The titration results at various pH values are shown in Fig. 3. A constant value was obtained in the pH range 4.5—10.5. For determination of the purity of LAS,

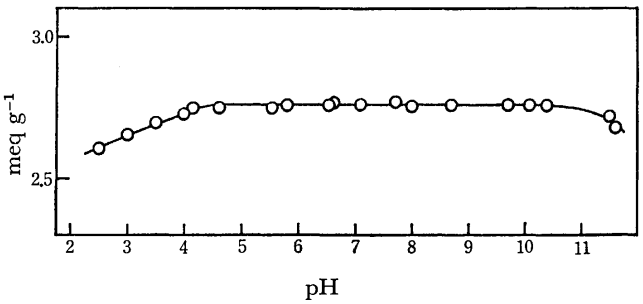

Fig. 3. Coloid titration results of LAS. Titrant: 1×10^{-3} N polysoap. Titrating solution: 2×10^{-4} N LAS.

the LAS solution can be used as it is because of its neutrality. Titration values of the standard LAS solution are given in Table 1. The concentration of LAS and polysoap is shown to have an effect on the titration value, when lower than 7.5×10^{-5} and 1.25×10^{-3} N respectively, the results becoming lower than the calculated value. Titration is impossible when the concentration of polysoap and LAS becomes higher than 10^{-2} and 10^{-3} N, respectively, since the solution becomes strongly turbid from the beginning of titration. The concentration of polysoap and LAS should be 2.5×10^{-3} and $1—7.5 \times 10^{-4}$ N, respectively.

Purity of LAS. The purity of samples was determined under the conditions described above with a 2.5×10^{-3} N polysoap solution. The results of the analysis of commercial LAS are given in Table 2. The

Table 2. Determination of the purity of LAS samples

Sample	LAS		Polysoap		LAS purity %
	concentration mg/ml	amount ml	normality $N \times 10^3$	amount ml[a]	
A	88.2/100	10.00	2.402	3.74±0.01	35.3
B_1	432.2/500	10.00	2.434	9.99±0.01	98.0

a) Average value of three determinations.

purity of Sample A, over twenty years old, was an abnormally low 35.3%. B_1 was an ultra pure reagent (Tokyo Kasei Kogyo Co., Ltd.). The others were of chemical pure grade, the purity being 81—84%.

Other Anionic Surfactants. As described in JIS K 0102-1974, sodium bis(2-ethylhexyl) sulfosuccinate (SSS) is used as a standard substance for the determination of anionic surfactants in water. SSS can also be titrated by the present method. The purity of SSS was found to be 95.7%. This is in line with the value 96.3% confirmed by the Japan Oil Chemists' Society.

On the other hand, the titration values of sodium dodecyl sulfate (LS) varied with the concentration of LS. The titration curve of sodium myristate show no clear end-point. These anionic surfactants can not form stable polyion complexes with polysoap.

A Synthetic Study of the Solid Solutions in the Systems $La_2(CO_3)_3 \cdot 8H_2O$-$Ce_2(CO_3)_3 \cdot 8H_2O$ and $La(OH)CO_3$-$Ce(OH)CO_3$

Hisanobu WAKITA* and Setsuko KINOSHITA

(Received, June 15, 1978)

The solid solutions in the systems $La_2(CO_3)_3 \cdot 8H_2O$-$Ce_2(CO_3)_3 \cdot 8H_2O$ and $La(OH)CO_3$-$Ce(OH)CO_3$ have been synthesized by the hydrolysis of the lanthanum–cerium trichloroacetates. The X-ray diffraction data of the solid solutions of $La_2(CO_3)_3 \cdot 8H_2O$-$Ce_2(CO_3)_3 \cdot 8H_2O$ indicated a lanthanite-type structure while the data of $La(OH)CO_3$-$Ce(OH)CO_3$ indicated a bastnaesite-type structure. The correlations between lanthanite, bastnaesite, and calkinsite, and the lanthanite-bastnaesite transformation are discussed.

Rare-earth carbonate minerals being mainly composed of lanthanum and cerium which have been reported are lanthanite, $(La,Ce)_2(CO_3)_3 \cdot 8H_2O$, calkinsite, $(La,Ce)_2(CO_3)_3 \cdot 4H_2O$, and bastnaesite, $(La,Ce)(F,OH)CO_3$.[1] Several double carbonate minerals, *e.g.*, ancylite, $(La,Ce)_x(Sr,Ca)_{2-x}(CO_3)_2(OH)_x \cdot (2-x)H_2O$, have also been described. However, because of the rare occurence and preparatory diffculties the existence and relationships between the minerals have not always been clear. The crystal structures of lanthanum carbonate octahydrate, $La_2(CO_3)_3 \cdot 8H_2O$,[2] and lanthanite, $(La,Ce)_2(CO_3)_3 \cdot 8H_2O$,[3] have been determined from X-ray diffraction studies. Despite differences in the representations of the unit cell parameters and space group, they were found to be isostructural. The principal structural features are infinite layers of RE–O(RE=La,Ce) coordination polyhedra and CO_3^{2-} groups. However the disordering of lanthanum and cerium has not been confirmed in the lanthanite-type carbonates. Furthermore, in spite of the existence with lanthanite, calkinsite which is considered to be the solid solution of lanthanum and cerium has not yet been the subject of chemical and mineralogical studies. It is not always apparent whether the structure of hydroxy-bastnaesite is isostructural with fluoro-bastnaesite or with ancylite ($x=2$).[4,5,13] Moreover, the existence of hydroxy-bastnaesite has not always been proposed.

In order to investigate the above mentioned points, solid solutions of the carbonates, changing the molar ratio of lanthanum to cerium have been synthesized at various temperatures and pressures, and the products examined by X-ray diffractometry, thermal analysis, and infrared spectroscopy.

Experimental

Synthesis of Rare-earth Carbonates. There are several precipitants for preparing rare-earth carbonates: alkali carbonates and bicarbonates, trichloroacetic acid, urea, *etc.*[6,14] Trichloroacetic acid was used as a precipitant in the present work, since it gives good crystalline products. An appropriate amount of 0.1 mol dm^{-3} lanthanum chloride solution and of 0.1 mol dm^{-3} cerium chloride solution were mixed together, maintaining a total volume of 10 cm^3. After the addition of a 5 cm^3 portion of 2.0 mol dm^{-3} trichloroacetic acid solution, the solution was adjusted with ammonia to pH 5—6 and the volume made up to 50 cm^3 with water. The solutions were placed in a thermostatted bath for a week at temperatures ranging from 50 to 80 °C and in glass autoclaves for four days at 100, 115, and 150 °C. The precipitates were filtered off, washed with water and air-dried.

X-Ray Powder Diffractometry. The X-ray powder diffractions were recorded on a Rigaku Denki Geigerflex Diffractometer, using Ni-filtered Cu $K\alpha$ radiation.

Chemical Analysis. The carbonates were analyzed by igniting weighed samples in a muffle furnace at a temperature of *ca.* 1000 °C. Loss on ignition corresponds to the CO_2+H_2O content of the sample. Both CO_2 and H_2O were determined by the routine procedure for elemental analysis for organic compounds. The ignited oxides were dissolved in perchloric acid. The determination of lanthanum and cerium in the dissolved solution was conducted according to the conventional method.

Infrared Spectra. The infrared absorption spectra of the carbonates were obtained by means of a JASCO IRA-1 spectrophotometer, using KBr pellets and the nujol mull techniques.

Thermal Analysis. The thermal decomposition processes of the carbonates were investigated with a Rigaku Denki Thermoflex thermalanalyzer. About twenty milligramme samples in shallow platinum crucibles were heated in air or in a stream of nitrogen at a heating rate of 5 °C/min.

Electron Probe Microanalysis. The compositional analyses of the carbonates were conducted by means of a JEOL JXA-5 scanning electron microscopic analyzer, using the characteristic X-rays of La $L\alpha$ and Ce $L\alpha$.

Results and Discussion

X-Ray Powder Diffractometry. The carbonates synthesized at 50 and 65 °C gave patterns similar to that of lanthanite, while the carbonates synthesized at 100 °C (5.5 atm) and 115 °C (8 atm) gave patterns similar to that of bastnaesite. The carbonates synthesized from lanthanum-rich solutions at 80 °C gave patterns consisting of those of lanthanite and bastnaesite. The molar ratio of lanthanum to cerium in the lanthanum-rich solutions was 6 or more. No precipitates appeared when the mixed solutions were kept at 150 °C. The X-ray data of the carbonates synthesized at 100 °C (5.5 atm) are shown in Table 1. An observed increase in d values with increasing molar ratio of lanthanum indicates that the carbonates formed solid solutions. Furthermore, when samples of the synthesized carbonates were physically mixed with the two end-members (*i.e.* bastnaesite lanthnum and cerium carbonate) the position and intensity of the diffraction peaks from the synthesized material could be described as just the average and sum, respectively, of the two end-members. The electron probe microanalysis also

M_2O_3 is the sum of lanthanum and cerium oxides.

indicated that the bastnaesite-type carbonates formed solid solutions over the whole series. Assuming a hexagonal symmetry,[12] the unit cell parameters, *a* and *c*, were calculated from 300 and 002 diffractions respectively (Table 1). These cell parameters indicated, semiquantitatively, the molar ratios of lanthanum and cerium in bastnaesite-type carbonates. The shift of the diffraction peaks of the lanthanite-type carbonates were too small to analyze, however, the results of the electron probe microanalysis indicated that lanthanite-type carbonates formed solid solutions.

Chemical Analysis. From the results shown in Table 2, the molar ratios of lanthanum to cerium contained in the synthesized carbonates were almost equal to those in the starting solutions. In addition, it was found that the molar ratio M_2O_3: CO_2: H_2O was almost 1:3:8 for the carbonates synthesized at 50 °C under atmospheric pressure and 1:2:2 for those synthesized at 100 °C, 5.5 atm. The chemical composition of the carbonates synthesized at 50 °C agreed with the composition of lanthanite, while the composition of those synthesized at 100 °C, 5.5 atm agreed with the composition of hydroxy-bastnaesite, assuming one water molecule of adhesive moisture. From the results of X-ray diffractometry and chemical analysis, it became apparent that $La_2(CO_3)_3 \cdot 8H_2O$ and $Ce_2(CO_3)_3 \cdot 8H_2O$ form a complete series of lanthanite-type solid solutions by the isomorphous replacement of lanthanum by cerium, and that $La(OH)CO_3$ and $Ce(OH)CO_3$ form a complete series of bastnaesite-type solid solutions by the isomorphous replacement of lanthanum by cerium.

Infrared Spectroscopy. The infrared spectra of the lanthanite-type and bastnaesite-type carbonates are shown in Fig. 1. The frequencies for the four modes of the free carbonate ion are: ν_1, 1063 cm^{-1}; ν_2, 879 cm^{-1}; ν_3, 1415 cm^{-1}; and ν_4, 680 cm^{-1}. The vibrations ν_3 and ν_4 are degenerate while ν_1 is infrared-inactive for

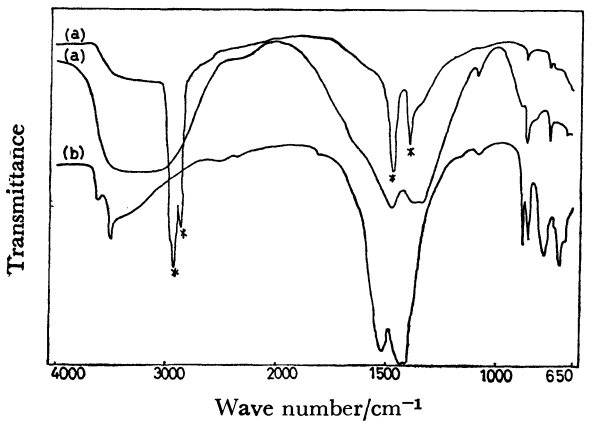

Fig. 1. Infrared absorption spectra of synthesized carbonates.
(a) Lanthanite-type (in KBr disk and in Nujol mull),
(b) bastnaesite-type (in KBr disk).

the free ion.[8] For the lanthanite-type carbonate, the ν_1 mode was just detectable while the ν_3 mode split, indicating that the D_{3h} symmetry of the free carbonate ion was lowered either to C_{2v} or to C_s. The bands in the region 2900—3500 cm^{-1}, appeared even in nujol mull, and were assigned to the absorption of water. Bands marked by a star (*) in Fig. 1 are the absorptions attributable to Nujol. For the bastnaesite-type carbonate, the ν_1 mode appeared faintly and the degenerate mode, ν_3, split. The splitting of the non-degenerate mode, ν_2, indicated that non-equivalent carbonate groups existed.[9] The sharp absorption bands at 3630 and 3480 cm^{-1} were attributed to absorptions by the OH group.[5] The shifts and changes of the absorption spectra caused by the formation of solid solutions were not observed over all the absorptions.

Thermal Analysis. The thermal analysis of the carbonates having various molar ratios of lanthanum and cerium are shown in Fig. 2-a. On the thermogravimetric curve (TG) for the lanthanite-type La10 carbonate, the following abbreviations are used: La10, $La_2(CO_3)_3 \cdot 8H_2O$; Ce10, $Ce_2(CO_3)_3 \cdot 8H_2O$; La5Ce5, $(La_{1.00}Ce_{1.00})_2(CO_3)_3 \cdot 8H_2O$. Initially there was loss of water, which corresponded to the formation of the anhydrous carbonate. Continuous raising of the temperature led to the formation of the dioxide carbonate. The final product of the decomposition was La_2O_3. From the differential scanning calorimetric curve (DSC) for the La10 carbonate, it has been established that the dehydration and decarbonatation in this decomposition process were endothermic. As for the lanthanite-type Ce10 carbonate, the loss of the CO_2 molecules after dehydration was accompanied by the oxidation of Ce^{3+}. That no peaks appeared in the DSC at *ca.* 250 °C appear to be the net result of an endothermic decomposition due to decarbonation coupled with an exothermic reaction due to the oxidation of Ce^{3+} to Ce^{4+}. Although the continuous raising of the temperature in air did not lead to the formation of the dioxide carbonate, it did lead to the formation of the dioxide carbonate, $Ce_2O_2CO_3$ at *ca.* 400 °C in a stream of nitrogen (Fig. 2-c). However, the dioxide carbonate decomposed immediately to CeO_2. The lanthanite-type La5Ce5 carbonate lost eight water molecules at one time under the heating rate used here (5 °C/min), while the formation of the dioxide carbonate did not appear in air. It did, however, appear in a stream of nitrogen. No clear peak attributable to decarbonatation appeared in the DSC at *ca.* 450 °C. As in the course of the decomposition of the Ce10 carbonate, this is the net result of endothermic and the exothermic reactions. The results of the thermal analysis of the lanthanite-type carbonates of other molar ratios were similar to that of the La5Ce5 carbonate. The end product of the La5Ce5 carbonate was a mixed La(III)-Ce(IV)-oxide. The intermediate $Ln_2O_3 \cdot xCO_2 (x<1)$ reported by other workers was not observed.[9]

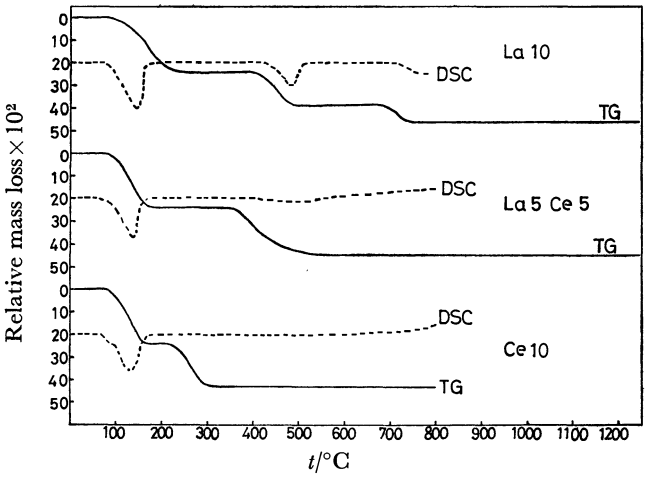

Fig. 2a. TG and DSC curves of lanthanite-type carbonates (in air).

In air:

$$La_2(CO_3)_3 \cdot 8H_2O \xrightarrow{ca.\ 80\ °C} La_2(CO_3)_3 \xrightarrow{ca.\ 400\ °C} La_2O_2CO_3\text{(IA type)} \xrightarrow{ca.\ 680\ °C} La_2O_3$$

$$(La_{1.00}Ce_{1.00})_2(CO_3)_3 \cdot 8H_2O \xrightarrow{ca.\ 80\ °C} (La_{1.00}Ce_{1.00})_2(CO_3)_3 \xrightarrow{ca.\ 330\ °C} La_2O_3 + CeO_2$$

$$Ce_2(CO_3)_3 \cdot 8H_2O \xrightarrow{ca.\ 70\ °C} Ce_2(CO_3)_3 \xrightarrow{ca.\ 210\ °C} CeO$$

In a stream of nitrogen:

$$Ce_2(CO_3)_3\cdot 8H_2O \xrightarrow{ca.\ 60\ ^\circ C} Ce_2(CO_3)_3 \xrightarrow{ca.\ 400^\circ C} Ce_2O_2CO_3 \xrightarrow{ca.\ 500\ ^\circ C} CeO_2$$

$$(La_{1.00}Ce_{1.00})_2(CO_3)_3\cdot 8H_2O \xrightarrow{ca.\ 70\ ^\circ C} (La_{1.00}Ce_{1.00})_2(CO_3)_3 \xrightarrow{ca.\ 430\ ^\circ C} (La_{1.00}Ce_{1.00})_2O_2(CO_3) \xrightarrow{ca.\ 540\ ^\circ C} La_2O_3 + CeO_2$$

Figure 2-b shows the decomposition of bastnaesite-type carbonates. For the bastnaesite-type La10 carbonate, the following abbreviations are used here: La10, $La(OH)CO_3\cdot H_2O$; Ce10, $Ce(OH)CO_3\cdot H_2O$; La5Ce5, $(La_{0.50}Ce_{0.50})(OH)CO_3\cdot H_2O$. The bastnaesite-type La10 carbonate started losing adhesive moisture *ca.* 100 °C and the main decomposition occurred at *ca.* 430 °C accompanying the formation of the dioxide carbonate. The evolution of the remaining one mole of CO_2 began at *ca.* 740 °C. The decomposition of the Ce10 carbonate was accompanied by the oxidation of Ce^{3+}. The small peak that appeared in the DSC at *ca.* 300 °C appeared to be the net result of an endothermic decomposition reaction due to the dehydration and decarbonatation and an exothermic reaction due to the oxidation of Ce^{3+} to Ce^{4+}. The La5Ce5 carbonate continuously lost weight from *ca.* 70 °C. The dioxide carbonate decomposed from the lanthanite-type and bastnaesite-type samples showed different infrared and X-ray powder diffraction spectra. According to the literature, the former was found to be IA type (monoclinic) and the latter, to be II type (hexagonal).[9]

In air:

$$La(OH)CO_3\cdot H_2O \xrightarrow{ca.\ 100\ ^\circ C} La(OH)CO_3 \xrightarrow{ca.\ 430\ ^\circ C} La_2O_2CO_3(\text{II type}) \xrightarrow{ca.\ 740\ ^\circ C} La_2O_3$$

$$(La_{1.00}Ce_{1.00})(OH)CO_3\cdot H_2O \xrightarrow{ca.\ 70\ ^\circ C} (La_{1.00}Ce_{1.00})(OH)CO_3 \xrightarrow{ca.\ 290\ ^\circ C} La_2O_3 + CeO_2$$

$$Ce(OH)CO_3\cdot H_2O \xrightarrow{ca.\ 70\ ^\circ C} Ce(OH)CO_3 \xrightarrow{ca.\ 230\ ^\circ C} CeO_2$$

In a stream of nitrogen:

$$Ce(OH)CO_3\cdot H_2O \xrightarrow{ca.\ 70\ ^\circ C} Ce(OH)CO_3 \xrightarrow{ca.\ 370\ ^\circ C} Ce_2O_2CO_3 \xrightarrow{ca.\ 510\ ^\circ C} CeO_2$$

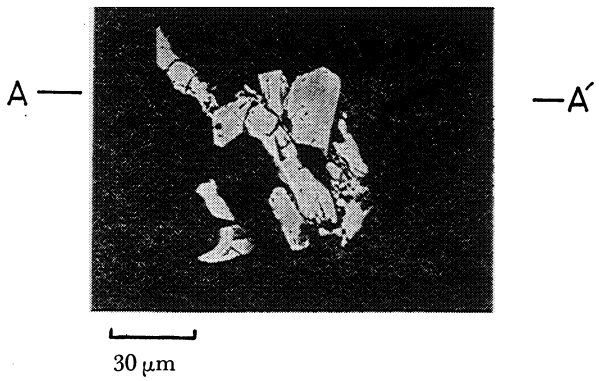

Fig. 3a. The compositional figure of the bastnaesite-type La4Ce6 carbonate.

$$(La_{1.00}Ce_{1.00})(OH)CO_3\cdot H_2O \xrightarrow{ca.\ 100\ ^\circ C} (La_{1.00}Ce_{1.00})(OH)CO_3 \xrightarrow{ca.\ 390\ ^\circ C} (La_{1.00}Ce_{1.00})_2O_2CO_3 \xrightarrow{ca.\ 550\ ^\circ C} La_2O_3 + CeO_2$$

Calkinite[10] was discovered as a late mineral associated with lanthanite in the veins in Bearpaw Mountains of Montana. Although its occurrence is very similar to that of lanthanite and the other hydrated rare earth orthocarbonate minerals synthesized, calkinsite has not been obtained as a product of the La5Ce5 carbonate or as an intermediate of the thermal decomposition of any of the synthesized rare-earth carbonates.

Lanthanite is usually rarely found associating with bastnaesite. The reason for its rare occurrence becomes clear from the above discussions and experiments. Lanthanite changed its structure and chemical composition from lanthanite- to bastnaesite-type when heated with water at 100 °C.[11,12] Thus, it is presumed that lanthanite is lacking in nature due to this thermal metamorphism.

Electron Probe Microanalysis. The compositional figure of the bastnaesite-type La4Ce6 carbonate and its characteristic X-ray figures of La $L\alpha$ and Ce $L\alpha$ are shown in Fig. 3. From the characteristic X-ray figures of La $L\alpha$ and Ce $L\alpha$ and the line profiles in a grain of the La5Ce5 carbonates, the same grain was found to contain equal molar ratios of lanthanum and cerium, indicating that the carbonate formed a solid solution. Semiquantitative analysis suggested that there was a slight difference in the composition of each grain, which might be a reflection of some "fluctuation" in this solution. The molar ratio of lanthanum to cerium contained in the crystal was also microscopically equal to that of the starting solution.

We wish to express our deep gratitude to Professor Isao Masuda, Fukuoka University and Professor Kozo Nagashima, The University of Tsukuba, for their encouragement through the course of this work.

Preparation and Optical Resolution of $[Co(en)_x(dmbpy)_{3-x}]^{3+}$ ($x=0, 1$) and Related Complexes

Toshishige M. Suzuki

Government Industrial Research Institute, Tohoku, Nigatake, Haranomachi, Sendai 983

(Received June 28, 1978)

The optical resolution of $[Co(dmpy)_3]^{3+}$, $[Co(en)(dmbpy)_2]^{3+}$, $[Co(en)(bpy)_2]^{3+}$, and $[Rh(dmbpy)_3]^{3+}$(dmbpy =3,3′-dimethyl-2,2′-bipyridine) has been achieved using $(-)_D$ tris(L-cysteinsulfinato)cobaltate(III). The dmbpy complexes consist of a pair of stereo-selective enantiomers. The absorption and CD spectra of two series of complexes, $[Co(en)_x(dmbpy)_{3-x}]^{3+}$ and $[Co(en)_x(bpy)_{3-x}]^{3+}$ ($x=0$, 1, 2, 3) and also $[Rh(dmbpy)_3]^{3+}$ have been investigated. The complexes containing more than two aromatic ligands showed an exciton CD in the ligand π-π^* transition region and the band has been related to the absolute configuration of the complexes. The spectral features of dmbpy complexes are different from those of the bpy complexes and such differences have been discussed with reference to the twisting nature of dmbpy chelates.

The metal chelates of 3,3′-dimethyl-2,2′-bipyridine (dmbpy) are expected to take a non-coplanar conformation owing to the steric interactions of the substituted methyl groups. Some bis(diamine) and tetramine cobalt(III) complexes with dmbpy have been prepared and resolved.[1] It has been found that dmbpy coordinates to the cobalt(III) ion with a stereospecific conformation depending on the given configuration.[1] The absolute configurations of $(+)_D[Co(en)_2(dmbpy)]Cl(ClO_4)_2\cdot H_2O$[2] and $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)]Br(ClO_4)_2\cdot H_2O$[3] (en=enthylenediamine, chxn=1,2-cyclohexanediamine) have been determined by an X-ray method to be $\Lambda(\delta\text{-dmbpy})$ and $\Delta(\lambda\text{-dmbpy})$,[4] respectively. The empirical assignments of the absolute configurations on the basis of the Cotton effects in the first d-d absorption band region[5] are consistent with the X-ray results.

Recently, $[Co(dmbpy)_3]^{3+}$, $[Co(en)(dmbpy)_2]^{3+}$, $[Co(en)(bpy)_2]^{3+}$, and $[Rh(dmbpy)_3]^{3+}$ (bpy=2,2′-bipyridine) have been prepared and resolved. The resolution of the series of complexes, $[Co(en)_x(dmbpy)_{3-x}]^{3+}$ and $[Co(en)_x(bpy)_{3-x}]^{3+}$ where $x=0$, 1, 2, 3 has now been completed. The absolute configuration of the bis and tris(diimine) cobalt(III) complexes can be estimated from the sign of the CD bands in the d-d absorption region[5] as well as in the ligand π-π^* transition region.[6] Data for the complete series of mixed complexes is necessary to elucidate the electronic state, optical activity and absolute configuration of the complexes.

In order to understand the twisted effects of dmbpy chelates, the absorption and CD spectra of dmbpy complexes have been compared with the corresponding bpy complexes, in which chelate conformation is believed to be planar.

Experimental

Materials. 3,3′-Dimethyl-2,2′-bipyridine was prepared as stated previously.[1]

$[Co(dmbpy)_3](ClO_4)_3$. This was prepared by air oxidation as described in a previous paper.[1] Oxidation with PbO_2 in place of bubbling air improved the yield. Approximately 50 mg of the complex was adsorbed on a SP-Sephadex column ($\phi 2.5\times 50$ cm) and eluted with 0.15 mol·dm^{-3} potassium $(+)_D$-tartratoantimonate(III). The eluate was fractionated and the visible absorption spectra measured. All the fractions showed very similar spectra, indicating the absence of geometrical isomers.

$(-)_D[Co(dmbpy)_3](ClO_4)_3\cdot H_2O$. The complex perchlorate (3.6 g) was converted into the bromide by treatment with an anion exchanger, Dowex 1-X8 in the bromide form. A mixture of the solution of the bromide (50 cm^3) and $K_3[Co(L\text{-cysu})_3]$(cysu=cysteinsulfinato)[7] (1.0 g) was stored in a refrigerator overnight. Needlelike crystals of the $(-)_D$-diastereoisomer were filtered, washed with water and acetone (1.4 g). The second crop of crystals (0.3 g) was obtained by concentrating the filtrate to half volume. The first and the second crystal crops were combined, recrystallized twice from hot water to give a reproducible CD spectrum. The $(-)_D$-diastereoisomer in water (20 cm^3) was treated with concentrated hydrochloric acid (1 cm^3). Yellow precipitate of $H_3[Co(L\text{-cysu})_3]$ was filtered off. The filtrate was treated with 70% perchloric acid (2 cm^3) and the yellow crystals of the perchlorate salt were collected and recrystallized from hot water. Found: C, 46.38; H, 4.25; N, 8.84%. Calcd for $C_{36}H_{36}N_6Cl_3O_{12}Co\cdot H_2O$: C, 46.59; H, 4.13; N, 9.06%.

Preparation of $[Co(en)(dmbpy)_2](ClO_4)_3$. To a solution of $[Co(dmbpy)_3](ClO_4)_3$ (1.83 g in 400 cm^3 of water) was added a 10% solution of ethylenediamine (1.2 g) and activated charcoal (0.5 g). The solution was stirred at room temperature for 15 min and then filtered. The filtrate was acidified with a few drops of concentrated hydrochloric acid and poured onto a column of SP-Sephadex ($\phi 3.0\times 40$ cm). The adsorbed band was washed with water and eluted with 0.15 mol·dm^{-3} sodium sulfate solution. The column gave four separate bands in the order of elution, I, II, III, and IV, which were $[Co(en)_3]^{3+}$, $[Co(en)_2(dmbpy)]^{3+}$, $[Co(dmbpy)_3]^{3+}$, and $[Co(en)(dmbpy)_2]^{3+}$, respectively. The eluatant of band IV was fractionated and the absorption spectra recorded. No indication for the presence of the geometrical isomer was found. The fractions were collected, evaporated to dryness and the yellow residue extracted with methanol (50 cm^3) and the extract was evaporated to dryness. The residual solid was dissolved in water (20 cm^3) and 70% perchloric acid was added (1 cm^3). The orange-yellow precipitate was filtered off and recrystallized from hot water (300 mg) Found: C, 39.52; H, 4.41; N, 10.34%. Calcd for $C_{26}H_{32}N_6Cl_3O_{12}Co$: C, 39.74; H, 4.10; N, 10.69%.

$(+)_D[Co(en)(dmbpy)_2](ClO_4)_3$. 1.2 g of perchlorate was converted into the bromide using the anion exchanger Dowex 1-X8 in the bromide form. To the solution of the bromide (50 cm^3) was added $K_3[Co(L\text{-cysu})_3]$ (0.64 g in 10 cm^3 of water) and the solution stored in a refrigerator for 3 h. The yellow crystals of the $(-)_D$-diastereoisomer were

filtered off, washed with a small amount of ethanol and finally ether, (400 mg). The filtrate was evaporated to half volume and stored in a refrigerator overnight and a second crop of crystals (60 mg) were obtained. The crystals were combined and recrystallized from hot water (300 mg). The $(+)_D$-diastereoisomer was suspended in water (5 cm^3) and stirred for 1 h with 3 $mol \cdot dm^{-3}$ hydrochloric acid (1 cm^3). The yellow precipitate was filtered off and the filtrate was treated with 70% perchloric acid (0.5 cm^3). The orange crystals of $(+)_D[Co(en)(dmbpy)_2](ClO_4)_3$ were collected and recrystallized from hot water. Found: C, 39.74; H, 4.34; N, 10.71%. Calcd for $C_{26}H_{32}N_6Cl_3O_{12}Co$: C, 39.74; H, 4.10; N, 10.69%.

[Co(en)(bpy)$_2$](ClO$_4$)$_3$·4H$_2$O. To a solution of [Co-$Cl_2(bpy)_2]Cl$ (3.8 g in 100 cm^3 of water) was added 10% ethylenediamine solution (4.8 g) and the mixture warmed at 60 °C for 3 h. Concentrated hydrochloric acid (0.5 cm^3) was added to the solution and resulting solution diluted to 1000 cm^3 and poured onto a column of SP-Sephadex (ϕ 3.5×80 cm). The adsorbed band was washed with water and eluted with 0.2 $mol \cdot dm^{-3}$ hydrochloric acid. The column gave three separate bands, I, II, III, in the order of elution, which were $[Co(bpy)_3]^{3+}$, $[Co(en)(bpy)_2]^{3+}$, and $[Co(en)_2(bpy)]^{3+}$, respectively. The effluent of band II was evaporated to dryness, the residue dissolved in water (10 cm^3) and filtered. After the addition of 70% perchloric acid (2 cm^3), the solution was placed in a refrigerator overnight and the yellow crystals were collected and recrystallized from hot water (1.3 g). Found: C, 33.16; H, 3.74; N, 10.59%. Calcd for $C_{22}H_{24}N_6$-$Cl_3O_{12}Co \cdot 4H_2O$: C, 32.96; H, 3.99; N, 10.47%.

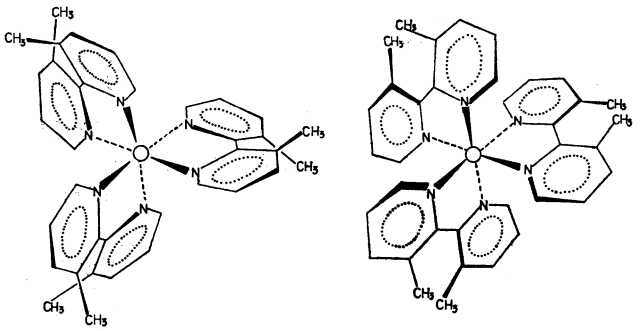
(+)$_D$[Co(en)(bpy)$_2$](ClO$_4$)$_3$. This complex was resolved by a similar method as that for $[Co(en)(dmbpy)_2]^{3+}$ using $K_3[Co(L\text{-}cysu)_3]$. Found: C, 35.20, H, 3.28; N, 11.36%. Calcd for $C_{22}H_{24}N_6Cl_3O_{12} \cdot H_2O$: C, 35.34; H, 3.47; N, 11.23%.

(−)$_D$[Rh(dmbpy)$_3$](ClO$_4$)$_3$. This complex was prepared by a similar method to that for $[Rh(bpy)_3](ClO_4)_3$ using dmbpy instead of bpy.[8] Optical resolution was achieved using $K_3[Co(L\text{-}cysu)_3]$. Found: C, 45.29; H, 3.75; N, 8.92%. Calcd for $C_{36}H_{36}N_6Cl_3O_{12}Rh$: C, 45.33; H, 3.68; N, 8.81%.

Measurements. Absorption and CD spectra were recorded at room temperature on a Shimadzu Double 40-R spectrometer and a JASCO J-20 spectropolarimeter, respectively. PMR spectra were measured with a JNM-PMX60 and a JEOL Model 4H-100 spectrometer using DSS as the internal standard.

Results and Discussion

A 3,3′-dimethyl-2,2′-bipyridine chelate can assume dissymmetric conformations (δ and λ) and consequently eight optical isomers arise from the conformational and configurational dissymmetry are possible for a tris complex. The PMR spectra of $[Co(dmbpy)_3]^{3+}$ and $[Rh(dmbpy)_3]^{3+}$ in D_2O gave a single methyl signals at 2.55 and 2.67 ppm, respectively, indicating all the methyl groups in the complex are equivalent. Chromatographic separation of the isomers of $[Co(dmbpy)_3]^{3+}$ suggests that the complex consists of only one geometrical isomer; *i.e.*, a pair of enantiomers. Four of the eight possible isomers, $\Delta(\lambda\lambda\lambda)$, $\Lambda(\delta\delta\delta)$, $\Delta(\delta\delta\delta)$, and $\Lambda(\lambda\lambda\lambda)$, two pairs of enantiomers have D_3 symmetry in which all the methyl groups are equivalent. Figure 1 shows a schematic drawing of the two isomers, (a) $\Lambda(\delta\delta\delta)$ (*lel*) and (b) $\Lambda(\lambda\lambda\lambda)$ (*ob*). The 2C–2C′ bond of each dmbpy chelate in (a) is pseudo-parallel (*lel*) to the three-fold axis whereas in (b) it is oblique. A molecular model examination suggests that the (b) configuration has appreciable non-bonded atomic interactions between dmbpy chelates in contrast to the (a) configuration. Clearly the same relationship holds for $\Delta(\delta\delta\delta)$ and $\Lambda(\delta\delta\delta)$. Thus the tris complexes are most likely to consist of a pair of enantiomeric forms, $\Delta(\lambda\lambda\lambda)$ and $\Lambda(\delta\delta\delta)$.



(a) (b)

Fig. 1. Schematic drawings of the two isomers of $[Co(dmbpy)_3]^{3+}$; (a) $\Lambda(\delta\delta\delta)(lel)$, (b) $\Lambda(\lambda\lambda\lambda)(ob)$.

The bis(dmbpy) complex, $[Co(en)(dmbpy)_2]^{3+}$ was obtained by treating the tris complex in aqueous solution with ethylenediamine in the presence of activated charcoal. Other species, such as $[Co(en)_2(dmbpy)]^{3+}$, $[Co(en)_3]^{3+}$ formed by disproportionation were separated on a Sephadex column. No indication for the presence of more than a pair of enantiomers was found for the bis(dmbpy) complex. Two dmbpy chelates in $[Co(en)(dmbpy)_2]^{3+}$ are expected to take the (*lel*, *lel*) form exclusively owing to similar steric requirements as described for the tris complexes.

In addition to the series of dmbpy complexes, the optical resolution of the bpy complex series, $[Co(en)_x(bpy)_{3-x}]^{3+}$ was completed by the resolution of $[Co(en)(bpy)_2]^{3+}$. Figures 2 and 3 show the absorption and CD spectra of the series where $[Co(en)_3]^{3+}$ has been excluded to avoid complications. The numerical data is listed in Table 1. The first absorption maximum for the dmbpy complex appears always at longer wavelengths than that of the corresponding bpy complex. Since the first d-d peak positions for the dmbpy complex series do not significantly vary with x (see Table), except for the $[Co(dmbpy)_3]^{3+}$ ion, dmbpy appears to lie close to ethylenediamine in the spectrochemical series. The torsional strain of the dmbpy chelate induced by twisting about the 2C–2C′ bond should more or less affect the strength of the coordination bond.

For the dmbpy complexes, strong bands have been observed in the region, 27000—31000 cm^{-1}, In the case of $[Co(dmbpy)_3]^{3+}$, the first absorption band is obscured by overlapping. The nature of the band should be a charge transfer transition, since the free ligand does not have a band in this region.[9] The peak maxima shifts to lower energy and the intensities decrease in the order, $[Co(en)_2(dmbpy)]^{3+}$, $[Co(en)(dmbpy)_2]^{3+}$, and $[Co(dmbpy)_3]^{3+}$. This is also the

order of increasing steric interaction. In the case of the bpy complexes, such bands are less marked than for dmbpy complexes.

The intense absorption at about 32000—33000 cm^{-1} for all complexes is ascribed to the ligand π-π^* transition.[9,10] The band maxima for the dmbpy complexes always have lower intensities and appear at shorter

wavelengths compared with those of the bpy complexes. Single bond twisting in a conjugated system away from coplanarity is known to affect the position and/or the intensities of the π-π^* absorption bands.[11] Therefore, the spectral differences between the bpy and dmbpy series are mainly attributable to the differences in conformation of the chelate rings.

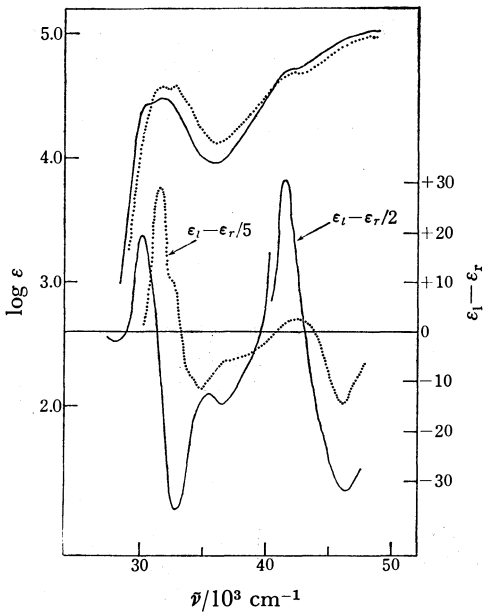

Fig. 4. Absorption and CD spectra of (——) $(-)_D$-$[Rh(dmbpy)_3]^{3+}$, and (·····) $(+)_D[Rh(bpy)_3]^{3+}$ in water.

All the CD spectral data given in Table 1 and Figs. 2—4 are for isomers derived from the less soluble diastereoisomeric salt with $[Co(L\text{-cysu})_3]^{3-}$ ion. Of these, the absolute configuration of $(+)_D[Co(en)_3]^{3+}$ [12] and $(+)_D[Co(en)_2(dmbpy)]^{3+}$ [2] have been assigned Λ by X-ray method. The empirical assignment of the absolute configuration on the basis of the dominant CD peaks in the first d-d region are consistent with Λ. The complexes containing two or three bpy or dmbpy units always give a positive-negative CD couplet from the longer wavelength side in the ligand π-π^* region. The exciton couplet CD of the π-π^* transition has been related nonempirically to the absolute configurations of the complexes; when the configuration is Λ, the negative component of the π-π^* couplet lies at a higher energy, while it lies at lower energy when the chirality is Δ.[6] From this rule, the present complexes have been assigned the Λ-configuration.

The bis complexes, $(+)_D[Co(en)(bpy)_2]^{3+}$ and $(+)_D$-$[Co(en)(dmbpy)_2]^{3+}$ exibit one positive CD band in the first d-d absorption band region, giving an assignment of Λ-configuration which is consistent with that predicted from the π-π^* exciton CD bands. On the contrary, $(+)_D[Co(bpy)_3]^{3+}$ [13] and $(-)_D[Co(dmbpy)_3]^{3+}$ gave the negative CD in the first absorption band region, which contradicts the configuration predicted from the exciton CD. The charge-transfer bands have however been located close to or overlapping the first absorption band region for the present tris complexes leading that the CD bands in this region would be complicated by the CD components associated with the charge-transfer bands. The d-d absorption bands of the bis and mono (bpy or dmbpy) complexes are relatively clear compared with those of the tris complexes and the CD bands beneath the d-d absorption appear less affected by adjacent transitions. Many bis(bpy or 1,10-phenanthroline) complexes of cobalt(III),[13–16] whose d-d absorption bands are rather isolated from adjacent bands give CD consistent with the ligang exciton CD for assigning the absolute configuration. The CD in the first absorption band region is at times greately affected by the steric and electronic circumstances of surrounding ligands,[17,18] whereas the exciton CD of tris complexes is usually very intense and not significantly affected by other transitions.[6c] Comparing the exciton CD of the present tris and bis pairs, the absolute configurations of $(+)_D[Co(bpy)_3]^{3+}$, $(+)_D[Co(en)(bpy)_2]^{3+}$, $(-)_D$-$[Co(dmbpy)_3]^{3+}$, and $(+)_D[Co(en)(dmbpy)_2]^{3+}$ have been assigned as Λ

The absorption and CD spectra of $(-)_D[Rh$-$dmbpy)_3]^{3+}$ are shown in Fig. 4 along together those of $(+)_D[Rh(bpy)_3]^{3+}$. [7] The CD patterns of the two complexes are quite similar over all the wavelength region. The intense exciton couplet CD is centered at about 33000 cm^{-1} for the bpy complex and 32000 cm^{-1} for the dmbpy complex. The patterns indicate that the absolute configuration of the complexes are assignable to Λ.

Kinetics of the Oxidative Addition Reaction of Iodine to (Dimethyldithiocarbamato)bis(2,4,6-trimethylphenyl isocyanide)rhodium(I)

Ryosho KUWAE, Toshio TANAKA,* and Katsuhiko KAWAKAMI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received June 23, 1978)

The reaction of $Rh(dtc)L_2$ (dtc=$S_2CN(CH_3)_2$, L=2,4,6-$(CH_3)_3C_6H_2NC$) with an equimolar amount of iodine yields a *trans* adduct, $RhI_2(dtc)L_2$. The rate of this reaction was measured in benzene, employing a stopped-flow technique under pseudo-first-order conditions with excess iodine. The result indicates that the reaction proceeds *via* a charge transfer complex $Rh(dtc)L_2 \cdot I_2$, which is rearranged in two consecutive zero-order reactions with respect to the I_2 concentration; the rearrangement of $Rh(dtc)L_2 \cdot I_2$ to a *cis* adduct followed by isomerization to the *trans* adduct. This mechanism is supported from kinetic data for the reaction of $Rh(acac)L_2$ (acac=$CH_3COCHCOCH_3$) with I_2. It is also described that $RhI(I_3)(dtc)L_2$ and $RhI(I_3)(acac)L_2$ were obtained by reactions of $Rh(dtc)L_2$ and $Rh(acac)L_2$ with excess iodine, respectively.

Coordinatively unsaturated rhodium(I) complexes undergo oxidative addition reactions with various organic and inorganic molecules.[1,2] The interest in these reactions stems partly from their catalytic implications.[3] Recently, kinetic studies have been reported for the reactions of Rh(I) substrates with hydrogen,[4,5] oxygen,[5] organic halides,[5-7] and olefins.[5,8,9] However, little is known concerning the mechanism of the addition reactions of halogen, although various halogen adducts of Rh(I) have been isolated.[2,10-14]

This paper reports the kinetic study on the reactions of (dimethyldithiocarbamato)bis(2,4,6-trimethylphenyl isocyanide)rhodium(I), $Rh(dtc)L_2$, and (acetylacetonato)bis(2,4,6-trimethylphenyl isocyanide)rhodium(I), $Rh(acac)L_2$, with iodine giving *trans*-$RhI_2(dtc)L_2$ and -$RhI_2(acac)L_2$, respectively. The isolation of $RhI(I_3)(dtc)L_2$ and $RhI(I_3)(acac)L_2$ is also described.

Experimental

Materials. $Rh(dtc)L_2$[15] and $Rh(acac)L_2$[16] (L=2,4,6-$(CH_3)_3C_6H_2NC$, dtc=$S_2CN(CH_3)_2$, acac=$CH_3COCHCOCH_3$) were prepared as described previously. Iodine was sublimed three times. Benzene was purified by the usual method.[17]

Equimolar Reactions of $Rh(dtc)L_2$ and $Rh(acac)L_2$ with Iodine. Iodine (0.74 mmol) was added to a suspension of $Rh(dtc)L_2$ (0.74 mmol) in diethyl ether (70 ml), and the mixture was stirred for 10 h. The resulting precipitate was recrystallized from a mixture of benzene and cyclohexane to give reddish brown crystals of $RhI_2(dtc)L_2$ in a 69% yield. Found: C, 36.38; H, 3.63; N, 5.41%; mol wt, 798 in $CHCl_3$ at 37 °C. Calcd for $C_{23}H_{28}I_2N_3S_2Rh$: C, 36.00; H, 3.68; N, 5.48%; mol wt, 767.

The analogous acac complex, $RhI_2(acac)L_2$, was similarly obtained by the reaction of $Rh(acac)L_2$ with an equimolar amount of I_2 in a 68% yield. Found: C, 40.48; H, 3.97; N, 3.83%; mol wt, 754 in $CHCl_3$ at 37 °C. Calcd for $C_{25}H_{29}I_2N_2O_2Rh$: C, 40.24; H, 3.92; N, 3.75%; mol wt, 746.

Reaction of $Rh(dtc)L_2$ or $Rh(acac)L_2$ with Excess Iodine. To a suspension of $Rh(dtc)L_2$ (0.74 mmol) in diethyl ether (40 ml) was added large excess iodine (7.4 mmol), and the mixture was stirred for 15 h. The resulting precipitate was washed with diethyl ether to remove unreacted iodine and recrystallized from tetrahydrofuran (THF)–petroleum ether to give dark brown crystals of $RhI_4(dtc)L_2 \cdot 3/4THF$ in a 64% yield. Found: C, 28.85; H, 3.13; N, 3.79%. Calcd for $C_{26}H_{34}I_4N_3O_{3/4}S_2Rh$: C, 29.04; H, 3.19; N, 3.91%. This compound was prepared also by the reaction of $RhI_2(dtc)L_2$ with excess iodine in diethyl ether, and recrystallized from THF–petroleum ether.

The corresponding acac complex, $RhI_4(acac)L_2$, was similarly obtained by the reaction of $Rh(acac)L_2$ with excess iodine in a 41% yield. Found: C, 29.84; H, 2.91; N, 2.87%. Calcd for $C_{25}H_{29}I_4N_2O_2Rh$: C, 30.03; H, 2.92; N, 2.80%.

Kinetic and Other Measurements. Kinetic runs were performed by using a Union RA-413 stopped-flow spectrophotometer equipped with a 0.2 cm quartz cell in a cell holder thermostated to ±0.2 °C, under pseudo-first-order conditions by mixing a benzene solution of the Rh(I) substrate (1.0×10^{-4} M) with excess iodine in benzene ($1.0-4.0\times10^{-3}$ M). The rate of reaction was measured by following the decay of absorbance at 370 nm with time. At least five reaction curves were accumulated by a Union System-71 kinetic data processor and an average curve was recorded on a National VP-6421A X-Y recorder.

Molecular weights, infrared, and ^1H NMR spectra were measured as described elsewhere.[18] Electronic spectra in benzene or toluene were recorded on a Hitachi 124 spectrophotometer.

Results and Discussion

Characterization of Reaction Products. Table 1 shows relevant infrared frequencies (in $CHCl_3$) and ^1H NMR chemical shifts (in $CDCl_3$) of the four adducts obtained here. The 1:1 adducts exhibit two $\nu(N\equiv C)$ bands, whose frequencies are higher than those of the Rh(I) substrates, confirming the occurrence of oxidative addition reactions[10,12,13] with the retention of mutual *cis* positions of the two isocyanide ligands. The ^1H

Table 1. $\nu(N\equiv C)$ frequencies (in $CHCl_3$, cm^{-1}) and ^1H NMR chemical shifts (in $CDCl_3$, ppm) of the adducts

Adduct	$\nu(N\equiv C)$[a]	δ(dtc- or acac-Me)	δ(2,6-Me)	δ(4-Me)	δ(3,5-H)
$RhI_2(dtc)L_2$	2187, 2203	3.32	2.51	2.30	6.88
$RhI_2(acac)L_2$	2199, 2215	2.11	2.52	2.32	6.92

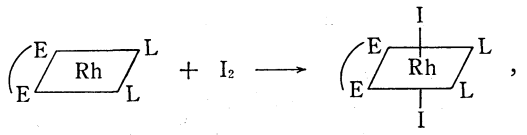
$RhI_4(acac)L_2$	2200, 2215	2.12	2.51	2.32	6.95

a) $Rh(dtc)L_2$: 2057 and 2120 cm^{-1}, $Rh(acac)L_2$: 2082 and 2147 cm^{-1}.

NMR spectrum of $RhI_2(dtc)L_2$ shows only a signal for the dtc-methyl and the isocyanide protons, respectively (Table 1), suggesting that both of the two dtc-methyl groups and the two isocyanide ligands are magnetically equivalent, respectively. These results imply that $RhI_2(dtc)L_2$ assumes an octahedral geometry, in which dtc and two isocyanides are located in an equatorial plane with the two iodide ligands in axial positions. The same geometry is suggested for $RhI_2(acac)L_2$ on the basis of infrared and ^1H NMR spectra. The ^1H NMR spectrum of a benzene-d_6 solution containing equimolar amounts (5.0×10^{-2} M) of $Rh(dtc)L_2$ or $Rh(acac)L_2$ and I_2 showed no signal other than those assignable to $RhI_2(dtc)L_2$ or $RhI_2(acac)L_2$. Thus, the stoichiometry for the addition reaction of equimolar iodine to the rhodium substrate is expressed by



where E–E stands for dtc (E=S) or acac (E=O).

The $RhI_4(dtc)L_2$ and $RhI_4(acac)L_2$ complexes may be formulated as $RhI(I_3)(dtc)L_2$ and $RhI(I_3)(acac)L_2$ respectively, both of which involve a triiodide anion, since trivalent rhodium is known to assume a hexacoordinated geometry. Coordination of I_3^- to metal ions has been proposed for some Pt(II)[19,20] and Fe(III)[21] complexes.

Kinetics and Mechanism. As shown in Fig. 1, benzene solutions of $Rh(dtc)L_2$ and I_2 exhibit absorption maxima at 352 (ε 14000) and 500 nm (ε 1200) in the electronic spectra, respectively. Immediately after mixing of these solutions, however, appeared an absorption maximum at 370 nm, which decreased with a half-life of about 3 ms, as shown in Fig. 2. This Figure was obtained by plotting A_t-A_∞ at nine different wavelengths in the 340—400 nm range against time,

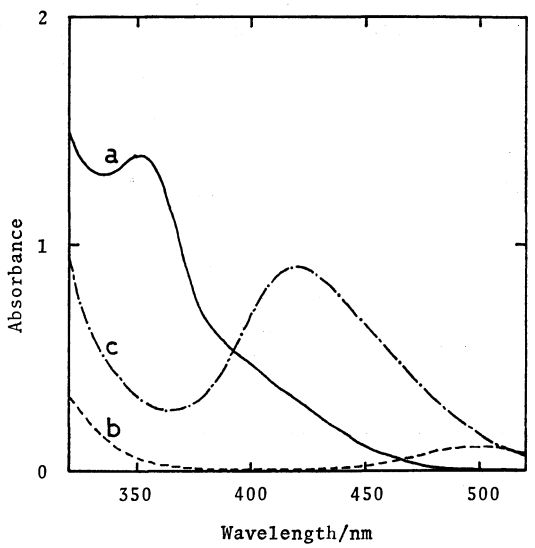


Fig. 1. Electronic spectra of $Rh(dtc)L_2$ (**a**), I_2 (**b**), and *trans*-$RhI_2(dtc)L_2$ (**c**) in benzene (1.0×10^{-4} M) at 25.1 °C; cell length 1.0 cm.

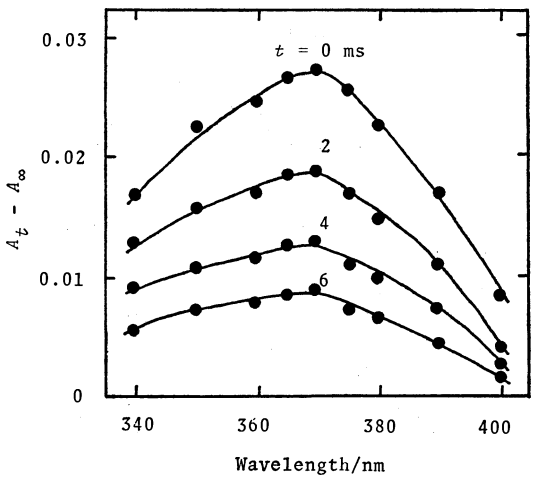

Fig. 2. Decay of the absorption band with time after mixing $Rh(dtc)L_2$ (1.0×10^{-4} M) with I_2 (1.0×10^{-3} M) in benzene at 10.0 °C.

where A_t and A_∞ are absorbances at a given wavelength at the time "t" and at the end of reaction. This result indicates the formation of a transient intermediate during the dead time of the instrument, followed by its rapid degradation. The mixing of $Rh(acac)L_2$ with excess I_2 in benzene also gave a similar short-lived absorption maximum at 360 nm (half-life; about 4 ms at 25.1 °C). In view of the fact that the absorption maxima observed in the two reaction systems do not coincide in wavelength with each other, those bands may not be associated with a common chemical species, such as the I_3^- anion, although this anion formed by mixing $(n\text{-}C_4H_9)_4NI$ with I_2 in benzene[22] exhibited an absorption maximum at 367 nm. Alternatively, the 370 nm band which occurred in the $Rh(dtc)L_2$–I_2 system may be assigned to the charge transfer (CT) transition from the dtc-sulfur atom to the I_2 molecule, by analogy with the fact that both $(CH_3)_2Sn\{S_2CN(C_2H_5)_2\}_2$[23] and $Zn\{S_2CN(n\text{-}C_4H_9)_2\}_2$[24] react with I_2 to yield short-lived absorptions at 385 and 360 nm, respectively, assignable to CT transitions of the same

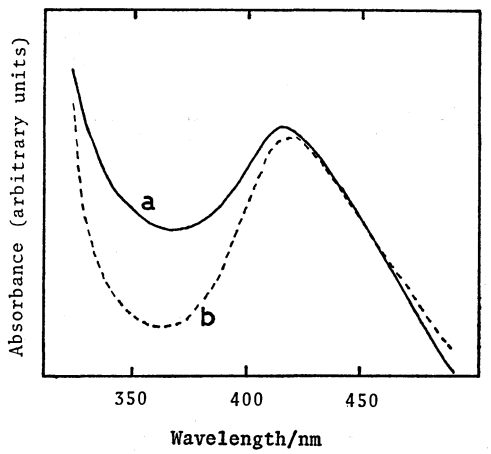

Fig. 3. Electronic spectra of toluene solutions containing equimolar quantities of $Rh(dtc)L_2$ and I_2 at −60 °C; **a** and **b** are those of the solutions prepared at −60 °C and at room temperature, respectively.

type. Similarly, the 360 nm band observed in the $Rh(acac)L_2$–I_2 system may be due to the CT transition from the acac-oxygen to I_2. This is supported from the fact that ethanol, *N*,*N*-dimethylformamide, and related oxygen-containing compounds have been reported to form CT complexes with iodine; the CT bands were observed around 250 nm.[25]

Figure 3 shows the electronic spectra of two toluene solutions both containing equimolar quantities of $Rh(dtc)L_2$ and I_2 at −60 °C; one was prepared at −60 °C (solution **a**) and the other at room temperature followed by cooling (solution **b**). No absorption maximum is observed around 370 nm for these solutions, indicating that the CT complex had already decomposed even at −60 °C. It is to be noted, however, that the absorbance in the 370 nm region is different between the spectra of solution **a** and **b**, despite the similarity in those spectra. In addition, the same spectrum as solution **b** was observed in solution **a** which was allowed to stand at room temperature for several minutes, followed by cooling down to −60 °C. The spectrum of solution **b** can be ascribed to *trans*-$RhI_2(dtc)L_2$, because it showed no change at all even in prolonged standing at room temperature. Thus, the spectrum of solution **a** may arise from another intermediate frozen at −60 °C. No direct evidence has been obtained for the configuration of the intermediate, because in nonpolar solvents such as toluene $Rh(dtc)L_2$ is not soluble at low temperatures enough to measure the ^1H NMR and infrared spectra. The intermediate is presumably assigned to *cis*-$RhI_2(dtc)L_2$. A similar *cis* addition was reported to occur in the reaction of hydrogen with some Vaska-type complexes, $IrX(CO)\{P(C_6H_5)_3\}_2$ (X=halide).[26]

The two intermediates in the present reaction were confirmed to exist also from kinetic measurements. A typical decay curve of the absorbance at 370 nm after mixing $Rh(dtc)L_2$ and excess I_2 in benzene at 10.0 °C is depicted in Fig. 4, which indicates the reaction proceeds *via* two consecutive processes with the half-lives of about 3 ms and 3 s, respectively. These two processes were followed by a much slower one in which the

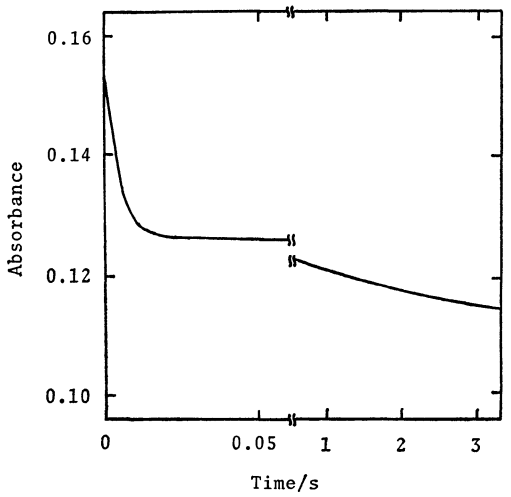

Fig. 4. Decay of the absorbance at 370 nm with time for the reaction of $Rh(dtc)L_2$ (1.0×10^{-4} M) with I_2 (1.0×10^{-3} M) in benzene at 10.0 °C.

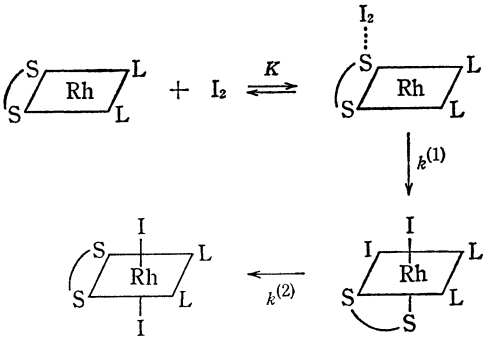
a) Average values in parentheses. $k^{(1)}_{obsd}$ and $10^3\,k^{(2)}_{obsd}$ are 197±1 and 83.2±0.6, respectively, for the reaction of $Rh(acac)L_2$ (1.0×10^{-4} M) with I_2 (1.0×10^{-3} M) at 25.1 °C.

trans-$RhI_2(dtc)L_2$ further reacted with excess I_2 to give $RhI(I_3)(dtc)L_2$. The last process, however, has not been kinetically analyzed, because there was little change in absorbance. The reaction rate in the two initial processes is different from each other sufficiently enough to allow the graphical determination of rate constants.[27] Plots of $\ln(A_t-A_\infty)$ *vs.* time for each process were found to be linear. Pseudo-first-order rate constants, $k^{(1)}_{obsd}$ and $k^{(2)}_{obsd}$ were obtained by the least-squares method. The results are shown in Table 2; the $k^{(1)}_{obsd}$ and $k^{(2)}_{obsd}$ are both essentially independent of the concentration of I_2 at a given temperature. Thus, the equimolar reaction of $Rh(dtc)L_2$ with I_2 is suggested to proceed *via* the CT complex, $Rh(dtc)L_2\cdot I_2$, which undergoes a rapid rearrangement probably to give *cis*-$RhI_2(dtc)L_2$, followed by isomerization to the *trans* adduct, as shown in the following scheme. The isomeri-



zation of the *cis* adduct to the *trans* one may be a site exchange between the equatorial iodide ligand and the axial dtc-sulfur atom *via* a rhombic twist or by a metal-sulfur bond rupture mechanism. According to this reaction scheme, $k_{obsd}^{(1)}$ can be expressed by Eq. 1.

$$k_{obsd}^{(1)} = \frac{Kk^{(1)}[I_2]}{1+K[I_2]} \quad (1)$$

When $K[I_2]$ is much greater than unity, $k_{obsd}^{(1)}$ can be reduced to $k^{(1)}$. This is consistent with the present result that $k_{obsd}^{(1)}$ is little dependent on the I_2 concentration. Since the *cis-trans* isomerization proceeds intramolecularly, the scheme also predicts $k_{obsd}^{(2)}$ being independent of $[I_2]$, which is in agreement with the results obtained. Activation parameters obtained by the Arrhenius plots for the two processes are: $\Delta H_{298}^{\ddagger(1)} = 57.7 \pm 2.0$ kJ mol^{-1}, $\Delta S_{298}^{\ddagger(1)} = 4.0 \pm 6.9$ J mol^{-1} K^{-1} for the decomposition of CT complex, and $\Delta H_{298}^{\ddagger(2)} = 75.5 \pm 3.9$ kJ mol^{-1}, $\Delta S_{298}^{\ddagger(1)} = 8.0 \pm 9.9$ J mol^{-1} K^{-1} for the *cis–trans* isomerization. The small positive values of $\Delta S_{298}^{\ddagger(1)}$ and $\Delta S_{298}^{\ddagger(2)}$ are consistent with the two proposed intramolecular processes. In addition, the $\Delta H_{298}^{\ddagger(2)}$ value is comparable to the activation enthalpies (75 to 104 kJ mol^{-1}) of *cis-trans* isomerizations of $Cr(CO)_4\{C(OCH_3)CH_3\}(PR_3)$ ($R = C_2H_5$, C_6H_{11}),[28] $Ru(CO)_4(SiCl_3)_2$,[29] and $Os(CO)_4\{Si(CH_3)_3\}_2$,[29] which have been proposed to proceed *via* intramolecular manners, supporting the formation of the *cis* isomer as a short-lived species as suggested above.

Proton Magnetic Resonance Studies of 4-(2-Pyridylazo)resorcinol (PAR) and Its Cobalt(III) Complexes†

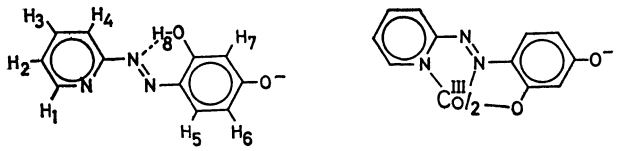
Katsura Mochizuki, Tasuku Ito,†† and Masatoshi Fujimoto*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 6, 1978)

The ^1H NMR spectra of PAR, $[Co^{III}(par)_2]^-$, and $[Co^{III}(par)(dien)]^+$ were measured in D_2O solutions. The signals were assigned. The deuteration of H_7 was observed in D_2O solutions of free ligand PAR around pD 9—10, where PAR exists in the form of LH^- having an intramolecular hydrogen-bond. The significant up-field shift for the resonance of H_1 was observed in $[Co^{III}(par)_2]^-$ but not in $[Co^{III}(par)(dien)]^+$. The shift was interpreted in terms of the magnetic anisotropy due to the π-electron system of the neighboring PAR molecule in the complex. The down-field shift for the resonance of the H_5 signal of the cobalt(III) complexes reflects the structural change of PAR upon chelate-ring formation. PAR coordinates to cobalt(III) ion in planar terdentate fashion, *viz.*, in a *mer* configuration.

4-(2-Pyridylazo)resorcinol (PAR, Fig. 1(a)) has widely been used as a metallochromic indicator.[1] A number of data on the compositions and the stability constants of the PAR-chelates have been reported.[1-5] In a previous paper,[6] we confirmed in the course of the reactions between Co^{2+} and PAR and its analogs the fast formation of a transient intermediate cobalt(II) complex and the subsequent slower oxidation to cobalt(III) complex. The measurements of magnetic susceptibility have also confirmed the formation of cobalt(III) complex in the solution prepared from Co^{2+} and PAR.[7]



(a) (b)

Fig. 1. Structural formulae of (a) PAR with numbering of the protons and (b) its cobalt(III) complex.

As a part of serial studies on the metal chelates of PAR and its analogs,[6-8] the ^1H NMR spectra of PAR and its cobalt(III) complexes were studied in the present paper. Figure 1 shows the suggested structures of a free ligand PAR and the metal complexes of PAR. A form with an intramolecular hydrogen-bond (Fig. 1(a)) has been suggested for a free ligand PAR in solutions.[1,9] On the other hand, no direct evidence on the structures of the PAR chelates has been reported so far. The crystal structures of $[Cu(pan)(OH_2)]ClO_4$,[10] $[Ni(tan)_2]$,[11] $[Fe(tan)_2]$,[12] $[PdCl(tan)]$,[13] $[Co(tan)_2]ClO_4$,[14] and $[Cu(tan)(OH_2)_2]ClO_4$[15] have been reported, where pan and tan denote 1-(2-pyridylazo)-2-naphthol and 1-(2-thiazolylazo)-2-naphthol, respectively. The results of the X-ray analyses of these complexes suggest that the cobalt–PAR complex has the structure shown in Fig. 1(b), since PAN and TAN, as well as PAR, are *o*-hydroxy azo compounds and the PAR complexes can have the same chelate structure as the PAN and TAN complexes. Therefore, a structural change of the ligand PAR occurs upon coordination; breaking of the intramolecular hydrogen-bond and subsequent internal rotation of the resorcinol ring around the C–N bond by 180°. The main interest of the present work is to elucidate the structures of PAR and its cobalt(III) complexes in solutions by ^1H NMR measurements.

Experimental

Materials. PAR and $[Co^{III}(par)_2]$ were prepared as reported in the previous paper.[6] Deuterium oxide (99.7%), DMSO-d_6 (99.5%), and *ca.* 40% NaOD in D_2O were purchased from E. Merck, Ltd. Reagent grade materials were used unless otherwise specified.

A new complex $[Co^{III}(par)(dien)]Cl\cdot NaCl$ was prepared from $[Co^{III}Cl_3(dien)]$ after the synthetic route described for the preparation of $[Co^{III}(ida)(dien)]$ from $[Co^{III}Cl_3\cdot(dien)]$[16] (ida=iminodiacetate ion). Two grams of the monosodium salt of PAR in 75 ml H_2O were added to 50 ml of suspended aqueous solution containing 2.1 g of $[Co^{III}Cl_3(dien)]$ and 0.6 g of charcoal at 50 °C with stirring. The addition of 20 ml of 20% aqueous solution of $AgNO_3$ produced a deep red solution. The reaction mixture was stirred for 2 h at 50 °C and cooled. After the further addition of 0.3 g of NaCl, the solution was filtered. The pH of the filtrate was adjusted to 7—8 with NaOH and the solution was diluted to 400 ml with water. One hundred milliliters of this solution were passed through a column of a cation-exchange resin SP-Sephadex C-25 in the Na-form (400 mm × 30 mm i.d.) and eluted with a 0.1 mol dm^{-3} aqueous solution of NaCl at pH 7—8 (NaOH). The eluates from the main band were collected and evaporated to a small volume at 40—50 °C. The precipitated sodium chloride was filtered off and the filtrate was evaporated to dryness. A small amount of ethanol was added to the residue. The extract was filtered to remove sodium chloride. Successive filtration and extraction yield *ca.* 30 mg of deep red black crystals with golden luster. The yield was very low because of the high solubilities of the product in H_2O and ethanol. Found: C, 38.44; H, 4.74; N, 17.96%. Calcd for $C_{15}H_{21}N_6O_2Cl_2CoNa$: C, 38.40; H, 4.30; N, 17.91%. The elemental analysis shows that the isolated complex contains one mole of sodium chloride.

† Presented in part at the 1976 Summer Meeting in Hokkaido of the Chemical Society of Japan and the Japan Society for Analytical Chemistry, Kitami, July 19, 1976, Abstracts p. 12.

†† Present Address: Institute for Molecular Science, Okazaki 444.

[$Pd^{II}Cl$(par)] was synthesized by the reaction between monosodium salt of PAR and palladium(II) chloride in an aqueous solution at pH 1—2 (HCl). The precipitate which formed upon mixing of the stoichiometric amounts of the reagents was filtered off, washed with water, and dried in a desiccator over silica gel. Found: C, 36.09; H, 2.65; N, 11.43%. Calcd for $C_{11}H_8N_3O_2ClPd \cdot 0.5H_2O$: C, 36.19; H, 2.49; N, 11.51%.

Measurements. 100 MHz ^1H NMR spectra were measured with a JEOL PS-100 spectrometer. Tetramethylsilane (TMS) and sodium trimethylsilylpropanesulfonate (DSS) were used as internal standards in DMSO-d_6 and D_2O solutions, respectively. The pD (pH-meter reading $+0.40$)[17] of the D_2O solutions was adjusted with NaOD and measured in nitrogen atmosphere with a Horiba pH-meter model M-7 equipped with a small glass electrode type 1826 05T and a reference electrode type 2410.

The ^1H NMR spectra of [Co^{III}(par)$_2$] and [Co^{III}(par)-(dien)] in D_2O solutions were measured at pD *ca.* 10, where the coordinated PAR in [Co^{III}(par)$_2$] and [Co^{III}(par)-(dien)] exists in the same chemical form (*vide infra*) and the solubilities of the complexes were enough for the ^1H NMR measurements.

The ^1H NMR spectra of the 1:1 PAR-complexes, [La^{III}-(par)] and [Zn^{II}(par)], were measured with the alkaline-DMSO-d_6–D_2O solutions. The mixture of the monosodium salt of PAR and about fifty-fold excess of anhydrous La-$(NO_3)_3$ or anhydrous $ZnCl_2$ was dissolved as much as possible in 50%(v/v) DMSO-d_6–D_2O. One drop of 10% D_2O solution of NaOD was added. The solution was filtered. The red filtrate was subjected to the measurements.[18]

The ^1H NMR spectrum of [$Pd^{II}Cl$(par)] was measured with a red DMSO-d_6–D_2O solution, which was prepared by adding a small amount of 10% D_2O solution of NaOD to a green solution of the complex in 50%(v/v) DMSO-d_6–D_2O.[21]

Absorption spectra were measured at 25 °C and $I=0.1$ ($NaClO_4$) with a Hitachi recording spectrophotometer Model EPS-3T. The pH of the aqueous solution of [Co^{III}(par)-(dien)]Cl was measured with a Radiometer pH-meter 4d (Copenhagen) equipped with a glass electrode type G 202B and a reference electrode type 410.

Results and Discussion

^1H NMR Spectra of the Free Ligand. The 100 MHz spectrum of the monosodium salt of PAR in DMSO-d_6 at 90 °C is given in Fig. 2. Under these conditions the spectrum was highly resolved. Since the observed signals were well-separated from each other as compared with the coupling constants, the first-order analysis of the spin-spin coupling constants and the values of the chemical shifts allowed the assignments of the signals. The assignments were further confirmed by applying the method of double irradiation at the resonance frequencies for the protons, H_1, H_2, H_3, H_4, and H_6. In Table 1 are listed the values of the chemical shifts measured for band centers or maxima and the coupling constants evaluated from the spacings of the split signals (for numbering of the protons, see Fig. 1(a)). The significant difference in the values of J_{12} and J_{23} permitted the unambiguous assignments of H_2 and H_3. Though no direct evidence has been reported so far, the following facts suggest the presence of intramolecular hydrogen-bond for the free ligand PAR (Fig. 1(a)) in solutions: The pK_a value of the *o*-hydroxyl group (12.31) is much higher than that of the *p*-hydroxyl group (5.6)[1] and also higher than the value of pK_{a2} for resorcinol (11.06);[22] the proton-transfer reaction of the *o*-hydroxyl group of PAR proceeds slowly;[9] the IR spectrum of 4-(phenylazo)resorcinol in CCl_4 shows a broad band due to an intramolecular hydrogen-bond –OH···N= around 2860 cm^{-1}.[23] Furthermore, we observed the following facts: The resonance for the H_8, the proton of the *o*-hydroxyl group, appeared at very low field at 25 °C (see Table 1); The chemical shift of this resonance was not affected on dilution; The resonance disappeared by addition of one portion of

D_2O. These results directly show the presence of an intramolecular hydrogen-bond in the free PAR.[24]

^{1}H NMR spectra of PAR in D_2O solutions were measured in the range of pD 9—14, where PAR exists in the form of LD^- and L^{2-} as revealed in the electronic absorption spectra.[1)†††] In the pD range, where two species of PAR are in equilibrium, only the averaged ^{1}H NMR spectrum of LD^- and L^{2-} was observed instead of the simple sum of each spectrum. The chemical shifts of the protons H_1, H_5, and H_7 moved to lower field with increasing concentration of NaOD, while that of H_6 was almost invariable with varying pD. Figure 3 shows the plots of the chemical shifts of H_5 and H_7 *vs.* pD. From these plots, the pK_a value for the acid-dissociation of the *o*-hydroxyl group in D_2O

$$LD^- \overset{K_a}{\rightleftharpoons} L^{2-} + D^+$$

was determined to be 12.8 ± 0.3, which is reasonable compared with the literature value 12.31 determined spectrophotometrically in H_2O.[1)] Figure 4(a) shows the ^{1}H NMR spectrum of the free ligand PAR in D_2O solution at pD 9.3, which corresponds to the spectrum of LD^- as is clear from Fig. 3.

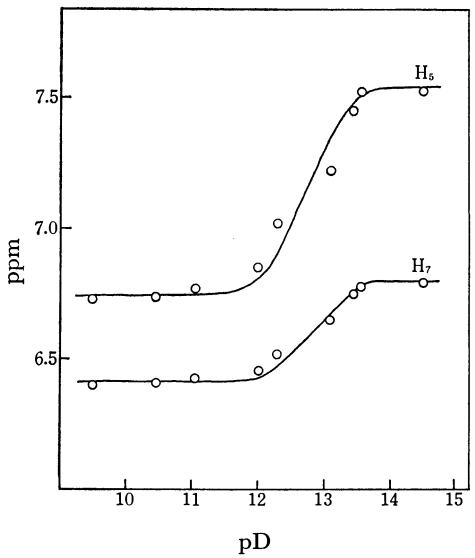

Fig. 3. Plots of the chemical shifts corresponding to H_5 and H_7 *vs.* pD.

In the course of the experiments on the pD-dependency of the ^{1}H NMR spectra, it was found that the proton H_7 was deuterated in D_2O solutions. The intensity of the signal for H_7 decreased with the lapse of time. At the same time, the signal shape of the H_6 resonance changed gradually. The rate of the deuteration depended strongly on the pD of the solution. The deuteration of H_7 can be distinctly observed in Fig. 4(a). The integrated intensity for the signal of H_7 in the spectrum (a) is considerably less than that for one proton. In addition the H_6–H_7 coupling observed in the resonance for H_6 has almost disappeared (see the signal shape of the H_6 resonance in Fig. 2). The plot of the integrated intensity of the H_7 signal *vs.* time allowed the kinetic measurements of the deuteration. The half-times of the deuteration at room temperature at pD 9.3 and *ca.* 14 were found to be 80 min and 2.5 day, respectively. The deuteration proceeds much faster in LD^- than in L^{2-}. The LD^- species of PAR has an intramolecular hydrogen-bond, which may affect the electronic state of the carbon atom bonded to H_7 so as to facilitate the H–D exchange in D_2O. In fact, no corresponding deuteration was observed in L^{2-}, $[Co^{III}(par)_2]$, and $[Co^{III}(par)(dien)]$ containing no intramolecular hydrogen-bond.

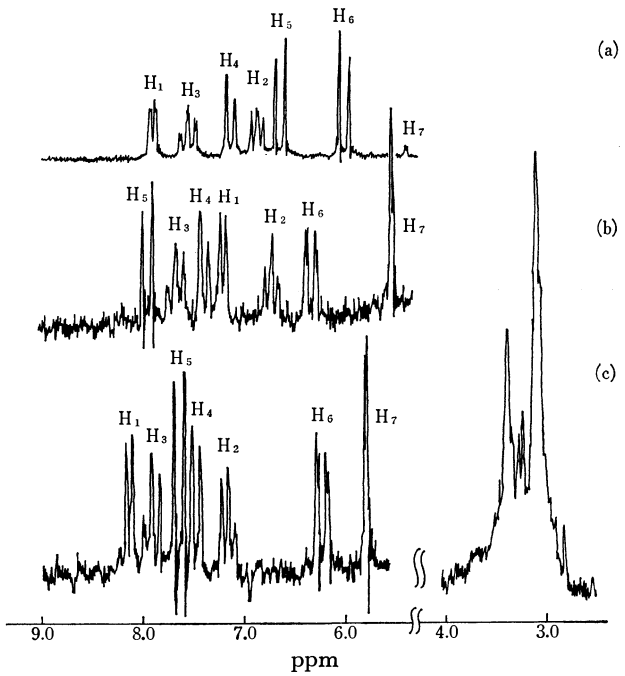

Fig. 4. ^{1}H NMR spectra in D_2O solution of (a) PAR at pD 9.3, (b) $[Co^{III}(par)_2]$, and (c) $[Co^{III}(par)(dien)]$ at pD *ca.* 10.

^{1}H NMR Spectra of the Cobalt(III) Complexes. Figure 4(b) shows the ^{1}H NMR spectrum of $[Co^{III}(par)_2]$ in D_2O solution at pD *ca.* 10. Under this condition $[Co^{III}(par)_2]$ exists in the form of $[Co^{III}L_2]^-$.[6)] The spectrum indicates that two ligand molecules in $[Co^{III}L_2]^-$ are magnetically and chemically equivalent. The ^{1}H NMR spectrum of $[Co^{III}(par)(dien)]$ at pD *ca.* 10 is shown in Fig. 4(c). The integrated intensities of the signals showed the presence of seven aromatic protons and six methylene protons (complex multiplet centered at *ca.* 3.2 ppm) corresponding to the coordinated ligands PAR and dien, respectively. As will be described later, $[Co^{III}(par)(dien)]$ exists in the form of $[Co^{III}L(dien)]^+$ at pD *ca.* 10.

Small couplings were not clearly observed in the spectra of $[Co^{III}L_2]^-$ and $[Co^{III}L(dien)]^+$ because of the low solubilities of the complexes in D_2O. However, comparison of the spectrum of the free ligand with those of the cobalt(III) complexes revealed that the spin-spin couplings in PAR remained essentially unchanged upon coordination, though the chemical shifts of some protons changed considerably. All the

††† Hereafter, "PAR" stands for L^{2-}, LH^-, LH^{*-}, LHH^*, and/or LD^-, where H* denotes the proton of the *p*-hydroxyl group.

signals of $[Co^{III}L_2]^-$ and $[Co^{III}L(dien)]^+$ were unambiguously assigned by the analysis of the coupling constants. The coupling constant J_{12} is smaller than J_{23} in the cobalt(III) complexes as well. The assignments are given in Table 2.

Table 2. ^1H NMR chemical shifts of LH^-, $[Co^{III}L_2]^-$, and $[Co^{III}L(dien)]^+$ a)

	H_1	H_2	H_3	H_4	H_5	H_6	H_7

d) Chloride. At pD *ca.* 10.

The resonance of H_1 in $[Co^{III}L_2]^-$ shows a definite up-field shift compared with that in free PAR. On the other hand, such an up-field shift was not observed for the H_1 resonance of $[Co^{III}L(dien)]^+$ (see Table 2). In order to clarify whether the difference in chemical shift of H_1 is caused by the number of PAR molecules in the complex, we measured ^1H NMR spectra of the PAR chelates of other metal ions containing only one PAR ligand, $[Pd^{II}ClL]^-$, $[La^{III}L]^+$, and $[Zn^{II}L]^0$, in 50%(v/v) DMSO-d_6–D_2O mixed solvents containing one drop of *ca.* 10% NaOD.[18,21] No up-field shift of the H_1 signal was observed for these complexes. Spectral pattern of these complexes was very similar to that of $[Co^{III}L(dien)]^+$ but not to that of $[Co^{III}L_2]^-$. A careful inspection of molecular models reveals a plausible explanation for the up-field shift of the H_1 signal of $[Co^{III}(par)_2]$. The proton H_1 of one PAR molecule in $[Co^{III}(par)_2]$ is disposed close to and above the azo group of the other PAR molecule, only when two PAR molecules coordinate to cobalt(III) ion in planar fashion as terdentate ligands. In view of this fact and the above-mentioned observations, the large up-field shift can reasonably be explained as being caused by the magnetic anisotropy due to the π-electron system of the azo group in the neighboring ligand PAR. The up-field shift of the H_1 signal would not be expected for free PAR, $[Co^{III}L(dien)]^+$, $[Pd^{II}ClL]^-$, $[La^{III}L]^+$, and $[Zn^{II}L]$, since the proton H_1 in these compounds cannot experience the chemical environment as described above.

Similar up-field shifts have been observed for the *ortho*-protons of pyridyl nitrogen in $[M(phen)_3]^{n+}$ [25] (M=Fe(II), Ru(II), Zn(II), and Co(III)), in $[Co^{III}(phen)_2(en)]^{3+}$,[26] and in $[Fe^{II}(bipy)_3]^{2+}$.[27] One of the β-methylene protons in tris-(*N*,*N'*-dibutyl-2,3-butanediimine)iron(II) complex has been also reported to show similar large up-field shifts.[28] The up-field shifts observed in these complexes have been interpreted in terms of the ring current of the neighboring aromatic ligands[26,27] or in terms of the magnetic anisotropy due to the imine bonds of the neighboring ligands.[28]

Another remarkable feature found in the ^1H NMR spectra of cobalt(III)–PAR complexes in comparison with that of the free PAR is a large difference in the chemical shift of the proton H_5. The H_5 signal appears at 6.63 ppm in the free ligand at pD 9.3, while the corresponding signal appears at 7.98 ppm in $[Co^{III}L_2]^-$ and 7.64 ppm in $[Co^{III}L(dien)]^+$ at pD *ca.* 10. As was discussed before, around pD 10 the free ligand PAR and the cobalt(III) complexes have the structures shown in Figs. 1(a) and 1(b), respectively. The terdentate and planar coordination of PAR molecule is accompanied by an internal rotation of resorcinol ring moiety around C–N axis by 180°. The molecular model suggests that the coordination of PAR causes a fairly strong strain in the complexes especially for the bond angle around cobalt(III) ion. The bond angles, N(pyridine)–Co–N(azo) and N(azo)–Co–O, are expected to be significantly smaller than 90°. As a result, a fairly close contact appears between the proton H_5 and the azo group. The proton H_5 in such a chemical environment would be susceptible to the effect of the magnetic anisotropy due to the π-electron system of the azo group in addition to the effect of the ring current of the resorcinol ring. The location of the proton H_5 in such an environment causes a down-field shift when the complexes are in the magnetic field.

Very similar situation has been found in the crystal structure of $[Co^{III}(tan)_2]$.[14] The X-ray analysis of $[Co^{III}(tan)_2]$ shows that the bond angles around the cobalt atom within the chelate ring are compressed to 84.9 and 81.6° and that the coordinated TAN is deformed due to the in-plane close contact around the azo group. The significant down-field shift of the H_5 signal observed for the cobalt(III) complexes of PAR can be ascribed to the structural change of PAR upon chelate-ring formation.

On the basis of the ^1H NMR studies, it is concluded that PAR coordinates to cobalt(III) ion in planar fashion as a terdentate ligand, namely, in the *mer* configuration.

Acid-Base Behavior of $[Co^{III}(par)(dien)]$. In order to confirm the chemical species of $[Co^{III}(par)(dien)]$ present under the conditions of the ^1H NMR measurements, the absorption spectra were measured in aqueous solutions at various pH. Figure 5 shows the pH-

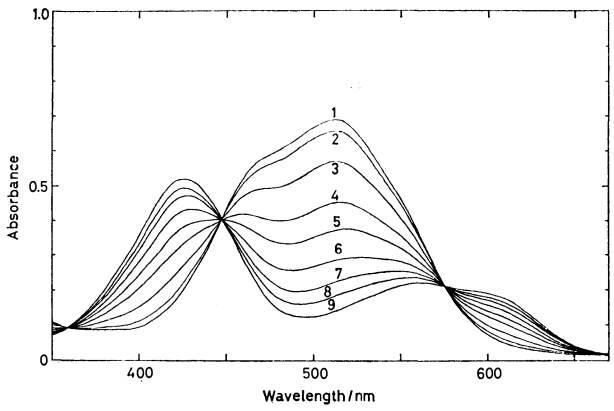

Fig. 5. Absorption spectra of the aqueous solution of $[Co^{III}(par)(dien)]$ as a function of pH at 25 °C and I=0.1 ($NaClO_4$). pH=8.88 (1), 5.79 (2), 5.06 (3), 4.60 (4), 4.33 (5), 4.01 (6), 3.67 (7), 3.34 (8), and 2.36 (9).

dependence of the absorption spectrum of [Co^{III}(par)-(dien)]. Well-defined isosbestic points were observed at 359, 447, and 576 nm, which demonstrate the presence of a simple equilibrium. The spectral change with varying pH was fully reversible. In view of the inertness of the cobalt(III) complexes against the ligand dissociation, the pH-dependence of the spectrum can be attributed to the protonation-deprotonation equilibrium of a *p*-hydroxyl group of the coordinated PAR in [Co^{III}(par)(dien)]. From the plot of absorbance at 500 nm *vs.* pH, the value of pK_a for the acid-dissociation

$$[Co^{III}LH^*(dien)]^{2+} \overset{K_a}{\rightleftharpoons} [Co^{III}L(dien)]^+ + H^+$$

was determined to be 4.52±0.03. The average value of the acid-dissociation constants for pK_{a1}([Co^{III}-(LH^*)$_2$]$^+$) and pK_{a2}([$Co^{III}L(LH^*)$]) has been reported to be 4.1.[6] Around pH 10, where the ^{1}H NMR measurements were carried out, [Co^{III}(par)(dien)] exists only in the form of [$Co^{III}L$(dien)]$^+$.

A Study of the Ligand Exchange Reaction of Tetrakis(μ-trifluoroacetato)-dimolybdenum(II) in Acetonitrile by ^{19}F NMR Spectroscopy

Kazunori TERAMOTO, Yoichi SASAKI,* Kouto MIGITA,† Masamoto IWAIZUMI,† and Kazuo SAITO*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

†*Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980*

(Received July 5, 1978)

The dimeric molybdenum(II) complex, $Mo_2(CF_3COO)_4$, forms $Mo_2(CF_3COO)_4\cdot(CH_3CN)_2$ in acetonitrile, where solvent molecules are attached to positions trans to the metal–metal bond (apical positions). The rate of ligand exchange between $Mo_2(CF_3COO)_4$ ($(1.31—8.28)\times10^{-2}$ M; M=mol dm^{-3}) and CF_3COONa ($(1.31—4.56)\times10^{-1}$ M) was measured in acetonitrile by the use of ^{19}F NMR spectroscopy. The rate is independent of the total concentration of CF_3COONa and is linearly dependent on that of $Mo_2(CF_3COO)_4$. The first-order rate constant (k_{ex}) is $(1.1\pm0.2)\times10^4$ s^{-1} (25 °C), and the activation parameters are $\Delta H^{\ddagger}=(8.2\pm0.8)$ kcal mol^{-1} and $\Delta S^{\ddagger}=(-15\pm3)$ cal K^{-1} mol^{-1}. Under the given conditions the complex seems to exist as $Mo_2(CF_3COO)_4\cdot CF_3COO^-$, where the underlined ligand occupies one of the apical positions, and the following mechanism is proposed (solvent molecules are omitted; asterisks indicate the molecule substituting for the coordinated ligand).

$$Mo_2(CF_3COO)_4\cdot\underline{CF_3COO^-} + {}^*CF_3COO^- \overset{\text{fast}}{\rightleftharpoons} Mo_2(CF_3COO)_4\cdot{}^*\underline{CF_3COO^-} + CF_3COO^-$$

$$Mo_2(CF_3COO)_4\cdot{}^*\underline{CF_3COO^-} \xrightarrow{k_s} Mo_2(CF_3COO)_3({}^*CF_3COO)\cdot\underline{CF_3COO^-}$$

The k_{ex} corresponds to k_s.

Bivalent molybdenum forms diamagnetic compounds having strong metal–metal bonds such as $Mo_2(RCOO)_4$ (R=CH_3, CF_3, *etc.*), $Mo_2X_8^{4-}$ (X$^-$=Cl$^-$ and Br$^-$), and $Mo_2(SO_4)_4^{4-}$, with bond distances of about 2.1 Å.[1-5] Their structures in the crystalline state[1,2,4] and their spectroscopic properties[2,5] have been widely studied, but little attention has been drawn to their reactivities in solution.[6,7] The first and only report on the kinetics of the substitution reaction describes the substitution of acetate ions for the chloride ligands of $Mo_2Cl_8^{4-}$ to give $Mo_2(CH_3COO)_4$, and a dissociative mechanism was suggested.[7]

We have examined the solubility and stability of several dimeric molybdenum(II) complexes in various solvents in search of a simple system suitable for elucidating the substitution properties still further. Tetrakis(μ-trifluoroacetato)dimolybdenum(II), $Mo_2(CF_3COO)_4$ [I] (Fig. 1), in acetonitrile seemed suitable for our purpose. The Mo–Mo bond length of this compound is 2.090 Å, and the four trifluoroacetate ligands are equivalent in the crystalline state.[8] This paper reports on the results of a kinetic study of its ligand exchange reaction with sodium trifluoroacetate in acetonitrile by the use of ^{19}F NMR spectroscopy.

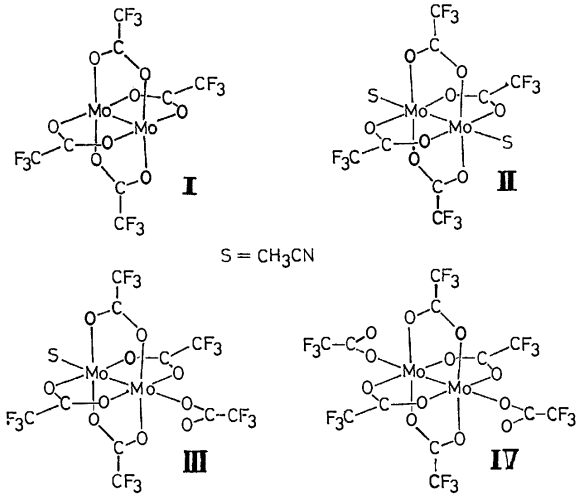

Fig. 1. Various forms of $Mo_2(CF_3COO)_4$ in solution. $Mo_2(CF_3COO)_4$ [I], $Mo_2(CF_3COO)_4\cdot(CH_3CN)_2$ [II], $Mo_2(CF_3COO)_4\cdot(CF_3COO)(CH_3CN)^-$ [III], and $Mo_2(CF_3COO)_4\cdot(CF_3COO)_2^{2-}$ [IV].

Experimental

Materials. Tetrakis(μ-trifluoroacetato)dimolybdenum(II) was prepared by the known method,[8] and sublimed before measurement of the ^{19}F NMR and electronic absorption spectra. Sodium trifluoroacetate (special grade reagent) was used without further purification. Acetonitrile was distilled twice over diphosphorus pentaoxide. Dichloromethane was distilled twice. Methanol (special grade reagent) was used without distillation. Each solvent was stored *in vacuo* over Linde 4a molecular sieves. The water content in each solvent was estimated to be as low as 5×10^{-3} M (M=mol dm^{-3}) using a Karl-Fischer titration.

Measurements. Electronic absorption spectra were measured using a Hitachi 323 Recording Spectrophotometer. The ^{19}F NMR spectra were recorded with a JEOL JNM-PM-100 high resolution NMR spectrometer operating at 94 MHz, with a variable temperature probe. Chemical shifts are recorded with respect to the internal standard CF_2Cl_2 (Freon 12).

Sample Preparation. Weighed samples of the complex and sodium trifluoroacetate were placed in an NMR tube, into which the solvent was introduced through a vacuum line. The molar concentration of each component was calculated from the volume of the prepared sample solution at room temperature, and expressed as $[Mo_2(CF_3COO)_4]_T$ and $[CF_3COO^-]_T$. Sample solutions were stored in liquid nitrogen for as long as a month without deterioration.

Evaluation of the Mean Life Time of the Coordinated and Free Ligands. A general method for studying a system involving two exchange sites[9] was applied to the present system. In the slow exchange region where two separate peaks are observed, the following equations were used:

$$\tau_c^{-1} = (W_c - W_c^{\circ}), \quad (1)$$

$$\tau_f^{-1} = (W_f - W_f), \quad (2)$$

where τ_c and τ_f are the mean life times of the coordinated and free ligands, and W_c and $W_c°$ (or W_f and $W_f°$) are the half line widths in Hz at half-height of the signal of the coordinated (or free) ligand of the sample solution and of the solution without free (or coordinated) ligand, respectively. In the fast exchange region where the two peaks coalesce completely, the following equation was used:

$$\tau_c^{-1} = \frac{4\pi p_c p_f^2 (\Delta\nu)^2}{W_{cf} - p_c W_c° - p_f W_f°}, \quad (3)$$

where p_c and p_f are the mole fractions of two exchanging species, W_{cf} is the half line width in Hz at half-height of the signal of the coalesced peak, and $\Delta\nu$ is the chemical shift difference in Hz between the signals of the coordinated and the free ligand (ν_c and ν_f) both measured in the absence of each other. The following equation should hold.

$$p_c/\tau_c = p_f/\tau_f \quad (4)$$

In the region of intermediate exchange, τ_c^{-1} was obtained by comparison of the observed spectra with the calculated spectra.[10] A Nihon-minicon NOVA-01 was used for the calculation.

The $W_c°$ and $W_f°$ values showed small temperature dependence. The values at any temperature between −40 and 70 °C were estimated from the calibration curves for the temperature dependence. The ν_c and ν_f gave no appreciable temperature dependence over the temperature range from −40 to 70 °C. The $\Delta\nu$ value was 306 Hz at all temperatures.

Results and Discussion

Structure of the Complex in Acetonitrile. Various compounds are known which have the general formula: $Mo_2(CF_3COO)_4 \cdot L_n^{m-}$ ($n=1$, $m=0$, L=$(C_6H_5)_3P$;[11] $n=2$, $m=0$, L=pyridine (py)[12] and CH_3OH;[11] $n=1$, $m=1$, $L^-=Cl^-$, CF_3COO^- *etc.*; $n=2$, $m=2$, $L^-=Br^-$ and Cl^-[13]). X-Ray crystallography disclosed that $Mo_2(CF_3COO)_4 \cdot (py)_2$ has two weakly coordinated pyridine molecules at both positions trans to the metal–metal bond (hereafter called apical positions).[12] The other L's are believed to coordinate similarly to the molybdenum ion.[11,13]

The ν(Mo–Mo) stretching frequency observed by Raman spectroscopy is sensitive to the apical ligand. The ν(Mo–Mo) value of solid $Mo_2(CF_3COO)_4$ is 397 cm^{-1},[8] while those of the compounds containing apical ligands are between 386 ($n=2$, L=CH_3OH) and 368 cm^{-1} ($n=2$, L=py) in the solid state.[11-13] The value for the solid $Mo_2(CF_3COO)_4 \cdot (CH_3OH)_2$ is 386 cm^{-1}.[13] On the other hand $Mo_2(CF_3COO)_4$ has ν(Mo–Mo) values of 397 and 383 cm^{-1} in dichloromethane and methanol respectively.[12] The two apical positions must be occupied by solvent molecules in methanol and remain vacant in dichloromethane. The ν(Mo–Mo) values in acetone and diethylether are 385 and 383 cm^{-1} respectively,[12] and these solvent molecules are also likely to occupy the apical positions. Acetonitrile solution could not be used in similar studies because the solvent itself gives strong Raman bands in the region of interest. On the other hand, Cotton and Norman found that the energy of the electronic transition of $Mo_2(CF_3COO)_4$ at *ca.* 430 nm in various solvents decreases as the ν(Mo–Mo) decreases.[12] Thus the coordination of solvent molecules at the apical positions lowers the energy of electronic transition. The electronic absorption spectra of $Mo_2(CF_3COO)_4$ in dichloromethane, methanol and acetonitrile are shown in Fig. 2. The peak positions are at 428 (ε, 95 cm^{-1} M^{-1}), 434 (118), and 434 nm (112), respectively. From these spectra it is concluded that $Mo_2(CF_3COO)_4$ is present as $Mo_2(CF_3COO)_4 \cdot (CH_3CN)_2$ (II) (Fig. 1) in acetonitrile.

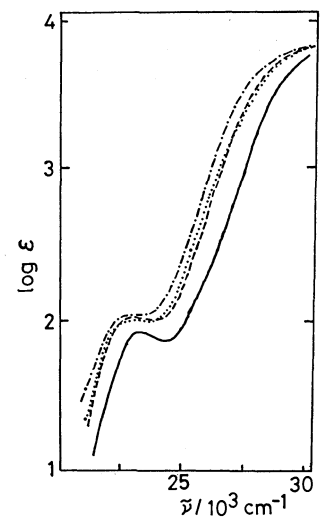

Fig. 2. The electronic absorption spectra of $Mo_2(CF_3COO)_4$ in CH_2Cl_2 (——), methanol (– – –), acetonitrile (·····) and in acetonitrile containing 4.6×10^{-2} M of CF_3COONa (-·-·-).

The Species in the Presence of the Free Ligand. A complex, $[(C_2H_5)_4N][Mo_2(CF_3COO)_4 \cdot (CF_3COO)]$, has been isolated from an equimolar mixture of $Mo_2(CF_3COO)_4$ and $[(C_2H_5)_4N][CF_3COO]$ in dichloromethane.[12] On addition of sodium trifluoroacetate to an acetonitrile solution of $Mo_2(CF_3COO)_4$, the peak position at 434 nm shifts to slightly longer wavelengths with an increase in strength (Fig. 2). This change may be caused by the substitution of trifluoroacetate ion(s) for acetonitrile in apical position(s). The following reactions are believed to be involved,

$$[Mo_2(CF_3COO)_4 \cdot \underline{(CH_3CN)_2}] + CF_3COO^- \overset{K_1}{\rightleftharpoons} \underset{(II)}{} \quad [Mo_2(CF_3COO)_4 \cdot \underline{(CF_3COO)}\,\underline{(CH_3CN)}]^- + CH_3CN, \quad (5)$$
$$\underset{(III)}{}$$

$$[Mo_2(CF_3COO)_4 \cdot \underline{(CF_3COO)}\,\underline{(CH_3CN)}]^- + CF_3COO^- \overset{K_2}{\rightleftharpoons} [Mo_2(CF_3COO)_4 \cdot \underline{(CF_3COO)_2}]^{2-} + CH_3CN. \quad (6)$$
$$\underset{(III)}{} \qquad \underset{(IV)}{}$$

The underlined ligands denote the ligand at the apical positions. The change in electronic absorption spectra is too small to enable the evaluation of K_1 and K_2. However, as Fig. 3 shows, appreciable amounts of III and/or IV (Fig. 1), must be present when the free ligand concentration is ≧0.01 M in the *ca.* 5×10^{-3} M complex solution.

^{19}F NMR Spectra in Acetonitrile. The ^{19}F NMR spectrum of the complex in acetonitrile (*ca.* 4×10^{-2} M)

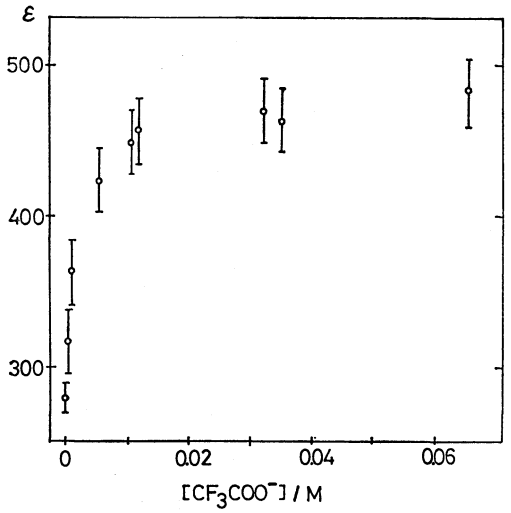

Fig. 3. The change in apparent molar absorption coefficient (ε) at 390 nm of $Mo_2(CF_3COO)_4$ in acetonitrile with a change in concentration of added CF_3COONa.

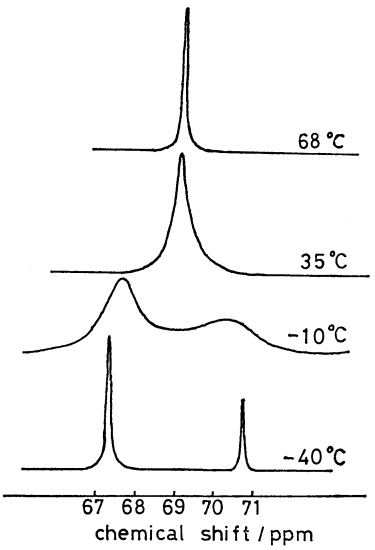

Fig. 4. An example of the temperature dependence of the ^{19}F NMR spectra of an acetonitrile solution of $Mo_2(CF_3COO)_4$ and CF_3COONa ($[Mo_2(CF_3COO)_4]=5.26\times10^{-2}$ M and $[CF_3COONa]=0.146$ M). Chemical shifts are shown with respect to CF_2Cl_2 as an internal reference.

shows one sharp peak upfield from the reference peak at 67.6 ppm over a temperature range of −40 to 70 °C, suggesting that the four trifluoroacetate ligands are magnetically equivalent. Hence, no significant change in the basic structure of I occurs, except for coordination of the solvent molecules at the apical positions. Sodium trifluoroacetate (*ca.* 0.58 M) has one sharp band at 71.0 ppm in acetonitrile.

The temperature dependence over the temperature range from −40 to 70 °C of the ^{19}F NMR spectra of the solutions (Table 1) containing both the complex and the free ligand is exemplified in Fig. 4 (run 2 in Table 1). A similar dependence was observed for runs 1 and 3—7. The following observations were made for these solutions: (a) the positions of the two peaks (67.2—67.5 and 70.8—70.9 ppm) at a low temperature (−40 °C in Fig. 4) coincide with those of the complex and of the free ligand; (b) the p_c and p_f values obtained from the ratio of the integral strengths of the two peaks can be expressed by

$$p_c/p_f = 4[Mo_4(CF_3COO)_4]_T/[CF_3COO^-]_T; \quad (7)$$

(c) the chemical shift of the coalesced peak at a high temperature (68 °C in Fig. 4) is close to the value determined from the expression, $67.6\times p_c+71.0\times p_f$; (d) the τ_c^{-1} values estimated from each of the two separate peaks (Eqs. 1 and 2) are in reasonable agreement with each other; (e) plots of log (τ_c^{-1}) against T^{-1} give straight lines (Fig. 5). All of these observations support the conclusion that the temperature dependence of the ^{19}F NMR spectra can be interpreted by chemical exchange of the bridging trifluoroacetate with "free" CF_3COO^- ("free" includes both the apical and the free ligands).

The values of τ_c^{-1} at 25 °C and the activation energy (E_a) were calculated from the best fit lines of Arrhenius plots, and are summarized in Table 1. In order to see the kinetic salt effect, $(C_2H_5)_4NClO_4$ was added to the reaction mixture (run 7). Addition of 0.7 M $(C_2H_5)_4NClO_4$ did not change the pattern of the temperature

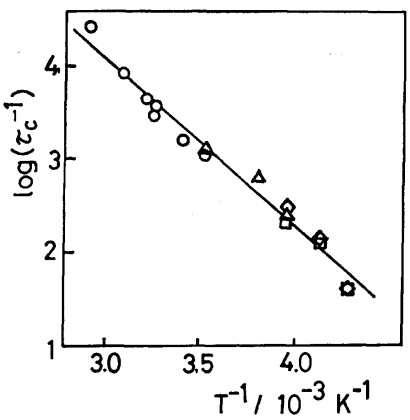

Fig. 5. An example of a plot of log (τ_c^{-1}) *vs.* T^{-1}. τ_c^{-1} values were obtained from Eq. 5 from the coalesced peak (○), by spectral simulation (△), from Eq. 1 from the peak in the coordinated ligand region (□), or from Eqs. 2 and 3 from the peak in the free ligand region (◇) ($[Mo_2(CF_3COO)_4]=5.81\times10^{-2}$ M and $[CF_3COONa]=0.456$ M). The solvent is acetonitrile.

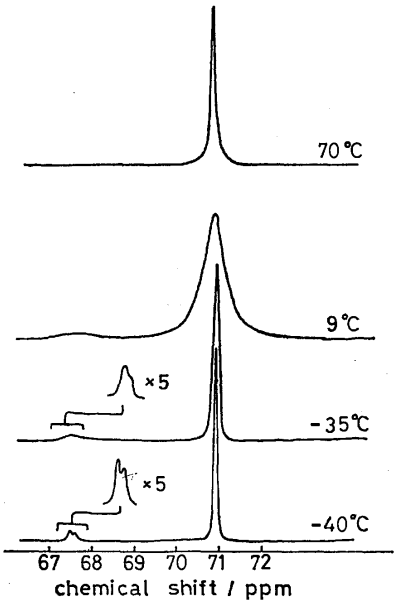

Fig. 6. Temperature dependence of the ^{19}F NMR spectra of an acetonitrile solution of $Mo_2(CF_3COO)_4$ (3.41 $\times10^{-2}$ M) and CF_3COONa (1.04 M) (run 9 in Table 1).

dependence of the signals, but gave a slight increase in τ_c^{-1}.

The Arrhenius plot for run 8 gave a concave curve. In run 9, the signal peak in the coordinated ligand region splits at a low temperature (Fig. 6). Thus, the ^{19}F NMR spectra of the solutions containing more than 0.8 M sodium trifluoroacetate cannot be interpreted by simple chemical exchange.

Rate Law for the Exchange Reaction. The result of run 7 indicates that the kinetic salt effect is not significant over the range of concentrations of reactants in runs 1—6. Sodium trifluoroacetate is almost completely dissociated into sodium and trifluoroacetate ions in acetonitrile (dielectric constant: 35.95 at 25 °C).[13]

The τ_c^{-1} values in Table 1 are almost equal to one another, and seem to be independent of both $[CF_3COO^-]_T$ and $[Mo_2(CF_3COO)_4]_T$. The τ_f^{-1} value depends linearly on the ratio p_c/p_f, as is expected from Eq. 4. This was confirmed from the τ_f^{-1} values obtained from the peak in the free ligand region by Eq. 2. Thus the rate (R) of the exchange reaction is independent of $[CF_3COO^-]_T$ and is linearly dependent on $[Mo_2(CF_3COO)_4]_T$,

$$R = 4\tau_c^{-1}[Mo(CF_3COO)_4]_T = k_{ex}[Mo_2(CF_3COO)_4]_T, \quad (8)$$

where R and k_{ex} are the rate and the first order rate constant of the exchange, respectively, of one of the four coordinated ligands. The rate constant and activation parameters were determined to be $k_{ex}=(1.1\pm0.2)\times10^4$ s^{-1} (25 °C), $\Delta H^*=(8.2\pm0.8)$ kcal mol^{-1} and $\Delta S^*=(-15\pm3)$ cal K^{-1} mol^{-1}.

Mechanism of Ligand Exchange. The electronic absorption spectra showed that an appreciable amount of III and/or IV is present in the solutions of runs 1—7. Therefore, more than three non-equivalent circumstances are involved for the trifluoroacetate. Only two ^{19}F NMR signals were observed at −40 °C, however, for runs 1—7. The ratios of the integral strengths of the two signals (Eq. 7) suggest that the signal due to the apical ligand must be included in the peak in the free ligand region.

The solution of run 9 which contained a larger amount of the "free" ligand, gives two peaks in the complex region. The two peaks are most likely due to the bridging ligands of III and IV, and the single peak of runs 1—7 in this region to the bridging ligand of III.[14]

Equation 9 can be applied to the runs 1—7.

$$[CF_3COO^-]_T = [CF_3COO^-]_F + [CF_3COO^-]_A = [CF_3COO^-]_F + [Mo_2(CF_3COO)_4]_T, \quad (9)$$

where the suffices A and F denote the apical ligand of III and uncoordinated free ligand, respectively. An appreciable amount of added trifluoroacetate exists as the apical ligand (48.4% for run 6). The peak position of the apical ligand is very close to that of the free ligand, since, at −40 °C, no shift of the "free" ligand peak (coalesced peak of the free and the apical ligand) is observed upon addition of the complex (Table 1). This suggests very weak coordination at the apical positions.

The following mechanism is proposed for runs 1—7.

$$[Mo_2(CF_3COO)_4\cdot\underline{CF_3COO}]^- + {}^*CF_3COO^- \overset{\text{fast}}{\rightleftharpoons} [Mo_2(CF_3COO)_4\cdot{}^*\underline{CF_3COO}]^- + CF_3COO^-, \quad (10)$$

$$[Mo_2(CF_3COO)_4\cdot{}^*\underline{CF_3COO}]^- \xrightarrow{k_s} [Mo_2(CF_3COO)_3({}^*CF_3COO)\cdot\underline{CF_3COO}]^-, \quad (11)$$

where the asterisks indicate the molecule substituting for the coordinated ligand. The first process is proposed to be fast, and the exchange rate is expressed by

$$R = k_s[Mo_2(CF_3COO)_4\cdot CF_3COO^-] = k_s[Mo_2(CF_3COO)_4]_T. \quad (12)$$

This equation is of the same form as the experimentally

obtained equation (Eq. 8). The observed rate constant, k_{ex}, is equal to k_s.

An alternative assignment for the ^{19}F NMR spectra of runs 1—7 could be proposed by considering that both II and III are present in the solutions and that their interconversion (Eq. 5) was fast with respect to the ^{19}F NMR time scale (so that the signals of coordinated CF_3COO^- of II and III coalesced completely). However, such a consideration does not account for the rate law (Eq. 8), unless II and III give identical exchange rates.

Comparison with Other Reactions. Few kinetic studies are reported on the substitution reactions of the compounds containing strong metal–metal bond such as Mo^{II}–Mo^{II} or Re^{III}–Re^{III}. Mureinik studied the reaction of acetate ions with $[Mo_2Cl_{8-n}(H_2O)_n]^{(4-n)-}$ (partially aquated form of $Mo_2Cl_8^{4-}$) to give $Mo_2(CH_3COO)_4$ in aqueous acid solutions ($[H^+]=0.05$—1.95 M with HCl or *p*-toluenesulfonic acid) at 25 °C by the stopped-flow method.[7] The entry of the first and the third acetate ions was kinetically analyzed. At a constant $[H^+]$, the following rate law (Eq. 13) was obtained for the first step.

$$k_{obsd} = \frac{b[CH_3COOH][Mo_2Cl_{8-n}(H_2O)_n^{(4-n)-}]}{1+a[CH_3COOH]} \quad (13)$$

The rate law was explained by the following dissociative mechanism.

$$[Mo_2Cl_{8-n}(H_2O)_n]^{(4-n)-} \rightleftarrows [Mo_2Cl_{8-n}(H_2O)_{n-1}]^{(4-n)-} + H_2O$$

$$[Mo_2Cl_{8-n}(H_2O)_{n-1}]^{(4-n)-} + CH_3COOH \longrightarrow [Mo_2Cl_{8-n}(H_2O)_{n-2}(CH_3COO)]^{(5-n)-} + H_3O^+ \quad (14)$$

A similar proposal was also put forth for the third step. We suggest that the rate law (Eq. 13) may also be explained by the following mechanism, which is similar to that proposed for our reaction.

$$[Mo_2Cl_{8-n}(H_2O)_n]^{(4-n)-} + CH_3COOH \overset{fast}{\rightleftarrows} [Mo_2Cl_{8-n}(H_2O)_n\cdot\underline{CH_3COO}]^{(5-n)-} + H^+$$

$$[Mo_2Cl_{8-n}(H_2O)_n\cdot\underline{CH_3COO}]^{(5-n)-} \longrightarrow [Mo_2Cl_{8-n}(H_2O)_{n-2}(CH_3COO)]^{(5-n)-} + 2H_2O \quad (15)$$

Further information, such as activation parameters, would be necessary to make a more definitive conclusion about the mechanism of this reaction.

The kinetics of the substitution of tributylphosphine or thiourea for the halide ligands of $Re_2X_8^{2-}$ ($X^-=Cl^-$ or Br^-), and of chloride ions for the bromide ligands of $Re_2Br_8^{2-}$ in methanol at 25 °C, have been studied by the stopped-flow method.[16] The following general rate law was given:

$$k_{obsd} = \frac{k_s+k_LK[L]}{1+K[L]}, \quad (16)$$

where L is the incoming ligand. The following mechanism was proposed (the charges are omitted, and S denotes methanol).

$$\begin{array}{ccc} Re_2X_8(S) & \xrightarrow{k_s} & Re_2X_7(S) + X^- \\ K\uparrow\downarrow +L & & +L\downarrow \text{fast} \\ Re_2X_8L & \xrightarrow{k_L} & \text{product} \end{array}$$

Although the detailed structure of the species Re_2X_8L was not given, L coordinates most likely at the apical position. Thus, we suggest that the rate-determining-step is the intramolecular rearrangement between X and either S or L, for the k_S or k_L path, respectively. Such a mechanism is similar to that proposed for our reaction.

Mono-oxo metal ions, such as $Mo^{V}O^{3+}$ and $V^{IV}O^{2+}$ have strong metal–oxygen bonds comparable to the metal–metal bond Mo–Mo, and their trans (apical) sites are vacant or weakly coordinated. The substitution of Cl^- for $OP(C_6H_5)_3$ in $Mo^{V}OCl_3\{OP(C_6H_5)_3\}_2$ and for $OP\{N(CH_3)_2\}_3$ in $Mo^{V}OCl_3[OP\{N(CH_3)_2\}_3]_2$ was claimed to occur first at the apical position followed by an intramolecular rearrangement to the basal position.[17] This process is similar to that of our ligand exchange. A similar mechanism is also proposed for the substitution reactions of oxovanadium(IV) complexes at the basal site.[18] The activation parameters for these reactions are close to those of our reaction. A substitution mechanism involving initial attack at the apical position, followed by rearrangement to the basal position would be a common feature of complexes containing strong metal–metal and metal–oxo bonds.

The rate of halide substitution at the apical positions of $Re_2(C_2H_5COO)_4\cdot X_2$ ($X^-=Cl^-$ or Br^-) in acetonitrile was reported to be *ca.* 10^{-3} s^{-1} at 25 °C.[19] On the other hand, the rate of process (10) for our Mo(II) complex is fast ($>10^4$ s^{-1}). It is difficult to explain such a big difference at the present stage. The difference in the oxidation state of metal ions, the electronic charge of the $M_2(RCOO)_4$ unit, and/or the d-orbitals involved (3d or 4d) may be important.

We are grateful to the Ministry of Education for a Grant-in-aid. We thank Mrs. R. Tanaka of the Institute of Non-aqueous Solution, for operating the NMR spectrometer, and Professor N. Tanaka and Dr. Y. Kato of the Department of Chemistry for simulation of the NMR spectra.

15) The assignment means that $W_f°$, $W_c°$, ν_f and ν_c are not appropriate to evaluate τ_f^{-1} and τ_c^{-1} (Eqs. 1—3), and the corresponding values of the coalesced peak of the free and apical ligands and of the bridging ligand of III should be used instead. However since the latter values are not estimated (even at −40 °C the chemical exchange is not frozen), the former values were used without any correction. The τ_f^{-1} and τ_c^{-1} values obtained do not appear to be unreasonable.

(Received July 22, 1978)

A new complex, aquaoxo[*N*-(2-pyridylmethyl)iminodiacetato]vanadium(IV) dihydrate [VO(pmida)(H_2O)]·$2H_2O$ has been synthesized and its crystal structure determined by the X-ray method. The triclinic crystals obtained from water or aqueous ethanol solution are twinned and contain 2 mol of lattice water. The unit cell contains four formula units and the structure was analyzed on the assumption that the space group is $P\bar{1}$. The positional and thermal parameters were refined to $R=0.115$. The vanadium atom has a distorted octahedral coordination and deviates by 0.39 Å from the equatorial plane, which is composed of two cis carboxylate oxygens, a water molecule and the pyridine nitrogen. Vanadyl oxygen and tertiary nitrogen occupy the axial sites. Absorption spectra indicated that the structure is maintained in an aqueous solution of pH 3.0 to 4.9. This geometrical isomer seems to be formed selectively in an aqueous medium.

Many vanadium(IV) complexes have strong V=O bonds[1] and exhibit characteristic distorted molecular structure. X-Ray crystallography has disclosed that the V=O bond length (1.56 to 1.63 Å)[2–11] is shorter than that of the trans ligand to vanadium (2.18 to 2.51 Å). Sometimes the trans site remains vacant. The vanadium(IV) ion is above the equatorial plane by 0.26 to 0.41 and 0.48 to 0.58 Å in the complexes with coordination numbers 6[2–11] and 5,[12] respectively.

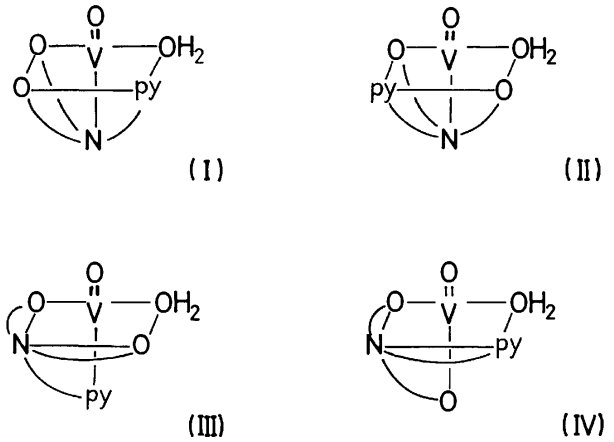

Fig. 1. The possible geometrical isomers of [VO(pmida)(H_2O)].

With a view toward studying the kinetics of direct ligand substitution at the equatorial site,[13] we have synthesized a new complex aquaoxo[*N*-(2-pyridylmethyl)iminodiacetato]vanadium(IV) dihydrate [VO(pmida)(H_2O)]·$2H_2O$. There can be four geometrical isomers depending on the coordination mode of the quadridentate $pmida^{2-}$ ion (Fig. 1). The structure has been determined by the X-ray method, and the properties in aqueous solution have been studied spectroscopically.

Experimental

Materials. The ligand, 2-pyridylmethyliminodiacetic acid H_2pmida,[14] and bis(acetylacetonato)oxovanadium(IV) [$VO(acac)_2$][15] were synthesized by known methods. Equimolar amounts of [$VO(acac)_2$] and H_2pmida (0.01 mol) were heated in acetonitrile (200 cm^3) at 83 °C for 30 min with vigorous stirring. The blue violet precipitate was filtered off, washed with aqueous ethanol and recrystallized by the following two methods. When a large amount of ethanol was added to the aqueous solution of the raw product, a pale violet powder was obtained within a few hours, which was washed with aqueous ethanol (1+1, v/v) and ethanol, and dried *in vacuo* at room temperature. (Yield 60%) Found C, 38.86; H, 4.11; N, 8.98%. Calcd for $C_{10}H_{12}N_2O_6V$: C, 39.10; H, 3.91; N, 9.12%.

When a small amount of ethanol was added to the aqueous solution, blue violet crystals precipitated very slowly (*e.g.* 10 days) with 2 mol of lattice water. Found C, 34.70; H, 4.64; N, 8.12%. Calcd for $C_{10}H_{16}N_2O_8V$: C, 35.00; H, 4.67; N, 8.17%.

The magnetic moment of the dihydrate was 1.7 Bohr magnetons at room temperature. This value is normal to those of VO^{2+} complexes with a $3d^1$ configuration.

Structure Determination. *Crystal Data*: $C_{10}H_{16}N_2O_8V$, $M=343.19$, Triclinic, $a=19.54(2)$, $b=10.846(4)$, $c=6.829(3)$ Å, $\alpha=102.56°(4)$, $\beta=87.64°(8)$, $\gamma=92.84°(9)$, $D_m=1.62$, $D_c=1.62$ g/cm^3, $Z=4$, μ(Cu $K\alpha$)$=149.9$ cm^{-1}, space group $P\bar{1}$ or P1. The structure analysis was carried out on the basis of the $P\bar{1}$ space group.

The Laue symmetry was determined from the Weissenberg and precession photographs. The unit cell dimensions were obtained by a least-squares analysis of fifteen 2θ values measured on a Philips PW 1100 four circle diffractometer by the use of Cu $K\alpha$ radiation.

The blue violet plate-like crystals of the dihydrate were usually twinned. Recrystallization was repeated in an attempt to obtain single crystals by taking precession photographs, but all the efforts were unsuccessful.

The precession photographs showed clearly the presence of two individuals in twin orientation. Both have a common a* axis and the reciprocal lattice of one crystal of the twin is related to that of the other by a rotation of 180° about the a* axis. This was confirmed by the intensity measurements ($2\theta \leq 40°$) for each constituent in a twinned crystal. The intensities of the corresponding reflections were different from each other in every twin crystal; in the crystal used for X-ray data measurements, the intensity ratio was found to be 6.88: 1.

Data Collection: Intensity data for the major individual of the twin were collected on the diffractometer by use of nickel-filtered Cu $K\alpha$ radiation. A crystal with dimensions $0.07\times 0.10\times 0.13$ mm^3 was mounted so that the a axis is roughly parallel to ϕ axis. The crystal-to-detector distance and the

detector aperture were 195 mm and 3×3 mm, respectively. The scan rate and the scan width are 0.030° s^{-1} and (0.7+0.2 tan θ)°, respectively. Background counts were measured for (scan time/2)$\sqrt{I_b/I_{int}}$ at each side of the scan range (I_b, mean background intensity obtained from the preliminary background measurements for 5 s at each side of the peak; I_{int} is the total number of counts divided by total scan time). A total of 3080 reflections having $I_t-2\sqrt{I_t}>I_b$ were collected in the $2\theta\leq120°$ range (I_t, intensity at the top of the peak), but 2584 reflections for which $I>2\sigma(I)$ were used in the structure analysis. Intensity data were corrected for the *Lp* factor[16] but not for absorption.

For each reflection no estimation was made of the error derived from the diffraction due to the minor crystal. However, a tentative calculation suggested that under these experimental conditions the intensity from a reciprocal lattice point is liable to suffer from disturbance due to the diffraction from the minor individual; the disturbance is possibly significant unless a reciprocal lattice point of the major is separated from the neighboring point due to the minor by more than 0.013 $Å^{-1}$. Of the 2584 reflections 1027 were under such circumstances but the error induced in the structure amplitude is about 8% on an average.[17] Therefore, all 2584 reflections were used for the structure analysis in the initial stage.

Structure Determination and Refinement: The positions of V atoms were obtained from the Patterson map and those of the remaining nonhydrogen atoms were found from successive Fourier syntheses. The positional and isotropic thermal parameters were refined by the least-squares method. The minimized function was $\sum W(|F_o|-|F_c|)^2$. The weighting scheme was as follows: $W=0.3$ for $F_o<9.8$ and $W=1.0$ for $F_o>9.8$. Several cycles of the least-squares calculations reduced R to 0.109. In the subsequent refinement, zero weight was assigned to the 1027 reflections. The structure converged with $R=0.115$. In the final cycle no parameters were varied by more than 0.3 σ.

Atomic scattering factors of V^0, O, N, and C were taken from Ref. 18. Observed and calculated structure factors are available (Document No. 7902; in the F_o-F_c table those reflections for which zero weight was given in the leasts quares calculation, are marked with asterisks). Table 1 lists final atomic parameters. All computations were carried out on the FACOM 230-60 computer of Osaka City University, by the use of the RSSFR-5, HBLS-IV, and DAPH programs in the UNICS.[19]

Other Measurements. The electronic spectra were recorded with a Hitachi 323 Spectrometer in aqueous solution and by the reflectance method. Infrared spectra were recorded with a JASCO IR-Al Spectrometer in KBr disks. The pH titration was performed with a Metrohm E300B titrator under nitrogen atmosphere. The Magnetic susceptibility was measured by the Gouy method.

Results and Discussion

Crystal Structure. The crystal structure viewed down from the c axis is shown in Fig. 2. Although no H atoms were found in the structure analysis, possible hydrogen bonds are indicated by dotted lines. The unit cell comprises two crystallographically independent complexes which are discerned by atom numberings primed and unprimed. They are very similar in geometry and have virtually equal dimensions, except that they are enantiomeric to each other. Table 2 indicates that chemically equivalent bond lengths and angles are in reasonable agreement with each other. The elevation and projection of the complex are shown in Fig. 3 in which one antipode is depicted. The vanadium ion has a distorted octahedral coordination; the vanadyl oxygen and tertiary amino nitrogen occupy axial positions, while the equatorial plane consists of the pyridine nitrogen, water oxygen and two cis carboxylate oxygen atoms. The bond lengths and angles are listed in Table 2, and the deviation of the atoms from the least-squares plane in Table 3.

The V atom deviates from the equatorial plane by 0.39 Å toward the oxo ligand. This value is comparable with that (0.39 Å) in $Na_2[(VO)_2(ttha)]\cdot10H_2O$[2] ($H_6$ttha, triethylenetetraaminehexaacetic acid), in which the complex has a centrosymmetric dimer structure but is similar to the present complex in the context that each V atom is surrounded octahedrally by 4O and 2N (cis

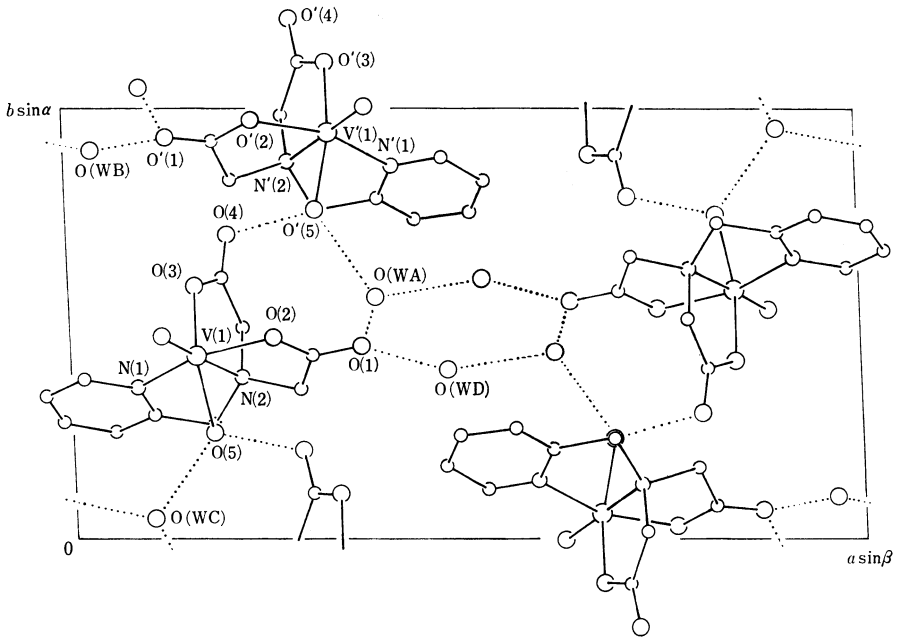

Fig. 2. The crystal structure viewed down the c axis. The dotted lines indicate possible O–H···O hydrogen bonds.

positions) atoms. In square pyramidal oxovanadium(IV) complexes the deviation of V atom from the equatorial plane ranges from 0.48 to 0.58 Å,[12] whereas in the octahedral complexes this deviation is in the range 0.26—0.41 Å.

The axial ligation thus decreases the deviation, with the O donor giving more marked effect than the N donor. This is in accord with the larger mean L_{eq}–V–L_{eq} angles for *trans*(*O*) than for *trans*(*N*). The V=O bond length (1.60 Å) agrees well with that in the ttha complex.[2] The lengths in the 6-coordinate complexes range from 1.56 to 1.63 Å, differing little from those in the 5-coordinate complexes.[12] The salpn complex [VO(salpn)] (salpn, *N*,*N*′-disalicylidene-1,2-propanediamine) has V=O··· V=O chain in the crystals, and a rather strong intermolecular interaction is expected. Even in this compound the V=O length (1.633(9) Å) is not significantly different from those in the 5-coordinate complexes.

Selbin *et al.* summarized IR frequencies of various oxovanadium(IV) complexes and indicated that the ν(V=O) depends on the variety of ligands.[20] However, there seems to be an overall trend as follows: (1) VO^{2+} complexes with coordination number 5 give ν(V=O) higher than 995 cm^{-1};[21] (2) on the other hand, VO^{2+} complexes with coordination number 6 give lower ν(V=O)'s; *e.g.*, 976, 955,[22] and 854 cm^{-1} for $(NH_4)_2$-$[VO(oxalato)_2(H_2O)]\cdot H_2O$, $[VO(acac)_2$(4-phenylpyridine)] and [VO(salpn)], respectively. The present complex with coordination number 6 gives ν(V=O) at 985 cm^{-1}. It appears as if VO^{2+} complexes with coordination number 5 and 6 have ν(V=O) values higher than and lower than 990 cm^{-1}, respectively, and this figure can serve as a criterion for discriminating the coordination number of VO^{2+} complexes.[23] Correlation could be also expected between the V=O bond length and ν(V=O). However, the variation of the bond length should be very small and a more accurate measurement is desirable.

The axial V–N(2) bond with the tertiary amino nitrogen agrees in length with the corresponding value in $[(VO)_2(ttha)]^{2-}$ but is longer by 0.15 Å than the equatorial V–N(sp^3) bond in the ttha complex. Such a difference is attributed to the trans influence of the oxo ligand.

The 5-membered chelate rings are of the envelope conformation, the ring composed of O(3), C(10), C(9), N(2), and V has relatively planar structure. However, the other two rings are considerably puckered up. Figure 4 shows, as an example, the projection and elevation of the chelate ring which includes the pyridine moiety. The firm disposition of the equatorial bonds may be responsible for such a puckering. Bond lengths and angles in the pmida ligand are normal. The length of the hydrogen bonding (Table 2) range from 2.59 to 2.85 Å, which are normal for lattice waters in coordination compounds.

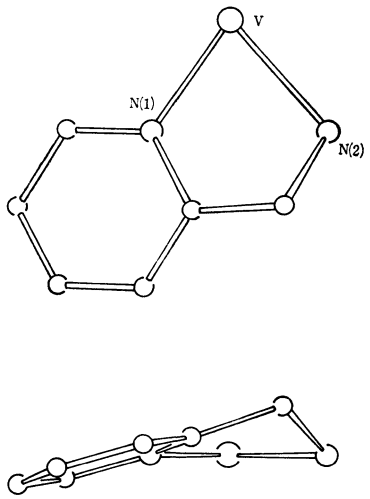

Fig. 4. The projection and elevation of the chelate ring in which pyridine moiety participates.

a) Present work. b) The deviation of the V atom from the equatorial plane; in every complex four atoms defining the equatorial plane are disposed in a more or less tetrahedral configuration with respect to the plane. The four atoms in the 2,6-pyridinedicarboxylato complex have significant deviations (±0.196 Å), and hence it might be inadequate here to define an "equatorial" plane. However, as is seen in the Table, the "devia tion" of the V atom as well as the L_{eq}–V–L_{eq} value in the 2,6-pyridinedicarboxylato complex have features similar to those of the other complexes with an axial N ligand. c) Mean value of two L_{eq}–V–L_{eq} angles; the two L_{eq}'s denote the ligand atoms which are trans to each other in the equatorial plane. d) In case there are more than two chemically equivalent bonds, the average value of their lengths is listed.

Of the four possible isomers of this complex, the present product seems to involve the least strain, because coordination of the two acetate oxygens in trans positions (II and III in Fig. 1) brings about a larger strain in the chelates. The pyridine ring is parallel to the z-axis. The d^1 electron of VO(2+) is believed to occupy d_{xy} orbital and the delocalization of this electron to the π-orbital of the pyridine moiety should be favorable.

Structure in the Aqueous Solution. The complex gave a pK_a value 6.4 at 25 °C and an ionic strength of 1.0 ($NaClO_4$). Hence, the complex is mostly (>98%) present in the aqua from below pH 4.7. The electronic absorption peaks are at 258, 350, 572, and 765 nm with molar extinction coefficients of 4940, 304, 16, and 27 cm^{-1} M^{-1}, respectively at pH 3.0 to 4.9. The reflectance spectrum of the solid dihydrate in the range from 340 to 700 nm gave peaks at 354 and 570 nm, suggesting that the complex maintains the same skeletal structure in aqueous solution of pH below 4.7 as in the crystalline state.

Complex formation between the aqueous solution of oxovanadium(IV) sulfate (0.008 M) and $pmida^{2-}$ (0.01 M) is indicated by the visible absorption peaks at 572 and 765 nm with molar extinction coefficients 15 and 26 cm^{-1} M^{-1}, respectively (*vide supra*) at pH 3.0. The visible peaks are so sensitive to the environment of oxovanadium(IV) ions as to be useful for identifying the complexes.[1] Therefore, it appears as if the present product was formed selectively from among the four possible structures.

The authors wish to thank Dr. Hiroshi Yokoi, Chemical Research Institute of Non-aqueous Solutions, Tohoku University for the measurement of the magnetic moment.

Phase Equilibria in the Er_2O_3–V_2O_3–V_2O_5 System at 1200 °C

Kenzo KITAYAMA,* Tadashi SUGIHARA, and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 8, 1978)

The phase equilibria in the Er_2O_3–V_2O_3–V_2O_5 system have been established at 1200 °C. In this system, Er_2O_3, $Er_8V_2O_{17}$($4Er_2O_3 \cdot V_2O_5$), $ErVO_3$, $ErVO_4$, V_nO_{2n-1}(n: 2 to 7), and VO_2 found to be stable, $Er_8V_2O_{17}$, $ErVO_4$, V_2O_3, and VO_2 of which had non-stoichiometric compositions. On the basis of the phase equilibria, the standard Gibbs energies for the reactions,

$$ErVO_3 + 1/2O_2 = ErVO_4, \quad (1)$$

$$3Er_2O_3 + 2ErVO_3 + O_2 = Er_8V_2O_{17}, \quad (2)$$

have been determined to be -121 ± 1 and -256 ± 1 kJ, respectively. It has been shown that the standard Gibbs energy for Sm, Er, and Lu in Eq. 1 decreases linearly with increasing ionic radius of lanthanoid.

In previous papers,[1,2] the phase equilibria in the Sm_2O_3–V_2O_3–V_2O_5 and the Lu_2O_3–V_2O_3–V_2O_5 systems were reported at 1200 °C. In both systems, the existence of the V_nO_{2n-1} (n: 2 to 7) phases were confirmed. In the former system, $Sm_{10}V_2O_{20}$($5Sm_2O_3 \cdot V_2O_5$), $SmVO_3$, and $SmVO_4$, and in the latter, $LuVO_3$, $LuVO_4$, $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8 were stable as ternary compounds. On the basis of these phase equilibria, the standard Gibbs energies for the reactions related to the ternary compounds have been determined.

It has been reported that $ErVO_3$ is only the stable ternary compound in the Er_2O_3–V_2O_3 system, and that it belongs to the orthorhombic crystal system.[3,4] Recently, Brusset *et al.*[5,6] have studied the phase equilibria in the Er_2O_3–V_2O_5 system in the temperature range from 600 to 1500 °C, and found the existence of $4Er_2O_3 \cdot V_2O_5$ and $5Er_2O_3 \cdot V_2O_5$ in addition to the established tetragonal $ErVO_4$ phase, and concluded that $4Er_2O_3 \cdot V_2O_5$ is stable at temperatures from 1350 to 1500 °C, and $5Er_2O_3 \cdot V_2O_5$ from 1250 to 1500 °C.[5] Brusset *et al.*[7] reported that the $4Er_2O_3 \cdot V_2O_5$ phase belongs to the monoclinic system, and determined the relative intensities, spacings and assignments of the index of this phase. The precise phase equilibria in the Er_2O_3–V_2O_3–V_2O_5 system have, however, not been investigated.

The objectives of the present study have been (1) to establish the detailed phase equilibria in the Er_2O_3–V_2O_3–V_2O_5 system at 1200 °C in order to clarify the stable ternary compounds, (2) to calculate the Gibbs energies of the reactions for ternary compounds, and (3) to ascertain, prior to pursuing the complete studies of the Ln–V–O system (Ln: La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, and Y), wether or not there exists a linear relationship between the standard Gibbs energy of reaction and the ionic radius of the lanthanoid, as found in the Ln–Fe–O system.[8] Er_2O_3 has been selected as one of the lanthanoid sesquioxides in this paper.

Experimental

Analytical grades of Er_2O_3 (99.9% purity) and V_2O_5, made by heating guaranteed reagent grade NH_4VO_3 in air for 24 h at 500 °C, have been employed as starting materials. The desired ratios of Er_2O_3/V_2O_5 were obtained by mixing the appropriate quantities thoroughly in an agate mortar under ethyl alcohol. The mixtures thus obtained were treated by procedures previously described.[1]

Apparatus and procedures for controlling the partial pressure of oxygen, for keeping the temperature constant, the method of thermogravimetry, the criterion for establishing equilibrium, the method of identification of solid phases after quenching, of lattice constant determination, the method of measurement of the actual oxygen partial pressure, and the method of wet chemical analysis are the same described in previous papers.[1,9–11] On the basis of the previous results,[1] the weight of sample measured at an oxygen partial pressure of 10^{-12} atm has been chosen as the standard reference weight for thermogravimetry.

Results and Discussion

Phase Equilibria. Seven starting samples with different Er_2O_3/V_2O_5 ratios of 5.67, 4.00, 2.33, 1.50, 1.00, 0.667, and 0.250 were prepared. Figure 1 illustrates, as an example, the relationship between the oxygen partial pressure and the composition change, W_{O_2}/W_T, for samples with Er_2O_3/V_2O_5 ratios of 5.67, 1.50, and 0.250. W_{O_2} represents the weight gain of the samples assuming the reaction, $V_2O_3+O_2=V_2O_5$, were completed. Table 1 gives the results of the phase identification after quenching, and Fig. 2 illustrates the phase diagram. The following phases were found to be stable under the present experimental conditions; Er_2O_3(R), $ErVO_4$(B), $ErVO_3$(C), V_2O_3(D), V_3O_5(E), V_4O_7(F), V_5O_9(G), V_6O_{11}(H), V_7O_{13}(I), VO_2(J), and $Er_8V_2O_{17}$(N) ($4Er_2O_3 \cdot V_2O_5$). The letters in parentheses are the abbreviations of compounds. The existence of the $4Er_2O_3 \cdot V_2O_5$ phase contradicts the results of Brusset *et al.*[5] The stoichiometric existence of Er_2O_3 has been certified by Kitayama and Katsura.[12] As seen in Fig. 2, the phases $ErVO_4$, V_2O_3, VO_2, and $Er_8V_2O_{17}$ are of non-stoichiometric composition. The relationship between N_O/N_d and log P_{O_2} values for the solid solutions has been obtained using the results of thermogravimetric analysis and the method of least squares. Here, N_O/N_d indicates the deviation of the oxygen atoms from the stoichiometric composition d.[1,10] The empirical equations for $Er_8V_2O_{17}$ and $ErVO_4$ have been obtained as

$$N_O/N_{Er_8V_2O_{17}} = 0.0443 \log P_{O_2} + 0.108$$

and

$$N_O/N_{ErVO_4} = 0.0236 \log P_{O_2} + 0.180,$$

Table 2. Compositions, stability ranges in oxygen partial pressures, and activities in solid solutions

Component	Composition	Symbol	$-\log P_{O_2}$	$\log a_i$
$Er_8V_2O_{17}$	$Er_8V_2O_{17.0}$	N	0.68[a]—2.44[b]	0.489
	$Er_8V_2O_{16.8}$	N_1	9.08	0
$ErVO_3$	$ErVO_{3.00}$	C	8.55 —12.00[c]	0
$ErVO_4$	$ErVO_{4.00}$	B	0.68[a]—7.63[b]	5×10^{-3}
	$ErVO_{3.98}$	B_1	8.55	0

a) Stability range in log P_{O_2} may be higher than -0.68. b) These values were obtained by extrapolation using the thermogravimetric values. c) Stability range in log P_{O_2} may be lower than -12.00.

respectively.

In Table 2, the compositions, the stability ranges in oxygen partial pressures, and the abbreviations of the compounds are tabulated. As given in Table 2, $Er_8V_2O_{17}$ has a composition ranging from $Er_8V_2O_{16.8}$ at $\log P_{O_2}=-9.08$ to $Er_8V_2O_{17.0}$ at $\log P_{O_2}=-2.44$. $ErVO_3$ exhibites no deviation from the stoichiometric composition within the limits of experimental error. The deviation from the stoichiometric composition of $ErVO_4$ extends up to $ErVO_{3.98}$ at $\log P_{O_2}=-8.55$.

The lattice constants for $ErVO_4$, $ErVO_3$, and $Er_8V_2O_{17}$ are given in Table 3 together with the previous data.[3-5,7,13] The values obtained in this study are in reasonable agreement with previous results. As seen from Table 3, the non-stoichiometric dependence of the lattice constants for $Er_8V_2O_{17}$ has not been observed, and this may be due to compensation of the V^{4+} ion for the V^{5+} ion and the corresponding oxygen deficiency on the cell volume. The results for the V–O binary system have been reported in a previous paper.[1]

Calculation of Standard Gibbs Energy of Reaction. On the basis of the phase equilibria, the standard Gibbs energy of reaction to form the $ErVO_4$ and $Er_8V_2O_{17}$ compounds can be calculated by referring to the following reactions:

$$ErVO_3 + 1/2O_2 = ErVO_4, \quad (1)$$

$$3Er_2O_3 + 2ErVO_3 + O_2 = Er_8V_2O_{17}. \quad (2)$$

The standard Gibbs energies of these reactions can be directly calculated by adopting the equilibrium oxygen partial pressures corresponding to Eqs. 1 and 2. Here, the activity of each component, $ErVO_4$ and $Er_8V_2O_{17}$ at the composition of B_1 and N_1 in Fig. 2, respectively, was set equal to unity. The standard Gibbs energy of each reaction was calculated from the equation, $\Delta G^\circ=-RT\ln K$, where R is the gas constant, T the absolute temperature, and K the equilibrium constant. The detailed method of obtaining the equilibrium constant K, has been described by Kimizuka and Katsura.[14] In this study, the standard Gibbs energy for Reactions 1 and 2 found to be -121 ± 1 and -256 ± 1 kJ, respectively.

In similar studies,[1,2] Kitayama and Katsura determined the standard Gibbs energies of reaction for $SmVO_4$ and $LuVO_4$ to be -127 ± 1 and -116 ± 1 kJ, respectively. Thus by utilizing this data, the relationship between the standard Gibbs energy of reaction (expressed as $LnVO_3+1/2O_2=LnVO_4$ (Ln; Sm, Er, and Lu)) and the ionic radius of Ln^{3+} ion may be found. The value of each ionic radius has been determined by Shannon and Prewitt[15] to be Sm^{3+} 1.09, Er^{3+} 1.00, and Lu^{3+} 0.97Å with a coordination number of 8. Although the data was limited, the standard Gibbs energy of the reaction was found to decrease linearly with increasing ionic radius. A similar trend in the Fe-lanthanoid-perovskite system has been established.[8,16] It is conceivable that the thermodynamic properties of Ln–V–O compounds are closely related to the structural stability. In order to demonstrate this the study of the phase equilibria in the Ln–V–O system needs further research.

The authors wish to thank Dr. Tadao Kanzaki, Tokyo Institute of Technology, for the reading of this manuscript.

Reaction of Bis[2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] Ethers with Tosyl Chloride

Munehiro NAKATANI and Tsunao HASE*

Department of Chemistry, Faculty of Science, Kagoshima University, Kagoshima 890

(Received March 8, 1978)

In the reaction with tosyl chloride in pyridine, the meso isomer (**2a**) of bis[2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] ether rearranged to give arylacetaldehyde (**3**) and 2-arylmethyl-4-aryl-1,3-dioxolane (**4**), and the racemic isomer (**2b**) afforded **3**, **4**, and 2,6-diaryl-1,4-dioxane. The aryl migration in this reaction has been confirmed by the use of the deuterated compounds, **2a-D** and **2b-D**, respectively, substituted with deuteriums at the 2,2-positions.

The meso (**1a**) and racemic (**1b**) isomers of bis(2-hydroxy-1-mesitylethyl) ether gave the corresponding tosylates with tosyl chloride in pyridine at 80 °C in high yields, respectively.[1] The reaction of the *p*-methoxy compounds, **2a** and **2b**, with the same reagent, on the contrary, gave no tosylate. At 80 °C or higher, these compounds afforded the rearranged products, in which migration of a *p*-anisyl group was observed. Under reflux, **1a** and **1b** were also observed to give results similar to those of **2a** and **2b**, except for the formation of the tosylates. The reaction of **2a** and **2b** with tosyl chloride by a mechanism similar to that reported by earlier investigators for the solvolysis of *p*-methoxyneophyl tosylate will be reported.[3i]

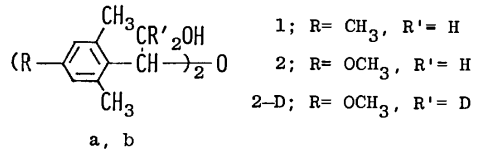

Fig. 1.

Results and Discussion

Synthesis of Bis[2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] Ethers (2). The meso **2a** and racemic compound **2b** have been synthesized from 2,6-dimethyl-4-methoxybenzaldehyde[2] by a method similar to the synthesis of bis(2-hydroxy-1-mesitylethyl) ethers (**1a** and **1b**).[1] Deuterated compounds **2a-D** and **2b-D** were prepared by the reduction of *meso*- and *dl*-bis(α-methoxycarbonyl-2,6-dimethyl-4-methoxybenzyl) ethers with lithium aluminium deuteride. With a large excess of the deuteride, 3,3,5,5-tetradeuterio-2,6-bis(2,6-dimethyl-4-methoxyphenyl)-1,4-dioxanes (**5a-D** and **5b-D**) were obtained as by-products, respectively. From a comparison of the PMR spectra of **2a** and **2b** with those of the *p*-methyl compounds, **1a** and **1b**, it became clear that the low-melting isomer, **2a**, is meso and the high-melting one, **2b**, is racemic.

Reaction of Bis[2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] Ethers (2) with Tosyl Chloride in Pyridine. The mild refluxing of **2a** with five equivalents of tosyl chloride in pyridine afforded 2,6-dimethyl-4-methoxyphenylacetaldehyde (**3**) in a 57% yield, and 2-(2,6-dimethyl-4-methoxyphenylmethyl)-4-(2,6-dimethyl-4-methoxyphenyl)-1,3-dioxolane (**4**) in a 42% yield. A similar treatment of the racemic isomer **2b** gave **3**(5%), **4**(24%) and 2,6-bis(2,6-dimethyl-4-methoxyphenyl)-1,4-dioxane (**5**) in a 42% yield. The IR spectrum of **3** shows the presence of a formyl group (1716, 2720, and 2830 cm^{-1}) and the PMR spectrum the presence of two benzyl protons (δ 3.55 ppm) coupling (2 Hz) to a formyl proton (δ 9.60 ppm).

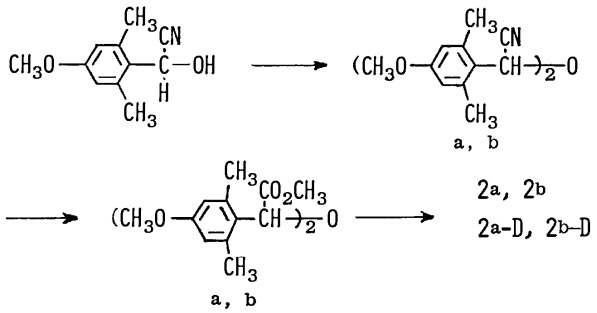

Fig. 2.

Since the IR spectra of **4** and **5** show no absorption band attributable to hydroxyl and carbonyl groups, the oxygen atoms are probably present as ether linkages. The PMR spectrum of **4** revealed the acetal moiety. The signal (δ 5.00 ppm) for the proton at C-2 is coupled (4 Hz) to the benzyl protons (δ 3.10 ppm), whereas the C-4 proton (δ 5.28 ppm) is coupled (each 8 Hz) to C-5 protons (δ 3.75 and 3.99 ppm) which are coupled (8 Hz) to each other. These nuclear spin-spin interactions have been confirmed by spin-decoupling techniques. Treatment of **4** with hydrochloric acid gave **3**. The PMR spectrum of **5** shows a overlapped ABX system for the protons on C-3 and C-5 (AB part), and C-2 and C-6 (X part) (see Experimental) which led to the tentative assignment of the 2,6-diarylsubstituted-1,4-dioxane structure, **5**. This structure was confirmed by the reaction of **2b** with concd hydrochloric acid to give **5**

The route to **3** and **4** must involve a *p*-anisyl migration to the adjacent carbon atom, and this assumption has been proved by the use of deuterated compounds, **2a-D** (meso) and **2b-D** (racemic). The reaction of **2a-D** with tosyl chloride gave a mixture of two aldehydes (the ratio of **3-D-1** and **3-D-2** was 1 : 1); **3-D-1** [PMR: δ 9.97 ppm (br s, Ar–CD_2C<u>H</u>O)] and **3-D-2** [PMR: δ 3.55 (br s, Ar–C<u>H</u>D–CDO)], a 1,3-dioxolane **4-D** and a small amount of tosylate (7%) with a composition of $C_{36}H_{38}D_4O_9S_2$, mp 118 °C. The reaction of **2b-D** also afforded **3-D-1**, **3-D-2**, **4-D**, and a tosylate (14%), mp 115 °C, but did not give **5-D**. Compared with the reaction of

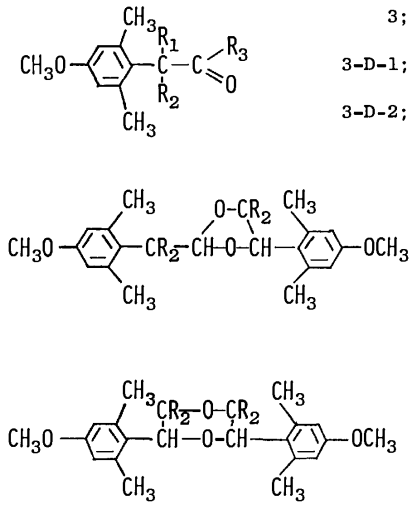

Fig. 3.

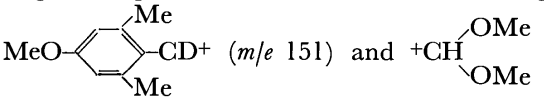
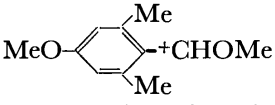
2a and **2b**, there may be present the isotope effect of deuterium in these reactions, but no conclusion may be drawn from these experimental results. The hydrolysis of dioxane **4-D** with concd hydrochloric acid in methanol afforded a mixture of the aldehydes(the ratio of **3-D-1** and **3-D-2** was 1: 1), 2,2-dideuterio-2-(2,6-dimethyl-4-methoxyphenyl)ethanal dimethyl acetal (**6**), and 1,1-dideuterio-2-methoxy-2-(2,6-dimethyl-4-methoxyphenyl)ethanol (**7**). The mass spectrum of the mixture of **3-D-1** and **3-D-2** showed a molecular ion peak at *m/e* 180 and these ratios of the **3-D-1** and **3-D-2** aldehydes were established by estimating the peak areas of the signals due to benzyl and formyl protons in the PMR spectra. Structure **6** and **7** have been assigned on the basis of the spectral data. The mass spectrum of **6** displayed fragment peaks which have been assigned to



(*m/e* 151) and (*m/e* 75).

The PMR spectrum showed the proton (δ 4.50 ppm) at C-1 and two equivalent methoxyl groups (δ 3.39 ppm) in the dimethyl acetal moiety, but did not show a benzyl proton. The mass spectrum of **7** however showed a fragment peak which has been assigned to



(*m/e* 179) and the PMR spectrum showed one benzyl proton (δ 4.86 ppm). This structure has been confirmed by direct comparison with a specimen synthesized by an established route. The tosylate of **2b-D** afforded a mixture of the aldehydes (the ratio of **3-D-1** and **3-D-2** was *ca.* 1: 1) in pyridine under reflux.

Many studies have been reported on the aryl migration in the solvolysis of tosylates.[3] Winstein *et al.*[3i] investigated the solvolysis rates of *p*-methoxyneophyl tosylate on various solvents and established that it underwent ionization in pyridine to give a rearranged product. In these experiments, it may be assumed that the tosylate formed from **2** undergoes ionization followed by the migration of the *p*-anisyl group to the adjacent carbon atom to give the rearranged products, **3** and **4**. Although there may be several mechanisms by which the formation of **3**, **4**, and **5** can be explained, Scheme 1 is the simplest.

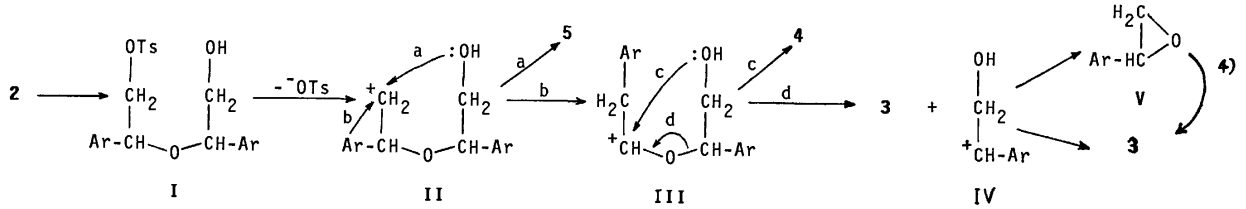
Experimental

All the melting points are uncorrected. IR and UV spectra were recorded with Shimadzu IR-27C and Shimadzu UV-210A spectrophotometers. PMR spectra were measured with JEOL JNM 60 and JNM 100 apparatus (with TMS as an internal standard).

Cyanohydrin of 2,6-Dimethyl-4-methoxybenzaldehyde. A mixture of 2,6-dimethyl-4-methoxybenzaldehyde[2] (2 g) and anhydrous HCN (2 ml) was kept with CaO (400 mg) in a sealed tube at 50 °C for 2 h. The reaction mixture was acidified with dil H_2SO_4 followed by extraction with ether to give the cyanohydrin (1.8 g, 79%) as needles, mp 122—123 °C (acetone–petroleum ether). Found: C, 69.23; H, 6.91; N, 7.30%. Calcd for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33% IR (Nujol); 3380 and 2250 cm^{-1}. PMR ($CDCl_3$); δ 2.53 (6H, s, Ar–C$\underline{H}_3$), 3.02 (1H, s, –O$\underline{H}$), 3.82 (3H, s, –OC$\underline{H}_3$), 5.83 (1H, s, –C$\underline{H}$OH), and 6.60 ppm (2H, s, Ar–$\underline{H}$). From the mother liquor, yellow crystals were obtained in a 2% yield, mp 215 °C. Found: C, 66.11; H, 5.66; N, 22.23%. Calcd for $C_{14}H_{14}N_4O$: C, 66.12; H, 5.55; N, 22.04%. IR (Nujol): 3580, 3400, 2360, and 2306 cm^{-1}. UV $(EtOH)_{max}$: 251.5 (ε 13500), 260 (15900), and 277 nm (18900). PMR (DMSO): δ 2.50 (6H, s), 3.43 (2H, br), 3.82 (4H, s), 6.72 (2H, s), and 7.35 ppm (2H, br).

Bis(α-cyano-2,6-dimethyl-4-methoxybenzyl) Ethers. The cyanohydrin (2 g) was refluxed with a catalytic amount of TsOH in dry benzene (500 ml) for 6 h. The crude product gave a mixture of ethers in a 65% yield (the ratio of meso and racemic forms was 5: 7), which was recrystallized from EtOH to give the racemic isomer as plates, mp 132—133 °C. Found: C, 72.74; H, 6.58; N, 7.97%. Calcd for $C_{22}H_{24}N_2O_3$: C, 72.50; H, 6.64; N, 7.69%. IR (Nujol): 1378, 1140, and 1050 cm^{-1}. PMR ($CDCl_3$): δ 2.38 (12H, s, Ar–C$\underline{H}_3$), 3.80 (6H, s, –OC$\underline{H}_3$), 5.75 (2H, s, –C$\underline{H}$–O–), and 6.59 ppm (4H, s, Ar–$\underline{H}$).

meso- *and* dl-*Bis(α-methoxycarbonyl-2,6-dimethyl-4-methoxybenzyl) Ethers.* Into a mixture of the above ethers (2 g) in abs EtOH (100 ml), dry HCl gas was passed for 5 h at 45—50 °C. The solvent was removed *in vacuo*, and the residue hydrolyzed with 30% aq KOH in ethylene glycol for 3 h. After acidification with dil HCl, the reaction mixture was extracted with ether and the ether extract methylated with



Scheme 1.

diazomethane. The crude product was chromatographed over silica gel. Elution with $CHCl_3$ containing acetone (0.5% v/v) gave a meso ester (1.3 g, 52%) as prisms from EtOH, mp 123—124 °C. Found: C, 66.79; H, 7.08%. Calcd for $C_{24}H_{30}D_7$: C, 66.96; H, 7.02%. IR (Nujol): 1765, 1745, 1380, 1200, 1140, and 1070 cm^{-1}. PMR ($CDCl_3$): δ 2.16 (12H, s, Ar–C$\underline{H}_3$), 3.71 (6H, s, –$CO_2C\underline{H}_3$), 3.77 (6H, s, Ar–O$C\underline{H}_3$), 5.45 (2H, s, Ar–C$\underline{H}$–O–), and 6.54 ppm (4H, s, Ar–$\underline{H}$). Further elution with $CHCl_3$ containing acetone (3% v/v) gave the racemic isomer (0.9 g, 39%) as prisms from EtOH, mp 173—174 °C. Found: C, 67.04; H, 7.13%. IR (Nujol): 1750, 1380, 1220, 1190, 1140, and 1065 cm^{-1}. PMR ($CDCl_3$): δ 2.19 (12H, s, Ar–C$\underline{H}_3$), 3.68 (6H, s, –$CO_2C\underline{H}_3$), 3.79 (6H, s, Ar–O$C\underline{H}_3$), 5.24 (2H, s, Ar–C$\underline{H}$–O–), and 6.56 ppm (4H, s, Ar–$\underline{H}$).

*Bis[2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] Ethers (**2a** and **2b**).* The meso and racemic ethers (1 g) were reduced with $LiAlH_4$ (0.5 g) in ether to give **2a** (760 mg, 87%) and **2b** (810 mg, 93%) respectively as needles from acetone–hexane. **2a**; mp 114—115 °C. Found: C, 70.31; H, 8.20%. Calcd for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08%.

IR (Nujol): 3300, 1195, 1145, 1100, and 1067 cm^{-1}. PMR ($CDCl_3$): δ 2.20 (12H, br s, Ar–C$\underline{H}_3$), 2.92 (2H, br s, –O$\underline{H}$), 3.63 (2H, dd, J=4.5 and 12 Hz, –CH–C(H)–OH), 3.72 (6H, s, –O$C\underline{H}_3$), 4.15 (2H, dd, J=9 and 12 Hz, –CH–C($\underline{H}$)–OH), 5.07 (2H, dd, J=4.5 and 9 Hz, Ar–C$\underline{H}$(–CH_2–)O–), and 6.43 ppm (4H, s, Ar–$\underline{H}$). **2b**; mp 167—168 °C. Found: C, 70.51; H, 8.12%. IR (Nujol): 3250, 1310, 1196, 1140, 1090, 1068, and 1045 cm^{-1}. PMR ($CDCl_3$): δ 1.50 (6H, br s, Ar–C$\underline{H}_3$), 2.51 (6H, br s, Ar–C$\underline{H}_3$), 2.17 (2H, br s, –O$\underline{H}$), 3.66 (2H, dd, J=5 and 11.5 Hz, –CH–C(H)–OH), 3.72 (6H, s, –O$C\underline{H}_3$), 4.05 (2H, dd, J=9 and 11.5 Hz, –CH–C($\underline{H}$)–OH), 4.70 (2H, dd, J=5 and 9 Hz, Ar–C$\underline{H}$(–CH_2–)O–), and 6.53 ppm (4H, br s, Ar–$\underline{H}$).

Reduction of meso- *and* dl-*Bis(α-methoxycarbonyl-2,6-dimethyl-4-methoxybenzyl) Ethers with Lithium Aluminium Deuteride.* i) The meso and racemic ethers (430 mg, 1 mmol) were reduced with $LiAlD_4$ (76 mg, 2 mmol) in ether under reflux to give **2a-D** (352 mg, 93%) and **2b-D** (349 mg, 92%), respectively. **2a-D**; mp 114—115 °C. PMR ($CDCl_3$): δ 2.20 (12H, br s, Ar–C$\underline{H}_3$), 2.75 (2H, br s, –O$\underline{H}$), 3.73 (6H, s, –O$C\underline{H}_3$), 5.09 (2H, s, Ar–C$\underline{H}$(–CD_2–)O–), and 6.52 ppm (4H, s, Ar–$\underline{H}$). **2b-D**; mp 166—167 °C. PMR ($CDCl_3$): δ 1.57 (6H, br s, Ar–C$\underline{H}_3$), 2.27 (1H, s, –O$\underline{H}$), 2.57 (1H, s, –O$\underline{H}$), 2.58 (6H, br s, Ar–C$\underline{H}_3$), 3.75 (6H, s, –O$C\underline{H}_3$), 4.74 (2H, s, Ar–C$\underline{H}$(–CD_2–)O–), and 6.58 ppm (4H, br s, Ar–$\underline{H}$).

ii) The meso ether (200 mg, 0.47 mmol) was allowed to react with $LiAlD_4$ (180 mg, 4.7 mmol) in ether under reflux and the complex decomposed with dil HCl to give **2a-D** (163 mg, 91%) and **5a-D** (8 mg, 5%). **5a-D**; mp 243—244 °C. Found: C, 73.52; H, 7.77%. Calcd for $C_{22}H_{24}D_4O_4$: C, 73.31; H, 8.03%. IR (Nujol): 1306, 1280, 1142, 1100, and 1060 cm^{-1}. MS: *m/e* (rel intensity) 360 (M^+, 1),164 (100), 148 (18), 135 (23), 121 (29), 105 (25), and 91 (35). The racemic isomer (200 mg, 0.47 mmol) was treated with $LiAlD_4$ (180 mg, 4.7 mmol) in a manner similar to that described above to give **2b-D** (142 mg, 72%) and **5b-D** (37 mg, 22%). **5b-D**; mp 252—253 °C. Found: C, 73.35; H, 7.71%. IR (Nujol): 1306, 1280, 1150, 1135, 1090, 1062, and 1000 cm^{-1}. MS: *m/e* (rel intensity) 360 (M^+, 4), 180 (1), 164 (100), 148 (13), 135 (17), 121 (23), 105 (14), and 91 (25).

*Reaction of Bis[2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] Ethers (**2a** and **2b**) with Tosyl Chloride.* i) The ether **2a** (110 mg, 0.29 mmol) was mildly refluxed with tosyl chloride (550 mg, 2.3 mmol) in pyridine (10 ml) for 1 h. The reaction mixture was poured into ice water and extracted with ether. The ether layer was washed with dil HCl and water, and dried. The crude product afforded an oily **3** (29 mg, 56%) and **4** (43 mg, 42%), mp 113—114 °C. **3**; IR ($CHCl_3$): 2830, 2720, 1716, 1200, 1140, and 1060 cm^{-1}. PMR ($CDCl_3$): δ 2.17 (6H, s), 3.55 (2H, d, J=2 Hz), 3.64 (3H, s), 6.49 (2H, s), and 9.6 ppm (1H, t, J=2 Hz). 2,4-Dinitrophenylhydrazone of **3**; mp 168—169 °C. Found; C, 56.91; H, 5.04; N, 15.61%. Calcd for $C_{17}H_{18}N_4O_5$: C, 56.98; H, 5.06; N, 15.64%. Oxidation of **3** with chromium(VI) oxide in acetic acid gave 2,6-dimethyl-4-methoxy-phenylacetic acid, mp 144—145 °C. Found: C, 68.13; H, 6.55%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 6.74%. **4**; Found: C, 74.23; H, 8.09%. Calcd for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92%. IR ($CHCl_3$): 1180, 1140, 1118, and 1040 cm^{-1}. MS: *m/e* (rel intensity) 356 (M^+, 2), 207 (25), 179 (28), 162 (10), 149 (100), 138 (11), 119 (18), 105 (8), and 91 (18). PMR ($CDCl_3$): δ 2.39 (12H, s), 3.10 (2H, d, J=4 Hz), 3.75 (1H, t, J=8 Hz), 3.78 (6H, s), 3.99 (1H, t, J=8 Hz), 5.00 (1H, t, J=4 Hz), 5.28 (1H, t, J=8 Hz), and 6.68 ppm (4H, br s). Both evaporation to dryness of the water layer and acetylation of the residue did not give any isolable product.

ii) The racemic isomer **2b** (110 mg, 0.29 mmol) was treated with tosyl chloride (550 mg, 2.3 mmol) in a manner similar to that described above to give **3** (5 mg, 10%), **4** (24 mg, 23%) and **5** (43 mg, 42%). **5**; mp 244 °C. Found: C, 73.96; H, 7.86%. Calcd for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92%. IR ($CDCl_3$): 1190, 1177, 1148, 1100, and 1065 cm^{-1}. MS: *m/e* (rel intensity) 356 (M^+, 15), 178 (14), 163 (34), 162 (100), 149 (88), 105 (6), and 91 (13). PMR ($CDCl_3$): δ 2.46 (12H, s), 3.66 (6H, s), 3.79 and 3.88 (4H, AB in ABX, J_{AX}=10, J_{BX}=6 Hz, $J_{AB}\simeq 0$), 4.99 (2H, X in ABX, J_{AX}=10 and J_{BX}=6 Hz), and 6.46 ppm (4H, s).

*Reaction of Bis[2,2-dideuterio-2-hydroxy-1-(2,6-dimethyl-4-methoxyphenyl)ethyl] Ethers (**2a-D** and **2a-D**) with Tosyl Chloride.* i) The meso compound, **2a-D** (210 mg, 0.56 mmol), was allowed to react with tosyl chloride (1.1 g, 4.6 mmol) in pyridine (20 ml) for 1 h. After the usual work-up, when the crude product was dissolved in a solution of benzene–hexane (1: 1), a tosylate (28 mg, 8%) precipitated, mp 128 °C from EtOH. Found: C, 63.31; H, 6.39%. Calcd for $C_{36}H_{38}D_4O_9S_2$: C, 62.94; H, 6.29%. PMR ($CDCl_3$): δ 1.94 (6H, br s, Ar–C$\underline{H}_3$), 2.04 (6H, br s, Ar–C$\underline{H}_3$), 2.48 (6H, s, Ar–C$\underline{H}_3$), 3.78 (6H, s, –O$C\underline{H}_3$), 5.20 (2H, s, Ar–C$\underline{H}$–O–), 6.57 (4H, br s, Ar–$\underline{H}$), 7.58 (4H, d, J=9 Hz, Ar–$\underline{H}$), and 8.05 ppm (4H, d, J=9 Hz, Ar–$\underline{H}$). The mother liquor afforded a mixture (79 mg) of **3-D-1** and **3-D-2**, and **4-D** (42 mg, 21%). The mixture of **3-D-1** and **3-D-2**; PMR ($CDCl_3$): δ 2.27 (6H, s), 3.55 (0.5H, br s), 3.79 (3H, s), 6.71 (2H, s), and 9.97 ppm (0.5H, s). **4-D**; PMR ($CDCl_3$): δ 2.41 (12H, s), 3.80 (6H, s), 5.13 (1H, s), 5.42 (1H, s), and 6.73 ppm (2H, s).

ii) The racemic isomer **2b-D** (214 mg, 0.57 mmol) afforded a mixture (50 mg) of **3-D-1** and **3-D-2** (1: 1), **4-D** (52 mg, 26%), and a tosylate (55 mg, 15%), mp 115 °C. Found:

C, 62.77; H, 6.03%. PMR ($CDCl_3$): δ 1.47 (6H, br s, Ar-C$\underline{H}_3$), 2.38 (6H, br s, Ar-C$\underline{H}_3$), 2.43 (6H, br s, Ar-C$\underline{H}_3$), 3.77 (6H, s, -OC$\underline{H}_3$), 4.70 (2H, s, Ar-C$\underline{H}$-O-), 6.50 (2H, br d, J=2 Hz, Ar-$\underline{H}$), 6.59 (2H, br d, J=2 Hz, Ar-$\underline{H}$), 7.40 (4H, d, J=8.5 Hz, Ar-$\underline{H}$), and 7.80 ppm (4H, d, J=8.5 Hz, Ar-$\underline{H}$).

*Hydrolysis of Acetal (**4-D**) with Hydrochloric Acid in Methanol.* Acetal **4-D** (30 mg) was refluxed with 4 M HCl (6 ml) in MeOH (10 ml) for 1 h. The crude product afforded a mixture (7 mg) of **3-D-1** and **3-D-2**, and an oil **6** (8 mg) and **7** (15 mg). **6**; Found: C, 68.72; H, 8.80%. Calcd for $C_{13}H_{18}D_2O_2$: C, 69.00; H, 9.06%. MS: *m/e* (rel intensity) 226 (M^+, 2), 151 (9), and 75 (100). IR ($CHCl_3$): 1315, 1180, 1145, 1130, 1065, and 1000 (sh) cm^{-1}. PMR ($CDCl_3$): δ 2.38 (6H, s), 3.39 (6H, s), 3.83 (3H, s), 4.50 (1H, br s), and 6.74 ppm (2H, s). **7**; Found: C, 67.52; H, 8.53%. Calcd for $C_{12}H_{16}D_2O_3$: C, 67.90; H, 8.70%. MS: *m/e* (rel intensity) 213 ($M+1^+$, 2), and 179 (100). IR ($CHCl_3$): 3580, 3460, 1305, 1140, 1095, 1085, 1000, and 963 cm^{-1}. PMR ($CDCl_3$): δ 2.33 (1H, br s), 2.42 (6H, s), 3.30 (3H, s), 3.83 (3H, s), 4.86 (1H, s), and 6.72 ppm (2H, s).

*Preparation of 1,1-Dideuterio-2-methoxy-2-(2,6-dimethyl-4-methoxyphenyl)ethanol (**7**).* α-Cyano-2,6-dimethyl-4-methoxybenzylalcohol (1.3 g) was refluxed with a catalytic amount of TsOH in abs MeOH for 12 h. The crude product gave 0.72 g (52%) of α-cyano-2,6-dimethyl-4-methoxybenzyl methyl ether, bp 204—206 °C/27 mmHg. Found: C, 70.19; H, 7.39; N, 7.17%. Calcd for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.37; N, 6.82%. PMR ($CDCl_3$): δ 2.45 (6H, s), 3.48 (3H, s), 3.76 (3H, s), 5.41 (1H, s), and 6.69 ppm (2H, s). The methyl ether (500 mg) was hydrolyzed in abs EtOH (50 ml) with dry HCl at 50 °C for 3 h. The crude product gave 420 mg (75%) of α-methoxy-(2,6-dimethyl-4-methoxyphenyl)-acetamide, mp 156—157 °C from benzene. Found: C, 64.59; H, 7.70; N, 6.16%. Calcd for $C_{12}H_{17}NO_3$: C, 64.55; H, 7.68; N, 6.27%. IR (Nujol): 3350, 3130, and 1675 cm^{-1}. PMR ($CDCl_3$): δ 2.38 (6H, s), 3.30 (3H, s), 3.83 (3H, s), 5.20 (1H, s), 6.74 (2H, s), and 6.5—7.1 ppm (2H, br s, -N$\underline{H}_2$). The amide (240 mg) was hydrolyzed in ethylene glycol (10 ml) with aq 30% KOH to give α-methoxy-(2,6-dimethyl-4-methoxyphenyl)acetic acid, mp 101—102 °C from benzene–hexane. Found: C, 64.12; H, 7.21%. Calcd for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19%. IR (Nujol): 3300—2200 and 1718 cm^{-1}. PMR ($CDCl_3$): δ 2.00—2.40 (1H, -O$\underline{H}$), 2.40 (6H, s), 3.37 (3H, s), 3.82 (3H, s), 5.30 (1H, s), and 6.73 ppm (2H, s). The carboxylic acid (85 mg) was reduced with $LiAlD_4$ (40 mg) in ether to give 68 mg (81%) of **7**.

Treatment of the tosylate of **2b-D** in pyridine. The tosylate (70 mg) of **2b-D** was boiled in pyridine (10 ml) for 4 h and gave a mixture (17 mg) of **3-D-1** and **3-D-2** (54:46).

The authors would like to express their deep gratitude to Dr. M. Nakayama, Hiroshima University, for the mass spectra and Dr. K. Shibata, Osaka City University, for the elemental analyses.

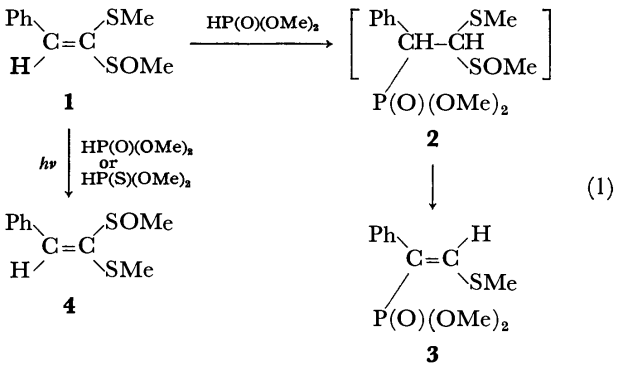
(Received May 6, 1978)

Reaction of dimethyl phosphonate with phenylketene dimethyl dithioacetal derivatives have been investigated to prepare *s*-alkylphosphonates. The addition reactions of phosphonate were accelerated in dithioacetal derivatives in the following order: –SMe<–SOMe≪–SO_2Me. The reaction of β,β-bis(methylsulfonyl)styrene (**7**) with dimethyl phosphonate followed by the catalytic reduction afforded dimethyl α-methylbenzylphosphonate in 74% yield from compound **7**. The reaction of 1-methylsulfinyl-1-methylthio-4-phenyl-1-butene with dimethyl phosphonate gave dimethyl (2-methylthio-1-phenethylvinyl)phosphonate in 21% yield.

Dialkyl phosphonates rapidly add to strongly activated C=C double bonds in the presence of basic catalysts, and the initial adducts are generally protonated to give phosphonates.[1] In previous papers, the reaction of phosphorus compounds with the 5,6-unsaturated 6-nitro-*xylo*-hexofuranose derivatives to give the 5-phosphino and 5-phosphinyl derivatives of D-glucose, that were *s*-alkylphosphorus derivatives, were reported.[2] The present paper deals with an alternative preparative method for *s*-alkylphosphonate.

Results and Discussion

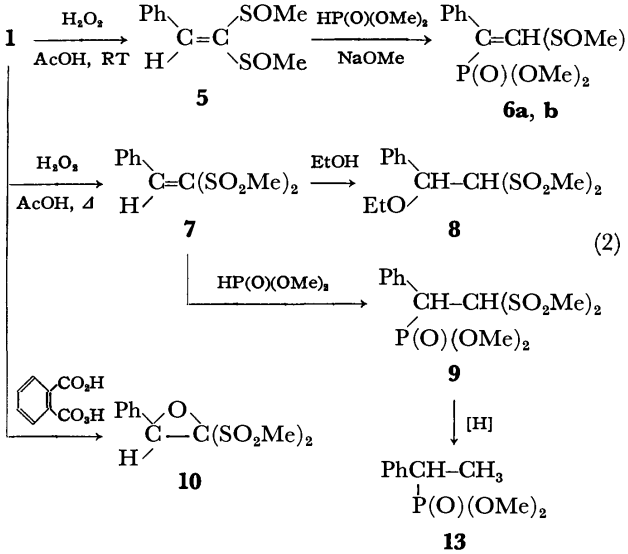
The reaction of (*E*)-β-methylsulfinyl-β-methylthiostyrene (**1**)[3] with dimethyl phosphonate in the presence of sodium methoxide under a nitrogen atmosphere at room temperature for a month afforded dimethyl (*Z*)-(2-methylthio-1-phenylvinyl)phosphonate (**3**) in 10% yield, but no corresponding initial adduct **2** was isolated. The photochemical reaction of compound **1** with dimethyl phosphonate or *O,O*-dimethyl thiophosphonate[4] afforded no such addition products as compound **2**, but gave the (*Z*)-isomer **4**,[3a] where the SMe signal in the NMR spectrum shifted from δ 2.25 to 2.45.



(1)

β,β-Bis(methylsulfinyl)styrene (**5**) has been prepared from compound **1** by the action of hydrogen peroxide in acetic acid.[5] The reaction of **5** with dimethyl phosphonate in the presence of sodium methoxide at room temperature for 2 weeks gave dimethyl (2-methylsulfinyl-1-phenylvinyl)phosphonate (**6**, 10% yield), which contained *E* and *Z* stereoisomers in the ratio of 1 : 1. The acid catalyzed reactions (*e.g.*, *p*-toluenesulfonic acid) of compounds **1** and **5** with dimethyl phosphonate were unsuccessful.

Oxidation of **1** with hydrogen peroxide in refluxing acetic acid afforded β,β-bis(methylsulfonyl)styrene (**7**) in 30% yield.[6] Compound **7** reacted with ethanol to give 1-ethoxy-2,2-bis(methylsulfonyl)-1-phenylethane (**8**) in excellent yield. The reaction of **7** with dimethyl phosphonate under a nitrogen atmosphere at 60 °C for 16 h gave the corresponding adduct **9** in 95% yield. It appears that the addition of phosphonate to ketene dimethyl dithioacetal derivatives is accelerated in the order –SMe<–SOMe≪–SO_2Me bearing in mind the reaction conditions.



(2)

The oxidation of **1** with hydrogen peroxide in acetic anhydride–acetic acid (1 : 1 v/v), or monoperoxyphthalic acid in ether gave the epoxide **10** in moderate yields. The reaction of 1-methylsulfinyl-1-methylthio-4-phenyl-1-butene (**11**)[7] with dimethyl phosphonate at 120 °C for 30 h afforded dimethyl (2-methylthio-1-phenethylvinyl)phosphonate (**12**) in 21% yield. The catalytic reduction of **3**, **6**, and **9** with Raney nickel gave dimethyl

α-methylbenzylphosphonate (**13**) in 70—90% yields.

The Michaelis-Arbuzov and Michaelis-Becker reactions are important processes to prepare compounds having phosphorus-carbon bonds.[8] However, in some instances the reactions have been unsuccessful *e.g.*, the reaction of 3-*O*-benzyl-5-bromo-5,6-dideoxy-1,2-*O*-isopropylidene-β-L-idofuranose with sodium methylphosphide gave only olefinic products.[9] The addition reactions of phosphonates to ketones or hydrazones followed by 1 or 2 steps afforded *s*-alkylphosphonates in moderate yields.[10] The reaction described in this paper is an alternative method for the preparation of *s*-alkylphosphonates from esters as well as aldehydes.

The reaction of **1** and **5** with dimethyl phosphonate to give compounds **3** and **6** may be written as Eq. 1, *i.e.*, the initially formed adduct spontaneously loses methanesulfenic acid.[11] Compound **7** gave the corresponding adduct **9** attributed to the slow departure of methanesulfinic acid in this reaction condition.

Experimental

Material. Methyl methylthiomethyl sulfoxide was supplied by Nippon Soda Company, Ltd.

Measurements. Melting and boiling points were uncorrected. The ^{1}H-NMR spectra were run on Hitachi-Perkin-Elmer R-20 (60 MHz) and Hitachi R-24 (60 MHz) spectrometers with tetramethylsilane as an internal standard. The IR spectra were measured by Hitachi-Perkin-Elmer 337 and Japan Optics Laboratory A-3 infrared spectrophotometers.

*Reaction of (E)-β-Methylsulfinyl-β-methylthiostyrene (**1**) with Dimethyl Phosphonate.* Compound **1**[3] (1.5 g) was added to the mixture of dimethyl phosphonate (2 g) and sodium methoxide (1 g). After the introduction of nitrogen gas, the mixture was allowed to stand for 1 month at room temperature. Neutralization of the reaction mixture followed by extraction of the chloroform solution with saturated sodium chloride solution and evaporation of the volatile materials *in vacuo* afforded a syrup (R_f value 0.2, silica gel, eluent; benzene: ethyl acetate=1: 1 v/v). Purification of the syrup by column chromatography afforded 0.2 g of dimethyl (*Z*)-(2-methylthio-1-phenylvinyl)phosphonate (**3**, 10% yield). IR (neat) 1250 cm^{-1} (P=O); NMR ($CDCl_3$) δ 2.43 (s, 3H, SMe), 3.73 (d, J_{POCH}=12.0 Hz, 6H, POMe), 7.24 (d, J_{PCCH}=44.3 Hz, 1H, CH), and 7.34 (5H, Ph).

*Synthesis of β,β-Bis(methylsulfinyl)styrene (**5**).*[5] Treatment of **1** (5 g) with 35% aqueous hydrogen peroxide (4 ml) in acetic acid (15 ml) at room temperature for 30 h afforded the oxidation product, which was extracted with chloroform. Evaporation of the solvent followed by recrystallization from ethanol afforded 2.7 g of compound **5** (*meso* form, 51% yield), mp 113—115 °C (lit,[5] mp 112—113 °C).

*Synthesis of β,β-Bis(methylsulfonyl)styrene (**7**).*[6] Treatment of **1** (1.3 g) with 35% aqueous hydrogen peroxide (2.5 ml) in refluxing acetic acid (5 ml) for 6 h followed by neutralization of the reaction mixture, extraction of the chloroform solution with water, and evaporation of the solvent *in vacuo* afforded 1.3 g of a crude product (87% yield). Recrystallization from benzene–hexane gave 0.47 g of the pure compound **7** (30% yield), mp 136—137 °C. IR (KBr) 1330 and 1160 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 3.20 and 3.30 (s, 6H, SO_2Me), 7.6 (5H, Ph), and 8.48 (s, 1H, CH).

Found: C, 45.83; H, 4.66%. Calcd for $C_{10}H_{12}O_4S_2$: C, 46.15; H, 4.65%.

*Synthesis of 1,1-Bis(methylsulfonyl)-2-phenyloxirane (**10**).* Treatment of **1** (6 g) with 35% aqueous hydrogen peroxide (10 ml) in acetic anhydride (25 ml)–acetic acid (25 ml) for 5 days at room temperature followed by the same work-up as cited above afforded 3.5 g of **10** (42% yield), mp 158—160 °C. IR (KBr) 1330 and 1160 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 2.55 and 3.08 (s, 6H, SO_2Me), 4.98 (s, 1H, CH), and 7.38 (5H, Ph).

Found: C, 43.33; H, 4.54%. Calcd for $C_{10}H_{12}O_5S_2$: C, 43.48; H, 4.35%.

Oxidation of **1** (3 g) with monoperoxyphthalic acid (5.6 g) in ether at room temperature for 4 days afforded **10** (2.6 g) in 70% yield.

*Reaction of **5** with Dimethyl Phosphonate.* The mixture of dimethyl phosphonate (4.7 g), sodium methoxide (0.6 g), and **5** (1.5 g) in tetrahydrofuran (8 ml) under a nitrogen atmosphere was allowed to react for 2 weeks at room temperature. After the work-up as described for **1** with dimethyl phosphonate, the *E* and *Z* isomers of dimethyl (2-methylsulfinyl-1-phenylvinyl)phosphonate (**6a** and **6b**, 0.14g) were obtained in 10% yield. NMR ($CDCl_3$) δ 2.30 and 2.58 (s, 3H, SOMe), 3.63 and 3.65 (d, J_{POCH}=12.0 Hz, 6H, POMe), and 6.70—7.68 (m, 6H, Ph and CH).

*Reaction of **7** with Dimethyl Phosphonate.* A mixture of **7** (0.5 g) with an excess of dimethyl phosphonate (2 g) was heated for 16 h at 60 °C under a nitrogen atmosphere in a sealed tube. The removal of excess phosphonate *in vacuo* afforded dimethyl 2,2-bis(methylsulfonyl)-1-phenylethylphosphonate (**9**, *dl*-form, 0.67 g) in 95% yield, mp 154—157 °C. NMR ($CDCl_3$) δ 3.13 and 3.48 (s, 6H, SO_2Me), 4.15 and 4.35 (d, J_{POCH}=12.0 Hz, 6H, POMe), 4.50—6.00 (m, 2H, CH–CH), and 7.75—8.75 (m, 5H, Ph).

Found: C, 38.86; H, 5.17%. Calcd for $C_{12}H_{19}O_7PS_2$: C, 38.92; H, 5.14%.

*Reaction of **7** with Ethanol.* Reaction of **7** (1.3 g) with a large excess of hot ethanol (10 ml) afforded 1.36 g of adduct **8** (87% yield) in 72% yield from compound **1**, mp 145—149 °C. NMR ($CDCl_3$) δ 1.34 (t, J_{HH}=7.5 Hz, 3H, C–Me), 3.40 (s, 6H, SO_2Me), 3.83 (q, J_{HH}=7.5 Hz, 2H, O–CH_2), 4.45 and 5.84 (m, 2H, CH–CH), and 7.65 (m, 5H, Ph).

Found: C, 46.92; H, 5.96%. Calcd for $C_{12}H_{18}O_5S_2$: C, 47.04; H, 5.92%.

*Reaction of **11** with Dimethyl Phosphonate.* The reaction of **11**[7] (0.4 g) with dimethyl phosphonate (2.0 g) proceeded at 120 °C for 30 h. Evaporation of excess dimethyl phosphonate *in vacuo* afforded a syrup, which on separation by preparative TLC (silica gel, eluent: ethyl acetate) afforded phosphonate **12** in 21% yield. The reaction in the presence of *p*-toluenesulfonic acid gave a similar result. NMR (CCl_4) δ 2.12 (s, 3H, SMe), 2.00—2.90 (m, 4H, CH_2CH_2), 3.73 (d, J_{POCH}=12.0 Hz, 6H, POMe), and 7.05—7.50 (m, 6H, Ph and CH).

*Catalytic Hydrogenolysis of **9**.* Treatment of **9** (0.50 g) with hydrogen in the presence of Raney nickel (W-2) for 6 h in refluxing ethanol (20 ml) followed by filtration and evaporation afforded an oily material. The product in chloroform was washed with aqueous sodium hydrogencarbonate, and then dried over sodium sulfate. Evaporation of the solvent *in vacuo* gave dimethyl α-methylbenzylphosphonate (**13**) in 78% yield, bp 119—120 °C/1.5 mmHg (lit,[10b] bp 150—152 °C/2 mmHg). NMR (CCl_4) δ 1.40 (dd, J_{PCCH}=18.6 Hz and J_{HH}=7.5 Hz, 3H, C–Me), 3.00 (dq, J_{PCH}=23.0 Hz and J_{HH}=7.5 Hz, 1H, CH), 3.30 and 3.48 (d, J_{POCH}=10.3 Hz, 6H, POMe), and 7.16 (m, 5H, Ph).

Similar treatment of **3** and **6** afforded the same phosphonate in 70 and 90% yields, respectively.

Electron-transfer Reduction of α-Substituted Ketones and 1,2-Diketones with Benzenethiol Mediated by Iron Polyphthalocyanine

Hiroo INOUE,* Tadashi NAGATA, Hiroyuki HATA, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received May 10, 1978)

Iron polyphthalocyanine (Fe-poly PC) has been found to act as an electron-transfer reagent in the reductions of α-substituted ketones, α-bromodeoxybenzoin (**1a**), 2-bromopropiophenone (**1b**), α,α-bis(phenylthio)deoxybenzoin (**4**), and 1,2-diketones, benzil (**5**) and 4,5-octanedione (**8**), with benzenethiol. The α-bromo ketones (**1a** and **1b**) have been debrominated to their parent ketones. **4** has been reduced to α-(phenylthio)deoxybenzoin and deoxybenzoin *via* the cleavage of the carbon-sulfur bond, and **5** and **8** to the corresponding α-hydroxy ketones. The ability of Fe-poly PC to perform these reactions is superior to that of iron phthalocyanine (Fe-PC), particularly those reactions in dry benzene. The catalytic action of Fe-poly PC and Fe-PC becomes evident when methanol or 80 vol % aqueous methanol is used as solvent. Furthermore, the reductions of related compounds by the Fe-poly PC-benzenethiol system are described.

Iron polyphthalocyanine (Fe-poly PC) is an electroconductive polymer which has iron(II) ions in a conjugated system.[1] It has been shown that Fe-poly PC is catalytically active for the oxidation of hydrocarbons with oxygen[2] and the reductive dehalogenation of α-halo ketones with 1-benzyl-1,4-dihydronicotinamide.[3] In these reactions, Fe-poly PC assists the transfer of the electron from an electron donor to an electron acceptor to promote the reduction of the electron acceptor coupled to the oxidation of the electron donor. Furthermore, the catalytic effects increase with an increase in the degree of the conjugation of the phthalocyanine polymer. The function of Fe-poly PC may be due to the nature of iron ions bridged with an electron-transferring ligand.[4] Similar phenomena have been observed in the catalytic action of copper polyphthalocyanine on the decomposition of hydrogen peroxide[5] and the exchange reaction between hydrogen and deuterium.[6]

To further explore the catalytic behavior of Fe-poly PC, the reactions of α-substituted ketones and 1,2-diketones (electron acceptors) with benzenethiol (electron donor) have been conducted in the presence of Fe-poly PC. In this paper, the characteristic of Fe-poly PC as an electron-transfer reagent is reported. Some of the results described here have been communicated in a preliminary report.[7]

Results and Discussion

The Properties of Fe-PC and Fe-poly PC. The visible absorption spectrum of Fe-PC and Fe-poly PC using a KBr disk showed absorption maxima at 677 and 725 nm respectively which agrees with previous data.[2] The absorption of Fe-poly PC is shifted towards the longer wavelength by 48 nm at 725 nm compared with Fe-PC. Thus, Fe-poly PC is a stronger electron donor than Fe-PC.

The value of ρ_{20} of the electrical conductivity of Fe-poly PC was 2×10^6 ohm-cm and it is apparent that Fe-poly PC has a better electron-conducting property than Fe-PC ($>10^9$ ohm-cm[8]). Furthermore, the catalytic activity of Fe-poly PC in the oxidation of acetaldehyde ethylene acetal with oxygen at room temperature was similar to that of the previously prepared Fe-poly PC.[2] On the other hand, Fe-PC did not show any activity. In this paper, Fe-PC and Fe-poly PC which have these properties have been used.

Reductive Dehalogenation of α-Halo Ketones. Function of Fe-poly PC: In the absence of Fe-poly PC, α-bromodeoxybenzoin (**1a**) and 2-bromopropiophenone (**1b**) did not react under nitrogen with benzenethiol in dry benzene at 80 °C. In 80 vol % aqueous methanol, α-phenylthio ketones (**2a** and **2b**) were obtained in high yields, as Table 1 shows. The reaction of 2-bromoacetophenone (**1c**) with benzenethiol gave 2-(phenylthio)-acetophenone (**3c**) even in dry benzene. In these reactions, the reductive debromination of **1a**, **1b**, and **1c** did not occur. Furthermore, Fe-poly PC did not react under similar conditions with **1a**, **1b**, and **1c**. When Fe-poly PC (iron ion: α-bromo ketone molar ratio=1 : 1) was suspended in a solution containing α-bromo ketones (**1**) and benzenethiol in dry benzene or 80 vol% aqueous methanol and the solution heated at 80 °C (under conditions similar to those used in the absence of Fe-poly PC), the debromination products (**2**) were produced (Table 1).

$$\underset{\mathbf{1}}{\mathrm{PhCOCHR}}(\mathrm{Br}) + \mathrm{PhSH} \xrightarrow{\text{Fe-poly PC}} \mathrm{PhCOCH_2R} + \underset{\mathbf{3}}{\mathrm{PhCOCHR}}(\mathrm{SPh}) + \mathrm{PhSSPh}$$
$$\mathbf{2}$$

(**a**, R=Ph; **b**, R=CH_3; **c**, R=H)

The product yields decreased in the following order; **2a**>**2b**>**2c**, while those of the α-phenylthio ketones increased inversely. Benzenethiol was oxidized to diphenyl disulfide when the α-bromo ketones were reduced to the parent ketones, respectively. However, the amount of diphenyl disulfide was ambiguous, since benzenethiol was readily oxidized to diphenyl disulfide in air in the presence of Fe-poly PC.

The reaction of **1a** with benzenethiol in the presence of Fe-poly PC conducted at a molar ratio of iron ion to **1a** of 1: 10 selectively produced **2a**, as shown in Table 1. From this it is apparent that Fe-poly PC acts

Table 1. The effects of Fe-poly PC on the reactions of α-bromo ketones with benzenethiol[a)]

as a catalyst for the reductive debromination. It has been reported that the organic halogen compounds are reduced by iron porphyrins[9)] and thiols are oxidized by $Fe(CN)_6^{3-}$ and iron(III) octanoate to disulfides.[10)] Furthermore, the carbon-halogen bond reductions with metals and metal complexes and electrolysis have been explained in terms of an initial conversion of RBr to R· by one-electron reduction.[11)] The formation of the ketone (**2**) along with diphenyl disulfide indicates that Fe-poly PC undergoes cleavage of the C–Br bond of the α-bromo ketones (**1**), followed by hydrogen abstraction from benzenethiol to give the parent ketone (**2**). This reaction is coupled to the reduction of the oxidized Fe-poly PC with benzenethiol giving the original Fe-poly PC and diphenyl disulfide. For **1a** and **1b**, the rate of reduction of the C–Br bond

$$\mathbf{1} + \text{Fe-poly PC} \longrightarrow [\text{PhCOĊHR}][\text{Fe-poly PC}]^{\text{oxd}}\text{Br}^- \xrightarrow{\text{PhSH}} \mathbf{2} + \text{Fe-poly PC} + \text{HBr}$$

promoted by Fe-poly PC is considerably faster than that for the formation of the α-phenylthio ketones (**3a** and **3b**).

The function of Fe-poly PC accelerating the reductive debromination of **1a** was compared with that of Fe-PC.

Table 2. A comparison of the catalytic action between Fe-poly PC and Fe-PC in the reduction of **1a** with benzenethiol[a)]

Fe-complex	Solvent	Temp, °C	Time, h	Yield, %[b)]	
				2a	**3a**
Fe-poly PC	B	80	12	67	0
Fe-poly PC	WM	80	1/12	87	0
Fe-poly PC	WM	25	1/2	47	0
Fe-PC	B	80	24	37	17
Fe-PC	WM	80	1/12	59	40
Fe-PC	WM	25	1/2	31	13

a) **1a**; 2.8×10^{-2} mol/l. PhSH: **1a** molar ratio; 4: 1. Fe ion: **1a** molar ratio; 1: 1. Solvent; 6 cm³. b) The amounts were determined by means of GLC. Based on **1a**.

As Table 2 shows, Fe-PC underwent the reduction of **1a** with benzenethiol to **2a**, but the reduction rate was slower than that in the case of Fe-poly PC. In addition, the reaction was accompanied by the formation of **3a**. Thus, it has been concluded that Fe-poly PC is more effective than Fe-PC as an electron-transfer reagent in the reductive debromination of **1a**.

Acceleration Using Ethyl Iodide: In order to make possible the reduction of **1c** with benzenethiol in dry benzene in the presence of Fe-poly PC, ethyl iodide was added to the reaction system, since the exchange of the bromo substituent with iodine was expected to facilitate the reduction by Fe-poly PC. As is to be expected, after a reaction of 72 h, **2c** was obtained in 88% yield, along with **3c** in 16% yield (**1c**; 2.8×10^{-2} mol/l, PhSH; 1.1×10^{-1} mol/l, the ethyl iodide: **1c** molar ratio; 10: 1, the iron ion: **1c** molar ratio; 1: 1, and 80 °C). The reaction of **1c** with ethyl iodide in the presence of Fe-poly PC without benzenethiol in dry benzene gave 2-iodoacetophenone in a quantitative yield after a reaction time of 6 h (**1c**; 2.8×10^{-2} mol/l, the ethyl iodide: **1c** molar ratio; 10: 1, the iron ion: **1c** molar ratio; 1: 1, and 80 °C). When Fe-PC, Cu-PC, K_2-PC, and H_2-PC were used instead of Fe-poly PC, 2-iodoacetophenone was not obtained under similar conditions. 2-Iodoacetophenone was reduced instantaneously with benzenethiol in the absence of Fe-poly PC at room temperature to give **2c**

$$\mathbf{1c} + \text{EtI} \xrightarrow[C_6H_6]{\text{Fe-poly PC}} \text{PhCOCH}_2\text{I} + \text{EtBr}$$

quantitatively. Thus, Fe-poly PC performs the reduction of **1c** to **2c** by promoting the exchange reaction of the bromo substituent with iodine of ethyl iodide.

$$\text{PhCOCH}_2\text{I} + \text{PhSH} \longrightarrow \text{PhCOCH}_3 + \text{PhSSPh} + \text{HI}$$

Reductive Cleavage of Carbon-Sulfur Bond of α,α-Bis(phenylthio)deoxybenzoin (4). Fe-poly PC and Fe-PC made possible the reduction of **4** with benzenethiol in dry benzene to give mainly **3a**, as illustrated in Table 3. Furthermore, in the case of Fe-poly PC, **2a** was produced in addition to **3a**, although the yield of **2a** was lower. The ability of Fe-poly PC to form **2a** and/or **3a** was

Table 3. The reduction of **4** with benzenethiol in the presence of Fe-poly PC or Fe-PC in dry benzene (24 h)[a]

superior to that of Fe-PC. When the reaction was conducted using methanol as a solvent, however, **2a** was not produced even in the presence of Fe-poly PC (**3a** was obtained in 48% yield after a reaction of 24 h at

$$\underset{\text{SPh}}{\overset{|}{\text{PhCOCPh}}}\underset{\text{SPh}}{\overset{|}{}} + \text{PhSH} \xrightarrow{\text{Fe-poly PC}} \mathbf{2a} + \mathbf{3a} + \text{PhSSPh}$$

4

14—16 °C). In these reactions, benzenethiol was oxidized to diphenyl disulfide. Fe-poly PC and Fe-PC acted as a catalyst in reactions conducted in an iron ion: **4** molar ratio of 1: 10 in methanol.

In an analogy with α-halo ketones, the reaction proceeds *via* the reductive cleavage of the carbon-sulfur bond of **4** by Fe-poly PC or Fe-PC, followed by the reaction with benzenethiol to give **3a**.

$$\mathbf{4} + \text{Fe-poly PC} \longrightarrow [\text{PhCOC}^{\cdot}(\text{SPh})\text{Ph}][\text{Fe-poly PC}]^{\text{oxd}}\text{PhS}^{-} \xrightarrow{\text{PhSH}} \mathbf{3a} + \text{PhSSPh} + \text{Fe-poly PC}$$

Reduction of 1,2-Diketones and Their Related Compounds. Benzil (**5**) was reduced with benzenethiol in the presence of Fe-poly PC (the iron ion: **5** molar ratio; 1: 1) in dry benzene at 80 °C to afford benzoin (**6**) as the reduction product. The amount of **6** produced increased slowly with time until an almost constant value. The maximum yield of **6** was 70% with Fe-poly PC and 16% with Fe-PC. This phenomenon was not observed when methanol was substituted for benzene where the reaction proceeded much more rapidly than in benzene.

As Table 4 illustrates, results at the iron ion: **5** molar

$$\underset{\mathbf{5}}{\text{PhCOCOPh}} + \text{PhSH} \xrightarrow{\text{Fe-poly PC}} \underset{\mathbf{6}}{\overset{\text{OH}}{\overset{|}{\text{PhCOCHPh}}}} + \text{PhSSPh}$$

ratio of 1: 10 indicate that Fe-poly PC and Fe-PC act as catalysts for the reduction of **5** with benzenethiol in methanol. The rate of the formation of **6** catalyzed by Fe-poly PC was faster by a factor of about 25. Furthermore, the reduction of **5** by the Fe-poly PC- or Fe-PC–benzenethiol system in dry benzene was promoted by triethylamine, as shown in Table 5.

Table 5. The effect of triethylamine on the reduction of **5** by the Fe-poly PC or Fe-PC–benzenethiol system[a]

Fe-PC	5	80	88	12

a) **5**; 0.5 mmol. PhSH/**5** molar ratio; 10. $n=1$. Solvent; C_6H_6 (10 cm^3). Time; 24 h. b) Isolated yields. Based on **5**.

The catalytic reaction is best rationalized by assuming either a partial or complete electron transfer to form either a charge-transfer complex or the ion radical (**7**), followed by the reaction of **7** with benzenethiol giving **6** and the original Fe-poly PC. The benzenethiolate anion produced by triethylamine facilitates the regeneration of the original Fe-poly PC from **7**.

$$\mathbf{5} + \text{Fe-poly PC} \longrightarrow [\text{PhCOC}^{\cdot}\text{Ph}][\text{Fe-poly PC}]^{\text{oxd}} \quad \underset{\mathbf{7}}{\overset{|}{\text{O}^-}} \xrightarrow{\text{PhSH}} \mathbf{6} + \text{Fe-poly PC}$$

4,5-Octanedione (**8**) and ethyl benzoylformate (**9**) were reduced to the corresponding α-hydroxy carbonyl compounds by the Fe-poly PC–benzenethiol system in methanol at 80 °C (Table 6). The reduction of **9**

proceeded very slowly. 1,4-Diphenyl-2-butene-1,4-dione (**10**) was reduced under similar conditions to 1,4-diphenyl-1,4-butanedione in low yield, because of the addition of benzenethiol to the double bond of **10** giving 1,4-diphenyl-1-phenylthio-1,4-butanedione. Furthermore, the Fe-poly PC–benzenethiol system was favorable for reducing the >C=N– bond of the Schiff's base (**11**) of **5**, as illustrated in Table 6.

A Characteristic of Fe-poly PC. As described above, Fe-poly PC and Fe-PC assisted the transfer of an electron from benzenethiol to the electron-accepting group at the α-position in the carbonyl group. However, Fe-poly PC differed from Fe-PC in the following respects:

(1) The electron-transfer reduction by Fe-poly PC proceeded more smoothly than by Fe-PC and in particular, a remarkable difference in reactivity was observed in the reduction of the 1,2-diketone **5** in aprotic solvents such as benzene.

(2) Fe-poly PC showed higher selectivity than Fe-PC for the reductive debromination of the α-bromo ketone **1a** giving the parent ketone **2a**.

(3) The reduction of **4** with the benzenethiol–Fe-poly PC system gave **2a** in addition to the α-phenylthio ketone **3a**, while, in the case of Fe-PC, **2a** was not obtained.

The last observation, (3) cannot be explained by the difference in oxidation-reduction potential between Fe-poly PC and Fe-PC. In the case of Fe-poly PC, there is the possibility that the reduction of **4** and the oxidation of benzenethiol may occur on a separate iron site with the assistance of the electron-transfer between iron ions bridged by the conjugated ligand. This probable function of Fe-poly PC may permit the reduction of **4** to **2a**.

Experimental

Materials. α-Bromo ketones (**1**), α-phenylthio ketones (**3**), **4**, **8**, **10**, **11**, and Fe-PC were prepared as described in the literature.[12] **5** and **9** were purchased. Fe-poly PC was prepared by the method described in a previous paper[2]: C, 53.16; H, 2.72; N, 17.71; Fe, 6.6%: λ_{max} (KBr method); 725 nm: ρ_{20}; 2×10^6 ohm-cm. Powdered Fe-poly PC and Fe-PC, reprecipitated from sulfuric acid solution with water, were used for the above reactions.

General Procedure for Reaction and Isolation of Product. All reactions were performed similarly in reaction tubes (90-cm³ total capacity). A typical reaction is described: a solution of a mixture of **5** (0.105 g; 0.5 mmol) and benzenethiol (0.551 g; 5 mmol) in dry benzene (10 cm³) was placed in the reaction tube and cooled with liquid nitrogen; the air was removed under a reduced pressure of 1 mmHg and, after melting the tube, was filled with nitrogen gas. The replacement by nitrogen gas procedure was repeated 4—5 times. The resulting solution was cooled with liquid nitrogen and to the frozen solution. Fe-poly PC (432 mg) corresponding to 0.5 mmol of Fe was added under nitrogen and degassed under a reduced pressure of 1 mmHg. After the reaction tube was sealed, the solution was melted and vigorously stirred at 80 °C. After a reaction time of 72 h, the Fe-poly PC was filtered and washed with dry benzene. The filtrate was extracted with a 10% sodium carbonate solution, dried over magnesium sulfate, and the benzene removed. The residue was submitted to chromatography on silica gel. Elution with benzene and chloroform gave 0.143 g of diphenyl disulfide (mp 58—59 °C), 0.040 g (38% recovery) of **5** (mp 94—95 °C), and 0.017 g (60%) of **6** (mp 131—132 °C). When methanol was used instead of benzene as a reaction solvent, and excess of benzene was added to the filtrate and the resulting solution worked up in a similar manner to that described for benzene.

The reactions of **1** with benzenethiol in the absence or presence of Fe-poly PC and Fe-PC in 80 vol % aqueous methanol were conducted as follows. Benzenethiol was added under nitrogen to degassed 80 vol % aqueous methanol dispersed by Fe-poly PC or Fe-PC. The resulting solution was frozen, the α-bromo ketones (**1**) added the reaction tube sealed. After the reaction, the products were isolated in a manner similar to that described above.

Analyses. The determination of the products and the unreacted materials in most experiments were conducted by means of GLC, using a silicone HV grease, 80—100 mesh column. After the Fe-poly PC or Fe-PC was removed by filtration, the filtrate was treated with a 10% sodium carbonate solution and submitted to GLC analysis, with biphenyl or 1,2-diphenylethane as an internal standard. The amounts of the products derived from **4**, **5**, **8**, **9**, **10**, and **11**, respectively, were determined satisfactorily by means of chromatography on silica gel. The products were eluted with carbon tetrachloride, benzene, and chloroform, and identified by comparing the IR and NMR spectra with that authentic specimens.

Ligand Effects of Amine Chelates in the Decomposition of 1,2,3,4-Tetrahydro-1-naphthyl Hydroperoxide Catalyzed by Cobalt(II) and Copper(II) Salts

Teruaki YAMADA and Yoshio KAMIYA*

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received May 15, 1978)

The ligand effects of 2,2′-bipyridine, ethylenediamine, and diethylenetriamine on the rate of decomposition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide catalyzed by cobalt(II) decanoate and copper(II) decanoate in chlorobenzene were kinetically studied. The results were compared with the redox potentials measured in nonaqueous media and the spectral data of cobalt(II) and copper(II) complexes. It was found that the catalytic activity of Me(II) decanoate–ethylenediamine, or –diethylenetriamine complex (Me=Co, Cu) becomes maximum at 1/2 the molar ratio of ethylenediamine to Me(II), or at 1/3 that of diethylenetriamine to Me(II), and that further addition of these amines deactivates the catalysts. The activity of copper(II) decanoate increased from $k=0$ to $k=1.4\times10^{-3}$ s^{-1} on addition of 2,2′-bipyridine when the molar ratio of 2,2′-bipyridine to copper(II) decanoate was 0—4. No maximum activity was observed in copper(II) decanoate–2,2′-bipyridine system. A large excess of 2,2′-bipyridine, 150 times the quantity of copper(II) salt, did not decrease the decomposition rate in contrast to the case of the cobalt(II) decanoate–2,2′-bipyridine system. The difference in ligand effect of ethylenediamine, diethylenetriamine and 2,2′-bipyridine on cobalt(II) ion and copper(II) ion was discussed on the basis of the properties of these complexes.

The decomposition reaction of hydroperoxide catalyzed by transition metal complex, regarded as an important initiation reaction in autoxidation, has been extensively studied[1] during the last decade. Most of the studies afforded kinetic data presenting many kinds of reaction schemes and disclosing the outline of the reaction. However, no detailed account was given, and the relation between the structure and property of metal complex and its catalytic activity in the decomposition of hydroperoxide not being made clear. Clarification of this problem would be profitable not only for industrial chemistry but also for a new field of autoxidation in life science.

In a previous paper,[2] we reported the new finding of maximum activity in the decomposition reaction of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide catalyzed by cobalt(II) decanoate–2,2′-bipyridine in chlorobenzene, giving explanation on the basis of the change of redox potentials, spectral data and structural variations of catalysts. In this paper we report the ligand effect of 2,2′-bipyridine and aliphatic amines such as ethylenediamine, diethylenetriamine on cobalt(II) decanoate and copper(II) decanoate.

Experimental

Materials. Cobalt (II) decanoate ($CoDe_2$) and copper (II) decanoate ($CuDe_2$) were prepared by the conventional method[3] and used after being dried in a vacuum at 70 °C for 5 h. Elemental analyses were carried out on $CoDe_2$ and $CuDe_2$. Found: C, 58.2; H, 10.0%. Calcd for $CoDe_2[Co(C_{10}H_{19}O_2)_2]$: C, 59.8; H, 9.0%. Found: C, 58.0; H, 9.6%. Calcd for $CuDe_2[Cu(C_{10}H_{19}O_2)_2]$: C, 59.1; H, 9.4%. 1,2,3,4-Tetrahydro-1-naphthyl hydroperoxide (THP) was prepared by the autoxidation of 1,2,3,4-tetrahydronaphthalene (tetralin) and recrystallized from heptane.[4] Ethylenediamine (en), diethylenetriamine (dien), 1,6-hexanediamine, 1,4-butanediamine, 2,2′-bipyridine (bpy) and 2,2′: 6′,2″-terpyridine (tpy) were purified before use. A mixed solution of the metal decanoate and the amine chelate were allowed to stand at room temperature for 15 h to equilibrate and then subjected to reactions and measurements.

Measurements. The decomposition of THP proceeded in chlorobenzene at 45 °C, the rate of decomposition being determined by iodometry. The redox potentials of catalysts were measured by cyclic voltammetry in dichloromethane at room temperature with use of tetrabutylammonium perchlorate as a supporting electrolyte. A saturated calomel electrode was used as a reference electrode. The concentration of complex was less than 10 mM. Infrared spectra were recorded as Nujol mulls on a JASCO-IRA 2 spectrophotometer. Details of experimental procedures were reported.[2]

Results and Discussion

Effect of Ethylenediamine and Diethylenetriamine on Cobalt(II) Salt. The effect of ethylenediamine and that of diethylenetriamine on the rate of the $CoDe_2$-catalyzed decomposition of THP in chlorobenzene are shown in Figs. 1 and 2, respectively. The rate of decomposition increases with the addition of the amines, maximum activities being found at the molar ratio [en]/[$CoDe_2$]=

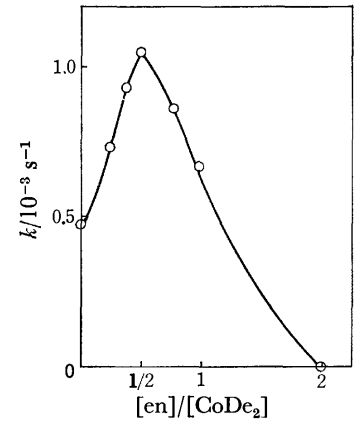

Fig. 1. Effect of ethylenediamine on the rate of decomposition of THP catalyzed by $CoDe_2$ in chlorobenzene at 45 °C.
[$CoDe_2$]$=2\times10^{-4}$ M, [THP]$=5\times10^{-2}$ M.

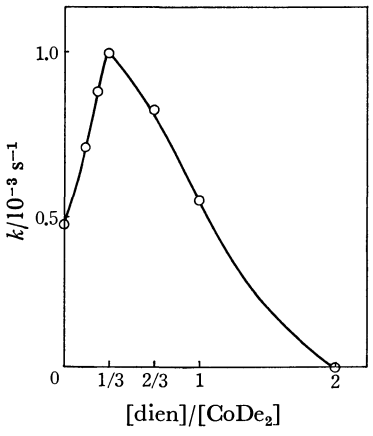

Fig. 2. Effect of diethylenetriamine on the rate of decomposition of THP catalyzed by $CoDe_2$ in chlorobenzene at 45 °C.
[$CoDe_2$]$=2\times10^{-4}$ M, [THP]$=5\times10^{-2}$ M.

1/2, [dien]/[$CoDe_2$]$=1/3$. The maximum value, almost the same in both systems, is one third of that of $CoDe_2$–bpy system. Unlike the case of the $CoDe_2$–bpy system, the $CoDe_2$ catalyst was deactivated by the amines at the raios [en]/[$CoDe_2$], [dien]/[$CoDe_2$] higher than 2.

The difference in activation of catalyst between the $CoDe_2$–bpy system and the $CoDe_2$–en, –dien systems can be attributed to the difference in electron donative force between 2,2′-bipyridine and two aliphatic amines; coordination of 2,2′-bipyridine having strong electron donative force causes an increase in the reductive force of cobalt(II) ion and weakening in the Co–O(decanoate) bond strength, resulting in facile coordination of hydroperoxide to the central cobalt(II) ion as well as the acceleration of cleavage of hydroperoxide molecule. Since ethylenediamine and diethylenetriamine do not have such a strong electron donative force as 2,2′-bipyridine, they can only change the reductive force of cobalt(II) ion moderately and not weaken the Co–O (decanoate) bond strength, resulting in smaller catalytic activities of the $CoDe_2$–en, –dien than that of the $CoDe_2$–bpy system. The IR data of the $CoDe_2$–en and $CoDe_2$–dien complexes given in Table 1 support our view. The shift of C–O stretching band to a higher wave number with an increase in the amount of 2,2′-bipyridine added as in the case of $CoDe_2$–bpy system shows the weakening in the Co–O(decanoate) bond strength. No shift of C–O stretching band upon the addition of ethylenediamine or diethylenetriamine suggests a very small effect due to the amines on the Co–O(decanoate) bond strength. The redox potentials of the $CoDe_2$–en complexes and the $CoDe_2$–dien complexes in dichloromethane or in *N,N*-dimethylformamide could not be obtained. No new C-T band or remarkable change in visible and ultraviolet spectra could be found.

The difference in the deactivation of catalyst between the $CoDe_2$–bpy complex and the $CoDe_2$–en, –dien complexes can be attributed to the difference in their steric factors. In the $CoDe_2$–bpy system, the steric hindrance makes it difficult for the second 2,2′-bipyridine to coordinate to a cobalt(II) ion. But in the $CoDe_2$–en, –dien systems, the steric hindrance of the amines smaller than that of 2,2′-bipyridine makes easier the coordination of the second ethylenediamine, diethylenetriamine to a cobalt(II) ion. Occupation of the coordination site by the amines may inevitably result in the deactivation of the $CoDe_2$ catalyst.

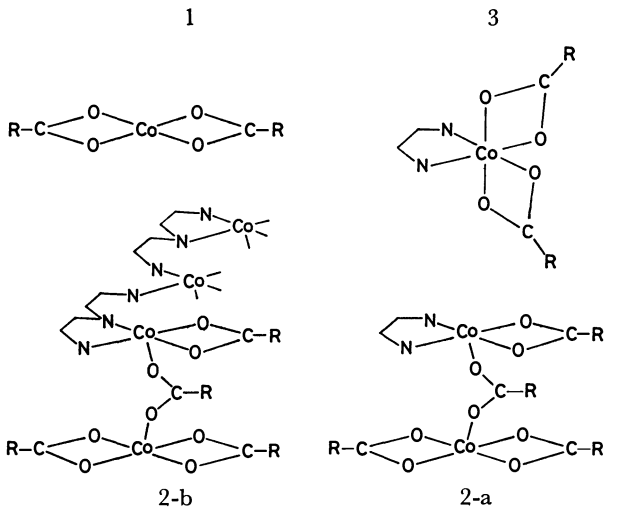

Fig. 3. Proposed structure of $CoDe_2$–en, –dien complexes.
1) $CoDe_2$, 2-a) $CoDe_2$–en (1: 1/2), 2–b) $CoDe_2$–dien (1: 1/3), 3) $CoDe_2$–en (1: 1).

Table 1. Infrared absorption bands and decomposition rates of THP for $CoDe_2$–en, $CoDe_2$–dien and $CoDe_2$–bpy complexes

Complex	C–$O_{st.}$, cm^{-1}	$k/10^{-3}$ s^{-1}
$CoDe_2$	1550	0.5
$CoDe_2$–en(1: 1/2)	1550	1.1
(1: 1)	1550	0.7
(1: 2)	1550	0.0
$CoDe_2$–dien(1: 1/3)	1550	1.1
(1: 2/3)	1550	0.9
(1: 1)	1550	0.5
(1: 2)	1550	0.0
$CoDe_2$–bpy(1: 1/2)	1570	3.7
(1: 1)	1590	1.3
(1: 2)	1595	1.3

The appearance of maximum suggests that the same structural variation[2] as that of the $CoDe_2$–bpy system occurs. Figure 3 shows the proposed structures of $CoDe_2$–en, –dien complexes. $CoDe_2$ (Structure 1) has a lower activity, which can be attributed to its poor reductive force. $CoDe_2$–en (1: 1/2) or $CoDe_2$–dien (1: 1/3) (Structure 2-a, 2-b) has the highest activity. This structure has a vacant coordination site and an adequate reductive force. $CoDe_2$–en (1: 1) (Structure 3) shows relatively low activity, the structure having a strong reductive force but no vacant coordination site.

From the value of the ratio [Chelate]/[Metal] of maximum activity in $CoDe_2$–bpy, $CoDe_2$–en, and $CoDe_2$–dien systems, one metal to one N atom complex seems to have the highest activity. An exceptional case is the $CoDe_2$–2,2′: 6′,2″-terpyridine system. A maximum

value was found at the ratio [tpy]/[$CoDe_2$]=1/2 instead of 1/3. Steric difficulty would not allow all the pyridine rings to coordinate to a cobalt(II) ion.

Figure 4 shows the effect of the length of carbon chain in aliphatic amine on the rate of the $CoDe_2$–catalyzed decomposition of THP in chlorobenzene. The ability of activation or deactivation of the added amines decreases with an increase in the carbon number of the carbon chain. This can be explained by the fact that their chelate effect decrease with increase in the carbon number of the carbon chain; the decrease of the chelate effect would decrease the ability of activation and deactivation.

Effect of 2,2′-Bipyridine on Copper(II) Salt. The effect of 2,2′-bipyridine on the rate of the $CuDe_2$–catalyzed decomposition of THP in chlorobenzene is shown in Fig. 5. The catalytic activity of $CuDe_2$ increases monotonously with the addition of 2,2′-bipyridine, the activity curve becoming a gradual slope in the ratio [bpy]/[$CuDe_2$] higher than 1. The k value at [bpy]/[$CuDe_2$]=1—2 is close to that of the $CoDe_2$–bpy complexes at [bpy]/[$CoDe_2$]=1—2 (Table 2).

