at 585 °C, an ESR spectrum grew, as illustrated in Figs. 5(b) and 5(c). In the sample obtained by the thermal decomposition under a vacuum, an ESR spectrum appeared, as is shown in Fig. 5(d). By further treatment of the sample by SO_2, the spectrum changed, as illustrated in Figs. 5(e) and 5(f).

Discussion

The ESR Spectra in the CO–O_2–V_2O_5 System. The ESR spectrum with the hfs of 15-lines was found in the V_2O_5 crystal, which was prepared under the mixture of CO and O_2 (rather weakly reductive), as is shown in Fig. 1(a). After the contact with the mixture of CO and O_2 for a short time, the same spectrum appeared in the crystal in which no ESR signal had been detected initially as is shown in Fig. 2(a). A quite similar spectrum has also been found in the crystal treated with a mixture of SO_2 and O_2 at the initial stage. The spectrum was assigned to a V^{4+}—V^{5+} pair, accompanied by an oxygen defect.[30] On the other hand, in the two cases in which the V_2O_5 crystal was prepared under the mixture of CO and O_2 (rather strongly reductive) and was brought into contact with such a mixture, a new sharp spectrum appeared in the crystal, together with the hf-lines, as shown in Figs. 1(b), 2(c), and 2(d). Since the centers of both spectra were different, the sharp line did not seem to be ascribed simply to the exchange narrowed line of the hfs of 15-lines. The sharp line could be ascribed to a lower oxide phase or a lower oxide state of vanadium oxides, by taking into consideration the results that the ESR parameters of the sharp spectrum are constant without regard to the intensity of the spectrum, as was mentioned above.

According to the phase diagram of the vanadium–oxygen system by Kachi and Kosuge *et al.*,[31] the only phase which can coexist thermodynamically with V_2O_5 is V_3O_7. They[8] also measured the magnetic susceptibility (χ_{mol}) of V_3O_7, V_6O_{13}, and VO_2 and estimated μ_{eff} by using these equations: $\chi_{mol}=C/T-\theta$ and $\mu_{eff}=2.83\sqrt{C}$. The μ_{eff} (=1.32) in V_3O_7 seems to be rather well in accordance with the μ_{calcd} (=1.00), calculated under the assumption that V^{4+} ions were isolated and their concentration was given by the composition of ($V_2O_4 \cdot 2V_2O_5$). In the case of V_6O_{13} the μ_{eff} (=1.92) is not very consistent with the μ_{calcd} (=1.41) calculated using similar procedures, and in the case of VO_2 the μ_{eff} (=2.96) and the μ_{calcd} (=1.73) are quite different from each other. In V_6O_{13} and VO_2, therefore, the spin state of V^{4+} ions in the crystals would not be so simple as that of V_3O_7. From these considerations, the sharp spectrum can be ascribed to the V_3O_7 phase. The slight difference between the μ_{eff} and μ_{calcd} in V_3O_7 suggests that V^{4+} ions are not isolated completely in the V_3O_7 phase. If the V^{4+} ions were isolated completely in the crystal, it should give the hf-coupling with a nuclear spin of ^{51}V ($I=7/2$) and thus the hfs of 8-lines should be found. But infact only a sharp line has been found because of the exchange narrowing.

On heating the pure V_2O_5 crystal at 160 °C and 300 °C under high vacuum (10^{-6} Torr) for a long period, Gillis and Boesman[38] observed the growth of a new sharp spectrum, the center of which was approximately consistent with that of hfs of 15-lines. From the consistency of both centers of the spectra, the growth of the spectrum seems to correspond to a preliminary step before the phase transition, $V_2O_5 \rightarrow V_3O_7$: for instance, the clustering of the oxygen vacancies.

The ESR Spectra Found for the Thermal Decompositions of the Pure NH_4VO_3 and Then for the Reductions by SO_2. In the DTA and TGA studies on NH_4VO_3 by Taniguchi *et al.*,[24] NH_4VO_3 changed to V_2O_5 by the decompositions in the air stream and to V_3O_7 *in vacuo*. Furthermore, their results suggested that the V_3O_7 was reduced to V_6O_{13} by a butadiene stream, and the V_2O_5 was reduced by SO_2 stepwise : $V_2O_5 \rightarrow V_4O_9 \rightarrow V_6O_{13} \rightarrow VO_x$ ($x \fallingdotseq 2$). With reference to these results, the changes in the ESR parameters with the thermal decompositions and then with the reductions by SO_2, as shown in Table 4, might be explained as follows. The spectrum of $\langle g \rangle = 1.956$, obtained on the thermal decomposition *in vacuo*, is ascribed to the V_3O_7 phase and the decrease in the g-value on the reduction by SO_2, $\langle g \rangle = 1.956 \rightarrow 1.947$, is caused by the process, $V_3O_7 \rightarrow$

Table 4. The ESR spectrum found for the thermal decomposition of a pure NH_4VO_3 and the change in the spectrum with the reduction by SO_2

Condition of reaction	ESR parameter g-tensor $\langle g \rangle$	Line widths (mT)	
In air dec	No spectrum		
$+SO_2$ heating for 45 h	1.949	4.9	5.4
Evac. dec	1.956	4.2	6.2
$+SO_2$ at RT standing for 4 days	1.953	4.6	5.3
$+SO_2$ heating for 59 h	1.947	4.5	6.0

V_4O_9 or V_6O_{13}. The decrease in the g-value, accompanied by the appearence of some lower oxides or some lower oxide states, can be understood by taking a change in the symmetry of the crystal field around the vanadium(IV) ion into consideration, as is discussed below.

The V_2O_5 crystal is constructed from a kind of octahedron unit, which distorts quite a bit, as shown in Fig. 6.[32] In VO_2 (rutile type)[33] the octahedron is close to a proper one. In the intermediate phases : V_3O_7,[21] V_4O_9,[22] and V_6O_{13},[34] three or four types of the octahedron unit are contained in the crystals. To show the comparisons of the V–O distances in the octahedron among the phases, Table 6 was prepared. For the intermediate phases, the V–O distances were evaluated as the simple means of those in all octahedrons. In Table 6, the V–O(1) increases gradually, except for the V_6O_{13}, and on the contrary the V–O(6) decreases with the progress in the reduction. This means that the octahedron in the vanadium oxides changes gradually from a highly distorted structure to a proper one with the progress in the reduction, that is, the degree of the deviation of the V(IV) ion from the O(2)–O(3)–O(4)–O(5) plane becomes small, except for V_6O_{13}. The crystal field splittings of V(IV) ions in TiO_2(rutile) and VO_2 crystals have been given by Simizu[36] and Grunin *et al.*,[37] as in Fig. 7(a). In the higher oxides the splittings probably change as in Fig. 7(b), because the V(IV) ion deviates further

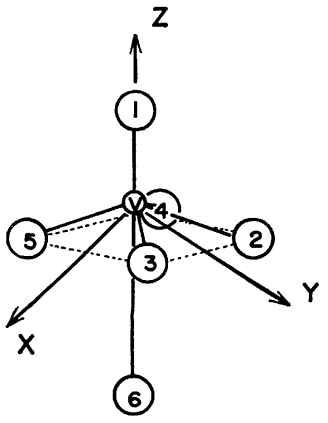

Fig. 6. The VO_6 octahedron unit in V_2O_5 crystal (Ref. 32); small circle: vanadium ion and large circle: oxygen ions.

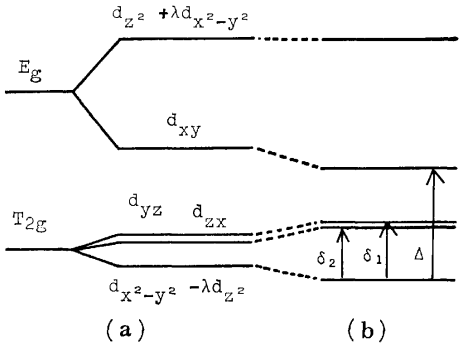

Fig. 7. Schematical view on the changes in the energy diagram for the d-orbitals of the vanadium ion in the VO_6 octahedron with the progress in the oxidation and the reduction of vanadium oxides; (a) the energy diagram for the VO_6 unit in the VO_2 crystal (Refs. 36 and 37) and (b) that in higher oxides than VO_2.

up from the oxygen square plane. The higher the oxidation states, the larger the δ becomes, while the Δ becomes a little smaller (or remains almost constant). The g-value can be roughly estimated by the familiar equations : $g_{zz}=g_0-4\lambda/\Delta$, $g_{xx}=g_0-\lambda/\delta_1$ and $g_{yy}=g_0-\lambda/\delta_2$, where λ is the spin-orbit coupling constant. Therefore, with the progress in the reduction, the following changes in the g-values will be expected : $g_{zz}\rightarrow$increase slightly (or remain constant), and g_{xx} and $g_{yy}\rightarrow$decrease quite a bit.

For the V(IV) ion in the V_2O_5 crystals, $\langle g\rangle \fallingdotseq 1.975$ and g_{xx}, $g_{yy}>g_{zz}$ have been reported.[38] On the other hand, in the V(IV) ion in VO_2 crystal, $\langle g\rangle=1.916$ was given.[37] The g-values of the V(IV) ions deped in TiO_2, SnO_2, and GeO_2 were $\langle g\rangle=1.927$, 1.928, and 1.935, respectively.[39] The tendency of the changes in the g-values is quite consistent with that expected above. The g-value in the spectrum found for the thermal decomposition of NH_4VO_3 *in vacuo*, $\langle g\rangle=1.956$, and also that for the reduction by SO_2, $\langle g\rangle=1.947$, given in Table 4, are also well understood according to the above discussion. That is, the changes in the g-values from 1.975 to 1.956 may correspond to the process, $V_2O_5\rightarrow V_3O_7$, and the change from 1.956 to 1.947, to the process, $V_3O_7\rightarrow V_4O_9$ or V_6O_{13}.

Recently, Kawashima *et al.*[25] examined in detail the process of the reduction of V_2O_5 by SO_2 by means of the TGA and the X-ray analysis. The processes

TABLE 5. THE COMPARISONS OF THE V-O DISTANCES AMONG THE VO_6 OCTAHEDRON UNITS CONTAINED IN THE VANADIUM OXIDES BETWEEN V_2O_5 AND VO_2 (V_3O_7, V_4O_9, and V_6O_{13} are constructed from two or three kinds of the octahedron units. The simple mean values of the octahedrons were given in the oxides.)

Compound	V-O_1	V-O_2	V-O_3	V-O_4	V-O_5	V-O_6	Ref.
V_2O_5	1.595	1.780	1.878	1.878	2.021	2.785	32)
V_3O_7	1.624	1.812	1.946	1.952	1.984	2.690	21)
V_4O_9	1.629	1.891	1.897	1.931	1.974	2.531	22)
V_6O_{13}[a]	1.906	1.835	1.865	1.835	2.086	2.375	34)
VO_2(rutile)	1.76	1.87	1.86	2.01	2.03	2.05	33)

a) Since certain values of the V-O distances have not been given for the V_6O_{13}, the authors estimated roughly, according to the data of Aebi.

in the reduction were found to occur stepwise and the phases described by the general formula of V_nO_{2n-1} appeared successively. However, the appearance and disappearance of the intermediate phases depended delicately and complicatedly upon the experimental conditions: for instance, the flow rates of the reductants, the partial pressures, the temperatures, the states of the pilling of the powder, and so on. According to their results, the present ESR spectra and the parameters found on the thermal decomposition of NH_4VO_3 and then on the reduction, are probably composite values.

The Growth of the V_2O_5 Crystal and Its Coexisting Phase under Oxidative and Reductive Atmospheres. Similar spectra to those shown in Figs. 1(a) and 1(b) have been found in the pure and doped V_2O_5 crystals. Ioffe *et al.*[38] have regarded the spectrum as caused by metal impurities, since the spectrum became more intensive in proportion to the contents of metal impurities. On the other hand, the spectrum was ascribed to the oxygen defect by Gillis *et al.*,[38] as was mentioned above. The fact that no ESR signal was found in the crystal of the V_2O_5 prepared in the tube opened to the air suggests that the concentrations of the impurities and the oxygen defects were below the sensitivity in the detection, that is, the starting material had been fully purified and the growth of the single crystal was accomplished under the condition of equilibrium. It means, furthermore, that the equilibrium pressure of the oxygen at the decomposition of the non-stoichiometric phase ($V_2O_{5-\delta}$) was very low, as compared to the partial pressure of oxygen in the air even at such a high temperature as the melting point of the V_2O_5 (*ca.* 670 °C).

