×10^{-4} M. At the β-cyclodextrin concentration of 9.0×10^{-4} M, an enhancement of the CD intensity is observed when the temperature is raised from 10 to 15 °C, but after that, the intensity decreases with the increase of the temperature. At the β-cyclodextrin concentrations of 2.0×10^{-3} and 1.0×10^{-3} M, an intensity decrease was observed during the temperature increase up to 70 °C. In the least-squares calculation, the intensity data measured at temperatures less than 20 °C were not included because of the reasons mentioned above. The molecular ellipticity of the complex is $3.88(7)\times10^{4}$ deg·cm²·dmol⁻¹, and the dissociation constant at 25 °C was determined to be $2.7(2)\times10^{-3}$ mol. The free energy at 25 °C, enthalpy, and entropy are −14.6(2), −25.5(8) kJ·mol⁻¹, and −37(2) J·K⁻¹·mol⁻¹, respectively.

β-Cyclodextrin–Potassium 2-Naphthylacetate Complex.

TABLE 1. MOLECULAR ELLIPTICITY AND THERMODYNAMIC PARAMETERS OF β-CYCLODEXTRIN COMPLEXES WITH 2-SUBSTITUTED NAPHTHALENES

	λ_{max}	$[\theta]$	K_d(298 K)	ΔG(298 K)	ΔH	ΔS
	nm	10^4 deg·cm²·dmol^{-1}	10^{-3}·mol	kJ·mol^{-1}	kJ·mol^{-1}	J·K^{-1}·mol^{-1}
2-Naphthol	222	5.7(1)	2.0(2)	−15.4(3)	−26.8(9)	−38(3)
2-Naphthyloxyacetic acid	224	4.20(4)	2.7(1)	−14.6(1)	−22.2(5)	−24(2)
Potassium 2-naphthoate	230	3.88(7)	2.7(2)	−14.6(2)	−25.5(8)	−37(2)
Potassium 2-naphthylacetate	224	5.5(1)	3.1(2)	−14.3(2)	−23.0(6)	−29(2)

In the longer wavelength region, a very weak CD band is centered at 318 nm. The larger negative peak is observed at 279 nm, while a shoulder is observed at 288 nm. In the shorter wavelength region, a positive CD band is found at 224 nm. The temperature dependence of the 224 nm band was measured at the guest concentration of 1.96×10^{-4} M, as shown in Fig. 4d. At the β-cyclodextrin concentration of 9.0×10^{-3} M, the CD intensity increased with the temperature up to 20 °C, then decreases with increasing temperature. Only an intensity decrease was observed at the β-cyclodextrin concentrations of 2.0×10^{-3} and 1.0×10^{-3} M. The least-squares calculation was done by using the intensity data measured at the temperatures higher than 30 °C for the β-cyclodextrin concentration of 9.0×10^{-3} M and 20 °C for the concentrations of 2.0×10^{-3} and 1.0×10^{-3} M. The molecular ellipticity of the complex is $5.5(1)\times10^4$ deg·cm²·dmol^{-1}, and the dissociation constant at 25 °C is $3.1(2)\times10^{-3}$ mol. The free energy at 25 °C, enthalpy, and entropy are −14.3(2), −23.0(6) kJ·mol^{-1}, and −29(2) J·K^{-1}·mol^{-1}, respectively.

Discussion

Structure and Stoichiometry of the Complex. β-Cyclodextrin complexes with four 2-substituted naphthalenes give similar CD spectra: two negative CD bands in the 250—350 nm region and a positive CD band in the 200—250 nm region. The origin of induced CD by cyclodextrins is reasonably interpreted in terms of the Kirkwood-Tinoco coupled oscillator model.[5-7] The rotational strength with an electric transition-dipole-moment of μ_{oa} is given by

$$R_{oa} \approx (A_{oa}+B_{oa}\cos 2\theta)\mu_{oa}^2 \qquad (1)$$

where A_{oa} and B_{oa} are constants dependent only on the wavelength, and θ is the angle made by the dipole moment and the molecular axis of β-cyclodextrin. Since A_{oa} and B_{oa} are positive values and A_{oa} is about one-third of B_{oa}, the sign of the induced CD is determined only by the relative orientation of the dipole moment in the β-cyclodextrin cavity. The dipole moment parallel to the molecular axis of β-cyclodextrin gives a positive CD and the perpendicularly polarized dipole moment produces a negative CD. The CD bands observed in the 200—250 and 250—300 nm regions indicate that the guest molecule is included with the naphthyl group parallel to the molecular axis of β-cyclodextrin. The CD band found in the 300—350 nm region may be ruled out since the Kirkwood-Tinoco model should be applied to the transition with a strong electric dipole moment.

In the complexes with 2-naphthol, the temperature dependent CD intensity change can not be fully explained on the basis of a 1:1 complex model. The 1:1 stoichiometry predicts the monotonous decrease of the CD intensity with the increase of the temperature. But, an intensive enhancement of the CD intensity is observed in the lower temperature region. The discrepancy in these results may be interpreted in terms of the structural change of the complex with the temperature increase and/or the formation of the complexes with higher stoichiometry than a 1:1 molar ratio. But the structural change seems to be less likely in this case if we consider only a 1:1 complex. The guest molecule must rotate around the axis perpendicular to the naphthyl plane to reduce the CD intensity of the 222 nm band. But such a rotation also decreases the intensity of the 285 nm band, although the observed intensity change clearly shows the opposite tendency. The displacement of the naphthyl group either to the primary hydroxyl side or to the secondary hydroxyl side also decreases the intensity of both 222 and 285 nm bands. Moreover, according to the inspection of molecular models, the naphthyl group is expected to be tightly packed in the β-cyclodextrin cavity. The tight packing may impose a strong restriction upon the translational and rotational freedom of the naphthyl group because of the repulsive interaction between hydrogen atoms of β-cyclodextrin and the naphthyl group.

The formation of a complex with higher stoichiometry than a 1:1 molar ratio is more plausible. The temperature which gives the intensity maxima of positive CD bands becomes lower with the increase of β-cyclodextrin concentration. The discrepancy found between observed and calculated intensities is more remarkable at higher β-cyclodextrin concentrations. These facts suggest that the association at lower temperature produces a complex in which two or more β-cyclodextrin molecules are bound to one guest molecule. It seems unlikely that β-cyclodextrin binds two or more guest molecules since the concentration of the guest is lower than one-fifth of the β-cyclodextrin concentration. In the crystalline complexes,[9-11] two β-cyclodextrin molecules are linked by many hydrogen bonds between secondary hydroxyl groups to form a dimer structure with a head-to-head arrangement. Therefore, the β-cyclodextrin dimer with the same structure may be formed in aqueous solutions.[11] The rotational strengths of a 2:1 complex were estimated by assuming that the transition-dipole-moment is located at the center of the dimer; the structure of β-cyclodextrin and the parameters used in the calculation were those used in the earlier work.[5] For the transition-dipole-moments parallel and perpendicular to the β-cyclodex-

trin axis, the rotational strengths are $1.25\times10^{-4}\,\mu_{\parallel}^2$ (at 222 nm) and $-0.26\times10^{-4}\,\mu_{\perp}^2$ (at 285 nm), respectively. On the other hand, the corresponding rotational strengths in the 1:1 complex are $1.53\times10^{-4}\,\mu_{\parallel}^2$ and $-0.15\times10^{-4}\,\mu_{\perp}^2$. Therefore, the formation of the 2:1 complex may decrease the intensity of positive CD and enhance the negative CD, giving an explanation for the observed intensity change.

In the 2-naphthyloxyacetic acid complex, the calculated CD intensity based on the thermodynamic parameters determined by the least-squares method is in good agreement with the observed intensity (Fig. 4d). This indicates that the association of two or more β-cyclodextrin molecules does not occur in this case. The guest molecule has a relatively large substituent, so that the substituent group may hinder the formation of complexes with higher stoichiometry.

Thermodynamic Parameters and Binding Force in the Complex. Free energies at 298 K are in the range from −14.3 to −15.4 kJ·mol^{-1}, a remarkably narrow region in spite of the different guest molecules. Enthalpy and entropy are in the range from −22.2 to −26.8 kJ·mol^{-1} and −24 to −38 J·K^{-1}·mol^{-1}, respectively. A plot of ΔH against ΔS is given in Fig. 5. ΔH is linearly correlated to ΔS. A similar correlation has been also observed in the α-cyclodextrin complexes.[12] Changes in ΔH are almost compensated by changes in ΔS. Therefore, the free energy is restricted in a quite narrow region. Such compensation phenomena are widely observed in water solutions.[13]

The thermodynamic parameters indicate that ΔH and ΔS are strongly correlated to the molecular volume of the guest. Figure 6 shows plots of ΔH and ΔS against the van der Waals volume of the substituent in the guest molecule. The volumes were estimated according to Bondi.[14] ΔH and ΔS decrease in magnitude with an increase of the substituent volume. Changes in ΔH and ΔS can be explained on the basis of the β-cyclodextrin–guest interaction and solute–solvent interaction. Owing to the cylindrical cavity of β-cyclodextrin, a guest molecule with a smaller substituent may fit better into the cavity. A bulky substituent seems to inhibit the close packing of the guest molecule, and to impose an unfavorable conformational change on β-cyclodextrin. The tight inclusion of the guest molecule also imposes restrictions on the conformational flexibility of β-cyclodextrin as well as on translational and rotational freedom of the guest molecule.[15] Therefore, a guest molecule with a small substituent may give large values of enthalpy and entropy of complex formation compared with the guest molecule having a bulky substituent.

In the uncomplexed state, the guest molecule is surrounded by solvent molecules, while some water molecules are included in the β-cyclodextrin cavity.[16] These water molecules may be removed by the complex formation and become bulk water. The enthalpy change for the process is expressed as

$$\Delta H^{s} = H^{s}(\beta\text{-cyclodextrin–guest}) + H^{s}(n\mathrm{H_2O}) - H^{s}(\beta\text{-cyclodextrin–}n\mathrm{H_2O}) - H^{s}(\text{guest}) \quad (2)$$

$$= \Delta H_{c}^{s} + \Delta H_{e}^{s} + \Delta H_{v}^{s}. \quad (3)$$

H_{c}^{s} is the energy required to create a cavity to accomodate the solute molecule in solution, and is calculated according to Pierotti.[17] H_{e}^{s} and H_{v}^{s} are the electrostatic interaction energy and the van der Waals interaction energy, respectively, between solute and solvent molecules. The detailed descriptions of H_{e}^{s} and H_{v}^{s} are given in the earlier paper.[18] In the crystalline state, the uncomplexed β-cyclodextrin contains 2.5 water molecules in the center of the cavity.[16] Therefore, $n=2.5$ was assumed in this calculation. The calculated enthalpy, which is in the range from −21.9 to −24.3 kJ·mol^{-1} (Table 2), suggests that the bulky substituent group decreases the enthalpy of complex formation.

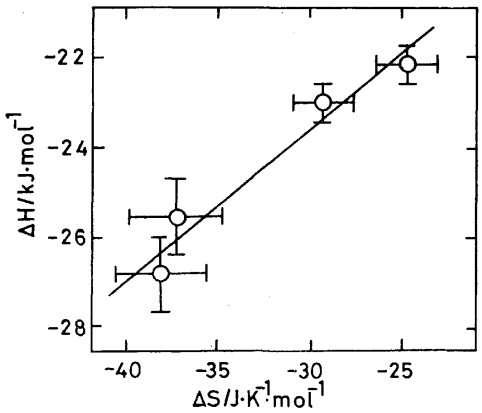

Fig. 5. Plot of ΔH against ΔS. Vertical and horizontal bars indicate error limits.

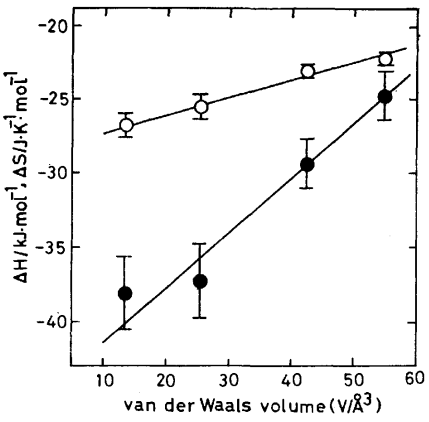

Fig. 6. Plots of ΔH (○) and ΔS (●) against van der Waals volumes of substituent in naphthalene derivatives. Vertical bars indicate error limits.

Table 2. Calculated solvation effects on ΔH for the complex formation of β-cyclodextrin with 2-substituted naphthalenes

	$V^{a)}$ / Å^3	ΔH / kJ·mol^{-1}
2-Naphthol	13.4	−24.3
2-Naphthoate ion	25.6	−21.9
2-Naphthylacetate ion	42.5	−24.1
2-Naphthyloxyacetic acid	55.1	−22.1

a) The van der Waals volume of the substituent.

The calculated results also indicate that the naphthyl group is highly hydrophobic, so that it may be more favorable for the group to be located in the hydrophobic cavity of β-cyclodextrin than in the aqueous environment.

Appendix

When β-cyclodextrin forms a 1:1 complex with a guest in an aqueous solution,

$$\beta\text{-cyclodextrin} + \text{guest} \rightleftarrows \beta\text{-cyclodextrin–guest}, \quad \text{(A1)}$$

the dissociation constant at the temperature of T_i K is given by

$$K_{di} = (a-x_{ij})(b_j-x_{ij})/x_{ij} \quad \text{(A2)}$$

where a, b_j, and x_{ij} are the concentrations of the guest, β-cyclodextrin, and the complex, respectively. The observed CD intensity is expressed by using the molecular ellipticity of θ_m: as

$$\theta_{ij} = \theta_m x_{ij}. \quad \text{(A3)}$$

Then, by substituting Eq. A3 to Eq. A2,

$$K_{di} = \frac{ab_j\theta_m}{\theta_{ij}} - a - b_j + \frac{\theta_{ij}}{\theta_m} \quad \text{(A4)}$$

If we assume that the enthalpy (ΔH) and entropy (ΔS) for the complex formation are independent of temperature under the experimental conditions, the free energy for the complex formation is given by

$$\Delta G_i = \Delta H - T_i\Delta S \quad \text{(A5)}$$

$$= RT_i \ln K_{di}. \quad \text{(A6)}$$

By substituting Eq. A4 to Eq. A6, we obtain

$$\ln\left(\frac{ab_j\theta_m}{\theta_{ij}} - a - b_j + \frac{\theta_{ij}}{\theta_m}\right) - \frac{\Delta H}{RT_i} + \frac{\Delta S}{R} = 0 \quad \text{(A7)}$$

θ_m, ΔH, and ΔS can be determined by the least-squares technique if we know the rough values of θ_m°, ΔH°, and ΔS°:

$$\theta_m = \theta_m^\circ + \Delta\theta_m \quad \text{(A8)}$$

$$\Delta H = \Delta H^\circ + \Delta(\Delta H) \quad \text{(A9)}$$

$$\Delta S = \Delta S^\circ + \Delta(\Delta S). \quad \text{(A10)}$$

Then, by expanding $\ln K_{di}$, we obtain

$$\ln K_{di} = \ln K_{di}^\circ + \Delta\theta_m\left(\frac{ab_j}{\theta_{ij}} - \frac{\theta_{ij}}{\theta_m^{\circ 2}}\right)\Big/K_{di}^\circ \quad \text{(A11)}$$

where

$$K_{di}^\circ = \frac{ab_j\theta_m^\circ}{\theta_{ij}} - a - b_j + \frac{\theta_{ij}}{\theta_m^\circ} \quad \text{(A12)}$$

Therefore, the quantity to be minimized is given by

$$M = \sum_{ij}\left[\left(\frac{ab_j}{\theta_{ij}} - \frac{\theta_{ij}}{\theta_m^{\circ 2}}\right)\Delta\theta_m/K_{di}^\circ - \frac{\Delta(\Delta H)}{RT_i} + \frac{\Delta(\Delta S)}{R} + \Delta_{ij}\right]^2 \quad \text{(A13)}$$

with

$$\Delta_{ij} = \ln K_{di}^\circ - \frac{\Delta H^\circ}{RT_i} + \frac{\Delta S^\circ}{R} \quad \text{(A14)}$$

If θ_{ij} is measured at more than two β-cyclodextrin concentrations, θ_m°, ΔH°, and ΔS° are determined by Eqs. 4, 5, and 6. But if the measurement is carried out without changing the concentration, θ_m° may be estimated on the basis of the observed θ_{ij}. By solving the simultaneous equation of

$$\partial M/\partial\Delta\theta_m = 0, \quad \partial M/\partial\Delta(\Delta H) = 0,$$

and

$$\partial M/\partial\Delta(\Delta S) = 0 \quad \text{(A15)}$$

$\Delta\theta_m$, $\Delta(\Delta H)$, and $\Delta(\Delta S)$ are obtained. This procedure should be repeated until the magnitudes of $\Delta\theta_m$, $\Delta(\Delta H)$, and $\Delta(\Delta S)$ are sufficiently smaller than the corresponding standard deviation, which is given by

$$\sigma_p = [m_{pp}^{-1}(\sum_{ij}\Delta_{ij}^2)/(N-3)]^{1/2} \quad \text{(A16)}$$

where m_{pp}^{-1}, Δ_{ij}, and N are the p-th diagonal element of the inverse matrix, the residual for θ_{ij}, and the number of data, respectively. Usually, the convergence is achieved within ten cycles.

Acidic Property and Oxidation Activity of MoO_3-V_2O_5-P_2O_5 Ternary Oxides

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received December 13, 1978)

The relationship between the acid-base properties and the oxidation activity of a series of ternary oxide catalysts, MoO_3-V_2O_5-P_2O_5, with different V/Mo composition and a constant phosphorus content, P/(Mo+V)=0.1, was investigated. The acidity was determined by means of the NH_3 adsorption and by studying the catalytic activity for acid-catalyzed reactions, such as dehydration of isopropyl alcohol and isomerization of 1-butene, in the presence of an excess of air. A new acidic site is generated by the combination of two binary oxides, *i.e.*, MoO_3-P_2O_5 and V_2O_5-P_2O_5, and a broad maximum in the acidity occurs at V/(Mo+V)=0.4—0.9. The basic property is so small that no satisfactory data can be obtained from the adsorption of acidic molecules such as CO_2, SO_2, and acetic acid. The catalysts, regardless of composition, are inactive for reactions which are accelerated by basic sites, such as oxidative dehydrogenation of isopropyl alcohol to acetone, oxidative decomposition of formic acid to CO_2, and oxidation of methanol to CO_2. The oxidation activities for butadiene and methanol can be tied to the acidity of the catalysts.

A variety of multi-component oxides containing more than three kinds of metal oxides have been proposed as being effective as practical catalysts. Why can a good performance be obtained only by the combination of several oxides? What is the role of each component in the catalytic action of a multi-component oxide? Moreover, what are the functions universally required for an oxidation catalyst?

We have studied selective oxidations on the basis of the idea that an acid-base-type interaction between the catalyst surface and the organic substance to be oxidized plays the determining role in mild oxidations, and as a result, the combination of metal oxides contributes to an enhancement or modification of the acid-base properties.[1]

MoO_3, V_2O_5, and P_2O_5 are all typical acidic oxides. Therefore, composite oxides consisting of these oxides, naturally, are characterized by their acidic property. Actually, they have been proposed as catalysts suited only for "acid-formation" reactions, such as syntheses of maleic anhydride, phthalic anhydride, acrylic acid, and methacrylic acid.[2-4]

As for the three binary systems made up by two of the three oxides, *i.e.*, MoO_3-V_2O_5, MoO_3-P_2O_5, and V_2O_5-P_2O_5, the relationship between the acid-base properties and the catalytic behavior in mild oxidations has been studied earlier.[5-7]

In this work, we were interested in seeing how the replacement of molybdenum in the MoO_3-P_2O_5 (P/Mo=0.1) catalyst by vanadium induces a change in the catalytic behavior and, then, in confirming whether or not the change in the catalytic activity can be interpreted by the change of the acid-base properties.

Experimental

The catalysts used in this study were a series of ternary oxides, MoO_3-V_2O_5-P_2O_5, with nine different V/Mo compositions and a constant phosphorus content, P/(Mo+V)=0.1 (atomic ratio). The method of the preparation was the same as that employed in the previous studies.[5-7] That is, the required quantities of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, NH_4VO_3, and 85 wt % H_3PO_4 were dissolved in hot water by using oxalic acid, if necessary, and to this was added 10—20 mesh pumice. Then, the mixture was evaporated with stirring. The catalyst were calcined in a stream of oxygen at 500 °C for 4—5 h.

The techniques of acidity measurement and the reaction procedures were the same as those employed earlier.[8]

Results

Surface Properties. In Table 1 are shown the specific surface areas. They are of the order of 1 m^2/g over the entire range of composition and the effect of composition is found to be small.

Table 1. Surface areas of the MoO_3-V_2O_5-P_2O_5 catalysts

Composition[a] V/(Mo+V)	Surface area (m^2/g)	Composition[a] V/(Mo+V)	Surface area (m^2/g)
0	1.2	0.60	1.0
0.05	1.1	0.80	0.9
0.10	1.2	0.90	0.9
0.20	1.0	1.0	1.5
0.40	1.1		

a) P/(Mo+V)=0.10: atomic ratio.

The acidity (number of acidic sites) was measured directly by the irreversible adsorption of NH_3 at 200 °C using the static method.[8] The results are shown in Fig. 1.

It seems difficult to determine in this way the acidity with satisfactory accuracy. Therefore, another attempt was made to determine the acidity indirectly, that is, the catalytic activity for certain acid-catalyzed reactions was investigated. The dehydration of isopropyl alcohol (IPA) to propylene and the isomerization of 1-butene to 2-butenes, in the presence of an excess of air, were chosen as the model reactions, as in the previous studies.[4-8]

The reactions were carried out at the IPA and 1-butene concentrations of 1.33 and 1.0 mol% in air, respectively, and the total flow rate of 1.0 l/min, by changing the amounts of the catalysts in the range of 1

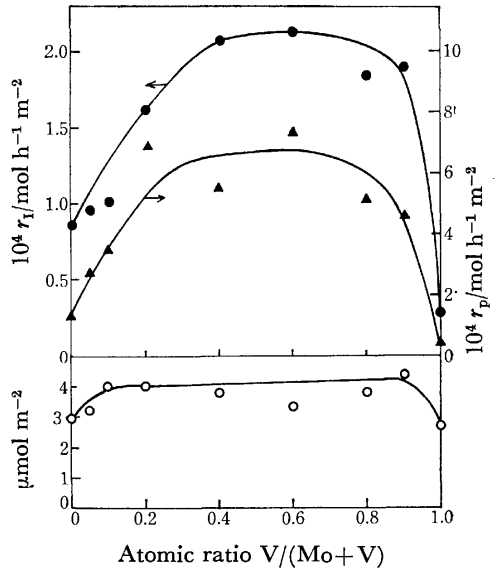

Fig. 1. Acidity of MoO_3–V_2O_5–P_2O_5 as a function of the V/(Mo+V) ratio. P/(Mo+V)=0.1.
○: Irreversible adsorption of NH_3 at 200 °C, ▲: dehydration activity for IPA at 145 °C, r_p, ●: isomerization activity for 1-butene at 172 °C, r_I.

to 20 g. The MoO_3–V_2O_5–P_2O_5 catalysts exhibit a very high activity for the two reactions and, therefore, the reactions can occur, to a considerable extent, at a fairly low temperature. Propylene is the sole product in the reaction of IPA. The initial rate of IPA dehydration at 145 °C, r_p, and the rate of butene isomerization at 172 °C, r_I (mol/h·m² of catalyst), are plotted together with the amounts of adsorbed NH_3 in Fig. 1.

As for the basicity, we tried to measure it by the adsorption of SO_2 as well as CO_2, using the static method, and by the adsorption of acetic acid using the pulse method.[8] However, the amounts were so small that the effect of catalyst composition could not be obtained.

Decomposition of Formic Acid. It has been reported that the catalytic activity for decomposition of formic acid to CO and that for the oxidative decomposition to CO_2 can be tied to the acidic and basic properties, respectively, of the metal oxide catalysts.[9] Because of the simplicity of the reaction system, the catalytic activity for these reactions was tested.

The reaction was carried out at the concentration of 1.8 mol% HCOOH in air and the total flow rate of 1.0 l/min. The catalysts weighed 2 to 20 g. Details of the reaction procedures were described earlier.[9] The products were CO and H_2O, and the amount of CO_2 was negligibly small regardless of the catalyst composition. The initial rate of CO formation at 259 °C, r_{CO} (mol/h·m² of catalyst), are plotted in Fig. 2.

Oxidation of Butadiene. Since the MoO_3–V_2O_5–P_2O_5 catalysts are fairly acidic and rarely basic, satisfactory results can be expected merely for the activity in the oxidation of basic reactants and for the selectivity in the "base to acid" type reactions.[1] Therefore, the oxidation of butadiene was chosen as a model reaction.

The reaction was carried out in an excess of air (C_4H_6=1.0 mol%) at 360—450 °C and at a constant

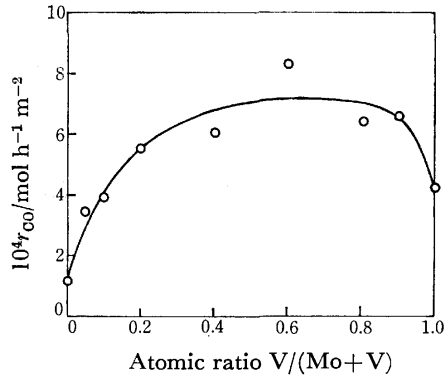

Fig. 2. Catalytic activity for the decomposition of formic acid to CO at different V/Mo compositions. r_{CO}: Rate of CO formation at 259 °C and 1.8 mol % HCOOH in air.

total flow rate (1.0 l/min). The amounts of the catalysts were varied in the range of 1 to 20 g to achieve a proper conversion. The rate of butadiene consumption at 365 °C, r_B (mol/h·m² of catalyst), was adopted as a measure of the activity, for convenience in the experimental procedures. The results are shown in Fig. 3.

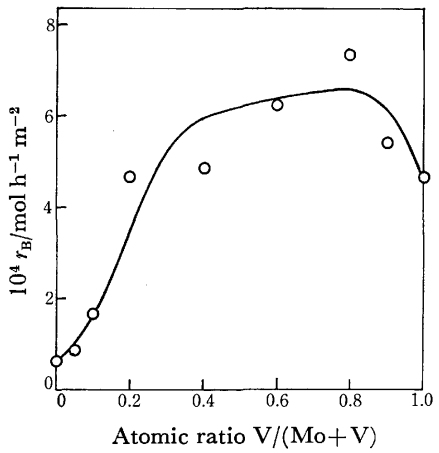

Fig. 3. Oxidation activity for butadiene as a function of the V/(Mo+V) ratio. r_B: Consumption of butadiene at 365 °C and 1.0 mol % C_4H_6 in air.

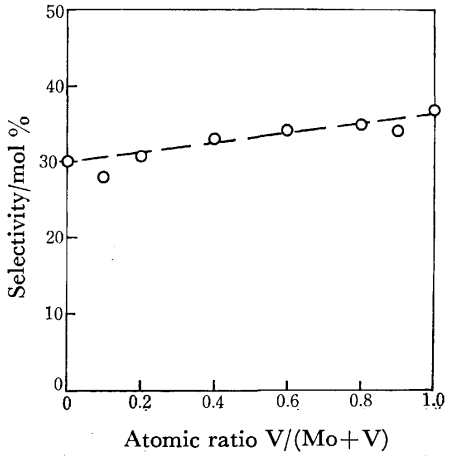

Fig. 4. Selectivity of butadiene to maleic anhydride at a total conversion of 40—50 %. T=360—450 °C, C_4H_6=1.0 mol % in air.

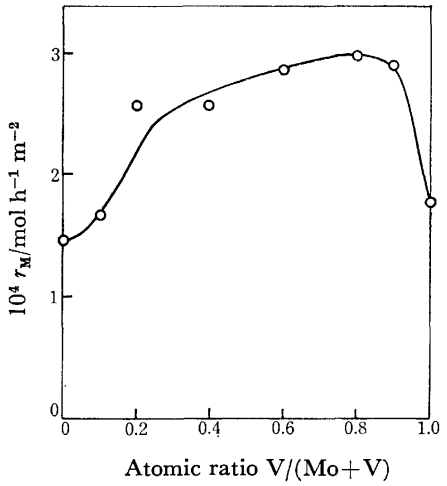

Fig. 5. Oxidation activity for methanol as a function of the V/(Mo+V) ratio. r_M: Rate of formaldehyde formation at 250 °C and 2.6 mol % CH_3OH in air.

The main products were maleic anhydride, CO, and CO_2. The selectivity of butadiene to maleic anhydride at a fixed conversion, 40—50%, was measured with each catalyst; it is shown in Fig. 4.

Oxidation of Methanol. The oxidation of methanol was tested, because the catalytic activity for this reaction was found to be correlated with the acid-base properties of the catalysts.[10]

The reaction was carried out at 2.6 mol% CH_3OH in air. Formaldehyde was almost the sole product and the amounts of CO_2 and CO were very small, even when the conversion was about 50%. The rate of formaldehyde formation at 250 °C, r_M (mol/h·m^2 of catalyst), is shown in Fig. 5.

Discussion

The activities for the two acid-catalyzed reactions vary in the same fashion with the variation of V/Mo composition. However, the shape of the NH_3-curve in Fig. 1 is not the same as that of the activity-curves. With regard to these results, one may be led to consider that the catalytic activities reflect the true acidity better than the amounts of NH_3, because the surface areas of the catalysts are so small that it is difficult to measure, with satisfactory accuracy, the amounts of adsorbed NH_3. In the following, it is sure that a new acidic site is generated by the combination of the MoO_3–P_2O_5 (P/Mo=0.1) and the V_2O_5–P_2O_5 (P/V=0.1) or by the replacement of molybdenum in the MoO_3–P_2O_5 by vanadium. The acidity attains a broad maximum at V/(Mo+V)=0.4—0.9. This feature of the acid-generation is different from that observed in the case of MoO_3–V_2O_5 binary system, where a sharp maximum in acidity occurs at V/(Mo+V)=0.85—0.90[5].

The possession of a very high activity for the two acid-catalyzed reactions proves that the MoO_3–V_2O_5–P_2O_5 catalysts are eminent in acidic property, as can easily be expected from the natures of MoO_3–P_2O_5 and V_2O_5–P_2O_5. On the other hand, the absence of the catalytic activity for the reactions which are promoted by basic sites, for example, the oxidative dehydrogenation of IPA to acetone,[1] the oxidative decomposition of formic acid to CO_2,[9] and the oxidation of methanol to CO_2,[10] indicates that the catalysts regardless of the V/Mo composition are very poor in basic property. The basic property of MoO_3 and V_2O_5 may be extinguished completely by P_2O_5.[7]

The presence of a parallelism between the activity for decomposition of formic acid to CO (Fig. 2) and the acidity (the activities for IPA dehydration and butene isomerization) supports the earlier view that catalytic activity for the CO formation is tied to the acidic property of the catalyst.[9]

The catalytic activity for the oxidation of butadiene (Fig. 3) also varies in the same fashion as do the activities shown in Fig. 1, except for the V/(Mo+V)=1 catalyst. This finding suggests that the oxidation of butadiene is decided mainly by the activation of butadiene by the acidic sites, as has been pointed out earlier.[1]

The selectivity to maleic anhydride is relatively high over the entire range of composition. This can easily be understood from the fact that the catalysts, regardless of composition, are fairly acidic and rarely basic, because one of requirements for an effective catalyst suited for "acid-formation" reactions is the possession of a sufficient acidic property.[1]

The catalysts, regardless of the composition, exhibit a very good selectivity in the oxidation of methanol to formaldehyde, which is consistent with the earlier proposal that formaldehyde is the sole product as long as the catalyst is acidic enough.[10] The presence of a parallelism between the catalytic activity for the formaldehyde formation (Fig. 5) and the acidities shown in Fig. 1 also supports the view that the activity for formaldehyde formation is decided mainly by the activation of methanol on acidic sites.[10]

It is concluded that the MoO_3–V_2O_5–P_2O_5 catalysts are eminent in acidic property but poor in basic property, regardless of the V/Mo composition, that a new acidic site is generated by the combination of the MoO_3–P_2O_5 and the V_2O_5–P_2O_5, and that the acidity attains a broad maximum at V/(Mo+V)=0.4—0.9. The catalytic behavior in the oxidation of butadiene and methanol can be explained relatively well in terms of the acid-base properties of the catalysts.

Solvent Effects and Hyrogen-bonding Interactions on Absorption and Fluorescence Spectra of 1-Methyl-2-pyridone

Akira FUJIMOTO and Kozo INUZUKA*

Department of Applied Science, Faculty of Technology, Tokyo Denki University, Kanda, Chiyoda-ku Tokyo 101

(Received December 21, 1978)

The electrostatic solvent effects and hydrogen-bonding interactions on IR and UV absorption and fluorescence spectra of 1-methyl-2-pyridone has been investigated. It was found that the UV absorption and fluorescence bands of 1-methyl-2-pyridone shifted towards the shorter-wavelength region with increasing solvent polarity and that these bands exhibited a blue shift on hydrogen bond formation with alcohols and chloroform. The excited-state dipole moment of 1-methyl-2-pyridone, and the equilibrium constants in the ground and excited states and enthalpy change in the ground state for hydrogen-bond formation between 1-methyl-2-pyridone and ethanol have been determined from the spectroscopic studies.

Kimura *et al.*[1] have suggested from fluorescence data, that the lowest excited singlet state of 1-methyl-2-pyridone (abbreviated to MPD) is π-π^* in character in alcoholic solution. It was not reported that the fluorescence band characterized by the π-π^* transition shifted towards the shorter-wavelength region with increasing solvent polarity and that the band exhibited a blue shift on hydrogen bond formation with alcohols.

As part of this study[2] on the electronic spectra of heterocyclic compounds, the solvent effects and hydrogen-bonding interactions on UV absorption and fluorescence spectra of MPD in isooctane (2,2,4-trimethylpentane) have been investigated. The presence of an intermolecular hydrogen bond between MPD and ethanol has been confirmed by IR analysis.

Experimental

MPD was purified by vacuum distillation to give a sample of boiling point 103.0—103.5 °C/930 Pa. The solvents used were commercially available and further purified by distillation. IR spectra were measured using a Hitachi Model 260-30 infrared spectrophotometer; measurements were conducted at ambient temperature, a cell of 0.5 mm path length being used. Measurements of UV absorption and fluorescence were conducted with the spectrophotometers reported previously.[2a] The temperature of the UV absorption cells (10 mm) was regulated by a Komatsu-Yamato Model CTR-120 electronic cooling circulator within the temperature range 8 to 50 °C.

Results and Discussion

The C=O absorption bands of MPD observed in the several solvents at room temperature are given in Table 1. As may be seen the C=O band shifted to the lower-frequency region with increasing polarity of the solvents; notably the frequency shift of the corresponding band is appreciably larger in alcohols and chloroform than in other solvents. As Fig. 1 illustrates remarkable changes are produced in the IR spectra of MPD by the addition of ethanol to the carbon tetrachloride solution: the C=O streching band of MPD was observed at 1667 cm^{-1} in CCl_4, while the corresponding band shifted to the lower-frequency region with increasing ethanol concentration (1660 cm^{-1}, ethanol concentration=2.14 mol dm^{-3}). A similar frequency-shift was observed on the addition of chloroform to a carbon

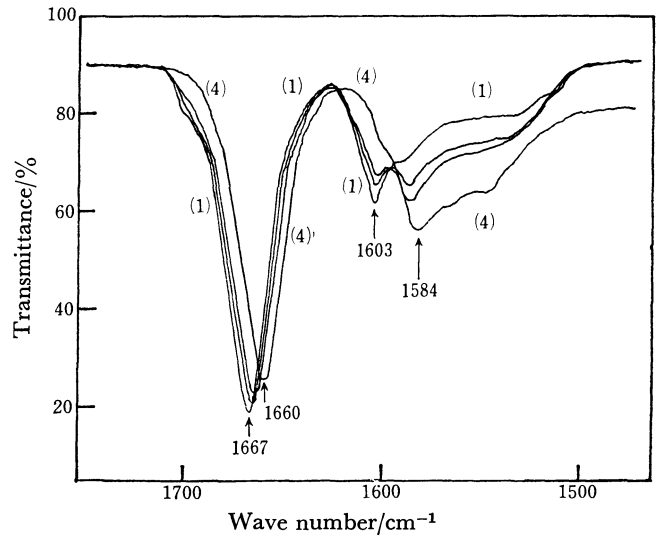

Fig. 1. IR spectra of the MPD–ethanol–carbon tetrachloride system. Concentration of MPD: 8.26×10^{-3} mol dm^{-3}. Concentrations of ethanol (mol dm^{-3}): (1) 0, (2) 8.8×10^{-2}, (3) 1.76×10^{-1}, (4) 2.14.

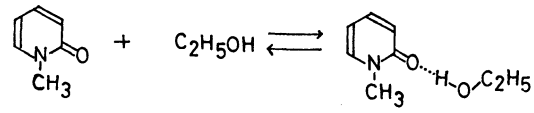
tetrachloride solution of MPD. Such frequency-shifts in alcohol and chloroform may be attributed to intermolecular hydrogen bonding between the C=O group of MPD and alcohol, and between the C=O group of MPD and chloroform. The hydrogen bond between MPD and ethanol is represented by the following equilibrium:



(1)

Here MPD acts as a proton acceptor and ethanol as a proton donor. In Fig. 1, the absorption band at 1603 cm^{-1}, corresponding to the ring streching vibration of MPD[3] disappeared, while a new band maximum was observed at 1584 cm^{-1}, attributed to the redistribution of the ring electrons as a result of hydrogen-bond formation with the OH group of ethanol.

The solvent effects on the electronic spectra of organic compounds have been studied by many workers: Lippert,[4] Mataga *et al.*,[5] and McRae[6] proposed the following equation (Eq. 2) for the evaluation of the

difference in the dipole moments of the excited and ground states, *i.e.* $\Delta\mu = \mu_e - \mu_g$.

$$hc\Delta\sigma = \text{const} + 2F(D, n)(\Delta\mu)^2/a^3, \quad (2)$$

where

$$\Delta\sigma = \sigma_a^m - \sigma_f^m$$

and

$$F(D, n) = \left(\frac{D-1}{2D+1} - \frac{n^2-1}{2n^2+1}\right).$$

In Eq. 2 σ_a^m and σ_f^m represent the wave number of the peak of the UV absorption band and the fluorescence band maximum, respectively. D and n represent the dielectric constant and refractive index of the solvent and a represents Onsager's reaction radius of the solute molecule.

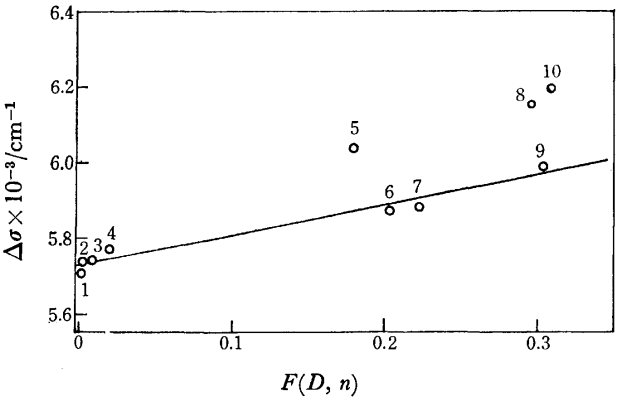


Fig. 2. The plot of $\Delta\sigma$ *vs.* $F(D, n)$.

Table 1. Wave numbers of the C=O band maxima (ν), UV absorption maxima (σ_a^m), and fluorescence band maxima (σ_f^m) of MPD measured in solvents of different polarity at room temperature

No.	Solvent	$F(D,n)$	ν / cm^{-1}	σ_a^m / cm^{-1}	σ_f^m / cm^{-1}
1	Isooctane	0.000	1677	32410	26700
2	Benzene	0.002	1667	32440	26700
3	Carbon tetrachloride	0.010	1667	32440	26700
4	Dioxane	0.020	1666	32420	26700
5	Chloroform	0.185	1660	32840	26800
6	Ethyl acetate	0.202	—[a]	32570	26700
7	Dichloromethane	0.218	1665	32680	26800
8	Ethanol	0.298	1660	32950	26800
9	Acetonitrile	0.304	1664	32790	26800
10	Methanol	0.308	1659	33000	26800

a) The C=O band of MPD was hidden by the intense absorption band of the C=O group of ethyl acetate.

The observed values of σ_a^m and σ_f^m are given in Table 1, together with the values of $F(D,n)$.[4,5] It may be seen that the UV absorption and fluorescence band maxima tend to shift towards the shorter-wavelength region with increasing solvent polarity and the blue shift of the UV absorption band maximum is much larger than that of the fluorescent counterpart. A similar phenomenon has been observed for the UV absorption and fluorescence spectra of pyridine *N*-oxide in several solvents.[7] In analogy with pyridine *N*-oxide the above experimental facts indicate that the π-electron transfer from the oxygen atom to the pyridine ring is much larger in the excited state than in the ground state. Accordingly, the dipole moment appears to be larger in the ground state than in the excited state, $\mu_g > \mu_e$. In Fig. 2 the $\Delta\sigma$ has been plotted against $F(D,n)$ and as can be seen there is a linear relationship between $\Delta\sigma$ and $F(D,n)$ except for alcohols and chloroform. The linear relationship between $\Delta\sigma$ and $F(D,n)$ corresponds to Eq. 2 and may be approximately represented as follows:

$$\Delta\sigma = 5730 + 770F(D, n). \quad (3)$$

From this equation, the $\Delta\mu$ value for MPD has been evaluated as -1.1 D, assuming 2.5 Å for a. μ_e has been estimated to be 2.94 D, using the values $\Delta\mu$ and μ_g (4.04 D) determined by Krackov *et al.*[8] In Fig. 2 the solvents such as alcohol and chloroform cause a large deviation and this has been attributed to hydrogen-bonding as described in the experimental section.

The equilibrium constant in the ground state (K_g),

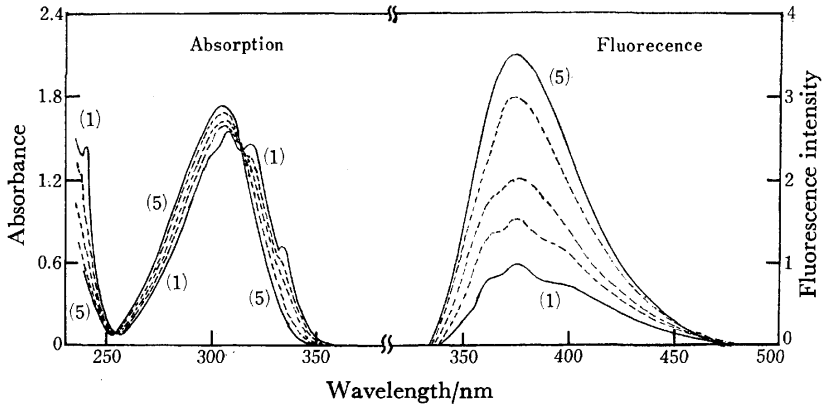

Fig. 3. UV absorption and fluorescence spectra of the MPD–ethanol–isooctane system at ambient temperature. Concentration of MPD: 4.2×10^{-4} mol dm^{-3}. Concentrations of ethanol (mol dm^{-3}): (1) 0, (2) 7.0×10^{-2}, (3) 1.5×10^{-1}, (4) 5.0×10^{-1}, (5) 2.0. Excitation wavelength: 300 nm.

enthalpy change ($-\Delta H$), and entropy change ($-\Delta S$) due to hydrogen-bond formation have been obtained by UV spectroscopy.[9] As shown in Fig. 3, considerable changes are produced in the UV spectra of MPD by the addition of ethanol to the isooctane solution. In order to eliminate the interference of the ordinary solvent effect, a three-component system was employed.[9] Consequently, it may be assumed that the spectral changes are due to the formation of a hydrogen-bonded complex between MPD and ethanol. It has been found that the UV absorption spectra, characterized by the π-π^* transition[1] exhibits a large blue-shift and an increase in total absorption intensity with increasing ethanol concentration. The values, 5.91 mol^{-1} dm^3 for K_g, 18 kJ mol^{-1} for $-\Delta H$, and 45.6 J K^{-1} mol^{-1} for $-\Delta S$ which were interpolated at 25.0 °C, were obtained from the UV spectra of the MPD-ethanol-isooctane system.

The fluorescence spectra of the MPD-ethanol-isooctane system are presented in Fig. 3. A blue shift of the fluorescence band maximum is evident and the intensity of the fluorescence band increases with increasing concentration of ethanol. The degree of spectral shift of the band maximum caused by hydrogen bonding is smaller in the fluorescence spectrum than in the absorption one. Experimentally it has been established that the addition of ethanol to the isooctane solution of MPD does not change either the fluorescence or absorption spectra when the concentration of ethanol is more than 2.0 mol dm^{-3}. From the fluorescence and absorption band spectra and the concentration of ethanol being 2.0 mol dm^{-3}, the fluorescence and absorption band maxima wave numbers were found to be 26800 and 32950 cm^{-1}, respectively. These values agree with the values of σ_f^m and σ_a^m in ethanol, respectively (Table 1).

The equilibrium constant of the hydrogen-bond formation in the excited state (K_e) may be related to K_g using the UV absorption and fluorescence spectral data in Eq. 4:[10]

$$\log K_e = \log K_g - 0.625\,\delta\sigma/T, \qquad (4)$$

where

$$\delta\sigma = (\delta\sigma_a + \delta\sigma_f)/2.$$

$\delta\sigma_a$ (540 cm^{-1}) is the difference between the UV absorption band maxima of MPD in isooctane and ethanol, and $\delta\sigma_f$ (100 cm^{-1}) corresponds to the difference between the fluorescence band maxima in the above two solvents and T is the absolute temperature. The value of K_e at 25.0 °C has been estimated to be 1.3 mol^{-1} dm^3 from Eq. 4. The equilibrium constant in the excited state may also be obtained *via* Eq. 5.[11]

$$[1-(f_0/f_m)(d_m/d_0)]/[D] = -K_e + \alpha K_e(f_0/f_m)(d_m/d_0) \qquad (5)$$

$$\alpha = \Phi_a/\Phi_c,$$

where f_m and f_0 correspond to the fluorescence intensities with and without the addition of donor, and d_m and d_0, the absorbances at a definite wavelength with and without the addition of donor, respectively. Φ_c and Φ_a correspond to the quantum yields of fluorescence of the acceptor and hydrogen-bonded complex, respectively, and [D] is the concentration of donor. The analysis of the fluorescence intensities is shown in Fig. 4 where it may be seen that K_e is approximately 1.8 mol^{-1} dm^3. This value is in reasonable agreement with the K_e value obtained by Eq. 4. Both K_e values are smaller than the K_g value indicating that the hydrogen-bonding is weaker in the excited state than in the ground state.

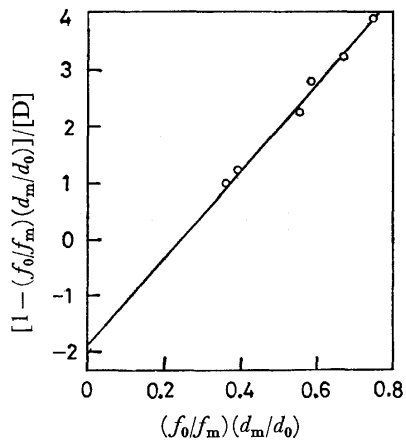

Fig. 4. The plot of $[1-(f_0/f_m)(d_m/d_0)]/[D]$ *vs.* $(f_0/f_m)(d_m/d_0)$. From the observed change of fluorescence intensity at 375 nm, the equilibrium constant of hydrogen bond formation in the excited state (K_e) was obtained.

This work was supported by grants from the Tokyo Denki University Research Fund.

Spectroscopic and Equilibrium Dialysis Studies of the Poly(acrylic acid)-Cu(II) Complex in the pH Range 3.5—7[1)]

Kiwamu YAMAOKA* and Tsutomu MASUJIMA

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 25, 1978)

The complex formation between poly(acrylic acid), poly(Acr), and Cu^{2+} ion was studied in 150 mM NaCl solutions at 25 °C and at the mixing ratios of Acr residues-to-Cu^{2+}, *R*, of 32, 16 and 8, in the pH range of 3.5—7 by the spectroscopic and equilibrium dialysis methods. The dialysis results showed that more than 90% of the Cu^{2+} ions remain bound to the polymer at pH's higher than 4.5, but the bound Cu(II) begins to dissociate at lower pH values. The data also revealed that the true absorption spectra of poly(Acr)–Cu(II) complexes varied with pH and *R* in a complicated manner. The analysis of the bound Cu(II) spectra disclosed the presence of three different kinds of Cu(II)–Acr complexes over the entire pH range. It is the relative amounts of these three complexes that vary with pH and *R*. With a newly devised plot of the dialysis data, the stability constant for each Cu(II)–Acr complex was determined. In the poly(Acr)–Cu(II) macrocomplex, each Cu(II) was estimated to bind to two or four carboxylato ligands.

In a previous investigation in which the complex formation of poly(α-L-glutamic acid), poly(Glu), with Cu^{2+} was studied in the pH range between 7 and 3, poly(acrylic acid), poly(Acr), was chosen as the polymeric model of poly(Glu).[2)] The absorption spectra of poly(Glu)- and poly(Acr)–Cu(II) systems were both found to vary with pH in an unexpectedly complicated manner, but their pH dependence differed from each other. The finding was qualitatively attributed to the difference in the conformational change between poly(Glu) and poly(Acr) to which Cu(II) is bound, and also to the fact that the peptide nitrogen, a likely ligand to Cu(II), is lacking in the poly(Acr) residue. The finding also indicated that Cu(II)-residue complexes of various types are present in each polyanion–Cu(II) system. It is thus quite significant to study the structural details of poly(Glu)- and poly(Acr)–Cu(II) complexes by analyzing their absorption spectra quantitatively.

Spectroscopic and structural studies of the poly(Acr)–Cu(II) system in solutions are numerous;[2–10)] however, some conflicting views have been given on the nature of the binding of Cu(II) to poly(Acr). For example, the pH variation of the absorption intensity was attributed either to the conformational change of the macromolecular complex[3)] or to the change in the amount of bound Cu(II).[8)] Two binding schemes between Cu^{2+} and the side-chain carboxylato groups of poly(Acr) have been presented: Cu(II) binds to two adjacent[3,7)] or distant[8)] carboxylato groups. In addition, the number of the ligands participating in the complex formation has been suggested to be either two carboxylato groups[3,7–10)] or more than two,[4)] or both depending on the conditions.[6)] The same points of controversy have also been noted in the reports on the poly(methacrylic acid)–Cu(II) complex.[4,5,11–16)]

In order to clarify those unresolved questions, the visible-UV absorption spectra of poly(Acr)–Cu(II) solutions were measured in the pH range 7—3.5. The concentration and the molar absorption coefficient of the *bound* Cu(II), ε^b, were directly determined by the equilibrium dialysis method. The ε^b values vary in a complicated way, but systematically depend on both pH and the mixing ratio of Acr residues-to-Cu^{2+} ion. The ε^b *vs.* pH curves could be explained reasonably well as the interplay of three limiting spectra which characterize three types of Cu(II)–Acr complexes in poly(Acr). The binding schemes between Cu^{2+} and poly(Acr), the dissociation constants of poly(Acr), and the stability constants of poly(Acr)–Cu(II) complexes were also determined by means of graphical plots. The schemes of two and four side-chain carboxylato groups bound by a Cu(II) are sufficient to explain the binding data. By comparing those new data with the spectra of such low molecular weight models as the glutaric acid- and malonic acid–Cu(II) complexes, the nature of the poly(Acr)–Cu(II) complex will be discussed.

Experimental

Materials. Poly(sodium acrylate), abbreviated simply as poly(Acr), was purchased from Nakarai Chemical Co., Kyoto, and purified from an aqueous solution by means of dialysis against redistilled water for 24 h. The sample solution was freeze-dried and then vacuum-dried at 56 °C for 7 h. The degree of polymerization was determined to be *ca.* 7700 from the intrinsic viscosity in 1 M (=mol dm^{-3}) NaCl.[17)] Reagent grade copper(II) chloride dihydrate was crystallized from redistilled water before use. All other chemicals were of reagent grade and used without further purification.

Preparation of Sample Solutions. Each of the NaCl, $CuCl_2$, and HCl solutions was added to a stock polymer solution in this order. In every poly(Acr)–Cu(II) solution, the concentration of the polymer and the total of the concentrations of HCl and NaCl were always kept constant at 8 mM and 150 mM, respectively. The mixing ratio, *R*, defined as the mean residue weight concentration of Acr residues to the total concentration of Cu^{2+} in the sample solution, was adjusted by changing the initial Cu^{2+} concentration. The pH of the sample solution was adjusted by the addition of 0.125 M HCl.

Equilibrium Dialysis. The procedures and device for equilibrium dialysis were described elsewhere.[18)] The volumes of the two chambers of the dialysis cell were designed to be *ca.* 14 and 3.5 ml. The poly(Acr)–Cu(II) solution (13 ml) and the 150 mM NaCl solution (3.3 ml) were filled in the larger and smaller chambers, respectively, in order to minimize the changes in both *R* and pH of the poly(Acr)–Cu(II) solution during dialysis. The assembled dialysis cells were rotated continuously for 45 h at 15 rpm and at 25 °C. A period of 24 h was sufficient for a Cu^{2+} solution to reach a complete equilibrium. The adsorption of Cu^{2+} on the dialysis membrane was negligible. When the dialysis was completed, the absorp-

tion spectra and pH of the sample solution in the larger cell chamber were measured in sequence. The colorimetric determination of unbound Cu^{2+} ions in the smaller chamber was carried out as described below.

Colorimetric Determination of Cu^{2+} Ions. 2,2'-Biquinoline (Merck Co., Ltd.) was used as a chelating agent to determine the Cu^{2+} concentration. The procedure for this colorimetry is given in Merck Cat. No. 2955. A molar absorption coefficient of 5780 at 546 nm was used for the chelated Cu(II). The calibration curve obeyed Beer's law up to 15 μM of Cu^{2+}. With the concentration of the unbound Cu^{2+}, $[Cu]_f$, thus determined from the dialysate, the concentration of the bound Cu(II) in the dialyzed poly(Acr)–Cu(II) solution, $[Cu]_b$, was calculated as:

$$[Cu]_b = [Cu]_0 - [Cu]_f\frac{(V_1+V_2)}{V_1}, \quad (1)$$

where $[Cu]_0$ is the initial concentration of Cu^{2+} in the poly(Acr)–Cu(II) solution; V_1 and V_2 are the initial volumes of the poly(Acr)–Cu(II) and 150 mM NaCl solutions, respectively. The volume change in the poly(Acr)–Cu(II) solution before and after dialysis was *ca.* 1.5 % at most, even in the high pH and R range where the Donnan effect could possibly be appreciable. Thus, the Donnan effect should be negligible under the present experimental conditions. The binding fraction of Cu(II), f_b, is obtained as follows:

$$f_b = \frac{[Cu]_b}{[Cu]_b+[Cu]_f}. \quad (2)$$

Measurements of Absorption Spectra and pH. The absorption spectra and pH of sample solutions were measured as described elsewhere.[2] The pH calibration was made against the standard pH solutions (pH 6.88 and 4.00). All experiments were carried out at 25±1 °C.

Results

Absorption Spectra of Poly(Acr)–Cu(II) Solutions. The absorption spectra of poly(Acr)–Cu(II) solutions at various pH and R are shown in Fig. 1. The spectra are characterized by three new bands: a peak at 250—260 nm ($\varepsilon \leq 5000$), a weak shoulder near 370 nm ($\varepsilon \leq 40$), and a peak at 680—710 nm ($40 \leq \varepsilon \leq 120$). These bands are denoted as the UV-, near UV-, and visible bands from the short wavelength end. The spectrum of the $CuCl_2$ solution in 150 mM NaCl (pH 3.45—5.74) shows a shoulder near 250 nm ($\varepsilon \approx 230$) and a weak peak near 800 nm ($\varepsilon \approx 13$) (Fig. 1(a)). The spectrum of the poly(Acr) solution in 150 mM NaCl also shows only an ascending curve below 250 nm (Figs. 1(a)—(c)). The new three bands clearly reflect the formation of the poly(Acr)–Cu(II) complex. However, no isosbestic point was observed in either band in the pH range 4—7.

The spectra of poly(Acr)–Cu(II) solutions vary in a complicated manner depending on pH and R. In Fig. 2, the apparent molar absorption coefficients, ε_i, at 250 and 710 nm are plotted against pH. The wavelengths are close to the peaks of the UV- and visible bands, respectively. The ε values at the two wavelengths vary differently in the pH range 6.5—4.3. As the pH is lowered from 6, the visible band intensity increases and reaches a maximum at a pH of 4.4—4.3, while the UV-band intensity remains almost unchanged. At the pH lower than 4.3, however, all of the ε *vs.* pH curves descend monotonically.

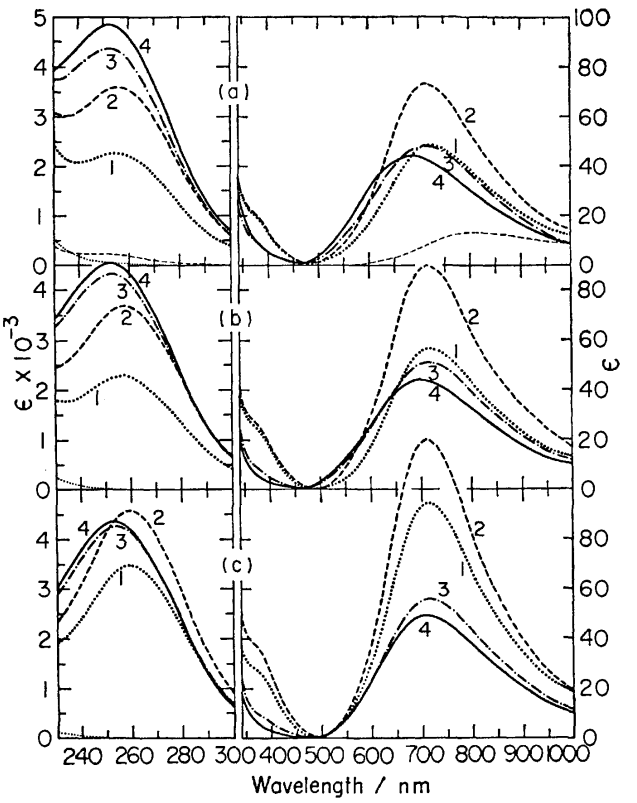

Fig. 1. The UV and visible absorption spectra of Cu^{2+} in the presence of poly(Acr) in 150 mM NaCl at various pH. (a): R=32; pH=3.85 (1), 4.11 (2), 5.50 (3), and 6.60 (4). (b): R=16; pH=3.90 (1), 4.17 (2), 5.87 (3), and 6.51 (4). (c): R=8; pH=3.94 (1), 4.21 (2), 6.09 (3), and 6.42 (4). The numeral in the parentheses corresponds to the numbered spectrum. The molar absorption coefficient, ε, is expressed in terms of the total concentration of Cu^{2+} present in solution. The dotted curves (without number) in the UV region are the spectra of poly(Acr) expressed in terms of $\varepsilon \cdot R$. The spectra of $CuCl_2$ solutions are constant in the pH range 3.54—5.74. An example is given in (a) (—— without number).

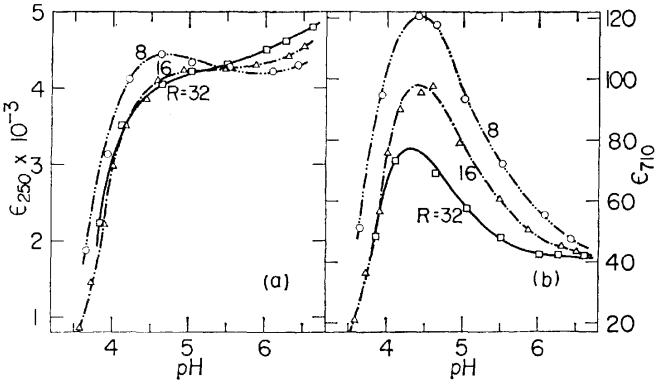

Fig. 2. The variation of the molar absorption coefficients of Cu^{2+}, ε, with pH in the presence of poly(Acr) at various R and at selected wavelengths of (a) 250 nm and (b) 710 nm.

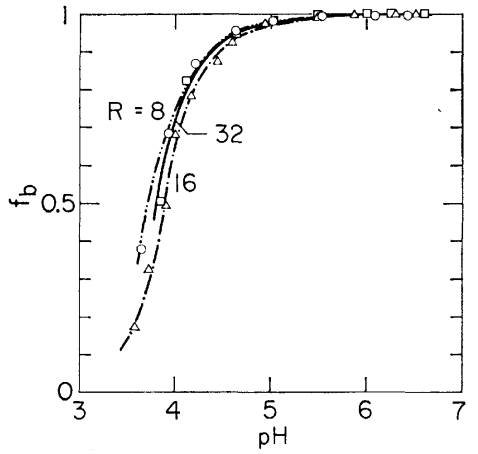

Fig. 3. The variation of the binding fraction of Cu(II), f_b, with pH at various R.

The Binding Fraction of Cu^{2+} and Its Variation with pH. In order to express the pH dependence of the absorption intensity in terms of the amount of the *bound* Cu(II), the binding fraction, f_b, was estimated from the dialysis data with the aid of Eq. 2. The results are shown in Fig. 3. Almost all the Cu^{2+} ions added in the poly(Acr) are bound to the polymer at pH values higher than 5.5, and more than 90% of the total Cu^{2+} indeed remain bound in the pH range 5.5—4.5. The bound Cu(II) begins to dissociate from the polymer site with the further decrease in pH. Only at a pH lower than 4.5 do the f_b *vs.* pH curves behave similarly to the ε *vs.* pH curves (*cf.* Fig. 2). These dialysis results show that the variation in ε at a pH higher than 4.5 is not due to the change of the amount of the bound Cu(II), but to the change in the ε of the bound Cu(II) itself.

The pH *Dependence of the Molar Absorption Coefficient and the Peak Position of the Bound Cu(II).* Since the bound and unbound Cu^{2+} concentrations are now available, the molar absorption coefficient of the *bound* Cu(II), ε^b, can be determined by using f_b in the following equation:

$$\varepsilon_\lambda^b = \frac{1}{f_b}(\varepsilon_\lambda - \varepsilon_\lambda^f) - \frac{[Cu]_0}{[Cu]_b} R \cdot \varepsilon_\lambda^p + \varepsilon_\lambda^f, \qquad (3)$$

where ε_λ, ε_λ^p, and ε_λ^f are the molar absorption coefficients at wavelength λ of the poly(Acr)–Cu(II), poly(Acr), and unbound Cu^{2+} in 150 mM NaCl solutions, respectively. The ε^b values are evaluated at four wavelengths: 250 and 710 nm (near the peaks of UV- and visible bands), 370 nm (the shoulder of near UV-band), and 880 nm (a hump of the visible band). The results are shown in Figs. 4(a)—(d), together with the peak wavelengths of the UV- and visible bands, denoted as λ_{max}, in Figs. 4(e) and (f). It should be noted that these ε^b *vs.* pH curves demonstrate the real changes in the optical property of the *bound* Cu(II) in poly(Acr)–Cu(II).

The ε_{250}^b *vs.* pH curves are peculiar in that they show a U-type change (Fig. 4(a)). On the other hand, the ε_{710}^b and ε_{880}^b curves are sigmoidal (Figs. 4(b) and (d)). In both sets of these curves, however, the ε^b converges to the limiting ε^b values on the high and low pH sides, as indicated by broken lines I and III. The limiting

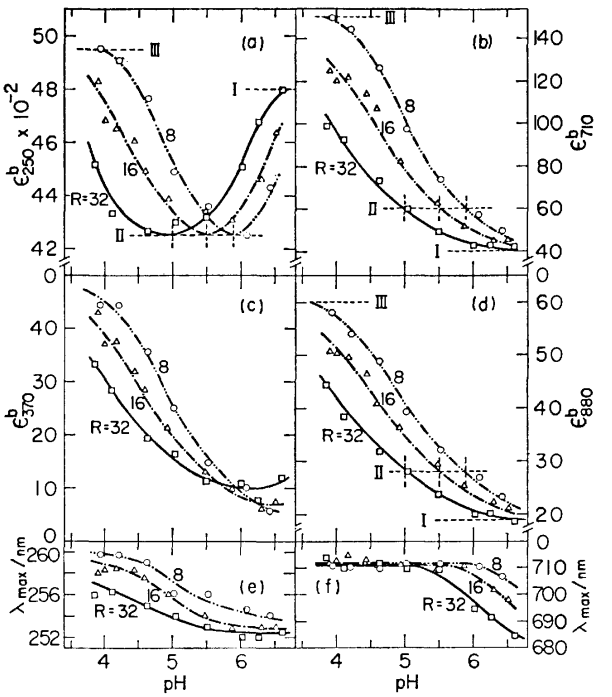

Fig. 4. The pH variation of the absorption coefficients of bound Cu(II), ε^b, at selected wavelengths of (a) 250 nm, (b) 710 nm, (c) 370 nm, and (d) 880 nm, and the variation of the peak positions of (e) the UV- and (f) visible-bands, λ_{max}. The ε^b and λ_{max} were estimated by applying Eq. 3 to each absorption spectrum of poly(Acr)–Cu(II) solution. The broken lines in (a), (b), and (d) show the characteristic values of ε^b at three pH regions of I, II, and III.

ε_{250}^b values are 4800 (pH$\geq$6.8 and R=32) and 4950 (pH$\leq$3.6 and R=8) in Fig. 4(a), while the limiting ε_{710}^b and ε_{880}^b values are 40 and 19 (pH$\geq$6.8 and R=32), and 150 and 60 (pH$\leq$3.6 and R=8) in Figs. 4(b) and (d), respectively. The minimum points in the ε_{250}^b *vs.* pH curves yield a constant value of 4250 regardless of R (pH=5.0 and R=32, pH=5.5 and R=16, and pH=5.9 and R=8), as indicated by broken line II in Fig. 4(a). Interestingly, the ε_{710}^b and ε_{880}^b values are also constant regardless of R at these respective pH values, becoming 60 and 28 respectively, as indicated by broken line II in Figs. 4(b) and (d).

Concurrently with the changes in ε^b, the peak positions, λ_{max}, in the spectra of bound Cu(II) vary with pH in two steps, as shown in Figs. 4(e) and (f). The λ_{max} of the UV-band is almost constant (252.5 nm (R=32), 253 nm (R=16), and 254 nm (R=8)) in the

Table 1. The molar absorption coefficients, ε_λ^b in $cm^{-1}\cdot mol^{-1}\cdot dm^3$, and the peak positions, λ_{max} in nm, in the spectra of Cu(II) bound to poly(Acr) in three pH regions I, II, and III

pH	ε_{250}^b	λ_{max}	ε_{710}^b	ε_{880}^b	λ_{max}
I	4800	252.5—253.5	40	19	685
II	4250	254.0—254.5	60	28	710—713
III	4950	260	150	60	710—713

pH range between 6.8 and 5.9—5.5, where the ε^b_{250} values are lowest, and then begins to shift to *ca.* 260 nm with the further lowering of pH. On the other hand, the λ_{max} of the visible band varies from 685 nm (R=32 at pH=6.8) to near 711 nm and remains constant in the lower pH range (pH≤5.0). These data are summarized in Table 1. The two-step change of the respective absorption peaks of the visible and UV-bands for the bound Cu(II) suggests the presence of two or three kinds of the Cu(II)–Acr complexes in poly(Acr)–Cu(II).

Assignment of ε^b-Values to the Three Complexes. The complicated variations of the ε^b_λ of bound Cu(II) with pH in Fig. 4 can be best explained as an interplay of three limiting ε^b_λ-values over the entire pH range under consideration of the data given in the preceding section. These limiting ε^b_λ-values may then be either characteristic of three different chemical species of the Cu(II)–Acr complexes or representative of three different states of a single or a mixture of Cu(II)–Acr complex(es) formed in poly(Acr)–Cu(II).

On the assumption that three limiting values of ε^b_λ in Table 1 specify three structurally different Cu(II)–Acr complexes, which are denoted as complexes I, II, and III, the fraction of each complex i (i=I, II, III) to the total of the bound Cu(II), f_I, f_{II}, and f_{III}, may be calculated at a given pH and at a selected wavelength of λ as follows:

$$\varepsilon^b_\lambda = \sum_{i=I}^{III} f_i(\varepsilon^b_\lambda)_i \text{ and } \sum_{i=I}^{III} f_i = 1, \quad (4)$$

where $(\varepsilon^b_\lambda)_i$ is the ε^b_λ-value characteristic of complex i. With the values of $(\varepsilon^b_\lambda)_i$ at 250 and 710 nm in Table 1, Eq. 4 can be written explicitly as follows:

$$\begin{aligned} \varepsilon^b_{250} &= 4800f_I + 4250f_{II} + 4950f_{III}, \\ \varepsilon^b_{710} &= 40f_I + 60f_{II} + 150f_{III}, \text{ and } f_I + f_{II} + f_{III} = 1. \end{aligned} \quad (5)$$

By solving these simultaneous equations for f_I, f_{II}, and f_{III} with the observed ε^b_{250} and ε^b_{710} at given pH and R values, the pH dependence of the f_i's may be obtained.

Figure 5 shows the variation of the fraction of complex i, f_i, with pH at three different R. At R=32 (Fig. 5(a)), complex I is dominant at high pH(≥6.1) and then its fraction decreases on lowering the pH. Simultaneously, the fraction of complex II, f_{II}, increases to unity at pH=5 and then decreases in the lower pH range where complex III now becomes dominant. With decrease in R (Figs. 5(b) and (c)), the f_i *vs.* pH curves shift to the high pH region as compared with the curves for R=32. These shifts may result from the lowering of the degree of dissociation, α^*, of the side-chain carboxylato groups by the binding of Cu(II) even at the same pH. In order to test this hypothesis, the pH should be converted into the α^*, which is defined as

$$\alpha^* = 1 - \frac{[HCl]_{add} + 2[Cu]_b}{[Acr]_0}, \quad (6)$$

where $[Acr]_0$ is the initial residue concentration of poly(Acr), and $[HCl]_{add}$ is the concentration of HCl added to the solution.

The dependence of f_i on α^* is shown in Fig. 5(d). The f_i *vs.* α^* curves at three R do not coincide with one another in this plot. Thus the horizontal displacement of the f_i toward higher pH is not due solely to the

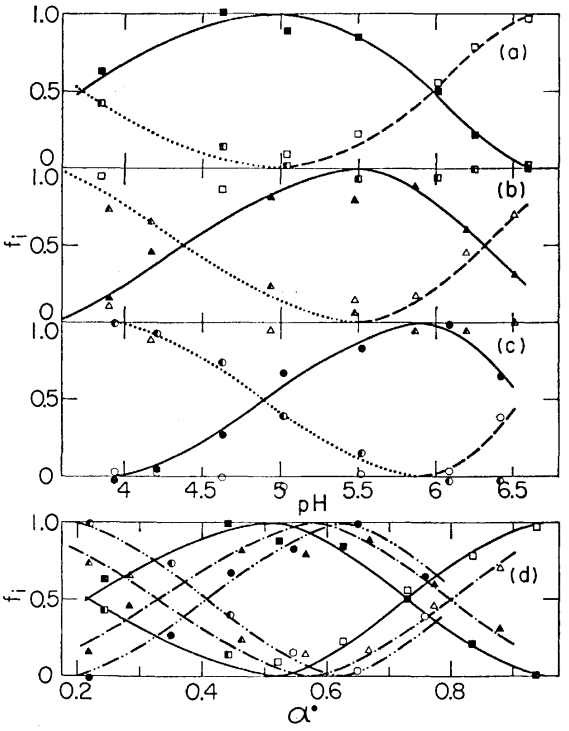

Fig. 5. The pH dependence of the fraction of the Cu(II)–Acr complex i (i=I, II, and III) to the total bound Cu(II), f_i, at various R; (a) R=32, (b) 16, and (c) 8; Complex I (—— and open symbols), complex II (—— and filled symbols), and complex III (····· and half-filled symbols), together with the variation of the f_i with the degree of dissociation of poly(Acr), α^*, at various R (32 —, 16 –·, 8 –··) in (d).

neutralization of the carboxylato group by Cu(II) but due also to the change in the ε^b of the bound Cu(II) with R. In any case, complex II is most dominant when about half of the carboxyl groups of poly(Acr) are ionized, while complexes I and III become a major entity in the fully ionized and un-ionized conformations of poly(Acr)–Cu(II), respectively. Accordingly, the pH region may also be divided into three subregions, *i.e.*, pH regions I, II, and III.

Component Spectra of the Bound Cu(II) in Poly(Acr)–Cu(II). Since the overall spectrum of the bound Cu(II) in the poly(Acr)–Cu(II) could be obtained in terms of ε^b_λ (Eq. 3), it is now possible to divide it into three component spectra characteristic of complexes I, II, and III by using the results shown in Fig. 5. For the poly(Acr)–Cu(II) at a given R (=32, 16 or 8), the pH-independent component spectra can be calculated from Eq. 4 first by solving simultaneous equations for $(\varepsilon^b_\lambda)_I$, $(\varepsilon^b_\lambda)_{II}$, and $(\varepsilon^b_\lambda)_{III}$ at a wavelength of λ with both ε^b_λ- and f_i-values at any three pH, and then by repeating the same calculations at other wavelengths in the 940—230 nm regions. Several of those spectra were derived by employing the data at different sets of three pH values and averaged. The mean spectra were designated as component spectra I, II, and III for complexes I, II, and III at a given R. The results are shown for the visible and UV-bands in Fig. 6. It should be noted that each of the component spectra is

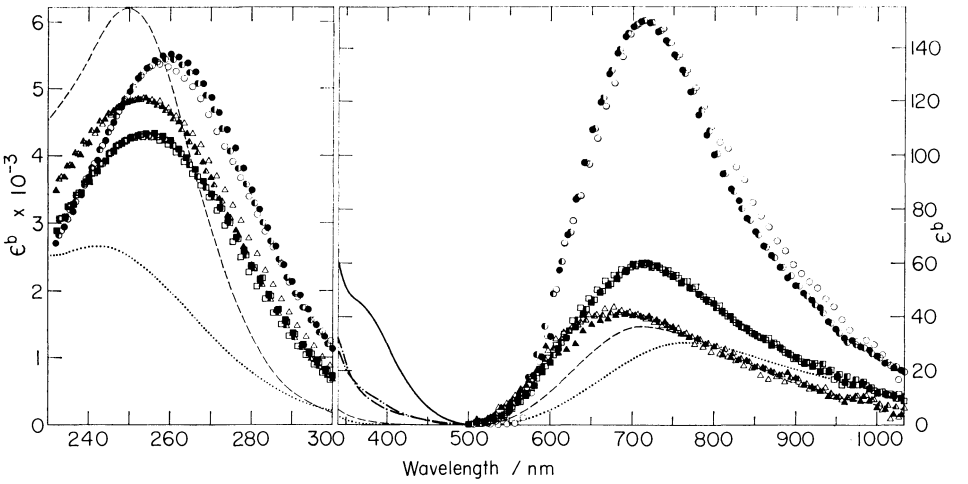

Fig. 6. The spectra of complexes I, II, and III in poly(Acr)–Cu(II). Complex I: R=32 (△), 16 (▲), and 8 (▲). Complex II: R=32 (□), 16 (◧), and 8 (■). Complex III: R=32 (○), 16 (◐), and 8 (●). For the procedure of the determination of these spectra, see text. This procedure could not be applied to the near UV-band because of the low absorption intensity. Instead, some typical spectra, which are closest to f_i=1, are shown (Complex I –·–·, Complex II –···–, and Complex III ——). The spectra of Cu(II)–glutarate (·····) and –malonate (–––––) complexes (R=[carboxyl group]/$[Cu^{2+}]_0$=80) are also shown for comparison.

nearly independent of the R and pH values. It is component spectrum III, which represents the dominant complex in the low pH region, that is most intense in the visible wavelength and gives rise to a considerable shoulder in the near UV-band. Although component spectra II and III both show the peak of the visible band at the same wavelength of 710 nm, they differ from each other in that II is weaker but broader than III.

The spectra of the bound Cu(II) in the glutaric acid- and malonic acid–Cu(II) complexes are also shown in Fig. 6 for comparison. Glutaric acid was chosen as the model for the nearest neighbor ligands of poly(Acr), because it has the same number of carbon atoms between two carboxylato groups. Malonic acid is known to form a four-coordinated complex with Cu(II) at the high carboxylate-to-Cu(II) ratio.[19] The spectra of the glutaric acid–Cu(II) complex with the R values up to 60 never resemble any of those component spectra I, II, and III as regards the peak position and intensity. However, the spectra of malonic acid–Cu(II) complexes at high R are quite similar to component spectrum II of the Cu(II)–Acr complex in the poly(Acr)–Cu(II) as regards the general spectral features in the visible band. This similarity is suggestive of the structure of complex II.

Formation of Cu(II)–Acr Complexes in Poly(Acr)–Cu(II). The structure of the Cu(II)–Acr complex may be reflected in the stoichiometry of the complex formation between the Acr residue and Cu^{2+}. On the basis that the equilibrium constant depends inversely on the first power of $[Acr]_0$, Wall and Gill[3] have concluded that a pair of the intramolecular adjacent carboxylato groups is chelated with a Cu(II). On the other hand, Tamaoki *et al.*[8] considered that two carboxyl ligands separated from each other on a single polyanion are associated with a Cu(II), because the Cu(II) showed almost the same binding strength for polycarboxylates of varying tacticities. In order to clarify the binding process between Cu^{2+} and poly(Acr) from the equilibrium dialysis data, some graphical methods were devised.

The following equilibrium schemes are considered for the binding between Cu^{2+} and carboxylato ligands of poly(Acr).

$$\text{Scheme A: } \mathrm{COOH} \overset{K_1}{\rightleftharpoons} \mathrm{COO^-} + \mathrm{H^+},$$

$$(\mathrm{COO^-})_2 + \mathrm{Cu^{2+}} \overset{K_2}{\rightleftharpoons} (\mathrm{COO})_2\mathrm{Cu}. \quad (7)$$

$$\text{Scheme B: } \mathrm{COOH} \overset{K_1}{\rightleftharpoons} \mathrm{COO^-} + \mathrm{H^+},$$

$$2(\mathrm{COO^-}) + \mathrm{Cu^{2+}} \overset{K_3}{\rightleftharpoons} \mathrm{COOCuOOC}. \quad (8)$$

In these schemes, the K_1, K_2, and K_3 are the dissociation constant of poly(Acr) and the stability constants of two different Cu(II)-residue complexes and are given as

$$K_1 = \frac{[\mathrm{COO^-}][\mathrm{H^+}]}{[\mathrm{COOH}]}, \quad (9)$$

$$K_2 = \frac{[(\mathrm{COO})_2\mathrm{Cu}]}{[(\mathrm{COO^-})_2][\mathrm{Cu^{2+}}]}, \quad (10)$$

and

$$K_3 = \frac{[\mathrm{COOCuOOC}]}{[\mathrm{COO^-}]^2[\mathrm{Cu^{2+}}]}. \quad (11)$$

In Scheme A, a Cu^{2+} ion binds to two adjacent carboxylato groups, whereas in Scheme B it binds to any two carboxylato groups. All the values of K_1, K_2, and K_3 are only apparent, since they are expressed in terms of concentrations and include the contribution of the electrostatic potential field of the polyanion. The total concentration of the ligands of poly(Acr) is given as

$$P_0 \equiv [\mathrm{Acr}]_0 = [\mathrm{COO^-}] + [\mathrm{COOH}] + 2[(\mathrm{COO})_2\mathrm{Cu}]. \quad (12)$$

The concentration of the pairs of nearest-neighbor carboxylato groups in poly(Acr), $[(COO^-)_2]$, may be given as:

$$[(COO^-)_2] = q[COO^-]. \quad (13)$$

Equations 9, 10, 12, and 13 are combined for Scheme A:

$$\frac{q(P_0-2\beta)}{\sigma} = \frac{[H^+]}{K_1K_2} + \frac{1}{K_2}, \quad (14)$$

or

$$\log\left(\frac{q(P_0-2\beta)K_2}{\sigma} - 1\right) = -pH + pK_1. \quad (15)$$

Equations 9, 11, and 12 are combined for Scheme B:

$$\frac{P_0-2\beta}{\sqrt{\sigma}} = \frac{[H^+]}{K_1\sqrt{K_3}} + \frac{1}{\sqrt{K_3}}, \quad (16)$$

or

$$\log\left(\frac{(P_0-2\beta)\sqrt{K_3}}{\sqrt{\sigma}} - 1\right) = -pH + pK_1, \quad (17)$$

where β is the concentration of bound Cu(II) or Cu(II)–Acr complex, and σ is the ratio of the concentration of the bound Cu(II) to that of unbound Cu^{2+}. The quantities P_0, β, σ, and $[H^+]$ are all obtained experimentally. When the left-hand side of Eq. 14 or 16 is plotted against $[H^+]$, a straight line would result, provided that the complex formation occurs according to Scheme A or B. The intercept and tangent of this line give the K_2 or K_3 together with K_1. The results are shown in Fig. 7, where the value of q is assumed to be 0.5.[3] Alternatively, Eqs. 15 and 17 may be utilized, in the cases where the intercepts are too small to estimate K_1, K_2, and K_3 unambiguously. With a number of assumed K_2 and K_3 values, the left-hand side of Eq. 15 or 17 is plotted against pH, until a straight line with a slope of -1 is obtained. Then the assumed

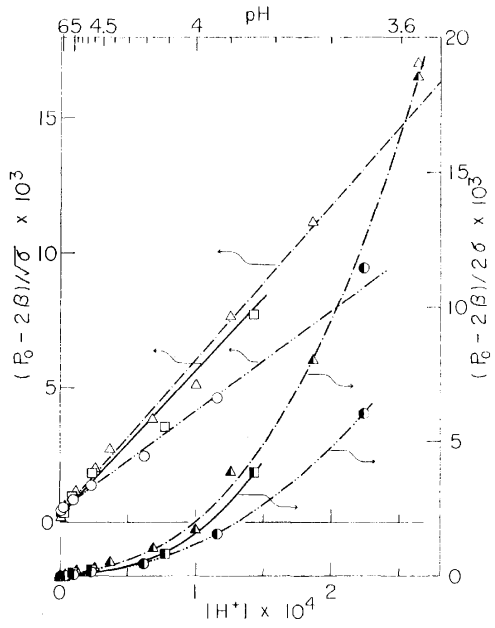

Fig. 7. The binding plots at three R for Scheme A (the right ordinate) and for Scheme B (the left ordinate). R=32 (◧ and □), 16 (◭ and △), and 8 (◐ and ○). See text for other details.

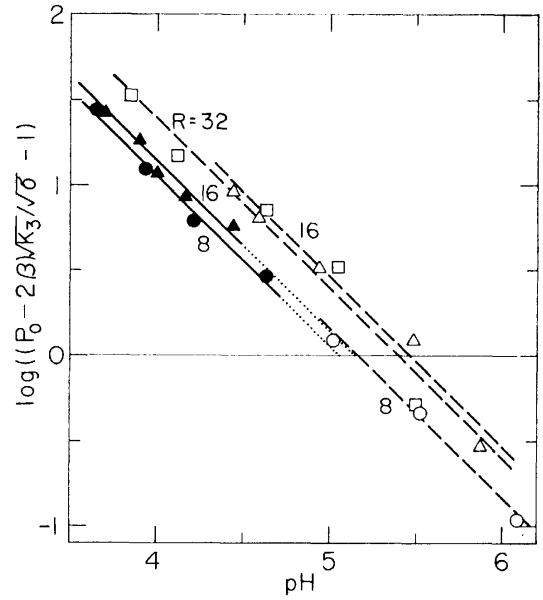

Fig. 8. The logarithmic binding plot at various R for Scheme B in pH regions II (open symbols) and III (filled symbols). The straight lines are best fitted by the f_i-weighted least-squares method. See text for other details.

K_2 or K_3 is the desired value and, in this case, the pK_1 is equal to the pH at which the straight line crosses the abscissa. The results are shown in Fig. 8.

If Scheme A describes the complex formation between Cu^{2+} and Acr ligands in all three pH regions I, II, and III, the above plot (Eq. 14) should give rise to a straight line over an entire range of $[H^+]$. This is not the case, as is demonstrated in Fig. 7. Scheme A may tentatively be concluded not to describe adequately the complex formation in the lower pH regions II and III, at least, under the assumption that the concentration of the adjacent two carboxylato groups is proportional to the concentration of the side-chain carboxylato groups remaining on poly(Acr),[3] *i.e.*, q is constant in Eq. 13. However, the validity of this assumption is believed open to further investigations. On the other hand, Scheme B is adequate to describe the complex formation in pH regions II and III, because the points of the R=32, 16, and 8 complexes fall approximately on straight lines which yield positive intercepts as required by Eq. 16. From those graphic methods, however, no clear conclusion can be given on whether or not Scheme A is the correct one in pH region I. This is mainly because the unbound Cu^{2+} ion is almost undetectable in the high pH ($\geq$6) region, regardless of R, and also because the intervals between experimental points become narrow exceedingly as the pH becomes larger than about 5. These factors introduce large errors in the plots in Fig. 7.

From the logarithmic plots shown in Fig. 8, the values of K_1 and K_3 were estimated in pH regions II and III and are summarized in Table 2. It is interesting to note that the apparent dissociation constants, pK_1, of poly(Acr)–Cu(II) vary from pH region II to pH region III, as the R=8 and 16 plots indicate in Fig. 8. The

Table 2. The pK_1, log K_3, and log $(K_2 \cdot K_4)$ of Cu(II)–Acr complexes in poly(Acr)–Cu(II) at various R in pH regions II and III

	pH	II (Scheme B)		III (Scheme B)		II (Scheme C)	
		pK_1 / mol·dm^{-3}	log K_3 / (mol·dm^{-3})$^{-2}$	pK_1 / mol·dm^{-3}	log K_3 / (mol·dm^{-3})$^{-2}$	pK_1 / mol·dm^{-3}	log$(K_2 \cdot K_4)$ / (mol·dm^{-3})$^{-2}$
R	32	5.4	7.3	—	—	5.4	8.0
	16	5.5	7.2	5.1	6.8	5.5	7.9
	8	5.2	6.8	5.1	6.9	5.2	7.8

pK_1 values are in good agreement with those previously obtained for poly(Acr)–Cu(II) by the potentiometric titration method (4.91 in 0.2 M $NaNO_3$[5] and 5—6 in 0.25 M $NaNO_3$[6]). The stability constants, log K_3, are quite large as compared with those for Cu(II)–dicarboxylic acid complexes, suggesting a strong binding of Cu(II) to two carboxylato ligands of poly(Acr).

A slightly more complicated class of the binding reaction schemes involves four Acr residues per Cu(II). On the assumption that the four ligands are paired and each pair consists of two adjacent carboxylato groups of poly(Acr), the binding scheme may be written as

$$\text{Scheme C: } \mathrm{COOH} \overset{K_1}{\rightleftharpoons} \mathrm{COO^-} + \mathrm{H^+},$$

$$(\mathrm{COO^-})_2 + \mathrm{Cu^{2+}} \overset{K_2}{\rightleftharpoons} (\mathrm{COO})_2\mathrm{Cu},$$

$$(\mathrm{COO})_2\mathrm{Cu} + (\mathrm{COO^-})_2 \overset{K_4}{\rightleftharpoons} [(\mathrm{COO})_2\mathrm{Cu}(\mathrm{COO})_2]^{2-} \quad (18)$$

The overall stability constant $K_2 \cdot K_4$ is then given as

$$K_2 \cdot K_4 = \frac{[\mathrm{Cu(COO)_4^{2-}}]}{[(\mathrm{COO^-})_2]^2[\mathrm{Cu^{2+}}]}. \quad (19)$$

By combining K_1 and $K_2 \cdot K_4$, the following expression results:

$$\frac{2q((P_0/2)-2\beta)}{\sqrt{\sigma}} = \frac{[\mathrm{H^+}]}{K_1\sqrt{K_2 \cdot K_4}} + \frac{1}{\sqrt{K_2 \cdot K_4}}. \quad (20)$$

This expression is close to Eq. 16. The plots at three R values also give straight lines in pH region II similar to those in Fig. 8, when a value of 0.5 is again assumed for q throughout pH regions II and III (*cf.* Table 2). It should be noted then that the coordination of any two residues by a Cu(II), *i.e.*, Scheme B, can not be discriminated from the coordination of any two pairs of four residues by a Cu(II), *i.e.*, Scheme C, provided that each pair consists of two nearest neighbor carboxylato groups.

Discussion

The Absorption Spectra of Poly(Acr)–Cu(II) Macrocomplex. The UV-, near UV-, and visible bands have been reported for poly(Acr)- and poly(methacrylic acid)–Cu(II) systems.[2-4,8,10,12,15,16] The UV- and visible bands are commonly observed in the Cu(II)-complexes with low molecular weight carboxylic acids of various types.[20,21] The UV-band at 250 nm may be assigned to an allowed charge-transfer band between the carboxyl ligands of poly(Acr) and Cu(II) on the basis of its peak position and high intensity.[2,20] The skewed visible band at 700 nm should be the d-d transition on the basis of its peak position and low absorption intensity.[10,15,20] The skewed shape suggests the composite nature of this band, which should involve two or more d-d transitions.[20,22] The existence of such multiple transitions was noted in the 860—890 nm region for the poly(methacrylic acid)–Cu(II) complex.[15]

Leyte *et al.*[15] have observed the near UV-band at 380 nm in the poly(methacrylic acid)–Cu(II) system and suggested a binuclear Cu(II) complex of the acetate type by comparing their results with the studies of the Cu(II) complexes with acetate,[23] unsaturated acid,[24] and α,ω-dicarboxylic acid.[25,26] However, the appearance of the near UV-band can not be considered as conclusive evidence of the binuclear Cu(II) complex.[21] On the contrary, Graddon[27] has assigned this band to the d_{xy}, $d_{yz} \rightarrow d_{x^2-y^2}$ transition of the planar, coordinated cupric ion from the results of the Cu(II)-acetylacetonate complex which has no dimeric structure. Hence, it is still unresolved whether or not the 370 nm band reflects the presence of the binuclear Cu(II) complex in poly(Acr)–Cu(II). This band appears even at a high ratio of the side-chain carboxyl groups to bound Cu(II) and is remarkable only in the low pH region III. Therefore, the Cu(II)–Acr complexes, which give rise to component spectra II and III (Fig. 6), could possibly be related structurally to the Cu(II)-acetylacetonate complex.

Structures of Cu(II)–Acr Complexes in Poly(Acr)–Cu(II) and Their Dependence on pH. The presence of three kinds of Cu(II)–Acr complexes in poly(Acr)–Cu(II) has been unraveled in the present work. However, it is not verified at present whether or not complexes, I, II, and III have unique structures. It is possible that each kind of complex i (i=I, II, III) is a mixture of several chemical species whose structures differ from each other slightly but do not affect the optical spectra appreciably. Figure 9 shows some of the likely chemical species for Cu(II)–Acr complexes. The structures of the species are by no means a complete list nor a conclusion introduced by this work, but should be considered as a working hypothesis. As regards the number of the ligands bound by a Cu(II), two carboxylato groups of poly(Acr) are normally considered because of the electric charge neutrality.[3,8,10] As the remaining ligands to Cu(II), the solvent water, hydroxide ion, counter-ion (Cl^-), and the additional carbonyl and carboxyl groups of poly(Acr) are all possible participants in the coordination with Cu(II), on the analogy of the Cu(II)–complexes with the small-molecular-weight ligands.[19-21] The Cl^- ion may be discounted because the spectra of poly(Acr)–Cu(II)

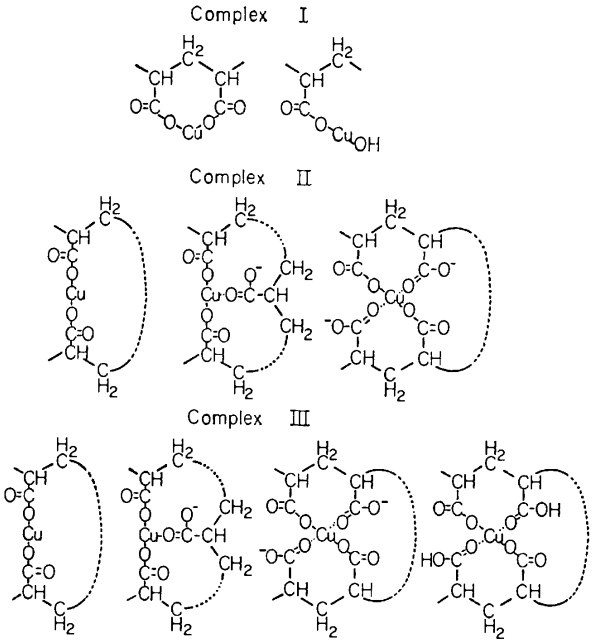

Fig. 9. Some possible structures of Cu(II)–Acr complexes in poly(Acr)–Cu(II). Neither hydration of water nor geometric isomer was explicitly considered. Complexes were assumed to be formed between Cu(II) and the side-chain carboxyl groups of a single poly(Acr) strand.

in 150 and 7.5 mM[2] NaCl solutions show no essential differences.

Although the present data fail to confirm that the complex formation reaction involves the $[Acr]^{-1}$-term in the high pH region (Scheme A), complex I is likely to be a bidentated-type complex, as already reported.[3,7] Poly(Acr) is in a rather extended conformation in this pH region because of the charge repulsion, so that the Cu(II) may bind to a pair of nearest-neighbor carboxylato groups. Nevertheless, the binding of Cu^{2+} to a carboxylato groups and an OH^- ion could not be omitted. The complex formation reaction depends on the $[Acr]^{-2}$-term (Scheme B) in the intermediate and low pH regions II and III where complexes II and III are dominant, respectively. This finding substantiates the notion that a bound Cu(II) is associated with the two carboxylato groups which are separated from, and independent of, each other on a single polymer strand (or possibly on different strands). The Cu(II) may also be coordinated by four carboxylato groups, as indicated by Scheme C. The profile of the component spectrum for complex II is very close to the spectrum of the Cu(II)–malonate complex which is also coordinated by four carboxylato groups (Fig. 6).[19]

It is impossible at present to discriminate whether or not the chemical species for complexes II and III are formed between carboxylato groups of intra- or inter-chains. The poly(Acr)–Cu(II) complex may take on a compact or aggregated conformation, as the ionization of the side-chains is suppressed by the added protons. This view is supported by the remarkable decrease in the viscosity of poly(Acr) solutions in the presence of Cu^{2+} or H^+.[8,10] However, the bound Cu(II) can also bridge two polymer-strands by forming a planar, four-coordinated complex with two each out of four carboxylato groups (Scheme C). The overall conformation of the poly(Acr)–Cu(II) macro-ion should be studied by the light-scattering or sedimentation method to draw a definite conclusion on the role of the bound Cu(II) in the low pH regions.

The stability constants, in terms of $\log K_3$, of the Cu(II)–Acr complexes (*cf.* Table 2) are three to four orders of magnitude greater than the $\log K$ of Cu(II)–glutarate [3.16 (no salt),[28] 3.88 (no salt), and 3.64 (in 0.2 M $NaNO_3$)[5]] and are comparable with those of Cu(II)–malonate and –oxalate complexes (*ca.* 8 and 5.54[5]). Gregor *et al.*[5] considered that the enormous electrostatic attraction of poly(Acr) toward Cu^{2+} contributes to the formation of a Cu(II)–Acr complex in poly(Acr) as stable as the Cu(II)–alkanoate complexes composed of five- and six-membered rings. However, it is also possible that the electrostatic repulsion is effectively suppressed in the presence of 150 mM NaCl and the conformation of poly(Acr) becomes either in the compact-coil or in the multi-stranded aggregates. The peculiar feature of the ligand field of the carboxyl groups of poly(Acr) toward the Cu^{2+} ion and the flexible backbone structure thereof may be the important cause to produce stable and large-ring Cu(II)–Acr complexes in poly(Acr).

Conclusion

The complicated pH dependence of the absorbance and peak position of the UV and visible absorption spectra of poly(Acr)–Cu(II) solutions was verified to be due partly to the dissociation of bound Cu(II) from the polymer sites in the low pH range ($\leq$4.3), but mostly to the genuine variation of the spectra of the bound Cu(II) with pH. This variation with pH was interpreted as being due to the interplay of three component spectra characteristic of Cu(II)–Acr complexes I, II, and III. The fractions of complexes I, II, and III vary with pH, becoming most dominant in the high, intermediate, and low pH regions, respectively. The analysis of the binding reactions showed that the chemical species constituting those complexes involve both chelation and coordination of two to four side-chain carboxylato groups of poly(Acr). The present study strongly suggests the possibility that the bound Cu(II) also bridges two or more poly(Acr) strands to form multi-strand aggregates.

Molecular Dynamics of Polystyrene Model Molecules; Reorientational Correlation Times of Phenyl Groups of 2,4-Diphenylpentane

Shinbu KODA,† Hiroyasu NOMURA,* and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
†*Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464*

(Received December 27, 1978)

The reorientational correlation times of phenyl groups in 2,4-diphenylpentane in solution were measured as a function of the temperature by means of Raman line-shape analysis. The reorientational correlation times of both isomers increase as the temperature increases, that is, the reorientational motion of phenyl groups in molecules gradually become active. In the low-temperature region, the reorientational correlation times of the meso 2,4-diphenylpentane are longer than those of the racemic one. This fact that the molecular motion of phenyl groups of the racemic isomer rotates more easily than that of the meso one is in agreement with the results obtained from ultrasonic study by Monnerie *et al.* On the other hand, in the higher-temperature region, the reorientational correlation times of the meso isomer are shorter than those of the racemic one. In addition, the potential barriers for the reorientational motion of phenyl groups are found to be (3.3±0.3) kcal/mol for the meso isomer and (2.0± 0.3) kcal/mol for the racemic isomer.

Ultrasonic absorption studies of vinyl polymers in solution, especially of polystyrene, have shown that local segmental motions of the backbone and motions of the side chains themselves were observed for the ultrasonic relaxation phenomena in the megahertz region.

Recently, in order to clarify the nature of the elementary motion of polymer chains in solution, Monnerie *et al.*[1] have reported very interesting results on the ultrasonic relaxation of 2,4-diphenylpentane in solution. The 2,4-diphenylpentane is the simplest polystyrene model molecule; two configurational isomers are present of the racemic and meso types. Monnerie *et al.* have indicated that the single relaxation observed for both racemic and meso types of 2,4-diphenylpentane in solution is due to the equilibrium reaction of the rotational isomers between g^-t and tt, and between tt and g^-g^-, conformations for the meso and racemic isomers respectively. Though they have suggested that the observed ultrasonic relaxation can be explained by taking into account the rotational motions of phenyl groups, the ultrasonic studies did not give any detailed information.

In our previous papers,[2,3] we reported that the reorientational correlation times of phenyl groups in polystyrene chains in solution could be determined by means of laser Raman spectroscopy. The same quantities can also, in principle, be determined by means of NMR relaxation experiments, infrared-band-shape analysis, and depolarized Rayleigh scattering. Compared with these methods, however, Raman studies can give information of interest more directly.

In the present paper, we will report on the temperature dependence of the reorientational correlation times of phenyl groups in *racemic*- and *meso*-2,4-diphenylpentane in solutions and will discuss the molecular motions of the phenyl groups in these molecules in solution.

Experimental

The apparatus used consisted of an argon-ion laser (800 mW at 488 nm) manufactured by the Coherent Radiation Co., Ltd. and a JRS-U1 Laser Raman Spectrometer of the Japan Electron Laboratory Co., Ltd. The Raman spectrum was observed at 90° with respect to linearly polarized incident light. In the analysis of the Raman line shape of the $\nu_2(a_{1g})$ mode of the phenyl group, all the experiments were carried out with a fixed slit width (40 μm).

The measuring temperatures were in the range from −90 °C to 40 °C. A variable-temperature Raman cell of the Harney-Miller type was used. The details of the experimental procedures were described previously.[4]

The meso and racemic 2,4-diphenylpentane, abbreviated *m*-DPP and *r*-DPP respectively, were kindly provided by Prof. Monnerie; these samples were the same as those used for ultrasonic studies. The detailed properties of the samples used have been given in detail in the literature.[5,6,7] By means of NMR and IR studies, the samples used have been confirmed for the following points; for *m*-DPP, the twofold degenerated g^-t (or tg^+) state is predominant, and the other conformations of *r*-DPP are 75% in the tt state and 25% in the g^-g^- state at room temperature.

The chloroform used as a solvent was commercial product, a spectral-grade regent. The concentrations of *m*-DPP and *r*-DPP were both 20.0 wt %.

Results and Data Analysis

Before we determined the reorientational correlation times of phenyl groups of *m*- and *r*-DPP in solution, we confirmed that the Raman spectra of DPP did not change in the pure liquid state nor in chloroform solutions over the whole temperature range. This fact clearly indicate that the conformational changes of *m*- and *r*-DPP in solution do not occur in these experiments.

The reorientational correlation times (τ(or)) of the phenyl group of DPP were determined by means of the Raman-line-shape analysis of stretching mode. For example, the Raman-line-shapes of $I_\parallel(\omega)$ and $I_\perp(\omega)$ of the $\nu_2(a_{1g})$ band are shown in Fig. 1, where $I_\parallel(\omega)$ and $I_\perp(\omega)$ represent the paralleled and polarized Raman intensities respectively with respect to the linearly polarized incident light.

As the ν_2 band of DPP shown in Fig. 1 overlapped the other bands, it was extracted by resolving these Raman lines into their components with Lorentzian functions, using the non-linear least-mean squares method of

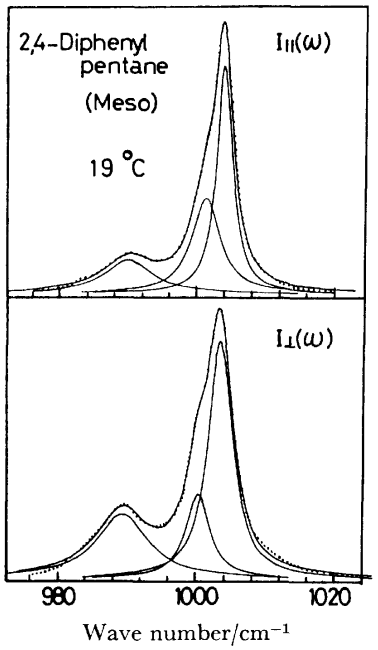

Fig. 1. Raman line shape of ν_2 band meso 2,4-diphenylpentane at 19 °C. Dotted line; observed, solid line; composed and decomposed with Lorentzian functions.

Fletcher-Powell.[8] After the correction for the line-boading effects of the instrumental slit width,[9] the true half-widths were determined for each one, $I_{\parallel}(\omega)$ and $I_{\perp}(\omega)$. As we found the depolarization ratio, $\rho_s(=I_{\perp}(\omega)/I_{\parallel}(\omega))$, to be about 0.02 for each isomer in throughout the temperature range, the intrinsic vibrational line shape, $I_{isot}(\omega)$, and the measured line shape, $I_{\parallel}(\omega)$, can be considered to be the same without the introduction of any significant errors.

The temperature dependences of the half-width of the isotropic and anisotropic parts of the Raman scattering, $\omega_{1/2}$(isot) and $\omega_{1/2}$(anis), are shown in Fig. 2. As was seen in Fig. 1, the Raman line shapes of $I_{\parallel}(\omega)$ and $I_{\perp}(\omega)$ can be represented by the Lorentzian curve within the limits of experimental error, also, we can estimate

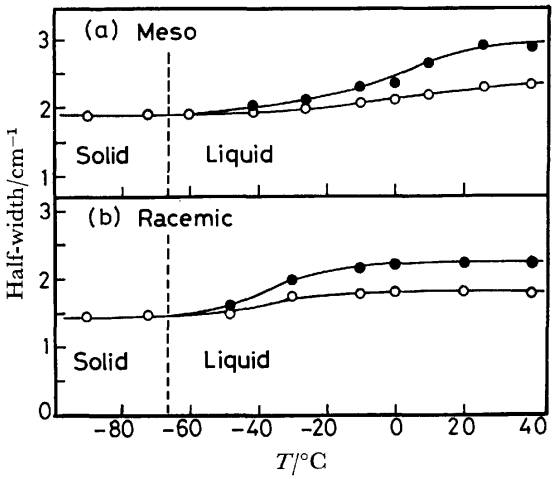

Fig. 2. Temperature dependence of $\omega_{1/2}$(isot) (○) and $\omega_{1/2}$(anis) (●) for each isomer. a); Meso isomer, b); racemic isomer.

the reorientational correlation times, τ(or), by means of the following relations;

$$\omega(\text{or}) = \omega_{1/2}(\text{anis}) - \omega_{1/2}(\text{isot}), \quad (1)$$

$$\tau(\text{or}) = (\pi c\omega(\text{or}))^{-1}, \quad (2)$$

where c is the velocity of light.

The molecular symmetries of *r*- and *m*-DPP are C_1 and C_2 respectively. As has clearly been mentioned by Nafie and Peticolas,[10] in the DPP molecule the reorientational correlation time obtained from the $\nu_2(a_{1g})$ band of the ring-stretching vibration of phenyl groups should be related to a set of motions about the axes which diagonalize the moment-of-inertia tensor and also diagonalize the rotational diffusion tensor. However, the reorientation about the axis of the phenyl group, $C–C_{ring}$, will be faster than those about the other axes, taking into account the moment-of-inertia of each axis in the *m*- and *r*-DPP molecules. Accordingly, we may consider that the reorientational correlation time obtained from the $\nu_2(a_{1g})$ mode of the phenyl group is mainly concerned with the motion about the $C–C_{ring}$ axis.

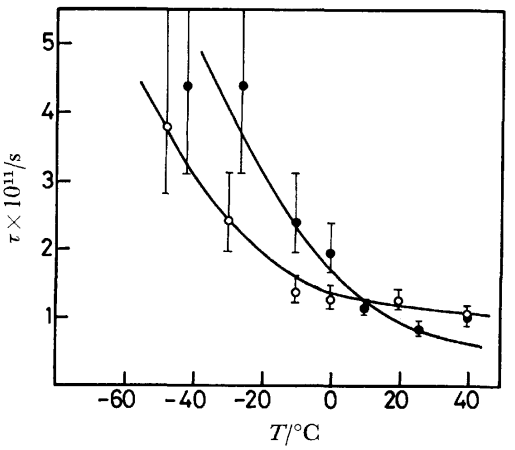

Fig. 3. Temperature dependence of the reorientational correlation time. ○; Racemic isomer, ●; meso isomer.

The temperature dependence of τ(or) for each isomer of DPP in solution shown in Fig. 3. In the low-temperature region, the reorientational correlation times, τ(or), of both isomers decrease sharply with an increase in the temperature and the values of τ(or) of the racemic-type DPP are longer than those of the meso-type DPP at the same temperature. On the contrary, with an increase in the temperature, the temperature dependences of their τ(or) become smaller and the τ(or) values of meso-type DPP are longer than those of the racemic-type one.

Discussion

At the lowest temperature measured (−90 °C), of course, the solution was in a solid state (the melting point of chloroform is −63.5 °C), therefore, all the molecular reorientational motions were frozen out, that is, $\omega_{1/2}(\text{anis}) \simeq \omega_{1/2}(\text{isot})$.

Even in the liquid state, below temperatures of

about −30 to −40 °C, the differences between $\omega_{1/2}$(isot) and $\omega_{1/2}$(anis) can hardly be distinguished, taking the experimental accuracy into account. This fact clearly indicated that the reorientational motion of phenyl groups in *m*- and *r*-DPP is frozen out and/or is extremely slow. In both isomers, as the temperature inceases, the differences between $\omega_{1/2}$(isot) and $\omega_{1/2}$(anis) increase. The reorientational motion of phenyl groups in a molecule gradually becomes active.

In the low-temperature region, the reorientational correlation times, τ(or), of *m*-DPP are longer than those of *r*-DPP; that is, the molecular motion of phenyl groups of the latter in the tt state rotates more easily than that of the former in the tg^- state. This fact is in agreement with the results obtained by ultrasonic study.

However, at higher temperature, it seems that the reorientational motion of the phenyl groups of *m*-DPP becomes faster than that of racemic ones. As has been mentioned above, the conformational changes in each isomer could not be observed at any temperature. This suggests that there are some changes in the intermolecular relations in solution and open the way to further investigation of this subject.

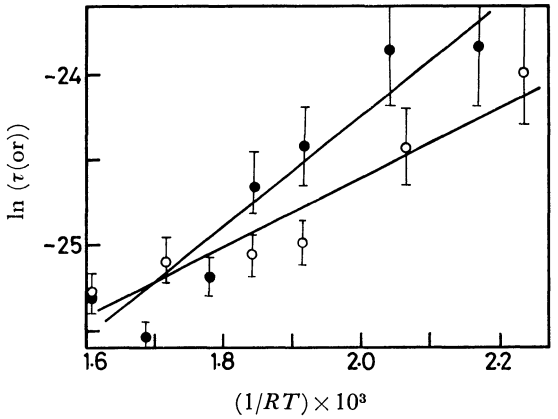

Fig. 4. Natural logarithmic reorientational correlation time *versus* $1/RT$. ○; Racemic isomer, ●; meso isomer.

The potential barrier for the reorientational motin of phenyl groups can be estimated from the following equation;[11]

$$\tau(\text{or}) \propto \exp(U_r/RT) \quad (3)$$

where R is the gas-constant, T is the absolute temperature, and U_r is the potential barrier. Figure 4 shows the relationship between ln (τ(or)) and $1/RT$. As may be shown in Fig. 4, the difference between the meso and racemic isomers can be observed. The values obtained are (3.3±0.3) kcal/mol and (2.0±0.3) kcal/mol for the meso and racemic isomers respectively.

Usually, in solution the rotational relaxation time can be expressed by the Debye-Einstein relation;

$$\tau(\text{or}) = 4\pi a^3\eta/(3RT) \quad (4)$$

where η is the viscosity coefficient of the solvent in a dilute solution. For chloroform, the activation energy obtained from the viscosity data[12] is 1.65 kcal/mol. This value is comparable to that obtained from the plot of ln(τ(or)) *vs.* $1/RT$ for *r*-DPP. The value of U_r for *m*-DPP is larger than that for the racemic one. The intramolecular interaction of phenyl groups in *m*-DPP may contribute to this difference in the rotational potential barrier. This fact shows that the rotational molecular motion of phenyl groups in *m*-DPP is hindered more than that of *r*-DPP.

TABLE 1. REORIENTATIONAL CORRELATION TIME

Sample	τ(or)/s
Toluene	0.60×10^{-11}
1,2-Diphenylethane	0.96
2,4-Diphenylpentane	2.4
Polystyrene M_w = 600	4.6
2200	6.4

(20 wt % in $CHCl_3$).

In Table 1, the τ(or) of DPP at room temperature is compared with those of several other molecules.[2,3] As the two phenyl groups in DPP are located at the 2 and 4 positions in normal pentane, the interaction between phenyl groups in DPP is much stronger than that of the 1,2-diphenylethane, where the two phenyl groups are located at the terminal carbon atoms. Therefore, the τ(or) of DPP is much longer than those of 1,2-diphenylethane and toluene, in which the phenyl group rotates freely. Moreover, the τ(or) values of polystyrene are longer than that of DPP and increase with the molecular weights, because of the short-range interaction between phenyl groups in the polymer chain.

In conclusion, the molecular motion of phenyl groups in DPP is very slow, and the rotation is almost completely hindered at low temperatures, where the single relaxation has been observed by ultrasonics. Accordingly, the single relaxation observed by ultrasonics should be considered to be due to the chain-conformational change in the molecule, as has mentioned by Monnerie *et al.* This is because the reorientational relaxation time of phenyl groups is of an order of 10^{-11} s, therefore, this motion should not be coupled with the rotational motion of the alkyl chain itself.

In addition, we can not consider that the elementary motion of polymer chains in solution is a conformational change, tt and tg^+ and/or tg^- and g^-g^-, observed in 2,4-diphenylpentane. Usually in polystyrene solutions, the ultrasonic relaxations have been observed in the regions of MHz and several hundred MHz at room temperature.[13] Extrapolating the data obtained by Monnerie *et al.* to room temperature, the relaxation should be observed at 204 MHz in the $tg^-(tg^+)\rightarrow tt$ process and at 575 MHz in $tt\rightarrow g^-g^-$. Besides, the relaxation amplitude, A, in those frequency regions is of an order of $1—2\times10^{-17}$ neper/s^2 cm^{-1}; this value can hardly be detected at higher frequencies by means of present-day experimental techniques. Therefore, the unit of elementary motion of polymer chains in solution must be longer than the 2,4-diphenylpentane molecule.

The authors wish to thank Professor Lucien Monnerie for supplying the meso and racemic 2,4-diphenylpentane.

Metal Complexes with Amino Acid Amides. IV. Relationship between the CD Spectra of Palladium, Nickel, and Copper Complexes with *cis*-Bis(amino carboxamidato)metal(II) Type

Takashi KOMORITA* and Yoichi SHIMURA

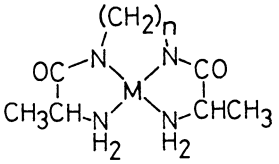
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 6, 1978)

Square planar complexes of [ML] type, where M=Pd^{2+}, Ni^{2+}, and Cu^{2+} for L=*N,N'*-bis(L-alanyl)-1,3-propanediaminate anion and M=Ni^{2+} and Cu^{2+} for L=*N,N'*-bis(L-alanyl)-1,2-ethanediaminate anion, were synthesized. Their absorption and CD spectra were measured in aqueous, ethanol, and DMF solutions. The results are discussed in comparison with those of *cis*- and *trans*-bis(amino carboxamidato)complexes. Definite correspondence is found between the component d-d bands of *N,N'*-bis(L-alanyl)-1,3-propanediaminatopalladium(II) and those of its nickel analog, in line with a similar correspondence for the corresponding *trans*-bis(L-amino carboxamidato) complexes. Assignment of the component d-d bands has been reexamined for the copper complexes of bis(amino carboxamidato) type by comparing their CD data with those for the palladium and nickel analogs.

Solvent effects on CD spectra have been studied for a large number of square planar bis(amino carboxamidato) complexes.[1-4] A definite correspondence has been found between the ligand field bands of trans palladium(II) complexes and those of nickel(II) analogs.[3,4] However, no similar examination has been carried out on the cis type or copper(II) complexes, due to the labile nature of the copper(II) and nickel(II) complexes.

This paper presents spectral relationship found for the nickel(II), palladium(II), and copper(II) complexes of *cis*-bis(L-amino carboxamidato) type. The work was achieved by use of tetradentate ligands, *N,N'*-bis(L-alanyl)-1,3-propanediamine and -1,2-ethanediamine, which make the complexes take the *cis* geometry.



Experimental

Materials. The ligands, *N,N'*-bis(L-alanyl)diamines were synthesized according to Scheme 1.

N,N'-Bis(N-benzyloxycarbonyl-L-alanyl)-1,2-ethanediamine (1): *N*-Benzyloxycarbonyl-L-alanine (31.6 g, 0.14 mol) was dissolved in 700 cm^3 of absolute tetrahydrofuran (THF). The resulting solution was cooled to the temperature range −10—−5 °C, and 14.4 g (0.14 mol) of triethylamine was added to it under stirring. The temperature was kept in the range, stirring being continued. A solution of 19.4 g (0.14 mol) of isobutyl chloroformate in 60 cm^3 of absolute THF was added dropwise to the reaction mixture. After the addition had been completed, the mixture was stirred for 20 min, and a solution of 3.3 g (0.055 mol) of 1,2-ethanediamine in 250 cm^3 of absolute THF was added dropwise. The mixture which turned curdy was gradually warmed to room temperature under stirring for several hours and then allowed to stand overnight.

The white precipitate, which contained triethylammonium chloride as well as the desired compound, was separated by a glass filter, washed with water three times and recrystallized from ethanol: the compound crystallizes in needles if it is of adequate purity. The samples for elemental analyses were dried *in vacuo* over $CaCl_2$. Another crop of the product was obtained from the mother liquor. Total yield, 19.1 g (74 %); mp 188.5—190.5 °C (uncorr.).

Found: C, 61.15; H, 6.45; N, 11.82 %. Calcd for $C_{24}H_{30}N_4O_6$: C, 61.26; H, 6.43; N, 11.91 %.

This compound is readily soluble in ethanol, ethyl acetate, chloroform, and THF only when hot.

N,N'-Bis(L-alanyl)-1,2-ethanediamine Dihydrobromide Hemihydrate, L,L-balaenH_2·2HBr·0.5H_2O (2): A 1:2 mixture (100 g) of hydrogen bromide–acetic acid was added to 23.0 g of **1** previously damped with 50 cm^3 of gracial acetic acid. On stirring the whole mixture for 80 min, the starting material **1** was dissolved and the desired product deposited as a resinous mass. An additional amount of the product was precipitated as a powder by adding 300 cm^3 of ether. Recrystallization of the crude product from ethanol–ether yielded colorless microcrystals. These were washed with a 1:2 mixture of ethanol–ether and dried *in vacuo* over P_2O_5 at about 75 °C overnight. Yield, 15.4 g (86 %); $[\alpha]_{589}^{16}$ =+4.1° (*c*=0.114; water); mp *ca.* 135 °C (dec).

Found: C, 25.81; H, 5.67; N, 15.03 %. Calcd for $C_{16}H_{42}N_8O_5Br_4$: C, 25.75; H, 5.67; N, 15.02 %.

N,N'-Bis(N-benzyloxycarbonyl-L-alanyl)-1,3-propanediamine (3). A solid product was obtained by a procedure similar to that for the 1,2-ethanediamine analog **1**, except for the use of 1,3-propanediamine in place of 1,2-ethanediamine. It was separated by a glass filter and washed with THF, water, aqueous 5 % $NaHCO_3$ solution, and water, successively. Recrystallization from THF yielded fibrous crystals which were dried *in vacuo* over $CaCl_2$. An addtional amount of the compound was obtained from the mother liquor. Total yield was 8.00 g (88 %) starting with 11.2 g (50 mmol) of *N*-benzyloxycarbonyl-L-alanine and 1.4 g (19 mmol) of 1,3-propanediamine: mp 192.5—193.5 °C (uncorr).

Found: C, 61.86; H, 6.74; N, 11.44 %. Calcd for $C_{25}H_{32}N_4O_6$: C, 61.97; H, 6.66; N, 11.56 %.

This compound is easily soluble only in hot THF, chloroform, and ethanol.

N,N'-Bis(L-alanyl)-1,3-propanediamine Dihydrobromide, L,L-balatnH_2·2HBr (4): This compound can be derived from **3** by a similar procedure to that for the 1,2-ethanediamine analog **2**, but does not seem to be so easily crystallizable as **2**: Thus, the resinous mass of the crude product **4** was obtained from an appropriate amount of **3** each time before the preparation of metal complexes.

Cu(L,L-balaen)·2H_2O: A solution containing 1.5 g (4.1

mmol) of **2** in 25 cm³ of water was poured into a column (1.3 cm × 10 cm) packed with Amberlite IRA-410 of OH^- form and the column was eluted with water. To the eluate was added $Cu(OH)_2$ freshly prepared from 1.03 g (4.1 mmol) of $CuSO_4 \cdot 5H_2O$, and the mixture was stirred until it turned red. The solution was evaporated to dryness below 35 °C *in vacuo*. To the residual reddish violet powder was added 20 cm³ of water, and a small amount of insoluble substances was filtered off. From the filtrate diluted with 80 cm³ of ethanol, a small amount of less soluble bluish precipitate and a large amount of brick-red needles (or plates), the desired complex, were deposited successively by careful addition of ether. After the supernatant suspension of the bluish precipitate had been decanted, the brick-red crystals were washed with ether by decantation and dried in air. Additional crops of these crystal, were obtained by fractional treatment of the supernatant solution with ether. Total yield, 0.78 g (72 %).

Found: C, 31.97; H, 6.73; N, 18.63 %. Calcd for $C_8H_{20}N_4O_4Cu$: C, 32.05; H, 6.72; N, 18.69 %.

*Cu(*L,L*-balatn)·3H₂O*: An aqueous solution (40 cm³) containing **4** derived from 4.84 g (10 mmol) of **3** was neutralized with an aqueous KOH solution and mixed with $Cu(OH)_2$ prepared from 2.25 g (9 mmol) of $CuSO_4 \cdot 5H_2O$. To the resulting violet solution was added such an amount of aqueous KOH solution as necessary to raise the pH to 8.5, where the color of the solution turned pink. The solution was evaporated to dryness on a rotary evaporator below 35 °C. The desired complex was extracted with ethanol from the residue and recrystallized as shiny reddish violet plates, the trihydrate, by addition of ether. The crystals were dried in air: yield, 1.80 g (64 %).

Found: C, 32.23; H, 7.20; N, 16.94 %. Calcd for $C_9H_{24}N_4O_5Cu$: C, 32.57; H, 7.29; N, 16.88 %.

*Cu(*L,L*-balatn)·2H₂O*: The crystals of the trihydrate, described above, released a part of the water of crystallization to give an orange solid upon exposure to dry atmosphere. The sample for elemental analyses was prepared by drying the trihydrate over $CaCl_2$ overnight.

Found: C, 34.06; H, 6.99; N, 17.75 %. Calcd for $C_9H_{22}N_4O_4Cu$: C, 34.44; H, 7.07; N, 17.85 %.

*Ni(*L,L*-balaen)·2H₂O*: A solution of 2.00 g (5.5 mmol) of **2** in 10 cm³ of water was neutralized with a solution containing 0.62 g (11.1 mmol) of KOH in 10 cm³ of water. To the resulting solution was added a solution of 1.50 g (5.2 mmol) of $Ni(NO_3)_2 \cdot 6H_2O$ in 10 cm³ of water. The blue solution was neutralized with a KOH solution (0.62 g in 10 cm³ of water). A green precipitate appeared immediately, disappearing almost within 40 min under stirring. Desalting was performed from the resulting dark yellow solution by a few cycles of successive procedures: evaporation to dryness and extraction of the desired complex into ethanol. Brown yellow needles were separated from the ethanol extract by adding a small amount of water and a large amount of ether and dried in air: yield, 0.71 g (47 %).

Found: C, 32.26; H, 6.75; N, 18.70 %. Calcd for $C_8H_{20}N_4O_4Ni$: C, 32.57; H, 6.83; N, 18.99 %.

*Ni(*L,L*-balatn)·2H₂O*: An ethanol solution containing the complex was prepared by a similar procedure described for the balaen analog, by use of 2.62 g (9 mmol) of $Ni(NO_3)_2 \cdot 6H_2O$ and 4.84 g (10 mmol) of **3**, the volume being reduced *in vacuo* to a few cubic centimeters. Orange-yellow microcrystals of the desired complex were separated from the concentrated solution by adding several drops of water. These were collected on a glass filter, washed with a mixture of water–ethanol–ether (roughly 1 : 4 : 3) and dried in air: yield, 1.97 g (71 %).

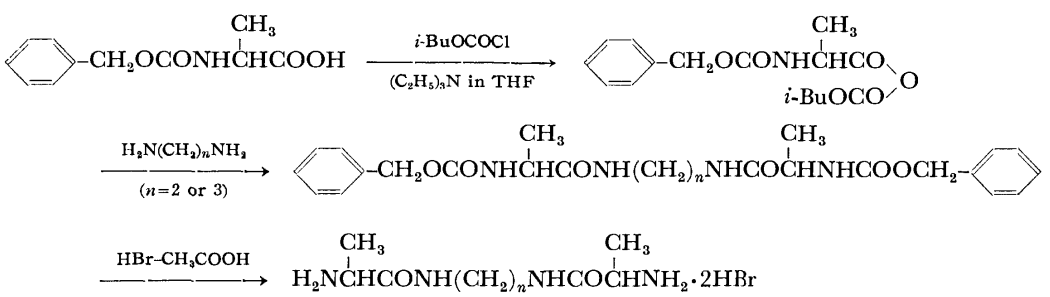
Found: C, 34.73; H, 7.24; N, 18.10 %. Calcd for $C_9H_{22}N_4O_4Ni$: C, 34.98; H, 7.18; N, 18.13 %.

*Pd(*L,L*-balatn)·2.5H₂O*: The crude compound **4** derived from 2.42 g (5 mmol) of **3** was dissolved in 25 cm³ of water and neutralized with 10 cm³ of a 1 M NaOH solution. To the resulting solution was added a solution containing 1.18 g (4 mmol) of Na_2PdCl_4 in 10 cm³ of water. A brownish precipitate was immediately formed. The solution suspending the precipitate was subjected to a similar neutralization procedure, by use of 1 M NaOH.[4] During the course of procedure followed by stirring for 2.5 h, most of the precipitate was dissolved. The residue was then filtered off. Mixed salts and yellow sirup were obtained by evaporating the yellow solution *in vacuo*. Most of the salts were removed by a similar procedure to that described for Ni(L,L-balaen)·$2H_2O$, except for the use of methanol in place of ethanol. The resulting methanol extract was evaporated to dryness. The residue was dissolved in a small amount of water, poured into a column (1.3 cm × 23 cm) packed with Amberlite IRA-410 of OH^- form and eluted with water. The eluate was concentrated *in vacuo* below 35 °C to give pale yellow needles which were washed with a small amount of cold water and dried over $CaCl_2$: yield, 0.42 g (29 %).

Found: C, 29.46; H, 6.37; N, 15.19 %. Calcd for $C_{18}H_{46}N_8O_9Pd_2$: C, 29.56; H, 6.34; N, 15.32 %.

Measurements. The absorption and CD measurements were made with a Shimadzu UV-200 spectrophotometer and a JASCO MOE-1 spectropolarimeter, respectively, at room temperature. The solvents employed were the same as those reported.[2]

Gaussian Analyses. Gaussian analyses for selected absorption and CD curves were performed by use of a slightly modified version of program LGNS:[5,6] best fit between the observed and calculated curves was obtained by use of 35—49 spectral points per curve; each point was weighted with the square of ε in the least-squares treatment in absorption-curve analyses, but not in CD analyses. The number of components of ligand field ansorption and CD bands was fixed to three and four for the nickel and palladium complexes, respectively. All the calculations were performed at Computation Center, Osaka University.



Scheme 1.

Results and Discussion

Absorption and CD data of the complexes are shown in Tables 1 and 2 and Figs. 1—5. The absorption and CD spectra of [Cu(L,L-balaen)] in aqueous solution have been recorded by Parris and Hodges, without isolation of the complex.[7] Our data do not differ much from theirs.

Gaussian Analyses. Gaussian analyses were performed for the CD spectra of the palladium and nickel complexes and for the absorption spectra of [Ni(L,L-balatn)] in three kinds of solvents. The results are given in Table 3.

For the analysis of CD curves of the palladium complex, the position of the first component, a spin-forbidden band,[1] was assumed to be equal to the corresponding output value[8] of *cis*-bis(L-valinamidato)-palladium(II). This does not seem to affect the overall results seriously, since the component is small enough. Overlapping of the intense charge transfer bands might affect the results seriously if inappropriate data in the overlapping region were chosen as inputs.

All the standard deviations of $\Delta\varepsilon$ values (Table 3) are within experimental error. On the other hand, those of ε values are, seemingly, of considerable magnitude, but the deviations in the region of relatively large ε values should be much smaller due to the weight scheme adopted.

The results of absorption- and CD-curve analyses for [Ni(L,L-balatn)] coincide with each other as regards the positions. This shows the validity of the assumption of three components in the ligand field band region of this or similar nickel complexes.

Absorption Spectra. The complex, [Ni(L,L-balatn)], exhibits an absorption maximum with a little higher intensity at a slightly lower wave number than the *trans*-bis(amino carboxamidato)nickel(II) complexes,[1,4] in each of the solvents (Table 1 and Fig. 1). This behavior is in line with that found between the absorption spectra of *cis*- and *trans*-bis(amino carboxamidato)-palladium(II) complexes.[1,4] Consequently, the absorp-

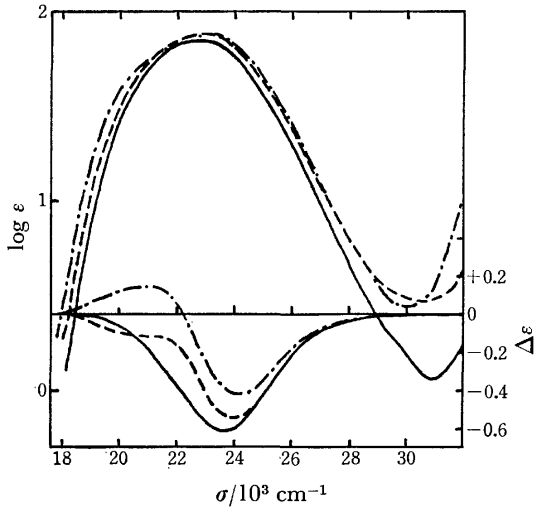

Fig. 1. Absorption and CD spectra of [Ni(L,L-balatn)] in water (——), in ethanol (----), and in DMF(-·--·).

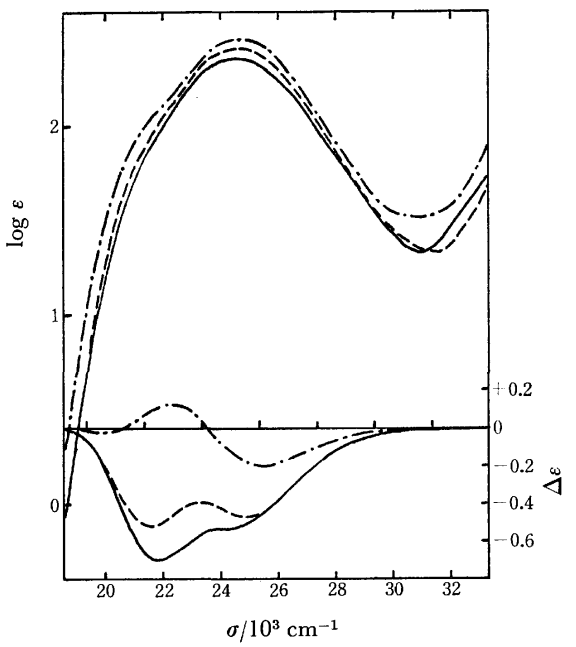

Fig. 2. Absorption and CD spectra of [Ni(L,L-balaen)] in water (——), in ethanol (----), and in DMF (-·--·).

tion spectra of [Ni(L,L-balatn)] are considered to correspond to those of a *cis*-bis(amino carboxamidato)-nickel(II) complex, which has not been isolated so far.

The absorption spectra of [Ni(L,L-balaen)] (Table 1 and Fig. 2) suggest an abnormally strong ligand field in this complex. The absorption maximum shifts toward blue by 1000—1500 cm^{-1} as compared with those of the *trans*-bis(amino carboxamidato)nickel(II) complexes, in each solvent. Such a blue shift is found also for each component band of the balaen complex (Table 3). This suggests that the ligand fits a nickel(II) ion so closely as to cause a constrictive effect found in different kinds of macrocyclic complexes.[9]

In contrast with the complexes of nickel(II) ion, both ligands, balatn and balaen, give ligand field strengths of the same order of magnitude as the copper(II) ions. The absorption peak of [Cu(L,L-balaen)] lies near that of the balatn analog in each solvent (Table 1 and Figs. 3 and 4). This is in line with the fact that metal–nitrogen bonds are longer for copper(II) than for nickel(II) by roughly 8 pm[10] in square-planar complexes of similar type.

The absorption spectra of [Pd(L,L-balatn)] (Table 1 and Fig. 5) essentially coincide with those of the *cis*-bis(amino carboxamidato)palladium(II) complexes in

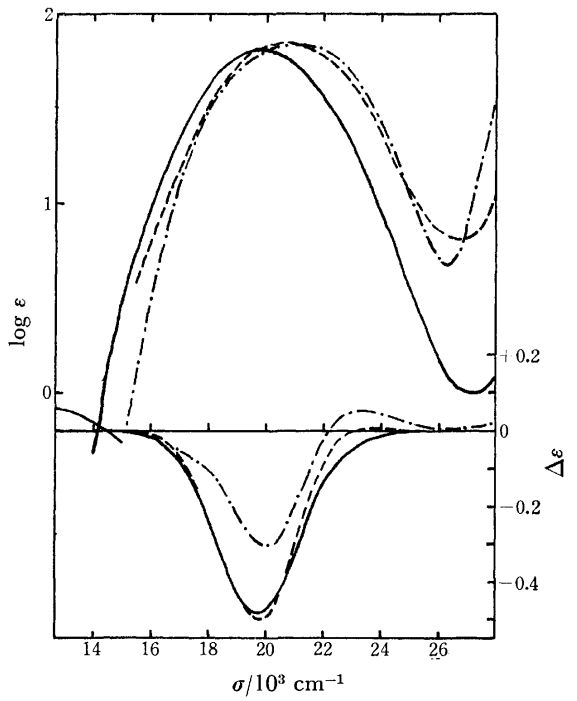

Fig. 3. Absorption and CD spectra of [Cu(L,L-balatn)] in water (——), in ethanol (----), and in DMF (-·-·).

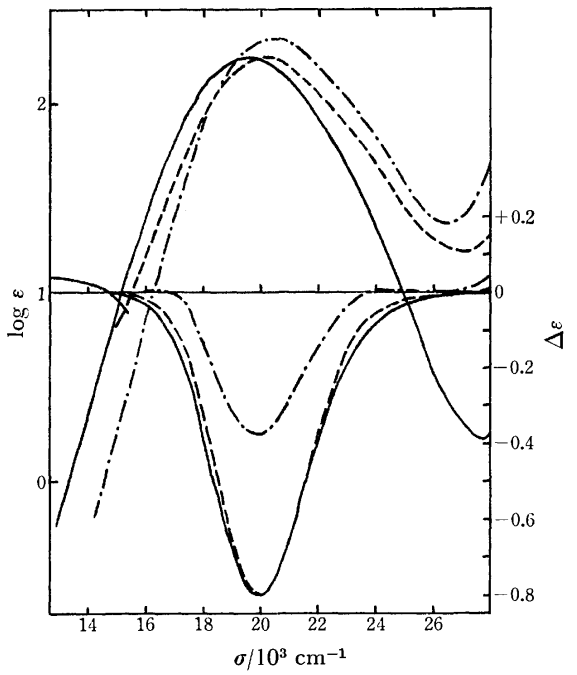

Fig. 4. Absorption and CD spectra of [Cu(L,L-balaen)] in water (——), in ethanol (----), and in DMF (-·-·).

respective solvents. However, attempts to prepare the monomeric balaen complex, [Pd(L,L-balaen)], under similar conditions to those adopted for the balatn analog, have so far been unsuccessful. The results are understandable if palladium(II) ion were of favorable size for balatn to form a stable mononuclear complex but not for balaen. However, this is not the case, since available data of X-ray analyses[11] show that metal–nitrogen distances are nearly equal to each other

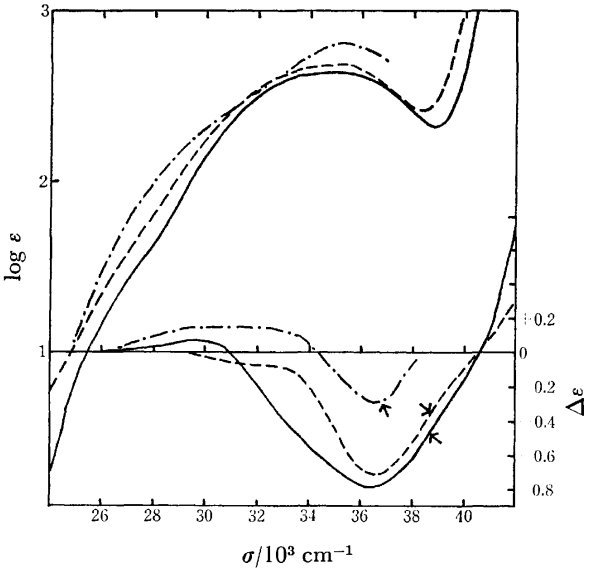

Fig. 5. Absorption and CD spectra of [Pd(L,L-balatn)] in water (——), in ethanol (----), and in DMF (-·-·). Arrows signify the terminal points of input data used in the Gaussian analyses.

between some square-planar complexes of palladium(II) and of copper(II).

CD Correspondence between Palladium and Nickel Complexes. The CD spectra of [Pd(L,L-balatn)] apparently resemble those of the nickel analog (Figs. 1 and 5). Thus Gaussian analyses (Table 3) are expected to disclose the relationship between the spectra of both complexes in more detail. Since the three component bands of the nickel complex have comparable absorption intensities, they should correspond to the second, third, and fourth components (Table 3) of the palladium complex. For the corresponding components of *cis*-bis(amino carboxamidato)palladium(II) complexes, three of the four spin-allowed d-d transitions, ν_3', ν_2', and ν_4', respectively, have already been assigned.[4,12] As regards the three components, the CD sign patterns for the nickel complex coincide with those for the palladium complex in ethanol and in DMF solutions.[13] It might be concluded that the first, second, and third components of [Ni(L,L-balatn)] should correspond to the second, third, and fourth of the palladium analog, respectively. Thus a definite correspondence was found between the ligand field bands of nickel(II) and of palladium(II) complexes with *cis*-bis(amino carboxamidato) type, as already found for the trans analogs.

The CD-sign patterns of [Ni(L,L-balaen)] differ from those of the balatn analog in aqueous and DMF solution (Table 3 and Figs. 1 and 2), but differ from that of *cis*-bis(L-valinamidato)palladium(II) only in aqueous solution. Gaussian analyses for the last complex showed (−,+,−) pattern in water, ethanol and DMF. A question still remains about the (−,−,−) pattern of the balaen complex in aqueous solution.

Band Assignment for the Copper Complexes. There are at least three components at roughly 17000, 19000, and 21000—22000 cm^{-1} in the ligand field band region of bis(amino carboxamidato)copper(II) complexes and the three components have been tentatively assigned to

the electronic transitions, ν_2, ν_3, and ν_4, respectively.[4] However, there are many copper complexes that exhibit a small positive extremum on the longer wavenumber end of CD spectrum.[2,4] In most cases it seems inadequate to regard the extremum as a residue of compensation among those three components. This is also the case for [Cu(L,L-balaen)] in DMF (Fig. 4).

Let us reexamine the four components inferred to exist in the ligand field band region of the copper complexes. The balatn and the balaen complexes (Figs. 3 and 4) display similar CD patterns to the bis(L-amino carboxamidato) complexes with alaninamidato, leucinamidato, and valinamidato ligands, although the latter complexes may be trans or predominantly so in the solutions. It seems reasonable to assume that the d-level orderings are essentially the same for the *trans* and *cis* complexes of bis(amino carboxamidato) type.

The order $\nu_2<\nu_3<\nu_4$ has been inferred for the trans complexes.[4] The corresponding order $\nu_2'<\nu_3'<\nu_4'$ should hold for the *cis*-type complexes with balatn and balaen.

The second and third CD components, which closely overlap each other to give a negative extremum in most of the complexes including [Cu(L,L-balatn)] and [Cu(L,L-balaen)], are much larger than the others, having net negative sign.[2] For most of the similar nickel or palladium complexes, the two components due to ν_3 and ν_4 (or ν_3' and ν_4') exhibit large and net negative CD, irrespective of the geometrical structures.

Thus it is preferable to assign the four components of the copper complexes to the transitions ν_2', ν_3', ν_4', and ν_1' (or ν_2, ν_3, ν_4, and ν_1), respectively, in the order of increasing wavenumbers.

The assignment is supported by the following observations: (1) The component due to ν_2 corresponds to a positive CD band in most of the bis(L-amino carboxamidato)-type complexes irrespective of the central metal ions and geometrical structures, (2) the component due to ν_1, which can be found only in the copper complexes, exhibits a small positive CD extremum or none in most cases (Table 2 and Figs. 3 and 4).[2] This is in line with the theory that the transition ν_1 is magnetically forbidden in first-order approximation.[14] Remarkable exceptions to (2) are the ν_1 components of the L-prolinamidato, L-phenylalaninamidato, and (*S*)-2-amino-4-methyl-*N*-methylpentanamidato complexes; the ν_1 component seems to correspond to a large negative CD extremum in these complexes.

12) ν_1, ν_2, ν_3, and ν_4 denote transitions from (z^2), (xy), (xz), and (yz) to (x^2-y^2), and ν_1', ν_2', ν_3', and ν_4' those from (z^2), (x^2-y^2), (xz), and (yz) to (xy), respectively, where (k) indicates a molecular orbital composed mainly of d_k-orbital. The x axis is fixed to be nearly colinear with metal–N(amido) linkage in *trans*-bis(amino carboxamidato) complex, but to bisect N–metal–N angle within each chelate ring in *cis* complex. The y axis is fixed also within coordination square in both *trans* and *cis* complexes.
13) The output data of CD analysis for [Ni(L,L-balatn)] in aqueous solution may be relatively unreliable regarding the first two components since these heavily overlap each other.
14) This means that the matrix element of electronic angular momentum, $\langle d_{x^2-y^2}|l_i|d_{z^2}\rangle$, is equal to zero irrespective of chromophore symmetries, where i=x, y, or z.

Palladium(II) Complexes Derived from the Reactions of Bis-(3-hydroxy-2-methyl-4-pyronato)palladium(II) with Several Nitrogen Bases

(Received November 8, 1978)

The preparation and properties of the palladium(II) amine complexes containing 3-hydroxy-2-methyl-4-pyronate ions as the counter anions, $[Pd(N)_4]L_2$ and $[Pd(NN)_2]L_2 \cdot nH_2O$, are reported, where N=propylamine or benzylamine, NN=ethylenediamine, trimethylenediamine or *N,N*-dimethylethylenediamine, HL=3-hydroxy-2-methyl-4-pyrone, and n=2—4. The unidentate-amine complex, $[Pd(N)_4]L_2$, reacts with NaI to afford $[PdI_2(N)_2]$, whereas the bidentate-amine complex, $[Pd(NN)_2]L_2 \cdot nH_2O$, reacts with NaI to give $[Pd(NN)_2]I_2$. The mixed-ligand complexes, [PdL(bpy)]X and [PdL(phen)]X (where bpy=2,2′-bipyridine, phen=1,10-phenanthroline, X=ClO_4 or $B(C_6H_5)_4$), are also reported. On the basis of the PMR spectra, the IR spectra, and the electric conductivities, the structures of the isolated complexes are discussed.

3-Hydroxy-2-methyl-4-pyrone (HL) has some resemblance to the β-diketones, all being monobasic acids and usually functioning as O,O′-chelating agents.[1,2] The bis-chelates of these ligands with bivalent metal ions, such as Co(II), Ni(II), and Zn(II), react with nitrogen bases to form five- or six-coordinate adducts.[3,4] On the other hand, the corresponding Pd(II) complexes, $[Pd(\beta\text{-dik})_2]$, react with an excess of amine to afford $[Pd(\beta\text{-dik})(amine)_2](\beta\text{-dik})$ or $[Pd(amine)_4](\beta\text{-dik})_2$, depending upon whether the amine is secondary or primary respectively.[5] As was reported in a preliminary communication,[6] the Pd(II) complex of 3-hydroxy-2-methyl-4-pyrone, PdL_2, also reacts with ethylenediamine to result in $[Pd(en)_2]L_2 \cdot 2H_2O$. As an extension of this study, the present paper will report on the syntheses and properties of several Pd(II) amine complexes containing the 3-hydroxy-2-methyl-4-pyronate anion as a counter ion. The complexes obtained by the reactions of the above Pd(II) amine complexes with sodium iodide or lithium bromide will also be described.

Experimental

*Preparation of Complexes. Bis(3-hydroxy-2-methyl-4-pyronato)palladium(II), $[PdL_2]$ (**1**).* Palladium(II) chloride (10 mmol) was dissolved in a hot aqueous solution (100 ml) of NaCl (15 g), after which the mixture was cooled to 0—5 °C in an ice-bath. Into this solution we then vigorously stirred, a cold aqueous solution (0—5 °C, 50 ml) containing HL (20 mmol) and NaOH (20 mmol). A brown precipitate was formed immediately. After the solution had been stirred for 1 h at room temperature, a crude precipitate was filtered; this was then dissolved in chloroform (400 ml) at 40—50 °C. After the filtration of the insoluble materials, the solvent was evaporated at 35 °C. The brown residue was washed with ethanol and ether and then dried *in vacuo*. Yield: 86 %.

*Tetrakis(propylamine)palladium(II) 3-Hydroxy-2-methyl-4-pyronate, $[Pd(pa)_4]L_2$ (**2a**)*: Complex **1** (1.5 mmol) was dissolved in 10 ml of benzene containing propylamine (8 mmol) at room temperature. After the removal of the insoluble materials by filtration, the solvent was evaporated at *ca.* 25 °C. A white residue was collected on a glass filter, washed with cold acetone, and dried *in vacuo*. Yield: 40 %. By using benzylamine instead of propylamine, a white precipitate of $[Pd(ba)_4]L_2$ (**2b**) was also obtained in a 50 % yield.

*Bis(ethylenediamine)palladium(II) 3-Hydroxy-2-methyl-4-pyronate Dihydrate, $[Pd(en)_2]L_2 \cdot 2H_2O$ (**3a**)*: To a stirred suspension of Compound **1** (1.5 mmol) in chloroform (10 ml) we added a chloroform solution (10 ml) of ethylenediamine (10 mmol), after which the mixture was stirred for 30 min. A pale yellow precipitate was filtered and washed with cold ethanol and ether. The precipiate was then dissolved in warm ethanol (15 ml). After the removal of the insoluble materials by filtration, ether (100 ml) was added to the pale yellow filtrate. The white precipitate thus obtained was filtered, washed with cold ethanol and ether, and then dried *in vacuo*. Yield: 64 %.

*Bis(trimethylenediamine)palladium(II) 3-Hydroxy-2-methyl-4-pyronate–Water(1/2.5), $[Pd(tn)_2]L_2 \cdot 2.5H_2O$ (**3b**)*: To a stirred suspension of Compound **1** (1.5 mmol) in benzene (6 ml) we added a benzene solution (20 ml) of trimethylenediamine (40 mmol), after which the mixture was stirred for *ca.* 2 h. The crude pale yellow precipitate thus obtained was filtered and washed with ether. The precipitate was then dissolved in ethanol (15 ml). After the removal of the insoluble materials by filtration, ether (150 ml) was added to the pale yellow filtrate to obtain a white precipitate, which was then filtered washed with ether, and dried *in vacuo*. Yield: 67 %.

*Bis(N,N-dimethylethylenediamine)palladium(II) 3-Hydroxy-2-methyl-4-pyronate Tetrahydrate, $[Pd(N,N\text{-}Me_2en)_2]L_2 \cdot 4H_2O$ (**3c**)*: To a stirred suspension of Compound **1** (1.5 mmol) in benzene (6 ml) we added a benzene–ethanol (5:2 by volume) solution (14 ml) containing *N,N*-dimethylethylenediamine (10 mmol), after which the mixture was stirred for *ca.* 1 h. After the removal of the insoluble materials by filtration, the solvent was evaporated at *ca.* 27 °C. The white residue was collected on a glass filter, washed with ether, and dried *in vacuo*. Yield: 74 %.

*(2,2′-Bipyridine)(3-hydroxy-2-methyl-4-pyronato)palladium(II) 3-Hydroxy-2-methyl-4-pyronate, [PdL(bpy)]L (**4a**)*: To a stirred suspension of Compound **1** (3 mmol) in chloroform (15 ml) we added a chloroform solution (2 ml) of 2,2′-bipyridine (3 mmol), after which the mixture was stirred for *ca.* 1 h. The yellow precipitate thus obtained was filtered, washed with chloroform and ether, and then dried *in vacuo*. Yield: 76 %. This compound is fairly hygroscopic, and a color change from yellow to reddish yellow occurs in the presence of moisture. By using 1,10-phenanthroline instead of 2,2′-bipyridine, a yellow precipitate of [PdL(phen)]L (**4b**) was also obtained in a 43 % yield. This compound is also hygroscopic, and a change in color to reddish yellow also takes place in the presence of moisture.

Although we could not isolate Compounds **4a** and **4b** in a satisfactory purity, as the analytical data in Table 1 indicate, we obtained stable complex salts, **4c**—**4f**, by replacing the counter ion, L, with a perchlorate or tetraphenylborate anion.

(2,2'-Bipyridine)(3-hydroxy-2-methyl-4-pyronato)palladium(II) Perchlorate, [PdL(bpy)]ClO$_4$ (4c): To an aqueous ethanol (1: 1 by volume) solution (40 ml) of 2,2'-bipyridine (1.5 mmol) we added Compound **1** (1.5 mmol); then we stirred the mixture for *ca.* 1 h at room temperature. After the removal of the insoluble materials by filtration, an aqueous solution (10 ml) of $NaClO_4$–H_2O (1.5 mmol) was added to the yellow filtrate. The yellow precipitate thus obtained was filtered, washed with water, ethanol, and ether successively, and then dried *in vacuo*. Yield: 73 %. By using $NaB(C_6H_5)_4$ in place of $NaClO_4 \cdot H_2O$, a yellow precipitate of $[PdL(bpy)]B(C_6H_5)_4$ (**4d**) was also obtained in a 71 % yield.

The corresponding 1,10-phenanthroline complexes, [PdL(phen)]ClO$_4$ (**4e**) and $[PdL(phen)]B(C_6H_5)_4$ (**4f**), were obtained as yellow precipitates by the same methods as were used for Compounds **4c** and **4d** respectively, using 1,10-phenanthroline instead of 2,2'-bipyridine. The yields were 80 and 76 % respectively.

Reactions of [Pd(N)$_4$]L$_2$ (2) and [Pd(NN)$_2$]L$_2 \cdot n$H$_2$O (3) with Sodium Iodide. To an ethanol solution (5 ml) containing Compound **2a** (0.5 mmol) we added an ethanol solution (3 ml) of NaI (1.0 mmol), after which the mixture was stirred for *ca.* 45 min. The red brown precipitate thus obtained, $[PdI_2(pa)_2]$, was filtered, washed with ethanol and then ether, and dried *in vacuo*. Yield: 60 %. (Found: C, 14.95; H, 3.84; N, 5.60 %. Calcd for $[PdI_2(pa)_2] = C_6H_{18}N_2I_2Pd$: C, 15.06; H, 3.79; N, 5.86 %.) Other compounds, $[PdI_2(ba)_2]$, $[Pd(en)_2]I_2$, $[Pd(tn)_2]I_2$, and $[Pd(N,N\text{-}Me_2en)_2]I_2$, were also obtained similarly from the reactions of Compounds **2b**, **3a**, **3b**, and **3c** with NaI, in the mole ratio of one to two in each case. (Found for $[PdI_2(ba)_2]$: C, 29.08; H, 3.13; N, 4.90 %. Calcd for $C_{14}H_{18}N_2I_2Pd$: C, 29.27; H, 3.16; N, 4.88 %. Found for $[Pd(en)_2]I_2$: C, 10.41; H, 3.45; N, 11.72 %. Calcd for $C_4H_{16}N_4I_2Pd$: C, 10.00; H, 3.36; N, 11.66 %. Found for $[Pd(tn)_2]I_2$: C, 14.19; H, 4.08; N, 10.84 %. Calcd for $C_6H_{20}N_4I_2Pd$: C, 14.17; H, 3.96; N, 11.02 %. Found for $[Pd(N,N\text{-}Me_2en)_2]I_2$: C, 17.92; H, 4.52; N, 10.39 %. Calcd for $C_8H_{24}N_4I_2Pd$: C, 17.91; H, 4.51; N, 10.44 %.)

Reaction of [PdL(bpy or phen)]L with Lithium Bromide and Sodium Iodide. An ethanol solution (10 ml) of LiBr–H_2O (15 mmol) was stirred into a yellow aqueous ethanol solution (1: 3 by volume) of [PdL(bpy)]L (1.5 mmol) *in situ*. After the stirring had continued for *ca.* 40 min, the yellowish brown precipitate thus obtained was filtered, washed with ethanol and ether, and then *in vacuo*. Yield: 70 %. (Found: C, 28.42; H, 1.89; N, 6.43 %. Calcd for $[PdBr_2(bpy)] = C_{10}H_8N_2Br_2Pd$: C, 28.44; H, 1.91; N, 6.63 %.) By using phen instead of bpy, a yellowish brown precipitate of $[PdBr_2(phen)]$ was obtained in an 82 % yield (Found: C, 33.29; H, 1.98; N, 6.03 %. Calcd for $[PdBr_2(phen)] = C_{12}H_8N_2Br_2Pd$: C, 32.29; H, 1.81; N, 6.28 %.). The corresponding iodo complexes, $[PdI_2(bpy)]$ and $[PdI_2(phen)]$, were also obtained similarly as red brown precipitates from the reactions of [PdL(bpy or phen)]L with twice as many moles of NaI (Found: C, 23.92; H, 1.75; N, 5.32 %. Calcd for $[PdI_2(bpy)] = C_{10}H_8N_2I_2Pd$: C, 23.26; H, 1.56; N, 5.42 %. and Found: C, 27.49; H, 1.56; N, 5.18 %. Calcd for $[PdI_2(phen)] = C_{12}H_8N_2I_2Pd$: C, 26.67; H, 1.49; N, 5.18 %.).

Measurements. The IR spectra in the 200—4000 cm^{-1} region were recorded on a JASCO DS-701G infrared spectrophotometer in Nujol mulls between CsI plates. The PMR spectra were obtained with a JEOL JNM-PS-100 spectrometer. The water contents in the hydrated complexes were determined from the thermogravimetric curves, which had themselves been obtained with a Shimadzu TGA-30 thermobalance at a heating rate of 5 °C/min in an atmosphere of nitrogen flowing at 50 ml/min. The electric conductivities of the solutions were measured with a Toa Electronics CM-2A conductivity meter. The molecular weight was determined with a Hitachi Perkin-Elmer 115-type vapor-pressure osmometer, employing benzil as the reference substance.

Results and Discussion

Bis(3-hydroxy-2-methyl-4-pyronato)palladium(II), $[PdL_2]$ (**1**), reacts with an excess amount of an aliphatic amine to give a complex of the $[Pd(N)_4]L_2$ type (**2**) (where N is propylamine (pa) (**2a**) or benzylamine (ba) (**2b**)) or the $[Pd(NN)_2]L_2 \cdot n$H$_2$O type (**3**) (where NN is ethylenediamine (en) (**3a**), trimethylenediamine (tn) (**3b**), or *N,N*-dimethylethylenediamine(*N,N*-Me$_2$en) (**3c**)). These Pd(II) amine complexes contain the 3-hydroxy-2-methyl-4-pyronate ion as counter anions. When Compounds **2a** and **2b**, which have monodentate amines, were reacted with twice as many moles of NaI, two of the coordinated amines were replaced by two iodide anions to afford neutral complexes, $[PdI_2(pa)_2]$ and $[PdI_2(ba)_2]$ respectively. On the other hand, when Compounds **3a**, **3b**, and **3c**, which have bidentate amines, were treated with twice as many moles of NaI, the 3-hydroxy-2-methyl-4-pyronate ions were replaced by iodide anions to give $[Pd(en)_2]I_2$, $[Pd(tn)_2]I_2$, and $[Pd(N,N\text{-}Me_2en)_2]I_2$ respectively.

The parent complex, Complex **1**, reacts with an equimolar amount of a heterocyclic nitrogen base such as bpy and phen to give rise to [PdL(bpy or phen)]L, (**4a**, **4b**). Even when twice as many or more moles of bpy or phen were used, a complex of the $[Pd(NN)_2]L_2$ type was not afforded, but **4a** or **4b** resulted. Although Compounds **4a** and **4b** could not be isolated in a satisfactory purity, their PMR spectra in the intact solutions indicate unequivocally that two kinds of L exist, one in the coordination sphere and the other in the outer sphere (Table 2). By replacing the counter ion, L, with perchlorate and tetraphenylborate anions, stable complex salts, **4c**—**4f**, were obtained. When the ethanol solutions of **4a** and **4b** *in situ* were treated with an excess amount of LiBr$\cdot$H$_2$O or twice as many moles of NaI, the coordinated 3-hydroxy-2-methyl-4-pyronate ligand was replaced by two bromide or iodide ions to give $[PdX_2(bpy \text{ or } phen)]$, where X is Br or I. The analytical and IR data of the newly isolated compounds are listed in Tables 1 and 3 respectively.

[PdL$_2$] (1). Compound **1** exhibits strong IR bands at 1600, 1564, and 1545 cm^{-1}; the former band can be assinged to the C=O, and the latter two, to the C=C stretching vibrations, by reference to the data of the other metal complexes of 3-hydroxy-2-methyl-4-pyrone.[1] The band observed at 419 cm^{-1} can tentatively be assigned to the Pd–O stretching vibration by reference to the data of the bis(acetylacetonato)palladium(II).[7]

In the PMR spectrum of Compound **1** in $CDCl_3$, the signal of the 5-position proton is composed of two doublets, the area ratio of which is 1: 1, as is listed in

TABLE 1. COLOR AND ANALYTICAL DATA OF THE PALLADIUM(II) COMPLEXES

Complex		Color	Found (Calcd), %			
			C	H	N	H_2O
1	$[PdL_2]$	brown	40.26 (40.42)	2.90 (2.83)		
2a	$[Pd(pa)_4]L_2$	white	48.44 (48.61)	7.92 (7.82)	9.33 (9.45)	
2b	$[Pd(ba)_4]L_2$	white	61.41 (61.18)	6.15 (5.91)	6.99 (7.14)	
3a	$[Pd(en)_2]L_2 \cdot 2H_2O$	white	37.52 (37.47)	5.99 (5.90)	10.83 (10.92)	6.78 (7.03)
3b	$[Pd(tn)_2]L_2 \cdot 2.5H_2O$	white	39.01 (39.32)	6.67 (6.42)	10.61 (10.19)	7.43 (8.19)
3c	$[Pd(N,N\text{-}Me_2en)_2]L_2 \cdot 4H_2O$	white	39.80 (39.71)	7.16 (7.00)	9.15 (9.26)	11.69 (11.91)
4a	[PdL(bpy)]L	yellow	47.33 (51.53)	3.23 (3.54)	4.87 (5.46)	
4b	[PdL(phen)]L	yellow	51.11 (53.70)	3.31 (3.37)	4.87 (5.22)	
4c	$[PdL(bpy)]ClO_4$	yellow	38.91 (39.45)	2.68 (2.69)	5.67 (5.75)	
4d	$[PdL(bpy)]B(C_6H_5)_4$	yellow	67.90 (67.96)	4.68 (4.71)	3.83 (3.96)

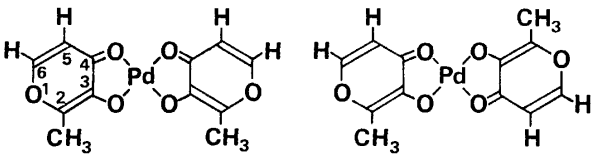
4f	1598	1566	1548		410			1633	1520		

Table 2. The spectral pattern suggests the coexistence of two different magnetic environments for the 5-position protons. The complex may exist as a mixture of *cis* and *trans* isomers, as is shown below:



cis *trans*

Whether the two carbonyl groups occupy mutually *cis* or *trans* positions seems to exert a different influence on the proton in question. The nearly equal intensities of the two signals at 6.29 and 6.52 ppm indicate that the *cis* and the *trans* isomers exist in equal amounts in chloroform, although the signal assignments to the two isomers are not possible. The methyl protons and the 6-position protons resonate as a singlet and a doublet respectively. Their insensitivity to the geometrical structure might arise from the fact that they are farther from the donor atoms than the 5-position protons.

Table 4. Molar conductivities of the palladium(II) complexes[a)]

Complex	Solvent	Λ_M
2a	H_2O	119

a) Molar conductivity of the 10^{-3} M solution at 25 °C ($ohm^{-1}\cdot cm^2\cdot mol^{-1}$).

$[Pd(N)_4]L_2$ (2). As may be seen in Table 3, these complexes exhibit the ν(C=O) and ν(C=C) bands at 1612 cm^{-1}, and at 1573 and 1515 cm^{-1}, respectively. The ν(C=O) frequency is slightly higher than that for **1**, but it is not diagnostic for the presence of L in the outer sphere. On the other hand, no band is observed in the Pd–O stretching region (400—500 cm^{-1}), suggesting that the 3-hydroxy-2-methyl-4-pyronate anion is not coordinated to the Pd(II) ion. The molar conductivity data (Table 4) indicate that Compound **2a** is a 1:2 electrolyte in water, while Compounds **2a** and **2b** do not dissociate completely in ethanol.[8)] The molecular-weight data of these complexes (Table 5) also show that they are partially dissociated in ethanol. During the measurements of the conductivity and the molecular

Table 5. Molecular-weight data for the $[Pd(N)_4]L_2$ complexes[a)]

Compound	Solvent	Temp °C	Concentration ($\times 10^{-3}$ M)	Calcd	Found
2a	EtOH	40	1.33	593	342
	EtOH	40	3.32		401
	EtOH	40	4.65		435
	$CHCl_3$	30	1.70		606[b)]
2b	EtOH	40	2.51	758	367
	$CHCl_3$	30	2.53		256[c)]

a) The molecular-weight values listed were determined *ca.* 30 min after dissolution. b) This value changed with the time, reaching 538 and 399 *ca.* 1 and 25 h after dissolution respectively. c) This value changed with the time, reaching 240 *ca.* 25 h after dissolution.

weight in ethanol, the color of the solution gradually changed from faintly yellow to yellow orange. These results seem to be caused by ionization and the following ligand substitution:

$$[Pd(N)_4]L_2 \rightleftarrows [PdL(N)_2]L + 2N \quad (1)$$

The molecular weight of **2a**, determined *ca.* 30 min after dissolution in chloroform, nearly coincides with the calculated value, reflecting poor ionization in this solvent, but the value diminishes with time, suggesting the gradual progress of the ligand substitution of **2a** according to Eq. 1.

In the PMR spectrum of **2a** in D_2O, the signals of the methyl, 5-position, and 6-position protons of 3-hydroxy-2-methyl-4-pyronate anion were observed at 2.75 s, 6.78 d ($J_{5,6}$=5.2 Hz), and 8.23 d ppm respectively. These values coincide with those for the protons of L in $[Pd(NN)_2]L_2\cdot nH_2O$ (**3**), which are 1:2 electrolytes in D_2O, suggesting again that **2a** dissociates completely in D_2O.

On the other hand, Table 5 shows that **2a** exists as the ion aggregate for at least 30 min after dissolution in chloroform; thereafter the substitution and decomposition occur gradually with time. Compound **2b** changes more rapidly in chloroform than does **2a**. The PMR data for **2a** and **2b** in chloroform (Table 2) were taken immediately after dissolution. The protons of L in **2b** resonate at a much higher field than these in **2a**. The benzylamine molecules in the coordination sphere may exert an anisotropic magnetic effect on L in the outer sphere.

Recently, Okeya *et al.*[9)] found that hydrogen exchange occurs between $CDCl_3$ and amine protons in palladium(II) amine complexes containing a β-diketonate anion in the outer sphere, $[PdL_4](\beta\text{-dik})_2$ and $[Pd(\beta\text{-dik})L'_2](\beta\text{-dik})$, where L=primary amine, L'=secondary amine, and β-dikH=acetylacetone or trifluoroacetylacetone. In the present PMR studies of **2a** and **2b** in $CDCl_3$, the hydrogen-exchange reactions between $CDCl_3$ and propylamine and benzylamine are also observed, the signal due to the amine proton diminishing and the peak due to $CHCl_3$ growing concurrently with time (Fig. 1). The pK_a value of HL (8.61)[10)] is near that of acetylacetone (8.82),[10)] and the pyronate anion, L, in

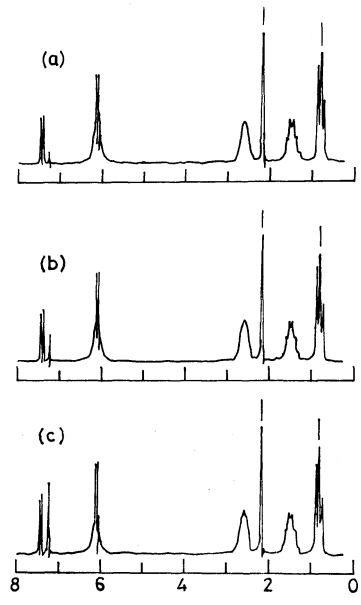

Fig. 1. The PMR spectra of $[Pd(pa)_4]L_2$ [**2a**] in $CDCl_3$ 5 min (a), 30 min (b) and 100 min (c) after dissolution, respectively.

the outer sphere may accept a hydrogen ion from the amine in the coordination sphere:

$$[Pd(RNH_2)_4]^{2+}(L^-)_2 \rightleftarrows [Pd(RNH)(RNH_2)_3]^+L^-(HL) \quad (2)$$

$$[Pd(RNH)(RNH_2)_3]^+L^-(HL) + CDCl_3 \longrightarrow [Pd(RNHD)(RNH_2)_3]^{2+}(L^-)_2 + CHCl_3 \quad (3)$$

$[Pd(NN)_2]L_2 \cdot nH_2O$ (3). The water contents of **3a**, **3b**, and **3c** were determined from the thermogravimetric curves of these complexes. The TG curves show that the liberation of the water occurs at around 45—110 °C in either case. In the IR spectra of the dehydrated complexes, the intensity of the fairly strong and broad bands which appeared at 3170 (**3a**), at 3460 and 3340 (**3b**), and at 3325 and 3180 (**3c**) cm^{-1}, diminished, although none of these bands except the 3460 and 3340 cm^{-1} bands disappeared completely. These results suggest that the bands observed in the 3170—3460 cm^{-1} region are mainly due to the O–H stretching vibration, although the NH_2 stretching bands also appear in this region. These complexes exhibit no band in the Pd–O stretching region, but they do show the Pd–N stretching and N–Pd–N bending bands, suggesting that L is contained in the outer sphere, as in the cases of **2a** and **2b**. The tentative assignment of the ν(Pd–N) and δ(N–Pd–N) bands is based on the data for $[Pd(en)_2]X_2$ (where X=Cl, Br, or I).[11] The molar conductivity data of these complexes also indicate that all three complexes are 1:2 electrolytes in water.

In the PMR spectra of these complexes in D_2O, the signals due to the methyl, 5-position, and 6-position protons of the 3-hydroxy-2-methyl-4-pyronate anion were observed at about 2.72 s, 6.75 d, and 8.22 d ppm respectively, as is shown in Table 2. Although *cis* and *trans* isomers are possible for Compound **3c**, the methyl and methylene $-C\underline{H}_2-NH_2$ protons of *N,N*-dimethylethylenediamine appear as a kind of singlet and a kind of multiplet at 3.05 and 3.26 ppm respectively, while the methylene $-C\underline{H}_2-N-(CH_3)_2$ protons overlap with the methyl protons of *N,N*-Me_2en. This spectral behavior seems to suggest that **3c** exists in D_2O solely as the *trans* or *cis* isomer or that, alternatively, the two isomers exhibit identical chemical shifts by chance.

The counter anion, L, in $[Pd(NN)_2]L_2 \cdot nH_2O$ (**3**) can readily be replaced by treating it with double the molar amount of sodium iodide in ethanol to precipitate the $[Pd(NN)_2]I_2$ complex in a 75—85% yield. This behavior is contrasted with that of the unidentate-amine complex, Complex **2**, which readily reacts with sodium iodide in ethanol to precipitate $[PdI_2(N)_2]$. The bidentate-amine in **3** is bonded to Pd(II) much more strongly than is the unidentate-amine in **2** and resists being displaced by the iodide ion.

$[PdL(bpy\ or\ phen)]X$ ($X=ClO_4$ or $B(C_6H_5)_4$) (4). The infrared data of these complexes suggest that: (a) The perchlorate ion is not coordinated to the palladium ion, since the bands at 1070—1110 *vs.* and 622 cm^{-1} assigned to the perchlorate ion are not split in Compounds **4c** and **4e**. (b) The bpy ligand is coordinated to the palladium ion, since the characteristic band (751 cm^{-1}) of the free bpy is shifted and split to 765 and 720 cm^{-1} in **4c** and **4d**.[12] (c) The phen ligand is coordinated to the palladium ion, since the characteristic bands (1505 and 1605 cm^{-1}) of the free phen are shifted to 1520 and 1632 cm^{-1} respectively in **4e** and **4f**.[13] (d) The 3-hydroxy-2-methyl-4-pyronate anion is coordinated to the palladium ion, since the band (410 cm^{-1}) assignable to the Pd–O stretching vibration is observed for all the complexes, **4c**, **4d**, **4e**, and **4f**. The molar conductivity data of **4c** and **4e** indicate that these complexes are 1:1 electrolytes in dimethyl sulfoxide,[8] supporting the idea that the perchlorate ion is not coordinated to the palladium ion. Compounds **4d** and **4f** are not soluble in common solvents and prevent any conductivity measurement. In the PMR spectrum of **4c** in $(CD_3)_2SO$, the signals of the methyl protons and the 5-position proton of the pyronate ligand were observed at 2.20 s and 6.53 d ppm ($J_{5,6}=5.2$ Hz) respectively, but no signal of the 6-position proton is discernible because of overlapping with the bpy resonances. The appearance of one kind of doublet due to the 5-position proton is in accordance with the lack of geometrical isomers for this complex, contrary to the coexistence of the *cis*- and *trans*-$[PdL_2]$ isomers in the $CDCl_3$ solution. Unfortunately, **4e**, like **4d** and **4f**, is not soluble enough in common solvents to give PMR spectra.

The authors would like to thank Miss Yoshimi Murooka and Miss Keiko Fujita for their experimental assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Separation of Tin from Water and Sea-water by Flotation and the Determination of Tin by Atomic Absorption Spectrophotometry Following Stannane Generation

Susumu NAKASHIMA

Institute for Agricultural and Biological Sciences, Okayama University, Kurashiki-shi, Okayama 710

(Received November 30, 1978)

A method is described for the separation and determination of sub-microgram levels of tin in water. A sub-microgram amount of tin(II, IV) in a 1000-ml sample of water is coprecipitated with iron(III) hydroxide at pH 4.0 ± 0.2. The precipitate is floated with the aid of sodium dodecyl sulfate and small air bubbles, and then separated and dissolved in 2 ml of 6 M hydrochloric acid and diluted to 10 ml with water. Finally, the tin content is determined by the generation of stannane, using sodium borohydride as a reductant, followed by atomic absorption spectrophotometry with a long absorption cell (60×1.2 cm i.d.). This separation technique has also been successfully applied to the determination of sub-microgram amounts of tin in natural sea-water. The time required for the pre-concentration of tin from a 1000-ml volume of solution is about 15 min per sample after 15 min of stirring.

It is important to establish a rapid, sensitive, and accurate method to determine tin in natural waters from the viewpoints of environmental chemistry, geochemistry, marine biology, and limnology. Tin has so far received little attention as an environmental pollutant in natural waters. Furthermore, almost nothing is known about the tin content in natural waters. Tin probably exists at concentrations below 1 $\mu g\ l^{-1}$ in natural water samples. At such low concentrations, a precise, direct determination is impractical, even by the atomic absorption spectrophotometry of stannane, which has a high sensitivity.[1-3] In addition, nickel(II) causes serious negative interference in the determination of tin by the above hydride-generation method. Hence, it is necessary to pre-concentrate tin from water and separate it from nickel(II) prior to determination.

Coprecipitation with iron(III) hydroxide[4-6] or zirconium hydroxide[7,8] is used as a pre-concentration technique for the determination of tin in aqueous systems. These bulky amorphous precipitates, however, are difficult to filter, and centrifugation is cumbersome for larger volumes.

Mizuike and Hiraide[9] reported a flotation technique carried out with the aid of a hot ethanolic paraffin solution and small nitrogen bubbles for the separation of the tin(IV) coprecipitated with iron(III) hydroxide. This separation technique was successfully applied to the spectrophotometric determination of tin at the ppb level in high-purity zinc metal.

In a previous paper,[10] a flotation technique[9,11,12] in which the precipitate of iron(III) hydroxide is floated with the aid of sodium oleate and small air bubbles was used for the pre-concentration of arsenic in natural non-saline waters.

This communication will describe the application of this separation technique, with suitable modifications, to the pre-concentration of sub-microgram amounts of tin(II, IV) in water. The precipitate is readily separated from the mother liquor and then dissolved in dilute hydrochloric acid for the atomic absorption spectrophotometry by the generation of stannane, using sodium borohydride as a reductant. The various parameters that affect the flotation and determination of tin were investigated. This method is simple and rapid, and it is applicable to the extraction of tin at low ppb levels from large volumes of water and sea-water.

Experimental

Apparatus. A Nippon Jarrell-Ash, Model AA-1 Mark II, atomic absorption spectrophotometer equipped with a Jarrell-Ash tin hollow-cathode lamp and a custom-made silica absorption cell (60×1.2 cm i.d.) was used, along with a Beckman burner supplied with nitrogen and hydrogen.

The apparatus used for the stannane generation was a modified Nippon Jarrell-Ash, Model ASD-1A, hydride-measurement unit coupled to a custom-made hydride-generating cell. The schematic diagram of the analytical system is similar to that described previously.[10]

All the pH measurements were carried out with a Hitachi-Horiba, Model M-5, pH meter, together with a combined glass electrode.

The flotation and separation apparatus was similar to that described by Mizuike and his coworkers.[11,12] The flotation cell was a glass cylinder, 40×6.5 cm i.d., which was fitted with a sintered-glass filter (No. 4) to generate small bubbles. A side arm was added near the bottom of the cell in order to drain out the mother liquor rapidly after the flotation, as is shown in Fig. 1.

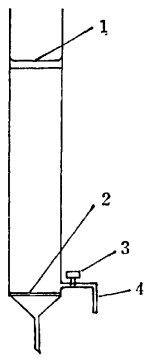

Fig. 1. Flotation cell for pre-concentration of tin.
1: Foam layer containing iron(III) hydroxide and tin, 2: sintered-glass disk (porosity 4), 3: cock, 4: drain pipe.

Reagents. All the reagents were of an analytical-reagent grade except for sodium dodecyl sulfate and sodium oleate. The aqueous reagents were prepared in de-ionized, distilled water. The tin standard solutions were freshly prepared by diluting stock solutions before use.

Tin(IV) Stock Solution (1 mg ml^{-1}): Some (500 mg) high-purity tin metal was dissolved in 40 ml of concentrated sulfuric acid by heating. After cooling, the solution was made up to 500 ml with 2 M hydrochloric acid.

Tin(II) Stock Solution (1 mg ml^{-1}): Some (950 mg) stannous chloride dihydrate was freshly dissolved in 50 ml of concentrated hydrochloric acid, and then the solution was made up to 500 ml in 2 M hydrochloric acid.

Iron(III) Solution (5 mg ml^{-1}): Some (43.17 g) ammonium iron sulfate was dissolved in water, after which the solution was diluted to 1000 ml in 1 M hydrochloric acid.

Sodium Dodecyl Sulfate Solution (1 mg ml^{-1}): Sodium dodecyl sulfate (powder, extra-pure reagent, Wako Pure Chemical Industries, Ltd.) was dissolved in 99.5 v/v % ethanol.