The redox potentials of $CuDe_2$–bpy complexes measured in dichloromethane by cyclic voltammetry are given in Table 2 with the values of $CoDe_2$–bpy complexes. The shift of redox potentials to the negative direction with the addition of 2,2′-bipyridine, a tendency similar to the case of $CoDe_2$–bpy system, will help to elucidate the increase in activity. The decomposition of hydroperoxide by copper(II) complex has been studied extensively.[5] Some workers reported that the coordination of 2,2′-bipyridine to copper(II) ion increases the catalytic activity of copper(II) complex.[6] The decomposition reaction of hydroperoxide by copper(II) ion proceeds with Cu(II)/Cu(I) redox reaction, the difficulty of reproduction of copper(I) ion giving new schemes differing from those of cobalt(II) and manganese(II) systems. The rate-determining step seems to be the decomposition process of the copper–

hydroperoxide complex. The redox force of copper ion might be the main factor of catalytic activity. The shift of redox potential to the negative direction shows an increase of reductive force of copper(I) ion which accelerates the cleavage of the hydroperoxide molecule, and also an increase of electron density of the copper ion which stabilizes[7] the copper–hydroperoxide complex. The increase in activity can be attributed to the change of the redox potential of catalyst.

The fact that the redox potential of copper(II) complexes is smaller than that of cobalt(II) complex is reasonable from their ionization potentials. The increase of catalytic activity upon the addition of 2,2′-bipyridine in the $CuDe_2$–bpy system or in the $CoDe_2$–bpy system can be explained by the change of their redox potentials. From a comparison of the activity of copper(II) complexes with that of cobalt(II) complexes, the small defference between the two activities can not be explained by the large difference between their redox potentials; the $CuDe_2$–bpy (1 : 2) complex has almost the same activity as that of the $CoDe_2$–bpy (1 : 2) complex, in spite of the large difference in the redox potential between the $CuDe_2$–bpy (1 : 2) complex and the $CoDe_2$–bpy (1 : 2) complex. This suggests that the $CuDe_2$–bpy system has a reaction mechanism differing from the $CoDe_2$–bpy system.

A maximum activity observed in the $CoDe_2$–bpy system[2] was absent in the $CuDe_2$–bpy system This is explained as follows: With an increase of added 2,2′-bipyridine the concentration of the inactive $CuDe_2$ may change to the active $CuDe_2$–bpy complex having a different structure from the five coordination $CoDe_2$–bpy (1 : 1/2) type complex. Formation of the five coordination complex with 2,2′-bipyridine will be difficult for $CuDe_2$. In acetic acid, no catalytic activity was found on both $Cu(OAc)_2$ and $Cu(OAc)_2$–bpy (1 : 1) complex.

The effect of a large amount of 2,2′-bipyridine on $CoDe_2$ and $CuDe_2$ is given in Table 3. The activity of $CoDe_2$ decreases to half the value of $CoDe_2$ with the addition of one hundred times of 2,2′-bipyridine. However, $CuDe_2$ could not be deactivated by the addition of one hundred fifty times of 2,2′-bipyridine. This can be explained by the difficult addition of three 2,2′-bipyridine to copper(II) ion. The $CuDe_2$–bpy (1 : 1) complex has no absorption band in the 350 —400 nm region. However, C-T band (λ_{max}=380 nm) was found on the $CuDe_2$–bpy (1 : 100) complex.

Table 3. Decomposition rates of THP for $CoDe_2$–bpy and $CuDe_2$–bpy complexes in chlorobenzene at 45 °C

Complex	$k/10^{-3}$ s^{-1}
$CoDe_2$	0.49
$CoDe_2$–bpy(1 : 1)	1.32
(1 : 50)	0.56
(1 : 100)	0.28
(1 : 150)	0.27
$CuDe_2$	0.00
$CuDe_2$–bpy(1 : 1)	1.40

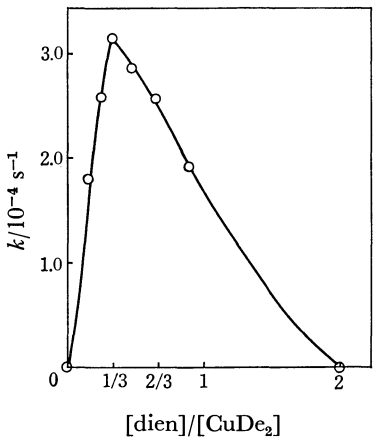

Fig. 7. Effect of diethylenetriamine on the rate of decomposition of THP catalyzed by $CuDe_2$ in chlorobenzene at 45 °C.
[$CuDe_2$]=2×10^{-4} M, [THP]=5×10^{-2} M.

Effect of Ethylenediamine and Diethylenetriamine on Copper(II) Salt. The effect of ethylenediamine and that of diethylenetriamine on the rate of the $CuDe_2$-catalyzed decomposition of THP in chlorobenzene are shown in Figs. 6 and 7, respectively. They show the same pattern as that of the $CoDe_2$–en and $CoDe_2$–dien systems. The rate increases with the addition of ethylenediamine or diethylenetriamine, the maximum activities being found at the ratio of [en]/[$CuDe_2$]=1/2 and [dien]/[$CuDe_2$]=1/3. $CuDe_2$ was deactivated by the amines at the ratio [en]/[$CuDe_2$], [dien]/[$CuDe_2$] higher than 2. The maximum values were one third of those of the $CoDe_2$–en, –dien systems. Appearance of a maximum in these systems suggests that the same structural variation occurs as in the $CoDe_2$–bpy system in $CuDe_2$–en, –dien systems. The order of maximum values is $CoDe_2$–bpy>$CoDe_2$–en, –dien>$CuDe_2$–en, –dien.

The following conclusions on the ligand effect were obtained from our results. 1) The catalytic activities of cobalt(II) ion and copper(II) ion in the deocmposition

of THP change with the concentration of amine chelate added. 2) Aliphatic amine chelate acts as a deactivator and aromatic amine chelate as an activator. 3) In most cases a maximum activity was found at the molar ratio of [Chelate]/[Metal] = 1/(Number of N atom of chelate). 4) All the effects of chelate ligands can be explained in terms of the variation of structure or electrochemical and spectral property of catalyst.

Further Study of Methanol Carbonylation Catalyzed by Cobalt, Rhodium, and Iridium Catalysts

Tsutomu MIZOROKI,* Toshio MATSUMOTO, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received May 31, 1978)

The effect of iodide ion was examined in methanol carbonylation with use of Co-, Rh-, and Ir-catalysts. Sodium iodide gives no noticeable effect on carbonylation catalyzed by Rh-catalyst to give acetic acid, and retards that catalyzed by Ir-catalyst. Methyl iodide is effective for methanol carbonylation with Co-catalyst in the presence of hydrogen to give mainly acetaldehyde, which is readily hydrogenated to ethanol during the course of carbonylation on addition of a catalytic amount of $Ru_3(CO)_{12}$. Sodium iodide is also effective for acetaldehyde formation, although it strongly retards the hydrogenation of acetaldehyde with Ru-catalyst. The different effect of iodide ion on methanol carbonylation catalyzed by Co-, Rh-, or Ir-catalyst is discussed in terms of neucleophilicity of the active catalyst species.

Methyl iodide is known as an efficient promoter for methanol carbonylation with Co-, Rh-, or Ir-catalyst. A reaction scheme involving an oxidative addition of methyl iodide has been accepted in Rh- or Ir-catalyzed carbonylation.[1] It has been pointed out that the presence of iodide ion promotes the oxidative addition of methyl iodide to rhodium(I) complexes.[2] The rate of methanol carbonylation with Co-catalyst increases with addition of iodide ion,[3] although no detailed discussion has been made on the role of iodide ion. It has not been clarified why Co- catalyst gives preferentially acetaldehyde when methanol carbonylation is performed in the presence of hydrogen,[4] while all attempts for acetaldehyde formation were unsuccessful with the use of Rh- or Ir-catalyst.

The present work was undertaken to elucidate the effect of iodide ion on methanol carbonylation as well as the significance of Co-catalyst in the acetaldehyde formation.

Experimental

Carbonylation was carried out according to the procedure described in a previous paper.[5] $Co_2(CO)_8$, $RhCl_3 \cdot 3H_2O$, and $IrCl_4 \cdot H_2O$ were used as catalyst precursors. $Co_2(CO)_8$ was prepared by reduction of cobalt carbonate suspended in toluene with a synthesis gas ($CO/H_2=1$, 150 kg/cm^2) at 170 °C. Methyl iodide (extra pure grade, Tokyo Kasei), $Ru_3(CO)_{12}$ (Strem Chemicals) and all the other materials were commerical products and used without purification. Acetophenone has been found to be useful solvent for preventing the formation of dimethyl ether during the course of Rh- of Ir-catalyzed methanol carbonylation.[5] However, it was readily hydrogenated to give 1-phenylethanol and ethylbenzene during the course of carbonylation when a mixture of carbon monoxide and hydrogen was used. Thus, methyl benzoate was used as the solvent in the present work. It was also partially transformed into benzoic acid during the carbonylation. The amount of benzoic acid formed was taken into account to evaluate the methyl-balance of product solutions.

The product solutions were analyzed by means of gas chromatography (carrier gas of He). A glass column of Diethylene Glycol Succinate Polyester (3 mmϕ, 3 m) was used at 100—200 °C for carboxylic acids, and two copper columns of 3,3′-oxydipropionitrile (3 mmϕ, 5 m) and PEG-400 (3 mmϕ, 3 m) were separately used at 70 °C for acetaldehyde, methyl iodide, acetaldehyde dimethyl acetal, methyl acetate, ethyl acetate, methanol, and ethanol. Methane in gaseous products was also analyzed by gas chromatography using a copper column of VZ-7 (3 mmϕ, 3m) at room temperature.

Results and Discussion

Carbonylation with $Co_2(CO)_8$. The carbonylation of methanol (125 mmol) with $Co_2(CO)_8$ (1 mmol) in the presence of methyl iodide (10 mmol) was carried out in methyl benzoate (20 ml) at 173 °C under 30—75 kg/cm^2 of carbon monoxide (CO 98%) for 3 h, giving practically no acetic acid. Under the same reaction conditions, both Rh- and Ir-catalysts almost quantitatively converted methanol into acetic acid (115 mmol, 90% yield) within a shorter reaction period (0.5 h). When a mixture of carbon monoxide and hydrogen (100 kg/cm^2, $CO/H_2=1$) was used for the $Co_2(CO)_8$-catalyzed carbonylation of methanol under similar conditions, appreciable amounts of C_2-oxygenated compounds such as methyl acetate, acetaldehyde and ethanol were obtained. The results are shown in Fig. 1. Analytical results of product solutions are represented by S_1, S_2, and M with the following definitions.

$$\text{total AcOH (mmol)} = [\text{AcOH}] + [\text{AcOMe}] + [\text{AcOEt}]$$

$$\text{total AcH (mmol)} = [\text{AcH}] + [\text{DMA}]$$

(DMA = acetaldehyde dimethyl acetal)

$$\text{total EtOH (mmol)} = [\text{EtOH}] + [\text{AcOEt}]$$

$$\text{total } C_2 \text{ (mmol)} = [\text{total AcOH}] + [\text{total AcH}] + [\text{total EtOH}]$$

$$S_1\ (\%) = 100 \times \{([\text{total AcH}] + [\text{total EtOH}])/[\text{total } C_2]\}$$

$$M\ (\%) = 100 \times \{([\text{AcOH}] + [\text{EtOH}] + 2[\text{AcOEt}] + 2[\text{AcOMe}] + 3[\text{DMA}] + [\text{CH}_3\text{I}] + [\text{CH}_3\text{OH}])/([\text{CH}_3\text{OH}]_0 + [\text{CH}_3\text{I}]_0 + [\text{PhCO}_2\text{H}])\}$$

$$S_2\ (\%) = 100 \times [\text{total EtOH}]/[\text{total } C_2]$$

S_1 and S_2 are the selectivities to total C_2-oxygenated products and ethanol respectively, and M is the percent methylbalance, where $[CH_3OH]_0$ and $[CH_3I]_0$ are molar amounts of methanol and methyl iodide initially charged. The amount of methyl group introduced from methyl benzoate during the course of carbonylation is evaluated from the amount of benzoic acid, $[PhCO_2H]$,

a) Without $Co_2(CO)_8$.

remaining in the product solutions. A low methyl-balance indicates an increase in dimethyl ether and methane formed, since neither C_3 nor C_4-compounds were detected in product solutions. Figure 1 shows that the selectivity to ethyl alcohol (S_2) increases with increase in the amount of $Co_2(CO)_8$, despite no increase in total C_2-compounds, suggesting that the Co-catalyst mostly works as a hydrogenation catalyst for the acetaldehyde formed. In fact, $Co_2(CO)_8$ and its tertiaryphosphine derivatives are known to be active for the hydrogenation of aldehydes under oxo reaction conditions,[6] where the active species is the hydridocarbonyl.

A rapid hydrogenation of the acetaldehyde formed is desirable in order to examine the effects of methyl iodide and iodide ion on the methanol carbonylation to give acetaldehyde, otherwise the acetaldehyde is readily transformed into dimethyl acetal, resulting in consumption of 3 mol of methanol for a dimethylacetal formation ($2CH_3OH+CH_3CHO \rightarrow CH_3CH(OCH_3)_2+H_2O$). Since the hydrogenation catalyst should work in the presence of carbon monoxide, some carbonyl compounds were examined. It was found that $Ru_3(CO)_{12}$ is much more efficient for the hydrogenation of acetaldehyde than $Co_2(CO)_8$ under the methanol carbonylation conditions[7] as shown in Table 1. It is apparent that the selectivity to ethanol is remarkably increased by the addition of a catalytic amount of $Ru_3(CO)_{12}$. Although $Ru_3(CO)_{12}$ shows a small activity for methanol carbonylation (run 4), its contribution can be neglected in runs 2 and 3. The effects of methyl iodide and sodium iodide on the Co-catalyzed carbonylation were then examined in the presence of $Ru_3(CO)_{12}$. The results are summarized in Table 2. The favorable effect of methyl iodide on methanol carbonylation levels off at higher concentration as shown by the change in total C_2-compounds (runs 1—3). The increase in methyl iodide lowers the methyl-balance, presumably due to an increase in dimethyl ether formation. Sodium iodide is also effective for carbonylation without lowering the methyl-balance (runs 4—6), where small amounts of methyl iodide were detected in the product solutions. The amount of total C_2-compounds is the largest when both methyl iodide and sodium iodide are added (runs 7 and 8). It should be noted, however, that the $Ru_3(CO)_{12}$-catalyzed hydrogenation of acetaldehyde is almost completely inhibited by the addition of sodium iodide. Since the $Ru_3(CO)_{12}$-catalyzed hydrogenation of acetaldehyde takes palce in the absence of sodium iodide (runs 1—3), it can be concluded that methyl iodide supplies no appreciable amount of iodide ion during the course of Co-catalyzed methanol carbonylation, the rate of which is enhanced by both methyl iodide and iodide ion (runs 7 and 8).

In this respect, the chemical reaction of $Co_2(CO)_8$, the catalyst precursor, with iodides should be referred

Table 2. Effect of iodide ion on the $Co_2(CO)_8$–$Ru_3(CO)_{12}$ catalyzed methanol homologation CH_3OH 125 mmol, press. 100 kg/cm² ($CO/H_2=1$) at room temp, $Co_2(CO)_8$ 1 mmol, $Ru_3(CO)_{12}$ 0.075 mmol, $PhCOOCH_3$ 20 ml, temp 173 °C, and time 2 h.

to. It is known that $Co_2(CO)_8$ undergoes disproportion in polar solvents to give $Co(CO)_4^-$ ($3Co_2(CO)_8+2nL\rightarrow 2[CoL_n][Co(CO)_4]_2+8CO$, L=solvent).[8] In fact, $Co_2(CO)_8$ dissolves in methyl benzoate with evolution of carbon monoxide. When sodium iodide is present in the solution, the carbon monoxide ligands of $Co(CO)_4^-$ may be partly replaced by iodide ion giving rise to an increase in nucleophilicity of the complex. It is also known that methyl iodide undergoes an oxidative addition to $Co(CO)_4^-$ to give $CH_3Co(CO)_4$,[9] the oxidation state of which is lower than that of methyl rhodium(III) and iridium(III) complexes. The difference of oxidation state seems to constitute the main reason why cobalt catalyst behaves differently.

$$CH_3I + Co(CO)_4^- \longrightarrow CH_3Co(CO)_4 + I^-$$
$$\Updownarrow$$
$$CH_3COCo(CO)_3$$

If the methanol carbonylation with Co-catalyst proceeds through a nucleophilic attack of the anion complex on the carbon of methyl iodide, the observed enhancement with iodide ion is reasonable. In view of the low oxidation state of the cobalt intermediate, an electrophilic oxidative addition of hydrogen would take place readily giving rise to the predominant formation of acetaldehyde.

Carbonylation with Rh- or Ir-catalysts. In the acetic acid synthesis catalyzed by Rh-complex, kinetic[5,10] and spectroscopic studies[2] have made it clear that the rate-determining step is the oxidative addition of methyl iodide to Rh(I) complex. The oxidative addition seems to take place through a nucleophilic attack of rhodium(I) species on the carbon of methyl iodide to give methyl rhodium(III) complex, which is readily transformed into the acetyl complex. Coordination of iodide ion evidently produces a highly nucleophilic rhodium(I) anion, resulting in an increase in the rate of oxidative addition of methyl iodide. The enhancement by iodide ion has been found by Forster upon addition of Bu_4NI in the oxidative addition of methyl iodide to $[Rh(AsPh_3)_2(CO)I]$ or $[Rh(SbPh_3)_2(CO)I]$ in dichloromethane solvent.[11]

The effect of iodide ion on the rate of Rh-catalyzed methanol carbonylation was examined by adding sodium iodide under the conditions given in Table 3 except that $RhCl_3\cdot 3H_2O$ was used instead of $IrCl_4\cdot H_2O$ as the catalyst precursor. No appreciable effect of iodide ion was found on the rate of carbonylation. The inconsistency, however, can be understood by taking into account the fact that the predominant species during the course of the Rh-catalyzed carbonylation in the presence of an excess methyl iodide is anionic rhodium(I) complex, $[Rh(CO)_2I_2]^-$, spectroscopically verified by Forster.[11] Thus, no appreciable enhancement was observed by the addition of sodium iodide.

On the other hand, in the acetic acid synthesis with Ir-catalyst in acetophenone solvent, the predominant species is an Ir(III) complex, acetyl iridium(III) being a plausible form with its methanolysis being rate-determining.[12] If the methanolysis proceeds *via* an electrophilic attack of the acetyl iridium(III) complex on the oxygen of methanol, replacement of the neutral ligands such as carbon monoxide and solvent molecule by iodide ion should lower the rate of methanolysis because of the decrease in the electrophilicity of iridium(III) species. Thus the effect of iodide ion on the Ir-catalyzed acetic acid synthesis was examined (Table 3). It is apparent that the addition of sodium iodide decreases the yield of acetic acid. The observed retardation of acetic acid synthesis by iodide ion is reasonably explained by the electrophilic attack of acetyl iridium(III) species on methanol being the rate-datermining step as discussed in a previous paper.[12]

As regards the lack of hydrogen activation by Rh- and Ir-catalysts in methanol carbonylation in spite of their high catalytic activities for olefin hydroformylation, the carbonylation of ethylene with Rh- or Ir-catalyst was carried out under methanol carbonylation conditions. The results are summarized in Table 4. Methanol carbonylation as well as ethylene hydroesterification which forms methyl propionate (propionic acid was not detected) take place (runs 1 and 2). Hydrogen, however, gives no appreciable effect on either carbonylation (runs 3 and 4), since the amounts of total acetic acid and methyl propionate are almost the same regardless of introduction of hydrogen. Hydroformylation of ethylene proceeds under the same conditions (runs 5 and 6), while it is completely suppressed by addition of methyl iodide (runs 7 and 8). The results are explained by the following simplified scheme on the assumption that the oxidative addition of methyl iodide takes place on rodium(I) and iridium(I) complexes and that acetyl complexes of high oxidation state(III) thus formed are more rapidly attacked by methanol than hydrogen molecule. Preferential formation of methyl propionate can also be realized by an electrophilic attack of propionyl rhodium(III) and iridium(III) complexes,

Table 3. Effect of iodide ion on the Ir-catalyzed acetic acid synthesis

Thermal and Acid-catalyzed Decomposition of 3,6-Diphenyl-1,4-bis-(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine[1]

Suketaka Ito,* Akikazu Kakehi, Yumo Tanaka, Kazuyoshi Yoshida, and Toshiyuki Matsuno

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received June 5, 1978)

Thermolysis of the title dihydrotetrazine in boiling toluene gives benzenesulfonic anhydride, *S*-phenyl benzenethiosulfonate, and small amounts of diphenyl disulfide and a rearrangement product, 3,6-diphenyl-1,2-bis(phenylsulfonyl)-1,2-dihydro-1,2,4,5-tetrazine, together with 3,6-diphenyl-1,2,4,5-tetrazine. On the other hand, the treatment with concentrated sulfuric acid affords 3,6-diphenyl-1,4-dihydro-1,2,4,5-tetrazine in good yield. On the basis of the kinetic parameters obtained for the thermolysis, the mechanism was discussed.

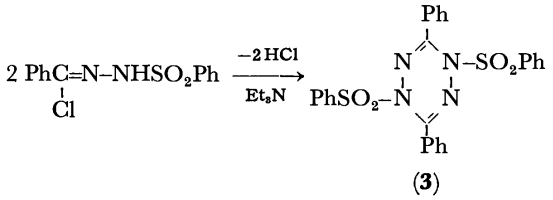
3,6-Diphenyl-1,4-bis(*p*-tolylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine (**1**), obtained by the reaction of 5-phenyltetrazole with *p*-toluenesulfonyl chloride, yields 3,6-diphenyl-1,2,4,5-tetrazine (**2**) when heated at its melting point or treated with ethanolic potassium hydroxide at room temperature, and *p*-toluenesulfonic acid alone was isolated as a by product.[2]

The thermal decomposition of 2-*p*-tolylsulfonyl-5-phenyltetrazole[3] was also reported:[4] this reaction gave traces of **2** together with other products and should not proceed *via* **1** as an intermediate, and further details are unavailable for the decomposition reaction of **1** and its homologs.

The present paper deals with the thermolysis and the acid-catalyzed dephenylsulfonylation of 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine (**3**).

Results and Discussion

Preparation and Thermolysis of Dihydrotetrazine. Dihydrotetrazine (**3**) was obtained in good yields by treating *N*-(phenylsulfonyl)benzohydrazonoyl chloride with triethylamine in THF[4,5] (Scheme 1).



Scheme 1.

In the IR spectra, dihydrotetrazine **3** exhibits a characteristic peak at 1320 cm^{-1} (strong) which should be assigned to the 1,4-dihydrotetrazine ring vibration. Compound **3** is thermolabile and melt with decomposition to give tetrazine **2**; a partial decomposition is also observed below the melting point. Furthermore, **3** altered gradually to **2** at room temperature when dissolved in a polar solvent such as DMF or DMSO.

The thermolysis of **3** was carried out in the following two procedures: (A) Keeping at 150—155 °C for 30 min in a sealed tube without solvent; (B) refluxing a toluene solution for 20 h. The IR spectrum of the resulting dark red solid from Procedure A showed the formation of benzenesulfonic anhydride (**4**), a portion of which could be isolated as a sparingly soluble part in benzene.

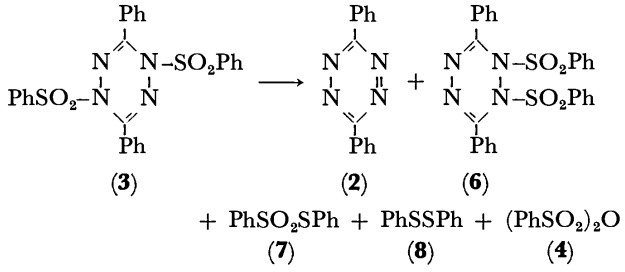
The precipitation of anilinium benzenesulfonate (**5**) was observed when aniline was added to the chloroform solution of the product from Procedure A or the reaction mixture in toluene from Procedure B. Work-up gave 3,6-diphenyl-1,2-bis(phenylsulfonyl)-1,2-dihydro-1,2,4,5-tetrazine (**6**), *S*-phenyl benzenethiosulfonate (**7**), diphenyl disulfide (**8**), and benzenesulfonanilide (**9**) along with 3,6-diphenyl-1,2,4,5-tetrazine (**2**) and anilinium benzenesulfonate (**5**). The results are summarized in Table 1.[6]

Table 1. Thermolysis of dihydrotetrazine **3**

Reaction condition[a]	Yield (%) of product[b]					
	2	**6**	**7**	**8**	**9**	**5**
A	98	0	24	6	62	70
B	88	3	26	3	58	52

a) A: Kept at 150—155 °C for 30 min in a sealed tube without solvent with subsequent treatment with aniline. B: Refluxed in toluene for 20 h with subsequent treatment with aniline. b) Yield as mole per cent based on **3**.

When ethanol was added to the primary reaction mixture from Procedure A or B, ethyl benzenesulfonate was obtained. Compounds **5** and **9** or ethyl benzenesulfonate should be derived from **4** formed in the reaction. Thus, the thermal decomposition reaction may be formulated as follows (Scheme 2).



Scheme 2.

Compound **6** decomposed when heated at its melting point, giving the same products as those obtained from **3**. No promotion of reaction was observed when benzoyl peroxide was added in the thermolysis of **3** in toluene

Kinetics and Mechanism. In order to obtain some kinetic data, the thermolysis of **3** in toluene was conducted in Pyrex tubes under nitrogen atmosphere at 110,

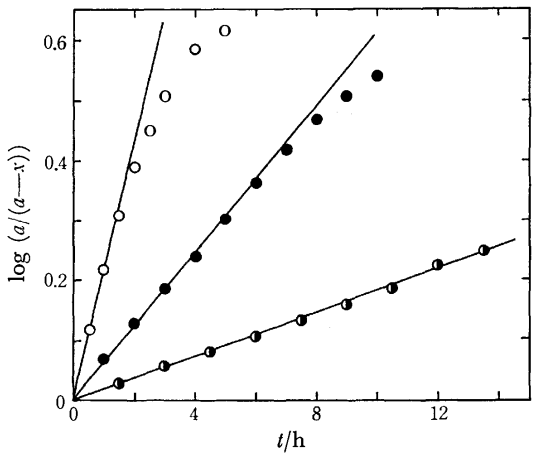


Fig. 1. First order plots for the thermolysis of dihydrotetrazine **3** in toluene.
○: 130 °C, ●: 120 °C, ◑: 110 °C; $[3]_0=1.95$ mmol·l^{-1}.

120, and 130 °C. The course of decomposition was followed by measuring the tetrazine absorption at 550 nm.

Since the reaction is not simple as has been shown above, the integral method cannot be employed for the kinetic determination: thus any good linear relationship may be hardly found in the first order plots (Fig. 1) and also in the second order ones for the reaction.

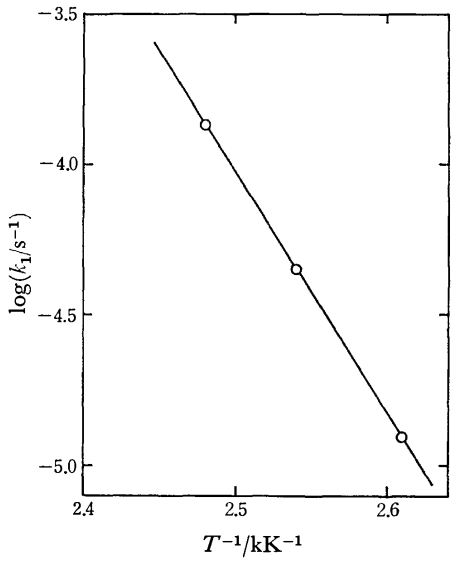

Fig. 2. Arrhenius plots for the thermolysis of dihydrotetrazine **3** in toluene.

The decomposition reaction of **3** to **2** was analyzed by the initial rate method, which showed the reaction to obey good first order kinetics and gave $k_1(h^{-1})=0.493$(130 °C); 0.162(120 °C); 0.0447(110 °C). The plots of log k_1 *vs.* $1/T$ are given in Fig. 2, from which the Arrhenius parameters, $E_a(=154$ kJ/mol) and $\Delta S^*(=61$ J/(K mol)), were obtained.

When the solvent toluene was replaced by DMSO, plots of yield of tetrazine *vs.* time gave a curve with an inflection point (Fig. 3, Curve II), but almost no

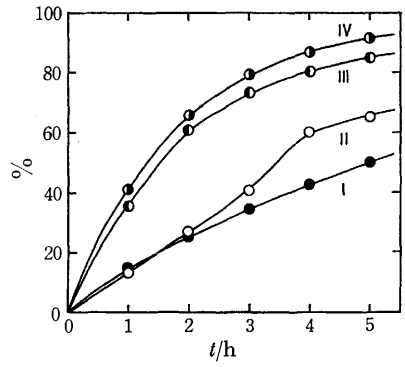

Fig. 3. Plots of yield of tetrazine **2** *vs.* time for the thermolysis of dihydrotetrazine **3**.
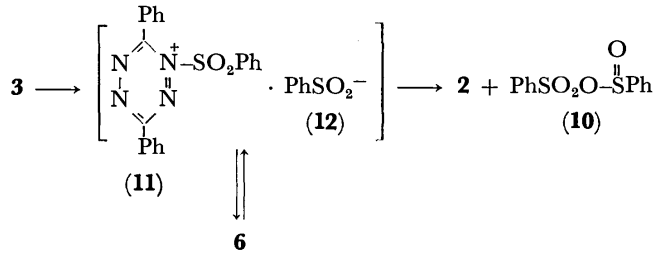
●: In toluene/N_2, ○: in DMSO/N_2, ◐: in DMSO with TosOH/N_2, ◑: in DMSO with TosOH/O_2; $[3]_0=1.95$ mmol l^{-1}, [TosOH]=2.0 mmol l^{-1}; temp: 120 °C.

difference in the reaction rate at the initial period between DMSO and toluene could be detected.

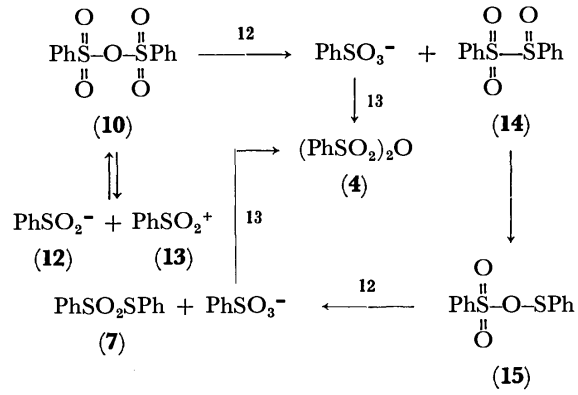
In view of the fact that the reaction is not promoted by a radical initiator and that the ΔS^* value is positive, the following route can be given as a possible mechanism for the thermolysis of **3**, in which benzenesulfonic benzenesulfinic anhydride (**10**) is postulated as an intermediate for **4** and **7**.



Scheme 3.

Since, as has been described, little difference in the rate at the initial reaction period is found between DMSO (polar) and toluene (less polar), the intermediate, [**11**·**12**], should exist as an intimate ion pair.[8] The formation of **6** can be explained by the recombination of **11** and **12** (internal return).

The thermolability of **3** is possibly due to the nonaromaticity of eight-electron dihydrotetrazine system,



Scheme 4.

which alters to a stable aromatic six-electron one by releasing **12**.[9] Mass spectroscopic data (*vide post*) may be consistent with the collapse of **3** to **11** and **12**.

The formation of *S*-phenyl benzenethiosulfonate (**7**) and benzenesulfonic anhydride (**4**) can be well interpreted by the intermediacy of benzenesulfonic benzenesulfinic anhydride (**10**) (Scheme 4).

p-Toluenesulfonic *p*-toluenesulfinic anhydride has been postulated as the primary intermediate in the reaction of *p*-toluenesulfonyl chloride with sodium *p*-toluenesulfinate, from which *S*-*p*-tolyl *p*-toluenethiosulfonate and sodium *p*-toluenesulfonate are formed.[10] Anhydride **10** corresponds to carboxylic *p*-toluenesulfinic anhydride which has been proposed as an intermediate for the formation of carboxylic anhydride and *S*-*p*-tolyl *p*-toluenethiosulfonate in the reaction of sodium *p*-toluenesulfinate with acyl chloride.[11]

The intermediacy of sulfinyl sulfone **14** and sulfenic sulfonic anhydride **15** and the rearrangement **14** to **15** have been also proposed for the formation of *S*-*p*-tolyl *p*-toluenethiosulfonate in the disproportionation of *p*-toluenesulfinic acid under acidic conditions.[12]

From Scheme 4, the following stoichiometric formula can be obtained:

$$3[PhSO_2^+ + PhSO_2^-] \longrightarrow \underset{(4)}{2(PhSO_2)_2O} + \underset{(7)}{PhSO_2SPh}$$

This formula is consistent with that of the disproportionation of *p*-toluenesulfinic acid,[12] and in agreement with the experimental results obtained (Table 1). The formation of diphenyl disulfide (**8**) can be explained in terms of the air oxidation of benzenethiolate ion[13] generated by the hydrolysis of thiosulfonate **7**.[12]

The characteristic feature of Curve II shown in Fig. 3 suggests that the reaction in DMSO may involves an autocatalyzed process as a parallel one,[14] which may be due to benzenesulfonic acid formed from traces of moisture and **4**. In the initial presence of *p*-toluenesulfonic acid a pronounced catalysis took place (Fig. 3, Curve III), and a further promotion of reaction was observed under oxygen atmosphere (Curve IV).

In general, DMSO accelerates ionic processes and can also function as an oxidizing agent itself, thus the primary product of the acid-catalyzed reaction in DMSO may be dephenylsulfonylated dihydrotetrazine, which would be oxidized to **2** by DMSO.[15] The acid-catalyzed dephenylsulfonylation will be discussed later.

An acceleration of reaction was observed also when a small amount of *p*-toluenesulfonic acid was added in the thermolysis of **3** in toluene, but this effect of acid was less remarkable than when DMSO was used as the solvent.

Structure Assignment of **6**. Compound **6** also decomposes somewhat higher temperature, giving the same products as those of **3**. The IR spectrum of **6** is simpler than that of **3**, and shows a medium peak at 1284 cm^{-1} (νSO_2: 1370, 1171 cm^{-1}) and none at near 1320 cm^{-1}. The peak at 1284 cm^{-1} might be attributed to the 1,2-dihydrotetrazine ring vibration.

The mass spectrum of **6** also differs from that of **3** in some respects: it is particularly characteristic that the peaks of *m/e* 105, 222, and 244 of **6** are far weaker than those of **3** in intensity (Table 2). The fragment ions

Table 2. Mass spectral data of dihydrotetrazines **3** and **6** (Major peaks)

m/e	Assignment	Relative abundance[a]	
		3	**6**

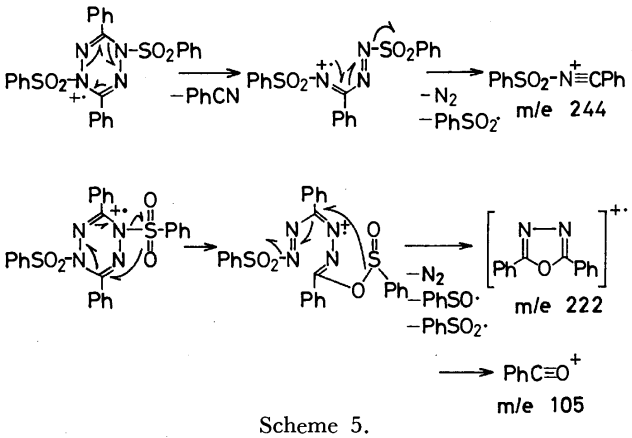
51	$C_4H_3^+$	19	26

a) Ionizing energy: 75 eV.

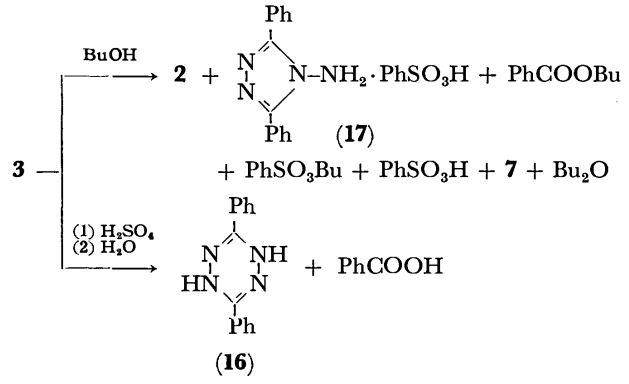
of *m/e* 105, 222, and 244 as assigned in Table 2 may be produced from the 1,4-dihydrotetrazine structure as shown in Scheme 5. In conclusion, compound **6** must be a structural isomer of **3**, thus **6** can be assigned to be 3,6-diphenyl-1,2-bis(phenylsulfonyl)-1,2-dihydro-1,2,4,5-tetrazine. The peak of *m/e* 250 is possibly the parent peak of *S*-phenyl benzenethiosulfonate (**7**) formed by the partial thermolysis of **3** and **6** in the ionization chamber, which may be supported by the appearance of its fragment ions, *m/e* 125, 109, and 65.[16,17]



Scheme 5.

Acid-catalyzed Decomposition of **3**. When **3** was treated with concentrated sulfuric acid at room temperature, 3,6-diphenyl-1,4-dihydro-1,2,4,5-tetrazine (**16**: 86%) and benzoic acid (12%) were obtained. Treatment of **3** with refluxing 1-butanol gave 4-amino-3,5-diphenyl-1,2,4-triazole (as benzenesulfonate, **17**: 54%), butyl benzoate (42%), and **2** (24%) together with small amounts of butyl benzenesulfonate, benzenesulfonic acid,

and **7**. The formation of dibutyl ether was also confirmed (Scheme 6).



Scheme 6.

The formation of **16** can be interpreted in terms of the *N*-protonation of **3** followed by the removal of benzenesulfonyl ion. The reaction in refluxing 1-butanol is explained as follows: the thermal decomposition of **3** takes place in part to give **2** and benzenesulfonic anhydride (**4**), and acid catalysis by benzenesulfonic acid generated from **4** leads to the formation of **16** as an intermediate The acid-catalyzed rearrangement[18] and hydrolysis[19] of the intermediate **16** should afford **17** and benzoic acid, respectively. A part of **2** obtained here may be derived from **16** by air-oxidation.

Experimental

Melting points were determined with a Yanagimoto micro-melting point apparatus Model MP-S3 and are uncorrected. The microanalysis was performed on a Perkin-Elmer elemental analyzer Model 240. The IR, VIS, and MS spectra were recorded with a JASCO DS-301, a Hitachi EPU-2A, and a JEOL JMS-013G-2 spectrometer, respectively. *N*-(Phenylsulfonyl)benzohydrazonoyl chloride was prepared by the method reported.[20]

Preparation of **3**. A solution of triethylamine (5.5 g, 54 mmol) in THF (20 ml) was added dropwise to a solution of *N*-(phenylsulfonyl)benzohydrazonoyl chloride (14.8 g, 50 mmol) in THF (60 ml) under cooling (ice water) and stirring. The reaction mixture was stirred additionally for 1 h at room temperature. After removal of the separated triethylamine hydrochloride by filtration, the THF solution was concentrated and washed with aqueous ethanol to give fairly pure dihydrotetrazine **3** as yellow solids. The product was purrified by crystallization from benzene–hexane (Yield: 11.6 g, 22 mmol, 45 mol %).

Mp 151—156 °C (dec), IR (KBr, cm^{-1}): 1320 (Ring); 1367, 1183 (νSO_2). Found: C, 60.21; H, 3.93; N, 10.81%; M^+, 516. Calcd for $C_{26}H_{20}N_4O_4S_2$: C, 60.44; H, 3.90; N, 10.84%; M, 516.

Thermolysis of **3**. *Procedure A*: Dihydrotetrazine **3** (2.58 g, 5 mmol) was heated in a sealed tube at 150—155 °C for 30 min. The resulting dark red mass was dissolved in chloroform (50 ml). To the chloroform solution, aniline (2 g) was added and the mixture was allowed to stand for a few hours. The separated precipitates (anilinium benzenesulfonate, **5**: 0.89 g, 3.5 mmol) were filtered, and the filtrate was washed with 10% sodium hydroxide solution followed by dilute hydrochloric acid and dried. After removal of the solvent, the residue was dissolved in hot ethanol. Diphenyltetrazine **2** (1.11 g, 4.7 mmol) separated upon cooling was filtered, and the filtrate was concentrated and then chromatographed on a silica gel (15 g) column, using hexane and benzene as the eluents, to give diphenyl disulfide (**8**: 0.06 g, 0.3 mmol), **2** (0.05 g, 0.2 mmol), and *S*-phenyl benzenethiosulfonate (**7**: 0.30 g, 1.2 mmol). Benzenesulfonanilide (**9**: 0.72 g, 3.1 mmol) was isolated by acidification from the aqueous sodium hydroxide washings above obtained. Treatment of the primary product (dark red mass) with benzene gave a small amount of benzenesulfonic anhydride (**4**) as a sparingly soluble matter.

All the products obtained were identified by comparison with authentic specimens.

Procedure B: A solution of **3** (2.58 g) in 15 ml of toluene dried over sodium wire was refluxed for 20 h. Addition of a solution of aniline (2 g) in toluene (5 ml) to the red reaction mixture led to the precipitation of **5** (0.64 g, 2.6 mmol), which was filtered from the hot toluene solution. Removal of the solvent from the toluene filtrate followed by treatment with chloroform gave pale cream-colored precipitates (**6**: 0.07 g, 0.14 mmol) which after recrystallization from DMF–ethanol melted at 168—171 °C with decomposition.

IR (KBr, cm^{-1}): 1284 (Ring); 1370, 1171 (νSO_2). Found: C, 60.45; H, 3.92; N, 11.00%; M^+, 516. Calcd for $C_{26}H_{20}N_4O_4S_2$: C, 60.44; H, 3.90; N, 10.84%; M, 516.

The chloroform filtrate was worked up in the same manner that used in Procedure A. **2**: 1.04 g (4.4 mmol); **7**: 0.32 g (1.3 mmol); **8**: 0.03 g (0.14 mmol); **9**: 0.68 g (2.9 mmol).

The results of thermolysis are summarized in Table 1.

Thermolysis of **6**. Compound **6** (0.52 g, 1 mmol) was heated in a sealed tube at 170—173 °C for 20 min. The resulting dark red mass was treated in the same manner that used in the thermolysis of **3** (Procedure A). **2**: 0.21 g (0.90 mmol); **5**: 0.18 g (0.72 mmol); **7**: 0.04 g (0.16 mmol); **8**: trace; **9**: 0.14 g (0.60 mmol).

Kinetic Measurement. Rates for the formation of **2** in toluene (and in DMSO[21]) were determined spectrophotometrically by the usual sealed-ampoule technique. In a typical experiment, 10 ampoules each containing *ca.* 6.5 ml of solution of **3** in dry toluene were prepared. They were sealed after being flashed with dry nitrogen. The reaction mixture was taken out from each ampoule after quenching by cooling, and the absorbance of the mixture was determined at 550 nm. The rate constants were obtained by means of the initial rate method.

Reaction of **3** *with Sulfuric Acid*. A solution of **3** (2.58 g, 5 mmol) in chloroform (15 ml) was stirred vigorously with concentrated sulfuric acid (10 ml) for 1 h at room temperature. The sulfuric acid layer was poured into water to give light fine needles, which were filtered and identified to be 3,6-diphenyl-1,4-dihydro-1,2,4,5-tetrazine (**16**). Yield: 1.01 g (4.3 mmol); mp 194—195 °C (lit,[22] mp 191—193 °C).

From the aqueous filtrate, salting-out with sodium sulfate followed by extraction with ether gave benzoic acid (0.07 g, 0.6 mmol).

Reaction of **3** *with Boiling Butanol*. A solution of **3** (2.58 g) and 1-butanol (15 ml) was refluxed for 15 h. Dibutyl ether was detected from the reaction mixture by means of GLC. Addition of ethanol (15 ml) followed by cooling the solution led to the precipitation of **2** (0.28 g, 1.2mmol). Removal of the solvent from the alcohol filtrate gave a residue, which was treated with ether and filtered. The solids (**17**: 1.07 g; 2.7 mmol) obtained were confirmed to be fairly pure by IR spectroscopy, and melted at 193—195 °C after recrystallization from ethanol.

IR (KBr, cm^{-1}): 3240 (brd)(νNH_3^+); 1240, 1158, 1120 (νSO_2). Found: C, 60.68; H, 4.56; N, 14.41%. Calcd for

$C_{20}H_{18}N_4O_3S$: C, 60.90; H, 4.60; N, 14.20%. Dissolution of this product in pyridine followed by dilution with water gave 4-amino-3,5-diphenyl-1,2,4-triazole, mp 260—262 °C. (lit,[18] mp 263 °C).

Benzenesulfonic acid was removed by washing with water from the ether filtrate above obtained; butyl benzoate (0.37 g, 2.1 mmol), butyl benzenesulfonate (0.02 g, 0.09 mmol), **7** (0.04 g, 0.16 mmol), and **2** (trace) were determined by means of gas or liquid (column) chromatography.

Radiation-induced Reactions of Pyridinecarboxylic Esters in Acidic Alcoholic Solutions. Substitution by Alkyl and Hydroxyalkyl Groups and Reduction of Carboxylic Esters to Alcohol[1)]

Kazuhito NAKAMURA, Yukari MORITA, Toru SUZUKI, Toru SUGIYAMA, and Akira SUGIMORI*

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102

(Received October 4, 1978)

The main reactions of pyridinecarboxylic esters induced by Co-60 γ-rays in acidic alcoholic solutions are: 1) substitution on the pyridine ring by alkyl or hydroxyalkyl groups derived from solvent alcohols, and 2) reduction of carboxylic esters to alcohol (hydroxymethyl group). Substitution is dominant in methanol solutions and reduction is dominant in 2-propanol solutions. Carboxylic esters at the 2- and 4-positions are selectively reduced to alcohols. Alkylation results from the attack by hydrogen atoms and hydroxylalkyl radicals. Reduction of carboxylic esters to alcohol is effected by the hydroxyalkyl radicals derived from the radiolysis of alcohols.

Radiation-induced reactions of pyridinecarboxylic acid derivatives including biologically important nicotinamide and nicotinic acid have not yet been thoroughly investigated at least on the basis of product analysis. Schachinger and Heindle reported the radiation-induced hydroxylation for the model compounds of NAD (nicotinamide adenine dinucleotide) in aqueous solutions.[2)] Swallow suggested the formation of a "dimer" during the X-ray irradiation of certain model compounds for NAD.[3)] By means of pulse radiolysis technique, intermediates formed by the reaction of pyridinecarboxylic acid derivatives with reactive species from the radiolysis of water and with the hydroxyalkyl radicals formed during the irradiation of aqueous alcohol have been investigated.[4,5)]

The radiation-induced reactions of esters of 2-, 3-, and 4-pyridinecarboxylic acids and of 2,5-pyridinedicarboxylic acid have been studied and compared with the work of Minisci *et al.* on the free radical substitution,[6)] and our work on the photochemical reactions.[7)]

Experimental

Materials. 2-Pyridinecarboxylic esters were synthesized by the reaction of acid chloride prepared from 2-pyridinecarboxylic acid (GR grade reagent of Tokyo Kasei Co.) with alcohols. The esters were purified by means of vacuum distillation and finally by preparative TLC before use. Commercial methyl and ethyl esters of 3- and 4-pyridinecarboxylic acid (GR grade reagent of Tokyo Kasei Co.) were purified by vacuum distillation. Dimethyl 2,5-pyridinedicarboxylate prepared by the esterification of 2,5-pyridinedicarboxylic acid (GR grade reagent of Tokyo Kasei Co.) in the presence of hydrogen chloride was used after recrystallization from methanol (mp 158 °C).

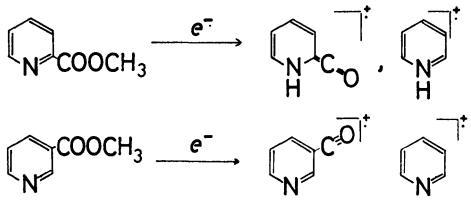
Gamma-irradiation. Solutions containing 0.03 mol dm^{-3} of pyridinecarboxylic esters and 0.05 mol dm^{-3} of sulfuric acid were deaerated by bubbling nitrogen gas for 20 min before irradiation. The solutions were irradiated with the Co-60 γ-irradiation facility of Japan Atomic Energy Research Institute in Takasaki. The normal dose rate and dose were 5×10^5 rad h^{-1} and 1.0×10^7 rad, respectively.

Isolation of Products. The irradiated solutions (each *ca.* 100 cm^3) were concentrated under reduced pressure to about 3 cm^3. After the neutralization with aqueous sodium hydrogencarbonate or sodium carbonate solutions, the products were extracted 7 times each with 5 cm^3 of dichloromethane. The extract was dried over anhydrous sodium sulfate. After concentrating the solution, the products were separated by means of TLC. Except for the methylated products of methyl 3-pyridinecarboxylate, products were obtained in pure form.

Identification of Products. Reduction Products: The identification of 2- and 4-hydroxymethylpyridine was carried out by the comparison of their NMR and IR spectra with those of authentic ones.

Methyl 6-hydroxymethyl-3-pyridinecarboxylate from dimethyl 2,5-pyridinedicarboxylate was identified from the following basis. IR (KBr disc) 3350 (OH), 1725 cm^{-1} (ester C=O); NMR ($CDCl_3$) δ=9.26 (1H, d, J=2.1 Hz, H at 2-position), 8.38 (1H, dd, J=8.0 and 2.1 Hz, H at 4-position), 7.46 (1H, d, J=8.0 Hz, H at 5-position), 4.90 (2H, s, $C\underline{H}_2$-OH), 4.02 (3H, s, $C\underline{H}_3OCO$-); MS (70 V) *m/e* (relative intensity) 167 (77), 166 (100), 138 (57), 137 (23), 136 (36), 108 (15), 106 (11), 79 (35), 78 (45), 59 (11), 53 (12), 52 (15), 51 (30), and 50 (16).

The position of the reduction was confirmed by MS. The difference of the mass-spectrometric behavior between methyl esters at the 2- and 3-positions on the pyridine ring is seen in the following fragmentation patterns.



For the methyl ester of 2-pyridinecarboxylic acid, McLafferty-type fragmentation (intramolecular hydrogen abstraction by the N atom of pyridine) occurs and the peak of $(M-30)^+$ and $(M-58)^+$ are observed, whereas for the methyl ester of 3-pyridinecarboxylic acid the intramolecular hydrogen abstraction cannot occur and the peaks of $(M-31)^+$ and $(M-59)^+$ are observed. This assignment was supported by using methyl-d_3-2-pyridinecarboxylate.

In the mass spectra of the reduction product from dimethyl 2,5-pyridinedicarboxylate, the $(M-59)^+$ peak was observed but the peak of $(M-58)^+$ was very low and the peak of $(M-31)^+$ was higher than that of $(M-30)^+$. Peaks of $(M-29)^+$, $(M-30)^+$, and $(M-31)^+$ can be partly ascribed to the decomposition of the hydroxymethyl moiety of the product. This fact indicates that the reduction occurred at the 2-position.

Alkylation Products: Methyl 6-methyl-3-pyridinecarboxylate was identified by comparison with the authentic sample synthesized by the method of Graf.[8]

Methyl esters of 4-methyl-2-pyridinecarboxylic, 6-methyl-3-pyridinecarboxylic and 2-methyl-4-pyridinecarboxylic acids were identified by the accordance of their NMR spectra with those obtained by Deady *et al.*[9] The alkylated products in the reaction in alcohols other than in methanol were identified by the comparison of NMR spectra with the corresponding methylated products from the reaction of methyl esters in methanol solutions.

The structures of methyl 4,6-dimethyl-2-pyridinecarboxylate which was obtained only in a small amount and methyl 4,6-dimethyl-3-pyridinecarboxylate which was obtained only in a mixture was presumed on the basis of NMR spectra.

Methyl 4,6-dimethyl-2-pyridinecarboxylate, NMR ($CDCl_3$) δ=7.75 (1H, s, H at 3-position), 7.12 (1H, s, H at 5-position), 3.98 (3H, s, $C\underline{H}_3OCO$–), 2.60 (3H, s, $C\underline{H}_3$), and 2.38 (3H, s, $C\underline{H}_3$)

Methyl 4,6-dimethyl-3-pyridinecarboxylate, NMR ($CDCl_3$) δ=8.88 (1H, s, H at 2-position), 6.95 (1H, s, H at 5-position), 3.90 (3H, s, $C\underline{H}_3OCO$–), 2.59 (3H, s, $C\underline{H}_3$), and 2.54 (3H, s, $C\underline{H}_3$).

Methyl 2-hydroxymethyl-4-pyridinecarboxylate was identified by the comparison of its spectral data with those obtained by Ninomiya *et al.*[10]

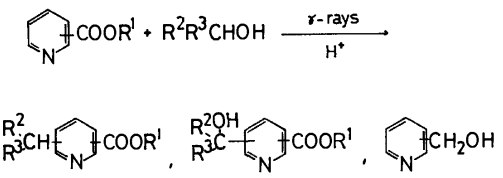
Methyl 6-hydroxymethyl-4-methyl-2-pyridinecarboxylate: mp 27.0—28.5 °C; IR (KBr disc) 3350 (OH) and 1725 cm^{-1} (ester C=O); NMR ($CDCl_3$) δ=7.81 (1H, d, J=1 Hz, H at 3-position), 7.30 (1H, d, J=1 Hz, H at 5-position), 4.79 (2H, s, $HOC\underline{H}_2$–), 3.98 (3H, s, $C\underline{H}_3OCO$–), 2.45 (3H, s, $C\underline{H}_3$–); MS (70 V), *m/e* (relative intensity), 181 (38), 180 (57), 166 (13), 152 (8), 151 (9), 148 (11), 124 (8), 123 (100), 122 (11), 121 (10), 120 (14), 119 (7), 105 (35), 93 (8), 92 (8); Found: C, 60.80; H, 4.87; N, 7.68%; M^+, 181 Calcd for $C_9H_{10}NO_3$: C, 59.94; H, 5.59; N, 7.77%; M, 181.

Determination of the Yields of Products. For the determination of the yields of the alkylated and hydroxyalkylated products the gravimetric method after the separation by TLC was applied. The composition of the methylation products from methyl 3-pyridinecarboxylate, which could not be separated by means of TLC was estimated by NMR. For the study of the effect of the acid concentration on the reaction of ethyl 2-pyridinecarboxylate in ethanol, the yields of the products were determined by means of gas-chromatography (column, Carbowax 20M or Triton QS 15; temperature, 160—180 °C). For the determination of the yields of hydroxymethylpyridines, gas-chromatography was employed.

Calculation of the Electronic States. The electronic states of pyridinecarboxylic esters were calculated using the CNDO/2 program (Q.C.P.E. 141) prepared by Pople, Beveridge and Dobosh and arranged by Kihara, Fujikawa, and Aoyama. The structural parameters obtained for 3-pyridinecarboxylic acid[11] was used as a basis. For the other structural parameters, the generally accepted values are substituted, and the structure of the ester group in 3-pyridinecarboxylic ester is assumed for 2- and 4-pyridinecarboxylic esters.

Results and Discussion

The main reactions of pyridinecarboxylic esters in acidic alcoholic solutions under Co-60 γ-irradiation are: 1) the substitution on the pyridine ring by alkyl and/or hydroxyalkyl groups which originate from the solvent alcohols, and 2) the reduction of alkoxycarbonyl group to hydroxymethyl group. Whether reduction or alkylation (or hydroxyalkylation) is predominant depends on the structure of the substrates and on the alcohols used as the solvents.



Alkylation and Hydroxyalkylation. Results on the radiation-induced alkylation and hydroxyalkylation in 2-, 3-, and 4-pyridinecarboxylic esters are summarized in Table 1. Except for 4-pyridinecarboxylic ester, alkyla-

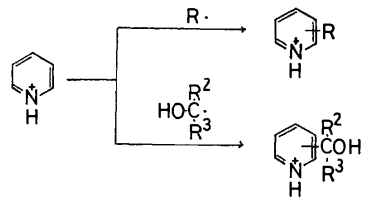
-△- Ethyl 4-ethyl-2-pyridinecarboxylate, -○- 2-hydroxymethylpyridine. [Ethyl 2-pyridinecarboxylate]= 0.03 mol dm^{-3}; dose rate, 4×10^5 rad h^{-1}; dose, 8×10^6 rad.

tion is dominant over hydroxyalkylation. Figure 1 shows that the alkylation occurs in an acidic environment where pyridinecarboxylic ester is in the cationic pyridinium form.

The fact that the alkylation is completely inhibited by iodine and iron(III) chloride shows that the reaction proceeds *via* free radical intermediates. However, there is a difference between the radiation-induced reaction and the free radical reaction of pyridine derivatives in alcohol, where hydroxyalkylation is dominant over alkylation.[6] In both cases hydroxyalkyl radicals are expected to play an important role.

Free radical substitution of pyridinium compounds has been investigated by Minisci and his coworkers.[6] According to them, alkyl radicals bring about alkylation and hydroxyalkyl radicals hydroxyalkylation.



Reported *G*-values (radiation-chemical yield) for primary reactive species from the radiolysis of methanol are 2.0 for electron, 1.1 for H·, 0.2 for ·OH, 0.2 for $\cdot CH_3$, and 2.7 for $\cdot CH_2OH$, respectively.[12] The fact that alkylation is favored over hydroxyalkylation in radiation-induced reactions is not consistent with the higher *G*-value of $\cdot CH_2OH$ and lower *G*-value of $\cdot CH_3$.

The difference between the radiation-induced reaction and the free radical-initiated reaction in alcohol is the participation of hydrogen atoms in the former. (Under the acidic conditions which we employed, electrons should be very effectively converted to hydrogen atoms and the formation of 3.1H· per 100 eV of absorbed radiation energy is expected.) Radiation-induced alkylation can be explained by the initial attack of H

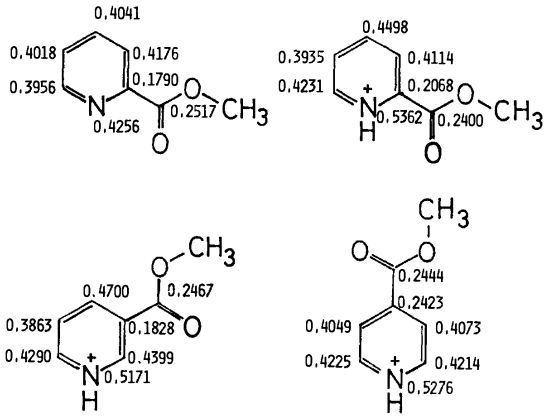


Fig. 2. Free valence in π-electronic systems of pyridine carboxylic esters calculated by CNDO/2.

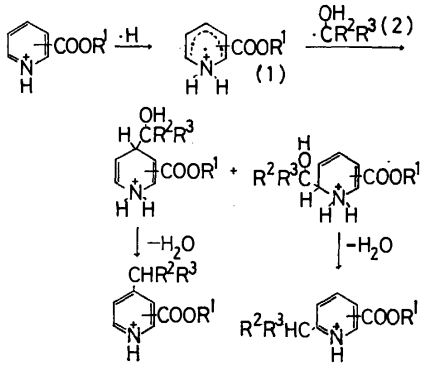
atoms to the nitrogen atom, which has the greatest free valence among the atoms constituing the pyridine ring (Fig. 2), followed by the attack of hydroxyalkyl radicals and the elimination of water.



As to the alkylation and hydroxyalkylation, the radiation induced reaction is similar to the photoreaction;[13] alkylation is predominant over hydroxyalkylation and the alkylation occurs at α- and γ-position of pyridine nucleus. Photochemically excited pyridinium abstracts a hydrogen atom from alcohol to give the intermediate (**1**) and hydroxyalkyl radical (**2**). This should be the reason of the similarity between the radiation-induced reaction and the photochemical reaction.

Reduction of Carboxylic Ester to Alcohol. The remarkable reaction induced by ionizing radiation is the reduction of the carboxylic ester group to the hydroxymethyl group. In Table 2, *G*-values for the reduction of methyl esters of pyridinecarboxylic acids in several alcohols are summarized.

Among the esters of monocarboxylic acids, 2- and 4-pyridinecarboxylic esters are reduced to alcohols, whereas 3-pyridinecarboxylic ester is not reduced. In dimethyl 2,5-pyridinedicarboxylate, the carboxylic ester at the α-position is selectively reduced. The efficiency of the reduction is higher in the secondary alcohol than in the primary alcohols.

As to the intermediacy of the aldehyde, no conclusion has been made: among the products from methyl 2-pyridinecarboxylate we could not identify 2-pyridinecarbaldehyde and the irradiation of 2-pyridinecarbalde-

Table 2. Dependence of G-values for reduction of alkyl pyridinecarboxylates to hydroxymethylpyridines on alcohol

[Substrate]$=0.03$ mol dm^{-3}; [H_2SO_4]$=0.05$ mol dm^{-3}; dose rate, 5×10^5 rad h^{-1}; dose, 10^7 rad.

Substrate	Alcohol	G(Hydroxymethylpyridine)
Methyl 2-pyridinecarboxylate	MeOH	0.012
	EtOH	0.54
	n-PrOH	0.46
	n-BuOH	0.40
	i-PrOH	0.93
Ethyl 3-pyridinecarboxylate	MeOH	0.0
	EtOH	0.0
Ethyl 4-pyridinecarboxylate	EtOH	0.13
Dimethyl 2,5-pyridinedicarboxylate[a)]	MeOH	0.03
	i-PrOH	0.26

a) Reduction product is methyl 6-hydroxymethyl-3-pyridinecarboxylate (the product reduced at 2-position of the substrate).

hyde in 2-propanol gave only small amount of 2-hydroxymethylpyridine.

The reduction is brought about by free radicals produced by ionizing radiation, because the reduction is inhibited by iodine and iron(III) chloride. As is seen in Fig. 1, the reduction occurs in acidic conditions.

As the reducing species, hydroxyalkyl radicals and hydrogen atoms should be taken into consideration. Solvated electrons cannot participate in the reduction, because they should react with H^+ rather than with the substrate.

A small amount of 2-hydroxymethylpyridine was obtained in the sun-light irradiation of methyl 2-pyridinecarboxylate in ethanol in the presence of acetone. In this system, the formation of hydroxymethyl radicals is expected.

Table 3. Pai-electron density and π-bond order of the carbonyl moiety in pyridinecarboxylic esters calculated by CNDO/2

Compound	π-Electron density		π-Bond order
	C	O	
Methyl 2-pyridinecarboxylate (neutral form)	0.8243	1.3043	0.8818
Methyl 2-pyridinecarboxylate (pyridinium form)	0.8576	1.2553	0.8885
Methyl 3-pyridinecarboxylate (pyridinium form)	0.8468	1.2769	0.8885
Methyl 4-pyridinecarboxylate (pyridinium form)	0.8546	1.2419	0.8913

The above fact suggests that the reducing species are hydroxyalkyl radicals. The series of $E_{1/2}$ *vs.* SCE -1.30 V ($(CH_3)_2\dot{C}OH$), -1.18 V (CH_3–$\dot{C}HOH$), and -0.98 V ($\cdot CH_2OH$)[14] correlates well with the G-values for the reduction.

The correlation between the reactivity for the reduction and the electronic state of pyridinecarboxylic esters (Table 3) is not so significant. Among the calculated π-electron densities and π-bond orders, the π-electron densities at O atoms of the carbonyl moiety of the substrates show the correlation to the reactivities.

The authors wish to express their hearty thanks to Professor L. W. Deady of La Trobe University in Australia and Professor Ichiya Ninomiya of Kobe Women's College of Pharmacy for sending us the spectral data of pyridinecarboxylic acid derivatives. We also would like to thank Mr. Susumu Kumon and Miss Kuniko Yamada of Shin-Nihon Jitsugyo Co. for obtaining the mass spectra.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education Science and Culture (No. 147026).

Thermal Decomposition of Coal-related Aromatic Compounds in Hydrogen-donating Solvent

Tadashi YAO and Yoshio KAMIYA*

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 23, 1978)

In order to elucidate the reaction mechanism of coal dissolution in the hydrogen-donating solvent, twenty aromatic compounds related to coal were treated at 450 °C in the presence of tetralin. Diphenylmethane and bibenzyl slowly decomposed giving alkylbenzenes almost quantitatively. Diphenylmethanol and benzophenone were hydrogenated to diphenylmethane, and benzyl phenyl ketone to a mixture of diphenylmethane and bibenzyl. Diphenyl ether and dibenzofuran are very stable, di-2-naphthyl ether decomposing slowly and benzyl phenyl ether or dibenzyl ether very rapidly. The conversion of aromatic compounds by thermolysis can be correlated as a function of bond dissociation energy. The bond rupture of coal-related polynuclear aromatic compounds at 450 °C was concluded to occur mainly at methylene or ether structures. Addition of phenolic compounds or quinoline is very effective for the decomposition of di-2-naphthyl ether. The effect of phenolic compounds and quinoline on the thermal decomposition of aromatic ether was discussed on the basis of stabilization of transition state due to solvation.

Thermal treatment of coal at 400—450 °C in hydrogen-donating solvent results in successful dissolution of coal and high yield of solvent refined coal[1] (SRC) containing small amounts of sulfur compounds and mineral matters. This is a most promising coal liquefaction process because of very simple and non-catalyzed reaction.

However, the fundamental chemistry of coal liquefaction has received little attention, a very limited number of compounds[2,3] being subjected to thermal treatment. Recently, the thermolysis[4–6] of a number of diarylalkanes and phenolic compounds was studied to elucidate the reaction mechanism.

The most important and interesting reaction in coal liquefaction[7,8] should be the deoxyganation and subsequent dissolution reaction of coal, which starts at 400 °C and almost finishes at 450 °C, resulting in the formation of the solvent refined coal with carbon contents of 86—88% on maf basis independent of coalification grade of the feed coal. Oxygen containing structures should play an important part in the coal liquefaction reaction. It is essential to know what kinds of oxygen containing structure are decomposed and what kind of structure is formed at coal liquefaction temperatures.

We wish to report in this work on the thermal decomposition of diaryl ethers along with other types of coal model structure, and also on the additive effect of phenols and quinoline for the scission of ether linkage. We found that a diaryl ether with polynuclear aromatic is decomposed at coal liquefaction temperature, and that phenols[9] accelerate the liquefaction of coal strongly depending on the character of coal. The effect of additives would be most important for finding out good solvent character for coal liquefaction.

Experimental

Tetralin and 1-methylnaphthalene of reagent grade were used after washing with sulfuric acid, alkali, and water and the subsequent distillation at 70 °C under reduced pressure. Various additives and model compounds were of grade. Some of them were used after recrystallization.

Samples were put into a 300 ml magnetic stirring (500 rpm) autoclave. After being pressurized with 15 kg/cm² of hydrogen, the autoclave was heated to the reaction temperature within 45 min and maintained at the temperature for the desired reaction time.

At the completion of a run, the autoclave was cooled by an electric fan to room temperature and the autoclave gases were vented through a gas meter and analyzed by gas chromatography. Liquid portions of the samples were subjected to gas chromatographic analysis in order to determine the composition of solvent.

Results and Discussion

Thermal Treatment of Tetralin and 1-Methylnaphthalene. In order to investigate the stability of solvent, thermal treatment of tetralin and 1-methylnaphthalene was carried out at 450 °C for 30 min. Their conversion was 3.0 and 1.5%, respectively, indicating that they are very stable under the reaction conditions.

The consumed tetralin was explained to be converted into naphthalene (23%), decalin (40%) and alkylbenzenes (30%), although thermal decomposition of tetralin has been reported by many workers[6,10,11] to yield dihydronaphthalene, decalin, methylindane and ethylbenzene. Only 44% of consumed 1-methylnaphthalene was recovered as naphthalene, indicating considerable formation of polymerized products according to GLC analysis.

Thermal Treatment of Various Aromatic Compounds. In order to study the reaction of coal structure, twenty aromatic compounds were chosen as the coal model and treated at 450 °C. Conversion of the reaction and the detected products are given in Table 1.

Polynuclear aromatic was found to be partially hydrogenated by tetralin. Heredy and coworkers[12] demonstrated that –CHR–, $-CH_2-$, and $-CH_2-CH_2-$ bridges connect aryl groups in coal. However, diphenylmethane and bibenzyl were thermally decomposed slowly giving benzene and toluene almost quantitatively.

Recently, the thermal decomposition of diarylalkanes such as bibenzyl and 1,3-diphenylpropane has been studied by Sato and coworkers[6] and Collins and coworkers.[4,5] These compounds were confirmed to decompose into alkylbenzenes very slowly as a function of carbon chain length at 400 °C.

When the molar ratio of tetralin to a mixture of 1-methylnaphthalene and tetralin were increased from zero to 1.0, the conversion of bibenzyl increased from 14 to 30%. This can be attributed to the capability of hydrogen donation of solvent, since the conversion reaches almost a constant value at the equimolar mixture of tetralin and 1-methylnaphthalene.

Although diphenyl ether and dibenzofuran were very stable at 450 °C, di-2-naphthyl ether decomposed slowly and benzyl ethers completely.

The apparent activation energy for the thermal decomposition of benzyl phenyl ether was calculated to be about 50 kcal/mol from the data obtained at 320—350 °C, since the first order rate constants were 1.39×10^{-4} at 320 °C, 5.19×10^{-4} at 340 °C and 9.52×10^{-4} s^{-1} at 350 °C, respectively.

These results indicate that highly aromatic ether linkages will be broken to a great extent at coal liquefaction temperatures resulting in a main source of phenolic groups of the dissolved coal.

Naphthols were confirmed to be very stable against thermal treatment. Diphenylmethanol and benzophenone were stable against decomposition but hydrogenated to form diphenylmethane quantitatively. Benzyl phenyl ketone was found to be paritally hydrogenated or decarbonylated to form diphenylalkanes. 1,4-Naphthoquinone was completely eliminated and hydrogenated to naphthol and dihydroxynaphthalene as reported by Brower.[13]

Carboxylic acid and carboxylate were completely decarboxylated to the parent hydrocarbons. Carboxylic acid is quite stable in a glass apparatus, but decomposes completely in a stainless steel autoclave.[13]

Generally, the conversion of aromatic compounds by thermal treatment can be correlated as a function of bond dissociation energy of the weakest structure of the substrate as shown in Table 2 and Fig. 1. A few exceptions observed in the cases of benzophenone, benzyl benzoate and naphthoic acid can be ascribed to hydrogenation or the wall effect.

Effect of Phenolic Compounds on the Thermal Decomposition of Aromatic Ethers. According to the results given in Table 1, the bond scission of oxygen containing polynuclear aromatic structure of coal at coal liquefaction

temperature 400—450 °C seems to occur mainly at methylene or ether structures. Thus, a study of the characteristics of these structures in the thermolysis is important.

It has been proposed that the units of coal structure are linked by ether linkages.[17,18] Recently, Ruberto and his coworkers[19] concluded that a significant portion of the oxygen in solid subbituminous coal occurs in saturated ether functional groups α- or β- to the aromatic moieties or as furan systems. Ignasiak and Gawlak[20] concluded from the increase in hydroxyl functions in the protonated coal concentrate that for each 4.6 ruptured covalent bond two were ether linkages.

As shown in Table 1 the decomposition of di-2-naphthyl ether proceeds slowly. We have chosen this ether and studied in detail the effect of various phenols on the decomposition of the aromatic ether since phenols remarkably enhance coal dissolution among the several types of oxygenated compounds.[9]

The thermal decomposition of bibenzyl is not affected by the addition of phenol or *p*-cresol (Table 3). In contrast, the decomposition of di-2-naphthyl ether increases remarkably in the presence of phenolic compounds (Table 4). The effect seems to increase with increase in the electron donating property of substituent on the benzene nucleus.

The effect of hydroquinone and *p*-methoxyphenol is remarkable. However, no decisive argument can be made since they can not be recovered sufficiently, indicating that very complicated side reactions take place.

Although 1-naphthol is quite stable against thermal decomposition (Table 1), its recovery after the thermolysis of dinaphthyl ether is not successful. This is in line with our previous findings[9] that about half the amount of naphthol can be recovered after the dissolution of coal in contrast to the very high recovery of phenol and *p*-cresol. This indicates that a naphthyloxyl radical is decomposed into alkylbenzene or alkylnaphthalene after reacting with some other free radicals.

Phenolic compounds might enhance the rate of decomposition of aromatic ether by solvating transition state of the scission of ether linkage and by hydrogen transfer to the formed alkoxyl radicals.

Effect of Quinoline. Quinoline shows no effect on the decomposition of bibenzyl, but considerably increases the conversion of dinaphthyl ether as in the cases of phenols (Tables 3 and 4).

The yield of 2-naphthol from dinaphthyl ether was

Table 3. Effect of phenol and quinoline on the thermal decomposition of bibenzyl at 450 °C for 60 min

Charge (mmol)				Conversion (%)

a) *p*-Methoxyphenol was converted into phenol, hydroquinoline, and benzene. b) Hydroquinone was mostly converted into phenol and benzene.

lowered in the presence of quinoline, suggesting that a considerable amount of naphthyloxyl radical was reacted with quinoline as a result of close interaction between the ether and quinoline during the course of thermal decomposition reaction.

Accelerating Effect Due to Additives on the Rupture of Ether Linkage. Phenols are weak acids and polar solvent, and often enhance the thermal decomposition of covalent bond. However, we could observe no accelerating effect due to phenol on the decomposition of bibenzyl. Pyridine bases accelerate the depolymerization of coal.[10,21] Thus, phenols and quinoline should participate directly in the scission of ether linkage.

Huyser and Van Scoy[22] observed that the thermal decomposition of di-*t*-butyl peroxide is remarkably accelerated in acetic acid or *t*-butyl alcohol. They ascribed this effect to the solvation of *t*-butoxyl radical by the solvents.

Mahoney and Da Rooge[23] found that the hydrogen abstraction from phenols by phenoxyl radicals proceeds very rapidly in spite of very low enthalpy change. Howard and Furimsky[24] suggested that the hydrogen atom transfer between peroxyl radical and phenol involves the formation of a hydrogen bonded free radical reactant complex.

A phenoxyl radical from the thermal decomposition of aromatic ether can be stabilized by solvation or hydrogen bonding with phenolic compounds, giving rise to the subsequent hydrogen transfer reaction from phenols or hydrogen donor solvents.

Stabilization of the transition state of bond dissociation or the formed alkoxyl radical might be the best explanation for the rate enhancement, since quinoline also remarkably accelerates the decomposition of dinaphthyl ether. Alkoxyl radical would be electron donor and phenols or quinoline electron acceptors.

In view of bond dissociation energy, phenolic compounds having electron supplying substituent such as naphthol and *p*-methoxyphenol can be easily converted into phenoxyl radicals by reacting with the phenoxyl radicals resulting from the thermal decomposition of ether structure, and will result in further decomposition reaction including deoxygenation reaction.

Easiness of bond rupture of an ether depends strongly on its chemical structure. Diphenyl ether and dibenzofuran are quite stable against thermal treatment at 450 °C, while dibenzyl ether and benzyl phenyl ether can be completely decomposed at 400 °C.

Almost all $-CH_2-O-$ linkages in coal structure would be ruptured at temperatures below 400 °C and diaryl ether with polynuclear aromatic moderately at coal liquefaction temperatre. Some coals containing aliphatic ether structure would be decomposed remarkable at lower temperatures and their decomposition would not be affected by the addition of phenols or pyridine bases. Some coals containing polynuclear aromatic diaryl ethers would be decomposed effectively by the addition of phenolic compounds or pyridine bases.

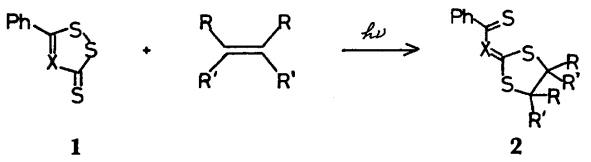
Synthesis and Reactions of *o*-Benzothioquinonemethides

Renji OKAZAKI, Kazuhiko SUNAGAWA, Kyung-Tae KANG, and Naoki INAMOTO*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received June 26, 1978)

Photoreactions of 1,2-benzodithiole-3-thione with olefins (cyclopentene, cyclohexene, cyclooctene, and 2,3-dimethyl-2-butene) afforded deep blue *o*-thioquinonemethides (**4**) in high yields. The thione **4** is equilibrated with a colorless head-to-head dimer having an eight-membered ring. The mode of the dimerization has been discussed in comparison with other *o*-quinonoid compounds. Cycloaddition reactions of **4** with electron-deficient acetylenes and olefins gave rise to [4+2] adducts. It was confirmed that these cycloadditions proceeded stereoselectively as well as regioselectively. Reactions of **4** with diphenylketene, phenyl isocyanate, and phenyl isothiocyanate led to six-membered 1:1 adducts. Reduction by hydride reagents has been also described.

Chemistry of *o*-quinonoid compounds has extensively been investigated in recent years because of the interesting chemical and physical properties and the synthetic application.[1,2] However, there had been no report concerning *o*-thioquinonemethides, when we started this study, except those which described their existence as a transient species.[3]

Our previous study on the photochemical reactions of 1,2,4-dithiazole-3-thiones or 1,2-dithiole-3-thiones (**1**) with olefins leading to the corresponding 1:1 adducts (**2**)[4] suggested that a similar ring-opening-cycload-



1 **2**

X=N, CH, CPh

dition reaction with 1,2-benzodithiole-3-thione (**3**) would give 6-methylene-2,4-cyclohexadiene-1-thione (referred to *o*-thioquinonemethide hereafter) (**4**) (see below), and indeed this expectation was fulfilled.[5,6] The purpose of this paper is to describe a detailed account of the preparation and some reactions of *o*-thioquinonemethides (**4**) thus formed.

Results and Discussion

Synthesis of o-*Benzothioquinonemethides and Equilibrium with Dimers.* Irradiation of benzo-1,2-dithiole-3-thione (**3**) in the presence of an olefin (cyclopentene, cyclohexene, cyclooctene or 2,3-dimethyl-2-butene) afforded deep blue *o*-thioquinonemethide (**4**). The structure of **4** was established by its cycloaddition leading to [4+2] adduct (see below) and analogy with the photoproducts from **1** and olefins.[4] The color of the

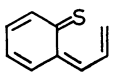
solution of **4** depends on solvent, temperature, and irradiation with light (Tables 1 and 2). For example, the color of **4b** is deep blue in dichloromethane or tetrahydrofuran (THF) at room temperature, but in cyclohexane it is almost colorless. Recrystallization of **4b** from carbon tetrachloride at −23 °C affords white crystals, the dissolution of which in an appropriate solvent, however, leads to a deep blue solution. The colorless cyclohexane solution of **4b** turns blue on heating or irradiation, but the blue color is discharged when the solution is left at room temperature. These facts and the dependence of the UV spectrum of **4b** on the concentration suggest that **4** is equilibrated with a colorless aggregate. It was found that the aggregate was a dimer on the basis of cryoscopic measurement of the molecular weight for the adduct with cyclohexene (**5b**) in cyclohexane (Found 542, Calcd 532). Other *o*-thioquinonemethides **4a**, **4c**, and **4d** behave similarly, although the blue color of the solution of **4d** is the strongest in any solvent as expected by the highest apparent molar extinction coefficient among **4a**—**4d** (Table 2). It is obvious that the 580 nm band responsible for the blue color is due to the monomer. Although the value of 580 nm is in the range of n-π^* band of conjugate thiones,[4,7] the absorption of **4** is considered to be of π-π^* nature, because the extinction coefficient is too high

for n-π^* bands. In this connection, it is interesting that the visible absorption of **4** bears a close resemblance to that of 6-allylidene-2,4-cyclohexadiene-1-thione (**6**) generated from a photoreaction of 2*H*-thiochromene at 77 K in a rigid matrix (a broad band with its center around 570 nm), though no molar extinction coefficient was given for the latter.[3b]

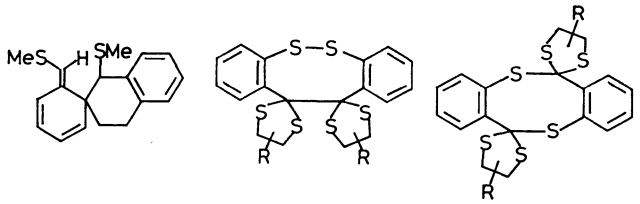


6

Since the intensity change of the 270 and 350 nm bands parallels that of the 580 nm band, the former two are also due to the monomer.

When **4b** was heated in refluxing xylene for 45 min under argon, **3** was formed in a quantitative yield.

Structure of the Dimer. Since the NMR spectrum of the cyclohexene adduct (**5b**) in carbon tetrachloride at −20 °C, where it is almost colorless and hence essentially dimeric, shows eight proton signals between δ 7.3—9.0 ascribed to aromatic or olefinic protons, the dimerization should occur using the thiocarbonyl and/or ketene thioacetal units. The absence of the 580 nm band in the spectrum of **5b** in cyclohexane suggests that it represents that of the dimer, which shows no strong absorption above 300 nm. These facts imply that [4+2] and [2+2] type adducts can be eliminated among many possible structures of the dimer, because they must have a conjugated ketene thioacetal(s) which should have a strong band above 350 nm [*e.g.*, for **7**, λ_{max} 345 nm (ε 6760)][8] or a conjugated thione(s) which should have an absorption in the visible region.[4,7] The dimer, therefore, must be **8** or **9** of [4+4] type.

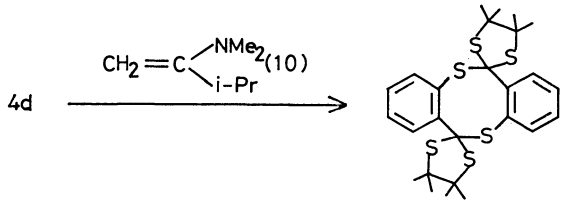


7 **8** **9**

Since it is reasonably assumed that **4a**—**4d** have almost identical molar extinction coefficients each other, irrespective of the substituents of the 1,3-dithiolane ring, the data in Table 2 show that the proportion of the monomer increases with increasing bulkiness of the added olefins, that is, the dissociation into the monomer increases with bulkiness of the thioacetal moiety of the dimer **5**. This fact is more compatible with a head-to-head dimer (**8**) than a head-to-tail dimer (**9**) in view of the higher steric repulsion between the two dithiolane rings in the former.

Desulfurization of **4b** with Raney nickel leading to bibenzyl (5%) along with toluene (41%) is another piece of evidence for the head-to-head structure, although the possibility can not be excluded that the former may be formed from the monomer.[9]

More confirmative evidence comes from isolation of another [4+4]dimer of **4d**.[5b] When **4d** was allowed to react with enamine (**10**) at 60 °C in THF–acetonitrile, a colorless crystalline compound (**11**) with a molecular formula of $(C_{13}H_{16}S_3)_2$ (from elemental analysis and molecular weight determination) was obtained in 38% yield.

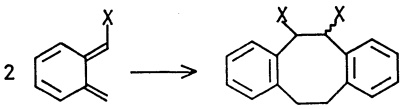


11

The NMR spectrum of the dimer (**5d**) obtained from the photochemical reaction showed four singlets due to the methyl groups (δ 1.22, 1.33, 1.57, and 1.76), while the new dimer (**11**) from above reaction had a singlet (δ 1.52) in the methyl region along with aromatic multiplet (δ 7.0—8.3). The difference can be readily accounted for if we consider that the 11*H*,12*H*-dibenzodithiocin ring of **5d** is less symmetric than that of **11** because of the steric interaction between the two dithiolane rings. Thus, we conclude that the photodimer (**5d**) and the new dimer (**11**) are a head-to-head and a head-to-tail [4+4] type dimers, respectively, although X-ray analysis will be necessary for the final answer.

Dimer (**11**) is thermally stable and does not show thermal equilibrium with the monomer, although it dissociates into an equilibrium mixture of **4d** and **5d** as evidenced by UV and NMR spectra.

It should be noted here that the mode of dimerization of **4** under normal conditions (*i.e*, the formation of a head-to-head dimer) parallels that of *o*-quinodimethanes (**12a-c**)[8,10,11] rather than that of benzothietes (**13a, b**) leading to **14a,b**,[12,13] which might proceed *via* *o*-thioquinonemethide.



12

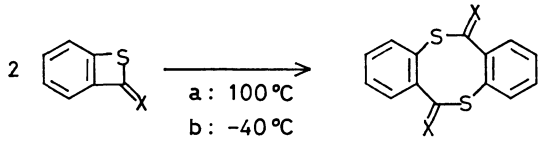
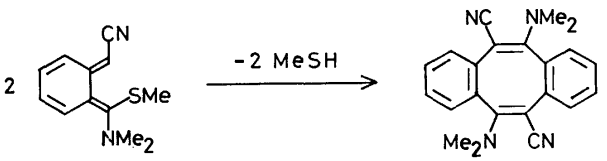
c: X=P(O)(OMe)$_2$[11]



13 **14**

a: X=H_2
b: X=O

It has been reported that quinodimethane (**15**) is stable at −40 °C in *N*,*N*-dimethylformamide but undergoes dimerization, followed by elimination of methanethiol, to give **16**.[14]



15 16

The reason for these different chemical behaviors is not clear, but one possible explanation is involvement of homolytic processes in the dimerization of **4** and **12**.

Reactions of o-*Thioquinonemethides. a) Reactions with Acetylenes or Olefins*: The *o*-thioquinonemethide (**4**) is a strong enophile and rapidly reacts with acetylenes and olefins having electron-withdrawing groups at room temperature to afford 1,4-cycloaddition adducts. The reaction of **4b** with dibenzoylacetylene and *N*-phenylmaleimide gave **17** (83%) and **18** (93%) respectively. The regioselectivity and stereoselectivity of the cycloaddition were examined with mono- and di-substituted olefins, respectively. Reaction of **4b** with methyl vinyl ketone in refluxing benzene for 5 min afforded only one kind of 1: 1 adduct (**19**) in a quantitative yield. Raney nickel desulfurization of the product gave 3-methyl-4-phenyl-2-butanone (**20**, 64%) and 3-methyl-4-phenyl-2-butanol (**21**, 12%), thus establishing the regioselectivity of the reaction. Acrylamide reacted with **4b** to give 1: 1 adduct (**22**, 64%), the similarity of whose NMR spectrum to that of **19** suggested the same regioselectivity also in this case.

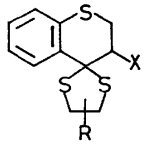
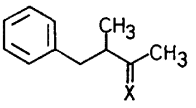
18

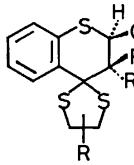


19: X=$COCH_3$
22: X=$CONH_2$



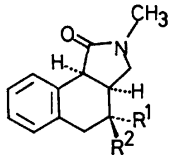
20: X=O
21: X=H, OH

When maleonitrile and fumaronitrile were allowed to react with **4b** in dichloromethane at room temperature for 1 or 2 days, *cis*- (**23a**) and *trans*-adducts (**23b**) were obtained in 66 and 88% yields, respectively. The NMR spectra of the crude reaction products from both dicyanoolefins showed the presence of two methine protons α to a cyano group which appeared as two sets of double doublets of AX type. The intensity ratio of the two double doublets was about 4: 1 (J_{AX}=3.4 Hz for the both doublets) for **23a** and about 5: 1 (J_{AX}= 9.1 Hz for the both doublets) for **23b**. In light of the reported values[10] of 4.5 ($J_{HR'}$) and 10 Hz ($J_{H,R'}$) for similar compounds **24** and **25** respectively, the coupling constants observed for **23a** and **23b** indicate they are *cis*- and *trans*-adducts respectively, the stereoselectivity of the cycloaddition thus being established.



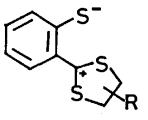
23

a: R^1=CN, R^2=H
b: R^1=H, R^2=CN



24: R^1=H, R^2=Cl
25: R^1=Cl, R^2=H

The stereoselectivity for cycloaddition of **4** with olefins is noteworthy, because it means the cycloaddition of **4** proceeds probably in a concerted manner, although possible contribution of ionic canonical structure (**26**) might lead to a stepwise ionic reaction resulting in non-stereoselective addition.



26

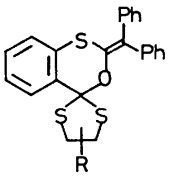
The two sets of the spectra for **23a** and **23b** are considered to correspond to two isomers with respect to the direction of the cyclohexane ring. We previously isolated such a sort of isomers in cycloadditions of similar conjugated systems.[15] Recrystallization of **23a** and **23b** gave pure specimens of the corresponding major isomers.

We previously reported that **4** also reacted with electron-rich olefins (*i.e.*, enamines) to give [4+2]adducts.[16]

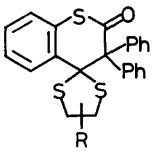
b) Reactions with Heterocumulenes: Reaction with diphenylketene proceeds very rapidly at room temperature to afford a mixture of **27** and **28** in 73% yield. The primary product (**27**) is unstable and easily isomerizes to **28** or decomposes to **4b** when heated or left on silica gel for a long time. The thioester (**28**) is stable and purified by usual work-up.

4b reacts with phenyl isocyanate at room temperature for 6 days to afford **29** in 88% yield.

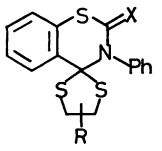
Major reaction product with phenyl isothiocyanate in benzene at 80 °C for 21 h was **31** (73%). Although **31** is stable in the presence of the excess isothiocyanate,



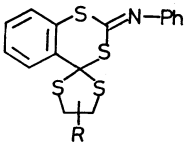
27



28



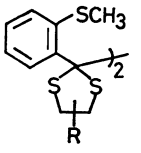
29: X=O
30: X=S



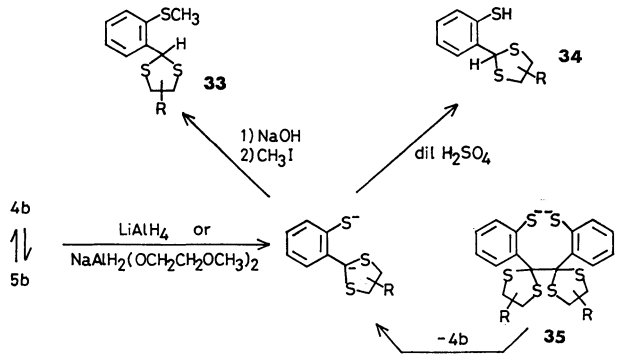
31

it decomposes mainly to **4b** and phenyl isothiocyanate when the isothiocyanate is removed. A compound tentatively assigned as **30** was also isolated in the decomposition product.

c) Reduction and Other Reactions: Reduction with hydride reducing reagents (lithium aluminum hydride and sodium bis(2-methoxyethoxy)dihydridaluminate) followed by methylation were carried out in order to get **32** which would be formed from the dimer (**5b**). The product, however, was not an expected one but **33** (64%) when quenched with aqueous alkali and methyl iodide or **34** (24%) when quenched with dilute sulfuric acid. The formation of these products can be explained in terms of the preferential attack of the hydride on **4b** because of much higher reactivity of **4b** than that of **5b** and/or of facile decomposition of intermediate **35**, even if it is formed from the dimer **5b**.

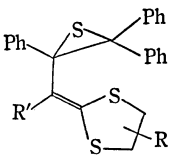


32



Thiophenol (**34**) was unstable and was gradually oxidized by atmospheric oxygen to afford **4b**.

4b did not react with diphenyldiazomethane or phenyldiazomethane, which readily reacts with thiones to afford episulfides.[17] This is in marked contrast with the reactivity of similar conjugate thiones **2** (X=CH, CPh) which react with diphenyldiazomethane to give **36**.[15]



36: R′=H, Ph

Inertness of **4b** toward these diazomethanes is indicative of a greater contribution of the ionic resonance structure of type **26** for **4** as expected from its aromatic stabilization.

Experimental

NMR spectra were recorded with a Hitachi R-20B or R-24 spectrometer using tetramethylsilane as an internal standard. UV and visible absorption spectra were recorded on a Hitachi ESP-3 spectrophotometer. IR spectra were taken with a Hitachi EPI-G2 spectrometer (beam energy 70 eV). Molecular weights were measured with a Hitachi 117 Molecular Weight Apparatus (vapor pressure osmometry in benzene at 40 °C). All the melting points were not corrected.

Synthesis of o-Thioquinonemethides (4). A solution of 1,2-benzodithiole-3-thione (**3**)[18] (460 mg, 2.5 mmol) and cyclohexene (7 ml) in ether (70 ml) was irradiated under nitrogen for 45 min with 100 W medium pressure mercury lamp through Pyrex filter. After 35 or 40 min the color of the solution turned deep blue. The reaction mixture was subjected to dry column chromatography (DCC) (SiO_2, 2: 1 benzene–hexane) to give **4b** (614 mg, 89%). Essentially the same result was obtained when benzene was used as solvent. Recrystallization from carbon tetrachloride at −23 °C afforded white crystals, whose color gradually changed pale blue upon standing under diffused light. Mp 166—167 °C (dec); NMR (CCl_4): δ 1.0—2.5 (br s, 8H), 3.3—4.4 (m, 2H), and 6.8—7.8 (m, 4H); UV (cyclohexane at 7 °C): λ_{max} 260 nm (ε 1.04×10^4). For the spectra in other solvents, see Table 2. Found: C, 58.99; H, 5.20; S, 35.59%. Calcd for $C_{13}H_{14}S_3$: C, 58.60; H, 5.30; S, 36.10%. There formed slightly green crystals when the reaction solution in ether was stood overnight at −5—0 °C. The crystals thus formed, after filtration and washing with ether, were pure enough for further use without purification. The yield of the crystals was about 60%.

Photoreactions of **3** with cyclopentene, cyclooctene, and tetramethylethylene were carried out in a similar way, the yield, after DCC, being 68, 84, and 87%, respectively. In the case of the last olefin, the color of the reaction solution turned deep blue after 10 minutes' irradiation. These *o*-thioquinonemethides were purified by recrystallization from dichloromethane and methanol. **4a**: mp 159—161 °C (dec); NMR ($CDCl_3$): δ 1.7—2.3 (br s, 6H), 3.8—4.4 (m, 2H), and 6.8—7.9 (m, 4H). Found: C, 57.65; H, 4.90; S, 37.35%. Calcd for $C_{12}H_{12}S_3$: C, 57.10; H, 4.79; S, 38.10%. **4c**: mp 153—154 °C (dec); NMR ($CDCl_3$): δ 1.1—2.4 (m, 12H), 3.3—3.9 (m, 1H) 4.0—4.4 (m, 1H), 6.9—7.1 (m, 2H), and 7.25—7.90 (m, 2H). Found: C, 61.46; H, 6.30; S, 32.22%. Calcd for $C_{15}H_{18}S_3$: C, 61.18; H, 6.16; S, 32.66%. **4d**: mp 137—140 °C (dec); NMR ($CDCl_3$): δ 1.22, 1.33, 1.57, and 1.76 (s, 3H each), 6.8—7.4 (m, 3H), and 7.8—8.0 (m, 1H). Found: C, 58.38; H, 6.33; S, 35.06%. Calcd for $C_{13}H_{16}S_3$: C, 58.16; H, 6.01; S, 35.83%.

Desulfurization of 4b. Tetrahydrofuran (THF) solution (8 ml) of **4b** (576 mg, 2.16 mmol) and 5 g of Raney nickel (W-4) were stirred for 6 h at room temperature and then refluxed for 4 h. The reaction solution was analyzed by high speed liquid chromatography (Hitachi 634; column: Hitachi 3010; solvent: 10: 1 methanol–28%NH_4OH (v/v)) for toluene (41%) and bibenzyl (4.6%).

Reaction of 4d with 2-Dimethylamino-3-methyl-1-butene. To **4d** (523 mg, 1.95 mmol) in a mixture (13 ml) of THF and acetonitrile (1: 3) was added 2-dimethylamino-3-methyl-1-butene (**10**; 410 mg, 3.6 mmol) and the solution was heated at reflux temperature for 6.5 h. DCC (SiO_2, 1: 1 hexane–

dichloromethane) afforded **11** (200 mg, 0.745 mmol, 38%) as white crystals. Mp 190—191 °C (from hexane); NMR ($CDCl_3$): δ 1.52 (s, 24H), 7.1—7.6 (m, 6H), and 7.9—8.1 (m, 2H). UV (EtOH): λ_{max} (log ε) 250 (sh) nm (4.22); mol wt: Found 568. Calcd for $(C_{13}H_{16}S_3)_2$ 537. Found: C, 58.02; H, 6.26; S, 35.75%. Calcd for $C_{26}H_{32}S_6$: C, 58.16; H, 6.01; S, 35.83%.

*Reaction of **4b** with N-Phenylmaleimide.* A benzene solution (4 ml) of **4b** (55 mg, 0.21 mmol) and *N*-phenylmaleimide (38 mg, 0.22 mmol) was stood overnight at room temperature. After evaporation of the solvent, the residue was purified by preparative layer chromatography (PLC) (SiO_2, benzene) to give white crystals **18** (82 mg, 93%). Mp 217—218 °C (ethanol); NMR ($CDCl_3$) δ 1.0—2.2 (m, 8H), 3.6—4.0 (m, 1H), 4.0—4.3 (m, 1H), 4.45 (s, 2H), 6.8—7.4 (m, 8H), and 8.1—8.4 (m, 1H). IR (KBr): 1710 cm^{-1} (C=O); MS: *m/e* 439 (M^+, 5%), 326 (45), and 184 (100). Found: C, 62.98; H, 4.80; N, 3.08; S, 21.67%. Calcd for $C_{23}H_{21}NO_2S_3$: C, 62.84; H, 4.82; N, 3.19; S, 21.88%.

*Reaction of **4b** with Dibenzoylacetylene.* A solution of dibenzoylacetylene (51 mg, 0.22 mmol) and **4b** (53 mg, 0.20 mmol) in benzene (4 ml) was stood overnight at room temperature. Purification by PLC (SiO_2, benzene) and recrystallization from benzene-ethanol gave **17** (83 mg, 83%) as pale yellow crystals: mp 181—183 °C; NMR ($CDCl_3$): δ 0.9—2.3 (m, 8H), 3.7—4.1 (m, 2H), and 7.0—8.2 (m, 14H); IR (KBr): 1650 and 1665 cm^{-1} (C=O); MS: *m/e* 500 (M^+, 4%), 370 (100), and 105 (80). Found: C, 69.59; H, 4.95; S, 19.13%. Calcd for $C_{29}H_{24}O_2S_3$: C, 69.57; H, 4.83; S, 19.21%.

*Reaction of **4b** with Methyl Vinyl Ketone.* A benzene solution (100 ml) of the ketone (0.82 ml, 10 mmol) and **4b** (1.01 g, 3.8 mmol) was refluxed for 5 min. The solvent was evaporated and the residue was recrystallized from benzene to afford **19** (835 mg). The filtrate was subjected to PLC (SiO_2, 1:1 dichloromethane-hexane) to afford **19** (438 mg). The total yield was 1.273 g (100%). Mp 155—156 °C (from benzene); NMR ($CDCl_3$): δ 1.0—2.5 (m, 8H), 2.25 (s, 3H), 2.8—4.4 (m, 5H), 6.8—7.4 (m, 3H), 8.1—8.4 (m, 1H); IR (KBr): 1715 cm^{-1} (C=O); MS: *m/e* 336 (M^+, 2%), 184 (81), and 43 (100). Found: C, 60.79; H, 6.07; S, 28.49%. Calcd for $C_{17}H_{20}OS_3$: C, 60.67; H, 6.00; S, 28.58%.

*Raney Nickel Desulfurization of **19**.* To a solution of **19** (803 mg, 2.4 mmol) in benzene (50 ml) was added Raney nickel (W-4) prepared from Raney alloy (7 g) and the mixture was refluxed for 2.5 h with stirring. Raney nickel was removed by filtration and the filtrate was evaporated under reduced pressure. The residue was subjected to DCC (SiO_2, 1:1 dichloromethane-hexane) to afford oily compounds **20** (246 mg, 63.5%) and **21** (45 mg, 11.5%). **20**: NMR (CCl_4): δ 1.04 (d, J=6 Hz, 3H), 1.95 (s, 3H), 2.1—3.0 (m, 3H), and 7.0—7.3 (m, 5H); MS: *m/e* 162 (M^+, 5.9%) and 43 (100); IR (neat): 1710 cm^{-1} (C=O). **21**: NMR (CCl_4): δ 0.79, 0.83 (a pair of doublet due to diastereomers, J=7 Hz, 3H), 1.15 (d, J=5 Hz, 3H), 1.64 (br s, 1H, disappeared by D_2O), 2.0—3.1 (m, 3H), 3.4—3.9 (m, 1H), and 7.1 (br s, 5H); MS: *m/e* 164 (M^+, 2.3%) and 91 (100); IR (neat): 3100—3600 cm^{-1} (OH).

*Reaction of **4b** with Acrylamide.* A dichloromethane solution (50 ml) of acrylamide (1.163 g, 16.4 mmol), **4b** (248 mg, 0.94 mmol), and a small amount of hydroquinone was allowed to stand at room temperature for a week. The solution was washed with water, dried (Na_2SO_4), and the solvent was evaporated. The residue was washed with a small amount of dichloromethane to give white crystals **22** (198 mg, 63.8%). Mp 242.5—243.0 °C (dec) (from ethanol); NMR (DMSO-d_6): δ 1.0—2.3 (m, 8H), 2.9—4.2 (m, 7H), 6.7—7.6 (m, 3H), and 8.0—8.4 (m, 1H); MS: *m/e* 337 (M^+, 11%), 184 (84), and 179 (100); IR (KBr): 3480, 3370 (NH), 1695 cm^{-1} (C=O). Found: C, 56.95; H, 6.09; N, 4.10; S, 28.11%. Calcd for $C_{16}H_{19}NOS_3$: C, 56.94; H, 5.67; N, 4.15; S, 28.50%.

*Reactions of **4b** with Fumaronitrile and Maleonitrile.* Fumaronitrile (238 mg, 3.05 mmol) and **4b** (396 mg, 1.48 mmol) dissolved in dichloromethane (30 ml) were stood for 2 days at room temperature. After removal of the solvent, the NMR (in $CDCl_3$) of the residue was taken for methine protons of the dihydrobenzothiopyran ring. The two methine protons appeared as two sets of AX type double doublet whose intensity ratio was 5:1; the major one: δ 3.69, 3.84, 4.67, and 4.82; the minor one: δ 3.80, 3.54, 4.52, and 4.67. No signal due to *cis*-isomer **23a** was observed. In order to remove excess fumaronitrile the crude reaction mixture was twice washed with ethanol giving **23b** (453 mg, 88%). Since some isomerization was observed during purification by TLC (SiO_2), **23b** thus obtained was purified by repeated recrystallization from ethyl acetate to give a pure specimen of the major isomer; mp 154—157 °C; NMR ($CDCl_3$): δ 1.78 (m, 8H), 4.27 (m, 2H), 3.76 (d, J=9.1 Hz, 1H), 4.74 (d, J=9.1 Hz, 1H), 7.25 (m, 3H), and 8.25 (m, 1H); IR (KBr): 2240 cm^{-1} (CN); MS: *m/e* 344 (M^+, 17%) and 184 (100). Found: C, 59.43; H, 4.57; N, 8.26; S, 27.87%. Calcd for $C_{17}H_{16}N_2S_3$: C, 59.27; H, 4.68; N, 8.13; S, 27.92%.

Dichloromethane solution (20 ml) of maleonitrile (154 mg, 1.97 mmol) and **4b** (263 mg, 0.99 mmol) was stood for 1 day at room temperature. The crude reaction mixture was checked for the methine protons by NMR as above. There were found two sets of double doublets, the chemical shifts being δ 4.06, 4.12, 5.07, and 5.13 for the major one, and 4.12, 4.19, 4.92, and 4.99 for the minor one with no signal of **23b**. The reaction mixture was washed with ethanol to afford **23a** (276 mg, 66%), which was recrystallized from ethyl acetate to give the major isomer contaminated with a small amount of the minor isomer (by NMR); mp 168—170 °C; NMR ($CDCl_3$): δ 1.84 (m, 8H), 3.98 (m, 2H), 4.04 (d, J=3.4 Hz, 1H), 5.08 (d, J=3.4 Hz, 1H), 7.15 (m, 3H), and 8.17 (m, 1H); IR (KBr): 2240 cm^{-1} (CN); MS: *m/e* 344 (M^+, 17%) and 184 (100). Found: C, 59.54; H, 4.76; N, 8.20; S, 27.68%. Calcd for $C_{17}H_{16}N_2S_3$: C, 59.27; H, 4.68; N, 8.13; S, 27.92%.

*Reaction of **4b** with Diphenylketene.* Diphenylketene (260 mg, 1.34 mmol) in benzene (10 ml) was added slowly to a solution of **4b** (261 mg, 0.98 mmol) in benzene (20 ml).

The color of the solution turned very rapidly from deep blue to yellow, but slowly reverted to blue. After all the solution was added the color did not revert to blue. The solution was kept at 40 °C for 30 min. After removal of the solvent, the residue was subjected to DCC (SiO_2, 1:3 chloroform-carbon tetrachloride) at about 0 °C to give two fractions, one (201.8 mg) containing **27** and **28** and the other (126.8 mg) containing **28**. PLC (SiO_2, 1:1 hexane–ether) was twice carried out at about 0 °C to obtain **27**, but it was unstable because of isomerization to **28** or decomposition to **4b** when heated in solution or left on silica gel for a long time. The total yield of **27** and **28** was 73%. **28** was stable and purified by recrystallization from ethanol. **28**: mp 222.0—223.5 °C (from ethanol); NMR ($CDCl_3$): δ 1.0—2.5 (m, 8H), 2.5—3.0 (m, 1H), 3.2—4.6 (m, 1H), 6.7—7.6 (m, 13H), and 8.3—8.7 (m, 1H); MS: *m/e* 460 (M^+, 3%) and 184 (100); IR (KBr): 1670 cm^{-1} (C=O). Found: C, 69.92; H, 5.20; S, 20.56%. Calcd for $C_{27}H_{24}OS_3$: C, 70.40; H, 5.25; S, 20.88%. **27**: NMR ($CDCl_3$): δ 1.0—2.3 (m, 8H), 3.3—3.7 (m, 2H), 6.7—7.5 (m, 13H), and 7.6—8.1 (m, 1H); IR (KBr): 1587 1580 cm^{-1} (C=C).

*Reaction of **4b** with Phenyl Isocyanate.* A benzene solution (50 ml) of **4b** (536 mg, 2.0 mmol) and phenyl isocyanate

(242 mg, 2.0 mmol) was allowed to stand for 6 days at room temperature. The solvent was evaporated under reduced pressure and the residue was subjected to DCC (SiO_2, chloroform) to give **29** (677 mg, 88%). Mp 164.5—166.0 °C (from benzene); NMR ($CDCl_3$): δ 1.0—2.3 (m, 8H), 3.5—3.9 (m, 2H), 7.1—7.6 (m, 8H), and 8.1—8.4 (m, 1H); IR (KBr): 1650 cm^{-1} (C=O); MS: *m/e* 385 (M^+, 0.4%) and 119 (100). Found: C, 62.20; H, 4.86; N, 3.53; S, 24.70%. Calcd for $C_{20}H_{19}NOS_3$: C, 62.30; H, 4.97; N, 3.63; S, 24.95%.

*Reaction of **4b** with Phenyl Isothiocyanate.* A solution of **4b** (246 mg, 0.92 mmol) and phenyl isothiocyanate (249 mg, 1.84 mmol) in benzene (25 ml) was refluxed for 21 h under argon atmosphere. The solvent was evaporated and the residue was subjected to PLC (SiO_2, benzene) to give crude **31** (269 mg, 73%). Although **31** was stable in solution in the presence of excess phenyl isothiocyanate, it was unstable, if the isothiocyanate was removed, and slowly decomposed to **4b** and phenyl isothiocyanate, thus precluding the isolation of an analytically pure specimen. Among the decomposition product there was formed a small amount of product (15 mg, 4%) tentatively assigned as **30**. **31**: mp 46—52 °C (white crystals from hexane); NMR (CCl_4): δ 1.0—2.4 (m, 8H), 3.6—4.1 (m, 2H), 6.7—7.5 (m, 8H), and 7.9—8.3 (m, 1H); UV (cyclohexane): λ_{max} (ε) 318 (7330), 275 (11400), and 244 (sh) nm (17200); IR (KBr): 1565 cm^{-1} (CN). **30**: NMR (CCl_4): δ 1.0—2.0 (m, 8H), 3.6—3.9 (m, 2H), 7.1—7.5 (m, 8H), and 7.9—8.3 (m, 1H); IR (KBr): no band due to C=N.

*Reduction of **4b** with Lithium Aluminum Hydride.* Lithium aluminum hydride (120 mg, 3.2 mmol) was added to a THF solution (50 ml) of **4b** (269 mg, 1.0 mmol) with stirring under nitrogen atmosphere, and the mixture was refluxed for 5 h. Though a small amount of **4b** still remained, 10% aq sodium hydroxide and methyl iodide (0.5 ml) were added successively with stirring. The solvent was evaporated under reduced pressure, and ether was added. The ethereal solution was washed with water, dried and the ether was evaporated. The residue was subjected to DCC (SiO_2, 1: 1 hexane–ether) to give **33** (184 mg, 64.4%) and a trace amount of 2-methylthiobenzyl alcohol (by NMR). When the reaction mixture was treated with dil sulfuric acid instead of aq sodium hydroxide and methyl iodide, the product was **34** (24%), which was unstable and was rapidly oxidized by air to afford **4b**. **33**: mp 107.0—109.0 °C (from ethanol); NMR ($CDCl_3$): δ 1.0—2.5 (m, 8H), 2.49 (s, 3H), 3.7—4.1 (m, 2H), 6.38 (s, 1H), 7.1—7.4 (m, 3H), and 7.8—8.2 (m, 1H); MS: *m/e* 282 (M^+, 19%) and 153 (100). Found: C, 59.60; H, 6.17; S, 33.89%. Calcd for $C_{14}H_{18}S_3$: C, 59.53; H, 6.42; S, 34.05%. **34**: NMR ($CDCl_3$): δ 1.0—2.5 (m, 8H), 3.55 (s, 1H), 3.6—4.0 (m, 2H), 6.14 (s, 1H), 7.0—7.5 (m, 3H), and 7.7—8.2 (m, 1H).

(Received June 28, 1978)

Although bis[2(1*H*)-pyridinethionato]zinc (**1**) is prepared by the reaction of 2(1*H*)-pyridinethione with zinc chloride in the presence of stoichiometric amount of sodium hydroxide, a similar reaction in the presence of a large excess amount of the base gave μ_4-oxo-hexakis-μ-[2(1*H*)-pyridinethionato-(*N*,*S*)]-tetrazinc (**2**) which is the first example of L_6Zn_4O (L=ligand) type complexes having heterocyclic thiolato groups as ligands. The complex **2** was also prepared by several routes, which involve hydrolysis of **1** and the reaction of **1** with zinc oxide. In these complexes 2(1*H*)-pyridinethionato ligand acts as a bidentate or bridging ligand. Attempts to convert bis-(4,6-dimethyl-2-pyridylthio)zinc or bis(1-oxido-2-pyridylthio)zinc into a complex of L_6Zn_4O type were failed. Complexes of L_6Zn_4O type were also prepared when L were 2-thiazolidinethionato, 5-methyl-2-thiazolidinethionato, and 1-methyl-4-imidazoline-2-thionato.

In the previous papers,[1,2] the synthesis and the molecular structure of dichlorobis[2(1*H*)-pyridinethionato]-tin(IV) were reported. The 2(1*H*)-pyridinethionato ligands act as bidentate ligands in the complex, which has an octahedral structure resulted from the intra-molecular four-membered (Sn, S, C, and N) chelate rings formation.

Several metal (Ru,[3,4] Ir,[5] Fe,[6] Rh,[7] Hg[8]) derivatives of 2(1*H*)-pyridinethione have been reported. The 2-pyridylthio group acts as a bidentate,[3,5] unidentate,[6-8] or bridging ligand.[4]

We have studied zinc derivatives of 2(1*H*)-pyridinethione. This paper deals with the transformation of bis[2(1*H*)-pyridinethionato]zinc (**1**) into a new zinc complex, μ_4-oxo-hexakis-μ-[2(1*H*)-pyridinethionato-(*N*,*S*)]-tetrazinc (**2**) and an observation on the coordination of 2(1*H*)-pyridinethionato ligand in **1** and **2**. This paper also describes syntheses of several new zinc derivatives of heterocyclic thiols.

Results and Discussion

Syntheses. Bis[2(1*H*)-pyridinethionato]zinc (**1**) is briefly reported in a patent,[9] but no characterization of **1** is described. The zinc derivative **1** was obtained as a sole product when the molar ratio of the three reactants was stoichiometric (2: 1: 2), as shown in Eq. 1.

$$2PySH + ZnCl_2 + 2NaOH \longrightarrow (PyS)_2Zn + 2NaCl + 2H_2O \quad (1)$$

$$8PySH + 4ZnCl_2 + 10NaOH \longrightarrow (PyS)_6Zn_4O + 8NaCl + 2PySNa + 9H_2O \quad (2)$$

When the reaction was performed in the presence of a large excess amount of sodium hydroxide, a new complex μ_4-oxo-hexakis-μ-[2(1*H*)-pyridinethionato-(*N*,*S*)]-tetrazinc (**2**) was found to be formed according to Eq. 2.

The complex **2** was best prepared by the reaction in a molar ratio of 3: 2: 4 as shown in Scheme 1. The composition of **2** was determined by elemental analyses, alternative synthetic reactions, and the reaction with 2(1*H*)-pyridinethione giving again **1**. The complex **2** was alternatively prepared by several routes as shown in Scheme 1.

$$6PySH + 4ZnCl_2 + 8NaOH \xrightarrow{-8NaCl,\ -7H_2O} \mathbf{2}$$

$$4\,\mathbf{1} + H_2O \underset{}{\overset{-2PySH}{\rightleftharpoons}} \mathbf{2}$$

$$3\,\mathbf{1} + ZnO \longrightarrow \mathbf{2}$$

$$6PySH + 4ZnO \xrightarrow{-3H_2O} \mathbf{2}$$

Scheme 1. Syntheses of μ_4-oxo-hexakis-μ-[2(1*H*)-pyridinethionato-(*N*,*S*)]-tetrazinc (**2**).

When a suspension of **1** in water was refluxed for 1 h, **2** was obtained as an insoluble product and 2(1*H*)-pyridinethione was recovered from the aqueous solution in a quantitative yield based on the equation shown in Scheme 1. A treatment of **1** with zinc oxide in a molar ratio of 3: 1 in refluxing acetonitrile also gave **2**. A reaction of 2(1*H*)-pyridinethione and zinc oxide in a molar ratio of 3: 2 in 1,2-dichloroethane yielded **2**. In contrast, complex **1** was obtained by the reaction of the same reagents in a molar ratio of 2: 1 in boiling benzene with azeotropical removal of water formed.[10]

When **2** was treated with twice molar amount of 2(1*H*)-pyridinethione in boiling benzene under azeotropical removal of water produced, **1** was again obtained in a quantitative yield.

Bis(4,6-dimethyl-2-pyridylthio)zinc (**3**) was prepared from 4,6-dimethyl-2(1*H*)-pyridinethione by a reaction similar to Eq. 1 and by a reaction of bis(4,6-dimethyl-2-pyridyl) disulfide with zinc dust.[11] Transformations of **3** and bis(1-oxido-2-pyridylthio)zinc into the complexes of L_6Zn_4O (L=ligand) type were attempted by heating L_2Zn compounds in water, but the major amount of starting materials was recovered, and the expected complexes could not be obtained.

Although a large number of bis(organo ligand)zinc are known, there have been reported only four types of L_6Zn_4O complex formed with alkanecarboxylato,[12] *O*,*O*-dialkyl(or diaryl)phosphorodithioato,[13] dialkylphosphinothioato,[14] and 1,3-diphenyltriazenato.[15] The complex **2** is the first example of oxotetrazinc complex, where the ligand is a heterocyclic thiolato group. Syntheses of several other complexes of L_6Zn_4O type where L is a heterocyclic thiolato group were examined. Complexes of L_6Zn_4O type were synthesized by the re-

action of 2-thiazolidinethione (**4**), 5-methyl-2-thiazolidinethione (**5**), 1-methyl-4-imidazoline-2-thione (**6**) with zinc chloride in the presence of sodium hydroxide (molar ratio of 3: 2: 4) in an aqueous solution. The results are shown in Table 1. However, L_2Zn derivatives of these five membered heterocyclic thiols could not be prepared by the reaction of the thiols with zinc chloride in the molar ratio of 2: 1. Bis(1-methyl-4-imidazoline-2-thionato)zinc (**7**) could be prepared only by the reaction of hexakis-μ-(1-methyl-4-imidazoline-2-thionato)-μ_4-oxo-tetrazinc (**8**) with the thione **6**. Attempts to prepare L_2Zn derivatives of **4** and **5** were unsuccessful by analogous reactions from the corresponding L_6Zn_4O type complexes.

Observation on Structure. The MS spectrum (double focus) of **1** exhibits a very weak dizinc-containing polyisotopic molecular ion (*m/e* 568) as the highest mass feature, which corresponds to the parent peak of the dimer. Three dizinc-containing molecular ions observed at *m/e* 490 (M—Py), 458 (major peak, M—PyS), 426 (M—PyS—S) seem to be fragments derived from the dimer, and a monozinc-containing molecular ion at *m/e* 316 [$(PyS)_2ZnS$] is also indicative for dimeric structure of **1**. Molecular weight measurement (osmometry) showed that **1** was dimeric in 4-methyl-2-pentanone.[16]

The IR spectrum of **1** exhibits bands due to ring vibration at 1595 (s), 1545 (s), 1455 (s, doublet), 1420 (s, doublet), 1020 (m), 645 cm^{-1} (w), and the bands due to C–H bending vibration at 765(sh) and 755 cm^{-1} (s).[1,17] The bands at 1020 and 645 cm^{-1} have shoulders. The absorption pattern is close to that of dichlorobis[2(1*H*)-pyridinethionato]tin(IV).[18] This fact suggests that 2(1*H*)-pyridinethionato ligands act as bidentate ligands. These bands all shifted in higher frequency region in comparison with the corresponding bands of di-2-pyridyl disulfide.[1] The shift can be interpreted by the coordination of pyridine nucleus through nitrogen to tin atom. A strong intensity absorption band appears at 1135 cm^{-1} in the spectrum of **1**, which can be assigned to C=S stretching since 2(1*H*)-pyridinethione shows the strong absorption of C=S stretching at the same position.[19] This band indicates the presence of 2(1*H*)-pyridinethionato ligand of thione form, whose coordination to zinc through sulfur atom is weak as in the iridium complex.[5] Based on these spectral data 2(1*H*)-pyridinethionato ligands act as bidentate or bridging one and **1** seems not monomeric.

Molecular weight of **2** could not be determined owing to the low solubility to the ordinary solvent for osmometric measurement. The MS spectrum (chemical ionization with isobutane) of **2** exhibits the zinc-containing, polyisotopic molecular ion (*m/e* 839) as the highest mass feature which corresponds to species resulting from loss of one pyridyl group and one oxygen atom from [M+H]. The remaining major peaks (*m/e* 743, 568, 459) in the spectrum can be assigned to species resulting from loss of one or more 2(1*H*)-pyridinethionato groups, zinc atoms, and oxygen atom from [M+H] or [M].

The IR absorption pattern of **2** in the region higher than 600 cm^{-1} is very close to that of **1**, except that the bands at 1455, 1410, 1010, and 645 cm^{-1} in **2** are all single peaks. This fact seems to suggest that six 2(1*H*)-pyridinethionato ligands in **2** are in chemically similar states. The characteristic absorption band of **2** is a broad triplet with medium intensity, whose peaks are at 540, 530, and 515 cm^{-1}. The broad and strong intensity absorption bands of zinc oxide in the 540—400 cm^{-1} spectral region were replaced with the triplet bands, when zinc oxide was allowed to react with **1** to give **2**. The triplet bands can be ascribed to Zn–O bond, since the absorptions of zinc–sulfur vibrations have been described to appear in the region lower than 401 cm^{-1} in several compounds containing Zn–S bond,[20] and the absorptions due to Zn–N bond are found between 250 and 200 cm^{-1} in complexes of pyridine compound with zinc halides.[21] The band at 526 cm^{-1} in hexa-μ-acetato-(O,O')-μ_4-oxo-tetrazinc has been assigned to $\nu(Zn_4O)$.[22]

The structures of L_6Zn_4O complexes where L is AcO, $(BuO)_2PS_2$, or Ph_2N_3 have been determined by X-ray analyses.[12a,13a,15] The replacement of –O–C–O–, –S–P–S–, or –N–N–N– moiety in the structures of those complexes with –S–C–N– moiety gives a possible structure for **2** as shown in Fig. 1. The IR spectral observation mentioned above supports the structure for **2**.

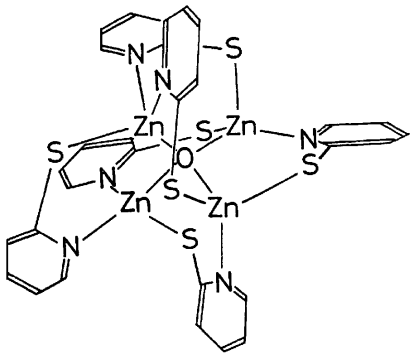

Fig. 1. A possible structure for **2**.

The transformation of **1** into **2** can be explained by the substitution of one 2(1*H*)-pyridinethionato ligand in the dimer of **1** with oxygen of water or zinc oxide and the simultaneous or subsequent coupling of two $(PyS)_3Zn_2$ group through the oxygen, as shown in Eq. 3 or 4.

$$2(PyS)_3Zn_2(SPy) + H_2O \longrightarrow [(PyS)_3Zn_2]_2O + 2HSPy \quad (3)$$

$$2(PyS)_3Zn_2(SPy) + ZnO \longrightarrow [(PyS)_3Zn_2]_2O + Zn(SPy)_2 \quad (4)$$

$$[2Zn(SPy)_2 \longrightarrow (PyS)_3Zn_2(SPy)]$$

Bis(4,6-dimethyl-2-pyridylthio)zinc (**3**) is monomeric based on the molecular weight (osmometry) and MS spectrum. No remarkable difference is observed in the IR spectrum of C=C/C=N stretching region and C=S stretching region between **3** and bis(4,6-dimethyl-2-pyridyl) disulfide. Furthermore, there was not recognized such a shift of bands due to ring vibration and C–H bending vibration as observed between **1** and the corresponding disulfide. These data show that **3** is a simple zinc salt of a thiol and no such strong coordination of pyridine ring through nitrogen on metal is observed as in the case of **1**. This may be a reason why **3** could not be converted to a complex of L_6Zn_4O type.

Experimental

All the melting points were determined in a liquid bath placing a cut edge of capillary outside of the bath, and were uncorrected. The IR spectra were measured with a Hitachi Perkin-Elmer 225 and a Hitachi EPI-G2 Grating Infrared Spectrometer. The molecular weight was determined in 4-methyl-2-pentanone with a Hitachi 115 Vapor Pressure Osmometer. The MS spectra were measured with a Hitachi M60 Mass Spectrometer equipped with computer system 002B, a Hitachi M52 Mass Spectrometer, or a JMS-01SG-2 Double Focus Mass Spectrometer.

Materials. Commercial anhydrous zinc chloride was used after drying over phosphorus pentaoxide. Commercial 2(1*H*)-pyridinethione, 2-thiazolidinethione (**4**), and 1-methyl-4-imidazoline-2-thione (**6**) were used after recrystallization. 5-Methyl-2-thiazolidinethione (**5**) was prepared by the procedure previously reported.[23]

Bis[2(1H)-pyridinethionato]zinc (1). a) Reaction of 2(1H)-Pyridinethione with Zinc Chloride in the Presence of Base: To an aqueous solution of sodium hydroxide (1/2 M, 20 ml) was added 2(1*H*)-pyridinethione (1.11 g, 10 mmol). To the resulting solution was added drop by drop a solution of zinc chloride (95%, 0.72 g, 5 mmol) in water (15 ml) with stirring at 20 °C and the mixture was stirred at 20 °C for 2 h. The resulting slightly yellowish precipitate was filtered and washed with water (50 ml) to give 1.41 g (99%) of **1**; mp 248—251 °C.[24] Mol wt, Found: 603; Calcd (dimer): 571. Found: C, 42.07; H, 2.75; N, 9.68; S, 22.46%. Calcd for $C_{10}H_8N_2S_2Zn$: C, 42.04; H, 2.82; N, 9.81; S, 22.45%.

b) Reaction of 2(1H)-Pyridinethione with Zinc Oxide: To a suspension of zinc oxide (0.81 g, 10 mmol) in benzene (150 ml) was added 2(1*H*)-pyridinethione (2.44 g, 22 mol). A mixture was stirred at room temperature for 1 h and then refluxed for 5 h, during which boiling benzene was gradually distilled out to remove water azeotropically, while dried benzene was supplied to the mixture at intervals. The precipitate was collected by filtration and washed with benzene (60 ml) to give 2.73 g (96%) of slightly yellowish powder. The IR spectrum of the powder was identical with that of **1**.

μ_4-Oxo-hexakis-μ-[2(1H)-pyridinethionato-(N,S)]tetrazinc (2). a) Reaction of 2(1H)-Pyridinethione with Zinc Salt in the Presence of Base in Water: A solution of zinc chloride (95%, 0.72 g, 5 mmol) in water (30 ml) was added drop by drop to a solution of 2(1*H*)-pyridinethione (0.83 g, 7.5 mmol) in 1/2 M aqueous sodium hydroxide (20 ml) with stirring at room temperature. After stirring the mixture at room temperature for 22 h, the precipitate was collected by filtration and washed with water (50 ml) to give 1.12 g (96%) of colorless crystalline powder: mp above 340 °C (gradually dec).[25] MS (CI): *m/e* 839 $[(PyS)_5Zn_4SH]$, 820 $[(PyS)_5(Py)Zn_3]$, 743 $[(PyS)_5Zn_3H]$, 727 $[(PyS)_4(Py)Zn_3OH]$, 664 $[(PyS)_4Zn_3S]$, 632 $[(PyS)_4Zn_3]$, 608, 568 $[(PyS)_4Zn_2]$, 554 $[(PyS)_3Zn_3S]$, 536 $[(PyS)_3(Py)Zn_2]$, 491 $[(PyS)_3Zn_2SH]$, and 459 $[(PyS)_3Zn_2H]$.

b) Hydrolysis of 1: A suspension of **1** (10.0 g, 35 mmol) in water (200 ml) was refluxed for 1 h. The precipitate was collected by filtration and washed with water (50 ml) to give 8.13 g (99%) of colorless crystalline powder. The IR spectrum of the solid was identical with that of **2**. The filtrate separated from **2** and washings were combined and concentrated under reduced pressure. The residue was extracted with acetone (100 ml). The acetone extract was concentrated under reduced pressure to give 1.95 g (100%) of 2(1*H*)-pyridinethione as yellow crystals; mp 124—126 °C (lit, mp 125 °C[26]). When **1** was treated in boiling water for 28 h, the same product was obtained without further decomposition. Found: C, 38.48; H, 2.66; N, 8.96; S, 20.25; Zn, 27.43%. Calcd: Zn, 27.87%.

c) Reaction of 1 with Zinc Oxide: A mixture of **1** (4.29 g, 15 mmol) and zinc oxide (0.41 g, 5 mmol) in acetonitrile (100 ml) was refluxed for 4 h. The precipitate was collected by filtration and washed with acetonitrile (40 ml) to give 4.54 g (97%) of colorless crystalline powder. The IR spectrum of the solid was identical with that of **2**.

d) Reaction of 2(1H)-Pyridinethione with Zinc Oxide: Zinc oxide (1.63 g, 20 mmol) was added to a solution of 2(1*H*)-pyridinethione (3.34 g, 30 mmol) in 1,2-dichloroethane (100 ml) and the mixture was stirred at room temperature for 5 h. The precipitate was collected by filtration and washed with 1,2-dichloroethane (40 ml) to give 4.41 g (94%) of crystalline powder. The IR spectrum of the solid was iden-

tical with that of **2**.

*Reaction of **2** with 2(1H)-Pyridinethione.* To a solution of 2(1*H*)-Pyridinethione (0.53 g, 4.8 mmol) in benzene (100 ml) was added **2** (1.88 g, 2 mmol) and the mixture was refluxed for 5 h, during which boiling benzene was gradually distilled out in order to remove water azeotropically, while dried benzene was supplied to the mixture at intervals. The precipitate was collected by filtration and washed with benzene (50 ml) to give 2.22 g (97%) of slightly yellowish solid. The IR spectrum of the solid was essentially identical with that of **1**.

Bis(4,6-dimethyl-2-pyridylthio)zinc (3). *a) Reaction of 4,6-Dimethyl-2(1H)-pyridinethione with Zinc Chloride in the Presence of Base*: To an aqueous solution of sodium hydroxide (1/2 M, 4.6 ml) was added 4,6-dimethyl-2(1*H*)-pyridinethione 0.28 g, 2 mmol). To the resulting solution was added drop by drop a solution of zinc chloride (95%, 0.14 g, 1 mmol) in water (20 ml) with stirring at 20 °C and the mixture was stirred for 2.5 h. The precipitate was collected by filtration and washed with water to give 0.29 g of colorless solid. The solid was recrystallized from 90 ml of ethanol to give 0.10 g (29%) of prisms; mp 250—252 °C (dec). IR (KBr): 1595s, 1545 s, 1450 m, 1395 m, 1370 m, 1275 m, 1205 m, 1135 m, 875 m, 840 m, 825 m, 535 w, 530 m, 430 w, 270 w(br), and 235 m(br) cm^{-1}. Mol wt, Found: 364; Calcd (monomer): 342. MS(EI): *m/e* 340 (M), 325, 307, and 202. Found: C, 49.15; H, 4.65; N, 8.24; S, 18.81%. Calcd for $C_{14}H_{16}N_2S_2Zn$: C, 49.20; H, 4.72; N, 8.20; S, 18.76%.

b) Reaction of Bis(4,6-dimethyl-2-pyridyl) Disulfide with Zinc Dust: A mixture of bis(4,6-dimethyl-2-pyridyl)disulfide (5.00 g, 18 mmol) and zinc dust (1.18 g, 18 mg atom) in benzene (100 ml) was refluxed for 26 h. The reaction mixture was filtered to give 4.53 g of a mixture of white powdery solid and zinc dust, which was extracted by Soxhlet's extractor with benzene for 10 h. Colorless crystals were obtained from the extract. Yield 3.08 g (50%); mp 251—252 °C (dec). The IR spectrum of the crystals was identical with that of **3** obtained in a).

Bis(1-methyl-4-imidazoline-2-thionato)zinc (7). A mixture of hexakis-μ-(1-methyl-4-imidazoline-2-thionato)-μ_4-oxotetrazinc (**8**) (0.96 g, 1 mmol) and 1-methyl-4-imidazoline-2-thione (**6**) (0.46 g, 4 mmol) in benzene (100 ml) was refluxed for 15 h, during which benzene was gradually distilled out in order to remove water azeotropically, while dried benzene was supplied to the mixture at intervals. The precipitate was collected by filtration and washed with benzene (50 ml) to give 1.11 g of colorless solid. The solid (0.48 g) was added again to a solution of **6** (0.46 g, 4 mmol) in benzene (200 ml). The mixture was refluxed for 2.5 h, during which benzene was distilled out and supplied in the same manner mentioned above. The precipitate was collected by filtration and washed with benzene (50 ml) to give 0.44 g of colorless solid; mp above 300 °C (gradually dec). IR (KBr): 1575w, 1535m, 1455s, 1410m, 1370s, 1315m, 1285s, 1145s, 1085w, 955m, 725m (br), 690s, 510m, 435w, 315w, and 250w cm^{-1}. MS(CI): *m/e* 853 [$(LS)_5Zn_4S$] (LSH=**6**), 837 [$(LS)_5LZn_3$-H], 547 [$(LS)_3LZn_2$-H], 467 [$(LS)_3Zn_2$], 403 [$(LS)L_2Zn_2$], 331, 291 [$(LS)_2ZnH$], and 115 [LSH_2]. Found: C, 33.16; H, 3.25; N, 19.26; S, 21.84%. Calcd for $C_8H_{10}N_4S_2Zn$: C, 32.94; H, 3.46; N, 19.26; S, 21.98%.

16) A referee pointed out a possibility that **1** may be polymeric and dissociates into dimeric form in 4-methyl-2-pentanone. Although a higher association of the dimer is possible in crystalline state, the dimeric form seems to be a basic unit for bis[2(1*H*)-pyridinethionato]zinc based on not only MS data of crystals and osmometric molecular weight determination, but also the reaction of **2** with benzoyl chloride giving chlorotris[2(1*H*)-pyridinethionato]dizinc and benzoylthiopyridine: S. Matsunami, S. Fujimura, K. Okimoto, and M. Masaki, submitted for publication to *Bull. Chem. Soc. Jpn.*

17) In a previous report,[1] we assigned the band at 710 or 720 cm^{-1} in di-2-pyridyl disulfide or 2(1*H*)pyridinethionatotin(IV) complex to a C-H bending vibration based on literatures: S. P. Sinha, *Spectrochim. Acta*, **20**, 879 (1964); H. Shindo and N. Ikekawa, *Chem. Pharm. Bull.*, **4**, 192 (1965). However, it seems to be more probable to assign these bands to C–C ring deformations: N. S. Gill and H. J. Kingdon, *Aust. J. Chem.*, **19**, 2197 (1966). Complexes **1** and **2** also exhibit medium intensity bands at 725 cm^{-1} assignable to the C-C ring deformation. The shift of the bands to higher frequency region compared with that of di-2-pyridyl disulfide seems also to indicate the coordination of pyridine nucleus to zinc.

18) The bands corresponding to those bands at 1455, 1420, 1020, and 645 cm^{-1} in **1** are singlets in the spectrum of dichlorobis[2(1*H*)-pyridinethionato]tin(IV).

Substituent Effects in Heterogeneous Catalysis. III. Competitive Hydrogenation of Cyclohexanone and 2-Alkylcyclohexanones over Platinum Group Metals

Teiji CHIHARA and Kazunori TANAKA*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 3, 1978)

Cyclohexanone (**1**) and one of its 2-alkyl (methyl, ethyl, or propyl) derivatives (**2**) were hydrogenated competitively at 30 °C in cyclohexane over platinum group metals. The alkyl derivatives **2** were all less reactive than **1** on all the catalysts used. The relative reactivity R_2/R_1 was given by $\log_{10}(R_2/R_1)=\sigma^{**}+\kappa$, with σ^{**} depending only upon the substituent and κ upon the catalyst. The greater the substituent size, the more negative was the substituent constant σ^{**}. The catalyst-dependent constant κ was in general more negative for a catalyst metal having a smaller atomic radius. The above empirical rate expression has been interpreted based on the absolute reaction rate theory. The σ^{**} values calculated on this theoretical ground were in excellent agreement with the observed values.

Substituent effects in homogeneous reactions have been extensively studied, but relatively little work on heterogeneous catalysis has been reported. Especially, the influence of catalyst properties on the substituent effects is still to be explored. Although the application of Hammett-type equations to heterogeneous catalysis was attempted by Kraus,[1] it was successful for only half of the data tested. Besides, it is not always clear why the relative hydrogenation rate should correlate with σ or σ^*. Thus it seems desirable to seek a new approach to the substituent effects in heterogeneous catalysis. The present series of studies has this primary aim. In the first paper[2] of this series, methyl substituent effects in cyclohexanone (**1**) hydrogenation were investigated by means of competitive reactions of cyclohexanone and one of its methyl derivatives over platinum group metals. The relative rates observed were discussed in relation to the reaction mechanism and the atomic radius of the catalyst metal.

The present work extends this comparative study to include 2-ethyl- and 2-propylcyclohexanone (**2e** and **2p**). The main purpose of this extension is to see how the substituent size affects the hydrogenation rate. The experiments with 2-methylcyclohexanone (**2m**) were repeated to make a comparison with **2e** and **2p** under strictly identical conditions including catalyst preparation and preservation.

Experimental

Materials. Cyclohexane (Wako Pure Chemical Ind., "special grade") was used without further purification after determining its purity to be 99.96% by GLPC on an Apiezon Grease L column. **1** and **2m** were also commercial products and distilled before use. **2e** was prepared by hydrogenation of 2-acetylphenol over Raney-Ni[3] followed by chromic acid oxidation.[4] Distillation under reduced pressure gave **2e** as a liquid: bp 71.0 °C/17 mmHg. **2p** was prepared in a similar manner using 2-allylphenol as the starting material. Distillation under reduced pressure gave **2p** as a liquid: 86.7 °C/17.5 mmHg. The purity of these ketones was greater than 99% by gas chromatography.

All the catalysts used were unsupported metal powders, and prepared by reduction of the corresponding metal oxides or hydroxides. The procedure for the preparation was described previously[2] except for Pt. The Pt catalyst was prepared using $PtCl_2$ (Mitsuwa Yakuhin Kagaku KK) as a starting material. To a hot suspension of $PtCl_2$ (1 g) in dilute HCl (2000 ml) was added 5—10% aqueous NaOH in small portions until the pH reached 8. The resulting black hydroxide suspension was simmered for 30 min and then filtered off. The hydroxide was washed repeatedly with water until the washings were neutral, transferred into a 100 ml autoclave, and about 20 ml of water was added. The hydroxide was reduced with stirring for 20 min at temperatures up to 30 °C and an initial hydrogen pressure of 80 atm. The resulting metal black was filtered off, washed with water until the washings were neutral, dried under reduced pressure, and stored over silica gel.

Kinetic Procedures. Competitive hydrogenations were conducted at 30 °C and in hydrogen of atmospheric pressure using an equimolar mixture of **1** and **2** in cyclohexane (0.5 mol/l of each ketone). Reaction mixtures were analyzed by gas chromatography on a column of 10 wt % bis(2,3-dihydroxypropyl) ether on 60—80 mesh C-22 SK. Of the two peaks due to the isomer mixture of any *cis*- and *trans*-2-alkylcyclohexanols, the one having the shorter retention time was assigned to the cis isomer and the other to the trans.[5] Details on the experimental procedure and the design of the glass reaction vessel have been given before.[2]

Data Treatments. In dealing with competitive reactions on solid catalysts it is usual to assume (i) that the reaction rate is proportional to the surface concentration of the adsorbed substrate, and (ii) that the substrate adsorption during reaction obeys the Langmuir isotherm. Applying these assumptions to our reaction systems leads to the following two rate expressions:

$$-\mathrm{d}C_1/\mathrm{d}t = k_1K_1C_1/(1+K_1C_1+K_2C_2), \quad (1)$$

$$-\mathrm{d}C_2/\mathrm{d}t = k_2K_2C_2/(1+K_1C_1+K_2C_2), \quad (2)$$

where C is the concentration, t is the time, k is the rate constant, and K is the adsorption equilibrium constant. Combining Eqs. 1 and 2 and defining R by

$$R_1 \equiv -\mathrm{d}C_1/C_1\mathrm{d}t, \quad (3)$$

$$R_2 \equiv -\mathrm{d}C_2/C_2\mathrm{d}t, \quad (4)$$

we obtain a relative rate expression such as

$$\frac{R_2}{R_1} = \frac{k_2K_2}{k_1K_1} = \log\left(\frac{C_{2(\mathrm{i})}}{C_2}\right)\Big/\log\left(\frac{C_{1(\mathrm{i})}}{C_1}\right), \quad (5)$$

where subscript (i) refers to the initial state at $t=0$. Equation 5 serves to calculate relative rates from competitive hydrogenation data.

For more rigor, the role of hydrogen should be taken into account in Eqs. 1 and 2. However, we can ignore this because whatever the involved hydrogen kinetics, we are always led to Eq. 5 by cancellation.

Results

Reaction Products. With respect to the cis/trans ratio for the product alcohol, Pd was rather cis selective (cis%; 85 for **2m**, 73 for **2e**, and 77 for **2p**). The other metals were less selective, and the observed cis% fell in the rather narrow range 58—73 for all the substrates **2m**, **2e**, and **2p**.

In the hydrogenation of **1** and **2** over Pt, more hydrogen was consumed than expected from stoichiometry for complete hydrogenation to the corresponding alcohols. This is probably due to accompanying hydrogenolysis. However, the extent of hydrogenolysis did not exceed 5% of the total conversion of the ketone. In the case of Pd, two unidentified gas chromatographic peaks (one from **1** and one from **2**) developed as the hydrogenation proceeded, but each of the by-products was always less than 2% of the corresponding alcohol. For the rest of the catalysts, there were no indications of any side reactions. Thus it is reasonable to evaluate R_2/R_1 based on Eq. 5 which ignores side reactions.

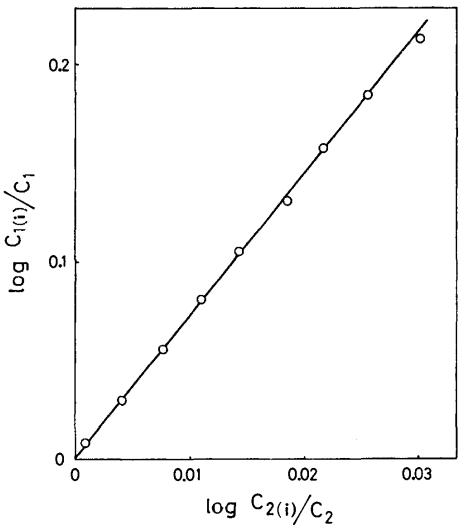

Fig. 1. A typical linear plot according to Eq. 5, observed for **1** and **2e** in competitive hydrogenation on Ir.

Substituent Effects. The log-log plots drawn according to Eq. 5 were linear, with the exception of that for Pt catalyst, which exhibited a slight curvature. Figure 1 shows a typical linear log-log plot observed on Ir. The values for relative reactivity R_2/R_1 were determined from the slope of the straight lines or from the tangent to the curved line at zero conversion. In repeated runs using the same reaction mixture and catalyst, the R_2/R_1 values observed were usually reproducible to within 5%. All the R_2/R_1 values for the same catalyst were averaged, and $\log(R_2/R_1)$ was plotted in Fig. 2a against the atomic radius of the catalyst metal. Here the atomic radius is one-half the internuclear distance between nearest neighbors in the metal crystal

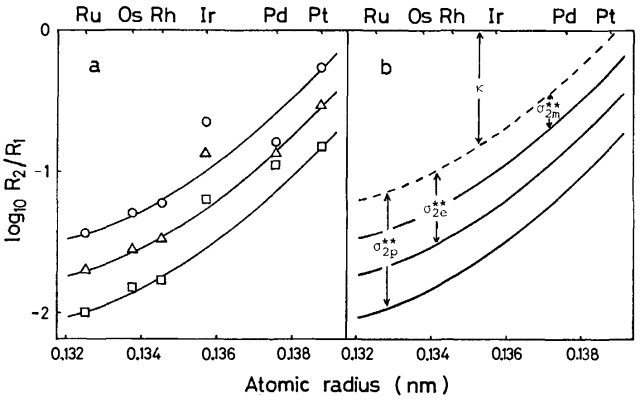

Fig. 2. Alkyl substituent effects in cyclohexanone hydrogenation.
○: **2m**, △: **2e**, □: **2p**.
κ: catalyst-dependent constant, σ^{**}: substituent constant.

which is stable under room conditions. In regard to the **2m/1** system, the general trend observed earlier (Fig. 2, Ref. 2) was reproduced here: the greater the atomic radius the greater the relative reactivity. In general the agreement on the R_{2m}/R_1 value itself is fairly good between the present and earlier experiments.

Of particular interest in Fig. 2a is the parallelism of the three correlation lines for the **2m/1**, **2e/1**, and **2p/1** systems with almost identical spacings. The distances between the adjacent data points for Ir also resemble these spacings. In what follows we are mainly concerned with explaining these apparent identities.

Discussion

Empirical Formulations. Figure 2b is a reproduction of Fig. 2a with omission of the data points. In order to derive an empirical expression for the observed relative rates, let us draw a reference line, shown as a dotted line in Fig. 2b: although the location and physical meaning of this reference line is defined later by our reaction model, at this point suffices it to say that the reference line lies between the horizontal line at $\log_{10}(R_2/R_1)=0$ and the correlation line for the **2m/1** system. We refer to the distance between the horizontal and reference lines as κ (catalyst-dependent constant) and the distances between the reference and correlation lines as σ^{**} (substituent constant): the subscript to σ^{**} indicates the substituted ketone. Obviously, the relative reactivity can be written as

$$\log_{10}(R_2/R_1) = \sigma^{**} + \kappa. \quad (6)$$

One may speculate that σ^{**} is related to the substrate size and κ to the catalyst property. It will be demonstrated below that such speculation may indeed be justified on the basis of the absolute reaction rate theory.

Theoretical Treatment. Now we aim at deriving Eq. 6. The argument developed herein is not intended to be very rigorous. Since we are dealing with heterogeneous catalysis in the liquid phase, we will be forced to be rather speculative and to employ a few ad hoc approximations. One of the basic assumptions we

make is that when converted to the activated complex, ketones **1** and **2** are adsorbed on the catalyst and are "immobile" with complete loss of translational and rotational freedom.

In deriving Eq. 5 we have assumed that both **1** and **2** are in adsorption equilibrium during reaction. Then, the overall hydrogenation rate must be controlled by one of the following steps: (i) the reaction of adsorbed ketone with adsorbed hydrogen to form a half-hydrogenated intermediate, (ii) the reaction of this intermediate with adsorbed hydrogen to form adsorbed alcohol, or (iii) the desorption of the adsorbed alcohol. If step (i) is rate-determining, the overall rate will be given by[6]

$$-\frac{dC_1}{dt} = C_{H_s}^{1/2} C_1 C_s \frac{kT}{h} \frac{f_1^{\neq}}{F_{H_s}^{1/2} F_{1(l)} f_s} \exp\left(\frac{-\varepsilon_1}{kT}\right), \quad (7)$$

$$-\frac{dC_2}{dt} = C_{H_s}^{1/2} C_2 C_s \frac{kT}{h} \frac{f_2^{\neq}}{F_{H_s}^{1/2} F_{2(l)} f_s} \exp\left(\frac{-\varepsilon_2}{kT}\right), \quad (8)$$

where factor kT/h has its usual meaning, f is the complete partition function, F is the partition function per unit volume, ε is the apparent activation energy, *i.e.*, the true activation energy subtracted by the heat of adsorption, subscript s indicates a vacant dual site that can accommodate both an adsorbed ketone molecule and a hydrogen atom, subscript l refers to the liquid state, and superscript $\neq$ indicates the activated complex. It is to be noted that we are dealing with competitive reactions and that **1** and **2** are not very much different in molecular size. This permits us to make an approximation that the adsorption site s is common to reactions of both **1** and **2**. Hence we can regard quantities C_s and f_s as identical for Eqs. 7 and 8. Combining Eqs. 7 and 8 and referring to Eqs. 3 and 4 we have

$$R_2/R_1 = (F_{1(l)} f_2^{\neq} / F_{2(l)} f_1^{\neq}) \exp\{-(\varepsilon_2 - \varepsilon_1)/kT\}. \quad (9)$$

Even if we consider step (ii) or (iii) as the rate-determining, we will still be led to Eq. 9 by cancellation. Thus, Eq. 9 can be regarded as a general expression which is applicable to different kinetics or different rate-determining steps.

Since the activated complex has been assumed to possess no translational and rotational freedom, we need to consider merely its vibration. Thus

$$f^{\neq} = f_{vib}^{\neq}. \quad (10)$$

We are not aware of any theories of liquids which permit us to formulate F_l exactly. However, what is needed herein is merely the ratio $F_{1(l)}/F_{2(l)}$, not the F_l formulation itself. The ratio can be estimated by an extension of Keii's idea.[7] As a rough approximation, let us suppose that Henry's law holds for the dissolution of **1** and **2** in cyclohexane and also that the Henry's-law constant is the same for these two ketones. Then

$$F_{1(l)}/F_{2(l)} = F_{1(g)}/F_{2(g)}, \quad (11)$$

where subscript g refers to the gas phase. The substitution of F_g for F_l underlies the conventional theoretical treatments of isotope effect problems in liquid phase reactions. A fair success in such treatments[8,9] gives indirect further support to Eq. 11. The F_g is usually expressed by

$$F_g = \frac{(2\pi mkT)^{3/2}}{h^3} \frac{8\pi^2 (8\pi^3 I)^{1/2} (kT)^{3/2}}{\sigma h^3} f_{vib}, \quad (12)$$

where m is the mass, I is the product of the three principal moments of inertia, and σ is the symmetry number. Applying Eq. 12 to both ketones **1** and **2**, taking Eqs. 9, 10, and 11 into account, and omitting the symmetry number[10] we obtain

$$\frac{R_2}{R_1} = \left(\frac{m_1}{m_2}\right)^{3/2} \left(\frac{I_1}{I_2}\right)^{1/2} \left[\frac{f_{2.vib}^{\neq} f_{1.vib}}{f_{1.vib}^{\neq} f_{2.vib}}\right] \exp\left\{\frac{-(\varepsilon_2 - \varepsilon_1)}{kT}\right\}. \quad (13)$$

Let us consider the magnitude of the quantity in the square brackets. Most stretching and bending molecular vibrations related to the C–C, C–H, and C=O bonds absorb at frequencies higher than 1000 cm^{-1}, and hence their contributions to the partition function are negligible. Some skeletal and adsorption-bond vibrations probably absorb at lower frequencies, thus contributing somewhat to the partition function. However, these contributions are expected to cancel out almost completely in the square brackets. Therefore, it might not be a serious error to set the quantity in the square brackets equal to unity. Based on this approximation Eq. 13 can be reduced to

$$\log_{10}(R_2/R_1) = \frac{3}{2}\log_{10}(m_1/m_2) + \frac{1}{2}\log_{10}(I_1/I_2) - \frac{\varepsilon_2 - \varepsilon_1}{2.303kT}. \quad (14)$$

The first and second terms of the right side of Eq. 14 depend only upon the substrates, while the third term probably reflects the catalyst property. Our empirical expression 6 becomes identical to the theoretical Eq. 14, if we put

$$\sigma^{**} = \frac{3}{2}\log_{10}(m_1/m_2) + \frac{1}{2}\log_{10}(I_1/I_2), \quad (15)$$

and

$$\kappa = -(\varepsilon_2 - \varepsilon_1)/2.303kT. \quad (16)$$

Substituent Constants. As evident from Eq. 15, σ^{**} depends only upon the m and I values of the substrates under comparison. In order to calculate I exactly, all the probable conformations of the cyclohexanone ring and the substituted alkyl group should be considered with the appropriate statistical weight. However, owing to a lack of necessary data for such a rigorous treatment, we had to be content with an approximation in which only the most likely conformation is considered. The actually assumed conformation was the chair form with the alkyl substituent in the equatorial position. For the sake of convenience, all the carbon atoms of the substituent were set so as to lie in the C(2)–C(1)=0 plane. The bond lengths and bond angles used were: r(C=C)=0.124 nm, r(C–C)=0.154 nm, r(C–H)=0.109 nm; ϕ{C(2)–C(1)–C(6)}=117°, ϕ{C(1)–C(2)–C(7)}=113.25°, any other ϕ (C–C–C)=109.5°, ϕ(H–C–H)=

Table 1. Theoretical values for σ^{**}

Paired substrates	$\frac{3}{2}\log_{10}\frac{m_1}{m_2}$	$\frac{1}{2}\log_{10}\frac{I_1}{I_2}$	σ^{**}

109.5°. The details of I calculations based on these data will be published elsewhere, and the σ^{**} values and related data are summarized in Table 1.

Turning back to Fig. 2b, it is seen that one can calculate $\Delta\sigma^{**}$ values ($\sigma^{**}_{2e}-\sigma^{**}_{2m}$ and $\sigma^{**}_{2p}-\sigma^{**}_{2m}$) from the experimental data. In Table 2 the experimental and theoretical $\Delta\sigma^{**}$ values are compared. The agreement between theory and experiment is remarkable except for Pd. The exceptional result with Pd is not unexpected since the reaction mechanism is complex for this metal.[11-13]

a) Averaged over all the metals except Pd.

Catalyst-Dependent Constant. We are now brought to the question why κ is invariant among the three reaction systems: **2m/1**, **2e/1**, and **2p/1**. This constancy means that ε is the same for the three **2**'s. The constancy of ε is explained by assuming a particular model for the activated complex of **2** that is adsorbed on the catalyst. Figure 3 illustrates the assumed model.

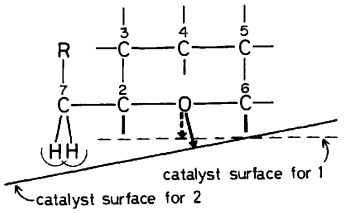

Fig. 3. Adsorption model for substituted (**2**) and unsubstituted cyclohexanone (**1**). R=H, methyl, or ethyl.

Important in this assumption is that in the case of **2m** one hydrogen at the C(7) position points away from the catalyst surface while the other two hydrogens point toward it. It must be this "pointing away" hydrogen that is replaced by a methyl or ethyl group upon going from **2m** to **2e** or **2p**. In this situation, no significant difference is expected among these **2**'s either in the heat of adsorption or in activation energy. As for **1**, however, it lacks the excess repulsive interaction between the substituent and the catalyst surface. Consequently, as shown in Fig. 3, the adsorption bond for **1** is probably shorter and hence stronger compared with that for **2**.

For both **1** and **2**, there must be two different forms of adsorption depending upon which face of the six-membered ring is directed toward the catalyst surface. By cis-addition of two hydrogen atoms from the catalyst side, one form is converted to the cis alcohol, and the other to the trans alcohol. In general both forms must be quite different from each other in adsorption strength. Thus, in principle, one should treat the rates of cis- and trans-alcohol formation separately in a theoretical consideration such as the one we made above. Nevertheless, we have been quantitatively successful in $\Delta\sigma^{**}$ correlation without such a separation. This is presumably aided by the observed fortuitous practical constancy of cis/trans ratio for different substrate ketones.

Concluding Remarks. Looking back at Eq. 14, let us remember that relative reactivity R_2/R_1 in a competitive reaction depends only upon the masses and the moments of inertia provided that $\varepsilon_1=\varepsilon_2$. Such conditions would be brought about if the substituent neither affects the functional group nor interacts with the catalyst surface. In other words, these conditions will be realized when the polar, steric, and "anchor" effects of the substituent are absent or negligible. The requirement for such substituent inertness may be fulfilled by an inactive substituent like alkyls unless they interact with the catalyst surface upon adsorption. Thus, the theoretical treatment presented in this paper would be expected to find a wider use even beyond ketone hydrogenation.

Measuring R_2/R_1 at various temperatures would provide a means to test the validity of our reaction model and its theoretical treatment: in Eq. 14 $\log(R_2/R_1)$ should vary linearly with the reciprocal of absolute temperature if $\varepsilon_1\neq\varepsilon_2$, and be temperature independent if $\varepsilon_1=\varepsilon_2$.

We are indebted to Mr. Okio Nomura of this laboratory for his help in deriving Eq. 14 and in making numerical calculations of the moment of inertia. It is a pleasure to acknowledge the helpful discussions with Dr. Takayoshi Kobayashi and Mr. Yasuaki Kawamura, both of this Institute, Professor Samuel Siegel of University of Arkansas, and Professor Robert W. Taft, Jr., of University of California at Irvine. Thanks are also extended to Dr. John M. Morris of University of Melbourne and Dr. F. Scott Howell of Sophia University for their linguistic comments on the original manuscript of this paper.

Substituent Effects in Heterogeneous Catalysis. IV. Adsorption Estimations during Competitive Hydrogenation of Cyclohexanone and Its 2-Alkyl Derivatives

Teiji CHIHARA and Kazunori TANAKA*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 3, 1978)

Cyclohexanone (**1**) and its 2-alkyl derivatives (2-methyl-, 2-ethyl-, and 2-propylcyclohexanone (**2m**, **2e**, and **2p**)) were hydrogenated both individually and competitively in pairs (**1**+**2**) in cyclohexane using Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3 as catalysts. For all the catalysts, the reaction rates in competitive reaction decreased in the sequence, **1**≫**2m**>**2e**>**2p**, while those in individual reaction were in the relation, **1**>**2m**≈**2e**≈**2p**. By the analysis of these kinetic data, the relative values of adsorption equilibrium constants have been estimated for **2m**, **2e**, and **2p**. These experimental values are in good agreement with the theoretical ones which have been derived on the basis of statistical mechanics using an adsorption model characterized by immobile adsorption of the substrate ketones.

The first[1] and third papers[2] of this series dealt with alkyl substituent effects in cyclohexanone (**1**) hydrogenation catalyzed by platinum group metals. The substituent effects were studied by means of competitive hydrogenation of **1** and its alkyl derivatives (2-methyl-, 2-ethyl-, and 2-propylcyclohexanone abbreviated subsequently to **2m**, **2e**, and **2p**). The logarithm of the observed relative rates was expressed as the sum of substituent constant σ^{**} and catalyst-dependent constant κ;

$$\log_{10}(R_2/R_1) = \sigma^{**} + \kappa. \quad (1)$$

A theoretical relative-rate expression corresponding to this empirical one (1) was derived on the basis of Eyring's rate equation using a simple reaction model in which the substrate ketones lose the translational and rotational freedom at the transition state. Comparing the empirical and theoretical relative-rate expressions, σ^{**} was quantitatively correlated as a function of the mass and the moment of inertia of the two substrate ketones under comparison. On the other hand, it is generally accepted in heterogeneous catalysis that the relative rate R_2/R_1 in competitive reaction can be expressed as

$$R_2/R_1 = (k_2/k_1)(K_2/K_1), \quad (2)$$

where k is the rate constant referred to the unit fraction of the surface covered and K is the adsorption equilibrium constant.

Thus we can now question whether k_2/k_1 or K_2/K_1 makes the chief contribution to σ^{**}. The main purpose of the present work is to resolve this question by estimating these relative values. The results are considered in the light of a statistical-mechanical treatment of adsorption equilibrium.

It is more or less conventional to compare the adsorption of the two reaction substrates by subjecting them to both individual and competitive reactions and by analyzing the obtained comparative data. This conventional technique was used in the present work. The catalysts chosen were Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3, all in the form of pellets. At the beginning, adsorption estimations on the same powder metal catalysts that were used in the previous work were attempted but failed owing to the difficulty in obtaining a good reproducibility in catalytic activity.

Experimental

Materials and Apparatus. Commercial cyclohexane (Wako Pure Chemical Ind., "Special grade") was used as received. Compounds **1** and **2m** were also commercial products and distilled before use. The preparation of **2e** and **2p** has been described previously.[2] The catalysts chosen were Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3, each containing 0.5 wt % of the metal. They were all purchased from Engelhard Industries in the form of pellets (1/8 inch diameter). The glass reaction vessel has already been illustrated in detail.[1]

Kinetic Procedure. In order to obtain reliable kinetic data from a series of individual reaction runs using the same kind but different batches of catalyst, the catalytic activity must be very similar for all the runs. Such a requisite was realized by pretreating the catalyst in the following fashion. One to ten catalyst pellets were weighed into a small glass test tube, and about 10 ml of cyclohexane was added. The test tube was placed in a 100-ml autoclave. The autoclave was charged with hydrogen to about 80 atm, heated to 80 °C, and allowed to stand at that temperature for 20 min with occasional gentle swirling by hand. No significant hydrogen consumption was observed during this pretreatment.

Then, the catalyst pellets were transferred to the glass reaction vessel pre-charged with cyclohexane that had already been made air-free by hydrogen flushing, care being taken to minimize the time of exposure of the catalyst to air. The reaction vessel was connected to a hydrogen reservoir and flushed repeatedly with hydrogen. Freshly distilled **1** and/or **2** were introduced into the reaction vessel by a syringe. The volume of the reaction solution thus prepared was made to be exactly 5 ml by adjusting the volume of the cyclohexane precharge and by standardizing the flushing procedure. The reaction was allowed to start by shaking the reaction vessel at 30 °C and in hydrogen of atmospheric pressure, and the reaction mixture was sampled at appropriate time intervals for the following 2 h (up to a conversion of *ca.* 5%). The activity of all the catalysts remained constant during this initial period of reaction. The reaction mixtures sampled were analyzed using a gas chromatograph.

Results

Relative Rates. Under our reaction conditions the rate of individual hydrogenations of **1** or **2** was proportional to the catalyst weight but unaffected by the fre-

Table 1. The observed rates

Catalyst	Competitive reaction		Individual reaction

a) Initial concentration of substrate ketone in mol/l.

quency at which the reaction vessel was shaken. It has also been observed that the hydrogenation rate is practically independent of ketone concentrations down to 0.5 mol/l or less for all the catalysts. The data on individual hydrogenations in Table 1 were all obtained in this concentration-independent region. Let us assume that R_1', the rate of individual hydrogenation of **1**, may be expressed by

$$R_1' = k_1K_1C_1/(1+K_1C_1), \quad (3)$$

where k is the rate constant. From the above-mentioned zero order kinetics in C_1, it follows that $K_1C_1 \gg 1$ in Eq. 3. Thus we have

$$R_1' = k_1. \quad (4)$$

Since the same argument holds for ketone **2**, we are led to

$$R_2'/R_1' = k_2/k_1. \quad (5)$$

Numerical values for R' were all estimated from the linear plot of product alcohol concentrations against reaction time. It is to be noted that R_2' represents the sum of the rates of cis- and trans-alcohol formation. The observed cis/trans ratio of product alcohols did not significantly differ for the three substrate ketones on a certain catalyst.

The observed values for R_1' and R_2' are given in Table 1. Interestingly enough, on each catalyst the R_2' values for **2m**, **2e**, and **2p** agree to within experimental error. In contrast R_1' is twice as great as R_2'.

Also included in Table 1 are the R_2/R_1 values, the relative rates in competitive reaction. The two characteristic features observed previously for unsupported metal catalysts were reproduced here with the Al_2O_3-supported catalysts. One of them is that, for all the catalysts, R_2/R_1 decreases in the sequence **2m**>**2e**>**2p**, *i.e.*, as the substituent size becomes larger. The other is that the R_2/R_1 value for a particular **2** decreases in the sequence Pt/Al_2O_3, Rh/Al_2O_3, Ru/Al_2O_3, *i.e.*, in the order of decreasing atomic radius of the catalyst metals. This indicates that the alkyl substituent effect in cyclohexanone hydrogenation is more pronounced for a metal having a shorter atomic radius.

Relative Adsorption. Let us derive equations which will serve to obtain some relative adsorption data. Applying Eqs. 2 and 5 to the **1-2m** pair system and combining the resulting equations yields

$$\log (K_{2m}/K_1) = \log (R_{2m}/R_1) - \log (R_{2m}'/R_1'). \quad (6)$$

Similarly for the **1-2e** pair system we have

$$\log (K_{2e}/K_1) = \log (R_{2e}/R_1) - \log (R_{2e}'/R_1'). \quad (7)$$

In these two equations we can equate the last terms to each other, as the fair agreement was obtained between R_{2m}' and R_{2e}'. Then, from Eqs. 6 and 7,

$$\log (K_{2e}/K_{2m}) = \log (R_{2e}/R_1) - \log (R_{2m}/R_1). \quad (8)$$

Analogous considerations with respect to the **1-2m** and **1-2p** pairs lead to

$$\log (K_{2p}/K_{2m}) = \log (R_{2p}/R_1) - \log (R_{2m}/R_1). \quad (9)$$

Equations 8 and 9 indicate that the relative adsorption equilibrium constants can be estimated experimentally using the relative rate data listed in Table 1. The results of actual calculations are given in Table 2 under the heading "Observed."

Table 2. Observed and calculated relative adsorption equilibrium constants

Catalyst		Obsd	Calcd

	$\log_{10}(K_{2p}/K_{2m})$	−0.54	−0.55

Discussion

We intend herein to derive theoretical expressions corresponding to Eqs. 8 and 9, based on statistical mechanics employing a simple model for competitive ketone adsorption during hydrogenation. Let us recall that our reaction systems consist of a solid catalyst and a

cyclohexane solution of **1** and **2** under hydrogen of atmospheric pressure. We assume that during reaction both **1** and **2** are in adsorption equilibrium competing for the same adsorption sites. We also assume that the adsorption of the solvent and the product alcohols is negligible. The latter assumption seems reasonable in view of the use of nonpolar cyclohexane as the solvent and of our concern about only the initial stage of reactions up to a conversion of 5%.

Employing the Langmuir adsorption model, the partition function Q_a for the adsorbed phase is given by

$$Q_a = \{L!/M_1!M_2!(L-M_1-M_2)!\}q_{1(a)}^{M_1}q_{2(a)}^{M_2}, \quad (10)$$

where L is the number of adsorption sites, M is the number of adsorbed molecules, q is the molecular partition function, and subscript a refers to the adsorbed state. The chemical potential of adsorbed molecules **1** is expressed as

$$\mu_{1(a)} = (-\partial kT \ln Q_a/\partial M_1)_{L,M_2,T,V} = -kT\{-\ln M_1+\ln (L-M_1-M_2)+\ln q_{1(a)}\}. \quad (11)$$

Similarly for adsorbed molecules **2**,

$$\mu_{2(a)} = -kT\{-\ln M_2+\ln (L-M_1-M_2)+\ln q_{2(a)}\}. \quad (12)$$

On the other hand, the partition function Q_l for a ternary solution containing N_1, N_2, and $N_{s(olvent)}$ molecules of the indicated constituents is approximately described by[3,4]

$$Q_l = \frac{(N_1+N_2+N_s)!}{N_1!N_2!N_s!}q_{1(l)}^{N_1}q_{2(l)}^{N_2}q_{s(l)}^{N_s}, \quad (13)$$

where the subscript l refers to the liquid state. Based on Eq. 13 the chemical potentials of **1** and **2** in the solution are given by

$$\mu_{1(l)} = -kT\{\ln (N_1+N_2+N_s)-\ln N_1+\ln q_{1(l)}\} \quad (14)$$

and

$$\mu_{2(l)} = -kT\{\ln (N_1+N_2+N_s)-\ln N_2+\ln q_{2(l)}\}. \quad (15)$$

Since at adsorption equilibrium the relations

$$\mu_{1(l)} = \mu_{1(a)}, \quad \mu_{2(l)} = \mu_{2(a)} \quad (16)$$

hold, Eqs. 11, 12, 14, and 15 yield

$$\frac{M_2/N_2}{M_1/N_1} \equiv \frac{K_2}{K_1} = \frac{q_{1(l)}q_{2(a)}}{q_{2(l)}q_{1(a)}}. \quad (17)$$

We now come to the problem of how to express the molecular partition functions in Eq. 17. If the adsorbed **1** and **2** are immobile with loss of translational and rotational freedom, only $q_{vib(ration)}$ should be considered. Thus

$$q_{2(a)}/q_{1(a)} = (q_{2,vib(a)}/q_{1,vib(a)}) \exp\{-(w_2-w_1)/kT\}, \quad (18)$$

where w is the heat of adsorption. On the other hand, until now no theories of liquids have been developed which allow one to express exactly the molecular partition function q for a molecule in the liquid phase. As an approximation, however, it is often assumed that the internal molecular motions of a molecule in the liquid phase are identical with those of the same molecule in the gas phase.[5,6] Employing this assumption for our reaction solutions would not be seriously in error, because nonpolar cyclohexane is used as the solvent and we eventually deal with only relative values of like olecules. The problem of seeking a q_l expression now reduces to that of evaluating merely the translational partition function $q_{tr(l)}$. According to Eyring and Hirschfelder[5] $q_{tr(l)}$ can be expressed as $q_{tr(gas)}$ times v_f, where v_f represents the free volume. Then we have

$$q_l = \frac{(2\pi mkT)^{3/2}}{h^3}v_f\frac{8\pi^2(8\pi^3I)^{1/2}(kT)^{3/2}}{\sigma h^3}q_{vib}, \quad (19)$$

where m is the mass, I is the product of the three principal moments of inertia, and σ is the symmetry number. Applying Eq. 19 to both ketones **1** and **2** we obtain

$$\frac{q_{2(l)}}{q_{1(l)}} = \left(\frac{m_2}{m_1}\right)^{3/2}\left(\frac{I_2}{I_1}\right)^{1/2}\left(\frac{v_{f,2}}{v_{f,1}}\right)\left(\frac{q_{2,vib}}{q_{1,vib}}\right), \quad (20)$$

where the symmetry numbers are omitted since we are eventually concerned with rate processes.[7,8] An approximation

$$v_{f,1} = v_{f,2} \quad (21)$$

reduces Eq. 20 to

$$\frac{q_{2(l)}}{q_{1(l)}} = \left(\frac{m_2}{m_1}\right)^{3/2}\left(\frac{I_2}{I_1}\right)^{1/2}\left(\frac{q_{2,vib}}{q_{1,vib}}\right). \quad (22)$$

Alternatively, one can derive Eq. 22, as was done in the preceding paper,[2] by assuming Henry's law and the identical Henry's-law constants for the dissolution of **1** and **2** in cyclohexane. Inserting Eqs. 18 and 22 into Eq. 17 yields

$$\frac{K_2}{K_1} = \left(\frac{m_1}{m_2}\right)^{3/2}\left(\frac{I_1}{I_2}\right)^{1/2}\left(\frac{q_{1,vib}q_{2,vib(a)}}{q_{2,vib}q_{1,vib(a)}}\right) \times \exp\left\{\frac{-(w_2-w_1)}{kT}\right\}. \quad (23)$$

Applying Eq. 23 to substrates **2m** and **2e** and combining the resulting equations gives

$$\frac{K_{2e}}{K_{2m}} = \left(\frac{m_{2m}}{m_{2e}}\right)^{3/2}\left(\frac{I_{2m}}{I_{2e}}\right)^{1/2}\left(\frac{q_{2m,vib}q_{2e,vib(a)}}{q_{2e,vib}q_{2m,vib(a)}}\right) \times \exp\left\{\frac{-(w_{2e}-w_{2m})}{kT}\right\}. \quad (24)$$

In Eq. 24 we assume as an approximation that

$$w_{2m} = w_{2e}, \quad (25)$$

$$q_{2m,vib}q_{2e,vib(a)}/q_{2e,vib}q_{2m,vib(a)} = 1. \quad (26)$$

Approximation 25 is consistent with the observed identity $R'_{2m}=R'_{2e}$ because this identity can be interpreted as indicating that **2m** and **2e** are similar not only in the transition state but also in the adsorbed state. Approximation 26 also seems to be justified based on this resemblance in the adsorbed state although we can hardly develop rigorous arguments based on the concept of normal vibrations. Let us divide each substrate molecule into two parts: the carbonyl group and the rest. The rest part would undergo little or no change when the substrate molecule goes from the dissolved to the adsorbed state. Thus, merely considering the carbonyl group will suffice for estimating the value for the left-hand side of Eq. 26. With this in mind we could equate $q_{2m,vib}$ to $q_{2e,vib}$ since there seems to be no significant difference between **2m** and **2e** in the nature of the carbonyl group. Nor can we expect any significant difference between $q_{2m,vib(a)}$ and $q_{2e,vib(a)}$ in view of the above-discussed resemblance between the adsorbed **2m** and **2e**. Thus we are led to approximation 26. Approximations 25 and 26 reduce Eq. 24 to

$$\log (K_{2e}/K_{2m}) = \frac{3}{2}\log (m_{2m}/m_{2e}) + \frac{1}{2}\log (I_{2m}/I_{2e}). \quad (27)$$

By applying a similar argument to the **2m-2p** pair system we are led to

$$\log (K_{2p}/K_{2m}) = \frac{3}{2}\log (m_{2m}/m_{2p}) + \frac{1}{2}\log (I_{2m}/I_{2p}). \quad (28)$$

Equations 27 and 28 correspond to Eqs. 8 and 9, respectively. In Table 2, the theoretical values for relative adsorption equilibrium constants predicted by Eqs. 27 and 28 are compared with the observed values based on Eqs. 8 and 9. The agreement between theory and experiment is excellent.

Concluding Remarks. The most important experimental results are summarized in two reactivity sequences: **1**$\gg$**2m**$>$**2e**$>$**2p** in competitive hydrogenation and **1**$>$**2m**$\approx$**2e**$\approx$**2p** in individual hydrogenation. The identity of the three **2**'s in the latter sequence suggests that the reactivity of the carbonyl group itself and the interaction of the substituent with the catalyst surface remain unchanged when the methyl is replaced by the ethyl or propyl group. In other words, these three substituents are very similar in their chemical nature, and can be considered as "pseudo-isotopes." The observed reactivity sequence in competitive reaction is regarded as reflecting the effect of these pseudo-isotopes upon substrate adsorption. Indeed, the results in competitive reaction have been quantitatively accounted for based on this concept by means of a statistical mechanical treatment. As for the immobile adsorption model employed in this theoretical treatment, it was referred to by Glasstone *et al.*[9] as early as 1941 as the "entropy of activation in adsorption."

We thank Dr. F. Scott Howell of Sophia University for his linguistic comments on the original manuscript of this paper.

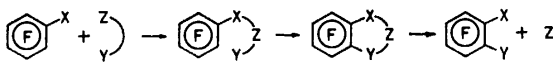
(Received July 3, 1978)

With the intention of achieving the selective *ortho*-disubstitution of *F*-aniline *via* intramolecular nucleophilic cyclization, syntheses of some requisite intermediate (*F*-phenyl)amino compounds and (*F*-benzo)heterocyclic compounds were investigated. 2-Phenyl-*F*-benzoxazole, 2-phenyl-*F*-benzimidazole, and 2,3-dihydro-1,4-(*F*-denz)-oxazin-3-one were obtained from the respective precursors: benz-*F*-anilide, *N*-(*F*-phenyl)benzamidine, and hydroxyacet-*F*-anilide. 2-Phenyl-*F*-benzothiazole was obtained by treating benz-*F*-anilide with phosphorus pentasulfide. Hydrolytic dehalogenation of haloacet-*F*-anilide failed to give hydroxyacet-*F*-anilide, but it was obtained successfully by catalytic debenzylation of benzyloxyacet-*F*-anilide. The reactions of iodoacet-*F*-anilide with silver nitrate and acetate yielded 2-nitrate and 2-acetate, respectively. The reaction with diamminesilver(I) nitrate resulted in a reductive deiodination which gave acet-*F*-anilide. This exceptional reactivity was ascribed to the strong electron-withdrawing effect of the *F*-phenyl group.

There have been reports of several procedures for attaining *ortho*-disubstituted *F*-benzenes;[1] rather inaccessible starting substances were used, however.[2] The reactions of monosubstituted *F*-benzenes with nucleophiles yielded predominantly *para*-disubstituted derivatives.[3] The *ortho*-disubstitution by nucleophilic reactions occurred only in a few cases where the attacking nucleophile was chemically bonded to the preceding substituent group so as to be oriented to the *ortho*-position.[4] This might constitute another useful procedure for obtaining *ortho*-disubstituted benzenes from readily available monosubstituted ones, if a wide variety of actual or potential nucleophiles could be bonded to the preceding substituent. The nucleophiles include not only actual nucleophilic agents but also their protected derivatives and the functional groups which are readily convertible to effective nucleophilic agents. As shown in Scheme 1, the nucleophile to be introduced into the *ortho*-position is linked to the substituent with one to three atoms in between, so that a five- to seven-membered heterocyclic ring is formed as an intermediate by nucleophilic cyclization. The resulting heterocyclic ring is cleaved to the final *ortho*-disubstituted *F*-benzene.[5,6]

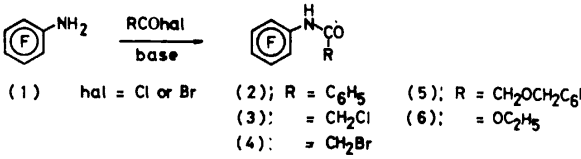


Scheme 1.

This paper will report on the *F*-benzo-heterocyclic compounds and precursory (*F*-phenyl)amino compounds which were obtained in the course of the investigation of the *ortho*-substitution on *F*-aniline (**1**) *via* intramolecular nucleophilic cyclization.

Results and Discussion

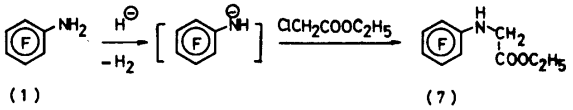
Preparation of Precursory (F-Phenyl)amino Compounds. Nucleophiles such as amine nitrogen, oxylate oxygen, and thiolate sulfur are regarded as the most effective cyclizing agents for replacing the fluorine atom on an *F*-phenyl nucleus. On the other hand, *F*-aniline nitrogen is also an actual nucleophile, and the linkage formation of *F*-aniline onto a ligand to prepare the precursory(*F*-phenyl)amino compounds can be achieved by nuclephilic attack of *F*-aniline nitrogen onto the carbocationic site of a ligand carrying a nucleophile. In a reaction of this type, the oxygen nucleophile has to be protected in the form of a carbonyl, ester, ether, or some other group containing oxygen, lest it should interfere with the *F*-aniline nitrogen nucleophile. The terminal halides can also be taken as equivalents, because they are hydrolyzable into a hydroxyl group.



(1) hal = Cl or Br (2); R = C_6H_5 (3); = CH_2Cl (4); = CH_2Br (5); R = $CH_2OCH_2C_6H_5$ (6); = OC_2H_5

Scheme 2.

Acylation was one of the most convenient methods to afford the requisite precursors. *F*-Aniline (**1**), whose amine nitrogen is much less basic than the ordinary one,[7] reacted with various acyl halides to give the corresponding amides (**2**—**5**) and carbamate (**6**) in a similar manner to that for ordinary aromatic primary amines. The reactions proceeded in the presence of bases such as pyridine or aqueous alkali generally in good yield.

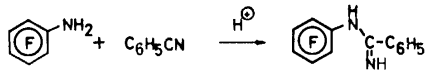


(1) (7)

Scheme 3.

Upon ethoxycarbonylmethylation on the amine nitrogen, *F*-aniline had to be activated by deprotonation; in practice, chloroacetate gave *N*-(*F*-phenyl)glycinate (**7**) by being refluxed with sodium hydride in DMF.

† Presented in part before the 8th International Symposium on Fluorine Chemistry at Kyoto, Japan, 1976.

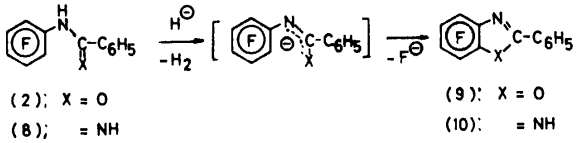


(1) (8)

Scheme 4.

The reaction with the nitrile carbon proceeded by the protonation of the nitrile; thus benzonitrile afforded *N*-(*F*-phenyl)benzamidine (**8**) in the presence of anhydrous *p*-toluenesulfonic acid.[8]

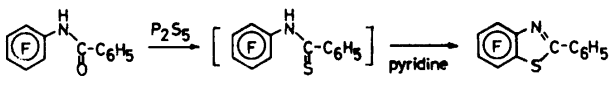
Intramolecular Nucleophilic Cyclization. The carbonyl oxygen in benz-*F*-anilide (**2**) and the imino nitrogen in benzamidine (**8**) could work as nucleophilic agents at the cyclization step. Upon being refluxed in the presence of sodium hydride in DMF, these two compounds gave strongly fluorescent 2-phenyl-*F*-benzoxazole (**9**) and 2-phenyl-*F*-benzimidazole (**10**), respectively, presumably by the nucleophilic attack of anionic intermediates to the *ortho*-fluorine on the *F*-phenyl nucleus. Since acet-*F*-anilide (**11**) yielded 2-methyl-*F*-benzoxazole (**12**) in much lower yield,[9] the phenyl group on the side chain favored the intramolecular cyclization reaction, probably due to the steric effect of its bulkiness and the resonance stabilization of the conjugated structure of the benzylideneamine type. The same effects have been invoked, in part, to explain the similar trend in the relative ease of formation of polyfluorinated benzofuran and indole derivatives from the base-catalyzed cyclization of the precursory β-(*F*-phenyl)ketones.[10]



(2): X = O (9): X = O
(8): = NH (10): = NH

Scheme 5.

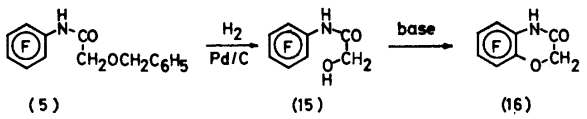
Introduction of sulfur atom as a nucleophilic agent was effected by replacing the carbonyl oxygen of benz-*F*-anilide (**2**) by refluxing with phosphorus pentasulfide in pyridine. The reaction proceeded to give directly the cyclized 2-phenyl-*F*-benzothiazole (**13**), without isolation of an expected intermediate, thiobenz-*F*-anilide (**14**).



(2) (14) (13)

Scheme 6.

The present heteroaromatic compounds were isolated in fairly good yields, but against our purpose they were so stable that the cleavage of these five-membered rings was unsuccessful.



(5) (15) (16)

Scheme 7.

Formation of six-membered heterocyclic rings was attained by the cyclization of hydroxyacet-*F*-anilide (**15**), which was derived from benzyloxyacet-*F*-anilide (**5**) by reductive debenzylation. Nucleophilic cyclization of the 2-hydroxy compound (**15**) gave 2,3-dihydro-1,4-(*F*-benz)oxazin-3-one (**16**) by way of alcoholate anionic intermediate. The ring fission of this compound seems more facile than the simple 2,3-dihydro-1,4-(*F*-benz)-oxazine (**17**), whose heterocyclic ring could not be cleaved.[5]

Scheme 8.

*Reactions of Haloacet-*F*-anilides with Nucleophiles.* Searching for a shorter route from *F*-aniline to the 2-hydroxy compound (**15**), we attempted to hydrolyze haloacet-*F*-anilides under various conditions. In the reactions of chloroacet-*F*-anilide (**3**) with potassium carbonate in anhydrous DMF, as well as that of bromoacet-*F*-anilide (**4**) with tetrabutylammonium hydroxide in a benzene–water mixture, the only isolated solid product was 1,4-di(*F*-phenyl)-2,5-piperazinedione (**18**). The attempted hydrolysis of haloacet-*F*-anilides (**3**) and (**4**) to the 2-hydroxy compound (**15**) in aqueous alkaline media afforded no definite products. Iodoacet-*F*-anilide (**19**), which was derived from chloroacet-*F*-anilide (**3**) by treatment with sodium iodide in acetone, gave the same result as above when treated with alkali in an aqueous solvent. In the reactions with silver nitrate and acetate, the haloacet-*F*-anilides (**19**) and (**4**) gave the respective esters (**20**) and (**21**). Hydrolytic fission at the O–N or O–C bond of the esters, however, did not proceed either in acidic or in basic media; instead the amide N–C bond was cleaved to give the parent *F*-aniline (**1**).

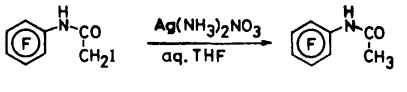
Scheme 9.

On the other hand, when treated with diamminesilver(I) in aqueous THF at room temperature in the dark, the 2-iodo compound (**19**) afforded unexpectedly acet-*F*-anilide (**11**), accompanied by immediate precipitation of yellow silver iodide, the yield being almost quantitative. This reductive dehalogenation seemed to proceed specifically in aqueous THF; otherwise, for example in aqueous dioxane, the 2-iodo compound (**19**)



(19) (11)

Scheme 10.

gave only the piperazinedione derivative (**18**) in poor yield.

This unusual reactivity of the iodoacet-*F*-anilide (**19**), in comparison with unfluorinated iodoacetanilide,[11] suggested that the *F*-phenyl group exerted its electron-withdrawing effect up to the γ-position. Evidence might be adduced for this in the reaction of di(*F*-phenyl)-methyl bromide[12] and bromomethyl *F*-phenyl ketone[13] with nucleophiles. Further studies of the cleavage of the heterocyclic rings and the effects of the *F*-phenyl group are under way in this laboratory.

Experimental

Melting points were uncorrected. IR spectra were obtained with a JASCO DS-403G spectrometer. ^{1}H-chemical shifts were recorded on a Varian A-60 against the internal TMS reference. ^{19}F-NMR shifts were recorded on a JEOL PS-100 as the positive values downfield from the internal *F*-benzene reference. MS were obtained with JEOL JMS-07 and 01SG spectrometers. Electronic absorption and fluorescence spectra were recorded on HITACHI 200-20 and MDF-4 spectrometers, respectively. *F*-Aniline (**1**) was prepared according to the methods by Forbes[14] and Birchall.[15]

Benz-F-*anilide* (**2**). A mixture of *F*-aniline (2.00 g, 11 mmol), benzoyl chloride (5.00 g, 40 mmol), and 20% aqueous potassium carbonate (50 ml) was heated under reflux for 2 h. The cooled mixture was poured into ice-water and a solid product was collected by filtration. Recrystallization from benzene gave white plates of benz-*F*-anilide (**2**) melting at 188—189 °C (2.45 g, 78%). IR (KBr): 1670 cm^{-1} (C=O). Found: C, 54.28; H, 2.29; N, 4.89%. Calcd for $C_{13}H_6NF_5O$: C, 54.37; H, 2.11; N, 4.88%.

Chloroacet-F-*anilide* (**3**). Into a mixture of *F*-aniline (4.00 g, 22 mmol), anhydrous pyridine (4.05 g, 51 mmol), and absolute ether (70 ml), chloroacetyl chloride (7.00 g, 62 mmol) was added dropwise over 30 min with stirring. The mixture was refluxed for an additional 1 h, cooled, and filtered. The filtrate was washed with water, 10% aqueous sodium hydroxide, and water, successively, and evaporated to dryness after being dried over magnesium sulfate. Recrystallization of the residual solid from cyclohexane gave white needles, mp 108—109 °C, of chloroacet-*F*-anilide (**3**) (4.67 g, 88%). IR (CCl_4): 2950 and 2920 (CH), 1720 cm^{-1} (C=O). Found: C, 37.02; H, 1.17; N, 5.40%. Calcd for $C_8H_3NClF_5O$: C, 37.07; H, 1.27; N, 5.26%.

Bromoaceto-F-*anilide* (**4**). *F*-Aniline (5.00 g, 27 mmol) was worked up with bromoacetyl bromide (14.56 g, 72 mmol) in a manner similar to the above. Recrystallization from cyclohexane gave white needles, mp 113—114 °C, of bromoacet-*F*-anilide (**4**) (7.55 g, 91%). IR (CCl_4): 2950 and 2920 (CH), 1715 cm^{-1} (C=O). Found: C, 31.67; H, 1.02; N, 4.49%. Calcd for $C_8H_3NBrF_5O$: C, 31.61; H, 1.00; N, 4.61%.

Benzyloxyacet-F-*anilide* (**5**). Into a mixture of *F*-aniline (5.00 g, 27 mmol), anhydrous pyridine (13.7 g, 173 mmol), and absolute ether (50 ml), benzyloxyacetyl chloride[16] (10.8 g, 58 mmol) was added dropwise over 30 min with stirring. The reaction mixture was refluxed for an additional 1 h, then cooled to room temperature and filtered. The filtrate was washed with water, 10% aqueous sodium hydroxide, diluted hydrochloric acid, and water, successively, and then dried over magnesium sulfate. The residue obtained after evaporation was recrystallized from cyclohexane to give benzyloxyacet-*F*-anilide (**5**) (8.30 g, 92%) of white plates, mp 129—130 °C. IR (KBr): 3000 (CH), 1670 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$): 4.2 (s, 2H, $COCH_2O$), 4.7 (s, 2H, OCH_2), 7.4 (s, 5H, arom.), 7.8—8.1 ppm (br s, 1H, NH). Found: C, 54.62; H, 3.19; N, 4.03%. Calcd for $C_{15}H_{10}NF_5O_2$: C, 54.39; H, 3.04; N, 4.23%.

Ethyl (F-*Phenyl*)*carbamate* (**6**). Into an ice-chilled solution of *F*-aniline (2.00 g, 10.9 mmol) in ethanol (20 ml) was added with stirring the separate solutions of ethyl chloroformate (2.00 g, 18.4 mmol) in ethanol (5 ml) and aqueous sodium carbonate (1.20 g in 2 ml) simultaneously over 10 min. The resulting solution was kept stirring for an additional 30 min at 0 °C. It was then diluted with ethanol and the resulting precipitates were filtered out. The filtrate was poured into a large amount of water to give crude precipitates, which were recrystallized from petroleum ether (bp 40—60 °C) to afford white fibrous ethyl (*F*-phenyl)carbamate (**6**), mp 81 °C (sublimable). The yield was up to 40%. Found: C, 42.37; H, 2.37; N, 5.49%. Calcd for $C_9H_6NF_5O_2$: C, 42.36; H, 2.51; N, 5.45%.

Ethyl N-(F-*Phenyl*)*glycinate* (**7**). A DMF solution of *F*-aniline (5.00 g, 27.3 mmol in 30 ml) was added dropwise into a suspension of sodium hydride (27.1 mmol) in DMF (20 ml) with stirring. Into the resulting green mixture, after the evolution of hydrogen ceased, was added ethyl chloroacetate (5.00 g, 40.8 mmol). The mixture was refluxed for 1 h with stirring, then cooled and extracted with ether. The ethereal extract was washed with diluted hydrochloric acid and water, successively, and dried over magnesium sulfate. The dried extract was distilled under reduced pressure, and the fraction boiling at 100—135 °C/5 Torr was crystallized from cyclohexane–ethanol to give ethyl *N*-(*F*-phenyl)glycinate (**7**) (1.56 g, 21%) of white needles, mp 64—65 °C. IR(KBr): 2990 (CH), 1728 (C=O), 1265 and 1230 cm^{-1} (C–N). Found: C, 44.90; H, 3.11; N, 4.98%. Calcd for $C_{10}H_8NF_5O_2$: C, 44.62; H, 3.00; N, 5.20%.

N-(F-*Phenyl*)*benzamidine* (**8**). A mixture of *F*-aniline (3.00 g, 16.4 mmol), benzonitrile (2.70 g, 26.2 mmol), and anhydrous *p*-toluenesulfonic acid (26.5 mmol) was kept stirring at 180—200 °C for 5 h. The resulting solid was washed with ether, 20% aqueous sodium hydroxide, and water, successively, and was recrystallized from cyclohexane–ethanol to give *N*-(*F*-phenyl)benzamidine (**8**) (2.55 g, 55%) in white needles melting at 127—128 °C. IR (CCl_4): 3500 and 3400 (NH), and 1640 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$): 4.8—5.2 (br s, 2H, NH), 7.0—8.0 ppm (m, 5H, arom.). Found: C, 54.47; H, 2.63; N, 9.76%. Calcd for $C_{13}H_7N_2F_5$: C, 54.56; H, 2.47; N, 9.79%.

2-Phenyl-F-*benzoxazole* (**9**). Benz-*F*-anilide (**2**) (0.50 g, 1.75 mmol) dissolved in anhydrous DMF (15 ml) was added dropwise into a mixture of sodium hydride (2.5 mmol) and anhydrous DMF (15 ml) over 30 min under a dry nitrogen atmosphere. The mixture was refluxed for an additional 2 h, then extracted with ether. The ethereal extract was washed with diluted hydrochloric acid and water, successively, dried over magnesium sulfate, and evaporated to dryness. The residual solid was chromatographed on a neutral alumina column. From the fraction eluted with benzene, 0.43 g (92%) of 2-phenyl-*F*-benzoxazole (**9**) was obtained. Recrystallization from methanol gave white needles melting at 125.2—125.7 °C.[17] IR (KBr): 1540 cm^{-1} (C=N). UV: λ_{max} (EtOH); 293 (log ε 4.40), 287.5 (4.40), 283 (4.40), 236 nm (3.99). Fluorescence spectra (EtOH): emission λ_{max}; 349 nm and exitation λ_{max}; 295 nm. ^{19}F-NMR ($CDCl_3$): 0.4 (1F), 2.5 (1F), 3.1 (1F), 11.2 ppm (1F). Found: C, 58.68; H, 2.09; N, 5.28; F, 29.3%; M$^+$, 267.

2-Phenyl-F-*benzimidazole* (**10**). The benzamidine (**8**) (0.50 g, 1.75 mmol) dissolved in anhydrous DMF (15 ml) was added dropwise into sodium hydride (2.5 mmol) in anhydrous

DMF (15 ml) over 30 min under a dry nitrogen atmosphere. The mixture was refluxed for an additional 2 h, and subsequently worked up in a manner similar to that described in the oxazole (**9**). A chromatographic fraction eluted with THF gave white needles of 2-phenyl-*F*-benzimidazole (**10**) (0.25 g, 54%), mp 221—222 °C after recrystallization from ethanol. UV: λ_{max} (EtOH); 293 (log ε 4.25), 288 (4.24), 242 nm (4.14). Fluorescence spectra (EtOH): emission λ_{max}; 332 nm and exitation λ_{max}; 312 nm. ^{19}F-NMR (ethyl acetate): 5.1 (2F), 8.0 ppm (2F). Found: C, 58.60; H, 2.39; N, 10.41; F, 28.4%; M$^+$, 266.055. Calcd for $C_{13}H_6N_2F_4$: C, 58.66; H, 2.27; N, 10.52; F, 28.6%; M, 266.058.

*2-Phenyl-*F*-benzothiazole (**13**).* A mixture of benz-*F*-anilide (**2**) (1.45 g, 5.0 mmol), phosphorus pentasulfide (2.20 g, 10.0 mmol), and anhydrous pyridine (20 ml) was refluxed for 12 h. The cooled mixture was poured into water. The resulting solid was filtered off, washed with water, and then chromatographed on a silica gel column. Evaporation of the solvent from a hexane–benzene fraction, and recrystallization from cyclohexane resulted in 2-phenyl-*F*-benzothiazole (**13**) (1.10 g, 77%) in a white powder, mp 133.0—133.5 °C. IR (KBr): 1640 cm^{-1} (C=N), UV: λ_{max} (EtOH); 295 (log ε 4.30), 253 nm (4.08). ^{19}F-NMR ($CDCl_3$): 3.2 (1F), 4.1 (1F), 15.4 (1F), 25.1 ppm (1F). Found: C, 55.19; H, 1.97; N, 4.77; F, 26.3%; M$^+$, 283. Calcd for $C_{13}H_5NF_4S$: C, 55.13; H, 4.95; F, 26.8%; M, 283. The sulfur test using sodium nitroprusside was positive.

*2,3-Dihydro-1,4-(*F*-benz)oxazine-3-one (**16**).* The 2-benzyloxy compound (**5**) (5.40 g, 16 mmol) dissolved in ethyl acetate (50 ml) was hydrogenated in the presence of 5% palladium on charcoal (1.00 g) under atmospheric pressure at room temperature. The catalyst was filtered out and the filtrate was evaporated to dryness. Recrystallization from benzene gave hydroxyacet-*F*-anilide (**15**) (3.50 g, 89%) in a white powder, mp 99—100 °C. IR (KBr): 3240 cm^{-1} (OH). ^{1}H-NMR ($CDCl_3$): 3.0—3.4 (br s, 1H, OH), 4.3 (s, 2H, CH_2), 7.9—8.3 ppm (br s, 1H, NH). Found: C, 39.86; H, 1.81; N, 5.64%. Calcd for $C_8H_4NF_5O_2$: C, 39.85; H, 1.67; N, 5.81%.

A mixture of hydroxyacet-*F*-anilide (**15**) (2.00 g, 8.3 mmol), anhydrous potassium carbonate (2.00 g, 14 mmol), and anhydrous DMSO (50 ml) was kept stirring at 110 °C for 22 h. Then the cooled mixture was poured into ether. The ethereal solution was washed with diluted hydrochloric acid and water, dried over magnesium sulfate, and evaporated to dryness. The resulting solid was purified by chromatography on a silica gel column. A fraction eluted by benzene was recrystallized from benzene to give 2,3-dihydro-1,4-(*F*-benz)-oxazin-3-one (**16**) (0.66 g, 36%) in white needles, mp 194.0—195.5 °C measured in a sealed tube. ^{1}H-NMR (acetone-d_6): 4.7 (s, 2H, CH_2), 9.5—10.3 ppm (br s, 1H, NH). UV: λ_{max} (EtOH); 240 (log ε 4.83), 209 nm (4.18). Found: C, 43.50; H, 1.53; N, 6.15; F, 35.5%; M$^+$, 221. Calcd for $C_8H_3NF_4O_2$: C, 43.46; H, 1.37; N, 6.33; F, 34.4%; M, 221.

*Iodoacet-*F*-anilide (**19**).* Chloroacet-*F*-anilide (**3**) (2.00 g, 8.2 mmol) dissolved in anhydrous acetone (10 ml) was treated with sodium iodide (2.00 g, 13 mmol) in anhydrous acetone (10 ml) for 3 h in the dark. The mixture was poured into ether and filtered. The filtrate was evaporated to give a solid, which was sublimed at 150—160 °C. The sublimate was recrystallized from benzene to give white needles, mp 152.5—153.0 °C, of iodoacet-*F*-anilide (**19**) (2.10 g, 80%). IR (CCl_4): 2910 and 2840 (CH), 1720 cm^{-1} (C=O). Found: C, 27.67; H, 0.89; N, 3.91%. Calcd for $C_8H_3NF_5IO$: C, 27.37; H, 0.86; N, 3.99%.

*(Nitrooxy)acet-*F*-anilide (**20**).* Into the iodoacet-*F*-anilide (**19**) (1.00 g, 3.0 mmol) in THF (10 ml) was added silver nitrate (1.00 g, 5.9 mmol) dissolved in water (10 ml). The solution was left standing in the dark for 9 h at room temperature. The mixture was then filtered and the filtrate was extracted with ether. Evaporation of the dried extract and recrystallization of the residue from aqueous methanol resulted in (nitrooxy)acet-*F*-anilide (**20**) (0.35 g, 41%) in white needles, mp 156.8—158.8 °C. IR (KBr): 3080, 3040, and 3000 (CH), 1690 (C=O), 1640 and 1630 cm^{-1} (ONO_2) ^{1}H-NMR ($CDCl_3$): 5.2 (s, 2H, CH_2), 7.2—7.5 ppm (br s, 1H, NH). Found: C, 33.67; H, 1.18; N, 9.87%. Calcd for $C_8H_3N_2F_5O_4$: C, 33.58; H, 1.06; N, 9.79%.

A mixture of bromoacet-*F*-anilide (**4**) (0.50 g, 1.6 mmol) dissolved in THF (10 ml) and silver nitrate (0.80 g, 4.7 mmol) dissolved in water (10 ml) was refluxed for 5 h in the dark with stirring. The subsequent working up gave the nitrate (**20**) (0.07 g, 15%), while 0.18 g (36%) of the starting material was recovered.

When chloroacet-*F*-anilide (**3**) was treated in the same manner as above, it remained unreacted and was recovered almost quantitatively.

*Acetoxyacet-*F*-anilide (**21**).* A mixture of bromoacet-*F*-anilide (**4**) (2.00 g, 6.6 mmol), silver acetate (2.00 g, 12 mmol), and acetic acid (32 ml) was refluxed with stirring for 5 h in the dark, and then left standing at room temperature overnight. The resulting precipitates were filtered out and the filtrate was evaporated to give an oily residue, which was solidified immediately. The residue was chromatographed on a neutral alumina column. An eluate with benzene–acetone (10: 1) was evaporated and the residue was recrystallized from benzene to give acetoxyacet-*F*-anilide (**21**) (1.40 g, 75%) in white needles, mp 85.5—87.0 °C. IR (KBr): 3000 (CH), 1760 (ester C=O), 1690 cm^{-1} (amide C=O). ^{1}H-NMR (acetone-d_6): 2.1 (s, 3H, CH_3), 4.8 (s, 2H, CH_2), 9.0—9.4 ppm (br s, 1H, NH). Found: C, 42.23; H, 2.29; N, 4.80%. $C_{10}H_6NF_5O_3$: C, 42.41; H, 2.14; N, 4.96%.

*Reactions of Haloacet-*F*-anilides with Bases.* *1*: A mixture of chloroacet-*F*-anilide (**3**) (1.00 g, 4.1 mmol), anhydrous potassium carbonate (0.25 g, 1.8 mmol), and anhydrous DMF (20 ml) was refluxed for 1 h with stirring. The cooled mixture was poured into ether. The ethereal solution was washed with diluted hydrochloric acid and water, successively, and evaporated to dryness. The residue was chromatographed on a neutral alumina column. The benzene eluate was evaporated and the residue was recrystallized from aqueous methanol to afford 1,4-di(*F*-phenyl)2,5-piperazinedione (**18**) (0.35 g, 41%) in white plates, mp 178—179 °C. Further purification was effected by recrystallization from cyclohexane–benzene to afford a specimen of white needles melting at 180.0—180.5 °C.[10b] IR (KBr): 2900 (CH), 1690 (C=O), 1330 and 1130 cm^{-1} (C–N). ^{1}H-NMR ($CDCl_3$): 4.5 ppm (s, CH_2). Found: C, 43.28; H, 1.09; N, 6.10%; M$^+$, 446.009.

When treated with potassium hydroxide in aqueous dioxane, chloroacet-*F*-anilide (**3**) was recovered unchanged almost quantitatively.

2: A mixture of bromoacet-*F*-anilide (**4**) (0.50 g, 1.6 mmol), benzene (15 ml), and aqueous tetrabutyl ammonium hydroxide (1.6 mmol, 10 ml) was heated for 4 h with stirring. The benzene layer was separated and the aqueous layer was extracted with ether. The organic layer were combined and evaporated to give 0.23 g (63%) of the piperazinedione (**18**) after recrystallization from cyclohexane–benzene.

3: Into the iodoacet-*F*-anilide (**19**) (0.50 g, 1.5 mmol) in 50% aqueous THF (10 ml) was added diamminesilver(I) nitrate (5.0 mmol) in 50% aqueous THF (50 ml); the solution was left standing for 20 h in the dark. The mixture was filtered and the filtrate was extracted with ether. Evapo-

ration of the dried extract (crude yield 0.35 g) and recrystallization of the residue from aqueous methanol afforded acet-*F*-anilide (**11**) (0.17 g, 51%) in white needles, mp 135—136 °C. IR(KBr): 3240 (NH), 3060, 3020, and 2980 (CH), 1685 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$): 2.2 (s, 3H, CH_3), 7.2—7.5 ppm (br s, 1H, NH). Found: C, 42.82; H, 1.81; N, 6.36%. The product was identified by comparison with an authentic specimen.[18]

4: Bromoacet-*F*-anilide (**4**) (0.50 g, 1.6 mmol) in 50% aqueous THF (10 ml) was added into diamminesilver nitrate (4.2 mmol) in 50% aqueous THF (10 ml); the mixture was refluxed for 5 h in the dark with stirring. After being worked up in the same manner as above, 0.06 g (16%) of the piperazinedione (**18**) was obtained.

5: When treated in the above manner, chloroacet-*F*-anilide (**3**) remained unreacted to be recovered almost quantitatively.

We wish to express our sincere thanks to Professor Keihei Ueno of Kyushu University for his continuous encouragement throughout this study. We are also grateful to Professor Nobuhiko Ishibashi of Kyushu University for use of the fluorescence spectrophotometer and to Messrs. Akira Kito and Atsushi Iyoda of the Government Industrial Research Institute at Osaka for the measurements of the ^{19}F-NMR spectra.

Spectroscopic Studies of Solvent Effects on Intramolecular Hydrogen Bonding in *N*-Substituted Salicylamides

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received July 6, 1978)

It has been found from absorption and emission spectra that the intramolecular hydrogen bonds between the phenolic hydroxyl and carbonyl group of *N*-methylsalicylamide and *N*-methyl-5-chlorosalicylamide survive in DMSO as well as in 1,2-dichloroethane, whereas those of *N,N*-dimethylsalicylamide and *N,N*-dimethyl-5-chlorosalicylamide are disrupted in DMSO. The solvent dependence of the ^{1}H and ^{13}C chemical shifts of these compounds are also well related to the intramolecular hydrogen bonding.

The first absorption bands of benzoic acid, benzamide, phenol, and salicylic acid are located at 280 (heptane),[1] 279 (solvent not identified),[2] 278 (hexane),[3] and 303 nm (0.1 M $HClO_4$),[4] respectively. The red shift of the first band of salicylic acid, compared with those of the other three compounds, have been ascribed to the intramolecular hydrogen bonding between the phenolic hydroxyl and carbonyl groups.

In salicylamide and *N*-methylsalicylamide, the first absorption bands are located very close to that of salicylic acid, suggesting a planar structure involving intramolecular hydrogen bonds as in salicylic acid molecules. In the case of *N,N*-dimethylsalicylamide, on the other hand, steric interaction between the ring proton-6 and the N–CH_3 group distorts the planar structure.

DMSO is known as a powerful solvent capable of forming intermolecular hydrogen bonds with various polar groups of solute molecules. An almost exclusive intermolecular hydrogen bond between the phenolic hydroxyl and DMSO molecules has been assumed for a number of *o*-substituted phenols.[5]

It is well established that a molecule having intramolecular hydrogen bonds, such as methyl salicylate[6] or *N*-methylsalicylamide,[7] undergo the so-called proton transfer in the excited singlet state, resulting in a significantly red-shifted emission band.

These observations suggest that the absorption and emission spectra of salicylamides are dependent upon the solvent wherein the intramolecular hydrogen bond is replaced by intermolecular hydrogen bonds with solvent molecules or not. In this paper, the spectroscopic behavior of *N*-methylsalicylamide (**1**), *N,N*-dimethylsalicylamide (**2**) and the corresponding amides of 5-chlorosalicylic acid (**3** and **4**) will be reported in the binary solvent system of 1,2-dichloroethane (DCE) and DMSO. The ^{1}H and ^{13}C NMR spectral changes of these compounds, upon changing the solvent from $CDCl_3$ to DMSO, will also be described.

	X=NHCH$_3$	N(CH$_3$)$_2$
Y=H	**1**	**2**
Cl	**3**	**4**

Experimental

N-methyl- and *N,N*-dimethylsalicylamide were prepared by the condensation of methyl salicylate with the appropriate amine in methanol. 5-Chlorosalicylamides were also prepared in a similar way. The absorption and emission spectra were recorded on a Hitachi spectrophotometer, Model 356, and a Hitachi fluorescence spectrophotometer, Model MPF-2, respectively. The ^{1}H and ^{13}C NMR spectra were recorded on a Varian XL-100A-15 spectrometer at room temperature. The sample concentrations were 2% for ^{1}H NMR and 5—10% w/v for ^{13}C NMR measurements, unless otherwise noted. The ^{13}C NMR spectra were recorded at FT mode operation.

Results and Discussion

Absorption Spectra. In Fig. 1 are shown the absorption spectra of **1** and **2** in the binary solvent system of DCE and DMSO. The first absorption band of **2** in DCE has a peak at 297 nm and comparison of this value with that for phenol and salicylic acid, suggests the existence of intramolecular hydrogen bonds. With increase in DMSO content, this band shows a progressive decrease in intensity accompanied by the appearance of a new band at 280 nm, an isosbestic point being clearly seen at 285 nm. This observation suggests the existence of an equilibrium between two molecular species in solution. Therefore, the new absorp-

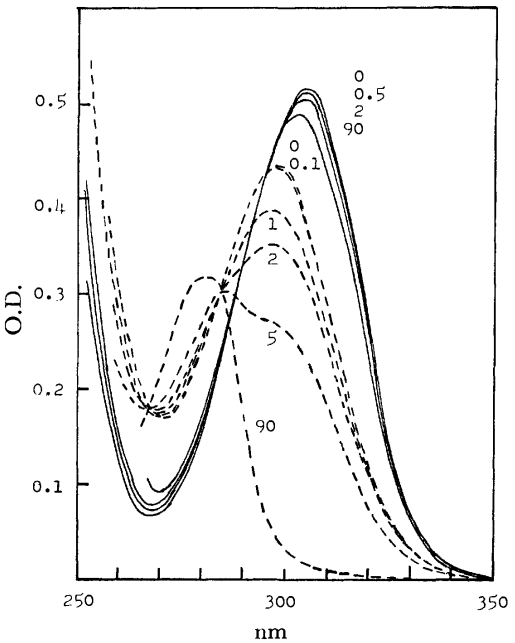

Fig. 1. The absorption spectra of **1** (——; 1.1×10^{-4} M) and **2** (-——; 1.1×10^{-4} M) in binary solvent system of DCE and DMSO. The numbers given on the curves indicate the contant of DMSO (% v/v).

ion band may reasonably be ascribed to molecules of which the intramolecular hydrogen bond is replaced by intermolecular hydrogen bonds with DMSO molecules. As anticipated the absorption spectrum of the methyl ether of **2** did not show any variation with the change in solvent composition.

A DCE solution of **1** shows the first absorption band at 304.5 nm, suggesting intramolecular hydrogen bonding. Addition of DMSO to this solution caused no appreciable change in both the position and intensity of this band. Even in a solution composed of 90% DMSO, the absorption maximum of **1** was located at 302 nm, with a trivial decrease in absorbance. The absorption spectrum of the methyl ether of **1** was almost independent of solvent composition and the first absorption band was located at 287 nm, much lower than that of **1** in 90% DMSO and higher by about 10 nm than that of benzamide. It may be concluded from these observations that the intramolecular hydrogen bond in **2** is almost disrupted in DMSO but not in **1**.

Similar behavior was observed for **3** and **4** in the same binary solvent system.

Emission Spectra. In DCE solution, the emission bands of **1**, **2**, **3**, and **4** are located at about 440, 460, 450, and 465 nm respectively. The large Stokes' shifts may be ascribed to the intramolecular proton transfer in the lowest excited state— often observed for many compounds having intramolecular hydrogen bonds.[6-8]

In 90% DMSO solution, **1** and **3** exhibited emission spectra similar to those in DCE solution, both in peak positions (429, 436 nm) and intensities. This similarity suggests that strong intramolecular interactions between the two substituents of **1** and **3** survive in the lowest excited singlet state in DMSO as well as in DCE and that intramolecular proton transfer takes place. The emission spectra of **2** and **4** in 90% DMSO solution were located at 348 and 400 nm, respectively and these large blue shifts suggest species without intramolecular hydrogen bonding between the phenolic OH and the carbonyl oxygen.

^1H NMR Spectra. The ^1H NMR spectral measurements were conducted on **3** and **4** because of easier analysis of the ring proton signals. The results are summarized in Table 1.

The phenolic hydroxyl proton of **3** appeared as a sharp signal at about the same field in $CDCl_3$ and DMSO (δ 12.11 and 12.68, respectively), much lower than the fields where **4** resonates, implying that the intramolecular hydrogen bond of **3** survives even in DMSO. The phenolic OH proton of **4** dissolved in $CDCl_3$ was observed as a very broad signal at about δ 9.6, indicating that the intramolecular hydrogen bond in **4** is much weaker than that in **3**. The broadness of this signal may be ascribed to the average of two molecular conformations, one with intramolecular hydrogen bonds and the other without, on the NMR time scale. Conversely in DMSO, the phenolic OH proton resonates at δ 8.8 as a broad signal. It can be said therefore that intermolecular hydrogen bonds between the phenolic OH of **4** and DMSO molecules exist exclusively.

Table 1. ^1H CHEMICAL SHIFTS IN ppm DOWNFIELD FROM TMS

Compd	Solvent	OH	NH	NCH_3	H-3	H-4	H-6

	DMSO	8.8[b]	—	2.59	6.67	7.17	7.63

s: Sharp. b: Broad.

The $N-CH_3$ signal for **4** was observed as a singlet in both solvents, $CDCl_3$ and DMSO. Hirota *et al.*[9] observed a singlet signal for the $N-CH_3$ groups of **2** in CD_2Cl_2 at room temperature but at low temperature discovered two discrete signals. The signal coalescence at room temperature was ascribed to the rapid rotation, on the NMR time scale, of the $N(CH_3)_2$ group around the amide bond, CO–N. From the MO calculation the bond, CO–N, is expected to have a reduced double bond character owing to the intramolecular hydrogen bonding of the carbonyl group with the phenolic OH group.[9] In DMSO the intramolecular hydrogen bond of **2** and **4** are considered to be disrupted from the UV spectroscopic point of view. Therefore, in terms of ^1H NMR spectroscopy it is expected that **2** and **4** dissolved in DMSO are very similar to *N,N*-dimethylbenzamide (**5**). It has been reported for **5** that $N-CH_3$ is a broad singlet at room temperature, when dissolved in $CDCl_3$.[10] However, two discrete signals were observed for an aqueous solution of **5**.[11] The methyl ether of **2**, the UV spectrum of which is very similar to that of **2** in DMSO, showed two discrete signals for the two $N-CH_3$ groups in both solvents, $CDCl_3$ and DMSO, at room temperature. This indicates that the intramolecular interaction of the phenolic OH with the $CON(CH_3)_2$ group in **2**

Table 2. ^{13}C CHEMICAL SHIFTS IN ppm DOWNFIELD FROM TMS

Carbon	**1**		**2**		**3**		**4**	
	$CDCl_3$	DMSO	$CDCl_3$[a]	DMSO	$CDCl_3$[a]	DMSO	$CDCl_3$[a]	DMSO
C-1	114.6	115.2	117.3	124.4	115.3	116.6	118.5	126.3
C-2	161.8	160.4	159.2	153.2	160.1	158.6	157.7	152.1
C-3	118.8	117.5	118.0	115.6	120.2	119.3	119.4	117.3
C-4	134.5	133.6	132.5	129.9	134.0	133.1	132.4	129.5

C=O	171.1	169.8	171.9	168.6	169.5	168.1	170.6	166.9
$N-CH_3$	26.5	26.0	38.2	b)	26.5	26.0	38.4	b)

a) Saturated solution. b) A very broad signal.

and **4** can not be neglected even in DMSO.

When the solvent was changed from $CDCl_3$ to DMSO the ring proton-6 of **3** shifted downfield, whereas that of **4** shifted a little upfield. With the same solvent change the amide proton signal of **3** shifted downfield as much as 2.71 ppm, while the phenolic OH signal shifted downfield much less. This indicates that strong intermolecular interactions of this compound with DMSO molecules occur through the amide proton. This intermolecular hydrogen bonding makes the ring proton-6 subject to the electric field due to the polar S–O group of the intermolecularly hydrogen bonded DMSO molecule, resulting in the lower field resonance of this proton. For the ring proton-6 in **4**, this type of deshielding may be negligible in DMSO. Possible internal rotation around the C_{ring}–CO bond, induced by the disruption of the intramolecular hydrogen bond, may be responsible for the slight upfield shift of proton-6.

^{13}C NMR Spectra. The ^{13}C chemical shifts of the four compounds are given in Table 2. Signal assignments for **3** and **4** could be readily made on the basis of the chemical shifts given for methyl salicylate in $CDCl_3$,[12] the chlorine-substituent constant, and the relative intensities. However, identification of the C-3 and C-5 signals of **1** and **2** is not so simple because of the close proximity. Fortunately, the C-3 signal showed additional fine splitting due to long range spin coupling with the OH proton when it was fixed by the intramolecular hydrogen bond with the carbonyl oxygen. This identified the C-3 signal in $CDCl_3$. Recording several ^{13}C spectra of **2** in mixed solvent systems of $CDCl_3$ and DMSO with varied compositions was applied to correlate the two sets of signals of C-3 and C-5 in $CDCl_3$ and DMSO solutions.

The pronounced DMSO-induced shifts (Table 3) were observed for C-1, C-2, and C–O in **2** and **4**; the carbonyl carbon and C-2 shifted upfield while the C-1 shifted downfield. These shifts can not be attributed to the usual solvent effects and since these carbons are closely related to the intramolecular hydrogen bond, it is reasonable to attribute the observed shifts to the replacement of intramolecular hydrogen bonds by the formation of intermolecular hydrogen bonds with DMSO molecules. It is reasonable to explain the observed upfield shifts of the carbonyl carbons in terms of the disruption of the intramolecular hydrogen bonds, since the carbonyl carbon of salicylaldehyde was shown to resonate at lower fields by 3.6 and 3.0 ppm than those of the *m*- and *p*-isomers, respectively.[13] Similarly, the upfield shifts of the carbonyl carbon, upon changing from acid to ester, has been ascribed to impossibility of hydrogen bond formation in the latter.[14]

Table 3. DMSO-induced shifts ($\delta_{DMSO} - \delta_{CDCl_3}$)

Carbon	**1**	**2**	**3**	**4**
C-1	0.6	7.1	1.3	7.8
C-2	−1.4	−6.0	−1.5	−5.6
C-3	−1.3	−2.4	−0.9	−2.1
C-4	−0.9	−2.6	−0.9	−2.9
C-5	−0.5	0.6	−1.1	−0.7
C-6	1.8	−0.8	2.1	−0.7
C=O	−1.3	−3.3	−1.4	−3.7
N–CH_3	−0.5	—	−0.5	—

Secondary effects, such as changes in the degree of conjugation between the ring and the substituents induced by the disruption of the intramolecular hydrogen bond, may be responsible for the observed shifts for the other carbons.

Reduction of 6,6-Disubstituted Fulvenes and 1,2-Benzoheptafulvene by Naphthalene Radical Anion

Akira Oku,* Mitsuhiro Yoshida, and Kenkichi Matsumoto

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received July 12, 1978)

Structural effects of fulvenes in the electron transfer reaction were examined by using naphthalene radical anion (**1**) as a homogeneous electron source in aprotic media. The reduction of 6,6-diphenylfulvene (**2**) with **1** in THF at −78 °C gave 3-benzhydrylcyclopentadiene (34%) and its 2-isomer (13%). The structures were determined by hydrogenation and by the reaction with *N*-phenylmaleimide. The reaction of 6,6-dimethylfulvene (**3**) with **1** gave bi(2-isopropylidene-3-cyclopentenyl) as the major product (39%) besides bi(2-isopropyl-1,3-cyclopentadienyl) (5%). The reaction of 3,3′,4′,5,5′,6,6′-heptamethyl-1,2-benzoheptafulvene (**4**) with **1** gave 3,3′,4,4′,5,5′,-6′,7-octamethyl-1,2-benzo-1,3,6-cycloheptatriene (32%) and 3,3′,4′,5,5′,6,6′,7-octamethyl-1,2-benzo-1,3,5-cycloheptatriene (18%). These product structures as well as the CH_3I- and D_2O-quenching of the reduction intermediates indicate that **2** is reduced by the EEC-mechanism and **3** by the ECC-mechanism, whereas the results are rather complicated in the case of **4** to distinguish between EEC and ECC mechanism.

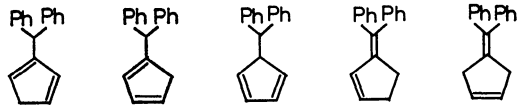
In the study of chemical reactions *via* electron transfer mechanism, it often turns out necessary to clarify the specificity of the reaction and correlate it with electrochemical processes. In the reduction of olefins by means of Birch-type reductions[1] and stable aromatic hydrocarbon radical anions[2] which proceeds quite rapidly under homogeneous and aprotic conditions,[3] the following mechanisms have hitherto been accepted: (i) two succeeding electron transfer steps followed by a chemical reaction (EEC mechanism), and (ii) an electron transfer step followed by two chemical reactions (ECC mechanism).[4] The ECE mechanism (two electron transfer steps intercepted by protonation) generally involved in electrolytic reductions is negligible in the case of reductions by aromatic radical anions. Nevertheless, radical anion $R^{\cdot-}$ is the initially formed common chemical species in all these routes, but its behavior thereafter varies depending upon the reaction conditions[5] and the structure of substrates.

$$R \xrightarrow{e} R^{\cdot-} \begin{cases} \xrightarrow{e} [R]^{2-} \xrightarrow{2H^+} RH_2 & \cdots\cdots\text{EEC} \\ \xrightarrow{H\cdot} [RH]^- \xrightarrow{H^+} RH_2 & \cdots\cdots\text{ECC} \\ \xrightarrow{H^+} [RH]\cdot \xrightarrow{e} [RH]^- \xrightarrow{H^+} RH_2 & \cdots\text{ECE} \\ \xrightarrow{e} [R]^{2-} \xrightarrow{R} [R\text{–}R]^{2-} \xrightarrow{2H^+} RH\text{–}RH & \cdots\cdots\text{EECC} \\ \xrightarrow{\text{coupling}} [R\text{–}R]^{2-} \xrightarrow{2H^+} RH\text{–}RH & \cdots\cdots\text{ECC} \end{cases}$$

In order to ascertain the structural effects that control the reaction paths and product structures, the authors chose some fulvenes as one type of olefin models, *i.e.*, 6,6-diphenylfulvene (**2**), 6,6-dimethylfulvene (**3**), and 1,2-benzoheptafulvene (**4**), and examined their behavior in chemical electron transfer reactions in aprotic media. Sodium naphthalene (**1**) in tetrahydrofuran (THF) was employed as a homogeneous electron source and was used with the reactant ratio of [reductant]/[fulvene]=2 in all reactions.