In the case of the crystal prepared under the mixture of CO and O_2 ($CO/O_2=4$) at the total pressure of 200 Torr, only the spectrum ascribed to the oxygen defect was found, as discussed above. Since in the system the (excess-CO/V_2O_5) ratio is estimated to be 0.025, the non-stoichiometric region of V_2O_5 will extend at least up to $V_2O_{4.975}$ near the temperature of 670 °C. On the other hand, in the crystal prepared under the mixture of CO and O_2($CO/O_2=16$) at the total pressure of 390 Torr, a strong sharp spectrum, ascribed to a phase like V_3O_7, appeared in addition to the hfs-lines, as discussed above. In this case, the (excess-CO/V_2O_5) ratio was estimated to be 0.10. Thus the composition of $V_2O_{4.90}$ should be realized, if the equilibrium between the gaseous phase and the solid has been kept fixed throughout the crystal growth. That is, the non-stoichiometric phase of V_2O_5 would not extend up to $V_2O_{4.90}$.

The Change in the Surface States of the Highly Purified V_2O_5 Crystal during the CO-oxidation. The pure V_2O_5 crystal, kept under the conditions of the CO-oxidation (rather reductive atmosphere), showed a sharp spectrum, accompanied with the spectrum with the hfs of 15-lines. The line shape and the *g*-value of the ESR spectra were completely consistent with that in the crystal grown under a similar atmosphere. Both the line shape and the $\langle g \rangle$ were kept constant from the beginning of the appearence without depending on the (CO/O_2) ratio, the partial pressures of CO, the temperatures, or the reaction time. From the beginning the center of the sharp spectrum already differed from that of the hfs-lines, as seen in Fig. 2(b) and Table 3. This finding suggests the coexistence of the non-stoichiometric phase of the V_2O_5 and the V_3O_7 near the surface from the initial stage of the reduction. The intensity of the sharp lines increased gradually with the time, while that of the hfs-lines did not vary, as the comparison of the intensity with DPPH in Figs. 2 and 3 will show. This means probably that the other phases of the lower oxides did not exist in the crystal even locally. This idea will be supported by the fact that, although the color of the crystal varied from bright brown to dark brown, the brilliance of the (010) surface was always kept. The results of the isotopic exchange of oxygen also suggest that the mobility of the lattice oxygen was stimulated abruptly at above 500 °C.[40] Therefore, at least at such a high temperature as 560 °C, the highly purified V_2O_5 crystal is reduced homogeneously and gradually from the surface toward the bulk during the CO-oxidation (under rather reductive atmosphere).

The result obtained in a previous paper,[27] the abrupt change in the activation energy from the lower value to the higher during the CO-oxidation, could be related to the change in the surface states from the nonstoichiometric V_2O_5 to a lower oxides like as V_3O_7. The fact that, on the contrary, such a change in the working state was not seen for the unpurified crystal,[27] suggests that very little amounts of metal impurities play some important roles in preventing the change in working state. This subject is a future problem for the solid state chemistry on vanadium bronzes.

Nuclear Magnetic Resonance Studies of the Cu-chlorophyllin Complex with Flavine Mononucleotide

Koe ENMANJI*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received September 1, 1978)

The NMR relaxation time of the Cu-chlorophyllin (Cu-chln)–flavine mononucleotide (FMN) complex was measured, and its geometrical structure was proposed. The complex has an absorption band at 700 nm which is attributed to complex formation by analogy with the chlorophyll a–FMN complex. Its binding constant is 330 l/mol at 25 °C; this value is larger than those of other Cu-chln complexes. From the analysis of its ESR data, it is clear that the greater part of the electron spin in Cu-chln is distributed on the Cu^{2+} ion. The distance between the nuclear and electron spins was calculated by measuring the spin-lattice relaxation times. From these results, the distance between the porphyrin ring and the isoalloxazine ring in the Cu-chln–FMN complex molecule is found to be 4.2 Å if the two rings are parallel to each other. The chlorophyll a–FMN complex is assumed to have a similar geometrical structure.

There are various kinds of chlorophylls in the lammela structure of the chloroplast. Most of these chlorophylls are called "antana chlorophylls," which harvest solar energy, and part of them exist as P700, which is the reaction center of Photosystem I. It is generally imagined that P700 is formed by interaction between chlorophyll a and an electron acceptor. Tu and Wang[1] have shown that the optical spectrum of the chlorophyll a–flavine mononucleotide (FMN) complex in an acetone–water mixture has a maximum peak at 700 nm and some characteristics of P700. Though the characteristics of this complex are thought to be related to its structure, the structure of the complex was not discussed in their paper. Because the ground state of this complex is not paramagnetic, it is difficult to presume a geometrical arrangement of each constituent molecule in the complex. Cu-chlorophyllin (Cu-chln) is an interesting molecule since the electron magnetism on it will make it easier to study its interaction with itself and with other molecules by means of magnetic resonance methods. Thus, the interaction of chlorophyllin molecules in solution may be studied easily with Cu-chln as a model compound. In the present study, the interaction of Cu-chln with FMN in an aqueous environment was studied in some detail by means of ESR, optical absorption and NMR spectroscopy.

Experimental

Materials. Mg-chlorophyllin was prepared from spinach by the method of Oster and his coworkers.[2] Cu-chln was obtained from Mg-chlorophyllin by the method of Burdick and Carroll.[3]

FMN, reagent grade (Nakarai Chem. Co.), was used without further purification.

Optical Measurement. The optical spectra were measured with a Hitachi PS-3T-type autorecording spectrometer.

NMR Measurement. The proton, phosphorus-31, and carbon-13 NMR spectra were recorded at 100, 40.5, and 25.15 MHz respectively on a JMN PS-100 system equipped with a pulse Fourier transform unit (PFT-100). The sizes of the sample tubes were 5 mm O.D. for ^1H, 8 mm O.D. for ^{31}P. The spin-lattice relaxation time (T_1) was measured by the 180°-τ-90° pulse method. The repetition times were 30 s for both the ^1H and ^{31}P measurements. The spectra were added 16 times for the ^1H and 64 times for the ^{31}P measurements respectively.

Theoretical

For a system containing paramagnetic metal ions and a large excess of free ligands, with magnetic coupling between the metal and a nucleus in the ligand, the following equation holds under appropriate conditions,[4,5]

$$\frac{1}{T_{1P}} = \frac{1}{T_1^*} - \frac{1}{T_1^\circ} = \frac{f}{T_{1M}+\tau_M}, \quad (1)$$

where T_{1M} is the spin-lattice relaxation time of the ligand in the complex, f is the fractional number of the complexed ligand to the total ligand, T_1° is the relaxation time without a paramagnetic substance, T_1^* is that with a paramagnetic substance, and T_{1P} is the apparent relaxation time. If we consider a system consisting of two spins that undergo an isotropic Brownian motion, the nuclear relaxation rate due to magnetic dipolar interaction between the nucleus and the electron spins is given by[5] (for $\omega_s\tau_c \gg 1$),

$$\frac{1}{T_{1M}} = \frac{2}{15}S(S+1)\frac{\gamma_I^2 g^2\beta^2}{r^6}\cdot\frac{3\tau_c}{1+\omega_I^2\tau_c^2}, \quad (2)$$

where ω_I and ω_s are the Larmor angular frequencies of the nucleous and the electron spin respectively. Hence, T_{1M} is proportional to the sixth power of the distance, r, between the unpaired electron and the nuclei. If τ_c is known, T_{1M} can be converted to the electron nuclear distance by means of Eq. 2. The electron-nuclear distance for various neclei in the molecule can give information as to the geometrical arrangement of the intermolecular complex when information about the distribution of the unpaired electron is available.

Results and Discussion

Distribution of the Unpaired Electron in Cu-chln. The ESR spectrum of Cu-chln in an aqueous solution (10 mmol/l) frozen at 77 K shows an almost smeared-out singlet because of the dipolar and the exchange interactions between electron spins on neighboring

* Present address: Central Research Laboratory, Mitsubishi Electric Corp., Amagasaki 661.

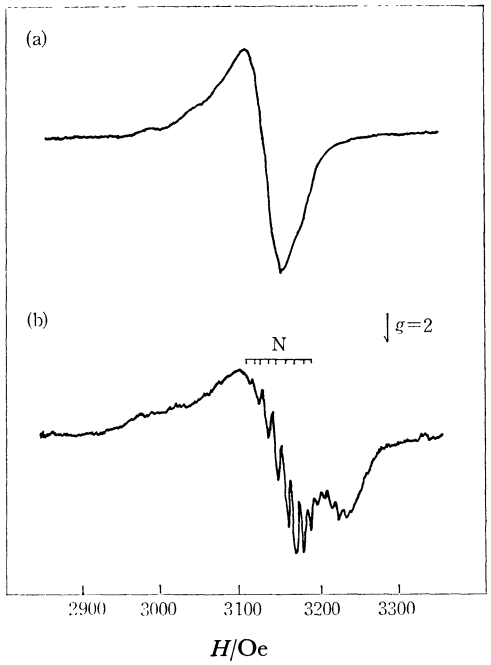

Fig. 1. ESR spectra of Cu-chln at liquid nitrogen temperature a) 0.01 mol/l Cu-chln only, b) 0.01 mol/l Cu-chln plus 0.1 mol/l FMN. Microwave frequency 9.1 GHz, power 2 mW. Modulation width 2.0 G at 100 kHz.

molecules of Cu-chln (Fig. 1(a)), when FMN of 0.1 mol/l is added to this Cu-chln solution and the ESR is measured at 77 K, however a clear superhyperfine structure due to nitrogen atoms is observed, as is shown in Fig. 1(b). The sharpening of the ESR spectrum by the addition of FMN indicates that FMN forms an intermolecular complex with Cu-chln in which the Cu-chln molecules are separated far enough from each other to make the dipolar and exchange interaction between electron spins negligible. The present author previously observed similar effects on the ESR spectrum for Cu-chln with poly(*N*-vinylpyrrolidone) in aqueous solutions and for Cu-chln with Mg-chln in ethanol, both at 77 K.

The hyperfine splitting due to the nitrogen atom is 16.7 G in the Cu-chln–FMN system (Fig. 1(b)). By following the treatment proposed by Koski *et al.*[6] for the ESR spectra of Cu-etioporphyrin and Cu-phthalocyanine, we may conclude that 65% of the unpaired electrons occupy the Cu $d_{x^2-y^2}$ orbital, and while 8.8% occupy each of the four nitrogen atoms, and that the spin density on the pheophytin ring carbons is negligibly small. These findings regarding the spin distribution in Cu-chln and the NMR relaxation measurements to be shown in a later section were used to simulate the structures of the molecular complex between Cu-chln and FMN.