Sodium Oleate Solution (1 mg ml^{-1}): Sodium oleate (powder, extra-pure reagent, Wako Pure Chemical Industries, Ltd.) was dissolved in 99.5 v/v % ethanol with stirring.

Sodium Borohydride Solution (5 w/v %): This solution was used in a 0.1 M sodium hydroxide solution.

Procedure for the Flotation Step. One thousand ml of acidified water is placed in a 1000-ml beaker, and 2 ml of an iron(III) solution is added. The pH of the solution is adjusted to 4.0±0.2 with an aqueous ammonia solution, while being stirred magnetically, in order to precipitate iron(III) hydroxide, and the mixture is stirred for 15 min. After adding 2 ml of a sodium dodecyl sulfate solution to the beaker, the contents of the beaker are transferred to a flotation cell and the residue in the beaker is washed into the cell by using three small portions of water. Air is passed through at a flow rate of 50 ml min^{-1} from the lower end of the cell for about 2 min in order to obtain a complete mixing and flotation of the precipitate. Most of the mother liquor is drained from the side arm by opening the cock of the drain pipe. After closing the cock, the residual mother liquor is sucked off through the sintered-glass disk, and the precipitate is washed with 30 ml of water. Two ml of 6 M hydrochloric acid is added to the cell to dissolve the precipitate, the filtrate is collected by suction in a 10-ml calibrated flask, the sintered-glass disk is washed with water, the washings are added to the flask, and the mixture is diluted to 10 ml with water.

Procedure for the Determination of Tin. One ml of a freshly prepared 5 w/v % sodium borohydride solution is transferred into a stannane-generating cell and the cell is attached to the apparatus. A plastic syringe containing 1 ml of the sample solution is inserted into the side-arm seal of the cell. The four-way stopcock of the apparatus is turned to the sweep position in order to introduce nitrogen into the system, and the sample is injected into the cell. The stannane thus generated is swept into the long absorption cell with nitrogen and then atomized in the nitrogen-hydrogen flame, and the absorption signal is recorded on a recorder. The stopcock is returned to the by-pass position. The cell is carefully rinsed with distilled water.

A calibration curve is constructed using 1.2 M hydrochloric acid solutions containing 1.0 mg ml^{-1} of iron(III) and 0—0.10 μg ml^{-1} of tin(IV); this curve is linear within the above range of tin. The detection limit of tin was found to be 0.5 ng ml^{-1}. No appreciable difference in sensitivity was observed between tin(II) and tin(IV). The coefficients of variations were 1.5 and 1.4 % in 10 replicate runs of 0.04 and 0.08 μg ml^{-1} of tin(IV) respectively.

The atomic absorption apparatus was operated under the following conditions: wavelength, 286.3 nm; lamp current, 8 mA; gas-flow rates: nitrogen, 1.5; hydrogen, 1.5, and auxiliary nitrogen, 6 liter min^{-1}; slit (spectral band width), 1 nm.

Results and Discussion

The Optimum Conditions for the Determination of Tin. The effect of the sodium-borohydride concentration on the evolution of stannane was investigated. As is shown in Fig. 2, it was found that more than 3 w/v % of the reductant concentration (1 ml volume) can quantitatively reduce up to 0.10 μg of tin to stannane. In this work, 1 ml of 5 w/v % of the solution was used.

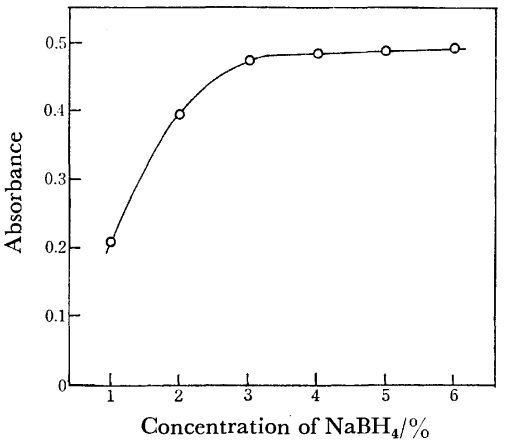

Fig. 2. Effect of sodium borohydride concentration on the evolution of stannane.
Solution containing 0.10 μg of Sn(IV), sample volume: 1 ml.

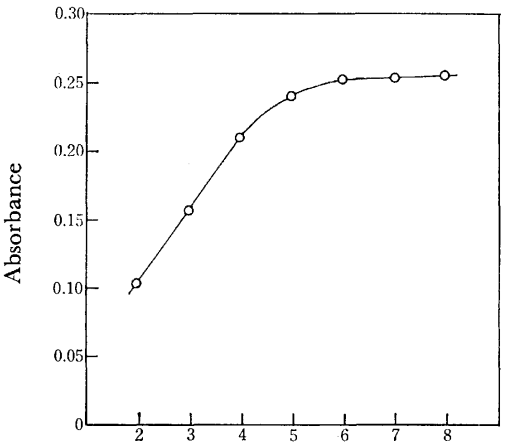

Fig. 3. Effect of nitrogen flow-rate on the evolution of stannane.
Solution containing 0.05 μg of Sn(IV), sample volume: 1 ml.

The optimum conditions for the sensitivity of tin were dependent on the flow rate of auxiliary nitrogen, as is shown in Fig. 3. The tin absorbance increased with an increase in the flow rate of auxiliary nitrogen up to 6 l min^{-1} when the flow rates of both nitrogen and hydrogen were 1.5 l min^{-1}. The optimum sensitivity was obtained with a flow rate of auxiliary nitrogen

between 6 and 8 l min^{-1}; a flow rate of auxiliary nitrogen of 6.0 l min^{-1} was, therefore, adopted throughout.

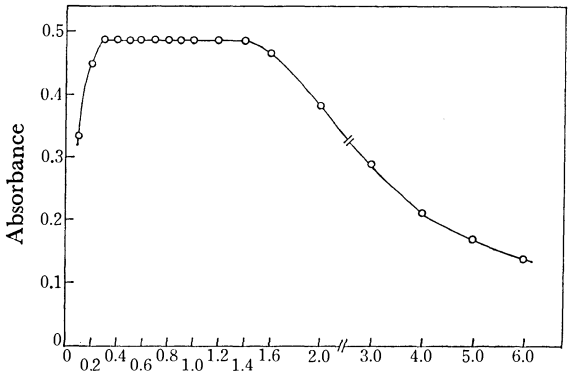

Fig. 4. Effect of hydrochloric acid concentration on the evolution of stannane.
Solution containing 0.10 μg of Sn(IV), sample volume: 1 ml.

Figure 4 shows the effect of the hydrochloric-acid concentration on the generation of stannane. The optimal concentration of hydrochloric acid is between 0.3—1.4 M and is critical because of the pronounced decrease in sensitivity with an increase in the acid concentration. Therefore, it is necessary to adjust the acid concentration of the sample solution carefully for reliable results. The use of a tin(II) solution gave similar results. Thus, the final acidity of hydrochloric acid was maintained at 1.2 M in further work.

The effect of iron(III) added as a collector on the generation of stannane was also studied. A slighter larger suppression (about 6%) of the tin absorbance was observed in the presence of 0.25—2.5 mg ml^{-1} of iron(III) in comparison with that in the absence of iron(III). Therefore, a calibration curve for tin was constructed using tin(IV) solutions containing 1.0 mg ml^{-1} of iron(III).

The Optimum Conditions for the Flotation of Tin.

Effect of pH: The effect of the pH of a 1000-ml solution containing 0.8 μg of tin(II, IV), 10 mg of iron(III) and 2.0 mg of surfactant on the coprecipitation of tin was studied. Hydrochloric acid and an aqueous ammonia solution was used to adjust the pH to values within the range of 3.4—10.0. The results are shown in Fig. 5. Quantitative recoveries of both the divalent and the tetravalent states of tin were obtained over this range, as well as in the case of arsenic(III, V).[10] The most stable layer of surface foam supporting the precipitate of iron(III) hydroxide when sodium dodecyl sulfate was

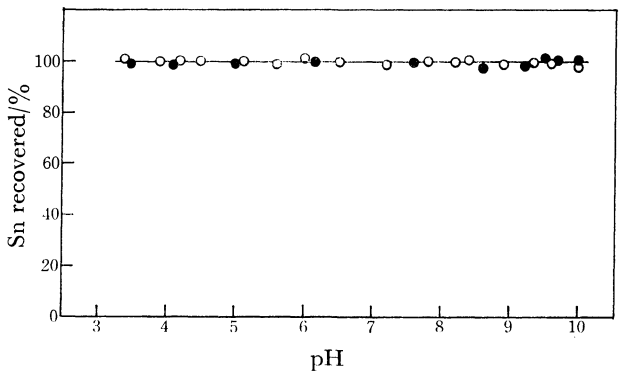

Fig. 5. Coprecipitation of tin with iron(III) hydroxide as a function of pH.
Solution containing 0.8 μg of Sn and 10 mg of Fe(III), sample volume: 1000 ml, ●: Sn(II), ○: Sn(IV).

used was found within the pH range of 3.4—7.0; the pH of 4.0±0.2 was, therefore, used throughout the work. At a pH above 7, a stable surface-foam layer was obtained by using sodium oleate as a surfactant.

Amounts of Iron(III) and Surfactant: The recovery of tin as a function of the amount of iron(III) added to the solution is given in Table 1. Quantitative recoveries of tin were obtained above 5.0 mg of iron(III). In this work, therefore, 10 mg of iron(III) was added to 1000 ml of a solution. The amount of sodium dodecyl sulfate required for the complete flotation of the precipitate was also studied. Quantitative recoveries of tin were obtained between 0.5—8.0 mg of sodium dodecyl sulfate, and so 2.0 mg of it in a 1000 ml solution was added in further work.

Stirring Time: The relation between the stirring time and the recovery of tin was investigated. The results are shown in Table 2. Coprecipitation was quantitative over the range of 5—40 min; stirring for 15 min was found best.

Table 2. Relation between stirring time and recovery of tin[a)]

Stirring time (min)	5	10	15	20	25	30	40
Sn recovered (%)	95	99	100	98	99	102	100

a) Solution containing 0.8 μg of Sn(IV) and 10 mg of Fe(III); pH, 4.0±0.2; sample volume, 1000 ml.

Effect of Foreign Ions: By following the proposed procedure, the effects of various ions on the separation and determination of tin(IV) were investigated. Table 3 compares the permissible amounts of foreign ions for the determination of tin(IV) with and without coprecipitation. As can be seen, when coprecipitation at

Table 1. Relation between amount of iron(III) added and recovery of tin[a)]

Fe(III) added (mg)	2.5	5.0	7.5	10.0	15.0	20.0	25.0
Sn recovered (%)	91	99	100	99	99	100	101

a) Solution containing 0.8 μg of Sn(IV) and 2 mg of sodium dodecyl sulfate; pH, 4.0±0.2; sample volume, 1000 ml.

Table 3. Comparison of permissible amounts of foreign ions for determination of tin with and without coprecipitation

Ion	Limit, [Ion]/[Sn]		Ion	Limit, [Ion]/[Sn]	
	Direct[a]	With copptn[b]		Direct[a]	With copptn[b]
Mo^{6+}	600	1000	Sb^{3+}	100	100
Hg^{2+}	400	1000	Cu^{2+}	60	800
Te^{4+}	400	400	As^{3+}	50	50
Se^{6+}	200	1000	As^{5+}	50	50
Bi^{3+}	100	100	Se^{4+}	40	40
Co^{2+}	100	1000	Ni^{2+}	2	800

The following are tolerable: Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, SO_4^{2-}, NO_3^-, SiO_3^{2-} (excess, $\times 10000$), Sr^{2+}, Ba^{2+}, Cd^{2+}, Zn^{2+}, Mn^{2+}, Al^{3+}, Cr^{3+}, Cr^{6+}, Pb^{2+}, V^{5+}, PO_4^{3-} (excess, $\times 1000$). a) Solution containing 0.10 μg of Sn(IV); sample volume, 1 ml. b) Solution containing 1.0 μg of Sn(IV) and 10 mg of Fe(III); sample volume, 1000 ml.

pH 4.0±0.2 is used, most foreign ions normally present in natural waters hardly interfere at all with the determination of tin(IV), and suppressive effects by diverse ions, especially, those by nickel(II), copper(II), cobalt(II), selenium(VI) and mercury(II), were found to be largely eliminated in comparison with those which occur when tin is directly determined without coprecipitation. The values of the permissible amounts (Ion/Sn in weight) of these ions in the proposed method increased from 2, 60, 100, 200, and 400 to 800, 800, 1000, 1000, and 1000 for nickel(II), copper(II), cobalt(II), selenium(VI), and mercury(II) respectively, compared with the values permissible in the direct determination. However, hydride-forming elements, such as selenium(IV), antimony(III), arsenic(III, V) and bismuth(III), are coprecipitated with iron(III) hydroxide in the same way as tin and had a relatively great effect on the generation of stannane.

Recovery of Tin: The solutions (1000 ml) at pH 4.0±0.2 containing 10 mg of iron(III), 2.0 mg of sodium dodecyl sulfate, and 0.2, 0.4, 0.6, 0.8, 1.0, 2.0, 4.0, 6.0, 8.0, 10.0, 15.0, and 20.0 μg of tin(IV) were analyzed by the procedure described above. The recoveries of the tin that had been added were greater than 95% in all instances. No blank value was detected throughout the whole analytical process. The proposed conditions, therefore, appear to be optimal for 1000-ml volumes of a solution containing up to 20 μg of tin(IV).

The relative standard deviations of ten-times-repeated analyses of the solutions containing 0.4 and 0.8 μg of tin(IV) per 1000 ml were 2.4 and 2.3% respectively.

Applications to Natural Sea-water: In order to investigate the applicability of this method to sea-water, the recoveries of known amounts of tin(IV) added to natural sea-water samples taken up at two different locations were examined by the above procedure. The analyses were carried out 1000-ml aliquots of clear, uncontaminated sea-water, filtered through 0.45 μm Millipore filters after the addition of hydrochloric acid immediately after sampling. Table 4 presents the recovery data of the tin. These results indicate that the analytical process had a satisfactory recovery of tin from sea-water at pH 4.0±0.2. The average tin concentrations for both sea-water samples were low, 0.07 and 0.14 μg l^{-1}.

Table 4. Recovery of tin added to natural sea-water samples[a]

Tin added (μg)	Tin[b] found (μg)	Tin recovered (μg)	Mean recovery (%)	Tin in sample (μg l^{-1})	
None	0.139±0.004			0.14	c)
0.200	0.338±0.008	0.199	100		
None	0.068±0.003			0.07	d)
0.400	0.459±0.009	0.391	98		

a) Volume of sample, 1000 ml. b) The mean value of four measurements. c) This sample was taken at Shibukawa, Okayama Prefecture. d) This sample was taken at Ajino, Okayama Prefecture.

Hamaguchi *et al.*[5,6] reported an average of 0.81 μg l^{-1} in the range of 0.30—1.22 μg l^{-1} of the tin concentrations in four sea-water samples collected from the Pacific Ocean. Moreover, Kodama and Tsubota[13] reported that the tin concentrations in six water samples from the North Pacific ranged from 0.63 to 1.93 μg l^{-1}, showing an average of 1.15 μg l^{-1}. The reason for the discrepancy between the values reported in this work and those in the literature is not clear. A possible explanation may be that the former sea-water samples were collected near the seashore, and the latter ones, in the ocean.

Conclusions

The flotation of sub-microgram amounts of tin(II, IV) coprecipitated with iron(III) hydroxide is useful as a pre-concentration technique for the extraction of tin(II, IV) from a large volume of water, and subsequent atomic-absorption measurement in a long absorption cell of the stannane from the tin(II, IV) is an accurate method for the determination of tin. In addition, the satisfactory isolation of tin from such interfering ions as nickel(II) and copper(II) present in water is the advantage of the proposed method.

The author wishes to thank Professor Atsushi Mizuike and Dr. Masataka Hiraide of Nagoya University for their helpful advice on the flotation technique, and Assistant Professor Fuji Morii of Okayama University for her useful discussions.

C_2^- Ion as Impurity from Halogen Ion Source and a Possibility of Its Application to Reaction Kinetics Studies

Nobuyuki KASHIHIRA*,† and Egon VIETZKE

Institut für Chemie der Kernforschungsanlage Jülich GmbH, Institut 1: Nuklearchemie, 5170 Jülich, FRG

(Received August 16, 1978)

Synopsis. Negative ions from a hot LaB_6 surface were studied with a quadrupole mass filter. C_2^- ion was formed *via* a charge exchange process. About 10^{-11} A of mass-selected C_2^- ion current was obtained above 40 eV of ion energies. A possibility of employing this to study a reaction kinetics is discussed.

We constructed an ion source for the negative atomic halogen ions based on surface ionization[1,2] and successfully applied it to a study on the ion-molecule reactions of $Br^- + CH_4$,[3] $Br^- + CH_3F$.[4] The ion source delivered *ca.* 10^{-8} A of the atomic halogen ion current above 20 eV of the ion energy with caesium halide as the source material and LaB_6 as ionizing material. The ion beam was checked in terms of energy spread and purity. The intrinsic energy spread at the zero energy was found to be 0.55 eV[2] from measurement of dependence of the energy spread on ion energy with an electrostatic energy analyzer of parallel plate type. The purity of the beam was studied by mass analysis with a RF quadrupole mass filter. The result indicated that the ion beam is quite pure, no measurable amounts of impurity ions being observed.

In the present paper we report on the ionic impurities in the ion beam observed with more sensitive electrometer under optimal conditions for the minority ions but not necessarily for the main ion, and discuss their possible use as an ion beam. In the case of caesium bromide as the source material such negative ions as F^- ($m/e=19$), C_2^- ($m/e=24$), CN^- ($m/e=26$), O_2^- ($m/e=32$), and Cl^- ($m/e=35$ and 37) were observed as the minority ions besides Br^- ion, although their ion intensities were less than 100 ppm of Br^- ion under normal operating conditions and *ca.* 10^{-11} A for C_2^- ion with a kinetic energy of 40 eV and less for others under optimal conditions. As the Br^- ion,[1,2] the halogen ions Cl^- and F^- are formed by a negative surface ionization on the hot LaB_6 surface which has a small work function of 2.6 eV,[5] due to the large electron affinities of their neutral species, Br, Cl, and F being 3.54 eV, 3.76 eV and 3.58 eV, respectively.[6] Since the neutral species of these minority halogens exist as an impurity in CsBr, the contribution of the corresponding ions can be in the same order of magnitude as an impurity content.

Of the minority ions, the particularly interesting one is C_2^- ion which is the second abundant ionic species next to Br^- ion in the mass spectrum. Contrary to the halogens, the neutral species for C_2^- and CN^- ions may not be impurities of the source material but are formed only at the hot graphite surface as seen in an emission study with a graphite electrode. Furthermore, C_2 has the electron affinity of 3.54 eV[6] which is large enough to be surface ionized on the hot LaB_6 surface. However, the experimental result shows that no such ion was formed when no CsBr was supplied. Thus, it is concluded that C_2^- ion is not produced by the surface ionization. As an alternative process for the formation of this ion we assign the accidental near resonance charge exchange between Br^- and C_2, since the electron affinity of C_2 matches that of Br. The cross section for this process is supposed to be large, possibly in the order of 10×10^{-16} cm^2.[7] However, the correct mechanism for C_2^- ion formation remains open to question.

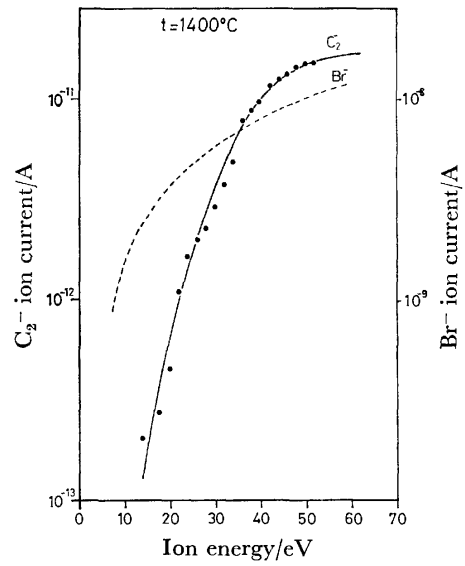

Fig. 1. Energy dependence of C_2^- ion current with CsBr at 1400 °C.

Although the ion source was originally designed and operated only for the sake of the major ion, we tested the possibility of employing it as the beam source for the minority ions. The C_2^- ion current was measured under the optimum operating conditions in order to get a maximum current. The variation of the ion intensity as a function of the ion energy is shown in Fig. 1. The ion intensity of C_2^- ion is *ca.* 10^{-11} A above 40 eV, declining sharply for lower ion energies. The behavior is similar to that of the major ion indicating a space charge effect. However, the intensities for these ions can not be directly compared since they were measured

* Present address: Training Institute for Environmental Pollution Control, 526 Tokorozawa, Tokorozawa 359.

under optimal conditions for each ion.

The energy spread of the C_2^- ion beam was also measured, an intrinsic energy spread of *ca.* 0.55 eV being obtained as the major ion by extrapolating an energy spread-ion energy curve to zero energy.

In applying this ion source to the reaction kinetics for the minority ions, however, a mass discrimination of the desired ion from others, especially the major ion, is necessary prior to the deceleration and focussing of ion beam onto a scattering cell. This can be easily achieved with a small permanent magnet or a RF quadrupole mass filter, since only a moderate mass resolution is required. Furthermore, a very small number of ionic products can be detected by mass analysis in combination with a pulse counting technique.

Since C_2^- ion is very stable and an important precursor in flame reactions reacting with such molecules as H_2, H_2O and hydrocarbons, it would be interesting to study such ion-molecule reactions by means of the present source.

Experimental

The apparatus consists of an ion emitter, a magnet, an acceleration-deceleration multistage lens and a RF quadrupole mass filter. The ion source chamber and the chamber which accomodates a mass filter are separately pumped with oil diffusion pumps. The operating pressures of both chambers are maintained below 10^{-6} Torr (1 Torr=133.322 Pa). The ion source, unless otherwise specified, is constructed of stainless steel. The main part of the ion source is the ion emitter made of a rear-fed layer of LaB_6 as the ionizing material (Fig. 2).

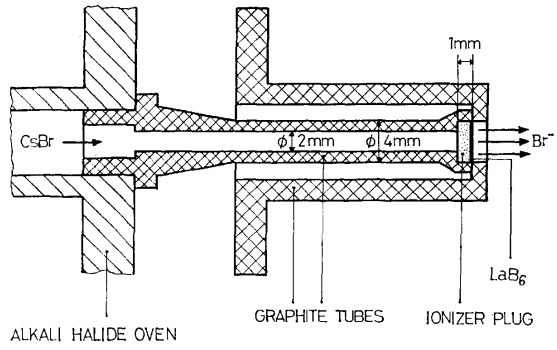

Fig. 2. Cross sectional view of the alkali halide type ion emitter.

Graphite (type EK 87, Ringsdorff, Bonn) was used as a structural material. However, since graphite does not bind firmly with LaB_6, LaB_6 powder was suspended in a small amount of methanol and then pressed onto the porous graphite plug; after evaporation of the solvent in a vacuum, it was heated to its operating temperature, affording a mechanically stable sedimentary layer of LaB_6. The concentric graphite tubes are in contact with each other at their front ends and heated by an alternating current of *ca.* 100 A to 1300 °C in the region of the ionizing area. The desired halogen is supplied as caesium halide from the oven heated by means of a molybdenum wire to 500 °C or higher. The vapor passes the inner graphite tube and diffuses through the porous graphite plug and the sedimentary layer of LaB_6, at which the alkali halide molecules are eventually surface ionized. The negative ions thus formed are extracted and simultaneously accelerated in order to avoid a space charge effect. After being focused by a couple of lenses and then decelerated to the desired ion energy equal to the voltage applied to the ion emitter, the ions are subjected to mass analysis with a RF quadrupole mass filter (Extranuclear Laboratries, Model 324-9) and collected on a cylindrical Faraday cup, the current from which is measured with a Keithley 414S Picoammeter. At the operating temperature 1300 °C, the LaB_6 surface also emits electrons, in a number at least three orders of magnitude greater than that of major negative ions. The electrons are removed from the ions by means of a magnetic field perpendicular to the beam axis. The ions proceed practically unaffected by the field due to their far larger masses. When necessary, energy analysis is carried out after deceleration by means of an electrostatic energy analyser.

The authors thank Professor G. Stöcklin for his encouragement and advice. One of them (N.K.) thanks him particularly for the opportunity to carry out the experiments at K.F.A.

The Crystal Structure of the 1: 2 Tetrapropylammonium Guanidinium Bromide Complex

Tooru TAGA,* Makoto OHASHI, Kenji OSAKI, Koichiro MIYAJIMA, and Hiromitsu YOSHIDA

Faculty of Pharmaceutical Sciences, Kyoto University Yoshidashimoadachi-cho, Sakyo-ku, Kyoto 606

(Received November 27, 1978)

Synopsis. The crystal of the title complex is monoclinic, $P2_1/a$ with these unit cell dimensions: $a=16.16$, $b=19.18$, $c=15.46$ Å, and $\beta=98°$. The crystal structure has layers of hydrogen-bond networks formed by the guanidinium and bromide ions. Two different conformers of the tetrapropylammonium ions are packed between the networks.

This work is one of a series of X-ray studies on the crystal structures of tetraalkylammonium guanidinium halide complexes.[1-3] Two kinds of the crystals of tetrapropylammonium guanidinium bromide complexes, 1 : 2 and 2 : 1 $(Pr)_4NBr$–GuBr, were obtained from the aqueous solutions of the mixed tetrapropylammonium bromide and guanidinium bromide salts.[1] The crystal structure of the 1 : 2 complex described in this note received attention in relation to that of the 2 : 1 complex reported previously.[2]

Experimental

The crystals obtained by the evaporation method were very unstable in the air. Thus, the X-ray experiments were performed by sealing the crystals in a capillary tube. The crystals are monoclinic, space group $P2_1/a$, as indicated by the systematic absences of $h0l$ for h odd and $0k0$ for k odd. The cell dimensions are $a=16.65(9)$, $b=19.18(5)$, $c=15.46(14)$ Å, and $\beta=98(2)°$. The observed crystal density is 1.415 g/cm^3, while the calculated density is 1.485 g/cm^3 if eight chemical unit, $[N(C_3H_5)_4][C(NH_2)_3]_2Br_3$, are assumed in the unit cell. The higher order reflections were not observed in the Weissenberg films taken by rotating the crystals about the b- and c-axes, using Ni-filtered Cu $K\alpha$ radiation. Intensity data of 1498 reflections were collected by the use of a SYNTEX AD-1 densitometer.

The structure was solved by the heavy-atom method. The six bromide ions were determined by the direct method using the program MULTAN. The structure was refined by successive cycles of the block-diagonal and full-matrix least-squares methods with the anisotropic thermal parameters of the bromide ions. The refinement was terminated at the stage where an R-value was reduced to 0.15, since the temperature factor of this crystal is large ($\bar{B}=4.9$). All computations were performed on a FACOM M-190 in the Data Processing Center of Kyoto University, using the program system KPAX which included the UNICS program.

Results and Discussion

Table 1 lists the positional parameters and their estimated standard deviations, and Figs. 1 and 2 show the crystal structures projected along the a- and b-axes, respectively.

The structure is composed of the two-dimensional hydrogen-bond network formed by the guanidinium ions and the bromide ions. The tetrapropylammonium groups are packed between these hydrogen-bond networks. This layer-like structure resembles that observed previously in the crystal of tetrabutylammonium guanidinium bromide monohydrate complex.[3] However, an interesting aspect of this crystal structure is found in its unique hydrogen-bond networks. Each guanidinium ion is bonded to three bromide ions by the six NH···Br hydrogen-bonds, and forms a rigid triangular $GuBr_3$ group; the average N···Br distance is 3.45 Å. The $GuBr_3$ groups are linked together in a

The two networks weaved into each other are viewed down the b-axis.

manner such that the bromide ion forms four hydrogen-bonds with the nitrogen atoms of the two adjacent guanidinium ions, and they form four-membered rings and eight-membered rings in an infinite two-dimensional network. As is shown schematically in Fig. 3, the two networks related by the $\bar{1}$ symmetry are, furthermore, interwoven with each other; the four-membered rings and the eight-membered rings in the different networks are entangled together. The closest approach of these networks is found between the antiparallel guanidinium planes at the entanglement point of the two rings.

When the crystal structure described above is compared with that of the 2 : 1 complex,[2] one of the common structural features is that two different conformers of tetrapropylammonium groups exist in both structures. The two conformers have approximately $\bar{4}$ mm and $\bar{4}$ symmetries, as reported previously.[2] This common fact will provide the evidence that these two conformations for tetrapropylammonium are energetically very close. The second point of the common features is that the guanidinium ion forms a $GuBr_3$ group with three bromide ions. A similar $GuCl_3$ group has been observed in the crystal structure of guanidinium chloride salt.[4] These facts may indicate that the $GuBr_3$ formation is favorable in a crystalline state. A definite difference between the three structures is how these stable $GuBr_3$ groups link in the structure. In the 2 : 1 complex, each $GuBr_3$ group is apart from the others and act as a divalent anion.[2] On the other hand, in the 1 : 2 complex, the $GuBr_3$ groups are linked together at the bromide ion, and they form a two-dimensional network as mentioned above. In the case of guanidinium chloride salt, three $GuCl_3$ groups are linked together at a chloride ion, and they form a complicate three-dimensional network as a whole.[4] The apparent charge of the $GuBr_3$ group in the 1 : 2 complex is smaller than in the 2 : 1 complex, since each bromide ion contributes half a unit of charge onto the $GuBr_3$ group in the network. Hence, the ionic character of the crystal of the 1 : 2 complex is considered to be smaller than that of the 2 : 1 complex.

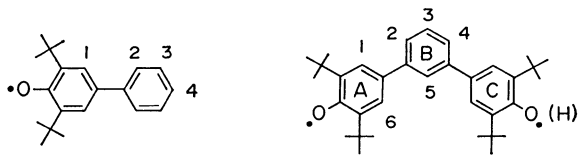
(Received December 9, 1978)

Synopsis. The new stable π-conjugated bisaryloxyl biradical, 4,4′-(*m*-phenylene)bis(2,6-di-*t*-butylphenoxyl), was prepared, and the ***g***- and ***D***-tensor values of the biradical were determined from an analysis of an asymmetric ESR spectrum of a frozen solution containing the biradical. A resolved hyperfine structure was observed in the ESR spectrum of a liquid solution of the biradical, giving the hyperfine splitting values theoretically expected for the triplet state of the biradical.

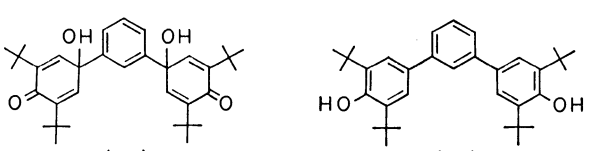
2,6-Di-*t*-butyl-4-phenylphenoxyl (aryloxyl (I)) (see Fig. 1) is a fairly stable phenoxyl radical, first prepared by Müller *et al.*, which can be separated as a solid with 90% radical concentration.[1] 4,4′,4″-(1,3,5-Benzenetriyl)tris(2,6-di-*t*-butylphenoxyl) (trisaryloxyl) is also known as a stable phenoxyl triradical prepared by Kothe *et al.*[2] The existence of a quartet state in the trisaryloxyl radical has been confirmed by ESR measurements in rigid media at 77 K.[3] These radicals can be prepared from their phenol and triphenol precursors by their PbO_2 oxidation in toluene under vacuum or nitrogen gas, respectively



(I) (II) and (II-AB)

Fig. 1. Molecular structures of aryloxyl radical (I), bisaryloxyl biradical (II), and monoradical precursor (II-AB) of the biradical (II), and the atomic numbering system.

We have prepared the bisphenol precursor (IV) which is related to the above phenol and triphenol precursors, and have succeeded in synthesizing the corresponding π-conjugated bisaryloxyl biradical (II), 4,4′-(*m*-phenylene)bis(2,6-di-*t*-butylphenoxyl), (see Fig. 1). Zero-field splitting parameters and hyperfine splitting constants of the biradical (II) have been determined from its frozen and fluid solution ESR spectra, respectively.



(III) (IV)

Experimental

m-*Bis(4-oxo-1-hydroxy-3,5-di*-t-*butyl-2,5-cyclohexadienyl)benzene (quinol (III))*. Quinol (III) was synthesized by a Grignard reaction of 2,6-di-*t*-butyl-*p*-benzoquinone with *m*-dibromobenzene and Mg in tetrahydrofuran (THF) under an atmosphere of nitrogen, following a method similar to that used with 4-hydroxy-2,6-di-*t*-butyl-4-phenyl-2,5-cyclohexadien-1-one.[4] The viscous reaction mixture obtained was added to an aqueous ammonia, then they were taken up in diethyl ether, washed with water, and dried over anhydrous sodium sulfate. After removal of the diethyl ether, a pasty solid remained. By adding petroleum ether (bp 50—70 °C) to the pasty residue, some white solids were precipitated. The solids were filtered off, washed with petroleum ether, and recrystallized from methyl alcohol. Mp 248—251 °C. (Found: C, 78.42; H, 9.16%. Calcd for $C_{34}H_{46}O_4$: C, 78.72; H, 8.94%). UV spectrum (λ_{max}=231 nm, log ε=4.50 in THF). NMR spectrum (δ=1.24 ppm (36 H, s, *t*Bu), 2.35 (2H, s, OH), 6.53 (4H, s, *m*-ring), 7.33 (3H, s, phenylene ring), 7.52 (1H, s, phenylene ring); δ in $CDCl_3$ with TMS as internal standard).

m-*Bis(3,5-di*-t-*butyl-4-hydroxyphenyl)benzene (bisphenol (IV))*. Bisphenol (IV) was synthesized by reduction of quinol (III) with Zn powder and concd HCl in methyl alcohol, following the same process as that of Rieker *et al.*[4] The white solids obtained were recrystallized twice from methyl alcohol. Mp 223—225 °C. (Found: C, 82.95; H, 9.73%. Calcd for $C_{34}H_{46}O_2$: C, 83.90; H, 9.53%). UV spectrum (λ_{max}=268 nm, log ε=4.57 in THF). NMR spectrum (δ=1.53 ppm (36H, s, *t*Bu), 5.24 (2H, s, OH), 7.42 (4H, s, *m*-ring), 7.42 (3H, s, phenylene ring), 7.65 (1H, s, phenylene ring); δ in $CDCl_3$ with TMS as internal standard).

All the ESR measurements were carried out using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter. The ESR splittings were determined using $(KSO_3)_2NO$ as a standard. The *g*-values were measured relative to the value of Li-TCNQ powder, calibrated with $(KSO_3)_2NO$ (g=2.0054).[5]

Results and Discussion

When the bisphenol precursor of the bisaryloxyl biradical (II) was oxidized with PbO_2 in toluene under vacuum, the color of the bisphenol solution immediately became purple. The ESR spectrum of this solution (see Fig. 2(a)) showed a sextet-doublet hyperfine pattern (g_{iso}=2.00419±0.00003), and we assigned the spectrum to the primary aryloxyl monoradical (II-AB) formed from the parent phenol by abstraction of a phenolic hydrogen atom. The large sextet splitting (a^H=1.72±0.04 G) in the primary radical will be due to five magnetically equivalent ring protons (H_1, H_2, H_4, H_5, H_6) and the doublet splitting (a^H=0.71±0.04 G) is explained by a ring proton (H_3). These hyperfine splittings and g_{iso}-value are in good agreement with those ($a^H_{1,2,4}$=1.74±0.04, a^H_3=0.74±0.04 G and g_{iso}=2.00415±0.00003) for the aryloxyl radical (I) in toluene. By further oxidation, the purple color changed to yellow-brown, and the sextet-doublet spectrum of the monoradical was altered to a twelve-line spectrum of the bisaryloxyl biradical (II) with an equivalent splitting distance of 0.86 G and with g_{iso}=2.00414±

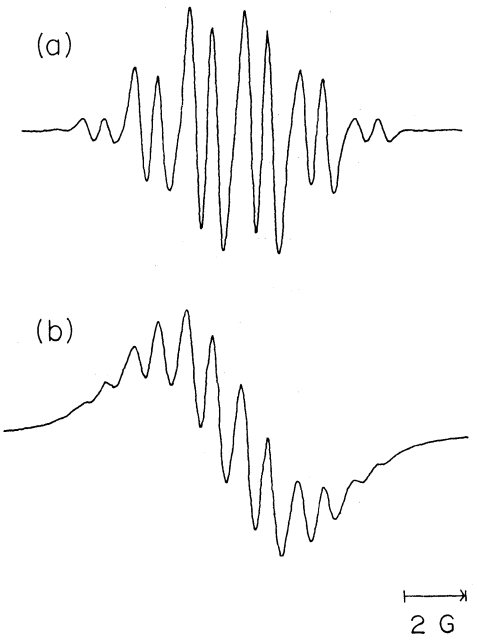


Fig. 2. (a) ESR spectrum of the monoradical precursor (II-AB) of the bisaryloxyl biradical (II) in toluene at 20 °C. (b) ESR spectrum of the bisaryloxyl biradical (II) in toluene at 20 °C.

0.00003, as shown in Fig. 2(b). The radical was stable for many weeks in toluene under vacuum at room temperature. The spectrum can be reconstructed with two sets of three and five equivalent protons ($a^{H}=1.72$ (3H), $a^{H}=0.86$ G (5H)).

Rather few triplet molecules show resolved proton hyperfine structure, because of the spin-spin dipolar broadening. The ESR spectrum of the bisaryloxyl biradical (II) shows twelve lines from the hyperfine interaction of the electrons with the eight ring protons, as described above. Kopf *et al.*[6] have proposed a simple theory to explain the hyperfine splitting of weakly π-conjugated verdazyl biradicals; their results indicate that the splitting constants of nuclei contained in rings connecting the two monoradical halves are the average of splittings from protons in corresponding positions in the monoradical, while the splitting constants for nuclei in other parts of the molecules were one-half of the monoradicals splittings. The bisaryloxyl biradical (II) is considered to be a strongly π-conjugated biradical consisting of two aryloxyl groups (AB- and BC-types) with two unpaired electrons in a molecular orbital, in which ring B is common to both monoradical-AB and -BC. Therefore, in the biradical (II), the theoretically expected values for the hyperfine splittings of the eight ring protons from those of the monoradical precursor (III-AB) are $a^{H}_{2,4,5}=1.72$ G (3H), $a^{H}_{1,6}=0.86$ G (4H), and $a^{H}_{3}=0.71$ G (1H); the observed hyperfine splittings ($a^{H}_{2,3,5}=1.72$ G (3H) and $a^{H}_{1,3,6}=0.86$ G (5H)) for the biradical (II) agree exceedingly well with the ones calculated from the monoradical precursor; this strongly supports the above explanation.

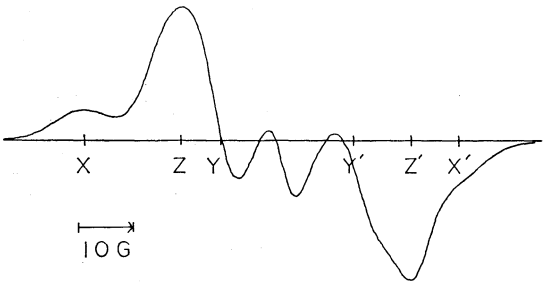

Fig. 3. ESR spectrum of the bisaryloxyl biradical (II) in toluene at 77 K.

When a solution containing the bisaryloxyl biradical (II) is frozen into glass at 77 K, one can observe dipolar splittings, as is shown in Fig. 3. A central weak line at $g=2$ is attributable to the monoradical impurity. Assuming non-axial symmetry, the zero-field splitting parameters D and E were tentatively estimated from the positions of the three pairs of turning points ZZ', YY', and XX' in Fig. 3, as performed for the bisgalvinoxyl biradicals in Refs. 7 and 8. The values are $D=34.0\pm1.0$ G and $E=3.0\pm1.0$ G. Because of the symmetry of the biradical molecule, we can expect that the principal axes of the $\boldsymbol{D}$- and $\boldsymbol{g}$-tensors are coaxial. Consequently, the frequency centers of these three pairs of absorption lines, ZZ', YY', and XX', give $g_{zz}=2.0024\pm0.0004$, $g_{yy}=2.0035\pm0.0004$, and $g_{xx}=2.0051\pm0.0004$, respectively. The average $g_{av}=1/3(g_{xx}+g_{yy}+g_{zz})=2.0037\pm0.0004$ is in agreement with the isotropic $g_{iso}=2.00414\pm0.00003$ value measured at room temperature, indicating that the $\boldsymbol{g}$-tensor values obtained by the above analysis are consistent.

Secondary Deuterium Isotope Effects in the Intramolecularly-competing Methoxymercuration of Ethylene-1,1-d_2 and *cis*-2-Butene-2-d_1

Sumio SHINODA, Masashi ISEMURA,† and Yasukazu SAITO*

Institute of Industrial Science, The University of Tokyo, 22-1, Roppongi 7-Chome, Minato-ku, Tokyo 106

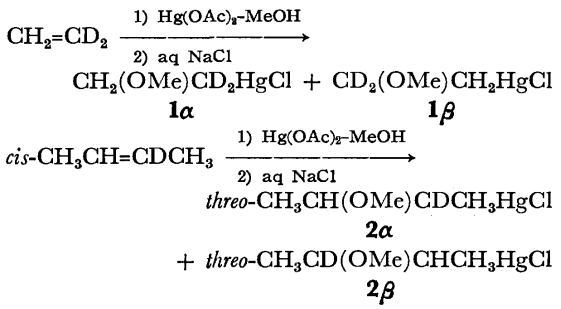
(Received December 19, 1978)

Synopsis. Secondary deuterium isotope effects in the intramolecularly-competing methoxymercuration of ethylene-1,1-d_2 and *cis*-2-butene-2-d_1, determined from the rate ratio (k(β-deuteriomercurial)/k(α-deuteriomercurial)=1.12, 1.06), indicate that the transition state for the methoxymercuration of ethylene and *cis*-2-butene does not have a symmetrical structure such as a mercurinium ion, but is accompanied by considerable C–O bond formation.

The oxymercuration of olefins followed by reductive demercuration with sodium borohydride is a synthetically important method for the synthesis of alcohols and ethers.[1] The remarkable feature of the oxymercuration is that the reaction has almost all the usual features of an electrophilic addition but structural rearrangement, substitution, and conjugate addition do not accompany the reaction.[2] The process is strictly a 1,2-addition in the Markownikov sense and occurs in a stereospecific anti fashion for unstrained simple olefins.[3]

Although extensive studies have been accumulated,[4] there is still dissension regarding the mechanism of this reaction, as was comprehensively reviewed by Ambidge *et al.* recently.[5] One convincing line of approach has involved an application of a linear free-energy relationship,[6] but the interpretation of the rate data seems rather diverse, and depends on the category of olefins selected. In order to remove the ambiguity in the mechanistic problem, it is important to determine accurately the mechanism for the most simple olefin, ethylene.

From this viewpoint, we utilized here the secondary deuterium isotope effect to elucidate the transition-state structure for the methoxymercuration of ethylene together with *cis*-2-butene. Isotopic substitution is unique in that it generates no variation of electronic potential-energy surfaces for molecules.[7] When ethylene-1,1-d_2 (**1**) or *cis*-2-butene-2-d_1 (**2**) is oxymercurated, two isomeric adducts are obtained, *i.e.*, α- and β-deuterio-oxymercurials where the designation of α and β is made from the mercurated carbon. Because the formation of these isomers is competitive, the ratio of the product isomers is equivalent to the corresponding rate constants, k_β/k_α.



Scheme 1.

Secondary deuterium isotope effects on reaction rates have been generally recognized as evidence of hybridization change at the position of isotopic substitution between reactant and transition state.[7,8] Accordingly, we can directly deduce the symmetry concerning the hybridization of α- and β-carbons in the transition state by examining the value of k_β/k_α.

Results and Discussion

Methoxymercuration of **1** and **2** was effected at 25 °C by standard procedures (Scheme 1).[9] In the absence of mineral acid, oxymercuration of olefins with mercury(II) acetate gives kinetically controlled products,[10] and there was no possibility of discrepancies of temperature or other conditions in the formation of the two isomers. The ratio of the product isomers was determined by using PMR spectroscopy carefully for the quantitative analysis.

The PMR spectrum of the methoxymercurials formed from **1** is shown in Fig. 1. Obviously two peaks with unequal intensity appear at δ 2.16 and 3.60; deuterium decoupling did not alter the peak ratio. It is evident from Fig. 1 that **1β** (δ 2.16) was formed in preference to **1α** (δ 3.60). The isomer ratio for the methoxymercuration of **2** was determined with methyl peaks. The results are tabulated in Table 1.

Table 1. Rate ratio for the intramolecularly-competing methoxymercuration of deuterio-olefins

Olefin	k_β/k_α
$CH_2=CD_2$	1.21
cis-$CH_3CH=CDCH_3$	1.06

For unsymmetrically deuterium-substituted symmetrical olefins such as **1** or **2**, the olefinic carbons are equivalent on the electronic potential-energy surface. If the transition state for the methoxymercuration of ethylene or *cis*-2-butene is symmetrical, retaining the equivalence of the two carbons, the secondary deuterium isotope effect would be identical for the two isomers. The observed substantial deviation of k_β/k_α from unity, therefore, indicates that the symmetrical transition state such as **3** or **4** is unfavorable for ethylene and *cis*-2-butene, despite the symmetry in substituents.

An intervention of oxy-addendum in the transition state has been claimed by several authors on the basis of the substituent effect on the rate of oxymercuration[2,11] On the assumption of the inverse α-deuterium

† Present address: Sumitomo Chemical Company Limited, 7-9, Nihonbashi 2-Chome, Chuo-ku, Tokyo 103.

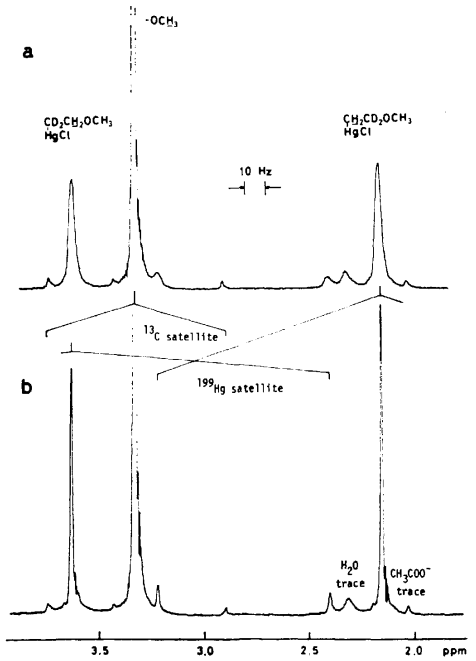


Fig. 1. PMR spectrum of the methoxymercurials of ethylene-1,1-d_2 at 25 °C and 100 MHz in $CDCl_3$ solution; (a) without deuterium irradiation; (b) with deuterium irradiation at 15.349345 MHz which corresponds to the center of the α- and β-deuterium resonance.

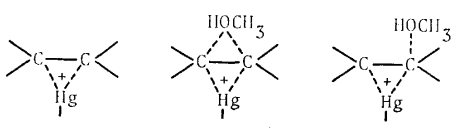
isotope effect ($k_H/k_D<1$), which has been usually observed when there is a change from sp^2 to sp^3 in the carbon bond hybridization,[7,8] the observed magnitude of the rate ratio for the intramolecularly-competing process, k_β/k_α, directly shows that the C–O bond is considerably formed in the transition state. Hence, the transition-state structure for the methoxymercuration of ethylene and *cis*-2-butene would be represented as **5**. The position of mercury along the C–C bond axis may be of interest, but seems to be a complicated problem since the molecular orbital calculation[12] suggests that rather small energy is required to shift the mercury along that axis (as compared with halonium ions), and that the ease of the displacement depends appreciably on the kind of the ligand bonded to mercury(II). The "mercurinium ion" intermediate, formulated frequently as **3** in analogy to olefin-Ag(I) π-complex or bromonium ion,[12] may be involved in the reaction path, possibly in the pre-rate-determining step equilibria,[13] but its formation is not a rate-determining step.[14]

It is noteworthy that **5** is similar to the transition-state structure proposed by Kreevoy and coworkers for the deoxymercuration reaction.[15] In view of the reversible nature of the oxymercuration of olefins and the deoxymercuration of the formed adducts, it is reasonable that their transition-state structures resemble each other, although the content of C–Hg and C–O bond formation may be variable with the kind of olefin substituents or mercury ligands.



3 **4** **5**

Experimental

Preparations of **1** and **2** were described elsewhere.[16,17] All the reagents and solvents were commercially available. PMR spectra were recorded on a JEOL PS-100 spectrometer. Deuterium decoupling was carried out with a JEOL OA-1 synthesizer.

In determining the isomer ratios, both radio-frequency power and sweep rate were selected to avoid saturation of signal intensity. Spectra were obtained in both the frequency-increasing and -decreasing conditions ten times on a 4- or 10-fold expanded scale of the standard sweep width, so as to secure the precision of area measurement. Reported values were the avarage of three independent runs with an error of 3% (standard deviation) for the total measurement.

Methoxymercuration was performed by introducing **1** or **2** *via* a vacuum line into the solution consisting of methanol (5 cm^3) and mercury(II) acetate (2 mmol) at 25 °C, which was stirred by a magnetic stirring bar until all the mercury(II) ions were consumed to yield a homogeneous solution. Mercurials were isolated in the form of chloride by the method described by Ichikawa *et al.*[9]

Crystal and Molecular Structure of Bis(1-diphenylphosphinothioyl-3-methylthioureato)nickel(II)

Toschitake IWAMOTO,* Fujio EBINA, Hiroshi NAKAZAWA, and Chiaki NAKATSUKA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo 153

(Received November 24, 1978)

Synopsis. The title compound [Ni{$(C_6H_5)_2$PSNCSNHCH$_3$}$_2$] was found to crystallize in the monoclinic space group C2/c with a=23.29(1), b=9.457(2), c=16.40(1) Å, β=121.33(8)°, Z=4. The six-membered chelate ring built of five kinds of atoms, Ni, 2S, P, N, and C, was demonstrated.

Ojima *et al.*[1,2] proposed that some diphenylphosphinothioylthioureatometal(II) complexes have a chelate structure consisting of five kinds of atoms, M(II), 2S, P, N, and C. In order to confirm the existence of such a chelate ring, the title compound was subjected to X-ray structural analysis.

Experimental

Among the complexes reported,[1,2] a complex previously described as bis(3-diphenylphosphinothioyl-1,1-dimethylthioureato)nickel(II) was chosen because of its good appearance as fine crystals. A 0.2×0.4×0.6 mm single crystal grown up from a dichloromethane–ethanol solution was used for the X-ray diffraction experiments. In the course of structure refinement, the crystal was confirmed to be that of the title compound, bis(1-diphenylphosphinothioyl-3-methylthioureato)nickel(II). After preliminary Weissenberg photographs were taken, precise determination of lattice parameters and collection of intensity data were carried out on a Rigaku automated four-circle diffractometer using Cu $K\alpha$ radiation, the procedure being similar to that reported.[3] Of 4142 observed reflections with $2\theta \leq 120°$, 1671 with $|F_o| \geq 3\sigma(|F_o|)$ were used for the structure refinement. The absorption corrections[4] were applied together with Lp ones. The density was measured by the flotation method using potassium tetraiodomercurate solution. Crystal data: $NiC_{28}H_{28}N_4P_2S_4$, $F.W.$=669.44. Monoclinic, space group C2/c, a=23.29(1), b=9.457(2), c=16.40(1) Å, β=121.33(8)°, Z=4. D_m=1.45, D_x=1.44 g cm^{-3}. Systematic absences: hkl, $h+k=2n+1$; $h0l$, $l=2n+1$. μ(Cu $K\alpha$)=45.36 cm^{-1}.

The structure was solved by the heavy-atom method. All the calculations were carried out on a HITAC 8800/8700 computer at the Computatinon Center of this University. The programs used were those in UNICS[5] and their local versions. The atomic scattering factors were taken from those of Cromer and Waber.[6] From the three-dimensional Patterson synthesis, the Ni atoms were located at the inversion centers in the c glide planes. In successive Fourier syntheses, the positions of all the remaining non-hydrogen atoms could be found out except that of the second methyl-C atom should have been found for the dimethyl compound around the N(2) atom of the side chain. Since the measured density was smaller by 0.02 g cm^{-3} than that calculated for the dimethyl compound, the refinement was progressed assuming this crystal to be that of the title compound. Several cycles of block-diagonal least-squares calculations were carried out to the final R=0.093, the real and imaginary parts of the anomalous dispersion

a) The positional and thermal parameters have been multiplied by 10^4 and 10^3, respectively, the numbers in parentheses being esd's in the last signigicant digits. The form of thermal parameters is $\exp[-2\pi^2(U_{11}h^2a^{*2}+U_{22}k^2b^{*2}+U_{33}l^2c^{*2}+2U_{12}hka^*b^*+2U_{13}hla^*c^*\cos\beta^*+2U_{23}klb^*c^*)]$.

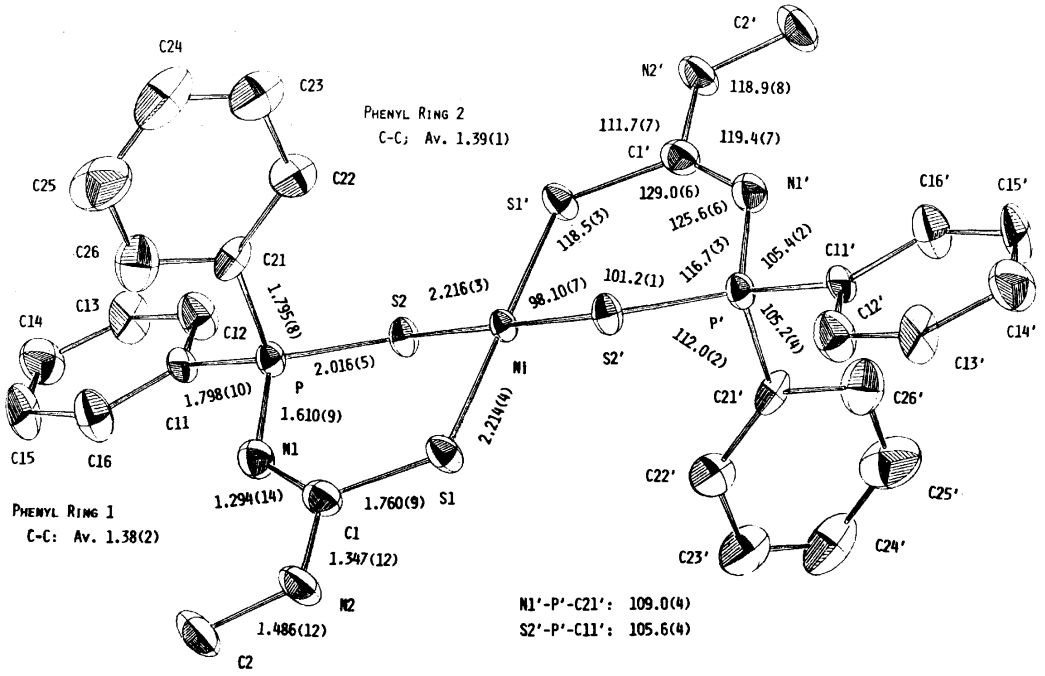

Fig. 1. An ORTEP view of $[Ni\{(C_6H_5)_2PSNCSNHCH_3\}_2]$ molecule using 50% probablity ellipsoids. The bond distances and angles are given in Å and degree, respectively, and the numbers in parentheses are esd's in the last significant digits.

correction being also made.[7] The shift of each atomic parameter was within one-third of the estimated standard deviation at the last two cycles. The final difference Fourier map showed no significant peak attributable to the "second" methyl-C atom. This shows that the analyzed crystal is composed of the title compound. The refinement with the Cc space group, another possible one for the observed systematic absences, afforded no improvement.

Description of the Structure

The final atomic parameters are given in Table 1. The molecular structure of the complex is shown in Fig. 1 with the values of important bond distances and angles. The Ni atom is bonded to S(1) and S(2) atoms of the ligands in a square-planar trans configuration. The six-membered chelate ring is built of Ni, S(1), C(1), N(1), P, and S(2) atoms as proposed by Ojima *et al.*[1,2] The chelate ring, the phenyl ring 1, and the methylamino side chain are roughly parallel to the ac plane, and the phenyl ring 2 protrudes from the P atom of the chelate ring into a direction approximately parallel to the b axis. The NiS_4 coordination sphere resembles that in bisdithioacetylacetonatonickel(II)[8] and other conjugated bis(thioketo-thiolato)nickel(II) complexes. The chelate ring has the following features of bond distances. The average Ni–S bond length 2.215 Å is longer than those in the conjugated thioketo-thiolato type complexes. The C(1)–S(1) bond is comparable in length to that in bismaleonitrildithiolatonickelate(II).[9] The P–S(2) and P–N(1) bonds appear to be partially double. The N(1)–C(1) bond is too short for a C=N bond. Although these features could support a partial conjugation of π-orbitals in the chelate ring, the unfavorable deviations of the relevant atoms from the calculated best plane are: P 0.59, N(1) 0.19, Ni 0.08, C(1) −0.11, S(1) −0.16, and S(2) −0.47 Å.

Studies of the Separation Mechanism in Ion-exchange Chromatography. I. Inversion of the Elution Order of cis and trans Isomers of Metal Complexes

Hayami YONEDA* and Shigeo YAMAZAKI

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received December 4, 1978)

Synopsis. The inversion of the elution order in ion-exchange chromatography was found for cis and trans isomers of $[Co(X)_2(en)_2]^+$ ($X=N_3^-$, NO_2^-, and NCS^-) by the addition of dioxane to NH_4Cl or $(NH_4)_2SO_4$ aqueous solution as eluent, and the separation mechanism was discussed.

Since King and Walters[1] reported the chromatographic separation of the cis and trans isomers of $[Co(NO_2)_2(NH_3)_4]^+$ by ion-exchange technique, it has been accepted as a general rule that the trans isomer is eluted earlier than the cis isomer.[2,3] This is quite understandable when we consider that the cis isomer has a dipole moment and is adsorbed more strongly than the trans isomer having no dipole moment. This explanation is based on the assumption that separation is carried out mainly by adsorption, although chromatography consists of two processes, adsorption and elution. Here it must be pointed out that the dielectric constant is fairly smaller in the stationary phase (resin phase) than in the moving phase (aqueous solution), so that ion association in the stationary phase should be more effective than in the moving phase, that is, adsorption should be more decisive than elution. Thus, it is natural to consider that the elution order is determined by the strength of adsorption. Therefore, if we set up conditions under which ion association in the moving phase is more effective than that in the stationary phase, the elution order of the cis and trans isomers is expected to be reversed.

Based on this consideration, we tried to chromatograph the cis and trans pairs of three cobalt(III) complexes through the column packed with SP-Sephadex C-25 using dioxane–water mixed solution of an electrolyte as an eluent. As such Sephadex contains many hydrophilic functional groups, the dielectric constant in the stationary phase should be fairly large and it can be easily overtaken by the dielectric constant in the moving phase (aqeuous solution) with the addition of some amount of dioxane to the eluent, which should result in the inversion of the elution order. This expectation was fulfilled in the present study.

Experimental

Samples. All the complexes were prepared according to the literature, and identified by UV absorption spectra and elemental analyses. Complexes used were the cis and trans pairs of $[Co(NO_2)_2(en)_2]ClO_4$, $[Co(NCS)_2(en)_2]Cl\cdot H_2O$, and $[Co(N_3)_2(en)_2]ClO_4$.

Sample solutions were prepared by dissolving 10 mg of the complex in a few ml of an eluent.

Eluent. The eluents were aqueous solutions of 0.4 mol dm^{-3} NH_4Cl, 0.4 mol dm^{-3} NH_4NCS and 0.05 mol dm^{-3} $(NH_4)_2SO_4$ containing various amounts of dioxane. Dioxane was distilled before use.

Apparatus. All the works were carried out on a laboratory-built chromatographic unit at room temperature. The column size was 25 cm long and 6.5 mm in diameter. SP-Sephadex C-25 (Pharmacia, Sweden) was used as a packing material. The flow rates were ranged from 0.8 ml/min for zero dioxane to 0.25 ml/min for 60% dioxane content. The detector was operated at the first absorption band of each complex. The adjusted retention volume was measured from the elution curve. $(NH_4)_3[Cr(NCS)_6]$ was used as a marker.[4] The sample solution 20 μl being typical was injected by a syringe into the column.

Results and Discussion

Fig. 1(a) shows the trend of the retention volumes of the cis and trans pairs of three cobalt(III) complexes with increasing dioxane content of 0.4 mol dm^{-3} NH_4Cl solution. As expected, in the low dioxane content region, the retention volume of the cis isomer having a dipole moment is larger in all three cases than that of the trans isomer having no dipole moment. This suggests that the electrostatic interaction between the complex cation and the functional group (SO_3^-) of Sephadex ion-exchanger plays a decisive role in chromatographic separation. The situation is reversed in the high dioxane content region where the retention volume of the cis isomer becomes smaller than that of the trans isomer. This means that the electrostatic interaction between the complex cation and the counter anion in the moving phase plays a dominant role in chromatographic separation.

The most important factors which govern the electrostatic interaction are the charge density of the counter ion (ionic charge times concentration) and the dielectric constant of the medium. In the case of SP-Sephadex C-25, the exchange capacity and the bed volume of the gel at ionic strength 0.4 are known to be 2.3 m equivalent/g(dry gel) and 6 ml/g(dry gel) respectively. Since the real volume of the swelling gel is estimated to be 2/3 of the bed volume, the concentration of the SO_3^- group in the swelling gel is calculated to be 0.57 mol dm^{-3} which is larger than 0.4 mol dm^{-3}, the Cl^- concentration of the eluent. In addition, the water caught in the Sephadex matrix is presumed to be less structured than the water in the moving phase. Since the electrostatic interaction is dependent upon the product of the charge density of the counter ion and the inverse of the dielectric constant, it should be larger in the stationary phase than in the moving phase in the absence or at the low content of dioxane.

Although the addition of dioxane decreases the magni-

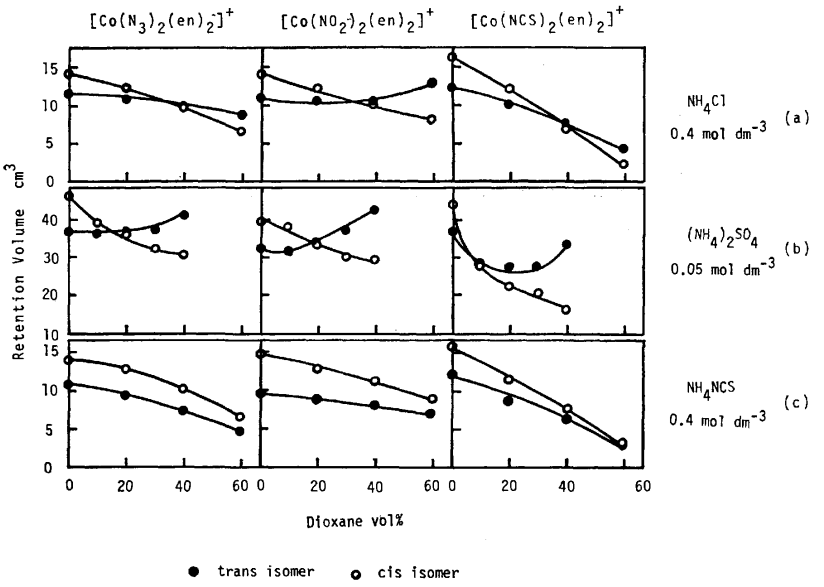

Fig. 1. Retention volume of trans(●) and cis(○) pairs of $[Co(X)_2(en)_2]^+$ ($X=N_3^-$, NO_2^-, and NCS^-) *vs.* dioxane content in 0.4 mol dm^{-3} NH_4Cl, 0.05 mol dm^{-3} $(NH_4)SO_4$ and 0.4 mol dm^{-3} NH_4NCS solution as eluent.

tude of the dielectric constant both in the stationary and moving phases, the rate of decrease should be larger in the moving phase. Since Sephadex contains many hydrophilic groups, it can hold much water strongly. Thus, the Sephadex matrix contains more water than the moving phase when the dioxane–water mixed solution is kept in equilibrium with Sephadex.[5] Therefore, the increase of dioxane content in the eluent results in a more gradual decrease of the dielectric constant in the stationary phase than in the moving phase. Thus, the magnitude of the dielectric constant in both phases becomes closer with the increasing content of dioxane, and at a certain content of dioxane the inversion of the magnitude of the dielectric constant takes place. The inversion of the elution order can be thus understood. In the case of 0.4 mol dm^{-3} NH_4Cl, the inversion of the elution order takes place at about 35—40% (v/v) dioxane content above which the cis isomer is eluted earlier than the trans isomer. The inversion should take place at much lower dioxane content for the bivalent anion SO_4^{2-} than for the univalent anion Cl^-. Thus, for 0.05 mol dm^{-3} $(NH_4)_2SO_4$ solution, the inversion takes place at about 10—20% dioxane content as shown in Fig. 1(b).

However, it must be noted that for $(NH_4)_2SO_4$ solution, the retention volume of the trans isomer does not decrease but rather increase with increasing content of dioxane. This means that the effective concentration of SO_4^{2-} to catch the complex cation decreases with increasing content of dioxane. The addition of dioxane decreases the dielectric constant of the moving phase which results in strengthening the association of SO_4^{2-} not only with the complex cation but also with NH_4^+. Since the cis isomer has a dipole moment and a great tendency toward association with SO_4^{2-}, it is not so much influenced by the presence of NH_4^+. However, for the trans isomer having no dipole moment, the existence of a large amount of NH_4^+ results in the decrease of the effective concentration of SO_4^{2-} in the eluent of high dioxane content, so that the retention volume increases.

If this interpretation is valid, the retention volume should decrease regularly with increasing content of dioxane, when an eluent contains a salt which has little tendency toward ion association even in the solution of high dioxane content. Ammonium thiocyanate solution as eluent is considered to be the case as shown in Fig. 1(c). Here, NCS^- solvates dioxane strongly and is presumed to be dissociated from NH_4^+ even in the high dioxane content. Such strong solvation of NCS^- anion causes the decrease in its association with the complex (cis and trans) too, so that the association-promoting tendency due to the decrease of the dielectric constant is almost cancelled. Thus the inversion of the elution does not take place.

EPR Studies of the Cobalt(II)-(N_2S_2)-Schiff Base Complex with Lewis Bases and CO

Matsujiro SAKURADA,* Yoshihiro SASAKI, Masakazu MATSUI, and Tunenobu SHIGEMATSU
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

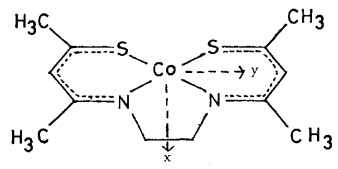
(Received December 6, 1978)

Synopsis. The EPR and optical spectra of *N,N'*-bis-3-thioxo-1-methylbutylidene) ethylenediaminatocobalt(II) in the presence of Lewis bases and CO were measured. The cobalt(II) complex formed five-coordinate adducts with Lewis bases and CO, which had a rhombic symmetry with a $(d_{x^2-y^2}, d_{xz}, d_{yz})^6(d_{z^2})^1$ ground configuration.

Basolo *et al.* have reported that several cobalt(II)–Schiff base complexes (N_2O_2 type) from monomeric oxygen adducts reversibly in the presence of nitrogen donors at a low temperature.[1,2] Recently, Corrigan *et al.* has demonstrated that *N,N'*-bis(2-mercaptobenzylidene)ethylenediaminatocobalt(II) (N_2S_2 type) reacts with molecular oxygen in the presence of pyridine at low temperatures.[3] We have found ourselves that *N,N'*-bis(3-thioxo-1-methyl-butylidene) ethylenediaminatocobalt(II) (N_2S_2 type) is capable of forming monomeric oxygen adducts in the presence of Lewis bases.[4] Here we will report the axial ligation of the cobalt(II) complex with Lewis bases and CO, as studied by the EPR method.

Experimental

N,N'-Bis(3-thioxo-1-methylbutylidene) ethylenediaminatocobalt(II), Co(tacacen), was prepared according to the literature.[5] (Found: C, 45.90; H, 6.06; N, 8.73%. Calcd for $C_{12}H_{18}N_2S_2Co$: C, 46.00; H, 5.79; N, 8.94%). Pyridine, piperidine, and *N*-methylimidazole obtained commercially were purified by distillation, but triphenylphosphine, tributyl phosphine, tributyl phosphite, and trimethyl phosphite were used without further purification. All the EPR samples except the CO sample were prepared by dissolving Co(tacacen) in a toluene solution containing a proper quantity of the Lewis base. Prior to measurements, the samples were degassed thoroughly. The CO sample was prepared by exposing a degassed Co(tacacen) toluene solution to CO gas (500 Torr) at room temperature for three days. The EPR spectra were measured with a JEOL-ME-3X EPR spectrometer at X-band frequencies and calibrated with Mn^{2+} in MgO and DPPH. The optical spectra were measured in dichloromethane with a Hitachi 323 automatic recording spectrophotometer.



N,N'-bis(3-thioxo-1-methylbutylidene)ethylenediaminatocobalt(II), Co(tacacen).

Results and Discussion

The EPR spectra for Co(tacacen) with pyridine, CO, and triphenylphosphine are shown in Fig. 1. The EPR parameters are tabulated in Table 1. The nitrogen-14 ($I=1$) superhyperfine structure, split into a triplet component, appears in the EPR spectrum for the pyridine system; this indicates that only one pyridine molecule coordinates to Co(tacacen). The phosphorus-31 ($I=1/2$) superhyperfine splitting similarly demonstrates that one triphenylphosphine molecule coordinates to Co(tacacen). Though we measured the EPR spectra of Co(tacacen) toluene solutions containing higher concentrations of these Lewis bases, no evidence for six-coordinate complexes, $Co(tacacen)(LB)_2$, was obtained. The CO adduct was obtained by exposing a Co(tacacen) toluene solution to CO gas, but it did not form in the presence of the Lewis bases.

When the $\boldsymbol{g}$- and $\boldsymbol{A}$-tensors have the same principal axes, the first-order relationships between an electronic structure for the $(d_{z^2})^1$ ground state and the EPR parameters are given according to the following equations:[6]

$$\begin{aligned} g_{xx} &= 2.002 - 6\lambda/\Delta E_{yz} \\ g_{yy} &= 2.002 - 6\lambda/\Delta E_{xz} \\ g_{zz} &= 2.002 \\ A_{xx} &= P[-K-2/7+(g_{xx}-2.002) \\ &\quad +(1/14)(g_{yy}-2.002)] \\ A_{yy} &= P[-K-2/7+(g_{yy}-2.002) \\ &\quad +(1/14)(g_{xx}-2.002)] \\ A_{zz} &= P[-K+4/7+(1/14)\{(g_{xx}-2.002) \\ &\quad +(g_{yy}-2.002)\}] \end{aligned} \qquad (1)$$

A: 10^{-4} cm^{-1}. ΔE: 10^3 cm^{-1} (in dichloromethane solvent).

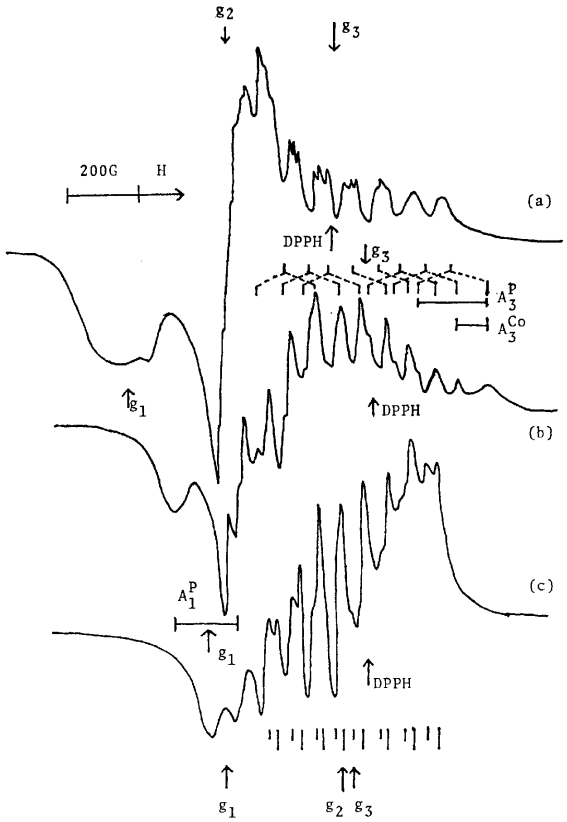

Fig. 1. EPR spectra of Co(tacacen) in the presence of Lewis bases at 77 K. (a) 10 % Pyridine; (b) 10^{-1} M triphenylphosphine; (c) CO gas (500 Torr).

where λ is the effective spin-orbit coupling constant, and where ΔE_{xz} and ΔE_{yz} are the energy separations for the $d_{z^2} \rightarrow d_{xz}$ and $d_{z^2} \rightarrow d_{yz}$ states respectively. $P = gg_n\beta\beta_n\langle r^{-3}\rangle_{3d}$ and PK is the Fermi contact term. The second-order contribution has little significance where $\Delta E \gg \lambda$. The g_3 values in the five-coordinate Co(tacacen) (LB) complexes we studied are nearly 2.002. This implies that the five-coordinate complexes have the $(d_{x^2-y^2}, d_{xz}, d_{yz})^6(d_{z^2})^1$ ground configuration.

The optical spectra for Co(tacacen) with N-donors and P-donors were measured in order to estimate the energy separations. The absorption bands were observed at 10200 cm^{-1} ($\varepsilon \simeq 80$) and 5,100 cm^{-1} ($\varepsilon \simeq 40$) for the N-donors, and at 10400 cm^{-1} ($\varepsilon \simeq 40$) and 5,200 cm^{-1} ($\varepsilon \simeq 10$) for the P-donors. Wayland *et al.* reported that the effective spin-orbit coupling constants for five-coordinate complexes of *N,N'*-disalicylideneethylenediaminato cobalt(II), Co(salen), with Lewis bases, which have the $(d_{z^2})^1$ ground state, are 20—30% less than the free-ion value.[7] In Co(tacacen)(pyridine), when it is assumed that $\Delta E_{xz} = 10200$ cm^{-1}, that $\Delta E_{yz} = 5100$ cm^{-1}, and that the spin-orbit coupling constant is less than the free-ion value by the same degree as in Co(salen)(pyridine), g_{xx}, g_{yy}, and g_{zz} for $(d_{z^2})^1$ ground state are equal to 2.425, 2.214, and 2.002 respectively. These values are in good agreement with the g values observed. No such consistency is found for the other ground states. Therefore, it is concluded that the five-coordinate complexes in this study have

$\%4s = (\rho_{4s}/\rho_{Co}) \times 100$.

the $(d_{x^2-y^2}, d_{xz}, d_{yz})^6$ $(d_{z^2})^1$ ground configuration.

The cobalt-59 spin densities can be evaluated from the EPR parameters. The Fermi term has two main factors: (1) the polarization of filled 1s, 2s, and 3s orbitals, which causes a negative spin on the cobalt nucleus because of the unpaired electron in the 3d orbital, and (2) the admixture of the $3d_{z^2}$ orbital into the 4s orbital, which causes a positive spin. Thus, $A_{contact}$ is written as follows:

$$A_{contact} = -PK = \rho_{4s}[A(\text{Co4s})] + \rho_{3d}[A(\text{Co3d})] \quad (2)$$

where $A(\text{Co4s}) = 0.1232$ cm^{-1} and $A(\text{Co3d}) = 0.00840$ cm^{-1}.[8] ρ_{3d} and ρ_{4s} are the spin densities of the cobalt $3d_{z^2}$ and 4s orbitals respectively. The cobalt $3d_{z^2}$ spin density is estimated by comparing the observed dipolar coupling constant with the theoretical value ($A_d = (4/7)P_0 = 0.0145$ cm^{-1}) according to this equation: $\rho_{3d} = (A_d)_{obsd}/(A_d)_{obsd}$. The results for the cobalt-spin density are given in Table 2. The total cobalt-spin densities increase in the order of: N-donors>CO>P-donors. This suggests that the N-donors have a smaller mixing between the cobalt $3d_{z^2}$ and the ligand σ-donor orbitals than do CO and the P-donors. This order also agrees with the tendency of the electronegativity of the ligand-donor atoms.

Diffusion Coefficients of Thallium(I) and Cadmium(II) Ions in Aqueous Nitrate Solutions Determined Chronoamperometrically with a Thin-walled Hanging Mercury Drop Electrode

Haruko IKEUCHI, Kyoichi IWAI, Mamoru KANEKO, Muneo MAYA, and Gen P. SATÔ*

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received January 12, 1979)

Synopsis. The diffusion coefficients (D) of Tl^+ in 0.1 and 0.5 mol dm^{-3} KNO_3 and of Cd^{2+} in 1.0 mol dm^{-3} KNO_3 in the temperature range 5 °C—35 °C are given with additional data including activation energies. $kT/D\eta$, where η is the viscosity of the nitrate solution, depends primarily on the diffusing species.

A stationary mercury drop electrode hanging from a thin-walled capillary (HMDE) was found to be one of the most suitable means for reliable electrochemical determination of diffusion coefficients.[1,2] This report gives the diffusion coefficients measured by the HMDE method for thallium(I) and cadmium(II) ions in aqueous nitrate solutions at several temperatures.

When the diffusion current I_d at a spherical electrode is plotted against $t^{-1/2}$, where t is the time of electrolysis, a straight line should be obtained.[3] From the slope and intercept of the plot, with the known size of the electrode, the diffusion coefficient (D) and the product nc are determined independently from a single chronoamperogram, n being the charge number of the electrode reaction and c the bulk concentration of the electroactive species. A comparison of the observed value, $(nc)_{obsd}$, with the known value, $(nc)_{calcd}$, provides a useful means of assessing the extent to which the obtained D is reliable.

The linearity of the I_d *vs.* $t^{-1/2}$ plot is a qualitative criterion of experimental validity, but it is not sufficient. An example is given to demonstrate the importance of the "nc test" in a reliable diffusion coefficient measurement. All the plots for $[Fe(CN)_6]^{3-}$ in 1.0 mol dm^{-3} KCl were quite linear even when the $(nc)_{obsd}$ values were incorrect. The D values calculated from such linear plots were unreasonably high, scattered, and varied with the cyanoferrate concentration. Thus, besides the reproducible surface of known area with high hydrogen overvoltage, an essential advantage of the use of an appropriately designed HMDE is its ability to approximate spherical diffusion satisfactorily.

Experimental

In earlier experiments a balanced-type HMDE[1] was used. Later a micrometer-type HMDE assembly MCI AS01 (Mitsubishi Chemical Industries, Ltd.) was adopted, its capillary end being drawn to give a tip of *ca.* 0.2 mm in outer diameter, from which a mercury drop of 0.8 mm—1.0 mm diam. was produced. The size of the drop was read by the rotation of the micrometer, which had been calibrated by weighing the mercury delivered. For such an HMDE the total error due to the shielding and the non-sphericity is estimated to be 1% or less.[2] Constancy and uniformity of the solution temperature were essential to maintain stagnancy. It was controlled within $\pm$(0.002—0.05) °C, the fluctuation being larger at lower and higher temperatures.

The potentiostat with a current follower was essentially the same as that used previously[1] except that the high-speed pen recorder was replaced by a digital memory device (Biomation, Transient Recorder, Model 802), and the current signals stored therein were printed out. This arrangement eliminated the positive deviation at $t<1.5$ s caused by the delay in response of the pen recorder.[1] Another type of positive error in current magnitude was observed at much shorter times, $t<20$ ms, attributable to the saturation of the current follower during the initial period of electrolysis. The difficulty was readily circumvented by appropriate adjustment in the gain

of the follower. The whole system is capable of recording diffusion currents from a few milliseconds. The time range 100 ms—10 s was used in the present set of experiments.

Preparation of the reagents and solutions and the procedure of chronoamperometry have been described in detail.[1)] The chronoamperograms were first examined for linearity against $t^{-1/2}$. The deviating points that reflected the convective disturbance of diffusion layer at longer times[1)] were omitted, and the values of $(nc)_{obsd}$ were calculated for each set of measurements. If the mean value of $(nc)_{obsd}$ agreed with $(nc)_{calcd}$ within the limits of experimental error for 95% confidence, the value of D that best reproduced the observed chronoamperogram was obtained by the least-squares method by using the value of $(nc)_{calcd}$.

Results and Discussion

The diffusion coefficients for thallium(I) and cadmium (II) ions in nitrate solutions (Tables 1 and 2, respectively) were critically selected from the data obtained in the authors' laboratory since 1970. The values for 0.1 mol dm^{-3} KNO_3 at 25 °C supersede the corresponding ones presented earlier.[1)]

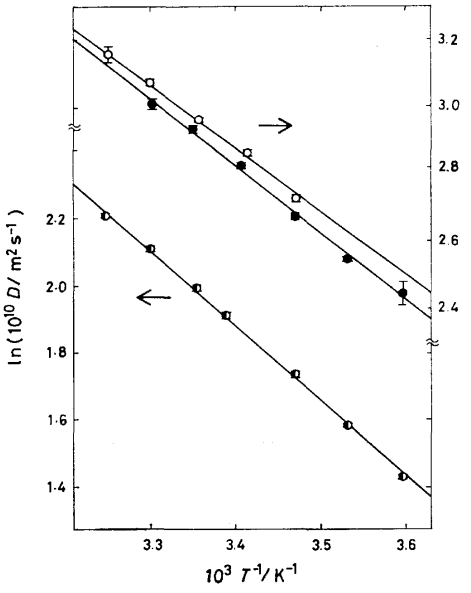

Fig. 1. Arrhenius plots of D.
○: Tl^+ in 0.1 mol dm^{-3} KNO_3, ●: Tl^+ in 0.5 mol dm^{-3} KNO_3, ◐: Cd^{2+} in 1.0 mol dm^{-3} KNO_3. The error bars correspond to the uncertainty at 95% confidence.

The Arrhenius plots of the three systems gave curves slightly convex upward (Fig. 1). The average experimental activation energies of diffusion, Δ^*E_A, are calculated by linearly approximating the curved plots. It is noted that these figures are comparable to 16.7 kJ mol^{-1} of the diffusion of water molecules in 0.1 mol dm^{-3} KNO_3.[4)]

According to Eyring's absolute rate theory, the intercept of the Arrhenius plot is related to $\lambda\exp(\Delta^*S/2R)$, where Δ^*S is the entropy of activation of diffusion, λ is the distance between two successive equilibrium positions of the diffusing particle in the solution, and R the gas constant.[5)] The values for this quantity falling around 0.3 nm suggest that Δ^*S cannot differ appreciably from zero. A similar value, 0.34 nm, is calculated from the data[4)] for the diffusion of water in 0.1 mol dm^{-3} KNO_3.

The viscosity, η, of the supporting electrolyte solutions was estimated by inter- and extrapolation of the tabulated data,[6)] and $kT/D\eta$ are calculated. The result seems to depend primarily on the diffusing species, being fairly insensitive to the temperature and concentration of the supporting electrolyte, as might be expected from the Einstein-Stokes relation or Eyring's theory.[5)]

The authors thank Sr. Jean Michalec for correcting the manuscript. One of the authors (H.I.) gratefully acknowledges financial support granted by the Saneyoshi Scholarship Foundation.

2-Alkylation Reactions of Thiophene and 1-Methylpyrrole with Trialkylboranes

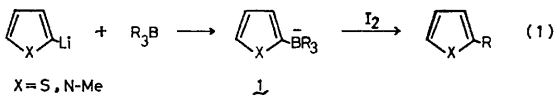
Toshiki SOTOYAMA, Shoji HARA, and Akira SUZUKI*

Department of Applied Chemistry, Faculy of Engineering, Hokkaido University, Sapporo 060

(Received December 9, 1978)

Synopsis. The reactions of iodine with ate-complexes prepared from trialkylboranes and 2-thienyllithium or 1-methyl-2-pyrrolyllithium were found to give the corresponding 2-alkylthiophenes or 1-methyl-2-alkylpyrroles, respectively, in good yields.

Useful methods for obtaining functionalized organic compounds can be found by employing a heterocycle with one hetero atom either as a precursor, reagent, or vehicle for the formation. The most general synthesis of pyrroles and thiophenes involves, as observed in the Knorr reaction, condensation of a carbonyl compound with the corresponding hetero atom containing compound.[1] On the other hand, probably the most available procedure for the synthesis of 2-alkylated derivatives of such heterocycles involves the reaction of the corresponding 2-lithio derivatives with alkyl halides.[2] However, the synthesis is satisfactory only for primary alkyl halides which readily undergo nucleophilic substitution reactions. In the case of *s*-alkyl halide, it may involve a competitive elimination reaction.[3] We wish to report that the reaction of 2-lithiothiophene or 2-lithio-1-methylpyrrole with trialkylboranes, followed by treatment with iodine gives the corresponding 2-alkylated derivatives in good yields (Eq. 1).[4]



(1)

Addition of an equimolar amount of butyllithium in ether to thiophene in ether containing tetramethylethylenediamine (TMEDA) at room temperature resulted in quantitative metalation to give 2-lithiothiophene, which was then treated at room temperature with a solution of triisobutylborane in THF. The reaction of the resulting solution of the ate-complex (**1**) thus obtained with iodine, followed by the usual alkaline hydrogen peroxide oxidation to remove the residual organoborane, provided 2-isobutylthiophene in a 95% yield. The results of reactions with representative trialkylboranes are summarized in Table 1.

In the present reaction, secondary alkyl and aryl groups appear to be introduced as readily as primary alkyl groups. It seems that the reaction proceeds through the same type of reaction path as considered in the reaction of 1-alkynyltriorganoborates with iodine,[5] *i.e. via* three stages: (1) coordination of trialkylboranes with the carbanion derived from the heterocyclic compound, (2) iodine cation attack of the 5-position in the hetero ring with migration of an alkyl group from boron to 2-position, and (3) intermediate (**2**) gives the product by the elimination of dialkyliodoborane (Eqs. 2, 3, and 4).

Experimental

Materials. All the chemicals and solvents were purified by distillation. Trialkylboranes were prepared by the usual procedure.[6]

The IR and NMR spectra were taken on a Hitachi-Perkin-Elmer Model 125 spectrophotometer and Hitachi R-22 spectrometer at 90 MHz using tetramethylsialne as an internal standard, respectively.

General Procedure. A representative procedure for the preparation of 2-butylthiophene is as follows. A dry 50 ml-flask equipped with a magnetic stirring bar, a septum inlet, and a reflux condenser was flushed with nitrogen. The flask

was charged under nitrogen gas with thiophene (0.378 g, 4.5 mmol), TMEDA (0.627 g, 5.4 mmol) and anhydrous ether (5 ml). Butyllithium (4.5 mmol, 3 ml of 1.5 M solution in ether) was then added at room temperature and the mixture was stirred for 1 h. After metalation was complete, tributylborane (3 mmol, 2 ml of 1.5 M solution in THF) was added at room temperature, followed by reflux for 2 h. The solution was cooled to −78 °C and iodine (1.143 g, 4.5 mmol) in 10 ml of dry ether was added. The reaction mixture was stirred for 30 min and allowed to warm to room temperature. After being stirred for 2 h, the mixture was treated with 5 ml of 3 M aqueous sodium hydroxide and 5 ml of 30% hydrogen peroxide at room temperature for 2 h. Saturation of the aqueous solution with potassium carbonate yielded an organic phase. The product was extracted with ether and analyzed by VPC. Analysis indicated the presence of 2.73 mmol (91%) of 2-butylthiophene. An analytically pure material was obtained by preparative VPC. (10% Carbowax 20 M on Uniport B, 3 m) with Varian autoprep Model-2800.

Identification of the Products. *2-Propylthiophene*: n_D^{20} 1.5060. Found: C, 66.48; H, 7.86%. Calcd for $C_7H_{10}S$: C, 66.61; H, 7.99%. Mass; *m/e*=126 (M^+). Steric Effect in 3,7-Disubstituted Tropolone. Chemical and Physical Properties of 3-Phenyl- and 3-Isopropyl-7-(2,4,6-cycloheptatrienyl)tropolones[1]

Takahiro TEZUKA*,† and Tetsuo NOZOE††

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received August 28, 1978)

Synopsis. The preparation and chemical and spectroscopic properties of 3-phenyl-7-(2,4,6-cycloheptatrienyl)-tropolone (**1**) and 3-isopropyl-7-(2,4,6-cycloheptatrienyl)-tropolone (**2**) are described. The somewhat unusual properties of **1** and **2** have been discussed in terms of the steric effect of the two substituent groups at positions 3 and 7 in the tropolone ring.

X-Ray crystallographic studies have revealed the distortion of the heptagon in tri and tetra-substituted tropolones.[2] In this connection, this report will show that the 3,7-disubstituted tropolones (**1** and **2**) possess chemical and physical properties which differ from the parent tropolone.

3-Phenyl- and 3-isopropyl-7-(2,4,6-cycloheptatrienyl)-tropolones (**1** and **2**) have been prepared in good yield from 3-phenyl- and 3-isopropyltropolones, respectively, by reaction with di(2,4,6-cycloheptatrienyl) ether. The structures of **1** and **2** have been assigned on the basis of the spectral and chemical data (see Experimental). Compounds **1** and **2** afforded azo derivatives **4a** (71%), **4b** (63%), and **5** (68%) by the action of the corresponding aryldiazonium chlorides. Compound **1** gave, on reaction with diazomethane, two kinds of methyl ethers **6** (61%) and **7** (24%), both of which reverted to **1** by acid hydrolysis. The isomeric structures of **6** and **7** have been tentatively assigned on the basis that a less hindered methyl ether would be formed in higher yield.[3] The methoxyl group of the ethers (**6** and **7**) was replaced by an amino group in the reaction of ammonia in methanol, giving amino derivatives **8** and **9**, the isomeric structures of which are again tentative. The properties of **1** and **2** described are consistent with those of the parent tropolone.[3]

The properties of **1** and **2**, however, differ from tropolone in the following respects: (i) the compounds do not show a ferric chloride coloration characteristic of tropolones in benzene and ethanol, but show a pale green coloration in 1-butanol. It is well documented that the ferric chloride coloration of tropolones in benzene and ethanol is due to the formation of the tropolone-iron (III) 3:1 or 2:1 complex.[3,4] (ii) The hydroxyl absorption bands of **1** and **2** do not appear in the ordinary region (3200—3500 cm^{-1}),[5] appearing at 3050 cm^{-1} in low intensity (CCl_4). The absorption bands of the conjugated carbonyl appear at 1600 and 1550 cm^{-1} for **1**, and 1590 and 1540 cm^{-1} for **2**. The band positions are as expected,[5] but the intensities are extremely small compared with those of tropolone. (iii) Compounds **1** and **2** are inert to nitration with nitric acid in acidic medium, with which tropolone readily reacts to give nitrotropolone.[3] Similar chemical and spectroscopic properties were found for 3,7-di(2,4,6-cycloheptatrienyl)tropolone (**3**)[6] prepared from 3-(2,4,6-cycloheptatrienyl)tropolone and di(2,4,6-cycloheptatrienyl) ether.

The distortion of the heptagon and bond fixation in crowded tropolones such as 3,5,7-tribromohinokitiol and 3,7-dibromohinokitiol have been reported by Itô *et al.*[2] The somewhat unusual properties of **1**, **2**, and **3** found in this study may be related to the steric effect of the bulky substituent groups at the 3 and 7 positions of the tropolone ring. The boat conformation of 2,4,6-cycloheptatriene is well documented and the steric hindrance caused by the 2,4,6-cycloheptatrienyl group may be comparable with that by the isopropyl group.[7]

Experimental

Preparation of 3-Phenyl-7-(2,4,6-cycloheptatrienyl)tropolone (1) and 3,7-Di(2,4,6-cycloheptatrienyl)tropolone (3). A mixture of 3-phenyltropolone (5 g, 0.025 mol) and di(2,4,6-cycloheptatrienyl) ether (3 g, 0.015 mol) in dry ethanol (5 ml) was refluxed for 20 min. The precipitate formed was collected by filtration and crystalized (6.8 g; 94%). Recrystallization from benzene gave **1** as yellow needles, mp 141—142 °C: λ_{max}^{MeOH} (log ε) 242 (4.36), 268 (4.33), 348 (3.84), 385 (3.86), and 410 (3.70) nm; δ (CCl_4) 3.63 (1H, t, J=4.8 Hz), 5.18 (2H, dd, J=4.8 and 8.2 Hz), 6.13 (2H, m), 6.37 (2H, broad t), and around 8 (8H). Found: C, 83.17; H, 5.38%. Calcd for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59%.

Similarly, heating a mixture of 3-(2,4,6-cycloheptatrienyl)-tropolone (250 mg, 1.2 mmol) and di(2,4,6-cycloheptatrienyl)-

† Present address: Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31.

†† Present address: Tokyo Research Laboratory, Kao Soap Ltd., Bunka, Sumida-ku, Tokyo 131.

ether (117 mg, 0.59 mmol) in dry ether (2.5 ml) under reflux for 3 h gave crystals (365 mg, 100%). Recrystallization from ethanol gave **3** as yellow needles, mp 137 °C, identical with an authentic sample.[6]

Preparation of 3-Isopropyl-7-(2,4,6-cycloheptatrienyl)tropolone (2). A mixture of 3-isopropyltropolone (12.6 g, 0.0768 mol) and di(2,4,6-cycloheptatrienyl) ether (8.6 g, 0.0434 mol) was heated on a water bath for 20 min. The reaction mixture was extracted with benzene and the extract treated with aqueous copper(II) sulfate. The precipitate formed was collected by filtration, giving copper salts of **2** (20 g, 91%) as green needles (mp 229 °C). Dry hydrogen sulfide gas was passed through a suspension of the copper salts of **2** (200 mg, 0.035 mmol) in chloroform (4 ml) for 30 min. and the mixture allowed to stand for 1 h. The copper(II) sulfide precipitate was filtered, and the filtrate was treated with active charcoal, washed with water and dried over sodium sulfate. Evaporation of the solvent gave crystals of **2** (91 mg, 51%). Recrystallization from a mixed solvent of ethanol and benzene gave **2** as colorless needles, mp 77—78 °C: λ_{max}^{MeOH} (log ε) 255 (4.18), 321 (3.70), 363 (3.68), 374 (3.72), and 396 (3.58) nm; δ (CCl_4) 1.24 (6H, d, J=4.0 Hz), 3.30 (1H, m), 3.42 (1H, t, J=4.2 Hz), 5.28 (2H, dd, J=4.2 and 8.8 Hz), 6.20 (2H, m), 6.54 (2H, m), and 7.25 (3H, m). Found: C, 80.52; H, 7.32%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

3-Phenyl-5-(p-tolylazo)-7-(2,4,6-cycloheptatrienyl)tropolone (4a). To a pyridine solution (1 ml) of **1** (100 mg, 0.35 mmol) was added with stirring at 0 °C an aqueous solution of *p*-toluenediazonium chloride, prepared from *p*-toluidine (41 mg, 0.38 mmol), 6 M hydrochloric acid (0.3 ml), sodium nitrite (35 mg, 0.51 mmol), and water (0.1 ml). The stirring was continued for 1—1.5 h at 0 °C. After the addition of a small amount of water, the reaction mixture was extracted with chloroform and the extract washed with water and dried over sodium sulfate. Evaporation of the solvent gave **4a** (100 mg, 71%) as crystals. Recrystallization from benzene afforded **4a** as orange needles, mp 201.5—202.5 °C. Found: C, 79.60; H, 5.36%. Calcd for $C_{27}H_{22}O_2N_2$: C, 79.78; H, 5.46%.

3-Isopropyl-5-(p-tolylazo)-7-(2,4,6-cycloheptatrienyl)tropolone (5). To a pyridine solution (1 ml) of **2** (100 mg, 0.39 mmol) was added with stirring at 0 °C an aqueous solution of *p*-toluenediazonium chloride, prepared from *p*-toluidine (46 mg, 0.43 mmol), 6 M hydrochloric acid (0.4 ml), sodium nitrite (40 mg, 0.58 mmol), and water (0.2 ml). The stirring was continued for 1.5 h at 0 °C. Work-up of the reaction mixture as described above gave **5** (100 mg, 68%) as crystals. Recrystallization from benzene afforded **5** as orange needles, mp 164—165 °C. Found: C, 77.65; H, 6.76; N, 7.49%. Calcd for $C_{24}H_{24}O_2N_2$: C, 77.39; H, 6.50; N, 7.52%.

3-Phenyl-5-(p-bromophenylazo)-7-(2,4,6-cycloheptatrienyl)tropolone (4b). To a pyridine solution (0.1 ml) of the sodium salts of **1** (100 mg, 0.32 mmol) was added with stirring at 0 °C an aqueous solution of *p*-bromobenzenediazonium chloride prepared from *p*-bromoaniline (62 mg, 0.36 mmol), 6 M hydrochloric acid (0.2 ml), sodium nitrite (30 mg, 0.43 mmol), and water (0.3 ml). The mixture was continuously stirred for 1 h at 0 °C. Work-up of the reaction mixture gave crystals of **4b** (95 mg, 63%). Recrystallization from benzene gave **4b** as orange needles, mp 197—198 °C. Found: C, 65.96; H, 4.20; N, 6.21%. Calcd for $C_{26}H_{19}O_2N_2Br$: C, 66.24; H, 4.03; N, 5.94%.

Formation of Methyl Ethers (6 and 7) from 1. To an ethereal solution of **1** (1 g, 3.5 mmol) was added an ethereal solution of diazomethane (8 ml) prepared from *N*-nitrosomethylurea and potassium hydroxide.[8] After the addition of methanol (one drop), the mixture was allowed to stand at room temperature for 30 min. The precipitate formed was collected by filtration giving crystals of **6** (640 mg, 61%). Recrystallization from ethanol gave **6** as yellow needles, mp 133—134 °C. Found: C, 83.22; H, 6.03%. Calcd for $C_{21}H_{18}O_2$: C, 82.42; H, 6.00%. Concentration of the filtrate gave crystals of **7** (250 mg, 24%). Recrystallization from ethanol gave **7** as yellow needles, mp 112—113 °C. Found: C, 83.23; H, 5.86%. Calcd for $C_{21}H_{18}O_2$: C, 83.42; H, 6.00%.

Hydrolysis of 6 and 7. A mixture of **6** (1 mg) or **7** (1.5 mg) and 3 M sulfuric acid (one drop) in ethanol (0.1 ml) was refluxed for 10 min. The reaction mixture was extracted with benzene and the extract washed with water and dried. Evaporation of the solvent gave a crystalline compound which had an R_f value identical with that of **1**.

Formation of Amino Derivatives 8 and 9. A mixture of the methyl ethers (**8** and **9**) (110 mg) prepared from **1** with diazomethane (*vide supra*) was dissolved in methanolic ammonia (25 volume %, 20 ml) and the mixture allowed to stand at room temperature for 48 h. Evaporation of the methanol and excess ammonia gave an oil which solidified on the addition of a small amount of ethanol to give crystals (65 mg). Recrystallization from a mixture of ethanol and benzene gave yellow prisms (**8**), mp 126—127 °C. Found: N, 4.54%. Calcd for $C_{20}H_{17}ON$: N, 4.88%. The filtrate gave, after alumina chromatographic purification, crystals of **9** (10 mg), mp 65 °C. Found: N, 4.50%. Calcd for $C_{20}H_{17}ON$: N, 4.88%.

Nitration of 1, 2, and 3. To an acetic acid solution (2 ml) of **1** (200 mg, 0.69 mmol) was added with stirring an acetic acid solution (0.5 ml) of 92% nitric acid (140 mg, 2.4 mmol) and the mixture continuously stirred for 3 h. The precipitate formed by the addition of water was collected by filtration giving crystals (200 mg). Recrystallization from benzene gave yellow needles, mp 142 °C, identical with **1**.

Under similar conditions the nitration of **2** and **3** was attempted which again leads to the quantitative recovery of the starting materials.

The Carbonylation of α-Haloacetophenones and Benzyl Halides by Disodium Tetracarbonylferrate

Yoshihisa WATANABE,* Kenichi TANIGUCHI, Masataka SUGA, Take-aki MITSUDO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received August 31, 1978)

Synopsis. α-Haloacetophenones and benzyl chlorides can be converted into derivatives of β-keto acid and phenylacetic acid respectively by two succesive reactions, with $Na_2Fe(CO)_4$ and then with nitrobenzenes or iodine-ethanol as the oxidizing reagents.

Tetracarbonylferrate, such as potassium tetracarbonylhydridoferrate and disodium tetracarbonylferrate, are excellent reagents for the carbonylation of alkyl halides.[1] These reactions involve acylcarbonylferrates as the key intermediates, from which the corresponding carbonylated products, such as aldehydes, ketones, and acid derivatives are derived.[2] The reaction of the ferrates with α-haloacetophenones and benzyl chloride, however, has been shown to give only alkyl complexes, β-oxoalkyl- (**1**)[3] and benzyltetracarbonylferrate (**2**).[1b] An attempt to prepare the cor-

$[Ph-\overset{\overset{O}{\|}}{C}-CH_2-Fe(CO)_4]^-$ **1** $\qquad [Ph-CH_2-Fe(CO)_4]^-$ **2**

responding acyl complexes from **1** and **2** in the manner described in the literature[1b] has been unsuccessful. **1** and **2** give acetophenone and toluene respectively upon protonation. **1** shows specific behavior in the reaction with acyl halides. The treatment of **1** with acyl halides and then with acetic acid gives enol esters.[3] Acyl- and carbamoyltetracarbonylferrates are excellent reagents for the reductive acylation and carbamoylation of nitro compounds into amides and ureas respectively.[2d,4]

$$[RCOFe(CO)_4]^- + ArNO_2 \longrightarrow RCONHAr$$

The present study will deal with the transformation of **1** and **2** into β-keto acid derivatives and phenylacetic acid derivatives respectively by the treatment of **1** and **2** with nitrobenzenes and iodine-ethanol as oxidizing reagents.

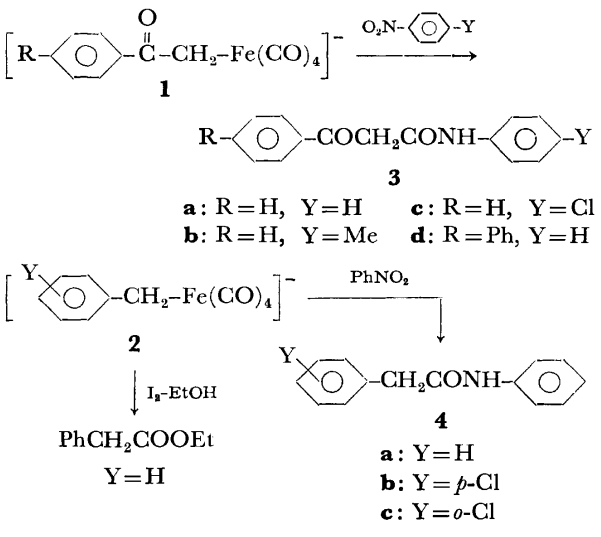
Results and Discussion

Derivatives of tetracarbonylferrates are powerful reducing reagents for the reduction of nitro compounds, giving amines, amides, and ureas. The alkyl complexes, **1** and **2**, also have a great reactivity for nitrobenzene, nitrotoluene, and *p*-chloronitrobenzene. The nitro compounds react smoothly with **1** and **2** at room temperature, with the evolution of gas. The reaction is completed in less than 30 min. The major products are β-keto amides (**3**) and phenylacetamides (**4**) from **1** and **2** respectively. The treatment of **2a** with iodine-ethanol gives ethyl phenylacetate. The results are summarized in Table 1.

Table 1. The carbonylation of α-haloacetophenones and benzyl chlorides with disodium tetracarbonylferrate

Run	Halide	Oxidizing agent	Product (Yield % per halide)
1	α-Chloroacetophenone	Nitrobenzene	**3a** (44) and *N*-Phenacylaniline (trace)
2	α-Chloroacetophenone	*p*-Nitrotoluene	**3b** (22)
3	α-Chloroacetophenone	*p*-Chloronitrobenzene	**3c** (11)
4	α-Bromo-*p*-phenylacetophenone	Nitrobenzene	**3d** (50) and 4-Acetylbiphenyl (50)
5	Benzyl chloride	Nitrobenzene	**4a** (35)
6	*p*-Chlorobenzyl chloride	Nitrobenzene	**4b** (24)
7	*o*-Chlorobenzyl chloride	Nitrobenzene	**4c** (16)
8	Benzyl chloride	Iodine-ethanol	Ethyl phenylacetate (38)

These results indicate that α-haloacetophenones and benzyl halides can be transformed into carbonylated derivatives by a two-step procedure, a reaction with the ferrate and then with an oxidizing agent. *N*-Phenacylaniline, an expected products from **1a**, was obtained, but in only a poor yield. Although the reaction mechanism is not clear, the alkyl groups of **1** and **2** appear to be transformed into the corresponding acyl types through the reaction. With the reaction of iodine, an oxidative addition of iodine to the alkyl ferrate(0) seems to be the first step; the coordination of iodine may cause an alkyl migration to one of the coordinated carbon mon-



oxides to give an acyl iron(II) complex such as [RCOFe-$(CO)_3I_2$], from which an acyl iodide may be formed. The cleavage of acylcarbonylmetal complexes with iodine and bromine has already been reported in manganese and cobalt series.[5] The reaction of nitrobenzenes also seems to involve an oxidizing step to iron(II) complexes, which may be favorable for the formation of acyl complexes.[6] Thus, the reduction of nitrobenzenes with the ferrate, **1** and **2**, is completed by *N*-acylation.

Experimental

Materials. The tetrahydrofuran was distilled over $LiAlH_4$ prior to use. The disodium tetracarbonylferrate was prepared according to the method described an earlier article.[1b] The benzyl chloride, *o*- and *p*-chlorobenzyl chloride, α-chloroacetophenone, α-bromo-*p*-phenylacetophenone, and nitrobenzenes were all commercial products. The nitrobenzenes were dried over a molecular sieve (3A) and distilled before use.

General Reaction Procedure. To the ferrate (11 mmol) in tetrahydrofuran (40 ml), were added an α-haloacetophenone or benzyl chloride (11 mmol) solution in tetrahydrofuran (10 ml); the reaction mixture was then stirred under an argon atmosphere at room temperature for 30 min. To this solution, an oxidizing agent, such as a nitrobenzene (11 mmol) solution in tetrahydrofuran (10 ml) or an iodine-saturated solution in ethanol (30 ml), was added drop by drop, and then the mixture was stirred for about 1 h until the evolution of gas ceased.

Analyses. The ethyl phenylacetate was analyzed by GLC using a column (3 mmϕ, 3 m) packed with Apiezone Grease L (10%) on Neopak 1A. The other products were isolated by chromatography and analyzed by means of IR, PMR, and elemental analysis. The IR spectra were recorded on a 215 Hitachi spectrometer. The ^1H NMR spectra were taken on a JEOL-PM-60 spectrometer. All the chemical shifts are given in δ values relative to a Me_4Si standard. All the melting points were taken on a Yanagimoto apparatus and are uncorrected. All the products (**3** and **4**) are known compounds and were identified by means of their IR and PMR spectra. The elemental analyses of the products gave satisfactory results.

*Benzoylacetanilide (**3a**).* The filtered and concentrated reaction mixture was chromatographed on a 2×30 cm florisil column. The elution of the chromatogram with benzene gave brown crystals: Found: C, 79.53; H, 5.90; N, 6.35; O, 8.22%. Calcd for $C_{14}H_{13}NO$: C, 79.62; H, 6.16; N, 6.64; O, 7.58%. This compound appeared to be *N*-phenacylaniline, but its yield was not big enough for further analysis. Further elution of the chromatogram with ether gave colored crystals (**3a**; yield, 44%), which was later recrystallized from ethanol/petroleum ether. The IR and PMR spectra of the crystals were identical with those of an authentic benzoylacetanilide (Aldrich). Mp, 107.5—108.5 °C.

N-*(p-Tolyl)benzoylacetamide (**3b**).* Chromatography on a 2×30 cm florisil column, using methanol as an eluant, gave crystals (**3b**; yield, 22%), which were later recrystallized from ethanol. Mp, 142.0—143.0 °C. IR (KBr): ν(NH) 3300(m), ν(COAr) 1690(s), ν(CONH) 1640(s) cm^{-1}. PMR (d^6 DMSO): δ 2.3 (s, 3H), 4.1 (s, 2H), 7.0—8.2 (m, 9H), 10.1 (s, 1H) ppm.

N-*(p-Chlorophenyl)benzoylacetamide (**3c**).* Chromatography on a 2×30 cm silica gel column, using ether as an eluant, gave crystals (**3c**; yield, 11%). Mp, 163.0—164.0 °C. IR (KBr): ν(NH) 3300(w), ν(CO) 1690(s) and 1660(s) cm^{-1}. PMR (d^6 DMSO): δ 4.2 (s, 2H), 7.2—8.1 (m, 9H) ppm.

*(p-Phenylbenzoyl)acetanilide (**3d**).* Chromatography on a 2×30 cm silica gel using dichloromethane gave yellow crystals (4-acetylbiphenyl; yield, 50%), identified by means of the IR and PMR spectra using an authentic sample. The further elution of the chromatogram with ethanol gave crystals (**3d**; yield, 50%), later recrystallized from chloroform. Mp, 181.0—184.0 °C. IR(KBr): ν(NH) 3300(m), ν(CO) 1690(s) and 1660(s) cm^{-1}. PMR (d^6 DMSO): δ 4.2 (s, 2H), 6.7—8.3 (m, 14H), 10.2 (s, 1H) ppm.

*Phenylacetanilide (**4a**).* The filtered and concentrated reaction mixture was extracted with ethanol to give crystals (**4a**; yield, 35%). Mp, 116.5—117.5 °C. IR (KBr): ν(NH), 3300(m), ν(CO) 1655(s) cm^{-1}. PMR ($CDCl_3$): δ 3.7 (s, 2H), 6.8—7.9 (m, 10H) ppm.

*(p-Chlorophenyl)acetanilide (**4b**).* Chromatography on a 2×30 cm silica gel column, using ether and ethanol as eluants, gave crystals (**4b**; yield, 24%). Mp, 169.5—171.5 °C. IR (KBr): ν(NH) 3300(m), ν(CO) 1660(s) cm^{-1}. PMR ($CDCl_3$): δ 3.7 (s, 2H), 6.8—7.7 (m, 9H), 10.1 (s, 1H) ppm.

*(o-Chlorophenyl)acetanilide (**4c**).* Chromatography on a 2×30 cm silica gel column, using dichloromethane and ether as eluants, gave crystals (**4c**; yield, 16%), which were then recrystallized from ethanol. Mp, 138.0—141.0 °C. IR (KBr): ν(NH) 3300(m), ν(CO) 1660(s) cm^{-1}. PMR ($CDCl_3$): δ 3.9 (s, 2H), 6.8—7.8 (m, 9H), 10.1 (s, 1H) ppm.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (6), 1871—1872 (1979)

Preparation of 1,3-Bis(4-aminobutyl)-1,3-dimethyl-1,3-diphenyldisiloxane and Siloxane-containing Polyamides

Toshio TAKIGUCHI,* Kazuo AMAGAI, and Hisashi KAWABATA

Department of Synthetic Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received October 4, 1978)

Synopsis. 1,3-Bis(4-aminobutyl)-1,3-dimethyl-1,3-diphenyldisiloxane has been readily obtained by the reduction of 1,3-bis(3-cyanopropyl)-1,3-dimethyl-1,3-diphenyldisiloxane, the hydrolysate of chloro(3-cyanopropyl)methylphenylsilane. The diamine reacted with abietic acid forming an equimolar crystalline adduct which gave a siloxane-containing polyamide by the conventional salt fusion technique.

Several preparations of compounds with the general formula $[NH_2–R–Si(R')(R'')]_2O$, (carbofunctional α,ω-diamino substituted disiloxanes) have been reported.

In the preparation of siloxane-containing α,ω-difunctional oligomeric compounds, 1,3-bis(4-aminobutyl) tetraorganodisiloxanes have been obtained in good yield by the reduction of the corresponding dinitriles by lithium aluminum hydride, followed by alkaline hydrolysis. The tetraorganodisiloxane segments were wholly retained during the procedure.

The preparation of α,ω-diamino compounds has been conducted according to the following scheme:

$$R'R''HSiCl \xrightarrow{CH_2=CHCH_2CN,\ H_2PtCl_6} ClSi(R')(R'')CH_2CH_2CH_2CN \xrightarrow{H_2O} [CNCH_2CH_2CH_2(R')(R'')Si]_2O \xrightarrow{LiAlH_4} [NH_2CH_2CH_2CH_2CH_2(R')(R'')Si]_2O$$

All products were well defined spectroscopically and the NMR and IR data were consistent with the assigned structures.

The obtained diamines further underwent polycondensation with organic dibasic acids to give modified polyamides containing disiloxane linkages in the chain backbone.

Experimental

Starting Materials. Dichloromethylsilane (bp 41 °C) and chlorodimethylsilane(bp 36 °C) in purified grades were received from Shin-etsu Chem. Ind. Co.; chloromethylphenylsilane(bp 66—67 °C/15 mmHg) was synthesized from Grignard reagents. 1,3-Dimethyl-1,3-diphenyldisiloxane (bp 90 °C/0.25 mmHg; n_D^{24} 1.5250) was prepared by the acid hydrolysis[2] of chloromethylphenylsilane (yield 86%). Commercial grade allyl cyanide (bp 119 °C) was purified by distillation immediately prior to use.

3-Cyanopropylchloromethylphenylsilane. A mixture of allyl cyanide (20 g, 0.30 mol), chloromethylphenylsilane (61 g, 0.39 mol), and hexachloroplatinic(IV) acid solution[3] (300 μl), was sealed in a stainless bomb maintained at 120 °C for 24 h. Fractionation of the resultant products gave 59 g (88%) pure 3-cyanopropylchloromethylphenylsilane (**1**), bp 95—96 °C/0.08 mmHg.

IR (neat): 2225 (ν_{CN}), 1425 (Si–C_6H_5), 1255 (Si–CH_3), 490 (Si–Cl).

NMR (CCl_4): δ=0.65 (3H, s, –CH_3), 1.12 (2H, m, Si–CH_2–), 1.72 (2H, m, C–CH_2–C), 2.23 (2H, t, –CH_2–CN), 7.40 (5H, m, –C_6H_5).

1,3-Bis(3-cyanopropyl)-1,3-dimethyl-1,3-diphenyldisiloxane. Hydrolysis of **1** under refluxing for 1 h, accompanied by conventional treatment gave quantitatively the dimeric product, 1,3-bis(3-cyanopropyl)-1,3-dimethyl-1,3-diphenyldisiloxane (**2**). (bp 193—195 °C/0.05 mmHg, n_D^{20} 1.5298).

IR (neat): 2225 (ν_{CN}), 1425 (Si–C_6H_5), 1255 (Si–CH_3), 1055 (Si–O–Si).

NMR (CCl_4): δ=0.33 (6H, s, –CH_3), 0.85 (4H, m, Si–CH_2–), 1.53 (4H, m, C–CH_2–C), 2.10 (4H, t, –CH_2–CN), 7.30 (10H, m, –C_6H_5).

1,3-Bis(4-aminobutyl)tetraorganodisiloxanes. A typical preparation will be given for 1,3-bis(4-aminobutyl)-1,3-dimethyl-1,3-diphenyldisiloxane (**3**):

To a suspension consisting of lithium aluminum hydride (4.3 g, 0.114 mol) and anhydrous ether (230 ml) cooled below 0 °C, a solution of **2** (18.7 g, 0.0476 mol) in anhydrous ether (30 ml) was added dropwise under vigorous stirring for 20 min. The resultant mixture was further stirred for an additional 40 min and water (5 ml). 20% aqueous sodium hydroxide solution (3.5 ml) and water (16 ml) were added in succession. The contents were stirred with continuous cooling to ensure completion of the reaction.

After removal of the inorganic salts formed by filtration, the ethereal layer was dried over anhydrous sodium sulfate and successively fractionated to give 14.9 g (78%) of **3** (bp 182—184 °C/0.1 mmHg; n_D^{20} 1.5312). **1**, **2**, and **3** are new compounds not found in the literature.

The preparation of the intermediate, **2** from the hydrosilylation of 1,3-dimethyl-1,3-diphenyldisiloxane and allyl cyanide in the presence of platinum catalyst was unsuccessful, yielding only a small amount of 3-cyanopropyl-1,3-dimethyl-1,3-diphenyldisiloxane as an addition product.

The use of chlorodimethylsilane in place of chloromethylphenylsilane in the platinum-catalyzed hydrosilylation of allyl cyanide followed by a similar procedure as above, unfailingly yielded the tetramethyl analog, 1,3-bis(4-aminobutyl)tetramethyldisiloxane (**4**), (bp 119—122 °C/0.04 mmHg; n_D^{20} 1.4360).

Compd 3:

Polymerization. Compound **3** behaved in a similar manner as the polymethylenediamines towards organic dibasic acids,

an example of which will be given as follows:

To a stirred solution of adipic acid (11.0 g, 75.4 mmol) in ethanol (85 ml), a solution of **3** (30.8 g, 77 mmol) in ethanol (60 ml) was added. On standing overnight the solution deposited a fine colorless crystalline mass from which was obtained by recrystallization from ethanol–benzene (1: 1) 31.7 g (77%) of the pure adipic acid salt of **3**, melting at 174—175 °C.

Found: C, 61.61; H, 8.29; N, 5.20; Si, 10.22%. Calcd for $C_{23}H_{46}N_2O_5Si_2$: C, 61.54; H, 8.42; N, 5.13; Si, 10.26%.

IR (neat): 1630, 1540 (NH_3^+), 1580, 1390 (COO^-), 1420 (Si–C_6H_5), 1250 (Si–CH_3), 1055 (Si–O–Si).

X-Ray powder pattern (Cu $K\alpha$/Ni)

Melt-polymerization of the salt was conducted according to the method of S. B. Speck,[4] and the final beating was conducted at 270 °C under a pressure less than 0.5 mmHg.

The polymer obtained was a pale yellow, transparent, tough solid softening over the range of temperature 100—150 °C to give a sticky highly viscous liquid with high spinnability and insolubility in ordinary organic solvents except for *m*-cresol. The intrinsic viscosity of the polyamide measured at 25 °C in *m*-cresol was [0.46].

IR (neat): 3300 (ν_{NH}), 1640 ($\nu_{C=O}$), 1540 (δ_{NH}), 1425 (Si–C_6H_5), 1255 (Si–CH_3), 1055 (Si–O–Si).

Terephthalic acid and sebacic acid were also found to give similar solids with different softening points when analogously treated.

The authors would like to thank Shin-etsu Chem. Ind. Co. for the supply of the organochlorosilanes.

Friedel-Crafts Reaction of Anisole with 2-*t*-Butyloxirane

Masashi INOUE, Masatsune HARADA,† Nobuyuki UMAKI, and Katsuhiko ICHIKAWA*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received November 2, 1978)

Synopsis. The title reaction in excess anisole gave a mixture composed of 3-(methoxyphenyl)-2,3-dimethyl-1-butanols (**2**) (a mixture of ortho and para isomers), 2-(*p*-methoxyphenyl)-2-methybutane (**3**), and oligomer of 2-*t*-butyloxirane, while the same reaction in nitromethane gave a product composed of **2** (only the para isomer) and hexylanisoles, but not **3**. The reaction sequences to give the products are discussed in terms of step-by-step and concerted alkylation mechanisms.

A recent paper has described that epoxides react competitively with the aromatic substance under Friedel-Crafts conditions *via* two different paths:[1] Path a; a nucleophilic attack of aromatics on epoxide to yield 2-aryl-1-alkanols,[2] and Path b; a rearrangement of the epoxide to a carbonyl compound, followed by condensation with aromatics. It was also found that the alkylation of anisole with epoxides in a nitromethane solvent takes place preferentially through Path b. In the course of our study of Friedel-Crafts reactions with epoxides, we found a curious behavior of 2-*t*-butyloxirane (**1**) under Friedel-Crafts conditions.

When **1** was allowed to react with an excess of anisole in the presence of aluminum chloride, 3-(methoxyphenyl)-2,3-dimethyl-1-butanols (**2**) (21% yield;[3] ortho isomer 50% and para isomer 50%) and 2-(methoxyphenyl)-2-methylbutane (**3**) (14% yield; only para isomer) were found, together with the oligomer (**4**).

The retention volumes on GLC suggested that **4** was a mixture of dimer (8 wt% on the basis of the weight of the **1** used) and trimer (8 wt%) of **1**. When the reaction was carried out in nitromethane, a 14% yield of **2** (only para isomer) and a 30% yield of a mixture of isomer of hexylanisole were obtained, but no formation of **3** was observed.

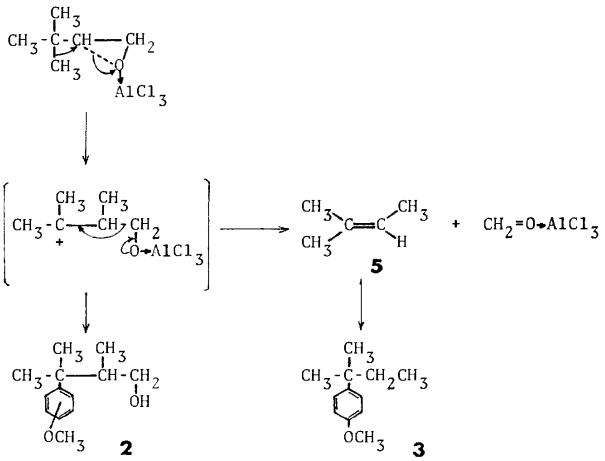
As the ring-opening and the rearrangement of simple epoxide are widely accepted as proceeding without the formation of a fully developed carbonium ion,[4] the formation of **2**, which appears to be derived from a neopentyl rearrangement, is interesting. Although the base-catalyzed ring-opening and polymerization of **1** have been well established,[5] no report concerning a reaction under acidic conditions has appeared to our knowledge. Therefore, several kinds of acid-catalyzed ring-openings of **1** were carried out in order to examine the possibility of such a rearrangement.

As is shown in Table 1, the products are those which are formed by the direct attack on the epoxide carbon of **1**; no product could be detected which is to be expected from the neopentyl rearrangement, followed by nucleophilic attack. The results of the alkylation reported here are the first example of this kind of rearrangement in a simple aliphatic epoxide.[6]

† Present address: Research Center, Osaka Gas Co., Ltd., Konohana, Osaka 554.

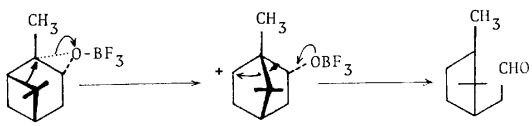
TABLE 1. ACID-CATALYZED RING-OPENING OF *t*-BUTYLOXIRANE (**1**)

Reaction condition	Product (isolated yield)
35% HCl, dioxane, 10 °C, 3 h.	1-Chloro-3,3-dimethyl-2-butanol (**10**) (90%)
$AlCl_3$, 1,2-dichloroethane, ice bath, 2.5 h.	**10** (8.4%)
Acetic acid, 70 °C, 48 h, then 10% NaOH.	3,3-Dimethyl-1,2-butanediol (**11**) (92%)
Formic acid, ice bath, 24 h.	*t*-Butylethylene diformate (18%), 2-hydroxy-3,3-dimethyl formate (19%), 1-(hydroxymethyl)-2,2-dimethylpropyl formate (8%), and **11** (8%)
Ethanol, a drop of H_2SO_4, room temp, 8 days.	1-Ethoxy-3,3-dimethyl-2-butanol (89%)



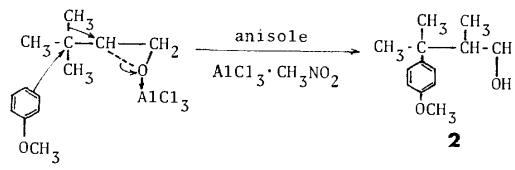
Scheme 1. Proposed reaction sequences for the reaction of **1** in excess anisole.

Product **3** is also an abnormal product. It is well known that undesired reactions always take place as the side reactions of Friedel-Crafts reaction.[7] The reaction sequences which have thus far been proposed to explain the side reactions, however, cannot explain the formation of **3**. The most probable reaction sequence is as follows: **1** undergoes ring-opening, rearrangement of methyl group, and β-cleavage to yield 2-methyl-2-butene (**5**), which then reacts with anisole to give **3** (Scheme 1). A similar cleavage was reported in the BF_3-catalyzed rearrangement of pinene oxide (**6**).[8] In the Lewis acid-catalyzed rearrangement of epoxide, the migrating groups are usually the substituents attached directly to



the epoxide ring. In contrast, the alkyl groups which are in the β-position to the epoxide ring shift in the reactions of **1** and **6**. As the backside of the epoxide C–O bond is shielded by the bulky *t*-butyl group in **1** or the methyl group on the bridge carbon in **6**, alkyl groups attached to the epoxide rings are prevented from approaching the carbonium-ion center.

As the reaction of anisole with 2,3-dimethyl-2-butene affords a product consisting of more than 95% para isomer (as shown by a separate control experiment), the high proportion of the ortho isomer in **2** formed in the reaction of excess anisole seems to be unusual. Kretchmer and McCloskey[9] found that ethyl allylmalonate and 5-hexen-2-one (**7**) react preferentially with anisole at the ortho position and explained the mechanism by a cyclic process, in which both anisole and the alkylating agent coordinate to an aluminum atom. A similar mechanism might be applied to the ortho alkylation of anisole with **1**. But in the reaction of **1**, the exchange of the solvent from excess anisole to nitromethane reduced the proportion of ortho alkylation from 50% to 0%, whereas the alkylation of anisole with **7** was reported to yield 65% and 55% ortho product in excess anisole and in 1-nitropropane respectively. The solvent effects of the reaction reported here seem to be too large to be explained by the ortho-alkylation mechanism.



Scheme 2.

Nakajima *et al.* reported an asymmetric induction in the reaction of benzene with optically active 1,2-epoxybutane to yield 3-phenyl-1-butanol.[10] From their results, one can consider that the hydride shift from the β to the α position occurs in concert with the alkylation step of benzene. In the reaction of **1** in nitromethane, the alkylation step seems similarly to occur in concert with the methyl migration and ring-opning of epoxide, as is shown in Scheme 2. An S_N2-like transition state favors an attack on the para position of anisole because of steric hinderance. Scheme 2 can also explain the fact that the reaction in nitromethane does not give **3**, because this reaction mechanism does not involve a fully developed carbonium ion. In the case of the anisole solvent, the reacting species have a more carbonium-ion character (Scheme 1) and the proportion of the ortho isomer increases.

Experimental

Into a mixture of aluminum chloride (2.7 g) and anisole (25 ml) held in an ice bath, a solution of **1** (1.00 g) in anisole (10 ml) was added dropwise under vigorous stirring over a period of 30 min; stirring was then continued for an additional 2 h at the ice-bath temperature. After the usual work-up, the products were separated by column chromatography on silica gel, using benzene as the elutant. The distillation of the least polar fraction by means of a ball-oven apparatus yielded 230 mg (13%) of **3**, which was identical with a sample prepared by the alkylation of anisole with **5**; NMR ($CDCl_3$): 0.6[7] (3H, t), 1.2[5] (6H, s), 1.6[0] (4H, q), 3.7[8] (3H, s), and 6.7—7.3 (4H, phenyl). MS *m/e* (rel intensity) 180 (M^+, 13), 149 (100), 121 (17), and 90 (10). IR; 830 cm [1]. Found: C, 81.09; H, 9.94%. From the middle fraction was obtained 170 mg of **4**; NMR ($CDCl_3$): 0.9[2] (3H, s) and 3.1—4.0 (unresolved multiplets, 1H). IR: 3600, 3450, 1480, 1365, 1120, 1095, and 1060 cm^{-1}.

The distillation of the most polar fraction by means of the ball-oven apparatus yielded 350 mg (17%) of two isomers of **2**. Para isomer of **2**: NMR ($CDCl_3$): 0.9[2] (3H, d, J=6.4 Hz), 1.7[2] (6H, s), 1.8 (2H, m, methine and OH), 3.3[5] (1H, d, d, J=7.6 and 10.6 Hz), 3.7[8] (1H, d, d, J=4.8 and 10.6 Hz), 3.7[8] (3H, s, OCH_3), and 6.7—7.3 (4H, AA'BB' coupling, phenyl). IR: 3350, 1610, 1580, 1518, 1300, 1260, 1190, 1030, and 830 cm^{-1}.

Oxidation-reduction Equilibrium between Anion Radicals. Electron-accepting Property of 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 18, 1978)

Synopsis. The electron affinity and the oxidation-reduction potential of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone were estimated by means of the equilibrium constant of the preferred electron transfer reaction between anion radicals in acetonitrile solution.

It is known that 7,7,8,8-tetracyanoquinodimethane (TCNQ) and cyano-substituted *p*-benzoquinone molecules are strong electron acceptors, forming stable anion radical salts with some diamagnetic counter cations.[1-6]

A method was worked out for determining the electron affinity values of electron acceptor molecules by means of preferred electron transfer reaction between anion radicals in solution.[1] By measuring the equilibrium constant of such a reaction, we can estimate the difference of the electron-accepting strengths between two acceptor molecules. The method was applied to the following electron-transfer (oxidation-reduction) reaction in acetonitrile solution:

$$\mathrm{TCNQ}^{\cdot} + p\text{-}\mathrm{X_2QCy_2} \rightleftarrows \mathrm{TCNQ} + p\text{-}\mathrm{X_2QCy_2}^{\cdot}, \quad (1)$$

where p-H_2QCy_2 (X=H) and p-Cl_2QCy_2 (X=Cl) stand for 2,3-dicyano-*p*-benzoquinone and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, respectively. The equilibrium constant K of this reaction is given by

$$K = \frac{[\mathrm{TCNQ}][p\text{-}\mathrm{X_2QCy_2}^{\cdot}]}{[\mathrm{TCNQ}^{\cdot}][p\text{-}\mathrm{X_2QCy_2}]}. \quad (2)$$

Chemical equilibrium was easily observable in the reaction between $TCNQ^{\cdot}$ and p-H_2QCy_2, when p-H_2QCy_2 was added to an acetonitrile solution of the sodium salt of TCNQ anion radical. The effect of cations was neglected, the activity coefficients of the solutes being assumed to be unity since their concentrations were of the order 10^{-5} mol/l. The concentrations of $[TCNQ^{\cdot}]$ and $[p$-$H_2QCy_2^{\cdot}]$ in the equilibrium state were easily estimated spectrophotometrically, the K value in acetonitrile being determined as $K=30$ at 20 ± 1 °C.

In the reaction between $TCNQ^{\cdot}$ and p-Cl_2QCy_2, however, the chemical equilibrium was not easily observed when p-Cl_2QCy_2 was added to an acetonitrile solution of TCNQ anion radical. An unpaired electron of TCNQ anion radical is transferred almost completely to p-Cl_2QCy_2, the equilibrium constant K being so great that we can hardly determine the $[TCNQ^{\cdot}]$ concentration in the equilibrium state by the usual spectrophotometric method. We could determine only the lower limit of K as $K\geq2\times10^3$ in acetonitrile solution at 20 ± 1 °C. This hampered the quantitative estimation of the electron affinity and the oxidation-reduction potential of p-Cl_2QCy_2. Yamagishi overcame the above difficulty and succeeded in determining the K value for the reaction between $TCNQ^{\cdot}$ and p-Cl_2QCy_2.[4] By adding p-Cl_2QCy_2 to an acetonitrile solution containing the TCNQ anion radical in the presence of large excess of TCNQ and p-$Cl_2QCy_2^{\cdot}$, the equilibrium concentration of $[TCNQ^{\cdot}]$ can be estimated spectrophotometrically. The equilibrium constant of Eq. 2 for the case of X=Cl was then determined to be $K=(4.7\pm1.0)\times10^5$ at 15 °C in acetonitrile solution.[4]

First, we estimate the oxidation-reduction potential of p-Cl_2QCy_2 by the use of the K value obtained and the equation

$$E_0(\mathrm{TCNQ},\ \mathrm{TCNQ}^{\cdot}) - \frac{RT}{F}\ln\frac{[\mathrm{TCNQ}^{\cdot}]}{[\mathrm{TCNQ}]} = E_0(p\text{-}\mathrm{Cl_2QCy_2},\ p\text{-}\mathrm{Cl_2QCy_2}^{\cdot}) - \frac{RT}{F}\ln\frac{[p\text{-}\mathrm{Cl_2QCy_2}^{\cdot}]}{[p\text{-}\mathrm{Cl_2QCy_2}]}, \quad (3)$$

where R, T, and F are the gas constant, the observed temperature and the Faraday constant, respectively, E_0 (TCNQ, $TCNQ^{\cdot}$) and E_0 (p-Cl_2QCy_2, p-$Cl_2QCy_2^{\cdot}$) representing the standard oxidation-reduction potentials in the formation of the anion radicals of $TCNQ+e \rightleftharpoons TCNQ^{\cdot}$ and p-$Cl_2QCy_2+e \rightleftharpoons p$-$Cl_2QCy_2^{\cdot}$, respectively. These reactions are assumed to be reversible electrode reactions in acetonitrile solution. When the value of $K=(4.7\pm1.0)\times10^5$ determined spectrophotometrically is put into Eq. 3, we have

$$E_0(p\text{-}\mathrm{Cl_2QCy_2},\ p\text{-}\mathrm{Cl_2QCy_2}^{\cdot}) = E_0(\mathrm{TCNQ},\ \mathrm{TCNQ}^{\cdot}) + 0.32\ \mathrm{V}. \quad (4)$$

The oxidation-reduction potential in the formation of p-H_2QCy_2 anion radical was obtained as E_0 (p-H_2QCy_2, p-$H_2QCy_2^{\cdot}$)$=E_0$ (TCNQ, $TCNQ^{\cdot}$)$+0.09$ V in acetonitrile solution. Thus, the value of E_0 (p-Cl_2QCy_2, p-$Cl_2QCy_2^{\cdot}$) is larger than E_0 (p-H_2QCy_2, p-$H_2QCy_2^{\cdot}$) by 0.23 V. The increase in the E_0 (p-Cl_2QCy_2, p-$Cl_2QCy_2^{\cdot}$) value is caused by the introduction of two chlorine substituents into 2,3-dicyano-*p*-benzoquinone. In view of the magnitudes of these oxidation-reduction potentials, the electron-accepting strengths of acceptor molecules lie in the range TCNQ$<p$-$H_2QCy_2<p$-Cl_2QCy_2.

Next, we examine the electron affinities of these acceptors. The observed equilibrium constant of Eq. 2 is related to electron affinity by

$$-RT\ln K = E_A(\mathrm{TCNQ}) - E_A(p\text{-}\mathrm{X_2QCy_2}) + \Delta\Delta G^{\circ}_{\mathrm{solv}}(\mathrm{TCNQ},\ \mathrm{TCNQ}^{\cdot}) - \Delta\Delta G^{\circ}_{\mathrm{solv}}(p\text{-}\mathrm{X_2QCy_2},\ p\text{-}\mathrm{X_2QCy_2}^{\cdot}), \quad (5)$$

where $E_A(M)$ is the electron affinity of neutral acceptor molecule M, and $\Delta\Delta G^{\circ}_{\mathrm{solv}}$ (M, $M^{\cdot}$) the difference in the free energy of solvation between the molecule and its anion radical. As long as the molecular sizes and

shapes of the acceptors are similar, we can reasonably assume $\Delta\Delta G^{\circ}_{solv}$ (TCNQ, TCNQ$^{\cdot-}$)$\approx\Delta\Delta G^{\circ}_{solv}$ (p-X_2QCy_2, p-$X_2QCy_2^{\cdot-}$), and we have

$$-RT\ln K = E_A(\text{TCNQ}) - E_A(p\text{-}X_2QCy_2). \quad (6)$$

Thus, the absolute values of E_A (p-X_2QCy_2), (X=H or Cl), will be determined from this relation if the value is once given for E_A (TCNQ). So far, Briegleb's value of E_A (TCNQ)=1.7 eV has been taken as a reference,[2,5] but the value appears to be underestimated. Farragher and Page measured the E_A (TCNQ) value by magnetron method and proposed E_A (TCNQ)=2.88 eV as a standard.[6] Their value is considered to be more reliable. If we take E_A (TCNQ)=2.88 eV, we can estimate the values of E_A (p-H_2QCy_2) and E_A (p-Cl_2QCy_2) by Eq. 6 to be 2.97 eV and 3.20 eV, respectively. The electron-accepting strength of p-Cl_2QCy_2 is very strong but somewhat weaker than that of hexacyanobutadiene; Farragher and Page reported the electron affinity of the latter compound to be 3.30 eV.[6]

It is of interest to compare the E_A (p-X_2QCy_2)$-E_A$ (TCNQ), (X=H or Cl), values obtained from Eq. 6 with those estimated from the charge-transfer absorption spectra. The acceptors of TCNQ, p-H_2QCy_2, and p-Cl_2QCy_2 form charge-transfer complexes with various electron donors in solution. For a common donor, D, the energy difference of the charge-transfer bands, $h\nu_{CT}$ (D, TCNQ)$-h\nu_{CT}$ (D, p-X_2QCy_2), (X=H or Cl), can be approximately written as

$$h\nu_{CT}(\text{D, TCNQ}) - h\nu_{CT}(\text{D, } p\text{-}X_2QCy_2) = E_A(p\text{-}X_2QCy_2) - E_A(\text{TCNQ}). \quad (7)$$

The charge-transfer complexes with various donor molecules of polycyclic aromatic hydrocarbons were examined in 1,2-dichloroethane. By observing the charge-transfer absorptions, together with Eq. 7, E_A (p-X_2QCy_2)$-E_A$ (TCNQ), (X=H or Cl), was evaluated for each common donor. For five donors, the average value of E_A (p-H_2QCy_2)$-E_A$ (TCNQ) was 0.05 ± 0.05 eV, while that of E_A (p-Cl_2QCy_2)$-E_A$ (TCNQ) was 0.29 ± 0.05 eV. On the other hand, from Eq. 6, the experimental results of oxidation-reduction equilibrium give E_A (p-H_2QCy_2)$-E_A$ (TCNQ)=0.09 eV and E_A (p-$Cl_2QCy)_2-E_A$ (TCNQ)=0.32 eV. The values agree, within experimental error, with those estimated from the charge-transfer absorptions, respectively. This, in return, supports the assumption $\Delta\Delta G^{\circ}_{solv}$ (TCNQ, TCNQ$^{\cdot-}$)$\approx$ $\Delta\Delta G^{\circ}_{solv}$ (p-X_2QCy_2, p-$X_2QCy_2^{\cdot-}$), (X=H or Cl), in deriving Eq. 6.

In conclusion, the present technique of oxidation-reduction equilibrium between anion radicals is useful for determining the electron affinity values of electron acceptor molecules as well as the oxidation-reduction potentials in the formation of anion radicals of these acceptors.

The author wishes to thank Dr. Akihiko Yamagishi for his helpful discussions.

Synthesis of Disubstituted Benzoquinones by the Photochemical Reaction of Acetylenes with $Fe(CO)_5$

Kazuhiro MARUYAMA,* Toru SHIO, and Yoshinori YAMAMOTO
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received November 17, 1978)

Synopsis. Internal acetylenes substituted with alkyl groups and terminal acetylenes substituted with alkyl, aryl, and functionallized alkyl groups are converted to disubstituted quinones by the photochemical reaction with $Fe(CO)_5$ followed by treatment with Ce(IV).

In the course of our investigations on quinonoid compounds,[1] we required a new synthetic methodology for disubstituted benzoquinone derivatives. Indirect methods,[2] whereby two substituents are introduced stepwise into benzoquinone, suffer from several difficulties, such as low yields and frequent need for long reaction steps. Direct conversion can be achieved by the photochemical reaction of acetylenes with $Fe(CO)_5$.[3] It appeared that this procedure would provide an attractive route to disubstituted benzoquinones because of a simple operation and a satisfactory yield. However, a curious thing was that any systematic investigations had not been performed and the ratio of products (2,5- and 2,6-isomers) had not been established. Consequently, we decided to explore the reaction of various types of acetylenes with $Fe(CO)_5$ in hopes of developing a practical procedure and establishing the scope and limitations.

Results and Discussion

A benzene solution of an acetylene and $Fe(CO)_5$ was irradiated by a high pressure Hg lamp under N_2, and the reaction was followed by GLPC. After most of the starting acetylene was consumed, treatment of the reaction mixture with ceric ammonium nitrate produced the desired quinones. The results are summarized in Table 1. The structure of 2,5-(**2**) and 2,6-isomers (**3**) was determined by the ^1H NMR spectra of their acetyl derivatives. Reductive acetylation of **2** and **3** produced **4** and **5**, respectively, in a good yield. Since the two acetyl groups of **4** possess an identical chemical shift and those of **5** two different chemical shifts, two isomers could be easily discriminated.

TABLE 1. REACTION OF VARIOUS ACETYLENES WITH $Fe(CO)_5$[a]

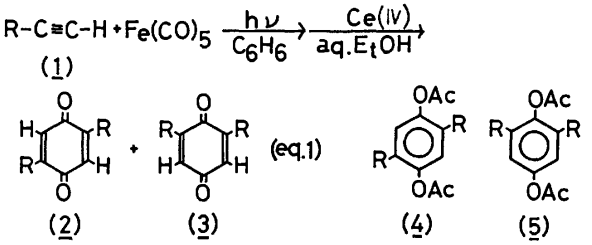
$-C_6H_4Cl$	(**1f**)	17	10	85

a) Conversion indicates the amounts of acetylene consumed after 2 h irradiation.



As is apparent from Table 1, the terminal acetylenes can be converted to the corresponding quinones and the functional groups can be introduced into the side chain. Normally, 2,5-isomer (**2**) is obtained predominantly, presumably owing to the steric reason. However, diphenylacetylene does not give the desired quinone, though dimethylacetylene can be converted to duroquinone.[3] Since the reaction of phenylacetylene, *p*-methylphenylacetylene, and *p*-chlorophenylacetylene proceeds in a similar fashion and the product distributions are nearly identical, it seems that the electronic circumstances around the triple bond do not influence the reaction cource. Other acetylenes such as 2-propyn-1-ol, 3-bromo-1-propyne, 3-methoxy-1-propyne, and 1-butyne-3-one, where the functional groups are involved in the alpha-position, did not produce the desired quinones.

We next examined the reaction of acyclic alkadiynes with $Fe(CO)_5$ in hopes of obtaining cyclophanes bearing quinonoid structure.[4] Unfortunately, however, similar treatment of 1,9-decadiyne with $Fe(CO)_5$ did not produce the desirable methylene bridged benzoquinone but afforded the normal intermolecular cyclization products. Other diynes such as 1,7-octadiyne and 1,11-dodecadiyne gave the similar results. Consequently, the intramolecular cyclization is an unfavorable reaction at least in the above three diynes.

Finally the reaction of trimethylethynylsilane was examined to explore a possibility of obtaining quinone metalloids bearing a silyl group. Such a metalloid may be converted further to a number of functionallized quinone derivatives, since the transformation of C–Si bond to various C–Hetero bonds and C–C bond is well established.[5] Unexpectedly, the reaction took an entirely different course. Cyclopentadienone derivative was isolated from among tarry materials. Although the structure was assigned as the cyclopentadienone–Fe complex (**6** or **7**), the discrimination between both isomers

a) Yes indicates that the product is obtained, and No means the reverse.
b) Our own works.

was not possible. The reaction of trimethylpropynylsilane or trimethyl-1-hexynylsilane was quite sluggish, and these acetylenes were recovered even after irradiation for 24 h.

In conclusion, the course of the reaction highly depends upon the structure of acetylenes. The results of our own experiments and others are summarized in Table 2. The requirement for obtaining quinone derivatives is that i) internal acetylenes are substituted not with aryl groups but with alkyl groups, and that terminal acetylenes are substituted with ii) alkyl groups, iii) aryl groups, and with iv) functionallized alkyl groups where the functional groups are separated from the quinone moiety at least by two methylene units.

Experimental

General Procedure for the Reaction of Acetylenes with $Fe(CO)_5$. Oxygen-free dry benzene solution of an acetylene (0.025 mol) and $Fe(CO)_5$ (4.9 g, 0.025 mol) was irradiated by a high pressure Hg lamp under N_2 at 20 °C. GLPC examination revealed that generally the acetylene was almost consumed after 2 h. Then, the solvent was removed under reduced pressure, giving black oil. To an acetone solution of this oil was added an ethanol–water (72: 25) solution of $(NH_4)_2Ce(NO_3)_6$ (13.7 g, 0.025 mol) with stirring and the resulting mixture was stirred overnight at room temperature. The organic materials were extracted with benzene and dried over anhyd. Na_2SO_4. The products were filtered through the column of silica, and benzene eluted the desired quinones in substantially pure form. These quinones (a mixture of 2,5- and 2,6-isomers) were further filtered through the column of silica to separate the isomers, and to obtain analytically pure materials. **2a** (yellow needles); mp 83—83.5 °C; NMR (CCl_4) 0.89 (t, 6H), 1.70—1.10 (m, 16H), 2.40 (t, 4H), 6.50 (s, 2H); IR (KBr) 1652, 1615 cm^{-1}; Mass *m/e* 276; Found; C, 78.38; H, 10.24%. A Convenient Method of Preparing *p*-Toluenesulfonates of Ethyl Esters of Amino Acids Using Ethyl *p*-Toluenesulfonate

Kazuo UEDA

Department of Chemistry, Faculty of Liberal Arts, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received November 4, 1978)

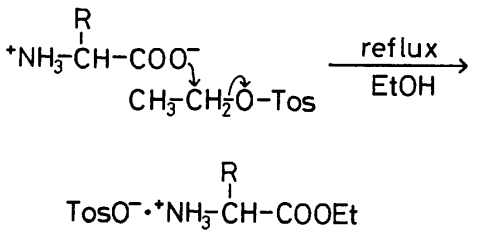
Synopsis. The treatment of amino acids with ethyl *p*-toluenesulfonate affords the *p*-toluenesulfonates of the ethyl esters in good yields. Tryptophan ethyl-ester *p*-toluenesulfonate was also prepared in an 81% yield.

In the peptide synthesis, the *p*-toluenesulfonates of ethyl esters of amino acids are of importance as starting materials.[1]

The *p*-toluenesulfonates of the ethyl esters of amino acids have previously been prepared by the use of *p*-toluenesulfonic acid as a catalyst; the synthesis involved the azeotropic distillation of a mixture of amino acid, *p*-toluenesulfonic acid, ethanol, and carbon tetrachloride.[2]

We have now found that amino acids are easily converted to the *p*-toluenesulfonates of the ethyl esters in good yields by treatment with ethyl *p*-toluenesulfonate. The results thus obtained are summarized in Table 1. The method was very convenient and required neither special apparatus nor complicated manipulation: the ethanolic suspension of amino acid was refluxed while being stirred for 24—30 h in the presence of ethyl *p*-toluenesulfonate. We have not observed any *N*-ethylation or *N*-tosylation of the amino acids under these conditions. Tryptophan ethyl-ester *p*-toluenesulfonate has not been synthesized previously, probably because of its instability to *p*-toluenesulfonic acid. However, we succeeded in synthesizing this compound in an 81% yield by the use of our method.

It has previously been reported that the reaction of 3β-steroidal tosylates with tetrabutylammonium acetate in acetone gives 3α-acetates in good yields and appears to be a nucleophilic bimolecular S_N2 displacement by acetate.[3] Taking into account the fact that the tosylate is a very good leaving group,[3-5] the esterification may be explained as is shown in the following reaction scheme.



Experimental

All the melting points were uncorrected. The TLC was carried out on a silica-gel 60 F_{254} pre-coated plate (Merck and Co.) with the following solvent systems: $R_{f,1}$ $CHCl_3$–MeOH (5: 1, v/v); $R_{f,2}$ *n*-BuOH–AcOH–pyridine–H_2O (15: 3: 10: 12, v/v). The optical rotations were measured on an Atago polarimeter Polax. The IR spectra were recorded on a Hitachi EPI-2 spectrometer. Ethyl *p*-toluenesulfonate was purified by distillation under reduced pressure, a fraction with a bp of 121 °C/2 mmHg being used. All the amino acids used in this experiment, except glycine and 4-aminobutyric acid (4-Abu), had an L-configuration.

General Esterification Procedure. A suspension of the amino acid (10 mmol) and ethyl *p*-toluenesulfonate (11 mmol) in absolute ethanol (40 ml) was refluxed while being stirred for 24—30 h, during which dissolution occurred. After the evaporation of the solvent, the residual material was treated with ether. The precipitate filtered off was recrystallized from hot ethanol–ether.

L-*Tryptophan Ethyl-ester* p-*Toluenesulfonate.* This was prepared from Trp (2.04 g, 10 mmol) and ethyl *p*-toluenesulfonate (2.20 g, 11 mmol) as has been described above. Yield 3.28 g (81%); mp 139—140 °C; $[\alpha]_D^{30}$ +15.4° (*c* 4, EtOH); IR (Nujol) 3370 (indole NH) and 1730 cm^{-1} (C=O); $R_{f,1}$ 0.49, $R_{f,2}$ 0.81. Found: C, 59.38; H, 6.09; N, 6.67%. Calcd for $C_{20}H_{24}O_5N_2S$: C, 59.39; H, 5.98; N, 6.92%.

^{14}N Nuclear Quadrupole Relaxation in Sulfuric Diamide and Methanesulfonamide

Hisao NEGITA,* Tsuneo KUBO, Michio MAEKAWA, Akinobu UEDA, and Tsutomu OKUDA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received July 20, 1978)

The ^{14}N nuclear quadrupole resonances (NQR) in sulfuric diamide (sulfamide), $H_2NSO_2NH_2$, and methanesulfonamide, $CH_3SO_2NH_2$, were studied by the pulse method. The resonance frequency and the spin-lattice relaxation time (T_1) were measured in the temperature range from liquid nitrogen temperature to room temperature. In the case of sulfuric diamide, T_1 decreases monotonously as the temperature rises, and is dominated by the thermal torsional motion below 140 K. On the other hand, T_1 is attributed to the reorientation of the amino group in the temperature range from 200 to 240 K, whereas it is due to the reorientation of the molecule above 240 K; the activation energies in these orientations are 43.5 and 61.5 kJ·mol^{-1} respectively. In the case of methanesulfonamide, the minimum of T_1 is found near 130 K. This is caused by the rotation of the methyl group. The activation energy for this motion is calculated to be 9.6 kJ·mol^{-1}. The dominant relaxation mechanism is attributed to the reorientation of the amino group from 200 to 240 K and to the reorientation of the molecule above 240 K. The activation energies for these motions are 19.2 and 40.6 kJ·mol^{-1} respectively.

Structural studies on sulfuric diamide (sulfamide), $H_2NSO_2NH_2$, and methanesulfonamide, $CH_3SO_2NH_2$, have been performed by various spectroscopic means. The ^{14}N nuclear quadrupole resonance (NQR) study on the former compound was recently reported by our group.[1] We hope to obtain further information on the dynamical properties of the two materials from ^{14}N nuclear quadrupole relaxation. We have measured the spin-lattice relaxation time (T_1) by the pulse method and will discuss the molecular motions in these compounds.

Experimental

^{14}N NQR measurements were carried out using a pulse spectrometer, consisting of a Matec gating modulator Model 5100, a R. F. gated amplifier Model 515, and a tuned receiver Model 615, which was designed by Petersen.[2,3] The resonance frequency and the spin-lattice relaxation time were measured in the temperature range from liquid nitrogen temperature to room temperature by the repeating 90° pulse method.[4] The pulse width was about 25—50 μs. The free induction decay signal was averaged in a Nicolet Instrument Model 527 signal averager. The temperature was controlled by the method of Abe[5] or Petersen.[2,3] The temperature was measured by the use of a copper-constantan thermocouple and stabilized within ±0.1 K. The frequency was checked by means of a frequency counter, TR-5104, from the Takeda Riken Co.

The sulfuric diamide was obtained by the reaction of sulfuryl chloride with liquid ammonia and was purified by recrystallization from acetone.[6] On the other hand, the methanesulfonamide was prepared by the reaction of methanesulfonyl chloride with liquid ammonia and was purified by recrystallization from 1:2 ethanol–benzene.[7] In the present measurements, we used about a 20-g portion of each sample melted in a glass ampoule.

Results and Discussion

Generally a pair of ^{14}N NQR frequencies, ν_- and ν_+, are observed for a species of nitrogen atom:

$$\nu_\pm = \frac{|e^2Qq|}{4h}(3\pm\eta), \qquad (1)$$

where $|e^2Qq/h|$ and η are the quadrupole coupling constant and the asymmetry parameter, respectively. In methanesulfonamide, a pair of resonance lines were found: $\nu_-=2442.1$ kHz and $\nu_+=3400.2$ kHz (at liquid nitrogen temperature). The quadrupole coupling constant and asymmetry parameter derived from these frequencies are as follows: $|e^2Qq/h|=3894.9$ kHz and $\eta=49.20\%$. These values are to be compared with those for sulfuric diamide: $|e^2Qq/h|=3905.3$ kHz and $\eta=50.82\%$.[1]

The temperature dependence of the resonance frequencies, ν_- and ν_+ lines, in sulfuric diamide and methanesulfonamide is shown in Fig. 1. The temperature dependence in sulfuric diamide is smaller than that in methanesulfonamide. This fact may be explained by the intermolecular interaction, probably by the difference in the number of the hydrogen bonds between sulfuric diamide and methanesulfonamide. That is, the vibration of the nitrogen atom in sulfuric diamide is more suppressed than in methanesulfonamide.

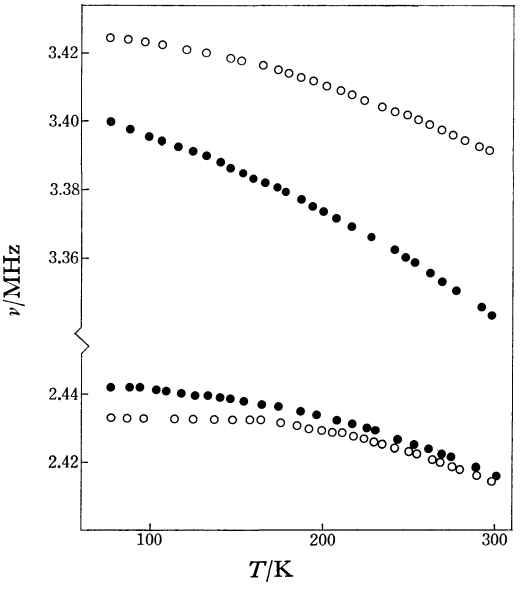

Fig. 1. The temperature dependence of the resonance lines in sulfuric diamide (○) and methanesulfonamide (●).

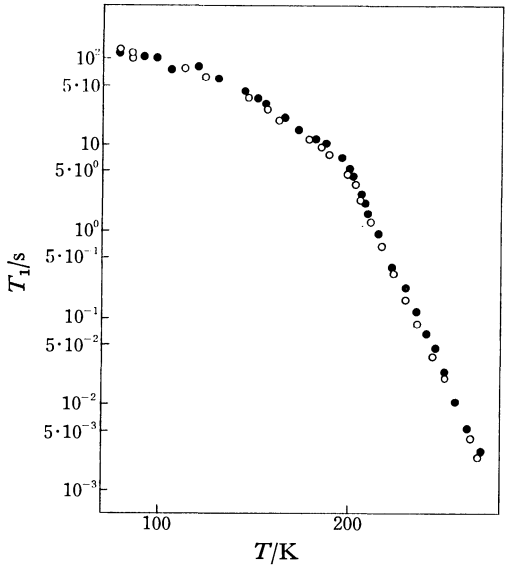

Fig. 2. The temperature dependence of the spin-lattice relaxation times in sulfuric diamide. ○: ν_- line; ●: ν_+ line.

The temperature dependence of the spin-lattice relaxation times (T_1) for ν_- and ν_+ lines in sulfuric diamide is shown in Fig. 2. Both curves are coincident within the experimental error. This fact suggests that the molecular motions equally contribute to T_1 for ν_- and ν_+ lines.

Below 140 K, the spin-lattice relaxation time is determined by torsional lattice vibration and is dominated by indirect two-phonon processes so that $1/T_1 \propto T^2$.

Above 200 K, the spin-lattice relaxation time drops exponentially as the temperature rises. This process can probably be attributed to the reorientation of the amino group around the S–N bond or to the reorientation of the molecule. In this case, the relaxation time is given by the following equation:[8]

$$1/T_1 = C\tau/(1+\omega_i^2\tau^2) \quad (i=+, -, \Delta), \tag{2}$$

where C is a constant related to the intrinsic nature of the molecular motion, τ is the correlation time, and ω_i is the resonance angular frequency. In the low temperature region of the T_1 minimum, $\omega_i\tau \gg 1$, and assuming the Arrhenius' relation for the correlation time, the following equation holds:

$$\tau = \tau_0 \exp(E_a/RT), \tag{3}$$

where τ_0 is the inverse frequency factor and E_a is the activation energy of the motion. Accordingly, we get

$$1/T_1 = f(\omega_i)\cdot\exp(-E_a/RT). \tag{4}$$

Equation 4 can be rewritten as follows:

$$\ln(1/T_1) = -E_a/RT + f'(\omega_i) \tag{5}$$

where $f'(\omega_i)$ is a function of ω_i, whose temperature dependence is negligible. In Fig. 3, the $\ln(1/T_1)$ value is plotted as a function of $1/T$. A break point is found near $10^3/T=4.2$/K (about 240 K) as is shown in Fig. 3. This suggests that T_1 above 240 K and T_1 below 240 K are dominated by different molecular motions. That is, the dominant relaxation mechanism below 240 K is considered to be caused by the reorientation of the amino group around the S–N bond, whereas that above 240 K is brought about by the reorientation

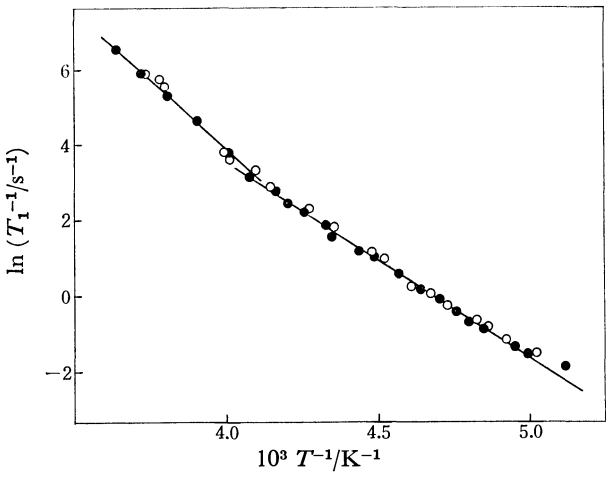

Fig. 3. $\ln(1/T_1)$ *vs.* $10^3/T$ in sulfuric diamide. ○: ν_- line; ●: ν_+ line.

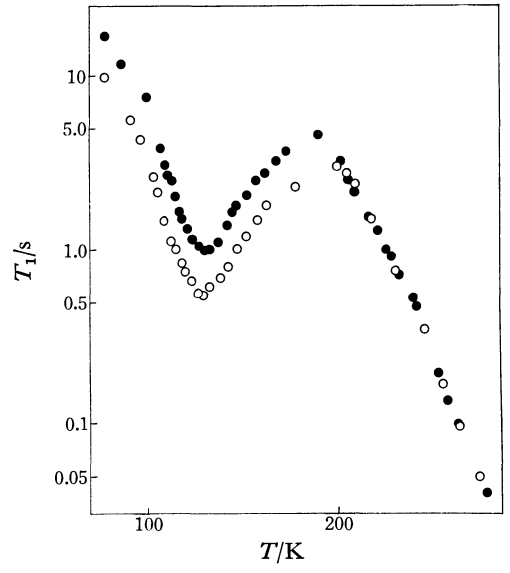

Fig. 4. The temperature dependence of the spin-lattice relaxation times in methanesulfonamide. ○: ν_- line; ●: ν_+ line.

of the molecule. In fitting Eq. 5 to the experimental T_1 values, the activation energies for these motions are determined: 43.5±4.3 kJ·mol^{-1} for the former motion and 61.5±6.2 kJ·mol^{-1} for the latter.

The temperature dependence of the spin-lattice relaxation times for ν_- and ν_+ lines in methanesulfonamide is shown in Fig. 4. In the temperature region from liquid nitrogen temperature to 200 K, T_1 for the ν_+ line, *i.e.*, $T_1(\nu_+)$, are longer than those for the ν_- line, *i.e.*, $T_1(\nu_-)$. However, above 200 K both relaxation times are coincident within the experimental error. This fact suggests that the molecular motion contributes differently to $T_1(\nu_-)$ and $T_1(\nu_+)$ below 200 K, but equally above 200 K.

In the temperature range from liquid nitrogen temperature to 170 K, a T_1 minimum is found near 130 K, as is shown in Fig. 4. This is caused by the introduction of the methyl group, and accordingly by the rotation of the group. The activation energy for this motion is calculated to be 9.6±0.9 kJ·mol^{-1} by

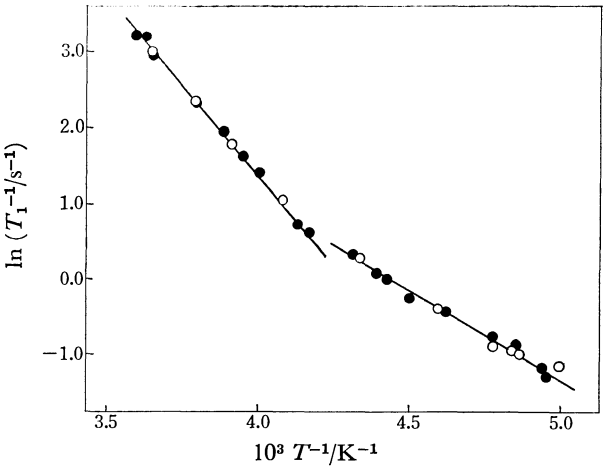

Fig. 5. $\ln(1/T_1)$ *vs.* $10^3/T$ in methanesulfonamide. ○: ν_- line; ●: ν_+ line.

the BPP theory.[9] This value is to be compared with 9.2 kJ·mol^{-1} for the rotation of the methyl group in acetonitrile.[10]

Above 200 K, T_1 drops exponentially as the temperature rises; this is shown in Fig. 4. As is shown in Fig. 5, in the $\ln(1/T_1)$ plot against $1/T$, a break point is found near $10^3/T$=4.2/K (about 240 K). This fact is explained in the same manner as for sulfuric diamide. That is, T_1 is dominated by the reorientation of the amino group around the S–N bond below 240 K and by the reorientation of the molecule above 240 K. In fitting Eq. 5 to the experimental T_1 values, the E_a values are determined: 19.2±1.9 kJ·mol^{-1} for the former motion and 40.6±4.1 kJ·mol^{-1} for the latter. These values are smaller than those in sulfuric diamide. This suggests that the intermolecular interaction in methanesulfonamide is weaker than that in sulfuric diamide, that is, the number of the hydrogen bonds per molecule in the former compound is smaller than that in the latter.

Takagi *et al.*[11] calculated the energy of the hydrogen bonds in sulfuric diamide to be 19.7 kJ·bond^{-1}, assuming that there are only two N–H···O hydrogen bonds per molecule, although there are other weak N–H···N hydrogen bonds.[12] Assuming that the activation energy (E_a) for the reorientation of the amino group comes mostly from breaking the hydrogen bonds, N–H···O, it is estimated to be 39.3 kJ·mol^{-1}, which is in good agreement with our experimental value, 43.5 kJ·mol^{-1}. In the case of methanesulfonamide, the E_a value for the reorientation of the amino group is 19.2 kJ·mol^{-1}, which is nearly equal to 19.7 kJ·bond^{-1}. Accordingly, it is concluded that there is one hydrogen bond, N–H···O, per molecule, although there may exist other weak hydrogen bonds, for example N–H···N.

Ultrasonic Absorption in Dodecane Solution of Aerosol OT

Teruyo YAMASHITA, Hiroshige YANO,* and Tatsuya YASUNAGA**

Daiichi College of Pharmaceutical Science, Minami-ku, Fukuoka 815

***Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730*

(Received August 2, 1978)

The ultrasonic absorptions of Aerosol OT in dodecane solution were measured in the frequency range 5—95 MHz at various temperatures. An excess absorption caused by single relaxation was observed above the second critical micelle concentration. This is attributed to the conformational change in structure of two kinds of Aerosol OT micelles, since the maximum excess absorption per wave length depends on the concentration and temperature. The thermodynamic and kinetic parameters were determined in relation to the reaction.

The kinetics of micelle formation in surfactant solutions have been extensively studied in aqueous solutions by means of various relaxation methods.[1-10] However, few studies have been performed on the kinetics of reverse micelles in nonpolar solvents.

Aerosol OT (sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate) forms reverse micelles in dodecane and its solution properties have been extensively investigated by static methods.[11-13] The purpose of the present investigation is to clarify the kinetic behavior of dodecane solutions of Aerosol OT by means of ultrasonic absorption.

Experimental

Dodecane was dried on P_2O_5 and distilled under reduced pressure (8 mmHg). Aerosol OT (guaranteed reagent grade) was dried at 105 °C under reduced pressure (8 mmHg) until the weight became constant. The concentration of the sample solution was given in terms of weight.

Ultrasonic absorptions were measured at the odd harmonics of 0.5, 5, and 20 MHz X-cut quartz transducers by means of pulse technique. The frequencies of the measurement were in the range 5—95 MHz. The major mechanical features of the apparatus were reported by Tatsumoto.[14] The sound velocity was measured by the sing-around method operating at 2.0 MHz, the density being determined with a pycnometer. All the measurements were carried out at concentrations 33.4—80 wt % and at temperatures 20—40 °C.

Results and Discussion

The concentration dependence of the ultrasonic absorption spectra of dodecane solution of Aerosol OT is shown in Fig. 1 and the temperature dependence of the absorption spectra in Fig. 2. All the spectra can be represented by

$$\alpha/f^2 = A/[1+(f/f_r)^2] + B, \quad (1)$$

where α is the absorption coefficient, f the frequency, f_r the relaxation frequency, A the amplitude of the excess absorption, and B the residual absorption. The ultrasonic parameters A, B, and f_r were so determined as to give the best fit of the experimental data to Eq. 1. The results are given in Table 1. Figure 3 shows the concentration dependence of the sound velocity at 20 °C. We see anomaly at concentrations of *ca.* 5 and 35%. The former is equal to the first critical micelle concentration(CMC) of Aerosol OT in dodecane reported by Mattoon and Mathews.[15] The latter can thus be assigned to the second CMC. Considering that the excess absorption appears near the second

CMC, the cause of the excess absorption is presumed to be associated with the second CMC of Aerosol OT. Peri[11] reported that two types of micelles exist in hydrocarbon solutions of Aerosol OT, their size changing slightly with concentration and temperature. Taking this into account together with our results in which the relaxation frequencies show no concentra-

tion dependence (Table 1), we postulate a two state model for the relaxation mechanism:

$$A \underset{k_b}{\overset{k_f}{\rightleftharpoons}} B, \tag{2}$$

where A and B are the two types of micelles. On the assumption that the relaxation strength is much smaller than unity and the total specific heat capacity is equal to the instantaneous specific heat capacity, the relaxation frequency and the maximum excess absorption per wave length μ_{max} are expressed by the following equations.[16]

$$2\pi f_r = k_f + k_b, \tag{3}$$

$$\mu_{max} = \psi\rho\pi c^2 V(\Delta V/V - \Delta H\beta/C_p)^2/2RT, \tag{4}$$

and

$$\psi = K(1-x_{1st\ CMC})/(1+K)^2, \tag{5}$$

where k_f and k_b are respectively the forward and backward rate constants, ρ is the density, c the sound velocity, V the molar volume, β the thermal expansion coefficient, C_p the specific heat at a constant pressure, and ΔV and ΔH are the standard volume change and the enthalpy change of the reaction, respectively. The equilibrium constant, K, is defined to be $K=x_b/x_a=$

	35	0.18			
	40	0.24			

a) Determined from the concentration dependence of μ_{max} in the concentration range 33.4—80%. b) Determined from the temperature dependence in 70% solution.

Table 3. Rate constants for the conformational change of the micelle

T (°C)	k_f (10^6 s^{-1})	k_b (10^7 s^{-1})
20	5.9	6.6
25	7.7	6.4
30	9.4	6.3
35	11	6.1
40	14	5.8

$k_f/k_b=\exp\{-(\Delta H-T\Delta S)/RT\}$, where x_a and x_b are the mole fraction of species A and B, respectively, and ΔS is the entropy change. With C_p values determined by the interpolation of the values given by Finke *et al.*[17] and Rihani and Doraiswamy,[18] the thermodynamic parameters, K, ΔV, ΔH, and ΔS were so determined as to give the best fit of the experimental values of μ_{max} to Eq. 4. The values obtained are given in Table 2; the yields are shown by solid lines in Figs. 4 and 5. The parameters were also determined from the temperature dependence of μ_{max} at a constant concentration (Table 2). The thermodynamic parameters determined by these two procedures are very close to each other, indicating that the interpretation of the excess absorption mechanism by the two state

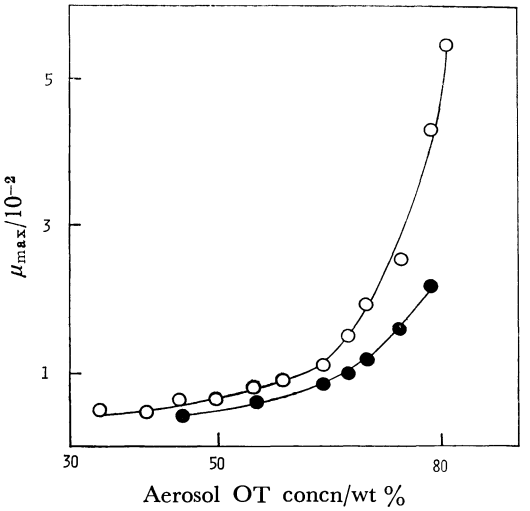

Fig. 4. Concentration dependence of the maximum excess absorption per wavelength at 20 °C (○) and 40 °C (●). The solid lines represent the theoretical curves calculated by Eq. 4 using the parameters in Table 2.

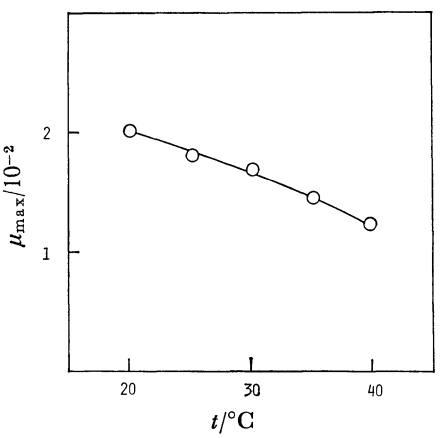

Fig. 5. Temperature dependence of the maximum excess absorption per wavelength in the 70% dodecane solution of Aerosol OT. The solid line was calculated from Eq. 4.

model is reasonable.

The forward and backward rate constants represent the rate of transition from the micelle formed above the first CMC to that above the second CMC and the rate of reverse transition, respectively. The rate constants were calculated from the relaxation frequency and the equilibrium constant at various temperatures (Table 3). The forward rate constant changes with temperature while the backward rate constant remains constant. This indicates that the free energy of activation of state B is almost constant and that of state A decreases with the temperature; micelles formed above the first CMC are destabilized with rise in temperature as compared with other micelles.

Intramolecular Charge-transfer Absorption Spectra of Tetracyanotetrathiafulvalene

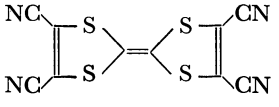
Shigeo YONEDA, Tokuzo KAWASE, and Zen-ichi YOSHIDA*

Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received August 28, 1978)

The electronic spectrum and structure of tetracyanotetrathiafulvalene have been investigated by the ASMO-SCF-CI method, in which the 3d orbitals of sulfur atoms are taken into account. The calculated results showed that the absorption band at the longest wavelength can be interpreted in terms of intramolecular charge-transfer.

In preceding papers,[1,2] we reported the syntheses of several electronegative substituted tetrathiafulvalenes such as tetracyanotetrathiafulvalene (**1**).



1

The compound **1** is composed of two parts, that is, the electron-donating part (the central electron-rich olefin moiety) and the electron-accepting part (the dicyanoethylene moiety). It seems reasonable to expect the appearance of an intramolecular charge-transfer[3] band in the electronic spectrum of **1**. In the present work, experimental and theoretical investigations of the electronic spectrum of **1** were carried out, and the absorption band at the longest wavelength (502 nm in benzene) was shown to be due to an intramolecular charge-transfer transition.

In addition, the electronic structure of **1** in the ground state will be discussed and compared with that of the parent tetrathiafulvalene (TTF).

Experimental

The compound, **1**, was prepared from 4,5-dicyano-1,3-dithiole-2-thione in the presence of triphenyl phosphite; mp 264—265 °C (dec).[2] The ultraviolet and visible absorption spectra of **1** were recorded on a Hitachi EPS-3T spectrophotometer in benzene, dichloromethane, acetonitrile, and methanol. The observed spectra were analyzed by assuming Gaussian curves for the absorption bands. Three absorption bands thus obtained and their molecular extiction coefficients are presented in Table 1.

Calculation

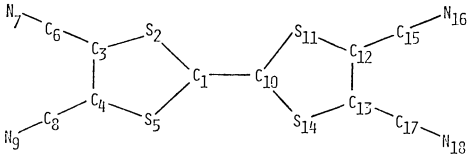
The calculations were carried out by the use of the semiempirical ASMO-SCF-CI method involving all valence electrons.[4] The sulfur atom has not only 3s and 3p, but also 3d orbitals in the valence shell. As regards unsubstituted TTF, it was pointed out that the inclusion of sulfur 3d orbitals is necessary to explain the relative bond lengths of the two carbon-carbon double bonds obtained from the X-ray analysis of TTF.[5] Accordingly, in this calculation the 3d orbitals of the sulfur atom were taken into account.

The overlap integrals were calculated using Slater-type atomic orbitals, where the orbital exponents are taken from Clementi and Raimondi.[6] The one-center exchange integrals were estimated from the Slater-Condon parameters evaluated by Hinze and Jaffé.[7] The Slater exponents (ζ_r), valence-state ionization potentials (I_r) of atomic orbitals, one-center Coulomb integrals (rr|rr), and one-center exchange integrals (rr'|rr') used in the present calculations are listed in Table 2.

The structural model for **1** is shown in Fig. 1. The molecule is assumed to have D_{2h} symmetry; the interatomic distances are taken from the X-ray data of TTF[5] and the book by Pople and Beveridge.[8]

The MO energies for each of the six occupied and vacant levels, and their approximate descriptions are shown in Table 3, although the LCAO coefficients of the MO's are not given.