Results and Discussion

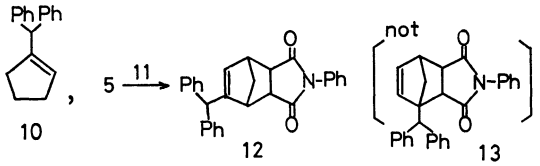
Reduction of 6,6-Diphenylfulvene (2) by Sodium Naphthalene. The reaction of diphenylfulvene (**2**)[6] with sodium naphthalene (**1**)[7] in THF at −78 °C gave a viscous oil as the major product (47%). Its mass spectrum showed the parent ion peak at m/e=232 which is equivalent to a hydrogenated structure, **2**+2H. The NMR spectrum indicated that the product molecule involves two allylic methylene hydrogen and has an unsymmetrical geometry. Therefore, among five possible [**2**+2H]-structures **5**—**9**, only **5** and **6** satisfy the NMR observations. In addition, VPC as well as NMR



5 6 7 8 9

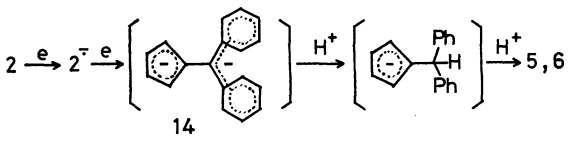
analysis indicated that the product consisted of two components with the ratio of *ca.* 3/1. Their separation was unsuccessful and the product was treated as a mixture in elucidating their structures in the following chemical transformations.

In catalytic hydrogenation (Pd/C), the mixture absorbed exactly 1 mol hydrogen per the molecular weight 232, giving the hydrogenated product **10** as the sole product. This supports that the structures of products are **5** and **6**, though the question of choosing the major isomer still remains unsolved. To know this answer, the mixture was treated with *N*-phenylmaleimide (**11**). The structure of the obtained adduct (isolated yield 40%) was ascribed to **12** with the support of mass spectrum (M^+=405) and NMR (the number of olefinic hydrogen per molecule was one), and consequently the major isomer was proved to be **5**, but not **6**. This structure agrees with the one previously proposed for the single reduction product isolated in the reaction of **2** with sodium metal in diethyl ether.[8]



10 12 13

The D_2O-quenching technique in this reaction system seems inadequate to elucidate the carbanion intermediates, because cyclopentadiene hydrogens are so susceptible to the H/D exchange that excessive amount of deuterium incorporated in **5** and **6** (d_3 28%, d_4 18%).[9] Instead, the reaction was quenched by methyl iodide (which was added until the reaction mixture was decolorized) to give methylated products, which consisted of dimethylated (**2**+2Me), and monomethylated (**2**+Me +H) products with the ratio of 88: 12 (isolated total yield was 42% after repeated column chromatography). In contrast, no methyl group was introduced into the H_2O-quenched products in the treatment with methyl iodide under basic conditions. These results support that the trapped intermediate is a dianion. Additionally, the product structures **5** and **6** are indicative of the formation of dianion **14** as their precursor in which negative charges are separated so that the repulsive force can be minimized and both benzhydryl and cyclopentadienyl systems are contributing to stabilizing the separated charge (Scheme 1). The intermediacy of **14** is also compatible with the polarographic data of **2** ($^1E_{1/2}$= −1.30, $^2E_{1/2}$= −1.78 V *vs.* SCE; *cf.* naphthalene −2.6 V),[10] although the structures of the electrolytic reduction products have not been reported yet.

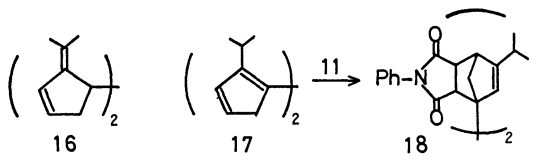


Scheme 1.

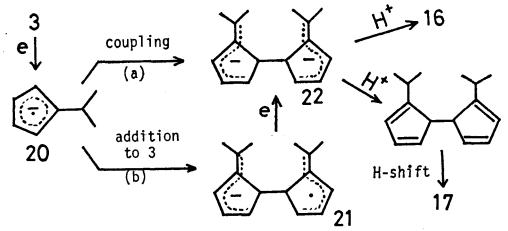
Reduction of 6,6-Dimethylfulvene (3) by Sodium Naphthalene. When 6,6-dimethylfulvene (**3**)[11] was treated under the same conditions as in the case of **2** (−78 °C in THF), only one product was detectable by VPC analysis (isolated yield 39%, air-sensitive) in addition to the formation of resinous solids. The mass spectrum showed M^+ peak at m/e=214, which is equivalent to the formula, 2×**3**+2H. In the NMR spectrum, the proton spin coupling pairs are: i) allylic methyl protons at 1.80 with olefinic proton at 5.90, ii) methylene protons at 2.20 with both olefinic protons at 5.90 and 6.26.[12] However, no coupling was observed between methine proton at 3.1 and olefinic proton at 6.26. Therefore, among several possible structures, **16** seems to be most explainable of the above-mentioned NMR observation.

Before isolating products, the crude reaction mixture was mixed with maleimide **11** at −50 °C and the mixture was warmed up to ambient tempeature. A solid product was isolated (5%), M^+ was 560. In its NMR spectrum, the absorption at 0.97 is ascribable to isopropyl methyl protons which couple with the methine proton (J=7.5 Hz) concealed in other protons around 2.0; this methine proton also couples with the olefinic proton at 5.90; a pair of doublet (AB-Type) appears at 1.45—2.10 which is ascribable to the apical methylene protons; the integrated intensity of the olefinic proton relative to the methyl is 1/6. These spectral data support the adduct structure **18**, thus proving the presence of another product **17** as a minor component.

When **3** was treated with **1** at 0 °C, a new product **19** (65%) was obtained in addition to **16** (15%). This product (mp 156 °C) showed the M^+ peak at 342 which is equivalent to [2×**3**+2H+naphthalene], but the structure is not elucidated yet. The same product was also formed when **3** was added into **1** at −78 °C (inverse dropping method).



In contrast to the reaction of **2**, **3** is anticipated to show an entirely different behavior and give different product due to the methyl substituents at C-6 position. In fact, no possible monomeric product was formed, but dimeric products **16** and **17** were obtained. These structures are entirely different from the reported one in the reduction of **3** by sodium metal.[8] The formation of dimers can be most reasonably explained in terms of ECC mechanism (route *a*) or ECEC mechanism (route *b*)[4] (Scheme 2), although the averaged polarographic two-electron reduction potential of **3** was reported to be −1.90 V *vs.* SCE,[13] so far not low enough to rule out an EECC mechanism. In this Scheme, the C–C bond



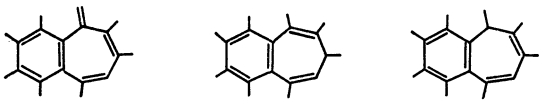
Scheme 2.

formation by either radical coupling (route *a*) or addition (route *b*) takes place more favorably between C-1 positions rather than between C-6 positions, because the latter position is sterically more crowded and the bonding at C-1 positions results in the formation of stable dienyl conjugation in **22** (or **21**). Another evidence against EEC mechanism was obtained in the reaction using an inverse dropping method (in which **3** was added into **1** at −78 °C); no monomeric product was obtained but **16**, **17**, and **19**. If any EEC mechanism had been involved, then a significant change in the products would have been observed. Scheme 2 postulates the derivation of **16** and **17** from an identical intermediate **22**; probably the protonation on the C-2 position of **22** takes place more favorably than on C-6 due to the difference in the stability between secondary and tertiary carbanions.

Reduction of 1,2-Benzoheptafulvene (4) by Sodium Naphthalene. Unsubstituted heptafulvene and its simple homologues are usually unstable and difficult to prepare.[14] In the present study, 3,3′,4′,5,5′,6,6′-heptamethyl-1,2-benzoheptafulvene (**4**)[15] was chosen as a model of seven-membered fulvene system, though not the most suitable, but because it is stable and has the unsymmetrically substituted structure easy to elucidate

the reduction products.

The reduction of **4** with **1** was carried out at −40 °C and two isomeric products, 3,3′,4,4′,5,5′,6′,7-octamethyl-1,2-benzo-1,3,6-cycloheptatriene (**23**) and 3,3′,4′,5,5′,6,6′,7-octamethyl-1,2-benzo-1,3,5-cycloheptatriene (**24**), were isolated (total yield 50%, **23**/**24**=64/36). Both of them showed the identical M^+ peaks in their mass spectra (254, equivalent to **4**+2H) and their NMR spectra did not show the presence of exo methylene protons. Thus the exo double bond was preferably reduced. These isomers were able to be separated by VPC and their structures were determined independently by the NMR analysis (see the Experimental section). Consequently,



4 23 24

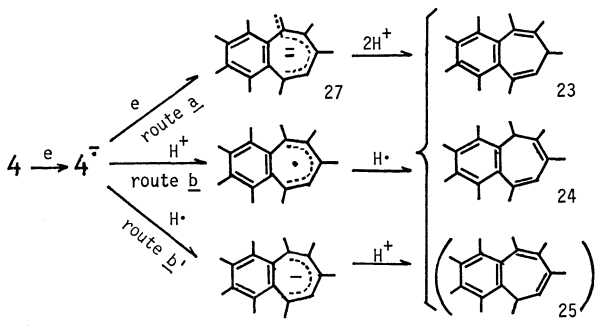
the major product was ascribed to the structure **23** and the minor to **24**. The fact that the isomer ratio **23**/**24** stayed almost unchanged (63—66/37—34) throughout the reaction period (3 h at −40—0 °C) and that deuterium was not incorporated when a mixture of **23** and **24** was treated by NaOD in D_2O, rules out the possibility of base-induced isomerization between products.

Table 1. *d*-Distribution in the D_2O-quenched products **23** and **24**

Run	Compound	Treatment	*d*-Distribution, %		
			d_0	d_1	d_2
1	**23**	—[a]	19	43.5	37.5
2	**24**	—[a]	26	40	34
3	**23**	D/H[b]	20.1	45.4	34.2
4	**23**	H/D[c]	20.2	45.2	34.6

a) After D_2O quenching. b) The D_2O-quenched product was treated with 15% $NaOD/D_2O$ at 25 °C for 10 h. c) The D_2O-quenched product was treated with 15% $NaOH/H_2O$ at 25°C for 10 h.

The geometrical and electronic structure of benzoheptafulvene **4** is essentially different from pentafulvenes and its immediate comparison with **2** and **3** in the reduction behavior seems complicated. The D_2O quenching technique of the reaction of **4** incorporated 34—37% d_2 and 40—44% d_1 in both products **23** and **24** (see Table 1), whereas the standard experiment in which the mixture of **23** and **24** was treated with 15% $NaOD/D_2O$ or $NaOH/H_2O$ did not show any appreciable H/D exchange. In so far as the formation of these dideuterio compounds is concerned, a rational species to be protonated seems to be dianion intermediate **27** which can be formed by the EEC mechanism (route *a* in Scheme 3). However, the extent of the d_2-incorporation was not high enough to exclude the ECC (route *b* or *b′* in Scheme 3) or ECEC mechanism.



Scheme 3.

Experimental

General. The NMR spectra were measured by Varian T-60A and HA-100 spectrometers and chemical shifts were expressed in δ units. The mass spectra were measured by Hitachi RU-6L GC-MS spectrometer with the chamber voltage of 80 eV. Generally, the reductions were carried out by the method of dropping the reductant into fulvenes (normal dropping method) unless otherwise stated.

Sodium Naphthalene (1). Under the atmosphere of purified nitrogen, a THF solution of **1** was prepared from sodium metal and naphthalene, the latter recrystallized repeatedly from methanol before use. The amount of reagents which were charged initially for the preparation of **1** was kept constant at 0.5 g atom Na/0.5 mol naphthalene/liter THF throughout all experiments.[16]

Pentafulvenes. 6,6-Diphenylfulvene (**2**) and 6,6-dimethylfulvene (**3**) were prepared from cyclopentadiene according to the reported methods.[6,11]

3,3′,4′,5,5′,6,6′-Heptamethyl-1,2-benzoheptafulvene (4). Heptafulvene **4** was prepared by the reduction of the corresponding 4-Cl derivative (**4a**) which was obtained by the reaction of octamethylnaphthalene (OMN) with dichlorocarbene. The alternative 4-Br derivative (**4b**)[17] can also be used though the reaction of OMN with CBr_2 yielded 6-Br isomer as a by-product.[15]

Under a gentle stream of purified N_2, a THF solution of **1** (10 ml) was added dropwise to a cooled (−78 °C) solution of **4a** (1.28 g, 4.5 mmol) in THF (50 ml) over 10 min. After additional stirring for 20 min, the solution was decolorized by a mixture of H_2O and THF (2+10 ml). Solvent was removed and the residue, dissolved in Et_2O, was washed with aq NaCl and dried. Naphthalene was removed by sublimation and the residue was chromatographed through a silica gel column (pet. ether) to yield 0.55 g of **4** (49%); mp 104—105 °C, M^+ 252. ^{1}H-NMR (CCl_4) 1.66 and 1.92 (3H each, q, J=0.5 Hz, 5- and 6-Me), 2.06 (3H, d, J=1.4 Hz, 3-Me), 2.18 (3H, s), 2.20 (3H, s), 2.21 (3H, s), 2.29 (3H, s), 4.75 and 5.03 (1H each, dd, J=2.2 Hz, exo CH_2), 5.99 (1H, bs, J=1.4 Hz, 4-H).

Reduction of 6,6-Diphenylfulvene (2) by 1. **2** (4.7 g, 20.4 mmol) was dissolved in 50 ml of dry THF and the solution was bubbled through by N_2 for 10 min at ambient temperature. The solution was cooled to −72——78 °C and a THF solution of **1** (40 mmol) was added dropwise over 30 min. After additional stirring (1 h at −78 °C) of the colored solution (dark crimson purple), a mixture of H_2O and THF (3+10 ml) was added and the solution was warmed up to ambient temperature. The solution was diluted by Et_2O (100 ml), washed with water repeatedly till the aq layer showed pH=7.0, and dried over anhyd $MgSO_4$. After removing solvents, the residue was chromatographed through a silica gel column (pet. ether). The first fraction consisted mainly of naphthalene and the second one contained reduction products 3-benzhydrylcyclopentadiene (**5**) and its 2-isomer (**6**) as a mixture. A resinous substance trapped in the column was incapable of being identified. The products **5** and **6** could not be

separated satisfactorily by such attempted means as TLC and VPC. Yield of the mixture, 2.2 g (47%). Isomer ratio **5**/**6**=34/13 (by NMR). M^+, 232. NMR (CCl_4) 2.80—3.00 (2H, m+m′, coupling with H at 5.15 and 5.7—6.0), 5.15 (1H, m, coupling with H at 2.80—3.0 and 6.45), 5.70—6.00 (1H, m+m′, coupling with H at 2.80—3.0 and 6.2—6.45), 6.20—6.45 (2H, d+m′, coupling with H at 5.70—6.0 and 5.15), 7.20 (10H, bs).

Reduction of **2** *by* **1**, *D_2O-Quenching*: The procedure was essentially the same with that described above except that 99.9% D_2O was used as the quencher instead of H_2O. The product mixture showed an analogous VPC chromatogram to that of the H_2O-quenched products. The deuterium content of the products was determined by mass spectrometry: d_0 5.0, d_1 14.6, d_2 26.1, d_3 28.8, d_4 18.2%.

Reduction of **2** *by* **1**, *CH_3I-Quenching*: The solution of the reaction mixture of **2** (4.7 g, 20 mmol) and **1** (50 mmol) was quenched by methyl iodide (5.7 g, 40 mmol in 30 ml of THF) at −78 °C. After stirring for 40 min, the temperature was gradually raised to 0 °C and the mixture was worked-up with water and Et_2O. The organic residue was chromatographed three times through silica gel columns (pet. ether) to isolate methylated products, 2.9 g (42%). The VPC-mass spectral analysis showed that this consisted of dimethylated (88%) and monomethylated product (12%). The NMR showed methyl protons (6H at 1.8—2.0) relative to other aliphatic protons (2H at 2.6—2.8 and 2H at 5.5—6.5) and aromatic protons (10H at 7.15). The mass spectral analysis of the isolated dimethyl-product showed the M^+ peak at 260 (**2**+2Me) consistent with the dimethylated structure and that of the monomethylated product at 246 (**2**+Me+H), although the methylated positions were not elucidated.

Catalytic Hydrogenation of the Mixture **5**+**6**: A mixture of **5** and **6** (0.64 g, 2.8 mmol) was hydrogenated over Pd/C (0.13 g) in EtOH (13 ml) at 25 °C. The solution absorbed 61.3 ml H_2 (calcd 61.6 ml for one double bond) over 6.5 h to afford 1-benzhydryl cyclopentene (**10**). IR (C=C) 1600 cm^{-1} (CCl_4). NMR (CCl_4) 1.5—2.3 (6H, m), 4.7 (1H, bs), 5.2 (1H, dd, J_1=4, J_2=2 Hz), 7.1 (10H, s). Only one eluting spot was shown by TLC.

*Reaction of the Mixture (***5**+**6***) with N-Phenylmaleimide (***11***)*: Under N_2 atmosphere, a solution of **11** (0.53 g, 3 mmol, in 5 ml of benzene) was mixed with a benzene solution of **5** and **6** (0.70 g, 3 mmol in 5 ml), (slightly exothermic). The mixture was heated in a sealed tube at 60 °C for 2 h to give colorless solids of adduct **12**. 0.49 g (40%), mp 247.0—248.5 °C. NMR (acetone-d_6) 1.60 and 2.00 (1H each, dd, J=9 Hz, apical CH_2), 3.23 (1H, m), 3.45—3.55 (3H, m, coupling with H at 1.60, 2.00, and 5.52, bridgehead), 4.60 (1H, d, J=2 Hz, coupling with H at 5.52, benzhydryl), 5.52 (1H, m, olefinic), 6.70—7.60 (15H, m, ArH). Found: C, 82.85; H, 5.64; N, 3.34%; M^+, 405. Calcd for $C_{28}H_{23}NO_2$: C, 82.94; H, 5.72; N, 3.45%; M, 405.

*Reduction of 6,6-Dimethylfulvene (***3***) by* **1**. Under N_2 stream, **1** (51 mmol in 92 ml of THF) was added over 30 min to a freshly distilled **3** (2.70 g, 25.5 mmol, in 50 ml of THF) at −76 °C. The rate of decoloration of the radical anion was slow compared with that in the case of **2**. After additional stirring for 30 min, H_2O (0.9 ml in 25 ml of THF) was added and the solution was warmed up to ambient temperature. After working-up, the obtained mixture showed three TLC spots. The ethereal solution of the products, 210 ml, was divided into two parts, 160 and 50 ml, and the former was chromatographed first through a silica gel column (pet. ether) to remove polymeric products, and then by VPC (PEG 20M) to separate three fractions corresponding to the TLC spots. The first two fractions were di- and tetrahydronaphthalene, and the third fraction, liquid, was determined to be a dimeric product **16**, bi(2-isopropylidene-3-cyclopentenyl), 1.05 g (39%), by the following spectral data. NMR (CCl_4) 1.80 (6H, bs, allylic Me, slightly coupling with H at 5.90), 2.20 (2H, m, coupling with H at 3.10, 5.90, and 6.26), 3.10 (1H, m, coupling with H at 2.20), 5.90 (1H, m, coupling with H at 2.20, 6.26 by J=6 Hz, and slightly with 1.80), 6.26 (1H, a pair of t, coupling with H at 5.90 by J=6, with H at 2.20 by J=2 Hz). M^+ 214.

Reaction of the Product Mixture Obtained from **3** *with* **11**: The latter of the divided solution (50 ml) prepared in the preceding experiment was mixed with **11** (0.65 g, 3.8 mmol) under N_2 at 0 °C and the mixture was stirred for 15 h. White solids of adduct **18** separated, 0.12 g (5.3%), mp 300 °C. NMR ($CDCl_3$) 0.97 (12H, splitted d, J=7.5 Hz, isopropyl Me), 1.62 and 1.93 (2H each, dd, J=8 Hz, apical), 1.45—2.10 (2H, concealed, coupling with Me), 3.46 (6H, m, coupling with H at 5.90, bridgehead), 5.90 (2H, m, olefinic, coupling with H at 1.45—2.10 and 3.46), 7.30 (10H, m, ArH). Found: C, 77.31; H, 6.59; N, 4.81%; M^+, 560. Calcd for $C_{18}H_{18}NO_2$: C, 77.12; H, 6.47; N, 5.00%; M, 560.

Reduction of **4** *by* **1**. A solution of **4** (200 mg, 0.83 mmol) in dry THF (30 ml) was treated by a THF solution of **1** (1.8 mmol) at −40 °C for 1 h under N_2. The initially dark-green colored solution turned brown-red, which was then decolorized by a mixture of H_2O and THF (1+3 ml) at −30 °C. The mixture was extracted with Et_2O, washed with water and dried ($MgSO_4$). After removing naphthalene by sublimation, the residue was analyzed by VPC (PEG 20M, 2 m) to show two products. They could not be separated by TLC but by preparative VPC, where the first eluting fraction was **23** and the second was **24** (total yield 50%, **23**/**24**=64/36). **23**, liquid, M^+ 254. NMR (CCl_4) 1.10 (3H, d, J=12 Hz), 1.80 (6H, bs), 1.85 (3H, d, J=1.2 Hz), 2.1—2.25 (12H, m, plus concealed 1H coupling with Me at 1.10 as well as with H at 5.54), 5.54 (1H, dq, J=7.0 and 1.2 Hz). **24**, liquid, M^+ 254. NMR (CCl_4) 1.10 (3H, d, J=12 Hz), 1.63 (3H, bs), 1.79 (3H, bs), 2.04 (3H, d, J=1.5 Hz), 2.11 (3H, s), 2.17 (6H, s), 2.24 (3H, s), 3.75 (1H, q, J=12 Hz), 6.05 (1H, bs, coupling with Me at 2.04). The product ratio **23**/**24** stayed almost constant (63−66/37−34) during the reaction period.

The financial support of this work from the *Asahi Glass Foundation for the Contribution to Industrial Technology* is acknowledged with gratitude. We are also grateful for the Grant-in-Aid for Scientific Research from the Ministry of Education (No. 355372).

Reactions of 2′-Hydroxyisoflavone and 2′-Hydroxy-2-methylisoflavones with Metal Salts

Kazu KUROSAWA* and Fukuo ARAKI

Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860

(Received July 17, 1978)

Reactions of four 2′-hydroxy-2-methylisoflavones with lead(IV) acetate gave the corresponding 10b-acetoxy-5a-methyl-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-ones in 21—25% yields and 2-(2-methyl-4-oxo-4*H*-chromen-3-yl)-*p*-benzoquinones in 27—46% yields. Reactions of the isoflavones with manganese(III) acetate gave the ketones in 1—25% yields. Reaction of 2′-hydroxy-4′,7-dimethoxyisoflavone with lead(IV) acetate gave 10b-acetoxy-3,8-dimethoxy-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one, and 3,8-dimethoxybenzofuro-[2,3-*b*][1]benzopyran-11-one.

In the lead(IV) acetate oxidation of organic compounds in which a hydroxyl group and a double bond or a hydrogen are located in a spatially suitable position, an oxidative cyclization has been found.[1,3-7] Manganese(III) acetate oxidations of the compounds have also been reported to give cyclic products.[2-5,7] It could be expected that the reaction of 2′-hydroxy-2-methylisoflavone with metal salts might give a dehydrorotenoid by the removal of hydrogens from the hydroxyl and methyl groups. The dehydrorotenoid can be transformed into a rotenoid, which is known as a fish poison. It is also expected that the reaction of 2′-hydroxyisoflavone with metal salts would give benzofuro-[2,3-*b*][1]benzopyran-11-one, which has been found in natural sources as Lisetin.[8] Lisetin was synthesized from Piscerythrone, which was also a natural product, by the oxidation with potassium hexacyanoferrate.[8] However, this method is not applicable to water insoluble 2′-hydroxyisoflavones (described later).

2′-Hydroxy- and 2′-hydroxy-2-methylisoflavones (Ia—e) were prepared by partial demethylation of the corresponding 2′-methoxyisoflavones with aluminium chloride. The structures of new isoflavones were determined by examining their NMR and IR spectra, and by elemental analyses.

The reaction of 2′-hydroxy-4′,7-dimethoxy-2-methylisoflavone (Ib) with lead(IV) acetate in hot acetic acid gave two products, IIb and IIIb (Table 1, entry 3). The NMR spectrum of IIb ($C_{20}H_{18}O_7$, mp 186—188 °C) indicated that it is an acetate (δ 2.20) with a methyl group (δ 1.79), two methoxyl groups (δ 3.71 and 3.81), and six aromatic protons {δ 6.3—6.8 (4H, m), 7.35 (1H, d, J=8.5 Hz) and 7.75 (1H, m)}. The IR spectrum showed carbonyl absorptions at 1710 and 1760 cm^{-1}. These spectroscopic properties are consistent with the structure of 10b-acetoxy-3,8-dimethoxy-5a-methyl-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one (IIb) (Fig. 1). The NMR spectrum of IIIb ($C_{18}H_{14}O_6$, mp 237 °C) indicated the presence of a methyl group (δ 2.29), two methoxyl groups (δ 3.90 and 3.95), two singlet protons (δ 6.11 and 6.72), and three aromatic protons {δ 6.85—7.05 (2H, m) and 8.13 (1H, d, J=8.5 Hz)}. The IR spectrum exhibited multiple absorptions at 1630—1660 cm^{-1} and a carbonyl absorption at 1700 cm^{-1}. The spectroscopic evidence suggested that the structure of IIIb is to be 2-(7-methoxy-2-methyl-4-oxo-4*H*-chromen-3-yl)-5-methoxy-*p*-benzoquinone (IIIb). The reactions of Ib with lead(IV) acetate in acetic acid at room temperature and in benzene at reflux temperature gave less satisfactory results (entries 4 and 5). When Ib was treated with aqueous potassium hexacyanoferrate, the starting material was recovered unchanged.

Three other 2′-hydroxy-2-methylisoflavones (Ia, Ic, and Id) also gave the corresponding 10b-acetoxy-5a-methyl-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-ones (IIa, IIc, and IId) and 2-(4-oxo-4*H*-chromen-3-yl)-*p*-benzoquinones (IIIa, IIIc, and IIId), respectively, in the oxidation with lead(IV) acetate. The reaction of Ib with manganese(III) acetate gave a dimeric compound, IV ($C_{40}H_{34}O_{14}$, mp 300 °C), together with IIb (entries 6, 7, and 10). IIIb was not obtained in these cases. The NMR spectrum of IV was similar to that of IIb, except for the presence of *para*-related protons {δ 7.24 (s) and 6.35 (s)} instead of the one set of three aromatic protons in IIb. The reactions of Ia, Ic, and Id with manganese(III) acetate gave IIa, IIc, and IId, respectively, in less satisfactory yields (entries 2, 12, and 14).

The reaction of 2′-hydroxy-4′,7-dimethoxyisoflavone (Ie) with lead(IV) acetate yielded two products, IIe and V. When the reaction was conducted at room temperature, IIe was the major product (entry 15). At reflux temperature, however, V was the major product (entry 17). The structures of these products were again elucidated by examining their NMR and IR spectra, and are shown in Fig. 1. It appears that the removal of acetic acid from IIe would give V and, in fact, the heating of IIe up to 250 °C yielded V in quantitative yield. The thermal elimination of acetic acid from IIe IIe suggests that the stereochemistry of the 5a-hydrogen and the 10b-acetoxyl group would be *cis*. This also leads to the prediction that the stereochemistry of 5a-methyl and 10b-acetoxyl groups in IIa—d would be *cis*, which is the more stable conformation predicted from molecular models.

In conclusion, the reactions of 2′-hydroxy-2-methylisoflavones (Ia—d) with lead(IV) acetate and manganese(III) acetate did not yield the expected dehydrorotenoids, but gave new dihydrobenzofuro-[2,3-*b*][1]benzopyran-11-ones (IIa—d), while the reaction of 2′-hydroxyisoflavone gave benzofuro[2,3-*b*][1]-benzopyran-11-one (V). The latter reaction can be utilized as a synthetic method for benzofuro[2,3-*b*][1]-benzopyran-11-one.

Table 1. The reactions of 2′-hydroxyisoflavones with metal salts

Entry	Compd	Reaction conditions: Oxidant	Molar ratio of I: oxidant	Solvent	Temp (°C)	Time (h)	Product (% yield)[a]			
1	Ia[9]	$Pb(OAc)_4$	1:1.5	AcOH	100	0.5	IIa (25)	IIIa (45)		
2	Ia	$Mn(OAc)_3 2H_2O$	1:3	AcOH	100	1.0	IIa (1)			
3	Ib	$Pb(OAc)_4$	1:1.5	AcOH	100	0.5	IIb (25)	IIIb (46)		
4	Ib	$Pb(OAc)_4$	1:1.5	AcOH	R.T.	2.0	IIb (21)	IIIb (28)		
5	Ib	$Pb(OAc)_4$	1:1.5	benzene	80	1.0	IIb (5)	IIIb (17)		
6	Ib	$Mn(OAc)_3 2H_2O$	1:1	AcOH	100	0.5	IIb (16)		IV (3)

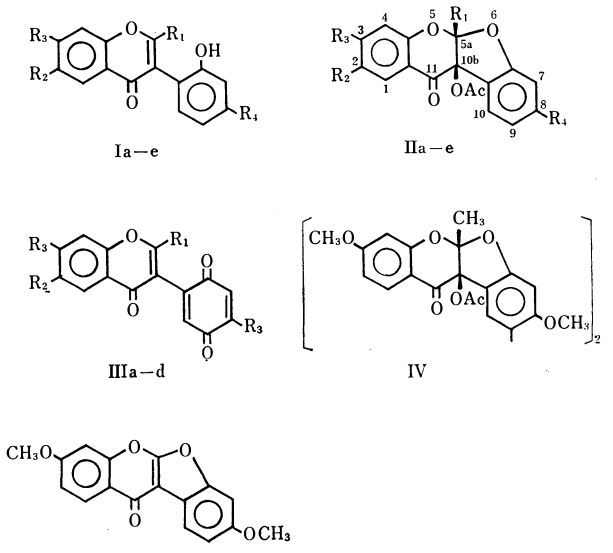
a) Yield is based on the amount of isoflavone consumed. b) Two equivalents of Ac_2O were added.



a $R_1=CH_3$, $R_2=R_4=H$, $R_3=OCH_3$
b $R_1=CH_3$, $R_2=H$, $R_3=R_4=OCH_3$
c $R_1=CH_3$, $R_2=R_3=OCH_3$, $R_4=H$
d $R_1=CH_3$, $R_2=R_3=R_4=OCH_3$
e $R_1=H$, $R_2=H$, $R_3=R_4=OCH_3$

Fig. 1.

Experimental

All ^1H NMR spectra were recorded with a Hitachi NMR spectrometer with TMS as an internal standard. The IR spectra were recorded with a JSACO grating spectrometer. The UV spectra were recorded with a Hitachi EPS-3T spectrophotometer, while the mass spectrum was recorded with a JEOL JMS-01 SG-2 mass spectrometer. Melting points were determined on a Yanagimoto hot-stage and are uncorrected.

Preparation of 2-Methylisoflavones. A typical procedure for the preparation of 2-methylisoflavone was as follows. A mixture of a phenyl benzyl ketone (0.5 g), sodium acetate (0.5 g) acetic anhydride (2 ml), and acetic acid (2 ml) was heated under reflux for 12 h. The reaction mixture was poured into ice water and the precipitates were collected.

2-Hydroxy-4,5-dimethoxyphenyl 2-methoxybenzyl ketone[11] gave 2-methyl-2′,6,7-trimethoxyisoflavone, mp 172—173 °C (EtOH) in a 31% yield. IR ($CHCl_3$) 1640 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 288 (11900) and 324 nm (10200); NMR ($CDCl_3$) δ=2.18 (3H, s, CH_3), 3.72 (3H, s, OCH_3), 3.92 (6H, s, $2\times OCH_3$), 6.83 (1H, s, $H_{(8)}$), 6.95—7.43 (4H, m, $H_{(3'-6')}$), and 7.51 (1H, s, $H_{(5)}$). Found: C, 69.94; H, 5.60%. Calcd for $C_{19}H_{18}O_5$: C, 69.92; H, 5.56%.

2-Hydroxy-4,5-dimethoxyphenyl 2,4-dimethoxybenzyl ketone[12] yielded 2-methyl-2′,4′,6,7-tetramethoxyisoflavone, mp 175—177 °C (EtOH) in a 31% yield. IR ($CHCl_3$) 1635 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 291 (12200) and 325 nm (9700); NMR ($CDCl_3$) δ=2.20 (3H, s, CH_3), 3.78 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), 3.95 (6H, s, $2\times OCH_3$), 6.4—7.4 (2H, m, $H_{(3')}$ and $H_{(5')}$), 6.89 (1H, s, $H_{(8)}$), 7.18 (1H, m, $H_{(6')}$), 7.57 (1H, s, $H_{(5)}$). Found: C, 67.10; H, 5.82%. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%.

Preparation of 2′-Hydroxy-2-methylisoflavones (Ib—d). A typical procedure for the preparation of 2′-hydroxy-2-methylisoflavone was as follows. A mixture of a 2′-methoxy-2-methyl isoflavone (10 mmol), aluminium chloride (20 mmol), and nitrobenzene (50 ml) was heated at 100 °C for 1 h. After the removal of the nitrobenzene under reduced pressure, the resulting mixture was triturated with 2 M hydrochloric acid. The precipitates were collected and recrystallized.

2′-Hydroxy-4′,7-dimethoxy-2-methylisoflavone (Ib): Mp 224—225 °C ($CHCl_3$); 44% yield; IR (KBr) 3300 (OH) and 1620 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 247 (25000), 251 (25300), and 290 nm (15700); NMR (CF_3COOH) δ=2.70 (3H, s, CH_3), 4.02 (3H, s, OCH_3), 4.17 (3H, s, OCH_3), 6.75—7.59 (5H, m), and 8.59 (1H, m, $H_{(5)}$). Found: C, 69.42; H, 5.05%. Calcd for $C_{18}H_{16}O_5$: C, 69.22; H; 5.16%.

2′-Hydroxy-6,7-dimethoxy-2-methylisoflavone (Ic): Mp 251—253 °C ($CHCl_3$); 27% yield; IR (KBr) 3240 (OH) and

1630 cm^{-1} (C=O), UV (MeOH) λ_{max} (ε) 298 (13600) and 324 nm (11700); NMR (CF_3COOH) δ=2.79 (3H, s, CH_3), 4.20 (3H, s, OCH_3), 4.28 (3H, s, OCH_3), 7.21—7.53 (4H, m, $H_{(3'-6')}$), 7.58 (1H, s, $H_{(8)}$), and 7.86 (1H, s, $H_{(5)}$). Found: C, 69.50; H, 5.20%. Calcd for $C_{18}H_{16}O_5$: C, 69.22; H, 5.16%.

2′-Hydroxy-2-methyl-4′,6,7-trimethoxyisoflavone (Id): Mp 241 °C ($CHCl_3$–C_6H_6); 23% yield; IR (KBr) 3200 (OH) and 1620 cm^{-1} (C=O); UV (MeOH) λ_{max}(ε) 291 (16100) and 324 nm (12900); NMR (CF_3COOH) δ=2.71 (3H, s, CH_3). 4.03 (3H, s, OCH_3), 4.19 (3H, s, OCH_3), 4.25 (3H, s, OCH_3), 6.72—6.98 (3H, m, $H_{(3')}$, $H_{(5')}$ and $H_{(6')}$), 7.51 (1H, s, $H_{(8)}$), and 7.80 (1H, s, $H_{(5)}$). Found: C, 66.36; H, 5.35%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

Oxidations of 2′-Hydroxy-2-methylisoflavanoes (Ia—d) and 2′-Hydroxyisoflavone with Lead(IV) Acetate. A typical oxidation of 2′-hydroxyisoflavone was as follows. A mixture of a 2′-hydroxyisoflavone (1 mmol), lead(IV) acetate[13] (1.5 mmol), and a solvent (20 ml) was heated at an appropriate temperature for the time shown in the Table 1. After the removal of the solvent, the resulting reaction mixture was triturated with water and extracted with chloroform. The chloroform solution was evaporated and separated on TLC using chloroform as developing solvent.

Ia yielded 10b-acetoxy-3-methoxy-5a-methyl-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one (IIa): mp 136—137 °C (EtOH); 25% yield; IR ($CHCl_3$) 1700 (C=O) and 1760 cm^{-1} (OAc); UV (MeOH) λ_{max} (ε) 287 nm (16900); NMR ($CDCl_3$) δ=1.79 (3H, s, CH_3), 2.20 (3H, s, OAc), 3.79 (3H, s, OCH_3), 6.51—7.50 (6H, m), and 7.68 (1H, d, J=8.5 Hz, $H_{(1)}$) (Found: C, 66.92; H, 4.73%. Calcd for $C_{19}H_{16}O_6$: C, 67.05; H, 4.75%); and 2-(7-methoxy-2-methyl-4-oxo-4*H*-chromen-3-yl)-*p*-benzoquinone (IIIa): mp 180 °C (C_6H_6–light petroleum); 45% yield; IR ($CHCl_3$) 1650 and 1680 cm^{-1} (C=O); UV (MeOH) λ_{max}(ε) 226 (30500), 246 (30400), 252 (30000), and 297 nm (14700); NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3), 3.91 (3H, s, OCH_3), 6.75—7.06 (5H, m, $H_{(3)}$, $H_{(5)}$, $H_{(6)}$, $H_{(6')}$, and $H_{(8')}$), and 8.05 (1H, d, J=8.5 Hz, $H_{(5')}$) (Found: C, 68.80; H, 4.10%. Calcd for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%).

Ib gave 10b-acetoxy-3,8-dimethoxy-5a-methyl-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one (IIb): mp 186—188 °C (EtOH); 5—25% yields; IR ($CHCl_3$) 1710 (C=O) and 1760 cm^{-1} (OAc); UV (MeOH) λ_{max} (ε) 233 (13700) and 284 nm (15800); NMR ($CDCl_3$) δ=1.79 (3H, s, CH_3), 2.20 (3H, s, OAc), 3.71 (3H, s, OCH_3), 3.81 (3H, OCH_3), 6.31—6.71 (4H, m, $H_{(2)}$, $H_{(4)}$, $H_{(7)}$, and $H_{(9)}$), 7.37, (1H, m, $H_{(10)}$), and 7.73 (1H, d, J=8.5 Hz, $H_{(1)}$) (Found: C 64.65; H, 4.90%. Calcd for $C_{20}H_{18}O_7$: C, 64.56; H, 4.90%); and 2-(7-methoxy-2-methyl-4-oxo-4*H*-chromen-3-yl)-5-methoxy-*p*-benzoquinone (IIIb): mp 237 °C (EtOH); 17—46% yields; IR ($CHCl_3$) 1630—1660 and 1700 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 223 (23700), 247 (25400), 252 (27200), and 298 nm (15900); NMR ($CDCl_3$) δ=2.29, (3H, s, CH_3), 3.90 (3H, s, OCH_3), 3.95 (3H, s, OCH_3) 6.11 (1H, s, $H_{(6)}$), 6.72 (1H, s, $H_{(3)}$), 6.85—7.05 (2H, m, $H_{(6')}$ and $H_{(8')}$), 8.13 (1H, d, J=8.5 Hz, $H_{(5')}$)(Found: C, 65.96; H, 4.32%. Calcd for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%).

Ic yielded 10b-acetoxy-2,3-dimethoxy-5a-methyl-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one (IIc): mp 207—209 °C (EtOH); 22% yield; IR ($CHCl_3$) 1700 (C=O) and 1760 cm^{-1} (OAc); UV (MeOH) λ_{max} (ε) 286 (14200) and 347 nm (8800); NMR ($CDCl_3$) δ=1.79 (3H, s, CH_3), 2.21 (3H, s, OAc), 3.82 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 6.61 (1H, s, $H_{(4)}$), 7.22 (1H, s, $H_{(1)}$), 6.70—7.50 (3H, m, $H_{(7)}$, $H_{(8)}$, and $H_{(9)}$), and 7.56 (1H, m, $H_{(10)}$) (Found: C, 64.63; H, 4.92%. Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%); and 2-(6,7-dimethoxy-2-methyl-4-oxo-4*H*-chromen-3-yl)-*p*-benzoquinone (IIIc): mp 192—193 °C (EtOH); 27% yield; IR ($CHCl_3$) 1650 and 1680 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 289 (12000) and 323 nm (13400); NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3), 3.95 (3H, s, OCH_3), 3.98 (3H, s, OCH_3) 6.79—6.83 (4H, m, $H_{(3)}$, $H_{(5)}$, $H_{(6)}$, and $H_{(8')}$, and 7.45 (1H, s, $H_{(5')}$) (Found: C, 66.10; H, 4.31%. Calcd for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%).

Id gave 10b-acetoxy-5a-methyl-2,3,8-trimethoxy-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one (IId): mp 180—183 °C (EtOH); 24% yield; IR (KBr) 1700 (C=O) and 1760 cm^{-1} (OAc); UV (MeOH) λ_{xam} (ε) 286 (14900) and 347 nm (9300); NMR ($CDCl_3$) δ=1.79 (3H, s, CH_3), 2.20 (3H, s, OAc), 3.75 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 6.57 (1H, s, $H_{(1)}$), 7.18 (1H, s, $H_{(1)}$), 6.29—6.59 (2H, m, $H_{(7)}$ and $H_{(9)}$), and 7.38 (1H, m, $H_{(10)}$) (Found: C, 62.80; H, 5.08%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%); and 2-(6,7-dimethoxy-2-methyl-4-oxo-4*H*-chromen-3-yl)-5-methoxy-*p*-benzoquinone (IIId): mp 222—227 °C (EtOH); 43% yield; IR (KBr) 1630 and 1700 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 322 nm (14900); NMR ($CDCl_3$) δ=2.29 (3H, s, CH_3), 3.85 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 3.98 (3H, s, OCH_3), 6.02 (1H, s, $H_{(6)}$), 6.73 (1H, s, $H_{(8')}$), 6.84 (1H, s, $H_{(3)}$), and 7.45 (1H, s, $H_{(5')}$) (Found: C, 63.74; H, 4.55%. Calcd for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%).

Ie yielded 10b-acetoxy-3,8-dimethoxy-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one(IIe): mp 150 °C (EtOH); IR ($CHCl_3$) 1710 (C=O) and 1760 cm^{-1} (OAc); UV (MeOH) λ_{max} (ε) 233 (13900), 283 (15500), and 311 nm (inf.) (8760); NMR ($CDCl_3$) δ=2.18 (3H, s, OAc), 3.77 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 6.45—6.70 (5H, m, $H_{(2)}$, $H_{(4)}$, $H_{(5a)}$, $H_{(7)}$, and $H_{(9)}$), 7.29 (1H, m, $H_{(10)}$), and 7.71 (1H, d, J=8.5 Hz, $H_{(1)}$) (Found: C, 63.95; H, 4.54%. Calcd for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%); and 3,8-dimethoxybenzofuro[2,3-*b*][1]benzopyran-11-one (V): mp 235 °C ($CHCl_3$); IR (KBr) 1658 cm^{-1} (C=O); UV (MeOH) λ_{max} (ε) 261 (30500), 287 (16600), and 311 nm (inf.) (9330); NMR (CF_3COOH) δ=4.08 (3H, s, OCH_3), 4.15 (3H, s, OCH_3), 7.10—7.60 (4H, m, $H_{(2)}$, $H_{(4)}$, $H_{(7)}$, and $H_{(9)}$), 8.10 (1H, d, J=8.5 Hz, $H_{(1)}$), and 8.52 (1H, d, J=8.5 Hz, $H_{(10)}$) (Found: C, 68.80; H, 4.10%. Calcd for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%).

Oxidations of Ia—e with Manganese(III) Acetate. A typical oxidation of 2′-hydroxyisoflavone with manganese(III) acetate was as follows. A mixture of 2′-hydroxyisoflavone (1 mmol), manganese(III) acetate dihydrate[14] (3 mmol), and a solvent (20 ml) was heated at an appropriate temperature for the time shown in Table 1. After the removal of the solvent, the resulting mixture was triturated with water and extracted with chloroform. The chloroform solution was evaporated and the resulting mixture was separated on TLC using chloroform as developing solvent and by recrystallization.

Ia gave IIa: mp 136—137 °C, 1% yield. Ib yielded IIb: mp 186—188 °C, 7—25% yields; and IV: mp 300 °C (EtOH–$CHCl_3$), 3—29% yields; IR ($CHCl_3$) 1710 (C=O) and 1760 cm^{-1} (OAc); UV (MeOH) λ_{max} (ε) 289 nm (33400); NMR ($CDCl_3$) δ=1.81 (3H, s, OCH_3), 2.20 (3H, s, OAc), 3.60 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), 6.35 (1H, s, $H_{(7)}$), 6.53—6.70 (2H, m, $H_{(2)}$ and $H_{(4)}$), 7.24 (1H, s, $H_{(10)}$), and 7.75 (1H, m, $H_{(1)}$) (Found: C, 64.79; H, 4.64%. Calcd for $C_{40}H_{34}O_{14}$: C, 65.03; H, 4.64%), *m/e* 738 (M^+). Ic gave IIc: mp 207—209 °C, 9% yield. Id yielded IId: mp 180—183 °C, 10% yield. Ie gave IIe: mp 150 °C, 10% yield; and V: mp 235 °C, 7% yield.

The Thermal Decomposition of IIe. 10b-Acetoxy-3,8-di-

methoxy-5a,10b-dihydrobenzofuro[2,3-*b*][1]benzopyran-11-one (IIe) (0.1 mmol) was heated at 250 °C for 10 min. The NMR spectrum of the residue was identical with that of V in every respect.

The authors wish to thank Mr. Shuichi Ueda at Taiho Pharmaceutical Co., Ltd., Tokushima, for measuring the mass spectrum.

Syntheses of Polymerizable Carbodiimides Bearing a Terminal Vinyl Group

Hiroyoshi KAMOGAWA,* Masato NANASAWA, Shigeki UEHARA, and Keisuke OSAWA

Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu, Yamanashi 400

(Received July 22, 1978)

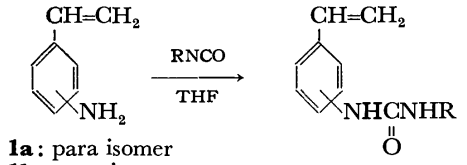
N-(*p*- or *m*-Vinylphenyl)-*N'*-isopropyl- and cyclohexylcarbodiimides (**3**) have been synthesized in reasonable yields by first synthesizing the substituted ureas by the reactions of *p*- or *m*-vinylaniline with isopropyl or cyclohexyl isocyanate in THF and the subsequent dehydration with *p*-toluenesulfonyl chloride in pyridine. The monomers **3** were found to polymerize smoothly with AIBN to afford vinyl polymers bearing the corresponding carbodiimide units as pendants in more or less cross-linked forms. The cross-linked insoluble polymers thus obtained can act as a dehydrative coupling agent in reactions such as the formation of peptide linkages.

Carbodiimides are one of the most versatile dehydrative coupling agents, especially for use in peptide syntheses.[1] An attempt to use carbodiimide units as pendants of vinyl polymers prepared by polymer reactions has been reported,[2] thereby assuring ready separation of carbodiimide reagents after reaction.

The authors have been interested in the syntheses of vinyl carbodiimide monomers and the preparation of vinyl polymers bearing carbodiimide units as pendants by the radical polymerization of the monomers thus synthesized. The carbodiimide polymers thus synthesized can act as polymer reagents in dehydration and other reactions characteristic of low molecular weight carbodiimides such as dicyclohexylcarbodiimide.

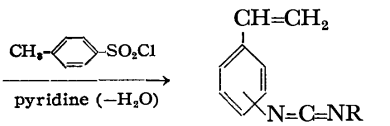
Results and Discussion

Carbodiimide monomers have been synthesized as follows.



1a: para isomer
1b: meta isomer

2a1: *p*-isomer; R=isopropyl
2a2: *p*-isomer; R=cyclohexyl
2a3: *p*-isomer; R=phenyl
2b1: *m*-isomer; R=isopropyl
2b2: *m*-isomer; R=cyclohexyl
2b3: *m*-isomer: R=phenyl



3a1: *p*-isomer; R=isopropyl
3a2: *p*-isomer; R=cyclohexyl
3b1: *m*-isomer; R=isopropyl
3b2: *m*-isomer; R=cyclohexyl

Substituted ureas (**2**) have been readily synthesized from vinylanilines (**1**) and isocyanates in tetrahydrofuran (THF) in satisfactory yields, as indicated in Table 1. The conversions of ureas to the corresponding carbodiimides (**3**) were however not successful in all cases. Thus, ureas **2a3** and **2b3** did not provide the corresponding carbodiimides in pure forms, presumably due to the poor stability of the products; the yields of other carbodiimides, as indicated in Table 1, were not high. The synthetic route described here however appears to be useful, since it can be easily conducted and, starting from the readily available **1**, the desired products (**3**) are obtained in two steps.

Table 1. Substituted ureas and carbodiimide monomers synthesized

Compound	Yield, %	Mp, °C	Bp, °C/mmHg
2a1	88.2	148—150	—
2a2	73.8	178—180	—
2a3	80.3	203—204	—
2b1	81.2	118—120	—
2b2	87.3	149—150	—
2b3	90.9	162—163	—
3a1	62.8	—	97/0.7
3a2	29.0	—	105/3.0
3b1	48.1	—	98/1.0
3b2	40.7	—	128/1.0

As indicated in Table 2, the solution polymerization of the monomer **3**, alone and in the presence of styrene, proceeded smoothly to give homogeneous polymer solutions. Monomers **3a1** and **3a2** were exceptional in that the solutions gave gels. The homopolymers of **3b** became insoluble in THF once precipitated into methanol, indicating that the N=C bonds of the carbodiimide portions in the monomers and polymers participated, more or less, in the polymerizations. The IR spectra of the **3a** polymers indicated a decrease in the intensities of the –N=C=N– absorptions at 2100 cm^{-1} compared with those of the corresponding monomers, together with characteristic absorptions for vinyl polymers containing carbodiimide units as pendant. Copolymerizations with styrene overcame the poor solubility characteristic: copolymers Nos. 4 and 7 in Table 2 are completely soluble in organic solvents, although the contents of the carbodiimide units are considerably lower than those calculated for the monomers employed. It appears, however, that the practical merits of the carbodiimide polymers are displayed when they are employed in the cross-linked insoluble forms and compensate for this fault.

The dehydrative coupling functions of the carbodiimide polymers have been investigated especially for the following amino acid combination:

TABLE 2. SOLUTION POLYMERIZATION OF **3** MONOMERS[a]

No.	Monomer	Conversion %	3-Content[c] in polymer, %	$[\eta]$[d] dl/g	Remark on polymer
1	**3a2**	52.2	100	—	Homogeneous polymerization but converted to an insoluble gel
2	**3b1**	52.0	100	0.22	Soluble in hot pyridine
3	**3b1**-St (50)[b]	64.8	44	0.18	Soluble in pyridine
4	**3b1**-St (33)[b]	44.2	15	0.23	Soluble in organic solvents

a) 30% Total monomers and 1% AIBN/monomers in THF; 70 °C×24 h. b) 3 mol % in monomers (St= styrene). c) By CHN analyses (mol %). d) In THF at 25 °C.

TABLE 3. FORMATION OF PEPTIDE LINKAGE WITH **3** POLYMER

No.	Polymer	**6** obtained, mol / g-polymer
1	**3b1**-St (1: 1) copolymer[a]	0.33
2	**3a1** Homopolymer[b]	0.25
3	**3a1**-St (1: 1) copolymer[b]	0.22

a) Obtained by solution polymerization. b) Obtained by precipitation polymerization.

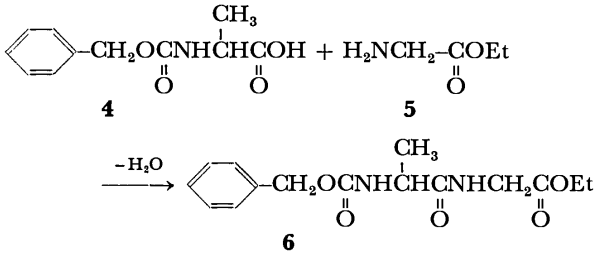

Table 3 indicates the results obtained which indicate that the cross-linked insoluble polymers of **3** play the role of polymer reagent inducing the desired reaction in a heterogeneous system. As expected, the capacity as a polymer reagent is dependent upon the origin of the **3** polymer. Thus, No. 1 polymer in Table 3 with a gel structure is superior to No. 3 with a somewhat macroreticular structure. A more detailed investigation is however required for a complete evaluation of the effects of both chemical and physical structures.

Experimental

The IR, ^{1}H-NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrophotmeter, and a Hitachi RMU-6 MG spectrometer, respectively, under standard measurement conditions. Elemental analyses were conducted using a Perkin-Elmer 250 instrument.

N-*(p-Vinylphenyl)*-N′-*isopropylurea* (**2a1**). To a solution of *p*-vinylaniline (2.0 g, 17 mmol), prepared by the alkaline dehydration of 2-(*p*-aminophenyl)ethanol,[3] in anhydrous THF (20 ml), isopropyl isocyanate (1.5 g, 17 mmol) was added gradually at room temperature with stirring, the resulting solution being allowed to stand overnight at room temperature. The solvent was then removed by evaporation *in vacuo* at 50 °C, followed by recrystallizations from THF–petroleum ether which gave white needles.

Found: C 70.54; H, 7.78; N, 13.24%. Calcd for $C_{12}H_{16}N_2O$: C, 70.56; H, 7.90; N, 13.71%. IR(KBr) 3300 (NH), 2860—3000 (alkyl), 1620 (C=O), 1580 (phenyl), 990, 900 (vinyl) cm^{-1}; NMR ($CDCl_3$) δ 1.1 (d, 6 H, Me), 3.8 (m, 1 H, CH), 5.1 (d, 1 H, C<u>H</u>$_2$=CH–), 5.5 (d, 1 H, C<u>H</u>$_2$=CH–), 5.7 (s, 1 H, N<u>H</u>CHMe$_2$), 6.6 (q, 1 H, CH$_2$=C<u>H</u>–), 7.2 (s, 4 H, ArH), 7.8 (s, 1 H, NHAr) ppm; Mass (*m/e*) 207 (M$^+$, 67), 118, 119 (100).

N-(*p*-Vinyl-phenyl)-*N*′-cyclohexylurea (**2a2**) and *N*-(*p*-vinylphenyl)-*N*′-phenylurea (**2a3**) were synthesized in the same manner to afford fine colorless needles and a colorless powder, respectively, their analytical data being also satisfactory.

N-*(m-Vinylphenyl)*-N′-*cyclohexylurea* (**2b2**). By applying the same reaction procedure as that for the synthesis of **2a1**, cyclohexyl isocyanate (5.2 g, 42 mmol) and *m*-vinylaniline (**1b**: 5.0 g, 42 mmol), prepared by the Al_2O_3 dehydration of 1-(*m*-aminophenyl)ethanol,[4] produced a white powder (**2b2**) which was recrystallized from THF–petroleum ether.

Found: C, 73.25; H, 8.39; N, 11.50%. Calcd for $C_{15}H_{20}N_2O$: C, 73.37; H, 8.52; N, 11.48%. IR(KBr) 3350 (NH), 2860, 2940 (cyclohexyl), 1620 (C=O), 1560 (phenyl), 995, 910 (vinyl) cm^{-1}; NMR (DMSO-d_6+$CDCl_3$) δ 1.1—1.9 (m, 10 H, 5 CH$_2$), 2.8 (s, 1 H, –CH ), 5.2 (d, 1 H, C<u>H</u>$_2$=CH–), 5.7 (d, 1 H, C<u>H</u>$_2$=CH–), 5.7 (s, 1 H, –NH– ), 6.6 (q, 1 H, CH$_2$=C<u>H</u>–), 6.8—7.6 (m, 4 H, ArH), 8.0 (s, 1 H, ArNH) ppm; Mass (*m/e*) 244 (M$^+$, 18), 119 (100). *N*-(*m*-Vinylphenyl)-*N*′-isopropylurea (**2b1**) and *N*-(*m*-vinylphenyl)-*N*′-phenylurea (**2b3**) were synthesized in the same manner to afford fine colorless crystals with satisfactory analytical data in both instances.

N-*(p-Vinylphenyl)*-N′-*isopropylcarbodiimide* (**3a1**). To a solution of **2a1** (1.5 g, 7.4 mmol) and 4-*t*-butylcatechol (0.1 g) in anhydrous pyridine (20 ml) *p*-toluenesulfonyl chloride (2.8 g, 15 mmol) was added dropwise and the resulting solution heated at 70 °C for 2 h. The reaction mixture was then poured into iced water and extracted with ether (200 ml), the organic layer being washed with water and dried over anhydrous sodium sulfate, followed by distillation *in vacuo* to afford a pale brown liquid. Found: C, 77.91; H, 7.50; N, 14.58%. Calcd for $C_{12}H_{14}N_2$: C, 77.38; H, 7.58; N, 15.04%. IR ($CHCl_3$) 2870—2920 (alkyl), 2120 (–N=C=N–), 1600 (phenyl), 990, 900 (vinyl) cm^{-1}; NMR ($CDCl_3$) δ 1.3 (d, 6 H, 2 Me), 3.7 (m, 1 H, CH), 5.2 (d, 1 H, C<u>H</u>$_2$=CH–), 5.6 (d, 1 H, C<u>H</u>$_2$=CH–), 6.6 (q, 1 H, CH$_2$=C<u>H</u>–), 6.8—7.5 (m, 4 H, ArH) ppm; Mass (*m/e*) 186 (M$^+$, 100). *N*-(*p*-Vinylphenyl)-*N*′-cyclohexylcarbodiimide (**3a2**) was synthesized in the same manner to afford a colorless liquid.

N-*(m-Vinylphenyl)*-N′-*cyclohexylcarbodiimide* (**3b2**). The same reaction procedure as that for **3a1** was applied to afford a colorless liquid.

Found: C, 79.60; H, 8.18; N, 12.23%. Calcd for $C_{15}H_{18}N_2$:

C, 79.61, H, 8.02, N, 12.38%. IR ($CHCl_3$) 2860—2930 (alkyl), 2120 (–N=C=N–), 1580 (phenyl), 990, 900 (vinyl) cm^{-1}; NMR ($CDCl_3$) δ 1.1—1.9 (m, 10 H, 5 CH_2), 3.5 (m, 1 H, –CH<), 5.3 (d, $C\underline{H}_2$=CH–), 5.8 (d, 1 H, $C\underline{H}_2$=CH–), 6.7 (q, 1 H, CH_2=C<u>H</u>–), 6.9—7.6 (m, 4 H, ArH) ppm. Mass (*m/e*) 226 (M^+, 13), 144 (100).

N-(*m*-Vinylphenyl)-*N'*-isopropylcarbodiimide (**3b1**, a colorless liquid) was synthesized in the same manner.

The analytical data for the synthesized carbodiimide monomers not shown above were satisfactory.

Solution Polymerization of 3 Monomers. A solution of the total monomers (1.0 g) and 2,2'-azobisisobutyronitrile (AIBN: 0.01 g) in THF (2.3 ml) was placed in a Pyrex glass ampoule, which was evacuated, flushed with nitrogen, sealed, and allowed to stand for 24 h at 70 °C. Precipitation of the contents into methanol provided the polymer. All polymers of **3** thus synthesized indicated IR absorptions at 2860 and 2930 cm^{-1} attributable to vinyl polymer backbones together with sharp peaks at 2100 cm^{-1} characteristic of –N=C=N– bonds. For the determination of intrinsic viscosities [η], 20% of the contents were set aside without precipitation and diluted with THF for use in viscosimetry (Ostwald).

Precipitation Polymerization of 3 Monomers. A solution of total monomers (5 g) containing 10% divinylbenzene and AIBN (0.05 g) in heptane (8—15 ml) was stirred at 70 °C for 6—8 h under a nitrogen atmosphere. After 3—4.5 h, heptane (8—10 ml) was further added and stirring continued. The precipitated polymer was washed with petroleum ether and extracted overnight with ether using a Soxhlet extractor. Yields of 60—75% were obtained.

Formation of Peptide Linkage with 3 Polymer. Typically, *N*-benzyloxycarbonyl-L-alanine (**4**: 0.8 g, 4 mmol) and glycine ethyl ester (**5**: 0.4 g, 4 mmol) were dissolved in THF (50 ml). The No. 1 copolymer in Table 3, extracted with anhydrous THF, was then added and the mixture stirred at room temperature overnight. The reaction mixture was centrifuged, the supernatant solution evaporated *in vacuo* at 50 °C, the residue dissolved in chloroform, and the resulting solution washed first with aqueous hydrochloric acid, then with aqueous sodium carbonate, followed by evaporation *in vacuo* to give colorless crystals.

Syntheses of Chlorozinc Complexes of 2(1*H*)-Pyridinethione and Their Mutual Transformations

Satoshi MATSUNAMI, Susumu FUJIMURA, Kiyomi OKIMOTO, and Mitsuo MASAKI*

Polymer Research Laboratory, Ube Industries, Ltd., Minami-Kaigan, Goi, Ichihara, Chiba 290

(Received July 22, 1978)

Three types of zinc complexes, chlorotris[2(1*H*)-pyridinethionato]dizinc (**3**), dichlorotetrakis[2(1*H*)-pyridinethionato]trizinc (**4**), and chloro[2(1*H*)-pyridinethionato]zinc (**5**) were produced by the reactions of bis[2(1*H*)-pyridinethionato]zinc (**2**) and zinc chloride. The product in the reactions varies depending on the solvent. The mutual transformation reactions among **3**, **4**, **5**, **2**, and oxohexakis[2(1*H*)-pyridinethionato]tetrazinc were described. The formations of **5**, **4**, and **3** were explained by stepwise additions of **2** to zinc chloride based upon a view that these complexes are the adducts of **2** with zinc chloride in molar ratios of 1: 1, 2: 1, and 3: 1. Analogously, the correlation of the known polynuclear zinc complexes was systematically rationalized by stepwise additions of L_2Zn (L=ligand) to ZnX_2 (X=Cl or OH) or ZnO.

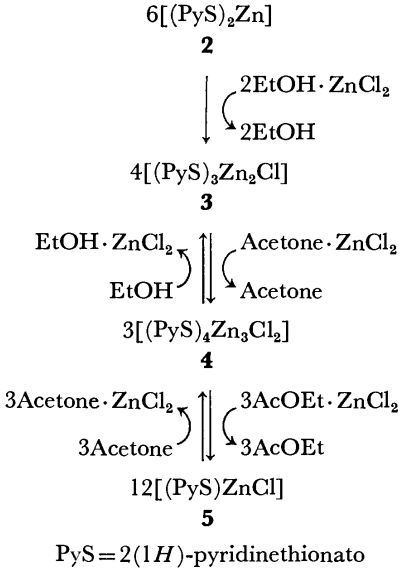
In a previous paper,[1] we reported on the formation of oxohexakis[2(1*H*)-pyridinethionato]tetrazinc (**1**) from bis[2(1*H*)-pyridinethionato]zinc (**2**)[2] and on the mutual transformations between **1** and **2**. Various types of polynuclear zinc complexes have been reported. They include L_8Zn_5O (L=ligand group),[2] L_6Zn_4O,[3] L_2Zn_2O,[4] L_5Zn_3X (X=chlorine atom or hydroxyl group),[5] $L_4Zn_4X_4$,[6] $L_4Zn_3X_2$,[7] and L_3Zn_2X[8] type complexes. The types of complexes are different depending on the kind of the ligand. Correlations between these types of complexes have not been elucidated, probably owing to the lack of report on the formation of different type of polynuclear zinc complexes formed with the same ligand.[9]

This paper describes the syntheses of chlorozinc complexes, L_3Zn_2Cl, $L_4Zn_3Cl_2$, and LZnCl where L is 2(1*H*)-pyridinethionato group, and mutual transformations among the three complexes and the complexes **1** and **2**, which contribute a systematization of polynuclear zinc complexes.

Results and Discussion

The transformation of **2** into oxocomplex **1** has been explained by the fission of one of four 2(1*H*)-pyridinethionato ligands in the complex **2**.[1,2] When **2** was treated with a half-molar equivalent of benzoyl chloride in 1,2-dichloroethane (EDC), one of four 2(1*H*)-pyridinethionato groups was removed as the *S*-benzoyl derivative, and chlorotris[2(1*H*)-pyridinethionato]dizinc (**3**) was obtained quantitatively. The complex **3** is a new complex and the characterization will be described later. The complex **3** was also obtained by a reaction of **2** with zinc chloride in a molar ratio of 3: 1 in diethyl ether. A treatment of **2** with a large excess molar amount of zinc chloride (in a molar ratio of 1: 1) in ethanol gave **3**, but the same reaction in acetone afforded another product, dichlorotetrakis[2(1*H*)-pyridinethionato]trizinc (**4**). The complex **4** could be obtained by the reaction of **3** with an excess molar amount of zinc chloride (in a molar ratio of 2: 3) in acetone. When **2** was treated with an excess molar amount of zinc chloride (in a molar ratio of 1: 2) in ethyl acetate, the third complex, chloro[2(1*H*)-pyridinethionato]zinc (**5**) was isolated. The complex **5** could be obtained also by the treatment of **4** with zinc chloride in ethyl acetate. The complexes **4** and **5** are also new compounds and the characterization will be described later. When **5** was treated in acetone, **4** was recovered. The treatment of **4** in ethanol gave **3**. The complexes **3**, **4**, and **5** all could be converted to oxocomplex **1** when they were treated in boiling water.

The experimental results for the formation of the complexes can be rationalized as shown in Scheme 1.



PyS=2(1*H*)-pyridinethionato

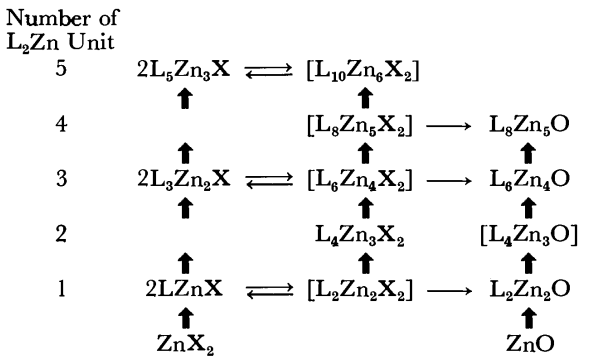
Scheme 1.

The formation of a product in a specific solvent can be rationalized by a ligand exchange reaction of zinc chloride between the reactant and the solvent.

The complexes **3**, **4**, and **5** can be viewed as adducts of bis[2(1*H*)-pyridinethionato]zinc with zinc chloride in molar ratios of 3: 1, 2: 1, and 1: 1, respectively. The complex **1** is on a same level with the complex **3**, since **1** is an adduct of bis[2(1*H*)-pyridinethionato]zinc with zinc oxide in a molar ratio of 3: 1.

In a similar idea various types of polynuclear zinc complexes reported hitherto can be made systematic as shown in Scheme 2, in which a thick arrow signifies an addition of a unit of L_2Zn. A stepwise addition of L_2Zn to ZnX_2 or ZnO leads to a formation of each level of zinc complexes. The several types of complexes put in brackets are not yet reported. The stability of

complex could be depend on the kind of the ligand and the conditions under which the formation was performed. The solvent is a very important factor as illustrated in Scheme 1 for 2(1*H*)-pyridinethionato zinc complexes. From Scheme 2, one can predict the presence of complexes containing four and five units of $(PyS)_2Zn$, $(PyS)_8Zn_5Cl_2$ or $(PyS)_8Zn_5O$ and $(PyS)_{10}Zn_6Cl_2$ or $(PyS)_5Zn_3Cl$, but they are not yet isolated. One may be able to isolate them when appropriate solvents are found.



Scheme 2. Complex types (complexes in brackets are unknown).

In a previous report,[1] we have described a probable formation of oxobis[2(1*H*)-pyridinethionato]dizinc in the reaction of 2(1*H*)-pyridinethione and zinc oxide in a molar ratio of 2: 1 in water. Oxotetrakis[2(1*H*)-pyridinethionato]trizinc can be estimated to be produced in an appropriate solvent, since the same level chlorocompound **4** is moderately stable.

Characterization of the Complexes. The compositions of the three complexes **3**, **4**, and **5** were determined by elemental analyses (C, H, Cl, N, and S). The complexes **3**, **4**, and **5** were obtained as powdery crystals, respectively. The powder X-ray analyses showed the independent spectrum for the three complexes and the contamination of free zinc chloride in the complexes was not observed.

Thermal analysis curves of **3**, **4**, and **5** show single and sharp endothermic peaks at 297, 303, and 295 °C, respectively. The mixture prepared by mixing any two of the complexes **2**, **3**, **4**, and **5** give thermal analysis curves showing broad endothermic peaks at temperatures different from those of the endothermic peaks for **2**, **3**, **4**, and **5**, except the mixture of **4** and **5** whose curve shows a sharp endothermic peak but at 287 °C. These facts indicate for the three complexes **3**, **4**, and **5** to be independent compounds, respectively.

The IR spectrum of the complex **3** exhibits bands due to C=C/C=N stretching vibration at 1595 (s), 1555 (s), 1445 (s), and 1420 cm^{-1} (s), a band due to C=S stretching vibration at 1135 cm^{-1} (s), bands due to ring vibration at 1020 (m) and 650 cm^{-1} (w), and bands due to C–H bending vibration at 770 (s), 765 (sh), and 760 cm^{-1} (sh). The absorption patterns of the corresponding bands in **1**, **2**, **4**, and **5** are similar to that of bands in **3**, except that the spectrum of **2** shows doublet peaks or peaks with a shoulder at 1455, 1420, 1020, and 645 cm^{-1} and that the spectrum of **4** and **5** show a doublet peak or a peak with a shoulder at 650 cm^{-1}. The fact thet the absorption patterns of these bands of **3**, **4**, and **5** are similar to that of the bands of **1** indicates that the 2(1*H*)-pyridinethionato ligands act as bidentates and bridging ligands in the complexes **3**, **4**, and **5**.[1]

The mass spectra of **3**, **4**, and **5** exhibit several fragmentation ions containing zinc, 2(1*H*)-pyridinethionato ligand, and/or chlorine. The peak pattern of the MS spectra of **3**, **4**, and **5** differ depending on the temperature of the inlet part to which the samples were introduced. The peak pattern of the MS feature higher than *m/e* 209[(PyS)ZnCl] are shown in Table 1. The changes of peak patterns of the three compounds depending on

a) The temperature at which the spectra were measured.

the temperature are clearly different, respectively. This phenomena can not be rationalized at present, but the results indicate that the complexes **3**, **4**, and **5** are independent compounds. Although there is no certain evidence, **5** seems to be not monomeric. This is suggested by the high melting point of **5** and by MS peak of **5** at *m/e* 284[$(PyS)_2Zn$] which was observed in the spectra measured even at 120 °C.

Experimental

All melting points were determined in a liquid bath unless otherwise mentioned and were uncorrected. The powder X-ray diffraction was measured on a Rigaku D_2 X-ray diffractometer. The thermal analyses were performed on a Rigaku 8085 differencial scanning calolimeter. The IR spectra were measured in KBr disks with a Hitachi Perkin-Elmer 225 and a Hitachi EPI-G2 grating infrared spectrometer. The mass spectra were measured with a Hitachi M52 mass spectrometer.

Materials. Commercial anhydrous zinc chloride was used after drying over diphosphorus pentaoxide. Bis[2(1*H*)-pyridinethionato]zinc (**2**) was prepared by the method previously reported.[1] Commercial benzoyl chloride was distilled before its use.

Chlorotris[2(1H)-pyridinethionato]dizinc (3). a) Reaction of 2 with Zinc Chloride in Ethanol: A solution of zinc chloride (95 %, 0.43 g, 3.0 mmol) in ethanol (30 ml) was added to a suspension of **2** (0.86 g, 3.0 mmol) in ethanol (40 ml) with stirring at room temperature and the mixture was stirred at room temperature for 12 h. The precipitate was collected by filtration, washed with ethanol (80 ml), and dried at 70 °C for 24 h under reduced pressure to give 0.98 g (98%) of colorless crystalline powder; mp 294—298 °C. Found: C, 36.35; H, 2.57; Cl, 7.09; N, 8.16; S, 19.14%. Calcd for $C_{15}H_{12}ClN_3S_3Zn_2$: C, 36.27; H, 2.44; Cl, 7.14; N, 8.46; S, 19.37%. Molecular weight of the product could not be determined owing to the poor solubility in most organic solvent except *N,N*-dimethylformamide, in which the product was partly hydrolyzed with a slight amount of water contained in the solvent.

b) Reaction of 2 with Zinc Chloride in Diethyl Ether: Zinc chloride (95%, 0.72 g, 5.0 mmol) was treated with **2** (4.29 g, 15.0 mmol) in diethyl ether (100 ml) at room temperature for 17 h. The precipitate was collected by filtration and washed with diethyl ether (20 ml) to give 4.93 g (99%) of **3** as colorless crystalline powder; mp 294—298 °C. The IR spectrum of the powder was identical with that of the product obtained in a). Thermal analysis curve of the solid exhibits an endothermic peak at 297 °C.[11]

c) Reaction of 2 and Benzoyl Chloride: A solution of benzoyl chloride (2.81 g, 20 mmol) in 1,2-dichloroethane (EDC) (40 ml) was added drop by drop to a suspension of **2** (11.43 g. 40 mmol) in EDC (110 ml) with stirring at room temperature and the mixture was stirred for 18.5 h. The precipitate was collected by filtration and washed with EDC (20 ml) to give 9.90 g (100%) of **3** as colorless crystalline powder. The IR spectrum of the powder was identical with that of the product obtained in a). The filtrate separated from **3** and washings were combined and concentrated under reduced pressure. Diethyl ether (70 ml) was added to the residue and filtered leaving insoluble materials. A solution of zinc chloride (95%, 1.38 g, 9.6 mmol) in diethyl ether (50 ml) was added to the filtrate and the mixture was stirred at room temperature for 21.5 h. The precipitate was collected by filtration and washed with diethyl ether (20 ml) to give 4.74 g (84%) of bis(2-benzoylthiopyridine)dichlorozinc (**6**) as colorless solid. The IR spectrum of the solid was identical with that of authentic sample.

Bis(2-benzoylthiopyridine)dichlorozinc (6). A solution of zinc chloride (95%, 0.72 g, 5 mmol) in diethyl ether (30 ml) was added drop by drop to a solution of 2-benzoylthiopyridine[12] (2.15 g, 10 mmol) in diethyl ether (20 ml) with stirring at room temperature. The precipitate was collected by filtration and washed with diethyl ether (20 ml) to give 2.73 g (96 %) of colorless powder; mp 182—185 °C. Found: C, 50.76; H, 3.05; Cl, 12.67; N, 4.70; S, 11.19%. Calcd for $C_{24}H_{18}Cl_2N_2O_2S_2Zn$: C, 50.85; H, 3.20; Cl, 12.51; N, 4.94; S, 11.31%.

Dichlorotetrakis[2(1H)-pyridinethionato]trizinc (4). a) Reaction of 2 with Zinc Chloride: A solution of zinc chloride (95%, 4.30 g, 30 mmol) in acetone (45 ml) was added to a suspension of **2** (8.57 g, 30 mmol) in acetone (150 ml) with stirring at room temperature and then the mixture was stirred at room temperature for 4 h. The precipitate was collected by filtration and washed with acetone (90 ml) to give 10.48 g (99%) of colorless crystalline powder; mp 305—308 °C. Thermal analysis curve of the powder exhibits an endothermic peak at 303 °C. Found: C, 33.72; H, 2.28; Cl, 10.13; N, 7.75; S, 17.89%. Calcd for $C_{20}H_{16}Cl_2N_4S_4Zn_3$: C, 33.94; H, 2.28; Cl, 10.02; N, 7.94; S, 18.12%. Molecular weight of the product could not be determined owing to the poor solubility in most organic solvent except *N,N*-dimethylformamide, in which the product was partly hydrolyzed with a slight amount of water contained in the solvent.

b) Reaction of 3 with Zinc Chloride: Zinc chloride (95%, 0.27 g, 1.8 mmol) was treated with **3** (0.60 g, 1.2 mmol as monomer) in acetone (110 ml) at room temperature. The mixture was refluxed for 3 h and stirred at room temperature for 7 h. The precipitate was collected by filtration and washed with acetone (50 ml) to give 0.63 g (99%) of **4** as colorless solid; mp 304—307 °C. The IR spectrum of the solid was identical with the product obtained in *a)*.

Chloro[2(1H)-pyridinethionato]zinc (5). a) Reaction of 2 with Zinc Chloride: A solution of zinc chloride (95%, 0.44 g, 3.0 mmol) in ethyl acetate (50 ml) was added to a suspension of **2** (0.43 g, 1.5 mmol) in ethyl acetate (40 ml) with stirring at room temperature and then the mixture was refluxed for 5 h. The precipitate was collected by filtration and washed with ethyl acetate (100 ml) under dried nitrogen atmosphere to give 0.62 g (98%) of colorless crystalline powder; mp 296—298 °C. Thermal analysis curve of the powder exhibits an endothermic peak at 295 °C. Found: C, 28.65; H, 1.66; Cl, 16.95; N, 6.50; S, 15.31%. Calcd for $C_5H_4ClNSZn$: C, 28.46; H, 1.91; Cl, 16.80; N, 6.64; S, 15.20%.[13]

b) Reaction of 4 with Zinc Chloride: Zinc chloride (95%, 0.43 g, 3.0 mmol) was treated with **4** (1.06 g, 1.5 mmol as monomer) in ethyl acetate (80 ml) at room temperature. The mixture was refluxed for 4 h and stirred at room temperature for 9 h. The reaction mixture was treated in the similar manner as in a) to give 1.19 g (94%) of **5** as colorless crystalline powder; mp 296—298 °C. The IR spectrum of the powder was identical with the product obtained in *a)*.

Transformation of 5 into 4 in Acetone. A suspension of **5** (4.22 g, 20 mmol as monomer) in acetone (100 ml) was refluxed for 35 h. The precipitate was collected by filtration and washed with acetone to give 3.43 g (5 mmol, 97%) of **4** as colorless crystalline powder; mp 304—307 °C. The IR spectrum of the powder was identical with that of **4** obtained above. A solution of triphenylphosphine oxide (1.26 g, 4.5 mmol) in acetone (50 ml) was added to a portion (30.0 g) of the combined solution (85.9 g) of the filtrate separated from **4** and washings. The mixture was concentrated under reduced pressure and the residue was treated with ethyl acetate (50 ml). The insoluble materials were collected by filtration and washed with ethyl

acetate (30 ml) to give 1.08 g of colorless solid; mp 236—241 °C (on a hot plate). The IR spectrum of the solid was identical with that of authentic dichlorobis(triphenylphosphine oxide)-zinc.[14] This result shows that at least 4.5 mmol (89%) of zinc chloride is generated by the above treatment of **5** in acetone.

*Transformation of **4** into **3** in Ethanol.* A suspension of **4** (4.25 g, 6 mmol as monomer) in ethanol (100 ml) was refluxed for 9 h. The precipitate was collected by filtration and washed with ethanol (50 ml) to give 3.83 g (7.7 mmol, 96%) of **3** as colorless crystalline powder; mp 298—300 °C. The IR spectrum of the powder was identical with that of **3** obtained above. A solution of triphenylphosphine oxide (1.45 g, 5.2 mmol) in ethanol (20 ml) was added to the combined solution of the above filtrate and washings. The mixture was concentrated under reduced pressure and the residue was treated with ethyl acetate (50 ml). The insoluble materials were collected by filtration and washed with ethyl acetate to give 1.36 g of colorless solid; mp 236—240 °C (on a hot plate). The IR spectrum of the solid was identical with that of authentic dichlorobis-(triphenylphosphine oxide)zinc.[14] This result shows that 2.0 mmol (100%) of zinc chloride is generated by the above treatment of **4** in ethanol.

*Hydrolysis of **3** in Water.* A suspension of **3** (1.49 g, 3 mmol as monomer) in water (100 ml) was refluxed for 1 h. The precipitate was collected by filtration and washed with water (40 ml) to give 1.06 g (1.1 mmol) of **1** as colorless crystalline powder; mp above 340 °C (gradually dec).[15] The IR spectrum of the powder was identical with that of authentic sample **1**. The filtrate separated from **1** and washings were combined and the mixture was concentrated under reduced pressure. Ethyl acetate (50 ml) was added to the residue and the mixture was stirred. The insoluble materials were collected by filtration and washed with ethyl acetate (15 ml) to give 0.38 g (1.1 mmol, of dichlorobis[2(1*H*)-pyridinethione]zinc (**7**) as slightly yellowish crystalline powder; mp 248—256 °C (on a hot plate). The IR spectrum of the powder was identical with that of authentic sample **7**.[16] The filtrate separated from **7** and washings were combined and mixed with a solution of triphenylphosphine oxide (0.31 g, 1.1 mmol) in ethyl acetate (30 ml). The precipitate was collected by filtration and washed with ethyl acetate to give 0.27 g (0.4 mmol) of dichlorobis(triphenylphosphine oxide)zinc as slightly yellowish solid; mp 235—239 °C (on a hot plate). The IR spectrum of the solid was identical with that of authentic sample.[14]

*Hydrolysis of **4** in Water.* A suspension of **4** (4.25 g, 6 mmol as monomer) in water (100 ml) was refluxed for 2 h. The reaction mixture was treated in a similar manner as in the hydrolysis of **3**. The products were 2.76 g (2.9 mmol) of **1**; mp above 340 °C (gradually dec),[15] 1.00 g (2.8 mmol) of **7**; mp 246—254 °C (on a hot plate), and 2.11 g (3.0 mmol) of dichlorobis(triphenylphosphine oxide)zinc; mp 236—239 °C (on a hot plate). The IR spectra of the products were identical with those of authentic samples.

*Hydrolysis of **5** in Water.* A suspension of **5** (1.69 g, 8 mmol as monomer) in water (70 ml) was refluxed for 1 h. The reaction mixture was treated in a similar manner as in the hydrolysis of **3**. The products were 0.93 g (1.0 mmol) of **1**; mp above 340 °C (gradually dec),[15] 0.32 g (0.9 mmol) of **7**; mp 245—255 °C (on a hot plate), and 2.04 g (2.9 mmol) of dichlorobis(triphenylphosphine oxide)zinc; mp 238—242 °C (on a hot plate). The IR spectra of the products were identical with those of authentic samples.

Synthesis of Viscumamide and Its Analogs

Atsushi SAKURAI* and Yasuaki OKUMURA

Department of Chemistry, Faculty of Science, Shizuoka University, Ohya, Shizuoka 422

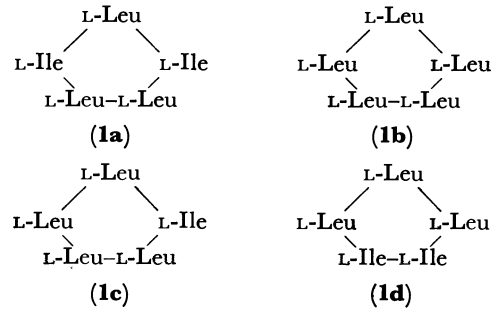
(Received July 26, 1978)

Viscumamide, cyclo(-L-Leu-L-Ile-L-Leu-L-Ile-L-Leu-) (**1a**) and its three analogs, cyclo(-L-Leu-L-Leu-L-Leu-L-Leu-L-Leu-), cyclo(-L-Leu-L-Ile-L-Leu-L-Leu-L-Leu-), and cyclo(-L-Ile-L-Ile-L-Leu-L-Leu-L-Leu-) were synthesized by the *N*-hydroxysuccinimide ester method. The yields in the cyclization step were low due to a strong intermolecular association even at high dilution, which causes cyclodimerization and other polymerization. Chromatographic and spectroscopic comparison of synthetic **1a** with natural viscumamide showed their identity. The structure of viscumamide was confirmed to be **1a**.

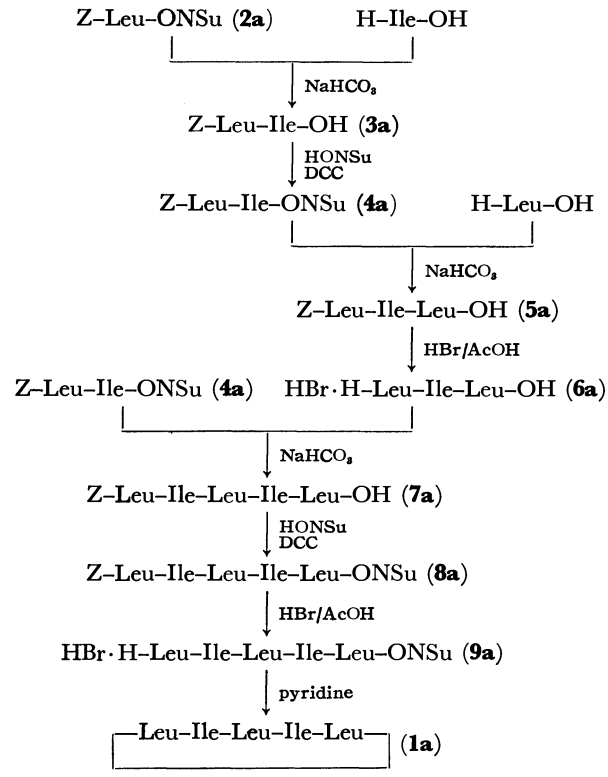
In a paper on the constituents of the mistletoe, *Viscum album* Linn. *var. coloratum* Ohwi, we reported on the isolation and structure of viscumamide, a new cyclic pentapeptide, which was assigned to be cyclo(-L-leucyl-L-isoleucyl-L-leucyl-L-isoleucyl-L-leucyl) (**1a**).[1]

In order to confirm the structure of viscumamide, we attempted to synthesize the cyclic peptide **1a** and three analogous cyclic peptides which consist of L-leucine and L-isoleucine.

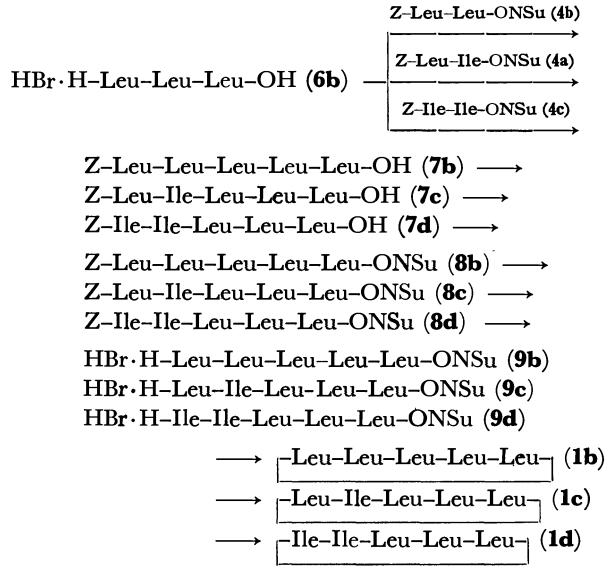
This paper deals with the synthesis of these cyclic pentapeptides, and the chromatographic and spectroscopic comparison of synthetic **1a** with natural viscumamide.



The synthesis of **1a** is outlined in Scheme 1. The *N*-hydroxysuccinimide ester method[2] was employed throughout the coupling reactions, the removal of benzyloxycarbonyl (Z) groups of the intermediates being performed by the action of hydrogen bromide in acetic acid.[3] Z-L-Leucine *N*-hydroxysuccinimide ester (-ONSu) (**2a**)[2] was coupled with L-isoleucine in the presence of sodium hydrogencarbonate to yield needles of Z-L-leucyl-L-isoleucine (**3a**) in 92% yield. Z-Dipeptide **3a** was then transformed into Z-L-leucyl-L-isoleucine *N*-hydroxysuccinimide ester (**4a**) as an oil by treatment with *N*-hydroxysuccinimide (HONSu) and dicyclohexylcarbodiimide (DCC) in dioxane. Purification of the substance by crystallization was unsuccessful. Z-Dipeptide ester **4a** was coupled with L-leucine in the same way as described above to yield Z-L-leucyl-L-isoleucyl-L-leucine (**5a**) as fine crystals in 67% yield based on **3a**. After removal of the Z group of the Z-tripeptide **5a** by the action of hydrogen bromide in acetic acid, the resulting tripeptide hydrobromide (**6a**) was coupled with Z-dipeptide ester **4a** to yield Z-L-leucyl-L-isoleucyl-L-leucyl-L-isoleucyl-L-leucine (**7a**) as fine crystals in 56% yield. Z-Pentapeptide **7a** was transformed into the corresponding *N*-hydroxysuccinimide ester (**8a**) as fine



Scheme 1.



Scheme 2.

crystals in 71% yield by the reaction with *N*-hydroxysuccinimide and dicyclohexylcarbodiimide in *N*,*N*-dimethylformamide (DMF) followed by separation from *N*,*N'*-dicyclohexylurea (DCU) by extraction with ethyl acetate. After removal of the Z group of the Z-pentapeptide ester **8a** in the same way as described above, the pentapeptide hydrobromide (**9a**) thus obtained was cyclized in pyridine at 40 °C by the high dilution method.[4] Purification through silica gel column, followed by chromatography on alumina, gave cyclo(-L-leucyl-L-isoleucyl-L-leucyl-L-isoleucyl-L-leucyl) (**1a**) as colorless needles in 6.5% yield.

Cyclic pentapeptides (**1b**, **1c**, and **1d**) were synthesized in the same way as described for the preparation of **1a** (Scheme 2). **2a** was chosen as the starting material and the peptide chains were extended stepwise to yield Z-L-leucyl-L-leucyl-L-leucine (**5b**). After removal of the Z group, the resulting tripeptide hydrobromide (**6b**) was coupled with the Z-dipeptide esters **4b**, **4a**, and **4c** to yield Z-pentapeptides **7b**, **7c**, and **7d**, respectively. The Z-pentapeptides were transformed into the corresponding *N*-hydroxysuccinimide esters **8b**, **8c**, and **8d**. After removal of the Z-groups, the resulting pentapeptide ester hydrobromides (**9b**, **9c**, and **9d**) were respectively cyclized and purified in the same way as described for the preparation of **1a** affording cyclic pentapeptides **1b**, **1c**, and **1d** as colorless needles in 6.5%, 4.5%, and 4.4% yields, respectively.

Cyclodimerization has been shown to occur predominantly with tripeptides and with pentapeptides.[5-7] Significant differences in the yield of cyclization have been observed to depend on the configuration of the amino acids in the open peptide chain.[8-10]

The yields in the cyclization step were low due to dimerization and other polymerization, since the pentapeptide esters (**9a**, **9b**, **9c**, and **9d**) consist of five L-amino acids, undergoing strong intermolecular association even at high dilution.

Racemization during this synthesis seems negligible, since the specific rotation value of synthetic **1a** is −56° which is identical with that of natural viscumamide.[11] Synthetic **1a** was identical with natural viscumamide in the infrared absorption spectrum (Fig. 1), the proton magnetic resonance spectrum (Fig. 2), and thin layer

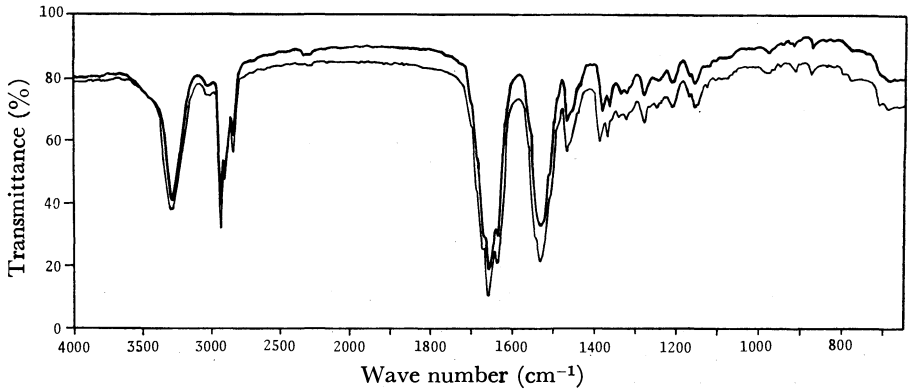


Fig. 1. Infrared absorption spectra of synthetic **1a** (heavy line) and natural viscumamide (light line) in KBr disk.

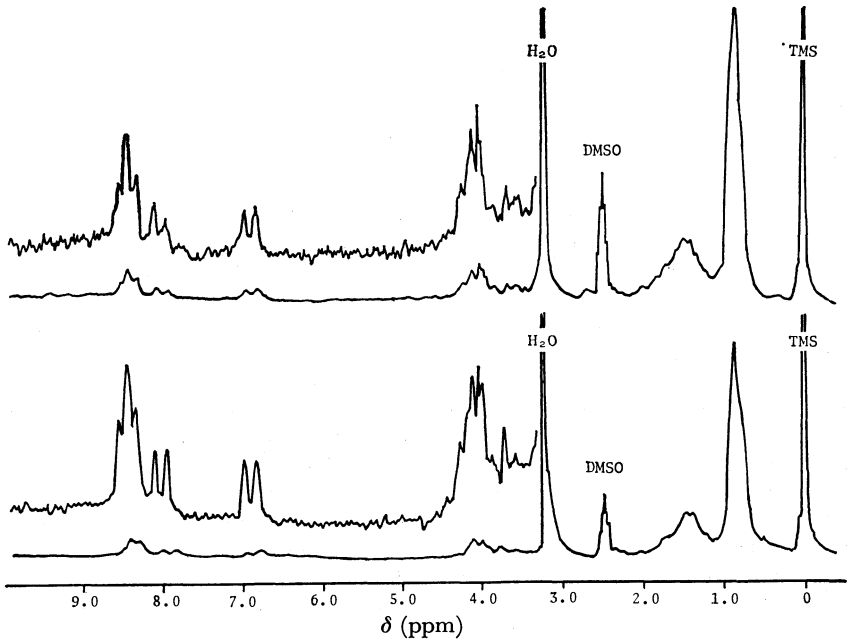

Fig. 2. Proton magnetic resonance spectra of synthetic **1a** (lower) and natural viscumamide (uper) in DMSO-d_6 at 30 °C.

chromatography with various solvent systems (Table 1). The results indicate that the structure of viscumamide is confirmed to be cyclo(-L-leucyl-L-isoleucyl-L-leucyl-L-isoleucyl-L-leucyl) (**1a**).

Experimental

All melting points are uncorrected. The proton magnetic resonance spectra were measured with a JEOL JNM PFT-60 NMR spectrometer at 60 MHz with tetramethylsilane as an internal standard. The infrared absorption spectra were measured with a Hitachi EPI-G3 recording spectrophotometer. The optical rotations were measured with a Union PM-101 polarimeter. Thin layer chromatography (TLC) was carried out on silica gel (Wakogel B-10).

Z-L-Leu-L-Lle-OH (3a). A solution of Z-L-Leu-ONSu[2] (**2a**) (72.5 g, 0.2 mol) in ethanol (1 l) was added to a solution of L-isoleucine (26.4 g, 0.2 mol) and sodium hydrogencarbonate (33.6 g, 0.4 mol) in water (1 l). After being stirred at room temperature overnight, the solution was acidified with 2M hydrochloric acid, and then ethanol was removed under reduced pressure below 40 °C. The precipitate separated from aqueous solution was dissolved in ethyl acetate (300 ml), and the solution was washed with water and dried over sodium sulfate. Hexane (300 ml) was added and the solution was chilled in a refrigerator. **3a** was obtained as colorless needles: mp 125—126 °C (lit,[9] 101—101.5 °C); yield, 62.8 g (83%); $[\alpha]_D^{25}$ $-5.0\pm0.2°$ (*c* 1.0, EtOH). (Found: C, 63.53; H, 8.19; N, 7.37%).

Z-L-Leu-L-Leu-OH (3b). **3b** was obtained in the same way as described above from **2a** (72.5 g, 0.2 mol) and L-leucine (26.4 g, 0.2 mol); colorless needles: mp 117—118 °C (lit,[9] 97.5—98.5 °C); yield, 63.5 g (88%); $[\alpha]_D^{25}$ $-25.0\pm0.2°$ (*c* 1.0, EtOH). (Found: C, 63.51; H, 8.22; N, 7.34%).

Z-L-Ile-L-Ile-OH (3c). **3c** was obtained in the same way as described above from Z-L-Ile-ONSu[2] (**2b**) (18.9 g, 50 mmol) and L-isoleucine (6.6 g, 50 mmol); colorless needles: mp 128—129 °C; yield, 16.7 g (88%); $[\alpha]_D^{25}$ $-8.9\pm0.2°$ (*c* 1.0, EtOH). (Found: C, 63.54; H, 8.20; N, 7.37%).

Z-L-Leu-L-Ile-ONSu (4a). DCC (30.9 g, 0.15 mol) was added at 0 °C to a solution of **3a** (56.8 g, 0.15 mol) and HONSu (17.3 g, 0.15 mol) in dry dioxane (300 ml). After being stirred at 0 °C for 4 h and then at room temperature overnight, DCU separated was filtered off and washed with dioxane. The combined filtrate and washings were evaporated to dryness under reduced pressure. **4a** was obtained as a colorless oil: yield, 67.8 g (95%); IR 1815 and 1785 (succinimide), and 1740 cm^{-1} (ester C=O).

Z-L-Leu-L-Leu-ONSu (4b). **4b** was obtained in the same way as described above from **3b** (62.5 g, 0.17 mol), HONSu (19.0 g, 0.17 mol), and DCC (34.0 g, 0.17 mol); colorless oil: yield, 76.9 g (98%); IR 1817 and 1787 (succinimide), and 1743 cm^{-1} (ester C=O).

Z-L-Ile-L-Ile-ONSu (4c). **4c** was obtained in the same way as described above from **3c** (15.1 g, 40 mmol), HONSu (4.6 g, 40 mmol), and DCC (8.3 g, 40 mmol); colorless oil: yield, 18.1 g (95%); IR 1817 and 1787 (succinimide), and 1742 cm^{-1} (ester C=O).

Z-L-Leu-L-Ile-L-Leu-OH (5a). L-Leucine (5.2 g, 40 mmol) and **4a** (15.0 g, 40 mmol) were treated in the same way as described for the preparation of **3a**. Concentration of the mixture under reduced pressure followed by chilling in a refrigerator gave the precipitate, which was collected and washed with water. Recrystallization from ethanol gave 13.2 g (67%) of **5a** as colorless fine crystals: mp 182—183 °C; $[\alpha]_D^{25}$ $-53.4\pm0.4°$ (*c* 0.5, EtOH). Found: C, 63.25; H, 8.52; N, 8.36%. Calcd for $C_{26}H_{41}N_3O_6$: C, 63.52; H, 8.41; N, 8.55%.

Z-L-Leu-L-Leu-L-Leu-OH (5b). **5b** was obtained in the same way as described above from **4b** (59.4 g, 0.13 mol) and L-leucine (16.4 g, 0.13 mol); colorless fine crystals: mp 102—104 °C; yield, 39.9 g (65%); $[\alpha]_D^{25}$ $-51.0\pm0.4°$ (*c* 0.5, EtOH). Found: C, 63.53; H, 8.63; N, 8.24%. Calcd for $C_{26}H_{41}N_3O_6$: C, 63.52; H, 8.41; N, 8.55%.

Z-L-Leu-L-Ile-L-Leu-L-Ile-L-Leu-OH (7a). **5a** (12.3 g, 25 mmol) was treated with 30% hydrogen bromide in acetic acid (25 g) at room temperature for 1 h, dry ether (100 ml) and dry hexane (200 ml) being added to the solution. Chilling of the solution gave the precipitate which was collected by filtration, washed with dry hexane, and dried in a desiccator over sodium hydroxide overnight; yellowish powder **6a**: yield, 11.9 g.

To a solution of **4a** (11.9 g, 25 mmol) in ethanol was added a solution of the tripeptide hydrobromide (**6a**) (11.9 g) and sodium hydrogencarbonate (6.3 g, 75 mmol) in a mixture of water (250 ml) and ethanol (200 ml). The mixture was treated in the same way as described for the preparation of **5a**. Recrystallization from 2-propanol gave **7a** as colorless fine crystals: mp 262—265 °C (dec); yield, 10.1 g (56%, based on **5a**); $[\alpha]_D^{25}$ $-57\pm2°$ (*c* 0.1, EtOH). Found: C, 63.39; H, 9.04; N, 9.63%. Calcd for $C_{38}H_{63}N_5O_8$: C, 63.57; H, 8.85; N, 9.76%.

Z-L-Leu-L-Leu-L-Leu-L-Leu-L-Leu-OH (7b). **7b** was obtained as colorless fine crystals in the same way as described above from the tripeptide hydrobromide (**6b**) prepared from **5b** (12.3 g, 25 mmol) and **4b** (11.9 g, 25 mmol): mp 263—266 °C (dec); yield, 12.4 g (69%, based on **5b**); $[\alpha]_D^{25}$ $-67\pm2°$ (*c* 0.1, EtOH). Found: C, 63.29; H, 9.08; N, 9.58%. Calcd for $C_{38}H_{63}N_5O_8$: C, 63.57; H, 8.55; N, 9.76%.

Z-L-Leu-L-Ile-L-Leu-L-Leu-L-Leu-OH (7c). **7c** was obtained as colorless fine crystals in the same way as described above from the tripeptide hydrobromide (**6b**) prepared from **5b** (12.3 g, 25 mmol) and **4a** (11.9 g, 25 mmol): mp 243—246 °C (dec); yield, 9.7 g (54%, based on **5b**); $[\alpha]_D^{25}$ $-31\pm2°$ (*c* 0.1, EtOH). Found: C, 63.33; H, 9.07; N, 9.61%. Calcd for $C_{38}H_{63}N_5O_8$: C, 63.57; H, 8.55; N, 9.76%.

Z-L-Ile-L-Ile-L-Leu-L-Leu-L-Leu-OH (7d). **7d** was obtained as colorless fine crystals in the same way as described above from the tripeptide hydrobromide (**6b**) prepared from **5b** (12.3 g, 25 mmol) and **4c** (11.9 g, 25 mmol): mp 256—258 °C (dec); yield, 9.5 g (53%, based on **5b**); $[\alpha]_D^{25}$ $-42\pm2°$ (*c* 0.1, EtOH). Found: C, 63.13; H, 9.13; N, 9.62%. Calcd for $C_{38}H_{63}N_5O_8$: C, 63.57; H, 8.55; N, 9.76%.

Z-L-Leu-L-Ile-L-Leu-L-Ile-L-Leu-ONSu (8a). DCC (2.7 g, 13 mmol) was added at 0 °C to a solution of **7a** (8.6 g, 12 mmol) and HONSu (1.7 g, 15 mmol) in DMF (500 ml). After being stirred at 0 °C for 8 h and then at room temperature for 16 h, deposited DCU was filtered off and washed with DMF. The combined filtrate and washings were evaporated to dryness under reduced pressure. The residue was extracted twice with hot ethyl acetate (150 ml) to remove DCU and then recrystallized from 2-propanol. **8a** was obtained as colorless fine crystals: mp 249—250 °C (dec); yield, 6.9 g (71%); $[\alpha]_D^{25}$ $-55\pm2°$ (*c* 0.1, EtOH); IR (Nujol) 1819 and 1789 (succinimide), and 1746 cm^{-1} (ester C=O). Found: C, 67.67; H, 8.41; N, 10.04%.

Calcd for $C_{42}H_{66}N_6O_{10}$: C, 61.89; H, 8.16; N, 10.31%.

Z-L-Leu-L-Leu-L-Leu-L-Leu-L-Leu-ONSu (8b). **8b** was obtained as colorless fine crystals in the same way as described above from **7b** (8.6 g, 12 mmol), HONSu (1.7 g, 15 mmol), and DCC (2.7 g, 13 mmol): mp 237—238 °C (dec); yield, 6.4 g (65%); $[\alpha]_D^{25}$ $-67\pm2°$ (*c* 0.1, EtOH); IR (Nujol) 1817 and 1790 (succinimide), and 1746 cm^{-1} (ester C=O).

Found: C, 61.75; H, 8.55; N, 10.13%.

Calcd for $C_{42}H_{66}N_6O_{10}$: C, 61.89; H, 8.16; N, 10.31%,

Z-L-Leu-L-Ile-L-Leu-L-Leu-L-Leu-ONSu (8c). **8c** was obtained as colorless fine crystals in the same way as described above from **7c** (8.6 g, 12 mmol), HONSu (1.7 g, 15 mmol), and DCC (2.7 g. 13 mmol): mp 248—250 °C (dec); yield, 6.7 g (69%); $[\alpha]_D^{25}$ −69±2° (*c* 0.1, EtOH); IR (Nujol) 1819 and 1790 (succinimide), and 1742 cm^{-1} (ester C=O). Found: C, 61.82; H, 8.49; N, 10.14%. Calcd for $C_{42}H_{66}N_6O_{10}$: C, 61.89; H, 8.16; N, 10.31%.

Z-L-Ile-L-Ile-L-Leu-L-Leu-L-Leu-ONSu (8d). **8d** was obtained as colorless fine crystals in the same way as described above from **7d** (8.6 g, 12 mmol), HONSu (1.7 g, 15 mmol), and DCC (2.7 g, 13 mmol): mp 243—245 °C (dec); yield, 6.8 g (70%); $[\alpha]_D^{25}$ −51±2° (*c* 0.1, EtOH); IR (Nujol) 1817 and 1788 (succinimide), and 1745 cm^{-1} (ester C=O). Found: C, 61.80; H, 8.41; N, 10.20%. Calcd for $C_{42}H_{66}N_6O_{10}$: C, 61.89; H, 8.16; N, 10.31%.

Cyclo(-L-Leu-L-Ile-L-Leu-L-Ile-L-Leu-) (1a). **8a** (5.7 g, 7 mmol) was treated with 20% hydrogen bromide in acetic acid (15 g) in the same way as described for the preparation of **6a**. The pentapeptide ester hydrobromide (**9a**) (yellowish powder; yield, 5.1 g (96%)) thus obtained was dissolved in DMF (1 l), and the solution was added dropwise into pyridine (2 l) with stirring at 40 °C over a period of 12 h; stirring at room temperature was then continued for 12 h. The solvent was removed under reduced pressure, and the residue was dissolved in hot chloroform (250 ml). The solution was subject ed to chromatography on a column of silica gel (100 g). After the column had been eluted with chloroform (400 ml), elution with a mixture of ethyl acetate and ethanol (19: 1) (400 ml) gave the desired product, as determined by TLC. The effluent was evaporated to dryness under reduced pressure, giving a brownish powder which was dissolved in chloroform (100 ml) and then further purified by column chromatography on alumina (100 g). The column was washed with chloroform (200 ml) and successively with ethyl acetate (200 ml). Elution with a mixture of ethyl acetate and ethanol (19: 1) (200 ml) followed by recrystallization from ethanol gave 257 mg (6.5 %) of cyclic pentapeptide (**1a**) as colorless needles: mp >300 °C; $[\alpha]_D^{20}$ −56±2° (*c* 0.1, EtOH); MS (70 eV), M^+ *m/e* 565; PMR (DMSO-d_6, amide protons, at 30 °C) δ=8.68 (1H, d, J=6.6 Hz), 8.58 (2H, d, J=7.2 Hz), 8.15 (1H, d, J=9.0 Hz), and 6.97 ppm (1H, d, J=9.0 Hz); IR (KBr) 3300, 3050, and 1535 (amide NH), 1680, 1661, and 1638 cm^{-1} (amide C=O). Found: C, 63.39; H, 9.89; N, 12.22%. Calcd for $C_{30}H_{55}N_5O_5$: C, 63.68; H, 9.80; N, 12.38%.

Cyclo(-L-Leu-L-Leu-L-Leu-L-Leu-L-Leu-L-Leu-) (1b). **1b** (238 mg, 6.0% based on **8b**) was obtained and purified in the same way as described above *via* HBr·H-L-Leu-L-Leu-L-Leu-L-Leu-L-Leu-ONSu (**9b**) (yellowish powder; 5.2 g (98%)) from **8b** (5.7 g, 7 mmol); colorless needles: mp >300 °C; $[\alpha]_D^{20}$ −67 ±2° (*c* 0.1, EtOH); MS (70 eV), M^+ *m/e* 565; PMR (DMSO-d_6, amide protons, at 30 °C) δ=8.71 (1H, d, J=7.2 Hz), 8.53 (1H, d, J=6.6 Hz), 8.18 (1H, d, J=6.6 Hz), 7.63 (1H, d, J=9.0 Hz), and 7.23 ppm (1H, d, J=9.0 Hz); IR (KBr) 3290, 3060, and 1540 (amide NH), and 1659, 1651, and 1640 cm^{-1} (amide C=O). Found: C, 63.85; H, 9.68; N, 12.40%. Calcd for $C_{30}H_{55}N_5O_5$: C, 63.68; H, 9.80; N, 12.38%.

Cyclo(-L-Leu-L-Ile-L-Leu-L-Leu-L-Leu-) (1c). **1c** (178 mg, 4.5% based on **8c**) was obtained and purified in the same way as described above *via* HBr·H-L-Leu-L-Ile-L-Leu-L-Leu-L-Leu-ONSu (**9c**) (yellowish powder; yield, 5.1 g (95%)) from **8c** (5.7 g, 7 mmol); colorless needles: mp >300 °C; $[\alpha]_D^{15}$ −71 ±2° (*c* 0.1, EtOH); MS (70 eV), M^+ *m/e* 565; PMR (DMSO-d_6, amide protons, at 30 °C) δ=8.59 (1H, d, J=7.8 Hz), 8.40 (1H, d, J=8.4 Hz), 8.33 (1H, d, J=7.8 Hz), 8.04 (1H, d, J=8.4 Hz), and 7.19 ppm (1H, d, J=8.4 Hz); IR (KBr) 3350, 3310, 3050, and 1520 (amide NH), and 1658 and 1652 cm^{-1} (amide C=O). Found: C, 63.59; H, 10.03; N, 11.98%. Calcd for $C_{30}H_{55}N_5O_5$: C, 63.68; H, 9.80; N, 12.38%.

Cyclo(-L-Ile-L-Ile-L-Leu-L-Leu-L-Leu-) (1d). **1d** (175 mg, 4.4% based on **8d**) was obtained and purified in the same way as described above *via* HBr·H-L-Ile-L-Ile-L-Leu-L-Leu-L-Leu-ONSu (**9d**) (yellowish powder; yield, 5.3 g (99%)) from **8d** (5.7 g, 7 mmol); colorless needles: mp >300 °C; $[\alpha]_D^{15}$ −52 ±2° (*c* 0.1, EtOH); MS (70 eV), M^+ *m/e* 565; PMR (DMSO-d_6, amide protons, at 30 °C) δ=8.53 (1H, d, J=7.8 Hz), 8.33 (1H, d, J=7.8 Hz), 8.11 (1H, d, J=9.0 Hz), 8.06 (1H, d, J=7.8 Hz), and 7.67 ppm (1H, d, J=9.0 Hz); IR (KBr) 3300, 3050, and 1530 (amide NH), and 1658 and 1650 cm^{-1} (amide C=O). Found: C, 63.66; H, 10.01; N, 12.26%. Calcd for $C_{30}H_{55}N_5O_5$: C, 63.66; H, 9.80; N, 12.38%.

Comparison of Viscumamide with Synthetic Cyclopentapeptides. The specific rotation value, mass spectrum, proton magnetic resonance spectrum, and infrared absorption spectrum of synthetic viscumamide **1a** were identical with those of the authentic sample. A thin layer chromatographic comparison of viscumamide with the synthetic cyclopentapeptides is given in Table 1.

Table 1. Thin layer chromatography of cyclopentapeptides

Solvents[a]	Substances

(Received August 11, 1978)

The Diels-Alder reaction of thiophene with maleic anhydride has been investigated under conditions of very high pressure. The Diels-Alder adduct was obtained in dichloromethane at 100 °C and 15 kbar; above a pressure of 15 kbar the reaction was highly accelerated. From the spectral data and chemical evidence it has been suggested that the adduct has the *exo*-configuration. The reactions in various solvents and with other dienophiles have also been examined.

Recently much attention has been focused on the application of high pressure techniques in the field of synthetic organic chemistry.[2] In general, the pressure dependence of the rate constant on the reaction may be written as follows:

$$\frac{\delta \ln k}{\delta P} = -\frac{\Delta V^*}{RT}$$

where ΔV^*, the activation volume, represents the difference in volume between the reactants and the transition state. If ΔV^* is negative, *i.e.*, the volume of the transition state is smaller than the volume of the reactants, the rate k will increase with increasing pressure. The activation volume for a number of organic reactions has been determined and [4+2] cycloaddition reactions, typically the Diels-Alder reaction, are known to have a relatively large activation volume (−25——50 cm³/mol)[2,3] being the most favorable case at high pressure.

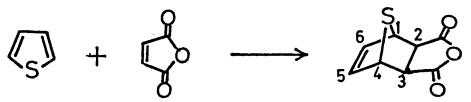
In line with this theory the [4+2] cycloaddition reactions at high pressures have been investigated and it has been shown that the use of high pressure (10—40 kbar) is a very valuable tool for synthetic organic chemistry.[4-6]

In a preliminary paper it was reported that the Diels-Alder reaction of thiophene with maleic anhydride, which had never undergone reaction under the usual conditions, had effectively proceeded at very high pressures.[1b] This paper will report a more detailed investigation.

Results and Discussion

Cycloaddition between Thiophene and Maleic Anhydride. It is well documented that thiophene itself does not undergo the Diels-Alder reaction.[7] Recently, however, there have been reports that some thiophene derivatives do combine with extremely reactive dienophiles such as dicyanoacetylene and dimethyl acetylenedicarboxylate.[8] The only recorded thiophene derivatives which are able to react with maleic anhydride in a Diels-Alder manner are thiophenc 1,1-dioxide[9] and 2,5-dimethoxythiophene.[10]

The authors anticipated that thiophene would react with maleic anhydride if the reaction were performed under high pressure conditions overcoming the high aromatic character.



1 2 3

Initially, the reaction of thiophene with maleic anhydride in dichloromethane at 15 kbar and room temperature was attempted considering the thermal lability of the cycloadduct or the enhancement of the reverse reaction. After 3 days, however, reaction had not occurred and reaction without solvent or with a Lewis acid catalyst (*e.g.* $MgCl_2$) was also fruitless. This demonstrates a striking absence of diene character in thiophene and contrasts remarkably with furan.[4b] The reaction was examined at higher temperatures at 15 kbar for 3 h in dichloromethane when the reaction did occur (Table 1). Inspection of Table 1 reveals that the most favorable

Table 1. Temperature dependence of the yield[a] in the adduct **3** between thiophene and maleic anhydride

a) The yield based on the isolated materials.

results are obtained at 100 °C. Thus, from the reaction mixture a highly crystalline compound **3**,[11] mp 159.5—161.5 °C, of molecular formula $C_8H_6O_3S$ (MS, M^+ 182) was obtained in yields of 37—47% after recrystallization from ether or chloroform. It is suggested that **3** has an *exo*-configuration from the spectral data and chemical evidence as follows. In the ^1H NMR spectra (Table 2), the C_2 and C_3 protons appear at δ 3.63 as a doublet (J=1 Hz) and when the dihedral angle between the protons at C_1 and C_2 (C_3 and C_4) is considered the indication is that **3** has an *exo*-configuration. This assignment is in good agreement with the data of the adducts between furan and maleic anhydride, showing that the *exo*-adduct **6** resembles **3** rather than the *endo*-adduct.[12]

Further supporting evidence has been obtained as follows. Adduct **3** was subjected to methanolysis to give the monomethyl ester **4**. As expected **4** did not undergo

iodolactonization (I_2–KI).[13] The corresponding dimethyl ester **5**, which is formally regarded as the Diels-Alder product of thiophene with dimethyl maleate, was prepared from **4** by careful methylation with diazomethane.[14] In the ^{1}H NMR spectra of **5** (Table 2) the C_2 and C_3 protons appeared at δ 3.16 as a singlet. In the ^{1}H NMR spectra of the *exo*-adduct **7** between furan and maleic acid the C_2 and C_3 protons were reported to appear at δ 2.61 as a singlet.[13,15] Moreover, in the case of the *endo*-adduct **8** between furan and dimethyl maleate, which was prepared under similar conditions as reported by Dauben and Krabbenhoft,[4b] the C_2 and C_3 protons appear at δ 3.43 as a doublet of doublets (J=2, 3 Hz)[16] and contrasts remarkably with these results.

The exclusive formation of the *exo*-adduct **3** in the Diels-Alder reaction of thiophene with maleic anhydride is predictable on the basis of the preferential production of the thermodynamically stable adduct at higher temperature.[17] However, it would be premature to say whether **3** represents the kinetic product.

Since the reaction of thiophene with maleic anhydride has been proven efficient in giving an adduct, an investigation of the reactions between thiophene and other dienophiles has been undertaken. However all attempted reactions of thiophene with dimethyl maleate, dimethyl fumarate, methyl acrylate, acrylonitrile, or acrylaldehyde under the same conditions (100 °C, 15 kbar, 3 h, the concentrations of the reactants were 3 M in CH_2Cl_2) were unsuccessful and no adduct formation was observed. At higher temperatures the reaction was too vigorous to give the adduct, thus dimethyl maleate isomerized completely to dimethyl fumarate. Acrylonitrile and acrylaldehyde readily polymerized even in the presence of an inhibitor such as hydroquinone.

Thus sole criterion of high pressure is insufficient to bring about the reaction of thiophene with dienophiles less reactive than maleic anhydride.

Effect of Solvent. It is usually recognized that the conventional Diels-Alder reaction is little affected by the solvent.[17] However, under high pressure conditions the choice of solvent becomes important and there have been various studies on the kinetic solvent effects in Diels-Alder reactions.[3,18] Unfortunately these studies have been limited to relatively low pressures (*ca.* 2 kbar max.), and little information is available in the pressure range from 10 to 20 kbar. Consequently an investigation of the solvent effect in the Diels-Alder reaction of thiophene with maleic anhydride has been undertaken and the results are summarized in Table 3. In a previous paper the low yield in benzene (Run 11) was assumed to be due to the freezing of the reaction medium at 15 kbar.[1b] According to the Simon equation the freezing temperature of substances is dependent on pressure.[19] The estimated freezing point of benzene at 4 kbar is *ca.* 100 °C, so that freezing of the reaction medium appears to be probable. The interpretation based on freezing temperature of solvent is plausible in the cases of dichloromethane, chloroform, and carbon tetrachloride (Runs

a) The values are the average of two or more runs. b) The estimated freezing point is 100 °C at this pressure. See Ref. 19. c) Only trace amounts of adduct were detected by TLC. d) A considerable amount of polymeric substances was obtained.

1—9). In this connection it can be seen that *at pressures above 15 kbar the reaction is highly accelerated!* The fact that at 20 kbar, a respectable increase of product yield was observed in carbon tetrachloride (Run 9) leads to the assumption that the reaction proceeds to some extent in the frozen state,[20] although further experiments were necessary. In addition the results in Table 3 suggest that the adduct formation should increase in aromatic solvents having an electron withdrawing substituent (Runs 13 and 15) rather than ones having an electron donating substituent (Runs 11 and 12). This may be explained in terms of the specific solute-solvent interactions such as the charge transfer complex formation between maleic anhydride and benzene or toluene which would become significant at high pressure.[21,22]

The very low yield of product in ether, acetone, and acetophenone can not be explained.

Experimental

Apparatus. Figure 1 shows a schematic version of the high pressure apparatus used which consists essentially of a press frame, the upper and bottom drive cylinders, an induction heater and a sample cylinder. The sample cylinder, shown in Fig. 2, has been fabricated from a SUS-27 multiplex cylinder subject to autofrettage and a hardened S-3 tool steel cylinder or sintered tungsten carbide cylinder (80 mm long and 50 mm diameter). The piston made from hardened S-3 tool steel or sintered tungsten carbide has a diameter of 12 mm. The reaction vessel has been made from Teflon which is a good container for most organic substrates and pressure transmitter at elevated temperatures (below 300 °C). Talc and stainless steel disks have been used to prevent leakage from the Teflon vessel. The pressure generated in the reaction vessel can not be directly read on the pressure gauge and so has been calibrated using the change in volume of $AgNO_3$ (9.8 kbar) and KBr (17.9 kbar) and the resistivity of Bi I–II (25.3 kbar) at room temperature. The leakage from the Teflon vessel containing the reactants and solvent has been checked and appears to be negligible.

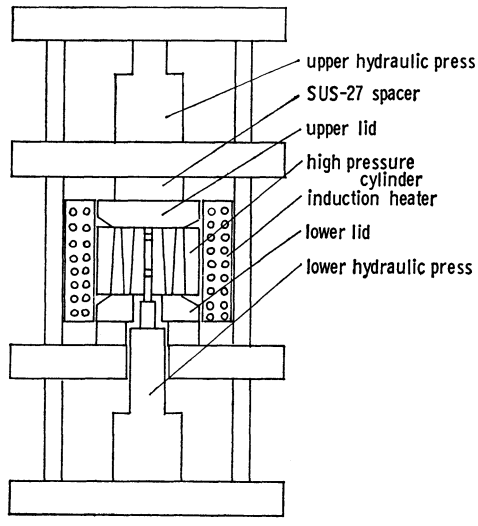

Fig. 1. Schematic version of high pressure apparatus.

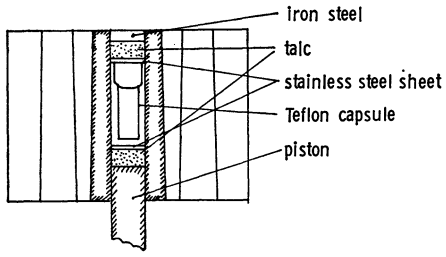

Fig. 2. Detailed schematic version of the sample cylinder.

The procedure for a high pressure reaction is as follows. The reaction vessel (*ca.* 0.85 ml capacity) is filled completely with the reactants dissolved in an appropriate solvent and covered with Teflon lid. The reaction vessel and the piston are forced into the bore of a sample cylinder by synchronously raising the upper and bottom drive cylinders hydraulically until the desired pressure is attained. To conduct a reaction at elevated temperatures, the sample cylinder system is inserted into the induction heater and heated to the desired temperature measured by an alumel-chromel thermocouple. After the experiment the sample cylinder is cooled to room temperature by a fan and the pressure released. A representative temperature-pressure diagram is shown in Fig. 3 in the experiment at 150 °C and 15 kbar for 3.5 h.

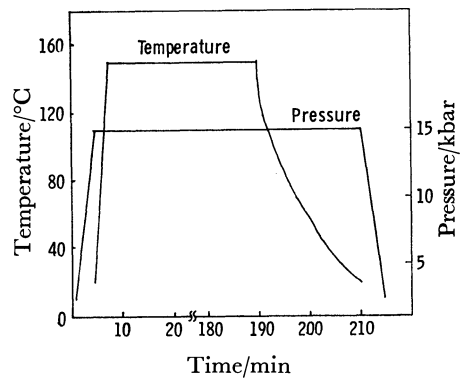

Fig. 3. Representative temperature-pressure diagram at 150 °C and 15 kbar for 3.5 h.

All high pressure reactions were performed at a concentration of 3 M of the reactants in the dried solvents.

General. All melting points are uncorrected. ^1H NMR spectra were obtained on a JEOL-MH-100 spectrometer using TMS as the internal standard. ^{13}C NMR spectra were obtained at 25.05 MHz on a JEOL-FX-100 spectrometer. The IR spectra were measured with a JASCO infrared spectrophotometer Model IRA-1 and the mass spectra on a Hitachi Model M-52 spectrometer.

TLC was conducted using Merck's precoated Kieselgel 60 (5721) and for column chromatography, Wakogel C-200 (74—149 μ) was employed.

Diels-Alder Reaction of Thiophene with Maleic Anhydride. The general procedure is as follows. A CH_2Cl_2 solution (1 ml) of thiophene (3 mmol) and maleic anhydride (3 mmol) was injected into the Teflon reaction vessel. The reaction vessel was heated to 100 °C at 15 kbar for 3 h. After cooling of the reaction mixture and the release of pressure, the solvent was evaporated and the product recrystallized from ether or chloroform to give pure **3** in 37—47% yield: mp 159.5—161.5 °C (from $CHCl_3$), 159—160 °C (from Et_2O); IR (Nujol) 1850, 1795, 1085, 943, and 920 cm^{-1}; ^1H NMR spectrum (Table 2); ^{13}C NMR spectrum (Table 4); MS (20 eV), *m/e* (rel intensity),

a) Chemical shifts are expressed in ppm downfield from the ^{13}C NMR of TMS.

182 (36, M^+), 110 (27), 84 (44), 78 (100), 66 (25), 45 (12).

Found: C, 52.80; H, 3.32%. Calcd for $C_8H_6O_3S$: C, 52.74; H, 3.32%.

Methanolysis of Adduct **3**. Two ml of an absolute MeOH solution of adduct **3** (200 mg) was stirred at 40 °C for 5 days under a N_2 atmosphere.[23] After removal of excess MeOH the crude product, which still contained a small amount of starting anhydride (R_f 0.61, 4: 1 C_6H_6–AcOEt) on TLC, was obtained as a viscous oil. A pure sample of the monomethyl ester **4** was obtained in crystalline form after column chromatography on silica gel: mp 123—124 °C (from Et_2O); IR (Nujol) 3200—2600, 1740, 1710, 1245, 1210, and 1185 cm^{-1}; ^1H NMR spectrum (Table 2); MS (30 eV), *m/e*, 214 (M^+).

Found: C, 50.42; H, 4.66%. Calcd for $C_9H_{10}O_4S$: C, 50.46; H, 4.70%.

Methylation of the Monomethyl Ester **4**. The monomethyl ester **4** (123 mg) was treated conventionally with a small excess of diazomethane. After the renewed addition of diazomethane succeeded in producing a pale yellow coloration (*ca.* 1 min on standing at 0 °C), the excess of reagent was instantly decomposed with the minimum amount of AcOH and the solution evaporated *in vacuo* (below 45 °C).[14] The crude product with an unpleasant odor was purified by column chromatography on silica gel (eluted with $CHCl_3$) and 100 mg of dimethyl ester **5** was obtained as a colorless and odorless oil which crystallized on standing in the refrigerator: mp 73—73.5 °C (from Et_2O–petroleum ether); IR (Nujol) 1745, 1585, 1335, 1225, 1215, 1160, and 1035 cm^{-1}; ^1H NMR spectrum (Table 2); ^{13}C NMR spectrum (Table 4); MS (70 eV), *m/e*, 228 (M^+).

Found: C, 52.67; H, 5.28%. Calcd for $C_{10}H_{12}O_4S$: C, 52.62; H, 5.30%.

22) A referee has pointed out the participation of the solvent in the activated complex rather than the charge transfer complex formation between maleic anhydride and

solvent. The importance of such a feature cannot be excluded. However, the authors have concluded that the charge transfer complex formation is significant in this reaction since the stability of the complex is enhanced at high pressure: A. H. Ewald, *Trans. Faraday Soc.*, **64**, 733 (1968). See also Ref. 21b.

23) A significant amount of the starting material (*ca.* 20%) remained unchanged on ^{1}H NMR even after refluxing for 2 days under a N_2 atmosphere. In this case the reaction mixture was colored yellow and difficult to purify.

Light-induced Conformational Changes of Polypeptides. Photoisomerization of Azoaromatic Polypeptides

(Received August 15, 1978)

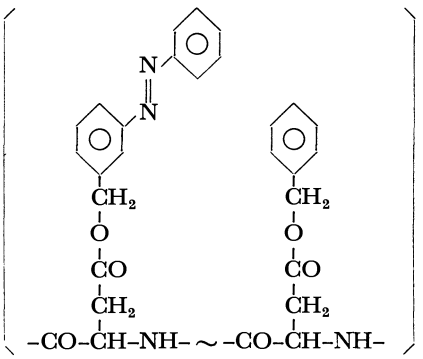
Copolymers of β-benzyl L-aspartate with β-*m*- or *p*-(phenylazo)benzyl L-aspartate were prepared in order to investigate the effect of side-chain photoisomerization on their conformations. These polymers in 1,2-dichloroethane show a CD band at 222 nm characteristic of left-handed α-helices. After irradiation, remarkable changes of the 222 nm band were observed for both *meta* and *para* copolymers with more than 50% azo residues. The decrease in ellipticity observed for the *meta* copolymers indicates that photoisomerization induces a significant instability in the left-handed α-helical conformation. On the other hand, the *para* copolymers change their sign from positive to negative by irradiation, confirming the reversal in the helix sense. In the course of subsequent relaxation of the irradiated *para* copolymer with 59% azo residues, an abrupt change in the CD spectra was found above 50% *cis* followed by a gradual change on decreasing the content of *cis* isomers. Concerning the polymers with azoaromatic side chains including copolymers with γ-benzyl L-glutamate, the helical sense seems to affect appreciably the sign of the side-chain CD bands.

The conformation of substituted benzyl esters of poly(aspartic acid) is determined by the nature and position of the substituent. Revesal in the helix sense from left- to right-handed α-helix is induced by the *para* substitution of the benzene ring of poly(β-benzyl L-aspartate) (PBLA) with a methyl, cyano, or nitro group.[1] Furthermore, the chlorine substituted PBLAs assume different handed helices depending on the position of the chlorine atom attached to the benzene ring.[2] From these observations a geometrical change such as *cis-trans* isomerization of the appropriate side chains might be expected to reverse the helix sense. Such a system, if realized, can be compared with visual purple, rhodopsin, since its polypeptide part (opsin) undergoes a conformational change induced by *cis-trans* photoisomerization of its chromophoric part (retinal). In nature, this light-induced conformational change is a trigger which excites the nerve cells of the retinal rods. From this view point, we prepared some copolymer series containing azobenzene moieties in their side chains. Photoisomerization of a polypeptide side chain itself was reported for the copolymers of L-*p*-(phenylazo)phenylalanine[3] and also for poly(γ-cinnamyl L-glutamate).[4] However, no conformational change could be induced by irradiation probably because of their conformational stability. In a previous paper,[5] we reported the results of the copolymer series of γ-benzyl L-glutamate with β-*m*- or *p*-(phenylazo)benzyl L-aspartate, and showed evidence supporting the following processes which occur independently.

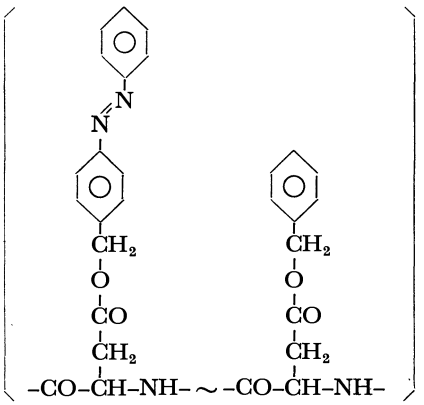
$$\text{random coil} \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} \text{right-handed helix} \qquad (1)$$

$$\text{left-handed helix} \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} \text{random coil} \qquad (2)$$

Reversal in helix sense could be attained for these copolymer series. In this paper, the results of copolymer series of β-benzyl L-aspartate with β-*m*- or *p*-(phenylazo)benzyl L-aspartate (*meta* or *para* copolymer series) are described. The following process which involves reversal in the helix sense has been confirmed to occur for some of these polymers.



meta copolymer series



para copolymer series

$$\text{left-handed helix} \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} \text{right-handed helix} \qquad (3)$$

The side-chain *cis* isomer, formed by irradiation, undergoes subsequent relaxation in the dark back to the original *trans* form. The light-induced conformational changes are, therefore, reversible, and provide a unique system which responds to light signals in an on-off fashion.

Results and Discussion

The ultraviolet and visible spectrum of poly[β-*m*-

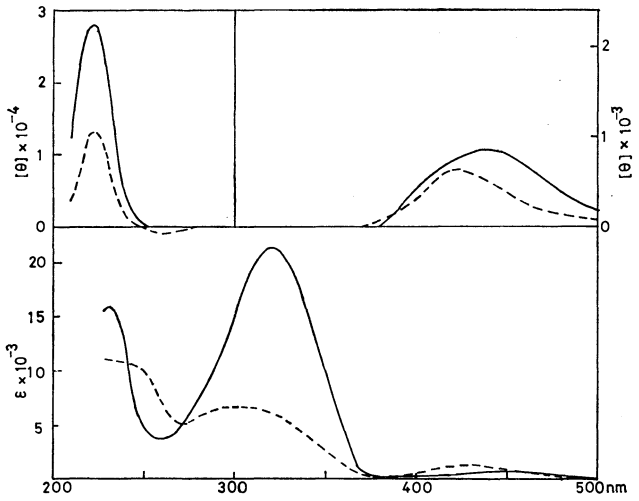


Fig. 1. CD and ultraviolet-visible spectra of mPALA in 1,2-dichloroethane before (——) and after (----) irradiation.

(phenylazo)benzyl L-aspartate] (mPALA) is essentially that of azobenzene itself (Fig. 1).[7] The band at 320 nm is attributed to π-π^* transition (ε=22000) and that at 450 nm to n-π^* transition (ε=700).[8] The irradiated polymer shows a spectrum resembling that of *cis*-azobenzene reported by Gerson *et al.*[7] The important aspect of the spectrum after irradiation is the decrease in absorption intensity in the π-π^* transition region. All of the *meta* and *para* copolymer series show similar spectra with various intensities corresponding to their content of azo residues.

The circular dichroism (CD) spectra of *meta* copolymer series before and after irradiation show dichroic bands associated with the n-π^* transitions of the main-chain amide and side-chain azo chromophores at 222 nm and 420—450 nm, respectively. No dichroic band was observed in the region of the π-π^* transition of the chromophore. The values of $[\theta]$ at the extrema are plotted against the content of azo residues (mol % of (phenylao)benzyl L-aspartate in copolymers) (Fig. 2).

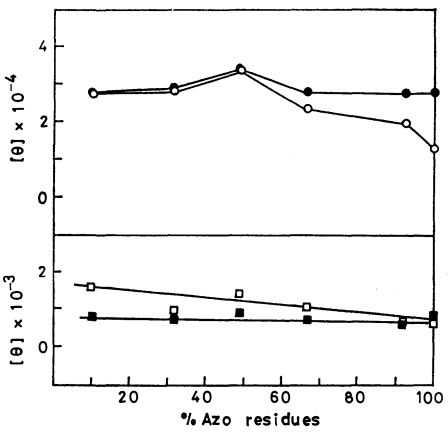

Fig. 2. Variation of maximum ellipticities associated with the side-chain n-π^* (■,□) and the amide n-π^* (●,○) transitions before (■,●) and after (□,○) iradiation for *meta* copolymer series as a function of the azo content.

Molar ellipticities of the side-chain band were calculated with use of the molar concentration of azo residues. The spectra around 222 nm before irradiation are almost independent of the copolymer composition, and are very similar to those of poly(β-methyl L-aspartate) which assumes a left-handed α-helical conformation.[9] These observations suggest that overlapping of allowed transitions of side-chain chromophores with those from the peptide backbone is either small or absent in the polymers.[10] The values of $[\theta]$ at 222 nm do not seem to be affected by irradiation for the copolymers with azo residues of smaller than 50%. However, the values decrease for the copolymers of 67 and 92% azo contents and mPALA (Figs. 2 and 7). The value of $[\theta]$ at 222 nm is generally used to characterize the helicity, the decreased values indicating the increase in instability for the left-handed α-helices of the polymers. The value of $[\theta]_{222}$=28000 for mPALA is reduced to 13000 by irradiation (Figs. 1 and 2), confirming the formation of an appreciable amount of random-coil form. Its reduced specific viscosity, η_{sp}/c (c=0.1 in 1,2-dichloroethane), measured at 25 °C changes from 0.23 to 0.49 by photoirradiation. This suggests the increased volume induced by collapse of the helical form.

Proton NMR spectra at 100 MHz were measured for mPALA (Fig. 3) in order to obtain further evidence for the partial helix-coil transition. The spectrum of the fully helical mPALA in 0.3% v/v trifluoroacetic acid/deuteriochloroform (TFA/$CDCl_3$) solution shows a peak at 4.37 ppm from α-CH proton and a broad doublet at 3.28 and 2.76 ppm from the β-CH_2 protons. The spectrum of the random-coil form of mPALA in 3% v/v TFA/$CDCl_3$ solution shows a peak at 4.86 ppm from the α-CH proton (shoulder of the peak from the benzyl CH_2

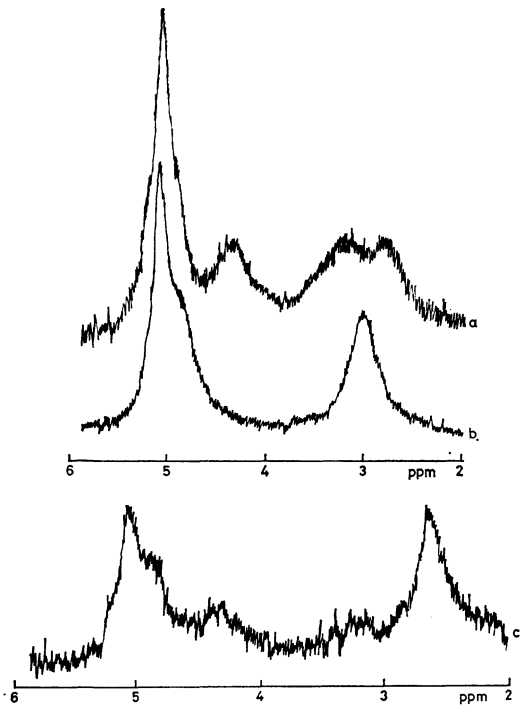

Fig. 3. 100-MHz NMR Spectra of mPALA. a; α-Helix (0.3% v/v TFA/$CDCl_3$), b; random coil (3% v/v TFA/$CDCl_3$), c; mPALA after irradiation ($CDCl_3$).

protons) and a single peak at 3.01 ppm from the β-CH_2 protons. The chemical shifts are close to those reported for the L-aspartate polymers.[11] The spectrum of mPALA after irradiation in $CDCl_3$ shows a complex pattern. The two α-CH chemical shifts observed at 4.40 and 4.90 ppm correspond to the α-helix and the random-coil peaks, respectively. Another change to be noted is that for the β-CH_2 resonance, which shows a sharp peak at 2.66 ppm probably from the random-coil form overlapped by the high field component of the β-CH_2 doublet of the helix. Compared with the chemical shift of the random coil caused by TFA addition, it is shifted upfield. The cause of the shift is unknown, but it might be due to the absense of TFA or a ring current effect of formed *cis* isomers. The results of NMR spectra might be in line with those of CD spectra.

The signs of the n-π^* CD band of the side-chain azo chromophores are always positive, not changing on photoirradiation (Fig. 2). The values of $[\theta]$ before and after irradiation are independent of the content of azo residues, which confirms side chain-main chain interactions as the origin of the dichroism band.

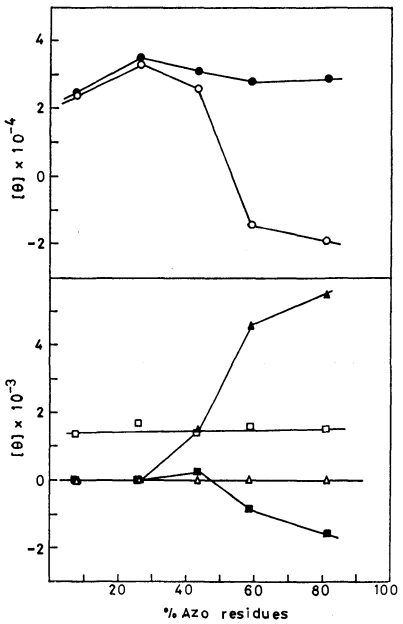

Fig. 4. Variation of maximum or minimum ellipticities associated with the side-chain n-π^* (■,□) π-π^* (▲,△) and the amide n-π^* (●,○) transitions before (■,▲,●) and after (□,△,○) irradiation for *para* copolymer series as a function of the azo content.

The CD spectra of *para* copolymer series show dichroic bands associated with the side-chain π-π^* transition as well as the n-π^* transitions of the main chain amide and side-chain azo chromophores. The values of $[\theta]$ at the extrema before and after irradiation are plotted against the content of azo residues (Fig. 4). All the spectra around 222 nm before irradiation are essentially those for the left-handed α-helices. The spectra after irradiation differ remarkably from those before irradiation for the copolymers of 59 and 81% azo contents (Fig. 7). These copolymers before irradiation display maxima with the values of $[\theta]_{222}=28000$ for 59% azo copolymer and $[\theta]_{215}=29000$ for 81% azo copolymer,[12] after irradiation minima with the values of $[\theta]_{224}=-14000$ for the former and $[\theta]_{222}=-19000$ for the latter. These observations demonstrate the reversal in the helix sense of these copolymers. Some indication of double trough is also consistent with helix reversal. Since the absolute values of $[\theta]$ are appreciably smaller than the value of $\approx$40000 reported for right-handed α-helices,[13] the copolymers after irradiation cannot be entirely right-handed helices. In contrast to the above polymers, the effect of irradiation on conformation is negligible for the polymers with smaller amount of azo residues. Certain amount of azo residues is necessary to cause the pronounced conformational changes. A critical azo content seems to exist at about 50%.

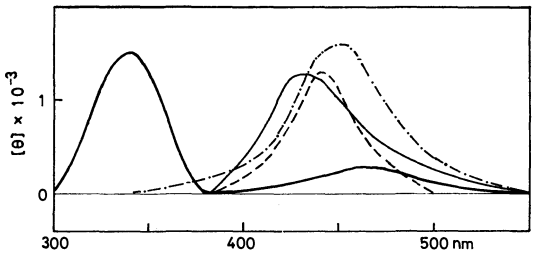

Fig. 5. CD spectra associated with the side-chain transitions of *para* copolymer series in 1,2-dichloroethane. Before irradiation: azo content 43% (——). After irradiation: azo content 7.4% (– – –), 26% (-·-·-), 43% (——).

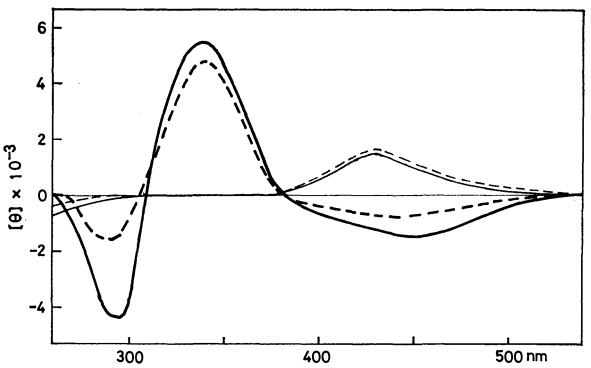

Fig. 6. CD spectra associated with the side-chain transitions of *para* copolymer series in 1,2-dichloroethane. Before irradiation: azo content 59% (– – –), 81% (——). After irradiation: azo content 59% (– – –), 81% (——).

The CD spectra associated with the side-chain n-π^* and π-π^* transitions of *para* copolymer series before and after irradiation are shown in Figs. 5 and 6.[14] Before irradiation, the CD spectra of the two copolymers with azo residues of 7.4 and 26% exhibit no dichroism in the region of the side-chain π-π^* transition, whereas the spectra of the copolymers with more azo residues exhibit distinct dichroism bands in the region. A distinct difference in the observed π-π^* CD bands exists between the copolymer with 43% azo residues and the copolymers

with more azo residues. A simple positive band is observed for the former while the spectra of the latter are rather complicated, showing a peak in the 340-nm region and a trough in the 295-nm region with a crossover near 310 nm. The separation of these bands is small, confirming the assignment of the band to exciton resonance coupling[15] of spatially adjacent azoaromatic chromophores.[16] The side chains of these polymers are allowed to arrange themselves in close packing in favor of the delocalization of the electronic excitation. Such exciton resonance coupling was also observed in the π-π^* transition region of azo chromophores by Goodman *et al.*[10] for some azoaromatic polypeptides composed of (phenylazo)phenylalanine or its analogues. In the case of (phenylazo)benzyl L-aspartate polymers, the exciton resonance coupling seems to be very difficult because of the allowed movement of the side chains and the relatively large distances between the side chains. In fact, it does not appear for other copolymer series of (phenylazo)benzyl L-aspartate involving the copolymer series with γ-benzyl L-glutamate. Thus it might be possible only when some steric requirements are satisfied concerning the side-chain conformation.

In the region of the side-chain n-π^* transition, circular dichroism is absent or small before irradiation for the copolymers with azo residues smaller than 40%. On further increase in azo residues, there appears a positive band and subsequently a negative band. It is difficult to explain the complicated spectral behavior. Nevertheless, we believe that the origin of the band is side chain-main chain interaction since there must be a profound difficulty for the electronic interactions between the adjacent side chains due to a small value for the transition moment of the n-π^* transition and the large distance between the side chains.

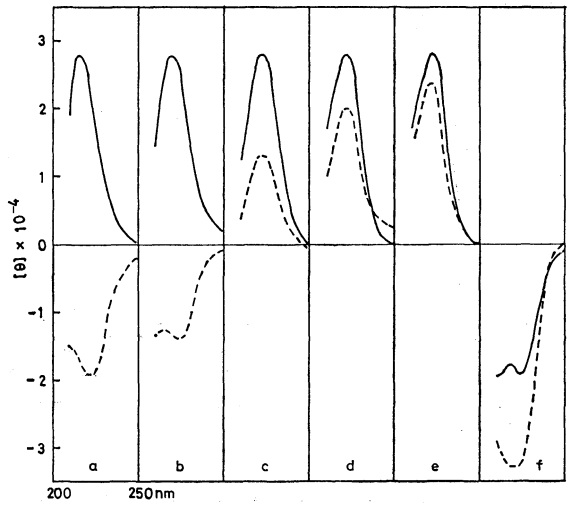

Fig. 7. CD spectra associated with the amide n-π^* transition before (——), and after (– – –) irradiation in 1,2-dichloroethane for the polymers which undergo light-induced conformational changes. a, b; *para* Copolymers with azo residues of 81 and 59% respectively. c, d, e; *meta* Copolymers with azo residues of 100, 92, and 67% respectively. f; Copolymer of *β-m*-(phenylazo)benzyl L-aspartate and γ-benzyl L-glutamate (89: 11).

Photoirradiation causes significant changes in the side-chain CD bands of the *para* copolymers. The dichroic band associated with the π-π^* transition vanishes. On the other hand, a positive band appears in the region of the n-π^* transition. The complete disappearance of the π-π^* CD band, in spite of the presence of about 20% *trans* isomers in the photostationary state, indicates the importance of *trans-trans* side-chain interactions for this CD band. The intensity of the azo n-π^* transition after irradiation does not depend on the content of azo residues in the copolymers (Fig. 4), which assumes side chain-main chain interactions as the origin of this band.

The CD spectra associated with the peptide n-π^* transition of the polymers which undergo light-induced conformational changes are summarized in Fig. 7. The spectral changes induced by irradiation can be classified into three types; left-handed to right-handed helix (*para* copolymers with azo residues of 59 and 81%), left-handed helix to random coil (*meta* copolymers with azo residues of 100, 92, and 67%) and random coil to right-handed helix (copolymer of *β-m*-(phenylazo)benzyl L-aspartate and γ-benzyl L-glutamate; 89: 11). We cannot obtain the spectra of pure *cis* azoaromatic polypeptides since 100% conversion could not be attained in our experimental conditions (about 80% *cis* in the photostationary state). Thus the conformational changes cannot be regarded as those occurring between pure *trans* and pure *cis* polypeptides.

TABLE 1. CD SIGNS OF THE SIDE-CHAIN n-π^* AND π-π^* BANDS[a]

Copolymer series[b]	Helix sense	Before irradiation		After irradiation
		n-π^*	π-π^*	n-π^*
meta	right	−		−
meta	left	+		+
para	right	−	−	+
para	left	+	+	+

a) Signs for the copolymers showing exciton resonance coupling are not included. b) Copolymer series of γ-benzyl L-glutamate with *β-m-* and *p*-(phenylazo)-benzyl L-aspartate are also designated as *meta* and *para* copolymer series.

The signs of the side-chain CD bands are summarized in relation to the helical senses in Table 1. Konishi and Hatano showed that the CD signs of the α-band on aromatic side-chain chromophores in many ester derivatives of poly(glutamic acid) and poly(aspartic acid) are determined by the helical sense of polymers, positive for left-handed helices and negative for right-handed helices.[17] Concerning the (phenylazo)benzyl L-aspartate copolymers including copolymers with γ-benzyl L-glutamate, we also find that the CD signs of the side-chain n-π^* and π-π^* bands are determined by the backbone conformation of the polymers, positive for left-handed helices and negative for right-handed helices though some exceptions are present. Exceptional behavior is encountered for the *para* copolymers which show exciton resonance coupling and the right-handed *para* copoly-

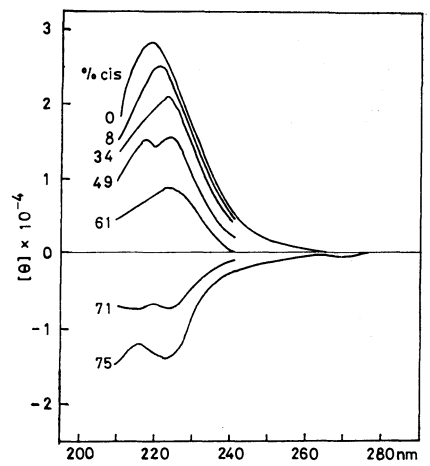

Fig. 8. CD Spectra of *para* copolymer with 59% azo residues at different *cis* contents in the course of relaxation.

mers after irradiation. So far there is no explanation for these exceptions.

The relaxation process back to the original state was studied for the *para* copolymer with 59% azo residues by CD spectra.[18] The CD spectra associated with the amide n-π^* transition change in a complicated manner in the course of relaxation (Fig. 8).[19] The behavior of the CD change can be attributed to the mixing of different conformations. After complete decay of the side-chain chromophores into the *trans* isomers the original CD spectrum was again obtained. The values of $[\theta]$ at 222 nm in the course of relaxation are plotted against the *cis* content (Fig. 9). It shows an abrupt change of $[\theta]_{222}$ at more than 50% *cis*. It should be noted that the transition is caused by variation in the ratio of different configurations of the side chains. The usual conformational transitions involving reversal in helix sense have been shown on copolymers composed of different amino acids such as β-benzyl L-aspartate and substituted benzyl L-aspartate by variation in the monomer ratios.[1] The present result demonstrates that the energy required for the conformational change comes

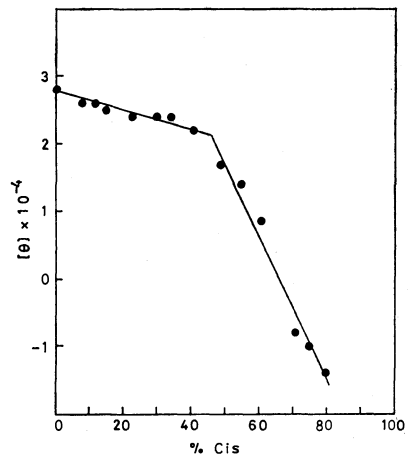

Fig. 9. Variation of $[\theta]$ values around 222 nm for *para* copolymer with 59% azo residues as a function of *cis* content.

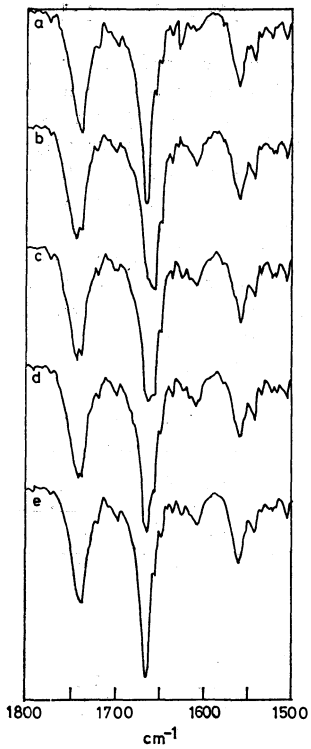

Fig. 10. Infrared spectra of the *para* copolymer with 59% azo residues before (a) and after (b; 0 min, c; 20 min, d; 50 min, e; 20 h) irradiation.

from *cis* forms in the side chain, or light energy.

The infrared spectra of the *para* copolymer with 59% azo residues in the course of relaxation are shown in Fig. 10. Before irradiation, the spectrum of the copolymer shows the amide I at 1665 cm^{-1}, the amide II at 1560 cm^{-1} and the ester carbonyl at 1738 cm^{-1} characteristic of left-handed α-helices.[1c] On the other hand, the spectrum after irradiation shows shifted bands, the amide I at 1655 cm^{-1}, the amide II at 1558 cm^{-1} and the ester carbonyl at 1744 cm^{-1}, characteristic of right-handed α-helices. In the spectrum, absorptions attributable to the left-handed helix remain as shoulders. Thus the polymer after irradiation is not purely right-handed helical but contains left-handed conformation. The spectrum after 20 min shows comparable absorption intensities of both helices. The spectrum is finally restored to the original one.

Conclusion

The light-induced reversal in polypeptide helix sense was observed for the *para* copolymers which contain more than 50% azo residues. The conformational change occurs abruptly at more than 50% *cis*. Thus, the light-induced conformational change enables the polypeptides to act as elements which response to light in an on-off fashion. The system as well as systems such as left-handed helix to random coil and random coil to right-handed helix can be compared with visual purple, rhodopsin. Return to the original state is promoted by an isomerase for rhodopsin, but occurs spontaneously in these systems.

Experimental

All polymers were prepared according to the procedure described previously[5] with various ratios of β-benzyl L-aspartate *N*-carboxy anhydride (NCA) and β-*m*- or *p*-(phenylazo)-benzyl L-aspartate NCA. Mole percentage of azo residues in the copolymers was estimated from their nitrogen contents obtained by elemental analyses. The reduced specific viscosity, η_{sp}/c, of each polymer was measured for a 0.1% 1,2-dichloroethane solution at 25 °C. Viscosity measurement could not be carried out for poly[β-*p*-(phenylazo)benzyl L-aspartate] and the *para* copolymer with 81% azo residues due to their poor solubility in 1,2-dichloroethane. The data on these polymers are summarized in Table 2.

Table 2. Yields and viscosities of azoaromatic polypeptides

Copolymer series	mol % azo NCA[a]	mol % azo residues[b]	Yield		η_{sp}/c[c]

a) mol % of β-*m*- or *p*-(phenylazo) benzyl L-aspartate NCA reacted with β-benzyl L-aspartate NCA. b) Determined from the nitrogen content of elemental analysis. c) Measured for 0.1% 1,2-dichloroethane solutions at 25 °C. d) Almost insoluble. e) Insoluble.

Photoirradiation was carried out with a 500-W xenon lamp. A Corning 7-37 filter was used to pass the light of 320—380 nm. The *cis* content was calculated from the absorbance at 320 nm assuming that the absorbance is essentially proportional to the concentration of the *trans* isomer in view of the low extinction of the *cis* isomer for the wavelength.[20] Ultraviolet and visible spectra were measured with a JASCO UVIDEC-1 spectrophotometer using 3×10^{-5} M (azo residues) solutions. NMR spectra were recorded on a JEOL PS-100 spectrometer. Solutions of *ca.* 10 mg/ml were prepared in $CDCl_3$ containing tetramethylsilane as an internal reference. CD spectra were recorded on a JASCO J-20 circular dichrograph apparatus at 25 °C with cell thickness 0.1 and 0.01 cm using 0.3—1 mg/ml solutions. Due to the absorption of solvent, no spectra could be obtained below 210 nm. Molar ellipticities were calculated for the band around 222 nm by use of molar concentration of the amide group, while the molar concentration of the azo residues was used for the calculation of the ellipticities associated with the extrinsic bands. No CD spectrum of poly[β-*p*-(phenylazo)benzyl L-aspartate] could be measured due to its insolubility in 1,2-dichloroethane. As for the *para* copolymer with 81% azo residues, soluble part was used. On the irradiated solutions, special care was taken in order to accomplish the spectral measurements quickly.

The Partial Reduction of Carboxylic Acids to Aldehydes *via* 3-Acylthiazolidine-2-thiones with Diisobutylaluminum Hydride and with Lithium Tri-*t*-butoxyaluminum Hydride

Toshio IZAWA and Teruaki MUKAIYAMA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 31, 1978)

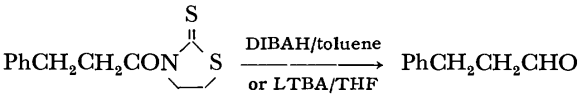
3-Acylthiazolidine-2-thiones, easily prepared from carboxylic acids and readily available thiazolidine-2-thione, were reduced to the corresponding aldehydes either with diisobutylaluminum hydride in toluene at −78—−40 °C in 70—90% yields or with lithium tri-*t*-butoxyaluminum hydride in tetrahydrofuran at −20—0 °C in 80—90% yields. The present method appears to be applicable to the synthesis of aldehydes from both aromatic and aliphatic derivatives having chloro, bromo, nitro, and noncojugated double bond, except for the reduction of α,β-unsaturated derivatives with lithium tri-*t*-butoxyaluminum hydride and of cyano derivative with diisobutylaluminum hydride. Completion of the reduction is indicated by disappearance of the original yellow color of the reaction mixture.

One of the most convenient synthetic routes to aldehydes is the utilization of readily available carboxylic acids. Many methods have been reported for the partial reduction of such acid derivatives to the corresponding aldehydes by catalytic hydrogenation (the Rosenmund reduction) or by use of various hydride reducing agents. For example, carboxylic esters were converted into the corresponding aldehydes with aluminum hydride reagents, such as diisobutylaluminum hydride (DIBAH),[1a] sodium aluminum hydride,[1b] sodium bis(methoxyethoxy)aluminum hydride,[1c] and bis(dialkylamino)aluminum hydride.[1d] The partial reduction of various carboxamides was also carried out with lithium aluminum hydride,[1e] lithium di- and triethoxyaluminum hydride,[1f] or bis(dialkylamino)aluminum hydride.[1g] Moreover, the lithium tri-*t*-butoxyaluminum hydride (LTBA) reductions of acyl halides[1h] and of phenyl esters[1i] provided mild synthesis of aldehydes. The reduction is widely applied to the syntheses of natural products.[2] However, in most cases the desired aldehydes are often contaminated by further reduced products, *i.e.*, alcohol and/or amine.

In the preceding communications,[3,4] we reported preliminary results of the partial reduction of 3-acylthiazolidine-2-thiones **1** to aldehydes **2** with DIBAH or with LTBA. We now wish to describe the reaction in detail.

In order to determine the optimum conditions for the synthesis of 3-phenylpropanal (**2a**) from 3-(3-phenylpropionyl)thiazolidine-2-thione (**1a**), the effect of molar ratio of the reducing agents to **1a** was studied first. The reduction with the hydrides, DIBAH and LTBA, was carried out in toluene at −78—−40 °C, and in tetrahydrofuran (THF) at −20—0 °C, respectively. The results are summarized in Table 1.

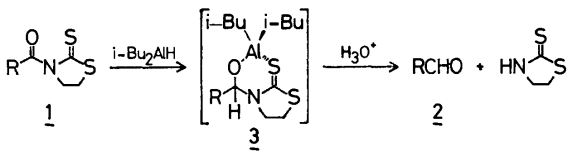
Table 1. Effects of molar ratio[a] of reducing agent to **1**



1a **2a**

DIBAH[b]			LTBA[c]		
Molar ratio	Mode of addn.[d]	Yield (%)[e]	Molar ratio	Mode of addn.[d]	Yield (%)[e]
1.2	N	91	1.1	N	87
1.2	R	85	1.15	N	89
1.5	N	93	1.2	R	85
2.1	N	90	2.4	N	57
4.0	N	69			

a) Hydride/**1a**. b) Reduction carried out at −78 °C for 0.25—4.5 h and then at −50—−40 °C for 1—1.5 h. c) Reduction carried out at −20 °C for 1—1.5 h and then at 0 °C for 1—4 h. d) N: normal addition (addition of **1a** in a solid state to hydride in solution); R: reverse addition (addition of DIBAH in solution or of LTBA in a solid state to **1a** in solution). e) Isolated yield by TLC (silica gel) or by distillation.



The table shows that no decrease in the yield of **2a** can be found with change in the molar ratio of DIBAH to **1a** from 1.2 to 2.1 equivalents. **2a** was isolated in 67% yield even when 4.0 equivalents of DIBAH were employed. The results are reasonably ratioalized by considering an aluminum-contained six-membered chelate intermediate **3** produced by the reaction of **1** with DIBAH. The chelate complex of the resulting aluminum alkoxide **3** is inert toward the further reduction under the reaction conditions. Thus, aldehyde **2** is liberated after quenching the reaction mixture with dilute acid. On the other hand, in the case of LTBA, employment of a slight excess amount of reducing agent gave the best results. The yield of **2a** decreased to 57% when 2.4 equivalents of LTBA were introduced. This is explained by assuming that the reduction of **1a** is much faster than that of **2a** generated in the reaction mixture before hydrolysis, in contrast with the case of DIBAH; the employment of excess LTBA causes the overreduction of **2a**. Moreover, longer reaction time and the mode of addition of the reactants did not significantly affect the yields of aldehydes. When a

stoichiometric amount of reducing agents was employed, the desired aldehyde was always contaminated with a small amount of starting material.

Thus, 3-acylthiazolidine-2-thiones **1** derived from representative carboxylic acids were converted into the corresponding aldehydes **2** with DIBAH by employing the optimum reduction conditions. In the case of DIBAH, when **1** is a solid mass, normal addition generally gave slightly better results than the reverse one (normal addition: **1** in a solid state added to DIBAH in toluene; reverse addition: DIBAH in toluene added to **1** in toluene). And when an oily substance, reverse addition gave better results than the normal one. On the other hand, in the case of LTBA, the mode of addition did not significantly affect the yields of aldehydes **2** (normal addition: **1** in a solid state added to LTBA in THF; reverse addition: LTBA in a solid state added to **1** in THF). The results are summarized in Table 2.

a) Isolated yield by TLC (silica gel). Numbers in parentheses indicate the yield by distillation. Bp (bath temp) °C/mmHg; **2a**: 120—140/20, **2b**: 105—135/24, **2c**: 110—130/21, **2f**: 130—140/30, and **2j**: 120—140/95. Bp of **2g**: 101—105 °C/0.9 mmHg. b) N: normal addition. c) R: reverse addition. d) Reaction carried out at −20 °C for 5 h. e) Reaction carried out at 0 °C for 4 h and then at room temp for 4 h. f) Reaction carried out at −40 °C for 2 h. g) Isolation of aldehydes not tried.

The yields of the reduction of 3-acylthiazolidine-2-thiones **1** to aldehydes **2** with DIBAH and with LTBA are generally good to high, *i.e.*, 70—90 and 80—90%, respectively, both in the cases of aliphatic and aromatic derivatives with a few exceptions. When the reduction of 3-(phenylacetyl)thiazolidine-2-thione (**1b**) with LTBA was carried out under similar conditions, only a polymerized product was obtained. Phenylacetaldehyde (**2b**) was isolated in 69% yield by keeping the reaction temperature −20 °C throughout the reduction. The α-benzyloxy derivative **1g** was very susceptible to the reduction with LTBA even at −40 °C to give 2-benzyloxyhexanal (**2g**) in 91% yield. The reduction of 3-(11-cyanoundecanoyl)thiazodine-2-thione (**1i**) with LTBA proceeded smoothly to afford 11-cyanoundecanal (**2i**) in 71% yield, but the same reaction was not observed with use of 1.2 equivalents of DIBAH and, when 2.2 equivalents of DIBAH were employed, 51% yield of dodecanedial was isolated. In the case of α,β-unsaturated derivatives, **1m** and **1n**, the reduction with LTBA gave no satisfactory results.

Various aldehydes possessing other substituents in the same molecules, such as bromo, chloro, nitro, and nonconjugated double bond, were easily obtained in good yields.

It is concluded that the present method is widely applicable to the partial reduction of various carboxylic acids *via* 3-acylthiazolidine-2-thiones, and the yields of the corresponding aldehydes are comparable or preferable to those of the conventional methods.[1] Further advantages of the present procedure is simplicity of the reaction, 3-acylthiazolidine-2-thione **1** being simply added to the reducing agent or *vice versa*, and that the completion of the reaction is clearly indicated by disappearance of the original yellow color of the reaction mixture.

Experimental

General. Melting and boiling points are uncorrected. ^1H NMR spectra were recorded on a Hitachi R-24 spectrometer with Me_4Si as an internal standard. IR spectra were taken on a Hitachi EPI-G2 spectrophotometer. MS data were obtained on a Hitachi RMU-6L at 70 eV. CH_2Cl_2 was dried over P_2O_5, distilled over CaH_2, and stored over molecular sieves 4A. Toluene was distilled over Na and then stored over molecular sieves 4A. THF was distilled over Na, followed by redistillation over $LiAlH_4$ before use.

DIBAH was synthesized by the pyrolysis of *i*-Bu_3Al according to the procedure of Ziegler *et al.*[5] LTBA was prepared from $LiAlH_4$ and *t*-BuOH according to a similar method of Brown and McFarlin.[6]

Reduction was carried out under argon atmosphere, all the apparatus being dried before use.

Materials. Acyl chlorides were either obtained commercially or synthesized from carboxylic acids and $SOCl_2$ according to standard methods.

*Preparation of 3-Acylthiazolidine-2-thiones **1a**—**1n**.* **A**: A CH_2Cl_2 (5 ml) solution of acyl chloride (20 mmol) was added dropwise to an ice-cooled, stirred CH_2Cl_2 (20 ml) suspension of thiazolidine-2-thione (2.38 g, 20 mmol) and Et_3N (2.12 g, 21 mmol) over the period of 1 h. The resulting mixture was stirred at room temperature for 1 h, and then washed with H_2O and brine, the organic layer being dried (Na_2SO_4) and concentrated. Purification of the products **1a**—**n** was accomplished by recrystallization or by column chromatography on silica gel using PhH as an eluent: yields 80—95%. The physical data for **1a**—**n** are given in Table 3.

a) $CDCl_3$ used as a sovent.

B: A CH_2Cl_2 (1 ml) solution of Et_3N (2.23 g, 22 mmol) was added at −20 °C to a stirred CH_2Cl_2 (20 ml) suspension of carboxylic acid (10 mmol), thiazolidine-2-thione (1.19 g, 10 mmol), and 2-chloro-1-methylpyridinium iodide (2.81 g, 11 mmol), and the mixture was stirred at room temperature for 1.5 h—overnight. The resulting mixture was washed with

H_2O, 1M HCl and brine, dried (Na_2SO_4), and evaporated. Purification of the products was performed by the method described above.

General Procedure for the Reduction with DIBAH. Normal Addition: 3-Acylthiazolidine-2-thione **1** (1.0 mmol) in a solid state was added in one portion to a stirred toluene (2 ml) solution of DIBAH (171 mg, 1.2 mmol) at −78 °C. The mixture was stirred for 0.25—2 h at this temperature, and then at −50—−40 °C till the yellow color of the reaction mixture disappeared (0.5—3 h). To the mixture were successively added 1M H_2SO_4 (*ca.* 0.5 ml), petroleum ether (*ca.* 20 ml) (or CH_2Cl_2 (*ca.* 20 ml) in the cases of **1i**, **1k**, **1l**, and **1n**), and Na_2SO_4 (*ca.* 1 g), and the resulting white precipitate was filtered off. The organic filtrate was dried (Na_2SO_4) and concentrated *in vacuo*, and the desired aldehyde **2** was purified by thin layer chromatography on silica gel using PhH and/or CH_2Cl_2 as a developing solvent.

Reverse Addition: A toluene solution (0.5 ml) of DIBAH (171 mg, 1.2 mmol) was injected to a stirred toluene (2 ml) suspension or solution of **3** at −78 °C, and the mixture was stirred at this temperature until completion of the reaction (1—2 h), followed by repetition of *Normal Addition* to give product **2**. The results and physical data for **2a**—**n** are given in Tables 2 and 3, respectively.

General Procedure for the Reduction with LTBA. Normal Addition: Crystalline **3** (1.0 mmol) was added at once to a stirred THF (2 ml) solution of LTBA (305 mg, 1.2 mmol) at −20 °C. The mixture was stirred for 0.5—5 h at this temperature and then at 0 °C until the orginal yellow color of the reaction mixture disappeared (0.5—7 h). After successive addition of 1M H_2SO_4 (*ca.* 0.5 ml), petroleum ether (*ca.* 20 ml) (or CH_2Cl_2 (*ca.* 20 ml) in the case of **1i**, **1k**, **1l**, and **1n**), and saturated Na_2SO_4 solution (*ca.* 0.5 ml), the organic layer was separated from the white pasty mass by decantation, dried (Na_2SO_4), and evaporated *in vacuo*. Thin layer chromatography of the residue on silica gel developed with PhH and/or CH_2Cl_2 gave aldehyde **2**.

Reverse Addition-A: Powdered LTBA (305 mg, 1.2 mmol) was added in one portion to a stirred THF (2 ml) solution or suspension of **3** (1.0 mmol) at −20 °C, followed by repetition of the procedure described above to afford compound **2**.

Reverse Addition-B: The preceding reaction was repeated with use of LTBA (1.53 g, 6.0 mmol), **3** (5.0 mmol), and THF (10 ml). After completion of the reaction, 1 M H_2SO_4 (*ca.* 2 ml), petroleum ether (*ca.* 80 ml), and saturated Na_2SO_4 solution (*ca.* 4 ml) were successively added to the resulting mixture, and the organic layer was decanted, washed with H_2O and brine, and dried (Na_2SO_4). Removal of the solvent *in vacuo*, followed by short-path distillation of the residual oil afforded aldehyde **2**. The results are given in Table 2, the physical data being identical with those of **2** prepared by the reduction with DIBAH.

Reduction of Some Sulfides and Ethers with Aromatic Rings by Electrochemically Generated Solvated Electrons

Mikio MIYAKE,* Yoshihiro NAKAYAMA, Masakatsu NOMURA, and Shōichi KIKKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 23, 1978)

The reduction of some sulfides and ethers has been investigated in 0.5 M LiCl–HMPA solutions with and without alcohol (methanol, ethanol, and 2-propanol). Diphenyl sulfide underwent cleavage to produce benzene as the main product. The hydrogenated products of benzene have been obtained in 35 and 50 mol % alcohol solutions, and the increased dependence on ethanol (*i.e.*, H^+) concentrations in the solutions has been established. The cleavage reaction was affected by the ease of α-hydrogen abstraction from the alcohol. The cleavage reaction has been elucidated as proceeding *via* a one-electron transfer mechanism, while the hydrogenation proceeded *via* a two-electron transfer mechanism. The estimation of current efficiencies supports this mechanism. Hexyl phenyl sulfide cleaved in the manner similar to that for diphenyl sulfide with a current efficiency of about 80% whereas only the hydrogenated products were obtained from benzo[*b*]thiophene and dibenzothiophene. Fission of the C–S bond of tetrahydrothiophene has been achieved by this method. Some ethers examined exhibited *approx.* the same behavior as the corresponding sulfides.

Aromatic clusters have been effectively reduced in hexamethylphosphoric triamide (HMPA)–ethanol solutions by electrochemically generated solvated electrons;[1–4] cyclohexane,[2] dihydronaphthalene,[3] and cyclooctane[4] were obtained mainly from benzene, naphthalene, and cyclooctadiene, respectively. The solvent system with HMPA and proton donor appears to provide the most strongly reducing conditions which cannot be achieved by ammonia and amine solvents.[5] Itoh *et al.* have reported the cleavage reactions of aryl decyl ethers in alkali metal–HMPA–THF systems.[6] From these reports, it appears that the solubilization of pitch and coal is efficiently conducted in HMPA solutions by solvated electrons in a manner similar to Benkeser reductions[7] and reductive alkylations.[8]

Prior to the investigation of the reactions of pitch and coal, it is necessary to obtain fundamental information about the reactions using model substances, *i.e.*, the factors which influence the two competitive reactions (the hydrogenation of aromatic clusters and the cleavage of C–X bonds where X denotes oxygen and sulfur atoms) and the reaction mechanisms. To this end, the reduction of some sulfides and ethers which contain aromatic rings has been performed using electrochemically generated solvated electrons in 0.5 M lithium chloride–HMPA solutions with and without alcohol. The reduction of diphenyl sulfide has been investigated thoroughly, since diphenyl sulfide is considered to be the simplest compound containing both aromatic rings and C–X (X: O, S) bonds.

In the investigation, the solvated electrons have been generated electrochemically, since this method achieves the desired rate and amount of solvated electrons easily by controlling the electrolytic current and the quantity of electricity passed, respectively. This feature is a great advantage for mechanistic investigations.

Experimental

Reagents. HMPA was dried on calcium oxide under vacuum and subsequently distilled from calcium hydride at 267 Pa. The middle fraction collected was then stored over molecular sieves 3A in a desiccator containing diphosphorus pentoxide. Methanol, ethanol, and 2-propanol were distilled from magnesium powder activated with iodine, and stored in the same manner as HMPA. The second distillation of the solvents was conducted prior to use. Lithium chloride was dried at 200 °C for 6 h prior to use.

Reactants such as diphenyl sulfide, benzo[*b*]thiophene, dibenzothiophene, tetrahydrothiophene, diphenyl ether, dibenzofuran, and tetrahydrofuran were obtained commercially. Isobenzofuran[9] and hexyl phenyl sulfide[10] were synthesized according to the general procedures. Dibenzothiophene and dibenzofuran were purified by recrystallization from methanol, and the others by distillation. The purity was checked by GLC.

Apparatus. The electrolytic vessel was a special H-type cell of 30 cm^3 total capacity. On the side wall, there were gas outlets with taps and a connecting glass tube to maintain the pressure of gas between the two rooms.

Pt electrodes (1×1 and 3×3 cm) served as cathode and anode, respectively. Before use, they were dipped in saturated sodium hydroxide solution, aqua resia, washed with deionized water, and dried in a desiccator under vacuum.

To generate the solvated electrons, a constant current of 5 mA/cm^2 was supplied by a galvanostat (Hokuto Denko Co., HA-104). When high currents (25 and 50 mA/cm^2) were needed, a DC power supply (Yamabishi Electric Co., Ltd, YVR-550) was used in place of the galvanostat. A linear scanning unit (Hokuto Denko Co., LS-2D) and a HA-104 potentiostat were employed for cyclic voltammometry experiments. The voltammograms were recorded by an X-Y recorder (Yokogawa Electric Works Ltd., 3077). In this case, the potential was measured against Ag/0.1 M $AgClO_4$ in HMPA with a sweep rate of 3.3 mV/s.

Procedure. The preparation of the solution and the electrolysis were performed in a drybox containing diphosphorus pentoxide. The reactant (6 mmol) and HMPA or HMPA–alcohol solution (6 cm^3) containing 0.5 M lithium chloride was poured into each compartment of the cell and immediately the rubber stoppers with the electrodes and gas inlets were set. The cell was placed in a paraffin liquid bath containing Dry Ice and the temperature of the electrolyte maintained at 15 °C. Before electrolysis, dried nitrogen gas was bubbled through the cell for about 30 min, and then the cell was sealed and the catholyte agitated with a magnetic stirrer. The electrolysis was performed with a constant current of 10 mA for 18 h, except when specified otherwise. The amount of electricity passed was checked by a copper coulomb meter. During electrolysis, the cathode potential was not measured, since it was reported as reasonably constant

in a similar system.[2]

Analyses of Products. The products were analyzed mainly by GLC without any treatment. The GLC analyses were performed on a Shimadzu GC-4BPTF with a 4.5 m × 3 mm column packed with 20% Silicone SE-30 on Uniport B. On occasion, GC-MS (GC: Hitachi M5201, column: Silicone OV-1 on Uniport KS, MS: Hitachi RMU-6MG) spectra were taken to identify the products. To obtain further information about the products, most of the catholytes were hydrolyzed by hydrochloric acid, and the aqueous solutions extracted with ether. The presence of lithium sulfide was examined by colorimetry using sodium pentacyanonitrosylferrate (III). Hydrogen sulfide and hydrogen gas were analyzed by GLC (Shimadzu GC-3AH with a 3 m × 3 mm column packed with Silica gel 60—80 mesh).

Results and Discussion

Cyclic Voltammometry. The electrolytic decomposition of ethanol in HMPA solution is thought to be suppressed by the preferential adsorption of HMPA on the electrode surface.[2] However, when the ethanol concentration becomes high, the ethanol decomposes, and the current efficiency for the generation of solvated electrons decreases. Therefore, in order to study the maximum alcohol concentration where the alcohol is not decomposed electrolytically, cyclic voltammograms were measured on the Pt electrode in 0.5 M lithium chloride–HMPA–ethanol solution with various ethanol concentrations, and the results are given in Fig. 1. The reduction waves at *approx.* −3.4 V *vs.* Ag/0.1 M Ag^+ are attributed to the generation of solvated electrons from the electrode, since the standard electrode potential of solvated electrons has been reported to be −3.4 V *vs.* Ag/0.1 M Ag^+ in HMPA,[12] and the solutions turned dark blue where the ethanol concentrations were less than 50 mol %.[1,13,14] When the ethanol concentration was increased up to 50 mol %, a further peak was observed at about −2.0 V. This peak became high in 67 mol % solution, and hydrogen gas evolved from the electrode surface in the potential region more negative than −1.5 V. This peak is apparently connected to the electrolytic decomposition of the ethanol.

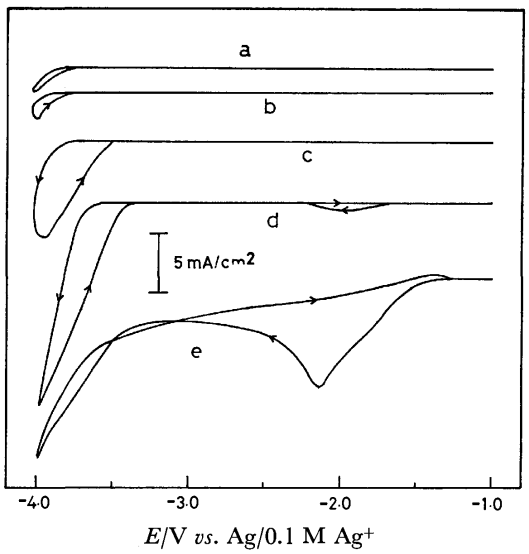

Fig. 1. Cyclic voltammograms on the Pt electrode in 0.5 M LiCl–HMPA–ethanol solutions. Ethanol concentration; a: 0, b: 14, c: 35, d: 50, and e: 67 mol %. Sweep rate: 3.3 mV/s.

On the basis of the above results, solutions with an alcohol concentration less than 50 mol % have been adopted for the following study. The detailed analysis of the cyclic voltammograms will appear in another report.

The cyclic voltammograms of solutions containing diphenyl sulfide gave the same pattern as in Fig. 1. Consequently, it was confirmed that no diphenyl sulfide was reduced electrolytically under the present experimental conditions.

Cleavage Reaction of Diphenyl Sulfide. Diphenyl sulfide was reduced by electrochemically generated solvated electrons. Tables 1 and 2 show the results in HMPA solutions with various ethanol concentrations and three types of 50 mol % alcohols, respectively. It should be remembered that in Table 2 the acidity of the alcohol, *i.e.*, the proton concentration in the solution decreased in the order, methanol > ethanol > 2-propanol, while the ease of α-hydrogen abstraction from the alcohol decreased in the reverse order.[15] It was found from Tables 1 and 2 that benzene was formed as the main product indicating that the cleavage reaction proceeded in preference to the hydrogenation of the aromatic ring of diphenyl sulfide.

Several reports have appeared on the cleavage reaction of diphenyl sulfide by solvated electrons.[16,17] Based on these reports, the following three reactions are possible for the present system:

$$\mathrm{Ph\text{–}S\text{–}Ph} + e^-_{solv} \longrightarrow [\mathrm{Ph\text{–}S\text{–}Ph}]^{\cdot-} \xrightarrow{e^-_{solv}} \mathrm{Ph}^- + {}^-\mathrm{S\text{–}Ph}, \quad (1)$$

$$\mathrm{Ph\text{–}S\text{–}Ph} + e^-_{solv} \longrightarrow [\mathrm{Ph\text{–}S\text{–}Ph}]^{\cdot} \longrightarrow \mathrm{Ph}\cdot + {}^-\mathrm{S\text{–}Ph} \quad (2)$$

$$\mathrm{Ph\text{–}S\text{–}Ph} + e^-_{solv} \longrightarrow [\mathrm{Ph\text{–}S\text{–}Ph}]^{\cdot} \longrightarrow \mathrm{Ph}^- + \cdot\mathrm{S\text{–}Ph} \quad (3)$$

where e^-_{solv} denotes the solvated electron.

The results in Tables 1 and 2 indicate that the higher the ethanol concentration and acidity of the alcohol, the lower the conversion and benzene yield. These results imply that the protons in the solutions have no effect on the rate of benzene formation. Moreover, Table 2 shows that both the benzene yield and conversion depend on the ease of α-hydrogen emission of the alcohol. It can therefore be presumed that benzene is formed mainly according to Eq. 2, followed by hydrogen abstraction by the phenyl radical from the solvent,

$$\mathrm{Ph}\cdot + \mathrm{RH} \longrightarrow \mathrm{PhH} + \mathrm{R}\cdot \quad (4)$$

where RH denotes the solvent (HMPA or alcohol). The detailed discussion of the further reaction of R· is beyond the scope of this paper.

Benzenethiol is expected *via* Eq. 2 as the pair product of benzene but remained undetected. It was detected quantitatively, however, after hydrolysis of the catholyte by hydrochloric acid. Since neither lithium sulfide nor hydrogen sulfide was detected in the products, the benzenethiolate formed by Eq. 2 is assumed to react with the lithium cation which is present in high concentration to produce lithium benzenethiolate.

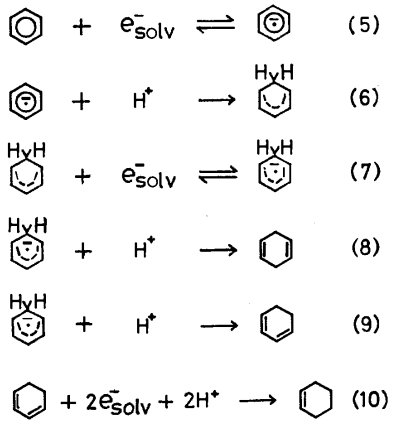
The formation of biphenyl, as minor products (Tables 1 and 2), is attributed to the coupling of the phenyl radicals and supports the validity of the reaction mechanism *via* Eq. 2. Cleavage of diphenyl sulfide was reported to proceed also by Eq. 2 when it was cleaved by potassium metal in liquid ammonia.[17]

Estimation of current efficiencies demonstrates almost conclusively that the cleavage reaction proceeds *via* the one-electron mechanism (Eq. 2), since the current efficiency for the formation of benzene estimated by the two-electron mechanism (Eq. 1) sometimes exceeds 100 % despite an ionic reaction without the existence of a radical chain reaction.

Hydrogenation Reaction of the Aromatic Ring. As shown in Table 1, 1,4- and 1,3-cyclohexadiene and cyclohexene were produced in 35 and 50 mol% ethanol–HMPA solutions. These products are believed to be formed by hydrogenation of the benzene, since no hydrogenated product of diphenyl sulfide without cleavage was detected. The ratio of hydrogenated products to benzene was high in 50 mol % ethanol solution compared with that in 35 mol %. Moreover, as may be seen from Table 2, the ratio increased depending on the acidity of the alcohol used. Therefore, the hydrogenation of the benzene is considered to be proton associated.

Krapcho and Bothner-By proposed a hydrogenation mechanism for benzene as shown in Scheme 1, which was obtained from alkali metal–liquid ammonia–alcohol systems.[18] The results in Tables 1 and 2 may be interpreted by this mechanism. The mechanism has also been supported by the hydrogenation of some unsaturated hydrocarbons in HMPA–alcohol solutions by electrochemically generated solvated electrons.[1–3] The rate determining step in this reaction is considered to be Eq. 6, since the availability of the hydroxyl proton of the alcohol will be rather low due to formation of a hydrogenated complex between alcohol and HMPA, in a manner similar to that for ethylenediamine solution,[19] and the hydrogenation was affected by the concentration and the acidity of the alcohol adopted. The same rate determining step was proposed by Krapcho and Bothner-By.[18]

According to the present mechanism, the production of one cyclohexadiene molecule from diphenyl sulfide requires three solvated electrons, *i.e.*, one for cleavage of diphenyl sulfide (Eq. 2) and two for hydrogenation of the benzene produced (Eqs. 5 and 7). Similarly, one cyclohexene molecule consumes five electrons. The total current efficiencies thus estimated are listed in Tables 1 and 2.



Scheme 1.

Effects of Current Density and Sulfide Concentration. Sternberg *et al.* proposed that the reduction rate of benzene by solvated electrons was proportional to benzene, solvated electron, and proton concentrations.[2] If a similar argument is applicable to the reduction of diphenyl sulfide, then the rate of cleavage of diphenyl sulfide is expected to increase when the concentration

Table 3. Effects of current density and diphenyl sulfide concentration on reduction of diphenyl sulfide[a)]

of diphenyl sulfide and the generation rate of solvated electrons (*i.e.*, current density) are raised. Therefore, to establish the most suitable reaction conditions for the reduction of diphenyl sulfide, the reactions were carried out at various current densities and diphenyl sulfide concentrations, the results of which are summarized in Table 3. The conversion and benzene yield increased as expected when the current density was raised from 5 to 25 mA/cm². On the contrary, when the current density was raised to 50 mA/cm², the total current efficiency, the conversion, and the yield of benzene derivatives decreased, and a large amount of hydrogen gas was evolved—the generation mechanism has been discussed by Sternberg *et al.*[2)] It was found that a large increase in the current density such as 50 mA/cm² was not suitable for the reduction of diphenyl sulfide.

Doubling of the concentration of diphenyl sulfide produced a doubling of the current efficiency of benzene production (denoted in the parentheses in Table 3).

Reduction of Some Other Sulfides. In the case of diphenyl sulfide, the cleavage reaction proceeded preferentially compared to the hydrogenation under the present experimental conditions. This result, however, is not applicable to all sulfides having a phenyl group. Therefore, the reduction of some sulfides has been investigated in a similar manner, the results of which are given in Table 4 where the main products and current efficiencies are summarized. Products obtained after hydrolysis are designated in parentheses.

a) Dihydro product. b) Tetrahydro product. c) Detected after hydrolysis.

Hexyl phenyl sulfide underwent cleavage in a similar manner to diphenyl sulfide, that is, the reduction was not accelerated in the presence of ethanol and benzenethiol was detected quantitatively after hydrolysis of the catholyte. The formation of hexane and the coupling of hexyl radicals as the main products suggests that β-cleavage took place predominantly (Eq. 11). The course

$$C_6H_{13}\overset{\beta}{-}S\overset{\alpha}{-}Ph \xrightarrow{e^-_{sol'v}} C_6H_{13}\cdot + {}^-S\text{–}Ph \qquad (11)$$

of cleavage of aryl decyl ethers by alkali metals was investigated in HMPA–THF solvents by Itoh *et al.* where it was suggested that highly polar solvents and small alkali metals favor β-cleavage.[6)] This suggestion is supported here.

In the case of benzo[*b*]thiophene and dibenzothiophene, only the hydrogenated products were obtained in 50 mol % ethanol–HMPA solution and in HMPA solution without ethanol, no reaction occurred. The C–S bonds of these sulfides are considered to be more stable than those of the alkyl phenyl and diphenyl sulfides. It has been reported that the hydrogenation of dibenzothiophene proceeds in preference to the cleavage of C–S bonds when reduced in ethylenediamine by

a) Notations of products are the same as in Tables 1 and 4.

electrochemically generated solvated electrons, and that no sulfur was eliminated until partial hydrogenation of the aromatic ring had taken place.[20]

The reduction of tetrahydrothiophene was attempted to establish whether the cyclic sulfide can be cleaved by the present method. This compound was selected because it was considered the simplest representative of the completely hydrogenated thiophenes. As shown in Table 4, tetrahydrothiophene cleaved, although the current efficiencies were relatively low compared with those of the diphenyl and hexyl phenyl sulfides.

Reduction of Some Ethers. The reduction of some ethers was conducted to compare the behavior with that of the sulfides. The results in Table 5 show that the ethers were reduced in the same way as the corresponding sulfides. In the case of tetrahydrofuran in HMPA solution without ethanol, the high resistivity of the solution caused no appreciable reaction.

The authors would like to express their sincere thanks to Professor Hideo Tamura and Associate Professor Hiroshi Yoneyama at Osaka University for their helpful suggestions and assistance with the DC power supply and linear scanning unit. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Thermodynamics of Steady States: "Resistance Change" Transitions in Steady-state Systems

R. J. TYKODI

Department of Chemistry, Southeastern Massachusetts University, North Dartmouth, Massachusetts 02747, U.S.A.

(Received August 1, 1977)

Some one-current steady-state systems showing a discontinuous change in flow resistance at a point of instability—forced vaporization of carbon tetrachloride, Bénard instability in a horizontal layer of fluid heated from below, Taylor instability in the Couette flow of a liquid between coaxial rotating cylinders—are analyzed from a thermodynamic point of view: the behavior of the rate of entropy production and of the local potential (thermokinetic potential) for the system at the point of instability is explored. A multi-current situation involving a flip-flop current *vs.* voltage relation for the flow of electric current across a porous charged membrane is also commented on briefly.

Continuing my studies[1-6] of the thermodynamics of steady-state systems, I examine here the thermodynamic properties of several one-current steady-state systems, each of which develops an instability in its flow behavior and undergoes a discontinuous change in flow resistance. The "resistance change" transition at a point of instability for a steady-state system is in some respects analogous[7-9] to a phase transition in a thermo-static system. I shall first briefly discuss the "resistance change" transition in general terms; and I shall then discuss specifically the forced vaporization of carbon tetrachloride, Bénard instability in a horizontal layer of fluid heated from below, and Taylor instability in the Couette flow of a liquid between coaxial rotating cylinders. Finally I shall comment briefly on a multi-current example showing a flip-flop current-voltage relation for the flow of electric current across a porous charged membrane.

1. General Considerations (One-current Situations). Consider a fluid in a state of thermo-static equilibrium characterized by the variables T_σ, P_σ, $\mu_\sigma^{(1)}, \cdots$—a fluid system in the equilibrium state σ, for short. Relabel the set of equilibrium state variables in the following fashion: $\{T_\sigma, P_\sigma, \mu_\sigma^{(1)} \cdots\} \equiv \{\sigma_1, \sigma_2, \sigma_3, \cdots\} \equiv \{\sigma_i\}$. By changing some of the boundary conditions, induce the steady flow of a current Y in the fluid system. Use the equilibrium state σ as a reference state; the current Y will then depend on the departure of variables of the type σ_i from their reference state values. For each state of steady current flow, the rate of entropy production $\theta \equiv \dot{S}$(system) $+\dot{S}$(surroundings) takes the form

$$\theta = Y\Omega \geq 0, \tag{1}$$

where Ω is the affinity[1] conjugate to the current Y; both Y and Ω measure, in a certain sense, the "distance" of the steady-flow state from the reference equilibrium state σ. In addition to the rate of entropy production, another thermodynamic concept, the local potential (also called the generalized entropy production or the thermokinetic potential[5,10,11])— first introduced by Glansdorff and Prigogine[7,12,13]— is of use in discussing "resistance change" transitions. When the Pfaffian differential form (for a one-current situation)

$$\mathrm{d}F_\sigma = Y\mathrm{d}\Omega \tag{2}$$

is integrable under the given experimental conditions, the resulting quantity F_σ is the local potential:[5,7,10-13]

$$F_\sigma = \int Y\mathrm{d}\Omega = \int_0^Y Y(\partial\Omega/\partial Y)_\sigma \mathrm{d}Y. \tag{3}$$

The local potential F_σ (when it exists) is never negative, has a minimum at the point where $Y=0$, and satisfies the condition

$$0 < (\partial^2 F_\sigma/\partial\Omega^2)_\sigma|_{Y=0} = (\partial Y/\partial\Omega)_\sigma|_{Y=0}. \tag{4}$$

Glansdorff and Prigogine[7,12,13] found the local potential concept to be very useful for discussing the temporal evolution of a system with fixed boundary conditions as it passed through a sequence of transient states toward some stable steady state. I discussed in an earlier paper[5] the role played by the local potential (thermokinetic potential) in thermodynamic analyses of *all steady state* situations. In this paper I am somewhat more interested in the behavior of the rate of entropy production at "resistance change" transitions than in the behavior of the local potential; I shall, however, keep both quantities in view.

Consider again a fluid system in the equilibrium state σ. By successive manipulations of the boundary conditions establish a series of steady-flow states in the system with monotonically increasing values of the current Y. Observe θ as Y increases. If the plot of θ *vs.* Y shows a jump or a kink — a point of discontinuity in θ or in $\partial\theta/\partial Y$ — we have a point of instability, a point at which the fluid system undergoes a "resistance change" transition. It is the thermodynamic properties of the fluid system at the point of instability that I intend to discuss — in macroscopic phenomenological terms.

Let $\partial\Omega/\partial Y$ be the (differential) flow resistance, let the subscript c refer to the point of instability, and let ΔZ be the jump in an arbitrary property Z at the point of instability, *i.e.* let $\Delta Z \equiv Z(Y_c+0) - Z(Y_c-0)$. We have then

$$\Delta\theta = Y_c\Delta\Omega, \tag{5}$$

$$\Delta\partial\theta/\partial Y = \Delta\Omega + Y_c\Delta\partial\Omega/\partial Y, \tag{6}$$

$$\Delta\partial^2\theta/\partial Y^2 = 2\Delta\partial\Omega/\partial Y + Y_c\Delta\partial^2\Omega/\partial Y^2, \tag{7}$$

$$\Delta\partial^m\theta/\partial Y^m = m\Delta\partial^{m-1}\Omega/\partial Y^{m-1} + Y_c\Delta\partial^m\Omega/\partial Y^m \quad (m = 2, 3, 4, \cdots). \tag{8}$$

In the canonical procedure, some parts of the boundary are maintained at the reference state values σ_i, and other parts are varied in condition so as to control the current Y. The partial derivatives in Eqs. 6—8

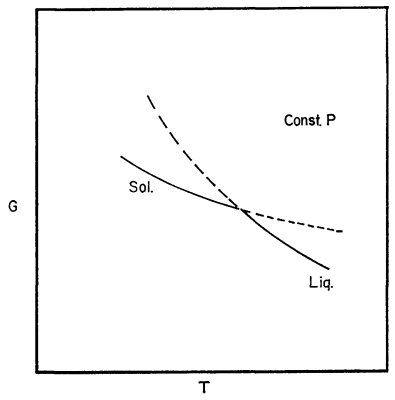

Fig. 1. Relative stability of the solid and liquid phases, at constant pressure, in a one-component system.

are thus at constant σ_i where appropriate.

"Resistance change" transitions in steady state systems are in some respects analogous[7-9] to thermostatic phase transitions where the phase with the lower Gibbs function value is the more stable one (see Fig. 1). Prigogine[7,8,12,13] considers the local potential F_σ to be the analog of the Gibbs function for "resistance change" transitions; for one-current steady-state situations there is no advantage in considering F_σ rather than θ, and I shall devote primary consideration to θ.

For stable steady states it is always true that[6,14]

$$\partial^2\theta/\partial Y^2 > 0, \quad \partial\Omega/\partial Y > 0; \tag{9}$$

and for "resistance change" transitions where both the upper ($Y > Y_c$) and lower ($Y < Y_c$) branches have metastable extensions beyond Y_c we anticipate that

$$\Delta\theta = 0, \quad \Delta\Omega = 0, \quad \Delta\partial\theta/\partial Y < 0, \tag{10}$$

i.e. we expect a kink in the θ *vs.* Y plot reflecting [Eq. 6] a discontinuous change in the flow resistance with $\Delta\partial\Omega/\partial Y < 0$: pipes spring leaks, vigorously rubbed paper tears, screwdrivers often shear the slotted heads of screws — in short, *processes usually take the path of least resistance.* If, however, the transition point is a point of intrinsic instability for one or both of the upper and lower branches, *i.e.* if one or both of the branches do not have metastable extensions beyond Y_c, then Eq. 10 must be modified — more about this later.

Rather than continuing in general terms, it will be better if we look at the special cases that we are interested in.

2. Forced Vaporization of Carbon Tetrachloride. Consider a pure liquid in equilibrium with its vapor in a glass cell in a thermostat of temperature T. Let P_0 be the equilibrium vapor pressure of the liquid at temperature T. Reduce the pressure of the vapor to a pressure $P < P_0$, and establish a steady rate of vaporization of the liquid:

$$\text{liquid}(T, P_0) \rightarrow \text{vapor } (T, P). \tag{11}$$

The rate of entropy production for the forced vaporization process[15] is

$$\theta = -\dot{G}/T = \dot{\xi}[(\mu_{liq} - \mu_{vap})T^{-1}] = Y\Omega, \tag{12}$$

where $\dot{\xi}$ is the reaction velocity (amount vaporized per unit time) for Reaction 11 and I have neglected

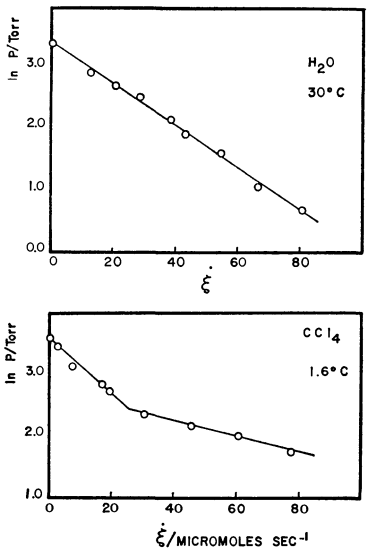

Fig. 2. Plots of $\ln P$ *versus* $\dot{\xi}$ for the steady forced vaporization of water at 30 °C and of carbon tetrachloride at 1.6 °C; P in Torr and $\dot{\xi}$ in μmol s^{-1}. Data of Alty and Nicoll.[17]

kinetic energy terms. Treating the vapor as an ideal gas $\{\mu_{liq} - \mu_{vap} = RT \ln (P_0/P)\}$ we have

$$\theta/R = \dot{\xi} \ln(P_0/P), \tag{13}$$

where R is the gas constant. Steady vaporization has been studied by Alty[15-17] and by Erikson;[15,18,19] nonsteady vaporization has been studied by Spangenberg and Rowland.[20]

Figure 2 shows the data of Alty and Nicoll[17] for the steady forced vaporization of water and of carbon tetrachloride; the current is given in micromoles per second and the pressure is measured in Torr. There is clear evidence in the carbon tetrachloride data for a discontinuous change in flow resistance at $\dot{\xi}_c = 25$ μmol/s; the two flow regimes show the following behavior:

$$\ln P = \ln P_0 - A\dot{\xi}, \qquad (0 \le \dot{\xi} \le \dot{\xi}_c), \tag{14}$$

$$\ln P = \ln P_* - B\dot{\xi}, \qquad (\dot{\xi}_c \le \dot{\xi}), \tag{15}$$

$$\theta/R = A\dot{\xi}^2, \quad F_\sigma/R = \frac{1}{2}A\dot{\xi}^2, \quad (0 \le \dot{\xi} \le \dot{\xi}_c), \tag{16}$$

$$\theta/R = B\dot{\xi}^2 + (A-B)\dot{\xi}_c\dot{\xi},$$

$$F_\sigma/R = \frac{1}{2}B\dot{\xi}^2 + \frac{1}{2}(A-B)\dot{\xi}_c^2, \quad (\dot{\xi}_c \le \dot{\xi}), \tag{17}$$

where $-A$ and $-B$ are the slopes of the two line segments and P_* is the intercept on the line $\dot{\xi} = 0$ of the (extrapolated) line segment with slope $-B$. Values for A and B, in seconds per micromole, are $A = 0.045$, $B = 0.013$. Figure 3 is a graph of $10^6\theta/R$ *vs.* $\dot{\xi}$ for the carbon tetrachloride data, calculated from Eqs. 16 and 17 after insertion of the appropriate numerical values of A, B, and $\dot{\xi}_c$. The dashed and dotted curves are potential hysteresis curves extending the observed behavior into unstable regions. We see that at the

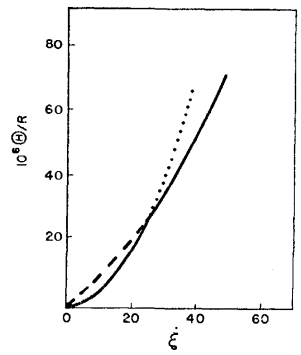

Fig. 3. Plot of $10^6\theta/R$ *versus* $\dot{\xi}$ for the steady forced vaporization of carbon tetrachloride at 1.6 °C. Data af Alty and Nicoll.[17]

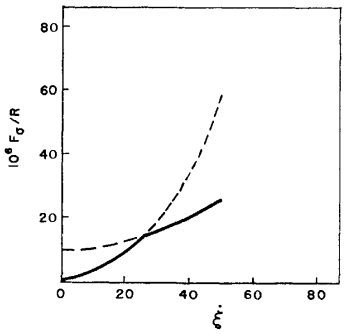

Fig. 4. Plot of $10^6F_\sigma/R$ *versus* $\dot{\xi}$ for the steady forced vaporiization of carbon tetrachloride at 1.6 °C. Data of Alty and Nicoll.[17]

transition point

$$\Delta\{\partial(\theta/R)/\partial\dot{\xi}\}_T = (B-A)\dot{\xi}_c < 0, \tag{18}$$

i.e. the discontinuous change is to a configuration of lower rate of entropy production.

Figure 4 shows that the behavior of the local potential F_σ at the transition point is somewhat similar to the behavior of θ: the branch with the lower value of F_σ is the more stable. In the case of F_σ, however, the metastable extension of the upper branch does not go through the origin of coordinates.[7]

In the carbon tetrachloride case, for fixed T, we have the transition point values θ_c, $\dot{\xi}_c$, P_c; if we repeat the experiment at another value of T we produce a new set of transition point values. In general then the thermodynamic data are the values of T, θ_c, $\dot{\xi}_c$, and P_c at the transition point (for a given apparatus configuration); and, from a thermodynamic point of view, we are interested in derivatives of the type $d\theta_c/d\dot{\xi}_c$, $d\dot{\xi}_c/dT$, $dP_c/d\dot{\xi}_c$, *etc.* Whereas in the somewhat analogous case of a phase transition in a thermo-static system we have the Clapeyron equation ($dP/dT = \Delta S/\Delta V$) to help us out in determining the slope of the phase coexistence line, in the present case we have no such useful general result.

2.1 Expectations and Queries: For the steady forced vaporization of carbon tetrachloride we have

$$\Delta\partial^2(\theta/R)/\partial\dot{\xi}^2 = 2(B-A) < 0, \tag{19}$$

$$\Delta\partial^n(\theta/R)/\partial\dot{\xi}^n = 0 \quad (n = 3, 4, 5, \cdots). \tag{20}$$

Equations 20 are consequences of the linear form of the given current-affinity relation; they, therefore, cannot be expected to have any *general* validity. Relation 19 will merit further investigation; is it generally true that

$$\Delta\partial^2\theta/\partial Y^2 < 0\ ? \tag{21}$$

The physics of the steady forced vaporization process supplies us with some reasonable expectations concerning the behavior of the transition point variables. If the dominant feature of the transition point is the temperature gradient in the liquid in the vicinity of the liquid-vapor interface, then, since the heat of vaporization is a decreasing function of the temperature, we expect to find that

$$d\dot{\xi}_c/dT > 0, \tag{22}$$

to establish the same sort of temperature gradient at a higher temperature we have to pump off the vapor faster because the heat of vaporization now has a lower value. Note that

$$\frac{d(\theta_c/R)}{dT} = \frac{d\dot{\xi}_c}{dT}(\ln P_0 - \ln P_c) + \dot{\xi}_c\left(\frac{d\ln P_0}{dT} - \frac{d\ln P_c}{dT}\right). \tag{23}$$

Now we expect the coefficient A in Eq. 14 to be a decreasing function of temperature,[15,18,19,21] so, given Eq. 22, $d\ln P_c/dT$ should be positive. It is conceivable, then, that $d\ln P_c/dT$ might be large enough to make the right hand side of Eq. 23 vanish, leading to the result that, for a given liquid and a given apparatus configuration,

$$\theta_c = \text{const.} \tag{24}$$

Relation 24 would imply, for this type of experiment, an intrinsic limit to the rate of entropy production that the initial liquid configuration could support; in order to pass beyond the critical rate of entropy production, the liquid would have to change its configuration. An observation analogous to this is that small droplets of liquid have an intrinsic limit (at low to moderate pressures) to the degree of superheat that they can sustain.[22]

If Relation 24 were found to hold, then it would follow that for forced vaporization

$$d\theta_c/dY_c = 0 \tag{25}$$

and, consequently, that

$$d\Omega_c/dY_c = -\Omega_c/Y_c < 0. \tag{26}$$

It is hard to see how Relation 26 could possibly be true, and in section 3 I show that it is very unlikely the Relation 24 can hold true.

The carbon tetrachloride data in Fig. 2 clearly show a "resistance change" transition; the studies of Spangenberg and Rowland[20] indicate that such behavior should regularly occur in forced vaporization experiments; yet the data for water in Fig. 2 and other published results of forced vaporization experiments[15,16,18,19] do not clearly show evidence of "resistance change" transitions. What controls the presence or absence of such transitions? I shall discuss this matter at the

end of the section on Bénard instability, but, to anticipate that discussion, what we need in forced vaporization experiments are a closer spacing of points in the ln P *vs.* $\dot{\xi}$ plots and more attention given to the depth of the liquid layer as an experimental parameter.

3. Bénard Instability. Sandwich a thin layer of fluid between two heat reservoirs (a, b) of temperatures T_a and T_b, with reservoir a above and b below the layer of fluid. By making $T_b \neq T_a$ we can generate a steady flow of heat through the fluid layer from one reservoir to the other. Characterize a reference thermo-static equilibrium state of the fluid by the variables T_a, P_a. Make T_b progressively larger than T_a. A sequence of states of steady heat flow results which ultimately shows an instability: thermal expansion causes the fluid to be less dense at the bottom of the layer than at the top— the layer becomes "top heavy;" eventually conductive heat flow gives way to convective heat flow. The sudden onset of a pattern of convective heat flow is referred to as the Bénard instability;[23,24] it is another example of a "resistance change" transition.

Let $T_b > T_a$ and let $\dot{Q}$ be the rate of influx of heat to the upper reservoir (reservoir a); take state a (T_a, P_a) as the reference state, then

$$\theta = Y\Omega = \dot{Q}\left(\frac{1}{T_a} - \frac{1}{T_b}\right) = \dot{Q}(T_b - T_a)/T_a T_b, \tag{27}$$

$$(\partial\Omega/\partial Y)_{T_a} = (1/T_b)^2[\partial(T_b - T_a)/\partial\dot{Q}]_{T_a}. \tag{28}$$

Schmidt and Milverton[25] immersed two circular brass plates, a fixed distance apart, into a tank of water. They passed a steady electric current I through a resistor of resistance ω affixed to the underside of the lower plate. If f is the fraction of the electrical energy dissipated per unit time by the resistor that passes directly from the lower plate to the upper one through the intervening layer of water, then

$$\dot{Q} = f\omega I^2, \tag{29}$$

$$\theta = \dot{Q}\left(\frac{1}{T_a} - \frac{1}{T_b}\right) = \frac{f\omega I^2(T_b - T_a)}{T_a T_b}, \tag{30}$$

$$T_0^2\theta/f\omega = I^2(T_b - T_a)(T_0^2/T_a T_b), \tag{31}$$

where T_0 is an additional reference temperature introduced for computational convenience. Figure 5 is a plot of $(T_b - T_a)(T_0^2/T_a T_b)$ *vs.* I^2, with $T_0 = 291$ K, of the data listed for Experiment 4 in the paper of Schmidt and Milverton;[25] the distance of separation between the plates was 5.5 mm. There is again clear evidence for a "resistance change" transition, and a plot of $T_0^2\theta/f\omega$ *vs.* I^2 would be qualitatively of the same shape as that of Fig. 3: at the point of transition the configuration of lower rate of entropy production is the more stable, and Relations 9, 10, and 21 are valid. Similarly a plot of $T_0^2 F_a/f\omega$ *vs.* I^2 would be qualitatively of the same shape as that of Fig. 4.

In the case of Bénard instability the thermodynamic variables characterizing the transition point are θ_c, $\dot{Q}_c$, $(T_a^{-1} - T_b^{-1})_c$ or $(T_b - T_a)_c$, T_a, and P_a (depending on the experimental setup, P_a may or may not be an independent variable). We are again interested in quantitites such as $\partial\theta_c/\partial\dot{Q}_c$, $\partial\Omega_c/\partial Y_c$, $\partial\dot{Q}_c/\partial T_a$, *etc.* We

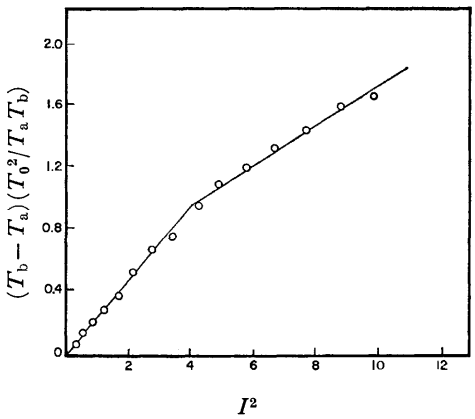

Fig. 5. Plot of $(T_b - T_a)(T_0^2/T_a T_b)$ *versus* I^2, with $T_0 = 291$ K. Data of Schmidt and Milverton.[25]

get some help from hydrodynamic stability theory[23] in this case. The (dimensionless) Rayleigh number $R_\#$ is defined to be

$$R_\# = g\alpha(T_b - T_a)\lambda^3/\kappa\nu, \tag{32}$$

where g is the gravitational acceleration, λ is the thickness of the fluid layer, and α, κ, and ν are the coefficients of volume expansion, thermometric conductivity, and kinematic viscosity, respectively. Stability theory[23] shows that at the point of Bénard instability

$$R_{\#c} = 1708. \tag{33}$$

In the conductive heat flow regime $\dot{Q} = D(T_b - T_a) \times \kappa\rho C_V/\lambda$, where D is the area through which the heat current flows, ρ is the density of the fluid, and C_V is the specific heat of the fluid; consequently

$$\theta_c \approx D(1708\nu/g\alpha T_a)^2(\kappa^3\rho C_V/\lambda^7), \tag{34}$$

where I have set $T_a T_b \approx T_a^2$. Since ν, α, κ, ρ, and C_V are all functions of the reference temperature T_a, the rate of entropy production θ_c for a given fluid with fixed values of D and λ, is apt to be a complicated function of T_a; and a relation such as Eq. 24 is not apt to be satisfied.

3.1 Forced Vaporization Reconsidered: With respect to the hydrodynamic stability of a layer of liquid, heating from below and cooling from above are much the same thing. The instability in the forced vaporization of carbon tetrachloride should thus be of the same nature as the Bénard instability, and the sensitivity of the Bénard instability to the thickness of the fluid layer [Eq. 32] indicates the advisability of treating the depth of the vaporizing liquid as an experimental variable in the forced vaporization case. (The forced vaporization problem is a more complicated one than the Bénard problem in that the temperature gradient in the vaporizing liquid has a complicated 3-dimensional structure[20] whereas the temperature gradient in the Bénard case is a simple 1-dimensional one.)

The data of Alty and Nicoll[17] displayed in Fig. 2 were all gathered in the same apparatus at the same fixed depth for the liquid layer. At the point of instability for the carbon tetrachloride the difference between the thermostat temperature T and the temperature T_s at the surface of the vaporizing liquid was $T - T_s = 7.5$ K. If we assume the geometric factors of

the two experiments displayed in Fig. 2 to be the same (same apparatus, same depth of liquid, same 3-dimensional structure for the thermal gradients) and if we scale the water data according to Eq. 33, relative to the carbon tetrachloride data, *i.e.* if we say that

$$[\alpha(T-T_s)/\kappa v]_{c,\ H_2O} = [\alpha(T-T_s)/\kappa v]_{c,\ CCl_4}, \qquad (35)$$

we find a predicted value of $T-T_s \approx 59$ K at the point of instability for water under the given experimental conditions at 30 °C — such a value is far outside the range of experimental conditions displayed in Fig. 2.

In Alty's other experiments[16] and in Erikson's experiments[18,19] the depth of the liquid layer was an uncontrolled variable, so the resulting data were not gathered in such a way as to highlight the onset of Bénard-type instability. Note that Erikson did see evidence of convection currents in some of his experiments.[18] As I mentioned previously, what is needed in forced vaporization experiments is strict control of the depth-of-liquid variable — and a closer spacing of experimental points in plots of $\ln P$ *vs.* $\dot{\xi}$ (for a fixed depth of liquid). Also, as I mentioned in my discussion of Eq. 34, Relation 24 is unlikely to have any validity whatsoever.

4. Taylor Instability. Place a sample of liquid between two coaxial cylinders; put the device in thermal communication with a thermostat of temperature T, and rotate one of the cylinders at a constant angular velocity γ by exerting on it a torque N. (The case of simultaneous rotation of both cylinders is also of interest, but I do not consider it in this paper.) The simple Couette flow between the cylinders ultimately becomes unstable at $\gamma=\gamma_c$, and toroidal Taylor vortices form at the point of instability[24,26-28] — another example of a "resistance change" transition. As in the previous case, the instability is correlated with the critical value of a dimensionless combination of fluid properties — the Taylor number.[26]

The rate of entropy production for a given angular velocity γ is

$$\theta = \gamma(N/T) = Y\Omega. \qquad (36)$$

To analyze the Taylor instability we need experimental data in the form of N *vs.* γ plots (plots of driving torque *versus* angular velocity) so as to be able to see discontinuities in N and/or $\partial N/\partial\gamma$ at $\gamma=\gamma_c$. The usual experimental procedure,[26-28] however, is to measure the torque on the *stationary cylinder* as a function of the angular velocity γ. The measurements of Donnelly[28] show a discontinuity in the torque on the stationary cylinder at γ_c, *i.e.* the fluid shows a discontinuous increase in apparent viscosity at the point of instability. What do these results imply concerning the variation of N with γ? Until we have some direct measurements or dependable calculations of the N, γ relationship, we cannot be sure of the implication; we can, however, explore some of the possibilities.

Suppose that the N, γ relation turns out to be similar in nature to the torque-on-the-stationary-cylinder, γ relation: suppose that $\Delta N\neq 0$, $\Delta\partial N/\partial\gamma>0$, and the configuration of *higher* rate of entropy production (and of higher local potential) is the more stable one beyond γ_c. What would be the thermodynamic implications of such a result? The idea here is to pursue the analogy to thermo-static phase transitions. If both phases have metastable regimes extending out beyond the transition point (Fig. 1, *e.g.*), then we are dealing with a problem of *relative stability* and the phase with the smaller Gibbs function value is the more stable. But it is also possible to have a phase transition point such that one of the phases reaches an *absolute limit of stability* at the transition point and has no metastable existence out beyond the transition point — the order-disorder transition in β-brass, for example.[29] For "resistance change" transitions, then, where each configuration has a metastable extension beyond the point of instability (in one direction or the other) the question of relative stability is decided by having the configuration of lower rate of entropy production (or lower local potential) more stable (Fig. 3, *e.g.*). But if a given configuration approaches an inflection point in the θ, Y plot, *i.e.* $\partial^2\theta/\partial Y^2$ approaches zero, it approaches an intrinsic limit of stability [see Eq. 9]: at the point where $\partial^2\theta/\partial Y^2=0$ the configuration must change to some other stable configuration; it is no longer a question of relative stability but an absolute requirement for a change of configuration. Under such circumstances $\Delta\partial\Omega/\partial Y$ could just as well be positive as negative, and we could even have a discontinuity in Ω (and F_σ): $\Delta\Omega\neq 0$ ($\Delta F_\sigma\neq 0$). The requirement for such a point of intrinsic instability would be

$$0 = \partial^2\theta/\partial Y^2 = 2(\partial\Omega/\partial Y) + Y_c(\partial^2\Omega/\partial Y^2), \qquad (37)$$

and we should have

$$Y_c = -2(\partial\Omega/\partial Y)/(\partial^2\Omega/\partial Y^2) \qquad (38)$$

as $Y\rightarrow Y_c-0$.

If the transition point is a point of intrinsic instability for both the upper ($Y>Y_c$) and lower ($Y<Y_c$) branches, we cannot say anything *a priori* about $\Delta\theta$ or $\Delta\partial\Omega/\partial Y$. If the transition point is a point of intrinsic instability for the lower branch and if the upper branch has a metastable extension below Y_c, then we can make the following observations relative to the transition point: i) it is not possible, under these circumstances, to have $\Delta\theta<0$ since the extension of the upper branch into the region $0\leq Y<Y_c$ would be more stable (would have a lower θ value) than the experimental lower branch; ii) it is not possible to have $\Delta\theta=0$ and $\Delta\partial\theta/\partial Y>0$ for the same reason as in i) — the extension of the upper branch into the region $0\leq Y<Y_c$ would be more stable than the experimental lower branch; iii) it is possible, but not likely, to have $\Delta\theta=0$ and $\Delta\partial\Omega/\partial Y<0$ — it is improbable to expect the lower branch to just "happen" to intersect the upper branch at the point of intrinsic instability; iv) it is possible, and likely, to have $\Delta\theta>0$ and either $\Delta\partial\Omega/\partial Y>0$ or $\Delta\partial\Omega/\partial Y<0$ — at the point of intrinsic instability it is highly probable that the lower branch will be some distance away from the upper branch, hence a jump discontinuity in θ (and in Ω) — and in F_σ — will occur, with no necessary restrinction on the sign of the change in slope $\Delta\partial\Omega/\partial Y$. Note that if $\Delta\partial\Omega/\partial Y>0$ then there *must* be a discontinuity in θ (and in Ω) — see Fig. 6.

If the N, γ relation for the Taylor instability proves to have $\Delta N\neq 0$ at $\gamma=\gamma_c$ the most likely explanation

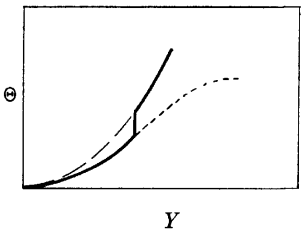

Fig. 6. Example: point of intrinsic instability with $\Delta\theta>0$ and $\Delta\partial\Omega/\Omega Y>0$.

will be that the transition point is a point of intrinsic instability for the lower branch. Points of intrinsic instability are special cases of the "bifurcations" and "catastrophes" discussed by Nicolis and Prigogine.[30]

5. A Multi-current Situation — Flip-Flop Current vs. Voltage Relation. Interpose a sintered glass membrane between aqueous sodium chloride solutions of concentrations 0.01 and 0.1 M; place inert electrodes on opposite sides of the membrane and impose a voltage $\Delta\phi$ between the electrodes; exert an excess pressure ΔP on the more concentrated solution. Keep the concentration difference and the pressure difference across the membrane fixed and measure the electric current I induced by the impressed voltage $\Delta\phi$. (Maintain the entire system at a constant temperature T.)