Equilibrium Binding Study between Cu-chln and FMN. The optical difference spectra of the Cu-chln–FMN complex shows a maximum at 700 nm and a minimum at 630 nm. The intensity of the maximum increases with an increase in the concentration of FMN and can be attributed to the complex formation of Cu-chln with FMN. As the change in the concentration of FMN induces no change in the position of the maximum peak, we may assume that the peak height of the difference spectra at 700 nm is proportional to the concentration of the Cu-chln–FMN complex. We further assume this equilibrium:

$$\text{Cu-chln} + n\text{FMN} \rightleftharpoons \text{Complex}, \tag{3}$$

for which the equilibrium constant, K, is given by:

$$K = \frac{C_{\text{chlb}}}{C_{\text{chlf}}} \times \frac{1}{C_{\text{F}}{}^{n}}, \tag{4}$$

where C_{chlb}, C_{chlf}, and C_{F} are the concentration of the bund Cu-chln, that of the free Cu-chln, and that of FMN respectively. Equation 4 can be rewritten as:[7]

$$\log \frac{C_{\text{chlb}}}{C_{\text{chlf}}} = \log C_{\text{F}} + \log K, \tag{5}$$

C_{chlb} can be determined from the ratio of the peak height at 700 nm at a given concentration of FMN to that in the presence of a large excess of FMN at a constant Cu-chln concentration. Thus, the plot of $\log C_{\text{chlb}}/C_{\text{chlf}}$ against $\log C_{\text{F}}$ gives the slope n, *i.e.* the number of FMN molecules bound per Cu-chln; it also gives the equilibrium constant, K. From Fig. 2, we obtain $n=0.91$ and $K=512$ l/mol at 9 °C, $n=0.94$ and $K=330$ l/mol at 25 °C, and $n=1.02$ and $K=101$ l/mol at 84 °C. We may thus conclude that, in this concentration range of FMN ($0—7.0\times10^{-2}$ mol/l), Cu-chln forms a one-to-one complex with FMN in this temperature range. Tsuchida *et al.* measured the Cu-chln–pyridine and poly(4-vinylpyridine) complexes with the same method, thus obtaining values of $K=39$ l/mol and $K=1500$ l/mol at pH 10 respectively.[8] The present author previously measured the Cu-chln–adenosine-5′-monophosphate complex and

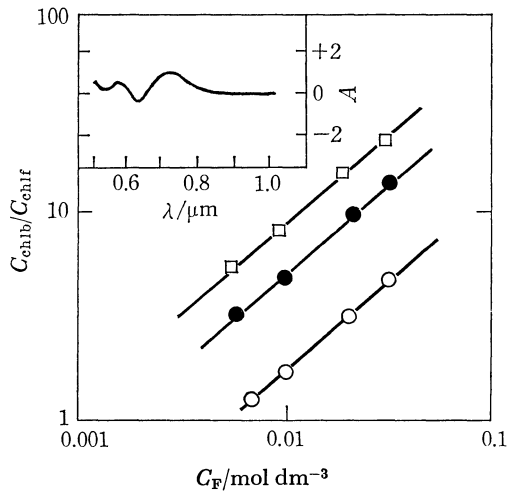

Fig. 2. Optical difference spectrum of Cu-chln–FMN complex and Hill plot for Cu-chln–FMN complex. Reference side: Cell A (Cu-chln 2.99×10^{-4} mol/l, phosphate buffer ,pH 7.0, 0.1 mol/l), Cell B (FMN 7×10^{-2} mol/l, phosphate buffer, pH 7.0, 0.1 mol/l). Sample side: Cell C (Cu-chln 2.99×10^{-4} mol/l, FMN 7×10^{-4} mol/l, phosphate buffer, pH 7.0, 0.1 mol/l), Cell D (phosphate buffer, pH 7.0, 0.1 mol/l) at 25 °C.

obtained $K=19$ l/mol at 30 °C.[9] The view of all these data, it can be said that the Cu-chln–FMN complex has a rather strong binding.

Spin-lattice Relaxation Times of ^1H and ^{31}P Nuclei of FMN. A Probable Structure of the Complex : The detail of the structure may be obtained from studies of FMN and Cu-chln at low concentrations where a one-to-one complex seems to be formed by optical titration. For this purpose, we have measured the spin-lattice relaxation times of nonexchangeable protons, *i.e.*, C(6)–H, C(9)–H, C(7)–CH_3, and C(8)–CH_3 of FMN at 70 mmol/l in the presence (0.9 mmol/l) and the absence of Cu-chln in a neutral D_2O solution (pH 5.8). The results are shown in Fig. 3 (as T_{1P}) as a function of the temperature. The T_1 values vary considerably among different protons, indicating that they are determined by T_{1M} rather than by a common value, τ_M, in Eq. 2. The T_{1P} of each proton shows a minimum at about 30 °C; and according to Eq. 2 we have $\tau_c \approx 1.6\times10^{-9}$ at this temperature. Using this τ_c value and the bound fraction of FMN (f) calculated from the association constant ($K_a=3.3\times10^2$ l/mol) for a one-to-one complex, we obtained the distances from the unpaired electron to the respective protons. The distance from the unpaired electron to the phosphorus atom was similarly calculated using the same τ_c and f value at 30 °C obtained from the T_1 data in Fig. 3. All the results are listed in Table 2.

The long distance obtained for the phosphorus (8.0 Å) indicated that the coordination of the phosphate group to Cu does not occur in the complex formation. The interaction primarily occurs with the known atomic coordinates of FMN and Cu-chln,[11,12] taking the electron-spin distribution of Cu-chln obtained from the ESR study into account.

For this purpose, a computer program developed in our laboratory[13] was applied to this complex. By assuming a parallel arrangement between the two

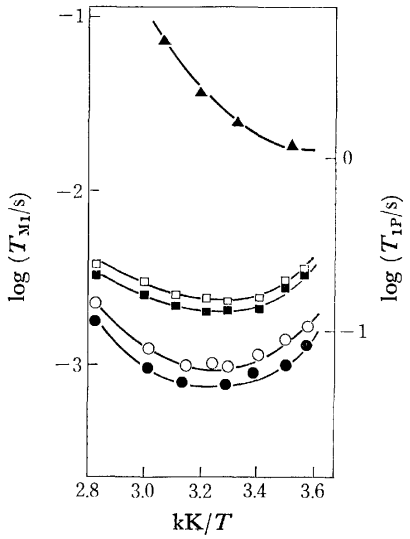

Fig. 3. Temperature dependence of proton and phosphorus relaxation.
FMN (70 mmol/l), Cu-chln (0.9 mmol/l), pH 5.8. C(9)-H: ●, C(6)-H: ○, C(8)-CH_3: ■, C(7)-CH_3: □, phosphorus: ▲.

Table 1. The distances from the electron spin on Cu-chln to the nonexchangeable protons and the phosphorous atom of FMN in the Cu-chln-FMN complex (30 °C, pH 5.8)

C(8)-CH_3	1.73×10^{-3}	0.68
P	1.50×10^{-2}	0.80

a) T_{1obsd} is the observed T_{1B}. b) R is the apparent distance between the protons or phosphorus and the electron spin.

planes of FMN and Cu-chln, we find that the central Cu atom is closer to the methylated ring and that the interplane distance is 4.20±0.05 Å. This interplane distance is a little longer than those of the π-π complex consisting of two aromatic compounds with carbon 2pπ orbitals, but considering the involvement of d-orbitals in the present system, the structure is essentially similar to the stacking arrangement of two aromatic compounds.

Barry *et al.* suggested that the family structures of the Co-mesoporphyrin IX dimethyl ester-2,4,7-trinitro-9-fluorenone complex with 4.00±0.02 Å are closely related to those determined for similar complexes in the crystalline state in that the planes of Co^{2+} MPDE and TNF are parallel.[14] We may, therefore, confirm that the interaction between FMN and Cu-chln in an aqueous environment is probably of hydrophobic origin, with the two planes mutually stacked.[15]

From the close similarity in the optical difference spectra between the Cu-chln–FMN system and the chlorophyll a–FMN system, we can expect that chlorophyll a also forms a similar complex with FMN in an aqueous environment.

The author is deeply indebted to Professor Hiroyuki Hatano for his continual encouragement throughout this work, and also to Dr. Kazuyuki Akasaka for his helpful advice and discussions. He also wishes to thank Mr. Hideaki Kusakawa for his advice on the writing of this paper.

The Vibrational Spectra and Rotational Isomerism of 3-Butenylsilane

Keijiro TAGA, Keiichi OHNO,* and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received September 9, 1978)

The infrared and Raman spectra of 3-butenylsilane, CH_2=$CHCH_2CH_2SiH_3$ (and $-SiD_3$), were measured for the gaseous, liquid, and solid states. The fundamental vibrations were assigned, and the normal vibrations were calculated in relation to the rotational isomerism. The calculations indicated that the *cis-trans* (CT), *skew-trans* (ST), and *skew-gauche* (SG and SG′) forms coexist in the gaseous and liquid states, while the CT form only persists in the solid state. From the temperature variation in the Raman intensities, the stability of the molecular conformations was found to be in this order: CT≳ST>SG′>SG in the liquid state, indicating that an appreciable interaction between the silicon atom and the C=C bond, such as in the case of allylsilane, is not present for 3-butenylsilane.

The properties of the UV and IR spectra of unsaturated organosilanes have long been investigated and have been commonly cited as evidence of the interaction between vacant 3d-orbitals of the silicon atom and the C=C π electron system, *i.e.*, (p→d)-π-bonding and long (p→d)π-bonding.[1] Recently, however, the bathochromic effect of the UV spectra and the abnormal high reactivity to the C=C bond of β-unsaturated organosilanes have been interpreted in terms of the σ-π hyperconjugation between the C=C π and the Si–C σ bonds.[2] The magnitude of this hyperconjugation varies with the dihedral angle about the axis between the carbon atoms in the α- and β-positions, and it is maximal at 90°,[3] indicating that the *skew* conformation is preferable to the *cis* conformation. Actually, in a previous paper[4] the analysis of the vibrational spectra has confirmed that, for allylsilane, only the form near the *skew* form predominantly exists in the gaseous, liquid, and solid states, although, for methylvinylsilane, the *cis* and *skew* forms coexist in the gaseous and liquid states. The same conclusion as to the molecular conformation of allylsilane has also been drawn from the electron-diffraction study[5] and the microwave spectral analysis.[6]

In the present paper, we will, then, deal with the molecular vibrations and rotational isomerism of 3-butenylsilane in order to obtain information on the interaction between the C=C bond and the silicon atom of the γ-position.

Experimental

The samples of 3-butenylsilane, CH_2=$CHCH_2CH_2SiH_3$, and its deuterated species, CH_2=$CHCH_2CH_2SiD_3$, were prepared as follows. Allyl bromide was converted to 3-buten-1-ol using magnesium and paraform, and the 3-buten-1-ol was then converted to 3-bromo-1-butene using PBr_3, by the method of Linstead *et al.*[7] A Grignard reagent prepared from the 3-bromo-1-butene was added to silicon tetrachloride in dry ether to yield 3-butenyltrichlorosilane. The resulting 3-butenyltrichlorosilane was reduced to 3-butenylsilane with $LiAlH_4$ or $LiAlD_4$ in dry dibutyl ether. The purities of the 3-butenylsilane-d_0 and -d_3 were checked by NMR analysis.[8]

The infrared spectra in the 250—4000 cm^{-1} region and the Raman spectra in the 10—4000 cm^{-1} region were recorded on a Perkin-Elmer instrument (Model 621) and a JEOL Raman spectrometer (Model JRS-400D) with an argon-ion laser respectively. The infrared and Raman spectra were measured for the gaseous, liquid, and solid states and for the liquid and solid states respectively, using the technique described in a previous paper.[4]

Results

Normal Coordinate Treatment. A molecule of 3-butenylsilane has two C–C axes and five possible isomers: *cis-trans* (CT), *cis-gauche* (CG), *skew-trans* (ST), *skew-gauche* (SG: stretched), and *skew-gauche'* (SG′: bent). In order to confirm the molecular forms and the assignments of the observed spectra to rotational isomers, the normal vibrations were calculated using the modified Urey-Bradley force field. The structural parameters used were transferred from those of 1-butene[9] and ethylsilane[10] determined by microwave study. All the valence angles except for the CH_2=CH group were assumed to be tetrahedral, and the dihedral angles were assumed to be 0° for the C form and 120° for the S form about the (CH_2=)CH–CH_2(CH_2) axis, and 60° for the G form and 180° for the T form about the (=CH)CH_2–CH_2-(SiH_3) axis. The force constants used in the present calculation were transferred from those of propylsilane,[11] allylsilane,[4] and olefins,[12] and the torsional force constants[13] of Y(C–C=) and Y(C–Si) were assumed from the barrier heights of 1.7 kcal/mol for 1-butene[9] and 2.04 kcal/mol for ethylsilane[10] respectively. Tables 1 and 2 give the observed and calculated frequencies of 3-butenylsilane-d_0 (BS-d_0) and 3-butenylsilane-d_3 (BS-d_3), together with the assignments based on the predominant potential energy distributions.

Rotational Isomerism. The molecule of 3-butenylsilane has 15 atoms and has the molecular symmetry of C_s for the CT form and that of C_1 for the CG, ST, SG, and SG′ forms. In the C_s symmetry, the 39 normal vibrations are reduced to 24 of the A′ species and 15 of the A″, while in the C_1 symmetry all 39 are of A. All the normal vibrations are infrared and Raman active.

Figures 1 and 2 show that several Raman lines in the liquid state disappear in the solid state, indicating the existence of the rotational isomers in the liquid state. On the other hand, almost all the frequencies observed in the solid state are assigned to the fundamental vibrations for one isomer, as Tables 1 and 2 show.

For such *n*-alkylsilanes as propylsilane and butyl-

(a): Liquid state at room temperature, (b): solid state at liquid nitrogen temperature.