In calculating the electronic transition energies, the 36 lowest singly-excited configurations were considered. The calculated singlet transition energies



$\angle S_5C_1S_2 = 114.5°$ C_1-C_{10} = 1.349 Å
$\angle C_1S_2C_3 = 94.4°$ C_1-S_2 = 1.757 Å
$\angle S_2C_3C_4 = 118.3°$ S_2-C_3 = 1.731 Å
$\angle C_6C_3C_4 = 120.0°$ C_3-C_4 = 1.314 Å
C_3-C_6 = 1.450 Å
C_6-N_7 = 1.160 Å

and oscillator strengths are presented in Table 4. For comparison, the results calculated both including and neglecting 3d orbitals of sulfur atoms are listed in Table 4.

The electron densities and overlap populations of **1** are also shown, together with those of parent TTF, in Fig. 2.

Discussion

In the calculations of transition energies of organic compounds with a bivalent sulfur atom, the contribution of sulfur 3d orbitals is usually not evaluated and often neglected. However, as seen in Table 4, the transition energies calculated with 3d orbitals were in better agreement with the observed ones than those calculated without 3d orbitals. This evidently suggests that the 3d orbitals of the sulfur atom are essential for the explanation of the electronic structure of the system **1**.

Intramolecular Charge-transfer Absorption Band. According to the calculated results, since the wave

	6.21	0.585			$\pi_{DTE}\rightarrow\pi^*_{TTE}$

a) Energy in eV. b) TTE: Tetrathioethylene component. DCNE: Dicyanoethylene component. TTF: Tetrathiafulvalene component. DTE: Dithioethylene component. c) The numbers in parentheses indicate $\log \varepsilon_{max}$, obtained from measurements.

π^*-MO are clearly represented. Thus, this $\pi_{TTE}\rightarrow\pi^*_{DCNE}$ transition is reasonably understood as the transition from the electron-rich moiety ($S_2C{=}CS_2$) to the electron-deficient moiety (NC–C=C–CN). Consequently, the absorption band at the longest wave length is well interpreted in terms of intramolecular charge-transfer.

A similar result was obtained in the calculations of **1** by the CNDO/2-CI method. If 3d orbitals of the sulfur atom are considered, the longest wave length absorption band can also be reasonably assigned to the $\pi_{TTE}\rightarrow\pi^*_{DCNE}$ transition.

This interpretation is also supported by the results that the absorption band at the longest wave length exhibits blue shifts upon changing the polarity of solvents from benzene (502 nm) to methanol (480 nm); these results are listed in Table 1.

The strong absorption band at 3.54 eV can be assigned to the excitation from the tetrathiafulvalene moiety to the tetrathioethylene moiety, since the molecular orbitals of the ground and excited states for this transition correspond to π_{TTF} and π^*_{TTE}, respectively (Table 4). Similarly, the absorption band at 4.77 eV is assigned to the excitation from the tetrathiafulvalene moiety to the dicyanoethylene moiety.

In the case of the TTF's substituted with electron-donating groups (such as methyl, hydroxyl and amino groups), the transition from the highest occupied MO to the lowest vacant MO could not be assigned to the $\pi\rightarrow\pi^*$ one; this is obviously a different result from that of the calculation for **1**. Therefore, it is reasonably concluded that the phenomenon of the intramolecular charge-transfer is characteristic of electronegatively substituted tetrathiafulvalenes.

Electron Population Analysis. As seen in Fig. 2(b), the total electron densities on the carbons, C_1 and C_3, in TTF are smaller than 4.0, but those of the 2pz orbitals are 1.058 and 1.027, respectively, indicating that TTF can be considered to be an electron-rich olefin so far as π-electron system is concerned. The formal charge of the sulfur atom in TTF, in spite of a rather large positive charge (+0.17) in the $3p_\pi$ net charge, is negative (−0.30) as a result of the back donation of the σ electrons. This back donation of electrons is mainly caused by the 3d orbitals of the sulfur atom, to which indeed considerable charge densities (about 0.24) are attributed.

With regard to the overlap populations of TTF, in comparing the values calculated by including 3d orbitals with those found by neglecting 3d orbitals, the values for C_1–C_3 and C_3–C_4 bonds are smaller. Those for C_1–S_2 and S_2–C_3 bonds reveal the most significant difference, in amount 0.25—0.29, between the case of including 3d orbitals and the case of neglecting them. This prominent difference of overlap populations can be explained by the concept of the partial overlap populations between 3d orbitals of sulfur and 2pz orbitals of carbon atoms, whcih distributes to the C–S bonds in the amount of 0.25. Such participations of 3d orbitals should strengthen the C–S bonds up to those comparable to the double bond. These results indicate that the 3d orbitals of sulfur atoms are quite important in tetrathiafulvalene systems.

Similar aspects in the electronic structure of **1** were obtained by comparing the results calculated by including and neglecting 3d orbitals with each other.

It may be expected that the charge density of the central ethylene carbon atom would be decreased by the substitution of an electron-withdrawing group (CN). However, the calculated result shows that the charge density of the central carbon atom increases and that of the sulfur atom decreases, which indicates a transfer of electrons from the sulfur atoms of the central tetrathioethylene part to the dicyanoethylene part. This suggests that **1** is composed of two separable components, namely, a dicyanoethylene part and a tetrathioethylene part, which is coincident with the result obtained from the study of the electronic absorption spectra of **1**.

The Determination of the Chemical Diffusion Coefficients for AgBr and α-AgI by Means of an Improved d.c. Polarization Cell

Junichiro MIZUSAKI,* Kazuo FUEKI,* and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 7, 1978)

In order to determine the chemical diffusion coefficients for AgBr and α-AgI, a new experimental technique was developed. A Pt probe was inserted into the middle of the AgX (X=Br or I) pellet in an improved d.c. polarization cell of the Ag/AgX/carbon type, and the applied potential difference between the Ag and carbon electrodes was changed abruptly. The accompanying change in $E(L/2)$, the EMF between the Ag electrode and the Pt probe, was followed, and the chemical diffusion coefficient, $\tilde{D}$, was determined by the analysis of the change in $E(L/2)$ with the time. In the temperature range from 325 to 400 °C, $\tilde{D}$ for AgBr with excess silver was found to be

$$\tilde{D} = 7.10 \times 10^{2} \exp\left(-\frac{1.96\times10^{4}\ \text{cal mol}^{-1}}{RT}\right) \text{cm}^2\ \text{s}^{-1}. \quad \text{(i)}$$

In the temperature range of 330 to 500 °C, $\tilde{D}$ for α-AgI was

$$\tilde{D} = 4.95 \times 10^{-1} \exp\left(-\frac{7.71\times10^{3}\ \text{cal mol}^{-1}}{RT}\right) \text{cm}^2\ \text{s}^{-1}. \quad \text{(ii)}$$

Using these chemical diffusion coefficients and the electronic conductivity data, the nonstoichiometry, and apparent mobility of electronic carriers of AgBr and α-AgI were determined.

Generally, the chemical diffusion coefficient for a solid compound is obtained from the measurement of the responding weight change or electrical conductivity change, both of which changes are caused by the sudden change in the chemical potential of its components. Gravimetric measurements are useful when the solid compound has a large nonstoichiometry, while the measurement of the electrical conductivity is effective when the conductivity of the sample is quite sensitive to the chemical potential of its components.

However, in the case of the silver halides, the nonstoichiometry is too small to be detected by the gravimetric method, and the electrical conductivity, which is essentially ionic, is constant, irrespective of the chemical potential of silver. Therefore, the chemical diffusion coefficients for silver halides cannot be determined by means of conventional techniques, and new techniques must be developed.

Weiss has carried out some pioneering work on the determination of the chemical diffusion coefficient for AgBr.[1,2] He employed a Hebb-Wagner d.c. polarization cell of the type:

(I) Ag/AgBr/carbon, inert atmosphere

and tried to determine the chemical diffusion coefficient by two methods. In the first method, a constant potential was applied to the cell until a stationary state was reached. Then, the potential was removed abruptly and the EMF decay was followed. From the decay constant, the chemical diffusion coefficient was then determined. In the second method, the current decay was followed after the step-like change in the potential difference applied between the electrodes. However, a large discrepancy was found between the results of these two measurements.

Recently, the present authors have investigated the cell of the (I) type. They have found that the electrical potential of the electrode attached to the surface of AgX pellet is quite sensitive to the activity of the halogen, X, in the atmosphere in contact with the AgX surface and does not show the activity of the X in the AgX.[3] Also, the ionic current due to the electrolysis of AgX was found not to be blocked completely in the cell of the (I) type, because the carbon electrode is exposed to an inert atmosphere and the halogen partial pressure around the electrode is considerably lower than that at the AgX/carbon interface.[4] These findings suggest problems with Weiss' experiments. In Weiss' first method, the carbon electrode was exposed to an inert atmosphere, so the EMF decay might have reflected the decomposition of AgBr at the AgBr/carbon interface. In his second method, an appreciable ionic current due to the decomposition of AgBr might have flowed in the cell.

The purpose of the present study is to present a new polarization technique, one which is free from the problems encountered in Weiss' experiments, and to report the results of measurements, made using a new technique, of the chemical diffusion coefficients for AgBr and α-AgI.

Theoretical

Distribution Profiles of Nonstoichiometry in a d.c. Polarization Cell. A schematic drawing of the d.c. polarization cell employed in the present study is shown in Fig. 1. It is constructed of an AgX pellet with the length, L, sandwiched between an Ag electrode and a so-called 'ion-blocking' electrode.[4] When an inactive electrode is inserted into AgX as a probe at a certain distance, x, from the Ag/AgX interface, and when a potential difference, $E(L)$, is then applied between the Ag electrode and the ion-blocking electrode, an electrical potential difference, $E(x)$, is observed between the Ag electrode and the probe. Denoting the electrochemical potential of electrons in AgX by η_e, we can express $E(x)$ by

$$E(x)F = -\{\eta_e(x) - \eta_e(0)\} \quad (1)$$

where $\eta_e(x)$ denotes η_e at the x position, $\eta_e(0)$ represents η_e at the Ag/AgX interface, and F denotes the Faraday constant. Expressing the chemical potential of silver in AgX by μ_{Ag}, and the electrochemical potential of silver ions in AgX by η_{Ag^+}, we obtain

$$\eta_e(x) = \mu_{Ag}(x) - \eta_{Ag^+}(x). \quad (2)$$

From Eqs. 1 and 2,

$$E(x)F = -\{\mu_{Ag}(x) - \mu_{Ag}(0)\} + \{\eta_{Ag^+}(x) - \eta_{Ag^+}(0)\}$$
$$= E'(x)F + E''(x)F, \quad (3)$$

where

$$E'(x)F = -\{\mu_{Ag}(x) - \mu_{Ag}(0)\}, \quad (4)$$

and

$$E''(x)F = \eta_{Ag^+}(x) - \eta_{Ag^+}(0). \quad (5)$$

When the ionic current in the cell is completely blocked, η_{Ag^+} in the cell is constant throughout the AgX pellet. Thus,

$$E'' = 0. \quad (5)'$$

From Eqs. 3, 4, and 5′,

$$E(x)F = -\{\mu_{Ag}(x) - \mu_{Ag}(0)\}. \quad (6)$$

When the chemical potential of silver in AgBr is close to that of metallic silver, AgBr is known to show the n-type electronic conduction. In this case, the electronic conductivity, σ_e,[4] is expressed by

$$\sigma_e = \sigma_e^\circ \exp\{(\mu_{Ag} - \mu_{Ag}^\circ)/RT\}, \quad (7)$$

where μ_{Ag}° and σ_e° are the μ_{Ag} and σ_e of AgBr in equilibrium with metallic silver, and where R is the gas constant, and T, the temperature. The n-type electronic conduction is caused by the conduction electrons released from the excess silver atoms. When we represent the nonstoichiometry of AgBr by δ, the metal–excess silver bromide is expressed by the chemical formula $Ag_{1+\delta}Br$ and the concentration of the conduction electrons and the conductivity, σ_e, of AgBr are both proportional to δ. Therefore,

$$\delta = \delta^\circ \exp\{(\mu_{Ag} - \mu_{Ag}^\circ)/RT\}, \quad (8)$$

where δ° is δ in AgBr in equilibrium with metallic silver. From Eqs. 6 and 8,

$$\delta(x) = \delta^\circ \exp\left\{-\frac{E(x)F}{RT}\right\}, \quad (9)$$

where $\delta(x)$ is δ at a ceretain distance, x, from the Ag/AgX interface. As α-AgI shows the p-type electronic conduction due to electron holes, the electronic conductivity, σ_h, can be expressed as[4]

$$\sigma_h = \sigma_h^\circ \exp\{(\mu_{Ag}^\circ - \mu_{Ag})/RT\}, \quad (10)$$

where σ_h° is the σ_h of AgI in equilibrium with metallic silver. The p-type conduction indicates that α-AgI is a metal-dificient compound with the chemical formula of $Ag_{1-\delta}I$. The hole concentration and electronic conductivity of α-AgI are proportional to δ. Thus,

$$\delta = \delta^\circ \exp\{(\mu_{Ag}^\circ - \mu_{Ag})/RT\}. \quad (11)$$

From Eqs. 6 and 11,

$$\delta = \delta^\circ \exp\left\{\frac{E(x)F}{RT}\right\}. \quad (12)$$

In a previous paper[3] the present authors have shown that, under ion-blocking conditions, $E(x)$ in the n-type region of AgBr shows a steady-state distribution

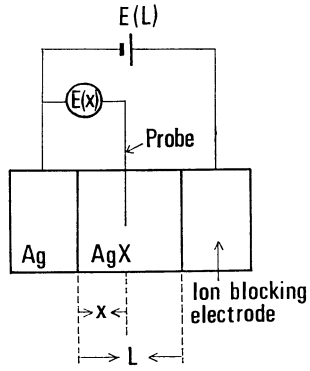

Fig. 1. Schematic diagram of experimental method.

$$\frac{x}{L} = \frac{1 - \exp\left\{-\frac{E(x)F}{RT}\right\}}{1 - \exp\left\{-\frac{E(L)F}{RT}\right\}}. \quad (13)$$

Similarly, for AgI with the p-type conduction,

$$\frac{x}{L} = \frac{\exp\left\{\frac{E(x)F}{RT}\right\} - 1}{\exp\left\{\frac{E(L)F}{RT}\right\} - 1}. \quad (14)$$

The combination of Eqs. 9 and 13 yields

$$\frac{x}{L} = \frac{\delta(x) - \delta^\circ}{\delta(L) - \delta^\circ}. \quad (15)$$

The combination of Eqs. 12 and 14 also results in the same equation. Equation 15 shows that when a steady state is reached under the ion-blocking conditions, the nonstoichiometry of AgBr and α-AgI is linearly distributed in the d.c. polarization cell.

Determination of the Chemical Diffusion Coefficient for AgBr and α-AgI. When a constant potential difference, $E_1(L)$, is applied between the electrodes of the cell in Fig. 1 for a time sufficient to attain the steady-state, and is then changed to $E_2(L)$ abruptly, the distribution of δ in AgX gradually changes with the time from one steady state to another steady state. This process is controlled by the chemical diffusion in AgX. If the molar amount of X in a unit volume of AgX is expressed by C, the amount of silver excess or silver deficit in a unit volume will be given by $C\delta$. Therefore, the diffusion equation is

$$\frac{\partial(C\delta)}{\partial t} = \tilde{D}\frac{\partial^2(C\delta)}{\partial x^2}, \quad (16)$$

where $\tilde{D}$ denotes the chemical diffusion coefficient, and t, the time. Because C is constant, Eq. 16 can be rewritten as

$$\frac{\partial\delta}{\partial t} = \tilde{D}\frac{\partial^2\delta}{\partial x^2}. \quad (17)$$

In the case of AgBr, the boundary conditions are

$$\frac{\delta(x, 0) - \delta^\circ}{\delta(L, 0) - \delta^\circ} = \frac{x}{L} \quad \text{for } t = 0 \quad (18)$$

$$\delta(L) = \delta^\circ \exp\left\{-\frac{E_1(L)F}{RT}\right\} \quad \text{for } t < 0 \quad (19)$$

$$\delta(L, t \geq 0) = \delta^\circ \exp\left\{-\frac{E_2(L)F}{RT}\right\} \quad \text{for } t \geq 0 \quad (20)$$

$$\delta(0,\ t) = \delta^{\circ} \qquad \text{for } x=0. \qquad (21)$$

Solving Eq. 17 under the condition of Eqs. 18—21, we obtain

$$\frac{\delta(L/2,t)-\delta(L/2,0)}{\delta(L/2,\infty)-\delta(L/2,0)} = \frac{4}{\pi}\sum_{n=1}^{\infty}\frac{(-1)^n}{2n-1}\exp\left\{-\frac{\tilde{D}\pi^2(2n-1)^2t}{L^2}\right\}, \qquad (22)$$

where n is the integer. The same solution as Eq. 22 is obtained in the case of α-AgI. When t becomes large, the $n>2$ terms in the series of Eq. 22 become negligibly small. It follows that

$$\frac{\delta(L/2,\infty)-\delta(L/2,t)}{\delta(L/2,\infty)-\delta(L/2,0)} = \frac{4}{\pi}\exp\left(-\frac{\tilde{D}\pi^2t}{L^2}\right). \qquad (23)$$

The change in $\delta(L/2)$ with the time can be calculated from $E(L/2)$ by using Eqs. 9 and 13. From the slopes of the plots of $\log[\{\delta(L/2,\infty)-\delta(L/2,t)\}/\{\delta(L/2,\infty)-\delta(L/2,0)\}]$ *versus* t, we can determine the chemical diffusion coefficient, $\tilde{D}$.

Chemical Diffusion Coefficient and Electronic Conductivity. According to Wagner's theory of metal oxidation,[5] the diffusion through the oxide layer is generally interpreted as consisting of migration processes of ions and electrons, and, in the case of diffusion-controlled oxidation, the chemical diffusion coefficient, $\tilde{D}$, is given by

$$\tilde{D} = \frac{V_m}{Z_1F^2}\frac{(\sigma_1+\sigma_2)\sigma_3}{\sigma_1+\sigma_2+\sigma_3}\frac{\partial\mu_M}{\partial\delta}, \qquad (24)$$

where σ_1, σ_2, and σ_3 are the conductivities of cations, anions, and electrons respectively, and where Z_1 is the number of the charge of the cations, μ_M is the chemical potential of metal, and V_M is the molar volume.

The same diffusion situation as in the metal oxidation is set up in the present experiment, except for the initial several seconds, where the transient current flows to charge or discharge the cell. For AgBr with the n-type conduction, the diffusion of Ag^+ ions and electrons contributes most to the chemical diffusion. Therefore,

$$\tilde{D} = \frac{\sigma_{Ag^+}\sigma_e V_m}{(\sigma_{Ag^+}+\sigma_e)F^2}\frac{\partial\mu_{Ag}}{\partial\delta}. \qquad (25)$$

Since σ_{Ag^+} is much larger than σ_e, Eq. 25 becomes

$$\tilde{D} = \frac{\sigma_e V_m}{F^2}RT\frac{1}{\delta}. \qquad (26)$$

Here Eq. 8 is used. Equation 26 indicates that the nonstoichiometry can be determined by chemical diffusion measurements and electronic conductivity measurements.

Similarly, the diffusion of Ag^+ ions and positive holes occurs during the chemical-relaxation process in α-AgI.

From Eq. 24,

$$\tilde{D} = \frac{\sigma_{Ag^+}\sigma_h V_m}{(\sigma_{Ag^+}+\sigma_h)F^2}\frac{\partial\mu_{Ag}}{\partial\delta}. \qquad (27)$$

Since $\sigma_{Ag^+} \gg \sigma_h$, using Eq. 10 we obtain

$$\tilde{D} = \frac{\sigma_h V_m}{F^2}RT\frac{1}{\delta}. \qquad (28)$$

Experimental

Cells and Samples. Figure 2 shows the cell structure and the block-diagram of the circuit used for the measurement. The samples were prepared in the way described elsewhere.[3] The cell construction was essentially the same as that of the improved d.c. polarization cell,[4] except that in the present work the platinum probe was placed in the middle of the AgX pellet. A hole, 0.8 mm in diameter, was drilled along the axis of the silver electrode to the middle of the AgX pellet. In this hole, a platinum wire 0.2 mm in diameter, protected by an alumina tube (0.8 mm in outer diameter and 0.4 mm in inner diameter), was buried as a probe so that only the tip of the wire was in contact with the AgX pellet.

Measurement Procedure. The cell was set in an electrical furnace, the temperature of which was controlled within ±1 °C. Then a constant potential difference, $E_1(L)$, was created between the silver and carbon electrodes by means of a potentiostat. The potential difference, $E(L/2)$, between the silver electrode and the platinum probe was recorded by means of high-input-impedance voltage follower and a recorder. After $E(L/2)$ had reached a steady value, $E_1(L)$ was changed abruptly to $E_2(L)$ by means of a function generator and the time change of $E(L/2)$ was recorded. In several runs, the time change in the current passing through the cell was also recorded. The chemical diffusion coefficient was determined by the analysis of the recorded curve of $E(L/2)$ *versus* the time.

The measurement for AgBr was performed in the temperature range from 325 to 400 °C, with $E(L)$ values of from 10 to 200 mV. Under these conditions, AgBr showed the n-type electronic conduction. The measurements for α-AgI were performed in the temperature range from 330 to 500 °C, with $E(L)$ values of from 300 to 550 mV.

Results and Discussions

Several examples of the time change of $E(L/2)$ for AgBr (L=6.0 mm) are shown in Figs. 3(a) and 3(b).

	40	16.6	17.8	14.0
	200	38.4	40.7	34.3

Table 2. Comparison of calculated and observed values of $E(L/2)$ in a steady state (α-AgI)

Temp °C	$E(L)$ mV	$E(L/2)$ mV Calcd	$E(L/2)$ mV Obsd $L=7.0$ mm	$E(L/2)$ mV Obsd $L=10.0$ mm
330	375	339	345	—
	400	364	364	375
	430	394	—	405
	500	464	470	—
	530	494	—	504
500	300	254	256	—
	400	354	363	345
	500	454	452	450

In Tables 1 and 2, the observed steady-state values are compared with those calculated by using Eqs. 13 and 14. Both agree within the limits of experimental error; this error can be attributed to the inaccuracy in the positioning of the platinum probe, because the platinum wire itself has a diameter of 0.2 mm and a slight plastic deformation of pellets prior to the experiments may also result in a small displacement of the probe.

As is shown in Fig. 4(b), the cell exhibits a transient current for several seconds after the sudden change of $E(L)$. It appears to be an ionic one which flows to charge or discharge the improved d.c. polarization cell.[4] The ionic current, i_{ion}, can be expressed by

$$i_{ion}=\frac{\sigma_{Ag^+}}{F}\frac{\partial\eta_{Ag^+}}{\partial x}=\sigma_{Ag^+}\frac{E''(x)}{x}=\sigma_{Ag^+}\frac{E''(L/2)}{L/2}. \quad (29)$$

Using the values of σ_{Ag^+} given by Biermann and Jost,[6] we can calculate the $E''(L/2)$ values, which are shown by the subscale in Fig. 4(b). Obviously $E''(L/2)$ decays to 0 ± 1 mV within 2 s after the sudden change in $E(L)$. When $E''(L/2)$ actually vanishes,

$$E(L/2)F=-\{\mu_{Ag}(L/2)-\mu_{Ag}(0)\}. \quad (30)$$

In the case of AgBr, Eq. 30 is found to hold within 0.5 s after the sudden change in $E(L)$.

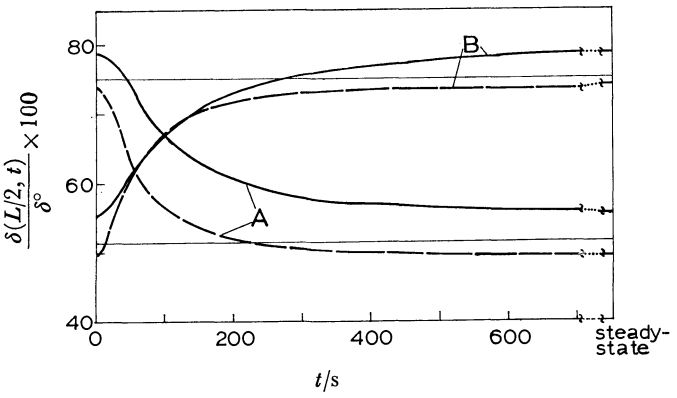

Fig. 5. Plots of $\delta(L/2,t)/\delta^\circ$ *versus* t for AgBr at 400 °C.
——; L=6.0 mm. — — —; L=4.7 mm.
Curves A; Step of $E(L)$ from 40 mV to 200 mV.
Curves B; Step of $E(L)$ from 200 mV to 40 mV.

Figure 5 shows some typical examples of the plot of $\delta(L/2)$ *versus* t. The plots of $\log[\{\delta(L/2,\infty)-\delta(L/2,t)\}/\{\delta(L/2,\infty)-\delta(L/2,0)\}]$ *versus* t are shown in Fig. 6. Clearly, the plots in Fig. 6 fall on a straight line. Thus, the chemical diffusion coefficient, $\tilde{D}$, is calculated from the slope of the plots. Figure 7 shows the $\tilde{D}$ values obtained in the present work. The $\tilde{D}$ values show a good linearity in the figure. $\tilde{D}$ for AgBr can be expressed by this equation

$$\tilde{D} = 7.10\times 10^{2}\exp\left(-\frac{1.96\times 10^{4}\ \text{cal mol}^{-1}}{RT}\right)\text{cm}^2\,\text{s}^{-1}, \quad (31)$$

and $\tilde{D}$ for α-AgI can be given by

$$\tilde{D} = 4.95\times 10^{-1}\exp\left(-\frac{7.71\times 10^{3}\ \text{cal mol}^{-1}}{RT}\right)\text{cm}^2\,\text{s}^{-1}. \quad (32)$$

Using Eq. 26, the nonstoichiometry of AgBr in equilibrium with metallic silver can be calculated from the σ_e° obtained by Ilschner.[7] The plot A in Fig. 8 shows δ° of AgBr. From the intercept of the plot at the ordinate and the slope of the plot, the molar entropy, $\Delta\overline{S}$, and the molar enthalpy, $\Delta\overline{H}$, of the dissolution of silver can be calculated. The results are $\Delta\overline{S}$= 2.87eu and $\Delta\overline{H}$= −21.4 kcal mol^{-1} respectively. Since the dissolution of silver into AgBr consists of the transfer of atoms between two solid phases, the entropy change is close to zero.

In a previous paper,[4] the present authors have determined σ_h*, the hole conductivity of α-AgI in equilibrium with 1 atm of iodine gas. We can calculate δ*, the nonstoichiometry of α-AgI in equilibrium with 1 atm of iodine gas, by using Eq. 28 and σ_h*. The calculated results are shown as the B plot in Fig. 8. The entropy and enthalpy of the dissolution of iodine into α-AgI in equilibrium with 1 atm of iodine gas are $\Delta\overline{S}$= −21.8 eu and $\Delta\overline{H}$=1.51 kcal mol^{-1} respectively. As iodine atoms are transferred from the gas phase to the solid phase, $\Delta\overline{S}$ takes a large negative value.

The apparent mobility of electrons in AgBr, m_e, and that of holes in α-AgI, m_h, are calculated by means of the following equations:

$$\sigma_e^\circ = \left(\frac{N\delta^\circ}{V_m}\right)m_e e, \quad (33)$$

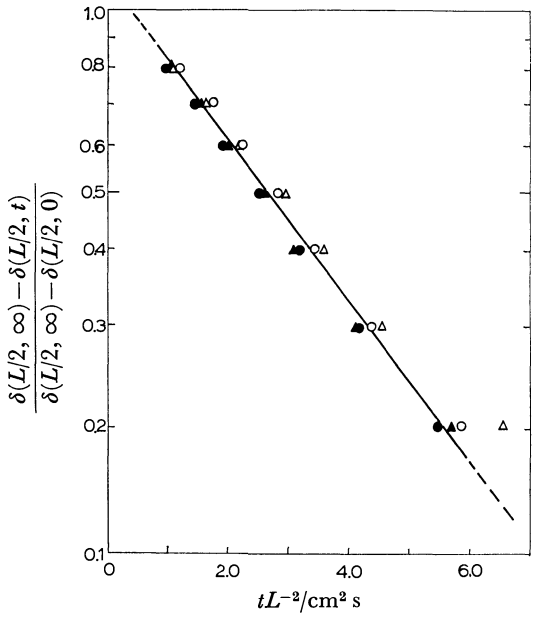

Fig. 6. Plots of $\{\delta(L/2,\infty)-\delta(L/2,t)\}/\{\delta(L/2,\infty)-\delta(L/2,0)\}$ *vs.* tL^{-2} for AgBr at 400 °C.

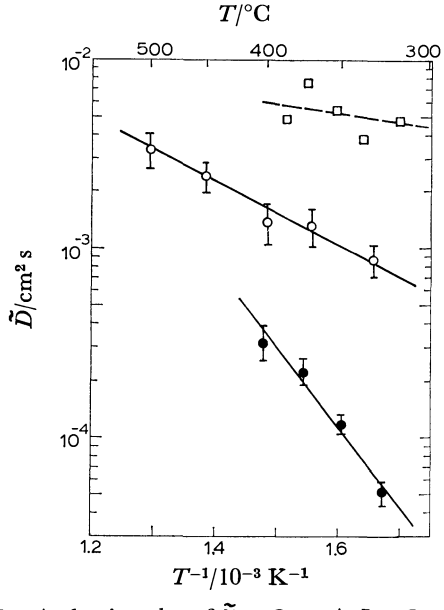

Fig. 7. Arrhenius plot of $\tilde{D}$. ○; α-AgI. ●; AgBr by this work. □; AgBr by Weiss.[1]

$$\sigma_h^* = \left(\frac{N\delta^*}{V_m}\right)m_h e, \quad (34)$$

where N denotes Avogadro's constant and where e denotes the charge of an electron. At 400 °C, m_e= 5.5×10^{-3} cm^2 V^{-1} s^{-1} for AgBr and m_h=2.5×10^{-2} cm^2 V^{-1} s^{-1} for α-AgI.

In Fig. 7, the $\tilde{D}$ values obtained by Weiss in his first work[1] are also plotted. His results showed larger $\tilde{D}$ values than those obtained in the present work, and the Arrehnius plot was not linear. When the applied potential difference is removed in Weiss'

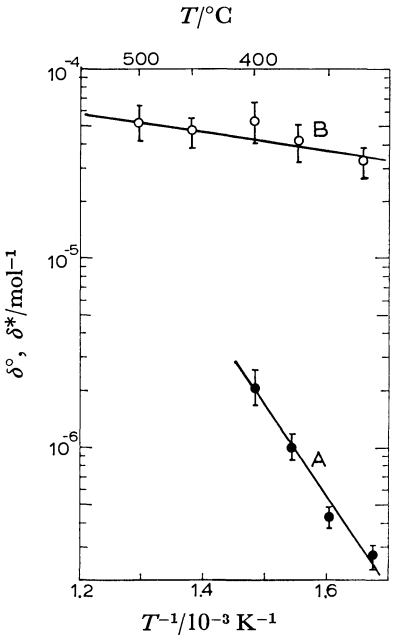

Fig. 8. Plots of δ° and δ^* *vs.* T^{-1}. A; δ° of AgBr. B; δ^* of α-AgI.

cell, the activity of the silver at the AgBr/carbon interface rises as a result of the diffusion of silver atoms toward the interface from the interior of AgBr, and also as a result of bromine gas be being released and silver atoms leaving at the interface due to the decomposition. This decomposition causes a faster decay of EMF, whcih results in the apparent $\tilde{D}$ values being larger than the real values. Because the decomposition rate is often controlled by the flow rate of the inert gas around the carbon electrode, the reproducibility may not be good. Figure 7 suggests the high probability that the measurements in Weiss' first work were disturbted by the decomposition of AgBr.

The $\tilde{D}$ values in Weiss' second work[2] were ten times or more larger than those in his first work. We can see in Fig. 4(b) that the decay in the current occurs much faster than the chemical relaxation of the sample. This fact can explain why Weiss' second work resulted in such extraordinarily large $\tilde{D}$ values.

Weiss' first method can be useful when the chemical relaxation due to the chemical diffusion in the sample occurs faster than the relaxation by other effects, while the second method can be applied to a sample in which the transient ionic current is small enough. However, it seems AgBr was not a sample suitable for either of these measuring methods.

Summary

1) A new technique for the detemination of the chemical diffusion coefficients in ionic crystals was devised and applied to AgBr and α-AgI. The chemical diffusion coefficient for AgBr was found to be much smaller than that reported by a previous investigator. 2) Using the chemical diffusion coefficient and electronic conductivity of AgX, the nonstoichiometry, electron and hole mobilities, and entropy and enthalpy of the dissolution of elements into AgX were calculated.

(Received September 18, 1978)

The crystal structure of *trans*-1,4-dibenzoyl-2,5-dimethyl-piperazine has been determined by the X-ray method. The space group is $P2_1/c$, with $a=7.483$, $b=6.577$, $c=19.939$ Å, $\beta=116.71°$ and $Z=2$. The structure was solved by the direct method and refined by the least-squares method to the final R factor of 0.094 for 2559 independent reflections. A nitrogen atom and three carbon atoms bonded to the nitrogen atom are approximately in a plane. The molecule is centrosymmetric, the piperazine ring having a *chair*-form. The methyl groups are in the axial position. The oxygen atom is approximately in a plane formed by N, C(carbonyl), and C(benzene). The dihedral angle between this plane and the benzene ring is approximetely 70°.

1,4-Dibenzoyl-2,5-dimethylpiperazine (DDP) has two isomers, the *trans*-form (mp 225 °C) and the *cis*-form (mp 146 °C). The crystal structure of the *cis*-form was reported by Sakurai *et al.*[1] We have studied the *trans*-form in order to discuss the molecular geometry in both forms. The results are given below.

Experimental

Colorless prisms elongated along the b axis were obtained by slow evaporation from an ethanol solution of *trans*-DDP. The crystal is built upon a monoclinic unit cell.

Crystal Data. Oscillation and Weissenberg photographs were taken with Cu $K\alpha$ radiation. The systematically absent reflections indicated that the space group is $P2_1/c$. The cell dimensions were refined by least-squares calculations on the basis of higher-order reflections measured on a diffractometer. The density of the crystal was measured by the flotation method. Since there are two formula units per cell, the molecule has a center of symmetry. The crystal data are summarized in Table 1.

Intensity Data. A prismatic crystal was ground to a cylinder 0.4 mm in diameter and 0.4 mm in length. This was mounted on a four-circle diffractometer (Rigaku AFC-III) with Nb-filtered Mo $K\alpha$ radiation from a graphite monochromator, and the intensity data were collected for 2559 independent reflections with $|F_o| \geqq 3\sigma(F_o)$ with $2\theta \leqq 60.0°$, using the ω-2θ scan technique with a scanning speed of 4° min^{-1} in 2θ. No corrections were made for absorption or extinction.

D_x	1.221
μ(Mo $K\alpha$)	0.856 cm^{-1}

Structure Determination

The structure was analyzed by the direct method using MULTAN.[2] Phases were determined for the 346 reflections with $|E|>1.50$, eight E maps being calculated. The phases set with the lowest residual (33.1) and the highest figure of merit (1.10) produced a significant E map, which revealed the positions of all the non-hydrogen atoms. The atomic coordinates and temperature factors were refined by the block-diagonal matrix least-squares method until R was reduced to 0.190. Locations of the hydrogen atoms were obtained by assuming a tetrahedral angle for each carbon atom and a bond length of 1.09 Å for each C–H bond. Further refinements were made on a CDC-6600 computer at Century Research Center Co., Tokyo, using anisotropic thermal parameters for the non-hydrogen atoms and isotropic B for the hydrogen atoms. Convergence was attained with $R=0.094$ after six cycles of the procedure. The atomic scattering factors were taken from International Tables for X-Ray Crystallography[3]. The final parameters with their standard deviations are given in Tables 2 and 3***.

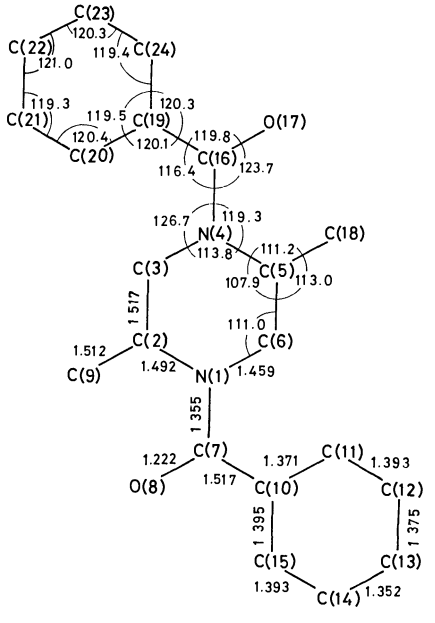

Fig. 2. Intramolecular interatomic distances and angles.

Discussion

Molecular Geometry and Conformation. Numbering scheme and the thermal ellipsoids of the non-hydrogen atoms are illustrated in Fig. 1, where thermal vibration ellipsoids are set to 50% probability. Bond distances and angles involving the non-hydrogen atoms are shown in Fig. 2. The standard deviations of these measurements are 0.004—0.008 Å for distances, and 0.1—0.4° for angles. Since the molecule is centrosymmetric, the piperazine ring has a *chair*-form.[4] The mean N–C bond length in the piperazine ring, 1.476 Å, is comparable to that of *cis*-1,4-dibenzoyl-2,5-dimethylpiperazine (*cis*-DDP).[1] The bond distances, 1.517 Å for C–C in the piperazine ring and 1.512 Å for C (piperazine)–C(methyl), are shorter than the C–C covalent bond length. The bond angles of carbon atoms in the piperazine ring are approximately tetrahedral. The value for C(5)–N(4)–C(3) is comparable to 115.7° of *cis*-DDP, or 112.6° of piperidine.[4,5]

The least-squares planes are given in Table 4 and the torsion angles in the molecule in Table 5. Exocyclic torsion angles for C(9)–C(2)–C(3)–N(4) and C(9)–C(2)–N(1)–C(6) show that C(9) is in the axial position. The shift of N(1) from the plane(1), containing C(2), C(3), C(5), and C(6), is 0.639 Å, and that of C(9) from the plane(1) is 1.383 Å.

The C–O distance of 1.222 Å is in agreement with 1.222 Å of *cis*-DDP, and 1.229 Å of *N,N'*-dibenzoyl-*p*-phenylenediamine(DPD).[6] The N–C(carbonyl) distance is 1.355 Å, corresponding to 1.357 Å in DPD, and 1.353 Å in *cis*-DDP. The C(carbonyl)–C(benzene) distance is 1.517 Å, being comparable to 1.499 Å of *cis*-DDP, and 1.502 Å of DPD.

The mean value of the C–C bond distance in the benzene ring is 1.380 Å, being shorter than 1.397 Å of benzene. The corresponding values for *cis*-DDP and DPD are both 1.386 Å.

The dihedral angle between the planes(2) and (3) is 70.5°. The angle in *cis*-DDP is about 55°. The dihedral angle between planes(1) and (2) is 56.0°, and that between planes(1) and (3) is 61.1°.

Adsorptive Mechanism on Activated Carbon in the Liquid Phase. I. Free Energy Change for Adsorption of Organic Compounds from Aqueous Solution on Activated Carbon

Ikuo ABE,* Katsumi HAYASHI, Mutsuo KITAGAWA,** and Toshihiro URAHATA

Osaka Municipal Technical Research Institute, Ogimachi, Kita-ku, Osaka 530

***Society for Activated Carbon Research, Ogimachi, Kita-ku, Osaka 530*

(Received October 12, 1978)

The adsorption isotherms, from aqueous solution onto activated carbon, have been determined for the 22 aliphatic monofunctional compounds; alcohols, carboxylic acids, ketones, ethers, esters, and aldehydes. The free energy change for the adsorption process has been calculated from the adsorption equilibrium constant at infinite dilution; a linear relationship exists between the free energy change and the number of carbon atoms in the solute. The free energy of adsorption has been divided into two contributions: the hydrocarbon and the functional group contribution. The free energy change for the adsorption process has been compared with the free energy change for the precipitation process from solution into the pure liquid solute. The free energy contribution per individual methylene group to the adsorption process shows an approximate agreement with that for the precipitation process indicating that the adsorption process of the hydrocarbon portion of the solute is analogous to the precipitation process. The free energy contribution of the functional group to the adsorption process is smaller than that for the precipitation process indicating that the functional group portion of the solute is not appreciably dehydrated in the adsorption phase.

The adsorption theory in the gas phase has been extensively investigated but not in the liquid phase. In gas phase adsorption Polanyi's potential theory[1] and its modifications[2-5] have been widely used. In the theory Polanyi considered the energy processes in transferring a molecule from the gas to the adsorbed state and concluded that the free energy change in passing from the gaseous to the saturated liquid state represents a valid criterion for the free energy change of the whole process.

In liquid phase adsorption the potential theory has been applied by Hansen and Fackler[6] to the adsorption of liquid mixtures on carbon black, and by Manes[7] *et al.* to the adsorption of solids from several solvents on activated carbon. Polanyi originally supposed that the adsorption of solid solutes from solution was analogous to the adsorption of gases with precipitation of the solid taking the place of liquefaction of the gas, *i.e.*, the adsorption process was identically equal to the reverse of the solution process. This suggests that the free energy change for the adsorption process is analogous to the reverse of the solution process.

In this study, the free energy change of the adsorption process for aliphatic monofunctional compounds has been determined and compared with the free energy change of the solution process.

Experimental

Materials. The adsorbent in all instances came from a single batch of Pittsburgh Activated Carbon (grade CAL) which was ground and sieved to yield 200×350 mesh size. After sieving, the carbon was washed with distilled water to remove all fines and dried at 110 °C. The BET surface area found from nitrogen adsorption at 77 K was 1010 m²/g. The pore volume was 0.575 ml/g, when calculated from the limiting vapor adsorption at $P/P_0 \rightarrow 1$. The experimental conditions and the pore volumes determined are listed in Table 1.

All organic compounds were purchased from commercial sources and distilled, if necessary, to a minimum purity of 99% as determined by gas chromatography. All aldehydes were used without further purification.

TABLE 1. PORE VOLUME OF THE ADSORBENT CALCULATED FROM THE LIMITING VAPOR ADSORPTION AT $P/P_0 \rightarrow 1$

Adsorbate	Temperature (K)	Pore volume (ml/g)
Nitrogen[a]	77	0.586
Methanol[b]	298	0.573
2-Butanone[b]	298	0.568
Benzene[b]	298	0.572
	Av	0.575

a) Measured with BET adsorption apparatus. b) Measured by a modification of Hirata's method.[8]

Procedure. Equilibration took place in 50-ml double stoppered flasks, which were shaken for a minimum of 14 h at 25 °C in a thermostated bath; check experiments at longer shaking times established that the shaking time sufficed for equilibration. In order to eliminate loss through evaporation, pressure filtration was chosen for removing the carbon from the solution. The concentration of solute was analysed by determining the total organic carbon in a Shimadzu Model TOC-10A analyzer. The amount of adsorbed solute (mg) on carbon (grams) was calculated from the following relation:

$$X = \frac{V \cdot \Delta C}{M} \tag{1}$$

where ΔC (mg/l) is the solute concentration decrease due to adsorption and V (l) is the volume of solution added to M (g) of carbon.

Results

Figures 1—6 illustrate the 25 °C adsorption isotherms for alcohols, carboxylic acids, ketones, ethers, esters, and aldehydes, from solution, onto CAL carbon. The adsorption isotherms have been approximated by the adsorption Eqs. 2 and 3:

$$\frac{C}{X} = a_0 + a_1 C \tag{2}$$

$$\frac{C}{X} = b_0 + b_1 C + b_2 C^2 \tag{3}$$

where C is the equilibrium concentration; X is the amount of adsorption at C; a_0, a_1, b_0, b_1, and b_2 are constants. The results of regression analysis using Eq. 2 or Eq. 3 are presented in Table 2.

The adsorbability (α) of solute at infinite dilution has been defined as follows:

$$\alpha \equiv \lim_{C \to 0} \frac{X}{C} \tag{4}$$

In order to determine the adsorbability, C/X has been plotted against C from the data of Figs. 1—6 and the result for butyl acetate shown in Fig. 7. The intercept of the adsorption isotherm gives the value of α. It is evident from Fig. 7 that the experimental data more closely approximates to Eq. 3 than to Eq. 2 and consequently the value of α has been taken from Eq. 3. The values of α ($1/b_0$) are presented in Table 2.

Equation 2 is of Langmuir type:

$$\frac{C}{X} = \frac{1}{aX_m} + \frac{C}{X_m} \tag{5}$$

where X_m is the amount of adsorption at saturation

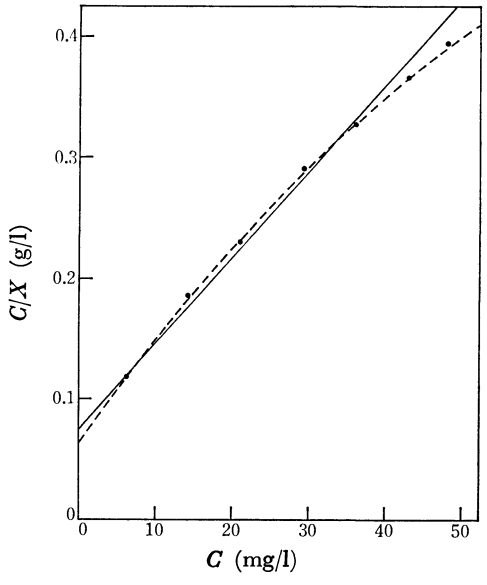

Fig. 7. Adsorption isotherm of butyl acetate on CAL activated carbon from aqueous solution, 25 °C. ●: Experimental, ——: best fitting model Eq. 2, ----: best fitting model Eq. 3.

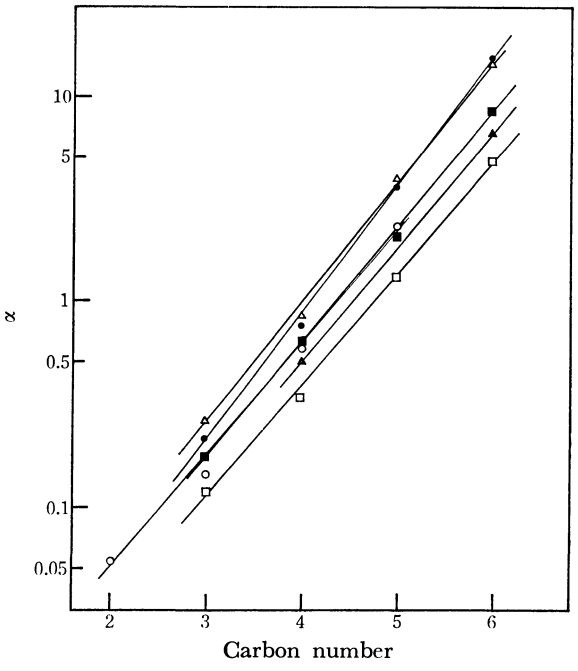

Fig. 8. Relationship between adsorption constant α and carbon atom number N. ○: Aldehydes, ●: carboxylic acids, △: esters, ▲: ethers, □: ketones, ■: alcohols.

and a is a constant. The value of α calculated by Eq. 2 is identical with X_m $(=1/a_0)$. As can be seen from Table 2, there is little difference between $1/b_0$ and $1/a_0$.

Figure 8 illustrates the relationship between log α and the number of carbon atoms in the solute. It can be seen from Fig. 8 that for a homologous series the following relation exists:

$$\log \alpha = \beta N + \gamma \tag{6}$$

where N is the number of carbon atoms and β and γ are constants. This demonstrates that Traube's rule[9] is valid in the adsorption of the homologous paraffin chain solutes.

For a thermodynamic study of adsorption from solution, it is necessary to determine the standard free energy change ΔG°. Alexander and Johnson[10] calculated ΔG° by the following equation:

$$\Delta G^\circ = -RT \ln\left(\frac{\Gamma}{tC_{bulk}}\right) \tag{7}$$

where Γ is the surface excess per unit area and t the thickness of the adsorbed layer. In this equation it is assumed that the adsorbed molecules behave ideally. Fu and Bartell[11] showed that the activity coefficient of the adsorbate on the solid greatly differed from unity, and proposed that the equilibrium constant K for the process (8) should be obtained from the limiting slope of the adsorption isotherms at zero concentration, in which the adsorbates behave ideally:

$$\text{Solute in solution} \rightleftharpoons \text{Solute in adsorption phase.} \tag{8}$$

In order to determine K, it is necessary to convert the amount of adsorption into concentration and for this purpose, the volume of the adsorption phase must be determined. Bartell[12] *et al.* used the product of the surface area of the adsorbent and the thickness of the adsorbed layer as the volume. In the case of high-porous adsorbents such as activated carbon, however, the adsorption process may be regarded as pore filling rather than monolayer coverage[13] and consequently the pore volume has been adopted as the volume of the adsorption phase. It has been assumed that the pore volume is equal to the volume calculated from the limiting vapor adsorption at $P/P_0 \rightarrow 1$, and that every pore contributes in the same manner to the adsorption of adsorbate. It may be seen from Table 1 that the volume is almost independent of the nature of vapor. Hence an average of the values obtained from four vapors has been adopted as the volume of CAL carbon (0.575 ml/g). After the volume of adsorption phase (V) has been obtained, K and ΔG° may be calculated from the following equation:

$$K = \alpha/V \tag{9}$$

$$\Delta G^\circ = -RT \ln K. \tag{10}$$

By substituting for K from Eq. 9 into Eq. 10 and for log α from Eq. 6 into Eq. 10, it may be shown that at a certain temperature:

$$\begin{aligned}\Delta G^\circ &= -RT(\ln \alpha - \ln V) \\ &= -2.303RT(\beta N + \gamma - \log V) \\ &= \beta_0 N + \gamma_0\end{aligned} \tag{11}$$

where β_0 and γ_0 are constants. The constants and the correlation coefficients calculated by regression analysis are given in Table 3. The overall statistics are excellent with an average correlation coefficient of 0.9990. The constant β_0 corresponds to the standard free energy change per individual methylene group (ΔG°_C) and γ_0 to the functional group contribution for ΔG°. Therefore, assuming that the hydrocarbon and functional portions contribute independently to the standard free energy change for monofunctional aliphatic compounds, it follows that:

$$\Delta G^\circ = \Delta G^\circ_{HY} + \Delta G^\circ_{FG}. \tag{12}$$

For the compounds examined in this study, ΔG°_{HY} may be expressed by the following equation:

$$\Delta G^\circ_{HY} = \Delta G^\circ_C \cdot N = \beta_0 \cdot N \tag{13}$$

As seen from Table 3, ΔG°_C and ΔG°_{FG} give similar values for all functional groups (the averages are -779 cal/mol and -1060 cal/mol, respectively).

Discussion

The free energy change for the solution process has been calculated by Amidon[14,15] *et al.* The molecular surface area for 158 aliphatic hydrocarbons, olefins, alcohols, ethers, ketones, aldehydes, esters, and fatty

Table 4. Free energy contribution per one methylene group to the solution process

acids were computed and correlated with the aqueous solubilities. For monofunctional aliphatic compounds the total surface area (*TSA*) may be divided into two contributions, namely the hydrocarbon (*HYSA*) and functional group (*FGSA*) contributions.

$$TSA = HYSA + FGSA \tag{14}$$

Assuming that the hydrocarbon and functional group portions contribute independently, the following generalized equation is suggested for use in solubility correlations:

$$\log S = \Theta_1 \cdot HYSA + \Theta_2 \cdot FGSA + \Theta_3 \cdot IFG + \Theta_0 \tag{15}$$

where S is the aqueous solubility, Θ_0 is the intercept, and *IFG* is the functional group index (zero for hydrocarbons and unity for a monofunctional compound). From the coefficients for the *HYSA* term in Eq. 15, the free energy contribution per individual methylene group to the solution process ($\Delta G^{\circ}_{C,sol}$) may be calculated (assuming 31.8 Å^2 as the area per CH_2 group). The value of $\Delta G^{\circ}_{C,sol}$ for each homologous series is shown in Table 4. The average $\Delta G^{\circ}_{C,sol}$ value is 791 cal/mol and shows approximate agreement with the value of $-\Delta G^{\circ}_{C,ad}$ (779 cal/mol) obtained from the adsorption of the same homologous series on CAL carbon from aqueous solutions. This suggests that the adsorption process of the hydrocarbon portion of solute is analogous to the precipitation process from the aqueous solution into the pure liquid solute, and that the solute in the adsorption phase is in the liquid form. The Polanyi adsorption potential theory is also based on the concept that the adsorption process is identical to the precipitation process.

For the six groups of compounds included in Table 4 the general tendency is that the more polar compounds give smaller methylene group hydrophobic effects. On the other hand, Table 3 indicates that the more hydrophobic compounds have smaller hydrophobic effects caused by the methylene group. This may be due to the different effect of a methylene unit on the solute-solute interaction between the adsorption phase and the pure liquid solute phase.

The free energy contribution of the functional group to the solution process ($\Delta G^{\circ}_{FG,sol}$) may be calculated from the *FGSA* and *IFG* terms in Eq. 15. The hydroxyl group contributes −3.81 kcal/mol to the free energy of solution for the addition of a hydroxyl group to a normal hydrocarbon in the 1-position.[14] The values of $\Delta G^{\circ}_{FG,sol}$ for other functional groups are similar in magnitude to that for the hydroxyl group.[15] The free energy contribution of the functional group to the adsorption process ($\Delta G^{\circ}_{FG,ad}$) is on average −1.06 kcal/mol for the six groups of compounds in Table 3, suggesting that the adsorption of the functional group portion of the solute differs from the precipitation process. There are, however, certain factors that influence the value of $\Delta G^{\circ}_{FG,ad}$. The first is the volume of the adsorption phase. The volume of the adsorption phase in liquid phase may differ from that in the gas phase. Assuming that the volume is half the value in Table 1, the value of $\Delta G^{\circ}_{FG,ad}$ decreases from −1.06 kcal/mol to −1.47 kcal/mol. Therefore, the influence of this factor on the value of $\Delta G^{\circ}_{FG,ad}$ would not be very large.

Table 5. Free energy contribution of functional groups to the adsorption process

Compound	Functional group	Number of methyl groups	γ_1 (cal/mol)	γ_2 (cal/mol)
Alcohols	-OH	1	230	230
Carboxylic acids	-COOH	1	381	−467
Ketones	>CO	2	1775	1035
Ethers	-O-	2	1660	1660
Esters	-COOR	2	1510	699
Aldehydes	-CHO	1	210	−545

The second factor is the validity of extrapolation of the linear relationship in Eq. 11. The estimation of $\Delta G^{\circ}_{FG,ad}$ from the intercept is based on the assumption that every carbon atom in a solute compound makes the same contribution to the free energy as one methylene group. It has, however, frequently been noted that a methyl group and a methylene unit make different contributions:[16–18] the contribution to the free energy of solution for a methyl group is greater by approximately 1.35 kcal/mol than that for a methylene group.[14] The value of γ_0 in Table 3 has been corrected on the basis that the adsorption process on hydrocarbons is identical with the precipitation process, the value of the corrected γ_0 being given in the fourth column of Table 5. A similar correction must be made for the carbon atom in the functional group. The value of γ_1 does not contain the free energy contribution of the carbon atom in the functional group and it is difficult to estimate this contribution. The free energy contribution of the functional group containing the carbon atom is given in the fifth column of Table 5.

The third factor is the effect of the surface oxygen complex of activated carbon on adsorption.[19–21] The dominant component of the driving force for adsorption is the dispersion component of the Van der Waals forces. However, the polarizing component of the Van der Waals forces also contributes to adsorption for polar or polarizable substances. Consequently it is assumed that the value of γ_2 for carboxylic acids and aldehydes is smaller than that of other functional groups due to these polar effects. Aldehydes may be converted in part to carboxylic acids by oxidation in aqueous solution.

It is necessary to take into further consideration other factors in order to exactly estimate the free energy contribution of the functional group. However, in

view of these three main factors, the following conclusions may be derived. The free energy contribution of the functional group to the adsorption process is smaller than the free energy contribution of the functional group to the precipitation process, *i.e.*, the functional group of the solute molecule in the adsorption phase is appreciably hydrated.

The functional groups of alcohols, carboxylic acids, and aldehydes suffer little dehydration and be present in the solution phase, since the functional groups are situated at terminal positions in the alkyl chain. On the other hand, the functional groups of ketones, ethers, and esters would be more dehydrated and be present in the pores of the activated carbon, since the functional groups are situated between the alkyl chains.

The potential theory in liquid phase adsorption assumes that the adsorption of solute take place by precipitation of the solute in the adsorption phase. From the present investigation, however, it has become apparent that the adsorption of solute takes place by precipitation of the hydrocarbon portion of the solute and that the functional group portion of the solute is not appreciably dehydrated in the adsorption phase.

The authors wish to express their thanks to Professor Nobuhiko Kuroki and Associate Professor Joichi Koga, The University of Osaka Prefecture, for their helpful discussions.

The Study of Carrier Effects on the ESR of Vanadium Ions Formed in Supported Catalysts, as Assisted by Spectrum Calculation

Hisashi UEDA

National Chemical Laboratory for Industry, 2-19-19 Mita, Meguro-ku Tokyo 153

(Received October 17, 1978)

In order to study the carrier effects on the supported catalysts of vanadium, the ESR spectra of vanadium ions supported on γ-Al_2O_3, SiO_2, ZrO_2, TiO_2, MgO, or CaO and reduced in H_2 at 500 °C were studied. When γ-Al_2O_3, SiO_2, ZrO_2, or TiO_2 were used as the carriers, the main spectral component could be assigned to the V^{4+} ion. The results of data analysis, assisted by spectrum calculation, showed that, on catalyst which had a high activity in the reduction of NO_x by NH_3, the V^{4+} ion had a highly populated d_{xy} orbital, while on catalyst of low activity, V^{4+} had a d_{xy} with a low spin density. If the carrier was MgO, the V ion was reduced to V^{2+}. If the carrier was CaO, no ESR signals due to V ions were observed. It has been suggested that an inhomogeneous and axially symmetric crystal-field model may interpret the intensity ratios among the hyperfine lines of the V^{4+} ESR absorption rather than a non-axial symmetry model of the V^{4+} unpaired electron.

A supported catalyst of vanadium can be prepared by adsorbing vanadate ions on the surface of the carrier from an aqueous solution and then calcining them to V_2O_5. The catalyst thus prepared has catalytic activities, *e.g.*, in the reduction of nitrogen oxide by NH_3. If this catalyst is placed in a reducing atmosphere, V^{4+} is formed in some cases, depending upon the carrier used. The V^{4+} ion thus formed may participate in the catalytic reaction cycles involved. The study of the supported states of the vanadium ion and its surface concentration can be important technique for elucidating the mechanism of the reaction and the catalytic activities.

There have been many reports about the ESR spectra of V^{4+} ions, including the principal values of g- and hyperfine tensors (the latter to be abbreviated simply as **A** in this paper).[1-8] Most of those data were obtained from the V^{4+} ion diluted in a diamagnetic-host single crystal. A few analyses of the ESR spectra of V^{4+} porphyrin compounds, which are found in crude petroleum, have also been reported.[8] Few detailed reports about the V^{4+} ion in supported catalysts have appeared, however. The characteristic feature of the ESR spectra of the V^{4+} ion is its approximately axial symmetry and the large differences between g_z (assumed to be the rotational axis) and g_x, and between A and B (or C).

As the vanadium nucleus, ^{51}V, has a nuclear spin of 7/2, eight spectral lines overlap each other in the ESR spectrum of a supported vanadium catalyst in which anisotropic g- and A- tensors are averaged. In addition, the ESR absorption due to some species other than V^{4+} will also overlap the V^{4+} absorption lines in most cases. In such cases, the subtraction of the calculated V^{4+} absorption from the entire spectrum observed will yield these secondary spectral components. Spectral subtraction, therefore, is an important method in spectral analysis. First derivative curves are not, to the knowledge of the present author, convenient when the addition or subtraction of two spectra is performed. Integrated curves are more easily normalized, and with them it is more easier to grasp the meaning of the spectral components. For this reason, the absorption curve obtained by the integration of a first derivative curve will hereafter be called the "true resonance curve" in this paper.

The subtraction of spectra was performed by using true resonance curves in this work. What the first derivative curve indicates is the slope of the true resonance curve. Therefore, if more than two absorption peaks partly or fully overlap each other, the precise determination of g_z and g_x (or g_y), and A and B (or C) is very difficult. In these instances, the values obtained from the peak and bottom positions of the first derivative curve are nothing more than a set of crude approximation values of g_z and g_x (or g_y). In order to get more accurate results, therefore, it is advisable to repeat the spectral simulation procedures.

In order to analyse the ESR spectra of the V^{4+} ion formed on the surface of γ-alumina powder, the spectral simulation method should be very useful for the reason stated above. However, only a little work has been done on this subject, using the type of samples described above. Campadelli and Bart analysed the line shape of the $MoO_3 \cdot Al_2O_3$ catalyst considering the g-value dispersion and the spin-spin interaction. Their calculation did not cover the entire region in which the experimental spectra had absorption intensities. It is not clear, therefore, if their assumption that the line width was caused only by the g-value dispersion and by spin-spin interactions was correct or not.[9]

Experimental, Data Processing, and Simulation

Preparation of ESR Samples. The oxides used as carriers of V_2O_5 were γ-alumina (Baikowski, A125-AS2, 148 m^2/g), silica gel (Fuji Davison, SP-No. 3, 153 cm^2/g), zirconium oxide (Mitsuwa Chemical Co., 99.9% pure, 8.5 m^2/g), titanium oxide (Kokusan Chemical Co., 7.4 m^2/g), magnesium oxide (Nihon Rikagaku, Inc., 89 m^2/g), and calcium oxide (Junsei Pure Chemicals, 3.0 m^2/g, containing alkali metals and magnesium as impurities, the sum being less than 2%). These oxides were mixed with an aqueous solution of ammonium vanadate from which mixture water was evaporated at room temperature. After drying at 100 °C, they were calcined at 550 °C in air to form V_2O_5. The final concentration in the solid mixtures obtained was 0.5%. The solid sample was then placed in a quartz tube 8 mm in inner diameter and was reduced at 500 °C with H_2 at 1 atm pressure and at the flowing rate of 50 ml/min for 1 h. Some of the V^{4+} ions contained in this sample were reduced to

some extent. The sample was cooled in the hydrogen atmosphere and was then taken out into the air. It was then placed in a ESR sample tube and ESR measurements were made while evacuating it to 10^{-5} Torr.

The results obtained are shown in Figs. 1—9, together with the simulated spectra. For the purpose of comparison, a sample of $VOSO_4$ supported on γ-alumina was prepared. In this case, 1.0 mg of $VOSO_4 \cdot 2H_2O$ was mixed with 5.0 ml of redistilled water and 1 g of γ-alumina. After the water has been evaporated, it was vacuum-dried and then used for ESR measurements. Although the official SI unit representation of the magnetic-field flux density is Tesla, T, a conventional symbol, G, is used in this report to represent 0.0001 T.

Data Processing. The output of an ESR spectrum from the spectrometer is in the form of DC voltage from 0 to 10 mV. This voltage is converted to natural numbers at the rate of 10 mV to 256. The numbers are stored in JEC-5 computer of JEOL and are then punched out on paper data tape. This spectrum is then integrated by a Fortran system of Hitac 10 II.

Spectrum Simulation. Several types of programming methods have been established to calculate the ESR spectra of the paramagnetic species existing in polycrystalline or multioriented substances.[10-13] These methods, however, have been contrived to be executed by large computers. Therefore, if one intends to handle the calculation problem simply as a matter of calculation, those past works will assist the researcher to a great extent. However, if one is intending to use the calculation as a part of his experimental system, it often happens that one cannot afford to use a large computer in his experimental system. In the present work, a calculation method which is essentially the same as those in the past reports, but which is modified so as to make it suitable for the computing system used in the present study, has been used.

The calculation was done by the Fortran system described above, and the result was displayed on a conventional paper chart recorder placed after a digital-analogue converter.[14] In the present problem, the spin Hamiltonian can be written:

$$\mathscr{H} = (g_z S_z + g_x S_x + g_y S_y)\beta H + (AS_z + BS_x + CS_y)I.$$

According to this equation, the calculation of the spectra may be carried out in three different ways. In the first case, $g_z \neq g_x \neq g_y$ and $A \neq B \neq C$. In the second case $g_z \neq g_x = g_y$ and $A \neq B = C$. In the third case $g_z = g_x = g_y$ and $A = B = C$. The third case does not have to be considered in the present work. The g-factor and coupling constant, *e.g.*, A, were surveyed in the $g \pm 0.001$ and $A \pm 0.0002$ regions, and the best combination was judged by a visual inspection.

Results

In Figs. 1—7 the spectra obtained by both experiments and calculations are shown. The true absorption of ESR is plotted, except in Fig. 1, with the magnetic field increasing from right to left. The parameters used for the calculations is shown in Table 1. The first derivative curve of the spectrum of Fig. 2 is shown in Fig. 1. The sample which gave these spectra was V_2O_5/TiO_2 reduced in H_2. The "OBS" in Fig. 1 means the observed spectrum, while "SIM" means that obtained by spectral simulation. The vertical lines shown in the figures indicate the positions of resonance, with $(h\nu/g_z\beta)+m_I A$ shown by longer lines and $(h\nu/g_x\beta)+m_I B$ shown by shorter lines, in which A and B are in the unit of the magnetic field, G. An axial symmetry is assumed, $B=C$. The z-direction is taken as the symmetry axis.

Table 1. The ESR constants found by spectral simulation

Carrier	Ion	g_z	g_x, g_y	A/cm^{-1}	B/cm^{-1}	Half-width/T[a]
TiO_2	V^{4+}	1.9400	1.9892	0.0160	0.0050	0.00632
ZrO_2	V^{4+}	1.9036	1·9735	0.0170	0.0070	0.00200
SiO_2	V^{4+}	1.9333	1.9807	0.0102	0.0048	0.00365
Al_2O_3	V^{4+}	1.9494	1.9828	0.0165	0.0055	0.00632
Al_2O_3	VO^{2+}	1.9490	1.9980	0.0174	0.0067	0.00316

a) Simulation by Lorentz function.

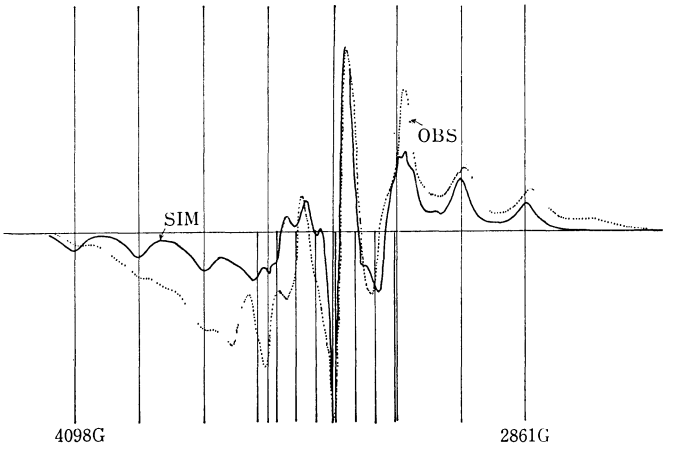

Fig. 1. The first derivative curve of ESR spectrum of hydrogen reduced 0.5% V_2O_5/TiO_2 sample. Microwave power was 0.4 mW, and at 9450 MHz. Vertical lines indicate the positions of the principal values, Table 1.

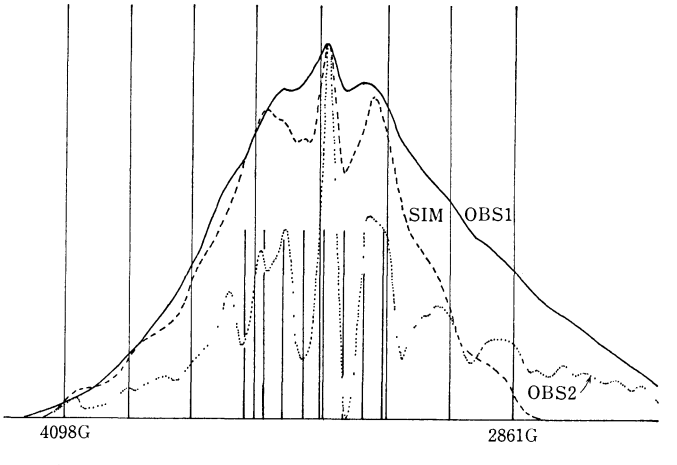

Fig. 2. True absortion curves of the spectra in Fig. 1.

The peak and the bottom positions in the outer part of the spectrum in Fig. 1 almost exactly coincide with the magnetic-field value given by the principal values of $\boldsymbol{g}$ and $\boldsymbol{A}$. Therefore, g and A may be found by solving this equation: $H=(h\nu-Am_I)/g_z\beta$ using a first derivative curve. However, the magnetic-field values for the $H=(h\nu-Bm_I)/g_x\beta$ equation are extremely difficult to find because the central part of the spectrum

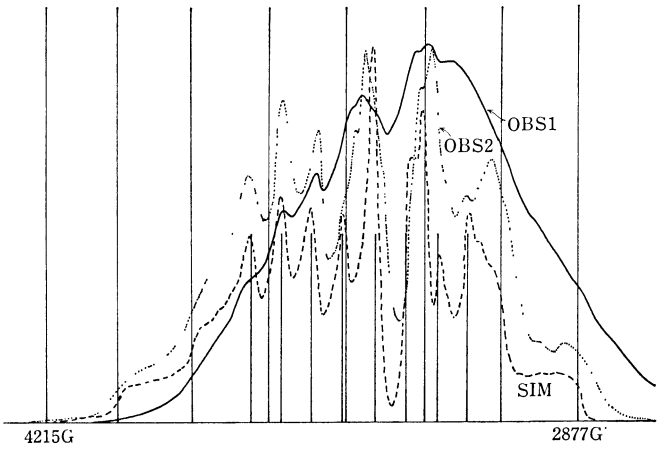

Fig. 3. 0.5% V_2O_5/ZrO_2. Other conditions identical with those of Fig. 2.

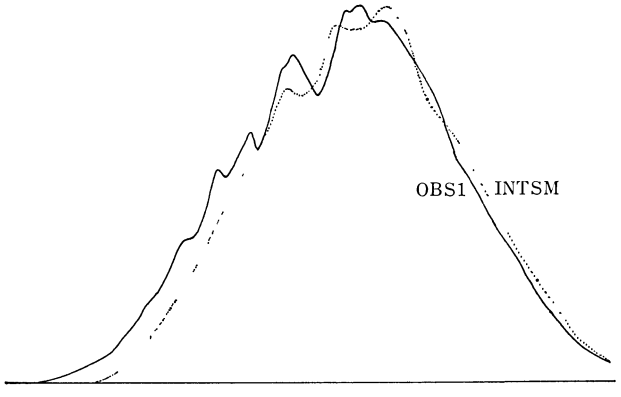

Fig. 4. Sample used was the same as that for Fig. 3.

is crowded overlapping spectral lines. In these cases, Kneubühl's equation is very hard to apply.[15]

In Fig. 2, OBSl is the observed spectrum. OBSSM was obtained from OBSl by the following processing method. At every magnetic-field point of the OBSl spectrum, the absorption intensities were integrated over the ±40 G region and were then averaged, the average being registered as the intensity of OBSSM at that field value. From this smoothed curve, OBS2′= OBSl−OBSSM was calculated. By the normalization

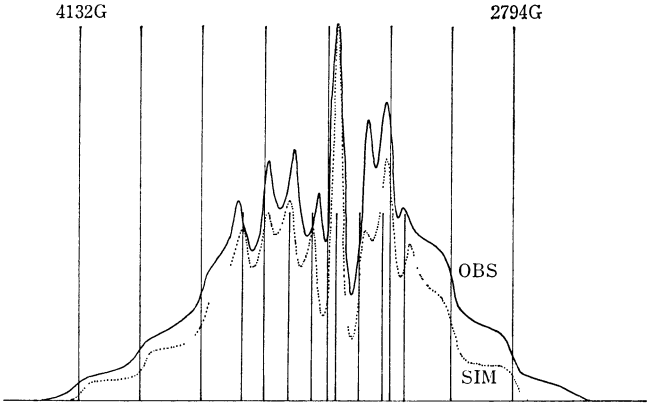

Fig. 7. 1.0 mg of $VOSO_4 \cdot 2H_2O$ dispersed on the surface of 1.0 g of γ-Al_2O_3.

of OBS2′, OBS2 was obtained. The hyperfine structures are found more clearly in OBS2, which makes the estimation of B and g easier.

The V^{4+} spectra formed in reduced V_2O_5/ZrO_2 are shown in Fig. 3. The observed spectrum is OBS1. The explanation for OBS2 will be made later. The SIM spectrum was obtained by calculations using the parameters found in OBS1. The OBS1 spectrum contains two component spectra. One of them has the hyperfine structure of the OBS2 of Fig. 2, or the normal V^{4+} hyperfine structure. The other component has a somewhat different structure. The INT spectrum, which is not shown in the figure, was made from OBS1 and SIM; INT=OBS−0.352 SIM. The INTSM spectrum was obtained by smoothing the INT spectrum in the same way as was used to get the OBS2 of Fig. 2. INTSM is shown in Fig. 4 with OBS1.

A hyperfine structure different from that of OBS1 is found in INTSM, but it was not analysed. The OBS2 spectrum of Fig. 3 was obtained as OBS1−0.813 INTSM. The parameters found in OBS2 were compared with those obtained from OBS1. Since there was some difference between these two groups of parameters, the SIM spectrum was again calculated from the data found in OBS2. By repeating the procedure described above, the INT, the INTSM, and the OBS2 spectra were again calculated. The

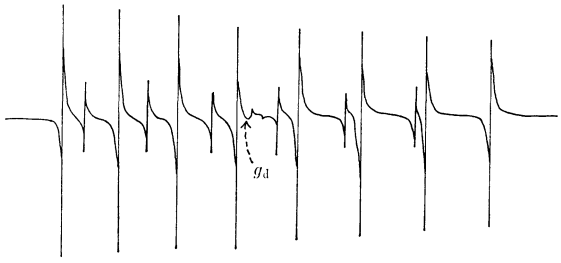

Fig. 8. 0.5% V_2O_5/MgO. Other conditions are identical with those of Fig. 3.

final agreement of OBS2 with SIM was fairly good.

The ESR spectrum of the V^{4+} ion formed in reduced V_2O_5 supported on SiO_2, OBS, and the spectrum calculated to fit it, SIM, are shown in Fig. 5. The silica gel used has some impurities. The intensity of the absorption by V^{4+} in this sample is not strong. For these two reasons, the background ESR spectrum, BG, which is not shown, was subtracted from the originally observed spectrum, OROBS, which is not shown, either. Therefore, OBS=OROBS−BG. A broad component, V, is found in the OBS spectrum in addition to the spectrum with the V^{4+} hyperfine structure. This circumstance is similar to those shown in Figs. 3 and 4.

The ESR spectra of the V^{4+} ion formed in the reduced V_2O_5 on γ-alumina are shown in Fig. 6. Since the carrier used in this sample was very pure and gave no appreciable absorption, and since the ESR absorption of V^{4+} on γ-alumina was relatively strong, the OBS spectrum itself could be fitted well by the calculated spectrum. The ESR spectrum of the VO^{2+} ion which was adsorbed on γ-alumina and the spectrum calculated to fit it are shown in Fig. 7. In Fig. 6 the half-width used for the calculation was 63.2 G, but in Fig. 7 31.6 G gave a good fit. Here the difference between VO^{2+} and V^{4+} is quite clear. No ESR spectra which are like those in Figs. 1—7 could be observed from the sample in which the carrier oxide was either CaO or MgO. If the carrier was CaO, no ESR signal due to V ions were observed. In the case of MgO, the spectrum shown in Fig. 8 was observed. It is not V^{4+} but V^{2+} that gives this spectrum.[16] The position of the magnetic field indicating $g=2.0036$ is marked by an arrow and g_d. The results obtained by CaO and MgO indicate that, on the surface of these alkaline earth oxides, V^{4+} is not stable.

Discussion

The Electronic State of the d-Electron and the Carrier Effects on It. The hyperfine splitting values observed from the V^{4+} ion have two components, the isotropic term and the anisotropic term. For the electron in a d^1 configuration, either the d_{z^2} or d_{xy} orbital is concluded to hold the unpaired electron.[5] The molecular orbital formed between the ligand orbital, $\psi_L(xy)$, and d_{xy} is denoted by π. Let β and β' be the proper coefficients, then:

$$\pi = \beta d_{xy} - \beta' \psi_L(xy).$$

Table 2. The K and β^2 values

Carrier	Ion	K/cm^{-1}	β^2
SiO_2	V^{4+}	0.0242	0.375
Al_2O_3	VO^{2+}	0.0229	0.727
ZrO_2	V^{4+}	0.0222	0.690
Al_2O_3	V^{4+}	0.0206	0.754
TiO_2	V^{4+}	0.0200	0.751

The β in this equation is different from that used in the spin Hamiltonian. The spin Hamiltonian is, if all the spectra are approximated by axially symmetric models:

$$\mathscr{H} = g_z\beta H_z S_z + g_x\beta[H_x S_x + H_y S_y] + A I_z S_z + B[I_x S_x + I_y S_y].$$

From the ESR spectrum, the hyperfine coupling constants, A and B, are obtained. A and B are shown by the following equations:[17-19]

$$A = -K - (4/7)\beta^2 P + (g-2.0023)P + (3/7)(g-2.0023)P$$

$$B = -K + (2/7)\beta^2 P + (11/14)(g-2.0023)$$

The value of P is equal to $2.0023 \cdot g_N \cdot \beta \cdot \beta_N \cdot \langle r^{-3} \rangle$, and the value for $^{51}V^{4+}$ is 0.0172 cm^{-1}.[20] Therefore, K and β^2 are solved from the above equations. Those values calculated from the data in Table 1 are shown in Table 2.

The isotropic contact term in the hyperfine interaction of paramagnetic ions has been the subject of many studies.[20-22] Abragam, Horowitz, and Pryce have observed that the quantity, χ, defined as:

$$\chi = \frac{4\pi}{S}(\psi | \sum \delta(r_1) S_{z1} | \psi)$$

is negative and nearly constant in magnitude for ions in the first transition series.[21] The χ value is related with K by means of the following equation:[21]

$$\chi = \left[-\frac{3}{2}\left(\frac{hca_0^3}{2.0023\, g_N \beta \beta_N} \right) K \right].$$

In this equation, h is Planck's constant, c is the velocity of light, a_0 is the Bohr radius, and g_N is 5.050 for ^{51}V. Therefore, the K value is proportional to the probabilities of the 2s and 3s electrons to be excited to the 3d orbital. In Table 2, the K value for V^{4+}/SiO_2 is the largest and the one for V^{4+}/TiO_2 is the smallest. The β^2 value is proportional to the spin density in d_{xy}, and the values are in a decreasing order when the samples are V^{4+}/Al_2O_3, V^{4+}/TiO_2, V^{4+}/ZrO_2, and V^{4+}/SiO_2.

The catalytic activity of V_2O_5 supported on TiO_2, ZrO_2, SiO_2, and Al_2O_3 greatly depends upon the carriers. It has been considered that the specific surface areas of these carriers are different. The TiO_2 used has only 7.4 m^2/g, while the SiO_2 used had 153 m^2/g. There are several types of reactions in which γ-alumina works as a good carrier. If used as a carrier of the supported catalyst applied to these types of reactions, the carrier effects of those oxides decrease in this order: γ-alumina, ZrO_2, TiO_2, and SiO_2. From the values of K and β^2 shown in Table 2, it may be concluded that the highly active V^{4+} ion has a d_{xy}

orbital which extends well toward the x and y directions, as an ideal d_{xy} orbital should, or that d_{xy} has a high spin density.

Axial Distortion or Inhomogeneous Crystal Field. Broad spectral components are found in Figs. 2—5 in addition to the hyperfine spectral components. Some of them are due to some impurities in the carrier. However, many of the broad components are caused by the minor distortions and the irregular crystal fields. The V^{4+} ions on the surfaces of TiO_2, ZrO_2, and SiO_2 particles may be surrounded by these partially distorted crystal fields. Another minor irregularities of the crystal field can also be expected from the half-width value of 63 G used in the calculation of the spectrum (Table 1). Sixty-three gauss, if it is caused by the irregular g-tensor, is equivalent to $\delta g=0.036$. Therefore, if we assume a mixture of two V^{4+} ions placed in two different environments which cause the principal values of the g-tensor to differ by some 0.036, the 63 G half-width can be explained.

The approximation of the calculated spectrum SIM in Fig. 7 is not satisfactory if the intensities of the absorption peaks are considered. The first thing to be examined is if the axial symmetry assumed in this work is effective or not. Figure 9 compares two spectra with and without axial symmetry. The WO spectrum was derived by the use of $g_z=1.9490$, $g_x=1.9955$, $g_y=2.0005$, $A=0.0174$, $B=0.0068$, $C=0.0066$ cm^{-1}, and a half-width of 23.62 G. The intensity ratios, especially that of the strongest peak to those of the remaining peaks, rather deviate from that of the OBS spectrum. Therefore, it does not seem possible to interpret the large line-width in terms of the axial distortion only. Among other factors to be considered is the inhomogeneity of the crystal field surrounding the V^{4+} ions, which might be located on the edge, on the ridge, or in the valley or the deep holes existing on the surface of the carrier particles. Figure 10 shows one attempt to study this subject. The OBS spectrum is identical with the one in Figs. 7 and 9. The SIM spectrum was derived from the two spectra as an arithmetic mean. The one of the component spectra was the Fig. 7-SIM spectrum. The other component spectrum was calculated by means of $g_z=1.9599$, $g_x=g_y=2.0092$, $A=0.00174$, $B=C=0.0067$ cm^{-1}, and a half-width of 31.62 G. The agreement of the intensity ratios have been fairly well improved.

The large line-width of the paramagnetic ions located on the surface of porous powders includes many factors which it is not easy to solve or to understand fully. In the case of a nucleus which has a large nuclear spin, such as V^{4+}, the spin Hamiltonian has a nuclear quadrupole term, *e.g.*, $Q'(I_z^2-63/12)$. If the axis of the magnetization is perpendicular to the z-axis, secondary transitions can occur between energy levels; therefore, the experimental ESR spectrum may not be accounted for by simply averaging the ESR spectra which are obtained from the V^{4+} ions oriented in random directions in the magnetic field. The strongest absorption peak of the OBS spectrum in Fig. 7 is relatively weaker than that which is to be expected by the calculated spectrum, SIM. This fact might be explained if one would consider the nuclear quadrupole term. However, it seems to the present author that the angular variation of the intensity ratio of the hyperfine lines should be studied by means of a system which is simpler than the supported catalysts used in this work. For this reason, such considerations have not been undertaken here. At any rate, the inhomogeneous crystal-field approach will solve a part of this problem.

CaO and MgO as Carriers. When used as the carrier of a catalyst for a reaction in which γ-alumina works as a good carrier of the catalyst, CaO and MgO are poor carriers. It seems there are no such sites as keep the V^{4+} ion stable on the surfaces of these oxides. In the case of MgO, a Mg^{2+} vacancy will be replaced by a V^{4+} ion, which is then reduced to the +2 oxidation state if placed in a H_2 atmosphere above 500 °C. The V^{2+} ion thus formed is stable, probably because it is somehow equivalent to Mg^{2+} with respect to the electrostatic field that is produced in the surrounding crystal lattice.

Effect of Methyl Substitution on the Electron Spin Resonance Spectra of Yang's Biradical

Kazuo MUKAI

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received November 4, 1978)

Mono- and dimethyl derivatives (II) and (III) of Yang's biradical (I) were prepared, and the methyl-substitution effects on the molecular symmetry and spin-density distribution of Yang's biradical have been studied. Resolved hyperfine structures were observed in the ESR spectra of liquid solutions of the biradicals (II) and (III), giving the hyperfine splitting values theoretically expected for their triplet states. In a fluid solution, the biradical molecules retain a three-fold symmetry, as has been reported for Yang's biradical, and the expected methyl-substitution effect is too small to induce any asymmetric, unpaired spin distribution. The ***g***- and ***D***-tensor values of the (II) and (III) biradicals were determined from analyses of the asymmetric ESR spectra of frozen solutions containing the biradicals. The results suggest that these biradicals must also lack a three-fold symmetry in a frozen solution, as has been observed for Yang's biradical. Essentially the same ***g***- and ***D***-tensor values as those of Yang's biradical are observed for the monomethyl derivative (II). On the other hand, the dimethyl derivative (III) shows quite different ***g***- and ***D***-tensor values.

Yang's biradical (I) is known as a fairly stable phenoxyl biradical; it has a structural three-fold symmetry and doubly degenerate non-bonding orbitals, each being half-filled.[1,2] This implies the possible existence of a triplet ground state ($S=1$), which has actually been confirmed by susceptibility measurements.[3] The fluid-solution ESR spectrum shows seven hyperfine splitting due to six equivalent *meta*-ring protons in the three benzene rings of the biradical.[4] The results of NMR[5] and ENDOR[6] studies in solution also indicate that the six *meta*-ring protons are magnetically equivalent, giving a hyperfine splitting attributable to the six *meta*-ring protons. However, the toluene rigid matrix ESR spectrum of Yang's biradical was recently reported to be a characteristic spectrum of a non-axially symmetrical triplet, with $|D|=34.1$ and $|E|=2.3$ G.[7] This result may be explained by assuming that at least one of the twist angles of the three benzene rings is different from the other two rings in the low-temperature rigid matrix. The notable solvent effects observed for the zero-field splitting parameters (D and E) suggest that the asymmetric environment due to frozen-solvent molecules contributes to the molecular distortion found for Yang's biradical.[8] In the previous papers, the effects of asymmetric deuterium and *t*-pentyl substitution on molecular distortion in Yang's biradical were also reported, indicating that the effects are negligible for the former and small for the latter.[7,9]

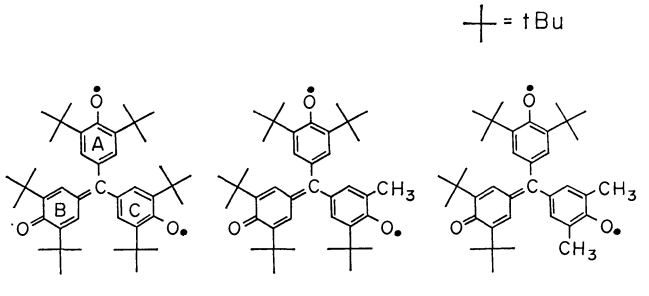

Fig. 1. Molecular structures of Yang's biradical (I), 1Me-Yang's biradical (II), and 2Me-Yang's biradical (III).

In the present work, in order to obtain further information on such molecular distortion, we have prepared the two methyl derivatives (hereafter called as the 1Me- and 2Me-Yang's biradicals (II) and (III); see Fig. 1) of Yang's biradical by the PbO_2 oxidation in toluene of the corresponding bisphenol precursors. The isotropic hyperfine splittings and ***g***- and ***D***-tensor values of these biradicals have been determined from their solution and asymmetric frozen ESR spectra respectively. The results provide direct experimental evidence for the symmetry and electronic structure of these radicals. The isotropic hyperfine splittings of the monoradical precursors of the (I), (II), and (III) biradicals have also been determined by means of their solution ESR spectra and compared with those of the corresponding biradicals.

In general, the effect of the methyl substitution on the unpaired spin distribution in free radicals, including phenoxyl radicals, is very small. However, as has been shown in ESR[10] and NMR[11] studies of the benzene anion and its methyl derivatives, the effect can be significant if the orbital ground state of the parent free radical is two-fold degenerate and if methyl substitution, by lowering the symmetry, removes the degeneracy. A notable methyl substitution effect has also been observed in ENDOR studies[12] of the pentaphenylcyclopentadienyl neutral radical, which has doubly degenerate non-bonding orbitals. By the asymmetric methyl substitution of Yang's biradical, therefore, we can expect a change in the unpaired spin distribution (the asymmetric spin distribution) and a lifting of the degeneracy.

Results and Discussion

Solution ESR Spectra of 1Me- and 2Me-Yang's Biradicals (II) and (III). As has been described in previous papers,[7-9] the oxidation product of the bisphenol precursor (bisphenol (I)) of Yang's biradical with PbO_2 in toluene in a sealed, degassed system initially gives a quintet ESR spectrum ($a_m^H=1.32\pm0.04$ G) attributable to the four equivalent *meta*-ring protons of the monoradical precursor. After further

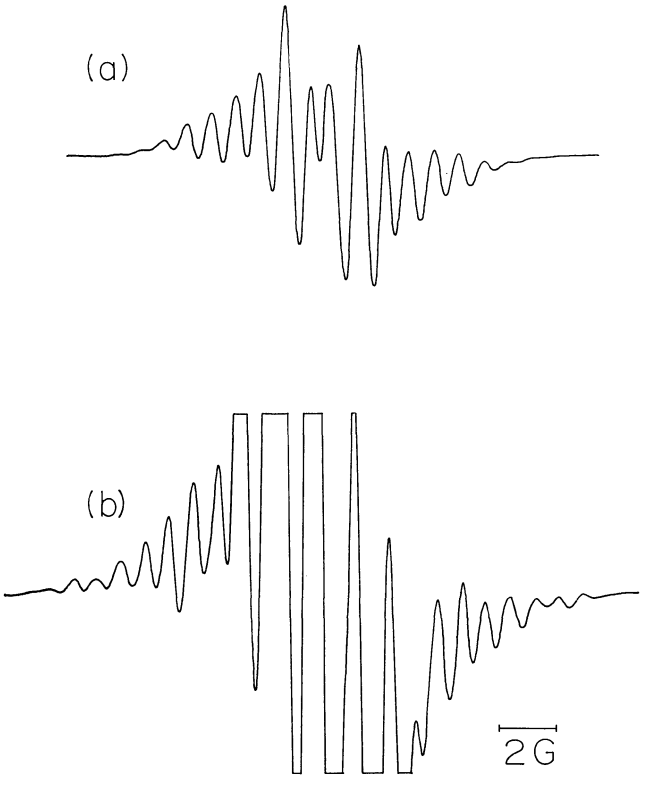

Fig. 2. Solution ESR spectra of (a) 1Me-Yang's biradical (II) and (b) 2Me-Yang's biradical (III) in toluene at 20 °C. Each spectrum includes a quintet signal due to remaining monoradical impurity.

oxidation, a five-line spectrum of the monoradical is altered to a seven-line spectrum of Yang's biradical, with an equivalent splitting constant of $a_m^H=0.91\pm0.04$ G.[4,7]

The initial partial oxidation of the bisphenol (II), the bisphenol precursor of the 1Me-Yang's biradical (II), gives ESR spectra consisting of (i) a central strong quintet and (ii) weak quartet-quintet patterns on both sides of the central quintet. The spectra are thought to be attributable to the two kinds of monoradicals (AB- and BC-types) produced when the oxidation proceeds from the A and C hydroxyphenyl rings in the bisphenol precursor respectively; the former monoradical is very stable, while the latter is unstable, disappearing within about 30 minutes at 20 °C. The spectra are readily analyzed, giving $a_m^H=1.30\pm0.04$ G for the (II-AB) monoradical and $a_{CH_3}^H=4.07\pm0.04$ G and $a_m^H=1.36\pm0.04$ G for the (II-BC) monoradical. As the oxidation proceeds further, the spectra of the two monoradicals are altered into a sixteen-line absorption signal which may be attributed to the 1Me-Yang's biradical (II). As this biradical is unstable, ESR measurements were performed on several samples, under slightly different conditions of oxidation, in order to obtain a better ESR spectrum. The best spectrum obtained is shown in Fig. 2(a). However, the spectrum indicates that a quintet signal caused by a monoradical impurity still remains. The sixteen-line absorption signal of the (II) biradical may be explained by three protons ($a_{CH_3}^H=2.59\pm0.04$ G) of a methyl group and six equivalently interacting protons ($a_m^H=0.86\pm0.04$ G) at the meta positions.

Table 1. Hyperfine splittings of Yang's biradical (I), the 1Me-Yang's biradical (II), and the 2Me-Yang's biradical (III), and their monoradical precursors (AB- and BC-types) in toluene at 20 °C (G)

	Biradical		Monoradical precursors		
			AB-type	BC-type	
	a_m^H a)	$a_{CH_3}^H$	a_m^H	a_m^H	$a_{CH_3}^H$
Yang's (I)	0.91	—	1.32	1.32	—
1Me-Yang's (II)	0.86	2.59	1.30	1.36	4.07
2Me-Yang's (III)	0.86	2.58	1.31	1.30	4.05

a) The experimental errors in the values of a_m^H and $a_{CH_3}^H$ are ±0.04 G.

Similarly, the oxidation of bisphenol (III), the bisphenol precursor of the 2Me-Yang's biradical (III), initially gives ESR spectra consisting of (i) a strong quintet and (ii) a weak septet-quintet splitting; the spectra are attributable to the two kinds of monoradicals (III-AB and -BC) produced when the oxidation proceeds from the A and C hydroxyphenyl rings in the bisphenol precursor respectively. The hyperfine splittings ($a_m^H=1.31\pm0.04$ G) and ($a_{CH_3}^H=4.05\pm0.04$ G, $a_m^H=1.30\pm0.04$ G) were observed for the (III-AB) and (III-BC) monoradicals respectively. After further oxidation, the ESR spectra of the two monoradicals were altered to an ESR spectrum, as is shown in Fig. 2(b). This spectrum may be explained by considering the contribution from both an absorption signal of the (III) biradical and a central strong quintet signal of the remaining monoradical. The stability of the (III) biradical with two methyl groups is even less than is the case for the (II) biradical, which has one methyl group, disappearing within about 20 minutes at 20 °C. The hyperfine splittings obtained for the (III) biradical are $a_{CH_3}^H=2.58\pm0.04$ G and $a_m^H=0.86\pm0.04$ G, arising from six protons of two methyl groups and six magnetically equivalent *meta*-ring protons respectively. All the hyperfine splittings are listed in Table 1. The *g*-values (g_{iso}) of these biradicals in toluene were also measured; they are listed in the last column of Table 2.

As is clear from the results listed in Table 1, the hyperfine splittings obtained for the monoradical precursors (AB- and BC-types) of Yang's biradical and its methyl derivatives in solution are equivalent to each other as resolved by the ESR experiments. The hyperfine splitting constants of Yang's biradical and its methyl derivatives in a fluid solution also show a good agreement with each other within the limits of experimental error. As has been observed for the benzene anion and its methyl derivatives,[10,11] the methyl-substitution effect can be significant if the two-fold degeneracy of the parent free radical is lifted by asymmetrical methyl substitution. Yang's biradical (I) has a structural three-fold symmetry and is orbitally degenerate.[2] By asymmetric methyl substitution, therefore, we can expect a lifting of the degeneracy, and thus a change in the unpaired spin dis-

Table 2. *D*- and *g*-tensor values of Yang's biradical (I), the 1Me-Yang's biradical (II), and the 2Me-Yang's biradical (III) in toluene at 77 K

	$\|D\|$[a]/G	$\|E\|$[a]/G	g_{xx}[b]	g_{yy}	g_{zz}	g_{av}[c]	g_{iso}[d]
Yang's (I)	34.1	2.3	2.0054	2.0054	2.0026	2.0045	2.00451
1Me-Yang's (II)	34.2	2.2	2.0052	2.0055	2.0030	2.0046	2.00447
2Me-Yang's (III)	23.3	1.4	2.0046	2.0041	2.0035	2.0040	2.00457

a) The experimental errors in the values of $|D|$ and $|E|$ are ± 0.2 and 0.4 G respectively. b) The experimental errors in the values of g_{xx}, g_{yy}, g_{zz}, and g_{av} are ± 0.0002. c) The average $g_{av}=(1/3)(g_{xx}+g_{yy}+g_{zz})$. d) The experimental errors in the values of g_{Iso} are ± 0.00005.

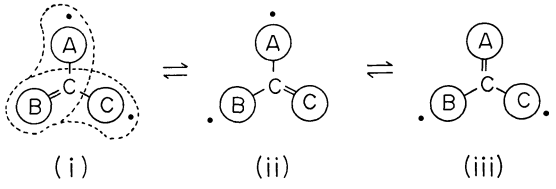

Fig. 3. Schematic representation of three valence-bond structures (i), (ii), and (iii) of the biradicals.

tribution (an asymmetric spin distribution). However, the present experimental results indicate that the expected methyl-substitution effect is too small to induce any asymmetric unpaired spin distribution in a fluid solution.

The hyperfine splitting ($a_m^H=0.91$ G) of the *meta*-ring protons of Yang's biradical is nearly two-thirds of the splitting ($a_m^H=1.32$ G) observed for the monoradical precursor. Similar results were observed for the 1Me- and 2Me-Yang's biradicals, (II) and (III). For instance, in the (III) biradical, the predicted values for the hyperfine splittings of the *meta*-ring protons and methyl protons from those of the monoradical precursor (III-BC) are 0.87 G and 2.70 G, while the observed values are 0.86 G and 2.58 G, respectively. The relative ratio (2/3) of the hyperfine splitting constants of the biradicals to the monoradicals can be predicted on the basis of simple resonance theory, as follows: one can, in principle, schematically draw three valence-bond structures, (i), (ii), and (iii) (see Fig. 3) for each biradical under study. The (i) structure is considered to be a strongly π-conjugated biradical consisting of two galvinoxyl groups (AB- and BC-types), with two unpaired electrons in a molecular orbital, in which the B ring is common to both monoradical-AB and -BC. If the nucleus, X, is in the B ring, the splitting constant ($a_{i\text{-}B}^{bi}$) in the biradical will be the arithmetic average of the splitting constants from the monoradical-AB and -BC, as was proposed by Kopf *et al.*:[13]

$$a_{i\text{-}B}^{bi}=\frac{1}{2}(a_{AB}^{mono}+a_{BC}^{mono})$$

If X is in the A ring (which is not included in the monoradical-BC), $a_{BC}^{mono}=0$, thus:

$$a_{i\text{-}A}^{bi}=\frac{1}{2}a_{AB}^{mono}$$

Similarly, for the splitting constant ($a_{i\text{-}C}^{bi}$) of the C ring,

$$a_{i\text{-}C}^{bi}=\frac{1}{2}a_{BC}^{mono}$$

For the (ii) and (iii) structures, the hyperfine splittings may be similarly represented, using the hyperfine splittings of the monoradical. If the (i), (ii), and (iii) structures are equally probable, the hyperfine splitting (for instance, a_A^{bi}) of a given nucleus, X, in the A ring of the biradical may be represented, taking the contribution from the three valence-bond structures, as:

$$\begin{aligned}a_{i\text{-}A}^{bi}&=\frac{1}{3}(a_{i\text{-}A}^{bi}+a_{ii\text{-}A}^{bi}+a_{iii\text{-}A}^{bi})\\&=\frac{1}{3}\left\{\frac{1}{2}a_{AB}^{mono}+\frac{1}{2}a_{AC}^{mono}+\frac{1}{2}(a_{AB}^{mono}+a_{AC}^{mono})\right\}\\&=\frac{2}{3}a_{AB}^{mono}\end{aligned}$$

This is what is experimentally observed for the methyl and *meta*-ring protons of the (I), (II), and (III) biradicals, as has been described above; the observed hyperfine splittings for the biradicals agree exceedingly well with those calculated from the corresponding monoradicals, thus strongly supporting the above explanation.

Rigid Matrix ESR Spectra of the 1Me- and 2Me-Yang's Biradicals (II) and (III). The observation and detailed analysis of the rigid matrix ESR spectrum of Yang's biradical have been reported in a previous paper.[7] When the bisphenol precursor (bisphenol (II)) of the 1Me-Yang's biradical (II) was oxidized with PbO_2 in toluene under a vacuum, the yellow-brown color of the phenol solution immediately became the yellow-orange of the (II-AB) and (II-BC) monoradicals. Upon further oxidation, the color was changed to yellow-green. By quickly freezing the yellow-green solution containing the (II) biradical into a rigid glass (77 K), one can observe some dipolar splittings, as is shown in Fig. 4(b). The spectrum consists of two pairs of lines disposed about $g=2$ and a weak line at $g=2$ from the monoradicals. As has been described in a previous section, the (II) biradical is unstable at 20 °C; thus, the ESR observations were performed for several samples in order to minimize the central monoradical signal and in order to get a better spectrum. The best spectrum obtained is shown in Fig. 4(b). This spectrum remained unchanged after a period of several hours at 77 K. Upon annealing at 20 °C for 30 min, however, the yellow-green color disappeared along with the biradical signal. The spectrum of the 1Me-Yang's biradical shows a shape essentially the same as that of Yang's biradical (see Fig. 4(a)), except for the difference

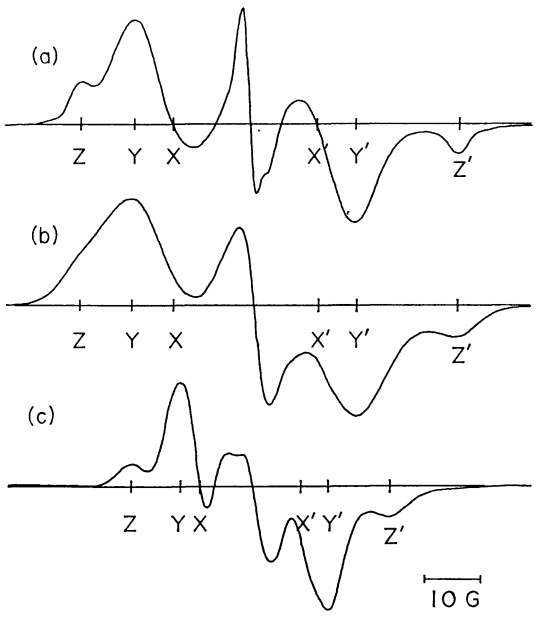

Fig. 4. Rigid matrix ESR spectra of (a) Yang's biradical (I), (b) 1Me-Yang's biradical (II), and (c) 2Me-Yang's biradical (III) in toluene at 77 K.

in the central monoradical intensity and the increase in the linewidth of each absorption line. The position and separation of the signals of the 1Me-Yang's biradical are quite similar to those of Yang's biradical. The zero-field splitting parameters (D and E) and $\boldsymbol{g}$-tensor values have been tentatively estimated from the positions of the three pairs of turning points (ZZ', YY', and XX'), as performed for Yang's biradical in a previous paper. These values are $D=34.2\pm0.2$ G, $E=2.2\pm0.4$ G, $g_{zz}=2.0030\pm0.0002$, $g_{yy}=2.0055\pm0.0002$, and $g_{xx}=2.0052\pm0.0002$. The average, $g_{av}=1/3(g_{xx}+g_{yy}+g_{zz})=2.0046\pm0.0002$, is in agreement with the isotropic $g_{iso}=2.00447\pm0.00005$ value measured at room temperature, indicating that the $\boldsymbol{g}$-tensor values obtained by the above analysis are consistent. Similarly, the toluene rigid-matrix ESR spectrum of the 2Me-Yang's biradical (III) has been measured. The ESR spectrum of the 2Me-Yang's biradical at 77 K is very different from those of Yang's biradical and the 1Me-Yang's biradical, as is shown in Fig. 4(c). The zero-field parameters and $\boldsymbol{g}$-tensor values were similarly estimated from the three pairs of turning points (ZZ', YY', and XX'), giving the values of $D=23.3\pm0.2$ G, $E=1.4\pm0.4$ G, $g_{zz}=2.0035\pm0.0002$, $g_{yy}=2.0041\pm0.0002$, $g_{xx}=2.0046\pm0.0002$, and $g_{av}=2.0040\pm0.0002$. The observed $\boldsymbol{D}$- and $\boldsymbol{g}$-tensor values of these biradicals, (II) and (III), are summarized in Table 2, together with those of Yang's biradical.

As has been described in a previous section, the results of the measurements of the solution ESR spectra of Yang's biradical (I) and its methyl derivatives (II) and (III) suggest that these radical molecules retain a three-fold symmetry in a fluid solution and show similar unpaired-spin distributions. On the other hand, since the axial spectra, *i.e.*, the spectra characterized by only one zero-field splitting parameter, D, could not be observed in any of these biradicals, (I), (II), or (III), these biradicals must lack a three-fold symmetry in a frozen solution. Yang's biradical and its methyl derivatives may be considered to have a propeller configuration, with a twist angle of about 30° in solution. Due to the delocalization of each unpaired electron, the principal Z axis of the $\boldsymbol{D}$-tensor, corresponding to the maximum $2D$ value (ZZ'), is probably parallel to the $2p_z$ orbital of the central triphenylmethyl carbon atom. Therefore, in the (I), (II), and (III) biradicals with non-zero E values, at least one of the twist angles of the three phenyl rings is different from those of the other two rings in the low-temperature rigid matrix. By substituting the methyl group for the tertiary butyl group, the steric interaction between the substituents will decrease to some extent. Consequently, the benzene ring into which the methyl groups are substituted will be twisted less than the other two benzene rings. Therefore, we can expect an increase in the D-parameter of the methyl derivatives in comparison with that of Yang's biradical.[14,15] However, in the 1Me-Yang's biradical, both the $\boldsymbol{g}$- and $\boldsymbol{D}$-tensor values are in good agreement with those of Yang's biradical. This, together with the results obtained in solution ESR spectra, gives further accurate evidence that monomethyl-substitution effects for molecular symmetry and spin-density distribution are negligible in Yang's biradical.

On the other hand, in the dimethyl derivative (III) of Yang's biradical, the change in the $\boldsymbol{D}$- and $\boldsymbol{g}$-tensor values is very remarkable. However, in contrast to the above expectation (an increase in the D-parameter), the D-parameter decreased 10.8 G compared to that (34.1 G) of Yang's biradical, suggesting an increase in the twist angle. In fact, the increase in the g_{zz} value and the decreases in the g_{yy} and g_{xx} values observed for the 2Me-Yang's biradical may also be explained by the increase in the twist angle. A notable solvent effect has been observed for the zero-field parameters of Yang's biradical; for instance, the D- and E-parameters vary from $D=34.6$ G and $E=1.5$ G in ethyl alcohol to $D=32.1$ G and $E=3.6$ G in diglyme.[8] The results suggest that the asymmetric environment due to frozen solvent molecules may contribute remarkably to a change in the conformation of the radical molecule. However, the change in the D-parameter of the 2Me-Yang's biradical is more remarkable than that due to the solvent effect. The reason why dimethyl-substitution effects are negligible in a fluid solution, while they are very remarkable in a frozen solution, is not clear at present.

Experimental

Measurements. The ESR spectra were obtained in the X band using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter, which was used to measure the klystron frequency. The ESR splittings were determined using $(KSO_3)_2NO$ ($a^N=13.05\pm0.03$ G) as a standard. The g-values were measured relative to the value of Li-TCNQ powder, calibrated with $(KSO_3)_2NO$ ($g=2.0054$).[16] The proton magnetic reso-

nance spectra were recorded on a JEOLCO 4H-100 100 MHz spectrometer. The NMR spectra were measured in a C_6D_6 solvent, with tetramethylsilane as the internal standard.

Preparation of Specimens. The bisphenol and trisphenol precursors of Yang's biradical (I) and its methyl derivatives (II) and (III) were prepared according to a procedure similar to that used by Yang and Castro.[1] The condensation of 2,6-di-*t*-butylphenol, 2-*t*-butyl-6-methylphenol, and 2,6-dimethylphenol with 2,6-di-*t*-butyl-4-(3,5-di-*t*-butyl-4-hydroxybenzylidene)-2,5-cyclohexadien-1-one[17,18] in H_2SO_4–CH_3COOH gave a solid mixture of the bisphenol and the trisphenol, respectively. The mixture was separated by silica-gel-column chromatography (using benzene as the eluent). The subsequent removal of the benzene from bisphenol solution left a brick-red crystalline solid; this was heated at 160 °C for 5 h under a vacuum (0.1 Torr) to remove the solvent completely. The evaporation of the benzene from the trisphenol solution left pale yellow crystals, which were subsequently recrystallized twice from ethyl alcohol.

Trisphenol (I), $R_1=R_2=t$Bu
Trisphenol (II), $R_1=t$Bu, $R_2=CH_3$
Trisphenol (III), $R_1=R_2=CH_3$

Bisphenol (I). Mp 278.5—280.5 °C, brick red crystals; UV max 434 nm (log ε 4.50) in tetrahydrofuran; NMR 1.32 (36 H, s, *t*Bu, rings A and C), 1.54 (18 H, s, *t*Bu, ring B), 5.30 (2 H, s, OH), 7.53 (4H, s, aromatic H, rings A and C), 7.77 ppm (2H, s, aromatic H, ring B). Found: C, 82.30; H, 10.10%. Calcd for $C_{43}H_{62}O_3$: C, 82.83; H, 9.97%.

Trisphenol (I). Mp 241.0—242.0 °C, pale yellow crystals; UV max 278 nm (log ε 3.77) in cyclohexane; NMR 1.35 (54 H, s, *t*Bu), 4.87 (3 H, s, OH), 5.70 (1 H, s, CH), 7.43 ppm (6H, s, aromatic H). Found: C, 81.61; H, 10.54%. Calcd for $C_{43}H_{64}O_3$: C, 82.11; H, 10.26%.

Bisphenol (II). Mp 269.0—271.0 °C, brick red crystals; UV max 432 nm (log ε 4.46) in tetrahydrofuran; NMR 1.32 (18 H, s, *t*Bu, ring A), 1.47 (9 H, s, *t*Bu, ring C), 1.53 (18 H, s, *t*Bu, ring B), 1.59 (3 H, s, CH_3), 4.58 (1H, s, OH, ring C), 5.30 (1 H, s, OH, ring A), 7.10 (1 H, s, aromatic H neighboring the methyl group), 7.52 (2 H, s, aromatic H, ring A), 7.55(1 H, s, aromatic H neighboring the *t*-butyl group, ring C), 7.73 ppm (2 H, s, aromatic H, ring B). Found: : C, 82.04; H, 9.79%. Calcd for $C_{40}H_{56}O_3$: C, 82.14; H, 9.65%.

Trisphenol (II). Mp 213.5—214.5 °C, pale yellow crystals; UV max 278 nm (log ε 3.78) in cyclohexane; NMR 1.37 (36 H, s, *t*Bu, rings A and B), 1.51 (9H, s, *t*Bu, ring C), 1.64 (3H, s, CH_3), 4.12 (1 H, s, OH, ring C), 4.87 (2 H, s, OH, rings A and B), 5.62 (1 H, s, CH), 7.02 (1 H, s, aromatic H neighboring the methyl group, ring C), 7.38 (1 H, s, aromatic H neighboring the *t*-butyl group, ring C), 7.40 ppm (4H, s, aromatic H, rings A and B). Found; C, 81.60; H, 10.12%. Calcd for $C_{40}H_{58}O_3$: C, 81.86; H, 9.96%.

Bisphenol (III). Mp 270.0—271.5 °C, brick red crystals; UV max 430 nm (log ε 4.44) in tetrahydrofuran; NMR 1.33 (18 H, s, *t*Bu, ring A), 1.51 (9 H, s, *t*Bu, ring B), 1.53 (9H, s, *t*Bu, ring B), 1.90 (6 H, s, CH_3, ring C), 4.37 (1 H, s, OH, ring C), 5.28 (1 H, s, OH, ring A), 7.11 (2H, s, aromatic H, ring C), 7.50 (2 H, s, aromatic H, ring A), 7.70 ppm (2 H, s, aromatic H, ring B). Found: C, 81.77; H, 9.52%. Calcd for $C_{37}H_{50}O_3$: C, 81.87; H, 9.29%.

Trisphenol (III). Mp 170.5—172.0 °C, pale yellow crystals; UV max 278 nm (log ε 3.77) in cyclohexane; NMR 1.37 (36 H, s, *t*Bu, rings A and B), 1.91 (6 H, s, CH_3), 3.95 (1H, s, OH, ring C), 4.88 (2 H, s, OH, rings A and B), 5.59 (1 H, s, CH), 7.05 (2 H, s, aromatic H, ring C), 7.38 ppm (4H, s, aromatic H, rings A and B). Found: C. 81.58; H, 9.83%. Calcd for $C_{37}H_{52}O_3$: C, 81.57; H, 9.62%.

We are very grateful to Professor Kazuhiko Ishizu and Professor Yasuo Deguchi for their kind advice and encouragement. We are also grateful to Mr. Jun Sakamoto for his kind help in preparing the bisphenol precursors.

The Combined Field Emission-Spin Trapping Method for Studying Reactions of Electrons in Organic Solutions

Shoji NODA, Yasunari OHTA, and Hiroshi YOSHIDA*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received November 20, 1978)

The reactions of electrons injected by field emission into solutions have been investigated. Free radicals generated by the dissociative electron attachment to chlorinated solutes in benzene solutions were detected by the spin trapping-ESR method, using pentamethylnitrosobenzene as a spin trapping agent. Nondissociative electron attachment to styrene caused by the field emission was also evidenced by detecting the α-methylbenzyl radical generated secondarily from the styrene radical anion. The electrons field-emitted into the solutions are captured almost quantitatively by the electron scavenging solutes. The field emission method has been found to be useful for generating authentically free radicals and for studying the anionic reaction induced by electrons without interference of countercations and of any reaction intermediates from solvent molecules. As an example of the chemical utilization of the field emission technique, the ESR parameters of the spin adducts of several hydrocarbon radicals have been collected by this technique.

The reactions of electrons in solutions have been a leading subject in a variety of fields in chemistry.[1-3] The irradiation with ionizing radiations has been widely used to generate the electrons in solutions, though it simultaniously generates countercations which sometimes complicate the electron reactions to be studied. The photo-injection[4-8] and the field emission[8-10] of electrons from a metal cathode into liquids can also be used as electron sources. These methods generate the electrons in the solutions without accompanying countercations, but have been employed almost solely for studying the physical properties of the electrons in liquids, *i.e.*, electron mobility[4,8,9] and quasifree electron energy.[5-7,10] The field emission, emission of electrons from a sharp edge or a sharp tip of a metal cathode (emitter) at a high negative field, readily gives a current as high as 10^{-5} A.[11] Nevertheless, the utilization of this method in chemical reaction study has been limited to the polymerization of styrene and α-methyl-styrene.[11-13]

In order to exploit the chemical utilization of the field emission method, we have recently studied the dissociative and nondissociative attachments to organic solutes of the electrons field-emitted into benzene solutions. Free radicals, the short-lived intermediate products of the electron attachment reactions, have been detected by the spin trapping-ESR technique, in which the short-lived free radicals are transformed into stable nitroxyl radicals (to be detected readily by conventional ESR measurements) through the reactions with a proper nitroso compound or a nitrone compound (spin trap) coexisting in the solutions.[14-17]

The present investigation will give several aspects of the electron attachment in solution for some model reaction systems studied by the combined field emission-spin trapping method, and will demonstrate the general prospect of the field emission method for chemical utilizations.

Experimental

A field emission cell was made of pyrex glass tubes equipped with an emitter (a razor blade of 0.7 cm length) and a collecting electrode (a brass rod, 1.0 cm diameter) facing each other at a distance of 0.1—0.2 cm, as shown in Fig. 1.

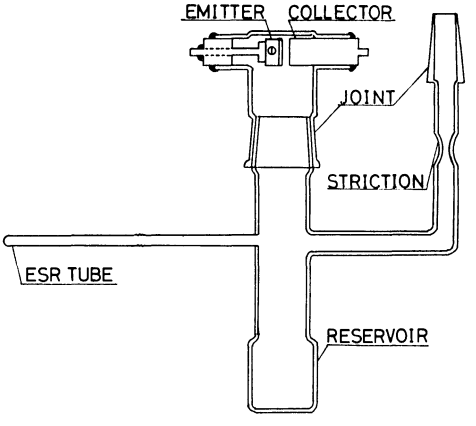

Fig. 1. Field emission cell.

The cell has a thin quartz tube (0.4 cm outer diameter) for ESR measurements. The emitter could be readily changed by disconnecting a part of the cell by means of a taper joint. The emitter and the collecting electrode could be completely covered with 3 ml of solution by turning the cell upside down. A high voltage, up to 15 kV, was applied by a stabilized high voltage supply. Typically *ca.* 5×10^{-5} F·dm^{-3} of electronic charge was field-emitted into a solution by generating for 1 h, a field emission current (monitored with an electronic microammeter) of 5 μA at a voltage of 5 to 6 kV applied to the emitter. Such a current induced a significant bulk flow of the solution, which was visible as a violent disturbance at the surface of the solution.

Benzene, ethanol, and cyclohexane of spectrograde were used as received. All organic halides used as solutes were purified by vacuum distillation. Styrene was purified as described elsewhere.[18] Pentamethylnitrosobenzene synthesized as described elsewhere[19] was used as a spin trap. The solutions were degassed by repeated freeze-pump-thaw cycles, sealed in the cell, subjected to a high applied voltage for the field emission, and examined by a conventional ESR spectrometer with a 100 kHz magnetic field modulation. All the experiments were carried out at ambient temperature.

Results and Discussion

Dissociative Electron Attachment. The dependence of the field emission current on the applied voltage is shown in Fig. 2, for the benzene solution of benzyl chloride (0.04 mol·dm^{-3}) and spin traps

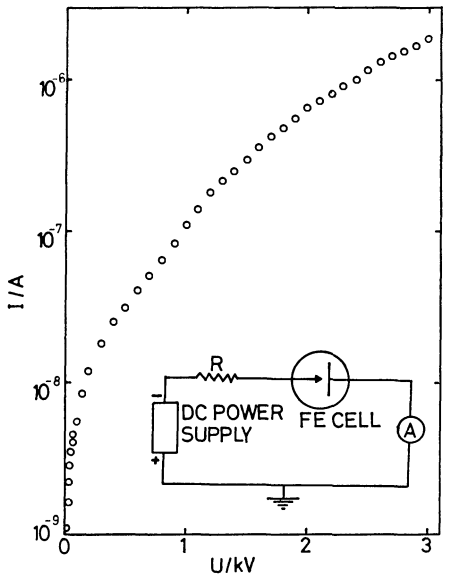

Fig. 2. Emission current-voltage curve for the benzene solution of benzyl chloride (0.04 mol·dm^{-3}) and the spin trap (0.002 mol·dm^{-3}). The electric circuit for the field emission experiment is also shown in the figure.

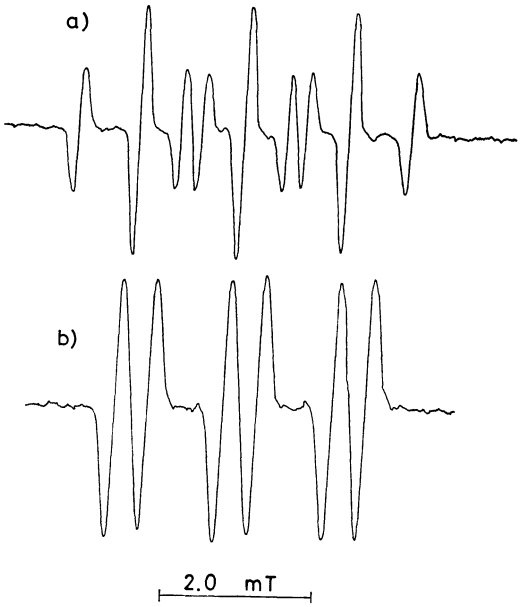

Fig. 3. ESR spectra of the spin-adduct radicals observed in a) the benzene solution of benzyl chloride (0.04 mol·dm^{-3}) and in b) the benzene solution of styrene (0.1 mol·dm^{-3}) and ethanol (0.2 mol·dm^{-3}). The concentration of the spin trap is 0.002 mol·dm^{-3} in both solutions.

(0.002 mol·dm^{-3}). The current increases with the applied voltage sharply in the low voltage region and then slowly in the higher region. The steep increase in the current indicates the onset of the field emission. The onset occurs at a high applied voltage for cyclohexane solutions. The characteristics of the current-voltage curve have been studied in detail for several liquids,[10] and the onset of the field emission has been found to depend on the quasifree electron energy in the liquids.

Spin adduct radicals were found by ESR to be generated in the solution to which electrons had been field-emitted (Fig. 3A). The spin adduct radicals indicated by hyperfine splitting due to a nitrogen nucleus (0.14 mT) and two equivalent protons (0.084 mT) have been identified to be the nitroxide radicals generated by the reaction between the spin trap and benzyl radical.[19] The latter are unquestionably the products of the dissociative electron attachment to benzyl chloride. The yield of the adduct radicals (5×10^{-5} mol·dm^{-3}) was very close to the field-emitted charge (2×10^{-7} F, or *ca.* 7×10^{-5} F·dm^{-3}). This indicates that 0.04 mol·dm^{-3} of benzyl chloride effectively scavenges all the emitted electrons. The spin trap can act as an electron scavenger.[14] In the present experiments, however, the concentration of electron-scavenging solutes is higher than that of the spin trap by one to three orders of magnitude, so that the solutes preferentially compete with the spin trap in reacting with the field-emitted electron. The field emission appears to provide a method to study selectively and quantitatively the electron reactions with the solutions.

Twelve free radicals were generated from the corresponding chlorinated compounds in benzene and studied by the combined field emission-spin trapping method. The ESR parameters of the spin adduct of these free radicals are summarized in Table 1, where some other spin adducts generated by other means[19] are also included for comparison. The spin-trapped free radicals were, in almost all the cases, those generated by the dissociative electron attachment (by the rupture of the C–Cl bond) to the solutes. No free radical from solvents was generated by field emission into benzene and cyclohexane solutions of the chlorinated compounds, whereas in γ-radiolysis the solvent radicals were also generated and spin-trapped. Field emission is a useful method to generate authentically free radicals. From *o*- and *p*-chlorotoluenes, both *o*- and *p*-chlorobenzyl radicals and *o*- and *p*-methylphenyl radicals were generated and spin-trapped. The former radicals may have been formed secondarily by the hydrogen abstraction of the latter.

Nondissociative Electron Attachment. When the benzene solution of styrene (0.1 mol·dm^{-3}), ethanol (0.2 mol·dm^{-3}), and the spin traps (0.002 mol·dm^{-3}) were subjected to the field emission, the α-methylbenzyl radical was identified by observing the ESR spectrum of its spin adduct (see Fig. 3B), which contained the hyperfine splitting due to a nitrogen nucleus (0.144 mT) and a proton (0.044 mT).[19] However, no ESR spectrum was observed in the absence of ethanol under the same conditions of measurement. Ethanol takes an essential role in the formation of α-methylbenzyl radical, which very probably results from the proton transfer from ethanol to a styrene radical anion generated by the nondissociative electron attachment to styrene. The presence of styryl radical was confirmed in the benzene–ethanol solution of phenyl acetylene. Its formation can be interpreted, in the same way, by the nondissociative electron attachment followed by the proton transfer. ESR parameters of these free radicals are also included in Table 1.

TABLE 1. HYPERFINE SPLITTING CONSTANTS AND *g*-VALUES FOR SPIN ADDUCTS (NITROXIDES) FORMED FROM PENTAMETHYLNITROSOBENZENE AS A SPIN TRAP IN BENZENE AT ROOM TEMPERATURE

Trapped radical	Radical sourse	*g*-value	a_N/mT	$a_{\beta H}$/mT

a) Ref. 19. b) 2,2,4-Trimethylpentane.

Schnabel and Schmidt[12] have studied the field emission into bulk styrene and found no indication of its anionic polymerization. They suggested that the electron attachment to styrene does not occur because it possesses a negative electron affinity in the gas phase. In this connection, Horloyd[20] has demonstrated that an electron can be localized on a single styrene molecule in liquid hydrocarbons, whereas Shinsaka and Freeman[21] have inferred that an electron cannot be localized on a single molecule in bulk aromatic compounds, but rather moves freely and is delocalized. The present result indicates that the field-emmitted electron in the benzene solution can be localized on a styrene molecule or a phenylacetyrene molecule to form the corresponding radical anion.

Based on the possible electron localization on a styrene molecule, we attempted the anionic polymerization of styrene by the field emission method in benzene, as well as in cyclohexane and in diethyl ether, all carefully purified and dried by the standard methods in polymer chemistry.[22] A small amount of polymer was actually obtained in benzene and cyclohexane with a field-emitted charge of *ca.* 10^{-5} F, but not in diethyl ether. The polymerization was inhibited by adding triethylamine, an inhibitor for the cationic polymerization, into the benzene and the cyclohexane solutions. In addition, nitroethylene could not be polymerized by the field emission in toluene or in diethyl ether. It is a monomer polymerizable exclusively by the anionic mechanism.[23] These results seems to indicate that the radical anions generated by the field emission have a lifetime too short to grow sufficiently long polymer chains before being neutralized at the collecting electrode.

Ionization by the Injected Electrons. The field emission into the benzene solution of 0.2 mol·dm^{-3} ethanol and 0.02 mol·dm^{-3} spin traps generated the spin adduct of the phenyl radical, while no ESR spectrum was observed without ethanol. The phenyl radical adduct formation was efficiently suppressed by an electron scavenger, such a *t*-butyl chloride or styrene. The phenyl radical formation from benzene cannot be interpreted by anionic reactions initiated by the field-emitted electron, but it tentatively attributed to the cationic mechanism: the ionization of benzene by an energetic electron giving a benzene radical cation, which transfers a proton to ethanol and transforms to a phenyl radical. The emitted electron can be accelerated by a locally high electric field near the sharp edge of the emitter. Since the initial kinetic energy of the field-emitted electron is 4 to 5 eV[24] and the local electric field is thought to be 10^7—10^8 V/cm, it is probable that the electron attains a kinetic energy of *ca.* 10 eV.

The ionization energy of a molecule in condensed media is generally less than that in the gas phase by the sum of the polarization energy of a resultant positive ion, P_t, and the quasifree electron energy in the media, V_0.[25] For benzene, the gas phase ionization energy is 9.6 eV,[26] and P_t and V_0 are roughly estimated

to be -2 eV[25] and -0.1 eV[27] in liquid phase. Thus, the ionization energy is expected to be about 7.5 eV for liquid benzene, which can be ionized by the field-emitted electron after being accelerated. Such an ionization process has been demonstrated by Schnabel and Schmidt[12] for the field emission into liquid styrene.

In the presence of an electron scavenger, the emitted electrons are scavenged before being accelerated to a significant kinetic energy. This is the reason why the anionic reactions occur only in the presence of the electron scavenger.

Conclusions. The field emission into liquid solutions is a promising technique to study dissociative and nondissociative electron attachment reactions in the solutions. This is superior to the radiation chemical techniques in that the anionic reactions exclusively occur in the solutions without being interferred with the reactive intermediate coming from solvent molecules. The field emission has been used, as an example of its chemical utilization, for the authentic generation of several free radicals, whose spin adducts were examined by the ESR method. The ESR parameters of the spin adducts thus determined (Table 1) will be helpful for the spin trapping studies using pentamethylnitrosobenzene as the spin trap.

The Solvent Extraction of Several Univalent Metal Picrates by 15-Crown-5 and 18-Crown-6

Yasuyuki TAKEDA* and Hiroshi GOTŌ

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received November 24, 1978)

The overall extraction equilibrium constants (K_{ex}) for 1:1:1 complexes of 15-crown-5 (15C5) and 18-crown-6 (18C6) with several univalent metal picrates between benzene and water have been determined at 25 °C. The K_{ex} sequences of the univalent metal ion with 15C5 and 18C6 are $Ag^+ > Na^+ > Tl^+ \gg K^+ > Rb^+ > Cs^+ > Li^+$ and $Tl^+ > K^+ > Rb^+ > Ag^+ > Cs^+ > Na^+ \gg Li^+$ respectively. The K_{ex} series for each same crown ether reflects the stability and the extractability of the univalent metal ion–crown ether complex in the aqueous phase. The K_{ex} sequences for the 15C5 system depends entirely on the extractability of the univalent metal ion–crown ether complex. In the case of the 18C6 system this largely depends on the stability of the univalent metal ion–crown ether complex.

It has been reported that crown ethers form stoichiometrically stable complexes with a variety of cations, especially those of the alkali and alkaline earths, and that the stability of the complexes, in which the cation is held in the center of the crown ether cavity, depends primarily on the ratio of the ionic size to the cavity size of the crown ether.[1)]

Solvent extraction is an available and convenient method for investigating the complexing ability of crown ethers for various cations, and several extraction studies have been reported to date.[2)] In some of the studies the extractability of the metal cation–crown ether complex as well as that of the metal cation have been discussed in detail.[2b,d)]

In this paper, the overall extraction equilibrium constant values for the univalent metal cation–15-crown-5 (15C5) and 18-crown-6 (18C6) systems have been determined and the overall extraction equilibria analyzed by constituent equilibria. Since a large anion is readily extracted into nonpolar solvents,[2d)] the picrate anion has been used as the counter ion. Benzene has been used as the solvent on account of its nonpolarity.

Experimental

Materials. 15C5 and 18C6 were purchased from Nisso Co., Ltd. and used without further purification. Analytical-grade benzene, HNO_3, $LiOH \cdot H_2O$, NaOH, KOH, and reagent-grade $TlNO_3$ were obtained from Wako-Pure Chemicals Ltd. $AgNO_3$ and picric acid were analytical grade reagents obtained from Koso Chemical Co., Ltd. Reagent-grade RbOH and CsOH were obtained from Mitsuwa Pure Chemicals Ltd., and Kanto Chemical Co., Inc., respectively. The purities of $AgNO_3$ and $TlNO_3$, and the concentrations of the alkali metal hydroxides and picric acid solutions were determined by means of KCl, EDTA, acid and basic titrations, respectively. Benzene was washed twice with distilled water.

Apparatus and Procedure. The organic phase of the crown ether (6.0×10^{-5}—6.6×10^{-2} M; 1 M=1 mol dm^{-3}) and the aqueous phase of the univalent metal hydroxide or nitrate (9.9×10^{-4}—3.2×10^{-2} M) and the picric acid (1.0×10^{-3}—1.1×10^{-2} M) in stoppered glass tubes (30 ml) were shaken in a thermostated water bath for approx. 30 min at 25±0.2 °C and centrifuged. The initial volume of each phase was 10 ml in all cases. A portion of the aqueous phase 8 ml was transferred to a 10 ml beaker and the hydrogen ion concentration determined by a Hitachi-Horiba F-5 pH meter. For the univalent metal hydroxide and nitrate systems the extractions were conducted at pH 9.7—12.1 and pH 2.3—2.8, respectively. For the systems of the alkali metals–15C5 and 18C6, a portion of the organic phase 8 ml was transferred to a 50 ml beaker and allowed to evaporate over several days. The residue was dissolved in 0.01 M NaOH aqueous solution 8 ml and the picrate concentration determined at 356 nm by a Shimadzu UV-200 spectrophotometer ($\varepsilon = 1.45 \times 10^4$ cm^{-1} M^{-1}). For the systems of Ag and Tl–15C5 and 18C6, the metal in the organic phase was back-extracted into 1 M nitric acid aqueous solution 8 ml and the metal concentration in the aqueous phase determined by a Seiko SAS-725 atomic absorption spectrophotometer. In control experiments in the absence of either the crown ether or picric acid, for the alkali metals and Tl–15C5 and 18C6 system, and for the Ag–15C5 and 18C6 system it was found that there was no extraction and a little extraction, respectively.

The Distribution Coefficient of the Crown Ether. A portion 13 ml of benzene solution containing the crown ether and an equal volume of distilled water were placed in a stoppered glass tube and shaken under the same conditions as above. The range of concentration of 15C5 and 18C6 were from 5.1×10^{-2} to 3.3×10^{-1} M and from 2.8×10^{-2} to 3.1×10^{-1} M, respectively. After centrifuging, a portion 12 ml of the organic phase was transferred to a 10 ml beaker, allowed to evaporate over several days, and the residue weighed. The average distribution coefficients determined in this way are given in Table 1.

Results

In an equilibrium between an aqueous solution of a univalent metal ion, M^+, a picrate ion, A^-, and a benzene solution of a crown ether, L, the equilibrium constants may be defined by the following equations:

$$K_{ex} = [MLA]_0[H^+]/[M^+][L]_0[HA]_0 \quad (1)$$

$$K_{D,L} = [L]_0/[L] \quad (2)$$

$$K_{ex}(HA) = [HA]_0/[H^+][A^-] \quad (3)$$

$$K_{ML} = [ML^+]/[M^+][L] \quad (4)$$

$$K_{ex'} = [MLA]_0/[ML^+][A^-] \quad (5)$$

where the subscript "0" and the lack of subscript designates the organic phase and the aqueous phase, respectively: square brackets indicate the molar concentrations. Thus K_{ex} can be written as follows:

$$K_{ex} = K_{D,L}^{-1}K_{ex}(HA)^{-1}K_{ML}K_{ex'} \quad (6)$$

From the mass balance, $[L]_0$, $[M^+]$, and $[A^-]$ may be given by;

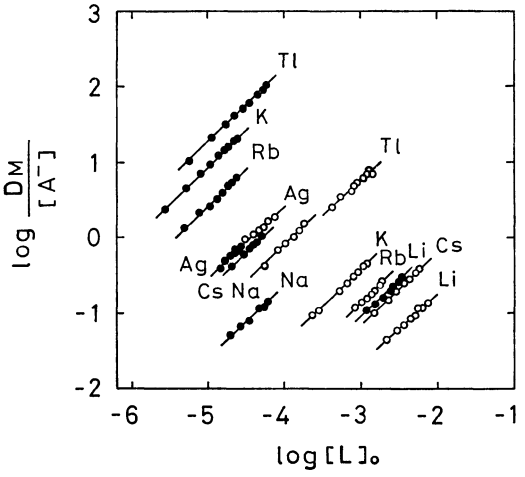

Fig. 1. Plots of log (D_M/[A$^-$]) *vs.* log[L]$_0$ for the 15C5 and 18C6 systems at 25 °C. ○: 15C5, ●: 18C6.

$$[L]_0 = ([L]_t - [MLA]_0)/(\alpha+\beta[M^+]) \quad (7)$$

$$[M^+] = ([M]_t - [MLA]_0)/(1+\beta[L]_0) \quad (8)$$

$$[A^-] = ([HA]_t - [MLA]_0)/\{1+(K_{HA}+K_{ex}(HA))[H^+]\} \quad (9)$$

where the subscript "t" denotes the total concentration, $\alpha=1+K_{D,L}^{-1}$, and $\beta=K_{ML}K_{D,L}^{-1}$. The value of K_{ex} (HA) has spectrophotometrically been determined as 247 using the association constant of picric acid ($K_{HA}=1.9_5$[3]). Substitution of Eq. 8 into Eq. 7 gives:

$$[L]_0 = [-\{\alpha+\beta([M]_t-[L]_t)\} + \sqrt{\{\alpha+\beta([M]_t-[L]_t)\}^2-4\alpha\beta([MLA]_0-[L]_t)}]/2\alpha\beta \quad (10)$$

The distribution ratio of the univalent metal may be represented by

$$D_M = [MLA]_0/([M^+] + [ML^+]) \quad (11)$$

In the case of $[M^+] \gg [ML^+]$, Eq. 11 becomes

$$D_M = K_{ex}K_{ex}(HA)[L]_0[A^-] \quad (12)$$

The log(D_M/[A$^-$]) *vs.* log[L]$_0$ plot in Fig. 1 shows a linear relationship with a slope of 1 in every case, indicating that the crown ether forms a 1:1 complex with the univalent metal ion. The values of [L]$_0$ and [A$^-$] in Eq. 12 were calculated from Eqs. 10 and 9, respectively. For the Li$^+$–15C5 and 18C6 systems, however, the value of [L]$_0$ has been calculated from Eq. 7, neglecting the term, β[M$^+$]. The equilibrium constants obtained from these data are summarized in Table 1, together with the literature values.

Discussion

From Table 1, the log K_{ex} series for 15C5 and 18C6 for the alkali metal ions are given by $Na^+ \gg K^+ > Rb^+ > Cs^+ > Li^+$ and $K^+ > Rb^+ > Cs^+ > Na^+ \gg Li^+$, respectively, indicating that the extractability of the alkali metal ion depends on the ratio of the ionic size to the cavity size of the crown ether, as can be seen in Table 2. Although the crystal radii of the Ag$^+$ and Tl$^+$ ions are nearly equal to that of the K$^+$ ion (Table 2), for the 15C5 system the log K_{ex} values for Ag$^+$ and Tl$^+$ are much larger than that for K$^+$, and for the 18C6 system the log K_{ex} value for K$^+$ is much larger than that for Ag$^+$ and a little smaller than that for Tl$^+$ (Table 1).

Table 1. Summary of equilibrium constants at 25 °C

Crown ether	$K_{D,L}$	Cation	log K_{ex}	log $K_{ex'}$	log K_{ML}[4]
15C5	0.15_6	Li$^+$	−1.10	—	—
		Na$^+$	1.51	2.40	0.70
		K$^+$	0.19	1.04	0.74
		Rb$^+$	−0.25	0.72	0.62
		Cs$^+$	−0.49	0.30	0.8
		Ag$^+$	2.06	2.71	0.94
		Tl$^+$	1.41	1.77	1.23
18C6	0.063_4	Li$^+$	−0.47	—	—
		Na$^+$	1.00	1.39	0.80
		K$^+$	3.58	2.74	2.03
		Rb$^+$	3.04	2.67	1.56
		Cs$^+$	1.99	2.19	0.99
		Ag$^+$	2.05	1.74	1.50
		Tl$^+$	3.91	2.83	2.27

Table 2. Crystal ionic radii of univalent metals and cavity radii of crown ethers (Å)

Cation	Crystal ionic radius[5]	Crown ether	Cavity radius[6]
Li$^+$	0.60	15-crown-5	0.85–1.1
Na$^+$	0.95	18-crown-6	1.3–1.6
K$^+$	1.33		
Rb$^+$	1.48		
Cs$^+$	1.69		
Ag$^+$	1.26		
Tl$^+$	1.40		

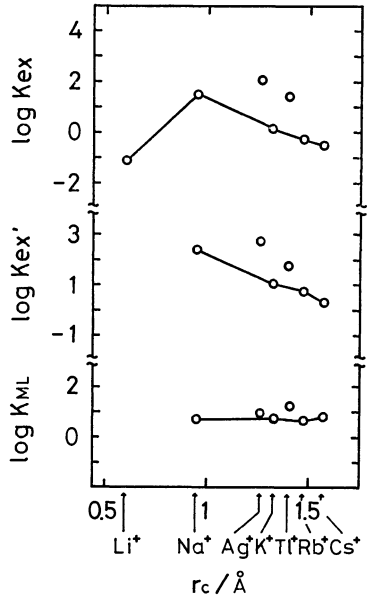

Fig. 2. Plots of logK_{ex}, log$K_{ex'}$, and logK_{ML} *vs.* crystal ionic radius, r_c, of univalent metal for the 15C5 system.

In the case of Ag$^+$ and Tl$^+$, it may be seen from Tables 1 and 2 that the univalent metal ion which has a more optimum size for the crown ether cavity shows a greater extractability, which is the same tendency for the alkali metal ions reported above.

It may be seen from Table 1 that the log $K_{ex'}$ se-

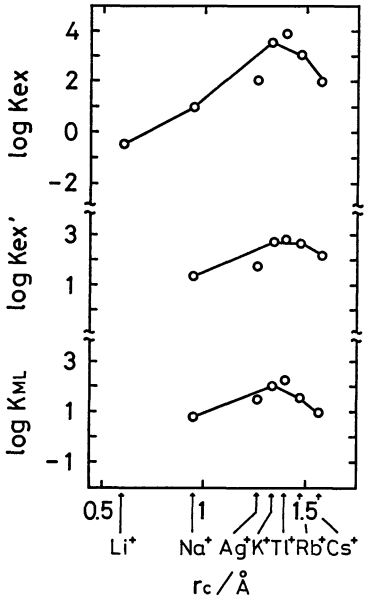

Fig. 3. Plots of $\log K_{ex}$, $\log K_{ex'}$, and $\log K_{ML}$ *vs.* crystal ionic radius of univalent metal for the 18C6 system.

quences of the alkali metal ions with 15C5 and 18C6 are $Na^+ \gg K^+ > Rb^+ > Cs^+$ and $K^+ \geq Rb^+ > Cs^+ > Na^+$, respectively. For the 15C5 system the $\log K_{ex'}$ value for Ag^+ is larger than that for Tl^+, and on the contrary for the 18C6 system (Table 1). The results show that the more closely the univalent metal ion fits into the crown ether cavity, the more extractable is the univalent metal ion–crown ether complex (Table 2). Consequently, the extractability of the univalent metal ion–crown ether complex is affected by the chemical nature of the univalent metal ion held in the cavity of the crown ether.

Equation 6 shows that the series for K_{ex} for the same crown ether for different univalent metal ions reflects the stability and the extractability of the univalent metal ion–crown ether complex in the aqueous phase. Plots of $\log K_{ex}$, $\log K_{ex'}$, and $\log K_{ML}$ *vs.* the crystal ionic radius for the 15C5 and 18C6 systems are given in Figs. 2 and 3, respectively. It may be seen from Figs. 2 and 3 that the $\log K_{ex}$ sequences for the 15C5 system depend completely on the $\log K_{ex'}$ sequences. On the other hand those for the 18C6 system largely depend on the $\log K_{ML}$ ones.

The authors would like to thank Mr. Fujio Takahashi of this laboratory for experimental assistance.

ESR Study of Molecular Oxygen Anion Radicals Produced on Cation-exchanged X-Type Zeolites by γ-Irradiation

Natsuko KANZAKI* and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received December 20, 1978)

Molecular Oxygen anion radicals (O_2^-) were produced on X-zeolites by γ-irradiation in the presence of O_2. Their properties were systematically investigated by means of ESR spectroscopy. Two kinds of O_2^- species with different g_z values were formed on monovalent cation-exchanged (LiX, KX, RbX, CsX) zeolites and MgX, while three and single O_2^- species were observed on divalent cation-exchanged (CaX, SrX, BaX) and trivalent cation-exchanged (LaX) zeolites, respectively. These O_2^- radicals showed different reactivities with N_2O or 1-butene, and their g_z values were classified into four groups. By considering the results from the g_z values and the effect of introduced high pressure O_2 on the O_2^- spectra, the adsorption sites for the radicals on zeolites were determined.

Many Studies have been done about O_2^- radicals adsorbed on various kinds of oxides and zeolites by the use of electron spin resonance technique.[1-11] Based on these studies, the influence of the electric charge of surface cations on the g-factor anisotropy for the adsorbed O_2^- radicals has been discussed.[1,2,5,7] Kasai found that O_2^- was formed on Y-type zeolites by γ-irradiation and the deviation of the maximum principal g value (g_z) for the adsorbed O_2^- on a monovalent zeolite NaY from that of a free electron (g_e) was twice as large as the deviation for O_2^- on a divalent zeolite BaY.[6]

Wang *et al.* have attempted to explain the change of g values for O_2^- formed on Y-type zeolites by γ-irradiation in terms of the crystal field induced by the cations.[7-8] In the case of alkaline earth cation exchanged Y-zeolites, the O_2^- radicals were found to be adsorbed on more than three different sites.[7] However, they could not clarify the nature of the respective sites. Not only on the alkaline earth Y-zeolites but also on NaY they observed three kinds of O_2^- species having different g_z values.[7] Kasai, on the other hand, reported his finding of single O_2^- species on NaY. The difference between these results has not yet been well explained. The formation of O_2^- radicals on trivalent cation-exchanged Y-type zeolites was also reported,[8] but no correlation among the changes of g values in NaY, alkaline earth Y-zeolites, and trivalent cation-exchanged Y-zeolites has yet been found.

More detailed investigations are necessary to find the correlation between the g_z values and the nature of adsorption sites for O_2^- on various kinds of cation-exchanged zeolites. Especially, studies about O_2^- on other monovalent cation-exchanged zeolites besides sodium-form zeolites should be done. In addition, no work has been carried out to examine the properties of O_2^- formed on X-type zeolites by γ-irradiation except that on NaX.[12] In this paper, O_2^- species formed on monovalent, divalent, and trivalent cation-exchanged X-type zeolites by γ-irradiation are systematically examined, and the properties of adsorption sites for the O_2^- are discussed.

Experimental

The cation-exchanged X-zeolites were prepared by immersing Linde 13X zeolite several times into the aqueous solutions of cations in the form of chloride, nitrate, or acetate. The obtained exchanged-zeolites were thoroughly washed with deionized water and dried at room temperature. The degree of ion exchange was determined by estimating the amount of sodium ions dissolved into the solution by means of flame spectrometry. The samples used and their exchange percentages are shown in Table 1.

The zeolite samples, placed in ESR quartz tubes, were degassed at 550 °C, and were exposed to oxygen after cooling to room temperature. The experimental details were similar to those described in the previous paper.[12] γ-Irradiation of samples was performed at room temperature by using a ^{60}Co source; the dose was 12 Mrad. Other samples were also irradiated by γ-rays without exposing them to oxygen. No ESR spectrum except a negligibly weak singlet line at $g=2.002$ was observed before γ-irradiation. Gaseous materials of high purity were obtained from Takachiho Chemical Co. and were used without further purification. The pressures of gases were adjusted to be within the range of 10—30 Torr when the samples were exposed to them. All gases were introduced into samples at room temperature. The ESR spectra were recorded at −196 °C with a JEOL JES-3BS X band spectrometer.

Results

Monovalent Cation-exchanged Zeolites. LiX γ-irradiated in the presence of O_2 gave a typical O_2^- ESR spectrum, as shown in Fig. 1(a).[1-12] All the spectra obtained from γ-irradiated KX, RbX, and CsX in the presence of O_2 have similar lines. Figure 1(a) also shows the low-field lines of their spectra; the estimated values of g_y and g_z are 2.009—2.007 and 2.003—2.001, respectively. The low-field lines (B and D) indicate the presence of two kinds of O_2^- species with different g_z values.[7] The spectra shapes were not changed by evacuation at room temperature.

When these alkali-cation exchanged samples were exposed to 1-butene, the O_2^-(B) spectra of the samples disappeared, whereas the other ones, O_2^-(D), were kept unchanged (Fig. 1(b)). The contact with N_2O only decreased the intensities of the O_2^-(B) spectra for RbX and CsX. All the O_2^-(B) spectra were broadened by exposing the zeolites to O_2 of 150 Torr. The γ-irradiation of LiX, KX, RbX, and CsX under vacuum gave ESR spectra almost similar to that for NaX,[12] though the relative intensity of each signal due to a V or F center was somewhat different in the respective samples.

Divalent Cation-exchanged Zeolites. Figure 2(a)

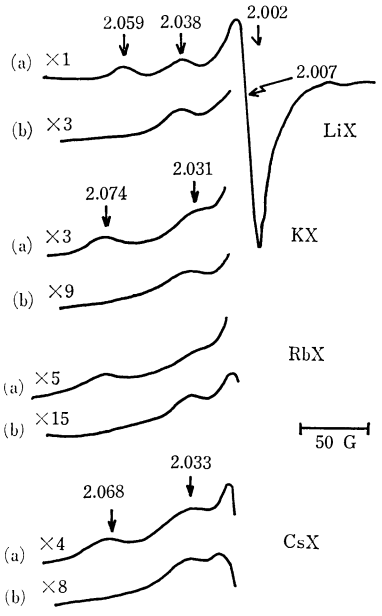

Fig. 1. ESR spectra of alkali cation-exchanged X-zeolites; (a) γ-irradiation in the presence of O_2, and (b) addition of 1-butene after (a) and evacuation.

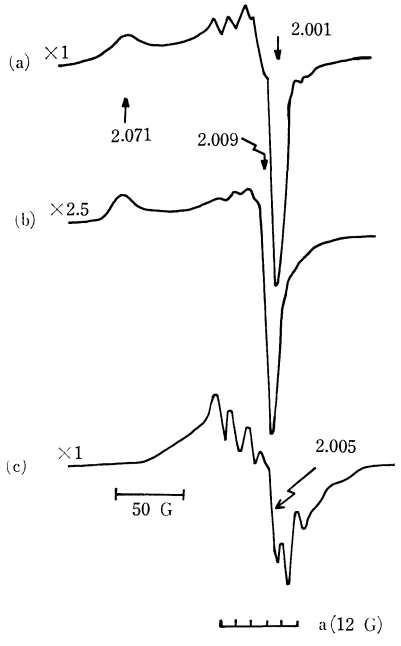

Fig. 2. ESR spectra of MgX; (a) γ-irradiation in the presence of O_2, (b) contact with N_2O after (a) and evacuation, and (c) γ-irradiation under vacuum.

shows the ESR spectrum of MgX γ-irradiated in the presence of O_2. When N_2O was added, the complicated lines in the central part ($g \approx 2.010$) of the spectrum disappeared and a typical O_2^- spectrum was observed (Fig. 2(b)). In the case of MgX γ-irradiated under vacuum, several lines due to V and F centers were observed, as is shown in Fig. 2(c). The broad asymmetric signal with six hyperfine lines ($|a(\mathrm{Al})| = 12$ G) in the figure is the same as that observed by Sogabe *et al.*[13] and can be attributed to an electron hole trapped on an oxygen atom which is bound to an aluminum atom.[9,13–16] Accordingly, the ESR spectrum shown

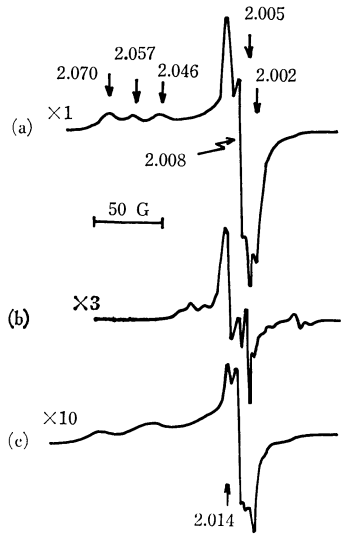

Fig. 3. ESR spectra of CaX; (a) γ-irradiation in the presence of O_2, (b) γ-irradiation under vacuum, and (c) addition of 1-butene after (a) and evacuation.

in Fig. 2(a) is recognized as this signal with hyperfine lines superposed on the signal due to O_2^-. The addition of O_2 (150 Torr) to the MgX γ-irradiated in the presence of O_2 confirmed this assignment, since the asymmetric signal with hyperfine lines became evident due to the broadening of the O_2^- signal. It was observed that the introduced 1-butene destroyed all the signals except a singlet at $g=2.005$.

When CaX was γ-irradiated in the presence of O_2, the spectrum shown in Fig. 3(a) was obtained. From the low-field shoulders ($g_z=2.070$, 2.057, and 2.046), the presence of three O_2^- species ($g_y \approx 2.008$ and $g_x \approx 2.002$) was confirmed.[1–12] Other signals ($g=2.014$, 2.005, 2.002 *etc.*) were ascribed to V and F centers,[7,9,12–16] since they were also obtained by γ-irradiation of CaX under vacuum (Fig. 3(b)). The complexity of the spectrum is due to the presence of the paramagnetic centers which interact with protons of the surface hydroxyl groups.[18,19] It was reported that the surface hydroxyl groups on alkaline earth zeolites remained even after evacuation at high temperature.[20–22]

Evacuation of the irradiated sample of CaX at room temperature decreased the intensity of the O_2^- signal with $g_z=2.070$ by 50%, but did not affect those of the other signals. When the sample was exposed to 1-butene, the intensities of the signals due to O_2^- with $g_z=2.070$ and 2.046 and the lines at $g=2.014$ and $g=2.005$ decreased, and, further, the O_2^- signal with $g_z=2.057$ disappeared (Fig. 3(c)). Upon heating at 200 °C, only the signal with $g_z=2.046$ ($g_y=2.008$ and $g_x=2.001$) remained. All the O_2^- signals were broadened by introducing O_2 of 150 Torr.

The spectrum obtained after the irradiation of SrX in the presence of O_2 was found to be composed of signals due to three O_2^- species ($g_z=2.062$, 2.054, and 2.048) and V and F centers (Fig. 4(a)). The contact with gaseous N_2O improved the resolution of the O_2^- signals, though their intensities decreased (Fig. 4(b)). By the addition of 1-butene, the O_2^- signals with $g_z=2.062$ and $g_z=2.048$ disappeared, while O_2^-

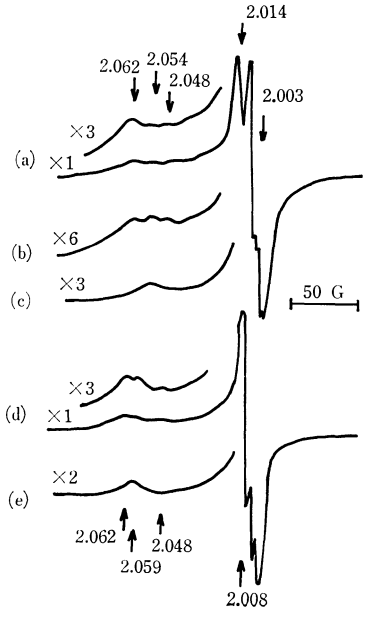

Fig. 4. ESR spectra of SrX; (a) γ-irradiation in the presence of O_2, (b) addition of N_2O after (a) and evacuation, and (c) addition of 1-butene after (a) and evacuation. ESR spectra of BaX; (d) γ-irradiation in the presence of O_2, and (e) addition of 1-butene after (a) and evacuation.

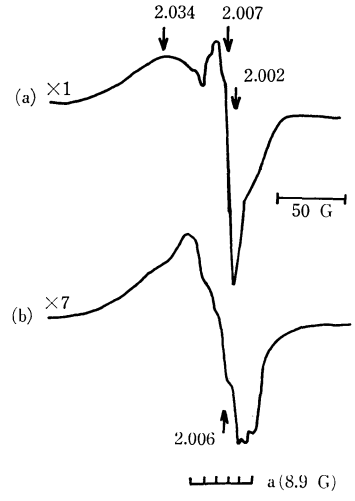

Fig. 5. ESR spectra of LaX; (a) γ-irradiation in the presence of O_2, and (b) addition of 1-butene after (a) and evacuation.

with g_z=2.054 (g_y=2.008, g_x=2.002) remained (Fig. 4(c)). The spectrum recorded at −196 °C shows that the O_2^- with g_z=2.048 was broadened by introducing O_2 (150 Torr). The broadening of other O_2^- signals (g_z=2.062 and 2.054) was not remarkable at that temperature. However, the broadening of the latter was confirmed to occur by observing the change in ESR spectra recorded at room temperature before and after the addition of O_2 (150 Torr).

The ESR spectrum of γ-irradiated BaX in the presence of O_2 indicated the formation of three O_2^- species (Fig. 4(d), g_z=2.062, 2.059, and 2.048). The shape of the O_2^- spectrum was more distinct in BaX as compared with other divalent zeolites, since the signals due to V and F centers were relatively weak. The intensity of the spectrum obtained in the γ-irradiated BaX under vacuum is about 15—20% of those obtained from the other divalent zeolites. The evacuation of O_2 attenuated the O_2^- signal with g_z=2.062 to about 65%. The O_2^- signals with g_z=2.062 and 2.048 disappeared after exposure of the zeolite to 1-butene (Fig. 4(e)). All the O_2^- signals underwent the line-broadening in the presence of O_2 (150 Torr).

Trivalent Cation-exchanged Zeolite (LaX). When LaX was irradiated in the presence of O_2, the spectrum of O_2^- with g_z=2.034, g_y=2.007, and g_x=2.002 was observed (Fig. 5(a)). Upon the addition of 1-butene, the O_2^- signal disappeared, and an asymmetric signal with 6 hyperfine lines with weak intensity became visible (Fig. 5(b)). This shows that the spectrum in Fig. 5(a) is composed of this asymmetric signal and the overlapping one due to O_2^-. The asymmetric signal was also observed by γ-irradiating LaX under vacuum. It may be attributed to electron holes similar to those produced in MgX by γ-irradiation, though the resolution of the hyperfine lines was rather lower.[9,13–16] The addition of O_2 (150 Torr) broadened the O_2^- signal.

Discussion

The ESR spectra observed on the cation-exchanged zeolites which were γ-irradiated in the presence of O_2 are sometimes complicated because of the overlapping of signals due to several O_2^- radicals which are adsorbed on different sites. The formation of V and F centers makes the spectra more complicated. For example, the presence of some O_2^-, especially those with g_z=2.035—2.040 on NaY and alkaline earth zeolites was ambiguous, since it was suggested only from the shoulders in the complicated spectrum. These O_2^- species and centers may show different stabilities on thermal treatments and reactivities with the introduced foreign gases.[12] By making use of these different reactivities and stabilities, we separated the spectrum for each individual O_2^- from the other, and provided the convincing evidence for the presence of each O_2^- species.

The g_z values for O_2^- obtained from γ-irradiated X-type zeolites in the presence of O_2 and those for NaX in our previous study[12] are classified into four groups, as is shown in Table 1. A theoretical analysis of the principal g values for O_2^- was carried out by Känzig and Cohen.[23] According to their result, the g_z component which shows the largest deviation from g_e, that of a free electron, is expressed by

$$g_z = g_e + \frac{2\lambda}{(\delta^2+\lambda^2)^{1/2}}.$$

Where λ is the spin-orbit coupling constant and is evaluated at 0.014 eV.[6] The z axis is chosen along the internuclear axis of O_2^-. The lowest electronic configuration of O_2^- is $\sigma_g^2\pi_u^4\pi_g^{*3}$. The originally degenerated π_u and π_g^* levels are split respectively into $\pi_u(2p_x)$, $\pi_u(2p_y)$ and $\pi_g^*(2p_x)$, $\pi_g^*(2p_y)$ in the adsorbed state by the asymmetric crystal field.[1,5,6,24]

a) The values were obtained in our previous work[12] under the same experimental conditions as used for the others.

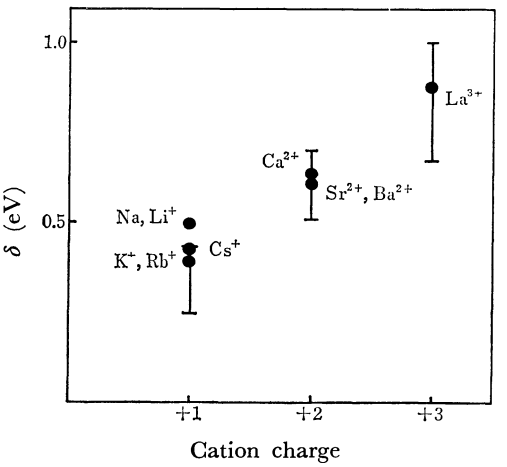

Fig. 6. Correlation between δ and the charge of metal ions. ●; cation exchanged X-zeolites: |——| ; the range of δ values previously obtained.[5]

In the above equation, δ is the energy separation between the $\pi_g^*(2p_x)$ and $\pi_g^*(2p_y)$ orbitals. When $\delta \gg \lambda$, the energy separation δ is given by $\delta=2\lambda/(g_z-g_e)$. Figure 6 shows the plot of δ values of the group B for alkali cation exchanged zeolites, the group C for alkaline earth zeolites and D for LaX against the charge of exchanged cation. The δ values summarized by Lunsford[5] are also shown in the figure as a measure of the distribution range for each value of cation charge. The δ values obtained in the present study fall almost in the ranges indicated by Lunsford. This result suggests that O_2^-(B) was adsorbed on the monovalent cation, O_2^-(C) on the divalent cation, and O_2^-(D) on the trivalent cation.

Table 1 also shows that O_2^-(D) was produced not only on LaX but also on alkali zeolites. O_2^-(D) of alkali zeolites, however, has a different character from those of the other O_2^-. In the atomosphere of O_2 (150 Torr), all the O_2^- spectra except O_2^-(D) of alkali zeolites were broadened. This indicates that the O_2^-(A, B, C, and D of LaX) are located in the supercage, while O_2^-(D) of alkali zeolites may be adsorbed on sites different from the others, possibly on those in the sodalite unit.[7] The signal of O_2^-(D) on NaX has the six hyperfine lines due to an Al nucleus,[12] and the g values for O_2^-(D) on alkali cation exchanged zeolites coincide well with those for O_2^- adsorbed on the aluminum ion in zeolite structure[8,10] and Al_2O_3.[25,26] From these facts, it can be concluded that these O_2^-(D) of the alkali zeolites were adsorbed by the lattice aluminum. The g_z value of O_2^-(D) for LaX is close to those for ScY and LaY[8] and, therefore, is characteristic of O_2^- adsorbed on the exchanged trivalent cation. The ScY and LaY have only one kind of adsorbed O_2^- species, and the observed superhyperfine structure indicates that the exchanged trivalent cations correspond to the adsorption sites.

The states of exchanged cations such as M^{2+}, $M(OH_2)_n^{2+}$, $M(OH)^+$, MO, and M^+–O–M^+ were suggested from the IR and X-ray studies of alkaline earth zeolites.[20,21,27,28] The O_2^-(B) species formed on alkaline earth zeolites have similar g_z values to those on alkali zeolites. These O_2^-(B) species may therefore be trapped on monovalent-like sites such as $M(OH)^+$ or M^+–O–M^+. It was confirmed that the $M(OH)^+$ site exists in the alkaline earth zeolites even after evacuation at high temperature.[29] The M^+–O–M^+ complexes were suggested to be formed in the sodalite unit upon mild dehydration; the M^{2+} ions located at site I′ and site II″ in the zeolite frame work are joined by an oxygen atom.[28] However, considering the movement of the cation due to dehydration at high temperature and γ-irradiation, it seems possible that the complexes with one of the M^{2+} ions in a supercage are also formed.

The O_2^-(C) species is characteristic of the divalent cation exchanged zeolites, and can be attributed to the O_2^- adsorbed on the cations in the state of M^{2+} (Fig. 6). The O_2^-(C) was not observed on MgX zeolite. It is known that the Mg^{2+} ion has a large hydration radius, and can dissociate the bound water more strongly than other divalent cations in zeolites.[13,31] The monovalent-cation like sites are formed by dissociating the bound water of hydrated cations. Most Mg^{2+} ions may take the monovalent-like form. The difference between MgX and other alkaline earth zeolites was also reported for the adsorbed states of CO_2^- and CO_2.[13,31]

Table 1 shows that the O_2^-(A) species is only obtained on NaX. Such O_2^- species with large g_z values were observed on the pretreated NaY and KY with Na and K vapor respectively.[32] The exposure of NaY to Na vapor was found to form the paramagnetic center Na_4^{3+}, and the O_2^- species is formed by taking an electron from the center. The paramagnetic center Na_4^{3+} was also formed by γ-irradiation of NaY and the adsorbed O_2^- has a large g_z value of 2.113.[6] It was suggested by Bentarrit *et al.* that the induced migration of the cation by water leads to the generation of an Na_4^{3+} center under γ-irradiation.[33] Stamires mentioned that $(Na_4)^{4+}$–$(H_2O)_x$ complex is formed in NaY zeolite after a proper degree of dehydration and is converted to $(Na_4)^{3+}$–$(H_2O)_x$ by trapping an electron.[17] As for NaX zeolite, Na_6^{5+} was found to be produced by exposing NaX to Na vapor.[34] These findings predict that the γ-irradiation produces the

$(Na_n)^{(n-1)+}$ center which become non-paramagnetic by transferring an electron to O_2; the number of atoms n depends on experimental conditions such as dehydration and γ-irradiation. The non-paramagnetic center may take the form of $(Na_n)^{n+}$ or a somewhat different configuration due to the movement of the cation after the adsorption of O_2^-, and induces a different crystal field from the usual monovalent Na^+ site. The O_2^-(A) seems to be that held at such a center. This assumption gives a reasonable explanation for the wide variety of g_z values for O_2^- on NaY. The pretreatments under different conditions may produce the sites of various configurations.[33] The O_2^-(A) species was not observed on the other alkali zeolites. The formation of $(M_n)^{n+}$ centers consisting of exchanged cations must be prevented by the remaining Na^+ cations.

By summarizing the consideration given above, the adsorption sites of O_2^- on γ-irradiated zeolites in the presence of O_2 can be assigned to the exchanged M^+ ion and the lattice aluminum cation in monovalent cation-exchanged zeolites (LiX, NaX, KX, RbX, CsX), M^{2+}, $M(OH)^+$ and M^+–O–M^+ in divalent cation-exchanged zeolites (MgX, CaX, SrX, BaX), and M^{3+} in trivalent cation-exchanged zeolites (LaX). The adsorption site $(M_n)^{n+}$ was also suggested for NaY zeolite. The lack of precise information on the electronic state and geometry of the zeolite surfaces makes the verification of these supposed adsorption sites difficult at present, but it is expected that their exact configuration and function will be revealed in the following studies using surface analytical techniques.

Antiferromagnetic Spin-exchange Interaction in Mixed-spin Trinuclear Cobalt(II) Complexes with Quadridentate Schiff Bases[1)]

Visit KASEMPIMOLPORN, Hisashi OKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received December 11, 1978)

Trinuclear cobalt(II) complexes, $[Co(R_1,R_2\text{-L})]_2CoX_2$ (R_1, R_2=H, Me; L=en, ch, ph; X=Cl^-, Br^-), have been synthesized, where $H_2(R_1,R_2\text{-L})$ denotes the Schiff bases obtained by condensing a 5(R_1), α(R_2)-substituted salicylaldehyde with a diamine ($H_2N\text{-L-}NH_2$) in a 2:1 mole ratio. From IR spectra and cryomagnetic properties, it was concluded that these complexes are in mixed-spin state of a Co(II)(s=1/2)–Co(II)(s=3/2)–Co(II)(s=1/2) system, strong antiferromagnetic spin-exchange interaction operating between low-spin and high-spin cobalt(II) ion *via* d_π(low-spin Co)-p_π(O)-d_π(high-spin Co) super pathway.

Low-spin cobalt(II) complexes have an electronic configuration of either $(d_{x^2-y^2})^2(d_{z^2})^1$ or $(d_{x^2-y^2})^2(d_{yz})^1$. In mixed-spin polynuclear cobalt(II) complexes in which high-spin and low-spin cobalt(II) ions are kept in close distance, spin-exchange interaction between the cobalt(II) ions would markedly depend upon the electronic structure of the low-spin cobalt(II) ion. We obtained mixed-spin binuclear cobalt(II) complexes, Co_2(fsaR)$(py)_3$, with *N,N'*-bis(3-carboxysalicylidene)alkanediamine(H_4fsaR) and demonstrated that no spin-exchange interaction operates between the metal ions.[2)] In these complexes low-spin cobalt(II) has an unpaired electron on the d_{z^2} orbital. Thus, it is worth while to examine spin-exchange interaction in mixed-spin polynuclear cobalt(II) complexes in which low-spin cobalt(II) has an unpaired electron on the d_{yz} orbital. However, no such mixed-spin polynuclear cobalt(II) complexes have yet been obtained.

Sinn and Harris[3)] synthesized mixed-metal trinuclear complexes of Cu(II)–M(II)–Cu(II) (M(II)=Cu(II), Ni(II), Co(II), Fe(II), Mn(II)) system by reacting copper(II) complexes of *N,N'*-disalicylideneethylenediamine or its homologues with an M(II) ion in a 2 : 1 mole ratio. Since the electronic structure of Co(salen) and its homologues was recently demonstrated to be $(d_{x^2-y^2})^2(d_{yz})^1$[1,4,5)] we have attempted to prepare Co(II)(s=1/2)–Co(II)(s=3/2)–Co(II)(s=1/2) complexes with the quadridentate Schiff bases in order to investigate their magnetic property in connection with the electronic configuration of the low-spin cobalt(II) ion.

N,N'-Disalicylidenealkanediamines are abbreviated to $H_2(R_1, R_2\text{-L})$ (R_1, R_2=H, Me; L=en, ch, ph), where R_1 and R_2 denote the substituents attached to the 5- and α-positions of salicylaldehyde moiety, respectively, and L denotes the chain combining the two nitrogen atoms.

Experimental

Preparation of Complexes. Co(H,H-en) was synthesized by the method of Bailes and Calvin.[6)] Other mononuclear cobalt(II) complexes were obtained in a similar way. The syntheses of all the trinuclear complexes, $[Co(R_1,R_2\text{-L})]_2CoX_2$, were nearly the same and are exemplified by that of $[Co(H,H\text{-en})]_2CoCl_2$ as follows.

Co(H,H-en) (500 mg) and $CoCl_2\cdot 6H_2O$ (219 mg) were dissolved in ethanol (100 ml) and the mixture was refluxed for *ca.* 2 h to give red-brown crystals. After the reaction mixture had been allowed to stand overnight, crystals were collected by filtration, washed with a small amount of ethanol and dried under reduced pressure. All operations were carried out in a nitrogen atmosphere by means of a VAC inert atmosphere & vacuum deposition equipment Model HE-43-2. Elemental analyses of $[Co(R_1,R_2\text{-L})]_2CoX_2$ are given in Table 1.

Measurements. Elemental analyses of carbon, hydrogen, and nitrogen were carried out at the Elemental Analysis Service Center, Kyushu University. Cobalt analyses were carried out with a Shimadzu atomic absorption-flame spectrophotometer Model 610S. The standard solution was prepared by decomposing Co(H,H-en) with nitric acid and diluting the decomposed mixture with water in a volumetric flask. Solutions of samples were also prepared by the same method. IR spectra were measured in the range 4000—650 cm^{-1} with a Hitachi infrared spectrophotometer Model 215 on a KBr disk. Magnetic susceptibilities were measured by the Faraday method in the temperature range 78—300 K, the apparatus being calibrated with $HgCo(NCS)_4$.[7)] Effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828(\chi_M\times T)^{1/2}$, in which χ_M

$[Co(H,H\text{-}ch)]_2CoBr_2$	orange	1540 (1530)

a) Value in parentheses is the skeletal vibration for $Co(R_1,R_2\text{-}L)$.

is molar magnetic susceptibility corrected for diamagnetism for all the constituent atoms by the use of Pascal's constants.[8]

Results and Discussion

Color and IR skeletal band near 1550 cm^{-1} are given in Table 2. A skeletal band at 1515—1530 cm^{-1} found for $Co(R_1,R_2\text{-}L)$ shifts to higher frequency (1540—1550 cm^{-1}) in $[Co(R_1,R_2\text{-}L)]_2CoX_2$, except for the complex with $H_2(H,H\text{-}ph)$. The shift of the skeletal vibration to higher frequency was elucidated by Sinn *et al.*[9-12] for binuclear copper(II) complexes and is used for diagnosis of a bridging mode of phenolic oxygen in homometal polynuclear complexes,[13-18] mixed-metal polynuclear complexes[19] and Cu(II)–Cu(I) mixed-spin complexes.[20] It is likely that in the present complexes metal ions are bridged by the phenolic oxygens. Except for this skeletal band, each IR spectrum of $[Co(R_1,R_2\text{-}L)]_2CoX_2$ resembles that of the corresponding $Co(R_1,R_2\text{-}L)$.

The complexes are insoluble in most nonpolar organic solvents. They are soluble in polar solvents such as pyridine and dimethyl sulfoxide, but they decompose in these solvents. Reflectance spectra of the complexes were not well resolved. No information was available on the structure of the complexes from the electronic spectra.

As pointed out by Gruber *et al.*,[21] steric requirement of $Co(R_1,R_2\text{-}L)$ as a bidentate ligand is nearly the same as that of 2,2′-biquinolyl (biq). Because of the steric hindrance between hydrogens attached to the 8-position, two 2,2′-biquinolyl molecules can not coordinate to a metal ion in a plane; *e.g.*, the coordination geometry of $[Cu(biq)_2](ClO_4)_2$ is pseudo-tetrahedral.[22] For the same reason, two molecules of $M(R_1,R_2\text{-}L)$ should assume a pseudo-tetrahedral or cis-octahedral coordination because of the steric repulsion between the hydrogens attached to the 3-position of salicylaldehyde moiety. In fact, the configurations of Na^+ in $[Cu(H,H\text{-}en)]_2NaClO_4$[23] and the central copper(II) in $[Cu(R_1,R_2\text{-}L)]_2Cu(H_2O)_2(ClO_4)_2$[24] are cis-octahedral. Thus, we assume that the present complexes have the structure shown in Fig. 1.

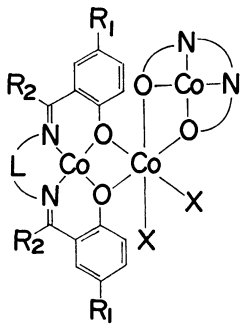

Fig. 1. Probable structure of $[Co(R_1,R_2\text{-}L)]_2CoX_2$.

Magnetic susceptibilities of the complexes were measured in the range from liquid nitrogen temperature to room temperature. Magnetic susceptibilities and magnetic moments at various temperatures are given in Table 3. Magnetic moments per molecule at room temperature fall in the range 5.83—6.02 BM, the moments decreasing with lowering of temperature. Since magnetic moments for mononuclear high-spin cobalt(II) (octahedral) and for mononuclear low-spin cobalt(II) complexes are known to be 4.5—5.2 and 2.0—2.8 BM, respectively,[25] the magnetic moment for a magnetically non-interacting Co(II)(s=1/2)–Co(II)(s=3/2)–Co(II)(s=1/2) mixed-spin system is estimated at 5.33—6.54 BM by the equation $\mu_M^2=\sum\mu_i^2$. The observed magnetic moments of $[Co(R_1,R_2\text{-}L)]_2CoX_2$ at room temperature fall in this range. On the other hand, moments near liquid nitrogen temperature are close to or less than the lowest limit 5.33 BM. Thus it is likely that $[Co(R_1,R_2\text{-}L)]_2CoX_2$ are mixed-spin trinuclear complexes, in which an antiferromagnetic spin-exchange interaction operates between the low-spin and high-spin cobalt(II) ions.

Molar magnetic susceptibility for Co(II)(s=1/2)–Co(II)(s=3/2)–Co(II)(s=1/2) system is given by

$$\chi_M=\frac{Ng^2\beta^2}{4kT}\cdot\frac{35+10\exp(-3J/kT)+10\exp(-5J/kT)+\exp(-8J/kT)}{3+2\exp(-3J/kT)+2\exp(-5J/kT)+\exp(-8J/kT)}+N\alpha,$$

which was first derived Gruber *et al.* for Cu(II)–Co(II) (s=3/2)–Cu(II) system.[26] In this equation J is the exchange integral between the low-spin and high-spin cobalt(II) ions and other symbols have their usual meanings, spin-exchange interaction between the therminal low-spin cobalt(II) ions being neglected. Magnetic susceptibilities for $[Co(R_1,R_2\text{-}L)]_2CoX_2$ can be explained by means of this equation. In Fig. 2 the best fit between empirical and theoretical inverse magnetic susceptibilities for $[Co(H,H\text{-}en)]_2CoCl_2$ is shown as an example. Magnetic parameters, J and g, obtained for $[Co(R_1,R_2\text{-}L)]_2CoX_2$ are given in Table 4; temperature independent paramagnetism, $N\alpha$, being estimated at 500×10^{-6} c.g.s./mol. It is evident that an antiferromagnetic spin-exchange interaction operates between low-spin and high-spin cobalt(II) ions. The exchange integrals (−10—−14 cm^{-1}) are appreciably large and comparable to the value (J=−16—−24 cm^{-1}) found for the Cu(II)–Co(II)(s=3/2)–Cu(II) complexes.[3,26]

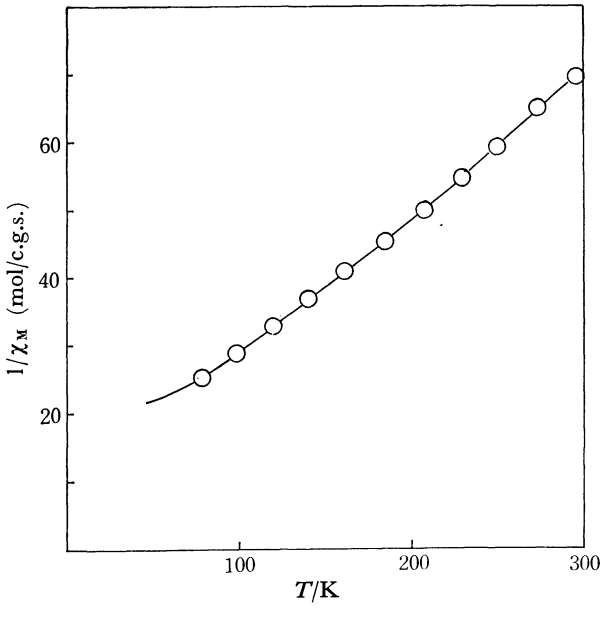

Fig. 2. Temperature variation of inverse molar magnetic susceptibility of $[Co(H,H\text{-}en)]_2CoCl_2$. The solid line represents the theoretical susceptibility with $J=-14$ cm^{-1}, $g=2.68$ and $N\alpha=500\times10^{-6}$ c.g.s./mol.