Let subscript 1 indicate water and subscript 2 indicate sodium chloride, and let a single prime designate the more concentrated solution and a double prime designate the less concentrated solution. Then, if the experiment is conducted in a steady-state fashion, we have[31]

$$T\theta = -(\dot{n}_1'\mu_1'+\dot{n}_2'\mu_2'+\dot{n}_1''\mu_1''+\dot{n}_2''\mu_2'') + I\Delta\phi, \tag{39}$$

and

$$\begin{aligned} T\theta &= \dot{n}_1'(\mu_1''-\mu_1') + \dot{n}_2'(\mu_2''-\mu_1') + I\Delta\phi \\ &= Y_1\Omega_1 T + Y_2\Omega_2 T + Y_3\Omega_3 T, \end{aligned} \tag{40}$$

since $\dot{n}_1'+\dot{n}_1''=0$ and $\dot{n}_2'+\dot{n}_2''=0$. If we treat the sodium chloride solutions as "ideal" we can say that

$$\begin{aligned} \mu_1' - \mu_1'' &= \int_{P''}^{P'} \overline{V}_1\,dP + RT\ln(X_1'/X_1'') \\ &= \langle\overline{V}_1\rangle\Delta P + RT\ln(X_1'/X_1''), \end{aligned} \tag{41}$$

$$\begin{aligned} \mu_2' - \mu_2'' &= \int_{P''}^{P'} \overline{V}_2\,dP + RT\ln(C_2'/C_2'') \\ &= \langle\overline{V}_2\rangle\Delta P + RT\ln(C_2'/C_2''), \end{aligned} \tag{42}$$

where X_i is the mole fraction, $\overline{V}_i$ the partial molar volume, $\langle\overline{V}_i\rangle$ the average partial molar volume over the pressure interval ΔP, and C_i the concentration (moles per liter) of component i. Let $\dot{n}_1'\langle\overline{V}_1\rangle+\dot{n}_2'\langle\overline{V}_2\rangle\approx\dot{V}'$ and evaluate X_1'/X_1'' by setting molarities approximately equal to molalities. Impose the restriction on $\dot{n}_1'$ and $\dot{n}_2'$ that they keep the ratio n_1'/n_2' constant (*i.e.* constant C_2'). Upon substitution of the appropriate numerical values, we get

$$T\theta \approx -\dot{V}'\Delta P - 1.4\,\dot{n}_2'RT + I\Delta\phi. \tag{43}$$

Experiments measuring the current-voltage relationship for this type of experiment were carried out by H. Jahnke and reported on by Franck.[32] Figure 7 shows the I *vs.* $\Delta\phi$ relation for various fixed pressure differences for one series of experiments carried out by Jahnke. The rather spectacular form of the I, $\Delta\phi$ relation is explained by Kobatake[8] in the following way: " ... under the external conditions studied here, the Poiseuille pressure flow transports fluid from the more concentrated to the less concentrated solution, while the electro-osmotic flow caused by the potential gradient tends to carry fluid in the opposite direction. With increasing $\Delta\phi$, the electro-osmotic flow becomes appreciable, outweighs the pressure flow, and eventually changes the direction of mass flow from negative to positive. Calculations show that this change of the direction of mass flow occurs discontinuously when $\Delta\phi$ reaches a certain value, when the pressure difference ΔP is larger than a critical value ΔP_c. Correspondingly, the average salt concentration in the membrane is lowered, *i.e.* the membrane is occupied with the less concentrated solution... The effect of this change in concentration in the membrane is reflected in the I *vs.* $\Delta\phi$ relationships depicted in [Fig. 7]."

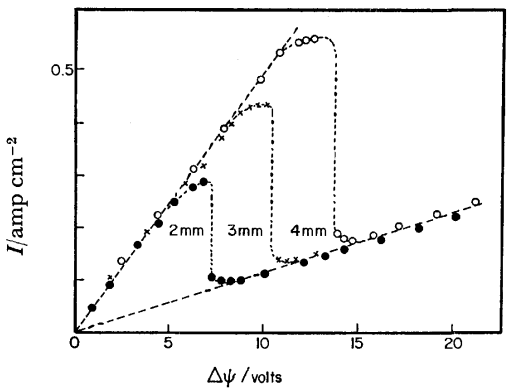

Fig. 7. Plots of I *versus* $\Delta\phi$ for the system of a sintered glass membrane and NaCl solutions of 0.01 and 0.1 M with various fixed pressure differences. Data of Jahnke as reported by Franck.[32]

The results reported by Franck[32] do not include data for $\dot{V}'$ and $\dot{n}_2'$ so we cannot actually calculate $T\theta$ for the experiment. It seems reasonable to expect, however, that at the critical value $\Delta\phi_c$ of the voltage $T\theta$ will actually show a discontinuous *decrease*. If such is indeed the case, it must be because the point $\Delta\phi=\Delta\phi_c$ is a point of intrinsic instability ($\partial^2\theta/\partial Y^2\to 0$) for *both* the upper ($\Delta\phi=\Delta\phi_c+0$) and lower ($\Delta\phi=\Delta\phi_c-0$) branches of the I *vs.* $\Delta\phi$ relation, *i.e. neither* branch has a metastable extension beyond the point $\Delta\phi=\Delta\phi_c$.

Kobatake[8] has analyzed Jahnke's experiments in terms of the local potential:

$$TF_\sigma = T\int\Sigma_i Y_i d\Omega_i = \int_0^{\Delta\phi} I d\Delta\phi + f(\Delta P, \Delta\mu_2). \tag{44}$$

By an elementary theorem of the calculus[33] the integral in Eq. 44 is continuous at the point $\Delta\phi_c$, so TF_σ does not have a discontinuity at the flip-flop point.

6. Summary. I have considered the behavior

of the rate of entropy production θ and the local potential F_σ for several one-current steady-state situations showing "resistance change" transitions — forced vaporization of carbon tetrachloride, Bénard instability, and Taylor instability. For these cases the behavior of the local potential is qualitatively similar to the behavior of the rate of entropy production. The complexity of the thermodynamic relations pertaining to the transition point depends upon whether the branches intersecting at the transition point have metastable extensions beyond that point. I also considered (briefly) a multi-current situation showing a flip-flop current-voltage relation at the transition point; here θ and F_σ seemingly show different kinds of behavior—F_σ is continuous at the transition point whereas θ appears to undergo a discontinuous change (it seems that *neither* of the branches intersecting at the transition point has a metastable extension beyond that point).

Synthesis and Sintering of Active Manganese(II) Zinc Ferrite Powders†

M. N. Sankarshana MURTHY,* C. E. DESHPANDE, P. P. BAKARE, and (Mrs.) J. J. SHROTRI

National Chemical Laboratory, Poona 411008, India

(Received January 10, 1978)

Manganese(II) monoxide which is spontaneously oxidized in air is stabilized by solid solution with zinc oxide and then employed as a raw material in the synthesis of manganese(II) zinc ferrites in an inert atmosphere, giving thereby no chance for Mn^{2+} to get oxidized. Sintering is done in a static controlled atmosphere created by the thermal dissociation of pellets of active iron(III) oxide kept in oxygen-free nitrogen along with the ferrite toroids. The ferrite formation and the sintering are performed at 950 and 1150 °C respectively by employing active oxide raw materials.

The synthesis of manganese(II) zinc ferrites is complicated by the need to have all the manganese as Mn^{2+}, while a small amount of Fe^{2+} is also needed in order to reduce the magnetocrystalline anisotropy or magnetostriction.[1,2] It is not possible to employ manganese(II) monoxide directly as the raw material since this oxide is not stable in air. Conventional methods employ a higher stable oxide of manganese as the raw material[3] or allow the manganese(II) monoxide to get oxidized during the initial calcination.[4] The reduction of Mn^{2+} is subsequently performed by a current of an inert gas such as nitrogen that sweeps off the oxygen produced by the thermal dissociation of the ferrite at the sintering temperature which is usually between 1200 and 1300 °C. Calculated small concentrations of oxygen are mixed with the nitrogen current in order to effect the optimum thermal reduction of Fe^{3+} to Fe^{2+}. This oxygen concentration has to vary with temperature during the sintering cycle so as to cope with the temperature variation of the partial pressure of oxygen in thermal equilibrium with the ferrite.

Quite apart from the complexity and expense of maintaining the flowing current of the controlled atmosphere with varying oxygen concentrations at different temperatures, it is difficult to know in such a process the stage at which the reduction of Mn^{3+} to Mn^{2+} is complete. Even if this reduction is complete, the Mn^{2+} may or may not be situated completely at the correct lattice sites in the spinel. The Mn^{2+} can enter the spinel lattice only after it is formed by the thermal reduction of Mn^{3+}; but the possibility of harmful non-spinel forming solid state reactions before such a reduction cannot be ruled out. The site-preference for Mn^{3+} is obviously different from that for Mn^{2+} during the solid state reaction among the component oxides. The manganese has to move to the correct lattice site in the ferrite spinel after the subsequent reduction of Mn^{3+} to Mn^{2+}; but this migration in the solid matrix may or may not be complete during the sintering run. One can then expect a considerable degree of non-reproducibility in the final properties of the ferrite even when all the synthetic parameters have been apparently kept constant; and in fact this non-reproducibility of properties is a bugbear in the synthesis of these ferrites.

This difficulty has been overcome in the present investigation by stabilizing the MnO by solid solution with ZnO. It is then possible to prepare the ferrite without oxidation of Mn^{2+}. There is subsequently no need to maintain a running current of the controlled atmosphere in order to reduce the Mn^{3+}. The controlled atmosphere is now necessary only to prevent the oxidation of Mn^{2+} as well as an undue thermal reduction of Fe^{3+}. A static controlled atmosphere suffices for this purpose; and this can be easily obtained by an inert gas in the presence of suitable metallic oxides placed in the high temperature zone. These oxides can supply the required oxygen to the ambient atmosphere by thermal dissociation.

Experimental

(1) Preparation of Raw Materials. Manganese(II) oxalate precipitated from filtered solutions of manganese(II) chloride (AnalaR) and ammonium oxalate (Laboratory Reagent) was washed free from chloride and dried in vacuum. Zinc oxalate prepared similarly could be dried in air at 70°C due to its greater thermal stability. Iron(III) oxide was prepared by adding a concentrated purified iron(III) nitrate solution into an excess of aqueous ammonia. After decanting the supernatent liquid, the precipitate was heated to 250 °C to give pure and active iron(III) oxide. These pure raw materials could be easily estimated gravimetrically; manganese as $MnSO_4$, zinc and iron as the respective oxides by direct ignition.

(2) Preparation of MnO-ZnO Solid Solution. The oxalates of manganese and zinc were mixed in the required proportion and decomposed in a flowing current of oxygen-free nitrogen obtained by passing the cylinder gas through a column of heated reduced copper.[5] The carbon monoxide was disposed off by direct burning. After the evolution of gases ceased, the powder was degassed at 750 °C in order to remove carbon monoxide in particular that is tenaciously chemisorbed by MnO.[6] The system was cooled before taking out the charge which had a fine orange colour and could be safely exposed to air. Chemical analysis revealed the presence of manganess fully as Mn^{2+}.

(3) Preparation of the Ferrite Powder. The above powder containing ZnO and MnO was thoroughly mixed with the requisite amount of iron(III) oxide, pressed as such into pellets and then heated to 950 °C for 8 h in a static atmosphere of pure nitrogen. After cooling, the pellets were found to have become strongly magnetic. They were ground and ball-milled.

(4) Sintering. The sintering of toroids pressed with this ferrite powder could also be done without allowing the Mn^{2+} to get oxidized. The powder was pressed into toroids —3.6 cm o.d., 1.6 cm i.d., 1 cm thickness, employing a

a) D.F.: Disaccommodation factor defined as $(\mu_1-\mu_2)/\mu_1^2 \log (t_2/t_1)$ where μ_1 and μ_2 are the initial permeabilities at 10 min (t_1) and 100 min (t_2) respectively after demagnetization at 23 °C. b) T.F.: Temperature factor defined as $1/\mu^2\, d\mu/dT$ where T is the temperature.

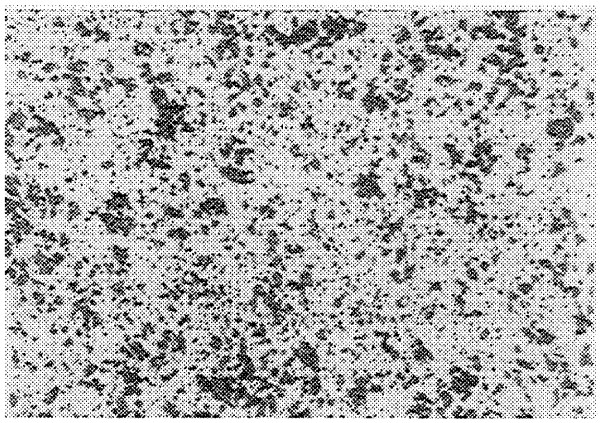

Fig. 1. Photomicrographs of ferrites (present technique) sintered at 1150 °C. Magnification × 100.

volatilizable binder such as camphor. The binder was distilled off in a current of purified nitrogen. The sintering was then done as per the technique given below.

It was however also possible to employ a binder such as polyvinyl alcohol that needs to be burnt out. The Mn^{2+} did of course get oxidized in the process, but subsequent satisfactory reduction could be effected in a run at 1050 °C for eight hours in a static atmosphere of oxygen-free nitrogen and in the presence of a calculated amount of iron powder (pressed as such into pellets) in the closed system. The iron in the hot zone got oxidized by the oxygen given out by the thermal dissociation of the oxidized ferrite; and the reduction of Mn^{3+} back to Mn^{2+} could be effected quantitatively as checked by subsequent chemical analysis. The amount of iron needed in the above reduction was not very critical and a little excess was found to do no harm. After cooling, the toroids contained all the manganese as Mn^{2+}.

These toroids were then sintered in static nitrogen at 1150 °C for 12 h in the presence of iron(III) oxide pellets meant to generate the required partial pressure of oxygen in the closed system. Here again it was found that the quantity of iron(III) oxide to be kept was not very critical so long as it exceeded a certain minimum amount depending on the quantity of ferrite to be sintered. This could be easily determined by slight trial. The temperature of 1150 °C proved to be the correct sintering temperature to give satisfactory grains (Fig. 1). The furnace was cooled after sintering, at a rate of about 25 °C per hour till about 500 °C when the power was switched off. The toroids were taken out after cooling to room temperature and examined for their properties (Table 1). Each of the compositions given in the table was repeated four times and the variation in any of their properties was never more than ±15% of the mean values given in the table. No additives were tried in order to reduce the losses still further.

Discussion

The above technique virtually enables us to use MnO itself as the raw material in the preparation of manganese(II) zinc ferrites. In fact, it was found that even 1 mol % of ZnO in MnO stabilizes the lattice in air[7] so that such an analysed solid solution can be prepared once and for all, and used regularly as a raw material for the synthesis of this ferrite, adding the required balance of ZnO along with the Fe_2O_3 afterwards. It is therefore possible to effect the spinel formation at a relatively low temperature and then sinter the ferrite at a higher temperature just as in the case of nickel zinc or any other ferrite. In a conventional technique on the other hand these two processes are combined into one since the thermal reduction of Mn^{3+} to Mn^{2+} at the sintering temperature is a prerequisite for the spinel formation. Since manganese is present as Mn^{2+} right from the start, the spinel formation occurs at the lowest temperature at which the component oxides can at all react with one another; and it is possible to lower this temperature considerably by employing very active oxides produced by the effervescent decomposition of precipitated compounds at low temperatures —MnO and ZnO by the decomposition of their respective precipitated oxalates, and Fe_2O_3 during the effervescent decomposition of ammonium nitrate produced at the time of precipitation from iron(III) nitrate with ammonia. The preparation of the ferrite powder could be accomplished even at a temperature lower than 950 °C used here. This temperature was employed in order to get the bigger particles necessary for a higher pressed density. The burning of the binder at 800 °C—while it oxidizes the Mn^{2+} and renders the burnt toroids totally non-magnetic—can be expected not to disturb the various ions from their lattice sites. Subsequent reduction at 1050 °C in a closed system filled with pure nitrogen and in the presence of iron powder in the hot zone effects an *in situ* reduction of Mn^{3+} to Mn^{2+}. The iron gets oxidized by the oxygen given out by the thermal dissociation of the oxidized ferrite and thereby reduces all the manganese to Mn^{2+}. It is obvious from the above that the Mn^{2+} should be expected to

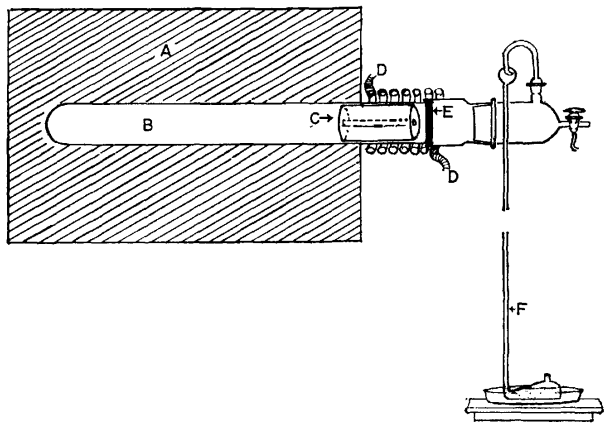

Fig. 2. Experimental arrangement for sintering manganese(II) zinc ferrites.

be fully present at the appropriate lattice sites in the spinel, thereby eliminating an important cause of uncertainty of the results. A little excess iron can obviously do little harm since reduction, if any, of Fe^{3+} to Fe^{2+} at this stage can be easily corrected during the final sintering at 1150 °C in the presence of an excess of active iron(III) oxide pellets. This iron(III) oxide dissociates at the sintering temperature into Fe_3O_4 and oxygen, thereby providing the correct partial pressure of oxygen required to leave an optimum small concentration of Fe^{2+} in the sintered ferrite. The relatively lower temperatures of processing minimise the loss of zinc oxide from the ferrite. Since the dissociation pressure of iron(III) oxide is independent of the quantity of the oxide and depends only on the temperature, the quantity of iron(III) oxide to be placed in the hot zone of the sintering furnace is not very critical provided however, it is sufficient to maintain the correct dissociation pressure of oxygen in the sintering chamber. The mercury seal (Fig. 2) employed during the sintering run and the previous reduction serves to release the pressure during the heating. Since the dissociation pressure of oxygen in equilibrium with the ferrite varies with temperature in the same way as for the iron(III) oxide, the composition of the ambient atmosphere during the entire sintering run adjusts itself automatically at each temperature. The concentration of Fe^{2+} in the sintered ferrite is therefore fixed only by its composition and sintering temperature but not the vagaries of an externally controlled atmosphere; thereby eliminating one uncertain and sensitive parameter determining the ferrite properties. These properties can be varied in other ways such as variation of composition. This simplifies the technique considerably in every way. As mentioned in the introduction, sintering in a static controlled atmosphere whose composition adjusts itself automatically at each temperature is a great advantage over a flowing current of gas whose composition has to be externally adjusted from time to time.

The authors are grateful to Dr. A. P. B. Sinha who has kindly encouraged this work with his keen interest and valuable suggestions. The P. P. U. of Armament Research and Development Establishment, Poona, have kindly prepared the dies and helped in pressing; and this valuable help is most gratefully acknowledged. Grateful thanks are also due to Mr. S. S. Ali, Merado, Poona, for taking the photomicrographs.

Medium Effect on the Ionisation Constants of Some Hydroxy Derivatives of 1-Ethyl-2-styrylpyridinium and -quinolinium Iodides

M. R. Mahmoud,* R. Abd-El-Hamide, and K. A. Idriss
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(Received February 13, 1978)

The pK_a values of 1-ethyl-2-(4 or 2-hydroxystyryl)pyridinium and -quinolinium iodides in different organic solvent–water mixtures were determined. The organic solvents used are methanol, ethanol, acetone, DMF and DMSO. The ionisation of the compounds under investigation depends largely on both the proportion and the nature of the organic co-solvent used. The ionisation constant decreases with increase in the proportion of the organic co-solvent in the medium. The major important effect responsible for this is the difference in the stabilization of base by donor hydrogen bond from solvent molecules. The free energy of solvation of both acid and proton by electrostatic interaction and that of the base by donor hydrogen bond from solvent molecules were calculated. The effect of the molecular structure of the compound on pK_a is also discussed.

So far only a few studies seem to have appeared on the ionisation of hydroxystyryl derivatives.[1] The pK_a values of some hydroxy derivatives of 1-ethyl-2-styrylpyridinium and -quinolinium iodides in pure aqueous medium were determined by Mahmoud *et al.*[2] However, it is known that the hydroxystyryl derivatives are quite interesting compounds because of their application as photosensitizers[3,4] and use as antiseptics, trypanocidal and anticarcinogenic agents.[5-8]

We have investigated the ionisation of some hydroxystyryls in aqueous solutions containing varying proportions of organic solvents (methanol, ethanol, acetone, *N*,*N*-dimethylformamide, dimethyl sulfoxide). The pK_a values have been determined and discussed in terms of solvent properties.

Experimental

Materials and Solutions. The hydroxystyryl dyes used are 1-ethyl-2-(4-hydroxystyryl)pyridinium iodide I, 1-ethyl-2-(2-hydroxystyryl)pyridinium iodide II, 1-ethyl-2-(4-hydroxystyryl)quinolinium iodide III and 1-ethyl-2-(2-hydroxystyryl)quinolinium iodide IV. These derivatives were synthesized by the reaction of the corresponding aldehyde with 1-ethyl-2-methylpyridinium iodide or 1-ethyl-2-methylquinolinium iodide using piperidine as a condensation reagent.[9,10] The products obtained were crystallized several times from ethanol. The compounds used for the preparation of the derivatives and the organic solvents were of high purity (A. R. or spectrograde). Stock solutions 10^{-3} M of the compounds were prepared by dissolving the solid in the solvent. pH control was achieved by using a modified universal buffer solution.[11]

To account for the difference in acidity, basicity, dielectric constant and ion activities in partially aqueous solutions relative to pure aqueous ones, the pH values of the former solutions were corrected making use of the attempts described by Douheret[12]

$$pH^* = pH(R) - \delta,$$

where pH* is the corrected reading and pH(R) is the meter reading obtained in a partially aqueous medium, where the pH-meter is standardized using aqueous buffer.

The values of δ of the aqueous buffer solutions containing varying proportions of each of the organic solvents under investigation were determined by Douheret.[12,13]

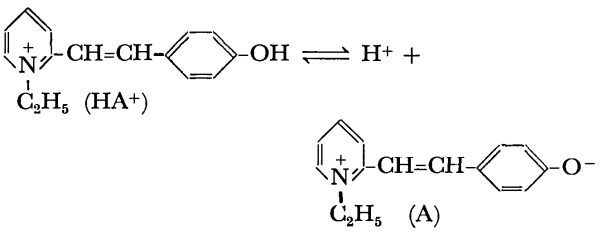
Apparatus. The absorption spectra were measured on a UNICAM S.P 8000 Spectrophotometer within the wavelength range 300—700 nm using 1 cm matched silica cells. The pH-measurements were carried out at 25 °C with a UNICAM MK_2 pH-meter, equipped with the usual glass and calomel electrodes, accurate to ±0.005 unit. The temperature was controlled by placing the solutions as well as the pH-meter in an air thermostat accurate to ±0.5 °C.

Results and Discussion

The visible absorption spectra of the compounds measured either in buffer solutions or in those containing different proportions of an organic solvent (methanol, ethanol, acetone, DMF, and DMSO) show mainly two bands (Fig. 1). The spectra of solutions with low pH are characterized by only one visible band mainly due to the absorption by species with non-ionised OH-group. This band was assigned to an intramolecular charge transfer transition.[2] Its intensity decreases with increase in pH in media of pH≥7. At the same time another band appears at longer wavelength, its intensity increasing with increase in pH. The behaviour can be explained as follows. With increase in the pH of the medium, the ionisation of the proton starts which in turn increases the proportion of the ionised form in solution, making the energy barrier of the intramolecular CT smaller.

The results (Tables 1 and 2) indicate that the λ_{max} of the band responsible for the absorption by the free base exhibits a clear red shift on increasing the proportion of the organic solvent in the medium, λ_{max} for the band of the acid shifting slightly.

The spectra of the compounds (I—IV) in all media investigated display clear isosbestic points, showing the existence of equilibrium of the form



The absorbance —pH curves obtained at selected wavelengthes (Fig. 2) are typical of dissociation and association types, revealing the existence of one acid-base equilibrium in each case.

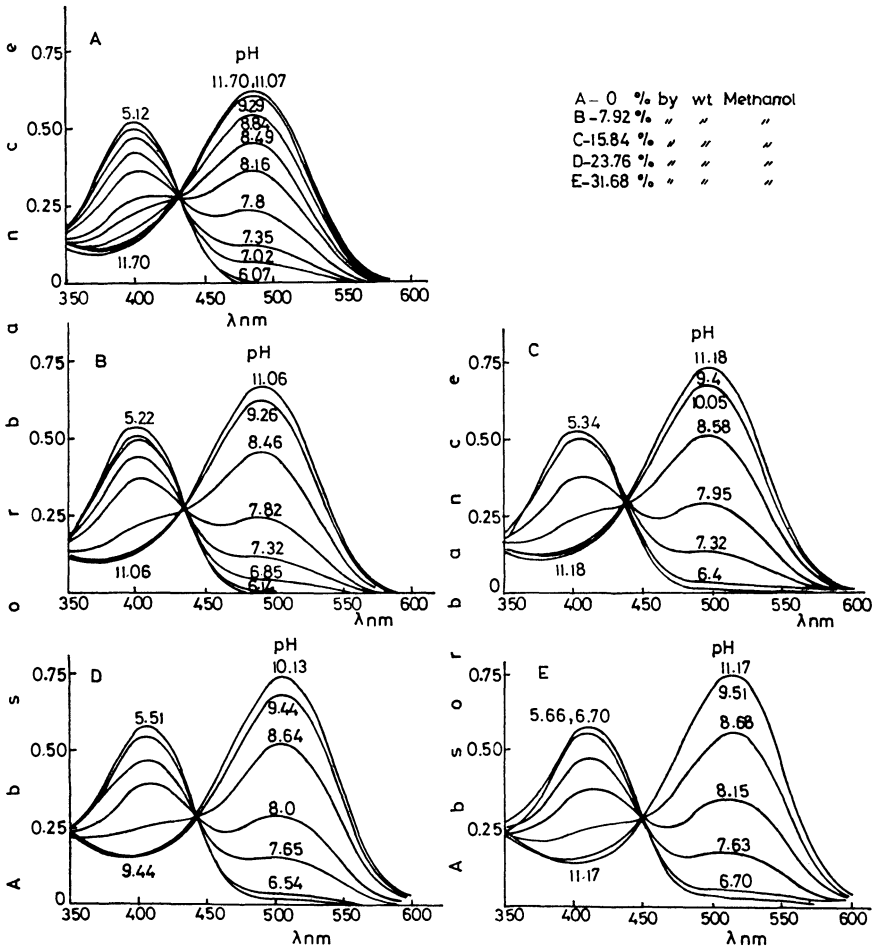

Fig. 1. Absorption spectra of 1.07×10^{-5} M 1-ethyl-2-(4-hydroxystyryl)quinolinium iodide III solution containing different percentages of methanol.

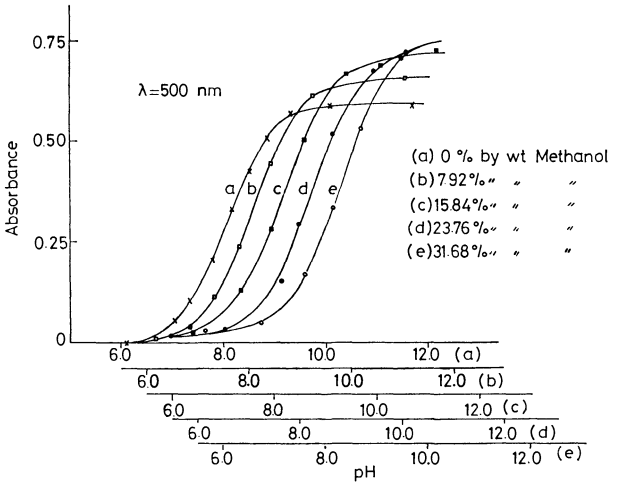

Fig. 2. Absorbance-pH curves for 1-ethyl-2-(4-hydroxystyryl)quinolinium iodide III in universal buffer solutions containing different percentages of methanol.

The acid dissociation constant, pK_a, of the compounds in different media was determined from the variation of absorbance with pH with use of three different spectrophotometric methods viz half-height, limiting absorbance and Colleter methods.[14,15] The results are given in Tables 1 and 2.

It is evident that the pK_a values depend largely on both the proportion and the nature of the organic solvent. The ionisation constant decreases with increase in the amount of solvent in the medium. This behaviour is the opposite of that observed with *p*-dimethylaminostyryl derivatives.[16]

According to Coetzee and Ritchie,[17] the acidity constant in aqueous medium $K_{a(1)}$ is related to that in partially aqueous medium $K_{a(2)}$ by means of

$$K_{a(1)} = K_{a(2)}\frac{\gamma_{H^+}\gamma_A}{\gamma_{HA^+}}, \quad (1)$$

where the γ is the activity coefficient of the subscripted species in a partially aqueous medium relative to that in a pure one. It is known that the electrostatic effect resulting from the change in dielectric constant of the medium will operate on the activity coefficient of the charged species only, its magnitude being inversely proportional to the radius of the ionic species considered.[18] Consequently the magnitude of this effect on the proton exceeds that on the acid (HA^+). Thus, the ionisation constant of the compounds is expected to decrease with increase in the proportion of the organic solvent in the medium, which is in line with the results given in Tables 1 and 2.

However, in the light of the relation given by Charlot and Tremillon,[19] giving the variation of pK_a with

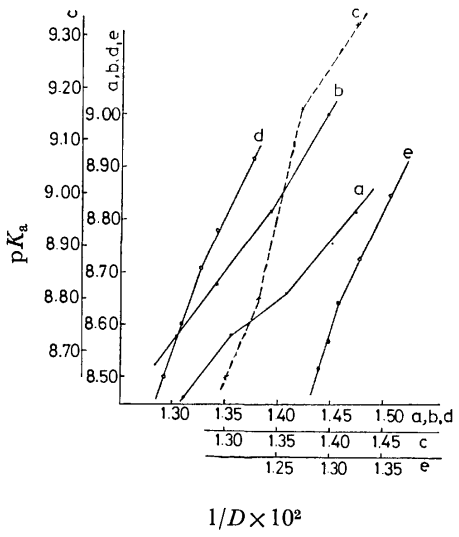

Fig. 3. Variation of pK_a of compound I in aqueous organic solvent mixture with $1/D$ of the medium at 25 °C.
a: Methanol, b: ethanol, c: acetone, d: DMF, e: DMSO.

dielectric constant (D), the plots of pK_a against $1/D$ are not strictly linear (Fig. 3). This indicates that the decrease in the ionisation constant of these compounds, though mainly governed by the dielectric constant effect, is strongly influenced also by other solvent effects. The behaviour can be interpreted by calculating the change in the ionisation constant produced by electrostatic effect (ΔpK_{el}) for compounds I and III in the presence of each organic solvent (31.60 % by wt). The calculation was made by means of the Bron equation,[18] valid for large radii,[20] and following the principles described by Tremillion.[21] The following equation is obtained for the calculation of ΔpK_{el} value:

$$\Delta pK_{el} = \frac{Ne^2}{4.6RT}\left[\frac{1}{r_{HA^+}} - \frac{1}{r_{H_3O^+}}\right]\left[\frac{1}{D_{mix}} - \frac{1}{D_{H_2O}}\right],$$

where N=Avogadro's number, e=electron charge, r=radius of ion expressed in Å, D=dielectric constant, $r_{H_3O^+}=r_{H_2O}=1.93$ Å. The radius of the monovalent cation (HA^+) was determined by assuming that its density is approximately equal to the one belonging to the corresponding non-quaternized derivative. The densities of the non-quaternized derivatives of compounds I and III were determined by means of the technique developed by Clark and White.[22]

$$d = \frac{m \times d_{Hg}}{m+w},$$

where d_{Hg}=density of mercury m=weight of the non-quaternized compound in the air, w=the weight to be added to the pan in order to level the fixed mark on the stem back to the surface of Hg. The density values obtained for the non-quaternized derivatives of compounds I and III are 1.1055 and 1.2685 gm/cm^3, respectively; thus the calculated radii are 4.30 and 4.42 Å respectively. Hydrogen bonding, solvent basicity, despersion forces and proton-solvent interaction effects are commonly recognized as influencing factors in the ionisation constants of acids in the presence of organic solvent.

We can attribute the decrease in the ionisation constant of each compound due to increase in the proportion of organic solvent in the medium to the following effects besides the electrostatic effect.

(a) Decrease in the ionisation of the OH group of the compound (*i.e.* high pK_a) caused by the relatively low basicity of alcohols or acetone with respect to water.

(b) The high stabilization of the base (A) by donor hydrogen bond in pure aqueous medium relative to that in presence of organic solvent. This is presumably due to the greater tendency of water molecules to donate hydrogen bond as compared with other solvent molecules.[17] Increase in solvent proportion in the aqueous medium will result in an increase in the activity coefficient of the base, thereby causing decrease in the ionisation constant of the compound (*i.e.* high pK_a).

Since the organic co-solvent is characterized by high polarizability relative to water, the base would be more highly stabilized by dispersion forces in solvent–water mixtures than in water. On the other hand, the proton is expected to be highly stabilized in partially aqueous media relative to pure ones through proton-solvent interactions. Thus, the ionisation constant of the compound should increase with increase in the amount of the organic co-solvent in the medium. However, this is not the case (Tables 1 and 2). We see that the dispersion forces and proton-solvent interactions do not appear to be of much importance in the ionisation of the hydroxystyryl derivatives.

The results (Tables 1 and 2) indicate that the variation of pK_a values in solutions containing either the same percentage or more or less the same mole fraction (≈ 0.1) of alcohol or acetone appears to be in the order:

methanol < ethanol < acetone.

This is presumably due to the decrease in the tendency of the solvent molecules to donate hydrogen bond to the base on going from methanol to acetone. This was deduced from the fact that the tendency of alcohol to associate with solutes through H- bond decreases with increase in the molecular weight of alcohol.[23] Acetone is characterized by a very weak tendency to donate hydrogen bond.[17]

The decrease in ionisation with decrease in the donor hydrogen-bond character of the organic co-solvent is in line with the fact that the difference in the stabilization of the base by donor-hydrogen bond from solvent molecules is a major factor responsible for the increase in pK_a resulting from the increase in the amount of the solvent in the medium.

It is evident that the pK_a value in presence of the poorer donor-hydrogen bond DMF or DMSO is less than either the one obtained in the presence of the same amount or nearly the same mole faction (≈ 0.10) of acetone or ethanol (Tables 1 and 2). This can be attributed to the high basic character of the former solvents, reflecting itself in the construction of a strong acceptor hydrogen bond from the OH group of the non-ionised form and thus facilitating the ionisation process of the OH group (*i.e.* low pK_a).

TABLE 3. VALUES OF ΔpK_{el}, ΔpK_{nonel}, ΔG_{el}, and ΔG_{nonel} OBTAINED FOR COMPOUNDS I and III

Solvent	$+\Delta pK_t$		$+\Delta pK_{el}$		$+\Delta pK_{nonel}$		$+\Delta G_{el}$ cal/mol 25 °C		ΔG_{nonel} kcal/mol 25 °C	
	I	III	I	III	I	III	I	III	I	III
31.68 wt % Methanol	0.50	0.36	0.065	0.067	0.435	0.293	89.1	91.8	0.60	0.40
31.64 wt % Ethanol	0.74	0.51	0.058	0.060	0.682	0.450	79.5	82.3	0.94	0.62
31.68 wt % Acetone	1.00	0.66	0.051	0.052	0.949	0.608	69.9	71.3	1.30	0.83
31.60 wt % DMF	0.52	0.26	0.023	0.024	0.497	0.236	31.5	32.9	0.68	0.32
31.60 wt % DMSO	0.41	0.31	0.017	0.018	0.393	0.292	23.3	24.7	0.54	0.40

The free energy of solvation of both the acid and proton by electrostatic interactions and that of the base, by donor hydrogen bond, which are equal to the free energy of transfer due to electrostatic (ΔG_{el}) and non-electrostatic (ΔG_{nonel}) interactions respectively were calculated for compounds I and III in the presence of each organic solvent (31.60% by wt) (Table 3). It is evident that the ΔG_{nonel} value of the same base becomes less positive on going from acetone→ethanol→methanol. This is in line with the increase in hydrogen bond donor character of the solvent in the same direction. On the other hand, the less positive value of ΔG_{nonel} obtained in the presence of DMF or DMSO with respect to the same percentage of the other solvents can be attributed to the high basicity of these solvents.

The observed red shift in λ_{max} belonging to the base and observed as the proportion of the organic solvent in the medium increases, can be interpreted as follows. Increase of the latter would cause an increase of the free negative charge on the oxygen atom of the base. This is due to the weak tendency of the molecules of the solvent in forming donor hydrogen bond with the oxygen atom relative to water moleucles. This in turn will reflect itself in the increase of the intramolecular charge transfer from oxygen atom to the delocalized molecular orbital of the pyridinium (I, II) and quinolinium (III, IV) cations (*i.e.* increase of the induced dipole moment of the molecule), and thus a lower excitation energy is required. This behaviour can be considered as further evidence for the fact that the donor hydrogen bond from solvent molecules to the base is important in the ionisation process of the hydroxystyryl derivatives.

Effect of Molecular Structure on pK_a. The results (Tables 1 and 2) show that the pK_a values of the 1-ethyl-2-(hydroxystyryl)quinolinium iodides (III, IV) are smaller than the corresponding ones belonging to the 1-ethyl-2-(hydroxystyryl)pyridinium iodides (I, II). This is presumably due to the high co-planarity of compounds III and IV resulting from the greater bulk of the heterocyclic moiety attached to the -CH=CH- centre. This leads to an increase in the intramolecular CT from the phenyl moiety, affording a lower negative charge density on the aromatic system resulting in weaker bonding of the proton (low pK_a value).

The pK_a values of the 4-hydroxy derivatives (I,III) are greater than the ones belonging to the 2-hydroxy derivatives (II, IV). This is probably due to the high inductive effect of the OH group on 2-position of styryl group which facilitates liberation of the proton from the compound (low pK_a value).

Temperature and Composition Dependences of Transport Processes in Glass-forming Molten Mixtures of $Zn(NO_3)_2 \cdot 6.27H_2O$ and $CoCl_2$

Nurul ISLAM,* Kunwar Pal SINGH, and Satendra KUMAR
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India

(Received May 31, 1978)

Density, viscosity, and electrical conductivity of glass-forming mixtures of zinc nitrate hexahydrate and anhydrous cobalt chloride were measured as functions of temperature and concentration. Non-Arrhenius temperature dependence of equivalent conductance, Λ and fluidity, ϕ has been discussed in terms of a three parameter equation derived from Adam-Gibbs model. A linear correlation has been obtained between the preexponential parameter, A_Y and the ideal glass transition temperature, T_0. The composition dependence of Λ and ϕ has been described by the expression derived from the Adam-Gibbs equation on the criteria of constant T/T_0, where T is the absolute temperature, and a modification to this expression has been made. An attempt has been made to describe the concentration dependence of $\Lambda\eta$ product in terms of modified Adam-Gibbs equation.

Much attention has been paid to describe the variation in mass transport properties of glass-forming melts with temperature. In doing so, several empirical and theoretical expressions[1-5] have been developed. On the other hand, expressions for describing the concentration dependence of transport properties are still in the process of development. In recent communications,[3,6,7] such expressions by modifying the basic equations for explaining the temperature dependence of transport behaviors of mixtures of molten salts have been proposed. The purpose of the present investigation on $Zn(NO_3)_2 \cdot 6.27H_2O$–$CoCl_2$ glass-forming melts is to test the applicability of these concentration-dependent equations and to improve them accordingly. Importance of selecting such systems has been discussed elsewhere.[3]

Experimental

Zinc nitrate hexahydrate (BDH; mp 36.4 °C) was used as solvent in molten state and the solute, anhydrous cobalt chloride was added to it at about 50 °C, to prepare mixtures of molten salts of several concentrations. Anhydrous cobalt chloride was prepared[8] from the recrystallized hexahydrate salt using purified thionyl chloride (Riedel). Water of crystallization of hydrated zinc nitrate was estimated volumetrically[9] before using in sample preparation. The ratio H_2O/Zn^{2+} was found to be 6.27. Accuracy of such an analysis was checked by taking hydrated calcium nitrate of known H_2O/Ca^{2+} ratio and was found to be within ± 0.01.

Densities were measured using pycknometer of 0.01 ml divisions. Viscosities and electrical conductivities were measured with calibrated Cannon-Ubbelohde viscometer[10] (β=6.26 cSt/s) and a Philips Model PR 9500 conductance bridge along with capillary-type cell[11] (cell constant= 758.5 cm^{-1} at 25 °C), respectively. Overall accuracy of these measurements were estimated to be better than $\pm 2.5\%$. Measurements were made in a descending as well as in an ascending order of temperature ranging between 298 to 358 ± 0.02 K.

Results and Discussion

It may be interesting to compare the extent of dissolution of $CoCl_2$ in molten $Zn(NO_3)_2 \cdot 6.27H_2O$ and $Cd(NO_3)_2 \cdot 4.1H_2O$.[7] Anhydrous $CoCl_2$ dissolves up to approximately 30 mol % in the former and approximately 12 mol % in the latter case. The difference in the solubilities of $CoCl_2$ in these molten solvents may be due to the presence of associated species like MNO_3^+, where M=Cd^{2+} and Zn^{2+}. Addition of anhydrous solute to the above hydrated melts appear to facilitate the formation of MNO_3^+ species through the dehydration of an equivalent amount of hydrated cations, $M(H_2O)_n^{2+}$. The maximum solubility of $CoCl_2$ may refer to the optimum concentration of MNO_3^+ obtained. Accordingly, higher solubility of $CoCl_2$ in $Zn(NO_3)_2 \cdot 6.27H_2O$ than in $Cd(NO_3)_2 \cdot 4.1H_2O$ is inferred to a higher association constant for $ZnNO_3^+$ than for $CdNO_3^+$ species. Furthermore, difference in the number of water molecules coordinated to the metallic cations may also be responsible for the difference in solubilities of $CoCl_2$ in these solvents.

The temperature dependence of measured densities of $Zn(NO_3)_2 \cdot 6.27H_2O$–$CoCl_2$ systems was found to be linear (*cf.* Table 1). The fluidity, ϕ and equivalent conductance, Λ show non-Arrhenius temperature behaviors in the range 298 to 358 K (*cf.* Table 2). These data can be expressed by the following expression,[5] when the exponential parameter, k_Y is almost constant:

$$Y = A_Y \exp\left[-k_Y/T \ln (T/T_0)\right], \quad (1)$$

where, $Y=\phi$ or Λ and A_Y, k_Y, and T_0 are empirical parameters. The values of the best fit parameters obtained in the condition described above are displayed in Table 3 along with standard deviation in Y. Plots of log Y *vs.* $1/T \ln (T/T_0)$ (Fig. 1) show linear relationship indicating the applicability of the above equation to the present system.

The values of A_ϕ and A_Λ decrease linearly with increasing composition of $CoCl_2$, whereas T_0 increases (Fig. 2). Such variations in A_ϕ, A_Λ, and T_0 are in accordance with the explanations given earlier.[3,6,12]

Based on the nature of composition dependences of A_Y and T_0, they may be correlated[13] as

$$A_Y = \alpha - \beta T_0, \quad (2)$$

where $\alpha = A_{0Y} + T_{0(0)} Q_{1Y}/Q_{2Y}$, and $\beta = Q_{1Y}/Q_{2Y}$. A_{0Y} and $T_{0(0)}$ are the values of A_Y and T_0 for the pure solvent, respectively. Q_{1Y} and Q_{2Y} are the slopes of the linear plots (Fig. 2) of A_Y and T_0 *versus* composition, respectively. Such an observation may be visualized through the inverse relationship[6] between preexponential factor, A_Y and the rigidity of the system and also the direct dependence[3,14] of ideal glass transition

A_Y terms with T_0 linearly but inversely. Linear plots of $A_{Y(=\phi \text{ or } \Lambda)}$ *versus* T_0 (an average of $T_{0,\phi}$ and $T_{0,\Lambda}$ has been taken) (Fig. 3) further emphasize the validity of Eq. 2.

To describe the composition dependence of transport processes, an isoenergetic equation was suggested in earlier publication[6] based upon the Vogel-Tammann-Fulcher equation. However, Eq. 1 which is based upon Adam-Gibbs model is more satisfactory in describing the physical changes in the properties of fused salts and supercooled liquids. In view of this notion Eq. 1 was modified recently[7] by considering T_0 as the basis for the corresponding temperature, T and at T/T_0=constant=c, to

$$Y = A_Y \exp[-k_Y/T_0 c \ln c], \quad (3)$$

and by substituting the linear variations[6] of A_Y and T_0 we obtain

$$Y = (A_{0Y}-Q_{1Y}N) \exp[-k_Y/(T_{0(0)}+Q_{2Y}N)c \ln c], \quad (4)$$

where the symbols have their usual significances. To test the applicability of Eq. 4, the values of $Y(=\phi$ or $\Lambda)$ at constant, c=1.5 were calculated from Eq. 3 and were in turn least-squares fitted to Eq. 4. Computer fitted values of empirical constants, A_{0Y}, $T_{0(0)}$, Q_{1Y}, and Q_{2Y} are given in Table 4. The linearity of the plots of $\log[(A_{0Y}-Q_{1Y}N)/Y]$ *versus* $1/(T_{0(0)}+Q_{2Y}N)$ which pass through origin (Fig. 4) supports the feasibility of Eq. 4. However, it may be noted that Eq. 4 is not capable of correlating directly the measured transport data with the composition. A prior calculation of the transport property at constant c value is

necessary and in order to remove this difficulty an alternative expression may be written as

$$Y = (A_{0Y} - Q_{1Y}N) \exp\{-k'_Y/T \ln [T/(T_{0(0)} + Q_{2Y}N)]\}. \quad (5)$$

The measured fluidity and equivalent conductance data at all concentrations were least-squares fitted to Eq. 5 and reasonably good fits were obtained. The values of empirical parameters, A_{0Y}, k'_Y, $T_{0(0)}$, Q_{1Y}, and Q_{2Y} are given in Table 5 and were found to be very close to those obtained from the corresponding plots. Furthermore, linear plots (Fig. 5) of $\log [(A_{0Y} - Q_{1Y}N)/Y]$ *versus* $1/T \ln [T/(T_{0(0)} + Q_{2Y}N)]$ provide graphical support to the validity of Eq. 5. Thus, we are able to describe satisfactorily the composition dependence of transport processes without depending upon the measurements as a function of temperature in the entire range of composition.

Having examined the individual behaviors of viscosity and electrical conductivity, their simultaneous representation may similarly be analysed. Walden's rule, $\Lambda\eta$=constant, fails to hold good in the cases of molten salt systems and is found to change both with temperature and concentration. The temperature dependence of $\Lambda\eta$ product for the system under investigation may quantitatively be described by the relations,[3,6]

$$\Lambda\eta = A_1 \exp [B_1/(T - T_0)] \quad (6)$$

and,

$$\Lambda\eta = A_2 \exp\left[B_2/(V-V_0)\right], \qquad (7)$$

essentially based upon the "Vogel-Tammann-Fulcher" (VTF) and the "Doolittle" equations, respectively. The empirical parameters A_1, B_1, A_2, and B_2 are the resultant of those for the individual Λ and η values in the VTF and the Doolittle equations. V is the molar volume and V_0 is the intrinsic volume at the ideal glass transition temperature, T_0. The values of the best-fit parameters for Eqs. 6 and 7 are given in Table 6. The computed values of the parameters $T_{0,\Lambda\eta}$ and $V_{0,\Lambda\eta}$ were in good agreement with those obtained independently from fluidity and conductance data, *i.e.*, $T_{0,\phi,\Lambda}$ and $V_{0,\phi,\Lambda}$ values, respectively, emphasizing further the thermodynamic nature of these parameters.

Moreover, the nature of $\Lambda\eta$ product may also be explained by Frenkel equation, $\Lambda^n\eta$=constant, K, where n is the ratio of activation energies for the viscous and the conductance flows, E_η/E_Λ. The least-squares fitted values of the parameters for this equation are given in Table 7.

An attempt has been made here to understand the composition dependence of the Walden product. It is worthy to note a monotonous decrease in $\Lambda\eta$ with increasing composition (Fig. 6) and is different from

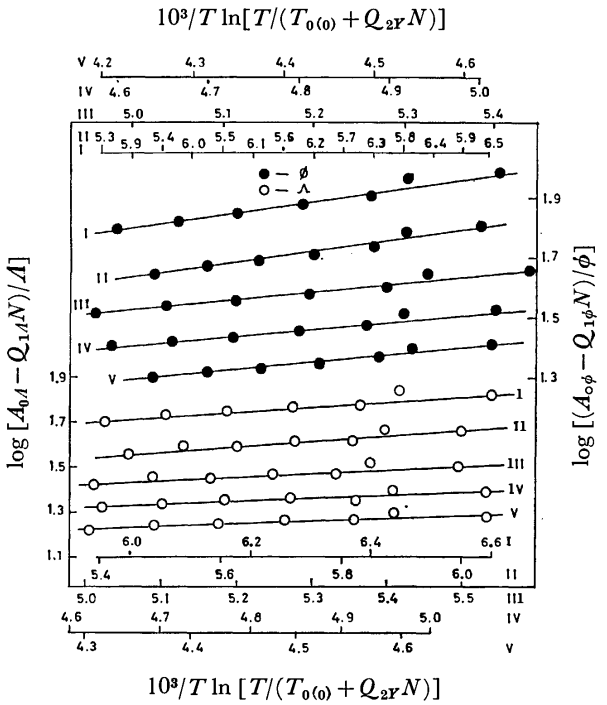

Fig. 5. Plots of $\log\left[(A_{0Y}-Q_{1Y}N)/Y\right]$ *vs.* $1/T$ $\ln\left[T/(T_{0(0)}+Q_{2Y}N)\right]$ for $Zn(NO_3)_2 \cdot 6.27H_2O$-$CoCl_2$ melts (I: 308 K, II: 318 K, III: 328 K, IV: 338 K, V: 348 K).

the behavior reported in $Ca(NO_3)_2 \cdot 3.91H_2O+CoCl_2$ and in $(C_4H_9)_4NI+CoCl_2$ melts.[3,15] As equivalent conductance decreases with increasing the composition of $CoCl_2$, the variation of $\Lambda\eta$ product of the present system seems to be mainly determined by the value of Λ. However, as the concentration increases the amount of decrease in $\Lambda\eta$ lessens thereby reflecting the contribution of viscosity as well.

Equation 5 may be written as

$$\Lambda\eta = \left(\frac{A_{0\Lambda}-Q_{1\Lambda}N}{A_{0\phi}-Q_{1\phi}N}\right)\exp\left[\frac{k'_\phi-k'_\Lambda}{T\ln[T/(T_{0(0)}+Q_{2Y}N)]}\right] \qquad (8)$$

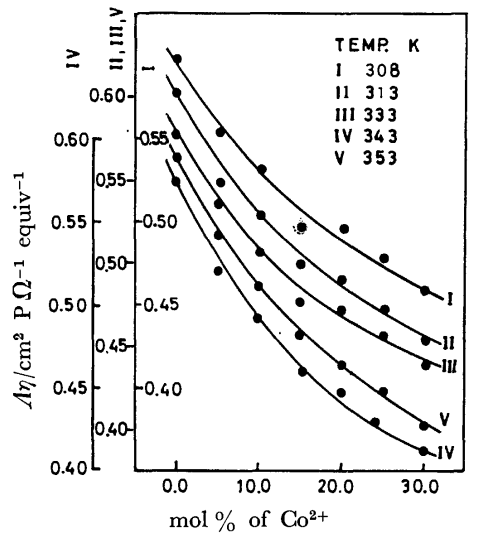

Fig. 6. Variation of $\Lambda\eta$ product with composition for $Zn(NO_3)_2 \cdot 6.27H_2O$-$CoCl_2$ melts.

for describing the composition dependence of $\Lambda\eta$ product. The ratios of the variation of A_Λ and A_ϕ with N seems to be almost independent of composition as the slopes of A_Λ and A_ϕ *vs.* N are nearly equal (Fig. 2). This indicates that the similar species are taking part in the processes of conductance and viscous flows as suggested earlier.[16] Adam and Gibbs[5] also suggested that identical species are responsible for the two kinds of flow. Therefore, the contribution of preexponential factor towards the variation of $\Lambda\eta$ with concentration seems to be negligible and Eq. 8 may be approximated to

$$\Lambda\eta = \left(\frac{A_{0\Lambda}}{A_{0\phi}}\right)\exp\left[\frac{k'_\phi - k'_\Lambda}{T\ln[T/(T_{0(0)}+Q_{2Y}N)]}\right]. \quad (9)$$

From above equation it is apparent that the difference in k_Y terms is almost constant while the denominator of the exponential term decreases with increase in concentration at a given temperature thereby resulting in a monotonous increase in the $\Lambda\eta$ product which is contrary to the observed trend. Instead, the ratio of activation energies for flow processes, $E_\phi/E_\Lambda = n$ is greater than unity, also the value of n increases with the increase in concentration of $CoCl_2$ may be responsible for the overall decrease of the $\Lambda\eta$ product with composition.

Authors are thankful to Professor W. Rahman, Head of the Department of Chemistry, for providing necessary research facilities. Financial assistance of CSIR (India) to two of them (K.P.S. and S.K.) is gratefully acknowledged. Authors are also thankful to Dr. Ismail K for his valuable suggestions during the progress of this work.

Solvent Extraction and Spectrophotometric Determination of Palladium with 3-(2-Hydroxy-5-methylphenyl)-5-(*p*-methoxyphenyl)isoxazoline

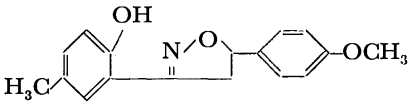
B. K. Deshmukh* and R. B. Kharat

Department of Chemistry, Nagpur University, Nagpur 440010, India

(Received December 23, 1977)

3-(2-Hydroxy-5-methylphenyl)-5-(*p*-methoxyphenyl)isoxazoline (HMPAO) is used for the simultaneous extraction and direct photometric determination of palladium. About 46 μg of palladium was quantitatively extracted at pH 1.0—2.0 with 10 ml of 1.0×10^{-3} M HMPAO in isobutyl alcohol as a yellowish complex. It was measured spectrophotometrically at 332 nm. The system conformed to Beer's law over the concentration range 1.0—20.0 μg of palladium per ml. The colour of the complex was stable for more than 48 h. Palladium was extracted quantitatively and was determined in the presence of large excess of ions which are associated with it. The extractable species was 1:2 (Pd: HMPAO) in nature. The equilibrium constants were determined according to the methods of Yatsimirskii and Leden with suitable modification.

3-(2-Hydroxy-5-methylphenyl)-5-(*p*-methoxyphenyl)-isoxazoline (HMPAO) is the isomer of 2'-hydroxy-4-methoxy-5'-methylchalcone oxime (HMMCO). The latter has been widely used and studied for the extraction of palladium[1-3] and copper.[3,4] HMPAO has the structural formula



The above reagent forms a light yellow complex with palladium around pH 2.0 which can be measured spectrophotometrically at 332 nm.

The present paper deals with extraction studies of palladium with HMPAO in isobutyl alcohol. The proposed method for determination of palladium is simple, selective and sensitive.

Experimental

Apparatus and Reagent. A model DU 2 Beckman spectrophotometer with 10.0 mm quartz cells, and a model LI-10, ELICO pH meter with glass electrode and saturated calomel electrode and a Ganson Shaker were used.

HMPAO was synthesised from 2'-hydroxy-4-methoxy-5'-methylchalcone as per the method of Borkhade[5] and was crystallised from ethanol. About 0.002 M reagent in isobutyl alcohol was used. Fresh solutions were used.

A stock solution of palladium was prepared by dissolving chloride-free palladium hydroxide obtained from 1 g palladium chloride (Johnson-Matthey) in perchloric acid and was standardized gravimetrically with dimethylglyoxime.[6] The dilute solutions were prepared by appropriate dilution.

General Procedure. An aliquot of solution containing about 46 μg of palladium was taken. After addition of water, the pH of the solution was adjusted to 2.0 with 0.1 M perchloric acid or sodium hydroxide and was made to 10 ml volume. It was then transferred into a 250 ml separatory funnel. The solution was equilibrated with 10 ml of 1.3×10^{-3} M HMPAO in isobutyl alcohol for about 10 min. The light yellow organic phase was measured spectrophotometrically at 332 nm against a reagent blank similarly processed. The amount of palladium was then calculated from the calibration curve.

For interference studies a solution containing the desired ion was added before the pH adjustment.

Table 1. Spectral properties of HMPAO in isobutyl alcohol

λ_{max} / nm	Molar extinction coefficient $\times10^{-4}$	Beer's law range $\times10^{5}$ M
230	2.85	0.4—5.5
258	0.96	0.2—17.0
312	0.50	1.0—23.0

Results and Discussion

Absorption Spectra of HMPAO. The reagent HMPAO exhibits peaks of absorption at 230, 258, and 312 nm in isobutyl alcohol. Spectral data are given in Table 1.

Distribution of Reagent. A 10 ml solution of HMPAO of known concentration, $[HMPAO]_{tot}$, in the isobutyl alcohol was equilibrated with equal volume of aqueous solutions at pH 1.0—12.5 and ionic strength 0.2 M ($NaClO_4$). The concentration of HMPAO in the organic phase, $[HMPAO]_{org}$ was determined by noting the absorbance of the solution at 258 nm against the similarly processed solvent as a blank and reading from the calibration curve. The distribution ratio of HMPAO is thus:

$$D_R = [HMPAO]_{org}/[HMPAO]_{tot} - [HMPAO]_{org}.$$

The results of HMPAO for isobutyl alcohol and water system are shown in Fig. 1. The distribution decreases above pH 11.0 which may be due to dissociation of the phenolic –OH.

Proton-Ligand Stability Constant of HMPAO. If K_1^H is the proton-ligand association constant and P_R the partition constant of HMPAO, then the distribution ratio D_R can be given by[7]

$$1/D_R = 1/P_R + 1/P_R \cdot K_1^H[H^+]. \quad (1)$$

At low pH, $D_R=P_R$, Thus Fig. 1 gives the value of $\log P_R$. The $\log P_R$ for HMPAO between isobutyl alcohol and water becomes 1.82.

The negative slope region of Fig. 1 satisfies the relation

$$\log\frac{(P_R-D_R)}{D_R} = pH - \log K_1^H. \quad (2)$$

This gives the value of $\log K_1^H$ (12.08) for HMPAO (Fig. 2).

Absorption Spectrum of Pd–HMPAO Complex. The

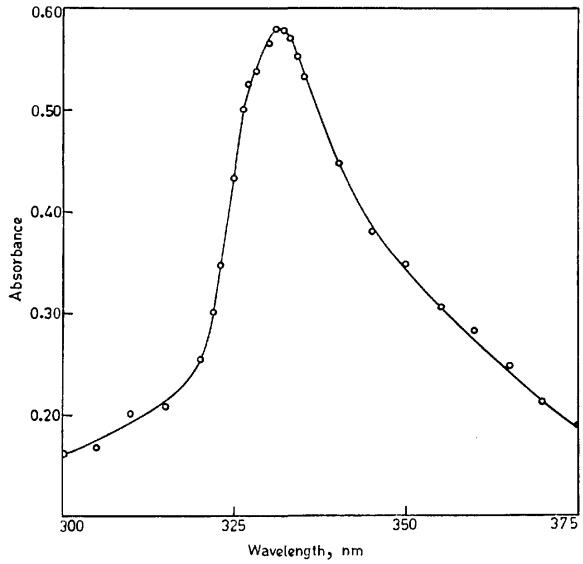

Fig. 3. Absorption spectrum of Pd(II)-HMPAO complex in isobutyl alcohol.

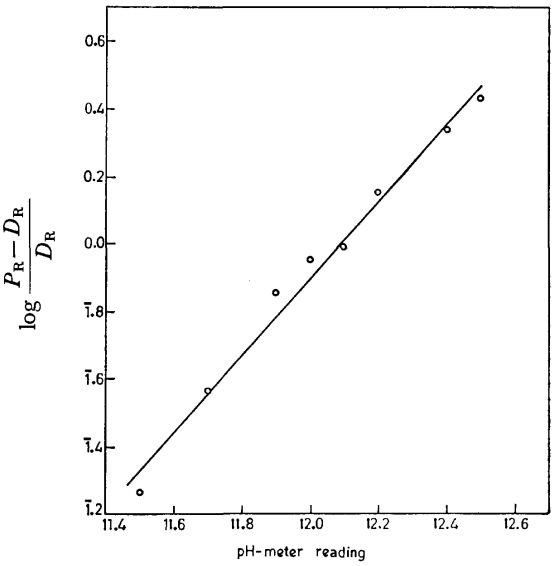

Fig. 2. Plot of $\log \frac{P_R - D_R}{D_R}$ *vs.* pH.

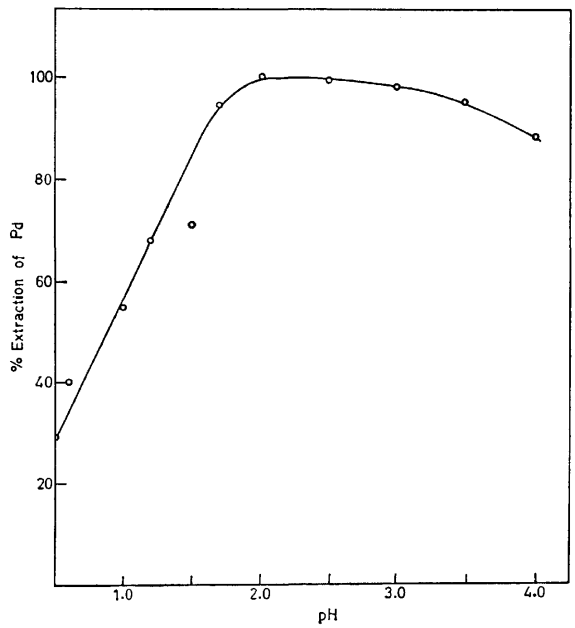

Fig. 4. Effect of pH on extraction of Pd(II).

absorption spectrum of Pd-HMPAO complex (Pd= 46 μg) extracted at pH 2.0 against the reagent similarly processed as a blank is shown in Fig. 3. The light yellow Pd-HMPAO chelate solution shows maximum absorption at 332 nm. The molar absorptivity is 1.3×10^4 at 332 nm and the sensitivity (as per Sandell's definition) is 0.0055 μg/cm^2.

Extraction as a Function of pH. The solvent extraction behaviour of Pd-HMPAO system was studied in the pH range 0.5—6.0 (Fig. 4). It was observed that the extraction is quantitative at pH 2.0. Beyond pH value 2.5 the percentage extraction decreases. Varying amounts of palladium ranging from 1.0 to 20.0 μg per ml were taken. They were extracted at pH 2.0 with 1.3×10^3 M HMPAO in isobutyl alcohol. The light yellow palladium HMPAO system followed Beer's law at 332 nm in the concentration range 1.0—20.0 μg/ml of palladium (Fig. 5). The effective working range from Ringbom curve is 1.0—6.0 μg/ml.

Stability of Colour of the Complex. The absorbance of the coloured complex was measured at interval of 0.5, 8, 16, 24, 48, 96, and 120 h. The value of the absorbance was found to be constant *viz.*, 0.575 until 48 h. The absorbance after 72 h was about 0.500.

Period of Equilibration. With all other factors constant the period of shaking was varied from 2—120 min. The extraction was quantitative when the period of equilibration exceed 10 min.

Effect of Reagent Concentration. The concentration of the reagent was varied from 2.5×10^{-4} to 2.0×10^{-3}M. Extraction was quantitative for the reagent concentration of greater than 1.3×10^{-3} M. It was incomplete

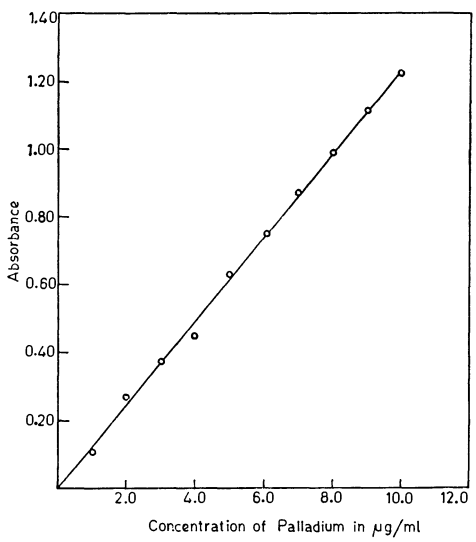

Fig. 5. Beer's law for Pd(II)-HMPAO in isobutyl alcohol.

for lower concentrations of the reagent.

Effect of Palladium Ion Concentration. The effect of Pd concentration on the extraction was examined at different pH values. It was found that the possibility of polymerization can be ruled out in the working range of metal ion concentration 1.0—20.0 μg/ml.

Effect of Ionic Strength. The distribution of palladium was studied at various concentrations of sodium perchlorate (0.2—2.0 M) at pH 2.0. The extent of extraction remains the same up to 0.8 M $NaClO_4$. Above 1.0 M, however, the extent decreases.

Effect of Solvents. Various solvents such as isobutyl methyl ketone, 1-butanol, ethyl acetate, isoamyl alcohol and cyclohexanol were also tried. However, isobutyl alcohol is preferred as it gives a clear separation of the two phases and a less reagent blank absorbance.

Effect of Diverse Ions. The interference of several ions on the extraction behaviour of palladium was studied. The tolerance limit was calculated as the amount necessary to cause ±2% error in the recovery of palladium. The results (Table 2) indicate that moderate amounts of many ions are tolerable. The ions showing strong interference include Cr(III), Sn(II), Ga(III), In(III), Tl(I), and Pt(IV).

Precision and Accuracy. The absorbance obtained for fifteen determinations of 46 μg Pd was 0.575 ±0.005 at 332 nm. Average relative and standard deviations were found to be 1.0 and 1.1%, respectively.

The method is rapid, simple and selective and permits separation and determination of palladium at tracer levels. The entire operation takes only 30 min.

Composition of the Extractable Species. The 1:2 (Pd: HMPAO) composition of the extractable species was determined by Job's[8] method as applied by Irving and Pierce[9] and slope ratio[10] method as modified by Bhatki *et al.*,[11] which was further supported by the distribution data analysis.

Metal-Ligand Formation Constants. The equilibrium constants of Pd–HMPAO chelate were determined from the spectrophotometric data by Yatsimirskii's[12,13] and Leden's[14] methods and are incorporated in Table 3.

It can be seen that the values of $\log k_1$, $\log k_2$, $\log \beta_{ext}$, and $\log \beta_{abs}$ obtained by different methods are in good agreement.

TABLE 3. PRIMARY PARAMETERS AND EQUILIBRIUM CONSTANTS FOR Pd(II)–HMPAO–ISOBUTYL ALCOHOL SYSTEM $\mu=0.2$ M (H^+, Na^+, ClO_4^-): Temperature $=30\pm1$ °C.

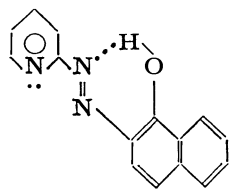
(Received January 23, 1978)

The rare earth complexes of 1-(2-pyridylazo)-2-naphthol (PAN=Hpan) are prepared in the solid state. The analytical, molecular weight and differential thermal analysis data of the complexes indicated the metal-ligand ratio as 1:3 with the general formulae $Ln(pan)_3 \cdot H_2O$ (Ln=Pr^{3+}, Nd^{3+}, and Sm^{3+}) and $Ln(pan)_3$ (Ln=La^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, and Yb^{3+}). Based on IR, UV, and visible absorption spectra, electrical conductance and magnetic susceptibility data, an octahedral structure having the metal ion bonded through nitrogen of azo and oxygen of carbonyl groups of the ligand has been postulated to these complexes.

The solvent extraction and the potentiometric studies of the complexes of lanthanoids with 1-(2-pyridylazo)-2-naphthol(I), (hereafter referred as PAN=Hpan) have been reported in the literature.[1-4] Besides, PAN has also been used for the detection and the spectrophotometric determination of a large number of metal ions.[5-11] But the synthesis and the characterization of its rare earth metal complexes in the solid state have not so far been reported. In this communication we report



I

the preparation of the lanthanoid complexes of PAN in the solid state. Their probable structures have been established using analytical, IR, UV, and visible spectra, magnetic moment, conductivity, differential thermal analysis, and molecular weights data.

Experimental

All the chemicals used are of Analar or chemically pure grade. PAN (Riedel) was recrystallised from ethanol.[12]

Preparation of the Complexes. On slowly mixing a solution of 1 mmol of rare earth chloride in ethanol (10 ml) with a solution of 1 mmol of PAN in ethanol (40 ml) and adjusting its pH between 8 and 10 by dropwise addition of NaOH solution(0.1 M),** a dark red coloured thick precipitate was obtained. The slurry was then cooled to about 3—4 °C and kept at this temperature for 24 h. The precipitate was separated by centrifugation and it was then extracted several times with ether until the ether layer acquired no colour. The combined ethereal extract was evaporated to dryness whereby the red coloured complex of the lanthanoid was obtained. It was then kept in vacuum desiccator for about 24 h and analysed. Yield 20—25%.

In the above preparation the amount of PAN added to the metal ion solution was always less than the stoichiometric amount (1:1, in place of 3:1). If excess PAN was used, it gets extracted along with the complex into the ether layer which was difficult to remove. By using excess lanthanoid salt, its hydroxide which precipitates along with the metal complex remained unextracted in the ethereal layer.

Analysis. The analyses of the metal ions were carried out gravimetrically by the standard oxalate method.[13,14]

Carbon, hydrogen and nitrogen analyses were performed by the Micro Analytical Section of the Indian Institute of Technology, Kanpur. The analytical results are given in Table 1.

Measurements. The molecular weights of the complexes were determined cryoscopically. The measurements were carried out in purified benzene. The results are given in Table 1.

Magnetic susceptibility measurements were made using a Gouy balance at room temperature (28 °C). Mercury tetrathiocyanatocobaltate(II) was used as a calibrant. The results are given in Table 1.

The conductivity of the complexes were measured in *N,N'*-dimethyl formamide using Philips PR 9500/90 type Conductivity Measuring Bridge. The results are given in Table 2.

The electronic spectra of the ligand and the complexes were obtained in chloroform solutions using a Cary Model 14 Recording spectrophotometer. Their IR spectra were recorded with a Perkin-Elmer 521 Infrared Diffraction Grating spectrophotometer in 4000—250 cm^{-1} range. The samples were prepared as KBr pellets. Positions and assignments of the IR spectral bands of the ligand and the complexes are given in Table 3.

The differential thermal analytical curves were taken on DTA-02 UNIVERSAL (VEB Laborelektronik, Halle, DDR).

Results and Discussion

The analytical data of the complexes indicate the metal ligand ratio as 1:3 with the general formulae $Ln(C_{15}H_{10}N_3O)_3 \cdot H_2O$ (Ln=Pr^{3+}, Nd^{3+}, and Sm^{3+}) and $Ln(C_{15}H_{10}N_3O)_3$ (Ln=La^{3+}, Eu^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Yb^{3+}, and Gd^{3+}). Their monomeric nature in solution is confirmed by the experimental values of the molecular weights (Table 1).

The equivalent conductance values of the complexes in DMF at 28 °C when compared with those already reported[15] indicate that they are non-electrolytes. This is further supported by their insolubility in water, and high solubility in most of the non-aqueous solvents like $CHCl_3$, CCl_4, ether, C_6H_6, *etc.* These complexes when dissolved in organic solvents are not very stable and the deep red coloured solution gradually changes to orange yellow.

PAN has been reported to be a tridentate ligand where the bonding sites to the metal ion are oxygen of the hydroxyl group after deprotonation, azo and the pyridine nitrogen atoms.[8,16-18] In order to investigate the bonding sites in the complexes the spectral and the magnetic studies have been carried out.

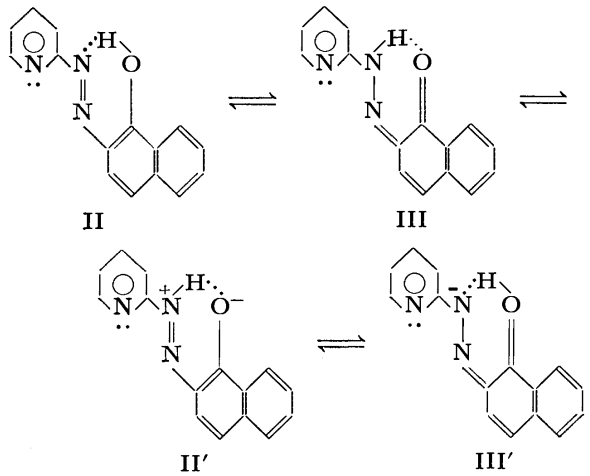
1450	1390—1375	ν(N=N)
1230	—	δ(C-O-H)
1615, 1600, 1525, 1415, 1325, 1310, 1270, 1150, 1040, 995, 880, 850, 800, 780, 765	Same position as in the spectrum of PAN (± 5 cm^{-1})	Bands due to pyridyl and naphthyl rings
—	450—555	Two bands due to ν(M-N) + ν(M-O)

Infrared Spectra. Although the spectra of PAN and its chelates are complicated owing to the extensive overlap of a number of bands arising due to ν(N=N), ν(C=N), ν(C=C), ν(C-H) and other bending modes in the region below 1700 cm^{-1}, the systematic shifts in the positions of a few ligand bands in the spectra of the complexes suggest the probable modes of bonding in the complexes. Some of these major shifts along with the conclusions drawn from them are given below.

a) The absorption bands observed at 3020 and 3080 cm^{-1} in the spectrum of PAN are due to ν(C-H). These bands are stable in position as well as in intensity when one goes from the ligand to the metal chelates indicating that these are purely due to ν(C-H). It is interesting to note that instead of a well defined band, only a very broad and weak band appeared in the spectrum of the ligand around 3300 cm^{-1} due to ν(O-H). This suggests a strong intramolecular hydrogen bonding in the ligand which was confirmed earlier by NMR studies.[5] In the spectra of all the metal chelates except those of Pr^{3+}, Nd^{3+}, and Sm^{3+}, the intensity of the very broad band further decreased; but in the spectra of Pr^{3+}, Nd^{3+}, and Sm^{3+} chelates, the weak and broad band was evident indicating the presence of water molecule in these chelates.

b) The ligand molecule can exist in equilibrium both in azo and hydrazone forms as shown in II and III. An intense band observed at 1620 cm^{-1} in the

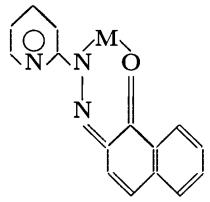


II III

II′ III′

spectrum of the ligand may be due to ν(C=O) of the hydrogen bonded ring systems of the hydrazone form. Although the carbonyl band normally should appear around 1700 cm^{-1}, such a bathochromic shift

is observed in hydrogen bonded ring systems.[19-20] The band at 1620 cm^{-1} in the ligand is shifted to lower frequencies (1550—1555 cm^{-1}) in the metal chelate spectra as a result of the involvement of the C=O··· linkage in metal chelate ring as shown in IV.



IV

c) The absorption bands due to azo linkage are generally observed at 1410 and 1570 cm^{-1}.[21] The main difficulty in the assignment of a frequency to azo linkage is that the band due to ν(N=N) would overlap with other absorption bands such as those of pyridine and/or naphthol rings. However, the positions of the two bands at 1570 and 1450 cm^{-1} present in the ligand spectrum are shifted to 1510 and 1375 cm^{-1}, respectively. These shifts suggest the linkage of the metal ion with the azo group of the ligand. Since the positions of the other pyridine bands are not changed in the spectra of the chelates, it further suggests that the pyridine moiety of the ligand is possibly not involved in bonding.

d) A band at 1230 cm^{-1} present in the spectrum of the ligand was missing from the spectra of all the chelates. Hadzi[22] has assigned a band at 1272 cm^{-1} in the spectra of similar azo compounds to the in-plane bending mode of C–O–H group. It is possible that the band at 1230 cm^{-1} may arise due to the in-plane bending mode of C–O–H and the fact that the corresponding band is missing in the spectra of metal chelates suggests the deprotonation of the C–O–H group for the bond formation. This is essential in order to keep a charge balance between the metal ion and the ligand molecules.

e) Two new bands appeared in the spectra of all the chelates between 450 and 550 cm^{-1}. They may be coupled bands having contributions from both ν(M–O) and ν(M–N).

The IR spectral study, thus, suggests the bonding of the metal ions with the oxygen atom of the carbonyl and the nitrogen of the azo groups of the ligand.

Electronic Spectra. The positions of absorption bands in the spectrum of PAN in the aqueous and non-aqueous media corresponded with those given in the literature.[7] It presented three well defined broad maxima in the visible region (555, 480, and 415 nm) besides other bands due to pyridine and 2-naphthol moiety in the UV region. The 480 nm band has two shoulders one at 465 nm and the other at 510 nm. The peaks at 555 and 510 nm may be attributed to the hydrazone form (III and III′) whereas the short wave maxima (480, 465, and 415 nm) due to azo (II and II′) chromophore.[22-25] In the spectra of all the chelates the bands at 555 nm and the shoulder band at 510 nm are intensified to a very large extent. Further, the shoulder band at 465 nm and the one at 415 nm showed a bathochromic shift ($\approx$10 nm). There was also a lowering in the intensity of the band at 460 nm. The positions of all the bands in the UV region remained practically constant. It, therefore, appears that in the chelate formation, the nitrogen atom of the azo group and the oxygen atom of the C–O–H group after deprotonation are taking part. It is interesting to note that the relative increase in the intensity of 555 and 510 nm bands and also the relative decrease in the intensity of 465 nm band compared to that of 485 nm band decreases with the increase in the atomic number of the metal ion. Similar effect is observed in the bathochromic shift of the 465 and 415 nm bands (the higher the atomic number, the lower the shift). This correlation may be due to the fact that the interaction of the metal ion decreases with the increase in atomic number.

The bands due to f-f transitions corresponding to the metal ions could not be located in the spectra of the chelates. This is what one should expect because the bands due to metal ions will be very weak ($\varepsilon\approx$ 1—10) and they will be masked by the intense bands of the ligand molecule.

Magnetic Moments. The values of the magnetic moments of the complexes are summarized in Table 1. These values compare very well with those measured for other simple compounds[26] and those calculated for the uncomplexed ions.[27,28] The relatively small differences from the calculated values of Van Vleck suggest either minor or no involvement of the 4f orbitals in the bonding.

The differential thermal analysis curves indicated in general the decomposition of the complexes around 250—300 °C. In case of Pr^{3+}, Nd^{3+}, and Sm^{3+} complexes a dehydration step beginning at about 80 °C is observed indicating the presence of water molecule in these complexes as water of hydration.

Thus, on the basis of the above studies, the octahedral structure of the complexes having metal ion bonded through nitrogen of azo and oxygen of carbonyl group of the ligand has been proposed.

The authors wish to thank Apache Chemicals, Inc. Illinois (USA) for providing rare earth oxides as gift. One of us (I. M. Rao) thank the Council of Scientific and Industrial Research, New Delhi, India, for the award of Junior Research Fellowship.

Extraction-Spectrophotometric Determination of Vanadium(V) Employing N^1-Hydroxy-N^1,N^2-diarylbenzamidines and Various Adduct-forming Substances

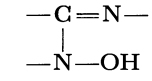
K. S. PATEL* and R. K. MISHRA

Department of Chemistry, Ravishankar University, Raipur, M.P., India

(Received March 13, 1978)

The reactions of 16 newly synthesized N^1-hydroxy-N^1,N^2-diarylbenzamidines with vanadium(V) in presence of various adduct-forming substances have been investigated photometrically in chloroform. The present study indicated the formation of 1:2:1 metal:reagent:acetic acid or phenol and 1:2:2 metal:reagent:thiocyanate complexes. On the basis of strong synergism, which is attributed to mixed-complex formation, simple, rapid, sensitive and selective methods for the spectrophotometric determination of microgram quantities of vanadium(V) have been developed. The influence of experimental variables on the procedures have been discussed.

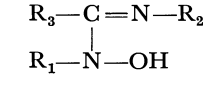
A number of monobasic and bidentate chelating agents[1-15] react with vanadium(V) to form 1:2 (metal: ligand) complex having a basic V=O group and an acidic V–OH group in the same molecule. The basic V=O group reacts with acidic substances like carboxylic acids, hydrogen chloride, phenols *etc.* to produce hyper- and bathochromic effects. N^1-Hydroxy-N^1,N^2-diarylbenzamidines, a new type of monobasic and bidentate chelating agents possessing the function, I, react with



Formula I.

vanadium(V) to form coloured 1 : 2 (metal : ligand) complexes. It is very likely that the basic V=O group of the complexes reacts with acidic substances such as acetic acid, phenol, *p*-chlorophenol and 2-naphthol to produce hyper- and bathochromic effects in chloroform solution, accompanied by synergism. The formation of both 1:2:1 (metal:ligand:acetic acid or phenol) and 1:2:2 (metal:ligand:thiocyanate) complexes is adaptable to the development of sensitive and selective methods for the spectrophotometric determination of traces of the metal.

The selectivity of the method for vanadium(V) employing N^1-hydroxy-N^1,N^2-diarylbenzamidines enables the direct determination of vanadium in steels and other materials.[16] This and other excellent qualities of *N*-hydroxyamidines as reagents for vanadium(V) gave us an encouragement to search for better reagents amongst the family of *N*-hydroxyamidines. A number of compounds of the general formula, II, have, therefore, been synthesized and examined as possible reagents for vanadium(V).



Formula II.

R_2 is phenyl, *p*-tolyl, *m*-tolyl, 2,5-dimethylphenyl, or 2-methyl-4-chlorophenyl; R_1 is phenyl, *p*-tolyl, *m*-tolyl, or *p*-chlorophenyl; R_3 is *p*-tolyl.

Of the 16 reagents examined in the present investigation N^1-hydroxy-N^1-(*p*-chlorophenyl)-N^2-(2-methyl-4-chlorophenyl)-*p*-toluamidine hydrochloride (HCPMCPTH), which has the largest molar absorptivity for its vanadium(V) complexes has been studied in detail.

Experimental

Apparatus and Solutions. A Carl Zeiss Specord recording ultraviolet-visible spectrophotometer and an ECIL UV-VIS spectrophotometer model GS-865 equipped with 1-cm quartz and silica cells were employed for recording spectra and absorbance measurements respectively. Systronic pH meter Type-322 was employed for the determination of pH values of the solutions. Twice distilled water and ethanol-free chloroform were used for solution preparations.

A stock solution of vanadium(V) was prepared by dissolving ammonium metavanadate in water and the solution standardized volumetrically with potassium permanganate.[20]

Solutions of cations were prepared from analytical reagent grade chlorides, sulfates or nitrates and those of anions were obtained by dissolving their sodium or potassium salts.

Reagents. N^1-Hydroxy-N^1,N^2-diarylbenzamidines were prepared by the condensation of equimolar quantities of *N*-aryl-*p*-toluimidoyl chloride and *N*-arylhydroxylamine in ether medium.[16,21] The resulting hydrochloride was filtered and crystallized from absolute alcohol. The free bases were obtained by treatment of hydrochlorides with dilute ammonia solution and crystallized from benzene:petroleum ether (2:1). All these compounds gave satisfactory C, H, and N analyses. 0.005 M (1 M=1 mol/dm^3) solutions of these reagents were used for extraction studies.

Procedure. Transfer an aliquot of vanadium(V) solution to a separatory funnel. Add suitable quantity of adduct-forming substance. Dilute to 25 ml with distilled water and add 10 ml of chloroform solution of the reagent. Shake the contents of the funnel vigorously for 2 min and allow the phases to separate. Dry the chloroform extract over anhydrous sodium sulfate and transfer to 25-ml volumetric flask. Dilute the extracts to 25 ml with chloroform and scan the absorption spectrum of the coloured extract against chloroform or reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of vanadium–HCPMCPTH complex in the absence and presence of adduct-forming substances are shown in Fig. 1. When adduct-forming substances are added to chloroform solution of vanadium–HCPMCPTH complex, a hyper- and bathochromic effect is noticed which is attributed to mixed complex formation. The λ_{max} and ε depend on the nature of *N*-hydroxyamidine and the adduct-forming substance. The spectral characteristics of vanadium complexes of HCPMCPTH

Table 1. Spectral characteristics of vanadium-HCPMCPTH complex in the presence of acetic acid, thiocyanate, and phenols

Adduct-forming substance	Optimum acidity ranges of acetic acid / M	Color	λ_{max} / nm	ε / $l\,mol^{-1}\,cm^{-1}$	Optimum concn ranges from Beer's law (Optimum concn ranges from Ringbom plot) ppm of V	Sensitivity $\mu g\,cm^{-2}$ of V	Relative standard deviation[a] / %
Acetic acid	1.0—10.0	BV	580	2900	1.0—16.0 (2.0—13.0)	0.017	±0.80

are recorded in Table 1.

Effect of Reagents Temperature and Time. For complete extraction of vanadium(V), acetic acid system requires a 12 fold molar excess of *N*-hydroxyamidine, whereas the optimal amount of *N*-hydroxyamidine required for quantitative transfer of the metal to organic phase following thiocyanate and phenol systems are 6 and 3 fold molar excess of the reagent respectively. The thiocyanate and phenol systems necessitate 8 and 250 fold molar excess of thiocyanate and phenols respectively for complete extraction of vanadium(V). Order of addition of reagents is not critical. Variation in temperature from 20 to 35 °C does not affect the λ_{max} and absorbance of coloured systems.

The extracts of acetic acid and thiocyanate systems are stable at least 50 and 35 h respectively. The HCPMCPTH–phenol–vanadium complexes are stable in chloroform for at least 30 h at 27±2 °C.

Nature of Adducts. The composition of the adducts were determined by various methods. The ratio of vanadium to *N*-hydroxyamidine was determined by mole ratio[22] and continuous variation methods,[23] and vanadium to adductant by curve fitting method.[24] In the thiocyanate system the ratio of vanadium to thiocyanate was determined by mole ratio method and slope ratio method.[25] The results indicate that V:HOAm:L (acetic acid or phenol) ratio in adduct is 1:2:1 and in thiocyanate system V:HOAm:SCN ratio is 1:2:2 as indicated in the V(V)–8-quinolinol–thiocyanate complex.[26]

N¹-Hydroxy-N¹,N²-diarylbenzamidines as Reagents for Vanadium(V). All the 16 newly synthesized reagents were tested for their potentialities towards the spectrophotometric determination of vanadium(V). Beer's law was tested and confirmed for each system. All these compounds reacted with vanadium in presence of adduct-forming substances in a similar manner with only slight variation in the value of λ_{max} and ε. The vanadium–*N*-hydroxyamidine–acetic acid complexes possess λ_{max} in the range 570—585 nm with molar absorptivities in the range 2900—4300 $l\,mol^{-1}\,cm^{-1}$. The thiocyanato–vanadium complexes of these reagents show maximum absorption at 605—610 nm (ε=5100—6500). The vanadium complexes of the present reagents in the presence of phenol, *p*-chlorophenol and 2-naphthol have absorption maxima at 590—595 (ε=4600—6650), 595—600 (ε=4950—6800), and 590—620 nm (ε=4600—6650) respectively. The substitution of N^1-phenyl group(R_1) or N^2-phenyl group(R_2) with aryl groups has only slight bathochromic effect. Of the various group tested, *p*-chlorophenyl causes highest hyperchromic shift, when attached to hydroxylamine nitrogen atom. Substitution of R_2 with 2-methyl-4-chlorophenyl group results into the highest hyperchromic shift in the thiocyanate, *p*-chlorophenol

and 2-naphthol complexes.

Effect of Diverse Ions. To evaluate the tolerance limits for different ions, solutions containing 4 ppm of vanadium(V) and varying amounts of other ions were analyzed as described above. Absorbance errors above 2% were considered to indicate interference.

In acetic acid system, tungsten(VI) seriously interfered. The system, however, tolerates the presence of the following ions, the tolerance limits of which are given in parentheses(ppm): citrate(500); tartrate(600); fluoride(500); chloride, bromide, nitrate, or sulfate (1500); phosphate(1000); arsenate(400); phthalate (800); triethanolamine or selenate(1000); alkali elements (1500); alkaline-earth elements(1000); lanthanoid elements(1000); Ni^{2+}, Zn^{2+}, Cd^{2+}, or Hg^{2+}(800); Cu^{2+}(600); Co^{2+}(700); Sb^{3+}(750); Bi^{3+}(600), Cr^{3+} (500); Th^{4+}(800); Tl^{3+}(1000); Pb^{2+}(800); Mn^{2+}(700); Fe^{3+}(800); Be^{2+}(1000); Ti^{4+}(20); Zr^{4+}(60), and Mo^{6+} (400).

In *p*-chlorophenol system iron(III) and tungsten-(VI) interfered. However, the interference due to Fe^{3+} was eliminated by masking with trisodium phosphate. The tolerance limits for various ions are shown in parentheses(ppm): Ni^{2+}, Co^{2+}, Zn^{2+}, Cd^{2+} Hg^{2+} (600); Pb^{2+}, UO_2^{2+}(500); Mo^{6+}(200); Zr^{4+}(100); Ti^{4+} (40); Cu^{2+}(200); Bi^{3+}, Fe^{3+}(800); Sb^{3+}(600); Al^{3+}, Cr^{3+}(500), and Th^{4+}(600). Alkali and alkaline-earth elements and lanthanoid elements, chloride, bromide, iodide, fluoride, nitrate, sulfate, citrate, tartrate, arsenate, phosphate, phthalate and borate have no interfering effect.

In thiocyanate system the interference due to Fe^{3+} was removed by masking with trisodium phosphate. The tolerance limits for other ions are indicated in parentheses(ppm): Cr^{3+}, Al^{3+}(500); UO_2^{2+}(400); Zr^{4+}(100); Mo^{6+}(300); Cu^{2+}(200); Co^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, Hg^{2+}(500); Ti^{4+}(60); W^{6+}(20); Fe^{3+}(800); Th^{4+} (800). Alkali metals, alkaline-earths, lanthanoid elements, chloride, bromide, fluoride, nitrate, sulfate, arsenate, phosphate, phthalate, borate, citrate and tartrate have no interfering effect on the determination.

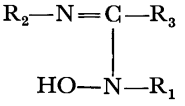
Studies on N^1-Hydroxy-N^1,N^2-diarylbenzamidines as Metal Complexing Agents: Extraction-Photometric Determination of Iron(III) as Thiocyanato and Azido Mixed Ligand Complexes with N^1-Hydroxy-N^1,N^2-diphenyl-*p*-toluamidine(HDPTA)

K. S. PATEL,* Kanak Kanti DEB, and Rajendra K. MISHRA
Department of Chemistry, Ravishankar University, Raipur, M.P., India
(Received June 3, 1978)

N^1-Hydroxy-N^1,N^2-diarylbenzamidines react with iron(III) in presence of thiocyanate and azide forming coloured complexes which are quantitatively extractable in benzene. The extraction of iron(III) as red Fe(III)–L–$(SCN^-)_2$ complex is quantitative at 0.1—0.6 M hydrochloric acid concentration, whereas the Fe(III)–L–$(N_3^-)_2$ complex gets quantitatively extracted into benzene at pH 1.0—2.5. The ternary iron(III)-thiocyanato complex of N^1-hydroxy-N^1,N^2-diphenyl-*p*-toluamidine(HDPTA) has a fairly large molar absorptivity (1.01×10^4 l mol^{-1} cm^{-1}) and the spectrophotometric method based on this colour reaction is highly selective as almost all common ions including Fe(II) do not interfere. The method employing the formation of ternary iron(III): HDPTA: azide complex is also highly selective.

Thiocyanate is frequently used for the spectrophotometric determination of traces of iron(III).[1] This method, which is simple, rapid, fairly sensitive and free from interference of Fe(II), and can be applied in strongly acidic medium, suffers from interference due to a large number of experimental factors. These include time of standing, thiocyanate concentration, non-linearity of Beer's law *etc.* Even the modified method[2] lacks selectivity as various elements such as manganese, zinc, cadmium, copper, nickel, coblat, titanium, uranium, and molybdenum interfere.[3,4] A recent investigation bases the formation of ternary iron(III)–thiocyanate–*N*-hydroxyethylenediamine-*N*,N^1,N^1-triacetate to develop a fairly selective spectrophotometric method,[5] but only at the expense of sensitivity.

N^1-Hydroxy-N^1,N^2-diarylbenzamidines,[6–8] a new type of reagents react with iron(III) forming blue[9] and red-purple[10] pH dependent complexes in ethanol. However, in the presence of thiocyanate these reagents produce an intensely red ternary complex which is quantitatively extractable into benzene from hydrochloric acid solutions. The present paper reports the use of N^1-hydroxy-N^1,N^2-diphenyl-*p*-toluamidine (HDPTA) and 18 analogous compounds possessing the general formula-I, for the extractive-spectrophotometric determination of microgram quantitities of iron(III). The present method is sensitive and highly



Formula I.

R_3 is *p*-tolyl; R_2 is phenyl, *p*-tolyl, *m*-tolyl, 2,5-dimethylphenyl, 2-methyl-4-chlorophenyl, or 2-methyl-5-chlorophenyl; R_1 is phenyl, *p*-tolyl, *m*-tolyl, or *p*-chlorophenyl.

selective as Fe(II) and almost all common ions including those which usually interfere with the parent thiocyanate method and other literature methods[11] do not interfere. The present paper also describes a new spectrophotometric method based on the benzene extraction of iron(III) as its ternary HDPTA and azide complex. This method, though relatively less sensitive is also very selective.

Experimental

Apparatus. A Carl-Zeiss 'Specord' UV-VIS spectrophotometer and an ECIL UV-VIS spectrophotometer model GS-865 with 1-cm matched quartz and silica cells were employed for recording the spectra and absorbance measurements respectively. A Systronic pH meter type-322 was used for determination of pH values.

Standard Iron(III) Solution. Stock solution of iron(III) was prepared by dissolving about 0.62 g of pure iron wire(E. Merck) in 50 ml of 1:3 nitric acid. It was boiled to expel oxides of nitrogen and diluted to 1 litre. This solution was standardised gravimetrically employing 8-quinolinol.[12]

One percent aqueous solutions of potassium thiocyanate and sodium azide were also prepared. All the chemicals used were of analytical reagent grade.

Preparation of N-*Hydroxyamidines.* N^1-Hydroxy-N^1,N^2-diarylbenzamidines were prepared by condensation of equimolar quantities of *N*-aryl-*p*-toluimidoyl chloride with *N*-arylhydroxylamine in ether.[13,14] The resulting hydrochloride was filtered and treated with dilute ammonia to liberate the free base. The free bases were recrystallised from petroleum ether (60—80 °C): benzene (1:2) and the hydrochlorides were crystallised from absolute ethanol. All these compounds showed infrared spectral bands characteristic of N^1-hydroxy-N^1,N^2-diarylbenzamidines.[13,14]

Solutions of *N*-hydroxyamidines (0.1%) in benzene were used for extraction purposes.

Procedure. Place an aliquot (10 ml) of iron(III) solution containing 50—120 μg of the metal in a separatory funnel. To this, add 5 ml of 1% potassium thiocyanate/sodium azide solution. Adjust the acidity to the required value and dilute to 25 ml. Introduce 25 ml of benzene solution of N^1-hydroxy-N^1,N^2-diphenyl-*p*-toluamidine (0.1%; 0.003 M) and equilibriate for 2 min. Dry the benzene extract over anhydrous sodium sulfate and measure the absorbance at the wavelength of maximum absorption against reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of ternary thiocyanate and azide complexes of iron(III) with HDPTA are shown in Fig. 1. HDPTA reacts

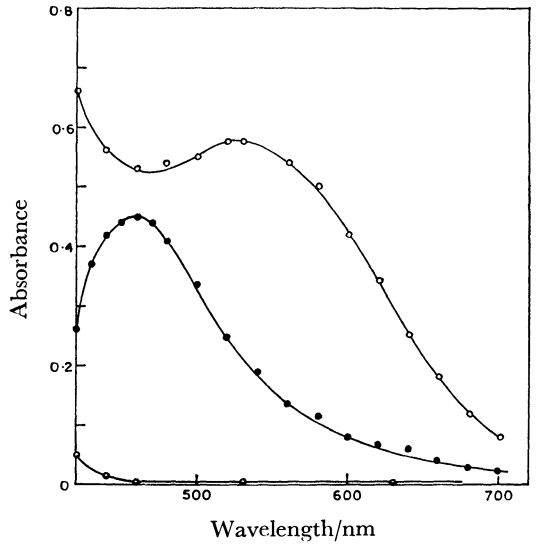


Fig. 1. Absorption spectra of ion(III) ternary complexes and reagent.
-○-: 8.47 ppm Fe(III)+0.1% HDPTA+azide,
-●-: 2.54 ppm Fe(III)+0.1% HDPTA+thiocyanate,
-◒-: 0.1% HDPTA(w/v) in benzene.

with iron(III) forming blue (λ_{max}, 580 nm) and red-purple (λ_{max}, 540 nm) pH-dependent ethanol-soluble complexes. However, in the presence of thiocyanate an intense red complex (λ_{max}, 460 nm) is developed. The wavelength of maximum absorption of the ternary iron(III)–azide–HDPTA complex is 520 nm. Both these complexes are quantitatively extractable in benzene. As the reagent (HDPTA) shows negligible absorption at 450 nm and onwards, the reagent blank can be replaced by benzene.

Effect of Variables. Various solvents such as chloroform, carbon tetrachloride, toluene, benzene *etc.* were found to extract the ternary complexes quantitatively. However, benzene was found to be the best extracting solvent as in this the sensitivity of the complexes is enhanced and complete extraction is relatively rapidly accomplished.

The acidity of the solutions were maintained with hydrochloric acid and ammonia. If the hydrochloric acid concentration of the aqueous phase in case of thiocyanate system lies in the range 0.01—1.0 M, the position of the absorption band of the benzene extract remains intact. However, the optimum acidity range was found to be 0.10—0.65 M HCl in which iron(III) was quantitatively extracted. The optimum pH range for complete extraction of iron employing HDPTA and azide was 1.0—2.5.

Generally a 30 fold molar excess of HDPTA was adequate for full colour development. In thiocyanate ternary system, a 30 and 130 fold molar excess of the ligand and thiocyanate respectively is necessary for complete extraction of iron(III). The azide ternary system requires a 25 and 100 fold molar excess of hydroxyamidine and azide respectively. The presence of HDPTA, thiocyanate, and azide in large causes no adverse effect. Order of addition of reagents was not critical in these systems.

An equilibriation period of 2 min was sufficient for complete extraction of iron(III) mixed ligand complexes. Prolonged extraction has no harmful effect on the determination. Variation of temperature of the aqueous phase from 20 to 35 °C did not affect the absorbance and λ_{max} of ternary complexes. Both the systems were stable for at least for 30 h at 27±2 °C.

Nature of Complexes. The composition of thiocyanate and azide mixed ligand complexes was determined by curve fitting method.[15] To determine the ratio of Fe(III) to HDPTA, the concentration of iron(III) was kept constant and X^- (SCN^- or N_3^-) was taken in excess and then, the concentration of HDPTA was varried. Log absorbance was plotted against log M of HDPTA. Similarly the number of X^- attached to Fe(III) were also found out. The results indicated the formation of 1:1:2 (metal: HDPTA: thiocyanate or azide) ternary complexes.

The molar absorptivities of the Fe(III): thiocyanate: HDPTA and Fe(III) : azide : HDPTA complexes are 1.01×10^4 and 4×10^3 l mol^{-1} cm^{-1} respectively. The Sandell sensitivities of the colour reactions are 0.0054 and 0.0140 μg cm^{-2} of Fe(III) for thiocyanate and azide systems respectively. The iron concentration ranges which follow Beer's law are 0.4—4.8 ppm for thiocyanate system and 0.6—12.0 ppm of Fe(III) for azide system. Ringbom plot[16] suggested optimum and effective metal concentration range of 0.8—4.0 and 2.0—11.0 ppm for thiocyanate and azide systems respectively. The relative standard deviation for the determinations based on thiocyanate and azide colour reactions are ±0.82 and ±0.60% respectively.

N^1-Hydroxy-N^1,N^2-diarylbenzamidines as Reagents for Iron(III). To study the influence of substituents on the complexing properties of the functional grouping, 18 analogues of HDPTA were synthesised and tested for their potentialities towards the extractive separation and spectrophotometric determination of iron. The absorption spectra of the ternary complexes of these reagents were scanned. The average molar absorptivities of the coloured complexes were evaluated at the wavelength of maximun absorption and on the basis of iron content. The experimental details are the same as described for HDPTA. Adherence to Beer's law was tested and confirmed for each system. It is observed that the ternary iron(III) thiocyanate complexes of N^1-hydroxy-N^1,N^2-diarylbenzamidines show maximum absorption at 460—465 nm having molar absorptivities in the range 10100—13400 l mol^{-1} cm^{-1}. Thus, substitution at azomethine or hydroxyl nitrogen atom has no effect on the position of λ_{max}. However, the substitution of the N^1-phenyl group of HDPTA with aryl substituents displayed hyperchromic effect in the order *p*-chlorophenyl>*p*-tolyl>*m*-tolyl. The replacement of the N^2-phenyl group with aryl groups also resulted into hyperchromic shifts, the order being 2-methyl-4-chlorophenyl>2,5-dimethylphenyl>2-methyl-5-chlorophenyl>*p*-tolyl>*m*-tolyl. Thus, N^1-hydroxy-N^1-(*p*-chlorophenyl)-N^2-(2-methyl-4-chlorophenyl)-*p*-toluamidine has the largest value for molar absorptivity. In azide ternary systems only slight variation in the value of λ_{max} and ε_{max} were noticed.

Effect of Diverse Ions. To study the influence

of various foreign ions, a fixed amount of iron(III) was mixed with varying amounts of diverse ions and the extraction of iron was carried out according to the recommended procedure. The tolerance limits of diverse ions(ppm) which cause an error less than ±2% are shown in parentheses.

Thiocyanate System. (0.4 M HCl; 2 ppm iron). Alkaline earth and lanthanoide elements (2000); Fluoride (800); phosphate or arsenate(1400); Cu^{2+}(100); Ni^{2+} or Co^{2+} (400); Zn^{2+}(1500); Cd^{2+}(1300); Al^{3+}(600); Cr^{3+}(500); Fe^{2+}(800); Mn^{2+}(600); Se^{4+}(300); Th^{4+} (200); Ti^{4+}(100); Zr^{4+}(700); V^{5+}(50); Mo^{6+}(15); W^{6+}(50); U^{6+}(600).

Manganese(II) inhibits colour development. However, its interference could be overcome by the addition of ammonium peroxomonosulfate.

Azide System. (pH 1.5±0.2; 6 ppm iron). Alkaline earth and lanthanoid elements (1600); Chloride (3000); sulfate(2500); Zn^{2+} or Cd^{2+}(800); phosphate (400); Ni^{2+} or Co^{2+}(400); Cu^{2+}(100); Al^{3+}(500); Cr^{3+} (450); Fe^{2+}(500); Mn^{2+}(200); Th^{4+}(500); Ti^{4+}(100); Zr^{4+}(500); Mo^{6+}(50); W^{6+}(200); U^{6+}(400).

The laboratory facilities provided by the authorities of Ravishankar University, Raipur are gratefully acknowledged.

Mutual Catalysis in the Chromium(III)–EDTA–Hydrogen Peroxide System

Mihály T. Beck* and Zoltán Tóth
Institute of Physical Chemistry, Kossuth Lajos University, H-4010 Debrecen, Hungary
(Received March 22, 1978)

Hydrogen peroxide catalyzes the reaction between hexaaquachromium(III) and ethylenediaminetetraacetic acid, while chromium(III)–EDTA complex accelerates the decomposition of hydrogen peroxide. A mechanism is suggested for the reaction on the basis of gasvolumetric and spectrophotometric experiments.

Yamamoto and Ohashi[1] reported that hydrogen peroxide accelerates the reaction between hexaaquachromium(III) and ethylenediaminetetraacetate in acidic medium. The effect was found proportional to the concentration of hydrogen peroxide. According to the mechanism suggested by the authors hydrogen peroxide oxidizes chromium(III) to chromium(IV) and/or chromium(V) which then reacts rapidly with EDTA. The chromium complex in higher oxidation state can react either with chromium(III) or with hydrogen peroxide:

$$\text{Cr(IV)-EDTA} \xrightarrow[\text{Cr(III)}]{} \text{Cr(III)-EDTA} + \text{Cr(IV)} \qquad (1)$$
$$\text{Cr(IV)-EDTA} \xrightarrow[H_2O_2]{} \text{Cr(III)-EDTA} + 1/4\,O_2$$

Analogous reactions are also assumed for the Cr(V)–EDTA complex.

However, the reactions with hydrogen peroxide were eliminated from the mechanism since no evolution of oxygen was observed for one half time. Since these reactions seem to be essential we have carried out measurements on the evolution of oxygen.

Experimental

The experimental conditions were the same as those reported by Yamamoto and Ohashi.[1]

Chromium(III) perchlorate was prepared in solution by the reduction of CrO_3 with hydrogen peroxide in perchloric acid medium.

For the experiments 0.1 M EDTA solution and 30% hydrogen peroxide solution were used. The pH was adjusted by use of 0.5 M acetate buffer. The volume of the reaction mixture was 10 ml in each case. Formation of the complex was followed by measring the absorbance of the thermostated reaction mixture (25 °C) at 545 nm using a Beckman Acta III spectrophotometer. From the measured absorbance the concentration was calculated by means of 210 $mol^{-1}\,dm^3\,cm^{-1}$ molar absorbance of the chromium(III)–EDTA complex.

The evolution of oxygen was followed gas-volumetrically. The hydrogen peroxide solution was first stirred for about 30 min to eliminate the over-saturation of solution by oxygen. Before each experiment the rate of self-decomposition of hydrogen peroxide was checked. The reaction was started when the rate became constant and—within the experimental error—equal to 0.19 ml min^{-1}. The rate of self-decomposition was considered in calculating the rate of the catalyzed reaction of hydrogen peroxide.

Results and Discussion

The decomposition of hydrogen peroxide is enhanced by hexaaquachromium(III) ions as shown in Fig. 1. The shape of the curve suggests that Cr(IV) and/or Cr(V) formed from Cr(III) are the catalysts of the decomposition of hydrogen peroxide in acidic medium. So far no information seemes to have been given on the effect of Cr(III).[2] Spitalsky[3] found that in the reaction between hydrogen peroxide and chromium(VI) the final ratio of Cr(VI): Cr(III) is determined by the initial concentration of hydrogen peroxide. He found that a considerable portion of chromium(VI) can be substituted by Cr(III) without substantial change in the catalytic effect. However, the effect of chromium(III) was not studied exclusively.

The rate of the evolution of oxygen decreases a great deal in the presence of EDTA, indicating that the EDTA complexes are less active catalysts of the decomposition than the corresponding aqua complexes. The difference in the shape of the curves in Fig. 2 shows that catalytically active EDTA complexes of the chromium are of higher oxidation state. The formation of the complex $CrEDTA(H_2O)^-$ is described by a saturation curve, the evolution of oxygen after an acceleration period becoming constant. In contrast to the result of Yamamoto and Ohashi the evolution of oxygen is considerable from the beginning of the reaction.[1]

We have also studied the effect of EDTA in the system chromium(VI)–hydrogen peroxide. Only semi-quantitative data could be obtained because of the lively evolution of oxygen. It is certain that in the presence of an excess of EDTA the total amount of chromium is present as chromium(III)–EDTA complex.

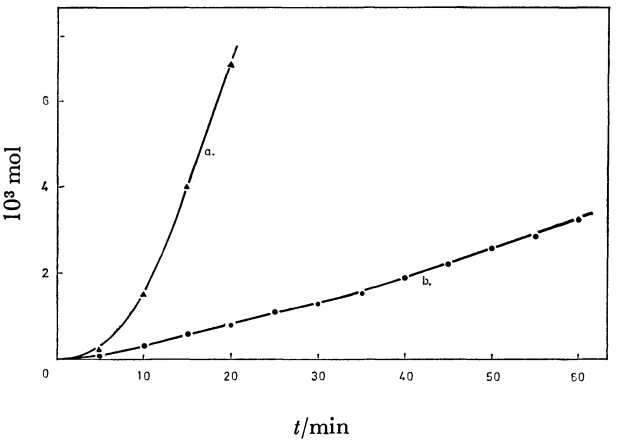

Fig. 1. Kinetic curves of evolution of oxygen in the Cr(III)–H_2O_2 system in the absence (a) and in the presence (b) of EDTA.
$[H_2O_2]=5.0$ M, $[Cr(III)]=7.35\times10^{-3}$ M, $[CH_3COO^-]=0.1$ M, $[EDTA]=2\times10^{-2}$ M, pH=3.8, $T=25.0\pm0.1$ °C, 10 ml.

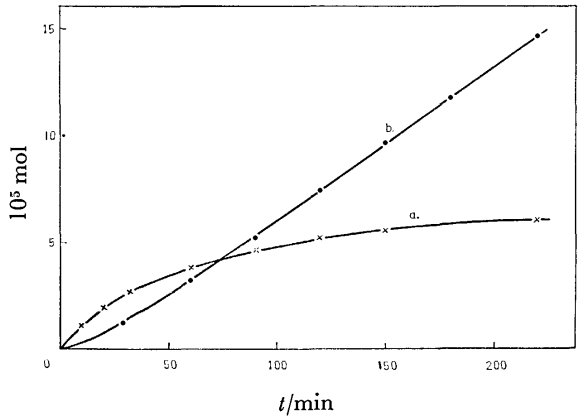

Fig. 2. Comparison of the kinetic curves of complex formation of Cr(III)-EDTA (a) and of evolution of oxygen (b) in the Cr(III)-EDTA-H_2O_2 system. Conditions are given in the legend of the Fig. 1.

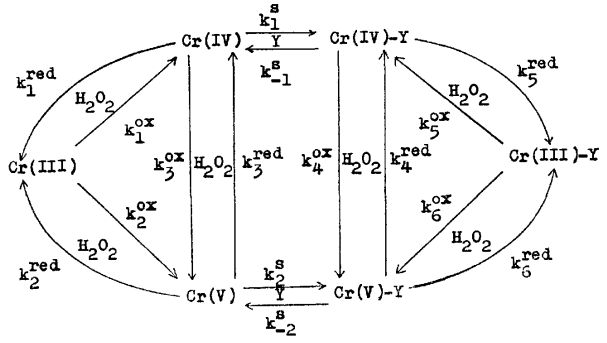
When no EDTA is present, there is an equilibrium between Cr(VI) and Cr(III). The fast initial evolution of oxygen diminishes and the value observed in the system chromium(III)-EDTA-hydrogen peroxide is attained. The formation of Cr(III)-EDTA complex takes place faster when chromium is initially present as chromate.

The reaction mechanism is extremely complicated. The following types of reactions should be taken into account:

1. Redox reactions between hydrogen peroxide and aquo ions of chromium in different oxidation states.
2. Disproportionation reaction of Cr(IV) and Cr(V).
3. Redox reactions between chromium ions in different oxidation states.
4. Substitution reactions with EDTA.
5. Redox reactions betweeen hydrogen peroxide and EDTA complexes of chromium in different oxidation states.
6. Other redox and disproportionation reactions involving EDTA complexes of chromium in different oxidation states.

Starting with Cr(III) in the presence of EDTA we can disregard reactions leading to Cr(VI). In the following scheme only those redox reactions which involve hydrogen peroxide are taken into consideration, visg., reactions of type 2, 3, and 6 are also disregarded. Thus the following scheme can be written:



Y: EDTA. (2)

The network of reactions can be greatly simplified if we bear in mind the data referring to the rate of the formation of the Cr(III)-EDTA complex and that of the evolution of oxygen:

1. According to the rate equation given by Yamamoto and Ohashi[1] the rate determining step is the reaction between $Cr(H_2O)_6^{3+}$ and H_2O_2, k_1^{ox} and k_2^{ox} being the smallest among the rate constants.
2. In order to explain the diminishing effect of EDTA on the rate of the oxygen evolution, we should assume that the equilibrium between Cr(IV) and Cr(V) and EDTA is shifted to the formation of the complex, viz., $k_1^s \gg k_{-1}^s$ and $k_2^s \gg k_{-2}^s$.
3. According to the spectrophotometric measurements (Fig. 2. curve a) the amount of Cr(III)-EDTA complex increases steadily: $k_5^{ox} < k_5^{red}$ and $k_6^{ox} < k_6^{red}$.
4. Since the experimental data do not permit separation of paths involving Cr(IV) and Cr(V), only reactions of Cr(IV) should be considered. This makes the handling of rate equations easier.

The following simple scheme can be written:

$$\text{Cr(III)} \xrightarrow[H_2O_2]{k_1^{ox}} \text{Cr(IV)} \xrightarrow[\text{EDTA}]{k_1^s}$$

$$\text{Cr(IV)-EDTA} \underset{H_2O_2}{\overset{k_5^{ox}}{\rightleftharpoons}} \text{Cr(III)-EDTA} \quad (H_2O_2,\ -1/4\,O_2;\ k_5^{red})$$

$$k_1^s > k_5^{red} > k_1^{ox} \approx k_5^{ox}. \tag{3}$$

The condition of the steady evolution of oxygen is as follows:

$$\frac{d[O_2]}{dt} = \text{constant} = k_5^{red}[\text{Cr(IV)-EDTA}]. \tag{4}$$

This requires that

$$\frac{d[\text{Cr(IV)-EDTA}]}{dt} = 0 = k_1^{ox}[\text{Cr(III)}] - k_5^{red}[\text{Cr(IV)-EDTA}] + k_5^{ox}[\text{Cr(III)-EDTA}]. \tag{5}$$

Since the concentration of the intermediates is so small that they cannot be detected spectrophotometrically and their existence is indicated only by the shape of the rate curves of oxygen evolution, we have

$$[\text{Cr(III)}] + [\text{Cr(III)-EDTA}] \approx [\text{Cr(III)}]_0. \tag{6}$$

Thus Eq. 5 can be written as follows.

$$k_5^{red}[\text{Cr(IV)-EDTA}] = k_5^{ox}[\text{Cr(III)}]_0 - [\text{Cr(III)}](k_5^{ox} - k_1^{ox}). \tag{7}$$

Considering Eqs 4 and 7, we get

$$k_5^{ox}[\text{Cr(III)}]_0 - [\text{Cr(III)}](k_5^{ox} - k_1^{ox}) = \text{constant}. \tag{8}$$

It follows that the steady evolution of oxygen follows from the simplified scheme, if

1. $k_5^{ox} \approx k_1^{ox}$ and/or
2. $[\text{Cr(III)}] \ll [\text{Cr(III)}]_0$.

In the first stage of the reaction, before the formation of the Cr(III)-EDTA complex is completed, only the first condition is fulfilled, while in the later stage of the reactions both conditions can be satisfied. The fact that the rate of the oxygen evolution becomes

constant before the complete transformation of Cr(III) to Cr(III)–EDTA indicates that the first condition is actually satisfied:

$$k_5^{ox}[\mathrm{Cr(III)}]_0 \gg [\mathrm{Cr(III)}](k_5^{ox} - k_1^{ox}), \quad (9)$$

causing Eq. 8 to be fulfilled.

The results show that mutual catalysis takes place in the Cr(III)–EDTA–H_2O_2 system. Hydrogen peroxide accelerates the formation of Cr(III)–EDTA, which in turn catalyzes the decomposition of H_2O_2.

Indirect Polarographic Estimation of Palladium

P. B. KALAPURNA

Department of Analytical Chemistry, Madras University, A.C. College Campus, Madras 600025, India

(Received April 10, 1978)

Chemical displacement of palladium by mercury at the DME, has been found to be quantitative (that is, instantaneous and proportional to the i_d of mercury). Therefore the mercury(I) wave has been exploited for the indirect estimation of palladium using the DME. The conditions of estimation are standardized and the method applied to a mixture (dental alloy) containing palladium. The results are within experimental accuracy. The indirect method has certain advantages over the direct methods.

Palladium has been directly estimated in the past by several workers mostly by the spectrophotometric technique using a variety of organic reagents, as for example, oximes,[1-3] azoles,[4] substituted ketones,[5-7] substituted phenols,[8-10] and sulfur compounds.[11-14] There has also been an indirect spectral method,[15] based on the catalytic action of palladium on the reduction of molybdophosphate to molybdenum blue. With but a few exceptions[16,17] the spectral estimations were restricted to ranges below 30 ppm. Another short-coming of the spectral method was that an extraction step was often necessary prior to the spectral reading, and this has been the cause to lengthen the procedure and introduce errors.

Less frequently adopted methods for the direct estimation of palladium are amperometry,[18] potentiometry,[19] stripping voltammetry,[20] and polarography.[21]

Polarographic estimations of palladium complexes at the DME (dropping mercury electrode), in the past have not been smooth-sailing. In some cases[22] the half-wave potential had been very close to the decomposition potential of the electrolyte, the wave itself being irregular at the top. In other cases,[23,24] the half-wave potential was reported to vary with concentrations of palladium, indicating the formation of more than one species. The present indirect polarographic method is free from these short-comings.

The direct polarographic estimation of palladium (without complexation) using a DME is difficult, for the reason that palladium salts are spontaneously reduced[22] to the metal by contact with mercury, the latter being more electronegative than palladium in the electromotive series of elements. An accurate method of estimation is outlined here for the indirect estimation of palladium, making use of the mercury(I) wave, which occurs due to the chemical displacement of palladium from solution. The practical range of estimation has been found to be between 10—210 ppm, (wider than many of the spectral methods, and also without encumbrance of the extraction step). This makes it a more rapid method than the conventional spectrophotometric methods.

When a solution of palladium chloride was subjected to polarography at a DME, a single wave was obtained with an half-wave potential of +0.06 V. This curve has been reported by previous workers[25] as due to mercury(I) ion liberated by the reaction.[26]

$$Pd^{2+} + 2\,Hg^0 \rightarrow Pd^0 + Hg_2^{2+}$$

This reaction is instantaneous up to 210 ppm, and the lower limit has been found to be 10 ppm, though theoretically the reaction may be stoichiometric even at much lower concentration ranges.

That the wave with a half-wave potential of +0.06 V is due to the mercury(I) ion, was confirmed by us as follows: Polarograms of palladium using a stationary platinum electrode, under the same conditions as before always showed a wave with an $E_{1/2}$ of +0.16 V. There was no wave at +0.06 V, unlike with the DME.

Polarograms of mercury(I) chloride (10^{-5} M) in the absence of palladium gave the same wave with a half-wave potential of +0.06 V, regardless, whether the electrode used was a DME or a platinum electrode.

Estimation of Palladium. A stock solution of 1×10^{-2} M palladium chloride was prepared from anhydrous palladium chloride (A.R.), by warming the aqueous solution with a drop of concentrated HCl, to ensure complete dissolution before making up to the required volume. This solution was diluted appropriately to get concentrations ranging from 10 to 225 ppm during polarography. Potassium chloride was used as a supporting electrolyte and also to keep the ionic concentration constant at 0.1 M. A 0.01% gelatin solution was used as a maximum suppressor. pH was maintained at 3.5 by the use of an appropriate Britton-Robinson buffer.[27] Polarograms were recorded after deaeration with oxygen-free nitrogen.

Instrument. A polariter PO3 Radiometer of the pen recording type with a built-in saturated calomel anode was used to record the polarograms.

The capillary characteristics were established as follows: $m=9$ mg/s, $t=1.4$ s, $h=25$ cm. A fast dropping capillary was found to be more suitable for the experiment, to minimize the chemical vitiation of the mercury surface.

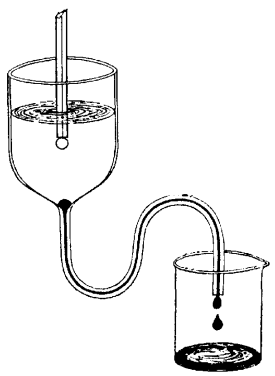

Fig. 1. Vessel used for the indirect polarographic estimation of palladium.

TABLE 1. COMPARISON OF RESULTS OBTAINED BY POLAROGRAPHY AND SPECTROPHOTOMETRY

No.	Quantity of Pd in the dental alloy (ppm)	Polarographically (ppm)	Spectrophotometrically (ppm)	Deviation between the two techniques (ppm)
1	10.65	10.55	10.60	+0.05
2	21.30	21.40	21.35	−0.05
3	31.95	32.00	32.00	0.00
4	53.05	53.00	53.05	+0.05
5	63.70	63.20	63.50	+0.30
6	74.35	74.20	74.30	+0.10
7	95.65	95.50	95.55	+0.05
8	106.30	106.40	106.20	−0.20
9	116.95	117.00	116.90	−0.10
10	137.65	137.50	137.60	+0.10
11	148.30	148.00	148.20	+0.20
12	158.95	159.80	160.00	+0.20
13	180.25	180.30	180.20	−0.10
14	190.90	191.00	190.90	−0.10
15	201.55	201.00	201.50	+0.50

Precaution was taken to avoid undue contact of solution with mercury other than the DME, so that the chemical reaction between palladium ions and non-electrodic mercury is made negligible. The polarographic vessel was drawn out into a capillary, so that the building up of the mercury pool by the drops of mercury was prevented by continuous tapping out of mercury, leaving only a droplet of negligible area of contact inside the capillary (Fig. 1). The scanning of the polarogram was done within 2 min.

The relationship between the diffusion current i_d and the concentration was found to be linear up to 210 ppm. Above this range the linearity is gradually lost by the vitiation of the surface of the mercury drop. A number of estimations were carried out with known concentrations of palladium, and the quantities were estimated by referring the i_d to the working graph.

The results obtained by the above method were checked by parallel determinations conducted by the well known spectrophotometric method[28,29] (λ_{max}= 525 nm), using *p*-nitrosodimethylaniline as the color developer and a Beckman Model B spectrophotometer as the instrument. The results of the two techniques were found totally within experimental error *vide* Table 1. In a series of fifteen experiments with 106.3 ppm of palladium, the standard deviation[30] was found to be 0.0876.

Analytical Applications. Indirect polarographic estimation of palladium through the mercury(I) wave is applicable to micro and semimicro quantities of palladium (below 50 mg). This quantity is below the macro-gravimetric limit. Micro-gravimetry is more tedious and hence the advantage of the polarographic estimation. This technique is suitable for the estimation of palladium present in hydrogenation catalysts and in dental and ornamental alloys. In alloys, palladium is generally found in association with gold, silver, and sometimes base metals like copper and zinc.

TABLE 2. R_f VALUES OF THE DIFFERENT IONS

Ion	R_f value	Remark
Gold	0.96	Moves with the solvent front
Palladium	0.84	Fine, thin band
Copper	0.74	Thin, well defined band
Zinc	0.30	Thick, diffused band, but far separated from the other ions

Before subjecting to polarography, it has to be isolated from its associates by any suitable method, a number of which are available in literature.[31-34] The method adopted in this laboratory was to separate the palladium by means of circular paper chromatography.

Isolation of Palladium from Gold, Copper, and Zinc in a Dental Alloy. The first investigation was to discover the R_f values of individual constituents, which alone will decide whether they can be separated at all. Solutions of pure metal constituents of the dental alloy (10^{-4} M) were prepared in aqua-regia. The solutions were evaporated to dryness to expel the oxides of nitrogen and made up to a required volume with 0.1 M HCl. Chromatograms were run on circular paper of diameter of 12 cm, with a central wick, and the eluent used was ethyl methyl ketone, concd HCl (A.R.) and isoamyl alcohol in the ratio of 6:3:1. After the paper was dried the bands were developed by spraying with the following reagents. (a) Hydrazinium chloride in dilute HCl for gold (Black band), (b) DMG in acid medium for palladium (Yellow band), (c) 0.1% Rubeanic acid in alcohol for copper (Green band), and (d) Dilute dithizone in chloroform for zinc (Pink band).

Table 2 shows the average R_f values of the different ions.

An appropriate quantity of the dental alloy was weighed, dissolved in 10 cm^3 of aqua regia, evaporated to expel the oxides of nitrogen and finally made up to 200 ml with 0.1 M HCl. The chromatogram was run as before. The brown band of palladium was clearly visible second from the outermost. It was cut out from the paper, and the metal extracted with 0.1 M HCl and utilized for quantitative estimation.

Quaternisation at an Sp^2 Nitrogen. II.[1] An Analysis on the Substituent Effect and on the Nature of the Transition State

G. B. BEHERA* and A. SHARMA†

Post-Graduate Department of Chemistry, Sambalpur University, Jyoti Vihar, Burla 768017, India

(Received August 1, 1977)

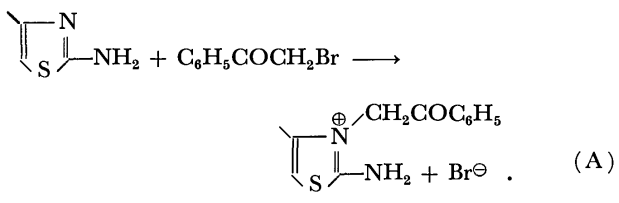
The kinetics of *N*-phenacylation of a number of substituted thiazoles and substituted phenacyl bromides have been investigated in nitrobenzene and in a number of other dipolar aprotic solvents. The rate constants of 2-amino-4-phenylthiazoles and 2-aminobenzothiazoles have been calculated with suitably developed equations. The deviation of the observed values from the calculated results has been ascribed to the steric effect. A seven membered hydrogen bonded transition state has been proposed on the basis of the results obtained from the substituent and medium effect.

In the field of quaternisation reactions pioneering and extensive work have been done by Menschutkin.[2] The reaction has been used successfully in the development and understanding of mechanistic principles. The quaternisation kinetics of pyridines with methyl iodide has been studied by Fischer and Vaughan[3] and Murai *et al.*[4] They observed the operation of normal substituent effect for the substituents at position 4 and a good correlation between the rate constant and pK_a with the exception of $-NH_2$, $-CO-C_6H_5$, $-COOR$, and $-CN$ groups. In an earlier study[5] on the quaternisation of thiazoles, the sulfur atom was observed to act as a resonance transmitter. The lower reactivity of 2-amino group over 2-methyl group was explained as due to the existence of an equilibrium between loose contact pairs and charge transfer complexes.

Deady *et al.*[6] also studied the rate of *N*-methylation of a number of heterocyclic compounds such as *N*-methylpyrazole, isothiazole, isoxazole and their 2 : 1 and 1 : 2 analogues; 2-methyl-benzothiazoles; 2,1,3-benzoxadiazoles; 2,1,3-benzothia (or selena) diazoles; 1,2,5-oxadiazole; and 1,2,5-thiadiazoles. They concluded a reactant-like transition state for the Menschutkin reaction. The present work was undertaken to investigate the nature of the transition state during the course of *N*-phenacylation reaction.

Results and Discussion

The reaction of 2-aminothiazole and phenacyl bromide takes place according to



(A)

The rate data, Arrhenius parameters and the entropy of activation values for this reaction are given in Table 1. The greater rate of reactivity of **5** over **1** is ascribed to the presence of a *p*-OMe group, which stabilizes the transition state by interacting through the sulfur atom. Substantial transmission of electronic effects through the sulfur atom has been clearly shown by Davis *et al.*[7] from the ultraviolet spectral data of some sulfur amides. A mechanism of through conjugation involving p-π, d-π, p-π conjugation has been suggested for phenyl vinyl sulfides[8] and supported by CNDO/2 calculations.[9] Discussions have been made by various workers.[10]

*2-Aminobenzothiazole(**1**), 2-Amino-4-phenylthiazole(**2**), 2-Amino-4,5-diphenylthiazole(**6**), and 2-Aminopyridine(**8**).* Since the sulfur atom acts as a resonance transmitter, it can be considered equivalent to a vinyl group. Therefore, the compounds **1**, **2**, and **6** can be considered equivalent to 2-amino-6-phenylpyridine, 2-aminoquinoline, and 2-amino-5,6-diphenylpyridine, respectively. Considering compound **8** as a standard, the rate constants of **1** and **2** can be calculated by means of

$$k_1(\text{calcd}) = \frac{\beta_s}{\beta_{\text{vinyl}}} \times \frac{K_B(\text{2Ph-pyridine})}{K_B(\text{Pyridine})} \times k_8, \qquad \text{(B)}$$

and

$$k_2(\text{calcd}) = \frac{\beta_s}{\beta_{\text{vinyl}}} \times \frac{K_B(\text{Quinoline})}{K_B(\text{Pyridine})} \times k_8, \qquad \text{(C)}$$

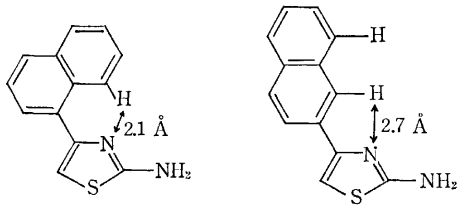
where β_s is the resonance integral of the S atom and the vinyl group, K_B is the basicity constant of base and k_8 is the observed rate constant for compound **8**. The values of k_1 and k_2 at various temperatures and the calculated and observed rate constants are given in Table 3. The ratio falls from 10.0 at 60 °C to 3.0 at 100 °C for compound **1** whereas it changes from 1.5 to 1.3 for compound **2**. The values of energy of activation obtained with the calculated rate constants are 6.45 and 8.64 kcal mol^{-1} as against 13.40 and 9.52 kcal mol^{-1} derived from observed rate constants for compounds **1** and **2**, respectively. The agreement between the observed and calculated rate constants appears reasonable in view of the assumptions: (1) steric effect during the course of protonation and phenacylation is the same and (2) an amino group at 2-position produces the same effect in both the processes. However, for compound **2** a greater divergence is noted than for compound **1**. The discrepancy might be due to the librational freedom of the phenyl group at position 4 in compound **2**. The free libration of the phenyl group becomes restricted during the course of phenacylation due to the steric interaction of ortho hydrogen atom and the phenacyl moiety. Therefore, the plane of the phenyl group will rotate to the thermodynamically favoured conformation, *i.e.*, the planes of the π MO of the phenyl and the thiazole ring will tend to be orthogonal, causing destabilisation of the transition state. Thus the energy of activation

† Junior Research Fellow, C.S.I.R., Government of India.

obtained with observed rate constant is much higher with **2** than with **1** as compared to the same obtained from calculated rate constants.

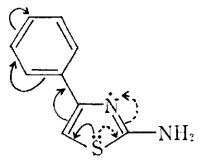
4-(1- and 2)-Naphthylthiazoles. The greater rate of reactivity of 1-naphthyl over 2-naphthyl group at position 4 of the thiazole ring can be ascribed to both steric and electronic factors. The ratio of F_r and Z_r values for position 1 and 2 of the naphthalene are 1.12 and 1.04, respectively.[11] Brown[12] showed a good correlation between F_r and Z_r values with the reactivity parameter, $\sigma_r(\log k/k_0=\sigma_r\rho^*)$ with a deviation $\simeq$6%. The ratio of logarithm of rate constants of 4-(1- and 2)-naphthylthiazole is 0.81. Examination of the model shows that H atom at C-8 in I is nearer by 1.3 times to the H atom at C-1 (II). Thus, the ratio of rate constants of 4-(1- and 2)-naphthylthiazole in the absence of the steric effect due to the nearness of C_α–H atom would have been $0.81\times1.3=1.053$, which is in good agreement with the ratio of F_r and Z_r values. Charton[13] also concluded that E_s parameters are a function of the Van der Waals radii only.

The increased rate of reaction of **6** over **2** can be ascribed to a buttressing effect on the phenyl group at position 4 due to the same group at position 5.



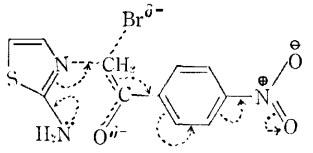
I II

The phenyl ring at position 4 interacts with the electron pair of the sulfur atom (III) and the electron density around nitrogen is relatively decreased.[14] The phenyl ring at position 5 decreases this electronic effect by sterically interfering with the group at position 4.



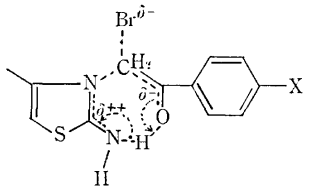
III

Reactivity of Phenacyl Bromide: The order of reactivity of the substituted phenacyl bromide is, *m*-$NO_2\simeq$ *p*-NO_2>*p*-Cl>*p*-OMe>-H (Table 3). The order of reactivity determined earlier by Rout *et al.* in the reaction of phenacyl bromides and aniline is, *p*-NO_2> *m*-NO_2>*p*-Cl>-H>-OMe.[15] The greater rate of reactivity of nitrophenacyl bromide over the unsubstituted one is in line with the transition state (IV) proposed by them and other workers[16] for similar reactions.



IV

The transition state is stabilised by an interaction with the $-NH_2$ group (arrows). However, it cannot explain the order of reactivity. If a hydrogen bonded structure (V) is proposed for the transition state then the effect of *p*-NO_2 and *p*-OMe groups can be understood: (i) in X=NO_2, electron withdrawing effect of

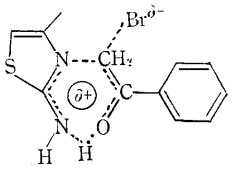


V

NO_2 is lowered by the electron movement shown in the cyclic transition state, (ii) in X=MeO, the electron movement in V is enhanced by electron donating effect of MeÖ. The possibility of such a hydrogen bonded structure is also further confirmed from IR data of 2-amino-3-phenacyl-4-phenyl-3-thiazolium bromide. The >C=O group stretching frequency occurs at 6.1—6.15 μ, whereas in acetophenone it is 5.95 μ. The shift in *o*-hydroxyacetophenone and salicylaldehyde, where chelation has been established is by 0.15 μ. Therefore, these is a case to believe that a hydrogen bonded structure also exists in the quaternary salt.

Medium Effect: With a view to understanding further the nature of the transition state, the *N*-phenacylation kinetics has been studied with 2-aminobenzothiazoles. The order of reactivity in different solvents was observed to be DMA>DMF>NB>BN>AN>BA>CB (Table 4). This is the order of decreasing dielectric constant of the solvents (AN being an exception). A plot of log *k vs.* $(D-1)/(2D+1)$, gives a straight line, AN and NB not lying on the line. This order of reactivity in different solvents also does not conform to the order of *Z* values[17] and E_T values[17] of these solvents, suggesting a nonquaternary salt-like structure for the transition state. However, there seems to be some correlation with the dipole moment of these solvents. The order of increasing dipole moment of these solvents is BN>NB>DMF>DMA>AN. There is a reversal in the order with respect to the first four solvents. Plots of ΔS^*, ΔH^* *vs.* dipole moment give straight lines whereas similar plots with $(D-1)/(2D+1)$ show a scatter.

On the basis of these evidences, a transition state (VI) is suggested for the phenacylation process of 2-aminothiazoles.



VI

Experimental

4-Substituted 2-aminothiazoles were prepared by condensation of appropriately substituted phenacyl bromide and

thiourea in ethanol. The thiazoles obtained were crystallised twice from alcohol. The 2-aminothiazoles prepared by this method are 4-phenylthiazole, mp 150 °C (lit,[18] mp 151 °C); 4-(1-naphthyl)thiazole, mp 144 °C (lit,[19] mp 144 °C); 4-(2-naphthyl)thiazole, mp 134 °C (lit,[19] mp 135 °C); 4-(*p*-methoxyphenyl)thiazole, mp 204 °C (lit,[20] mp 204 °C) and 4,5-diphenylthiazole, mp 180 °C. 2-Methylbenzimidazole and 2-aminopyridine were of Couchlight Renal grade. They were crystallised before use. 2-Methylbenzothiazole (Schudart and Co.) was distilled before use.

Phenacyl bromide was synthesised by the bromination of acetophenone.[21] The substituted phenacyl bromides prepared by this method are 4-nitro-, mp 90 °C (lit,[22] mp 91 °C); 4-chloro-, mp 110 °C (lit,[22] mp 110 °C); 4-methoxy-, mp 72 °C(lit,[22] mp 72 °C) and 3-nitro-, mp 95 °C(lit,[22] mp 96 °C).

Purity of all the synthesised compounds has been confirmed by silica gel G TLC plate.

All the solvents used were of BDH grade. Nitrobenzene was purified by the method of Leffek and Matheson,[23] acetonitrile by that of Coetzee,[24] *N*,*N*-dimethylformamide by that of Hurt and Simpson,[25] 1-butanol by that of Goldschmidt and Mathieson[26] and chlorobenzene by that of Vogel.[27] Benzonitrile was purified by shaking with silica gel and then stirring with calcium hydroxide for two hours. After decantation, it was distilled under reduced pressure. The middle portion was cut and used. *N*,*N*-Dimethylacetamide was also used after distillation under reduced pressure.

Kinetic Procedure: The method of rate measurement by conductance method is the same as reported.[5] The pseudo first order rate constants ([Base] = 0.0025 M and [α-halo-

a) $k\times10^4$ at 75 °C=13.2 in $M^{-1}s^{-1}$. The rate data in parentheses in DMF, DMA, and NB refer to the first order rate constants ($k\times10^5$ in s^{-1}) by conductometric methods.

ketone]=0.05 M) were calculated from the slopes of the linear plots of log $R_t/(R_t-R_\infty)$ *versus* time, where R_t and R_∞ are the electrical resistances at time 't' and infinite time, respectively. The rate constants were reproducible within ±0.2 units.

Since the measurements of rate constants in less polar solvents by the conductance method were less satisfactory, the argentometric method was also adopted. The rate constants by both titrimetric and conductometric methods were compared in a few cases and found to agree well in conformity to the observation made by Jones *et al.*[28] A thermostated solution of phenacyl bromide (0.05 M)and 2-aminobenzothiazole (0.05 M) were mixed and the course of the reaction was studied by pipetting aliquots from the reaction mixture at different intervals of time and estimating [Br^-] argentometrically. The rate constants were calculated by employing the bimolecular rate equation.

The activation parameters were calculated by using bimolecular rate constants.

Funds for this project were kindly provided by the Council of Scientific and Industrial Research, Government of India.

(Received March 6, 1978)

A stereocontrolled synthetic route to (±)-1,2,3,4,4a,9,10,10a-octahydro-7-methoxy-1,4a-dimethyl-10-oxophenanthrene-1β-carboxylic acid and its conversion to 1,2,3,4,4a,4b,5,6,7,9,10,10a-dodecahydro-10β-hydroxy-1,4a-dimethyl-7-oxophenanthrene-1β-carboxylic acid is described.

Functionalization of methyl group of abietic acid and podocarpic acid have been realized[3] with a view to synthesise potential intermediates of naturally occurring diterpenoids such as gibberellin and the diterpenoid alkaloids. Investigations towards the functionalization of C-1 methyl groups in the compounds possessing a rosane skeleton was undertaken for the construction of lactone ring of rosenonolactone[4] and the fundamental skeleton of erythroxydiol X.[5] In connection with our synthetic studies on diterpenes[6] attention was directed towards the functionalization of C-1β-methyl group of a hexahydrophenanthrene system (III) to C-1β carboxylic acid (XVI) derivative, a potential synthon for the entry into various tricyclic and tetracyclic diterpenes recently isolated.[7,8]

For the synthesis of the hexahydrophenanthrene system (III), the elimination of the carbonyl group of the ketone (I)[9] was attempted. The difficulties of the elimination of C-2 carbonyl group of I, without affecting $\Delta^{10,10a}$, by Huang-Minlon procedure or by thioacetal desulfurization sequence have already been noted by Ireland and coworkers[10] and thus requires no comment. The elimination of carbonyl groups by reduction of tosylhydrazone derivative (II) was thus attempted. The tosylhydrazone derivative II prepared following the procedure of Caglioti[11] was obtained in 85% yield. Reduction of the derivative II could not be effected either with $NaBH_4$ or $LiAlH_4$. Finally the desired hexahydrophenanthrene (III) was obtained in 60% yield by Clemmensen reduction[12] of the carbonyl group of I. In the IR spectrum the olefin (III) showed band at 1678 cm^{-1} (C=C) in and the NMR spectrum exhibited a triplet centered at δ 5.68 ppm, characteristic of C-10 hydrogen. Hydroboration of the olefin (III) under controlled conditions[13] afforded crystalline alcohol (IV) in 50% yield. When the hydroboration of the olefin (III) was carried for a prolonged period, a complex mixture was obtained from which a very little amount of the desired alcohol (IV) was obtained. The stereochemistry of this hydroxylation is important as only 10β-hydroxyl function is useful for transannular oxidation of 1β-methyl group. Inspection of molecular models of the olefin (III) shows that an approach of the hydroborating agent from α-side of the olefin is shielded by 4aα-CH_3 and 1α-CH_3. Thus the approach to β-side of 10a,10-double bond of the olefin (III) is more favoured to produce 10β-alcohol (IV). In the NMR spectrum the alcohol (IV) exhibited multiplet at δ 4.23 (m, H at C-10) with half-band width ($W_{1/2}$) of 8 Hz, characteristic of equatorial proton[14] of C-10. Further that the alcohol (IV) was indeed 10β-isomer was indicated by careful (−12 °C) Jones oxidation to the corresponding ketone (V). The ketone (V) on being equilibrated with acid or base was recovered unchanged. Many examples can be cited from the chemical literature[15] to illustrate that the low temperature Jones oxidation does not bring enolization of similar ketones and the configuration position adjacent to the carbonyl group remains undisturbed. The stability of the ketone (V) under enolizing conditions indicated that A/B ring fusion is in the more stable trans-configuration. The ketone (V) exhibited three methyl signals δ 0.96, 0.99, and 1.15 ppm which are consistent with trans A/B fusion[16] of the ketone (V). If the ketone (V) be with cis A/B ring fusion and steroidal conformation (VI) then one of the C-1 methyl groups would be present at a very high field (δ 0.52—0.56 ppm)[13] in the NMR spectrum owing to the shielding effect of aromatic ring. On the other hand the ketone (V) with cis A/B ring fusion and non-steroidal conformation (VII) would exhibit the signal of one of the C-1 methyl group in a very low field (δ 1.56 ppm) in the NMR spectrum[16] owing to the deshielding effect of C-10 carbonyl group. The benzyl protons at C-9 appeared as two doublets centered at δ 2.48 and 2.51 ppm indicating that C-10 carbonyl group is not equidistant from C-9 benzyl protons. This data is only consistent with half-boat conformation (VIII) for ring B because with half-chair conformation (IX) of ring B, these benzyl protons would appear magnetically equivalent and would appear as a singlet. The appearance of C-9 benzyl protons at δ 2.48 and 2.51 also indicated that the trans fusion of A/B ring of the ketone (V) because if A/B ring were cis-fused then the benzyl protons would have appeared at low field in the NMR spectrum. Thus the C-10a hydrogen of the ketone (V) must be β-oriented (axial) and hence also β-oriented (axial) in the alcohol (IV). The hydroboration reaction involves cis addition of B-H moiety to the double bond and this would also imply that C-10 hydroxyl group of the alcohol (IV) was also β-oriented. The reduction of the ketone (V) with $NaBH_4$ in alcohol afforded an

alcohol in 90% yield which was identical in all respects (IR and mp) with the alcohol (IV). These chemical and spectroscopic properties conclusively indicate that the alcohol (IV) bears axial 10 β hydroxy function. A byproduct of this hydroboration process that resulted in 12% yield appeared to be the olefin (X) exhibited a singlet at δ 6.01 ppm corresponding to two olefinic protons at C-10 and C-9 and a singlet at δ 2.42 ppm corresponding protons at C-10a. The olefin (X) showed absorption at λ_{max} 266 nm (log ε 3.96) characteristic of styrene band. This kind of addition-elimination sequence under mild hydroboration conditions has also been observed.[17] It is worthwhile to mention that though the addition-elimination-readdition sequences under mild hydroboration conditions have been reported previously[18] in the present case no such observation was made.

Reasonably confident that we had the alcohol (IV) with desired stereochemistry, attempt was made to oxygenate 1β-methyl group by intramolecular, transannular oxidation.[19] The alcohol (IV) was oxidized

in cyclohexane with lead tetraacetate in presence of iodine. The resulting product after chromatographic purification afforded cyclic ether (XI) in 10% yield whose structure was confirmed by the appearance of two doublets at δ 4.08 (1H, J=7 Hz) and δ 4.18 (1 H, J=8 Hz) (2 H at C-12) and by the disappearance of one of the methyl groups at C-1 CH_3 in the NMR spectrum. Further elution of the oxidised product afforded the ketone (V) in 42.7% yield and the lactone (XII) in 36% yield. When the alcohol (IV) was oxidized with lead tetraacetate in benzene in the absence of iodine the yield of the ether (XI) and the ketone (V) was increased to a certain extent along with the diminution in the yield of the lactone (XII).

Having obtained the ether (XI), the lactone (XII) and the ketone (V) from the photolytic oxidation of the alcohol (IV), attention was directed towards the transformation of these products to the desired keto acid (XVI). Treatment of the ether (XI) with pyridine hydrochloride and acetic anhydride at reflux yielded a gummy mass which on chromatographic purification afforded a product in poor yield which was identified as olefin acetate (XIII) since it exhibited IR band at 1735 (acetate C=O) and 1245 (C–O) cm^{-1} and the NMR signals at δ 2.06 (3 H, s, OAc), 4.18 (2 H, AB q, J=12 Hz, $C\underline{H}_2OAc$) and 5.55 (1 H, m, olefinic proton at C-10) ppm. Hydrolysis of this compound with 3% methanolic potassium hydroxide afforded an olefinic alcohol (XIV), the NMR spectrum of which showed peaks at δ 3.63 (2 H, AB q, J=11 Hz, CH_2OH) and 5.63 (1 H, m, olefinic proton at C-10). Beside the olefin acetate (XIII), a chlorine compound was obtained in 70% yield which was assigned to the structure (XV). The compound gave positive halogen test and in the NMR spectrum the compound (XV) showed an AB quartet of the acetate centered at δ 3.53 ppm. Refluxing of this chloro compound with 5% methanolic potassium carbonate solution gave back the ether (XI). The poor yield of the olefin acetate (XIII) can be accounted by the rapid addition of hydrogen chloride across the 10,10a-double bond of the olefin acetate (XIII). The ready transformation of the chloroacetate (XV) to the ether (XI) under weakly basic conditions strongly suggests that the halogen at position C-10 is α-oriented.

As the yield of the olefinic alcohol (XIV), which is a useful intermediate for the synthesis of keto acid (XVI), was poor, we investigated chromic acid oxidation of the ether (XI). On oxidation of the ether (XI) with chromic acid in acetic acid was obtained a nicely crystalline keto acid (XVI) in excellent yield. That the cleavage of 10β→12 ether linkage had occurred was evidenced by the disappearance of C-12

oxymethylene protons in the NMR spectrum. In the IR spectrum it showed an unresolved carbonyl band of high intensity of 1710 cm^{-1}. Its molecular weight as determined by mass spectrometry was found to be 302 which corresponded to the keto acid (XVI).

With a view to convert the ketone (V) to the keto acid (XVI) it was planned to subject the ketone (V) to photochemical reaction[20] with the hope of obtaining a cyclobutane derivative (A) which on ring cleavage would produce the keto alcohol (XVII) and this alcohol (XVII) on oxidation would afford the keto acid (XVI). Photolysis of the ketone (V) with a 200 W Hanovia high pressure mercury lamp with a Pyrex filter under oxygen free N_2 gave an oily material. Hydrolysis of the product with acetic acid yielded a gummy material which on chromatographic purification afforded an alcohol (as identified by mass spectrum and IR study) in 78% yield which was identical in all respects (IR and mp) with the alcohol (IV). Another product of this reaction showed OH band at 3320 cm^{-1} and no carbonyl band in the IR spectrum. Due to the low yield of the oily material it was not possible to investigate its chemical and spectroscopic properties. Thus the ketone (V) could not be utilised for the synthesis of keto acid (XVI).

Finally effort was made to cnovert the lactone (XII) to the desired keto acid (XVI). The lactone ring on being reduced with $LiAlH_4$ in tetrahydrofuran afforded the diol (XVIII) in excellent yield. In the NMR spectrum the diol (XVIII) exhibited an AB quartet centered at δ 3.53 ppm (2 H, J=8 Hz, CH_2OH) and the molecular weight determined by mass spectrum study was found to be 290 which corresponded to the alcohol (XVIII). The alcohol on oxidation with Jones reagent afforded the keto acid (XVI) in 50% yield and the keto aldehyde (XIX) in 35% yield. Oxidation of the keto aldehyde (XIX) with Jones reagent for a prolonged period afforded a negligible amount of the keto acid (XVI).

In order to confirm the structure of the keto acid (XVI), it was converted to its thioacetal (XX) which on desulfurization with Raney nickel afforded the acid (XXI) in 65% yield. The acid (XXI), identical in all respects (mp and IR) with authentic specimen prepared by Pelletier and Ogiso,[21] was utilized for the synthesis of resin acid degradation products. Thus keto acid (XVI) is not only a potential intermediate for the synthesis of pimarane and tetracyclic diterpenes but constitutes an alternative and elegant approach for the synthesis of resin acid degradation products.

The keto acid (XVI) on reduction with sodium borohydride[22] afforded only the alcohol (XXII) in 92% yield. In the NMR spectrum the alcohol, mp 245 °C, exhibited a multiplet at δ 4.30 (m, H at C-6) with half-band width ($W_{1/2}$) of 6 Hz, characteristic of equatorial proton. Reduction of the alcohol (XXII) by Birch procedure using lithium in liquid ammonia and ethanol afforded an oily material which without purification was treated with mineral acid to obtain α,β-unsaturated ketone (XXIII). In the IR spectrum the ketone (XXIII) showed a strong band at 1645 cm^{-1} characteristic of α,β-unsaturated ketone and in the NMR spectrum it exhibited olefinic proton at δ 5.93 (s, 1 H). The molecular weight of the ketone determined by mass spectrometry was found to be 292 which corresponded to the keto acid (XXIII). It was reported[21] that the Birch reduction of the acid (XXI) afforded α,β-unsaturated ketones (XXIV) in which hydrogen at C-4b and the methyl group at C-4a are trans to each other. By this analogy the trans relationship of C-4b hydrogen and C-4a methyl group of the keto acid (XXIII) was established. Besides the keto acid (XXIII), some oily material consisting a mixture of products (as observed from TLC) was obtained from the Birch reduction of the alcohol (XXII). The oily material exhibited a weak carbonyl band and complete absence of hydroxyl group in the IR spectrum. The formation of the oily material devoid of hydroxyl group can be explained by intramolecular participation of the hydroxyl group and examples in which a hydroxyl group influences reduction with lithium in liquid ammonia have been reported.[23]

The keto acid (XXIII) thus obtained with desired stereochemistry is a potential intermediate for the synthesis of pimarane diterpene[7] and other tetracyclic diterpene.[8] The utility of the keto acid (XXIII) in the synthesis of natural products will be reported.

Experimental

Mps were taken on a Kofler hot stage apparatus. Unless otherwise stated IR spectra measured in cm^{-1}, were recorded on a Perkin-Elmer 337 spectrometer for KBr discs of liquid films and UV spectra were measured with a Cary Model 15 spectrometer for EtOH solution, NMR spectra for solutions in deuteriochloroform on either Varian A-60 or XL-100 instrument. Chemical shifts are reported as δ units using

TMS as an internal standard. The form of signals is expressed as s=singlet, d=doublet, q=quartet and m=multiplet. Mass spectra were recorded on a Hitachi Perkin Elmer RMU-6H at 70 eV using a direct inlet system. Merck standardized alumina, activity II-III was used for column chromatography. For TLC, Merck Silica Gel G used and the spots were identified by exposure to iodine vapour. All organic extracts were washed with saturated NaCl solutions, dried over anhydrous $MgSO_4$ and evaporated under reduced pressure below 40 °C. Microanalyses were carried out by Dr. A. Bernhardt, Microanalytical Laboratory, 5251 Elbach über Engelskirchen, West Germany. The compounds described are all racemic forms.

1,2,3,4,4a,9-Hexahydro-7-methoxy-1,1,4a-trimethylphenanthrene (III). The ketone (I; 5.15 g) suspended in 20% HCl (125 ml) was heated under reflux for 24 h in the presence of amalgated mossy Zn [125 g, shaken for 15 min with $HgCl_2$ solution (120 ml containing 25 g $HgCl_2$ and 10 ml concd HCl)]. During the heating, five portions of concd HCl (6 ml) were added in 5 h intervals. After cooling, the mixture was extracted with chloroform. The chloroform extract was washed, dried and concentrated to give the olefin (III; 3.07 g, 60%), bp 110—112 °C at 0.2 mmHg (bath), *m/e* 256 (M^+) and 226 (M^+-2CH_3), δ 1.13 (3H, s), 1.22 (3H, s) 1.26 (3H, s) (1,1-CH_3), and 4a-CH_3 and 3.66 (3H, s; OCH_3). Found: C, 84.30; H, 9.42%. Calcd for $C_{18}H_{24}O$: C, 84.32; H, 9.44%.

Attempted Method for the Reduction of the Ketone (I). In a 50 ml round bottomed flask equipped with a condenser were placed ketone (I; 0.27 g), tosylhydrazine (0.25 g) and methanol (20 ml). The mixture was heated under reflux for 3 h, then cooled to room temperature. The tosylhydrazone (II; 0.39 g, 75%) obtained had mp (from methanol) 180 °C. Found: C, 86.32; H, 7.2%. Calcd for $C_{25}H_{32}O_3N_2S$: C, 86.15; H, 7.32%.

The tosylhydrazone derivative (II; 0.35 g) was dissolved in tetrahydrofuran (30 ml) and to it was added $LiAlH_4$ (0.42 g) slowly. The resulting mixture was refluxed for 8 h. The complex was decomposed by adding water followed by addition of a solution of 10% potassium hydroxide solution. The organic layer was separated and dried. On removal of the solvent a solid material was obtained which was identified as II by comparison (mp and IR).

1,2,3,4,4a,9,10,10a-Octahydro-7-methoxy-1,1,4a-trimethylphenanthren-10β-ol (IV). To a solution of the olefin (III; 2.01 g) in anhydrous ether (50 ml) at 0 °C was added $LiAlH_4$ (1.21 g). To the cold suspension was added dropwise freshly distilled boron trifluoride etherate (8 ml) in anhydrous ether (60 ml). The reaction mixture was stirred at 0 °C for 1 h and at room temperature for 4 h. The excess diborane was decomposed by addition of ice water and 10% aqueous sodium hydroxide solution (75 ml). The reaction mixture was cooled to 0 °C and then added dropwise 30% hydrogen peroxide (75 ml). The reaction mixture was allowed to warm to room temperature and stirred for 16 h. The aqueous layer was drawn off and extracted twice with ether and then combined with original ethereal solution, dried and then solvent removed. The oily material obtained was chromatographed over alumina. Elution with hexane: benzene (1:1) afforded oily olefin (X; 0.24 g, 12%), bp 115—120 °C at 0.2 mmHg (bath), *m/e* 256 (M^+), λ_{max} 266 nm (log ε 3.96), δ 1.12 (3H, s), 1.20 (3H, s), 1.24 (3H, s) (1,1-CH_3 and 4a-CH_3), 2.42 (1H, s, H-10a), 3.65 (3H, s, OCH_3) and 6.01 (2H, s) (H-10 and H-9). Found: C, 84.28; H, 9.43%. Calcd for $C_{18}H_{24}O$: C, 84.32; H, 9.44%. Further elution with benzene afforded the alcohol (IV; 1.09 g, 50%), mp (from ether) 128—130 °C, *m/e* 274 (M^+) and 256 (M^+-H_2O), ν_{max} 3480 (OH), δ 1.12 (3H, s) 1.20 (3H, s), 1.26 (3H, s) (1,1-CH_3 and 4a-CH_3), 3.68 (3H, s, OCH_3) and 4.23 (1H, m, $W_{1/2}$=8 Hz, H-10). Found: C, 78.76; H, 9.54%. Calcd for $C_{18}H_{26}O_2$: C, 78.79; H, 9.55%.

1,2,3,4,4a,9,10,10a-Octahydro-7-methoxy-1,1,4a-trimethylphenanthren-10-one (V). Jones chromic acid reagent (1 ml) was added to a solution (−12 °C) of the alcohol (IV; 0.22 g) in acetone (4 ml). The solution was stirred during 5 min maintaining the temperature −12 °C. 2-Propanol was added to destroy the excess oxidant and after the usual work-up afforded oily material which on chromatographic purification over alumina afforded the ketone (V; 0.18 g), mp 19—20 °C (from ether-hexane), *m/e* 272 (M^+), ν_{max} 1720 (C=O), δ 0.96 (3H, s), 0.99 (3H, s) and 1.15 (3H, s) (1,1-CH_3 and 4a-CH_3), 2.48 (1H), 2.51 (1H) (H-9) and 3.65 (3H, s, OCH_3). Found: C, 79.35; H, 8.86%. Calcd for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%.

Reduction of the Ketone (V). $NaBH_4$ (0.1 g) was added slowly to an ice-cooled solution of the ketone (V; 0.15 g) dissolved in methanol (20 ml). The solution was stirred at room temperature for 6 h. After acidification with dil HCl, the product was extracted with chloroform. Washing of the organic extract and evaporation yielded a solid material which on crystallization (from ether) afforded an alcohol (0.13 g, 90%) which was identical in all respects (mp and IR) with alcohol (IV).

Lead Tetraacetate Oxidation of 1,2,3,4,4a,9,10,10a-Octahydro-7-methoxy-1,1,4a-trimethylphenanthren-10β-ol (IV). A mixture of lead tetraacetate (3.70 g) and calcium carbonate (3.70 g) was dried under reduced pressure and then heated in cyclohexane (184 ml) under reflux for 30 min with stirring. Then a solution of the alcohol (IV; 2 g) in cyclohexane (40 ml) was added to the above suspension followed immediately by iodine (0.94 g). The mixture was heated under reflux 1 h with two philips 500-W photolamps. The cooled mixture was filtered and the filtered cake was washed thoroughly with ether. The combined organic solvents were washed with 1% sodium hydroxide solution and the colour of iodine was removed by washing with sodium thiosulfate solution. Subsequent washing and evaporation afforded an oily material which was chromatographed on alumina. Elution with hexane afforded the ether (XI; 0.21 g, 10%), mp (ether–hexane) 22—23 °C *m/e* 272 (M^+), δ 1.10 (3H, s), 1.23 (3H, s) (1-CH_3 and 4a-CH_3), 3.65 (3H, s, OCH_3), 4.08 (1H, d, J=7 Hz) and 4.18 (1H, d, J=8 Hz) (2H, H-12). Found: C, 79.34; H, 8.87%. Calcd for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%. Further elution with hexane: benzene (1:1) afforded the ketone (V; 0.88 g, 42.7%) Elution with benzene afforded the lactone (XII; 0.78 g, 36%), *m/e* 286 (M^+), ν_{max} 1765, δ 1.20 (3H, s) and 1.28 (3H, s) (1-CH_3 and 4a-CH_3) and 3.65 (3H, s, OCH_3). Found: C, 75.48; H, 7.72%. Calcd for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74%.

1,2,3,4,4a,9-Hexahydro-1β-acetoxymethyl-7-methoxy-1,4a-dimethylphenanthrene (XIII). The ether (XI; 0.91 g) was heated under reflux with acetic anhydride (20 ml) and pyridine –HCl (0.11 g) for 6 h. The mixture was treated with cold water and extracted with ether. The ether extract was washed till neutral and then evaporated to yield a liquid which gave a positive halogen test with a copper wire. The liquid was chromatographed on alumina. Elution with hexane gave the oily olefin acetate (XIII; 90 mg, 9%), bp 118—125 °C at 0.12 mmHg (bath), *m/e* 314 (M^+) and 254 (M^+-CH_3COOH). Found: C, 76.37; H, 8.32%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%. Hydrolysis of the acetate (XIII; 80 mg) with 3% methanolic potassium hydroxide afforded the alcohol (XIV; 50 mg) as a yellow oil, homogeneous in TLC, *m/e* 272 (M^+). Found: C, 79.35; H, 8.86%.

Calcd for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%. Further elution with hexane:benzene (1:1) afforded a chloro compound (XV; 0.81 g, 70%) which was obtained as semi-solid material. It gave positive halogen test, δ 1.13 (3H, s), 1.61 (3H, s) (1-CH_3 and 4a-CH_3), 3.53 (2H, AB q, J=12 Hz, CH_2OAc) and 3.65 (3H, s, OCH_3). Refluxing the chloro compound (XV; 0.70 g) with 5% methanolic potassium carbonate solution afforded ether (XI, 0.48, 90%).

1,2,3,4,4a,9,10,10a- Octahydro-7-methoxy-10-oxo - 1,4a - dimethylphenanthrene-1β-carboxylic Acid (XVI). To the ether (**XI**; 0.31 g) dissolved in acetic acid (6 ml, 98%) was added a solution of CrO_3 (0.25 g) in acetic acid (5 ml, 80%) and the mixture was kept at room temperature for 40 h. The usual work-up gave the acid (**XVI**; 0.27 g, 80%), mp 256—257 °C (from ether), *m/e* 302 (M^+) and 257 (M^+-COOH), ν_{max} 1710 (unresolved acid and ketonic C=O), δ 1.23 (3H, s), 1.26 (3H, s) (1-CH_3 and 4a-CH_3) and 3.65 (3H, s, OCH_3). Found: C, 71.48; H, 7.32%. Calcd for $C_{18}H_{22}O_4$: C, 71.50; H, 7.35%.

Photolysis of the Ketone (V). The ketone (V; 0.92 g) in 95% ethanol (790 ml) saturated with potassium carbonate was irradiated for 25 h with a 200 W Hanovia high pressure lamp with a Pyrex filter under oxygen free nitrogen. On removal of the ethanol a liquid (0.89 g) was obtained which was hydrolysed with a mixture of acetic acid (20 ml), methanol (80 ml) and water (15 ml) heating under reflux for 2 h. The crude product on chromatographic purification over alumina and elution with hexane: ether (1:1) afforded the alcohol (IV, 0.72 g, 78%) identical with the foregoing sample. Further elution with hexane: ether (2:8) afforded an oily material, ν_{max} 3320 (OH). Found: C, 74.42; H, 9.01%. Calcd for $C_{18}H_{26}O_3$: C, 74.44; H, 9.03%.

Oxidation of the Diol (XVIII). The diol (XVIII; 0.14 g) in acetone (15 ml) was added Jones reagent (2 ml) and stirred at room temperature for 4 h. 2-Propanol was added to destroy the excess oxidant and then the mixture was extracted with ether. The ether extract was washed with sodium hydrogencarbonate (5%). The alkaline extract after acidification afforded the keto acid (XVI; 70 mg, 50%) identical with the foregoing sample.

The ether extract was washed, dried and evaporated to obtain the aldehyde (XIX; 40 mg, 30%), as a semi-solid mass, homogeneous in the TLC, *m/e* 286 (M^+) and 257 (M^+-CHO), ν_{max} 1685 (C=O) and 1720 (CHO). Found: C, 75.46; H, 7.72%. Calcd for: C, 75.49; H, 7.47%.

1,2,3,4,4a,9,10,10a-Octahydro-7 - methoxy - 1,4a - dimethylphenanthrene-1β-carboxylic Acid (XXI). The keto acid (XVI; 0.11 g) dissolved in chloroform (5 ml) was treated with boron trifluoride etherate (1 ml) and 1,2-ethanedithiol (4 ml). The reaction mixture was stirred for 36 h and then treated with water. The organic extract was washed, dried and on removal of the solvent was obtained the thioacetal (**XX**; 0.16 g). The crude thioacetal, mp 98—105 °C, without purification, was dissolved in absolute ethanol (50 ml) and was added to a suspension of W2 Raney nickel (20 g) in absolute ethanol (100 ml). The mixture was stirred and refluxed for 18 h. The usual work-up afforded the acid (**XXI**; 60 mg, 65%), mp (from ether) 151—152 °C. Found: C, 74.95; H, 8.38%. Calcd for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39%. The mp of the acid (XXI) was not depressed on admixture with the authentic[21] sample (identical in IR and TLC properties).

1,2,3,4,4a,9,10,10a-Octahydro-10β-hydroxy-7-methoxy-1,4a-dimethylphenanthrene-1β-carboxylic Acid (XXII). To the keto acid (XVI; 0.1 g) dissolved in methanol (20 ml) and cooled to 0 °C was added sodium borohydride (15 mg) and the reaction mixture was stirred for 2 h at room temperature. After acidification with dil HCl, the product was extracted with chloroform. Washing of the organic extract and evaporating yielded the alcohol (**XXII**, 90 mg, 92%), mp (from ether) 245 °C *m/e* 304 (M^+) and 286 (M^+-H_2O), δ 1.18 (3H, s), 1.23 (3H, s) (1-CH_3 and 4a-CH_3), 3.65 (3H, s, OCH_3) and 4.30 (1H, m, $W_{1/2}$=6 Hz). Found: C, 71.01; H, 7.93%. Calcd for $C_{18}H_{24}O_4$: C, 71.02; H, 7.95%.

1,2,3,4,4a,4b,5,6,7,9,10,10a-Dodecahydro-10β-hydroxy-1,4a-dimethyl-7-oxophenanthrene-1β-carboxylic Acid (XXIII). The hydroxy acid (XXII; 0.2 g) dissolved in ether (30 ml) was added slowly to anhydrous liquid NH_3 containing lithium metal (30 mg). The mixture was stirred for 30 min and then added slowly absolute ethanol (95 ml). Stirring was continued until disappearance of the blue color; after the mixture had stood overnight at room temperature to allow the ammonia to evaporate, water was added and the reduced product was extracted with ether. The extracts were washed till neutral, dried and evaporated to obtain a semi-solid material (0.94 g) which without purification was hydrolysed on steam bath for 2 h in a mixture of methanol (20 ml), water (5 ml) and concd hydrochloric acid (10 ml). The mixture was poured into cold water and extracted with ether. The organic extract was washed till neutral, dried and evaporated. An oily material was obtained which was chromatographed over silica gel. Elution with benzene: ether (9:1) afforded α,β-unsaturated ketone (**XXIII**; 58 mg, 30%), mp (from ether) 292 °C, *m/e* 292 (M^+) and 274 (M^+-H_2O), λ_{max} EtOH 248 nm (log ε 15,500), ν_{max} 3540 (OH), 1725 (C=O) and 1665 (α,β-unsaturated C=O), δ 1.18 (3H, s), 1.23 (3H, s) (1-CH_3 and 4a-CH_3), 3.78 (1H, m, $W_{1/2}$= 8 Hz) and 5.93 (1H, s) (8-H). Found: C, 69.81; H, 8.25%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%.

We wish to thank Prof. R. E. Ireland, California Institute of Technology for helpful discussions during the preparation of manuscript and Consejo Nacional de Investigaciones Cientificas y Tecnologicas (CONICIT) for partial financial assistance.

(Received July 21, 1978)

Synopsis. Halobenzenes having such an electron-donating group as amino, hydroxyl or methoxyl group at their para position were thiocyanated with sodium thiocyanate under irradiation. Also, the ring isomer of *o*-thiocyanatoaniline, 2-aminobenzothiazole, was obtained by the photoreaction of *o*-chloroaniline with sodium thiocyanate.

In spite that photochemically induced nucleophilic aromatic substitution including the photocyanation has been extensively studied[1] very few examples of photothiocyanation of aromatic compounds are known other than the reaction of phenylthallium(III) compounds with potassium thiocyanate[2] and the formation of *p*-thiocyanatoaniline from *p*-chloroaniline.[3] We now report the photothiocyanation of monosubstituted halobenzene with thiocyanate anion.

By the irradiation of *p*-substituted halobenzenes and sodium thiocyanate in water or *t*-butyl alcohol-water through quartz by a high pressure mercury lamp the corresponding *p*-substituted thiocyanatobenzenes were obtained. The results are summarized in Table 1. Under the similar conditions, *m*-chloroaniline, *m*-chlorophenol, *m*-chloronitrobenzene, or *m*-nitroanisole did not give a detectable amount of *m*-thiocyanatobenzene derivatives.

TABLE 1. PHOTOTHIOCYANATION OF *p*-SUBSTITUTED HALOBENZENES

$$R\text{-}C_6H_4\text{-}X + NaSCN \xrightarrow{h\nu} R\text{-}C_6H_4\text{-}SCN + NaX$$

R	X	Solvent	Time (h)	Yield (%)
NH_2	Cl	20% *t*-butyl alcohol	6	10.5
NH_2	Br	20% *t*-butyl alcohol	6	5.0
OH	Cl	water	18	25.0
OH	Br	water	6	13.6
OCH_3	Cl	20% *t*-butyl alcohol	11	15.3
OCH_3	Br	60% *t*-butyl alcohol	3	7.0

Irradiation of a solution of *o*-chloroaniline and sodium thiocyanate in 20% aqueous *t*-butyl alcohol afforded 2-aminobenzothiazole. There was no remarkable acceleration in the photoreaction of *p*- or *m*-chloroaniline in the presence of 18-crown-6 ether potassium thiocyanate complex in anhydrous acetonitrile. As shown in Table 1, halobenzenes having an electron-donating group at their para position can be substituted by photothiocyanation.

Experimental

UV spectra were recorded on a Hitachi EPS-3T recording spectrophotometer and IR spectra on a Hitachi EPI-G3 spectrophotometer. A Taika 100W high pressure mercury lamp was used as the irradiation source.

General Procedure for Analysis of Photothiocyanation Products from Halobenzenes. A solution of a halobenzene (0.2 mmol) and sodium thiocyanate (2 mmol) in a solvent (20 ml) was irradiated. The reaction was cheked with TLC and UV spectrum. An aliquot of the reaction mixture was analyzed by liquid partition chromatography and UV spectrum to determine the yields of products. The reaction mixture was always proved to contain unreacted halobenzene.

Photothiocyanation of p-*Chloroaniline.* A typical example for isolation and identification of photothiocyanation products from monosubstituted halobenzenes is as follows. A solution of *p*-chloroaniline (5 mmol) and sodium thiocyanate (50 mmol) in 20% aqueous *t*-butyl alcohol (500 ml) was irradiated through quartz with stirring for 4.5 h. A small amount of dark brown precipitates which appeared during the irradiation was filtered off. The filtrate was concentrated to dryness. The residue was mixed with water and extracted with ether. The ethereal layer was dried over anhydrous sodium sulfate and ether was removed under reduced pressure. The residue was crystallized from ethanol water to give colorless crystals, mp 55.5 °C,[4] which was identified with an authentic sample by mixed-melting point, UV and IR spectrum: λ_{max}^{EtOH} 262 nm, ν(KBr) 2141 cm^{-1} (SCN).

Photothiocyanation of o-*Chloroaniline. Formation of 2-Aminobenzothiazole.* The preceding procedure was used except that the *t*-butyl alcohol solution was irradiated for 50.5 h to give colorless crystals, mp 128—129.5 °C,[5] which was identified with an authentic sample by mixed-melting point and UV spectrum: λ_{max}^{EtOH} 264 nm.

Photothiocyanation of p- *or* m-*Chloroanilne in the Presence of 18-Crown-6 Ether Potassium Thiocyanate Complex.* Potassium thiocyanate (1 mmol) and 18-crown-6 ether (1 mmol) were dissolved in methanol (10 ml) and then methanol was removed under reduced pressure to give a colorless complex. A solution of the complex and *p*- or *m*-chloroaniline (0.1 mmol) in acetonitrile (10 ml) was irradiated for 5 h. The yield of the product did not increase compared with that of the reaction product in the absence of the complex.

A Broad-line NMR Study on Some Pyrene Complexes: Molecular Motion and Isomorphism in the High-temperature Forms

Tamotsu INABE, Yoshio MATSUNAGA,* and Yuji YOSHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 14, 1978)

Synopsis. The pyrene complexes with six polynitro aromatic compounds are isomorphous to each other above the transition temperatures. The onset of a large degree of molecular motion has been shown from broad-line NMR measurements to occur at the transition temperature of all the six complexes.

As noted earlier,[1] crystalline pyrene complexes with 2,4-dinitrofluorobenzene (DNF), 2,4-dinitrochlorobenzene (DNC), 2,4-dinitrotoluene (DNT), 2,4-dinitrophenol (DNP), and 2,4,6-trinitrochlorobenzene (TNC) exhibit polymorphic transitions. These transitions are of considerable interest because of the isomorphism observed with the high-temperature forms. The disappearance of the specific interaction between the hydrocarbon molecule and the substituent on the acceptor molecule was speculated to be due to dynamical averaging of the interaction by the onset of a large degree of thermal motion at the transition temperature. The presence of such a molecular motion in the high-temperature forms was considered to be consistent with the relatively small enthalpy and entropy changes at the melting of these complexes. Solid state NMR has proven to be powerful tool for the detection and investigation of molecular motion in complexes;[2] therefore, this technique was employed to study the behavior in our cases.

^{1}H NMR spectra were recorded as the first derivatives at 40 MHz, using a JEOL model JES-ME-3X spectrometer with a broad-line NMR attachment, model JES-BE-1, which employs a crossed-coil system. For the measurements, the complexes were pressed in the form of rods with a diameter of 8 mm. Care was taken in recording the spectra to avoid saturation (where possible), and the modulation amplitude was kept small to avoid distortion of line shape. Second moments were calculated for both halves of the derivative curve and corrected for modulation broadening.

Differential scanning calorimetry (DSC) and X-ray diffraction measurements were made as described in a previous paper.[1] In addition to the five complexes mentioned above, the 2,4,6-trinitrotoluene (TNT) complex was found to exhibit a new phase transition at 59 °C, with an enthalpy change of 2.9 kcal mol^{-1}. The complex melts at 162 °C. The enthalpy of melting is 5.3 kcal mol^{-1}. The X-ray diffraction patterns measured using Cu $K\alpha$ radiation are schematically presented in Fig. 1 along with those of the TNC complex for comparison. Although the two acceptor molecules are almost the same in size, the patterns at room temperature are distinctly different, reflecting the nature of the particular substituent. On the other hand, the simple patterns above the transition temperatures are essentially identical and indicate that these high-temperature forms are isomorphous to each other.

The second moment of the measured spectrum is shown in Fig. 2 as a function of the temperature for each of the pyrene complexes. In all the cases, an abrupt reduction in the second moment was observed almost at the transition temperature determined by DSC. Only when the molecules in the high-tempera-

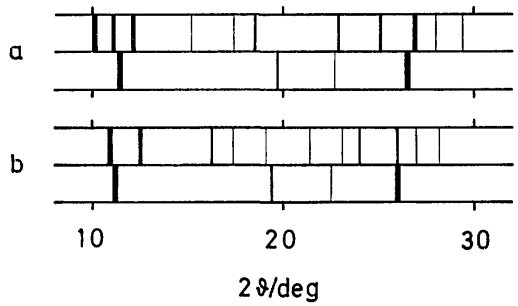

Fig. 1. X-Ray diffraction patterns of the pyrene complexes with a) TNC and b) TNT. The upper pattern for each complex was recorded at room temperature and the lower one, above the transition temperature.

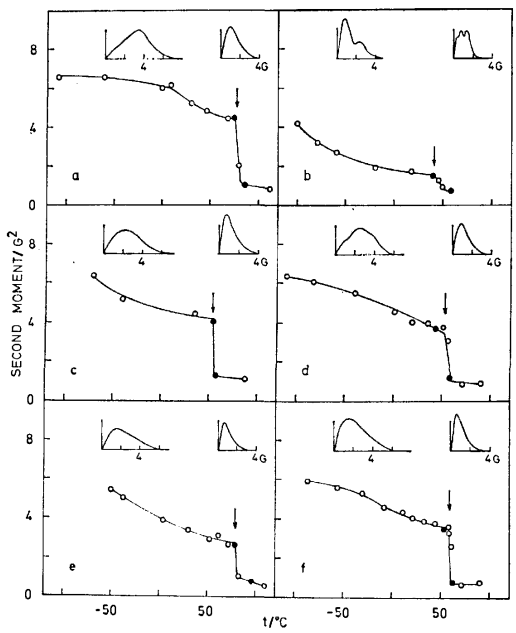

Fig. 2. Second moment values of the proton resonance for the pyrene complexes with a) DNF, b) DNC, c) DNT, d) DNP, e) TNC, and f) TNT with (inset) right halves of representative spectra recorded below (left) and above (right) the transition temperatures. The vertical arrows indicate the thermodynamic transition temperatures.

ture forms are moving fast on an NMR time-scale can one expect such coincidence of the temperatures. It must be noted that the moments observed with the high-temperature forms are in a narrow range around 1 G^2. The resonance line shape changes at the transition. Representative spectra below and above the transition temperature are inset in Fig. 2. The second moments given by these spectra are indicated by shaded circles. Thus, the presence of a large degree of molecular motion in the isomorphous high-temperature forms is now firmly established.

The largest reduction of second moment associated with the transition was found with the DNF complex, and the smallest with the DNC complex. The molecular motion in the low-temperature form of the former complex is clearly more restricted than that of the latter. This conclusion is consistent with the thermodynamic data. Although the enthalpies of melting are rather similar, namely, 5.0 kcal mol^{-1} at 119 °C and 4.2 kcal mol^{-1} at 87 °C respectively, there is a remarkable difference in the enthalpy of transition. The value for the DNF complex is as much as 4.3 kcal mol^{-1}, whereas that for the DNC complex is merely 0.57 kcal mol^{-1}. The enthalpies of transition observed for the other four complexes are in the range from 2.9 to 3.2 kcal mol^{-1}.

The second moment can be calculated from a knowledge of the positions of the nuclei in the lattice, using the formulation of Van Vleck. For such a calculation, the crystal structure is needed, but this is unknown for the present complexes. Nevertheless, the observed variation is so large that the motional characteristics may be discussed to some extent. The second moment in a polycrystalline molecular complex can be divided into an intramolecular part, from the atoms within a single donor molecule and a single acceptor molecule, and an intermolecular part between the atoms of different molecules. For the present complexes, only the former part can be approximately calculated from the molecular structure. The contribution in a pyrene molecule in a rigid lattice has been calculated to be 3.43 G^2 by Fyfe *et al.*[3] As for the acceptor molecule, we calculated the intramolecular contribution in DNF, by way of example, to be 1.5 G^2, taking bond distances of C–C=1.39, C–H =1.08, C–F=1.31, and C–N=1.46 Å, and all bond angles 120°. Then, the contribution in the basis unit of the pyrene–DNF complex becomes about 3.2 G^2 for the rigid lattice model. In order to explain the observed second moment in the high-temperature form, a reduction of the moment by some molecular motion has to be taken into consideration.

The rotation of the pyrene molecule in solids has been suggested to occur in pyrene itself and in some of the molecular complexes.[3,4] It has been pointed out that the rotational barriers found for complexes are lower than those for the parent compounds, possibly due to a general decrease in intermolecular steric effects;[2,5] thus the flat hydrocarbon molecule in the present complexes is probably rotating around the axis perpendicular to the ring plane at high temperatures. Such a motion would reduce the intramolecular contribution by a factor of one fourth.[6] Moreover, the intermolecular contribution is also significantly reduced by it. In the case of the DNF complex, the latter contribution appears to be almost nil. As has been suggested for the azulene-trinitrobenzene complex by Fyfe and Kupferschmidt,[7] it is likely that the acceptor molecule is also mobile in the high-temperature form. In addition to the pyrene complexes reported here, we have recently found a isomorphous high-temperature forms with the complexes of some other hydrocarbons. The work on these complexes is now in progress and will be the subject of forthcoming papers.

The authors wish to express their thanks to Miss Mikiko Nanba and Mr. Eiji Ochi for their collaboration.

Oxidation of Ammonia with Lattice Oxygen of Metal Oxides by Pulse Reaction Technique

Yukio KOSAKI,* Akira MIYAMOTO, and Yuichi MURAKAMI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received July 6, 1978)

Synopsis. On V_2O_5, MoO_3, and WO_3, lattice oxygen has been found to be the active oxygen species for the *catalytic* oxidation of NH_3, whereas on MnO_2, Co_3O_4, Fe_2O_3, and NiO, adsorbed oxygen also played a significant role in the reaction. NO has been found to be an intermediate in the reaction of NH_3 with lattice oxygen.

Many studies have been reported on the reaction of hydrocarbons with the lattice oxygen of metal oxides in connection with the *catalytic* oxidation of hydrocarbons. On a number of catalysts, lattice oxygen (O^{2-}) has been found to play an important role in the *catalytic* oxidation of hydrocarbons. In a previous paper,[1] the authors investigated the *catalytic* oxidation of NH_3 on various metal oxides by a flow technique, and found that NO is an important gas phase intermediate in the oxidation of NH_3. The *catalytic* oxidation of NH_3 was shown to have a specific character, in that NH_3 is first oxidized to NO (deep oxidation product) which then reacts with NH_3 (the NO–NH_3 reaction) to form N_2 and N_2O (partial oxidation products). This is in contrast with the oxidation of hydrocarbons. In the present work, the reaction of NH_3 with the lattice oxygen of metal oxides has been studied to determine the role of lattice oxygen in the oxidation of NH_3 and the importance of NO as an intermediate in the reaction of NH_3 with metal oxides.

Experimental

Materials. The method of preparation of metal oxides has been described previously.[1] Commercial ammonia (99.9 % purity) and oxygen (99.8% purity) were used as reactants without further purification.

Apparatus. Experiments were conducted with a pulse apparatus. The reactant and product components (NH_3, N_2, N_2O, and NO) were analyzed using gas chromatography. Helium as a carrier gas (116 ml/min) was purified with titanium metal sponge heated at 750 °C. Pulses of NH_3 with various concentrations were supplied to the reactor by a 6-way valve. 0.1 g of metal oxides were used. Before injection of each sample, the metal oxides were treated with oxygen in a gas stream for 30 min at the reaction temperature in order to regulate the oxidation state of the samples.

Results and Discussion

Activities of Metal Oxides for the Reaction with Ammonia. The conversion of NH_3 (X_{NH_3}) and the selectivities to N_2, N_2O, and NO (S_{N_2}, S_{N_2O}, and S_{NO}) have been obtained for various metal oxides as functions of the reaction temperature. In order to compare the activities of the metal oxides, the authors have defined T_L^{-1}, where T_L^{-1} represents the reciprocal of the absolute temperature at which X_{NH_3} attains 20% and is a measure of the reactivity of the lattice oxygen of the metal oxide with NH_3. In Fig. 1, the value of T_L^{-1} for a metal oxide is shown against the enthalpy change (ΔH_0) for the following reaction;

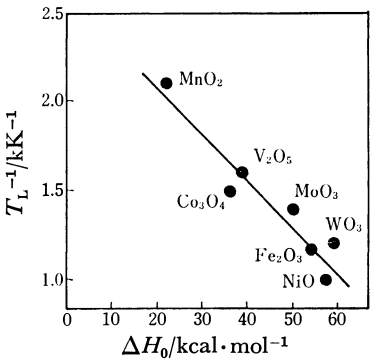

Fig. 1. Relationship between the reactivity of lattice oxygen of a metal oxide (T_L^{-1}) and the enthalpy change (ΔH_0) of the Reaction 1.

$$M_nO_m \longrightarrow M_nO_{m-1} + \frac{1}{2}O_2, \quad (1)$$

where M_nO_m represents a metal oxide before reaction. As shown in Fig. 1, a correlation was obtained between T_L^{-1} and ΔH_0 indicating that the reactivity of the metal oxide with NH_3 is determined by the enthalpy change of the Reaction 1.

In Fig. 2, the relation between T_L^{-1} and T_C^{-1} is shown, where T_C^{-1} is defined as the reciprocal of the absolute temperature at which the conversion of NH_3 in the *catalytic* oxidation of NH_3 by flow technique attains 20%.[1] As shown in Fig. 2, the metal oxides can be divided into two groups. In the first group (V_2O_5, MoO_3, and WO_3), a correlation is obtained between T_L^{-1} and T_C^{-1}, that is, T_L^{-1} is approximately equal to T_C^{-1} within the possible deviations due to the

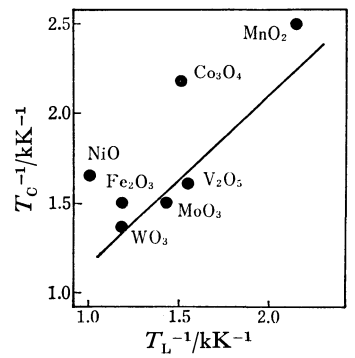

Fig. 2. Relationship between the reactivity of lattice oxygen of a metal oxide (T_L^{-1}) and the activity of the metal oxide for the *catalytic* oxidation of NH_3 (T_C^{-1}).

differences in the reaction technique (pulse or flow technique). The correlation indicates that, on a metal oxide in the first group, the oxygen species responsible for the *catalytic* oxidation of NH_3 is mainly the lattice oxygen of the metal oxide. In the second group (MnO_2, NiO, Fe_2O_3, and Co_3O_4), T_C^{-1} is greater than T_L^{-1} suggesting that on a metal oxide of the second group, in addition to the lattice oxygen, the adsorbed oxygen species such as O_2^- or O^- play a significant role in the *catalytic* oxidation of NH_3. This is in accordance with the results of thermal desorption, that is, the oxygen species, which desorbs at a lower temperature and is assigned to O_2^- or O^- species, was detected for the metal oxide of the second group.[2,3] This classification has been supported by pulse experiments on the effects of gaseous oxygen addition on pulses. The conversion of NH_3 with metal oxides of the second group was enhanced by the addition of O_2 in pulses, whereas X_{NH3} with the metal oxide of the first group was not changed. Concerning the reaction of NH_3 with metal oxides, the influence of adsorbed oxygen, formed by the treatment with gaseous oxygen before the pulse was negligibly small—the conversion of NH_3 in the first pulse was the same as that in the second pulse measured without the treatment with gaseous oxygen. Furthermore, it is considered that the lowering of the surface lattice oxygen concentration hardly occurred in the reaction of NH_3 with metal oxides at the temperature at which X_{NH3} attained 20%, since the yield of N_2, the only product at the temperature, was not changed by the increasing concentration of NH_3 in the pulse.

Nitrogen Oxide as an Intermediate in the Oxidation of Ammonia with the Lattice Oxygen of Metal Oxides. As reported in a previous paper,[1] NO plays an important role as a gas phase intermediate in the *catalytic* oxidation of NH_3 on metal oxides. This view agrees with that of Shelef *et al.*[4] and Schmidt *et al.*[5] In the oxidation of NH_3 with lattice oxygen of Co_3O_4 and V_2O_5 at 520 °C and 528 °C respectively, the conversion of NH_3 was 100

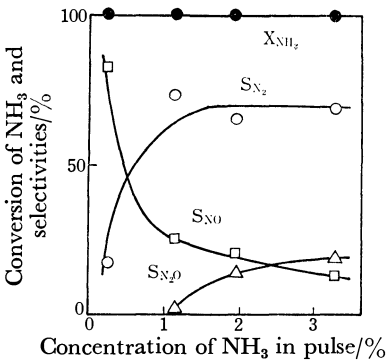

Fig. 4. Oxidation of NH_3 pulse with various NH_3 concentrations by lattice oxygen of V_2O_5.
Reaction temperature=528 °C. Pulse size=7.42 cm³.

% and all of NO, N_2, and N_2O were formed irrespective of the inlet concentration of NH_3. As the concentration of NH_3 in the pulse decreased (Figs. 3 and 4), S_{NO} increased to 100%, and S_{N2O} and S_{N2} decreased to 0%. The results can be explained by the following scheme;

$$NH_3 \xrightarrow[\text{I}]{\text{Lattice oxygen}} NO \xrightarrow[\text{II}]{NH_3} N_2,\ N_2O, \qquad (2)$$

where NH_3 is at first oxidized by lattice oxygen to NO which then reacts with NH_3 (the NO–NH_3 reaction) to form N_2 and N_2O (Step II). The NO–NH_3 reaction (Step II) takes place catalytically under the experimental conditions of the present work.[6] According to the scheme, the activity of a metal oxide is determined by Step I, whereas the selectivities to N_2 and N_2O are limited by the relative rate of Step II to that of Step I. Since Step I and Step II are a monomolecular and a bimolecular reactions respectively, the relative rate of Step II to that of Step I, should increase with an increase in the concentration of NH_3, which is in accord with the experimental results shown in Figs. 3 and 4. Furthermore, in Figs. 3 and 4, the S_{NO} on V_2O_5 decreases more markedly than that on Co_3O_4 with increasing concentration of NH_3, in accordance with the scheme, since the activity of V_2O_5 for the NO–NH_3 reaction is higher than that of Co_3O_4.[6] Thus, it is concluded that NO plays an important role as a gas phase intermediate in the reaction of NH_3 with metal oxides as well as in the *catalytic* oxidation of NH_3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (2), 619—620 (1979)

Preparation of Potassium Glycinatotrihydroxonitrosylruthenate(II)

Toshio ISHIYAMA* and Takashi MATSUMURA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received March 3, 1978)

Synopsis. A new mono-glycinato complex of hydroxonitrosylruthenium(II), K[Ru(gly)$(OH)_3$NO] was isolated by use of ion exchange resin from the product formed by the reaction of $[RuCl_3(H_2O)_2NO]$ with glycine. The complex was characterized by means of infrared, visible, and ultraviolet absorption spectra, capillary type isotachophoresis, magnetic moment and molar conductivity.

The hydroxonitrosylruthenium(II) complex with amino acid is not known. Belot and Pignon[1] studied the behavior of nitrosylruthenium in the presence of potentially complexing organic compounds. They reported that the mercapto carboxylic acids were the best complexing agents and that the complex formation of nitrosylruthenium(II) hydroxide with mercaptoacetic acid could evidenced by measuring the relative amount of dissolved species with ultra-filtration or gel chromatography. In the present paper we report on potassium glycinatotrihydroxonitrosylruthenate(II).

Experimental

Materials. Commercial ruthenium(III) chloride monohydrate (Mitsuwa Chemicals and Co.) and glycine (extra pure grade, Kishida Chemicals and Co., Ltd.) were used. Commercial Dowex 1×4 sieved to a fraction of 100—200 mesh was used as anion exchange resin. The resin was converted into the Cl-form by treatment with 2 M NaOH and 2 M NaCl in a beaker. The resin was washed with distilled water until the chloride ion was no longer detected in the washing. The Cl-form resin was dried at 60 °C for 48 h and then stored in a desiccator.

Preparation. Diaquatrichloronitrosylruthenium(II), [$RuCl_3(H_2O)_2NO$]: The complex was prepared by a modification of the method of Fletcher *et al.*[2] After the solution of nitrosyl derivative formed by the reaction of ruthenium(III) chloride with sodium nitrite has been adjusted to pH 6.4 with 2 M sodium hydroxide, the solution was evaporated to dryness and extracted with ethanol. The crystals formed by the removal of ethanol by distillation were dried *in vacuo*. (Found: Ru, 36.05; H, 1.74; N, 5.26; Cl, 39.36%. Calcd for $[RuCl_3(H_2O)_2NO]$: Ru, 36.95; H, 1.46; N, 5.12; Cl, 38.92%).

Potassium Glycinatotrihydroxonitrosylruthenate(II), K[Ru(gly)$(OH)_3$NO]: Diaquatrichloronitrosylruthenium(II) (3 g) was dissolved in 20 ml of distilled water. To this was added a solution obtained by dissolving 1.2 g of glycine in a small amount of distilled water. The resulting solution was refluxed on a hot-water bath for 3 h. This was concentrated and then cooled in a refrigerator for several days. The crystals formed were filtered and dissolved in 5 ml of distilled water. The solution was passed through a column (diam. 11 mm, height 245 mm) filled with Cl-form anion exchange resin. The adsorbed complex was eluted with 2 M KCl. After the eluent had been concentrated, potassium chloride deposited was filtered off. The crystals formed were filtered, recrystallized from water and dried *in vacuo*. The complex is insoluble in organic solvents. Found: K, 13.76; Ru, 33.80; C, 8.19; H, 2.60; N, 9.89; yield 36.84%. Calcd for K[Ru(H_2N–CH_2–COO)$(OH)_3$NO]: K, 13.24; Ru, 34.23; C, 8.13; H, 2.39; N, 9.49%.

Measurements. Potassium in the complex was determined as follows. Potassium was precipitated with 2% sodium tetraphenylborate solution. After being filtered and washed, the precipitate was dissolved in acetone. To this solution was added excess mercury(II)–EDTA, and the EDTA liberated was back-titrated with a standard zinc solution using a PAN indicator.[3] Ruthenium in the complex was determined spectrophotometerically by measuring the absorbance at 465 nm after thermal decomposition of the complex at 320 °C followed by alkali fusion.[4] Infrared absorption spectra were measured in KBr disks on a JASCO Model IR-S infrared spectrophotometer. Magnetic susceptibility was measured by the Faraday method[5] at 20 °C with a Cahn R. G. electrobalance. Molar conductivity was measured at 20 °C with Yanagimoto Model MY-7 conductivity outfit. Isotachophoresis was measured with a Shimadzu Model IP-1B capillary tube isotachophoretic analyzer as described below. 1.8 mg of potassium glycinatotrihydroxonitrosylruthenate(II) was dissolved in 500 μl of distilled water. A 10 μl portion of the aqueous solution of the sample was poured into a capillary tube, length 20 cm, inner diam. 0.57 mm. An aqueous mixture solution of 0.01 M ammediol–HCl adjusted to pH 8.8 was used as the leading electrolyte, and an aqueous mixture solution of 0.01 M β-alanine–$Ba(OH)_2$ adjusted to pH 10.9 as the terminal electrolyte. The electrophoreogram was recorded with migration current and migration time 100 μA and 20 min, respectively.

Results and Discussion

It was found from the electrophoreogram shown in Fig. 1 that the complex behaves like an anionic species in electrophoretic migration. A potential gradient inversely proportional to the mobility was obtained, the potential unit value (*PU* value) of the sample being calculated from the relative ratio of the potential gradient of leading electrolyte and the sample zone by means of the following equation:[6]

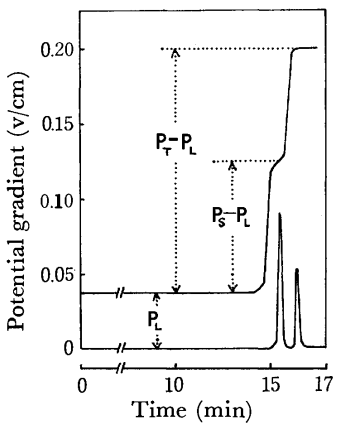

Fig. 1. Isotachophoresis of $[Ru(gly)(OH)_3NO]^-$.

$$PU \text{ value} = \frac{P_S - P_L}{P_T - P_L} = 0.531,$$

where P_S: potential gradient of the sample,
P_L: potential gradient of leading electrolyte,
P_T: potential gradient of terminating electrolyte.

The leading electrolyte has a mobility larger than that of the sample and the terminating electrolyte a smaller mobility. The *PU* value 0.531 indicates that the mobility of the complex anion is nearly intermediate between that of 0.01 M ammediol–HCl at pH 8.8 and 0.01 M β-alanine–$Ba(OH)_2$ at pH 10.9, assuming the formation of mono-glycinato complex anion of hydroxonitrosylruthenium(II) in weak alkali solution.

From the results of elemental analysis, the ratio of potassium, ruthenium, carbon, hydrogen and nitrogen of the complex was found to be 1 : 1 : 2 : 7 : 2. The molar conductivity of aqueous solution of the complex was 143.6 Ω^{-1} cm^2 mol^{-1}, showing that the complex is a 1 : 1 type electrolyte.

Table 1. The characteristic infrared absorption bands of the present Ru(II) complex (cm^{-1})

Assignment	Glycine	K[Ru(gly)$(OH)_3$NO]
ν(N–H)	3480	3400
ν(O–H)		3060
ν(O–D)		2140
ν(N–O)		1865s—1825br
Antisymmetric		
ν(COO)	1595	1603
Symmetric		
ν(COO)	1399	1395
ν(C–N)	1034	1030sh

s=strong, br=broad, sh=shoulder.

The main infrared absorption bands of the present complex are given in Table 1, together with those of the pure ligand. The absorption band at 1850 cm^{-1} was assigned to the NO^+ stretching vibration of nitrosyl group. The band shifted to the lower frequency side than that of the original complex, [$RuCl_3(H_2O)_2NO$] by the chelation of glycine. A similar observation has been reported for [$RuCl_3$(phen)NO] by Lewis *et al.*[7] The absorption band at 3400 cm^{-1} was assigned to N–H stretching vibration of the NH_2 group by comparison with the peak at 3480 cm^{-1} of glycine. The absorption band at 1030 cm^{-1} was assigned to C–N stretching vibration arising from skeleton stretching of glycine. The band at 3060 cm^{-1}, assigned to the OH stretching frequency, shifted after deuteration to 2140 cm^{-1}. The new glycinatohydroxonitrosylruthenate(II) complex was identified from the IR-data.

The electronic absorption spectrum of the complex, K[Ru(gly)$(OH)_3$NO] was measured in aqueous solution (pH=6.15), and compared with that of the starting complex, [$RuCl_3(H_2O)_2NO$] reported by Mercer *et al.*[8]

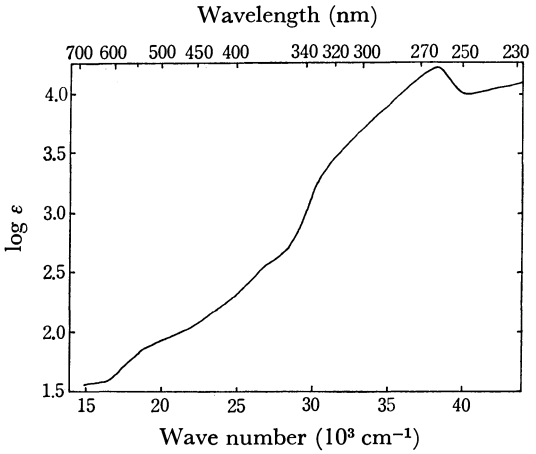

Fig. 2. Electronic spectrum of K[Ru(gly)$(OH)_3$NO] in H_2O (pH=6.15).

The spectrum is shown in Fig 2.. Potassium glycinatotrihydroxonitrosylruthenate(II), K[Ru(gly)$(OH)_3$NO] has three shoulders and a peak at 540, 390, 335, and 265 nm, respectively. The 540 nm shoulder may be assigned to the d-d transition. In spite of no appearance of an absorption band of [$RuCl_3(H_2O)_2NO$] in the ultraviolet region, the appearance of the characteristic peak of K[Ru(gly)$(OH)_3$NO] at 265 nm may be attributed to the ligation of glycine.

The observed diamagnetism of K[Ru(gly)$(OH)_3$NO] indicates that the ruthenium atom has spin-paired d^6 configuration, suggesting that the complex can be formulated by the donation from NO^+ ion. The stereochemical configuration of K[Ru(gly)$(OH)_3$NO] is not clear, but a facial or meridional formula can be proposed.

The authors wish to express their thanks to Prof. Masayasu Mori and Dr. Shigeichi Kubo, Osaka City University, for their guidance in the measurement of magnetic susceptibility. Thanks are also due to Dr. Yasuyo Shiogai, Shimadzu Seisakusho Ltd. for carrying out the isotachophoretic analysis.

Flux Growth of Double Oxide Crystals of Tantalum and Rare-earth Elements

Yuichi YAMASAKI* and Yoshinori SUGITANI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received July 5, 1978)

Synopsis. Crystals of $GdTaO_4$, $DyTaO_4$, and $ErTaO_4$, and those of Gd_3TaO_7, Y_3TaO_7, and Er_3TaO_7 have been grown by PbF_2–PbO flux. Solid solution crystals of $YTaO_4$ and $YNbO_4$ have been obtained for the starting composition of $YTa_xNb_{1-x}O_4$($x<0.5$).

Niobium and tantalum occur in nature as fergusonite $Y(Nb,Ta)O_4$, columbite $(Fe,Mn)(Nb,Ta)_2O_6$, and samarskite $Y_4[(Nb,Ta)_2O_7]_3$, *etc.*[1] It is common for these minerals to contain radioactive elements such as U and Th as minor elements, so that they are in most cases in the 'metamict' form, giving an X-ray pattern like that of an amorphous phase. It is generally known that in inorganic compounds solid solutions are formed at any atomic ratio for Nb and Ta, and that with an increase in Ta content, the melting point of the compound increases, abruptly over 2000 °C.

The flux growth of fergusonite type crystals[2,3] $LnNbO_4$, where Ln is a rare-earth element has been reported, as have the new compounds of Ln_3NbO_7, the columbite type crystals of MNb_2O_6 and MTa_2O_6, where M is divalent transition metal. Although these compounds have high melting points, growth at temperatures below about 1300 °C has been achieved. In this paper the flux growth of the double oxides of rare-earth elements and tantalum at temperatures below 1500 °C are reported. Above 1500 °C the Pt crucible is seriously damaged.

As a typical case, the growing method of $GdTaO_4$ is given here. Other compounds can be grown, in general, in a manner similar to that for $GdTaO_4$, with some minor changes in the conditions such as the composition of the starting materials, solute-flux ratio, *etc.* Reagents of Ln_2O_3 (purity 4N) and Ta_2O_5 (purity 4N) were used for the growth experiment. As flux materials, PbF_2–PbO, Bi_2O_3–V_2O_5, and B_2O_3–$Na_2B_4O_7$ were used at various flux ratios. The purity of PbF_2 and PbO was 3N, and the others were of chemical reagent grade.

A mixture of the starting material (Gd_2O_3 5 mM+Ta_2O_5 5 mM) was put into a 20 ml platinum crucible together with the flux material (PbF_2 40 mM+PbO 10 mM), and tightly covered with a platinum lid. The crucible was placed in an electric muffle furnace kept at 1350 °C for 10 h. Cooling to 900 °C was achieved at the rate of 1—3 °C/h, program controlled. At the final temperature the crucible was taken from the furnace and air quenched to room temperature. The products obtained were washed with hot dilute HNO_3 for several hours. The crystals thus obtained were identified as the desired materials by X-ray powder diffraction.

Figure 1 shows the crystals of $GdTaO_4$ obtained by using PbF_2–PbO flux. The regular crystals are octahedral in shape, ranging in size from 0.5—2.5 mm in the longest directions.

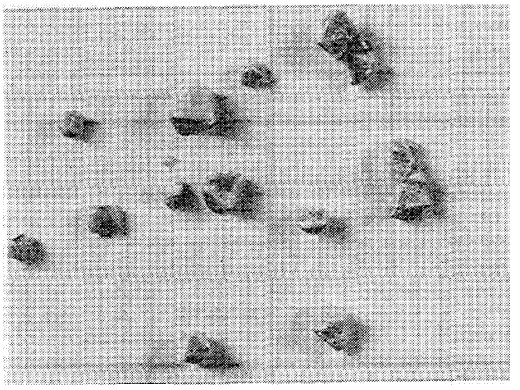

Fig. 1. Crystals of $GdTaO_4$ (1 division=1 mm).

Of the flux materials tried, only the PbF_2–PbO system was suitable for the growth of Ln–Ta–O system compounds. A list of crystals obtained from the PbF_2–PbO flux is given in Table 1, where the compounds presented in each row were obtained from the same melt. Crystals having $LnTaO_4$ composition are those with Ln=Gd, Dy, and Er. They were found to be monoclinic and isostructural with $LnNbO_4$ with a fergusonite structure, the cell parameters of which are given in Table 2. Attempts at growing other $LnTaO_4$ type compounds at higher temperatures (*i.e.* up to about 1500 °C) were not successful. Compounds of Gd_3TaO_7, Y_3TaO_7, and Er_3TaO_7 belong to the cubic system, and have been related to the Ln_3NbO_7 type crystals.[4] No analogue compounds of Ln_3TaO_7 are known in nature. Crystals which were obtained as by-products during the growth are $Pb_3Ta_2O_8$, $Pb_2Ta_2O_7$ and other unidentified crystals.

The growth of the solid solution phases of the $YTaO_4$–

Table 1. List of products obtained by flux method (PbF_2: PbO=80: 20)

Ln[a]	Products (color, shape)
La	$Pb_3Ta_2O_8$(brown, massive), $Pb_2Ta_2O_7$(yellow plates)
Ce	CeO_2(black, octahedral)
Nd	$Pb_3Ta_2O_8$[b]
Sm	$Pb_3Ta_2O_8$[b]
Eu	$Pb_3Ta_2O_8$[b]
Gd	Gd_3TaO_7(yellow plates), $GdTaO_4$(yellow, octahedral)
Dy	$DyTaO_4$(pale yellow, massive)
Y	Y_3TaO_7(pale brown, massive), $Pb_3Ta_2O_8$, $Pb_2Ta_2O_7$
Ho	$Pb_3Ta_2O_8$[b]
Er	Er_3TaO_7(pink plates), $ErTaO_4$(pale yellow, massive)

a) Ln means rare-earth element, the oxide form of which was added as one component of the starting materials. b) Compounds of rare-earth element and tantalum were not obtained.

Table 2. Lattice parameters of products having $LnTaO_4$ and Ln_3TaO_7 composition (1 Å=0.1 nm)

Product	Lattice parameter			
	a(Å)	b(Å)	c(Å)	β(°)
$GdTaO_4$	5.401(2)[a]	11.060(2)	5.071(2)	95.6(2)
$DyTaO_4$	5.352(2)	10.981(2)	5.060(2)	95.7(2)
$ErTaO_4$	5.313(2)	10.891(2)	5.040(2)	95.7(2)
Gd_3TaO_7	5.321(2)			
Y_3TaO_7	5.240(2)			
Er_3TaO_7	5.321(2)			

a) Numbers in parentheses here are estimated standard deviations in units of the last significant digit.

$YNbO_4$ series has been attempted in the temperature region below 1500 °C. Single phase crystals have been obtained for the compositions $YTa_xNb_{1-x}O_4$ with $x<0.5$. Here, the value x means the composition of the starting materials. For $x\geq 0.5$, products showing X-ray patterns corresponding to fergusonite type structure were not obtained. Significant changes in cell dimensions for the grown solid solutions were not observed within experimental error, but for a parallel increase in specific gravity with an increase in Ta content.

The authors wish to express their thanks to Professor Kozo Nagashima of the University of Tsukuba for his kind support of this work.

2,2′-Bipyridine Derivatives of Hexarhodium Carbonyl Cluster

Kenji NOMIYA* and Hisashi SUZUKI

Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229

(Received July 6, 1978)

Synopsis. The properties of $[Rh_6(CO)_{12}(bpy)_2]$(bpy: 2,2′-bipyridine), prepared recently from substitution of carbonyl ligands in $[Rh_6(CO)_{16}]$ by 2,2′-bipyridine have been investigated.

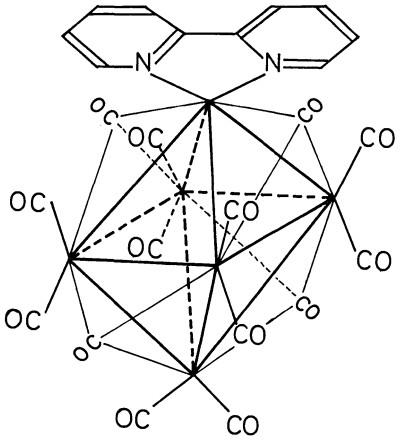
Though hexadecacarbonylhexarhodium is generally considered to be a stable, rather unreactive compound, its derivatives substituted by dienes, halogens, phosphines and phosphites have been reported.[1–5] Recently we have found that the treatment of $[Rh_6(CO)_{16}]$ with 2,2′-bipyridine in dichloromethane at room temperature under nitrogen atmosphere gives rise to a successive replacement of two carbonyl groups by 2,2′-bipyridine and results in the formation of $[Rh_6(CO)_{12}(bpy)_2]$. Further replacement of carbonyl groups did not occur. Darkbrick-colored crystals were isolated from the deep brown solution. This compound is more soluble in dichloromethane and chloroform than $[Rh_6(CO)_{16}]$, and stable to air oxidation on the solid state. In the synthetic reaction unis(bipyridine)-substituted cluster was not obtained.

The IR spectrum of $[Rh_6(CO)_{12}(bpy)_2]$ in the carbonyl stretching region shows ν(CO) at 2050, 2015 cm^{-1} (terminal) and 1785 cm^{-1} (face-bridging) in dichloromethane. In comparison with $[Rh_6(CO)_{16}]$ which has sharp bands at 2075 and 2025 cm^{-1} due to terminal carbonyls and at 1801 cm^{-1} due to face-bridging carbonyl group in chloroform, all bands were shifted to the lower frequency. The symmetry (A_1+B_1) of terminal carbonyls implies that two bipyridine ligands coordinate, in place of four carbonyl groups, to the terminal sites in the trans-position of the hexarhodium unit. The coordination mode of the bipyridine ligand is similar to that of the dienes such as norbornadiene, 1,4-cyclohexadiene and 1,5-cyclooctadiene in $[Rh_6(CO)_{14}(diene)]$.[1]

Under carbon monoxide atmosphere, the bipyridine ligand of $[Rh_6(CO)_{12}(bpy)_2]$ can be readily replaced with carbon monoxide at room temperature. By monitoring IR spectra it was found that the cluster had been returned to parent carbonyl $[Rh_6(CO)_{16}]$ *via* $[Rh_6(CO)_{14}(bpy)]$ as an intermediate, the existence of which was confirmed by ^{13}C-NMR data described later. The resulting $[Rh_6(CO)_{16}]$ is almost excluded from the solution because of its low solubility.

$$\begin{array}{ccc} [Rh_6(CO)_{16}] & \xrightarrow[-CO]{bpy} & [Rh_6(CO)_{12}(bpy)_2] \\ \uparrow CO,\ -bpy & & CO \downarrow,\ -bpy \\ & & [Rh_6(CO)_{14}(bpy)] \end{array}$$

Under carbon monoxide atmosphere the direct carbonyl exchange also proceeds on the cluster during the coordinated bipyridine-CO exchange. For 100 h reaction of $[Rh_6(CO_{12})(bpy)_2]$ (27 mg) in dichloromethane (4 ml) with excess ^{13}C-enriched carbon monoxide (*ca.* 91 atom%) at room temperature, the labelled unis(bipyridine)substituted cluster was predominantly existent in the solution. The proton-decoupled ^{13}C-NMR spectrum of the cluster showed the presence of two nonequivalent carbonyl resonances at a lower field (δ 231.8, 243.2 ppm: quartet J(Rh–C) *ca.* 26 Hz) and three nonequivalent carbonyl resonances at a higher field (δ 180.2, 181.6, 184.0 ppm: doublet J(Rh–C) 71.6±0.3 Hz). As observed for $[Rh_6(CO)_{16}]$ (terminal carbonyl; δ 180.1 ppm, doublet J(Rh–C) 70.2 ±0.6 Hz, face-bridging carbonyl; δ 231.5 ppm, quartet J(Rh–C) 24.4±0.6 Hz),[6] the lower field signals are due to the face-bridging carbonyl groups and the higher field signals due to the terminal carbonyl groups. The intensity ratio of the terminal carbonyls exhibits 4: 4: 2. Since these intensities should reflect the relative abundances in this region, the spectrum is compatible with Structure (1).



Structure (1).

The result that two resonances of the terminal carbonyls attached to the square plane in the Rh_6 unit are nonequivalent is similar to the result that two resonances of terminal carbonyls attached to the basal plane are nonequivalent relative to the apical rhodium in $[Rh_4(CO)_{12}]$.[7]

The reaction product between $[Rh_4(CO)_{12}]$ and dienes is reported to give the same product, $[Rh_6(CO)_{14}(diene)]$ obtained by the reaction of $[Rh_6(CO)_{16}]$ with dienes.[1] However, the reaction of $[Rh_4(CO)_{12}]$ with bipyridine under the aforementioned synthetic conditions produces exclusively an unidentified black solid, which is insoluble in almost organic solvents.

Experimental

^{13}C-NMR spectra were recorded in the Fourier transform

mode on a Varian Associates XL-100-15 spectrometer in dichloromethane-d_2 solution, using 0.05M $Cr(acac)_3$ as a relaxation reagent and using tetramethylsilane as an internal standard. IR spectra were recorded on a Model EPI–G3 of Hitachi Grating Infrared Spectrophotometer.

2,2′-Bipyridine was recrystallized from a mixture of ethanol and water. Hexadecacarbonylhexarhodium, $[Rh_6(CO)_{16}]$, was purchased from the commercial source (Strem Chemical Incorporated). The ^{13}CO (91 atom%) enclosed in a glass tube with a breakable seal, purchased from B.O.C. Ltd. (Prochem), was connected with vacuum line and used without further purification. Solvents, CH_2Cl_2 and CD_2Cl_2, were dried over P_2O_5, and were vacuum-distilled before use.

Preparation of $[Rh_6(CO)_{12}(bpy)_2]$. The 2,2′-bipyridine (bpy: 176 mg, 1.13 mmol) was added to $[Rh_6(CO)_{16}]$ (200 mg, 0.19 mmol) suspended in dichloromethane (10 ml) on stirring at room temperature. During the stirring the evolved carbon monoxide was evacuated from time to time and replaced with dry nitrogen. After the 100 h reaction at about 30 °C, the reaction mixture was filtered out under dry nitrogen. (The residue was dark-green and air-stable.) Excess hexane was added to the deep brown filtrate, the solution of which was kept overnight at −78 °C. The solid obtained was washed several times with hexane, recrystallized from a mixture of dichloromethane and hexane, and then dried *in vacuo*. The yield was about 30%. It was stored under nitrogen in an ice box. Found: C, 30.19; H, 1.99; N, 4.75%. Clacd for $C_{32}H_{16}O_{12}N_4Rh_6$: C, 30.33; H, 1.26; N, 4.42%.

Preparations and Paramagnetic Contact Shifts of Some Tris(β-diketonato)vanadium(III) Complexes

Katsuma HIRAKI,* Masayoshi ONISHI,* Yutaka NAKASHIMA, and Yayoi OBAYASHI

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received August 26, 1978)

Synopsis. New tris(dehydroacetato)-, tris(methyl acetoacetato)-, and tris(ethyl acetopyruvato)vanadium(III) complexes were prepared and characterized by IR and NMR spectroscopies. Paramagnetic contact shifts of these complexes were discussed.

Remarkable paramagnetic contact shifts have been observed for mononuclear trivalent vanadium complexes containing univalent chelate ligands such as β-diketonato,[1-3] salicylaldehydato,[4] and their related ligands,[4,5] and been applied to the investigations of the *fac-mer* stereochemistry and of electron distributions over the ligands of these complexes.[2,3,6,7] However, no work has been yet reported about a vanadium(III) complex coordinated with dehydroacetic acid (Hdac), alkyl acetoacetate, or alkyl acetopyruvate, each of which belongs to a β-diketone, possessing a characteristic substituent. This note will deal with the preparation and ^{1}H-NMR study of the new vanadium(III) complexes containing dac, methyl acetoacetato (maa), or ethyl acetopyruvato (eap) ligand.

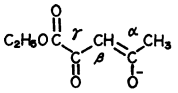
maa



eap

Experimental

Materials. Commercial grade vanadium(III) chloride, dehydroacetic acid, and methyl acetoacetate were used without further purification. Ethyl acetopyruvate was prepared accoding to the method of Marvel *et al.*[8]

General Procedures. IR and ^{1}H-NMR spectra were measured on a Hitachi Model 285 and a JEOL Model PS-100 (100 MHz) spectrometers, respectively. Since solutions of vanadium(III) complexes appeared to be sensitive to aerial oxidation, preparations and recrystallization were carried out under a dinitrogen atmosphere.

Preparation of $[V(dac)_3]$. An aqueous solution of dehydroacetic acid (57 mmol) and sodium carbonate (30 mmol) was added to an aqueous solution of vanadium(III) chloride (19 mmol). After the mixture was refluxed for 2 h, a resulting precipitate was separated, washed with water, and dried *in vacuo*. Recrystallization from dichloromethane–petroleum ether yielded an ochre-colored solid, $[V(dac)_3]$.

Preparation of $[V(maa)_3]$. An ethanol solution of methyl acetoacetate (19.2 mmol) and an aqueous solution of sodium carbonate were added to vanadium(III) chloride (6.4 mmol) in 32 cm^3 of an ethanol–water (3: 1) solution. The mixture was stirred for 2 h at room temperature. After the solvent was evaporated, a residue was recrystallized from benzene–petroleum ether to give a greenish yellow crystal, $[V(maa)_3]$.

Preparation of $[V(eap)_3]$. Sodium ethyl acetopyruvate (30 mmol) was added to an aqueous solution of vanadium(III) chloride (9 mmol). After the reaction mixture was refluxed for 1 h, a resultant precipitate was separated, washed with water, and dried *in vacuo*. Recrystallization from diethyl ether–petroleum ether afforded a reddish brown solid, $[V(eap)_3]$. This complex is considerably sensitive to air.

Results and Discussion

Table 1 shows the yields, elemental analyses, and some properties of the complexes prepared in the present study. IR spectrum of $[V(maa)_3]$ lacked ν(C=O) near 1700 cm^{-1}, revealing that the vanadium(III) ion was coordinated with a carbonyl oxygen of the ester group to form a β-diketonato chelate ring, but not with a methoxy oxygen of the same group. Moreover, IR spectra of the three complexes exhibited complicated bands near 1510 and 1590 cm^{-1}, which were assignable to the unsymmetrical β-diketonato chelate rings. The reasons for the complicacy of these bands were probably due to the coexistence of two kinds of bonding sites in the unsymmetrical β-diketonato ligand itself, the *fac-mer* isomerism, and the coordination of the three chelate rings in different circumstances in the *mer* isomer, as elucidated by ^{1}H-NMR spectra.

Table 2 shows ^{1}H-magnetic resonances of $[V(dac)_3]$, $[V(maa)_3]$, and $[V(eap)_3]$. Four signals were detected for a given substituent on the unsymmetrical chelate ring of each of these complexes. This fact indicates that these complexes consist of *fac* and *mer* isomers, similarly to the other vanadium(III) complexes with unsymmetrical β-diketonato ligands.[2,3] Three signals of an equal intensity were ascribed to the substituents on the three

unsymmetrical chelate rings in the disparate circumstances in the *mer* isomer. The fourth signal was ascribed to that on the three unsymmetrical chelate rings in the same circumstance, *i.e.* in C_3 symmetry in the *fac* isomer. Since the fourth signal is smaller than each of the former three ones, the *fac* isomer populates in a smaller ratio than that expected for a statistical formation, which would result in a *fac*: *mer* ratio of 1 : 3 and in four signals of an equal intensity for the ring substituents.