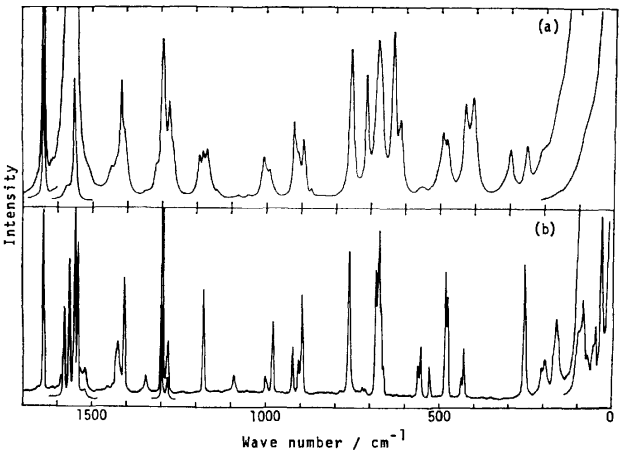

Fig. 2. Raman spectra of 3-butenylsilane-d_3 in the 10—1700 cm^{-1} region.
(a): Liquid state at room temperature, (b): solid state at liquid nitrogen temperature.

silane containing a $-CH_2CH_2SiH_3$ group, only the C–Si stretching and CH_2Si rocking vibrations have been observed in the 650—850 cm^{-1} region.[11] By analogy with the case of the C–Cl stretching vibration in alkyl chlorides,[14] the C–Si stretching vibration for the T form (P_C) has been assigned on a higher-frequency side than that for the G form (P_H), while the reverse is true for the CH_2Si rocking vibration,[15] as is shown in Fig. 3. The CH_2Si rocking vibration, however, is, in general, weak in the Raman scattering and is of medium strength in the infrared absorption. Thus, from a comparison of the spectra of BS-d_0 with those of propylsilane and butylsilane, the stronger Raman lines at 758, 699 (shoulder), and 693 cm^{-1} are assigned to the C–Si stretching vibration, while the Raman lines at 800, 790 (shoulder), and 745 cm^{-1} are assigned to the CH_2Si rocking vibration. The Raman lines at 800, 790, 699, and 693 cm^{-1}, vanishing in the solid state, belong to the G form, and the Raman lines at 758 and 745 cm^{-1}, persisting in the solid state, to the T form.

On the other hand, for 1-butene[12] and allyl chlo-

ride,[16] both containing the CH_2=$CHCH_2$– group, the C=CC skeletal bending vibration can be expected to be in the 400—550 cm^{-1} region; this vibration for the C form has been observed on a higher-frequency side than that for the S form, as is shown in Fig. 3. For BS-d_0, the Raman lines at 525 and 423 cm^{-1} are assigned to the C=CC skeletal bending vibration; the latter (the S form) disappears in the solid state, while the former (the C form) persists. Therefore, for 3-butenylsilane, it is indicated that the CT form persists in the solid state and that the CT and other forms coexist in both the gaseous and liquid states. The above results were confirmed from the normal coordinate treatment. The calculated frequencies of the CT form reproduced well the observed frequencies in the solid state. In the liquid state, the observed spectra were explained by the coexistence of the CT, ST, SG, and SG′ forms. Especially, the Raman lines at 305 cm^{-1} for BS-d_0 and at 300 cm^{-1} for BS-d_3 in the liquid state suggested the existence of the ST form, corresponding to the calculated frequencies of 321 cm^{-1} for BS-d_0 and 316 cm^{-1} for BS-d_3 given in Tables 1 and 2. The Raman lines at 800 and 693 cm^{-1} and the shoulder Raman lines at 790 and 699 cm^{-1} were assigned to the vibrations of the SG′ and SG forms respectively, as Fig. 4 shows. The existence of the CG form was not clear from the comparison of the observed frequencies with the calculated ones. However, this form is unlikely because of its large H···H nonbonded repulsion between the CH_2=CH and SiH_3 or SiD_3 groups.[12]

Stability of the Rotational Isomers. The enthalpy difference can be determined from the intensity ratios

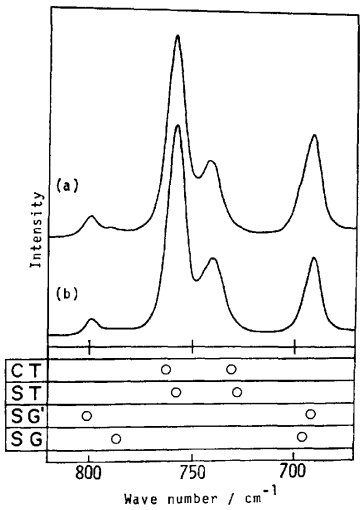

Fig. 4. Observed spectra in the 640—840 cm^{-1} region and calculated frequencies of each molecular form for 3-butenylsilane-d_0.
(a): Liquid state at −84 °C, (b): liquid state at −115 °C, ○: calculated frequency.

of the Raman lines belonging to different isomers.[17] However, only two pairs of the Raman lines were used for the determination because of the requirement that the pair of Raman lines be well separated from each other. The relative intensities were measured in the liquid state at different temperatures between −53 °C and −115 °C. The intensity ratios of the Raman lines at 758 (the CT and ST forms) and 693 cm^{-1} (the SG and SG′ forms) gave the apparent enthalpy difference, $\Delta H[(SG+SG')-(CT+ST)]=0.74\pm0.1$ kcal/mol, and those at 261 (the CT form) and 305 cm^{-1} (the ST form), $\Delta H(ST-CT)=0.22\pm0.2$ kcal/mol. On the other hand, Fig. 4 shows that the 800 and 693 cm^{-1} Raman lines assigned to the SG′ form increase in their relative intensities with a decrease in the temperature, as compared with those of the 790 and 699 cm^{-1} Raman lines assigned to the SG form. Therefore, for 3-butenylsilane, the stability of the rotational isomers is in this order: CT≳ST>SG′>SG in the liquid state.

Discussion

For 3-butenylsilane, it was found that only the CT form persisted in the solid state and that the stability of the rotational isomers was in this order : CT≳ST>SG′>SG in the liquid state. From the intensity ratios of the Raman lines belonging to the isomers, the enthalpy difference between the T and G conformations about the (=CH)CH_2–$CH_2(SiH_3)$ axis was estimated to be *ca.* 0.7 kcal/mol, and that the C and S conformations about the (CH_2=)CH–$CH_2(CH_2)$ axis, 0.22±0.2 kcal/mol. For propylsilane with the (CH_3)CH_2–$CH_2(SiH_3)$ axis, the T form has been found from the Raman spectral analysis[11] to be more stable than the G form by 0.60—0.65 kcal/mol. For 1-butene with the (CH_2=)CH–$CH_2(CH_3)$ axis, the enthalpy difference between the C and S forms has been reported to be ΔH(C–S)=0.15±0.15 kcal/mol from the microwave analysis[9] and ΔH(C–S)=−0.10±0.05 kcal/mol from the NMR analysis.[18] Therefore, 3-butenylsilane has a rough additivity of the enthalpy differences.

On the other hand, Harrah and Mayo[19] have reported, on the basis of their infrared spectral analysis of 1-alkenes, that the isomer with the S conformation persists in the solid state. The molecular form (the CT form) of 3-butenylsilane in the solid state differs from that of 1-pentene. This is, however, not peculiar, for the enthalpy difference about the (CH_2=)CH–$CH_2(CH_2)$ axis is quite small.

For 3-butenylsilane, the most and the least stable isomers in the liquid state were the CT and SG forms respectively. Therefore, the stability of the rotational isomers is mainly interpreted in terms of the steric repulsion between the nonbonded hydrogen atoms. The SG form has a considerable H···H nonbonded repulsion between the =CH– and CH_2Si groups. For the CT form, the silicon atom is more apart from the CH_2=CH group geometrically. Thus, there is no appreciable interaction between the C=C bond and the silicon atom of the γ-position for 3-butenylsilane.

The authors wish to express their thanks to Dr. Hiroatsu Matsuura for his valuable discussion.

The Visible-UV Absorption and Circular Dichroism Studies of Poly(α-L-glutamic acid)–Copper(II) Complexes with Emphasis on the Extrinsic Cotton Effect†

Kiwamu YAMAOKA* and Tsutomu MASUJIMA

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima, Hiroshima 730

(Received September 20, 1978)

The visible-UV absorption and circular dichroism, CD, of poly(α-L-glutamic acid)–Cu(II) solutions have been measured at 25 °C in the pH range 7 to 3.5 and at the mixing ratio, R, (Glu residues-to-Cu^{2+}) 32 to 4. Complex formation between poly(Glu) and Cu^{2+} was evident from the three absorption bands of bound Cu(II) around 700, 370, and 250 nm. The molar absorption coefficients, ε, varied with pH and R in a complicated but systematic manner. The pH dependence of ε, however, was not in parallel with the helix-coil transition of poly(Glu)–Cu(II) complexes. The extrinsic CD bands of bound Cu(II) have been detected in the three absorption band regions, and found to depend on both pH and R. The optical dissymmetry factor indicated that the 700 and 250 nm absorption bands of bound Cu(II) are associated with multiple CD bands of opposite signs. The intrinsic CD showed that the Cu(II)- and pH-induced helices of the poly(Glu)–Cu(II) complex are alike regarding the polymer backbone.

In order to understand the catalytic function of polypeptide–metal ion complexes, the detailed study of the binding of the transition metal ion to the poly (amino acid) appears to be indispensable. For this purpose, poly(α-L-glutamic acid), poly(Glu), and Cu^{2+} have been extensively utilized as a model system.[1–8] The conformation of the macromolecular complex, *i.e.*, the long-range or overall structure of poly(Glu) bound by Cu(II), and complex formation between Cu(II) and ligands, *i.e.*, the species of the Cu(II)–Glu residue complex, however, remain unclarified. Potentiometric titration is almost powerless from this viewpoint,[1] but optical spectroscopic studies should reveal changes in the configuration of Cu(II) bound by ligands and the conformational transition of poly(Glu) induced by bound Cu(II).

Optical absorption studies on complex formation between Cu(II) and simple polyelectrolytes such as polyacrylate (denoted as poly(Acr)) and polymethacrylate (denoted as poly(Methacr)) are numerous. In the presence of such polyanions, the absorption spectra of Cu(II) show three bands around 700, 360, and 250 nm.[9–15] The interaction between Cu(II) and poly(amino acids) has also been extensively studied, *i.e.*, poly(Glu),[2–4,8] poly(Lys),[16–18] poly(Arg),[19] poly(His),[20] poly(Gly),[21] and poly(Ala).[22,23] The circular dichroism, CD, method is valuable for studies of both complex formation and conformational transition, provided that the intrinsic CD of the chromophore of poly(Glu) and the extrinsic CD of the complex formed between the optically inactive metal ion and the active Glu residue appear separately but simultaneously in the respective wavelength regions. Hence, the conformational change of the macromolecular poly(Glu)–Cu(II) complex can be related to the formation of the ligand complex between Cu(II) and Glu residues. CD studies on the complex formation with Cu(II) have been reported for poly(Glu),[2] poly(Lys),[16–18] poly(Orn),[18] poly(Dbu),[18] poly(Arg),[19] poly(His),[20] poly(Ala),[23] and some Schiff-base derivatives of poly(Lys) and poly(Orn).[24]

† Macromolecule-Metal Ion Complexes. IV. For the preceding papers, see Refs. 5—7.

In the present work, both the absorption and CD spectra of poly(Glu)–Cu(II) solutions have been studied by varying the pH between 7 and 3.5 and the mixing ratio (Glu residues to Cu^{2+}) between 32 and 4. The poly(Glu)–Cu(II) complex exhibited three absorption bands in the 700, 370, and 250 nm regions. The pH dependence of the intensity of each band has been found to be more complicated than previously reported.[2] The extrinsic CD of bound Cu(II) has been observed in all three absorption bands, again contrary to a previous report.[2] The pH dependence of the CD of Cu(II) is not, however, completely in parallel, although closely related, to the helix-coil transition of the macromolecular poly(Glu)–Cu(II) complex. The present absorption and CD data suggest that the variation in the absorption intensity of the bound Cu(II) with pH results not only from the change in amount and species of Cu(II)–Glu ligand complexes but also from the conformational change. Moreover, another conformational transition, possibly helix-to-*aggregate*, has been shown to exist for the poly(Glu)–Cu(II) complex at low pH where the helix is already completed. The present data are discussed in terms of the feedback of the poly(Glu) conformation to the complex formation between Glu ligands and Cu(II), and *vice versa*.