We showed that no spin-exchange interaction operates between low-spin and high-spin cobalt(II) ions in $Co_2(fsaR)(py)_3$.[2] In these complexes low-spin cobalt(II) ion has an unpaired electron on its d_{z^2} orbital. The absence of magnetic interaction may be attributed to a negligibly small overlapping between the cobalt d_{z^2} orbital and the oxygen orbital. Thus, it is important to determine the ground-state electronic configuration of the low-spin cobalt(II) in antiferromagnetic $[Co(R_1,R_2\text{-}L)]_2CoX_2$. Since $[Co(R_1,R_2\text{-}L)]_2CoX_2$ shows no well-defined ESR signal owing to high-spin cobalt(II) ion, it is desirable to prepare a complex of Co(II)($s=1/2$)–M(II)–Co(II)($s=1/2$) system, in which the central cobalt(II) is replaced by a diamagnetic M(II) ion. However, we were unsuccessful in obtaining $[Co(R_1,R_2\text{-}L)]_2MX_2$. Thus, the electronic structure of the low-spin cobalt(II) was surmised by considering binuclear complexes related to the present complexes. It was

TABLE 4. MAGNETIC PARAMETERS FOR COMPLEXES

	$-J$ (cm^{-1})	g

$N\alpha$ is estimated at 500×10^{-6} c.g.s./mol.

shown[20] that $Cu(R_1,R_2\text{-L})$ and $[Cu_2(R_1,R_2\text{-L})CH_3CN]ClO_4$ (Cu(II)–Cu(I) complex bridged by the phenolic oxygen) show ESR spectra displaying substantially identical $g_\parallel$, $g_\perp$, and $A_\parallel$ values. This indicates that the electronic property of Schiff base complexes coordinated to another metal as a bidentate ligand is almost the same as that of the original mononuclear complexes, $M(R_1,R_2\text{-L})$. This is in line with the fact that in binuclear complexes of this type the distance between the phenolic oxygen and the metal bound to the N_2O_2-donating site is nearly the same as that for the original Schiff base complex $M(R_1,R_2\text{-L})$, while the distance between the phenolic oxygen and the second metal is much elongated.[27,28] A similar trend in bond distance is observed for the binuclear complexes with 1,3,5-triketone-diamine Schiff bases.[29–31] Recently we have found that the electronic spectrum of $[Co(R_1,R_2\text{-L})]_2MnX_2$ is almost the same as that of $Co(R_1,R_2\text{-L})$.[32] Thus, it is concluded that the electronic property of the low-spin cobalt(II) in $[Co(R_1,R_2\text{-L})]_2CoX_2$ is the same as that of $Co(R_1,R_2\text{-L})$, where an unpaired electron occupies d_{yz} orbital. Since high-spin cobalt(II) has unpaired electrons in $d_{x^2-y^2}$, d_{z^2} and one of the d_π orbitals, we may conclude that in the present complexes d_π(low-spin Co)-p_π(O)-d_π(high-spin Co) super pathway plays an important role in antiferromagnetic spin-exchange interaction.

Determination of Ultratrace Zinc by Enzymatic Activity of Carbonic Anhydrase

Kensei KOBAYASHI, Kitao FUJIWARA, Hiroki HARAGUCHI, and Keiichiro FUWA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 23, 1978)

A method for the determination of trace zinc has been investigated by using enzymatic activity of carbonic anhydrase. The recovery of enzymatic activity of apo-carbonic anhydrase was proportional to the amount of zinc in solution theoretically and experimentally, when it was monitored spectroscopically using the substrate, *p*-nitrophenyl acetate. The amount of zinc in the sample solutions was therefore determined from the curve, zinc concentration *vs.* the enzymatic activity. The limit of detection is 10 ng/ml or 2 ng. The method has been applied to the analysis of zinc in fruit juices and water samples.

Of many enzymes, the metalloenzymes have specific metal ions located at their active centers, and the metal ions play essential roles in determining the enzymatic activity and in the processes of enzymatic reactions. This allows the metalloenzymes to show their selectivity and specificity to substrates which are concerned in enzymatic reactions. Such characteristics of the metalloenzymes have been subjects of recent interest, particularly as regards their application to the determination of trace metals.[1,2]

The enzymatic activity of the metalloenzyme for substrates is determined by the amount of active metal ion in the enzyme. The assay of the metalloenzyme is performed by measuring the recovery of the enzymatic activity of the inactive metal-free apoenzyme, when the metal can be removed from the enzyme. The assay of the enzyme is very sensitive and selective to the amount and kind of metal ion added, being useful for the analysis of trace metal ions. Townshend and Vaughan reported the detection of zinc based on the re-activation of apo-alkaline phosphatase.[3] Lehky and Stein studied the determination of zinc in serum using aminopeptidase.[4] Several workers investigated the determination of zinc and copper by enzymatic activity of metalloenzymes.[5,6]

In the present paper, a theoretical consideration is given on the relationship between the recovery of enzymatic activity and the amount of zinc in the case of one active metal ion, taking into account the chemical equilibria between the apoenzyme and the metal ion. A general case, *i.e.*, one in which more than one metal ion is necessary, is given in Appendix II. The relationship is confirmed experimentally and applied to the determination of zinc in fruit juices and waters, where apo-carbonic anhydrase was used as one of the representative zinc-containing enzymes found widely in biological systems.[7]

Theoretical Consideration

The enzymatic reaction in the case of carbonic anhydrase can be described as follows (definitions of all the signs are summarized in Appendix I):

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} \mathrm{ES} \xrightarrow{k_{+2}} \mathrm{E} + \mathrm{P}. \tag{1}$$

The reaction velocity v in this system is given by the Michaelis-Menten expression:

$$v = \frac{V_{\max}[\mathrm{S}]}{K_{\mathrm{m}} + [\mathrm{S}]}, \quad \text{where} \quad K_{\mathrm{m}} = \frac{k_{-1} + k_{+2}}{k_{+1}}, \tag{2}$$

It is assumed that the following equilibrium between the apoenzyme and metal ion (zinc in the present case) exists in solution:

$$\mathrm{E_a} + \mathrm{M} \rightleftharpoons \mathrm{E} \tag{3}$$

$$K = [\mathrm{E}]/[\mathrm{E_a}][\mathrm{M}]. \tag{4}$$

Thus, the concentration of metalloenzyme is given by

$$[\mathrm{E}] = K([\mathrm{E_a}]_0 - [\mathrm{E}])([\mathrm{M}]_0 - [\mathrm{E}]). \tag{5}$$

Under the conditions $[\mathrm{S}] \gg [\mathrm{E_a}] \gg [\mathrm{M}]$, the equation is written as follows:

$$[\mathrm{E}] = \frac{K[\mathrm{E_a}]_0[\mathrm{M}]_0}{1 + K[\mathrm{E_a}]_0}. \tag{6}$$

If the concentration of substrate is sufficiently high as assumed in Eq. 6, the concentration of the product in Eq. 1 is proportional to that of the enzyme. Thus,

$$[\mathrm{P}] = k_0 t[\mathrm{E}], \tag{7}$$

where k_0 is molecular activity of enzyme and t the reaction time. Since we can assume that $K[\mathrm{E_a}]_0 \gg 1$, the following expression can be obtained from Eqs. 6 and 7.

$$[\mathrm{P}] = k_0 t \cdot \frac{K[\mathrm{E_a}]_0}{1 + K[\mathrm{E_a}]_0} \cdot [\mathrm{M}]_0 \simeq k_0 t[\mathrm{M}]_0. \tag{8}$$

Differentiating, we have

$$\frac{\mathrm{d}[\mathrm{P}]}{\mathrm{d}t} \simeq k_0[\mathrm{M}]_0. \tag{9}$$

This shows that the formation rate of the product in Eq. 1 is proportional to the initial concentration of metal ion in solution. Thus the metal concentration in the sample solution can be determined by measuring enzymatic activity, if the formation rate of the product can be obtained, for example, by absorption measurement of the product.

Since the absorption of substrate is not negligible in the present case because of the overlapped spectra, Eq. 9 should be modified. The total absorption of the substrate and product at λ is given by

$$A_\lambda = (e_{\mathrm{S}}^\lambda[\mathrm{S}] + e_{\mathrm{P}}^\lambda[\mathrm{P}])l. \tag{10}$$

By differentiation we have

$$\frac{\mathrm{d}A_\lambda}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}(e_{\mathrm{P}}^\lambda - e_{\mathrm{S}}^\lambda)[\mathrm{P}] \cdot l \simeq (e_{\mathrm{P}}^\lambda - e_{\mathrm{S}}^\lambda)k_0 l \cdot [\mathrm{M}]_0. \tag{11}$$

We see that the time-dependence of the total absor-

bance at λ (dA_λ/dt) is also proportional to the initial concentration of metal. The amount of zinc in the solutions can be determined from a plot of (dA_λ/dt) *vs.* $[M]_0$.

Experimental

Chemicals. Bovine carbonic anhydrase C-7500 (EC 4.2.1.1, abbreviation BCA, Sigma Chem. Co.) was used. Substrate (*p*-nitrophenyl acetate) and buffer (tris(hydroxymethyl)methanamine=Tris) were purified by means of solvent extraction using a 0.001% dithizone–chloroform solution.[8] *p*-Nitrophenyl acetate was dissolved in 0.03 M Tris buffer solution (pH 7.8).[9] (1 M=1 mol dm^{-3}.) The distilled water was prepared by a Daiken Sekiei subboiling distiller.[10] Zinc chloride was used for the preparation of standard solution of zinc.

Instruments. A Shimadzu UV-210 spectrophotometer with a SPR-5 temperature controller was used for the measurements of enzymatic activity of carbonic anhydrase, the optical path of the absorption cell being 10 mm. A Hitachi 170-50 atomic absorption spectrophotometer with a Jarrell-Ash FLA-100 carbon rod atomizer was used to determine the zinc content in the sample solutions.

Preparation of the Apoenzyme. A zinc-free enzyme (apoenzyme) was prepared by a modified method of Lindskog and Malmström[11] as follows. BCA (10 mg) was dissolved in 1 ml of water and dialyzed with 0.01 M 1,10-phenanthroline and 0.1 M of sodium acetate buffer (pH 5.0) for 5—10 days. After further dialysis with 10^{-4} M EDTA and 0.06 M Tris (pH 7.8) for half a day, the chelating reagents were eliminated by dialysis with water. The zinc content in the enzyme was reduced to less than 3% of the initial content. The concentration of enzyme protein was determined by measuring the absorbances at 260 nm and 280 nm.[12]

Measurement of Enzymatic Activity. The enzymatic reaction of BCA for the substrate, *p*-nitrophenyl acetate, proceeds as follows:

$$O_2N\text{-}C_6H_4\text{-}OCOCH_3 + H_2O \xrightarrow{BCA} O_2N\text{-}C_6H_4\text{-}OH + CH_3COOH \quad (12)$$

The absorbance of the product, *p*-nitrophenol, was measured at 348 nm.[9] We see from the Michaelis-Menten plot (reaction velocity *vs.* concentration of substrate) that 1 mM of *p*-nitrophenyl acetate is sufficient to satisfy the conditions for Eq. 6.

The procedure for enzymatic activity measurement was as follows: 2 ml of the substrate solution and 50—200 μl of the zinc-containing sample were mixed in a cuvette. 100 μl of 10^{-4} M apo-BCA was then added to the mixed solution, the time at which addition was made being taken as $t=0$. The increase in absorbance at 348 nm, which corresponds to the increase of the product in Eq. 12, was measured subsequently. All the experiments were carried out at 25 °C.

Results and Discussion

Calibration Curve for Zinc. The relationship between the change in absorbance at 348 nm (reaction rate) and the concentrations of zinc in the solution is shown in Fig. 1. The change in absorbance corresponds to the enzymatic activity. The change of absorbance per minute was adopted for measurement of enzymatic activity. The enzymatic activity was calculated from the absorbance change during the period 1—5 min after addition of enzyme.

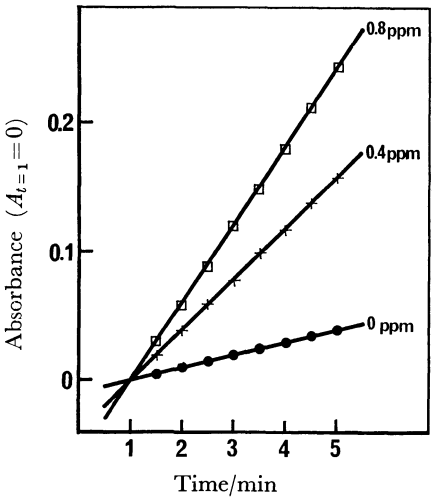

Fig. 1. Time dependence of absorbance change at several zinc concentrations. Absorbance at $t=1$ min ($A_{t=1}$) after the addition of apoenzyme was assumed zero.
Zinc solution: 100 μl, 1 mM substrate solution: 2 ml, 0.1 mM BCA solution: 100 μl. ●—●: [Zn]=0 μg/ml, ×—×: [Zn]=0.4 μg/ml □—□: [Zn]=0.8 μg/ml.

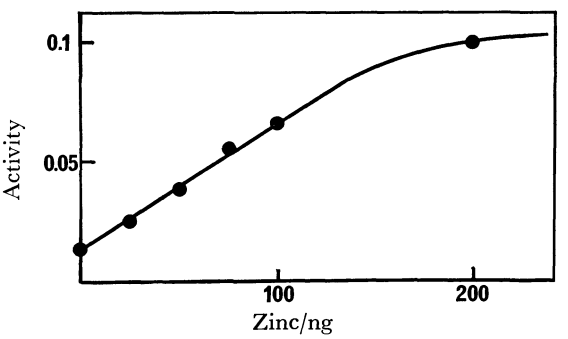

Fig. 2. Calibration curve for zinc measured by enzymatic activity of BCA. The enzymatic activity was measured as the change of absorbance (dA/dt) at 348 nm. 1 mM substrate solution: 2 ml, 0.1 mM BCA solution: 100 μl.

As shown in Fig. 2, the calibration curve is linear in the range 10—100 ng of zinc. For the amount of zinc over 100 ng, the condition $[E_a] \gg [Zn]_0$ is no longer valid and the calibration curve starts to bend. However, the dynamic range of the calibration curve can be extended by varying the amount of sample added to the buffer solution. The actual dynamic range, therefore, may be extended from 10 ng/ml to 1 μg/ml. A higher concentration of zinc ion might be determined if $[E_a]$ can be increased. However, increase of background absorption and difficulty of mixing the enzyme and sample homogeneously at the start of reaction result in poor accuracy. Thus 10 nmol enzyme is the maximum working amount for the determination of zinc under the present conditions.

The integral absorbance (A) can also be applied to the determination of zinc instead of the change in absorbance (dA/dt), as can be seen from Eq. 10.

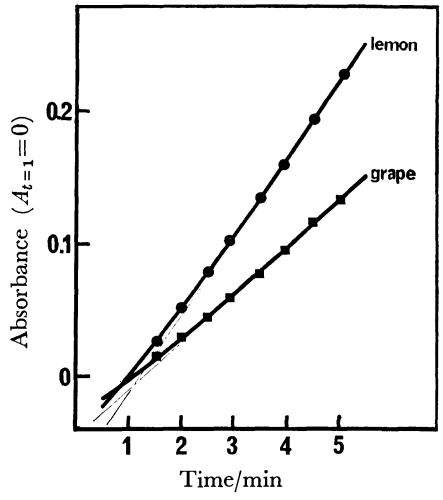

Fig. 3. Time dependence of absorbance change in grape and lemon juice samples. 1 mM substrate solution: 2 ml, 0.1 mM BCA solution: 100 μl, sample solution: 100 μl. ■—■: grape juice, ●—●: lemon juice.

However, zinc determination due to the integral absorbance causes large error in the analytical results. A typical example is shown in Fig. 3, where the absorbance changes at 345 nm are shown for grape and lemon juices. The rate of increase of absorbance is low at the initial stage of the reaction, and the amount of zinc obtained from the apparent absorbance might be less than the actual value. The slow increase of absorbance at the initial stage of the reaction might be due to the redistribution of zinc in the enzyme and sample. Measurement of the enzymatic activity should therefore be started after a few minutes (at least 1 min).

The sensitivity of the present method is *ca.* 10 ng/ml or 2 ng. As can be seen from Eq. 11, the sensitivity depends on the molecular activity (k_0) and absorption coefficient of the product (e_p). It may be improved by selection of a more appropriate substrate, although *p*-nitrophenyl acetate was used as a substrate for the sake of convenience.

In order to use the metalloenzyme method for metal determination, the following conditions should be satisfied: 1) A metal-free enzyme; 2) an enzyme stable in the metal-free state; 3) an enzyme easily obtained and convenient to work with; 4) little interference of other metal ions; and 5) linearity between the metal concentration and the rate of product formation. So far, alkaline phosphatase and aminopeptidase have been applied to zinc determination.[3,4] These enzymes can be easily obtained and are readily manipulated. The analytical sensitivity of the methods using aminopeptidase and alkaline phosphatase is comparable with that of the present method. However, more than one zinc atom is required for reactivating these enzymes from the zinc free state. As can be seen in Eqs. 2′ and 3′ in Appendix II, the relationship between zinc content and recovery of activity is complicated, not being linear. This indicates that the standard addition method may not be available, even when the interference of the matrices is large. For this reason, the use of carbonic anhydrase is preferable to these enzymes.

TABLE 1. EFFECT OF ANIONS ON ENZYMATIC ACTIVITY OF CARBONIC ANHYDRASE[a]

Anions	Amount/μmol	Relative activity[b]/%
Cl^-	1	88±18
NO_3^-	1	82±16
HSO_4^-	1	85±19
ClO_4^-	1	74±15
CN^-	0.2	12±2
CN^-	1	5±3

a) The amounts of zinc and apo-carbonic anhydrase were 1.5 nmol and 10 nmol, respectively. b) The ratio (%) of the enzymatic activities measured with and without the anions.

TABLE 2. EFFECT OF METAL IONS ON ENZYMATIC ACTIVITY OF CARBONIC ANHYDRASE[a]

Zinc amount/ng	Amount/ng		Relative activity[b]/%
0	Co(II)	0	10±3
0		100	55±12
100		20	95±18
100		100	145±22

0		100	12±3
100		20	74±5
100		100	59±7
0	Cu(II)	0	6±1
0		100	7±1
100		20	87±9
100		100	88±8

a) The amounts of zinc and apo-carbonic anhydrase were 1.5 nmol and 10 nmol, respectively. b) Enzymatic activities based on the activity when only 100 ng zinc is added.

Interference of Coexistent Ions. A few studies have been made on the effect of the coexisting cations[13] and anions[14] on the activity of carbonic anhydrase. The interference of the concomitants in the present system is summarized in Tables 1 and 2. Excess amounts of cyanide and perchlorate ions interfere severely with the analytical results.

In the case of cations, Fe^{2+}, Mn^{2+}, Ca^{2+}, Na^+, and Mg^{2+} do not interfere as long as their amounts are less than twice the amount of zinc ion. Hg^{2+} reduces the enzymatic activity by 50%, and Co^{2+} at a concentration equal to that of zinc ion increases the enzymatic activity by 50%. However, the level of mercury or cobalt in real samples is generally much lower than that of zinc (in the environmental and biological samples).[15,16] Thus, the selectivity of this method is maintained at such low levels in many cases. If the interference of the concomitants can not be avoided, the standard addition method should be employed. It would improve the accuracy of the procedure.

Application to Zinc Determination. The analytical results (the standard addition method) for the

Table 3. Determination of zinc in real sample

Sample	Zn content/(ng/ml)	
	present method[a)]	atomic absorption[b)]
Grape juice	340±50	370±20
Pear juice	180±50	250±20
Lemon juice	700±50	540±30

Drain water	260±90	190±20

a) The amount of apo-carbonic anhydrase was 10 nmol at pH 7.8. b) Determined by atomic absorption spectrometry.

fruit juices and natural waters are given in Table 3, together with the amount of zinc in the same samples determined by atomic absorption spectrometry. The analytical values obtained by the present method are in line with those obtained by atomic absorption spectrometry. This indicates that the present method can be applied to the determination of zinc in biological and environmental samples.

However, when the "metalloenzyme method" is applied to metal determination in biological samples, the same enzyme intrinsically existing in the sample interferes with the results. For example, the determination of zinc in serum would not be possible by the present method because of the high activity of carbonic anhydrase in serum. The same situation occurs in the case of other esterases, when the samples related to digestive organ are analyzed. The appropriate selection of enzyme should be made with regard to the kind of sample. Pretreatment of sample for eliminating or inactivating the intrinsic enzyme is necessary.

Conclusion

The present method shows promise for determining trace zinc. In general, biochemical amplification and specificity to the metal ion analysed are important characteristics of metal determination by the activity of metalloenzymes. In the present system, one zinc ion caught in the enzyme protein can react with many specific substrates and produce many specific products if the reaction time can be prolonged. The catalytic reaction of metalloenzyme may enhance the sensitivity of the method. This is a great advantage of the "metalloenzyme method" as compared to the usual colorimetric method. In practice, however, the present method has some limitations due to the natural hydrolysis of the substrate and incompleteness of zinc-elimination from the enzyme. Nevertheless, it is superior in selectivity and comparable in sensitivity to convenient colorimetric methods such as the dithizone method.[17] The preparation of enzyme electrodes for trace metal analysis is an interesting application of the metalloenzyme method.

The authors express their thanks to Dr. A. Ikai, Department of Biochemistry, The University of Tokyo, for helpful discussions. This research was supported by Grant-in-Aid for Scientific Research (B) under grant No. 249008 from the Ministry of Education, Science and Culture.

Appendix I

E: holoenzyme
S: substrate
P: product
ES: complex of substrate and holoenzyme
v: initial reaction rate
V_{max}: maximum reaction rate
K_m: Michaelis constant
$k_{\pm 1,+2}$: rate constant
k_0: molecular activity of enzyme
t: reaction time
E_a: apoenzyme (inactive)
M: metal ion
K: stability constant between enzyme protein and zinc
e_S^λ: absorption coefficient of substrate at λ
e_P^λ: absorption coefficient of product at λ
A^λ: absorbance at λ
l: light path length in the cuvette
$[\ ]_0$: concentration at the condition of initial stage
λ: wavelength

Appendix II

In a system where more than one zinc ion is necessary to attain recovery of enzymatic activity, Eq. 5 should be modified as follows:

i) In the case where enzymatic activity appears for n bindings of zinc ions such as in aminopeptidase:

$$[E] = K_1K_2\cdots K_n[Zn]^n[E_a] \simeq \frac{K_1K_2\cdots K_n[Zn]^n}{1+K_1[Zn]+\cdots+(K_1K_2\cdots K_n[Zn]^n)}\cdot[E_a]_0, \quad (1')$$

$$[P] \approx \frac{K_1K_2\cdots K_n[Zn]^n}{1+K_1[Zn]+\cdots+(K_1K_2\cdots K_n[Zn]^n)}[E_a]_0k_0t. \quad (2')$$

ii) In the case where the molecular activity (k_0) of the enzyme changes in terms of the binding number of zinc ions to the enzyme, such as found in alkaline phosphatase, Eq. 8 should be replaced by

$$[P] \approx \frac{K_1K_2\cdots K_n[Zn]^n}{1+K_1[Zn]+\cdots+(K_1K_2\cdots K_n[Zn]^n)}\{(K_{01}K_1[Zn]) + \cdots + (k_{0n}K_1\cdots K_n[Zn]^n)\}t[E_a]_0. \quad (3')$$

k_{0i}: molecular activity of enzyme when the binding number of zinc ions to enzyme is "i".

K_i: step-wise stability constant, $K_i = \dfrac{[E_aZn_i]}{[E_aZn_{i-1}][Zn]}$. (4')

Electrochemical Behavior of Ferredoxins Adsorbed on Mercury Electrode Surface. Cyclic d.c. and a.c. Voltammetric Studies with Hanging Mercury Drop Electrode

Tokuji IKEDA,* Kazunobu TORIYAMA, and Mitsugi SENDA

Department of Agricultural Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 25, 1978)

The electrochemical behavior of *Clostridium pasteurianum* ferredoxin and spinach ferredoxin was studied by cyclic d.c. and cyclic phase-selective a.c. voltammetry with a hanging mercury drop electrode. An irreversible adsorption of these ferredoxins on the electrode surface is described. In successive cyclic voltage scans both d.c. and a.c. voltammograms of ferredoxins change gradually in both height and form until a steady state is attained, indicating that the ferredoxins adsorbed on the electrode surface decompose to cluster-free ferredoxins. Apoferredoxins give the same voltammograms as the steady state voltammograms of ferredoxins. The steady state voltammograms are assigned to RSH/RSHg redox reaction of the cysteine residues in apoferredoxin. At pH lower than 8 the d.c. waves are explained by an equation for reversible one-electron surface redox reaction. Kinetic parameters of the redox reaction were determined by a.c. voltammetry.

Ferredoxins, iron-sulfur proteins, function as electron carriers in many metabolic reactions.[1] The standard oxidation-reduction potential, E_0', and the stoichiometry of electron equivalents, n', of various ferredoxins have been measured by equilibrium techniques.[2] Attempts to measure the E_0' value directly by polarography have also been made.[3-8] Although the technique may be an advantageous means of studying the oxidation-reduction reaction of ferredoxins, the exact relationship between half-wave potential and E_0' requires further examination. In this study the electrochemical reduction and oxidation of two types of ferredoxins were examined with use of cyclic d.c. and a.c. voltammetry to gain a better understanding of their electrochemical behavior. Here we use the term "cyclic d.c. voltammetry" in place of the ordinary cyclic voltammetry in order to distinguish this technique from "cyclic a.c. voltammetry,"[9] in which alternating voltage of small amplitude is superimposed upon the cyclic sweep voltage applied to the electrode and the alternating currents (both in-phase and out-of-phase components, using a phase-selective amplifier) are measured as a function of the cyclic sweep voltage in both cathodic and anodic sweeps.

Part A. Cyclic d.c. Voltammetry

Experimental

Materials. Clostridium Pasteurianum Ferredoxin (Cl.Fd) and Spinach Ferredoxin (sp.Fd): Ferredoxins from *Clostridium pasteurianum* (ATCC 6013) and spinach were prepared according to the method of Mayhew,[10] the Cl.Fd having an absorption ratio of 0.78 or greater (390/280 nm) and sp.Fd one of 0.45 or greater (420/275 nm). The ferredoxin concentrations of stock solutions were determined spectrophotometrically with molar extinction coefficients of 3.0×10^4 at 390 nm[10] and 9.7×10^3 at 420 nm[11] for Cl.Fd and sp.Fd, respectively. The stock solutions were stored at 4 °C anaerobically.

Apoferredoxin from Clostridium Pasteurianum (apo-Cl.Fd): Iron and acid-labile sulfide were removed from Cl.Fd by treatment of the protein with an acid. Thirty microliters of *ca.* 0.5 mM Cl.Fd was acidified with 30 μl of 0.4 M hydrogen chloride. Hydrogen sulfide evolved was expelled by passing nitrogen gas through the solution. The brown color of ferredoxin disappeared completely after *ca.* 10 min, a white precipitate being formed. The solution was neutralized with 0.4 M sodium hydroxide to dissolve the precipitate and 3 μl of 0.05 M disodium ethylenediaminetetraacetate was added to the solution.

All other chemicals used were highly pure commercial products (Nakarai Chemicals Co., Ltd.). Triply distilled water was used to prepare the electrolysis solution.

Instruments. Cyclic d.c. voltammograms were recorded on a Yanagimoto PE21-TB2S potentiostat with a built-in sweep voltage generator and a Yokogawa X-Y recorder. A Metrohm E410 hanging mercury drop electrode was used, the surface area of the electrode being 0.0187 ± 0.0003 cm^2.

Electrochemical Measurements. All measurements were made with a three-electrode potentiostat. Potentials were measured against a saturated calomel electrode (SCE). Buffer solutions (0.1 M hydrogen chloride–sodium acetate for pH 1.4—4.0, 0.1 M acetic acid–sodium acetate for pH 4.0—5.5, 0.1 M sodium dihydrogenphosphate–disodium hydrogenphosphate for pH 5.5—7.0, 0.1 M hydrogen chloride–tris(hydroxymethyl)aminomethane for pH 7.0—9.2 and 0.1 M glycine–sodium hydroxide for pH 9.2—11.0) were used as the base solution. The ionic strength of the base solution was adjusted to 0.5 mol/kg with sodium chloride. To avoid possible complications associated with the foaming of the solution, 3 ml of the base solution was transferred to the cell and deaerated for *ca.* 10 min by passing nitrogen gas, which had previously been passed through a solution of the same composition as that of the base solution. An aliquot of the stock solution of ferredoxin was then introduced into the base solution with a microsyringe under nitrogen atmosphere. A fresh mercury drop from the hanging mercury drop electrode (HMDE) was exposed to the solution for a given period of time (t_{exp}), while the potential of the HMDE was kept controlled at a constant potential (E_i). The voltage scan was then started from E_i, with a scan rate $v=0.36$ V s^{-1}, unless otherwise stated. All experiments were carried out at 25 °C.

Results

Cl.Fd. Figure 1 shows a typical single sweep voltammogram of 1.2 μM Cl.Fd in pH 6.6 phosphate buffer, which was recorded after $t_{exp}=2$ min at $E_i=-0.1$ V. In addition to a catalytic wave (a presodium wave) at -1.7 V, a peak-shaped wave appeared at -0.57 V. It grew up to a certain limit with increasing concentration of Cl.Fd at a constant exposure time or with increasing exposure time at a constant

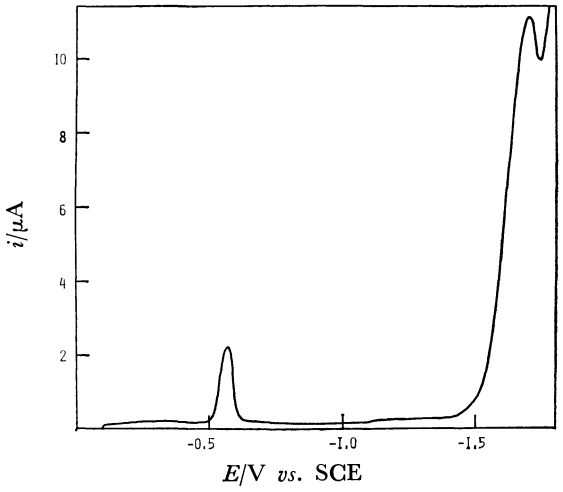

Fig. 1. d.c. voltammogram of 1.2 μM Cl.Fd in pH 6.6 phosphate buffer. Voltage scan was started from $E_i = -0.1$ V after $t_{exp} = 2$ min.

concentration of Cl.Fd, indicating that the wave is due to the Cl.Fd accumulated on the electrode surface. The dependence of peak height, i_p, of the wave on the Cl.Fd concentration, $C_{Cl.Fd}$, is shown in Fig. 2 for two t_{exp} values at pH 6.9. At lower concentrations of Cl.Fd the dependence of i_p on $C_{Cl.Fd}$ is linear, the product $C_{Cl.Fd} \times t_{exp}^{1/2}$ remaining constant for a given i_p value. This is evidence of the diffusion-controlled adsorption of Cl.Fd at the electrode surface, the current being assumed to be proportional to the surface concentration of Cl.Fd.[12-14]

Figure 3 shows cyclic voltammograms for Cl.Fd adsorbed on the HMDE at pH 9.2; the voltammograms were recorded after $t_{exp} = 1$ min at $E_i = -0.1$ V(Fig. 3A) and at -1.1 V (Fig. 3B). When the voltage scan was started from $E_i = -0.1$ V, two cathodic waves (Fig. 3A, I and II) were observed at -0.67 V and -0.78 V, respectively. Upon reversal of the scan at -1.1 V, two anodic waves(Fig. 3A, III and IV) appeared at -0.78 V and -0.63 V, respectively. In the second cycle of the voltage scan between -0.1 V and -1.1 V, the wave IV almost disappeared. In the successive voltage scans wave I decreased in height and finally disappeared, whereas the heights of waves II and III increased slightly until a steady

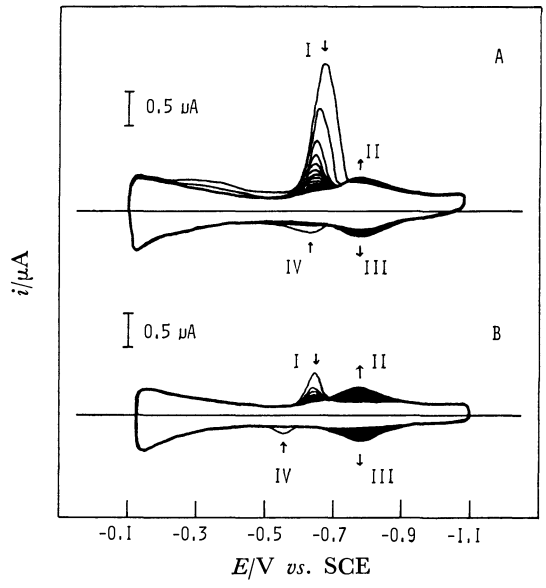

Fig. 3. Cyclic d.c. voltammograms of 1.9 μM Cl.Fd in pH 9.2 glycine buffer. Voltage scan was started from (A) $E_i = -0.1$ V and (B) $E_i = -1.1$ V after $t_{exp} = 1$ min.

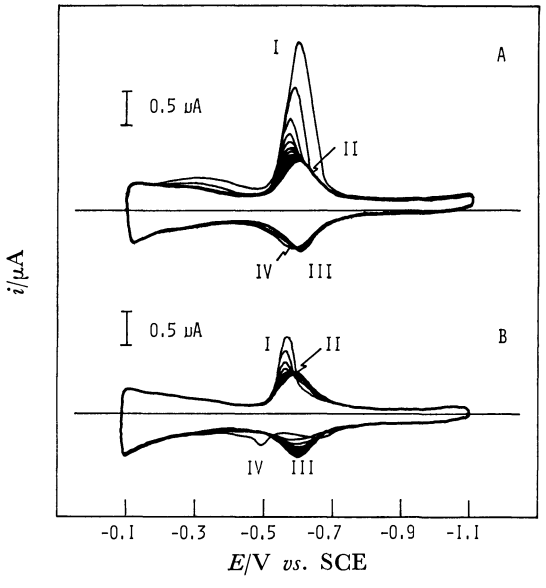

Fig. 4. Cyclic d.c. voltammograms of 1.9 μM Cl.Fd in pH 6.9 phosphate buffer. Voltage scan was started from (A) $E_i = -0.1$ V, (B) $E_i = -1.1$ V after $t_{exp} = 1$ min.

state was attained. When the voltage scan was started from $E_i = -1.1$ V after $t_{exp} = 1$ min (Fig. 3B), a small anodic wave IV was observed and a cathodic wave I in the reverse cathodic scan. However, wave IV disappeared in the second cyclic scan. In successive voltage scans, the height of wave I decreased and waves III (anodic) and II (cathodic) of nearly equal wave height appeared at -0.78 V, their heights increasing until a steady state was attained. The shape and height of the waves II and III at the steady state are independent of E_i.

Figure 4 shows cyclic voltammograms for Cl.Fd adsorbed on the HMDE surface at pH 6.9 after $t_{exp} =$

1 min at E_i=−0.1 V (Fig. 4A) and at −1.1 V (Fig. 4B). The two cathodic waves (I and II) and the two anodic waves (III and IV), though not well separated, changed in height in successive voltage scans in nearly the same way as at pH 9.2, waves II (cathodic) and III (anodic) with identical peak potential of −0.60 V appearing on the cyclic voltammogram in the steady state.

The behavior of successive cyclic voltammograms of Cl.Fd at pH 9.2 and 6.9 indicates that the Cl.Fd adsorbed on the HMDE surface decomposes irreversibly and that waves II and III are due to the redox reaction of the decomposition product. The scan rate dependence of the peak currents, i_p(II) and i_p(III), the peak potentials, E_p^{DC}(II) and E_p^{DC}(III), and the half-peak widths, $\Delta E_{p/2}^{DC}$(II) and $\Delta E_{p/2}^{DC}$(III), of waves II and III at the steady state at pH 6.9 are summarized in Table 1. Both i_p(II) and i_p(III) are proportional to v, the ratio i_p(II)/i_p(III) being unity. E_p^{DC}(II) and E_p^{DC}(III) coincide with each other and are independent of v. The half-peak widths of these waves are 91±2 mV over the scan-rate range 0.09 V s^{-1}—0.36 Vs^{-1}. The results indicate that the reaction corresponding to waves II and III at pH 6.9 is a reversible one-electron surface redox reaction.[15] The pH dependence of E_p^{DC}(II) (=E_p^{DC}(III)) is shown in Fig. 5. E_p^{DC} shifts by −60 mV/pH at pH lower than 8 but more at pH higher than 8. The integrated current at pH 6.9 was calculated to be Q(II)=9.5± 1.0 μC cm^{-2} for wave II and Q(III)=8.0±0.5 μC cm^{-2} for wave III.

Apo-Cl.Fd. Cyclic voltammetry was performed with apo-Cl.Fd solution under experimental conditions similar to those for the native Cl.Fd. When the voltage scan was started from E_i=−1.0 V after t_{exp}=1 min, only waves II and III (Fig. 6A) appeared on the cyclic voltammogram of the first cyclic scan, remaining unchanged on the successive scans. One more cathodic wave, that is wave I in Fig. 6B, was observed when the voltage scan was started from E_i=−0.1 V after t_{exp}=1 min. However the wave almost disappeared in the second cathodic scan. The behavior of waves II and III for apo-Cl.Fd was the same as that of waves II and III for Cl.Fd in the steady state.

Sp.Fd. The same series of experiments were performed with sp.Fd. The cyclic voltammogram for sp.Fd in the steady state is shown in Fig. 7. The scan rate dependence of the peak current, peak potential and half-peak width is summarized in Table 1. The integrated current of the waves was calculated to be Q=3.2±0.4 μC cm^{-2}.

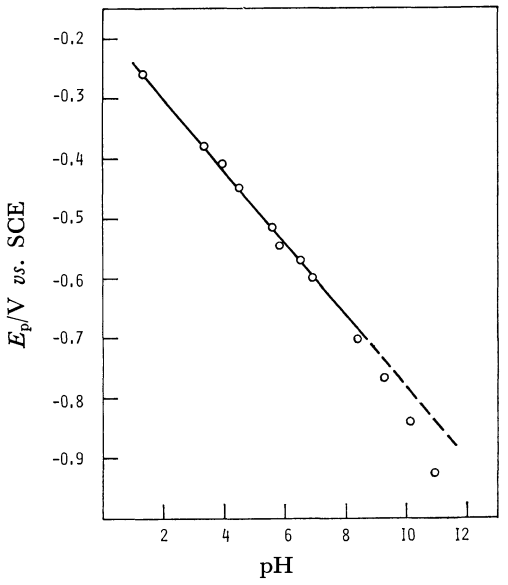

Fig. 5. Dependence of the peak potential, E_p^{DC}(II) (=E_p^{DC}(III)) on pH of the steady-state waves II and III.

Discussion

Adsorption of Ferredoxin on the Electrode Surface. Experimental results give evidence of an irreversible adsorption of ferredoxins on the surface of a mercury electrode. This was confirmed by the following experiment. After Cl.Fd had accumulated at the electrode surface, the electrode was removed from the protein-containing solution and washed with distilled water. The electrode was then placed in the base

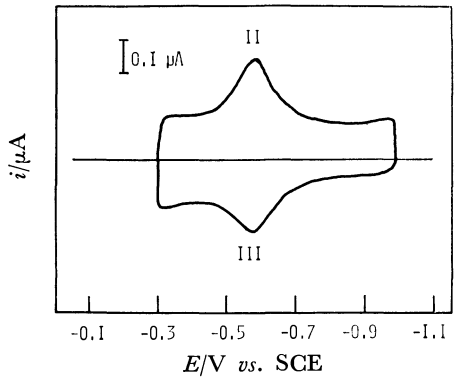

Fig. 7. Cyclic d.c. voltammogram at the steady state for sp.Fd at pH 6.6.

solution and voltammograms were recorded which were found to be the same as those in the case of an ordinary experiment with a solution containing Cl.Fd. Several workers[3,6,16] have suggested the adsorption of ferredoxins on a mercury electrode surface. Experimental results also indicate that the adsorption of ferredoxin is controlled by diffusion; at low concentrations of Cl.Fd $i_p=kq\Gamma=kq2(D_{Cl.Fd}/\pi)^{1/2}\ t_{exp}{}^{1/2}C_{Cl.Fd}$, where k is the proportionality constant, q the surface area of HMDE, Γ the surface concentration of Cl.Fd and $D_{Cl.Fd}$ the diffusion coefficient of Cl.Fd. At high concentrations a maximum current is attained, which can be given by $i_p^{max}=kq\Gamma^{max}$, where Γ^{max} is the maximum surface concentration of adsorbed Cl.Fd. Combining these two equations, we estimated the Γ^{max} value as 1.28×10^{-11} mol cm^{-2}, $D_{Cl.Fd}$ being calculated to be 1.4×10^{-6} cm^2 s^{-1} from the Svedberg equation with $s_{20.w}=1.4$ s, $v=0.63$ cm^3 g^{-1} [17] and $M.W.=6200$.[18] The value of Γ^{max} is in the order of magnitude comparable to that of other proteins.[19]

Waves I and IV. The value of integrated current of wave I was 19—30 μC cm^{-2} which is too large for this wave to be ascribed to the reduction of the biologically active cluster of Cl.Fd adsorbed on the electrode surface. A possible explanation is that the wave is due to the hydrogen evolution reaction catalyzed by the cluster of adsorbed Cl.Fd molecule, which decomposes in successive voltage scans. The large cathodic wave observed with apo-Cl.Fd in the first negative-going scan should be attributed to the residual amount of the active cluster.

The anodic wave IV may correspond to the oxidation of the cluster since it was not observed with apo-Cl.Fd. The corresponding cathodic wave may be concealed by the large cathodic hydrogen evolution current. It is difficult to study the redox reaction of the cluster by the present method.

Waves II and III. Waves II and III attain a steady state in successive voltage scans. Apo-Cl.Fd also gives the same waves as II and III of Cl.Fd in the steady state. The results indicate that waves II and III are due to the redox reaction of apoferredoxin produced by decomposition of the ferredoxin adsorbed on the electrode surface. Kuznetsov *et al.*[16] have also suggested the decomposition of the cluster of ferredoxin and the release of sulfhydryl groups on the electrode surface. The behavior of these waves (Table 1) can be explained by the equation for reversible one-electron surface redox reaction[15]

$$i = (n^2F^2/RT)qvn_c\Gamma^{max}\exp(\varphi)(1+\exp(\varphi))^{-2}, \quad (1)$$

where n is the number of electrons of the redox couple ($n=1$ in the present case), n_c the number of redox couples in one molecule of adsorbed ferredoxin and $\varphi=(nF/RT)(E-E_p^{dc})$. The results together with the pH-dependence of the peak potential indicate that the reversible one-electron wave may be assigned to RSH+Hg=RSHg+H$^+$+e$^-$. By substituting i_p values of Cl.Fd (Table 1) and $\Gamma^{max}=1.28\times10^{-11}$ mol cm^{-2} into Eq. 1 at $E=E_p^{dc}$, n_c was estimated to be 7.3±0.6. n_c was estimated to be 7.3±1.0 from the equation $Q=n_cF\Gamma^{max}$ with $Q=(1/2)(9.5+8.0)=8.7\pm1.0$ μC cm^{-2} and $\Gamma^{max}=1.28\times10^{-11}$ mol cm^{-2}. These n_c value are approximately 8, the number of cysteine residues of apo-Cl.Fd molecule. In the case of sp.Fd, n_c was estimated to be 5.2 with $Q=3.2$ μC cm^{-2} and $\Gamma^{max}=(1/2)1.28\times10^{-11}$ mol cm^{-2}, which is 5, the number of cysteine residues of apo-sp.Fd molecule. The redox mechanism corresponding to waves II and III can be assigned to (Apo-Fd(SH)$_{n_c}$)$_{ad}$+n_cHg⇌(Apo-Fd(SHg)$_{n_c}$)$_{ad}$+n_cH$^+$+n_ce$^-$, where $n_c=8$ for apo-Cl.Fd and 5 for apo-sp.Fd, at pH lower than 8.

At pH higher than 8 waves II and III become drawn out. Their wave heights decrease, the pH-dependence of the peak potential deviating from −60 mV/pH line. This indicates an involved nature of the surface redox reaction in basic solution Brown and Anson[20] have explained similar nonideal behavior of the cyclic voltammograms for reactions irreversibly attached to the surface of graphite electrode by introducing a nonideality parameter r; the surface activities used in place of the surface concentration are dependent on this parameter Another possible explanation is that the RSH/RSHg couples in apoferredoxin molecule may have different oxidation-reduction potentials which are distributed around the peak potential of the waves. Shift of the oxidation-reduction potentials associated with possible conformational changes of apoferredoxin adsorbed on the electrode surface should be taken into account.

Part B. Cyclic a.c. Voltammetry

Experimental

Experiments were performed with a Yanagimoto PE21-TB2S potentiostat with a built-in sweep voltage generator, an NF model LI572-B lock-in amplifier and a Yokogawa 3077 X-Y recorder. The amplitude of superimposed alternating voltage was adjusted to 10 mV (peak to peak) throughout the frequency range 100—700 Hz. Both resistive (in-phase) and capacitive (out-of-phase) components of the alternating currents (a.c.) were recorded against cyclic (d.c.) sweep voltage (usually $v=0.1$ V s^{-1}) applied to the HMDE For further details of the electrochemical measurements, *cf.* reference in part A.

Results

Figure 8 shows a typical cyclic in-phase a.c. voltammogram for Cl.Fd adsorbed on the HMDE surface

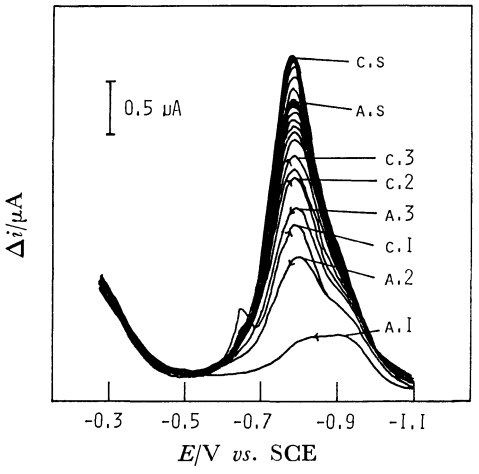

Fig. 8. Cyclic in-phase a.c. voltammogram of 1.9 μM Cl.Fd in pH 9.2 glycine buffer at f=500 Hz. d.c. voltage scan was started from E_i=−1.1 V after t_{exp}= 1 min. A1,A2,A3: Voltammograms of first, second and third anodic scan, C1,C2,C3: voltammograms of first, second and third cathodic scan and AS and CS: steady state voltammograms of positive-going (anodic) and negative-going (cathodic) scan, respectively.

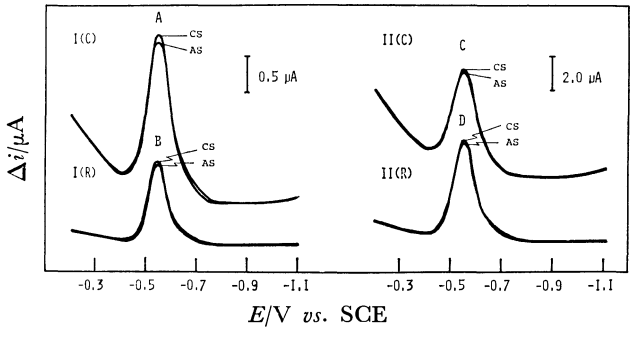

Fig. 9. Cyclic a.c. voltammograms at the steady state for Cl.Fd at pH 5.9. I(C) and I(R): Out-of-phase and in-phase component at f=100 Hz, II(C) and II(R): out-of-phase and in-phase component at f= 500 Hz. AS and CS show voltammograms of positive-going and negative-going scan, respectively.

at pH 9.2. A saturation coverage of the electrode surface with Cl.Fd was attained by exposing the electrode to the solution for one minute at E_i=−1.1 V, the voltammogram then being recorded. In the first positive-going scan a small a.c. wave appeared in the potential region −0.70 V——1.0 V. Upon reversal of the scan at −0.27 V, two a.c. waves were observed at −0.65 V and −0.78 V. The wave at −0.65 V disappeared in successive voltage scans between −0.27 V and −1.1 V, whereas the wave at −0.78 V attained a steady state in the same successive scans. Apo-Cl.Fd gave essentially the same voltammogram as that of Cl.Fd in the steady state. The results indicate that the a.c. waves of Cl.Fd in the steady state are due to the redox reaction of apo-Cl.Fd adsorbed on the electrode surface.

Figure 9 shows the cyclic a.c. voltammograms in the steady state for the adsorbed Cl.Fd at pH 5.9 at two a.c. frequencies. The peak potentials, E_p^{AC}, of the four a.c. waves (A, B, C, and D) are independent

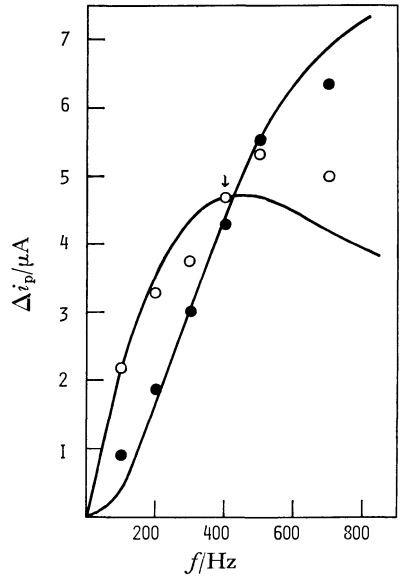

Fig. 10. Dependence of the a.c. peak currents on the a.c. frequency at pH 5.9. ○: Out-of-phase component and ●: in-phase component.

of a.c. frequency, coinciding with each other and with the peak potential of waves II and III of d.c. cyclic voltammogram at the same pH (Fig. 5). On the other hand, the peak height, Δi_p, and half-peak width, $\Delta E_{p/2}^{AC}$, of both in-phase and out-of-phase components are dependent on a.c. frequency (Fig. 10 and Table 2).

In basic solution of pH higher than 8, the a.c. voltammograms become drawn-out and decrease in height.

Discussion

According to theory of cyclic a.c. voltammetry[21] of a redox couple, ox/red, tightly adsorbed on the electrode surface, the capacitive (out-of-phase) and resistive (in-phase) components of the amplitude of a.c. currents, Δi(C) and Δi(R), are given by

$$\left.\begin{aligned}\Delta i(\mathrm{C}) &= \frac{mnF^2qn_c\Gamma_t 2\pi f\Delta E}{RT}\times\frac{\exp(\varphi)}{(1+\exp(\varphi))^2}\times\frac{1}{((2\pi f/(\vec{k}+\overleftarrow{k}))^2+1)}\\ \Delta i(\mathrm{R}) &= \frac{mnF^2qn_c\Gamma_t 2\pi f\Delta E}{RT}\times\frac{\exp(\varphi)}{(1+\exp(\varphi))^2}\times\frac{2\pi f/(\vec{k}+\overleftarrow{k})}{((2\pi f/(\vec{k}+\overleftarrow{k}))^2+1)}\end{aligned}\right\}\quad(2)$$

Here it is assumed that the redox reaction is expressed by a simple Butler-type equation $i/nFq=\overleftarrow{k}n_c\Gamma_{red}-\vec{k}n_c\Gamma_{ox}$ with $\overleftarrow{k}=k_s\exp((1-\alpha)\varphi)$, $\vec{k}=k_s\exp(-\alpha\varphi)$ and $\varphi=(nF/RT)(E^{DC}-E_0)$ and that the redox reaction is d.c.-voltammetrically reversible; $k_s/(nFv/4RT)\gg 1$. Γ_j is the surface concentration of j (j=ox and red, and $\Gamma_t=\Gamma_{ox}+\Gamma_{red}$), k_s the standard rate constant, α the transfer coefficient, m the proportionality constant,[21] in which the change of electrode charge associated with the change of Γ_j as well as n is involved, ΔE and f are the amplitude and frequency of superimposed alternating

pH	k_s[a]/10^2 s^{-1}
4.4	12.0±5.0[b]
5.9	13.4±3.7[b]
6.9	15.2±1.7[b]
6.9	10.1±3.1[c]
6.6	13.6±3.2[d]

a) Average value over the a.c. frequencies between 100 Hz and 700 Hz. b) Cl.Fd at the steady state. c) Apo-Cl.Fd. d) sp.Fd at the steady state.

voltage, respectively. At $E=E_0$, the ratio $\Delta i(\mathrm{R})/\Delta i(\mathrm{C})$ is given by

$$(\Delta i(\mathrm{R}))_{E=E_0}/(\Delta i(\mathrm{C}))_{E=E_0} = 2\pi f/2k_s \quad (3)$$

so that the k_s value can be determined experimentally provided that E_0 is known. As decribed above E_p^{AC} is independent of f and coincides with E_p^{DC} of corresponding *reversible* d.c. voltammograms, indicating that $E_p^{AC}=E_p^{DC}=E_0$ and α is at least not much different from 0.5. Application of Eq. 3 to experimental data, such as those shown in Fig. 10 gives k_s values summarized in Table 3. Solid lines in Fig. 10 are drawn by Eq. 2 at $E=E_0$ using $k_s=13.4\times10^2$ s^{-1} and $\Delta i_p(\mathrm{C})=4.7$ μA at 400 Hz. Values of $\Delta E_{p/2}^{AC}$ as calculated from Eq. 2 by assuming $n=1$ and $\alpha=0.5$ are also given in Table 2. Apparent agreement between theory and experiment is good in spite of the very simplified model of charge transfer kinetics. Kinetic study gives information on the protonation mechanism associated with the charge transfer, RSH+Hg=RSHg+H$^+$+e$^-$. When a very rapid (*i.e.* reversible) proton transfer to oxidized form is followed by the charge transfer as

$$\begin{aligned} &\mathrm{RSHg} + \mathrm{H^+} = (\mathrm{RSHg})\mathrm{H^+}, && K_\mathrm{I} \\ &(\mathrm{RSHg})\mathrm{H^+} + \mathrm{e^-} = \mathrm{RSH} + \mathrm{Hg}, && k_{s0\mathrm{I}} \end{aligned} \quad (\mathrm{I})$$

the "measured" or apparent standard rate constant k_s is given by

$$k_s = k_{s0\mathrm{I}}(1+K_\mathrm{I}/(\mathrm{H^+}))^{-(1-\alpha)} \quad (4)$$

where $k_{s0\mathrm{I}}$ is the standard rate constant and K_I the dissociation constant of (I). When the charge transfer is followed by a very rapid proton transfer to reduced form as

$$\begin{aligned} &\mathrm{RSHg} + \mathrm{e^-} = \mathrm{RS^-} + \mathrm{Hg}, && k_{s0\mathrm{II}} \\ &\mathrm{RS^-} + \mathrm{H^+} = \mathrm{RSH}, && K_\mathrm{II} \end{aligned} \quad (\mathrm{II})$$

the apparent standard rate constant k_s is given by

$$k_s = k_{s0\mathrm{II}}(1+(\mathrm{H^+})/K_\mathrm{II})^{-\alpha} \quad (5)$$

where $k_{s0\mathrm{II}}$ is the standard rate constant and K_II the dissociation constant of (II). k_s tends to increase with increasing pH (see Table 3). This supports mechanism (II). However, the change of k_s with pH is too small to be explained by Eq. 5. In view of the precision of determination of k_s value no conclusive statement can be given at present.

In a.c. voltammetry a slight difference in height between the waves of negative-going and positive-going voltage scan were observed (Fig. 9). This can be explained by assuming that there are two conformations I and II of adsorbed apoferredoxins each for oxidized form, Apo-Fd(SHg)$_{n_c}$, and reduced form, Apo-Fd(SH)$_{n_c}$,

$$\begin{array}{ccc} (\text{Apo-Fd(SHg)}_{n_c})_\mathrm{I} & \overset{n_c}{\rightleftharpoons} & (\text{Apo-Fd(SH)}_{n_c})_\mathrm{I} \\ \downarrow\uparrow & & \downarrow\uparrow \\ (\text{Apo-Fd(SHg)}_{n_c})_\mathrm{II} & \overset{n_c}{\rightleftharpoons} & (\text{Apo-Fd(SH)}_{n_c})_\mathrm{II}. \end{array}$$

The waves of negative-going and positive-going scan can be assigned to

$$(\text{Apo-Fd(SHg)}_{n_c})_\mathrm{I} \overset{n_c}{\rightleftharpoons} (\text{Apo-Fd(SH)}_{n_c})_\mathrm{I} \rightleftharpoons (\text{Apo-Fd(SH)}_{n_c})_\mathrm{II}$$

and

$$(\text{Apo-Fd(SH)}_{n_c})_\mathrm{II} \overset{n_c}{\rightleftharpoons} (\text{Apo-Fd(SHg)}_{n_c})_\mathrm{II} \rightleftharpoons (\text{Apo-Fd(SHg)}_{n_c})_\mathrm{I},$$

respectively. The difference between the two peak heights should be due to the difference between the apparant standard rate constants of the two processes.

We are grateful to Associate Professor Yoshiki Tani and Dr. Sakae Shimizu for help in growing the Clostridium pasteurianum and to Dr. Masaaki Takahashi for help in the purification of spinach ferredoxin. This work was supported by a Grant-in-Aid from the Ministry of Education.

Substituent Effect in the Ionization of *cis*-2-Substituted 1-Cyclopropanecarboxylic Acids

Yoshiaki KUSUYAMA

Department of Chemistry, Faculty of Education, Wakayama University, Masagocho 1-1, Wakayama 640

(Received August 26, 1978)

Ten *cis*-2-substituted 1-cyclopropanecarboxylic acids (substituents: H, CH_3, C_6H_5, CH_3O, C_2H_5O, Cl, Br, CH_3CO, CH_3OCO, and C_2H_5OCO) were prepared, and their pK_a values were determined in water at 25 °C, along with those of the *trans*-2-chloro and 2-methoxy derivatives. The pK_a values for cis isomers are somewhat larger than those for the corresponding trans isomers, except for the chloro and bromo derivatives. The substituent effects obtained were in the usual order in the sense of the electronic effects, except for the phenyl group, which produced a decrease in acidity relative to the unsubstituted acid. It was shown that the carbon-13 chemical shifts for the methylene carbon of the ethyl group in the ethyl *cis*-2-substituted 1-cyclopropanecarboxylate obtained in deuteriochloroform gave a reasonable linear relation with the pK_a(*cis*) values.

It is well established that the C–C bonds of cyclopropane ring have π double-bond character[1] and can extend the chain of conjugation when a cyclopropane ring is directly attached to a π system of bonds.[2] The degree of the contributions of the conjugative effect of the cyclopropane ring has been estimated by several workers.[3–6] The degree of the transmission of the electronic effects through the cyclopropane ring, however, is still uncertain, since conflicting results have been reported. For example, the effective transmission or a greater polarizability of the trans system was indicated by spectroscopic measurements[6,7] and by the chemical reactivities,[8] including the ionization of 2-phenyl-cyclopropanecarboxylic acids.[9] On the other hand, the alkaline hydrolysis of ethyl 2-phenyl-1-cyclopropanecarboxylates afforded larger Hammett's ρ values for cis isomers than for trans isomers.[10] Thus, the abilities of the cis isomer relative to the trans isomer in 1,2-disubstituted cyclopropane in transmitting electronic effects have been a continued subject of controversy.[8,11]

In attempt to resolve the contradiction in the reported results on transmitting polar effects through cyclopropylene, it appeared to be of interest to examine the effects of substituents in the ionization of 2-substituted 1-cyclopropanecarboxylic acids. In a previous paper,[12] the pK_a values of *trans*-2-substituted 1-cyclopropanecarboxylic acids and their linear relation with σ_m were reported. A study of the substituent effect in the pK_a values of *cis*-2-substituted 1-cyclopropanecarboxylic acids and in the carbon-13 chemical shifts of the methylene carbon of the ethyl group in ethyl *cis*-2-substituted 1-cyclopropanecarboxylates has been undertaken in the present study.

The system is a very interesting one from another point of view. The rigidity of the cyclopropane ring offers an interesting tool for elucidating the mechanistic problems in the acidity-structure relationship where substituents are in a close proximity to the carboxyl group. In this field of chemistry[13,14] less progress has been reported than in those concerning the effects of remote substituent groups, which have been well explained by both inductive (including the effects through both the field and bonds) and resonance effects. It appears that the data reported herein will provide useful information in order to elucidate interaction mechanisms between the proximate substituent and the carboxyl group.

Results and Discussion

Unsubstituted,[15] *cis*-2-methyl-,[13a] and *cis*-2-phenyl-1-cyclopropanecarboxylic acids[16] were synthesized by the methods described in the literature. Other substituted cyclopropanecarboxylic acids were obtained by the hydrolysis of the respective ethyl esters prepared by the appropriate methods. The cis isomers of ethyl esters were separated conveniently by a combination of fractional distillation and preparative GPLC. Cis and trans mixtures of ethyl 2-methoxy- and 2-ethoxy-1-cyclopropanecarboxylate were synthesized by the copper(I)-catalyzed decomposition of ethyl diazoacetate in methyl vinyl ether and ethyl vinyl ether respectively.[12] By using the method of McCoy,[17] diethyl and dimethyl 1,2-cyclopropanedicarboxylates were obtained. The remaining derivatives were prepared by the routes shown in the following scheme:

C_6H_5	0.12	−0.27	0.38

The pK_a values measured in water at 25 °C are listed in Table 1. The reproducibilities of the repeated runs are less than 0.01 pK_a unit except for the alkoxycarbonyls and the phenyl group (0.2 pK_a unit). This accuracy is considered to be sufficient for us to discuss the substituent effects. The values determined here for unsubstituted and *cis*-2-methyl derivatives showed a good agreement with those published by McCoy, within the limits of experimental error.[13a]

It is convenient to use the $\Delta pK_a^H(pK_a^X - pK_a^H)$ and $\Delta pK_a^{ct}(pK_{a_{cis}} - pK_{a_{trans}})$ values in discussing the substituent effects in comparison with various systems. These values are summarized in Table 2.

Since carbon-13 NMR chemical shifts are sensitive to changes in the electron density[18] and the stereochemical relationship of atoms in a molecule,[18,19] the application of this spectroscopic method to the methylene carbon of the ethyl group in ethyl 2-substituted 1-cyclopropanecarboxylates would provide additional insight into the substituent effect on pK_a values(*cis*) obtained here. Therefore, the substituent-induced chemical shifts(SCS)[20] for this carbon were determined under conditions essentially corresponding to an infinitive dilution in deuteriochloroform; the results are listed in Table 3, along with those of trans derivatives.[12] Both the cis and trans carbons showed "normal" substituent effects.

Table 3. ^{13}C Chemical shifts[a] for the methylene carbons of the ethyl group in ethyl 2-substituted cyclopropanecarboxylates in deuteriochloroform

Substituent	$\delta(cis)$[b,c]	$\delta(trans)$[d]	$\delta_{(cis)} - \delta_{(trans)}$

a) ppm from TMS as the internal standard. The errors are at least ±0.1 ppm. b) To be published in detail, along with the chemical shifts of cyclopropane-ring carbons. c) Measured on a Hitachi Perkin-Elmer R-22 spectrometer, with 22.6 MHz in the FT mode. d) Y. Kusuyama, *Bull. Chem. Soc. Jpn.*, **50**, 1784 (1977).

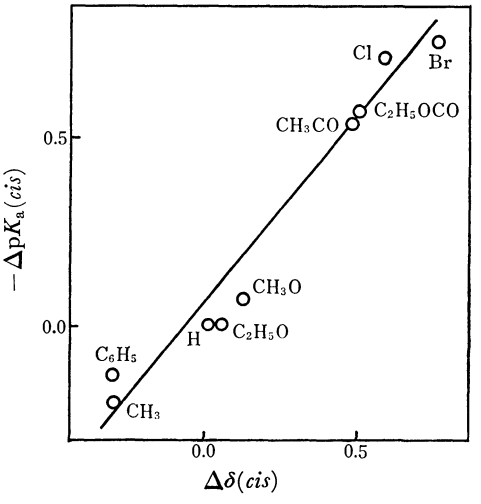

Fig. 1. Plots of ΔpK_a values for *cis*-2-substituted 1-cyclopropanecarboxylic acids at 25 °C in water *vs.* substituent induced ^{13}C chemical shifts of the methylene carbons of ethyl group in ethyl 2-substituted 1-cyclopropanecarboxylates.

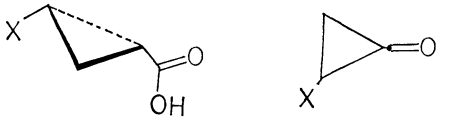
The general trend of the substituent effects obtained for $pK_a(cis)$ is similar to those in such 2-substituted cyclopropane systems[6,12,13a,21] as 2-substituted 1,2-dimethyl-1-cyclopropanecarboxylic acids; they may be explained by substituent electronic effects except for the case of the phenyl group.

The $\Delta pK_a(cis)$ values showed a good linear relation with the $\Delta\delta(cis)$ values (Fig. 1). Therefore, it is reasonable to consider that the special desolvation effect by the proximate *cis*-2-substituents does not contribute to the pK_a values. In the case of 2-substituted acrylic acids, appreciable contributions of the desolvation effect to the dissociation of cis isomers have been reported.[13d]

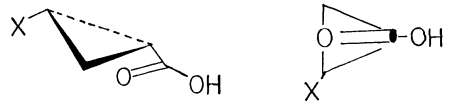
$\Delta pK_a(cis)$ values do not afford a linear relation with those of *o*-substituted benzoic acid, where the steric

inhibition of resonance between the benzene ring and the carboxyl group by the *o*-substituents causes a acid-strengthening effect relative to *p*-substituted benzoic acids.

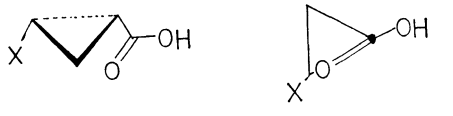
The cyclopropane ring is capable of overlaping with an adjacent p orbital of the substituents at the maximum in the *s-trans* or *s-cis* conformation.[6] In cyclopropanecarboxylic acid, the preferred conformation might be the *s-cis* conformer,[6] where the steric repulsion between the spherical *cis*-2-substituent and the carboxyl group is minor compared to those in ortho-substituted benzoic acids.[13c,22] Thus, spherical substituents would not prevent the resonance interaction between the cyclopropane ring and the carboxyl group. The acid-weakening effect of the *cis*-2-methyl group clearly



s-trans



s-cis



gauche

showed the same direction as that observed in the trans isomer. Moreover, it may be thought that the steric inhibition of resonance is not of major importance for chloro and bromo derivatives, although for these substituents the same acidity as in the cis and trans series respectively resulted from the compensation of contributing factors. Substituents with p-orbitals tend to have the maximum overlap with the cyclopropane ring in the bisected conformation. In *cis*-2-acetyl, methoxycarbonyl- and ethoxycarbonyl-1-cyclopropanecarboxylic acids, the steric repulsion between the substituent and the carbonyl group of the carboxyl group increases and prevents cis substituents from having the maximum overlap with the cyclopropane ring relative to the corresponding trans isomer. Such substituents could lead in the direction of acid weakening relative to the trans isomer (Table 2).

The pK_a values for alkoxy groups and phenyl group are quite high relative to that of the parent compound and the corresponding trans derivatives, if they are considered only in terms of normal electronic substituent effects. The origin for this phenomenon can not be explained clearly at the present time. Only the phenyl group deviated appreciably in the $\Delta\delta(trans)$-$\Delta\delta(cis)$ plots to the high field from the regression line (Fig. 2), while no significant difference in the plots was detected for alkoxy groups. It is considered that the methylene carbon of the ethyl group is more deshielded by the proximate phenyl group in the cis isomer.

The substituent effects can generally be analysed

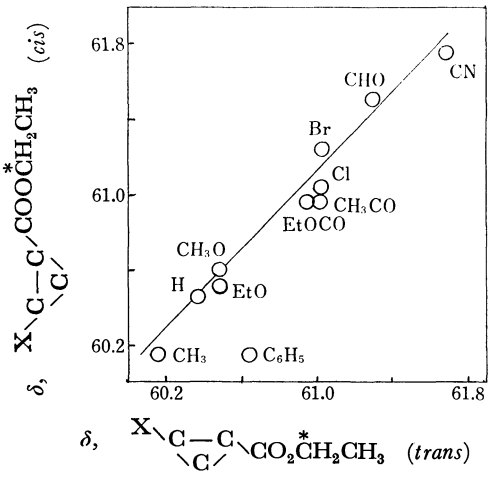


Fig. 2. Comparison of substituent-induced ^{13}C chemical shifts of the methylene carbons of ethyl group in ethyl 2-substituted 1-cyclopropanecarboxylates.

TABLE 4. THE SUBSTITUENT EFFECTS (ΔpK_a VALUES) OF METHOXYCARBONYL AND BROMINE IN THE *cis*-2-SUBSTITUTED CYCLOPROPYL FRAMEWORK

	(I)	(II)	(III)
H	0.00	0.00	0.00
CH_3OCO	−0.61	−1.019	−0.912
Br	−0.74	−1.276	−0.851

by the use of the linear free-energy relationship if only the electronic effect operates. The pK_a values for the trans series were excellently correlated by σ_m (correlation coefficient: 0.998; ρ: 1.99), indicating an appreciable contribution of the resonance effect.[12] The plots of the $\Delta pK_a(cis)$ against the substituent constants, σ^0, σ_p, and σ_I, failed to give a good linear relationship. The correlation coefficients proved to be from 0.83 to 0.89. A rather good correlation with the ρ value of 2.09 was obtained by means of σ_m with the correlation coefficient of 0.981. Although this correlation is not an excellent one, it appears that the special proximity effect is not of major importance in the dissociation of *cis*-2-substituted 1-cyclopropanecarboxylic acid.

In the series of *cis*-2-substituted 1-cyclopropanecarboxylic acids (I), the 2-substituted 1,2-dimethyl-1-cyclopropanecarboxylic acids (II), and 5-substituted bicyclo-[3.1.0]hexane-1-carboxylic acids (III)[14] effects of substituents (the values for methoxycarbonyl and bromo were available for comparison) increase in the order of I<III<II (Table 4), the same as the increasing order of the steric bulk of alkyl groups located behind the carboxyl group (hydrogen < trimethylene < two methyl groups). This order is also the same as that for the pK_a values for the parent acid of each series. Two explanations are possible for the phenomenon: (1) Bulky alkyl groups effectively desolvate the carb-

oxylate anion. The negative charge on the carboxylate does not disperse, though; accordingly, the electron density increases. (2) Alkyl groups shorten the distance between the substituent and the carboxyl group and increase the contribution of the field effect.

Experimental

The boiling points and melting points are uncorrected. The melting points were determined on a Yanaco Mp hot-stage melting-point apparatus. The ^{1}H NMR spectra were obtained on a JEOL JNM-C-60 HL spectrometer (60 MHz) and were reported in δ values relative to the internal TMS. The GLC analyses were carried out on a Yanaco GCG 550T, using a 1-m column of Silicone DC 550 or Silicone XF 1150. Preparative scale GLC separations were performed on a Yanaco G 80 aparatus equipped with an AP 11 collector.

The structure assignments for the geometrical isomers of alkyl 2-substituted 1-cyclopropanecarboxylates were made on the basis of the ^{1}H NMR spectra of ring protons by means of shift reagents, based on the generalization that the tendency of the shift of the signals of cis protons to carbonyl is larger than that of the shift of the trans protons.[23] The cis and trans isomers of alkyl 2-substituted 1-cyclopropanecarboxylates were well separated by GLC, and the cis isomer always showed a longer retention time than that of the corresponding trans isomer.

Ethyl cis-*2-Methoxy-1-cyclopropanecarboxylate.* The title compound was isolated by fractional distillation and by making two passes on the column (silicone DC 550 and silicone XF 1150) from a mixture of cis and trans isomers obtained by the reaction of ethyl diazoacetate with methyl vinyl ether.[12] Bp 81 °C/30 Torr, NMR (CCl_4) δ 0.75—1.75 (3H, m, ring), 1.24 (3H, t, J=8 Hz, CCH_3), 3.22 (3H, s, CH_3O), 3.23—3.65 (1H, m, ring), 4.05 (2H, q, J=8 Hz, CO_2CH_2C). Found: C, 58.72; H, 8.07%. Calcd: C, 58.31; H, 8.39%.

cis-*2-Methoxy-1-cyclopropanecarboxylic Acid.* Ethyl *cis*-2-methoxy-1-cyclopropanecarboxylate (1.3 g) was hydrolyzed by heating (40 °C) with sodium hydroxide (0.4 g) in 5 ml of water. After acidification to pH 3, extraction with ether, and the evaporation of the ether, *cis*-2-methoxy-1-cyclopropanecarboxylic acid was purified by short-column distillation; 0.3 g; bp 105 °C/10 Torr. NMR ($CDCl_3$) δ 0.90—2.70 (3H, m, ring), 3.34 (3H, t, J=7 Hz, CH_3), 3.30—3.7 (1H, m, ring, OCH), 7.75 (1H, s, OH). Found: C, 50.45; H, 7.55%. Calcd: C, 51.70; H, 6.94%.

Ethyl cis-*2-Ethoxy-1-cyclopropanecarboxylate.* The procedure used was the same as that employed above for the methoxy derivative; bp 103 °C/33 Torr. NMR (CCl_4) δ 0.7—1.75 (3H, m, ring), 1.10 (3H, t, J=8 Hz, $COCH_3$), 1.25 (3H, t, J=7 Hz, $COOCH_3$), 3.10—3.70 (3H, m, two methylene protons of the ethoxy group and one ring proton). Found: C, 60.76; H, 9.42%. Calcd: C, 60.74; H, 8.92%.

cis-*2-Ethoxy-1-cyclopropanecarboxylic Acid.* This compound was obtained by the alkaline hydrolysis of the corresponding ethyl ester; bp 135 °C/17 Torr. NMR ($CDCl_3$) δ 0.95—2.70 (3H, m, ring), 1.15 (3H, t, J=7 Hz, CH_3), 3.20—3.80 (3H, m, ring OCH and CH_2 of ethyl group) Found: C, 54.30; H, 7.86%. Calcd: C, 55.37; H, 7.74%.

Dimethyl and Diethyl cis-*1,2-Cyclopropanedicarboxylates.* These two esters were separated from mixtures[17] of the corresponding geometrical isomers. Dimethyl *cis*-1,2-cyclopropanedicarboxylate: bp 84 °C/4 Torr, 146—148 °C/45 Torr, lit, 110 °C/3 Torr.[24] Diethyl *cis*-1,2-cyclopropanedicarboxylate. Bp 138 °C/27 Torr, lit, bp 83—84 °C/1 Torr,[25] 124 °C/14 Torr.[24]

cis-*2-Methoxycarbonyl-1-cyclopropanecarboxylic Acid.* The alkaline hydrolysis[26] of dimethyl 1,2-cyclopropanedicarboxylate afforded *cis*-2-methoxycarbonyl-1-cyclopropanecarboxylic acid in a 30% yield; bp 147—148 °C/4.5 Torr, lit, 160 °C/3 Torr.[24]

cis-*2-Ethoxycarbonyl-1-cyclopropanecarboxylic Acid.* This compound was obtained by the alkaline hydrolysis of diethyl *cis*-1,2-cyclopropanedicarboxylate; bp 130—131 °C/3.5 Torr.

cis-*2-Ethoxycarbonyl-1-cyclopropanecarbonyl Chloride.* The treatment of *cis*-2-methoxycarbonyl-1-cyclopropanecarboxylic acid (9 g) with thionyl chloride (12 g) and subsequent distillation afforded the title compound (9 g); bp 84 °C/4 Torr. NMR (CCl_4) δ 1.00—2.00 (2H, m, ring CH_2), 1.25 (3H, t, J=7 Hz, CH_2 of the ethyl group).

Ethyl cis-*2-Acetyl-1-cyclopropanecarboxylate. A.* To dimethyl cadmium (*ca.* 0.05 mol) in benzene we added, drop by drop, 9 g (0.05 mol) of *cis*-2-ethoxycarbonyl-1-cyclopropanecarbonyl chloride in 10 ml of benzene. After a routine treatment, 3 g of crude ethyl *cis*-2-acetyl-1-cyclopropanecarboxylate were obtained. To this we then added 3 ml of water and stirred the mixture vigorously for 10 min. The organic layer was then separated and purified by distillation; 2 g; bp 95 °C/7 Torr.

Ethyl cis-*2-Acetyl-1-cyclopropanecarboxylate. B.* To a stirred mixture of 100 g of methyl vinyl ketone and 1 g of anhydrous copper(I) sulfate in 50 ml of hexane at 40 °C, 100 g of ethyl diazoacetate were added. After several minutes, the reaction took place suddenly. After the reaction was complete, the mixture was filtered and carefully distilled at atmospheric pressure in order to remove the excess methyl vinyl ketone and hexane. The residue was distilled *in vacuo* to yield 10 g of crude products; bp 70—88 °C/5.5 Torr. The fractional distillation afforded 3 g of the title compound, including 20% of impurities. Treatment with 2 ml of 0.5 M NaOH and subsequent GLC operation gave a pure material which showed essentially the same retention time in GLC and the same NMR spectrum as has been obtained by Method A.

cis-*2-Acetyl-1-cyclopropanecarboxylic Acid.* Ethyl *cis*-2-acetyl-1-cyclopropanecarboxylate (1 g) was hydrolyzed by heating (40 °C) with sodium hydroxide (0.24 g) in 6 ml of 50% ethanol to yield, after a routine treatment, *cis*-2-acetyl-1-cyclopropanecarboxylic acid (0.4 g); bp 143 °C/4 Torr. NMR ($CDCl_3$) δ 1.10—2.62 (m, 4H, ring), 2.24 (1H, s, CH_3), 8.30 (1H, s, OH). Found: C, 54.86; H, 6.62%. Calcd: C, 56.24; H, 6.30%.

1,1-Dichloro-2-vinylcyclopropane. This compound was prepared by adding potassium *t*-butoxide to a solution of 1,3-butadiene and chloroform and by a subsequent routine treatment,[27] bp 123—125 °C, lit, 122.5 °C/730 Torr.[28]

2,2-Dichloro-1-cyclopropanecarboxylic Acid. The oxidation of 1,1-dichloro-2-vinylcyclopropane with potassium permanganate in acetone gave a 2,2-dichloro-1-cyclopropanecarboxylic acid,[29] bp 92 °C/6 Torr, mp 74—75 °C, lit, mp 75—76 °C.[28]

Methyl 2,2-Dichloro-1-cyclopropanecarboxylate. This compound was obtained by the esterification of 2,2-dichloro-1-cyclopropanecarboxylic acid with methanol and sulfuric acid; bp 79 °C/23 Torr. NMR (CCl_4) δ 1.70—2.21 (2H, m, CH_2), 2.4—2.75 (1H, m), 3.76 (3H, s, CH_3).

Methyl cis-*2-Chloro-1-cyclopropanecarboxylate.* A mixture of 22 g (0.1 mol) of methyl 2,2-dichlorocyclopropane-carboxylate, 37 g (0.13 mol) of tributyltin hydride, and 1 g of AIBN was heated to about 90 °C. A vigorous reaction took place. After the mixture has then cooled to room temperature, cis and trans methyl 2-chloro-1-cyclopropane-carboxylate were obtained by fractional distillation through a small Widmer column; 8 g; bp 65—80 °C/33 Torr. A pure cis

isomer was obtained by a semi-preparative GLC operation; bp 100 °C/38 Torr. NMR (CCl_4) δ 1.10—1.68 (2H, m, CH_2), 1.73—2.15 (1H, m, CHCO), 3.00—3.45 (1H, m, CHCl), 3.70 (3H, s, CH_3). Ethyl *cis*-2-chloro-1-cyclopropanecarboxylate was prepared by the procedure described above for the methyl ester. NMR (CCl_4) δ 1.10—1.65 (2H, m, CH_2 of ring), 1.31 (3H, t, J=7 Hz, CH_3), 1.73—2.08 (1H, m, CHCO), 3.11—3.42 (1H, m, CHCl), 4.06 (2H, q, J=7 Hz, CH_2 of the ethyl group). Found: C, 48.75; H, 5.78%. Calcd: C, 48.52; H, 6.06%.

cis-*2-Chloro-1-cyclopropanecarboxylic Acid.* Ethyl *cis*-2-chloro-1-cyclopropanecarboxylate (1.1 g) was saponified by stirring with 0.4 g of sodium hydroxide in 6 ml of 30% ethanol to yield, after acidification, 0.7 g of *cis*-2-chloro-1-cyclopropanecarboxylic acid; bp 108—110 °C/5 Torr, mp 88—88.5 °C. NMR ($CDCl_3$) δ 1.2—1.6 (2H, m, CH_2), 1.6—2.27 (1H, q, J=7 Hz, CHCO), 3.13—3.57 (1H, q, J=7 Hz, CHCl), 5.5 (1H, s, OH). Found: C, 39.89; H, 3.97%. Calcd: C, 39.84; H, 4.17%.

Ethyl trans-*2-Chloro-1-cyclopropanecarboxylate.* This compound was obtained by GLC separation from a cis and trans mixture; bp 76—78 °C/36 Torr. NMR (CCl_4) δ 1.25 (3H, t, J=7 Hz, CH_3), 1.10—1.65 (2H, m, ring CH_2), 1.75—2.07 (1H, m, CHCO), 3.10—3.40 (1H, m, CHCl), 4.05 (2H, q, J=7 Hz, CH_2).

trans-*2-Chloro-1-cyclopropanecarboxylic Acid.* Ethyl *trans*-2-chloro-1-cyclopropanecarboxylate (1 g) was hydrolyzed with sodium hydroxide (0.4 g) in 40% ethanol (5 ml) to yield *trans*-2-chloro-1-cyclopropanecarboxylic acid; 0.5 g; bp 86 °C/4 Torr. Mp 59 °C. NMR ($CDCl_3$) δ 1.20—1.75 (2H, m, CH_2), 1.80—2.15 (1H, m, CHCO), 3.24—3.55 (1H, m, CHCl), 11.60 (1H, s, OH). Found: C, 40.05; H, 4.24%. Calcd: C, 39.85; H, 4.18%.

1,1-Dibromo-2-vinylcyclopropane. This compound was synthesized by the method described above for the chloro derivative; bp[30] 60 °C/22 Torr. lit, 69.5—70 °C/26 Torr[28] 53—56 °C/10 Torr.[31]

Methyl 2,2-Dibromo-1-cyclopropanecarboxylate. The oxidation of 1,1-dibromo-2-vinylcyclopropane (115 g), the same treatment as has been described for the preparation of 2,2-dichloro-1-cyclopropanecarboxylic acid, gave crude 2,2-dibromo-1-cyclopropanecarboxylic acid, which was then converted to the corresponding methyl ester by adding 200 ml of methanol and 5 ml of concentrated sulfuric acid and by refluxing the subsequent mixture for 10 h. After a routine work-up, methyl 2,2-dibromo-1-cyclopropanecarboxylate (40 g) was obtained; bp 90 °C/9 Torr. NMR (CCl_4) δ 1.76—2.70 (3H, m, ring), 3.73 (3H, s, CH_3). Found: C, 23.08; H, 2.25%. Calcd: C, 23.28; H, 2.35%.

Methyl cis-*2-Bromo-1-cyclopropanecarboxylate.* 34 g (0.13 mol) of methyl 2,2-dibromo-1-cyclopropanecarboxylate were added to 34 g (0.13 mol) of tributyltin hydride. The reaction took place immediately. After cooling to room temperature, methyl *cis*- and *trans*-2-bromo-1-cyclopropanecarboxylate were obtained by distillation; bp 65—95 °C/20 Torr. Subsequent distillation and GLC operation afforded pure methyl *cis*-2-bromo-1-cyclopropanecarboxylate; bp 108 °C/25 Torr. NMR (CCl_4) δ 1.25—1.58 (2H, m, CH_2), 1.75—2.15 (1H, q, J=8 Hz with a small splitting, CHCO), 2.95—3.33 (1H, q, J=8 Hz with a small splitting), 3.70 (3H, s, CH_3). Found: C, 33.80; H, 4.20%. Calcd: C, 33.52; H, 3.91%.

cis-*2-Bromo-1-cyclopropanecarboxylic Acid.* The alkaline hydrolysis of methyl *cis*-2-bromo-1-cyclopropanecarboxylate gave *cis*-2-bromo-1-cyclopropanecarboxylic acid; bp 120 °C/2 Torr; mp 68.5—70.5 °C. NMR ($CDCl_3$) δ 1.3—1.7 (2H, m, CH_2), 1.85—2.23 (1H, m, CHCO), 2.0—2.40 (1H, q, J=8 Hz with small spritting, CHBr), Found: C, 29.11; H, 2.82%. Calcd: C, 29.08; H, 3.05%.

The ionization constants were determined by the potentiometric titration of substituted cyclopropanecarboxylic acids (0.005 M) with sodium hydroxide (0.02 M) according to the previously outlined procedure.[3,12]

The ^{13}C NMR spectra were measured on a Hitachi Perkin-Elmer R-22 spectrometer, with 22.6 MHz in the FT mode. The measurement conditions will be described in detail elsewhere, along with the chemical shifts of the cyclopropane ring carbons.

The author wishes to thank Professor Yuho Tsuno and Dr. Masaaki Mishima (Kyushu University) for the measurements of the ^{13}C NMR spectra.

Kinetic Studies for the Acyloxy Exchange Reactions of Acyloxytrimethylsilanes with Carboxylic Acids

Seizi KOZUKA,* Takuro KITAMURA, Noboru KOBAYASHI, and Kenji OGINO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received September 22, 1978)

The acyloxy exchange reactions of acyloxysilane with carboxylic acids have been studied kinetically. The rate of reaction has been found to proceed faster with a stronger attacking acid and more basic leaving acyloxy group. The rate was markedly accelerated by the addition of base. The steric effect due to substituents on the silicon atom and hydrogen-deuterium kinetic isotope effects have been examined. A mechanism involving the 5-coordination of the silicon atom prior to the rate-determining proton transfer has been suggested.

A number of organic synthesis recently developed have included the silylation-desilylation reactions of functional groups.[1] An advantage of this reaction is the selectivity which has been demonstrated by the monothioketalization of dicarbonyl compounds[2] and the kinetic study of the silylations of hydroxyl groups.[3] In connection with this, the greater the knowledge of the mechanism of silylation or kinetics may make the reaction more applicable to organic synthesis. Thus, a kinetic study of the proton-silyl exchange reaction *i.e.*, the acyloxy exchange reaction of acyloxysilanes with carboxylic acids as one of the most simple model reactions for the trans-silylation reaction has been carried out. The aims has been to ascertain the kinetics of the exchange reaction and to clarify the mechanism.

Results and Discussion

The acyloxy exchange reaction was found to proceed almost quantitatively if the entering carboxylic acid was stronger than the leaving acid. The rate of

$$RCOOSiR'_3 + R''COOH \longrightarrow R''COOSiR'_3 + RCOOH$$

$$pK_a\ RCOOH > R''COOH$$

acyloxy exchange for acetoxytrimethylsilane with two equivalents of formic acid in chloroform-*d* was measured by monitoring the decrease ^1H NMR trimethyl signal of the starting acetoxysilane (δ 0.28 ppm) and the increase in the product *i.e.*, formyloxytrimethylsilane (δ 0.32 ppm): the rate constant found to be second order. Under the same conditions, the rate of the reverse reaction was too small to affect the kinetics since the exchange was found to proceed almost quantitatively and the reverse reaction of formyloxytrimethylsilane with acetic acid gave no acetoxytrimethylsilane. The rate of reaction with other carboxylic acids was similarly measured and the kinetic results are given in Table 1. The reaction was found to proceed faster with a stronger acid and the rates correlated well with the σ^* parameters with a ρ^* value +1.10 as shown in Fig. 1 formic acid was the exception. The deviation in rate for the reaction of formic acid may be ascribed to the release of the steric crowding change in the acyloxy moiety from the acetoxy to the formyloxy group. The effect of the leaving acyloxy groups of acyloxytrimethylsilanes reversed the rates of exchange *i.e.*, in the trimethylsilylations of trifluoroacetic acid by various acyloxytrimethylsilanes, the rates decreased in the order acetoxy, chloroacetoxy, and dichloroace-

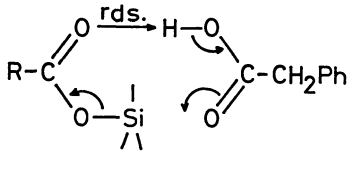
toxytrimethylsilanes as the starting materials; similar results were obtained for the silylations of the dichloro and trichloroacetic acids. The results are given in Table 2 and together with the negative assertion to support free silicenium ion[4] would rule out prior ionization of the substrate to exchange acyloxy group.

The effect of the silyl-substituent on the rate of the exchange was examined and it was found that the rate was depressed by the bulky substituent on the silicon atom as observed in the acyloxy exchange reactions of acetoxytrimethyl-, ethyldimethyl, benzyldimethyl, and dimethylphenylsilanes with dichloroacetic acid. The results together with the hydrogen-deuterium kinetic isotope effect observed in the exchange reactions are given in Table 3. The small isotope effect is in accordance with the rate determining proton transfer reaction of the carboxylic acid by a intramolecular cyclic process.[5]

Recently, Pola *et al.* reported the equilibrium constants of proton-silyl exchange *i.e.*, for the acyloxy exchange reaction between acyloxytrimethylsilanes and phenylacetic acid in carbon tetrachloride.[6] It was

$$RCOOSiMe_3 + PhCH_2COOH \overset{K}{\rightleftharpoons} RCOOH + PhCH_2COOSiMe_3$$

reported that the silylating ability of acyloxysilanes decreased with increasing electronegativity of the R group in the acyloxy moiety and the equilibrium constants were successfully correlated with the σ^* constants of the R groups giving a ρ^* value of -0.57. On the basis of these results, it was suggested that a transition state, similar to the carboxylic acid dimer existed in which proton transfer was the rate determining step. Similar results have been observed in the present kinetic study *i.e.*, the less electronegative acyloxy groups of the starting acyloxysilanes facilitate exchange (Table 2), reactions with stronger acids proceed faster (Fig. 1) and the positive kinetic isotope effect is in accordance with the rate determining proton transfer. The base catalysis of the reaction, however, as shown in Table 4, suggests a nucleophilic attack on the silicon atom which occurrs before or at the rate determining step. Since a kinetic isotope effect was observed, nucleophilic attack would be expected to occurr before the rate determining step.



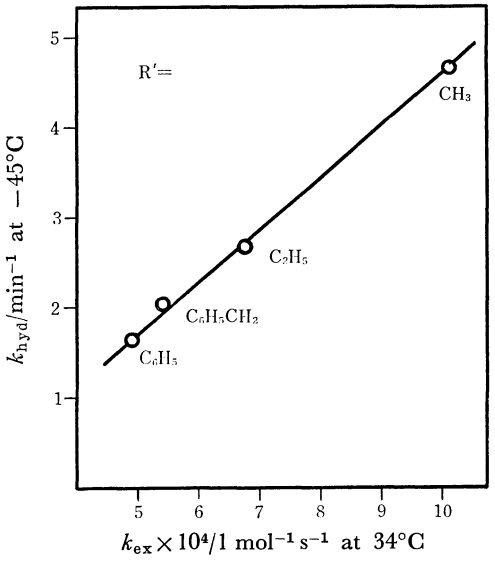


Fig. 2. Plot of rates of hydrolyses of $Me_2R'SiCl$ *vs.* rates of exchange reactions of $Me_2R'SiOAc$ with $CHCl_2CO_2H$.

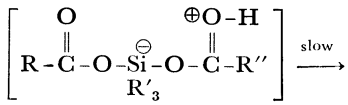
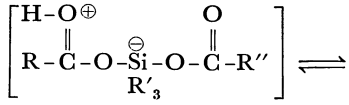
Nucleophlic attack finds further support when the results given in Table 3 are compared with the rates of the hydrolyses of the corresponding chlorosilanes which proceed *via* a 5-coordinated intermediate.[7] As shown in Fig. 2, the rates of acyloxy exchange correlate linearly to the hydrolyses of the corresponding chlorosilanes. This suggests that the two reactions are very similar in mechanism *i.e.*, 5-coordination of the silicon atom. The large negative entropy value observed in the present study is also in agreement with a 5-coordination mechanism.[8]

Based on the above considerations, the most plausible mechanism for acyloxy exchange is as follows:

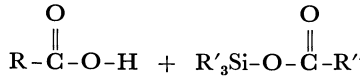
$$R-\overset{O}{\overset{\|}{C}}-O-SiR'_3 + R''-\overset{O}{\overset{\|}{C}}-O-H \rightleftharpoons$$



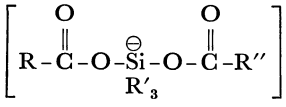
1



2



Nucleophilic attack of carboxylic acid on the substrate gives a 5-coordinated intermediate (**1**) which transfers a proton (the rate determining step) to give a second intermediate (**2**). The second intermediate collapses into the products. The latter intermediate (**2**) is expected to be more stable than **1** since the proton is bonded to a more basic site. The reverse reaction, for example, giving acetoxytrimethylsilane from formyloxytrimethylsilane and acetic acid would energetically unfavorable since an unstable intermediate would have to be formed from a stable intermediate. In the base catalyzed reaction, an intermediate **3** would be formed



3

by the attack of a stronger nucleophile, the carboxylate ion. Thus the reaction is enhanced by the addition of base.

Experimental

Materials. Acyloxytrimethylsilanes were prepared from chlorotrimethylsilane and silver or sodium carboxylates.[9] Me_3SiOAc; bp 102 °C, (lit,[10] 103.3—105 °C), $Me_3SiOCOCH_2Cl$; bp 124—126 °C, (lit,[11] 159 °C), NMR δ (ppm) 0.32 s (9H) 4.02 s (2H), $Me_3SiOCOCHCl_2$; bp 80 °C/30 mmHg (133.322Pa), (lit,[12] 63 °C/14 mmHg). Chloro(ethyldimethyl), (benzyldimethyl), and (dimethylphenyl)silanes were prepared from dichlorodimethylsilane and the appropriate Grignard reagent.[7,13] The reactions of the chlorosilanes with sodium acetate gave the corresponding acetoxysilanes. $Me_2(Et)SiOAC$; bp 115 °C, (lit,[14] 125—126 °C), $Me_2(Ph)SiOAc$; bp 85 °C/28 mmHg, (lit,[15] 127—130 °C/44 mmHg), $Me_2(PhCH_2)SiOAc$; bp 93—94 °C/4 mmHg, NMR δ (ppm) 0.25 s (6H), 1.98 s (3H), 2.32 s (2H), 6.85—7.20 m (5H), IR (cm^{-1}) 1720, 1260, $Me_2(Ph)SiOAc$; bp 85 °C/28 mmHg, (lit,[15] 127—130 °C/44 mmHg). The deuterated carboxylic acids were obtained by the hydrolysis of the carboxylic anhydrides with deuterium oxide and purified by distillation; the deuterium contents were determined by integration of ^1H NMR signals.

Product Analysis. The reaction of acetoxytrimethylsilane (0.27 mmol) with a small excess of the carboxylic acid (0.55 mmol) was conducted in chloroform-*d* (0.37 ml) solution. The mixture was allowed to stand for 5 h. Acyloxytrimethylsilane and acetic acid were detected as products by examination of the ^1H NMR spectrum of the solution. A small amount (5—7%) of hexamethyldisiloxane (δ 0.07 ppm) was detected as a side product which was probably formed by the moisture catalyzed decomposition of the acyloxysilane.

$$RCOOSiR'_3 + H_2O \longrightarrow RCOOH + R'_3SiOH$$

$$2R'_2SiOH \rightleftharpoons R'_3SiOSiR'_3 + H_2O$$

No other compound was detected in the solution. Dichloroacetoxytrimethylsilane was isolated from the reaction mixture of acetoxytrimethylsilane (7.6 mmol) and dichloroacetic acid (15 mmol) by GLC separation and the structure confirmed by comparison with an authentic sample.

Kinetic Procedure. A typical example is as follows: acetoxytrimethylsilane (35 mg; 0.27 mmol) was dissolved in $CDCl_3$ (0.370 ml) and the solution placed in a sample tube inside a NMR probe (Hitachi-Perkin-Elmer R-20 spectrometer). Dichloroacetic acid (71 mg; 0.55 mmol) was added to the solution and the trimethyl signals recorded at specified time intervals. The reaction temperature was the same as the probe temperature (34 °C). After reaction, the volume of the reaction mixture was measured and the concentrations of the components determined. Good reproduceability for the rate constant was obtained (within ±10%). The activation parameters were obtained using a variable temperature system (JEOL PS-100 spectrometer) and the temperatures measured by observing the chemical shifts of 1,2-ethanediol at that temperatures.

The Reactions of 2-(Trimethylsiloxy)furans with Orthocarboxylic Esters, Acetals, and Acylal in the Presence of Lewis Acids

Morio ASAOKA,* Naoyuki SUGIMURA, and Hisashi TAKEI
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsutacho, Midori-ku, Yokohama 227

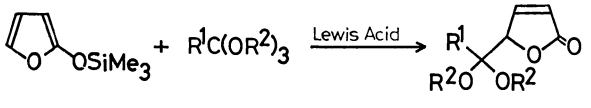
(Received October 6, 1978)

The reaction of 2-(trimethylsiloxy)furan (**1**) with orthocarboxylic esters, acetals, and acylal in the presence of Lewis acids afforded the corresponding 4-substituted 2-buten-4-olides. The reaction of 5-methyl-2-(trimethylsiloxy)furan with orthocarboxylic esters gave unstable 2-substituted 3-penten-4-olides as major products; these gave 2,5-alkanediones upon hydrolysis. The furan (**1**) also reacted with 1,1-diacetoxy-2-butene to give a mixture of 5-acetoxy-2,6-octadien-4-olide and 7-acetoxy-5-methyl-2,6-heptadien-4-olide. From the former compound, nigrosporalactone was synthesized.

In the preceding paper, we reported the synthesis of 2-(trimethylsiloxy)furans and their Diels-Alder reaction with maleic anhydride.[1] In the present paper, we will describe the reaction of some electrophiles with the furans in the presence of Lewis acids.

Results and Discussion

It was found that the reaction of 2-(trimethylsiloxy)-furan **1** with triethyl orthoacetate **2** (R^1=Me, R^2=Et) in dichloromethane, in the presence of catalytic amounts of a Lewis acid, afforded 5,5-diethoxy-2-hexen-4-olide **3** (R^1=Me, R^2=Et).



1 2 3

Scheme 1.

Among the Lewis acids examined, tin(IV) chloride and zinc chloride were found to be suitable catalysts for this reaction. That is, when the reaction was carried out at −40—10 °C for 2 h in the presence of tin(IV) chloride, **3** (R^1=Me, R^2=Et) was obtained in 71% yield, and **3** was obtained in 60% yield when the reaction was carried out at room temperature for 4.5 h in the presence of zinc chloride. But, when a stronger Lewis acid such as antimony(V) chloride or titanium(IV) chloride was used as a catalyst, the yield of **3** was low, probably because decomposition of **1** preferentially took place in contact with such a strong Lewis acid (Table 1). Next, we examined the reaction of **1** with various orthocarboxylic esters in the presence of zinc chloride or tin(IV) chloride. When triethyl orthocarboxylates were used, the yields of **3** decreased in the following order: R^1=H>Me>Et>Ph. When trimethyl orthoformate was used instead of triethyl orthoformate, **3** was obtained in higher yield. All these results suggest that the yields of **3** were markedly influenced by the size of the orthocarboxylic esters. These results are listed in Table 1.

Acetals also reacted with 2-(trimethylsiloxy)furan in the presence of tin(IV) chloride and afforded the corresponding 4-substituted 2-buten-4-olides in good yields.

Next, the reaction of 5-methyl-2-(trimethylsiloxy)-furan **6** with triethyl orthobenzoate was carried out. In this case, the formation of two compounds was confirmed by TLC, but the major product was found to be too unstable to isolate in a pure form. The acid hydrolysis of the reaction mixture afforded 1-phenyl-1,4-pentanedione as a major product and 4-benzoyl-2-penten-4-olide as a minor product. From this result, together with the NMR spectra of the crude mixture of the initially formed products, the major component of the unstable intermediate seems to possess the struc-

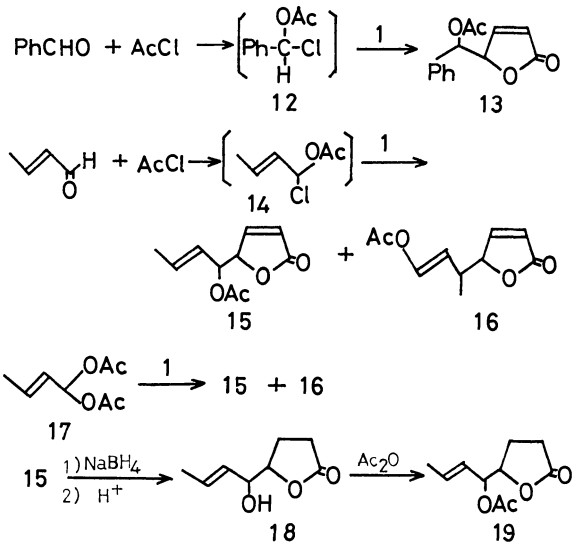
ture of **7** and/or **8**.[2] In contrast to the reaction of **1**, it is to be noted that the electrophile attacked preferentially at the 3-position of **6**. This fact can be explained by considering the steric repulsion between the methyl group at 5-position of the siloxyfuran and the electrophile. The effects of the reaction conditions, especially on the solvents and catalysts, were then examined. In this case, tin(IV) chloride was not a good catalyst. When the reaction was carried out in the presence of tin(IV) chloride, triethyl orthobenzoate still remained even after 24 h, though the other starting material, **6**, had disappeared. This suggests that the decomposition of **6** took place under the reaction conditions. When antimony(V) chloride was used instead of tin(IV) chloride, the yield was improved.



Scheme 4.

When trimethyl orthoheptanoate was used instead of orthobenzoate, 2,5-undecanedione **10**($R=C_6H_{13}$), which is known to be an important intermediate for the synthesis of dihydrojasmone,[3] was obtained in 37% yield. These results are summarized in Table 3.

Aldehydes are known to form adducts with acyl chloride.[4] So the reaction of **1** with such adducts was examined. Namely, the reaction of **1** with the mixture of benzaldehyde and acetyl chloride in the presence of a Lewis acid afforded 5-acetoxy-5-phenyl-2-penten-4-olide **13** in 57% yield. Similarly, the reaction of **1** with the mixture of crotonaldehyde and acetyl chloride afforded a 1:1 mixture of 5-acetoxy-2,6-octadien-4-olide **15** and 7-acetoxy-5-methyl-2,6-heptadien-4-olide **16** in 57% yield. When 1,1-diacetoxy-2-butene **17** was used instead of haloacetate **14**, a 1:1 mixture of **15** and **16** was obtained in 86% yield. Sodium borohydride reduction followed by acid hydrolysis of the mixture afforded threo and erythro isomers of **18** in over-all yields of 14 and 16%, respectively. The NMR spectrum of acetyl derivative of the erythro isomer

agreed with that of nigrosporalactone reported in the literature.[5] Thus, the natural nigrosporalactone was proved to be the erythro isomer.

In conclusion, 2-(trimethylsiloxy)furans reacted with various electrophiles similar to the silyl enol ethers[6] and afforded various substituted unsaturated lactones, which can be regarded as useful synthetic intermediates.

Experimental

A Typical Example of the Reaction of 2-(Trimethylsiloxy)-furan with Orthocarboxylates or Acetals. Triethyl orthoacetate (179 mg, 1.1 mmol) in dichloromethane (2 ml) was added to 2-(trimethylsiloxy)furan (172 mg, 1.1 mmol) and cooled to −40 °C. The reaction temperature was gradually raised to 10 °C after the addition of a few drops of tin(IV) chloride. Separation of the reaction mixture by silica gel TLC afforded 5,5-diethoxy-2-hexen-4-olide (155 mg, 71%).

1-Phenyl-1,4-pentanedione: To a solution of triethyl orthobenzoate (224 mg, 1 mmol) and 5-methyl-2-(trimethylsiloxy)furan (208 mg, 1.3 mmol) in dry dichloromethane (2.5 ml), was added one drop of antymony(V) chloride at room temperature. The reaction mixture was stirred at room temperature for 0.5 h, and the solvent was removed under reduced pressure. To the residue 5 ml of 40% of aqueous acetic acid was added and the resulting solution was refluxed for 45 min. After cooling to room temperature, the reaction mixture was extracted with three portions of ether. Removal of the solvent under reduced pressure gave a brownish oil, from which 1-phenyl-1,4-pentanedione was isolated in 55% yield by silica gel TLC (hexane–ether).

2,5-Undecanedione: The reaction of trimethyl orthoheptanoate with 5-methyl-2-(trimethylsiloxy)furan and the hydrolysis of the reaction products were carried out in a procedure similar to that mentioned above, and the isolation by TLC (hexane R_f=0.5) afforded 2,5-undecanedione in 37% yield.

5-Acetoxy-5-phenyl-2-penten-4-olide: Benzaldehyde (318 mg, 3 mmol) and acetyl chloride (238 mg, 3.03 mmol) were dissolved in 4 ml of dry dichloromethane, and the solution was stirred at room temperature for 15 min. Then the solution was cooled to −78 °C. 2-(Trimethylsiloxy)furan (515 mg, 3.3 mmol) was added to the solution and catalytic amounts of tin(IV) chloride were subsequently added. The mixture was allowed to warm to room temperature for 20 h with stirring. Ten ml of phosphate buffer (pH 7) was then added and the mixture was extracted with ethyl acetate. The organic layer was washed with water and dried over sodium sulfate. Ethyl acetate was removed under reduced pressure, and the residue was separated by silica gel column chromatography to give 5-acetoxy-5-phenyl-2-pentene-4-olide in 57% yield. IR (NaCl): 1750—1790 cm^{-1} (C=O), 1610 cm^{-1} (C=C); NMR($CDCl_3$): δ=2.10 (3H, s), 5.16—5.34 (1H, m), 5.86 (1H, d), 5.98—6.18 (1H, m), 7.10—7.60 (6H, m). Found: C, 67.24; H, 5.22%. Calcd for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%.

5-Hydroxy-6-octen-4-olide (Nigrosporalactone): To a solution of 2-(trimethylsiloxy)furan (2.43 g, 15.6 mmol) and 1,1-diacetoxy-2-butene (2.58 g, 15 mmol) in 20 ml of dry dichloromethane was added a catalytic amount of tin(IV) chloride at −40 °C. The mixture was allowed to warm to room temperature for 2 h, and was then stirred for 1 h at room temperature. Phosphate buffer (pH 7) was added to the mixture and the mixture was extracted with ethyl acetate. Ethyl acetate was removed under reduced pressure. Separation of the residue by column chromatography on silica gel gave 2.54 g of the mixture of 5-acetoxy-

2,6-octadien-4-olide and 7-acetoxy-5-methyl-2,6-heptadien-4-olide. This mixture was dissolved in 20 ml of methanol and cooled to 0 °C. Sodium borohydride(737 mg) was added to the solution in small portions and stirred for 0.5 h after the completion of the addition. The resulted mixture was acidified with 1 M hydrochloric acid (50 ml), and was stirred for 5 days. Methanol was removed under reduced pressure and the resulting mixture was extracted with ethyl acetate. The organic layer was washed with water and dried on sodium sulfate. After the removal of ethyl acetate under reduced pressure, the separation of the residue by TLC afforded erythro isomer (16%) and threo isomer (14%) of 5-hydroxy-6-octen-4-olide. Each of these were acetylated using an excess of triethyl amine and acetic anhydride. 5-Acetoxy-6-octen-4-olide (erythro): IR (NaCl): 1750 cm^{-1}, 1790 cm^{-1} (C=O); NMR ($CDCl_3$): $\delta=1.74$ (3H, d), 2.04 (3H, s), 2.20—2.54 (4H, m), 4.48 (1H, dq), 5.28 (1H, dd), 5,50 (1H, dd), 5.84 (1H, dq). Found: C, 60.10; H, 7.09%. Calcd for $C_{10}H_{14}O_4$: C, 60.59, H, 7.12%. 5-Acetoxy-6-octen-4-olide (threo); IR (NaCl): 1750 cm^{-1}, 1790 cm^{-1} (C=O); NMR ($CDCl_3$): $\delta=1.76$ (3H, d), 2.02 (3H, s), 2.00—2.54 (4H, m), 4.50 (1H, dq), 5.28 (1H, dd), 5.44(1H, dd), 5.82 (1H, dq). Found: C, 60.08; H, 6.95%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

The Revised Structure of Dispermol and Total Synthesis of Maytenoquinone, Dispermol, and Dispermone

Takashi MATSUMOTO,* Taishi OHMURA, and Shuji USUI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received October 18, 1978)

Condensation of β-cyclocitral with 2-isopropyl-3,4-dimethoxybenzyl chloride afforded an alcohol (**15**) which was converted into (±)-12,13-dimethoxytotara-8,11,13-trien-6-one (**18**). Demethylation of (±)-**18** followed by air oxidation gave (±)-maytenoquinone. Reductive cleavage of the hydroxyl group in (±)-**15** produced a phenethyl derivative which was cyclized to give (±)-12,13-dimethoxytotara-8,11,13-triene (**23**) and its *cis*-isomer (**24**). Oxidation of (±)-**23** with chromium trioxide, followed by demethylation of the resulting 7-oxo compound (**25**), afforded (±)-dispermone. The Wittig reaction of (*R*)-(−)-α-cyclocitral with 2-isopropyl-3,4-dimethoxybenzyltriphenylphosphonium chloride yielded a styrene derivative. This was partially hydrogenated and then cyclized to give (+)-**23** and (−)-**24**. The *trans*-isomer (**23**) was converted into (−)-dispermone (**3**) *via* (−)-**25** and also partially demethylated to (+)-12-methoxytotara-8,11,13-trien-13-ol (**2**), the proposed structure for dispermol. Since the synthetic (+)-**2** was not identical with the natural compound, (−)-**3** was then converted into (+)-13-methoxytotara-8,11,13-trien-12-ol, which was identical with natural dispermol. (−)-**25** was also converted into (+)-maytenoquinone.

Recently, three new tricyclic diterpenes possessing a totarane skeleton, maytenoquinone, dispermol, and dispermone, have been isolated from *Maytenus dispermus* by Martin.[1] Their structures were deduced to be **1**, **2**, and **3**, on the basis of chemical and spectroscopic studies. Among these natural diterpenes, maytenoquinone (**1**) is especially of interest, because it has a unique quinone-methide chromophore, such as that in taxodione (**4**)[2-5] which has shown a significant tumor-inhibiting activity. In connection with our synthetic studies on natural diterpenes, we attempted the syntheses of these natural compounds to confirm the proposed structures and to elaborate a new synthetic route for the tricyclic diterpenes with an aromatic C ring. This paper[6] describes the revision of the structure of dispermol and the total syntheses of maytenoquinone (**1**), dispermol (**5**), and dispermone (**3**) by the new route.

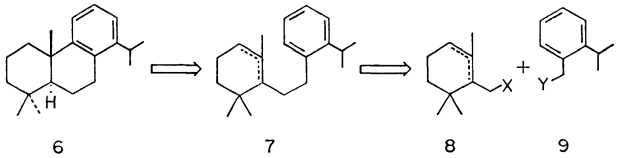
4

Our basic strategy for the synthesis of totara-8,11,13-triene skeleton (**6**) is shown in Scheme 1. That is, two C_{10} units (**8** and **9**), including A and C rings of natural compounds, were first condensed to give a C_{20} unit (**7**) and this, by intramolecular cyclization, was converted into an octahydrophenanthrene derivative (**6**) which was then transformed into the natural compounds.



6 7 8 9

Scheme 1.

*Syntheses of (±)-Maytenoquinone (**1**) and (±)-Dispermone (**3**).* β-Cyclocitral (**10**)[7,8] and 2-isopropyl-3,4-dimethoxybenzyl chloride (**11**),[9] prepared from 2-isopropyl-3,4-dimethoxybenzoic acid (**12**)[9] *via* three steps, were chosen as the starting materials. Condensation of **10** with **11** in the presence of lithium naphthalenide afforded the desired alcohol (**15**), together with a small amount of a demethoxylated alcohol (**16**). The alcohol (**15**) was oxidized with chromium trioxide–pyridine complex to yield the corresponding α,β-unsaturated ketone (**17**), which was then submitted to intramolecular cyclization with anhydrous aluminium chloride in refluxing toluene. Because of the formation of a phenolic by-product, the crude product was immediately methylated with methyl iodide and anhydrous potassium carbonate in refluxing methyl ethyl ketone to give (±)-12,13-dimethoxytotara-8,11,13-trien-6-one (**18**). Demethylation of (±)-**18** with boron tribromide in dichloromethane afforded (±)-13-hydroxytotara-7,9(11),13-triene-6,12-dione (**1**), whose spectral data were identical with those of natural maytenoquinone. On the other hand, the demethylation of (±)-**18** with hydrobromic acid in refluxing acetic acid yielded (±)-*cis*-maytenoquinone (**19**).[10] The *cis*-configuration of the A/B ring junction in (±)-**19** was supported by its NMR spectrum, which showed a signal due to one of the *gem*-dimethyl groups at the C-4 position in very high field (δ 0.62 ppm) owing to the shielding effect of the C ring.[11]

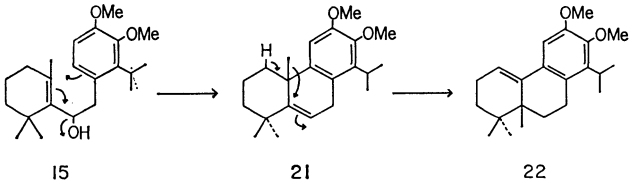
25

Our next effort was directed toward the syntheses of (±)-**2** and (±)-**3**. For reductive cleavage of the hydroxyl group, the alcohol (**15**) was treated at room temperature with dichloroaluminium hydride[12] in dry ether. Since the crude product contained a significant amount of diene compounds, it was hydrogenated over Pd–C in acetic acid to give the desired phenethyl derivative (**20**). In contrast to this result, when triethylsilane[13] was used at 0 °C in the presence of boron trifluoride etherate, the alcohol (**15**) was smoothly converted into **20** together with a small amount of (±)-12,13-dimethoxytotara-5,8,11,13-tetraene (**21**). The tetraene (±)-**21** was also obtained in moderate yield by treatment of (±)-**15** with boron trifluoride etherate at 0 °C. However, when the reaction of (±)-**15** with boron trifluoride etherate was carried out at room temperature, a rearranged product (**22**) was produced. This compound was also obtained by the similar treatment of (±)-**21**. Therefore, it is suggested that this rearrangement proceeded through the intermediate (±)-**21**. The NMR spectrum of (±)-**22** showed signals of an aromatic proton (δ 6.85), two methoxyl groups (δ 3.77 and 3.80), and an isopropyl group [δ 1.28 ppm (d, J=7 Hz)], suggesting the retention of the aromatic C ring. The compound, (±)-**22**, also showed a signal at δ 6.00 ppm (t, J=4 Hz) due to a vinylic proton attached to a trisubstituted double bond and signals at δ 0.90 (3H) and 0.93 ppm (6H) due to three tertiary methyl groups. The appearance of three tertiary methyl signals in the higher field, and of vinylic and aromatic protons in the lower field, than those in (±)-**21** suggested that the angular methyl group at the C-10 position rearranged to the C-5 position, resulting in the formation of a new trisubstituted double bond, as in Scheme 2. Thus, the structure



15 21 22

Scheme 2.

of (±)-**22** was tentatively assigned as 12,13-dimethoxy-5-methyl-10-nortotara-1(10),8,11,13-tetraene. Intramolecular cyclization of **20** with boron trifluoride etherate in dichloromethane afforded (±)-12,13-dimethoxytotara-8,11,13-triene (**23**) as a major product and its *cis*-isomer (**24**) as a minor one. When the cyclization was carried out with anhydrous aluminium chloride in refluxing benzene, **20** gave (±)-12-methoxytotara-8,11,13-trien-13-ol (**2**) in addition to the dimethoxy compounds, (±)-**23** and (±)-**24**. The phenol (±)-**2** was also obtained by partial demethylation of (±)-**23** with anhydrous aluminium chloride under similar conditions, and the methylation of (±)-**2** with methyl iodide and anhydrous potassium carbonate yielded (±)-**23**. The presence of a phenolic hydroxyl group at the C-13 position in (±)-**2** was supported by pyridine-induced solvent shifts[14] of the C-16 and C-17 methyls (Δ=−0.28 ppm) and an aromatic proton (Δ=−0.12 ppm) in its NMR spectrum, which was different from that of natural dispermol. This was further confirmed by the synthesis of optically active (+)-**2**, which is described later. Thus, the proposed structure (**2**) for dispermol should now be revised. Since the conversion of the optically active tetraene (**21**) into the trienes (**23** and **24**) by catalytic hydrogenation had already been reported,[1] (±)-**21** was also a useful intermediate for the present synthesis. The dimethyl ether (±)-**23** was oxidized with chromium trioxide in acetic acid to give the corresponding 7-oxo compound (**25**) and this was then demethylated with boron tribromide in dichloromethane to afford (±)-12,13-dihydroxytotara-8,11,13-trien-7-one (**3**), whose spectral data were identical with those of natural dispermone.

*Syntheses of (+)-Maytenoquinone (**1**), (+)-Dispermol (**5**), and (−)-Dispermone (**3**).* Subsequently, our attention was directed toward the total syntheses of the optically active natural maytenoquinone, dispermol, and dispermone. The starting materials chosen for these syntheses were (*R*)-(−)-α-cyclocitral (**26**)[15,16] and 2-isopropyl-3,4-dimethoxybenzyltriphenylphosphonium chloride (**27**), which was prepared from **11** and triphenylphosphine in refluxing benzene. The Wittig reaction of (−)-**26** with **27** in dry hexane in the presence of *n*-butyllithium gave the desired styrene derivative (**28**). In the NMR spectrum of (−)-**28** the vicinal coupling constant (J=15 Hz) of vinylic protons suggested the presence of a trans disubstituted double bond. Partial hydrogenation of (−)-**28** in ethanol over Pd–C afforded a phenethyl derivative (**29**), which was submitted to the intramolecular cyclization using anhydrous aluminium chloride in benzene. The crude product was then purified by column chromatography on silica gel to give (+)-**23**, $[\alpha]_D$ +50.2°, along with (−)-**24**. The conversion of (+)-**23** into (−)-dispermone (**3**) *via* the 7-oxo compound (**25**) was achieved by a method similar to that for the racemate.

(+)-**23** was partially demethylated to give (+)-**2**, mp 87—88.5 °C. The melting point of the synthetic (+)-**2** was quite different from that of natural dispermol (mp 164—166 °C). From the comparison of the NMR spectra of (+)-**2** and dispermol, the structure of natural product is expected to be 13-methoxytotara-8,11,13-trien-12-ol (**5**); this was successfully synthesized in the following manner. Partial benzylation of (−)-**3** with benzyl chloride in the presence of potassium iodide

and anhydrous potassium carbonate produced the corresponding 12-benzyl ether (**30**). The presence of a phenolic hydroxyl group at the C-13 position in (−)-**30** was supported by the solvent shifts[14] of the C-16 and C-17 methyls ($\Delta = -0.42$ ppm)[17] in its NMR spectrum. Methylation of (−)-**30** with methyl iodide and anhydrous potassium carbonate gave the 13-methyl ether (**31**) which, on hydrogenolysis over PtO_2 in ethanol containing a small amount of perchloric acid, afforded (+)-**5**, mp 166.5—167.5 °C, whose physical and spectral data were identical with those of natural dispermol. Thus, the structure of dispermol could be determined to be **5**.

(+)-Maytenoquinone (**1**) was synthesized as follows. The 7-oxo compound (−)-**25** was reduced with lithium aluminium hydride in dry ether and the resulting mixture of epimeric alcohols was dehydrated with dilute hydrochloric acid to give (−)-12,13-dimethoxytotara-6,8,11,13-tetraene (**32**). Oxidation of (−)-**32** with *m*-chloroperbenzoic acid in dichloromethane, followed by treatment with dilute hydrochloric acid in refluxing methanol, gave (+)-**18** which, on demethylation with boron tribromide in dichloromethane and subsequent oxidation with silver oxide in refluxing chloroform, afforded (+)-maytenoquinone (**1**).

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

*Methyl 2-Isopropyl-3,4-dimethoxybenzoate (**13**).* 2-Isopropyl-3,4-dimethoxybenzoic acid (**12**)[9] was methylated with diazomethane in ether to give **13**, IR: 1710 cm^{-1}; NMR: 1.31 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.80 (6H, s) and 3.83 (3H, s) (2-OCH_3 and $-CO_2CH_3$), 6.61 and 7.24 (each 1H, d, and J=9 Hz, aromatic protons).

*2-Isopropyl-3,4-dimethoxybenzyl Alcohol (**14**).* A solution of **13** (38.34 g) in dry ether (40 ml) was added to a stirred suspension of lithium aluminium hydride (6.11 g) in dry ether (150 ml) with cooling in an ice–water bath. The mixture was then refluxed for 2 h, cooled, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give **14** (33.21 g: 98%); IR: 3600, 3400 cm^{-1}; NMR: 1.29 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.87 (1H, s, -OH), 3.23 (1H, m, $-C\underline{H}(CH_3)_2$, 3.77 (6H, s, 2-OCH_3), 4.43 (2H, s, $-C\underline{H}_2OH$), 6.55 and 6.83 (each 1H, d, and J=9 Hz, aromatic protons).

*2-Isopropyl-3,4-dimethoxybenzyl Chloride (**11**).* A solution of thionyl chloride (17 ml) in dry ether (10 ml) was added at 5 °C to a stirred solution of **14** (33.21 g) in dry ether (40 ml) over a 30 min period. The solution was further stirred at room temperature for 1 h, diluted with dry benzene, and then evaporated *in vacuo* to give **11** (35.00 g: 97%); NMR: 1.35 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.23 (1H, m, $-C\underline{H}(CH_3)_2$), 3.81 (6H, s, 2-OCH_3), 4.51 (2H, s, $-CH_2Cl$), 6.57 and 6.83 (each 1H, d, and J=8 Hz, aromatic protons).

*Condensation of β-Cyclocitral (**10**) and 2-Isopropyl-3,4-dimethoxybenzyl Chloride (**11**).* A mixture of naphthalene (4.00 g) and small pieces of lithium (247 mg) in dry tetrahydrofuran (20 ml) was stirred at room temperature for 1 h in a stream of nitrogen. Into the above mixture a solution of β-cyclocitral[7,8] (1.36 g) and 2-isopropyl-3,4-dimethoxybenzyl chloride (2.250 g) in dry tetrahydrofuran (10 ml) was added at 0—5 °C over a 45 min period. The mixture was further stirred at 0—5 °C for 2 h in a stream of nitrogen diluted with ether, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (400 g) using ether–benzene (1 : 99) as the eluent to give phenolic fractions (463 mg). Further elution with ether–benzene (1 : 99 and then 3 : 97) gave an oily alcohol (**15**) (1.496 g: 48%) which was crystallized from hexane: mp 72—72.5 °C; IR: 3560 cm^{-1}; NMR: 0.94 and 1.08 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.89 (3H, s, $=\dot{C}CH_3$), 3.23 (1H, m, $-C\underline{H}(CH_3)_2$), 3.77 and 3.79 (each 3H and s, 2-OCH_3), 4.24 (1H, dd, J=4 and 9 Hz, $-\dot{C}\underline{H}OH$), 6.60 and 6.72 (each 1H, d, and J=9 Hz, aromatic protons). Found: C, 76.41; H, 9.86%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%.

The above phenolic fractions (463 mg) were combined and methylated for 6 h with methyl iodide (1.0 ml) and anhydrous potassium carbonate (3.0 g) in refluxing methyl ethyl ketone (10 ml). The mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was dissolved in ether, washed with brine, dried over sodium sulfate, and then evaporated to give a crude product which was purified by column chromatography on silica gel (50 g) using benzene as the eluent to yield a demethoxylated alcohol (**16**) (227 mg: 8%); IR: 3560 cm^{-1}; NMR: 0.95 and 1.09 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.22 and 1.24 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.90 (3H, s, $=\dot{C}CH_3$), 3.73 (3H, s, $-OCH_3$), 4.30 (1H, dd, J=4 and 9 Hz, $-\dot{C}\underline{H}OH$), 6.57 (1H, dd, J=2 and 8 Hz), 6.68 (1H, d, J=2 Hz), and 6.98 (1H, d, J=8 Hz) (aromatic protons). Further elution gave an additional alcohol (**15**) (168 mg: 5%).

*2,6,6-Trimethyl-1-cyclohexenyl 2-Isopropyl-3,4-dimethoxybenzyl Ketone (**17**).* A solution of (±)-**15** (1.500 g) in pyridine (3.0 ml) was added at 5—10 °C to a stirred chromium trioxide–pyridine complex prepared from chromium trioxide (2.17 g) and pyridine (30 ml). The mixture was stirred at 5—10 °C for 2 h, poured into a mixture of ice

and dilute hydrochloric acid, and filtered. The filtrate was extracted with ether and the extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (150 g) using benzene as the eluent to give an α,β-unsaturated ketone (**17**) (200 mg: 13%) which was recrystallized from hexane: mp 81—82.5 °C; IR: 1690 cm^{-1}; NMR: 1.07 (6H, s, $-C(CH_3)_2$), 1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.60 (3H, s, $=CCH_3$), 3.73 (2H, s, $-COCH_2-$), 3.82 and 3.84 (each 3H and s, $2\text{-}OCH_3$), 6.58 (2H, s, aromatic protons). Found: C, 76.88; H, 9.53%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%. Further elution with ether–benzene (1 : 99) afforded the starting alcohol (**15**) (1.020 g: 68%).

*(±)-12,13-Dimethoxytotara-8,11,13-trien-6-one (**18**).* A mixture of **17** (93 mg) and anhydrous aluminium chloride (72 mg) in dry toluene (10 ml) was refluxed for 6 h. The mixture was diluted with ether, washed successively with dilute hydrochloric acid and water, dried over sodium sulfate, and then evaporated *in vacuo* to give a crude product, whose IR spectrum showed a band at 3540 cm^{-1} due to a phenolic hydroxyl group.

The above crude product was refluxed for 6 h with methyl iodide (0.5 ml) and anhydrous potassium carbonate (3.0 g) in methyl ethyl ketone (5.0 ml). After the usual work-up, the product was purified by column chromatography on silica gel (10 g) using hexane–benzene (1 : 4) as the eluent to give (±)-**18** (49 mg: 53%) which was recrystallized from hexane: mp 144—145 °C; IR; 1710 cm^{-1}; NMR: 1.05 and 1.12 (each 3H and s, $-C(CH_3)_2$), 1.29 (3H, s, $C_{10}-CH_3$), 1.29(6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.35 (1H, s, C_5-H), 3.06 (1H, m, $-C\underline{H}(CH_3)_2$), 3.41 (2H, d, J=5 Hz, $-COCH_2-$), 3.78 and 3.80 (each 3H and s, $2\text{-}OCH_3$), 6.66 (1H, s, $C_{11}-H$). Found: C, 76.69; H, 9.33%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%. Further elution with benzene gave the starting ketone **17** (29 mg: 31%).

*(±)-Maytenoquinone (**1**).* A mixture of (±)-**18** (100 mg) and boron tribromide (1.0 g) in dichloromethane (10 ml) was stirred at 0—5 °C for 1 h and then at room temperature for 30 min. The mixture was poured into ice–water, extracted with ether, and the extract was washed successively with aqueous sodium thiosulfate and brine. The dried solution was evaporated to dryness. The residue was purified by repeated column chromatography on silica gel using hexane–benzene (1 : 1) as the eluent and then recrystallized from hexane to give (±)-maytenoquinone (**1**) (63 mg: 69%), mp 173—174 °C; IR: 3370, 1660, 1630 cm^{-1}; NMR ($CDCl_3$): 1.17 and 1.26 (each 3H and s, $-C(CH_3)_2$), 1.26 (3H, s, $C_{10}-CH_3$), 1.31 and 1.37 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.48 (1H, s, C_5-H), 3.06 (1H, m, $-C\underline{H}(CH_3)_2$), 6.37 and 6.59 (each 1H, d, and J= 2 Hz, C_7-H and $C_{11}-H$), 7.12 (1H, s, -OH). Found: C, 76.22; H, 8.42%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

*(±)-cis-Maytenoquinone (**19**).* A mixture of (±)-**18** (44.2 mg) and 47% hydrobromic acid (2.0 ml) in acetic acid (10 ml) was refluxed for 2.5 h and then evaporated *in vacuo*. The residue was extracted with ether and the extract was washed successively with aqueous sodium hydrogencarbonate and water, dried over sodium sulfate, and then evaporated. The crude product was purified by column chromatography on silica gel (10 g) using ether–benzene (1 : 99) to give (±)-**19** (33.9 mg: 82%) which was recrystallized from hexane: mp 184—187 °C (sintered at *ca.* 160 °C); IR: 3370, 1650, 1630 cm^{-1}; NMR ($CDCl_3$): 0.62 and 0.97 (each 3H and s, $-C(CH_3)_2$), 1.18 (3H, s, $C_{10}-CH_3$), 1.31 and 1.37 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.26 (1H, s, C_5-H), 6.45 and 6.64 (each 1H, d, and J=2 Hz, C_7-H and $C_{11}-H$), 7.23 (1H, s, -OH). Found: C, 76.68; H, 8.61%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

*Reductive Cleavage of a Hydroxyl Group in the Alcohol (**15**). With Triethylsilane in the Presence of Boron Trifluoride Etherate*: A solution of boron trifluoride etherate (3.34 ml) in dichloromethane (5.0 ml) was added at −10—0 °C to a stirred solution of (±)-**15** (1.830 g) and triethylsilane (1.230 g) in dichloromethane (50 ml). The mixture was further stirred at this temperature for 1 h, diluted with ether, and then washed with water. The dried solution was evaporated *in vacuo* and the residue was chromatographed on silica gel (100 g) using hexane–benzene (7 : 3) as the eluent to give 2-(2,6,6-trimethyl-1-cyclohexenyl)-1-(2-isopropyl-3,4-dimethoxyphenyl)ethane (**20**) (1.560 g: 89%); NMR: 1.04 (6H, s, $-C(CH_3)_2$), 1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.68 (3H, s, $=CCH_3$), 3.18 (1H, m, $-C\underline{H}(CH_3)_2$), 3.78 and 3.80 (each 3H and s, $2\text{-}OCH_3$), 6.56 and 6.74 (each 1H, d, and J= 8 Hz, aromatic protons). Found: C, 80.15; H, 10.53%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%. Further elution with hexane–benzene (1:1) afforded (±)-12,13-dimethoxytotara-5,8,11,13-tetraene (**21**) (132 mg: 8%); NMR: 1.16 and 1.22 (each 3H and s, $-C(CH_3)_2$), 1.26 (3H, s, $C_{10}-CH_3$), 1.27 and 1.32 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.78 (6H, s, $2\text{-}OCH_3$), 5.83 (1H, dd, J=2.5 and 5.5 Hz, C_6-H), 6.68 (1H, s, $C_{11}-H$). Found: C, 80.67; H, 9.94%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%.

With Dichloroaluminium Hydride: Lithium aluminium hydride (33 mg) was added to a solution of anhydrous aluminium chloride (345 mg) in dry ether (20 ml), and the mixture was stirred at room temperature for 1 h. To the above solution was added dropwise a solution of (±)-**15** (150 mg) in dry ether (4.0 ml). The mixture was further stirred at room temperature for 1 h, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (16 g) using hexane–benzene (4 : 1) as the eluent to give an oil (121 mg: 86%), which was hydrogenated at room temperature for 6 h with 5% Pd–C (130 mg) in acetic acid (10 ml) in an atmosphere of hydrogen. After the usual work-up, the crude product was purified by column chromatography on silica gel (15 g) using hexane–benzene (4 : 1) as the eluent to afford **20** (85 mg: 60%).

*(±)-12,13-Dimethoxytotara-5,8,11,13-tetraene (**21**).* Boron trifluoride etherate (0.18 ml) was added at −10—0° C to a solution of (±)-**15** (98 mg) in dichloromethane (10 ml). The mixture was stirred at this temperature for 1 h, poured into water, and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (10 g) to give (±)-**21** (55 mg: 60%), whose IR and NMR spectra were identical with those of the sample described above.

*(±)-12,13-Dimethoxy-5-methyl-10-nortotara-1(10),8,11,13-tetraene (**22**). From the Alcohol (**15**)*: A solution of (±)-**15** (75 mg) and boron trifluoride etherate (0.14 ml) in dichloromethane (10 ml) was stirred at room temperature for 2 h, and then poured into water. The mixture was extracted with ether, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (10 g) using hexane–benzene (4 : 1) as the eluent to give (±)-**22** (33 mg: 45%); NMR: 0.90 (3H, s) and 0.93 (6H, s) ($-C(CH_3)_2$ and C_5-CH_3), 1.28 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.77 and 3.80 (each 3H and s, $2\text{-}OCH_3$), 6.00 (1H, t, J=4 Hz, C_1-H), 6.85 (1H, s, $C_{11}-H$). Found: C, 80.31; H, 9.98%. Calcd for $C_{22}H_{32}O_2$:

C, 80.44; H, 9.83%.

*From the Tetraene (**21**)*: A solution of (±)-**21** (105 mg) and boron trifluoride etherate (0.20 ml) in dichloromethane (5.0 ml) was stirred at room temperature for 1 h. After a similar treatment to that described above, the crude product was purified by column chromatography on silica gel to give (±)-**22** (54 mg).

*Intramolecular Cyclization of **20**. With Boron Trifluoride Etherate*: A solution of **20** (313 mg) and boron trifluoride etherate (0.60 ml) in dichloromethane (5.0 ml) was allowed to stand at room temperature for 13.5 h, and then poured into water. The mixture was extracted with ether and the extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (30 g) using hexane–benzene (4 : 1) as the eluent to give the *cis*-isomer (**24**) (81 mg: 26%); NMR: 0.43 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.15 (3H, s, C_{10}–CH_3), 1.22 and 1.30 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.80 (6H, s, 2-OCH_3), 6.66 (1H, s, C_{11}–H). Found: C, 79.87; H, 10.53%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%. Further elution gave (±)-12,13-dimethoxytotara-8,11,13-triene (**23**) (222 mg: 71%) which was recrystallized from methanol: mp 133.5—134 °C; NMR: 0.92 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.19 (3H, s, C_{10}–CH_3), 1.26 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.73 (6H, s, 2-OCH_3), 6.58 (1H, s, C_{11}–H). Found: C, 80.22; H, 10.51%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

With Anhydrous Aluminium Chloride: A mixture of **20** (111 mg) and anhydrous aluminium chloride (51 mg) in dry benzene (4.0 ml) was refluxed for 4 h. The mixture was poured into ice–water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was chromatographed on silica gel (10 g) using hexane–benzene (4 : 1) as the eluent to give (±)-12-methoxytotara-8,11,13-trien-13-ol (**2**) (34 mg: 34%), which was recrystallized from hexane: mp 125—126 °C; IR: 3538 cm^{-1}; NMR ($CDCl_3$): 0.92 and 0.95 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.20 (3H, s, C_{10}–CH_3), 1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.84 (3H, s, $-OCH_3$), 5.62 (1H, s, C_{13}–OH), 6.70 (1H, s, C_{11}–H). NMR (C_5D_5N): 0.90 and 0.93 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.21 (3H, s, C_{10}–CH_3), 1.61 and 1.63 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.72 (3H, s, $-OCH_3$), 6.82 (1H, s, C_{11}–H). Found: C, 79.78; H, 10.38%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%. Further elution gave (±)-**24** (11 mg: 9%) and (±)-**23** (41 mg: 36%).

*Partial Demethylation of **23***. A mixture of (±)-**23** (102 mg) and anhydrous aluminium chloride (60 mg) in dry benzene (20 ml) was refluxed for 3 h. After the work-up described above, the crude product was chromatographed on silica gel (10 g) using hexane–benzene (4 : 1) as the eluent to give (±)-**2** (27 mg: 28%), whose IR and NMR spectra were identical with those of the sample described above. Further elution gave the starting (±)-**23** (44 mg).

*Methylation of **2***. A mixture of (±)-**2** (60 mg), methyl iodide (1.0 ml), and anhydrous potassium carbonate (3.0 g) in methyl ethyl ketone (10 ml) was refluxed for 14 h. After the usual work-up, the product was chromatographed on silica gel (6.0 g) using hexane–benzene (1 : 1) as the eluent to give (±)-**23** (51 mg: 82%), whose IR and NMR spectra were identical with those of the sample described above.

*(±)-12,13-Dimethoxytotara-8,11,13-trien-7-one (**25**)*. A mixture of (±)-**23** (209 mg) and chromium trioxide (190 mg) in acetic acid (20 ml) was stirred at room temperature for 2 h and then diluted with ether. The ether solution was washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried solution was then evaporated *in vacuo* and the residue was chromatographed on silica gel (20 g) using hexane–benzene (1 : 4) as the eluent to give (±)-**25** (118 mg: 54%), which was recrystallized from methanol: mp 129—130 °C; IR: 1660 cm^{-1}; NMR (90 MHz): 0.93 and 1.02 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.12 (3H, s, C_{10}–CH_3), 1.23 and 1.31 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.76 and 3.83 (each 3H and s, 2-OCH_3), 6.58 (1H, s, C_{11}–H). Found: C, 76.98; H, 9.27%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

*(±)-Dispermone (**3**)*. Boron tribromide (0.1 ml) was added at 0—5 °C to a solution of (±)-**25** (47 mg) in dichloromethane (2.0 ml). The mixture was allowed to stand at room temperature for 4 h, poured into ice–water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and water, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was chromatographed on silica gel (5.0 g) using chloroform as the eluent to give (±)-dispermone (**3**) (38 mg: 88%), which was recrystallized from ether–hexane: mp 242—245 °C (sintered at *ca.* 230 °C); IR: 3595, 3540, 3200, 1655 cm^{-1}; NMR (90 MHz: $(CD_3)_2CO$): 0.92, 1.01, and 1.08 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}–CH_3), 1.30 and 1.38 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.86 (1H, m, $-C\underline{H}(CH_3)_2$), 6.73 (1H, s, C_{11}–H). Found: C, 75.61; H, 8.72%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

*2-Isopropyl-3,4-dimethoxybenzyltriphenylphosphonium Chloride (**27**)*. A mixture of the benzyl chloride (**11**) (35.0 g) and triphenylphosphine (40.1 g) in dry benzene (35 ml) was refluxed for 5 min. The precipitated salt (**27**) (mp 243—245 °C, 29.0 g) was collected by filtration and the filtrate was further refluxed for 6 h to give some additional salt (38.5 g).

*(−)-3-(2-Isopropyl-3,4-dimethoxystyryl)-2,4,4-trimethyl-1-cyclohexene (**28**)*. A solution of *n*-butyllithium in dry hexane (15%: 2.1 ml) was added at room temperature to a stirred suspension of **27** (2.010 g) in dry hexane (6.0 ml) in a stream of nitrogen, and the mixture was stirred for 1 h. To the above mixture a solution of (*R*)-(−)-α-cyclocitral (**26**), $[\alpha]_D$ −712° (EtOH), (390 mg) in dry hexane (3.0 ml) was added at 8—10 °C over a 5 min period. The mixture was further stirred at this temperature for 4 h, exposed to air for a few min until the red solution turned yellow, then poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was triturated with hexane, and the precipitated triphenylphosphine oxide was removed by filtration. The filtrate was evaporated *in vacuo*. The crude product was chromatographed on silica gel (40 g) using hexane–benzene (7:3) as the eluent to give (−)-**28** as an oil (647 mg: 77%), $[\alpha]_D$ −258°; NMR: 0.91 and 0.96 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.67 (3H, bs, $=\dot{C}CH_3$), 3.37 (1H, m, $-C\underline{H}(CH_3)_2$), 3.77 and 3.80 (each 3H and s, 2-OCH_3), 5.42 (1H, m, $-CH=\dot{C}-$), 5.55 (1H, dd, J=9 and 15 Hz, $-\dot{C}H-C\underline{H}=CH-$), 6.61 (1H, d, J=15 Hz, $-\dot{C}H-CH=C\underline{H}-$), 6.58 and 6.90 (each 1H, d, and J=9 Hz, aromatic protons). Found: C, 80.46; H, 9.93%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%.

*(−)-2-(2,6,6-Trimethyl-2-cyclohexenyl)-1-(2-isopropyl-3,4-dimethoxyphenyl)ethane (**29**)*. A suspension of (−)-**28** (2.012 g) and 5% Pd–C (1.0 g) in ethanol (20 ml) was stirred at room temperature in an atmosphere of hydrogen. After

one mole equivalent of hydrogen had been absorbed (*ca.* 1.5 h), the mixture was filtered. The filtrate was evaporated *in vacuo* and the residue was purified by column chromatography on silica gel (200 g) using hexane–benzene (7:3) as the eluent to afford (−)-**29** as an oil (1.705 g: 84%), $[\alpha]_D$ −90.3°; NMR: 0.91 and 1.01 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.73 (3H, bs, $=\dot{C}CH_3$), 3.24 (1H, m, $-C\underline{H}(CH_3)_2$), 3.80 (6H, s, 2-OCH_3), 5.30 (1H, m, $-CH=\dot{C}-$), 6.53 and 6.69 (each 1H, d, and J=9 Hz, aromatic protons). Found: C, 80.21; H, 10.11%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

*Intramolecular Cyclization of (−)-**29**.* A mixture of (−)-**29** (1.705 g) and anhydrous aluminium chloride (690 mg) in dry benzene (17 ml) was stirred at 25—30 °C for 30 min and then poured into a mixture of ice and dilute hydrochloric acid. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (170 g) using hexane–benzene (4:1) as the eluent to give (−)-**24** (581 mg: 34%), $[\alpha]_D$ −36.4°, whose IR and NMR spectra were identical with those of (±)-**24**. Found: C, 79.77; H, 10.63%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%. Further elution gave (+)-**23** as a solid (739 mg: 43%), $[\alpha]_D$ +32.4°, which was recrystallized from methanol: mp 89—91 °C, $[\alpha]_D$ +50.2° (lit,[1] mp 89—90 °C, $[\alpha]_D$ +35°). The IR and NMR spectra were identical with those of (±)-**23**. Found: C, 79.93; H, 10.67%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

*(+)-12-Methoxytotara-8,11,13-trien-13-ol (**2**).* A mixture of (+)-**23** (93 mg) and anhydrous aluminium chloride (40 mg) in dry benzene (4.0 ml) was refluxed for 3 h with stirring. After the usual work-up, the crude product was purified by column chromatography on silica gel (15 g) using hexane–benzene (9:1) as the eluent to give (+)-**2** (68 mg: 77%), which was recrystallized from methanol: mp 87—88.5 °C, $[\alpha]_D$ +50.2°, whose IR and NMR spectra were identical with those of (±)-**2**. Found: C, 79.87; H, 10.32%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

*(−)-12,13-Dimethoxytotara-8,11,13-trien-7-one (**25**).* A solution of (+)-**23** (124 mg) in acetone (3.0 ml) was oxidized at 16—20 °C for 30 min with Jones reagent (8N: 0.20 ml) and then diluted with ether. The ether solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (15 g) using hexane–benzene (1:4) as the eluent to give the starting (+)-**23** (14 mg: 11%). Further elution gave (−)-**25** (95 mg: 74%), $[\alpha]_D$ −19.2°, NMR ($CDCl_3$): 0.92 and 1.01 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.13 (3H, s, C_{10}–CH_3), 1.29 and 1.38 (each 3H, d, and J= 7 Hz, $-CH(C\underline{H}_3)_2$), 3.67 (1H, m, $-C\underline{H}(CH_3)_2$), 3.83 and 3.89 (each 3H and s, 2-OCH_3), 6.72 (1H, s, C_{11}–H). NMR (C_5D_5N): 0.81 and 0.89 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.03 (3H, s, C_{10}–CH_3), 1.46 and 1.60 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.85 (6H, s, 2-OCH_3), 4.17 (1H, m, $-C\underline{H}(CH_3)_2$), 6.81 (1H, s, C_{11}–H). The IR and NMR spectra were identical with those of (±)-**25**.

*(−)-Dispermone (**3**).* A solution of (−)-**25** (95 mg) and boron tribromide (0.10 ml) in dichloromethane (1.0 ml) was allowed to stand at 0—5 °C for 2 h and then treated as described for the preparation of (±)-**3**. The crude product was purified by column chromatography on silica gel using chloroform as the eluent to give (−)-dispermone (**3**) (80 mg: 92%), which was recrystallized from acetone–hexane: mp 262—267 °C, $[\alpha]_D$ −47.3° (EtOH) (lit,[1] mp 263—265 °C, $[\alpha]_D$ −48°), whose IR and NMR spectra were identical with those published.[1] Found: C, 75.75; H, 8.92%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

*(−)-12-Benzyloxy-13-hydroxytotara-8,11,13-tricn-7-one (**30**).* A mixture of (−)-**3** (204 mg), benzyl chloride (90 mg), potassium iodide (110 mg), and anhydrous potassium carbonate (1.0 g) in methyl ethyl ketone (10 ml) was refluxed for 5.5 h with stirring. After the usual work-up, the product was purified by column chromatography on silica gel (30 g) using benzene as the eluent to give (−)-**30** (260 mg: 99%), $[\alpha]_D$ −17.8°; IR: 3540, 1660 cm^{-1}; NMR ($CDCl_3$): 0.93 and 1.01 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.11 (3H, s, C_{10}–CH_3), 1.33 and 1.44 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.86 (1H, m, $-C\underline{H}(CH_3)_2$), 5.15 (2H, s, $-OCH_2-$), 5.81 (1H, s, C_{13}–OH), 6.77 (1H, s, C_{11}–H), 7.42 (5H, s, aromatic protons). NMR (C_5D_5N): 0.81 and 0.90 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.07 (3H, s, C_{10}–CH_3), 1.74 and 1.87 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 4.44 (1H, m, $-C\underline{H}(CH_3)_2$), 5.25 (2H, s, $-OCH_2-$), 6.93 (1H, s, C_{11}–H). Found: C, 79.75; H, 8.44%. Calcd for $C_{27}H_{34}O_3$: C, 79.76; H, 8.43%.

*(−)-12-Benzyloxy-13-methoxytotara-8,11,13-trien-7-one (**31**).* A mixture of (−)-**30** (182 mg), methyl iodide (0.10 ml), and anhydrous potassium carbonate (500 mg) in methyl ethyl ketone (5.0 ml) was refluxed for 33 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (20 g) using hexane–benzene (1:1) as the eluent to give (−)-**31** (177 mg: 94%), $[\alpha]_D$ −15.1°, IR: 1660 cm^{-1}, NMR: 0.94 and 1.02 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.10 (3H, s, C_{10}–CH_3), 1.28 and 1.35 (each, 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.83 (3H, s, $-OCH_3$), 5.10 (2H, s, $-OCH_2-$), 6.69 (1H, s, C_{11}–H), 7.38 (5H, s, aromatic protons). Found: C, 80.23; H, 8.61%. Calcd for $C_{28}H_{36}O_3$: C, 79.96; H, 8.63%.

*(+)-Dispermol (**5**).* A mixture of (−)-**31** (101 mg), PtO_2 (40 mg), and 60% perchloric acid (4 drops) in ethanol (10 ml) was stirred at room temperature for 2.5 h in an atmosphere of hydrogen. After the usual work-up, the crude product was chromatographed on silica gel (15 g) using benzene as the eluent to give (+)-dispermol (**5**) (50 mg: 66%), which was recrystallized from hexane: mp 166.5—167.5 °C, $[\alpha]_D$ +43.5° (lit,[1] mp 164—166 °C, $[\alpha]_D$ +37°); IR: 3550, 3360 cm^{-1}; NMR ($CDCl_3$): 0.95 (6H, s, $-\dot{C}(CH_3)_2$), 1.19 (3H, s, C_{10}–CH_3), 1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.37 (1H, m, $-C\underline{H}(CH_3)_2$), 3.79 (3H, s, $-OCH_3$), 5.2 (1H, br, C_{12}–OH), 6.80 (1H, s, C_{11}–H). NMR (C_5D_5N): 0.88 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.20 (3H, s, C_{10}–CH_3), 1.49 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.43 (1H, m, $-C\underline{H}-(CH_3)_2$), 4.05 (3H, s, $-OCH_3$), 7.13 (1H, s, C_{11}–H). Found: C, 79.44; H, 10.25%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

*(−)-12,13-Dimethoxytotara-6,8,11,13-tetraene (**32**).* A mixture of (−)-**25** (250 mg) and lithium aluminium hydride (30 mg) in dry ether (5.0 ml) was refluxed for 2 h. The mixture was poured into dilute hydrochloric acid, extracted with ether, and the ether extract was washed with brine, dried over sodium sulfate, and then evaporated. The residue was recrystallized from methanol to give (−)-**32** (174 mg: 73%), mp 96—97 °C, $[\alpha]_D$ −100°; NMR: 0.99 and 1.01 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.06 (3H, s, C_{10}–CH_3), 1.33 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.46 (1H, m, $-C\underline{H}(CH_3)_2$), 3.73 and 3.81 (each 3H and s, 2-OCH_3), 5.83 (1H, dd, J= 3 and 10 Hz, C_6–H), 6.54 (1H, s, C_{11}–H), 6.76 (1H, dd, J=3 and 10 Hz, C_7–H). Found: C, 80.19; H, 9.95%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%. The mother

liquor of crystallization was evaporated and the residue was chromatographed on silica gel (25 g) using hexane–benzene (1:1) as the eluent to give some additional (−)-**32** (29 mg: 12%).

*(+)-12,13-Dimethoxytotara-8,11,13-trien-6-one (**18**).* A solution of (−)-**32** (202 mg) and 70% *m*-chloroperbenzoic acid (170 mg) in dichloromethane (5.0 ml) was allowed to stand at 5—7 °C for 1.5 h and then diluted with ether. The solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and water. After the solvent had been removed *in vacuo*, the residue was dissolved in methanol (5.0 ml) containing dilute hydrochloric acid (10%: 0.5 ml). The solution was refluxed for 30 min in an atmosphere of nitrogen, cooled, and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was chromatographed on silica gel (20 g) using benzene as the eluent to give (+)-**18** (146 mg: 69%), $[\alpha]_D$ +117°, whose IR and NMR spectra were identical with those of (±)-**18**. Found: C, 76.91; H, 9.28%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

*(+)-Maytenoquinone (**1**).* A mixture of (+)-**18** (146 mg) and boron tribromide (0.14 ml) in dichloromethane (3.0 ml) was stirred at 0—5 °C for 1 h, poured into ice–water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and water, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (30 g) using benzene as the eluent to give (+)-maytenoquinone (**1**) (12.2 mg: 9.1%). Further elution with ether–benzene (1:9) afforded 12,13-dihydroxytotara-8,11,13-trien-6-one (117 mg: 87%); IR: 3540, 3250, 1705 cm^{-1}; NMR ($CDCl_3$): 1.10 (6H, s, $-\underset{|}{C}(CH_3)_2$), 1.35 (3H, s, C_{10}–CH_3), 1.36 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.50 (1H, s, C_5–H), 3.10 (1H, m, $-C\underline{H}(CH_3)_2$), 3.55 (2H, bd, J=2 Hz, $-COCH_2-$), 5.54 (s) and 6.21 (bs) (each 1H, C_{12}–OH and C_{13}–OH), 6.80 (1H, s, C_{11}–H).

The above phenol (117 mg) was stirred and refluxed for 1 h with silver oxide (170 mg) in chloroform (10 ml). The mixture was then filtered and the filtrate was evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (20 g) using benzene as the eluent to give (+)-maytenoquinone (**1**) (60 mg: 51%) (total 72.2 mg: 54% overall yield from (+)-**18**), which was recrystallized from methanol: mp 156—158 °C, $[\alpha]_D$ +407° (lit,[1] mp 158—160 °C, $[\alpha]_D$ +298°). Found: C, 76.48; H, 8.63%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%. The IR and NMR spectra were identical with those of (±)-**1**.

The Transformations of Terpene Ketones by Oxygen. I. The Autoxidation of Fukinone

Akio HORINAKA and Keizo NAYA*

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662

(Received November 14, 1978)

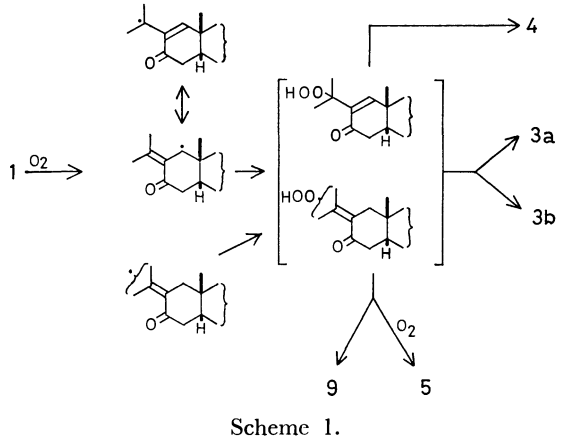
Fukinone, possessing a cisoid enone system, is susceptible to air oxidation. The oxidation products have been extensively examined and have been established as including diastereomeric epoxides, a hydroxy ketone (petasitolone), a lactol (8β-hydroxyeremophilenolide), and a peroxy hemiacetal. Also, the products were compared with those derived from the autoxidation of pulegone, a monoterpenic analogue of fukinone.

A fragrant oil, fukinone (**1**),[1] $C_{15}H_{24}O$, is rather sensitive to air. Even on storage, several polar spots appear on TLC. We have been interested in the autoxidation in connection with the biogenetic-type oxidation process. Furthermore, as little is known about the autoxidation of α,β-unsaturated ketones with an exo-cyclic double bond, we have studied the autoxidation of **1** in parallel with the base-catalyzed autoxidation.[2] Pulegone (**2**), with a similar enone system, has been widely studied;[3,4] hence, the autoxidation was reinvestigated in order to compare it with the products from **1**.

The autoxidation of the title compound, **1**, was achieved by heating it at 80—90 °C under a bubbling of air for 44 h. From the reaction mixture we isolated epoxides, $C_{15}H_{24}O_2$ (**3**), a hydroxy ketone, $C_{15}H_{22}O_2$ (**4**), and a lactol, $C_{15}H_{22}O_3$ (**5**) in 24.5, 3, and 3.5% yields respectively by column chromatography on silica gel.

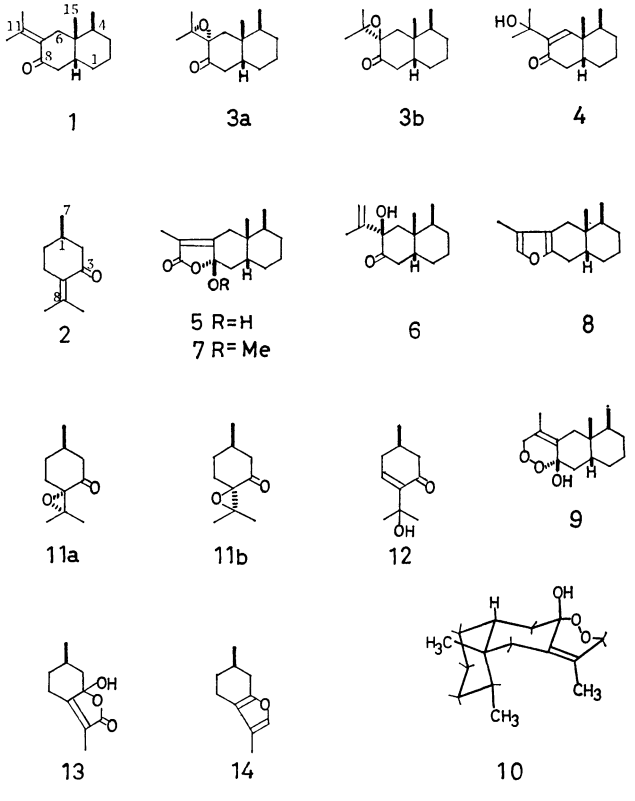
The epoxides, **3**, was shown by GLC analysis to be mixtures comprising approximately equal amounts of the diastereomers. **3** was separated into (**3a**) (mp 66—67 °C) and (**3b**) (mp 83—84 °C)[5] by repeated chromatogrphy on deactivated silica gel. Both the epoxides were identified by comparison with the authentic samples prepared by treating **1** with hydrogen peroxide in an alkaline solution.[6] The absolute configurations[5] previously proposed for fukinone epoxides, **3a** and **3b**, were finally settled by the X-ray analysis of the 7β-hydroxy-8-oxoeremophil-11(12)-ene (**6**)[7] prepared by the stereospecific cleavage of **3b** in the presence of *p*-toluenesufonic acid in dry benzene.[8]

The oily hydroxy ketone, **4**, was found to be identical with natural petasitolone[9] by a comparison of the IR and GLC.



Scheme 1.

The lactol, **5**,[10] showed a wide melting range (mp 180—200 °C), even after repeated recrystallizations. Therefore, **5** was transformed into the methoxylactone (**7**) by refluxing in methanol in the presence of a catalytic amount of hydrochloric acid, which was identical with 8β-methoxyeremophilenolide[10] prepared by the photosensitized oxygenation of furanoeremophilane (**8**)[11] in methanol. Accordingly the 8-hydroxyl and 8-methoxyl groups in both the lactones can be identified as β-configurations as in the **5** and **7** formulas.



In addition, **1** left in air for a long time afforded a peroxy hemiacetal (**9**) (mp 100—103 °C) besides **3**, **4**, and **5**. The structure for **9** was readily determined from the spectral and chemical properties. In the Dreiding-model inspection, the 8α- or 8β-substituents in the peroxy hemiacetal will force the *cis*-decalin system to adopt a nonsteroidal or a steroidal A/B *cis* chair/chair configuration respectively in a manner similar to that used in the case of eremophilenolides.[10,12] Therefore, on the basis of a similar relationship between the chemical shifts of 14- and 15-methyls, the peroxy hemiacetal was tentatively assigned to the stereoformula (**10**) bearing an 8β-hydroxyl group. The reduction

of **10** with triphenylphosphine gave furanoeremophilane (**8**), which occurs with **1** in the same plant,[11] implying a biosynthetic pathway to **8** from **1**. The hemiacetal, **9**, was itself rather stable in the crystalline state at room temperature, but it decomposed considerably in solution. The isolation of **9** suggests that the primary oxidation products of **1** are hydroperoxides; hence, the epoxides, **3a** and **3b**, the main products, are probably produced by the attack of the hydroperoxides on the alternate fukinone molecule.

The reinvestigation of the autoxidation of **2** was performed in a manner similar to that used for **1** and proved to afford products similar to those from **1**. Thus, the reaction mixture was separated to give epoxides (**11**), an oily hydroxy ketone (**12**), and a lactol (**13**) in 15, 6.4, and 28% yields respectively. The absolute configurations of α-epoxide (**11a**) (mp 57—58 °C) and β-epoxide (**11b**) (mp 53—54 °C) have previously been established.[13,14] The physical properties of **12** and **13** (mp 186—187 °C) were in good agreement with those of the photooxygenation product of **2**,[15] and of the autoxidation[4] or the photooxygenation[16] product of menthofuran (**14**) respectively.

From the above results, it seems that the autoxidation of **1** and **2** should proceed in the same manner, and that the autoxidation process of **1** is as depicted in Scheme 1.

Experimental

All the melting and boiling points are uncorrected. The IR, UV, and mass spectra were taken with Hitachi EPI-G3, Shimadzu Spectronic 505, and Hitachi RMU-6 spectrophotometers respectively. The PMR spectra were recorded with a Hitachi R-20B (60 MHz) spectrometer, and the chemical shifts are reported in δ-values, with TMS as the internal reference. The optical rotations were measured with a Perkin-Elmer 141 polarimeter. The analytical and preparative GLC were performed with a Shimadzu GC-1C apparatus on a stainless steel column (ϕ=3 mm). The TLC were run on silica gel (Merck Kieselgel G). The microanalyses were carried out in the analytical section of the Research Laboratory, Toyo Jozo Co., Ltd.

Autoxidation of Fukinone (1). Fukinone (**1**) (3.759 g) was oxidized without a solvent under the bubbling of air at 80—90 °C for 44 h. The resulting mixture (3.637 g) was chromatographed on silica gel (70 g). Elution with benzene afforded, successively, the recovered fukinone (**1**), a mixture of epoxides (**3a** and **3b**) (982 mg), a hydroxy ketone (**4**) (119 mg), and a lactol (**5**) (150 mg).

Each of the epoxides, (**3a**) and (**3b**), was obtained by repeated column chromatography on deactivated silica gel (Grade II), followed by recrystallization from light petroleum. Both epoxides, **3a** (mp 66—67 °C) and **3b** (mp 83—84 °C), were identical in all respects (IR, PMR, and mixed-melting-point determination) with authentic samples.[5]

The hydroxy ketone (**4**) was found to be identical with natural petasitolone[9] by a comparison of the IR and GLC results.

Lactol (5):[10] Mp 180—200 °C, colorless prisms (from ethyl acetate), $[\alpha]_D^{28}$ +155° (*c*, 1.03, $CHCl_3$); IR($CHCl_3$): 3550, 3330, 1750, 1696, 1230 cm^{-1}; UV: λ_{max}^{MeOH} 223 nm (ε, 25000); PMR ($CDCl_3$): 3.53 (s, OH), 1.77 (d, *J*=1.5 Hz, 12-Me), 1.02 (s, 15-Me), 0.77 (d, *J*=5.0 Hz, 14-Me).

Found: C, 72.15; H, 8.72%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

Methoxy Lactone (7). A solution of the lactol (**5**) (86 mg) in methanol containing a catalytic amount of concentrated hydrochloric acid was refluxed for 2.5 h. The reaction mixture was then poured into water, and the deposited crystals (77 mg, 84%) were recrystallized from aqueous methanol; mp 99.5—100 °C as colorless needles; $[\alpha]_D^{23}$ +192° (*c*, 1.00, $CHCl_3$); MS: *m/e* 264 (M^+), *m/e* 236 (base peak); IR(KBr): 1760, 1695, 1180, 990 cm^{-1}; (CCl_4): 1763, 1700, 1177 cm^{-1}; UV: λ_{max}^{MeOH} 223 nm (ε, 15000); PMR (CCl_4): 3.07 (s, OMe), 1.80 (d, *J*=1.5 Hz, 12-Me), 1.04 (s, 15-Me), 0.80 (d, *J*=6.0 Hz, 14-Me).

Found: C, 72.84; H, 9.07%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%. This compound was identical with the 8β-methoxyeremophilenolide (**7**) prepared from furanoeremophilane (**8**) by photosensitized oxygenation;[10] this was determined by a comparison of the IR, UV, and PMR, and by a mixed-melting-point determination.

Isolation of Peroxy Hemiacetal (9). Fikinone (**1**) (13.591 g) was left in air and in a dark place at room temperature for several months. The resulting oil was chromatographed on silica gel, and a polar part (with R_f values less than 0.3; silica gel, benzene) was collected. The yellow viscous oil (3.164 g) was repeatedly chromatographed on silica gel, with benzene as the eluent, to give two fractions, one containing **3**, **4**, and **9**, and the other containing **4** and **5**. From each fraction, **5** and **9** were deposited as crystals in 131 mg and 107 mg yields respectively. **9** was recrystallized from light petroleum; mp 100—103 °C; long, colorless leaflets, $[\alpha]_D^{24}$ −46° (*c*, 0.98, $CHCl_3$); MS: *m/e* 252 (M^+), *m/e* 110 (base peak); IR ($CHCl_3$): 3555, 1055, 1048 cm^{-1}; PMR ($CDCl_3$): 4.74 and 3.99 (each dd, *J*=3.0 and 16 Hz, 12-CH_2), 2.90 (br s, OH), 1.67 (br s, 13-Me), 0.92 (s, 15-Me), 0.78 (d, *J*=6.0 Hz, 14-Me).

Found: C, 71.21; H, 9.46%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

Reduction of Peroxy Hemiacetal (9) with Triphenylphosphine. A solution of **9** (113 mg) and triphenylphosphine (229 mg) in benzene was refluxed for 8 h, and subsequently the solvent was evaporated *in vacuo*. The residue was extracted with light petroleum, and the extract (169 mg) was chromatographed on deactivated silica gel (Grade II, 5 g). Subsequent elution with light petroleum–ether (50:1) gave an oil (120 mg). Further purification by preparative TLC (silica gel; light petroleum–ether, 20:1) afforded furanoeremophilane (**8**) (16 mg, 17%), which was found to be identical with an authentic sample[11] by a comparison of the IR and GLC (SE-30, 2.6 m; column temperature, 155 °C; H_2-flow rate, 40 ml/min; retention time, 6.7 min).

Autoxidation of Pulegone (2). Pulegone (**2**) (1.330 g) was subjected to oxidation for 62 h in the same fashion as in the case of **1**. The resulting mixture (1.121 g) was chromatographed on silica gel (25 g) with benzene to give a mixture of epoxides (**11**) (222 mg) and a hydroxy ketone (**12**) (95 mg). Subsequent elution with benzene–ethyl acetate (50:1) gave a lactol (**13**) (44 mg).

A mixture of epoxides (**11**) was separated into two diastereomers, (**11a**) and (**11b**), by preparative GLC (PEG 20 M, 2.6 m; column temperature, 145 °C; H_2-flow rate, 45 ml/min; retention time; β-epoxide (**11b**): 12.4 min, α-epoxide (**11a**): 19.1 min). Both the epoxides, **11a** (mp 57—58 °C) and **11b** (mp 53—54 °C), were found to be identical with authentic samples[13] by a comparison of the IR, PMR, and GLC, and by a mixed-melting-point determination.

Hydroxy Ketone (12):[15] Bp 130—140 °C (bath temperature)/15 mmHg, preparative GLC (PEG 20 M, 1.1 m; column temperature, 130 °C; H_2-flow rate, 72 ml/min; reten-

tion time, 6.8 min); IR(film): 3410, 1660 cm^{-1}; UV: λ_{max}^{MeOH} 234 nm (ε, 7900); PMR(CCl_4): 6.83 (m, 5-H), 3.73 (s, OH), 1.30 (s, 9- and 10-Me), 1.06 (d, J=4.0 Hz, 7-Me).

*Lactol (**13**)*:[4] Mp 186—188 °C, colorless prisms (from acetone); IR(KBr): 3325, 1735, 1693, 1195, 1120, 960 cm^{-1}; UV: λ_{max}^{MeOH} 219 nm (ε, 16100); PMR (acetone-d_6): 2.95 (s, OH), 1.70 (d, J=1.0 Hz, Me–C=C), 0.93 (d, J=7.0 Hz, Me–CH). (Found: C, 65.75; H, 7.95%).

The authors wish to thank the staff of the Research Laboratory, Toyo Jozo Co., Ltd., for the microanalysis and for the measurement of the mass spectra.

Nucleophilic Ion Pairs. 6. Catalytic Hydrolysis of *p*-Nitrophenyl Acetate by Zwitterionic Hydroxamate Nucleophiles in Representative Micellar Systems[1]

Toyoki KUNITAKE,* Yoshio OKAHATA, Shoichi TANAMACHI, and Reiko ANDO
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received November 17, 1978)

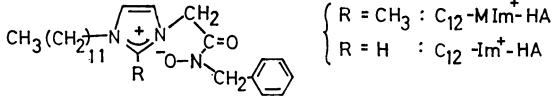
Several surfactant-like zwitterionic hydroxamates were synthesized and their reactions with *p*-nitrophenyl acetate were studied in water in comparison with those of simple, anionic hydroxamates. The zwitterionic hydroxamates showed enhanced reactivities in cationic, zwitterionic and nonionic micelles: 20—100 times relative to the nomicellar rate at pH 8.9, 30 °C. The rate enhancement was attributed to lowered pK_a values and to activation of the hydroxamate anion in the hydrophobic domain. The rate was suppressed in an anionic micelle because of the enhanced pK_a value. Deacylation of the acetyl hydroxamate intermediate was hydroxide-catalyzed. The enhanced reactivity of the zwitterionic hydroxamate in organic media was less sensitive to the water concentration than that of the hydroxamate ion pair. These results can be explained in terms of "*hydrophobic ion pair.*"

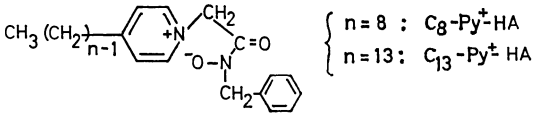
Anionic nucleophiles such as oximates, hydroxamates, thiolates and imidazole anions possess remarkably enhanced reactivities in the presence of cationic micelles and cationic polysoaps.[2] The increase in rate cannot be attributed to the peculiar microenvironment of these aqueous micelles, and we proposed that the formation of nucleophilic ion pairs in the hydrophobic microenvironment— "*hydrophobic ion pairs*" is essential for the rate enhancement. This is supported by the extremely high reactivity of tetraalkylammonium hydroxamate ion pairs in dry aprotic solvents[3,4] and by activation of hydrophobic anionic nucleophiles in the presence of the nonmicellar (in the conventional meaning) aggregate of trioctylmethylammonium chloride.[5]

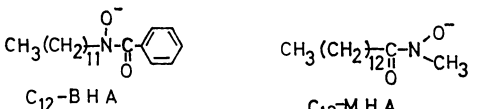
Zwitterionic nucleophiles may form hydrophobic ion pairs by themselves and could show high reactivities. Several papers describe their unexpectedly high nucleophilicities in the micellar[2,6] and polymeric[7—10] systems. However, no unified interpretation has so far been given.

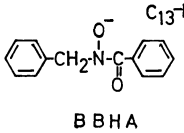
In the present study, we have systematically examined the reactivity of four zwitterionic nucleophiles in representative aqueous micelles (cationic, anionic, zwitterionic, and nonionic micelles) and in organic media. The structures of the nucleophiles and surfactants used are as follows.

Nucleophile:

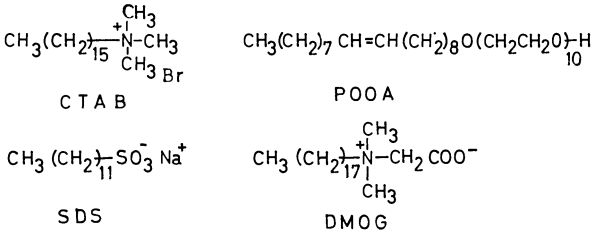








Surfactant:



Experimental

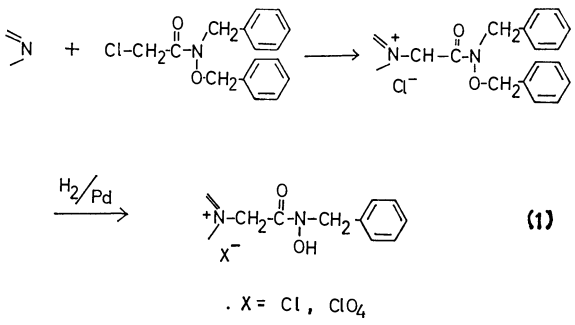
Materials. The preparation and purification of *N*-dodecylbenzohydroxamic acid(C_{12}-BHA),[11] *N*-benzylbenzohydroxamic acid (BBHA),[12] *N*-methylmyristohydroxamic acid(C_{13}-MHA),[13] and *p*-nitrophenyl acetate[11] has been described. Commercial CTAB was recrystallized from ethanol several times. *N,N*-Dimethyl-*N*-octadecylglycine (DMOG) was prepared by the reaction of *N,N*-dimethyloctadecylamine and chloroacetic acid and recrystallized twice from ethyl acetate, mp 140—142 °C. Its IR and NMR spectra were in line with the structure. Commercial SDS and POOA were used without further purification.

N-Dodecylimidazole was prepared as follows according to the procedure of Härig:[14] Imidazole (20 g, 0.3 mol) was dissolved in a mixture of ethanol (70 ml) and aqueous 20 M (1 M=1 mol dm^{-3}) NaOH (30 ml), and 99 g (0.4 mol) of dodecyl bromide was added at 80—85 °C with stirring over 2.5 h. Stirring was continued at room temperature for 5 h. The solvent was then removed *in vacuo* and the residue was extracted twice with chloroform. The extract was dried over Na_2SO_4, solvent removed and the residue distilled: yield 65%; bp 158—168 °C/35 mmHg (1 mmHg=133.322 Pa). IR and NMR spectra were in line with the expected structure.

A similar procedure was used for preparing *N*-dodecyl-2-methylimidazole from dodecyl bromide and 2-methylimidazole: bp 147—148 °C/3 mmHg (lit,[15] bp 174—176 °C/3 mmHg).

4-Octylpyridine was obtained from pyridine and octanoic anhydride according to the procedure of Arens and Wibaut[16] in 7% yield: bp 112—114 °C/4 mmHg (lit,[16] bp 265—268 °C). 4-Tridecylpyridine was prepared from 4-pyridylmethyllithium and dodecyl bromide by the procedure of Wibaut and Hey:[17] yield 26%, mp 129—131 °C (as hydrochloride). Found: C, 67.82; H, 10.09; N, 4.57%. Calcd for $C_{18}H_{31}N \cdot HCl \cdot H_2O$; C, 68.43; H, 10.84; N, 4.43%.

These alkylamines were quaternized by benzyl *N*-benzylchloroacetohydroxamate (bp 150—155 °C/0.03 mmHg)[9] in acetone at 50 °C for 2 h, the benzyl group being removed by hydrogenation in ethanol over 5% $Pd/SrCO_3$.



(1)

. X= Cl, ClO_4

C_{12}-Im$^+$-HA; mp 157—158 °C (from acetonitrile). Found: C, 66.03; H, 8.80; N, 9.66%. Calcd for $C_{24}H_{38}N_3O_2Cl$: C, 66.11; H, 8.78; N, 9.64%.

C_{12}-MIm$^+$-HA; mp 176—177 °C (from acetonitrile). Found: C, 66.75; H, 9.01; N, 9.29%. Calcd for $C_{25}H_{40}N_3O_2Cl$: C, 66.72; H, 8.96; N, 9.34%.