Holm *et al.*[2)] reported that in the NMR paramagnetic shifts of tris(β-diketonato)vanadium(III) complexes, π-contact part was dominant and pseudo-contact one was negligible, and that unpaired spin of the metal was delocalized to the β-diketonato ligand. In connection with the Holm *et al.*'s explanations, the paramagnetic shifts of α-CH_3 protons of $[V(maa)_3]$, $[V(eap)_3]$, and the related (β-diketonato)vanadium(III) complexes[1–3)] were correlated to the electronic effect of the corresponding γ-substituent of the β-diketonato ligand. A value σ_R^m[9)] was used as a parameter for the electronic effect of the γ-substituent, since the β-diketonato conjugated system was reported to have a quasi-aromatic character[10)] and σ_R^m represents the term of the resonance effect of each *meta* substituent, composing Hammett value σ^m.[9)]

Figure 1 presents the paramagnetic shifts of the α-CH_3 protons[11)] against the σ_R^m values of the γ-substituents. As for $[V(maa)_3]$, α-CH_3 protons show a small shift, indicating that the methoxy group at the γ-position of the chelate ring suppresses the electron delocalization from the metal to the ligand. This is consistent with a negative σ_R^m value of the methoxy group, representing the donation of the resonance electron from this group. However, as for $[V(eap)_3]$ in which the ethoxycarbonyl group has a positive σ_R^m, meaning the small donating ability of the resonance electron, the contact shift of α-CH_3 protons is large. The linearity shown in Fig. 1 is consistent with the quasi-aromatic character of the β-diketonato systems, and supports the Holm *et al.*'s explanations[2)] about the paramagnetic shifts of the tris-(β-diketonato)vanadium(III) complexes.

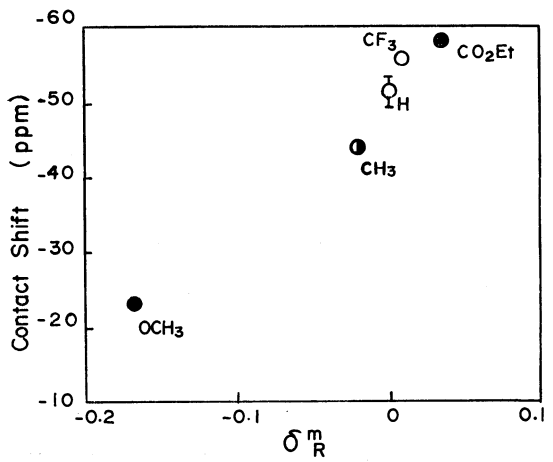

Fig. 1. Relationship between the paramagnetic shift of the α-protons and the σ_R^m value of the γ-substituent.

11) The paramagnetic shifts of the α-CH_3 protons were determined from a difference between δ-value of the complex and that of the corresponding free ligand. The δ-values for the *fac*-type complexes were used as for the γ-substituents of OCH_3, CF_3, and CO_2Et. As regards the γ-substituents of CH_3 and H, δ-value of the acetylacetonato complex and the range of four δ-values for the *fac* and *mer* isomers were adopted, respectively.

O-Methylation of Aromatic (*E*)-Oximes by Dimethylsulfonium Methylide

Shigeo TANIMOTO,* Takashi YAMADERA, Toyonari SUGIMOTO, and Masaya OKANO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received May 18, 1978)

Synopsis. The reactions of dimethylsulfonium methylide with (*E*)-aldoximes and (*E*)-ketoximes proceeded smoothly at room temperature and gave moderately good yields of *O*-methyl (*E*)-aldoximes and *O*-methyl (*E*)-ketoximes, respectively. A possible scheme for the formation of *O*-methyl (*E*)-oximes has been discussed.

Metzger and coworkers[1] published a brief report on a facile methylation of nitrobenzene by dimethyloxosulfonium methylide. Additional methylation reactions with several substituted nitrobenzenes have been described by Traynelis and McSweeney.[2] Analogous *O*-methylation reactions with *o*-hydroxybenzaldehyde have been found by Holt and Lowe,[3] *i.e.*, when *o*-hydroxybenzaldehyde and dimethylsulfonium methylide (**1**) were allowed to react, *o*-methoxybenzaldehyde was isolated. The methylation reactions of anthracene and benzaldehyde phenylhydrazone with dimethyloxosulfonium methylide are also known.[1]

In this paper the facile *O*-methylation of (*E*)-aldoximes (**2a**—**2e**) and (*E*)-ketoximes (**2f**—**2k**) are reported employing **1** prepared *in situ* by the action of *t*-BuOK on trimethylsulfonium iodide in dimethyl sulfoxide (DMSO).

Hitherto, various *O*-methyl (*E*)-oximes (**3**) have been synthesized either by the reaction of a sodium (*E*)-oximate with methyl iodide[4,5] or by the action of methyl sulfate on an (*E*)-oxime under alkaline conditions.[6]

However, the above reactions proceeded with the accompanying formation of *N*-methylated oxime derivatives.[6] The present method provides an exclusive *O*-methylated (*E*)-oxime derivative (**3**). This reaction not only presents an alternative method[7] for the selective *O*-methylation of **2**, but is also of interest as an example of the utility of sulfur ylides.

When an (*E*)-oxime and **1** (generated *in situ* from trimethylsulfonium iodide and *t*-BuOK in DMSO) were allowed to react at room temperature, the corresponding *O*-methyl (*E*)-oxime (**3**) was formed in a moderately good yield. The results are listed in Table 1.

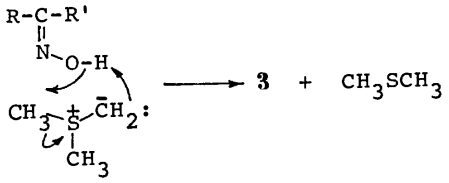
On the other hand, when a potassium (*E*)-oximate (prepared *in situ* by mixing 1 equivalent of an (*E*)-oxime

and 1.5 equivalents of *t*-BuOK in DMSO) and 1.5 equivalents of trimethylsulfonium iodide were allowed to react at room temperature, the corresponding *O*-methyl (*E*)-oxime (**3**) was obtained, but the yield was very poor compared with the result in Table 1. For example, the yield of *O*-methyl (*E*)-benzaldoxime (**3a**) in this procedure was 25%. Consequently, it has to be assumed that the formation of an (*E*)-oximate anion and its subsequent attack on a trimethylsulfonium cation with the loss of neutral dimethyl sulfide occurs simultaneously in the reaction involving **1** and an (*E*)-oxime. Thus, the transition state might be represented as follows:



It has been reported that the methylation of sodium (*E*)-oximate by methyl iodide in ethanol always accompanies some degree of *N*-methylation, which is attributable to the ambifunctional nucleophilic character of the (*E*)-oximate anion.[8,12] However, **2** has been exclusively methylated on oxygen by the method described in this paper. The *N*-methylated oxime derivative could not be detected by NMR spectra. The selective *O*-methylation in the present reaction can be understood taking into consideration the formation of the cyclic transition state.

Experimental

Preparation of O-*Methyl* (E)-*Oximes* (*3*). *General Procedure*: A solution of trimethylsulfonium iodide (8.10 g, 39.6 mmol) in DMSO (20 ml) was placed in a 100 ml four-necked flask equipped with a reflux condenser, thermometer, gas-inlet tube, dropping funnel, and magnetic stirrer. Finely powdered *t*-BuOK (4.44 g, 39.6 mmol) was slowly added with efficient stirring at 5—10 °C, under a nitrogen atmosphere, to the solution. A DMSO solution (5 ml) of an (*E*)-oxime (26.4 mmol) was subsequently introduced dropwise at that temperature. The reaction mixture was then stirred for 5—6 h at room temperature, quenched with saturated aqueous Na_2SO_4 solution and extracted with ether. The organic extract was washed and dried over $MgSO_4$, the solvent evaporated and the residue distilled under reduced pressure.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (2), 629—630 (1979)

The Structure of Yahazunol, a New Sesquiterpene-substituted Hydroquinone from the Brown Seaweed *Dictyopteris undulata* Okamura

Masamitsu Ochi,* Hiyoshizo Kotsuki, Kiyoshi Muraoka, and Takashi Tokoroyama†

Faculty of Science, Kochi University, Asakura, Kochi 780

†*Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558*

(Received May 29, 1978)

Synopsis. The structure of yahazunol, an antimicrobial substance isolated from the brown seaweed *D. undulata* Okamura, was established on the basis of spectral and chemical evidence.

Fenical and coworkers have recently reported the isolation of five sesquiterpene-substituted phenols from *D. undulata* Okamura ("Shiwayahazu" in Japanese), and noted that the occurrence of these constituents was dependent upon the growth localities of the alga.[1-3] Our investigation of the phenolic components of the seaweed collected in the Bay of Tosa led to the isolation of a new sesquiterpene-substituted hydroquinone, designated as yahazunol, together with zonarol (**1**),[1] isozonarol (**2**),[1] and zonaroic acid (**3**).[3] These were all obtained in the crystalline state, contrary to previous descriptions. In this note, we will deal with the structure of this new compound. This compound was found to have a strong antimicrobial activity against some yeasts.[4]

Yahazunol (**4**), $C_{21}H_{32}O_3$, mp 127—129 °C, $[\alpha]_D^{27}$ −12° (*c* 0.10, $CHCl_3$), was isolated in 0.008% yield from a methanol extract of the fresh alga by careful silica-gel column chromatography and fractional crystallization. **4** shows hydroxylic absorptions in the IR spectrum at 3400 and 3280 cm^{-1} and forms a diacetate (**5**), $C_{25}H_{36}O_5$, mp 95—96 °C, the IR spectrum of which still shows the presence of a hydroxyl group at 3560 cm^{-1}. The ^1H NMR spectrum of **5** shows signals due to three methyl groups attached to quaternary carbon atoms at δ 0.80, 0.87, and 0.89 (3H each, s), one methyl group on an oxygenated carbon atom at δ 1.25 (3H, s), two acetoxyl groups at δ 2.28 and 2.34 (3H each, s), one benzyl methylene group at δ 2.61 and 2.68 (1H each, dd, J=15 and 5 Hz), and one 1,2,4-trisubstituted benzene ring at δ 6.90 (1H, dd, J=9 and 2 Hz), 6.96 (1H, d, J=9 Hz), and 7.12 (1H, d, J=2 Hz). In addition, the ^{13}C NMR data of **4**, as summarized in Fig. 1, indicate the presence of five methylene groups, two methine groups, one oxygen-bearing tertiary carbon atom, and two quaternary carbon atoms.

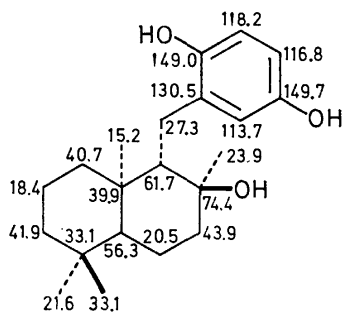

Fig. 1. Yahazunol; ^{13}C NMR data (δ/ppm) for CD_3COCD_3 solution.[5]

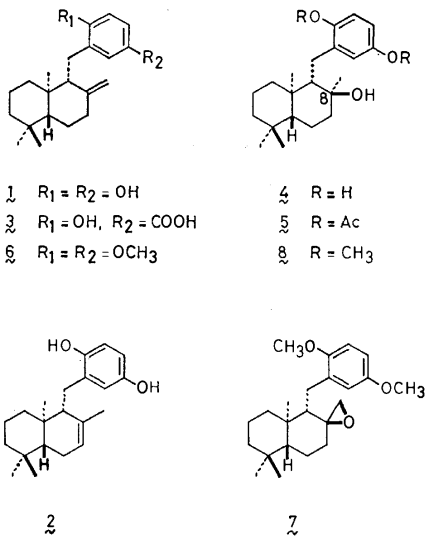
These facts suggest that **4** has a structure analogous to that of zonarol (**1**), in which the exocyclic methylene of **1** is displaced by a grouping $\overset{OH}{\underset{CH_3}{C}}$. This was confirmed by the following chemical correlation of **4** with **1**. The methylation of **1** with CH_3I–K_2CO_3 gave a dimethyl ether (**6**), $C_{23}H_{34}O_2$, mp 74—74.5 °C. The epoxidation of **6** with *m*-$ClC_6H_4CO_3H$ and the reduction of the resulting epoxide (**7**) with $LiAlH_4$ afforded a tertiary alcohol (**8**), which was found to be identical with the compound derived from **4** by the treatment with CH_3I–K_2CO_3.

These correlation reactions also define the configuration at C-8 of **4**. The epoxidation of **6** should occur predominantly on the sterically less crowded β-side and, hence, the C-8 hydroxyl group of **4** is β-oriented. Therefore, yahazunol must be represented by the structure **4**.



Experimental

All mp's are uncorrected. The IR spectra were recorded on a JASCO model IRA-1 spectrophotometer. The ^1H NMR spectra were determined using a JEOL PS-100 spectrometer in $CDCl_3$ solutions, with TMS as an internal standard. A Union Giken apparatus, model PM-101 was used for the measurement of the rotations.

Isolation. Fresh alga (4.3 kg), collected in the Bay of Tosa in May 1977, was chopped up and extracted with 13 liter

of methanol for 10 days. The aqueous methanol solution was washed with petroleum ether, concentrated up to about 1.5 liter and extracted with dichloromethane. The dichloromethane layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. The residue (27.9 g) was subjected to repeated chromatography over silicic acid. The fractions eluted with benzene–ether (19: 1) gave zonarol (**1**)[6] (1.49 g), needles (from ether–petroleum ether), mp 173.5—174.5 °C, $[\alpha]_D^{27}$ +18° (*c* 0.10, $CHCl_3$), isozonarol (**2**)[6] (322 mg), spherulites (from benzene), mp 116—117 °C, $[\alpha]_D^{27}$ +30° (*c* 0.10, $CHCl_3$), and zonaroic acid (**3**)[6] (1.28 g), needles (from aqueous methanol), mp 108—109 °C, $[\alpha]_D^{27}$ +32° (*c* 0.10, $CHCl_3$). The fractions eluted with benzene–ether (9: 1) yielded yahazunol (**4**) (343 mg), needles (from acetone–ether), mp 127—129 °C, $[\alpha]_D^{27}$ −12° (*c* 0.10, $CHCl_3$); IR (KBr) 3400, 3280, 1625, 1507, and 1240 cm^{-1}. Found: C, 76.07; H, 9.82%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

Acetylation of ***4***. A solution of **4** (50 mg) in acetic anhydride (0.5 ml) and pyridine (0.5 ml) was allowed to stand at room temperature overnight and then worked up in the usual way to give a diacetate (**5**) (39 mg), needles (from ether–petroleum ether), mp 95—96 °C; IR (Nujol) 3560, 1760, 1745, and 1250 cm^{-1}. Found: C, 72.27; H, 8.94%. Calcd for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71%.

Methylation of ***1***. To a solution of **1** (1 g) in dry acetone (10 ml) were added methyl iodide (5 ml) and anhydrous K_2CO_3 (5 g). The mixture was refluxed for 8 h, diluted with water, and extracted with ether. The ether layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. The resulting gum was subjected to chromatography over silicic acid with benzene as solvent to give a dimethyl ether (**6**) (415 mg), needles (from methanol), mp 74—74.5 °C; IR (Nujol) 3080, 1645, and 890 cm^{-1}; ^1H NMR δ 3.74 and 3.80 (3H each, s). Found: C, 80.64; H, 10.01%. Calcd for $C_{23}H_{34}O_2$: C, 80.65; H, 10.01%.

Conversion of ***6*** *into* ***8***. A mixture of **6** (200 mg) and *m*-$ClC_6H_4CO_3H$ (138 mg) in dichloromethane (5 ml) was stirred at room temperature for 4 h under nitrogen atmosphere. The reaction mixture was worked up in the usual way and the resulting product was chromatographed over silicic acid with petroleum ether as solvent to give an epoxide (**7**) (110 mg). The ^1H NMR spectrum of this compound no longer showed the presence of the exocyclic methylene but the presence of a grouping $\rangle C(O)CH_2$ at δ 2.51 and 2.62 (1H each, d, J=6 Hz).

To a solution of **7** (90 mg) in dry ether (4 ml) was added $LiAlH_4$ (180 mg) dissolved in dry ether (9 ml). The mixture was stirred for 2 h at room temperature, refluxed for 1 h, and then poured into ether floated on water. The organic layer was separated, washed with water, dried over Na_2SO_4, and evaporated to dryness. The residue was subjected to chromatography over silicic acid and subsequent elution with benzene–ether (49: 1) gave a tertiary alcohol (**8**) (42 mg), oil, $[\alpha]_D^{14}$+4° (*c* 0.42, $CHCl_3$); IR (neat) 3480 cm^{-1}; ^1H NMR δ 1.28 (3H, s, $\rangle C(CH_3)OH$, which was also obtained by the tratment of **4** with CH_3I–K_2CO_3 in a similar manner to that described.

We are grateful to Professor W. Fenical, University of California, for the extract of *D. undulata* and for the IR and ^1H NMR spectra of zonarol, isozonarol, and related compounds, and to Dr. S. de Stefano, Consiglio Nazionale Delle Ricerche, Italy, for a sample of zonaroic acid. We also thank Dr. M. Taniguchi, Osaka City University, for carrying out the antimicrobial activity test.

Oxidation of 2,6-Dialkyl-*p*-cresols by Metal Acetates

Toshio ITAHARA* and Tsutomu SAKAKIBARA

Institute of Chemistry, College of Liberal Arts, Kagoshima University, Kagoshima 890

(Received May 30, 1978)

Synopsis. The oxidation of 2,6-dialkyl-*p*-cresols by silver(I) and palladium(II) acetate afforded the corresponding *p*-hydroxybenzyl acetates and *p*-hydroxybenzaldehydes.

Recently much attention has been focused on the selective oxidation of the methyl group of *p*-cresols. However, the selective side-chain oxidation of alkylphenols is generally attained with difficulty, *e.g.*, coupling reactions predominantly occur when 2,6-di-*t*-butyl-*p*-cresol (**1a**) is oxidized by metal salts,[1] although the oxidation of **1a** to 3,5-di-*t*-butyl-4-hydroxybenzaldehyde (**3a**) using bromine,[2] 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ),[3] or oxygen in alkaline medium[4] has been reported. The oxidation of toluenes to benzyl acetates or benzaldehydes by palladium(II) acetate is however well known.[5] These observations and an interest in metal salt-catalyzed oxidations of aromatic compounds[6] led to this examination of the oxidation of *p*-cresols with palladium(II) acetate and other metal acetates. The side-chain oxidations of *p*-cresol itself and 2,4-dimethylphenol led to failure,[7] however, it was found that the *p*-methyl group of **1a** and 2,4,6-trimethylphenol (**1b**) were oxidized by silver(I) acetate and palladium(II) acetate in acetic acid. There appears to be no other reports that the products from the side-chain oxidation of *p*-cresols change depending on the amount of the oxidant used, although the oxidation of **1b** with $S_2O_8^{2-}$–Ag^+ gives 3,5-dimethyl-4-hydroxybenzylalcohol[8] and with DDQ[3] or with oxygen[4] gives 3,5-dimethyl-4-hydroxybenzaldehyde (**3b**).

Treatment of **1a** and **1b** with silver(I) acetate in acetic acid under nitrogen at 118 °C afforded 3,5-di-*t*-butyl-4-hydroxybenzyl acetate (**2a**) and 3,5-dimethyl-4-hydroxybenzyl acetate (**2b**), respectively, in good yields. When the oxidation was conducted with an excess of the metal acetate, **3** was obtained in good yield. Furthermore, the oxidation of **2** gave the corresponding **3**. The oxidation of **1** by palladium(II) acetate also resulted in the formation of **2** and **3**, but the yield of **2b** from **1b** was reduced. These results are summarized in Table 1. The attempted oxidations with other metal acetates, listed in Table 1, were unsuccessful.

Substituent Effects in Heterogeneous Catalysis. V. Steric Hindrance of Bulky Alkyl Substituents in Cyclohexanone Hydrogenation

Teiji CHIHARA and Kazunori TANAKA*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 3, 1978)

Synopsis. The reactivities of 2-isopropyl- and 2-*t*-butylcyclohexanone were measured relative to cyclohexanone in both individual and competitive hydrogenation over Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3. The results obtained suggest that alkyl substitution sterically hinders much more significantly the ketone adsorption than the following surface reaction. A molecular model is presented for adsorption of each ketone.

In the preceding two reports[1,2] of this series, we studied the effect of alkyl substitution in cyclohexanone hydrogenation using 2-methyl-, 2-ethyl-, and 2-propylcyclohexanone (**2m**, **2e**, and **2p**), along with cyclohexanone (**1**) itself. Since ethyl and propyl substituents are rather flexible, little or no additional steric hindrance to adsorption is expected when going from **2m** to **2e** or **2p**. In support of this speculation, our previous work indicated that **2m**, **2e**, and **2p** exhibit almost the same reactivity in their individual hydrogenations. However, increasing the branching degree of the alkyl substituent might cause a marked increase in steric hindrance to adsorption and reactions. The main purpose of the present work is to test this anticipation by conducting individual and competitive hydrogenations of 2-isopropyl- and 2-*t*-butylcyclohexanone (**2ip** and **2tb**).

Interest in enzymatic and related reactions is growing. Although it is acknowledged that steric factors play an important role in these reactions, little is known concerning the correlation of steric factors with complexation and catalysis.[3] In heterogeneous catalysis as well, there seem to be many cases where steric factors play a part. Especially, a rigid bulky group in close proximity to the functional group in general ought to exert steric hindrance to adsorption and reactions. However, few studies have been reported about the extent of such steric hindrance. This paper describes our first attempt to study this problem.

Experimental

Compound **2ip** was prepared by hydrogenation of *o*-isopropylphenol over Raney-Ni,[4] followed by chromic acid oxidation.[5] Distillation under reduced pressure gave **2ip** as a liquid: bp 82.0 °C/20 mmHg. **2tb** was similarly prepared from *o*-*t*-butylphenol: bp 89.0 °C/19 mmHg. The catalysts used were the same commercial products that were employed in the previous work:[2] they were pelletized Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3, each containing 0.5 wt % of the metal. Hydrogenation runs, either individual using a single ketone substrate or competitive using two ketone substrates, were conducted in cyclohexane at 30 °C and in hydrogen of atmospheric pressure. The procedure has been detailed previously.[2]

Results and Discussion

Individual Reactions. Preliminary experiments confirmed that in individual hydrogenation the reaction rate is zero order in ketone over a wide concentration range down to or even lower than 0.5 mol/l. The rate measurements were all made in this zero-order region, and the rates of **2** relative to **1** are plotted in Fig. 1A against the atomic radius of the catalyst metal. For comparison, the data on **2e** and **2p** obtained previously[2] are also given in Fig. 1A. It is seen that in general the relative rate R_2'/R_1' in individual reaction is not very different from metal to metal, and depends only upon the substituent itself. Another characteristic feature is that R_2'/R_1' decreases in the order **2m**=**2e**=**2p**>**2ip**>**2tb**.

In considering this activity sequence it should be noted that R_2'/R_1' is related to the reactivity of the adsorbed species by

$$R_2'/R_1' = k_2/k_1, \quad (1)$$

where k is the rate constant referred to the unit fraction of the surface covered. The observed identity **2m**=**2e**=**2p** has already[1,2] been explained by assuming for these ketones a particular adsorption model in which no additional steric hindrance is brought about when going from **2m** to **2e** and to **2p**.

Now let us consider why R_2'/R_1' decreases in the order **2m**>**2ip**>**2tb**. For these ketones we assume those adsorption models that are illustrated in Fig. 2 which represents the projection of the alkyl substituents on a

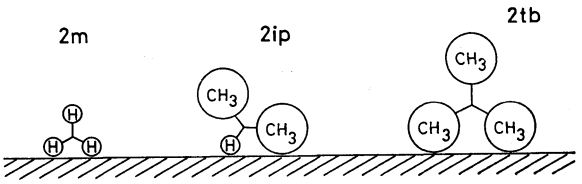

Fig. 2. The orientation of a C(7)–H or C(7)–CH_3 bond in the alkyl substituent relative to the catalyst surface for adsorbed **2m**, **2ip**, and **2tb**.

plane perpendicular to the catalyst surface. It seems very likely that the steric hindrance to adsorption due to the alkyl substituents is minimized in the assumed model. A comparison of the three ketones indicates that the bulkier the substituent, the greater the steric hindrance to adsorption that would be exerted; by bringing a C(7)–H bond more perpendicular to the catalyst surface plane when going from **2m** to **2ip**, and by directing two methyl groups toward the catalyst when going from **2ip** to **2tb**. In antiparallel with this increasing steric hindrance the adsorption strength of ketones is expected to decrease in the order **2m**>**2ip**>**2tb**. The observed order of decreasing R_2'/R_1' probably reflects this order of decreasing adsorption strength and, in turn, decreasing reactivity.

Table 1. Direct and indirect measurements of relative rate $\log_{10}(R_{2tb}/R_{2m})$

Catalyst	$\log_{10}(R_{2ip}/R_{2m})$	$\log_{10}(R_{2tb}/R_{2ip})$	$\log_{10}(R_{2tb}/R_{2m})$	
			Indirect	Direct
Pt/Al_2O_3	−1.36	−1.59	−2.95	−2.89
Rh/Al_2O_3	−1.35	−1.64	−2.99	−3.04
Ru/Al_2O_3	−1.38	−1.64	−3.02	−2.88

Competitive Reactions. The observed relative rate R_2/R_1 in competitive reaction is plotted in Fig. 1B against the atomic radius of the catalyst metal. The data for **2m**, **2e**, and **2p** were obtained directly by competitive hydrogenation with **1**, but the data for **2ip** and **2tb** were determined indirectly by hydrogenating each competitively with **2m** and then by allowing for the relative rate R_{2m}/R_1 measured by a separate experiment. The validity of this indirect procedure for determining R_2/R_1 is confirmed by the data of Table 1 which compare the directly and indirectly determined R_{2tb}/R_{2m} values. It is seen that for all the catalysts the agreement is satisfactory. Fig. 1B shows that the magnitude of the substituent effect based on **1**, *i.e.*, $\log(R_2/R_1)$, depends upon the catalyst metal whereas those for any **2** based on another, such as $\log(R_{2ip}/R_{2m})$ and $\log(R_{2tb}/R_{2ip})$, are independent of the catalyst.

As previously shown,[6] the relative rate in competitive reaction may be given by

$$R_2/R_1 = (K_2/K_1)(R_2'/R_1'), \quad (2)$$

where K is the adsorption coefficient in Langmuir's adsorption isotherm. Combining Eqs. 1 and 2 we obtain

$$\log(R_2/R_1) = \log(K_2/K_1) + \log(k_2/k_1). \quad (3)$$

Equation 3 means that the substituent effect in competitive reaction is divided into two terms; the substituent effect in adsorption and that in surface reaction. Such a division is also feasible in a comparison between different **2**'s. The extents of the two terms worked out for a few ketone pairs are given in Fig. 1C. It is seen that only b_1 varies with the catalyst. This indicates that an increase in adsorption hindrance due to methyl substitution leading **1** to **2m** varies with the catalyst, whereas that caused by further methyl substitution leading **2m** to **2ip** or leading **2ip** to **2tb** is independent of the catalyst. The reason for this unique behavior of the methyl substituent on **2m** is obscure at present although it must be related to the close proximity of that substituent to the carbonyl group. Figure 1C also shows that bulky alkyl groups hinder the adsorption markedly but the following surface reaction to a much smaller extent. Interestingly, the same trend has been observed in olefin hydrogenation by Hussey *et al.* (Table 3 or 4 in Ref. 7).

We thank Dr. F. Scott Howell of Sophia University for his linguistic comments on the original manuscript of this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (2), 635—636 (1979)

Oxidation of Organic Compounds with Perborates or H_2O_2–Boric Acids[1)]

Yoshiro OGATA* and Hideo SHIMIZU

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

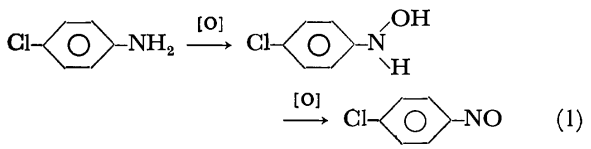
(Received July 24, 1978)

Synopsis. Perborate oxidation of *p*-chloroaniline to 4,4′-dichloroazobenzene and H_2O_2–boric acid hydroxylation of aromatics have been studied. The kinetic behavior suggests that the so-called sodium perborate is not peroxoborate but borate peroxyhydrate, H_2O_2 acquiring stronger electrophilicity by the coordination with boric acid which acts as Lewis acid rather than protic acid.

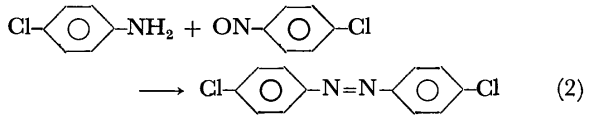
Perborates have received little attention as reagents for organic oxidations. Metha and Vakilwala reported that sodium perborate is a satisfactory reagent for the oxidation of anilines to azo compounds.[2)] However, no report seems to have appeared on the mechanism of perborate oxidation and the systems of H_2O_2–boric acids (boric acids: H_3BO_3, HBO_2, and B_2O_3). The present note deals with our attempt to elucidate the mechanism for the oxidation of *p*-chloroaniline with perborates and hydroxylation of aromatics with H_2O_2–boric acids reagents.

Results and Discussion

Oxidation of p-*Chloroaniline.* *p*-Chloroaniline was oxidized by sodium or ammonium perborates in acetic acid to give 4,4′-dichloroazobenzene. Azobenzene is obtained as a condensation product of unreacted aniline with nitrosobenzene formed *via* phenylhydroxyamine[3,4)] (Eqs. 1 and 2).



(1)



(2)

Oxidation can also be achieved by H_2O_2–AcOH. The rates of disappearance of perborates or H_2O_2 (0.02—0.04 M) were measured iodometrically in 100 or 75% aq AcOH at 50 °C, where *p*-chloroaniline is in large excess (0.5 M) (Table 1). The rates are pseudo-first order in perborates or H_2O_2: $v=k_{obsd}$[perborates or H_2O_2]. There is no possibility that the actual oxidizing agent is peracetic acid,[5)] since the rate for peracetic acid formation (Table 2) is smaller than that of aniline oxidation. Azobenzene should be produced mainly by direct oxidation of aniline with another oxidizing species.

In 100% AcOH, apparent first-order rate constants (k_{obsd}) for sodium and ammonium perborates are respectively 6.7 and 4.7 times greater than those for H_2O_2, but in 75% aq AcOH the rate constants become comparable to those with H_2O_2. This can be explained as follows: the so-called perborate is not peroxoborate but borate peroxyhydrate.[6)] Thus, in excess water, H_2O_2 is readily separated from borate, the oxidation being performed by liberated H_2O_2, where the rate is analogous to that by H_2O_2 alone. In 100% AcOH, H_2O_2 remains coordinated with boric acid which is formed from metal borate in AcOH, the electrophilicity of H_2O_2 thus increasing. When an equivalent amount of boric acid is added to H_2O_2–75% aq AcOH system, the rate increases slightly (Table 1). The protonation of H_2O_2 by boric acid is negligible in AcOH, since acetic acid is a much stronger acid than boric acid.[7)] In conclusion, boric acid should coordinate with H_2O_2 as Lewis acid but not protic acid to increase the electrophilicity of H_2O_2.

NH_4BO_3	3.30	1.17
H_2O_2	1.75	1.05
H_2O_2–H_3BO_3[b)]	—	1.25

a) The pseudo-first order rate constant with respect to the oxidizing agent. b) H_2O_2: H_3BO_3=1:1. H_3BO_3 is insoluble in 100% AcOH.

Hydroxylation of Aromatics. It has been reported that aromatic hydroxylation occurs by H_2O_2 in the presence of Lewis acid such as BF_3[8a)] or $AlCl_3$,[8b)] where the hydroxylation might take place by HO^+ formed from H_2O_2 by the coordination of Lewis acid. Aromatic compounds were hydroxylated also with H_2O_2 in ether in the presence of H_3BO_3, HBO_2, or B_2O_3 (heterogene-

Table 3. Hydroxylation of anisole and toluene by H_2O_2–boric acids in ether at 100 °C for 1 h

Substrate[a]	Yield of monohydroxylated products (%)		
	H_3BO_3	HBO_2	B_2O_3
	54.6 (56:44)[b]	35.7 (51:49)[b]	84.5 (55:45)[b]
	6.7 (73:27)[c]	4.8 (67:33)[c]	45.1 (66:34)[c]

a) Substrate is in large excess. b) Ortho *vs.* para ratio. *m*-Isomer was not detected. c) Ortho *vs.* para-meta ratio. *m*- and *p*-isomers could not be separated. *m*-Isomer would not be produced because of the electrophilic nature of the reagent.

ous) at 100 °C (Table 3),[9] no reaction taking place by H_2O_2 alone under similar conditions.

Boric acids act as Lewis acid, but not protic acid in H_2O_2–boric acids, since the yield is the highest in the case of B_2O_3, which has no proton but is considered to the strongest Lewis acid among the three. For example with H_3BO_3:

$$ArH + H_2O_2 + B(OH)_3 \xrightarrow{\text{Ether}} \begin{matrix} H \\ Ar \end{matrix}\!\!>\!O\cdots O\!<\!\begin{matrix} B(OH)_3 \\ H \end{matrix} \longrightarrow ArOH + H_2O + B(OH)_3 \quad (3)$$

On the other hand, sodium and ammonium perborates are basic and unable to form HO^+ from H_2O_2, although they can give free boric acid in acetic acid.

Experimental

Materials. The chemicals except ammonium perborate are commercial products of first grade. Ammonium perborate was prepared from ammonium borate and H_2O_2 by Tsal's method.[10] Guaranteed boric anhydride free of water was used.

Oxidation of p-*Chloroaniline.* The reactions of large excess *p*-chloroaniline (0.5 M) with sodium and ammonium perborates or H_2O_2 (0.02—0.04 M) were carried out in 100% and 75% aq AcOH at 50 °C. The reaction with H_2O_2 by addition of an equivalent amount of H_3BO_3 was carried out in 75% aq AcOH. The products were identified by GLC analysis in comparison with the corresponding authentic specimen. The rates were followed by determining the disappearance of the oxidizing agent by iodometry.

Rate for Formation of Peracetic Acid. The rates for peracetic acid formation from oxidizing agents (0.02—0.04 M) and AcOH were followed by determining the disappearance of the oxidizing agents by titration with $KMnO_4$.[11] The oxidizing agents were oxidized by $KMnO_4$, but peracetic acid formed was not oxidized.

Hydroxylation of Aromatics. A large excess of anisole (370 mmol) or toluene (435 mmol) was mixed with H_2O_2 (6 mmol) in Et_2O (10 ml). The solvent ether was removed in a vacuum until a pressure of 40 mmHg was attained. The reaction mixture was stirred vigorously with H_3BO_3, HBO_2, or B_2O_3 (15 mmol) at 100 °C for 1 h. The products were identified by GLC analysis with the authentic specimen.

The Reaction of Methyl *cis*-Decahydro-5,8-dioxonaphthalene-1-carboxylates

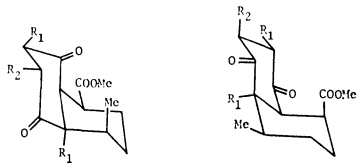
Hajime IRIKAWA,* Tsuyoshi KOYAMA, and Yasuaki OKUMURA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya 836, Shizuoka 422

(Received July 31, 1978)

Synopsis. Methyl *cis*-decahydro-5,8-dioxonaphthalene-1-carboxylates (**1b** and **1c**) were derived from the Diels-Alder adducts of *p*-toluquinone or *p*-xyloquinone and methyl sorbate, respectively. The ^{13}C NMR spectra of **1b** and **1c** suggest the existence of **1b** and **1c** in the form (A), which is in line with the formation of the keto γ-lactone from **1b** and of the keto alcohol from **1c**.

In our previous paper, the compound **1a**, derived from the Diels-Alder adduct of *p*-benzoquinone and methyl sorbate, was indicated to exist in the form (A) shown below.[1a] This paper deals with the conformation and reaction of methyl *cis*-decahydro-5,8-dioxonaphthalene-1-carboxylates (**1b** and **1c**).

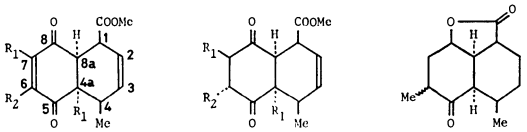


(A) (B)

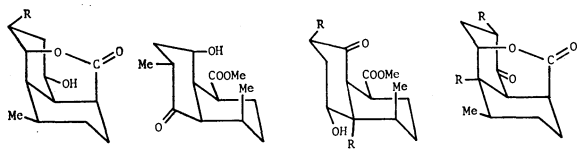
1a $R_1,R_2=H$
1b $R_1=H$, $R_2=Me$
1c $R_1=Me$, $R_2=H$

The adduct (**2a**) of *p*-toluquinone and methyl sorbate was reduced with zinc to **3a**, which was converted into **1b** by catalytic hydrogenation with palladium-carbon. The Diels-Alder reaction of *p*-xyloquinone and methyl sorbate was catalyzed by aluminium chloride to afford **2b**, which was similarly reduced to **3b** and **1c**. The cis ring junction of **2b** is supported by the comparison of the physical data with those of the C-8a epimer of **2b**.[2]

The treatment of **1b** with sodium borohydride at room temperature for 2 h gave the keto γ-lactone (**4**), and that for 3 days afforded the δ-lactone (**5a**), which was also obtained from **4** by further treatment with sodium borohydride. The formation of **4** suggests that the methyl group originally in *p*-toluquinone is situated at C-6 in the adduct **2a**, since the C-8 carbonyl group was reduced more easily than the C-5 carbonyl group in **1b**. The ^{13}C NMR chemical shifts of **5a** are similar to those of **5b**[1a] within 1 ppm except for C-5, -6, and -7, which are shifted downfield by the α- and β-effects of the methyl group at C-6 in **5a**. Absence of the γ-effect on C-4a and -8 by the methyl group at C-6 in **5a** indicates the equatorial orientation of the methyl group.[3] The



2a $R_1=H$, $R_2=Me$ **3a** $R_1=H$, $R_2=Me$ **4**
2b $R_1=Me$, $R_2=H$ **3b** $R_1=Me$, $R_2=H$



5a R=Me **6** **7a** R=Me **8a** R=Me
5b R=H **7b** R=H **8b** R=H

^{13}C chemical shift differences within 1 ppm for C-1, -3, -4, -4a, and -8a between **1a**[1a] and **1b** indicate that **1b** also exists in the form (A) with the stable equatorial methyl group at C-6. Accordingly, **4** is formed from the reduction intermediate (**6**) which is unstable because of the steric interaction between the hydroxyl group at C-8 and the methyl group at C-4. Formation of **5a** proceeds through the ring inversion, epimerization at C-6, and reduction of the C-5 carbonyl group in **6**.

On the other hand, sodium borohydride reduction of **1c** afforded the keto alcohol (**7a**), which was converted into the δ-lactone (**8a**) by methanolic hydrogen chloride. The formation of **8a** from **1c** *via* **7a** is similar to that of **8b** from **1a** *via* **7b**.[1b] It is supported by the ^{13}C NMR spectra of **7a** and **1c** that two methyl groups originally in *p*-xyloquinone are situated at C-4a and -7 in the adduct **2b**, since the signals for C-4a and -6 in **7a** are shifted upfield compared with those in **1c**. Comparison of the ^{13}C chemical shifts of **1c** with **1b** suggests that **1c** also exists in the form (A), since the signal for C-3 in **1c** is shifted upfield by the γ-gauche effect of the methyl group at C-4a. The axial proton signal at 4.02 ppm (–CH–OH, q, $J=11$ and 6 Hz) in the ^1H NMR spectrum of **7a** is in line with the ^{13}C signal for C-4 in **7a**

TABLE 1. ^{13}C CHEMICAL SHIFTS OF **1b**, **1c**, AND **7a**

Compound	**1b**	**1c**	**7a**
C-1	40.82*	38.39*	38.59*
2	17.89	18.38	19.19

C_4–Me	15.05	16.80	18.50
C_{4a}–Me		26.01	28.81
C_6–Me	13.31		
C_7–Me		16.80	14.36

*, ** Assignments are not unambiguous within indicated pair(s).

which is shifted upfield (−2.11 ppm) compared with that in **1c** by the γ-gauche effect of the hydroxyl group. Accordingly, lactonization of **7a**, which is stable in contrast to **6**, proceeds by the aid of acid through the ring inversion and epimerization at C-7.

Therefore, the formation of **4** and **7a** is in line with the structures of **1b** and **1c** in the form (A).

Experimental

Melting points are uncorrected. The IR spectra were recorded on a Hitachi infrared spectrometer EPI-G_3 in Nujol, unless otherwise stated. The ^1H and ^{13}C NMR spectra were obtained on a JEOL JNM-PFT-60 in $CDCl_3$. All the chemical shifts are expressed in term of δ (ppm downfield from internal TMS).

Preparation of ***2a***. A solution of 12.2 g of *p*-toluquinone and 12.6 g of methyl sorbate in 150 ml of benzene was refluxed for 30 h, and concentrated *in vacuo* to afford 7.80 g of **2a**: mp 108—110 °C (from EtOH); IR 1730 and 1678 cm^{-1}; ^1H NMR 0.78 (3H, d, J=7 Hz), 2.01 (3H, d, J=1.5 Hz), 3.74 (3H, s), 5.70 (1H, m), 6.20 (1H, br d, J=11 Hz), and 6.67 ppm (1H, d, J=1.5 Hz). Found: C, 67.59; H, 6.48%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

Preparation of ***3a***. Treatment of 2.00 g of **2a** with 10 g of zinc in 50 ml of AcOH at room temperature for 3 h afforded 1.86 g of **3a**: mp 148—150 °C (EtOH); IR 1734 and 1708 cm^{-1}; ^1H NMR 0.74 (3H, d, J=7 Hz), 1.16 (3H, d, J=6 Hz), 3.73 (3H, s), 5.70 (1H, m), and 6.10 ppm (1H, br d, J=10 Hz). Found: C, 67.09; H, 7.35%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Preparation of ***1b***. Hydrogenation of 1.22 g of **3a** with 150 mg of 5% Pd–C in 70 ml of MeOH afforded 1.04 g of **1b**: mp 169—170 °C (in a sealed tube) (EtOH); IR 1732 and 1707 cm^{-1}; ^1H NMR 0.67 (3H, d, J=7 Hz), 1.13 (3H, d, J=6 Hz), and 3.70 ppm (3H, s). Found: C, 66.71; H, 8.07 %. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%.

Preparation of ***2b***. To an ice-cold suspension of 1.3 g of powdered anhydrous $AlCl_3$ in 50 ml of dry benzene was added 4.04 g of *p*-xyloquinone and then 3.61 g of methyl sorbate. The mixture was stirred at room temperature for 3 days. Work-up in the usual manner[4] afforded 1.48 g of **2b**: mp 134—136 °C (EtOH); IR 1738 and 1673 cm^{-1}; ^1H NMR 0.75 (3H, d, J=7 Hz), 1.41 (3H, s), 1.99 (3H, d, J=1.5 Hz), 3.75 (3H, s), 5.60 (1H, m), 6.20 (1H, dd, J=10 and 1 Hz), and 6.57 ppm (1H, d, J=1.5 Hz). Found: C, 68.68; H, 6.95 %. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

Preparation of ***3b***. Treatment of 1.11 g of **2b** with 5 g of zinc in 50 ml of AcOH at room temperature for 2 h afforded 0.88 g of **3b**: mp 102—103 °C (EtOH); IR 1733 and 1075 cm^{-1}; ^1H NMR 0.77 (3H, d, J=7 Hz), 1.15 (3H, d, J=6 Hz), 1.36 (3H, s), 3.73 (3H, s), 5.60 (1H, m), and 6.16 ppm (1H, br d, J=10 Hz). Found: C, 67.89; H, 7.64%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

Preparation of ***1c***. Hydrogenation of 783 mg of **3b** with 81 mg of 5% Pd–C in 40 ml of MeOH afforded 681 mg of **1c**: mp 78—79 °C diisopropyl ether); IR 1730 and 1708 cm^{-1}; ^1H NMR 0.73 (3H, d, J=7 Hz), 1.16 (3H, d, J=7 Hz), 1.40 (3H, s), and 3.68 ppm (3H, s). Found: C, 67.41; H, 8.40%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

$NaBH_4$ Reduction of ***1b*** *to* ***4***. Treatment of 620 mg of **1b** with 170 mg of $NaBH_4$ in 50 ml of MeOH at room temperature for 2 h afforded 457 mg of **4**: mp 187—188 °C (benzene); IR 1764 and 1701 cm^{-1}; ^1H NMR 1.19 (6H, d, J=6 Hz) and 4.70 ppm (1H, m, W_H=10 Hz). Found: C, 70.05; H, 8.31 %. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

$NaBH_4$ Reduction of ***1b*** *to* ***5a***. Treatment of 507 mg of **1b** with 520 mg of $NaBH_4$ in 50 mg NeOH at room temperature for 3 days afforded 211 mg of **5a**: mp 169—170 °C (benzene); IR($CHCl_3$) 3430 and 1723 cm^{-1}; ^1H NMR 1.07 (6H, d, J=5 Hz), 2.97 (1H, br s, W_H=8 Hz), 3.21 (1H, br s, OH), 3.80 (1H, m, W_H=18 Hz), and 4.42 ppm (1H, br s, W_H=4 Hz); ^{13}C NMR 17.81 (C_6–Me), 19.23 (C_4–Me), 29.09 (C-3), 31.57 (C-2), 34.25 (C-7), 34.81 (C-4), 36.19 (C-6*), 36.56 (C-1*), 40.21 (C-4a), 44.35 (C-8a), 70.24 (C-8), 79.09 (C-5), and 175.63 ppm (COO). Found: C, 69.60; H, 9.22%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%. In a similar way, **5a** was obtained from **4** (95 mg from 173 mg of **4**).

$NaBH_4$ Reduction of ***1c*** *to* ***7a***. Treatment of 504 mg of **1c** with 160 mg of $NaBH_4$ in 20 ml of MeOH at room temperature for 4 h afforded 380 mg of **7a**: mp 124—125 °C (diisopropyl ether); IR 3510, 1728, and 1711 cm^{-1}; ^1H NMR 0.95 (3H, d, J=7 Hz), 1.00 (3H, d, J=6 Hz), 1.37 (3H, s), 3.65 (3H, s), and 4.02 ppm (1H, q, J=11 and 6 Hz). Found: C, 66.93; H, 9.22%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

Lactonization of ***7a*** *to* ***8a***. Treatment of 339 mg of **7a** with 3 ml of 5% methanolic hydrogen chloride at room temperature overnight afforded 195 mg of **8a**: mp 74—75 °C (diisopropyl ether); IR 1717 and 1709 cm^{-1}; ^1H NMR 0.90 (3H, s), 1.10 (6H, d, J=6 Hz), and 4.68 ppm (1H, d, J=2 Hz, W_H=6 Hz); ^{13}C NMR 13.59 (C_7–Me), 15.42 (C_4–Me), 24.06 (C_{4a}–Me), 29.62 (C-3), 31.08 (C-2), 36.60 (C-7*), 37.17 (C-6), 38.63 (C-4a), 41.55 (C-1 and -4*), 59.53 (C-8a), 78.84 (C-5), 172.87 (COO), and 211.26 ppm (C-8). Found: C, 71.12; H, 8.77%. Calcd for $C_{14}H_{20}O_3$; C, 71.16; H, 8.53%.

Stereoselectivity in Hydride Reduction of [*n*.3.2]Propellanones

Yoshito TOBE,* Akifumi DOI, Koji KIMURA, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka 565

(Received July 31, 1978)

Synopsis. Stereoselectivity in hydride reduction of [*n*.3.2]propellanones is described. The observed stereoselectivity is attributed to conformational flexibility of the third ring, that is, from five- to eight-membered alicyclic rings.

Propellanes are compounds having three rings conjoined along a common σ bond and serve as good models for examination of steric and electronic effects among three dimensionally arranged rings.[1] From this point of view, much works have been done on the reactivity of unsaturated propellanes such as heterocyclic[2a] and [4.4.2]propellane derivatives.[2b] As part of studies on relationship between structure and reactivity of propellanes,[3] we wish to report here stereoselectivity in hydride reduction of [*n*.3.2]propellanones (**1**)—(**4**) involving a cyclobutane ring, a cyclopentanone moiety, and one of alicyclic rings from five to eight-membered rings as the third ring, and wish to emphasize that conformational flexibility of the third ring plays a key role in determining the stereochemistry of products.

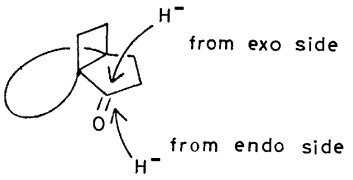
[*n*.3.2]Propellanones **1**—**4** were prepared in good yields by photocycloaddition of the corresponding bicyclic enones to ethylene. Reduction of **1**—**4** with $LiAlH_4$ in ether or $NaBH_4$ in methanol gave two epimeric alcohols (exo; (**5X**)—(**8X**), endo; (**5N**)—(**8N**)), in quantitative yields, and the exo and endo stereochemistry of them were assigned on the basis of the α-hydroxy proton coupling constants according to the data reported for derivatives of bicyclo[3.2.0]heptan-2-ol.[4] The ratios of exo and endo propellanols are summarized in Table.

	exo	endo
1 n=5	**5X**	**5N**
2 n=6	**6X**	**6N**
3 n=7	**7X**	**7N**
4 n=8	**8X**	**8N**

TABLE 1. STEREOSELECTIVITY IN HYDRIDE REDUCTION OF [*n*.3.2]PROPELLANONES **1**—**4**

Propellanone	Exo: endo ratio	
	$LiAlH_4$	$NaBH_4$
1	91.4:8.6	87.5:12.5
2	96.4:3.6	93.5: 6.5
3	98.6:1.4	97.2: 2.8
4	99.3:0.7	98.3: 1.7

As shown in Table 1, exo alcohols are always formed almost stereoselectively and, more interestingly, the ratio of exo alcohols increases in order as the size of the third ring increases. Taking the above facts and the mechanism for metal hydride reduction of carbonyl groups into account,[6] it is reasonable to consider that endo side of propellanones **1**—**4** is sterically less hindered than exo side and the difference in the steric hindrance at exo and endo sides of each propellanones becomes greater as the third ring changes from five- to eight-membered ring. In the present system, the difference in the steric hindrance at each side of cyclopentanone moiety may be attributed to the difference in nonbonded interaction



in the transition state between hydrogens of individual alicyclic ring and a hydride, which can be associated with conformational flexibility of ring systems. Namely, on account of the greater degree of conformational flexibility of the third ring in comparison with that of cyclobutane ring, such nonbonded interaction in the transition state at the endo side may be remarkably reduced compared with the exo side. In addition, the nonbonded interaction at the endo side may become smaller in order of increase in conformational flexibility of the third ring, in other words, in the increasing order in size of the third ring. Consequently, it must be concluded that conformational flexibility of the third ring plays a key role in determining the stereochemistry of the resulting alcohols in hydride reduction of [*n*.3.2]-propellanones.

Experimental

Materials. Ketones **1**,[7] **2**,[8] **3**, **4**, and 1,5-dimethylbicyclo[3.2.0]heptan-2-one were prepared in 51—73% yields by photocycloaddition of the corresponding bicyclic enones to ethylene in ether at −70 °C. **3**, IR 1710 cm^{-1}; NMR δ (CCl_4) 1.00—2.80 (m); MS *m/e* 178 (M^+). Semicarbazone, mp 203—204 °C; Found: C, 66.24; H, 8.87; N, 17.95%. Calcd for $C_{13}H_{21}ON_3$: C, 66.35; H, 9.00; N, 17.86%. **4**, IR 1710 cm^{-1}; NMR δ (CCl_4) 1.00—2.90 (m); MS *m/e* 192 (M^+). Semicarbazone, mp 216—218 °C; Found: C, 67.31; H, 9.43; N, 16.96%. Calcd for $C_{14}H_{23}ON_3$: C, 67.43; H, 9.30; N, 16.85%. 1,5-Dimethylbicyclo[3.2.0]heptan-2-one, IR 1710 cm^{-1}; NMR δ (CCl_4) 0.95 (s, 3H), 1.15 (s, 3H), 1.40—2.80 (m, 8H); MS *m/e* 138 (M^+). Semicarbazone, mp 202—204 °C; Found: C, 61.51; H, 8.78; N, 21.52%. Calcd for $C_{10}H_{17}ON_3$: C, 61.39; H, 8.88; N, 21.33%.

*$LiAlH_4$ Reduction of **1**—**4**.* A solution of a ketone in ether was added dropwise to the suspension of 5 molar excess of $LiAlH_4$ in ether and the mixture was stirred at room temperature for 12 h. Water and dilute hydrochloric acid was added carefully and the aqueous solution was extracted with

ether. The combined ethereal solution was washed with aqueous sodium hydrogencarbonate and brine, and then dried (Na_2SO_4). After evaporation of the solvent, the residue was distilled under reduced pressure to give a mixture of alcohols in 90—97% yields. Exo alcohols were separated by preparative GLC (10% FFAP or 10% DEGS) and endo ones were identified with the authentic materials prepared by Meerwein-Ponndorf reduction of ketones. The ratios of them are listed in Table.

5X, mp 95—96 °C; IR 3250, 1040 cm^{-1}; NMR δ (CCl_4) 1.00—2.40 (m, 15H), 3.72 (t, J=8.0 Hz, 1H); MS *m/e* 152 (M^+); Found: C, 77.63; H, 10.60%. Calcd for $C_{10}H_{16}O$: C, 77.89; H, 10.59%. **6X**, mp 55—57 °C; IR 3300, 1050 cm^{-1}; NMR δ (CCl_4) 1.10—2.20 (m, 16H), 3.40 (s, 1H), 3.70 (q, J=7.2 Hz, 1H); MS *m/e* 166 (M^+); Found: C, 79.15; H, 10.88. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%. **7X**, mp 58—60 °C; IR 3350, 1165 cm^{-1}; NMR δ (CCl_4) 1.00—2.10 (m, 18H), 2.82 (s, 1H), 3.75 (q, J=7.6 Hz, 1H); MS *m/e* 180 (M^+); Found: C, 79.79; H, 11.33%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%. **8X**, mp 95—96 °C; IR 3300, 1040 cm^{-1}; NMR δ (CCl_4) 0.90—2.00 (m, 20H), 2.75 (s, 1H), 4.10 (q, J=7.6 Hz, 1H); MS *m/e* 194 (M^+); Found: C, 80.27; H, 11.41%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

*$NaBH_4$ Reduction of **1**—**4**.* A solution of a ketone in methanol was added dropwise to a solution of 2 molar excess of $NaBH_4$ in methanol and the mixture was stirred at room temperature for 12 h. The solution was poured into dilute hydrochloric acid and extracted with ether. The organic layer was washed with aqueous sodium hydrogencarbonate and brine and then dried (Na_2SO_4). Similar work-up as above gave a mixture of alcohols in 87—90% yields. The ratios of them are listed in Table.

*Preparation of **5N**—**9N** and **9X** by Meerwein-Ponndorf Reduction.* A mixture of a ketone and 2.2 molar excess of aluminum isopropoxide in isopropyl alcohol was heated until isopropyl alcohol began to distill slowly, while more alcohol was added. Heating was continued until no ketone remained (monitored by GLC). The solution was poured into ice-cooled aqueous sodium hydroxide and extracted with ether. The ether extract was washed with water and brine, and then dried (Na_2SO_4). Evaporation of the solvent afforded a mixture of alcohol in 84—89% yields. Products were separated by column chromatography on silica gel and purified by preparative GLC. The ratios of alcohols are as follows; **5X**: **5N**=32: 68, **6X**:**6N**=32: 68, **7X**: **7N**=58: 42, **8X**: **8N**=58: 42, **9X**: **9N**=35: 65.

5N, mp 93—94 °C; IR 3250, 1040 cm^{-1}; NMR δ (CCl_4) 1.00—2.60 (m, 15 H), 3.72 (d, J=3.7 Hz, 1H); MS *m/e* 152 (M^+); Found: C, 77.63; H, 10.58%. Calcd for $C_{10}H_{16}O$: C, 77.89; H, 10.59%. **6N**, mp 53—55 °C; IR 3300, 1050 cm^{-1}; NMR δ (CCl_4) 1.10—2.40 (m, 17H), 3.75 (d, J=4.0 Hz, 1H); MS *m/e* 166 (M^+); Found: C, 79.45; H, 11.16%. The Reaction of 1-(1-Pyrrolidinyl)acenaphthylene with Electrophilic Acetylenes[1)]

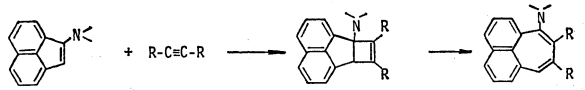
Otohiko TSUGE* and Haruyuki WATANABE

Research Institute of Industrial Science, Kyushu University 86, Hakozaki, Higashi-ku, Fukuoka 812

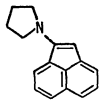
(Received August 25, 1978)

Synopsis. 1-(1-Pyrrolidinyl)acenaphthylene (**1**), which was prepared from acenaphthenone and pyrrolidine, reacted with dimethyl acetylenedicarboxylate to give the dihydrocyclohepta[*de*]naphthalene and dihydrofluoranthene. The reaction of **1** with methyl propiolate in benzene afforded the dihydrocyclohepta[*de*]naphthalene (**8**) and its isomeric cyclohepta[*de*]naphthalenol (**9**), whereas the Michael type adduct was formed in methanol. An interconversion between **8** and **9** was also described.

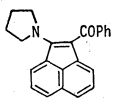
It is known that enamines derived from cyclic ketones react with activated acetylenes to yield intermediate cyclobutene adducts which undergo rearrangement with expansion of the carbocyclic ring by two carbon atoms.[2)] Application of this process to 1-aminoacenaphthylene derivatives, which might exhibit enamine-like properties, seems to provide a one-pot synthesis of cyclohepta[*de*]naphthalene compounds which are nonalternant hydrocarbons. However, no 1-aminoacenaphthylenes appeared in the literature. We now report the preparation of 1-(1-pyrrolidinyl)acenaphthylene (**1**) and its reaction with electrophilic acetylenes.



When a benzene solution of acenaphthenone was refluxed with a slight excess of pyrrolidine in the presence of *p*-toluenesulfonic acid for 1 h, the expected enamine **1** as reddish violet viscous oil was obtained quantitatively. Benzoylation of **1** with benzoyl chloride afforded 1-benzoyl-2-(1-pyrrolidinyl)acenaphtylene (**2**), mp 178—180 °C, in 87% yield.



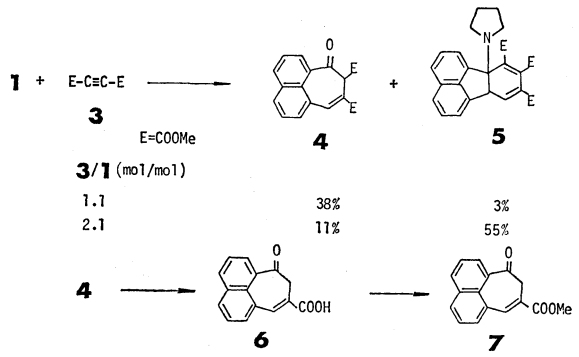
1



2

The reaction of **1** with dimethyl acetylenedicarboxylate (**3**) in benzene at room temperature for 3 h gave dimethyl 7-oxo-7,8-dihydrocyclohepta[*de*]naphthalene-8,9-dicarboxylate (**4**), mp 131—132 °C, and the dihydrofluoranthene (**5**), mp 191—192 °C, together with tarry materials. The compound **4** was evidently formed by hydrolysis of an initial cyclohepta[*de*]naphthalene. As shown in Scheme 1, the yields of **4** and **5** depended on the amounts of **3** used. Structural elucidation of **4** and **5** was accomplished on the basis of their spectral data.

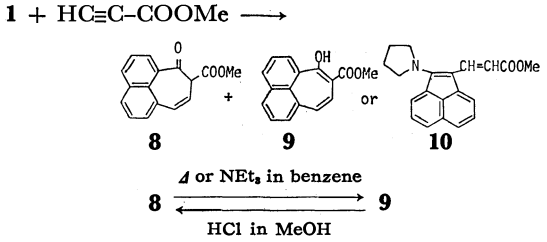
Treatment of **4** with 3% aqueous sodium hydroxide solution under reflux for 30 min gave 7-oxo-7,8-dihydrocyclohepta[*de*]naphthalene-9-carboxylic acid (**6**), mp



Scheme 1.

229—230 °C, in a 78% yield, evidently by hydrolysis and followed by decarboxylation. The carboxylic acid **6** was converted into the methyl ester **7**, mp 102—103 °C.

In the reaction of **1** with an equimolar amount of methyl propiolate in benzene at room temperature for 1 h, two isomers were isolated. The minor product (2.3 %), mp 115—125 °C (turned to red), as colorless prisms was proven to be methyl 7-oxo-7,8-dihydrocyclohepta[*de*]naphthalene-8-carboxylate (**8**), which is an isomer of **7**, and the major product (21%), mp 87—88 °C, as red needles was assigned to be a tautomer of **8**, methyl 7-hydroxycyclohepta[*de*]naphthalene-8-carboxylate (**9**). On the other hand, the same reaction in methanol at room temperature for 3 h gave the Michael type adduct **10**, mp 157—158 °C, in a 49% yield. (Scheme 2).



Scheme 2.

As mentioned above, dihydrocyclohepta[*de*]naphthalene **8** melted at 115—125 °C with color change to red, which suggests the transformation into red colored cyclohepta[*de*]naphthalenol **9**. In fact, heating of **8** at 130 °C for 3 h afforded **9** in a 73% yield. When treated with silica gel or triethylamine in benzene at room temperature, **8** was also converted into **9**. On the treatment with catalytic amounts of hydrochloric acid in methanol, however, **9** was partially converted into **8**.

In contrast to **8**, attempts to isomerize **7** to a cyclohepta[*de*]naphthalenol under various conditions were unsuccessful.

Experimental

1-(1-Pyrrolidinyl)acenaphthylene (1). A solution of acenaphthenone (9.1 g, 0.054 mol), pyrrolidine (4.6 g, 0.065 mol), and *p*-toluenesulfonic acid (0.9 g) in benzene (100 ml) was boiled with azeotropic removal of water. After being boiled for 1 h, the reaction mixture was concentrated *in vacuo*, and the residue was extracted with petr. ether. The extract was concentrated to give 11.8 g (*ca.* 100%) of the enamine **1** as reddish violet viscous oil. Bp 185 °C/4 mmHg; NMR (CCl_4) δ 1.85—2.25, 3.40—3.75 (each 4H, m), 5.26 (1H, s, =CH), 6.85—7.86 (6H, m); MS *m/e* 221 (M^+). Picrate of **1**: mp 164—166 °C. Found: C, 58.60; H, 4.05; N, 12.19%. Calcd for $C_{22}H_{18}N_4O_7$: C, 58.66; H, 4.03; N, 12.44%.

Benzoylation of the Enamine 1. A solution of **1** (1.3 g, 0.006 mol) and benzoyl chloride (1.3 g, 0.009 mol) in benzene (20 ml) was stirred with NEt_3 (0.9 g, 0.009 mol) at room temperature for 3 h. The reaction mixture was filtered to remove triethylamine hydrochloride, and the filtrate was evaporated *in vacuo*, followed by addition of petr. ether to give crystals. Recrystallization from EtOH afforded 1.7 g (87%) of 1-benzoyl-2-(1-pyrrolidinyl)acenaphthylene (**2**), mp 178—180 °C, as red prisms. IR (KBr) 1600 cm^{-1} ($\nu_{C=O}$); MS *m/e* 325 (M^+). Found: C, 84.89; H, 5.88; N, 4.30%. Calcd for $C_{23}H_{19}NO$: C, 84.89; H, 5.89; N, 4.30%.

Reaction of the Enamine 1 with Dimethyl Acetylenedicarboxylate (3). A solution of **1** (13.0 g, 0.059 mol) and the acetylene **3** (9.2 g, 0.065 mol) in benzene (100 ml) was stirred at room temperature for 3 h. The reaction mixture was concentrated *in vacuo*, and MeOH (20 ml) was added to the residue, giving 7.0 g (38%) of colorless crystals, mp 128—130 °C. Recrystallization from cyclohexane afforded dimethyl 7-oxo-7,8-dihydrocyclohepta[*de*]naphthalene-8,9-dicarboxylate (**4**), mp 131—132 °C, as colorless prisms. IR (KBr) 1680, 1720, 1780 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 3.25, 3.99 (each 3H, s), 5.46 (1H, s, >CH), 7.22 (1H, s, =CH), 7.30—8.20 (6H, m); UV λ_{max}^{EtOH} nm (log ε) 208 (4.5), 237 (4.5), 325 (4.0); MS *m/e* 310 (M^+). Found: C, 69.64; H, 4.58%. Calcd for $C_{18}H_{14}O_5$: C, 69.67; H, 4.55%.

The MeOH filtrate was concentrated *in vacuo*, and the residue was chromatographed on alumina using benzene as an eluent, giving 0.9 g (3%) of crystals. Recrystallization from MeOH afforded the dihydrofluoranthene **5**, mp 191—192 °C, as colorless prisms. IR (KBr) 1740, 1750 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 1.60—1.96, 3.20—3.60 (each 4H, m), 3.65, 3.72 (each 6H, s), 5.35 (1H, s, >CH), 7.25—8.20 (6H, m); UV λ_{max}^{EtOH} nm (log ε) 215 (4.8), 330 (3.8); MS *m/e* 505 (M^+). Found: C, 66.78; H, 5.45%. Calcd for $C_{28}H_{27}NO_8$: C, 66.52; H, 5.38%.

A similar reaction of **1** (11.7 g, 0.053 mol) with **3** (16.5 g, 0.116 mol) in benzene (100 ml) afforded 1.8 g (11%) of **4** and 14.8 g (55%) of **5**.

7-Oxo-7,8-dihydrocyclohepta[de]*naphthalene-9-carboxylic Acid (6) and Its Methyl Ester (7).* A suspension of dihydrocyclohepta[*de*]naphthalene **4** (5.0 g) in 3% NaOH aq solution (200 ml) was refluxed for 30 min; during which time it turned to a red solution. The solution was acidified with hydrochloric acid to give brown precipitates, which extracted with hot EtOH (150 ml). The extract was concentrated *in vacuo* to leave the residue, which on recrystallization from EtOH using charcoal afforded 1.5 g (39%) of **6**, mp 229—230 °C, as yellow prisms. IR (KBr) 2700—3100 (ν_{OH}), 1690 cm^{-1} ($\nu_{C=O}$); NMR (DMSO-d_6) δ 3.80 (2H, s, CH_2), 7.60—8.45 (7H, m, ArH+=CH); UV λ_{max}^{EtOH} nm (log ε) 225 (4.5), 243 (4.4), 320 (3.9); MS *m/e* 238 (M^+). Found: C, 75.90; H, 4.35%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

Esterification of **6** in MeOH containing H_2SO_4 afforded the methyl ester (**7**) in a 92% yield. Mp 102—103 °C; yellow prisms; IR (KBr) 1670, 1704 cm^{-1} ($\nu_{C=O}$), NMR ($CDCl_3$) δ 3.82 (2H, s, CH_2), 3.89 (3H, s), 7.30—8.20 (7H, m, ArH+=CH); MS *m/e* 252 (M^+). Found: C, 76.07; H, 4.78%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80%.

Reaction of the Enamine 1 with Methyl Propiolate. i) A solution of **1** (2.65 g, 0.012 mol) and methyl propiolate (1.0 g, 0.012 mol) in benzene (20 ml) was stirred at room temperature for 3 h. The reaction mixture was concentrated *in vacuo*, and the residue was chromatographed on silica gel using benzene as an eluent to give crystals. The crystals were washed with hexane (50 ml) to leave red crystals. Recrystallization from petr. ether afforded 0.65 g (21%) of methyl 7-hydroxycyclohepta[*de*]naphthalene-8-carboxylate (**9**), mp 87—88 °C, as red needles. IR (KBr) 1660 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 3.80 (3H, s), 6.02, 6.28 (each 1H, d, =CH, J=12 Hz), 6.85—8.20 (6H, m), 14.50 (1H, s, OH); UV λ_{max}^{EtOH} nm (log ε) 217 (4.5), 250 (4.2), 370 (3.7), 450 (3.3); MS *m/e* 252 (M^+). Found: C, 76.47; H, 4.79%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80%.

The hexane washings were evaporated *in vacuo* to leave colorless crystals, which on recrystallization from hexane afforded 0.07 g (2.3%) of methyl 7-oxo-7,8-dihydrocyclohepta[*de*]naphthalene-8-carboxylate (**8**), mp 115—125 °C (turned to red), as colorless prisms. IR (KBr) 1690, 1755 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 3.78 (3H, s), 4.48 (1H, dd, >CH, J=2, 5 Hz), 6.41 (1H, dd, =CH, J=5, 11 Hz), 6.98 (1H, dd, =CH, J=2, 11 Hz), 7.28—8.25 (6H, m); UV λ_{max}^{EtOH} nm (log ε) 220 (4.6), 317 (3.8), 340 (3.8), 355 (3.8); MS *m/e* 252 (M^+). Found: C, 76.29; H, 4.84%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80%.

ii) A solution of **1** (2.65 g) and methyl propiolate (1.0 g) in MeOH (20 ml) was stirred at room temperature for 3 h; during which time crystals precipitated. Recrystallization of the crystals from EtOH afforded 1.8 g (49%) of the Michael type adduct **10**, mp 157—159 °C, as violet prisms. IR (KBr) 1690 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 1.69—2.05, 3.55—3.90 (each 4H, m), 3.79 (3H, s), 6.08, 8.17 (each 1H, d, =CH, J=15 Hz), 7.19—7.90 (6H, m); UV λ_{max}^{EtOH} nm (log ε) 227 (4.7), 254 (4.4), 320 (4.3), 357 (4.5), 390 (4.2), 520 (3.8); MS *m/e* 305 (M^+). Found: C, 78.04; H, 6.22; N, 4.69%. Calcd for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%.

Isomerization of Dihydrocyclohepta[de]*naphthalene (8) to Cyclohepta*[de]*naphthalenol (9). i)* Dihydrocyclohepta[*de*]naphthalene (**8**) (0.15 g) in a test tube was heated at 130 °C (bath temperature) under nitrogen for 3 h. The mixture was washed with hexane (20 ml) to leave 20 mg of unchanged **8**. From the hexane washing 0.11 g (73%) of **9** was obtained.

ii) A solution of **8** (80 mg) in benzene (20 ml) was stirred with NEt_3 (3 drops) at room temperature for 6 h. After the reaction mixture was evaporated *in vacuo* below 40 °C, a similar treatment of the residue with hexane gave 50 mg (62.5%) of **9**.

Isomerization of Cyclohepta[de]*naphthalenol (9) to Dihydrocyclohepta*[de]*naphthalene (8).* A solution of **9** (0.5 g) in MeOH (50 ml) was stirred with hydrochloric acid (1 drop) at room temperature for 7 days. The reaction mixture was poured into water, and extracted with $CHCl_3$. The extract was washed with water, dried over Na_2SO_4, and evaporated *in vacuo*. A similar treatment of the residue with hexane gave 0.15 g (30%) of **8**, together with recovery of **9** (0.3 g).

A Novel Synthesis of δ-Amino Acid Derivatives

Takeshi IMAGAWA* and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 19, 1978)

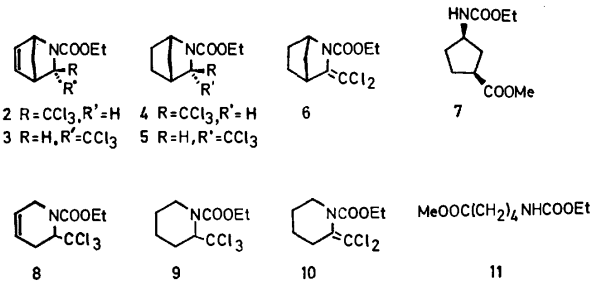
Synopsis. The Diels-Alder adducts of "anhydrochloral-urethane" with some 1,3-dienes were successfully utilized for the synthesis of some δ-amino acid derivatives by the sequence of the reactions, *viz.*, hydrogenation, dehydrochlorination, and ozonolysis.

Polar cycloaddition reactions are ingeniously utilized for the introduction of a substituent at the specific position.[1] We describe here a method of synthesis of δ-amino acid derivatives making use of the Diels-Alder adducts between "anhydrochloral-urethane" *N*-(2,2,2-trichloroethylidene)carbamates (**1**) and 1,3-dienes reported by us previously.[2]

The *exo*- and *endo*-adducts (**2** and **3**) of **1** with cyclopentadiene[2] were hydrogenated over Pd–C to afford in about 90% yields ethyl *exo*- and *endo*-3-trichloromethyl-2-azabicyclo[2.2.1]heptane-2-carboxylates (**4** and **5**), respectively. Upon treatment of **4** and **5** with sodium methoxide in refluxing benzene, ethyl 3-dichloromethylene-2-azabicyclo[2.2.1]heptane-2-carboxylate (**6**) in 60—75% yields. When **6** was oxidized with ozone in methanol, followed by treatment with dimethyl sulfide, methyl *cis*-3-ethoxycarbonylamino-1-cyclopentanecarboxylate (**7**) was obtained in 76% yield. The *cis*-configuration of **7** is evident from the consideration of the reaction course. This product (**7**) is a potential intermediate for the synthesis of an antibiotics "amidinomycin."[3]

In a similar manner, 1-ethoxycarbonyl-2-trichloromethyl-1,2,3,6-tetrahydropyridine (**8**) obtained from **1** and butadiene was converted into methyl 5-(ethoxycarbonylamino)pentanoate (**11**) by the sequence of the reactions, *viz.*, hydrogenation, dehydrochlorination, and ozonolysis.

Consequently, the present procedure has merged into a powerful synthetic route to δ-amino acid derivatives.



Experimental

Ethyl exo-*3-Trichloromethyl-2-azabicyclo[2.2.1]heptane-2-carboxylate (4).* A solution of 1.956 g of **2**[2] in 50 ml of ethanol was hydrogenated over 500 mg of Pd–C until 154 ml (1.0 equiv.) of hydrogen-uptake (5 min). Removal of the catalyst and the solvent, followed by distillation, gave 1.793 g (91%) of **6**: bp 132.5—135 °C/3 Torr; IR (neat): 1725 cm^{-1}; MS: *m/e* 242 (small), 240 (small), 168 (100), 140 (38), 68 (31%); NMR (CCl_4): δ 4.31 (m, H_1), 4.16 (s, H_3), 2.98 (m, H_4), 1.62 (4H, m, $2\times H_5$ and $2\times H_6$), 2.68 (bd, 10 Hz, syn-H_7), 1.23 (bd, 10 Hz, anti-H_7), 4.18 (q, 7 Hz, $COO\underline{H}_2CH_3$), 1.31 (t, 7 Hz, $COOC\underline{H}_2CH_3$). Found: C, 42.14; H, 4.93; N, 4.71%. Calcd for $C_{10}H_{14}NO_2Cl_3$: C, 41.91; H, 4.92; N, 4.89%.

Ethyl endo-*3-Trichloromethyl-2-azabicyclo[2.2.1]heptane-2-carboxylate (5).* A solution of 1.0 g of **3**[2] in 30 ml of ethanol was hydrogenated over 500 mg of 5% Pd–C until 1.14 equiv. of hydrogen-uptake. Removal of the catalyst and the solvent, followed by recrystallization from ether–petroleum ether 894 mg (89%) of **5**, mp 63.5—65.0 °C; IR (CCl_4): 1722 cm^{-1}; MS: *m/e* 242 (small), 240 (small), 168 (100), 140 (34), 96 (21), 68 (36), 67 (28%); NMR (CCl_4): δ 4.61 (m, H_1), 4.67 (d, 4.0 Hz, H_3), 3.09 (m, H_4), 1.2—2.3 (6H, m, $2\times H_5$, $2\times H_6$, and $2\times H_7$), 4.12 (q, 7.3 Hz, $COOH_2$–), 1.27 (t, 7.3 Hz, $COOCH_2$-$C\underline{H}_3$). Found: C, 42.08; H, 4.92; N, 4.66%. Calcd for $C_{10}H_{14}NO_2Cl_3$: C, 41.91; H, 4.92; N, 4.89%.

Ethyl 3-Dichloromethylene-2-azabicyclo[2.2.1]heptane-2-carboxylate (6). *From 4*: To a solution of 1.356 g of **4** in 50 ml of benzene, was added 505 mg (2 equiv.) of methanol-free sodium methoxide, and heated under reflux for 40 h. The reaction mixture was washed twice with water, dried (Na_2SO_4), and distilled to give 888 mg (75%) of **6**, bp 128—130 °C/3 Torr; IR (neat): 1740 (broad), 1646 cm^{-1}; MS: *m/e* 249 (M^+, 43), 251 (M+2, 27), 254 (M+4, 5), 214 (87), 177 (24), 151 (33), 150 (68), 149 (51), 148 (100), 144 (27), 142 (53), 114 (37), 67 (34%); NMR (CCl_4): δ 4.52 (m, H_1), 3.47 (m, H_4), 1.74 (6H, m, $2\times H_5$, $2\times H_6$, and $2\times H_7$), 4.18 (q, 7 Hz, $COOC\underline{H}_2CH_3$), 1.34 (t, $COOCH_2C\underline{H}_3$). Found: C, 47.86; H, 5.12; N, 5.32%. Calcd for $C_{10}H_{13}NO_2Cl_3$: C, 48.02; H, 5.24; N, 5.60%. *From 5*: To a solution of 582 mg of **5** in 20 ml of benzene, was added 220 mg (2 equiv.) of sodium methoxide, and heated under reflux for 9 h. The reaction mixture was worked up as described above, giving 324 mg (64%) of **6**.

Methyl cis-*3-Ethoxycarbonylamino-1-cyclopentanecarboxylate (7).* A slow stream of ozonized oxygen was bubbled into a solution of 888 mg of **6** in 40 ml of dichloromethane and 10 ml of methanol cooled to −50 °C until the blue color persisted. The solution was flushed with oxygen for 10 min, removed from the cooling bath, and added with 2 ml of dimethyl sulfide. The mixture was allowed to warm to room temp for 4 h. After evaporation of the solvent, distillation gave 715 mg (76%) of **7**, bp 137—141 °C/3 Torr; MS: *m/e* 215 (M^+, 16), 156 (20), 142 (100), 138 (25), 129 (55), 128 (30), 84 (20), 83 (21), 67 (52), 57 (23), 56 (55), 55 (23%); NMR ($CDCl_3$): δ 1.5—2.5 (8H, m), 1.26 (3H, t), 3.73 (3H, s), 4.15 (2H, q); IR (neat): 3325, 1730 (broad) cm^{-1}. Found: C, 55.58; H, 7.86; N, 6.41%. Calcd for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51%.

2-Trichloromethyl-1-(ethoxycarbonyl)piperidine (9). A solution of 6.156 g of **8** in 50 ml of ethanol was hydrogenated over 3.0 g of 5% Pd–C until 538 ml (1.07 equiv.) of hydrogen-uptake. After removal of the catalyst and the solvent, distillation gave 5.578 g (90.4%) of **10**, bp 121—122 °C/4 Torr; $n_D^{25.6}$ 1.5020; IR (neat): 1720, 1735 (shoulder) cm^{-1}; MS: *m/e* 163 (100), 154 (33), 128 (30), 84 (50%). Found: C, 39.37; H, 5.15; N, 4.95%. Calcd for $C_9H_{14}NO_2Cl_3$: C, 39.37; H, 5.14; N, 5.10%.

*2-Dichloromethylene-1-(ethoxycarbonyl)piperidine (**10**).* To 1.026 g of **9** in 30 ml of benzene, was added 400 mg (2 equiv.) of sodium methoxide, and refluxed for 23 h. The reaction mixture was poured into water, and extracted with dichloromethane. The organic layer was washed with water, dried (Na_2SO_4), and distilled to give 672 mg (75%) of **10**, which solidified on standing; mp 54.0—54.7 °C; IR (Nujol): 1740 (broad), 1635 cm^{-1}; NMR (CCl_4): δ 2.82 (2H, m, $-N-CH_2-$), 1.2—2.5 (6H, complex m, $3\times CH_2$), 4.12 (bq, $COOC\underline{H}_2CH_3$), 1.28 (t, $COOCH_2CH_3$); MS: *m/e* 237 (M^+, small), 239 (M+2, small), 204 (23), 202 (75), 176 (31), 174 (100%). Found: C, 45.53; H, 5.54; N, 5.61%. Calcd for $C_9H_{13}NO_2Cl_2$: C, 45.39; H, 5.52; N, 5.88%.

*Methyl 5-(Ethoxycarbonylamino)pentanoate (**11**).* A slow stream of ozonized oxygen was bubbled into a solution of 1.427 g of **10** in 30 ml of methanol at room temp for 2 h. After the solution was flushed with oxygen for 20 min, 3 ml of dimethyl sulfide was added to the reaction mixture, and allowed to stand overnight. After evaporation of the solvent, fractional distillation gave 889 mg of crude **11**, bp 125—128 °C/3 Torr. Pure sample of **11** was obtained by preparative GLC; MS: *m/e* 203 (M^+, 14), 172 (20), 171 (22), 130 (22), 126 (27), 115 (47), 102 (100), 100 (67), 98 (54), 82 (22), 74 (37), 70 (22), 59 (37), 58 (26), 56 (61), 55 (60), 44 (23), 43 (45), 42 (30), 41 (36). Found: C, 53.35; H, 8.56; N, 6.60%. Calcd for $C_9H_{17}NO_4$: C, 53.19; H, 8.43; N, 6.89%.

Synthesis and Magnetic Behavior of Three Novel Di-μ-halobis[halo(1,2-benzoquinonedioxime)copper(II)] Complexes. Ferromagnetic Exchange Coupling

Michel MÉGNAMISI-BÉLOMBÉ
Department of Physics, Stanford University, Stanford, California 94305, U.S.A.

(Received April 8, 1978)

Synopsis. Variable-temperature magnetic susceptibilities measured from 4.2 to 300 K on the new dimeric clusters indicate ferromagnetic exchange coupling with $J=+4.63$ cm^{-1} and $J=+0.14$ cm^{-1} for di-μ-bromobis-[bromo-(4-chloro-1,2-benzoquinonedioxime)copper(II)] and di-μ-chlorobis[chloro-1,2-benzoquinonedioxime) copper(II)], respectively, and antiferromagnetic exchange coupling with $J=-0.11$ cm^{-1} for di-μ-bromobis[bromo(1,2-benzoquinonedioxime)copper(II)].

The investigation of exchange effects in paramagnetic cluster compounds has recently developed into a topic of focal and increasing interest to inorganic chemists, as well in theoretical[1] as in experimental[2,3] respect. Lately we reported[4] antiferromagnetic exchange coupling in di-μ-bromobis[bromo(dimethylglyoxime)copper(II), $[CuBr_2(dmgH)]_2$. This dimeric cluster, the first adduct of $CuBr_2$ with a 1,2-dionedioxime ligand, is isostructural[4] with the di-μ-chloro analogue.[5] We now have employed 1,2-benzoquinonedioxime(bqdH) ligands[6] to prepare the three new dimers listed above. We show in the following that, as a specific result of scientific innovation, it is possible to bring about desirable changes in magnetic properties of cluster compounds (in particular ferromagnetic orderings) by controlled chemical modifications of appropriate ligand systems.

Experimental

The brown solids were obtained in good yield by reacting equimolar solutions of the analytical grade reactants according to the equation $RR'bqdH+CuX_2 \xrightarrow[20°C]{(acetone)} CuX_2(RR'bqdH)$ (dimeric structure sketched in the Fig. 1). After washing with cold acetone and drying at ≈ 50 °C, the materials analyze as in the Table 1. The compounds are remarkably air stable, though the bromo derivatives show signs of decomposition after several weeks of exposure to air and light.

Near infrared spectra (KBr pellets) were recorded with a Perkin-Elmer 621 Grating Spectrophotometer, and X-band electron spin resonance spectra with a Varian Assoc. E-12 instrument at room temperature. Variable-temperature susceptibility data were collected at 36 different points from 4.2 to 300 K with a Superconducting Technology, Inc. SQUID-type susceptometer operating at ≈ 2 kG.[4]

Results and Discussion

The spectroscopic data are taken as conclusive evidence to infer the dimeric structure sketched in the Fig. 1. This is done by comparing the spectra with those recorded on the analogous, well-characterized

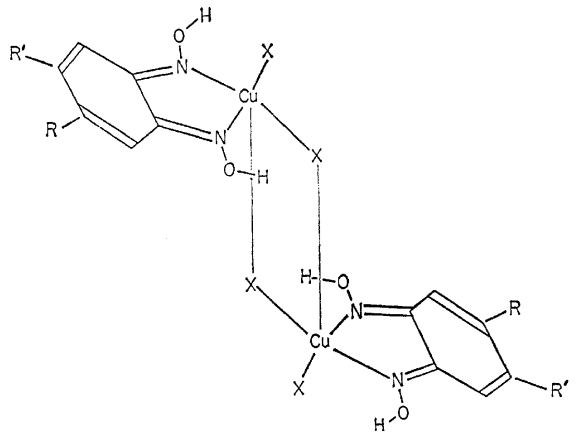

Fig. 1. Infrerred schematic structure of the $[CuX_2(RR'bqdH)]_2$ dimers (bqdH=1,2-benzoquinonedioxime):
a) R=Cl, R'=H, X=Br$^-$: $[CuBr_2(ClbqdH)]_2$,
b) R=R'=H, X=Cl$^-$: $[CuCl_2(bqdH)]_2$,
c) R=R'=H, X=Br$^-$: $[CuBr_2(bqdH)]_2$.

dimethylglyoxime Cu(II) dimers.[4,5] The striking resemblance of the two sets of spectra is interpreted as an intimate reflection of the similar ligand field geometry surrounding the Cu sites in both dimer types. This is rationalized by considering the two analogues $[CuCl_2(bqdH)]_2$ and $[CuCl_2(dmgH)]_2$,[5] which exhibit the same ESR line shape with the identical parallel g factor of 2.207, but have, as to be expected, the different perpendicular g factors of 2.056 and 2.039, respectively.

The corrected molar susceptibility data, χ_m, were fitted with a standard non-linear least-squares computer program[4,7] to the singlet-triplet equation

$$\chi_m = \frac{Ng^2\beta^2}{3k(T-\theta)}\left[1+\frac{1}{3}\exp\left(-\frac{2J}{kT}\right)\right]^{-1} + N\alpha,$$

where the exchange parameter J is defined by the Heisenberg Hamiltonian $H_{ex}=-2JS_1\cdot S_2$. The van Vleck constant, $N\alpha$, was fixed at 60×10^{-6} emu/mol for all three dimers, and the best fits gave a) $J=+4.63$ cm^{-1}, $g=1.99$, $\theta=-5.53$ K for $[CuBr_2(ClbqdH)]_2$; b) $J=+0.14$ cm^{-1}, $g=1.95$, $\theta=-0.29$ K for $[CuCl_2(bdqH)]_2$; c) $J=-0.11$ cm^{-1}, $g=1.95$, $\theta=+0.22$ K for $[CuBr_2(bqdH)]_2$. The fitting g factors differ slightly from the correspeonding isotropic values of 2.050, 2.106, and 2.050 observed with ESR, but the deviations of less than ±0.2 lie within the range expected for the observed J values to be regarded as reliable and "meaningful measurements of the exchange interaction."[3] The experimental magnetic data agreed to within 3% or less with the corresponding theoretical values

Table 1. Microanalytical data

Element	$[CuBr_2(ClbqdH)]_2$		$[CuCl_2(bqdH)]_2$		$[CuBr_2(bqdH)]_2$	
	Found(%)	Calcd(%)	Found(%)	Calcd(%)	Found(%)	Calcd(%)
C	18.20	18.20	26.35	26.44	20.09	19.94
H	1.33	1.27	2.19	2.22	1.64	1.67
N	6.95	7.08	10.16	10.28	7.68	7.75
Cl	8.90	8.95	25.82	26.01		
Br	40.12	40.37			43.63	44.21
Cu	15.70	16.05	23.11	23.31	17.50	17.58

calculated using the above equation. The intradimer exchange coupling, measured by J, is presumably mediated by a *super exchange* mechanism involving the valence orbitals of the bridging halide ligands. Substitution of the bqdH rings (Fig. 1) with electron withdrawing Cl stoms is accompanied by a remarkable increase in J value which passes from -0.11 cm^{-1} in $[CuBr_2(bqdH)]_2$ to $+4.63$ cm^{-1} in $[CuBr_2(ClbqdH)]_2$ Obviously this result demonstrates that the reported ligand-induced nephelauxetic effect[8] may provide a mechanism for modulating electron spin orderings in paramagnetic cluster compounds.

Provided this trend could prove to be generally valid, the present effect might be anticipated to have a far-reaching significance with respect to the better understanding of solid state magnetic phenomena as well as in connection with sounder studies of bonding mechanisms in coordination chemistry for the years ahead. Synthetic details of these and other new Cu(II) dimeric clusters will appear in a subsequent, more comprehensive report.

Synthesis and Reduction of 3-Bromoflavanones

N. J. REDDY and T. C. SHARMA*
School of Studies in Chemistry, Vikram University, Ujjain, M.P., India

(Received April 14, 1978)

Synopsis. Bromination of flavanone, 6-methylflavanone, 6-methyl-4′-methoxyflavanone, and 6-methyl-3′,4′-dimethoxyflavanone with pyridinium tribromide in glacial acetic acid gives the corresponding 3-bromoflavanones, which when refluxed with thiourea in ethanol undergo reduction to flavanones.

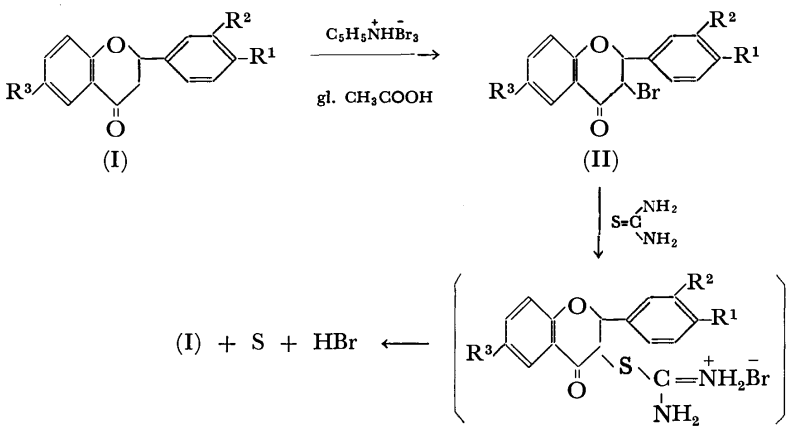
Several reagents such as pyridinium tribromide,[1] phenyltrimethylammonium tribromide,[2,3] 2-pyrrolidone hydrotribromide,[4] (2-carboxyethyl)triphenylphosphonium tribromide,[5] and 2-bromo-2-cyano-*N*,*N*-dimethylacetamide[6] have been employed for the selective bromination of C–H α to a carbonyl group. All these reagents, however, are not equally effective and their reactivity varies with the presence of other functional groups prone to bromine reactivity.

Because of the asymmetric centres, 3-bromoflavanones exist in two racemic forms having different configurations for C_3-bromine. These compounds have been synthesized by the bromination of flavanones with bromine dissolved in a suitable solvent[7–11] or with a brominating agent like dioxane dibromide,† [12] trimethylphenyl ammonium tribromide,[13] and *N*-bromosuccinimide.[10,14–16] 3-Bromoflavanones have also been obtained by the cyclization of 2′-acetoxychalcone dibromides[17–19,22] as well as of 2-bromo-3-ethoxy-1,3-diphenyl-1-propanone.[20] A 3-bromoflavanone was synthesized by the action of copper(II) bromide on 2′-hydroxychalcone.[21] All the methods gave a mixture of cis and trans isomers.

In the present work, we have brominated four variedly substituted flavanones (I) with pyridinium tribromide in acetic acid medium. Three cases gave only the trans isomer, whereas, in the case of 6-methyl-3′,4′-dimethoxyflavanone a mixture of *trans*- and *cis*-bromoflavanones has been obtained.

Keeping in view the biological importance of thio compounds, we examined the reaction of thiourea with 3-bromoflavanones (II). Thiourea reacts with α-halo ketones[24–27] and chalcone dibromides to afford the corresponding thiazoles and chalcones[28] respectively. However, under the reaction conditions employed, the 3-bromo-flavanones undergo conversion to the corresponding flavanones (I).

In addition to flavanone only sulfur could be isolated from the reaction mixture and a positive test was obtained for the presence of HBr. In the light of these facts, a likely reaction path can be as follows.



where
(a) $R^1=R^2=R^3=H$, (b) $R^1=H$; $R^2=H$, $R^3=CH_3$, (c) $R^1=OCH_3$; $R^2=H$; $R^3=CH_3$,
(d) $R^1=R^2=OCH_3$; $R^3=CH_3$

It may be mentioned that all the attempts to detect the presence of urea in the reaction mixture met with failure.

Experimental

All melting points are uncorrected. Pyridinium tribromide was prepared by following the reported procedure.[1]

trans-3-Bromoflavanone (IIa). Flavanone (Ia; 1.1 g) was dissolved in glacial acetic acid (5 ml) by warming on water-bath. To the hot solution was added pyridinium tribromide (1.6 g) in equimolar ratio in small amounts shaking the contents to expel the HBr formed. After the complete addition of the reagent, the reaction mixture was kept at room temperature for 30 min with occasional shaking. It was then diluted with cold water and 3-bromoflavanone thus obtained was crystallized from ethanol to give white crystals (0.9 g) mp 111—112 °C (lit,[12] mp 111 °C).

trans-3-Bromo-6-methylflavaone (IIb). Flavanone (Ib; 1 g) was dissolved in glacial acetic acid (5 ml) by warming on water-bath. To the hot solution was added pyridinium tribromide (1.5 g) under the conditions described above.

† *p*-Dioxane and bromine in equimolar ratio.

After 1/2 h crystals of 3-bromoflavanone separated, which were filtered, washed with water and recrystallized from ethanol to give white glistering leaflets (0.85 g) mp 127—128 °C (lit,[23] mp 127—128 °C). The dilution of the mother liquor gave (0.1 g) more of the product (IIb).
Found: C, 60.4; H, 4.3; Br, 25.1%. Calcd for $C_{16}H_{13}O_2Br$: C, 60.5; H, 4.1; Br, 25.23%.

trans-3-Bromo-4'-methoxy-6-methylflavanone (IIc). Flavanone (Ic; 1.3 g) was dissolved in glacial acetic acid (5 ml) by warming on water-bath. To the hot solution was added pyridinium tribromide (1.3 g) in small amounts. The reaction mixture was worked up as described for IIb. The solid thus obtained was crystallized from ethanol to afford white hexagonal plates (0.8 g) mp 141—142 °C (lit,[22] mp 138 °C).
Found: C, 58.6; H, 4.2; Br, 22.8%. Calcd for $C_{17}H_{15}O_3Br$: C, 58.7; H, 4.3; Br, 23.05%.

3-Bromo-3',4'-dimethoxy-6-methylflavanone (IId). Flavanone (Id, 1 g) was dissolved in glacial acetic acid (5 ml) by warming on water-bath. To the hot solution was added pyridinium tribromide (1 g) in small amounts. The reaction mixture was worked up as described for IIb. The solid thus obtained gave *cis*-3-bromo-3',4'-dimethoxy-6-methylflavanone as colourless plates (0.97 g), mp 158—159 °C (lit,[22] mp 155—156 °C) and *trans*-3-bromo-3',4'-dimethoxy-6-methylflavanone (0.21 g), mp 144—145 °C (lit,[22] mp 142—143 °C) from ethanol.
Found: C, 56.8; H, 4.4; Br, 21.6%. Calcd for $C_{18}H_{17}BrO_4$: C, 57.3; H, 4.5; Br, 21.2%.

Action of Thiourea on 3-Bromo-4'-methoxy-6-methylflavanone. A mixture of the bromoflavanone (1.7 g), thiourea (0.4 g) and ethanol (20 ml) was refluxed on water-bath for three hours. The reaction mixture was then allowed to cool to room temperature and poured into cold water. The solid thus separated was filtered and washed with water. Crystallization from ethanol afforded two products. The sparingly soluble compound on recrystallization from benzene gave yellow needles of free sulfur (0.1 g, mp 120 °C). The soluble product was found to be 4'-methoxy-6-methylflavanone (1.12 g), mp 109 °C (lit,[11] mp 108—109 °C). A mixed melting point determination with an authentic sample of flavanone showed no depression.

Action of Thiourea on 3-Bromoflavanone. A mixture of 3-bromoflavanone (1 g), thiourea (0.3 g), and ethanol (20 ml) was refluxed on water-bath for three hours. The reaction mixture was allowed to cool to room temperature and poured into cold water. The usual work up of the reaction mixture gave sulfur (0.04 g, mp 119—120 °C) and flavanone (0.62 g, mp 76 °C) (lit,[29] mp 76 °C). A mixture melting point determination with an authentic sample of flavanone showed no depression.

Action of Thiourea on 3-Bromo-6-methylflavanone. A mixture of the bromoflavanone (1.6 g), thiourea (0.5 g), and ethanol (20 ml) was refluxed on water-bath for three hours. The reaction products were worked up as usual to afford yellow needles of sulfur (0.12 g, mp 120 °C) and 6-methylflavanone (0.95 g), mp 104—105 °C (lit,[30] mp 105 °C). No depression was observed when a mixture melting point determination with an authentic sample was carried out.

Action of thiourea on 3-Bromo-3',4'-dimethoxy-6-methylflavanone. A mixture of the bromoflavanone (0.6 g), thiourea (0.3 g) and ethanol (20 ml) was refluxed on water-bath for three hours. The reaction product when worked up as described above gave sulfur (0.05 g, mp 120 °C) and 3',4'-dimethoxy-6-methylflavanone (0.34 g), mp 108 °C (lit,[11] mp 108—109 °C). The identity of flavanone was further confirmed by mixture melting point determination with an authentic sample.

Authors are thankful to Prof. M. M. Bokadia for providing laboratory facilities and to U. G. C. (New Delhi) for the award of Junior Research Fellowship to (N. J. Reddy).

NMR Studies on Molecular Interactions Involved in Alkali Metal Halide–Amide–Glycol Ternary Systems

Naoru HAMAGUCHI, Terumichi NAKAGAWA,* and Toyozo UNO
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 16, 1978)

Interactions in a ternary solution of alkali metal halide–amide–glycol have been investigated on the basis of NMR measurement of chemical shifts of OH proton of glycol and amidic protons of acetamide. Measurements were carried out with various alkali metal halides (MX, M=Li, Na, K, X=Cl, Br, I) and glycols (mono-, di-, tri-, and tetraethylene glycol). The dependency of the chemical shifts on solute concentration was examined with a ternary solution of potassium iodide–acetamide–ethylene glycol. The addition of alkali metal halide to respective glycols or glycolic solutions of acetamide gave rise to a change in chemical shift values. The observed changes were related to the ionic sizes of cations and anions of alkali metal halides and to the number of oxyethylene units in a glycol molecule. It was found that a large ion induces a higher magnetic field shift of resonance positions of glycolic OH proton and amidic proton at trans position than a small ion, the magnitude of the shift change being almost proportional to the concentration of ion, and halogen anion formed in glycolic solution tending to interact with hydrogen at trans position rather than at cis position. From a comparison with the values for chemical shifts of water proton in aqueous alkali metal halide solution, it is suggested that the contribution of alkali metal halide to the chemical shift changes in glycolic solution is similar to those in aqueous solution.

Some aliphatic amides interact with various inorganic salts to form stable complexes. Investigations have been made on their isolation,[1] X-ray analysis,[2,3] electric conductivity,[4–7] heat of solution,[8–14] and infrared spectra.[15] In the preceeding paper,[16] we reported that a similar interaction takes place also in gas-chromatographic stationary phase and is applicable to the specific separation of amides. The interaction between acetamide and lithium iodide in polyethylene glycol (PEG) is as strong as −2.5 kcal/mol of partial molar free energy of transfer from PEG to LiI-containing PEG, which is large enough to attain specific retardation of acetamide elution. It is difficult, however, to consider the structural aspects of the interaction from gas-chromatographic findings.

NMR spectroscopy has been extensively used for the study of aqueous electrolyte and non-electrolyte solutions. Shoolery and Alder[17] discussed the chemical shift of water proton in aqueous diamagnetic salt solution. Fabricand and Goldberg[18] investigated the relationship between proton resonance position and the ionic charge, radius, and concentration of alkali metal halide in aqueous solution, and Hinton and Ladner[19] the structure of a series of amides in aqueous solution. Sunners *et al.*[20] found the non-equivalence of two amide protons of formamide owing to the energy barrier hindering C–N bond rotation. The non-equivalence of two amide protons was also observed when the bromide ion was added to acetonitrile solution of formamide.[21] Hindman[22] studied the effect of the change in concentrations of salts of diamagnetic ions on the chemical shift of water proton. It is known from NMR measurements of ethylene proton of polyethylene glycol (PEG) that PEG associates with potassium iodide in methanol solution to behave as a polyelectrolyte. This phenomenon has been ascribed to ion-dipole interaction between potassium cation[23,24] (or, iodide anion[25]) and etherate oxygen of PEG. No paper seems to have described NMR studies on glycol solution of acetamide and/or alkali metal halide.

In connection with our gas-chromatographic studies on alkali metal halide–amide interaction in PEG stationary phase, we have attempted to consider the interaction from the NMR data of the ternary solution and to compare the results with those obtained in aqueous solution.

Experimental

A Varian A-60 NMR spectrometer operating at 60 MHz and 33.7±1.0 °C was used. Since the chemical shift of glycolic methylene proton determined by use of TMS as an internal standard is independent of addition of alkali metal halide and acetamide, it was used as a standard signal for the chemical shifts of glycolic OH proton and amidic protons.

Ethylene glycol(EG) and triethylene glycol(triEG)(Wako Pure Chemical Industry, Osaka, Japan), diethylene glycol (diEG)(Nakarai Chemicals, Kyoto, Japan), and tetraethylene glycol(tetraEG) (Tokyo Kasei Kogyo, Tokyo, Japan) were dried with sodium metal or anhydrous sodium sulfate and purified by double distillation under a reduced pressure with dry nitrogen gas bubbling. The gas-chromatographic analysis of the distilled glycols on Tenax GC column indicated no impurity peaks within the full scale recorder response of the main peak. The purity of acetamide(AA) (Wako Pure Chemical Industry) was also checked by GC using PEG 20 M column, showing a single clear peak. Alkali metal halides of reagent grade were completely dried over phosphorus pentoxide before use.

Results

The chemical shift change, $\Delta\sigma(-\Delta\delta)$, was calculated by

$$\Delta\sigma = -(\delta-\delta_0), \quad (1)$$

where δ and δ_0 are the chemical shifts(ppm) of protons in sample solution and in reference solution, respectively. Pure glycol and a solution of AA/glycol=1/9 by mole ratio were used as a reference for the measurements of the chemical shift changes of glycolic OH proton($\Delta\sigma_{OH}$) and of trans and cis (geometrical position to amide oxygen) amide protons ($\Delta\sigma_{NH,t}$, $\Delta\sigma_{NH,c}$),

respectively. The results obtained in KI–EG and AA–EG binary solutions and in KI–AA–EG ternary solution, where mole fractions of KI(X_{KI}) and AA(X_{AA}) are varied from 0 to 0.2 and from 0 to 0.15, respectively, are given in Table 1. The addition of KI to EG (Fig. 1) gave rise to a high field shift of glycolic OH proton resonance position ($\Delta\sigma_{OH}>0$) proportional to the increase in its molality, whereas the addition of AA had little effect on $\Delta\sigma_{OH}$. In an aqueous solution, a linear relationship between salt concentration and $\Delta\sigma_{OH}$ of water proton was found by Fabricand and Goldberg,[18] the relationship deviating from the linearity in relatively high salt concentration range. The deviation was attributed to the shielding effect of more than one ions on a water proton. Such an effect was not clearly observed in the present case. The interstitial effect,[19] which leads to low field shift of water proton resonance position in dilute aqueous amide solution indicating the stabilization of water structure, was not observed in EG solution. The results for chemical shifts and shift changes of trans and cis amide protons with change in the concentration of KI, are also given in Table 1. It was found that two amide protons of AA give distinct resonance positions ($\delta_{NH,t}>\delta_{NH,c}$), suggesting their non-equivalence. The relationship between $\Delta\sigma_{NH,t}$ or $\Delta\sigma_{NH,c}$ and molality of KI (m_{KI}) is shown in Fig. 2 where X_{AA} is fixed at 0.05. The increasing molality of KI produces almost linear increase in both $\Delta\sigma_{NH,t}$ and

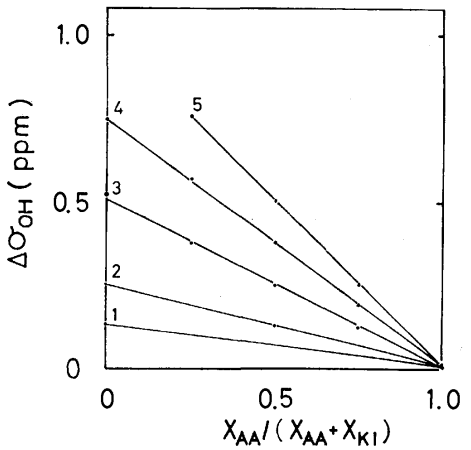

Fig. 3. Relationship between chemical shift change of glycolic OH proton and mole fraction of acetamide with varying total mole fraction of KI and acetamide in ethylene glycol solution (1; $X_{KI}+X_{AA}=0.025$, 2; 0.05, 3; 0.1, 4; 0.15, and 5; 0.2).

$\Delta\sigma_{NH,c}$, the magnitude of increase in $\Delta\sigma_{NH,t}$ being larger than that in $\Delta\sigma_{NH,c}$.

Linear relationship also holds between $\Delta\sigma_{OH}$ and mole fraction of KI (or AA) with change in total mole fraction of KI and AA in KI–AA–EG ternary solution (Fig. 3). This suggests that the contribution of KI and AA to $\Delta\sigma_{OH}$ can be expressed by a linear combination of respective molalities in the form

$$\Delta\sigma_{OH} = A\,m_{KI} + B\,m_{AA} + C, \qquad (2)$$

where the coefficients A and B represent the degree of contribution and C is the intercept. The optimum values for the coefficients were estimated by means of the least squares method using the data given in Table 1. The resulting equation is given in Table 2 along with those for $\Delta\sigma_{NH}$ in the same solution. The value for A coefficient (0.26) is almost equal to the slope of the line(a) in Fig. 1 and is far larger than coefficient B. This means that KI exerts a predominant effect on $\Delta\sigma_{OH}$ and the contribution of AA is as small as that of the intercept which should essentially be zero. With $\Delta\sigma_{NH}$, the trans amide proton seems to be more affected by the addition of KI than the cis proton.

$\Delta\sigma_{OH}$ values for four glycols added with various alkali metal halides at a mole ratio of MX/glycol=1/9 are given in Table 3. The addition of alkali metal halide except lithium chloride to EG produces high field shift of glycolic OH proton. A certain relationship seems to hold between the magnitude of the shift change and the ionic size. Thus, on the assumption that the surface charge of ion is involved in the electrostatic interaction, the squared reciprocals of ionic radii (r_c^{-2}) of anions and cations of alkali metal halides added are plotted against $\Delta\sigma_{OH}$ in EG solution (Fig. 4). It was found that the increasing r_c^{-2} of halogen anion having a cation in common is proportional to the decrease in $\Delta\sigma_{OH}$. The relationship between $\Delta\sigma_{OH}$ and cationic size indicates that the larger cation causes the more positive shift change in resonance position of glycolic OH proton (Fig. 4). However, the effect, as a whole, is smaller than that of anions; the size effect of anion on $\Delta\sigma_{OH}$ is greater than that of cation. It is of interest to compare such behavior of ions in glycolic solution with that in aqueous solution. The contribution of individual ion to $\Delta\sigma_{OH}$ of water proton in aqueous alkali metal halide solution is shown in Fig. 5. A strong resemblance is found between Figs.

TABLE 3. CHEMICAL SHIFT CHANGE OF GLYCOLIC OH PROTON OF MONO-, DI-, TRI-, AND TETRAETHYLENE GLYCOL IN THE PRESENCE OF VARIOUS ALKALI METAL HALIDES AT MOLE RATIO OF MX/GLYCOL=1/9

a) Calculated from twice the $\Delta\sigma_{OH}$ value obtained from a solution of MX/glycol=1/19 by mole ratio. b) Calculated from four times the $\Delta\sigma_{OH}$ value obtained from a solution of MX/glycol=1/39 by mole ratio.

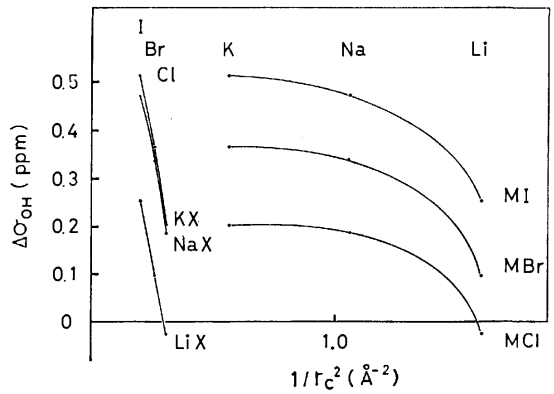

Fig. 4. Ionic size effect on the chemical shift change of glycolic OH proton in a solution of MX/EG=1/9 by mole ratio.

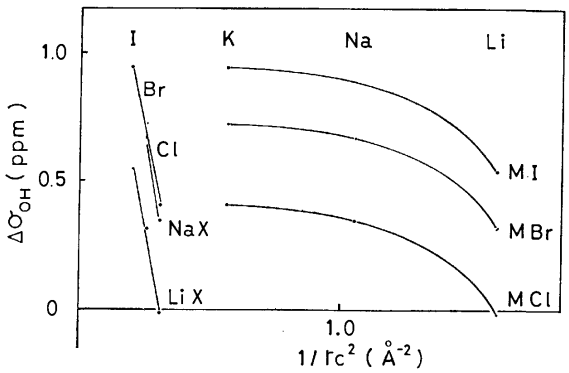

Fig. 5. Ionic size effect on the chemical shift change of water proton in a solution of MX/H_2O=1/9 by mole ratio. The data were obtained from Ref. 18 and corrected with respect to salt susceptibilities[26] according to Wiedeman law.

4 and 5.

Figure 6 shows the relationship between $\Delta\sigma_{OH}$ measured in a solution of MX/AA/EG=1/1/18 by mole ratio and the ionic sizes of alkali metal halides. As compared with Fig. 4 where mole ratio is MX/EG=1/9, Fig. 6 indicates that the general profile of $\Delta\sigma_{OH}$ remains unchanged against the variation of molality of each component, whereas the magnitude of the shift change is about half of those in Fig. 4. This suggests the additive property of $\Delta\sigma_{OH}$ with respect to the concentration of alkali metal halide in relatively low concentration region, since AA has little contribution to $\Delta\sigma_{OH}$. Figure 7 shows the cases of $\Delta_{NH,t}$ and $\Delta\sigma_{NH,c}$; $\Delta\sigma_{NH,t}$ is obviously more dependent on the ionic sizes of alkali metal halides especially on anionic size than $\Delta\sigma_{NH,c}$, although both magnitudes are smaller than that of $\Delta\sigma_{OH}$.

The contribution of individual ions to the change in $\Delta\sigma$ values was evaluated by means of analysis of variance using the data given in Figs. 6 and 7. The presumed values for $\Delta\sigma_{OH}$ and $\Delta\sigma_{NH,t}$ given as a sum of respective ions are in agreement with the observed values. The variance ratios for $\Delta\sigma_{OH}$ and $\Delta\sigma_{NH,t}$ among cations and anions are larger than the value for a level of significance at 5% ($F_4^2(0.05)=6.94$), but the variance ratio of $\Delta\sigma_{NH,c}$ is too small to recognize

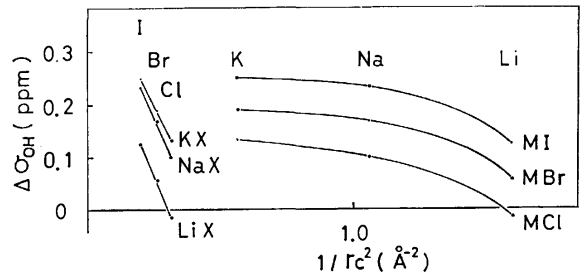

Fig. 6. Ionic size effect on the chemical shift change of glycolic OH proton in a solution of MX/AA/EG=1/1/18 by mole ratio.

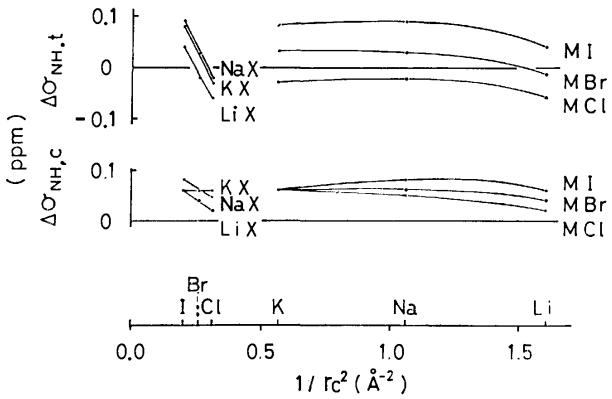

Fig. 7. Ionic size effect on the chemical shift change of amide protons in a solution of MX/AA/EG=1/1/18 by mole ratio.

significant difference. The results seem to support the idea of ionic dissociation of alkali metal halide in glycolic solution.

Experiments were also carried out for higher glycolic solutions (di-, tri-, and tetraEG). It was observed that the increase in the number of oxyethylene units in a glycol molecule is accompanied by a high field shift of OH proton resonance position of pure glycol (EG; δ=5.20, diEG; δ=4.95, triEG; δ=4.50, and tetraEG; δ=4.31). Figure 8 gives the plots of chemical shifts (δ) of glycolic OH and amide protons *vs.* mole fraction of AA (or KI) ($X_{AA}+X_{KI}=0.1$) in di, tri, and tetraEG solutions, showing the linear relationships between δ and X_{AA} (or X_{KI}) in each glycolic solution. It was found that the increase in the oxyethylene unit number is accompanied by high field shifts (decrease in δ value) of all the proton resonance positions, with which the slope, δ/X_{AA}, becomes small. As for the amide protons, the resonance positions are less dependent on the variation in X_{AA} (or X_{KI}) than that of glycolic OH proton.

The chemical shift changes ($\Delta\sigma_{OH}$, $\Delta\sigma_{NH,t}$, and $\Delta\sigma_{NH,c}$) in di-, tri-, and tetraEG solutions are expressed as functions of m_{KI} and m_{AA} as in Eq. 2 according to the method of least squares. The resulting equations, given in Table 2, indicate that $\Delta\sigma_{OH}$ receives a positive contribution($A>0$) from m_{KI} in all the glycolic solutions and a negative contribution($B<0$) from m_{AA} in di-, tri-, and tetraEG solutions. With amide protons, the A coefficient for $\Delta\sigma_{NH,t}$ decreases with increase in the number of oxyethylene units, becoming

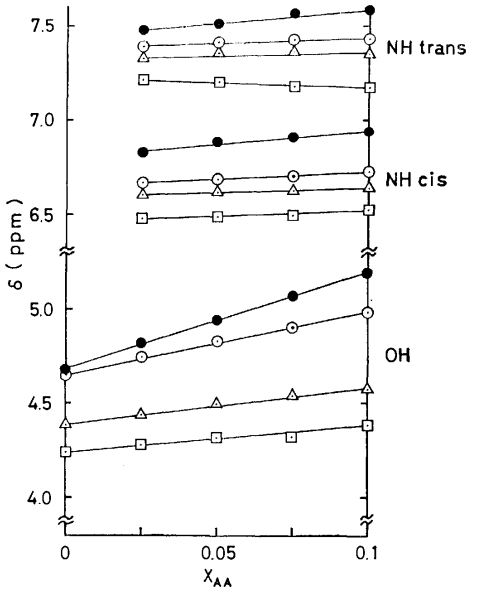

Fig. 8. Relationship between chemical shifts of glycolic OH and amide protons and mole fraction of KI (or AA) with varying oxyethylene unit number in glycol molecule. ($X_{AA}+X_{KI}=0.1$) ●; EG, ⊙; diEG, ◬; triEG, and ⊡; tetraEG.

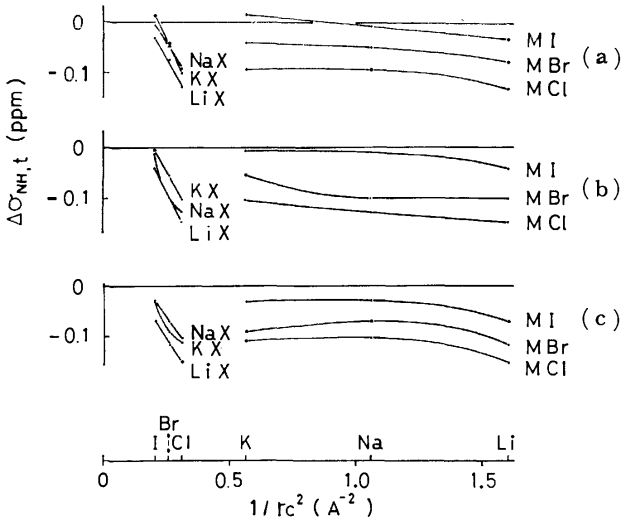

Fig. 9. Ionic size effect on the chemical shift change of trans amide proton in a solution of MX/AA/glycol= 1/1/18 by mole ratio (a; diEG, b; triEG, c; tetraEG).

negative in tetraEG solution. No such explicit change is observed in $\Delta\sigma_{NH,c}$.

The change in OH proton resonance positions of mono to tetraEG (*i.e.*, $\Delta\sigma_{OH}$) decreases with the increase in the number of oxyethylene unit in a glycol molecule with different rate among alkali metal halides added (Table 3). The tendency is almost unchanged irrespective of the addition of AA to alkali metal halide–glycol binary system. In a ternary solution consisting of MX/AA/glycol=1/1/18 by mole ratio, the variation in alkali metal halide causes a more significant difference in $\Delta\sigma_{OH}$ and $\Delta\sigma_{NH,t}$ values than in $\Delta\sigma_{NH,c}$ values in each glycol solution. This suggests that the contribution of alkali metal halide to $\Delta\sigma_{OH}$ and $\Delta\sigma_{NH,t}$ may be delivered to the individual ions. The results thus obtained by means of analysis of variance prove that the larger the anionic size, the larger the $\Delta\sigma$ values. The general profile of ionic size effect on $\Delta\sigma_{OH}$ in di-, tri-, and tetraEG solutions are similar to those in EG solution (Fig. 6). However, the magnitude of $\Delta\sigma_{OH}$ decreases with the increase in the oxyethylene unit number. A similar trend was observed in the relationship between ionic size and $\Delta\sigma_{NH,t}$ in di-, tri-, and tetraEG solutions. The difference in molecular weight of glycol produces almost no change in the ionic size effect on $\Delta\sigma_{NH,t}$ (Fig. 9). In all the glycolic solutions, the increase in anionic size gives rise to more increase in $\Delta\sigma_{NH,t}$ than in $\Delta\sigma_{NH,c}$. The $\Delta\sigma_{NH,t}$ value, however, is negative in higher glycolic solutions.

Discussion

Let us first consider the effects which might cause the change in the resonance position of glycolic OH proton. If acetamide is added to glycol, it may affect the hydrogen bondings of glycol. Since acetamide is a non-electrolyte, glycolic OH proton resonance position may be dominated by the change in the hydrogen bondings. Thus, it is assumed that a high field shift of OH proton resonance position ($\Delta\sigma_{OH}>0$) indicates a decrease in hydrogen bondings in the system. The results (Table 1 and Fig. 1) in which little increase in $\Delta\sigma_{OH}$ accompanies the addition of acetamide to ethylene glycol over the concentration range examined, suggest that the AA–EG hydrogen bond may be as strong as the EG–EG hydrogen bond. The addition of alakli metal halide to glycol, on the other hand, produces a different situation, since dissolution of alkali metal halide in glycol is accompanied by ionic dissociation. Approaching glycol molecule, the ions can interact with dipole of glycol molecule, inducing polarization of OH group, decreasing electronic shielding of OH proton to result in an apparent low field shift of OH resonance position. Thus, the observed value for the chemical shift (δ_{OH}) can be expressed as a function of the electrostatic interaction in addition to the effect on hydrogen bondings. A similar but more detailed consideration has been made with respect to water proton resonance position in aqueous electrolyte solution, the salt-effect on water structure being discussed.[22] Some physico-chemical properties of glycol (*i.e.* heat of vaporization, boiling point, and viscosity)[27] suggest that glycol as well as water may have a certain structure due to hydrogen bondings, although there is no explicit evidence. In this connection, it is interesting to note that the strong resemblance found between Figs. 4 and 5 may give a clue for understanding the behavior of ion in glycol solution.

A linear increase in $\Delta\sigma_{OH}$ with increasing KI concentration (Fig. 1) suggests that EG–EG hydrogen bondings may be decreased by the addition of KI. The results given in Table 3 and Fig. 4 indicate that, as compared with a large anion, a small anion (with large surface charge) induces more decrease in the electronic shielding of glycolic OH proton to give a smaller $\Delta\sigma_{OH}$ value.

Amidic protons at the trans and cis positions of acetamide are also involved in hydrogen bonding with glycol molecule. The addition of alkali metal halide, therefore, may have an influence on amide protons as well. The results shown in Figs. 2 and 7 may be interpreted as follows: When alkali metal halide is dissolved in an EG solution of acetamide, the ions formed give rise to apparent decrease in hydrogen bondings of amidic protons to result in high field shifts ($\Delta\sigma_{NH}>0$), halogen anion tending to interact with amide at trans position rather than at cis position.

From the results in Tables 2 and 3 and Fig. 8, it seems that the increase in the number of oxyethylene units in a glycol molecule is accompanied by enhancement of electrostatic interaction of alkali metal halide with acetamide. Such effect may be responsible for the specific retention of amide on an alkali metal halide-containing PEG as a gas-chromatographic stationary phase.

Ultrasonic Properties of Aqueous Solutions of Butylamines

Sadakatsu NISHIKAWA* and Mitsuo MASHIMA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received April 27, 1978)

Ultrasonic absorption and velocity measurements were performed in aqueous solutions of *t*-butylamine and isobutylamine at 20 °C. Two relaxational absorptions were found in both solutions. One is associated with the proton transfer reaction, the rate constants being determined together with the standard volume change of the reaction. No effect was observed on K_f with change in molecular structure. The other, associated with the peak sound absorption concentration, is ascribed to the association-dissociation reaction mechanism of unionized amine molecules. The results are discussed in comparison with those of butylamine.

Ultrasonic investigations for liquid properties provide useful information on kinetic behavior. Two kinds of relaxational processes exist in aqueous solutions of amines, depending upon the concentration and molecular structure.[1,2] One is due to the proton transfer reaction observed in relatively dilute solutions. The other is associated with the peak sound absorption concentration (PSAC). These processes have been treated independently because of the complexity of the interaction between fast and slow processes. A report was given on the ultrasonic absorption of aqueous solutions of some amines. This investigation was undertaken in order to clarify the ultrasonic properties of three butylamines with different molecular structures.

Experimental

Commercial *t*-butylamine and isobutylamine (G. R. grade, Wako Chemicals Industries, Ltd.) were distilled, the purity being confirmed to be higher than 99.9% by gas chromatography. The solutions were prepared with twice distilled water.

The ultrasonic absorption measurement was carried out at the odd harmonics of 0.5, 5, and 20 MHz x-cut quartz transducers by means of pulse technique in the frequency range 6.5—220 MHz, absorption coefficient being reproducible to within ±3%. The sound velocity was measured by a sing-around method operated at 1.92 MHz. The major mechanical features of the apparatus have been reported.[3] The cells for absorption and velocity measurement were immersed in a water bath maintained at a constant temperature within ±0.001 °C. All the measurements were carried out in a dry nitrogen gas atmosphere in order to prevent the contamination of air, since the aqueous solutions of amines are highly basic.

Results and Discussion

In general, the sound absorption caused by several relaxation processes can be expressed by

$$\alpha/f^2 = \sum_i A_i/[1+(f/f_{ri})^2] + B, \quad (1)$$

where α is the absorption coefficient, f frequency, A_i relaxation amplitude for the i-th process, f_{ri} relaxation frequency and B residual absorption amplitude. Figures 1 and 2 show the representative ultrasonic absorption spectra in aqueous solutions of *t*-butylamine and isobutylamine at 20 °C. In both solutions, only a single relaxtional absorption was observed in relatively dilute solutions (less than 0.9 mol dm^{-3}). However, with increasing concentration, the experimental

values of the absorption coefficients deviate from the single relaxational equation, *viz.*, another excess absorption appears in the same frequency range. In the case of the single relaxation process, the ultrasonic parameters, A, f, and B, were determined from the

plots of α/f^2 *vs.* $[1+(f/f_r)^2]^{-1}$ so as to obtain a straight line. On the other hand, the ultrasonic parameters associates with more than one process are not easily determined because the two processes are close together. In Fig. 3 only the concentration dependence of α/f^2 at 15 MHz in the aqueous solutions is shown along with that of butylamine.[5] The most plausible mechanism of the excess absorption in the lower concentration range is the perturbation of the equilibrium associated with proton transfer[1,2,6,7] expressed by the formula

$$R\text{-}NH_3^+ + OH^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R\text{-}NH_2 + H_2O. \quad (2)$$

The relaxation frequency for the above process can be related to the forward and backward rate constants, k_f and k_b, as repredented by

$$2\pi f_r = k_f\gamma^2([R\text{-}NH_3^+]+[OH^-]) + k_b, \quad (3)$$

$$= 2k_f\gamma^2[OH^-] + k_b, \quad (3')$$

where γ is the mean activity coefficient, which is assumed to be identical for $R\text{-}NH_3^+$ and OH^- ions,[8] and is calculated from the equation, $-\log\gamma=0.5[\sqrt{I}/(1+\sqrt{I})-0.3I]$ where I is the ionic strength. Equation 3 can be rewritten as follows, using the analytical

TABLE 2. RATE CONSTANTS AND STANDARD VOLUME CHANGE OF PROTON TRANSFER REACTION OF BUTYLAMINES

	k_f (mol dm^{-3} s^{-1})		k_b (s^{-1})			K_b (mol^{-1})	ΔV (cm^3 mol^{-1})	Ref.
	(a)	(b)	(a)	(b)	(c)			
Butylamine	4.1×10^{10}	2.5×10^{10}	1.4×10^{8}	1.1×10^{8}	1.1×10^{7}	4.44×10^{-4}	32	4
Isobutylamine	1.2×10^{10}	3.4×10^{10}	3.2×10^{8}	3.0×10^{8}	1.1×10^{7}	3.22×10^{-4}	29	This work
t-Butylamine	1.9×10^{10}	2.0×10^{10}	2.1×10^{8}	2.9×10^{8}	1.0×10^{7}	5.17×10^{-4}	24	This work

The values in column (a) were determined from the slope and intercept using Eq. 3, those in column (b) from Eq. 4, and the backward rate constants in column (c) were calculated using the dissociation constant.

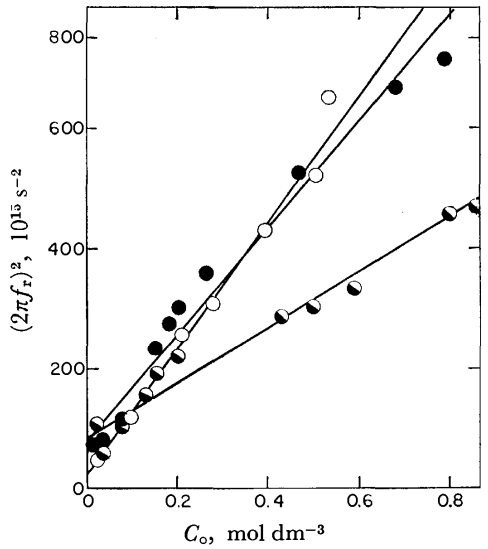

Fig. 5. Plots of $(2\pi f_r)^2$ *vs.* C_o. ○: Butylamine, ●: *t*-butylamine, ◒: isobutylamine.

concentration, C_o, on the assumption that the activity coefficient is unity and only one equilibrium exists in the aqueous solution.

$$(2\pi f_r)^2 = 4k_f k_b C_o + k_b^2 \quad (4)$$

Figure 4 shows the plots of f_r *vs.* $\gamma^2[OH^-]$, the slope and intercept of which provide the rate constants. Figure 5 shows those of $(2\pi f_r)^2$ *vs.* C_o, from which the rate constants were also determined. In proton transfer investigations so far, the latter procedure of rate determination was carried out by means of the dissociation constants in the literature because of the uncertainty of the intercept. The forward rate constants are approximately the same in both determinations and reasonable values are obtained for the diffusion-controlled reaction. However, there are some questions in the latter determination of the backward rate constants for the following reasons. First, Eq. 4 is derived with numerous approximations. Second, the backward rate constant is determined from Eq. 4 without use of dissociation constant. However, ratio k_b/k_f is not in line with the dissociation constant even when the experimental error is taken into account. The cause of disagreement has been interpreted by the introduction of intermediate of Eq. 5.[2]

$$R\text{-}NH_3^+ + OH^- \rightleftharpoons R\text{-}NH_3^+\cdots OH^- \rightleftharpoons R\text{-}NH_2\cdots H_2O \rightleftharpoons R\text{-}NH_2 + H_2O \quad (5)$$

Actually, the rate constants, k_f and k_b, can be related by those of each steps of Eq. 5, assuming that the second and third steps equilibrate so rapidly or the stationary states are established. However, detailed discussions for each step of Eq. 5 from the rate constants obtained may not be appropriate at this stage since the rationalized mechanisms are too complicated.

The determination of the rate constants from Eq. 3, on the other hand, is a direct procedure even if the intermediate exists. The dissociation constants were calculated from the concentration dependence on pH and are very close those in the literature.[9] This means that the determination of the concentration of OH^- ion in the solutions is correct. The rate constants calculated from the above two methods (from Eqs. 3 and 4) are given in Table 2 along with the dissociation constants and the standard volume changes of the reaction which are determined from the maximum excess absorption per wavelength.[2] It can be concluded that the diffusion-controlled rate constants of butylamines may be independent of the molecular structures, *viz.*, the mobilities of butylamine molecules in aqueous solvent are approximately the same.

We consider next the absorptions which appear in the concentrated solutions of the amines. Figure 6 shows the concentration dependence of the sound velocity at 20 °C. The values of α/f^2 increase rapidly near the maximum of the sound velocity, reaching a maximum in all the solutions. The peak sound veloc-

ity concentration increases in the order, butylamine, isobutylamine and *t*-butylamine. The peak sound absorption concentration stands in the same order. We have proposed an association-dissociation reaction of unionized amine molecules as the cause of the excess absorption mechanism, since no peak sound absorption concentration is observed in aqueous solutions of amines with low hydrophobicity,[2] nor excess absorption in aqueous solution of the amine hydrochloride and in organic solvent.[1] In the cases of aqueous solutions of butylamine and pentylamine, the two relaxation processes could be treated independently since the two relaxation frequencies are far apart. However, in the aqueous solutions of *t*-butylamine and isobutylamine, the relaxation times are close to each other and can not be determined precisely. It is likely that the structure of liquid solution is altered by addition of solute molecules near the peak sound velocity concentration and the solute molecules with hydrophobicity aggregate in aqueous media. The hydrophobicity seems to be in the order of peak sound velocity concentration or peak sound absorption concentration. Williams *et al.*[10] reported the ultrasonic absorption data of various amines in the liquid phases and interpreted them in terms of conformational changes of molecules. However, no excess absorption has been observed in the pure liquids of amines. Thus, the absorption mechanism with conformational change has been ruled out from the cause of the excess absorption.

The authors wish to thank Professor Paul Hemmes, Rutgers University, for reading the manuscript and helpfull discussions.

Determination of Magnetic Susceptibilities of Paramagnetic Gases by an Improved Viscometer Method

Kazuo SUEOKA* and Toshio IKEDA†

Department of Chemistry, Johsai University, Sakado, Saitama 350-02

† *Department of Chemistry, Shizuoka University, Shizuoka 422*

(Received July 7, 1978)

An improved viscometer method has been applied to the determination of the magnetic susceptibility of a paramagnetic gas and found to be of use in the analysis of a paramagnetic gas mixed in a diamagnetic gas. The magnetic susceptibilities of oxygen and nitrogen monoxide have been determined to within ±0.5% using a saturated aqueous solution of sodium chloride as the working liquid.

The present authors reported an improved viscometer method[1] for the determination of the magnetic susceptibilities of diamagnetic liquids by measuring the time of flow of liquid under nitrogen through the capillary of a modified Ubbelohde type viscometer under an external magnetic field.

In the present study, some applications of the viscometer method will be described concerning the magnetic susceptibilities of paramagnetic gases and the analysis of paramagnetic species in a gaseous mixture, *e.g.*, oxygen in air.

Theoretical

A capillary viscometer cell of modified Ubbelohde type as shown in Fig. 1 was placed in a magnetic field so that the lower end of the capillary was in the center of the pole gap of an electromagnet, while the capillary extended vertically, through the inhomogeneous region, outside the field. The liquid in the capillary of the cell was forced to flow down by the dual action of the gravitational and magnetic forces acting on it and its enviromental gas which was in contact with the liquid and circulating in the dead space below the capillary.

Assuming a liquid of certain volume requires time t_H to flow through the capillary of the viscometer under action of an external magnetic field of strength, H, then it follows that

$$\frac{1}{t_H} = C\left[\rho_L g\tilde{h} + \frac{1}{2}(\kappa_L - \kappa_G)H^2\right], \tag{1}$$

where C is a constant determined by the geometry of the cell and the viscosity of the flowing liquid, g is the acceleration due to gravity, $\tilde{h}$ is the mean effective head of liquid, ρ_L is the density of the liquid, κ_L represents the volume magnetic susceptibility of the liquid phase (L) in equilibrium with the gas phase (G) whose susceptibility is κ_G, where the gas is supposed to dissolve in the liquid without chemical reaction (solbility β). In the absence of a field, $1/t_0 = C\rho_L g\tilde{h}$ which gives from Eq. 1:

$$\tau_G \equiv \left(\frac{t_0 - t_H}{t_H}\right)_G = \frac{H^2}{2g\tilde{h}\rho_L}(\kappa_L - \kappa_G), \tag{2}$$

where

$$\kappa_L = \kappa_L^\circ + \beta\kappa_G', \tag{3}$$

κ_L° is the volume magnetic susceptibility of the pure liquid and κ_G' that for the dissolved gas. Generally speaking, the gas considered may be mixture, the most simple case being the two component system consisting of, from the magnetic point of view, a diamagnetic (D) and a paramagnetic (P) species with respective volume fractions x_D and x_P. It is apparent that

$$x_D + x_P + x_V = 1, \tag{4}$$

where x_V is the volume fraction of the working liquid vapor with which the gases are in contact. Denoting by κ_D° and κ_P° the volume magnetic susceptibilities of the dia- and paramagnetic species respectively both in the gaseous pure states at a given temperature T and pressure P, the apparent susceptibility, κ_G, of a gas mixture may thus be written as follows:

$$\kappa_G = \kappa_D^\circ x_D + \kappa_P^\circ x_P + \kappa_V^\circ x_V, \tag{5}$$

where κ_V° denotes the susceptibility of the saturated vapor of the working liquid in the pure state at a given condition of T. Assuming the gas is in equilibrium in contact with the working liquid in the viscometer at constant temperature and pressure and denoting by β_D° and β_P° the solubilities of the two gaseous species D and P, in the pure states respectively, (under the same conditions of T and P) the solubility of a gaseous mixture composed of D and P in a certain liquid may be written as follows:

$$\beta = \beta_D^\circ x_D + \beta_P^\circ x_P. \tag{6}$$

Then, the volume fractions x_D' and x_P' of the two species (D and P) dissolved in the liquid may be expressed as follows:

$$x_D' \equiv \frac{\beta_D^\circ}{\beta}x_D, \qquad x_P' \equiv \frac{\beta_P^\circ}{\beta}x_P, \tag{7}$$

and

$$x_D' + x_P' = 1. \tag{8}$$

For the magnetic contribution, κ_G', from the gas dissolved in the liquid (L) assuming that the intermolecular interaction between the liquid and dissolved gas is not strong, in analogy to Eq. 5, it may be written as

$$\kappa_G' = \kappa_D^\circ x_D' + \kappa_P^\circ x_P'. \tag{9}$$

Converting the magnetic susceptibility of the i-th species, κ_i, per unit volume into that, χ_i, per unit mass by definition $\kappa_i \equiv \rho_i\chi_i$, and putting $\rho_L \fallingdotseq \rho_L^\circ$ (ρ_L° is the density of the pure liquid), Eq. 2 may be rewritten with the abbreviation $H^2/2g\tilde{h} \equiv K$:

$$\tau_G = K\left[\chi_L^\circ - \frac{\rho_D^\circ x_D}{\rho_L^\circ}(1-\beta_D^\circ)\chi_D^\circ - \frac{\rho_P^\circ x_P}{\rho_L^\circ}(1-\beta_P^\circ)\chi_P^\circ - \frac{\rho_V^\circ x_V}{\rho_L^\circ}\chi_V^\circ\right], \tag{10}$$

where ρ°_L, ρ°_P, and ρ°_V are the densities of the dia- and paramagnetic gases, D and P, and the vapor of the liquid in the pure states, respectively, at a given T and P. For the paramagnetic gas system ($x_P = 1-x_V$, $x_D=0$);

$$\tau_P = K\left[\chi^\circ_L - \frac{\rho^\circ_P(1-x_V)}{\rho^\circ_L}(1-\beta^\circ_P)\chi^\circ_P - \frac{\rho^\circ_V x_V}{\rho^\circ_L}\chi^\circ_V\right], \quad (11)$$

and for the diamagnetic gas system ($x_P=0$, $x_D=1-x_V$);

$$\tau_D = K\left[\chi^\circ_L - \frac{\rho^\circ_D(1-x_V)}{\rho^\circ_L}(1-\beta^\circ_D)\chi^\circ_D - \frac{\rho^\circ_V x_V}{\rho^\circ_L}\chi^\circ_V\right], \quad (12)$$

assuming t_H is measured under the same field strength, *i.e.*, with a common K. Then invariably, irrespective of the working liquid used;

$$\frac{\tau_G-\tau_D}{\tau_P-\tau_D} = \frac{x_P}{x_P+x_D} = \phi_P, \quad (13)$$

where Eq. 4 is considered and ϕ_P is the volume fraction of the paramagnetic component in the gaseous sample. From Eq. 13, it is now possible to make a magnetic a nalysis of a gaseous mixture which is known to involveonly one paramagnetic species. (See below).

In addition to this, the susceptibility of the paramagnetic species in the gaseous state may be obtained in four ways:

(i) from Eq. 10,

$$\chi^\circ_P = -\frac{\rho^\circ_L(\tau_G - K\chi^\circ_L)}{K\rho^\circ_P\phi_P(1-x_V)(1-\beta^\circ_P)}, \quad (14)$$

(ii) from Eq. 11,

$$\chi^\circ_P = -\frac{\rho^\circ_L(\tau_P - K\chi^\circ_L)}{K\rho^\circ_P(1-x_V)(1-\beta^\circ_P)}, \quad (15)$$

(iii) from Eqs. 10 and 12,

$$\chi^\circ_P = -\frac{\rho^\circ_L(\tau_G - \tau_D)}{K\rho^\circ_P\phi_P(1-x_V)(1-\beta^\circ_P)}, \quad (16)$$

(iv) from Eqs. 11 and 12,

$$\chi^\circ_P = -\frac{\rho^\circ_L(\tau_P - \tau_D)}{K\rho^\circ_P(1-x_V)(1-\beta^\circ_P)}, \quad (17)$$

where the second terms of Eqs. 10 and 12 and the last terms of Eqs. 10, 11, and 12 have been considered negligible. Allowing for a deviation of 0.5—1% (approximately -0.5×10^{-6} e.m.u.), one may use Eq. 16 or 17.

Experimental

Materials. Nitrogen and oxygen were obtained from commercial sources with purities exceeding 99.9%. The mixed gases were prepared from these. The gases and air were dried by passage through silica gel and phosphorus pentoxide; commercial 99.0% nitrogen monoxide was used without further drying. Benzene, carbon tetrachloride, 2,2,4-trimethylpentane, and cyclohexane were Dotite Primasol solvents, while toluene, ethyl acetate, hexane, heptane, and acetone were Dotite Spectrosol solvents (Dojindo Co.) and used without purification. Sodium chloride (G. R. grade) was recrystallized twice from water. The water was purified by sub-boiling distillation from a quartz still after deionization.

Capillary Cells. A detailed figure of the cell has been given in a previous paper.[1] The two types of cell used in the present work were found to have slightly different cell-

constants, K, *i.e.*, 38.9_3 and 38.7_2 $Oe^2\,dyn^{-1}\,cm^{-1}$, respectively, at 1 kOe and $13.7_6\times10^3$ and $14.7_2\times10^3$ $Oe^2\,dyn^{-1}\,cm^{-1}$, respectively, at the respective maximum magnetic field strengths. The cell constants were determined from Eq. 12 for water under nitrogen, ignoring the second and last terms in Eq. 12 and using -0.720×10^{-6} e.m.u. for the magnetic susceptibility of pure water.[2] Figure 1 and Tables 1 and 2 are derived from using the first type cell and Fig. 2 and Table 3 from the second type.

Magnet. The electromagnet is the same type as used in the previous work.[1] The pole pieces of the magnet were set at a separation of approximately 8 mm for the first type cell and approximately 7 mm for the second type. The highest magnetic field strengths available at a maximum current of 4 A were 18.8 and 19.5 kOe, calibrated with

a Yokogawa gauss meter, type 3251. The magnetizing current was automatically kept at a constant value ($\pm0.01\%$) throughout the measurements.

Measurements. Prior to the measurements the liquid in the cell was saturated with the gas under study by passing the gas through the liquid for about 10 min and the dead space of the cell fully replaced by the gas by means of an operation tube connected to the cell. The τ-value was measured for nitrogen before and after every measurement of τ to check for changes in the liquid under study. Exchange of the two gases was achieved by means of 3-way stop valve that allowed either of the two gases to flow continuously through the operation tube so that the gases and the liquid in the cell was never exposed to the air. The temperature and pressure were kept constant at 20 ± 0.01 °C, and 785 ± 1 mmHg and 798 ± 1 mmHg for the first and second type cells respectively. Details of the automatic measurements have been fully described in a previous paper.[1] The density of the liquid was measured using a Shibayama Scientific Co. densimeter, type SS-D-200; more than 20 measurements were conducted to yield a mean flow time from which the magnetic susceptibility could be calculated.

Results and Discussion

The experimental results obtained at different mixing ratios of oxygen and nitrogen are shown in Fig. 2. In all cases a straight line relation may be seen, which can be expressed by the following empirical formula;

$$\tau_G = [\tau(O_2)-\tau(N_2)]\phi(O_2) + \tau(N_2), \quad (18)$$

where $\tau(O_2)$ and $\tau(N_2)$ represent the τ-values measured with a working liquid under flowing of pure oxygen and pure nitrogen, respectively, and $\phi(O_2)$ represents the volume fraction of oxygen in the gas. This equation is identical with that of Eq. 13. The volume fraction of oxygen in air was calculated with the aid of Eq. 13 from the τ-values measured on various working liquid, and the results are shown in Table 1. The observed values of $\phi(O_2)$ for air are found to be reproducible within $\pm1\%$ and are in good agreement with the literature as well as those given by gas-chromatographic analysis.

The magnetic susceptibility of pure oxygen was estimated with the aid of Eq. 15, from the experimental τ-values as listed in Table 1, where the volume fraction ϕ_P is assumed equal to 0.999, the purity of the oxygen in the gas cylinder used here, the results of which are shown in Table 2 together with the necessary physical data. In most cases, the τ-values obtained were always reproducible to within $\pm0.05\%$ and the estimated values of χ for oxygen were found to be reproducible to within $\pm0.5\%$, in good agreement with the literature except for the case of toluene. Thus, it has been demonstrated that the magnetic susceptibility

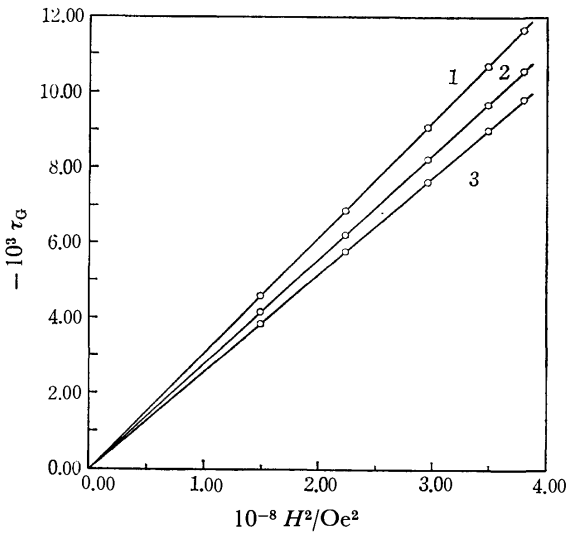

Fig. 3. Relationship between the τ-values found in different gases and the external magnetic-field strength at 20 °C when water saturated with sodium chloride was used as a working liquid. 1, Oxygen; 2, nitrogen monoxide; 3, nitrogen.

of a paramagnetic species mixed singly in diamagnetic gases may be determined by the viscometer method when the working liquid is selected and the gas non-reactive and the vapor pressure and solubility data of the gas in the liquid available. At least, all liquids used here appeared not to be denaturalized throughout the measurements, since no changes in the $\tau(N_2)$-value could be found before and after the measurement of the $\tau(O_2)$-value, were concluded.

In the case of toluene as the working liquid, a considerably low magnetic susceptibility was obtained for oxygen, the deviation being up to 6%. Such a large deviation can not be accounted for by intermolecular interactions such as the charge transfer between the dissolved oxygen and the liquid. A possible explanation may be that the solubility value of oxygen in toluene used here is somewhat erroneous since the value is too small compared with other liquids. On the other hand, the solubility data for the less-familiar gases, *e.g.*, nitrogen monoxide, are rarely found in the literature. Consequently it is advisable to use a liquid in which the solubility of gases is negligibly small, the limit of $\beta<0.001$ being sufficient. Concentrated aqueous solutions of inorganic salts having strong salting out effects may be of use. Water saturated with sodium chloride may be a liquid that can be used conveniently; *i.e.*, one volume of saturated aqueous solution dissolves only 0.00107 volumes of oxygen at 20 °C and 1 atm.[3]

The experimental results obtained by the viscometer method using saturated aqueous solutions of sodium chloride and various gases are shown in Fig. 3. In every case a straight line relation can be seen between τ and H^2, passing through the origin in agreement with Eq. 2. The saturated solution used here was found by analysis to dissolve sodium chloride at 26.17_6 wt% with a density 1.1990 g cm^{-3}, only slightly lower than that reported in the literature,[4] 26.43 wt% and 1.1999 g cm^{-3}, respectively. The magnetic susceptibility, χ_L, of this solution, measured by the present method was found to be $-0.667_8\times10^{-6}$ e.m.u., very closely in agreement with $-0.667_6\times10^{-6}$ e.m.u. estimated by Wiedemann's additivity law using the magnetic susceptibilities of -0.720 and -0.520×10^{-6} e.m.u.,[2] respectively for water and solid sodium chloride. Furthermore, the use of a saturated sodium chloride solution as the working liquid in the viscometer method at the same field strength using the same cell and measuring τ_G and τ_D separately, allowing for a maximum error of approximately ±0.5% at most, the following conventional equation, may be used instead of the more rigorous Eq. 16,

$$\kappa_P^\circ = \rho_P^\circ\chi_P^\circ = \frac{0.800_7}{(1-x_V)\phi_P}\left(\frac{\tau_G}{\tau_D}-1\right)\times10^{-6}\text{ e.m.u.}, \quad (19)$$

where two approximations, $\beta_P^\circ=0$ and $\tau_D=K\chi_L^\circ$ are assumed. From the experimental values of τ measured at different magnetic field strengths, the magnetic susceptibilities of oxygen and nitrogen monoxide have been computed using Eq. 19 and are listed in Table 3. In the range of magnetic fields investigated the results obtained were found to be in good agreement with

each other in either species of gases and those reported in the literature. However, according to the experience of the authors, the stronger the field in which the measurements are conducted, the more reliable are the results obtained. Consequently, for the magnetic susceptibilities of oxygen and nitrogen monoxide the values 107.3 and 48.4×10^{-6} e.m.u., respectively are prefered, found at 19.5 kOe, the highest level of the magnetic field strength available in the present study.

The advantages of the present method are: (1) no structural delicacy of the apparatus for its simple mechanism; (2) the measuring system since it is fully automatic, the successive analysis of a gas with respect to paramagnetic species may be possible; (3) it is easy to obtain results with considerable accuracy without taking a lot of precision; (4) the use of saturated aqueous solution of sodium chloride is very convenient for determining the susceptibility of paramagnetic gas species to a sufficient accuracy avoiding considerations of the solubility effect of gases. In addition pure sodium chloride is readily available and ample physicochemical data of its aqueous solutions exists.

The Photochemical Reaction of Benzo[c]cinnoline. III. Mechanism of Carbazole Formation

Hiroyasu INOUE,* Yukimi HIROSHIMA, and Kiyoto MIYAZAKI

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received July 22, 1978)

5,6-Dihydrobenzo[*c*]cinnoline is an intermediate in the photochemical formation of carbazole from benzo[*c*]cinnoline. The mechanism of the photo-induced carbazole formation from 5,6-dihydrobenzo[*c*]cinnoline has been studied in acidic aqueous 2-propanol of the reactant previously produced by the photo-reduction of benzo[*c*]cinnoline. It has been established that only the protonated species of the reactant undergoes photoreaction. The results of quenching experiments on quantum yields for the reaction and on the fluorescence of the reactant have shown that the reactive state is the first excited singlet state of protonated 5,6-dihydrobenzo[*c*]cinnoline. The initial step in the reaction is the hydrogen atom abstraction followed by elimination of the amino radical.

It has been reported that benzo[*c*]cinnoline in acidic alcohol solutions gives rise to carbazole under ultraviolet light irradiation.[1] 5,6-Dihydrobenzo[*c*]cinnoline has been found to be an intermediate in the carbazole formation. This intermediate is obtained in acidic 2-propanol with visible light irradiation. No subsequent reaction occurs,[2] hence the photo-induced carbazole formation from 5,6-dihydrobenzo[*c*]cinnoline can be studied using the solution thus obtained. In strongly acidic solution such as 4 M HCl aqueous 2-propanol, 5,6-dihydrobenzo[*c*]cinnoline exists in the monoprotonated form and has absorption bands at 240, 270, and 315 nm.

The purpose of this paper is to clarify the mechanism regarding the photochemical reaction of 5,6-dihydrobenzo[*c*]cinnoline to carbazole. The reactive excited state of the reactant and the mode of elimination of fragments from the reactant are of particular interest.

Experimental

Materials. Benzo[*c*]cinnoline, naphthalene, anthracene, pyrene, and 2-propanol were the same as those used previously.[2] Phenanthrene and fluorene were recrystallized from ethanol. Acetophenone was purified by distillation. *trans*-1,3-Pentadiene was used without further purification.

Irradiation. To convert benzo[*c*]cinnoline into 5,6-dihydrobenzo[*c*]cinnoline, an acidic aqueous 2-propanol solution of the former was irradiated with light of a wavelength in excess of 400 nm, obtained from a 500 W high pressure mercury arc lamp and a Corning glass filter (CS 3-73). The solution of the reactant thus prepared was irradiated with 315 nm light from a Shimadzu excitation apparatus GF-16E, equipped with a 500 W Xe lamp and a grating monochromator. All irradiations were conducted at room temperature under nitrogen to prevent oxidation of the reactant.

Measurements and Analysis. Ultraviolet spectra were measured with a Shimadzu UV-200 spectrophotometer using 1 cm cells. Fluorescence and phosphorescence spectra were recorded on a Shimadzu RF-500 spectrofluorimeter at room temperature and 77 K, respectively. The quantum yield for the carbazole formation was determined as follows. Acidic aqueous 2-propanol solution (4 M HCl) of benzo[*c*]cinnoline (1.0×10^{-4} M) was irradiated, first with light of a wavelength in excess of 400 nm for 3 h to give 5,6-dihydrobenzo[*c*]cinnoline quantitatively, and then the resulting solution was irradiated with light of wavelength 315 nm for 15 min. The actionmetry was performed together with the spectrophotometric determination of the amount of carbazole produced, a potassium ferrioxalate solution being employed as the actinometer.[3]

Results and Discussion

The quantum yield for the carbazole formation was determined to be 0.15 and this did not change with variation in the initial concentration of reactant in the range 7.5×10^{-5}—2.0×10^{-4} M. In order to estimate the energies of the lowest excited singlet and triplet states of the reactant, the fluorescence and phosphorescence spectra were measured. From the observed emission spectra presented in Fig. 1 the energies of the lowest excited singlet and triplet states were evaluated to be 82.7 and 63.4 kcal/mol, respectively. These values were determined from the wavelengths of the emission band shoulders indicated by the arrows in Fig. 1, since the emission bands have no distinct fine structures.

To identify the reactive state of the photoreaction, quenching experiments were conducted using several compounds, *e.g.* fluorene, naphthalene, acetophenone

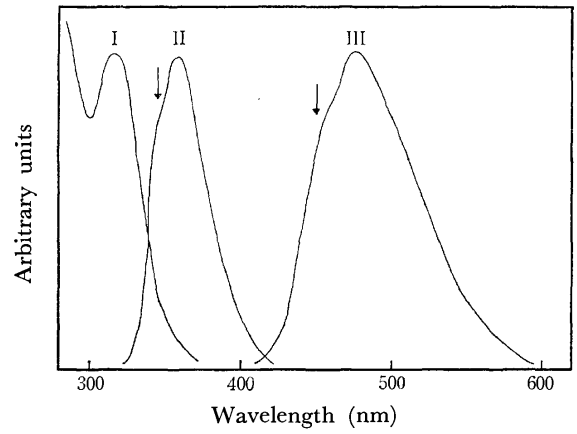

Fig. 1. Absorption and emission spectra of 5,6-dihydrobenzo[*c*]cinnoline in 4 M HCl aqueous 2-propanol. Excitation wavelength: 315 nm. I: Absorption, II: fluorescence, III: phosphorescence.

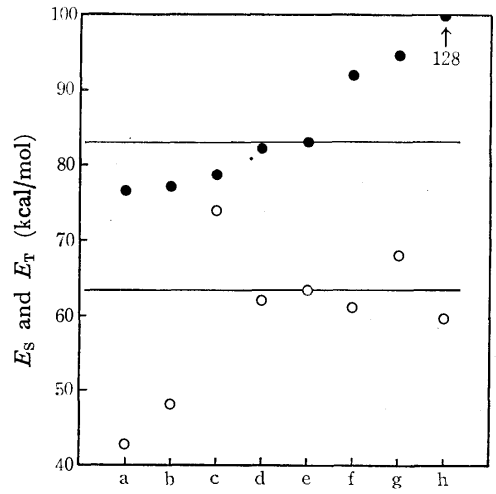

Fig. 2. Energies of the lowest excited singlet (●) and triplet (○) states for 5,6-dihydrobenzo[*c*]cinnoline and the quenchers. a: Anthracene, b: pyrene, c: acetophenone, d : phenanthrene, e : 5,6-dihydrobenzo-[*c*]cinnoline, f : naphthalene, g : fluorene, h : *trans*-1,3-pentadiene (The singlet energy was estimated from the absorption band at 223 nm).

◐: Pyrene, ○: anthracene, ◑: phenanthrene, ●: acetophenone.

pyrene, phenanthrene, anthracene, and *trans*-1,3-pentadiene. The energies of the lowest excited singlet and triplet states for these compounds in polar solvents[4] and the estimated values for 5,6-dihydrobenzo[*c*]-cinnoline are presented in Fig. 2. Fluorene, naphthalene and *trans*-1,3-pentadiene have no quenching effect, whereas phenanthrene, acetophenone, pyrene, and anthracene were found to reduce the quantum yield of the reaction. The quenching data is presented in Fig. 3 for each quencher, and the Stern-Volmer plots give straight lines.

The results can be interpreted in terms of the energy levels illustrated in Fig. 2. All effective quenchers studied have singlet energies lower than that of the reactant, whereas fluorene, naphthalene, and *trans*-1,3-pentadiene have higher singlet energies. Naphthalene and *trans*-1,3-pentadiene have triplet energies

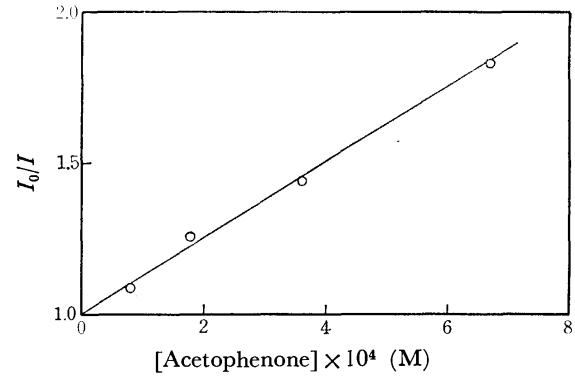

Fig. 4. Fluorescence quenching plot of 5,6-dihydrobenzo[*c*]cinnoline by acetophenone. [5,6-Dihydrobenzo[*c*]cinnoline] = 1.0×10^{-4} M.

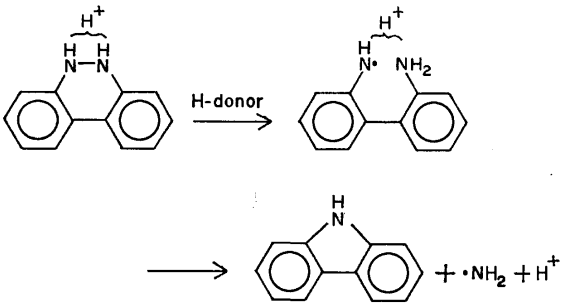
lower than that of the reactant and do not quench the reaction, indicating the unsuitability of the triplet-triplet energy transfer as a mechanism for the quenching effect. This is also indicated in the case of acetophenone as a quencher, since this molecule has a triplet energy higher than the reactant. Consequently, the observed quenching may be ascribed to an energy transfer from the lowest excited singlet 5,6-dihydrobenzo[*c*]cinnoline to the quenchers. Further evidence for this mechanism can be given from the fluorescence quenching study using acetophenone as a quencher, the results of which are shown in Fig. 4, where the quantities I and I_0 are fluorescence intensities at 356 nm with and without acetophenone, respectively. From this figure it is evident that the fluorescent state of the reactant is deactivated with acetophenone through singlet-singlet energy transfer.

The indication is that the photoreaction proceeds through the lowest excited singlet state of the reactant and that the triplet state does not participate in the reaction.

Although benzo[*c*]cinnoline is reduced photochemically to 5,6-dihydrobenzo[*c*]cinnoline in neutral ethylene glycol[5] and poly(vinyl alcohol) film,[6] the subsequent reaction to lead carbazole does not occur in these media with the light of wavelength 315 nm. Consequently only the protonated species of the reactant undergoes the photochemical formation of carbazole.

Ammonia (NH_4Cl in acidic solution) has been found to be generated in carbazole formation. Trace amounts of ammonia in the irradiated solution have been detected using a thymol indicator,[7] but hydrazine was not detected. Subsequently the mode of the photo-elimination was examined through the determination of the fragment which participated in the ammonia formation. The amino radical ($\cdot NH_2$) is known to react with alcohol or hydrochloric acid to yield ammonia.[8] Therefore, the fragment produce in the photo-elimination is presumed to be the amino radical. If this is the case, the initial step in the reaction may be abstraction of the hydrogen atom from the solvent molecule by the reactant as illustrated below. The necessity of hydrogen atom donors in the initial step of the carbazole formation has been examined as follows. Benzo[*c*]cinnoline has been photo-reduced in poly(vinyl alcohol) film as earlier



reported,[6] and the 5,6-dihydrobenzo[*c*]cinnoline thus produced has been extracted with acidic aqueous acetonitrile (4 M HCl) under nitrogen.[9] The resulting solution of 5,6-dihydrobenzo[*c*]cinnoline was irradiated with light of wavelength 315 nm, the carbazole formation was not observed at all. This supports the above assertion and consequently the direct elimination of the imino radical (NH) from the reactant can be ruled out as the mechanism of the photo-elimination to yield carbazole.

Miexd Monolayers of Long Normal Chain Fatty Acids with Long Normal Chain Esters. I. Fatty Acids–Ethyl Hexadecanoate System

Hirosi MATUO,* Noriaki YOSIDA, Kinsi MOTOMURA, and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received July 28, 1978)

Surface pressure-area(π-A) curves of the two-component surface films of long normal chain fatty acids with ethyl hexadecanoate were measured at various compositions and temperatures. It was found that the π-A curves of the mixed monolayers vary characteristically with the number of carbon atoms of the film-forming acid. The two-dimensional phase diagrams of these systems and their partial molar enthalpy changes were obtained by taking advantage of the thermodynamic treatment of multicomponent surface films.[1,2] It was concluded that the chain length of the acid plays an important role in the thermodynamic state of the mixed monolayer.

There have been many studies of mixed monolayers at the air–water interface, aimed at elucidating the effect of the molecular structure on their state and properties.[3–5] But few studies using long normal chain esters have been reported. So we investigated mixed monolayers of long normal chain fatty acids with a long normal chain ester in order to clarify the effect of the chain length of the acid on the thermodynamic state of the two-component monolayers.

In the present study, tridecanoic(C_{13}), tetradecanoic(C_{14}), pentadecanoic(C_{15}), hexadecanoic(C_{16}), heptadecanoic(C_{17}), and octadecanoic(C_{18}) acids were employed as the fatty acids, and ethyl hexadecanoate (EH) was used as the ester. From these experiments, we constructed two-dimensional phase diagrams and calculated the partial molar enthalpy change for the respective systems. Consequently, systematic information concerning the effect of the number of carbon atoms of acid on fatty acid–ester mixed monolayers could be obtained.

Experimental

Long normal chain fatty acids employed in this experiment were obtained from Tokyo Kasei Co., Ltd. and purified by recrystallization from petroleum ether three times. Ethyl hexadecanoate(EH) was synthesized from recrystallized hexadecanoic acid and distilled ethanol by the usual method and purified by distillation. Benzene was used as the spreading solvent. To prevent the ester from hydrolysis, a 0.1 M NaCl solution was used as the substrate; this was prepared from twice distilled water and sodium chloride (Wako super special grade).

The π-A curves were measured by a Wilhelmy type surface balance. The temperature was maintained constant within ± 0.2 K during the experiment. The monolayer was compressed continuously with a constant velocity of 2.79×10^{-2} nm^2 molecule^{-1} min^{-1} and the π-A curves were reproducible within ± 0.2 mN m^{-1} at the same mean molecular area.

Results and Discussion

Surface pressure-area(π-A) curves were obtained for the C_{13}–EH, C_{14}–EH, C_{15}–EH, C_{16}–EH, C_{17}–EH, and C_{18}–EH systems at various compositions and temperatures. Typical π-A curves are shown in Fig. 1 for the C_{14}–EH system and in Fig. 2 for the C_{18}–EH system, both at 298.15 K.

For the C_{13}– EH system, the monolayers of pure

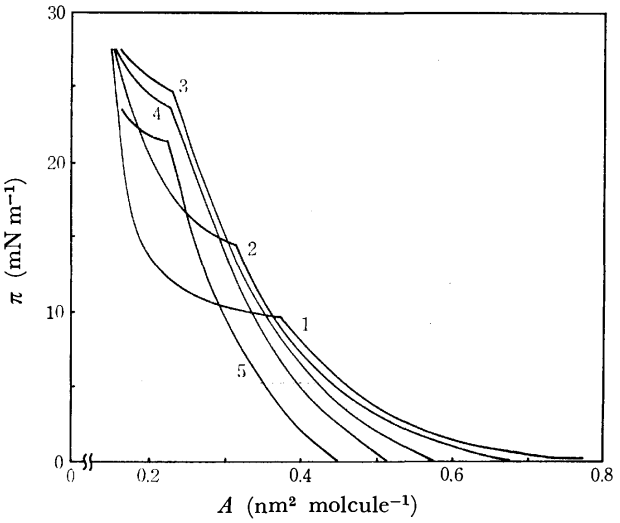

Fig. 1. Surface pressure *vs.* mean area curves of the tetradecanoic acid-ethyl hexadecanoate mixed monolayer at 298.15 K: 1, $x_2^{\pi}=1$ (ethyl hexadecanoate); 2, 0.8; 3, 0.3; 4, 0.15; 5, 0 (tetradecanoic acid).

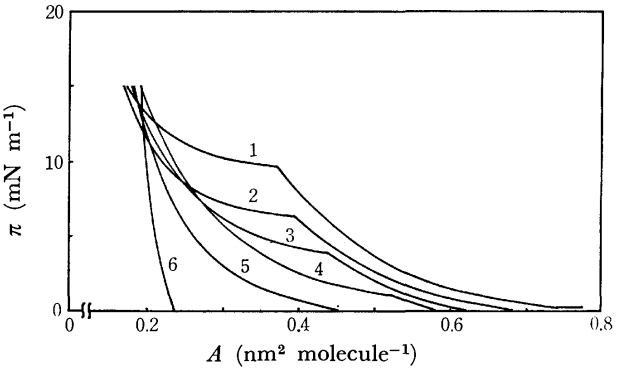

Fig. 2. Surface pressure *vs.* mean area curves of the octadecanoic acid-ethyl hexadecanoate mixed monolayer at 298.15 K: 1, $x_2^{\pi}=1$(ethyl hexadecanoate); 2, 0.9; 3, 0.8; 4, 0.7; 5, 0.5; 6, 0(octadecanoic acid).

C_{13} and EH are of the expanded type and a phase transition from liquid expanded to liquid condensed state is found over the whole range of composition at 298.15 and 288.15 K. The π^{eq}-$x_2^{\pi,e}$ curve for this system at 298.15 K is shown in Fig. 3, where π^{eq} is the phase equilibrium surface pressure which corresponds to that of the break point of π-A curve and $x_2^{\pi,e}$ indicates the mole fraction of the EH in the expanded mixed monolayer. It is seen that the curve

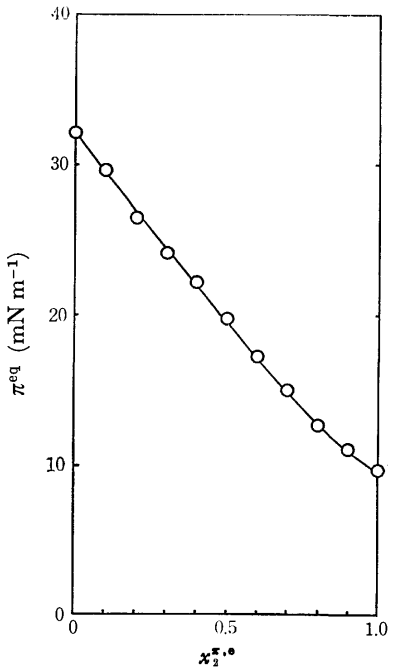

Fig. 3. π^{eq}-$x_2^{\pi,e}$ curves of the tridecanoic acid-ethyl hexadecanoate mixed monolayer at 298.15 K.

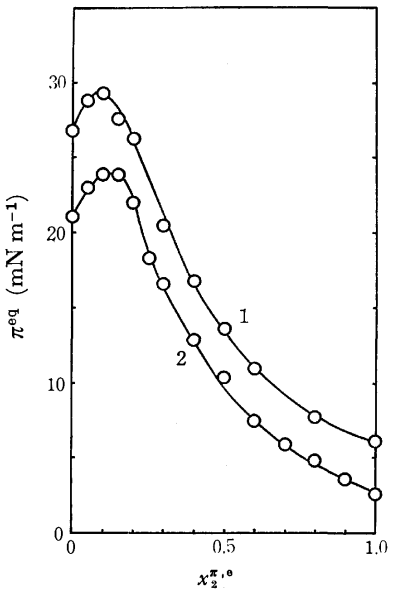

Fig. 4. π^{eq}-$x_2^{\pi,e}$ curves of the tridecanoic acid-ethyl hexadecanoate mixed monolayer at 293.15 and 288.15 K: 1, 293.15 K; 2, 288.15 K.

is of the simple, monotonous type. When the temperature is lowered, the shape of the π^{eq}-$x_2^{\pi,e}$ curve changes; it is noteworthy that at 293.15 and 288.15 K a maximum appears on the curve, as is shown in Fig. 4.

For the C_{14}–EH system, as can be seen from Fig. 1, the π^{eq}-$x_2^{\pi,e}$ curve has a maximum even at 298.15 K. The shape of the curve is similar at 293.15 and 288.15 K to that at 298.15 K, although the equilibrium surface pressure decreases gradually as the temperature is lowered, as shown in Fig. 5. We see that the composition of the maximum point is almost independent of temperature.

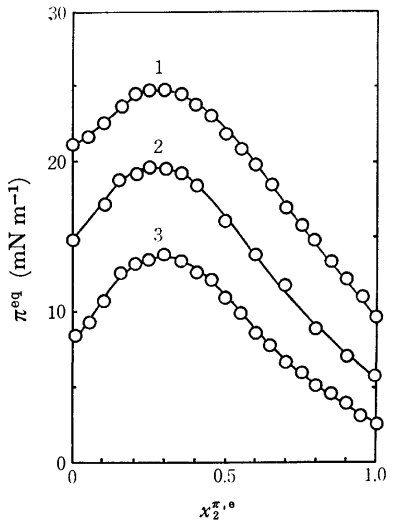

Fig. 5. π^{eq}-$x_2^{\pi,e}$ curves of the tetradecanoic acid-ethyl hexadecanoate mixed monolayer at several temperatures: 1, 298.15 K; 2, 293.15 K; 3, 288.15 K.

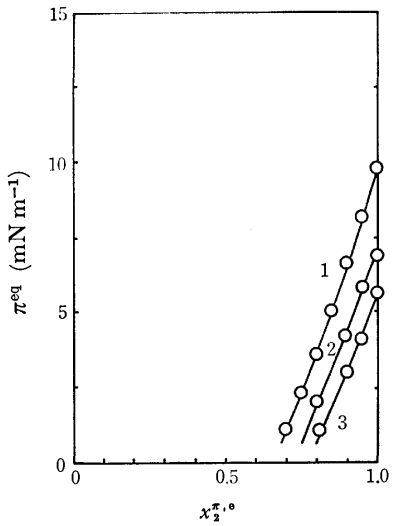

Fig. 6. π^{eq}-$x_2^{\pi,e}$ curves of the octadecanoic acid-ethyl hexadecanoate mixed monolayer at several temperatures: 1, 298.15 K; 2, 293.15 K; 3, 288.15 K.

For the C_{15}–EH and C_{16}–EH systems, the π^{eq}-$x_2^{\pi,e}$ curve is similar to that for the C_{14}–EH system, except that the maximum point shifts to the right along the $x_2^{\pi,e}$ axis; that is, the composition of the maximum becomes richer in EH as the carbon number of the fatty acid increases.

Figure 2 represents π-A isotherms of the C_{18}–EH system at 298.15 K. The π-A curve of this system is very different from the curves of the above-mentioned lower fatty acids–EH systems, in that the phase transition takes place only in a limited range of compositions. This difference may be caused by the fact that pure shorter-chain fatty acids give rise to the expanded film, while long-chain fatty acids form the condensed film at 298.15 K. The π^{eq}-$x_2^{\pi,e}$ curves for the C_{18}–EH system at various temperatures are shown in Fig. 6. It is found that the π^{eq} decreases monotonously with the decrease of $x_2^{\pi,e}$, and the lowering

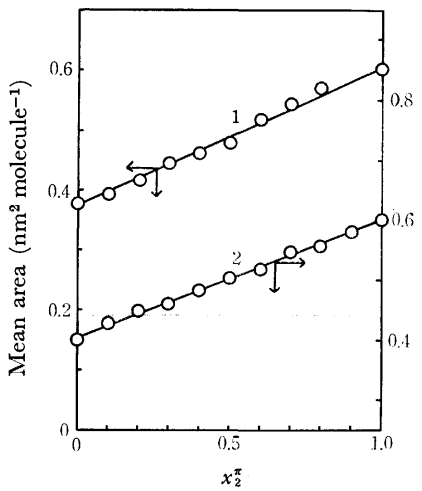

Fig. 13. Additivity of area at 2 mN m^{-1} for C_{14}–EH and C_{15}–EH systems at 298.15 K : 1, C_{14}–EH; 2, C_{15}–EH.

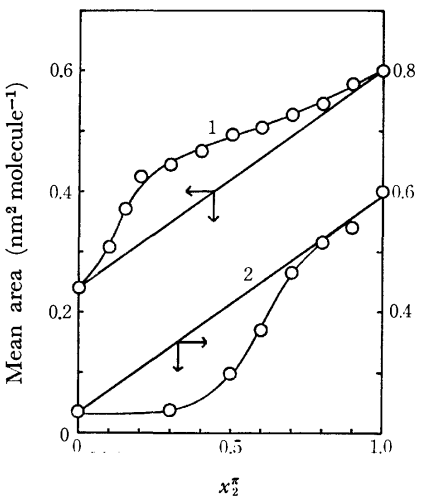

Fig. 14. Additivity of area at 2 mN m^{-1} for C_{16}–EH and C_{18}–EH systems at 298.15 K : 1, C_{16}–EH; 2, C_{18}–EH.

of temperature causes the parallel decrease in π^{eq} of this mixed monolayer. The π^{eq} disappears finally at a certain $x_2^{\pi,e}$, below which the phase transition from the expanded to the condensed film is not observed any more.

For the C_{17}–EH system we have a π^{eq}-$x_2^{\pi,e}$ curve similar to that for the C_{18}– EH system, although the phase transition region is a little wider for the former than for the latter.

Now the entire phase diagram can be constructed for each system by using thermodynamic equations previously described.[1,2] In Figs. 7 to 12 are shown the two-dimensional phase diagrams for C_{13}–EH to C_{18}–EH systems, respectively, at 298.15 K. The experimental points are indicated by open circles which give the π^{eq}-$x_2^{\pi,e}$ curve and the corresponding π^{eq}-$x_2^{\pi,c}$ curve calculated is shown by the solid line, where $x_2^{\pi,c}$ indicates the mole fraction of the EH in the condensed mixed monolayer.

The phase diagram for the C_{13}–EH system (Fig. 7) at 298.15 K is of an ideally mixing type; tow components form a continuous series of mixtures in the condensed as well as in the expanded phase. For C_{14}–EH, C_{15}–EH, and C_{16}–EH systems, a maximum appears on the phase diagram (Figs. 8, 9, and 10), where the composition of the expanded phase is equal to that of the condensed one. Therefore, this maximum may be called a two-dimensional positive azeotropic point. At this point the phase transition pressure $(\pi^{eq})_{max}$ decreases, while the mole fraction of ester $(x_2^{\pi})_{max}$ increases, with increase in the number of carbon atoms of fatty acid, as shown in Table 1. The positive azeotropy suggests that there are mutual interactions between two components in the mixed monolayer which are weaker than the interactions between the pure component molecules themselves.

In contrast to this positive azeotropy, we have observed negative azeotropy in C_{14}–D,L-α-dipalmitoyl lecithin(DPL), EH–DPL, hexadecyl acetate(HA)–DPL, 1-monopalmitin–DPL, and EH–HA systems; these results will be reported in a separate paper.

For C_{17}–EH and C_{18}–EH systems at 298.15 K the phase transition from expanded to condensed states appears only in a limited range of composition, and so the phase diagram is incomplete, as shown in Figs. 11 and 12. Because of the strong condensing effect of longer chain fatty acids, C_{17} or C_{18}, the phase transition pressure decreases remarkably with increase in the amount of the fatty acid, resulting finally in the disappearance of the expanded phase at a certain composition of the mixed monolayer.

The situation of the interaction and miscibility of two components in the mixed monolayer may also be obtained from mean molecular area A_m at constant surface pressure *vs.* mole fraction x_2^{π} relations. The A_m-x_2^{π} curves were obtained for the C_{13}–EH, C_{14}–EH, C_{15}–EH, C_{16}–EH, C_{17}–EH, and C_{18}–EH systems at 2 mN m^{-1}. Several examples are shown in Figs. 13 and 14. From these results, it is found that at 2 mN m^{-1} the simple additivity is nearly established for the C_{13}–EH, C_{14}–EH, and C_{15}–EH systems, but the curves of the C_{16}–EH, C_{17}–EH, and C_{18}–EH systems

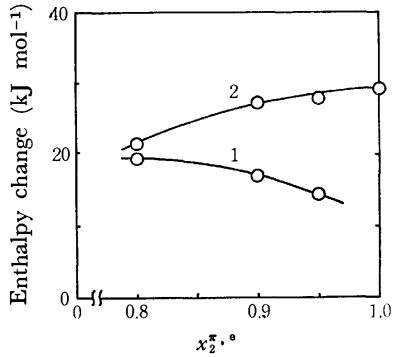

Fig. 18. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^c - \bar{h}_i^e)$ *vs.* mole fraction in the expanded monolayer, $x_2^{\pi,s}$, curves of the octadecanoic acid–ethyl hexadecanoate at 295.65 K: 1, octadecanoic acid; 2, ethyl hexadecanoate.

evidently deviate from this rule. Judging from this fact and the appearance of phase transition, it is concluded that in the former group the miscibility of two components is quite good, but in the latter group it gradually decreases with an increase in the difference of carbon number between the two components.

By the use of a thermodynamic treatment (Eqs. 38, 42, and 43 in Ref. 2), the partial molar enthalpy change accompanying the phase transition form the expanded to the condensed state was calculated for the C_{14}–EH, C_{15}–EH, C_{16}–EH, and C_{18}–EH systems; the results are shown in Figs. 15 to 18. It is difficult to make such a calculation over the whole range of composition with sufficient accuracy, and so in these figures data are shown for some limited ranges.

In the C_{14}–EH system (Fig. 15), the partial molar enthalpy change of C_{14} is small and decreases slightly, while that of EH is large and increases considerably, with increase of the composition of EH. The value of EH in the pure monolayer is larger than that of EH in the mixed monolayer. This shows that EH is more condensed in the mixed monolayer than in the pure monolayer.

In the C_{15}–EH system (Fig. 16), the partial molar enthalpy change of C_{15} decreases but the value of EH increases with the increase of $x_2^{\pi,s}$ to almost the same extent. This indicates that both C_{15} and EH are more condensed in the mixed monolayer than in the pure monolayer, respectively. In other words, the mixed monolayer of C_{15} and EH at relatively high pressure is less stable in the condensed state than in the expanded state and needs less heat for the transition from the condensed to expanded state than does the monolayer of pure components. On the contrary, in the system of negative azeotropy, such as EH–HA, EH–DPL, and so on, the monolayer is more stable in the condensed state than in the expanded state at relatively high pressure and needs much heat for the transition from the condensed to expanded state than does the monolayer of pure components.

In the C_{16}–EH system(Fig. 17), the partial molar enthalpy change of C_{16} decreases more than that of C_{15} in the C_{15}–EH system and the value of EH increases more than that of EH in the C_{15}–EH system, with increase of $x_2^{\pi,s}$. The tendency is much more pronounced in the C_{18}–EH system (Fig. 18). From these results it is seen that the partial molar enthalpy changes of acids and EH vary more rapidly with increase of the chain length of the acid. From Figs. 15 to 17, it was found that the values of partial molar

enthalpy change of acids and EH are quite close to each other at the composition of the maximum point.

In conclusion, the chain length of the acid plays an important role in the thermodynamic state of the mixed monolayer. Taking advantage of the thermodynamic treatment it is seen that the C_{13}–EH system has a cigar type phase diagram at 298.15 K, while it comes to have a maximum point when the temperature is lowered. C_{14}–EH, C_{15}–EH, and C_{16}–EH systems have maximum points in their phase diagrams at 298.15 K. They correspond to the positive azeotrope in the three-dimensional phase diagram. This result suggests that there are mutual interactions between two components in the mixed monolayer which are weaker than the interactions between the pure component molecules themselves. The composition of the maximum point gradually shifts towards the ester side, with increase of the number of carbon atoms of acids. Finally it disappears in the C_{17}–EH and C_{18}–EH systems. It was found that the miscibility, phase diagram, and the partial molar enthalpy change of these systems change successively with the difference of the chain length.

(Received July 28, 1978)

In order to clarify the effect of molecular structure on states and properties of mixed monolayers, surface pressure-area(π-A) curves of the two-component surface films of long normal chain fatty acids with hexadecyl acetate were measured at various compositions and temperatures. By use of thermodynamic analysis, the phase diagrams and partial molar enthalpy changes were calculated. For four systems studied in the present paper it was found that the diagram and enthalpy change vary characteristically with the number of carbon atoms of acids, but the dependence on the chain length of acid in fatty acid–hexadecyl acetate systems was very different from that in fatty acid–ethyl hexadecanoate systems.

In our previous studies of fatty acid–fatty acid,[1,2] fatty acid–fatty alcohol,[3] and fatty acid–fatty ester[4] systems, it was found that the interaction, the miscibility, the state, and the thermodynamic quantities in mixed monolayers change successively with increase in the chain length of the film-forming acid. The present work has been undertaken to investigate the difference between fatty acid–hexadecyl acetate and fatty acid–ethyl hexadecanoate[4] systems, in order to elucidate the effect of molecular structure on mixing.

Experimental

The long normal chain fatty acids employed in this experiment were tetradecanoic(C_{14}), pentadecanoic(C_{15}), hexadecanoic(C_{16}), and octadecanoic(C_{18}) acids. They were purified by repeated recrystallization. Hexadecyl acetate (HA) was synthesized from distilled acetic acid and 1-hexadecanol of Tokyo Kasei Co., Ltd., and purified by distillation.

Experimental conditions were the same as described in the previous paper.[4]

Results and Discussion

Surface pressure-area(π-A) curves obtained for C_{14}–HA, C_{15}–HA, C_{16}–HA, and C_{18}–HA systems at 298.15 K are shown in Figs. 1 to 4. It was observed that in the C_{14}–HA system (Fig. 1) there is a maximum equilibrium surface pressure, similar to the C_{14}–EH system[4] at $x_2^{\pi,e}=0.05$, where $x_2^{\pi,e}$ is the mole fraction of the second component(HA) in the expanded monolayer and EH indicates ethyl hexadecanoate, as described in the previous paper.[4] In the C_{15}–HA system (Fig. 2) there is a unique result: *i.e.*, the curve has a maximum and a minimum point at $x_2^{\pi,e}=0.3$ and 0.87, respectively. This phenomenon is peculiar to the C_{15}–HA system and we have not observed it in any other systems until now. In the C_{16}–HA(Fig. 3) and C_{18}–HA(Fig. 4) systems the equilibrium surface pressure, π^{eq}, decreases monotonously with the decrease of $x_2^{\pi,e}$, but the extent of decreasing is larger in the C_{18}–HA system than in the C_{16}–HA system.

In the preceding papers[5,6] the thermodynamic equations of multicomponent monolayers were derived. Taking advantage of them (Eqs. 38, 42, and 43 in Ref. 6), we obtained the two-dimensional phase diagram and partial molar enthalpy change associated with the phase transition from an expanded to a condensed state. The diagrams of the C_{14}–HA, C_{15}–HA, C_{16}–HA, and C_{18}–HA systems are shown in Figs. 5 to 8, respectively.

The C_{14}–HA system (Fig. 5) has a maximum point in the phase diagram which is analogous to the C_{14}–EH system,[4] but the composition of the maximum

point in the former system is $x_2^{\pi,e}=0.05$ while that in the latter system $x_2^{\pi,e}=0.3$. From the molecular structural point of view, the hydrocarbon chain of HA is longer than that of EH. It seems that C_{14} and HA are less miscible with each other than C_{14} and EH in mixed monolayer, and so in the C_{14}–HA system the composition of maximum point shifts towards the acid side more than that in the C_{14}–EH system. By using ethyl heptadecanoate, which has the same hydrocarbon chain length as HA, we investigated the mixed monolayer with C_{14}; it was found that in the C_{14}–ethyl heptadecanoate system there existed a maximum at $x_2^{\pi,e}=0.2$.[7]

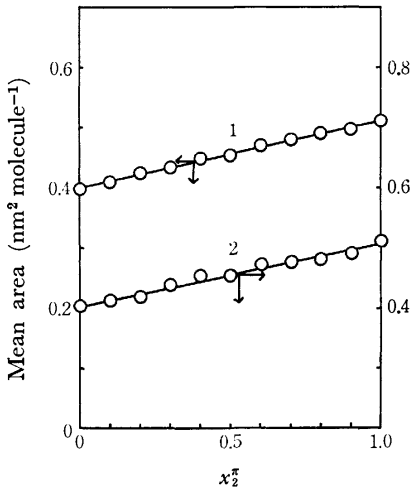

Fig. 9. Additivity of area at 2 mN m^{-1} for C_{14}–HA and C_{15}–HA systems at 298.15 K: 1, C_{14}–HA; 2, C_{15}–HA.

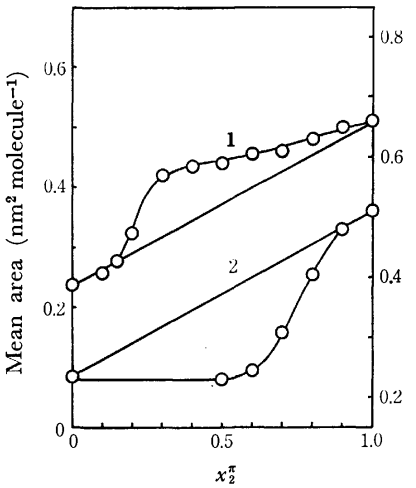

Fig. 10. Additivity of area at 2 mN m^{-1} for C_{16}–HA and C_{18}–HA systems at 298.15 K: 1, C_{16}–HA; 2, C_{18}–HA.

The diagram of the C_{15}–HA system at 298.15 K is shown in Fig. 6. There exist maximum and minimum points in this diagram at $x_2^{\pi,e}=0.3$ and 0.87, respectively. This is particularly surprising from the thermodynamic point of view and we have not observed such a result in any other system. This phase diagram shows that in the C_{15} rich region the excess free energy of the monolayer in the expanded state ($G^{E,e}$) is smaller than that in the condensed state ($G^{E,c}$), and in the HA rich region the $G^{E,e}$ is larger than $G^{E,c}$ at relatively high pressures.[8] According to thermodynamic analysis,[7] it is easily understandable that in a positive azeotrope system, which has a maximum point in the phase diagram, the mutual interaction between film-forming substances in the mixed monolayer is weaker than the interaction between the pure component molecules themselves. In other words, in the C_{15} rich region C_{15} and HA are likely to be located apart from each other, since the hydrophilic group of HA is so different from that of C_{15} that C_{15} and HA are difficult to pack together. It is thus more stable as the expanded

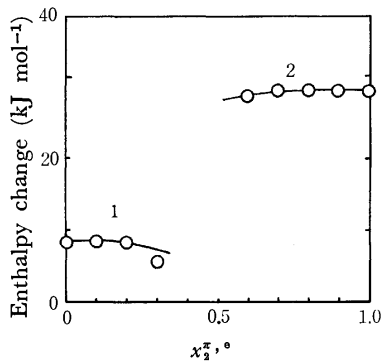

Fig. 11. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^e-\bar{h}_i^c)$ *vs.* mole fraction in the expanded monolayer, $x_2^{\pi,e}$, curves of the tetradecanoic acid–hexadecyl acetate at 293.15 K: 1, tetradecanoic acid; 2, hexadecyl acetate.

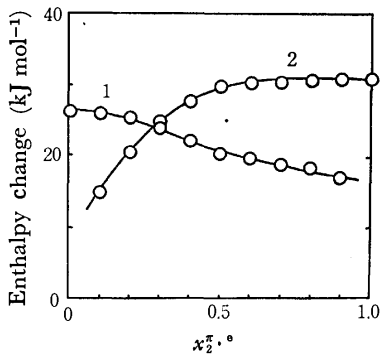

Fig. 12. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^e-\bar{h}_i^c)$ *vs.* mole fraction in the expanded monolayer, $x_2^{\pi,e}$, curves of the pentadecanoic acid–hexadecyl acetate at 295.65 K: 1, pentadecanoic acid; 2, hexadecyl acetate.

state in this region than as the condensed state. But in the HA rich region, it seems that C_{15} and HA are likely to pack together owing to the ease of packing of C_{15} and HA. In this way it is seen that the thermodynamic state of the monolayer is very much influenced by the molecular structure of the components. This is also revealed by the difference in phase diagrams between the C_{15}–HA(Fig. 6) and C_{15}–EH[4] systems.

Figure 7 represents the phase diagram of the C_{16}–HA system. This is also very different from that of the C_{16}–EH system.[4] π^{eq} decreases gradually with the decrease of $x_2^{\pi,e}$. It seems that the interaction between C_{16} and HA is complicated. In the C_{18}–HA system (Fig. 8), the diagram is analogous to that of the C_{18}–EH system.[4] But the π^{eq} decreases more rapidly with the decrease of $x_2^{\pi,e}$ than that of the C_{18}–EH system. This indicates that in the mixed monolayer HA is more condensed than EH. This can also be seen from the result of mean area *vs.* mole fraction curves (Fig. 10) and the partial molar enthalpy changes (Fig. 14).

The mean area *vs.* mole fraction curves of the mixed monolayers at 2 mN m^{-1} are shown in Figs. 9 and 10. In C_{14}–HA and C_{15}–HA systems (Fig. 9) the additivity rule is approximately established under these conditions. Owing to this result and the phase dia-

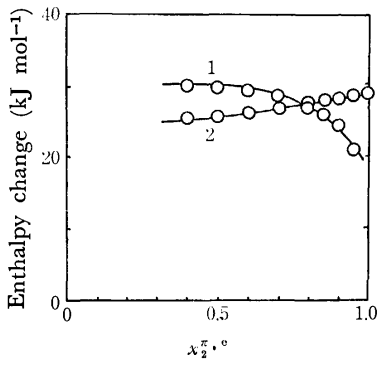

Fig. 13. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^c - \bar{h}_i^e)$ *vs.* mole fraction in the expanded monolayer, $x_2^{\pi,e}$, curves of the hexadecanoic acid–hexadecyl acetate at 298.15 K: 1, hexadecanoic acid; 2, hexadecyl acetate.

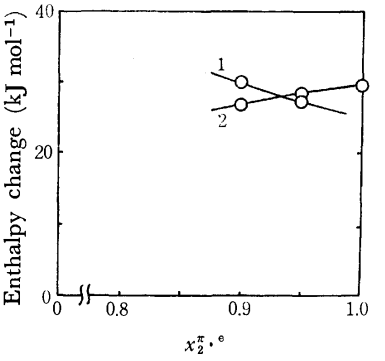

Fig. 14. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^c - \bar{h}_i^e)$ *vs.* mole fraction in the expanded monolayer, $x_2^{\pi,e}$, curves of the octadecanoic acid–hexadecyl acetate at 298.15 K: 1, octadecanoic acid; 2, hexadecyl acetate.

grams (Figs. 5 and 6), it may be said that these systems are nearly ideal at low surface pressures, but deviate appreciably from ideal behaviors as the pressure increases. In the C_{16}–HA system (Fig. 10) there is a considerable positive deviation from the additivity rule, similar to that of the C_{16}–EH system.[4] The C_{18}–HA system shows a considerable negative deviation in the expanded state, as shown by the solid line (Fig. 10), and the deviation is larger in the C_{18}–HA system than in the C_{18}–EH system.[4]

The partial molar enthalpy change was obtained from the thermodynamic analysis(Eqs. 38, 42, and 43 in Ref. 6), and they are shown in Figs. 11 to 14. In the C_{14}–HA system (Fig. 11), the enthalpy change of C_{14} gradually decreases, and that of HA slightly increases, with increase of $x_2^{\pi,e}$. Although the C_{15}–HA system has maximum and minimum points in the phase diagram, the nature of the enthalpy change, as shown in Fig. 12, is very similar to that of the C_{15}–EH system[4] which has only one maximum point in the phase diagram. The partial molar enthalpy change of C_{15} decreases, and that of HA increases considerably, with increase of $x_2^{\pi,e}$. In the C_{16}–HA system (Fig. 13), the enthalpy change of C_{16} also decreases, and the value of HA increases, with increases of $x_2^{\pi,e}$. This system shows the same tendency as the C_{16}–EH system[4] but the degree of variation of the partial molar enthalpy change is larger in the C_{16}–EH system than in the C_{16}–HA system. The characteristics of the enthalpy change of the C_{18}–HA system(Fig. 14) are similar to those of the C_{15}–HA and C_{16}–HA systems.

In conclusion, it was found that the phase diagram and partial molar enthalpy change vary with the chain length of the film-forming acid. There exists a maximum point in the C_{14}–HA system and this result is analogous to that of the C_{14}–EH system. However, in the C_{15}–HA system there is not only a maximum point but also a minimum point. This phenomenon was not observed in the C_{15}–EH or other systems, but is peculiar to the C_{15}–HA system. The C_{16}–HA system is also very different from the C_{16}–EH system. But the C_{18}–HA system is similar to the C_{18}–EH system. In this way, it is seen that the state of mixed monolayers is very much influenced by the molecular structure of film-forming components, especially by the chain length of the acid and the structure of the hydrophilic group of the ester. It seems that the structure effect is larger in mixed monolayers as the difference of the chain length between acid and ester becomes smaller.

(Received August 7, 1978)

The structures of 6-deoxyversicolorin A, $C_{18}H_{10}O_6$, and versicolorin A, $C_{18}H_{10}O_7$, both isolated from *Aspergillus versicolor*, have been determined by the X-ray diffraction method. Both compounds crystallized in the space group $P2_12_12_1$, with four molecules per unit cell. The cell dimensions of 6-deoxyversicolorin A are $a=9.588$, $b=18.083$, $c=7.769$ Å, and those of versicolorin A are $a=9.524$, $b=18.629$, $c=7.629$ Å. The structure was refined to $R=0.055$ for 6-deoxyversicolorin A and to $R=0.043$ for versicolorin A. Both structures are in agreement with those assigned by chemical and spectroscopic methods. There are two intramolecular hydrogen bonds in each molecule. Although an intermolecular hydrogen bond is present in versicolorin A, both structures are isotypic. The dimensions of the anthraquinone skeleton and the dihydrofuro[2,3-*b*]furan moiety are compared with those in related compounds whose structures have been determined.

The dihydrofuro[2,3-*b*]furan moiety is the common structural unit in an important class of fungel metabolites which includes aflatoxins, B_1[1] and G_1,[2] and sterigmatocystin.[3,4] The structures of these metabolites have been extensively investigated by chemical, spectroscopic, and X-ray methods. The present compounds, 6-deoxyversicolorin A (I) and versicolorin A (II), were isolated from *Aspergillus versicolor* (Vuillemin) Tiraboschi, and the structures were proposed by Elsworthy *et al.*[5] and Hamasaki *et al.*[6] respectively by means of chemical and spectroscopic methods. Both the compounds have a dihydrofuro-[2,3-*b*]furan moiety with an anthraquinone skeleton, and were shown to be biogenetic precursors of sterigmatocystin and aflatoxins.[7] The present X-ray structure analysis was carried out to compare the structures of the title compounds with those of the related metabolites of this mold which have been studied in our laboratory.

II: R=7OH

Experimental

Crystallographic Measurements. 6-Deoxyversicolorin A and versicolorin A were crystallized from acetone solution in the forms of orange red prisms and orange red plates respectively. Although the crystals of versicolorin A appeared to be well-developed plates, the diffraction profiles were broad and not symmetrical about the peaks. The cell constants were obtained from the least-squares treatment of the angular settings of 13 reflections. The crystal data and details of experimental conditions for each compound are summarized in Table 1. The intensities of each compound were measured on a Rigaku-Denki computer-controlled four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. Attenuators were automatically inserted to keep the counting rate below 8000 cps. Backgrounds were counted for 10 s at the both sides of the scan range. The intensities were corrected for the Lorentz and polarization factors, but were not corrected for absorption.

TABLE 1. CRYSTAL DATA AND DETAILS OF EXPERIMENTAL CONDITIONS

	6-Deoxyversicolorin A	Versicolorin A
Molecular formula	$C_{18}H_{10}O_6$	$C_{18}H_{10}O_7$
Molecular weight	322.3	338.3
Crystal system	orthorhombic	orthorhombic
Space group	$P2_12_12_1$	$P2_12_12_1$
a	9.588(4) Å	9.524(5) Å
b	18.083(6) Å	18.629(7) Å
c	7.769(4) Å	7.629(5) Å
Z	4	4
D_x	1.589 g/cm³	1.659 g/cm³
μ(for Cu $K\alpha$)	10.4 cm⁻¹	11.2 cm⁻¹

Scan speed (ω)	2° min⁻¹	2° min⁻¹
Maximum 2θ	120°	127°
No. of reflections measured	1180	1296
No. of non-zero reflections	1046	1160

Structure Determination of 6-Deoxyversicolorin A. The structure was solved by application of the vector-search method;[8] the rigid group used in the calculations was an anthraquinone skeleton with two oxygen atoms. A three-dimensional Fourier synthesis based on the phases due to the rigid group revealed the positions of the remaining non-hydrogen atoms. The structure was refined by the block-diagonal least-squares calculations,[9] first with isotropic and subsequently with anisotropic temperature factors for non-hydrogen atoms. All hydrogen atoms were found in a difference electron density map, and included in the subsequent refinement with isotropic temperature factors. The final refinement was made using the following weighting scheme: $w=0.0$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 22$, and $w=[1.0+0.33(F_o-22)]^{-1}$ for $22<F_o$. However, the two strongest reflections, 022 and 032, were omitted from the calculations. The final R value was 0.055 for 1044 non-zero reflections. The final atomic parameters are listed in Tables

TABLE 2. FINAL ATOMIC PARAMETERS AND e.s.d.'s ($\times 10^4$) FOR NON-HYDROGEN ATOMS

The anisotropic temperature factors are of the form: $\exp(-\beta_{11}h^2-\beta_{22}k^2-\beta_{33}l^2-\beta_{12}hk-\beta_{13}hl-\beta_{23}kl)$.

a) Length of covalent bond involving hydrogen atom in Å.

2(a) and 3(a).†††

Structure Determination of Versicolorin A. The structure was solved by the direct method with program MULTAN.[10] The refinement of versicolorin A was made in the same way as that of 6-deoxyversicolorin A. All hydrogen atoms were found in a difference electron density map after the anisotropic refinement for non-hydrogen atoms. The weighting scheme adopted in the final cycle of the refinement was: $w=0.0$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 17$, and $w=[1.0+0.11\times(F_o-17)]^{-1}$ for $17<F_o$. However, zero weight was given to the two strongest reflections, 022 and 032. The final R value was 0.043 for 1158 non-zero reflections. The final atomic parameters are listed in Tables 2(b) and 3(b).† The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[11]

Results and Discussion

The present crystallographic analysis has verified the structures of 6-deoxyversicolorin A and versicolorin A proposed by the chemical and spectroscopic methods.[5,6] The absolute configuration adopted is based on the assumption that the configuration of the dihydrofuro[2,3-*b*]furan moiety of the present molecules is the same as that of related molecules which has been established by X-ray method.[1,4,12] The crystal structure of versicolorin A is shown in

††† Lists of the observed and calculated structure factors are available from the authors on request and also kept as Document No. 7905 at the Chemical Society of Japan.

Fig. 1. The bond lengths and angles for non-hydrogen atoms are given in Table 4, the equations of the least-squares planes and perpendicular displacements of atoms from each plane in Table 5, and intermolecular distances in Table 6.

Hydrogen Bonds. There are two intramolecular hydrogen bonds in each molecule. The lengths of O(2)···H(O1) and O(2)···H(O3) are 1.67 and 1.87 Å respectively in 6-deoxyversicolorin A, and 1.97 and 1.75 Å respectively in versicolorin A. The angles of O(1)-H(O1)···O(2), O(3)-H(O3)···O(2), H(O1)···O(2)-C(4), and H(O3)···O(2)-C(4) are 137, 145, 105, and 101° respectively in 6-deoxyversicolorin A, and 126, 148, 107, and 102° respectively in versicolorin A. In the crystal of versicolorin A there is an intermolecular hydrogen bond, O(7)-H(O7)···O(6), which connects the molecules related by the screw axis along the b axis. The distance of H(O7)···O(6) is 1.93 Å, and the angles of O(7)-H(O7)···O(6), H(O7)···O(6)-C(15), and H(O7)···O(6)-C(16) are 143, 117, and 105° respectively. A short contact (2.865 Å) is observed in the crystal of versicolorin A between the atoms O(7) and O(1) of the molecule at $(-1+x, y, z)$; however, the final difference electron density map showed no peak in the region between these atoms. The molecular arrangements in both crystals are similar in spite of the existence of the intermolecular hydrogen bond in the crystal of versicolorin A.

a) Not included in the least-squares calculation.

dihydrofuro[2,3-*b*]furan moiety has been widely found in fungal metabolites. The interatomic distances of this moiety for 10 molecules, whose structures were determined by means of X-ray crystallography, have been compared by a half-normal probability plot.[13] The slopes of the plots range from *ca.* 1.2 to 3.0 with intercept 0.0, and some of them are not straight. The plots for 6-deoxyversicolorin A-sterigmatocystin and for 6-deoxyversicolorin A-sterigmatin are shown in Fig. 2 as typical examples.†† Most of the extreme values are found between non-bonded atoms, especially between the atoms C(1), C(14), or O(5) and the atoms C(17), C(16), or O(6). This fact suggests that the environments affect the conformation of such a simple moiety.

The conformation of this moiety may be defined by the torsion angles about the C(18)–C(15) bond, and the values for these angles are listed in Table 7. The torsion angles of C(1)–C(18)–C(15)–O(5) and C(17)–C(18)–C(15)–O(6) are apt to be right-handed in helicity. However, it is difficult to generalize the conformation of this moiety, since there is no rule for the distribution of the torsion angles about the C(18)–C(15) bond except the right-handed helicity.

Structure of Anthraquinone Skeleton. The structure of the anthraquinone skeleton was also examined by the half-normal probability method. The slope of the plot (1.8) between the anthraquinone skeletons of the present compounds is not much greater than 1.0, which is in accordance with the result that the skew-senses of the skeletons of each of these compounds are similar to each other, as shown in Table 5. The slopes of the plots between the skeletons of the other molecules, averufin,[18] and versicolorin C,[19] are larger than that of the present compounds (1.8—2.5). The plot for versicolorins A and C is shown in Fig. 2 as an example. When interatomic distances greater than

†† The figures of 55 plots among these molecules are available from the authors on request.

Abbreviation: 6DVA, 6-deoxyversicolorin A; VA, versicolorin A; ST(A) and ST(B), two crystallographically independent molecules (A and B) of sterigmatin;[15] STERIG, sterigmatocystin;[4] OMST, *O*-methylsterigmatocystin;[4] DMST, demethylsterigmatocystin;[17] MTST, 5-methoxysterigmatocystin;[16] AF(C), aflatoxin B_1 (chloroform-solvated);[1] AF(O), aflatoxin B_1 (orthorhombic form);[1] AF(M), aflatoxin B_1 (monoclinic form).[1] The sign convention of the torsion angle is such that the sign is positive if a clockwise rotation is requested of the atom (1) to eclipse atom (4) whilst looking down the (2)-(3) bond. The configurations of the moiety in these molecules are assumed to be similar to each other.

3.0 Å were excluded from the drawing, most of the extreme values were eliminated and the slopes decreased slightly to 1.6—2.2. This fact shows that the structure of the skeleton is affected by the environment, as in the case of the dihydrofuro[2,3-*b*]furan moiety. However, the difference of substituents attached to the atoms C(1), C(8), and C(14) of this skeleton does not seem to affect the short interatomic distances.

Although the interatomic distances are dependent on the cell constants, the underestimation (about 1/1.6) of e.s.d.'s can scarcely be ascribed to their error. The underestimation may be due to other sources, such as the effect of thermal motion and/or the inherent tendency of underestimation in a block-diagonal least-squares technique. The same underestimation has been reported by several authors.[14]

Average Dimensions of Dihydrofuro[2,3-b]furan Moiety and Anthraquinone Skeleton. The average dimensions of the dihydrofuro[2,3-*b*]furan moiety and the anthraquinone skeleton were calculated by using the e.s.d.'s of each length as a weight (Fig. 3). Although the e.s.d. is underestimated, this may be reasonable weighting, because the underestimation of e.s.d. for each bond length is not so different. The dimensions of the anthraquinone skeleton seem to be affected by two hydroxyl groups, O(1)H and O(3)H; the lengths of the C(3)–C(4) and C(4)–C(5) bonds are shorter than those of the C(10)–C(11) and C(11)–C(12) bonds, while the lengths of the C(4)–O(2), C(2)–C(3), and C(5)–C(6) bonds are longer than those of the C(11)–O(4), C(12)–C(13), and C(9)–C(10) bonds. Such an

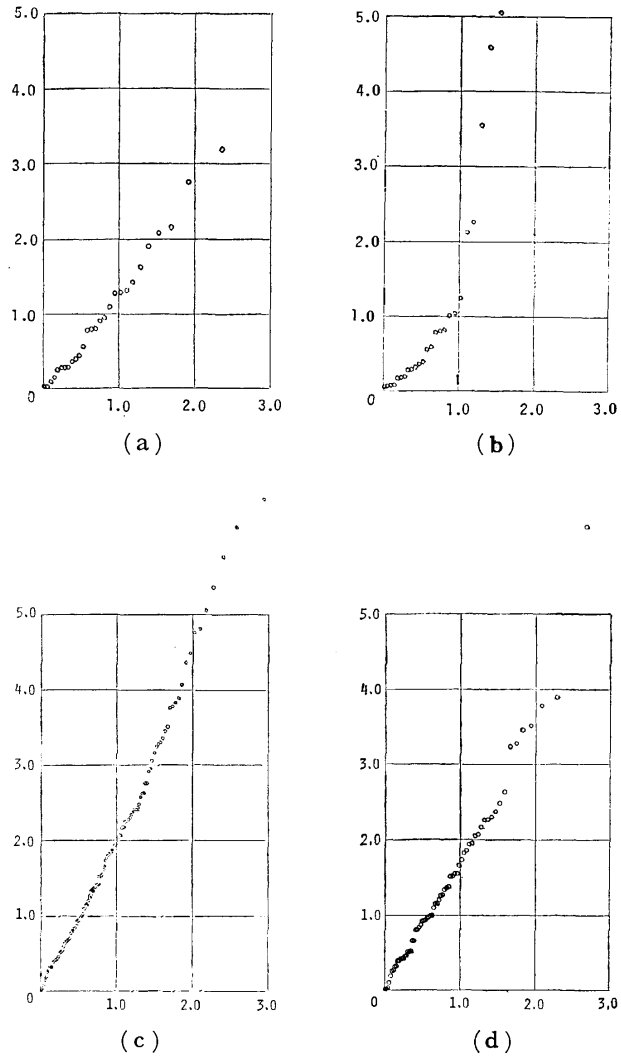

Fig. 2. Half-normal probability plot : the vertical axis is observed δp_i; the horizontal axis is the expected δp_i. $\delta p_i = |d(1)-d(2)|/\{\sigma^2(1)+\sigma^2(2)\}^{1/2}$, where d and σ are the interatomic distance and its e.s.d. respectively. (a) 6-Deoxyversicolorin A-sterigmatocystin as an example that the conformation of the dihydrofuro[2,3-*b*]furan moiety is similar to each other, (b) 6-deoxyversicolorin A-sterigmatin (B molecule) as an example that the conformation is different. (Table 7) (c) Half-normal probability plot for the anthraquinone skeletons of versicolorin A-versicolorin C including all data, and (d) that excluding the data of interatomic distances greater than 3.0 Å.

unequivalence of bond lengths in the anthraquinone skeleton is also found in 1,5-dianilinoanthraquinone and 1,8-dianilinoanthraquinone.[20] As expected from the chemical structure, however, the symmetry of the dimensions of the skeleton about the vector O(2)–

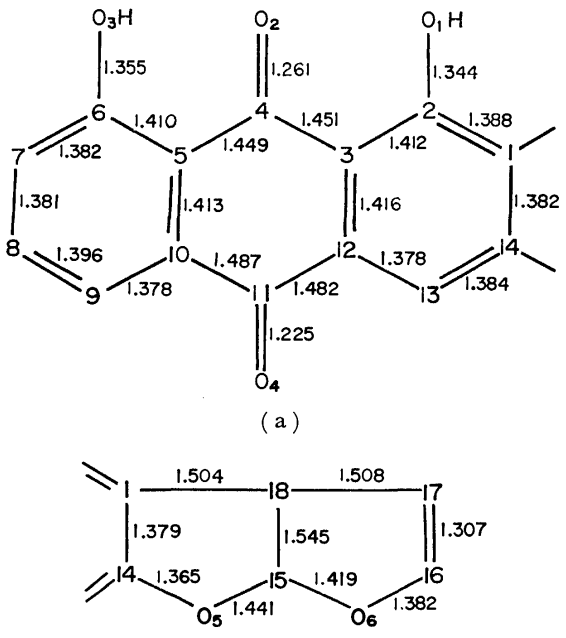

Fig. 3. Averaged dimensions of (a) anthraquinone skeleton and (b) dihydrofuro[2,3-*b*]furan moiety. Taking account of the underestimation of e.s.d. of bond length of individual molecule, the e.s.d. of the mean length may be about 0.004 Å for both anthraquinone skeleton and dihydrofuro[2,3-*b*]furan moiety.

O(4) is excellent.

The computations were performed, using programs written by the authors, on a TOSBAC-3400 computer at the Tottori University Computing Center, and on a NEAC2200-N700 computer at the Computation Center of Osaka University.

The authors wish to thank Professor Yuichi Hatsuda and Dr. Takashi Hamasaki for supplying the samples.

Transport of Picrate Anion against Its Concentration Gradient through a Dichloroethane Membrane

Masaaki SUGIURA* and Toshio SHINBO
National Chemical Laboratory for Industry, Nishiyawata, Hiratsuka 254
(Received August 9, 1978)

The rate of picrate transport coupled to a diffusion of potassium ions through a bulk 1,2-dichloroethane membrane has been measured. The membrane, containing a potassium ionophore separated two aqueous phases, one containing picrate and potassium salt and the other containing picrate and lithium salt. The picrate anion was accumulated against the concentration gradient in the aqueous phase containing the lithium salt. The rate of picrate transport incrased with increasing ionophore concentration and in the absence of the ionophore, the transfer of picrate did not occur. The effect of potassium and lithium counter-ions such as chloride, nitrate and sulfate on the transport of picrate has been examined. The combination of potassium sulfate and lithium nitrate showed the highest rate of transport. In the potassium nitrate–lithium nitrate system, the transport of picrate was appreciably depressed by the transfer of nitrate ions across the membrane. The decrease in concentration of potassium ion in the aqueous phase brought about a lowering of the rate of picrate transport. The rate of picrate transport rose according to the following order of ionophore : dicyclohexyl-18-crown-6 > dicyclohexyl-24-crown-8 > dibenzo-18-crown-6 > dibenzo-24-crown-8 > valinomycin.

When the chemical potential difference of ions is imposed across an oil membrane, a lipophilic ion or a specific ion which binds to a transport carrier can be moved against the concentration gradient to one side of the membrane. The uphill transport of alkaline cations[1,2] and amino acids[3] through bulk organic liquid membranes has been reported and in these systems, the energy for transport was the chemical potential difference of the protons across the membrane. Kusaka *et al.*[4] have observed the accumulation of alanine and proline into phospholipid vesicles containing hydrohobic proteins as transport carriers, in response to a membrane potential introduced by the diffusion of potassium ions *via* valinomycin.

In the present paper, the uphill transport of picrate anion through the bulk 1,2-dichloroethane membrane has been investigated. In this system, the transport of picrate has been coupled to a diffusion of potassium ions *via* various potassium ionophores.

Experimental

Apparatus. The apparatus used for measuring the transport of picarte is shown in Fig. 1. It is a modification of the apparatus described by Behr and Lehn.[3] The cell consisted of a cylindrical glass vessels (7 cm i.d.; height 7 cm) containing a central glass wall which separated the two aqueous phases (50 ml each). The dichloroethane phase (phase III, 100 ml) lay under these aqueous phases and bridged across the central separation. The aqueous phase I in the cell contained initially 10^{-4} M potassium picrate, a 0.01 M Tris-H_2SO_4 buffer of pH 8.3 and a 0.1 M potassium salt (the experiment on the effect of potassium ion concentration was different) while phase II contained 10^{-4} M potassium picrate, a 0.01 M Tris-H_2SO_4 buffer and a 0.1 M lithium salt. To the dichloroethane phase, an appropriate quantity of potassium ionophore was added. The cell was placed in a water bath adjusted to 25±0.1 °C. All three phases were agitated at 180 r.p.m. with a pair of glass stirrers.

Materials. The potassium ionophores, dicyclohexyl-18-crown-6 and dicyclohexyl-24-crown-8 were commercial products from Nihon Soda Co., dibenzo-18-crown-6 and dibenzo-24-crown-8 from Aldrich Chemical Co. and valinomycin from Sigma Chemical Co. All other chemicals were reagent grade and not subsequently purified.

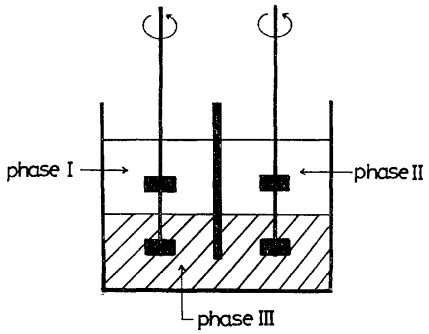

Fig. 1. Apparatus for measuring the transport of picrate. Initial composition of each phase;
phase I : aqueous solution (50 ml) containing 10^{-4} M K-picrate, 0.01 M Tris-H_2SO_4 buffer (pH 8.3) and 0.001—0.1 N K-salt,
phase II : aqueous solution (50 ml) containing 10^{-4} M K-picrate, 0.01 M Tris-H_2SO_4 buffer (pH 8.3) and 0.1 N Li-salt,
phase III : 1,2-dichloroethane (100 ml) containing 0—10^{-3} M ionophore.

Procedure. The dichloroethane used for phase III was pre-equilibrated with 10^{-4} M potassium picrate solution containing a Tris-H_2SO_4 buffer and potassium and lithium salts, whose concentrations were equal to those in the aqueous phases I and II. 1,2-Dichloroethane (100 ml) containing an appropriate quantity of ionophore was shaken with the above-mentioned picrate solution(250 ml) for *ca.* 6 h at 25 °C. During this treatment, the picrate solution was occasionally renewed until the picrate concentration in the aqueous solution became constant. After attainment of equilibrium, the picrate solution was removed, after which dichloroethane (100 ml) was placeed in the cell. Two kinds of aqueous solution used for phases I and II were subsequently poured into either side, as shown in Fig. 1. The transport of picrate was initiated by the addition of the aqueous solutions. The concentration of picrate in both the aqueous phases and the membrane potential were measured at regular time intervals, the determination being conducted on a Hitachi Model 100-10 spectrophotometer at 420 nm and that of the membrane potential using a Keithley Model

Table 1. Initial concentration of picrate in the 1,2-dichloroethane phase and concentration 7 h after the start of picrate transport for various membrane systems

K, Li salts Phase I-Phase II	Ionophre (Concn, M)	Picrate concentration (M) Initial	After 7 h

610C or a Toadenpa Model PM-19A electrometer, with calomel electrodes connected to the aqueous phase, *via* salt bridges made of polyethylene tubing containing agar saturated with potassium chloride. The picrate concentrations in the dichloroethane phase before and after the measurement of picrate transport were also determined spectrophotometrically.

Results

Effect of Ionophore Concentration. The picrate concentrations in both aqueous phases and the membrane potential against time curves for various concentration of dicyclohexyl-18-crown-6 are shown in Fig. 2. The polarity of the membrane potential was positive in phase II with respect to phase I. In these systems, phase I contained 0.1 M potassium chloride and phase II 0.1 M lithium chloride. The picrate concentration in phase I decreased with time [dotted line in Fig. 2 (a)], while that in phase II increased [solid line in Fig. 2 (a)]. Thus the picrate anion was transferred from phase I to phase II against the concentration gradient through the dichloroethane membrane. The increment of picrate in phase II however was larger than the decrement in phase I attributable to the liberation of picrate from the dichloroethane phase into phase II. The initial concentrations of picrate in the dichloroethane phase and the concentrations 7 h after the start of picrate transport are listed in Table 1, together with those for the other transport systems.

The rate of picrate transport increased with increasing ionophore concentration. In the absence of ionophore, the transfer of picrate was not observed. In this case, the membrane potential was about 25 mV.

Effect of Potatsium and Lithium Counter-ions. When the nitrates and sulfates of potassium and lithium were added in the aqueous phases in place of the chlorides, the transport of picrate was affected by the counter-ions, the effect of which is shown in Fig. 3.

In these systems, dicyclohexyl-18-crown-6 was used as an ionophore at a concentration in dichloroethane of 10^{-4} M.

In the potassium sulfate–lithium nitrate system, the highest rate of picrate transport was observed. On the contrary, a considerable decrease in the rate of picrate transport occurred in the potassium nitrate–lithium nitrate system.

Effect of Potassium Ion Concentration. The effect of varying the concentration of potassium chloride in phase I from 0.001 to 0.1 M on the transport of picrate is shown in Fig. 4. In this system, lithium chloride was added to compensate for the lack of chloride ion in phase I. The ionophore used was dicyclohexyl-18-crown-6 and the concentration in the dichloroethane phase was 10^{-4} M.

The rate of picrate transport decreased with decreasing potassium ion concentration. The change in membrane potential with time also decreased according to the reduction of the rate of picrate transport.

Effect of Ionophores. The picrate concentrations in the aqueous phases and the membrane potential against time curves for various ionophores are shown in Fig. 5. In these systems, phase I contained 0.1 M potassium chloride and phase II 0.1 M lithium chloride. The concentrations of ionophores in the dichloroethane phase were 10^{-4} M in all cases.

The rate of picrate transport increased according in the following order of ionophore; dicyclohexyl-18-crown-6 > dicyclohexyl-24-crown-8 > dibenzo-18-crown-6 > dibenzo-24-crown-8 > valinomycin. This order, with the exception of valinomycin, agreed with that for

the permeability ratio of potassium ion to sodium ion across the liqiud membrane consisting of dioleyl phosphate and oleyl alcohol.[5]

Discussion

It has been reported that picrate is a lipophilic anion and that it permeates the phospholipid membrane electrophoretically.[6] In the present experiments, however, the transport of picrate through the dichloroethane membrane containing no ionophore was not observed: picrate was transferred only in the presence of potassium ion and potassium ionophore. The rate of picrate transport increased with increasing ionophore concentration suggesting that the picrate anion in phase I was dissolved in the dichloroethane phase forming an ion-pair with a complexed cation consisting of ionophore and potassium ion and then liberated into phase II by the dissociation of the ion-pair.