Experimental

Materials. Sodium poly(α-L-glutamate), abbreviated simply as poly(Glu), was kindly supplied from Ajinomoto Co., Ltd. (Tokyo) and purified by dialyzing against redistilled water for 24 h, freeze-drying, and vacuum-drying at 56 °C for 7 h. The weight-average degree of polymerization DP_w was determined to be *ca.* 700 from the intrinsic viscosity in 2 M NaCl solution. The stock poly(Glu) solution was prepared by weighing the anhydrous sample with a mean residue weight of 151. Sodium polyacrylate, abbreviated simply as poly(Acr), was purchased from Nakarai Chemicals Co. (Kyoto) and purified by fractional precipitation,[7] (DP_w 7700). In the CD study the poly(Glu) sample with a DP_w of 610, purchased from Pilot Chemicals, Inc., was exhaustively dialyzed against distilled water and freeze-dried. Reagent grade copper(II) chloride dihydrate was dissolved in distilled water prior to use.

Preparation of the Polymer-Cu(II) Solutions. Typically, a sample solution at the appropriate pH, mixing ratio, R, and ionic strength was prepared by adding appropriate amounts of NaCl, $CuCl_2$, and HCl solutions, in this order, to either poly(Glu) or poly(Acr) solutions. The value of R, defined as the ratio of the molar residue concentration of polymer to the total concentration of added Cu^{2+}, was varied by adjusting the amount of Cu^{2+}. The final concentration of the polymer residue was maintained constant at 8 mM throughout. The salt concentration in the polymer-Cu(II) solution was maintained constant at 7.5 mM in terms of the sum of HCl and NaCl by adjusting either of them. The effect of the mixing order was tested by interchanging the order of addition between $CuCl_2$ and HCl at room temperature. No difference was observed in the absorption and CD spectra, unless the pH of the solution was very low. However, the temperature effect on the absorption spectra of poly(Glu)-Cu(II) solutions was remarkable at low pH in that the temperature cycle between 4 and 70 °C showed irreversible changes. Therefore, the solutions were all prepared and stored at 25 °C.

Measurements of Absorption Spectra and pH. The absorption spectra were measured on a Hitachi Model EPS-3T recording spectrophotometer in the wavelength region 1200—210 nm at 25 °C, temperature-controlled water being circulated through the cell holder. The slit width was set at 0.18 mm at 700 nm. An integrated-sphere attachment was used to minimize the effect of scattered light from poly(Glu)-Cu(II) solutions at low pH (<3.8). The absorption was expressed in terms of the apparent molar absorption coefficient, ε ($cm^{-1}\cdot mol^{-1}\cdot dm^3$), of the total Cu^{2+} added. Matched pairs of quartz cells, 1—50 mm in length were used. The pH of the solutions used for absorption measurements was determined on a Hitachi-Horiba Model N-5 pH meter. A one minute wait preceded by two minutes' stirring was necessary before the reading of the pH, because of a slight time dependence.

Measurements of the CD Spectra and pH. The CD spectra of poly(Glu)-Cu(II) solutions were measured on a Cary Model 60 spectropolarimeter with a Model 6001 CD accessary at 25 °C. The visible and UV CD spectra at 750—240 nm have been expressed in terms of the molar ellipticity, $[\theta]$ ($deg\cdot cm^2\cdot dmol^{-1}$), of the total Cu^{2+} added, the far UV CD spectra at 250—185 nm being expressed in terms of $[\theta]$ of the mean residue concentration of poly(Glu). Quartz cells of 5 cm (700—300 nm), 0.5 and 0.2 cm (340—240 nm), and 0.05 cm (below 250 nm) have been used. The slit width was set manually at 0.3 mm between 750 and 600 nm (the dispersion being 15 nm at 750 nm and 8.5 nm at 600 nm). The slit width was automatically varied at a preset dispersion of 1.7 nm in the visible and UV regions, and was set at 2.4 mm in the far UV region. The pH of the solutions used for CD measurements was determined on either a Radiometer TTT-1 or a Corning Digital Research pH meter in a manner similar to above.

Results

Absorption Spectra of Cu^{2+} in the Presence of Poly(Glu). Figures 1(a—c) and 2(a—c) illustrate the absorption spectra of poly(Glu)-Cu(II) solutions at three values of R. In the presence of poly(Glu), three absorption maxima appear in the spectra of Cu^{2+}: a broad band (ε=40—150) around 700 nm, a weak band (ε=10—50) around 370 nm, and a strong band (ε=3000—5500) around 250 nm. The formation of the complex between poly(Glu) and Cu^{2+} is thus evident. The spectrum of poly(Glu) exhibits only an ascending lobe below 250 nm (Fig. 2(f)). The spectrum of $CuCl_2$ shows a weak and broad peak (ε=10—20) around 800 nm and an ascending lobe below 250 nm (Figs. 1(a) and 2(f)).

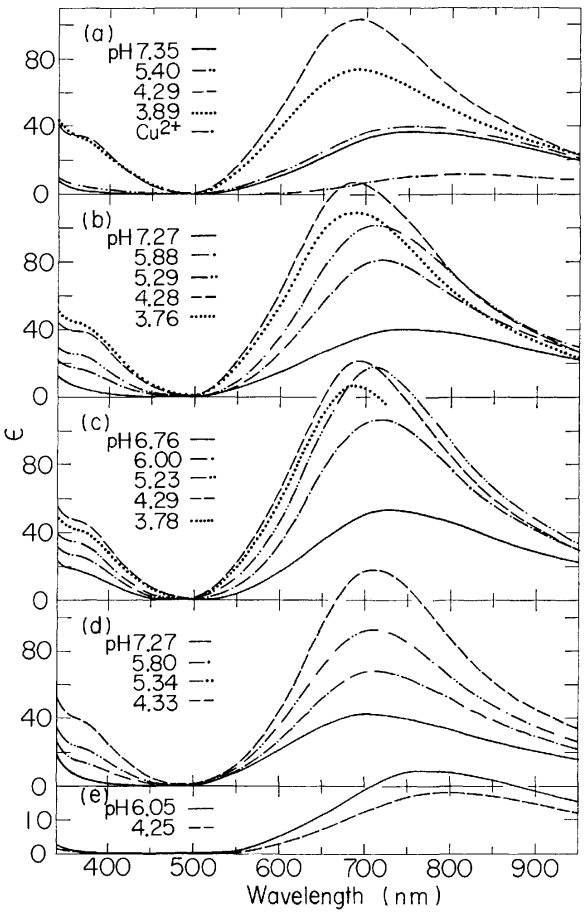

Fig. 1. The visible absorption spectra of Cu^{2+} in the presence of poly(Glu) ((a) R=32, (b) R=16, and (c) R=8), poly(Acr) ((d) R=16), and butyrate ((e) R=16) at various pH. The spectrum of Cu^{2+} at pH=3.81 in the absence of polymer is also shown in (a) for comparison. The pH=3.78 spectrum in (c) was taken with the integrated-sphere attachment which limits the wavelength to 800 nm. The concentration of added HCl plus NaCl is 7.5 mM in terms of the total Cl^- throughout. The molar absorption coefficient, ε, is expressed in terms of the total concentration of Cu^{2+} present in solution.

The 700, 370, and 250 nm bands, in the spectra of poly(Glu)-Cu(II) solutions at R=32 essentially remain unchanged in the pH range 7—5 but become most intense at pH 4.2—4.3 (Figs. 1(a) and 2(a)). In contrast, all the three bands of the R=16 and 8 solutions increase in intensity steadily with decreasing pH (Figs. 1(b—c) and 2(b—c)). The shape of the 700 nm band at each value of R is skewed, tailing towards the long wavelength side. The family of spectra showed no isosbestic point in any of the three absorption bands in the entire pH range 7—3.5.

Absorption Spectra of Cu^{2+} in the Presence of Poly(Acr) and Butyric Acid. The absorption spectra of Cu^{2+} were measured in the presence of either poly(Acr) (polymeric model lacking in the amide group),

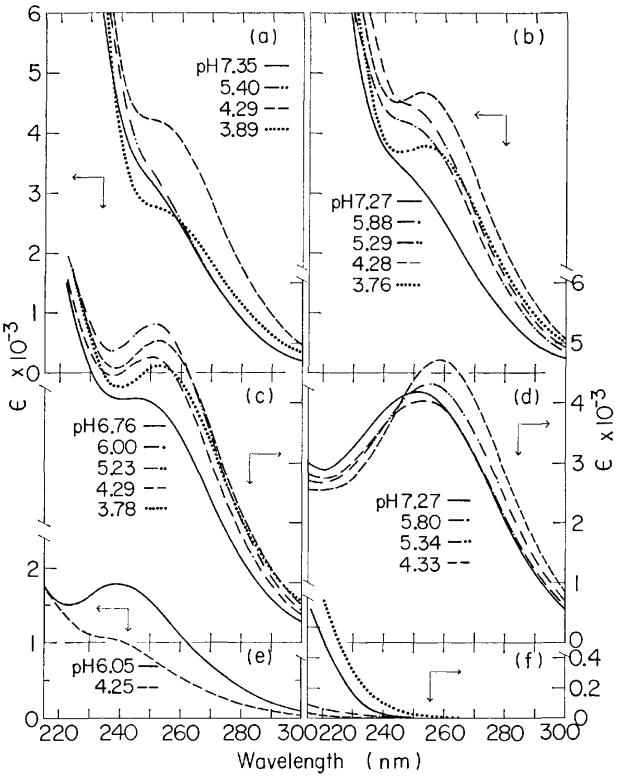

Fig. 2. The UV absorption spectra of Cu^{2+} in the presence of poly(Glu) ((a) R=32, (b) R=16, and (c) R=8), poly(Acr) ((d) R=16), and butyrate ((e) R=16) at various pH. The spectra of poly(Glu) at pH 7.09 (——), poly(Acr) at pH 5.39 (—·—), butyrate at pH 5.25 (----), and $CuCl_2$ at pH 3.81 (·····) are shown in (f) for comparison.

or butyric acid (model of the side-chain carboxylate of poly(Glu)). Figures 1(d) and 2(d) show that the three absorption bands appear again around 710 nm (a broad band ε=40—150), 370 nm (a weak band ε=10—40), and 250 nm (a strong band ε=2000—4500) in the spectra of poly(Acr)–Cu(II) solutions. The 250 nm peak is distinct because of the weaker background absorption of poly(Acr) (Fig. 2(f)). There is no clear isosbestic point in the 250 nm or 700 nm band in the entire pH range 7.3—3.8. The spectrum of Cu^{2+} in the presence of butyric acid shows two bands: one in the region 800—750 nm (ε=12—25) and one around 240 nm (ε=1000—2000) as indicated in Figs. 1(e) and 2(e). In contrast with the two polymer–Cu(II) systems, the spectrum of butyric acid–Cu(II) decreased steadily with decrease in pH, becoming close to that of the Cu(II) aquo-complex. No measurement was carried out at a pH higher than 6.5 because of the secondary reaction of precipitation.

pH *Dependence of the Absorption of Poly(Glu)–Cu(II).* Each spectrum of poly(Glu)–Cu(II) complex may be characterized by three absorption bands, and the variations in ε with pH at four selected wavelengths are shown in Figs. 3(a—d). At R=32 the ε at 680 nm, ε_{680}, is approximately constant in the pH range 7--5.5, but increases sharply attaining a maximum at pH=4.3 and decreasing with a further lowering of pH. At R=16, however, the ε_{680} begins to increase at pH=7 reaching a maximum at pH=4.1 after a marked shoulder near pH=5. At R=8, the ε_{680} becomes still larger between pH=7 and 5 showing a shoulder around pH 5.6, maxima at pH=4.8 and between 4.1—4.3. These peculiar changes in ε have been found for the first time. The intermediate shoulder may have been previously overlooked or mistaken for maxima.[2] It is now clear that the absorption of poly(Glu)–Cu(II) complexes depends on both pH and R in a complicated but systematic manner hitherto unreported.

The pH dependence of ε has also been determined at 880 nm (Fig. 3(b)), because the 700 nm band exhibits a marked skewness. The ε_{880} values generally behave in parallel with the ε_{680} values at R=32 but not at R=16 and 8. This difference may be attributed to the development of a long-wavelength component band around 900 nm with a decrease in R. The ε_{370} *vs.* pH curve at R=8 shows a maximum at pH=4.1 but none at pH=4.8, as illustrated in the ε_{680} *vs.* pH curve. This peculiarity offers two possible explanations, *viz.*, the origin of the 370 nm band differs from that of the remainder, or the maxima in the ε *vs.* pH curves at R=8 are only apparent and actually result from a delicate interplay of two or more processes involved in the formation of Cu(II)–Glu ligand complexes.