C_8-Py$^+$-HA; mp 88—89 °C (crystallized as perchlorate salt from ethanol and ether). Found: C, 57.69; H, 6.87; N, 6.12%. Calcd for $C_{22}H_{31}N_2O_6Cl$: C, 58.08; H, 6.87; N, 6.16%.

C_{13}-Py$^+$-HA; mp 176—177 °C (from acetonitrile). Found: C, 70.04; H, 8.90; N, 6.06%. Calcd for $C_{27}H_{41}N_2O_2Cl$: C, 70.33; H, 8.96; N, 6.08%.

Kinetics. The hydrolysis of PNPA in the aqueous system was conducted in 3 v/v% EtOH–H_2O at 30 °C, μ=0.01 (KCl) in the pH range 6—10. The reaction was followed by the appearance of *p*-nitrophenolate at 401 nm (Hitachi 200 UV-visible spectrophotometer with a thermostated cell compartment). In the presence of excess nucleophile the reaction followed the pseudo first-order rate law for more than 90% completion. The pseudo first-order rate constant was divided by the total nucleophile concentration to give the apparent second-order rate constant of acylation, $k_{a,obsd}$. In the case of the hydrolysis performed in organic media, the nucleophiles were neutralized by addition of 10 times excess of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).

Burst-type kinetics were observed in the presence of excess substrate. The rate constants of acylation and deacylation were determined according to the procedure reported.[11]

Calculations were carried out with the aid of a programmable desk calculator, the least-squares procedure being applied wherever possible. The correlation coefficient was always better than 0.99. The pH measurement was carried out with a Toa Digital pH meter (Type HM-10A), pH variation of the aqueous reaction medium being confirmed to be smaller than ±0.05. The water content in the organic media was determined with a coulometric Karl-Fischer apparatus (Hiranuma Aquacounter, AQ-1).

Results

Acylation. The reaction of PNPA with excess hydroxamate nucleophiles gives the apparent rate constant of acylation as

$$k_{a,obsd} = \frac{k_{obsd} - k_{spont}}{[HA]_{total}} \quad (2)$$

where k_{obsd} and k_{spont} are pseudo first-order rate constants of *p*-nitrophenol release in the presence and absence of the nucleophile, respectively, and $[HA]_{total}$ is the total hydroxamic acid concentration.

TABLE 1. SECOND-ORDER RATE CONSTANTS OF ACYLATION IN THE MICELLAR SYSTEMS[a]

Hydroxamate	$k_{a,obsd}$ ($M^{-1}s^{-1}$)				
	Nonmicellar	SDS	CTAB	POOA	DMOG
C_{12}-Im$^+$-HA	12	1.2	1000	270	1200
C_{12}MIm$^+$-HA	13	0.8	1300	250	1100

C_{13}-MHA	—	1.3	1300	32	45
BBHA	12	—	1500	13	23

a) 30 °C, 3 v/v% EtOH–H_2O, μ=0.01(KCl), pH 8.90 ±0.05 (0.01 M Borate). [PNPA]=9.46×10^{-6} M, [catalysts]=$(3.05—7.08)\times10^{-5}$ M. Surfactant concentrations are 1×10^{-3} M except for ([SDS]=1×10^{-2} M).

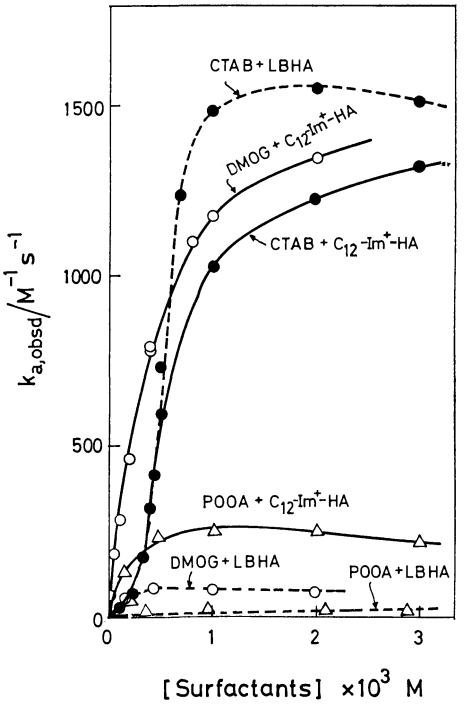

Fig. 1. Rate dependence on surfactant concentration. 30 °C, 3 v/v%EtOH–H_2O, μ=0.01 (KCl), pH 8.90± 0.05 (0.01 M Borate). [C_{12}-Im$^+$-HA]=7.08×10^{-5} M [LBHA(C_{12}-BHA)]=7.49×10^{-5} M

The $k_{a,obsd}$ values obtained in various micellar systems at pH 8.9 are summarized in Table 1. In the absence of micelles, the nucleophilic reactivity of the zwitterionic hydroxamates is similar to that of the simple hydroxamate (BBHA). $k_{a,obsd}$ of all hydroxamates was enhanced *ca.* 100 times by the cationic micelle (CTAB) and lowered to *ca.* 1/10 of the original value by the anionic micelle (SDS). As an exception, C_8-Py$^+$-HA was activated only *ca.* 30 times by the CTAB micelle because of its lower hydrophobicity. The non-zwitterionic hydroxamates (C_{12}-BHA, C_{13}-MHA, and BBHA) are not particularly activated in the nonionic and zwitterionic micelles, whereas the zwitterionic hydroxamates are activated to a greater extent. Since the nucleophiles cannot form micellar aggregates by

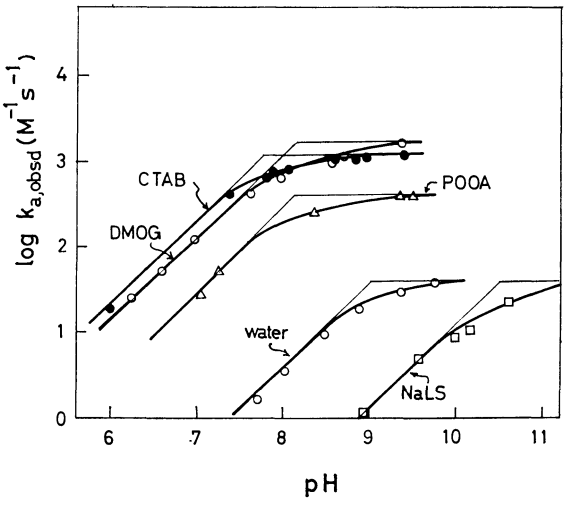

Fig. 2. pH-rate profile of the acylation of C_{12}-Im^+-HA. 30 °C, 3 v/v% EtOH-H_2O, μ=0.01 (KCl), [C_{12}-Im^+-HA]=7.08×10^{-5} M, [PNPA]=9.46×10^{-6} M. Surfactant concentration: 1×10^{-3} M for CTAB, DMOG and POOA. 1×10^{-2} M for NaLS (SDS).

themselves under these conditions, the rate enhancement is closely related to the micelle formation of added surfactants. Figure 1 shows the dependence of $k_{a,obsd}$ on the surfactant concentration for C_{12}-BHA and C_{12}-Im^+-HA, $k_{a,obsd}$ increasing rapidly at the surfactant concentration near the critical micelle concentration: 8×10^{-4} M for CTAB,[11] 3×10^{-4} M for DMOG[18] and *ca.* 10^{-6} M for POOA.[19]

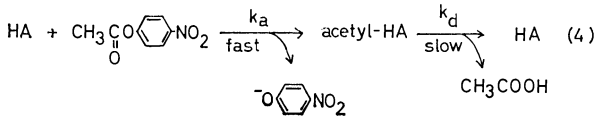
C_{12}-Im^+-HA was selected as a representative zwitterionic nucleophile and its pH rate prophiles were studied in the presence of various micelles (Fig. 2). The solid curves were obtained by means of

$$k_{a,obsd}=\frac{K_a}{K_a+a_H}\cdot k_a \qquad (3)$$

where K_a and k_a are the acid dissociation constant of the hydroxamic acid and the second-order rate constant of acylation for the effective hydroxamate species, respectively, and determined by the best-fit of the theoretical and experimental curves. The results are summarized in Table 2. As compared to the nonmicellar value, the pK_a value in the anionic micelle is increased by *ca.* 1 pK unit and decreased by the nonionic, cationic and zwitterionic micelles. The k_a value in the anionic SDS micelle is similar to the nonmicellar value, but large increases are observed in other micelles: *ca.* 10 fold in POOA; 30—40 fold in CTAB and DMOG.

The influence of ionic strength on $k_{a,obsd}$ is shown in Fig. 3. $k_{a,obsd}$ decreases with increasing ionic strength in all the micellar systems studied. However, the decrease was smaller than that observed for the C_{12}-BHA–CTAB system.

Deacylation. In the reaction of C_{12}-Im^+-HA with excess PNPA, the *p*-nitrophenol release follows the burst kinetics: *i.e.*, rapid acylation and subsequent, slow deacylation.



(4)

Table 2. Rate constants of acylation and dissociation constant in the reaction of PNPA and C_{12}-Im^+-HA[a]

Surfactant	C_{12}-Im^+-HA		λ_{max} of Methyl Orange in micelles (nm)

a) 30 °C, 3 v/v% EtOH-H_2O, μ=0.01 (KCl), [C_{12}-Im^+-HA]=7.08×10^{-5} M.

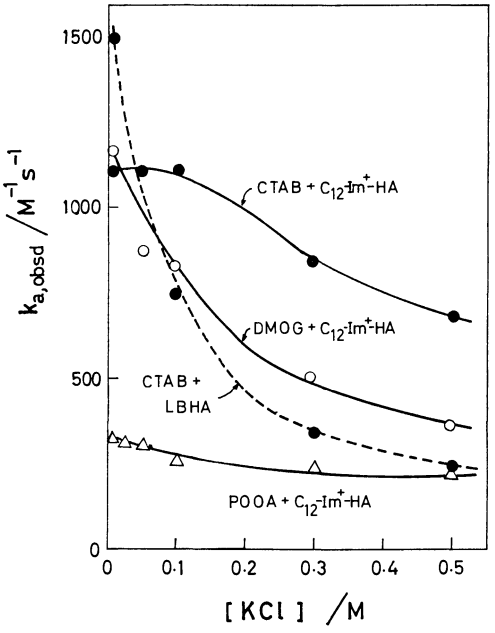

Fig. 3. Effect of ionic strength on the acylation rate. 30 °C, 3 v/v% EtOH-H_2O, pH 8.90±0.05 (0.01 M Borate). [C_{12}-Im^+-HA]=7.08×10^{-5} M, [LBHA(C_{12}-BHA)]=7.49×10^{-5} M. Surfactant concentration; 1×10^{-3} M.

The apparent rate constants of acylation and deacylation can be estimated by the following equations.

$$k_{a,obsd}=\frac{b\sqrt{B}}{[PNPA]_0\sqrt{[HA]_0}} \qquad (5)$$

$$k_{d,obsd}=b-k_a[PNPA]_0 \qquad (6)$$

where B is the extrapolation at t=0 of the steady-state *p*-nitrophenol release, and b is the pseudo first-order rate constant of the presteady state curve.[11,12]

Results obtained from analysis of the burst kinetics are given in Table 3. The $k_{a,obsd}$ values estimated by Eq. 5 agree fairly well with those obtained under the pseudo first-order conditions (Table 1).

The burst type experiment was carried out at pH 8—10. The resulting pH-rate profile of deacylation is shown in Fig. 4. In all the systems, log $k_{d,obsd}$ is a linear function of pH with the slope +1. This indicates that the deacylation process is hydroxide-catalyzed.

TABLE 3. RATE CONSTANTS OF ACYLATION AND DEACYLATION DETERMINED FROM THE BURST KINETICS[a)]

Hydroxamate	Micelle	$k_{a,obsd}$ ($M^{-1}\,s^{-1}$)	$k_{d,obsd}$ ($\times 10^2\,s^{-1}$)

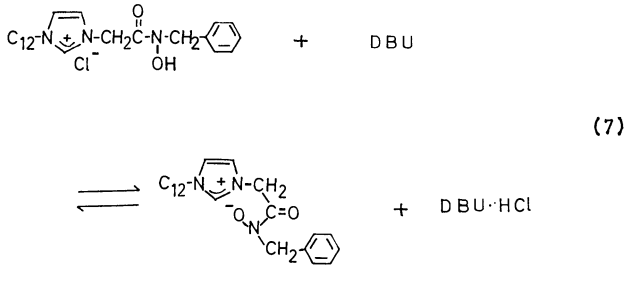
a) 30 °C, pH 8.9±0.1(0.01 B Borate), 3 v/v% EtOH-H_2O, μ=0.01(KCl), [C_{12}-Im^+-HA]=1.42×10^{-5} M, [PNPA]=1.89×10^{-4} M. [Surfactant]=1×10^{-3} M.

TABLE 4. REACTION OF HYDROXAMATES WITH PNPA IN ORGANIC MEDIA[a)]

Solvent	[H_2O] (mM)	k_a ($M^{-1}\,s^{-1}$)	
		C_{12}-Im^+-HA	C_{12}-BHA
Benzene	1.0	1200	606
	10	900	105
	40	680	25
Dimethylformamide	15	3300	1000
Acetonitrile	10	*ca.* 4000	1500
Ethanol	33	160	0.1

a) 30 °C, [Hydroxamic acid]=1.42×10^{-5} M, [PNPA]=1.89×10^{-4} M, [DBU]=$(1.42—13.2)\times10^{-4}$ M.

Reaction in Organic Media. The reaction of C_{12}-Im^+-HA with PNPA was studied in dry organic solvents. The hydroxamate anion was produced by addition of strongly basic DBU. Figure 5 shows the increase in the hydroxamate absorbance at 270 nm with increasing amounts of DBU added. We see that 10 times excess of DBU is sufficient to neutralize the hydroxamic acid completely.



(7)

The apparent rate constant of acylation shows the same trend as that of the absorbance change. The *p*-nitrophenol release is thus effected solely by the hydroxamate anion. It was confirmed in a separate experiment that DBU alone can cause no *p*-nitrophenol release.

Values of the second-order rate constant of acylation k_a for C_{12}-Im^+-HA, determined in several organic media, are given in Table 4 together with those for C_{12}-BHA for the sake of comparison. The k_a values of these two nucleophiles differ by factors of 2—3 in dry aprotic solvents, a large reactivity difference being observed in moist benzene and in ethanol. Thus, the reactivity of the C_{12}-BHA anion in benzene decreases drastically with increase in water concentrations. However, the reactivity of the C_{12}-Im^+-HA anion is much less sensitive to the water concentration. In the same vein, k_a for C_{12}-Im^+-HA anion is 1600 times larger than that of C_{12}-BHA anion in ethanol.

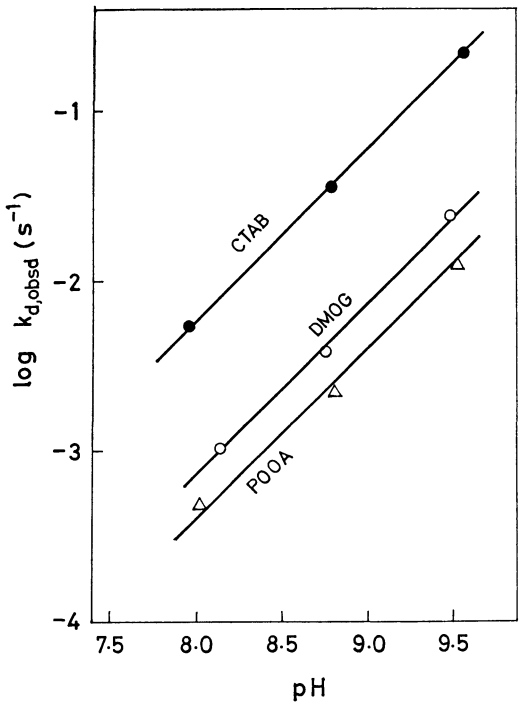


Fig. 4. pH-rate profile of the deacylation. 30 °C, 3 v/v% EtOH-H_2O, μ=0.01 (KCl). Surfactant concentration, 1×10^{-3} M.

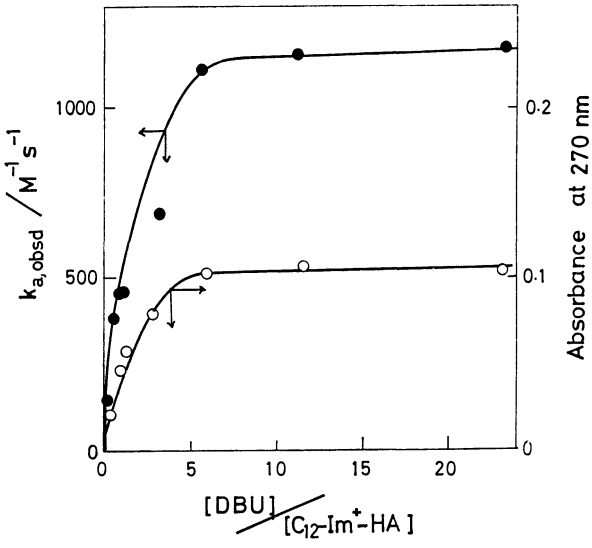

Fig. 5. Effect of DBU concentration in the reaction of C_{12}-Im^+-HA and PNPA in dry benzene. 30 °C, [H_2O]=1—3 mM, [C_{12}-Im^+-HA]=4.75×10^{-5} M, [PNPA]=6.90×10^{-6} M.

Discussion

The results on the reactivity of zwitterionic nucleophiles are wholly consistent with the concept of "*hydrophobic ion pair*." As shown in Table 1, simple hydroxamates such as C_{12}-BHA and C_{13}-MHA are highly activated in the cationic micelle due to the ion pair formation with the ammonium surfactant, but this activation mechanism cannot operate in other types of micelle. The zwitterionic hydroxamates are activat-

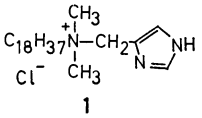
ed in the presence of the cationic, zwitterionic and nonionic micelles to various extents. In this case, the countercation is provided in the form of the intramolecular ammonium group. What is required is the hydrophobic microenvironment. The structure of the cationic moiety (imidazolium *vs.* pyridinium) does not affect the reactivity. The activation mechanism is better understood by examining the data in Table 2. The enhanced rate constant for C_{12}-Im$^+$-HA in the three micelles is produced by lower pK_a values and increased k_a values. The k_a value is correlated with the hydrophobic microenvironment estimated by the absorption maximum of Methyl Orange. A smaller increase in k_a in the nonionic micelle is in line with the limited hydrophobic nature of this micelle. The lowering of reactivity observed in the anionic micelle is caused by the increased pK_a value. k_a is not affected by the anionic micelle.

The reactivity of hydroxamate ammonium ion pairs in dry aprotic solvents is greatly reduced by minute amounts of water.[3,4] Similar data have been obtained in this study for C_{12}-BHA in benzene (Table 4). k_a decreases by a factor of 24 with increasing water concentrations from 1 mM to 40 mM. However, the rate-depressing effect of water is much less pronounced for the zwitterionic nucleophile; it retained more than 50% of the original reactivity during the same increase in water.

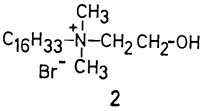
The large k_a difference (1600 fold) in ethanol between C_{12}-Im$^+$-HA and C_{12}-BHA should be related to the varied sensitivity of their reactivities to water. It is concluded that the zwitterionic hydroxamate forms a stable intramolecular ion pair which is deactivated less readily by protic solvents.

The deacylation reaction of the acetyl hydroxamate intermediate is mainly hydroxide-catalyzed. Figure 4 shows that the deacylation step is accelerated by the micellar microenvironment in the order: CTAB$\gg$ DMOG>POOA, reflecting the concentration effect of the hydroxide anion in the micellar phase.

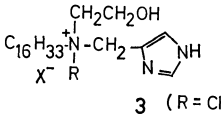
The enhanced reactivity of the zwitterionic nucleophile has been utilized in several polymer catalysts.[7-8] In micellar catalysis, use of the well-defined zwitterionic nucleophile has been limited in number.[2,6] However, some of the reported functional micelles seem to show high reactivity because of their zwitterionic nature. The first example was reported by Tagaki *et al.* for an imidazole-containing ammonium surfactant micelle (**1**).[20] Since then several papers have appeared on the enhanced nucleophilicity of the hydroxyethyl and/or imidazole groups attached to the ammonium surfactant (**2**, **3**).[21-27]



1



2



3 (R = CH_3, C_2H_5)

Rate enhancements in these examples should also arise from lowered pK_a values and activation of the anionic nucleophiles formed.[22] However, zwitterionic hydroxamates are the particularly effective nucleophile since their pK_a values are in the weakly alkaline region. The second-order rate constants of acyl transfer from PNPA to the other zwitterionic nucleophiles **1**, **2**, **3** are not quite as large, because the effective zwitterionic species are formed only in small amounts in the neutral pH region due to their high pK_a values.

Reactions of 3-Acetyltropolone and Its Methyl Ethers with Hydrazine

Akio YAMANE,† Masatoshi NAGAYOSHI,†† Kimiaki IMAFUKU,* and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received December 1, 1978)

3-Acetyltropolone (**1**) was synthesized from 3-isopropenyltropolone by treatment with sodium azide in concentrated sulfuric acid. Methylation of **1** by diazomethane gave two isomers, 3-acetyl-2-methoxytropone (**2a**) and 2-acetyl-7-methoxytropone (**2b**). **1**, **2a**, and **2b** reacted with hydrazine to give some 1,8-dihydrocycloheptapyrazol-8-one derivatives.

Doi reported that 4-isopropenyltropolone affords 4-acetyltropolone by treatment with one equivalent of hydrazoic acid in concentrated sulfuric acid.[1] By the application of this reaction to 3-isopropenyltropolone, we successfully obtained 3-acetyltropolone (**1**). Schenck *et al.* synthesized chloro-substituted 3-acetyltropolone by another method.[2] Since 3-acetyltropolone (**1**) has an active methyl group and β-diketone structure, several interesting reactions are expected. Its two isomeric methyl ethers, **2a** and **2b**, would behave as active troponoid. On the other hand, Matsumoto obtained 1,8-dihydrocycloheptapyrazol-8-one derivatives by the reactions of 3-formyltropolone derivatives with hydrazines.[3] We have investigated the reactions of **1**, **2a**, and **2b** with hydrazine.

Scheme 1.

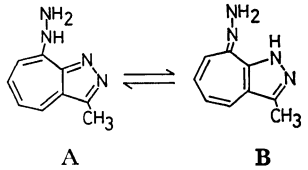
Results and Discussion

*Synthesis of 3-Acetyltropolone (**1**) and Its Methyl Ethers (**2a** and **2b**).* 3-Isopropenyltropolone was obtained by the method of Asao *et al.*[4] Treatment of 3-isopropenyltropolone with 1.5 equivalents of sodium azide in concentrated sulfuric acid gave 3-acetyltropolone (**1**) in a fairly good yield (70%). The structure was confirmed by means of spectral and analytical data. The IR spectrum showed a strong acetyl carbonyl band at 1715 cm^{-1} and a characteristic band for tropolone at 1620 cm^{-1}. The UV and NMR spectra also supported the structure of 3-acetyltropolone (**1**).

Being a β-diketone, 3-acetyltropolone (**1**) reacts with diazomethane to give two methyl ethers (**2a** and **2b**). As to the two methyl ethers, one is 3-acetyl-2-methoxytropone and the other 2-acetyl-7-methoxytropone. Generally, in ^1H NMR spectrum the signal of the proton situated in a β-position to a carbonyl group appears in a lower field. The NMR spectrum of **2a** showed a multiplet for seven-membered ring protons at 6.9—7.3 ppm, while that of **2b** showed a doublet of doublets for H-3 at 7.58 ppm. Thus, **2a** was assigned to 3-acetyl-2-methoxytropone and **2b** to 2-acetyl-7-methoxytropone.

*Reactions of 3-Acetyltropolone (**1**) and 3-Acetyl-2-methoxytropone (**2a**) with Hydrazine.* Refluxing of a mixture of **1** and 2 equivalents of hydrazine hydrate in methanol afforded 3-methyl-1,8-dihydrocycloheptapyrazol-8-one (**3**) in 76% yield. The reaction at room temperature also gave **3** in 62% yield. Though **3** can be considered to be another tautomeric form, 3-methylcycloheptapyrazol-8-ol, its IR, NMR, and UV spectra support the form of 3-methyl-1,8-dihydrocycloheptapyrazol-8-one. **2a** also reacted with hydrazine hydrate to give **3**, the difference between the reactivities of **1** and **2a** not being observed.

*Reaction of 2-Acetyl-7-methoxytropone (**2b**) with Hydrazine.* When a mixture of **2b** and 2 equivalents of hydrazine hydrate in methanol was refluxed, 3-methyl-1,8-dihydrocycloheptapyrazol-8-one azine (**4**) precipitated and 3-methyl-1,8-dihydrocycloheptapyrazol-8-one hydrazone (**5**) was obtained from the filtrate. The reaction with equimolar hydrazine hydrate gave only **4** (34%), **2b** being recovered (36%). The azine (**4**) was purple plates and insoluble in organic solvents except acetic acid. Nozoe *et al.*[5] obtained 3-phenyl-1,8-dihydrocycloheptapyrrol-8-one azine by the reaction of 8-chloro-3-phenylcycloheptapyrrole with hydrazine hydrate, the UV spectrum of which being very similar to that of **4**. The IR spectrum of **4** has a few absorption bands because of high symmetry but no bands at near 1600 cm^{-1} for tropone nor at near 1720 cm^{-1} for acetyl group. However, it has an absorption band near 3200 and 3400 cm^{-1} for NH. Mass spectrum of **4** shows a molecular ion peak at 326. The structure of **4** is reasonable from the above-mentioned evidence and analytical data. **5** has two tautomeric forms such as A and B. The UV spectrum of **5** in visible region shows absorption maxima at fairly shorter wavelength[6] and the NMR spectrum the signal for NH of pyrazole ring at *ca.* 12.4 ppm, indicating that **5** exists mainly in the form B.



A B

Treatment of **5** with acetone yielded a tricyclic compound (**6**). The NMR spectrum of **6** showed the

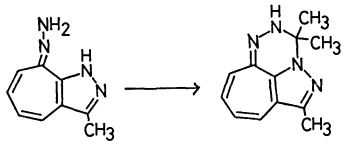
presence of three methyl group [δ 1.61 (6H), 2.36 (3H)]. Two methyl groups at 1.61 ppm suggest that they exist at sp^3 carbon atom. The mass spectrum showed the parent peak at 214 and the elemental analysis also gave a satisfactory result. Accordingly, **6** was identified as 1,3,3-trimethyl-3,4-dihydro-2,2a,4,5-tetraazabenz[*cd*]azulene.



5 **6**

Experimental

The melting points were determined with a Yanagimoto hot-stage apparatus and are uncorrected. All ^1H NMR spectra were recorded with a Hitachi R-24 spectrometer (60 MHz) with TMS as an internal standard. The IR and UV spectra were recorded with a JASCO IRA-1 and a Hitachi EPS-3T spectrophotometer, respectively. The mass spectra were taken on a JEOL JMS-OI-SG-2 spectrometer.

*Preparation of 3-Acetyltropolone (**1**).* Sodium azide (10 g) was added to a stirred mixture of 3-isopropenyltropolone (16.2 g), concentrated sulfuric acid (50 ml) and chloroform (50 ml) under cooling with water. The mixture was stirred at 60—70 °C for 2 h. After removal of the chloroform layer, the acid layer was diluted with water and then left to stand overnight. The crystals deposited were recrystallized from methanol to give 11.6 g (70%) of 3-acetyltropolone (**1**) as pale yellow needles: mp 131—132 °C; λ_{max}^{MeOH} nm (log ε): 245 (4.25), 350 (3.80), 415 (3.75); IR ($CHCl_3$): 1715 (C=O), 1620 cm^{-1} (C=O); NMR ($CDCl_3$): δ 9.0 (br, s, 1H, OH), 7.76 (d, 1H, J=9.0 Hz, H-4), 6.9—7.6 (m, 4H), 2.69 ppm (s, 3H, CH_3). Found: C, 65.68; H, 4.94%. Calcd for $C_9H_8O_3$: C, 65.85; H, 4.91%.

*Methylation of 3-Acetyltropolone (**1**).* An ethereal solution of diazomethane was slowly added to a solution of **1** (11.1 g) in chloroform until the resulting mixture gave no coloration with iron(III) chloride. After removal of the solvents *in vacuo*, the residue was chromatographed on a silica gel column (Wakogel C-100, 900 g) using ethyl acetate as eluant. The former fractions were combined and recrystallized from hexane–benzene to give 5.37 g (45%) of 3-acetyl-2-methoxytropone (**2a**) as colorless needles: mp 45—46 °C; λ_{max}^{MeOH} nm (log ε): 235 (4.21), 330 (3.87); IR ($CHCl_3$): 1730 (C=O), 1587 cm^{-1} (C=O); NMR ($CDCl_3$): δ 6.9—7.3 (m, 4H), 4.00 (s, 3H, OCH_3), 2.53 ppm (s, 3H, $COCH_3$). Found: C, 67.34; H, 5.69%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%. The latter fractions were also combined and recrystallized from hexane–benzene to give 4.92 g (41%) of 2-acetyl-7-methoxytropone (**2b**) as pale yellow needles: mp 105—106 °C; λ_{max}^{MeOH} nm(log ε): 235 (4.24), 330 (3.84), 365 (3.83); IR ($CHCl_3$): 1716 (C=O), 1601 cm^{-1} (C=O); NMR ($CDCl_3$): δ 7.58 (dd, 1H, J=11.2 and 2.0 Hz, H-3), 6.7—7.4 (m, 3H), 3.96 (s, 3H, OCH_3), 2.53 ppm (s, 3H, $COCH_3$). Found: C, 67.22; H, 5.72%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%.

*Reaction of 3-Acetyltropolone (**1**) with Hydrazine.* a) A mixture of **1** (213 mg, 1.30 mmol) and 80% hydrazine hydrate (167 mg, 2.67 mmol) in methanol (10 ml) was refluxed for 1 h. After removal of the solvent the residue was recrystallized from benzene to give 158 mg (76%) of 3-methyl-1,8-dihydrocycloheptapyrazol-8-one (**3**) as orange plates: mp 183—184 °C; λ_{max}^{MeOH} nm (log ε): 235 (4.35), 296 (3.82), 308 (3.81), 365 (3.85); IR ($CHCl_3$): 3200 (NH), 1580 cm^{-1} (C=O); NMR ($CDCl_3$): δ: 12.0—13.5 (br, 1H, NH), 6.6—7.3 (m, 4H), 2.60 ppm (s, 3H, CH_3). Found: C, 67.35; H, 5.07; N, 17.74%. Calcd for $C_9H_8ON_2$: C, 67.48; H, 5.03; N, 17.49%. b) At room temperature, the reaction of **1** (205 mg, 1.25 mmol) with 80% hydrazine hydrate (80 mg, 1.28 mmol) in methanol (10 ml) gave the same product **3** (124 mg, 62%) after 48 h.

*Reaction of 3-Acetyl-2-methoxytropone (**2a**) with Hydrazine.* a) A mixture of **2a** (330 mg, 1.85 mmol) and 80% hydrazine hydrate (295 mg, 4.72 mmol) in methanol (10 ml) was refluxed for 1 h. After removal of the solvent the residue was recrystallized from benzene to give 206 mg (68%) of **3**. b) The same reaction of **2a** (206 mg, 1.26 mmol) with 80% hydrazine hydrate (67 mg, 1.07 mmol) at room temperature for 48 h also gave **3** (90 mg, 51%).

*Reaction of 2-Acetyl-7-methoxytropone (**2b**) with Hydrazine.* a) When a mixture of **2b** (722 mg, 4.05 mmol) and 80% hydrazine hydrate (496 mg, 7.92 mmol) in methanol (40 ml) was refluxed, a purple precipitate was formed. After 1 h the precipitate was filtered off and recrystallized from dimethyl sulfoxide–water to give 82 mg (13%) of 3-methyl-1,8-dihydrocycloheptapyrazol-8-one azine (**4**) as purple plates: mp >300 °C; λ_{max}^{MeOH} nm (log ε): 224 (4.32), 283 sh (3.69), 450 (4.13); IR (KBr): 3300 (NH), 1540 cm^{-1}; NMR (CF_3COOH): δ 7.4—8.1 (m, 8H), 2.98 ppm (s, 6H, $CH_3\times2$). Found: C, 67.98; H, 5.10; N, 26.28%. Calcd for $C_{18}H_{16}N_6$: C, 68.33; H, 5.10; N, 26.57%. M^+ 316. The filtrate was evaporated and the red residue was recrystallized from methanol to give 479 mg (68%) of 3-methyl-1,8-dihydrocycloheptapyrazol-8-one hydrazone (**5**) as red needles: mp 199—202 °C; λ_{max}^{MeOH} nm(log ε): 215 (4.42), 335 (3.98); IR (KBr): 3340 (NH), 3200 (NH), 1640 cm^{-1}; NMR (DMSO-d_6): δ 12.4 (br, 1H, NH), 5.6—6.7 (m, 6H), 2.28 ppm (s, 3H, CH_3). Found: C, 61.98; H, 5.81; N, 31.90%. Calcd for $C_9H_{10}N_4$: C, 62.05; H, 5.79; N, 32.17%. b) Refluxing of **2b** (409 mg, 2.30 mmol) with 80% hydrazine hydrate (137 mg, 2.19 mmol) in methanol (20 ml) for 1 h afforded **4** (130 mg, 34%), **2b** (148 mg, 36%) being recovered. c) At room temperature, the reaction of **2b** (348 mg, 1.96 mmol) with 80% hydrazine hydrate (197 mg, 3.15 mmol) in methanol (20 ml) gave **4** (61 mg, 18%) and **5** (189 mg, 51%) after 24 h. d) At room temperature, **2b** (405 mg, 2.28 mmol) reacted with 80% hydrazine hydrate (135 mg, 2.16 mmol) in methanol (20 ml) for 72 h to afford **4** (133 mg, 31%), **2b** (127 mg, 31%) being recovered.

*Reaction of 3-Methyl-1,8-dihydrocycloheptapyrazol-8-one Hydrazone (**5**) with Acetone.* Acetone (117 mg) was added to a solution of **5** (160 mg) dissolved in hot methanol (10 ml), and the mixture was refluxed for 2 h. The resulting solution was concentrated to dryness and the residue was recrystallized from benzene–petroleum ether to afford 127 mg (66%) of 1,3,3-trimethyl-3,4-dihydro-2,2a,4,5-tetraazabenz[*cd*]-azulene (**6**) as orange prisms: mp 152—155 °C; λ_{max}^{MeOH} nm(log ε): 222 (4.48), 293 (3.68), 350 (4.01); IR ($CHCl_3$): 3270 (NH), 1630, 1600 cm^{-1}; NMR ($CDCl_3$): δ 5.8—6.6 (m, 4H), 5.7 (br, 1H, NH), 2.36 (s, 3H, CH_3), 1.61 (s, 6H, $CH_3\times2$). Found: C, 67.33; H, 6.56; N, 25.96%. Calcd for $C_{12}H_{14}N_4$: C, 67.26; H, 6.59; N, 26.15%. M^+ 214.

We wish to express our thanks to Dr. Tetsuo Nozoe, Professor Emeritus of Tohoku University, for his advice and encouragement. We are also indebted to Dr. Kazu Kurosawa in this Laboratory for helpful suggestions and Mr. Shuichi Ueda of Taiho Pharmaceutical Co., Ltd. for the measurements of mass spectra.

The Reaction of ω-Ethoxyalkyl Bromides with Silver(I) Cyanide and Nitrite. The Participation of an Oxonium Ion

Nanao WATANABE,** Sakae UEMURA, and Masaya OKANO*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
***Koei Chemical Co., Ltd., Joto-ku, Osaka 536*

(Received January 5, 1979)

The reaction of ω-ethoxyalkyl bromides (C_n: n=2—5) with silver(I) cyanide or nitrite in less polar solvents to give the corresponding isocyanide or a mixture of the corresponding alkyl nitrite and nitroalkane respectively, proceeded with ease only when n=4. In the latter reaction, the ratios of O- and N-attack (O/N) were 16—18/82—84 and 31—46/54—69 when $n\neq4$ and n=4 respectively. The facile reaction in both cases when n=4 and the increasing O-attack in the case of silver(I) nitrite may suggest that the reaction proceeds through the initial formation of a five-membered oxonium ion, the *O*-ethyltetrahydrofuranium ion, and a subsequent attack by CN^- and NO_2^- or their silver(I) bromide complex.

Previously, we have shown that various alkyl halides reacted with mercury(II) thiocyanate to give an isomeric mixture of alkyl thiocyanate and isothiocyanate.[1] This ambident behavior of the mercury(II) salt has also been observed in the reaction with 4-alkoxybutyl halide where the isomer ratio (N/S) of the products is nearly 1, in contrast to the results for unsubstituted primary halides (N/S=*ca.* 1/4).[2] This difference has been explained by considering the attack of an ambident anion of the mercury(II) salt upon a tetrahydrofuranium ion intermediate. In order to establish further examples of the ambident reaction of metal salt with such an oxonium ion, we have carried out the reactions of ω-alkoxyalkyl halides (C_n: n=2—5) with silver(I) cyanide and nitrite, both metal salts being well known to have an ambident reactivity on alkyl halide.[3] As a result, it was found that the reaction proceeded smoothly when n=4 and that silver(I) nitrite showed a different ambident behavior on the halide of n=4 and the halides of $n\neq4$.

Results and Discussion

The reaction of ω-alkoxyalkyl halides or butyl bromide with silver(I) cyanide was carried out by stirring a heterogeneous mixture of both reagents in dichloromethane or without a solvent at 75—85 °C for appropriate times. At least under these conditions, the reaction proceeded only in the case of 4-ethoxybutyl bromide to give the corresponding isocyanide, the formation of the cyanide being scarcely observed (Table 1 and Scheme 1).[4] Although we have already found

$$EtO(CH_2)_4Br + AgCN \longrightarrow EtO(CH_2)_4NC \quad (1)$$

that mercury(II) thiocyanate, acetate, and chloride reacted with alkyl halides in tetrahydrofuran (THF) to give the THF-incorporated compounds,[2,5] no such reaction has been observed by stirring mercury(II) or silver(I) cyanide and ethyl iodide in THF at a reflux temperature for 24 h.

The reaction of ω-ethoxyalkyl or butyl bromide with silver(I) nitrite was also carried out by stirring them in 1,2-dichloroethane, diethyl ether, or THF at 15—25 °C for 1—7 days, the mixture being heterogeneous. The products were the corresponding alkyl nitrite(**1**) and nitroalkane (**2**), the ambident character of the metal salt being clearly observed (Table 2 and Scheme 2). Here also, the reaction proceeded smoothly when

$$EtO(CH_2)_nBr + AgNO_2 \longrightarrow EtO(CH_2)_nONO + EtO(CH_2)_nNO_2 \quad (2)$$
$$\mathbf{1}(n=2-5) \qquad \mathbf{2}(n=2-5)$$

n=4. The isomer ratio (O/N) depended on the kind of alkyl bromide, an increase of the O-attack being observed in the case of n=4: namely, 31—46/54—69 from 4-ethoxybutyl bromide and 16—19/81—84 from the other halides. In contrast to the reaction with mercury(II) thiocyanate,[2] the reaction in THF as

Table 1. Reaction of RX with AgCN[a]

RX (10 mmol)	Solvent (10 ml)	React. temp (°C)	React. time (h)	Yield[b] of RNC
$EtO(CH_2)_2Br$	$(CH_2Cl)_2$	80	24	0

a solvent did not show any THF-incorporation.

It is generally known, in the reaction of alkyl halide with silver(I) nitrite, that a side reaction producing alkyl nitrate ester, alcohol, ketone, *etc.* occurs in some cases.[6] We observed, however, the formation of only a small amount of the corresponding nitrate ester and alcohol, even in the reactions continued for several days or a week. Further, when we plotted the yields of both alkyl nitrite and nitroalkane against the reaction time in the reaction with 4-ethoxybutyl bromide, the ratio between the two isomeric products was almost constant with an increase in the yield of the products (Fig. 1). These facts show that no further reaction of the initially produced alkyl nitrite occurs under these conditions and, consequently, that the O/N ratio is the kinetically controlled one in these reactions. When the reaction of ethyl iodide with silver(I) nitrite was carried out in THF at 25 °C for 6 h, an isomeric mixture of 4-ethoxybutyl nitrite and 4-ethoxy-1-nitrobutane was obtained in a 4% yield (O/N=55/45). Although the yield was low because of the rapid formation of ethyl nitrite and nitroethane, this finding shows that the THF-incorporation reaction occurs as in the cases of similar reactions with various mercury(II) salts.[2,5]

Because the silver(I) salts are almost completely insoluble in any solvent used, the reactions are generally quite slow. However, the reactions of 4-ethoxybutyl bromide proceeded smoothly. The reason for the comparatively facile reaction of this halide can be ascribed to the involvement of the *O*-ethyltetrahydrofuranium ion intermediate, as has been found in the cases of the reactions of similar halides with various mercury(II) salts.[2,5] The formation of **1** (n=4) and **2** (n=4) in the reaction of ethyl iodide in THF, though the yield was low, also supports this assumption. As to the isomer ratio of the products from the reaction of 4-ethoxybutyl bromide with silver(I) nitrite, the ratio for the O-attack was higher than that from other primary halides. This can be understood by considering that the isomer ratio is determined by the step of the attack on the intermediate oxonium ion;[2] that is, the carbon bearing a harder ligand as the leaving

group (R_2O in R_3O^+) is more apt to be attacked by a harder atom in an ambident ion, the O atom being harder than the N atom in the attacking species of NO_2^- or $AgBr(ONO)^-$. At present, the question of which is the more likely species must be left unresolved.

Experimental

The O/N ratios in mixtures of alkyl nitrites and nitroalkanes were determined by GLC. The GLC analyses were carried out on a Shimadzu 4BMPF and a Yanagimoto G800-T apparatus, using EGSS-X (1 or 3 m), Apiezon-L (1 m), and SE-30(1 m) columns(carrier gases, N_2 and H_2 respectively). The ^{1}H-NMR spectra (60 MHz) were recorded with a Varian EM-360 and a Hitachi R-24 spectrometer in CCl_4, using TMS as the internal standard.

Materials. The diethyl ether (dried over Na), 1,2-dichloroethane (over K_2CO_3), and THF (over KOH) were used after distillation, while the other organic and inorganic substances were used without further purification. The ω-alkoxyalkyl halides were prepared by a previously reported method.[6] Authentic samples of alkyl nitrite were prepared from the corresponding alcohols by a previously reported method,[7] while nitroalkanes and 4-ethoxybutyl isocyanide were separated from the reaction products by distillation and then analyzed. All the compounds except **1**(n=2), **2**(n=2), hexyl nitrite, and 1-nitrohexane are new; their boiling points and ^{1}H-NMR and analytical data are summarized in Table 3. Although **2**(n=2) could not be isolated in a pure state, the retention time in the GLC and the NMR spectrum support the assigned structure.

Reaction of 4-Ethoxybutyl Bromide with $AgNO_2$. A suspension of $AgNO_2$(1.52 g, 10 mmol) and 4-ethoxybutyl bromide(1.82 g, 10 mmol) in diethyl ether or 1,2-dichloroethane(10 ml) containing tetralin (1.07 g) as an internal standard for GLC analysis was stirred at 15—20 °C in the dark. At appropriate time intervals an aliquot was analyzed by GLC to determine the amounts of **1**(n=4) and **2**(n=4) produced (see Fig. 1). In order to isolate the products, a similar reaction was carried out without the addition of tetralin. After the precipitated AgBr had been filtered off, the filtrate was distilled to give a mixture of **1**(n=4) and **2**(n=4).

Reaction of 4-Ethoxybutyl Bromide with AgCN. A suspension of 4-ethoxybutyl bromide (3.60 g, 20 mmol) and AgCN(2.65 g, 20 mmol) in 1,2-dichloroethane (10 ml) was kept at 80—85 °C for 24 h under stirring. After being cooled down to room temperature, an aqueous KCN solution was added, the separated oil layer was extracted with ether, and the ether extract was dried over $MgSO_4$. Subsequent distillation gave 1.53 g(60% yield) of 4-ethoxybutyl isocyanide.

Hydrolytic Reactions of *p*-Nitrophenyl Esters in Reversed Micellar Systems

Hirotada FUJII,* Tohru KAWAI, and Hiroyasu NISHIKAWA†

Department of Polymer Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

†*Department of Physiology, Kyoto Prefectural University of Medicine, Kyoto 602*

(Received September 6, 1978)

Hydrolytic reactions of several *p*-nitrophenyl esters were studied with and without catalysts in reversed micellar systems consisting of sodium octanoate, 1-hexanol and water. Hydrolytic rate constants become very large as compared with those in aqueous solutions, increasing with decrease in the molar ratio of water to sodium octanoate (*R*-value). The results of kinetic measurements were discussed in terms of the behavior of water molecules and polar groups of sodium octanoate as revealed by means of IR and ^{1}H, ^{13}C and ^{23}Na-NMR spectroscopy. It was concluded that the decrease in the *R*-value induces the increase in the mobility of water molecules and the decrease in the polarity of the water core, which affects the partition coefficient of *p*-nitrophenyl esters between the 1-hexanol phase and the water phase, enhancing hydrolytic reactions.

A number of works[1] have been published concerning the enhancement of reaction rates at the critical micellar concentration in normal micellar systems. Attention has also been paid to reversed micellar systems, in which several reactions are much accelerated.[2–4] Fendler *et al.*[5] who extensively examined catalytic reactions in reversed micelles, pointed out that water molecules solubilized in polar cavities of reversed micellar systems are less polar than those in the bulk phase, and suggested that this is closely related to the catalytic effect. Thus, it is of interest to investigate the behavior of molecules involved in reversed micellar systems, especially the behavior of water molecules and sodium octanoate at the boundary phase between the water core and the 1-hexanol phase. This does not seem to have been fully elucidated in relation to the acceleration of chemical reactions in the systems.

We have kinetically investigated hydrolytic reactions of *p*-nitrophenyl esters in reversed micellar systems consisting of sodium octanoate, 1-hexanol and water, and also measured the catalytic activity of L-histidine and imidazole solubilized in the water core in the same system for hydrolysis of *p*-nitrophenyl acetate. The behavior of water molecules in reversed micelles was studied by means of IR and ^{1}H-NMR spectroscopy, and that of the polar group of sodium octanoate, *i.e.*, sodium ions and carbonyl groups, by ^{23}Na and ^{13}C-NMR spectroscopy. Except for the movement of the methylene group in the case of Aerosol OT in chloroform,[6] the behavior of polar groups of surfactants has scarcely been studied. The results obtained in measurements of reaction rates were discussed in terms of the characteristic behavior of molecules, ions and polar groups present at the boundary phase between the water core and the 1-hexanol phase.

Experimental

Materials. Sodium octanoate, 1-hexanol, *p*-nitrophenyl acetate (PNPA), L-histidine and imidazole (analytical grade) were used without further purification. *p*-Nitrophenyl octanoate (PNPO) and L-alanine *p*-nitrophenyl ester hydrochloride (APNP) were prepared by the condensation reaction between the corresponding acid and *p*-nitrophenol in tetrahydrofuran. Water was distilled and buffered with 0.03 M phosphate aqueous solution.

Measurements of Reaction Rates. PNPA, PNPO, and APNP were used as substrate. The initial concentration of these esters in 1-hexanol was 5×10^{-4} M. Reversed micelles were prepared by mixing three components, water (buffer solutions), 1-hexanol and sodium octanoate, and allowing them to stand at 30 °C for 24 h. 1-Hexanol solution of *p*-nitrophenyl ester was added to reversed micellar solutions, and the hydrolytic reaction rates of esters with and without catalyst were observed by measuring the absorption (OD_t) of *p*-nitrophenolate ions (400 nm) at 30 °C as a function of time with a Hitachi EPS-3T spectrophotometer. When the reaction was complete, the absorption (OD_∞) was determined from the absorption *vs.* time curve after a sufficiently long time. The results were analyzed as first order kinetics by plotting ($OD_\infty - OD_t$) in a logarithmic scale against time *t*. The slope of the line afforded the rate constant *K*. When L-histidine or imidazole was used as a catalyst, the difference in rate constants between the catalytic and noncatalytic reactions both in reversed micelles divided by the concentration of the catalyst was taken as K_c.

Spectroscopic Measurements. Infrared spectra were obtained with a Hitachi EPS-3G infrared spectrophotometer. The liquid cell used was equipped with CaF_2 windows, the optical path length being 0.05 mm. ^{1}H, ^{13}C, and ^{23}Na-NMR spectra were measured with a JEOL JNM-PS FT-NMR spectrometer operating at 100, 25 and 24 MHz, respectively. Measurement conditions for ^{13}C and ^{23}Na-NMR: spectral width 6250 and 1000 Hz, repetition 10 and 2.5 s, data point 8192 and 4096, numbers of scans 256 and 200, respectively. UV spectra of pyridine 1-oxide were observed with a Hitachi spectrophotometer model EPS-3T using a thermostated cell.

Results and Discussion

Hydrolytic Reactions of p-*Nitrophenyl Esters in Reversed Micelles.* Rate constants of hydrolysis of PNPA together with weight ratios of three components of reversed micellar systems and pH values of the phosphate buffer solution solubilized into the systems are given in Table 1. The results indicate that the rate constant increases with increase in pH. This tendency in reversed micellar systems is analogous to that in aqueous solutions.

Rate constants of hydrolysis of PNPA, PNPO, and APNP in reversed micelles are given in Table 2. When the buffer solution of the same pH is used, the hydrolytic reaction of PNPA is much more accelerated in reversed micelles as compared with that in aqueous

Table 1. Rate constants and weight ratios of the three components of reversed micelles

Water	1-Hexanol	Na Oct.	pH[a]	$K\times10^3$ (min^{-1})
2.5	6.5	1	7.7	10.3
2.5	6.5	1	7.9	14.0
2.5	6.5	1	8.0	14.5
3.0	6.0	1	7.7	9.7
3.0	6.0	1	7.9	13.0
3.0	6.0	1	8.0	13.6

a) Values of the phosphate buffer solutions solubilized into reversed micellar systems.

Table 2. Rate constants for *p*-nitrophenyl acetate (PNPA), *p*-nitrophenyl octanoate (PNPO), and L-alanine *p*-nitrophenyl ester hydrochloride (APNP) in aqueous solutions and reversed micelles

	PNPA[a]	PNPA[b]	PNPO[b]	APNP[b]	APNP[a]
$K\times10^3$ (min^{-1})	1.38	18.7	0.1	800	2.4
pH	7.9	7.9	7.9	6.5	6.5

a) In aqueous solutions. b) In reversed micelles. Concentrations of water and sodium octanoate are 12.9 and 1.38 M, respectively, in 1-hexanol ($R=9.2$).

Table 3. The catalytic rate constant of L-histidine in hydrolysis of *p*-nitrophenyl acetate in reversed micelles

R-value	$K\times10^3$ (min^{-1})	[L-his]$\times10^4$ (M)[a]	K_c ($min^{-1}\,M^{-1}$)
9.2	18.7	5.0	7.5
		20.0	7.3
13.9	16.7	5.0	6.5
18.4	13.8	5.0	3.3
		10.0	2.9

a) The concentration of L-histidine in the water core of reversed micelles. Concentrations of water and Na Oct are, respectively, 12.9 and 1.38 M in 1-hexanol for $R=9.2$, 12.9 and 0.93 M for $R=13.9$, and 12.9 and 0.69 M for $R=18.4$.

solutions. The hydrolytic reaction of APNP is remarkably accelerated, while that of PNPO is very slow. The order of rate constants for three *p*-nitrophenyl esters in the same reversed micellar systems (Table 2) is in line with the order of the solubility of these esters in water. The partition of the substrate between the water core and the 1-hexanol phase plays an important role in the acceleration of reaction. Ionic interaction between negative charges of sodium octanoate (carboxylate anion) and positive charges of L-alanine *p*-nitrophenyl ester hydrochloride (ammonium cation) is also an important factor in the prominent acceleration observed in the case of APNP. Judging from the fact that PNPO is hydrolyzed a little in spite of its very low solubility in water, the reaction is considered to take place at the boundary phase between the water core and the 1-hexanol phase.

In order to know how the structure of the water core and its surroundings affects the hydrolytic reaction, the dependency of the rate constant of hydrolysis of PNPA on the molar ratio of water to sodium octanoate, $R=[H_2O]/[Na\ Oct]$, was studied (Fig. 1). The rate constant increases linearly with decrease in *R*-value. An increase in the amount of sodium octanoate in the system seems to increase the amount of PNPA partitioned into the water core and its surrounding layer of the surfactant, accelerating the hydrolytic reaction. Reduction of the molar ratio of water to sodium octanoate at the same concentration of water decreases the diameter of the water core in reversed micelles, increasing the total surface area of the core in the system. The increase in the surface area of the water core is considered to raise the hydrolytic reaction rate.

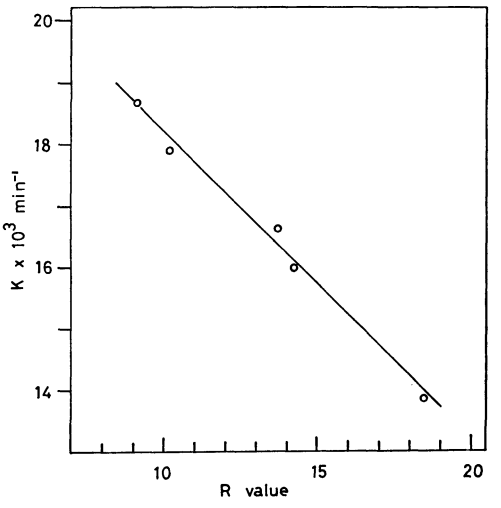

Fig. 1. Rate constant of hydrolysis of PNPA as a function of *R*-value ($[H_2O]/[Na\ Oct]$). In all cases, water concentration is 12.9 M in 1-hexanol.

Catalytic activities of L-histidine and imidazole added as a catalyst into the water core of reversed micelles were measured only in hydrolysis of PNPA. The results obtained for L-histidine are given in Table 3. The catalytic rate constant, K_c, increases with decrease in *R*-value as in the case of hydrolysis without catalyst, giving a nearly constant value in the L-histidine concentration range 5×10^{-4}—20×10^{-4} M. In the case of $R=9.2$, the catalytic rate constant is 7.5 $min^{-1}\,M^{-1}$, larger than the corresponding rate constant (5.7 $min^{-1}\,M^{-1}$) in aqueous solutions of the same pH values. In the case of $R=18.4$, however, the value of K_c (3.3 $min^{-1}\,M^{-1}$) is smaller than the catalytic rate constant (5.7 $min^{-1}\,M^{-1}$) in aqueous solutions. Thus, the probability of the presence of L-histidine at the boundary phase between the water core and the 1-hexanol phase in the above two cases would differ. Imidazole, a very active catalyst to hydrolyze PNPA in aqueous solutions, shows no catalytic activity in hydrolysis of PNPA in reversed micelles. The results reveal that the catalytic activity is dependent on the probability of the presence of the catalyst at the boundary phase in reversed micellar systems. In order to study the distribution of catalysts between 1-hexanol and water, partition coefficients, $K(C_{1\text{-hex}}/C_{aqu})$, of imidazole and L-histidine were measured and found to be 0.92 and 0, respectively. The results indicate

Table 4. Chemical shifts of protons of 1-hexanol and H_2O, and line width of H_2O peak

R-value	Chemical shift (δ)			Line width of H_2O (Hz)

11.6	1.25	3.90	5.24	6.31
10.3	1.27	3.90	5.24	6.01
9.2[a)]	1.28	3.90	5.26	4.95
9.2[b)]	1.28	3.90	5.27	4.95

a) Concentrations of water and sodium octanoate are 12.9 and 1.38 M, respectively. b) Concentrations of water and sodium octanoate are 14.9 and 1.61 M, respectively.

Table 5. Relative intensities of IR bands of HOD at the three wavelengths

R-value	Wavelength (cm^{-1}) of HOD band		
	3400	3550	3800
18.4	0.87	1.0	0.06
11.6	0.88	1.0	0.07
9.2	0.98	1.0	0.10

The intensity of the bond at 3550 cm^{-1} was taken as a standard.

that L-histidine molecules are concentrated at the boundary phase between the water core and the 1-hexanol phase, but not imidazole molecules due to their higher solubility into 1-hexanol. The ionic force between negative charges at the boundary phase (carboxylate anions of sodium octanoate) and positive charges of L-histidine molecules (ammonium cations) increase the probability of the presence of L-histidine at the boundary phase between the water core and the 1-hexanol phase. Thus, L-histidine molecules are concentrated at the boundary phase of reversed micelles due to their solubility and ionic force, so that L-histidine shows catalytic activity, depending on its concentration relative to that of the surfactant. This would not apply to the case of imidazole since it has higher solubility into 1-hexanol, but no positive charges.

The Structure and Behavior of Water Molecules and Polar Groups of Sodium Octanoate. In order to understand the role of the water molecule in reversed micelles in the hydrolytic reaction, their mobility and chemical environment were studied by means of ^{1}H-NMR for different values of *R*. The results are given in Table 4. The resonance peak of the water proton moves to a lower field, the line width of the water proton peak decreasing with decrease in *R*-value. For a given *R*-value, however, the line width does not change with the change in the molar ratio of water to 1-hexanol. The chemical shifts of C-1 methylene protons (-CH_2-OH) and methyl protons of 1-hexanol do not vary appreciably with *R*-value. This indicates possible structural changes in water cores of reversed micelles with change in *R*-value. The decrease in the line width of the water proton peak, *i.e.*, the increase in the mobility of water molecules in reversed micelles

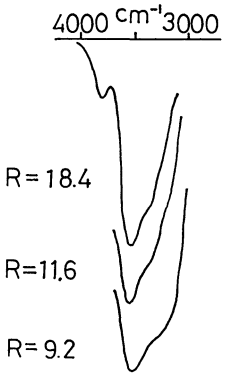

Fig. 2. Infrared spectra of HOD in reversed micelles. These spectra were taken as difference spectra between octanoic acid in 1-hexanol (reference cell) and reversed micellar solutions (sample cell).

with lowering in *R*-value seems unreasonable, since the size of the water core is considered to become smaller and consequently the relative amount of free water molecules seems to decrease with the decrease in *R*-value. For the sake of clarification, infrared spectrum due to the water molecule was taken. All the measurements were made on the uncoupled OH stretching vibration of HOD by using the solution of 5.5 M in D_2O.[7] The advantage of this approach lies in the fact that each species of water molecules gives a single, nearly gaussian absorption band. The results are shown in Fig. 2. From the absorption band due to the water molecule dispersed in pure 1-hexanol, the band at 3800 cm^{-1} is assigned to the water molecule dispersed in 1-hexanol. The band at 3400 cm^{-1} is assigned to the usual mobile (free) water by comparing the IR spectrum of pure water. Thus, the absorption band observed at 3550 cm^{-1} is due to the water molecule bound to the polar head group of the surfactant. The relative intensities of three bands, intensity of the band at 3550 cm^{-1} being taken as the standard, are given in Table 5. The relative intensity of the band at 3400 cm^{-1}, which is a measure of the mobile water molecule, increases with decrease in *R*-value. This is in line with the fact that the line width of the water proton peak decreases with decrease in *R*-value, as obtained by ^{1}H-NMR measurements.

The resonance peak of the water proton moves to a lower field with decrease in *R*-value, indicates that the property of the water molecule changes with *R*-value. Pyridine 1-oxide is a water soluble compound, the absorption maxima of which are correlated with *Z* values in several solvents.[8] The polarity of the water core of reversed micelles, measured by the absorption band shift of pyridine 1-oxide solubilized into reversed micelles (Fig. 3), depends on the ratio of water to sodium octanoate, *i.e.*, the polarity of the water core decreases with decrease in *R*-value.

In order to study the behavior of the entities at the boundary phase between the water core and the 1-hexanol phase, the mobility of the carbonyl carbon and the sodium ion of sodium octanoate was examined by means of ^{13}C and ^{23}Na-NMR, respectively. Figure 4 shows the ^{23}Na-NMR spectrum of sodium

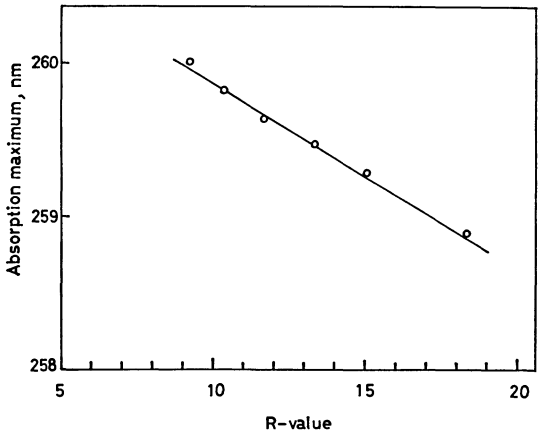

Fig. 3. Plots of absorption maxima due to pyridine 1-oxide against *R*-value. The absorption maxima due to pyridine 1-oxide in water, methanol and ethanol are 255.4, 263.3 and 265.1 nm, respectively.

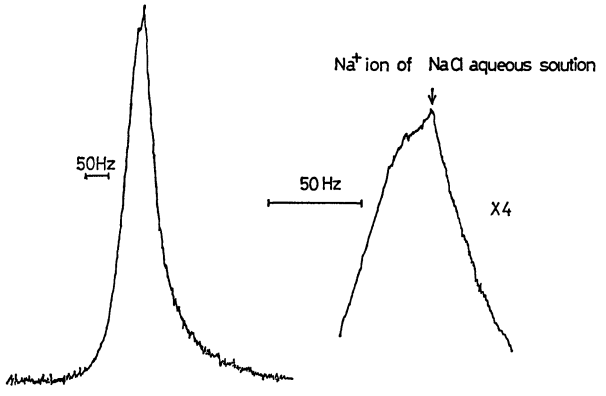

Fig. 4. ^{23}Na-NMR spectra of sodium octanoate in reversed micellar systems.

octanoate in reversed micellar system. The aqueous solution of sodium chloride was taken as an external standard, and the chemical shift of the peak due to the sodium ions in reversed micelles from the standard peak was evaluated. By using the pulse and Fourier transform technique, it has become possible to separate the resonance peak of the sodium ion in reversed micelles from that of the external standard. The chemical shifts and the line widths of the resonance peaks due to the carbonyl carbon and the sodium ion of sodium octanoate as a function of *R*-value are summarized in Table 6. When *R* is large (for instance $R=18.4$), the line width of the water proton peak in the ^{1}H-NMR spectrum (Table 4) reveals that the bound water molecules are rich. The line width and the chemical shift of the sodium ion in the ^{23}Na-NMR spectrum indicate that the mobility of the sodium ion in reversed micelles is high and the physicochemical environment of the sodium ion resembles that of a sodium ion in aqueous solutions (*i.e.*, the sodium ion is fully dissociated). When *R* is small (for instance $R=9.2$), water molecules are rather mobile, and the mobility of the sodium ion is low, so that the physicochemical environment of the sodium ion is different from that in aqueous solutions. Thus the increase in the mobility of water molecules with

Table 6. Chemical shifts and line widths of the carbonyl carbon and sodium of sodium octanoate

R-value	^{13}C-NMR[a]		^{23}Na-NMR[b]	
	Chemical shift (ppm)	Line width (Hz)	Chemical shift (ppm)	Line width (Hz)
18.4	183.4	38.4	2.08	5.4
11.6	183.1	39.7	2.79	7.3
9.2	182.6	42.7	2.97	9.8

a) Expressed in ppm using TMS as an external standard. b) Expressed in ppm using an aqueous solution of sodium chloride as an external standard.

decreasing *R*-value results from the decrease in the amount of hydrated sodium ions in the water core. The degree of dissociation of sodium ions of sodium octanoate becomes higher as *R*-value increases, and the amount of the water molecule hydrated by the sodium ion released from sodium octanoate increases with increase in *R*-value. Such a situation is also reflected in the results of ^{13}C-NMR spectra. The line width of the resonance peak of the carbonyl carbon of the surfactant decreases and the peak position is shifted to a lower field as *R* increases. The increase in the mobility and the down field shift of the carbonyl carbon signal are caused by the sodium ion released from sodium octanoate as *R* increases. Namely, the carbonyl group of the octanoate anion can move more freely and the electron density of the carbonyl group of the octanoate anion decreases by releasing the sodium ion from sodium octanoate.

In aqueous micellar systems[9] and surfactant aggregate systems in organic solvents[10] the exchange between monomers and surfactant micelles is thought to be relatively fast. However, the exchange in reversed micellar systems containing water molecules has not been clarified. The aggregation number in this system has not been measured, but from the results shown above and the fact that sodium octanoate is hardly soluble in 1-hexanol, the equilibrium constant *K* ($K=[S_m]/[S]^m$, where S_m, S, and m are the concentration of micelles, the concentration of surfactants and the aggregation number, respectively) seems to be relatively large.

Relationship between Hydrolytic Activity and the Structure of Reversed Micelles. Acceleration of the hydrolytic reaction caused by decrease in *R* may be explained as follows. The substrate becomes more soluble when the mobility of water molecules increases and the polarity of water cores decreases. The amount of substrate transferred from the 1-hexanol phase to the water core then increases. Hence, the hydrolysis is enhanced. The results of ^{23}Na and ^{13}C-NMR indicate that polar head groups of surfactants aggregate more tightly for a smaller *R*-value. Thus, the water core seems smaller for a smaller *R*-value, but this has not been confirmed by light scattering. The decrease in the diameter of the water core in reversed micelles gives rise to an increase in the specific surface area of reversed micelles, enhancing the rate of hydrolytic reaction. It was found that L-histidine is active, but not imidazole as a catalyst of hydrolysis of PNPA.

L-Histidine molecules are considered to be located at the boundary phase between the water core and the 1-hexanol phase through the ionic force between positive charges of the ammonium ion of L-histidine and negative charges of sodium octanoate and its low solubility in 1-hexanol. However, this does not apply to imidazole, since it has high solubility in 1-hexanol but no positive charge. Thus, L-histidine molecules can act as a catalyst of hydrolysis at the boundary phase of reversed micelles, but not imidazole molecules transferred from the water core to 1-hexanol phase. Hydrolytic reaction is remarkably enhanced when APNP is used as a substrate. The concentration of APNP at the boundary phase due to the ionic interaction and its high solubility in the water core may enhance the hydrolytic reaction. It is important for the reaction in reversed micellar systems to concentrate the catalyst or substrates at the boundary phase between the water core and the 1-hexanol phase.

We thank Prof. Hiroshi Watari for his interest in this work and Dr. Tetsurou Asakura for his valuable discussions.

Solvent Assisted Oxy-Cope Rearrangement of Diastereomeric 1,5-Hexadien-3-ols. A New Industrial Process for Polyprenyl Ketones

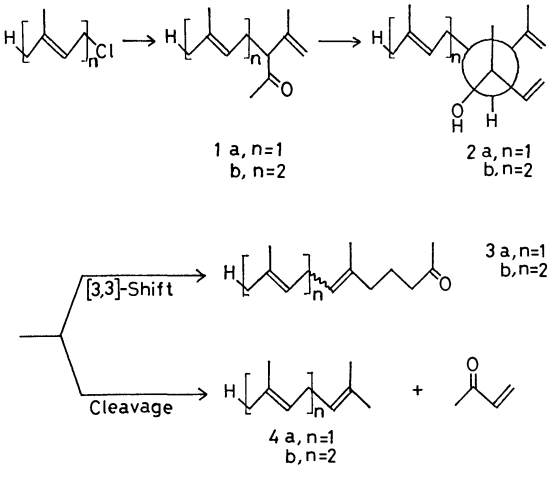
Yoshiji FUJITA,* Shigetoshi AMIYA, Takashi ONISHI, and Takashi NISHIDA
Central Research Laboratories, Kuraray Co. Ltd., Sakazu, Kurashiki, Okayama 710

(Received September 20, 1978)

Oxy-Cope rearrangement of diastereomeric 1,5-hexadien-3-ols, new key intermediates for terpenoids production in industrial scale, were investigated in neat systems and solvent assisted systems. Various solvents affecting the selectivity of [3,3]-shift were classified by means of NMR studies on hydroxyl proton exchange time.

The carbon-carbon elongation reactions based on [3,3]-sigmatropic rearrangement, such as the Carroll reaction[1] as well as Saucy-Marbet method[2] (C-3 extension) or Thomas[3] and Faulkner-Petersen[4] methods (C-5 extension), proceed after the loss of eliminating groups (*e.g.* CO_2, ROH) which decrease the efficiency of chain extenders particularly in lower molecules. Recently, mesityl oxide has been utilized in full as a C-6 chain extender *via* synthetically equivalent transpositions of Cope[5,6] and oxy-Cope[7] reactions.

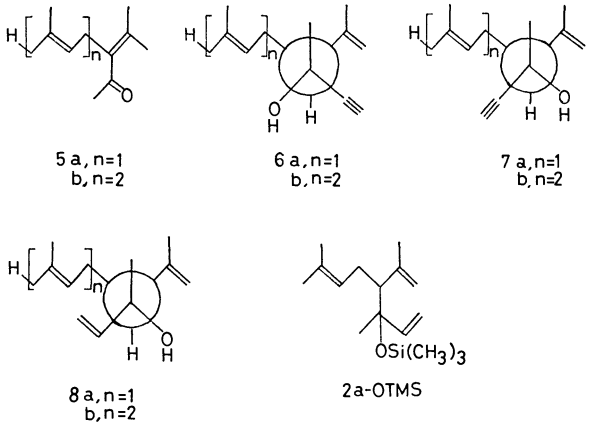
Synthetic utility of oxy-Cope rearrangement is considerably reduced owing to the β-hydroxyolefin cleavage reaction. In order to avoid the cleavage, several modifications such as siloxy-Cope processes[8] or anionic processes[9] have been developed. On the other hand, no attention has been paid to solvent effects in oxy-Cope processes although such effects have been studied in the case of other [3,3]-sigmatropic rearrangement.[10] A report was given on a convenient solvent assisted method to increase the selectivity of [3,3]-shift of some 1,5-hexadien-3-ol systems.[7,11] We have further elaborated this method by comparing the behavior of diastereomeric dienols (**2** and **8**), and various solvents affecting the selectivity of this reaction were classified by means of NMR studies on hydroxy proton exchange time. A new process for polyprenyl ketones (**3**) useful for squalane and isophytol, which may be manufactured in the near future together with pseudoionone from intermediates **6** and **7** *via* acetylenic oxy-Cope reaction,[12] is presented in this paper.



Results and Discussion

Preparation of Diastereomeric 1,5-Hexadien-3-ols and Siloxy Compound. The condensation reaction of prenyl or geranyl chloride with mesityl oxide gave the desired ketone (**1**) together with α,β-unsaturated isomer (**5**).[13,14] Reaction of **1** with vinylmagnesium bromide in tetrahydrofuran and subsequent hydrolysis afforded the only product **2** in *ca.* 80% yield. Diastereomer **2** is also obtainable by partial hydrogenation of the stoichiometric sodium acetylide ethynylation product of **1** [**1**/**5**/**6**/**7**=5/15/78/2].[13]

Semicatalytic potassium hydroxide ethynylation of **1** or **5** in liquid ammonia under pressure gave two diastereomeric alcohols in the composition **1**/**5**/**6**/**7**= 6/16/45/33. However, fractional distillation and silica gel column chromatography were ineffective for the separation of **6** and **7**. After partial hydrogenation of the mixture, careful fractional distillation gave pure dienol **8a** (50 g) from 1500 g of **2a**/**8a**=55/45.



Treatment of **2a** with dry pyridine/trimethylchlorosilane in ether gave **2a**-OTMS (OTMS=trimethylsiloxy) in 78% yield.

*Thermolysis of **2**, **8a**, and **2a**-OTMS.* Thermolysis of **2a** in the temperature range 160—190 °C in neat system gave **3a** (E/Z=59.5/40.5; 170 °C) in approximately 55% yield, along with cleavage products (**4a**, methyl vinyl ketone, and polymer). Below this temperature range, the reaction was too slow for synthesis and above it the cleavage reaction occurred predominantly. The selectivity of [3,3]-shift decreased to a small extent with progress of the reaction (Fig. 3). The result of thermolysis of **2b** is similar to that of **2a**. However, dienol **8a**, in comparison to its diastereomer **2a**, shows interesting behavior: No appreciable difference in yield of **3a** was observed, but the ratio of stereoisomer of **3a** inclined to the *E*-form (E/Z=65.8/34.2; 170 °C).[15] The reaction of **8a** occurred slightly faster than **2a** [k=0.404 and 0.858 s^{-1} at 170 and 180 °C, respectively].

a) E/Z ratio of **3** from **2a**-OTMS was obtained by GC analyses after the hydrolysis of **9**. b) First order rate constant [disappearance of **2**, **8a**, **2a**-OTMS]. c) By weight.

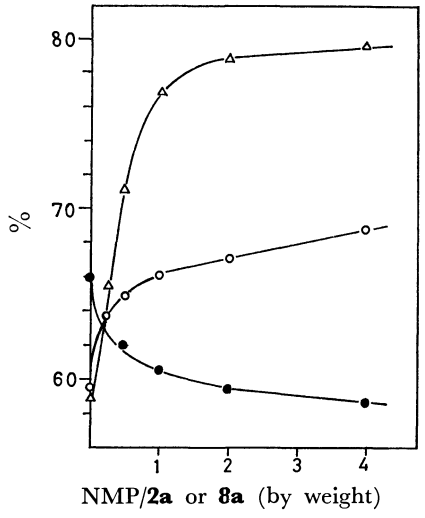

Fig. 1. Solvent effect on oxy-Cope rearrangement of **2a** and **8a** (180 °C) △: Selectivity of **3a**. ○: E-isomer of **3a** from **2a**. ●: *E*-isomer of **3a** from **8a**.

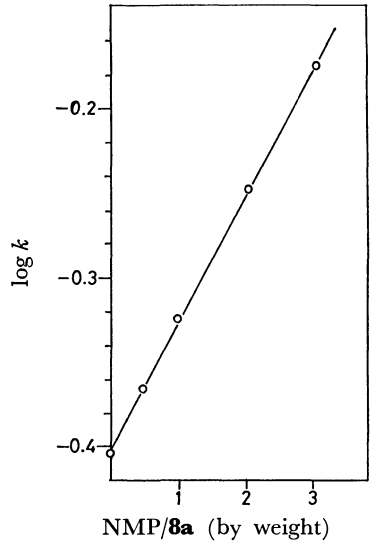

Fig. 2. Rate acceleration of **8a** by NMP (170 °C).

The siloxy-Cope rearrangement of **2a**-OTMS afforded **9** in *ca.* 97% yield, with a little rate acceleration owing to its steric factor. Hydrolysis of **9** with 1M-hydrochloric acid at 0 °C yielded **3a** quantitatively as a mixture of E/Z=63/37.

9

Ozonolysis of **3a** gave mainly 4-methyl-3-pentenal and 2,6-heptanedione, and hydrogenation of **3a** with Pd/C afforded 6,10-dimethyl-2-undecanone.

Solvent Assisted Oxy-Cope Rearrangement of 2 and 8a. Increase of the selectivity of [3,3]-shift without troublesome and costly handling is our essential problem. In this respect, the solvent assisted modification seems to be suitable for large scale production.

The use of *N*-methyl-2-pyrrolidone (NMP) as a solvent in various amounts, as shown in Fig. 1, increased the yield of **3a** to 80% with the amount of the *E*-isomer increasing from 59 to 71% in the case of **2a**, while with **8a** it decreased from 66 to 58%. A small acceleration in rate was observed (Fig. 2). Further addition of NMP, even as much as fifty-fold, caused neither increase in yield, variation in the E/Z ratio,

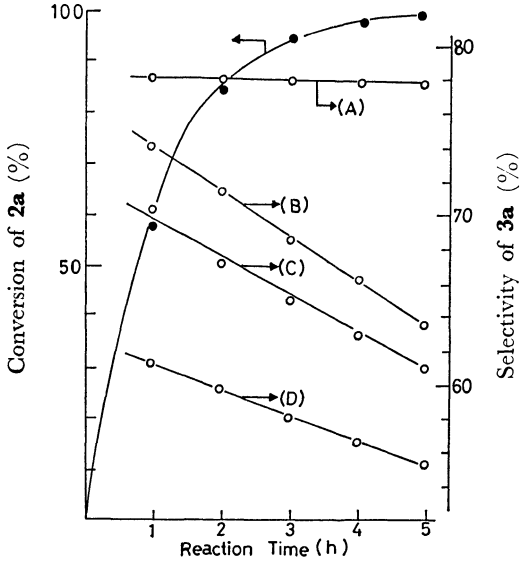

Fig. 3. Effect of the addition of *n*-decyl alcohol on selectivity of **3a** from **2a** (180 °C). ●: Conversion of **2a**. ○: Selectivity of **3a**; (A) NMP/**2a**=2/1. (B) NMP/**2a**/*n*-$C_{10}H_{21}OH$=2/1/1.5. (C) NMP/**2a**/*n*-$C_{10}H_{21}OH$=2/1/1. (D) NMP/**2a**=0 by weight.

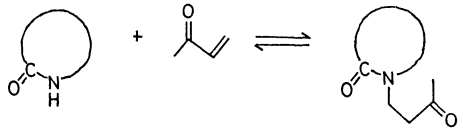
or acceleration in rate. The decrease in the selectivity of the [3,3]-shift during the reaction observed in the neat system [initial stage 62%, end of reaction 53%] was not observed upon addition of NMP. This solvent effect was considerably reduced by the addition of primary alcohols (*e.g.* 1-decanol, ethylene glycol), even though there was no effect on the selectivity of [3,3]-shift in the neat system (Fig. 3).

A similar result was obtained by using ε-caprolactam (or 2-pyrrolidone) instead of NMP with some difference in the reaction rate and selectivity of [3,3]-shift. However, under the reaction conditions, ε-caprolactam reacted with methyl vinyl ketone derived from cleavage reaction to yield *N*-(3-oxobutyl)-ε-caprolactam which showed similar activity to that of ε-caprolactam.



Other solvents such as glycerol, triphenylamine, decane, diethylene glycol diethyl ether[17] *etc.*, were ineffective for increasing the yield of **3** (Table 2). In the case of hydrocarbon solvent, *E*/*Z* ratio of **3** changed to 54/46. Solvents such as istain and benzotriazole were effective contrariwise for cleavage reaction.

Classification of Solvents Affecting the Selectivity of [3,3]-Shift: NMR-studies on Proton Exchange Time. The fact that the effect changes with the amount of solvent and diminishes considerably by the addition of primary alcohols indicates that there is interaction between solvent and hydroxy proton. We have studied the effect of solvent on hydroxy proton exchange by NMR wherein 10 mg of solvent was added to 0.5 ml of a solution of **2** in dimethyl-d_6 sulfoxide (DMSO-d_6) of purity higher than 99.5% and containing water as a contaminant.

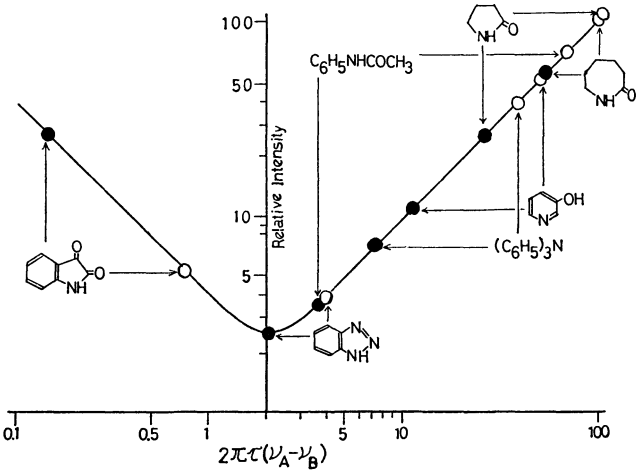


Fig. 4. Solvent effects on hydroxy proton exchange time of **2a**. ○: At 30 °C. ●: At 100 °C.

In calculating the proton exchange time (the time of exchange between the hydroxy proton of **2** and water in DMSO-d_6), the line shape [$g(\nu)$] of the NMR spectrum, chemical shift being taken into account, is theoretically a function of ν_A, ν_B, τ_A, and τ_B, where A is the change site on **2**, B is the exchange site on water; τ_A and τ_B are the times during which the protons are detained at each site, and ν_A and ν_B represent the chemical shifts. Assuming that $\tau_A=\tau_B=2\tau$ and that the line width has no broadening throughout the process except for the change, we get the following Bloch-equation.[18]

$$g(\nu) = K\frac{\tau(\nu_A-\nu_B)^2}{[1/2(\nu_A-\nu_B)-\nu]^2+4\pi^2\tau^2(\nu_A-\nu)^2(\nu_B-\nu)^2}$$

$$K = \int_{-\infty}^{\infty} g(\nu)\mathrm{d}\nu$$

The equation was solved approximately with the assumption that proton exchange occurs mainly between the hydroxyl proton of **2** and water in DMSO-d_6. The line shape was calculated with $\nu_A=\nu_B=90$ Hz and on varying the value of $2\pi\tau(\nu_A-\nu_B)$ from 100 to 0.1. The proton exchange time can be obtained by comparing the values obtained by calculation with measured line shape values. By comparing the results of thermolysis of **2** in neat system and solvent assisted system (Table 2), solvents effective for [3,3]-shift can be defined to be those for which proton exchange time is not less than 10^{-1} s at 30 °C and not less than 10^{-2} s at 100 °C. Figure 4 shows some results in which the logarithm of the value of $2\pi\tau(\nu_A-\nu_B)$ is horizontally plotted and the logarithm value of signal height based 100 with $2\pi\tau(\nu_A-\nu_B)=100$ is vertically plotted to give the curve. The relative value of the measured line shape, based on the height of hydroxyl proton of **2a** in the presence of 2-pyrrolidone, is plotted on the curve. Solvent plotted on the right of the center line of Fig. 4 would be effective for increasing the selectivity of [3,3]-shift. On the contrary, solvent plotted on the left would decrease [3,3]-shift. Benzotriazole plotted near the center at 100 °C can not be a favorable solvent for [3,3]-shift in consideration of the fact that

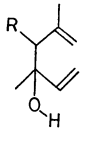
a) A; 180 °C for 4 h. B; 175 °C for 6 h. C; 170 °C for 2 h. b) Determined by GC analyses: PEG-20 M 10% on Chromosorb W (AW) or Silicone DC-550 10% on Chromosorb W (AW). c) Results of GC analyses were confirmed by isolation in large scale experiments (50—500 g).

the reaction temperature is above 160 °C. Solvent in which the hydroxyl proton exchange time largely depends upon temperature, such as acetanilide or triphenylamine, would not be preferable for [3,3]-shift. This classification is applicable to the other systems **10**—**12**.[7]



10, R=p-$CH_3C_6H_4CH_2$-
11, R=furfuryl
12, R=2-thenyl

Despite the difference in the conditions between NMR measurement and oxy-Cope reaction, it might be postulated that the added solvents effective for increasing the selectivity of [3,3]-shift fix the hydroxyl proton, slowing down the rate of proton exchange.

Synthetic utility of the process was confirmed by large scale production (semi-commercial) of geranylacetone (**3a**), and application to other naturally occurring compounds is under investigation in our laboratory.

Experimental

Boiling points are uncorrected. Infrared spectra were determined on a JASCO (DC-403G) spectrometer. NMR spectra were taken with a Varian Associate HA-100 or Varian Model A-60 spectrometer and MS with a Finnigan 9500 instrument. GC analyses were made with a Shimadzu GC-4A using 3 mm × 300 cm column. Separation of the reaction products was made with a Shimadzu GC-5A using 7 mm × 200 cm column of 10% Silicone DC-550 or 10% PEG-20M on Chromosorb W (AW). Rectification of the reaction products was carried out with a Shibata Automatic Packing Column, Model HPC-A-1500-B having 70 theoretical plates. Oxy-Cope rearrangements were carried out in nitrogen atmosphere.

*(3S)-4-Isopropenyl-3,7-dimethyl-1,6-octadien-3-ol (**2a**).* The compound was obtained according to the method reported previously[11b] by the reaction of **1a** (1 mol) with vinylmagnesium bromide (1.2 mol) in THF (1.5 l) at 40 °C for 3 h (yield 79%): bp 60—63 °C/0.5 mmHg.

*(3S)-4-Isopropenyl-3,7,11-trimethyl-1,6,10-dodecatrien-3-ol (**2b**).* The compound was obtained by the same procedure described above, from **2b** (0.5 mol) and vinylmagnesium bromide (0.6 mol): yield 81%; bp 104—106 °C 0.3 mmHg (*E*-form). IR (neat) 3480, 1640, 1450, 1375, 920, and 895 cm^{-1}. NMR (CCl_4) δ 1.15 (s, CH_3, 3H), 1.54, 1.62, 1.67 (s, CH_3, 12H), *ca.* 1.92—2.30 (m, CH_2CH and CH_2CH_2, 7H), *ca.* 4.75—5.10 (m, CH and CH_2, 4H), 5.00(dd, CH, 1H, J=2, 10 Hz), 5.18 (dd, CH, 1H, J=2, 18 Hz), and 5.90 (dd, CH, 1H, J=10, 18 Hz). MS (70 eV) *m/e* (rel intensity) 262 (M^+, 1.6), 244 (6.1), 191 (9.4), 149 (11.7),

123 (55.3), 81(41.5), and 71 (100).

Found: C, 82.62; H, 11.58%. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%.

*4-Isopropenyl-3,8-dimethyl-6-octen-1-yn-3-ol (**6a**).* Acetylene gas was bubbled into a solution of sodium metal (69 g; 3 mol) in liquid ammonia (3 l) until the reaction mixture turned grey. Introduction of acetylene was then suspended and 517 g (3.1 mol) of **1a** was added over a period of 30 min. The reaction was continued for 3 h, acetylene being bubbled through the reaction system maintained at −33 °C. After removal of ammonia, the residue was neutralized with ammonium chloride, water was added, and then the mixture was extracted with ether. Distillation gave 519 g of a mixture of **1a**/**5a**/**6a**/**7a**=5/15/78/2 [analyzed by GC; PEG-20M, 160 °C], which was purified by careful fractional distillation to afford a mixture of **5a**/**6a**/**7a**=4/94/2. Pure **6a** was obtained by silica gel column chromatography (C_6H_6/*n*-C_6H_{14}=4/6; **6a**/**7a**=97/3) or preparative GC [PEG-20M, 170 °C]: bp 59—61 °C/0.5 mmHg.[13]

*4-Isopropenyl-3,7,11-trimethyl-6,10-dodecadien-1-yn-3-ol (**6b**).* The compound was obtained as a mixture of **1b**/**5b**/**6b**/**7b**=10/30/57/3 by the same procedure as described above, except for the use of **1b** (0.5 mol) in 500 ml of ether solution. Separation of **6b** by preparative GC [PEG-20M, 210 °C] was unsuccessful owing to the accompaniment of acetylenic oxy-Cope rearrangement. Pure **6b** was obtained by silica gel column chromatography (C_6H_6/*n*-C_6H_{14}=4/6): bp 120—125 °C/0.3 mmHg (**6a**/**7a**=95/5).[13]

General Procedure for Partial Hydrogenation. Hydrogen was bubbled into a mixture of **1a**/**5a**/**6a**/**7a**=5/15/78/2 (300 g) in hexane (900 ml), in the presence of 5 g of 2% Pd Lindlar catalyst at 35—40 °C for 7 h. After checking the completion of reaction by GC [PEG-20M, 160 °C], the catalyst was filtered and mother liquid evaporated under reduced pressure. Distillation gave 294 g of a mixture of **1a**/**5a**/**2a**/**8a**=6/14/78/2.

*(3R)-4-Isopropenyl-3,7-dimethyl-1,6-octadien-3-ol (**8a**).* In a 5 l autoclave, 335 g (2 mol) of **1a** was added to liquid ammonia (3.3 l) in contact with 20 wt% of aqueous KOH (45 g; 0.16 mol) as a catalyst, acetylene gas (*ca.* 260 g) being introduced with stirring at −33 °C. The reaction temperature was raised to 5 °C, stirring being continued for 32 h. The reaction mixture was cooled to −33 °C and neutralized with ammonium chloride. After removal of ammonia, water was added, and the mixture was extracted with ether. Distillation gave 319 g of a mixture of **1a**/**5a**/**6a**/**7a**=6/16/45/33: bp 59—63 °C/0.5 mmHg. Pure **7a** was obtained only by preparative GC.[13] After partial hydrogenation of the mixture (315 g) by the same method as described above, distillation [bp 82—91 °C/1.5—2 mmHg] afforded 310 g of a mixture of **1a**/**5a**/**2a**/**8a**=7/15/44/34. Careful rectification of 1500 g of a mixture [bottom temp, 128—134 °C; top temp, 94—95 °C; pess., 4 mmHg; reflux ratio=25] afforded 52 g of pure **8a**. IR (neat) 3480, 1639, 1450, 1375, 1110, 1000, 922, and 897 cm^{-1}. NMR (CCl_4) δ 1.18 (s, CH_3, 3H), 1.55, 1.60, 1.63 (s, CH_3, 9H), *ca.* 2.02—2.17 (m, CH_2CH, 3H), *ca.* 4.73—5.00 (m, CH and CH_2, 3H), 5.00 (dd, CH, 1H, J=2,10 Hz), 5.15 (dd, CH, 1H, J=2, 18 Hz), and 5.98 (dd, CH, 1H, J=10, 18 Hz). MS fragmentation pattern of **8a** was analogous to that of **2a**.

Found: C, 80.07; H, 11.18%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

*(3R)-4-Isopropenyl-3,7,11-trimethyl-1,6,10-dodecatrien-3-ol (**8b**).* The compound was obtained as a mixture of **1b**/**5b**/**2b**/**8b**=8/18/42/32 by the same procedure as described above. Separation and purification of **8b** by preparative GC [PEG-20 M, 210 °C] or by fractional distillation was unsuccessful owing to the occurrence of oxy-Cope rearrangement.

*3-Trimethylsiloxy-4-isopropenyl-3,7-dimethyl-1,6-octadiene (**2a**-OTMS).* The compound was obtained according to the method reported previously[11b] by the reaction of **2a** (58.2 g; 0.3 mol) with dry pyridine (28.4 g; 0.36 mol)/trimethylchlorosilane (38.9 g; 0.36 mol) in ether (200 ml) at 35 °C for 4 h; yield 78%; bp 68—70 °C/0.5 mmHg.

*6,10Dimethyl-6,9-undecadien-2-one (**3a**). General Procedure of Oxy-Cope Rearrangement in Neat System.* 800 g of **2a** (purity 93%) was placed in a 1 litre 3-necked flask and heated to 185—187 °C for 4 h in nitrogen atmosphere. The reaction mixture was cooled and distilled *in vacuo* to remove 305 g of a mixture of 2,6-dimethyl-2,5-heptadiene (**4a**)/methyl vinyl ketone, and 47 g of **5a** (impurity in the starting material, as the low-boiling fraction). As a higher boiling product [bp 77—79 °C/0.5 mmHg], 394 g (53%) of **3a** was obtained. GC analysis of **3a** [Silicone DC-550, 160 °C] showed two peaks (11.5 and 13.0 min) in the ratio 41.1 : 58.9. Separation of these compounds by fractional distillation [bottom temp, 143—147 °C; top temp, 77—83 °C; press., 0.3 mmHg; reflux ratio=30] and spectral analyses showed that the former peak is *Z*-isomer and the latter *E*-isomer.[11b]

*6,10,14-Trimethyl-6,9,13-pentadecatrien-2-one (**3b**).* The compound was obtained by the same procedure described above in 52% yield (180 °C for 3.5 h): bp 123—128 °C/0.1 mmHg (*E*/*Z*=57.5/42.5). IR (neat) 1715, 1672, 1440, 1158, 985, 970, 890, and 830 cm^{-1}. NMR (CCl_4) δ 1.50, 1.56 (s, CH_3, 12H), *ca.* 1.70—2.05 (m, CH_2CH_2, 8H), 1.92 (s, CH_3, 3H), 2.13—2.30 (m, CH_2, 2H), 2.55 (t, CH_2, 2H, J=7 Hz), and *ca.* 4.94 (broad t, CH, 3H).

Found: C, 81.99; H, 11.71%. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%.

General Procedure of Oxy-Cope Rearrangement in Solvent Assisted System. A solution of 350 g of **2a** (purity 92%) in 700 g of NMP was subjected to reaction at 180 °C for 5 h with stirring. The reaction mixture was poured into water (1500 ml) and extracted with ether (500 ml×4). Distillation of the products gave 245 g (76%) of **3a** (*E*/*Z*=67/33). Quantitative analyses were carried out with gas chromatography: In the case of **2a** and **8a**, *n*-decyl alcohol was used as an internal standard to obtain the calibration curve [PEG-20M, 160 °C]. Reactions of **2b** in NMP solvent were monitored by using NMP itself as an internal standard.

We wish to express our thanks to Dr. Fumio Wada for technical assistance, and Mr. Masaya Oka for mass spectral analyses.

A Rapid Esterification by Means of Mixed Anhydride and Its Application to Large-ring Lactonization[1)]

Junji Inanaga, Kuniko Hirata, Hiroko Saeki, Tsutomu Katsuki, and Masaru Yamaguchi*

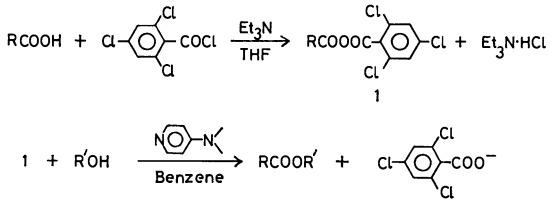
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 29, 1978)

A rapid and mild esterification method using carboxylic 2,4,6-trichlorobenzoic anhydrides in the presence of 4-dimethylaminopyridine was developed. The method was also successfully applied to the synthesis of large-ring lactones, including DL-2,4,6-tridemethyl-3-deoxymethynolide.

For the preparation of large-ring lactones from the corresponding open-chain hydroxy acids, a rapid esterification reaction is necessary to overcome the unfavourable entropy factors leading to the formation of polymers. The mildness of the reaction conditions is also important if the method is to be applied to the synthesis of complex natural substances with sensitive functionalities. Most of the conventional methods have found only a limited use for this purpose. Recently, intensive studies in this field have commenced and several good lactonization methods using different types of reagents have been developed,[2)] some of them having been successfully applied to the synthesis of macrolides.[3)]

In the course of our studies of the synthesis of macrocyclic lactones, the remarkably high catalytic activity of 4-dimethylaminopyridine in acyl transfer reactions[4)] attracted our attention, and so the esterifications with combinations of this reagent and the appropriate mixed anhydrides were examined. This paper will describe the rapid and mild esterification method using 2,4,6-trichlorobenzoic carboxylic anhydride (**1**) as the anhydride counterpart in the above combination, and its successful application to the synthesis of medium- and large-ring lactones, including DL-2,4,6-tridemethyl-3-deoxymethynolide (**8**).



Results and Discussion

Mixed Anhydrides. The esterification by means of mixed anhydride consists of two steps: the formation of the mixed anhydride, and the alcoholysis of the anhydride. Since the first step has been well-documented,[5)] our effort was mainly directed toward the second step. In the choice of the acids to be examined as the components of the mixed anhydrides, the following two factors were considered: the component should be a good leaving group, and the carbonyl group of the component should be sterically hindered from the nucleophilic attack to some extent. The following acid chlorides which seemed to meet the above requirements were preliminarily examined by comparing the rate of the alcoholysis of the corresponding mixed anhydrides in the presence of 4-dimethylaminopyridine: 2,4,6-trichlorobenzoyl (**2**),[6)] 2,3,6-trimethyl-4,5-dinitrobenzoyl (**3**), 2,6-dichloro-3-nitrobenzoyl (**4**),[7)] 2,4,6-tribromobenzoyl (**5**),[8)] 2,6-dichloro-4-nitrobenzoyl,[9)] 2,6-dichlorobenzoyl,[10)] 2,4,6-trichloro-3-nitrobenzoyl,[11)] 2,4,6-trichloro-3,5-dinitrobenzoyl, 2,4,6-tribromo-3-nitrobenzoyl, 2,4,6-tribromo-3,5-dinitrobenzoyl, 2,6-dinitrobenzoyl,[12)] 2,4,6-trimethyl-3,5-dinitrobenzoyl,[13)] 2,3,6-trimethylbenzoyl,[11)] 2,6-dimethoxybenzoyl,[15)] and pivaloyl chloride. 2,4,6-trinitrobenzoyl[12)] and 3,5-dimethyl-2,4,6-trinitrobenzoyl chloride were also examined, but these two acyl chlorides did not give well-defined mixed anhydrides with 2-methylpentanoic acid. Among the above acid chlorides, the chlorides (**2**), (**3**), (**4**), and (**5**) gave the most promising results. Figure 1 shows the relative rates of ester formation, as followed by GLPC, in the alcoholysis of the corresponding four mixed anhydrides with 2-methylpentanoic acid by 2-methyl-2-propanol at room temperature.

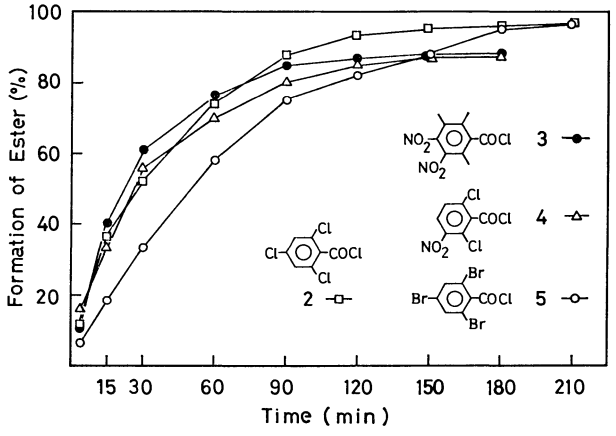


Fig. 1. Relative rates of the 2-methyl-2-propanolysis of mixed anhydrides formed from 2-methylpentanoic acid and four acid chlorides, **2**, **3**, **4**, and **5**.

2,4,6-Trichlorobenzoyl chloride (**2**) was proved to be the most satisfactory one in rate and in the yield of the alcoholysis. The reaction using the chloride (**3**) was fast but incomplete; however, it was later found that the chloride can also be used for the large-ring lactonizations.

Reaction Conditions. The following experiments were carried out by using the acid chloride (**2**) unless otherwise mentioned. Table 1 shows the relative rates of the formation of *t*-butyl 2-methylpentanoate in various solvents. Aromatic hydrocarbons, such as

benzene or toluene, were found to be the most suitable solvents for the alcoholysis step.

When the temperature of the reaction was raised, the rate of alcoholysis increased markedly without affecting the final yield; for example, *t*-butyl 2-methylpentanoate was formed almost quantitatively in 1 or 2 min in toluene at 100 °C (*cf.* entries, 1, 3, and 4 in Table 2). The amount of dimethylaminopyridine also had a significant influence on the rate of the reaction, and it was preferable to use more than one equivalent of the reagent per mole of the mixed anhydride, especially when the method was applied to large-ring lactonizations.

Table 1. Effect of solvents on the rate of ester formation[a]

Solvent	Ester formation (%)			
	4 min	15 min	30 min	60 min
Benzene	37	62	81	91
Toluene	37	59	79	95
Dioxane	20	49	71	89
Dichloromethane	10	39	59	77
Carbon tetrachloride	18	39	52	68
Pyridine	6	22	37	53
Cyclohexane	3	12	23	39
Acetonitrile	3	7	15	28

a) The formation of *t*-butyl 2-methylpentanoate was followed by GLPC.

Esterification. The results of the esterification by this method are summarized in Table 2.

As is shown in Table 2, the esters of secondary and tertiary alcohols were prepared rapidly at room temperature in good yields. In the case of primary alcohols, however, a small amount of an undesired trichlorobenzoic acid ester was formed as the by-product. The rates of the formation of benzoic acid esters were smaller than those of aliphatic acid esters. Sterically very crowded *t*-butyl pivalate could not be prepared by this method.

Lactonization. The method was then applied to

Table 2. Yields and reaction conditions of esterification using 2,4,6-trichlorobenzoyl chloride

Entry	Acid (0.3 mmol)	Alcohol[a]		Dimethyl-aminopyridine (mmol)	Time[b] (min)	Yield[c] (%)
1	2-Methyl-pentanoic acid	2-Methyl-2-propanol		0.6	90	>95
2			(2 eq.)	1.2	20	89
3			(2 eq.)	0.6	10 (80 °C)	>95
4			(2 eq.)	0.6	2 (100 °C)[d]	>95
5		2-Butanol		0.6	5	>95
6		Cyclohexanol		0.6	5	>95
7		Methanol		0.6	10	95[e]
8		Ethanol		0.6	3	95[f]
9	Cyclohexanecarboxylic acid	2-Methyl-2-propanol		0.6	20	>95
10		Cyclohexanol		0.6	20	>95
11	Benzoic acid	2-Methyl-2-propanol		0.6	270	89
12		Cyclohexanol		0.6	20	>95
13	Methyl hydrogen *meso*-2,4-dimethyl-glutarate	2-Methyl-2-propanol	(2 eq.)	0.6	60	>95[g]
14			(2 eq.)	0.6	5 (80 °C)	84[g]

a) One equivalent of alcohols to acids was used unless otherwise mentioned. b) The alcoholysis reactions were carried out at room temperature in benzene unless otherwise mentioned. c) The yields were determined by GLPC in the presence of the appropriate internal standards. d) The alcoholysis step was carried out in toluene. e) Methyl trichlorobenzoate (1.5%) was also formed. f) Ethyl trichlorobenzoate (3%) was also formed. g) No isomerization occurred at room temperature, but isomerization occurred (22%) when the reaction was carried out at 80 °C.

Table 3. Isolated yield in lactonization by trichlorobenzoyl chloride method

a) 4-Dimethylaminopyridine.

Table 4. Isolated yield in lactonization by trimethyldinitrobenzoyl chloride method

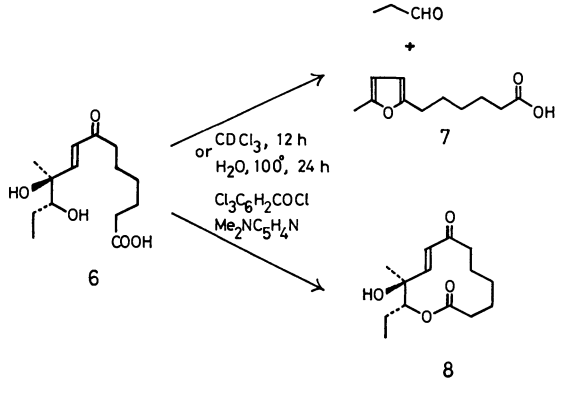
Hydroxy acid (Ring size)	Catalyst[a] (mol. equiv.)	Time of addition (h)	Yield (%) Monomer	Dimer
$HO(CH_2)_7CO_2H$ (9)	3	7	18	41
$C_6H_{13}CH(OH)(CH_2)_{10}CO_2H$ (13)	6	8	58	8
$C_6H_{13}CH(OH)CH_2CH{=}CH(CH_2)_7CO_2H$ (13)	3	7	58	9

a) 4-Dimethylaminopyridine.

the synthesis of macrocyclic lactones. The mixed anhydrides of the long-chain hydroxy acids could be prepared in a manner similar to that used in the above esterification. After the removal of triethylamine hydrochloride, the solution of the mixed anhydride was diluted with toluene and slowly added to a refluxing solution of dimethylaminopyridine in toluene under high-dilution conditions. In this way, nine- to thirteen-membered ring lactones were prepared. They are shown in Table 3.

The results of the experiments carried out by using 2,3,6-trimethyl-4,5-dinitrobenzoyl chloride as the condensing agent are given in Table 4. As can be seen from the table, this acid chloride is as useful as 2,4,6-trichlorobenzoyl chloride, at least for the lactonization.

Finally, the method was applied to the lactonization of the seco-acid (**6**) of DL-2,4,6-tridemethyl-3-deoxymethynolide (**8**). The seco-acid has an acid-sensitive dihydroxy enone structure, and it has been shown that the compound decomposes easily to a furan derivative (**7**) and propionaldehyde on contact with a catalytic amount of hydrochloric acid.[16] When the seco-acid was cyclized under conditions similar to those used in lactonization with 2,4,6-trichlorobenzoyl chloride, the desired DL-lactone (**8**) was isolated in 46% yield, without the formation of the furan derivative.



Experimental

All the procedures for the esterifications and the lactonizations were carried out under an atmosphere of nitrogen in order to exclude moisture. The melting points or boiling points are uncorrected. The IR spectra (Hitachi R-215) were obtained in liquid films or potassium bromide disks. The PMR spectra (Hitachi R-20B) were taken in deuteriochloroform solutions. The mass spectra (Hitachi RMU-6MG) were recorded with a direct-inlet system operating at 10—30 eV. The solvents were purified and dried by the standard methods.

Materials. 8-Hydroxyoctanoic acid was prepared by the hydrolysis of its methyl ester, which had been obtained by reducing methyl 7-chloroformylheptanoate with sodium borohydride in dioxane, and was purified by recrystallization from methanol. Mp 61 °C (lit, 58—58.5 °C).[17]

11-Hydroxyundecanoic acid was prepared by the sodium borohydride reduction of methyl 10-chloroformyldecanoate or by the diborane reduction of methyl hydrogen undecanedioate in THF at 0 °C, followed by the saponification of the resulting hydroxy ester, and was purified by sublimation. Mp 65—67 °C (lit, 65.5—66 °C).[18]

Commercial 12-hydroxyoctadecanoic acid and ricinoleic acid were purified by recrystallization and distillation, respectively.

*2,4,6-Trichlorobenzoyl Chloride (**2**).* According to the method in the literature, 2,4,6-trichloroaniline was converted into 2,4,6-trichlorobenzonitrile,[19] whcih was then hydrolysed to 2,4,6-trichlorobenzoic acid.[6] The acid was refluxed with thionyl chloride for 3 h. Bp 110—114 °C/9 mmHg.

*2,3,6-Trimethyl-4,5-dinitrobenzoyl Chloride (**3**).* Fuming nitric acid (4 ml) was added to a cold mixture of 2,3,6-trimethylbenzoic acid[20] (3.3 g) and concentrated sulfuric acid (12 ml), after which the mixture was kept at 40 °C for 30 min. The reaction product was then poured onto ice, and the precipitate was filtered and recrystallized from ethanol–water to give the dinitro acid (4.1 g). Mp 222 °C(dec). The acid (1.6 g) was heated with thionyl chloride (10 ml) for 12 h at 60 °C, and after the removal of thionyl chloride, the crude product was purified by sublimation. Mp 102—103 °C.

2,4,6-Trichloro-3,5-dinitrobenzoyl Chloride. 2,4,6-Trichloro-3-nitrobenzoic acid[11] (2 g) was dissolved in sulfuric acid (12 ml) heated at 85 °C, and sodium nitrate (1.7 g) was added over a period of 15 min. The mixture soon solidified. The temperature was kept at 80—90 °C for 2 h. The mixture was then worked up as usual, and the product was recrystallized from toluene. Mp 224—225 °C, 2.4 g. The dinitro acid was converted into the acid chloride by the method using phosphorus pentachloride and phosphoryl chloride and was purified by sublimation. Mp 150—152 °C.

2,4,6-Tribromo-3-nitrobenzoyl Chloride. 2,4,6-Tribromobenzoic acid[8] (3.56 g) was suspended in sulfuric acid (10 ml) and nitrated with a mixture of nitric acid (2 g) and sulfuric acid (4 g) at 0—7 °C. The mixture was kept at room temperature for 1 h, poured onto ice, filtered, and washed with dilute hydrochloric acid. Mp 186—187 °C (from toluene); 3.6 g. It was then converted into the acid chloride with phosphorus pentachloride and phosphoryl chloride. Mp 129—131 °C (from benzene–hexane).

2,4,6-Tribromo-3,5-dinitrobenzoyl Chloride. This was prepared by the method described in the case of 2,4,6-trichloro-3,5-dinitrobenzoyl chloride. 2,4,6-Tribromo-3,5-dinitroben-

zoic acid; mp 275—276 °C. The acid chloride; mp 245—246 °C.

3,5-Dimethyl-2,4,6-trinitrobenzoyl Chloride. 1,3,5-Trimethyl-2,4,6-trinitrobenzene (1 g) was boiled with concentrated nitric acid (63%, 60 ml) for 80 h. The evaporation residue of the reaction mixture was then extracted with aqueous sodium carbonate, and the extract was acidified with hydrochloric acid. The acid was recrystallized from water. Mp 224—226 °C, 0.42 g. The acid chloride (phosphorus pentachloride and phosphoryl chloride) was purified by sublimation. Mp 157—159 °C.

The IR and analytical data of the new acids and acid chlorides are summarized in Table 5.

Relative Rates of Alcoholysis of Mixed Anhydrides. The acid chloride (0.3 mmol) to be examined was added to a mixture of 2-methylpentanoic acid (37 μl, 0.3 mmol) and triethylamine (42 μl, 0.3 mmol) in THF (2 ml), after which the mixture was stirred for 20 min at room temperature. After the removal of triethylamine hydrochloride by filtration, the filtrate was evaporated under nitrogen and the residue was dissolved in dichloromethane (1 ml). To this solution we added a mixture of 2-methyl-2-propanol (56 μl, 0.6 mmol) and 4-dimethylaminopyridine (73 mg, 0.6 mmol) in dichloromethane (1 ml), and the resulting mixture was stirred at room temperature. The formation of the ester was followed by GLPC by the addition of bromobenzene (50 μl) as an internal standard. The results are partly exhibited in Fig. 1.

Comparison of Solvents. The experiments were carried out in the manner described above, except that 2,4,6-trichlorobenzoyl chloride was used as the acid chloride and that dichloromethane was replaced by the other solvents (2 ml) to be examined. The results are summarized in Table 1.

Preparation of Carboxylic Esters. Carboxylic acids (0.3 mmol) and triethylamine (0.3 mmol) reacted with trichlorobenzoyl chloride (0.3 mmol) in THF (1 ml) in the same manner as above. After the removal of triethylamine hydrochloride and the solvent,[21] the resulting anhydrides were treated with alcohols (0.3—0.6 mmol) and dimethylaminopyridine (0.6—1.2 mmol) in benzene. The yields obtained by GLPC are given in Table 2. For the isolation of the esters, the reaction mixture was diluted with ether, washed successively with 3% aqueous hydrochloric acid, water, an aqueous sodium hydrogencarbonate solution, and water, dried, and distilled. They were identified by means of the PMR and IR spectra.

Preparation of Lactones. 2,4,6-Trichlorobenzoyl (or 2,3,6-trimethyl-4,5-dinitrobenzoyl) chloride (1.0 mmol) was added to a mixture of a hydroxy acid (1.0 mmol) and triethylamine (1.1 mmol) in THF (10 ml), after which the mixture was stirred for 1—2 h (or 12 h in the case of 2,3,6-trimethyl-4,5-dinitrobenzoyl chloride) at room temperature. After removal of triethylamine hydrochloride, the filtrate was diluted with toluene (500 ml) and added under the high-dilution conditions to a refluxing solution of 4-dimethylaminopyridine (3—6 mmol) in toluene (100 ml) over a period of 1.5—8 h. The reaction mixture was worked-up in a manner similar to that used in the case of the esterification and was separated by preparative TLC (silica gel G, Merck). The crude products were purified by distillation or recrystallization (Tables 3 and 4).

8-Octanolide:[22] A colorless oil; IR 1735 cm^{-1}; PMR δ 4.28 (2H, t, J=5.2 Hz, $-CH_2O-$); MS 142 (M). The dimer:[22] Colorless needles (from petroleum ether); mp 93—93.5 °C; IR 1735 cm^{-1}; PMR δ 4.15 (4H, broad t); MS 284 (M).

11-Undecanolide:[22] A colorless oil; IR 1730 cm^{-1}; PMR δ 4.2 (2H, broad t); MS 184 (M). The dimer:[22] Colorless needles (from hexane); mp 71—72 °C; IR 1730 cm^{-1}; PMR δ 3.9—4.4 (4H, broad t); MS 368 (M).

12-Octadecanolide: A colorless oil; bp 140 °C (bath temp) /20 mmHg; IR 1730 cm^{-1}; PMR δ 4.7—5.2 (H, m, –CHO–); MS 282 (M). Found: C, 76.40; H, 12.06%. Calcd for $C_{18}H_{34}O_2$: C, 76.54; H, 12.13%. The dimer: Colorless needles (from petroleum ether); mp 64—65 °C; IR 1730 cm^{-1}; PMR δ 4.6—5.2 (2H, m); MS 564 (M). Found: C, 76.55; H, 12.23%. Calcd for $C_{36}H_{68}O_4$: C, 76.54; H, 12.13%.

cis-*9-Octadecen-12-olide*: A colorless oli; bp 120 °C (bath temp)/12 mmHg; IR 1720 cm^{-1}; PMR δ 4.6—5.3 (H, m, –CHO–); 5.3—5.8 (2H, m, –CH=CH–); MS 280 (M). Found: C, 76.74; H, 11.54%. Calcd for $C_{18}H_{32}O_2$: C, 77.09; H, 11.50%. The dimer: A colorless oil; bp 160 °C (bath temp)/0.3 mmHg; IR 1720 cm^{-1}; PMR δ 4.6—5.8 (6H, m, –CHO– and –CH=CH–); MS 560 (M).

2,4,6-Tridemethyl-3-deoxymethynolide (8). A mixture of the seco-acid[16] (**6**, 272 mg, 1.0 mmol) and triethylamine (153 μl, 1.1 mmol) in THF (10 ml) was stirred for 10 min at room temperature, and then 2,4,6-trichlorobenzoyl chloride (160 μl, 1.0 mmol) was added. After stirring for 2 h at room temperature, the resulting precipitate was filtered and washed with a small amount of THF. The filtrate was diluted with benzene (500 ml) and slowly added to a refluxing solution of 4-dimethylaminopyridine (732 mg, 6 mmol) in benzene (100 ml) over a period of 40 h. The reaction mixture was washed successively with a saturated aqueous citric acid solution, water, an aqueous sodium hydrogencarbonate, and water, dried with magnesium sulfate, and evaporated. The crude product (247 mg) was separated by preparative TLC (silica gel G, Merck), with an ether–benzene mixture (2 : 1) used as the developer, to give the monomeric lactone (**8**, 116 mg, 46%), the dimer (65 mg, 26%), and the polymer (21 mg).

The Monomeric Lactone (8): Colorless needles (from dichloromethane–diisopropyl ether); mp 123 °C; IR 3520, 1725, 1680, 1620, 1225, 1150, 1085, 980 cm^{-1}; PMR δ 0.93 (3H, t, J=7.1 Hz, methyl protones of 11-ethyl), 1.2—3.0 (12H, m), 1.38 (3H, s, 10-methyl), 3.15 (H, broad s, 10-hydroxyl), 4.80 (H, dd, J=9.0 and 3.1 Hz, 11-methine), 6.29 and 6.66 (2H, q, J=16.0 Hz, 8-double bond); MS 255 (M+1), 237, 211, 196, 178, 151, 136, 135. Found: C, 65.96; H, 8.68%. Calcd for $C_{14}H_{22}O_4$: C, 66.11; H, 8.72%. Acetate (acetic anhydride and 4-dimethylaminopyridine in dichloromethane): Colorless prisms (from dichloromethane–diisopropyl ether); mp 146—147 °C; MS 296 (M), 254, 237, 225, 211, 196, 178.

The Dimer: A colorless oil; IR 3450, 1720, 1670, 1630, 975 cm^{-1}; PMR δ 0.91 (6H, t, J=7.1 Hz), 1.36 (6H, s), 1.1—3.0 (26H, m), 4.85 (2H, dd, J=9.2 and 3.2 Hz), 6.30 and 6.84 (2H, q, J=16.0 Hz); MS 508 (M), 491, 490, 237. Diacetate: Colorless needles (from dichloromethane–diisopropyl ether); mp 182.5 °C; MS 532 (M−60), 490, 472.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Carbon-13 NMR Spectra of Stereoisomeric Substituted 2-Methylcyclohexanols and Their Acetates: A Comparison of the Observed and Predicted Chemical Shifts

Yasuhisa SENDA,* Jun-ichi ISHIYAMA, and Shin IMAIZUMI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai 980

(Received October 12, 1978)

The ^{13}C NMR spectra of stereoisomeric 4-*t*-butyl-2-methylcyclohexanols, 5-*t*-butyl-2-methylcyclohexanols, 2-methylcyclohexanols, and their acetates were measured. The observed chemical shifts were compared with the values estimated by using the substituent parameters of methyl, *t*-butyl, and hydroxyl groups. An appreciable deviation by vicinal substitution was found between the predicted and observed chemical shifts of C-1 and C-2. The substituent parameters of the acetoxyl group on the cyclohexane ring were estimated by means of a comparison of the chemical shifts of *cis*- and *trans*-4-*t*-butylcyclohexyl acetate, and those of *t*-butylcyclohexane.

The simple additivity relationships for carbon chemical shifts within specific families of compounds are very useful for the assignment of a certain signal to a specific carbon atom and for the prediction of the chemical shift of a certain carbon atom.[1] However, when the two substituents on a cyclohexane ring are at a geminal or vicinal position, the predicted values deviate from the observed ones.[2,3] This may be supposed to be caused by the interaction between these two groups. For two methyl groups on the adjacent or the same carbon atoms of cyclohexane, the substituent parameters of vicinal and geminal substitution were reported by Dalling and Grant.[2]

The ^{13}C NMR spectra of four stereoisomers of 5-*t*-butyl-2-methylcyclohexanols (**1**—**4**) and their acetates (**11**—**14**) were measured in order to study the effects of the steric structure of the molecule and of the vicinal substitution of the methyl and hydroxyl or acetoxyl groups on the carbon chemical shifts. The ^{13}C chemical shifts for these compounds are collected in Table 1. The assignments were based on standard methods, *i.e.*, the relative intensities, the off-resonance CW decoupling, and a comparison of the signal shift between closely related compounds. The chemical-shift differences ($\Delta\delta$) between the observed values and those calculated by using the substituent parameters of the methyl,[2] *t*-butyl, hydroxyl[3] and acetoxyl (*vide infra*) groups are also tabulated. Appreciable shift differences were found in the chemical shifts of C-1 and C-2. The chemical-shift differences of most of the other carbons were within ± 1.0 ppm.

The chemical shifts of substituted carbon atoms varied appreciably according to the orientation of the substituent. The signals of carbinol carbon and C-2 with axial substituents appeared at higher fields than those having equatorial ones. For the carbons bearing the *t*-butyl group, the signals appeared at around δ 47 when the hydroxyl or acetoxyl group was in an equa-

a) The values in parentheses were reported by Buchanan and Stothers (G. W. Buchanan and J. B. Stothers, *Can. J. Chem.*, **47**, 3605 (1969)). b) The carbon numbering relates, for the purposes of comparison, to the equivalent carbon in the cyclohexanol series. c) The values in parentheses were reported by Roberts *et al.* (J. D. Roberts, F. J. Weigert, J. I. Kroschwitz, and H. J. Reich, *J. Am. Chem. Soc.*, **92**, 1338 (1970)).

torial position, but at around δ 40—41 when it was in an axial position.

The NMR spectra of stereoisomeric 2-methylcyclohexanols (**5**, **6**), 4-*t*-butyl-2-methylcyclohexanols (**7**, **8**), and their acetates (**15**—**18**) were also measured (Tables 2 and 3). Most of the carbon resonances of the isomers whose hydroxyl or acetoxyl group is equatorial appeared at lower fields than those of the axial isomers.

The carbon-chemical shifts of stereoisomeric 4-*t*-butylcyclohexyl acetates (**9**, **10**) are listed in Table 4. The acetoxyl groups of *cis*- and *trans*-4-*t*-butylcyclohexyl acetates have been supposed to take exclusively an axial and an equatorial orientation respectively, judging from the confromational free energies of the acetoxyl and *t*-butyl groups.[4] Comparisons of the carbon-chemical shifts of t-butylcyclohexane, the chemical shifts of which are also tabulated in Table 4, with those of **9** and **10** give the substituent parameters for the axial and equatorial acetoxyl groups of the individual carbons of cyclohexane.

Substituent parameters of the acetoxyl group (ppm)

	Axial	Equatorial
C-1	42.3	46.6
C-2	3.4	4.8
C-3	−6.0	−2.2
C-4	−0.7	−1.2

The distribution of the conformational isomers of **5** and **15** is simply estimated from the conformational free energies[4] of the methyl, hydroxyl, and acetoxyl groups as being approximately 84% axial and 16% equatorial hydroxyl or acetoxyl conformers, while the corresponding values of **6** and **16** are 2% axial and 98% equatorial. The predicted chemical shifts of the ring carbons for each conformer are calculated using

the substituent parameters. The predicted values for these isomers can be obtained from the above conformational distribution by using the Eliel equation.[5] Similarly to the case of *t*-butylmethylcyclohexanols, appreciable shift differences between the observed and predicted values are found for the chemical shifts of C-1 and C-2.

In order to examine the correlation of the $\Delta\delta$ values with the stereochemical relationship of the methyl and hydroxyl or acetoxyl groups on the vicinal position, these values of *t*-butylmethylcyclohexanols and their acetates, the substituents of which are conformationally rigid, were compared with each other. The chemical-shift deviation of C-1 and C-2, the substituents on which are in a gauche-*cis* relation, is larger than that in gauche-*trans*, while that in anti is the smallest. These findings indicate that the dihedral angle between the methyl and hydroxyl or acetoxyl groups contributes to the magnitude of the γ-effect.

The chemical shifts for the equatorial 2-methyl groups are around δ 18—19 for **1**, **3**, **7**, **8**, and their acetates. The resonance signals for the axial methyl groups shift to higher fields, appearing at δ 10.6 for **2**, 11.5 for **12**, 16.7 for **4**, and 16.3 for **14**. The NMR spectra of stereoisomeric 1-*t*-butyl-4-methylcyclohexanes show that the chemical shift for an axial methyl group on the cyclohexane ring is δ 17.5 and that for an equatorial methyl group is δ 22.8.[6] By comparing the chemical shifts on the 2-methyl groups of **1**—**4**, **7**, **8**, and their acetates with those of the corresponding 1-*t*-butyl-4-methylcyclohexanes, the deviation can be regarded as the γ-effect parameters of the hydroxyl group on the methyl group. The values, -3.9——-6.9 ppm for gauche- and -0.8——-1.2 ppm for anti-relation, are smaller than those of the corresponding γ-effect parameters of the hydroxyl group on the cyclohexane-ring carbons, which are found to be -7.2 ppm for gauche- and -2.5 ppm for anti-relation. This is similar to the case of the methyl group, the γ-gauche effect of which has been reported to be -6.37 ppm on the cyclohexane-ring carbons and -2.82 ppm on the vicinal methyl carbon.[2] Such a difference is attributable to the situation of γ-carbons; the 2-methyl group, which can rotate freely around the carbon–carbon bond, is less restricted than the ring carbons. The predicted chemical shifts of the methyl carbons of **5**, **6**, **15**, and **16** were obtained by taking account of the conformational distributions and the carbon chemical shifts of the methyl group in stereoisomeric 1-*t*-butyl-4-methylcyclohexanes.

The ^{1}H NMR spectra of cyclohexanols **1**—**4** were also examined in search of any possible spectral correlation with their configurational structures. These compounds showed no appreciable difference in the stereochemical heterogeneity. The signals of the C-1 protons of **1** and **2**, which have an equatorial hydroxyl group, appeared at δ 3.64 and 3.67 respectively as a multiplet, while those of **3** and **4**, which have an axial hydroxyl, appeared at δ 3.77 as a broad singlet. The signals of the 2-methyl protons partially overlapped with those of the 5-*t*-butyl methyl protons, so that it is impossible to read their positions accurately from the spectra. On the other hand, the carbon-chemical shifts for the 2-methyl groups reported here have made it possible to determine the confirgurations of all the stereoisomers of the molecule.

The $\Delta\delta$ values of *t*-butylmethylcyclohexanols and their acetates are regarded as the parameters of the vicinal substitution of methyl and hydroxyl or acetoxyl groups. These values are useful for the prediction of the chemical shifts of those compounds which have 2-methylcyclohexanol or its acetate moiety.

Experimental

NMR Spectra. The ^{13}C FT-NMR spectra were obtained at 25.15 MHz with a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory; the instrument was controlled by means of a JEC-6 spectrum computer. The samples were dissolved in $CDCl_3$, the deuterium signal of which provided a field-frequency lock; the concentrations were 30% (w/v). The measurement conditions were as follows: pulse width, 27.5 μs (*ca.* 45°); repetition time, 4 s; spectral width, 6250 Hz; data point, 8192; acquisition time, 0.65 s. Noise-modulated proton decoupling was carried out at a nominal power of 20 W. All the chemical shifts are expressed in δ (ppm downfield from internal Me_4Si). Each observed chemical shift is estimated to be accurate to $\pm$0.1 ppm.

5-t-Butyl-2-methylcyclohexanols[7,8] ***(1)—(4) and Their Acetates***[7] ***(11)—(14).*** The hydrogenation of *cis*-5-*t*-butyl-2-methyl-2-cyclohexenol[9] over Raney Ni in ethanol gave a mixture of **1** and **2** (**1**, 73%; **2**, 27%); yield, 85%. The hydrogenation of *trans*-5-*t*-butyl-2-methyl-2-cyclohexenol[9] over PtO_2 in ethanol gave a mixture of **3** and **4** (**3**, 66%; **4**, 34%); yield, 91%. The mixtures were separated by preparative GLC. Alcohols **1** and **4** were identified by a comparison of the relative retention times of GLC with those of the hydroboration products[10] of 4-*t*-butyl-1-methylcyclohexene. Alcohols **2** and **3** were identified by a comparison of the relative retention times of GLC with those of the LAH-reduction products[11] of *cis*- and *trans*-5-*t*-butyl-2-methylcyclohexanone (**1**, 70%; **3**, 30% from *cis*-ketone: **2**, 95%; **4**, 5% from *trans*-ketone). The acetates were prepared with Ac_2O in pyridine.

4-t-Butyl-2-methylcyclohexanols,[12] ***(7) and (8), and Their Acetates,***[13] ***(17) and (18).*** The hydrogenation of 4-*t*-butyl-2-methylphenol over the Rh–Al_2O_3 catalyst in ethanol, followed by Al_2O_3 column chromatography using benzene as the eluent, gave pure **7**; yield, 42%. *cis*-4-*t*-Butyl-2-methylcyclohexanone, which had been prepared by the $Na_2Cr_2O_7$ oxidation of **7**, was reduced with LAH to give a mixture of **8**[10] (86%) and **7** (14%); yield, 89%. The mixture was separated by Al_2O_3 column chromatography, using benzene as the eluent. The acetates were prepared with Ac_2O in pyridine.

The structure of each isomer was confirmed by the ^{1}H NMR spectra and by the analytical GLC.

(Received November 7, 1978)

Reaction of 2,4-di-*t*-butyl-6-methylaniline (**3**) with disulfur dichloride afforded 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**4**) as a stable compound in 80% yield. Reaction of 2,4,6-tri-*t*-butylaniline (**1**) with disulfur dichloride gave in 70% yield 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene, which in solution, exists as a tautomeric mixture with 2,4,6-tri-*t*-butyl-*N*-thiosulfinylaniline (**2b**) as a minor component. In the reactions with 2,4-di-*t*-butyl-6-isopropyl- or 2,4,6-trimethylaniline, *N*-thiosulfinylanilines obtained were unstable at ambient temperature. Aniline **1** reacted with sulfur dichloride to give **2** and the corresponding sulfur diimide and *N*-sulfinylaniline. The reaction of **4** with the dichloride afforded **4** and the corresponding sulfur diimide.

p-Dimethylamino-*N*-thiosulfinylaniline has been the only compound that has thiosulfinylamino group.[1] However, the reported yield in the reaction of *p*-dimethylaminonitrosobenzene or *p*-dimethylamino-*N*-sulfinylaniline with phosphorus pentasulfide was poor (15 or 1% respectively). Moreover, this compound could not be purified by chromatography, and appeared to be air-sensitive.[2]

Protection of a reactive group by bulky substituents often stabilizes the compounds and has an advantage over stabilization brought about by introduction of a strongly electron-donating or -withdrawing group, since the nature of a functional group to be studied is electronically less perturbed. As part of our study on poly-*t*-butylbenzene derivatives,[3] we undertook an investigation on steric protection of thiosulfinylamino group and a stable thiosulfinylamino compound was obtained in a high yield by a reaction of disulfur dichloride with a sterically hindered aniline. Although the reaction of disulfur dichloride with aniline leading to the formation of 1,2,3-benzodithiazol-2-ium chloride (Herz compound) is known as the Herz reaction[4] and has been extensively studied, there has been no report on the reaction of S_2Cl_2 with anilines bearing two ortho substituents. This paper describes the results of the reaction with such hindered anilines.

Results and Discussion

Reaction of 2,4,6-tri-*t*-butylaniline (**1**) with disulfur dichloride (S_2Cl_2) in the presence of triethylamine in ether at 0 °C for 1 h afforded a compound with a molecular formula $C_{18}H_{29}NS_2$ in 70% yield; the molecular weight was determined by mass spectrometry (M^+: *m/e* 323) and vapor pressure osmometry in benzene at 39.4 °C (323). In solution, this compound was found to be a mixture of two isomers (**2a** and **2b**) on the following basis.

1) The compound is yellow crystalline material but reddish in solution: a very weak absorption at 535 nm was observed in a fairly concentrated solution (*ca.* 2.5×10^{-2} M). This absorption around 540 nm is considered to be characteristic of the *N*-thiosulfinylanilines (see Ref. 1 and the data listed in Table 1).

2) The NMR spectrum shows the presence of two compounds; the major one (**2a**) has three singlets due to nonequivalent *t*-butyl groups at δ 0.83, 1.18, and 1.38, and two pairs of doublet due to nonequivalent olefinic protons at 5.87 and 6.39, while the minor one (**2b**) has two singlets due to *t*-butyl groups at δ 1.31 (2 and 6 positions) and 1.34 (4 position), and a singlet due to the two equivalent aromatic protons. The molar ratio of the two species was calculated based on the NMR signal intensities of the two olefinic protons of **2a** and the two aromatic protons of **2b** and found to vary reversibly with temperature. The typical results are shown in Table 2. The compound (**2**) exists only as a monomer in the solid state and the structure of **2a** was confirmed by X-ray crystallographic analysis.[5]

Table 1. Electronic spectra of *N*-thiosulfinylanilines

Compound	Solvent	λ_{max} nm, (ε)
2a+**2b**	hexane	268(2610), 292(2580), 340(2050), 410(3480), 535(weak)
4	hexane	270 sh(1470), 310 sh(1940), 343(5590), 476(2190), 536 sh(1190)
8	pentane	272 sh(2060), 305 sh(2330), 343(6960), 483(1810), 542 sh(1130)
10	pentane	336(5700), 462(1900), 540 sh(870)

Table 2. Equilibrium constant in CD_2Cl_2 (0.48 M)

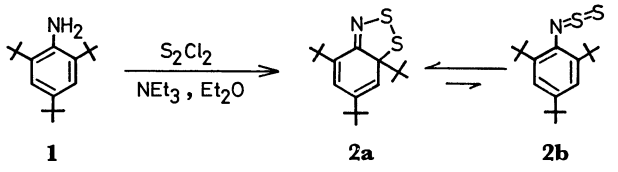
35 °C	14.2	1.62
0 °C	33.7	1.91



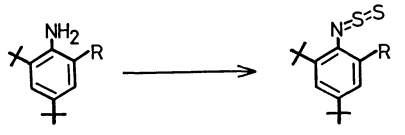
1 **2a** **2b**

Unlike the case of **1**, a similar reaction with 2,4-di-*t*-butyl-6-methylaniline (**3**) gave the corresponding *N*-thiosulfinylaniline (**4**) in 80% yield, which was deep purple crystals and stable at ambient temperature. The electronic spectra are tabulated in Tables 1 and 3; the visible part of the spectra did not show any appre-

Table 3. Solvent effect on electronic spectra of **4**

Solvent	λ_{max} nm, (ε)		
Hexane	343(5590),	476(2190),	536 sh(1190)
CCl_4	345(5830),	480(2230),	548 sh(1280)
EtOH	343(6000),	478(2170),	544 sh(1260)

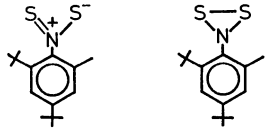
ciable solvent effect (Table 3). No evidence for the ring-chain tautomerism as observed for **2** was obtained for this compound. X-Ray analysis established the structure (**4**).[5]



3: R=Me
7: R=*i*-Pr

4: R=Me
8: R=*i*-Pr

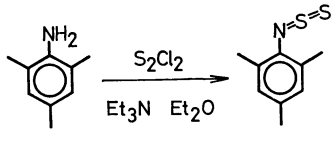
thus eliminating other possible structures, *i.e.*, (dithionitro)benzene (**5**) or dithiaziridine (**6**).



5 **6**

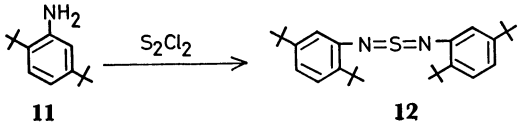
A similar reaction of 2,4-di-*t*-butyl-6-isopropylaniline (**7**) gave the corresponding *N*-thiosulfinylaniline (**8**) as a purple oil (14%), which decomposed slowly at room temperature. The electronic spectrum is listed in Table 1. The isolation of analytically pure specimen was difficult because of its instability. The fact that more sterically hindered *N*-thiosulfinylaniline (**7**) was less stable than **4** is noteworthy and this point will be discussed in the accompanying paper[8] in connection with the thermolysis of these *N*-thiosulfinylanilines.

The reaction of 2,4,6-trimethylaniline (**9**) with disulfur dichloride under similar conditions gave no *N*-thiosulfinylaniline. However, lowering of both reaction temperature (−78 °C, 2 h) and work-up temperature (−2 °C) enabled us to isolate **10** in 2% yield as a reddish purple oil (see Table 1 for the electronic spectrum), although satisfactory analytical data could not be obtained because of its instability.



9 **10**

Unlike both aforementioned reactions and the Herz reaction, the reaction of 2,5-di-*t*-butylaniline (**11**) with disulfur dichloride under conditions similar to those for the reaction of **1** gave *N*,*N*′-bis(2,5-di-*t*-butylphenyl)sulfur diimide (**12**) in 70% yield as orange crystals.



11 **12**

The above results indicate that the reactions of disulfur dichloride with anilines substituted at both ortho positions gave *N*-thiosulfinylanilines, although they are fairly unstable in the absence of bulky substituents. Therefore, existence of a highly electron-donating group (as in *p*-dimethylamino-*N*-thiosulfinylaniline)[1] is not essential for preparation of a thiosulfinylamino compound.

N-Thiosulfinylanilines were obtained also by the reactions of **1** and **3** with sulfur dichloride (SCl_2). In these cases, considerable amounts of the sulfur diimides were obtained. The *N*-sulfinylaniline (**15**) was formed as well.

$$\mathbf{1} \xrightarrow[Et_3N,\ Et_2O]{SCl_2} \mathbf{2}\ (23.7\%) + Ar^1\text{-}N{=}S{=}N\text{-}Ar^1\ (12.6\%) + Ar^1\text{-}N{=}S{=}O\ (\mathbf{14},\ 11.9\%) + \mathbf{1}\ (\mathbf{15},\ 45\%)$$

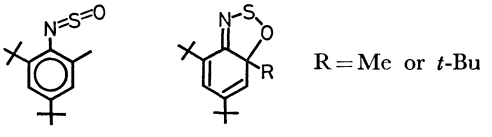
$Ar^1 = 2,4,6\text{-}(t\text{-}Bu)_3C_6H_2$

$$\mathbf{3} \xrightarrow[Et_3N,\ Et_2O]{SCl_2} \mathbf{4}\ (16.9\%) + Ar^2\text{-}N{=}S{=}N\text{-}Ar^2\ (50.1\%) + \mathbf{3}\ (26.3\%)$$

$Ar^2 = 2,4\text{-}(t\text{-}Bu)_2\text{-}6\text{-}MeC_6H_2$

Formation of **2** or **4** may be ascribed to the reactions of **1** or **3** with disulfur dichloride, because sulfur dichloride is known to dissociate partly into disulfur dichloride and chlorine molecule.[6]

Reactions of **1** and **3** with thionyl chloride gave *N*-sulfinylanilines **15** (83.0%) and **16** (72.3%), respectively. These *N*-sulfinylanilines showed no tendency to undergo intramolecular cyclization into **17** unlike the case of **2**.



16 **17** R=Me or *t*-Bu

Experimental

All melting points were uncorrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and Hitachi EPS-3 spectrophotometers, respectively. The NMR spectra were measured with a Hitachi R-20B spectrometer using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer. Molecular weights were determined with a Hitachi 117 Molecular Weight Apparatus. Reactions were performed under nitrogen, and chromatographic separations were carried out by dry column chromatography (Woelm silica gel for dry column chromatography).

*Reaction of 2,4,6-Tri-t-butylaniline (**1**) with S_2Cl_2.* A solution of S_2Cl_2 (261 mg, 1.94 mmol) in ether (1.7 ml) was added dropwise to a solution of 2,4,6-tri-*t*-butylaniline[7] (500 mg, 1.91 mmol) and triethylamine (399 mg, 3.95 mmol) in ether (20 ml) with stirring at 0 °C. After being stirred for 1 h, the reaction mixture was washed with water, and dried ($MgSO_4$). Removal of the solvent gave a brown tarry material, which was chromatographed on silica gel with hexane. The first fraction gave 16 mg of sulfur. The second fraction afforded 434 mg (1.34 mmol, 70.2%) of 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene (**2a**) as yellow crystals (mp 92.5—94 °C), which were recrystallized three times from ethanol; mp 96—97 °C; IR (KBr):

2950, 1625, 1475, 1455, 1385, 1360, 1255, 835, 665, and 638 cm^{-1}; NMR (CCl_4): the major component (**2a**) δ 0.83 (s, 9H), 1.18 (s, 9H), 1.38 (s, 9H), 5.87 (d, J=2 Hz, 1H), and 6.39 (d, J=2 Hz, 1H); the minor component (**2b**): 1.31 (s, 18H), 1.34 (s, 9H), 7.34 (s, 2H); λ_{max}^{hexane} (ε): 240 sh (4720), 268 (2610), 292 (2580), 340 (2050), 410 nm (3480), and 535 sh (very weak); *m/e* 323 (M^+, trace), 291 (4.4%), 266 (72), 251 (49), 244 (100), and 236 (49): mol wt (vapor pressure osmometry in benzene, 39.4 °C); 322.9 (Calcd: 323.55).

Found: C, 66.64; H, 8.96; N, 4.08; S, 19.72%. Calcd for $C_{18}H_{29}NS_2$: C, 66.84; H, 9.04; N, 4.33; S, 19.79%.

The third fraction gave 10 mg of orange crystals, which were identified as *N,N'*-bis(2,4,6-tri-*t*-butylphenyl)sulfur diimide (**14**)[8] by the IR spectrum and TLC. From the last fraction aniline (**1**) (52 mg, 10.4%) was recovered.

Reaction of 2,4-Di-t-butyl-6-methylaniline (3) with S_2Cl_2. A solution of S_2Cl_2 (624 mg, 4.62 mmol) in ether (4.2 ml) was added dropwise to a solution of **3**[7] (993 mg, 4.52 mmol) and triethylamine (839 mg, 8.3 mmol) in ether (40 ml) with stirring at 0 °C. After being stirred for 1 h, the reaction mixture was poured into water, and the organic layer was dried ($MgSO_4$). Removal of the solvent gave a dark purple tar, which was subjected to chromatographic separation (silica gel, hexane). The first fraction gave 27 mg of sulfur. The second purple fraction gave 1.021 g (80.1%) of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**4**) as a dark purple tar, which crystallized on standing (mp 53—54 °C). Repetitive recrystallizations from aq methanol afforded analytically pure specimen, mp 67—68 °C; IR (KBr): 2950, 1590, 1455, 1360, 1222, 1169, 995, 940, 870, 780, 760, 690, 650, and 620 cm^{-1}; NMR (CCl_4): δ 1.33 (s, 18H), 2.02 (s, 3H), and 7.22 (ABq, $\Delta\delta$=0.22, J=2 Hz, 2H); λ_{max}^{hexane} (ε): 270 sh (1270), 310 (1940), 343 (5590), 476 (2190), and 536 sh nm (1190); *m/e*: 281 (M^+, 0.5%), 266 (20), 224 (100), 217 (18), 209 (18), and 204 (20); mol wt (vapor pressure osmometry in benzene at 39.4 °C): 295. Found: C, 64.01; H, 8.46; N, 5.10; S, 22.97%. Calcd for $C_{15}H_{23}NS_2$: C, 64.01; H, 8.24; N, 4.98; S, 22.78%.

The third fraction gave 86 mg of orange tar, which was treated with preparative TLC (silica gel, benzene) to give 28 mg (2.6%) of *N,N'*-bis(2,4-di-*t*-butyl-6-methylphenyl)-sulfur diimide (**13**), which was identified by comparison of the NMR, IR, and mass spectra with those of an authentic sample obtained by photolysis of **4**.[9] The fourth fraction gave 49 mg (4.9%) of **3**.

This reaction was performed in a larger scale using 20 g of **3**, where conventional column chromatography was used to separate **4** from the reaction mixture for the purpose of preparative convenience. Hexane could also be used as reaction solvent instead of ether.

Reaction of 2,4-Di-t-butyl-6-isopropylaniline (7) with S_2Cl_2. To an ice-cold solution of **7**[10] (517 mg, 2.09 mmol) and triethylamine (460 mg, 4.55 mmol) in ether (30 ml), a solution of S_2Cl_2 (294 mg, 2.18 mmol) in ether (10 ml) was added dropwise with stirring. After additional stirring for 45 min at 0 °C and then usual work up, the resulting residue was chromatographed (silica gel, pentane). A red purple part of the column was eluted with pentane to give a red purple solution, which was used for measurement of an electronic spectrum. Removal of the solvent gave 93 mg (14.4%) of 2,4-di-*t*-butyl-6-isopropyl-*N*-thiosulfinylaniline (**8**) as a purple oil. IR (neat): 1595, 1360, 1128, and 1000 cm^{-1}; NMR (CCl_4): δ 1.12 (d, J=6.5 Hz, 6H), 1.34 (s, 9H), 1.36 (s, 9H), 2.58 (sep, J=6.5 Hz, 1H), and 7.27 (ABq, $\Delta\delta$=0.13, J=2 Hz); $\lambda_{max}^{pentane}$ (ε): 272 sh (2060), 305 sh (2330), 343 (6960), 483 (1810), and 542 sh nm (1130).

Reaction of 2,4,6-Trimethylaniline (9) with S_2Cl_2. To a solution of **9** (998 mg, 7.38 mmol) and triethylamine (1.495 g, 14.8 mmol) in ether (50 ml), a solution of S_2Cl_2 (1.247 g, 9.24 mmol) in ether (30 ml) was added dropwise with stirring at −78 °C. After additional stirring for 40 min at −78 °C, an insoluble part was filtered off at −78 °C. The red-purple filtrate was condensed under reduced pressure at −10 °C. The residue was chromatographed (silica gel, pentane) at −2 °C. A red-purple fraction which contained 2,4,6-trimethyl-*N*-thiosulfinylaniline (**10**) was eluted with pentane at −2 °C to give a red solution (100 ml), which was immediately used for measurement of an electronic spectrum. The concentration of the solution was determined to be 0.3 g/l on the basis of the weight of the residue from a 5 ml-portion of the eluted solution. Thus the yield of **10** was 30 mg (2%). Removal of the solvent at −10 °C afforded a red purple oil, which was immediately subjected to NMR measurement in carbon tetrachloride. **10**; NMR (CCl_4, at 0 °C): δ 2.01 (s, 6H), 2.31 (s, 3H), and 6.90 (s, 2H); $\lambda_{max}^{pentane}$ (ε): 336 (5700), 462 (1900), and 540 sh nm (870).

The pentane solution of **10** obtained as above was decolorized by none of the following reagents suggesting no reaction: dimethyl acetylenedicarboxylate, *N*-phenylmaleimide, cyclohexene, or norbornadiene.

Reaction of 2,5-Di-t-butylaniline (11) with S_2Cl_2. A solution of S_2Cl_2 (1.001 g, 7.49 mmol) in ether (10 ml) was added to a solution of **11**[12] (996 mg, 4.85 mmol) and triethylamine (1.59 g, 15.7 mmol) in ether (50 ml) dropwise with stirring at 0 °C. After stirring for 1 h and usual work-up, the residue was chromatographed on silica gel with hexane. The first effluent (50 ml) gave 35 mg of sulfur. A red fraction gave 749 mg (70.4%) of *N,N'*-bis(2,5-di-*t*-butylphenyl)sulfur diimide (**12**) as a red tarry material, which was purified by TLC (silica gel, hexane) to give vermilion crystals, which were recrystallized three times from acetone; mp 86—87 °C; IR (KBr): 2960, 1475, 1385, 1355, 1280, 1095, and 822 cm^{-1}; NMR (CCl_4): δ 0.87 (s, 18H), 1.46 (s, 18H), 6.36 (d, J= 2 Hz, 2H), 6.89 (dd, J=8 and 2 Hz, 2H), and 7.16 (d, J= 8 Hz, 2H); λ_{max}^{hexane} (ε): 241.5 nm (14300), 252 sh (12900), 392 (9350); *m/e*: 438 (M^+, 13.7%), 381 (21), 203 (100), 188 (32), 146 (30), and 132 (39). Found: C, 76.96; H, 9.86; N, 6.38; S, 7.38%. Calcd for $C_{28}H_{42}N_2S$: C, 76.66; H, 9.65; N, 6.38; S, 7.31%. Aniline **11** (104 mg, 10.4%) was also recovered.

Reaction of 2,4-Di-t-butyl-6-methylaniline (3) with Sulfur Dichloride. To an ice-cold solution of **3** (908 mg, 4.14 mmol) and triethylamine (1.041 g, 10.31 mmol) in ether (40 ml), a solution of SCl_2 (432 mg, 4.19 mmol) in ether (10 ml) was added dropwise with stirring. After additional stirring for 1.5 h and usual work-up, the residue was chromatographed on silica gel with hexane. A red purple fraction gave 197 mg (16.9%) of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**4**) as dark purple crystals (identified by IR and NMR). An orange fraction gave 484 mg (50.1%) of *N,N'*-bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide (**13**) as orange crystals (identified by IR and NMR).[8] From the subsequent fraction 239 mg (26.3%) of **3** was recovered.

Reaction of 2,4,6-Tri-t-butylaniline (1) with SCl_2. To an ice-cold solution of **1** (1.605 g, 6.15 mmol) and triethylamine (1.26 g, 12.5 mmol) in ether (40 ml), a solution of SCl_2 (640 mg, 6.21 mmol) in ether (10 ml) was added dropwise with stirring, and the mixture was stirred for 1.25 h at 0 °C. After usual work-up, the residue was chromatographed on silica gel with hexane. The first fraction gave 471 mg (23.7%) of **2**. The second fraction was rechromatographed (silica gel, hexane) to give 213 mg (12.6%) of *N,N'*-bis(2,4,6-tri-*t*-butylphenyl)sulfur diimide (**14**) and 224 mg (11.9%) of

2,4,6-tri-*t*-butyl-*N*-sulfinylaniline. From the third fraction, 722.4 mg (45%) of **1** was recovered.

14; mp 202.5—203.5 °C; IR (KBr): 2960, 1590, 1470, 1405, 1385, 1360, 1265, 1235, 1130, 875, and 770 cm^{-1}; NMR (CCl_4): δ 1.31 (s, 18H), 1.38 (s, 36H), and 7.26 (s, 4H); λ_{max}^{hexane} (ε): 332 (7650) and 414 nm (4960); *m/e* 550 (M^+, 3.8%), 291 (100), 259 (58), and 244 (48).

Found: C, 78.45; H, 10.37; N, 4.80; S, 6.04%. Calcd for $C_{36}H_{58}N_2S$: C, 78.49; H, 10.61; N, 5.08; S, 5.82%.

*Preparation of 2,4-Di-*t*-butyl-6-methyl-*N*-sulfinylaniline (**16**).* To an ice-cold solution of 2,4-di-*t*-butyl-6-methylaniline (**3**) (5.01 g, 22.9 mmol) and triethylamine (5.08 g, 50.3 mmol) in hexane (250 ml), a solution of thionyl chloride (2.97 g, 25 mmol) in hexane (50 ml) was added dropwise with stirring. After additional stirring for 70 min, the reaction mixture was washed with water, and dried ($MgSO_4$). Removal of the solvent afforded orange crystals, which were recrystallized once from aq. methanol to give 4.39 g (72.3%) of **16** (mp 54—55.5 °C), which was recrystallized three times from aq. methanol for an analytical specimen; mp 55.5—56.5 °C; IR (KBr): 1272 and 1182 cm^{-1} (NSO); NMR (CCl_4): δ 1.31 (s, 9H), 1.43 (s, 9H), 2.25 (s, 3H), and 7.20 (ABq, $\Delta\delta$= 0.13, J=2 Hz, 2H); λ_{max}^{hexane} (ε): 226 (10100), 255 (5390), 282 sh (2700), and 392 nm (2590); *m/e* 265 (M^+, 23%), 250 (77), 209 (42), 208 (81), 202 (32), and 57 (100). Found: C, 67.92; H, 8.92; N, 5.52; S, 11.95%. Calcd for $C_{15}H_{23}NOS$: C, 67.88; H, 8.73; N, 5.28; S, 12.08%.

*Preparation of 2,4,6-Tri-*t*-butyl-*N*-sulfinylaniline (**15**).* To an ice-cold solution of 2,4,6-tri-*t*-butylaniline (5.33 g, 20.4 mmol) and triethylamine (5.04 g, 49.9 mmol) in hexane (170 ml), a solution of thionyl chloride (2.70 g, 22.7 mmol) in hexane (30 ml) was added dropwise with stirring. After additional stirring for 40 min at 0 °C, usual work-up afforded 6.13 g (97.7%) of 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**15**), which was recrystallized once from aq ethanol to give 5.21 g (83.0%) of **15** as orange crystals: mp 120.5—122 °C; IR (KBr): 1295 and 1180 cm^{-1} (NSO); NMR (CCl_4) δ 1.27 (s, 9H), 1.38 (s, 18H), and 7.28 (s, 2H); λ_{max}^{hexane} (ε): 230.5 (12400) and 410 nm (350); *m/e*: 307 (M^+, 13%), 292 (65), 251 (100), and 245 (90). Found: C, 70.61; H, 9.61; N, 4.86; S, 10.53%. Calcd for $C_{18}H_{29}NOS$: C 70.31; H, 9.51; N, 4.56; S, 10.43%.

Chemistry of *N*-Thiosulfinylanilines. II.[1] Thermolysis and Photolysis of *N*-Thiosulfinylanilines

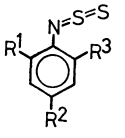
Yoshio INAGAKI, Renji OKAZAKI, and Naoki INAMOTO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

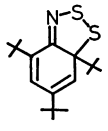
(Received November 7, 1978)

Thermolysis of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**1**) in refluxing benzene afforded 2,4-di-*t*-butyl-8-thia-9-azabicyclo[4.3.0]nona-2,4,6,9-tetraene (**6**) and 2,4-di-*t*-butyl-6-methylaniline (**7**), while its photolysis resulted in the formation of *N*,*N*′-bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide (**17**) and **7**. The mechanism of the thermolysis involving 1,5-hydrogen migration and *o*-quinonoid intermediate has been proposed. The electronic spectrum of the initial intermediate in the photolysis was obtained in EPA matrix and tentatively assigned to a dithionitro compound (**42**) or a dithiaziridine (**41**). Thermolysis of 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene (**4b**) equilibrated with 2,4,6-tri-*t*-butyl-*N*-thiosulfinylaniline (**4a**) gave 4,6-di-*t*-butyl-3*H*-1,2,3-benzodithiazole 2-oxide (**26**) and 2,4,6-tri-*t*-butylaniline (**27**). The reaction in the presence of a catalytic amount of *p*-toluenesulfonic acid improved the yield of both **26** and **27**, suggesting the ionic decomposition pathway. However, an ESR signal was observed during the thermal decomposition of **4** in the absence of oxygen, implying a concurrent homolytic pathway if not a major one. The mechanism of these reactions are briefly discussed. The photolysis of **4** led to **27** and *N*,*N*′-bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide (**43**).

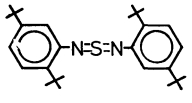
In a previous paper,[1] we described the preparation of sterically hindered *N*-thiosulfinylanilines (**1**—**4**) by the reactions of the corresponding anilines with disulfur dichloride. Of these, **1** is a stable crystalline compound, while **2** and **3** are unstable at ambient temperature.



1 $R^1=R^2=t$-Bu, R^3=Me
2 $R^1=R^2=t$-Bu, $R^3=i$-Pr
3 $R^1=R^2=R^3$=Me
4a $R^1=R^2=R^3=t$-Bu



4b



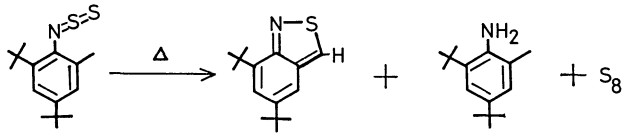
5

Furthermore, **4a** exists as a cyclized form (**4b**) in the solid state and an equilibrium between **4a** and **4b** is established in solution. In the case of 2,5-di-*t*-butylaniline, the product was not the *N*-thiosulfinylaniline but the sulfur diimide (**5**).

We disclose in this paper the thermal and photochemical behaviors of **1** and **4** and discuss the factors influencing the thermal stabilities of these *N*-thiosulfinylanilines.[2]

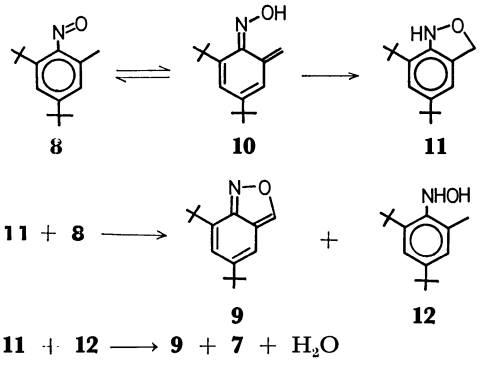
Results and Discussion

Thermolysis of N-*Thiosulfinylaniline (1).* Heating **1** in refluxing benzene for 21 h gave 2,1-benzisothiazole (**6**) (32%), the corresponding aniline (**7**) (26%), and sulfur. When the reaction was conducted in toluene at 70 °C (28 h), the yields of **6** and **7** were 40% and 46%, respectively.



1 **6** **7**

During the reaction a trace of hydrogen sulfide was detected (as PbS). This reaction is reminiscent of the thermolysis of 2,4-di-*t*-butyl-6-methylnitrosobenzene (**8**) leading to **9** and **7**,[3] which was found by us to proceed as shown in Scheme 1.[4]



8 **10** **11**

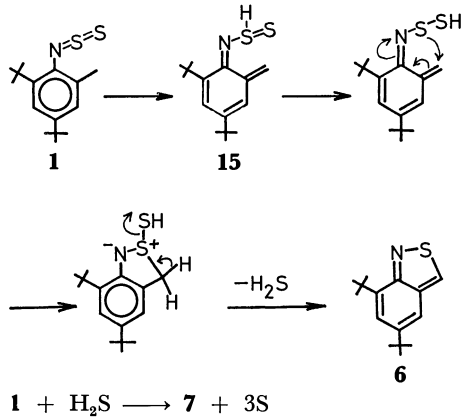
11 + **8** → **9** + **12**

11 + **12** → **9** + **7** + H_2O

Scheme 1.

Furthermore, 2,4-di-*t*-butyl-6-ethyl- (**13**) and 2,4-di-*t*-butyl-6-isopropylnitrosobenzenes (**14**) have been found to be less stable than **8** to decompose even at 0—5 °C;[4] this order of stability is consistent with the above scheme in which the decomposition starts with 1,5-hydrogen shift, for the initially formed *o*-quinone imine (**10**) is thought to be more stable for **13** or **14** than for **8**.

Considering the similar order of stability observed in the case of *N*-thiosulfinylanilines (*i.e.*, **2** is less stable than **1**), the following mechanism (Scheme 2) starting with 1,5-hydrogen shift seems to be the most probable pathway also here.

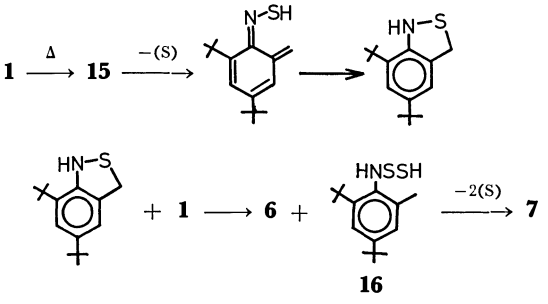


1 **15** **6**

1 + H_2S → **7** + 3S

Scheme 2.

The last step (reduction of **1** with hydrogen sulfide) was confirmed by a separate experiment.

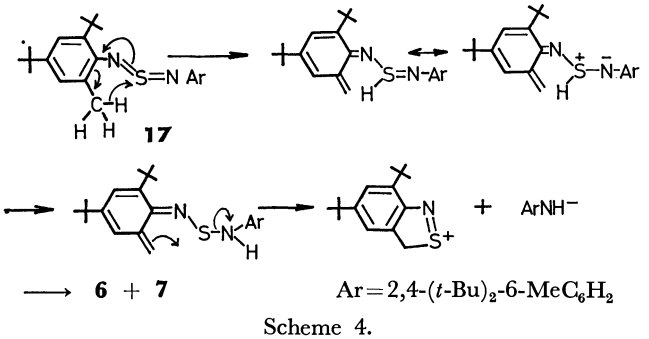


Scheme 3.

The following alternative pathway (Scheme 3) involving the thiooxime is also possible; extrusion of sulfur from such types of compounds as **15** and **16** are known.[5] However, there is no experimental evidence so far to distinguish these two mechanisms. Whichever mechanism is operative, these pathways starting with 1,5-hydrogen shift explain the instability of *N*-thiosulfinylanilines with ortho benzylic hydrogens.

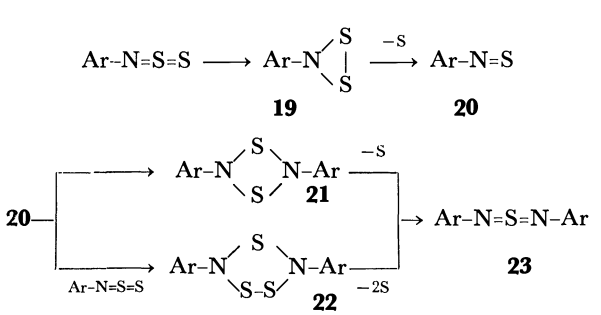
Such a 1,5-hydrogen shift involving ortho benzylic hydrogens seems a general type of reaction; sulfur diimide (**17**) obtained by the photolysis of **1** (*vide infra*) cleanly disproportionated (refluxing benzene, 3 h) to yield **6** (94%) and **7** (91%). Essentially the same results were obtained also in refluxing methanol, the yields of **6** and **7** being 97 and 87% respectively.

This new mode of reaction of sulfur diimide presumably proceeds also *via* 1,5-hydrogen shift from methyl group to sulfur atom followed by prototropy and cyclization as depicted in Scheme 4.

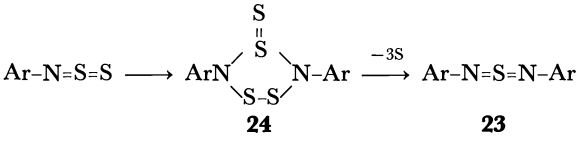


Scheme 4.

In connection with the thermal behavior of **1**, it is an interesting problem why the reaction product of 2,5-di-*t*-butylaniline with disulfur dichloride is sulfur diimide (**5**) instead of the *N*-thiosulfinylaniline **18** which would be no doubt the initial product. There are two conceivable routes leading to **5**. The one (Scheme 5) proceeds *via* three-membered ring isomer (**19**), which loses a sulfur atom to give thionitroso compound (**20**), followed by dimerization to give **21** or by cycloaddition to thiosulfinylamino group to give **22**. Subsequent extrusion of sulfur from **21** or **22** would lead to sulfur diimide (**23**). Another route consists of dimerization of the *N*-thiosulfinylaniline followed by extrusion of sulfur (Scheme 6).

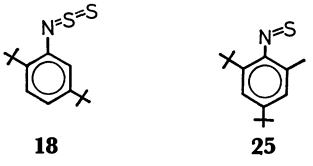


Scheme 5.



Scheme 6.

Cyclization to three-membered ring followed by extrusion of a sulfur atom has been commonly observed for other thiocumulenes: thiocarbonyl ylides give olefins,[6] thiocarbonylimines give imines,[7] a sulfine gives a ketone,[8] and *N,N'*-diphenylsulfur diimide gives azobenzene.[9] Cyclic sulfur imides such as **21** or **22** with six or less than six-membered ring appear to be unstable.[10] Bulky groups around the thiosulfinylamino group may hinder the formation of three-membered ring isomer (**19**) as well as dimerization to **24**. These considerations can thus explain the instability of **18** compared to **1**—**4**.



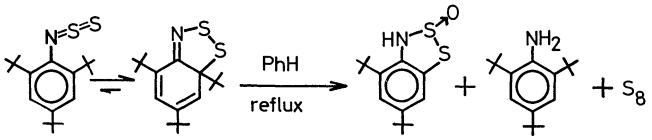
Thermolysis of **1** into **6** and **7** may be rationalized also in terms of an intermediacy of (thionitroso)benzene (**25**), which would give **6** and **7** quite similarly to the case of nitrosobenzene **8** (Scheme 1). A mercaptoamine, thio analog of **12**, is known to lose the sulfur atom to give the corresponding amine.[5a] Alternatively, formation of the sulfur diimide **17** followed by its disproportionation is also a possible route giving **6** and **7**. However, these two pathways involving the formation of **25** cannot explain the fact that 6-isopropyl derivative **2** is less stable than 6-methyl derivative **1**.

Taken together, we consider that *N*-thiosulfinylanilines decompose *via* pathways starting with 1,5-hydrogen shift if steric protection of a thiosulfinylamino group is sufficient and benzylic hydrogens are present in the ortho substituent. In the case where steric protection is insufficient, the *N*-thiosulfinylanilines would undergo decomposition into the thionitroso intermediate (**20**) *via* cyclization into the dithiaziridine (**19**) to give the sulfur diimide as the final product.

Thermolysis of N-*Thiosulfinylaniline (**4a**) Equilibrated with 1,2,3-Dithiazole (**4b**).* The above argument suggests that an *N*-thiosulfinylaniline with enough steric protection and with no ortho benzylic hydrogen would enjoy considerable thermal stability. Thus, we have examined the thermolysis of **4a** which not only

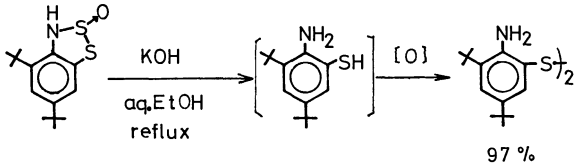
meets these requirements, but also is in equilibrium with **4b** with the latter as a major component.[1)]

Thermolysis of **4** in refluxing benzene under nitrogen for 9.7 h gave **26** (20.6%), **27** (34.2%), and sulfur (27%).

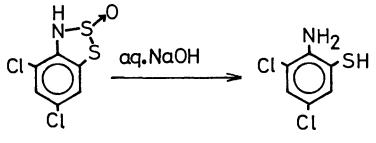


4a **4b** **26** **27**

The structure of **26** was determined by the elemental analysis, the spectral data, and the following chemical behavior. Alkaline hydrolysis of **26** followed by chromatography gave the disulfide (**28**), suggesting the 2-oxide structure of **26**; a similar hydrolysis of **30** into **31** has been reported.[11)] In the present case, **29**, a primary product, is thought to be oxidized into **28** during the work-up procedure.

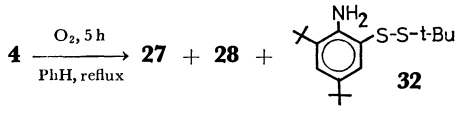


26 **29** **28**



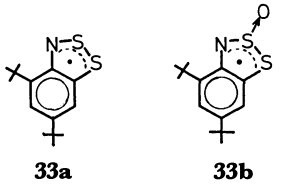
30 **31**

Thermolysis of **4** in the presence of a catalytic amount of *p*-toluenesulfonic acid improved the yield of **26** and **27** up to 39.0 and 56.1%, respectively, with 71% conversion. However, thermolysis of **4** under a stream of oxygen gave a complex reaction mixture, from which **27** (11.5%), **28** (12.2%), and **32** (9.5%) were isolated but no **26** was obtained.



32

Thermolysis of **4** in degassed benzene at 110 °C for 5 min afforded a persistent ESR signal (a_N=8.2 G, g=2.008) as shown in Fig. 1. This signal was considered to be due to a nitrogen-centered radical **33a**, although alternative structure **33b** cannot rigorously be excluded. In any case, the large g-value (2.008) suggests that an unpaired electron is delocalized on two sulfur atoms as in the case of **34**,[12)] for which a large g-value (2.0082) was reported.



33a **33b**

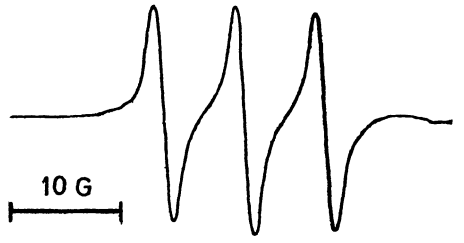


Fig. 1. An ESR spectrum of **33a**.

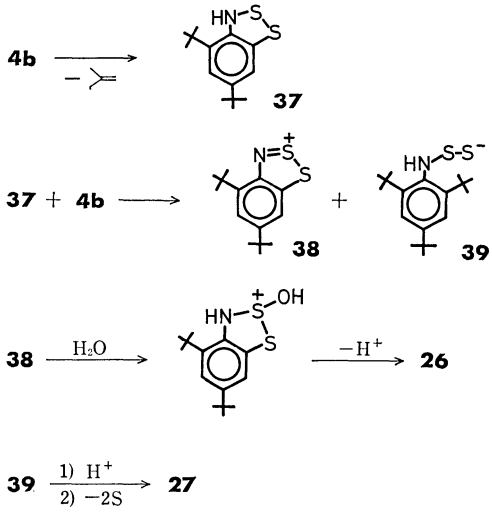
Table 1. ESR data of some nitrogen centered radicals

Radical	a_N (G)	g
33a	8.2	2.008
Ph-S-Ṅ-S-Ph (**34**)	11.41	2.0082
Ph-Ṅ-S-Ph (**35**)	9.59	2.0059
Ph-S-Ṅ-*t*-Bu (**36**)	11.70	2.0069

Ph-S-Ṅ-S-Ph
34

The hyperfine splitting constant (hfsc) due to a nitrogen nucleus of **33a** (8.2 G) is smaller than those of **34**,[12)] **35**,[13)] and **36**[14)] (see Table 1) suggesting the extensive delocalization of an unpaired electron into the aromatic ring and two sulfur atoms due to the planarity of the molecule.

Although the mechanism to form **26** and **27** is obscure, the following pathway shown in Scheme 7 is conceivable. Elimination of 2-methylpropene from **4b** by retro-ene reaction gives **37**, which reduces **4b** to give **38** and **39**. Then **39** may be unstable and loses the sulfur atoms to give **27** on protonation, while **38** reacts with moisture in a solvent to give **26** on deprotonation.



Scheme 7.

The fact that yields of **26** and **27** increased in the presence of a small amount of the acid is consistent with the above scheme, since formation of **37** appears to be catalyzed by acid.

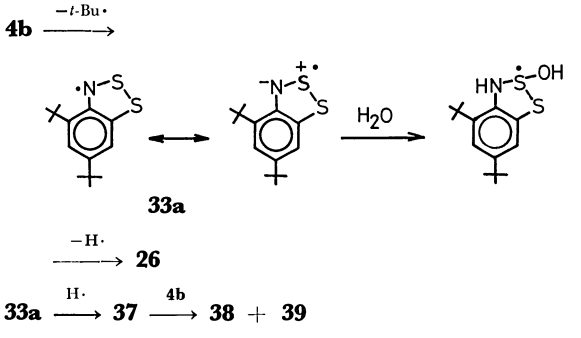
The following free radical mechanism (Scheme 8) is also conceivable, in view of the observation of an ESR

Table 2. Yields of the photolysis products of **1**

Solvent	Concentration (g/l)	Irradiation time (h)	Isolated yields (%) **17**	**7**	S_8
Pentane	4.7	35.3[a)]	70.9	26.5	16.0
Pentane	0.7	9[b)]	42.4	17.1	11.2
Benzene	4.8	30[a)]	34.7	25.3	23.4
2-Propanol	4.7	32[a)]	36.8	28.5	19.8

a) 100 W lamp. b) 400 W lamp.

signal of what is believed to be **33a** although its importance is probably minor. The fact that the presence of oxygen did not favor the formation of **26** suggests that oxygen atom in **26** did not come from atmospheric or dissolved oxygen molecule, but from moisture in the solvent.



Scheme 8.

Photolysis of N-*Thiosulfinylaniline* (**1**) *and Related Compounds.* Photolysis of organic thiocumulenes of type X=S=Y has not been reported except for that of thiobenzophenone *S*-oxide, whose products are benzophenone and sulfur.[15)]

Irradiation of **1** with Pyrex-filtered light from a medium pressure mercury lamp below 25 °C afforded the sulfur diimide (**17**), aniline (**7**), and sulfur. The yields and conditions are summarized in Table 2.

$$\underset{\mathbf{1}}{\text{Ar–N=S=S}} \xrightarrow{h\nu} \underset{\mathbf{7}}{\text{ArNH}_2} + \underset{\mathbf{17}}{\text{Ar–N=S=N–Ar}} + S_8$$

$$\text{Ar} = 2,4\text{-}(t\text{-Bu})_2\text{-}6\text{-MeC}_6\text{H}_2$$

Irradition of **1** in EPA matrix was carried out at 77 K, and the change in the electronic spectra was monitored intermittently. Recorded spectra are shown in Fig. 2. During irradiation, the intensity of absorption at 340 nm decreased, while a very intense band appeared at 473 nm; isosbestic points were observed at 300 and 355 nm suggesting the species showing an absorption at 473 nm arose directly from **1**. Molar extinction coefficient of this species was estimated to be *ca.* 15000 or more on the basis of the increase of the absorption at 473 nm and the decrease of the absorption at 340 nm. Since absorption due to the nitrene **40** would be around 400 nm or below with the molar extinction coefficient of a few hundreds,[16)] and sulfur atom or its oligomers have their absorption below 420 nm,[17)] neither of these is responsible for the absorption at 473 nm. Consequently, unlike the photolysis of azides, where a nitrene is formed by elimination of nitrogen molecule, simultaneous elimination of two sulfur atoms from thiosulfinylamino group to give a nitrene can be excluded. The absorption at 473 nm may be due to one of three species (**25**, **41**, and **42**), although we have no experimental evidence to determine which is correct. In view of the well

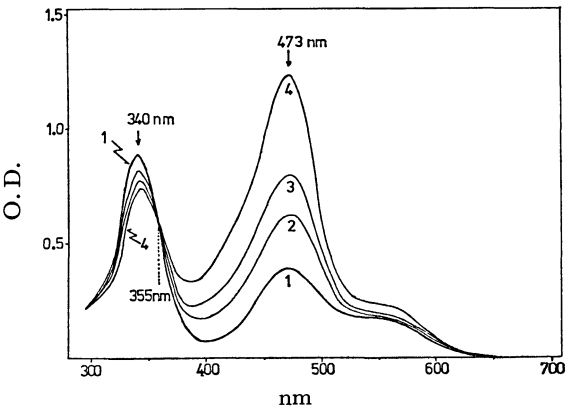


Fig. 2. Change in the electronic spectra of **1** during irradiation.

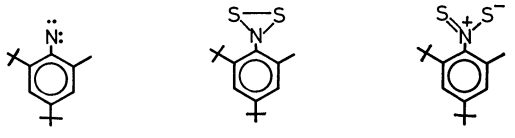

40 **41** **42**

known tendency of thiocumulenes to extrude sulfur *via* a three-membered ring in photolysis and thermolysis,[6–9,15,18)] it is reasonable to assume that **1** would change into **41** or **42** at first, then loses one sulfur to give **25**, which further reacts through pathways depicted in Scheme 5.

The aniline **7** is probably formed from photodecomposition of **17** because irradiation of **17** in pentane for 33 h gave 18.2% of **7** with recovery of **17** (68.3%). As shown in Table 3, the product ratio **7**/**17** decreases with increasing concentration. The reason for this concentration effect is not clear to us, but one explanation seems due to self quenching of **17**.

Table 3. Concentration effect of the photolysis of **1** in pentane

Concentration (g/l)	Irradiation time (h)	Molar ratio **7**/**17**
0.67	4	1.1
3.3	11.5	0.58
16.7	24.5	0.27

Photolysis of **4**. Irradiation of **4** in pentane afforded sulfur diimide (**43**) (7.5%) and aniline (**27**) (10.5%) together with some unidentified products. Since these products are very similar to those of the photoreaction of *N*-thiosulfinylaniline (**1**), the precursor of these products is considered to be the *N*-thiosulfinylaniline (**4a**).

$$\underset{\mathbf{4b}}{\overset{\mathbf{4a}}{\downarrow\uparrow}} \xrightarrow{h\nu} \underset{\mathbf{27}}{\text{Ar–NH}_2} + \underset{\mathbf{43}}{\text{Ar–N=S=N–Ar}}$$

$$\text{Ar} = 2,4,6\text{-}(t\text{-Bu})_3\text{C}_6\text{H}_2$$

Experimental

All melting points were uncorrected. The IR, UV, NMR, and mass spectra were taken with the same spectrometers as used in a previous paper.[1] ESR spectra were recorded with JEOL JES-ME spectrometer. Reactions were carried out under nitrogen unless otherwise stated.

*Thermolysis of 2,4-Di-t-butyl-6-methyl-N-thiosulfinylaniline (**1**).* *N*-Thiosulfinylaniline (**1**)[1] (404 mg, 1.44 mmol) was heated for 21 h in refluxing benzene (20 ml). Removal of the solvent followed by dry column chromatography (DCC) (silica gel, hexane) afforded 38 mg of sulfur in the first fraction. From the second fraction, 15 mg (3.7%) of **1** was recovered. The third fraction was rechromatographed (silica gel, CCl_4) to give 115 mg (32.3%) of 2,4-di-*t*-butyl-8,9-thiazabicyclo[4.3.0]nona-2,4,6,9-tetraene (**6**) which was identified by the IR, NMR, and mass spectra (mp 52—53.5 °C, recrystallized three times from methanol). Spectral and analytical data of this compound are listed in the description of thermolysis of *N,N'*-bis(2,4-di-*t*-butyl-6-methylphenyl)-sulfur diimide (**17**) (*vide infra*). The fourth fraction gave 81 mg (25.6%) of 2,4-di-*t*-butyl-6-methylaniline (**7**) which was identified by comparison of the IR and NMR spectra with those of the authentic sample.[19]

In a similar reaction, when nitrogen stream passed through the refluxing solution was led into aq lead(II) acetate, slight darkening of the solution was observed.