The rate of picrate transport depended on various factors such as the concentration of ionophore and potassium ion and the type of potassium and lithium counter-ions and ionophore. To investigate the mechanism of this transport system, the change in potassium ion concentration in phase II with time was measured by means of flame analysis, the results of which for the potassium chloride–lithium chloride and potassium chloride–lithium sulfate systems are shown in Fig. 6. The change in chloride ion concentration in phase II for the potassium chloride–lithium sulfate system was also determined by a titrimetric method. It was found that increment of potassium ion concentration in phase II was approximately 10^{-3} M for 7 h and that for chloride ion concentration also approximately 10^{-3} M indicating that approximately 1% of the potassium chloride in phase I was transferred to phase II across the membrane. Using the assumption of electroneutrality, the number of moles of potassium ions diffusing into phase II must equal the sum

of those of chloride and picrate ions transferred into phase II. The effect of potassium and lithium counter-ions on the transport of picrate can be explained by the difference in permeability across the membrane. To obtain the order of permeability for the counter-ions, the membrane potential of the dichloroethane membrane in the absence of picrate and Tris-H_2SO_4 buffer was measured. The membrane potentials for the potassium chloride–lithium chloride, potassium nitrate–lithium nitrate, potassium sulfate–lithium sulfate and potassium sulfate–lithium nitrate systems were found to be approximately 70, 50, 80, and 160 mV, respectively. The polarity of the potential was positive in phase II with respect to phase I. Using the relationship between the membrane potential and permeability coefficient derived by Hodgkin and Katz,[7] the following order of permeability for the counter-ions was established: $NO_3 > Cl > SO_4$— in fact, the rate of picrate transport decreased according to the same order for the potassium counter-ions. In the case of the potassium nitrate–lithium nitrate system, the liberation of picrate from the ion-pair at the phase II-dichloroethane interface was depressed by the co-transport of nitrate with potassium ion, whereas, in the case of the potassium sulfate–lithium nitrate system, the transfer of nitrate from phase II to phase I facilitated the transport of picrate.

In general , the membrane potential has been shown to be important in transport across the membrane. In the present experiments, the membrane potential gradually increased with time attaining a steady value. To examine the role of the membrane potential, the potential difference between phases I and II was set 0 mV by a short circuit method.[8] No difference in the results was observed , as shown in Fig. 7. Furthermore, only a slight decrease in the rate of picrate

transport occurred, even when a potential difference of 300 mV was applied between both the aqueous phases in the reverse direction of the membrane potential (Fig. 7), *i.e.* the transport of picrate is largely unaffected by the membrane potential. The explanation for this is that the transport of picrate occurs only by the diffusion of potassium ions across the membrane and therefore, the decrease in concentration gradient of the potassium ion across the membrane brings about a lowering of the rate of picrate transport, as seen from Fig. 4.

The effect of ionophores on the transport of picrate is associated with the permeability ratio of the potassium ion to the lithium ion for the dichloroethane membrane. This permeability ratio depends on the ionic selectivity of ionophore, the mobility of the potassium– and lithium–ionophore complexes in the dichloroethane membrane and the partition coefficient of the complexes.[9] It is thought that the behavior of the above-mentioned crown compounds for the dichloroethane membrane system is similar to that for the dioleyl phosphate–oleyl alcohol membrane system previously described.[5] In that system, the oleyl phosphate–oleyl alcohol membrane in the presence of valynomycin showed the highest permeability ratio of potassium ion to sodium ion. In the present experiment, the rate of picrate transport was extremely small in the presence of valinomycin and bearing in mind that the membrane potential is very samll in the presence of valinomycin, this may be attributed to a lowering of the potassium-ion selectivity of valinomycin, based on the interaction between valinomycin and picrate.

Phase Transition and Electronic States of Solid Ion Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 16, 1978)

Such crystalline ion radical salts as Würster's Blue perchlorate and K^+ *p*-Chloranil$^-$ are known to undergo phase transitions in the solid state. There are distinct differences in their optical and magnetic properties between the low- and high-temperature phases. Using Hubbard Hamiltonian, the electronic states of the high-temperature phases of those solid ion radical salts were explained in terms of an infinite non-alternant linear chain model, while those of the low-temperature phases, in terms of a dimer model.

The prominent magnetic, electrical and optical properties of a number of solid ion radical salts have been the subject of many theoretical and experimental investigations over the past fifteen years.[1-17] In such ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into columns so as to make a large overlap between their half-occupied molecular orbitals.[11-13] There have been known several crystalline ion radical salts that undergo solid-state phase transitions. For example, a stable cation radical salt of Würster's Blue (*N,N,N',N'*-tetramethyl-*p*-phenylenediamine) perchlorate undergoes a phase transition at 186 K,[1-3] while an anion radical salt of K^+ *p*-Chloranil$^-$, around 210—260 K.[4,8,9] In both of these salts, because of the structural change in the phase transition, the optical and magnetic properties of the high-temperature phases differ distinctly from those of the low-temperature phases.[1-10]

In previous papers,[14-17] we applied half-filled Hubbard model to the segregated stack of ion radical molecules and investigated the optical and magnetic properties of a number of crystalline ion radical salts. In the present paper, we shall apply this method to Würster's Blue perchlorate and K^+ *p*-Chloranil$^-$ crystals and explain the electronic states and the optical and magnetic properties of their high- and low-temperature phases. This kind of approach will be very important to investigate the mechanism of the phase transitions of those ion radical salts.

Würster's Blue Perchlorate

At room temperature the crystal is known to be orthorhombic and to be built up from non-alternant one-dimensional columns composed of equivalent Würster's Blue cation radicals along the a-axis, the intermolecular spacing between nearest neighbor cation radicals being 3.550 Å.[11] A phase change into the monoclinic form occurs at 186 K, and in the monoclinic phase the a- and c-axes are almost doubled in length in comparison with the orthorhombic modification.[11]

The magnetic susceptibility of Würster's Blue perchlorate and its temperature dependence were measured by Duffy and by Okumura.[1,2] In the region above the transition temperature, the salt had been considered to be a normal paramagnet. The paramagnetic susceptibility above the transition temperature has been reported to be consistent with a Curie-Weiss law with a Curie constant C=0.325 emu deg/mol and a Curie temperature $\theta = -23 \pm 5$ K.[2] However, the observed paramagnetism is often short of the expected 100% free radical value. For example, Duffy found it to be 94%, and Okumura, as low as 81%.[1,2] The reason for this is that, although the cation radicals have almost free spins, there may act weak antiferromagnetic exchange interaction between the cation radicals. Soos and Hughes considered the salt of the high-temperature phase to be non-alternant one-dimensional antiferromagnet with exchange interaction $2J\sum_i \boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1}$, ($S$= 1/2).[10] They used their pseudo-spin method to derive theoretical magnetic susceptibility *versus* temperature curve. The pseudo-spin result with J=70 cm^{-1} gave excellent agreement between the observed and theoretical magnetic susceptibility curves in the high-temperature phase.

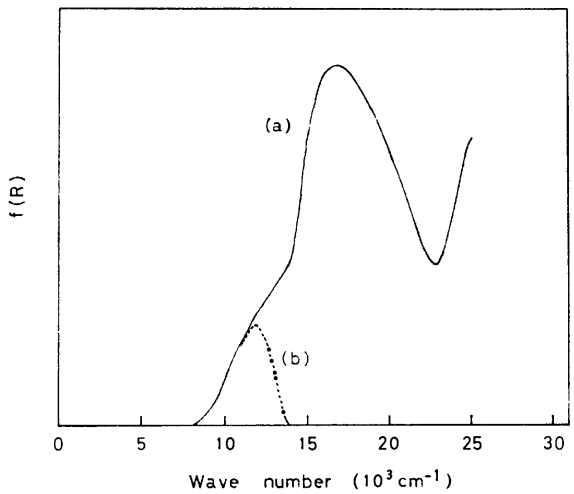

Fig. 1. (a) The observed diffuse reflection spectrum of solid Würster's Blue perchlorate salt at room temperature. The value of Kubelka-Munk function, $f(R) = (1-R)^2/2R$, was plotted *versus* wave number. (b) The intermolecular charge-transfer band of the salt. It was obtained by subtraction of the monomer absorption of the cation radical. See text and Ref. 5.

Earlier, we measured the electronic spectrum of Würster's Blue perchlorate crystal at room temperature (*i.e.*, the high-temperature phase) by means of diffuse reflection method.[5] The observed spectrum is reproduced in Curve (a) of Fig. 1, where we note a strong absorption at 16700 cm^{-1} and a weak shoulder around 12000 cm^{-1}. The strong absorption at 16700 cm^{-1} corresponds well to the 16400 cm^{-1} band of the monomer spectrum of Würster's Blue cation radical,

while the shoulder around 12000 cm^{-1} was assigned to the charge-transfer transition between the cation radicals in the solid state.[5-7,9] By subtracting the 16700 cm^{-1} monomer absorption from the observed solid-state spectrum, the intermolecular charge-transfer band of the high-temperature phase is given by Curve (b) of Fig. 1, and its peak position appears to be at 11900 cm^{-1}.

In order to understand those optical and magnetic properties of the high-temperature phase of Würster's Blue perchlorate crystal, we consider the system of non-alternant one-dimensional stack of Würster's Blue cation radicals in terms of Hubbard Hamiltonian, which can be written by[14,16]

$$\mathscr{H} = \sum_{i,j,\sigma} T_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\uparrow} n_{i\downarrow}, \tag{1}$$

where $n_{i\sigma}=C_{i\sigma}^{+}C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where $T_{ij}(<0)$ is the transfer matrix element between the i-th and j-th sites. The Coulomb repulsion potential, I, appears only when two electrons with up and down spins are at the same site. For non-alternant one-dimensional column of ion radicals, we consider the half-occupied molecular orbital of the unpaired electron as one site of ion radical molecule, and only take into account the transfer matrix element between the nearest neighbor sites. Hereafter, it is simply denoted by T (<0). We consider a paramagnetic state for our system, and further assume a δ-function for each elementary transition in which the spin and the wave vector of an electron are conserved. The intermolecular charge-transfer absorption of this system, $\sigma(\omega)$, is then given by[14]

$$\sigma(\omega) \propto \frac{e^2}{4} \frac{I^2}{\omega^2\sqrt{\omega^2-I^2}} \sqrt{4T^2-\omega^2+I^2}. \tag{2}$$

A schematic representation of the absorption line shape has been given in Fig. 1 of Ref. 14. The theoretical charge-transfer absorption has a sharp divergent peak at $\omega=I$, and has a band width of $\sqrt{I^2+4T^2}-I$ in the region of $\omega>I$. On the other hand, we examine the magnetic properties of the same system. In a region of small $|T|$ limit, the Hubbard model leads to a stabilization of the antiferromagnetic state between ion radical molecules.[16,17] For a pair of nearest neighbor ion radicals, if the small direct exchange is neglected, the energy gap between the parallel and antiparallel spin states is given by $2J=4T^2/I$. Therefore, we can well consider our solid Würster's Blue perchlorate salt as one-dimensional antiferromagnet with an exchange interaction, J. In this respect, Soos and Hughes' treatment of regular one-dimensional antiferromagnetic model is quite adequate. Therefore, if we combine the experimental data on the peak energy of the observed charge-transfer absorption and the exchange interaction parameter derived from the magnetic susceptibility measurement, we can uniquely determine the magnitudes of I and T of Eq. 1 for our system.

We apply this approach to the high-temperature phase of the Würster's Blue perchlorate crystal. The observed peak energy of the charge-transfer absorption, 11900 cm^{-1}, thus corresponds to $I=11900$ cm^{-1}. As for the magnitude of the transfer matrix element, by putting the estimated $I=11900$ cm^{-1} and $J=70$ cm^{-1} values into $J=2T^2/I$, we obtain $T=-650$ cm^{-1} for the one-dimensional system of the Würster's Blue perchlorate salt. The $|T|$ value thus estimated is found to be much smaller than the $|T|$ values estimated with a number of other ion radical salts,[14-17] indicating weak intermolecular interaction between the Würster's Blue cation radicals.[18] This is supported by the fact that the intermolecular distance between the cation radicals in the perchlorate salt is as large as 3.550 Å and also by the spectroscopic features that the 16700 cm^{-1} band of the solid salt corresponds well to the monomer spectrum of the Würster's Blue cation radical and that the intermolecular charge-transfer band appears very weakly as a shoulder in the solid-state spectrum.

Next, we consider the low-temperature phase of the same salt. As the phase transition occurs, the non-alternant one-dimensional stack of Würster's Blue cation radicals alternates strongly in the low-temperature phase.[11] The Würster's Blue cation radicals stack predominantly in a pair-by-pair manner, so that the crystal system can be practically confined to a dimer of the cation radicals. In fact, Thomas *et al.* observed the triplet-state fine structures in the ESR spectrum below the transition temperature and determined the energy gap between the ground singlet state and the excited triplet state to be 246 cm^{-1}.[3] On the other hand, Sakata *et al.* and Ishii *et al.* measured the crystal electronic spectrum of the perchlorate salt below the transition temperature.[6,9] With decreasing temperature, they found marked increase in intensity of the low-energy charge-transfer absorption, whose peak position was at 12100 ± 400 cm^{-1}. This absorption was assigned to the charge-transfer transition between the Würster's Blue cation radicals in the dimer.

On the basis of these experimental results, we consider the electronic state of the low-temperature phase of the Würster's Blue perchlorate salt in terms of a dimer model of Hubbard Hamiltonian, which can be written by[16]

$$\mathscr{H} = \sum_{\sigma} T(C_{1\sigma}^{+}C_{2\sigma} + C_{2\sigma}^{+}C_{1\sigma}) + I(n_{1\uparrow}n_{1\downarrow} + n_{2\uparrow}n_{2\downarrow}), \tag{3}$$

where the notations are common to those in Eq. 1. The suffixes, 1 and 2, denote two sites of ion radicals in a dimer, and $T(<0)$ is the transfer matrix element between ion radicals in the dimer. If we only take the half-occupied molecular orbital of ion radical for each site, there are six bases of the wave functions for the dimer. After solving the eigenvalue problem, we have three singlet states and one triplet state. A detail of the wave functions and the energy levels was described in a previous paper.[16] The energy of the charge-transfer absorption, $h\nu_{CT}$, and the singlet-triplet energy separation, δ, are given by

$$h\nu_{CT} = \left\{\left(\frac{1}{2}I\right)^2 + (2T)^2\right\}^{1/2} + \frac{1}{2}I, \tag{4}$$

$$\delta = \left\{\left(\frac{1}{2}I\right)^2 + (2T)^2\right\}^{1/2} - \frac{1}{2}I. \tag{5}$$

This dimer model was then applied to the above experimental results of the low-temperature phase of

the Würster's Blue perchlorate salt. By putting the observed values of $h\nu_{CT}=12100\pm400\ cm^{-1}$ and $\delta=246\ cm^{-1}$ into Eqs. 4 and 5, we obtain $I=h\nu_{CT}-\delta=11900\pm400\ cm^{-1}$ and $T=-865\pm15\ cm^{-1}$, respectively. The I value thus estimated almost coincides with the $I=11900\ cm^{-1}$ value of the high-temperature phase, while the $|T|$ value of the dimer is found to be appreciably larger than the $|T|=650\ cm^{-1}$ value of the high-temperature phase. In view of these results, the 186 K phase transition associated with slight crystal structure modification scarcely changes the magnitude of Coulomb repulsion energy, but increases significantly the magnitude of transfer matrix element of the dimer in the low-temperature phase.

K^+ *p*-Chloranil$^-$

At room temperature, although there are several polymorphs, in the structure of the orthorhombic α-form the *p*-chloranil anion radicals are stacked with equal intervals, forming non-alternant one-dimensional columns parallel to the c-axis, the interplanar spacing being 3.47 Å.[12] The optical and magnetic properties and the electronic state of the room-temperature (high-temperature) phase of the K^+ *p*-Chloranil$^-$ salt have been already discussed in a previous paper.[16] The Hubbard Hamiltonian of Eq. 1 was applied to the non-alternant one-dimensional column of the *p*-chloranil anion radicals, and the values of $I=11800\ cm^{-1}$ and $T=-820\ cm^{-1}$ were obtained.

As temperature is lowered, the K^+ *p*-Chloranil$^-$ salt undergoes a phase transition at 210 K.[4] With increasing temperature, however, a large hysteresis occurs and the low-temperature phase changes into the high-temperature phase around 260 K. The magnetic susceptibility and its temperature dependence in the low-temperature phase were measured by Andre *et al.* and were well explained in terms of an equilibrium between ground singlet state and excited triplet state lying $\delta=400\ cm^{-1}$ above the singlet state.[4] In the low-temperature phase, although there have been no crystal structure data, the magnetic behavior strongly suggests a dimeric structure of the *p*-chloranil anion radicals. The electronic spectrum of the solid salt below the transition temperature was measured by Hiroma and Kuroda.[8] With decreasing temperature, they found marked increase in intensity of the low-energy charge-transfer absorption, whose peak position was reported to be at $11500\ cm^{-1}$. This absorption was assigned to the charge-transfer transition in the dimer. In order to explain those optical and magnetic properties, the dimer model of Hubbard Hamiltonian of Eq. 3 was again applied. By taking the same procedure as described in the preceding section, together with Eqs. 4 and 5, the values of $I=11100\ cm^{-1}$ and $T=-1070\ cm^{-1}$ were estimated for the low-temperature phase of the K^+ *p*-Chloranil$^-$ salt. We can also see that the $|T|$ value of the low-temperature phase is larger than the $|T|$ value of the high-temperature phase. The phase change causes a slight decrease of the I value in the low-temperature phase.

Concluding Remarks

In both of the Würster's Blue perchlorate and K^+ *p*-Chloranil$^-$ crystals, the high-temperature phases correspond to non-alternant one-dimensional stacks of ion radical molecules, while the phase transitions cause alternate stacks of ion radicals in the low-temperature phases. In the present paper, we cannot explain the detailed mechanism of these phase transitions, but can understand the electronic states of both high- and low-temperature phases in terms of Hubbard Hamiltonian. The motive force of the phase changes probably comes from Peierls instability in one-dimensional system of segregated stacks of ion radical molecules.

As for the transfer matrix element of the high-temperature phase, the $|T|$ value of Würster's Blue perchlorate is found to be smaller than that of K^+ *p*-Chloranil$^-$. In this respect, the intermolecular interaction between Würster's Blue cation radicals appears to be weaker than that between *p*-chloranil anion radicals. We can understand this difference, because the intermolecular distance between Würster's Blue cations, 3.550 Å, is longer than that between *p*-chloranil anion radicals, 3.47 Å.

In the low-temperature phases, alternate stacks of ion radical molecules cause shorter intermolecular distance in a dimer and longer distance between dimers, compared to the intermolecular distance in non-alternant stacks. On this basis, it is reasonable that, in both of the Würster's Blue perchlorate and K^+ *p*-Chloranil$^-$ salts, the $|T|$ values estimated with the low-temperature phases are appreciably larger than those of the high-temperature phases. Concerning the magnitude of the $|T|$ values in the low-temperature phases, the $|T|$ value of K^+ *p*-Chloranil$^-$ is larger than that of Würster's Blue perchlorate, so that the singlet-triplet energy separation of the former salt is wider than that of the latter. Although we have no structural information, the *p*-chloranil anion radicals may stack in the dimer more closely than do the Würster's Blue cation radicals.

The theoretical consideration made in the present paper will be useful to investigate the mechanism of the phase transitions of those solid ion radical salts.

18) J. Tanaka, M. Inoue, M. Mizuno, and K. Horai, *Bull. Chem. Soc. Jpn.*, **43**, 1998 (1970). In this paper, they discussed the interaction parameter between the ground and charge-transfer configurations in terms of dimer model of Würster's Blue cation radicals. Although their dimer model was not applied directly to the high-temperature phase of Würster's Blue perchlorate, they estimated the magnitude of the interaction parameter as 645 cm^{-1}, which should approximately correspond to $2|T|$ of our Hubbard model. Their value is somewhat smaller than the 1300 cm^{-1} value derived from our one-dimensional Hubbard model, thus giving a J value much smaller than the observed $J=70$ cm^{-1}.

Delayed Excimer Fluorescence of Acridine Orange Bound to DNA

Yuko MOTODA and Yukio KUBOTA*

Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753

(Received August 23, 1978)

The temperature dependence of long-lived emissions of Acridine Orange bound to DNA has been investigated. Only phosphorescence with a maximum close to 620 nm is observed in the range 77—*ca.* 150 K. With a rise in temperature, the delayed thermal fluorescence around 530 nm is observed in addition to phosphorescence at a high ratio of DNA phosphate to dye (P/D). With a decrease in P/D value, the delayed thermal fluorescence is replaced by a new delayed emission band around 640 nm. Its maximum wavelength is very close to that of dimer fluorescence of Acridine Orange in water. It has been shown that the emission results from two processes: (1) thermal excitation of the triplet state of the dimer to the excimer state and (2) excimer formation after the thermal excitation of the triplet state of the monomer to the first excited singlet state.

The binding of Acridine Orange (AO) to DNA has been extensively studied because of its biological effects.[1,2] Like many acridine derivatives, AO binds to DNA to form two types of complexes; one (Complex I) results from external binding where electrostatic forces play an important role,[3,4] while the other (Complex II) occurs at high DNA phosphate/dye (P/D) ratios, generally considered as an intercalation process.[5,6] As compared to other related dyes, the binding of AO presents a particularly complex aspect due, in part, to its high tendency to dimerize.[7,8] It is well known that fluorescence spectra of AO in aqueous solutions at room temperature strongly depend on its concentration.[9] With increasing concentration of the dye, its green fluorescence with a maximum near 540 nm is replaced by a red fluorescence with a maximum close to 650 nm.[9] AO, especially when bound to single-strand polynucleotides or denatured DNA at a low P/D value, also shows red fluorescence.[10-13] Such emission properties of the dye have been applied to studies of the conformational change of DNA and the nearest neighbor dye-dye interactions.[10-13]

In order to understand biological action of AO, it is of significance to clarify the nature of its excited state and the character of the interaction of the dye with the binding site, as well as the nearest neighbor dye-dye interactions. In previous papers,[14,15] reports were given on the phosphorescence, the delayed fluorescence due to triplet-triplet annihilation and the sensitized delayed fluorescence in the DNA–acridine dye complexes at 77 K. A study at low temperatures is of particular interest, since the radiationless processes which compete with the radiative processes (fluorescence and phosphorescence) are largely suppressed. Further, it is of interest to investigate the temperature dependence of the emission properties in order to elucidate the excited states of the bound dye.

The present paper describes the emission properties of AO bound to DNA over a wide temperature range and the newly-observed delayed emission.

Experimental

AO (Chroma) was purified by the method of Zanker.[9] No trace of impurity was detected by thin-layer chromatography on silica gel. Calf thymus DNA was obtained from Worthington Biochemical Corporation. The concentration of DNA was determined spectrophotometrically at 260 nm with the extinction coefficient per mole of DNA phosphate ($\varepsilon_p = 6600\ M^{-1}\ cm^{-1}$).[16] The thermal denaturation of DNA was performed by heating the DNA solution for 20 min in boiling water and then rapidly cooling in ice water. The solutions of the complexes were made up in 5 mM phosphate buffer at pH 6.9.

All the solutions were degassed by freezing, pumping, and thawing under a high vacuum. The solutions were placed in a quartz tube (inner diam. 1 mm) mounted in a Dewar flask with provision for the excitation and detection of the delayed emissions at right angles. For studies at 77 K the sample tube was immersed in liquid nitrogen. For measurements at various temperatures the temperature was controlled by a constant flow of cold nitrogen gas through the Dewar. The temperature was monitored by a copper-constantan thermocouple attached to the outside of the sample tube. The precision of the quoted values is $\pm 1°$.

The emission and excitation spectra were measured with a Hitachi MPF-2A fluorescence spectrophotometer; the detector was a red-sensitive photomultiplier tube, R446-UR (Hamamatsu Television Co.). Both spectra are given with corrections on the quantum response of detecting and exciting systems. A rotating-shutter phosphoroscope was used to separate the delayed emissions from normal fluorescence. The intensity of the exciting light was varied by introducing calibrated wire screens.

The absorption spectra at 77 K and at room temperature were measured with a Shimadzu MPS spectrophotometer with a 0.1 cm quartz cell.

Results and Discussion

Absorption Spectra of the Complexes. First, absorption spectra of the complexes were measured at room temperature and at 77 K in order to confirm the binding states of AO. It was found that the bound dye molecules predominantly exist as the monomeric species at a sufficiently high P/D value, tending to associate with a decrease in the P/D value. The association tendency is more remarkable in the denatured DNA and at 77 K than in the native one and at room temperature. Typical absorption spectra at 77 K are shown in Fig. 1. They exhibit a red shift of about 5 nm, being well resolved as compared with those at room temperature.[7,8,17] The 0-1 band around 470 nm in the monomer absorption spectrum generally overlaps the dimer absorption band.[7,9,18] As the P/D value decreases ($P/D<50$), the band around 470 nm becomes marked, while the 0-0 band around 500 nm is suppressed. This is ascribed to the formation of dye dimers. In the case $P/D<20$, the absorption

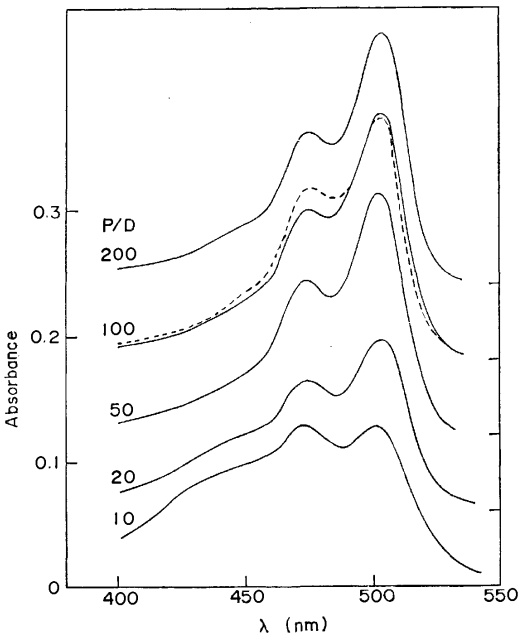

Fig. 1. Absorption spectra of DNA-AO complexes in 5 mM phosphate buffer at 77 K. The light-path length of the cell was 0.1 cm. For clarity of presentation the upper curves are displaced by a constant amount. Each line on the right ordinate corresponds to a base line. AO: 5.0×10^{-5} M, ——: native DNA, ----: denatured DNA.

band due to higher aggregates of the dye develops at wavelengths shorter than the 0-1 band around 470 nm.

Delayed Emission Spectra of the Complexes. Total emission and delayed emission spectra obtained under various temperatures are shown in Figs. 2A, 2B, and 2C. The spectral distribution of total emission shows little dependence on the temperature except that its maximum is slightly shifted to longer wavelength with increasing temperature. Total emission seems to be mainly composed of normal fluorescence, since its intensity is several ten times that of the delayed emission.

The delayed emission of the complexes consists only of phosphorescence with a maximum close to 620 nm in the range 77—*ca.* 150 K. With an increase in temperature, another delayed emission appears in addition to the phosphorescence; this phenomenon depends on the *P/D* value.

At a high *P/D* value (*P/D*>100), the delayed emission peaking at 530 nm becomes remarkable above *ca.* 200 K (Fig. 2A). The spectral distribution of delayed emission is very similar to that of normal fluorescence. The intensity of the delayed emission was found to be proportional to the first power of the intenisty of the exciting light, decaying exponentially with a lifetime equal to that of the phosphorescence. Thus, the delayed emission around 530 nm is due to the mechanism in which there is thermal activation from the lowest triplet state to the first excited singlet state followed by radiative transition from there to the ground state.[19,20] In the present study the delayed emission is called delayed thermal fluorescence

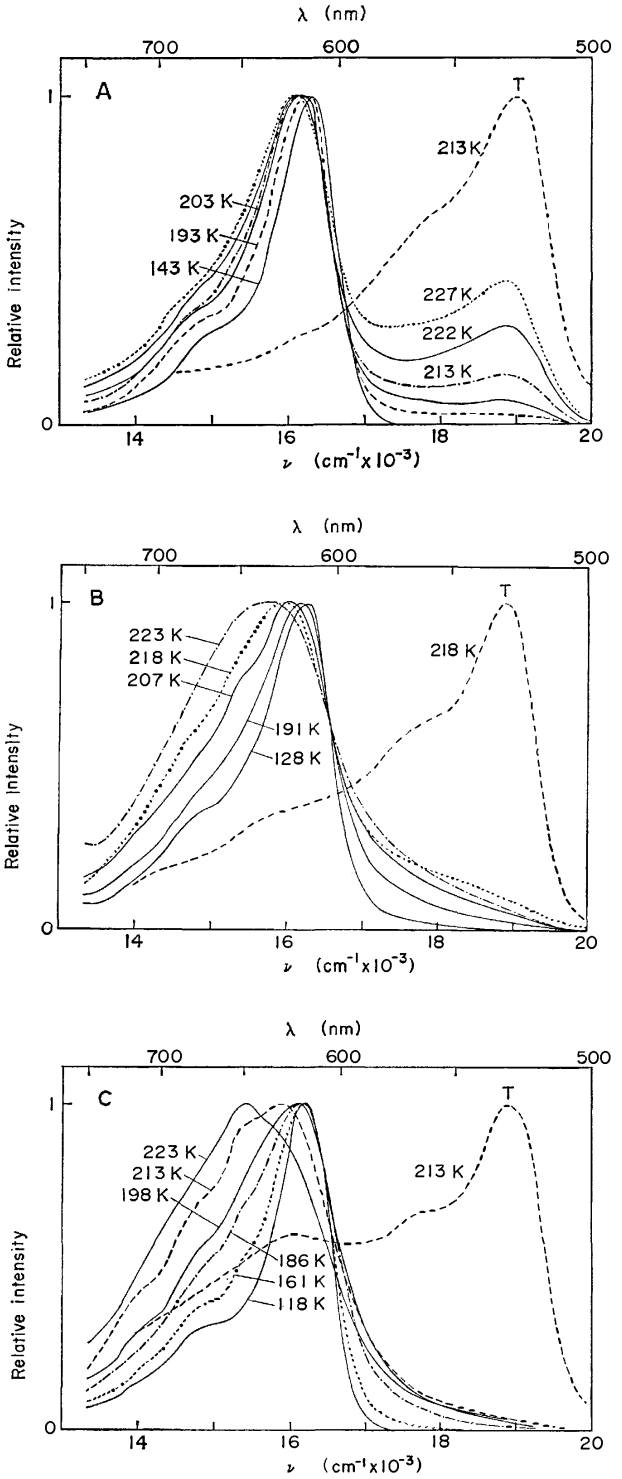

Fig. 2. (A) Normalized delayed emission spectra of DNA-AO complex (*P/D*=302) as a function of temperature. Excitation wavelength: 470 nm, AO: 5.0×10^{-5} M, T: total emission spectrum. (B) Same, *P/D*=100. (C) Same, *P/D*=50.

according to the terminology of McGlynn *et al.*[20] The Arrhenius plot of ϕ_f/ϕ_p against $1/T$ were linear and the activation energy was obtained as 7.1 kcal mol^{-1}; here, ϕ_f and ϕ_p are the efficiencies of the delayed thermal fluorescence and phosphorescence, respectively. On the other hand, the peak-to-peak

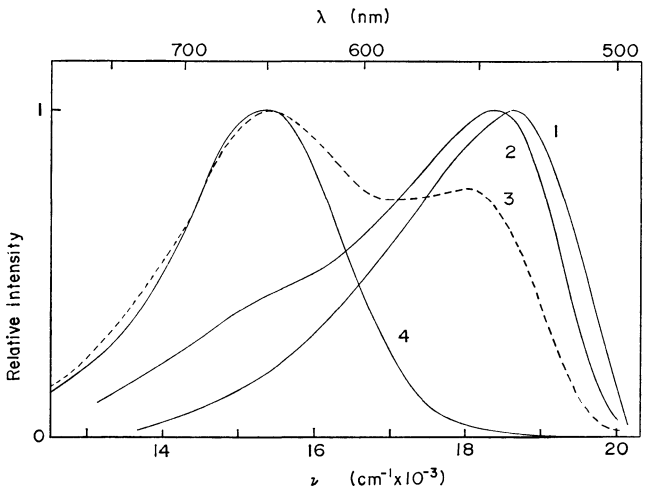

Fig. 3. Normalized fluorescence spectra of AO in 5 mM phosphate buffer at 25 °C. Excitation wavelength: 400 nm, AO: (1) 1.1×10^{-6} M, (2) 2.1×10^{-4} M, (3) 1.0×10^{-3} M, (4) 1.1×10^{-2} M.

separation between the delayed thermal fluorescence and the phosphorescence was 7.5 kcal mol^{-1}. Both values agree within experimental error, confirming the proposed mechanism.

With a decrease in P/D value ($P/D<120$), two interesting effects are observed (Figs. 2B and 2C): (1) a marked decrease in the intensity of the delayed thermal fluorescence as compared with the results at a high P/D value (Fig. 2A), and (2) appearance of a new emission band around 640 nm at elevated temperatures. AO easily associates to form a dimer or higher aggregates.[9] As shown in Fig. 3, fluorescence spectra of AO in aqueous solution highly depend on its concentration. With an increase in the concentration of dye, the green fluorescence with a maximum near 540 nm is replaced by a red fluorescence with a maximum close to 650 nm. The former is due to the dye monomer and the latter to the dye dimer or higher aggregates.[9] It should be noted that the shape of the delayed emission spectra peaking around 640 nm is very similar to that of a red fluorescence of the dye itself (Figs. 2B, 2C, and 3).

Excitation Spectra of the Delayed Emissions. Figure 4 shows typical results obtained with $P/D=50$. The excitation spectra of both the phosphorescence at 77 K and the delayed thermal fluorescence at 213 K ($\lambda_{max}=$ 530 nm) are almost the same as the absorption spectrum at 77 K. On the other hand, the excitation spectrum of the delayed emission observed at 640 nm and at 213 K differs from that of the delayed thermal fluorescence at 530 nm. The excitation spectrum of the delayed emission at 640 nm shows an increase of the band at 470 nm, accompanied by the corresponding decrease of the band at 500 nm. This shape of the excitation spectrum is similar to that of the absorption spectrum at a low P/D value (Fig. 1).

Delayed emission around 640 nm was observed more remarkably in the case of denatured DNA and at lower P/D values where the absorption band due to the dye dimer becomes pronounced (Fig. 1).

Mechanism of the Newly-observed Delayed Emission.

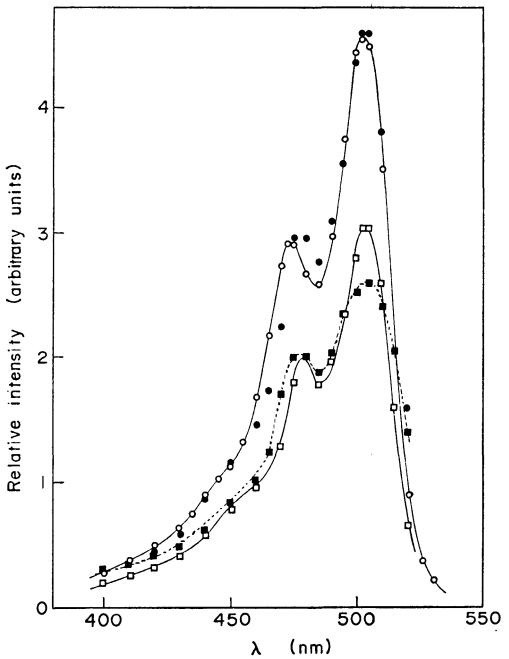

Fig. 4. Excitation spectra of delayed emissions of DNA–AO complex ($P/D=50$). ○: Absorption spectrum at 77 K, ●: excitation spectrum of phosphorescence observed at 610 nm and at 77 K, □: excitation spectrum of delayed thermal fluorescence observed at 530 nm and at 213 K, ■ : excitation spectrum of delayed emission observed at 640 nm and at 213 K.

A comparison of absorption, total emission and excitation spectra of the delayed emissions suggests that the dye dimer formed in the ground state may contribute to the newly-observed delayed emission. However, even at $P/D=100$ and $P/D=50$ where the monomeric form of the dye predominates, there is an intense delayed emission around 640 nm (Figs. 2B and 2C). This indicates that the newly-observed delayed emission can not be explained only by ground-state dimerization of the dye. An alternative explanation is that the newly-observed band is due, in part, to another type of dimeric species, known as excimer.

In the present case, the intensity of the delayed emission around 640 nm varies not with the second power but with the first power of the intensity of the exciting light. Thus, it seems that the delayed emission observed anew in this study is not due to triplet-triplet annihilation.[19]

It has been shown that the dimerization of AO leads to a red shift of *ca.* 30 nm in the peak of phosphorescence.[21] If we compare the phopshorescence spectra at 77 K, the shoulder around 660 nm becomes manifest at a low P/D value and in the case of denatured DNA where ground-state dimerization becomes significant; this is due to the dimer phosphorescence.[21]

In view of these findings, a mechanism similar to that of delayed thermal fluorescence may provide a good explanation for the above results.[22,23] The delayed emission around 640 nm can be interpreted as a result of two processes: 1. The thermal excitation from the triplet state of the dimer (D^t) to the excimer

state (E), followed by an emission. 2. The excimer formation, $M_1+M_0 \rightarrow E$, after the thermal excitation of the triplet state of the monomer (M^t) to the first excited singlet state (M_1), followed by an emission; here, M_0 is the monomer in the ground state. The delayed emission due to this mechanism is then called delayed thermal excimer fluorescence. Because of the very small energy gap between D^t and E, the delayed thermal excimer fluorescence according to process 1 is expected to show up at considerably lower temperatures than the delayed thermal fluorescence (Figs. 2A, 2B, and 2C).

Formation of the Excimer. The bound dye is not uniformly distributed in DNA, but has a tendency to form clusters.[12] The freezing of the DNA–dye solutions may accelerate the formation of clusters.[12] The dye molecules in clusters exist closely and thus seem to be responsible for the dimer formation both in the ground and excited states.

In general, the bound dye molecules are considered to be intercalated between adjacent DNA base pairs at a high P/D value. Two models for the intercalation process have been proposed: complete intercalation model[5,6] and partial intercalation model in which partly intercalated dye molecule is a possible binding site for additional, non-intercalated dye molecule.[7] In the case of the former, the closest distance between bound dye molecules could be 10.2 Å assuming the exclusion of adjacent intercalation sites,[7,24] while the closest distance could be 3.4 Å in the case of the latter. The mutual orientation and extent of overlap of adjacent dye molecules might be very important for the formation of the excimer. Observation of triplet-singlet and triplet-triplet energy transfers between DNA bases and dyes at 77 K shows that the structure of complexes at low temperatures is very similar to that at room temperature.[25,26] If we judge from the distance between two bound dye molecules, the partial intercalation model seems favorable for the formation of the excimer.

In conclusion, it is evident that the nearest neighbor dye-dye interactions produce the excimer state of the dye. Such interactions may play an important role in the biological actions of AO.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Heterogeneous Catalysis in the Liquid-phase Oxidation of Olefins. III. Activity of Supported Vanadium–Chromium Binary Oxide Catalyst for the Oxidation of Cyclohexene

Katsuomi TAKEHIRA,* Takashi HAYAKAWA, and Toshio ISHIKAWA
Catalysis Division, National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received August 24, 1978)

The liquid-phase oxidation of cyclohexene has been conducted in benzene using a vanadium–chromium binary oxide supported on γ-Al_2O_3 or SiO_2 as the catalyst. Three series of catalysts have been prepared by a kneading method using the following combinations of raw materials; NH_4VO_3+$Cr(NO_3)_3\cdot 9H_2O$+alumina hydrate (Catalyst G), NH_4VO_3+$(NH_4)_2CrO_4$+alumina hydrate (H), and NH_4VO_3+$Cr(NO_3)_3\cdot 9H_2O$+silica sol (I). It has been found that the activity of the supported binary system is due to the interactions between the metal oxides and the carrier. The contributions of compounds such as the chromium isopolyvanadates appear to add to the above activity. The order of catalytic activity has been established as : I>H>G. The V_2O_5–SiO_2 system in the I series showed the highest activity, but rapidly became depleted in the course of reaction. The second highest activity was given by Cr_2O_3–SiO_2 system, on which Cr^{5+} species was observed. In both cases, the vanadium and chromium metal ions may be coordinated tetrahedrally on SiO_2. The Cr_2O_3–Al_2O_3 in the H series contained Cr^{5+} ions and exhibited high activity which may be attributed to the tetrahedral configuration. It is thought that the tetrahedral complexes catalyze the autoxidation of cyclohexene by decomposing 1-cyclohexenyl hydroperoxide.

Vanadium–chromium binary oxides (V–Cr) have shown activities in the liquid-phase oxidations of acrylaldehyde[1] and cyclohexene.[2,3] The activities were found to be largely influenced by the method of catalyst preparation, *i.e.*, the use of a more acidic medium promoted the formation of chromium isopolyvanadate which contained a more condensed vanadate anion, resulting in the increase in catalytic activity.[3]

With practical catalysts, the active components are generally supported on carriers such as silica and alumina which possess a high surface area; that the carriers have a profound effect on the activity of catalyst has been demonstrated. A one component system, *i.e.*, supported V_2O_5 or Cr_2O_3, has been extensively used as a catalyst for example in gas-phase oxidation of hydrocarbons and in the polymerization of ethylene, respectively. The dependency of the activity of γ-Al_2O_3- or SiO_2-supported one component systems on the surface structure has been investigated in detail.[4-10] In the present work, the liquid-phase oxidation of cyclohexene has been conducted using γ-Al_2O_3- or SiO_2-supported V–Cr system as the catalyst. The effects of the carriers and the methods of preparation on the activity have been discussed.

Experimental

Catalysts. The supported binary system catalysts were prepared by the kneading method as follows; aqueous solutions of the raw materials of vanadium and chromium oxide components were poured into alumina hydrate (Shokubai Kasei Co., Ltd.) or silica sol (Snowtex, Kokusan Kagaku Co., Ltd.), and the mixture kneaded at 80 °C for 6 h, dried at 100 °C for one day, and calcined at 450 °C for 5 h in air. The resulting catalyst was pulverized and used (30—40 mesh particle size powder). NH_4VO_3, $Cr(NO_3)_3\cdot 9H_2O$, and $(NH_4)_2CrO_4$ were used as the raw materials for the metal oxide components. The symbol, concentration (calculated as V_2O_5+Cr_2O_3 (wt %)) and composition of supported metal oxides (in terms of atomic % of Cr/(V+Cr)), and specific surface area (S_s) are given in Tables 1 and 2.

Apparatus and Procedure. The oxidation was conducted at 60 °C for 4 h under 1 atm of O_2 using the batch system.[2] Cyclohexene (20.0 ml, purified by passing it over activated alumina to eliminate the hydroperoxide), benzene as solvent (50.0 ml), *t*-butyl hydroperoxide (BHPO) (0.1 ml), and the catalyst (50.0 mg) were used in each reaction. BHPO purified by distillation (40.0 °C/25 mmHg) was added such that reproducible results of oxidation were obtained.

Analyses of Reaction Products and Catalysts. The reaction products; 1-cyclohexenyl hydroperoxide (HPO), 2-cyclohexen-1-one (ONE), 2-cyclohexen-1-ol (OL), and cyclohexene oxide (OXIDE) were determined by the iodometric method and gas chromatography.[2]

The surface area of the catalyst was measured by the BET method, the structure being studied by means of X-ray diffraction and infrared absorption.[2] X-Ray photoelectron spectroscopy (XPS) measurements were carried out on a Du Pont ESCA 650 B using monochromatic Al $K\alpha$ radiation in order to clarify the surface properties of the catalyst. The power of X-ray radiation was 300 W (7.5 kV, 40 mA) in all measurements. All binding energy values were referred to the contamination C 1s line (285.0 eV).

Results and Discussion

Surface Area of Catalyst. Both γ-Al_2O_3 and SiO_2 prepared in the present work gave similar values of S_s. This value increased by supporting metal oxides on γ-Al_2O_3, and decreased on SiO_2 (Table 1). On the γ-Al_2O_3 carrier, the use of $(NH_4)_2CrO_4$ caused a small increase in S_s, compared with that of $Cr(NO_3)_3\cdot 9H_2O$ (Table 2).

Addition of BHPO. The results of using the G-5 catalyst are shown in Table 3 (Run Nos. 6 and 7). In the absence of BHPO, the induction period of oxygen uptake showed no fixed value, resulting in no reproducibility for the conversion. By adding a small amount of BHPO, reproducible results were obtained (Run No. 7). No oxygen absorption was observed for 5 h in the absence of catalyst and BHPO; the addition of 1 ml of BHPO caused a small amount of oxygen

a) Cyclohexene (20.0 ml), benzene (50.0 ml), and catalyst (50.0 mg) were used. The reaction temperature was 60 °C, the reaction time 4 h, and the oxygen pressure 1 atm. b) V–Cr–D-5 is the unsupported catalyst reported in a previous paper.[3] Cr/(V+Cr); 50 atom %, and S_s; 8.3 m^2/g. c) The value of conversion was not precisely obtained, as the induction period was not constant. The values of selectivity are average values.

absorption (Run No. 1). Both γ-Al_2O_3 and SiO_2 showed no activity. V–Cr–D-5 is the unsupported binary oxide catalyst which showed high activity in a previous report[3] (Run Nos. 4 and 5, S_s 8.3 m^2/g). The activity of the V–Cr system of G-5 showing a S_s of 265 m^2/g may be attributed to the large surface area.

The effect of the addition of BHPO is shown in Fig. 1. The induction period was greatly reduced by the addition of a small amount of BHPO, producing an almost constant induction period when the amount of BHPO exceed 0.1 ml. There is the possibility that the BHPO affects the reaction reults, *e.g.*, the product distribution may be changed by a stoichiometric epoxidation of cyclohexene with BHPO, *etc.* In order to avoid such possibilities, the amount of BHPO was fixed at 0.1 ml (9.2×10^{-4} mol) which is extremely small compared with the amount of cyclohexene (20 ml; 1.97×10^{-1} mol). The values of selectivity were not affected as shown in the two pairs of reaction (Run Nos. 4 and 5 and Run Nos. 6 and 7). BHPO appears to work mainly as an initiator by way of its decomposition on the catalyst. In all subsequent reactions, 0.1 ml of BHPO was added to obtain reproducible results.

Oxygen Uptake. The curves of oxygen uptake

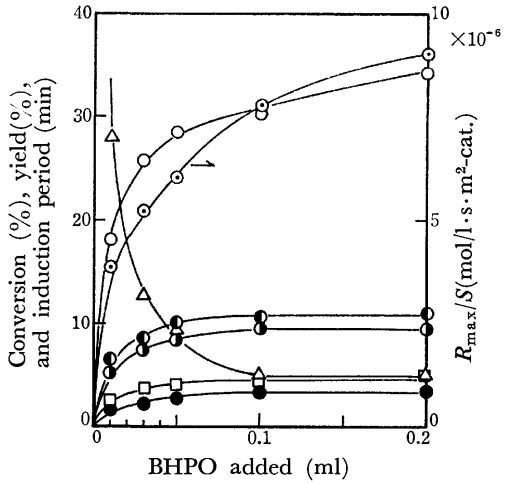

Fig. 1. Effect of the addition of BHPO. 20.0 ml of cyclohexene, 50.0 ml of benzene, and 50.0 mg of G-5 catalyst were used. The reaction temperature was 60 °C, the reaction time was 4 h, and the O_2-pressure was 1 atm.

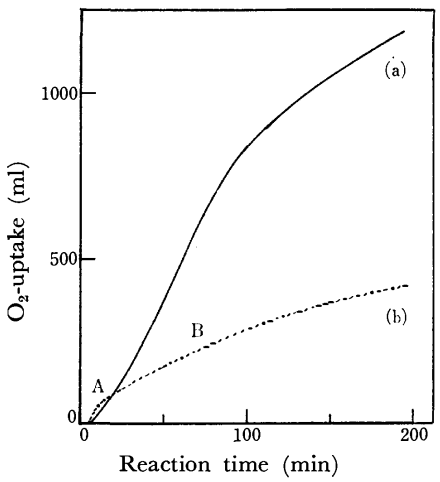

Fig. 2. Oxygen absorption.
(a) Catalyst: G-5, (b) catalyst: I-0. 20.0 ml of cyclohexene, 50.0 ml of benzene, and 50.0 mg of the catalyst were used. The reaction temperature was 60 °C, and the O_2-pressure was 1 atm.

are shown in Fig. 2. Most of the catalysts used gave a typical S-shaped oxygen absorption curve (a); I-0, I-2, and I-4 show different types of absorption (b). In the latter type, rapid absorption was observed immediately after the induction period (A), followed by a linear decrease in the rate of oxygen uptake (B). As the V_2O_5–SiO_2 system illustrates the high activity for the decomposition of BHPO into radicals[11] (Eq. 1), the rapid reaction at A may be due to a chain reaction (Eqs. 2, 3, and 4) induced by the radicals formed from BHPO.

M indicates the metal on the catalyst. Evidence for such an induction period was conducted with several oxidations with a I-0 catalyst and a changing amount of BHPO, the results of which are given in Fig. 3 (A is magnified). As can be seen, the maximum rate of O_2-uptake at A (R_{max}-A) showed a first order dependency on the amount of BHPO added, supporting the above mechanism. The rate at B, which suggests a steady state in the oxidation, was independent of the amount of BHPO added. As BHPO was decomposed rapidly on V_2O_5–SiO_2,[11] the O_2-uptake at B may be uniquely due to the radical chain of cyclohexene oxidation, the rate of which is shown by R_{max}-B. The specific activity, *i.e.*, the maximum rate per unit surface area of the catalyst, and the induction period of O_2-uptake are shown in Figs. 4 and 5.

Effect of Amount of Metal Oxides Supported. Figure 4 illustrates the effect of the amount of metal oxides supported on γ-Al_2O_3 or SiO_2. It is of interest that the activity on SiO_2 increased rapidly when a small amount (about 1 wt %) of metal oxides was supported, and remained almost constant with further additions. On γ-Al_2O_3, however, high acitivity was obtained only when a sufficient amount of metal oxides was supported. The product distributions are shown in Figs. 6 and 7. The formations of the two types of active site, *i.e.*, one effective for the autoxidation and another for the selective epoxidation of cyclohexene with HPO, on V–Cr system catalyst have been reported.[2,3] For the present catalysts, two types of active site appear to form, because the OXIDE formation was accompanied with that of OL, suggesting selective epoxidation. The autoxidation which produces HPO and ONE appears to be well catalyzed on the catalyst including a small amount of metal oxides.

Effect of Composition of Metal Oxides. Figure 5 shows the influence of the composition of metal

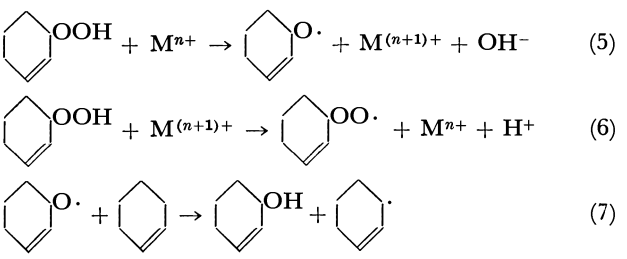
oxides supported. In the case of the I-series catalyst, the two types of reaction rate, *i.e.*, R_{max}-A and R_{max}-B, are shown together. The activity of the binary system on SiO_2 was higher than that on γ-Al_2O_3, when adopting the value of R_{max}-A/S. According to the oxygen uptake in B, the activities (R_{max}-B/S) of only two catalysts I-0 and I-2 showed similar values to those of the γ-Al_2O_3-supported system, *i.e.*, the two catalysts exhibited high activities at the start of oxygen uptake, being largely deactivated during the oxidation. It is noteworthy that V_2O_5–SiO_2 (I-0) showed a high activity (R_{max}-A/S) in comparison with V_2O_5–Al_2O_3. In the activity of the γ-Al_2O_3-supported systems, clear difference between the G- and H-series catalysts including the large amount of Cr was observed, H-series prepared from $(NH_4)_2CrO_4$ being more active than the G-series from $Cr(NO_3)_3 \cdot 9H_2O$. The difference was observed in both the R_{max}/S and the induction period.

Reaction Scheme. The product distributions obtained with the three series of catalysts are shown in Figs. 8, 9, and 10. The results can be interpreted by the following reaction scheme which has been proposed in the literatures.[2,13-18]



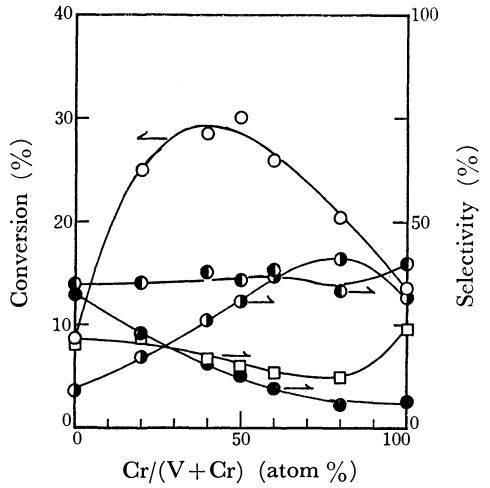


Fig. 8. Product distributions in the oxidation with G-series catalysts.
20.0 ml of cyclohexene, 50.0 ml of benzene, 50.0 mg of the catalyst, and 0.1 ml of BHPO were used. The reaction temperature was 60 °C, the reaction time was 4 h, and the O_2-pressure was 1 atm.

For the purpose of studying the action of the catalysts on hydroperoxide, the decomposition of BHPO was conducted at 60 °C in a N_2 atmosphere. All the catalysts used except I-0—I-6** gave *t*-butyl alcohol (85%), di-*t*-butyl poerxide (10%), and acetone (5%), showing that the decomposition of BHPO proceeds *via* a homolytic mechanism.[12] The homolytic decomposition of

** When using these catalysts, isobutylene and di-*t*-butyl ether were formed together with three products mentioned above. The details of the decomposition of BHPO will be reported in a later paper.

HPO (Eqs. 5 and 6) must also be considered. Reactions 3 and 4 are chain propagating and Reaction 8 is a biradical termination, by which equimolar amounts of ONE and OL are formed. Reaction 9 is the addition of the peroxyl radical to cyclohexene, although the contribution is very small.[13] Reactions 10 and 11 are an adaptation of the mechanism recently proposed by Mizukami *et al.* in the oxidation of tetralin.[18] The dehydration of HPO on the catalyst

(Eq. 12) must also be considered as reported by Neuburg *et al.*[17] and Reaction 13 is the selective epoxidation already reported.[2] It may be easily understood that the selective epoxidation proceeded well on the catalyst containing large amount of vanadium. On γ-Al_2O_3, a higher value of conversion was obtained with the H-series , the G- and H-series showing a similar pattern of product distribution up to a Cr content of about 70 atom %. Beyond this value, ONE increased in the H-series and the formation of HPO and OL took precedence over the G-series. Thus, a higher ratio of ONE/OL and simultaneously higher activity (Fig. 5) given by the H-series at higher Cr content, suggests that Reactions 10, 11, and 12 may be useful together with the biradical termination (Eq. 8) as the mechanism for ONE formation. On the other hand, OL is considered to form mainly by Reactions 7 and 8 and the selective epoxidation when using catalysts containing a lot of vanadium. The stabilities of ONE and OL under reaction conditions were examined: separate solutions with 10 ml of ONE and OL in benzene (50 ml containing BHPO (0.1 ml)) were prepared and oxidized at 60 °C with G-5 catalyst (50 mg). ONE did not show any conversion to further oxidized products after 4 h of reaction, whilst an extremely small amount (about 0.8 mol %) of OL was converted into the ketone after 4 h.

I-0 and I-2 showing the high activities at the beginning were deactivated quickly as described above, resulting in low conversion. This suggests the instability of the active species on I-0 and I-2.

Structure of Catalysts. It has already been reported[1-3] that several chemical compounds, *e.g.*, chromium divanadate ($Cr_4(V_2O_7)_3$), chromium metavanadate ($Cr(VO_3)_3$), and chromium polyvanadates, together with V_2O_5 and Cr_2O_3 form in the catalysts of the V–Cr system. These species largely influence catalytic activity. In the present binary system supported on γ-Al_2O_3 or SiO_2, the contributions of the species formed by the interaction between metal oxides and carrier may be reasonably expected together with those of the above chemical compounds. The former contributions have been extensively studied by many researchers.[4-10] When each of V_2O_5 andCr_2O_3 was supported on γ-Al_2O_3 or SiO_2 by impregnation, various problems were encountered, among which one can quote the stabilization and the role of different valency states of metals. The system under study appears to show further complexity due to the binary oxide being supported on γ-Al_2O_3 or SiO_2 by the kneading method.

X-Ray diffraction diagrams of the I-series catalysts are shown in Fig. 11. Several weak diffraction lines of V_2O_5, $Cr_4(V_2O_7)_3$, and Cr_2O_3 were observed together with two broad lines of fine SiO_2 crystals. The γ-Al_2O_3 supported systems (G- and H-series) did not exhibit any lines other than the broad lines of γ-Al_2O_3. The indication is that the crystal of the metal oxides developed better on SiO_2 than on γ-Al_2O_3, the interspacing of the lattice planes of each metal oxide being the same as that of each pure oxide. Yoshida *et al.*[5] reported that γ-Al_2O_3 interacts with V_2O_5 more strongly than SiO_2 as a carrier of the impregnated catalyst. In the system here, prepared by the kneading method, further interaction may be expected as observed in the case of the coprecipitated Cr_2O_3–Al_2O_3 (Cr_2O_3; 19.6 mol %) system, in which the only structure detected by X-ray diffraction measurement was γ-Al_2O_3.[9] Infrared absorption spectra of the γ-Al_2O_3-supported system showed a strong broad band of γ-Al_2O_3 below 1000 cm^{-1} which covered the characteristic absorption bands of V_2O_5, Cr_2O_3, and chromium isopolyvanadates.[3] The binary systems supported on SiO_2; I-0—I-7, exhibited weak absorption bands centered at about 950 and 870 cm^{-1}, together with the strong absorption bands at 1100 and 800 cm^{-1} of SiO_2. The weak bands may be assigned to the vibrations of VO_3 in $Cr_4(V_2O_7)_3$,[3] the formation of $Cr_4(V_2O_7)_3$ together with V_2O_5 and Cr_2O_3 being thus clarified in the binary system of I-series. Such formation need not be excluded from the γ-Al_2O_3-supported system, though it may not be detected.

Recently, XPS studies have been conducted to elucidate the surface properties of γ-Al_2O_3-[7] or SiO_2-[6] supported chromia systems. The advantages of the XPS technique are its ability in simultaneously detemining the valencies of metal ions on the surface layer (−10 Å) of the catalyst and the interaction between the catalyst and the support. The first XPS spectra of Cr^{5+} were observed by Okamoto *et al.*[7] who emphasized that the spin-orbit splitting of the Cr 2p level (ΔE) is useful together with the binding energy for discriminating the valence states of chromium. Moreover, it was pointed out that the chromium species on the catalyst surface can readily be photo-reduced by X-ray radiation during XPS measurements.[6,7] In order to avoid surface reduction, all spectra of the Cr 2p level were measured within 10 min exposure to X-ray flux, in which the photo-reduction

Table 4. Binding energy of Cr 2p3/2 and V 2p3/2, spin-orbit splitting of Cr 2p level, and assignment of valency of chromium

a) Cyclohexene (20.0 ml), benzene (50.0 ml), the catalyst (50.0 mg), and BHPO (0.1 ml) were used. The reaction temperature was 60 °C, the reaction time 4 h, and the O_2-pressure 1 atm. b) The catalysts (Me-Cr-γ-Al_2O_3) were prepared from the following raw materials; NH_4VO_3, $(NH_4)_6Mo_7O_{24}\cdot4H_2O$, $5(NH_4)_2O\cdot12WO_3\cdot5H_2O$, $Co(NO_3)_3\cdot6H_2O$, $Mn(NO_3)_3\cdot xH_2O$, $Cr(NO_3)_3\cdot9H_2O$, and alumina hydrate by the kneading method. The concentration of metal oxides supported on each catalyst was 20 wt % when calculated as V_2O_5, MoO_3, WO_3, Co_2O_3, Mn_2O_3, and Cr_2O_3. The composition of the binary system (Cr/(Me+Cr)) was 30 atom %.

was found to be negligible. The results of XPS measurements are shown in Table 4, the assignment of the valence states of chromium being done according to the results by Okamoto *et al.*[7] In the valence state of vanadium, Larrson *et al.*[19] observed a shift of the V 2p3/2 binding energy between V_2O_5 (516.6 eV) and $VO(acac)_2$ (515.1 eV), but it was not observed here (Table 4). Valdelievre *et al.*[20] obtained the V 2p3/2 values of 515.5 eV for V_2O_5 and 516.0 eV for V_2O_4 when studying the V_2O_5 catalyst in the oxidation of propylene. Therefore, it may be difficult to determine the valence state of vanadium, importance being given to the fact that the V 2p3/2 binding energy is lower on SiO_2 than on γ-Al_2O_3.

Active Sites. The active sites on the supported V–Cr binary oxide catalyst may be classified into two types; autoxidation and selective epoxidation.[2] The latter site may consist mainly of vanadium species, although the details have not been clarified. The activities of several Me–Cr systems, when Me is V, Mo, W, Co, and Mn, have been compared (Table 5), exhibiting the following order of activity for selective epoxidation; Mo–Cr-γ-Al_2O_3>V–Cr-γ-Al_2O_3>W–Cr-γ-Al_2O_3. The order of metals, *i.e.*, Mo>V>W, agrees well with that observed in the selective epoxidation of olefins with organic hydroperoxide using soluble metal complexes.[21] Co, Mn, and Cr species did not contribute to the epoxidation but accelerated the autoxidation. Thus, the Mo–Cr or V–Cr binary system showed a high yield of OXIDE whose formation may

have been aided by the dual functions of the systems, as observed in the homogeneous mixed catalyst system by Fusi *et al.*[22] and Arzoumanian *et al.*[23]

The former site appears more complex than the latter since the the value of R_{max}/S depends largely on the carrier (Figs. 4 and 5) and the composition of the binary system (Fig. 5). The activity of the G-series showed a maximum value at a composition of 50 atom % Cr, which may be due to the formation of chromium isopolyvanadates, as reported in the unsupported system.[3] Such an increase in the activity due to chemical compound formation may be also expected in the H-series and especially in the I-series, in which the formation of $Cr_4(V_2O_7)_3$ was clearly observed. A more important problem, however, appears to be the effect of the carrier on the activity. At high Cr content on γ-Al_2O_3, the H-series gives a higher rate and a simultaneously higher valence state of chromium (Table 4) than the G-series, suggesting the active species of highly charged chromium ions. The high valence state of chromium (Cr^{5+}) was also observed in the I-series supported on SiO_2 which showed high activity. One of the active species for autoxidation appears, therefore, to be the Cr^{5+} ions which form on the catalyst during preparation. The role of the Cr^{6+} species which still remains in the H-series (prepared from $(NH_4)_2CrO_4$) after calcination can not be ignored, but it is not so clear. The Cr^{5+} ions observed on G-4 and G-6 catalysts may mainly form in the interaction between the catalyst and carrier, since the unsupported system (V–Cr–D-5) does not show such evidence.

Van Reijen *et al.*[4] reported that Cr^{5+} is coordinated mainly tetrahedrally when supported on SiO_2 and square-pyramidally on γ-Al_2O_3, and that the tetrahedral complex (CrO_4) is more reactive than the squarepyramidal one (CrO_5). Such phenomena has also been confirmed in the literature.[8,10] Also the vanadium (V^{4+}) species is coordinated in (VO_4) on SiO_2 and in (VO_5) on γ-Al_2O_3,[4,5,24] and the (VO_4) on SiO_2 is highly reactive towards, *e.g.*, C_2H_4, being subsequently transformed into the stable (VO_5).[4] By contrast, the (VO_5) is more stable than the corresponding configuration of Cr^{5+}, *i.e.*, (CrO_5).[4] Moreover, when considering the coordination state in aqueous solution of the catalyst preparation, the tetrahedral $(CrO_4)^{3-}$ ion may be preferentially found in highly alkaline solution[25] whereas the coordination is square-pyramidal in acid solution, as well known for V^{4+} in many vanadyl complexes.[26] A part of the Cr^{5+} ions on H-10 and H-7 can be reasonably coordinated in the tetrahedral configuration, whereas those on G-8 in the square-pyramidal configuration. The order of reactivity of these configurations has been given by van Reijen *et al.*[4] as follows; (VO_4)>(CrO_4)>(CrO_5)>(VO_5), in which only the (VO_4) is unstable. This order appears to explain the activity of the supported V–Cr binary system catalyst, when the configurations of vanadium and chromium complexes might be allowed on the carriers as described above. On SiO_2, the catalyst abundant in vanadium exhibited high activity (Fig. 5, R_{max}-A/S) at the beginning of reaction, which decreased (R_{max}-B/S) in the course of reaction. This may be due to the high reactivity and instability of the (VO_4) complex. The subsequently high activity of the chromium abundant catalyst on SiO_2 may be due to the (CrO_4) species which is reactive and simultaneously stable. When supported on γ-Al_2O_3, the catalysts of the H-series expected to contain the (CrO_4) complex in abundance exhibited higher activities than those of the G-series rich in chromium. It has been reported that the (CrO_4) complex was formed on SiO_2 even when small amounts of chromia was supported,[6] and therefore, the rapid increase in activity of the V–Cr–SiO_2 systems (Fig. 4) may be due to the (CrO_4) species formed. The tetrahedral complexes are thought to catalyze the autoxidation of cyclohexene through HPO decomposition (Reactions 5 and 6) which proceeds *via* coordination of HPO to a vacant site in the complex. The low activities of the G- and H-series of high vanadium content and also of the G-series of high chromium content may be attributed to the (VO_5) and (CrO_5) species, respectiviely, on γ-Al_2O_3 (Fig. 5). Thus, the activity of the supported V–Cr binary catalyst can be thought principally due to the formation of the two types of configuration; tetrahedral on SiO_2 and square-pyramidal on γ-Al_2O_3. It is supposed that the two modes of configuration are performed against the surroundings of the carrier, *i.e.*, the tetrahedral structure of SiO_2 and the spinel structure of γ-Al_2O_3.[10] The contribution of chemical compounds, such as chromium isopolyvanadates, appear to overlap the principal contribution of the two configurations, as observed in the G-series (Fig. 5).

Population Analysis of (*R*)-Thiazolidine-4-carboxylic Acid

Jun KAMO,† Nobuo TANAKA,* Yoshiki MATSUURA, Tamaichi ASHIDA,††
and Masao KAKUDO

Institute for Protein Research, Osaka University, Suita 565

(Received August 31, 1978)

The structure of (*R*)-thiazolidine-4-carboxylic acid was refined at 111 and 293 K, respectively. Population analysis, which refines the population of the electrons in the molecule, was carried out, the result being compared with that of theoretical calculation.

In studies on structure by means of X-ray diffraction, the recent development of the diffractometer has afforded intensity data accurate enough for discussion of the distribution of the electron cloud. The population analysis[1] deals with the observed electron density distribution quantitatively. The number of electrons in each non-bonded and bonded orbital is derived from the refinement, from which bond orders and charge distribution of the molecule can be discussed.

(*R*)-Thiazolidine-4-carboxylic acid is an analogue of the proline and cysteine, and the structure was determined by Chacko.[2] In this paper, the structure of this molecule at both 293 and 111 K was refined by the population analysis method, the electronic structure being discussed in comparison with the theoretical one.

Experimental

Two sets of intensity data were measured at 293 and 111 K with a four circle diffractometer. Each set has 4 octants of the reciprocal space measured in 2θ-θ mode. The crystal data and experimental conditions are given in Tables 1 and 2, respectively. The crystal was treated with liquid nitrogen before the data collection in order to prevent from suffering of the extinction effect. The average structure amplitudes among the equivalent reflections in each set was used for further calculations. The estimated standard deviations, $\sigma(|F_o|)$ of the amplitudes are given by

$$\sigma(|F_o|) = \sqrt{\sum_i \sigma_i(|F_i|)^2/N},$$

where σ_i denotes the e.s.d. of i-th equivalent reflection.

Structure

The structure was determined independently with the program of automatic structure determination.[3] The conventional refinement of the structure was carried out by the full matrix least squares method, applying the following weighting scheme.

$$\text{wt} = c \text{ when } |F_o| = 0$$

$$\text{wt} = 1.0/(\sigma(|F_o|)^2 + a|F_o| + b|F_o|^2) \text{ when } |F_o| > 0$$

a, b, and c were adjusted in such a way that the differences between the calculated and observed structure amplitudes are uniform in any region of the reciprocal space. The absolute configuration of the molecule was also determined to be the *R*-configuration from the anomalous scattering of the sulfur atom (Table 3).

After the refinement with all reflections, the structure was refined using the higher order reflections only at 111 K ($\sin\theta/\lambda \geqq 0.65$, hereafter HOR) to reduce the effect of the bonding electrons. In comparison with the case of the low-temperature refinement based on all the reflections, all the positional parameters showed no significant shifts , the values of the temperature factors becoming smaller than those of all the reflections as expected (Table 5).

The bond lenghts and angles, shown in Fig. 1, are essentially the same as those reported by Chacko.

final parameters of HOR (Figs. 2 and 3). Some density humps probably due to the bonding electrons are found on the C_3–S–C_4 plane. Peaks A and B are situated off the bonds S–C_3 and S–C_4, respectively, in particular deviating from the S–C_4 bond direction. This was found in both the high and low temperature maps, the angles of A–S–B being 105 and 97°, respectively. This indicates that the 3p atomic orbital of the sulfur atom is hybridized with the 3s orbital, the humps due to the bonding electrons deviating from the interatomic vectors as seen in cyclopropane.[5] The

Each value was estimated from the anisotropic temperature factors.[4]

difference maps contain some peaks at the center of each atom. This might be caused by the poor accuracy of reflections intensities of high order. This is verified by the difference Fourier synthesis shown in Fig. 4 which was carried out by means of the reflections of $\sin\theta/\lambda<0.65$. No peaks were observed at the atomic positions. The three maps (Figs. 2, 3, and 4) contain peak D which may be assigned to the lone pair electrons of the sulfur atom.

Population Analysis

The distribution of electron density is defined as a sum of the square of the absolute value of the occupied molecular orbitals.

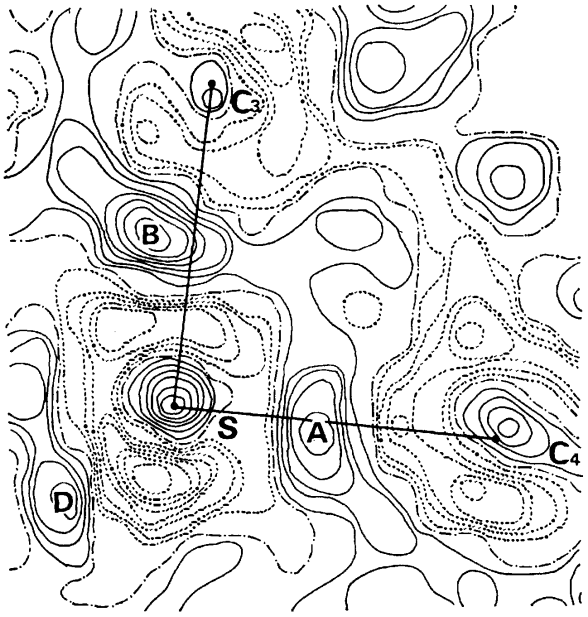

Fig. 2. Difference electron density map in the C_3–S–C_4 plane (111 K). Contours are drawn at the interval of 0.05 e/Å^3. The solid lines are above 0 e/Å^3 and the broken lines are below 0 e/Å^3.

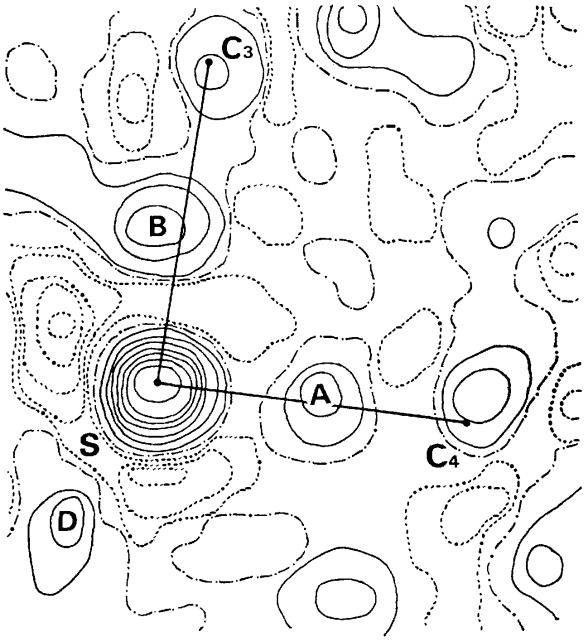

Fig. 3. Difference electron density map in the C_3–S–C_4 plane(293 K).

$$\rho = \sum_{i}^{\text{occupied}} \Psi_i^* \Psi_i \tag{1}$$

The molecular orbital is represented as a liner combination of the atomic basis function ϕ_μ

$$\Psi_i = \sum_{\mu} C_{\mu i} \phi_\mu \tag{2}$$

Substituting Eq. 2 into Eq. 1, we have

$$\rho = \sum_{i}^{\text{occupied}} \sum_{\mu,\nu} C_{\mu i}^* C_{\nu i} \phi_\mu^* \phi_\nu = \sum_{\mu,\nu} P_{\mu\nu} \phi_\mu^* \phi_\nu \tag{3}$$

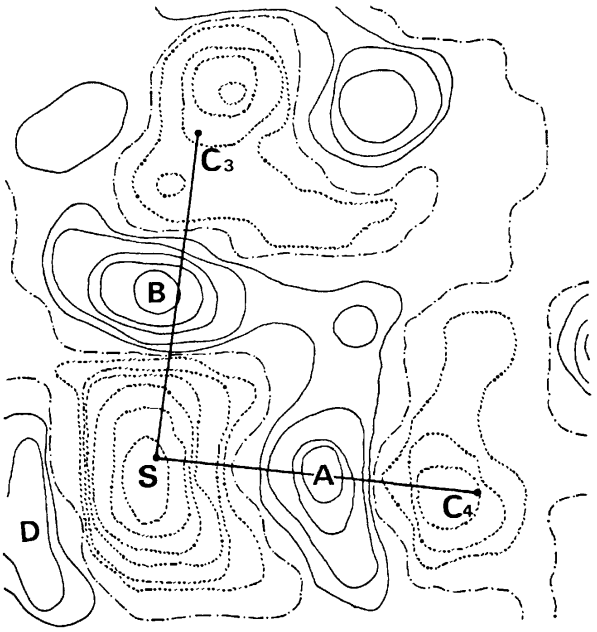

Fig. 4. Difference electron density map in the C_3–S–C_4 plane using only low order reflections($\sin\theta/\lambda < 0.65$) at 111 K.

$$P_{\mu\nu} = \sum_{i}^{\text{occupied}} C_{\mu i}^* C_{\nu i} \tag{4}$$

where $P_{\mu\nu}$ is a population parameter. The structure factor of the crystal is represented by

$$F_h = \sum_{j,k} \boldsymbol{F}[\rho_k] \cdot T_{kj} \cdot \exp(i\boldsymbol{s} \cdot \boldsymbol{r}_{kj}) \tag{5}$$

j: atom
k: symmetry operation
$\boldsymbol{F}[\rho_k]$: molecular transform
T_{kj}: temperature factor

where

$$\begin{aligned} \boldsymbol{F}[\rho] &= \sum_{\mu,\nu} P_{\mu\nu} \boldsymbol{F}[\phi_\mu^* \phi_\nu] \\ &= \sum_{\mu,\nu} P_{\mu\nu} \int \phi_\mu^* \phi_\nu \exp(i\boldsymbol{s} \cdot \boldsymbol{r}) d\boldsymbol{r} \\ &= \sum_{\mu,\nu} P_{\mu\nu} X_{\mu\nu} \end{aligned} \tag{6}$$

$X_{\mu\nu}$ is called the generalized structure factor. In the population analysis developed by Stewart,[1] the structure factor, F_h, is separated into two parts, F_h(atom) and F_h(bond), the former consisting of the atomic orbitals from one atom only, and the latter showing the effect of the overlap between orbitals of the bonded atoms. As a whole, considering the anomalous effects, F_h is written as follows.

$$F_h = F_h(\text{atom}) + F_h(\text{bond}) = A + iB, \tag{7}$$

$$\begin{aligned} A = \sum_{j,k} [&(f_{\text{core},j} + f_j' + P_{vj} f_{vj} - 3 f_{np,np,j} Q_{kj}) \cdot \\ &\cos(2\pi h r_{kj}) \cdot T_{kj} - (f_j'' + \sqrt{3} f_{ns,np,j} D_{kj}) \cdot \\ &\sin(2\pi h r_{kj}) \cdot T_{kj}] + \sum_m b_m f_{\text{bond},m} \sum_k \cos(2\pi h r_{km}) \cdot T_{km}, \end{aligned}$$

$$\begin{aligned} B = \sum_{j,k} [&(f_{\text{core},j} + f_j' + P_{vj} f_{vj} - 3 f_{np,np,j} Q_{kj}) \cdot \\ &\sin(2\pi h r_{kj}) \cdot T_{kj} - (f_j'' + \sqrt{3} f_{ns,np,j} D_{kj}) \cdot \\ &\cos(2\pi h r_{kj}) \cdot T_{kj}] + \sum_m b_m f_{\text{bond},m} \sum_k \sin(2\pi h r_{km}) \cdot T_{km}, \end{aligned}$$

$$f_{\text{core}} = 2X_{1s,1s} \text{ or } 2X_{1s,1s} + 2X_{2s,2s} + 6X_{2p,2p},$$

$f_v = aX_{ns,ns} + bX_{npx,npx} + cX_{npy,npy} + dX_{npz,npz}$,

a, b, c, d: the scattering of electrons in each orbital

$f_{ns,np}$: the scattering effect due to the overlap between ϕ_{ns} and ϕ_{np}

$f_{np,np}$: the scattering effect due to the overlap between ϕ_{npx} and ϕ_{npy}, or ϕ_{npy} and ϕ_{npz}, or ϕ_{npz} and ϕ_{npx}

f_{bond}: the scattering factor of the postulated orbital at the center of the bond (r_m)

D_{kj} and Q_{kj} in Eqs. are expressed in terms of parameters d and q in this table.

$D_{kj} = d_{xj}S_{xsj} + d_{yj}S_{ysj} + d_{zj}S_{zsj}$

$Q_{kj} = q_{1j}(S_{xsj}^2 - S_{ysj}^2) + q_{2j}(S_{zsj}^2 - 1/3) + q_{3j}S_{xsj}S_{ysj} + q_{4j}S_{xsj}S_{zsj} + q_{5j}S_{ysj}S_{zsj}$

S_{xsj}, S_{ysj}, and S_{zsj} are direction consines of the scattering vector to the principal axes of the p_x, p_y, and p_z orbitals of the j-th atom, respectively.

a) Calculated from the differences in electronegativity of the neighboring atoms with Mulliken's equation.

The parameter P_v is the number of valence electrons associated with the j-th atom. A dipole distortion of these spherical valence electrons is described by D and a quadrupole distortion by Q. The extended L-shell method(ELS) refines P_v after the usual refinement of the positional and thermal parameters. P, Q, and D are treated as adjustable parameters in the one-center refinement(OCR). The two-center refinement (TCR) includes the b_{mk} term as variables in addition to those of OCR.

In the present calculation, the $f_{core,j}$'s of the carbon and nitrogen atoms are taken from those calculated by use of Clementi's analytical SCF atomic orbitals.[6] f_{vj}'s of these atoms being taken from these calculated by use of the Slater-type atomic orbitals.[7] f_v of the hydrogen atom is taken from Stewart-Davidson-Simpson's value,[8] f_{core} and f_v of the sulfur atom are from the Roothaan-Hartree-Fock wave function by Fukamachi[9] and $f_{ns,np}$ and $f_{np,np}$ are those of Stewart.[10] In the case of TCR, f_{bond} is taken as $\overline{X_{ns,ns}(s\cdot r)}$ at the center of each bond where $\overline{X_{ns,ns}(s\cdot r)}$ is a spherically averaged value of the overlapping function between the ns-orbital. The population analysis of the present molecule at 111 and 293 K was carried out after the usual refinement, using ELS, OCR, and TCR, successively. The computer program was written by one of the authors (J.K.). The positional and thermal parameters of OCR and TCR are fixed to the values of ELS. The R factors and scale factors after the refinement are given in Table 6. The R factor decreased from that of the usual refinement, the scale factor of $|F_o|$ becoming close to that of HOR.

The population parameters, thus refined, are compared with the theoretical values calculated by the CNDO method (Table 7). Experimental and theoretical charges are given in Table 8. The experimental values show as a whole the same distribution as the theoretical values except for the hydrogen atoms. However, the charge of the sulfur atom in the low-temperature data deviates considerably from that of CNDO and EN, because of errors in $|F_o|$'s and inaccuracy in the scattering factor of the sulfur atom.

The dipole moment of the molecule can be calculated from the charge distribution in the density map. The absolute values of the dipole moment of the molecule, 11.4 Debye at 111 K and 9.3 Debye at 293 K are roughly in line with the theoretical value (13.2 Debye). However, their directions do not agree with each other.

Discussion

In the present work, we used the higher order reflections refinement to reduce the effect of the spread of the electron cloud. The effect, however, still remains in the parameters, in spite of the considerable depression of the temperature factor (Table 5). The population analysis seems to refine the electronic structure of the molecule; the overall scale factor is improved so as to become close to the value of the HOR, the R factor decreasing significantly from the usual refinement. Some discrepancy in distribution is found between the X-ray and theoretical results. In particular, the sulfur atom at 111 K has a more negative charge than that at 293 K and CNDO. This may be explained as follows:

1) The population analysis treats the small differences between the conventionally calculated structure factors and the observed. The data at 111 K have four times weaker intensities than those at 293 K, depending on the size of the crystal used. Though the smaller crystal gives less systematic errors due to absorption and extinction in the data, the experimental errors in the weaker intensities at 111 K may give rise to some discrepancies.

2) The discrepancy may be due to the neglect of the d-orbital of the sulfur atom and the different character between the L- and M-shell orbitals which are not distinguished in the present analysis.

In spite of these discrepancies we can say that the population analysis throws light on the character of the molecule.

The authors wish to express their thanks to Professor Nobutami Kasai and Dr. Noritake Yasuoka for the use of their diffractometer equipped with a crystal cooling system.

Molecular Structure and Internal Rotation of Trimethylamine-Boron Trifluoride. A Combination of Electron Diffraction and Spectroscopic Data

Kinya IIJIMA and Shuzo SHIBATA*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received September 7, 1978)

The molecular structure of trimethylamine-boron trifluoride $(CH_3)_3N \cdot BF_3$ was determined from gas electron-diffraction data with vibrational and rotational spectroscopic data. The geometric parameters of the molecule were found to be very close to those inferred from the preliminary analysis of the diffraction data alone. The structural parameters and uncertainties were r_g(N–B)=1.674(4) Å, r_g(B–F)=1.374(2) Å, r_g(C–N)=1.485 (2) Å, r_g(C–H)=1.100(3) Å, r_g(F···F)=2.288(2) Å, and r_g(C···C)=2.420(4) Å. The potential barrier about the N–B axis was estimated to be 4.3±0.3 kcal/mol in the gas phase; this value is much larger than that from NMR spectra.

Several studies have recently been carried out on the gas-phase structure of trimethylamine-boron trifluoride $(CH_3)_3N \cdot BF_3$,[1-3] which is a representative of donor-acceptor molecular complexes, in order to clarify the difference in the molecular structure between the gas and the solid. However, there are considerable discrepancies among the results from electron diffraction[2,3] and microwave spectra:[1] *e.g.*, the N–B distance determined by microwave spectroscopy is about 0.03 Å shorter than that from electron diffraction. The electron diffraction study by Hargittai and Hargittai[3] also gave different results from ours,[2] especially for the B–F and C–N distances, though the rotational constant calculated using their results did not agree well with the observed one. On the other hand, this molecule has an internal rotation about the N–B bond, and the rotational barrier was found to be 1.7 kcal/mol from the NMR study in the solid phase.[4] The height of the barrier seems to be too small, compared with those in other ethane-like molecules.[5] The height of the potential barrier about the N–B bond cannot be estimated from IR or Raman vibrational spectroscopic studies, because the torsional vibration is inactive in these spectra. It is therefore very desirable to estimate it from a combined analysis of electron diffraction intensities with spectroscopic data. Thus, the molecular structure of $(CH_3)_3N \cdot BF_3$ was reinvestigated in order to determine more accurate molecular parameters as well as the height of the potential barrier about the N–B bond, by means of a joint analysis of gas-electron diffraction and spectroscopic data.

Experimental

Trimethylamine and boron trifluoride gases, which were prepared by the procedures described in the literature,[6,7] were condensed in a flask cooled by liquid air and were allowed to react while being warmed slowly to room temperature. A white product was purified by sublimation under vacuum, and its infrared spectrum[8,9] revealed no impurities. In the electron-diffraction experiment the sample was vaporized at about 130 °C by means of a high tepmerature nozzle, and photographs were taken with an r^3-sector at the camera distances of 144 and 294 mm. The accelerating voltage was 40 kV. The exposure time at the short camera distance was 60 s, using an electron-beam current of 0.8 μA, and that at the long camera distance was 20 s, using a beam current of 0.6 μA. The pressure of the diffraction chamber was below 1×10^{-5} Torr during the experiment. The electron wavelength was measured using diffraction patterns of thallium chloride powder.[10] Photographs were recorded on Fuji spectroscopic plates, and the optical densities of four short and three long camera distance plates were measured at 0.4 mm intervals by means of a digital microphotometer. The electron-diffraction unit and digital microphotometer used in the present study were described elsewhere.[11]

Analysis and Results

Molecular Intensity and Radial Distribution. The scattering intensities were obtained in the range of s=2.5—17.3 and 5.0—33.0 Å^{-1} from the photographic plates at long and short camera distances, respectively. They were leveled by the theoretical backgrounds, and then the leveled intensities of several plates for each camera distance were averaged. The background curves were drawn smoothly by hand for the long distance data and were fitted by a polynomial of 7th degree[12] for the short distance data, and then the molecular intensities for each camera distance were joined at s=14.8 Å^{-1}. Figure 2 shows the observed intensities and Fig. 3 shows the experimental radial distrubution curve. The elastic and inelastic scattering factors were taken from the tables prepared by Kimura *et al.*[13] and Cromer and Mann,[14] respectively. The inelastic scattering factor for the hydrogen atom was taken from Ref. 15.

Mean Amplitude of Vibration and Shrinkage Effect. Several workers have measured the vibrational spectra of $(CH_3)_3N \cdot BF_3$ in the solid phase and calculated the force field.[9,16] However, these calculations seem not to be reasonable because a large number of

unknown parameters were used; *e.g.*, Laswick and Taylor obtained forty force constants on the basis of twenty wave numbers measured for each of five isotopic species.[9] In the present study, a modified Urey-Bradley force field was adopted in order to reduce the variable parameters. The force constants used are shown in Table 1, and the calculated wave numbers are listed in Table 2, where the spectra were assigned according to the notation suggested by Laswick and Taylor.[9] The mean amplitudes of vibration and shrinkage effects,[17] r_a-r_α, at 130 °C, which were calculated using the above force constants, are shown in Table 3. The calculated mean amplitudes of most atomic pairs agreed well with the observed ones, but the observed mean amplitude of the N–B bond is significantly larger than the calculated one. The reason for this disagreement is that the calculation was carried out on the basis of the vibrational spectra observed in the solid state, where the N–B bond strength is probably enhanced.

a) Results from joint analysis of electron diffraction data and rotational constant.

were treated in a high barrier approximation.[18] However, the torsional vibration around the N–B axis which was completely isolated from other vibrations contributes greatly to the *gauche* F···C mean amplitude. The mean amplitude of the *gauche* F···C calculated without consideration of this motion resulted in 0.099 Å. The electron diffraction experiment gave the mean amplitude of 0.154±0.003 Å, as listed in Table 5. The difference between the two values suggests a significant contribution of the torsional vibration around the N–B bond. Therefore, the force constant Y in the formula $V=(1/2)Y\Delta t^2$, where V is a potential energy and Δt is an internal coordinate in the torsional vibration, was chosen so that the calculated mean amplitude of the *gauche* F···C was in agreement with the observed one. Thus the force constant Y and the wave number of the vibration were estimated to be 0.134±0.010 mdyn·Å and 67±3 cm^{-1}, respectively. The errors were estimated from that of the observed *gauche* F···C mean amplitude. If the potential function around the N–B bond is assumed to be $V(t)=(1/2)V_0(1-\cos 3t)$, where V_0 is the height of the potential barrier, V_0 can be estimated to be 4.3±0.3 kcal/mol using the relation $V_0=(2/9)Y$.

On the other hand, the torsion around the N–B bond was also treated in a low barrier approximation,[18] and then the molecular intensities were calculated by the average over the torsional angle at 5° intervals, using the weight of the Boltzmann factor $\exp(-V/kT)$. The *gauche* F···C mean amplitude was assumed to be 0.099 Å at each torsional angle. Thus radial distributions were obtained from the molecular intensites calculated using assumed values of V_0, as shown in Fig. 3. The radial distribution obtained from $V_0=$ 4.5 kcal/mol gave the same shape of the *gauche* F···C peak as in the experimental radial distribution, and the value of V_0 was consistent with that obtained from the analysis of a high barrier approximation.

Analysis of Electron Diffraction Intensities and Rotational Constants. Shrinkage effects were considered and the molecular parameters in the r_α structure were determined by the least-squares analysis of the molecular intensities; these are shown in Table 4. It is assumed that the molecule of $(CH_3)_3N \cdot BF_3$ has a staggered form with C_{3v} symmetry, and that the methyl group also has local C_{3v} symmetry in the staggered form with respect to the C–N axis. The mean amplitudes (except those listed in Table 5) were fixed as shown in Table 3, and the asymmetry parameters κ for the C–H, B–F, N–B, and C–N bonds were estimated to be 12, 2.4, 11, and 2.5×10^{-6} Å^3, respectively, by a diatomic approximation.[19] The κ parameters for other atomic pairs were ignored.

Bryan and Kuczkowski obtained the rotational constant B_0 value of 1756.073±0.01 MHz for the normal species of $(CH_3)_3N \cdot BF_3$.[1] The vibrational correction for the rotational constant[20] was made by the library program in the Computer Center of the University of Tokyo; B_z was 1756.17 MHz. The uncertainty in the vibrational correction was tentatively assumed to be 80%. The r_α parameters in Table 4 was transformed to r_α^0 parameters by extrapolating $r_a - r_\alpha$ to zero kelvin.[17] Here the anharmonic contributions were estimated by a diatomic approximation. The rotational constant calculated from the r_α^0 parameters was 1758±12 MHz, which was in good agreement with the experimental B_z. Although the parameters obtained from the above electron diffraction analysis

a) Observed rotational constants, Ref. 1; the vibrational corrections, $\Delta B=B_0-B_\alpha^0$, are adout 0.1 MHz. b) Rotational constants caluculated from the r_α^0 parameters in Table 4. The correlations between the parameters were taken into consideration in calculating the errors. c) The C–D distance and NCD angle were assumed to be equal to r(C–H) − 0.0015 Å and ∠NCH − 0.16°, respectively.[21]

were quite compatible with the rotational constant determined by the microwave experiment, the joint analysis of electron diffraction intensities and rotational constant was performed. The relative weight for the observed rotational constant in the least-squares calculation was estimated to be 6×10^8, in such a way that 2.5 times the standard deviation of the rotational constant obtained from the least-squares calculation is nearly equal to the uncertainty in B_z. The r_α^0 parameters and mean amplitudes determined by the joint analysis are given in Tables 4 and 5, together with the r_g parameters and their associated errors. The errors were estimated from random errors in the least-squares calculations and systematic errors originating from the measurements of camera distance and electron wavelength. The correlation matrix is listed in Table 6. The results from the joint analysis were the same as those obtained from the preliminary analysis.[2] The errors for the molecular parameters were much smaller than those from the study by Hargittai and Hargittai,[3] though there seems to be systematic devitation between the two sets of data. The calculated rotational constants were in quite good agreement with the observed ones, as listed in Table 7. Recently, the microwave spectra of deuterium and carbon-13 enriched samples of $(CH_3)_3N\cdot BF_3$ have been studied.[1] The rotational constants for these isotopic species were calculated using the parameters obtained by the above joint analysis, and their calculated values are also in agreement with the observed values, as shown in Table 8. The best-fit theoretical intensity curve is shown in Fig. 2.[22]

Discussion

The joint analysis of electron diffraction and vibrational spectra gave the result that the height of the potential barrier hindering the internal rotation of $(CH_3)_3N\cdot BF_3$ is 4.3 kcal/mol in the gas phase. This corresponds to that of Cl_3CSiCl_3.[18] The height of the potential barrier of $(CH_3)_3N\cdot BF_3$ is considerably larger than that of $H_3P\cdot BH_3$, 2.47 kcal/mol, which was obtained from microwave spectroscopy.[23] The increase of the potential barrier can be attributed to the large size of fluorine atoms and methyl groups and the smaller N–B distance in $(CH_3)_3N\cdot BF_3$. A wide line NMR study of $(CH_3)_3N\cdot BF_3$ in the solid phase showed that the barrier around the N–B axis was rather small, 1.7 kcal/mol.[4] The reason for this discrepancy is unknown, though one should be careful in comparing the values obtained by the two different methods.

Comparing the molecular structure of $(CH_3)_3N \cdot BF_3$ with those of the component molecules of $(CH_3)_3N$ and BF_3[24,25] (Table 4), the C–N and B–F distances increase by the complex formation by 1.6 and 4.5%, respectively, and the CNC and FBF angles decrease by 1.4 and 5.8%, respectively. This shows that the changes in the molecular parameters of the acceptor are much larger than those of the donor. In the solid phase, the molecule takes the same configuration as in the vapor phase, but the bond distances and the angles in the crystal[26] are considerably different from those in the vapor phase (Table 4). The C–N and B–F bond distances are longer and the N–B bond distance is shorter than those in the vapor phase. These changes indicate that the donor-acceptor bonding is enhanced in the solid state. The increments of the C–N and B–F bond distances are 2.9 and 6.0%, respectively, and the rate of the decrease of the FBF angle is 10.8%; these results are obtained by comparing the structural data from X-ray with those for the gaseous component molecules.

The authors are indebted to Dr. Tsutomu Fukuyama of the University of Tokyo for his advice in the computer calculation.

High-resolutional Calorimetric Study on Solid Solutions $SnCl_2(H_2O)_x(D_2O)_{2-x}$

Masami TATSUMI,† Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received September 4, 1978)

Heat capacities of the system of solid solutions $SnCl_2$ $(H_2O)_x(D_2O)_{2-x}$ (x=2.00, 1.97, 1.75, 0.96, 0.50, 0.25, and 0.03) were measured by an adiabatic calorimeter capable of determinations of heat capacity with the temperature step of 5—10 mK. The heat capacity peak due to order-disorder change of hydrogens becomes broader and its transition temperature rises as the deuteron concentration is increased. A small first-order component was found in the crystals of x=2.00, 1.97, and 1.75. Measurements were repeated for aged crystals of x=0.96, 0.50, and 0.03. Nature of the phase transition has been discussed in analogy with the liquid-vapor critical point. From the heat capacity data around the glass transition it is concluded that the motion of the hydrogen atoms is strongly correlated with each other over a range whose size is large enough that fluctuation of the local isotopic composition from the average is negligible.

The phase transition in tin(II) chloride dihydrate $SnCl_2 \cdot 2H_2O$ (abbreviated as TCD) was discovered by Kiriyama *et al.*[1] The complete crystal structure was determined by them by using the X-ray[2] and the neutron diffraction[3] techniques. The crystal consists of layers of tin(II) chloride molecule alternating with layers of water molecules. There are two types of water molecules in the layers. One of them, designated as H_2O (1), is coordinated to the tin(II) ion and the other, H_2O (2), is a water of crystallization. Each type of water molecules is hydrogen-bonded to three others of different type in the same layer parallel to the (100) plane. In the hydrogen bonding network, there are seven kinds of positions which deuterons can occupy and the three types of hydrogen bond with different bond length.[4-7] The O(2)···O(1′) hydrogen bond differs from the other two in that its bond length increases anomalously below T_c, in contrast to the other two which contract as the temperature is lowered.

An unusual property of the phase transition in TCD is that there occurs no change of symmetry of the crystal at the transition, including that pertaining to the hydrogen atom. The space group is $P2_1/c$ both below and above the transition. No symmetry elements are lost or gained on passing through the transition. It is generally assumed that a phase transition of any substance is accompanied by a change of symmetry of the substance. The symmetry in question may be that of the distribution function of the atoms in the crystals or that of the average spin orientation in magnetic substances. More abstract symmetry of wave function is relevant to superconductivity and the λ-transition of liquid helium. It is generally observed that one or more of the symmetry elements disappear as the substance undergoes the phase transition. The symmetry change is thus a general characteristic of phase transitions.[8] In fact, Landau theory of the phase transitions of the second kind connects the symmetry change with the thermodynamics of the phase transition through appropriate definition of the order parameters. If there is no change in the symmetry of the crystal, how can one distinguish one phase from the other? One cannot tell one phase from the other from the atomic distribution function alone because there is no qualitative difference between the distribution functions of the two phases. A question thus arises as to whether the two phases are really different from each other.

From the calorimetric point of view, the phase transition in TCD is characterized by a sharp peak of the heat capacity.[9,10] The anomalous heat capacity increases symmetrically from both sides of the transition point. This has been recognized as a distinguishing feature of the two-dimensional phase transition. A small isothermal increment of the enthalpy (33.0 J mol^{-1} or 3.5% of the total transition enthalpy) was observed at the very transition temperature of x=2.00.[9] Thus, the phase transition occurs gradually but is of the first-order nature. These observations suggest formal similarity of the transition in TCD with vaporization of a typical liquid. Thus the liquid and vapor have the same continuous translational symmetry. Below the critical pressure, the vaporization is, of course, a first-order transition. Far below the critical point, there is no gradual increase of enthalpy in the isobaric process both below and above the vaporization temperature. Only the latent heat of vaporization dominates in that process. However, gradual increase of the enthalpy appears as the critical pressure is approached. At the critical point the isothermal change of enthalpy disappears and the heat capacity at the critical pressure diverges strongly. The region beyond the critical point is called supercritical. Here, the heat capacity as a function of temperature will be still large but remains finite. If the analogy between the phase transition in TCD and vaporization of liquid is something more than superficial, one should expect existence of a critical point at an appropriate value of some external parameter of the TCD crystal. In the present study, we have chosen the hydrogen-deuterium isotopic composition as the adjustable "external" parameter and made heat capacity measurement of the mixed crystals of $SnCl_2(H_2O)_x(D_2O)_{2-x}$ for x=2.00, 1.97, 1.75, 1.50, 0.96, 0.50, 0.25, and 0.03.

High resolution measurements of the heat capacity including that of the crystals aged for four years have established that the critical composition does really exist near x=1.50. The phase transition in TCD provides thus an example of a new class of solid state phase transition for which there is no concomitant

† Present address: Sumitomo Electric Industries Ltd., Osaka 541.

change of the symmetry of the crystal. It should be mentioned that the dimer model of Salinas and Nagle[11] which gives a logarithmic singularity of heat capacity at the transition point T_c seems to have a similar property in that the symmetry of the dimer distribution is the same for $T>T_c$ as for $T<T_c$. A relevant problem of the difficulty of defining the order parameter for a certain class of the dimer lattice was first pointed out by Kasteleyn.[12]

Another aspect of interest of TCD crystal is that the anomalous heat capacity has an appreciable magnitude even at a lower temperature where the motion of the hydrogen atom is so slow that it falls out of thermal equilibrium when the temperature is varied at a typical rate of the calorimetric experiment.[10] The temperature at which the average lifetime of the proton (or deuteron) configuration is equal to the time required for the heat capacity measurement, *i.e.*, the temperature where the calorimetric Deborah number[13] is equal to unity, is called the glass transition temperature T_g. Below T_g only the vibrational degree of the crystal is active and contributes to the observed heat capacity. This is a particularly fortunate property of the crystal, because it leads to unambiguous determination of the lattice heat capacity. Occurrence of the glass transition in TCD is intimately related to the structure of the hydrogen-bond network of the crystal. The network structure is such that the hydrogen atoms can change their positions without violating the ice conditions if eight of them move in unison.[10,14] A very different behavior is observed in copper formate tetrahydrate, a similar hydrate crystal with layer structure, in which the ice condition prohibits redistribution of finite number of the hydrogen atoms in the low-temperature phase. The anomalous heat capacity is essentially zero below T_c because the ordering is complete in the whole range of the low-temperature phase. It has been pointed out previously that Bjerrum and ionic defects can have only minor effect that scarcely affects the bulk thermodynamic properties of the copper formate tetrahydrate crystal, although they may be responsible to the dielectric dispersion in the low temperature phase.[15] In the present study the isotope effect on the glass transition in TCD has also been investigated by the heat capacity measurement. It will be shown that the relaxational properties depend on the isotopic composition in a monotonous way. The experimental result presented in this paper will be analysed in the subsequent paper[16] in terms of the general consideration discussed above.

Experimental

Sample Preparation. The single crystals of solid solution of TCD and DTCD were prepared in the following manner. Commercial TCD (extra pure grade from Wakō Pure Chemical Co., Ltd.) was first dehydrated by evacuation for a week. The extent of dehydration was determined by measurement of the weight loss. An appropriate amount of mixture of normal and 99.75% heavy water (E. Merck) having desired composition was added to the dehydrated crystal together with a small quantity of normal or deuterated hydrochloric acid. The slurry was heated to about 45 °C in a closed glass vessel giving a clear solution and cooled slowly after addition of a small piece of single crystal. The crystal was grown in the water bath thermostatted by the proportional controller (within ± 10 mK) for a month. The sample for the calorimetry was cut from a large single crystal, shaped into a cylinder with 25 mm diameter and 40 mm height, and enclosed in a calorimeter cell under atmosphere of helium. All the six single crystals having different isotopic composition were prepared in the same manner.

Determination of the Isotopic Composition. The H_2O concentration in $SnCl_2(H_2O)_{0.96}(D_2O)_{1.04}$ was determined by means of the quantitative absorption intensity measurements of the proton magnetic resonance by use of the high resolution NMR spectrometer (Varian 60). Several mixtures of D_2O and H_2O having different compositions were used as standards for making the calibration curve. The isotopic mixture of water was collected into the NMR tube by vacuum distillation from the calorimetric crystal after completion of the heat capacity measurement. The error in the determination of the deuterium content was estimated to be $\pm 2\%$ from the scatter in the calibration. The mole ratio of H_2O and D_2O in solid solution thus determined agreed with that of the initial mixture. The other solid solutions were assumed to have the same isotopic composition as the slurry.

Calorimeter. The design and construction of the high resolution calorimeter used in the present work was described in detail elsewhere.[17] One of the feature of the adiabatic calorimeter is that it is equipped with two thermometers, that is, a platinum resistance thermometer and a thermistor-thermometer. The former is employed to determine heat capacity with ordinary resolution ($\Delta T \approx 1-2$ K) and the inaccuracy and the imprecision of the heat capacity measurement by use of the platinum resistance thermometer is less than ± 0.1 and $\pm 0.05\%$,[18] respectively, between 50 and 275 K. The latter, the thermistor-thermometer, is essential for high resolution measurement with the temperature step of 10—20 mK. The temperature resolution attained by this thermometer was about 3 μK at 220 K. Meticulously careful attention had to be paid to the adiabatic control in order to exploit the good temperature resolution of the thermistor-thermometer. When the control was left undisturbed, the cell temperature remained constant within 0.3 mK over a period of 24 h. Temperature steps as small as 5 mK could be attained without introducing unduely large imprecision in the result. The performance of the calorimeter was improved by several modifications made since the previous publication of the apparatus. Some of them are briefly described here.

i) Use of an indium O-ring facilitates the vacuum-tight closure of the calorimeter cell.

ii) In order to ease the procedure of assembling the calorimeter cell especially in the dry-box, two gold electric contacts were attached to the hermetic seal as the terminal for the calorimeter-heater-leads.

iii) In order to decrease the heat transfer to the calorimeter cell by conduction along the electrical leads, one of the thermocouple junctions, which was previously located between the calorimeter cell and bottom cone, was fixed to the inner jacket. The copper leads of the two thermometers were replaced by the constantan leads with smaller thermal conductivity.

iv) The significant temperature drift was caused by the stray E.M.F. induced at the terminal of the thermocouple-lead in the previous high resolution measurement. The stray E.M.F. was reduced by decreasing the number of binding-post between the calorimeter and the microvolt amplifier.

TABLE 1. SUMMARY OF SOLID SOLUTIONS AND AGING PERIOD

Abbreviation	Formula	t/month[a)]

$x=0.50$(II)	$SnCl_2(H_2O)_{0.50}(D_2O)_{1.50}$	10
$x=0.25$	$SnCl_2(H_2O)_{0.25}(D_2O)_{1.75}$	1
$x=0.03$	$SnCl_2(H_2O)_{0.03}(D_2O)_{1.97}$	1
$x=0.03$(II)	$SnCl_2(H_2O)_{0.03}(D_2O)_{1.97}$	48

a) Time elapsed before starting the measurement after the preparation of the crystal.

v) The ASL AC double bridge works adequately when the resistance ratio (n_A) is between 0.2 and 0.8. Previously, we used two home-made standard resistors (6.238453 and 0.390430 Ω) and a commercial one of 100 Ω (Shimadzu Electrical Measuring Instruments Co., Ltd.). The first resistors were replaced by three card-type precision resistors (10, 1, 0.1 Ω, General Radio Company) resulting in ample overlap between the intervals of the recommended ratio value. This modifications did not influence the temperature scale because the new resistors were calibrated against the 100 Ω resistor which remained as before.

vi) The maximum temperature coefficient of the card-type standard resistor has been stated ±20 ppm/K by the manufacturer. The improved thermostat was constructed, which consisted of the double-walled-aluminium box temperature-regulated by proportional controllers. The temperature was kept constant within ±50 mK.

vii) The effect of the self-heating is corrected more reproducibly by monitoring the accurate power dissipated in the thermometer. For this purpose the bridge carrier voltage was measured by an AC voltmeter (Yokogawa Electric Works Ltd.).

viii) Temperature constancy of the bridge components was found to be essential for the high resolution measurement especially in the vicinity of critical points where thermal equilibrium is reached very sluggishly. In order to stabilize the temperature of the bridge components (two 1 kΩ resistors for the fixed arms and a seven-decade 111.11110 kΩ variable resistor) against the change of the room temperature, they were housed in an air thermostat. The temperature of the thermostat was regulated within ±0.1 K by a controller equipped with a thermistor throughout a series of heat capacity measurements. Temperature gradient in the air thermostat was minimized by a fan driven by a remote motor through a flexible torque transmitter.

Heat Capacity Measurements. The heat capacity measurements were performed on crystals of seven different compositions in addition to $x=2.00$ already reported. Table 1 summarizes the isotopic composition of the samples and the time elapsed between preparation of the crystal and the heat capacity measurement. The abbreviatiated designation for each of the solid solutions is also given there.

In all of the isotopic compositions studied, the heat capacity behaved anomalously in two temperature regions. One is around 220—230 K region and is due to the order-disorder change of proton (deuteron) in the hydrogen bonding network. The other is a relaxational anomaly (glass transition) around

150 K due to loss of equilibrium in rearrangement of protons in that network at the lower temperature. Both anomalies change smoothly with the isotopic composition in their characters including the temperature and the interval of their occurrence. Each measurement was carried out both with ordinary resolution ($\Delta T \approx 1$—3 K) from 11 to 300 K and with high resolution ($\Delta T \approx 10$—50 mK) in the vicinity of the transition temperature. Prior to the high resolution measurement, the transition temperature was located by the measurement with ordinary temperature step. It took about fifteen minutes for all crystals to attain thermal equilibrium after switching off the heater current. Longer time was required to determine the final temperature in the high resolution measurement. Calorimetric operations around the glass transition were performed according to the procedure already reported.[10] Thus the calorimeter was first cooled rapidly to 130 K, some 25 K below the anomalous region. The cooling rate was about 2 K min^{-1}. In the measurements in the exothermic region, temperature drifts were followed for 30—60 min after the energy input for heat capacity measurements. These periods were kept constant for a series of measurement. In the endothermic region, heat capacities were measured in the same way as in normal region but by following temperature drift for longer time (2—3 h). Details of the heat capacity measurement for each of the samples are described in the following. The numerical values of the heat capacity are given in Tables 2, 3, and 4 for $x=2.00$, $x=1.50$, and $x=0.03$, respectively. The

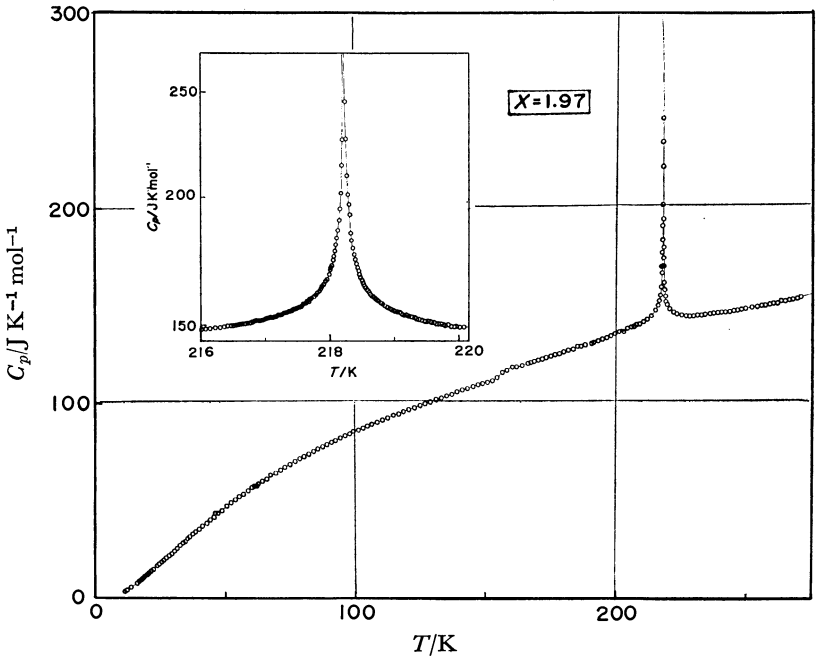

Fig. 3. Heat capacity of $x=1.97$. The inset shows an expanded view close to T_c.

complete data of other crystals amounting in number to 2096 are all kept as Document No. 7913 at the Chemical Society of Japan. Figure 1 shows the results of heat capacity measurements of $x=2.00$, $x=0.96$, and $x=0.03$ with ordinary resolutions.

(i) $x=2.00$: The highly symmetrical shape of the anomaly was observed at 218.01 K with a quasi-isothermal absorption of energy amounting to 32.4 J mol^{-1}. It is somewhat difficult to distinguish experimentally the small isothermal enthalpy increase (*i.e.* the first-order component) from the very large heat capacity. The first-order component is calorimetrically detected by abrupt increase of large endothermic drift with longer equilibration time and by the steep rise in the enthalpy or entropy curve plotted against temperature (see Ref. 16). The present measurements are precise enough to detect the quasi first-order component. In Fig. 2 the heat capacities are plotted as a function of $(T-T_c)$ in successively expanded scales.

(ii) $x=0.03$: This crystal exhibited no first-order component. The heat capacity curve is rounded at the peak temperature (234.64 K). The anomalous heat capacity was broader than those found in any other crystal and the maximum value of the peak, 220 J K^{-1} mol^{-1}, is the smallest in the series of the mixed crystals.

(iii) $x=1.97$: The phase transition occurred at 218.22 K. A quasi-isothermal absorption of energy was found around ± 15 mK of the peak temperature. In this region the equilibration time increased by a factor of 4—6 with a sudden increase

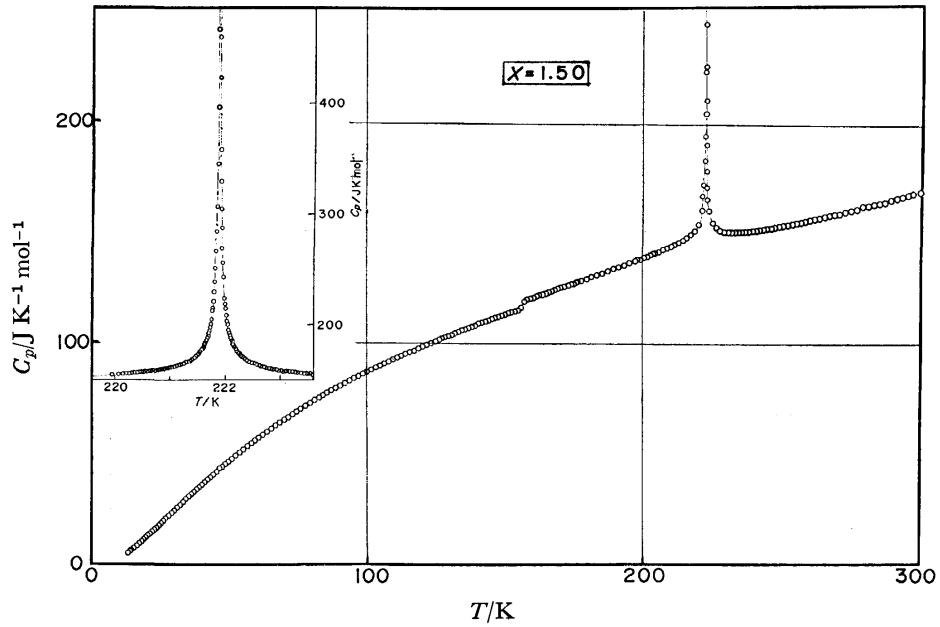

Fig. 5. Heat capacity of $x=1.50$. The inset shows an expanded view close to T_c.

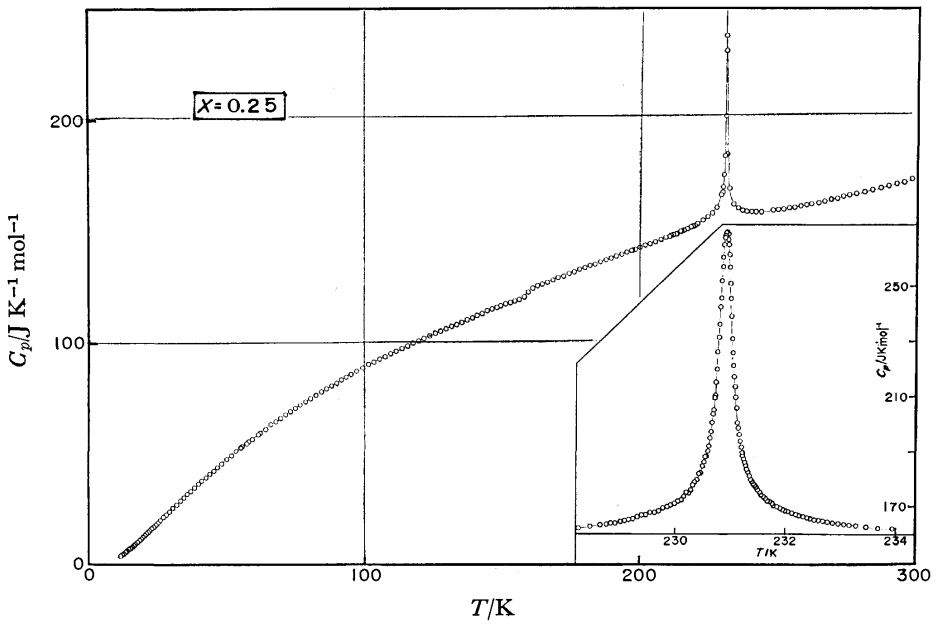

Fig. 6. Heat capacity of $x=0.25$. The inset shows an expanded view close to T_c.

of the apparent heat capacity. The latent heat absorbed quasi-isothermally was 33.12 J mol^{-1}. These behaviorsare similar to those observed for $x=2.00$. The heat capacity curve is given in Fig. 3.

(iv) $x=1.75$: Figure 4 shows the results of heat capacity measurements on this crystal. The transition temperature was 219.96 K. The first-order component was again observed at the transition temperature. The latent heat of transition is 29.24 J mol^{-1}. In the first measurement a small hump was observed around 224 K, some 4 K above the phase transition temperature. In view of the reproducibility of the small peak, presence of impurity in the calorimetric specimen was suspected. Therefore, the heat capacity was measured on a crystal having the same composition but prepared from TCD of a different commercial source. However, in the newly prepared crystal the shoulder appeared at the same temperature. Consequently it was concluded that this phenomenon was intrinsic in the crystal with the composition of $x=1.75$. In the temperature region of this anomally, it took longer time (about 100 min) for the equilibrium with the endothermic temperature drift of 0.3—0.6 mK during the drift period (about 1 h). The phenomenon was reproducible and depended on the pre-cooling condition. It was observed repeatedly when the crystal was cooled below the transition temperature prior to the measurement. When the measurement was started after coolling the sample crystal just 1 K above the transition temperature, the hump in the heat capacity and the associated endothermic effect were not observed.

(v) $x=1.50$: Although latent heat was not observed around the phase transition temperature 221.88 K, the crystal exhibited the highest peak of anomalous heat capacity (500

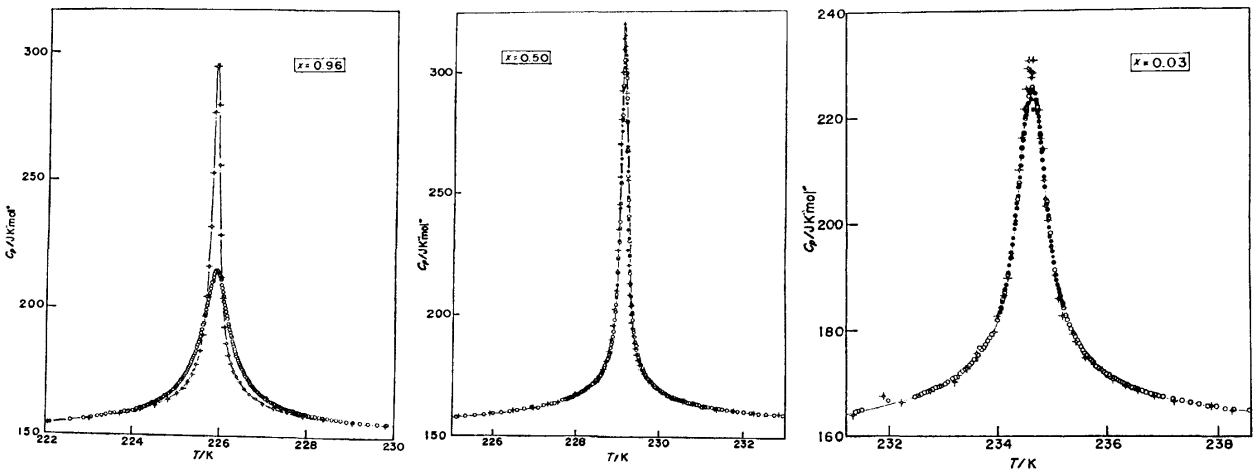

Fig. 7. Aging effect on heat capacity of (a) $x=0.96$, (b) $x=0.50$ and (c) $x=0.03$.
○ and ● : first measurement, -○- : measurement for aged crystals.

J K^{-1} mol^{-1}) among the crystals having no distinguishable first-order component. However, the equilibration time increased gradually up to 90 min with increase of the heat capacity. Rounding of the heat capacity peak was not observed. At 3 K above the peak temperature, the same phenomena as that found for $x=1.75$ appeared in the temperature drift but the heat capacity hump was not observed. The heat capacity curve is given in Fig. 5.

(vi) $x=0.96$: The anomalous heat capacity due to phase transition is located at 225.92 K and its maximum value is 220 J K^{-1} mol^{-1} which is smaller than those of any other crystal though the annealed crystal shows higher and sharper peak (see below). The peak was rounded within +0.2 K of the transition temperature. The rounding region is slightly wider than those of other crystals. The magnitude and the shape of the heat capacity are similar to those of $x=0.03$.

(vii) $x=0.50$: In this crystal the high resolution measurements were carried out twice before and after the cooling of the crystal down to nitrogen temperature, in order to check the effect of thermal history. Reproducibility of the heat capacity was excellent in all respects including the transition temperature, the maximum value of heat capacity and the rounding region. Rounding phenomenon was found within ±20 mK of the transition temperature (229.15 K) but the maximum of the heat capacity reached 290 J K^{-1} mol^{-1} and is larger than that of $x=0.96$. This corresponds to the narrower region of the peak rounding at this composition of the crystal.

(viii) $x=0.25$: The transition temperature is 230.92 K and the maximum of the peak is 260 J K^{-1} mol^{-1} which is intermediate between those of $x=0.96$ and $x=0.50$ (see Fig. 6). The rounding region is nearly the same as the case of $x=0.50$, and outside of this region the heat capacity due to phase transition is similar to that of $x=0.50$ in respect to the peak width and the sharpness. The measurements of $x=0.03$, $x=0.25$, $x=0.50$, and $x=0.96$ were performed within one month after the preparations of the single crystals. In order to study any effect of aging of the crystals we repeated high resolution measurements for these compositions near the transition temperatures. The sample crystal that had been measured before was used in the renewed measurement for $x=0.50$ and new single crystals of $x=0.03$ and $x=0.96$ were cut from the same ingot from which single crystals used in the earlier measurements were prepared. The time elapsed between the first and the second measurements were four years, ten months, and two years for the $x=0.03$, $x=0.50$, and $x=0.96$, respectively. The crystals had been kept in closed glass jars separately during these periods. For $x=0.96$ and $x=0.50$, the transition temperatures decreased by 30 and 10 mK. In view of the stability of the thermometers discussed earlier,[17] one can attribute the shifts of the transition temperatures to change in the isotopic compositions. The amount of the normal water that had replaced the heavy water during the aging was estimated from the change of the transition temperatures. They are 14 mg in the 47 g crystal of $x=0.96$ and 6 mg in the 60 g crystal of $x=0.50$. It would be reasonable to assume that water of these amount might well had been absorpted on the inner surface of the glass jars when the ingots of the crystal were placed in them and equilibrated with the mixed crystal during the storage. Figure 7 shows the aging effects in anomalous heat capacity of $x=0.96$, $x=0.50$, and $x=0.03$. The anomalous heat capacity in crystal $x=0.96$ increased by a factor of two and became sharper with accompanying the decrease of the rounding region. The peak height of $x=0.50$ increased 3% in the rounding region but the heat capacity was in agreement with the previous results within 0.1% outside the rounding region. In the crystal $x=0.03$ the anomalous heat capacity was reproduced (to 0.1%) in both the temperatures as well as the shape of peak.

temperature of the present substance ($T_c^D/T_c^H=1.076$) is of the same order of magnitude as that of a group of hydrogen-bonded ferro- and antiferroelectrics such as $Cu(HCO_2)_2\cdot 4H_2O$,[14] $K_4Fe(CN)_6\cdot 3H_2O$,[19] TGS,[20] TGSe,[21] and Rochelle salt.[22] The relatively small change of T_c on deuteration suggests that the transition is associated with the ordering of the protonic position but is not related to the tunneling motion as in KDP.[23] Figure 8 shows a dependence of transition temperature upon the composition of solid solutions. The observed behavior of T_c against x for the present system is similar to that reported for TGS–DTGS[20] and TGSe–DTGSe[21] systems, where the transition temperature increases monotonously with increasing x.

Glass Transition. Figure 9 shows the heat capacities in the region of the glass transition for each of the crystals in which those of $x=2.00$ and $x=0.03$ are the results by Matsuo *et al.*[10] The glass transition temperature was found to depend on the isotopic composition (Fig. 10). Here, the glass transition temperature was defined as the temperature where the temperature drift changed from the exothermic to the endothermic.

Conclusion

We have thus shown that the heat capacities of the mixed crystals $SnCl_2(H_2O)_x(D_2O)_{2-x}$ exhibit two thermal anomalies for the entire range of the isotopic composition. The small isotope effect on the temperature of the relaxational anomaly ($T_g(H_2O)=152.9$ K and $T_g(D_2O)=158.8$ K) may be understood in terms of the smaller vibrational frequency of the deuterium atoms in comparison with the hydrogen. It is important to recognize that glass transition region of the mixed crystals does not split into two. This means that the motions of the hydrogenic atoms are strongly correlated with each other. They migrate in the

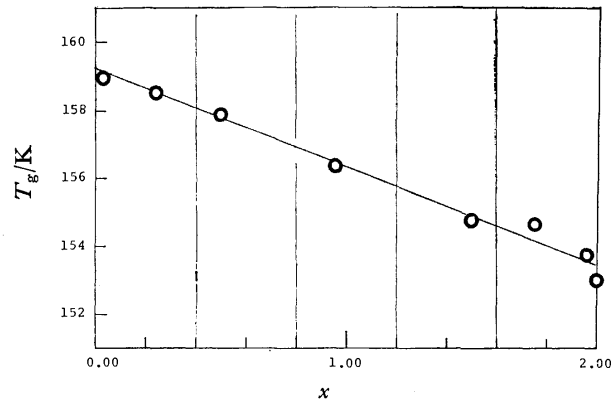

Fig. 10. Concentration dependence of the glass transition temperature.

crystal as a unit whose mobility depends on the local isotopic composition. It appears that the size of the correlation region is large enough that the local composition can be approximated well by the average composition. The smallest unit, and as such the most probable one, is the eight-membered ring of the hydrogen-bonded water molecules, as pointed out previously in relation to the ice condition.[10] The molecular model proposed earlier for the pure $SnCl_2\cdot 2H_2O$ and $SnCl_2\cdot 2D_2O$ thus fits in with the present result on the mixed crystals. Probably the most interesting property of the phase transition in the solid solution is that the first-order component disappears at the composition of 25% deuterium. The disappearance of the first-order nature is not due to inhomogeneity of the isotopic concentration. For, if this were the case, we would have observed the first-order transition also in the D_2O-rich crystals because the compositional inhomogeneity is small here again. The experimental fact is that the rounding of the anomalous heat capacity of $x=0.03$ is most extensive. Aging of the crystal for four years did not alter this result. The glass transition at 150 K indicates that the motion of the hydrogen atoms at the transition temperature, ≈ 220 K, is rapid enough that they find the equilibrium distribution during the experimental time scale, provided that possible nonuniformity in the initial isotopic distribution has been homogenized by the aging. The existence of the first-order component in the H_2O-righ crystals, its disappearance around $\approx 25\%$ D_2O concentration and the gradual increase of rounding of the anomalous heat capacity in the D_2O-rich region are the principal results of the present high resolutional measurements. The correspondence between the liquid-vapor critical point and the phase transition in TCD discussed above has been hinted upon from the structural data. The thermodynamic measurement presented in this study give strong support to the analogy. In the subsequent paper the experimental result will be analysed and discussed in terms of this correspondence.

Phase Transition of $SnCl_2(H_2O)_x(D_2O)_{2-x}$ as Studied by High Resolution Heat Capacity Measurement

Masami TATSUMI, Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 28, 1978)

The previously published heat capacity data on $SnCl_2(H_2O)_x(D_2O)_{2-x}$ (x=2.00, 1.97, 1.75, 1.50, 0.96, 0.50, 0.25, 0.03) were analyzed to derive anomalous contribution due to the phase transitions that occur between 218 and 235 K depending on the isotopic composition. The phase transition is of the first-order for x=2.00, 1.97, and 1.75. The entropy discontinuities at the transitions are (0.149±0.005), (0.152±0.005), and (0.133±0.010) J K^{-1} mol^{-1}, respectively, out of the total transition entropies of 3.98, 3.90, and 3.89 J K^{-1} mol^{-1}. The first-order transition does not occur for the other crystals for which the heat capacity anomaly is rounded. Apparent critical exponent α of the heat capacity was calculated for all of the crystals. They are in the range from 0.43 to 0.80 and have the same value below and above the transition temperature for each of the crystals in agreement with the spatial two dimensionality of the crystal structure. No evidence was found for crossing-over to the three dimensional ordering. Change of the transitional behavior with the isotopic composition was discussed in analogy with the liquid-vapor critical phenomenon. An argument based on the crystallographic symmetry of the actual crystal and the corresponding dimer lattice was advanced for this interpretation of the unusual isotope effect.

In the previous paper[1] we reported on the high resolution measurement of the heat capacity of the solid solution system $SnCl_2(H_2O)_x(D_2O)_{2-x}$ in which the heat capacity was measured from 10 to 300 K with an adiabatic calorimeter that is capable of measurement with a temperature step smaller than 10 mK. We obtained the following result from the measurement. The phase transition temperature defined as the temperature of the entropy discontinuity or, in case of absence of the discontinuity, as the temperature of the maximum of the heat capacity, increased smoothly from 218.0 to 234.6 K as the deuterium content increased from the natural abundance to 98.5%. The anomalous heat capacity became broader at the same time. Small first-order transition portion was found in the hydrogen-rich solid solutions, x=2.00, x=1.97, and x=1.75. In order to reveal their differences, the anomalous heat capacities are displayed in Fig. 1 as a function of reduced temperature T/T_c. Increasing the proton concentration x tends to increase sharpness of the anomalous heat capacity. The heat capacities of x=2.00 and x=1.97 and also x=1.50, x=0.96, x=0.50, and x=0.25 lie on the same smooth curves, respectively.

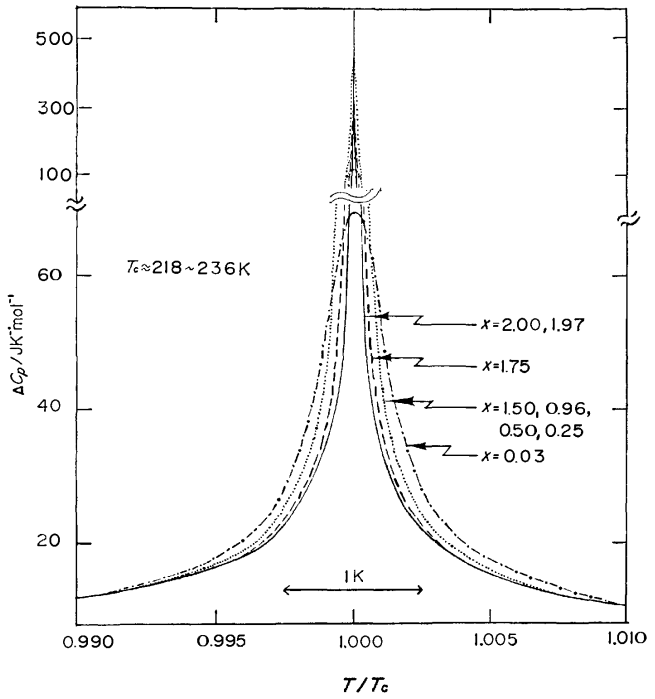

Fig. 1. Anomalous heat capacity (ΔC_p) *versus* reduced temperature (T/T_c).

Annealing effect was found in the crystal with x=0.96 (annealing period; two years), but not for x=0.50 (ten months) and x=0.03 (four years). The difference in the annealing behavior is due partly to the difference in the time intervals between the crystal preparation and the first measurement and partly to the difference in the isotopic composition. Naturally one does not expect much inhomogeneity in the x=0.03 crystal because only 1.5% of the deuterium is replaced by hydrogen. It will be significant that this crystal exhibits extensive rounding while the conjugate crystal (x=1.97) has a first-order transition without any rounding. Thus, inhomogeneous distribution of the isotopes did contribute to the rounding but it was removed by annealing.

It was concluded that the first-order transitions in the hydrogen-rich crystals and the rounded heat capacity in the deuterium-rich ones are genuine equilibrium properties of the solid solutions. This conclusion will be corroborated later by the smooth and regular behavior of the entropy surface as a two-dimensional function of the temperature and the isotope composition. It is to be noticed in particular that the behavior of the crystal is asymmetric with respect to the substitution of deuterium for hydrogen. In this paper, we will analyse the heat capacity data with an emphasis on the isotope effect on the phase transition.

We showed in earlier papers[2-4] that the first-order transition in $Cu(HCO_2)_2\cdot 4H_2O$ remains of the first-order when the H_2O is replaced by D_2O, and the second-order transition in $K_4Fe(CN)_6\cdot 3H_2O$ remains to be second-order after similar substitution. The isotope effects on the transition temperature are of the same magnitude for these three substances and are much

smaller than in *e.g.* KH_2PO_4 where tunneling motion of the proton is incorporated. Disappearence of the first-order transition is thus the most unique aspect of the isotope effect in this solid solution system.

Salinas and Nagle[5] reported a statistical mechanics of the phase transition of $SnCl_2 \cdot 2H_2O$ (TCD), using the isomorphism between the proton distribution allowed by the Bernal-Fowler ice condition and close-packed dimer distribution on the 4—8 lattice. The theory succeeded in predicting the correct ground state configuration of the proton arrangement and reproducing the symmetrical heat capacity anomaly characteristic of the two-dimensional system. However, quantitative prediction of the theory—logarithmic divergence of the heat capacity— was not supported by the experiment.

Determination of the Critical Parameters. The heat capacity C is assumed to have the asymptotic form near the critical temperature T_c,

$$C = (A/\alpha)(|t|^{-\alpha}-1)(1+D|t|^{\beta}) + B + Et, \qquad (1)$$

where

$$t = (T-T_c)/T_c$$

is the reduced temperature. The parameters A, B, D, E, α, β are allowed to take different values above and below T_c. In the latter case, the primed notations are used. The term $(A/\alpha)|t|^{-\alpha}$ represents the leading contribution to the singularity of C. The positive value of α corresponds to a heat capacity diverging to infinity. The smaller the magnitude of α, the sharper the heat capacity becomes and it is called weaker divergence. Negative value of α corresponds to a cusped singularity where the heat capacity curve has an infinite slope but finite value. In the case of $\alpha=0$, there are two possibilites. One is the logarithmic divergence and the other a finite discontinuity. $D|t|^{\beta}$ is the correction term which represents a singular contribution that vanishes at T_c. The lattice contribution to the heat capacity is expressed by the last two terms, $B+Et$, where the constant B may contain a contribution associated with the phase transition.

We calculated the critical exponents from the experimental data in the range of $|t| \leq 10^{-2}$. The first-order phase transition and rounding were excluded from the fitting. The discontinuous increase of the entropy at the first-order transition is about 4% of the total transition entropy and was disregarded for this purpose.

To simplify the fitting procedure, we imposed several constraints. We assumed that the correction term is negligible, $D=D'=0$. The lattice contribution in Eq. 1 was assumed to be smooth through the transition. This assumption should be more legitimate for this crystal than is usual for other crystal because there is no major change in the crystal structure at the transition.[6] We put $E=E'$ and $B=B'$. The latter term includes the quantity $-A/\alpha$. Thus the final form used in the fitting is

$$C = (A/\alpha)|(T-T_c)/T_c|^{-\alpha} + B + ET. \qquad (2)$$

The terms B and E in this equation have slightly different meaning from that in Eq. 1. Determination

of the lattice terms $B+ET$ is discussed in appendix II.

The $\log\{C_p-(B+ET)\}$ was plotted as a function of $\log|(T-T_c)/T_c|$ for various values of T_c and B. The best combination was chosen with the linearity of the plot as the measure of the good fit. Combined uncertainty in α due to uncertainty in determining T_c and the lattice heat capacity would be about 5% of its value.

For $|t|>10^{-2}$, the plot deviated from Eq. 2. This may imply that contribution from the higher

order correction terms is significant and/or that the lattice heat capacity deviates from the assumed linearity in T. This is not a serious problem as far as determination of α is concerned. Figures 2—9 show the logarithmic plots for the crystals $x=2.00$ to 0.03. The plot for $x=2.00$ is reproduced here for the sake of completeness.[7]

Rounding of the anomalous heat capacity and hence deviation of the logarithmic plot from the linearity in

the small $|t|$ region occurs for the crystals $x=1.50$, 0.96, 0.50, 0.25, and 0.03. The rounding of the first crystal is limited to $|t|<10^{-4}$ and those of the second, third, and fourth were to $|t|\leq 3\times 10^{-4}$. The last crystal had a wider rounding region $|t|\leq 10^{-3}$. It is interesting to remember that in most magnetic transitions a larger rounding region occurs below T_c than above. Heller[8] pointed out that this may be an intrinsic effect related with the formation of domain structure. The rounding in the present crystal occurs in the same temperature interval on both sides of the transition temperature and cannot be due to a domain structure.

We attempted to interpret the rounding on an assumption that the crystal behaves as if it were composed of microcrystals which have distributed transition temperatures.[9] The heat capacity of the entire crystal is then given by

$$C(T,\ T_c) = \sum_i C(T,\ T_{ci}) f(T_c,\ T_{ci}) / \sum_i f(T_c,\ T_{ci}), \qquad (3)$$

where $C(T,T_{ci})$ is the heat capacity at T of a microcrystal having the transition temperature T_{ci}. This is assumed to have the form of Eq. 2. $f(T_c,T_{ci})$ is the distribution function of the critical temperature T_{ci} and assumed to be gaussian centering at T_c.

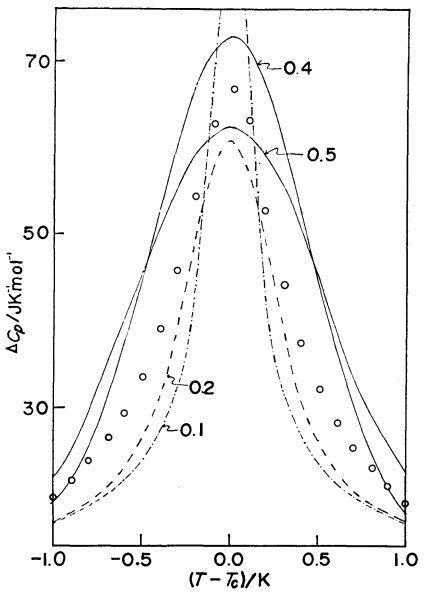

Fig. 10. Comparison of the experimental heat capacity with the model calculation assuming gaussian distribution of T_c. The numbers are the values of adjustable parameter corresponding to the half-width d of the gaussian distribution.

Some of the results for $x=0.96$ are shown in Fig. 10. Evidently the fit is very poor. A similar attempt[10] on KDP was also reported to be unsuccessful. If one wishes to save the model of the distributed transition temperature, one would have to modify Eq. 2 and/or Eq. 3. Modification of Eq. 2 is not acceptable because it describes the heat capacity of the $x=2.00$ crystal accurately. On the other hand, it is impossible to refute every modification of the distribution function in Eq. 3. However, so far as the model was applicable at all, it was applicable with the gaussian distribution.[11]

It will not be fruitful to look for the distribution function that reproduces the experimental result. Distributed T_c implies, as an underlying picture, quenched distribution of chemical or physical impurities and inhomogeneities in the crystal. In view of the manner in which the eight crystals were prepared, the only possibility is the inhomogeneity of the isotope distribution. This inhomogeneity was leveled off

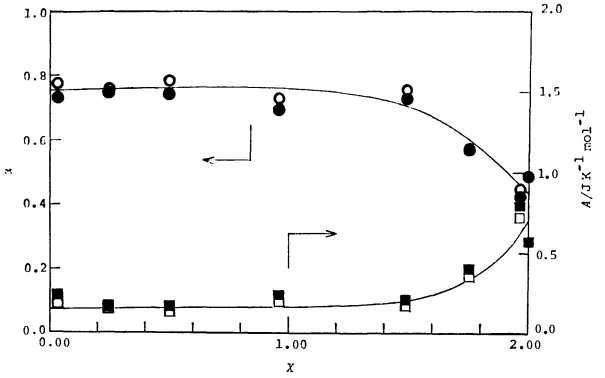

Fig. 11. Composition dependence of the critical parameters. ●: α', ○: α, ■: A', □: A.

by annealing (see Ref. 1). It is important to note that occurrence of the phase transition contradicts the assumption of quenched distribution of the isotopes. The phase transition occurs because the protons (or deuterons) jump around in the hydrogen bonded layer, not just among a few localized states. We conclude that the model of distributed transition temperature is not appropriate for the present crystal.

Recently, it was suggested from dielectric measurement[12,13] that TCD shows a cross-over from two to three dimensional ordering around $t=10^{-3}$. However, the logarithmic plot of the heat capacity is smooth without any irregularity. This is true not only for the $x=2.00$ crystal but also for all of the other crystals except the $x=0.03$ crystal for which the rounding extends out to this region.

The critical parameters thus determined are given in Table 1 and Fig. 11. The critical exponent has the same value below and above T_c as expected from the symmetric shape of the heat capacity curves. In the region where the rounding is appreciable, physical meaning of the critical exponent is not clear because the region of small t where Eq. 2 is expected to be most appropriate is excluded from the fitting. However, the logarithmic plot is on a straight line over more than a decade of $|t|$ even for the most rounded case. Its physical meaning will be hopefully understood in future. The α values are in the range 0.43—0.8. They are much larger than typical value for magnetic systems. Comparable magnitude of α are

found in KDP,[10] DKDP,[14] NH_4Cl,[15] NH_4Br,[16] and $NaNO_2$.[17] The crystals with $x=2.00$ and $x=1.97$ resemble KDP with respect to the value of α and occurrence of the first-order phase transition, but do not exhibit the logarithmic singularity which KDP[18] does. This indicated that dominant interaction in TCD is strong short-range forces that express themselves as the ice condition.

Order of the Phase Transition and Entropy Change near the Transition Temperature. It is often noticed that thermal equilibrium in the crystal is attained very slowly at a first-order transition. This is usually attributed to slow progress of the first-order transition. In the present study, slow equilibration was observed in the crystals with high hydrogen content. At the transition temperature of the crystals of $x=2.00$, 1.97, and 1.75, the equilibration time was 5—7 times as long as those in the normal temperature region. Such anomalous equilibration behavior was not found in the crystals with $x=0.96$, 0.50, 0.25, and 0.03. The crystal $x=1.50$ was the boundary case where the long equilibration time was observed only at one point of the measurement at the peak of the transition. A more quantitative evidence of the change in character of the phase transition with increasing deuterium content is shown in Fig. 12 as the anomalous entropy plotted as a function of the temperature and the isotopic composition. The surface was calculated by integration of the anomalous heat capacity divided by T. Evidently the transition is of the first-order for $x=2.00$, 1.97, and 1.75. The entropy discontinuities for these three crystals are (0.149±0.005), (0.152±0.005), and (0.133±0.010) J K^{-1} mol^{-1}, respectively. The crystal with $x=1.50$ did not show distinct jump, but as noted above its equilibration behavior was similar to that of the crystal with the first-order transition. Thus $x=1.50$ corresponds to the critical composition where the first-order transition disappears.

We shall change subject for a while to the problem of classification of phase transitions. A phase transition

is of the n'th order if the n'th derivative of the free energy is discontinuous at the phase transition. This is the classification due to Ehrenfest. Discontinuity in the higher-order derivative is not easy to detect experimentally. Therefore, phase transitions which are not of the first-order are classified collectively as the higher-order. This classification is not general enough to be applicable to all of the phase transitions, since it does not contain the divergent anomalies.

In another classification, a phase transition is called isothermal if it occurs at a fixed temperature, and gradual if the anomaly occurs over a range of temperature. An isothermal transition is of the first-order, but gradual transition can be of the first-order, higher-order or divergent type. This classification is more convenient than the first classification, because gradual first-order transitions are more closely related to higher-order and divergent transitions than to the strictly first-order transitions. The first-order transitions are divided into strongly first-order and weakly first-order.

As a quantitative measure of the strength of the "first-orderedness," we propose the entropy discontinuity divided by the total transition entropy. Thus the fusion of a pure substance is a strongly first-order transition because all of the entropy change occurs at the melting temperature. In Table 2 we collected some of the weakly first-order transitions of ferroelectric and related substances including the present crystals. It is interesting that, so far as is known, magnetic transitions are rarely of weakly first-order. It should be added that we singled out the entropy from among other thermodynamic quantities that may possibly behave anomalously at the transition. This is because this quantity is amenable to direct experimental measurement irrespective of the atomic mechanism of the transition so far as we choose the temperature as the independent variable.

Comparison with the Dimer Model Calculation. Salinas and Nagle[5] gave an expression for the internal energy of the dimer model. We calculated the heat capacity C from the energy U,

$$C=\mathrm{d}U/\mathrm{d}T. \tag{4}$$

The explicit expression is too lengthy to be reproduced here. For the sake of checking the calculation, we computed S_∞ numerically from the equation

$$S_\infty=\int_0^\infty (C/T)\mathrm{d}T, \tag{5}$$

using the heat capacity given above. The result agreed with the direct calculation[19] given earlier, $S_\infty/R=0.3769956\cdots$. Figure 13 compares the experimental heat capacity with the dimer model calculation. The calculated heat capacity is too sharp, corresponding to the logarithmic divergence as noted by Salinas and Nagle.[5] However, agreement between the experiment and the theory is excellent at 150 K where the glass transition (see Appendix I) allowed determination of the lattice heat capacity without ambiguity. The experimental entropy at $T=T_c$ and $T=2T_c$ are (3.00 ± 0.12) and (3.94 ± 0.23) J K^{-1} mol^{-1}, respectively, for the $x=2.00$ crystal. These are compared with the dimer model calculation $S(T_c)=2.34$ and $S(2T_c)=3.02$ J K^{-1} mol^{-1}.

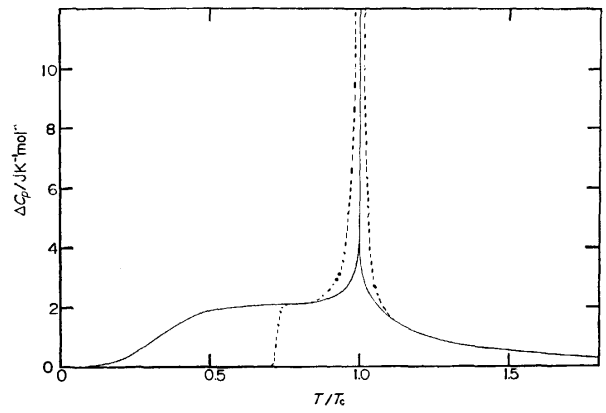

Fig. 13. Comparison of the heat capacity of $SnCl_2\cdot 2H_2O$ with the dimer model calculation.

Problem of Tricritical or Bicritical Phenomenon. In this section we are concerned with interpretation of the disappearance of the first-order transition in the deuterium-rich crystals. In order to be sufficiently general, we consider a phase diagram in three dimensions.[20] A first-order phase transition is described by a coexistence surface in the space. The coexistence surface may terminate in following ways. i) The coexistence surface intersects another coexistence surface in a triple line at which three phases are in equilibrium. ii) The coexistence surface passes into another surface which continues to separate two phases but which has the property that all extensive variables are continuous at the surface. iii) The coexistence surface terminates in a line of critical point. In the two dimensional phase diagram, these three correspond to i) triple point, ii) tricritical point and iii) bicritical point. Our result corresponds to ii) or iii).

a) Tricritical Point: The three axes in the phase diagram are temperature T, the field η conjugate to the order parameter and a secondary variable ζ. η is often a fictious field uncontrollable in the laboratory. For instance we have no direct means of controlling the orientational order of the ammonium ion in NH_4Cl crystal. ζ is taken as a controllable variable such as pressure, magnetic field or chemical potential. The phase diagram looks schematically like Fig. 14. The three curves meeting at the tricritical point represent

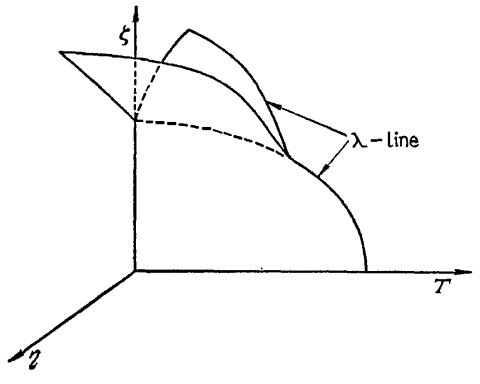

Fig. 14. Schematic phase diagram of a system with a tricritical point.

lines of the critical point. The three coexistence surfaces meets in a line of triple point represented by the broken line. The surface at $\eta=0$ is the coexistence surface of the positively and negatively ordered phases.

The behavior of $SnCl_2(H_2O)_x(D_2O)_{2-x}$ appears to fit in well with the phase diagram if one identifies the ζ axis with the isotopic concentration. The first-order transition line (the broken line) disappears as the tricritical point is approached by changing the ζ value.

However, there is a difficulty in this correspondence arising from the peculiarity of this crystal. We cannot define order parameters because the symmetry of the two phases involved are the same. Therefore, it is impossible to define its conjugate field η.

In order to illustrate the point, we shall take NH_4Cl as an example. The two phases coexisting on the surface $\eta=0$ are related with each other by changing the orientation of all the ammonium ions by 90° relative to the crystal axis. In the disordered phase this produces an equivalent state. Such an operation is not possible in TCD. A proton in the crystal occupies one of the seven sites but none of them are equivalent with each other. Tricritical points have been discussed in NH_4Cl,[21] ND_4Cl,[22] NH_4Cl–NH_4Br,[23] and other systems where a first-order transition changes to a higher-order one as an external parameter changes. The same argument can not be applied in the present case in spite of the similarity of the thermodynamic behavior.

b) Bicritical Point and Super Critical State: This type of critical point always exists in a simple liquid-vapor system. If one chooses an appropriate path in the pressure-temperature plane, one can obtain vapor phase from the liquid phase without discontinuity. This is possible because the vapor and liquid have the same spatial symmetry.[24] The same would be true in the crystalline state. Non-existence of the critical point between liquid and crystal was rationalized by the same argument.[24] In the case of TCD, Kiriyama *et al.*[25] showed that the space group $P2_1/c$ and the unit cell size remain the same as the crystal undergoes the phase transition. This is a very peculiar property of this crystal, since change of symmetry is believed to be the most essential characteristic of solid state phase transitions in general. On the other hand, thermodynamic property of this phase change is also unusual. As shown in Fig. 12 the first-order transition disappears at $x\simeq 1.5$, beyond which the heat capacity is rounded and genuine singularity does not occur any more. This behavior is similar to that of a simple liquid-vapor system at least qualitatively. The region $x\geq 1.5$ where the first-order transition occurs corresponds to subcritical region and the region $x<1.5$ to the supercritical region.

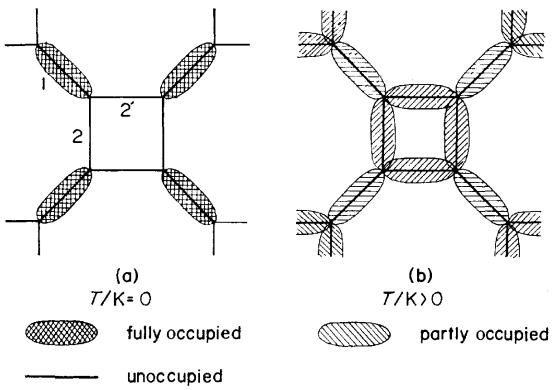

Fig. 15. Dimer distribution at $T=0$ K (a) and $T>0$ K (b) on the 4—8 lattice.

Thus, two peculiarities of the phase transition in TCD, one crystallographic and the other thermodynamic, are interpreted coherently by an analogy with the liquid-gas critical point. At present, however, how the correspondence comes about between the isotope concentration in TCD and pressure in the liquid-vapor system is not understood.

It will be pertinent here to point out that a phase transition is possible at all between two phases of the same spatial symmetry. As an example we show in Fig. 15 a part of the dimer lattice studied by Salinas and Nagle.[5] Figure 15(a) shows the distribution of the dimers at 0 K where all of the dimer sites (1) and none of the (2) and (2′) are occupied. Two dimensional space group of this distribution is P4mm. At higher temperature, some of the dimers occupy the sites (2) and (2′) as shown in Fig. 12(b). This dimer distribution has the space group P4 mm again. Salinas and Nagle showed there is a phase transition between (a) and (b) in the sense that the thermodynamic function behaves singularly at a temperature determined by the energy of the dimer site (2) and (2′). It is evident that the low-temperature-phase is more ordered than the high-temperature-phase because it has a lower entropy. However we cannot define the order parameter for this lattice, since there is no symmetry breaking coordinate. Difficulty of defining order parameters in some dimer lattices was discussed also by Kasteleyn.[26] Thus, the dimer model gives some theoretical credential to the isomorphous transition found experimentally.

It is not clear how the nuclear mass influences the critical behavior of the hydrogen bonded system. It has been known that thermodynamic property of Ising model changes substantially if one assumes a distance-dependent coupling between the spins on a compressible lattice. Specifically, a first-order phase transition is possible if the lattice is sufficiently compressible.[27] It will be extremely interesting to investigate a compressible dimer lattice on the 4—8 lattice of Salinas and Nagle.

Conclusion

The heat capacity data discussed in the present paper was obtained with an adiabatic calorimeter using platinum and thermistor thermometers. High sensitivity of the thermistor allowed the heat capacity measurement close to the transition temperature without distorting the true temperature dependence of the anomalous heat capacity. Long term stability of the platinum thermometer and the resistance measuring apparatus enabled us to measure the heat capacity reproducibly over many years, which was essential for the investigation of the annealing effect. Adiabatic calorimetry rather than transient and temperature

oscillation method was particularly suitable for studying the phase transition where thermal equilibration time was long at the transition temperature as in the present case. Use of the single crystals is also believed to be of essential importance not only in the thermal aspect but also for the homogeneity of the solid solutions. With these experimental set-up we believe that we have established the occurrence of a liquid-vapor type critical point in a crystalline substance for the first time.

Several problems are yet to be studied. We do not know physical meaning of the formal correspondence between the isotopic concentration in the present solid solution and pressure in the liquid-vapor system. This will be related to an equally interesting problem of phase transition in isotopic mixture in general. How can a phase transition temperature be defined accurately in the isotopically impure system? Position-exchangeability of the different isotopic atoms must be involved in this problem.

Finally, calorimetric and dielectric measurements at higher pressure will be informative for investigation of the critical behavior of the present system and are now in progress at the laboratory.

Appendix I. The Glass Transition

The glass transition is not a phase transition. It is a change from a non-equilibrium to equilibrium state. The glass transition in TCD occurs when, around 150 K, positional change of the protons (or deuterons) becomes so slow that they cannot find the equilibrium distribution within the experimental time. The glass transitions in normal and deuterated TCD were discussed in an earlier paper.[19] In this appendix we add some comments on the glass transition of the solid solutions.

Occurrence of the glass transition in TCD is a fortunate phenomenon for interpretation of the phase transition in two respects. First, we can be sure that the motion of the protons (or deuterons) at the phase transition temperature is rapid enough for their equilibrium distribution to be attained within the experimental time. For the phase transition occurs at much higher temperature than the glass transition. This is particularly important for the solid solutions because we can be sure that we are dealing with an annealed system rather than quenched one. Second, the glass transition allows experimental determination of the vibrational heat capacity below the glass transition temperature. This is a useful piece of information for separating the anomalous heat capacity from the total experimental heat capacity. Appendix II deals with this problem.

As the glass transition *per se*, the relaxational behavior deserves a comment. The heat capacity of the solid solutions around the glass transition and the glass transition temperature as a function of the composition were given in the previous paper. From the exothermic drift rate the relaxation time was determined by the method described previously[19] and plotted in Fig. A1. These figures show that the glass transition in $SnCl_2 \cdot 2D_2O$ occurs at ≈ 5 K higher than in $SnCl_2 \cdot 2H_2O$ and that the glass transition interval in the solid solutions is not broader than in the hydrate or deuterate crystal. This means that correlation region of the atomic motion is so large that the local isotopic concentration does not deviate from the average concentration. This supports the earlier discussion based on the structure of the hydrogen bond network that the smallest unit of the atomic motion consists of eight hydrogen atoms.

Appendix II. Determination of the Lattice Heat Capacity

It was found that the heat capacity jump at the glass transition is reproduced correctly by the dimer model using the experimental transition temperature as the only adjustable parameter. The dimer model calculation was assumed to be correct up to 190 K and above 250 K where the anomalous heat capacity is small again. The dimer model gave too small a heat capacity in the intermediate region involving the phase transition. Interpolation of the normal heat capacity into this region was facilitated by spectroscopic data.[28,29] The vibrational frequencies used are as follows. Internal vibration of the two water molecules: 3125, 2975, 1545, and 3505, 3375, 1610 cm^{-1}, librational modes of the two water molecules: 945, 853, 542, and 710, 486 and 415 cm^{-1}, internal and external vibrations of $SnCl_2 \cdot H_2O$: 323, 198, 134, 101, 67, 58, and 254, 250, 164, 139, 121, and 111 cm^{-1}.

The Crystal and Molecular Structure of (Carboxymethyl)(pyridine)-(triphenylphosphine)palladium(II) Dichloromethane Solvate, $[Pd(C_2H_2O_2)(PPh_3)(py)]\cdot 0.6\,CH_2Cl_2$

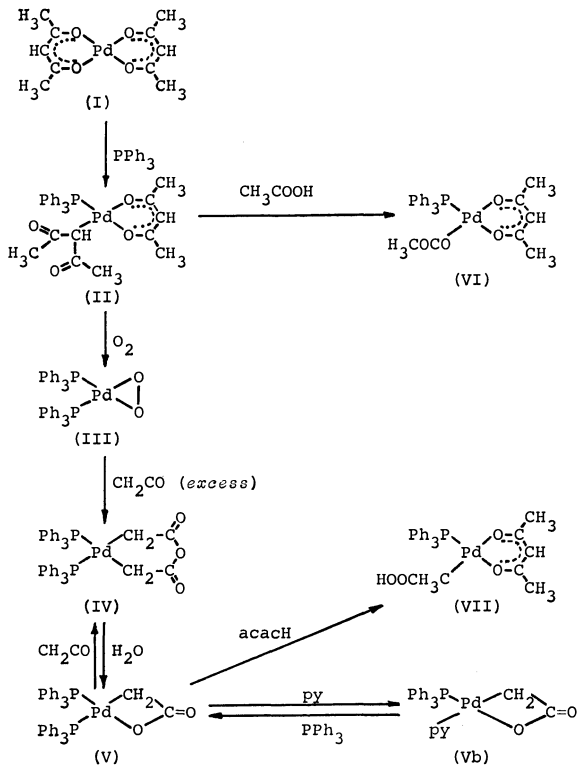
Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received October 2, 1978)

The molecular structure of carboxymethylpalladium(triphenylphosphine)pyridine has been determined by X-ray crystal structure analysis of its dichloromethane solvate, $[Pd(C_2H_2O_2)(PPh_3)(py)]\cdot 0.6\,CH_2Cl_2$. The crystal belongs to the monoclinic system, space group $P2_1/c$, with four formula units in a cell with dimensions of $a=8.791(4)$, $b=14.623(7)$, $c=19.862(5)$ Å, and $\beta=101.53(4)°$. $R=0.091$ for 2806 non-zero reflections. The feature of the structure is that the palladium atom is C,O-chelated by an acetic acid to form a four-membered ring [Pd–C=2.004 (16) and Pd–O=2.093 (11) Å], and the palladium atom has approximately square-planar geometry.

In a series of palladium complexes (Scheme) prepared by the reaction of ketene and triphenylphosphine with bis(acetylacetonate)palladium(II),[1] the molecular structures of I,[2] II,[3] IV,[4] and VII[5] have been determined by means of X-ray diffraction. The crystal structure analysis of V has been first attemped, however, all the crystals examined were decomposed by X-ray irradiation. Therefore, the more stable crystals of Vb, which is also a palladium C,O-chelate of acetic acid, has been selected. This paper deals with the structure of Vb, of which preriminary result has been reproted briefly.[6]



Experimental

Pale yellow, polyhedral crystals of $[Pd(C_2H_2O_2)(PPh_3)(py)]\cdot 0.6\,CH_2Cl_2$ were kindly supplied by Professor S. Kawaguchi and his coworkers of Osaka City University. Preliminary X-ray work showed that the crystals belong to the monoclinic system and that the space group is $P2_1/c$ (No. 14, absent reflections, $h0l$; $l=2n+1$ and $0k0$; $k=2n+1$). Unit-cell dimensions were determined by 2θ values of 12 strong reflections measured on a Rigaku automated, four-circle single crystal diffractometer.

Crystal Data. $(C_{25}H_{22}NO_2PPd+0.6\,CH_2Cl_2)$, $F.W.=556.8$, monoclinic, space group, $P2_1/c$, $a=8.791(4)$, $b=14.623(7)$, $c=19.862(5)$ Å, $\beta=101.53(4)°$, $D_m=1.474$ g cm^{-3} (by flotation in aqueous solution of zinc bromide), $Z=4$, $D_c=1.478$ g cm^{-3}.

For the intensity measurement, a crystal with approximate dimensions of $0.20\times 0.175\times 0.15$ mm was used. Intensity data were collected on the Rigaku diffractometer using Zr-filtered Mo $K\alpha$ radiation. All data within a 2θ sphere of 44° ($\sin\theta/\lambda=0.527$) were measured using the θ-2θ scan technique. The integrated intensity was determined by scanning over the peak at a rate of 4° min^{-1} and subtracting the background obtained by averaging the two values measured for 10 s at both ends of a scan; the scan width of each reflection was $\Delta(2\theta)=(2.0+0.7\tan\theta_c)°$, where θ_c is the calculated Bragg angle for Mo $K\alpha_1$ ($\lambda=0.70926$ Å). The intensities of two standard reflections (080 and 300) were measured after every 25 reflections. After about 2400 reflections with lower Bragg angles were measured, these standard reflections showed a sudden drop down in their intensities. Therefore, the second crystal with approximately the same dimensions was cut out from the same mother crystal as the first, which was then used to collect about 900 more reflections with high angles. A total of 3053 independent reflections was collected of which the number of non-zero reflections was 2806. Usual Lorentz and polarization corrections were made, but the absorption correction was ignored ($\mu=6.37$ cm^{-1} for Mo $K\alpha$).

Solution and Refinement of the Structure

The structure was solved by the heavy atom method. The palladium and phosphorus atoms were located from a three-dimensional Patterson function. The remaining non-hydrogen atoms of the $[Pd(C_2H_2O_2)(PPh_3)(py)]$ molecule were located by succesive Fourier syntheses. However, three low and broad peaks remained undefined, which could be assigned as non-hydrogen atoms of dichloromethane, the recrystallization solvent. The structure was then refined by the block-diagonal least-squares procedure. The HBLS-V program[7] was used, the function minimized being $\Sigma(|F_o|-k|F_c|)^2$, where k is a single scale factor. Several cycles of isotropic refinement followed by the several more cycles of anisotropic refinement reduced

a) The isotropic temperature factors of each hydrogen atom is taken equal to that of equivalent temperature factor of its parent atom.

the R_1 factor ($R_1=\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 0.090 for non-zero reflections. The difference Fourier synthesis, based on the atomic parameters at this stage, revealed all the hydrogen atoms except those of dichloromethane. Three cycles of refinement including those 22 hydrogen atoms gave $R_1=0.082$. However, equivalent isotropic thermal parameters of non-hydrogen atoms of the solvent molecule were exceptionally large, and the calculated density for four formula weights of [Pd-$(C_2H_2O_2)(PPh_3)(py)$, CH_2Cl_2] per unit-cell [1.56 g cm^{-3}] is much larger than the observed value of 1.474 g cm^{-3}. These facts suggested a lower occupancy of dichloromethane than unity. Assuming the occupancy as 0.6. which gives the calculated density of 1.478 g cm^{-3} and a good fit with the observed values, the refinement converged: R_1 being 0.091 ($R_2=\Sigma||F_o|-|F_c||^2/\Sigma|F_o|^2=0.106$) for non-zero reflections. The atomic scattering factors used in the calculations were taken from International Tables for X-Ray Crystallography, Vol. IV.[8] The final atomic parameters of non-hydrogen atoms are listed in Tables 1 and 2, and those of hydrogen atoms in Table 3.†

atoms. The stereoscopic drawing of the $[Pd(C_2H_2-O_2)(PPh_3)(py)]$ molecule is given in Fig. 2. Bond lengths and bond angles are given in Table 4. Least-squares planes of some groups of atoms, deviations of atoms from, and dihedral angles between these planes are listed in Table 5.

The remarkable feature of the molecular structure is that this complex contains a C,O-chelate ring of acetic acid (Fig. 1). The palladium atom has an approximately square-planar geometry coordinated by an oxygen and an sp^3 carbon atoms of the chelate ring and a phosphorus and a nitrogen stoms; the mean and maximum deviations of atoms from the best plane being 0.057 and 0.078 Å, however, the planarity is not so good as that of IV, a C,C′-chelate of acetic anhydride.[4]

The Pd–C(2) bond lengths [2.004(16) Å] is much shorter than those in IV [2.141(13) and 2.124(11) Å], which is probably the shortest of the observed Pd–C σ-bond. The Pd–O(2) length [2.093(11) Å] is longer than those of O,O′-chelate of acetylacetone [1.989(2) and 1.986(2) Å],[2b] which is considered as due to trans-influence of the pyridine ligand. The C(2)–Pd–O(2) angle [67.3(5)°] is much smaller than 90°.

The Pd–P bond [2.230(4) Å] is equal in length to that of 2.235(1) Å in VII,[5] and this is shorter than that

of 2.267(1) Å in $[PdCl(CH_2SCH_3)(PPh_3)]$.[9] The Pd-N bond length [2.144(12) Å] is comparable to those in $[PdCl(CH_2COCH_2COOCH_2Ph)(py)_2]$ [2.027(6) and 2.120(6) Å]. The P-Pd-N angle of 100.2(3)° is much larger than 90° because of steric interaction between the triphenylphosphine and pyridine ligands.

In the C,O-chelate ring of acetic acid, the C(1)-C(2) bond length of 1.487(22) is equal to those in IV of 1.473(18) and 1.479(19) Å, which can be compared with those observed in C-C=O moieties in many organic compounds [av 1.506(5) Å]. The C(1)-O(2) bond length [1.322(19) Å] is shorter than those in IV [1.412(16) and 1.386(17) Å]. The C(1)=O(1) double bond length of 1.201(20) is equal to those of 1.192(18) and 1.202(17) Å in IV, which is normal value in aldehydes and ketones [av 1.215(5) Å],[10] and α-oxalic acid [1.207(1) Å].[11] Both the Pd-C(2)-C(1) and Pd-O(2)-C(1) angles are around 90° [91.1(9) and 92.9(9)°, respectively]. The C(2)-C(1)-O(2) angle [107.6(13)°] is much smaller, whereas the C(2)-C(1)-O(1) angle [129.3(15)°] is much larger than 120°. However, the sum of the three angles around

Absorption and Fluorescence Spectra of Anthracenecarboxylic Acids. II. 1- and 2-Anthroic Acids

Satoshi SUZUKI,* Tsuneo FUJII, Shigeru YAMANAKA, Nobuyuki YOSHIIKE,† and Zenro HAYASHI††

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received October 9, 1978)

The absorption and fluorescence spectra of 1- and 2-anthroic acids (1- and 2-anthracenecarboxylic acids) in alcoholic solvents have been observed as a function of solute concentration. It was revealed that 1- and 2-anthroic acids form hydrogen-bonded dimers in their ground states. The equilibrium constants for dimer formation are : 1.2×10^4 mol^{-1} l for 1-anthroic acid in methanol and 2.0×10^4 mol^{-1} l for 2-anthroic acid in ethanol. Owing to dimer formation, the lowest frequency absorption band of 1-anthroic acid was uniformly displaced to the red, while that of 2-anthroic acid was distinctly resolved into two bands. The band assignment was confirmed by the method of photoselection. No excimer-type fluorescence was observed in 1- and 2-anthroic acids. The lack of mirror-symmetry relationship between the absorption and fluorescence spectra of 1-anthroic acid is explained by the geometrical relaxation in its excited state.

The fluorescence spectrum of 9-anthroic acid (9-anthracenecarboxylic acid) in ethanol shows a remarkable concentration dependence. At a concentration below 10^{-5} mol/l the spectrum has an anthracene-like structure, while at a concentration above 10^{-3} mol/l it largely shifts to the red, turning into a broad structureless band. Some attempts to elucidate the origin of this spectral change have been made.[1-5] In connection with this, the electronic spectra of 1- and 2-anthroic acids (1- and 2-anthracenecarboxylic acids) were also investigated.[6]

In the preceding paper[4] of this series, an excimer-type mechanism was presented for the broad fluorescence of 9-anthroic acid. In alcoholic solvents, 9-anthroic acid forms a hydrogen-bonded dimer in its ground state. The hydrogen-bonded dimer is excited and then associates with an unexcited hydrogen-bonded dimer to form an excited tetramer from which the broad fluorescence occurs. A polarization study also supports the excimer mechanism.[5]

This paper presents the concentration and temperature dependence of the absorption and fluorescence spectra of 1- and 2-anthroic acids. In the ground state, 1- and 2-anthroic acids form hydrogen-bonded dimers as does 9-anthroic acid. They do not, however, show any excimer-type fluorescence in contrast to 9-anthroic acid.

Experimental

1-Anthroic acid was prepared from benzanthrone[7,8] and was purified by repeated recrystallization. 1-Anthroic acid from K & K Laboratories was purified by repeated recrystallization . Methanol (Wako fluorometric grade) was used without further purification. Ethanol (Wako super special grade) and propylene glycol (1,2-propanediol, Wako JIS S grade) were stored over molecular sieves 3A and passed through a silica gel column. The absorption spectra were recorded on a Hitachi EPS-3 recording spectrophotometer. The fluorescence and excitation spectra were obtained by means of a Hitachi MPF-2A fluorescence spectrophotometer and are given without corrections on the quantum response of the detecting and exciting systems and on reabsorption. The degree of polarization, P, was measured by the method of photoselection.[9-12]

Results and Discussion

Absorption Spectra and Dimer Formation. The absorption spectra of 1-anthroic acid in methanol are shown in Fig. 1 as a function of concentration. The absorption spectrum of 1-anthroic acid has an anthracene-like structure at lower concentration. The spectra become less sharp on increasing the concentration. Several isosbestic points appear in the spectra. The most probable origin of the isosbestic points in the absorption specta of 1-anthroic acid may be monomer-dimer equilibrium in consideration of the results of 9-anthroic acid. When one ascribes the spectral changes to monomer-dimer equilibrium, the equilibrium constant of dimer formation, K_D, can be determined by the usual procedure.[13] The K_D of 1-anthroic acid was 1.2×10^4 mol^{-1} l in methanol at 290 K.

The concentration dependence of the absorption spectra of 2-anthroic acid in ethanol is given in Fig. 2. The absorption spectrum of 2-anthroic acid has four

vibrational peaks at lower concentration, while it has five vibrational peaks at higher concentration. From an analysis of the data on the concentration dependence of the absorption spectra, the K_D of 2-anthroic acid was determined to be 2.0×10^4 mol^{-1} l in ethanol.

By using the observed spectral data at various concentrations and the K_D value, we can estimate the monomer and dimer absorption spectra.[13] The estimated monomer and dimer absorption spectra of 1- and 2-anthroic acids are included in Figs. 1 and 2.

Figure 1 shows that the monomer absorption spectrum of 1-anthroic acid has an anthracene-like progression spaced by 1400 cm^{-1}. The dimer absorption spectrum is displaced to the red with keeping the vibrational structure. The monomer absorption band of 1-anthroic acid in this region may safely be assigned to the ^1L_a transition.

The monomer absorption spectrum of 2-anthroic acid has four vibrational peaks in the region of the lowest-frequency absorption band, while the dimer absorption spectrum has five vibrational peaks. It has well been established that the ^1L_b and ^1L_a bands of 2-anthrol lie closely in this region.[14–16] The lowest-frequency absorption band of 2-anthrol was assigned to the ^1L_b transition and the next one to the ^1L_a transition. The ^1L_a band of 2-anthrol holds an anthracene-like vibrational structure which is characterized by equal spacings of about 1300 cm^{-1}. The ^1L_b band of 2-anthrol is greatly displaced to the red due to hydrogen bonding, while the ^1L_a band is slightly displaced to the blue. As a consequence of this, the ^1L_b and ^1L_a bands are resolved distinctly. The assignment of the absorption bands of 2-anthroic acid can be made as follows, by reference to that of 2-anthrol. Band b of the monomer absorption spectrum is composed of two vibrational bands, one of which belongs to the ^1L_b transition and the other to the ^1L_a transition. Owing to dimer formation, the ^1L_b band is greatly displaced to the red yielding Bands p and q, while the ^1L_a band is displaced to the blue yielding Bands r, s, and t. Band a and a part of Band b of the monomer absorption band may reasonably be assigned to the ^1L_b and a part of Band b and Bands c and d to the ^1L_a transition. This assignment was confirmed

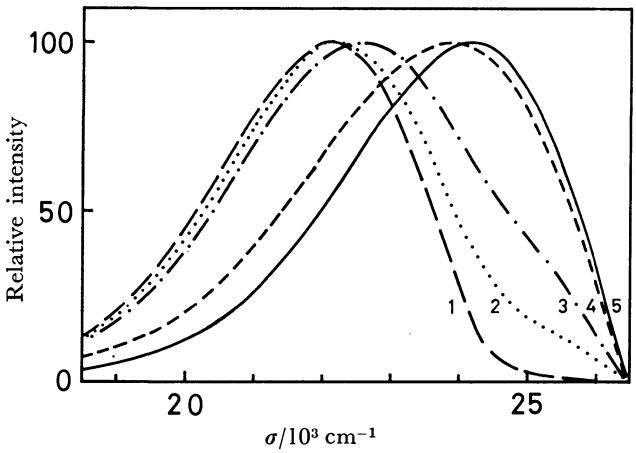

Fig. 3. The fluorescence spectra of 1-anthroic acid in methanol at various concentrations. 1 : 8.8×10^{-4} mol/l, 2 : 4.4×10^{-5} mol/l, 3 : 2.2×10^{-5} mol/l, 4 : 1.1×10^{-5} mol/l, 5 : 4.4×10^{-7} mol/l. Excitation wavelength : 360 nm.

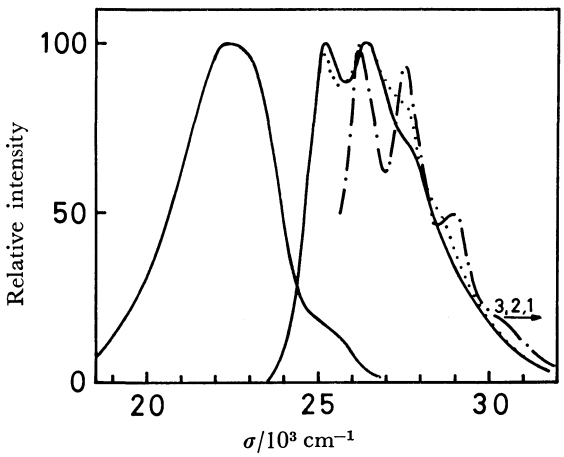

Fig. 4. The fluorescence and excitation spectra of 1-anthroic acid in methanol at 181 K. Solute concentration : 5.0×10^{-6} mol/l. 1 : Observed at 396 nm, 2 : observed at 440 nm, 3 : observed at 490 nm.

by the polarization study (see below).

It has well been established that carboxylic acids have pK_a values in ethanol larger by about 5.8 than in water.[17–19] The reported pK_a's are 3.7[20] and 3.69[21] for 1-anthroic acid and 4.2[20] and 4.18[21] for 2-anthroic acid. The pK_a's of 1- and 2-anthroic acids in ethanol are estimated to be 9.5 and 10.0, respectively. Proton dissociation can, therefore, be ruled out as the origin of the spectral changes in these solvents.

Fluorescence Spectra. Figure 3 shows the concentration dependence of the fluorescence of 1-anthroic acid in methanol. The fluorescence of 1-anthroic acid exhibits no vibrational structure at lower concentration and the mirror-image relationship between the absorption and fluorescence spectra is lost. A large Stokes shift is observed on increasing the concentration.

The excitation spectra of 1-anthroic acid in methanol at 181 K are shown in Fig. 4. The excitation spectrum monitored at the maximum of the fluorescence band

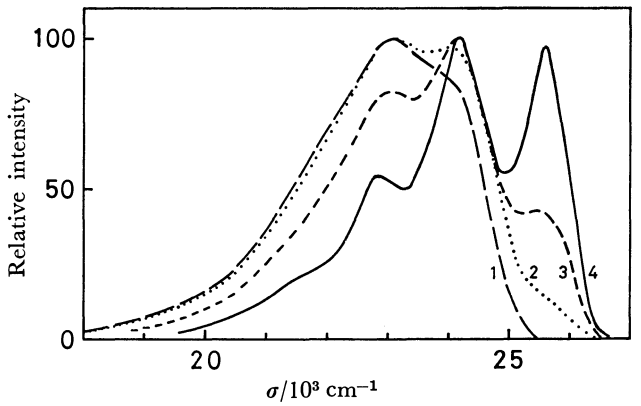

Fig. 5. The fluorescence spectra of 2-anthroic acid in ethanol at various concentrations. 1 : 4.0×10^{-4} mol/l, 2 : 9.9×10^{-5} mol/l, 3 : 4.0×10^{-5} mol/l, 4 : 4.0×10^{-6} mol/l. Excitation wavelength : 354 nm.

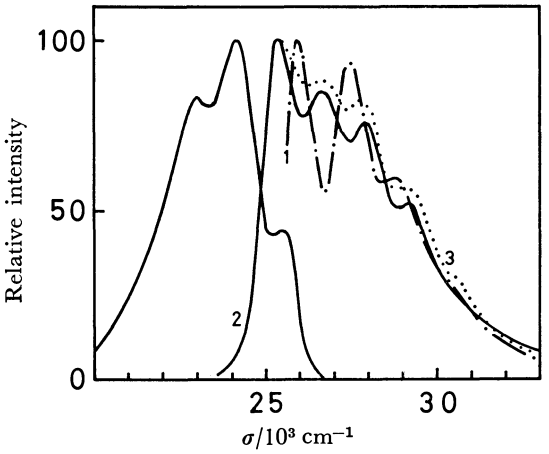

Fig. 6. The fluorescence and excitation spectra of 2-anthroic acid in ethanol at room temperature. Solute concentration : 4.0×10^{-5} mol/l. 1 : Observed at 395 nm, 2 : observed at 430 nm, 3 : observed at 460 nm.

corresponds to the dimer absorption spectrum. On the other hand, the excitation spectrum monitored at 396 nm corresponds to the monomer absorption spectrum. This indicates that the fluorescence observed at higher concentration is attributed to the dimer species.

The spectral dependence of the fluorescence of 2-anthroic acid on concentration is given in Fig. 5. The fluorescence of 2-anthroic acid has a vibrational structure at lower concentration. An approximate mirror-image relation of the fluorescence spectrum to the ^1L_b absorption band is observed. The fluorescence observed at lower concentration may therefore be assigned to the ^1L_b transition. On increasing the concentration, the fluorescence spectrum shifts to the red and becomes structureless. Figure 6 shows the excitation spectra of 2-anthroic acid in ethanol. The excitation spectrum corresponds to the monomer absorption band when monitored at 395 nm, while it corresponds to the dimer one when monitored at 430 nm. These findings indicate that the broad fluorescence can be assigned to the dimer fluorescence.

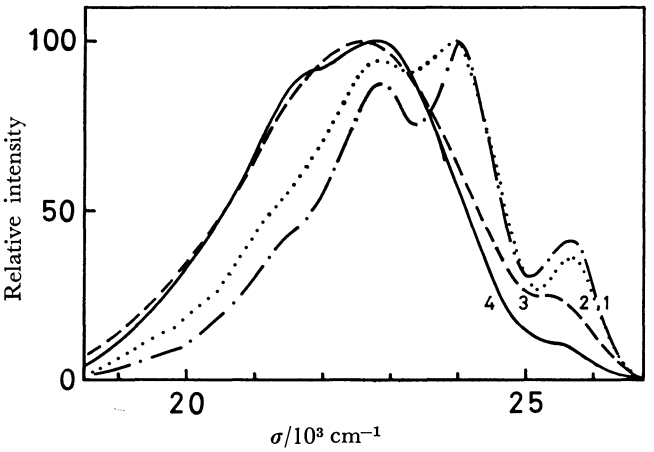

Fig. 7. The fluorescence spectra of 2-anthroic acid in ethanol at various temperatures. Solute concentration : 5.0×10^{-6} mol/l. Excitation wavelength : 360 nm. 1 : 293 K, 2 : 141 K, 3 : 109 K, 4 : 77 K.

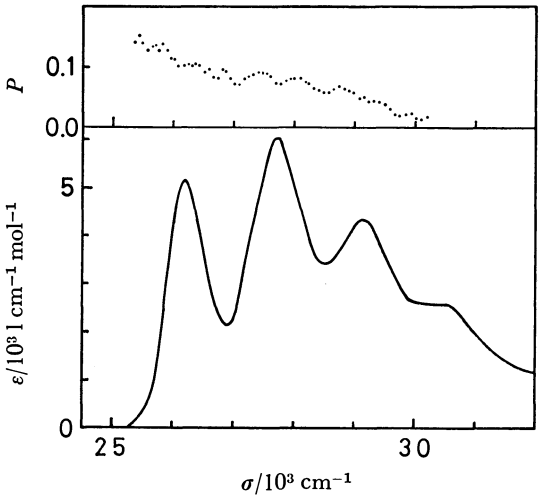

Fig. 8. The fluorescence excitation polarization spectra of 2-anthroic acid in ethanol at 152 K (upper) and the estimated monomer absorption spectrum (lower). Solute concentration : 6.8×10^{-6} mol/l. Observation wavelength : 420 nm.

Figure 7 shows the temperature dependence of the fluorescence of 1-anthroic acid in ethanol. Below the temperature at which the solvent freezes, the fluorescence of 1-anthroic acid has a vibrational structure. A mirror-image relationship between the absorption and fluorescence spectra is observed at lower temperature, although it is lost at room temperature. On the contrary to this, a mirror-image relation between the absorption and fluorescence spectra is observed in 2-anthroic acid at room temperature. These indicate that some geometrical relaxation occurs in 1-anthroic acid during its fluorescence lifetime.

X-Ray analysis of 1-naphthoic acid shows that the angle between the planes of the naphthalene ring and carboxyl group is 11°.[22] Steric hindrance in 1-anthroic acid to coplanarity of the carboxyl group and an aromatic ring should be similar to that of 1-naphthoic acid. An excited-state rotation of the carboxyl group into the plane of the anthracene ring may occur and

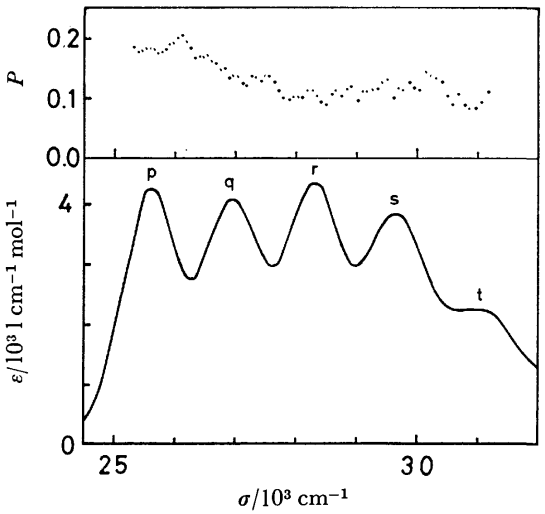

Fig. 9. The fluorescence excitation polarization spectra of 2-anthroic acid in ethanol at 156 K (upper) and the estimated dimer absorption spectrum (lower). Solute concentration : 4.7×10^{-5} mol/l. Observation wavelength : 480 nm.

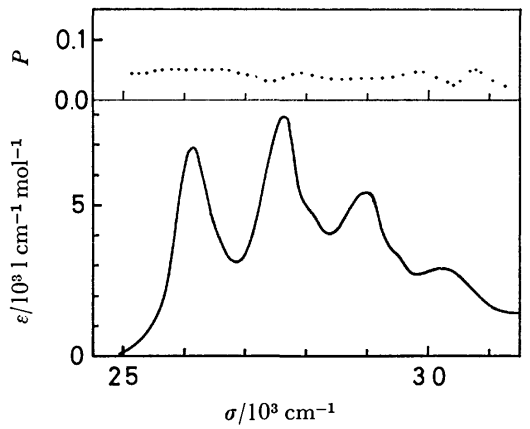

Fig. 10. The fluorescence excitation polarization spectra of 1-anthroic acid in methanol at 171 K (upper) and the estimated monomer absorption spectrum (lower). Solute concentration : 4.4×10^{-5} mol/l. Observation wavelength : 425 nm.

a structureless fluorescence is observed. Steric hindrance in 2-anthroic acid seems to be negligible and no geometrical relaxation upon excitation is expected to occur in 2-anthroic acid. Indeed, a mirror-symmetry relationship is observed in 2-anthroic acid even at room temperature. Any geometrical relaxation is impossible at sufficiently low temperature and, consequently, a mirror-symmetry relationship is observed in 1-anthroic acid at low temperature.

Figure 8 shows the fluorescence excitation polarization spectrum of 2-anthroic acid in ethanol at a concentration of 6.8×10^{-6} mol/l, together with the estimated monomer absorption spectrum. At such a low concentration, 2-anthroic acid exists substantially in the monomer form. The degree of polarization, P, decreases with increasing excitation energy. This suggests that two different electronic bands lie in this region. Figure 9 shows the fluorescence excitation spectrum of 2-anthroic acid at a concentration of 4.7×10^{-5} mol/l, together with the estimated dimer absorption spectrum. It appears from Fig. 2 that the 4.7×10^{-5} mol/l solution contains considerable amounts of dimer species. Furthermore, a 480-nm observation predominantly detects the fluorescence from dimer species. The polarization spectrum indicates that Bands p and q and Bands r, s, and t belong to different transitions.

The fluorescence excitation polarization spectrum of 1-anthroic acid in methanol is given in Fig. 10, together with the estimated monomer absorption spectrum. The concentration of the sample solution was 4.4×10^{-5} mol/l; 1-anthroic acid predominantly exists in monomer form. The value of P is relatively small, since the temperature is high compared with the freezing point of the solvent. The polarization spectrum has almost the same P values over the whole region of the lowest-frequency absorption band. The lowest-frequency absorption band appears to consist of a single electronic transition. The ^1L_a and ^1L_b bands of 1-derivatives of anthracene, in general, lie closely, the ^1L_b band being found at the lower energy side of the ^1L_a band.[13-15] There is no evidence of the ^1L_b band lying under the ^1L_a band in 1-anthroic acid. The ^1L_b band of 1-anthroic acid seems to have a very small oscillator strength owing to the steric hindrance described above. The same situation was encountered in 9-anthroic acid.

Kinetic Consideration. An excimer mechanism has been presented for the pronounced concentration dependence of 9-anthroic acid in alcoholic solvents.[4] 9-Anthroic acid forms a hydrogen-bonded dimer in its ground state. The monomer species show the structured fluorescence. The red-shifted broad fluorescence was assigned to the excimer which is formed by the association of the excited and unexcited hydrogen bonded dimers. It was shown that the ratio of the intensity of the excimer fluorescence to that of the monomer fluorescence, $R=I_E/I_M$, is proportional to $[D]^{3/2}$ at low dimer concentrations, where I_E and I_M refer to the fluorescence intensity of the excimer and the monomer, respectively.[4] When the broad fluorescence is attributed to the dimer, on the other hand, it can easily be shown that the ratio R is proportional to [D].

The corrected fluorescence spectra at various concentrations were divided into the monomer and dimer components, the spectral shapes of which are assumed to be the same as the corrected fluorescence spectra observed at the lowest and the highest concentration. Figure 11 gives the log R plots *vs.* log [D] for 1- and 2-anthroic acids. It is seen from the figures that the slope of the plots is 1 for both 1- and 2- anthroic acids. These observations indicate that no excimer-type fluorescence is observed in 1- and 2-anthroic acids in contrast to 9-anthroic acid.

The sufficient overlap of the two anthracene rings constituting the hydrogen-bonded dimers is essential to the formation of stable excimers. The hydrogen-bonded dimers of 1- and 2-anthroic acids may have two types of conformations which are *cis-* and *trans-*

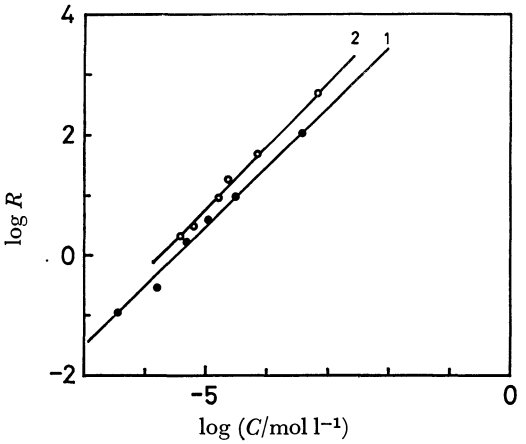

Fig. 11. The log R plots *vs.* log [D]. 1 : 1-Anthroic acid in methanol, 2 : 2-anthroic acid in ethanol.

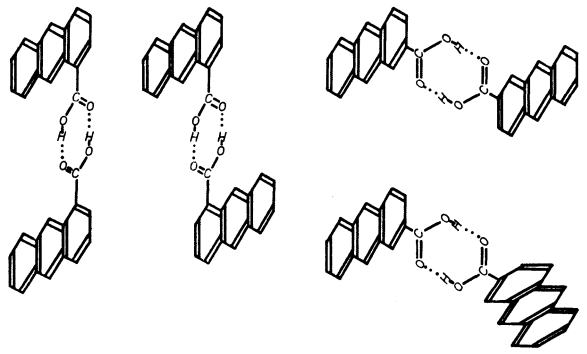

Fig. 12. The types of dimer conformations.

forms relative to $-C\begin{matrix}\diagup O\cdots HO\diagdown \\ \diagdown OH\cdots C\diagup\end{matrix}C-$ linkages, while 9-anthroic acid forms a single type of dimers (see Fig. 12). This decreases the possibilities of excimer formation in 1- and 2-anthroic acids compared with 9-anthroic acid, because the presence of two types of dimer conformations decreases the possibility for encounter of the same type of dimers. Furthermore, the molecular rotation necessary for the two pairs of anthracene rings to overlap sufficiently is generally greater in 1- and 2-anthroic acids than in 9-anthroic acid. For example, when the planes of two dimers are parallel, the complete overlap of two anthracene rings can be realized by the in-plane rotation less than 45° with respect to the other in 9-anthroic acid. In the case of 1- and 2-anthroic acids, on the other hand, the complete overlap is not always realized by the in-plane rotation; sometimes it is necessary to reverse one dimer molecule with respect to the other. This further decreases the possibility of excimer formation in 1- and 2-anthroic acids than in 9-anthroic acid.

The ground-state dimer formation in alcoholic solvents is confirmed in 1- and 2-anthroic acids as well as in 9-anthroic acid. No excimer-type fluorescence is observed in 1- and 2-anthroic acids in contrast to 9-anthroic acid. This is interpreted by the variety of dimer conformations in 1- and 2-anthroic acids. The lack of mirror-symmetry relationship between the absorption and fluorescence spectra of 1-anthroic acid is explained by the geometrical relaxation in its excited state.

The Formation of Mg-bearing Ferrite by the Air Oxidation of Aqueous Suspensions

Ken KANEKO* and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 21, 1978)

When the Mg^{2+}/Fe_{total} molar ratio in the initial aqueous suspension is below 0.1 at pH 9.0 and 65 °C, almost all Mg^{2+} is incorporated into the spinel type ferrite by the air oxidation of $Fe(OH)_2$. The chemical composition of the Mg-bearing ferrite thus obtained is not stoichiometric, and is expressed as the $MgFe_2O_4$–Fe_3O_4–γ-Fe_2O_3 system. When the Mg^{2+}/Fe_{total} ratio exceeds 0.1, the excess Mg^{2+} produces a basic magnesium sulfate which has a composition of $[Mg^{2+}_{1.00}, Na^{+}_{0.64}]\,[OH^{-}_{1.36}, (SO_4^{2-})_{0.64}]$. At pH 8.0, a small amount of the Mg^{2+} is incorporated into the ferrite, between pH 9.0 and 10.0 only the Mg-bearing ferrite is formed, and at pH 11.0, the α-FeOOH type compound is formed together with the Mg-bearing ferrite.

Recently, the formation of the spinel type ferrites from aqueous suspensions have been extensively studied.[1–5] Mn and Co ferrites have been synthesized by the air oxidation of the $Fe(OH)_2$ aqueous suspensions containing these metal ions by Kiyama.[5]

Feitknecht[6] studied in detail the formation of the iron oxides and presented the optimum conditions to form magnetite (Fe_3O_4) from the aqueous suspension of $Fe(OH)_2$. Kiyama[7] clarified the temperature dependence of the formation of Fe_3O_4 and pointed out that higher temperatures are more favorable. Recently, more favorable reaction conditions for the formation of Fe_3O_4 have been studied using some weak dispersing reagents.[8] The optimum conditions for the formation of the spinel type ferrites containing various heavy elements from aqueous suspensions appears to differ from those of Fe_3O_4, and are dependent on the pH value, temperature and the concentration of the metal ions in the $Fe(OH)_2$ aqueous suspension.

The complete removal of the heavy metal ions by means of the ferrite formation process is important not only for the basic study but also for the treatment of the concentrated waste water by the "Ferrite Process."[9]

In this study, the formation of the Mg-bearing ferrite from the aqueous suspension of $Fe(OH)_2$ by air oxidation has been investigated in the presence of various concentrations of magnesium at pH values ranging from 8 to 11 at 65 °C. On the basis of these results, the most favorable conditions for the formation of the Mg-bearing ferrite are presented.

Experimental

Reagents. Chemical reagents of analytical grades were used. A 2 mol/dm³-NaOH solution was prepared by dissolving NaOH in distilled water free from CO_2 and O_2. A 0.863 mol/dm³ of $MgSO_4$ solution was prepared using $MgSO_4 \cdot 7H_2O$.

Apparatus. The Dewar reaction vessel used is shown in Fig. 1. The temperature of the vessel was kept constant at 65 °C by circulating warm water at just 65 °C through the outer jacket. The inner flask with a semi-spherical bottom (300 cm³) was closed with a silicone-rubber stopper incorporating a stirring apparatus(A), a N_2- or air-introducing tube (B), a condenser(C), a platinum electrode(D), a glass electrode (E), a calomel electrode with double junction(F) and a buret(G).

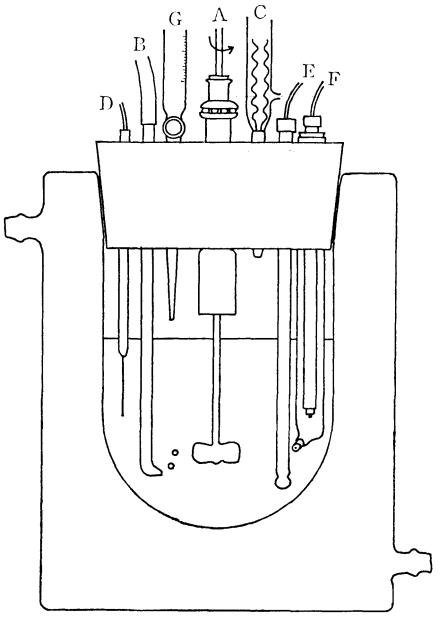

Fig. 1. The reaction vessel with a silicone stopper. A : Stirring apparatus, B : N_2- or air-introducing tube, C : reflux condenser, D : platinum electrode, E : glass electrode, F : calomel electrode(double junction type), G : buret.

Procedure. After addition of the distilled water and the solutions of $MgSO_4$ and Na_2SO_4, nitrogen gas was bubbled into the solution with stirring at 1000 r.p.m. for 1 h to remove the dissolved gases of carbon dioxide and oxygen. Then, $FeSO_4 \cdot 7H_2O$ (12 g) was added to the solution and dissolved completely. The resultant volume of the solution was 200 cm³, and the total concentration of SO_4^{2-} was fixed at 65 mmol/200 cm³ (this solution is termed the initial solution). The pH was adjusted using 2 mol/dm³ NaOH solution. After standing for 1 h with stirring under nitrogen 65 °C, the oxidation of the ferrous ion was initiated by passing air into the suspension instead of nitrogen at the rate of 0.20 dm³/min. During the oxidation, the pH value was kept constant by the addition of 2 mol/dm³ NaOH or 0.5 mol/dm³ H_2SO_4 solution, and the oxidation potential(ORP) was measured. At the end of the oxidation reaction, the ORP value increased rapidly from about −800 mV to nearly 0 mV (measured by Pt-calomel electrodes). Figure 2 illustrates the relationship between the Fe^{2+}/Fe_{total} value and the oxidation time (min). As seen the rapid increase of the ORP indicates an abrupt change in the oxidation rate. The detailed study of the ORP change will be reported in the near future. In

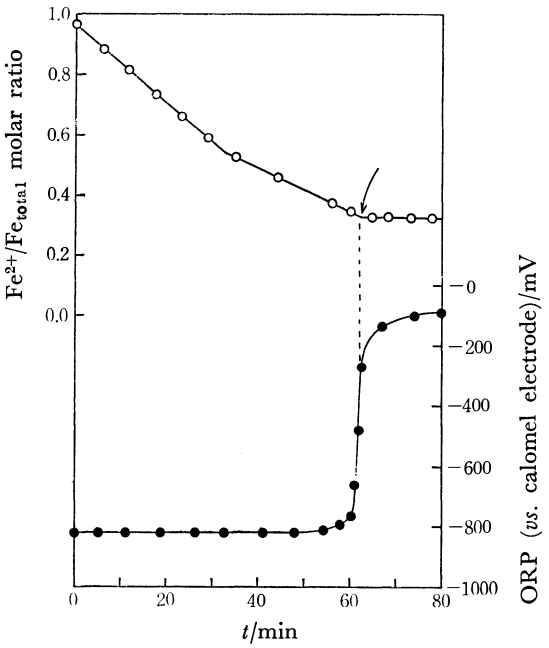

Fig. 2. The relationship between the Fe^{2+}/Fe_{total} molar ratio in suspension (the initial solution contains $Fe(OH)_2$ alone). An arrow means the end point of the formation of ferrite.

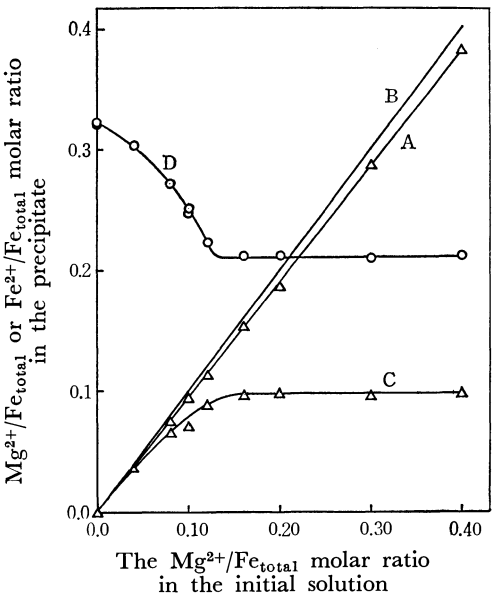

Fig. 3. The relationship between the Mg^{2+}/Fe_{total} molar ratio in the initial solution and the Mg^{2+}/Fe_{total} or Fe^{2+}/Fe_{total} molar ratio in the Precipitates A and B. Curve A: The Mg^{2+}/Fe_{total} molar ratio in the Precipitate A, Curve B: the Mg^{2+}/Fe_{total} molar ratio in the initial solution, Curve C: the Mg^{2+}/Fe_{total} molar ratio in the Precipitate B, Curve D: the Fe^{2+}/Fe_{total} molar ratio in the Precipitate B.

the present study, the air oxidation was stopped 10 min after the abrupt change in the ORP value and then nitrogen gas was passed through the suspension in place of the air. An aliquot of the suspension was removed and immediately centrifuged (3000 r.p.m.). The precipitate thus obtained is referred to as Precipitate A in this paper. The suspension containing Precipitate A was treated with 0.5 mol/dm^3-H_2SO_4 solution to lower the pH value of the suspension to 5.0. At this time, 0.5 mol/dm^3 H_2SO_4 solution was added very slowly at the rate of 0.1—1.0 cm^3/15 min. The obtained suspension was then centrifuged (3000 r.p.m.). The precipitate thus obtained is referred to as Precipitate B. Precipitates A and B were dried *in vacuo* at room temperature.

Chemical Analysis. The Fe^{2+} and Fe^{3+} contents in the Precipitates A and B were determined by the method described by Katsura.[10] When necessary, the spectrophotometric method using 2,2′-bipyridyl[11] or the gravimetric method was applied. The magnesium content was determined by EDTA titration after removal of iron from solution as tris(8-quinolinolato)iron(III) or iron(III) hydroxide. Sodium and sulfate ions were determined by flame-photometry and gravimetry(as $BaSO_4$), respectively.

Precipitates A and B were examined by the X-ray powder diffraction method using Fe *Kα* radiation. The Curie point of Precipitate B was measured *in vacuo*, and the saturation magnetization was measured at room temperature in comparison with Ni as standard.

Results and Discussion

The Oxidation Products at pH *9.0.* Mg-bearing ferrites were prepared at pH 9.0 and at 65 °C by varying the Mg^{2+}/Fe_{total} molar ratio, the results of which are shown in Fig. 3. As shown by Curve A in Fig. 3, the Mg^{2+} content in Precipitate A increases linearly with increasing concentration of Mg^{2+} in the initial solution. The initial concentration of Mg^{2+} before the air oxidation is also given by Curve B in Fig. 3, and Curve B is very similar to Curve A, indicating that almost all the Mg^{2+} added to the initial solution was incorporated into Precipitate A. The Mg^{2+}/Fe_{total} ratio in Precipitate B is also given by Curve C in Fig. 3. As seen in Curve C, the concentration of Mg^{2+} in Precipitate B increases with increasing concentration of Mg^{2+} in the initial solution when the Mg^{2+}/Fe_{total} ratio in the initial solution is sufficiently low. However, when the Mg^{2+}/Fe_{total} ratio is higher than 0.1, the ratio in Precipitate B gives a constant value of about 0.1, suggesting that Precipitate A is composed of a heterogeneous mixture of a soluble and an insoluble Mg compound at pH 5.0.

The X-ray diffraction patterns of Precipitates A and B at conditions below the Mg^{2+}/Fe_{total} ratio of 0.15 were almost identical and all peaks corresponded to those of the spinel type structure. An example is given by A in Fig. 4. In the patterns of Precipitate A which has a Mg^{2+}/Fe_{total} ratio of 0.3, there are two distinct additional peaks other than those of the Mg-bearing ferrite. An example is given by B in Fig. 4. These small and broadened peaks could not assigned, but in the patterns of Precipitate B having the same Mg^{2+}/Fe_{total} ratio, these two peaks disappeared as shown by C in Fig. 4. This suggests that Precipitate A contains some Mg-bearing compound which is soluble at pH 5.0. In addition, the amount of iron dissolved from Precipitate A was negligibly small at pH 5.0, indicating the absence of iron-bearing compounds in Precipitate A other than Mg-bearing ferrite. The chemical composition of the soluble Mg-bearing compound was determined to be $[Mg^{2+}_{1.00}, Na^{+}_{0.64}][OH^{-}_{1.36}, (SO_4^{2-})_{0.64}]$ on the basis of the differences between the

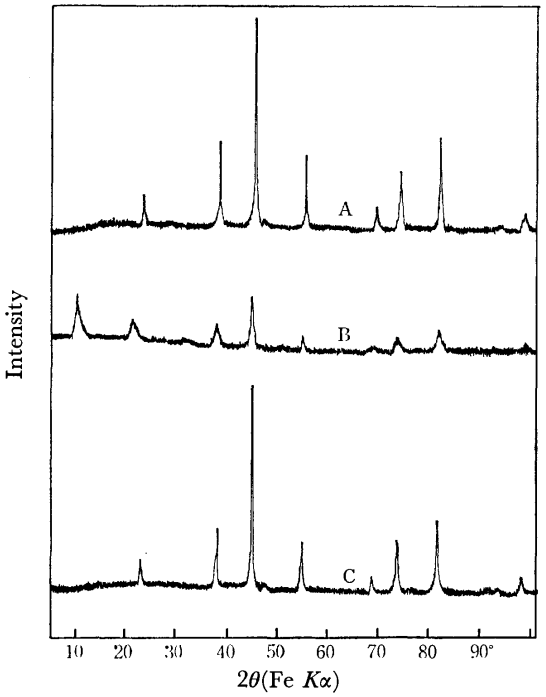

Fig. 4. The X-ray powder diffraction patterns of the Precipitates A and B. Pattern A : For the Precipitate A obtained at the Mg^{2+}/Fe_{total} molar ratio of 0.1, Pattern B : for the Precipitate A at the ratio of 0.3, Pattern C : for the Precipitate B obtained at the ratio of 0.3.

chemical compositions of Precipitates A and B. Here the number of hydroxy entities has been estimated based on the electrical neutrality. This estimation will be discussed in a later section of this paper.

The relationship between the Fe^{2+}/Fe_{total} molar ratio in Precipitate B and the Mg^{2+}/Fe_{total} ratio in the initial solution is given by Curve D in Fig. 3. As seen the amount of Fe^{2+} relative to the total concentration of iron in Precipitate B decreases with increasing concentration of Mg^{2+} in the initial solution becoming constant at approximately 0.21 of the Fe^{2+}/Fe_{total} ratio. Thus, Curves C and D are in good agreement with each other. Moreover, the fall in concentration of Fe^{2+} is approximately equal to the rise in concentration of Mg^{2+}. These results indicate the high possibility that the Mg-bearing ferrite is formed during the course of the air oxidation and that the Mg^{2+} replaces the Fe^{2+} in the crystal lattice of the spinel structure. The formation of the solid solution between Fe_3O_4 and $MgFe_2O_4$ is narrowly limited to below 0.1 measured by the Mg^{2+}/Fe_{total} ratio. It is easy however to synthesize the complete solid solution at high temperatures above 1000 °C.[12] In addition, the composition of Fe_3O_4 (magnetite), formed from the $Fe(OH)_2$ suspended solution by air oxidation, is usually non-stoichiometric, tending to form the γ-Fe_2O_3 component with a spinel structure. Thus, it is necessary to analyze Fe^{2+}, Fe^{3+}, and Mg^{2+} in solid solution to obtain the composition as a ternary system. In the present work, the maximum solid solubility of the component $MgFe_2O_4$ has been caluculated to be 0.249 $MgFe_2O_4 \cdot 0.541$ $Fe_3O_4 \cdot 0.210$ γ-Fe_2O_3 implying that the solid solution is appreciably non-stoichiometric in

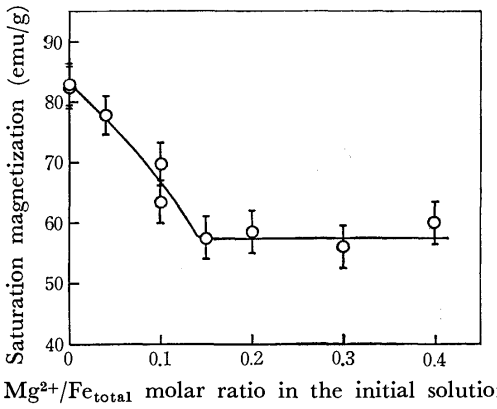

Fig. 5. The magnetization of the Precipitate B with various amounts of Mg^{2+} (at room temperature).

composition.

Saturation Magnetization. Precipitate B is a ferromagnet at room temperature. The temperature dependence of the magnetization of Precipitate B obtained at the Mg^{2+}/Fe_{total} ratio of 0.3 was measured under 4000 Oe of the external magnetic field(1 Oe= $(1000/4\pi)$A/m) and *in vacuo*. The Curie temperature was found to be approximately 568 °C. The magnetization of Precipitate B formed from the initial solution with varying Mg^{2+}/Fe_{total} ratios was also measured at room temperature, the results of which are shown in Fig. 5. As seen the magnetization at room temperature decreases with increasing concentration of Mg^{2+} in the initial solution, but in the range of Mg^{2+}/Fe_{total} ratio from 0.1 to 0.4, the magnetization becomes constant at about 60 emu/g(1 emu/g=10^{-7} Tm^3/kg). This value is intermediate between those of $MgFe_2O_4$ (27 emu/g at 20 °C), Fe_3O_4(92 emu/g at 20 °C), and γ-Fe_2O_3(82.5 emu/g at 0 K). The results obtained from the magnetic properties are in good agreement with those obtained from chemical analysis and the X-ray analysis previously described. It may thus be concluded that at the Mg^{2+}/Fe_{total} ratio below 0.1, almost all Mg^{2+} in the initial solution is incorporated into the spinel type structure by replacement of Fe^{2+}. Above 0.1, the excess Mg^{2+} does not replace the Fe^{2+} which is constructing the spinel type structure.

Non-stoichiometry in the Mg-bearing Ferrite Composition. It is convenient to illustrate the non-stoichiometry in the Mg-bearing ferrite using three components as the Fe_3O_4–Fe_2O_3–$MgFe_2O_4$ system. The results are shown in Fig. 6. The letter at each point in Fig. 6 corresponds to the Mg^{2+}/Fe_{total} in the initial solution, and the broken line indicates an oxygen reaction lines as an example. When the stoichiometric composition of the Fe_3O_4–$MgFe_2O_4$ solid solution was obtained, the composition of the product must be on the Fe_3O_4–$MgFe_2O_4$ line. As clearly seen in Fig. 6, the Mg-bearing ferrite is appreciably oxidized while maintaining a spinel type structure, and the degree of oxidation increases with increasing $MgFe_2O_4$ component.

pH *Change during Reaction.* In general, as indicated by Katsura *et al.*,[9] the pH of the suspension decreases with air oxidation. However, when the initial solution contains Mg^{2+}, the pH increases gradually in the early stages of the air oxidation and then falls.

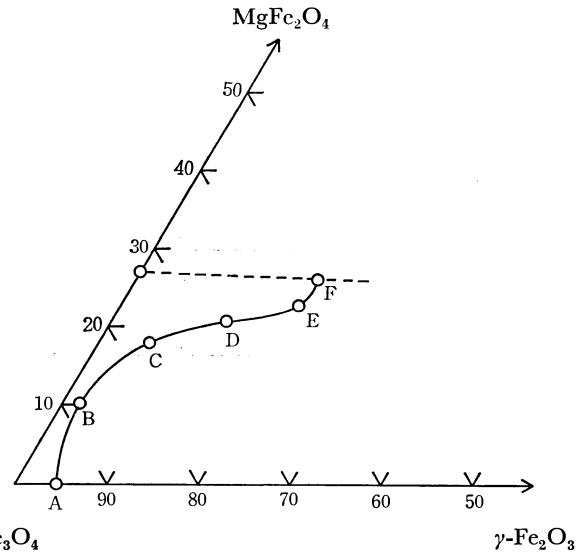

Fig. 6. The chemical compositions of the Precipitates B expressed as the Fe_3O_4–Fe_2O_3–$MgFe_2O_4$ system. Points A, B, C, D, E, and F were obtained at the Mg^{2+}/Fe_{total} molar ratios of 0.00, 0.04, 0.08, 0.10, 0.12, and above 0.15, respectively. The broken line shows *the oxygen reaction line.*

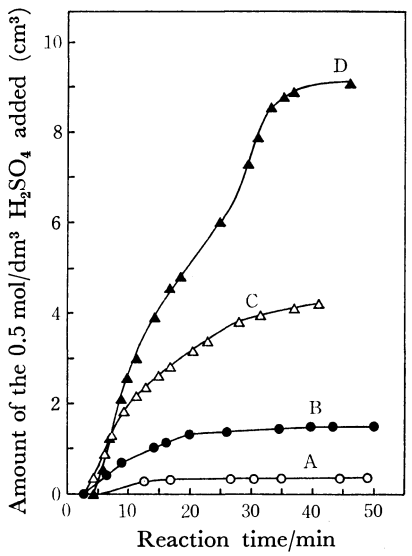

Fig. 7. The relationship between the reaction time and the amount of 0.5 mol/dm³ H_2SO_4 solution added to the suspension to keep the pH value of the initial solution constant at pH 9.0. Curves A, B, C, and D were obtained at the Mg^{2+}/Fe_{total} molar ratios of 0.1, 0.2, 0.3, and 0.4, respectively.

In this study, a 0.5 mol/dm³ H_2SO_4 solution was added at an early stage in the reaction to maintain the pH at 9.0. Figure 7 illustrates the relationship between the reaction time and the amount of 0.5 mol/dm³ H_2SO_4 solution necessary to maintain the pH at 9.0. The amount of 0.5 mol/dm³ H_2SO_4 solution in Fig. 7 indicates the total amount of solution added at each reaction time. The curves A, B, C, and D show the results corresponding to varying the Mg^{2+}/Fe_{total} ratios; 0.1, 0.2, 0.3, and 0.4, respectively. As seen in Fig. 7, the pH did not change for about 4 min from the starting time irrespective of the Mg^{2+}/Fe_{total} ratio. However, when the Mg^{2+}/Fe_{total} ratio exceeded 0.1, rapid increases in the 0.5 mol/dm³ H_2SO_4 solution were necessary to maintain the pH at 9.0, and the amount of 0.5 mol/dm³ H_2SO_4 solution added depended on the Mg^{2+}/Fe_{total} ratio in the initial solution. In the case of A, the amount of the H_2SO_4 solution added was very small (0.36 cm³), and the addition of H_2SO_4 solution ceased at about 15 min after the reaction was initiated. In a previous section, it was suggested that Precipitate A contains a basic Mg-bearing sulfate with the composition of $[Mg^{2+}_{1.00}, Na^{+}_{0.64}][OH^{-}_{1.36}, (SO_4^{2-})_{0.64}]$ (hereafter compound A). On the basis of these experimental results, the following schematic equation has been postulated for the change in pH of the suspension in the early stages of oxidation,

$$3Fe(OH)_2 + 3x\cdot Mg(OH)_2 + 1.92(x-y)\cdot Na_2SO_4 + \frac{1+y}{2}\cdot O_2 \rightarrow (1+y)\cdot[Mg^{2+}_{3y/(1+y)}Fe^{2+}_{(1-2y)/(1+y)}Fe^{3+}_2O_4] + 3(1-y)\cdot A + 1.92(x-y)\cdot NaOH + 3(1+x-0.64)\cdot H_2O \quad (x>0.1), \quad (1)$$

where x and y are the Mg^{2+}/Fe_{total} ratios in the initial solution and the spinel type Mg-bearing solid solution, respectively. It is evident from Eq. 1 that some amount of Na_2SO_4 in the initial solution should be consumed to form compound A. The calculated amount of 0.5 mol/dm³ H_2SO_4 solution was obtained on the basis of Eq. 1 at the molar ratios of 0.2, 0.3, and 0.4 and the values obtained are summarized in Table 1. As seen in Table 1, the calculated values are in reasonable agreement with the experimental values within experimental error strongly supporting the validity of Eq. 1 in representing the oxidation process occurring in the suspension at the early stage when the Mg^{2+}/Fe_{total} ratio in the solution exceeds 0.1.

TABLE 1. TOTAL AMOUNTS OF THE 0.5 mol/dm³ H_2SO_4 SOLUTION CONSUMED TO KEEP THE pH CONSTANT IN THE COURSE OF THE OXIDATION REACTION

Amount of Mg^{2+} in the initial solution (Mg^{2+}/Fe_{total})	Experimental value (cm³)	Theoretical value evaluated from Eq. 1 (cm³)
0.20	1.5	2.42
0.30	4.15	5.33

As previously reported when the Mg^{2+}/Fe_{total} ratio in the initial solution is below 0.1, all the Mg^{2+} is completely incorporated into the spinel type structure to form Mg-bearing ferrite solid solution. Consequently there is no need to consume H_2SO_4 solution to maintain the pH in the suspension, and no magnesium basic sulfate A is formed. Thus, the oxidation reaction may be represented as the following when the Mg^{2+}/Fe_{total} ratio in the initial solution is below 0.1.

$$3Fe(OH)_2 + 3x\cdot Mg(OH)_2 + \frac{(x+1)}{2}\cdot O_2 \rightarrow (x+1)\cdot[Mg^{2+}_{3x/(x+1)}Fe^{2+}_{(1-2x)/(x+1)}Fe^{3+}_2O_4] + 3(x+1)\cdot H_2O \quad (x<0.1). \quad (2)$$

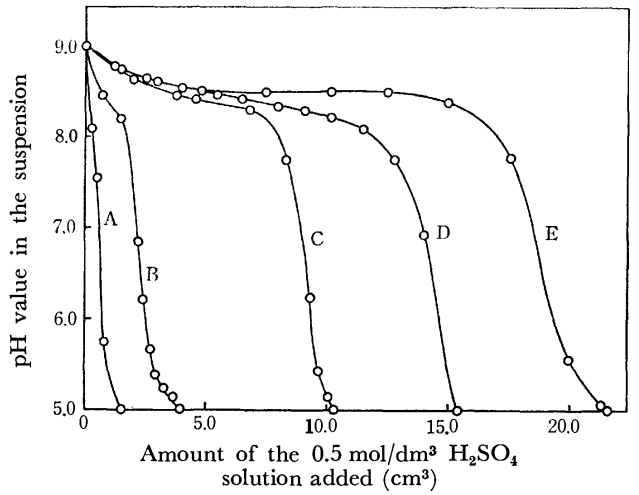

Fig. 8. The relationship between the pH changes of the suspensions containing the Precipitate A and the amount of 0.5 mol/dm³ H_2SO_4 solution. Curves A, B, C, D, and E were obtained at the Mg^{2+}/Fe_{total} molar ratios of 0.04, 0.1, 0.2, 0.3, and 0.4, respectively.

Dissolution of Compound A. Figure 8 demonstrates the relationship between the change in pH of the suspended solution containing Precipitate A and the added amount of 0.5 mol/dm³ H_2SO_4 solution. The curves A, B, C, D, and E show the pH change curves at Mg^{2+}/Fe_{total} ratios of 0.04, 0.1, 0.2, 0.3 and 0.4 at pH 9.0, respectively. As seen in Fig. 8, a smooth plateau exists in the pH range from 8.0 to 8.5 when the Mg^{2+}/Fe_{total} ratios are above 0.2. These results may indicate that compound A is formed at higher concentrations of Mg^{2+} and that compound A appears to consist of one phase considering the smooth plateau at pH 8.5. It is reasonable to assume that the amounts of 0.5 mol/dm³ H_2SO_4 solution consumed to lower the pH of the suspension to 5.0 correspond to the amounts of OH^- of compound A. Consequently the OH^-/Mg^{2+} ratio has been determined in each suspension for Mg^{2+}/Fe_{total} ratios of 0.2, 0.3, and 0.4, and 1.30 obtained as an average value. This ratio is in good agreement with that estimated by chemical analysis, $[Mg^{2+}_{1.00}, Na^{+}_{0.64}][OH^{-}_{1.36}, (SO_4^{2-})_{0.64}]$.

The pH Dependence of Precipitate A. In the preceding sections, the properties of Precipitate A formed at pH 9.0 and 65 °C have been discussed. In subsequent experiments the pH was changed from 8.0 to 11.0 at constant temperature. The Mg^{2+}/Fe_{total} ratio in the initial solution was fixed at 0.1. Curve A in Fig. 9 illustrates the relationship between the Mg^{2+}/Fe_{total} ratio in Precipitate A and the pH value of the suspension, and Curve B that for Precipitate B. As seen in Curves A and B in Fig. 9, the Mg^{2+}/Fe_{total} ratio in Precipitates A and B is almost constant (0.1 to 0.095) in the pH range 9.0 to 11.0, but at pH 8.0 the ratio was lowered to 0.02 and 0.01 in Precipitates A and B, respectively. The implication is that the incorporation of Mg^{2+} into Precipitate B having a spinel type structure is strongly influenced by a lowering of the pH. Some appreciable but small differences in composition are seen between Precipitates A and B, even in the high pH range 9.0 to 11.0. This small

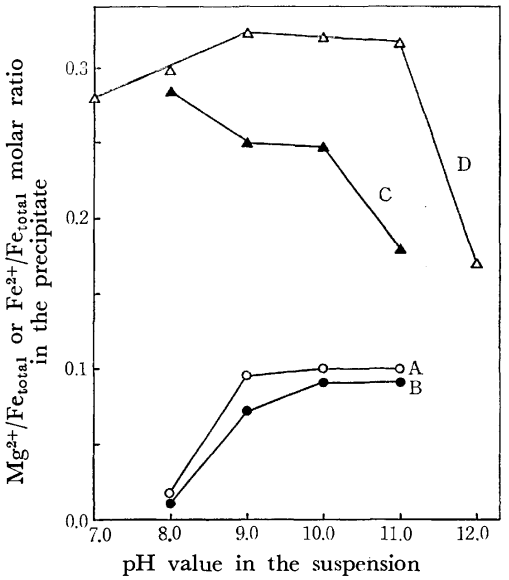

Fig. 9. The relationship between the pH value of the suspension and the chemical composition of the Precipitates A and B. The Mg^{2+}/Fe_{total} molar ratio in the initial solution is fixed to 0.1. Curve A : The ratio in the Precipitate A, Curve B : the ratio in the Precipitate B, Curve C : the Fe^{2+}/Fe_{total} molar ratio in the Precipitate B, Curve D : the Fe^{2+}/Fe_{total} molar ratio in the precipitate formed by the air oxidation of the $Fe(OH)_2$ suspension without Mg^{2+}.

difference may be attributed to the presence of small amounts of compound A included in Precipitate A.