Contour Diagram of the Absorption of Poly(Glu)–Cu(II). A typical contour diagram is shown in Fig. 4, where the ε_{710} values for a number of poly(Glu)–Cu(II) solutions are related to pH and R. Similar diagrams may also be drawn for other wavelengths. Figure 4 clearly shows that there are two distinct ridges which lead to two separate summits indicated by X and X′ respectively. The first (AX) is along the R path at a slightly varying value of pH and the second (BX′) is along the pH path at an almost constant R value of approximately 4. In addition, a third, broader and less distinct ridge (CX′) leading to the summit X′ exists. This path depends on both pH and R in clear contrast with the two other paths and represents the marked hump observed in the ε *vs.* pH curves for the R=16 and 8 poly(Glu)–Cu(II) solutions (Figs. 3(a—d)). The slope stretching out between R=50 and 4 and below pH 4.4—4.2 on the left side of the first ridge (AX) is only apparent and should be a plateau with an approximate height of 150 in terms of the ε of the bound Cu(II).[25] The appearance of this slope has been attributed to the dissociation of the bound Cu(II) from the polymer site at low pH.[25]

Extrinsic CD of Bound Cu(II) in the 750—300 nm Region. The appearance of the extrinsic CD of Cu(II) should attest to the formation of Cu(II)–Glu ligand complexes. Two positive extrinsic CD bands are shown in Figs. 5(a—d): the long-wavelength CD band between 750 and 500 nm (designated as the visible CD band) and the short-wavelength band between 500 and 300 nm (designated as the near UV CD band). These CD bands correspond to the broad 700 nm and weak 370 nm absorption bands shown in Figs. 1(a—c) and have not hitherto been reported.

At a high value of R of 32, the peaks of the visible

and near UV CD bands center at 660 and 375 nm (Fig. 5(a)). The intensity increases with a decrease in pH becoming highest at pH 4.60, below which it decreases largely due to dissociation of the bound Cu(II).[25] At R=8, the CD bands have already appeared in the high pH range 6—7. The peak position and intensity depend on pH (Fig. 5(b)). At a value of R=4, CD bands with peaks at 670 nm and *ca.* 365 nm appear in the high pH range (Fig. 5(c)). The effect of R on the extrinsic CD band is shown in Fig. 5(d) at pH 5.75±0.05, which corresponds approximately to the midpoint of the helix-coil transition of poly(Glu) in the absence of Cu^{2+}. The highest value of $[\theta]$ for the visible CD band is approximately 430, when the Glu residues greatly exceed the Cu(II), *i.e.*, R=32 rather than 4, and when the pH of poly(Glu)–Cu(II) solution is low such that the helical structure of poly(Glu) is completed. Hence, the optical activity induced in the Cu(II) bound to poly(Glu) depends on both the backbone conformation of the macromolecular poly(Glu)–Cu(II) complex and the species of the Cu(II)–Glu ligand complex.

Extrinsic CD of Bound Cu(II) in the 310—240 nm Region. Corresponding to the UV absorption band of Cu(II) bound to poly(Glu) (Fig. 2), an extrinsic CD band appears in the 290—250 nm region (designated as the UV CD band) as shown in Fig. 6. The R 32 poly(Glu)–Cu(II) complex is in a helical conformation at pH 5.10 (*vide post*); yet, the negative $[\theta]$ increases only steadily. A shallow minimum and

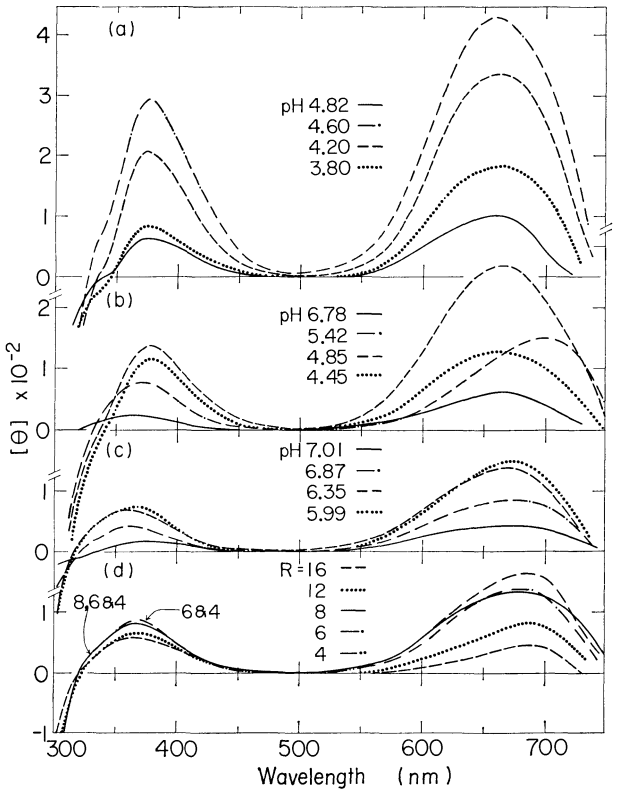

Fig. 5. The visible and near UV extrinsic CD spectra of Cu(II) bound to poly(Glu) at various R and pH. (a) R=32, (b) R=8, (c) R=4, and (d) pH=5.75. The molar ellipticity $[\theta]$ is expressed in terms of the total Cu^{2+} concentration in each poly(Glu)-Cu(II) solution.

maximum appear at 280 and 258 nm with the decrease in pH, respectively, and fully develope at pH 4.60 (Fig. 6(a)). The UV CD band represents a double extrinsic Cotton effect (*cf.* Fig. 10). The UV CD band at R 8 and 4 is shown in Figs. 6(b) and (c). This CD band is not seen at higher pH where the overall conformation is mostly in the random-coil, it however gradually appears as the pH of the solution is lowered. At pH 5.75, where the formation of the helical structure is half completed, the UV CD band becomes discernible as the value of R is decreased (Fig. 6(d)). This is an indication that the helical structure is fostered by the binding of Cu^{2+} to poly(Glu).

Intrinsic CD of the Glu Residue of Poly(Glu)-Cu(II) in the 250—185 nm Region. The conformation of macromolecular poly(Glu)-Cu(II) complexes is reflected in the intrinsic Cotton effect of the peptide chromophore in the far UV CD spectra as shown in Fig. 7. The CD spectra of poly(Glu) are also given as a reference (Fig. 7(a)). An isoelliptic point appears at 203.5 nm in the pH range 7.5—5.1 but deviation occurs at lower pH (<3.8). The intrinsic CD spectra behave essentially the same as the reference poly(Glu) when the Glu residues are in excess (R=32 in Fig. 7(b)). The general shapes of the CD spectra indicate that the helical conformation of poly(Glu)-Cu(II) is not altered by the formation of the Cu(II)-Glu ligand complex.

The intrinsic CD spectra exhibit a pH dependence when the bound Cu(II) is more densely populated on poly(Glu) (R=8 in Fig. 7(c)), indicating the existence of helix-coil transition. The $[\theta]$ values at 192 and 222 nm of a solution containing four peptide residues per Cu^{2+} manifest partial formation of the helix at pH 7 (R 4 in Fig. 7(d)). The R 4 CD spectrum is the largest at pH 5.75 where the reference poly(Glu) is still partly in a random-coil (a further lowering of pH promoted fibrous floats). Deviation from the isoelliptic point at 203.7 nm occurs, however, and does not develop as high as the CD spectra for the complete helical conformation (R ∞ and 32). Induction of the helix by bound Cu(II) is evident from the CD spectra of poly(Glu)-Cu(II) solutions (R 8 at pH 7.10 and R 4 at pH 6.87 in Figs. 7(c) and (d)) to which no proton was added.

Mixing-ratio Dependence of the Far UV CD of Poly(Glu)-Cu(II) and the Visible Absorption of Bound Cu(II). In order to clarify the effect of Cu^{2+} on the conformational changes of poly(Glu)-Cu(II) complexes at various values of R, the far UV CD spectra were measured at a fixed pH of 5.75±0.05 which corresponds approximately halfway to the helix-coil transition of poly(Glu). The results are shown in Fig. 8, where the CD spectra show a typical helix-coil transition pattern. All CD spectra cross at 204 nm with the exception of the R 4 spectrum. The pattern of the spectral change is similar to that of the proton-induced helix-coil transition of poly(Glu) (Fig. 7(a)), indicating that the Cu(II)-induced helix is approximately the same as the proton-induced helix. Hence, the Cu(II) bound to the random-coil or partially helical poly(Glu) probably promotes, but does not alter, the original helical structure in the macromolecular complex assuming the ionizable carboxyls are not completely un-ionized by the protons. This condition is fulfilled even at R 4 and pH 5.75 where approximately 70% of the carboxyls are uncharged.[26]

Corresponding to the increase in CD intensity, the visible absorption band of Cu(II) also steadily develops (inset Fig. 8). The correlation between CD and absorption is, however, not linear as shown in Fig. 9, where the values of $[\theta]$ at the positive and negative maxima (192 and 223 nm) are plotted against R, together with the change in the ε_{710} of the visible band. Both $[\theta]_{192}$ and $-[\theta]_{223}$ run in parallel approaching the limiting values of the complete helix as R becomes less than 4, as indicated by the horizontal line. The curve shows a sharp increment when R is around and below 10, suggesting that the induction of helical structure by the bound Cu(II) is cooperative in nature, *i.e.*, chelation and charge neutralization being responsible.[25,26] The ε_{710} values change almost linearly with R between 25 and 5. Since the amount of unbound Cu^{2+} is very small,[25,26] the ε_{710} *vs.* R curve indicates that complex formation between Cu(II) and the ligands is less cooperative than in helix formation. Thus, the latter may be essentially an overall phenomenon, while the former may be the sum of various local phenomena regarding complex species and binding modes.

Comparison between Electronic Absorption, Extrinsic CD

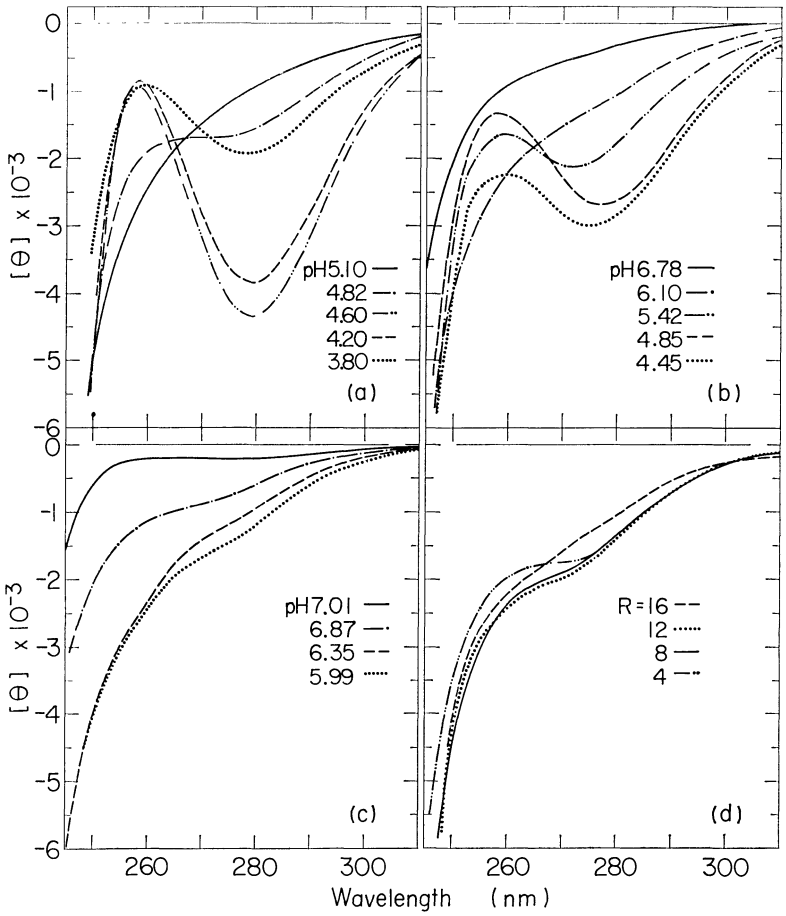

Fig. 6. The UV extrinsic CD spectra of Cu(II) bound to poly(Glu) at various R and pH. Notations are all the same as those in Fig. 5.

and Optical Dissymmetry Factor of Bound Cu(II). In order to realize the spectroscopic property of Cu(II) bound to Glu residues, a typical CD spectrum of Cu(II) bound to the complete helix (R 32 and pH 4.6) is compared with the corresponding absorption spectrum in Fig. 10. The optical dissymmetry factor, g,[27] is expressed as the ratio of the molar CD, $\Delta\varepsilon$, to the molar absorption coefficient, ε. The peak of the visible CD band is at 660 nm, while the absorption band is located at 690 nm, tailing toward the red. This unparalleled situation is reflected on the g-factor which is constant only in the 650—550 nm region descending toward zero around 740 nm. This indicates that the visible absorption band of bound Cu(II) is a composite of two or more optically active component bands. The g-factors of the visible Cu(II) band are generally larger for the R 32 complex than for the R 8 or 4 complex, indicating that optical dissymmetry for the visible band is more pronounced when the bound Cu(II) is less densely populated on the polymer.