Heating of **1** (401 mg, 1.42 mmol) in toluene (10 ml) at 70 °C for 28 h gave 46.2% of **8**, 39.9% of **6**, and 50 mg of sulfur after a similar work-up.

*Thermolysis of N,N'-Bis(2,4-di-t-butyl-6-methylphenyl)sulfur Diimide (**17**).* Compound **17** (224 mg, 0.48 mmol) was heated for 3 h in refluxing benzene (15 ml). After removal of the solvent, the residue was chromatographed (silica gel, hexane). The first fraction gave 112 mg (94.3%) of **6** as white crystals (mp 49—52 °C), which were recrystallized three times from methanol at −78 °C to give colorless prisms, mp 52.5—53.0 °C; IR (KBr): 3080, 2900, 1358, 1245, and 745 cm^{-1}; NMR (CCl_4): δ 1.38 (s, 9H), 1.60 (s, 9H), 7.34 (ABq, J=2 Hz, $\Delta\delta$=0.14, 2H), and 8.92 (s, 1H); λ_{max}^{hexane} (ε): 232 (26900), 289.5 (8310), 300.5 (9960), and 324 nm (5230); *m/e*: 247 (M^+, 21.7%), 232 (100), 205 (12), 204 (16), 190 (15), 176 (19), 57 (16), and 41 (11). Found: C, 72.64; H, 8.64; N, 5.64; S, 12.88%. Calcd for $C_{15}H_{21}NS$: C, 72.82; H, 8.56; N, 5.66; S, 12.96%.

The second fraction gave 96 mg (91.2%) of **7**.

Thermolysis of **17** (319 mg, 0.683 mmol) in refluxing methanol (140 ml) followed by similar work-up afforded **6** (164 mg, 97.1%) and **7** (130 mg, 86.8%).

*Thermolysis of 2,4,6-Tri-t-butyl-7,8-dithia-9-azabicyclo[4.3.0]-nona-2,4,9-triene (**4b**).* Heating of **4b** (481 mg, 1.49 mmol) in refluxing benzene (25 ml) for 9.7 h gave orange solution. Removal of the solvent followed by treatment with hexane afforded 4,6-di-*t*-butyl-3*H*-1,2,3-benzodithiazole 2-oxide (**26**) as white crystals (41 mg). The filtrate was chromatographed (silica gel, hexane). The first fraction gave 15 mg of sulfur. The second fraction gave 24 mg of **4b**. The other fraction, on treatment with CCl_4 followed by filtration, gave 25 mg of **26** as white crystals, and the filtrate was chromatographed (silica gel, CCl_4). A slightly pale yellow fraction gave 133 mg (34.2%) of 2,4,6-tri-*t*-butylaniline (**27**) (identified by IR and NMR). The subsequent fraction gave 95 mg of yellow tar, which, on treatment with hexane, gave 21 mg of **26**. Thus, the total yield of **26** was 87 mg (20.6%); **26**: mp 160 °C (dec) (recrystallized four times from aq methanol); IR (KBr): 3280 (NH) and 1110 cm^{-1} (SO); NMR (CCl_4): δ 1.34 (s, 9H), 1.45 (s, 9H), 7.21 (ABq, J=1.2 Hz, $\Delta\delta$=0.12, 2H), and 7.50 (broad s); λ_{max}^{hexane} (ε): 284 sh (2130) and 294 sh nm (1560); *m/e*: 283 (M^+, 15%), 268 (23), 266 (100), 251 (39), 236 (15), 57 (21), and 41 (16); mol wt (vapor pressure osmometry, in benzene at 39.8 °C): 293.3 (calcd: 283.43). Found: C, 59.38; H, 7.69; N, 4.90; S, 22.21%. Calcd for $C_{14}H_{21}NOS_2$: C, 59.33; H, 7.47; N, 4.94; S, 22.62%.

*Thermolysis of **4b** in the Presence of p-Toluenesulfonic Acid.* A mixture of **4b** (303 mg, 0.94 mmol), *p*-toluenesulfonic acid (14 mg, 0.08 mmol), ethanol (2 ml), and benzene (20 ml) was refluxed for 3 h. Removal of the solvent followed by treatment with hexane afforded 73 mg (27.5%) of **26** as white crystals. The hexane-soluble part was chromatographed (silica gel, hexane) to give 89 mg (29.4% recovery) of **4b** and 97 mg (39.6%) of **27**.

*Thermolysis of **4b** under a Stream of Oxygen.* In refluxing benzene (20 ml), 302 mg (0.93 mmol) of **4b** was heated for 5 h under a stream of oxygen. After the solvent was removed, the residue was treated with hexane; no precipitates (**26**) were obtained. Chromatography (silica gel, CCl_4) of the residue afforded 29 mg (9.5%) of 2-amino-3,5-di-*t*-butylphenyl *t*-butyl disulfide (**32**) as a yellow tarry material, which was identified by the following spectral data: IR (neat): 3495 and 3360 cm^{-1} (NH_2); NMR (CCl_4): δ 1.27 (s, 9H), 1.35 (s, 9H), 1.43 (s, 9H), 4.45 (broad s, 2H), and 7.21 (ABq, J=2.4 Hz, $\Delta\delta$=0.08, 2H); *m/e* 325 (M^+, 2%), 293 (3), 269 (7), 254 (5), 237 (19), 236 (12), 222 (51), and 57 (100).

A crystalline material (176 mg) obtained from the second fraction was subjected to preparative TLC (silica gel, CCl_4) to give 28 mg (11.5%) of **27** and 27 mg (12.2%) of bis-(2-amino-3,5-di-*t*-butylphenyl) disulfide (**28**). These compounds were identified by comparison of the IR and NMR spectra with those of the authentic samples. Spectral and analytical data of **28** were listed in the description of hydrolysis of **26** (*vide infra*).

*Hydrolysis of 4,6-Di-t-butyl-3H-1,2,3-benzodithiole 2-Oxide (**26**).* A solution of **26** (57 mg, 0.2 mmol), potassium hydroxide (189 mg, 3.37 mmol), water (2 ml), and ethanol (7 ml) was refluxed for 2 h. The reaction mixture was neutralized by dil. HCl, and extracted with ether. The extract was washed with aq. sodium hydrogencarbonate, then with water, and dried ($MgSO_4$). After the solvent was removed, the residue was purified by preparative TLC (silica gel, CCl_4) to give 46 mg (97%) of **28** as pale yellow needles (mp 87.7—89.7 °C), which were recrystallized three times from methanol: IR (KBr): 3490 and 3370 cm^{-1} (NH_2); NMR (CCl_4): δ 1.19 (s, 18H), 1.40 (s, 18H), 4.45 (broad s, 4H), and 7.10 (ABq, $\Delta\delta$=0.08, J=2.5 Hz, 4H); *m/e*: 472 (M^+, 21%), 236 (100), 222 (48), 206 (10), 179 (10), 57 (36), and 41 (16). Found: C, 71.22; H, 9.59; N, 6.12; S, 13.67%. Calcd for $C_{28}H_{44}N_2S_2$: C, 71.13; H, 9.38; N, 5.93; S, 13.56%.

ESR Measurements. An ESR sample tube containing *ca.* 0.2 ml of benzene solution (0.05 M) was degassed by four freeze-pump-thaw cycles and heated for 5 min at 110 °C. After the sample solution was cooled to room temperature, the ESR spectra were recorded. Hyperfine splitting constants and *g*-values were determined on the base of Mn^{2+} in MnO_2.

*Photolysis of 2,4-Di-t-butyl-6-methyl-N-thiosulfinylaniline (**1**).* Typical procedures are described below. a) A pentane solution (70 ml) of **1** (329 mg, 1.17 mmol) was irradiated for 32.3 h with Pyrex-filtered light from a 100 W medium pressure mercury lamp immersed in the solution, whose temperature was controlled by external cooling with ice–water not to exceed 25 °C. After removal of the solvent, the residue was subjected to DCC (silica gel, hexane). The first fraction

gave 12 mg (16%) of sulfur. An orange fraction gave 193 mg (70.9%) of **17** as orange crystals, which were recrystallized four times from aq ethanol and once from acetone; mp 122—123 °C; IR (KBr): 2950, 1360, 1280, 1265, and 1238 cm^{-1}; NMR (CCl_4): δ 1.29 (s, 36H), 2.24 (s, 6H), 6.91 (d, J=2 Hz, 2H), and 7.17 (d, J=2 Hz, 2H); λ_{max}^{hexane} (ε): 317 (5530) and 409 nm (6560); *m/e* 466 (M^+, 0.5%), 451 (7), 247 (13), 232 (47), 219 (37), 204 (100), 57 (27), and 41 (23). Found: C, 77.05; H, 10.12; N, 5.86; S, 6.94%. Calcd for $C_{30}H_{46}N_2S$: C, 77.20; H, 9.93; N, 6.00; S, 6.87%.

The last fraction gave 83 mg of tarry metarial, which was purified by TLC (silica gel, benzene) to give 68 mg (26.5%) of 2,4-di-*t*-butyl-6-methylaniline (**7**).

b) Effect of Concentration. A solution of **1** in pentane (1.5 ml) was placed in a quartz tube, flashed with nitrogen, immersed in a water bath to keep the temperature of the solution below 20 °C, and irradiated with Pyrex-filtered light from a 400 W medium pressure mercury lamp. In this way, several solutions were irradiated at the same time. Determination of molar ratios (**7**/**17**) was performed by high speed liquid chromatography (1-m column packed with Hitachi 3010 gel, eluted with methanol). The results were shown in Table 3.

*Photolysis of **1** in EPA Matrix.* An EPA solution in a Pyrex cell was degassed by four freeze-pump-thaw cycles. This sample solution was immersed in liquid nitrogen in a Dewar vessel made of quartz which was placed in a Cary-14 spectrophotometer, and irradiated by focused light from a medium pressure mercury lamp through the Dewar vessel. Electronic spectra were recorded intermittently.

*N,N'-Bis(2,4-di-t-butyl-6-methylphenyl)sulfur Diimide (**17**).* A pentane solution (70 ml) of **17** (187 mg, 0.40 mmol) was irradiated for 33 h with a 100 W medium pressure mercury lamp immersed in the solution, whose temperature was controlled not to exceed 15 °C. The irradiated solution was examined by high speed liquid chromatography (column material: Hitachi 3010; column length: 1 m; column pressure: 45 kg/cm^2; flow rate: 1.2 ml/min; solvent: methanol) and found to show three peaks: corresponding to **7**, an unknown compound which did not correspond to **6**, and **17**. Molar ratio **7**/**17** was estimated to be 0.215. The reaction mixture was subjected to preparative TLC (silica gel, hexane, developed three times) to give 128 mg (68.3% recovery) of **17** and 28 mg of brown tarry material, which was purified by TLC (silica gel, benzene) to give 16 mg (18.2%) of **7**.

*Photolysis of **4b**.* A pentane solution (70 ml) of **4b** (402 mg, 1.24 mmol) was irradiated by Pyrex-filtered light from a 100 W medium pressure mercury lamp for 32.8 h. Temperature of the solution was controlled not to exceed 20 °C by cooling with ice-water. After removal of the solvent, the residue which was composed of many components was subjected to DCC (silica gel, hexane). From an orange fraction was obtained 38 mg of orange crystalline material, which was recrystallized from acetone to give 26 mg (7.5%) of *N,N'*-bis(2,4,6-tri-*t*-butylphenyl)sulfur diimide (**43**) (identified by comparison of the spectral data with those of an authentic sample).[1] From a pale yellow fraction, 35 mg (10.6%) of aniline (**27**) was obtained.

Chemistry of *N*-Thiosulfinylanilines. III. Thiosulfinylamine—5*H*-1,2,3-Dithiazole Equilibrium as Studied by NMR Spectroscopy

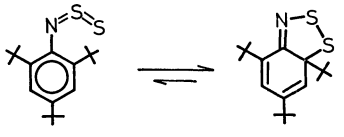
Yoshio INAGAKI, Renji OKAZAKI, Naoki INAMOTO,* Koh-ichi YAMADA,† and Hiroshi KAWAZURA†

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113,
† *Faculty of Pharmaceutical Sciences, Josai University, Keyaki-dai, Sakado, Saitama 350-02*

(Received November 7, 1978)

Thermodynamic parameters ($\Delta H = -4.9$ kcal mol^{-1}, $\Delta S = -11.3$ cal mol^{-1} deg^{-1}) were determined for cyclization of 2,4,6-tri-*t*-butyl-*N*-thiosulfinylaniline (**1b**) (the minor component) into 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene (**1a**) (the major component) by means of NMR spectroscopy. Using these values, π-bond of thiosulfinylamino group (–N=S=S) was estimated to be weaker than that of sulfinylamino group (–N=S=O) by, at least, 25 kcal mol^{-1}. The equilibrium ratio [**1a**]/[**1b**] is subject to considerable solvent effect, polar solvents favoring the cyclic form (**1a**). Similarity of the thiosulfinylamine–dithiazole equilibrium to that of azidoimine–tetrazole has been pointed out.

In the previous papers,[1,2] we reported that 2,4,6-tri-*t*-butyl-*N*-thiosulfinylaniline (**1b**) is in equilibrium with a cyclized form, 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene (**1a**) in solution, while in the solid state only **1a** exists. This is, to our knowledge, the first example where aromaticity of the benzene ring is destroyed during intramolecular 1,3-dipolar cyclization, although many examples of such a ring-chain isomerization are known for azidoimine-tetrazole systems.[3] We became interested in factors influencing the equilibrium between **1b** and **1a** and this paper describes the thermodynamic properties and solvent effects of this equilibrium.



1b **1a**

Experimental

The NMR spectra were recorded with a JEOL C60-HL spectrometer (60 MHz) equipped with a variable temperature apparatus. 2,4,6-Tri-*t*-butyl-7,8-dithia-9-azabicyclo-[4.3.0]nona-2,4,9-triene (**1a**, mp 98.5—99.5 °C) was prepared as described previously.[2]

Results and Discussion

Temperature Effect. As interconversion between **1a** and **1b** was slow enough to show two sets of NMR signals due to the two tautomers (see Fig. 1), equilibrium constants were calculated based on NMR signal intensity of the two olefinic protons of **1a** and the two aromatic protons of **1b**. Table 1 shows the temperature dependence of the equilibrium constant and the free energy of isomerization measured in carbon tetrachloride solution (0.31 M) over a temperature range of 11—63 °C, where ΔG's correlate with temperatures linearly. Over the temperature range studied the major component was **1a** but the relative amount of **1b** increased with increasing temperature. Slight decomposition was observed above 60 °C. Based on the data in Table 1, the heat of isomerization (ΔH) and the entropy of isomerization (ΔS) were estimated to be -4.9 kcal mol^{-1} and -11.3 cal mol^{-1} deg^{-1}, respectively. These thermodynamic quantities bear a striking resemblance to those reported for the azidoimine–tetrazole equilibrium;[3] for instance, for the equilibrium between 2-azidopyrimidine (**2b**) and tetrazolo-

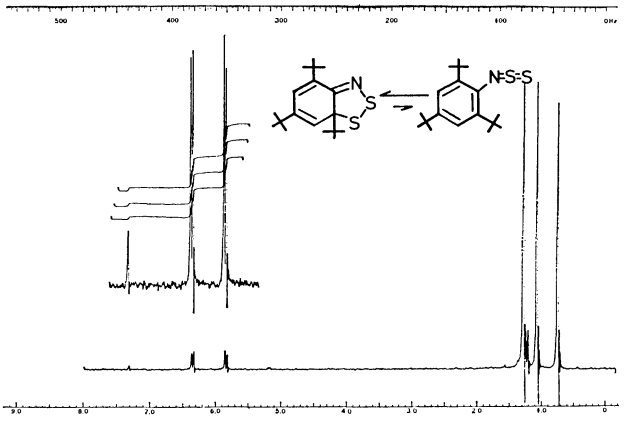


Fig. 1. NMR spectrum of an equilibribrium mixture **1a**+**1b** in CD_2Cl_2 (0.48 M) at 35 °C.

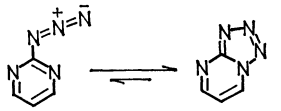
TABLE 1. TEMPERATURE DEPENDENCE OF K AND ΔG IN CCl_4

Temp (°C)	$K=\frac{[\mathbf{1a}]}{[\mathbf{1b}]}$	$-\Delta G$ (kcal mol^{-1})
11	19.5	1.68
23	14.1	1.56
30	12.0	1.50
33	10.7	1.44
38	9.9	1.42
43	9.2	1.39
48	8.2	1.34
52	6.6	1.22
58	5.7	1.14
63	5.1	1.09

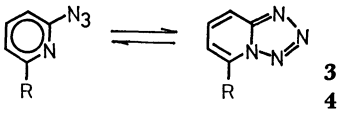
At lower temperatures (*e.g.*<0 °C), linear correlation between T and ΔG did not hold because the equilibrium was reached much slower.

[1,5-*a*]pyrimidine, ΔH and ΔS have been reported to be −5.1 kcal mol^{-1} and −11.3 cal mol^{-1} deg^{-1}, respectively, in dimethyl sulfoxide-d_6.[4]



2b **2a**

For equilibria **3b**⇌**3a** and **4b**⇌**4a**, ΔH's of −4.2 and −3.4 kcal mol^{-1} have been reported.[5]

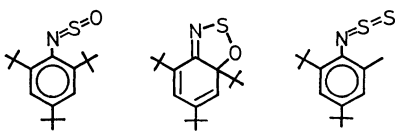


3 R=NO_2
4 R=Cl

3b, 4b **3a, 4a**

The similarity of these thermodynamic quantities, however, is somewhat surprising considering that the azidoimine–tetrazole reaction is a 6π-to-10π conversion without loss of aromaticity, at least in a formal sense, while the thiosulfinylamine–dithiazole reaction is accompanied by complete loss of aromaticity.

The exothermicity of this unusual ring formation of **1b** into **1a** may be attributable to both decreased aromaticity due to steric congestion by the three bulky groups ajacent to each other and high reactivity of the thiosulfinylamino group towards a double bond as demonstrated by 1,3-dipolar addition of *p*-dimethylamino-*N*-thiosulfinylaniline to olefins.[6] Since 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**5**)[2] was found to have no tendency to isomerize into its cyclic form **5a**, steric congestion alone is not sufficient for ring formation. But the lack of aromaticity due to the steric congestion is an essential factor for cyclization because in the case of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**6**) no evidence for the ring formation was obtained by NMR over a temperature range of −102—70 °C.



5 **5a** **6**

Difference between the π-bond energy of sulfinylamino group (–N=S=O) and that of thiosulfinylamino group (–N=S=S) can be roughly estimated using the thermodynamic data obtained above. Assuming that 1% (limit of detection) of 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**5**) exists in its cyclic form **5a**, the free energy of isomerization of **5** into **5a** (ΔG^{NSO}) is calculated to be 2.79 kcal mol^{-1} (endothermic) at 33 °C. On the other hand, free energy of isomerization of **1b** into **1a** (ΔG^{NSS}) was −1.44 kcal mol^{-1} (exothermic) at 33 °C. If we assume that entropy changes in both isomerizations are equal and that σ bond energies of the N–S, S–O, and S–S bonds do not change through isomerization, the following equation can be given,

$$\Delta\Delta G = \Delta G^{NSO} - \Delta G^{NSS} = \Delta H^{NSO} - \Delta H^{NSS}$$
$$= (\sigma^{CO} - \pi^{NSO}) - (\sigma^{CS} - \pi^{NSS})$$
$$= 4.23 \text{ kcal mol}^{-1},$$

Table 2. Solvent effect on K at 43 °C

Solvent	ε	$K=\frac{[\mathbf{1a}]}{[\mathbf{1b}]}$
Hexane	1.89	6.3
Cyclohexane	2.02	8.6
Carbon tetrachloride	2.23	9.2
Ethyl acetate	6.02	14.5
Dichloromethane-d_2	9.08	12.2
Acetone-d_6	20.7	17.7
Acetonitrile	37.5	25

where σ^{CO} is C–O single bond energy to be gained on cyclization of **5**, σ^{CS} is C–S single bond energy to be gained on cyclization of **1b**, π^{NSO} is π bond energy of –N=S=O group, and π^{NSS} is π bond energy of –N=S=S group to be lost on cyclization. Substitution of reported values −86 and −65 kcal mol^{-1}[7] for σ^{CO} and σ^{CS}, respectively, in the above equation gives $\pi^{NSS}-\pi^{NSO}=25$ kcal mol^{-1}. Thus π-bond of –N=S=S group is weaker than that of –N=S=O group by, at least, 25 kcal mol^{-1}.

Solvent Effect. Equilibrium constants at 43 °C in various solvents are shown in Table 2, where it is demonstrated that polar solvents greatly enhance the preference of cyclic isomer **1a**, suggesting that the dipole moment of **1a** is larger than that of the *N*-thiosulfinylaniline **1b**. Actually, the dipole moment of **1a** (*ca.* 2.9 D)[8a] is larger than that of **1b** which was reasonably assumed to be nearly equal to the dipole moment of **6** (1.51 D).[8b] Interestingly, quite a similar solvent effect has been reported for azido-tetrazole equilibria;[9] in less polar solvents, the equilibrium is shifted towards the side of an azido form, suggesting that the dipole moment of an azido form is smaller than that of a tetrazole form. This situation is in line with the fact that dipole moment of phenyl azide (1.56 D)[10] is smaller than that of 1,2,3-benzotriazole (4.10 D).[10]

(Received November 20, 1978)

The crystal structure of 3-amino-2-hydroxy-1-propanesulfonic acid was determined by MULTAN system with X-ray intensity data on a diffractometer and refined by the least-squares method to an *R*-value 0.087 for 1620 reflections. The crystals were orthorhombic, space group Pbca, $Z=8$, with $a=9.909$, $b=12.032$ and $c=10.251$ Å. The molecule takes the zwitterionic form, $H_3{}^+NCH_2CH(OH)CH_2SO_3{}^-$. The skeletal conformation of the molecule is planar trans zigzag. The molecules are held together by three-dimensional network of hydrogen bonds.

3-Amino-2-hydroxy-1-propanesulfonic acid acts to lower blood pressure[1] and is a hydroxy derivative of 3-amino-1-propanesulfonic acid, homotaurine, which has strong activity towards the behavior of neurones when applied extracellularly.[2]

It is of interest to investigate systematically the molecular structures of related compounds and elucidate the relationship between the molecular conformations and their physiological functions.

We previously reported the molecular and crystal structures of 3-guanidino-2-hydroxy-1-propanesulfonic acid[3] and 3-guanidino-1-propanesulfonic acid.[4]

In this paper, the authors describe the molecular and crystal structure of 3-amino-2-hydroxy-1-propanesulfonic acid.

Experimental

The compound was recrystallized from aqueous solution as colorless, transparent crystals.

Crystallographic Measurement. The space group was determined from rotation and Weissenberg photographs, and lattice constants were obtained from precise measurement on a diffractometer with Mo $K\alpha$ radiation. Density was measured by the flotation method in a mixture of 1,2-dibromoethane and carbon tetrachloride. The crystal data are listed in Table 1. Three-dimensional intensity data were collected on a computer controlled four-circle diffractometer (Rigaku Denki Co., Ltd.) with Zr-filtered Mo $K\alpha$ radiation. A total of 1749 independent reflections limited within $\sin\theta/\lambda=0.700$ Å^{-1} was scanned by ω-2θ technique at a scan speed of 2° per minute. All the reflections were recorded and corrected for usual Lorentz and polarization effects, no absorption correction being made.

Structure Determination and Refinement. The structure determination was done by MULTAN system.[5] As the average value of E^2 with h=even, k=odd and l=odd parity has significantly large one, we tried to rescale the E's so as the average E^2 value of each parity group to have unity, which revealed all the non-hydrogen atoms. Continuation of successive Fourier syntheses with overall isotropic temperature factor reduced the *R*-factor to 0.21.

Refinement was carried out for all reflections by the block-diagonal least-squares procedure with unit weight. The *R*-factor was reduced to 0.16 with isotropic temperature factors for all non-hydrogen atoms and decreased further with anisotropic temperature factors to 0.11. In this state, a difference Fourier synthesis revealed the locations of all the 9 hydrogen atoms. They were included in the final least-squares cycles with isotropic temperature factors. The final *R*-value was 0.087. The observed and calculated structure factors are listed in Table 2.**

Calculations were carried out on NEAC 2200-700 computer, Osaka University, and IBM 360, Seoul National University, Seoul, Korea. The atomic scattering factors were taken from the "International Tables for X-Rav Crystallography."[6]

Results and Discussion

The final atomic parameters are given in Tables 3 and 4, together with their estimated standard deviations. The difference Fourier map is shown in Fig. 1. As shown in Fig. 1, one hydrogen atom of sulfo group is transfered to the amino group. Thus, the molecule occurs in the zwitterionic form, $H_3{}^+NCH_2CH(OH)$-$CH_2SO_3{}^-$, as in the cases of related compounds.

Bond Distances and Angles. The interatomic distances and angles are listed in Table 5, together with their standard deviations, and those are acceptable as a whole. In the $-SO_3{}^-$ group, the average of three S–O distances, three O–S–O angles and three O–S–Cl

** Table 2 is kept as a Document at the Office of the Chemical Society of Japan (Document No. 7923).

a) Bifurcated hydrogen bond.

angles are 1.460 Å, 112.2° and 106.5°, respectively. These values are very similar to those of other compounds containing a sulfonato group. The C–H, N–H, and O–H distances are within the ranges 1.05—1.13 Å, 0.86—1.00 Å, and 0.99 Å, respectively. It is notable

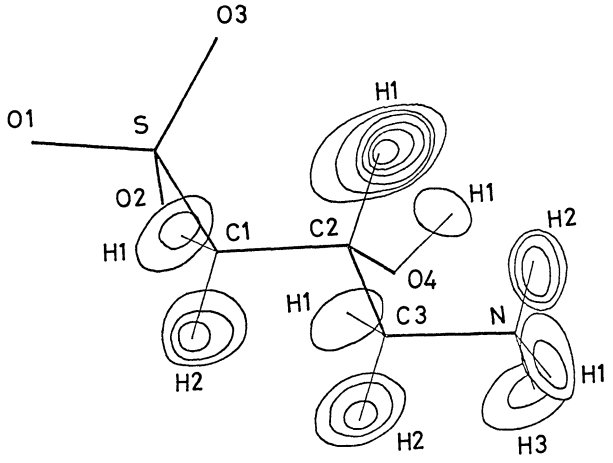

Fig. 1. Difference Fourier map of 3-amino-2-hydroxy-1-propanesulfonic acid. Contours are drawn at intervals of 0.2 e Å^{-3} starting with the contour of 0.4 e Å^{-3}.

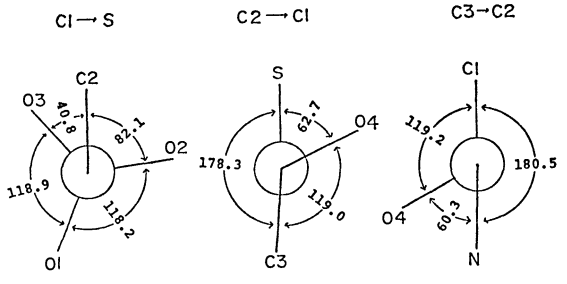

Fig. 2. Torsion angles around three bonds.

that C2–O4 distance of the hydroxyl group is 1.409 Å, slightly shorter than that found in 4-amino-3-hydroxybutyric acid[7] (1.425 Å) which is normal C–O single bond, and slightly longer than that of 3-guanidino-2-hydroxy-1-propanesulfonic acid (1.381 Å).

Conformation. The skeletal conformation of this molecule is trans-trans. The tortion angles around C1–C2 and C2–C3 are 178.3 and 180.5°, respectively. However, the corresponding values of 4-amino-2-hydroxybutyric acid and 3-guanidino-2-hydroxy-1-propanesulfonic acid, which contain β-hydroxyl group are 173.7 and 168.8°, 161.9 and 177.8°, respectively.

The torsion angles of sulfonato group are shown in Fig. 2. These values are significantly different from those of homotaurine,[8] 3-guanidino-1-propanesulfonic acid and 3-guanidino-2-hydroxy-1-propanesulfonic acid.

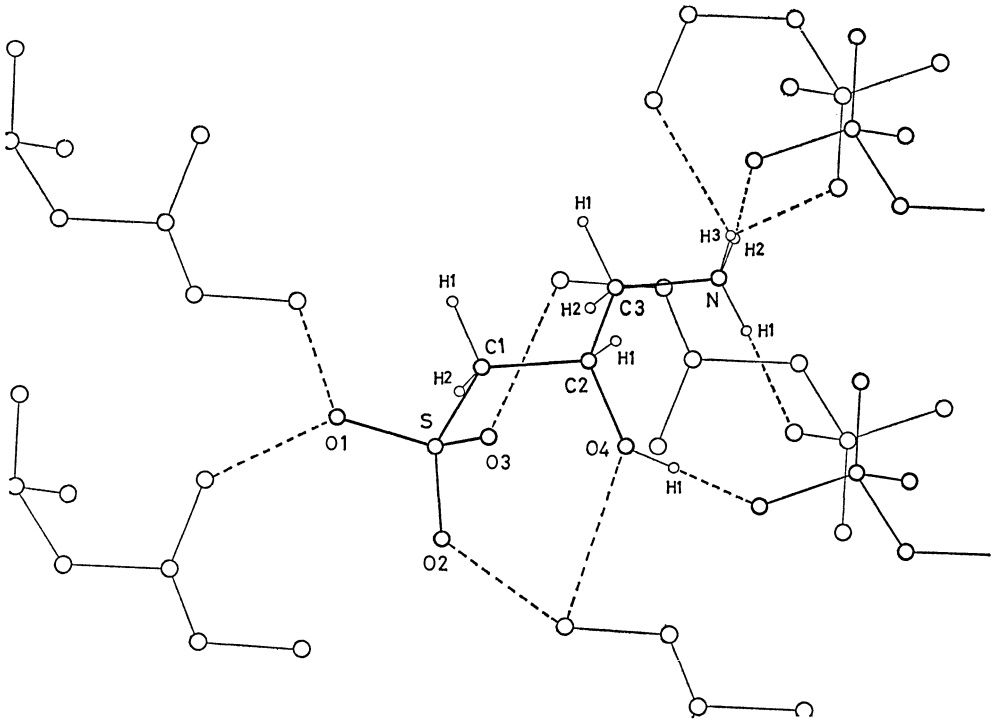

Fig. 3. Hydrogen bonds around original molecule.

Crystal Structure. Distances and angles of hydrogen bonds are listed in Table 6. All feasible hydrogen atoms in the molecule are utilized to form hydrogen bonds, in which one hydrogen atom (NH_3) on the amino group takes part in bifurcated hydrogen bond, and the molecules are held together by a three-dimensional network of NH···O and OH···O hydrogen bonds, as shown in Fig. 3.

The intermolecular contacts between adjacent molecules are in normal van der Waals distances.

This work was partly suported by a research grant from the Ministry of Education of Japan and also one of the authors, Y. B. Kim is a short-term research fellow at Osaka University sponsored by the Ministry of Education of Japan.

A New Synthesis of Arylacetic Esters Starting from Aromatic Aldehyde by the Use of Methyl (Methylthio)methyl Sulfoxide[1)]

Katsuyuki OGURA,*,† Yoko ITO, and Gen-ichi TSUCHIHASHI*

Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229

(Received January 12, 1979)

Methyl (methylthio)methyl sulfoxide was found to react with benzaldehyde in the presence of benzyltrimethylammonium hydroxide (Triton B), sodium hydroxide, or potassium hydroxide, affording 1-(methylsulfinyl)-1-(methylthio)-2-phenylethylene. Treatment of this product with hydrogen chloride in an alcohol gave the corresponding alkyl phenylacetate in high yield. The whole reaction sequence provides a new method for synthesizing phenylacetic esters starting from benzaldehyde. In a similar manner, (alkoxy-, halogen-, or alkyl-substituted phenyl)acetic esters could be synthesized from the corresponding aromatic aldehydes. The present method was shown to be also applicable to the production of (2-thienyl)acetic esters.

Methyl (methylthio)methyl sulfoxide (**1**) was first synthesized by substitution of chloromethyl methyl sulfoxide with methanethiolate anion[2)] and it was later disclosed that **1** could be more conveniently produced by oxidation of bis(methylthio)methane with hydrogen peroxide.[3)] To date, many papers on organic syntheses using **1** have been published and **1** has appeared to be a versatile reagent for making a variety of organic compounds, such as aldehydes,[4)] cyclic or acyclic ketones,[5)] α-hydroxy aldehydes,[6)] α-amino acids,[7)] and α-keto acids.[8)]

$$CH_2O + 2CH_3SH \xrightarrow{H^+} CH_2(SCH_3)_2 \xrightarrow{H_2O_2} CH_2(SCH_3)(SOCH_3)$$

1

Most of these synthetic methods involve the treatment of **1** with a strong base such as sodium hydride, potassium hydride, or butyllithium to form the carbanion which, then, is subjected to the reaction with various types of functional groups, followed by the acid-catalyzed hydrolysis, to give the product having a new functional group. For example, an aldehyde (**4**) or its acetal derivative (**5**) can be respectively synthesized by sequential treatment of **1** with sodium hydride in the coexistence of an alkyl halide (**2**) in tetrahydrofuran (THF) to form an alkylated product (**3**) followed by the acid-catalyzed decomposition of **3** either in the absence or in the presence of an orthoformate.[4)]

$$\underset{\mathbf{2}}{1} + RX \xrightarrow[THF]{NaH} \underset{\mathbf{3}}{RCH(SCH_3)(SOCH_3)} \xrightarrow{H^+} \underset{\mathbf{4}}{RCHO}\ \underset{\mathbf{5}}{[RCH(OR')_2]}$$

During the course of our investigation to search further synthetic utility of this new reagent (**1**), we observed that **1** underwent the Knoevenagel-type condensation with an aromatic aldehyde (**6**) in the presence of a base such as benzyltrimethylammonium hydroxide (Triton B), sodium hydroxide, or potassium hydroxide to give a 2-aryl-1-(methylsulfinyl)-1-(methylthio)ethylene (**7**) in high yield. Furthermore, the condensate (**7**) was found to be converted to an arylacetic ester (**8**) on treatment with hydrogen chloride in an alcohol. This whole reaction sequence provided a new synthetic route for conversion of aromatic aldehydes into the corresponding arylacetic esters. In this paper, we wish to report a full experimental detail on synthesis of arylacetic esters starting from aromatic aldehydes by the use of **1**.

$$\underset{\mathbf{6}}{ArCHO} + \mathbf{1} \xrightarrow{base} \underset{\mathbf{7}}{ArCH{=}C(SCH_3)(SOCH_3)} \xrightarrow[ROH]{HCl} \underset{\mathbf{8}}{ArCH_2COOR}$$

Results and Discussion

Transformation of Benzaldehyde into Phenylacetic Esters. When a mixture of benzaldehyde and methyl (methylthio)methyl sulfoxide (**1**) was treated with Triton B in refluxing THF, 1-(methylsulfinyl)-1-(methylthio)-2-phenylethylene (**10**) was formed: To a solution containing 2.57 g of **1** and 3 ml of benzaldehyde (**9**) in 5 ml of THF, was added 2 ml of 40% methanolic solution of Triton B, and then the resulting mixture was refluxed for 4 h. Separation by column-chromatography on silica gel gave 3.99 g (91% yield) of **10** as a colorless oil, bp 149—150 °C/0.08 Torr. When one mol-equiv of **9** was used in this condensation reaction, the yield of **10** was 80%. The structure of **10** was assigned on the basis of the following evidence.

$$\mathbf{1} + \underset{\mathbf{9}}{PhCHO} \xrightarrow{base} \underset{\mathbf{10}}{Ph(H)C{=}C(SCH_3)(SOCH_3)} \underset{h\nu}{\rightleftharpoons} \underset{\mathbf{11}}{Ph(H)C{=}C(SOCH_3)(SCH_3)}$$

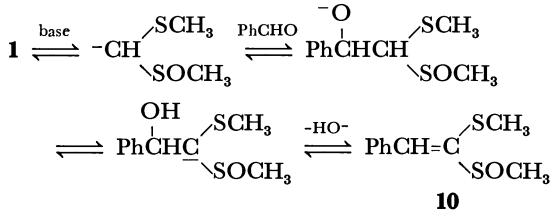
Molecular formula, $C_{10}H_{12}OS_2$, for this oil was confirmed by its mass spectrum (parent peak, *m/e* 212) and elemental analysis. The NMR and IR spectra proved that it consisted of only one stereoisomer and that it had a phenyl group [NMR in CCl_4: δ=7.32 (3H, m) and 7.85 (2H, m); IR: 756 and 692 cm^{-1}], an olefinic proton [δ=7.51 (1H, s)], a methylsulfinyl group [δ=2.62 (3H, s); 1062 cm^{-1}], and a methylthio group [δ=2.26 (3H, s)]. Reduction of this oil with lithium aluminium hydride afforded 1,1-bis(methylthio)-2-phenylethane.[9)]

Another stereoisomer (**11**) was obtained by irradiation of **10** in methanol with a low-pressure mercury arc lamp (Vycor filter) as a mixture with **10**. The stereochemical structures of **10** and **11** were assigned by the comparison of the pseudo-contact effects of the shift reagent, tris(dipivaloylmethanato)europium [Eu(dpm)$_3$], which formed complexes at the oxygen atom of a sulfoxide,[10)] on the NMR chemical shifts of their olefinic protons. The singlet at δ=7.51 of **10** was shifted downfield to δ=16.49 by adding 0.51

equiv of $Eu(dpm)_3$, while the olefinic proton (δ=7.02 in CCl_4) of **11** appeared at δ=9.71 in CCl_4–$Eu(dpm)_3$ (0.51 equiv). These facts indicate that the olefinic proton and the sulfinyl group of **10** are much closer in space than those of **11**. Hence, the stereochemical structure of **10** is established to be of *E*-configuration.

The condensation reaction of benzaldehyde with **1** could be also achieved under various basic conditions. Reflux of a solution containing **1**, benzaldehyde, and potassium hydroxide (1.3 equiv) in methanol gave **10** in 44% yield. When benzaldehyde was treated with sodium hydroxide (0.6 equiv) in two mol-equiv of **1** at 70 °C, **10** was obtained in 84% yield. Furthermore, it was found that stirring a mixture of benzaldehyde, **1**, and sodium hydride either in THF at 60 °C or in *N*,*N*-dimethylformamide at room temperature gave **10** in 56% or 43% yield, respectively.

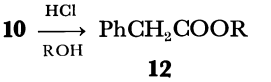
This condensation reaction is very interesting because the reaction proceeds smoothly without removal of the formed water, and even in methanol. This may be accounted for by the incapability of **10** toward the Michael-type addition of hydroxide anion, that is, the irreversible nature of the final stage of the process, *i.e.* the elimination of hydroxide anion, as shown in Scheme 1.



10

Scheme 1.

The degradation of **10** with hydrogen chloride took place easily in an alcohol. A solution containing 300 mg of **10** in 10 ml of ethanol was bubbled with hydrogen chloride gas under ice-cooling and then was allowed to stand at room temperature. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel to give 179 mg (78% yield) of ethyl phenylacetate (**12a**).[11] In a similar manner, methyl phenylacetate (**12b**) and butyl phenylacetate (**12c**) were obtained in 75% and 79% yields by the reaction with hydrogen chloride in methanol and 1-butanol, respectively.



12

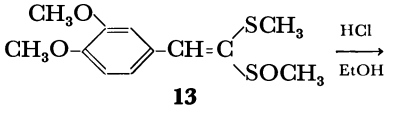
a	$R=C_2H_5$	78%
b	$R=CH_3$	75%
c	$R=n\text{-}C_4H_9$	79%

It should be noted that saturation of hydrogen chloride was not always necessary to the conversion of **10** into **12**. The concentration of hydrogen chloride in the system could be reduced to 0.1 M although a higher temperature was required in order to complete the reaction within a short time: Ethyl phenylacetate (**12a**) was produced in 75% yield by refluxing a solution of **10** in ethanol containing hydrogen chloride at the concentration of 0.1 M. When a solution of **10** in 1,2-dimethoxyethane was treated with conc. hydrochloric acid at room temperature, phenylacetic acid was isolated in 63% yield.

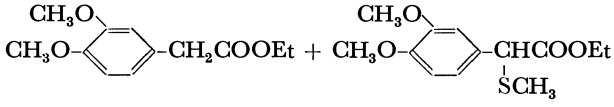
Thus, methyl (methylthio)methyl sulfoxide (**1**) was shown to be a novel reagent for the transformation of benzaldehyde into phenylacetic acid and its alkyl esters. The generality of this transformation was further investigated by examination of the reactions starting from a wide variety of aromatic aldehydes, and the results are described in the following.

Synthesis of (Alkoxy-substituted phenyl)acetic Esters. Many of (alkoxy-substituted phenyl)acetic acids are known as key-intermediates for the syntheses of isoquinoline alkaloids,[12] and it seemed very important to examine the production of these acids or their esters by using the above-mentioned procedure. The alkoxy-substituted benzaldehydes which we investigated were *p*-methoxybenzaldehyde, *p*-butoxybenzaldehyde, *p*-(benzyloxy)benzaldehyde, 3,4-dimethoxybenzaldehyde, 3,4-(methylenedioxy)benzaldehyde, and 3,4,5-trimethoxybenzaldehyde. The results are summarized in Tables 1 and 2, showing that all the aldehydes examined can be transformed in good yields into the corresponding arylacetic esters *via* the condensates with **1**.

When the condensate **13** derived from 3,4-dimethoxybenzaldehyde was treated with a saturated ethanolic solution of hydrogen chloride, ethyl (3,4-dimethoxyphenyl)(methylthio)acetate (**15**) was produced as a by-product (27% yield), resulting in formation of the expected ethyl (3,4-dimethoxyphenyl)acetate (**14**) in relatively low yield (40%). This could be overcome by reducing the concentration of hydrogen chloride: **14** was obtained in 91% yield on treatment of **13** with 0.5 M hydrogen chloride in ethanol.

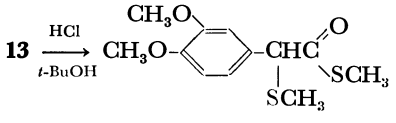


13



14 **15**

On the other hand, when a solution of **13** in *t*-butyl alcohol was saturated with hydrogen chloride, methanethiol ester (**16**) of (3,4-dimethoxyphenyl)(methylthio)acetic acid was isolated in 67% yield instead of *t*-butyl (3,4-dimethoxyphenyl)acetate.



16

Miscellaneous. By the present procedure, (halogen- or alkyl-substituted phenyl)acetic esters could be synthesized. On treatment with saturated alcoholic solution of hydrogen chloride, 2-(*p*-chlorophenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene which was derived from *p*-chlorobenzaldehyde and **1** was transformed into ethyl, methyl, or butyl ester of (*p*-chlorophenyl)acetic acid in 92%, 78%, or 80% yield, respectively. In analogous manners, ethyl (*o*-bromophenyl)acetate and ethyl (*p*-isopropylphenyl)acetate were also obtained, starting from *o*-bromobenzaldehyde and

a) Triton B=benzyltrimethylammonium hydroxide. b) The amount of **1** was 2.0 mol-equiv to the aldehyde. c) The aldehyde: **1**=1 : 2.56. d) Based on the unrecovered **1**. e) The aldehyde: **1**=1 : 1.5.

p-isopropylbenzaldehyde, as shown in Tables 1 and 2.

The present method was also applied to synthesis of (2-thienyl)acetic acid which was especially useful as a reagent for chemical modification of antibiotic penicillins and cephalosporins.[13] It was found that 2-thiophenecarbaldehyde underwent the condensation reaction with **1** in the presence of Triton B (86% yield) or potassium hydroxide (83% yield) in THF or methanol, respectively, under refluxing with heating, and then, on treatment of the resulting 1-(methylsulfinyl)-1-(methylthio)-2-(2-thienyl)ethylene (**17**) with 1 M hydrogen chloride in ethanol, ethyl (2-thienyl)acetate (**18**) was produced in 80% yield.[14] This method is suitable for making (2-thienyl)acetic esters, since 2-thiophenecarbaldehyde is easily available by the Vilsmeier-Haak reaction of thiophene.[15]

18

Experimental

*Condensation of Benzaldehyde with **1**. (a) Triton B in THF*: To a solution containing 2.572 g of **1** and 3 ml of benzaldehyde in 5 ml of THF, was added a 40% methanolic solution (3 ml) of Triton B and the resulting mixture was refluxed for 4 h. After adding 100 ml of dichloromethane, the mixture was washed with 0.5 M sulfuric acid, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was separated by column-chromatography on silica gel (using dichloromethane as an eluent) to afford 3.994 g of **10** as a colorless oil which was further purified by distillation *in vacuo*: bp 149—150 °C/0.08 Torr; IR (neat) 1052 cm^{-1}; NMR (CCl_4) δ=2.26 (3H, s), 2.62 (3H, s), 7.32 (3H, m), 7.51 (1H, s), and 7.85 (2H, m); MS (70 eV), *m/e* (relative intensity), 212 (M^+, 7), 197 (5), 149 (100), 134 (96), 116 (18), 115 (14), and 89 (11). Found: C, 56.56; H, 5.70; S, 30.20%. Calcd for $C_{10}H_{12}OS_2$: C, 56.65; H, 5.72; S, 30.33%.

The above-mentioned reaction was repeated using an equimolar amount of benzaldehyde to **1**. To a solution containing benzaldehyde (1.007 g) and **1** (1.17 g) in THF (10 ml), was added a 40% methanolic solution (1.2 ml) of Triton B and the resulting mixture was refluxed for 4 h. After the addition of dichloromethane (50 ml), the solution was washed with 0.5 M sulfuric acid (20 ml) and water (50 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (benzene–dichloro-

a) Methanethiol ester of (3,4-dimethoxyphenyl)(methylthio)acetic acid was isolated in 67% yield. b) Room temp → reflux.

methane (1 : 3)] to give **10** (1.606 g: 80% yield) as a pale yellow oil.

(b) KOH in Methanol: A solution containing benzaldehyde (505 mg) and **1** (585 mg) in methanol (5 ml) was refluxed for 4 days after potassium hydroxide (350 mg) was added. Dichloromethane (30 ml) was added and the resulting mixture was washed with 0.5 M sulfuric acid (10 ml) and water (30 ml×2). After being dried (Na_2SO_4) and evaporated *in vacuo*, the residue was column-chromatographed on silica gel [benzene–dichloromethane (1 : 2)] to give **10** (442 mg: 44% yield) as a pale yellow oil.

(c) NaOH and Excess of 1: After a mixture of **1** (2.34 g) and powdered sodium hydroxide (0.32 g) was stirred at 70 °C for 30 min, benzaldehyde (0.98 g) was added and then the resulting mixture was further stirred at 70 °C for 1 h. After the addition of dichloromethane (50 ml), the mixture was washed with 0.5M sulfuric acid (20 ml) and water (50 ml×2) and, the organic layer was dried (Na_2SO_4). Evaporation *in vacuo* gave a yellow oil which was column-chromatographed on silica gel [benzene–dichloromethane (1 : 3)] to afford **10** (1.654 g: 84% yield) as a pale yellow oil.

(d) NaH in DMF: To a solution containing **1** (6.00 g) in DMF (20 ml), was added sodium hydride (65% oil-dispersion; 1.80 g) and the resulting mixture was stirred at room temperature for 1.5 h. After the dropwise addition of benzaldehyde (4.80 g) over 10 min under ice-cooling, the mixture was further stirred at room temperature for 2 h, and then dichloromethane (100 ml) was added. After being washed with water (70 ml×2), the organic layer was dried ($MgSO_4$) and evaporated *in vacuo* to give an oily residue which was separated by column-chromatography on silica gel [benzene–dichloromethane (1 : 3)] to afford **10** (4.11 g: 43% yield) as a pale yellow oil.

(e) NaH in THF: To a solution of **1** (6.00 g) in THF (20 ml), was added sodium hydride (65% oil-dispersion; 1.80 g) and the resulting mixture was stirred at room temperature for 1 h. After the dropwise addition of benzaldehyde (4.90 g) over 10 min at room temperature, the reaction mixture was further stirred at 60 °C for 1.5 h and then dichloromethane (100 ml) was added. After insoluble matters were filtered off, the filtrate was washed with water (70 ml×2), dried ($MgSO_4$), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel [benzene–dichloromethane (1 : 3)] to afford **10** (5.50 g: 56% yield) as a pale yellow oil.

Photochemical Isomerization of 10: A solution of the 1-(methylsulfinyl)-1-(methylthio)-2-phenylethylene (**10**, 276 mg), which was obtained by the above-mentioned reaction, in methanol (200 ml) was irradiated with a low-pressure mercury arc lamp (10 W) through Vycor filter for 2 h and 45 min. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel (dichloromethane) to give a pale yellow oil (211 mg) which was shown by an NMR analysis to consist of **10** and its geometric isomer (**11**) in the ratio of 58 : 42. Found: C, 56.66; H, 5.71; S, 30.02%.

Calcd for $C_{10}H_{12}OS_2$: C, 56.56; H, 5.70; S, 30.20%.

The NMR signals of **11** appeared at δ=2.60 (3H, s), 2.47 (3H, s), 7.02 (1H, s) and 7.26 (5H, s) in CCl_4.

*Decomposition of **10** with Hydrogen Chloride (HCl). (a) In Saturated Methanolic Solution of HCl*: HCl gas was bubbled in a solution of **10** (514 mg) in methanol (5 ml) under cooling with ice–water until HCl was saturated. The resulting solution was stirred at room temperature for 19 h and then was evaporated *in vacuo*. The residue was column-chromatographed on silica gel [hexane–benzene (1 : 1)] to give methyl phenylacetate (271 mg: 75% yield) as a colorless oil which was identified by the comparison of its IR and NMR spectra with those of the authentic sample prepared from phenylacetic acid by the usual method (HCl–methanol).

(b) In Saturated Ethanolic Solution of HCl: A solution containing **10** (300 mg) in ethanol (10 ml) was saturated with HCl gas. The introduction of the gas was performed under ice-cooling. The resulting solution was stirred at room temperature for 8 h and concentrated *in vacuo*. The residue was separated by column-chromatography on silica gel (benzene) to give ethyl phenylacetate (179 mg: 77% yield) which was identified by the comparison of its IR and NMR spectra with those of the authentic sample obtained by saturation of HCl in ethanolic solution of phenylacetic acid.

(c) In 0.1M Ethanolic Solution of HCl: To a solution of **10** (505 mg) in ethanol (10 ml), was added a saturated ethanolic solution (0.1 ml) of HCl and the resulting solution was refluxed for 25 h. After evaporation *in vacuo*, the residue was subjected to column-chromatography on silica gel [hexane–benzene (1 : 1)] to afford ethyl phenylacetate (291 mg: 75% yield) as a pale yellow oil. Since a further elution with ethyl acetate afforded the starting material (**10**, 77 mg), the conversion yield of ethyl phenylacetate was calculated to be 88%.

(d) In 1-Butanol: A solution of **10** (1.763 g) in 1-butanol (10 ml) was saturated with HCl gas under cooling with ice–water and then the resulting solution was stirred at room temperature for 3 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel [hexane–benzene (4 : 1)] to give butyl phenylacetate (1.418 g: 89% yield) as a colorless oil, which was identified by the comparison of its IR and NMR spectra with those of the authentic sample.[16]

(e) Concd Hydrochloric Acid: To a solution containing **10** (191 mg) in 1,2-dimethoxyethane (1.5 ml), was added concd hydrochloric acid (1 ml) and the resulting mixture was stirred at room temperature for 3 h. Then, dichloromethane (50 ml) and water (5 ml) were added. The aqueous layer was separated and further extracted with dichloromethane (50 ml). The organic layers were combined, dried (Na_2SO_4), and evaporated *in vacuo*. After the addition of ether (30 ml) to the residue, the solution was extracted with a saturated aqueous solution (10 ml×2) of sodium hydrogen carbonate. The aqueous layer was acidified with hydrochloric acid and extracted with dichloromethane (30 ml×3). The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to afford phenylacetic acid (77 mg: 63% yield) as colorless crystals having mp 69—75 °C. The identification was achieved by the comparison of its IR and NMR spectra with those of an authentic sample and the mixture mp.

Condensation of p-*Methoxybenzaldehyde with **1**. (a) Triton B in THF*: To a solution of **1** (951 mg) and *p*-methoxybenzaldehyde (1.17 g) in THF (10 ml), was added a 40% methanolic solution (1 ml) of Triton B and the mixture was refluxed for 5 h. Then, dichloromethane (100 ml), water (5 ml), and 4.5 M sulfuric acid (2 ml) were added and the mixture was shaken. The organic layer was separated, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was subjected to column-chromatography on silica gel (dichloromethane) to obtain 2-(*p*-methoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**19**; 1.51 g: 82% yield) as a pale yellow oil: bp 170—173 °C/0.20 Torr; IR (neat) 1059 cm^{-1}; NMR (CCl_4) δ=2.30 (3H, s), 2.63 (3H, s), 3.84 (3H, s), 6.86 (2H, d, J=8.4 Hz), 7.43 (1H, s), and 7.86 (2H, d, J=8.4 Hz); MS (70 eV), *m/e* (relative intensity), 242 (M^+, 6), 179 (87), 164 (100), 149 (41), 146 (39), and 121 (15). Found: C, 54.55; H, 5.84; S, 26.50%. Calcd for $C_{11}H_{14}O_2S_2$: C, 54.52; H, 5.82; S, 26.46%.

Further elution gave **1** (176 mg). Therefore, the conversion yield of **19** was calculated to be 100%.

*(b) NaOH and Excess of **1***: After a mixture of **1** (9.13 g) and powdered sodium hydroxide (0.45 g) was stirred at 70 °C for 30 min, *p*-methoxybenzaldehyde (4.87 g) was dropwise added and the resulting mixture was further stirred at 70 °C for 1.5 h. After the addition of dichloromethane (100 ml), the mixture was washed with 0.5 M sulfuric acid (30 ml) and water (100 ml×2) and then the organic layer was dried (Na_2SO_4). Evaporation *in vacuo*, followed by column-chromatography on silica gel [dichloromethane–ethyl acetate (4 : 1)], gave **19** (8.068 g: 93% yield) as a yellow oil.

*Decomposition of 2-(*p*-Methoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**19**) with HCl.* A solution containing **19** (274 mg) in ethanol (10 ml) was saturated with HCl gas under cooling with ice–water and allowed to stand overnight at room temperature. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel [hexane–benzene (1 : 1)] to give ethyl (*p*-methoxyphenyl)acetate (206 mg: 94% yield). This ester was identified by the comparison of its IR and NMR spectra with those of the authentic sample which was obtained by the usual esterification (HCl–ethanol) of (*p*-methoxyphenyl)acetic acid given in the following.

To a solution containing **19** (460 mg) in 1,2-dimethyoxyethane (2 ml), was added concd hydrochloric acid (1 ml) and the resulting mixture was stirred for 15 h at room temperature. After the reaction mixture was shaken with diethyl ether (50 ml), the organic layer was separated, which was extracted with an aqueous solution of potassium carbonate. The aqueous layer was acidified with concd hydrochloric acid, and then extracted with dichloromethane (50 ml×3). The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to give 62 mg of colorless crystals, which were identified as (*p*-methoxyphenyl)acetic acid by the comparison of their IR and NMR spectra with those reported in the Sadtler spectra.

Condensation of p-*Butoxybenzaldehyde with **1**.* To a solution of *p*-butoxybenzaldehyde (5.05 g) and **1** (4.26 g) in THF (50 ml), was added a 40% methanolic solution (4 ml) of Triton B and the resulting solution was refluxed for 24.5 h. Dichloromethane (50 ml) was added and the mixture was washed with 0.5 M sulfuric acid. After being dried (Na_2SO_4) and evaporation *in vacuo*, the residue was subjected to column-chromatography on silica gel [benzene–dichloromethane (1 : 1)] to give 2-(*p*-butoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**20**; 5.94 g: 74% yield) as a pale yellow oil which soon crystallized and was further purified by recrystallization from hexane to afford colorless crystals: mp 47—48 °C; IR (KBr) 1055 cm^{-1}; NMR($CDCl_3$) δ=0.94 (3H, t, J=6 Hz), 1.20—1.88 (4H, m), 2.22 (3H, s), 2.64 (3H, s), 3.90 (2H, t, J=6 Hz), 6.84 (2H, d, J=9 Hz), 7.49 (1H, s), and 7.83 (2H, d, J=9

Hz); MS (70 eV), *m/e* (relative intensity), 284 (M^+, 13), 222 (17), 221 (100), 220 (11), 206 (37), 165 (50), 151 (11), 150 (99.7), 149 (27), 132 (40), 131 (29), 121 (24), 89 (11), 77 (12), 41 (18), and 29 (38). Found: C, 58.83; H, 7.02; S, 22.57%. Calcd for $C_{14}H_{20}O_2S_2$: C, 59.12; H, 7.09; S, 22.54%.

*Decomposition of 2-(p-Butoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**20**) with HCl.* To a solution of **20** (492 mg) in ethanol (9 ml), was added a saturated ethanolic solution (1 ml) of HCl and the resulting solution was refluxed for 3 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel (benzene) to give ethyl (*p*-butoxyphenyl)acetate (330 mg: 81% yield) as a pale yellow oil: IR (neat) 1783 cm^{-1}; NMR ($CDCl_3$) δ=0.93 (3H, t, J=7 Hz), 1.19 (3H, t, J=7 Hz), 1.20—1.86 (4H, m), 3.46 (2H, s), 3.86 (2H, t, J=6 Hz), 4.06 (2H, q, J=7 Hz), 6.76 (2H, d, J=9 Hz), and 7.11 (2H, d, J=9 Hz).

This ester was hydrolyzed without further purification. The ester (212 mg) was dissolved in 1,2-dimethoxyethane (5 ml) and 1 M aqueous solution (2.5 ml) of potassium hydroxide was added. The reaction mixture was stirred at room temperature for 45 h. After the addition of water (10 ml) and acidification with 0.5M sulfuric acid, the mixture was extracted with diethyl ether (30 ml×2). The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to give crude (*p*-butoxyphenyl)acetic acid as pale yellow crystals which were further purified by recrystallization from hexane to give colorless crystals: mp 87.5—88.5 °C; IR (KBr) 1701 cm^{-1}; NMR ($CDCl_3$) δ=0.94 (3H, t, J=7 Hz), 1.25—1.88 (4H, m), 3.50 (2H, s), 3.88 (2H, t, J=6 Hz), 6.78 (2H, d, J=8 Hz), 7.11 (2H, d, J=8 Hz), and 10.56 (1H, broad s). Found: C, 69.41; H, 7.72%. Calcd for $C_{12}H_{16}O_3$: C, 69.23; H, 7.68%.

Condensation of p-*(Benzyloxy)benzaldehyde with **1**. (a) Triton B in THF*: To a solution containing *p*-(benzyloxy)-benzaldehyde (999 mg) and **1** (590 mg) in THF (5 ml), was added a 40% methanolic solution of Triton B and the resulting solution was refluxed for 24 h. After the addition of dichloromethane (50 ml), the solution was washed successively with 0.5 M sulfuric acid (20 ml) and water (50 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to give 2-(*p*-benzyloxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**21**; 935 mg: 62% yield) as a yellow oil: IR (neat) 1063 cm^{-1}; NMR ($CDCl_3$) δ=2.24 (3H, s), 2.66 (3H, s), 5.03 (2H, s), 6.94 (2H, d, J=9 Hz), 7.2—7.5 (5H, m), 7.51 (1H, s), and 7.86 (2H, d, J=9 Hz). Found: C, 63.96; H, 5.73; S, 19.87%. Calcd for $C_{17}H_{18}O_2S_2$: C, 64.12; H, 5.70; S, 20.14%.

*(b) NaOH and Excess of **1**:* A mixture of **1** (8.89 g) and sodium hydroxide (0.67 g) was stirred at 70 °C for 30 min, and then *p*-benzyloxybenzaldehyde (5.00 g) was added. The resulting mixture was further stirred at 70—80 °C for 1.5 h. After the addition of dichloromethane (100 ml), the mixture was washed with a saturated aqueous solution of sodium chloride and dried (Na_2SO_4). Evaporation *in vacuo*, followed by column-chromatography on silica gel [dichloromethane–ethyl acetate (19 : 1)], afforded **21** (6.909 g: 92% yield) as a pale yellow oil.

*Decomposition of 2-(p-Benzyloxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**21**) with HCl.* To a solution of **21** (495 mg) in ethanol (9 ml), was added a saturated ethanolic solution (1 ml) of HCl and the resulting solution was refluxed for 3 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel [benzene-hexane (4 : 1)] to afford ethyl (*p*-benzyloxyphenyl)acetate (343 mg: 82% yield) as a colorless oil: IR (neat) 1735 cm^{-1}; NMR ($CDCl_3$) δ=1.24 (3H, t, J=7 Hz), 3.56 (2H, s), 4.15 (2H, q, J=7 Hz), 5.07 (2H, s), 6.95 (2H, d, J=9 Hz), 7.24 (2H, d, J=9 Hz), and 7.3—7.5 (5H, m); MS (70 eV), *m/e* (relative intensity), 270 (M^+, 4), 92 (7), 91(100), and 65 (6).

This ester was hydrolyzed by the usual manner: The ester (198 mg) was dissolved in 1,2-dimethoxyethane (3 ml) and 1M aqueous solution (3 ml) of potassium hydroxide was added. The resulting mixture was stirred at room temperature for 19 h and then, water (10 ml) and 0.5 M sulfuric acid (5 ml) were added. After extraction with ethyl acetate (30 ml×3), the organic layer was dried (Na_2SO_4) and evaporated *in vacuo*. The residue was column-chromatographed on silica gel [dichloromethane–ethyl acetate (2 : 1)] to give (*p*-benzyloxyphenyl)acetic acid as colorless crystals: mp 124—125 °C (from chloroform–hexane)(lit,[17] mp 120—121 °C); IR (KBr) 3200—2300 and 1688 cm^{-1}; NMR ($CDCl_3$) δ=3.48 (2H, s), 4.95 (2H, s), 6.85 (2H, d, J=9 Hz) 7.15 (2H, d, J=9 Hz), 7.2—7.4 (5H, m), and 11.44 (1H, broad s). Found: C, 74.18; H, 5.78%. Calcd for $C_{15}H_{14}O_3$: C, 74.37; H, 5.82%.

Condensation of m-*Phenoxybenzaldehyde with **1**. (a) Triton B in THF*: To a solution of *m*-phenoxybenzaldehyde (2.00 g) and **1** (1.27 g) in THF (10 ml), was added a 40% methanolic solution (1 ml) of Triton B and the solution was refluxed for 26 h. Dichloromethane (50 ml) was added and the resulting solution was washed with 1.5 M sulfuric acid. The organic layer was dried (K_2CO_3) and evaporated *in vacuo*. The residue was subjected to column-chromatography on silica gel (dichloromethane) to give 1-(methylsufinyl)-1-(methylthio)-2-(*m*-phenoxyphenyl)ethylene (**22**; 1.88 g: 61% yield) as a pale yellow oil. An analytical sample was obtained by rechromatography as a colorless oil: IR (neat) 1062 cm^{-1}; NMR ($CDCl_3$) δ=2.20 (3H, s), 2.66 (3H, s), 6.88—7.60 (9H, m), and 7.52 (1H, s); MS (70 eV), *m/e* (relative intensity), 304 (M^+, 5), 242 (19), 241 (100), 227 (13), 226 (77), 197 (12), 165 (19), 148 (35), 147 (22), 89 (30), 77 (22), 63 (11), 51 (20), and 39 (10). Found: C, 63.20; H, 5.30; S, 21.06%. Calcd for $C_{16}H_{16}O_2S_2$: C, 63.13; H, 5.30; S, 20.83%.

*(b) NaOH and Excess of **1**:* After a mixture of **1** (2.44 g) and powdered sodium hydroxide (120 mg) was stirred at 70 °C for 30 min, *m*-phenoxybenzaldehyde (1.99 g) was added and then the resulting mixture was further stirred at 70 °C for 3 h. After the addition of dichloromethane (50 ml), the mixture was washed successively with water (50 ml×2) and 0.5 M sulfuric acid (50 ml), dried ($MgSO_4$), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to give **22** (2.23 g: 73% yield) as a pale yellow oil.

*Decomposition of 1-(Methylsulfinyl)-1-(methylthio)-2-(m-phenoxyphenyl)ethylene (**22**) with HCl.* To a solution of **22** (492 mg) in ethanol (9 ml), was added a saturated ethanolic solution (1 ml) of HCl, and the solution was refluxed for 2.5 h. After evaporation *in vacuo*, the residue was subjected to column-chromatography on silica gel (benzene) to give ethyl (*m*-phenoxyphenyl)acetate (351 mg: 85% yield) as a colorless oil: IR (neat) 1736 cm^{-1}; NMR ($CDCl_3$) δ=1.14 (3H, t, J=7 Hz), 3.45 (2H, s), 4.02 (2H, q, J=7 Hz), and 6.60—7.40 (9H, m). Found: C, 74.50; H, 6.32%. Calcd for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29%.

*Condensation of 3,4-Dimethoxybenzaldehyde with **1**. (a) Triton B in Dioxane*: To a solution containing 3,4-dimethoxybenzaldehyde (1.43 g) and **1** (1.078 g) in dioxane (7 ml), was added a 40% methanolic solution (1 ml) of Triton B and then the mixture was stirred for 25 h at 80 °C. After the addition of dichloromethane (100 ml), the resulting solution was washed with *ca.* 2 M hydrochloric acid (10.5

ml), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to afford 2-(3,4-dimethoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**13**) (1.118 g: 47% yield) as a colorless oil which crystallized on standing and was further purified by recrystallization from diethyl ether–hexane to give colorless crystals: mp 61.5—62.5 °C; IR (KBr) 1057 cm^{-1}: NMR ($CDCl_3$) δ=2.31 (3H, s), 2.72 (3H, s), 6.90 (1H, d, J=8.3 Hz), 7.46 (1H, dd, J=8.3 and 2.4 Hz), 7.55 (1H, s), and 7.73 (1H, d, J=2.4 Hz). Found: C, 52.83; H, 5.88%. Calcd for $C_{12}H_{16}O_3S_2$: C, 52.91; H, 5.92%.

Since **1** (493 mg) was recovered, the yield of **13** based on the consumed **1** was calculated to be 87%.

(b) Triton B in THF: To a solution containing 3,4-dimethoxybenzaldehyde (1.007 g) and **1** (0.75 g) in THF (5 ml), was added a 40% methanolic solution (0.75 ml) of Triton B and then the resulting solution was refluxed for 48 h. After the addition of dichloromethane (50 ml), the mixture was washed with 0.5 M sulfuric acid (20 ml) and water (50 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was subjected to column-chromatography on silica gel [dichloromethane and dichloromethane–ethyl acetate (4 : 1)] to give **13** (1.085 g: 66% yield) as a yellow oil which crystallized.

*(c) NaOH and Excess of **1***: After a mixture of **1** (7.48 g) and powdered sodium hydroxide (0.36 g) was stirred at 70 °C for 30 min, 3,4-dimethoxybenzaldehyde (5.007 g) was added and then the resulting mixture was further stirred at 70 °C for 1.5 h. After the addition of dichloromethane (100 ml), the mixture was washed with 0.5 M sulfuric acid (50 ml) and water (100 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel [dichloromethane–ethyl acetate (4 : 1)] to give **13** (6.714 g: 82% yield) as a yellow oil which crystallized after a while.

*Decomposition of **13** with HCl. (a) in Saturated Ethanolic Solution of HCl*: A solution of **13** (260 mg) in ethanol (10 ml) was saturated with HCl gas at room temperature. The temperature of the solution rose up to *ca.* 50 °C. The reaction mixture was allowed to stand overnight at room temperature and then evaporated *in vacuo*. The residue was subjected to column-chromatography on silica gel (benzene) to give ethyl (3,4-dimethoxyphenyl)acetate (**14**) (86 mg: 37% yield) and ethyl (3,4-dimethoxyphenyl)(methylthio)acetate (**15**) (135 mg: 49% yield). The identification of **14** was achieved by the comparison of its IR spectrum with that of the authentic sample prepared by the usual esterification (HCl–ethanol) of commercially available (3,4-dimethoxyphenyl)acetic acid. The structure of **15** was deduced by the following physical data: IR (neat) 1727 cm^{-1}; NMR (CCl_4) δ=1.26 (3H, t, J=7.5 Hz), 2.00 (3H, s), 3.79 (3H, s), 3.83 (3H, s), 4.15 (2H, q, J=7.5 Hz), 4.28 (1H, s), and 6.55—7.05 (3H, m).

In the above reaction, when HCl gas was passed into the system under ice-cooling until the solution turned yellow, the yields of **14** and **15** were 40% and 25%, respectively.

(b) In 0.5 M Ethanolic Solution of HCl: To a solution of **13** (2.00 g) in ethanol (20 ml), was added a saturated ethanolic solution (1 ml) of HCl and the solution was stirred at room temperature for 22 h and refluxed for 2 h. After evaporation *in vacuo*, the residue was subjected to column-chromatography on silica gel (benzene) to afford **14** (1.51 g: 91% yield) as a yellow oil.

(c) In t-Butyl Alcohol: After a solution of **13** (505 mg) in *t*-butyl alcohol (5 ml) was saturated with HCl under cooling with ice-water, the resulting solution was stirred at room temperature for 2 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel [benzene–hexane (1:4)] to give a yellow oil (338 mg: 67% yield) which was assigned as **16** from the following properties: IR (neat) 1680 cm^{-1}; NMR (CCl_4) δ=2.05 (3H, s), 2.15 (3H, s), 3.78 (3H, s), 3.82 (3H, s), 4.49 (1H, s), 6.62—6.93 (3H, m). Found: C, 53.09; H, 5.69%. Calcd for $C_{12}H_{16}O_3S_2$: C, 52.91; H, 5.92%.

*Condensation of 3,4-(Methylenedioxy)benzaldehyde with **1**. (a) Triton B in THF*: To a solution containing **1** (674 mg) and 3,4-(methylenedioxy)benzaldehyde (895 mg) in THF (5 ml), was added a 40% methanolic solution (0.7 ml) of Triton B and then the resulting mixture was refluxed for 9 h. Dichloromethane (50 ml) was added and the mixture was washed with 0.5 M sulfuric acid, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to afford 2-(3,4-methylenedioxyphenyl)-1-(methylsulfinyl)-1-(methylthio)-ethylene (**23**; 870 mg: 62% yield) as a pale yellow oil: IR (neat) 1058 cm^{-1}; NMR ($CDCl_3$) δ=2.34 (3H, s), 2.76 (3H, s), 6.05 (2H, s), 6.87 (1H, d, J=8 Hz), 7.30 (1H, dd, J=8 and 2 Hz), 7.54 (1H, s), and 7.75 (1H, d, J=2 Hz). Found: C, 51.27; H, 4.65; S, 25.20%. Calcd for $C_{11}H_{12}O_3S_2$: C, 51.54; H, 4.72; S, 25.02%.

Further elution with dichloromethane gave **1** (151 mg). Therefore, the yield based on the unrecovered **1** was calculated to be 81%.

*(b) NaOH and Excess of **1***: After a mixture of **1** (2.44 g) and powdered sodium hydroxide (0.12 g) was stirred at 70 °C for 30 min, 3,4-(methylenedioxy)benzaldehyde (1.502 g) was added and then the resulting mixture was further stirred at 70 °C for 3 h. After the addition of dichloromethane (50 ml), the mixture was washed with water (50 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to give **23** (2.143 g: 84% yield) as a pale yellow oil.

*Decomposition of 2-(3,4-Methylenedioxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**23**) with HCl. (a) In Ethanol*: A solution of **23** (522 mg) in ethanol (10 ml) was bubbled by HCl gas under ice-cooling until the solution turned yellow (about 20 min). The reaction mixture was evaporated *in vacuo* and subjected to column-chromatography on silica gel (benzene) to afford ethyl (3,4-methylenedioxyphenyl)acetate (386 mg: 91% yield) as a pale yellow oil. Identification of the product was achieved by the comparison of its IR spectrum with that of the authentic sample prepared by the usual esterification (HCl–ethanol) of (3,4-methylenedioxyphenyl)-acetic acid which was obtained by the following procedure.

To a solution containing ethyl (3,4-methylenedioxyphenyl)-acetate (333 mg) in 1,2-dimethoxyethane (10 ml), was added 1 M aqueous solution (5 ml) of sodium hydroxide and the resulting mixture was refluxed for 2 h. After being poured into ice–water (50 ml) containing 3.5% hydrochloric acid (10 ml), the mixture was extracted with ethyl acetate (50 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel [dichloromethane–ethyl acetate (1:1)] to afford (3,4-methylenedioxyphenyl)-acetic acid (278 mg: 97% yield) as pale yellow crystals, which were further purified by recrystallization from diethyl ether–hexane to give colorless crystals: mp 132—133 °C (lit,[18] mp 128—129 °C); IR (KBr) 3300—2700 and 1703 cm^{-1}; NMR ($CDCl_3$) δ=3.50 (2H, s), 5.86 (2H, s), 6.66 (2H, diffused s), and 6.70 (1H, diffused s). Found: C, 60.10; H, 4.45%. Calcd for $C_9H_8O_4$: C, 60.00; H, 4.48%.

(b) In Methanol: A solution of **23** (309 mg) in methanol (4 ml) was saturated under ice-cooling with HCl and the resulting solution was stirred at room temperature for 15.5 h. After evaporation *in vacuo*, the residue was subjected to column-

chromatography on silica gel [benzene–hexane (1:4)] to afford methyl (3,4-methylenedioxyphenyl)acetate (183 mg: 80% yield) as a pale yellow oil which was identified by the comparison of its IR and NMR spectra with those of the authentic sample prepared by the usual esterification (HCl–methanol) of (3,4-methylenedioxyphenyl)acetic acid.

Condensation of 3,4,5-Trimethoxybenzaldehyde with ***1***. To a solution of **1** (3.353 g) and 3,4,5-trimethoxybenzaldehyde (5.016 g) in THF (50 ml), was added a 40% methanolic solution (5 ml) of Triton B and the resulting solution was refluxed for 12 h. After the addition of dichloromethane (50 ml) followed by acidification with 4.5 M sulfuric acid, the organic layer was separated, washed with water, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was separated by column-chromatography on silica gel (dichloromethane) to give 2-(3,4,5-trimethoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**24**; 5.465 g: 71% yield) as a yellow oil, which was crystallized from diethyl ether–hexane to afford colorless crystals: mp 86.5—87.5 °C; IR (KBr) 1058 cm^{-1}; NMR ($CDCl_3$) δ=2.30 (3H, s), 2.70 (3H, s), 3.83 (9H, s), 7.21 (2H, s), and 7.47 (1H, s). Found: C, 51.71; H, 6.00; S, 20.80%. Calcd for $C_{13}H_{18}O_4S_2$: C, 51.92; H, 6.00; S, 21.20%.

*Decomposition of 2-(3,4,5-Trimethoxyphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**24**) with HCl.* *(a) 1 M Ethanolic Solution of HCl*: To a solution of **24** (502 mg) in ethanol (9 ml), was added a saturated ethanolic solution (1 ml) of HCl and then the resulting solution was refluxed for 1.5 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel (benzene) to give ethyl (3,4,5-trimethoxyphenyl)acetate (248 mg) as a pale yellow oil and a mixture (98 mg) which was shown to consist of ethyl (3,4,5-trimethoxyphenyl)acetate and an unknown compound in the ratio of 3:2. This unknown compound exhibits NMR signals in $CDCl_3$ at δ=1.25 (3H, t, J=7 Hz), 2.06 (3H, s), 3.81 (9H, s), 4.11 (2H, q, J=7 Hz), 4.38 (1H, s), and 6.67 (2H, s), and it was deduced to be ethyl (3,4,5-trimethoxyphenyl)(methylthio)acetate. Therefore, the total yield of ethyl (3,4,5-trimethoxyphenyl)acetate was calculated to be 72%. An analytical sample was obtained by further column-chromatography and short-path distillation (bath temperature 150 °C/0.09 Torr): IR (neat) 1737 cm^{-1}; NMR ($CDCl_3$) δ=1.23 (3H, t, J=7 Hz), 3.48 (2H, s), 3.78 (9H, s), 4.11 (2H, q, J=7 Hz), and 6.46 (2H, s); MS (70 eV), *m/e* (relative intensity), 254 (M^+, 75), 181 (100), 167 (28), and 29 (33). Found: C, 61.31; H, 7.15%. Calcd for $C_{13}H_{18}O_5$: C, 61.41; H, 7.13%.

(b) In Saturated Ethanolic Solution of HCl: A saturated ethanolic solution (10 ml) of HCl was added to **24** (495 mg) and the resulting mixture was stirred at room temperature for 1.5 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel (benzene) to give ethyl (3,4,5-trimethoxyphenyl)acetate (34 mg) as a yellow oil and a mixture (111 mg) which was shown by an NMR analysis to consist of ethyl (3,4,5-trimethoxyphenyl)acetate and ethyl (3,4,5-trimethoxyphenyl)(methylthio)acetate in the ratio of 42:35. The yield of the ethyl (3,4,5-trimethoxyphenyl)-acetate was calculated to be 62%.

Condensation of p-*Chlorobenzaldehyde with* ***1***. *(a) Triton B in Dioxane*: To a solution containing **1** (1.17 g) and *p*-chlorobenzaldehyde (1.33 g) in dioxane (7 ml), was added a 40% methanolic solution (1 ml) of Triton B and the mixture was stirred at 80 °C for 25 h. After the addition of dichloromethane (100 ml), the resulting mixture was washed with *ca.* 2 M hydrochloric acid (10.5 ml), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to give 2-(*p*-chlorophenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**25**; 1.19 g: 51% yield) as a colorless oil: IR (neat) 1062 cm^{-1}; NMR (CCl_4) δ=2.32 (3H, s), 2.68 (3H, s), 7.36 (2H, d, J=8.7 Hz), 7.48 (1H, s), and 7.82 (2H, d, J=8.7 Hz). Found: C, 48.63; H, 4.81%. Calcd for $C_{10}H_{12}OS_2Cl$: C, 48.67; H, 4.49%.

Since **1** (354 mg) was recovered, the yield based on the consumed **1** was calculated to be 73%.

(b) Triton B in THF: To a solution containing *p*-chlorobenzaldehyde (501 mg) and **1** (445 mg) in THF (5 ml), was added a 40% methanolic solution (0.5 ml) of Triton B, the resulting mixture was refluxed for 6 h. After the addition of dichloromethane (30 ml), the mixture was washed with 0.5 M sulfuric acid (10 ml) and water (30 ml×2), dried (Na_2SO_4), and evaporated *in vacuo*. By column-chromatography on silica gel [dichloromethane–ethyl acetate (3:1)], **25** (574 mg: 65% yield) was given as a yellow oil.

(c) NaOH and Excess of ***1***: After a mixture of **1** (8.83 g) and powdered sodium hydroxide (0.46 g) was stirred at 70 °C for 30 min, *p*-chlorobenzaldehyde (4.99 g) was added and the resulting mixture was further stirred at 70 °C for 1 h. After the addition of dichloromethane (100 ml) followed by being washed with 0.5 M sulfuric acid (20 ml) and water (100 ml×3), the organic layer was dried (Na_2SO_4) and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to afford **25** (6.118 g: 70% yield) as a pale yellow oil.

*Decomposition of 2-(*p*-Chlorophenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**25**) with HCl.* *(a) In a Saturated Ethanolic Solution of HCl*: A solution containing **25** (260 mg) was saturated with HCl gas under ice-cooling. The reaction mixture was allowed to stand at room temperature overnight. Evaporation *in vacuo*, followed by column-chromatography on silica gel [benzene–hexane (1:1)], gave ethyl (*p*-chlorophenyl)acetate (193 mg: 92% yield) which was identified by the comparison of its IR spectrum with that of the authentic sample prepared by the usual esterification (HCl–ethanol) of commercially available (*p*-chlorophenyl)acetic acid.

(b) In Saturated Methanolic Solution of HCl: After a solution of **25** (517 mg) in methanol (6 ml) was saturated with HCl under cooling with ice–water, the resulting solution was stirred at room temperature for 2.5 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel [benzene–hexane (1:4)] to give methyl (*p*-chlorophenyl)-acetate (303 mg: 78% yield) as a colorless oil which was identified by the comparison of its IR and NMR spectra with those of the authentic sample prepared by the usual esterification (HCl–methanol) of (*p*-chlorophenyl)acetic acid.

(c) In 1-Butanol: After a solution of **25** (538 mg) in 1-butanol (5 ml) was saturated with HCl under cooling with ice–water, the resulting solution was stirred at room temperature for 2.5 h. Evaporation *in vacuo*, followed by column-chromatography on silica gel [benzene–hexane (1:4)], afforded butyl (*p*-chlorophenyl)acetate (396 mg: 80% yield) as a colorless oil: IR (neat) 1740 cm^{-1}; NMR ($CDCl_3$) δ= 0.8—1.8 (7H, m), 3.45 (2H, s), 3.99 (2H, t, J=7 Hz), and 7.19 (4H, s). Found: C, 63.80; H, 6.41%. Calcd for $C_{12}H_{15}O_2Cl$: C, 63.57; H, 6.67%.

Condensation of o-*Bromobenzaldehyde with* ***1***. To a solution of **1** (7.01 g) and *o*-bromobenzaldehyde (9.99 g) in THF (50 ml), was added a 40% methanolic solution (4 ml) of Triton B and the resulting mixture was refluxed for 46 h. After the addition of dichloromethane (100 ml), the mixture was washed with 0.5 M sulfuric acid (20 ml), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was subjected to column-chromatography on silica gel (dichloromethane and

ethyl acetate) to give 2-(*o*-bromophenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**26**; 8.026 g: 51% yield) as a pale yellow oil: bp 167—170 °C/0.15—0.2 Torr; IR (neat) 1036 cm^{-1}; NMR ($CDCl_3$) δ=2.32 (3H, s), 2.77 (3H, s), 7.0—7.8 (4H, m) and 7.98 (1H, diffused s). Found: C, 41.08; H, 3.76%. Calcd for $C_{10}H_{11}S_2OBr$: C, 41.24; H, 3.81%.

*Decomposition of 2-(o-Bromophenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**26**) with HCl.* To a solution of **26** (505 mg) in ethanol (4.5 ml), was added a saturated ethanolic solution (0.5 ml) of HCl and the resulting solution was refluxed for 3 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel and elution with hexane–benzene (9:1) gave ethyl (*o*-bromophenyl)acetate (390 mg: 92% yield) as a colorless oil: bp 75—80 °C/0.1 Torr; IR (neat) 1737 cm^{-1}; NMR ($CDCl_3$) δ=1.20 (3H, t, J=7 Hz), 3.49 (2H, s), 4.08 (2H, q, J=7 Hz), and 7.00—7.42 (4H, m). Found: C, 49.25; H, 4.53; Br, 33.06%. Calcd for $C_{10}H_{11}O_2Br$: C, 49.41; H, 4.56; Br, 32.87%.

Condensation of p-*Isopropylbenzaldehyde with **1**. (a) Triton B in THF*: To a solution of **1** (2.24 g) and *p*-isopropylbenzaldehyde (2.65 g) in THF (30 ml), was added a 40% methanolic solution (2 ml) of Triton B and the resulting solution was refluxed for 25 h. After the addition of dichloromethane (50 ml) and being washed with 1.5 M sulfuric acid (20 mi), the organic layer was dried (K_2CO_3) and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (dichloromethane) to give 2-(*p*-isopropylphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**27**; 3.013 g: 68% yield) as a pale yellow oil: bp 170—172 °C/0.2 Torr; IR (neat) 1063 cm^{-1}; NMR ($CDCl_3$) δ=1.25 (6H, d, J=7 Hz), 2.28 (3H, s), 2.70 (3H, s), 2.89 (1H, septet, J=7 Hz), 7.32 (2H, d, J=7 Hz), 7.57 (1H, s), and 7.81 (2H, d, J=7 Hz). Found: C, 61.24; H, 7.14; S, 24.95%. Calcd for $C_{13}H_{18}OS_2$: C, 61.38; H, 7.13; S, 25.20%.

*(b) NaOH and Excess of **1***: To a mixture of **1** (12.6 g) and powdered sodium hydroxide (1.35 g), was added *p*-isopropylbenzaldehyde (10.1 g) dropwise over 20 min under being stirred at 60 °C, and the resulting mixture was further stirred at 60 °C for 5 h. After dichloromethane (100 ml) was added, the mixture was washed with 0.5 M sulfuric acid (25 ml) and water (100 ml×2). The organic layer was dried (Na_2SO_4), evaporated *in vacuo*, and column-chromatographed on silica gel [benzene–dichloromethane (3:1)] to give **27** (14.45 g: 83% yield) as a yellow oil.

*Decomposition of 2-(p-Isopropylphenyl)-1-(methylsulfinyl)-1-(methylthio)ethylene (**27**) with HCl.* To a solution of **27** (1.01 g) in ethanol (9 ml), was added a saturated ethanolic solution of HCl and the solution was refluxed for 3 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel (hexane) to give ethyl (*p*-isopropylphenyl)-acetate (789 mg: 96% yield) as a colorless oil. An analytical sample was obtained by a short-path distillation (bath temperature 110—115 °C/0.3 Torr): IR (neat) 1738 cm^{-1}; NMR ($CDCl_3$) δ=1.20 (3H, t, J=7 Hz), 1.20 (6H, d, J=7 Hz), 2.83 (1H, septet, J=7 Hz), 3.50 (2H, s), 4.08 (2H, q, J=7 Hz), and 7.12 (4H, s). Found: C, 75.52; H, 8.81%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

*Condensation of 2-Thiophenecarbaldehyde with **1**. (a) Triton B in THF*: To a solution containing 2-thiophenecarbaldehyde (10.315 g) and **1** (11.42 g) in THF (50 ml), was added a 40% methanolic solution (3 ml) of Triton B and then the resulting mixture was refluxed for 6 h. After the addition of dichloromethane (100 ml), the mixture was washed with 0.5 M sulfuric acid, dried (Na_2SO_4) and evaporated *in vacuo*. The residue was distilled *in vacuo* to afford **17** (17.31 g: 86% yield) as a pale yellow oil: bp 147—152 °C/0.11—0.13 Torr; IR (neat) 1055 and 710 cm^{-1}; NMR ($CDCl_3$) δ=2.35 (3H, s), 2.70 (3H, s), 7.05 (1H, m), 7.40 (2H, m), and 7.86 (1H, s). Found: C, 43.81; H, 4.83; S, 44.00%. Calcd for $C_8H_{10}OS_3$: C, 44.00; H, 4.62; S, 44.06%.

(b) KOH in Methanol: After 2-thiophenecarbaldehyde (1.043 g) and **1** (1.221 g) were dissolved in methanol (15 ml), potassium hydroxide (440 mg) was added and the resulting solution was refluxed for 24 h. The solution was evaporated *in vacuo* and dichrolomethane (100 ml) was added. The deposited insoluble matter was filtered off and the filtrate was evaporated *in vacuo*. The residue was separated by column-chromatography on silica gel (dichloromethane) to afford **17** (1.689 g: 83% yield) as a pale yellow oil.

*Decomposition of **17** with HCl. (a) At Room Temperature*: To a solution of **17** (872 mg) in ethanol (10 ml), was added a saturated ethanolic solution (1 ml) of HCl and the resulting solution was stirred under ice-cooling for 2 h and then at room temperature for 66 h. The solution was evaporated *in vacuo* and separated by column-chromatography on silica gel [hexane–benzene (1:1)] to give ethyl (2-thienyl)acetate (544 mg: 80% yield) as a pale yellow oil. This ester was identified with the authentic sample prepared by the usual esterification (HCl–ethanol) of (2-thienyl)acetic acid.

(b) Under Refluxing: To a solution of **17** (1.762 g) in ethanol (30 ml), was added a saturated ethanolic solution (2 ml) of HCl and the solution was refluxed for 22.5 h. After evaporation *in vacuo*, the residue was column-chromatographed on silica gel [benzene–hexane (1:1)] to give a pale yellow oil (1.172 g) which was shown by an NMR analysis to consist of ethyl (2-thienyl)acetate (1.039 g: 79% yield) and ethyl (methylthio)(2-thienyl)acetate (133 mg: 8% yield).[19]

Condensation of p-*Chlorobenzaldehyde with Phenyl (Phenylthio)-methyl Sulfoxide.* To a solution containing *p*-chlorobenzaldehyde (446 mg) and phenyl (phenylthio)methyl sulfoxide[3] (545 mg) in THF (5 ml), was added a 40% methanolic solution (0.5 ml) of Triton B and the mixture was refluxed for 5.5 h. After the addition of dichloromethane (100 ml), the mixture was washed with 0.5 M sulfuric acid, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was separated by column-chromatography on silica gel (dichloromethane) to give 2-(*p*-chlorophenyl)-1-(phenylsulfinyl)-1-(phenylthio)-ethylene (**28**; 708 mg: 60% yield) as colorless crystals: mp 97.5—98.5 °C; IR (KBr) 1042 cm^{-1}: NMR (CCl_4) δ=7.06 (5H, s), 7.15—7.80 (9H, m), and 7.98 (1H, s). Found: C, 64.36; H, 3.85; S, 17.47%. Calcd for $C_{20}H_{15}OS_2Cl$: C, 64.76; H, 4.08; S, 17.29%.

*Decomposition of 2-(p-Chlorophenyl)-1-(phenylsulfinyl)-1-(phenylthio)ethylene (**28**) with HCl.* A solution containing **28** (180 mg) in ethanol (10 ml) was saturated with HCl gas under ice-cooling. The reaction mixture was allowed to stand overnight at room temperature, and then evaporated *in vacuo*. The residue was separated by column-chromatography on silica gel (hexane and benzene) to give diphenyl disulfide (94 mg: 89% yield) and ethyl (*p*-chlorophenyl)-acetate (82 mg: 90% yield).

(Received January 23, 1979)

The Diels-Alder reaction of five derivatives of 2-methoxytropone with dimethyl acetylenedicarboxylate proceeds regiospecifically giving dimethyl 1-methoxy-2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylates, except in the case of 5-isopropyl-2-methoxytropone. The adducts undergo rearrangement selectively to dimethyl 7-methoxy-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates, upon heating under reflux in xylene. Regiochemical aspects of the cycloaddition and mechanistic aspects of the rearrangement are discussed.

Tropone (2,4,6-cycloheptatrien-1-one, **1**) is known to react with various kinds of olefins giving Diels-Alder type 1,4-addition products.[1–12] Kinstle and Carpenter, and Uyehara *et al.* found independantly that **1** reacts with an acetylenic dienophile, dimethyl acetylenedicarboxylate (DMAD), to give dimethyl 6,7-dicarboxylate of bicyclo[3.2.2]nona-3,6,8-trien-2-one (homobarrelenone), (**2**).[13] The adduct is thermally labile, undergoing rearrangement selectively to dimethyl 1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate (**3**) upon heating under reflux in xylene.[13b] Dihydroindenone **3** is stable under acidic conditions, but is extreemly sensitive to the base, sodium methoxide.[14] When **3** was treated with the base in methanol at 0 °C, dimethyl 3-oxo-1,7-indandicarboxylate (**4**) was formed within a minute.

In order to know the mechanism of the rearrangement, we required a series of dimethyl 1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates. There are two prerequisites for the synthesis of the dihydroindenones from tropones in practical yield: regioselective Diels-Alder reaction to give homobarrelenones and selective rearrangement of the adducts to the corresponding dihydroindenones.

When 2-methoxytropone (**5**) was heated with DMAD at 90 °C, a regiospecific Diels-Alder reaction proceeded giving dimethyl 1-methoxyhomobarrelenone-6,7-dicarboxylate (**6**) in an excellent yield.[15] Similar specificity of the reaction positions of tropone **5** was observed for a reaction with methyl propiolate.[16] When the adduct **6** was heated under reflux in xylene, dimethyl 7-methoxy-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate (**7**) was formed selectively.[15] These results prompted us to investigate a synthesis of the dihydroindenones from 2-methoxytropones.

Results and Discussion

Diels-Alder Reaction of 2-Methoxytropones with Dimethyl Acetylenedicarboxylate (DMDA). 2-Methoxytropone **5** is obtained by careful treatment of tropolone (2-hydroxy-2,4,6-cycloheptatrien-1-one) with diazomethane.[17] A series of alkyltropolones, 3-, 4-, and 5-isopropyl derivatives, is easily available.[18] Diazomethane treatment of 3-isopropyltropolone gives only 7-isopropyl-2-methoxytropone (**8d**).[19] A similar treatment of 4-isopropyltropolone gives a miture of 4- and 6-isopropyl-2-methoxytropones (**8a** and **8c**, respectively), which can not be separated from each other.[20] Compounds **8a** and **8c** have been prepared from 7-iodo-4-isopropyl and 3-iodo-6-isopropyl-2-methoxytropones, respectively, by catalytic hydrogenolysis.[21] 5-Isopropyl-2-methoxytropone (**8b**) is derived from 5-isopropyltropolone with diazomethane.[22]

The conditions and the results of the Diels-Alder reaction of 2-methoxytropones (**8a**—**8d**) with DMAD are given in Table 1. Each reaction temperature was kept as low as possible, since once a homobarrelenone derivative undergoes rearrangement to the corresponding dihydroindenone in the presence of DMAD, they react easily and a complex mixture of polysubstituted

† Deceased February 4, 1976.

benzenes is formed.[12b,15] The structures of the addition products (**9a**, **9b**, **9c**, and **9d**) were deduced by means of their spectral data, mainly of the ^{1}H-NMR spectra.

Regioselectivity of the 1,4-additions is surprisingly high. DMAD underwent addition to **8a**, **8c**, and **8d** only at the 2,5-position, and to **8b** only at the 4,7-position. For explanation of the regiospecificity, we propose three major factors: 1) the difference between both primary interaction energies due to the methoxyl group, an electron-donating substituent; 2) the favorable secondary interaction between the ether oxygen of the tropones and the carbonyl carbon of the dienophile (an n-pi interaction); 3) the steric repulsion between the isopropyl group and the methoxycarbonyl group, in the transition states of addition.

Ethylene, a simple and symmetrical dienophile, underwent addition to 2-methoxytropone at 2,5- and 4,7-positions in the ratio of 87.7 and 12.3.[23] No secondary interaction would take place in the transition states leading to the adducts. The preferential addition of ethylene to the 2,5-position rather than to the 4,7-position was supported by the difference between the calculated interaction energies[23] by means of PMO equation proposed by Salem.[24] Maleic anhydride, a symmetrical dienophile, reacted with **5** only at the 2,5-position.[25] Thus, Diels-Alder type 1,4-addition of symmetrical dienophiles is favorable at the 2,5-position of 2-methoxytropone. Each isopropyl-2-methoxytropone could be regarded as a perturbed 2-methoxytropone. The difference between primary interaction energies of both reaction positions of **8a**, **8b**, **8c**, and **8d** with the dienophile should be similar to that of 2-methoxytropone with the dienophile.

Low regio- and stereoselectivities have been observed for the reactions of **5** and asymmetrical oleficic dienophiles, such as acrylonitrile and methyl acrylate.[3] However, methyl propiolate, an asymmetrical acetylenic dienophile, underwent addition regioselectively to **5** giving the adduct (**10**) in 67.5% yield with a small amount of the isomer (**11**).[16] Calculated interaction energies for the four possible regiochemical combinations of **5** and methyl propiolate suggest that the major product should be **11**. Disagreement with experimental results indicates that the regioselectivity can not be explained only by primary orbital interactions. In the transition state leading to **10**, the distance between the ether oxygen and the carbonyl carbon of the dienophile should be remarkably short, because of an acetylenic dienophile, and the secondary interaction between them could not be negligible. The same interaction seems to contribute to the selective addition of DMAD to the 2,5-position of 2-methoxytropones **5**, **8a**, **8c**, and **8d**.

Reversal of regiospecificity during the addition of DMAD to **8b** may be explained by large steric repulsion between the bulky isopropyl group and the methoxycarbonyl group in the transition state leading to the addition of the 2,5-position of **8b**, again because of the linear dienophile. This steric repulsion also contributes to the preferential formation of **9a** and **9d** from **8a** and **8d**, respectively.

DMAD underwent addition to the 2,5-position of 2,5-dimethoxytropone (**8e**) giving the homobarrelenone (**9e**) with dihydroindenone (**12e**) even at 80 °C. Formation of **9e** reflects the contribution of that secondary interaction.

Thermal Rearrangements of the Homobarrelenones to cis-*3a,7a-Dihydroinden-1-ones.* The process of the thermal rearrangement of **2** to the dihydroindenone **3**, proposed by Kinstle and Carpenter, involves a [3,3]-sigmatropic shift to 7-*syn*-norcaradienylketene (**13**) followed by a [3,5]-sigmatropic shift (antarapfacial or Möbius) to **3**.[13a] If the mechanism is correct, there are four possible routes, each of them giving a paticular isomer as shown in Scheme 1. Preferential formation of **3** follows path a and path 1. Dimethyl 1-oxoindan-

4,5-dicarboxylate (**14**), a minor product from **2**,[13b] should be formed through path a and path 2, followed by aromatization. Thus, preferential formation of **3** from **2** is interesting from a synthetic point of view. Study on the substituent effects for both sigmatropic rearrangements is of interest.

The rearrangement of **2** to **3** was performed by gas-phase[13a] or solution thermolysis.[13b] A concentrated solution of **2** gave many by-products, in the latter. The conditions and the results of the thermolysis of the homobarrelenones are given in Table 2. Compound **8b** was stable under the same conditions for the solution thermolysis of other isomers and at 350 °C *in vacuo*. Gas-phase thermolysis of **8b** at 450 °C gave unidentified decomposed products. The other homobarrelenones underwent rearrangement to the corresponding dihydroindenones through path a and path 1.

Thermal reactions of the monosubstituted homobarrelenone (**15**), derived from **1** and methyl propiolate,[16] yielded methyl 1-oxoindan-4-carboxylate (**16**). The process of the rearrangement involves path a and path 2 and aromatization. Gas-phase pyrolysis of **10** gave dihydroindenone (**17**). ^{1}H-NMR spectrum shows a multiplet at δ=3.97 (dddd, $J_{9,2}$=2.5 Hz, $J_{9,3}$=2.7, $J_{9,4}$=4.8, and $J_{9,5}$=1.7), a typical pattern of H_9 in *cis*-3a,7a-dihydroinden-1-ones.[26] The yield of **17** decreased when **10** was heated in a solution. The machanism of the process involves path a and path 1.

The regioselectivity of the [3,3]-sigmatropic shifts (path a is preferred) seems to be due to the electron-withdrawing substituents at the 8 and/or the 9 positions. The substituents should decrease the energy level of the HOMO of the acceptor radical fragment[27] in the transition state giving intermediates such as **13** through path a.

The other selective sigmatropic shifts (path 1 is preferred) may be caused by the differences between the pi-electron densities and the magnitude of the coefficients of each reaction position of the HOMO of the migrating framework.[27]

Experimental

General. Melting points were determined on a Thomas Hoover MP Apparatus, and are uncorrected. Infrared spectra were recorded on Hitachi EPI-3 and Model 215 spectrophotometers. Ultraviolet spectra were recorded on a Hitachi EPS-2T spectrometer. NMR spectra were obtained on Varian A-60 and HA-100 spectrometers equipped with spin decouplars, using tetramethylsilane as an internal standard. The mass spectral studies were conducted using a Hitachi RMU-6D spectrometer.

*2,5-Dimethyl-2,4,6-cycloheptatrien-1-one (**8e**).* Dimethyl sulfate (3.7 g) was added to a solution of 5-hydroxytropolone[28] (1.5 g) in 2 M-sodium hydroxide (20 ml) over a period of 2.5 h at 0 °C, and the mixture was stirred at room temperature for 2 h. After being heated under reflux for 30 min, the solution was cooled to room temperature, acidified (pH 5) with 10% hydrochloric acid and extracted with three portions of dichloromethane (20 ml each). The extracts were combined, dried ($MgSO_4$) and concentrated giving brown oil (1.6 g), a mixture of methoxytropones and **8e**. The mixture was dissolved in dichloromethane and treated with an ethereal solution of diazomethane. Evaporation of the solvents and crystallization from hexane–benzene gave pale yellow prisms (1.5 g, 83% yield). **8e**: mp 74—75 °C; IR (KBr) 1630, 1595, 1563, and 1518 cm^{-1}; NMR ($CDCl_3$) δ=3.86 (3H, s, OCH_3), 3.96 (3H, s, OCH_3), and 6.35—7.27 (4H, m).

*Preparation of Homobarrelenone Derivatives (**9a**—**9e**). General Procedure*: Each 2-methoxytropone and DMAD (0.9—1.1 equiv) were placed in a Pyrex tube, sealed, and heated at 90±0.5 °C for 40 h (**8a**—**8d**) or at 80±0.5 °C for 100 h (**8e**). Isolation of each product was performed with chromatography on a silica-gel column or an alumina (neutral) column (for **9a** and **12a**) using gradient mixtures of benzene and ethyl acetate.

*Physical Properties of the New Homobarrelenones. A) Dimethyl 9-Isopropyl-1-methoxy-2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylate (**9a**)*: Pale yellow oil; UV_{max} (CH_3OH) 215 (log ε 4.13), 285 (3.15)^{sh} and 345 nm (2.60); IR (film) 1740, 1722, 1692, 1666, and 1640 cm^{-1}; NMR ($CDCl_3$) δ=1.11 (6H, d, J=7.0 Hz, $CH_3\times2$), 2.46 (1H, sept of d, J=7.0 and 1.5 Hz, $CH(CH_3)_2$), 3.61 (3H, s), 3.80 (3H, s), 3.84 (3H, s), 4.32 (1H, ddd, J=8.1, 1.5 and 0.9 Hz, H_5), 5.44 (1H, dd, J=10.8 and 0.9 Hz, H_3), 6.09 (1H, dd, J=1.5 and 1.5 Hz, H_8), and 7.15 (1H, dd, J=10.8 and 8.1 Hz, H_4). Found: M$^+$, 320.

*B) Dimethyl 9-Isopropyl-3-methoxy-2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylate (**9b**)*: Yellow oil; UV_{max} (CH_3OH) 227 (log ε 3.96), 289 (3.41) and 364 nm (2.58)^{sh}; IR (film) 1720, 1685, and 1640 cm^{-1}; NMR($CDCl_3$) δ=1.09 (6H, d, J=6.7 Hz, $CH_3\times2$), 2.49 (1H, broad sept, J=6.7 Hz, $CH(CH_3)_2$), 3.40 (3H, s), 3.74 (6H, s), 3.96 (1H, dd, J=9.5 and 2.3 Hz, H_5), 4.42 (1H, d, J=7.4 Hz, H_1), 5.98 (1H, ddd, J=7.3, 2.3 and 1.5 Hz, H_8), and 6.05 (1H, d, J=9.5 Hz, H_4). Found: M$^+$, 320.

*C) Dimethyl 4-Isopropyl-1-methoxy-2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylate (**9c**)*: Pale yellow oil; UV_{max} (CH_3OH) 224 (log ε 4.25), 287 (3.22)^{sh} and 335 nm (2.55)^{sh}; IR (film) 1740, 1720, 1678, 1658, and 1621 cm^{-1}; NMR ($CDCl_3$) δ=1.11 (3H, d, J=6.5 Hz, CH_3), 1.13 (3H, d, J=6.5 Hz, CH_3), 2.49 (1H, sept, J=6.5 Hz, $CH(CH_3)_2$), 3.53 (3H, s), 3.71 (6H, s), 4.37 (1H, ddd, J=6.0, 1.8 and 0.9 Hz, H_5), 5.01 (1H, dd, J=0.9 and 0.9 Hz, H_3), 6.56 (1H, dd, J=8.4 and 1.8 Hz, H_8), and 6.70 (1H, dd, J=8.4 and 6.0 Hz, H_9). Found: M$^+$, 320.

*D) Dimethyl 3-Isopropry-1-methoxy-2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylate (**9d**)*: Colorless needles (from CH_3OH), mp 107.5—108.5 °C; UV_{max} (CH_3OH) 222 (log ε 4.43), 292 (2.82)^{sh} and 362 nm (2.27); IR (KBr) 1729, 1715, 1672, 1657, and 1620 cm^{-1}; NMR ($CDCl_3$), δ=0.89 (3H, d, J=7.0 Hz, CH_3), 0.91 (3H, d, J=7.0 Hz, CH_3), 2.78 (1H, sept, J=7.0 Hz, $CH(CH_3)_2$), 3.59 (3H, s), 3.78 (3H, s), 3.82 (3H, s), 4.44 (1H, ddd, J=8.0, 6.5, and 1.2 Hz, H_5), 6.58 (1H, dd, J=8.5 and 1.4 Hz, H_8), 6.84 (1H, dd, J=8.0 and 1.2 Hz, H_4), and 6.88 (1H, dd, J=8.5 and 6.5 Hz, H_9). Found: C, 63.45; H, 6.29%; M$^+$, 320. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%; M, 320.

*E) Dimethyl 1,5-Dimethoxy-2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylate (**9e**)*: colorless prisms (from CCl_4), mp 101–102 °C; UV_{max} (CH_3OH) 214 (log ε 3.90), 285

(2.85)^{sh} and 360 nm (1.91); IR (KBr) 1740, 1693, 1652, and 1620 cm^{-1}; NMR ($CDCl_3$) δ=3.45 (3H, s), 3.53 (3H, s), 3.78 (3H, s), 3.83 (3H, s), 5.24 (1H, d, J=11.8 Hz, H_3), 6.55 (1H, J=9.3 Hz, H_8), 6.97 (1H, d, J=9.3 Hz, H_9), and 7.07 (1H, d, J=11.8 Hz, H_4). Found: C, 58.61; H, 5.06%; M$^+$, 308. Calcd for $C_{15}H_{16}O_7$: C, 58.44; H, 5.23%; M, 308.

Thermal Rearrangements of Homobarrellenones. General Procedure. A) Solution Thermolysis: A solution of each homobarrelenone in dry xylene (0.04—0.046 M) was heated under reflux for 40 h. After removal of the solvent, purification of the product was performed by chromatography on a silica-gel column and/or by recrystallization.

B) Gas-phase Thermolysis: A sample of each homobarrelenone was placed in a goose-necked small flask attached to a 2×15 cm oven-heated Pyrex tube, placed obliquely (45°), packed with Pyrex tips. The other end of the tube was connected to a Dry-Ice trap. The end of the trap was connected to a vacuum pump. The system was evacuated (0.15—0.2 Torr), and the Pyrex tube was heated to 350 °C. The flask containing the sample was then heated with a nichrome wound heating jacket to 100—150 °C. The pyrolysate was purified by chromatography and/or recrystallization.

Physical Properties of the New cis-*3a,7a-Dihydroindenones. A) Dimethyl 5-Isopropyl-6-methoxy-1-oxo-*cis-*3a,7a-dihydroindene-3a,7a-dicarboxylate (**12a**)*: Colorless needles (from CH_3OH), mp 149—150 °C; UV_{max} (CH_3OH) 215 (log ε 4.13), 282 (3.61) and 347 nm (2.92); IR (KBr) 1725, 1704, 1658, and 1595 cm^{-1}; NMR ($CDCl_3$) δ=1.06 (3H, d, J=7.6 Hz, CH_3), 1.07 (3H, d, J=7.6 Hz, CH_3), 2.36 (1H, sept of d, J=7.6 and 2.0 Hz, $CH(CH_3)_2$), 3.48 (3H, s), 3.66 (3H, s), 3.68 (3H, s), 5.18 (1H, d, J=1.8 Hz, H_6), 5.19 (1H, dd, J=2.0 and 1.8 Hz, H_4), 6.45 (1H, d, J=5.8 Hz, H_2), and 7.43 (1H, d, J=5.8 Hz, H_3). Found: C, 64.03; H, 6.42%; M$^+$, 320. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%; M, 320.

*B) Dimethyl 3-Isopropyl-7-methoxy-1-oxo-*cis-*3a,7a-dihydroindene-3a,7a-dicarboxylate (**12c**)*: Colorless needles (from CH_3OH), mp 139–140 °C; UV_{max} (CH_3OH) 221 (log ε 4.16), 284 (3.57) and 338 nm (2.75); IR (KBr) 1732, 1705, 1655, and 1622 cm^{-1}; NMR ($CDCl_3$) δ=1.32 (3H, d, J=6.9 Hz, CH_3), 1.35 (3H, d, J=6.9 Hz, CH_3), 2.61 (1H, broad sept, J=6.9 Hz, $CH(CH_3)_2$), 3.67 (3H, s), 3.69 (3H, s), 3.70 (3H, s), 5.23 (1H, dd, J=6.5 and 0.8 Hz, H_6), 5.88 (1H, dd, J=10.0 and 0.8 Hz, H_4), 6.18 (1H, J=10.0 and 6.5 Hz, H_5), and 6.35 (1H, d, J=0.8 Hz, H_2). Found: C, 63.54; H, 6.38%; M$^+$, 320. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%; M, 320.

*C) Dimethyl 2-Isopropyl-7-methoxy-1-oxo-*cis-*3a,7a-dihydroindene-3a,7a-dicarboxylate (**12d**)*: Colorless needles (from CH_3OH), mp 123.5–124.5 °C; UV_{max} 220 (log ε 4.16), 283 (3.68) and 340 nm (2.86); IR (KBr) 1739, 1720, 1651, and 1594 cm^{-1}; NMR ($CDCl_3$) δ=1.09 (3H, d, J=7.1 Hz, CH_3), 1.16 (3H, d, J=7.1 Hz, CH_3), 2.76 (1H, sept of d, J=7.1 and 1.0 Hz, $CH(CH_3)_2$), 3.68 (9H, s), 5.23(1H, d, J=6.6 Hz, H_6), 5.52 (1H, d, J=10.0 Hz, H_4), 6.07 (1H, dd, J=10.0 and 6.6 Hz, H_5), and 7.01 (1H, d, J=1.0 Hz, H_3). Found: C, 63.73; H, 6.30%; M$^+$, 320. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%; M, 320.

*D) Dimethyl 4,7-Dimethoxy-1-oxo-*cis-*3a,7a-dihydroindene-3a,7a-dicarboxylate (**12e**)*: Pale yellow needles (from CH_3OH), mp 166—167 °C; UV_{max} (CH_3OH) 217 (log ε 4.00), 290 (3.73) and 365 nm (2.83); IR (KBr) 1746, 1712, 1662, and 1593 cm^{-1}; NMR ($CDCl_3$) δ=3.61 (3H, s), 3.66 (3H, s), 3.67 (3H, s), 3.71 (3H, s), 5.14 (2H, s, H_5 and H_6), 6.55 (1H, d, J=5.9 Hz, H_2), and 7.71 (1H, d, J=5.9 Hz, H_3). Found: C, 58.68; H, 5.09%; M$^+$, 308. Calcd for $C_{15}H_{16}O_7$: C, 58.44; H, 5.23%; M, 308.

*E) Methyl 4-Methoxy-3-oxo-*cis-*3a,7a-dihydroindene-3a-carboxylate (**17**)*: Colorless needles (from ether), mp 89—90 °C; UV_{max} (CH_3OH) 210 (log ε 4.10), 279 (3.63) and 344 nm (2.69); IR (KBr) 1736, 1704, 1651, and 1590 cm^{-1}; NMR ($CDCl_3$) δ=3.65 (3H, s) 3.72 (3H, s), 3.97 (1H, dddd, J=4.8, 2.7, 2.5, and 1.7 Hz, H_9), 5.17 (1H, d, J=6.7 Hz, H_6), 5.42 (1H, dd, J=9.7 and 4.8 Hz, H_4), 5.98 (1H, ddd, J=9.7, 6.7, and 1.7 Hz, H_5), 6.35 (1H, dd, J=5.7 and 2.5 Hz, H_2), and 7.49 (1H, dd, J=5.7 and 2.7 Hz, H_3). Found: C, 65.27; H, 5.53%; M$^+$, 220. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49%; M, 220.

*Methyl 1-Oxo-indan-4-carboxylate (**16**)*: Colorless needles (from CH_3OH), mp 102—103 °C; IR (KBr) 1710, 1580, and 760 cm^{-1}; NMR ($CDCl_3$) δ=2.70 (2H, m), 3.48 (2H, m), 3.95 (3H, s), 7.45 (1H, ddt, J=10.0, 10.0 and 0.75 Hz), 7.95 (1H, ddd, J=10.0, 1.3 and 0.5 Hz), and 8.27 (1H, dd, J=10.0 and 1.3 Hz). Found: M$^+$, 190.

*Hydrolysis of Methyl 1-Oxoindan-4-carboxylate (**16**).* A mixture of a solution of **16** (100 mg) in dioxane (5 ml) and 2 M-sodium hydroxide (30 ml) was heated under reflux for 12 h, and washed with dichloromethane. The aqueous layer was acidified with 10% hydrochloric acid, and extracted with two portions of dichloromethane. Drying over $MgSO_4$, and concentration of the solution gave a reddish solid (83 mg), which was recrystallized from hot-water. The melting point and IR spectrum of the product, colorless needles (40 mg), were identical with those of 1-oxoindan-4-carboxylic acid:[29] mp 224.5—225.5 °C; IR (KBr) 3100, 1715 and 1687 cm^{-1}.

A Study of the Interactions between Free Radicals and Cobalt Complexes

Kenji YOSHINO, Yasukazu OHKATSU, and Teiji TSURUTA*

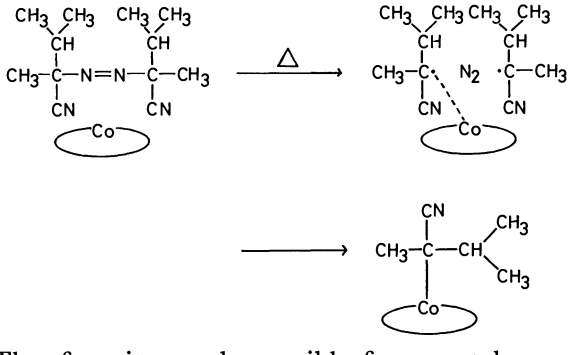
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received February 10, 1979)

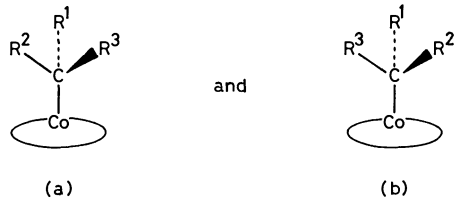
The interaction between free radicals and cobalt complexes (Co(II)TPP and Co(II)(sal)$_2$(*R*-CHXDA)) has been studied using (*S,S*)-(−)-, (*R,R*)-(+)-, and *meso*-1,1′-diphenylazoethane as a radical source. The decomposition of *meso*-1,1′-diphenylazoethane by heat or UV-light in the presence of Co(II)(sal)$_2$(*R*-CHXDA) having an asymmetric ligand produced an optically active (+)-2,3-diphenylbutane. The suggestion is that the α-methylbenzyl radical formed from the azo compound is stereoselectively stabilized by the Co(II)(sal)$_2$(*R*-CHXDA).

The literature cites several addition reactions of polyhaloalkanes to olefins using organometallic catalysts, 1:1 adducts being formed in good yield. In the absence of the organometallic complex, there is negligible formation of the 1:1 adducts.[1] Nagai *et al.*[2] postulated that the reaction proceeded *via* a free radical mechanism and concluded that the high selectivity in the 1:1 adduct was a direct consequence of the restricted freedom of movement of a radical which was restrained in the coordination sphere of the complex. Furthermore, Murai *et al.*[3] reported an optically active adduct in the addition reactions of bromotrichloromethane to 1-alkenes using a rhodium complex with (−)-diop as the asymmetric ligand.

It accepted that a free radical is stabilized by reacting with several metal ions (including metal complexes).[4] For example, the radicals derived from the decomposition reactions of several azo compounds are stabilized in the presence of metal complexes, especially cobalt, such as Co(II)TPP and Co(II)(sal)$_2$(*R*-CHXDA).[5]



Therefore, it may be possible for a metal complex having an asymmetric ligand to stabilize radicals in two stereochemically different formes as follows:



(a) and (b)

Either of these two stabilized radicals, (**a**) or (**b**), will enter a reaction preferentially owing to the difference in their reactivities resulting in the formation of an optically active product. The interactions between radicals and metal complexes, especially the effect of interaction on the yield and specific rotation of 2,3-diphenylbutane, have been studied using (*S,S*)-(−)-, (*R,R*)-(+)-, and *meso*-1,1′-diphenylazoethane as the radical source and Co(II)(sal)$_2$(*R*-CHXDA) as the asymmetric metal complex.

Experimental

Materials. The azo compounds ((*S,S*)-(−)-, (*R,R*)-(+)-, and *meso*-1,1′-diphenylazoethane[6]) and the metal complexes (Co(II)TPP and Co(II)(sal)$_2$(*R*-CHXDA)[6]) have been prepared as described in a previous paper. (−)-2,3-*O*-Isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane ((−)-diop) has been prepared according to the method of Kagan *et al.*[7] The (−)-diop–Rh(I) has been prepared by mixing (−)-diop and di-μ-chloro-bis(π-1,5-cyclooctadiene)dirhodium(I) in benzene under nitrogen.

Decomposition of Azo Compound. The decomposition of the azo compounds in the presence or absence of metal complex has been conducted as described in a previous paper.[6] In the photo-decomposition reactions, the azo compound, contained in an ampoule under nitrogen was decomposed completely by UV-light and the volume of nitrogen released was measured.

Analysis of Decomposition Products. 2,3-Diphenylbutane, a coupling product, was separated by TLC (hexane–silica gel) and the optical rotation was measured. 2,3-Diphenylbutane was qualitatively analyzed by PMR and GC-MS.[6]

Quantitative analyses of the decomposition products were conducted by GLC (Silicone DC-550). The column temperatures were 120 °C for the non-coupling products (styrene and ethylbenzene) and 200 °C for the coupling product (2,3-diphenylbutane).

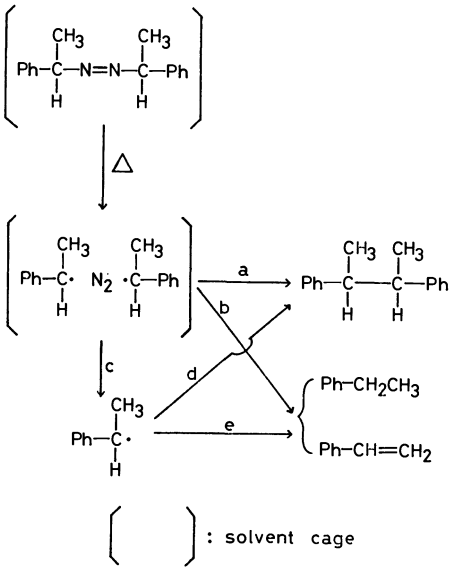
Measurement of Decomposition Rates. The decomposition rates of the azo compounds were measured as described in a previous paper.[6]

Measurement of Visible Spectra. The visible spectra of benzene solutions containing the cobalt complex (Co(II)-TPP or Co(II)(sal)$_2$(*R*-CHXDA)), (*S,S*)-(−)-1,1′-diphenylazoethane and/or nitrosobenzene were measured under nitrogen using 1 mm thick quartz glass cell.

Results and Discussion

Decomposition of 1,1′-Diphenylazoethane. According to a previous report,[6] the decomposition products from the thermolysis of 1,1′-diphenylazoethane (Azo compound) in the absence of metal complex were 2,3-diphenylbutane, styrene, and ethylbenzene. In the presence of a metal complex, an additional product, namely acetophenone α-methylbenzylhydrazone was formed.

The formation mechanism[8] of these products may be illustrated by Schemes 1 and 2.



Scheme 1.

Routes **a** and **b** show the coupling and disproportionation reactions of the two radicals in a classical solvent cage, respectively. Routes **d** and **e** are, on the other hand, the corresponding reactions for radicals diffused from the cage. Scheme 2 is a possible route for the decomposition reaction in the presence of the metal complex as reported previously.[6)]

The amount of 2,3-diphenylbutane formed was less in the presence of the complex, since a part of the starting azo compound was converted into acetophenone α-methylbenzylhydrazone (Scheme 2). The complex can interact with three types of radical such as $PhCH(CH_3)$, $Ph–C(CH_3)–N=N–CH(CH_3)Ph$, and $Ph–C(CH_3)=N–\underset{\cup}{N}–CH(CH_3)Ph$. In the presence of nitrosobenzene, the only radical produced was the α-methylbenzyl radical; no acetophenone α-methylbenzylhydrazone was produced (Table 1). In order to understand the interaction between the complex and

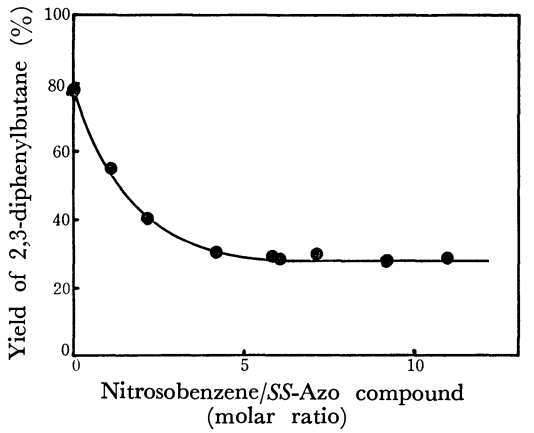


Fig. 1. Yield of 2,3-diphenylbutane in the presence of nitrosobenzene. Reaction conditions: in benzene at 104 °C for 2 days; *SS*-Azo compound: 3.7×10^{-2} M.

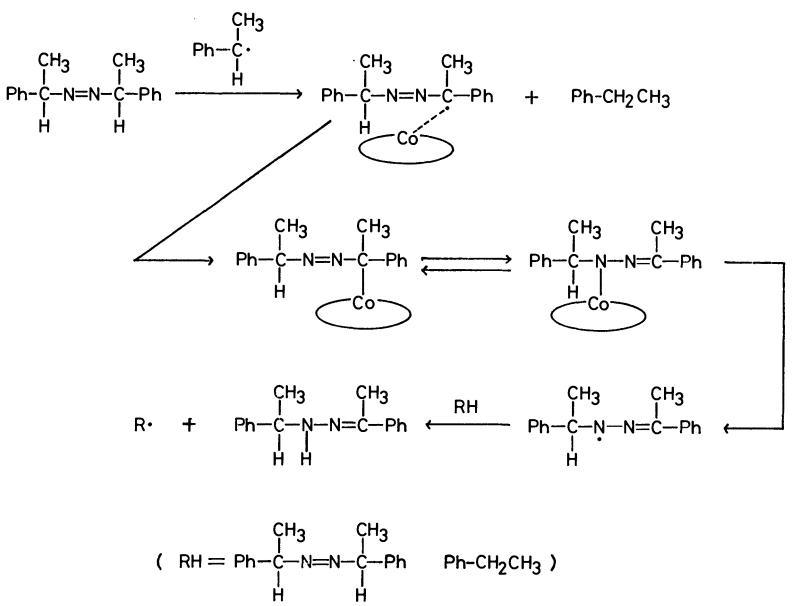
the α-methylbenzyl radical, the thermal decomposition has been examined in the absence and presence of nitrosobenzene.

2,3-Diphenylbutane Obtained in the Presence of Nitrosobenzene. (*S,S*)-1,1′-Diphenylazoethane (*SS*-Azo compound) was thermally decomposed in the presence of nitrosobenzene with and without the metal complex. Figure 1 illustrates the effect of nitrosobenzene on the yield of 2,3-diphenylbutane and as may be seen, the yield of 2,3-diphenylbutane decreases with the increase in the concentration of nitrosobenzene, up to six times the amount of azo compound. After this, the yield of 2,3-diphenylbutane did not vary, even in the presence of a great excess of nitrosobenzene. Twenty eight percent of 2,3-diphenylbutane is estimated to be formed in the solvent cage. Under these conditions, a trace amount of the disproportionation products was obtained and no acetophenone α-methylbenzylhydrazone was formed, even in the presence of the metal complex (Table 1).

From the result in Fig. 2, it appears there



Scheme 2.

b) Measured in benzene at 20 °C. Co*: Co(II)$(sal)_2$(*R*-CHXDA).

Table 2. Decomposition rate of azo compounds in the presence of cobalt complex in benzene at 70 °C

Azo compd	Complex	Complex/Azo compd (molar ratio)	Obsd (mol s^{-1})
SS	0	0	1.11×10^{-6}
SS	Co*	2.7×10^{-3}	1.5×10^{-6}
SS	Co(II)TPP	8.2×10^{-3}	1.4×10^{-6}

Co*: Co(II)$(sal)_2$(*R*-CHXDA).
SS-Azo compound: 2.15×10^{-1} M.

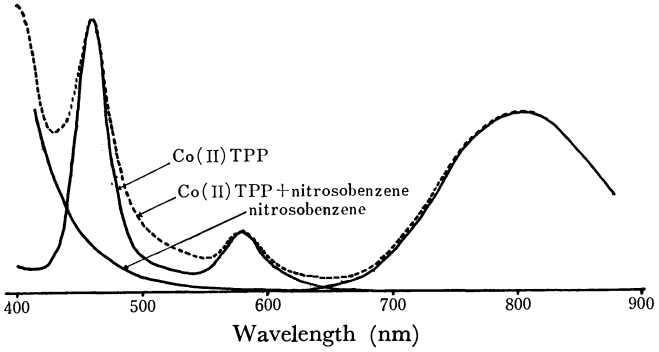

Fig. 2. Visible spectra of Co(II)TPP and/or nitrosobenzene in benzene at 20 °C. Co(II)TPP: 8.45×10^{-5} M, nitrosobenzene: 3.74×10^{-2} M.

is little, if any, interaction between nitrosobenzene and the cobalt complex, the spectrum of the binary system being a simple overlapping of the two individual spectra.

There is however, evidence which suggests a possible interaction between the metal complex and the Azo compound: (1) the visible spectra of a benzene solution of the *SS*-Azo compound and the cobalt complexes exhibited isosbestic points (Figs. 3(a) and (b)), a part of the Azo compound, at least, being thought to react with the cobalt complex, and (2) the decomposition rate of the Azo compound in the presence of a metal complex is higher than that in the absence of the metal complex (Table 2). The increase in the rate is regarded as a consequence of the increased reactivity of the Azo compound which interacts with the cobalt complex.

The specific rotation and yield of 2,3-diphenylbutane obtained from the *RR* and *SS*-Azo compounds in the

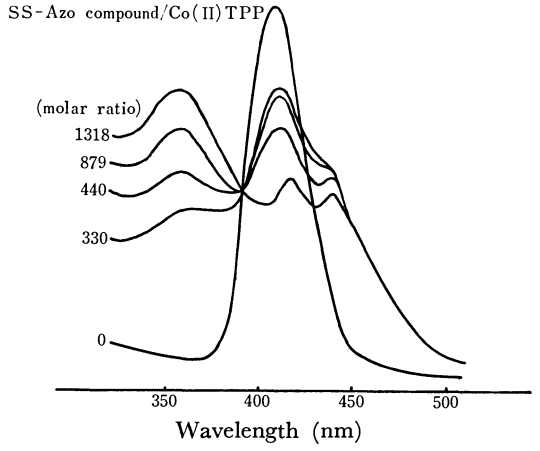

Fig. 3(a). Visible spectra of Co(II)TPP in the presence of *SS*-Azo compound in benzene at 20 °C. Co(II)TPP: 8.45×10^{-5} M.

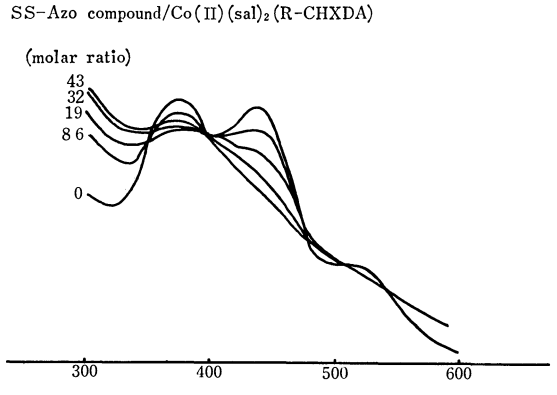

Fig. 3(b). Visible spectra of Co(II)$(sal)_2$(*R*-CHXDA) in the presence of *SS*-Azo compound in benzene at 20 °C. Co(II)$(sal)_2$(*R*-CHXDA): 5.65×10^{-4} M.

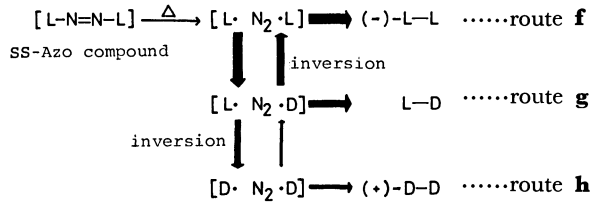
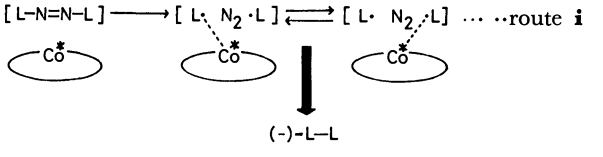
presence of both Co(II)$(sal)_2$(*R*-CHXDA) and nitrosobenzene are shown in Figs. 4 and 5, respectively. In the coupling reaction within a solvent cage, the value of $[\alpha]_D$ and the yield of 2,3-diphenylbutane, derived from the *RR*-Azo compound were negligibly changed. Little dependency upon the concentration of Co(II)-$(sal)_2$(*R*-CHXDA) was established. In the case of

the *SS*-Azo compound, however, an increase in the concentration of the metal complex caused a decrease in both the yield and the optical rotation (Fig. 4). The results may be explained by assuming the following mechanism: In the absence of the metal complex, the *SS*-Azo compound is decomposed as shown in Scheme 3, and the product consists of three coupled compounds, L-L, D-D, and L-D. Therefore, the specific rotation of the product will depend on the relative rates of coupling and inversion.[8]

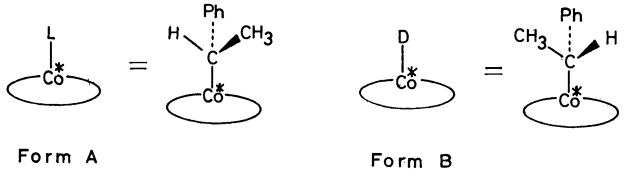


Scheme 3.

In the presence of Co(II)(sal)$_2$(*R*-CHXDA), the radicals within a solvent cage may interact with the metal complex as discussed above and consequently, the inversion and coupling reactions will be more difficult for these radicals. The results shown in Figs. 4 and 5 suggest, therefore, that the ratio of (—)-2,3-diphenylbutane ((—)-L-L) obtained from reaction route **i** is greater than that from reaction route **f** as in Scheme 3.



The cobalt complex, Co(II)(sal)$_2$(*R*-CHXDA), may have greater interaction with a radical from the *SS*-Azo compound compared with that from the *RR*-Azo compound, a more favorable stabilization operating in Form **A** than Form **B**.



The decrease in optical rotation of 2,3-diphenylbutane from the *SS*-Azo compound (Fig. 4) may be explained by assuming that the radical formed from the *SS*-Azo compound is immediately stabilized by the Co(II)-(sal)$_2$(*R*-CHXDA) and that the inversion is suppressed. Since the stabilized radical on the complex less readily undergoes coupling, the yield of coupled product decreases.

2,3-Diphenylbutane Obtained in the Absence of Nitrosobenzene. The mechanism of formation of 2,3-diphenylbutane outside the solvent cage may be elucidated using the *meso*-Azo compound in place of the *RR* and *SS*-Azo compounds. Table 3 shows the yield and the $[\alpha]_D$ of 2,3-diphenylbutane formed from the

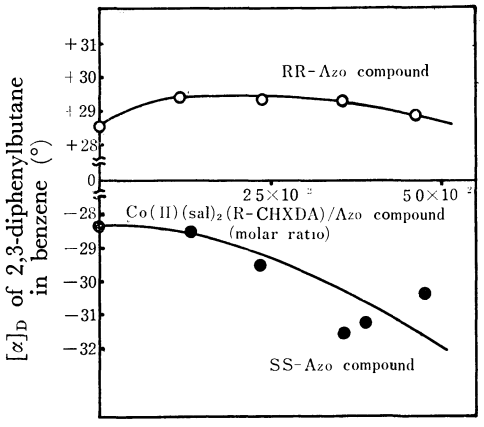


Fig. 4. The specific rotation of 2,3-diphenylbutane formed from Azo compound in the presence of Co(II)-(sal)$_2$(*R*-CHXDA) and nitrosobenzene.
Reaction conditions: Azo compound: 4.2×10^{-2} M nitrosobenzene: 3.27×10^{-1} M in benzene at 104 °C for 4 days.

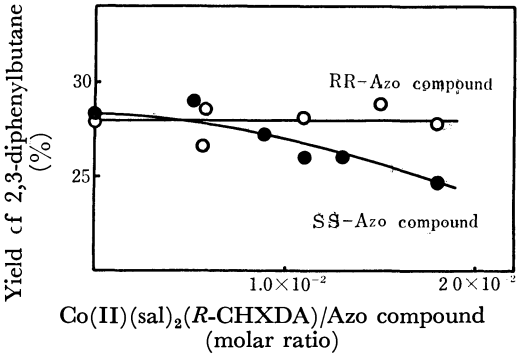

Fig. 5. Yield of 2,3-diphenylbutane formed from Azo compound in the presence of Co(II)(sal)$_2$(*R*-CHXDA) and nitrosobenzene.
Reaction conditions: Azo compound: 4.2×10^{-2} M; nitrosobenzene: 3.27×10^{-1} M, in benzene at 104 °C for 4 days.

meso-Azo compound in the presence of an optically active complex such as Co(II)(sal)$_2$(*R*-CHXDA) or (—)-diop-Rh(I). 2,3-Diphenylbutane formed in the presence of Co(II)(sal)$_2$(*R*-CHXDA) or (—)-diop-Rh(I) was optically active. With the former metal complex, the optical rotation of 2,3-diphenylbutane obtained in the absence of nitrosobenzene showed an opposite and higher absolute value compared to that obtained in the presence of nitrosobenzene (Table 1, run 6). This suggests that the major part of the optical rotation of 2,3-diphenylbutane formed in the absence of nitrosobenzene is ascribable to 2,3-diphenylbutane which was formed by the stereoselective coupling reaction of diffused radicals outside the solvent cage. The diffused radicals stereoselectively stabilized by the metal complex (probably Form **A**) are considered to undergo coupling with the other radicals with inversion of stereochemistry as shown in Scheme 4.

In the presence of nitrosobenzene, because there are relatively few diffusion radicals, the reaction in the cage predominates to form (—)-2,3-diphenylbutane as shown in route **i**.

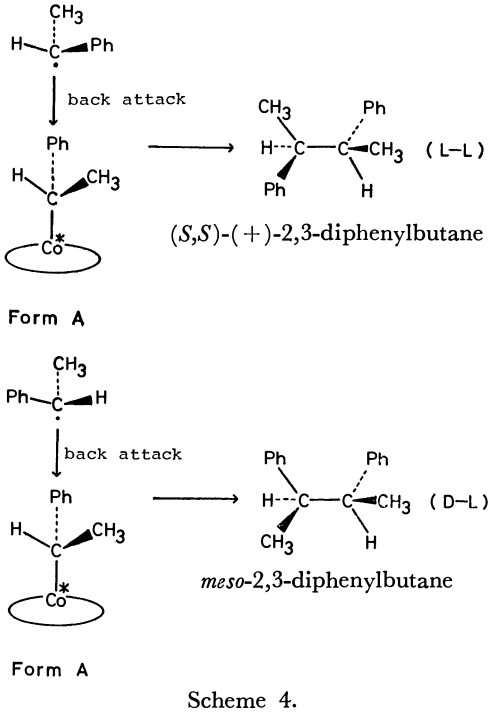

Scheme 4.

Conclusion. This study has revealed that an organometallic complex having asymmetric ligands stabilizes a free radical from an Azo compound and produces stereoselective coupling products. The optical yield of the coupling product is very low, but the optical purity may be improved by controlling the rate of decomposition of the azo compound, thereby increasing the possibility of interaction between the free radical and the complex. The use of metal complexes having more suitable chirality is another method of attaining a high value of optical purity of product.

Absorption Spectra of Heterocyclic Compounds. Some 6-Hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazoles and Their Quaternary Derivatives

R. P. SONI and J. P. SAXENA*

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received May 1, 1978)

Some 2-alkyl-6-hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazoles have been synthesised. Their absorption spectra at different pH show bathochromic shift of the absorption band in the longer wavelengths, which is more pronounced in basic medium. This is ascribed to the dipolar nature of the compounds. Quaternary derivatives of the compounds show a further red shift in the absorption band in the visible region, which further corroborates their dipolar nature.

Imidazoles long considered to be cyclic amidines[1] are the most basic of the imide containing azoles.[2] Since imdazole derivatives occupy an important position with respect to the constitution of heterocyclic as well as in biochemistry, their physical properties have been investigated extensively. Although it has not been established unequivocally that the nucleus has true conjugated double bond character, imidazoles have been shown to be cyclic amidines with charges present on the nitrogen atoms in a system possessing some degree of hindered resonance. It is also apparent that the ring system possesses greater polarity than the related pyrazole but not to the extent expected from classical polar formula.

During the course of spectral study and synthesis of some donor acceptor systems in our laboratory,[3–6] benzimidazole moiety with two nitrogen atoms was selected as donors for further investigations. A perusal of literature reveals that no work has been done on the reaction of 5-alkyl-2-amino-1,3,4-thiadiazole with *p*-benzoquinone. We now report the synthesis of some new 6-hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazoles. The structure is of particular interest as it possesses the phenolic hydroxyl group as an acceptor and the two nitrogen atoms of the imidazole moiety as a donor, thereby facilitating the molecule to assume dipolar structure through internal charge transfer reaction. The hydroxythiadiazolobenzimidazoles were quaternized with ethyl bromide giving the corresponding 2-alkyl-9-ethyl-6-hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazolium bromides. The quaternary compounds gave intense yellow colour with dilute aqueous alkali due to the formation of internal charge transfer compounds, phenol betaines.[7,8]

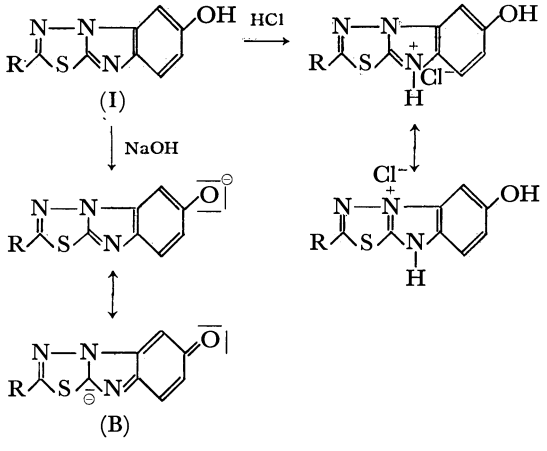
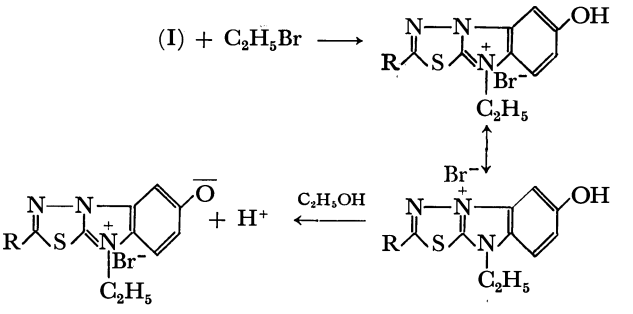
Results and Discussion

The gross structure of these compounds has been determined on the basis of infrared spectra and elemental analysis. The spectra showed the following characteristic bands at 3200, 1210 (phenolic–OH), 1610 (C=N, C=C), 1315 (C–N), 1505 cm^{-1} (aromatic ring breathing).

We see from Table 1 that the absorption spectra of various 2-alkyl-6-hydroxythiadiazolobenzimidazoles in ethanol at different pH show a characteristic bathochromic shift of the absorption maxima in the longer wavelengths in both acidic as well as alkaline medium. No zwitterionic structure is expected in strongly alkaline medium. The observed bathochromic shift might be explained by the following canonical quinoid structure (B).



The same phenomenon is observed when these compounds are quaternized with ethyl bromide which gives rise to further red shift of absorption maxima in the visible region. This should be caused by the partial dissociation of quaternary *N*-ethylimidazoliumbromides into the dipolar betaine structure in ethanol (Table 2).



Reaction Mechanism. The following reaction mechanism is suggested for the formation.

(1) Amino group by nucleophilic addition and elimination of water gives intermediate (a)

(2) (a) on reaction with proton of acid gives (b) which causes shift of electrons, giving the final product (c).

Experimental

All the reagents were thoroughly dried and purified before use. Melting points were determined on a Kofler instrument and are uncorrected. IR spectra were recorded on a Perkin-Elmer 677 Spectrophotometer in KBr. UV absorption spectra were recorded on a Beckman Spectrophotometer, Model DU-2, using 1 cm path length quartz cells.

5-Alkyl-2-amino-1,3,4-thiadiazole. The compounds were prepared by known methods.[9]

*2-Alkyl-6-hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazoles (I).* A solution of *p*-benzoquinone (0.01 mol) in glacial acetic acid (10 ml) was added in small portions to the 5-alkyl-2-amino-1,3,4-thiadiazole (0.01 mol) in acetic acid (10 ml) with shaking. The mixture was left to stand for 2 days. To this was added 20 ml of 50% HCl and the solution was diluted with water. It was extracted with ether to remove any unreacted quinone and hydroquinone. The resulting solution was made alkaline with sodium carbonate solution when the desired compound precipitated. After treatment with charcoal in ethanol, the compound was recrystallised from ethanol. The yields, mp *etc.* are given in Table 1.

*2-Alkyl-9-ethyl-6-hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazolium Bromides (II).* The requisite amount of 2-alkyl-6-hydroxy[1,3,4]thiadiazolo[2,3-*b*]benzimidazole was dissolved in 1:1 ethanol–acetone solution and was boiled under reflux with excess of ethyl bromide on a water bath for 3 h, when the desired *N*-ethylimidazolium bromide was partly separated out. Excess solvent was removed by distillation on a water bath and the product was recrystallised from acetone or ethanol. The yields, mp *etc.* are given in Table 2.

Thanks are due to Prof. R. C Kapoor, Head of Chemistry Department, for providing necessary laboratory facilities and to the University Grants Commission, New Delhi, for the award of a Junior Research Fellowship to R. P. Soni.

Chemistry of Dienyl Anions. I. Crystalline Dienyl Anions by Direct Reaction of Conjugated and Non-conjugated Dienes with Alkali Metals in the Presence of Et_3N

Hajime YASUDA, Yasuo OHNUMA, Michihide YAMAUCHI, Hisaya TANI, and Akira NAKAMURA*

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

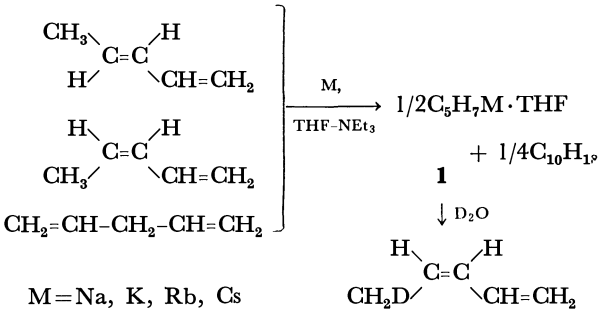
(Received December 6, 1978)

Series of acyclic and cyclic dienyl anions were prepared from both conjugated and non-conjugated dienes by direct metalation with alkali metals (Li, Na, K, Rb, and Cs) in tetrahydrofuran in the presence of triethylamine or *N,N,N′,N′*-tetramethylethylenediamine. Eight different dienyl anions of open chain or cyclic structures were isolated as crystals. All the acyclic potassium dienides of pentadienes, 2-methylpentadienes, 3-methylpentadienes, hexadienes and 2,4-dimethylpentadienes gave the corresponding 1,3-dienes upon hydrolysis, while the potassium cyclic dienide of cycloheptadienes and cyclooctadienes gave 1,4-dienes exclusively. The result of methylation of dienyl anions with methyl iodide agreed with that of hydrolysis. The reaction path for formation of these dienyl anions was studied based on the carbon skeleton and the molar ratio of the reduced diene dimers produced together with the dienyl anions. Selective oxidative coupling of the dienyl anions occurred with CuX or CuX_2 to give linear tetraenes in good yield.

Dienyl anions have been postulated as intermediates in base-catalyzed isomerization of 1,3- and 1,4-dienes[1] or in nucleophilic substitution of aromatics.[2] Their conformational stabilities have recently been studied by simple and extended Hückel MO calculations.[3] The route for preparation of dienyl monoanions has been limited to the metalation of non-conjugated 1,4-dienes with butyllithium[4] in tetrahydrofuran(THF) or with potassium in liquid ammonia.[5] Although conjugated 1,3-dienes[6] are available more readily than the 1,4-dienes, they have not yet been used for this purpose because the well-known "alkali metal catalyzed polymerization[7]" or diene dimer dianion formation[8] occurs preferentially. The only exceptional case is the reaction of cyclopentadiene with sodium to give cyclopentadienyl anion[9] whose cyclopentadienyl group was stabilized by 5π-conjugation. We wish to present here a general method for the preparation of dienyl anions from both conjugated and non-conjugated dienes. All the dienyl anions prepared were isolated as crystals for the first time and their conformation in solution were studied in order to verify the MO prediction. The present method has the advantage of performing the following: 1) preparation of special dienes such as monodeuterated and alkyl-substituted dienes, 2) interconversion reactions between *cis*- and *trans*-dienes, 3) stereoselective synthesis of di- and trisubstituted dienes, 4) selective synthesis of new type of open chain tetraenes which are useful as ligands for transition metals and 5) preparation of other dienyl metal (*e.g.*, Be, Mg, Sn, Si, *etc.*) compounds which serve as reagent for various types of selective organic syntheses.

Results and Discussion

The reaction of 1,3-pentadiene with alkali metals (Na, K, Rb, and Cs) in tetrahydrofuran gave poly(1,3-pentadiene).[10] However, we found that in the presence of an equimol of aliphatic tertiary amines, it gave pentadienyl anions **1** and reduced pentadiene dimers, $C_{10}H_{18}$, in a 2 : 1 molar ratio. The addition of a tertiary amine inhibits the polymerization completely. Trimethylamine, triethylamine, tripropylamine and *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) were favorable as the tertiary amine over pyridine or 2,2′-bipyridyl with regard to yield. All the pentadiene isomers, *cis*-1,3-pentadiene, *trans*-1,3-pentadiene and 1,4-pentadiene, gave the identical pentadienyl anion $C_5H_7M\cdot THF$ **1** and $C_{10}H_{18}$ quantitatively, irrespective of the alkali metal except for lithium. Based on the molar ratio of **1** to $C_{10}H_{18}$ determined by GC and/or chemical characterization of the hydrolysis products (Tables 1 and 3), the following equation is given for the reaction.



For preparation of the lithium compound, the use of 1,4-pentadiene is pertinent, since 1,3-pentadiene affords lithium pentadienide only in 30—60% yield even in the presence of two moles of TMEDA. Polymerization occurred competitively in this case. A series of pentadienyl anions thus obtained was isolated as yellow needle crystals and their structures were confirmed to be $C_5H_7M\cdot THF$ by GC and chemical characterization of the hydrolysis products (Tables 1 and 2).

The solubility of $C_5H_7M\cdot THF$ in THF decreased in the order Li>Na>K>Rb>Cs with increasing ionic characters of the metal–carbon bond. The THF molecule in $C_5H_7M\cdot THF$ (where M=K, Rb, and Cs) was easily removed by heating at 80—100 °C in a vacuum, while that of Li and Na compounds was strongly coordinated to metals even at 120 °C in a vacuum. This behavior may be explained by Pearson's principle.[11] The affinity of ligands determined by the ligand exchange reaction can also be explained by this principle; *i.e.*, the affinity of ligand to the relatively

Table 2. Distribution of hydrolysis products of pentadienyl anions[a]

Counter ion	Solvent	1,3-Pentadiene (%) *trans*	*cis*	1,4-Pentadiene (%)
Li	THF	70	20	10
Li	TMEDA	66	22	12
Na	THF	62	38	0
K	THF	2	98	0
K	Isooctane[b]	98	2	0
Rb	THF	2	98	0
Rb	Isooctane	98	2	0
Cs	THF	1	99	0
Cs	Isooctane[b]	100	0	0

a) Hydrolyzed at 0 °C. b) A dispersion of THF-free carbanion was hydrolyzed in 2,2,4-trimethylpentane.

soft lithium compound falls in the order TMEDA> triethylamine>THF, while to the more electropositive K, Rb, and Cs compounds, it is reversed.

The distribution of the hydrolysis products of pentadienyl anions distinctly reflects the nature of their counter cations and the ligands. Potassium, rubidium and caesium pentadienide gave *cis*-1,3-pentadiene stereoselectively upon hydrolysis in THF, but the corresponding THF free anions gave only *trans*-1,3-pentadiene upon hydrolysis in 2,2,4-trimethylpentane or diethyl ether (Table 2). Thus interconversion between *cis*- and *trans*-diene was first accomplished by using the present method. In contrast, the lithium compound gave a mixture of three pentadiene isomers as reported by Bates *et al.*[4] and sodium compound gave a *trans-cis* mixture of 1,3-pentadiene. In the case of the lithium compound, the negative charge of the pentadienyl anion should be delocalized over terminal C_1 and internal C_3 carbon atoms. The following equilibrium is considered. The formation of both *cis*- and *trans*-1,3-pentadiene may be explained by the rotation around the inside C_2-C_3 carbon bond.

In a similar manner, hexadienyl anions having K^+ as a counter cation were prepared from *trans,trans*-2,4-hexadiene, *trans,cis*-2,4-hexadiene, *trans*-1,4-hexadiene, 1,3-hexadiene or 1,5-hexadiene. Conjugated dienes were more reactive than non-conjugated one. The reaction of 2,4-hexadiene occurred at 0 °C while 1,5-hexadiene required higher temperatures (>60 °C). The structures of **2** obtained from the four isomeric hexadienes were identical with each other, as evidenced by GC analysis of dienes obtained upon hydrolysis and the characterization of potassium with Kalignost (sodium tetraphenylborate). The most striking feature of this reaction is that **2** gave *cis,trans*-2,4-hexadiene selectively (94%) upon hydrolysis. The result of deuterolysis of **2** which gave *cis,trans*-2,4-hexadiene-1-*d* is in line with the structure of the *cis*-methylpentadienyl anion prepared from 1,4-hexadiene in liquid ammonia.[5b]

$\downarrow D_2O$

$CH_2DCH{=}CHCH{=}CHCH_3$ (*cis,trans*)

The present method is applicable to the preparation of the octadienyl anion from non-conjugated 1,7-octadiene. A mixture of 1,7-octadiene, potassium and triethylamine (3 : 2 : 2 molar ratio) was heated for 20 h at 70 °C, **3** being precipitated as orange powder in 78% yield by the addition of excess pentane. *cis*-3-Octene (76% yield), 2,6-octadiene (9% yield) and unreacted 1,7-octadiene were obtained from the pentane fraction. Based on the molar ratio, the following equation is given for the reaction.

$$3\,CH_2{=}CH(CH_2)_4CH{=}CH_2 + 2\,K \xrightarrow[\text{THF-NEt}_3]{70\,^\circ C}$$

$$2\,C_8H_{13}K \cdot THF + CH_3CH_2CH{=}CHCH_2CH_2CH_2CH_3$$

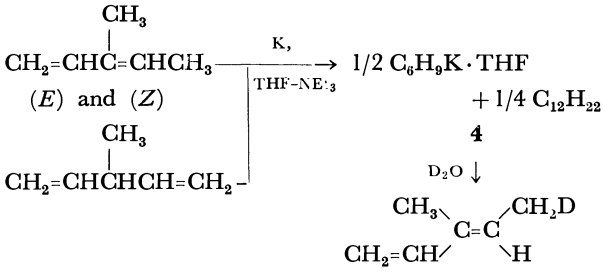
3

$$\mathbf{3} \xrightarrow{D_2O} CH_2DCH{=}CHCH{=}CHCH_2CH_2CH_3 + CH_3CH{=}CHCHDCH{=}CHCH_2CH_3$$

The resulting octadienyl anion **3** gave 2,4-octadiene-1-*d* (90%) and a small amount of 2,5-octadiene-4-*d* (10%) upon deuterolysis. No reduced octadiene dimer was obtained. The yield of 2,6-octadiene became maximum (30 mol% to 1,7-octadiene used) after the mixture had been heated at 70 °C for 8 h, decreasing with continuous heating of the solution with an increase of **3**. This strongly suggests that 1,7-octadiene isomerizes stepwise to 2,4- or 2,5-octadiene to give **3** *via* 2,6-octadiene as postulated by Birch and Phil.[12] Thus, the present method has the advantage to perform the reaction at high temperatures, at which 1,5-, 1,6-,

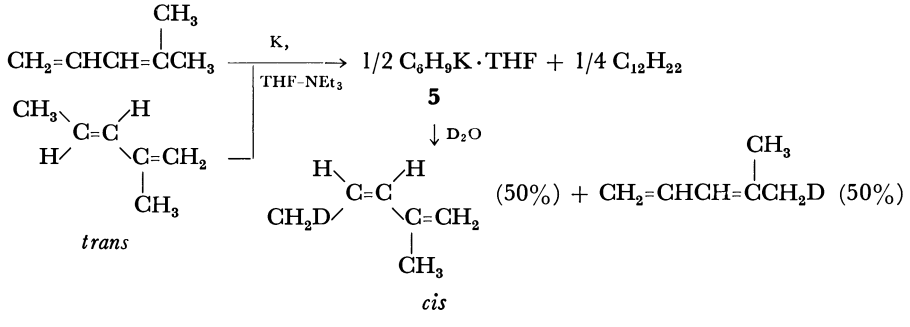
and 1,7-dienes can be converted into 1,3- or 1,4-dienes. Olefines, 1-octene and 2-octene, underwent no reaction under these reaction conditions.

An important feature of the present reaction is that the potassium dienides prepared from trans-conjugated dienes gave thermodynamically unfavorable *cis*-1,3-dienes selectively upon hydrolysis as shown in the hydrolysis of **1** and **2** in THF. The results led us to examine the stereoselective synthesis of di- and trisubstituted dienes by the protonation of anions. Metalation of 3-methyl-1,4-pentadiene with potassium gave 3-methylpentadienyl anion **4** and the reduced dimer, $C_{12}H_{22}$, in 93—95% yields. Deuterolysis of **4** in THF gave (*E*)-3-methyl-1,3-pentadiene-5-*d* selectively (99.5 %) in line with the hydrolysis of the corresponding lithium compound.[13] Differentiation between (*E*) and (*Z*) isomers was done chemically with maleic anhydride according to the method of Bartlett *et al.*[14]

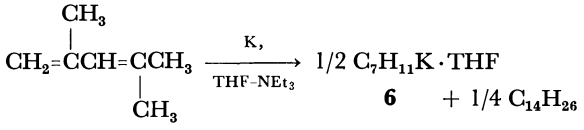


Thus, substitution with the methyl group on C_3-carbon atom of pentadiene largely effects the geometry of the product. If 3-methyl-1,4-pentadiene behaves similarly to 1,3- or 1,4-pentadiene, the hydrolysis product should be (*Z*)-3-methyl-1,3-pentadiene. This suggests that rotation around the C_2–C_3 carbon bond is inhibited by introducing the methyl group on C_3-carbon atom. A mixture of (*Z*)- and (*E*)-3-methyl-1,3-pentadiene (3 : 7 molar ratio) also gave the same products, but the yield was only 50—60% since the reaction proceeded in competition with polymerization. The substitution of methyl group on the C_3 carbon of pentadiene brings about an increased tendency to promote the polymerization since its chemical structure involves that of isoprene which gives only polymers by the reaction with alkali metals even in the presence of excess tertiary amine.[15]

Both *trans*-2-methyl- and 4-methyl-1,3-pentadiene gave the identical 2-methylpentadienyl anion **5** and reduced dimer, $C_{12}H_{22}$, by metalation with potassium in THF–triethylamine at 0 °C. Hydrolysis of **5** in THF gave *cis*-2-methyl-1,3-pentadiene and 4-methyl-1,3-pentadiene in 1 : 1 ratio. This suggests that the negative charge densities on C_1 and C_5 carbon atoms of **5** are nearly equal. No detectable amount of *trans*-2-methyl-1,3-pentadiene was obtained as evidenced by GC using a capillary column, while the corresponding lithium compound[4] gave *trans*-2-methyl-1,3-pentadiene (45%), 2-methyl-1,4-pentadiene (45%), and 4-methyl-1,3-pentadiene (10%) due to the rapid 1,3-shift present at equilibrium. The yield of **5** from 4-methyl-1,3-pentadiene (92%) is superior to that from *trans*-2-methyl-1,3-pentadiene (60%) since the latter tends to polymerize.



A trisubstituted diene, 2,4-dimethyl-1,3-pentadiene, gave 2,4-dimethylpentadienyl anion **6** and $C_{14}H_{26}$ in high yield (85% and 87% respectively) by the reaction with potassium in THF–triethylamine at 10 °C. The anion **6** afforded the starting diene upon hydrolysis quantitatively, no other isomer being detected. In contrast to di- and trisubstituted dienes, a tetrasubstituted diene, 2,5-dimethyl-2,4-hexadiene, was inert to the metalation even at higher temperatures (100—120 °C in a sealed tube). The acidity of its methyl group is probably not so high as to induce the reaction.



The behavior of cyclic dienes markedly differs from that of linear dienes. Although cyclopentadiene is known to give the cyclopentadienyl carbanion by the reaction with potassium or sodium evolving hydrogen,[9] both 1,3- and 1,4-cyclohexadiene gave no cyclohexadienyl anion **7** by the reaction with potassium at 0—50 °C. They isomerized completely to an equal amount of benzene and cyclohexane as was observed in the reaction with butyllithium.[16] Although no detectable amount of potassium was consumed during the course of reaction, the cyclohexadienyl anion can be considered to exist as an intermediate, since **7** was obtained by Kloosterziel and vanDrunen[17] by the reaction with potassium amide in liquid ammonia below −20 °C. At 0 °C, it decomposed thermally to benzene and cyclohexene due to the great electronic stabilization by aromatization.

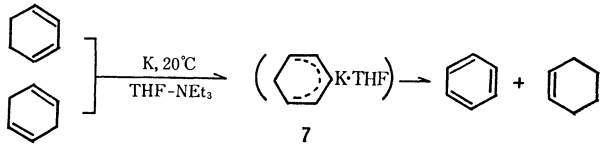


Table 3. Distribution of the reduced diene dimers obtained together with dienyl anions

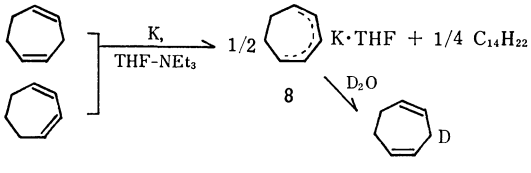
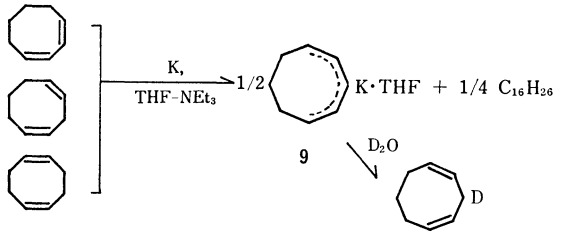
Dienyl anion	Reduced diene dimer	Total yield/%
1	 (37%) (37%) (26%)	98
2	 (52%) (38%) (10%)	95
4	 (96%)	92[a] 60[b]
6	 (98%)	87
5[c]	 (38%) (46%) (16%)	92
5[d]	 (55%) (45%)	60
8	 (97%)	99
9	 (98%)	99

a) Reaction of 3-methyl-1,4-pentadiene.
b) Reaction of 3-methyl-1,3-pentadiene.
c) Reaction of 4-methyl-1,3-pentadiene.
d) Reaction of 2-methyl-1,3-pentadiene.

By the present method, however, cycloheptadienes and cyclooctadienes gave the corresponding anions. Both 1,3- and 1,4-cycloheptadienes readily reacted with potassium in THF–triethylamine to produce cycloheptadienyl anion **8** and reduced dimers, $C_{14}H_{22}$, in 96—98% yields. The anion **8** is also prepared by the 1,6-sigmatropic rearrangement of the 1,3,5-heptatrienyl anion.[5d] The significant difference between **8**, lithium cycloheptadienide and linear dienyl carbanions observed in hydrolysis is that **8** gave a 1,4-diene predominantly (80%) but the latter two gave conjugated 1,3-dienes.



Cyclooctadienyl anion **9** was prepared from 1,3-, 1,4-, and 1,5-cyclooctadienes quantitatively (92—99% yield). Non-conjugated 1,5-cyclooctadiene requires higher temperature (>60 °C) for the completion of the reaction, while 1,3- and 1,4-dienes react with potassium at 10 °C. Cyclooctadienyl anion **9** also gave 1,4-cyclooctadiene exclusively (82%) upon hydrolysis. Thus the negative charge is concluded to be relatively large on the C_3 carbon atom of cyclic dienyl anions as postulated by Hine[18] The anion **9** is thermally stable as compared to the corresponding lithium compound[19]



which isomerizes irreversibly to *cis*-bicyclo[3.3.0]oct-3-en-2-yl lithium at 35 °C by electrocyclization.[20] The interconversion to bicyclo[3.3.0]oct-3-en-2-yl anion should be ascribed to the equal sharing of the negative charge to C_1 and C_3 carbons of the cyclooctadienyl anion. The production of an equal amount of 1,3- and 1,4-cyclooctadienes upon the hydrolysis of the lithium compound[21] at low temperatures supports this conclusion.

As an extension of the present method, the metalation of *trans,trans,trans*- and *cis,cis,cis*-1,5,9-cyclododecatrienes was examined, 1,3,5-cyclododecatriene being obtained in 40—50% yield together with three isomeric cyclododecatrienes of unknown structures. Quantitative isomerization of these trienes into the conjugated one was unsuccessful.

Process for the Formation of Dienyl Anions. In the preparation of dienyl anions by the present method, reduced diene dimers were obtained. Although 1,3-butadiene, styrene and α-methylstyrene give their

dimer[8] or tetramer dianions[22] by the reaction with sodium, no dianions were detected by means of mass spectroscopy of the deuterolysis products. The mass number, (M^+), of reduced pentadiene dimers obtained upon deuterolysis of the reaction mixture is the same as that obtained by hydrolysis with an error of 2%. The reduced pentadiene dimers produced together with **1** are composed of three isomers (Table 3). The carbon skeleton of the dimer strongly suggests that they are formed by the homo or cross coupling of pentadiene radical anions, (I) and/or (II), and by

$$\overset{\ominus}{C}H_2CH{=}CH\underset{\displaystyle CH_3}{\underset{|}{C}}H\cdot \quad (I) \qquad \cdot CH_2CH{=}\overset{\ominus}{C}HCHCH_3 \quad (II)$$

the succeeding rapid proton abstraction from free pentadiene with the resulting dianions. As an example, the process for formation of 4-methyl-2,6-nonadiene is expressed by the following equation.

$$I + II \longrightarrow \overset{\ominus}{C}H_2CH{=}CH\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH{=}C\overset{\ominus}{H}CHCH_3$$

$$\downarrow 2\,C_5H_8$$

$$2\,C_5H_7^{\ominus} + CH_3CH{=}CH\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH{=}CHCH_2CH_3$$

The production of similar compounds by the reaction of 1,3-pentadiene with lithium naphthalene[23] may also be explained by the same concept. The radical anions corresponding to I and II were reported by Bauld.[24] The carbon skeleton and distribution of the reduced diene dimers (Table 3) strongly suggest that the mode of coupling of the radical anions is the same in principle as that of the allyl radical[25] since both of their dimers formed obey the stability of the aliphatic radical, tertiary>secondary>primary. In agreement with the behavior of pentadienes, hexadienes also gave three isomeric hexadiene dimers in a 11 : 8 : 2 ratio, the ratio being the same irrespective of the four hexadienes used. Both 2-methyl- and 4-methylpentadienes gave two or more isomeric reduced dimers but 3-methyl-1,3-pentadiene and 2,4-dimethyl-1,3-pentadiene gave only one isomer. The process for the formation of these dimers may be explained by the same principle as that described above. Cyclic dienes also gave their reduced dimers regioselectivity; 1,3-cycloheptadiene gave 3-(2-cycloheptenyl)cycloheptene and both 1,3- and 1,5-cyclooctadiene gave 3-(2-cyclooctenyl)cyclooctene. Separation of the meso-isomer from racemate by GC was unsuccessful. The structure of the reduced cyclooctadiene dimer was identical with that obtained with lithium naphthalene.[26]

Alkylation of Dienyl Anions. Alkylation with methyl iodide and *t*-butyl bromide was carried out (Table 4) to know the location of the highest negative charge density on the carbon atoms in the dienyl anions. The result of methylation is in line with that of hydrolysis and of the CNDO-II calculations[3c] of dienyl anions. In the case of the acylic dienyl anions, methylation occurs on C_1 carbon atoms in preference to the C_3 carbon atom, but, occurs exclusively on the C_3 carbon atoms for the cyclic dienyl anions. In contrast, alkylation with *t*-butyl bromide gave reversed result: *i.e.*, alkylation occurred exclusively on the C_3 carbon atom of pentadienyl carbanion. This can be explained not by the steric factor, but by considering the attack of *t*-butyl cation on the free pentadienyl anion since the result is consistent with data of Hückel MO calculations.[3a]

Table 4. Alkylation of dienyl anions on C_1 and C_3 carbon atoms with methyl iodide and *t*-butyl bromide[a]

Dienyl anion	Methyl iodide		*t*-Butyl bromide	
	C_1 (%)	C_3 (%)	C_1 (%)	C_3 (%)
1	65	35	22	78
2	62[b]	8	8[b]	92
	30			
4	85	15	3	97

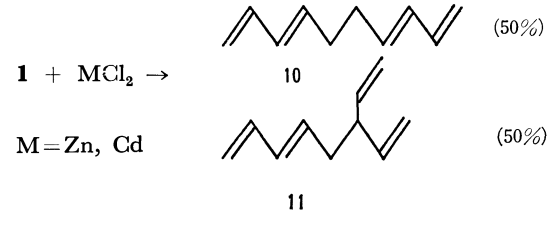
8	10	90	50	50
9	5	95	47	53

a) Reaction carried out at 20 °C in THF. b) Alkylation on the C_5 carbon atoms.

Table 5. Coupling reaction of **1** or **9** with metal halides

Metal halide	Distribution (%)		Total yield/%	Distribution (%)	Total yield/%
	10	**11**		**12**	
$MgBr_2$	0	0	0	0	0
$ZnCl_2$	50	50	98	95	95
$CdCl_2$	68	32	88	90	85
CuCl	99	1	52	100	80
$CuCl_2$	98	2	50	99	73
$NiCl_2$	95	5	18	92	68
$CoCl_2$	97	3	10	91	59

Coupling Reaction of Dienyl Anions. Selective oxidative coupling of dienyl anions is an attractive organic synthesis.[27] Oxidation of alkyl mono- and dianions with metal halides or metal oxides[28] has been reported. We present here the coupling reaction of dienyl anions with a variety of metal halides using **1** as a typical acyclic dienyl anion and **9** as a cyclic dienyl anion (Table 5). The reaction of **1** with a half mol of zinc chloride or cadmium chloride gave quantitatively the tetraene composed of two isomers, **10** and **11**, in a



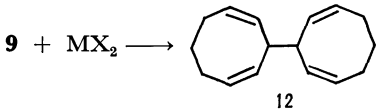
1 : 1 ratio. Thermally unstable bis(pentadienyl)zinc and bis(pentadienyl)cadmium are considered to be an intermediate in the reaction. The mechanism of these homo and cross couplings should be the same as that of allyl radicals produced by the thermal cracking of bis(allyl)zinc compounds.[29] In order to realize se-

Table 6. Tetraenes obtained by the coupling of **1** with $Br(CH_2)_nBr$

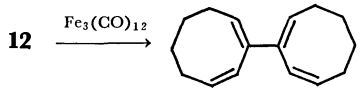
n	Tetranes (%)			Total yield/%
	14	**15**	**16**	
3	20	42	38	96
4	14	50	36	98
5	15	46	39	99

lective coupling, the reaction of **1** with various kinds of metal halides was examined.

Copper(I), copper(II), and nickel(II) halides were found to be useful for the selective production of **10**. Pentadienyl metal cluster compounds are the most possible intermediates for the coupling reaction as postulated in the alkyl coupling reaction.[30] The high selectivity should arise from the steric repulsion between the neighboring dienyl groups. The behavior of **9** differs from that of **1** giving 3-(2,7-cyclooctadienyl)-1,4-cyclooctadiene **12** regioselectively even when zinc chloride or cadmium chloride is used as an oxidant. Metal oxides, zinc oxide, and nickel oxide also assist the coupling reaction of **9** effectively. The non-conjugated dimer **12** could be easily converted into conjugated 2-(1,7-cyclooctadienyl)-1,3-cyclooctadiene **13** with a catalytic amount of $Fe_3(CO)_{12}$.

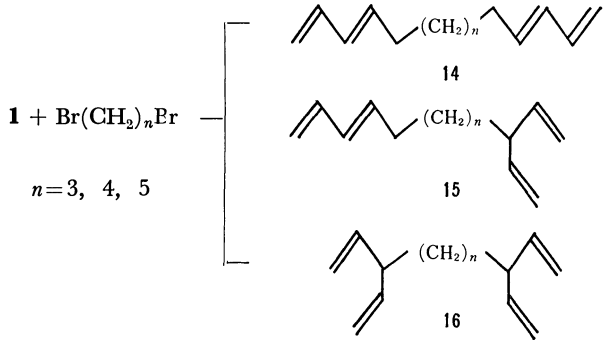


12



13

For the synthesis of the tetraenes separated with a carbon chain, the coupling of **1** with dibromoalkane, $Br(CH_2)_nBr$ (n=1,2,3,4,5), was examined. Coupling of two pentadienyl groups with dibromomethane and 1,2-dibromoethane was not successful since **1** was converted into **10** and **11** in a 7:3 ratio evolving ethylene. However, 1,3-dibromopropane, 1,4-dibromobutane and 1,5-dibromopentane provided the coupling compounds, **14**, **15** and **16** (Table 4).



It is noteworthy that tetraene **16** was obtained though **1** did not give a tetraene with such a branched structure as **16** by the oxidative coupling with metal halides, presumably due to steric repulsion.

Experimental

All the dienes (Aldrich Chem. Inc.) and tertiary amines (Nakarai Chem. Co.) were dried over calcium hydride and distilled before use. Tetrahydrofuran was refluxed over sodium/potassium alloy and distilled under nitrogen. Finely dispersed sodium and potassium were prepared by heating them in toluene and the lithium dispersion in mineral oil. Anhydrous metal halides were prepared by heating the hydrates at prescribed temperatures. 3-Methyl-1,4-pentadiene, 1,4-cycloheptadiene, and 1,4-cyclooctadiene were obtained by the method described in this paper. All the procedures were performed under argon by means of high vacuum technique. GC analysis and separation of the reaction products were carried out with a Hitachi Model K-53 gas chromatograph using a glass capillary column (Silicone OV-101 and HB-2000) and a Varian-Aerograph Model 700 gas chromatograph using a column packed with Silicone DC-550. NMR spectra were taken with a Varian Model A-60 instrument and MS with a Hitachi RMU-7HR spectrometer. IR spectra were recorded on a Hitachi EPI-2 spectrometer. Elemental analysis of the products (bp *ca.*> 120 °C) was carried out with a Yanagimoto Model MT-2 CHN analyzer using a glass ampoule.

Preparation of Pentadienyl Anion ***1***. To the potassium (3.9 g, 0.1 g-atom) dispersed in a mixture of THF (40 ml, 0.5 mol) and triethylamine (21 ml, 0.15 mol) was added 1,3- or 1,4-pentadiene (20 ml, 0.2 mol) dropwise at 0—5 °C over a 1 h period. Vigorous stirring was necessary in order to avoid explosive reaction and polymerization. After allowing the mixture to attain room temperature in 2—4 h, THF (40 ml) was added and the mixture was heated to 60 °C for completion of the reaction and for dissolution of the suspension of **1**. Orange needle crystals of **1** were precipitated by cooling the solution to 0 °C. Typical yield of **1** was 80% (14.2 g) based on potassium. From the THF soluble fraction, 2.9 g of **1** was further obtained as crystals by addition of hexane (50 ml). The anion **1** was purified by recrystallization in 2:1 THF-hexane. From the hexane soluble fraction, a mixture of reduced pentadiene dimers (described later), $C_{10}H_{18}$, was obtained in 98% yield (6.8 g, 49% conversion based on 1,3-pentadiene). The use of trimethylamine or TMEDA instead of triethylamine also gave **1** in 90—96% yield while the use of pyridine or 2,2′-bipyridyl afforded **1** in 20—30% yield and the polymer in 70—80% yield. Rubidium and caesium compounds were prepared by the same procedure, but crystallization of the sodium compound carried out at −20——40 °C after addition of hexane (40 ml) to the resulting solution. Yield: 96—99%. Their analytical data are given in Table 1. In the metalation of 1,3-pentadiene (10 ml, 0.1 mol) or 1,4-pentadiene (10 ml, 0.1 mol) with lithium (0.7 g, 0.1 g-atom), TMEDA (30 ml, 0.2 mol) was used instead of triethylamine. The reaction was carried out in THF (20 ml) at 0 °C for 5 h and then at 30 °C for 8 h. After separating the resulting solution from unreacted lithium, hexane (40 ml) was added to the solution and the mixture was cooled to −20 °C to induce the crystallization of $C_5H_7Li \cdot TMEDA$. Yields from 1,3- and 1,4-pentadiene were 52 and 90%, respectively.

THF free alkali metal (K, Rb, Cs) pentadienides were obtained by heating **1** at 90 °C for 1 h in a vacuum (0.05 mmHg). They are explosive in the air and more unstable than the corresponding tetrahydrofuran complexes even in an argon atmosphere. A spontaneous solid state polymerization occurred gradually at room temperature, poly(3-methyl-1-butenylene) being obtained in 90% yield upon hydrolysis by keeping them for 60 days. Deuterolysis of **1** in THF

at 0 °C gave *cis*-1,3-pentadiene-5-*d* in 98% yield and that of THF free potassium pentadienide in 1,2,3,4-tetrahydronaphthalene gave *trans*-1,3-pentadiene-5-*d* in 99% yield as evidenced by GC, NMR (position of the deuterium was determined from the peak area ratio), and MS, *m/e* 69 (M^+). The purity of the *cis*- and *trans*-1,3-pentadiene-5-*d* was determined to be >97% by reference to the value of M^+ of 1,3-pentadiene.