Curve C in Fig. 9 illustrates the relationship between the Fe^{2+}/Fe_{total} ratio in Precipitate B and the pH value in the suspension. At pH 8.0 the Fe^{2+}/Fe_{total} ratio was 0.285. This means that the $(Mg^{2+}+Fe^{2+})/(Mg^{2+}+Fe_{total})$ ratio for this sample is 0.292 which is close to that for the Fe_3O_4 compound. In the case of pH 11.0, the Mg^{2+}/Fe_{total} ratio was 0.1 and the Fe^{2+}/Fe_{total} ratio 0.180, and so the $(Mg^{2+}+Fe^{2+})/(Mg^{2+}+Fe_{total})$ ratio becomes 0.254. This decrease in value is caused by the oxidation of Precipitate B with or without change in crystal structure. Thus, it is evident from Curve C in Fig. 9 that Precipitate B, prepared at relatively high pH is oxidized.

According to the powder X-ray diffraction patterns, the peaks were all of the spinel type when Precipitate B was prepared in the pH range 8.0 to 10.0. Precipitate B prepared at pH 11.0 however contained the α-FeOOH type together with the spinel type compound. Thus it is evident that when Precipitate A is prepared at relatively high pH, such as 11 or greater, then the Fe^{2+} in the Precipitate A is oxidized to form the α-FeOOH type but not the γ-Fe_2O_3 type compound.

As a comparison, the results shown in Curve C in Fig. 9, the Fe^{2+} content in the precipitate formed by the air oxidation of the $Fe(OH)_2$ suspension without magnesium at various values of pH(7 to 12) and at 65 °C were determined, the results of which are shown by Curve D in Fig. 9. As seen the Fe^{2+}/Fe_{total} ratio in the precipitates gradually increased with increasing pH of the suspension (from 7 to 9), after which the ratio remained constant (0.323) in the pH interval

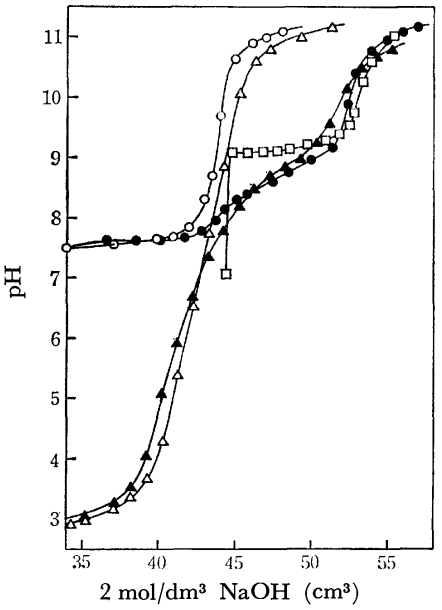

Fig. 10. Titration curves of Fe(II), Fe(II)+Mg(II), Fe(III), Fe(III)+Mg(II) and Mg(II) solutions by the 2 mol/dm³-NaOH solution. Open circle: 4.31×10^{-2} mol of Fe(II), Closed circle : 4.31×10^{-2} mol Fe(II)+ 8.63×10^{-3} mol Mg(II), Open triangle : 2.88×10^{-2} mol Fe(III), Closed triangle : 2.88×10^{-2} mol Fe(III) $+8.63\times10^{-3}$ mol Mg(II) and Open square : 8.63×10^{-3} mol Mg(II). The titration curve of Mg-(II) solution is shown from the titer of 44.3 cm³ to compare with the others. The initial volume of the solutions was fixed to 200 cm³.

from 9 to 11. At pH 12.0 however the ratio sharply decreased to 0.170. From a comparison of Curve C and Curve D, it may be concluded that the α-FeOOH type compound is liable to form in the presence of Mg^{2+}.

Hydrolysis of Magnesium in $Fe(OH)_2$ Suspension. The hydrolysis of Mg^{2+} in the course of formation of Precipitate A, was studied using the titration curves of the solution containing only Mg^{2+} and $Mg^{2+}+Fe^{2+}$ at 65 °C. The hydrolysis may enable an interpretation of the low concentration of Mg^{2+} in the Precipitates A and B when the precipitates were prepared at relatively low pH, the results of which are shown in Fig. 10. As evident from Fig. 10, Mg^{2+} was titrated at pH 9.1 to 9.3, but when the solution contained Fe^{2+} together with Mg^{2+}, both ions were titrated at 8.0 to 9.0. This lowering of the pH value is due to the co-precipitation of Mg^{2+} with Fe^{2+}. In the presence of Fe^{2+}, the hydrolysis of Mg^{2+} is therefore completed at pH 9.0, but not at 8.0, suggesting that the unhydrolyzed Mg^{2+} is not incorporated into the spinel type ferrite structure.

Feitknecht[6] demonstrated that Fe_3O_4 is formed *via* the intermediate "green rust" in neutral solution, but in slightly alkaline solutions, Fe_3O_4 is formed directly from the $Fe(OH)_2$ suspension. In the present experiments, greenish precipitates were seen in the early stages of the oxidation in the presence of the Mg^{2+} at pH 8.0. No incorporation of Mg^{2+} into the ferrite structure at pH 8.0 may, therefore, account for the formation of the "green rust" in the course of reaction.

Conclusion

From the experimental results, several conditions concerning the formation of Mg-bearing ferrite by the air oxidation of the $Fe(OH)_2$ aqueous suspension may be drawn:

1. At pH 9.0 and at 65 °C, almost all Mg^{2+} is incorporated into the spinel type ferrite when the Mg^{2+}/Fe_{total} ratio in the initial solution is less than 0.1. The chemical composition thus obtained may be expressed as the $MgFe_2O_4$–Fe_3O_4–γ-Fe_2O_3 ternary system, implying that the Mg-bearing ferrite which is a ferromagnet is not stoichiometric in its composition. The degree of oxidation increases with increasing Mg^{2+}/Fe_{total} ratio while the spinel type structure is maintained.
2. When the Mg^{2+}/Fe_{total} ratio exceeds 0.1 at pH 9.0 and 65 °C, the excess Mg^{2+} produces a basic magnesium sulfate which readily dissolves at pH 5.0. The chemical composition of this compound has been estimated as $[Mg^{2+}_{1.00}, Na^{+}_{0.64}][OH^{-}_{1.36}, (SO_4^{2-})_{0.64}]$.
3. At pH 8.0, a small amount of Mg^{2+} is incorporated into the ferrite, attributed to the formation of "green rust" in the course of reaction, indicating an absence of interaction between Mg^{2+} and the "green rust." In connection with this, the Mg^{2+} incorporated must be hydrolyzed before producing the ferrite.
4. Between pH 9.0 and 10.0, only the Mg-bearing ferrite is formed, but at pH 11.0, the α-FeOOH type compound is formed together with the Mg-bearing ferrite. Thus, the pH interval for Mg-bearing ferrite formation is limited from 9.0 to 10.0.

The authors would like to express their thanks to Drs. T. Kanzaki, Y. Tamaura, and T. Sugihara, Tokyo Institute of Technology, for the kind advice and helpful cooperation throughout the study.

Preparation and Characterization of *uns-cis*-Trimethylenediamine-*N,N'*-diacetato Cobalt(III) Complexes with Several L-Amino Acids

Minahiro OKABAYASHI,* Kozo IGI,† and Jinsai HIDAKA*
Department of Chemistry, University of Tsukuba, Ibaraki 300-31
(Received May 26, 1978)

Five *uns-cis-mer* and two *uns-cis-fac* complexes of (trimethylenediamine-*N,N'*-diacetato)(L-amino carboxylato)cobalt(III) were prepared, where L-amino carboxylate denotes L-alaninate, L-valinate, L-prolinate, L-hydrogen aspartate, or L-hydrogen glutamate ion. The complexes were separated into the fourteen isomers, *Δ*-, *Λ-uns-cis-mer* for the L-alaninato, L-valinato, and L-prolinato complexes, and *Δ*-, *Λ-uns-cis-mer* and *Δ*-, *Λ-uns-cis-fac* for the L-hydrogen aspartato and L-hydrogen glutamato complexes. They were characterized by their proton magnetic resonance, absorption and circular dichroism spectra. Each of the *uns-cis-mer* and *uns-cis-fac* isomers showed the characteristic CD behavior in the second absorption band region. The *Λ-uns-cis-mer* and *Δ-uns-cis-fac* isomers of the L-aspartato and L-glutamato complexes were stereoselectively formed, the formation ratios of the isomers being estimated spectrophotometrically.

Cobalt(III) complexes with the trimethylenediamine-*N,N'*-diacetate ion (tmdda) have been investigated in the past few years.[1,2] The trimethylenediamine-*N,N'*-diacetate ion is an O–N–N–O type ligand and similar to the ethylenediamine-*N,N'*-diacetate ion (edda) except that the former has a longer diamine moiety. The tmdda complexes were obtained only in *uns-cis* geometry except the ethylenediamine complex[3] while the edda complexes have been isolated in both geometries, *uns-cis* and *s-cis*.[4-16] In these circumstances, a synthetic work of the complexes containing tmdda, which forms a six-membered diamine backbone, and an L-amino carboxylate ion is significant for the stereoselective formation of the complexes[17] and CD behavior in the d-d transition band region.[18,19]

In the present study, the *uns-cis*-tmdda-Co(III) complexes containing the L-aspartate, L-glutamate, L-prolinate, L-valinate, or L-alaninate ion in the remaining two coordination sites were prepared and their isomers, *Δ*-, *Λ-uns-cis-mer* and *Δ*-, *Λ-uns-cis-fac* types for L-aspartato and L-glutamato complexes and *Δ*-, *Λ-uns-cis-mer* types for L-alaninato, L-valinato and L-prolinato complexes were chromatographically separated. The stereoselectivity of the complex with the L-aspartate or L-glutamate ion is discussed on the basis of the formation ratios of their isomers. Absorption and proton magnetic resonance spectra of the complexes are discussed in relation to their structures. The configurational CD contribution of the isomers was separated from the vicinal CD contribution due to the optically active ligand and the CD spectra are discussed in relation to their configurations.

Experimental

Preparation and Separation of Isomers of uns-cis-*(Trimethylenediamine-*N,N'*-diacetato) (L-hydrogen aspartato)cobalt(III)*, [*Co(tmdda)(L-aspH)*]. A solution containing 1.00 g (3.05 $\times 10^{-3}$ mol) of hydrogen dichloro(trimethylenediamine-*N,N'*-diacetato)cobaltate(III) hemihydrate,[1] H[Co(tmdda)Cl_2]·0.5H_2O in 50 cm^3 of water was heated at *ca.* 65 °C for 20 min. The color of the solution turned from green to blue and finally violet. To the solution was added a solution containing 0.50 g (3.79$\times 10^{-3}$ mol) of L-aspartic acid in 100 cm^3 of water. The pH of the solution was adjusted to 8.0 by addition of 1 mol dm^{-3} NaOH aqueous solution. After 0.5 g of activated charcoal had been added to the solution, the mixture was mechanically stirred at *ca.* 65 °C for 20 min. The charcoal and insoluble material were removed by filtration and washed with hot water until the washings became colorless. The combined filtrate and washings were concentrated to *ca.* 50 cm^3 with a rotary evaporator. The resulting violet solution was poured into a column (50 mm$\times$450 mm) containing anion-exchange resin (Dowex 1-X8, 200—400 mesh, CH_3COO^- form). The adsorbed band was separated into three bands (violet, violet, and red in the order of elution) by elution with *ca.* 0.05 mol dm^{-3} CH_3COOK solution. From their absorption and CD spectra, it was found that the first and second violet bands consist of *Λ*- and *Δ-mer*-[Co(tmdda)(L-asp)]$^-$, respectively, and the third band consists of *Δ-fac*-[Co(tmdda)(L-asp)]$^-$. The yield of each of the three isomers being very small, the chromatographic separation was repeated several times in order to store up the same eluates.

Each of the stored eluates was concentrated to a small volume with a rotary evaporator and the precipitated CH_3COOK was removed by filtration. The filtrate was then poured into a column (30 mm$\times$530 mm) packed with Sephadex G-10 resin and the adsorbed band was eluted with water in order to remove the residual CH_3COOK in the filtrate. The eluate was passed through a column (30 mm$\times$100 mm) containing cation-exchange resin (Dowex 50W-X8, 200—400 mesh, H^+ form). The passed solution was concentrated and kept in a refrigerator for two or three days after the addition of ethanol and ether. The resulting crystals were collected, washed with ethanol and then ether and dried in the air. The crystals were recrystallized from an ethanol–water (5:1) mixture by addition of acetone. Potassium salt of the *Λ-uns-cis-mer* isomer for the PMR measurement was isolated before being passed through a column containing cation-exchange resin.

The fourth isomer, *Λ-uns-cis-fac*-[Co(tmdda)(L-aspH)], not formed by the above procedure, was obtained in the following way. A reaction solution was prepared from a solution containing 2.6 g (7.93$\times 10^{-3}$ mol) of H[Co(tmdda)Cl_2]·0.5H_2O in 100 cm^3 of water and a solution containing 1.4 g (1.05$\times 10^{-2}$ mol) of L-aspartic acid in 150 cm^3 of water. The solution was mechanically stirred at *ca.* 65 °C for 60 min, no activated charcoal being used. After a small amount of insoluble material had been filtered off, the filtrate was concentrated to *ca.* 50 cm^3 with an evaporator. The solution was chromatographed on an anion-exchange column (Dowex 1-X8, 200—400 mesh, CH_3COO^- form). A large amount

of complex unreacted, presumably $[Co(tmdda)(OH_2)_2]^+$, was swept out with water. The adsorbed band was separated into four bands, violet, violet, red, and red, by elution with *ca.* 0.05 mol dm^{-3} CH_3COOK solution. It was confirmed from the absorption and CD spectra that the red band eluted last contains *Λ-uns-cis-fac*-[Co(tmdda)(L-asp)]$^-$. The last eluate was desalted and passed through a cation-exchange column (Dowex 50W-X8, 200—400 mesh, H^+ form). After the eluate had been concentrated, the solution was applied to the Sephadex G-10 column once again. This eluate was used for the absorption and CD measurements. The concentration of the eluate was determined with a Hitachi 208 atomic absorption spectrophotometer.

Preparation and Separation of Isomers of uns-cis-*(Trimethylenediamine-*N,N′*-diacetato)(*L*-hydrogen glutamato)cobalt(III)*, [*Co(tmdda)(*L*-gluH)*]. The complex was prepared and separated into four isomers in the same procedure as that for [Co(tmdda)(L-aspH)] using L-glutamic acid instead of L-aspartic acid. The reaction solution was concentrated and chromatographed on an anion-exchange column. The adsorbed band was separated into four bands (violet, violet, red, and red in the order of elution). From their absorption and CD spectra, the first and second violet bands turned out to be *Λ-* and *Δ-mer* isomers, respectively, and the third and fourth red bands *Δ-* and *Λ-fac* isomers, respectively. The four isomers have been isolated in the same procedure as that for L-aspartato complex. Since the yield of each isomer was very small, the isomers were treated in the same way as in the case of [Co(tmdda)(L-aspH)].

Preparation and Separation of Isomers of uns-cis-*(Trimethylenediamine-*N,N′*-diacetato)(*L*-prolinato)cobalt(III)*, [*Co(tmdda)(*L*-pro)*]. The complex was prepared in the same way as that for [Co(tmdda)(L-aspH)] using 0.05 g (1.52×10^{-3} mol) of H[Co(tmdda)Cl_2]·0.5H_2O[1] and 0.22 g (1.89×10^{-3} mol) of L-proline. The separation of the diastereomers was carried out by use of a column (QAE-Sephadex A-25, Cl^- form). The adsorbed band was progressively separated into three bands by elution with water. It was shown, from the absorption and CD spectra, that the first and second violet bands contain *Λ-mer* and *Δ-mer* isomers, respectively. A trace amount of the third red band was confirmed to be *fac* isomers. The two *mer* isomers have been isolated as follows.

Λ-uns-cis-mer-[*Co(tmdda)(*L*-pro)*]: The first eluate was concentrated to a small volume with a rotary evaporator and the violet complex was deposited by adding ethanol to the concentrated solution. The complex was recrystallized from an ethanol-water (3:1) mixture by adding acetone. Yield: 0.06 g.

Δ-uns-cis-mer-[*Co(tmdda)(*L*-pro)*]·*2.5H$_2$O*: The second eluate was concentrated and the violet crystals were deposited by adding ethanol and acetone to the solution. The crystals were recrystallized from an ethanol-water mixture and dried in a desiccator. Yield: 0.33 g.

Preparation and Separation of Isomers of uns-cis-*(Trimethylenediamine-*N,N′*-diacetato)(*L*-valinato)cobalt(III)*, [*Co(tmdda)(*L*-val)*]. The complex was prepared in the same way as that for [Co(tmdda)(L-aspH)] using 2.6 g (7.93×10^{-3} mol) of H[Co(tmdda)Cl_2]·0.5H_2O[1] and 1.2 g (1.00×10^{-2} mol) of L-valine. The reacted solution was evaporated to *ca.* 20 cm^3 with a rotary evaporator. The resulting violet solution was chromatographed on a column (30 mm×850 mm, QAE-Sephadex A-25, Cl^- form). The adsorbed band was separated into two bands. It was confirmed from absorption and CD spectra that the first violet band contains *Δ-mer* and *Λ-mer* isomers, and the second red band *Λ-fac* and *Δ-fac* isomers. The two *mer* isomers were isolated as follows. The first violet eluate was concentrated and the solution was kept at room temperature overnight after the addition of ethanol and ether to the concentrated solution. The purple precipitate (F 1) was separated by filtration and washed with acetone and then ether and dried in the air. Further fractions (F2—7) were obtained from the mother liquor by further addition of ethanol and ether and subsequent cooling. It was found from absorption and CD spectra that F 1, F 5, and F 6 contain both *Δ-mer* and *Λ-mer* isomers, F 2 *Λ-mer* isomer, and F 3, F 4, and F 7 *Δ-mer* isomer. Yield: 0.25 g for *Λ-mer* isomer, 1.11 g for *Δ-mer* isomer. The *Λ-mer* isomer is less soluble in water or ethanol than the *Δ-mer* isomer. The *Δ-uns-cis-mer* isomer was recrystallized from an ethanol–water (10:1) mixture and *Λ-uns-cis-mer* isomer from an ethanol–water (5:2) mixture by adding a small amount of acetone. The CD intensities of the isomers were unchanged by repeated recrystallization.

Preparation and Separation of Isomers of uns-cis-*(Trimethylenediamine-*N,N′*-diacetato)(*L*-alaninato)cobalt(III)*, [*Co(tmdda)(*L*-ala)*]. The complex was prepared by the same procedure as that for the L-valinato complex using 0.89 g (1.00×10^{-2} mol) of L-alanine in 100 cm^3 of water. Two *mer* isomers were isolated as follows. Separation of the *mer* isomers from a trace amount of *fac* isomers was carried out using a QAE-Sephadex column. The first eluate containing *Λ-mer* and *Δ-mer* isomers was concentrated and the solution

was kept at room temperature overnight, after the addition of ethanol and ether. The purple precipitate (F 1) was separated by filtration and washed with ethanol and then ether. F 2 and F 3 were obtained from the mother liquor by further addition of ethanol and ether and subsequent cooling. It was found from absorption and CD spectra that F 1 contains *Λ-mer* isomer, F 2 *Δ-mer* isomer, and F 3 both *Δ-mer* and *Λ-mer* isomers. Yield: 0.60 g for *Δ-mer* isomer, 0.60 g for *Λ-mer* isomer. Recrystallization was carried out twice for the *Δ-mer* isomer and three times for the *Λ-mer* isomer, giving no change in CD intensity from a mixture of ethanol and water by adding a small amount of acetone.

Measurements. Electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer and CD spectra with a JASCO J-20 spectropolarimeter. PMR spectra were recorded on a JEOL JNM-MH-100 NMR spectrometer at probe temperature in D_2O as solvent. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference. For determination of the concentration of *Λ-uns-cis-fac*-[Co(tmdda)(L-aspH)] aqueous solution, a Hitachi 208 atomic absorption spectrophotometer was used. The formation ratios for the L-aspartato and L-glutamato complexes were evaluated on the basis of the absorption measurements of the bands separated chromatographically.

Results and Discussion

Structural Assignments for Isomers of [Co(tmdda)(L-am)]. Three geometrical isomers, *uns-cis-mer*, *uns-cis-fac*, and *s-cis*, are possible for the [Co(tmdda)(L-am)] type complex as shown in Fig. 1. Only the *uns-cis* isomers were obtained for the $[Co(tmdda)(N\text{–}N)]^+$ and $[Co(tmdda)(O\text{–}O)]^-$ type complexes except for the ethylenediamine complex in which the *s-cis* isomer was obtained as a minor product.[1-3] It is presumed that the *uns-cis* isomers would be dominantly formed in the present series unless there is any special interaction between the L-amino carboxylate ion and tmdda.

The CD and absorption spectra of the complexes obtained are shown in Figs. 2—6. Of the *uns-cis-mer*, *uns-cis-fac*, and *s-cis* isomers of [Co(tmdda)(L-am)] complex, the *s-cis* isomer should take only *mer* configuration with respect to the coordination atoms because of the regulated coordination of tmdda (Fig. 1). The *mer* and *fac* isomers can be easily assigned from their d-d electronic absorption spectra; the holohedrized symmetry[20] of the *fac* isomer is cubic, whereas that of the *mer* isomer is rhombic. The former can be expected to show a sharp first absorption band and the latter a broad one[19] (Figs. 2—6). The two *mer* isomers, the *s-cis* and the *uns-cis*, can not be distinguish-

ed from the patterns of their first absorption bands. Therefore, each was investigated on the basis of their PMR spectra.

The geminal proton coupling constants (J_{AB}) for (amino carboxylato)cobalt(III) complexes are classified into two groups, those in the vicinity of 16 Hz for in-plane (G) rings and those of 18 Hz for out-of-plane (R) rings.[27] This was also investigated for the *s-cis* and *uns-cis* isomers of edda Co(III) complexes.[9,11,16] Coleman *et al.*[9] and Kuroda[11] reported that *s-cis*-[Co(edda)A_2] complex shows only one AB pattern (J_{AB}=*ca.* 18 Hz) due to the R rings, and *s-cis*-[Co(edda)AB] complex two AB patterns (J_{AB}=*ca.* 18 Hz) due to two different unidentate ligands, A and B, in contrast to which the *uns-cis* isomers of [Co(edda)A_2] show a single intense peak due to the G ring protons superimposed on one AB pattern of the R ring protons. The singlet was considered to be an extreme case of an AB pattern in which the environments of the two protons are very similar.[9] A similar spectral behavior was also observed for the *uns-cis* isomer of [Co(tmdda)$(NH_3)_2$]Cl.[3] PMR data we obtained for tmdda Co(III) complexes are given in Table 4. All the *mer* isomers show two four-line AB patterns with J_{AB}, 16.0—16.5 Hz and 18.0—18.5 Hz for the glycinate protons. As an example, the spectrum of *mer*-K[Co(tmdda)(L-asp)] is shown (Fig. 7a). The resonance line with J_{AB}=*ca.* 18 Hz is assigned to the R ring protons and that with J_{AB}=*ca.* 16 Hz to the G ring protons. Thus it is concluded that the *mer* isomers obtained are all *uns-cis* one (Table 4). For the *fac*

isomers of [Co(tmdda)(L-am)] assigned from the first absorption band pattern, one AB pattern (J_{AB}=*ca.* 18 Hz) and a single intense peak superimposed on an AB pattern are observed. The spectrum of *fac*-[Co(tmdda)(L-aspH)] is shown as an example in Fig. 8. The singlet intense peak is assigned to the G ring and the AB pattern to the R ring (Table 4). It is concluded that the *fac* isomers are also *uns-cis*. The information from the PMR spectrum is consistent with the consideration based on the molecular model construction that the *fac* isomer takes an *uns-cis* arrangement (Fig. 1). Another support for the assignments of *uns-cis* isomers is based on the selective deuteration of R ring proton.[9,28-31] H_A (the less sterically hindered proton) of the R ring protons is selectively deuterated in the course of heating of the sample solution. The PMR spectra of *mer*-K[Co(tmdda)(L-asp)] are shown in Fig. 7 (7a is the spectrum of a freshly prepared D_2O solution and 7b the spectrum of the sample solution after being heated in boiling water for 30 min). In

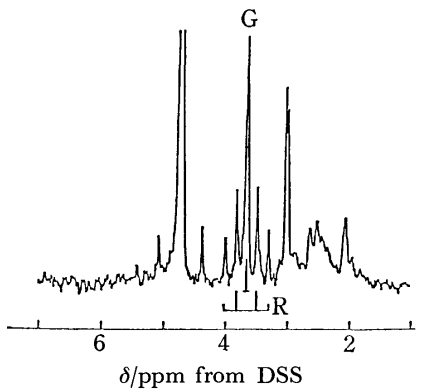

Fig. 8. Proton magnetic resonance spectra of *Δ-uns-cis-fac*-[Co(tmdda)(L-aspH)] in D_2O solution (after heating the sample in boiling water for 30 min).

the spectrum, the AB pattern ($J_{AB}=16.0$ Hz) due to the G ring protons is observed at 3.94, 3.78, 3.68, and 3.52 ppm, and another AB pattern ($J_{AB}=18.0$ Hz) due to the R ring protons is observed at 3.84, 3.66, 3.38, and 3.20 ppm. On the other hand, the 7b spectrum shows a new peak at 3.30 ppm, the intensity of the AB pattern due to the R ring protons decreasing drastically. The new peak increases to an integrated value equivalent to one proton, the AB pattern due to the R ring disappearing completely after being heated in boiling water for 2.5 h. The new peak is assigned to the resonance for decoupled H_B. The AB pattern due to the G ring protons ($J_{AB}=16.0$ Hz) is not deuterated under the same conditions. This indicates that *mer*-K[Co(tmdda)(L-asp)] takes the *uns-cis* configuration. The same behavior is also observed for *mer*-K[Co(tmdda)(L-glu)]. From the results of absorption and PMR measurements, all of the complexes obtained can be assigned to the *uns-cis* configuration.

Stereochemistry of the Isomers. On the basis of the CD spectra in the first absorption band region, the absolute configurations of *uns-cis*-$[Co(tmdda)A_2]^+$ ($A_2=(NH_3)_2$, en, and tn) and *uns-cis*-$[Co(edda)A_2]^+$ were discussed in the same category, though the difference in the backbone diamine ring of the quadridentate ligands gives rise to a slight change in the shape of CD curves.[1)] Thus, the absolute configurations of the isomers are assigned tentatively from the sign of a major CD band in the first absorption band region as shown in Table 3 and Figs. 2—6.

A remarkable CD difference between the *mer* and

Table 5. Calculated configurational CD data of *Λ-uns-cis*-[Co(tmdda)(L-am)] complexes

Table 6. Formation ratios (percent compositions) of reaction mixture

Complex	Isomer			
	Λ-mer	*Δ-mer*	*Λ-fac*	*Δ-fac*
uns-cis-[Co(tmdda)(L-asp)]$^-$	81%	6%	0%	13%
uns-cis-[Co(tmdda)(L-glu)]$^-$	51%	40%	3%	6%

fac isomers appears in the second absorption band region. The *uns-cis-fac*-[Co(tmdda)(L-aspH)] shows three CD bands (+, −, and + from the lower energy side) for the *Λ* isomer, while the *uns-cis-mer* isomer shows a negative band for the *Λ* isomer (Fig. 2). The CD difference substantiates the configurational CD curves estimated from the observed CD curves of *Λ-* and *Δ-uns-cis-fac*-[Co(tmdda)(L-aspH)] and the observed CD curves of *Λ-* and *Δ-uns-cis-mer*-[Co(tmdda)(L-aspH)] (Table 5). A similar CD behavior in the second absorption band region is also observed for the isomers of *uns-cis*-[Co(tmdda)(L-gluH)] (Table 5). The behavior seems to be a characteristic pattern reflecting the arrangement of ligands. A similar behavior was pointed out for the CD spectra of the C_1-*cis* and C_2-*cis* isomers of $[Co(am)_2ox]^-$ or $[Co(am)_2en]^+$.[26] However, no CD difference in the second absorption band region is observed for the CD spectra of the *mer* and *fac* isomers of *uns-cis*-[Co(edda)(L-am)]. The CD difference in the present isomers is not due to the difference of the *mer* and *fac* arrangements, but can be attributed to the chelate ring conformations of the backbone diamine of the coordinated tmdda.

It was suggested that the tmdda Co(III) complexes prefer the *uns-cis* configuration to the *s-cis* one and the backbone diamine chelate ring of tmdda has a marked effect on the distribution of geometrical isomers.[1] This is also applicable to the present work. Of the *uns-cis-mer* and *uns-cis-fac* configurations, the *uns-cis-mer* isomer was formed dominantly. For the L-alaninato, L-valinato, and L-prolinato complexes, the *uns-cis-mer* isomer was easily formed, while the *uns-cis-fac* isomer was hardly formed. The reason for the *uns-cis-mer* configuration dominancy is unknown at present. In the case of the L-aspartate and L-glutamate ions which have three functional groups, both the *uns-cis-mer* and *uns-cis-fac* isomers were obtained, though the *uns-cis-mer* isomers were also formed dominantly. The formation ratios (percent compositions) of their possible isomers are given in Table 6. A marked stereoselectivity was found for the *Λ* configuration of *uns-cis-mer*-[Co(tmdda)(L-asp)]$^-$ (*Λ-mer* : *Δ-mer*=81 : 6) and for the *Δ* configuration of the *uns-cis-fac* isomer (*Λ-fac* : *Δ-fac*=0 : 13). A similar trend was also observed for the isomers of the L-glutamato complex, though it was to a much smaller extent (Table 6). The stereoselectivities might be explained on the basis of the enhanced stabilization of *Λ-uns-cis-mer* and *Δ-uns-cis-fac* isomers caused by the formation of interligand hydrogen-bond in the isomer.[17,21-24] In the alkaline condition employed for the preparation of the complexes, the dangling *β*-carboxylato group of the coordinated L-aspartate ion is deprotonated. As a result, the *β*-carboxylato group can form a hydrogen-bond with the imino group of tmdda in the case of *Λ-uns-cis-mer* and *Δ-uns-cis-fac* isomers of L-aspartato complexes. The same consideration can be applied to the isomers of L-glutamato complex. The selectivity of L-glutamato complex is lower than that of L-aspartato one (Table 6). It can be presumed that the lower selectivity in comparison to that of L-aspartato complex is due to the longer dangling group of the coordinated L-glutamate ion.[21,24]

Preparation and Resolution of a Series of Chromium(III) Complexes Containing 2,2′-Bipyridyl *N,N′*-Dioxide and Ethylenediamine

Hideaki KANNO, Kazuo KASHIWABARA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received September 11, 1978)

A series of chromium(III) complexes of the type, $[Cr(bpdo)_n(en)_{3-n}]^{3+}$ was obtained by preparing two new complexes, $n=1$ and 2, where bpdo denotes 2,2′-bipyridyl *N,N′*-dioxide. Each of the bpdo complexes gave only one pair of enantiomers, which were resolved by an SP-Sephadex column chromatographic or a chemical method. The circular dichroism spectra of the resolved complexes were compared with those of the related complexes of the known absolute configuration. The $[Cr(bpdo)_3]^{3+}$ complex in water racemizes spontaneously in dark. The rate is independent of the concentrations of the complex, acid, and the free ligand, and an intramolecular racemization mechanism is suggested.

Although a number of metal complexes with 2,2′-bipyridyl *N,N′*-dioxide(bpdo) have been known,[1] no optically active complexes have ever been obtained. This paper is concerned with the preparation and properties of optically active chromium(III) complexes containing bpdo.

The ligand bpdo forms a skew seven-membered chelate ring upon coordination. The skew conformer can exist in a pair of enantiomers which can be designated by δ and λ, as shown in Fig. 1. Simpson *et al.*[2] and Vinciguerra *et al.*[3] prepared first bpdo complexes with a variety of metal ions including chromium(III) and suggested that the bpdo moiety in metal complexes takes the skew conformation on the basis of IR spectra. ^{1}H-NMR spectra of $[M(bpdo)_3]^{2+}$ ($M=Co^{2+}$ and Ni^{2+}) were also best interpreted by assuming the skew conformation of the ligand.[4] A tris-type complex with the chiral conformers of bpdo results theoretically in four diastereomers, each of which has a pair of enantiomers. In this paper, we describe such optical isomerism in the chromium(III) complexes on the basis of the circular dichroism (CD) spectra.

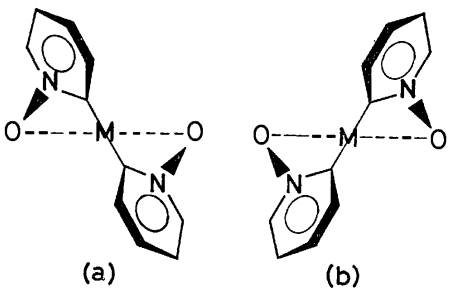

Fig. 1. The conformation of bpdo, (a) δ- and (b) λ-skew form.

Experimental

Preparation and Resolution of the Complexes. The chromium(III) complexes containing ethylenediamine (en) are photo-sensitive to occur hydrolysis. The $[Cr(bpdo)_3]^{3+}$ complex in solution does not hydrolyze in light, but its active isomer racemizes by exposure of ultraviolet light. Hence the following procedures should be done in dark, if necessary.

(1) $[Cr(bpdo)_3]^{3+}$: The racemic complex was prepared by a method similar to those of Simpson *et al.*[2] and Madan and Bull.[5] The solid of bpdo·H_2O[6] (3.5 g, 17 mmol) was dissolved in an aqueous solution (20 cm^3) of $Cr(NO_3)_3\cdot 9H_2O$ (2.0 g, 5 mmol). The solution was adjusted to pH *ca.* 2 with hydrochloric acid to avoid the formation of hydroxo complexes, kept at 90 °C for 1 h, and cooled to room temperature. Sodium perchlorate was then added to the solution to yield green precipitate, which was recrystallized from hot water and air-dried. Yield: 4 g (88%). Found: C, 37.78; H, 2.73; N, 9.53%. Calcd for $C_{30}H_{27}N_6O_{19.5}Cl_3Cr=[Cr(bpdo)_3](ClO_4)_3\cdot 1.5H_2O$: C, 38.25; H, 2.89; N, 8.92%.

The complex was resolved with $(+)_{589}$-Ag_3[Co(L-cysteinesulfinato(2−)-SN)$_3$].[7] The resolving agent (0.9 g, 1.1 mmol) was added to an aqueous solution (20 cm^3) of $[Cr(bpdo)_3]Cl_3$ which was prepared from the perchlorate (1.0 g, 1.1 mmol) and the anion exchanger, Dowex 1X8 in the chloride form. White precipitate of AgCl was filtered off and a small amount of ethanol was added to the filtrate to yield greenish orange precipitate, which was recyrstallized from water by adding ethanol. The product was dissolved in water and sodium perchlorate was added to the solution to give green crystals, which were filtered, washed with cold water and then ethanol, and air-dried. The crystals showed positive rotation at 589 nm in water. This complex loses gradually its optical activity in water. Found: C, 37.69; H, 2.58; N, 9.55%. Calcd for $C_{30}H_{27}N_6O_{19.5}Cl_3Cr=(+)_{589}$-$[Cr(bpdo)_3](ClO_4)_3\cdot 1.5H_2O$: C, 38.25; H, 2.89; N, 8.92%.

Attempts to separate possible diastereomers were all unsuccessfull by SP-Sephadex column chromatography. The column gave only one band of $[Cr(bpdo)_3]^{3+}$, all fractions of which showed the same pattern in the absorption spectra. The resolution was not achieved by the column chromatography because of racemization of the complex (*vide infra*).

(2) $[Cr(bpdo)_2en]^{3+}$: To an aqueous solution (10 cm^3, pH *ca.* 2) of $[CrCl_2(H_2O)_2(en)]Cl$[8] (1.1 g, 4 mmol) was added bpdo·H_2O (1.7 g, 8.2 mmol) and the solution was stirred at 50 °C for 4 h. Sodium perchlorate was then added to the solution to yield violet crystals, which were filtered. Yield: 1.1 g (34%). The product was contaminated with a small amount of $[Cr(bpdo)_3](ClO_4)_3$, and purified by SP-Sephadex column chromatography. The crude product dissolved in water was poured on an SP-Sephadex column, and the adsorbed band was eluted with a 0.3 mol dm^{-3} Na_2SO_4 solution. The violet fractions were collected, concentrated under reduced pressure to a small volume, and mixed with sodium perchlorate to yield violet crystals. They were washed with a mixture of water and ethanol (1:1), then ethanol and air-dried. Yield: 0.7 g (20%). Found: C, 32.46; H, 2.89; N, 10.11%. Calcd for $C_{22}H_{27}N_6O_{17.5}Cl_3Cr=[Cr(bpdo)_2en](ClO_4)_3\cdot 1.5H_2O$: C, 32.46; H, 3.35; N, 10.33%.

The resolution was achieved by use of the complex chloride and $(-)_{589}$-$K[As(cat)_3]$[9] (cat=1,2-benzenediolate ion). An aqueous solution (20 cm^3) of the chloride which was

prepared from the perchlorate (1.2 g, 1.5 mmol) and a Dowex 1X8 anion exchanger in the chloride form was adjusted to pH 7—8 with potassium carbonate. To this solution was added an aqueous solution (30 cm^3) of the resolving agent (0.66 g, 1.5 mmol) to yield violet precipitate, which was filtered off. The filtrate was stirred for a while with a Dowex 1X8 anion exchanger in the chloride form to remove the resolving agent remained. The resulting solution gave positive rotation at 589 nm and was used for the CD measurement. The absorption spectrum of the solution was identical with that of the racemic complex and remained constant, but the optical activity was lost gradually at room temperature. Hence the procedure of resolution was carried out at a temperature as low as possible. The violet precipitate obtained above by the addition of the resolving agent was quite insoluble in water and the resolving agent could not be removed by usual methods. The optically active complex was isolated as perchlorate by the addition of sodium perchlorate to the filtrate obtained above. Found: C, 32.95; H, 2.94; N, 10.51%. Calcd for $C_{22}H_{26}N_6O_{17}Cl_3Cr=(+)_{589}$-$[Cr(bpdo)_2en](ClO_4)_3\cdot H_2O$: C, 32.83; H, 3.26; N, 10.44%. The resolution by SP-Sephadex column chromatography was not achieved and the column showed only one band of racemic $[Cr(bpdo)_2en]^{3+}$.

(3) $[Cr(bpdo)(en)_2]^{3+}$: To an aqueous solution (30 cm^3) of *cis*-$[CrCl_2(en)_2]Cl$[10] (1.5 g, 5 mmol) was added bpdo·H_2O (1.7 g, 8.2 mmol) and the solution was stirred at 50 °C for 1 h. Sodium perchlorate was then added to the solution to yield red orange crystals, which were filtered and recrystallized from warm water (50 °C). Yield: 1.7 g (50%). Found: C, 24.21; H, 3.88; N, 12.39%. Calcd for $C_{14}H_{28}N_6O_{16}Cl_3Cr=[Cr(bpdo)(en)_2](ClO_4)_3\cdot 2H_2O$: C, 24.20; H, 4.07; N, 12.10%.

The complex was resolved completely by SP-Sephadex column chromatography. The complex perchlorate (*ca.* 0.35 g) was loaded on a column (ϕ 2.7×80 cm) of SP-Sephadex C-25 in the sodium form and the adsorbed red orange band was eluted with a 0.2 mol dm^{-3} sodium $(+)_{589}$-tartratoantimonate(III) solution. When the band was separated into two, the column was washed with water to remove the eluent. Two parts of the resin adsorbed the complex were separately taken out from the column and poured into small columns (ϕ 2.7×30 cm). Each of the adsorbed complexes (a pair of enantiomers) was eluted with a 3 mol dm^{-3} lithium chloride solution and the eluate was mixed with sodium perchlorate to give red orange precipitate. The isomer obtained from the fast eluted band showed positive rotation at 589 nm. The optical activity of this complex remains unchanged in dark at room temperature. Found: C, 24.37; H, 3.51; N, 12.01%. Calcd for $C_{14}H_{28}N_6O_{16}Cl_3Cr=[Cr(bpdo)(en)_2](ClO_4)_3\cdot 2H_2O$: C, 24.20; H, 4.07; N, 12.10%.

(4) $[Cr(en)_3]^{3+}$: This complex was prepared by the method described previously[11] and resolved by an SP-Sephadex column chromatographic method similar to that for $[Co(en)_3]^{3+}$.[12] The complex chloride (*ca.* 0.5 g) was loaded on a column (ϕ 2.7×50 cm) of SP-Sephadex C-25 resin in the sodium form and the complex was eluted with a 0.3 mol dm^{-3} sodium $(+)_{589}$-tartratoantimonate(III) solution. Each eluate of the two separate bands was collected and diluted with water. The solution was poured on a small column of SP-Sephadex C-25 in the hydrogen form. The adsorbed complex was eluted with a 3 mol dm^{-3} lithium chloride solution and the eluate was concentrated under reduced pressure to yield orange crystals of the active chloride. The isomer obtained from the fast moved band showed positive rotation at 589 nm.

Kinetic Runs. Decrease in the CD strength of $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ at the CD peak (485 or 575 nm) was continuously recorded on a JASCO model J-20 spectropolarimeter with a cell jacket to keep the temperature constant within ±0.1 °C using a Haake thermostat Type FSe. A Takara Thermister Type SPD-10 thermometer was placed inside the CD cell. The pH and ionic strength of the solution were adjusted with an aqueous solution of $NaClO_4$–$HClO_4$. The rate of decrease obeyed the first order kinetic law and the observed rate constant (k_{obsd}) is expressed as follows: $k_{obsd}=-\ln[(\alpha_t-\alpha_\infty)/(\alpha_0-\alpha_\infty)]/t$ where α's are CD strengths at the time denoted by the suffixes.

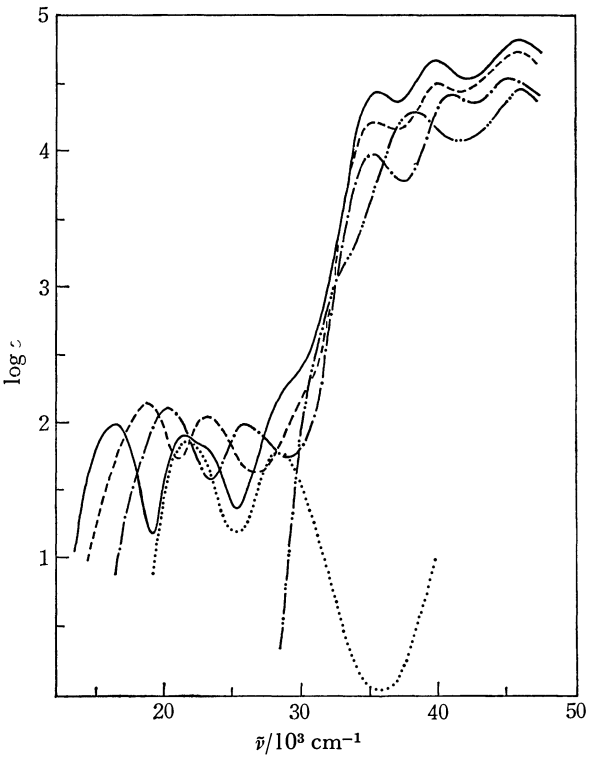

Fig. 2. Absorption spectra of $[Cr(bpdo)_3]^{3+}$ (——), $[Cr(bpdo)_2en]^{3+}$ (----), $[Cr(bpdo)(en)_2]^{3+}$ (—·—), $[Cr(en)_3]^{3+}$ (·····), and bpdo (—··—) in water.

Absorption and circular dichroism spectra were recorded on a HITACHI 323 spectrophotometer and a JASCO model J-20 spectropolarimeter, respectively.

Results and Discussion

Two new complexes, $[Cr(bpdo)_n(en)_{3-n}]^{3+}$ (n=1 and 2) were prepared from *cis*-$[CrCl_2(en)_2]^+$ and $[CrCl_2(H_2O)_2en]^+$, respectively, by replacing the chloride ions and water molecules with bpdo. The reactions should be carried out at below *ca.* 50 °C to reduce the formation of $[Cr(bpdo)_3]^{3+}$. The pure complexes were easily isolated from the crude products by SP-Sephadex column chromatography using a 0.3 mol dm^{-3} Na_2SO_4 solution as an eluent. The tris- and bis-en complexes were resolved by SP-Sephadex column chromatography, while the tris- and bis-bpdo complexes were not done by this method, but achieved by the chemical method with $(+)_{589}$-[Co(L-cysteinesulfinato-(2−)-SN)$_3$]$^{3-}$ and $(-)_{589}$-$[As(cat)_3]^-$, respectively. The former two complexes are optically stable in water at room temperature in dark, while the latter two complexes lose slowly the optical activity under

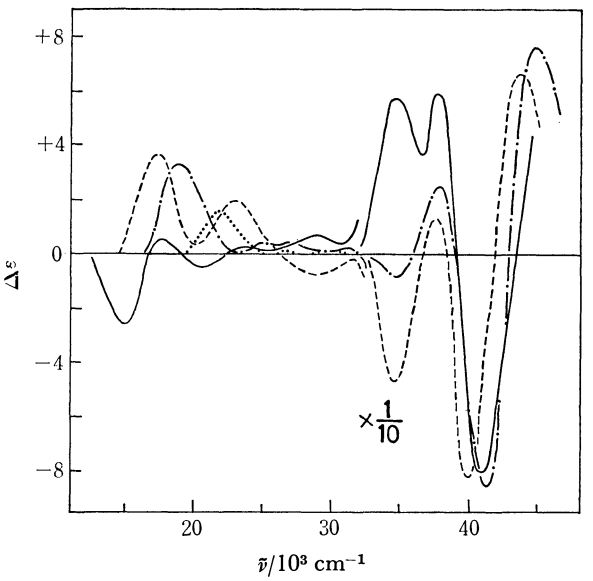

Fig. 3. CD spectra of $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ (——), $(-)_{589}$-$[Cr(bpdo)_2en]^{3+}$ (----), $(+)_{589}$-$[Cr(bpdo)(en)_2]^{3+}$ (—·—), and $(+)_{589}$-$[Cr(en)_3]^{3+}$ (·····) in water.

the same conditions (*vide infra*).

The bpdo ligand forms a skew seven-membered chelate ring upon coordination. The skew conformation is chiral and can exist in a pair of enantiomers which are designated by δ and λ, as shown in Fig. 1. The δ-(or λ-)skew conformers in the Λ- and Δ-configurations form the *lel*(or *ob*) and *ob*(or *lel*) structures, respectively, as seen in $[Co(en)_3]^{3+}$ which is constituted by the gauche conformers of en.[13] For $[Cr(bpdo)_3]^{3+}$, therefore, there are four possible diastereomers, each of which has a pair of enantiomers (lel_3 : $\Lambda(\delta\delta\delta)=\Delta(\lambda\lambda\lambda)$, lel_2ob : $\Lambda(\delta\delta\lambda)=\Delta(\lambda\lambda\delta)$, $lelob_2$: $\Lambda(\delta\lambda\lambda)=\Delta(\lambda\delta\delta)$, and ob_3 : $\Lambda(\lambda\lambda\lambda)=\Delta(\delta\delta\delta)$). Similarly, $[Cr(bpdo)_2en]^{3+}$ and $[Cr(bpdo)(en)_2]^{3+}$ have three (lel_2 : $\Lambda(\delta\delta)=\Delta(\lambda\lambda)$, *lelob* : $\Lambda(\delta\lambda)=\Delta(\lambda\delta)$, and ob_2 : $\Lambda(\lambda\lambda)=\Delta(\delta\delta)$) and two (*lel* : $\Lambda(\delta)=\Delta(\lambda)$ and *ob* : $\Lambda(\lambda)=\Delta(\delta)$) diastereomers, respectively. However, each of the bpdo complexes gave only one diastereomer. These results suggest that the bpdo chelate ring changes easily its conformation ($\delta\rightleftharpoons\lambda$) in solution, and that each complex crystallizes in a particular diastereomer. The structures of the diastereomers are not certain at present. However, molecular models indicate that the *lel* isomers are always less crowded than the *ob* isomers. The tris-, bis- and mono-bpdo complexes isolated will have the lel_3, lel_2 and *lel* structures, respectively in the solid state, but will be in equilibrium among the isomers involving the *ob* conformation in solution. The bis-(ethylenediamine)cobalt(III) complex containing 2,2′-diaminobiphenyl which forms a similar seven-membered chelate ring is also known to yield only one pair of enantiomers, $\Lambda(\delta)$ and $\Delta(\lambda)$.[14,15]

Figure 2 shows the absorption spectra of the complexes and the free ligand. Table 1 gives the spectral data. The first and the second absorption bands shift to lower wave numbers by replacing en with bpdo, but the magnitudes of the shift are not proportional to the number of the bpdo ligand, the first absorption

$[Cr(ox)_3]^{3-}$	18.2	7	1.75	66.2	−100	23)

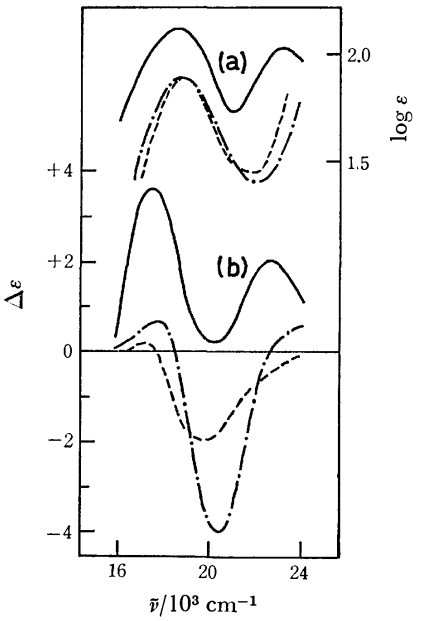

Fig. 4. Absorption (a) and CD (b) spectra of $[CrO_4N_2]$ complexes in the region of the first absorption band, $(-)_{589}$-$[Cr(bpdo)_2en]^{3+}$ (——), Λ-$[Cr(acac)_2en]^+$ (—·—), and Λ-$[Cr(ox)_2en]^-$ (----).

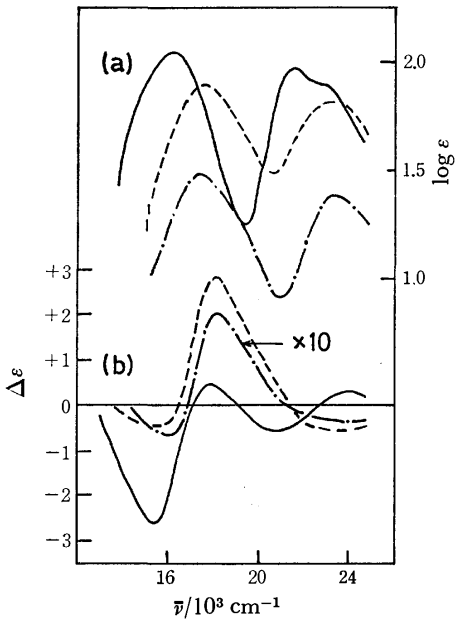

Fig. 5. Absorption (a) and CD (b) spectra of $[CrO_6]$ complexes in the region of the first absorption band, $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ (——), Λ-$[Cr(mal)_3]^{3-}$ (—·—), and Λ-$[Cr(ox)_3]^{3-}$ (----).

band of $[Cr(bpdo)_3]^{3+}$ being at lower wave numbers by 1000 cm^{-1} than those expected from other complexes of the present series. In a series of complexes, $[Cr(ox)_{3-n}(en)_n]^{2n-3}$ (ox=oxalate ion),[16,17] the first absorption bands shift regularly with nearly the same interval. In the ultraviolet region, the bpdo complexes exhibit three strong absorption bands, while the free ligand two bands, the lower wave number band of which seems to split into two in the complexes. The intensities of the bands in the complexes are nearly proportional to the number of the bpdo ligand.

Figure 3 compares the CD spectra of $(+)_{589}$-$[Cr(bpdo)_{3-n}(en)_n]^{3+}$ (n=0, 2, and 3) and $(-)_{589}$-$[Cr(bpdo)_2en]^{3+}$. The last isomer is opposite to that used for the measurement. The tris- and bis-bpdo complexes racemize spontaneously in solution so that the spectral variations with time are corrected at each wave number (*vide infra*). Since $(+)_{589}$-$[Cr(en)_3]^{3+}$ has been assigned to the Λ-configuration,[18] $(+)_{589}$-$[Cr(bpdo)(en)_2]^{3+}$ which gives a similar positive CD band in the region of the first absorption band can be assigned to the same Λ-configuration. The analogous complexes of the type, $[CrO_2N_4]$ such as Λ-$(+)_{589}$-$[Cr(acac)(en)_2]^{2+}$[19] (acac=acetylacetonate ion) or Λ-$(+)_{589}$-$[Cr(ox)(en)_2]^+$[20] also give a positive CD band in this region. The CD patterns of $(-)_{589}$-$[Cr(bpdo)_2en]^{3+}$ and $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ isomers in the region of the first absorption band are quite different from those of complexes of the type, $[CrO_4N_2]$ and $[CrO_6]$, respectively, whose absolute configurations have been known, as shown in Figs. 4 and 5. However, these isomers show the same CD pattern in the ultraviolet region as that of $(+)_{589}$-$[Cr(bpdo)$-

$(en)_2]^{3+}$ except the positive band at 34700 cm^{-1} of $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$. Therefore, both $(-)_{589}$-$[Cr(bpdo)_2en]^{3+}$ and $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ may be assigned to the Λ-configuration. In Fig. 5 is compared the CD spectrum of $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ in the region of the first absorption band with those of Λ-$[Cr(ox)_3]^{3-}$[17,20] and Λ-$[Cr(mal)_3]^{3-}$[17,20] (mal=malonate ion). All of the isomers show a negative and a positive CD band from the smaller wave number side. The CD strength of the malonato complex is extremely weak and the sign of the main CD band of the bpdo complex is negative and opposite to that of the oxalato complex. Such a change in the CD spectra among the complexes of five-, six-, and seven-membered chelate rings is very similar to that observed for a series of complexes, $[Co(NH_2(CH_2)_nNH_2)_3]^{3+}$ (n=2, 3, and 4).[21] On the other hand, the CD pattern of $(-)_{589}$-$[Cr(bpdo)_2en]^{3+}$ is quite different from those of analogous complexes and is not given any plausible discussion at present.

As stated previously, the optically active $[Cr(bpdo)_3]^{3+}$ and $[Cr(bpdo)_2en]^{3+}$ lose their activity in solution. The rates of decrease in the optical activity for $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ were obtained under the conditions described in Experimental part in dark so as to avoid photo-induced reactions. During the loss of optical activity, the absorption spectrum of the complex was unchanged. The rates obeyed the first order kinetic law and the rate constants (k_{obsd}) were calculated from the slopes of time *vs.* $\Delta\varepsilon$. The data are given in Table 2 together with the activation parameters, and with data for other chromium(III) complexes for comparison. The loss of optical activity should be caused by racemization of the complex, and the racemization will involve both inversions of the complex ion and the ligand, $\Delta \rightleftharpoons \Lambda$ and $\delta \rightleftharpoons \lambda$. The rates were independent of the concentrations of the complex, acid, and the free ligand. Hence, the racemization is suggested to proceed by an intramolecular twist mechanism.[22] The activation parameters are similar to those of other complexes given in Table 2, for which intramolecular mechanisms have been postulated.[23]

Thermochromism of Metal Chelates with Triphenylmethane Complexons in Aqueous Solutions. I. Copper(II)–Xylenol Orange System†

Shoji NAKADA, Mutsuo YAMADA, Tasuku ITO,†† and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 18, 1978)

Reversible thermochromisms are found for about thirty kinds of metal complexes of triphenylmethane complexons in aqueous solutions. The thermochromism observed in the aqueous solution of copper(II) complex with 3,3′-bis[*N*,*N*-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein (Xylenol Orange, XO) was primarily ascribed to the temperature-dependence of the protolytic equilibria between a complex species AH having an uncoordinated free phenolic hydroxyl group and a complex species A having a coordinated phenolate group: $AH \rightleftarrows A + H$. The equilibrium constant K of the reaction was determined to be $p(K/\text{mol dm}^{-3}) = 4.40$ at 25 °C. The thermodynamic parameters ΔH and ΔS for the reaction were calculated to be 26 ± 2 kJ mol^{-1} and 1 ± 3 J mol^{-1} K^{-1} (298 K), respectively. The rate constant of the proton dissociation of the phenolic hydroxyl group in the complex AH was estimated to be *ca.* 2×10^5 s^{-1}.

In the course of a series of research works on the complexation reactions of metal ions with the multidentate ligands of triphenylmethane complexon††† type, Yamada discovered a phenomenon of thermochromism in the aqueous solution of copper(II)–XO complex.[1] In the previous communication, we reported that the complexes of other triphenylmethane complexons with some bivalent metal ions are also thermochromic.[2]

In the present paper, we report the thermochromism of the complexes of bivalent metal ions with various triphenylmethane complexons in aqueous media. We studied in detail the mechanism of the thermochromic change for the copper(II)–XO complex by means of the spectrophotometric and the temperature-jump method.

The mechanism was found to be quite different from that of the thermochromisms observed so far in the metal complexes in solutions, which were ascribed to the change in the configurational requirements on the central metal ions or the change in the ligand-field stabilization energies.[3,4]

Experimental

Materials. All chemicals used were of analytical grade, unless otherwise specified. Water was deionized and distilled. Xylenol Orange was synthesized by Mannich condensation from *o*-Cresol Red, iminodiacetic acid (IDA), and formaldehyde.[5] The crude sample of the synthesized XO was purified beforehand by means of cellulose column chromatography and finally by means of high-performance liquid chromatography.[6] The purity of the specimen of XO was confirmed by elemental analyses and melting point measurements.[6] Melting point was measured with a Rigaku Denki Differential Scanning Calorimeter Model 8001 SL/C. The purified XO was used as a free acid form. A 1.0×10^{-3} mol dm^{-3} stock solution of XO was prepared by dissolving a desired amount of XO in water.

The perchlorates of bivalent metals were prepared by heating the chlorides with small excess of perchloric acid until no trace of chloride ion was detected. The perchlorate was recrystallized from water. The stock solution was standardized titrimetrically with EDTA.

The pre-purified sodium perchlorate[7] was heated in an oven at *ca.* 200 °C to prepare an anhydrous salt. A desired amount of the anhydrous perchlorate was dissolved in water to prepare a stock solution. Buffer solutions were prepared from 0.1 mol dm^{-3} acetic acid and 0.1 mol dm^{-3} sodium acetate.

Measurements. The equilibria were measured with Hitachi recording spectrophotometers Model EPS-3T and Model 323 equipped with a cell thermostated at high temperatures. A 1 cm quartz cell was used. The kinetic measurements were carried out with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105.[8] The pH values of the solutions were adjusted with acetate buffers and measured with a Hitachi-Horiba pH-meter Model F-7SS. For the pH measurements at high temperatures a glass electrode 1027-05T and a saturated calomel electrode 2631-05T were used. Temperature of the solution was measured with a copper-constantan thermocouple and a millivoltmeter. The ionic strength of the solution was adjusted to 0.1 mol dm^{-3} with sodium perchlorate.

Results and Discussion

Equilibria. In Table 1 are summarized the results of the thermochromism observed for the metal complexes of triphenylmethane complexons, which include both sulfonphthalein complexons and phthalein complexons. The structures and the abbreviated nomenclatures of the ligands are shown in Fig. 1(a) and Table 2. The results observed for the complexes of bivalent metal ions, Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}, were included in the table. Color changes of the aqueous solutions containing triphenylmethane complexons and 10—100 fold excess of metal ions have been studied at various buffered pH as a function of temperature by the measurements of visible absorption spectra as well as by visual observation. The thermochromic changes were observed only in the narrow pH range characteristic of the individual system.

The systems No. 1—29 in Table 1 include the com-

a) Observed for the solutions containing $(1—5)\times10^{-5}$ mol dm^{-3} ligand and 10—100 fold excess of metal perchlorate. b) The pH, at which the remarkable thermochromic change was observed. Acetate buffer (CH_3COOH-CH_3COONa) and phosphate buffer (NaH_2PO_4-Na_2HPO_4) were used for the pH adjustment. c) λ_{max}'s represent the positions of the absorption maxima of the shorter- or the longer-wavelength absorptions. — denotes no, weak, or broad absorption. d) s: strong, vs: very strong. e) Purified by preparative thin-layer chromatography. See Ref. 9. f) Kindly supplied by Professor H. Nakayama, Kagawa Nutrition College. g) Purified by cellulose column chromatography. h) The commercial specimens of PC, PPC, and TPC (Dojindo, Kumamoto) were used.

TABLE 2. TRIPHENYLMETHANE COMPLEXONS LISTED IN TABLE 1 (See Fig. 1(a))

Ligand	R_1[a)]	R_2[a)]	R_3	R_4	R_5
Xylenol Orange (XO)	A	A	CH_3	H	SO_3H
Methylxylenol Blue (MXB)	A	A	CH_3	CH_3	SO_3H
Methylthymol Blue (MTB)	A	A	$CH(CH_3)_2$	CH_3	SO_3H
Cresol Orange (CO)	A	A	H	H	SO_3H
Glycine Cresol Red (GCR)	B	B	CH_3	H	SO_3H
Sarcosine Cresol Red (SCR)	C	C	CH_3	H	SO_3H
Semi-Xylenol Orange (SXO)	A	H	CH_3	H	SO_3H
Phthalein Complexon (PC)	A	A	CH_3	H	COOH
Phenolphthalein Complexon (PPC)	A	A	H	H	COOH
Thymolphthalein Complexon (TPC)	A	A	$CH(CH_3)_2$	CH_3	COOH

a) A=$CH_2N(CH_2COOH)_2$, B=CH_2NHCH_2COOH, C=$CH_2N(CH_3)CH_2COOH$.

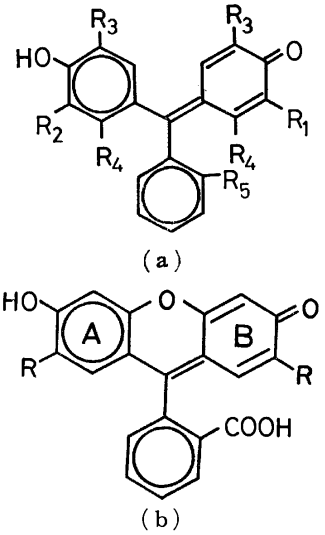

Fig. 1. The structures of the triphenylmethane complexons used. (a) Sulfonphthalein and phthalein complexons listed in Table 2. (b) Phthalein complexons with an ether linkage between two benzene rings. Calcein ($R=CH_2N(CH_2COOH)_2$) and Methyl Calcein ($R=CH_2N(CH_3)CH_2COOH$).

plexes of sulfonphthalein complexons. The absorption spectra of these complexes in visible region consist of two absorption bands. Temperature-dependencies of the spectra of these complexes were similar to the dependency shown in Fig. 2(a), *i.e.*, with a temperature-rise, the absorptions at longer wavelength increased, whereas those at the shorter wavelength decreased. The absorption spectra of the systems No. 30—36, which include the complexes of phthalein complexons, have only one absorption band in the visible region; The absorptions in the region 550—620 nm increased in intensities with a temperature-rise. The high-temperature color of the metal complexes of these one-color complexons strongly resembles the alkaline color of the corresponding parent phthalein dyes. The positions of the visible absorption bands suggest that the complexes responsible for the absorptions at high temperatures have a coordinated phenolate group. In order to clarify the mechanism of the thermochromism, the quantitative measurements have been carried out for the copper(II)–XO system.

It should particularly be emphasized that for the quantitative studies the use of the highly purified specimen of the ligand was essential. The use of commercial crude specimens of the triphenylmethane complexons, which are available only as metallochromic indicators or as colorimetric reagents, gave no definite quantitative results, though the qualitative observations of the thermochromic changes were still possible.

Figure 2(a) shows the visible absorption spectra at various temperatures of an aqueous solution containing 3.0×10^{-5} mol dm^{-3} XO and 1.2×10^{-4} mol dm^{-3} Cu^{2+} ion, the pH of the solution being adjusted at 3.94± 0.05. The most remarkable thermochromic change was observed in the pH region 3.8—4.5. In this pH region the solutions are orange at lower temperatures

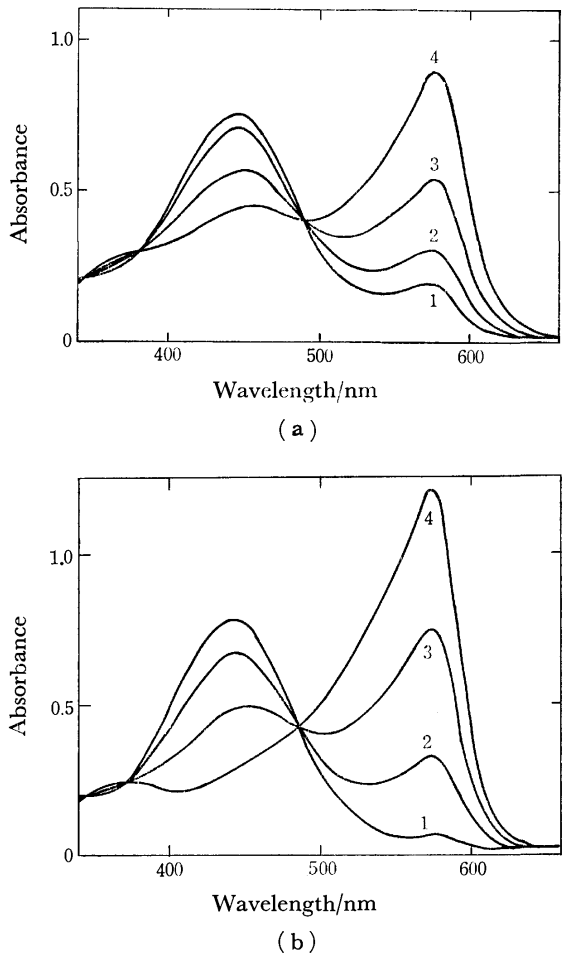

Fig. 2. Absorption spectra of the Cu(II)-XO. (a) Temperature-dependence. At 7 (1), 20 (2), 48 (3), and 78 °C (4). [Cu]$=1.2\times10^{-4}$ mol dm^{-3}; [XO]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). At pH$=3.94\pm0.05$. (b) pH-Dependence. At pH 2.99 (1), 3.93 (2), 4.49 (3), and 5.04 (4). [Cu]$=1.2\times10^{-4}$ mol dm^{-3}; [XO]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). At 25 °C. Cell length=1 cm.

and reddish violet at higher temperatures. The absorption spectrum changes reversibly with a distinct isosbestic point at 491 nm, showing the existence of an equilibrium between two chemical species. As the temperature rises the absorbance at 450 nm decreases accompanied with a large increase in the absorbance at 574 nm. The absorbance at 574 nm increases about 4.5-fold for the temperature-rise from 7 to 78 °C.

Figure 3 shows the results of the molar-ratio method for the Cu(II)–XO complex measured at 574 nm, at various temperatures, and at pH 4.58±0.02. The metal-to-ligand ratio of the complex species formed in the solution was found to be invariably 2 : 1 irrespective of the temperature. For the solutions containing more than two-fold excess of Cu^{2+} ion over XO, the absorbance at a constant temperature increases only slightly even with the large increase in the concentration of Cu^{2+} ion, whereas for the solution at an arbitrary definite [Cu(II)] to [XO] ratio the absorbance increases markedly with the rise of temperature. This

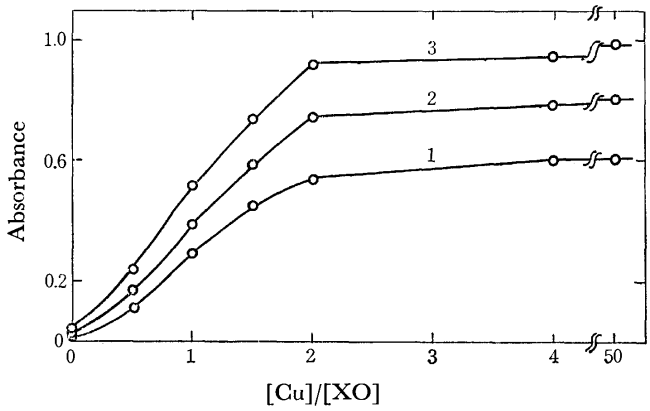

Fig. 3. Molar-ratio method at 574 nm for the Cu(II)-XO at various temperatures. At 25 (1), 50 (2), and 80 °C (3). $[XO]=3.0\times10^{-5}$ mol dm^{-3}. pH=4.58±0.02. I=0.1 mol dm^{-3} ($NaClO_4$). Cell length=1 cm.

fact indicates that the observed thermochromism should be ascribed to the temperature-dependence of an equilibrium between two 2 : 1 complex species, *i.e.*, between the low-temperature and the high-temperature form of a 2 : 1 complex species, but not to the step of complex formation between Cu^{2+} ion and the free ligand. In fact, the absorption maximum at the shorter wavelength observed in the presence of a large excess of Cu^{2+} ion (λ_{max}=450 nm) distictly differs from that of the free ligand in the given pH region (λ_{max}=434 nm).

The feature of the temperature-dependence of the absorption spectrum at a constant pH (Fig. 2(a)) was quite similar to that of the pH-dependence of the spectrum at a constnat temperature as depicted in Fig. 2(b). For the increase in the pH value of the solution from 3.93 to 5.04 the absorbance at 574 nm considerably increased about 3.7-fold accompanied with the corresponding decrease in the absorbance at 450 nm, and with a distinct isosbestic point at 491 nm. The observed wavelengths for the absorption maxima and the isosbestic point were found to be all the same as those for the temperature-dependence of the spectra at constant pH (Fig. 2(a)). It should be noted in this connection that the pH value of the acetate buffer solution used changed only slightly upon heating, *e.g.*, the solution of pH 4.55 at 20 °C shows the pH 4.62 even upon heating at 70 °C. The similarity of the temperature- and the pH-dependencies of absorption spectra suggests that the effect of heating of the solution essentially corresponds to the effect of the increase in pH of the same solution.

These facts indicate clearly that the observed thermochromism is primarily due to the temperature-dependence of the protolytic equilibria between the complex AH having an uncoordinated phenolic hydroxyl group and the complex A having a coordinated phenolate group

$$\underset{\text{(at lower temperatures)}}{AH} \overset{K}{\rightleftharpoons} \underset{\text{(at higher temperatures)}}{A + H.} \quad (1)$$

The complex A is predominant at higher temperatures.

When the experiments were carried out in unbuffered aqueous solutions of the complex, the pH of the solution decreased with the rise of temperature. For example, if the pH of the solution containing 1.6×10^{-2} mol dm^{-3} $Cu(ClO_4)_2$ and 4.0×10^{-3} mol dm^{-3} XO (I=0.1 mol dm^{-3} ($NaClO_4$)) was adjusted at 4.53 at 25 °C only with $HClO_4$ and NaOH, the pH of the solution did decrease to 4.20 by heating the solution to 70 °C. The value of the pH at 70 °C accorded approximately with the calculated value of pK based on the ΔH and ΔS (see below). The same color change of the solution was observed as in the case of the buffered solution. These results directly confirm the dissociation of the proton from the species AH upon heating, which forms the hydrated proton in the unbuffered aqueous solution to lower the pH value of the solution as to be expected from the reaction mechanism (1).

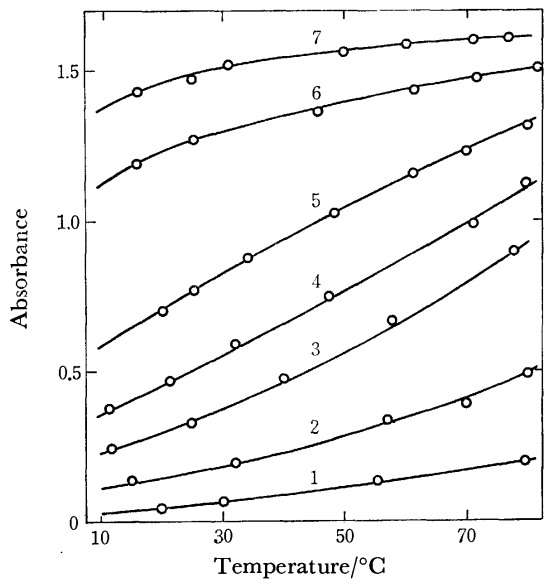

Fig. 4. The temperature-dependence of the absorbance at 574 nm of the Cu(II)-XO at various pH. At pH 2.99 (1), 3.53 (2), 3.94 (3), 4.21 (4), 4.49 (5), 5.04 (6), and 5.58 (7). $[Cu]=1.2\times10^{-4}$ mol dm^{-3}; $[XO]=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). Cell length=1 cm.

Figure 4 shows the temperature-dependence of the absorbance at 574 nm of the solution of the 2 : 1 Cu(II)-XO chelate at various buffered pH values. Upon heating the solution at pH higher than 5.0 or lower than 3.5 the absorbance increases only slightly. The largest increase in the absorbance was observed only in a narrow pH range between 3.9 and 4.5. This tendency suggests the existence of an optimum pH range for the given thermochromism. From the given temperature-dependence of the absorbance we can derive the pH-dependence of the absorbance at various temperatures as reproduced in Fig. 5. From the pH-dependences of the absorbance we calculated the values of pK for the equilibrium (1) at 15, 25, 35, 50, and 70 °C, which are listed in Table 3.

The uncomplexed free ligand XO did not show a thermochromic behavior at all around the pH region where its metal complexes are strongly thermochromic. However, in neutral or weakly basic media, *i.e.*, at

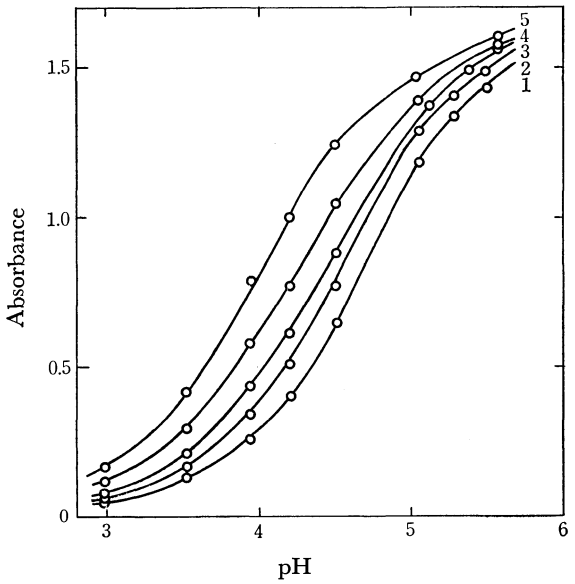

Fig. 5. The pH-dependence of the absorbance at 574 nm of the Cu(II)–XO at various temperatures. At 15 (1), 25 (2), 35 (3), 50 (4), and 70 °C (5). [Cu]= 1.2×10^{-4} mol dm^{-3}; [XO]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). Cell length=1 cm.

Table 3. Temperature-dependence of the acid-dissociation constants for the Cu(II)–XO and the free XO at I=0.1 mol dm^{-3} ($NaClO_4$)

Temperature °C	p(K/mol dm^{-3}) for Cu(II)–XO	p(K_a/mol dm^{-3}) for free XO
15	4.62	6.66
25	4.40, 4.55[a)]	6.57, 6.70[b)]
35	4.27	6.50
50	4.11	—
70	3.83	—

a) See Ref. 10. b) See Ref. 11.

pH in the vicinity of the pK_a value of the phenolic proton, the free ligand XO were weakly thermochromic. Figure 6 shows the absorption spectra of the solution of the free ligand XO at two different temperatures and at three pH values. The temperature-dependence of the spectra was similar to the pH-dependence also in this case, the isosbestic point being identical in both cases. However, the thermochromic effect in the free ligand XO was much weaker compared with that in the Cu(II)–XO complex. Whereas upon heating from 15 to 35 °C the absorbance at 574 nm of a solution of the free ligand at pH 6.40, *viz.*, near the pK_a value of the phenol protons of the free ligand XO, increased only by 19%, the absorbance at 574 nm of the Cu(II)–XO system at pH 4.50 increased by so large as 36% for the same temperature-rise. The values of pK for the reaction AH$\rightleftarrows$A+H between two 2 : 1 Cu(II)–XO chelates decreases remarkably with the rise of temperature, whereas pK_a value of the phenol proton in the free ligand does not decrease so remarkably (Table 3).

The thermodynamic parameters ΔH and ΔS for the Reaction 1 and for the acid-dissociation of the phenol

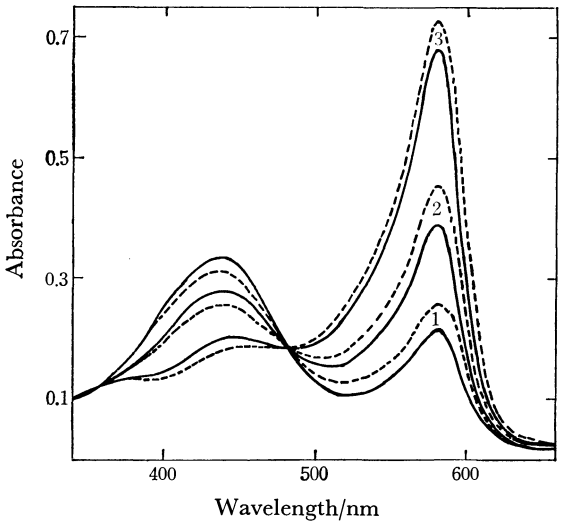

Fig. 6. Absorption spectra of the free ligand XO at various pH and temperatures. At pH 6.27 (1), 6.67 (2), and 7.14 (3). Temperature : 15 (—) and 35 °C (---). [XO]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). Cell length=1 cm.

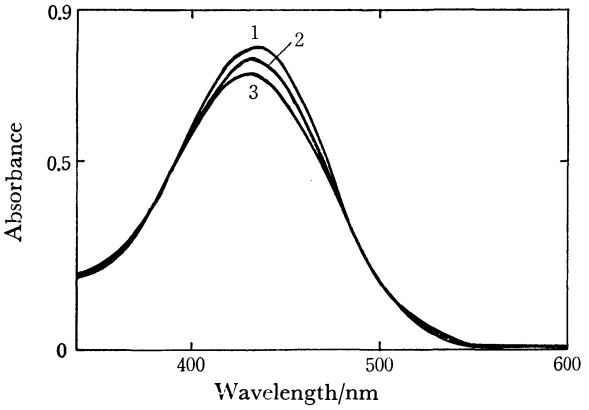

Fig. 7. Temperature-dependence of the absorption spectra of the free ligand XO at pH 3.47—3.97. [XO]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). At 6 (1), 25 (2), and 63 °C (3). Cell length=1 cm.

proton in the free ligand were graphically determined by plotting the values of log K and log K_a against $1/T$ to be 26±2 and 14±1 kJ mol^{-1} and 1±3 and −78±1 J mol^{-1} K^{-1} (298 K), respectively. The positive values of the enthalpy show that the observed thermochromic changes are endothermic. The value of the enthalpy for the Cu(II)–XO complex is about twice as large as that for the free ligand. These results correspond to the fact that the more remarkable thermochromism is observed for reaction (1) than for the protolytic equilibrium of the free ligand. A small value of ΔS obtained for Eq. 1 would be due to the compensation of the increase in the entropy by a water molecule released from the coordination sphere of the metal ion upon coordination of the phenolate oxygen and the decrease in the entropy by the hydration of a dissociated proton. The values of ΔH and ΔS obtained for the free ligand are reasonable as the values for the usual proton-transfer reactions of the phenolic

groups in aqueous media.[12]

In addition, molar absorptivity of the free ligand XO were found to depend on the temperature. In the pH region between 3.47 and 3.97 corresponding to the pK_a of the carboxyl proton of the free ligand[11] where the absorption spectra show no pH-dependency, the definite temperature-dependence of the spectra was clearly observed (see Fig. 7). This would be attributed to the change in molar absorptivity of the free ligand. Therefore, the temperature-dependency of the molar absorptivity might also contribute to the thermochromic behavior of the present complexes, though the effect is not so strong.

It is interesting to note that the metal complexes of the triphenylmethane complexons with the two benzene rings A and B tightly linked together, say, *e.g.*, through an ether linkage as shown in Fig. 1(b), were not thermochromic. This fact shows the possibility that the change in resonance structure of the π-system of the triphenylmethane skeleton could also contribute to the thermochromic changes.

Kinetics. The temperature-jump studies were carried out for the thermochromic changes of the Cu(II)–XO complex together with the Co(II), Ni(II), and Zn(II) complexes of XO, and also for the acid-dissociation of the free ligand in the pH range where the thermochromic changes were observed. The relaxation times τ observed in 5 μs region can be expressed as

$$\tau^{-1} = k_1 + k_{-1}([\overline{H}]+[\overline{A}]). \quad (2)$$

As regards the acid-dissociation of phenolic proton in the free ligand in aqueous media, we obtained the values of the rate constants for the deprotonation and for the protonation $k_1=(1.0\pm0.6)\times10^4\ s^{-1}$ and $k_{-1}=(3.0\pm0.1)\times10^{10}\ mol^{-1}\ dm^3\ s^{-1}$, respectively (Fig. 8). The value of k_1 lies in the same order of magnitude as the values of the rate constants reported for the acid-dissociation of the phenolic ligands of similar structure[13] and the quotient $k_1/k_{-1}=10^{-6.5}\ mol\ dm^{-3}$ is in good agreement with the acid-dissociation constant, K_a, of the phenolic proton of XO.[11] However, from the signals of the temperature-jump observed for the thermochromic changes of the metal chelates we could evaluate only the approximate values of the rate constants for reaction (1), since the values of τ as derived from the exponential signals (see Table 4) lie just near the time constant τ_c for the temperature-rise of our apparatus. The value of k_1 estimated for reaction (1) was *ca.* $2\times10^5\ s^{-1}$. Similar temperature-jump studies were also carried out preliminarily for the Co(II)–XO, Ni(II)–XO, and Zn(II)–XO systems. The corresponding k_1 values for these systems were found to be *ca.* $2\times10^5\ s^{-1}$, essentially independent of the metal ion involved. Thus the kinetic measurements also suggest that the phenomena of the thermochromism observed in the presence of a large excess of metal ions are primarily due to the process involving a protonation-deprotonation in the coordinated ligand. The quantitative studies for other thermochromic systems are now in progress and will be reported elsewhere.

For the kindness in the DSC measurements, the authors thank Professor Yoshio Matsunaga. They also thank Professor Mitsuo Shimoji and Professor Yoshio Nakamura for aid in the use of a spectrophotometer for the measurements at high temperatures.

Circular Dichroism Spectra of Cobalt(III) Complexes of the Type, *trans*-[CoX_2(1,3-Diamine)$_2$]$^{n+}$ (X=Cl^-, CN^-, or NH_3)

Kazuo KASHIWABARA, Masaaki KOJIMA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received September 27, 1978)

Four new complexes of the type, *trans*-[$Co(CN)_2$(1,3-diamine)$_2$]$^+$ were prepared, where 1,3-diamine is (*S,S*)-1,3-diphenyl-1,3-propanediamine, (*R,R*)-2,4-pentanediamine, (*S*)-1,3-butanediamine, or (*S*)-1-phenyl-1,3-propanediamine. Two diammine complexes of the same type with (*S*)-1,3-butanediamine and (*S*)-1-phenyl-1,3-propanediamine, and *trans*-[$Co(CN)_2$((*R,R*)-1,2-diphenyl-1,2-ethanediamine)$_2$]$^+$ were also newly prepared. The circular dichroism(CD) spectra of the new complexes measured in several solvents were compared with those of the corresponding dichloro and diammine complexes. The CD spectra of the dicyano complexes of (*S*)-1,3-butanediamine and (*S*)-1-phenyl-1,3-propanediamine showed remarkable solvent dependence, while those of the other complexes small or little dependence.

Bosnich and Harrowfield[1] found that the sign of circular dichroism(CD) under the $^1A_{2g}\leftarrow{}^1A_{1g}$ transition in the first absorption band of *trans*-[$CoCl_2$(*R*-pn)$_2$]$^+$ (*R*-pn=(*R*)-1,2-propanediamine) is negative in methanol, but positive in dimethyl sulfoxide(DMSO), and suggested that the effects of chiral distortions of the donor atoms and of chiral arrangements of the amino hydrogen atoms caused by solvation are important for such solvent dependence. Recently, Hawkins *et al.*[2] reported by both CD and PMR studies of the same complex and its related complexes in various solvents that the solvent dependence of the CD will be cussed by stereoselective solvation at the equatorial amino hydrogen atoms of the diamines, rendering the donor nitrogens chiral. This paper is concerned with the CD spectra of complexes of the type, *trans*-[CoX_2(1,3-diamine)$_2$]$^{n+}$ (X=Cl^-, CN^-, or NH_3) in several solvents, the abbreviations and the absolute configurations of the 1,3-diamines being shown in Fig. 1. The flexibility of six-membered chelate rings formed with the 1,3-diamines will affect the CD spectra of their complexes in a different way from that of the complexes of five-membered chelate rings. The *R*-pn and (*R,R*)-1,2-diphenyl-1,2-ethanediamine (*R,R*-dpen) complexes of the same type were also prepared to compare their CD spectra with those of the 1,3-diamine complexes.

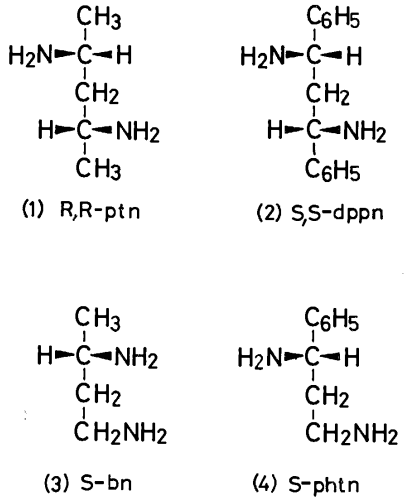

Fig. 1. Absolute configurations of the 1,3-diamines, (1) (*R,R*)-2,4-pentanediamine(*R,R*-ptn), (2) (*S,S*)-1,3-diphenyl-1,3-propanediamine(*S,S*-dppn), (3) (*S*)-1,3-butanediamine(*S*-bn), and (4) (*S*)-1-phenyl-1,3-propanediamine(*S*-phtn).

Experimental

Preparation of Ligands. Optically active diamines were prepared according to the references reported previously; *S,S*-dppn,[3] *R,R*-ptn,[4] *S*-phtn,[5] *S*-bn,[6] *R*-pn,[7] and *R,R*-dpen.[8]

Preparation of Complexes. *1)* The following complexes were prepared by the methods described previously; *trans*-[$CoCl_2$(*S,S*-dppn)$_2$]Cl·HCl·H_2O,[3] *trans*-[$CoCl_2$(*R,R*-ptn)$_2$]ClO_4,[9] *trans*-[$CoCl_2$(*S*-phtn)$_2$]Cl·H_2O,[5] *trans*-[$CoCl_2$(*R*-pn)$_2$]ClO_4,[1] *trans*-[$CoCl_2$(*R,R*-dpen)$_2$]ClO_4,[1] *trans*-[$Co(CN)_2$(*R*-pn)$_2$]Cl·1.5H_2O,[10] *trans*-[$Co(NH_3)_2$(*S,S*-dppn)$_2$]$(ClO_4)_3$·3H_2O,[11] and *trans*-[$Co(NH_3)_2$(*R,R*-ptn)$_2$]$(ClO_4)_3$·H_2O.[12]

2) trans-[*$CoCl_2$*(S-*bn*)$_2$]*ClO_4*: This complex was prepared by adding sodium perchlorate to an aqueous solution of the complex chloride.[13] Found: C, 23.88; H, 6.19; N, 13.56%. Calcd for [$CoCl_2(C_4H_{12}N_2)_2$]ClO_4 : C, 23.69; H, 5.98; N, 13.82%.

3) trans-[*$Co(CN)_2$*(S,S-*dppn*)$_2$]*Cl*·*2H_2O*: To sodium cyanide (30 mg) in 12 cm^3 of DMSO was added *trans*-[$CoCl_2$-(*S,S*-dppn)$_2$]ClO_4 (140 mg) with stirring at 40 °C. The solution changed from green to orange instantly and was kept at 40 °C for 10 min. After cooling to room temperature, the solution was poured into a column (ϕ3×60 cm) of an SP-Sephadex C-25 ion exchanger and then the column was washed with water to remove DMSO. The adsorbed orange product was eluted with 0.1 mol/dm^3 sodium chloride in a mixture of methanol and water (1:4). The column showed only one orange yellow band. The eluate was concentrated under reduced pressure to give orange yellow crystals, which were recrystallized from a small amount of water. The yield was almost quantitative. Found: C, 60.36; H, 6.19; N, 13.15%. Calcd for [$Co(CN)_2(C_{15}H_{18}N_2)_2$]Cl·2$H_2O$: C, 60.51; H, 6.35; N, 13.23%.

4) trans-[*$Co(CN)_2$*(R,R-*ptn*)$_2$]*ClO_4*·*H_2O*: This complex was prepared from *trans*-[$CoCl_2$(*R,R*-ptn)$_2$]ClO_4 and sodium cyanide by the same method as that for *trans*-[$Co(CN)_2$-(*S,S*-dppn)$_2$]Cl·2H_2O except that the eluent was an aqueous solution of 0.05 mol/dm^3 sodium perchlorate. The yield was almost quantitative. Found: C, 33.62; H, 7.10; N, 19.65%. Calcd for [$Co(CN)_2(C_5H_{14}N_2)_2$]ClO_4·H_2O: C, 33.30; H, 6.94; 19.42%.

5) trans-[*$Co(CN)_2$*(S-*bn*)$_2$]ClO_4·H_2O: This complex was prepared from *trans*-[$CoCl_2$(*S*-bn)$_2$]ClO_4 and sodium cyanide according to the same method as described for the above *R,R*-ptn complex. Found: C, 29.94; H, 6.63; N, 20.80%.

Calcd for $[Co(CN)_2(C_4H_{12}N_2)_2]ClO_4\cdot H_2O$: C, 29.67; H, 6.49; N, 20.76%.

6) trans-$[Co(CN)_2(S\text{-}phtn)_2]ClO_4\cdot H_2O$: The procedure was the same as that for the *R,R*-ptn complex. However, two light yellow bands (probably the *cis*-Δ and *cis*-Λ isomers on the basis of the absorption spectra) followed after an orange band (*trans* isomer) by eluting with a 0.05 mol/dm^3 aqueous solution of sodium perchlorate. Yield: about 40%. Found: C, 45.65; H, 5.34; N, 15.69%. Calcd for $[Co(CN)_2(C_9H_{14}N_2)_2]ClO_4\cdot H_2O$: C, 45.42; H, 5.72; N, 15.89%.

7) trans-$[Co(CN)_2(R,R\text{-}dpen)_2]ClO_4\cdot 2H_2O$: To a DMSO solution (20 cm^3) of sodium cyanide (60 mg) was added *trans*-$[CoCl_2(R,R\text{-dpen})_2]ClO_4\cdot H_2O$ (180 mg) at 50 °C with stirring. The solution changed from green to orange instantly and was kept at 50 °C for 10 min. After cooling to room temperature, the solution was poured into a column ($\phi 3\times$ 90 cm) of an SP-Sephadex C-25 ion exchanger. DMSO in the column was washed out with water. The adsorbed orange product was eluted with an aqueous solution of 0.1 mol/dm^3 sodium acetate. An orange yellow band (the *trans* isomer) was eluted first and then two light yellow bands (the *cis* isomers) followed. The orange yellow eluate was mixed with a small amount of sodium perchlorate and concentrated under reduced pressure to give crystals. Yield: 50 mg. Found: C, 53.98; H, 5.39; N, 12.67%. Calcd for $[Co(CN)_2(C_{14}H_{16}N_2)_2]ClO_4\cdot 2H_2O$: C, 53.70; H, 5.41; N, 12.52%.

8) trans-$[Co(NH_3)_2(S\text{-}bn)_2](ClO_4)_3$: When *trans*-$[CoCl_2(S\text{-bn})_2]ClO_4$ (100 mg) was dissolved in liquid ammonia (20 cm^3), the solution changed from green to orange instantly. After removal of liquid ammonia at room temperature, the residue was mixed with 2 mol/dm^3 hydrochloric acid (5 cm^3). The solution was diluted with water (500 cm^3) and passed through a column ($\phi 3\times 120$ cm) of an SP-Sephadex C-25 ion exchanger. The adsorbed orange product was eluted with a 0.15 mol/dm^3 aqueous solution of sodium $(+)_D$-tartratoantimonate(III), yielding two orange yellow bands. The first eluting orange yellow band appeared to consist of one isomer because the CD patterns of all the fractions remained constant. On the other hand, the initial and final fractions of the second orange band gave different CD patterns, suggesting the presence of more than two isomers in this band. The fractions of the first orange yellow band were collected and concentrated to give crystals. Yield: 40 mg. Found: C, 16.94; H, 5.40; N, 14.67%. Calcd for $[Co(NH_3)_2(C_4H_{12}N_2)_2](ClO_4)_3$: C, 16.93; H, 5.33; N, 14.80%. The ^{1}H-NMR spectrum of the crystals in D_2O showed only one kind of methyl signal. Thus, we tentatively assigned this complex to the *trans* isomer. The chromatographic behavior that this isomer was eluted faster than did the other isomer(s) will support this assignment.[11,12]

9) trans-$[Co(NH_3)_2(S\text{-}phtn)_2](ClO_4)_3\cdot 0.5H_2O$: This complex was prepared by the same method as that for the above *S*-bn complex. By eluting the product, the column gave five orange bands. The complex isolated from the first eluted orange band was tentatively assigned to the *trans* isomer, although no definite evidence for this structure was obtained from ^{1}H-NMR spectroscopy. Found: C, 30.82; H, 5.23; N, 11.67%. Calcd for $[Co(NH_3)_2(C_9H_{14}N_2)_2](ClO_4)_3\cdot 0.5H_2O$: C, 30.84; H, 5.03; N, 11.99%.

Measurements. Visible and ultraviolet absorption spectra were recorded on a HITACHI 323 spectrophotometer. CD spectra were obtained with JASCO J-20 and J-40 spectropolarimeters and ^{1}H-NMR spectra with a JEOL PMX-60 spectrometer. All the solvents for optical measurements are of spectroscopic grade and used without further purification.

Results and Discussion

Figure 2 shows the absorption spectra of ptn and dppn complexes of the type, *trans*-$[CoX_2(diamine)_2]^+$ ($X=Cl^-$ or CN^-). Except the absorptions due to the phenyl group in the near ultraviolet region, the ptn and dppn complexes with the same X ligand show the same spectral pattern. The first absorption band ($^1T_{1g}\leftarrow{}^1A_{1g}$) in an octahedral field, CoN_6^{3+} splits into two components, $^1A_{2g}+{}^1E_g\leftarrow{}^1A_{1g}$ in a tetragonal field, *trans*-$CoX_2N_4^+$. According to Yamatera's theory,[14] the ^1E_g component should have lower energy than the $^1A_{2g}$ component when the axial ligand, X is lower than the ligating N atoms in the spectrochemical series, and inversely the ^1E_g component should be at higher energy for a complex in which the X ligand has a higher position than N in the series. All the complexes studied here obey this prediction as seen in Table 1. In the present paper, the CD spectra in this region are discussed . The CD spectra in the ultraviolet region are not described, because the spectra are complicated and no significant discussion can be made at present. The absorption and CD data of all the complexes are summarized in Table 1.

For the complexes of the present type with *R*-pn, *S*-bn, and *S*-phtn, there are two possible geometrical isomers, *cis* and *trans* with respect to the alignment of the substituents. The experiments gave neither the indication for the presence of these isomers nor the information for assigning such geometrical isomerism of the complexes obtained. The structure of *trans*-$[CoCl_2(R\text{-pn})_2]Cl\cdot HCl\cdot 2H_2O$ was determined by X-ray work to have a *trans*(CH_3, CH_3) configuration.[15] On the other hand, Boucher and Bosnich[16] reported that the *trans*-$[CoCl_2(R,S\text{-ptn})_2]^+$ complex prepared by oxidizing an aqueous solution containing cobalt(II) chloride and *R,S*-ptn with air consists mainly (>95%) of the *cis*(*R,R*) isomer (C_{2h}). The stable conformer of the *R,S*-ptn chelate ring is expected to be the *chair* form with the equatorially disposed methyl groups. In the crystals, *trans*-$[CoX_2(trimethylenediamine)_2]^+$ ($X=Cl^-$ [17] and NO_3^- [18]) also have the same skeletal structure as that of the *cis*(*R,R*) isomer. The *trans*-dichloro complexes of *S*-bn and *S*-phtn were prepared from cobalt(II) chloride and the diamines by air-oxidation. The stable conformations of these diamine chelate rings will be the *chair* form. (*vide post*) Therefore, these complexes may be assigned to the *cis*(CH_3,CH_3) and *cis*(phenyl, phenyl) isomers which correspond to the *cis*(*R,R*) isomer of the *R,S*-ptn complex. The corresponding dicyano and diammine complexes which were derived from the dichloro complexes may also have the same geometrical arrangement.

(1) Complexes of Five-membered Chelate Diamines. As Fig. 3 shows, the dichloro complex of *R*-pn in methanol gives a positive and a negative CD band in the ^1E_g and $^1A_{2g}$ transitions, respectively, while the *R,R*-dpen complex in the same solvent two positive CD bands in these transitions. Other dichloro complexes of *R*-1- or *R,R*-1,2-dialkyl-substituted 1,2-diamines

show the same CD patterns as that of the *R*-pn complex, and the CD pattern of the *R*-1-phenyl-1,2-ethanediamine(*R*-pen) complex is the same as that of the *R,R*-dpen complex.[19] The absolute configurations of *R,R*-dpen[20] and *R*-pen[21] have been determined

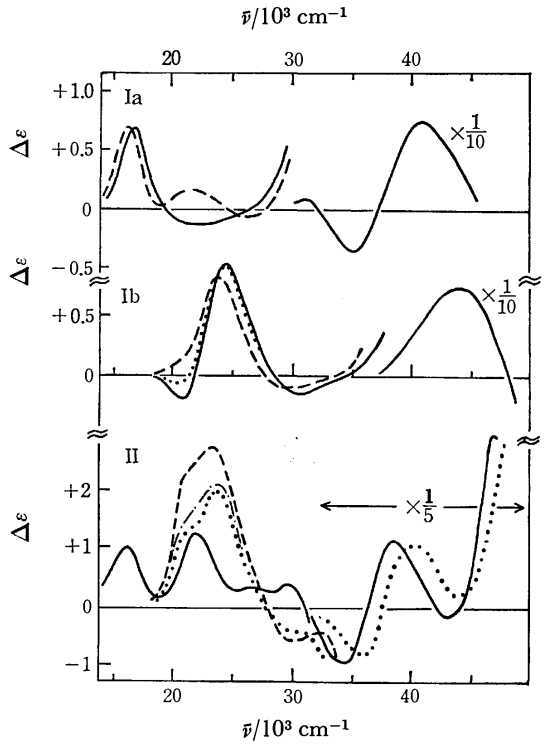

Fig. 3. CD spectra, (Ia) *trans*-$[CoCl_2(R\text{-pn})_2]^+$ in methanol (——) and in DMSO (— — —), (Ib) *trans*-$[Co(CN)_2(R\text{-pn})_2]^+$ in methanol (——), in DMF (·····), and in DMSO (— — —), (II) *trans*-$[CoCl_2(R,R\text{-dpen})_2]^+$ in methanol (——) and *trans*-$[Co(CN)_2(R,R\text{-dpen})_2]^+$ in methanol (·····), in DMF (—·—·—), and in DMSO (— — —).

by the X-ray and chemical methods, respectively, and these diamines will form chelate rings with the same λ-gauche conformation as that of *R*-pn upon coordination. Nevertheless, the *R,R*-dpen and *R*-pen complexes give the positive CD sign in the $^1A_{2g}$ band opposite to that of the *R*-pn complex. The corresponding dicyano complex of *R*-pn in methanol also exhibits a negative and a positive CD band in the $^1A_{2g}$ and ^1E_g transitions, respectively, and that of *R,R*-dpen two positive CD bands. Bosnich and Harrowfield,[1] however, found that in DMSO, the CD sign of the $^1A_{2g}$ band in *trans*-$[CoCl_2(R\text{-pn})_2]^+$ changes to positive, and the corresponding CD band of the dichloro *R,R*-dpen complex increases in the strength. The same phenomena are observed for the dicyano complexes as seen in Fig. 3. The weak negative CD band at 20410 cm^{-1} of *trans*-$[Co(CN)_2(R\text{-pn})_2]^+$ in methanol decreases its strength in *N,N*-dimethylformamide (DMF), and changes to positive sign in DMSO. The *R,R*-dpen complex shows the same trend. This fact suggests that the variations in CD sign or pattern with changes in solvent will be little related to the axial ligands in the complexes. As suggested by Bosnich and Harrowfield,[1] such solvent effect on CD spectra of the *trans*-bis(diamine) complexes may be caused by solvation of solvent molecules in chiral arrangements to the complex ions. Recently, Hawkins *et al.*[2] claimed that the solvation occurs stereoselectively at the equatorial amino hydrogens, rendering the donor nitrogens chiral. The new

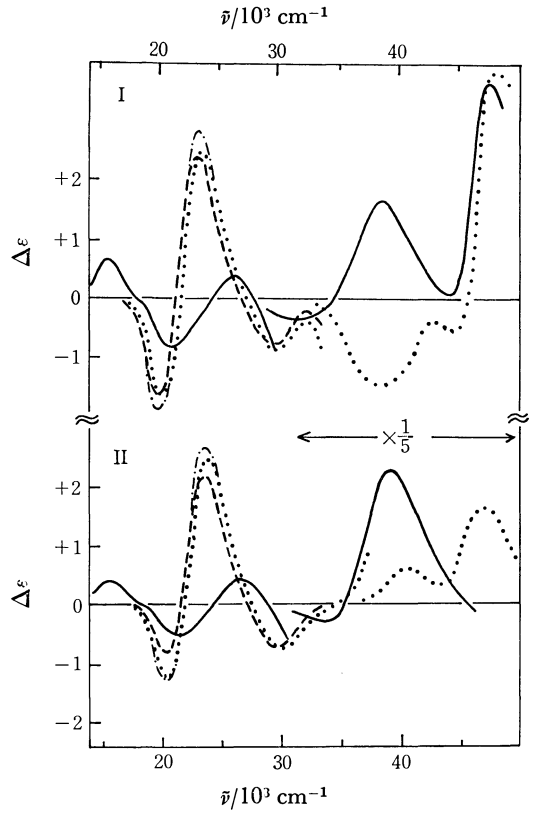

Fig. 4. CD spectra, (I) *trans*-$[CoCl_2(S,S\text{-dppn})_2]^+$ in methanol (——), and *trans*-$[Co(CN)_2(S,S\text{-dppn})_2]^+$ in methanol (·····), in DMF (—·—·—), and in DMSO (— — —). (II) *trans*-$[CoCl_2(R,R\text{-ptn})_2]^+$ in methanol (——), and *trans*-$[Co(CN)_2(R,R\text{-ptn})_2]^+$ in methanol (·····), in DMF (—·—·—), and in DMSO (— — —).

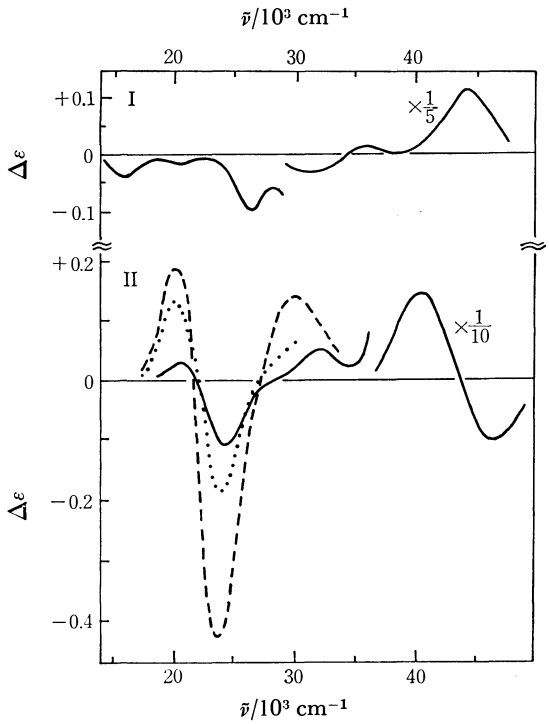

Fig. 5. CD spectra, (I) *trans*-$[CoCl_2(S\text{-bn})_2]^+$ in methanol (——), (II) *trans*-$[Co(CN)_2(S\text{-bn})_2]^+$ in water (——), in DMF (·····), and in DMSO (----).

chiral nitrogen atoms will affect the CD spectra of the diamine complexes. The dicyano complexes are probably the same case, since the variations in their CD spectra with changes in solvent quite resemble those in the CD spectra of the dichloro complexes.

(2) Dichloro and Dicyano Complexes of Six-membered Chelate Diamines. A 1,3-diamine chelate ring is known to take either the *chair* or the *skew* (δ or λ) conformation. When the chelate ring has substituent(s) attached to the skeletal carbon atom(s) of the ring, the conformation with the equatorially oriented substituent(s) will be more stable than the other. Thus the *R,R*-ptn and *S,S*-dppn chelate rings will be the most stable in the λ-*skew* conformation. The designation (*R* or *S*) of dppn which forms a chelate ring with the same conformational chirality as that of the ptn chelate ring is opposite to that of ptn according to the sequence rule.[22] The λ-*skew* form of the *R,R*-ptn chelate ring has been confirmed by X-ray crystallographic studies on $(-)_{546}$- and $(+)_{546}$-$[Co(R,R\text{-ptn})_3]^{3+}$.[23] On the other hand, the *S*-bn and *S*-phtn chelate rings can take the equatorially disposed substituent both in the *chair* and *skew* conformations. The δ-*skew* of the former diamine and the λ-*skew* of the latter diamine have the equatorial substituent on the basis of the sequence rule. Since a diamine chelate ring in the *chair* form is achiral in the skeleton, its vicinal effect should be much weaker than that of a diamine ring in the *skew* form.

Figure 4 shows the CD spectra of the dichloro and dicyano complexes of *R,R*-ptn and *S,S*-dppn. The dichloro complexes of all the 1,3-diamines studied here are stable in methanol, but unstable in DMF and DMSO to change the CD spectra during the measurement. The CD patterns of the dichloro complexes of *R,R*-ptn and *S,S*-dppn are very similar to each other and also to that of the *R*-pn complex, indicating the λ-chirality of the chelate rings, although the negative CD bands ($\approx$21000 cm^{-1}) assignable to the $^1A_{2g}$ transition are much stronger than that of the *R*-pn complex. The positive CD bands ($\approx$16000 cm^{-1}) can be assigned to the ^1E_g transition. The sign of the $^1A_{2g}$ band of the *S,S*-dppn complex is opposite to that of the *R,R*-dpen complex which gives the $^1A_{2g}$ band with the same sign as that of the ^1E_g band. The dicyano complexes of *R,R*-ptn and *S,S*-dppn also give a similar CD pattern to each other in the region of the first absorption band. The spectra show little variations with changes in solvent. The negative ($\approx$20000 cm^{-1}) and positive ($\approx$24000 cm^{-1}) CD bands can be assigned to the $^1A_{2g}$ and ^1E_g transitions, respectively, and these signs coincide with those of the corresponding CD bands of the dichloro complexes.

On the other hand, the dichloro complexes of *S*-bn and *S*-phtn give quite different CD spectra from each other, and from those of the *R,R*-ptn and *S,S*-dppn complexes, as seen in Figs. 5 and 6. The CD intensities of these complexes are very weak. The weakness suggests that the predominant conformations of the *S*-bn and *S*-phtn chelate rings are in the *chair* form. The CD pattern of the *S*-bn complex, however, is nearly enantiomeric to that of the *R*-pn complex in

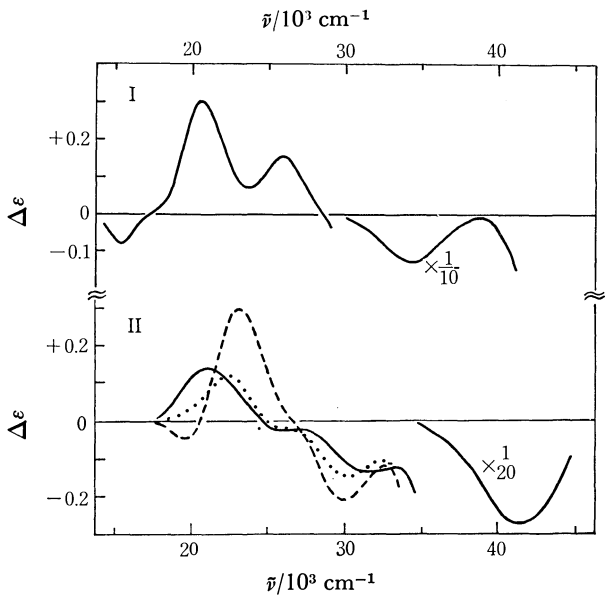

Fig. 6. CD spectra, (I) *trans*-$[CoCl_2(S\text{-phtn})_2]^+$ in methanol (——), (II) *trans*-$[Co(CN)_2(S\text{-phtn})_2]^+$ in water (——), in DMF (·····), and in DMSO (— — —).

DMSO. Hence the *S*-bn chelate ring will be in equilibrium between the *chair* and *δ-skew* forms in solution, the former being predominant. As stated previously, the *S*-bn chelate ring can have the equatorial methyl group in both the *δ-skew* and the *chair* conformations. The CD pattern of the *S*-phtn complex is nearly enantiomeric to that of the *S,S*-dppn complex, although the positive CD band at 20620 cm^{-1} ($^1A_{2g}$) is strong relative to the negative one at 15390 cm^{-1} (^1E_g). Such a pattern suggests the *δ-skew* conformation for the *S*-phtn chelate ring. This suggestion, however, is very unlikely, because the big phenyl group disposed axially interacts strongly with the apical ligand, Cl^-. The absolute configuration of *S*-phtn was confirmed by preparing an authentic sample from (*S*)-3-amino-3-phenyl propionic acid of known absolute configuration.[24] The reason for the anomalous CD of the *S*-phtn complex remains unknown. The vicinal effect of the asymmetric carbon atom, which has never been made clear but recognized to be weak, may appear on CD spectra explicitly to vary CD patterns of weak intensity.

The dicyano complexes of *S*-bn and *S*-phtn in water also show weak CD in the region of the first absorption band, indicating that the predominant conformations of these diamine chelate rings are the *chair* form. However, the CD patterns of the *S*-bn and the *R,R*-ptn complexes are nearly enantiomeric to each other, and it is concluded that the chelate rings will be in equilibrium between the *chair* and *δ-skew* conformations. The *S*-phtn complex gives again an anomalous pattern of only one CD band, although the positive sign of the band indicates the *λ-skew* conformation which is expected for the *S*-phtn chelate ring. The CD patterns of the *S*-bn complex in DMF and DMSO are the same as that in methanol, but the CD strengths increase to a large extent. Such variations in CD may be attributed to that the conformational equilibrium between the two forms, *chair* and *δ-skew* shifts toward the latter in these solvents. The *S*-phtn complex decreases the CD strength of smaller wave number side of the band in DMF, and exhibits a negative CD band in DMSO. The pattern in DMSO resembles that of the *S,S*-dppn complex, and suggests that the stability of the *λ-skew* conformer increases in such organic solvents.

The variations in CD for the dicyano complexes with changes in solvent seem to depend on the kind of diamines. In general, six-membered chelate rings formed with 1,3-diamines will be more flexible than five-membered ones with 1,2-diamines. Therefore, if the conformational change of a chelate ring is responsible for such variations in CD, the spectra of 1,3-diamine complexes should vary more remarkably than those of 1,2-diamine complexes. The dicyano complexes of *S*-bn and *S*-phtn will be this case. As stated previously, these chelate rings can have two stable conformations, the *chair* and the *skew* forms. The energy difference between these conformers has been calculated to be very small, the *chair* form being a little more stable than the other.[25] Hence, the relative stability of these conformers will be affected by many factors involving interactions with solvent molecules. The solvent dependence of the CD of the dicyano complexes of *S*-bn and *S*-phtn may be caused by such conformational changes of the chelate rings. In fact, the complexes of *R,R*-ptn and *S,S*-dppn which are expected to form less flexible six-membered chelate rings than those diamines show little solvent dependence in the CD spectra.

However, the solvent dependence of the *R,R*-ptn and *S,S*-dppn complexes seems to be even smaller than that of the complexes of 1,2-diamines, *R*-pn and *R,R*-dpen, although the chelate rings of the former 1,3-diamines may be more flexible than those of the latter 1,2-diamines. As suggested by Hawkins *et al.*,[2] if the variation in CD is caused by the stereoselective solvation of solvent molecules at the equatorial amino-hydrogens of diamines, the little solvent dependence of the *R,R*-ptn and *S,S*-dppn complexes indicates the followings; weak solvation, no stereoselective solvation, or weak contribution of new chiral nitrogen atoms introduced by stereoselective solvation to the CD. Details are not clear at present. However, molecular models indicate that in a *trans*-bis(1,3-diamine) complex, the distance between two equatorial amino-hydrogens in the *cis*-positions from each diamine chelate becomes much shorter than that in the corresponding 1,2-diamine complex. The crowded structure resulted from the shortening of distance between these hydrogen atoms may prevent them from strong interactions with solvent molecules. The little solvent dependence in the CD spectra of the *R,R*-ptn and *S,S*-dppn complexes may be interpreted by such a weak solvation effect.

(3) Diammine Complexes of Six-membered Chelate Diamines. Figures 7 and 8 show the CD spectra of diamine complexes of *R,R*-ptn and *S,S*-dppn, and *S*-bn and *S*-phtn, respectively. The *S,S*-dppn and *S*-phtn complexes were only stable in acidic solution, so that all

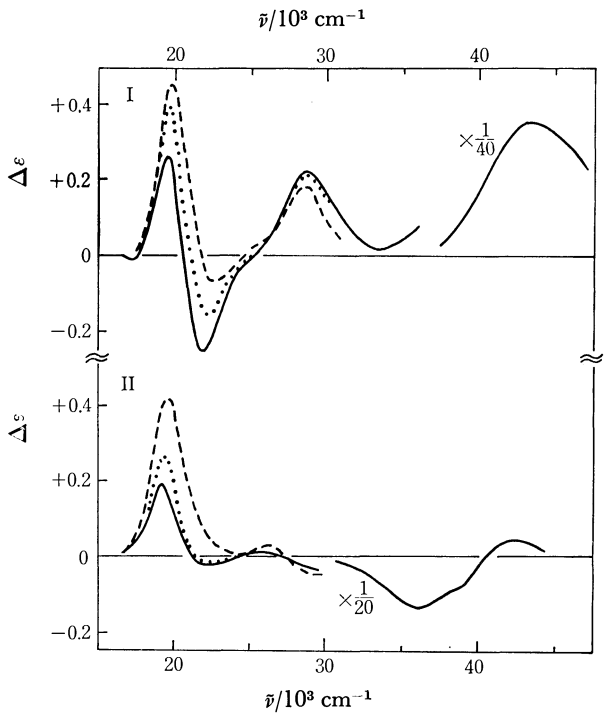

Fig. 7. CD spectra, (I) *trans*-$[Co(NH_3)_2(R,R\text{-ptn})_2]^{3+}$ in water (——), in DMF (·····), and in DMSO (- - - -). (II) *trans*-$[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ in methanol (——) in DMF (·····), and in DMSO (- - - -).

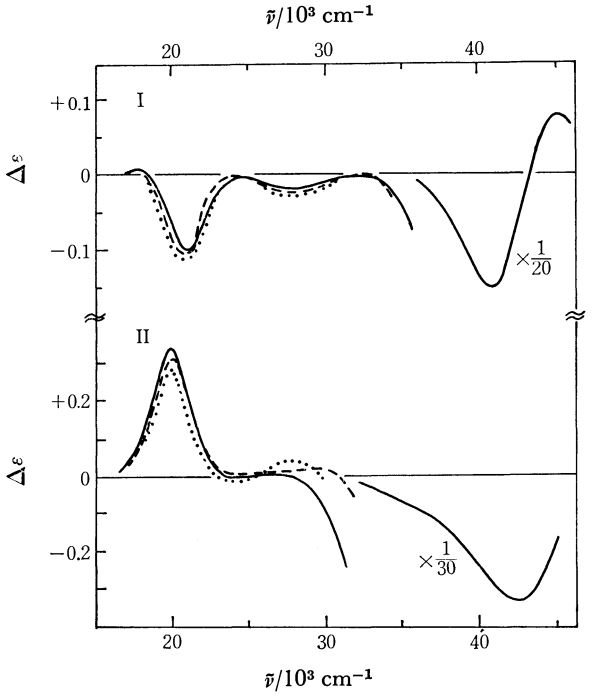

Fig. 8. CD spectra, (I) *trans*-$[Co(NH_3)_2(S\text{-bn})_2]^{3+}$ in water (——), in DMF (·····), and in DMSO (- - - -). (II) *trans*-$[Co(NH_3)_2(S\text{-phtn})_2]^{3+}$ in water (——), in DMF (·····), and in DMSO (- - - -).

the solutions were acidified with perchloric acid. The signs of the main CD bands or the patterns of CD spectra in the region of the first absorption band of these complexes suggest the *skew* conformation of the chirality expected from the equatorial preference of the substituent for the chelate rings, as stated previously. The CD strength of the *S*-bn complex is smaller than those of the other diamine complexes, indicating that the chelate rings are in equilibrium between the *chair* and the *δ-skew* conformations. In contrast to the cases of the *trans*-dicyano complexes, the CD spectra of the *S*-bn and *S*-phtn complexes show little solvent dependence, while those of the *R,R*-ptn and *S,S*-dppn complexes change the strength fairly remarkably with changes in solvent. Hawkins *et al.*[2] measured the CD spectra of *trans*-$[Co(NH_3)_2(R\text{-pn})_2]^{3+}$ in various solvents and concluded that for such a tri-positive complex ion, ion-association with its counter anions is more important for the solvent dependence in CD rather than the stereoselective solvation as seen in the dichloro complexes. The *R,R*-ptn and *S,S*-dppn complexes increase the strengths of the positive CD components in DMF and DMSO compared with those in water or methanol. Since the vicinal effect due to a chiral chelate ring in the *λ*-conformation is known to exhibit positive CD in the region of the first absorption band, these rings may be more stabilized in the *λ-skew* form by ion-association in the former solvents.[13] The ion-association should be facilitated in organic solvents compared with that in water. However, the *S*-bn and *S*-phtn complexes show little solvent dependence, as seen in Fig. 8. Neither the ion-association nor the stereoselective solvation appears to operate in the CD spectra of these complexes. These systems should not be greatly different from those of *R,R*-ptn and *S,S*-dppn. The reason why these complexes show little solvent dependence is unknown at present.

The authors wish to thank the Ministry of Education for Scientific Research Grant-in-Aid No. 243013 and the Kurata Research Grant.

The Acid-catalyzed Reaction of Alicyclic Ketones with Formaldehyde. III.[1] The Reaction of 3- and 3,5-Methyl-substituted Cyclohexanones with Formaldehyde

Fukumi HIRANO* and Shoji WAKABAYASHI

Department of Chemistry, Faculty of Science, Okayama College of Science, 1-1 Ridai-cho, Okayama 700

(Received December 20, 1977)

The reaction of 3- and 3,5-methyl-substituted cyclohexanones with formaldehyde in acid media has been studied. The acid-catalyzed reaction gave 2,4,12,14-tetraoxatricyclo[8.4.0.0^{1,6}]tetradecane, 2,4-dioxaspiro-[5.5]undecan-7-one, and 2,4,8,10-tetraoxatricyclo[4.4.4.0^{1,6}]tetradecane derivatives. The effect of the methyl groups on the product distribution has been discussed.

In previous papers,[1,2] the acid-catalyzed reaction of cycloalkanones or alkyl-substituted cycloalkanones with formaldehyde has been reported. The reaction involved an aldol condensation analogous to the Prins reaction to afford spiro mono(1,3-dioxanes), fused di-(1,3-dioxanes), and hydroxymethyl derivatives. The yield and distribution of the products were strongly influenced by the ring-size of the cycloalkanones, the alkyl-substituents on the alicyclic ketones and the reaction conditions. This paper deals with the reaction of 3- and 3,5-methyl-substituted cyclohexanones with formaldehyde, together with the effect of the methyl substituent affecting the distribution of the products in the acid-catalyzed reaction.

Results and Discussion

Reaction of Methylcyclohexanones with Formaldehyde. The reaction of 3-methylcyclohexanone(**1a**) with formaldehyde has been conducted in a mixture of acetic acid and acetic anhydride in the presence of phosphoric acid at 60—65 °C for 10 h. The resulting products were isolated by column chromatography over silica gel and purified by preparative gas chromatography. The reaction of **1a** gave 7-methyl-2,4,12,14-tetraoxatricyclo[8.4.0.0^{1,6}]tetradecane(**2a**), 9-methyl-2,4-dioxaspiro[5.5]undecan-7-one (**3a**), 14-methyl-2,4,8,10-tetraoxatricyclo[4.4.4.0^{1,6}]tetradecane (**4a**), 11-methyl-2,4-dioxaspiro[5.5]undecan-7-one (**5a**), and 12-methyl-2,4,8,10-tetraoxatricyclo[4.4.4.0^{1,6}]tetradecane (**6a**). 3,3-Dimethylcyclohexanone (**1b**), *cis*-3,5-dimethylcyclohexanone(**1c**), *trans*-3,5-dimethylcyclohexanone (**1d**), 3,3,5-trimethylcyclohexanone (**1e**) and 3,3,5,5-tetramethylcyclohexanone(**1f**) were similarly treated with formaldehyde to give the same type of products as those of the reaction of **1a**. The yields are summarized in Table 1.

Fig. 2.

Structures of Reaction Products. The structure of the spiro mono(1,3-dioxane) (**3a**) has been identified by the synthesis of an authentic specimen from 2,4-dioxaspiro[5.5]undecan-7-one.[2] The structure of **3b** or **3e** has also been confirmed by direct comparison with an authentic specimen prepared from **3a** or **3d** (see Experimental). The spiro mono(1,3-dioxanes) (**5**) have been characterized as the structural isomers of **3**, which differ only from the substituted position of a spiro(1,3-dioxane) ring, on the basis of similar spectral data and elemental analyses.

The acid-catalyzed hydrolysis of fused di(1,3-dioxanes) (**4** or **6**) quantitatively afforded the corresponding spiro mono(1,3-dioxanes) (**3** or **5**), respectively (see Experimental). On this basis, the structure of the fused di(1,3-dioxanes) (**4** or **6**) has been characterized. Fused di(1,3-dioxanes) (**2**) were presumed to be the structural isomers of **4** or **6**, on the basis of similar spectral data and elemental analyses.

Methyl-substituent Effect. As seen in Table 1, the methyl groups adjacent to the reaction points (C_2- and C_6-positions in methyl-substituted cyclohexanones) play an important role in the individual reactions. When the C_5-position of cyclohexanone has no methyl groups, *e.g.*, **1a** or **1b**, the reactivity is the largest in the reactions studied. When both C_3- and C_5-positions are substituted by a methyl group, *e.g.*, **1c** or **1d**, the reactivity decreases to one-half of that of **1a** or **1b**. As the methyl group is further introduced, *e.g.*, **1e** or **1f**, the reactivity becomes very poor.

The substituent also influences the product distribution. The reaction of **1a** or **1c**, which has no C_3-

cis-3,5-Dimethylcyclohexanone (**1c**)	3	5	42	—	—	50	48
trans-3,5-Dimethylcyclohexanone (**1d**)	26	25	3	—	—	54	41
3,3,5-Trimethylcyclohexanone (**1e**)	—	4	1	2	—	7	89
3,3,5,5-Tetramethylcyclohexanone (**1f**)	—	3	—	—	—	3	95

or C_3,C_5-axial substituents, mainly affords **4**; **1b**, which has two C_3-substituents, chiefly affords **4**, accompanied by **3**; **1d**, which has an axial and an equatorial substituent at each of the C_3- and C_5-positions, chiefly yields **2**, together with **3**, and very little **4**; **1e** or **1f** mainly affords **3**, although the yield is very low.

These results have been interpreted as follows; (i) The first step in the acid-catalyzed reaction is the enolization of the cyclic ketone, followed by the axial attack of a hydroxymethyl cation ($^+CH_2OH$) on the enolic double bond. The attack takes place predominantly at the α-methylene position where the steric interference caused by the C_3- or C_5-methyl substituent is very small (steric approach control). (ii) The resulting intermediate, a *cis* fused hemiacetal, attains equilibrium with the *trans* fused isomer as shown below. The hemiacetal is dehydrated preferentially according to the Sayzeff rule to give an olefin. The olefin is again attacked by the cation in an antiparallel attack[3] to give the fused di(1,3-dioxane) (**4**).

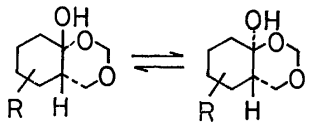

Fig. 3.

(iii) The axial methyl groups at C_3- or C_3,C_5-positions interfere with the formation of **4** and promote that of **3**, because of the 1,3-diaxial interactions between a 1,3-dioxane ring and the axial methyl groups (product development control). (iv) The formation of **5** is more unfavored than that of **3**. However, the reaction of **1e** affords **5e** in a fairly high ratio. This may be explained by the steric approach control and product development control described above, that is, there is no remarkable differences between the two controls on the formation of **3e** or **5e**. (v) In a series of this reaction, the fused di(1,3-dioxane) (**2**) is produced in only small quantities and has been attributed to the fact that **2** is more thermodynamically unstable than **4**, in addition to the reasons given in (ii). However, the reaction of **1d** gave **2d** in an exceptionally good yield but the explanation for this remains unknown.

Experimental

All the boiling and melting points are uncorrected. PMR spectra were taken with a JEOL LMN-MH-60 II spectrometer (60 MHz) with tetramethylsilane as an internal reference. IR spectra were recorded with a Japan Spectroscopic IR-A spectrophotometer. The molecular weight was determined by Rast's method. Preparative GLPC was performed with a Shimadzu GC-3AH using a 3 m×3 mmφ column with 30% diethylene glycol succinate polyester on 60/80 kamelite operating at 160 °C with a H_2 pressure of 0.2 kg/cm². Preparative column chromatography was conducted over silica gel (Wakogel C-200) with a mixture of hexane and ether (5:1 v/v) as an eluent.

Materials. Commercial 3-methylcyclohexanone(**1a**) of analytical grade was used. 3,3-Dimethylcyclohexanone(**1b**),[4] *cis*-3,5-dimethylcyclohexanone(**1c**),[5] *trans*-3,5-dimethylcyclohexanone(**1d**),[5] 3,3,5-trimethylcyclohexanone(**1e**),[6] and 3,3,5,5-tetramethylcyclohexanone(**1f**)[7] were prepared according to reported methods. **1c** and **1d** were obtained as a mixture of their isomers and each isomer was isolated by preparative GLPC. **1b**: bp 51—52 °C/4 mmHg, n_D^{25} 1.4460. **1c**: n_D^{25} 1.4400. **1d**: n_D^{25} 1.4456 (mixture of **1c** and **1d**: bp 174—176 °C). **1e**: bp 72—73 °C/8 mmHg, n_D^{25} 1.4426. **1f**: bp 196—197 °C, n_D^{25} 1.4512.

*Reaction of Methylcyclohexanones(**1a**—**1f**) with Formaldehyde.* A mixture of methylcyclohexanone(10 mmol) and acetic anhydride (1.02 g, 10 mmol) was added to a stirred solution of 95% paraformaldehyde (1.58 g, 50 mmol) and 85% phosphoric acid (0.58 g, 5 mmol) in glacial acetic acid(10 ml) at room temperature, stirring being continued at 60—65 °C for 10 h. After the usual work-up, each product was isolated by column chromatography and subsequent preparative GLPC.

*Hydrolysis of Fused Di(1,3-dioxanes)(**4** or **6**).* A solution of the fused di(1,3-dioxane)(**4** or **6**) (10 mmol) in 10% aqueous hydrochloric acid(10 ml) and cyclohexane(10 ml) was stirred under reflux for 5 h. The mixture was extracted with ether (20 ml×3), the combined extracts washed with 5% aqueous sodium carbonate and saturated brine (10 ml×2), and dried. Removal of the solvent gave crude spiro mono(1,3-dioxane) (**3** or **5**), which was isolated by preparative GLPC. The yields of hydrolyzed products are given in Table 6.

*Authentic Sample of **3a**.* A solution of 2,4-dioxaspiro-[5.5]undecan-7-one(**7**) (1.07 g, 10 mmol) in ethylene glycol (20 ml) was treated with bromine(1.60 g, 20 mg atom) according to the method of Garbisch Jr.[8] The work-up gave crude crystals of 8-bromo-2,4-dioxaspiro[5.5]undecan-7-one ethylene acetal(**8**), which were recrystallized from benzene-petroleum ether to give white crystals of **8**(2.87 g, 98%); mp 110.5—111.5 °C. PMR[C_6H_6–CCl_4(4 : 1 v/v)]: δ 1.1—2.7(br m, 6H), 3.2—4.2(m, 9H), 4.64 (AB-q, J=5.8 Hz, 2H). IR(Nujol): 2764(w), 1153(s), 1027(s), 748(w), 680(m) cm^{-1}. Found: C, 45.41; H, 5.84%; mol wt: 295. Calcd for $C_{11}H_{17}O_4Br$: C, 45.06; H, 5.85%; mol wt: 293.3. Ethylene acetal (**8**) (2.93 g, 10 mmol) was stirred with sodium methoxide(1.62 g, 30 mmol) in dimethyl sulfoxide(30 ml)

Glucosidation of Tetra-*O*-benzyl-α-D-glucose with Chlorosilane and Silver Sulfonate

Shinkiti KOTO,* Naohiko MORISHIMA, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received February 7, 1978)

Glucosidation of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose with methanol or cyclohexanol in the presence of chlorosilane and silver sulfonate is described. As by-products, octa-*O*-benzyl-α,α- and -α,β-trehaloses are also formed. Possible reaction pathways are discussed.

The development of methods for the synthesis of glycosides has always been very important in carbohydrate chemistry.[1] The Fischer method[1] appears to have the methodological advantage that it can be performed by a direct dehydration between glycose and alcohol in the presence of an acid catalyst. Modified methods[2-4] using acid with a dehydrating agent have been developed for the glycosidation of appropriately protected precursors having a reducing hydroxyl group. Such methods suggested a novel glucosidation of a stable precursor, 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose (**1**), with alcohol by using strongly dehydrating chlorosilanes,[5-7] which was investigated[8] as a part of our continuing studies.[9]

Results and Discussion

On treating **1** with methanol at 0 °C in dichloromethane containing dichlorodiphenylsilane (DCPS) and methanesulfonic acid as catalyst, methyl glucosides (**2a** and **2b**) of **1** were formed with a moderate efficiency. As the dehydration with DCPS and methanesulfonic acid was insufficient, the reaction was carried out with DCPS and silver methanesulfonate, from which more reactive bis(methylsulfonyloxy)diphenylsilane[10] was expected to be formed. The reaction proceeded well without addition of the acid.

A series of experiments were then done using stoichiometric amounts of **1** (αGOH), aglucon (methanol or cyclohexanol), chlorosilane, and silver sulfonate according to Eq. 1, where *n* denotes the number of chlorine atom(s) in the silanes and G represents a tetra-*O*-benzyl-D-glucopyranosyl moiety.

$$\alpha\mathrm{GOH} + \mathrm{ROH} + \frac{2}{n}\mathrm{R'_{4-n}SiCl_n} + 2\mathrm{R''SO_3Ag} \longrightarrow \mathrm{GOR} + \frac{2}{nx}\text{-}\left[\mathrm{R'_{4-n}SiO_{n/2}}\right]_x\text{-} + 2\mathrm{R''SO_3H} + 2\mathrm{AgCl} \quad (1)$$

The results are shown in Table 1 and Fig. 1. Yields are based on the amounts of the products obtained on column chromatography, in reference to the amount of **1** charged. In every case, self-condensation products identified as octa-*O*-benzyl-α,α- and -α,β-trehaloses (**3a** and **3b**) and unchanged **1** were obtained on chromatography.

Treatment of **1** with DCPS and silver sulfonate without alcohol led to efficient self-condensations which can be described by Eq. 2, where GOG expresses the trehalose derivatives (**3a** and **3b**).

$$2\alpha\mathrm{GOH} + (\mathrm{C_6H_5})_2\mathrm{SiCl_2} + 2\mathrm{R''SO_3Ag} \longrightarrow \mathrm{GOG} + \frac{1}{x}\text{-}\left[(\mathrm{C_6H_5})_2\mathrm{SiO}\right]_x\text{-} + 2\mathrm{R''SO_3H} + 2\mathrm{AgCl} \quad (2)$$

Results are shown in Table 2.

As shown in Fig. 1, DCPS was almost exhausted within 1 h and the amount of dimethoxydiphenylsilane (DMPS)[11] hardly exceeded 6%. Siloxanes[12] such as **4** and **5**[8,13] were detected by TLC throughout the reaction.

A filtrate of the reaction mixture of DCPS and silver methanesulfonate was able to condense **1** with methanol to give **2a** and **2b** as well as by-products **4** and **5**. Treatment of **4** with methanesulfonic acid in dichloromethane gave **2a** and **2b** in 78% yield, and **5** treated similarly gave **3a** and **3b** in 74% yield. DMPS with methanesulfonic acid in dichloromethane also transformed **1** into **2a** and **2b** in 63% yield. Consequently, the scheme of glucosidation of **1** with methanol in the presence of DCPS and silver methanesulfonate can be postulated as in Fig. 2, the bis(methylsulfonyloxy)-diphenylsilane formed reacts with methanol and **1** to

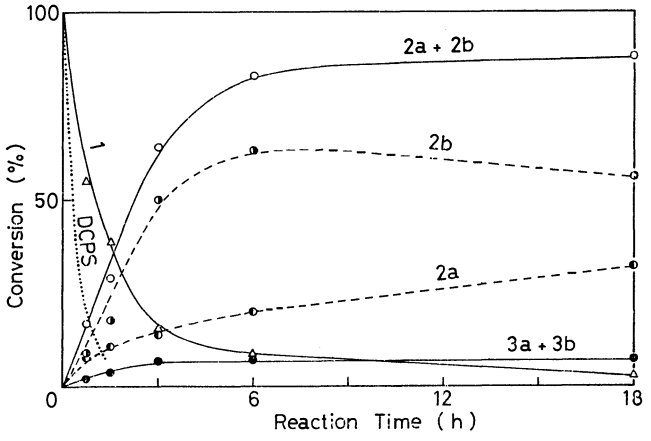

Fig. 1. Time-dependence of glucosidation of **1** with methanol in the presence of DCPS and silver methanesulfonate at 0 °C, plotted from the data of runs 1—5 in Table 1 except the GC data for DCPS (·····).

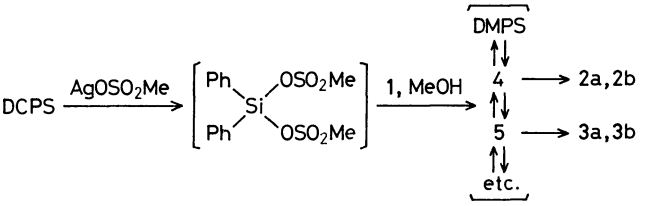

Fig. 2. A scheme of glucosidation of **1** with methanol in the presence of DCPS and silver methanesulfonate.

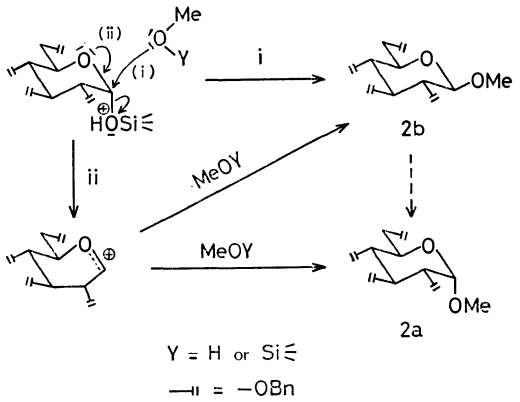

Fig. 3. Pathways of glucosidation of **1** with methanol in the presence of chlorosilane and silver sulfonate.

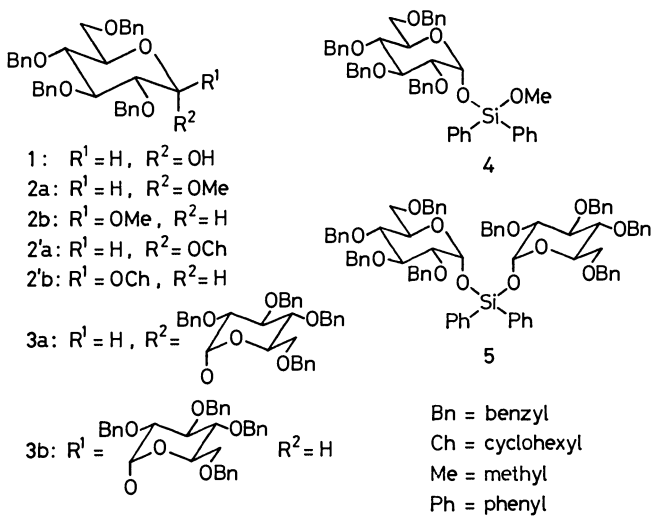
generate a mixture of methanesulfonic acid and siloxanes, such as DMPS, **4**, and **5**, the latters of which eventually produce the glucosides. Dimeric 1,3-dichloro-1,1,3,3-tetraphenyldisiloxane was also effective for the glucosidation of this kind. This suggests that a part of the glucosidation is likely to proceed by way of oligosiloxanes structurally related to **4** and **5**, which were actually detected in the reaction mixture.

The role of the liberated acid is essential for the glucosidation, since no glucosides, but only siloxanes **4** and **5**, formed when a base such as pyridine was first added to the reaction mixture.

An inefficient condensation of **1** and methanol with methanesulfonic acid alone proceeded to give **2a** and **2b** in 12 and 13% yields, respectively, indicating that the condensation of **1** and methanol with DCPS and silver methanesulfonate goes partly at least through a pathway i leading directly to **2b**, as shown in Fig. 3. Tables 1 and 2 show that ratios of **2a** to **2b** are mostly smaller than those of **3a** to **3b**, reflecting the idea that the less bulky methanol has more chances to take pathway i than the bulky **1** does.[14] The decrease of the amount of **2b** which accompanied the increase of that of **2a** occurred during a longer reaction period, as seen in Fig. 1, obviously indicating that a part of **2b** is isomerized into **2a** by the methanesulfonic acid generated. Actually, about 10% of **2b** was anomerized with two equivalents of methanesulfonic acid in dichloromethane at 0 °C within 3 h. No appreciable amount of the β,β-isomer[4] formed in the self-condensation reaction of **1**, suggesting that the α-configuration of **1** was mostly retained during the condensation reaction.

The results thus summarized in Table 1 allow the following remarks. Of the dichlorosilanes so far examined, DCPS was best for the glucosidation. The trends in the efficiency of the reaction appear to follow the order of stability of the siloxane[15] to be formed.

The efficiency of the reaction was also affected by the number, *n*. The order of the efficiency, 3—4> 2≫1, roughly correlates with the relative ease of the hydrolytic formation of polysiloxanes.[16] The high efficiencies favoring **2b** in the cases where $n \geqslant 2$ could partly be attributable to the direct pathway i in Fig. 3. The ratios of **2a** to **2b** increased progressively with the larger *n*; this seems to imply a generation of the glucosyl cation as indicated by pathway ii. The remarkably low yield of the glucosides with a fair increase of the anomer ratio in Run 8 may be due to

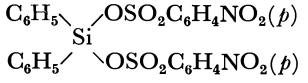


a steric effect caused by three phenyl groups on the silicon atom retarding the formation of the intermediary glucosylsiloxane which would afford the glucosides.

Silver arenesulfonates were also of use. The stronger liberated acid gave the greater efficiency. This was also observed in the self-condensation of **1**, as seen in Table 2. When silver trifluoromethanesulfonate was used, the self-condensation reaction had practically finished after 20 min at −20 °C.

As might be expected, the formation of self-condensation products became significant in the glucosidation of **1** with less reactive cyclohexanol, as shown in Table 1. Treatment with silver *p*-nitrobenzenesulfonate and DCPS yielded mostly **2'a**, agreeing with the fact that **2'b** is less resistant than **2b** to anomerization by acid.[17]

Finally, it should be mentioned that crystalline bis(*p*-nitrophenylsulfonyloxy)diphenylsilane (**6**) was successfully used as a reagent for glucosidation of **1** in a direct fashion :[18] a mixture of **1**, methanol, and **6** in dichloromethane furnished the glucosides, **2a** and **2b**, in 71% yield, favoring the latter.



6

Experimental

Instruments used are the same as those previously described,[9] except for a DIP-180 (Japan Spectr.) for optical rotation.

Each aliquot of the reaction mixture was diluted with benzene, and powdered $NaHCO_3$ was added before application to TLC (silica gel No. 7731 (Merck)). Two kinds of solvent systems, consisting of benzene and butanone (solvent A) and of hexane and ethyl acetate (solvent B), were used for column chromatography (silica gel (Kanto Kagaku)), and each fraction was examined by TLC. GLC was carried out by a F6-D (Hitachi Perkin-Elmer): 10% Silicone SE-30 on Chromosorb W AW HMDS (80—100 mesh), 3 mm × 1 m (U-tube), 165 °C, 30 ml/min N_2.

Predistilled solvents and alcohols were stored over molecular sieves (Linde 3A). Silanes were distilled before use. Compound **1**,[19] whose C-13 NMR in $CDCl_3$ showed a single peak at 91.2 ppm, and silver sulfonate prepared from silver carbonate (Wako) and an appropriate sulfonic acid (Tokyo Kasei) were kept *in vacuo* over P_2O_5. Experiments were carried out at 0 °C, unless otherwise stated.

A General Procedure for the Preparation of 2(2')a and 2(2')b (Eq. 1). To a mixture of **1** (0.33 mmol) with alcohol (0.33 mmol) and silver sulfonate (0.67 mmol) in dichloromethane (0.9 ml), chlorosilane (0.67/*n* mmol, stated by Eq. 1) was added with stirring at 0 °C. The mixture was then diluted with benzene and an excess of $NaHCO_3$ was added with stirring. The filtrate was evaporated and chrmatographed over silica gel. Yields were based on the weight of fractions after removing the solvent and were reproducible within 5%. Reaction conditions and results are summarized in Table 1.

Methyl 2,3,4,6-Tetra-O-benzyl-α- and -β-D-glucopyranosides (2a and 2b). A mixture of **1** (180 mg), methanol (14 μl), silver methanesulfonate (136 mg), and DCPS (69 μl) in dichloromethane (0.9 ml) was stirred for 3 h. The processed mixture of products was chromatographed. After elution of **4** and **5** (R_f=0.75 and 0.67, solvent A (40 : 1), respectively) with solvent A (80 : 1), **2b**, **2a**, and then **3a** (R_f=0.55, 0.45, and 0.40, solvent A (40 : 1)) were eluted with solvent A (40 : 1), followed by the elutions of **3b** (R_f=0.30, solvent A (40 : 1)) with solvent A (20 : 1) and of **1** with solvent A (10 : 1). On recrystallization from hexane, **2b** was obtained as colorless needles : 92 mg (50%), mp 74—75 °C, $[\alpha]_D^{20}$ +14° (*c* 1.0, dioxane) [lit,[20] mp 68—69 °C, $[\alpha]_D^{20}$ +11° (*c* 5.3, dioxane)]. Found: C, 75.20; H, 6.92%. Calcd for $C_{35}H_{38}O_6$: C, 75.79; H, 6.90%. Syrupy **2a** (26 mg, 14%) had a NMR spectrum ($CDCl_3$)[21] identical with that of **2a**[20] prepared from methyl α-D-glucopyranoside. Syrupy **3a** (6 mg, 3%) had an R_f value identical with that of **3a** prepared from α,α-trehalose. On recrystallization from hexane, **3b** was obtained as colorless needles : 9 mg (5%), mp 100—101 °C, with an IR spectrum (KBr) identical with that of **3b** prepared as noted below. Crystalline **1** (27 mg, 15%) was recovered.

Glucosidation by the Filtrate of the Reaction Mixture of DCPS and Silver Methanesulfonate. A mixture of silver methanesulfonate (149 mg, 2.2 eq.) and DCPS (76 μl, 1.1 eq.) in dichloromethane (1.8 ml) was stirred for 2 h. Then the resulting mixture was filtered onto **1** (180 mg) kept in a cooling bath. Methanol (14 μl, 1 eq.) was immediately added and the resulting mixture was stirred for 3 h to give **2a** (28 mg, 15%) and **2b** (23 mg, 17%). Fractions containing **4** and **5** were eluted prior to the appearance of **2a** and **2b** on the chromatography.

Evaporation of the solvent from the above-mentioned filtrate (NMR(CH_2Cl_2)δ=3.05 (s, CH_3SO_3Si)[22]) gave a clear syrup, which rapidly turned into a white paste in air.

Glucosidation with DCPS and Methanesulfonic Acid. Treatment of a mixture of **1** (180 mg), methanol (14 μl, 1 eq.), and DCPS (69 μl, 1 eq.) in dichloromethane (0.9 ml) with methanesulfonic acid (1.0—2.0 eq.) for 3 h gave **2a** and **2b**. The following data were obtained : [the acid used, **2a**, **2b**] 22 μl (1.0 eq.), 13 mg (7%), 24 mg (13%); 33 μl (1.5 eq.), 22 mg (12%), 37 mg (20%); and 44 μl (2.0 eq.), 32 mg (17%), 46 mg (25%).

Glucosidation with DMPS and Methanesulfonaic Acid. A mixture of **1** (180 mg) and DMPS (38 μl, 1 eq.) in dichloromethane (0.9 ml) was treated with methanesulfonic acid (44 μl, 2 eq.) to afford **2a** (44 mg, 24%) and **2b** (72 mg, 39%), after 3 h.

Glucosidation with Methanesulfonic Acid. A solution of **1** (180 mg) in dichloromethane (0.9 ml) containing methanol (14 μl, 1 eq.) was treated with methanesulfonic acid (44 μl, 2 eq.) for 3 h to give **2a** (22 mg, 12%) and **2b** (24 mg, 13%).

*Glucosidation with Bis(p-nitrophenylsulfonyloxy)diphenylsilane (**6**).* A mixture of silver *p*-nitrobenzenesulfonate (51.5 mg) and DCPS (18 μl) in acetone (0.5 ml) was stirred at 27 °C for 1 h. Filtration and evaporation gave **6** : hygroscopic prisms, mp 98—101 °C, IR (KBr) 1435 (C_6H_5Si),[23] 1520, 1365 cm^{-1} (NO_2). Found: N, 4.44%. Calcd for $C_{24}H_{28}N_2O_{10}S_2Si$: N, 4.77%.

A mixture of **1** (90 mg) and **6** (98 mg) in dichloromethane (0.9 ml) and methanol (7 μl) was stirred. *p*-Nitrobenzenesulfonic acid soon deposited. After 3 h, the reaction mixture was diluted with benzene, filtered, and chromatographed to give **2a** (11.1 mg, 14%), **2b** (54.2 mg, 57%), **3a**+**3b** (14.3 mg, 16%), and **1** (8.5 mg, 9%).

Glucosidation with 1,3-Dichloro-1,1,3,3-tetraphenyldisiloxane[24] and Silver p-Nitrobenzenesulfonate. A mixture of **1** (90 mg), the siloxane (75 mg), and silver *p*-nitrobenzenesulfonate (103 mg) in dichloromethane (0.45 ml) and methanol (7 μl) was stirred for 3 h to give **2a** (17 mg, 18%), **2b** (35 mg, 38%), **3a**+**3b** (18 mg, 20%), and **1** (4 mg, 5%).

*Conversion of **4** into **2a** and **2b** with Methanesulfonic Acid.* A solution of **4** (47 mg) in dichloromethane (0.24 ml) was treated with methanesulfonic acid (8.2 μl, 2 eq.) for 3 h to give **2a** (8.3 mg, 24%) and **2b** (19 mg, 54%).

*Anomerization of **2b** with Methanesulfonic Acid.* A mixture of **2b** (46 mg) and methanesulfonic acid (11 μl, 2 eq.) in dichloromethane (0.23 ml) was stirred for 3 h to give **2a** (4.7 mg, 10%) and **2b** (36.5 mg, 79%).

*Cyclohexyl 2,3,4,6-Tetra-O-benzyl-α- and -β-D-glucopyranosides (**2'a** and **2'b**).* A mixture of **1** (180 mg), cyclohexanol (35 μl), silver methanesulfonate (136 mg), and DCPS (69 μl) in dichloromethane (0.9 ml) was stirred for 3 h. The processed mixture of products was chromatographed. After elution with the solvent A (80 : 1), a mixture of **2'a** and **2'b** appeared with solvent A (40 : 1), followed by **3a** and **3b** (49 mg, 28%) with solvent A (20 : 1), and unchanged **1** (18 mg, 10%) with solvent A (10 : 1). The mixture of **2'a** and **2'b** was separated by chromatography with solvent B (3 : 1) to afford **2'b** and then **2'a**. On recrystallization from diisopropyl ether, **2'b** was obtained as colorless needles : 77 mg (37%), mp 104—105 °C, $[\alpha]_D^{20}$ +8°(*c* 1.0, $CHCl_3$). Syrupy **2'a** (38 mg, 18%), $[\alpha]_D^{20}$ +43°(*c* 1.0, $CHCl_3$), showed a NMR spectrum identical with that of **2'a** prepared in the alternative fashion described below. Found: for **2'a**, C, 76.74; H, 7.25%. For **2'b**, C, 77.17; H, 7.64%. Calcd for $C_{40}H_{46}O_6$: C, 77.14; H, 7.45%.

*Alternative Synthesis of **2'a**.* A mixture of cyclohexyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside[25] (92 mg), KOH (260 mg), and benzyl chloride (3 ml) was heated at 110 °C for 5.5 h. Filtration and evaporation gave a yellow syrup which was chromatographed over silica gel. After one elution with solvent A (100 : 1), another with solvent A (40 : 1) furnished **2'a** (73 mg, 60%), $[\alpha]_D^{20}$ +41° (*c* 2.3, $CHCl_3$). Found: C, 76.14; H, 7.25%. Calcd for $C_{40}H_{46}O_6$: C, 77.14; H, 7.45%.

*Octa-O-benzyl-α,α- and -α,β-trehaloses (**3a** and **3b**).* To a stirred mixture of **1** (180 mg, 0.33 mmol) and silver methanesulfonate (64 mg, 0.03 mmol) in dichloromethane (0.9 ml), DCPS (35 μl, 0.17 mmol) was added; the resulting mixture was stirred for 6.5 h. The processed mixture of products was chromatographed. After one elution with solvent A (80 : 1), **3a** was eluted again with solvent A (40 : 1). Further elution with solvent A (20 : 1) gave **3b**. **3a** was colorless syrup, 41 mg, (23%), $[\alpha]_D^{20}$ +84° (*c* 1.0, $CHCl_3$), having a NMR spectrum identical with that of the sample prepared as given below. On recrystallization from hexane, **3b** was obtained as colorless needles : 80 mg (45%), mp 100—101 °C, $[\alpha]_D^{20}$ +52° (*c* 1.0, $CHCl_3$); its IR and NMR spectra were identical with those of the sample prepared as given below.

Hydrogenation of syrupy **3a** over Pd-black in a mixture of aq ethanol and dioxane containing acetic acid, followed by heating with acetic anhydride and sodium acetate, gave octa-*O*-acetyl-α,α-trehalose: mp 94—97 °C, $[\alpha]_D^{20}$ +163° (*c* 1.0, $CHCl_3$) [lit,[26] mp 98—100 °C, $[\alpha]_D^{23}$ +160° (*c* 1.0, $CHCl_3$)]. Found: C, 49.26; H, 5.57%. Calcd for $C_{20}H_{38}O_{19}$: C, 49.56; H, 5.60%. Similar treatment of **3b** gave octa-*O*-acetyl-α,β-trehalose: mp 138—140 °C, $[\alpha]_D^{20}$ +78° (*c* 1.0, $CHCl_3$) [lit,[26] mp 140—142 °C, $[\alpha]_D^{22}$ +84.5° (*c* 0.68, $CHCl_3$)]. Found: C, 49.54; H, 5.65%. Calcd for $C_{20}H_{38}O_{19}$: C, 49.56; H, 5.60%.

Reaction conditions and results of analogous self-condensations of **1** stated by Eq. 2 using other silver sulfonates are shown in Table 2.

*Conversion of **5** into **3a** and **3b** with Methanesulfonic Acid.* A solution of **5** (156 mg) in dichloromethane (0.78 ml) was treated with methanesulfonic acid (19 μl, 1 eq.) for 4 h to afford **3a** (20 mg, 22%) and **3b** (67 mg, 51%).

*Alternative Synthesis of **3a**.* Crystalline α,α-trehalose dihydrate (Wako, 96.3 mg) was dried *in vacuo* at 90 °C and then heated with benzyl chloride (0.9 ml), crushed KOH (0.71 g), and Drierite (0.7 g) in *N*,*N*-dimethylformamide (1 ml) at 60 °C for 5 h. After filtration and evaporation, chromatography over silica gel with solvent A (gradient, 80 : 1→40 : 1) afforded **3a** (151 mg, 56%), $[\alpha]_D^{20}$ +88° (*c* 1.3, $CHCl_3$). Found; C, 76.42; H, 6.61%. Calcd for $C_{68}H_{70}O_{11}$: C, 76.81; H, 6.64%.

*Alternative Synthesis of **3b**.* A mixture of acetobromoglucose (94 mg), **1** (108 mg), $Hg(CN)_2$ (50 mg), and $HgBr_2$ (72 mg) in nitromethane (1 ml) was stirred at room temperature for 70 h. The product (132 mg) was treated with sodium methoxide (10 ml, 0.02 M) and then benzylated with benzyl bromide (0.25 ml) in *N*,*N*-dimethylformamide (0.5 ml) in the presence of BaO (0.2 g) and $Ba(OH)_2 \cdot 8H_2O$ (0.1 g).[27] After removal of insoluble material by filtration and evaporation *in vacuo* at 98 °C, the residue obtained was chromatographed over silica gel with solvent A (gradient, 100 : 1→30 : 1) to give **3b** (69 mg, 32%). Recrystallization from hexane afforded **3b** : Colorless needles, mp 100—101 °C, $[\alpha]_D^{20}$ +53° (*c* 1.4, $CHCl_3$). Found: C, 76.93; H, 6.62%. Calcd for $C_{68}H_{70}O_{11}$: C, 76.81; H, 6.64%.

*Methoxydiphenyl(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyloxy)silane (**4**) and Bis(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyloxy)diphenylsilane (**5**).* A mixture of **1** (180 mg, 0.33 mol), pyridine (93 μl, 0.67 mmol), silver *p*-toluenesulfonate (186 mg, 0.67 mmol), and DCPS (69 μl, 0.33 mmol) in 1,2-dichloroethane (0.9 ml) was stirred at 0 °C for 1 h. Methanol (14 μl, 0.33 mmol) was then added to the mixture. After stirring for 3 h, the mixture was treated with an excess of sodium acetate, filtered, evaporated, and then chromatographed over silica gel. After one elution with benzene, another with solvent A (100 : 1) gave **4** as a syrup: 53 mg (24%), $[\alpha]_D^{20}$ +47° (*c* 0.9, $CHCl_3$), IR (film) 1422 cm^{-1} (C_6H_5Si),[23] NMR ($CDCl_3$) δ=3.61 (3H, s, OCH_3), 5.48 (1H, d, anomeric H, J=3.2 Hz), 7.1—7.5 (phenyl), and 7.6—7.8 (4H, m, H's β to Si in $=Si(C_6H_5)_2$.[28] Found: C, 74.86; H, 6.44%. Calcd for $C_{47}H_{48}O_7Si$: C, 74.97; H, 6.43%.

Elution with solvent A (80 : 1) gave **5** as a syrup: 74 mg (35%), $[\alpha]_D^{20}$ +64° (*c* 1.0, $CHCl_3$), IR(film) 1432 cm^{-1} (C_6H_5Si),[23] NMR($CDCl_3$) δ=5.54 (1H, d, anomeric H, J=3.0 Hz), 7.0—7.4 (phenyl), and 7.6—7.8 (2H, m, H's β to Si in $=Si(C_6H_5)_2$[28]). Found: C, 75.55; H, 6.34%. Calcd for $C_{80}H_{80}O_{12}Si$: C, 76.16; H, 6.39%.

Isolation of Hexaphenylcyclotrisiloxane. The mixture of

Run 3 was poured onto a column of silica gel, and eluted with benzene. On evaporation, crystals were obtained (28 mg, 43%), mp 188—189 °C, [lit,[29] 190 °C], whose IR(KBr)[30] was identical with that of a sample prepared by the known procedure.[29]

Examination of Volatile Components in the Reaction Mixture of Run 3. Aliquots of the supernatant were injected into the GLC-apparatus without quenching to give the data: ([reaction time, DMPS (3.8 min), DCPS(4.4 min)] 8 min, 3%, 74%; 15 min, 5%, 48%; 45 min, 6%, 20%, and 60 min, 4%, 10%.

Examination of the Fractions Containing Siloxanes.[31] The reaction mixture of Run 2 (**1**, 180 mg) quenched with excess benzene and powdered $NaHCO_3$ was poured onto a column of silica gel, which was eluted with solvent A (100 : 1) to give a syrup (94 mg). Rechromatography with solvent B (gradient, 100 : 1→10 : 1) afforded three fractions: A, B, and C. The fastest-moving fraction A (19 mg) was a mixture (*ca.* 1 : 2) of **4** (NMR(CCl_4) δ=3.57 (s, OCH_3)) and 1-methoxy-3-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyloxy)-1,1,3,3-tetraphenyldisiloxane (NMR(CCl_4) δ=3.45 (s, OCH_3), 5.40(d, anomeric H, J=4 Hz), overlapping to that of **4**). Fraction B (23 mg) had a NMR spectrum consistent with the structure of 1,5-bis(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-1,1,3,3,5,5-hexaphenyl trisiloxane (NMR(CCl_4) δ= 5.23 (d, anomeric H, J=4 Hz), 7.5—7.7 (6H, m, H's β to Si in $=Si(C_6H_5)_2$[28]). The slowest-moving fraction C (13 mg) was a mixture of (1 : 1) of **5** (NMR(CCl_4) δ=5.47 (d, anomeric H, J=4 Hz)) and 1,3-bis(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyloxy)-1,1,3,3-tetraphenyldisiloxane (NMR (CCl_4) δ=5.23 (d, anomeric H, J=2 Hz), 7.5—7.7 (m, H's β to Si in $=Si(C_6H_5)_2$[28]).

We thank the Toray Silicone Co. for the gifts of silanes.

Photolysis of Organic Azides. IV.[1] Formation of *o*-Xylylene Derivatives from 2,3-Diazidonaphthalenes. Direct Observation by Low-temperature and Flash Photolysis

Akira YABE

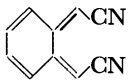
National Chemical Laboratory for Industry, Hiratsuka Branch, Nishiyawata 1-3-4, Hiratsuka, Kanagawa 254

(Received June 3, 1978)

The photolysis of 2,3-diazidonaphthalene (**3a**) in a rigid matrix at 77 K gave the product having absorption bands in the 400—500 nm region, which has been assigned as α,ω-dicyano-*o*-xylylene (**2a**) by use of another precursor 1,2-dicyano-1,2-dihydrobenzocyclobutene. **2a** has been also observed by the flash photolysis of **3a** in fluid solution at room temperature, and the lifetime in methanol at 20 °C was 62 s. The dominating factor in the lability of **2a** was the rigidity of the medium rather than the temperature. The reaction mechanism for the formation of **2a** from **3a** has been proposed as a monophotonic process involving the attack of the nitreno group on the azido group at the *ortho* position. Similarly, direct observations of α,ω-dimethoxy- and α,ω-diacetoxy-α,ω-dicyano-*o*-xylylenes have been given from 1,4-dimethoxy- and 1,4-diacetoxy-2,3-diazidonaphthalenes respectively.

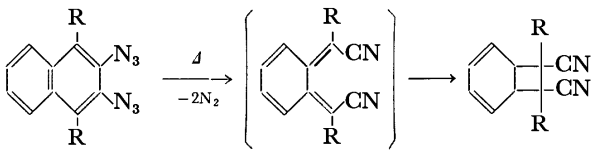
o-Xylylene (*o*-quinodimethane, **1**) and the wide variety of derivatives have evoked theoretical and experimental interest.[2–13] The reactive species have been proposed as intermediates in a number of re-

1



2

actions. In the thermal decomposition of 2,3-diazidonaphthalenes (**3**) to give 1,2-dicyano-1,2-dihydrobenzocyclobutenes (**4**), the α,ω-dicyano-*o*-xylylenes (**2**) have been considered intermediates. Flash pyrolysis in the vapor phase of **3a** has been reported to yield *trans*-1,2-dicyano-1,2-dihydrobenzocyclobutene in 55% yield,[14] and the thermolysis of **3b** in refluxing *o*-dichlorobenzene has given the *trans*- and *cis*-1,2-diacetoxy-1,2-dicyano-1,2-dihydrobenzocyclobutenes (23% and less than 3% yields, respectively),[15] possibly through the intermediate **2**.



3 **2** **4**

a: R=H
b: R=OCOCH$_3$
c: R=OCH$_3$

The α,ω-dicyano-*o*-xylylene (**2a**), which is a simple derivative of **1**, would itself be of interest since it has not been observed directly and there is the possibility that the dicyano substituents might stabilize the *o*-xylylene system sufficiently to allow isolation. In the course of the work on the low-temperature photochemistry of aromatic diazido compounds, the formation of **2a** was observed in the photolysis of **3a** in rigid matrices at low temperatures. The present paper reports the direct observation of **2a** by matrix isolation and flash photolysis, and the mechanism of the low-temperature photochemical reaction of **3a**, together with two derivatives 1,4-diacetoxy-2,3-diazidonaphthalene (**3b**) and 2,3-diazido-1,4-dimethoxynaphthalene (**3c**).

Results and Discussion

Low-temperature Photolysis. In the thermal reactions of **3** mentioned above, the evidence for dicyano-*o*-xylylene had been indirect, based on speculation from the final products. No study on the photolysis of 2,3-diazidonaphthalenes has been reported. The photolysis of **3a** in methanol or hexane at room temperature did not yield any trace of the expected 1,2-dicyano-1,2-dihydrobenzocyclobutenes, as distinct from the thermolysis. In view of the reactivity of *o*-xylylenes, matrix isolation and flash photolysis techniques appeared appropriate for the direct observation of **2**.

A rigid glassy solution of **3a** in EPA was irradiated at 77 K with a high-pressure mercury lamp with a Toshiba UV-D2 filter (transmission in the 300—400 nm region), and the low-temperature photochemical reaction was followed by absorption spectroscopy. With an increase in irradiation, new absorption bands in the 400—500 nm region were observed as shown in Fig. 1. The melting of the glassy solution containing the photoproduct having the new absorption bands to room temperature resulted in the disappearance of the absorption bands. The photoproduct showed strong fluorescence (λ_{max} 485 and 506 nm) similar to the parent *o*-xylylene and the spectral shape was independent of the excitation wavelength. The excitation spectrum followed the shape of the absorption band and was independent of the monitoring wavelength. Therefore, it has been suggested that all of the absorption curve, at least below 35000 cm^{-1}, belongs to one photoproduct.

On the prolonged irradiation of **3a**, the corresponding 1,2-dihydrobenzocyclobutene derivatives were not obtained, while Flynn and Michl[2] reported that upon strong irradiation the 373 nm band of the photoproduct **1** was replaced by the UV absorption spectrum of 1,2-dihydrobenzocyclobutene. After melting of the glassy solution containing the 400—500 nm bands, no azido group was detected among the reaction products while cyano groups were detected by IR spectroscopy.

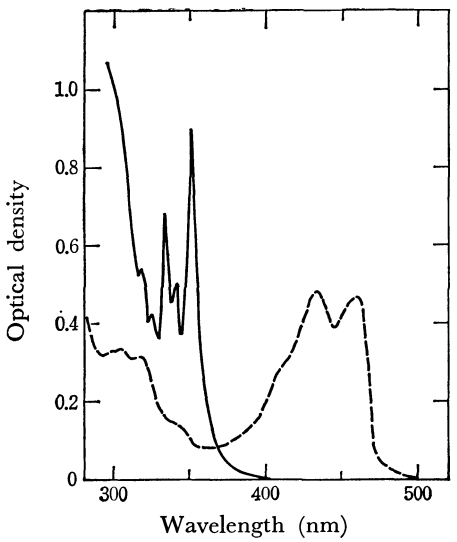


Fig. 1. Absorption spectrum of **3a** in EPA at 77 K before (——) and after (– – –) irradiation.

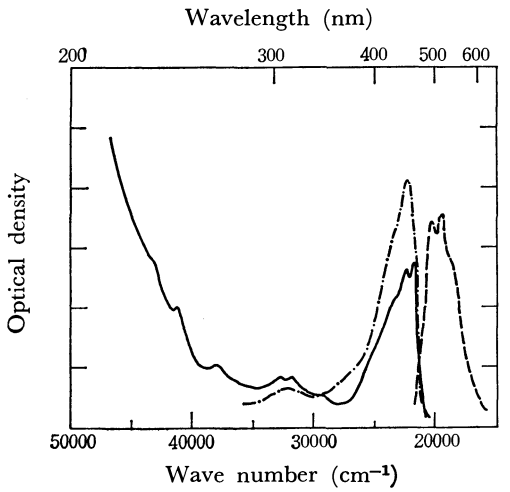

Fig. 2. Absorption (——), excitation (—·—), and emission (– – –) spectra of **2a** in EPA at 77 K. Excitation and emission spectra are not corrected for instrument response (arbitary scale).

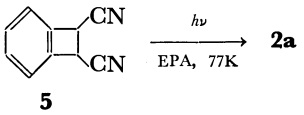
The identity of **2a** for the transient absorption was shown by the photolysis of another precursor. The irradiation of *trans*-1,2-dicyano-1,2-dihydrobenzocyclobutene (**5**) with a low-pressure mercury lamp (253.7 nm) in EPA at 77 K gave a spectrum similar to that obtained in the low-temperature photolysis of **3a**.[16] Moreover, the behavior on warming to room temperature and the fluorescence spectrum were consistent with that observed for **3a**. Thus, the transient absorption has been assigned to the expected **2a**.



5

The conversion of **5** to **2a** was considerable compared with that of 1,2-dihydrobenzocyclobutene to **1**.[17] Upon irradiation of a rigid solution of **5** (10^{-4} M) in EPA at 77 K (15 W low-pressure mercury lamp), the conversion to **2a** was virtually complete after 1 h.

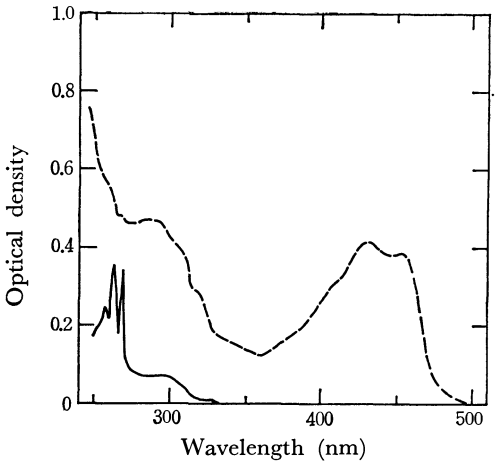


Fig. 3. Absorption spectra of **5** in EPA at 77 K before (——) and after (– – –) irradiation.

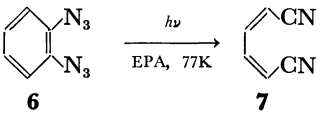
These results which have been attributed to the dicyano substituents are consistent with the fact that **2a** was not converted to **5** in the matrices upon continued irradiation, as mentioned previously.

The spectral shifts compared with **1** can be explained in terms of the substitution of the two cyano groups conjugated with the *o*-xylylene system. The absorption of **2a** is shifted by about 50 nm to a wavelength longer than that of the parent *o*-xylylene, which absorbs at 313—417 nm.[2] In the case of *cis,cis*-1,4-dicyano-1,3-butadiene (λ_{max} 258, 268 nm) and butadiene (λ_{max} 217 nm), a similar shift was observed.

The assignment for **2a** is further supported by the following results. Previously the formation of *cis,cis*-1,4-dicyano-1,3-butadiene (**7**) by the photolysis of 1,2-diazidobenzene (**6**) as well as the results of thermal reactions has been established,[18,19] the photolysis of



6 **7**

6 in a rigid matrix at 77 K being quantitative. In a low-temperature matrix **7** was not converted to cyclobutenes on prolonged irradiation, whereas the cyclization of **7** proceeded readily in fluid solution at room temperature.

In the case of the two derivatives **3b** and **3c**, the appearance of photoproducts could also be observed by the absorption spectra in the 400—500 nm region. Furthermore, the photoproduct from **3c** exhibited strong fluorescence in the 500—600 nm region (λ_{max} 540 nm), such as **2a**. In the low-temperature photolysis of **3b** in a rigid matrix the photolysis differed from the others. After the expected **2b** was generated as a primary photoproduct, some secondary reactions proceeded at considerable rate as shown in Fig. 4. Among the secondary photoproducts the corresponding 1,2-dihydrobenzocyclobutene derivatives (**4b**) were not detected. Details of the secondary reactions will be reported in a separate paper.

Although the stereochemical constitutions of **2** have not been unambigously established, three stereoisomers **2**(*Z,Z*), **2**(*E,E*), and **2**(*Z,E*) of α,ω-dicyano-*o*-xylylenes

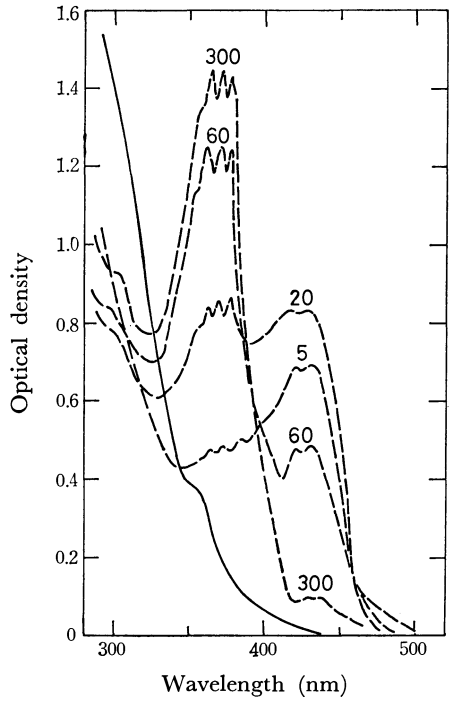


Fig. 4. Absorption spectra of **3b** in EPA at 77 K before (——) and after (– – –) irradiation. Numbers refer to irradiation time in second.

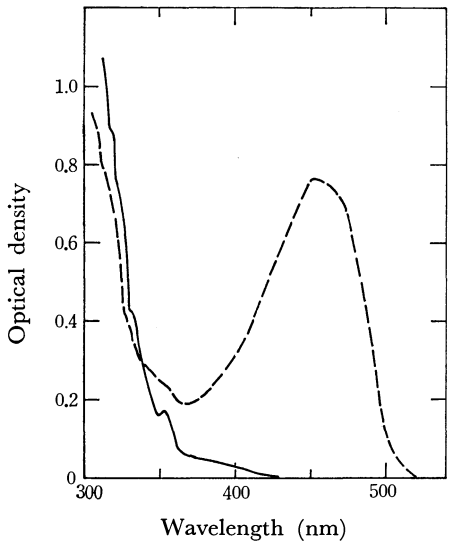

Fig. 5. Absorption spectra of **3c** in 3MP–IP (1 : 4) at 77 K before (——) and after (– – –) irradiation.

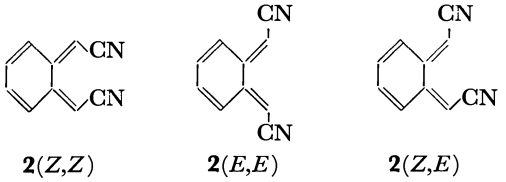
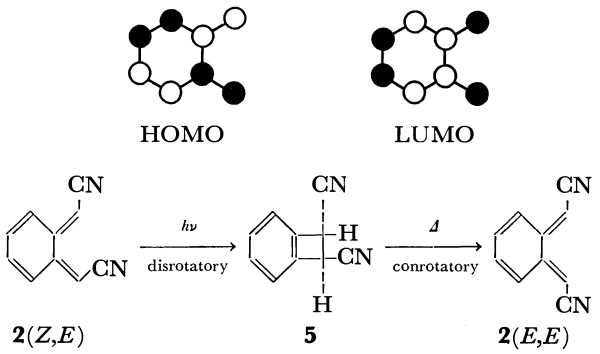
need consideration. One would predict that the



2(*Z*,*Z*) **2**(*E*,*E*) **2**(*Z*,*E*)

isomer generated in the photolysis of **3a** was exclusively **2**(*Z*,*Z*), from an analogy to the photolysis of **6** where the photoproduct **7** was assigned as the *cis*,*cis*-isomer by comparison with an authentic sample. The isomer of **2a** generated in the photolysis of **5** is presumed to be **2**(*Z*,*E*) from a consideration of the orbital symmetry. The whole spectra of **2a** generated from **3a** and **5** are consistent with each other



2(*Z*,*E*) **5** **2**(*E*,*E*)

as shown in Figs. 1 and 3. However, there is a slight difference observed in the longest absorption maxima, *i.e.*, the isomers generated from **3a** and **5** have absorption bands at 458 and 454 nm respectively (Table 1). This spectral shift could be explained in terms of the different configurations, as reported in the case of α,ω-diphenyl-*o*-xylylenes by Quinkert and coworkers.[9e]

Table 1. Absorption maxima of α,ω-dicyano-*o*-xylylenes by photolysis at 77 K

Reactant	Solvent	Absorption maxima (nm) (>400 nm)
3a	EPA (5:5:2)	432, 458
	3MP–IP (1:4)	427 (broad)
5	EPA (5:5:2)	432, 454
	3MP–IP (1:4)	427 (broad)
3b	EPA (5:5:2)	425, 448
	3MP–IP (1:4)	425
3c	EPA (5:5:2)	452
	3MP–IP (1:4)	450

Temperature and Rigidity Dependence of the Stability of **2**. The dicyano-*o*-xylylenes formed in rigid matrices at 77 K are indefinitely stable under these conditions but as yet have been isolated at room temperature. In order to study the stability and the conditions for the isolation of **2a**, the photolyses of **3** were conducted in media of different viscosities at various temperatures. In the photolysis at 77 K the matrices dependence was not observed in such glassy solvents as ether–isopentane–ethanol (EPA, 5 : 5 : 2), isopentane–3-methylpentane (IP–3MP, 4 : 1, 3 : 1, 1 : 1, 1 : 3, 1 : 4), 3-methylpentane (3MP), or methylcyclohexane–isopentane (MCH–IP, 1 : 3) matrix, which showed a viscosity ranging from 10^2 to 10^{10} Pa s.[20] Although the shape of the absorption bands in the 400—500 nm region was slightly different, the rates of formation of **2a** were virtually similar.

Figure 6 shows the absorption spectra of **3a** irradiated in 3MP–IP (1 : 4) (8 min, 500 W high-pressure mercury lamp, Toshiba UV-D2 filter, several temperatures). At 100 K, although the spectral shape was considerably different from that generated at 77 K, the concentration of **2a** was deduced to be 60—70% compared with that generated at 77 K. At 170 K, **2a** was no longer detect-

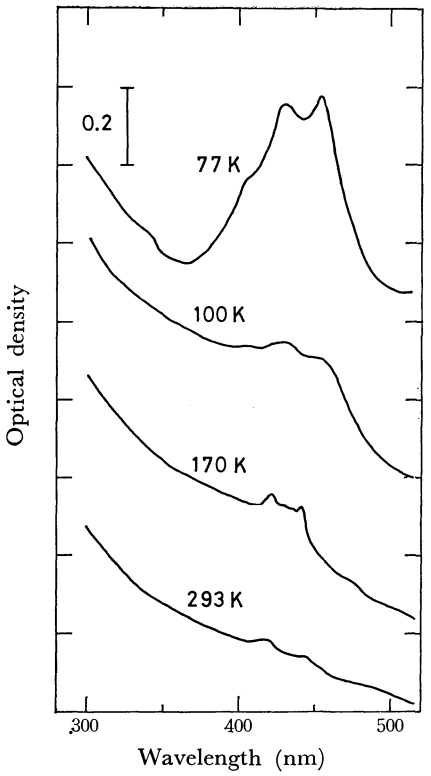


Fig. 6. Absorption spectra of the photoproducts of **3a** in 3MP–IP (1 : 4) by irradiation at several temperatures.

able by fluorescence spectroscopy and therefore the small peaks of the absorption spectra at 170 and 293 K in the 400—500 nm region are not ascribable to **2a**.

The photolysis of **3a** in a glycerol matrix at 180 K (viscosity; 10^{12} Pa s[20]) gave **2a** quantitatively and it was indefinitely stable in this medium. Figure 7 shows the libility of **2a** plotted against the rise in temperature. The change in the absorbance of **2a**, formed by the photolysis in rigid matrices (3MP and MCH–IP) at 77 K, was monitored at 432 nm with an increase in temperature allowing the matrices to grow warmer. The difference in lability of **2a** on 3MP and MCH–IP (1 : 3) matrices may be explained in terms of the rigidity of the medium, since the former had a higher viscosity than the latter (3MP : 9.4×10^{10} Pa s at 77 K, 3.0×10^{9} Pa s at 87 K; MCH–IP : 1×10^{2} Pa s at 89.5 K).[20] The appreciable decrease in absorbance began at 100 K in MCH–IP and at 120 K in 3MP, and the viscosities at these temperatures were estimated to be about 1 Pa s in both media from the literature.[21] Thus, it has been concluded that the rigidity of the medium is a dominating factor for the isolation of **2a**.

Flash Photolysis. Flash photolysis showed the presence of **2** in fluid solution at room temperature. The absorption spectra of **3a** (4×10^{-5} M) in methanol after flash photolysis at 293 K are shown in Fig. 8. These spectra are consistent with those obtained by low-temperature photolysis although the fine structures have disappeared. The lifetimes of **2a** and **2c** in methanol at 293 K were 62 s (monitored at 432 nm) and 33 s (monitored at 455 nm) respectively. The final photoproducts by room-temperature photolysis

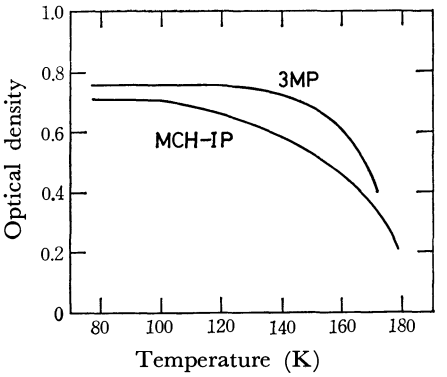

Fig. 7. Change in the absorbance at 432 nm of **2a** with temperature. Temperature-rise time : *ca.* 5 min (77—110 K) and *ca.* 4 min (110—180 K).

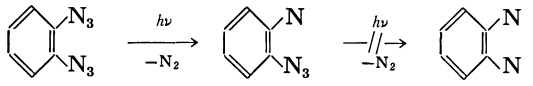
were not 1,2-dicyano-1,2-dihydrobenzocyclobutenes as reported above, and the decay of **2a** did not exhibit first-order kinetics. A detailed description of the kinetic study of **2** will be presented in a separate paper together with the reactivity of **2**. The decay of **2b** after the flash photolysis of **3b** was complicated, and the monitoring of the transient (**2b**) was difficult since the absorption bands of the secondary photoproducts interfered with those of **2b**.

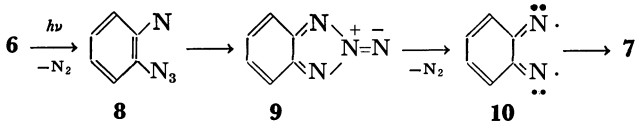
Reaction Mechanism. Although the photochemistry of azido compounds has been the subject of considerable interest, little is known about the photochemical reactions of vicinal diazido compounds. In the photolysis of **3** which results in the formation of **2**, it is of interest to examine whether the two neighboring azido groups participate with each other, whether the two azido groups are decomposed by a single quantum or the photolysis proceeds in two separate steps, and

whether the mononitrene and/or the dinitrene are included as intermediates. The low-temperature reaction mechanism of **3** has been investigated by a comparison with the preliminary results of 1,2-diazidobenzene.[18]

The photolysis of **6** in a rigid matrix at 77 K yielded 1,4-dicyano-1,3-butadiene (**7**) in one step, *i.e.* no intermediate was observed in the process from **6** to **7** by the absorption spectra. The spectral change by irradiation at low temperature was quite similar to that in the fluid solution at room temperature. Moreover, the dependence of the formation rate of **7** on the incident-light intensity showed a monophotonic process. These results exclude the following reaction mechanism which is a biphotonic process involving the stepwise loss of nitrogen. This is distinct from the mechanism which is a biphotonic process involving the mononitrene and the dinitrene as in the case of 1,4-diazidobenzene.[22,23]



The possibility that the two azido groups were simultaneously decomposed by a single photon was excluded by comparison with the results of 1,4-diazidobenzene[22,23] and 2,2′-diazidobiphenyls.[24] Only one of the two azido groups was decomposed by a single photon. It is well known that nitreno groups located *ortho* to groups with α,β-unsaturation undergo cyclization to give five-membered hetero cyclic rings, as observed in the decompositions of 2-azidonitrobenzene[25] and *o,o′*-diazidoazobenzene.[26,27] Thus, the intermediate such as **9** appears to be the result of nitreno groups on azido groups. The intermediate **9** would be readily converted to **7** *via* **10** at room



8 **9** **10**

temperature or 77 K by the consecutive homolytic cleavage of the nitrogen–nitrogen bonds and the carbon–carbon bond in a nonphotonic process, since the elimination of nitrogen from **9** is exothermic.[28]

An attempt has been made to establish the spin states of the intermediates. In the room-temperature photolysis of methanol solutions of **6** (2×10^{-4} M) involving 1,3-pentadiene (2×10^{-4}—10^{-3} M) or oxygen saturated by bubbling as a triplet quencher, the rate of formation of **7** was not affected. Hence, it may be considered that the azidonitrene **8** is produced in the singlet state from the excited singlet **6**, as reported in the direct photolysis of phenyl azide.[29,30] However, it is still uncertain that the participation of triplet states is excluded, since each process in the formation of **7** from **6** might be much faster than the energy transfer, and since the photochemical reaction from **6** to **7** occurs by triplet sensitization. Moreover, it is possible that the actual precursor of **9** is the triplet **8**, although it may be transferred from the singlet **8** by intersystem crossing. The multiplicity of the diradical (**10**) which was produced by nitrogen elimination would

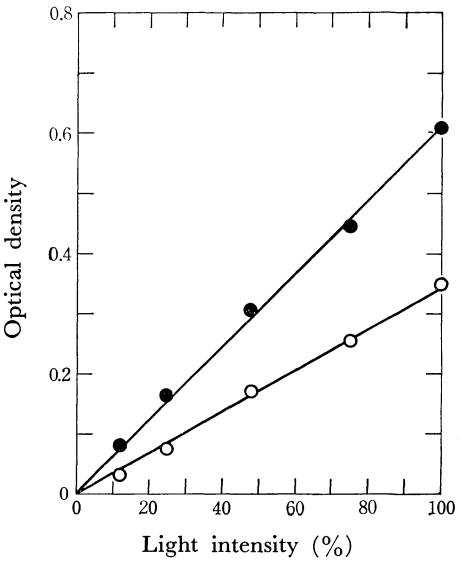


Fig. 9. Dependence of the formation rates of **2a** (○) and **2c** (●) on the light intensity by the photolyses of **3a** and **3c** in 3MP–IP (1 : 4), respectively. The yields of **2a** and **2c** correspond the optical densities at 432 and 452 nm respectively.

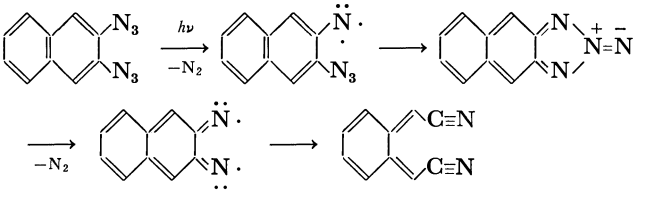
be the singlet state, since the energy required to break the carbon–carbon bond of **10** would be lost if the triplet nitrogen, which is 590 kJ/mol above the ground state, were produced by the decomposition of **9**. That is to say, since the elimination of nitrogen in the singlet ground state is an energetically favored process, **10** must be produced in the singlet state from the spin conservation rule.

The preceding mechanism for 1,2-diazidobenzene may be adapted to the photolysis of **3** in rigid matrices at low-temperature and in fluid solutions at room temperature. In the photolysis of **3** in a rigid matrix at 77 K, no intermediate was observed by absorption spectroscopy. The dependence of the formation rates of **2a** and **2c** on the light intensity is shown in Fig. 9 and as good linearity was obtained in the both cases, it was concluded that the formation of **2** from **3** was a monophotonic process similar to that for **7** from **6**. In an attempt to establish the spin state, the flash photolysis of the solutions of **3** involving 1,3-pentadiene or oxygen were studied. The absorbance belonging to the formed **2**, that is, the yield of **2**, was not affected. Although the spin states of the intermediates were not established by this quenching experiment alone, the pathway from **3** to **2** will be given below.



Experimental

IR and UV absorption spectra were recorded on JASCO IR-S and Shimadzu UV-300 spectrophotometers respectively.

Fluorescence and excitation spectra were recorded on a Hitachi MPF-1 spectrophotometer. In the above measurements, optical densities were uncorrected for volume contraction accompanied by the variation in temperature. NMR spectra were recorded on a Hitachi R-24A spectrometer at 60 MHz using TMS as an internal standard. Mass spectra were recorded on a Shimadzu GCMS-9000 spectrometer. The microanalyses were performed at the Institute of Physical and Chemical Research.

Materials. *2,3-Diazidonaphthalene (**3a**)*,[14] *1,4-diacetoxy-2,3-diazidonaphthalene (**3b**)*,[15] *1,2-diazidobenzene (**6**)*,[19b] and trans-*1,2-dicyano-1,2-dihydrobenzocyclobutene (**5**)*[14] were prepared according to the literature. The crude materials were purified by column chromatography on silica gel and recrystallized.

*2,3-Diazido-1,4-dimethoxynaphthalene (**3c**)* : **3c** was prepared from 2,3-diazido-1,4-naphthoquinone[15] through 2,3-diazido-1,4-naphthalenediol, which was not isolated. A solution of sodium dithionite (12 g; 0.069 mol) in water (20 ml) was added to a well-stirred suspension of the quinone (8 g; 0.033 mol) in ether (200 ml) and methanol (50 ml) at room temperature under an atmosphere of nitrogen. The mixture was vigorously stirred until the color stopped fading after about 30 min. The organic layer containing the 1,4-naphthalenediol was separated and the aqueous layer washed quickly several times with ether. The combined organic layers were then cooled in an ice bath and the cooled solution added dropwise to a cooled ether solution containing diazomethane (about 3 g) prepared from *p*-tolylsulfonylmethylnitrosamide (21.5 g). The reaction mixture was stirred for 1 h in an ice bath and for 1 h at ambient temperature. The solvent was evaporated under vacuum to afford purple crystallites, which were purified by column chromatography on silica gel. Elution with petroleum ether–ether (9 : 1) gave 2.4 g (26.9%) of **3c**: mp 54—55 °C; UV_{max} (CH_3OH) 300 sh, 260 nm (ε 49000); IR(KBr) 2130 cm^{-1} (N_3); NMR ($CDCl_3$) δ=8.2—7.3 (m, 4H, aromatic), 3.95 (s, 6H, OCH_3); MS, *m/e* 270 (M^+), 242 ($M-N_2$), 220, 214($M-2N_2$), 199. Found : C, 53.79; H, 3.75; N, 30.03%. Calcd for $C_{12}H_{10}N_6O_2$: C, 53.33; H, 3.73; N, 31.10%.

The solvents used in the spectroscopic study and in the low-temperature photolysis were dried over sodium wire or a molecular sieve and finally passed through a column of alumina.

Irradiation at Low-temperatures. The light sources were an Ushio USH-500D 500 W high-pressure mercury lamp equipped with a Nikon G-250 monochromator and a Toshiba GL-15 15 W low-pressure mercury lamp. The quartz cells of 10 mm path length were immersed in a quartz Dewar vessel equipped with optical windows containing liquid nitrogen and used for absorption and emission spectroscopy at 77 K. Instead of the quartz Dewar vessel, an Oxford Instrument DN-704 liquid nitrogen cryostat was used for spectroscopy at variable low-temperatures. It was equipped with an Oxford Instrument DTC-2 digital temperature controller, and temperatures in the range from 77 K to room temperature could be controlled and measured by a cryogenic linear temperature sensor and carbon resistor.

Flash Photolysis. All flash measurements were made using cylindrical, jacketed quartz cells of 10 cm path length and 25 ml capacity. The flash photolysis system consisted of an Applied Photophysics K-10 flash equipment, a M-300 monochromator, and a Textronix T-912 storage oscilloscope. The two 12 cm length flash lamps fitted in the K-10 equipment are rated at a maximum energy of 1000 J, corresponding to a maximum charged voltage of 22.4 kV. In these experiments, the lamps were discharged at 20 kV and had a half-life of 10 μs. The absorbance and the decay of the transients were followed quantitatively by monitoring the transmittance of the light with the oscilloscope through the monochromator from a tungsten iodine lamp (Osram A 1/125, 12 V/100 W). The absorption spectra of the transient **2a** generated by the flash photolysis of **3a** were recorded on the Shimadzu UV-300 spectrophotometer, after the cell was immediately transferred from the flash cavity to the sample bench of the spectrophotometer (Fig. 8).

Syntheses of *N*-Acyl Dipeptide Derivatives by Metalloproteinases†

Yoshikazu Isowa and Tetsuya Ichikawa*
Sagami Chemical Research Center, Sagamihara, Kanagawa 229
(Received May 10, 1978)

X–Dipeptides (X=Z, Z(OMe), or Z(3Me)) have been catalytically synthesized by several microbial metalloproteinases. Among the enzymes used, Thermolysin showed the most remarkable ability in the coupling reactions of the esters or the amides of phenylalanine, leucine, isoleucine, and valine (and methionine in the case of the amide) with various X–amino acids. This method has been applied to the syntheses of ZPhePheOMe and ZPheIleOMe on a practical scale. Ammonium sulfate and sodium chloride had a marked effect on the condensed products, increasing the yield.

Since Bergmann and Fraenkel-Conrat[1] first demonstrated the papain catalyzed amide-bond formation between an acylamino acid and an amino acid anilide, the enzymatic syntheses of peptides have received much attention. However, only a few papers have appeared in which the substrates had the proper protecting groups for the elongation of the peptide chains, for example Z, Z(OMe), BOC, the methyl or ethyl ester, the non-sustituted amide, *etc.*[2,3] There appears to be two reasons for this. Firstly, the most investigations have used papain (thiol proteinase) or α-chymotrypsin (serineproteinase), both of which catalyze the hydrolysis of carboxylic esters comprising the primary alcohol or the non-substituted amide. Consequently the peptides containing those groups are not easily obtainable in high yields except the peptides which show extremely low solubilities in buffer solution.[2] When those peptides are once formed, they are barely subjected to hydrolysis of the C-terminal protecting groups. Secondly, many *N*-acylamino acid derivatives (acyl= Z, Z(OMe), BOC, *etc.*) are almost insoluble in water and troublesome on operating the enzymatic reaction. Recently, it has been reported that the peptides whose N- and C-terminal groups were protected by such groups were readily obtained in certain cases by several enzymes.[4]

In the course of the current study to extend the enzymatic syntheses of peptides, it has been found that several microbial metalloproteinases catalyze the formation of X–dipeptide methyl esters or amides (X=Z, Z(OMe), or Z(3Me)). The C-terminal groups in these dipeptides are not hydrolyzed by metalloproteinases, so it is anticipated that the syntheses of these peptides would be smoother using metalloproteinases than by thiol- or serineproteinases.

For inhibiting the action of serineproteinase contained in the crude metalloproteinases, potato inhibitor was used as reported previously.[4c]

Materials and Methods

Thin layer chromatography was performed on precoated TLC plates Silica Gel F_{254} (Merck) using the following solvent systems : AcOEt–$CHCl_3$ (10 : 1), AcOEt, *s*-BuOH–3% aqueous ammonia (8 : 3) (see Ref. 4c for other analytical procedures). Protease activity was assayed by the method of Tsuru *et al.*[5]

Potato Inhibitor. See Ref. 4c.

Proteinases. See Ref. 4c for Prolisin A (*Bacillus subtilis var. amyloliquefacience*), Thermolysin (*Bacillus thermoproteoliticus*), Thermoase (*Bacillus thermoproteoliticus*), and Tacynase N (*Streptomyces caespitosus*). Dispase I (*Bacillus polymyxa*, Godo Shusei Co., Tokyo, Japan, 4.93×10^6 PU/g) had little esterase action and was used without further purification. The partially purified metalloproteinase of *Bacillus subtilis* was obtained by treating Prolisin A with DEAE-Sephadex A-50[6] and freeze-drying. The protease activity was 5.3×10^6 PU/g and the esterase action was almost completely inhibited by the potato inhibitor in one tenth the weight of enzyme. Commercial Thermoase was purified by dissolving it in 0.01 M $Ca(OAc)_2$ aqueous solution, removing the insoluble materials and precipitating from acetone. The protease activity was 1.0×10^7 PU/g and the esterase action was suppressed almost completely by the potato inhibitor in one tenth the weight of enzyme.

Reagents. Z– or Z(OMe)–amino acids, amino acid methyl ester hydrohalogenides were all prepared by the ordinary methods. Z(3Me)–His(Bzl)–OH was prepared by the method previously reported.[4b]

Enzymatic Syntheses of Peptides (General Procedures). An enzyme and potato inhibitor, if necessary, were dissolved in a buffer solution and the insoluble materials filtered off. In a mixture of this solution, two appropriate substrates and 4 M NaOH aqueous solution were incubated and the product collected on a suction filter, washed thoroughly in succession with 1 M aqueous ammonia, 1 M HCl, and water, and dried *in vacuo* over P_2O_5 at room temperature. The product was recrystallized, if necessary, from organic solvents and weighed.

Results

Enzymatic reactions between X–AA_1–OH (X=Z, Z(OMe), or Z(3Me); AA_1=Ala, Val, Leu, Ile, Phe, Glu(OBzl), Asp(OBzl), Gln, Asn, Lys(Z), His(Bzl), Met, Cys(Bzl), Tyr, Trp, and Pro) and H–AA_2–OMe·HCl or H–AA_2–NH_2·HX (X=Cl or Br; AA_2=Ala, Val, Leu, Ile, Phe, Met, Cys(Bzl), Tyr, Trp, and Ser) have been investigated, although all combinations of both components were not examined for each enzyme. In many cases the high purity of the product from the reaction mixture was assured by physical constants and elemental analysis without further purification (Table 1). If necessary, the product was recrystallized

from ethyl acetate and petroleum ether.††

Dipeptide Syntheses with Thermolysin. As shown in Table 2, the methyl esters of amino acids such as Phe, Val, Leu, and Ile condensed with various amino acids of the type X-AA_1-OH to give the desired products in good yields. Interestingly, the yields often increased, in some cases to a great extent, by the addition of 20% (wt/v) ammonium sulfate or sodium chloride (*vide infra*). In the cases of the methyl esters of tryptophan, tyrosine, and other amino acids the

†† The raw products were sufficiently pure in most cases, and if further purification was required, the simple removal of the materials insoluble in organic solvents was sufficient to give the pure products. However, the yields of the pure products were often considerably reduced by this procedure.

Table 2. Synthesis of X-AA_1-AA_2-OMe with thermolysin[a]

a) A mixture of substrates (1 mmol each), Thermolysin (10 mg), 4 M NaOH aqueous solution (0.25 ml), and 0.2 M Tris·HCl (pH 8, containg 5×10^{-2} M $Ca(OAc)_2$, 10 ml) was incubated at 38—40 °C for 16 h. b) Ammonium sulfate (0.8 g) was added and the buffer (4 ml) was used. c) Ammonium sulfate (2 g) was added. d) After recrystallization. e) The buffer (4 ml) was used.

condensed products were not produced even in the presence of ammonium sulfate or sodium chloride. Similarly the X–dipeptide amides were obtained in higher yields than those of the corresponding esters (Table 3). The amide of methionine, in contrast with the ester, also gave various dipeptides, except those of alanine and proline.

Effect of Ammonium Sulfate on the Yield of Peptides with Thermolysin. The effect of ammonium sulfate described above was examined in the following two cases. The reaction of Z–Phe–OH with either H–Leu–OMe·HCl or H–Val–OMe·HCl gave the expected products in 40 and 29% yields, respectively; in contrast, the yields of both reactions were increased by the addition of ammonium sulfate in 5—30% (wt/v), especially in the case of 20% (Fig. 1).

Dipeptide Syntheses with Metalloproteinases Other than Thermolysin. The peptides given by these proteinases in Table 4 were highly limited and other peptides were hardly obtained by each enzyme. These results demonstrate that Dispase I, Prolisin A, and Tacynase N are not such effective catalysts in the coupling reactions as Thermolysin. The amino acids appropriate for the amine components are all hydrophobic for the synthesis of peptides by using those proteinases.

Syntheses on a Practical Scale. The method was examined as to its suitability for practical peptide syntheses of the two peptides with two proteinases (Table 5). The Table shows that both peptides are easily obtained in good yields. Moreover, it was found that aqueous ammonium sulfate solution can be substituted for the buffer in the reaction with Thermoase and that the reaction can be conducted at room temperature (20 °C).

Discussion

In general, microbial metalloproteinases specifically catalyze the "hydrolysis" of the peptide bond with a hydrophobic amino acid residue at the amino side of the linkage.[7] However, the "hydrolysis" of the bond with tyrosine or tryptophan is catalyzed at rather a slow rate.[8] In the present study, all the amino acids of the amine components which readily formed the peptide bond with various X–amino acids were

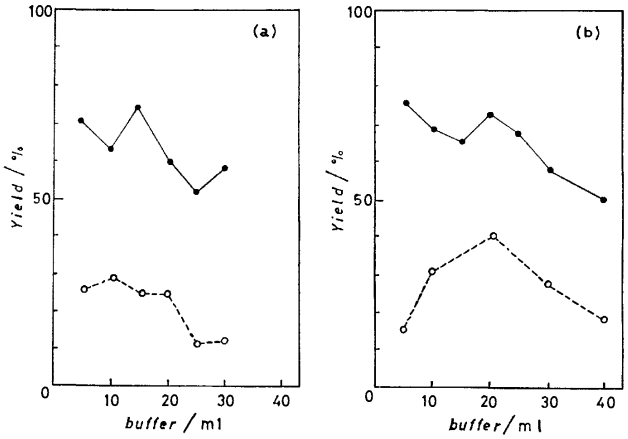

Fig. 1. The effect of ammonium sulfate on the yield of peptide synthesis with Thermolysin. a) ZPheOH+HValOMe·HCl; b) ZPheOH+HLeuOMe·HCl. A mixture of substrates (1 mmol each), Thermolysin (10 mg), 0.2 M Tris·HCl (pH 8, containing 5×10^{-2} M $Ca(OAc)_2$, 5—40 ml), ammonium sulfate (20% wt/v for the buffer), and 4 M NaOH aqueous solution (0.25 ml) was incubated at 40 °C for 16 h and treated under the general procedures. $(NH_4)_2SO_4$: ●—● present; ○--○ absent.

hydrophobic, while the derivatives of tyrosine or tryptophan were practically inert to the coupling reaction. Consequently, the most scissile bond is the most suitable point for the condensation. It is clearly seen in Table 2 that the isoleucine methyl ester in its amine component is the most suitable, and the susceptibility of the methyl esters of phenylalanine, valine, and leucine are successively decreasing in that order. For the carboxyl component, various amino acid derivatives except those of valine, isoleucine, proline, and tryptophan are applicable and there appears to be no difference in susceptibility towards the metalloproteinases used. Better results were obtained in the syntheses of the *N*-acyl dipeptide amides (Table 3) and the methionine amide was also found appropriate to this reaction. The different sensitivity of the enzymes towards the ester or the amide is attributed to the properties of the enzymes as endopeptidases.†††

Table 4. Synthesis of Z-AA_1-AA_2-OMe with several enzymes[a]

AA_1AA_2	Enzyme	Yield (%)	Mp (°C)
PheLeu	Dispase I	37.5	105—107
PhePhe	Dispase I	62	134—137

The dissimilarities in catalytic ability in the syntheses of dipeptides by Thermolysin and the other enzymes are interesting when compared to those in the hydrolysis of the peptide bond.[9] Morihara *et al.*[9b] reported that Z-Gly-Leu-NH_2 is hydrolyzed by Thermolysin and also by *B. sub.* metalloproteinase at approximately the same rate and that Z-Gly-Phe-NH_2 is hydrolyzed by Thermolysin 10 times faster than by *B. sub.* metalloproteinase. Feder and Shuck[9d] reported that the most pronounced difference between Thermolysin and *B. sub.* metalloproteinase at the dipeptide level was observed when phenylalanine is the amino acid donating the amino group to the cleaved bond. Accordingly, in the "hydrolysis" of the peptide bond, there is only

††† An endopeptidase catalyzes the hydrolysis of the peptide bond containing the C-terminal residues (whose carboxyl group is free or protected by the ester group) either very slowly or not at all.

Table 5. Synthesis in large scale[a]

Peptide (mmol)	Enzyme (mg)	Solvent (ml)	Additive (g)	Yield (%)	Mp (°C)
ZPhePheOMe (30)	Th[b] (600)	buffer[d] (600)	—	73	133—135

a) A mixture of substrates, enzyme, solvent, additive, and 4 M NaOH aqueous solution of equimolar quantity with the amine component was stirred in a three-necked flask at 20 °C for 16 h and treated under the general procedures. b) Partially purified Thermoase and the potato inhibitor (60 mg). c) Partially purified metalloproteinase of *B. sub.* and the potato inhibitor (70 mg). d) 0.2 M Tris·HCl (pH 8, containing 5×10^{-2} M $Ca(OAc)_2$). e) With continuous control of the pH at 7.2 by the addition of 4 M NaOH. f) Pure product was not obtained.

a slight difference in efficiency between the two enzymes. As shown *B. sub.* metalloproteinase (Prolisin) was far less capable of catalyzing the peptide "synthesis" than Thermolysin.

An examination of the variation of the Thermolysin activity caused by ammonium sulfate or sodium chloride, shows an increment in the peptidase activity,[10] in contrast to the remarkable decrease in protease activity.[10] This effect, coupled with the salting out effect of the salt, seems to play a major role in the increased yield of the product.

The authors wish to express their thanks to Mr. Masanari Satoh for the enzyme purification and to Miss Reiko Matsumoto and Miss Noriko Shutoh for technical assistance.

(Received June 19, 1978)

The photochemical *trans-cis* isomerization of methyl 3-(1- and 2-naphthyl)acrylate (**1Me** and **2Me**) and the intramolecular (2+2) cycloaddition of ethylene bis[3-(1- and 2-naphthyl)acrylates] (**1E** and **2E**) have been studied in cyclohexane and methanol. The quantum yield of the *trans-cis* isomerization of **2Me** and **2E** in methanol was larger than that in cyclohexane, while the yield of the cyclization of **2E** showed the reverse. The isomerization is thought to occur *via* the triplet state, while the cyclization is *via* the singlet excited state. The triplet yield of **2Me** in the polar solvent has been estimated to be larger than in nonpolar solvent. The cyclization of **1E** was much slower than that of **2E**, and the quantum yield of the reaction of **1Me** and **1E** did not appreciably depends on the polarity of the solvent.

The Photodimerization of cyclic α,β-unsaturated carbonyl compounds has been studied extensively, but the acyclic ones have not, due to the rapid *trans-cis* isomerization making quantitative analysis of the dimerization impossible.[1-4] The quantum yield of dimerization is usually very small compared with that of the isomerization, and most of the dimerization occurs from the equilibrium mixture of *trans* and *cis* isomers.[5,6] In the crystalline state or in the solid monolayer assemblies the *trans-cis* isomerization is greatly diminished and the dimerization proceeds more efficiently.[7,8] In solution, however for example, methyl cinnamate or ethyl cinnamylideneacetate does not dimerize but rapidly isomerizes.[9] In dimerization, the distance between the chromophores is an important factor. If two cinnamate groups are incorporated in the same molecule, namely, in the bichromophoric system, the cinnamate groups dimerize intramolecularly in solution.[10,11] Bichromophoric systems are recently attracting wide interest because they provide a method for controlling bimolecular reactions—model systems for polymer photochemistry such as DNA, and give information on chain dynamics.[12] Several bichromophoric systems bearing photodimerizable chromophores have been reported recently and most of them are cyclic compounds such as coumarin,[13] anthracene,[14] maleimides,[15] and thimine.[16]

In this study, the photoisomerization and photodimerization of 3-(1- and 2-naphthyl)acrylate have been studied in bichromophoric systems; ethylene bis[3-(1-naphthyl)acrylates] (**1E**) and ethylene bis[3-(2-naphthyl)acrylates] (**2E**) have been studied along with methyl 3-(1-naphthyl)acrylate (**1Me**) and methyl 3-(2-naphthyl)acrylate (**2Me**).

Results and Discussion

trans-cis *Isomerization.* In a previous paper, the solvent effect on the *trans-cis* isomerization and fluorescence of **2Me** was reported.[17] The quantum yield of the *trans-cis* isomerization, ϕ_{t-c} of **2Me** increased with increase in the solvent polarity, while the fluorescence quantum yield, ϕ_f decreased remarkably.

Table 1 shows the ϕ_{t-c} for **1Me** and **2Me** in cyclohexane and methanol. The ϕ_{t-c} of **1Me** in methanol is only slightly larger than that in cyclohexane and the dependency on solvent polarity for **1Me** is much smaller than that for **2Me**.

Table 2 shows the quantum yield of the fluorescence in cyclohexane and methanol where solvent dependency was observed for **2Me**, but not for **1Me**.

The solvent polarity effect on *trans-cis* isomerization has been demonstrated for stilbenes having electron-withdrawing and electron repelling groups.[18-22] For molecules having large dipole moments in the ground state, the quantum yield of the *trans* to *cis* isomerization was small in polar solvents due to stabilization of the excited trans isomer. Here the opposite tendency was observed— the quantum yield of the *trans* to *cis* isomerization of **2Me** was large in polar solvents and small in nonpolar solvents.

The isomerization was little affected by aerobic oxygen but enhanced by pure oxygen. The enhancement of the isomerization by oxygen has been observed

Table 1. The quantum yield of isomerization and cyclization

		In cyclohexane			In methanol			In methanol–*n*-PrBr
		Argon	Air	Oxygen	Argon	Air	Oxygen	Air
1E	ϕ_{cy}	0.0075	0.010		0.0085	0.013		0.001

cis-**2Me**	0.041		0.030		

more remarkably in the case of styrylnaphthalenes.[23,24] The explanation for this has been that $O_2(^3\Sigma_{-g})$ increased the population of the triplet state by quenching the excited singlet state which has been attributed to direct intermolecular exchange interaction or the inhomogeneous field of the O_2 triplet ground state. As shown in Table 2, oxygen and heavy atom solvents, *e.g.*, propyl bromide strongly quenched the fluorescence. The heavy atom solvent remarkably increased the ϕ_{t-c} and the intensity of the phosphorescence of **2Me** by quenching the fluorescence suggesting that the isomerization takes place from the triplet state. The corrected fluorescence spectra for **2Me** in cyclohexane and methanol are shown in Fig. 1.

The fluorescence spectrum of **2Me** in cyclohexane is a good mirror image of the absorption spectrum and therefore, the lowest singlet excited state is thought to lie near 355 nm (28169 cm^{-1}). This resembles the ^1L_b state of naphthalene in the weakness of the absorption and the long-lifetime of the fluorescence (107 ns in cyclohexane from the quenching of the fluorescence by aerobic oxygen). In methanol and in other polar solvents, a large Stokes' shift is observed and the maximum of the fluorescence shifts to 400 nm indicating that the dipole moment of the fluorescence state in polar solvents is larger than in cyclohexane. The separation between the singlet and triplet state may be small in polar solvent. The above solvent effects lead to the conclusion that the isomerization occurs from the triplet state, and that the triplet yield in polar solvents may be larger than in nonpolar solvents due to the small separation between the singlet and triplet states. The enhancement of ϕ_{t-c} by oxygen has been observed only in nonpolar solvents; in polar solvents, the triplet yield is sufficiently large before enhancement by oxygen.

Phosphorescence of **2Me** was too weak to be observed in EPA [ether–isopentane–ethanol (5 : 5 : 2) mixed solvent] at 77 K, but was observed in propyl bromide–ethanol (1 : 1 mixed solvent). The phosphorescence spectrum has three peaks at 544, 593, and around 650 nm as shown in Fig. 1, the first peak rising from 533 nm (53.5 kcal/mol).

For *cis*-**2Me** the fluorescence was very weak and the measurement was always interfered from by the strong fluorescence of the *trans*-**2Me** which was produced during the measurement. No phosphorescence was observed in the heavy atom solvent.

That the fluorescence yield of the *cis*-**2Me** is markedly smaller than the *trans* form (Table 2) implies that the singlet excited state of the *trans* and *cis* form may be different from each other, *i.e.* there may exist an energy barrier between the two excited singlet states.

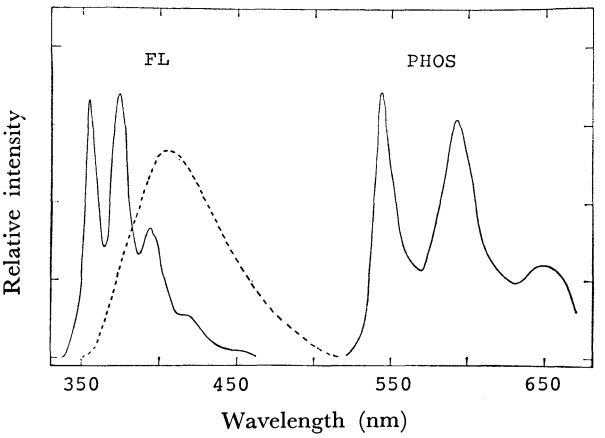

Fig. 1. Corrected fluorescence (—— in cyclohexane, ---- in methanol) and phosphorescence (in propyl bromide–ethanol 1:1 mixed solvent) spectra of **2Me**.

If the *trans* to *cis* isomerization of **2Me** occurs only from the triplet state, the triplet yield can be estimated using the following equation:

$$\frac{\phi_{isc}}{\phi^s_{isc}} = \frac{\phi_{t-c}}{\phi^s_{t-c}}, \quad (1)$$

where ϕ^s_{t-c} is the quantum yield of the *trans* to *cis* isomerization for sensitized reaction and ϕ^s_{isc} is the triplet yield of the sensitizer. (ϕ^s_{isc} is known for Michler's ketone in several solvents.[25]) The triplet energy of Michler's ketone is 72 kcal/mol in cyclohexane, 61 kcal/mol in ethanol.[26] Since the triplet energy of **2Me** has been estimated to be 53.6 kcal/mol from the phosphorescence spectrum, the energy transfer from Michler's ketone to **2Me** is considered to be a diffusion controlled process. The concentration of **2Me**, 5×10^{-4} mol/l is sufficiently large to completely accept the energy from Michler's ketone within the lifetime (20—40 μs). Therefore, under the experimental conditions, the energy transfer from Michler's ketone to **2Me** occurs with an efficiency of nearly unity. Thus the ϕ_{isc} of **2Me** has been estimated to be 0.41 in cyclohexane and 0.81 in ethanol by measuring ϕ_{t-c}/ϕ^s_{t-c}. The radiationless deactivation of the singlet excited state cannot be ignored, and consequently the sum of ϕ_f and ϕ_{isc} should be less than unity, but here the sum becomes 1.02 in cyclohexane, 1.06 in ethanol. This may be caused by an impurity or incomplete degassing which would decrease ϕ^s_{isc}, and thus ϕ_{isc} of **2Me** might have been overestimated. The value obtained however are thought to be qualitatively reliable.

The quantum yield of the *cis* to *trans* isomerization, ϕ_{c-t} of *cis*-**2Me** is small as shown in Table 1.

The fluorescence yield of **1Me** is far smaller than that of **2Me** and is not appreciably diminished by aerobic oxygen as found for **2Me**, suggesting that the lifetime of the excited state of **1Me** is much shorter than that of **2Me** and that the triplet yield does not depend on solvent polarity.

The difference in oxygen effect between **1Me** and **2Me** is analogous to the results between 1- and 2-styrylnaphthalene. The ϕ_f of 2-styrylnaphthalene

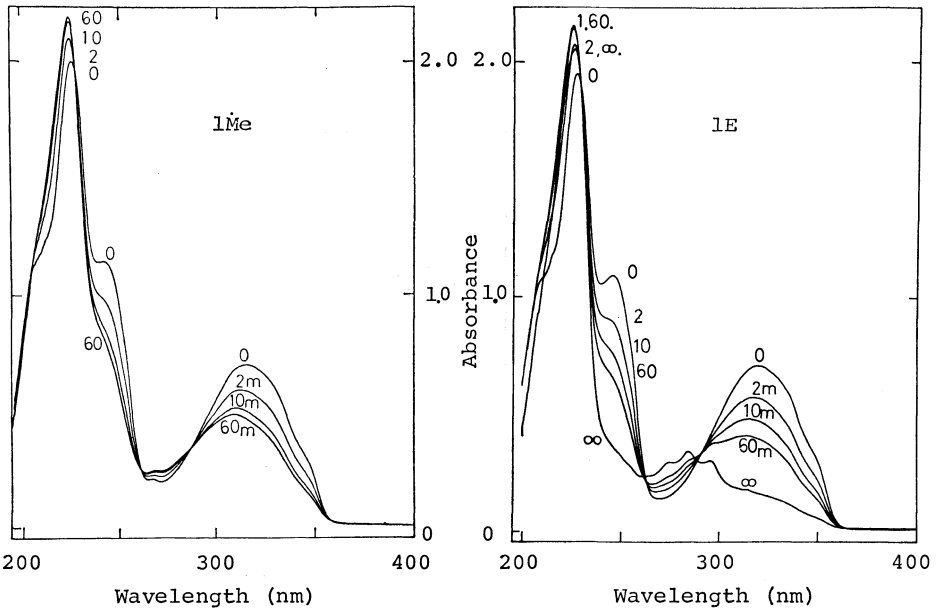

Fig. 2. UV absorption spectral change of **1Me** (0.31×10^{-4} mol/l) and **1E** (0.15×10^{-4} mol/l) in cyclohexane on the irradiation with 313 nm light.

decreased to one third, and ϕ_{t-c} doubled when aerobic oxygen was used, while ϕ_f and ϕ_{t-c} of 1-styrylnaphthalene changed very little.[24] The lifetime of the fluorescence of the former is 20 ns and that of the latter is 2 ns.[27]

*Photochemical Reactions of **1E** and **2E**.* The photochemical reaction of **1E** in solution was a rapid *trans-cis* isomerization followed by a slow intramolecular (2+2) cycloaddition giving *cis,cis*-**1E** (18%) and **1ED** (53%) as final products. The photoproduct *cis,cis*-**1E** was assinged on the basis of the NMR spectrum and **1ED** on the basis of the NMR, UV, and IR spectra.

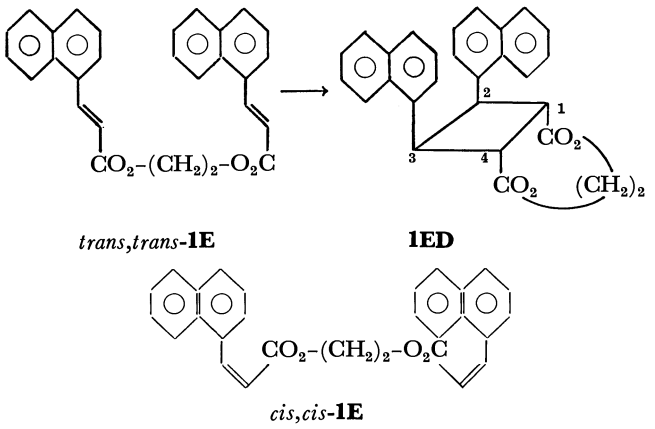

Figure 2 shows that UV absorption spectral change of *trans,trans*-**1E** and -**1Me** when irradiated with 313 nm light. A rapid *trans-cis* isomerization occurs and isosbestic points are observed at 260 and 290 nm until the equilibrium state is attained since cyclization proceeds very slowly. In the equilibrium state, the *cis* isomers predominate (approximately 70% *cis*, 30% *trans*) under the irradiation conditions since the *cis* isomer has an absorption maximum at a shorter wavelength (296 nm) and a smaller extinction coefficient. In the ^{1}H NMR spectrum, the peak for the methylene protons of *cis,cis*-**1E** shift to a higher field (3.58 ppm) compared with 4.54 ppm for *trans,trans*-**1E** suggesting that the methylene chain of the *cis,cis*-**1E** is more strongly affected by the naphthalene nuclei than the *trans,trans*-**1E**. The Stuart molecular model shows that the double bond of the *cis* isomer is twisted out of the two naphthalene nuclei and therefore the methylene chain may possibly interfere in the accessability of the two double bonds on dimerization. A further consequence of the steric hindrance, is that *cis,cis*-**1E** is considered to be poorly photocyclizable. In the photo-stationary mixture, the *cis,cis*-**1E** probably photocyclizes *via* the *trans,trans*-**1E**. Thus **1ED** may be largely formed from the photo-stationary mixture.

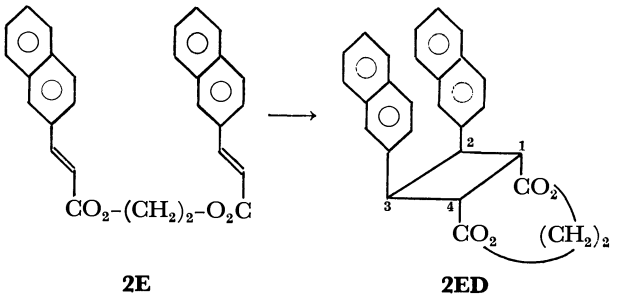
The photochemical reaction of **2E** was a slow *trans-cis* isomerization followed by a rapid intramolecular (2+2) cycloaddition of 3-(2-naphthyl)acrylate giving a single product, **2ED**. The structure of **2ED** was assinged by the method analogous with that for **1ED**. Figure 3 shows the UV absorption spectral changes of **2E** and **2Me** on irradiation with 313 nm light. The cyclization is so rapid that the reaction is considered to take place from the original *trans,trans*-**2E**.