Nozawa and Hatano[16] have observed the double CD band for a poly(Lys)–Cu(II) complex in the visible region. Garnier and Tosi[19] have shown that the extrinsic CD of poly(Arg)–Cu(II) is either double or separable into two components in the visible region. The sign, position, and magnitude of the visible CD of Cu(II) bound to poly(Glu) differ from those data previously reported. The difference probably results from the specificity of the ligands participating in complex formation, *i.e.*, γ-carboxylate *vs.* ε-amino or 4-guanidinium, and the stereoselectivity of a particular poly(amino acid) for chelation, but not from the ability of forming helical structures.[19]

It is not self-evident that the near UV CD band is a double type, because the absorption of bound Cu(II) is weak and discernible only as a shoulder so that the wavelength dependence of the g-factor is only apparent. The greater g-value for the 370 nm band may indicate that the contribution of the magnetic transition moment to the rotatory power is greater in the near UV CD band (450—350 nm) than in the visible CD band (700—550 nm). A similar trend has been observed at all values of R and pH. Thus, the near UV CD band is more optically dissymmetric.

The net CD band of bound Cu(II) in the 320—240 nm region may be obtained by subtracting the background intrinsic CD of the Glu residue. The far UV intrinsic CD spectrum of the R 32 poly(Glu)–Cu(II) at pH 4.6 differs from that of the same at pH 5.1 by a constant factor of 1.25 ± 0.05 between 250 and 200 nm. Therefore, the background ellipticity of the pH 4.6 complex is considered to be 1.25 times larger than that of the pH 5.1 complex which shows no extrinsic UV CD band (Fig. 6(a)). The net CD band of the bound Cu(II) thus cleared of background

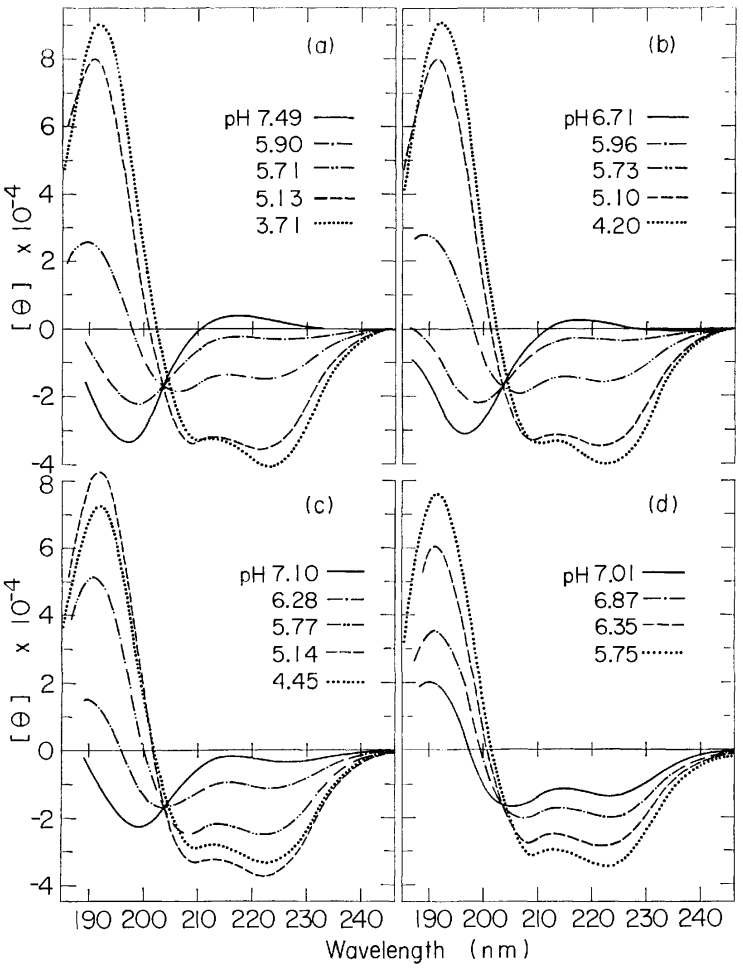

Fig. 7. The far UV intrinsic CD spectra of the peptide chromophore of poly(Glu)-Cu(II) solutions at various R and pH. (a) $R=\infty$ (no Cu^{2+} present), (b) $R=32$, (c) $R=8$, and (d) $R=4$. The molar ellipticity $[\theta]$ is expressed in terms of the mean molar residue concentration of poly(Glu) in the presence and absence of Cu^{2+}.

is double : a negative component with a peak at 280 nm followed by a positive peak around 256 nm. This doublet feature appears to be retained in most of the UV extrinsic CD spectra in Fig. 6. It has also been observed in the poly(Lys)- and poly(Arg)-Cu(II) complexes,[16-18] although the respective signs are probably reversed relative to the poly(Glu)-Cu(II) complex.

Discussion

Conformational Transitions of Poly(Glu)-Cu(II) Complex and the Formation of Cu(II)-Glu Ligand Complex. In order to relate the pH- and Cu(II)-induced conformational transitions of poly(Glu)-Cu(II) to the formation of Cu(II)-Glu ligand complex, the extrinsic CD and absorption data are compared with the far UV intrinsic CD in Fig. 11. The ε_{680}, $[\theta]_{680}$, and $[\theta]_{370}$ values of bound Cu(II) are also plotted against $[\theta]_{223}$ in Fig. 12, which directly shows the dependence of the optical properties of bound Cu(II) on the conformation of macromolecular complexes. For the R 32 complex, both the visible CD ($[\theta]_{680}\approx 0$) and electronic absorption ($\varepsilon_{680}\approx 30$) of bound Cu(II) are weak and remain constant over a wide pH range 7—5 (Fig. 11). The helix-coil transition of the macromolecular complex does occur in the narrow pH range 5.1 and 6.5; however, the bound Cu(II) hardly affects the transition, as clearly seen in Fig. 12. Thus, the feedback-effect of the macromolecular complex on the Cu(II)-Glu ligand complex, and *vice versa*, is weak when the bound Cu(II) is populated sparsely on poly(Glu). This effect however becomes pronounced for the macromolecular complex in which Cu(II) is distributed in a high proportion (R 8 or 4), since both the extrinsic CD and absorption of the bound Cu(II) and the $[\theta]_{223}$ of the Glu residue are already large around pH 7 where the poly(Glu) without Cu(II) is in the extended-coil form (Fig. 11).

As Figs. 11 and 12 indicate, the optical properties of bound Cu(II) for the R 8 and 4 complexes vary together in parallel, but *never* change linearly with respect to the helix content of the poly(Glu) backbone. (It is assumed that $[\theta]_{223}$ is equal to -35400 for a 100% helix.) In fact, the optical properties change with pH (Fig. 11) and helix content (Fig. 12), in a manner which is unexpectedly complicated, in the helix-coil transition, contrary to a previous report.[2] For example, the distinct hump in the ε_{680} curve around

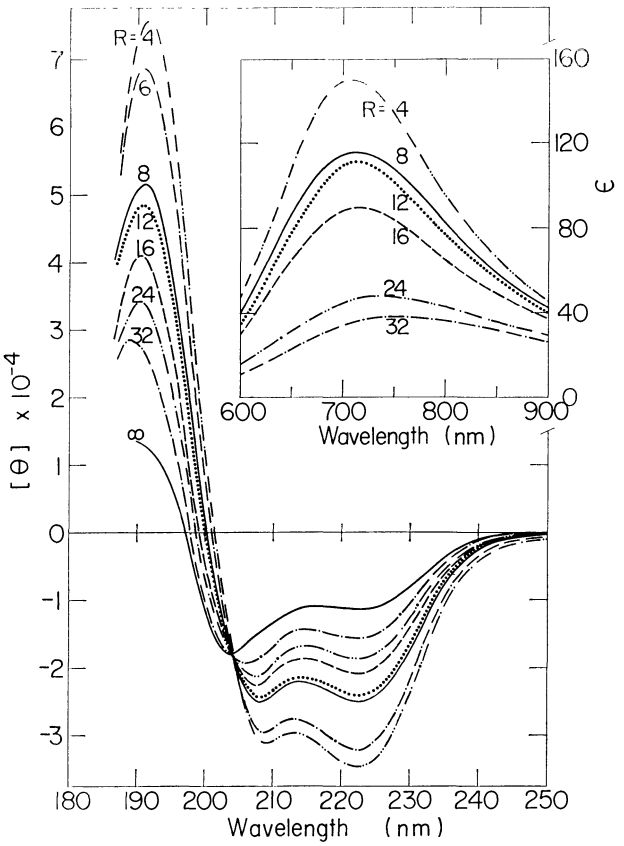

Fig. 8. The variation in the far UV intrinsic CD spectra of poly(Glu)-Cu(II) solutions with R at a pH of 5.75±0.05. The molar ellipticity is expressed as in Fig. 7. The corresponding visible absorption spectra are given in the inset.

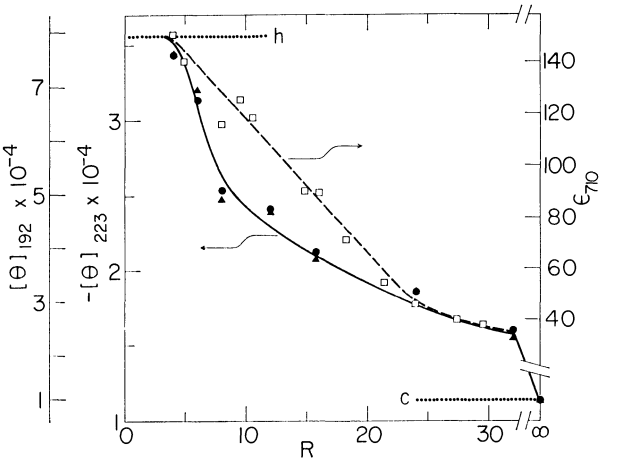

Fig. 9. The effect of added Cu^{2+} on the induction of helical structure in poly(Glu) and the formation of Cu(II)–Glu ligand complex at a constant pH of 5.75. The two horizontal lines (·····h and c·····) indicate the values of $[\theta]_{192}$ (—●—) and $[\theta]_{223}$ (—▲—) for the poly(Glu) solutions without Cu^{2+} ions at pH 5.10 and 7.49, respectively. The molar absorption coefficient ε_{710} (--□--) is the same as plotted in Fig. 4.

pH 5.3—6.0 (Figs. 3, 4, and 11(b)) probably corresponds to the second stage of the helix-coil transition after the midpoint, but not to the completion of the helix or to the midpoint as previously concluded.[2)]

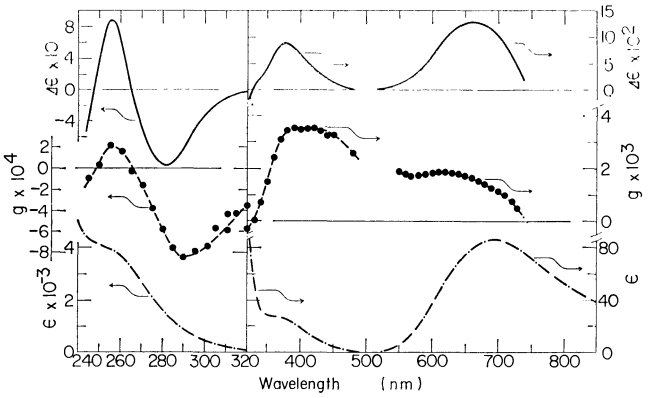

Fig.10. Comparison between extrinsic CD spectrum, $\Delta\varepsilon$, electronic absorption spectrum, ε, and optical dissymmetry factor, g, of a poly(Glu)–Cu(II) solution at R=32 and pH=4.60. The extrinsic CD spectrum is expressed in terms of the molar circular dichroism $\Delta\varepsilon$ (=[θ]/3305).