Preparation of Hexadienyl Anion **2**. In essentially the same way as described above, the reaction of 1,3-hexadiene (5:3 *trans-cis* mixture), *trans,trans*-2,4-hexadiene, *trans,cis*-2,4-hexadiene, or *trans*-1,4-hexadiene (5.7 ml, 50 mmol) with potassium (1 g, 25 mg-atom) was carried out in a mixture of THF (9 ml) and triethylamine (5 ml) at 5—10 °C for 10 h, while that of 1,5-hexadiene was carried out at 60 °C for 20 h. After the completion of the reaction by heating the resulting suspension to 65 °C for 2 h, excess hexane (20 ml) was added and cooled to −20 °C in order to precipitate **2** as orange powder. Yield: 94% (4.5 g) for 2,4- and 1,4-hexadiene; 84% (4.0 g) for 1,3-hexadiene. The anion **2** thus obtained was washed with two portions of 20 ml hexane and then recrystallized in THF–hexane at 0 °C. Hydrolysis of **2** in 2,2,4-trimethylpentane, Found: hexadiene 43.7%; THF, 37.8% (by GC); K, 18.5% by $NaB(C_6H_5)_4$. Calcd for $C_6H_9K \cdot C_4H_8O$: hexadiene, 42.2%; THF, 37.5%; K, 20.3%. Distributions of the hydrolysis products of **2** prepared from the above four isomers were identical with each other; *trans,cis*-2,4-hexadiene (94%), *trans,trans*-2,4-hexadiene (3%) and *cis,cis*-2,4-hexadiene (3%). Purity of the deuterolysis products, *cis,trans*-2,4-hexadiene-1-*d* (or *trans, cis*-isomer), was >98% by MS. From the hexane soluble fraction, reduced hexadiene dimers were obtained by distillation (1.9 g, 95% yield).

Preparation of Dienyl Anions **4**—**9**. The reaction of 3-methyl-1,3-pentadiene, 3-methyl-1,4-pentadiene, *trans*-2-methyl-1,3-pentadiene, 4-methyl-1,3-pentadiene, 2,4-dimethyl-1,3-pentadiene, 1,3-cycloheptadiene, 1,4-cycloheptadiene, 1,3-cyclooctadiene, or 1,4-cyclooctadiene with potassium (2:1 ratio) was carried out in the same manner as in the preparation of **2**, since the solubility of their carbanions in THF is larger than that of **1**. Addition of 3-methyl-1,3-pentadiene and 2-methyl-1,3-pentadiene was made over a period of 3 h. The resulting crude crystals were recrystallized in THF–hexane at −40—0 °C. Characterization of **4**—**9** was carried out in the same way as described for **1** and **2**. Analysis of K by $NaB(C_6H_5)_4$ method, Found: 19.2, 18.8, 18.1, 17.3, and 17.8% for **4**, **5**, **6**, **8** and **9**. Calcd: 20.3, 20.3, 18.9, 19.1, and 17.9% respectively. GC analysis of dienes obtained by the hydrolysis of **4**—**9** is in line with the calculated values with errors of 2%. These dienes were identified with GC, NMR, and IR using commercial authentics amples (Aldrich Chemicals and Tokyo Kasei Co.) except for the following dienes.

(E)-3-Methyl-1,3-pentadiene: IR (neat) 1645, 1601 (C=C), 990, 894 (CH_2=CH), 764, 747 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 6.40 (d of d, 1, CH), 5.53 (q, 1, CH), 5.02 (m, 2, CH_2), 1.79 (s, 3, CH_3), 1.73 (d, 3, CH_3); MS, Found: 82 (M^+) for C_6H_{10} and 83 (M^+) for the deuterolysis product, (*E*)-3-methyl-1,3-pentadiene-5-*d* (97% purity).

cis-*2-Methyl-1,3-pentadiene*: IR (neat) 1645, 1601 (C=C), 895 (CH_2=C), 749 cm^{-1} (*cis* CH=CH); PMR ($CDCl_3$) δ 5.90 (d, 1, J=11.9, CH), 5.57 (d, of q, 1, J=11.9, CH), 4.92 (d, 2, CH_2), 1.90 (d, 3, CH_3), 1.86 (s, 3, CH_3); MS, Found: 82 (M^+) for C_6H_{10} and 83 (M^+) for the deuterolysis product, *cis*-2-methyl-1,3-pentadiene-5-*d*.

1,4-Cycloheptadiene: IR (neat) 1630 (C=C), 850, 772, 760, 711 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.54 (m, 4, CH), 2.79 (t, 2, CH_2), 2.23 (m, 4, CH_2); MS, Found: 94 (M^+) for C_7H_{10} and 95 (M^+) for 1,4-cycloheptadiene-3-*d*.

1,4-Cyclooctadiene: IR (neat) 1646 (C=C), 810, 790, 762, 716 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.73 (d of q, 2, J=6.3, CH), 5.56 (d of t, 2, J=6.3, CH), 2.77 (t, 2, CH_2), 2.23 (m, 4, CH_2), 1.46 (m, 2, CH_2); MS, Found: 108 (M^+) for C_8H_{12} and 109 (M^+) for 1,4-cyclooctadiene-3-*d*. Deuteration occurred in 98% purity.

Preparation of Octadienyl Anion **3**. 1,7-Octadiene (22 ml, 0.15 mol) was added to potassium (3.9 g, 0.1 g-atom) dispersed in a mixture of THF (40 ml, 0.5 mol) and triethylamine (21 ml, 0.15 mol). The mixture was allowed to react at 70 °C for 20 h and the resulting solution was concentrated by distillation. The anion **3** was precipitated by the addition of pentane (60 ml) to the residue. Yield: 78% (8.5 g, 52% conversion based on 1,7-octadiene). The position of deuterium in the following deuterolysis products of **3** was determined from the PMR peak area ratio by reference to the corresponding hydrolysis products.

2,5-Octadiene-4-d: IR (neat) 1658 (C=C), 963, 900, 719 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.02 (m, 2, J=7.5, CH), 5.00 (m, 2, J=7.9, CH), 2.24 (m, 1, CHD), 1.59 (m, 2, CH_2), 1.22 (d, 3, CH_3), 0.53 (t, 3, CH_3); MS, Found: *m/e* 111. Calcd for $C_8H_{13}D$: M, 111.

2,4-Octadiene-1-d: IR (neat) 1650 (C=C), 945, 926, 816 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.60 (d of d, 1, J=13.0, CH), 5.35 (d of d, 1, J=7.2, CH), 4.98 (m, 2, CH), 1.70 (d of t, 2, CH_2), 1.28 (d, 2, CH_2D), 1.06 (m, 2, CH_2), 0.57 (t, 3, CH_3); MS, Found: *m/e* 111. Calcd for $C_8H_{13}D$: M, 111.

3-Octene (76% yield, 25% conversion based on 1,7-octadiene), 2,6-octadiene (9% yield), and unreacted 1,7-octadiene (15%) were obtained from the distillate and pentane extract and characterized after isolation by GC.

3-Octene: IR (neat) 1658 (C=C), 964 (CH=CH); PMR (CCl_4) δ 5.00 (m, 2, J=7.9, CH), 1.60 (m, 4, CH_2), 0.95, 0.93 (m, 4, CH_2), 0.57 (t, 3, CH_3), 0.53 (t, 3, CH_3); MS, Found: *m/e* 112 (M^+). Calcd for C_8H_{16}: M, 112.

2,6-Octadiene: IR (neat) 1660 (C=C), 962, 898, 720 (CH=CH); PMR (CCl_4) δ 4.98 (m, 4, CH), 1.58 (bs, 4, CH_2), 1.16 (d, 6, CH_3); MS, Found: *m/e* 110. Calcd for C_8H_{14}: M, 110.

Reaction of Cyclohexadienes with Potassium. The reaction of 1,3-cyclohexadiene (2.4 ml, 25 mmol) or 1,4-cyclohexadiene (2.4 ml, 25 mmol) with potassium (1 g, 25 mg-atom) in a mixture of THF (10 ml) and triethylamine (5 ml) was carried out at 50 °C for 20 h. Both 1,3- and 1,4-hexadiene were converted into benzene (1.1 ml, 99%) and cyclohexene (1.2 ml, 98%), 98% of potassium used being recovered.

Alkylation of **1**, **2**, **4**, **5**, **6**, **8**, *and* **9**. A typical experiment is as follows: To potassium cyclooctadienide **9** (4.1 g, 20 mmol) in THF (20 ml) was added a THF solution (10 ml) of methyl iodide (1.3 ml, 21 mmol) at 0 °C over a 20 min period. The mixture was stirred at 0 °C for 3 h, then heated up to 50 °C for 2 h and concentrated by evaporation. The products were extracted with pentane and distilled. Yield, 99% by GC; isolated yield, 2 g (80%). Alkylation with *t*-butyl bromide was carried out under the same reaction conditions. All the alkyl-substituted dienes were obtained in 95—99% yield as evidenced by GC and separated into their respective isomers by preparative GC to determine the structure by PMR, IR, and MS. Relative ratio of the products (Table 4) was determined by a high sensitive GC using glass capillary column (Silicone OV-101). For the isolation of low boiling methyl-substituted compounds of **1**—**5**, diethylene glycol dimethyl ether was used as a solvent instead of THF since the peaks of the products and THF

overlapped each other in preparative GC.

1,3-Hexadiene from **1**: IR (neat) 1655, 1606 (C=C), 1002, 898 ($CH=CH_2$), 950, 776, 756 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.30—4.89 (m, 5, CH and CH_2), 2.20 (d of q, 2, CH_2), 1.02 (t, 3, CH_3).

3-Methyl-1,4-pentadiene from **1**: IR (neat) 1641 (C=C), 997, 910 cm^{-1} ($CH=CH_2$); PMR ($CDCl_3$) δ 5.63 (m, 2, CH), 4.87 (m, 4, CH_2), 2.77 (m, 1, CH), 1.03 (d, 3, CH_3); MS, Found: M^+, 82.

2,4-Heptadiene from **2**: IR (neat) 1650, 1610 (C=C), 817, 765, 720 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.30—6.30 (m, 4, CH), 2.20 (d of q, 2, CH_2), 1.78 (d, 3, CH_3), 1.02 (t, 3, J=7.2, CH_3); MS, Found: M^+, 96.

5-Methyl-1,3-hexadiene from **2**: IR (neat) 1655, 1605 (C=C), 1002, 898 cm^{-1} ($CH=CH_2$); PMR ($CDCl_3$) δ 6.17 (m, 1, CH), 5.80 (m, 2, J=8.6, CH), 5.38 (m, 2, CH_2), 2.15 (m, 1, CH), 0.90 (d, 6, CH_3); MS, Found: M^+, 96.

3-Methyl-1,4-hexadiene from **2**: IR (neat) 1636 (C=C), 958, 913 ($CH=CH_2$), 800, 730 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.64 (m, 1, CH), 5.50 (d of d, 1, J=6.9, *cis* CH), 5.31 (d of q, 1, CH), 4.89 (m, 2, CH_2), 2.76 (m, 1, CH), 1.74 (d, 3, CH_3), 0.99 (d, 3, CH_3); MS, Found: M^+, 96.

3-Methyl-1,3-hexadiene from **4**: IR (neat) 1646, 1609 (C=C), 999, 915, 892 cm^{-1} ($CH=CH_2$); PMR ($CDCl_3$) δ 6.41 (m, 1, CH), 5.53 (t, 1, J=7.0, CH), 5.06 (m, 2, CH_2), 2.17 (d of q, 2, CH_2), 1.76 (s, 3, CH_3), 1.02 (t, 3, J=7.6, CH_3); MS, Found: M^+, 96.

3,3-Dimethyl-1,4-pentadiene from **4**: IR (neat) 1642 (C=C), 995, 912 cm^{-1} ($CH=CH_2$); PMR ($CDCl_3$) δ 5.85 (m, 2, CH), 5.00 (m, 4, CH_2), 1.03 (bs, 6, CH_3).

4-Methyl-1,3-hexadiene from **5**: IR (neat) 1650, 1610 (C=C), 984, 964, 895 cm^{-1} (CH=CH, $CH=CH_2$); PMR ($CDCl_3$) δ 6.60 (m, 1, CH), 5.96 (d, 1, CH), 4.98 (m, 2, CH_2), 2.15 (q, 2, J=7.8, CH_2), 1.75 (s, 3, CH_3), 1.00 (t, 3, J=7.8, CH_3); MS, Found: M^+, 96.

2,3-Dimethyl-1,4-pentadiene from **5**: IR (neat) 1641 (C=C), 995, 915, 805 cm^{-1} (CH=CH, $CH=CH_2$); PMR ($CDCl_3$) δ 5.71 (m, 1, CH), 4.93 (m, 2, CH_2), 4.73 (bs, 2, CH_2), 2.86 (d of q, 1, CH), 1.78 (s, 3, CH_3), 1.35 (d, 3, CH_3).

2,4-Dimethyl-1,3-hexadiene from **6**: IR (neat) 1645, 1635 (C=C), 889, 850, 800 cm^{-1} (CH=CH, $CH=CH_2$); PMR ($CDCl_3$) δ 5.83 (s, 1, CH), 5.02 (d, 2, J=7.0, CH_2), 2.44 (q, 2, J=7.6, CH_2), 1.95—1.97 (two-s, 6, CH_3), 1.21 (t, 3, J=7.6, CH_3); MS, Found: M^+, 110.

2,3,4-Trimethyl-1,4-pentadiene from **6**: IR (neat) 1645 (C=C), 890 cm^{-1} ($CH=CH_2$); PMR ($CDCl_3$) δ 5.06 (bs, 4, CH_2), 3.04 (q, 1, J=7.0, CH), 1.89 (bs, 6, CH_3), 1.40 (d, 3, J=7.0, CH_3).

3-Methyl-1,4-cycloheptadiene from **8**: IR (neat) 1638 (C=C), 763, 715 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.62 (m, 2, CH), 5.41 (d of d, 2, J=11.5, CH), 3.30 (m, 1, CH), 2.21 (m, 4, CH_2), 1.14 (d, 3, J=7.2, CH_3); MS, Found: M^+, 108.

3-Methyl-1,4-cyclooctadiene from **9**: IR (neat) 1645 (C=C), 800, 763, 732, 717 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.33 (m, 2, CH), 5.09 (d of d, 2, J=10.7, CH), 2.88 (d of q, 1, CH), 1.97 (d of t, 4, CH_2), 1.19 (m, 2, CH_2), 0.85 (d, 3, CH_3); MS, Found: M^+, 122.

6,6-Dimethyl-1,3-heptadiene from **1**: IR (neat) 1655, 1602 (C=C), 1002, 896 ($CH=CH_2$), 760 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 6.05 (m, 1, CH), 5.81 (m, 2, CH), 4.89 (m, 2, CH_2), 1.85 (d, 2, CH_2), 0.79 (bs, 9, CH_3); MS, Found: *m/e* 124. Calcd for C_9H_{16}: M, 124.

3-t-Butyl-1,4-pentadiene from **1**: IR (neat) 1642 (C=C), 997, 912 ($CH=CH_2$), 780 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 6.11 (d of d of d, 2, CH), 4.94 (m, 4, CH_2), 2.78 (t, 1, CH), 0.92 (bs, 9, CH_3); MS, Found: M^+, 124.

5,6,6-Trimethyl-1,3-heptadiene from **2**: IR (neat) 1652, 1603 (C=C), 1000, 950, 899, 758 (CH=CH, $CH=CH_2$); PMR ($CDCl_3$) δ 5.82—6.03 (m, 3, CH_2), 4.88 (m, 2, CH_2), 2.15 (d of q, 1, CH), 0.90 (d, 3, CH_3), 0.81 (bs, 9, CH_3); MS, Found *m/e* 138. Calcd for $C_{10}H_{18}$: M, 138.

3-Butyl-1,4-hexadiene from **2**: IR (neat) 1640 (C=C), 995, 910 ($CH=CH_2$), 968, 788, 715, 703 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.79 (m, 1, CH), 5.39 (m, 2, CH), 5.00 (m, 2, CH_2), 2.75 (t, 1, CH), 1.67 (d, 3, CH_3), 0.83 (bs, 9, CH_3); MS, Found: M^+, 138.

3-Methyl-3-t-butyl-1,4-pentadiene from **4**: IR (neat) 1641 (C=C), 996, 911, 785 cm^{-1} ($CH=CH_2$); PMR ($CDCl_3$) δ 6.12 (m, 2, CH), 4.99 (m, 4, CH_2), 1.07 (s, 3, CH_3), 0.90 (bs, 9, CH_3); MS, Found: *m/e* 138. Calcd for $C_{10}H_{18}$: M, 138.

2-Methyl-3-t-butyl-1,4-pentadiene from **5**: IR (neat) 1645 (C=C), 968, 910, 890, 789 cm^{-1} (CH=CH, $CH=CH_2$); PMR ($CDCl_3$) δ 5.93 (m, 1, CH), 5.07 (bs, 2, CH_2), 4.80 (m, 2, CH_2), 2.42 (d, 1, J=10.0, CH), 1.78 (s, 3, CH_3), 0.90 (s, 9, CH_3); MS, Found: 138. Calcd for $C_{10}H_{18}$: M, 138.

2,4-Dimethyl-3-t-butyl-1,4-pentadiene from **6**: IR (neat) 1643 (C=C), 890 cm^{-1} ($C=CH_2$); PMR ($CDCl_3$) δ 4.99 (m, 4, CH_2), 1.07 (bs, 6, CH_3), 0.90 (s, 9, CH_3); Found: C, 86.52; H, 13.45%; M^+, 152. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%; M, 152.

3-t-Butyl-1,4-cycloheptadiene from **8**: IR (neat) 1638 (C=C), 807, 760, 715 cm^{-1} (CH=CH); PMR δ 5.79 (d of d, 2, J=7.0, CH), 5.73 (m, 2, CH), 3.00 (m, 1, CH), 2.27 (m, 4, CH_2), 0.89 (s, 9, CH_3); Found: C, 87.35; H, 12.29%; M^+, 150. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%; M, 150.

5-t-Butyl-1,3-cycloheptadiene from **8**: IR (neat) 1639, 1600 (C=C), 764, 715 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.73 (m, 4, CH), 2.43 (m, 1, CH), 1.92 (m, 2, CH_2), 1.50 (m, 2, CH_2), 0.98 (s, 9, CH_3); MS, Found: M^+, 150.

3-t-Butyl-1,4-cyclooctadiene from **9**: IR (neat) 1660 (C=C), 790, 745, 716 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.50 (m, 4, J=6.8, CH), 2.91 (t, 1, CH), 2.00 (m, 4, CH_2), 1.31 (m, 2, CH_2), 0.87 (s, 9, CH_3); Found: C, 87.70; H, 12.52%; M^+, 164. Calcd for $C_{12}H_{20}$: C, 87.73; H, 12.27%; M, 164.

5-t-Butyl-1,3-cyclooctadiene from **9**: IR (neat) 1650 (C=C), 815, 790, 758 cm^{-1} (CH=CH); PMR (CCl_3) δ 5.48 (m, 4, CH), 2.35 (m, 1, CH), 2.13 (m, 2, CH_2), 1.29 (m, 4, CH_2), 0.78 (s, 9, CH_3); MS, Found: M^+, 164.

Characterization of Reduced Diene Dimers. Excess pentane (50 ml) was added to the reaction solution of dienes (0.2 mol) and potassium (3.9 g, 0.1 g-atom) in order to precipitate dienyl anions. Reduced diene dimer compounds obtained from the pentane soluble fraction were separated into their respective isomers by preparative GC after distillation. Yields and distribution of the products determined by GC are given in Table 3. Isolated yields by preparative GC, 40—70% of the distillate.

3,7-Decadiene from 1,3-Pentadiene: IR (neat) 1661 (C=C), 963, 719 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.36 (m, 4, CH), 1.96 (m, 8, CH_2), 0.99 (t, 6, CH_3); Found: C, 86.53; H, 13.22%; M^+, 138. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%; M, 138.

4-Methyl-2,6-nonadiene from 1,3-Pentadiene: IR (neat) 1660 (C=C), 718 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.09 (m, 4, CH), 2.11 (m, 1, CH), 1.65 (m, 4, CH_2), 1.17 (d, 3, CH_3), 0.60 (t, 3, CH_3), 0.58 (d, 3, CH_3); Found: C, 86.50; H, 13.30%; M^+, 138.

4,5-Dimethyl-2,6-octadiene from 1,3-Pentadiene: IR (neat) 1611 (C=C), 964, 718 cm^{-1} (CH=CH). PMR (CCl_4) δ 5.00 (m, 4, CH), 1.95 (m, 2, CH), 1.23 (d, 6, CH_3), 0.52 (d, 6, CH_3). Found: C, 86.68; H, 13.08%; M^+, 138.

The above three isomers were also obtained from 1,4-pentadiene by the reaction with potassium (see Table 3) in the same ratio with an error of 5%.

5,6-Dimethyl-3,7-decadiene from 1,4-Hexadiene: IR (neat) 1660 (C=C), 965, 900, 738 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.03 (m, 4, CH), 1.90 (m, 2, CH), 1.72 (m, 4, CH_2), 0.72 (d, 6, CH_3), 0.68 (t, 6, CH_3); MS, Found: *m/e* 166. Calcd for $C_{12}H_{22}$: M, 166.

5,6-Dimethyl-2,7-decadiene from 1,4-Hexadiene: IR (neat) 1688 (C=C), 963, 736 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.10 (d of q, 1, J=6.2, CH), 5.07 (d of t, 1, J=6.2, CH), 5.08 (m, 2, CH), 1.85 (m, 2, CH), 1.70 (m, 4, CH_2), 1.32 (d, 3, CH_3), 0.64 (t, 3, CH_3), 0.62 (d, 6, CH_3); MS, Found: *m/e*, 166. Calcd for $C_{12}H_{22}$: M, 166.

5,6-Dimethyl-2,8-decadiene from 1,4-Hexadiene: IR (neat) 1655 (C=C), 964 cm^{-1} (CH=CH); PMR (CCl_4) δ 5.25 (d of q, 2, J=6.3, CH), 5.23 (d of t, 2, J=6.3, CH), 1.88 (m, 6, CH_2C=C and CH), 1.38 (d, 6, CH_3), 0.75 (d, 6, CH_3); MS, Found: M^+, 166.

The structure and relative ratio of reduced hexadiene dimers, $C_{12}H_{22}$, obtained from 1,5- and 2,4-hexadienes were identical with those obtained from 1,4-hexadiene.

3,4,7-Trimethyl-2,6-nonadiene from 3-Methyl-1,3-pentadiene: IR (neat) 1655 (C=C), 965, 832 cm^{-1} (CH=C); PMR ($CDCl_3$) δ 5.10 (m, 2, CH), 2.46 (t of q, 1, CH), 1.88 (m, 4, CH_2), 1.51 (s, 6, CH_3), 1.49 (d, 3, CH_3), 0.87 (d, 3, CH_3), 0.85 (t, 3, CH_3); Found: C, 86.59; H, 13.40%; M^+, 166. Calcd for $C_{12}H_{22}$: C, 86.66; H, 13.34%; M, 166.

2,4,5,7-Tetramethyl-2,6-octadiene from 2-Methyl-1,3-pentadiene: IR (neat) 1669 (C=C), 908, 842 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 4.96 (bd, 2, CH), 2.19 (m, 2, CH), 1.61 (bs, 12, CH_3), 0.83(d, 6, CH_3); Found: C, 86.20; H, 13.68%; M^+, 166. Calcd for $C_{12}H_{22}$: C, 86.66; H, 13.34%; M, 166.

2,4,6-Trimethyl-2,6-nonadiene from 2-Methyl-1,3-pentadiene: IR (neat) 1670 (C=C), 835, 735 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.25 (t, 1, CH), 4.93(d, 1, CH), 2.52(m, 1, CH), 2.01(m, 2, CH_2), 1.89(d, 2, CH_2), 1.62(bs, 9, CH_3), 0.91 (t, 3, CH_3), 0.87(d, 3, CH_3); MS, Found: M^+, 166.

4,4,8-Trimethyl-2,6-nonadiene from 4-Methyl-1,3-pentadiene: IR (neat) 1655 (C=C), 970, 885 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.34 (m, 4, CH), 2.20 (m, 1, CH), 1.89 (two-d, 2, CH_2), 1.61(d, 3, CH_3), 0.95(d, 6, CH_3), 0.89(s, 6, CH_3); Found: C, 86.58; H, 13.37%; M^+, 166. Calcd for $C_{12}H_{22}$: C, 86.66; H, 13.34%; M, 166.

2,6,6-Trimethyl-2,7-nonadiene from 4-Methyl-1,3-pentadiene: IR (neat) 1670 (C=C), 972, 832 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ=5.34 (m, 2, CH), 5.10 (t, 1, CH), 1.90 (m, 2, CH_2), 1.62(m, 9, CH_3), 1.24 (m, 2, CH_2), 0.93 (s, 6, CH_3); MS, Found: M^+, 166.

2,4,5,5-Teramethyl-2,6-octadiene from 4-Methyl-1,3-pentadiene: IR (neat) 1670, 1650 (C=C), 970, 884, 830, 713 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.33 (m, 2, CH), 5.12 (d, 1, CH), 1.96(m, 1, CH), 1.63(bs, 6, CH_3), 1.61(d, 3, CH_3), 1.09 (s, 6, CH_3), 0.92 (d, 3, CH_3); MS, Found: M^+, 166.

2,4,4,6,8-Pentamethyl-2,7-nonadiene from 2,4-Dimethyl-1,3-pentadiene: IR (neat) 1670, 1655 (C=C), 965, 832 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.10 (m, 2, CH), 2.43 (m, 1, CH), 1.61 (m, 12, CH_3), 1.24 (d, 2, CH_2), 1.04 (s, 6, CH_3), 0.86 (d, 3, CH_3); Found: C, 86.10; H, 13.75%; M^+, 194. Calcd for $C_{14}H_{26}$: C, 86.51; H, 13.49%; M, 194.

3-(2-Cycloheptenyl)cycloheptene from 1,3-Cyloheptadiene: IR (neat) 1650 (C=C), 786, 684 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.73 (m, 4, CH), 2.38 (m, 2, CH), 2.16 (m, 4, CH_2), 1.35—1.65 (m, 12, CH_2); Found: C, 88.20; H, 11.59%; M^+, 190. Calcd for $C_{14}H_{22}$: C, 88.35; H, 11.65%; M, 190.

3-(2-Cyclooctenyl)cyclooctene from 1,3-Cyclooctadiene: IR (neat) 1650 (C=C), 762, 710, 662 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.42 (m, 4, J=6.3, CH), 2.42 (m, 2, CH), 2.05 (m, 4, CH_2), 1.51 (m, 16, CH_2); Found: C, 87.75; H, 11.90; M^+, 218. Calcd for $C_{16}H_{26}$: C, 88.00; H, 12.00; M, 218. The same compound was obtained also from 1,4- and 1,5-cyclooctadienes in 99 and 92% yield, respectively.

Coupling Reaction of ***1*** *and* ***9*** *with Metal Halides.* A solution of **1** (8.9 g, 50 mmol) in THF (120 ml) was added with use of a syringe to the vigorously stirred suspension of anhydrous copper(I) chloride (5.9 g, 60 mmol in THF (50 ml) at 0 °C over 30 min period. The resulting solution was quenched with water (7 ml), filtered quickly (contact of THF to the air for a long time should be avoided in order to prevent the formation of thermally unstable peroxide) and concentrated by vacuum distillation at temperatures below 30 °C after adding 1,4-benzenediol (0.18 g) to the filtrate to inhibit the radical polymerization of the tetraene. The products were separated by LCG using a column (30× 3 cm) packed with silica gel (Wako gel C-200) and using pentane as elution solvent. Separation by LCG is preferable to distillation since 10—40% of tetraenes is polymerized by heating to 150 °C. When zinc chloride or cadmium chloride was used as a coupling reagent, the resulting mixture was heated to 80 °C for 1 h in order to induce thermal cracking after **1** (50 mmol) had been added to the THF solution of the metal halide (30 mmol) at 0 °C.

1,3,7,9-Decatetraene: Bp 108 °C/48 mmHg. IR (neat) 1650, 1604 (C=C), 1004, 968, 951, 900 cm^{-1} ($CH=CH_2$, CH=CH); PMR ($CDCl_3$) δ 6.13 (m, 2, CH), 5.50—5.93 (m, 4, CH), 5.07 (m, 4, CH_2), 2.05 (t, 4, CH_2); Found: C, 89.10; H, 10.50%; M^+, 134. Calcd for $C_{10}H_{14}$: C, 89.49; H, 10.51%; M, 134.

6-Vinyl-1,3,7-octatriene: Bp 103 °C/49 mmHg. IR (neat) 1645, 1635, 1600 (C=C), 1000, 950, 915, 900, 833 cm^{-1} ($CH=CH_2$, CH=CH); PMR ($CDCl_3$) δ 5.71—6.21 (m, 5, CH), 5.01, 5.03 (m, 6, CH_2), 2.77 (t of t, 1, CH), 2.15 (t, 2, CH_2); Found: C, 89.44; H, 10.50%; M^+, 134. Calcd for $C_{10}H_{14}$: C, 89.49; H, 10.51%; M, 134.

In essentially the same way, **9** (10.9 g, 50 mmol) in THF (150 ml) was allowed to react with copper(I) chloride (5.9 g, 60 mmol) in THF (50 ml) at 0 °C for 2 h, the products being separated by LCG. Yield, 8.7 g (80%). Results of the coupling reaction with the other metal halides are given in Table 5. Zinc oxide and nickel oxide also gave **12** in 50—60% yield under the same reaction conditions.

3-(2,7-Cyclooctadienyl)-1,4-cyclooctadiene: Bp 101 °C/0.5 mmHg. IR (neat) 1640 (C=C), 718, 679 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.55 (m, 8, CH), 3.30 (bs, 2, CH), 3.23 (d of t, 8, CH_2), 1.52 (m, 4, CH_2); Found: C, 89.65; H, 10.20%; M^+, 214. Calcd for $C_{16}H_{22}$: C, 89.65; H, 10.53%; M, 214. Isomerization to the following conjugated tetraene occurred by keeping the compound at 180—200 °C for 3 h in 35% conversion. Complete isomerization was proceeded by the addition of $Fe_3(CO)_{12}$ (5 mol %) and heating the mixture at 170 °C for 15 h. Conversion, 97%.

2-(1,7-Cyclooctadienyl)-1,3-cyclooctadiene: Bp 103 °C/1 mmHg. IR (neat) 1642, 1697 (C=C), 920, 845, 800, 765, 690 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ=5.49—5.86 (m, 6, CH), 2.15—2.35 (m, 8, CH_2), 1.50 (bs, 8, CH_2); Found: C, 89.48; H, 10.30%; M^+, 214. Calcd for $C_{16}H_{22}$: C, 89.65; H, 10.35%; M, 214.

Tetraenes Obtained by the Reaction of ***1*** *with Dibromoalkanes.* A solution of 1,3-dibromopropane (1.0 ml, 10 mmol) in THF (30 ml) was added to a solution of **1** (3.6 g, 20 mmol) in THF (60 ml) with stirring at 0 °C. The mixture was heated at 40 °C for 1 h, quenched with water (2 ml) and then filtered. The resulting teraenes were separated with GC into their

individual isomers. The reactions of 1,4-dibromobutane and 1,5-dibromopentane were carried out under the same conditions.

1,3,10,12-Tridecatetraene: IR (neat) 1640, 1605 (C=C), 988, 947, 894, 830, 784, 735 cm^{-1} (CH=CH_2, CH=CH); PMR ($CDCl_3$) δ 5.60—5.30 (m, 6, CH), 5.03, 4.88 (m, 4, CH_2), 2.17 (m, 4, CH_2), 1.44 (m, 6, CH_2); Found: C, 87.99; H, 11.42%; M^+, 176. Calcd for $C_{13}H_{20}$: C, 88.56; H, 11.44%; M, 176.

9-Vinyl-1,3,10-undecatriene: IR (neat) 1640, 1604 (C=C), 995, 912 (CH=CH_2), 949, 830, 785, 731 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 6.30 (m, 1, CH), 5.73(d of q, 2, CH), 5.64 (m, 2, CH), 5.05, 5.01, 4.87(m, 6, CH_2), 2.68(t of t, 1, CH), 2.12(m, 2, CH_2), 1.35(m, 6, CH_2); MS, Found: M^+, 176.

3,7-Dwinyl-1,8-nonadiene: IR (neat) 1637(C=C), 994, 912 cm^{-1} (CH=CH_2); PMR ($CDCl_3$) δ 5.71 (d of q, 4, CH), 5.04, 4.86 (m, 8, CH_2), 2.67 (t of t, 2, CH), 1.31 (m, 6, CH_2); MS, Found: M^+, 176.

1,3,11,13-Tetradecatetraene: IR (neat) 1640, 1603 (C=C), 1000, 987, 907 (CH=CH_2), 967, 947, 830, 783 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.61—6.31 (m, 6, CH), 5.08, 4.87 (m, 4, CH_2), 2.11 (d of t, 4, CH_2), 1.33 (m, 8, CH_2); Found: C, 88.30; H, 11.60%; M^+, 190. Calcd for $C_{14}H_{22}$: C, 88.35; H, 11.65%; M, 190.

10-Vinyl-1,3,11-dodecatriene: IR (neat) 1642, 1637, 1604 (C=C), 1000, 995, 912 (CH=CH_2), 949, 831, 783, 729 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.60—6.30 (m, 3, CH), 5.73 (d of q, 2, CH), 5.07, 4.85(m, 6, CH_2), 2.70(t of t, 1, CH), 2.12(d of t, 2, CH_2), 1.31(m, 8, CH_2); MS, Found: M^+, 190.

3,8-Divinyl-1,9-decadiene: IR (neat) 1636 (C=C), 990, 914 cm^{-1} (CH=CH_2); PMR ($CDCl_3$) δ 5.71 (d of q, 4, CH), 5.06, 4.84 (m, 8, CH_2), 2.67 (t of t, 2, CH), 1.29(s, 8, CH_2); MS, Found: M^+, 190.

1,3,12,14-pentadecatetraene: IR (neat) 1638, 1602 (C=C), 987, 910(CH=CH_2), 945, 840, 785, 764, 737 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.60—6.32 (m, 6, CH), 5.08, 4.88 (m, 4, CH_2), 2.08 (m, 4, CH_2), 1.33 (bs, 10, CH_2); Found: C, 88.65; H, 12.25%; M^+, 204. Calcd for $C_{15}H_{24}$: C, 88.16; H, 11.84%; M, 204.

11-Vinyl-1,3,12-tridecatriene: IR (neat) 1635, 1602 (C=C), 989 912 (CH=CH_2), 945, 785, 764, 737 cm^{-1} (CH=CH); PMR ($CDCl_3$) δ 5.60—5.32 (m, 3, CH), 5.74 (d of q, 2, CH), 5.10, 4.88 (m, 6, CH_2), 2.69 (t of t, 1, CH), 2.12 (bt, 2, CH_2), 1.34(bs, 10, CH_2); MS, Found: M^+, 204.

3,9-Dwinyl-1,10-undecadiene: IR (neat) 1635 (C=C), 995, 912 cm^{-1} (CH=CH_2); PMR ($CDCl_3$) δ 5.74 (d of q, 4, CH), 5.08, 4.86 (m, 8, CH_2), 2.68 (bt, 2, CH), 1.30 (bs, 10, CH_2); MS, Found: M^+, 204.

We are gratefull to Emeritus Prof. T. Nozoe, Tohoku University, for his valuable discussion and Prof. P. Heimbach, Max Plank Institute, for the supply of 1,5,9-cyclododecatrienes. We thank Messrs. A. Kashihara, S. Otake, T. Narita, and I. Iwase for their technical assistance.

The Characterization of the Hydroxyl Surface of Silica Gel

Seiichi KONDO,* Kazuo TOMOI, and Chynryon PAK

Laboratory of Physical Chemistry, Osaka University of Education, 43 Minamikobore-cho, Tennoji-ku, Osaka 543

(Received September 4, 1978)

The properties of silica gel were studied as a function of the hydrothermal treatment of hydrogel by means of the nitrogen-adsorption isotherm, the mechanical strength, thermodilatometry, and infrared spectroscopy. As a result, the number of contact points between primary particles of silica was found to decrease, and closed pores were found to be produced, by this treatment. The analysis of the infrared absorption spectra of the OH groups of this material showed that there are three kinds of OH groups in silica gel; (1) free OH groups on the outer surface of primary particles, which can adsorb molecules easily, (2) weakly perturbed OH groups inside closed pores, and (3) strongly hydrogen-bonded OH groups on the surface around the contact points. The relative concentration of these OH groups changes drastically upon the hydrothermal treatment; this is in accord with the change in the macroscopic properties mentioned above.

The properties, such as the specific surface area and the pore-size distribution of silica gel, are highly sensitive to its history, starting from the polymerization of monomeric silicic acid to the physical and chemical treatment before and during use.[1] Many of these characteristics are controlled by surface OH groups of this material. For instance, the infrared absorption band of the OH stretching vibration is changed in shape not only by heat treatment,[2,3] but also by different methods of synthesis. However, the reason for this change is not yet fully understood. Another example is the values of the surface OH densities of various colloidal silicas, which fluctuate widely from less than 4 nm^{-2} to even more than 10 nm^{-2} from one sample to another.[4] The purpose of this paper is to try to clarify the complex nature of the OH groups of silica gel and its relation to the surface and pore structures through the infrared spectroscopy of silica gel, which has been prepared by the hydrothermal treatment of hydrogel. Three different kinds of sites have been found for OH groups on the surface in various kinds of slica gel, as will be described below.

Experimental

Fractionally distilled silicon tetraethoxide was used as the raw material for synthesizing silica gel of a high purity. Silicon tetraethoxide (1 mol) was hydrolyzed at 70 °C for 95 to 105 min with 10 mol of distilled and deionized water, whose pH has been adjusted to 2.0 with hydrochloric acid. Silica sol thus obtained was rapidly cooled to about 0 °C and then poured into flat vessels with air-tight covers in order to make a thin liquid film of the desired thickness. This sol was kept still for 24 h at 17 °C, by which time it set to hydrogel. This hydrogel was washed with water to remove the hydrochloric acid and ethanol, and was then stored in water below 10 °C. This hydrogel was sealed in Pyrex glass ampoules with distilled and deionized water of pH 5.9 and was then heated in an autoclave at various temperatures. The hydrogel thus treated was dried slowly at 10 °C for 48 h. Finally thin plates of xerogel less than 0.05 mm thick and 1—2 cm^2 wide were obtained. The influence of Pyrex glass seemed negligible, since the properties of this product were almost the same as those of substances made in ampoules of high-purity quartz glass under the same conditions.

The infrared spectra of these samples were taken after the desorption of adsorbed water at 180 °C *in vacuo* and *in situ* in a cell described elsewhere,[2]

Results and Discussion

The specific surface area and the total pore volume of this material change remarkably upon the hydrothermal reaction of hydrogel. Figure 1 shows nitrogen-adsorption isotherms of silica gel hydrothermally treated at various temperatures for 2 h. These curves indicate that this material changes from the micropore type to the macropore type with an increase in the temperature of treatment, as is well known. Figure 2 shows the curves of the specific surface area and the total pore volume against the reaction time during hydrothermal treatment at 100 °C. The specific surface area increased in the beginning, reached a maximum after a few hours, and then decreased slowly, while the pore volume increased continuously from the beginning. Figure 3 shows the change in the specific surface area and the total pore volume as a function of the temperature of the reaction for 2 h. The specific surface area increased from 10 °C, reached a maximum at about 100 °C, and then decreased gradually, while the pore volume increased continuously from 10 °C. These increases in the surface area in Figs. 2 and 3 can be explained reasonably as will be done below. Silica hydrogel is an aggregate of fine primary particles of silica loosely chained to each other with a small number of contact points per particle (coordination number). When aging is insufficient, the dehydration of water produces a xerogel with a very high packing density and with a high coordination number, since the strength of the contact points is weak and the reorientation of primary particles is easy. However, a mild hydrothermal treatment of hydrogel below 100 °C, such as is shown in the above experiments, can make the contact points stronger and does not make the size of primary particles larger, because silicic acid migrates from the convex surface of the particle to the points of contact with a concave shape and fills these narrow gaps. This produces stronger interparticle bonds than those before aging. These strong bonds make it difficult for the primary particles to reorient when hydrogel is dried, and thus give rise to a lower packing density and a smaller coordination number of xerogel. The number of coordination can be estimated from the packing density of xerogel, assuming this xerogel to be a mono-

dispersed system of primary particles with a density of about 2.2 g/cm².[5] For example, the hydrothermal reaction at 10 °C and 100 °C for 2 h gives coordination numbers of about 9 and 6 respectively.

The reinforcement of these interparticle bonds by aging is reflected in the increase in the mechanical strength of silica gel as a bulk. Figure 4 shows the values of the strength of the silica gel per bond against the hydrothermal temperature, values obtained from the Vickers hardness (the pressure, kg/cm², neccessary to make a tiny hole of a known cross-section area on the flat surface of a specimen using a small diamond piece with a quadrangular pyramidal shape) divided by the total coordination number per unit of volume of the silica gel. In this figure, the bond strength increases as the hydrothermal temperature is raised. Another example of the increase in the bond strength is the thermodilatometric analysis of this material in Fig. 5, the experimental details of which were described

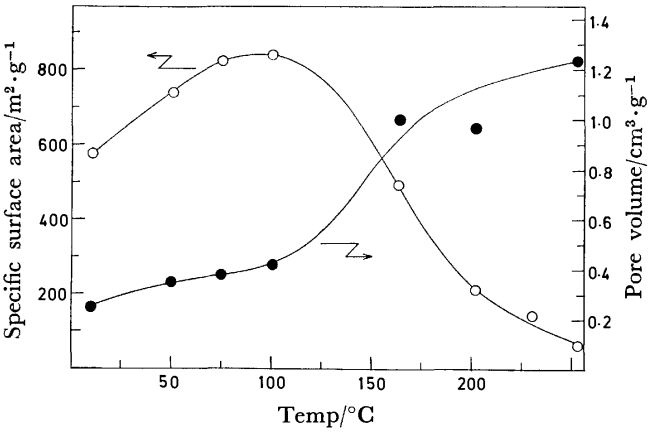

Fig. 3. The specific surface area and the pore volume of silica gel versus the temperature of hydrothermal reaction for 2 h.

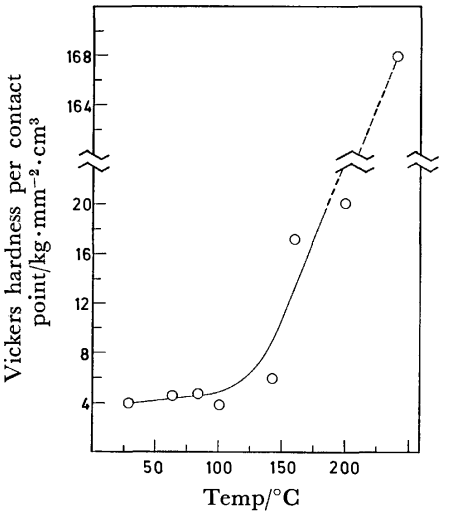

Fig. 4. The Vickers hardness per interparticle bond as a function of hydrothermal temperatures.

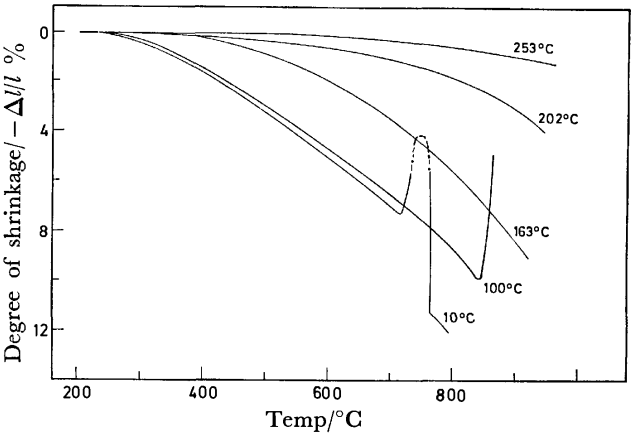

Fig. 5. The curves of thermodilatometric analysis of silica gel hydrothermally treated at various temperatures.

elsewhere.[6] This figure shows that the degree of shrinkage of silica gel by heat treatment was smaller for materials of a high hydrothermal temperature, because the deformation or the shrinkage of bulk

structure by sintering would be smaller for materials with stronger interparticle bonds.

The gaps around the contact points between primary particles are so narrow that molecules such as nitrogen and water can not be adsorbed on a certain area around these points, depending upon the size of the molecules to be adsorbed. This area, which can not be measured by the adsorption of nitrogen gas, amounts to a considerable portion of the total surface area of the primary particles when these primary particles are small and possess a large number of coordination. Therefore, the specific surface area, as measured by the gas-adsorption method, will be generally larger for the materials having a smaller number of coordination when the diameters of the particles are equal, which seems to be true in case of mild hydrothermal treatment.

Figure 6 shows the number of OH groups per nm², which is obtained from the weight loss of the silica gel during heating between 180 °C (the temperature of the dehydration of adsorbed water) and 1200 °C divided by the specific surface area, as measured by the B. E. T. method using nitrogen gas. In this figure, the surface OH density is relatively larger for materials treated below 100 °C than those between 100 °C and 160 °C, because the specific surface area used for this calculation is smaller than the total surface area for the material hydrothermally treated at a lower temperature, as has been discussed in the above section. Above 100 °C, where the B. E. T. specific surface area approaches the total surface because of the decrease in coordination number, the OH density becomes smaller than 5. Surprisingly high values of OH density were obtained above 200 °C; the reason for this will be discussed below in terms of infrared spectroscopy.

Figure 7 shows the infrared spectra of the OH stretching vibration of silica gel treated hydrothermally at various temperatures for 2 h. The shapes of these OH bands changed markedly as the hydrothermal temperature was raised. As was shown in an earlier paper,[3] these bands can mainly be resolved into three component bands with absorption maxima at about 3750 cm⁻¹, 3670 cm⁻¹, and between 3500 and 3300 cm⁻¹; those maxima can be assigned to free OH groups, weakly perturbed OH groups, and strongly hydrogen-bonded OH groups respectively. As the hydrothermal temperature was raised, the intensity of free and strongly hydrogen-bonded OH components became smaller in comparison with the weakly perturbed components. The intensities and shapes of these OH bands of various

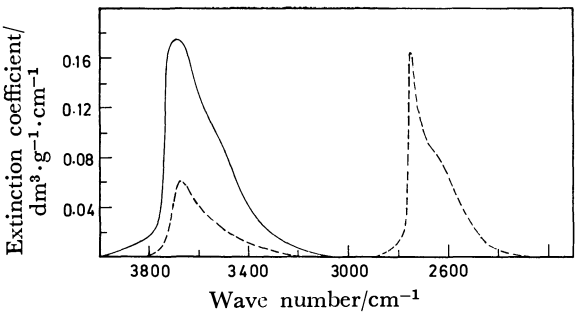

Fig. 9. The change of OH band of silica gel hydrothermally treated at 163 °C by the isotope exchange reaction by the absorption-desorption cycles of 20 times of heavy water. The full and the dotted lines show the absorption bands before and after the isotope exchange, respectively.

samples changed by heat treatment *in vacuo* as is shown in Figs. 8a and 8b. The OH band of silica gel hydrothermally treated at 100 °C in Fig. 8a became sharper when the temperature of heat treatment was raised, because of the decrease in the intensity of the strongly hydrogen-bonded component. By the heat treatment at 800 °C, the free OH component was clearly seen besides a small weakly perturbed component. On the other hand, the OH band hydrothermally treated at 250 °C in Fig. 8b obviously has two components at 3750 and 3670 cm^{-1} upon heat treatment at 600 °C, but it has almost no component below 3600 cm^{-1}. After this sample was heated at 800 °C, there remained only 3750 cm^{-1} component. The decrease in the strongly hydrogen-bonded OH component against the hydrothermal temperatures seems to be roughly parallel to that of the coordination number. Therefore, it seems reasonable to assume that most of these strongly hydrogen-bonded OH groups lie on the surface around the contact points and contribute to the formation of interparticle bonds.

The intensity of the 3670 cm^{-1} band increased as the temperature and the time of hydrothermal reaction were increased, and the shape of this component became clearly visible at higher hydrothermal temperatures. This component can also be made visible by a sufficient isotope exchange of protons of OH groups by the adsorption of heavy water, as is illustrated in Fig. 9. A similar result was reported by Abramov and others.[7] Figure 9 shows the infrared spactra after a sufficient isotope exchange of the OH band of silica gel hydrothermally treated at 163 °C. According to our qualitative observation, the 3750 cm^{-1} component seems to shift to 2750 cm^{-1} most quickly; this seems to suggest that the sites of the free OH groups are on outer convex surface, so that heavy water can be adsorbed there directly. The exchange rate of protons of the strongly hydrogen-bonded OH groups seems to be slower. This indicates that these OH groups lie on the surface near the contact points where heavy water can not be directly adsorbed, and that the H–D exchange can be carried out by the diffusion of protons and deutrons through hydrogen-bond chains of the OH groups. The exchange equilibrium was almost attained after about 20 cycles of the adsorption-desorption processes of heavy water; there remained only an OH band at about 3670 cm^{-1}. This behavior suggests that these OH groups are on the surface inside closed pores that have been produced by hydrothermal treatment, by which not only the concave surfaces at the contact points, but also small openings surrounded by a few contact points of a dense aggregate of primary particles are filled with a siloxane net work. Not even the heavy-water molecules can migrate into these closed pores.

The reason for the weak perturbation of these inner OH groups might be that the OH vibration is perturbed by a local dielectric field, which seems to be rather strong inside these small closed pores.[8] The intensity of the 3670 cm^{-1} component grew larger when the hydrothermal temperature was raised, as can be seen in Fig. 7. This suggests an increase in the area of the surface in the closed pores or an increase in the number of closed pores. There are two more pieces of evidence for the existence of the closed pores. By impregnating this material with impurities such as the sodium cations, the temperature of sintering is considerably lowered; even the free OH band disappears above about 800 °C, while the 3670 cm^{-1} band remains as it was, or its intensity even increases a little.[2] This phenomenon was interpreted as resulting from the occurence of closed pores by high-temperature sintering. Another example is the ion-exchange experiment of the OH groups of this materials with Co^{2+} ions.[9] After immersing the silica gel being hydrothermally treated at about 150 °C in a saturated aqueous solution of cobalt(II) acetate, the OH groups which were not ion-exchanged were mainly inner OH groups, together with a small part of the strongly hydrogen-bonded OH component.

The surface area inside these closed pores can not be measured by the nitrogen-adsorption method, since nitrogen molecules can not easily migrate into these pores, although the amount of OH groups can be measured by means of the weight loss of this material, as has been mentioned before, at 1200 °C, at which temperature all the OH groups including those inside the closed pores can be dehydrated by the explosion of closed pores at high temperatures, as has been mentioned elsewhere.[2] Upon hydrothermal treatment at high temperature, the fraction of the surface area inside the closed pores compared to that of the total surface increases greatly; this proves the extraordinarily large values of the OH density of silica gel at high hydrothermal temperatures. Exactly the same behavior was observed during the sintering process of this material, in which the surface area dropped to very low values, while the OH density increased highly at the same time, accompanied by the production of closed pores.[2] The amount of these inner OH groups can be estimated from the intensity of the 3670 cm^{-1} band after sufficient isotope exchange of OH group, assuming that the absorption intensity per OH group is the same for all three types of OH groups, although the degree of perturbation is different for these OH vibrations. The results of this estimation, together with the other properties of this material are shown in Table 1. In Column 5 of this table, the number

Table 1. The surface areas and the number of OH groups per nm^2 of silica gel hydrothermaly treated at various temperatures

10	579.5	4.13	0.85	3.5	6.1	1033
50	742.1	4.13	0.84	3.5	4.7	1033
75	825.4	4.20	0.81	3.4	4.1	1050
100	839.4	3.83	0.76	2.9	3.5	958
163	495.1	2.48	0.73	1.8	3.7	620
202	214.3	1.67	0.43	0.73	3.4	418
230.5	146.6	1.49	0.27	0.40	2.7	373
253.0	63.5	1.13	0.26	0.29	4.6	283

of OH groups which can be exchanged with OD groups can be estimated from the intensity of the total OH band subtracted by that of the inner OH band. The surface densities of outer OH groups can be calculated from these values in Column 5, divided by the outer surface area, which is nearly equal to the B. E. T. specific surface area in Column 2; the results are shown in Column 6. These values of the OH surface density are less than $4/nm^2$ above 100 °C, where the surface area around the particle contacts is negligible, but are more than 4 below 100 °C, where the number of coordination is so large that the area around these points can not be neglected. It is interesting to see that the OH density of non-porous aerosil is about $3.8/nm^2$, which is almost equal to the values shown in the table.

If the bulk siloxane structure of primary particles of silica gel was homogeneous everywhere inside the particle, the surface density of OH groups would be the same all over the particle surface. Therefore, it seems possible to obtain the total surface areas of the primary particles of this material by dividing the number of the total OH groups per unit of weight in Column 3 of Table 1 by the surface OH density of $4/nm^2$. The total surface areas thus estimated are shown in the last column of Table 1. It is interesting to see that the total surface area below 100 °C is nearly equal to that calculated by taking the area around the contact points into account, as will soon be reported elsewhere.[10] The number of OH groups, $4/nm^2$, obtained here is also in good agreement with that obtained from the study of the heat of the immersion of silica gel thermally treated under various conditions.[11] The pore structure of silica gel proposed in this investigation is in fair agreement with the view given by Barby.[12]

Conclusion

The surface OH groups of silica gel are found to consist mainly of three types; the free OH groups on the outer convex surface exposed to the molecular adsorption and with an infrared absorption band at about 3750 cm^{-1}, the inner OH groups on the concave surface inside the closed pores at about 3670 cm^{-1}, and the strongly hydrogen-bonded OH groups on the surface around the contact points between primary particles with a broad absorption band at about 3500—3300 cm^{-1}. The pore structure and its change upon the hydrothermal and thermal treatment seem to influence the relative concentrations of these three types of OH groups of silica gel.

The authers are grateful to Mr. Hirofumi Fujiwara, Miss Misako Fujikawa, and to Miss Hiromi Okada of the Osaka University of Education for their discussions and experimental help.

(Received September 21, 1978)

A new method for the determination of pH in reversed micellar systems was proposed. The degree of dissociation (α) of Phenol Red in the systems was observed spectrophotometrically. The value of pH can be obtained by use of the Henderson-Hasselbach equation with the aid of pK_a of Phenol Red measured by means of ^{31}P-NMR in the systems containing phosphate buffer solutions. The method was applied to systems consisting of sodium octanoate, 1-hexanol, and water and some buffer solutions other than phosphate buffer solutions, and found to be effective within a wide pH range. Analysis of the fluorescence spectra of 8-anilino-1-naphthalenesulfonic acid indicates that Phenol Red molecules are present at the interface between the water core and the 1-hexanol phase in reversed micelles. The hydrolytic reaction of *p*-nitrophenyl acetate was also studied kinetically and found to change slightly with pH.

The rates of the chemical reactions are drastically accelerated in the reversed micelle.[1–5] Recently, an effective energy transfer was observed in the reversed micellar system.[6]

Hydrolytic reactions of *p*-nitrophenyl esters were studied in the reversed micelle consisting of sodium octanoate, 1-hexanol, and water. It was found that the rate of the reaction is much more enhanced as compared with that in the aqueous solution. Favorable partitioning of the substrate into the water core, the orientation of the catalyst at the interface between the water core and the 1-hexanol phase and the polarity of the water molecules are important factors to accelerate the reaction. NMR studies on the behavior of water molecules and the polar headgroup of sodium octanoate in the reversed micelle showed that the mobility and polarity of water molecules change with hydration of sodium ions.

The purpose of this study is to measure the pH in the reversed micelle in order to know the effect of pH on the hydrolytic reaction. This will also be relevant to elucidating the activity of the water molecule in the reversed micelle. The pH in the reversed micelle cannot be measured with a glass electrode. The pH value in the interior of cell membranes also cannot be measured with a glass electrode, but have been determined by several alternate methods.[7–9] ^{31}P-NMR technique has been used to measure the pH values in the interior or exterior of cell membranes.[10,11] On the other hand, the acid-base indicator is useful for measuring pH of the aqueous solution. In this case, pH is determined by the Henderson-Hasselbach equation

$$\mathrm{pH} = \mathrm{p}K_a + \log \frac{\alpha}{1-\alpha} \qquad (1)$$

where K_a is the dissociation constant of the indicator, and α the degree of dissociation of the indicator. Since K_a of the indicator in the reversed micelle is not the same as that in the aqueous solution, the pH value in the reversed micelle cannot be measured only by means of indicator. The pH value in the reversed micelle consisting of the buffer solution other than the phosphate buffer solution cannot be measured by ^{31}P-NMR technique. In this study, α of Phenol Red and the pH value in the reversed micelle consisting of the phosphate buffer solution were determined by the spectrophotometry method and ^{31}P-NMR, K_a of Phenol Red being obtained by substituting α and pH in Eq. 1. Thus, the use of Phenol Red makes the pH measurement in the reversed micelle not only easier but the evaluating of the pH value in the reversed micelle consisting of any buffer solution in a wide pH range possible.

A hydrophobic probe,[12] 8-anilino-1-naphthalenesulfonic acid (ANS), is an amphiphilic compound with a chemical structure similar to that of Phenol Red. The position of Phenol Red can thus be estimated from the measurement of the fluorescence of the system.

Experimental

Materials. Analytical grade reagents of sodium octanoate, 1-hexanol, Phenol Red, adenosine-5′-triphosphate (ATP), 8-anilino-1-naphthalenesulfonic acid (ANS), and L-tryptophan were used without further purification. 2-[4-(2-hydroxyethyl)-1-piperazinyl] ethanesulfonic acid (HEPES, $pK_a = 7.5$), 3-(cyclohexylamino)-1-propanesulfonic acid (CAPS, $pK_a = 10.4$) and 3-[2-hydroxy-1,1-bis(hydroxymethyl)-ethylamino]-1-propanesulfonic acid (TAPS, $pK_a = 8.4$, DOJINDO Laboratories) were used. Reversed micellar solution was prepared by mixing three components, the buffer solution (phosphate or HEPES–TAPS–CAPS buffer solution), 1-hexanol and sodium octanoate, and allowing the mixture to stand at 30 °C for 24 h. In the measurements of the absorption spectra, ^{31}P-NMR spectra and the fluorescence spectra, the buffer solution containing Phenol Red (the concentration of Phenol Red is 10^{-4} M), adenosine-5′-triphosphate (10^{-2} M) and the fluorescence probe (10^{-4} M) was cosolubilized into the reversed micelle. The quencher, carbon tetrachloride, was added directly to the reversed micellar solution containing ANS molecules.

Measurements. ^{31}P-NMR was measured with JNM-PS type spectrometer at 40 MHz, the following setting of the pulse unit being employed; spectral width 4000 Hz, repeat time 2.5 s, pulse width 18.0 μs, 100 times accumulation. The absorption spectra were recorded on an EPS-3T Hitachi spectrophotometer at 30 °C. The fluorescence spectra were measured with a Shimadzu RF-502 type spectrofluorimeter at 30 °C.

Results and Discussion

Determination of pH *Value.* Figure 1 shows the dependence of the chemical shift of phosphorus in

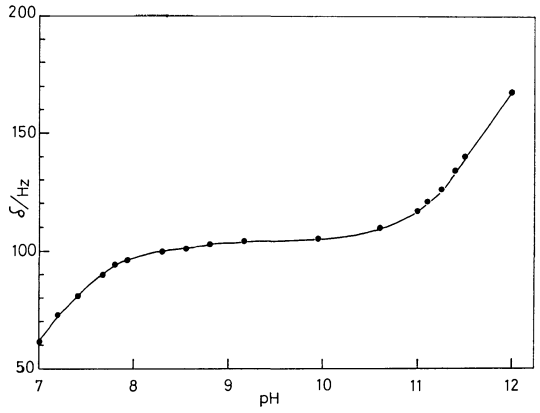

Fig. 1. The chemical shifts of phosphorus in the phosphate buffer solutions plotted as a function of pH of the buffer solution.

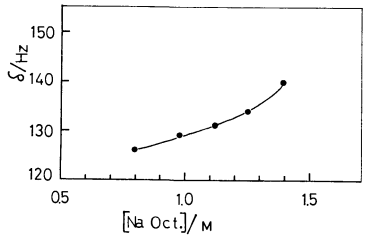

Fig. 2. Plots of the chemical shifts of phosphorus in the phosphate buffer solutions solubilized into reversed micelles against the concentration of sodium octanoate. The pH value of the phosphate buffer solution used is 7.9.

the phosphate buffer solution on the pH of the buffer solution. The steps in the chemical shift plots correspond to the processes

$$H_2PO_4^- \rightleftharpoons HPO_4^{2-} \rightleftharpoons PO_4^{3-}.$$

The chemical shifts of phosphorus were measured as a function of concentration of sodium octanoate for reversed micelles prepared by the use of phosphate buffer solutions of pH 7.9. The results are shown in Fig. 2. The chemical shift increases with increase in the concentration of sodium octanoate. This indicates that the pH value in the reversed micelle is higher than the initial pH value of the phosphate buffer solution used for the preparation of reversed micellar solutions. The activity of water molecules in the reversed micelle should decrease with increase in sodium octanoate content. However, the pH value obtained from ^{31}P-NMR method is much higher than that calculated by $[H^+]=\sqrt{K_wK_a/C}$, where K_w is the ion-product constant of water, K_a the dissociation constant of octanoic acid, and C the concentration of sodium octanoate. Such large chemical shifts of phosphorus as observed in the reversed micelle may be due to the ionic effect of the polar headgroup of sodium octanoate. Since the chemical shift of α-phosphorus of adenosine-5′-triphosphate (ATP) does not change with pH,[13] the chemical shift induced by sodium octanoate was evaluated by the following method. By means of this property of α-phosphorus of ATP, the difference between the α-P chemical shift of ATP in the aqueous solution and in the reversed micelle

Table 1. The observed chemical shift (δ), the chemical shift induced by sodium octanoate (δ′), δ−δ′ and pH obtained from (δ−δ′) for reversed micellar samples

was measured, and used as the chemical shift induced by sodium octanoate. The real chemical shift of phosphorus in the reversed micelle should be obtained by subtracting the shift thus obtained from the chemical shift observed for the reversed micelle. From the result, the real pH value (pH′) in the reversed micelle can be obtained by means of Fig. 1. The results are given in Table 1.

The absorption spectra of Phenol Red in reversed micelles show a peak at 450 nm due to unionized form and a peak at 571 nm due to ionized form of Phenol Red and the isosbestic point at 490 nm. The absorbance at 571 nm (OD_B) due to the ionized form of Phenol Red in the reversed micelle against the initial pH value of the buffer solution (phosphate buffer or HEPES–TAPS–CAPS buffer) solubilized into the reversed micelle is plotted in Fig. 3. Although the pH values of the phosphate buffer solution containing Phenol Red vary in the range 7—12, the absorbance due to the ionized form of Phenol Red does not appreciably change with pH. This indicates that pH at the position where Phenol Red exists does not change much with pH of the phosphate buffer solution. Thus, pH in the reversed micelle is determined by the buffer capacity of sodium octanoate rather than that of the phosphate buffer solution. A similar experiment was carried out in the reversed micelle with use of another buffer solution, HEPES–TAPS–CAPS. The results are shown in Fig. 3. The transformation of Phenol Red from the acid form (unionized form) to the basic form

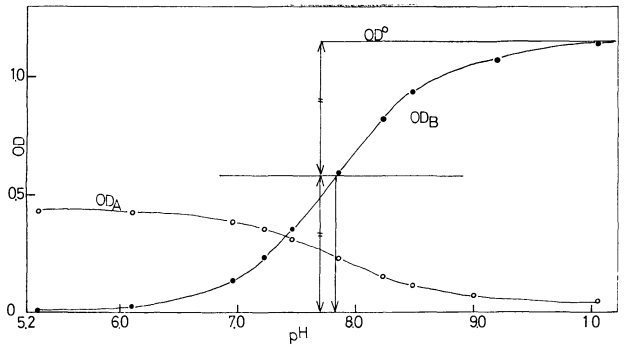

Fig. 4. Plots of the absorbance of Phenol Red due to the ionized (OD_B) and the unionized (OD_A) forms against pH of the phosphate buffer solution. This figure shows pK_a of Phenol Red in the phosphate buffer solution is 7.82.

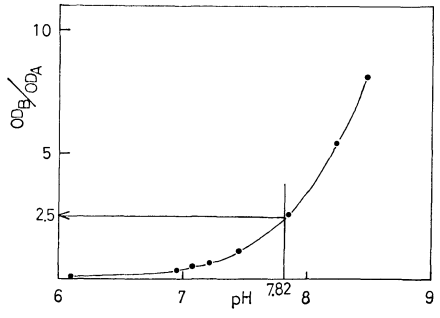

Fig. 5. Plots of OD_B/OD_A against pH of the phosphate buffer solution.

(ionized form) takes place to a greater extent than in the phosphate buffer solution, especially in the pH range 7—9. In order to estimate the degree of dissociation (α) of Phenol Red, it is necessary to measure the absorbance due to the completely ionized form of Phenol Red ($OD_B°$). However, the value of OD_B at the highest pH (pH=12) showed no constant value (Fig. 3). The following experiment was made in aqueous solutions. The absorbances of Phenol Red at 571 nm and at 450 nm were measured as a function of the pH of the buffer solution (Fig. 4). The dissociation constant *K*a of Phenol Red in this buffer solution (phosphate buffer solution) was found to be 7.82 by means of Eq. 1. The ratio of the absorbance at 571 nm (OD_B) to that at 450 nm (OD_A) is plotted against pH of the buffer solution (Fig. 5). We see that OD_B/OD_A is 2.5 for pH 7.82. The values of OD_B/OD_A were obtained for the four buffer solutions; phosphate buffer solution, HEPES–TAPS–CAPS, 90% phosphate buffer solution +10% ethanol, and 90% phosphate buffer solution +10% dioxane; the results are summarized in Table 2. The OD_B/OD_A value becomes 2.5 at the point pH=pK_a where OD_B is equal to a half of $OD_B°$. Thus, $OD_B°$ can be obtained from the value of OD_B at the pH where the value of OD_B/OD_A becomes 2.5. In the four buffer solutions, the value of $OD_B°$ thus obtained was equal to that estimated from Fig. 4. In the reversed micelle, $OD_B°$ was evaluated with the assumption that OD_B at pH of OD_B/OD_A=2.5 is also equal to a half of $OD_B°$. The following procedure was taken to determine pH

Table 2. The dissociation constant pK_a and the ratio OD_B/DA_A for four buffer solutions

	pK_a	OD_B/DA_A
Phosphate buffer	7.82	2.50±0.02
90% phosphate buffer+10% ethanol	7.90	2.50±0.02
90% phosphate buffer+10% dioxane	7.88	2.51±0.02
HEPES-TAPS-CAPS	7.82	2.48±0.02

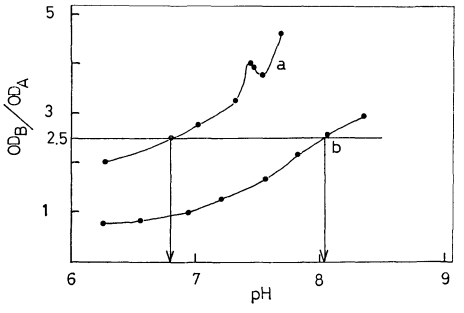

Fig. 6. Plots of OD_B/OD_A of Phenol Red against the original pH value of the buffer solution solubilized into the reversed micelle. a) Phosphate buffer, b) HEPES–TAPS–CAPS.

in the reversed micelle.

1. The values of OD_B/OD_A were determined as a function of the pH of the original buffer solution solubilized into the reversed micelle. The results are shown in Fig. 6.

2. The pH of the buffer solution giving the value OD_B/OD_A=2.5 was obtained from the OD_B/OD_A *vs.* pH curve shown in Fig. 6.

3. The OD_B value corresponding to the pH value obtained from step 2 was obtained from the OD_B *vs.* pH curve given in Fig. 3. Thus, the value of $OD_B°$ can be obtained as twice the value of OD_B.

4. The degree of dissociation (α) of Phenol Red in the reversed micelle is thus obtained as $OD_B/OD_B°$.

5. The dissociation constant K_a of Phenol Red in the reversed micelle can be calculated from the degree of dissociation of Phenol Red and the pH value obtained by ^{31}P-NMR, by means of Eq. 1. When the phosphate buffer solution of pH 7.9 was solubilized into the reversed micelle, the α and pH values were found to be 0.65 and 8.6 by spectrometric method and ^{31}P-NMR, respectively. By substituting these values into Eq. 1, the pK_a value of Phenol Red was found to be 8.3.

6. By use of α and pK_a (8.3) of Phenol Red, the real pH value (pH′) in the reversed micelle containing a buffer solution was obtained in a wide pH range. The pH′ values in the reversed micelle containing phosphate buffer solutions and HEPES buffer solutions are shown in Fig. 7.

Fluorescence Spectra. It is important to study the position of Phenol Red molecule. It may be in the water core, 1-hexanol phase or at the interface between the water core and 1-hexanol phase. Fluorescence has been used for elucidating the position. 8-Anilino-1-naphthalenesulfonic acid (ANS), which is an amphiphilic compound with a structure similar to that of Phenol Red, was used. The positions of

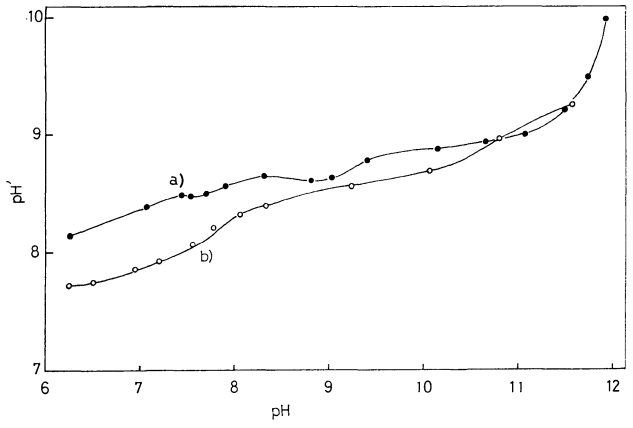

Fig. 7. Plots of the real pH value (pH') against the original pH value of the buffer solution solubilized into the reversed micelle. a) Phosphate buffer, b) HEPES–TAPS–CAPS buffer.

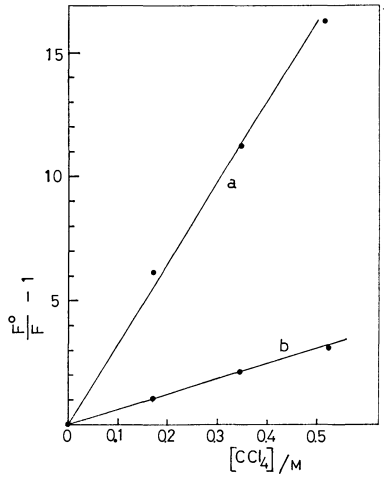

Fig. 8. The Stern-Volmer plots in 1-hexanol and the reversed micelle. The fluorescence probe used is ANS. a) 1-Hexanol, b) in the reversed micelle.

the emission maxima and the relative intensities of ANS in 1-hexanol, water, and the reversed micelle are given in Table 3. The position of the emission maximum and the very low intensity in water as compared with those in the reversed micelle indicates that ANS molecules do not exist in the water phase of the reversed micelle.

Carbon tetrachloride can quench the fluorescence of ANS in 1-hexanol. Quenching of the excited state of ANS can be quantitatively treated by the Stern-Volmer equation[14] $F^\circ/F-1=k^\circ\tau[Q]$, where F and F° are the fluorescence intensities of the probe with and without the quencher, respectively, k° the rate constant of quenching, τ° the fluorescence lifetime of the probe in the absence of the quencher, and [Q] the concentration of the quencher. Figure 8 shows the plots of the data obtained by means of this equation in 1-hexanol and in the reversed micelle. Carbon tetrachloride quenches the fluorescence of ANS in 1-hexanol to a greater extent than in the reversed micelle. The results indicate that no appreciable amount of ANS exists in the 1-hexanol phase of the reversed

Table 3. Position of emission maximum and the relative intensity of ANS in water, 1-hexanol and the reversed micelle

	Water	1-Hexanol	Reversed micelle[a]	
			A	B
Emission maximum/nm	515	460	465	470
Relative intensity	1	254	131	109

a) A; 1.38 M of sodium octanoate in 1-hexanol.
B; 0.69 M of sodium octanoate in 1-hexanol.

micelle. Thus, the probe molecules should exist at the interface between the water core and the 1-hexanol phase.

The same experiment was carried out in the reversed micellar system with use of L-tryptophan, an amphiphilic compound. L-Tryptophan is not soluble in 1-hexanol, but can be quenched a little by carbon tetrachloride in the reversed micelle. The results indicate that L-tryptophan molecules also exist at the interface between the water core and the 1-hexanol phase. Thus, the amphiphilic molecules are considered to be located at the interface between the water core and the 1-hexanol phase, due to the balance of the hydrophobic and lyophilic interactions. Phenol Red exists at the interface between the water core and the 1-hexanol phase as in the case of L-tryptophan and ANS, the real pH (pH') given in Fig. 7 being pH at the interface of the reversed micelle.

Dissociation Constant of Phenol Red and the Surface Potential in the Reversed Micelle. By substituting the pH value obtained by ^{31}P-NMR and the degree of dissociation of Phenol Red by spectrometric methods in Eq. 1, we have obtained the dissociation constant of Phenol Red as 8.3, which is larger than that in the aqueous solution (7.8). The dissociation constant of Methyl Red measured by Montal and Gitler[15] in the aqueous solution of sodium dodecyl sulfate was also larger than that in the aqueous solution. By means of the gel filtration technique, they showed that Methyl Red is influenced by the surface charges of the micelle. The concentration of H^+ ion at the surface of the micelle would differ from that in the bulk phase of the system due to the difference in electrical potential between that on the micellar surface and that in the bulk phase. The dissociation constant of Methyl Red on the micellar surface, K_s, is given by the equation $pK_s=pK_b-\varepsilon\psi/2.3\,kT$, where K_b is the dissociation constant of Methyl Red in the bulk phase, ψ the surface potential, ε the electrical charge, T the absolute temperature, and k the Boltzmann constant. For Methyl Red in the aqueous solution of sodium dodecyl sulfate, $\psi=-86$ mV, and for Phenol Red, $\psi=-30$ mV in the reversed micelle. The difference in surface potential between Methyl Red and Phenol Red would be caused by the difference in the location of the indicators and in the nature of the headgroups of the surfactants, *i.e.*, the sulfate group of sodium dodecyl sulfate and the carboxylate group of sodium octanoate.

Effect of pH *on the Reaction in the Reversed Micelle.* The rate constant of the hydrolytic reaction of *p*-

nitrophenyl acetate in the reversed micelle in which the phosphate buffer solution is solubilized is as large as that in which the HEPES buffer solution is solubilized. On the other hand, pH′ in the reversed micelle in which the phosphate buffer solution is solubilized is higher than that in which the HEPES buffer solution is solubilized (Fig. 7). Thus it appears that, although the hydrolytic reaction depends slightly on the pH in this system, it is not an important factor in the enhancement of this reaction rate in the reversed micelle.

Copper(I) Chloride Complex Containing *p*-Benzoquinone as a Ligand

Hiroko YAMAGUCHI,* Hiroshi KIMURA, and Kazuo YASUKOUCHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, 2-39-1, Kurokami, Kumamoto 860

(Received October 4, 1978)

A new complex $[(NH_4)Cu_3Cl_4(C_6H_4O_2)_{3/2}\cdot H_2O]$ was synthesized from $CuCl_2$, hydroquinone, and NH_4Cl in an aqueous solution, and its structure was characterized on the bases of its UV, IR, and ESR spectra and TGA. On heating, this complex was stable up to 100 °C, but above 120 °C *p*-benzoquinone was released quantitatively. The complex was found to be a polynuclear copper(I) complex containing *p*-benzoquinone molecules and chlorides as ligands, and to be a charge-transfer complex in which π-electrons of the ring carbons of *p*-benzoquinone form coordinate bonds with Cu(I). The formation process of the complex was:

$$3CuCl_2 + 3/2(C_6H_6O_2) + H_2O + NH_4Cl = (NH_4)Cu_3Cl_4(C_6H_4O_2)_{3/2}\cdot H_2O + 3HCl$$

Deep red crystals are inadvertently obtained when $CuCl_2$, hydroquinone, and NH_4Cl are mixed in an aqueous solution. They were found to be a new-type Cu(I) complex, $[(NH_4)Cu_3Cl_4(C_6H_4O_2)_{3/2}\cdot H_2O]$ (to be called BQ-Red hereafter), in which the π-electrons of *p*-benzoquinone form coordinate bonds with Cu(I).

A complex containing a ligand of *p*-benzoquinone has been synthesized by Hashimoto *et al.*[1] In this complex, both of the oxygen atoms of *p*-benzoquinone are coordinated to Cu(I). The IR spectrum of BQ-Red, however, indicates that the oxygens can not be the donor atoms, because the shift of the C=O stretching absorption caused by complexation is only 8 cm^{-1}.

The aim of this paper is to describe a method for synthesizing this interesting complex and its chemical and spectral characteristics. The information obtained from the latter is all in harmony with its structure, which was recently established by an X-ray diffraction study.† The reaction mechanism for the formation of BQ-Red will also be discussed.

Experimental

Materials. The reagents, $CuCl_2$, hydroquinone, and NH_4Cl (Wako special grade), were used without further purification. All the solvents used were purified by repeated distillations.

Apparatus. The IR spectra were taken with Hitachi perkin Elmer Model 125(4000—400 cm^{-1}) and JASCO DS-403G grating(600—200 cm^{-1}) spectrometers. The ESR spectra were measured with a JEOL, Model JES-3BSX, X-band spectrometer. The UV and visible spectra were obtained with a Hitachi EPS-2U spectrometer. The TG and DTA measurements were carried out using a Rigaku denki DPA-001D apparatus, with α-alumina as the standard and in a quartz cell. The elemental analysis of C, H, and N was carried out by means of an auto CHN corder, Model MT-2(Yanagimoto).

Synthesis. NH_4Cl, $CuCl_2$, and hydroquinone were mixed in an aqueous solution. The total concentration of the three components in 100 ml was kept constant(2 M), while the molar ratios of the three were varied as is shown in Fig. 1. Deep red crystals separated out from the solution when 5 M NaOH (10—20 ml) was slowly added to the mixed solution with constant stirring. The crystals were obtained only when the molar ratio of the components lay inside the enclosed area shown by a dotted line (Fig. 1); no red crystals were formed outside of this area. This indicates that the formation of the red crystals depends mainly upon the amount of hydroquinone. When the amount of hydroquinone was smaller than the theoretical one (△), red crystals were easily formed. All the red crystals thus formed has the same composition. The molar ratio at which the largest amount of red crystals(BQ-Red) was formed was, $CuCl_2$: hydroquinone: NH_4Cl=3 : 1 : 1.

BQ-Red is soluble only in aqueous NH_4Cl, and the higher the concentration of NH_4Cl, the better it dissolves. The solution is reddish orange. On the other hand, when the concentration of NH_4Cl is less than 2 M, it is hardly soluble, and it decomposes gradually, forming a yellow solution after 20—30 min. In water, BQ-Red decomposes at once and becomes greenish, with the formation of $CuCl_2$. In methanol, the crystals become white CuCl, and a similar but partial decomposition occurs either in ethanol or in acetone. In 1-pentanol, benzene, ligroin, ether, or petroleum ether, however, the crystals are stable and remain deep red. Since no solvent for the recrystallization was found, the sample of BQ-Red for the analyses was purified by scrubbing it with 1-pentanol and with ether to remove all unreacted substances. Deep-red crystalline plates of BQ-Red were obtained in this way.

Analysis. The copper was determined by titrating it with EDTA after decomposition with a mixture of nitric

acid and perchloric acid(3 : 1).[5] The chlorine was also determined by chelate titration, after the decomposition of the BQ-Red by the Schöniger method[6] and the absorption of the evolved chlorine gas into a basic H_2O_2 solution.[7] Found: C, 20.06; H, 2.31; N, 2.62; Cl, 29.68; Cu, 35.71%. Calcd for $C_9H_{12}NCl_4O_4Cu_3$: C, 20.36; H, 2.26; N, 2.64; Cl, 26.73; Cu, 35.94%.

Results and Discussion

ESR Spectrum (Solid State). The ESR spectra of BQ-Red and $CuCl_2\cdot 2H_2O$ in the solid state were measured. Since the intensities of the obtained spectra depend upon the content of Cu(II), the content of Cu(II) in BQ-Red could be estimated from the data; it was found to be about fiftieth of the total amount of copper in BQ-Red. Thus, the copper in BQ-Red is present as a univalent ion, and BQ-Red appears to be a charge-transfer complex.

Thermogravimetric Analysis. BQ-Red decomposes, with the sublimation of the yellow crystals of *p*-benzoquinone, leaving a green copper salt, within a month at room temperature in the summer. When BQ-Red is heated, the yellow crystals of *p*-benzoquinone sublime from it at about 100 °C. Figure 2 and Table 1 show the TG curves and related data. Experiment (I) was performed in air, and (II), under flowing argon. Both sets of data show that *p*-benzoquinone sublimes endothermically at about 100 °C and that the lattice water is then lost at about 230 °C.

In air (I), the ammonium cation is lost as ammonia at about 390 °C and the chloride anion is lost as HCl at about 450 °C endothermically, and finally stable CuO (F) is obtained.

Under an inert gas, Ar (II), however, these two steps are indistinct, and the weight loss of 37.7% at the (D) point indicates that a compound with the composition of $(Cu_3Cl_3)\cdot HCl$ is formed; this compound remains stable between 270 and 595 °C. Then, at 595 °C, the weight loss suddenly increases until it becomes constant (83.9%, that is, 16.1% of the initial weight of BQ-Red); thereafter, it does not change until 800 °C. In N_2 gas, the TG curve is similar to that obtained in Ar, as is shown in Fig. 2, and the final weight of BQ-Red is 16.1% of the initial weight of BQ-Red, too. Under the inert gases, the final compound probably changes to elementary copper, corresponding to 1/2 of the initial copper content, while the rest sublimes away as chlorides.

Thus, the TG data can be explained in terms of the $[(NH_4)Cu_3Cl_4(C_6H_4O_2)_{3/2}\cdot H_2O]$ formula.

Infrared Spectrum. The IR spectrum of BQ-Red is shown in Fig. 3, while the assignments are sum-

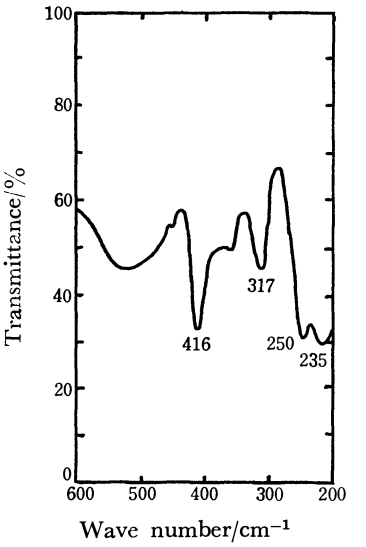

Fig. 4. Far-IR spectrum of BQ-Red.

marized in Table 2. Many bands of BQ-Red are similar to those of *p*-benzoquinone; this indicates that the starting material, hydroquinone, changes to *p*-benzoquinone upon the formation of BQ-Red. In the spectrum of BQ-Red, the C=C stretching band of *p*-benzoquinone (1592 cm^{-1}) shifts to 1476 cm^{-1}. It is interesting to note that this kind of shift to lower frequencies is more remarkable in Pt complexes.[8] For example, the C=C stretching frequency of the asymmetrical olefins observed at about 1600 cm^{-1} shifts to 1504 cm^{-1} in $K[PtCl_3(C_3H_6)]H_2O$,[9] although C=C bands of symmetrical olefins are not observed even in such complexes as $K[PtCl_3(C_2H_4)]H_2O$. This suggests that the C=C of the *p*-benzoquinone in BQ-Red is asymmetrically coordinated to Cu. In fact, the results of the X-ray structural analysis shown in Fig. A show clearly that the *p*-benzoquinone(1) has a symmetrical, but *p*-benzoquinone(2) has an asymmetrical, interaction with NH_4^+; this fact may cause some resemblance between them and symmetrical and asymmetrical olefins respectively.

On the other hand, the shift of the C=O stretching absorption caused by complexation is only 8 cm^{-1} in BQ-Red. It can thus easily be deduced that the oxygen atoms of the carbonyl groups of *p*-benzoquinone are not coordinated to Cu(I), but only make hydrogen bonds with NH_4^+. This agrees with the fact that BQ-Red readily decomposes to give *p*-benzoquinone when heated.

In addition, the intensities of the IR bands due to C–H [in-plane(1308, 1084 cm^{-1}) and out-of-plane(892 cm^{-1})] are almost equal to each other in *p*-benzoquinone, but in BQ-Red those of the latter (899 and 869 cm^{-1}) are much weaker than those of the former (1288 and 1056 cm^{-1}). Thus, in the crystals of BQ-Red, the *p*-benzoquinone molecules are arranged in a certain order, so that in-plane deformation vibration is promoted and out-of-plane deformation vibration is disturbed.

The bands of water and the ammonium cation in BQ-Red are clearly observed, as is shown in Fig. 3 and Table 2.

Far-infrared Spectrum. The characteristic band of a chloride anion bridging two metals is generally observed between 150—350 cm^{-1}, and it is slightly split into two strong bands. It is known[10] that the wave number of the stretching frequency of the bridging chloride, $\nu(M\text{–}Cl)_b$, is lower than that of terminal chloride, $\nu(M\text{–}Cl)_t$. The far-IR spectrum of BQ-Red is shown in Fig. 4. The absorption bands at 235 and 250 cm^{-1} can be assigned to those of $\nu(Cu\text{–}Cl)_b$, and the band at 317 cm^{-1}, to that of $\nu(Cu\text{–}Cl)_t$. Since the former bands are stronger than the latter, most of the chloride ions seem to be combined directly with two Cu atoms. However, the structure shown in Fig. A has no terminal chloride. Since the central Cl(4) is different from the other three (1, 2, and 3) in coordinate number, the band at 317 cm^{-1} may be assigned to the vibration of the central Cl(4).

The band at 416 cm^{-1} is due to the skeletal vibration of *p*-benzoquinone.

UV and Visible Spectra. The spectra of BQ-Red, *p*-benzoquinone, and hydroquinone in 4 M NH_4Cl solutions were also observed. The *p*-benzoquinone is characterized by maxima at 246 nm ($\log\varepsilon=3.95$) and 428 nm ($\log\varepsilon=1.4$), while hydroquinone is characterized by maxima at 222 nm and 290 nm. The spectrum of BQ-Red in the solution has maxima at 246 nm ($\log\varepsilon'=3.8$), 275 nm (shoulder, $\log\varepsilon'=3.3$), 438 nm ($\log\varepsilon'=2.5$), and 800 nm ($\log\varepsilon'=1.6$); this indicates that BQ-Red forms *p*-benzoquinone in solution. However, the red shift of the maximum at 428 nm and the presence of a shoulder at 275 nm suggest the interactions of *p*-benzoquinone with NH_4^+ and H_2O, which are in both the molecule and the solvent.

Molecular Structure. Since copper in BQ-Red is univalent, a tetrahedral arrangement of ligands like that in other Cu(I) complexes seems most probable;[11–13] this expectation conforms to the results of the X-ray analysis (Fig. A).

It is known that the coordination number of Cl is usually 1[11,14] or 2.[15] Moreover, Cu(I) complexes

with a three-coordinate chloride,[13] and a complex (Cu_4Cl_4)[12] with two two-coordinate and two three-coordinate chlorides, have been reported. However, BQ-Red is different from those reported previously,[11-15] for it contains three two-coordinated and one three-coordinated chlorides.

Although the oxygen of the carbonyl group is usually one of the well-known donor atoms, in this complex the π-electrons of the ring carbons of *p*-benzoquinone coordinate to Cu(I) as was reported in the case of a duroquinone complex,[16] in which the π-electrons of C=C of duroquinone coordinate to Ni(II). The coordination of the π-electron of C=C with Cu(I) has often been reported in aromatic complexes;[17-20] for example, the $(C_6H_6)[Cu(OSO_2CF)]_2$ complex[18] is stable up to 100 °C.

Thus, it is established that π-complexing occurs in BQ-Red, though little has been reported with regard to the fact that the copper(I) is π-bonded to a *p*-benzoquinone ring.[21]

Reaction Mechanism. The hydroquinone which is added as a starting material in the synthesis changes to *p*-benzoquinone in the complex formation, but no BQ-Red is formed when *p*-benzoquinone is used instead of hydroquinone, and Cu(II) changes to Cu(I). Thus, the formation process of BQ-Red is:

(1)

(2)

Then, three Cu(I) ions and three chloride ions make a ring:

$$3Cu^+ + 3Cl^- = \text{Ring } (-Cu-Cl-)_3 \quad (3)$$

As $Cu^+(d^{10})$ favors sp^3-hybridization, each Cu(I) accepts an electron pair from a *p*-benzoquinone around it and also combines with another chloride which is located at a center of the crown like ring (Cu_3Cl_3) (*cf.* Fig. A) to give a stable tetrahedral coordination structure:

$$\text{Ring } (Cu_3Cl_3) + NH_4Cl = (Cu_3Cl_3)Cl^- \cdot NH_4^+ \quad (4)$$

Thus, the overall reaction is:

$$3CuCl_2 + 3/2\, C_6H_4(OH)_2 + H_2O + NH_4Cl = \text{BQ-Red} + 3HCl \quad (5)$$

21) The fact that BQ-Red is a polymer, as is shown in Fig. A, agrees with the finding that BQ-Red is insoluble in any common solvent. The volumes of the holes in a polymer which is packed with so many molecules and ions (such as *p*-benzoquinone, Cu_3Cl_3, H_2O, NH_4^+, and Cl^-) may reasonably be said to be similar to those of the NH_4^+ and Cl^- ions; this may be the reason why it is easily soluble only in an aqueous NH_4Cl solution.

Surface Activity of Complex in Mixed Surfactant Solution

Kazuo TAJIMA*, Akio NAKAMURA, and Takao TSUTSUI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received October 19, 1978)

The dissociation constant of the complex formed in the mixed and very dilute surfactant solution of 3-(dodecylammonio)-propionate (NDA) and sodium alkylsulfates (C_{10}, C_{12}, C_{14}) (SAS) was determined by measuring surface tension and adsorbed amounts of the solution. The composition in the surface and bulk phases did not coincide at the equimolar mixture. The adsorbed monolayer on the solution consists of the coadsorption of NDA–SAS complex (1:1) and free NDA, while the adsorption of free SAS was almost zero in various concentrations studied. Under these conditions the surface activity of the complex alone was obtained. The relationship between the surface activity and bulk concentration for each mixed solution was discussed in terms of relative adsorbability. The surface activity of the complex was one order of magnitude higher than that of NDA and two orders higher than that of SAS.

The mixed surfactant in the aqueous solution has been found to have a more surface-active character than that of each component:[1–10] in particular, the solution containing oppositely charged surfactants considerably changes by the formation of an ionic complex. There are a few papers which have described the dissociation constant of a surfactant complex, which is formed in a solution.[7,11,12] Corkill *et al.*,[2,3] who studied the solution of mixed surfactant of sodium alkyl sulfates and hexadecyltrimethylammonium bromide (HTAB), found that an adsorbed layer composed of the equimolar complex of these surfactants was independent of the bulk compositions, but that the complex formation did not take place in the bulk phase.

The surface activity of a surfactant solution is remarkably enhanced even in dilute solution when a complex is formed, but the concentration of each single species decreases only slightly. Thus a direct measurement of concentration reliable enough for determining the dissociation constant is impossible in some cases. In view of such properties of surfactant solutions, the present work was carried out to determine the dissociation constant of a surfactant complex in a mixed and very dilute solution by the surface chemical method, and to decide the surface activity due to the complex in the solution. Further, an attempt was made to elucidate the relationship between the surface activity and the bulk compositions in the solution.

Experimental

The pure and synthetic surfactants 3-(dodecylammonio)-propionate (NDA) and sodium alkyl sulfates (SAS) containing 10 (De), 12 (D), and 14 (T) carbon atoms were used. Surface tension and adsorbed amounts were measured by the Wilhelmy and the radiotracer methods, respectively. In radiometry, NDA was labelled with tritium and SAS with ^{35}S, respectively. The details of these measurements were described in previous papers.[13–15] The temperature was maintained at 30.0±0.2 °C, and the pH of the solutions was 5.8±0.2. A part of the data obtained in the present studies has been reported elsewhere.[16,17]

Results and Discussion

The complex formation in the mixed solution of NDA and SAS was confirmed by the electrophoresis study using radioactive surfactants.[17] The conductivity measurements for the solution, however, did not show any indication of complex formation in the solution, as had been found in the mixed SAS–HTAB solution,[3] probably because the concentration of complex is too low for the detection method.

In order to study the composition of the complex of NDA and SAS (*e.g.* SDS), the surface tension was measured for the single and mixed solutions of NDA and SDS. The results are shown in Fig. 1. The dotted line in the figure represents the difference in the surface tensions between the mixed and the (ideal) hypothetical mixed solutions of NDA and SDS. The maximum deviation occurred at the equimolar composition of the mixed solution. This fact leads to the conclusion that the NDA–SDS complex in the bulk phase has a stoichiometric composition in 1:1 molar ratio. This coincided with the results of elemental analysis on the precipitate which was prepared by mixing the NDA and SDS solutions at high concentrations.[17]

Determination of the Dissociation Constant of Complex. A complex, if it is surface-active, always coadsorbs at its solution surface, independently of the surface behaviors of the other species in the solution. Hence, the Gibbs adsorption isotherm may be applied to such a surface-active solution.[18] In present adsorption system, the solute species in the solution are limited

to sodium (Na), alkyl sulfate (A), ampholyte (D), and complex (C) ions, and these are related to:

$$A^- + D^\pm \underset{K}{\rightleftharpoons} C^-$$

Previous observations[15,19] showed that the hydrolyses of the surfactants did not have to be considered under the present experimental conditions. Since the activity coefficients of these ions may be put at unity due to the low concentration, the dissociation constant of the complex, K, in the bulk phase can be defined in terms of the surface-chemical parameters as follows (see Appendix):

$$K = \frac{1}{4C}\left[\left(\frac{\Gamma^D+\Gamma^A}{2I-3\Gamma^D-\Gamma^A}\right)^2 - 1\right] \quad (1)$$

where

$$\left.\begin{aligned} I &= -(d\gamma/RT d\ln C)_{1:1}, \\ C &= C_A + C_C = C_D + C_C = C_{Na}, \\ \Gamma^D &= \Gamma_D + \Gamma_C, \end{aligned}\right\} \quad (2)$$

and

$$\left.\begin{aligned} \Gamma^A = \Gamma_A + \Gamma_C = \Gamma_{Na}. \end{aligned}\right\}$$

C is the concentration in the apparent equimolar mixed solution of NDA and SAS, γ the surface tension, Γ the surface excess, R the gas constant, and T the absolute temperature. The subscripts and superscripts mean the effective and apparent quantities for each species, respectively. K in Eq. 1 may be estimated, if the surface tension and the adsorbed amounts are

measured as a function of the concentration C. Figure 2 shows the γ *vs.* logarithmic concentration plot for the NDA and SAS solutions. Γ^D and Γ^A measured by radiometry are shown in Fig. 3. Similar tendencies were observed for the NDA–SDeS and NDA–STS solutions. The K values obtained are listed in Table 1. The effective concentrations, then, can be estimated for each species in the mixed surfactant solutions of NDA and SAS by using the K values.

Surface Composition. As shown in Fig. 3, the adsorption isotherms, Γ^D and Γ^A, which were independently measured with respect to each radioactive solution of ^{3}H labelled NDA–SAS and NDA–^{35}S labelled SAS at the same concentration C, did not coincide with each other even at the equimolar mixed solution. To study this difference, the surface activity was examined for each single solution of NDA and SAS at the concentrations corresponding to those which were estimated for each NDA–SAS solution by the K values. Neither surface excess nor surface tension lowering was observed for the SAS solutions, within the experimental error (see Fig. 4).[14,15,20] Then, it may be fairly asserted that Γ_A is zero at various concentrations under consideration. Since Γ_A was zero, the difference, $\Delta\Gamma$, of the Γ^D and Γ^A isotherms in Fig. 3 was compared with the surface excess, Γ^0_D, measured at the same effective concentration of the single NDA solution. The results are shown in Fig. 4. The $\Delta\Gamma$ values obtained for all NDA–SAS systems are in fairly good coincidence with the Γ^0_D values. Then $\Gamma_A \simeq 0$ and $\Delta\Gamma \simeq \Gamma^0_D$; therefore, Γ^A is Γ_C. Consequently, the difference of isotherms in Fig. 3 can be explained by

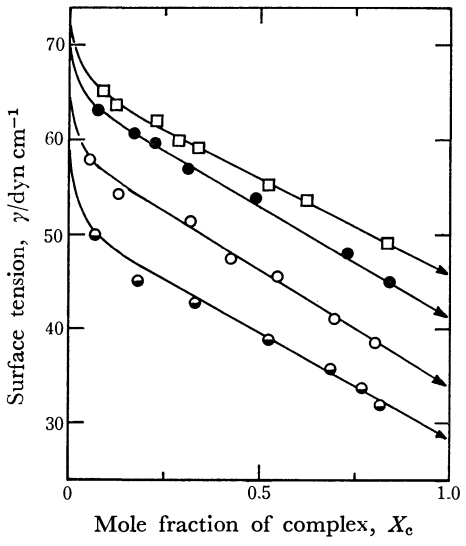

Fig. 5. Dependence of surface tension on complex concentration. Concentration of NDA ($M \times 10^5$) was kept at 0.60(□), 1.00(●), 2.00(○) and 3.60(◒). Arrows show the surface tension of complex alone.

the facts that the adsorbed monolayer from the mixed solution consists of the coadsorption of the complex of NDA–SDS and NDA, while the adsorption of SDS owing to the single dispersion in the solution is almost zero, as shown experimentally for SDS and STS in Fig. 4.

Surface Activity of Complex. Attempts were made to determine the surface activity of the complex alone, though direct measurements are of course impossible. The dependence of surface tension on composition of the film which consists of several species has not been elucidate for the adsorbed monolayer. However, the following linear relation is frequently found, in the bulk ternary system, between its surface tension and the mole fraction of solutes (1,2) at constant amount of solvent:[21]

$$\gamma = X_1\gamma_1 + X_2\gamma_2 \tag{3}$$

If γ is measured as a function of mole fraction, the extrapolated surface tensions for each single solution can be obtained at various concentrations:

$$\gamma_2^0 = (\lim_{X_2 \to 1} \gamma)_C$$

By this manner the surface tension of a complex may be obtained. The complex solutions for this purpose were prepared at various concentrations by adding varying amounts of SAS to the NDA solution of the constant concentration. The fraction of complex formation, X_C, in the solution was calculated from $X_C = C_C/C^D$ by using the K values shown in Table 1. Figure 5 is the plot of surface tension against X_c. Though the present solution contains four species, the apparent additivity expressed by Eq. 3 was well established in a wide region of mole fraction for the complex.[22] The surface tension obtained by extrapolating X_C to 1, corresponding to that for the solution of complex alone, is shown in Fig. 6 as a function of complex concentration, C_C, though only two points were obtained for SDeS and STS complexes. The surface excess, Γ_C^0, of complex was calculated from

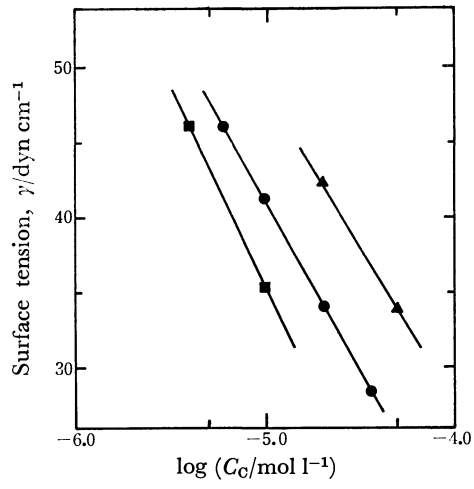

Fig. 6. Surface tension *vs.* concentration curves for the complex solutions. ▲: NDA–SDeS, ●: NDA–SDS, ■: NDA–STS.

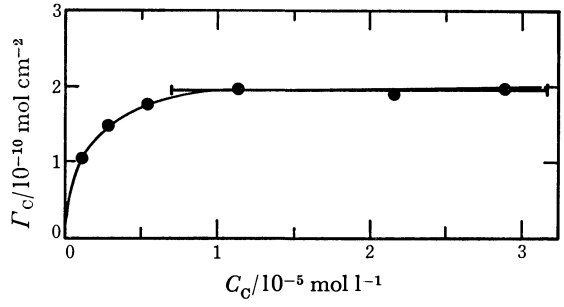

Fig. 7. Adsorption isotherm of NDA–SDS complex. Heavy solid line is the Γ_C^0 values calculated from Eq. 4.

Fig. 6 by Eq. 4, assuming an ideal solution for the complex:

$$\Gamma_C^0 = -\frac{1}{2RT}\left(\frac{\partial\gamma}{\partial \ln C_C}\right)_{NDA} \tag{4}$$

On the other hand, the Γ^A isotherm in Fig. 3 is seen to be the Γ_C isotherm, according to the argument in the previous section. The Γ_C^0 values calculated from Eq. 4 are compared with the "observed" isotherm for the NDA–SDS complex in Fig. 7. Both curves were in good agreement for either the NDA–SDeS or the NDA–STS complex. This is an experimental approval for the present approach.

In order to compare the surface activity of a complex to that of NDA, the relative adsorbability, α, was obtained by means of Eq. 5, which was defined so as to eliminate the concentration dependence near the close-packing adsorption:

$$\alpha = \lim_{C_I \to 0}\frac{\Gamma_I}{C_I} \Big/ \lim_{C_D \to 0}\frac{\Gamma_D}{C_D} \tag{5}$$

The results are shown in Table 2. It was found that the surface activity of complex is larger by one order of magnitude than that of NDA and also larger by two orders of magnitude than that of SAS. The increment of chain-length of alkyl sulfates incorporated in the complex is likely to enhance exponentially the surface activity of complex, as in free SAS. It is of interest that the increasing rate of α values for a series

Table 2. Relative adsorbability of complex and SAS to NDA

Surfactant	$\lim_{C\to 0}(\Gamma/C)$, $1/cm^2\times 10^{-5}$	α
NDA	0.313	1
SDeS	0.028	0.089
SDS	0.041	0.13
STS	0.059	0.19
NDA-SDeS	5.02	16.0
NDA-SDS	10.3	32.9
NDA-STS	20.5	65.5

of free SAS is rather less than that in the state complexed with NDA. This tendency might be reasonable, because the initial inclination in the isotherm is expected to increase more or less exponentially with increasing chain-length of surfactant.[14,23,24]

The present method will be applicable in general to the determination of the dissociation constant of a complex which is formed either by the chelation or by the association reaction, if at least one of the species in the solution is surface-active.

Appendix

The Gibbs adsorption isotherm is written for the present system as follows:

$$-\frac{d\gamma}{RT} = \Gamma_A d\ln C_A + \Gamma_D d\ln C_D + \Gamma_{Na} d\ln C_{Na} + \Gamma_C d\ln C_C \quad (A1)$$

In the equimolar mixed solution, when a complex is formed at 1 : 1 molar ratio, K is written

$$K = \frac{C_C}{C_A \cdot C_D} = \frac{C_C}{C'^2} \quad (A2)$$

where, $C'=C_A=C_D>0$. Substituting Eqs. 2 and A2 into Eq. Al, we have

$$I = (\Gamma^A+\Gamma^D)\frac{2KC}{1+4KC-(1+4KC)^{1/2}} + \Gamma^A \quad (A3)$$

By introducing the substitution $(1+4KC)^{1/2}=A$, $(A\neq 1)$, we have

$$A = \frac{\Gamma^A+\Gamma^D}{2I-3\Gamma^A-\Gamma^D} \quad (A4)$$

Then, we may obtain Eq. 1.

Both Oxidation and Reduction of Aromatic Hydrocarbons by an Electrolysis Cell Designed for Low-temperature ESR Studies

Hiroaki OHYA-NISHIGUCHI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received November 24, 1978)

A simple two-electrode cell for low-temperature electron spin resonance (ESR) measurements has been designed. A helical gold wire, the working electrode with large surface area (12 cm^2), generated *intra muros* enough positive or negative ions to measure the ESR spectra of unstable radical ions at low temperatures. To test the electrolysis conditions of the cell, the ESR spectra of about 20 aromatic compounds have been observed at temperatures as low as −90 °C. It has been shown that the cell can be applicable to the compounds with half-wave potential of 1.5 to −3.7 V SCE, provided that the ions produced are not reactive. The experimental conditions of the dimer cation generation have also been checked in polar or nonpolar solvents.

The electrochemical generation of organic radical ions for ESR studies has some advantages over the usual chemical methods.[1] The application of this method to the compounds with high ionization potential or with low electron affinity, however, has been severely limited by the following difficulties. One of the principal problems encountered in setting up an electrolysis cell inside the ESR cavity is the high dielectric loss caused by the large dielectric constants of the solvents commonly used in electrochemistry. This loss can have a very deleterious effect on the quality factor(Q) of the resonant cavity. Secondly, the conventional electrolysis cells so far used for ESR studies produced a large ohmic drop, which results in low electrolysis current. In 1975 Allendoerfer, Martinchek, and Bruckenstein[2] described a radically new design of a cell for simultaneous electrochemical-ESR(SEESR) measurements, based on a coaxial microwave cavity; this cell design has overcome the difficulties pointed out above. On the other hand, the use of low-temperature environments has proved to be of considerable value[3] for the observation of unstable species produced by electrochemical experiments. Modifying the cell developed by Allendoerfer *et al.*, Gerson, Ohya-Nishiguchi, and Wydler[4] have observed the ESR spectra of typical aromatic hydrocarbons at −90 °C to determine indirectly the half-wave reduction potentials ($E^r_{1/2}$) of benzene and paracyclophane, two compounds with low electron affinity. This modified cell was successfully used for the ESR measurements of the other compounds with high ionization potential or chemically unstable radical ions.[5] The purpose of this paper is to present a cell design which is useful for the low-temperature ESR measurements and to discuss its applicability according to the results obtained.

Cell Design

Optimum Conditions of Electrochemical ESR Measurements. We describe here the optimum conditions for electrochemical ESR measurements, assuming the linear diffusion model.[6] This assumption is not strictly applicable to our cell, but this model is adequate for qualitative understanding of the experimental conditions.

The radical concentration [R·] produced during a constant current electrolysis can be described simply by the rate equation:

$$\frac{d[R\cdot]}{dt} = \frac{i(T)}{VF} - k(T)[R\cdot] \quad (1)$$

where V is the effective volume of the diffusion layer of the radical ions produced, F the Faraday constants, and $k(T)$ and $i(T)$ are the decay constant of R· and the electric current producing R·, respectively, at temperature T. When $i(T)$ is assumed to be controlled by the linear diffusion process only, $i(T)$ can be derived from Fick's first law:

$$i(T) = \frac{D(T)A}{l(T)}nFC \quad (2)$$

where A is the surface area of the working electrode, C, $D(T)$, and $l(T)$ are the concentration, the diffusion coefficient, and the effective thickness of the diffusion layer, respectively, of parent molecules R, and n is the number of electrons involved in the electrode reaction. Hereafter n is assumed to be one, because ESR observation of the electrolysis means the one electron reaction on the electrode surface. Using the steady state condition $d[R\cdot]/dt=0$, and substituting Eq. 2 into Eq. 1, the radical concentration $[R\cdot]_s$ can be estimated from the next equation,

$$[R\cdot]_s = \frac{D(T)}{Vl(T)}\cdot\frac{AC}{k(T)} \quad (3)$$

In order to obtain high concentrations of $[R\cdot]_s$, A has to be made as large as possible without any appreciable disturbance of the microwave mode inside the cavity. Allendoerfer *et al.* succeeded in obtaining large A values by using a finely wound shallow pitched helix as a working electrode. Secondly, it can be deduced from Eq. 3 that a high concentration of the parent compound is desirable to increase $[R\cdot]_s$. High resolution ESR spectroscopy in solution requires usually a concentration not higher than 1 mmol dm^{-3}, because in the high concentration range the electron transfer effect on the ESR line width becomes predominant, in addition to the problem of the inhomogeneity of the solution.[7] Such effect, however, can be safely suppressed if the temperature of the solution is lowered below about −60 °C to the region where the electron transfer effect becomes negligible. Thirdly, Eq. 3 shows also the necessity of low temperature measurements to suppress mainly the radical decay. Strictly speaking, Eq. 3 has a maximum at a temperature (T_m) slightly higher than freezing point of the solution,

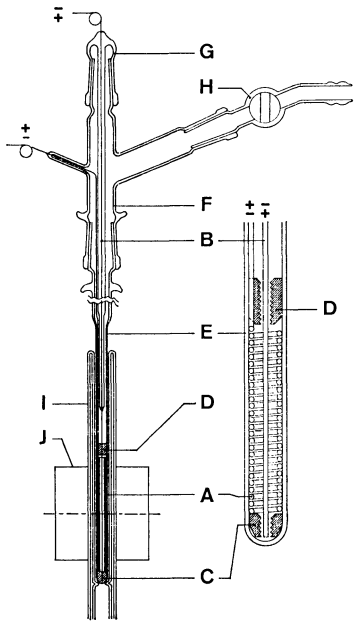

Fig. 1. Schematical diagram of the electrolysis cell mounted in a TE_{011} cylindrical cavity (J) with a temperature control dewar (I). See text about the other notations.

because of the rapid increase of viscosity and solution resistance near the melting point. This requires the development of pertinent solvent-supporting electrolyte systems possessing reasonably high conductivity over a wide low temperature range.[3] Taking such conditions into account a simple cell for the low-temperature ESR study has been designed.

Apparatus. Figure 1 shows a schematic diagram of the electrolysis cell mounted in a TE_{011} cylindrical cavity (J) with a temperature control dewar (I). The cell consists of four parts, (E) to (H): (E) contains a helical electrode wound of a 0.5 mm diameter gold wire (A) and a straight platinum wire of a 0.5 mm diameter (B) supported by two Teflon holders (C) and (D) along the tube axis. By changing the polarity of these electrodes either cations or anions can be produced on the working electrode. (F) and (G) hold the terminals for (A) and (B), respectively, which are connected to a potentiostat with a sensitive current meter. (A) is wound to fit against the inner wall of the 3.5 mm i. d. pyrex tube (E), its length and surface area being about 50 mm with 80 turns and 12 cm^2, respectively. The mercury amalgamation of (A) was carried out as required in the case of the anions. It should be noted in this figure that no reference electrode was used in order to simplify the electrolysis apparatus. If necessary one can estimates $E_{1/2}$ from a linear relationship between $E_{1/2}$ and the minimum voltages applied between two electrodes, V_a, at which the ESR spectra of the radicals appear during the electrolysis.[4]

Procedure

Each solution prepared under a nitrogen atmosphere was degassed by the freeze-pump-thaw cycles three or four times. After the cell was pumped and flushed with dry nitrogen through the stop cock in Fig. 1, the solution of about 0.7 ml was transferred into (E) through (F) with a pipette under the dry nitrogen atmosphere. Then the cell containing the solution was inserted into the cavity. After the solution temperature was decreased, the voltage was applied between two electrodes and gradually increased until ESR signals could be observed. The observation of the ESR signals was carried out with the field modulation of 1.0×10^{-4} T, which was appropriate to observe the appearance of the signals. As the voltage applied reached V_a, the electric current of the circuit also increased appreciably, its amount depending on the temperature, solvent used, and the concentration of the substrates (see Eq. 2). Several solvents were tested for the generation of both radical cations and anions. 1,2-dimethoxyethane(DME) with 0.1 mol tetrabutylammonium perchlorate (TBAP) is recommended for anions, and dichloromethane(CH_2Cl_2) including 10% trifluoroacetic acid (TFAc) and 10% trifluoroacetic anhydride(TFAn) with or without 0.01 mol TBAP[8] are recommended for cations. It should be noted in the latter case that the pertinent ratios of these solvents depend on the stability of the parent compound to be oxidized and solubility of the radical cations produced in the solvent, as will be discussed in the following section.

Experimental

DME was refluxed with $LiAlH_4$ for two days, followed by distillation onto the Na–K alloy. Dry DME was distilled into a bottle with 0.1 mol supporting reagent, and flushed with dry nitrogen gas. Spectrograde CH_2Cl_2, TFAc, and TFAn were used without further purification. ESR spectra were measured with a Varian E-9 spectrometer.

Results and Discussion

Effects of the Cell on the Cavity Properties. When this cell was inserted into the cavity, the resonance frequency became only 0.22 GHz higher than that without the cell (9.07 GHz). Such a small shift means that the cell can be treated in a similar manner to the usual sample tube containing the solution for the ESR measurements. The Q factor, on the other hand, depended on the solution to be electrolyzed as well as on the design of working electrode. Tight fitting of the helix electrode to the inner wall of (E) in Fig. 1 was most important to maintain the high Q. The loaded Q in the case of polar solvents, *i.e.* H_2SO_4, H_2O, and *N*,*N*-dimethylformamide(DMF), were measured as 2200, 2500, and 3200, respectively. Even in the case of H_2SO_4, Q was high enough to measure the ESR spectra.

Oxidation of Some Aromatic Hydrocarbons. The electrolytic oxidation of aromatic hydrocarbons was more difficult than the electrolytic reduction was, mainly because in nonpolar solvents the cations produced deposited on the surface of the electrode, while in polar solvent such as CF_3COOH, on the other hand, substrates sometimes decomposed. The most

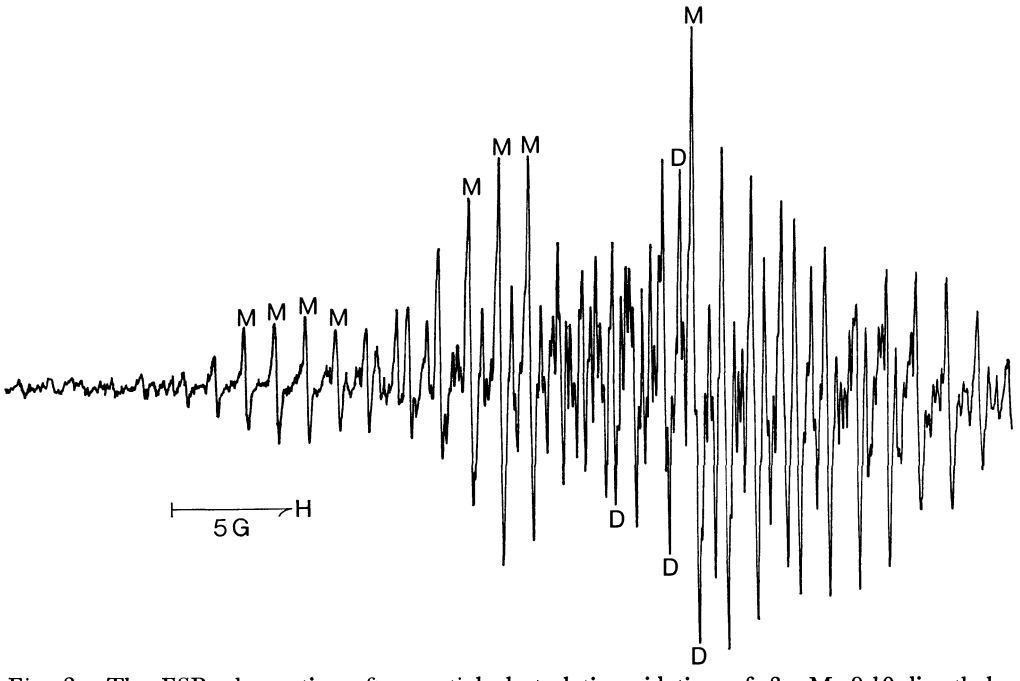

Fig. 2. The ESR observation after partial electrolytic oxidation of 3 mM 9,10-dimethylanthracene in CH_2Cl_2 with 10% CF_3COOH and 10% $(CF_3CO)_2O$ at −80 °C. Supporting reagent: Tetrabutylammonium perchlorate, field modulation: 0.1 G. M and D in the figure correspond to the representative lines due to the monomer and the dimer cation radicals, respectively. The ratio of $[DMA^{+\cdot}]$ to $[(DMA)_2^{+\cdot}]$ is about 1 : 6. Slight difference of their *g*-values leads to an asymmetric ESR spectrum.

effective solvent for electro-oxidation of aromatic hydrocarbons was the mixture CH_3NO_2 or CH_2Cl_2/TFAc/TFAn, with TBAP as a supporting reagent. The ratios of these reagents were changed, corresponding to the stability of the parent molecules and cation radicals produced. The compounds with oxidation potential ($E^{\circ}_{1/2}$) lower than *ca.* 0.9 V SCE, hereafter called Category I, were oxidized partially when dissolved in the solvent mixture (ratios: 10/(1—10)/1/0) without any application of voltage. When the voltage larger than $E^{\circ}_{1/2}$ was applied, the ESR signals increased substantially, and sometimes became highly resolved. Secondly, the compounds with $E^{\circ}_{1/2}$ between 0.9 and 1.3 V SCE (Category II) could be oxidized at temperatures as low as −60 °C in the solvent with ratios of 10/1/1/0. V_a roughly corresponded to $E^{\circ}_{1/2}$. Thirdly, the compounds of Category III having $E^{\circ}_{1/2}$ higher than *ca.* 1.3 V SCE gave the spectra at −70 to −90 °C (ratios: 10/1/1/0.01 mol dm^{-3}). Durene was the compound with the highest $E^{\circ}_{1/2}$ of all the compounds which successfully gave the resoved ESR spectra. This means that the ESR spectra of the compounds with $E^{\circ}_{1/2}$ lower than 1.5 V SCE can be observed provided that no chemical reactions of the cation produced occur. It should be pointed out here that the ESR spectra of the dimer radical cations can also be observed under the conditions a) high concentration, b) low temperature, c) nonpolar solvents, d) low voltage available, and e) the beginning of electrolysis, unlike the situation of monomer production. In some cases, i.e. pyrene, acenaphthene, and tetramethylparacyclophane, the ESR spectra due to monomer cations could not be observed even if the conditions mentioned above were changed. This means that in CH_2Cl_2, nonpolar solvent, the dimer configuration is quite stable compared with the corresponding monomer cations. The ESR observation after the oxidation of 9,10-dimethylanthracene(DMA), a typical example, showed clearly the existence of the dimer species in addition to that of the monomer under the conditions mentioned above: a) to e) (see Fig. 2). It should be noted that Van Duyne and Reilley[3] also measured the steady-state cyclic voltammograms of DMA on a platinum electrode at low temperatures. From these results they postulated an equilibrium between monomer and dimer cations of DMA:

$$DMA^{+\cdot} + DMA \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (DMA)_2^{+\cdot} \qquad (4)$$

which is in good agreement with our results. In Table 1 the coupling constants of the monomer and dimer cations of typical aromatic compounds are summarized, with some experimental conditions. From this table one can say roughly that V_a corresponds to $E^{\circ}_{1/2}$ in the range of the error +0.2 V, in spite of different conditions. On oxidations of benzene and naphthalene a broad line with the line width of 5 to 6 G has been observed.

Reduction of Aromatic Hydrocarbons. In order to check the applicability of the cell, the reduction of aromatic hydrocarbons, whose $E^{r}_{1/2}$ values were known by the polarographic measurements, was carried out under the same conditions (C: 5 mmol, DME/0.1 mol TBAP, −90 °C), followed by the observation of both V_a and its high-resolution ESR spectrum. The proton hyperfine coupling constants which were used for the

identification of the anion produced, coincided with those previously published, within the range of experimental errors. In the previous paper[4] we described the relationship between V_a and $E^r_{1/2}$. The pertinent regression line has an equation

$$V_a = (1.92 \pm 0.06) E^r_{1/2} \quad (5)$$

with a correlation coefficient of 0.991 and a deviation from the origin (0.007). V_a defined above can be alternatively described as the voltage at which [R·] reaches the minimum radical concentration detectable. If the radical decay becomes appreciably larger, i.e. irreversible in terms of cyclic voltammetry, one has to apply a voltage lower than the real one, which causes a deviation from the linear relationship of Eq. 5. Such a good relationship as in Eq. 5, therefore, has two significant meanings: One is a good correspondence of V_a and $E^r_{1/2}$, which was successfully applied to the indirect determination of $E^r_{1/2}$ of benzene and other aromatic hydrocarbons with low electron affinity (Table 2). The other is that if $E^r_{1/2}$ of a compound is higher than that of *p*-xylene (−3.7 V SCE), it is possible to observe the ESR spectrum by applying V_a corresponding to its $E^r_{1/2}$ given by Eq. 5. This is in contrast with the cell used by Levy and Myers,[9] who applied voltage as large as 110 V to reduce the pyridines and diazines.

It should be mentioned finally that DMF with 0.1 mol tetraethylammonium perchlorate(TEAP) was also a good solvent for chemically unstable radicals, because the electrolysis current is *ca.* 10 times larger than that in DME at the same temperature, although its freezing point (−60 °C) is a little high.

This work was mostly carried out at Physikalisch-Chemisches Institut der Universitaet Basel. The author would like to express his appreciation to Professor Fabian Gerson for his continual discussion and encouragement. He also wishes to thanks Drs. Jurg Bruhin, George Plattner, and Crystoph Wydler for their illuminating discussions.

The Reaction between SO_2 and MnO_2 and the Role of the Sulfato Complex in the SO_2-induced Isomerization of *cis*-2-Butene

Kiyoshi Otsuka,* Kimiaki Tanaka, and Akira Morikawa

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 16, 1979)

The reaction between SO_2 and MnO_2 has been studied by measuring the consumption of SO_2-gas and the infrared spectra of the wafer of MnO_2. In the low-temperature range (<200 °C) the reaction is completed within one or two surface layers of MnO_2, and the reaction products are the bidentate sulfato complex (C_{2v}) and the sulfato complex in Td symmetry. In the high-temperature range, on the other hand, the reaction progresses deep into the bulk and can be described by this stoichiometric equation; $MnO_2+SO_2\rightarrow MnSO_4$. The catalysis of MnO_2 for the SO_2-induced isomerization of *cis*-2-butene is closely related to the formation of the sulfate ion. The initiation step proposed for the isomerization is a polarization of the charge-transfer complex of SO_2 and butene under the influence of the strong electrostatic field caused by the generation of the surface sulfato complex.

The absorption of SO_2 from flue gas by an activated manganese oxide has become of interest in the field of SO_2-emission control.[1,2] In relation to this subject several kinetic studies of SO_2 absorption by manganese dioxide has been published.[3–5] However, no study of the chemistry of the reaction between SO_2 and manganese dioxide has been reported.

Otsuka *et al.* reported that, in the presence of SO_2, MnO_2 gains a very high catalytic activity in the cis-trans selective isomerization of various olefins, which is accompanied by copolymerization between SO_2 and olefins in the adsorption layer.[6] They hypothesized that the high catalytic activity of MnO_2 may be caused by a strong electrostatic field on the surface brought about by the formation of a sulfato complex.

The purpose of the present work is to investigate the reaction between SO_2 and MnO_2 by measuring the consumption of SO_2-gas and the infrared spectra of the wafer of MnO_2, and to verify the above hypothesis as to the high catalytic activity of MnO_2 in the copolymerization-accompanying isomerization of *cis*-2-butene.

Experiments

Materials. Commercial MnO_2 prepared by the reduction of $KMnO_4$ was used as the catalyst. The surface area, as determined by the BET method with nitrogen after degassing treatment at 100 °C, was 104 m^2/g. The $MnSO_4\cdot 4$—$6H_2O$ was a product of Wako Pure Chemical Ind., Ltd. The reagent SO_2 gas, of an anhydrous grade and supplied by the Matheson Chemical Co., and the *cis*-2-butene gas, a high-purity product of the Phillips Petroleum Co., were purified by trap-to-trap distillation in a vacuum apparatus.

Procedure. The catalyst in the reactor was degassed in a vacuum for 2 h at 0 or 100 °C prior to each run. The amount of the consumption of SO_2-gas by MnO_2 was determined by measuring the pressure change by means of glass Boulden Gauge attached to a conventional glass apparatus with a volume of 320 ml. The polysulfone-accompanying isomerization of *cis*-2-butene was carried out in a conventional mercury-free gas-circulation system using a mixture of SO_2 and *cis*-2-butene (1:2.5) under a total initial pressure of 175 Torr. After the addition of SO_2 to 0.05 g of MnO_2 at a required temperature for 30 min under 50 Torr of SO_2, the temperature at the catalyst bed was decreased to 20 °C or to −10 °C; then, the two reactions (the copolymerization of SO_2 and *cis*-2-butene and the isomerization of the latter) were initiated by feeding in *cis*-2-butene and circulating the gas mixture through the catalyst bed. The rate of the cis-trans isomerization was determined from the concentration of the *trans*-2-butene formed in the initial 3 min, as analyzed by gas chromatography. The amount of the copolymer generated in the 30-min period after the initiation of the reaction was estimated by measuring the infrared-absorption spectra of the MnO_2 used for the reaction. Prior to the infrared-spectra measurement, the MnO_2 sample was ground to a fine powder, and then mixed with KBr. A KBr-supporting wafer was made by pressing the mixture in 2-cm-diameter stainless steel dies at 1.9 t/cm^2. The spectra were recorded at 25 °C using a Shimadzu IR-430 grating spectrometer.

Results and Discussion

SO_2-absorption Measurement by Volumetric Method. The changes in the amount of SO_2 absorbed by MnO_2 with the time have been shown in Fig. 1; the experiment was carried out by introducing 1.38×10^{-3} mol of SO_2-gas into the system. After the initial rapid absorption of SO_2 for 1 min, a small increase in the absorbed amount is observed at the temperatures lower than 200 °C, but significant amount of SO_2 are absorbed further at 250 and 350 °C in the range

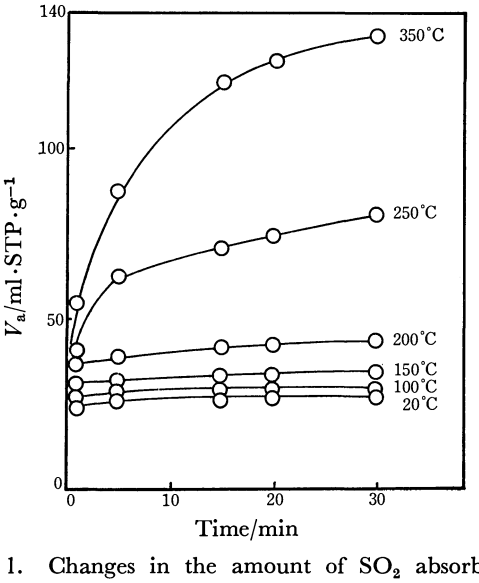

Fig. 1. Changes in the amount of SO_2 absorbed by MnO_2 with time at various experimental temperatures.

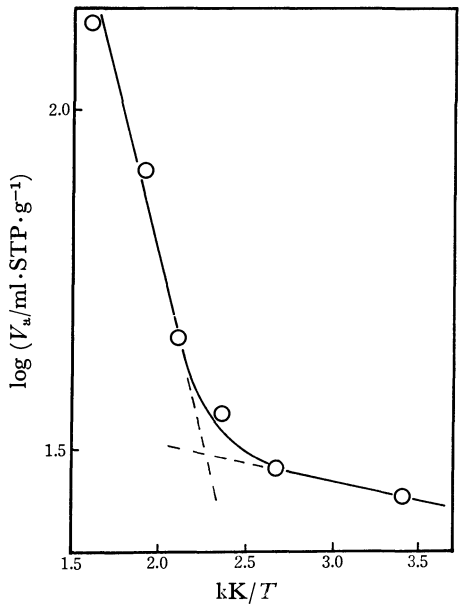

Fig. 2. log (V_a) against $1/T$ plot.

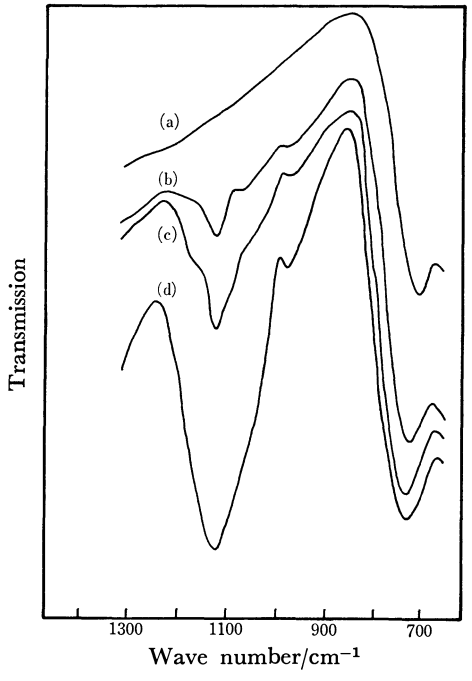

Fig. 3. Infrared spectra of the MnO_2 wafer with absorbed SO_2 at different θ_{SO_2}: (a); MnO_2 without SO_2, (b); MnO_2 with absorbed SO_2 ($\theta_{SO_2}=0.021$), (c); $\theta_{SO_2}=0.21$, (d); $\theta_{SO_2}=0.74$. The SO_2 absorption was carried out at 20 °C with MnO_2 pretreated at 100 °C.

of the absorption time from 1 to 30 min. Figure 2 shows the log (V_a) against $1/T$ plot, where V_a is the amount of SO_2 absorbed in 30 min and where T is the absorption temperature in Kelvin. The quite different slopes of the curve in the low-temperature (<150 °C) and high-temperature ranges (>200 °C) in Fig. 2 suggest that the natures of the SO_2-absorption on MnO_2 are different between the two temperature ranges. The apparent surface coverage by SO_2, θ_{SO_2}, for various absorption temperatures was

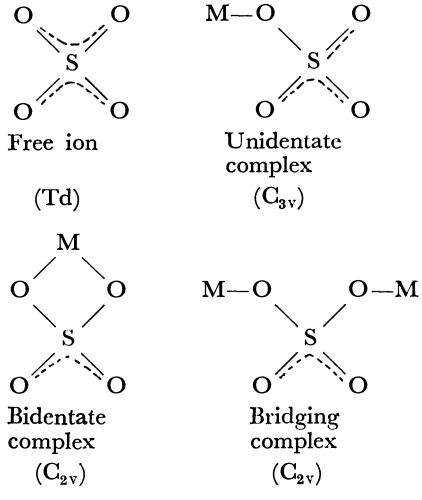
Table 1. The apparent surface coverage by SO_2, θ_{SO_2}, for the MnO_2 used in the experiments of Fig 1

Temperature (°C)	20	100	150	200	250	350
θ_{SO_2}	1.35	1.47	1.74	2.27	4.01	6.52

estimated from the amount of SO_2 absorbed in 30 min, and the BET surface area of the catalyst, from the nitrogen adsorption, where the molecular cross sections of N_2 and SO_2 were taken as 16.2 and 19.2 Å^2 respectively.[7] The results are summarized in Table 1. The large θ_{SO_2} values at the high temperatures listed in the table indicate that SO_2 penetrates into many layers of the surface.

Infrared Spectroscopic Study of the Reaction of SO_2 with MnO_2. Figure 3 shows a series of changes in the spectra of the KBr-supporting wafer of the catalyst after the absorption of the required amount of SO_2 at 20 °C for 30 min. The preparation of the wafer and the recording of the spectra were carried out in air as has been described previously. To examine the effect of air on the spectra of the SO_2-absorbing catalyst, the spectra of the air-free sample deposited on the surface of the KBr-wafer, which has been placed in a vacuum cell, has been recorded. It has been confirmed that the introduction of air into the cell does not change the absorption bands caused by the addition of SO_2. The spectra of the catalysts with a low coverage ($\theta_{SO_2}<\approx 0.21$) show four absorption bands at around 980, ≈1070, 1115, and 1180 cm^{-1}. For the catalyst with θ_{SO_2} of 0.74, however, the absorption bands at ≈1070 and 1180 cm^{-1} are obscured by the selectively developed 1115 cm^{-1} band.

Nakamoto[8] indicated that the SO_4-complex in Td symmetry shows the ν_1(very weak), ν_3(very strong), and ν_4(strong) absorption bands at 973, 1130—1140, and 617 cm^{-1}. The lowering of symmetry for the SO_4-complex caused by coordination splits the ν_3 band into two or three bands, depending on whether the unidentate or bidentate and bridging complexes respectively are involved.



(1)

Many bidentate and bridging sulfato complexes, such as $[Cu(bpy)SO_4]\cdot 2H_2O$, $Pd(NH_3)_2SO_4$, and $[(NH_3)_4$-

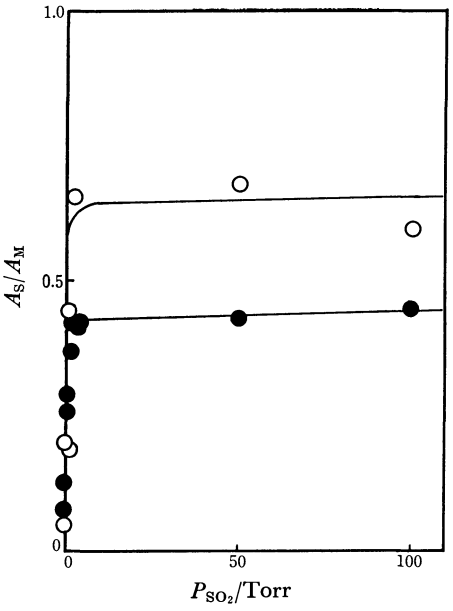


Fig. 4. Effect of SO_2-pressure on the relative amount of SO_4^{2-} complex formed at 20 °C: (○); MnO_2 degassed at 0 °C, (●); MnO_2 degassed at 100 °C.

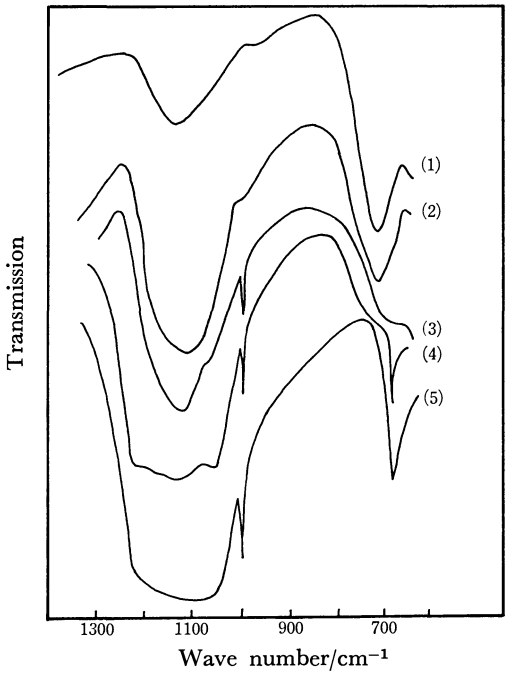

Fig. 5. Infrared spectra of SO_4-complex formed at different temperatures over MnO_2: (1); 20 °C, (2); 200 °C, (3); 300 °C, (4); 350 °C, (5); the spectra of $MnSO_4 \cdot 4—6H_2O$.

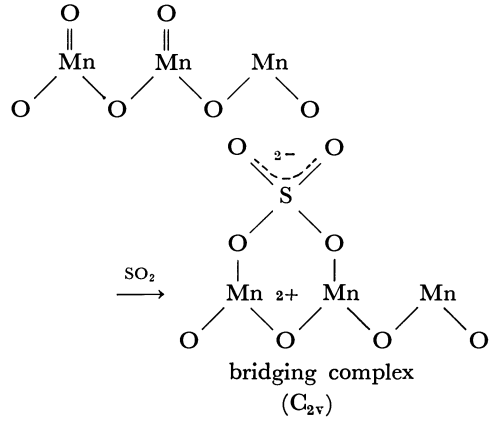
$Co\langle^{NH_2}_{SO_4}\rangle Co(NH_3)_4](NO_3)_3$, show the three bands at 1030—1060, ≈1105, and ≈1180 cm^{-1}.[8] Hence, the spectra observed at a low θ_{SO_2} in Fig. 3 can be ascribed to the bidentate or bridging SO_4^{2-}-complex on MnO_2. On the other hand, the selective increase in the intensity of the band at 1115 cm^{-1} with an increase in θ_{SO_2} indicates that SO_4^{2-}-complex in Td symmetry is a main species formed at a high θ_{SO_2}.

A_S/A_M, the optical density for the strongest absorption band at 1115 cm^{-1} divided by that for the 710 cm^{-1} band, caused by the Mn–O vibration in the MnO_2 lattice,[9] represents the relative amount of the SO_4^{2-}-complex on a unit weight of the catalyst. This value has been plotted in Fig. 4 as a function of the SO_2 pressure applied in the SO_2-absorption experiments at 20 °C for the catalysts degassed at 0 and 100 °C. The formation of the SO_4^{2-}-complex reaches a plateau at less than 1 Torr, and the amount of the SO_4^{2-}-complex formed is larger for the MnO_2 pretreated at a lower temperature.

Figure 5 shows the infrared spectra of the catalysts after SO_2 absorption under the same experimental conditions as those used to obtain the results in Fig.1. The relative amount of the SO_4^{2-}-complex increases as the absorption temperature is raised, accompanied by a decrease in the intensity of the 710 cm^{-1} band due to the Mn–O lattice vibration. The catalysts used for the experiment at the high temperatures (>300 °C) show spectra quite similar to that of $MnSO_4$. On the other hand, the spectra for the catalysts used for SO_2-absorption at low temperatures (<≈200 °C) do not show sharp bands at 1000 and 690 cm^{-1}, suggesting that the SO_4^{2-}-complex (Td symmetry) is different in its nature from the one observed on the catalyst used for the SO_2-absorption at high temperatures.

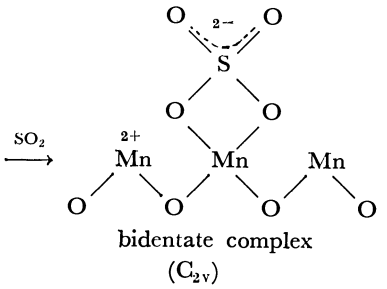
The results in Fig. 2 demonstrate that the reaction mechanism for the SO_2-absorption changes with the temperatures above ≈200 °C. At low temperatures, after a very rapid absorption of SO_2 within 1 min, only a small increment in the absorbed amount was observed (Fig. 1) and the amount of the SO_4^{2-}-complex formed did not change with the SO_2 pressure above 1 Torr (see Fig. 4). The apparent coverage of the surface by SO_2 remains less than 2.3 at low temperatures. These facts suggest that the progress of the reaction between SO_2 and MnO_2 at low temperatures (<≈200 °C) is restricted to only one or two surface layers of MnO_2. Accordingly, we consider that the initial stage of SO_2-absorption by MnO_2 may be demonstrated by the following schemes at low temperatures:

at a low θ_{SO_2},



bridging complex (C_{2v}) (2)

or



(3)

at a high θ_{SO_2},

$$MnO_2 \text{ (surface)} \xrightarrow{SO_2} SO_4^{2-}\text{-complex (surface)} \quad (4)$$
(Td)

At high temperatures, the fact that the spectra observed are quite close to that of pure $MnSO_4$ (Fig. 5) indicates that SO_2 penetrates into the bulk of MnO_2 and forms $MnSO_4$ as is shown by this stoichiometric equation:

$$MnO_2(\text{bulk}) + SO_2 \longrightarrow MnSO_4(\text{bulk}) \quad (5)^{3,5)}$$

Both the amount of SO_2 absorbed by MnO_2 and A_S/A_M, measured for the catalysts used for the SO_2-absorption experiments for 30 min in Fig. 1, have been plotted in Fig. 6 as functions of the experimental temperature; the A_S/A_M values have been corrected by considering the fraction of MnO_2 converted to $MnSO_4$, which was estimated from the amounts of SO_2 absorbed by the catalyst at each temperature. The similarity between the shapes of the two curves supports the idea that the reaction between SO_2 and MnO_2 can be described by the stoichiometric Eq. 5.

The Role of the SO_4^{2-}-complex in Butene Isomerization. The cis-trans isomerization and the copolymerization have been carried out over catalysts on which SO_2 had been preabsorbed at various temperatures (20—350 °C) for 30 min under the same experimental conditions as those used in Fig. 1. The rate of the cis-trans isomerization, $R_{c\to t}$, and the relative concentration of the formed polysulfone, A_P/A_M, the optical density for the band at 1300 cm^{-1} due to the polysulfone[6] divided by that at 710 cm^{-1} due to Mn–O, have been plotted in Fig. 7 as functions of the temperature for the SO_2 absorption. The circles and the triangles are the data obtained for the MnO_2 pretreated in a vacuum at 100 and 0 °C respectively. The dotted curve illustrates the relative amount of the SO_4^{2-}-complex (arbitrary unit), already shown in Fig. 6. The similar dependence on the absorption temperature between the rate of isomerization and the polysulfone formation illustrated in Fig. 7 can be explained by the fact that the latter reaction accompanies the former, as is demonstrated below:[6]

cis- or *trans*-2-butene + $\cdot SO_2[CH(CH_3)CH(CH_3)SO_2]_n$
$$\rightleftharpoons \cdot CH(CH_3)CH(CH_3)\text{-}SO_2[CH(CH_3)CH(CH_3)SO_2]_n \quad (6)$$

For the catalysts on which SO_2 has been preadsorbed at temperatures lower than 200 °C, the rate of the cis-trans isomerization increases in parallel with the increase in the amount of the SO_4^{2-}-complexes as the absorption temperature is raised. The catalyst outgassed at 0 °C shows a higher catalytic activity than that outgassed at 100 °C; this corresponds to the fact that the former catalyst demonstrates a higher concentration of SO_4^{2-}-complexes than the latter (Fig. 4). These results suggest that the catalytic activity of MnO_2 in the copolymerization, and accordingly for the cis-trans isomerization, is closely related to the formation of sulfate ions on the catalyst. The surface manganese must be positively charged by the

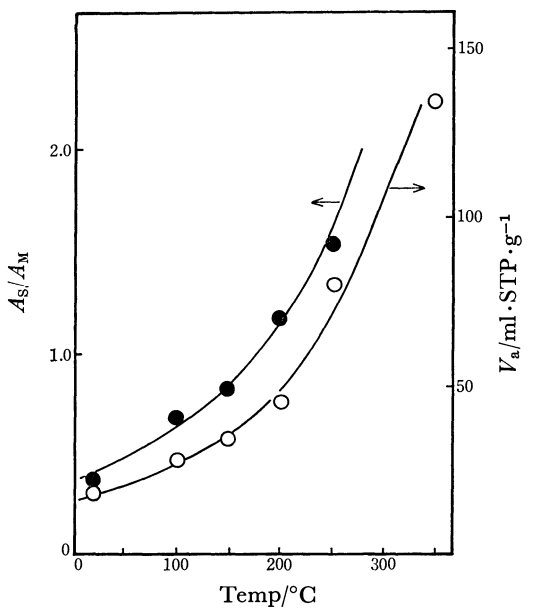


Fig. 6. Effect of temperature on the relative amount of SO_4^{2-} complex and the amount of SO_2 absorbed by MnO_2: (●); A_S/A_M, (○); V_a.

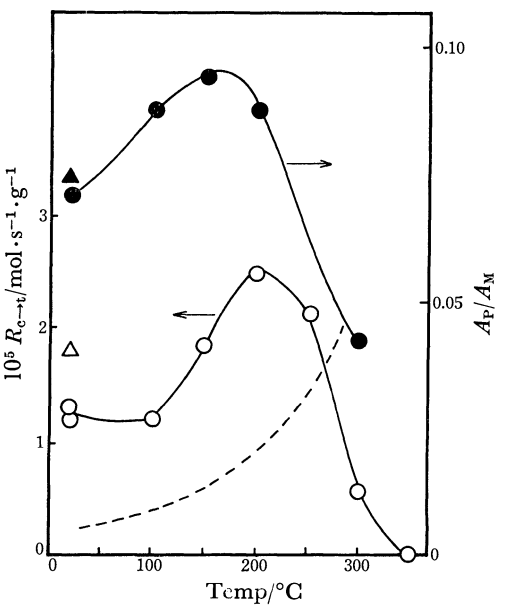

Fig. 7. The rate of isomerization, $R_{c\to t}$, and the amount of formed polysulfone, A_P/A_M, as a function of temperature for SO_2 absorption: circles; data for MnO_2 pretreated at 100 °C, triangles; data for MnO_2 pretreated at 0 °C. (●) and (▲); A_S/A_M, (○) and (△); $R_{c\to t}$. The dotted curve represents A_S/A_M (arbitrary unit) shown in Fig. 6.

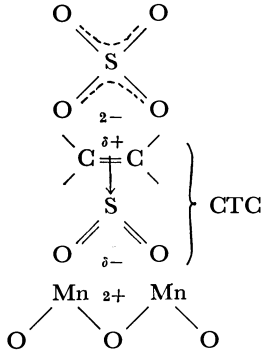
formation of sulfate ions because of an electron transfer from the surface to the sulfate ions (Schemes 2—4), resulting in a generation of strong electrostatic fields on the surface. The picture of the initiation step for the reactions hypothesized previously,[6,10] *i.e.*, a polarization of the charge-transfer complex (CTC) of SO_2 and butene under the influence of the electrostatic field on the surface, can also be adopted in the present work. The CTC positioned between the manganese cation and the sulfate anion on the surface may be strongly polarized and activated by a concerted action of the anion-cation pairs, as is illustrated below:



(7)

The catalytic activities of MnO_2 on which SO_2 has been preabsorbed at high temperatures ($>\approx 200$ °C) decrease, however, as the SO_2-treatment temperature is raised (Fig. 7). The catalytic activity of pure $MnSO_4$, pretreated in the presence of SO_2 at 200 °C, has been tested for the cis-trans isomerization. The activity per unit of surface area was less than 1/15 of that for MnO_2, which was tested under the same experimental conditions, implying that the decrease in the activity of MnO_2 pretreated with SO_2 at the high temperatures might result from a considerable transformation of MnO_2 to $MnSO_4$ deep into the bulk of MnO_2; eventually, then, the character of the surface becomes quite close to that of pure $MnSO_4$. The low catalytic activity of $MnSO_4$ can be attributed to a low affinity of its surface to the adsorption of SO_2 and, consequently, to a low concentration of CTC, which is necessary for the two reactions.

Photolyses of Tetraphenylcyclobutanes at 254 nm

Haruo SHIZUKA,* Ichiro SEKI,† Toshifumi MORITA, and Takeshi IIZUKA††

Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received January 22, 1979)

Photolyses of 1,2,3,4-tetraphenylcyclobutanes (TPCB) at 254 nm in hydrocarbon solvents have been studied by means of fluorometry, nanosecond time-resolved spectroscopy, and measurements of the reaction quantum yields. The photolysis of TPCB originates from the $S_1(\pi,\pi^*)$ state to give *trans*-stilbene nearly concertedly at higher temperatures (>200 K). Significant temperature and cis-effects were observed. The radiationless rate constants for the dissociation (k_r) and the other radiationless (k_n) processes decreased with lowering temperature. The value of k_r for γ-1,*t*-2,*t*-3,*c*-4-TPCB at 300 K, for example, was 4.7 times greater than that for γ-1,*t*-2,*c*-3,*t*-4-TPCB. The Arrhenius parameters of the relaxation processes were also determined. No intramolecular excimer emission was observed.

The photochemistry of four-membered rings has been extensively studied.[1] Cyclobutane photochemistry involving selectivities in cleavage orientations upon irradiation is one of the most interesting fields among them. A number of studies on photolyses of cyclobutanes have been reported.[2-10] Kaupp[3] has shown that there is a clear preference for photochemical fission of the cyclobutane bond bearing the chromophore and the substituent which sterically interacts most effectively with the chromophore (cis-effect) and that the photolysis proceeds *via* short-lived 1,4-biradicals. As for tetraphenylcyclobutanes, they undergo photochemical cycloreversion to yield *trans*-stilbene.[2,3] However no quantitative work on photolyses of tetraphenylcyclobutanes has been performed.

In the course of our studies of photochemistry of benzene derivatives,[11-13] the title compounds (see below) were chosen in the present work from the following interests:

(1) How about the reactive state and the dissociation rate?

(2) How about the relaxation processes of the excited state of tetraphenylcyclobutanes?

(3) Is there cis-effect[2,3] on photochemical and photophysical processes of the molecules?

and (4) How about intramolecular excimer formation? In a previous work,[13] an weak intramolecular excimer emission of [2.2]metacyclophane is observed, which is an exception of the $n=3$ rule.[14] A large internal conversion of [2.2]metacyclophane occurs due to a conformational change in the excited state.

This paper reports the relaxation processes of excited tetraphenylcyclobutanes (**1** and **2**) studied by means of fluorometry, nanosecond time-resolved spectroscopy, and measurements of the reaction quantum yields under various temperatures.

Experimental

Starting materials (1,2,3,4-tetraphenylcyclobutanes (**1** and **2**)) were prepared by the photodimerization of transstilbene in benzene,[15] and purified by silica-gel column chromatography using a mixture of benzene and cyclohexane (1:3) as the eluent. Methylcyclohexane, cyclohexane and isopentane (G.R.-grade products from Tokyo Kasei) were purified by passing them through a silica-gel column and then distillations. In the measurements of degassed samples, the solutions were thoroughly degassed by the freeze-pump-thaw-cycles.

A low-pressure mercury lamp (20 W) with a Vycor glass filter was used as the 254-nm radiation source. Acitnometry was carried out using a ferric oxalate solution (0.006 M).[16] The quantum yields for the product formation were measured by spectrophotometry. For the measurements of temperature effects upon the reaction quantum yields and fluorescence lifetimes, a quartz Dewar flask designed for spectrometry was used, the temperature being controlled to within ±2 °C. Measurements of absorption and fluorescence spectra were the same as reported previously.[17] The fluorescence quantum yields were measured by comparison with that of toluene in cyclohexane ($\phi_F=0.14$).[18] The fluorescence decay was recorded with a Hitachi nanosecond time-resolved spectrophotometer (pulse width 11 ns), and the lifetime was determined by the convolution method when it was shorter than 20 ns.[19]

Results

The spectrum of a 3.4×10^{-4} M cyclohexane solution of γ-1,*t*-2,*t*-3,*c*-4-tetraphenylcyclobutane (**1**) changed markedly upon irradiation with the 254-nm light at 300 K as shown in Fig. 1. A new band with maximum at 295 nm (ε: 2.74×10^4 M^{-1} cm^{-1}) appeared. The spectral change shows the formation of *trans*-stilbene as a sole photoproduct, as reported by Kaupp.[2,3] The geometric isomer (**2**) was scarcely observed by the TLC method. The quantum yields for the product formation in cyclohexane at 300 K was 0.84± 0.04. The quantum yields at 300 K did not change with variation in irradiation time (1—10 min), concentration of the starting material (10^{-4}—10^{-2} M), addition of 1,3-pentadiene ($<2\times10^{-2}$ M), and light intensity (10^{14}—10^{16} quanta ml^{-1} s^{-1}). Dissolved oxygen had no effect on the reaction quantum yields. The quantum yield Φ_r in MP (methylcyclohexane: isopentane=3:1 in volume) was the same as that in cyclohexane. Similar results were obtained in the

case of γ-1,*t*-2,*c*-3,*t*-4-tetraphenylcyclobutane (**2**).

Figure 2 shows the absorption (**1**: $\lambda_{max}=261$ nm, $\varepsilon=1.03\pm0.02$ M^{-1} cm^{-1}; **2**: $\lambda_{max}=261$ nm, $\varepsilon=1.15\pm0.02$ M^{-1} cm^{-1}) and fluorescence ($\lambda_{max}=284$ nm for **1** and **2**) spectra of the starting materials in cyclohexane, which are very similar to those of toluene. No intramolecular excimer emission could be detected. No phosphorescence could be observed in MP at 77 K, as reported by Kaupp.[2]

The reaction quantum yields Φ_r, fluorescence quantum yields Φ_f, fluorescence lifetimes τ_f and radiative rate constants k_f in MP at 300 K are listed in Table 1. The significant temperature effects upon Φ_r and τ_f in MP were observed as shown in Figs. 3 and 4, respectively. The Φ_r values decreased with lowering temperature. In contrast, the values of τ_f increased with lowering temperature, and they were 48±3 ns (**1**) and 46±3 ns (**2**) at 77 K. The photolyses of the samples took place even at 77 K in MP rigid matrices, although the Φ_r values were very small. The Φ_r values of **1** were greater than those of **2** at various temperatures as shown in Table 1 and Fig. 3.

Discussion

Kinetic Analyses. The presence of triplet quenchers ([1,3-pentadiene]$<2\times10^{-2}$ M and [dissolved oxygen]$\approx2\times10^{-3}$ M)[20] do not affect the Φ_r values. The results indicate that the photolyses of 1,2,3,4-tetraphenylcyclobutanes (**1** and **2**) proceed *via* the

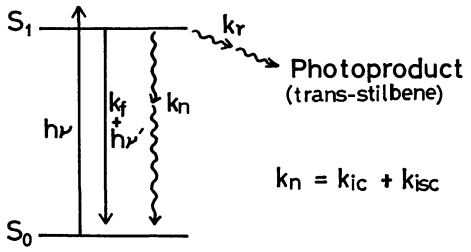

Fig. 5. A schematic energy state diagram for the photolyses of tetraphenylcyclobutanes.

excited singlet state and/or very short-lived triplet state. The fact that no phosphorescence of tetraphenylcyclobutanes could be observed suggests the existence of a relatively fast radiationless channel (probably cleavage) in the lowest triplet state. There may be two pathways of photochemical cleavage of the starting materials via the excited singlet and triplet states. However, the radiationless processes (cleavage and internal conversion) other than intersystem crossing are very predominant in the S_1 state at higher temperatures (>200 K), as will be discussed later. Accordingly, the reaction quantum yield *via* the triplet state must be small in comparison with that *via* the excited singlet state at higher temperatures (>200 K). That is, the reactive state at higher temperatures (>200 K) should be the lowest excited singlet state $S_1(\pi,\pi^*)$.

The experimental results at higher temperatures (>200 K) can be accounted for by the scheme shown in Fig. 5, where S_0 and S_1 are the ground and the lowest excited singlet states of the starting materials respectively, k_f radiative rate constant, k_r dissociation rate constant, and k_n radiationless rate constant of internal conversion k_{ic} plus intersystem crossing k_{isc}. From the usual steady-state approximation, the reaction quantum yield Φ_r is given by

$$\Phi_r = \frac{2k_r}{k_f+k_n+k_r} = 2k_r\tau_f \qquad (1)$$

The dissociation rate k_r may be expressed by Eq. 2,

$$k_r = k_r^0 + A_r\exp\left(\frac{-\Delta E_r}{RT}\right) \qquad (2)$$

where k_r^0 is the dissociation rate constant independent of temperature, A_r frequency factor of dissociation, and ΔE_r potential barrier in the dissociation process. At higher temperatures (>200 K), the value of k_r^0 is negligible compared with that of the second terms in Eq. 2, since the Φ_r values is very small at 77 K. Equation 3 is derived from Eqs. 1 and 2.

$$\log\left(\frac{\Phi_r}{2\tau_f}\right) = \log A_r - \frac{\Delta E_r}{2.303RT} \qquad (3)$$

The plot of $\log\{\Phi_r(2\tau_f)^{-1}\}$ *vs.* T^{-1} obtained experimentally, which agrees with Eq. 3, is shown in Fig. 6a. The values of A_r and ΔE_r obtained from the linear plot in Fig. 6a are listed in Table 2.

Similarly, the rate constant k_n may be written as the following equation:

$$k_n = k_n^0 + A_n\exp\left(\frac{-\Delta E_n}{RT}\right) \qquad (4)$$

where k_n^0 is the rate constant for the radiationless processes of k_{ic} plus k_{isc} independent of temperature, A_n frequency factor and ΔE_n potential barrier in the radiationless processes. The k_n^0 values for **1** and **2** are estimated to be about 1.5×10^7 s^{-1} from the data of τ_f at 77 K and k_f. Therefore, one can derive Eq. 5.

$$\log(k_n-k_n^0) = \log A_n - \frac{\Delta E_n}{2.303RT} \qquad (5)$$

where the values of k_n can be evaluated experimentally by the following equation: $k_n=\tau_f^{-1}-(k_r+k_f)$. The plot of $\log(k_n-k_n^0)$ *vs.* T^{-1} is shown in Fig. 6b, which agrees with Eq. 5. The values of A_n and ΔE_n are also summarized in Table 2.

Dissociation Process. Let us consider the dissociation process k_r in the S_1 state. It is well-known that benzene derivatives undergo the β-bond fission upon irradiation[21] and the predissociation proceeds *via* the lowest excited singlet state $S_1(\pi,\pi^*)$ $^1B_2$ to give

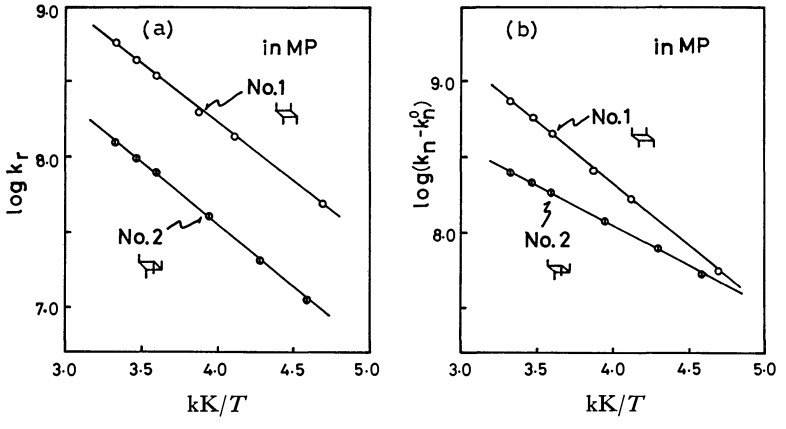

Fig. 6. (a) Plots of $\log k_r$ *vs.* T^{-1} and (b) plots of $\log(k_n-k_n^0)$ *vs.* T^{-1}.

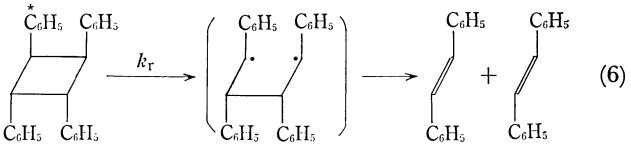
Table 2. Frequency factors A_r and A_n and potential barriers ΔE_r and ΔE_n for k_r and k_n, respectively

Samples	$A_r/10^{11}$ s^{-1}	ΔE_r/kcal mol^{-1}	$A_n/10^{11}$ s^{-1}	ΔE_n/kcal mol^{-1}
1	2.0 (±0.3)	3.5 (±0.2)	4.2 (±0.5)	3.7_5 (±0.3)
2	0.79 (±0.07)	3.8_3 (±0.2)	0.13_8 (±0.03)	2.3_8 (±0.3)

the geminate radicals.[11,12] It seems that the photochemical cleavage of tetraphenylcyclobutanes has analogy to those of benzene derivatives. Kaupp[2,3] suggests that the photochemical reaction of tetraphenylcyclobutanes proceeds *via* a short-lived 1,4-biradical. Thus, the β-bond fission *via* the $S_1(\pi,\pi^*)$ of γ-1,*t*-2,*t*-3,*c*-4-tetraphenylcyclobutane (**1**), for example, can be expressed by Eq. 6. Of course, the β-bond fission of



(6)

1 1,4-biradical *trans*-stilbene

the starting molecule to produce the 1,4-biradical occurs from the vibrationally relaxed S_1 state judging from the values of τ_f. It is known that the vibrational relaxation times in condensed media are of the order of 10^{-12} s.[22] If the biradical had a lifetime enough to yield the starting material *via* the back reaction, the geometrical isomer (**2**) of the starting molecule besides *trans*-stilbene would be yielded as a photoproduct resulting from rotational diffusion and subsequent recombination of the biradical. However, such photochemical isomerization was scarcely observed during the photolysis of **1**. Similar result was obtained in the case of **2**. Thus, it is reasonable to consider that the biradical is very unstable and is instantaneously broken to yield two molecules of *trans*-stilbene as shown in Eq. 6. The dissociation quantum yields are, therefore, nearly equal to $\Phi_r/2$. It can be said that the β-bond fission of tetraphenylcyclobutanes proceeds nearly concertedly to give two molecules of *trans*-stilbene. This mechanism supports the assertion that there may be a significant concerted component to the cycloreversion reaction in the excited singlet state of *cis*-1,2-diphenylcyclobutane as reported by Jones and Chow.[23]

The experimental results show quantitatively cis-effect in that **1** undergoes dissociation only to *trans*-stilbene and the values of k_r for **1** are greater than those for **2** (Fig. 6a). For instance, the dissociation rates k_r for **1** and **2** at 300 K can be estimated to be 5.5×10^8 s^{-1} and 1.2×10^8 s^{-1}, respectively. The frequency factor A_r for **1** is greater than that for **2**, and the potential barrier ΔE_r is small in comparison with that for **2** as shown in Table 2. The cis-effect may be caused by a steric strain between adjacent benzene rings of **1**. The crossing probability from the S_1 state to the repulsive state of the β-bond between proper carbon atoms in cis-form may be larger than that in trans-form.

Radiationless Processes. The rate constant k_n is comprised of k_{ic} (internal conversion $S_1\rightarrow S_0$) plus k_{isc} (intersystem crossing $S_1\rightarrow T_1$). The k_n values increase considerably with elevating temperature according to Eq. 4. At higher temperatures (>200 K), the temperature dependent rate $(k_n-k_n^0)$ becomes very much greater than that of k_n^0 and the values of $(k_n-k_n^0)$ for **1** are large compared with those for **2**, as can be seen in Fig. 6b. The values of k_n for **1** and **2** at 300 K, for example, are evaluated to be 7.8 $(\pm0.7)\times10^8$ s^{-1} and 2.5 $(\pm0.3)\times10^8$ s^{-1}, respectively. These facts indicate that steric effect is responsible for k_n as well as k_r at higher temperatures (>200 K).

The internal conversion rate constant k_{ic} is markedly enhanced due to a conformational change in the excited state.[13,24] In a similar manner, the k_n value may increase according to the enhancement of internal conversion. A conformational change among the substituted benzene rings of tetraphenylcyclobutanes in the S_1 state would be expected. However, the fact that no intramolecular excimer emission could be observed suggests the existence of large steric hindrance among the benzene rings in the S_1 state. Other possible mechanism for the large value of k_n at higher temperatures is explained by the "channel 3" decay where energy levels of isomers are incorporated as intermediate states of $S_1\rightarrow S_0$ internal conversion.[25]

The lifetimes τ_f (0.8±0.5 ns for **1** and 2.5±0.4 for **2**) are very shorter than that of toluene (34±2 ns in MP) at 300 K.

Finally, one can understand that such short lifetimes of the starting materials result from the large values of k_r and k_n (probably k_{ic}) at room temperature.

Conclusion

The photolyses of 1,2,3,4-tetraphenylcyclobutanes at higher temperatures (>200 K) proceed *via* the $S_1(\pi,\pi^*)$ state to give *trans*-stilbene nearly concertedly. The relaxation processes of the excited molecules are mainly comprised of the dissociation k_r and the other radiationless processes k_n, which are markedly dependent upon temperature. Significant cis-effect was also observed in photochemical and photophysical processes of the sample molecules.

The authors are grateful to Dr. N. Kanamaru of Nagoya University for his helpful discussion.

Conformational Analysis of Intramolecular Fluorescence Quenching of α-(9-Carbazolyl)-ω-[p-(methoxycarbonyl)benzoyloxy]alkanes

Toshiji KANAYA, Yoshihiko HATANO,† Masahide YAMAMOTO,* and Yasunori NISHIJIMA

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 9, 1979)

Equilibrium distribution of conformations of the series of compounds, α-(9-carbazolyl)-ω-[p-(methoxycarbonyl)benzoyloxy]alkanes in the ground state was calculated to explain the intramolecular fluorescence quenching of these compounds in a rigid medium. It was found that when the radius of active sphere R_0 for the intramolecular fluorescence quenching is taken to be 8.8—9.0 Å, the experimentally observed chain length dependence of the fluorescence quenching can be well simulated by this calculation. The active sphere for the dynamic intermolecular fluorescence quenching in solution was also discussed to compare with that of the intramolecular fluorescence quenching.

Since Leonhardt and Weller[1] first reported the intermolecular exciplex formation between perylene in its excited singlet state and *N,N*-dimethylaniline in the ground state, extensive studies have been carried out on the intermolecular exciplex formation. Recently, intramolecular exciplexes have been studied to investigate the geometry of exciplexes and their electronic structures for various exciplex systems, *e.g.*, $(CH_3)_2N$-$(CH_2)_n$-(naphthyl) (n=2—4),[2] *p*-$(CH_3)_2N$-C_6H_4-$(CH_2)_n$-(9-anthryl) (n=0—3),[3] *p*-$(CH_3)_2N$-C_6H_4-$(CH_2)_n$-(1-pyrenyl) (n=1—3),[3] (9,10-dicyanoanthryl)-$(CH_2)_3$-(naphthyl).[4] In the previous reports,[5] we have studied the intramolecular fluorescence quenching and exciplex formation for a series of α-(9-carbazolyl)-ω-[*p*-(methoxycarbonyl)benzoyloxy]alkanes (Fig. 1). It was found in these investigations that intramolecular fluorescence quenching of the system can be separated into "static quenching" and "dynamic quenching," and only the static quenching is observed in a rigid medium where the Brownian motion of the methylene chain is frozen.

The present investigation was undertaken to see if the experimentally observed chain length dependence of the static fluorescence quenching[5] can be simulated by the calculation of the equilibrium conformations of the intramolecular exciplex system. Equilibrium distribution of conformations for individual compounds in the ground state was determined by the calculation of potential energy of each conformation[6] and the degree of intramolecular static fluorescence quenching was estimated by the calculation of the probability of end-to-end encounter in all the conformations.

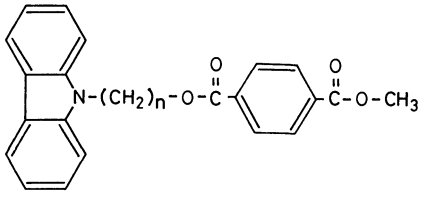

Fig. 1.

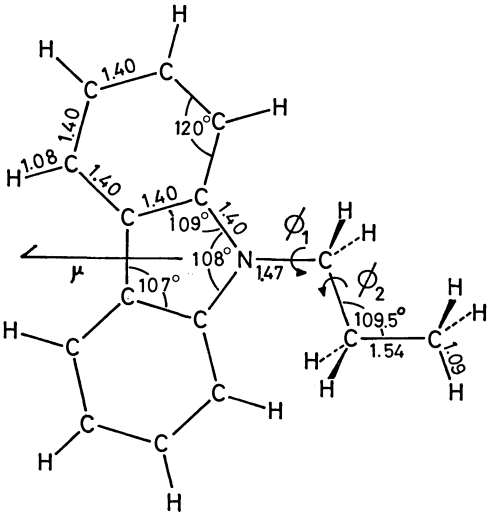
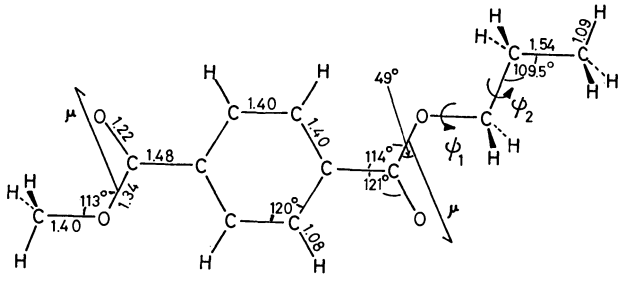
Procedures for Calculation

Structural parameters used in this calculation are shown in Figs. 2(a) and 2(b). In this calculation we assume that the ester groups are coplaner with the benzene ring and the trans conformation is predominant over the cis. This assumption has been taken routinely in conformational calculations.[7,8] Generally, conformations of methylene chain are treated by the trans(t)-gauche(g) rotational isomer model, where the statistical weight for two gauche states (g^+ and g^-) is estimated by $\exp(-500/RT)$, since the energy difference between g and t is about 500 cal/mol. However, for relatively short methylene chain having large



(a)



(b)

Fig. 2. Structural parameters of *N*-propylcarbazole (a) and methyl propyl terephthalate (b).

† Present address: Niigata College of Pharmacy, Kamishinei-cho, Niigata 950-21.

end groups, rotations about each C–C bond is related so strongly to one another that the statistical weight for gauche states may differ from $\exp(-500/RT)$. Hence, we calculated the conformational energy, considering that the rotations about all bonds are correlated, though we employed the t-g rotational isomer model in these calculations.

Potential energies due to the van der Waals interactions between nonbonded atoms and due to the electrostatic dipole-dipole interaction between polar end groups were calculated for all of $2\times3^{n+1}$ conformations where n denotes the number of methylene units. For the compound having $n=10$, we adopted the Monte Carlo method, since the number of possible conformation of this compound is too large. In this method we selected randomly 14500 conformations out of $2\times3^{n+1}$ conformations and calculated the potential energy of each one.

Calculation of the Potential Energy due to the Van der Waals Interaction. We adopted a potential function of the Lennard-Jones type. The potential energy P_{ij} between ith and jth nonbonded atoms is given as follows

$$P_{ij} = B_{ij}/r_{ij}^{12} - A_{ij}/r_{ij}^{6}, \tag{1}$$

where, r_{ij} is the distance of separation between ith and jth nonbonded atoms, A_{ij} and B_{ij} are parameters. The parameters A_{ij} have been estimated, using the Slater-Kirkwood equation modified by Scott and Scheraga,[9]

$$A_{ij} = \frac{(3/2)(e\hbar/m^{1/2})\alpha_i\alpha_j}{(\alpha_i/N_{\mathrm{eff}}^{(i)})^{1/2}+(\alpha_j/N_{\mathrm{eff}}^{(j)})^{1/2}}, \tag{2}$$

where, e is the charge of an electron, m is the mass of an electron, $\hbar$ is equal to $h/2\pi$ where h is the Planck's constant, α_i and $N_{\mathrm{eff}}^{(i)}$ are the polarizability and the effective number of electrons of ith atom, respectively. The values of $N_{\mathrm{eff}}^{(i)}$ were graphically determined using Pitzer's data[10] according to Scott and Scheraga.[9] The parameter B_{ij} is obtained by requiring P_{ij} to be minimum at a distance $r_{ij}=r_{ij}^{\circ}$, which is the sum of the van der Waals radii of the interacting atoms. Values of the van der Waals radius r_{w}, the polarizability α, and the effective number of electrons N_{eff} are summarized in Table 1.

Then, the potential function is modified in consideration of molecule-solvent interaction following Flory *et al.*[11] For a molecule in a solvent, intramolecular contact through alternation of conformation must occur at the expense of intermolecular interaction with the solvent. Since these latter interactions are necessarily attractive, the effect would suppress the attractive term P_{ij} occurring at the greater distance r_{ij} between the ith and the jth atoms. Thus the minimum in this function would be eliminated. Calculations have, therefore, been carried out using the potential function modified as follows

$$\begin{aligned} P_{ij}^{*} &= P_{ij} - P_{ij}^{\circ} \quad (r_{ij} < r_{ij}^{\circ}) \\ P_{ij}^{*} &= 0 \qquad\qquad (r_{ij} \geq r_{ij}^{\circ}), \end{aligned} \tag{3}$$

where P_{ij}° is the value of P_{ij} at $r_{ij}=r_{ij}^{\circ}$. We obtained the total potential energy due to the van der Waals interaction as the sum over all pairs of nonbonded atoms.

$$V_n = \sum_{i<j}\sum P_{ij}^{*} \tag{4}$$

Calculation of the Potential Energy due to the Electrostatic Dipole-Dipole Interaction. The mutual potential energy D_{ij} of two point dipoles $\vec{\mu}_i$ and $\vec{\mu}_j$ separated by the vector $\vec{r}_{ij}$ is given by

$$D_{ij} = (1/\varepsilon)[(\vec{\mu}_i\cdot\vec{\mu}_j)/r_{ij}^{3} - 3(\vec{\mu}_i\cdot\vec{r}_{ij})(\vec{\mu}_j\cdot\vec{r}_{ij})/r_{ij}^{5}], \tag{5}$$

where ε is the dielectric constant of the solvent and r_{ij} is the scalar magnitude of $\vec{r}_{ij}$. The total potential energy V_{e} due to the dipole-dipole interaction is given by the sum over all pairs of dipoles as follows.

$$V_{\mathrm{e}} = \sum_{i<j}\sum D_{ij} \tag{6}$$

In the present calculation, the dipole moments of CZ residue and ester group were taken to be 2.09 D[12] and 1.83 D, respectively; the latter value is taken from the value for the dipole moment of methyl benzoate.[13] The angle between the dipole moment (indicated by μ in Fig. 2) and the O–CO bond was taken to be 49°.

Conformations of Methylene Chain in the Neighborhood of Carbazole (CZ) and Terephthalic Acid Methyl Ester (TPM) Residues. We calculated the conformational energy applying the t-g rotational isomer model to the methylene chain. However, the location of the potential minima in the neighborhood of the large end groups might somewhat deviate from that in the t-g rotational isomer model. Hence, we have calculated the potential energies of *N*-propylcarbazole and methyl propyl terephthalate, whose structures are shown in Fig. 2, at intervals of 5° for each rotation angle, starting from conformations shown in Fig. 2 ($\phi_1=\phi_2=0$, $\psi_1=\psi_2=0$).

The potential energy, $V(\theta_i)$, associated with rotation θ_i about ith bond is given by

$$V(\theta_i) = V_{\mathrm{r}}(\theta_i) + \sum_{i<j}\sum P_{ij}, \tag{7}$$

where $V_{\mathrm{r}}(\theta_i)$ is the intrinsic torsional potential attributable to the bond itself, P_{ij} is the potential energy between nonbonded atoms given by Eq. 1 and the sum is over all pairs, i,j of atoms. For threefold rotation, V_{r} is given by

$$V_{\mathrm{r}}(\theta_i) = (V_0/2)(1-\cos 3\theta_i), \tag{8}$$

where V_0 is the torsional barrier height. In this calculation the internal rotation having a sixfold

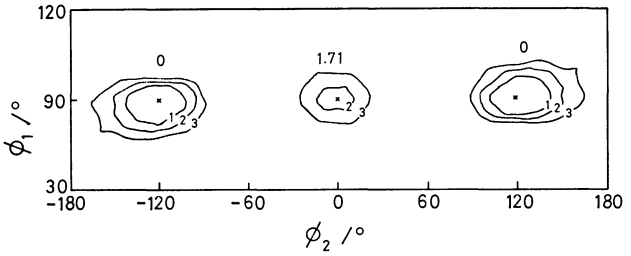

Fig. 3. Conformational energy map of *N*-propylcarbazole. Energy contours are given at interval of 1.0 kcal/mol. Numerals in the figure are the values of potential energy at its minimum position marked by X.