The quantum yield of the cyclization, ϕ_{cy}, and the isomerization, ϕ_{t-c}, of **1E** and **2E** are shown in Table 1. Taking into consideration the large triplet yield of **2Me** in methanol, the fact that **2E** in cyclohexane cyclized with a larger quantum yield than in methanol

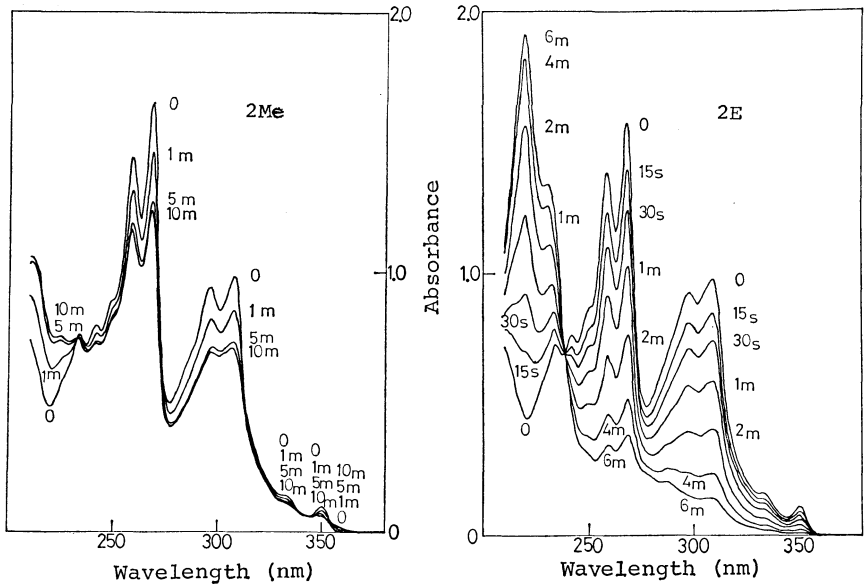


Fig. 3. UV absorption spectral change of **2Me** (0.39×10^{-4} mol/l) and **2E** (0.20×10^{-4} mol/l) in cyclohexane on the irradiation with 313 nm light.

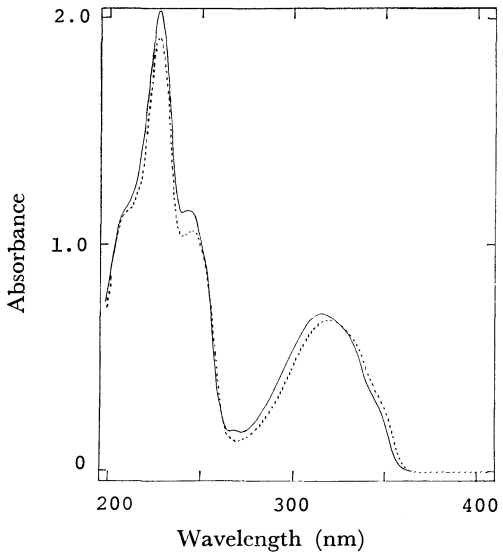

Fig. 4. UV absorption spectra of **1Me** (——, 0.29×10^{-4} mol/l) and **1E** (----, 0.14×10^{-4} mol/l) in cyclohexane.

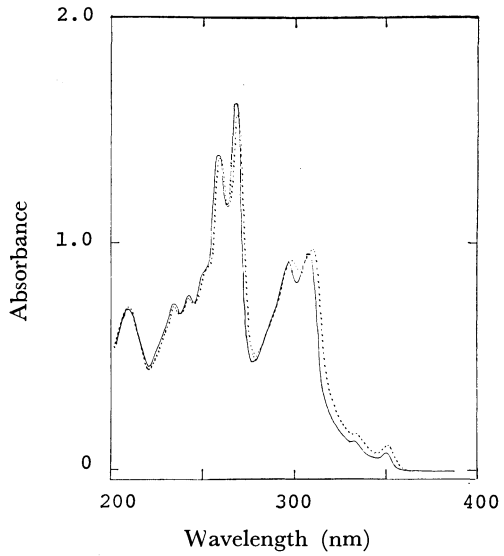

Fig. 5. UV absorption spectra of **2Me** (——, 0.39×10^{-4} mol/l) and **2E** (----, 0.20×10^{-4} mol/l) in cyclohexane.

suggests that the reactive state for the cyclization is the excited singlet state. Accordingly the cyclization was depressed while the *trans-cis* isomerization was accelerated by the heavy atom solvent which strongly quenches the fluorescence and accelerates intersystem crossing of the excited singlet state of **2Me**

In the case of **1E**, the solvent dependency of ϕ_{cy} is very small. The difference in the reactivity between **1E** and **2E** has been interpreted as follows : firstly, in the bichromophoric system, the quantum yield of the fluorescence was reduced to about half that of the corresponding methylesters and the amount of the decreased fluorescence is attributed to the cyclization. From Table 2, the difference in ϕ_f between **1Me** and **1E** is 0.03, while that between **2Me** and **2E** is 0.39 in cyclohexane the former being one tenth of the latter coinciding with the difference in the quantum yield of the cyclization. Secondly the lifetime of the fluorescence of **2Me** has been estimated from the quenching by aerobic oxygen to be much longer than that of **1Me** and because of this it is thought the two chromophores of **2E** cyclize more rapidly than **1E,** and the *trans-cis* isomerization proceeds slowly. A further consequence of the long-lifetime is that the cyclization of **2E** is susceptible to quenching by oxygen, while **1E** is not. In methanol, the lifetime of the fluorescence of **2Me** has been estimated to be shorter than in cyclohexane and consequently, the cyclization in methanol is not appreciably quenched by oxygen.

The above discussion demonstrates that the difference in reactivity between **1E** and **2E** can be explained by the difference in quantum yield and lifetime of the

fluorescence between **1Me** and **2Me**. The excited state of **1Me** is considered to be more rapidly deactivated by radiationless transitions than that of **2Me**. 1-Substituted naphthalene derivatives are considered to be sterically hindered owing to the protons at the 8 position in the naphthalene nucleus, which causes the rapid radiationless deactivations resulting in the short lifetime of the fluorescence.

The absorption spectra of the bichromophoric molecules, **1E** and **2E**, are shifted slightly into the red compared to the corresponding monochromophoric molecules as shown in Figs. 4 and 5 indicating the existence of a slight interaction between the chromophores in the ground state. The fluorescence spectra of **1E** and **2E** were accordingly shifted slightly into the red from those of **1Me** and **2Me**. Excimer fluorescence in the long wavelength side of the fluorescence spectra, frequently observed for aromatic bichromophoric molecules, was not observed for **1E** and **2E**.[14]

Experimental

Instrumentation. IR spectra were recorded on a JASCO model IR-S using KBr discs and UV absorption spectra on a Shimadzu model UV-300 and UV-200. NMR spectra were measured in $CDCl_3$ (otherwise indicated) with tetramethylsilane as an internal standard on a Hitachi model R-24A for ^1H, and a varian model NV-14 for ^{13}C. Emission spectra were recorded on a Hitach model MPF-1, and corrected for the photomultiplier (Hamamatsu TV Co. R446) response. Mass spectra were recorded on a Shimdzu model LKB-9000. High speed liquid chromatography was performed on a Waters Associate model equipped with a column, Michrobonda pack C-18 and a UV detector.

For the photolysis on a preparative scale, an immersion well type photoreactor was used. A naphthalene–ethanol solution ($\lambda>320$ nm) or cinnamylideneacetic acid–ethanol solution ($\lambda>360$ nm) was used as a filter.

For the photolysis on a analytical scale, a 4 ml rectangular cell equipped with an inlet tube about 10 cm was used. Pure argon or oxygen was bubbled through the tube for 5 min and immediately bottled. The period of bubbling (5 min) has been shown to be sufficient to change the air in the solution by measuring the intensity of the fluorescence. The light source was a 500 W high pressure mercury arc lamp (Ushio Electric Co.) with a monochromator (Nikon G250). Potassium ferioxalate system was used for actinometry.

Materials. 3-(1- and 2-Naphthyl)acrylic Acid: 3-(1- and 2-Naphthyl)acrylic acid were synthesized by the Knoevenagel condensation from the corresponding naphthaldehyde and recrystallized from methanol. 3-(1-Naphthyl)-acrylic acid, mp 206.0 °C (lit, 205.0 °C[21]). 3-(2-Naphthyl)-acrylic acid, mp 189.5 °C (lit, 196.0 °C[21])

*Methylesters (**1Me** and **2Me**)*: The acrylic acids were esterified in refluxing dry methanol with a trace of *p*-toluenesulfonic acid. Methyl 3-(2-naphthyl)acrylate (**2Me**), mp 91.0 °C. Methyl 3-(1-naphthyl)acrylate (**1Me**) was an oil at room temperature.

*Ethylene Bis[3-(1-naphthyl)acrylates] (**1E**) and Ethylene Bis-[3-(2-naphthyl)acrylates] (**2E**)*: **1E** and **2E** were synthesized from the corresponding acid chloride and ethylene glycol by heating in benzene with a trace amount of pyridine. ***1E***, mp 114—115 °C. ^1H NMR (ppm), 4.54(s, 4H, methylene), 6.51 (d, $J=5.6$, 2H, vinyl), 8.53 (d, $J=15.6$, 2H, benzyl), 7.2—8.2 (m, 14H, aromatic). IR (cm^{-1}), 1700 (s, carbonyl), 1620 (s, double bond), 1296, 1245, 1160, 1350, 770, 795, UV, $\lambda_{max}=323$ nm, $\varepsilon=4.80\times10^4$. MS, 422.

Found : C, 79.96; H, 5.2%. Calcd for $C_{28}H_{22}O_4$: C, 79.60; H, 5.21%.

2E, mp 148.0 °C. ^1H NMR (ppm), 4.60 (s, 4H, methylene), 6.60 (d, $J=16.0$, 2H, vinyl), 7.3—8.1 (m, 16H, aromatic and benzyl). IR (cm^{-1}), 1700 (s, carbonyl), 1630 (s, double bond), 1360, 1290, 1250, 1170, 1180, 860, 820. UV, $\lambda_{max}=307$ nm, $\varepsilon=5.00\times10^4$. MS, 422.

Found : C, 79.24, H, 5.25%. Calcd for $C_{28}H_{22}O_4$: C, 79.60; H, 5.21%.

*Photolysis of **1E***: **1E** (0.9 g) in acetone (990 ml) was irradiated with light ($\lambda>320$ nm) under nitrogen for 11 h and the solution concentrated in a rotary evaporator. On adding hexane, crystals precipitated out from the solution which were recrystallized from acetone–hexane to give **1ED**. 0.48 g, 53%. Concentration of the filtrate gave 0.16 g (18%) of *cis,cis*-**1E**.

1ED, mp 205—210.5 °C. ^1H NMR (ppm), 4.64 (s, 4H, methylene) 4.15—4.30 (d, 2H, cyclobutane), 5.45—5.65 (d, 2H, cyclobutane), 7.0—8.2 (m, 14H, aromatic). ^{13}C NMR (ppm), 65.20 (methylene C), 49.28 (carbon 1 and 4 on cyclobutane), 41.18 (carbon 2 and 3 on cyclobutane). IR (cm^{-1}), 1750 (s, carbonyl), 1603, 1250, 1225, 777. UV, λ_{max} 220 and 285 nm. MS, 422.

Found : C, 79.20; H, 5.30%. Calcd for $C_{28}H_{22}O_4$: C, 79.60; H, 5.21%.

cis,cis-***1E***, mp 107.0—108.0 °C ^1H NMR (ppm), 3.85 (s, 4H, methylene), 6.05 (d, $J=11.7$, 2H, vinyl), 7.0—8.5 (m, 16H, aromatic and benzyl). IR(cm^{-1}), 1723 (s, carbonyl), 1635 (s, double bond), 1180, 1214, 1420, 829, 814, 790. UV, $\lambda_{max}=296$ nm $\varepsilon=2.32\times10^4$. MS 422.

*Anhydride of **1ED** (**1EA**)*: **1ED** (0.21 g) was heated in 1M aqueous sodium hydroxide (50 ml) for 3 h at 60—70 °C. After filtration the filtrate was acidified. The precipitate (0.17 g 81%) was dried over P_2O_5 and refluxed in acetyl chloride (20 ml) for 3 h. Concentration of the solution gave crystals of **1EA** 0.10 g (48%). ***1EA***, mp 214.0—215.0 °C. ^1H NMR (ppm) in C_5D_5N, 4.63 (d, 2H, cyclobutane), 5.97 (d, 2H, cyclobutane), 7.0—8.0 (m, 14H, aromatic). IR (cm^{-1}), 1870 and 1795 (five membered ring anhydride), 1603, 1245, 1214, 1065, 903, 780, MS, 378.

Found : C, 78.35; H, 4.93%. Calcd for $C_{26}H_{18}O_3$: C, 80.53; H, 4.79%.

*Photolysis of **2E***: **2E** (1 g) was irradiated in the same way as **1E** for one hour and the reactant solution concentrated in a rotary evaporator. The addition of hexane precipitated crystals of **2ED**, 0.75 g in 75% yield. **2ED**, mp 190.0 °C. ^1H NMR (ppm), 4.62 (s, 4H, methylene), 4.1—4.8 (m, 4H, cyclobutane), 6.85 and 7.0, 7.2—8.2 (m, 14H, aromatic). ^{13}C NMR (ppm), 65.03 (methylene C), 49.02 (carbon 1 and 4 on cyclobutane), 44.63 (carbon 2 and 3 on cyclobutane).

*Anhydride of **2ED**, (**2EA**)*: **2ED** was converted into the anhydride (**2EA**) in the same way as **1ED**. **2EA**, mp 165.0—168.0 °C. ^1H NMR (ppm), 4.1 and 4.6 (m, 4H, cyclobutane), 6.84 and 6.97, 7.20—8.00 (14H, aromatic). IR(cm^{-1}), 1855 and 1775 (five-membered ring anhydride), 1235, 1210, 1060, 900. MS, 378.

Found : C, 79.45; H, 4.82%. Calcd for $C_{26}H_{18}O_3$: C, 80.53; H, 4.79%.

*Dimethyl Ester of **2ED** (**2EM**)*: The dicarboxylic acid of **2ED** was esterified by diazomethane. **2EM** mp 108.0—109.0 °C. ^1H NMR (ppm), 3.80 (s, 6H, methyl), 4.10 and 4.80 (m, 4H, cyclobutane), 6.90 and 7.07, 7.2—8.0 (14H, aromatic). IR (cm^{-1}), 1730 (s, carbonyl), 1600, 1430, 1270, 1200. MS, 378.

*Photolysis of a Concentrated Solution of **2Me***. **2Me** (1 g)

in 50 ml of benzene was irradiated with light ($\lambda > 320$ nm) for 24 h. After irradiation, evaporation of the solvent gave crystals. Thin layer chromatography and NMR methyl signals showed the presence of at least two kind of products and HLC retention times indicated that one product was **2EM**.

*Identification of **1ED** and **2ED*** : The compound **1ED** was assigned the proposed cyclobutane structure based on NMR, UV, and IR spectra. ^{13}C NMR spectrum of **1ED** showed a single peak at 65.20 ppm for the methylene carbons, 49.29 ppm for carbons 1 and 4, 41.18 ppm for carbons 2 and 3 on the cyclobutane ring. The hydrolyzed product of **1ED** gave an acid anhydride (**1EA**) in boiling acetyl chloride. **1EA** has IR peaks at 1795 and 1870 cm^{-1}, characteristic of a five-membered ring anhydride. The all-*cis* structure presumably can be neglected since the hydrolyzed product of **1ED** gave *trans*-3-(1-naphthyl)acrylic acid upon irradiation with 253.7 nm light. The structure of **2ED** was assigned by an analogous method. The ^{13}C NMR spectrum has a peak at 65.03 ppm for the methylene carbons, 49.02 ppm for carbons 1 and 4, 44.63 ppm for carbons 2 and 3 on the cyclobutane ring. The hydrolyzed product of **2ED** gave an anhydride (**2EA**) in boiling acetyl chloride. **2EA** has IR peaks at 1780 and 1855 cm^{-1}, characteristic of a five-membered ring anhydride. Photolysis of **2EM** by 253.7 nm light or thermolysis above 250 °C in a gas chromatograph gave *trans*-**2Me**. These facts support the proposed structure for **2ED**.

Quantum Yield Measurements. A) The quantum yield of *trans* to *cis* isomerization of **1Me** and **2Me** was calculated from the decrease in the UV absorbance. Molar extinction coefficients used are shown below.

	In methanol			In cyclohexane
trans-**1Me**	$\lambda_{max}=323$ nm	$\varepsilon=2.40$ ($\times 10^4$)	$\varepsilon_{313}=2.36$ ($\times 10^4$)	$\varepsilon_{313}=2.36$ ($\times 10^4$)
cis-**1Me**	$\lambda_{max}=296$ nm	$\varepsilon=1.16$	$\varepsilon_{313}=0.933$	$\varepsilon_{313}=0.933$
trans-**2Me**	$\lambda_{max}=307$ nm	$\varepsilon=2.52$	$\varepsilon_{313}=1.80$	$\varepsilon_{313}=1.48$
cis-**2Me**	$\lambda_{max}=298$ nm	$\varepsilon=1.11$	$\varepsilon_{313}=0.779$	$\varepsilon_{313}=0.967$

B) The quantum yield of the cyclization and *trans-cis* isomerization of **1E** and **2E** was calculated from the peak area in the HLC chart. Usually a 2×10^{-5} mol/l reactant solution in 4 ml rectangular cell was irradiated for 30 or 60 s with 313 nm light.

C) The fluorescence quantum yield was calculated by using 2-(1-naphthyl)-5-phenyloxazole (α**NPO**) in cyclohexane as standard,[22] $\phi_f=0.70$.

D) Michler's ketone photosensitized isomerization of **2Me**. A solution of Michler's ketone (1.1×10^{-3} mol/l) and **2Me** (5×10^{-4} mol/l) in cyclohexane or ethanol was purged with argon for 10 min and irradiated with light of wavelength 365 nm or 405 nm respectively. A solution of **2Me** of the same concentration without Michler's ketone was irradiated with 313 nm light. The ratio of *trans*- and *cis*-**2Me** was measured by HLC.

The authors wish to thank Dr. H. Nakanishi of this laboratory for the ^{13}C NMR measurements and Dr. K. Honda for his useful discussions.

The Reaction of Group V Metal Alkoxides with Sulfur Dioxide and Selenium Dioxide

Fumio Ando, Jugo Koketsu,* and Yoshio Ishii

Department of Industrial Chemistry, Chubu Institute of Technology, 1200 Matsumoto, Kasugai 487

(Received June 22, 1978)

Trialkoxyarsines (I) and -stibines (II) react with sulfur dioxide to give the corresponding dialkyl sulfites and arsenic trioxide or polymeric residues containing antimony. The reactivity of the compounds (I) is very low, and the yield is poor. Reactions of I and II with selenium dioxide afford dialkyl selenites together with arsenic trioxide or the same polymeric residues containing antimony as in the case of the reaction with sulfur dioxide. The reaction followed a stoichiometry of three moles of trialkyl phosphites (III) and one mole of selenium dioxide yields a 2 : 1 molar ratio of the phosphates : the phosphoroselenoates. A similar reaction of the phosphites with selenium dioxide in a 2 : 1 stoichiometry gives the phosphates and red selenium quantitatively. The rate of oxidation of the phosphorus compounds by selenium dioxide decreases in the order $Bu_3P > BuP(OEt)_2 > P(OEt)_3$. Based on these results, the possible mechanisms have been discussed.

In a previous paper,[1] the reaction of group V metal amides with sulfur dioxide was reported. In the reaction of phosphorus amide, the phosphorus atom is oxidized giving P=O, and P=S compounds. Tris-(dialkylamino)arsine and stibine, however, add across the S=O bond of sulfur dioxide and deoxygenation by the metal atom occurs giving the tetraalkylsulfurous diamides.

Selenium dioxide, a white crystalline solid, has been used as a selective oxidizing agent of organic compounds.[2] There are, however, few reports concerning the reaction of selenium dioxide with the group V metal compounds. Triaryl phosphines, arsines, and stibines react with selenium dioxide to give the corresponding oxides and selenides.[3,4] Esters of arsinous acids $R_2As(OR')$[5] and arsonous acids $RAs(OR')_2$[6] are also oxidized with selenium dioxide to arsinic acid esters $R_2As(O)OR'$ and arsonic acid esters $RAs(O)(OR')_2$, respectively. The oxidation of the cyclic esters of arsonous acid with selenium dioxide however, yields the spirocyclic esters of orthoarsonic acids instead of the normal arsonic acid esters.[7]

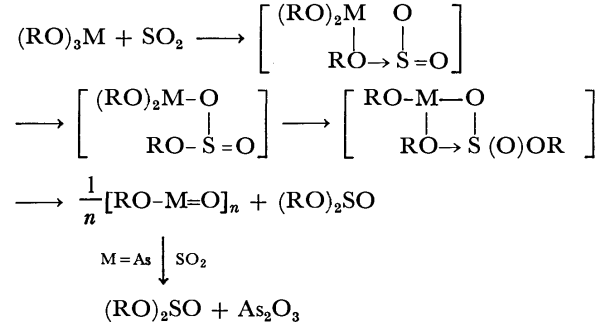
Trialkoxyarsines and -stibines are very reactive compounds and react with acetic anhydride[8] and heterocumulenes such as phenylisocyanate[9] and ketene.[10] However no study concerning the reaction between group V metal alkoxides and selenium dioxide has been found except for Dubrovia's report[11] concerning the reaction between triethoxystibine with selenium dioxide. Equally there are no reports of the reactions between group V metal alkoxides and sulfur dioxide. In this paper, the reactions between group V metal alkoxides and sulfur dioxide and selenium dioxide will be reported and discussed.

Results and Discussion

Trialkoxyarsines react very slowly with sulfur dioxide to give a precipitate of arsenic trioxide and dialkyl sulfites in low yields. The reaction was incomplete and large amounts of the starting materials were recovered, even on heating at 100 °C for several months.

The reaction of trialkoxystibines with sulfur dioxide proceeded more readily than that of the arsines to give the corresponding dialkyl sulfites and polymeric residues in place of antimony trioxide. The polymeric residues, which were formulated as $(ROSbO)_n$ on the basis of the elemental analysis showed infrared absorption bands assignable to the Sb–O–Sb[12–14] group (745, 618, and 540 cm^{-1} for $R=Pr^n$) and alkoxyl group. The residues were insoluble in many organic solvents and hydrolyzed in hot water to give antimony trioxide (identified by X-ray powder diffraction). It is interesting to note that the As–O bond is less reactive to sulfur dioxide than Sb–O, and this may be due to improved matching of the sizes of the reaction centers and also to the ionic properties of metal oxygen bonds. As the degree of ionic character in the metal oxygen bond increases when the central metal changes from arsenic to antimony, it appears that the nucleophilic property of the oxygen atom of antimony alkoxide is much greater than that of arsenic alkoxide.

The affinity of the metal atom for oxygen decreases in the order : As>Sb>Bi,[1] and therefore trialkoxystibine is more reactive than trialkoxyarsine, but the poor affinity for the oxygen atom results in the failure of Sb_2O_3 formation. Based on these considerations, one of the possible mechanisms consists of the nucleophilic attack by a alkoxyl group on the sulfur atom rather than the electrophilic attack by the metal on the oxygen atom of sulfur dioxide, to form an insertion product, and the reaction proceeds as follows :



Trialkoxyarsines reacted completely with selenium dioxide in boiling benzene to give arsenic trioxide and the corresponding selenites in poor yield due to the thermal decomposition of the selenites.[15] The reaction of the trialkoxystibines with selenium dioxide also gave the selenites and the polymers, which showed the same physical and spectral properties as those observed in the reaction with sulfur dioxide. An

analytical pure sample $(ROSbO)_n$ could not be obtained since it was impossible to completely remove the unreacted selenium dioxide. The structure was however shown to be the same as the product in the reaction of trialkoxystibine with sulfur dioxide. The stoichiometric results of the reactions studied with selenium dioxide are shown in the following equations :

$$2As(OR)_3 + 3SeO_2 \longrightarrow 3(RO)_2SeO + As_2O_3,$$

$$Sb(OR)_3 + SeO_2 \longrightarrow (RO)_2SeO + \frac{1}{n}(ROSbO)_n.$$

The reaction of trialkoxyarsines and -stibines with selenium dioxide may proceed *via* an identical pathway to that of sulfur dioxide.

The reaction of trialkyl phosphites with excess sulfur dioxide was performed at room temperature to yield trialkyl phosphates and trialkyl phosphorothioates in the ratio of 2 : 1, the results of which agree with those reported by Fluck and Binder.[16] The reaction of trialkyl phosphites with selenium dioxide, however, gave different products, depending on the proportions of the reagents used.

The reaction followed a stoichiometry of 3 mol of trialkyl phosphite and 1 mol of selenium dioxide yields a 2 : 1 molar ratio of trialkyl phosphate : trialkyl phosphoroselenoate. The phosphoroselenoates were identified by comparing the spectral data with those of authentic samples[17-19] prepared by the reaction between phosphite and selenium. Ethyl dibutylphosphinite was also oxidized with selenium dioxide to give ethyl dibutylphosphinate and ethyl dibutylphosphinoselenoate. The products from the oxidation in the 3 : 1 stoichiometric ratio are listed in Table 2.

Similar reactions of the phosphites with selenium dioxide in a 2 : 1 stoichiometry gave the phosphates and selenium in quantitative yields.

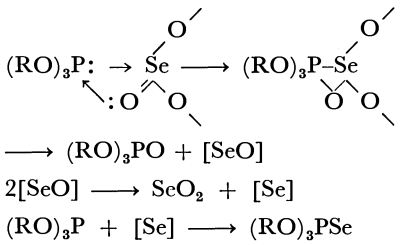
Trialkyl phosphoroselenoates reacted readily with selenium dioxide to yield the corresponding phosphites and selenium in good yields, the reactions of which are summarized in the following equations :

$$3(RO)_3P + SeO_2 \longrightarrow 2(RO)_3PO + (RO)_3PSe$$

$$2(RO)_3P + SeO_2 \longrightarrow 2(RO)_3PO + Se,$$

$$2(RO)_3PSe + SeO_2 \longrightarrow 2(RO)_3PO + 3Se.$$

The reactivity of trivalent phosphorus compounds toward selenium dioxide has been compared by means of GLC analysis by the same method used in a previous paper[1] and found to decrease in the order, $Bu_3P > BuP(OEt)_2 > P(OEt)_3$. This order is parallel with the order of electron density on the phosphorus atom, and consistents with the order found in the reaction of phosphorus compounds with sulfur dioxide.[1] It may be reasonable to consider the nucleophilic attack by the phosphorus atom on selenium occurs as the first step in the formation of cyclic intermediates followed by the formation of phosphoryl bonds to give trialkyl phosphates and selenium monoxide, which disproportionates into selenium and selenium dioxide. The selenium reacts with unreacted phosphites to provide phosphoroselenoates.



$$\longrightarrow (RO)_3PO + [SeO]$$

$$2[SeO] \longrightarrow SeO_2 + [Se]$$

$$(RO)_3P + [Se] \longrightarrow (RO)_3PSe$$

Experimental

All the reactions as well as preparations of trialkoxyarsines and stibines were conducted under an atmosphere of argon or nitrogen. The IR spectra were taken with a Shimadzu IR-430 spectrometer. The NMR spectra were run on a JEOL-C60 HL spectrometer in CCl_4 or $CHCl_3$ using TMS as internal standard. The analytical GLC was conducted with a Shimadzu GC 6A gas chromatograph using a 3 m glass column packed with 10% PEG 6000.

Materials. Trialkoxyarsines were prepared according to the method described by Brill and Campbell;[20] $As(OMe)_3$; bp 90—96 °C/35 mmHg, $As(OEt)_3$; bp 120—126 °C/18 mmHg, $As(OPr^n)_3$; bp 107—108 °C/43 mmHg, $As(OPr^i)_3$; bp 92—94 °C/12 mmHg, $As(OBu^n)_3$; bp 60—72 °C/0.05 mmHg. The preparation of the trialkoxystibines was conducted by the reaction between antimony trichloride and 3 mol of lithium alkoxide. $Sb(OEt)_3$; bp 89—96 °C/0.08 mmHg, $Sb(OPr^n)_3$; bp 70—74 °C/0.05 mmHg, $Sb(OPr^i)_3$; bp 39—44 °C/0.03 mmHg, $Sb(OBu^n)_3$; bp 81—89 °C/0.15 mmHg.

Triisopropyl phosphite,[21] triisobutyl phosphite,[21] diethyl butylphosphonite,[22] ethyl dibutylphosphinite,[23] and tributyl phosphine[24] were prepared by the methods previously reported. The other phosphorus compounds were obtained commercially and distilled prior to use.

Reaction of Trialkoxyarsines with Sulfur Dioxide. The triisopropoxyarsine (1.56 g, 6.24 mmol) was dissolved in an excess of liquid SO_2 and heated in sealed tube at 100 °C for 4 months during which time white precipitates of arsenic trioxide (0.20 g, 33% yield) were formed. The liquid part of the reaction mixture gave the fraction (0.76 g, bp 40—52 °C/50 mmHg) by distillation under reduced pressure. GLC analysis showed the presence of diisopropyl sulfite together with the starting material. These two compounds were identified by comparing the GLC retention times with those of authentic samples.

Reaction of Trialkoxystibines with Sulfur Dioxide. A mixture of triethoxystibine (2.76 g, 10.7 mmol) and excess sulfur dioxide was heated at 100 °C for 3 d in a sealed tube. After removal of the white precipitates and the excess sulfur dioxide, diethyl sulfite (1.00 g, 45%) was obtained by distillation under reduced pressure; bp 53—55 °C/16 mmHg, IR ν(S=O) 1205 cm^{-1}, NMR (CCl_4) δ=1.34 (3H, t), 4.05 (2H, q). The precipitates had strong infrared bands assignable to the Sb–O–Sb group (745, 618, 585 cm^{-1}) and the alkoxyl group (2980, 2940, 2900, 1225, 1170, 1120, 1065. 1015, and 920 cm^{-1}). Found; C, 13.8; H, 2.65%. Calcd for $C_2H_5O_2Sb$; C, 13.14; H, 2.76%. The reactions of other trialkoxystibines with sulfur dioxide were performed in the same way, the results of which are shown in Table 1. The white precipitates in each reaction also showed the same IR spectra as reported above and identified to be $(ROSbO)_n$.

Reaction of Trialkoxyarsines with Selenium Dioxide. A mixture of trimethoxyarsine (1.2 g, 7.20 mmol) and selenium dioxide (1.20 g, 10.8 mmol) in benzene (10 ml) was heated in a sealed tube at 100 °C for 2 d. The As_2O_3 precipitate was then filtered and the solvent removed using a rotary evaporator. The remaining product was distilled under vacuum to yield dimethyl selenite (1.41 g, 83%); bp 64—65 °C/15 mmHg, IR (neat) ν(Se=O) 926 cm^{-1}, ν(Se–O) 632 cm^{-1}; NMR (CCl_4) δ=3.70 (S).

Similar treatment of triethoxyarsine (1.45 g, 6.90 mmol) with selenium dioxide (1.15 g, 10.4 mmol) gave diethyl selenite (1.19 g, 62%); bp 76—76.5 °C/15 mmHg; IR (neat) ν(Se=O) 934 cm^{-1}, ν(Se–O) 632 cm^{-1}, NMR (CCl_4) δ=1.27 (3H, t), 4.03 (2H, m). The reaction of tri-*n*-propoxyarsine (1.90 g, 7.53 mmol) with selenium dioxide (1.26 g, 11.3 mmol) gave di-*n*-propyl selenite (1.58 g, 65%); bp 77—78 °C/2.5 mmHg; IR (neat) ν(Se=O) 930 cm^{-1}, ν(Se–O) 634 cm^{-1}; NMR (CCl_4) δ=0.98 (3H, t), 1.65 (2H, m), 3.94 (2H, m). The reaction of triisopropoxyarsine (1.76 g, 6.99 mmol) and tributoxyarsine (1.71 g, 5.80 mmol) with selenium dioxide gave the following products, respectively; diisopropyl selenite (1.08 g, 51%); bp 78—81 °C/14 mmHg; IR (neat) ν(Se=O) 940 cm^{-1}, ν(Se–O) 640 cm^{-1}; NMR (CCl_4) δ=1.30 (6H, m), 4.85 (1H, m), and dibutyl selenite (0.85 g, 41%); bp 127—129 °C/12 mmHg; IR (neat) ν(Se=O) 924 cm^{-1}, ν(Se–O) 635 cm^{-1}; NMR (CCl_4) δ=0.96 (t, 3H), 1.50 (m, 4H), 3.97 (m, 2H).

Reaction of Trialkoxystibines with Selenium Dioxide. A mixture of triethoxystibine (2.13 g, 8.29 mmol) and selenium dioxide (1.31 g, 11.8 mmol) was allowed to react at 100 °C for 3 d. After removal of the precipitates by filtration, the filtrate was distilled under vacuum to give diethyl selenite (0.76 g, 33%). Under similar conditions, tri-*n*-propoxystibine (2.09 g, 6.98 mmol) reacted with selenium dioxide and gave di-*n*-propyl selenite (0.76 g, 34%). Also diisopropyl selenite (0.88 g, 41%) and di-*n*-butyl selenite (0.52 g, 53%) were obtained by the reaction of selenium dioxide with triisopropoxystibine (1.99 g, 6.72 mmol) and tri-*n*-butoxystibine (1.15 g, 3.36 mmol), respectively.

The white precipitates obtained in each reaction exhibited the same IR absorptions as those obtained in the reaction of the corresponding trialkoxystibine with sulfur dioxide.

Reaction of Trialkyl Phosphites with Sulfur Dioxide. When an excess of dry sulfur dioxide was bubbled through trimethyl phosphite (2.20 g, 17.7 mmol) at −78 °C, an exothermic reaction took place which gave a colorless solution after standing for 30 min at room temperature. The reaction mixture was distilled to give a distillate (2.28 g) of boiling point range bp 71—78 °C/14 mmHg . From the mixture, trimethyl phosphate (1.35 g, 63%) and trimethyl phosphorothioate (0.75 g, 31%) were obtained by column chromatography (silica gel–chloroform). In a similar manner, triethyl phosphite (1.96 g, 11.8 mmol) reacted with sulfur dioxide to yield triethyl phosphite (1.14 g, 53%) and triethyl phosphorothioate (0.68 g, 29%). Triisopropyl phosphite (2.50 g, 11.7 mmol) also underwent a similar reaction to give triisopropyl phosphate (1.42 g, 54%) and triisopropyl phosphorothioate (0.76 g, 27%). These compounds were identified by comparing the physical (bp) and spectroscopic (IR and NMR) data with those of the authentic samples.[17]

Reaction of Trialkyl Phosphites with Selenium Dioxide in the Molar Ratio 3 : 1. Trimethyl phosphite (2.48 g, 20.0 mmol) was added slowly with stirring to selenium dioxide (0.74 g, 6.66 mmol) suspended in benzene (5 ml) at room temperature, and the solution stirred for 2 h. After removal of the solvent, the reaction mixture was distilled under reduced pressure. The distillate (3.04 g, bp 84—90 °C/15 mmHg) was subjected to column chromatography (silica gel–chloroform) to give trimethyl phosphate (1.39 g, 49%), and trimethyl phosphoroselenoate (1.10 g, 27%), IR (neat) ν(P=Se) 557, 502 cm^{-1}, NMR ($CHCl_3$) δ=3.74 (d, J_{POCH}=

14.4 Hz.

Further oxidations of phosphites with seleniium dioxide were conducted according to the same procedure as reported above, the results of which are shown in Table 2.

Reaction of Trialkyl Phosphites with Selenium Dioxide in the Molar Ratio 2 : 1. Trimethyl phosphite (1.77 g, 14.3 mmol) was added to selenium dioxide (0.79 g, 7.12 mmol) in benzene (5 ml) at room temperature. An exothermic reaction took place giving a red precipitate. The mixture was stirred overnight and the red selenium (0.47 g, 84%) was then filtered and the solvent removed from the filtrate using a rotary evaporator. The remaining product was distilled under reduced pressure to yield trimethyl phosphate (1.68 g, 84%); bp 77—78 °C/13 mmHg. Similar treatment of triethyl phosphite (1.94 g, 11.6 mmol) with selenium dioxide (0.65 g, 5.82 mmol) gave triethyl phosphate (1.89 g, 89%); bp 94—95 °C/12 mmHg and selenium (0.38 g, 82%).

Reaction of Trialkyl Phosphoroselenoates with Selenium Dioxide. The reaction of trimethyl phosphoroselenoate (0.87 g, 5.26 mmol) with selenium dioxide (0.24 g, 2.15 mmol) was conducted in benzene (5 ml) to produce trimethyl phosphate (0.46 g, 76%) and selenium (0.46 g, 91%). From triethyl phosphoroselenoate (1.29 g, 5.26 mmol) and selenium dioxide (0.29 g, 2.63 mmol) were obtained triethyl phosphate (0.92 g, 96%) and selenium (0.62 g, 100%).

Effect of Substituent on the Reactivity. A reactivity comparison of trivalent phosphorus compounds towards selenium dioxide was performed by mixing each reagent (0.05 mmol/l) in ethanol at −78 °C and determining by GLC analysis the remaining amount of trivalent phosphorus compound under the same conditions used in a previous paper.[1] The following figures show the remaining amounts of phosphorus compounds (mmol/l) after 30 min; Bu_3P : (0), $BuP(OEt)_2$: (0.0182), $P(OEt)_3$: (0.0485).

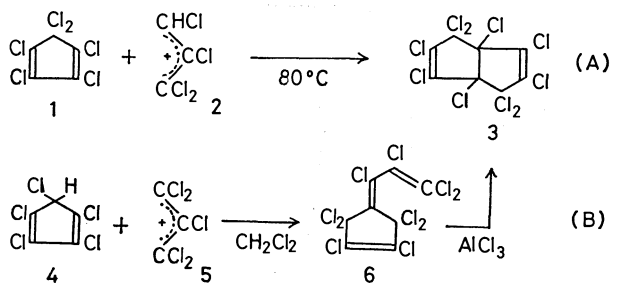
(Received June 23, 1978)

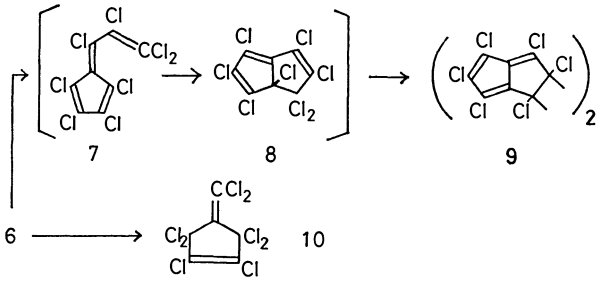
Decachloro-4-allylidenecyclopentene (**6**) was synthesized by the reaction of pentachlorocyclopentadiene with hexachloropropene in the presence of anhydrous aluminium chloride. Hexachloro-2-allylidene-4-cyclopentene-1,3-dione (**11**), prepared from **6** by treatment with concd nitric acid, cyclized to hexachloro-2,5-dihydrocyclopenta[*b*]pyran-5-one (**14**) on heating. In a solvent such as acetone and acetonitrile, **14** rearranged to hexachloro-2,5-dihydrocyclopenta[*b*]pyran-2-one (**18**) at room temperature. The mechanism of this rearrangement is discussed. Hydrolysis of **14** by 90% sulfuric acid afforded tetrachloro-2,5-dihydrocyclopenta[*b*]pyran-2,5-dione (**15**), which was obtained directly from **6** by treatment with sulfuric acid. The reactions of **11** with anhydrous methanol, and of **15** with diazomethane were investigated.

As a part of our study to synthesize new cyclic conjugated chlorocarbons, we have investigated the reaction of 1,1,2,3-tetrachloropropenium cation (**2**) with hexachlorocyclopentadiene (**1**) at 80 °C, obtaining decachlorobicyclo[3.3.0]octa-2,6-diene (**3**).[2)] The reaction of pentachloropropenium cation (**5**)[3)] with 1,2,3,4,5-pentachlorocyclopentadiene (**4**) has similarly attracted our interest.



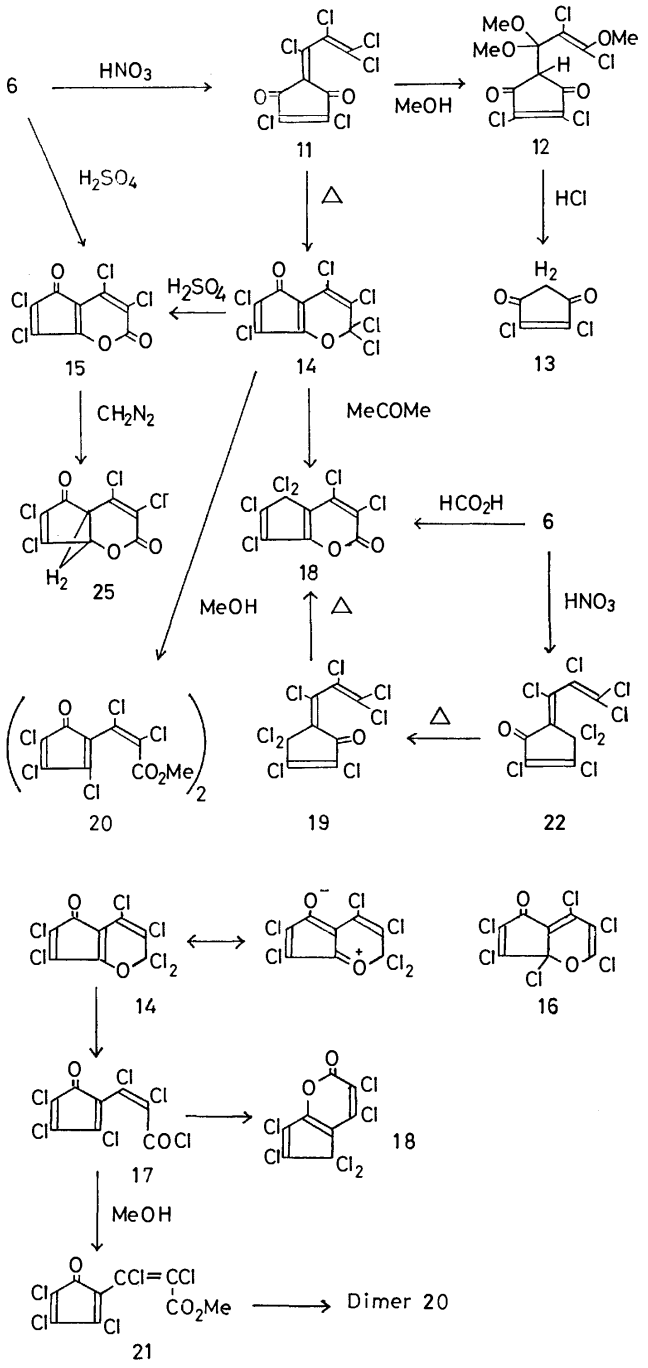
The reaction of **4** with **5** at 80 °C gave a mixture of **3** and a small amount of white crystals of unknown structure (**6**). When the reaction was carried out in refluxing dichloromethane, **6** was obtained in a 87% yield. Treatment of **6** with a catalytic amount of anhydrous aluminium chloride in refluxing carbon tetrachloride afforded **3** quantitatively. This cyclization suggests that **6** is a stable intermediate of reaction B. The mechanism of reaction A seemed to differ from that of B, because **6** could not be detected in the products of reaction A carried out in refluxing dichloromethane. The infrared spectrum of **6** shows three absorptions in the double bond region. Two peaks at 1207 and 1195 cm^{-1} are suggestive of polychlorinated five membered ring, and a peak at 810 cm^{-1} is seemingly due to a double allylic dichloromethylene.[5)] The UV spectrum of **6** (Fig. 1) shows that the three double bonds are not fully conjugated. The ^{13}C NMR spectrum of **6** (Table 1) shows the presence of six sp^2 carbons and two doubly allylic dichloromethylene carbons,[6)] both of which are under similar circumstances in the molecule.

Although chlorination of **6** in carbon tetrachloride was uncuccessful, treatment in liquid chlorine with irradiation by sunlight gave octachloro-4-methylenecyclopentene (**10**).[7)] Dechlorination of **6** with copper powder gave brownish red crystals of (**9**), which was identified with an authentic sample of the dimer of hexachloropentalene[3a,8)] by their IR spectra. This transformation is well interpreted by assuming intermediary formation of octachloro-6-vinylfulvene (**7**) followed by ring closure and dechlorinative dimerization. Structure **6** is fully consistent with the beforementioned spectral data and its chemical transformations.



When 1,2,3,4-tetrachlorocyclopentadiene was allowed to react with **5** in refluxing dichloromethane, a small amount of octachlorobicyclo[3.3.0]octa-1,4,6-triene[4)] was the only product isolated.

Treatment of **6** with 20% fuming nitric acid gave pale yellow crystals. Assignment of the structure (**11**) to the product follows from the elemental analysis, spectroscopic data, and the analogous reaction of **10** to give tetrachloro-2-methylene-4-cyclopentene-1,3-dione.[7)] In the reaction of this 1,3-dione with ethanol, an exocyclic dichloromethylene group is eliminated to give (**13**).[9)] Therefore, a similar reaction could be expected for **11**, which also has carbonyl groups on both sides of the exocyclic group. By heating 2 h in refluxing methanol, **11** was converted to the compound $C_{11}H_{10}Cl_4O_5$, the spectral data of which point to a monoketalized triketone (**12**) as shown. An attempted hydrolysis of the ketal group with hydrochloric acid in refluxing methanol gave a cyclopentenedione **13**.[10)] Identification of the product with an authentic sample was carried out by measurement of the mixed melting point and comparison of their IR spectra. The results suggests intermediary formation of an unstable triketone. When **11** was heated in refluxing carbon tetrachloride under anhydrous conditions, deep red crystals of (**14**) were formed in high yield. Assignment of the structure **14** was based on its IR, UV, and ^{13}C NMR spectra as well as on its formation from **11** and the conversion to (**15**) by 90% sulfuric acid.



The formation of **14** is significant in view of the mechanism of 1,5-pentadiene-oxygen rearrangements.[12] Because the pyran **14** is stabilized by mesomerism,[1] 1,5-sigmatropic chlorine shift followed by ring opening of the second pyran intermediate (**16**) to an acyl chloride (**17**) is not so favored.

Crystalline **14** decomposed slowly in the air with evolution of hydrogen chloride; however, the solution of **14** in a nonpolar solvent was stable in a dark place. In a polar solvent such as acetone, ethyl acetate, and acetonitrile, an unexpected rearrangement occurred leading to (**18**) at room temperature. Figure 2 shows UV spectra of these compounds. The longest wavelength maxima of both **14** and **15** seem to be due to a cyclopentadienone chromophore.[13] The broad

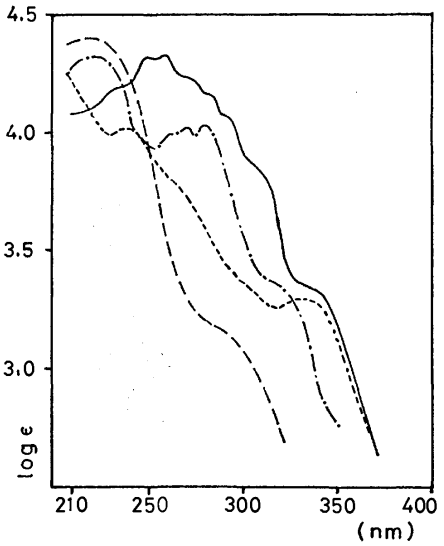


Fig. 1. Ultraviolet spectra of **6**, **11**, **19**, and **22**: — — — **6**; —— **11**; ------ **19**; —·—·— **22**.

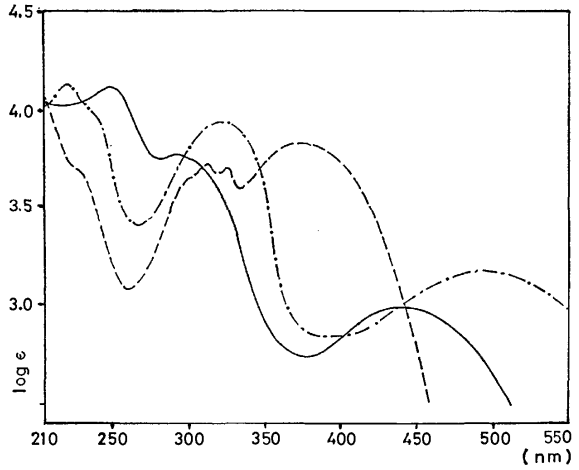

Fig. 2. Ultraviolet spectra of **14**, **15**, and **18**: —— **14**; —·—·— **15**; ———— **18**.

maximum of **18** at 380 nm is due to polychlorinated α-pyrone.[14] Cyclization of (**19**) under mild conditions, resulting in the formation of **18**, and the spectral data indicated the double bond location and the presence of α-pyrone ring in **18**.

When anhydrous methanol was added to **14**, a moderate exothermal reaction took place to afford white crystals, $C_{18}H_6Cl_{10}O_6$ (**20**). Although the structure is unknown, the high resolution mass spectrum of **20** indicates that it is a dimer of (**21**), $C_9H_3Cl_5O_3$, which corresponds to the base peak of the mass spectrum. Plausible mechanisms for the formation of **18** and **20** could be outlined as follows. In a polar solvent, a chlorine migration followed by ring opening takes place, giving an acid chloride **17**, which either reacts with methanol and dimerizes to **20** or, without any reactive materials in the reaction medium, cyclizes to **18**.

On the other hand, the reaction of **6** with dilute nitric acid yielded a pale yellow monoketone (**22**). The transformation is similar to that of **10** with nitric

Table 1. ^{13}C data of selected compounds[a,b]

acid or sulfuric acid.[7] Although **22** was stable at room temperature or during the chromatographic separation, vacuum distillation at 180 °C or heating in refluxing carbon tetrachloride promoted an (*E*)-(*Z*) rearrangement to **19**. In contrast to the (*E*)-ketone **22**, **19** cyclized to **18** during chromatographic separation on silica gel or in the air with the gradual liberation of hydrogen chloride. These chemical behavior as well as the IR, UV, and ^{13}C NMR spectra of both monoketones support the proposed structures. Reaction of **6** with fuming sulfuric acid yielded **15** and two kinds of dimers $C_{16}Cl_8O_6$, (**23**) and (**24**) of unknown structure, which could be distinguished by the IR spectra. It is interesting that **15** gave **23** in ether, while it gave **24** in acetone-d_6 at room temperature.

Since the 1,3-dipolar cycloaddition of diazomethane to tetraphenylcyclopentadienone has been reported,[16] we wanted to compare the reactivity of the two double bonds in the cyclopentadienone moiety of **15**. The structure (**25**) was assigned on the basis of its high resolution mass, IR, ^1H NMR, ^{13}C NMR, and UV spectra. The latter shows one absorption maximum at 257 nm, indicating the existence of α,β-unsaturated carbonyl chromophore. Addition of diazomethane[17] preferentially at the middle double bond of **15** may be explained in terms of the cationic quasi-aromatic character of the α-pyrone moiety.

Experimental

General. The melting points were determined on a Yanagimoto micro melting point apparatus and were uncorrected. Elemental analyses of carbon, hydrogen, and nitrogen were performed by Mr. J. Goda of Osaka City University. Chlorine analyses, when required, were carried out according to the combustion method by use of a modified flask.[18] IR spectra were recorded on a Perkin-Elmer Model 337 spectrophotometer as mulls in Nujol betweeen NaCl disks or as a solution of carbon tetrachloride. Only significant absorptions are reported. UV spectra were recorded on a Hitachi EPS-20 spectrophotometer as solutions in hexane. Nuclear quadrupole resonance spectra were recorded on a Decca Radar NQR spectrometer at 77 K. Both proton and ^{13}C NMR spectra were recorded on a JEOL FX-60 Fourier transform NMR spectrometer. Gas chromatographic analyses were performed on a Nikki Model G-77 gas chromatograph using a 2 m 10% SE-30 column with helium flow. Mass spectra were recorded on a JEOL JMS-D 300 high resolution mass spectrometer.

*Decachloro-4-allylidenecyclopentane (**6**).* To a solution of 50.3 g(0.211 mol) of hexachloropropene[20] in 50 ml of dried dichloromethane was added 2.0 g of powdered anhydrous aluminium chloride,[21] and the mixture was stirred at room temperature. Owing to an exothermal reaction, the mixture began to reflux after several minutes with the evolution of hydrogen chloride.[22] After the exothermal reaction had come to an end, the mixture was heated to reflux for 2 h with mechanical stirring . After having been kept at room temperature over night, the reaction mixture was poured into ice–water to decompose the complex. The organic layer was separated and the water solution was extracted with carbon tetrachloride. The combined solution was dried over anhydrous sodium sulfate and filtered, and evaporation of the solvent under reduced pressure afforded sludge. Crystals precipitated from the sludge by the

addition of ethanol were collected by vacuum filtration. Yield: 71.1 g. After the mother solution was evaporated under reduced pressure, the residue was distilled at 150 °C under 30—36 mmHg to collect a mixture of the starting materials (44.7 g). Crude **6**(13.4 g) was obtained from the crystalline residue by washing with ethyl alcohol. Total yield was 84.5 g(89%). Recrystallization from ethyl acetate gave an analytical sample. Mp 108 °C;[23] IR: 1648, 1620, 1565(-C=C-); UV: λ_{max} (nm, log ε) 221(4.41), 285(3.09); NQR: (MHz) (77 K) 37.220, 37.607. 37.618, 38.026, 38.100, 38.262, 38.520, 38.733, 38.854, 38.975; (Found: C, 21.47; Cl, 78.45%).

Chlorination of ***6*** *in Liquid Chlorine.* In an annealed glass tube (wall thickness: 4 mm, outside diameter: 19 mm × 180 mm), 10.0 g(2.22×10^{-2} mol) of **6** and about 10 ml of liquid chlorine were sealed at −70 °C. The mixture was exposed to the sunlight for two weeks at Osaka in May, giving a transparent liquid chlorine solution. Having been chilled in a Dry Ice–acetone bath, the tube was opened. The chlorine was allowed to evaporate at room temperature under atmospheric pressure and finally under reduced pressure by using an aspirator, and the light yellow residue was distilled at 150 °C(bath)/0.5 mmHg. The crystals which appeared in the distillate on standing at room temperature were collected by filtration, and washed with a small amount of ethanol. Yield : 3.9 g. The product was identified as octachloro-4-methylenecyclopentene by comparison of the IR spectrum with that of an authentic sample.[7]

Dechlorination of ***6*** *with Copper Powder.* A mixture of 5.0 g(8.0×10^{-2} g·atom) of copper powder and 9.0 g(2.0×10^{-2} mol) of **6** in petroleum ether (bp: 30—50 °C) was heated to gentle refluxing with brisk mechanical stirring for 4 days. Insoluble materials were removed by filtration and washed with hot petroleum benzine (bp : 100—140 °C). The solvent was evaporated under vacuum and the residue was triturated with a mixture of petroleum benzine and ethyl alcohol, giving 4.6 g of brown powder. The crude product was dissolved in chloroform and then the small amount of insoluble materials was removed by filtration. After the red solution had been concentrated, petroleum ether was added to precipitate orange crystals. The mother solution was cooled in an ice-bath, and the crystals which precipitated from the solution were collected by filtration. The product was identified as a dimer of hexachloropentalene by means of its IR spectra.

Isomerization of ***6*** . To a solution of 3.22 g(1.6×10^{-2} mol) of **6** in 10 ml of carbon tetrachloride was added a catalytic amount of anhydrous aluminium chloride. The greenish color of a complex appeared immediately. The mixture was heated to gentle reflux with mechanical stirring for 6 h. The reaction mixture was treated in the usual way, giving 3.60 g of light brown crystals of **3**, from which a pure sample was obtained by washing with methanol.

*(E)-Octachloro-5-allylidene-2-cyclopenten-1-one (****22****).* A mixture of 5.0 g(11 mmol) of **6** and 15.0 mol of the nitric acid solution prepared by mixing 50 ml of fuming nitric acid (d=1.52) and 10 ml of nitric acid (d=1.38) was stirred for 40 min at room temperature(19 °C). The reaction mixture was poured into ice–water and the organic products were extracted with carbon tetrachloride. The solution was dried over sodium sulfate and evaporated under reduced pressure, giving 5.2 g of a yellow oily product. Addition of petroleum ether to the product precipitated 1.8 g of **6**, which was removed by means of vacuum filtration. The mother solution was chromatographed on a 22 mm × 35 cm column of silica gel (Mallinckrodt, 100 mesh) by use of petroleum ether at the beginning, followed by 5% acetone in petroleum benzine as an eluent. Unreacted **6** (0.52 g) was obtained from the first band. The second fraction, containing **6** and **22** was followed by a band containing 2.2 g of pure **22**. Evaporation of the solvent under reduced pressure at room temperature gave an analytical sample. IR: 1735 (>CO), 1640, 1590, 1570 (-C=C-), 1240, 1190, 800, 720, 710; UV: λ_{max} 224(4.30), 262 sh(3.91), 272(3.98), 281(3.99), 290sh(3.86), 310sh(3.39), 322sh(3.30); ^{13}C NMR : see Table 1. Found: C, 23.92; H, 0.16%. Calcd for C_8Cl_8O: C, 24.28%.

*(Z)-Octachloro-5-allylidene-2-cyclopentene-1-one (****19****).* 518 mg of **22** that had been purified by column chromatography on silica gel was sealed in a small glass tube. The tube was heated to 100 °C for 6 h in a water bath. The ampoule was opened and the oily product was taken up in petroleum ether. This solution was chromatographed on a column (13 mm × 10 cm) of silica gel by use of 50 ml of petroleum ether and then 40 ml of 3% acetone in petroleum ether as eluent. Pure **22** (180 mg) was recovered by evaporation of the first yellow eluate (25 ml). The second (20 ml) and the third(25 ml) fractions afforded small amounts of oily materials. A subsequent fraction, obtained from the deep yellow band, afforded 318 mg of **19**. Monoketone **22** isomerized to **19** on distillation at 170—180 °C(bath) under a pressure of 2 mmHg. IR: 1760(>CO), 1630, 1590, 1545 (-C=C-), 1230, 1155, 1105, 800, 710; UV: λ_{max} 240(4.00), 330(3.30); ^{13}C NMR: see Table 1. Found: C, 24.76; H, 0.12; Cl, 71.89%. Calcd for C_8Cl_8O: C, 24.28; Cl, 71.68%.

Reaction of ***22*** *with Anhydrous Aluminium Chloride.* A mixture of 50 mg of **22** and 50 mg of anhydrous aluminium chloride in 5 ml of dried carbon tetrachloride was refluxed for 4.5 h. The reaction complex was quenched by pouring into ice–water. The product, isolated by conventional extraction procedures, was crude **18**, which was purified by recrystallization from petroleum ether.

Reaction of ***6*** *with 89% Formic Acid; Hexachloro-2,5-dihydrocyclopenta*[b]*pyran-2-one (****18****).* A mixture of 5.0 g (1.1×10^{-2} mol) of **6** and 20 ml of commercially available formic acid(98%) was heated to gentle reflux with stirring for 3 h. The deep yellow reaction mixture was cooled to room temperature, precipitating black materials. The oily black mateirals separated from the formic acid solution by decantation, were triturated in a small amount of methanol to give 1.1 g of slightly gray crystals of **3**. The formic acid solution was diluted with 150 ml of water, and extracted 4 times with chloroform. The extract(50 ml) was washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The oily residue (1.77 g) solidified on standing at room temperature. The water layer was further extracted twice with ether, and the solvent was evaporated to yield 0.67 g of **18**. The combined crystals were recrystallized twice from a mixture of benzene and petroleum ether and once from benzene ; mp 117 °C. The mother solution containing crude product was chromatographed on a silica gel column by using chloroform as an eluent. The crystals obtained from the first fraction were recrystallized from petroleum ether to give an analytical sample, mp 118—120 °C. IR: 1745 broad(CO), 1610, 1560, 1500(-C=C-), 1405, 1360, 1188, 1178, 1132, 895, 883, 805; UV: λ_{max} 230 sh(3.75), 305sh(3.66), 317(3.74), 330(3.71), 380(3.85); ^{13}C NMR: see Table 1. Found: C, 28.30; H, 0.07%. Calcd for $C_8Cl_6O_2$: C, 28.20%.

Reaction of ***6*** *with Fuming Nitric Acid; Hexachloro-2-allylidene-4-cyclopentene-1,3-dione (****11****).* A mixture of 10 g (2.2×10^{-2} mol) of **6** and 30 ml of fuming nitric acid(d=1.53) was placed in a 100 ml Erlenmeyer flask equipped with a

magnetic stirring bar and a thermometer. The stirred mixture was heated on a hot plate. The temperature went up to 55 °C after 5 min, and the nitric acid began to reflux after 10 min. The homogeneous reaction mixture obtained by heating for 12 min was poured onto ice–water to precipitate a light yellow oily product. The organic materials were taken up in carbon tetrachloride and dried over sodium sulfate, and the solvent was evaporated on a rotary evaporator at room temperature. The residue (7.1 g) crystallized on standing at room temperature. Washing twice with methanol gave an analytical sample. Mp 88—92 °C; IR: 1710 (>CO), 1630, 1590 (–C=C–); UV: λ_{max} 230sh (4.16), 248(4.32), 255.5(4.32), 267sh(4.21), 277sh(4.16), 288sh(4.05), 300sh(3.84), 330sh(3.33); ^{13}C NMR: see Table 1. Found: C, 27.93; Cl, 61.66%. Calcd for $C_8Cl_6O_2$: C, 28.20; Cl, 62.42%.

Reaction of ***11*** *with Methanol.* A mixture of 4.03 g (1.18×10^{-2} mol) of **11** and 15.0 ml of anhydrous methanol was heated to gentle reflux for 2 h. The solution was concentrated under vacuum, affording a mixture of sticky oily substance and crystals. Washing the mixture with methanol yielded 0.82 g of white crystals of **12**. Recrystallization twice from petroleum benzine gave an analytical sample. Mp 110—111.5 °C; IR; 1740, 1710(>CO), 1640, 1595(–C=C–), 1450, 1310, 1250; UV: λ_{max} 218—220 (4.13), 285(4.06); ^{13}C NMR: see Table 1. Found: C, 36.55; H, 2.75%. Calcd for $C_{11}H_{10}Cl_4O_5$: C, 36.30; H, 2.70%.

Reaction of ***12*** *with Methanolic Hydrochloric Acid.* A mixture of 3 ml of methanol, 3 ml of concd hydrochloric acid, and 0.264 g (7.95×10^{-4} mol) of **12** was heated to reflux with stirring for 2 h. The reaction mixture was allowed to stand at room temperature, giving colorless needles, which were collected by filtration. Sublimation under reduced pressure gave 81 mg of a pure sample of **13**, mp 167—168 °C, which was identified as the authentic sample by means of infrared spectra.

Thermal Reaction of ***11*** *: Hexachloro-2,5-dihydrocyclopenta*[b]*pyran-5-one (****14****).* A solution of 2.5 g (7.3×10^{-3} mol) of **11** in 25 ml of carbon tetrachloride was heated to reflux for 1.25 h, to give a deep red solution. Evaporation of the solvent and recrystallization of the residue from petroleum benzine afforded an analytical sample. Mp 96.5—100 °C; IR: 1745(>CO), 1620, 1575, 1510(–C=C–), 1250, 1180, 1145, 1100; UV: λ_{max} 254 (4.11), 302 (3.76), 445 (2.97); ^{13}C NMR: see Table 1. Found: C, 28.51; H, 0.15; Cl, 62.40%. Calcd for $C_8Cl_6O_2$: C, 28.20; Cl, 62.42%.

Reaction of ***12*** *with Anhydrous Methanol.* When 10 ml of absolute methanol was added to 2.053 g of **12**, an exothermal reaction took place immediately, giving a yellow precipitate. The crude product (0.20 g) was separated by filtration and recrystallized from ethyl acetate. Mp 245—246 °C; IR : 1755, 1730, 1725 sh (>CO), 1645, 1575 (–C=C–), 1445, 1390, 1290, 1270; Mass: *m/e* 667.7243 (M^+, 31.4), 333.8522 (100); Found: C, 32.13; H, 0.92%. Calcd for $C_9H_3Cl_5O_3$: C, 32.14; H, 0.90%.

Reaction of ***14*** *with Concd Sulfuric Acid.* To a solution of 100 mg (2.93×10^{-4} mol) of **14** in 1 ml of carbon tetrachloride was added 4 ml of 90% sulfuric acid, and the mixture was vigorously stirred with a magnetic stirrer for 6 h at room temperature. After the addition of water, the organic product was separated and extracted with carbon tetrachloride. The combined solution was washed with water and dried over sodium sulfate. Evaporation of the solvent left 96 mg of crude **15**, which gave 45 mg of pure **15** by washing with a small amount of petroleum ether.

Reaction of ***6*** *with Sulfuric Acid : Hexachloro-2,5-dihydrocyclopenta*[b]*pyran-2,5-dione (****15****).* To a mixture of 20 ml of 98% sulfuric acid and 90 g of 20% fuming sulfuric acid was added 32.0 g (7.1×10^{-2} mol) of powdered **6**, whereupon a mild exothermal reaction took place and the mixture changed from dark green to brownish red during 3 h stirring. The mixture was stirred for an additional 45 h at room temperature, and poured onto ice. The precipitated brown solid was isolated by vacuum filtration and washed with water. After being dried overnight, the crude product was 25.5 g in weight. Carbon tetrachloride (200 ml) was added to the powdered product and the suspension was heated to reflux for a short time. Insoluble white crystals were separated by vacuum filtration, and the mother solution was concentrated. The addition of petroleum ether to the solution afforded dark reddish-brown crystals of **15**. Compound **15** dimerizes at approximately 180 °C without melting. IR : 1750 sh, 1730 (>CO), 1625, 1570, 1510 (–C=C–), 1390, 1340, 1160, 1130; UV: λ_{max} 228 (4.16), 332 (3.93), 240 sh (4.04), 488 (2.72); Mass: *m/e* 284 (M^+, 16.2), 256 (19.9), 221 (18.0), 200 (3.9), 193 (4.5), 165 (20.6), 87 (54.4), 43 (100); Found: C, 33.33; H, 0.23; Cl, 49.12%. Calcd for $C_8Cl_4O_3$: C, 33.61; Cl, 49.60%.

The product, which was insoluble in hot carbon tetrachloride, was extracted with 300 ml of benzene by the use of Soxhlet apparatus. The crystals which appeared in the benzene extract were removed by filtration and separated into two parts, powdery crystals **23** and rather big crystals **24**, according to their crystal shape. Compound **23**; mp 337 °C dec; IR: 1788, 1735, 1612, 1535, 1380, 1312, 1195; Found: C, 33.69; H, 0.37; Cl, 50.48%. Calcd for $C_8Cl_4O_3$: C, 33.61; Cl, 49.60%. Compound **24**; 335 °C dec; IR: 1790, 1750, 1617, 1532, 1380, 1310, 1195; Found: C, 33.04; H, 0.22; Cl, 49.60%. Calcd for $C_8Cl_4O_3$: C, 33.61; Cl, 49.60%. Mass: *m/e* 568 (M^+, 5.3), 533 (5.3), 505 (8.6), 371 (18.0), 343 (18.4), 284 (100), 256 (15.8).

Thermal decomposition of **23** was carried out under vacuum in a sublimation apparatus, and reddish brown crystals of **15** were collected on the cold finger condenser. Recrystallization of the product from a mixture of chloroform and petroleum benzine gave a mixture of **23** and **15**.

Reaction of ***15*** *with Diazomethane: 4,5,8,9-Tetrachloro-2-oxatricyclo*[$4.3.1.0^{1,6}$]*deca-4,8-diene-3,7-dione (****25****).* The ether solution of diazomethane, which had been prepared from 5.0 g of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide according to the conventional method,[24] was added to a suspension of 0.5 g (1.75×10^{-4} mol) of **15** in 5 ml of ether until the red solution became orange. About 1/3 of the diazomethane solution was needed. Excess diazomethane was decomposed with acetic acid, and the reaction mixture was worked up in the usual way. Evaporation of the solvent left a sticky light brown material, which was taken up in 3 ml of benzene, and the solution was chromatographed on a column (12 mm × 12 cm) of silica gel by using benzene. The benzene of the eluate was evaporated under vacuum, and the residue was recrystallized twice from a benzene-petroleum ether mixture. Yield: 0.22 g; IR: 3085 (–CH_2–), 1760, 1730(>CO), 1610, 1590(–C=C–), 1360, 1310, 1030; UV: λ_{max} 257 (4.08); ^{13}C NMR: see Table 1. ^{1}H NMR: ($CDCl_3$) 2.23 (d), 2.70 (d), $|J_{AB}|$=6.1 Hz. Mass: *m/e* 297.8749 (M^+, 34.0), 269.8806 (M^+—CO, 32.5), 262.9078 (M^+—Cl, 49.3), 51 (100); Found: C, 35.83; H, 0.90%. Calcd for $C_9H_2Cl_4O_3$: C, 36.04; H, 0.67%.

The authors wish to express their thanks to Dr. Takashi Tokuyama of Osaka City University for obtaining the mass spectra. We also would like to thank Mr. Junichi Goda for the elemental analysis

of carbon, hydrogen, and nitrogen. The present work was partially supported by a Grant-in-Aid for Public Universities from the Ministry of Education.

Nitrogen Compounds in Petroleum. IV. Distribution Profiles of Nitrogen Compounds in Petroleum by Solid-Liquid Chromatography†

Akira NOMURA,* Yazaemon MORITA, and Yukitoshi KOGURE

Department of Analytical Chemistry, National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received July 7, 1978)

A simple method for the characterization of nitrogen compounds in petroleum products by the investigation of the distribution profiles of nitrogen compounds using stepwise gradient elution on silica gel has been conducted. Samples were charged onto a $8\phi \times 150$ mm glass column containing 3 g of silica gel for column chromatography, followed by 15 ml of hexane to remove the non-polar bulk hydrocarbons from the sample. The eluate collected was removed from the solvent and analyzed for nitrogen, wt % yield and UV absorbance at 220 nm. The same procedure was followed by each 15 ml of 1, 3, 5, 10, 30, 60, 100%(v/v)-THF in hexane eluents. Plots of the nitrogen contents *vs.* the concentration of eluents gave characteristic patterns for petroleum distillates. The crude and residual oils from different geological sources exhibit similar nitrogen distribution profiles. There are two peak values; the peak at 3%-THF increases and that at 30%-THF decreases as the boiling range of the distillate decreases. Nitrogen compounds are distributed uniformly in a wide range of polar components with regard to adsorptivity on silica gel. The method was further applied to the reaction products of quinoline and indole by irradiation with UV light in isooctane (2,2,4-trimethylpentane) solution.

Organic nitrogen compounds in petroleum distillates poison many of the catalysts used in refining processes and cause undesirable deposits, color formation, odor, and poor storage properties. In addition, the nitrogen compounds produce on combustion fairly large amounts of nitrogen oxides (fuel NO_x), one of the sources of air pollution. Further knowledge of these nitrogen compounds should prove useful for the development of processes for their removal and of additives for their control.

Several studies have been made on the nature of nitrogen compounds in petroleum and several separation and identification schemes have been reported. Recently Snyder *et al.*[1-4] systematically studied nitrogen compounds in various petroleum distillates using liquid-solid chromatography combined with UV, IR, and mass spectrometry. Although it is desirable to isolate individual nitrogen compounds from petroleum distillates for the necessary identification by UV, IR, mass spectrometry *etc.*, the isolation is quite difficult in the cases of heavy oils, residual oils, and crude oils, since many nitrogen compounds are present and in small amounts. Therefore it is useful in practice to characterize and classify the nitrogen compounds, not each of them, in crude oil or high-boiling petroleum distillates. Potentiometric titration using perchloric acid has been applied in the characterization of basic nitrogen compounds in petroleum products.[5-8] Linear elution adsorption chromatography[9-12] has been investigated for both basic and non-basic nitrogen compounds by Snyder and Buell, and has proved a useful method for the characterization of nitrogen compounds. In previous papers, a concentration method for nitrogen compounds in various petroleum distillates using a silica gel adsorption technique and a method for the determination of trace nitrogen by Dumas method combined with a silica gel adsorption technique have been presented.[13,14]

This paper describes a simple method for the characterization of nitrogen compounds in petroleum distillates by distribution profiles of nitrogen contents in various petroleum distillates or crude oils using stepwise gradient elution, hexane–tetrahydrofuran (THF) as the eluent on a column of silica gel. The profiles of wt % yield and UV absorbance of eluate have also been determined and compared with the nitrogen contents. This method has been applied in the identification of the reaction products of quinoline and indole by the irradiation with UV light in isooctane solution. The method applies to the analysis of the mechanism in the denitrogenation[16] and characterization of coal liquefaction products and shale oils.

† A preliminary report of this work was presented at the 36th National Meeting of the Chemical Society of Japan, Osaka, April 1977.

Experimental

Reagents. Wako's hexane for liquid chromatography was used. Silica gel used was Wako C-200 for column chromatography (pore diameter : 70 Å). Other reagents were of reagent grade.

Apparatus. Hitachi type 356 double beam spectrophotometer was used to obtain UV absorbance. Nitrogen contents were obtained by either Kjeldahl method[15] or microcoulometric titration (Mitsubishi Kasei Model TN-01). Toshiba H400-PQ high pressure mercury lamp was used for the UV irradiation.

Procedure. Silica gel (3 g) for column chromatography was packed in a $8\phi \times 150$ mm glass column with a quartz wool plug at one end by the dry packing technique in tapping manner. The filled column (approximately 10 cm in length) was capped with quartz wool. The sample containing the nitrogen compounds (approximately 1 mg as N), diluted with isooctane, if necessary, was added into a separating funnel used as both a sample and eluent reservoir which was attached to the top of the column. A vacuum was applied and the sample was charged into the column by opening the stopcock of the reservoir. After loading of the sample, 15 ml of hexane was added to remove the non-polar bulk hydrocarbons from the sample, leaving all polar components including the nitrogen compounds adsorbed on the silica gel. An eluent flow rate of 5 ml/min or less was maintained through the elution. The eluate was collected in a suction bottle and solvent removed over a water bath. Quartz wool with solid components (asphaltenes) was removed from the column. The eluent was changed from hexane to 1%(v/v)-THF in hexane (15 ml) and the same procedure performed, followed

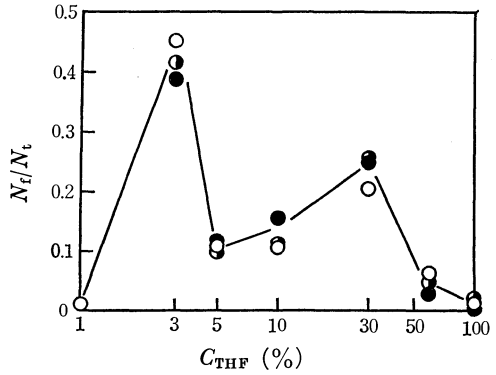

Fig. 1. Distribution profiles of nitrogen contents in crude oils. C_{THF}: Concentration of THF in hexane, N_f/N_t: relative nitrogen ratio (N_f: nitrogen in fraction, N_t: total nitrogen), ○: Kurokawa (Japan), ●: Duri (Indonesia), ◑: Shori (China).

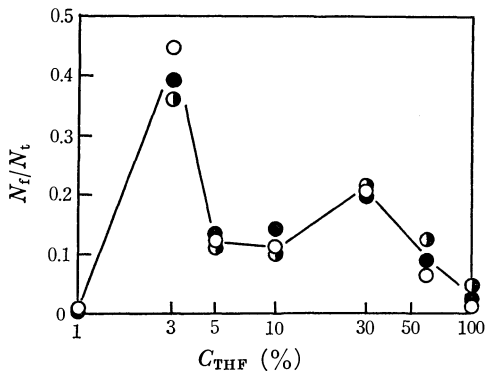

Fig. 2. Distribution profiles of nitrogen contents in residual oils. ○: Kurokawa (Japan), ●: Iranian light (Iran), ◑: Arabian heavy (Saudi Arabia).

by 15 ml of 3, 5, 10, 60, 100% (v/v)-THF in hexane eluents. Each fraction removed from the solvent was weighed and a portion used for the determination of the nitrogen content and another dissolved in THF for the determination of UV absorbance.

Results and Discussion

The silica gel pore diameter used for adsorption and separation of petroleum distillates with a wide boiling range has been investigated in detail previously.[13] A pore diameter ranging from 60 to 100 Å proved to be suitable. The silica gel used here was Wako gel C-200 with a pore diameter of 70 Å. The hexane–THF eluent system was selected because THF is one of the best solvents for petroleum and also the low boiling temperature enables simpler fractionation.

Distribution Profiles of Crude and Residual Oils. The distribution profiles for the nitrogen contents in three different geological crude and residual oils are shown in Figs. 1 and 2, respectively. The three different oils, both crude and residual, show almost the same patterns with regard to nitrogen content, and the patterns of the crude and residual oils are also the same, while the absolute nitrogen contents for each petroleum differ. The similarity in pattern between the crude and residual oils is expected since most nitrogen compounds exist in high-boiling distillates.

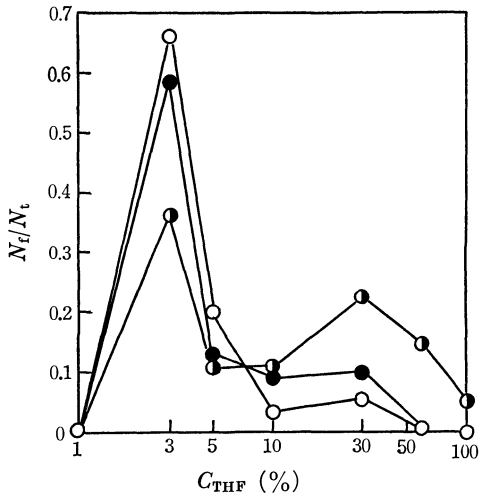

Fig. 3. Distribution profiles of nitrogen contents in different distillates.
Boiling range; ○: 170—340 °C, ●: 340—520 °C, ◑: 520 °C— tower bottom.

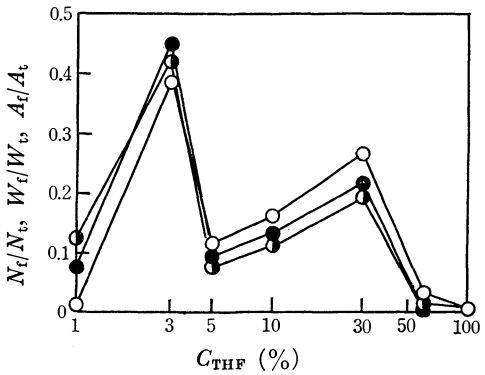

Fig. 4. Distribution profiles of polar components in crude oil. W_f/W_t: Relative weight ratio (W_f: weight of fraction, W_t: total weight), A_f/A_t: relative absorbance ratio (A_f: absorbance of fraction, A_t: total absorbance), ○: nitrogen, ●: weight, ◑: UV absorbance at 220 nm.

The two peak values (at 3 and 30%-THF eluents) are characteristic of crude and residual oils and the pattern is thought characteristic of all high-boiling distillates regardless of the fact that they come from different geological sources.

Distribution Profiles of Different Distillates. Distribution profiles for the nitrogen contents in three different distillates (boiling range : 170—340 °C, 340—520 °C, 520 °C— tower bottom) from the same sample of crude oil are shown in Fig. 3. As the boiling range of the distillate decreases, the nitrogen content at 3%-THF increases and that at 30%-THF decreases. This tendency is similar to the distillates from other crude oils. By examining the distribution profiles, the approximate boiling range can be estimated.

Distribution Profiles of Polar Components. Polar components in petroleum such as oxygen and sulfur compounds (except nitrogen compounds) are also adsorbed on silica gel and eluted with hexane–THF eluent. The relationship between the nitrogen compounds and polar compounds was investigated with

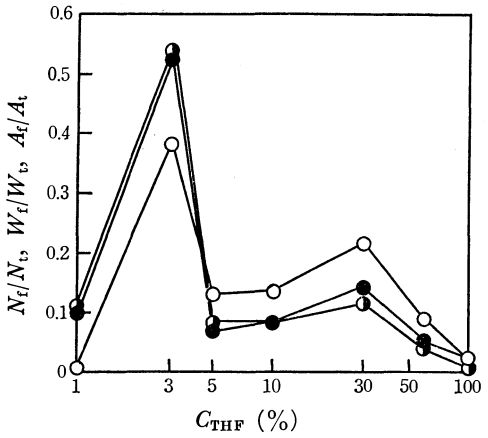

Fig. 5. Distribution profiles of polar components in residual oil. ○: Nitrogen, ●: weight, ◑: UV absorbance at 220 nm.

regard to nitrogen content, wt % yield and UV absorbance in THF at 220 nm. Since practically all fractions eluted with more than 3% THF concentration have a UV absorbance plateau between 215 and 230 nm, the absorbance at 220 nm was selected to characterize the polar components. Figures 4 and 5 indicate the relationship for crude and residual oils, respectively. The other crude and residual oils investigated exhibited similar relationships. Nitrogen compounds are considered to be distributed rather uniformly in a wide range of polar components with regard to adsorptivity on silica gel because of the good correlation among the three distribution profiles.

Application to Irradiated Products. The proposed method for the characterization of petroleum distillates was applied to the reaction products of quinoline and indole by irradiation with UV light in isooctane solution. Many reagents involving nitrogen have been examined in order to obtain standard samples for the calibration of the instrument determining nitrogen in petroleum. During the process heterocyclic nitrogen compounds were irradiated with UV light and the distribution profiles of nitrogen contents in the products were examined, the results of which are shown in Figs. 6 and 7 for quinoline and indole, respectively. Before irradiation most quinoline and indole are eluted with 10%- and 5%-THF, respectively, so the profiles are represented by single peak without a shoulder. The pattern of quinoline changed as the time of irradiation increased, and after 3 h the pattern of the products became similar to that for a typical crude oil. The pattern for indole remained rather unchanged after irradiation. It should not be concluded from the results that nitrogen compounds in crude oil are similar to the irradiated products of quinoline but the proposed method has been shown useful for the characterization of complicated products.

Dechlorination of Polychlorinated Biphenyls by UV-irradiation. V. Reaction of 2,4,6-Trichlorobiphenyl in Neutral and Alkaline Alcoholic Solution

Tohru NISHIWAKI,* Masao USUI, Kinji ANDA, and Mitsuhiko HIDA†

Organic Division, Tokyo Metropolitan Industrial Technology Center, Nishigaoka, Kita-ku, Tokyo 115

† *Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158*

(Received July 11, 1978)

2,4,6-Trichlorobiphenyl and seven other chlorobiphenyls have been photolyzed in both alkaline and neutral 2-propanol in order to investigate the reactivity and selectivity towards dechlorination. Predominant dechlorination at the 2-position has been confirmed for all PCBs in neutral solution and interpreted in terms of the steric and electronic effects of the phenyl group. In the presence of alkali, however, competitive elimination between the ortho and para chlorine atoms of 2,4-dichlorobiphenyl and 2,4,6-trichlorobiphenyl occurred. The photo-dechlorination of 2,3- and 2,5-dichlorobiphenyls took place however only at the ortho position. The dechlorination ratios (ortho/para) were 7.5 and 0.8 for 2,4-dichlorobiphenyl and 2,4,6-trichlorobiphenyl, respectively. This characteristic of the ortho chlorine atom has been elucidated assuming the steric and electronic effects of the phenyl group in the radical anion. A correlation has been found between the reduction potential and the reactivity of PCB in alkaline solution. The differences in reactivity among the chlorobiphenyls has been attributed to the electron acceptabilities in the ground states.

The authors have reported that a commertial PCB mixture (KC-300) dissolved in 2-propanol was successfully decomposed by ultraviolet radiation to biphenyl in the presence of sodium hydroxide,[1] the reaction proceeding rapidly by the chain degradative mechanism.[2–4] Some chlorobiphenyls, however, *e.g.* 2-chlorobiphenyl and 2,6-dichlorobiphenyl (2-CB and 2,6-DCB),[5] decomposed only slightly by the photolysis in alkaline solution and were detected in solution after other chlorobiphenyls had been completely decomposed to biphenyl.[4] In neutral alcoholic solutions the chlorine atom at the ortho position of tetrachlorobiphenyls was much more readily eliminated than at other positions.[6,7] No investigation has been undertaken on the difference in reactivities found among chlorobiphenyl homologues.

In the present study eight chlorobiphenyls (2-CB, 3-CB, 4-CB, 2,3-DCB, 2,4-DCB, 2,5-DCB, 2,6-DCB, and 2,4,6-TCB) have been photolyzed in both alkaline and neutral 2-propanol solutions in order to investigate the behavior of the ortho chlorine atom in detail.

Experimental

GLC analysis was conducted on a JEOL 20-K gas chromatograph with a flame ionization detector employing a 2 m × 3 mmϕ stainless steel column packed with 10% SE30 on 80—100 mesh chromosorb A (HMDS) or 15 m × 1 mmϕ glass capillary column with OV-101 (Chromato Research Co.). Preparative liquid chromatography was performed with a JAI LC-08 employing a 600 mm × 20 mmϕ stainless steel column packed with JAIGEL-1H; chloroform was used as the eluting solvent. Infrared spectra were obtained on a JASCO DS-701G spectrometer and mass spectra recorded at 24 eV on a JEOL Model D-100 mass spectrometer equipped with a gas chromatograph. UV spectra were taken with a Union Giken SM-401 spectrophotometer and melting points determined on a Yanagimoto micro melting apparatus.

Materials. The following reagents of special and guaranteed grade were used without further purification: 2,6-DCB (Nihon Chromato Co.), chloroanilines, 2-propanol and benzene (Wako Junyaku Co.). Isopentyl nitrite (Tokyo Kasei Co.) was distilled under a nitrogen atmosphere. 2-CB, 3-CB, 4-CB, 2,3-DCB, 2,4-DCB, 2,5-DCB, and 2,4,6-TCB were prepared by a modification of Cadogan's method,[8] the crude CBs being chromatographed over a silica-gel column using hexane as an eluent, and recrystallized from ethanol, ethanol-water, or petroleum ether. The melting points and UV spectra showed good agreement with the literature.[9] The purity was further checked by gas chromatography (>98%).

Irradiation Experiments. A solution of chlorobiphenyl (15 mmol/dm^3) and sodium hydroxide (30 mmol/dm^3) if necessary, in 2-propanol was photolyzed under the following conditions:

Procedure 1: After the solution (4.5 ml) in a quartz reaction cell was bubbled with purified nitrogen for 5 min, the cell was sealed and placed in a water bath kept at 30 °C. The solution was then irradiated through an interference filter (Nihon Shinku S50ϕ, 298 nm) with a 250 W high pressure mercury lamp (Ushio USH-250).

Procedure 2: A solution (400 ml) was photolyzed in a photochemical reaction vessel with an immersed 100 W high pressure mercury lamp (Ushio UM-102) without a filter under a stream of nitrogen at 30 °C.

Dechlorination Products. Irradiation of chlorobiphenyls gave low chlorinated biphenyls and biphenyl in both neutral and alkaline 2-propanol. 2,4,6-TCB gave, however, a biphenyl derivative having an alcoholic hydroxyl group together with the ordinary dechlorinated products in the alkaline solution. After evaporation of the solvent the residue was dissolved in chloroform. Preparative column chromatography and subsequent recrystallization from ethanol gave white needle crystals (mp 160—161 °C). NMR ($CDCl_3$), phenyl protons (δ 7.5—7.2, 7H, m), hydroxyl proton (δ 1.80, 1H, s), methyl protons (δ 1.60, 6H, s); IR (KBr), hydroxyl group (ν_{OH}, 3300 cm^{-1}, polymeric; ν_{C-O}, 1157 cm^{-1}, tertiary), methyl group (δ_{CH_3}, 1380, 1365 cm^{-1}; $\nu_{(CH_3)_2C}$, 1195 cm^{-1}, skelctal); MS (*m/e*), 282 (M^++2), 280 (M^+), 267 (M^+-CH_3), 262 (M^+-H_2O). On the basis of this data the compound has been identified as *xx'*-dichloro-*y*-(1-hydroxy-1-methylethyl)biphenyl. The substituted position in

the phenyl ring cannot be clarified from this data. When the alkaline solutions of 2,6- and 2,4-DCB were photolyzed, however, 2,4-DCB afforded an alcohol in a small amount while 2,6-DCB did not and from this, 2,6-dichloro-4-(1-hydroxy-1-methylethyl)biphenyl (**1**) was considered to be formed in the photolysis of 2,4,6-TCB. On irradiation in alkaline solution **1** was both dechlorinated and dehydrated and gave the following compounds; 2-chloro-4-isopropenylbiphenyl (**2**), MS (*m/e*), 230 (M^++2), 228 (M^+), 193 (M^+−Cl); 4-isopropenylbiphenyl (**3**), MS (*m/e*), 194 (M^+), 179 (M^+-CH_3), 153 ($M^+-C(CH_3)=CH_2$).

Results and Discussion

Dechlorination of CBs in Neutral Solution. The photolysis of 2,4,6-TCB in 2-propanol gave 2,4-DCB, 4-CB, and biphenyl as shown in Fig. 1. Elimination occurred predominantly at the ortho position, and indeed no para dechlorinated products, *e.g.* 2,6-DCB or 2-CB, were found in the photolyzed solution. This prominent feature of the ortho chlorine atom was also observed in the photolysis of other chlorobiphenyls as follows. The photo-products of 2,3-DCB, 2,4-DCB, and 2,5-DCB were 3-CB, 4-CB, and 3-CB, respectively. 2-CB showed an outstanding reactivity among the monochlorobiphenyls and all results indicate a preference for elimination at the ortho chlorine atom in the neutral solution. The selectivities of the dechlorination are summarized in Table 1. The results in neutral solution are understandable bearing in mind the steric and the electronic effects of the phenyl group. Since biphenyl is known to have a planar structures in the excited state,[10] involving a high degree of conjugation between the two phenyl rings, the ortho chlorinated biphenyl would be largely unstable in the excited state. Therefore, the departure of the chlorine atom from the ortho position stabilizes the conjugation system. Ruzo *et al.*,[6,7] on the basis of the photolysis of tetrachlorobiphenyls in neutral solution, concluded that the marked elimination of the ortho chlorine atom was caused by both electronic and steric effects of the phenyl group, especially the latter.

Table 1. Dechlorination of CBs[a]

Compound	Positional selectivity (%)		
	Neutral	Alkaline	
2,3-DCB	100 (ortho)	100 (ortho)	
2,4-DCB	100 (ortho)	88 (ortho)	12 (para)
2,5-DCB	100 (ortho)	100 (ortho)	
3,4-DCB	100 (meta)	100 (para)	
2,4,6-TCB	100 (ortho)	44 (ortho)	56 (para)

a) Photolysis was carried out by Procedure 1.

Dechlorination of CBs in the Presence of Alkali. In the presence of alkali the competitive elimination of the ortho and para chlorine atoms of 2,4,6-TCB occurred as indicated in Fig. 2. The primary products were 2,4-DCB and 2,6-DCB, and further irradiation resulted in the formation of 4-CB and 2-CB from 2,4-DCB. The photo-dechlorination of 2,3- and 2,5-DCBs took place only at the ortho position, even in the presence of alkali. The reactivities of 2,6-DCB and 2-CB were, however, much lower than that of 2,4-DCB and 4-CB. The selectivities of the dechlorination reaction in the presence of alkali are compared in Table 1. Thus the ortho chlorine atom was not predominantly eliminated, in contrast to the prominent feature in the neutral solution.

The following chain mechanism, proposed for the photoreaction of PCBs,[2-4] appears to help the understanding of the reactivity of ortho chlorinated biphenyls.

$$PCB(n) \xrightarrow{h\nu} PCB(n-1,j)\cdot + Cl\cdot \quad (1)$$

$$Cl\cdot + (CH_3)_2CHOH \longrightarrow HCl + (CH_3)_2\dot{C}OH \quad (2)$$

$$(CH_3)_2\dot{C}OH + (CH_3)_2CHO^- \longrightarrow (CH_3)_2CO^{\cdot-} + (CH_3)_2CHOH \quad (3)$$

$$(CH_3)_2CO^{\cdot-} + PCB(n) \xrightarrow{k_{red}} (CH_3)_2CO + PCB(n)^{\cdot-} \quad (4)$$

$$PCB(n)^{\cdot-} \xrightarrow{k_{el}(i)} PCB(n-1,i)\cdot + Cl^- \quad (5)$$

$$PCB(n-1,i)\cdot + (CH_3)_2CHOH \longrightarrow PCB(n-1,i) + (CH_3)_2\dot{C}OH \quad (6)$$

$$2(CH_3)_2\dot{C}OH \longrightarrow \text{Termination} \quad (7)$$

$PCB(n)$; n is the number of chlorine atoms substituted in the phenyl ring.
$PCB(n-1,i)\cdot$; CB radical formed by the chlorine elimination at the i-position.
$k_{el}(i)$; the rate constant of the chlorine elimination at the i-position of $PCB(n)^{\cdot-}$.

The radical anion of PCB would afford $PCB(n-1,i)\cdot$ by elimination of the chloride ion. Assuming steady state conditions for the CB radical $PCB(n-1,i)\cdot$, the rate of dechlorination may be written:

$$d[PCB(n-1,i)]/dt = k_{el}(i)[PCB(n)^{\cdot-}], \quad (8)$$

where, Reaction 1[11] is assumed negligible compared with Reaction 5, since the chain length is expected to be large in alkaline solution : the quantum yield at 298 nm for KC-300 has been determined to be 36 in alkaline solution and 0.09 in neutral solution.[12] Then the relative rate constant for dechlorination at the i-position to that at the j-position is given by

$$[PCB(n-1,i)]/[PCB(n-1,j)] = k_{el}(i)/k_{el}(j). \quad (9)$$

The value $k_{el}(i)/k_{el}(j)$ can be evaluated by the amount of two daughter CBs derived from the parent PCB. As considered above the chlorine atom at the ortho position was selectively eliminated in the photolysis. Therefore similar acceleration due to the steric effect of the phenyl group as observed in the neutral solution can be expected in the dechlorination of $PCB(n)^{\cdot-}$ to yield $PCB(n-1, i)\cdot$.

Photolysis of 2,4-DCB in Alkaline Solution: 2,4-DCB produced 2-CB and 4-CB by photolysis followed by degradation to biphenyl as shown in Table 2. These reactions proceeded simultaneously so that the concentration ratio [2-CB]/[4-CB] in the photolyzed solution did not give the true ratio of daughter CBs derived from 2,4-DCB. Therefore, in order to obtain the true value of $k_{el}(i)/k_{el}(j)$ it is necessary to find the respective rates of 4-CB and 2-CB to yield biphenyl. Assuming steady state conditions for $[2\text{-}CB^{\cdot-}]$, $[4\text{-}CB^{\cdot-}]$, [Biph(2-CB)$\cdot$], and [Biph(4-CB)$\cdot$], the rate of biphenyl formation attributed to 4-CB is given by

$$\frac{d[Biph(4\text{-}CB)]}{dt} = -\frac{d[4\text{-}CB]}{dt}, \quad (10)$$

$$\frac{d[Biph(4\text{-}CB)]}{dt} = \frac{d[Biph]}{dt}\cdot\frac{(k_{red}(4)/k_{red}(2))[4\text{-}CB]}{(k_{red}(4)/k_{red}(2))[4\text{-}CB]+[2\text{-}CB]}, \quad (11)$$

Table 2. Decomposition of 2,4-DCB in alkaline alcoholic solution[a,b]

Conversion of 2,4-DCB %	Biph	2-CB	4-CB	Biph+4-CB	(Biph+4-CB)/2-CB[c]
		c/mmol dm^{-3}			
6.4	0.14	0.13	0.70	0.84	6.5
7.0	0.17	0.17	0.76	0.93	6.1
16.5	0.94	0.25	1.32	2.25	9.0
39.3	1.97	0.77	3.23	5.20	6.8
49.3	3.70	0.93	2.87	6.57	7.1
61.4	5.23	1.13	2.98	8.21	7.3
72.0	8.02	1.17	1.75	9.78	8.4
72.2	8.40	1.16	1.42	9.82	8.5

a) Initial concentration of 2,4-DCB; 15.2 mmol/dm^3. b) Photolysis was carried out by Procedure 1. c) $((Biph+4\text{-}CB)/2\text{-}CB)_{av} = 7.5\pm1.0$.

where, [Biph(4-CB)] and [Biph] represent the concentration of biphenyl derived from 4-CB and the biphenyl concentration in the photolyzed solution, respectively. The formation rate of Biph(2-CB) can also be written by similar equations. Combination of these four equations results in Eq. 12, by which the $k_{red}(4)/k_{red}(2)$ can be determined.

$$\frac{\ln([4\text{-}CB]_0/[4\text{-}CB])}{\ln([2\text{-}CB]_0/[2\text{-}CB])} = k_{red}(4)/k_{red}(2) \quad (12)$$

4-CB and 2-CB were consequently decomposed competitively in alkaline solution in order to evaluate the left hand side of Eq. 12, the results of which are summarized in Table 3. The average value of 17.2± 4.5 suggests that 4-CB is far more reactive than 2-CB. Table 2 indicates that the concentration of 4-CB is always higher than that of 2-CB by a factor of 1.2 to 5.1. Consequently the following inequality can be assumed:

$$(k_{red}(4)/k_{red}(2))[4\text{-}CB] \gg [2\text{-}CB].$$

Resolving Eq. 11 under these conditions gives the simple relation ; [Biph(4-CB)]=[Biph]. This indicates that all biphenyl can be assumed to be derived from 4-CB, and that 2-CB makes a negligible contribution to the biphenyl formation. Thus the true amounts of 4-CB and 2-CB produced by the dechlorination of the radical anion $2,4\text{-}DCB^{\cdot-}$ are [Biph]+[4-CB] and [2-CB], respectively. These concentrations were then utillized to calculate the value of $k_{el}(2)/k_{el}(4)$ using Eq. 9. As Table 2 shows, in the dechlorination of $2,4\text{-}DCB^{\cdot-}$ the chlorine at the ortho position is more easily eliminated by a factor of 7.5± 1.0 than that at the para position, a result explainable on the assumption of the steric acceleration effect of the phenyl group.

Photolysis of 2,4,6-TCB in Alakline Solution: 2,4,6-TCB gave 2,4-DCB, 2,6-DCB, and compound **1**. These compounds were negligibly dechlorinated during the photolysis so that any further reduction of the compounds was neglected in the calculation of Eq. 9. As compound **1** has a 1-hydroxy-1-methylethyl group at position 4, the true ratio of daughter compounds derived from 2,4,6-TCB will be given by [2,4-DCB]/([2,6-

Table 3. Competitive dechlorination of 2-CB and 4-CB in alkaline alcoholic solution[e]

44.1	1.03	4.14	1.10	1.94

a) Initial concentration of 2,4,6-TCB were 15.7—13.7 mmol/dm^3. b) Photolysis was carried out by Procedure 1. c) $(2,4\text{-DCB}/(2,6\text{-DCB}+\mathbf{1}))_{av}=1.6\pm0.1$.

DCB]+[**1**]), the experimental results of which are shown in Table 4. The value of 1.6±0.1 was obtained as the average ratio from eight measurements. The $k_{el}(2)/k_{el}(4)$ is thus 0.8 since the elimination at the 2-, and 6-position of 2,4,6-TCB are equivalent. Contrary to expectations this indicates that the para chlorine atom is more active than the ortho chlorine atom. The explanation for this result is as follows. Since the presence of the chlorine atom at position 6 disturbs the release of the dihedral angle between the two phenyl rings by the dechlorination at position 2, the steric acceleration effect by the phenyl group cannot markedly affect the dechlorination.

Photolysis of 3,4-DCB. 3,4-DCB was dechlorinated exclusively at position 4 in the presence of alkali. Since this elimination cannot be explained only by the steric effect of the phenyl group, the electronic effect must be considered. As shown in Table 1 the elimination of para chlorine atom was also observed in the alkaline solution of 2,4-DCB and 2,4,6-TCB. From these results it has been assumed that the para position of PCB$^{\cdot-}$ is activated by the electronic effect.

In neutral solution 3,4-DCB did not eliminate the para chlorine atom and similar inactivity in the para position has been observed in 2,4-DCB and 2,4,6-TCB. This shows a remarkable contrast to the alkaline reaction. In the photolysis of 3,4-DCB only the meta chlorine atom was eliminated but 2,3-DCB and 2,5-DCB did not eliminate the meta chlorine. This suggests that the para chlorine atom may be stabilized by the electronic effect of the phenyl group in the photo-excited state, but that the steric acceleration effect is far more important than the electronic effect in the dechlorination at the ortho position from the photo-excited CB.

Relative Reactivities of PCBs in the Presence of Alkali. Successive dechlorination of 2,4,6-TCB produced 2,4-DCB, 2,6-DCB, 4-CB, and finally biphenyl in the presence of alkali as shown Fig. 2. Consequently the ease of dechlorination is expected to increase in the order : 2,4,6-TCB > 2,4-DCB > 4-CB > 2,6-DCB ≈ 2-CB. This reaction scheme suggests that the relative reactivities of PCBs in the presence of alkali will be determined by the k_{red} value. As described above the value of $(k_{red})_{4\text{-CB}}/(k_{red})_{2\text{-CB}}$ has been evaluated as 17.2±4.5 from Eq. 12. This shows 4-CB is more readily dechlorinated than 2-CB by a factor of 17.2. For di-, and poly-CBs, however, k_{red} is not easy to estimate experimentally due to further reaction of the daughter CBs. Since Reaction 4 is an electron transfer step from the radical anion $(CH_3)_2CO^{\cdot-}$ to PCB(n), the reactivity k_{red} will depend on the reduction potential of PCB(n). The reduction potentials of 2-CB, 4-CB, 2,6-DCB, 2,4-DCB, 2,4,6-TCB, and biphenyl have been reported[13] as −2.097, −2.056, −2.107, −1.983, −1.966, and −2.411 E/V *vs.* SCE, respectively. These reduction potentials are reasonably correlated with the ease of dechlorination of CBs. It was thus considered that the reactivities of the CB homologues largely depend on the electron acceptabilities in the ground state.

The authors wish to express their thanks to Mr. Haruo Inoue of Tokyo Metropolitan University for his valuable suggestions, and to Mr. Tsutomu Shinoda for his help in the preparation of this paper.

Electrochemical Synthesis and Reactivity of α-Alkoxy α-Amino Acid Derivatives[1,2]

Tameo IWASAKI,* Hiroshi HORIKAWA, Kazuo MATSUMOTO, and Muneji MIYOSHI

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89 Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received September 22, 1978)

α-Alkoxy α-amino acid derivatives were synthesized in good yields by anodic oxidation of acylaminomalonic acid monoesters in alcohols. Transformation of ethyl *N*-acetyl-α-methoxyalaninate into ethyl *N*-acetyl-α,β-dehydroalaninate was achieved in an excellent yield by thermal treatment of the former amino acid with a catalytic amount of ammonium bromide. Substitution of the α-alkoxy group of the α-alkoxy amino acids with nucleophiles was effected by tin tetrachloride to afford the α-substituted α-amino acids.

α-Functionalized α-amino acids such as α-methoxy or α-acetoxy α-amino acids[3a,b] have been found to be useful for the preparation of physiologically important amino acids. Some remarkable examples have been shown by Ben-Ishai *et al.*;[4] α-methoxyglycine derivatives undergo the reaction with a variety of nucleophiles to afford a novel class of α-substituted α-amino acids. However, the synthetic versatility of the α-methoxy α-amino acids other than the α-methoxyglycines in amino acid chemistry has not yet been explored.

Several α-methoxy α-amino acids were prepared by the addition reaction to α,β-dehydro amino acids,[5a,b] oxidation of *N*-acylamino acid derivatives with *t*-BuOCl,[6a-d] or oxidation of α-methylthio *N*-acylamino acids.[7] However, difficulty is still encountered in these reactions in which the starting materials and/or the reagents are not readily available, and the experimental procedures are often tedious. In the course of our synthetic studies by electrochemical method, Kolbe type oxidation has been found to be a suitable method for a selective replacement of carboxylic acid group with acetoxyl[3a] or olefinic functional group.[8] In the present paper, we wish to report a convenient synthesis of various types of α-alkoxy α-amino acid derivatives by anodic oxidation of substituted and nonsubstituted acylaminomalonic acid monoesters. Transformation of the α-alkoxy amino acids into α,β-dehydroalaninate and α-substituted α-amino acids is also described, the synthetic potentiality of the α-alkoxy amino acids in amino acid chemistry, being taken into account.

Results and Discussion

Electrochemical Synthesis. Synthesis of α-alkoxy amino acid derivatives **3** was carried out according to the reaction Scheme 1. Substituted acylaminomalonic acid monoesters **2b—f** were synthesized in good yields by the reaction of acylaminomalonates **1a, b** with alkyl halides in ethanol–sodium ethoxide, followed by the saponification of the coupling products with potassium hydroxide in ethanol. α-Acetamido-α-cyano-β-phenylpropionic acid (**2g**) was similarly prepared from **1c** in 68% overall yield. Anodic oxidation was carried out at 10—15 °C with use of a graphite anode-graphite cathode in a non-divided cell. On electrolysis of **2a** in methanol containing 1/20 molar equivalent of sodium methoxide to that of **2a**, ethyl *N*-acetyl-α-methoxyglycinate (**3a**) was obtained in 89% yield. The monoesters **2b—f** were also oxidized under the same conditions as above to afford the corresponding α-methoxy α-amino acid derivatives **3b—f** in 80—97% yield. The presence of the cyano group in electrolysis of **2g** did not obstruct methoxylation. In these reactions, the starting materials were consumed completely by passing a theoretical amount of current which is calculated as a two-electron

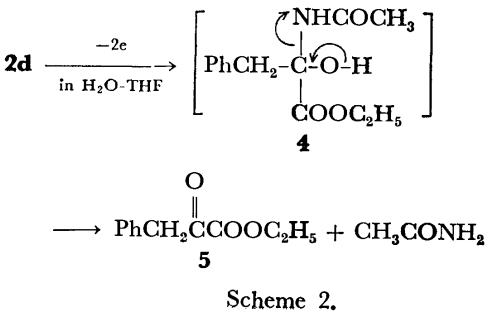
a) Upper lines show calculated values and lower lines found values.

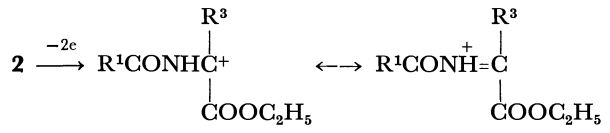
transfer. Furthermore, the use of ethanol or 2-propanol as an electrolysis solvent resulted in the formation of the corresponding alkoxylated products **3g,h** in excellent yields despite rather poor current efficiency (60—70%). No Kolbe dimer was observed throughout the alkoxylation. Furthermore, no elimination and rearrangement products were detected. Meanwhile, in the hope of preparing ethyl *N*-acetyl-α-hydroxyphenylalaninate (**4**), the electrolysis of **2d** was carried out in aqueous tetrahydrofuran. However, **4** was extremely unstable under the reaction conditions, and carbon–nitrogen bond cleavage ocurred to give ethyl phenylpyruvate (**5**) and acetamide[9] (Scheme 2).



Scheme 2.

The structural elucidation was carried out based on the spectral data and elemental analyses. The results are summarized in Table 1.

The electrode reaction in the alkoxylation is thought to be a typical abnormal Kolbe reaction in which the carbonium ion is generated *via* a two-electron transfer[3a,8,10a-c] (Scheme 3). The delocalization



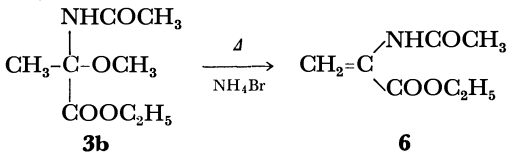
Scheme 3.

of the carbonium ion character onto the neighboring nitrogen atom would make the lifetime longer enough to be susceptible of nucleophilic attack of the solvent, though the inductive effect of both the *N*-acyl and the ethoxycarbonyl groups destabilizes the carbonium ion. Participation of the neighboring acylamino group in the anodic replacement of carboxylic acid group by methoxyl or acetoxyl group has been described by us[3a] and other workers.[11a,b]

The α-methoxy amino acid derivative **3d** was saponified with potassium hydroxide in methanol to afford *N*-acetyl-α-methoxyphenylalanine in 51% yield.

Conversion into α,β-Dehydroalanine Derivative. α,β-Dehydro amino acids, especially α,β-dehydroalanine derivatives, are used as important intermediates in the synthesis of natural peptides possessing antibacterial activity.[12] α,β-Dehydroalanine derivatives have hitherto been prepared by the methods involving the following: thermal condensation of primary amines with pyruvic acid;[13] base-catalyzed elimination of *N*-acyl-α-methoxyalanines,[5a] *N*-acyl-*N*-chloroalaninates prepared *in situ*,[5a] and *N*-acylserine derivatives.[14] These methods, however, are not suitable for large scale production[15] of α,β-dehydroalanine.

In order to develop a method for a convenient and large scale preparation of the α,β-dehydroalanines, thermal conversion of α-methoxyalaninate into α,β-dehydroalaninate was carried out. Ethyl *N*-acetyl-α-methoxyalaninate (**3b**) was heated at 120 °C for 20 min in the presence of a catalytic amount of ammonium bromide to afford the corresponding α,β-dehydro-

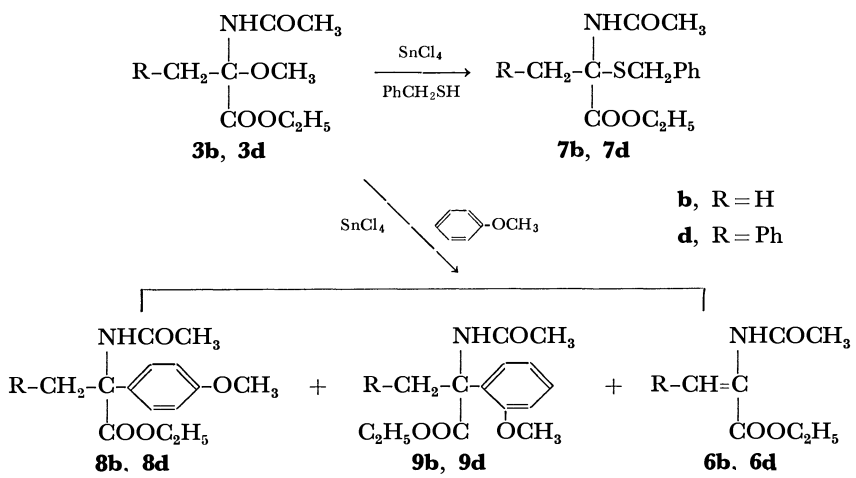


Scheme 4.

alaninate **6b** in 76% yield (Scheme 4). Prolonged heating or the use of a greater amount of ammonium bromide than that employed here resulted in a low yield, owing to the thermal polymerization of the product.

Reaction with Nucleophiles. *N*-Acyl-α-methoxyglycines have been reported to amidoalkylate olefins,[16a,b] active methylene compounds,[17] and aromatic compounds[18a-c] through *N*-acylimine intermediates in the presence of Lewis acid catalyst. The acylamino group functions to stabilize the carbonium ion generated at the α-carbon, thus providing enhanced reactivity toward nucleophiles. In α-amidoalkylation on tertiary carbon atom of the α-methoxy α-amino acids, however, the substitution as well as competitive elimination reactions should be considered. Thus, the reactions of the methoxy amino acids with typical nucleophiles have been investigated in the presence of Lewis acid, in order to examine the scope and limitation of amidoalkylation using the amino acids.

First of all, the reactions of the α-methoxy amino acid derivatives with thiols were carried out. Ethyl *N*-acetyl-α-methoxyalaninate (**3b**) was subjected to react with phenylmethanethiol in acetonitrile in the presence of $SnCl_4$ to afford ethyl *N*-acetyl-α-benzylthioalaninate (**7b**) in 92% yield. **3d** was similarly treated with phenylmethanethiol to give **7d** in 84% yield (Scheme 5). Careful analysis of the reaction mixture by liquid chromatography indicated no formation of the elimination and rearrangement products. Furthermore, α-amidoalkylation of aromatic compounds was carried out by using anisole as a typical example. Treatment of **3b** with anisole using a molar equivalent of $SnCl_4$ to that of **3b** gave the α-substituted product **8b** (para isomer) in 58% yield along with the ortho isomer **9b** (29%). In this case, α,β-dehydro amino acid **6b** was obtained in 5% yield. Furthermore, **3d** was allowed to react with anisole to afford a mixture



Scheme 5.

of **8d** and **9d** in 70% yield in a 4 : 1 ratio determined by NMR spectrum of the crude products. The α,β-dehydro amino acid derivative **6d** was detected.

Efforts to amidoalkylate benzene or toluene, a less reactive nucleophile, were made under the Lewis acid-catalyzed conditions. However, though no substitution product was detected, formation of the elimination product was observed. The reaction of **3j** with toluene gave the same result as above. Treatment of **3b** or **3d** with active methylene compounds such as diethyl malonate and ethyl acetoacetate did not lead to the formation of any substitution products. The results are in sharp contrast with those reported by Ben-Ishai *et al.*[16–18] in which α-methoxyglycine derivatives react easily with benzene as well as active methylene compounds to afford the α-substituted α-amino acids derivatives.

It may be concluded that the α-methoxy α-amino acid derivatives can be used as reagents for α-amidoalkylation by which various types of amino acid skeletons are introduced to afford α-substituted amino acids. However, formation of α,β-dehydro amino acids becomes overwhelming when a feeble nucleophile such as toluene is employed.

Experimental

Equipment. Melting points were measured with a Yamato melting point apparatus and are uncorrected. IR spectra were recorded on a Shimadzu IR-27G infrared spectrophotometer, and NMR spectra on a Hitachi Perkin-Elmer R-20 high resolution NMR spectrometer with tetramethylsilane as an internal standard. High performance liquid chromatography was taken by Waters ALC-GPC-244. The electrolyses were carried out with use of a Hokuto Potentio-Galvanostat HA 104 (1A-55V), PGS 2500 (2.5 A-60V) or PGS 2000 (2A-100V) equipped with a Hokuto HA 108A coulomb meter.

*Preparation of the Starting Materials **2a—g**.* **2a—f** were prepared according to the method reported previously.[3a] **2g**: Sodium hydride (65%) (4.4 g, 0.12 mol) was suspended in 100 ml of tetrahydrofuran. To this was added **1c** (17 g, 0.1 mol) dissolved in 30 ml of tetrahydrofuran at 10—15 °C under vigorous stirring. Stirring was continued for additional 1 h at the same temperature. To the mixture was added dropwise benzyl bromide (17 g, 0.1 mol) at 10—30 °C. After being stirred overnight, the reaction mixture was neutralized with acetic acid and the solvent was evaporated to dryness *in vacuo*. The residue was dissolved in ethyl acetate, and the solution was washed with water, dried over magnesium sulfate, then evaporated to dryness *in vacuo*. The resulting crystals were recrystallized from ethyl acetate–hexane to afford 22 g (90%) of ethyl α-acetamido-α-cyano-β-phenylpropionate as colorless needles: mp 111—113 °C; IR (Nujol) 3330, 1748, 1670, 1510 cm^{-1}; NMR ($CDCl_3$) δ 1.15 (t, 3H), 2.05 (s, 3H), 3.39 (s, 2H), 4.16 (q, 2H), 7.3 (m, 6H); Found: C, 64.61; H, 6.35; N, 10.48%. Calcd for $C_{14}H_{16}N_2O_3$: C, 64.60; H, 6.20; N, 10.76%.

Ethyl α-acetamido-α-cyano-β-phenylpropionate (10 g, 0.04 mol) obtained above was dissolved in **20** ml of ethanol. To this was added dropwise potassium hydroxide (2.3 g, 0.04 mol) dissolved in 5 ml of water at 5—10 °C under vigorous stirring. The reaction mixture was allowed to stand at room temperature for 3 days, and then concentrated to dryness *in vacuo* below 30 °C. The residue was dissolved in 10 ml of water and the solution was shaken once with ethyl acetate. The aqueous layer was acidified to Congo Red with 12 M hydrochloric acid. The acidified solution was shaken with three 50 ml portions of ethyl acetate, and the combined ethyl acetate layer was washed twice with 10 ml of brine, dried over magnesium sulfate, then evaporated to dryness *in vacuo* below 30 °C. The resulting crystals were recrystallized from ethyl acetate–hexane to afford 6.5 g (75%) of **2g** : mp 140—141 °C; IR (Nujol) 3350, 1730, 1630, 1540 cm^{-1} ; NMR ($CDCl_3$+DMSO-d_6) δ 2.02 (s, 3H), 3.43 (s, 2H), 7.30 (s, 5H), 8.17 (s, 1H); Found: C, 61.81; H, 5.35; N, 12.22%. Calcd for $C_{12}H_{12}N_2O_3$: C, 62.06; H, 5.21; N, 12.06%.

General Electrolysis Procedure. The general electrolysis procedure is the same as reported previously.[2] In the electrolysis in 2-propanol, a 50 mA of current was passed. For large scale (1 mol) electrolysis, electrodes of an area of 40 cm^2 were used in a non-divided cell.

*Electrolysis of **2d** in Aqueous Tetrahydrofuran.* **2d** (2.8 g, 0.01 mol) was electrolyzed in a mixture of 25 ml of water and 6 ml of tetrahydrofuran containing 0.38 ml of 1 M potassium hydroxide. The other electrolysis conditions were the same as those described above. The electrolyzed solution was evaporated to dryness *in vacuo* and the resulting residue was extracted with ethyl acetate, washed once with brine, dried over magnesium sulfate, then evaporated to dryness *in vacuo*. Extraction of the resulting residue with 100 ml of hexane gave 1.8 g (93%) of ethyl phenylpyruvate (**5**). The derivative of the 2,4-dinitrophenylhydrazone showed mp 130—131 °C (lit,[19] mp 132—133 °C).

*Saponification of Compound **3d**.* Compound **3d** (2.65 g, 0.01 mol) was dissolved in 30 ml of methanol. To this was added potassium hydroxide (0.56 g, 0.01 mol) dissolved in 3 ml of water under vigorous stirring at room temperature. The reaction mixture was allowed to stand at room temperature for 24 h, and then concentrated to dryness *in vacuo*. The residue was dissolved in 10 ml of water and the solution was shaken once with ethyl acetate. The aqueous layer was acidified to Congo Red with 6 M hydrochloric acid. The acidified solution was shaken with three 30 ml portions of ethyl acetate, and the combined ethyl acetate layer was washed once with brine, dried over magnesium sulfate, then concentrated to dryness *in vacuo*. The resulting crystals were recrystallized from ethyl acetate–hexane to afford 1.2 g (51%) of *N*-acetyl-α-methoxyphenylalanine: mp 133—135 °C; IR (Nujol) 3290, 1760, 1633, 1564 cm^{-1}; NMR (DMSO-d_6) δ 1.90 (s, 3H), 3.17 (s, 5H), 7.17 (s, 5H), 8.18 (broad s, 1H); Found: C, 60.77; H, 6.36; N, 6.01%. Calcd for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

*Conversion to **6b**.* Compound **3b** (80 g, 0.42 mol) and ammonium bromide (80 mg) were put into a distillation apparatus. The mixture was heated at 120 °C for 20 min at 70—100 mmHg under nitrogen atmosphere, methanol being distilled off. Subsequent distillation at 5 mmHg afforded 50 g (76%) of **6b**: bp 100—103 °C (5 mmHg). IR and NMR spectra of **6b** were identical with those of an authentic sample.[13]

*Reactions of **3b** and **3d** with Phenylmethanethiol.* Ethyl *N*-acetyl-α-methoxyalaninate (**3b**) (0.95 g, 5 mmol) and phenylmethanethiol (0.62 g, 5 mmol) were dissolved in 5 ml of acetonitrile. To this was added dropwise $SnCl_4$ (0.58 ml, 5 mmol) at 0—5 °C under vigorous stirring . Stirring was continued for 1 h at the same temperature and the reaction was quenched by addition of 5 ml of saturated aqueous sodium hydrogencarbonate solution. The insoluble materials were filtered off and the filtrate was evaporated to dryness *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with brine, dried over

magnesium sulfate, and then evaporated to dryness *in vacuo*. The resulting syrup was treated with silica gel chromatography using bezene–acetone (5 : 1) as eluent to afford 1.29 g (92%) of ethyl *N*-acetyl-α-benzylthioalaninate (**7b**). Recrystallization from ethyl acetate–hexane gave colorless needles: mp 79—80 °C; IR (Nujol) 3230, 1739, 1637, 1528 cm^{-1}; NMR ($CDCl_3$) δ 1.28 (t, 3H), 1.73 (s, 3H), 1.86 (s, 3H), 3.82 (s, 2H), 4.18 (q, 2H), 6.37 (broad s, 1H), 7.27 (s, 5H); Found: C, 59.61; H, 6.79; N, 4.69%. Calcd for $C_{14}H_{19}NO_3S$: C, 59.76; H, 6.81; N, 4.98%.

3d was also allowed to react with phenylmethanethiol under the same conditions as above to afford the substitution product **7d** in 84% yield. **7d**: mp 103—104 °C ; IR (Nujol) 3230, 1728, 1640, 1534 cm^{-1}; NMR ($CDCl_3$) δ 1.33 (t, 3H), 1.68 (s, 3H), 3.43 and 3.98 (AB q, 2H, J=13 Hz), 3.75 (s, 2H), 4.25 (q, 2H), 6.20 (broad s, 1H), 7.14 (s, 5H), 7.25 (s, 5H); Found: C, 67.37; H, 6.52; N, 3.90%. Calcd for $C_{20}H_{23}NO_3S$: C, 67.20; H, 6.49; N, 3.92%.

*Reactions of **3b** and **3d** with Anisole.* To a stirred solution of ethyl *N*-acetyl-α-methoxyalaninate (1.0 g, 5.3 mmol) dissolved in anisole (10 ml) was added dropwise $SnCl_4$ (0.61 ml, 5.3 mmol) at 0—5 °C. The reaction mixture was stirred for 1 h at the same temperature and the reaction was quenched by addition of 10 ml of saturated aqueous sodium hydrogencarbonate solution. The insoluble materials were filtered and washed thoroughly with acetonitrile. The filtrate was evaporated to dryness *in vacuo* and the residue was extracted with ethyl acetate. The extract was washed with water, dried over magnesium sulfate, and then concentrated to dryness *in vacuo*. The resulting syrup was treated with silica gel chromatography using chloroform as an eluent to afford 0.82 g, (58%) of **8b** (para isomer), 0.41 g (29%) of **9b** (ortho isomer), and 0.04 g (5%) of ethyl *N*-acetyl-α,β-dehydroalaninate **6b**. **8b**: mp 108—109 °C; IR (Nujol) 3240, 1736, 1632, 1560, 1513 cm^{-1}; NMR ($CDCl_3$) 1.17 (t, 3H), 1.96 (s, 3H), 2.01 (s, 3H), 3.77 (s, 3H), 4.14 (q, 2H), 6.75 (broad s, 1H), 6.83 (d, 2H), 7.34 (d, 2H); Found: C, 63.27; H, 7.01; N, 5.33%. Calcd for $C_{14}H_{29}NO_4$: C, 63.38; H, 7.22; N, 5.28%. **9b** : syrup; IR (film) 3410, 1730, 1660, 1600, 1490 cm^{-1}; NMR ($CDCl_3+D_2O$) δ 1.14 (t, 3H), 1.87 (s, 3H), 2.02 (s, 3H), 3.73 (s, 3H), 4.15 (q, 2H), 6.7—7.7 (m, 4H); MS (30 eV), *m/e* (rel intensity), 265 (M^+, 10), 192 (73), 150 (100), 133 (32), 118 (32), 105 (47), 43 (36). The physical constants of **6b** were identical with those of an authentic sample.

3d was also treated with anisole in the presence of $SnCl_4$. The work-up was the same as that described above. TLC of the reaction mixture showed the presence of the substitution products **8d** and **9d** and the elimination product **6d**. The resulting residue was treated with silica gel chromatography using benzene–acetone (5 : 2) as an eluent to afford a mixture of **8d** and **9d** as syrup in 70% yield, the ratio of **8d** to **9d** being 4:1, based on the NMR spectrum. Elemental analysis of the mixture showed a reasonable result. Found: C, 70.12; H, 6.80; N, 4.11%. Calcd for $C_{20}H_{23}NO_4$: C, 70.36; H, 6.79; N, 4.10%. We failed in separating each isomer by liquid chromatography under various conditions. As an example, liquid chromatography of the mixture by use of μ Porasil as resin (column: 4 mm × 30 cm; flow rate : 1 ml/min) showed a single peak at retention time of 10.5 min. The mixture was crystallized from ethyl acetate–hexane to afford **8d** as needles: mp 95—96 °C; IR ($CHCl_3$) 3420, 1726, 1675, 1608, 1593 cm^{-1} ; NMR ($CDCl_3$) δ 1.19 (t, 3H), 1.95 (s, 3H), 3.78 (s, 3H), 3.74 and 4.10 (AB q, 2H, J=14 Hz), 4.13 (q, 2H), 6.83 (d, 2H), 6.6—7.4 (m, 6H), 7.33 (d, 2H). **9d** could not be isolated as a pure form. The structure of **9d** was assigned by the NMR spectrum of the mixture of **8d** and **9d**. **9d**: NMR ($CDCl_3$) δ 1.17 (t, 3H), 1.88 (s, 3H), 3.65 (s, 3H), 3.32 and 4.50 (AB q, 2H, J=14 Hz), 4.13 (q, 2H), 6.6—7.4 (m, 10H).

We thank Prof. Mitsuyoshi Kawanishi, Kyoto University, for his valuable suggestion. We are also grateful to Dr. Ichiro Chibata, Director of our Research Laboratory, for his encouragement.

S_N2 Reactions in Dipolar Aprotic Solvents. VII. Kinetic and Equilibrium Secondary α-Deuterium Isotope Effects in Chlorine Isotopic Exchange Reactions of Substituted Chloromethanes in Acetonitrile[1)]

Jun-ichi HAYAMI,*,[2)] Nobuhisa HIHARA, Nobuo TANAKA, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received August 11, 1978)

Secondary α-deuterium isotope effects were studied in the symmetrical nucleophilic substitution of the substituted chloromethanes in acetonitrile. The apparent second order rate coefficients show a significant isotope effect for chloromethyl aryl ethers and sulfides (1.11—1.14 per D), and an intermediate value of 1.05 for cinnamyl chlorides. 2-Arylethyl chlorides were shown to give an appreciable isotope effect of 1.03—1.04, and arylchloromethanes to give varying amount of the isotope effect from 1.006 to 1.050 depending upon the ring substituent. The deuterium label also gave rise to a significant equilibrium isotope effect on the substrate-nucleophile association in the reaction mixture. The observation of an equilibrium isotope effect suggested a possibility that an apparent isotope effect was a composite of the thermodynamic and the kinetic isotope effects. Thus the dissection resulted in a uniform and a fairly large kinetic isotope effect for all the activated substrates studied and in a small kinetic isotope effect for 2-arylethyl chloride. The results are explained in a framework of loose-tight transition state.

In the studies of the Hammett type analysis of the Finkelstein reaction in a dipolar aprotic solvent acetonitrile, the present authors proposed the rate accelerating effect by the conjugative stabilization of the S_N2 transition state.[3)]

When a hetero atom[3a)] or an unsaturated linkage[3b,c)] adjacent to the reaction center is available, the conjugative stabilization may be operative, superposing upon the nucleophilic approach of the attacking nucleophile, in the displacement reaction that proceeds through a loose transition state. The looseness or the tightness of the transition state has often been postulated. A successful example is found in the study of the solvent effect on the rate of the bimolecular reactions.[4)]

Another approach to verify such a spectrum of the transition state may be tenable by the study of the secondary hydrogen isotope effect. The method, which was awarded with success, has mainly applied to the unimolecular solvolytic reactions.[5)]

Formerly, the rate ratio k_2^H/k_2^D of unity has been believed to be a criterion of the S_N2 reaction and the secondary isotope effect has been considered not existent in this class of reactions.[6)] Recent works show that the isotope effect is observable in some examples of the S_N2 reactions, and that the typical observed value is in the range of 0.95—1.06 per one α-deuterium atom.[7,8)] However, the study with a systematic variation in the substrate reactivity was scarcely undertaken in the study of bimolecular substitutions.

In the present work, the substituted chloromethanes with the deuterium label at the reacting carbon were subjected to the chlorine-chlorine isotopic exchange reaction. The deuterium label also affected substrate-nucleophile interaction which accompanied with the symmetrical exchange reaction.[9)] The kinetic deuterium isotope effect was discussed in relation to the reactivity of these model compounds and in relation to the potential role of the substrate-nucleophile association complex.

Results and Discussion

Substituted chloromethanes which have a variety of substituents adjacent to the reaction center were subjected to the chlorine isotopic exchange reaction in dry acetonitrile as shown in Scheme 1.

$$X\text{-}C_6H_4\text{-}Y\text{-}CZ_2Cl + Et_4N^*Cl \rightleftharpoons X\text{-}C_6H_4\text{-}Y\text{-}CZ_2{}^*Cl + Et_4NCl$$

X; H and other substituent

Z; H and D

Scheme 1.

The incorporation of the radioactive chlorine from the reagent tetraethylammonium chloride-^{36}Cl followed first-order kinetics and the plausible second-order rate coefficients were obtained as reported earlier.[3)] This result definitely shows that the rate determining transition state should involve both the organic chloride and the nucleophile, chloride ion.

The results of the exchange reactions with the deuterated substrates as well as that with the unlabeled substrates are given in Table 1. As shown in Table 1, normal isotope effect was observed in every case. The magnitude of the effect was about 11—14% for chloromethyl aryl ethers and chloromethyl aryl sulfides. 2-Arylethyl chlorides gave about 3—4% of the effect while arylchloromethanes gave diverse normal effect of 0.6—5.0%. Cinnamyl chloride gave an intermediate value of 5%.

The constancy of the secondary deuterium isotope effect for chloromethyl aryl sulfides is excellent and possibly indicates an operation of a single mechanism for all these sulfides as are also indicated by the establishment of the good linear free energy relationship for exchange reactions.[3a,10)]

The equilibrium constants for the formation of substrate-nucleophile complex were determined with deuterated substrates, as well as with unlabeled substrates. The formation of such a complex in the Finkelstein reaction mixture was already reported.[9)] Equilibrium deuterium isotope effects were observed for the representative substrates and the results are shown in Table 2. Except for 2-(*p*-nitrophenyl)ethyl chloride, which shows essentially the absence of equilibrium

isotope effect, chloromethyl *p*-nitrophenyl sulfide, cinnamyl chloride, and (*p*-nitrophenyl)chloromethane all show an inverse equilibrium isotope effect. The observation of the inverse equilibrium isotope effect is not unexpected.[11]

The data of substrate-nucleophile association allow one to calculate the intrinsic second order rate coefficient corrected for the change of the concentration of both the substrate and the reagent upon complex formation (*vide infra*). In Table 3, the corrected isotope effects are summarized for the representative classes of the compounds. Table 3 also contains the results of the Hammett type analyses of the corresponding unlabeled substrates.

a) Ref. 3b. X; H, at 20 °C. b) Ref. 3. c) k_{obsd} was corrected for the formation of substrate-nucleophile complex. d) Uncorrected valuc. e) Obtained for *m*-substituted compounds.

The inspection of the results in Table 3 is quite intuitive. The spectrum of the secondary deuterium isotope effect obtained in the present study seems to have a parallelism to the degree of the electron-donating conjugative stabilization of the transition state. As suggested from the Hammett type analysis, and from the relative rate of the substituted chloromethanes studied, such a stabilization is most prevailing in the ethers ($\rho=-1.56$, $k_{rel}=400000$) and in sulfides ($\rho=-0.92$, $k_{rel}=1020$), less effective but still significant in cinnamyl chlorides ($\rho^m=-0.19$, $k_{rel}=680$), and is apparently not operating in 2-arylethyl chlorides ($\rho=+0.57$, $k_{rel}=1$).

The difficulty is encountered for arylchloromethanes. The observed isotope effects in the Table 1 seem too small for these activated Finkelstein substrates. This is also the case with cinnamyl chlorides (*cf.* Table 3).

The behavior of the arylchloromethanes is often a matter of controversy.[12] The significant change from tight transition state (*p*-NO_2) into loose transition state (*p*-OCH_3 or *p*-CH_3) was suggested by the studies of the substituent effect upon the rate of the Finkelstein reaction[3b] and upon the solvent activity coefficient of the reaction.[4]

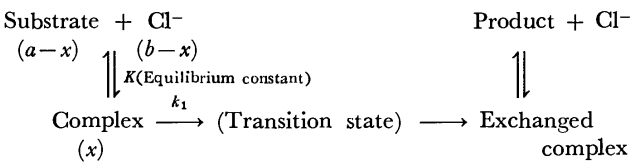
Table 1 shows the small and varying extent of the isotope effect. Thus (*p*-nitrophenyl)chloromethane, the transition state of which is considered to be tighter than that of (*m*-methyl- or unsubstituted phenyl)chloromethane, gives an appreciable isotope effect of about 3%. While (*m*-methylphenyl)chloromethane shows the isotope effect close to unity and phenylchloromethane shows a fair isotope effect of 2.6% contrary to the expectation from the looseness-tightness approach (*cf.* Table 1).

These findings seem to suggest that the (overall) isotope effect should tell something that is different from the implication of the rate studies.

A clue to answer this difficulty is found in an observation of an association complex in the Finkelstein reaction. The present authors have reported the presence of the substrate-reagent complex which possesses a structure quite similar to the traditional S_N2 transition state.[9] There are indications that the nucleophilic anion coordinates at the rear side of the potential leaving group resulting in the freezing of the intramolecular rotation, which is the necessary condition for the operation of an electron-donating *p*-π and(or) *p*-*p*

interaction by the neighboring functionality.

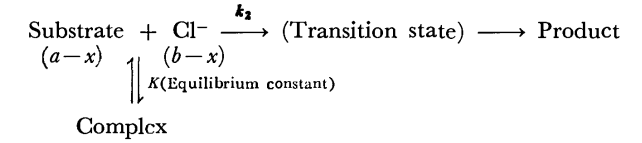
Such a complex can play one of the two quite distinct roles in the bimolecular reaction. One is the direct precursor that intervenes before the rate determining unimolecular scrambling (Scheme 2).



$$\text{Rate} = k_1 K(a-x)(b-x)$$

Scheme 2.

The other is the indifferent entity in the subsidiary or parasitic equilibrium with the free substrate and the free nucleophile (Scheme 3).



$$\text{Rate} = k_2(a-x)(b-x)$$

Scheme 3.

The equilibrium isotope effect in Table 2 seems to support the operation of the association mechanism (Scheme 2), giving the more comprehensive picture of the observed kinetic isotope effect. When one postulates an operation of the mechanism in Scheme 2, the observed second order rate coefficient k_2 can be separated into the equilibrium constant K for the substrate-nucleophile association, and the rate constant k_1 for the unimolecular scrambling, as is shown in Eq. 1.

$$k_2 = k_1 \cdot K \tag{1}$$

Accordingly the kinetic isotope effect observed can be dissected into the equilibrium isotope effect of bimolecular association(K_H/K_D) and the kinetic isotope effect of unimolecular scrambling (k_1^H/k_1^D, Eq. 2).

$$k_2^H/k_2^D = k_1^H/k_1^D \cdot K_H/K_D \tag{2}$$

Combining the data from Table 1 and Table 2, the kinetic isotope effect k_1^H/k_1^D can be calculated postulating the intervention of the substrate-nucleophile complex. Results are shown in Table 4.

For the activated substrates, reflecting the inverse equilibrium isotope effects, the kinetic isotope effects calculated (that correspond to the rate determining unimolecular scrambling of the complex) are now close to that of the limiting solvolysis.[13] For 2-(*p*-nitrophenyl)ethyl chloride, the equilibrium isotope effect of about unity substantiates the figure of the isotope effect observed (k_2^H/k_2^D) is essentially intrinsic.

Thus the explanation in the framework of the looseness of the transition state seems to hold for the whole classes of the compounds studied. In a significantly loose transition state, the carbon under attack has essentially little difference from the carbonium ion having negligible nucleophilic attachment to both the leaving and the incoming group (chloride ion).[14] Thus 15.7% might be the limiting value for the secondary deuterium isotope effect in S_N2 reactions as it is the case with the unimolecular limiting solvolysis of organic chlorides.[15]

Table 4. Dissection of the isotope effect
[X-C_6H_4-Y-CZ_2Cl]

Y	X	k_2^H/k_2^D a)	K_H/K_D a)	k_1^H/k_1^D a)
S	*p*-NO_2	1.119	0.976	1.147
CH=CH	H	1.048	0.928	1.129
None	*p*-NO_2	1.024	0.909	1.127
CH_2	*p*-NO_2	1.039	1.007	1.032

a) Per one D atom. There are some differences between the temperature for the kinetic measurement and that for the equilibrium measurement. However, the change of temperature in the range studied gave negligiblly small effect upon the equilibrium isotope effect, and an example is shown in Table 2 for (*p*-nitrophenyl)-chloromethane.

The S_N1 like behavior of the chloromethyl aryl ether was suggested in the nucleophilic displacement reaction of chloromethyl methyl ether.[16]

In the loose transition state, the change of the out-of-plane bending motion, caused by the bond breaking, may hardly be compensated by the bond formation with the incoming nucleophile.

The largest kinetic isotope effect observed in the present study, for chloromethyl aryl sulfides and ethers, is still smaller than the limiting value of S_N1 reactions. This is the indication of a nucleophilic interaction in the transition state.[7] The magnitude of the isotope effect seems to be smaller as the transition state becomes tighter. 2-(*p*-Nitrophenyl)ethyl chloride shows a small kinetic isotope effect which seems to be compatible with the implication from ρ_{k_1} (and with ρ_{k_2}).[17]

The nature of the unimolecular scrambling of the complex suggests that the nucleophile assists the expulsion of the leaving group. A quite similar suggestion was made by Schleyer as "nucleophilically assisted ion pair formation."[18]

Another explanation in a framework of traditional nucleophilic substitution may be pursued. The operation of an S_N2-C^+ or of the rate determining nucleophilic attack upon an ion pair may be one of the possibilities. The absence of a very high ρ value in the Hammett relationship[17] and the absence of k_Δ process[19] in the case of 2-arylethyl chlorides (and probably cinnamyl chloride) are the evidences against the classical S_N2-C^+ route.[3a]

As long as an S_N2-C^+ or an ion pair mechanism is operative, one should postulate a spontaneous ionization of the substrate.[20] Bearing in mind the existence of the substrate-nucleophile complex in the Finkelstein reaction mixture studied, and the feature of the complex which shows interesting similarities to the traditional S_N2 transition state, one can hardly imagine a spontaneous ionization without help of the nucleophile that locates at the rear side of the potential leaving group. The absence of the inert salt effect is also against the operation of S_N2-C^+ and(or) ion pair intervention.[3a] In addition, the classical explanation necessitates a significant attachment of the nucleophile for arylchloromethanes or cinnamyl chlorides, one of the classes of the activated substrates.

a) Ref. 3. b) X-C_6H_4-Y-CHDCl.

Thus the postulation of the substrate-nucleophile complex as the "intermediate" of the Finkelstein reaction opens up the new possibility to have a unified view of the behavior of the variety of the substrate. There is hardly available a good means to examine the possible equilibrium isotope effects of the substrate-nucleophile association in a protic medium. At present it is an open question if the present postulation can become a general proposal.

The preliminary result of the protic-aprotic solvent effect is also compatible with the association mechanism. Successive additions of the small amount of methanol to solvent acetonitrile give rise to the decrease in the equilibrium constant of the complex formation as well as the decrease in the rate of symmetrical exchange reactions (Table 5). However the decrease of the second order rate coefficient is much more profound than that of the equilibrium constant. According to the association mechanism (Scheme 2), the nucleophilic displacement reaction in the presence of methanol added should contain "deactivated anionic nucleophile"[4] both at the preliminary association and at the unimolecular scrambling, thus the overall rate should be doubly affected by the deactivation of the anionic nucleophile, as is envisaged by Eq. 1.

Experimental

Instruments. The radioactivity was measured with a Nuclear Chicago Model-6801 liquid scintillation counter. The PMR spectra were obtained on a JEOL JNM-PS-100 NMR spectrometer equipped with a Hetero Spin Decoupler JNM-SD-HC 1. The melting points were measured with a Yanagimoto Micro Melting Point Apparatus and were uncorrected.

Materials. Aryloxymethane-α,α-d_2-sulfonates were obtained as follows. Sodium p-chlorophenoxymethanesulfonate(8g) was dissolved in 10 ml of 1M-NaOD/D_2O (99.75% isotopic purity). The mixture was maintained at about 100 °C in a Teflon tube for four days. After cooling the solution was acidified with 1M-HCl and evaporated. The residue was subjected to the exchange once again according to the above procedure. Recrystallization from aqueous ethanol gave pure p-chlorophenoxymethane-α,α-d_2-sulfonate. The sulfonate was converted to p-chlorophenyl chloromethyl-d_2 ether with phosphorous pentachloride.[21]

Methyl-d_3 aryl sulfides were prepared from the corresponding thiophenols and CD_3I (99% isotopic purity) in ethanol in the presence of KOH. Chlorination of these sulfides with sulfuryl chloride gave chloromethyl-d_2 aryl sulfides.

(p-Nitro- and m-nitrophenyl)methan-α,α-d_2-ols were prepared from the corresponding methyl nitrobenzoates by mixed hydride reduction.[22] $LiAlD_4$(Merck, 99% isotopic purity, 0.75 g) was stirred in 40 ml of ether. To the solution anhydrous $AlCl_3$(2.5 g) in 40 ml of ether was added dropwise, and the solution was stirred for another few minutes. The methyl p-nitrobenzoate (3.2 g) in 20 ml of ether was added slowly. After stirring for an hour under reflux, the mixture was worked up as usual. The alcohols were purified by recrystallization or distillation after chromatographic purification on alumina.

(p-Nitrophenyl)methan-α-d-ol was prepared from p-nitrobenzaldehyde by mixed hydride reduction. (m-Methylphenyl)methan-α-d-ol was prepared from m-methylbenzaldehyde with $LiAlD_4$ as usual. Other arylmethan-α,α-d_2-ols were prepared from the corresponding methyl benzoates with $LiAlD_4$. Arylchloromethanes-α-d, and -α,α-d_2 were prepared from these alcohols by standard method.[23]

Cinnamyl-1,1-d_2 and cinnamyl-1-d derivatives were obtained by mixed hydride reduction from ethyl cinnamate and cinnamaldehyde, respectively.[24] Cinnamyl chlorides were proved to be trans isomers by PMR spectra and physical constants.

2-(p-Nitrophenyl)ethan-1,1-d_2-ol was prepared from ethyl (p-nitrophenyl)acetate by mixed hydride reduction. Other 2-arylethan-1,1-d_2-ols were obtained from the corresponding ethyl arylacetates by the reaction with $LiAlD_4$ as usual. The alcohols were subjected to the reaction with thionyl chloride which gave 2-arylethyl-1,1-d_2 chlorides.

After purification all these chlorides showed satisfactory NMR and IR spectra. Physical constants are listed in Table 6.

Kinetic Measurements. Batch method was undertaken as reported previously.[3a,b] In order to ensure the accuracy of the isotope effect measurement, the parallel reaction was always run with unlabeled compounds simultaniously in the same bath. The reproducibility of the isotope effect was within 0.01 for duplicate runs, though the difference in rate constants was within the range of 1.5% for independent series of measurements.

Equilibrium Measurements. Proton chemical shift measurements were undertaken as reported previously.[9] The shifts of α-proton of (*p*-nitrophenyl)chloromethane-α-*d*, (*m*-methylphenyl)chloromethane-α-*d*, and cinnamyl-α-*d* chloride were measured under the irradiation of D-frequences at 23000 G (15.349404, 15.349408, and 15.349589 MHz, respectively), noise-modulation was applied when necessary (white noise band width; 50 Hz).[25]

Some troubles are encountered in the preparation of chloromethyl-*d* *p*-nitrophenyl sulfide and of 2-(*p*-nitrophenyl)-ethyl-1-*d* chloride. Accordingly α,α-d_2 labeled substrates were utilized to measure the equilibrium isotope effect observing the chemical shift of ortho hydrogens on the phenyl ring. The control experiment with (*p*-nitrophenyl)chloromethane-α-*d*, and -α,α-d_2 resulted essentially the identical equilibrium isotope effect. In the case of 2-(*p*-nitrophenyl)-ethyl chloride two independent analyses from α- and *o*-proton(s) gave rise to the identical association constant.

Scott-Benesi-Hildebrand analyses for cinnamyl chlorides and 2-arylethyl chlorides were difficult because of their small low field shifts at the chloride concentrations studied.[26] However, the repeated measurements of the line position (up to 30 times and to the reproducibility of ±0.05 Hz or better) gave a reliable association constant.

Tracer experiments were undertaken at Radioisotope Research Center of Kyoto University. The authors are grateful to the staff of the institution. Supports by the Ministry of Education (No. 83151, 84076, 748167), Saneyoshi Shogakkai, and Ito Kagaku Shinkokai are gratefully acknowledged.

12) Ref. 3b, 3c and references cited therein.

13) Beside *p*-nitrophenyl derivatives, the substrates give only a small low field shift upon complexing, thus one is not allowed to determine equilibrium isotope effect accurately. However, after repeated measurements, (*m*-methylphenyl)-chloromethane gave K_H/K_D of about 0.91 (with fair error of ±5%). Dissection of k_2^H/k_2^D suggests a loose transition state for this arylchloromethane.

14) A. Streitwieser, Jr., "Solvolytic Displacement Reactions," McGraw-Hill Book Co., Inc., New York, N. Y. (1962), p. 5.

15) V. J. Shiner, Jr., and W. Dowd, *J. Am. Chem. Soc.*, **93**, 1029 (1971).

16) T. C. Jones and E. R. Thornton, *J. Am. Chem. Soc.*, **89**, 4863 (1967).

17) As a corollary, the ρ_{k_2} obtained can be split into ρ_K and ρ_{k_1}, provided the linear free energy relationships hold for both K and k_2.

$$\log(k_2/k_2^\circ) = \log(Kk_1/K^\circ k_1^\circ) = \log(K/K^\circ) + \log(k_1/k_1^\circ)$$
$$= \rho_K\sigma + \rho_{k_1}\sigma = (\rho_K + \rho_{k_1})\sigma = \rho_{k_2}\sigma$$

For 2-arylethyl chlorides; $\rho_K = 0.65$, $\rho_{k_2} = 0.57$, $\therefore \rho_{k_1} = 0.57 - 0.65 = -0.08$. For chloromethyl aryl sulfides; $\rho_K = 0.59$, $\rho_{k_2} = -0.92$, $\therefore \rho_{k_1} = -0.92 - 0.59 = -1.51$. The value of ρ_K for the equilibrium of the complex formation between modified methyl chlorides and chloride ion was found essentially constant.[9] Using the average value of $\rho_K = 0.57$, for chloromethyl aryl ethers; $\rho_{k_2} = -1.56$, $\therefore \rho_{k_1} = -1.56 - 0.57 = -2.13$.

24) M. J. Jorgenson, *Tetrahedron Lett.*, **1962**, 559.

25) The line position of the proton in question did not change with or without the irradiation for heteronuclear decoupling. (*p*-Nitrophenyl)chloromethane-α-d_1 gave rise to a beautiful 1 : 1 : 1 triplet on ^1H spectra, which, on heteronuclear decoupling, coalesced to a sharp singlet centering at the center of the triplet mentioned above. The successful heteronuclear decoupling was experienced in every case.

26) The low field shift of α-proton at the concentration, [substrate] = 0.1 M, [Et_4NCl] = 1.0 M, at 30 °C, was 0.079 ppm for cinnamyl chloride, 0.085 ppm for 2-(*p*-nitrophenyl)-ethyl chloride, whereas 0.398 ppm for chloromethyl *p*-nitrophenyl sulfide, 0.199 ppm for (*p*-nitrophenyl)chloromethane.

Photo-induced Transformation of Polyalkylbenzyl Thiocyanates into Polyalkylbenzyl Isothiocyanates. A Synthesis of Some Bis- and Tris(isothiocyanatomethyl)polymethylbenzenes by Multiple Thiocyanate Isomerization[1]

Hitomi SUZUKI,* Michiyo USUKI, and Terukiyo HANAFUSA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received August 21, 1978)

Polyalkylbenzyl thiocyanates, upon irradiation in acetic acid, readily undergo reversible photoisomerization, giving an equilibrium mixture composed mostly of the corresponding isothiocyanates. Several new bis- and tris(isothiocyanatomethyl)polymethylbenzenes have been prepared by utilizing the photoinduced multiple thiocyanate isomerization.

In connection with our studies on the *ipso*-thiocyanation of arenes, we needed several polyalkylbenzyl isothiocyanates as reference compounds for comparison. The classical synthesis of alkyl isothiocyanates[2] has been based on the reaction of alkyl halides with alkali thiocyanates,[3] thermal isomerization of thiocyanates,[4] and treatment of dithiocarbamate derivatives with heavy metal salts,[5] ethyl chloroformate,[6] aqueous potassium hydroxide,[7] sodium hypochlorite or chlorite,[8] and iodine.[9] Other methods of limited generality include the reaction of primary amines with thiophosgen,[10] action of sulfur and alkali cyanide upon alkyl halides,[11] addition of thiocyanic acid to olefins,[12] reaction of carbon disulfide and carbodiimide at high temperatures,[13] and treatment of isocyanates with phosphorus pentasulfide under pressure.[14] Recent proposals involve the reaction of primary amines with bis(trichloromethyl)pentathiodiperoxycarbonate,[15] treatment of dithiocarbamate derivatives with butyllithium,[16] phenylpropiolamidines,[17] phosphoryl chloride,[18] cyanuric chloride,[19] or dicyclohexylcarbodiimide,[20] pyrolysis of alkyldithiourethanes,[21] reaction of phosphoramidate anions with carbon disulfide,[22] and cleavage of secondary carboxamides by successive treatment with sodium hydride and carbon disulfide.[23] Many of these, however, suffer from either the lack of wide applicability, or the use of less common starting materials, and often require relatively tedious manipulative procedures.

Of the various methods previously reported, the isomerization of thiocyanates appeared attractive for our purpose, since the starting materials are easily accessible from aromatic hydrocarbons by chloromethylation and subsequent treatment with potassium thiocyanate. However, mild heating of polyalkylbenzyl thiocyanates in *N*,*N*-dimethylformamide (DMF) with or without potassium thiocyanate does not bring about isomerization; forced thermal isomerization under drastic conditions is accompanied by extensive decomposition. Conversions are generally slow and incomplete, rendering the reaction unfeasible for preparative purposes. Irradiation of benzyl thiocyanates in inert solvents in the absence of oxygen has been known to give a photo-stationary mixture of thiocyanate and isothiocyanate,[24] although the photoisomerization itself is not a general process for alkyl thiocyanates. In order to examine the synthetic potentials of obtaining polyalkylbenzyl isothiocyanates by a photochemical process, a series of polyalkylbenzyl thiocyanates were prepared from the corresponding chlorides and irradiated in dry acetic acid with a high-pressure mercury lamp. Solutions of 1.0—0.1 mM in compounds **1a**—**1d** afforded upon irradiation photo-equilibria which were composed mostly of the corresponding isothiocy-

a) Based on the isolated pure product.

anates **2a**—**2d**. Photo-equilibrium was reached within 1 h when these dilute solutions were used. Longer irradiations were not advantageous, since the formation of tarry substances began to occur. Acetic acid was apparently a solvent of choice; in hexane an insoluble polymeric solid deposited, while in ethanol the formation of side products was prominent. Ordinary work-up of the reaction mixture gave a light brown solid or oily substance, which was chromatographed on a short silica gel column using hexane as eluant, giving the isothiocyanates as an early eluate. Unchanged material and small amounts of benzyl acetate were retained on the column or eluted quite slowly.

In order to ascertain the scope of photochemical isothiocyanate synthesis, we extended the present procedure to some poly(thiocyanatomethyl)benzenes. Upon irradiation in acetic acid, bis(thiocyanatomethyl)-polymethylbenzenes **1e**—**1h** likewise underwent isomerization, giving the corresponding bis(isothiocyanatomethyl)polymethylbenzenes **2e**—**2h** in fair to moderate yields (Table 2). The two vicinally disposed thiocyanatomethyl groups did not seem to interfere with each other during isomerization, since **1e** was smoothly transformed into **2e**. When the reaction was interrupted at early stages, (isothiocyanatomethyl)(thiocyanatomethyl)benzenes were obtained as intermediates along with the expected diisothiocyanates. Until now, no direct method was available for the preparation of such mixed benzylic thiocyanate–isothiocyanates.

Under similar irradiation, tris(thiocyanatomethyl)-benzene **1i** readily isomerized to tris(isothiocyanatomethyl)benzene **2i**. A patent description claims that

a) Based on the isolated pure product. b) The PMR spectra were measured in carbon tetrachloride.

the reaction of poly(chloromethyl)benzenes with potassium thiocyanate in the presence of potassium iodide in *N*,*N*-dimethylformamide under reflux gives the corresponding poly(isothiocyanatomethyl)benzenes in high yields.[25] This procedure was carefully repeated using several poly(chloromethyl)polymethylbenzenes as substrate, and the products obtained were shown by TLC and PMR analyses to be a mixture of various benzylic compounds. Although polyisothiocyanates could be isolated pure by preparative thick-layer chromatography, this method was unsuitable for laboratory purposes, especially when pure compounds were needed. The photochemical conversion of polythiocyanates into polyisothiocyanates represents, to our knowledge, the first example of a multiple thiocyanate isomerization and the results summarized in Table 2 indicate the general character of this reaction. All the polyisothiocyanates obtained are colorless fine needles, slightly soluble in hexane, benzene, and carbon tetrachloride, and soluble in dichloromethane and hot

ethanol. They can be recrystallized without alteration from ethanol and stored indefinitely, without appreciable deterioration, when kept in a dessicator protected against the daylight.

Although yields were only fair to modest (no attempt was made to optimize the reaction conditions), the easy availability of the starting compounds, the ease of performance, and the mild reaction conditions render this procedure quite useful for the laboratory-scale preparation of various poly(isothiocyanatomethyl)-benzenes, which are otherwise only laboriously accessible.

Experimental

The melting points were taken on a hot-stage apparatus and are uncorrected. The IR spectra were determined in Nujol mulls on a Hitachi 215 spectrophotometer. The PMR spectra were obtained on a Varian T-60 spectrometer, using deuteriochloroform as solvent and TMS as internal standard, unless otherwise stated. The UV spectra were recorded on a Hitachi 124 spectrophotometer in 95% ethanol solutions. All photochemical reactions were conducted using a Halōs PlH 100 high-pressure mercury lamp in a water-cooled quartz immersion well. The solution was flushed with dry nitrogen prior to irradiation and was stirred during the reaction by a magnetic stirring bar.

The benzyl thiocyanates and poly(thiocyanatomethyl)-benzenes were prepared by the reaction of the corresponding chlorides with potassium thiocyanate and recrystallized from ethanol or hexane prior to use. All the new thiocyanates were characterized by elemental analyses as well as by the IR and PMR spectral data summarized in Table 1. The following is a typical experimental procedure.

*2,4,6-Tris(thiocyanatomethyl)-1,3,5-*trimethylbenzene (**1i**). A solution of 2,4,6-tris(chloromethyl)-1,3,5-trimethylbenzene (2.0 g (7.5 mM)) and potassium thiocyanate (15.0 g (156 mM)) in DMF (100 ml) was allowed to stand at room temperature for 4 h and then diluted with water (200 ml). The precipitated solid was filtered off and recrystallized from ethanol to give **1i** as white needles, mp 143—145 °C. Yield, 1.90 g (76%).

The general procedure of photo-induced transformation of thiocyanates into isothiocyanates is illustrated below with the representative preparation of two isothiocyanates. Other isothiocyanates obtained are shown in Table 2, along with the corresponding isolation yields as well as IR and PMR spectral data.

2,4,6-Trimethylbenzyl Isothiocyanate (**2b**). A solution of 2,4,6-trimethylbenzyl thiocyanate (**1b**; 100 mg (0.524 mM)) in acetic acid (40 ml) was irradiated with a high-pressure mercury lamp for 0.5 h in an atomosphere of nitrogen at room temperature. Thin-layer chromatography showed that the conversion to a single photo-product was nearly complete within this period of time, with only a little starting material recovered. A pale yellow photo-equilibrium mixture was diluted by the addition of water (200 ml) and the product was extracted with ether. The ethereal extract was washed successively with water, aqueous sodium hydrogencarbonate, and water again, dried over anhydrous magnesium sulfate, and evaporated to dryness on a rotary evaporator. The residue was placed on a top of a short silica gel column and eluted with hexane. Evaporation of early eluates followed by recrystallization of the residue from ethanol gave isothiocyanate **2b** as colorless needles, mp 33—34 °C. Yield, 54 mg (54%).

4,6-Bis(isothiocyanatomethyl)-1,2,3,5-tetramethylbenzene (**2g**). A solution of 4,6-bis(thiocyanatomethyl)-1,2,3,5,-tetramethylbenzene (**1g**; 100 mg (0.362 mM)) in dry acetic acid (100 ml) was irradiated under nitrogen for 0.5 h at room temperature and worked up in a manner similar to the above. The solid residue obtained after removal of the solvent was chromatographed on a short column of silica gel; evaporation of the early eluates gave bis(isothiocyanatomethyl) compound **2g** as fine needles, 55 mg (55%). Mp 110—111 °C (ethanol).

2-(Isothiocyanatomethyl)-4-(thiocyanatomethyl)-1,3,5-trimethylbenzene (**2j**). The photoisomerization was carried out essentially as described for **2b**, using 2,4-bis(thiocyanatomethyl)-1,3,5-trimethylbenzene (**1f**; 300 mg (1.1 mM)) and acetic acid (70 ml). After 15 min the reaction was stopped and the solution was diluted with water, extracted with ether, and the solvent removed *in vacuo*. The crude product mixture was separated by silica gel chromatography and further purified by preparative thin-layer chromatography to give **2j** (80 mg (27%)), mp 80—82 °C, and **2f** (57 mg (19%)), mp 99—100 °C.

Preparation of *S*-Vinylsulfilimines

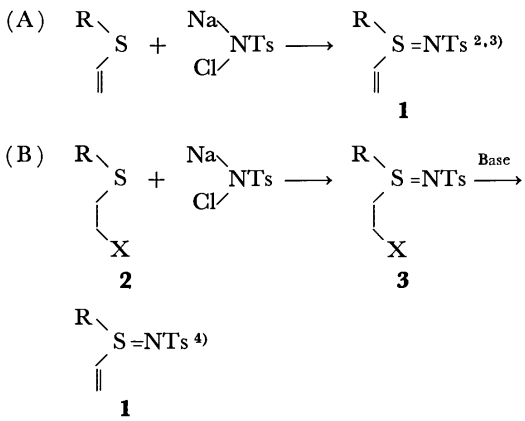
Tamotsu YAMAMOTO,*,† Masa-aki KAKIMOTO, and Makoto OKAWARA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227
(Received August 24, 1978)

For the preparation of *S*-vinylsulfilimines (**1**), mainly *S*-phenyl-*N*-tosyl-*S*-vinylsulfilimine, three routes were examined, *viz.*, (A) the reaction of vinyl sulfide with chloramine T, (B) that of 2-haloethyl phenyl sulfide with chloramine T followed by dehydrohalogenation, and (C) that of 2-hydroxyethyl sulfide with chloramine T followed by acetylation of the hydroxyl group and deacetoxylation. Route A has disadvantages of troublesome preparation of vinyl sulfides and low yield. Route B gives the precursor sulfilimine to **1** in good yield only by use of anhydrous chloramine T. Route C gives the best results in view of starting material and yield.

For the preparation of common *N*-tosylsulfilimines such as *S,S*-dialkyl-, *S,S*-diaryl-, and *S*-alkyl-*S*-aryl-*N*-tosylsulfilimines, the reaction of the corresponding sulfides with chloramine T is known to be a convenient method.[1]

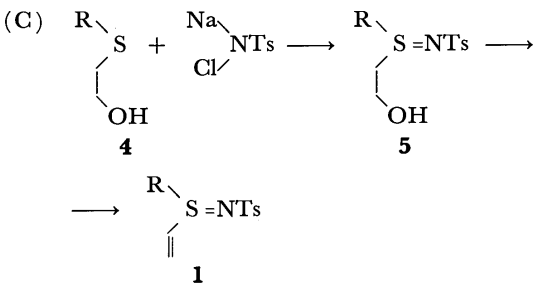
However, only a few reports have appeared on the preparation of *S*-vinylsulfilimines (**1**) which exhibit interesting behavior, *i.e.*, *S,S*-divinyl-*N*-tosylsulfilimine[2] prepared for the structural confirmation of divinyl sulfide and 2-substituted vinylsulfilimines, RS(CH=CHSO$_n$Ar)=NTs (n=0—2) prepared for antibiotics.[3] The sulfilimines have been prepared by the reaction of the corresponding vinyl sulfides with chloramine T (route A).

Recently, it was reported that *S*-phenyl-*N*-tosyl-*S*-vinylsulfilimine (**1a**) reacts with several protonic compounds to give the Michael-type adducts in good yields[4] and with Grignard reagents to give 2-substituted vinyl sulfides,[5] for the preparation of which the method *via* the reaction of 2-bromoethyl phenyl sulfide (**2a**) with chloramine T followed by dehydrobromination was employed (route B).



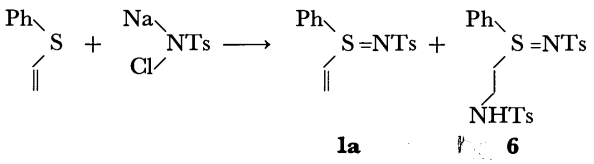
However, route A has such disadvantages as troublesome preparation of vinyl sulfide and low yield of *S*-vinylsulfilimine, and route B the unavoidable use of toxic (dermatitis) 2-bromoethyl sulfide (**2**) and anhydrous chloramine T. Since **2** can be prepared by the reaction of 2-chloroethanol with thiolate followed by the bromination of hydroxyl group, an alternative route to *S*-vinylsulfilimine (route C) *via* the reaction of 2-hydroxyethyl sulfide (**4**) with chloramine T followed by dehydration seems to be promising.

In the present paper we describe the results obtained by examination of the three routes A, B, and C mainly for the preparation of *S*-phenyl-*N*-tosyl-*S*-vinylsulfilimine (**1a**).



Results and Discussion

Method Using Vinyl Sulfide (Route A). Route A was first examined for the preparation of *S*-phenyl-*N*-tosyl-*S*-vinylsulfilimine (**1a**). Phenyl vinyl sulfide was allowed to react with an equimolar amount of chloramine T ($3H_2O$) in ethanol to give the corresponding sulfilimine **1a** in 44% yield. In this reaction, a by-product confirmed to be a Michael-type adduct, *S*-phenyl-*N*-tosyl-*S*-(2-tosylaminoethyl)sulfilimine (**6**), was obtained. The yield of **6** could be reduced by the addition of a trace amount of acetic acid. The structures of the compounds were confirmed by IR and NMR spectra and elemental analyses.

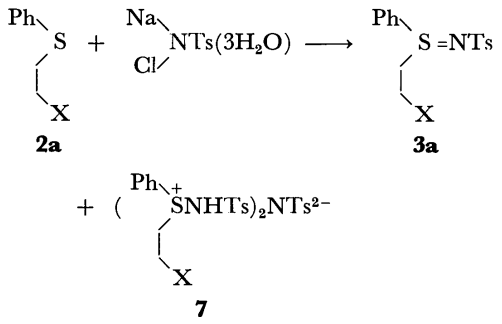


Method Using 2-Haloethyl Sulfide (Route B). Preparation of S-*(2-Bromoethyl)*-S-*phenyl*-N-*tosylsulfilimine (**3a**)*: 2-Bromoethyl phenyl sulfide (**2a**) and a slight excess of chloramine T ($3H_2O$) were allowed to react in methanol at 0 °C. After the reaction, the sulfilimine (**3a**) was isolated as white crystals in a 74% yield. The structure of **3a** was confirmed by IR and NMR spectra and elemental analysis.

The semi-solid compound (**7**) having the following structural characteristics was isolated besides **3a**. From the IR spectrum, **7** was assumed to have NH groups, two kinds of SO_2 groups, and S–N bond. From its NMR as well as IR spectra **7** was shown to

† Present address: Faculty of Engineering, Kanto Gakuin University, Mutsuura, Kanazawa-ku, Yokohama 236.

be formed from sulfide **2a** and chloramine T in the ratio 2 : 3.



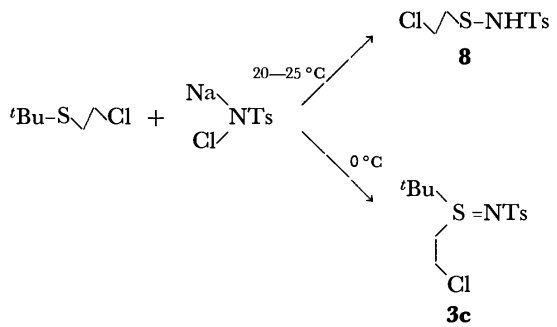
In this case, the starting sulfide **2a** was not recovered.

When the anhydrous chloramine T (dehydrated over phosphorus pentaoxide) was used, **3a** was obtained in a 62% yield and the starting sulfide **2a** was recovered in a 33% yield. Thus, the yield of **3a** based on reacted **2a** amounted to 93%.

The formation of **7** is attributable to the presence of water. This was also observed by Mann and Chaplin : triphenylphosphine reacts with anhydrous chloramine T to give the corresponding phosphine imide, while with hydrated chloramine T it gives a compound with the composition $(Ph_3\overset{+}{P}\text{–NHTs})_2NTs^{2-}$.[6]

In a similar manner, other *S*-(2-haloethyl)-*N*-tosylsulfilimines (**3**) were prepared. *S*-(2-Bromoethyl)-*S*-*p*-tolyl-*N*-tosylsulfilimine (**3a**) was prepared in a good yield from the corresponding starting materials. The reacation of *t*-butyl 2-chloroethyl sulfide with chloramine T($3H_2O$) is complicated. When the reaction was carried out at room temperature (20—25 °C), *S*-(2-chloroethyl)-*N*-tosylsulfenamide (**8**) was obtained quantitatively, while when carried out below 0 °C, *S*-*t*-butyl-*S*-(2-chloroethyl)-*N*-tosylsulfilimine (**3c**) was obtained in an 80% yield. The duality of the reaction seems to be caused by competition between nucleophilic substitution and elimination.

The structures of **3b**, **3c**, and **8** were confirmed by IR and NMR spectra and elemental analyses.



Dehydrohalogenation of S-*(2-Haloethyl)*-N-*tosylsulfilimines*: Dehydrobromination of *S*-(2-bromoethyl)-*S*-phenyl-*N*-tosylsulfilimine (**3a**) to *S*-phenyl-*N*-tosyl-*S*-vinylsulfilimine (**1a**) in dichloromethane was accomplished quantitatively by treatment with a slight excess of triethylamine at room temperature.

Similarly, dehydrobromination of **3b** gave the corresponding *S*-vinylsulfilimine (**1b**) almost quantitatively. However, dehydrochlorination of *S*-*t*-butyl-*S*-(2-chloroethyl)-*N*-tosylsulfilimine (**3c**) with triethylamine was not successful. In this case, a stronger base, DBU (1,8-diazabicyclo[5.4.0]undec-7-ene), acted to cause dehydrochlorination to *S*-*t*-butyl-*N*-tosyl-*S*-vinylsulfilimine (**1c**).

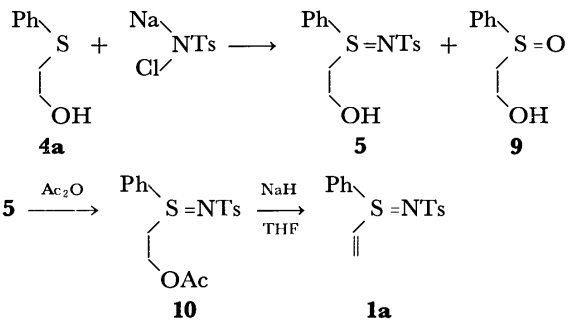
The structures of the *S*-vinylsulfilimines obtained, **1a, 1b**, and **1c** were confirmed by IR and NMR spectra and elemental analyses.

Method Using 2-Hydroxyethyl Sulfide (Route C). Routes A and B have some disadvantages : troublesome preparation of vinyl sulfide and low yield of *S*-vinylsulfilimine **1a** in route A, preparation of anhydrous chloramine T and toxicity of 2-haloethyl sulfide in route B.

2-Hydroxyethyl sulfide, which is an accessible and non-toxic sulfide source, was found to react with chloramine T ($3H_2O$) to give the corresponding sulfilimine, *S*-(2-hydroxyethyl)-*S*-phenyl-*N*-tosylsulfilimine (**5**), in a good yield. We examined a route to *S*-vinylsulfilimine from **5**.

The reaction of 2-hydroxyethyl phenyl sulfide with a slight excess of chloramine T ($3H_2O$) in methanol was carried out at 40 °C for 2 h to give the corresponding sulfilimine **5** in a 74% yield. The structure of **5** was confirmed by IR and NMR spectra and elemental analysis (Table 2). 2-Hydroxyethyl phenyl sulfoxide (**9**) was obtained in a 20% yield as a by-product, but no starting sulfide was recovered.

As a route to *S*-vinylsulfilimine **1a**, direct dehydration of **5** by use of *p*-toluenesulfonic acid (acidic catalyst) or phosphorus pentaoxide (dehydrating agent) was unsuccessful. **5** was found to undergo acetylation followed by deacetoxylation to give **1a**. Thus, acetylation of **5** with acetic anhydride was accomplished quantitatively in dichloromethane at room temperature. The acetylated compound (**10**) was deacetoxylated quantitatively with sodium hydride in THF. The structure of **10** was confirmed by spectral comparison with the authentic sample prepared from 2-acetoxyethyl phenyl sulfide and chloramine T ($3H_2O$) in 48% yield.



The results obtained from examination of the three routes together with those from the preparation of the starting sulfides are summarized in Scheme 1 and Table 1. The route starting from 2-chloroethanol gives the best result *via* path P–C, P–H, P–M, and P–N.

Experimental

General. All the melting and boiling points were uncorrected. The IR spectra were recorded on a Hitachi

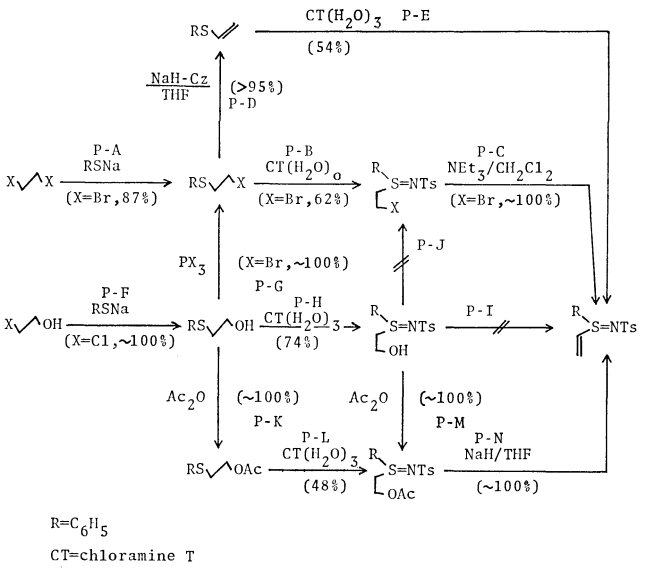
Materials. Sodium Salts of N-*Chloroarenesulfonamides*: Chloramine T and chloramine B of reagent grade were used. Sodium salts of *N*-chloro-*p*-chlorobenzenesulfonamide and *N*-chloromesitylenesulfonamide were prepared by treatment of the corresponding free amide with aq solution of sodium hypochlorite (7%).



Scheme 1.

Sulfides: 2-Bromoethyl phenyl sulfide was prepared by the reaction of sodium benzenethiolate with 1,2-dibromoethane[7] or 2-chloroethanol followed by bromination with PBr_3.[8] Bp 106 °C/4 Torr (132—136 °C/13 Torr).[7] 2-Bromoethyl *p*-tolyl sulfide was prepared by the reaction of sodium *p*-toluenethiolate with 1,2-dibromoethane. Yield 65%; bp 135—136 °C/6 Torr. *t*-Butyl 2-chloroethyl sulfide was prepared by the reaction of sodium 2-methyl-2-propanethiolate with 2-chlroroethanol followed by chlorination with thionyl chloride. Yield(overall) 77%; bp 79—82 °C/30 Torr (81—82 °C/30 Torr).[9] 2-Hydroxyethyl phenyl sulfide was prepared by the reaction of sodium benzenethiolate with 2-chloroethanol.[10] Yield 99%; bp 115—118 °C/3 Torr (115—116 °C/2 Torr).[10] 2-Acetoxyethyl phenyl sulfide was prepared by acetylation of 2-hydroxyethyl phenyl sulfide with acetic anhydride. Yield 20% (rt, 24 h) and 99% (160 °C, 3 h); bp 111—112 °C/1 Torr; NMR($CDCl_3$): δ 1.96 (s, 3H), 3.09 (t, 2H), 4.18 (t, 2H), 7.1—7.4 (m, 5H). Phenyl vinyl sulfide was prepared by dehydrobromination of **2a** with sodium hydride (more than equimolar amount) in THF in the presence of carbazole (1/10 mol to sulfide). Yield 90%; bp 75—77 °C/12 Torr (66—68 °C/6 Torr).[11]

*Preparation of **1a** from Vinyl Sulfide and Chloramine T.* To a stirred solution of chloramine T($3H_2O$)(2.82 g, 10 mmol) in EtOH (20 ml) was added phenyl vinyl sulfide (1.36 g, 10 mmol) and then 0.05 ml of acetic acid. After the reaction mixture had been stirred at 40 °C for 1 h, the mixture was stirred at room temperature for one day. The solution obtained was concentrated under reduced pressure and added to ice water to precipitate a white solid of **1a**. The solid was collected by filtration, washed with Et_2O–MeOH (1:1) and dried. Yield of **1a**: 1.65 g (54%). When this reaction was carried out without acetic acid, a mixture of **1a** and *S*-(2-tosylaminoethyl)-*S*-phenyl-*N*-tosylsulfilimine (**6**) was obtained which were separated by treatment with benzene. **1a** (1.34 g, 44%) was obtained from sparingly soluble part in benzene and **6** (1.7 g, 10%) from the soluble part. **1a**: mp 111—113 °C (CH_2Cl_2–Et_2O). **6**: mp 124—125.5 °C (CH_2Cl_2–Et_2O); IR(KBr): 3230 (NH), 1338 and 1282 ($\nu_{as}SO_2$), 1160 and 1140 (ν_sSO_2), 970 (S=N), 815 (*p*-C_6H_4), 748 and 688 cm^{-1} (C_6H_5); NMR($CDCl_3$): δ 2.40 (s, 3H), 2.48 (s, 3H), 3.0—3.7 (m, 4H), 5.9 (s, 1H), 7.19 (d, 2H, J=8 Hz), 7.4—7.8 (m, 5H), 7.31 (d, 2H, J=8 Hz), 7.69 (d, 4H, J=8 Hz). Found: C, 55.18; H, 5.20; N, 5.65%. Calcd for $C_{22}H_{24}N_2O_4S_3$: C, 55.43; H, 5.09; N, 5.88%.

*Preparation of **3a**.* [A] To a stirred solution of chloramine T($3H_2O$)(6.19 g, 22 mmol) in MeOH (50 ml) was added dropwise a solution of **2a** (4.34 g, 20 mmol) in MeOH (10 ml) at 20 °C. After 3 h stirring, the resulting mixture was evaporated to dryness under reduced pressure. The residue obtained was extracted with $CHCl_3$ (50 ml), washed with saturated aq solution of NaCl and dried over anhydrous Na_2SO_4. The dried $CHCl_3$ solution was evaporated to dryness under reduced pressure and the resulting oily residue was triturated with Et_2O (50 ml) until solid of **3a** was deposited. The white solid was collected by filtration and recrystalized from CH_2Cl_2–Et_2O. Yield of **3a**: 3.63 g (47% based on **2a**).

To the ethereal filtrate was added hexane (20 ml) to deposit 2.79 g (30% based on **2a**) of **7** which has low melting point. **7**: IR (neat): 3220 (NH), 1330 and 1280 ($\nu_{as}SO_2$), 1158 and 1140 (ν_sSO_2), 970 cm^{-1} (S=N); NMR($CDCl_3$): δ 2.33 (s, 6H), 2.37 (s, 3H), 3.1—3.7 (m, 8H), 7.15 (d, 4H, J=8 Hz), 7.25 (d, 2H, J=8 Hz), 7.3—7.8 (m, 16H); MS: *m/e* 605 and 601 (metastable ion), 388 and 386, 279, 278, 169.

[B] To a stirred solution of chloramine T (anhydrous, 5.01 g, 22 mmol) in absolute ethanol (50 ml) was added a solution of **2a** (4.34 g, 20 mmol) in absolute ethanol (10 ml) at 20 °C. The reaction mixture was worked up in a similar manner to that in [A]. By trituration with Et_2O followed by filtration, 4.79 g (62% based on **2a**) of **3a** was obtained. 1.43 g of **2a** (33%) was recovered from the filtrate. **3a**: mp 98—98.5 °C (CH_2Cl_2–Et_2O). The spectral and analytical data are given in Table 2.

*Preparation of **3b**.* **3b** was obtained in a similar manner to that for **3a**. Yield: 50%. Mp: 127—129 °C. The spectral and analytical data are given in Table 2.

*Preparation of **3c**.* To a solution of chloramine T ($3H_2O$) (987 mg, 3.5 mmol) in EtOH(30 ml) was added dropwise *t*-butyl 2-chloroethyl sulfide (458 mg, 3 mmol) in EtOH (10 ml) at 0 °C for 1 h. After 10 h stirring at 0 °C, the reaction mixture was concentrated to 10 ml under reduced pressure. The solution was added to 200 ml of ice water to precipitate white solid of **3c**, which was collected by filtration, washed with MeOH–Et_2O (1 : 1) and dried. Yield : 775 mg (80%). **3c**: mp 102—104 °C (CH_2Cl_2–Et_2O). When the reaction was carried out at room temperature, a white precipitate of *S*-(2-chloroethyl)-*N*-tosylsulfenamide (**8**) was obtained. The precipitate was collected by filtration and dissolved in ether (50 ml) followed by drying over anhydrous Na_2SO_4. The ethereal solution was concentrated to reprecipitate by addition of hexane. Yield 12.0 g (90%). **8**: mp 92—94 °C (Et_2O–hexane); IR(KBr): 3280 (NH), 1370 ($\nu_{as}SO_2$), 1160 (ν_sSO_2), 868 (S=N), 818 cm^{-1} (*p*-C_6H_4); NMR($CDCl_3$) : δ 2.44 (s, 3H), 3.02(t, 2H, J=7 Hz), 3.78 (t, 2H, J=7 Hz), 6.48 (s, 1H), 7.33 (d, 2H, J=8 Hz), 7.81 (d, 2H, J=8 Hz). Found: C, 41.00; H, 4.67; N, 5.26%. Calcd for $C_9H_{12}ClNO_2S_2$: C, 40.67; H, 4.56; N, 5.27%. MS: *m/e* 267 and 265 (M^+), 155 ($SO_2C_7H_7$).

*Dehydrohalogenation of **3**. General Procedure*: To a solution of **3** (3 mmol) in CH_2Cl_2 (30 ml) was added NEt_3 or DBU in more than an equimolar amount at room temperature. After 2—10 h stirring the reaction mixture was washed with brine and dried over anhydrous Na_2SO_4. The dried solution was evaporated to dryness under reduced pressure. The residue was triturated with ether (30 ml) to deposit the solid of *S*-vinylsulfilimine (**1**).

*Preparation of S-(2-Hydroxyethyl)-S-phenyl-N-tosylsulfilimine (**5**).* To a stirred solution of chloramine T ($3H_2O$) (3.10 g, 11 mmol) in MeOH (20 ml) was added a solution

of 2-hydroxyethyl phenyl sulfide (1.54 g, 10 mmol) in MeOH (10 ml) at room temperature. After the mixture was stirred at 40 °C for 2 h, the resulting solution was worked up as described above to give 2.38 g (74%) of **5** as white solid. **5**: mp 95—96 °C (CH_2Cl_2–Et_2O). The ethereal solution obtained by filtration of **5** gave 687 mg (20%) of 2-hydroxyethyl phenyl sulfoxide (**9**) after evaporation followed by chromatography (silica gel–CH_2Cl_2 followed by acetone). **9**: oil; IR(neat) : 3400—3300 (OH), 1040—1020 (S=O), 758 and 690 cm^{-1} (C_6H_5); NMR ($CDCl_3$): δ 2.9—3.4 (m, 2H), 3.9—4.4 (m, 3H), 7.5—7.8 (m, 5H); MS: *m/e* 171 (M^+), 170 (M^+-H), 126 ($M^+-CH_2CH_2OH$).

*Acetylation of **5** to **10**.* To a solution of **5** (3.23 g, 10 mmol) in CH_2Cl_2 (50 ml) was added 2 ml of acetic anhydride at room temperature. The mixture was stirred at room temperature for 24 h. The resulting solution was evaporated to dryness under reduced pressure. The residue was triturated with Et_2O (50 ml) to give 3.47 g (95%) of white solid **10**. **10**: mp 95—96 °C (CH_2Cl_2–Et_2O). The spectral and analytical data are given in Table 2.

*Authentic Sample of **10**.* To a solution of chloramine T ($3H_2O$) (3.10 g, 11 mmol) in MeOH (20 ml) was added 2-acetoxyethyl phenyl sulfide (1.96 g, 10 mmol) in MeOH (10 ml) at room temperature. The mixture was stirred at 40—50 °C for 2 h. The resulting solution was worked up in similar manner to that for **3a** to give 1.93 g (48%) of **10**.

*Deacetoxylation of **10** to **1a**.* To a solution of **10** (3.65 g, 10 mmol) in THF (50 ml) was added sodium hydride (0.5 g) at room temperature under nitrogen atmosphere. The mixture was stirred at room temperature for 24 h. The resulting mixture was filtrated, evaporated and triturated with ether (50 ml) to give 3.60 g (99%) of **1a**.

Syntheses of Polymerizable Acetals. II. Readily Hydrolyzable Acetals from Citronellol and Vitamins

Hiroyoshi KAMOGAWA,* Yuichiro HARAMOTO, and Masato NANASAWA
Department of Applied Chemistry, Yamanashi University, Takeda, Kofu 400
(Received August 31, 1978)

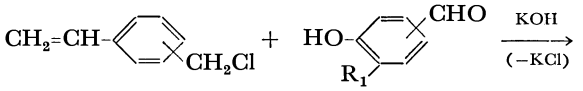
Three perfume acetals and four vitamin acetals have been synthesized by the acid-catalyzed reactions of vinylbenzyloxy- and methoxy-substituted benzaldehydes with citronellol and the reactions of vinylbenzaldehyde with vitamins B_6, C, B_1, and B_2, respectively. The acid hydrolyses of these novel acetals readily released citronellol and vitamins under mild conditions, some accelerations of the hydrolysis rate by the electron-donating para substituents being observed in the case of the perfume acetals.

The controlled release of functional compounds by means of the hydrolytic cleavage of chemical bonds is interesting since the susceptibility to cleavage is dependent upon chemical structure, thereby assuring a variety of release rates.

Some instances of the controlled release taking advantage of the ready hydrolysis of an ester linkage are known.[1,2] In a previous paper,[3] the syntheses of the polymerizable vinylbenzaldehyde acetals with perfume alcohols, which provided, by polymerization, the pendant polymers possessing the ability of the ready release of pendant portion (perfume) by acid hydrolysis, were reported.

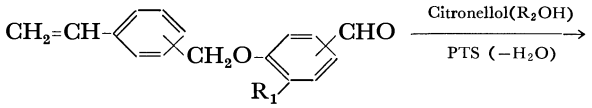
The present paper is intended to cover three perfume acetals synthesized from the benzaldehyde substituted with electron-donating groups and citronellol as well as four vinylbenzaldehyde acetals with vitamin alcohols, all acetals synthesized being novel.

Acetals of substituted benzaldehyde with citronellol have been synthesized *via* the following route.

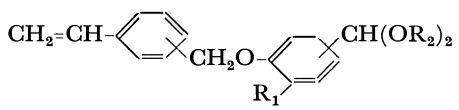


I: $m/p = 60/40$

IIa: R_1 = H (CHO, para to OH)
IIb: $R_1 = OCH_3$ (CHO, meta to OH and para to R_1)
IIc: $R_1 = OCH_3$ (CHO, para to OH)

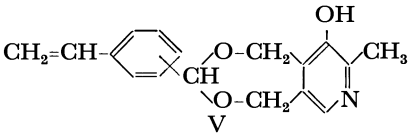


IIIa: R_1 = H (CHO, para to OCH_2)
IIIb: $R_1 = OCH_3$ (CHO, meta to OCH_2)
IIIc: $R_1 = OCH_3$ (CHO, para to OCH_2)

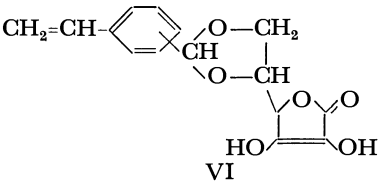


IVa: R_1 = H ($CH(OR_2)_2$, para to OCH_2)
IVb: $R_1 = OCH_3$ ($CH(OR_2)_2$, meta to OCH_2)
IVc: $R_1 = OCH_3$ ($CH(OR_2)_2$, para to OCH_2)

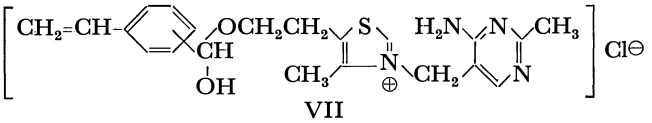
Vinylbenzaldehyde acetals with vitamin alcohols have been prepared from vinylbenzaldehyde (m/p= 60/40) and the corresponding vitamin alcohols in the same manner as that for IVa—c. The structures of the acetals conforming to the experimental data are as follows.



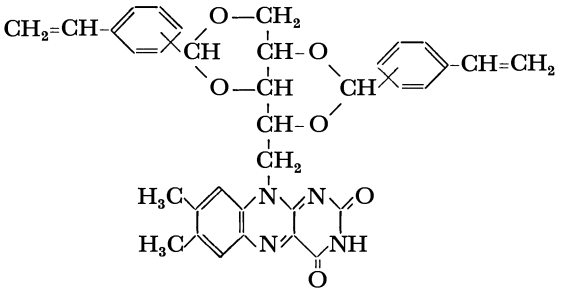
V
Acetal with vitamin B_6



VI
Acetal with vitamin C



VII
Hemiacetal with vitamin B_1



VIII
Acetal with vitamin B_2

The ring structure of acetal VIII is uncertain, due to insufficient analytical data sufficient to exactly determine the structures of the dioxa rings. Vinylbenzyl chloride (I) and vinylbenzaldehyde,[3] both of which were 60/40 mixtures of the meta and para isomers, were chosen as starting materials from the stand-point of availability, such that the acetals made should also be mixtures of the meta and para isomers. The isomers, however, could not be separated by chromatographic means; all attempts to determine the m/p ratios in the acetals isolated also failed. These problems, however, are not thought to pose any practical troubles.

Benzaldehyde acetals with citronellol, bearing two electron-donating alkoxyl substituents at both the para and meta positions (IVa—c), were synthesized smoothly. Despite the poor stabilities and limited solubilities of the vitamins employed, the vitamin acetals and a hemiacetal were isolated in low yields. Vitamin B_1

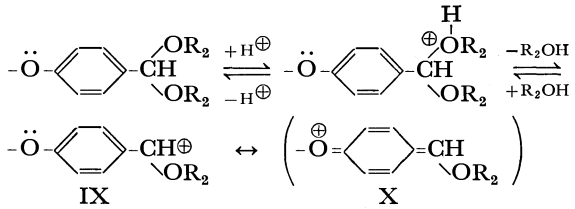
provided only a hemiacetal (VII), presumably due to the steric hindrance exerted by the bulky vitamin B_1 molecule and the electrostatic repulsion of the VII cation produced against the attack of another vitamin B_1 cation.

The ring structure of the acetal V involving a seven-membered dioxa ring appears to be correct, since a phenolic hydroxyl singlet (δ=5.9 ppm) exists in the NMR. The poor reactivity of the phenolic hydroxyl group in the acetalization also supports this structure.

The ring structure of acetal VIII with two six-membered dioxa rings, as presented here, is thought to represent the most strain-free structure. However, five-membered and seven-membered dioxa rings may also be possible, since it appears that little differences exist in the reactivity of acetalization among the three secondary hydroxyl groups in riboflavin and that the main factor determining the ring structure is a steric one.

In vitamin acetal syntheses, the poor solubilities of the vitamins employed in solvents appear to be the principal causes of the low yields found for VI, VII, and VIII. In the case of acetal V, the basicity of the ring nitrogen lowered the acidity of the reaction medium, thereby causing a low yield. However, a large amount of unreacted vitamin was recovered making recycling possible.

The hydrolytic behavior of the acetals has also been investigated. Thus, when subjected to acid hydrolysis with *p*-toluenesulfonic acid in water–tetrahydrofuran (1:2 vol/vol) at 20 °C, monomers IVa—c with electron-donating para substituents hydrolyzed more rapidly than vinylbenzaldehyde dicitronellyl acetal, indicating the resonance stabilization of the intermediate carbocation (IX) and the resulting acceleration of hydrolysis.



It appears reasonable that a more electron-donating *p*-methoxyl substituent (IVb) provides a higher rate than the *p*-benzyloxyl substituent (IVa and IVc).

Since the hydrolysis of acetals from aromatic aldehydes is generally rapid,[4] the differences observed in the rate of hydrolysis were small and all acetals synthesized underwent complete hydrolysis under mild acidic conditions, thereby assuring the controlled release of the functional portions (perfumes and vitamins).

The acetals and the hemiacetal synthesized possess polymerizable styrenic double bonds which, on polymerization, afford the vinyl polymers containing functional portions as pendant.

Experimental

IR, ^{1}H-NMR, and mass spectra were obtained with a Hitachi EPI-G spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively. Elemental analyses were conducted using a Perkin-Elmer 240.

4-(Vinylbenzyloxy)benzaldehyde (IIIa). A solution of 4-hydroxybenzaldehyde (IIa) (12.2 g, 100 mmol) in methanol (60 ml) containing potassium hydroxide (6.6 g, 100 mmol) was evaporated *in vacuo* at 50 °C to dryness. The residue was dissolved in *N,N*-dimethylformamide (60 ml). vinylbenzyl chloride (15.3 g, 100 mmol)(I ; Seibi Chem. Co., 60/40 mixture of meta and para isomers) and phenothiazine (0.1 g) added, and the solution kept at 90 °C for 2 h under nitrogen. The reaction mixture was then poured into a large quantity of water and the resulting oily mass extracted with ether. The extract was washed with dilute aqueous sodium hydroxide, then with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo* at 50 °C. The oily mass was washed with a large amount of petroleum ether and dried *in vacuo* to give a yellowish compound in 60% yield. Oxime: mp 95—96 °C (colorless crystals). This product was pure by TLC and all attempts to separate the meta and para isomers failed.

Found: C, 80.53; H, 6.00%. Calcd for $C_{16}H_{14}O_2$: C, 80.68; H, 5.88%. IR (CCl_4) 2840, 2740 (CHO), 1695 (C=O), 1600 (aryl), 990, 910 (vinyl) cm^{-1}. NMR (CCl_4) δ 5.1 (s, 2H, CH_2), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.7 (d, 1H, $C\underline{H}_2$=CH–), 6.6 (q, 1H, CH_2=C$\underline{H}$–), 7—8 (m, 8H, ArH), 9.9 (s, 1H, CHO) ppm. Mass (*m/e*) 283 (M^+, 3), 117 (100).

3-Vinylbenzyloxy-4-methoxybenzaldehyde (IIIb). Following the same procedure as for IIIa, a light brown viscous liquid was obtained in 50% yield. Oxime: oily.

Found: C, 76.04; H, 6.08%. Calcd for $C_{17}H_{16}O_3$: C, 76.12; H, 5.97%. IR (CCl_4) 2840, 2720 (CHO), 1690 (C=O), 1600 (aryl), 990, 910 (vinyl) cm^{-1}. NMR (CCl_4) δ 3.8 (s, 3H, OCH_3), 5.0 (s, 2H, CH_2), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.7 (d, 1H, $C\underline{H}_2$=CH–), 6.6 (q, 1H, CH_2=C$\underline{H}$–), 6.7—7.4 (m, 7H, ArH), 9.8 (s, 1H, CHO) ppm. Mass (*m/e*) 268 (M^+, 54), 117 (100).

4-Vinylbenzyloxy-3-methoxybenzaldehyde (IIIc). Following the same procedure as that for IIIa, a light brown solid was obtained in 40% yield. Oxime: mp 82—83 °C (white powder).

Found: C, 76.04; H, 6.06%. Calcd for $C_{17}H_{16}O_3$: C, 76.12; H, 5.97%. IR (CCl_4) 2830, 2720 (CHO), 1680 (C=O), 1590 (aryl), 990, 910 (vinyl) cm^{-1}. NMR (CCl_4) δ 3.8 (s, 3H, OCH_3), 5.1 (s, 2H, CH_2), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.7, (d 1H, $C\underline{H}_2$=CH–), 6.6 (q, 1H, CH_2=C$\underline{H}$–), 6.5—7.3 (m, 7H, ArH), 9.7 (s, 1H, CHO) ppm. Mass (*m/e*) 268 (M^+, 3), 117 (100).

4-(Vinylbenzyloxy)benzaldehyde Dicitronellyl Acetal (IVa). A solution of IIIa (3.0 g, 13 mmol), citronellol (3.9 g, 25 mmol), *p*-toluenesulfonic acid (PTS) (0.4 g), and phenothiazine (0.1 g) in chloroform (100 ml) was refluxed for 6 h in a flask fitted with a Soxhlet extractor charged with 3 A molecular sieves (1/16). The chloroform solution was then washed with aqueous sodium carbonate, dried over anhydrous sodium sulfate, and evaporated *in vacuo* at 50 °C to leave an oil. The oil was subjected to alumina column chromatography to collect petroleum ether eluates. Upon evaporation of the solvent, a pale yellow liquid, pure by VPC, was obtained. This could not be separated into the meta and para isomers (31% yield).

Found: C, 81.65; H, 9.24%. Calcd for $C_{36}H_{52}O_3$: C, 81.20; H, 9.77%. IR(CCl_4) 2960—2850 (alkyl), 1600 (aryl), 990, 910 (vinyl) cm^{-1}. NMR(CCl_4) δ 0.8—3.6 (m, 38 H, citronellyl), 5.1 (s, 2H, $ArCH_2O$), 5.1—5.6 (m, 2 H, $C\underline{H}_2$=CH–+–CH$\begin{matrix}\diagup O- \\ \diagdown O-\end{matrix}$), 5.7 (d, 1H, $C\underline{H}_2$=CH–), 6.5—7.6 (m, 9H, CH_2=C$\underline{H}$–+ArH) ppm. Mass (*m/e*) 377 ($M^+ - OC_{10}H_{19}$).

3-Vinylbenzyloxy-4-methoxybenzaldehyde Dicitronellyl Acetal (IVb). Following the same procedure as that for IVa, a pale yellow liquid was obtained in 27% yield.

Found: C, 79.16; H, 9.24%. Calcd for $C_{37}H_{54}O_4$: C, 79.00; H, 9.61%. IR(CCl_4) 2960—2860 (alkyl), 1600 (aryl), 990, 910 (vinyl) cm^{-1}. NMR(CCl_4) δ 0.8—3.5 (m, 38 H, citronellyl), 3.8 (s, 3 H, OCH_3), 5.0 (s, 2 H, Ar–CH_2O), 5.3 (s, 1H, $-\underset{}{\overset{\diagup O-}{CH}}\underset{\diagdown O-}{}-$), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.7 (d, 1H, $C\underline{H}_2$=CH–), 6.3—7.5 (m, 8H, CH_2=C$\underline{H}$–+ArH) ppm. Mass (*m/e*) 407 ($M^+-OC_{10}H_{19}$).

4-Vinylbenzyloxy-3-methoxybenzaldehyde Dicitronellyl Acetal (IVc). Following the same procedure as that for IVb, a pale yellow liquid was obtained in 28% yield.

Found: C, 79.17; H, 9.35%. Calcd for $C_{37}H_{54}O_4$: C, 79.00; H, 9.61%. IR(CCl_4) 2970—2850 (alkyl), 1600 (aryl), 990, 910 (vinyl) cm^{-1}. NMR(CCl_4) δ 0.8—3.5 (m, 38H, citronellyl), 3.8 (s, 3H, OCH_3), 5.0 (s, 2H, $ArCH_2O$), 5.1 (d, 1H, $C\underline{H}_2$=CH–), 5.3 (s, 1H, $-\underset{}{\overset{\diagup O-}{CH}}\underset{\diagdown O-}{}-$), 5.7 (d, 1H, $C\underline{H}_2$=CH–), 6.5—7.6 (m, 8H, CH_2=C$\underline{H}$–+ArH) ppm. Mass (*m/e*) 563 (M^+, 6), 286 (100).

Vinylbenzaldehyde Acetal with Vitamin B_6 (V). A mixture of vinylbenzaldehyde (3.0 g, 23 mmol) (*m/p*= 60/40),[3] pyridoxine (9.3 g, 45 mmol)(vitamin B_6), PTS (0.5 g), phenothiazine (0.1 g), and chloroform (100 ml) was stirred at 70 °C for 6 h under nitrogen in the presence of 3A molecular sieves (1/16). The reaction mixture was washed with aqueous sodium carbonate, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness *in vacuo* at 50 °C. The brown mass was purified by alumina column chromatography and the methanol eluates collected. Upon evaporation of the solvent, a brownish oily mass, which was pure by TLC, was obtained in 4% yield.

Found: C, 72.16; H, 6.28; N, 4.51%. Calcd for $C_{17}H_{16}NO_3$: C, 72.08; H, 6.01; N, 4.95%. IR(CCl_4) 3600 (OH), 1600 (aryl), 1120 (ether), 990, 910 (vinyl) cm^{-1}. NMR(CCl_4+DMSO-d_6) δ 2.4 (s, 3H, CH_3), 4.5(s, 1H, $-\underset{}{\overset{\diagup O-}{CH}}\underset{\diagdown O-}{}-$), 4.6—5.1 (m, 4H, CH_2), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.8 (d, 1H, $C\underline{H}_2$=CH–), 5.9 (s, ArOH), 6.5—6.8 (b, 1H, $-\underset{}{\overset{\diagup O-}{CH}}\underset{\diagdown O-}{}-$), 7.0—8.0 (m, ArH) ppm. Mass (*m/e*) 283 (M^+, 4), 43 (100).

Vinylbenzaldehyde Acetal with Vitamin C (VI). A mixture of vinylbenzaldehyde (3.0 g, 23 mmol), L-ascorbic acid (4.0 g, 23 mmol)(vitamin C), PTS (0.4 g), phenothiazine (0.1 g), and dioxane (50 ml) was stirred at room temperature for 24 h under nitrogen in the presence of 3A molecular sieves with the exclusion of light. Dioxane was then removed by freeze-drying, the residue extracted with ether, and the extract evaporated *in vacuo* at 50 °C. The oily mass, which was washed with petroleum ether, afforded a colorless sticky mass, which was pure by TLC, in 13% yield.

Found: C, 61.27; H, 5.60%. Calcd for $C_{15}H_{14}O_6$: C, 62.07; H, 4.83%. IR ($CHCl_3$) 3580 (OH), 1680 (C=O), 1120 (C–O–), 990, 910 (vinyl) cm^{-1}. NMR(CCl_4+DMSO-d_6) δ 3.4—3.5 (t, 2H, CH_2), 4.1 (b, 1H, $-O\underset{|}{C}\underline{H}CH_2-$), 4.8—4.9 (s, 1H, $-\underset{|}{CH}\underline{C}\underset{|}{H}O-$), 5.3 (s, 1H, $-\underset{}{\overset{\diagup O-}{CH}}\underset{\diagdown O-}{}-$), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.8 (d, 1H, $C\underline{H}_2$=CH–), 6.7 (b, 1H, CH_2=C$\underline{H}$–), 7.0—7.8 (m, 4H, ArH) ppm.

Vinylbenzaldehyde Hemiacetal with Vitamin B_1 (VII). A mixture of vinylbenzaldehyde (1.5 g, 11 mmol), thiamine hydrochloride (3.8 g, 11 mmol), PTS (0.5 g), phenothiazine (0.1 g), and acetonitrile (50 ml) was stirred at room temperature for 72 h under nitrogen in the presence of 3A molecular sieves (1/16). The reaction mixture was evaporated in vacuo at 50 °C to dryness and washed with petroleum ether and ether. The residue was thoroughly shaken with a mixture of aqueous sodium carbonate and sodium chloride and chloroform and the chloroform layer dried over anhydrous sodium sulfate. The sodium sulfate was filtered and extracted with acetonitrile to afford a white powder (mp 138—140 °C) in 10% yield upon evaporation of solvent.

Found : C, 56.77; H, 5.95; N, 12.99%. Calcd for $C_{20}H_{24}N_4O_2SCl$: C, 57.14; H, 5.73; N, 13.33%. IR(KBr) 3300 (OH+NH_2), 1650 (C=$\overset{+}{N}$<), 1000, 920 (vinyl) cm^{-1}. NMR ($CDCl_3$+DMSO-d_6) δ 2.3—2.6 (d, 6H, $2CH_3$), 2.9—3.2 (t, 2H, ), 3.4 (s, 1H, OH), 3.6—3.8 (t, 2H, $OC\underline{H}_2CH_2$), 5.2 (d, 1H, $C\underline{H}_2$=CH–), 5.5 (s, 3H, $-C\underline{H}O-+-\overset{\overset{\|}{N}}{\underset{\oplus}{}}-CH_2$), 5.8 (d, 1H, $C\underline{H}_2$=CH–), 6.6—7.0 (b, 1H, CH_2=C$\underline{H}$–), 7.0—7.6 (m, 4H, ArH), 7.6—7.8 (b, 2H, NH_2), 8.1 (s, 1H, ), 9.8 (s, 1H, ) ppm.

Vinylbenzaldehyde Acetal with Vitamin B_2 (VIII). A mixture of vinylbenzaldehyde (2.0 g, 15 mmol), riboflavin (2.9 g, 7.6 mmol)(vitamin B_2), PTS (0.4 g), phenothiazine (0.1 g), and dioxane (50 ml) was stirred at 50 °C for 5 h under nitrogen in the presence of 3A molecular sieves (1/16), followed by stirring at room temperature for 20 h. The dioxane was then removed by freeze-drying and the residue washed with petroleum ether and aqueous sodium hydrogen carbonate and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate, evaporated *in vacuo* at 50 °C to leave a reddish brown powder (mp 110—113 °C) in 8% yield.

Found: C, 70.62; H, 5.33 ; N, 8.09%. Calcd for $C_{35}H_{32}N_4O_6$: C, 69.54; H, 5.30; N, 9.27%. IR($CHCl_3$) 3380 (NH), 1680 (C=O), 990, 910 (vinyl) cm^{-1}. NMR($CDCl_3$+DMSO-d_6)δ 2.2—2.5 (s, 6H, $2CH_3$), 3.0—5.0 (m, 7H, $3CH+2CH_2$), 5.1—5.3 (d, 3H, $C\underline{H}_2$=CH–+$-\underset{}{\overset{\diagup O-}{CH}}\underset{\diagdown O-}{}-$), 5.8 (d, 2H, $C\underline{H}_2$=CH–), 6.5—7.7 (m, 12H, ArH), 8.3 (b, 1H, NH) ppm. Mass (*m/e*) 604 (M^+, 2), 18 (100).

Hydrolyses of Acetals. A solution of the acetal (1 mmol), PTS (0.05 g), and *t*-butylcatechol (0.001 g) in 30 ml of H_2O–THF (1 : 2 v/v) was stirred at 20 °C under nitrogen. The reaction mixture was neutralized with solid sodium carbonate and evaporated *in vacuo* at 50 °C to remove THF, followed by extraction with a mixture of aqueous sodium carbonate and chloroform. The chloroform layer was dried over anhydrous sodium sulfate and evaporation *in vacuo* at 50 °C afforded the sample for analysis. NMR-determinations using either methoxyl or aryl signals provided the degree of hydrolysis. Typical data are as follows.

IVa: 72.8% in 2 h and 100% in 10 h; IVb: 82.9% in 2 h and 100% in 10 h; IVc: 74.6% in 2 h and 100% in 10 h; V; 62.8% in 2 h and 100% in 10 h; vinylbenzaldehyde dicitronellyl acetal:[3] 64.0% in 2 h and 100% in 10 h.

Preparation of Diphenyl(tricyclohexylphosphine)manganese(II) and Its Reactions with Carbon Dioxide and Organic Carbonyl Compounds

Kazunori MARUYAMA, Takashi ITO, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received September 9, 1978)

Treatment of $Mn(acac)_3$ (acac=acetylacetonato ligand) with $AlPh_3 \cdot Et_2O$ in the presence of PCy_3 (Cy=*cyclo*-C_6H_{11}) gave a new diphenylmanganese(II) complex, Ph_2MnPCy_3 (**1**). Complex **1** reacted with allylic compounds, $CH_2=CHCH_2X$ (X=Br, OPh, $OCH_2CH=CH_2$, and $OCOCH_3$), to give allylbenzene. Carbon dioxide was found to be inserted into the phenyl-manganese σ-bond of **1** to give bis(benzoato)manganese complex, $(PhCOO)_2MnPCy_3$, **2**, which on successive treatment with HCl and diazomethane produced methyl benzoate. Complex **1** reacted with aldehydes, ketones, and esters having no active α-hydrogen atom to give alkoxomanganese species in solution, indicating that the insertion of C=O double bond into the phenyl-manganese σ-bond occurred. On the other hand, acetone and acetophenone reacted with Ph_2MnPCy_3 to give benzene and 2-oxoalkyl complexes, $(RCOCH_2)_2Mn(PCy_3)_m$ (R=Me, Ph), **3**. Reaction of alcohols with **1** afforded alkoxomanganese compounds which catalyze the Tishchenko type and Meerwein-Pondorf type reactions as well as transesterification reactions at room temperature.

Employment of alkylaluminium compounds in combination with transition metal acetylacetonates in the presence of stabilizing ligands has provided useful means in giving alkyl-, hydrido- and low valent transition metal complexes.[1] Extension of the method to the preparation of phenyl-transition metal complexes using triphenylaluminium etherate, $AlPh_3 \cdot Et_2O$, proved successful as well affording new phenyl-nickel,[2] chromium,[3] cobalt,[4] and iron[4] complexes. We now report the preparation of diphenylmanganese(II) complex having tricyclohexylphosphine (PCy_3) from a reaction system composed of $Mn(acac)_3$, $AlPh_3 \cdot Et_2O$ and PCy_3. Although there are many reports concerning organomanganese complexes, isolated examples of organomanganese complexes having other ligand than cyclopentadienyl and carbonyl are quite scarce. As a homoleptic phenylmanganese complex without stabilizing ligand, preparation of somewhat impure diphenylmanganese in 1956 presents the sole example,[5] but characterization of the complex and study of its chemical properties are by no means satisfactory.[6,7] We have found that binding of tricyclohexylphosphine ligand confers a considerable stability on the diphenylmanganese. Treatment of the new diphenylmanganese complex with various reagents, particularly organic carbonyl compounds, produced hitherto unknown new types of organic manganese complexes, some of which show catalytic activities for various reactions.

Results and Discussion

Preparation and Characterization of Ph_2MnPCy_3. Treatment of $Mn(acac)_3$ with $AlPh_3 \cdot Et_2O$ in the presence of PCy_3 in a mixture of diethyl ether and toluene at −50 °C gave a yellow complex of Ph_2MnPCy_3, **1**, in a good yield.

$$Mn(acac)_3 + PCy_3 + 3AlPh_3 \cdot Et_2O \xrightarrow{-50\,^\circ C} Ph_2MnPCy_3 \quad (1)$$

The complex is recrystallizable from hot toluene to give yellow-brown crystals which decompose under vacuum at 160—165 °C. Since the micro-analysis of Ph_2MnPCy_3 was not feasible due to its high sensitivity to air, characterization of this paramagnetic complex (μ_{eff}=2.73 B. M.) was achieved by means of macroscopic analysis of manganese content, infrared spectroscopy and some chemical reactions. The characteristic IR bands of **1** were assigned as follows: 3040 cm^{-1}, ν(C–H) of the phenyl group; 2925 and 2850 cm^{-1}, $\nu_{as}(CH_2)$ and $\nu_s(CH_2)$ of PCy_3; 1445 cm^{-1}, δ(C–H) of PCy_3; 430 cm^{-1}, ν(Mn–C). Treatment of Ph_2MnPCy_3 with gaseous HCl in diethyl ether gave 1.92 mol of benzene per manganese. Treatment of **1** with an excess amount of methyl iodide gave toluene (0.32 mol per mol of complex) and biphenyl (0.74 mol). A quantitative amount of tricyclohexylphosphine oxide was isolated on decomposition of **1** with aqueous H_2O_2. Pyrolysis of **1** at 220 °C under vacuum gave benzene (0.57 mol per mol of complex) and biphenyl (0.63 mol). The Mn^{2+} content in complex **1** determined by a chelate titration method was 11.4% (Calcd for $C_{30}H_{43}PMn$: Mn, 11.2%).

The reaction of $Mn(acac)_3$ and $AlPh_3 \cdot Et_2O$ without tertiary phosphine gave Ph_2Mn in a yield of 23%, which was already prepared from MnI_2 and PhLi by Beerman and Clauss.[5] Addition of PCy_3 in ether to the isolated Ph_2Mn also led to Ph_2MnPCy_3, **1**. However, less basic tertiary phosphines such as PPh_3, PPh_2Me and $Ph_2PCH_2CH_2PPh_2$ did not give isolable adducts of the phosphines with Ph_2Mn. It is noteworthy that the sensitivity of Ph_2MnPCy_3, **1**, towards air is considerably reduced as compared with that of Ph_2Mn which ignites spontaneously on contact with air.

Reaction of Ph_2MnPCy_3 with Allylic Compounds. Ph_2MnPCy_3, **1**, reacted with allylic compounds, $CH_2=CHCH_2X$ (X=Br, OPh, $OCH_2CH=CH_2$, and $OCOCH_3$), to give allylbenzene in fairly high yields (Table 1). Cleavage of C–X bond in $CH_2=CHCH_2X$ on reactions with transition metal complexes have been reported in the cases of *e.g.*, $PhNi(acac)PPh_3$,[8] $Ni(cod)_2$,[9,10] (cod=1,5-cyclooctadiene), and $RuH_2(PPh_3)_4$.[11] The reaction of Ph_2MnPCy_3 with $(CH_2=CHCH_2)_2O$ liberated mainly allylbenzene with small amounts of benzene and biphenyl, and gave a pale

Table 1. Reactions of Ph_2MnPCy_3 **1** with allyl compounds

Allyl compound	Reaction condition (Solvent)	Products (mol/mol of **1**)		
		Ph-H	Ph-$CH_2CH{=}CH_2$	Ph-Ph

yellow powder, which on treatment with acetyl chloride yielded allyl acetate, suggesting that it contains the allyloxomanganese bond.

Two alternative mechanisms are conceivable in accounting for the products. One involves the insertion of $CH_2{=}CHCH_2X$ into the Ph–Mn bond followed by β-elimination of X, not of hydrogen as one usually encounters in the decomposition of alkyltransition metal complexes carrying a β-hydrogen:

$$\underset{\mathbf{1}}{Ph_2MnPCy_3} \xrightarrow[\text{insertion}]{CH_2{=}CHCH_2X} \left[\begin{array}{ccc} CH_2 & -CH & -CH_2 \\ | & | & | \\ Ph & Mn & X \\ & | & \end{array}\right] \xrightarrow[\beta\text{-elimination}]{} PhCH_2CH{=}CH_2 + \text{-Mn-X} \qquad (2)$$

Similar mechanisms have been proposed in accounting for the reaction products of allylic compounds with $PhNi(acac)PPh_3$ and $RuH_2(PPh_3)_4$.[8,11] The alternative mechanism involves the oxidative addition of $CH_2{=}CHCH_2X$ to Ph_2MnPCy_3 with cleavage of the C–X bond followed by reductive elimination to give allylbenzene. Although a similar oxidative addition has been observed in the reactions of bis(cyclooctadiene)nickel(0) with phenyl carboxylate, alkenyl acetate[10] and allylic ethers,[9,12] it seems somewhat less likely that the manganese(II) complex attacks these allyl compounds to cause oxidative addition. In fact **1** did not react with benzyl phenyl ether and dibenzyl ether even by heating at 100 °C for 10 h, whereas under similar conditions the C–O bond in these ethers has been reportedly cleaved in the presence of $Ni(cod)_2$.[9]

Reaction of Ph_2MnPCy_3 with Carbon Dioxide. Carbon dioxide reacted with Ph_2MnPCy_3 at ambient conditions in toluene or diethyl ether at room temperature to give a dark brown precipitate. This precipitate, after isolation, turned to a white powder on drying *in vacuo*. The infrared spectrum of the complex was identical with that of $(PhCOO)_2MnPCy_3$, **2**, prepared by the reaction of Ph_2MnPCy_3 with PhCOOH. The result suggests that insertion of carbon dioxide into the phenyl-manganese σ-bond took place to give benzoatomanganese species. Formation of benzoate derivative of rhodium(I), $(PhCOO)Rh(PPh_3)_3$, has been reported by a similar insertion reaction of CO_2 into the Rh–C bond.[13] The characteristic IR bands of $(PhCOO)_2MnPCy_3$ were observed at 1550 and 1400 cm^{-1} which may be assigned to $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$, respectively. Although $(PhCOO)_2MnPCy_3$, **2**, did not react with methyl iodide at room temperature, treatment of **2** (0.17 g, 0.35 mmol) with gaseous HCl in diethyl ether followed by methylation with diazomethane gave methyl benzoate (0.43 mmol).

$(PhCOO)_2MnPCy_3$, **2**, is thermally very stable and liberates PCy_3 and only trace amounts of CO and CO_2 on heating at 200 °C *in vacuo* for 40 min. The residue is a dark brown powder, which was judged as $(PhCOO)_2Mn$ on the basis of its IR spectrum.

Although the insertion of carbon dioxide into the carbon-manganese σ-bond has been briefly reported for Me_2Mn,[7] the present result exhibits the first example of the isolation of the carboxylato manganese complex as a result of the CO_2 insertion reaction.

Reactions of Ph_2MnPCy_3 with Aldehydes and Ketones. Anionic nature of the phenyl ligand in Ph_2MnPCy_3, **1**, was demonstrated through its reactions with organic carbonyl compounds such as aldehydes, ketones and esters, where secondary alcohols from the first compound

Table 3. Reactions of Ph_2MnPCy_3 **1** with esters[a]

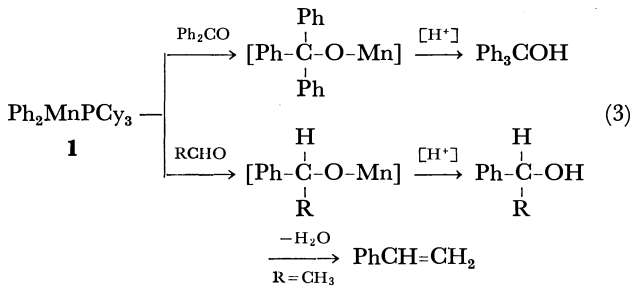
and tertiary alcohols from the last two compounds were detected as the main products (*vide infra*). The results indicate that the chemical property of phenylmanganese complex **1** resembles considerably to that of a phenyl Grignard reagent especially in respect of the stoichiometric reactions with carbonyl compounds.

Complex **1** reacted with benzophenone, acetaldehyde and propionaldehyde to give, after treatment with gaseous HCl or phenol, triphenylmethanol, 1-phenylethanol and 1-phenyl-1-propanol, respectively (Table 2). These results suggest the existence of alkoxomanganese intermediates in the reaction mixtures as shown in Eq. 3.

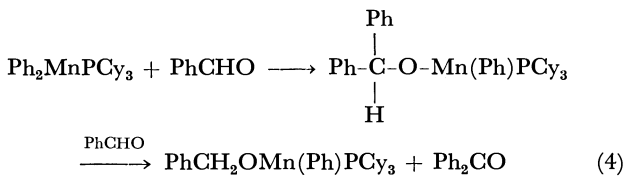


(3)

The formation of styrene after treatment of the reaction mixture of **1** and acetaldehyde with phenol is considered to be the result of dehydration of 1-phenylethylalcohol catalyzed by phenol which is a weak acid (Eq. 3). The acid-catalyzed dehydration reaction of alcohol is well known.[14]

The reaction of **1** with a large excess of acetaldehyde without solvent at −50 °C to room temperature afforded polyether of the type $-[CH(CH_3)-O]_n-$ probably as a result of consecutive insertion of acetaldehyde into Mn–O bond.[15]

Ph_2MnPCy_3, **1**, was found to convert benzaldehyde catalytically into benzyl benzoate at room temperature. The reaction was accompanied by formation of 0.21 equiv. of benzene, 1.33 equiv. of benzophenone and 1.36 equiv. of benzyl alcohol as Table 2 shows. The pale brown powder, isolated from this reaction system, liberated benzyl acetate on the reaction with acetyl chrolide. The result suggests that the powder contains benzyloxo group bonded to manganese. The reaction of **1** with benzaldehyde may be, again, explained by the insertion of the C=O double bond into the Ph–Mn σ-bond as shown in Eq. 4.



(4)

The benzyloxomanganese thus produced is considered to be responsible for the catalytic Tischchenko type reaction converting benzaldehyde into benzyl benzoate. A Tischchenko type reaction catalyzed by ruthenium complexes has been recently reported.[16]

The insertion of aldehydes and ketones into the metal-carbon σ-bond, a quite common reaction observed in the reactions of non-transition metal alkyls and aryls such as Grignard reagents, has some precedents also among the reactions involving organo-transition metal compounds.[3,17]

Formation of benzene in the reactions of **1** with benzaldehyde, acetaldehyde, and propionaldehyde may be accounted for by assuming a β-hydrogen elimination from the presumed intermediate, alkoxomanganese complex bearing a β-hydrogen, followed by reductive elimination with the remaining phenyl group bonded to manganese. The alternative to the above mechanism is the abstraction of protonic α-hydrogen at the α-carbon of aliphatic aldehydes. This type of reaction may be predominantly taking place in the reactions of **1** with acetone and acetophenone which carry active α-hydrogens. In these cases about two moles of benzene were liberated to leave white complexes. The IR spectrum of the complex derived from acetone showed the ν(C=O) band at 1690 cm^{-1} with a shift of 30 cm^{-1} from that of free acetone. Although insolubility of the complex in common organic solvents hindered its purification, this complex is considered to be (2-oxopropyl)manganese, since treatment of the complex with methyl iodide gave methyl ethyl ketone and acetonylacetone.