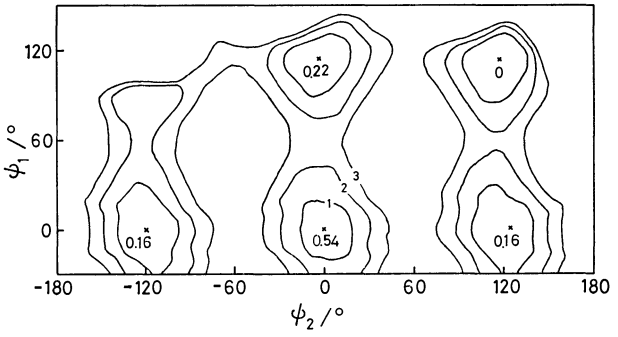

Fig. 4. Conformational energy map of methyl propyl terephthalate. Notations are the same as Fig. 3.

periodicity was neglected. Values of 2.8 kcal/mol and 1.8 kcal/mol were assigned to V_0 for C–C bond and C–O bond, respectively.[14]

Results are shown in Figs. 3 and 4. For *N*-propylcarbazole, the potential mimima are situated at rotations $\phi_1=90°$, $\phi_2=0°$, $\pm120,°$ and $\phi_1=-90°$, $\phi_2=0°$, $\pm120°$. The potential mimima for methyl propyl terephthalate are found to be about at $\psi_1=0°$, $\psi_2=0°$, $\pm120°$, $\psi_1=120°$, $\psi_2=0°$, $+120°$, and $\psi_1=-120°$, $\psi_2=0°$, $-120°$. For these two compounds, the locations of potential mimima are not so deviated from that in the t-g rotational isomer model, hence the use of the t-g rotational isomer model in the neighborhood of CZ and TPM residues appears to be justified.

Results and Discussion

The total potential energy, E, is given by the sum of the potential energy due to the van der Waals interaction and that due to the dipole-dipole interaction. Assuming that the distribution of conformations obeys the Boltzmann distribution, the fraction of ith conformation, W_i, is given by

$$W_i = \exp(-E_i/RT)/\sum_j \exp(-E_j/RT),$$

where E_i is the potential energy for ith conformation.

Distribution of End-to-end Distance. Distribution of the end-to-end distance, r, for each compound at 298 K is shown in Fig. 5, where r was defined as the distance between the center of five membered ring of CZ and the center of the benzene ring of TPM.

For the compounds having shorter methylene chains, I, II, III, the appearing conformations are so few that the distribution of end-to-end distance is very sharp. There is no conformation whose end-to-end distance

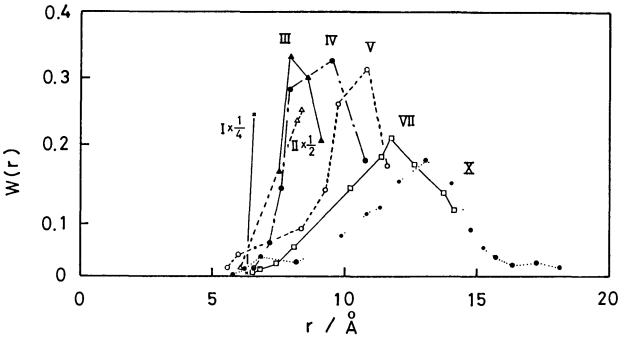

Fig. 5. Distribution of the end-to-end distance r of samples, I, II, III, IV, V, VII, and X at 298 K.

is less than 5 Å since the two end groups are large.

Static Fluorescence Quenching. We have shown[5] that the normal fluorescence of the series of compounds, I—X, is quenched by both the "static quenching" and the "dynamic quenching." The static quenching is caused by an electron transfer from CZ moiety to TPM moiety immediately after the excitation of CZ moiety regardless of the thermal motion of the methylene chain, when CZ moiety exists in the vicinity of TPM moiety. On the other hand, the dynamic quenching is diffusion controlled and reflects the frequency of intramolecular encounters between TPM moiety and the excited CZ moiety within its lifetime. We have estimated the magnitude of the static quenching from the measurement of the quantum yield of the normal fluorescence emission of CZ moiety at 77 K in a rigid 2-methyltetrahydrofuran (MTHF) matrix.

Now, the static quenching will be considered in terms of the active sphere model, in which fluorescence quenching occurs with the probability of one when the TPM moiety exists within the radius of the active sphere of CZ moiety and there is no interaction between CZ moiety and TPM moiety outside the active sphere (hard core approximation). According to this model, the static quenching occurs in the molecules having the conformation in which TPM moiety exists in the radius of the active sphere of CZ moiety immediately after the excitation of CZ moiety. In a rigid medium we observe only the static quenching, since no conformational change of molecules occurs. Therefore, the degree of the static quenching in a rigid medium reflects the distribution of conformations of these compounds immediately after the excitation of CZ moiety. In a rigid medium, it is valid to assume that the conformational distribution of these compounds in the excited state is equal to that in the ground state. Then, the magnitude of the static quenching for each compound corresponds to the fraction of conformation with the end-to-end distance, r, being shorter than the radius of the active sphere, R_0, in the conformational distribution in the ground state. So, the fraction of conformations with the end-to-end distance, r, shorter than the radius of the active sphere, R_0, for various values of R_0 was calculated for each compound. The results at 77 K and 136 K are shown in Figs. 6 and 7, respectively. At both temperatures, the best fit with experimental results was given when the value of the radius of active sphere is equal

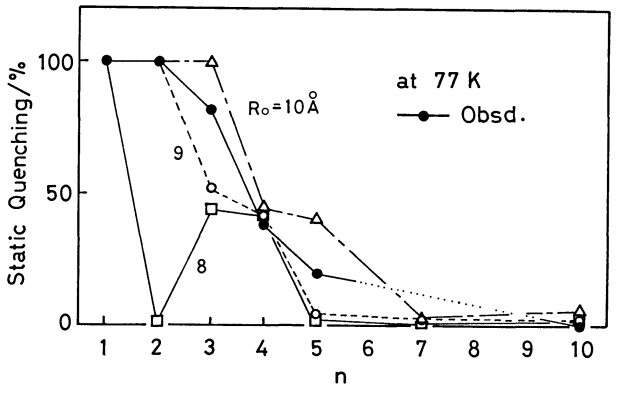

Fig. 6. Comparison of calculated fraction of the static quenching for 77 K with the observed fraction in MTHF at 77 K. (—●—): Observed value, (—△—): calculated value for $R_0=10$ Å, (--○--): calculated value for $R_0=9$ Å, (—□—): calculated value for $R_0=8$ Å.

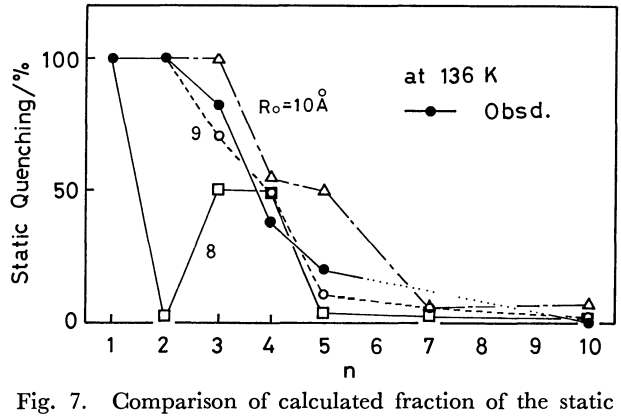

Fig. 7. Comparison of calculated fraction of the static quenching for 136 K with the observed fraction in MTHF at 77 K. Notations are the same as Fig. 6.

to 8.8—9.0 Å. The agreement between the calculated and experimental values is better at 136 K than at 77 K. This result might indicate that the equilibrium distribution of conformations at 136 K is conserved below 136 K, since the freezing point of MTHF is 136 K.

Active Sphere of the Dynamic Fluorescence Quenching in Solution. In this study, the active sphere model is used for the static fluorescence quenching of the intramolecular exciplex system. This model was first introduced by Perrin[15] for the static fluorescence quenching of the molecularly dispersed system. Smoluchowski's solution of diffusion-controlled reactions[16] are derived under the boundary condition of the hard core in the active sphere model: $c(r,0)=c_0$, $c(\infty,t)=c_0$, $c(R,t)=0$, where R is the sum of the collision radii and c_0 is the initial concentration of the diffusion species, and they have been applied to dynamic diffusion-controlled fluorescence quenching.[17]

Now, the active sphere of the dynamic fluorescence quenching of the intermolecular system: *N*-ethylcarbazole-dimethyl terephthalate will be compared with that of the static fluorescence quenching of the intramolecular exciplex system in a rigid medium. Radius of the active sphere of the dynamic fluorescence quenching of the intermolecular system was estimated in

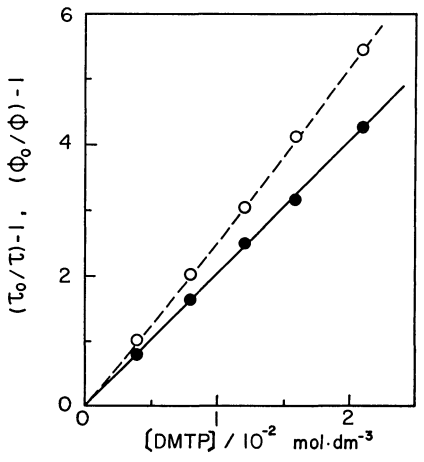

Fig. 8. Stern-Volmer plots of Φ (○) and τ (●) for the fluorescence of ECZ quenched by dimethyl terephthalate (DMTP) in THF solvent at 25 °C.

TABLE 2. RADIUS OF ACTIVE SPHERE (R') AND DIFFUSION CONSTANT (D) IN VARIOUS SOLVENTS

Solvent	Dielectric constant ε	R'/Å	$D/10^{-5}$ cm^2 s^{-1}
Toluene	2.4	5.6	2.83
Dibutyl ether	3.1	5.3	2.72
Diethyl ether	4.3	6.8	5.01
Tetrahydropyran	5.6	6.0	2.11
Tetrahydrofuran	7.6	7.3	2.32
Acetonitrile	36.7	6.4	3.34

various solvents at 25 °C by the method B of Ware and Novros,[18] *i.e.*, the Stern-Volmer plots were analyzed by the theory of diffusion-controlled fluorescence quenching including a transient term. An example of the analysis is as follows. Stern-Volmer plots of both steady-state fluorescence quantum yield Φ and fluorescence lifetime τ in THF solvent at 25 °C is shown in Fig. 8. The Stern-Volmer plot of τ gives $K_q=202$ dm^3 mol^{-1} and the lifetime in the absence of electron acceptors τ_0 was measured to be 15.8 ns, then $4\pi R'DN'=1.28\times10^{10}$ dm^3 mol^{-1} s^{-1} is obtained and furthermore, $4\sqrt{\pi D}R'^2N'=1.1\times10^5$ dm^3 mol^{-1} s$^{1/2}$ is estimated from the Stern-Volmer plot of Φ. Then the combination of these values gives $R'=7.3$ Å and $D=2.32\times10^{-5}$ cm^2 s^{-1}. The values obtained for other solvents are also shown in Table 2. As described in the previous section, the radius of active sphere $R_0=8.8$—9.0 Å was obtained for the intramolecular fluorescence quenching from the chain length dependence of the fluorescence quantum yield of CZ moiety in a rigid medium. The values of R' are slightly smaller than the intramolecular one R_0, but the agreement between the radius of active sphere for the intramolecular fluorescence quenching and the intermolecular one is fairly good.

Though we employed the hard core approximation ($c(R_0, t)=0$) for the active sphere at the present stage, neglecting the effect of the mutual orientation between CZ and TMP moieties, experimentally observed frac-

tions of the static quenching were well simulated with appropriate parameters of the radius of active sphere and the temperature of the system.

The calculations reported in this paper were carried out on the FACOM 230-75 computer at the Computer Center of Kyoto University.

Vibrational Spectra and Normal Coordinate Analysis of *N*-Methyl Thiourea

K. DWARAKANATH and D. N. SATHYANARAYANA*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

(Received July 14, 1978)

The infrared spectra of *N*-methylthiourea (NMTU) and its *N*-deuterated and *S*-methylated species were measured. Assignment of the infrared and Raman spectra of NMTU has been accomplished by correlation with thiourea and by use of infrared band shifts on *N*-deuteration as well as *S*-methylation. Normal coordinate analysis was performed for all the fundamentals of NMTU and NMTU-d_3, the assignments obtained from the force field calculations being discussed in relation to those in other related thioureas and thioamides. The potential barriers to the internal rotations for the $-NH_2$, $-CH_3$, and $-CN$ groups were estimated from the force constants.

There is continued interest in the study of thiourea derivatives and their metal complexes in recent years. This may be due to some unusual spectroscopic, magnetic and structural properties shown by the metal complexes of thiourea derivatives as well as to the potential ability of thioureas for ambidentate coordination.[1-4]

N-Methylthiourea (NMTU) is the simplest alkyl-substituted thiourea. An analysis of its vibrational spectrum is necessary for the investigation of the characteristic frequencies and the force field of thiourea derivatives. Lane *et al.*[4] tentatively assigned the infrared spectra of NMTU in the region 4000—700 cm^{-1}. Of particular interest is their assignment of the C=S stretching frequency at 780 cm^{-1}. Jensen and Nielsen,[5] however, attributed a band near 635 cm^{-1} to a coupled C=S stretching mode. There are differences in the assignments also of other bands for NMTU. No complete assignment of the infrared spectra of *N*-methyl thiourea is available although quantitative vibrational assignments of thiourea,[6-8] *N,N'*-dimethyl-,[9,10] and tetramethylthioureas[10,11] have been accomplished by normal coordinate treatments. Recently, detailed vibrational assignments for thiosemicarbazide[12,13] (H_2HNH–C(=S)–NH_2) and *N*-methylurea[14] (NMU), closely related to NMTU, have been published.

An appropriate description of the fundamental vibrations of NMTU arrived at with the aid of normal coordinate analysis of NMTU and NMTU-d_3 and the infrared spectrum of the *S*-methylated NMTU is discussed herewith. The potential barriers to the internal rotation about C–N and C–C bonds are estimated from the force constants.

Experimental

NMTU was prepared by the method of Moore and Crossley[15] and purified by recrystallization from absolute ethanol. NMTU-d_3 was obtained by dissolving NMTU in D_2O and evaporating the excess D_2O in vacuo. The process was repeated several times till the infrared spectrum showed no bands due to NH vibrations. The *S*-methyl derivative of NMTU was prepared by the procedure of Brand and Brand.[16]

Spectra: Infrared spectra were measured on a Carl Zeiss UR 10 spectrophotometer between 4000 and 400 cm^{-1} in Nujol mull and KBr pellet. Far infrared spectra from 400 to 30 cm^{-1} were recorded on a Polytec FIR 30 spectrometer as polyethylene pellet. The Raman frequencies of NMTU are quoted from recent data.[17]

Normal Coordinate Treatment. The GF matrix method of Wilson[18] was employed. A trans-planar –CSNH– conformation supported by nuclear magnetic resonance studies[19] with a molecular symmetry C_s was adopted. The 27 vibrations of NMTU then divide themselves into 18 a′ (in-plane) and 9 a″ (out-of-plane) modes, all being infrared and Raman active. The following molecular parameters transferred from those of NMU[14] and Pt(II) *N*-ethyl thiourea complex[1] were used: bond distances N–H 1.00; C–H 1.08; C′–N 1.465; C–N 1.351; C–S 1.73 Å. The angles around the methyl carbon atom were taken to be tetrahedral (109.47°) and those around the nitrogen of the NH_2 group 120°. The other angles were –NCN 117°; NCS and N′CS 121.5°; C′NH and CN′H 120°. The molecular structure and the internal coordinates are shown in Fig. 1. The symmetry coordinates were the same as those employed for NMU.[14,20]

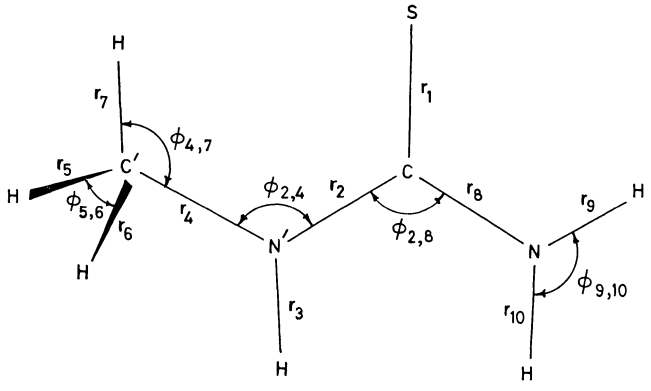

Fig. 1. Structure and internal coordinates of *N*-methyl thiourea.

The Urey-Bradley force field which gives satisfactory explanation of the spectra of thioamides[21-23] and thioureas[6,8,10] was employed. To begin with, zeroth order calculations were performed for the planar vibrations using the force constants transferred from (a) thioacetamide[21] (TAM), and (b) thiourea[6] (TU) and thioacetamide.[21] The zeroth order frequencies were similar in both cases and were reasonably close to the observed frequencies, the potential energy distributions (PED) being also comparable. For out of plane vibrations, the methyl group was treated by the Urey-Bradley force function, the valence force constants being employed for the planar molecular skeleton. The initial values of the valence force constants were taken from NMU.[14]

The force constants of set (a) were refined in order to get a good agreement between the calculated and observed frequencies for both NMTU and NMTU-d_3. The final force constants given in Table 1 are comparable with those of the initial ones, requiring only minor modifications.

Table 1. Force constants[a] for *N*-methylthiourea

Stretching		Bending		Repulsive

$f(\pi CS)$	0.090	$f(\tau CH_3)$	0.006		

a) K, H, and F are in mdyn/Å and the valence constants (f) in mdyn Å. Intramolecular tension $k(CH_3)$ −0.05 mdyn Å and interaction constant P(NH, NH) −0.12 mdyn/Å. b) w, τ, and π: As in Table 2.

The computations were carried out on an IBM 360/44 computer using programs similar to those of Schachtschneider.[24]

Results and Discussion

Agreement between the observed and calculated frequencies for NMTU-d_0 and -d_3 is satisfactory. The somewhat larger deviations for the deuterated compound can be attributed to the higher anharmonicity associated with the hydrogen-involving vibrations. As usual,[25] an interaction constant, P(NH,NH), was employed to get a better fit for the NH_2 stretching frequencies.

Band Assignments. The observed and calculated frequencies and an approximate description of the vibrations derived from the potential energy distributions amongst the symmetry coordinates are given for NMTU and NMTU-d_3 in Tables 2 and 3, respectively.

Alternate assignments for the frequencies below 700 cm^{-1} were considered by means of force field calculations. Final selection consistent with a satisfactory interpretation of all the bands was made by referring to the deuterium frequency shifts and the characteristic group frequencies in structurally related molecules.

In-plane Vibrations. Thioureide Group Vibrations. NH, NH_2 Stretching: The infrared spectrum of NMTU shows three bands in the region above 3000 cm^{-1} assignable to NH_2 and NH stretching vibrations. The bands at 3350 and 3189 cm^{-1} are easily assigned to asymmetric and symmetric NH_2 vibrations,respectively, and the band at 3280 cm^{-1} to NH stretching. On deuteration these bands are replaced by new ones at 2520, 2350, and 2415 cm^{-1}, respectively.

CN Stretching: According to the normal coordinate analysis, the band at 1567 cm^{-1} (near 1555 cm^{-1} in Raman) assigned by Lane *et al.*[4] to the thioamide II band of the –CSNH– group is due to a highly coupled vibration comprising of CN and CS stretching and NCN and CNC bending modes. The band as expected shifts to a higher frequency on *S*-methylation, being observed at 1590 cm^{-1} in the spectrum of *N*,*S*-dimethyl thiourea hydroiodide.

a) ν, stretching; a, asymmetric; s, symmetric; δ, bending; r, rocking; w, wagging; τ, torsion and π, out-of-plane bending. b) $100L_{ik}^2F_{ii}/\lambda_k$; those less than 20% are omitted when the individual or sum of the PED is higher than 50%. c) D is the deviation of ν as a percentage:

$$D = (|\nu_{obsd} - \nu_{calcd}|) \times 100/\nu_{obsd}.$$

The 1500 cm^{-1} band (at 1488 cm^{-1}, Raman spectrum) may be chiefly associated with C–N asymmetric stretching, which is higher than that in thiourea[6] assigned to 1472 cm^{-1}. The 1500 cm^{-1} band of NMTU is unaffected in the *S*-methyl derivative except for an increase in intensity.

NH, NH_2 Bending: Thereis a doublet in the infrared spectrum of NMTU in the 1250—1300 cm^{-1} region; the band at 1302 cm^{-1} is strong and that at 1262 cm^{-1} is medium in intensity. In the Raman spectrum also a strong band at 1296 cm^{-1} and a medium shoulder band at 1260 cm^{-1} are observed. The strong band at 1302 cm^{-1} is taken as the fundamental and the one at 1262 cm^{-1} may be due to an overtone, enhanced in intensity possibly due to Fermi resonance with the fundamental at 1302 cm^{-1}.

The present assignment of the 1302 cm^{-1} band to thioamide II band of the –CSNH– group agrees qualitatively with that of Lane *et al.*[4] According to the potential energy distribution, the 1302 cm^{-1} band arises mainly from N–H bending (65%). This band (as also does the 1262 cm^{-1} band) disappears on N-deuteration, a new band at 954 cm^{-1} due to ND bending being found in the spectrum of NMTU-d_3. The NH bending frequency of NMTU is lower than the one at 1354 cm^{-1} in NMU.[14]

The thioamide II band of the $-CSNH_2$ group due to NH_2 bending is observed at 1642 cm^{-1}.

NH_2 Rocking: The band at 1154 cm^{-1} may be assigned to a coupled NH_2 rocking. It is compatible with the 1160 cm^{-1} band of NMU. That the 1154 cm^{-1} band of NMTU undoubtedly has its origin in the NH_2 group is confirmed by deuteration studies. It shifts to 870 cm^{-1} in the infrared spectrum of NMTU-d_3. The normal coordinate analysis shows the 1125 cm^{-1} band as due to a mixed mode mainly of H_3C–N and symmetric C–N stretching vibrations.

CS Stretching: There are two bands in the infrared spectrum of NMTU, a strong sharp band at 778 cm^{-1} and a strong somewhat broad band at 725 cm^{-1}. In the present investigation, the 778 cm^{-1} band is assigned to the C=S stretching in line with that of Lane *et al.*[4] and the 725 cm^{-1} band to an out-of-plane NH_2 bending. According to the potential energy distribution, the C=S stretching contributes nearly 65% to the 778 cm^{-1} band. A very intense Raman band at 767 cm^{-1} is observed in support of this assignment. Further, if the 778 cm^{-1} band is assigned to the NH_2 out-of-plane bending, the calculated frequency for the corresponding ND_2 mode is at 570 cm^{-1}, whereas a new strong band observed on N-deuteration is at 510 cm^{-1}.

The assignment of C=S stretching (Thioamide I band) of NMTU at 778 cm^{-1} is comparable with the C=S stretching frequency in the isoelectronic thiosemicarbazide[10,11] assigned to 800 cm^{-1}. Similarly, *N*-ethylthiourea also exhibits a strong Raman band[17] in this region at 806 cm^{-1}, which may be assigned to the C=S stretching mode. Thus the C=S stretching frequency of NMTU is higher than that in thiourea[6] and *sym*-*N*,*N*′-dimethylthiourea[9,10] assigned near 730 cm^{-1}. As in NMTU, strong Raman bands are also observed near 730 cm^{-1} in these compounds. The 778 cm^{-1} band is nearly unaffected on *S*-methylation, the behavior being similar to the *S*-methylation of thiourea. The 727 cm^{-1} band of thiourea predominantly due to C=S stretching is unaffected in the spectrum of the *S*-methyl derivative.[5]

The C=S stretching vibration has been empirically assigned to 635 cm^{-1} by Jensen and Nielsen[5] from a comparison of the spectrum of NMTU with that of it seleno analogue. This is not supported by normal coordinate analysis. However, the 635 cm^{-1} band has contribution from NCS bending and therefore shifts to a lower frequency on selenation which explains their observation.

Skeletal Bending: The band at 496 cm^{-1} is due to NCN bending, a band assigned similarly being found at 487 cm^{-1} in thiourea.[6] The NCS bending occurs as a coupled mode, contributing to the bands at 635, 496 and 300 cm^{-1}. In contrast, TAM exhibits a nearly pure NCS bending vibration[21] near 470 cm^{-1}. The zeroth order calculations clearly showed the 635 cm^{-1} band to be a coupled vibration of NCS and CNC bending modes. The lowest in-plane fundamental at 300 cm^{-1} can be assigned to CNC bending as in NMU.[14]

Methyl Group Vibrations. The band at 980 cm^{-1} can be assigned to CH_3 rocking which is coupled with NH_2 rocking as in TAM.[21] The assignment differs from that of Lane *et al.*[4] who have attributed CH_3 rocking to 1154 and 1125 cm^{-1} bands (considered as a doublet). As expected, the 980 cm^{-1} band is absent in thiourea.[6] The other CH_3 group vibrations are easily assigned as shown in Tables 2 and 3.

Out-of-plane Vibrations. There are five a″ modes for the planar skeleton. The NH_2 torsional mode of NMTU assigned to 725 cm^{-1}, which on deuteration shifts to 510 cm^{-1}, is compatible with that of NMU[14] and TAM[21,22] where it has been assigned near 710 cm^{-1}. The 600 cm^{-1} band of NMTU arises from NH_2 wagging. This is lower than the NH_2 wagging in TAM[19,20] at 709 cm^{-1} but higher than that in NMU[14] at 531 cm^{-1} and in urea[26] at 555 cm^{-1}.

The potential energy distributions show the NH bending (thioamide V band) to be highly mixed with

CN torsion, contributing to the bands at 557 and 185 cm^{-1}. A similar coupling of NH bending with CN torsion has been noted for diacetamide.[27] The band at 400 cm^{-1} of NMTU is attributed to the C=S out of plane bending (thioamide VI band). The CH_3 torsion is associated with a band at 135 cm^{-1} which is lower than that in NMU[14] at 166 cm^{-1}.

Internal Rotation. The potential barriers for the internal rotation about the C–N bonds, V_{NH_2} and V_{CH_3}, of the $-CSNH_2$ and the $-NHCH_3$ groups, respectively, can be approximated from the values of the respective torsional force constants. Using the treatment employed for NMU[14] and acetamide,[25] the barrier heights can be calculated from the relation

$$V_{NH_2} = 2f(\tau NH_2) = 30.7 \text{ kcal mol}^{-1}$$

and

$$V_{CH_3} = 3/4f(\tau CH_3) = 0.6 \text{ kcal mol}^{-1}.$$

The values of V_{NH_2} and V_{CH_3} are comparable with those of NMU[14] (31.3 and 1.7 kcal mol^{-1}, respectively). Similarly the barrier to the internal rotation about the CN bond of the –CSNH– group is given by

$$V_{CN} = 2f(\tau CN) - \Delta V/4 = 26.0 \text{ kcal mol}^{-1},$$

where ΔV is the energy difference between the *cis*- and *trans*-isomers of NMTU estimated to be 9.0 to 12.0 kcal mol^{-1} by the NMR method.[19] By taking ΔV as 9.0 kcal mol^{-1}, the value obtained for V_{CN} of NMTU is comparable with that of NMU[12] and *N*-methylformamide[28] (25.6 and 28.0 kcal mol^{-1}, respectively).

(Received August 7, 1978)

An alternative method for solving the Rose-Drago equation for the determination of equilibrium constants of molecular complexes has been developed. It yields well-defined K values even for certain systems in which the Rose-Drago procedure for solving the R-D equation is not satisfactory. Our method is based on the transformation of the Rose-Drago equation into one involving three variables and using two linear plots. In applying the method to a wide variety of experimental data, the calculated values of the equilibrium constant have been found to be in excellent agreement with those computed by the well-known iterative procedure. With good data, the calculated values are in good agreement with those from the Benesi-Hildebrand or some other modified plots.

Molecular addition compounds formed by the interaction of electron donors and acceptors are generally characterized by intense electronic absorption attributable to neither component of the addition compound, but to a new molecular species, the compound—usually referred to as the molecular complex — itself. The interpretation of the occurrence of these absorption bands by Mulliken[1] in the light of his charge-transfer theory is now widely accepted. After the formulation of this theory, numerous workers were interested in determining the composition and stability of these complexes. Benesi and Hildebrand[2] formulated a spectrophotometric method and many investigators used it or some modification of it[3,4] to determine the equilibrium constants. Certain limitations of the Benesi-Hildebrand (B-H) method[5] became evident and new equations were derived. Of these, the most noteworthy one is the Rose-Drago equation,[6] which is perfectly general. This equation (Eq. 1; see next section) contains two unknowns, K and ε_c; they are, respectively, the equilibrium constant and the molar absorptivity of the complex. An analytical solution for ε_c could be derived by constructing two simultaneous equations, each representing different experimental trials. Alternatively Rose and Drago[6] developed a graphical procedure for solving their general equation. This consisted of random selection of ε_c values and calculation of K^{-1} from one set of experimental data, namely with one particular value of initial concentration of donor and acceptor, plotting K^{-1} as a function of ε_c, repetition of this procedure with other sets, and finally evaluating K^{-1} and ε_c values from the common point of intersection. But selection of a series of ε_c values at random for each set of experimental data renders this graphical method laborious and sometimes very difficult to employ. In addition, in many cases the Rose-Drago plot shows a wide scatter in the values of K and ε_c.[7]

In the present article, we report an alternative graphical method, based on the consideration of two linear plots, for solving the Rose-Drago equation. This procedure is straightforward, more convenient to use, and can be employed without any loss of generality of the equation.

Principle and Method

Drago and Rose[7] derived Eq. 1 relating K^{-1} and ε_c as

$$K^{-1} = \frac{C_D^\circ C_A^\circ(\varepsilon_c-\varepsilon_A)}{d-d_A^\circ} - C_D^\circ - C_A^\circ + \frac{d-d_A^\circ}{\varepsilon_c-\varepsilon_A}, \quad (1)$$

where C_D° and C_A° are the initial concentrations of the donor and acceptor respectively, ε_A is the molar absorptivity of the acceptor, d_A° is the absorbance of the initial concentration of the acceptor, and d corresponds to the total absorbance at any given wavelength for a cell of 1 cm path length.

Now, Eq. 1 can be written in the form:

$$y = L + Mx - M^2z, \quad (2)$$

where

$$y = \frac{C_A^\circ C_D^\circ}{d-d_A^\circ}, \quad x = C_A^\circ + C_D^\circ, \quad z = d - d_A^\circ,$$
$$L = K^{-1}/(\varepsilon_c-\varepsilon_A),$$

and

$$M = 1/(\varepsilon_c-\varepsilon_A).$$

Now, from definitions, it can be easily shown that z is a linear function of C_c, the equilibrium concentration of the complex, and at the lower range of donor concentration[8] or within the close range of donor concentration it is a reasonably good approximation to assume that C_c is a linear function of x in the range. Thus, to the first approximation, we can substitute $z=mx+n$ in Eq. 2, yielding

$$y = (L-M^2n) + (M-M^2m)x. \quad (3)$$

Equation 3 gives a linear plot of y *versus* x with slope,

$$S = M - M^2m, \quad (4)$$

and intercept,

$$I = L - M^2n, \quad (5)$$

where m and n can be obtained from the slope and intercept of z *vs.* x plot.

Now, from Eq. 4,

$$M = \frac{1\pm\sqrt{1-4mS}}{2m}. \quad (6)$$

The root $(1+\sqrt{1-4mS})/2m$ is discarded because its value differs widely from that given by the approximate equation $y=L+Mx$, and also because it yields inadmis-

† A preliminary account of this work was presented at the 26th Congress of the IUPAC held in September, 1977.

sible values of ε_c. Substituting the value of M from Eq. 6 into Eq. 5, we get L, and finally $K=M/L$ and $\varepsilon_c=M^{-1}+\varepsilon_A$.

Results and Discussion

The Rose-Drago curve for the naphthalene–picric acid system, constructed from the data by Foster,[9] is shown in Fig. 1. As can be seen from the figure, well-defined values of K and ε_c are not obtainable from the plot. We also observed similar scatter in the Rose-Drago curve for the systems pyridine–iodine and 2-methylpyridine–iodine from the data of Nagchandhuri and Basu.[10]

Using our graphical procedure, we have calculated the equilibrium constant and molar absorptivity values of a large number of a wide variety of molecular complexes, using the experimental data of different investigators for different systems, such as the iodine complexes of polycyclic aromatic hydrocarbons[11] and aza-aromatics,[10] complexes of tetrachlorophthalic anhydride (TCPA) with aza-aromatics,[12] the naphthalene–picric acid complex,[9] and the chloranil–indole complex.[13] A representative linear plot of z *vs.* x and of y *vs.* x for the systems naphthalene–picric acid, iodine–pyridine, and TCPA–quinoline are shown in Figs. 2 and 3 respectively. In all other cases examined by us reasonably good linearity was obtained in these two plots. The calculated values of K and ε_c of various systems are presented in Table 1, which also contains, for comparison, the values of these quantities obtained by various authors by applying either the Benesi-Hildebrand or some other modified plot. We have also computed the values of K and ε_c of these systems with the help of the iterative technique as followed by Arnaud and Bonnier.[14] The iteratively computed values of K, computed by the IBM 1130 computer, are also presented in Table 1. In almost all the cases we examined, the values of K obtained by our procedure are in very good agreement with those obtained by the iterative procedure. Except in the case of TCPA–aza-aromatic systems we failed to obtain a reasonably good common point of intersection by the Rose-Drago procedure for the systems under consideration. In the case of the pyrene–iodine complex a K-value of 43 l mol^{-1} with a standard deviation of ± 7 was obtained by Drago and Rose[7] by applying their own procedure. Calculation by our method yields $K=42.9$ l mol^{-1}. For the biphenyl–iodine complex the Rose-Drago procedure yields $K=0.39\pm0.15$, whereas the reported value is 0.37;[11] our method gives $K=0.28$. For the naphthalene–

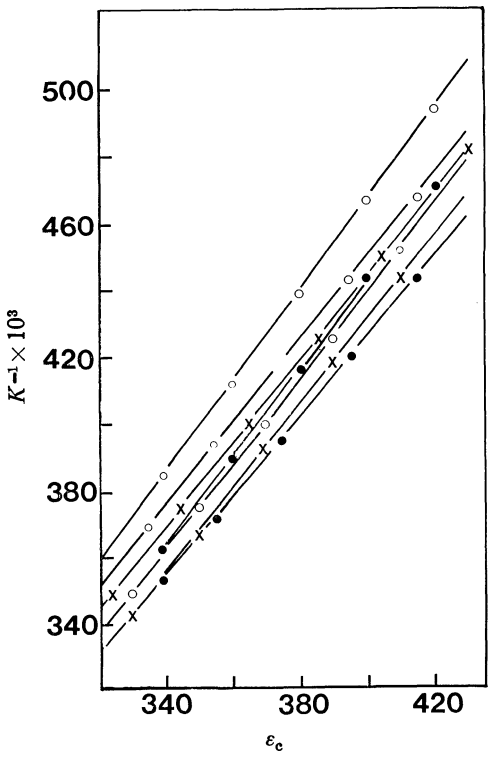

Fig. 1. Rose-Drago plot for the picric acid–naphthalene system. The different lines correspond to the different experimental trials, each a definite value of C_A° and C_D°.

Table 1. Equilibrium constants and molar extinction coefficients (ε_c) of various molecular complexes

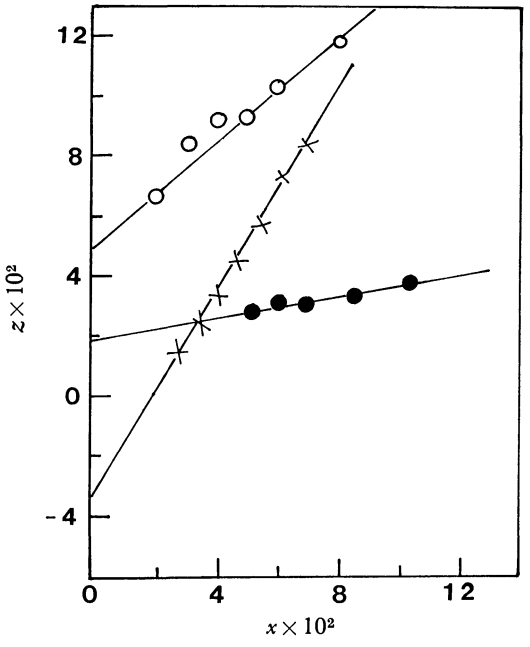

Fig. 2. z *vs.* x plot for the system TCPA–quinoline (●), picric acid–naphthalene (×), and iodine–pyridine (○).

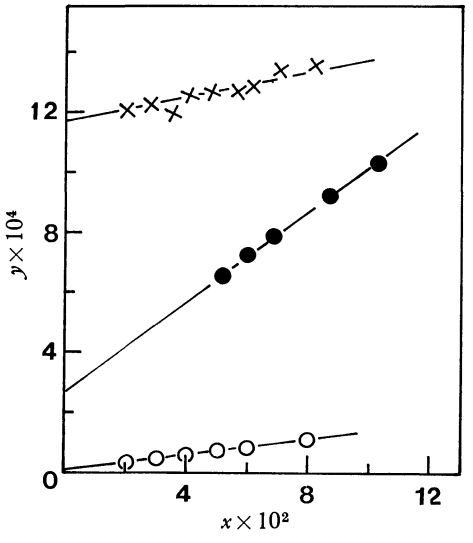

Fig. 3. y *vs.* x plot for the system TCPA–quinoline (●), picric acid–naphthalene (×), and iodine–pyridine (○).

iodine complex the recalculated K by our method is 0.21 which is close to the value, 0.25, quoted by Drago.[7] The K value of 0.62 for this system, obtained by Bhattacharya and Basu[11] from the Benesi-Hildebrand plot, is considerably higher. For the iodine–anthracene system the Rose-Drago equation, solved by our method, yields a much lower value of K than that obtained by Bhattacharya and Basu.[11] This might be due to some specific assumptions in deriving the Benesi-Hildebrand equation rendering it unsuitable for general application.[15]

Drago and Rose[7] felt that a recalculation with many reported data was necessary for yielding meaningful thermodynamic quantities from spectrophotometric investigations. These calculations can be carried out by our procedure for solving the Rose-Drago equation more easily and effectively than by their own graphical procedure.

From the excellent agreement of computed results between our procedure and the iterative procedure, it is apparent that our one-step approximation of linearity between C_c and x is somehow almost equivalent to successive approximations in the process of iteration.

The time and service made available by the Computer Center of the University of Calcutta are gratefully acknowledged. Sincere thanks are also due to Prof. S. K. Siddhanta, Head of the Department of Chemistry, Birdwan University, for constant encouragement during the progress of the work.

Pre-exponential Factor in Semiconducting Vitamin A (Alcohol and Acetate)

Biswanath MALLIK, Alpana GHOSH, and T. N. MISRA*

Optics Department, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India

(Received August 30, 1978)

The semiconductive properties of vitamin A (alcohol and acetate) on adsorption of various vapors have been studied. The adsorbed vapors increase the semiconduction currents by several orders of magnitude and decrease the semiconduction activation energies. Such change depends on the chemical nature and also on the amount of vapor adsorbed. Semiconducting vitamin A follows the three-constant equation

$$\sigma(T) = \sigma_0' \exp(E/2kT_0) \exp(-E/2kT)$$

where the conventional pre-exponential factor σ_0 has been replaced by $\sigma_0' \exp(E/2kT_0)$ (the so called compensation effect). Here T_0 and σ_0' are constants for the substance and T_0 is called the characteristic temperature. Various methods used for evaluating these constants have yielded consistent results with $T_0 \approx 402$ K and $\sigma_0' \approx 2.8 \times 10^{-9}\ \Omega^{-1}\ \mathrm{cm}^{-1}$ for vitamin A alcohol and $T_0 \approx 335$ K and $\sigma_0' \approx 1.5 \times 10^{-10}\ \Omega^{-1}\ \mathrm{cm}^{-1}$ for vitamin A acetate. Excellent correlation obtained between the relevant parameters in semiconducting vitamin A indicates that σ_0 and E are physically related. Various models for conduction mechanism leading to compensation effect have been discussed. The measured activation energies on adsorption of same amount of various vapors show a linear relationship with the ionization potential of the adsorbed molecules suggesting that charge-transfer interaction is responsible for the semiconductivity enhancement.

The electrical conductivity of conjugated π-electronic organic compounds follows the operational definition of a semiconductor

$$\sigma(T) = \sigma_0 \exp(-E/2kT) \quad (1)$$

where $\sigma(T)$ is the specific conductivity at any absolute temperature T, σ_0 is a pre-exponential factor, E the semiconduction activation energy and k is Boltzmann constant ($E/2$ is often written as E', however, we shall use the former throughout this paper). Experimentally, E is obtained from the slope of the linear plot of $\log \sigma(T)$ *vs.* $1/T$. Recently, the so called pre-exponential factor σ_0 has been the subject of much discussion[1-6] as experimental evidence accumulated shows that σ_0 contain exponential functions. Gutmann and Lyons[7] showed a linear relationship of the form

$$\log \sigma_0 = \alpha E + \beta \quad (2)$$

holds good for one entire class of organic compounds, α and β being constants. Rosenberg[2,8] *et al.* showed evidence that if E is varied by hydration or complex formation relation (2) is valid for a single organic substance as well and they suggested an expression for the specific conductivity of the form

$$\sigma(T) = \sigma_0' \exp(E/2kT_0) \exp(-E/2kT) \quad (3)$$

thus introducing an additional constant T_0, called characteristic temperature. σ_0' and T_0 for the same compound remain invariant. The linear relationship between the logarithm of the pre-exponential factor and the activation energy is called the compensation effect. σ and E change in such a manner that their effect on σ_0 are mutually compensated. It has been pointed out by Johnston and Lyons[4] that the linear relationship between $\log \sigma_0$ and E may originate solely from the calculation of these parameters and the compensation effect requires no physical interpretation. However, they have suggested that if σ_0 and E are physically related, one should get a linear relationship between $\log \sigma$ and E yielding the semiconductive parameters in agreement with the values obtained from other sources. From Eq. 3, for any particular temperature T_1, the specific conductivity is given by

$$\log \sigma(T_1) = \log \sigma_0' + \left(\frac{1}{T_0} - \frac{1}{T_1}\right)\frac{E}{2k}.$$

Thus, the plot of $\log \sigma(T_1)$ *vs.* E is expected to be linear with a slope $(1/T_0 - 1/T_1)/2k$ and an intercept of $\log \sigma_0'$. The value of σ_0' obtained from this plot should also show a good agreement with the values obtained from the $\log \sigma_0$ *vs.* E and $\log \sigma$ *vs.* $1/T$ plots. In the experiment of Johnston and Lyons[4] the $\log \sigma_0$ *vs.* E plots were linear, but a very poor correlation between $\log \sigma$ and E was observed[4] in one component crystal of anthracene by changing its purity and doping with tetracene. Some recent theoretical works[9,10] suggest that in biological semiconductors the compensation effect arises due to the dark conduction process. In view of the scanty experimental works available on this effect, it was thought worthwhile to investigate the conduction process in more biological semiconductors. To test the validity of the compensation effect, E is generally varied by various ways and $\log \sigma_0$ is plotted against E. The adsorption of gases is known[8,11] to change the activation energies of organic semiconductors. Recently, being motivated to examine the hypothesis that vitamin A is involved in olfactory transduction mechanism,[12] we have studied the effect of adsorption of gases on solid vitamin A. Such adsorption changes the activation energy and enhances the conductivity. In this paper we present experimental evidence to indicate that the compensation rule is valid for solid vitamin A and that σ_0 and E are indeed physically related. Further, the formation of donor-acceptor complex between vitamin A and the adsorbed gas molecule is shown to be responsible for the observed activation energy change.

Experimental

High purity vitamin A alcohol and vitamin A acetate were obtained from Hoffmann-La Roche and Co., Ltd., Switzerland. These were used without any further purification. Sandwich cell technique with a conducting glass and/a

stainless steel electrode was used. There was a gas inlet and an outlet in the conductivity chamber, made of brass and fashioned with Teflon, for gas adsorption study. The temperature of the sandwich cell could be controlled from outside. Temperature measurements were made using a copper-constantan thermocouple attached at the top of the metal electrode. The semiconduction currents were measured with an electrometer amplifier EA815 of the Electronic Corporation of India Ltd. Vapors of methanol, ethanol, heptane, ethyl acetate, benzene, and toluene were allowed to be adsorbed on the semiconductors. The reagent chemicals of spectrograde (E. Merck, B. D. H.) quality were used without further purification; otherwise repeated fractional distillation was done before use. To pass various vapors inside the chamber, dry nitrogen gas was used as carrier which was passed through a bubbler containing the reagent chemical. The partial pressure of the reagent vapor in the conductivity chamber was kept constant during adsorption at a pressure less than the saturation vapor pressure at the sample cell temperature by carefully adjusting the temperature of the bubbler. The partial pressure of the vapor was the saturation vapor pressure of the reagent chemical at the temperature of the bubbler. The same partial pressure (40 mm) was maintained inside the chamber for various vapors. Under this condition it is a valid assumption that the same amount of various vapors are adsorbed on the semiconductors. Repeated heating and cooling of the sample initially in vacuum and finally in dry nitrogen atmosphere ensured desorption of water vapor or any other adsorbed gases. Temperature (12.5 °C) of the sample cells and the inlet flow were kept constant during adsorption.

To determine the effect of adsorbed vapor on the semiconduction activation energy, the sample was allowed to come to a steady state in the chamber atmosphere containing the vapor with nitrogen. The pressure of the total gas mixture in the chamber was atmospheric pressure. The saturation current, after vapor adsorption was found to be almost constant even after four hours indicating that the conduction in the system is mainly electronic.[13,14] The sample cell was then rapidly cooled to about −40 °C and then the chamber was flushed gently with dry nitrogen gas. Semiconduction current was measured with increasing temperature of the sample cell. The outlet of the chamber was kept open to maintain atmospheric pressure inside the chamber.

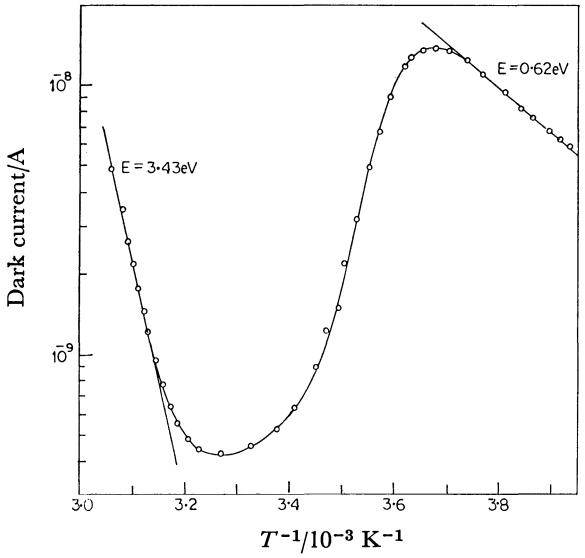

Fig. 1. Semiconductivity in a vitamin A acetate powder cell with desorption of ethyl acetate vapor as the temperature increases.

Results and Discussion

The semiconduction activation energy of crystalline powders of vitamin A (alcohol and acetate) has been measured several times in dry nitrogen atmosphere. The observed values are 2.06 and 3.50 eV (approx.) for the alcohol and acetate respectively. The adsorption of gases enhances the semiconduction current (by several orders of magnitude in some cases) and decreases the activation energy appreciably. The results of one such typical experiment is shown in Fig. 1. The straight line portion in the low temperature region shows the semiconducting properties of vitamin A acetate powder with adsorbed ethyl acetate vapor and the slope of this line gives the activation energy (0.62 eV) of this semiconducting system. The straight line portion in the high temperature region gives the activation energy of vitamin A acetate in nitrogen atmosphere. The observed value (3.43 eV) is slightly lower possibly due to incomplete desorption of adsorbed vapors. The intermediate portion shows the semiconduction behavior

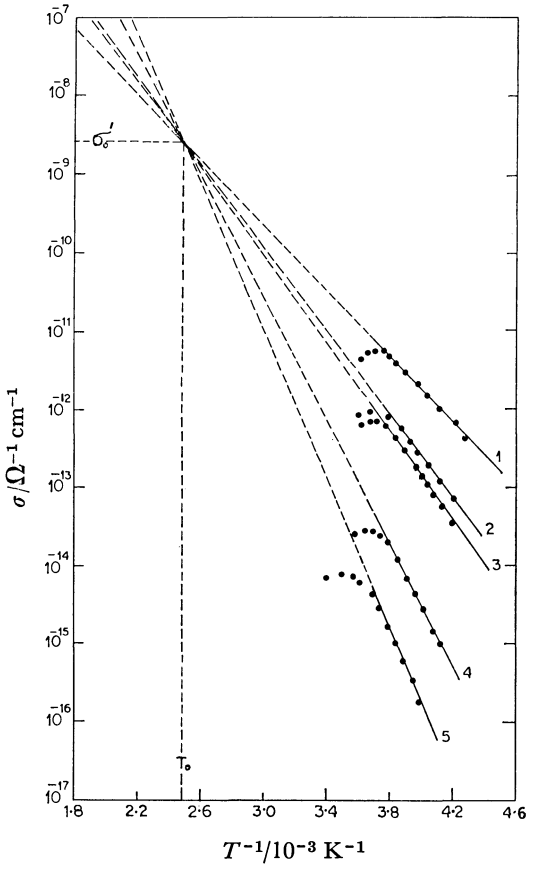

Fig. 2(a). Semiconductivity in vitamin A alcohol powder cell (steady state condition) with the adsorption of same amount of different vapors. Solid lines represent temperature region of measurements, dashed lines are extrapolations. Each line refers to a specific vapor adsorbed state. Vapors are (1) toluene; (2) ethyl acetate; (3) heptane; (4) ethanol; and (5) methanol. To avoid overlapping with (2) the line corresponding to benzene vapor is not shown. The value of $T_0 \approx 402$ K; $\sigma_0' = 2.65 \times 10^{-9}$ Ω^{-1} cm^{-1}.

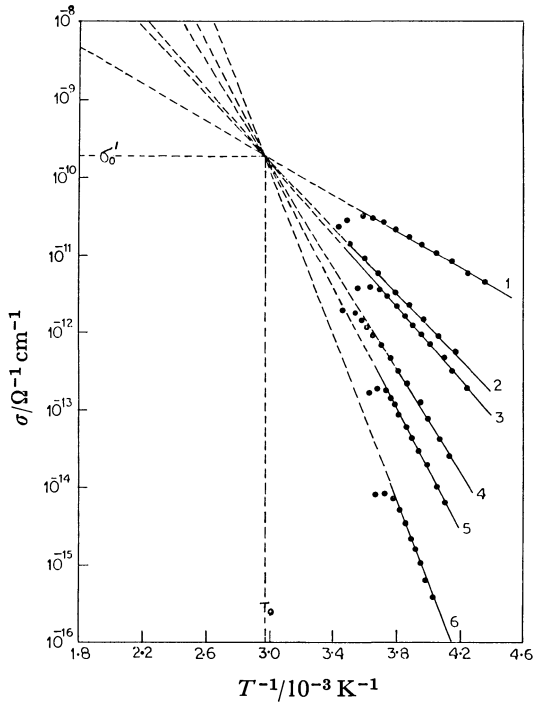

Fig. 2(b). Same as Fig. 2(a) for vitamin A acetate with adsorbed vapors (1) toluene; (2) benzene; (3) ethyl acetate; (4) heptane; (5) ethanol; and (6) methanol. $T_0 \approx 335$ K; $\sigma_0' = 1.8 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$.

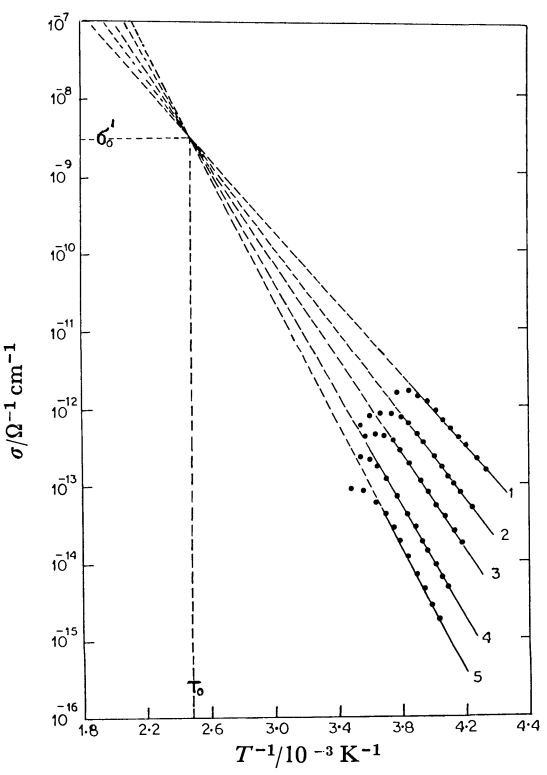

Fig. 3(a). Semiconductivity data for vitamin A alcohol powder cell (steady state condition) with adsorption of different amount of ethyl-acetate vapor. The lines (1) $\rightarrow$(5) refer to the states with the decreasing amount of adsorbed vapor. $T_0 \approx 403$ K; $\sigma_0' = 3.1 \times 10^{-9}\ \Omega^{-1}\ cm^{-1}$.

of the sandwich cell during desorption process. Similar curves were also obtained with other vapors.

The Characteristic Temperature for the Semiconducting Vitamin A. In Figs. 2(a) and 2(b) we show the straight portion in the low temperature region for a number of adsorbed vapors in vitamin A alcohol and acetate respectively. It is observed that with the same amount of vapor adsorbed, the activation energy values are different for different vapors. In this case no single value of σ_0 is found if either $T \rightarrow \infty$ or $E \rightarrow 0$ as is expected from Eq. 1. The extrapolated lines intercept the ordinate at a wide varieties of positions, but they all pass approximately through a single point at a temperature T_0, characteristic of the semiconductor. This is exactly what is expected from Eq. 3. Figs. 2(a) and 2(b) show $T_0 \approx 402$ K for vitamin A alcohol and $T_0 \approx 335$ K for vitamin A acetate. At these characteristic temperatures $\sigma(T_0) = \sigma_0'$ values of vitamin A alcohol and acetate are 2.65×10^{-9} and $1.8 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$ respectively. Adsorption of different amount of same vapor also changes the semiconduction activation energy to different extent. The plots of $\log \sigma(T)$ *vs.* $1/T$ for different amount of ethyl acetate vapor adsorbed on vitamin A alcohol and acetate semiconductors are shown in Figs. 3(a) and 3(b). These two sets also give values of T'_0's and σ'_0's [403 and 334 K and 3.1×10^{-9} and $1.65 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$ for vitamin A alcohol and acetate respectively] in good agreement with those obtained earlier.

If plotted in alternate fashion as $\log \sigma_0$ *vs.* E, the plots are linear as expected [since $\log \sigma_0 = E/(2kT_0) + \log \sigma_0'$] and are shown in Fig. 4. The value of T_0 obtained from the slopes are 404 and 333 K for vitamin A alcohol and

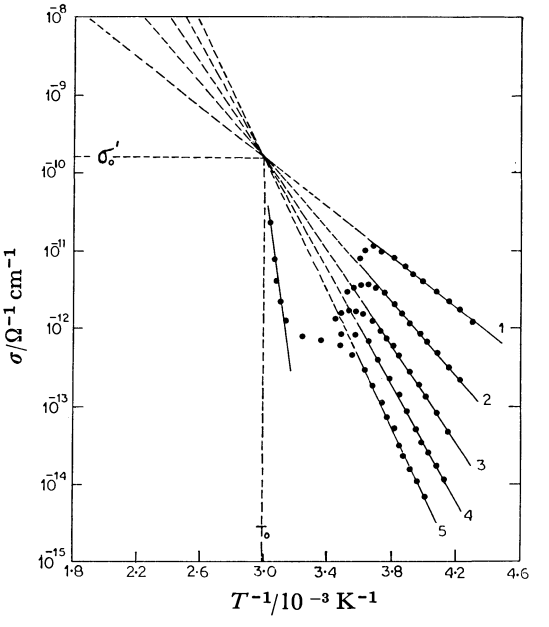

Fig. 3(b). Same as Fig. 3(a) for vitamin A acetate. Here, $T_0 \approx 334$ K; $\sigma_0' = 1.65 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$.

acetate respectively. The σ_0' values obtained from the intercepts of these plots are 2.8×10^{-9} and 1.5×10^{-10} $\Omega^{-1}\ cm^{-1}$ for vitamin A alcohol and acetate respectively. Thus the values of T_0 and σ_0' obtained from various plots are consistent and show excellent agreement.

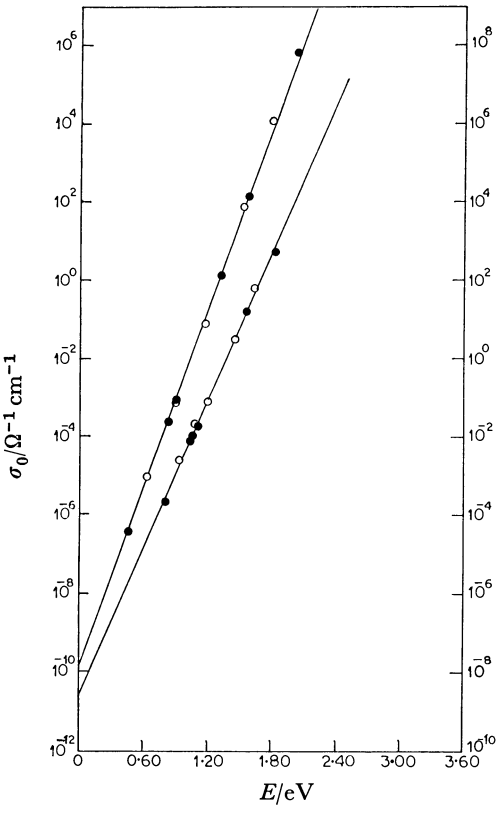

Fig. 4. Plot of the log σ_0 values [from Eq. 1] *vs.* the activation energies for vitamin A (alcohol and acetate) at a constant temperature [$1/T=3.8\times10^{-3}$ K^{-1}] The lower line is for vitamin A alcohol (right scale) and the top line is for vitamin A acetate (left scale). The dark circles refer to different vapors and the open circles to different amounts of same vapor. Slopes and σ_0' values are 14.45 eV^{-1} and 2.8×10^{-9} Ω^{-1} cm^{-1} for vitamin A alcohol and 17.52 eV^{-1} and 1.5×10^{-10} Ω^{-1} cm^{-1} for vitamin A acetate respectively.

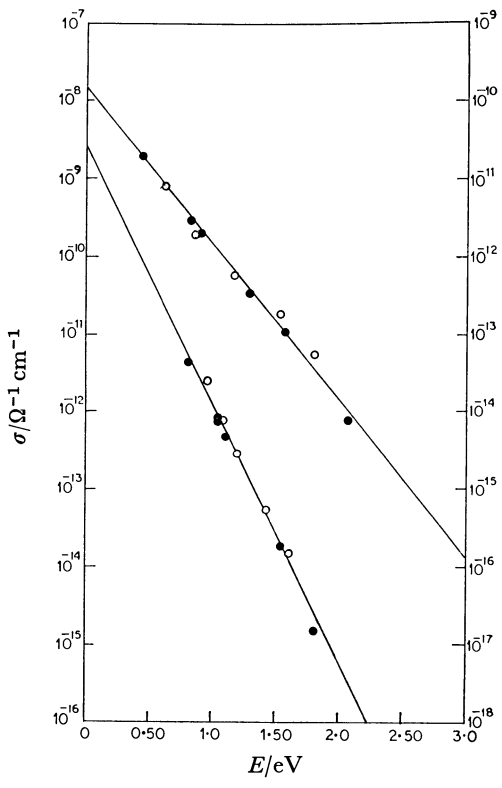

Fig. 5. Plot of the log σ values for vitamin A (alcohol and acetate) *vs.* E at a constant temperature ($1/T_1=3.8\times10^{-3}$ K^{-1}). The lower line refers to vitamin A alcohol (left scale) and the top line to vitamin A acetate (right scale). The dark circles refer to different vapors and the open circles to different amounts of same vapor. Slopes and σ_0' values are 7.70 eV^{-1} and 2.85×10^{-9} Ω^{-1} cm^{-1} for vitamin A alcohol; 4.55 eV^{-1} and 1.6×10^{-10} Ω^{-1} cm^{-1} for vitamin A acetate respectively.

Using the values of $1/2kT_0\approx14.45$ eV^{-1} and $\sigma_0'=2.8\times10^{-9}$ Ω^{-1} cm^{-1} for vitamin A alcohol, $1/2kT_0=17.52$ eV^{-1} and $\sigma_0'=1.5\times10^{-10}$ Ω^{-1} cm^{-1} for vitamin A acetate, we calculate the expected σ_0 values and compare these with experimentally measured values as obtained from the intercepts of the log σ *vs.* $1/T$ plots. These are shown in Tables 1 and 2. These data confirm the validity of Eq. 3 for vitamin A semiconductor.

The plots of log σ (T_1) *vs.* E are shown in Fig. 5 for $1/T_1\approx3.8\times10^{-3}$ K^{-1}. Taking $1/(2kT_0)\approx14.45$ and 17.52 eV^{-1} from Fig. 4, the expected slopes are 7.73 and 4.66 eV^{-1} for vitamin A alcohol and acetate respectively. The observed slopes in Fig. 5 are 7.70 and

5	1.62	4.11×10^{1}	3.0×10^{1}	5	1.80	7.43×10^{3}	1.2×10^{3}

Curve No. 1→5 corresponds to the decreasing amount of adsorbed ethyl acetate vapor.

4.55 eV^{-1} for these two compounds respectively. The agreement is excellent. Also the intercepts give $\sigma_0' \approx 2.85\times10^{-9}\ \Omega^{-1}\ cm^{-1}$ for vitamin A alcohol and $\sigma_0' \approx 1.6\times10^{-10}\ \Omega^{-1}\ cm^{-1}$ for vitamin A acetate. These values agree well with the values obtained from the log σ_0 *vs.* E and log σ *vs.* $1/T$ plots. Thus the high correlation between the relevant parameters in semiconducting vitamin A powder on adsorption of various vapors indicates that Compensation rule is valid in these biological semiconductors and that σ_0 and E are indeed physically related.

Type of Interaction between the Adsorbed Gas and the Semiconducting Material. It needs to be pointed out that the reason for the semiconduction activation energy change is not quite settled.[8,11] However, donor-acceptor complex formation has been widely held responsible for the increase of current in some semiconductors[15-17] due to gas adsorption. As the vapors used in this present investigation are good electron donors and polyenes are known to act both as electron donor and electron acceptor,[18,19] formation of charge-transfer complexes of vitamin A (alcohol and acetate) with the adsorbed vapors may be possible. It had generally been observed[20,21] that in solid charge-transfer complexes with a particular acceptor and a number of similar type of donors, the semiconduction activation energy as obtained from relation (1) and the energy ($h\nu_{CT}$) of the lowest charge-transfer band are linearly related by the expression

$$E = h\nu_{CT} - \delta = I_D - E_A + C_1 - \delta \quad (4)$$

where, I_D is the vertical ionization potential of the donor, E_A is the vertical electron affinity of the acceptor, C_1 is a constant[22] and δ is also another constant of very low value.[20] In Fig. 6, we show a plot of E *vs.* I_D. A linear relationship is obtained as expected from Eq. 4. The slope of the line (0.6) however, is much less than unity. Such a value for the slope is a rather general observation[23,24] in $h\nu_{CT}$ *vs.* I_D plots. The intercept of this plot is −3.8 eV. The value of $-C_1$ is usually[22,25] around 3 eV. The electron affinity of anhydro vitamin A which is expected to be close to that of vitamin A (alcohol and acetate) has been reported to be[26] 0.7 eV. This gives a value of 0.1 eV for δ which is a very reasonable value.[21,23] This adds further credence to the proposed charge-transfer concept.

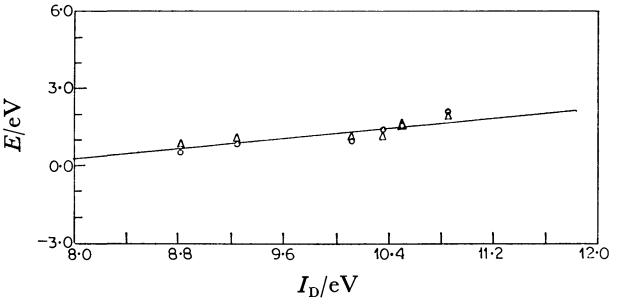

Fig. 6. Semiconductive activation energy (E) *vs.* ionization potential (I_D) of the adsorbed vapor molecules.

—○—: Vitamin A acetate.

There are number of theses about the mechanism of conduction in organic semiconductors leading to compensation effect. The carrier injection model of Green[27] produces the type of activation energy dependence of the pre-exponential factor as observed experimentally, but does not provide any physical basis for the interpretation of T_0. Significant difference in T_0 values for these two compounds suggests that T_0 is a molecular characteristic of these organic semiconductors. Kemeny and Rosenberg[28] observed compensation law in tunneling of small polaron through molecular barrier from thermally activated energy levels of molecules. Their model predicts that $T_0=\theta/2$ (where θ is the Debye temperature) and that at $T>T_0$, small polaron tunneling is not possible and compensation effect is not expected to be observed. No experimental study seems to have been reported on the semiconductive behavior of organic compounds at $T>T_0$. Debye temperature for vitamin A alcohol and acetate are not known. It has been reported[29] that the Debye temperature for a series of crystals of large aromatic molecules lie in the range 100—130 K. It seems that the T_0 values measured are far too high to justify the polaron tunneling model.

An interaction between the electrons and the vibrational motion has been thought[9,10] to be the mechanism behind compensation effect. A change in the electronic state (due to complex formation) gives rise to an activation entropy because of a change in vibrational frequencies. The variation in both the electronic energy gap

(E_g) and the activation entropy (S) can account for compensation effect if the changes in these parameters are given by

$$E_g = E_{g_0} + nE_{g_1} \text{ and } S = S_0 + nS_1$$

where n is a definite number for each system and E_{g_0}, E_{g_1}, S_0 and S_1 are same for all the systems. In this case the characteristic temperature is given by

$$T_0 = E_{g_1}/(2S_1).$$

Unfortunately due to the fact that the nature of the activated complex is not precisely known, the activation entropy S (hence S_1) is a relatively obscure quantity and any quantitative estimate of T_0 is not possible.

We thank the Council of Scientific and Industrial Research, India for a Senior Research Fellowship (to B. M.) and Prof. G. S. Kastha for his kind interest in this problem. Thanks are also due to M/s Hoffmann-La Roche and Co., Switzerland for a kind gift of the polyenes.

Diffusion Thermoeffect in Gases (The Dufour Effect)

Ali BOUSHEHRI* and A. ABBASPOUR
Department of Chemistry, Shiraz University, Shiraz, Iran

(Received July 24, 1978)

A study of the Dufour effect was made for four different gas mixtures: SF_6–N_2O, SF_6–N_2, SF_6–CO_2, and He–CO_2. Measurements were made at 300 K under 700 Torr. The values of the thermal diffusion factor were calculated for the above mixtures from experimental data on the basis of the thermodynamics of irreversible processes. A theoretical study was made also to calculate the thermal diffusion factor from kinetic theory.

The diffusion thermoeffect arises when a concentration gradient exists in a gas mixture. This gradient leads to a transient nonuniform temperature. Therefore, this effect is related to thermal diffusion, where a concentration gradient arises as a result of an initial temperature gradient. The thermal diffusion factor can be obtained from the diffusion thermoeffect which is a supplement to the more usual methods of measuring thermal diffusion factors.[1]

The Dufour effect[2] was not extensively investigated until after its rediscovery by Waldmann in 1942.[3] Although the possibility of this effect is contained in the Chapmann-Enskog theory[4] of non-uniform gases, only recently have its experimental measurements been made. For the measurement of the temperature gradient (which is a result of an initial concentration gradient) an apparatus similar to that used by Boushehri and Afrashtehfar[5] was constructed for the work discussed here. Apart from Rastogi and Madan's work,[6] and the classic studies of Waldmann, very little work in this area has been done. Mason *et al.*[7] made a study of the pressure dependence of this effect and, more recently, Sawford *et al.*[8] and Boushehri[5,9] have published more measurements. There is obviously a need for further independent studies, both to verify and to extend these few experimental studies.

Suppose two gases (labelled with subscripts 1 and 2), initially at the same temperature, diffuse into each other. On the basis of irreversible thermodynamics,[5,10] it may be shown that

$$\frac{\rho_1 RTD_{12}\alpha}{C_1\{M_1-C_1(M_1-M_2)\}}\frac{\Delta C_1}{\Delta X}+\lambda\frac{\Delta T}{\Delta X}=K, \qquad (1)$$

where ρ_1 and C_1 are the mass density and mass franction of component 1, respectively; α is the thermal diffusion factor; λ and D_{12} are heat conductivity and diffusivity coefficients, respectively; M_1 and M_2 are the molar weights; ΔX is the distance between thermocouples; and ΔT is the maximum temperature difference. K is a constant which depends on the geometry of the cell (in particular, the position of thermocouples); K has to be experimentally determined from experimental data. It is possible to leave $K=0$ as Rastogi and Madan[6] did, but this would not be the most general case.

Thermal diffusion factors have been estimated from the experimental data. Calculations for the first approximation to the thermal diffusion factor in binary mixtures was done on an IBM 370 model 135 computer for all four systems to check the values of the thermal diffusion factors deduced from Dufour effect against the values predicted by the Chapmann-Enskog kinetic theory. The experimental value for the thermal diffusion factor is comparable with its theoretical value for equimolar mixtures.

Experimental

The apparatus employed was similar to that used by Boushehri and Afrashtehfar.[5] The apparatus consisted of two double-walled glass bulbs (1, 2) of capacity 50-ml each. The two half-cells were connected by a narrow tube via stopcock having a bore of 8 mm diameter. A three junction thermocouple and a Leeds and Northrup potentiometer (± 1 μV) was used by which ΔT could be estimated to ± 0.01 °C. The thermocouples were parallel to the diffusion interface. The distance between two thermocouples was equal to 18.5 cm. The apparatus was kept in an oil bath. The temperature of bath was controlled to ± 0.1 °C. The apparatus was kept in a thermostat for two hours to insure thermal equilibrium. The annular space between the double walls of the bulbs was then evacuated to minimize heat dissipation. The apparatus was allowed to remain for further two hours to insure constancy of temperature. When the stopcock connecting the two half-cells was opened, diffusion of the gases caused a temperature gradient. This was measured as indicated above.

SF_6, N_2, and CO_2 were supplied by the Matheson Co. He and N_2O were supplied by the Fluka Co. The gases were used without further purification, since the results were not expected to be sensitive to small impurities. The purity was at least 99.9%.

Results and Discussion

The mixtures studied were: SF_6–N_2O, SF_6–N_2, SF_6–CO_2 for which the Dufour effect has not been measured previously. A CO_2–He mixture was used to determine the apparatus constant. Thermo-emf was measured using a three junction thermocouple in conjunction with the potentiometer. The temperature of the half-cell containing the lighter component always rose. The values of maximum temperature $(\Delta T)_{max}$ are given in Table 1. No measurement of $(\Delta T)_{max}$ other than for pure gases were made.

The diffusion thermoeffect is of interest in its own right and because it enables us to obtain quantitative information of the other transport coefficients, especially the thermal diffusion factor. An explicit derivation of the thermal diffusion factor on the basis of irreversible thermodynamics is given in Ref. 5. All measurements were made at 300 K and 700 Torr.

From irreversible thermodynamics the relationship between the temperature gradient and concentration gradient is shown by Eq. 1, where K is an apparatus

Table 1. Dufour effect in gaseous systems at 300 K and 700 Torr

System	$(\Delta T)_{max}$ in K($\pm$0.01)	Warm side
$He+CO_2$	0.11	He
N_2+SF_6	0.12	N_2
N_2O+SF_6	0.16	N_2O
CO_2+SF_6	0.18	CO_2

Table 2. Comparison of the values of α for different systems

System	α, from Eq. 1	α, from thermal diffusion measurement	α, from Equation (8.2—50) of Ref. 12
$He+CO_2$	0.42	0.45[a)]	0.398
N_2+SF_6	0.13	—	0.192
N_2O+SF_6	0.12	—	0.073
CO_2+SF_6	0.12	—	0.075

a) The value of α was obtained using Table 2 of Boushehri.[9)]

constant which depends on the position of thermocouples and the geometry of the cell. It may be possible to get an expression for this constant by studying variation of ΔT with both position of thermocouples and the geometry of the cell. Equation 1 can be used to estimate the value of α from the values of $(\Delta T)_{max}$ provided that ΔC_1 is known. ΔC_1 can be obtained by using the integrated form of Fick's second law of diffusion,[11)] which is given by

$$C_t = \frac{1}{2} C_0 \left[1 - erf \frac{X}{2\sqrt{Dt}} \right] \qquad (2)$$

D is the diffusion coefficient and t is the time in seconds when reaches a maximum value and is known from expcriment. C_t is the concentration of the particular component in the second chamber at time t, C_0 is the concentration of the component in the original chamber, and X is the distance from thermocouple to the plane of initial separation of components. For λ and ρ_1 in Eq. 1, we had some difficulty in assigning the values since these were not known at various concentrations. Therefore, the values for pure components were used. By setting the value of α=0.45 for carbon dioxide–helium mixture in Eq. 1, the apparatus constant K was estimated to be 3.05×10^{-5}. This point was not considered by Rastogi and Madan who left K=0 in their work. Since the distance between two thermocouples was the same in all experiments, this value of K was used for calculation for other systems. The values of α obtained in this way are recorded in the second column of Table 2. These are of the same order of magnitude as the values of thermal diffusion factors for equimolar mixture obtained from Equation (8.2—50) of the treatise of Hirschfelder *et al.*[12)] (Column 4).

In our system, a rather large concentration gradient was present which may be eliminated by taking a binary mixture in two half cells instead of pure gases. Also there was a convective mixing effect. In choosing the values of λ and ρ_1 in Eq. 1 there was some arbitrariness, the values of these parameters used being the values of the pure components.

The interpretation of the diffusion thermoeffect is more complicated than thermal diffusion since there is heat conductivity involved in the former but not in the latter. This is the disadvantage of this method compared to the thermal diffusion measurements. On the other hand, the Dufour effect gives the value of α at specific temperatures. In short, this method shows considerable promise as a means of obtaining the value of gas transport coefficients.

We thank the Iranian Ministry of Higher Education Research Foundation and the Department of Chemistry of Shiraz University for the research facilities.

Infrared Studies on Water Adsorption Systems with the Use of HDO. II. Na-Y Zeolite

Masao HINO* and Yasuko MIKAMI

Government Industrial Development Laboratory, Hokkaido, Higashi-tsukisamu, Toyohira-ku, Sapporo 061-01

(Received July 5, 1978)

Infrared spectra of the systems of Na-Y zeolite–H_2O, D_2O, and HDO were measured. It was shown that there are three types of adsorbed water in the zeolite–water system. Type I: adsorbed in a state in which two hydroxyl bonds are highly non-equivalent; it gives absorptions at 3695, 3400, and 1645 cm^{-1}, and is the same type as that on the Molecular sieve 13X.[1] Type II: adsorbed in another state in which the bonds are nearly equivalent; it gives bands at 3610, 3540, and 1645 cm^{-1}. Type II was more resistant to dehydration than Type I, and was irreversible for the back-adsorption of a small amount of water at room temperature, whereas Type I was almost completely reversible. Type III was observed for back-adsorption under this condition; it gives bands at 3635, 3500, and 1655 cm^{-1}. Type III can be transformed into Type II by heat treatment at a temperature which varies depending on the amount of adsorbed water. The other bands were assigned as follows: Bands at 3750 and 3645 cm^{-1} correspond to stretching of surface structural OH, and that at 3240 cm^{-1} to overtone deformation of adsorbed water. The sites of adsorbed water molecules of Types I and II were discussed.

In a previous paper[1] one of the authors showed that HDO could be effectively used for the IR analysis of water adsorption systems through the analysis of the system on Molecular sieves 13X and 4A. In the present paper, the water adsorption system on Na-Y zeolite will be analyzed by employing the same technique.

A number of IR studies have been published on the water adsorption system.[2–5] However, not all of the bands have been clarified, and there are some disagreements about the spectra observed and their assignments. The purpose of the present work is to analyze the spectra of the system on the basis of information obtained from a new technique employing HDO. The sites of the adsorbed water molecules will also be discussed.

Experimental

Linde Molecular sieve SK-40 (UNION SHOWA Co., Ltd.), which is a synthetic Na-Y zeolite, was used as the sample. Major components of the material were SiO_2 63.5, Al_2O_3 23.5, and Na_2O 13.0 in wt %. The crystallinity of the sample was confirmed to be sufficiently high by the measurements of X-ray diffraction and surface area (903 m^2/g, N_2).

Two IR spectrophotometers, a DIGILAB Model 15-B FTS and a JASCO Model 402-G, were used for recording the spectra. The latter instrument was calibrated against the former by use of ammonia, water vapor, and hydrogen bromide.

Other materials, apparatus, and procedures were the same as described before.[1]

Results

Spectra for the Desorption Process. The spectra of Na-Y zeolite–D_2O and H_2O systems after being evacuated at various temperatures are shown in Figs. 1 and 2. As seen in the Figs. various bands observed in the spectra of the two systems after the corresponding evacuation treatments can be easily matched with each other. These matching bands will be referred to using the same letters: a, b,···, and g for the spectra of both systems. Frequencies of these observed bands

1,12), 3): OD(OH) stretching of structural deuteroxyl groups. 2,13), 6,15), 9,19): OD(OH) stretching and deformation of Type-I water. 4), 5), 10): OD(OH) stretching and deformation of Type-II water. 7,16): DOD(HOH) overtone deformation of adsorbed water. 8, 17): Overtone deformation of adsorbed HDO. 11): Arising from D_2O impurity. 14), 18): OD(OH) stretching and deformation of Type-III water.

are summarized in Table 1-(1) together with those of the corresponding bands observed for the HDO system and also with their assignments. The spectra observed for the H_2O system were similar to those reported by Ward,[2] with the exception that the band appearing at 3630 cm^{-1} in his spectra was observed to be clearly separated into two bands at 3645 (c) and 3610 cm^{-1} (d) in our spectra. Bands which were equivalent to these appeared at 2692 and 2668 cm^{-1} for the D_2O system.

Spectra observed for the HDO system in the OD, OH stretching and the HOD deformation regions are shown in Figs. 3 and 4. Those spectra shown in Figs. 3 and 4 were measured after the same evacuation treatments as those performed prior to the measurements of the spectra shown in Figs. 1 and 2, respectively, so that a comparison between the spectra of the D_2O or H_2O system and of the HDO system should be reasonable.

Correlations between the spectra in the OD stretching region of the HDO system and those of the D_2O system were analogous to those between the spectra in the OH stretching region of the HDO system and those of the H_2O system.

As in the case of the Molecular sieve 13X–water system,[1] bands a and c in the spectra of the D_2O or H_2O system appeared at just the same frequencies for the HDO system (bands a′ and c′ in Figs. 3 and 4). Band b shifted toward the lower frequency side by 16 cm^{-1} in the OD stretching region and by 5 cm^{-1} in the OH region for the HDO system. The weak absorption at 2730 cm^{-1} in Fig. 3 arises obviously from the D_2O present in the sample water mixture (about 6.3%). Band g disappeared from the spectra of the HDO system. A new band appeared for the HDO system at 2940 cm^{-1} in the OH stretching region; it can be attributed to an overtone deformation or a combination band of adsorbed HDO, like the band at 2945 or 2910 cm^{-1} which appeared in other zeolite–HDO systems.[1] Bands at 2668 (d) and at 2586 cm^{-1} (e) in the spectra of the D_2O system disappeared from the OD stretching region of the HDO system. Two

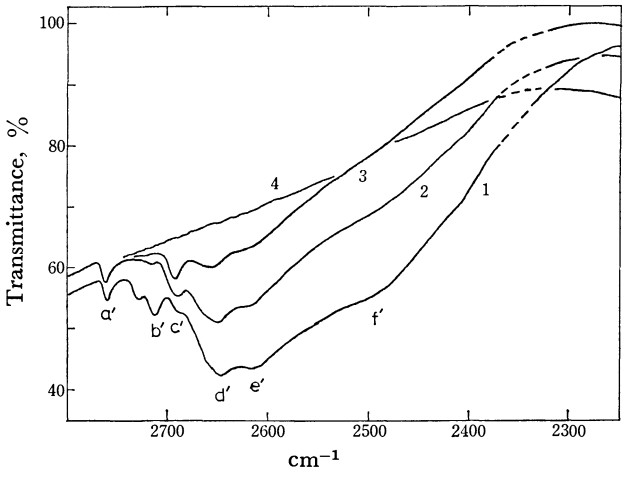

Fig. 3. Spectra of the Na-Y–HDO system in the OD stretching region, on the desorption process.
Evacuated for (1) 1 h at 90 °C, (2) 1 h at 120 °C, (3) 30 min at 165 °C, (4) 3 h at 500 °C after exposure to the vapor of H_2O–D_2O mixture of a molar ratio of 3 to 1. Sample piece "thickness" 40 mg/cm².

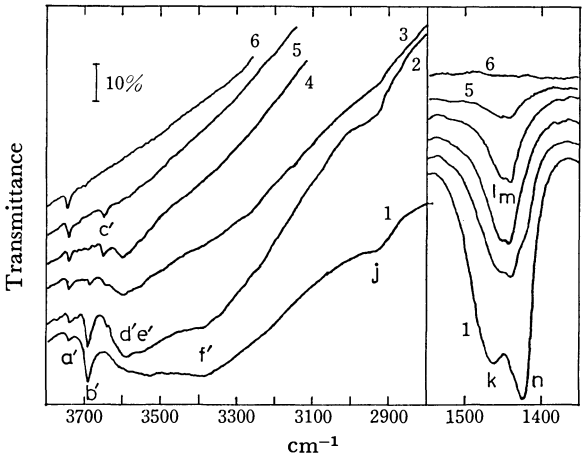

Fig. 4. Spectra of the Na-Y–HDO system in the OH stretching and deformation regions, on the desorption process.
Evacuated for (1) 10 min at 90 °C, (2) 1 h at 90 °C, (3) 1 h at 120 °C, (4) 30 min at 165 °C, (5) 45 min at 200 °C, (6) 3 h at 500 °C after exposure to the vapor of H_2O–D_2O 1 to 5 mixture. The spectra shown in the deformation region were obtained by rationing each observed spectrum against that after 500 °C evacuation of the Na-Y–H_2O system. Sample piece "thickness" was 26 mg/cm².

new bands, presumably corresponding to bands d and e, appeared at 2647 (d') and 2615 cm^{-1} (e') in the OD stretching region. In the OH region these bands d' and e' were detected in the spectra after evacuation at lower temperatures (curves 1 and 2 in Fig. 4) at 3600 and 3540 cm^{-1}, which were nearly the same frequencies as those of d and e in the spectra of the H_2O system. After the evacuation at higher temperatures, however, the band e' could not be observed, probably because the absorption was weak and broad. In the deformation region four absorptions (k, l, m, and n) appeared at 1460, 1450, 1440, and 1422 cm^{-1} in the HOD deformation region for

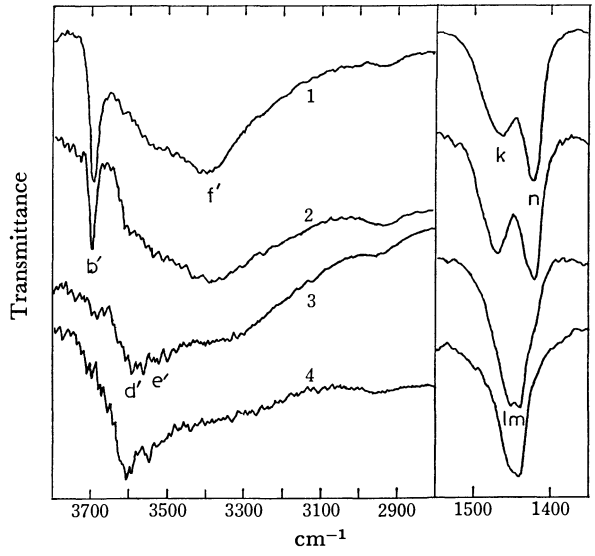

Fig. 5. Ratioed spectra of the Na-Y–HDO system in the OH stretching and deformation regions, on the desorption process. Obtained rationing (1) curves 1 and 2, (2) 2 and 3, (3) 3 and 4, (4) 4 and 5 of Fig. 4. The scale of the intensity is arbitrary as each curve is "auto expanded" into an identical hight in the frequency ranges indicated.

the HDO system, whereas only one at 1645 cm^{-1} (h) was found for the H_2O system.

On evacuation in a series where the evacuation temperature was elevated step by step, the intensity of the bands b and f for the D_2O (H_2O) system and also of the bands b', f', k, and n for the HDO system decreased preferentially in the initial steps, followed by the decrease of the bands d and e for the D_2O (H_2O) system and of d', e', l, and m for the HDO system. The intensity of band h decreased at a constant rate through the dehydration treatments. This can be seen directly in the ratioed spectra shown in Fig. 5. Those spectra were obtained for the HDO system by calculating the intensity differences between each curve shown in Fig. 4 by use of a computer system included in the FTS-15 spectrometer. Thus, it was suggested that bands b, f, and h for the H_2O (D_2O) system (corresponding bands b', f', k, and n for the HDO system) should have the same origin, while bands d, e, and the residual part of h (d', e', l, and m) came from another origin.

Spectra for the Adsorption Process. Spectral measurements on the adsorption process were also made for the systems of various kinds of water in the surface coverage of about 0—1.2 mmol/g. The general features of the spectra were almost identical irrespective of the degree of coverage in each of the systems, but were somewhat different from those of the spectra for the desorption process, as is seen in the typical examples shown in Figs. 6 and 7. Differences were found in two regions: one is the region where bands d and e appeared for the desorption process and the other is the deformation region. In the former, two relatively broad bands (o and p) appeared at 2675 and 2575 cm^{-1} for D_2O adsorption, and at 3635 and 3500 cm^{-1} for H_2O adsorption. Each of the former

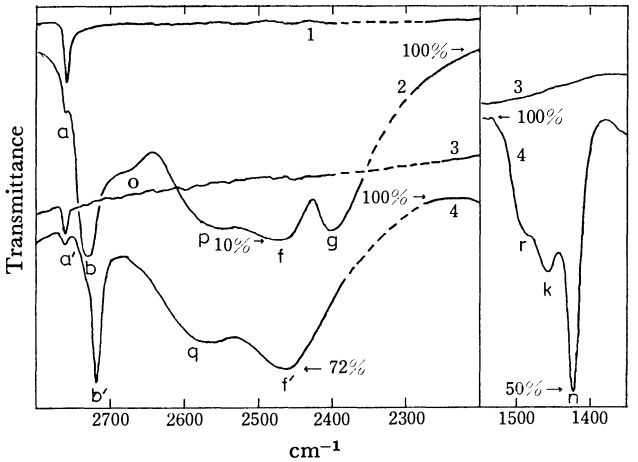

Fig. 6. Spectra of the Na-Y–D_2O and HDO systems in the OD stretching and the HOD deformation regions, on the adsorption process.
(1,3) Evacuated for 3 h at 500 °C, (2) 40 μmol of D_2O, (4) 40 μmol of H_2O–D_2O 7 to 1 mixture were readsorbed. All the curves were obtained by rationing the observed spectra against that after 500 °C evacuation of the Na-Y–H_2O system. Sample piece "thickness" 17 mg/cm².

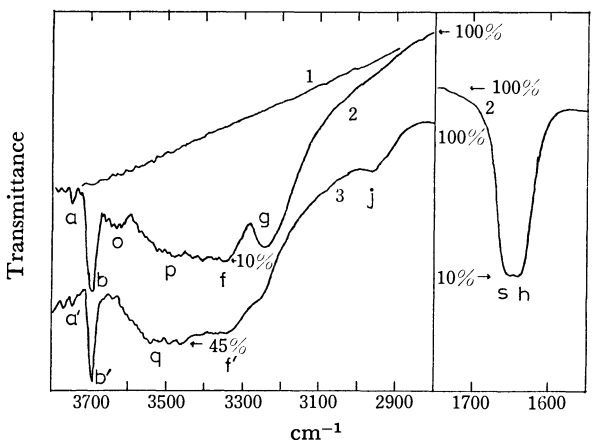

Fig. 7. Spectra of the Na-Y–H_2O and HDO systems in the OH stretching and the deformation regions, on the adsorption process. (1) Evacuated for 3h at 500 °C, (2) 24 μmol of H_2O, (3) 24 μmol of H_2O–D_2O 1 to 5 mixture were readsorbed. Curve 2 in the deformation region was obtained by rationing the observed spectra against that after 500 °C evacuation. Sample piece "thickness" was 17 mg/cm².

bands was very weak. For HDO only one broad band (q) was observed in the region around 2580 cm^{-1} for the OD region and around 3520 cm^{-1} for the OH region. Three deformation bands were observed for the HDO system, at 1495 (r), 1460 (k), and 1422 cm^{-1} (n), while two were found at 1655 (s) and 1640 cm^{-1} (h) for the H_2O system.

Observed frequencies of the various bands are summarized in Table 1-(2).

Discussion

Spectra for the Desorption Process. First, bands a and c can be assigned to the stretching vibrations of surface structural OH (OD) groups, while the remaining absorptions b, d, e, f, g, and h are attributable to some vibrations arising from adsorbed water molecules. This is because of the fact that each pair of corresponding bands, one appearing in the H_2O (D_2O) system and the other in the HDO system, of the former group appeared at the same frequency in the corresponding regions of the spectra of the H_2O, D_2O, and the HDO systems, while in the latter group the bands did not appear at the same frequency in at least one region of the spectra.

Thus there is just the same type of adsorbed water (Type I, adsorbed in a state in which its two hydroxyl bonds are highly non-equivalent) in the Na-Y zeolite–water system as the Type WX-I in the Molecular sieve 13X–water system which was reported in a previous paper.[1] That is, bands b, f, g, and h in the spectra of the present work are apparently attributed to the same vibrations as bands b, e, f, and at 1650 cm^{-1}, respectively, in the spectra of the 13X system. Each pair of these matching bands showed an almost identical behavior with the partial deuteration of the adsorption systems.

Absorptions d and e have been observed and reported only by Ward.[2] He assumed that they were due to some adsorbed water molecule, but no details were described. Our results in the present experiments support his assignment. Moreover, they give further information on the state of the adsorbed molecules as described below. When a water molecule is adsorbed in a state in which its two hydroxyl bonds are completely equivalent, the molecule is expected to give two stretching bands of ν_3 and ν_1 and one deformation band of ν_2 for H_2O (D_2O), as well as single OH and OD stretching bands which are located between the ν_3 and the ν_1 frequencies and one HOD deformation band for HDO. On the other hand, when the molecule is adsorbed in another state in which the hydroxyl bonds are not equivalent, H_A–O–H_B, it is expected that two OH stretching bands (one is rather characteristic of νOH_A and the other of νOH_B) and a single deformation band arise for H_2O and D-equivalent bands forD_2O. For HDO molecules in this state four stretching bands: νOH_A, νOH_B, νOD_A, and νOD_B and two deformation bands: $\delta H_A OD_B$ and $\delta H_B OD_A$ will occur. The degree of frequency difference between the vibrations νOH_A and νOH_B or between the two D-equivalent bands, as well as between the two deformation bands, will be larger, the larger the degree of the non-equivalency between the two hydroxyl (deuterioxyl) bonds. In the present results, bands d′ and e′, presumably corresponding to the $\nu OD_A(\nu OH_A)$ and the $\nu OD_B(\nu OH_B)$ of the HDO, appeared close to each other, being located between the frequencies of the corresponding bands d and e of the D_2O (H_2O). Thus, bands d and e can be assigned to the ν_3 and ν_1 vibrations of water molecules adsorbed in a state in which its two hydroxyl bonds are nearly equivalent (Type II). The result in the deformation region also supports this assignment. Two deformation bands (l and m) were observed to be very close to each other, with a difference of only

10 cm^{-1}, for the Type II adsorbed HDO. The corresponding difference was 38 cm^{-1} for the Type I water, in which the difference between the two OD stretching bands was 224 cm^{-1}. Hence, such a small difference of 10 cm^{-1} will be reasonable for the Type II water, in which the difference between the two OD stretching bands was 32 cm^{-1}.

In a previous paper[1] it was suggested that the weak absorption at 3590 cm^{-1} (D-equivalent band at 2645 cm^{-1}) in the spectra of the Molecular sieve 13X–water system was due to some type of adsorbed water molecule, but with no details. It is almost certain that the band arose from a similar type of adsorbed water to the present Type II water.

Spectra for the Adsorption Process. From a comparison with the spectra of the desorption process, the deformation band at 1640 cm^{-1} (h) in the H_2O system should correspond to those at 1460 (k) and 1422 cm^{-1} (n) of the HDO system, and the new band at 1655 (s) to that at 1495 cm^{-1} (r). This speculation is in harmony with the appearance of the bands in the stretching regions. Bands b, f, and g did appear at almost the same positions as those in the spectra of the desorption process; moreover, they showed similar behavior to those of the latter bands for the partial deuteration. On the other hand, bands o and p for the H_2O (D_2O) system and q for the HDO system are quite different in their spectral aspects from bands d, e, d′, and e′ of the desorption process. These facts indicate that the Type I water is almost reversible while the Type II is not, for readsorption of a small amount of water at room temperature.

The new bands o (3625, D-equivalent 2675 cm^{-1}), p (3500, D-2575 cm^{-1}), and s (1655 cm^{-1}) would be assigned to the ν_3, ν_1 and ν_2 vibrations of water adsorbed in some state with its hydroxyl groups equivalent (Type III), and bands q at 3520 and 2580 cm^{-1} and r (1495 cm^{-1}) to the OH stretching, OD stretching, and the deformation of the corresponding HDO molecules.

The state of these adsorbed molecules is obviously different from that of the Type II water, even if somewhat similar to it. In order to investigate this irreversibility a simple experiment was carried out. After 0.83 mmol/g of D_2O was back-adsorbed at room temperature, the sample piece, *in situ*, was heated up to 95 °C or 200 °C once, and then cooled slowly down to room temperature. It was found that the treatment at 200 °C gave rise to a great change in the spectrum, giving a similar spectrum to that on the desorption process with bands at 2694 (c), 2674 (d), and 2590 cm^{-1} (e). This indicates the rearrangement of the adsorbed water molecule, probably from the Type III to the Type II, and the formation of certain structural hydroxyl groups caused by dissociation of adsorbed water. And also it suggests that the Type II water is more stable than the Type III water. However, in the 95 °C treatment no spectral change occurred, whereas our spectra for the desorption process were obtained by 10 min of evacuation at 90 °C after the dried sample piece was saturated with water vapor. Thus, it is suggested that the occurrence of the rearrangement of adsorbed water and the formation of the hydroxyl groups depend on the degree of surface coverage as well as temperature. The details can not be known without further experiments.

Sites of Adsorbed Water Molecules. Mutual comparison of the results obtained for the present Na-Y zeolite and for the Molecular sieves 13-X (Na-X zeolite) and 4-A (Na-A zeolite)[1] makes it possible to discuss the sites of adsorbed water molecules.

Type I and Type II water existed on both the zeolites of Na-X and Na-Y, while on the Na-A zeolite Type I water could not be found. The single main type of adsorbed water observed on the Na-A is regarded to be similar to the Type II water in its symmetry.

Under such a condition of much lower surface coverage,[6] it is almost sure that the adsorption of water molecules occurred mainly on the zeolitic cations in such a manner that the lone pair electrons of the water oxygen atom are attracted to the positive charge of the cations, whether or not the hydrogen atoms are hydrogen bonded to the negatively charged oxygen of the zeolite lattice. Hence, it will be reasonable that the variety in the modes of adsorption should be discussed in connection with the kind of cation sites.

It is well known that the crystal structures of zeolites X and Y are essentially identical, but differ only in the number of their cations and the strength of the electrostatic force field around the cations. According to Rabo *et al.*,[7] there are three kinds of possible cation sites, S_I, S_{II}, S_{III}, in the zeolite structure. The number of each site is 16, 32, and 48, respectively, for a X type zeolite of which the ratio of Al and Si equals unity. These sites are occupied by exchangeable cations, fully or partially, depending on the type of the zeolite. On the other hand, Na-A zeolite[8] has another structure. But it includes sodalite cages similarly to the structure of the Na-X or Na-Y. There are two kinds of sites, S_1 and S_2, in the type A zeolite. For the Na-A, 12 Na cations are required per unit cell for electrical neutrality, of which 8 Na cations occupy the former site and the remaining 4 Na the other site.

Among those five kinds of sites, the site S_I can be ruled out of consideration because the cations positioned at that site will not be able to accept any adsorbate due to its small space. Site S_{II} is regarded to be similar to site S_1. Both are situated on the center of the six-membered rings of the sodalite cages facing toward the super cages of the zeolite structure, and have a C_{3v} symmetry in relation to the neighboring lattice oxygens. Site S_{III} is characteristic of zeolites X and Y, which is located on the center of four-membered rings of the sodalite cages and has a symmetry of C_{2v} in relation to the neighboring oxygens. Zeolite A has no such site.

From both the similarity and the differences among the three zeolites in the geometry around the possible cation sites and in the observed spectra, it is suggested that the Type I water is situated on the cations occupying the site S_{III}, whereas the Type II is on those of site S_{II}.

These attributions are supported by a comparison between the intensity of the spectra of each type of adsorbed water and the number of the cations occupying each site, as described below. The relative

amount of the Types I and II water on the Na-X and Na-Y zeolites can be estimated from the results shown in the present Fig. 1 or 2 and those shown in Fig. 1 or 2 of the previous report.[1] In that case, the intensity of the spectra of the 13-X water system must be compared with the other after being multiplied by a factor of 1.6, which appears from the differences in the sample thickness and the molecular weight per their unit cells.[9] Then, it can be seen that there is a much smaller amount of Type I adsorbed water on the Na-Y zeolite than on the Na-X. The Type II water is estimated to be present in much the same amount on both zeolites, or at least not so much less on the Na-X than on the Na-Y zeolite, though this is not very clear because of the overlapping of the spectra of the Types I and II water. On the other hand, according again to Rabo *et al.*,[7] the order of preference for cation occupation is $S_I > S_{II} > S_{III}$, which may lead to the conclusion that our Na-X sample (Si/Al=1.23) includes 16, 32, and 38 Na ions per unit cell for the respective sites, while the Na-Y sample (Si/Al=2.3) includes 16, 32, and 10, respectively. That is, the ratios of the cation number positioned on the same site in Na-X and Na-Y are 1:1 for the site S_{II} and 38:10 for the S_{III}. This may be comparable with the relative intensity of the spectral bands described above.

The molar absorptivity for the Type II water appears to be weaker than for the Type I water. This is probably due to the fact that the Type I water is more strongly polarized than the other. It has been shown by Dempsey[10] that the electrostatic force fields around the site S_{III} is some 50% stronger than that around site S_{II}.

It is obscure at present why and in what geometrical arrangements the Types I and II water are adsorbed on the sites, yielding such modes as described before. To answer this question, further experiments with the use of other techniques are necessary.

The Performance Characteristics of a Permeation Membrane Device for the Preparation of Dilute Standard Gas Mixtures

Takashi IBUSUKI,* Fumitoshi TOYOKAWA, and Kazunari IMAGAMI

National Research Institute for Pollution and Resources, Kawaguchi, Kawaguchi-shi, Saitama 332

(Received July 25, 1978)

The performance chracteristics of the permeation membrane device for the preparation of dilute standard gas mixtures developed by us was investigated in detail from the practical standpoint. By selecting a silicone-rubber and a TFE Teflon for CO or CH_4, and NO or SO_2, respectively, the steady permeation state was rapidly attained. The small quantities of the gases permeating through the membranes were precisely determined within a relative standard deviation of 1% based on a pressure-differential method. It was confirmed that the permeation rates were reproducible after repeated membrane-temperature, gas-pressure, and gas-cycle changes during an experimental period of more than five months. By changing the gas pressure and the membrane temperature, and by introducing 1—2 l min^{-1} of a diluent gas, N_2 or air, standard gas mixtures containing 0.5—10 ppm of CO or CH_4 and 0.05—0.7 ppm of NO or SO_2 were easily obtained. The standard gases concerning CO, CH_4, and NO were compared with those in cylinders prepared by the weighing method, and for SO_2 the concentration of the gas was checked by the West-Gaeke method. A good agreement in concentration was observed for CO, CH_4, and SO_2; the discrepancy found for NO was explained in terms of the decrease in the NO concentration in the cylinder.

For the accurate determination of the concentrations of gaseous pollutants at ppm and ppb levels, standard reference materials are needed to calibrate the air-monitoring instruments. Accurate gas mixtures in cylinders at 10 ppm levels have been prepared by the weighing method for various gases.[1] However, mixtures of nitrogen dioxide (NO_2) or sulfur dioxide (SO_2) change greatly in concentration with the time because of their adsorption or reaction with the cylinder wall. Permeation tubes for the condensable gases were proposed by O'Keeffe and Ortman,[2] and their performance characteristics have been widely investigated.[3—10] Unfortunately, several months or more are required to calibrate the low gas-permeation rates of the tubes by means of standard gravimetric methods at a constant, strictly controlled temperature. Dietz *et al.* recently proposed a rapid calibration method using the pressure-differential technique to measure microgram quantities of gas permeating through the plastic membrane or diffusion devices.[11,12] The device using the membrane can also be applied to non-condensable gases, such as nitrogen monooxide (NO), carbon monooxide (CO), and methane (CH_4). However, the performance characteristics of the device in the preparation of dilute standard gas mixtures have not yet been reported. We have previously studied the performance characteristics of a commercial apparatus based on the permeation method and have pointed out some of its defects from the standpoint of practical value.[13] The permeability of gaseous pollutants through various kinds of plastic membranes has, therefore, been investigated.[14] It was shown that various kinds of standard gas mixtures, ranging widely in concentration, can be prepared by selecting an appropriate combination of pure pollutant gas and membrane, together with an appropriate gas pressure and membrane temperature.

We wish to report here the performance characteristics of the permeation membrane device we have developed with regard to the following subjects: precision in the measurement of a gas-permeation rate, the dependence of the rate on the gas pressure or the membrane temperature,[13] the long-term stability of the rate under many temperature changes,[8] the procedure and the length of time to reach a steady permeation rate,[10] and, especially, whether or not the gas-permeation phenomenon will change because of the different conditions of the membrane in the measurement of the permeation rates of gas and in the preparation of dilute gas mixtures. Silicone-rubber and TFE Teflon membranes are used for CO or CH_4, and for NO or SO_2, respectively, since their permeation rates and the length of time to reach steady permeation rates have been suggested to be favorable for the precise and rapid preparation of very dilute gas mixtures.[14] Moreover, the concentrations of the dilute gases are examined by using analyzers and standard gas mixtures in cylinders for CO, CH_4, and NO, because it is important to compare the standard gases prepared by the permeation device with those in cylinders prepared by the weighing method. For SO_2, the concentration is determined by the West-Gaeke method because of the lack of reliable dilute standard gas mixtures in cylinders. The results are also discussed with respect to the development of a practical type of the permeation device.

Experimental

Apparatus. The apparatus used here is shown schematically in Fig. 1. It consists of a test cell (C), a vacuum system, a differential pressure transducer (VG), and gas-feed systems for a pure pollutant gas and a diluent gas. A flat plastic membrane (M, with an effective area for permeation of 3.14 cm^2) is held between two metal flanges and sealed with Viton-O-rings. Thin stainless steel screens are inserted between the membrane and the flanges in order to avoid the deformation of the membrane. One flange is connected to the pollutant gas source, and the other one, to the fixed-volume system (the shaded part) and the diluent-gas source. The cell is placed in a constant-temperature water bath (TB) controlled within ±0.05 °C (Riko-Kagaku Co., Model UH-1000E). The vacuum system is of Pyrex glass tubes, and the stopcocks (1—11) are made of glass and Teflon (Young Co.) in order to avoid the ad-

sorption of the pollutant gases on the grease of the usual vacuum cocks. The system can be evacuated below 5×10^{-6} mmHg (1 mmHg=133.32 Pa) by means of an oil-diffusion pump (DP), an oil-rotary pump (RP), and a liquid-nitrogen trap. The volume of the shaded part was determined to be 215 ± 2 cm^3 by using the known volume of the glass vessel (H, 1188 ± 8 cm^3). The pressure transducer is composed of an MKS Baratron 310 AH sensor head and an 170 M-7A electronic unit, measuring the pressure range from 3×10^{-5} to 1 mmHg within a 1% accuracy. The pure pollutant gas is introduced to the cell through the 1 cock, the Hg bubbler (B), and the 2 cock. The pressure is precisely read by the Hg manometer (P). The diluent gas (very purified nitrogen or air) passes through the 4 cock, the upper compartment of the cell, and the 5 cock, and is then introduced into an analyzer. The flow rate of the diluent gas is controlled by a mass-flow-rate controller (F, Ohkura Electronic Co., Model MFC-1), which is usually calibrated by means of a soap-bubble flow-meter.

Operational Procedures. Measurement of the Gas-permeation Rate: All the systems, including the cell and membrane are usually conditioned until vacuum readings of less than 5×10^{-6} mmHg are obtained, and a very low baseline drift of the shaded-part pressure with no feed gases is checked by means of the transducer. Following the baseline determination, the pollutant gas is introduced at the pressure of p_1, while simultaneously the pressure build-up (h) of the shaded part is recorded. The permeation test is carried out about four times, the time needed to reach the permeation-rate equilibrium.

Preparation of Dilute Gas Mixtures and Measurements of the Concentration: After a sufficient evacuation of the system, the diluent gas is introduced into the cell at an appropriate flow rate and is led to an analyzer. The pollutant gas is then introduced into the lower compartment of the cell in the same manner described above.

The concentrations of CO and CH_4 in the prepared dilute gases are determined by means of a total hydrocarbon analyzer(Beckmann Co., Model 6800 FID gas chromatograph equipped with a convertor of CO to CH_4). Standard gas mixtures in cylinders (7.79 ppm CH_4 in air and 9.60 ppm CO in air), prepared by the weighing method, are used for the calibration of the analyzer. An NO chemiluminescent analyzer (Bendix Co., Model 8101-B) is used for the measurements of NO in the diluent gas. The standard gas mixture in a cylinder (8.4 ppm of NO in nitrogen) is diluted to 1.68 ppm by using a STEC Model SGD-75 (Standard Technology Co.) for the calibration of the analyzer. A very purified air is used to adjust the analyzer to zero. The concentration of SO_2 is determined according to the West-Gaeke method.[15,16] The gas-flow rate of 0.5—1.5 l min^{-1} passing through the scrubber of SO_2 is controlled by means of mass-flow-rate air sampler (Milab Co., Model 69).

Reagents: All the reagents used in the West-Gaeke method were obtained from the Tokyo Kasei Co. and were used without further purification except for pararosaniline dye. TFE (tetrafluoro ethylene) Teflon and silicone-rubber membranes were obtained from the Nitto Rika Co. and the Toray Silicone Co. respectively. The pure pollutant gases in the cylinders were from the Takachiho Kagaku Co., for CH_4 (99.999%), CO (99.999%), and NO(99.8%), and from the Matheson Co. for SO_2 (99.98%).

Theoretical

According to Fick's gas-diffusion theory, q (the permeation rate of gas through a flat plastic membrane with a thickness of l and a certain area of A) is expressed as follows:[17,18]

$$q = DS(p_1-p_2)(A/l) \quad (1)$$

where D is the diffusion constant, S, the solubility coefficient, and p_1 and p_2, the partial pressures at the lower and upper compartments of the cell in Fig. 1 respectively. The permeability coefficient, P, is the product of D and S:

$$P = D \times S \quad (2)$$

The temperature dependence of the P, D, and S parameters follows an Arrhenius relationship:

$$P = P_0 \exp(-E_p/RT)$$
$$= D_0 \exp(-E_d/RT)\cdot S_0 \exp(H_s/RT) \quad (3)$$

where E_p and E_d are the activation energies for permeation and diffusion respectively, and H_s, the heat of solution.

Table 1. Lag-times in gas-permeation procedure for silicone-rubber–CO and CH_4 and teflon–NO and SO_2 at a gas pressure of about 70 cmHg

Membrane temp	Gas			
	CO	CH_4	NO	SO_2
30.0 °C	2.93 min	3.28 min	4.58 min	38.2 min
45.0 °C	2.43	2.48	2.64	18.9
55.0 °C	2.06	2.30	2.18	11.3

Results and Discussion

Procedure and the Length of Time to Reach a Steady State of the Permeation. The permeation procedures (time *vs.* the pressure build-up, h, of the known volume part) found for the silicone rubber (thickness l=1080 μm)–CO or CH_4 and for the Teflon (l=200 μm)–NO or SO_2 were in good accordance with the Ficksian-type permeation.[14] In Table 1, the so-called lag-time, θ, in the permeation procedure is listed for each combination of gases and membranes. Apparently the time becomes shorter with an increase in the membrane temperature. About three times as long as the lag-time is the length of time needed to reach steady

permeation rates.[13] Even for SO_2 at 30.0 °C, the time of about two hours required for calibration is much shorter than that required using conventional gravimetric or volumetric procedures for usual SO_2 permeation tubes.[11] It should further be noted that, with regard to CO, CH_4, and NO, the time needed to reach the steady-permeation state is remarkably shortened in comparison with that estimated for the use of a commercial apparatus using a FEP Teflon membrane.[13]

Precision in Measurement, Repeatability, and Long-term Stability of Permeation Rates. The permeation rates (q) were calculated from the values of dh/dt at the steady-pressure build-up state and the volume employed. The values of q obtained for CO, CH_4, NO, and SO_2 at about 70 cmHg of p_1 are summarized in Table 2, together with the standard deviations. The very small quantities of gas permeating, less than 10^{-4} cm^3 min^{-1}, were precisely measured within a relative standard deviation of 1%. It is also confirmed that the values of q obtained under various gas pressures less than 70 cmHg changed linearly with the gas pressure of p_1 in Eq. 1. This suggests that the gas pressure in the upper compartment (p_2) is negligibly small compared to p_1 [Eq. 1 can, then, be rewritten as $q = DS(p_1)(A/l)$] and that P ($D \times S$) is constant regardless of the pressure changes.

In order to ascertain the repeatability of the permeation rates, the values of q at various gas pressures of p_1 were converted to the permeability coefficients (P) according to Eqs. 1 and 2. The values of P concerning CO, CH_4, NO, and SO_2 as well as the standard deviations are summarized in Table 3. Each value of P was derived by averaging all the values of P obtained periodically for more than five months at the membrane temperatures of 30.0, 45.0, and 55.0 °C. It has been ascertained that the permeation rates are reproducible within small deviations after repeated temperature, pressure, and gas cycles for a long experimental period.

The long-term stability of the device differs in meaning from that for the conventional permeation tubes of SO_2, NO_2, *etc.* In the former device, the gas permeating through the membrane is fed and removed in each experiment, while the liquefied gases are always stored in the tubes. It is, therefore, considered that the long-term stability of the device is also confirmed by the results on the repeatability. The excellent repeatability and the long-term stability arise from the better storage condition of the membranes than in the conventional permeation tubes; that is, the membranes are in contact with the pollutant gases only at use and, moreover, can be protected from moisture or air.

The maximum uncertainty was found with respect to the SO_2–Teflon system, as can be seen from Tables 2 and 3. The precision of the temperature control of the membrane and the laboratory is considered to be an important factor in this experiment, affecting the uncertainty in the determination of q or P. The magnitude of the activation energy for permeation, E_p, is associated with the required level of the membrane-temperature control, as is suggested by Eq. 3. The values of E_p concerning CO, CH_4, NO, and SO_2 were found to be 2.0, 1.3, 5.1, and 5.9 kcal mol^{-1} (1 kcal mol^{-1}=4.184 kJ mol^{-1}), in that order, from the plots of log P *versus* the reciprocal temperature of the membrane shown in Table 3. The value for SO_2–TFE Teflon agreed well with that of 6.5 kcal mol^{-1} reported by Felder.[19] If an error of less than a 1% in the measurement of P is desired, the temperature should be maintained within ±0.36 and ±0.18 °C when the values of E_p are 5.0 and 10.0 kcal mol^{-1} respectively. The temperature control within 0.05 °C in our experiment is too much to realize less than a 1% relative standard deviation. The uncertainty can, then, be attributed to the deviation of the ambient temperature of our laboratory (±1.0 °C during 1 h). The largest uncertainty in P observed for SO_2 is related to the result shown in Table 1 that the time required to determine the permeation rate of SO_2 is much longer than those required for the other gases.

Preparation of Dilute Standard Gas Mixtures and Measurements of the Concentration. CO and CH_4 Standard Gas Mixtures: The flow rate of a diluent air (Q) was precisely measured at each experiment by means of a soap-bubble flow-meter. The air was mixed with the small quantity of CO or CH_4 (q) permeating through the silicone-rubber in the cell. The dilute gas thus prepared was then introduced into the gas chromatograph and was analyzed at intervals of 5 min. It was confirmed that the steady state of the observed concentration was achieved at the second sampling time (10 min), which is in accordance with the results shown in Table 1. The concentration of CO or CH_4 was maintained for more than four hours, long enough to calibrate the analyzer. Concentrations of CO or CH_4 ranging 0.5 to 10 ppm were easily realized by only changing the gas pressure from about 10 to 76 cmHg. The change in the membrane temperature

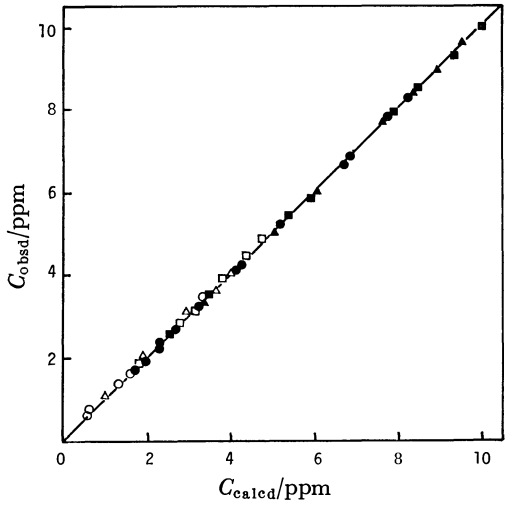

Fig. 2. Comparison of C_{calcd} with C_{obsd} for CO (unfilled symbols) and CH_4 (filled symbols)-silicone rubber. The membrane temperature were 30.0 °C (○), 45.0 °C (△), and 55.0 °C (□).

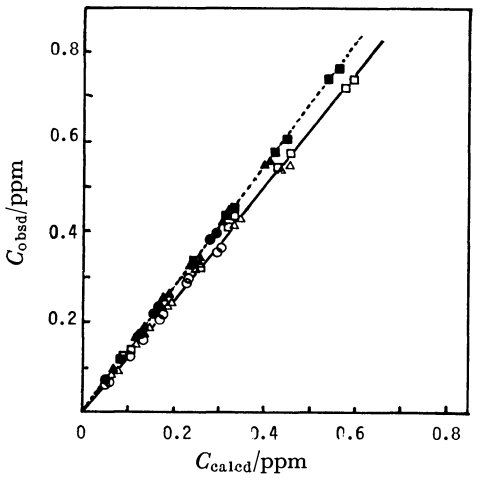

Fig. 3. Comparison of C_{calcd} with C_{obsd} for NO–Teflon at temperatures of 30.0 °C (○), 45.0 °C (△), and 55.0 °C (□). The filled symbols were obtained about two months later when the unfilled symbols were done.

was found to be less effective than that of the pressure, which reflects the very small value of E_p obtained for CO or CH_4. The observed CO or CH_4 concentrations of the dilute gas mixtures (C_{obsd}) are plotted against the calculated ones ($C_{calcd}=q/q+Q=q/Q$) in Fig. 2. By the use of the least squares method, $C_{obsd}/C_{calcd}=0.998$ and the correlation coefficient $r=0.999$ for CO and $C_{obsd}/C_{calcd}=1.01$ and $r=0.999$ for CH_4 were obtained. As has previously been pointed out, the CO or CH_4 concentrations of the dilute gas mixtures in cylinders scarcely changed with the time because of their low adsorbilities and reactivities. It is generally accepted that standard gas mixtures containing such low concentrations of CO or CH_4 prepared by the weighing method are reliable. The excellent agreement of C_{obsd} with C_{calcd} for both gases thus supports the validity of the gas-permeation rates determined here.

NO Standard Gas Mixtures: A very purified nitrogen was used as a diluent gas. By introducing less than 1 l min^{-1} of N_2, dilute gas mixtures containing 0.05—0.7 ppm NO were generated at various gas pressures and at various membrane temperatures. The steady state of the concentration of NO was reached within 20 min at the lowest temperature of 30.0 °C and was maintained more than four hours as well as both CO and CH_4. The concentrations observed by the NO analyzer (C_{obsd}) are plotted against the calculated concentration (C_{calcd}) in Fig. 3. While the correlation coefficient, r, was found to be 0.999 by the least-squares method, a large discrepancy between C_{obsd} and C_{calcd} ($C_{obsd}/C_{calcd}=1.26$) appeared. The same experiment was, therefore, performed about two months later by using the same standard cylinder gas for the span calibration of the NO analyzer. The results obtained are depicted by the dotted line in Fig. 3. The linearity ($r=0.99$) was confirmed to be good, but the C_{obsd}/C_{calcd} ratio increased from 1.26 to 1.37. This can be explained as being due to the decrease in the NO concentration in the cylinder, taking into consideration the fact that the permeability coefficient, P or q, is constant within 2% for 6 months, as has been mentioned above. NO probably adsorbs or reacts with the cylinder wall or an impurity gas such as oxygen and so decreases in concentration.[1] However, it is necessary to rule out the possibility that the discrepancy may result from the change in the quantity of gas permeating through the membrane on account of the different environmental conditions of the Teflon membrane; the determination of the permeation rate was carried out *in vacuo*, but the preparation of the dilute gas mixture was done in a diluent gas (N_2) flowing in the upper compartment of the test cell.

The values of the diffusion constant under the two environmental conditions of the membrane were, therefore, determined and were compared each other, since the diffusion constant is the factor governing the process of the permeation. The diffusion constant, D_v, in the evacuated condition can be calculated from the lag-time, θ, in Table 1 according to the following equation:

$$D_v = l^2/6\theta \quad (4)$$

The lag-time, θ, in the case of the preparation of the dilute gas mixtures can also be obtained by analyzing the change in the concentration of NO with the time.[13,20] The diffusion constants, D_d, in N_2 flowing thus were calculated according to Eq. 4. The values of both D_v and D_d, determined at the temperatures of 30.0, 45.0, and 55.0 °C, are summarized in Table 4(a). It is found that D_d agrees well with D_v within in the limits of experimental error. The possibility mentioned before can thus be excluded; the large discrepancy between C_{obsd} and C_{calcd} is attributable to the decrease of NO in the cylinder.

SO_2 Standard Gas Mixtures: A diluent nitrogen was introduced into the cell at the flow-rate of 1—2.5 l min^{-1}. As soon as the pure SO_2 was fed into the cell, the gas sampler began to operate. In Fig. 4, the observed concentration of SO_2 at the steady-permeation rate determined by the West-Gaeke method (C_{obsd}) is plotted against the calculated values (C_{calcd}).

Table 4(a). Comparison of D_v with D_d for NO-Teflon

Diffusion constant	30.0 °C	45.0 °C	55.0 °C
D_v	2.42±0.16	3.47±0.11	4.69±0.32
D_d	2.02±0.10	3.41±0.46	4.50±0.17

D_v and D_d: $cm^2/s \times 10^{-8}$

Table 4(b). Comparison of D_v with D_d for SO_2-Teflon

Diffusion constant	30.0 °C	45.0 °C	55.0 °C
D_v	2.87±0.10	5.81±0.23	8.56±0.62
D_d	2.58±0.28	5.17±0.59	7.85±1.74

D_v and D_d: $cm^2/s \times 10^{-8}$

Although some scatter is found, C_{obsd} agrees well with C_{calcd} ($C_{obsd}/C_{calcd}=0.997$ and $r=0.995$). About 6% of the relative standard deviation in the observed concentration is considered to be due to the analytical method. Although the purification of the parasoaniline dye used here was performed and a freshly prepared parasoaniline stock solution was used, the relatively large and irreproducible blank values, ranging from 0.057 to 0.078 absorbance, were not satisfactorily decreased. A better quality of the dye and a more rigorously reproducible analytical procedure will be needed to decrease the experimental error.

The diffusion constants, D_v and D_d, were also compared in the same manner as with NO; the values are listed in Table 4(b). They agreed well with each other within the limits of experimental error. The large difference in D between NO and SO_2, shown in Tables 4(a) and 4(b), is particularly noteworthy. The activation energies for diffusion (E_d) were determined to be 8.7 kcal mol^{-1} and 5.8 kcal mol^{-1} for SO_2 and NO, in that order, while those for permeation (E_p) were similar in both NO and SO_2. This reflects the difference in the gas-permeation property between SO_2 and NO. The longer time needed to reach the steady-permeation rate for SO_2 and the more rapid decrease of it with an increase in the temperature are interpreted in terms of the magnitude of D and E_d.

In conclusion, the permeation membrane device using silicone-rubber and TFE Teflon membranes shows excellent performance characteristics in the preparation of dilute standard gas mixtures. The stable and reproducible permeation rates for long periods of time are useful for the examination of the changes in the concentration of the standard gases in cylinders with time. An important characteristics of the device is that the permeation rate, *i.e.*, the concentration of the gaseous pollutants in the mixture, can easily be changed by changing the gas pressure. The calibration line and/or curve of air-monitoring instruments can be obtained more easily and rapidly than with conventional calibration devices. The use of a gas pressure lower than 76 cmHg enables us to apply the device to such condensable gases as SO_2, NO_2, H_2S, NH_3, and so on, which are not suitable for study with the commercial permeation device because of their liquefaction at 2—5 atmospheric pressures. In addition, a portable type of permeation device is expensive to fabricate. The present device consists of only a cell including a membrane whose gas-permeation rates have been measured, a simple constant-temperature oven (the precision in control is about 0.3 °C because of the small values of E_p), a flow-rate controller for a diluent gas, a pressure gauge for a pollutant gas, and a vacuum pump.

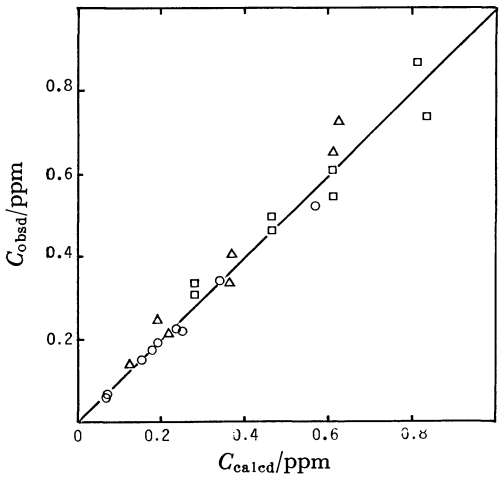

Fig. 4. Comparison of C_{calcd} with C_{obsd} for SO_2-Teflon at temperatures of 30.0 °C (○), 45.0 °C (△), and 55.0 °C (□).

Chemical Reaction of Electron Donor-Acceptor System: Reaction Mechanism of the Tricyanovinylation Reaction of *N,N*-Dimethylaniline with Tetracyanoethylene

Takashi Nogami,* Yoshio Nakano, Yoshiki Hasegawa,
Yasuhiko Shirota, and Hiroshi Mikawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received August 28, 1978)

The decay of the charge-transfer (CT) absorption band in the tricyanovinylation reaction of *N,N*-dimethylaniline (DMA) with tetracyanoethylene (TCNE) in 1,2-dichloroethane was followed by the electronic absorption measurement. Primary hydrogen isotope effect was observed for the decay of the CT-band in line with the mechanism:

$$[D + A \rightleftharpoons DA] \longrightarrow I$$
$$I + D \longrightarrow NA$$
$$NA + D \xrightarrow[\text{slow}]{} P$$

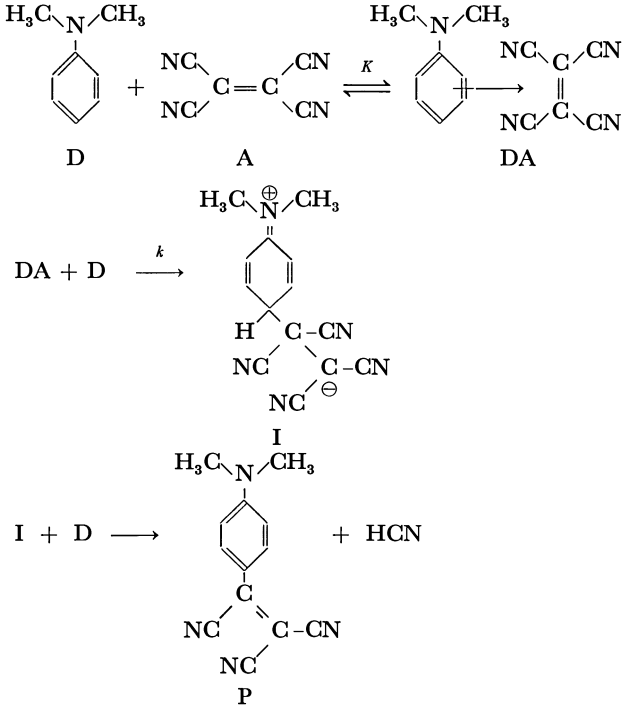
D: DMA; A: TCNE; DA: CT-complex; I: zwitterionic intermediate; NA: *p*-(1,1,2,2-tetracyanoethyl)-*N,N*-dimethylaniline; P: *p*-tricyanovinyl-*N,N*-dimethylaniline.

The tricyanovinylation reaction of several aromatic amines with tetracyanoethylene (TCNE) is a typical thermal reaction involving the formation of a charge-transfer (CT) complex.[1] The reaction proceeds in two steps, (1) formation of an accumulating intermediate, and (2) slow formation of the final product. Because of the large difference in reaction rate, the steps can be followed independently by an electronic absorption measurement. Rappoport measured the decay of the CT-absorption band for the *N,N*-dimethylaniline (DMA)–TCNE system in chloroform, and found that the pseudo first order rate constant for the decay of the CT-complex (k_{obsd}) obeys the relation

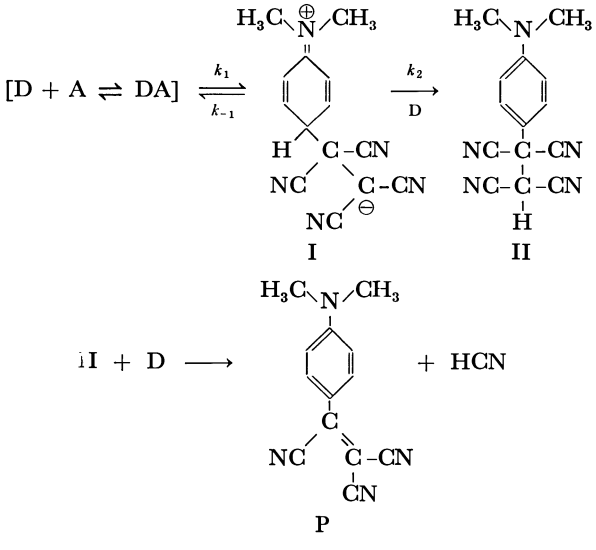
$$k_{obsd} = \frac{kK[D]^2}{1+K[D]}. \quad (1)$$ [2)]

Here, k, K, and $[D]$ denote the second order rate constant for transformation from the CT-complex into a zwitterionic intermediate (I), the association constant for the formation of the CT-complex, and the initial donor concentration, respectively. The following reaction (Scheme 1) has been proposed to explain the above kinetic result, which involves the bimolecular reaction of the CT-complex with another free donor (amine) molecule to give I.

The mechanism proposed by Rappoport indicates that the CT-complex is a true intermediate in the reaction. However, it is generally recognized that kinetic data alone cannot tell whether the CT-complex is a true intermediate in chemical reactions involving the formation of the CT-complex, *e.g.*, Diels-Alder and [2+2] cycloaddition reactions.[3] From the viewpoint that this may be the case also for the tricyanovinylation reaction of aromatic amines, we have proposed an alternative mechanism (Scheme 2) which can also explain the above kinetic data.[1,4] Either the monomolecular transformation of the CT-complex or the bimolecular reaction between the free donor and acceptor molecules produces a zwitterionic intermediate (I) which reversibly returns to either the CT-complex or the component molecules,[5] and then an accumulat-



Scheme 1.



Scheme 2.

ing intermediate, *p*-(1,1,2,2-tetracyanoethyl)-*N,N*-dimethylaniline (II) (neutral adduct), is produced.[7] The formation of II is induced by the deprotonation of I with another amine (donor) molecules, followed by back proton transfer from the quarternary amine to carbanion resulting from I. The neutral adduct (II, NA) then turns gradually to the final tricyanovinylated product by another free-amine catalysed dehydrocyanation.

The kinetic result alone cannot distinguish whether the CT-complex is a true intermediate in the reaction.[11] The decay of the CT-complex following the mechanism (Scheme 2) is expressed by Eqs. 2 and 3, which are kinetically indistinguishable from each other.

$$[DA] = [DA]_0 \exp(-k_{obsd}t)$$

In the case of unimolecular transformation of the CT-complex:[12]

$$k_{obsd} = \frac{(k_1k_2/k_{-1})K[D]^2}{1+K[D]} \quad (2)$$

In the case of bimolecular reaction between free donor and acceptor molecules:[12]

$$k_{obsd} = \frac{(k_1'k_2/k_{-1}'K)K[D]^2}{1+K[D]} \quad (3)$$

In order to confirm which of Schemes 1 and 2 is more reasonable, we have carried out the measurement of the kinetic hydrogen isotope effect on the decay of the CT-complex for the DMA–TCNE and 4-deuterio-*N,N*-dimethylaniline (*d*-DMA)–TCNE systems in 1,2-dichloroethane. No primary hydrogen isotope effect will be observed for the mechanism shown in Scheme 1, since the decay process of the CT-complex involves only the exchange reaction of a complexed amine with a free amine, although a slight secondary hydrogen isotope effect might be observed. On the other hand, the primary hydrogen isotope effect will be observed for the mechanism shown in Scheme 2, since k_{obsd} involves the rate constant k_2 for the C–H and C–D bond breaking process.

Experimental

4-Deuterio-*N,N*-dimethylaniline (*d*-DMA) was synthesized according to the methods reported.[13] Purification of samples and solvents and the experimental procedures are described in a previous paper.[1]

Results and Discussion

Decay Kinetics of the CT-Band. The decay of the CT-absorption band at 675 nm was followed at 30, 35, and 40 °C for the DMA–TCNE and *d*-DMA–TCNE systems in 1,2-dichloroethane with a donor concentration much greater than that of TCNE. The measurement was made by varying the concentration of the donor (DMA and *d*-DMA), keeping that of TCNE constant. The plot of log I_{CT} (I_{CT}: absorbance of the CT-band at 675 nm) against time gave a straight line for each run. This shows that the decay of the CT-complex is of first order with respect to the concentration of the CT-complex. Typical plots of log I_{CT} against time for both DMA–TCNE and *d*-DMA–TCNE systems are shown in Fig. 1. A marked hydrogen isotope effect is observed for the decay of the CT-complex. The association constant for the formation of the CT-complex was obtained from the extrapolation of the decay of the CT-complex to time zero in order to get a Benesi-Hildebrand plot by the least squares method.[14] As expected from Eq. 1 for Scheme 1 or Eq. 2 or 3 for Scheme 2, the plot of $k_{obsd}(1+K[D])/[D]$ against $K[D]$ should give a straight line. Figures 2 and 3 show the plots of $k_{obsd}(1+K[D])/[D]$ against $K[D]$ by means of the least squares method for the DMA–TCNE and *d*-DMA–TCNE systems, respectively, both of which show a linear relation. The plots show two characteristics, *i.e.*, (1) a kinetic hydrogen isotope effect exists for the decay of the CT-complex as is evident from the marked decrease in the slope of the straight line in the *d*-DMA–TCNE system as compared with the DMA–TCNE system; (2) the plots do not pass through the origin, but have definite positive intercepts.

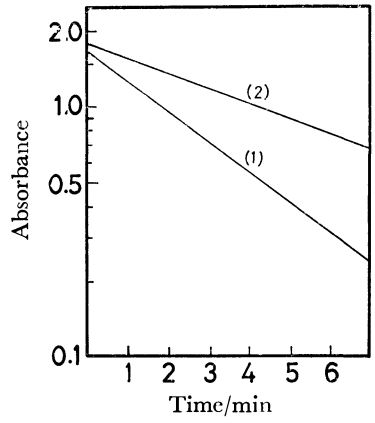


Fig. 1. The plot of log I_{CT} against t.
(1) DMA–TCNE system. [DMA]=0.2 M, [TCNE]=9.75×10^{-4} M. (2) *d*-DMA–TCNE system. [*d*-DMA]=0.2 M, [TCNE]=1.011×10^{-3} M.

Primary Hydrogen Isotope Effect. The slopes of the linear plots in Figs. 2 and 3 give the values of k (for Scheme 1) or k_1k_2/k_{-1} (for Scheme 2, in the case of monomolecular transformation of the CT-complex; hereafter, discussion will be made simply in terms of this mechanism for the sake of convenience). The ratio of the slopes of the straight lines (denoted by s^H/s^D)[15] in Figs. 2 and 3 is expressed as Eqs. 4 and 5 for the mechanism shown in Schemes 1 and 2, respectively. Since the substitution of hydrogen by deuterium at the *para*-position of DMA is assumed to give a minor effect on the rate constants k_1 and k_{-1} for the mechanism shown in Scheme 2, Eq. 5 can be approximated as Eq. 6.

$$s^H/s^D = k^H/k^D \quad \text{for Scheme 1} \quad (4)$$

$$s^H/s^D = (k_1^Hk_2^Hk_{-1}^D/k_1^Dk_2^Dk_{-1}^H) \quad \text{for Scheme 2} \quad (5)$$

$$s^H/s^D \approx k_2^H/k_2^D \quad \text{for Scheme 2} \quad (6)$$

The values of s^H/s^D obtained from Figs. 2 and 3 are 3.35, 3.32, and 3.17 at 30, 35, and 40 °C, respectively, showing a large kinetic hydrogen isotope effect. The Arrhenius plot for the observed s^H/s^D values gave an activation energy of about 1.04 kcal/mol,

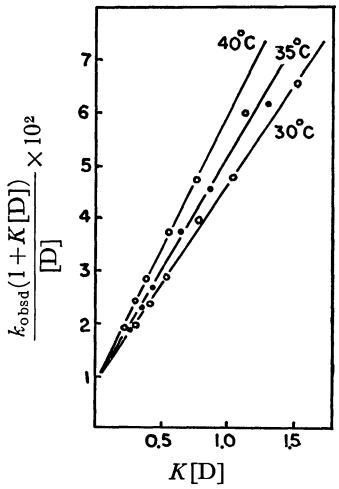

Fig. 2. The plot of $k_{obsd}(1+K[D])/[D]$ against $K[D]$ in DMA–TCNE system in 1,2-dichloroethane measured at the temperatures indicated. [TCNE]$=9.75\times10^{-4}$ M.

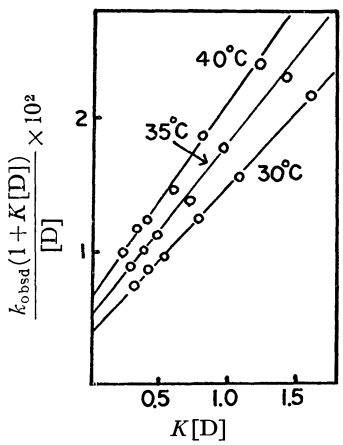

Fig. 3. The plot of $k_{obsd}(1+K[D])/[D]$ against $K[D]$ in *d*-DMA–TCNE system in 1,2-dichloroethane measured at the temperatures indicated. [TCNE]$=1.011\times10^{-3}$ M.

which is roughly equal to the zero point energy difference between the C–H and C–D stretching vibrations. The results are attributed to the primary hydrogen isotope effect. They can be explained more satisfactorily in terms of Scheme 2, since s^H/s^D roughly represents k_2^H/k_2^D,[15] the ratio of the rate constants for the C–H and C–D bond breakage.[16]

On the Positive Intercept of the Linear Plot of $k_{obsd}(1+K[D])/[D]$ *against* $K[D]$. The fact that the linear plot of $k_{obsd}(1+K[D])/[D]$ against $K[D]$ has an intercept has not so far been discussed as regards reaction mechanism. Experimental results show that the plots have negative intercepts for *e.g.*, the indole–TCNE system in dichloromethane,[17] and DMA–TCNE system in dichloromethane.[18] The present study of the DMA–TCNE system in 1,2-dichloroethane gives definite values of positive intercepts (Figs. 2 and 3), indicating that k_{obsd} is more rigorously given by Eq. 7. The k_3 term in Eq. 7 will probably arise from the following reactions: (1) the formation of unknown species X from the initial equilibrium between the CT-complex and free donor and acceptor molecules, (2) the monomolecular reaction of I to give probably NA and/or another unknown species X (Scheme 3).

$$[D + A \rightleftharpoons DA] \xrightarrow{(1)} X \qquad [D + A \rightleftharpoons DA] \xrightarrow{(2)} I \longrightarrow NA$$

$$k_{obsd} = \frac{(k_1/k_{-1})K[D]}{1+K[D]}(k_2[D]+k_3) \tag{7}$$

Scheme 3. Conceivable reactions which contribute to the k_3 term in Eq. 7.

Table 1 gives the values of k_{obsd} obtained from Fig. 1 (three plots are chosen for the sake of simplicity), and $(k_1k_2/k_{-1})K[D]^2/(1+K[D])$ (denoted by $k_{obsd(bi)}$) calculated by using the values of the slopes of the linear plots in Figs. 2 and 3. Calculation using the values of intercepts of the linear plots in Figs. 2 and 3, or substraction of $k_{obsd(bi)}$ from k_{obsd} will give $(k_1k_3/k_{-1})K[D]/(1+K[D])$ (denoted by $k_{obsd(mono)}$). It should be noted that the values of the intercepts are much less reliable than those of the slopes in Figs. 2 and 3; the values of $k_{obsd(mono)}$ are much less reliable than those of $k_{obsd(bi)}$.[19] Although no quantitative discussion on the k_3 process can be made, it is shown that the k_3 process contributes significantly under the reaction conditions of a low donor concentration ($[D]\approx0.06$ mol dm^{-3} with constant [TCNE]$\approx10^{-3}$ mol dm^{-3}). Under the reaction conditions of a high donor concentration ($[D]>0.1$ mol dm^{-3} with constant [TCNE]$\approx10^{-3}$ mol dm^{-3}), however, the contribution of the k_2 process is dominant as shown in the values of $k_{obsd(bi)}/k_{obsd}$ in Table 1, the main reaction mechanism being explained in terms of the mechanism shown in Scheme 2.

Summary. The primary kinetic hydrogen isotope effect observed for the decay of the CT-complex in the tricyanovinylation reaction of the DMA–TCNE system in 1,2-dichloroethane is explained by Scheme 2.

We are grateful to Dr. Takashi Ando, The Institute of Scientific and Industrial Research, Osaka University, for his helpful discussion.

19) A small variation in the values of the slopes yields a large variation in the values of intercepts. This arises from the fact that the values of $k_{obsd(bi)}$ are much greater than those of $k_{obsd(mono)}$.

Magnetic and Spectral Properties of Binuclear Nickel(II) Nitrato and Acetato Complexes of Tridentate Schiff Bases Derived from Salicylaldehydes and *N*-Substituted Trimethylenediamines

Tadashi Tokii, Shuji Emori, and Yoneichiro Muto*

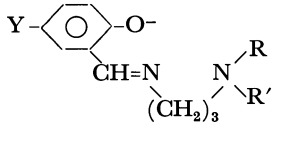
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received November 28, 1978)

A new series of binuclear Ni(II) complexes with the empirical formula Ni(5-Y-sal·pr·NRR′)X has been prepared by the reaction of the parent complexes, Ni(5-Y-sal·pr·NRR′)$_2$ with metal salts NiX_2, where 5-Y-sal·pr·NRR′=Schiff base ligand derived from 5-substituted salicylaldehyde and *N*-substituted trimethylenediamine, R=H or CH_3, R′=CH_3, Y=H or Cl and X=NO_3 or CH_3COO. The nature of the complexes has been confirmed to be dimeric on the basis of the results of molecular weight, magnetic and spectral measurements. The values of exchange integral, $J=-10$——15 cm^{-1}, have been evaluated for the Ni(II) complexes from their temperature dependences of magnetic susceptibilities. The antiferromagnetic property has been discussed in terms of structural considerations. For comparison, the corresponding Cu(II) complexes Cu(5-Y-sal·pr·NRR′)X have been prepared and investigated.

Although a large number of phenolic oxygen-bridged binuclear Cu(II) complexes with *N*-substituted salicylideneaminato ligands have been synthesized and characterized,[1,2] relatively few Ni(II) complexes analogous to the Cu(II) complexes have been prepared, the work of Butcher and Sinn[3] represents an attempt at investigation; the Ni(II) complexes are represented by the formula [Ni(bsb)NO_3·C_2H_5OH]$_2$, where bsb represents a bidentate Schiff base.

In a previous paper,[4] it was reported that bis[*N*-(3-dimethylaminopropyl)salicylideneaminato]copper(II), Cu(Sal·pr·NMe_2)$_2$, reacts with copper(II) chloride to yield a binuclear complex with the formula [Cu(Sal·pr·NMe_2)Cl]$_2$ in which the phenolic oxygen atoms act as bridges and each of the two organic ligands is tridentately coordinated to a single metal ion. Attempts to prepare the corresponding Ni(II) complex, [Ni(Sal·pr·NMe_2)Cl]$_2$, however, were unsuccessful. Six complexes with the stoichiometry of Ni(5-Y-sal·pr·NRR′)X, where X=NO_3 or CH_3COO and 5-Y-sal·pr·NRR′ represents the tridentate salicylideneaminato ligand of the general formula, have now been isolated



Abbreviation:
Sal·pr·NHMe; R=H, R′=CH_3, Y=H
Sal·pr·NMe_2; R=R′=CH_3, Y=H
5-Cl-sal·pr·NHMe; R=H, R′=CH_3, Y=Cl
5-Cl-sal·pr·NMe_2; R=R′=CH_3, Y=Cl

The dimeric octahedral structure has been established by comparing the IR and electronic reflectance spectra, molecular weights, and magnetic susceptibilities with those of the corresponding Cu(II) complexes, Cu(5-Y-sal·pr·NRR′)X, which have been prepared in the present study and confirmed to be monomeric. It is noteworthy that the Ni(II) complexes exhibit antiferromagnetism in contrast to [Ni(bsb)NO_3·C_2H_5OH]$_2$ which shows intramolecular ferromagnetic interaction.[3]

The results of characterization studies on the newly prepared complexes will be reported and the differences in magnetic properties between Ni(5-Y-sal·pr·NRR′)X and [Ni(bsb)NO_3·C_2H_5OH]$_2$ will be discussed from structural considerations.

Experimental

Syntheses. Ni(5-Y-sal·pr·NRR′)NO_3 Complexes: A typical synthetic method is as follows. A solution of Ni$(NO_3)_2$·$6H_2O$ (11 mmol) in ethanol (50 ml) was added to a solution of one of the parent Ni(5-Y-sal·pr·NRR′)$_2$ complexes (10 mmol) in ethanol (100 ml), and the mixture was stirred on a hot plate for 1/2 h. The green crystals thus precipitated were collected, washed repeatedly with ethanol and dried.

Ni(5-Y-sal·pr·NHMe)CH_3COO Complexes: A solution of Ni$(CH_3COO)_2$·$4H_2O$ (11 mmol) in ethanol (50 ml) was added to one of the parent Ni(5-Y-sal·pr·NHMe)$_2$ complexes (10 mmol) suspended in chloroform (50 ml). The solution was stirred at *ca.* 50 °C for 1/2 h and concentrated to one-third of the volume. After the solution had been allowed to stand overnight at *ca.* 5 °C in a freezer, the separated green crystals were collected and washed twice with a small quantity of ethanol and once with ether.

Cu(Sal·pr·NMe_2)NO_3 Complex: This complex was prepared by the reaction of Cu(Sal·pr·NMe_2)$_2$ and Cu$(NO_3)_2$·$3H_2O$ using the same procedure as for Ni(5-Y-sal·pr·NRR′)-NO_3 complexes. The purification was made by recrystallization from ethanol.

Cu(5-Y-sal·pr·NHMe)X Complexes: A solution of CuX_2·nH_2O (11 mmol) in ethanol (50 ml) was added to a mixture of bis(5-substituted salicylaldehydato)copper(II) (10 mmol) and *N*-methyl-1,3-propanediamine (20 mmol) in ethanol (50 ml). The solution was stirred at *ca.* 70 °C for 1/2 h and concentrated to one half of the volume. After the solution had been allowed to stand overnight at *ca.* 5 °C in a freezer, the separated green crystals were collected and recrystallized from ethanol.

The elemental analyses for the new compounds are summarized in Table 1.

Physical Measurements. The molecular weights of the complexes **5**—**9** listed in Table 1 were determined osmometrically with a Hitachi Molecular Weight Apparatus 117, the results of which are given in Table 2. Magnetic susceptibilities of all the complexes **1**—**10** were determined by the Gouy method in the temperature range 80—300 K. For complex **2**, the susceptibilities in the temperature range 4.2—80 K were determined by the Faraday method. Effective magnetic moments were calculated from the equation:

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N_\alpha)\cdot T} \qquad (1)$$

where χ_A is the molar magnetic susceptibility corrected for the diamagnetism of the constituted atoms using Pascal's

a) The value was evaluated from the magnetic susceptibility data in the temperature range 4.2−300 K (*cf.* text).

constant[5] and N_α is the temperature-independent paramagnetism per gram-ion of Ni(II) or Cu(II). The N_α value of 200×10^{-6} and 60×10^{-6} cgs, emu were assumed for Ni(II)[6] and Cu(II),[7] respectively, and a set of the results is given in Table 3. The reflectance spectra were recorded with a Hitachi Recording Spectrophotometer 323. IR spectral measurements were made with a Hitachi EPI-G2 IR Spectrophotometer in the 400—4000 cm^{-1} region using Nujol mulls.

Results and Discussion

Molecular Weights. Molecular Weight measurements of the Ni(II) acetato complexes **5** and **6** listed in Table 1 were made osmometrically in chloroform, the results of which are given in Table 2. The molecular weights were found to be twice the empirical formula of Ni(5-Y-sal·pr·NHMe)CH_3COO, indicating the presence of a dimeric structure. The low solubility of the Ni(II) nitrato complexes **1**—**4** in chloroform or any other conventional solvents, however, did not allow an accurate determination of the molecular weights. The molecular weight determination for the Cu(II) complexes **7**—**9** showed the compounds to be monomeric (*cf.* Table 2).

Magnetic Susceptibilities. The magnetic susceptibilities of the complexes **1**—**10** were determined over the temperature range 80—300 K. The susceptibility data for complexes **1** and **3**—**10** are shown in Figs. 1 and 2 as plots of the reciprocal susceptibility corrected for diamagnetic contribution and temperature-independent magnetism, $(\chi_A-N_\alpha)^{-1}$, *vs.* temperature, T. The data for complex **2** in Fig. 3 is shown as a χ_A *vs.* T plot.

In the temperature range 80—300 K, the susceptibilities of the Ni(II) complexes **1**—**6** follow the Curie-Weiss law. The Curie (C) and Weiss constants (θ) have been evaluated from the slopes of $(\chi_A-N_\alpha)^{-1}$ *vs.* T plots, and the g values calculated from the

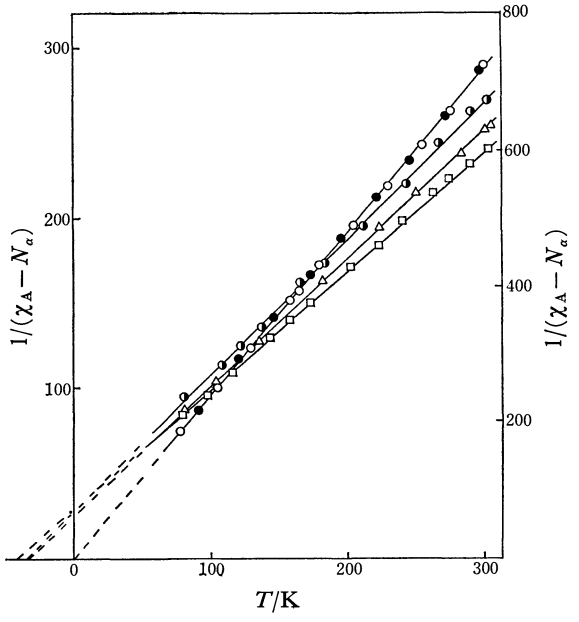

Fig. 1. Variation of magnetic susceptibilities with temperature. Left-hand scale: (◑) Ni(Sal·pr·NHMe)NO_3, (□) Ni(5-Cl-sal·pr·NHMe)NO_3, (△) Ni(5-Cl-sal·pr·NHMe$_2$)NO_3. Right-hand scale: (○) Cu(Sal·pr·NHMe)NO_3 (●) Cu(Sal·pr·NMe$_2$)NO_3.

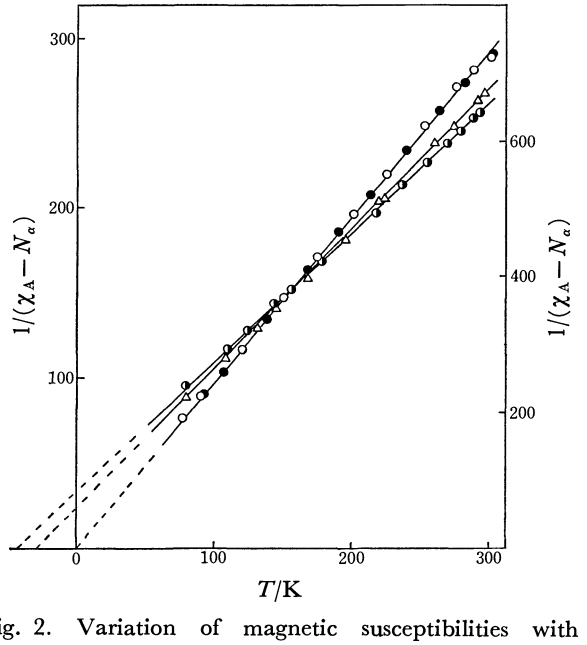

Fig. 2. Variation of magnetic susceptibilities with temperature. Left-hand scale: (△) Ni(Sal·pr·NHMe)CH_3COO, (◑) Ni(5-Cl-sal·pr·NHMe)CH_3COO. Right-hand scale: (○) Cu(Sal·pr·NHMe)CH_3COO, (●) Cu(5-Cl-sal·pr·NHMe)CH_3COO.

Curie constants using the relationship $C=N\beta^2g^2[S(S+1)]/3k$ where $S=1$; the results are listed in Table 3. The negative values of the observed Weiss constants (*ca.* −30——50 K) are indicative of the presence of antiferromagnetic coupling in the Ni(II) complexes. In order to obtain further information about the magnetic interaction, the magnetic susceptibility measurement has been extended for complex **2** from the temperature of liquid nitrogen to that of liquid helium. As can be seen in Fig. 3, the susceptibility χ_A increases with decreasing temperature until a maximum in χ_A is reached at 27 K. At temperatures below 27 K χ_A decreases markedly with decreasing temperature. It has been found that the susceptibility data could be fitted to the susceptibility equation for a Ni(II) dimer:[8]

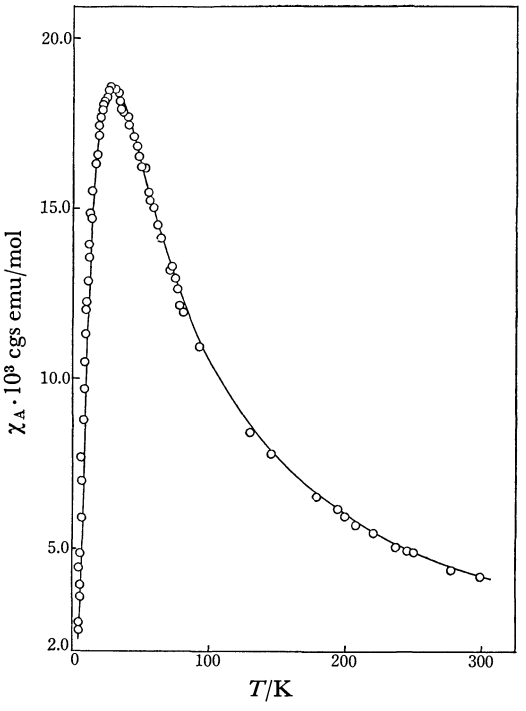

Fig. 3. Observed and calculated magnetic susceptibilities of Ni(Sal·pr·NMe$_2$)NO_3: ○, experimental; solid line, calculated by Eq. 2 (*cf.* text).

$$\chi_A = \frac{N\beta^2g^2}{kT}\left[\frac{5+\exp(-4J/kT)}{5+3\exp(-4J/kT)+\exp(-6J/kT)}\right] + N_\alpha \quad (2)$$

where J is exchange integral. The values of $J=-9.6$ cm^{-1} and $g=2.27$ have been evaluated from the best fit of the experimental data to Eq. 2, assuming $N_\alpha = 200\times10^{-6}$ cgs emu.[6] The solid line in Fig. 3 represents the susceptibility curve calculated using the parameters. The value of g agrees well with the experimental value of 2.28 determined from the $(\chi_A-N_\alpha)^{-1}$ *vs.* T plot in the temperature range 80—300 K (*cf.* Table 3). The magnetic behavior with a negative J value indicates the presence of antiferromagnetic spin coupling between the Ni(II) ions in the dimeric unit of [Ni(Sal·pr·NMe$_2$)NO_3]$_2$. For the other Ni(II) complexes **1** and **3**—**6**, the 80—300 K data gave a good fit to the theoretical curve based on Eq. 2 when the following values were used: the g value evaluated from the $(\chi_A-N_\alpha)^{-1}$ *vs.* T plot, the N_α of 200×10^{-6} cgs emu and the J value listed in Table 3.

The close agreement between the observed and calculated temperature dependences of magnetic susceptibility can be taken as evidence for the presence of a binuclear structure in the Ni(II) complexes.

The susceptibility data of the Cu(II) complexes **7**—**10** follow the Curie law as is seen in Figs. 1 and 2, indicating magnetic dilution in the crystals. Con-

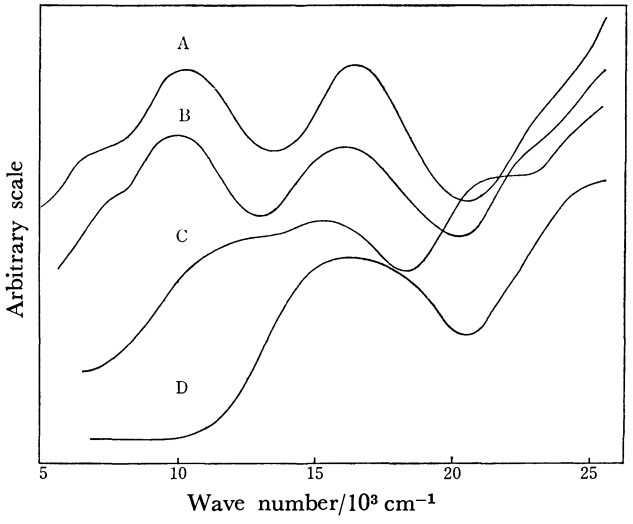

Fig. 4. Reflectance spectra of Ni(Sal·pr·NHMe)NO_3 (A), Ni(Sal·pr·NHMe)CH_3COO (B), Cu(Sal·pr·NHMe)NO_3 (C) and Cu(Sal·pr·NHMe)CH_3COO (D).

sequently in contrast to the Ni(II) complexes, the Cu(II) complexes are considered to be mononuclear.

Diffuse Reflectance Spectra. The present complexes give rise to several bands in the 5000—25000 cm^{-1} region in the diffuse reflectance spectra. The wave numbers of the band maxima are given in Table 4 and the spectral curves for complexes **1**, **5**, **7**, and **9** are shown in Fig. 4.

The Ni(II) complexes investigated all show essentially the same spectral characteristics, two well resolved maxima at *ca.* 16000 and 10000 cm^{-1} with a shoulder at *ca.* 8000 cm^{-1} (*cf.* Table 4 and Fig. 4). This type of spectra is similar to those of the distorted octahedral Ni(II) complexes,[9,10] but quite different from those of the four- or five-coordinated Ni(II) complexes.[11,12] The spectra of the Cu(II) complexes **7** and **8** show a broad band at *ca.* 15500 cm^{-1} with a shoulder at *ca.* 12500 cm^{-1} (*cf.* Table 4 and Fig. 4). This type of spectra is indicative of a five-coordination geometry around the Cu(II) ion and is to be compared with the spectra reported for some distorted square-pyramidal Cu(II) complexes.[4,13,14] The spectral feature of the Cu(II) complexes **9** and **10** is apparently that of a square planar type (*cf.* Fig. 4).

IR Spectra. The wave number of the intense band around 1540 cm^{-1} observed for complexes **1**—**10** are listed in Table 4. For all the Ni(II) complexes studied (**1**—**6**), the absorption energy of the IR band around 1540 cm^{-1} was observed to shift towards higher energies by 15—20 cm^{-1} as compared with that of the corresponding parent bis-complexes Ni(5-Y-sal·pr·NRR′)$_2$, indicating the presence of bridging phenolic oxygen atoms in the nitrato and acetato complexes (*cf.* Table 4).[1-4] No significant band shift was observed for the Cu(II) complex **8**, however, indicating that, in this complex, no phenolic oxygen-bridge exists (*cf.* Table 4). The strong band around 1540 cm^{-1} for each of the Cu(II) complexes **7**,**9**, and **10** also indicates the non-existence of any bridging phenolic oxygen in these complexes.

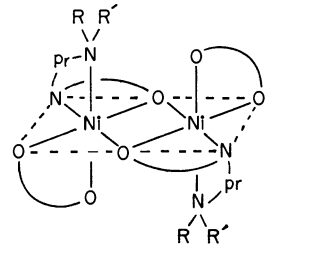
For the Ni(II) acetato complexes **5** and **6** and the Cu(II) acetato complexes **9** and **10**, the assignment of the IR bands due to the antisymmetric ($\bar{\nu}_{as}CO_2$) and symmetric ($\bar{\nu}_{s}CO_2$) carboxylate stretching vibrations has been made by comparing the bands of the complexes with those of the parent bis-complexes and the corresponding nitrato complexes; the wave numbers are listed in Table 4 together with the separation (Δ_{as-s}) between $\bar{\nu}_{as}CO_2$ and $\bar{\nu}_{s}CO_2$. The correlation between the carboxylate stretching frequencies and structure in Ni(II) acetato complexes has been well established by Curtis.[15] A comparison of the frequencies of $\bar{\nu}_{as}CO_2$, $\bar{\nu}_{s}CO_2$, and Δ_{as-s} for the acetato complexes in this study with those for the Ni(II) acetato complexes of known structure may yield information on the carboxylate coordination in the complexes **5** and **6**. The Ni(II) complexes exhibit $\bar{\nu}_{as}CO_2$ and $\bar{\nu}_{s}CO_2$ bands in an energy region very similar to that reported for the [Ni(tet)CH_3COO]-$ClO_4\cdot 1/2H_2O$ complex ($\bar{\nu}_{as}CO_2$ 1550 cm^{-1}, $\bar{\nu}_{s}CO_2$ 1448 cm^{-1}, Δ_{as-s} 102 cm^{-1}, tet=*dl*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane),[15] in which the acetato group is coordinated in a symmetrical chelating mode to the metal ion,[16] and also similar to those reported for the [Ni(en)$_2CH_3COO$] ClO_4 com-

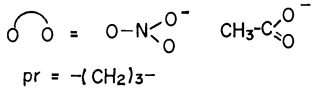
plex ($\tilde{\nu}_{as}CO_2$ 1540 cm^{-1}, $\tilde{\nu}_{s}CO_2$ 1445 cm^{-1}, Δ_{as-s} 95 cm^{-1})[15] and the $[Ni(1,3\text{-pr})_2CH_3COO]ClO_4$ complex ($\tilde{\nu}_{as}CO_2$ 1540 cm^{-1}, $\tilde{\nu}_{s}CO_2$ 1450 cm^{-1}, Δ_{as-s} 90 cm^{-1}),[15] for both of which a symmetrical chelation of the acetato group has been assigned.[15] Thus the close similarity in absorption energy between these complexes leads to the conclusion that the carboxylate coordination mode in the Ni(II) acetato complexes in the present study is of a symmetrical chelating type.

In the case of the Cu(II) acetato complexes **9** and **10**, the $\tilde{\nu}_{as}CO_2$ and $\tilde{\nu}_{s}CO_2$ bands appear at higher and lower frequencies respectively than those of the ionic acetato ($\tilde{\nu}_{as}CO_2$ 1578 cm^{-1}, $\tilde{\nu}_{s}CO_2$ 1414 cm^{-1})[17] (*cf.* Table 4), indicating the presence of unidentate coordination of the acetato group in the complexes.[18] The unidentate coordination is consistent with their reflectance spectra showing a four-coordinated planar Cu(II) geometry.

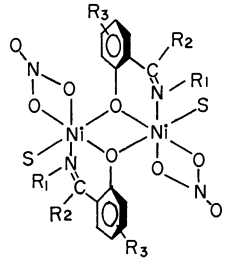
For the nitrato coordination in the Ni(II) nitrato complexes **1**—**4**, no unambiguous assignment could be drawn from the IR spectra, since the 1200—1500 cm^{-1} region was so complicated that no NO stretching bands of the nitrato group could be recognized. The reflectance spectral feature of the complexes is very similar to those of the corresponding acetato complexes indicating a six-coordinated Ni(II) geometry and thus the nitrato coordination mode is considered to be of the symmetrical chelating type. Similarly, the nitrato coordination mode in the Cu(II) nitrato complexes **7** and **8** is presumably a symmetrical chelating type based on the reflectance spectra which show a five-coordinated Cu(II) geometry.

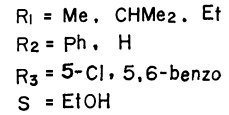
Structure and Magnetic Properties. On the basis of the molecular weight, magnetic and spectral data, the most probable structure for the present Ni(II) complexes **1**—**6** is considered to be I in which the phenolic oxygen atoms act as bridges between the two metal ions and the tridentate ligand 5-Y-sal·pr·NRR′ spans facially due to the long $-(CH_2)_3-$ chain in a manner similar to that in the $Ni(Sal\cdot pr\cdot NMe_2)_2$ complex.[19]





I





II

Structure I should be compared with that of the $[Ni(bsb)NO_3\cdot C_2H_5OH]_2$ complexes which display intramolecular ferromagnetic interaction,[3] the structure of which is shown schematically in II.[3] The most significant difference in structure between I and II is the bonding mode around the bridging phenolic oxygen atoms. As is seen from I and II, the phenolic

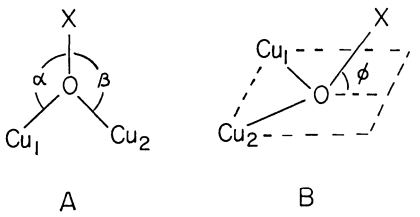


Fig. 5. Geometries around the atom bridging metal ions in phenolic oxygen-bridged binuclear copper(II) complexes.

C–O bonds in the former are coplanar with the plane of the four membered Ni_2O_2 ring due to the chelation of the 5-Y-sal·pr·NRR′ ligand with the phenolic oxygen and azomethine nitrogen atoms at the base of a distorted octahedron, whereas the C–O bonds in the latter are approximately perpendicular to the Ni_2O_2 plane, since the phenolic oxygen atom of the bsb ligand occupies one corner of the basal plane and thus the azomethine nitrogen atom takes one of the axial positions.

In previous papers,[20,21] it was reported that, in binuclear Cu(II) complexes with tridentate salicylaldehyde Schiff bases, the geometry around the atom bridging metal ions is one of the most important factors determining the strength and sign of the magnetic interaction. The structural factors which promote the antiferromagnetic interaction in the complexes are those such as the equality of the angles α and β in Fig. 5A, and the size of the angle ϕ in Fig. 5B (*i.e.*, coplanarity of the O–X bonds with the Cu_1OCu_2O coordination plane, where X is the atom linked to the bridging O atom). These factors may bring about an increase in overlap of the non-orthogonal orbitals involved in the exchange pathways. Recently, Lintvedt *et al.*[22] noted the importance of the planarity of the bridging atom in binuclear Cu(II) complexes for magnetic interaction, and Curtis *et al.*[23] reported that the weak magnetic interaction in di-μ-[4,6,6-trimethyl-3,7-diazanon-3-ene-1,9-diolato(1—)-ONN′, μ-O′]-dicopper(II) diperchlorate ($\theta\approx-25$ K) can be attributed to the nonplanarity of the bridging atom.

From the above structural considerations, the difference in magnetic properties between $[Ni(5\text{-Y-sal}\cdot pr\cdot NRR')X]_2$ and $[Ni(bsb)NO_3\cdot C_2H_5OH]_2$ is attributable to the different bonding mode of the phenolic C–O bond in the complexes, although, as is the case of $[Ni_2(en)_4Cl_2]Cl_2$,[6] the possibility of the 90° cation-anion-cation type ferromagnetic superexchange interaction as discussed by Kanamori[24] and Goodenough[25] is not excluded since the Ni–O–Ni angle has not been reported in Ref. 3.

For the Cu(II) complexes in the present study, a monomeric five-coordinated structure can be assigned for the nitrato complexes **7** and **8**, and a monomeric square planar structure for the acetato complexes **9** and **10** on the basis of the molecular weight, magnetic, and spectral data. The weaker tendency of Cu(II) to form a six-coordinated complex, as compared with Ni(II), is probably the main factor for the metal to produce the monomeric species.

(Received December 12, 1978)

The adsorption of the chromate ion on cured diphenyl phosphonate–aldehyde resins has been investigated. Phosphorus-containing novolak type resins, obtained from the reaction of diphenyl phosphonate with aldehydes have been cured with additional hexamethylenetetramine. The adsorption of the chromate ion on the cured resins decreased in the order: propionaldehyde≈acrylaldehyde>butyraldehyde>crotonaldehyde>acetaldehyde>furfural>formaldehyde. The optimum pH for the adsorption of the chromate ion was in the range 3.0 to 4.0. In the case of the cured diphenyl phosphonate–propionaldehyde resin, the amount of the adsorption of the chromate ion was 20.5 mg Cr/g resin. Under the same conditions, the amounts of the adsorption of molybdate and tungstate ions were 40.5 mg Mo/g resin and 80.0 mg W/g resin, respectively. The adsorbed chromate ion was recovered at approximately 80 wt% as chromium by elution with 1.0 mol/l aqueous HCl solution. The adsorbed molybdate and tungstate ions were desorbed with 2.0 and 3.0 mol/l aqueous H_2SO_4 solutions, respectively. The recovery rate for Mo and W was 100 wt%. The mechanism of adsorption of the chromate ion on the cured resins having phosphinylden groups, >P(O)H, has been discussed.

In a previous paper,[1] diphenyl phosphonate (abbreviated to DPP) was reported to react with several aldehydes, *e.g.*, formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, acrylaldehyde, crotonaldehyde and furfural to produce phosphorus-containing novolak type resins (abbreviated to DPP resin). The DPP resins were cured with additional hexamethylenetetramine at 120 to 180 °C to give insoluble resins containing phosphinylden groups, >P(O)H. In the present paper, it has been observed that the cured DPP resins selectively adsorbed Group VIB oxide ions, *e.g.*, chromate, dichromate, molybdate and tungstate ions.

The literature is extensive concerning ion exchange resins based upon organophosphorus polymers.[2–6] Organophosphorus resins have been prepared by the treatment of three-dimensional unsaturated aromatic hydrocarbon polymers with phosphorus trichloride in the presence of aluminum chloride, or by the treatment of polymers containing halogenated methyl groups with trialkyl phosphates, followed by oxidation and hydrolysis of the reaction products.[3] The phosphorus-containing ion exchange resins based on phenolic resins have also been prepared by condensing the product obtained from the reaction of *m*-hydroxyphenyl dihydrogenphosphate with formaldehyde.[4] In addition, the ion exchange resins prepared from styrene–divinylbenzene copolymers and phosphorus trichloride[6] are commercially available under the names of Duolite-62 and 63. The phosphorus-containing resins are three-dimensional high molecular weight compounds which contain free phosphonic acid [–P(O)$(OH)_2$] and phosphinic acid [>P(O)(OH)] groups. The active centers for ion exchange are the P–OH bonds and consequently the phosphorus-containing resins adsorb mainly metallic ions, behaving as cation exchangers. To date there are very few reports on phosphorus-containing anion exchangers.[7]

In this paper, the adsorption of chromate, molybdate and tungstate ions on cured DPP resins has been studied. The effect of pH on the adsorption of Group VIB oxide ions, the rate of adsorption, the amount of adsorption and elution of adsorbed Group VIB oxide ions have been examined. Furthermore, the mechanism of the adsorption of the chromate ion on the cured DPP resins has been discussed.

Experimental

Materials. All chemicals used for the preparation of the cured DPP resins were extra-pure grade reagents. Potassium chromate(GR) and dichromate(GR), potassium molybdate(GR) and potassium tungstate(GR) were used without further purification. Other chemicals used for colorimetric determination and preparation of buffer solutions were of analytical reagent-grade.

Preparation of the Cured DPP Resins. The cured DPP resins used for the adsorption were phosphorus-containing resins cured with additional hexamethylenetetramine.

DPP Resins: The phosphorus-containing novolak type resins have been prepared by a method described previously;[1] *i.e.*, DPP has been allowed to react with formaldehyde or acrylaldehyde in water at 80 °C for 3 h. Acetaldehyde, propionaldehyde, butyraldehyde and crotonaldehyde resins were prepared by the direct reaction of DPP with each aldehyde at 80 °C for 8 h. The furfural resin was produced at room temperature in 6 h.

Curing: The curing of the DPP resins was conducted by the method described previously;[1] *i.e.*, to the crude DPP resins, 10 to 15 wt% hexamethylenetetramine was added, and the mixture heated in an oil bath at 120—180 °C for 1 h to give the insoluble DPP resin. The optimum curing rates and temperatures are shown in Table 1. The products were washed with 3-pentanone, 1.0 mol/l aqueous HCl solution, and water to near the point of neutrality. The cured DPP resins were dried at 60 to 80 °C for 4 h, ground and milled to 100—150 mesh.

Procedure. The method for the adsorption of chromate, molybdate and tungstate ions was a batch type as follows; an amount of the cured DPP resin, 10—100 mg, and an aliquot of K_2CrO_4, K_2MoO_4, and K_2WO_4 solutions were added to a 100 cm^3 volumetric flask and diluted to 100 cm^3. The solutions were stirred at room temperature for 24 h. After removal of the resin, the concentrations of chromate, molybdate and tungstate ions were determined by colorimetric

Table 1. Properties of cured DPP-aldehydes resins

Compound R	Utmost curing rate wt%	Cured temp °C	P %	Amount of Cr to resin[a] mg/g	Resistance to 50 vol% H_2SO_4 Residual weight wt%

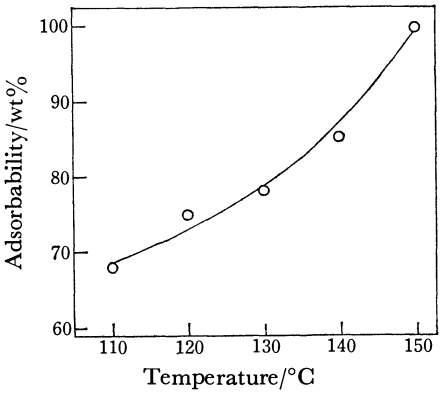

Fig. 2. Relation between adsorption of chromate ion and curing temperature. Conditions; resin: DPP-PA, curing time: 30 min, amount of hexamine: 20 wt%.

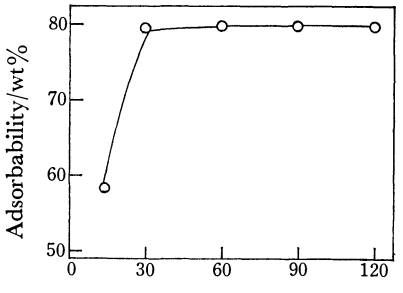

Fig. 3. Relation between adsorption of chromate ion and curing time. Conditions; resin: DPP-PA, curing temp: 120 °C, amount of hexamine: 20 wt%.

and atomic absorption. The rate of adsorption was calculated from the ratios of the concentration before and after the adsorption of each ion. The concentration of Cr(VI) was determined by the diphenylcarbazide method. The total Cr content was determined by atomic absorption. The concentrations of molybdate and tungstate ions were determined by tin(II) chloride and dithiol methods.[8]

Buffer Solution.[9] Sulfuric acid was added for the preparation of the solution bellow pH 2. The buffer solutions (pH 2.0—3.0) were prepared from chloroacetic acid and KOH, succinic acid and KOH (pH 3.0—7.0), and tris-(hydroxymethyl)methanamine and HCl (pH 7.0—9.0).

Measurements. The resin adsorbing chromate ion was washed with water, and dried under vacuum for 24 h. The IR and ESR spectra for the treated samples were recorded on JASCO IR-G, and JEOL-3BSX-ESR spectrometers.

Results and Discussion

Adsorption Characteristics of the Cured DPP Resins. For the seven DPP resins, cured at a temperature giving maximum curing, the adsorptions were conducted as follows; the cured DPP resins (100 mg) and K_2CrO_4 solution containing 1 mg Cr(VI) were added to a 100 cm^3 volumetric flask, the pH adjusted to 3.2 and then diluted to 100 cm^3. The rates of adsorption were calculated and the results are shown in Table 1. As may be seen the chromate ion is comparatively well adsorbed on the cured DPP–propionaldehyde and DPP–acrylaldehyde resins. The adsorption of the chromate ion on seven kinds of cured DPP resins decreased in the order, propionaldehyde resin≈acrylaldehyde resin > butyraldehyde resin > crotonaldehyde resin > acetaldehyde resin > furfural resin > formaldehyde resin. Therefore, subsequent adsorption experiments were conducted using the cured DPP–propionaldehyde resin (abbreviated to cured DPP–PA resin).

The Effect of Curing Conditions on the Degree of Adsorption. The DPP–PA resins have been cured under several conditions, *e.g.*, the amount of curing agent, the curing temperature and the curing time. The effect of each of the conditions on the degree of adsorption of the chromate ion has been examined. Figure