The most prominent change in the optical properties of the bound Cu(II) probably occurs after completion of the intramolecular helix of poly(Glu)–Cu(II) complex regardless of the amount of the Cu(II) bound to the Glu residues (Figs. 11 and 12). The ascending trend in the visible CD and absorption of Cu(II) is closely related to the second transition in the $[\theta]_{223}$ *vs.* pH curve (Fig. 11). Evidently, the backbone of the macromolecular complex undergoes a further conformational transition, probably, helix to *aggregates*, at low pH 5—4.4.[26,28-31)] It is however undeterminable from optical measurements alone whether or not the changes in optical properties arise from the transition of the intra- or interhelical conformation. In summary, it is probably the dissymmetric conformation of the Cu(II)–Glu ligand complex that is primarily responsible for the induced optical activity. Such a dissymmetry may be conferred on Cu(II) by stereospecific binding (or chelation) to the side-chain carboxylates and backbone amides bi- or tridentately. The overall conformation of a macromolecular complex would promote such binding. These conclusions are new and important.

The processes which are most responsible for the change in optical properties of the Cu(II)–Glu ligand complexes probably belong to two regions: the first half of the helix-coil transition region where the backbone of poly(Glu)–Cu(II) attains a compact-coil form due to the formation of fragmental helices, and the second transition region where the backbone undergoes a further conformational transition, possibly, from helix to *aggregates*. Thus, the species of Cu(II)–Glu ligand complexes are multiple, probably three or more altogether. It is a delicate interplay of these processes and the concentrations of the complex species involved that are responsible for the very involved dependence of the optical properties of poly(Glu)–Cu(II) on both pH and R.

The Cu(II)–Glu Ligand Complex and Its Absorption and CD Spectra. Complex formation between Cu(II) and Glu residues is evident from the absorption

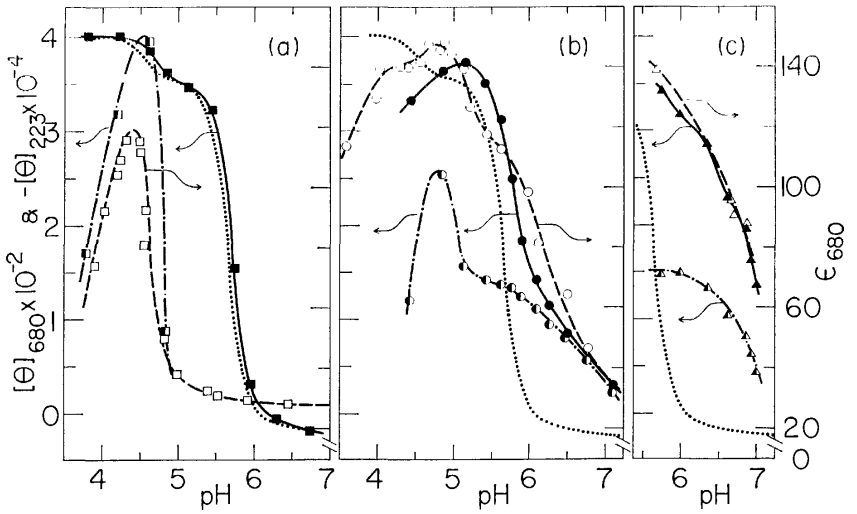

Fig. 11. Comparison of the pH-induced helix-coil transition curves of poly(Glu)–Cu(II) at three values of R (a) 32 (squares), (b) 8 (circles), and (c) 4 (triangles) with the pH variation of the corresponding visible CD and absorption of Cu(II). ε_{680} (——), $[\theta]_{680}$ (—·—), $[\theta]_{223}$ (——), and $[\theta]_{223}$ at $R=\infty$ (·····).

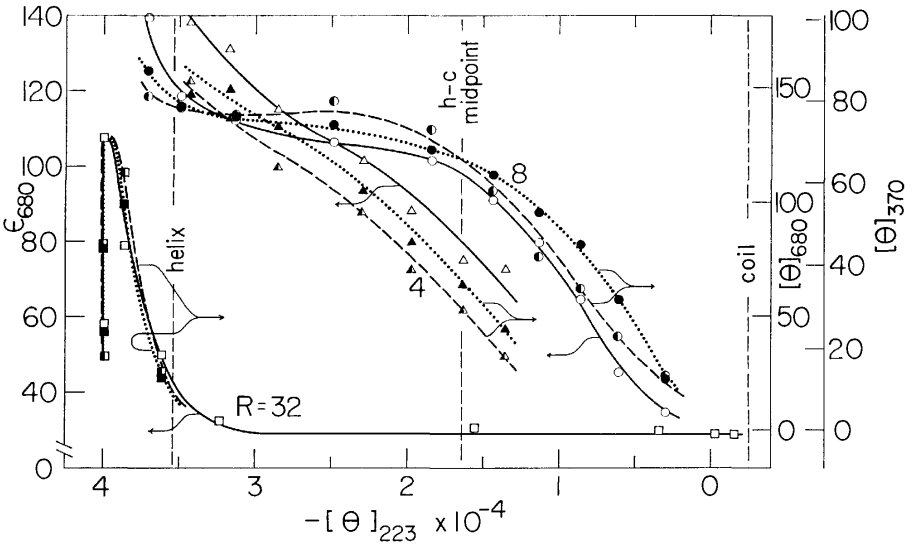

Fig. 12. Correlation between the intrinsic CD of poly(Glu)–Cu(II), $[\theta]_{223}$, and the absorption and extrinsic CD of the Cu(II)–Glu residue complex at three R values of 32 (squares), 8 (circles), and 4 (triangles). ε_{680} (——), $[\theta]_{370}$ (——), and $[\theta]_{680}$ (·····). The actual values of $[\theta]_{370}$ and $[\theta]_{680}$ at $R=32$ should be quadrupled. Regardless of the mixing ratios between Glu residues and Cu^{2+}, the $[\theta]_{223}$ values of +2500, −16500, and −35400 are assumed for the extended-coil, the midpoint of helix-coil transition, and the complete helix, respectively.

and extrinsic CD spectra of Cu(II) (Figs. 1, 2, 5, and 6). The present data manifest that previous reports have unraveled only a part of the whole process involved in the complex formation.[2,3] The absorption band at 700 nm results from the binding of Cu^{2+} by the ionized carboxylate (and possibly amide) groups, as the data of poly(Acr)– and butyrate–Cu(II) solutions (Fig. 1) and poly(carboxylic acid)–Cu(II) complexes have indicated.[9–15] The number of the ligand carboxylates participating in complex formation may range from one to four, most likely two ionized carboxylates.[26] An absorption study is insufficient to ascertain the mechanism of carboxylate neutralization and chelation and the role of the amide group of the Glu residue in chelation. Detailed studies of equilibrium dialysis and electron spin resonance are needed.

The skewed 700 nm band of the poly(Glu)–Cu(II) complex (Figs. 1 and 5) is not simple but composite revealing another component band on the long-wavelength side around 900 nm (Figs. 1 and 3), as reported for the poly(Methacr)–Cu(II) complex.[13] The multiple band structure has also been supported by CD data (Figs. 5 and 10). Hirasawa and Kon[32] analyzed the apparent 700 nm band of Cu(II) doped in L-histidine into three component bands centering at 714, 781, and 901 nm; these component bands may or may not correspond to the 685 and *ca.* 900 nm bands of the Cu(II)–Glu ligand complex. The CD

spectrum of a poly(Glu)–Cu(II) solution at R 32 was scanned to 800 nm with a red-sensitive Hamamatsu R446 photomultiplier. At the longest attainable wavelength, the *negative* CD component was only steadily increasing. Hence, the possibility still exists that the 700 nm absorption band of the bound Cu(II) is a composite of two, instead of three, out of four component bands. The actual situation may be very complicated, since the chemical species of the Cu(II)–Glu ligand complexes would be numerous in the poly(Glu)–Cu(II) macro-complex as indicated by the pH and R dependence of ε (Figs. 3 and 11). For instance, two side-chain carboxylates can chelate to a Cu(II) either in the *cis* or *trans* position. The absorption peaks for these isomers are known to be slightly different in amino acid–Cu(II) complexes.[33]

The origin of the near UV band of the Cu(II)–carboxylic acid complex remains a point of controversy[34] and, therefore, the 370 nm band of the poly(Glu)–Cu(II) complex deserves comment. Leyte *et al.*[13] suggested the presence of binuclear Cu(II) complexes of Cu(II)–acetate type dimeric structure in the poly(Methacr)–Cu(II) complex on the basis of the appearance of the 380 nm band. The optical absorption studies alone however can not resolve the question whether or not the 370 nm band reflects the presence of the binuclear Cu(II) complex in which direct Cu(II)–Cu(II) interaction exists.[34] The 350—380 nm shoulder appears in the absorption spectra of the Cu(II) bound to poly(Lys),[17] poly(Arg),[19] and poly(His),[20] all of which lack the carboxyl side-chain group. It should also be noted that the 370 nm band is associated with Cu(II)–β-diketone complexes which form a monomeric structure in solution.[35] Model buildings with CPK atomic models indicate that the dimer structure of the Cu(II)–acetate type is impossible with four side-chain carboxylates in a single-stranded poly(Glu) which may exist as the α-helix at low pH. The dimer is quite likely to occur if Cu(II) bridges two poly(Glu) strands by binding to two carboxylates of each polymer-chain. Comparative work by ESR and other magnetic methods is necessary here to identify the individual chemical species of Cu(II)–Glu ligand complexes.

The 370 nm CD band shows a slight hump in the shorter wavelength region suggesting a doublet structure (Fig. 5), although the absorption reveals no such feature (Fig. 1). Dubicki[36] reported that the 370 nm band of the Cu(II)–acetate complex is a doublet, assigning it to the charge-transfer transition of ligand-to-metal nature. Graddon[35] considered the 370 nm band of Cu(II)–ethyl acetoacetate complex as originating from the higher energy d-d transition (d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ type). His term-scheme is compatible with the present CD data of poly(Glu)–Cu(II) complexes assuming a weakening of degeneracy of the near UV d-d transition and that the low energy 700 nm band consists of two of the four d-d components. The final assignment of the d-d transition of Cu(II) and, consequently, the most likely coordination of the Cu(II)–Glu ligand complex remains unclear. The detailed CD study of a number of polypeptide–Cu(II) complexes in the near IR region is necessary for solving these problems.

The 250 nm band has been studied because of the high absorption intensity and existence in the spectra of Cu(II) in the presence of polyanions such as poly(Glu),[2,3,8] poly(Methacr)[11–13] and poly(Lys).[17] The band has been assigned to the allowed charge-transfer transition between carboxyl ligands and the metal ion.[2] The 250 nm charge-transfer band is composite, as indicated by the positive and negative CD component bands (Fig. 10). The unambiguous determination of the number and polarization of the optical transition moments involved in the poly(Glu)–Cu(II) complex are important for the understanding of the origin of induced optical activity associated with bound Cu(II). Such studies may be conducted by means of film dichroism.[37]

Conclusion

The Cu^{2+} ion bound to poly(Glu) exhibits the extrinsic Cotton effects of multiple type in three characteristic absorption bands in the visible, near UV, and UV regions. The effect of bound Cu(II) on the polymer conformation induces a helical structure but reduces the cooperative nature of the helix-coil transition. The absorption and CD spectra of bound Cu(II) in this transition region are related but the behavior is not in parallel with the backbone conformation. In addition to the ordinary helix-coil transition, a second conformational transition is involved in the macromolecular poly(Glu)–Cu(II) complex in the pH range <5.3—5.2. Complex formation between Cu(II) and Glu residues is strongly affected by this transition. The pH dependence of absorption and CD intensities results largely from the interplay of the two conformational transitions of the macrocomplex which affect the number of species and stereospecific configurations of the Cu(II)–Glu ligand complexes populated on the poly(Glu).

One of the authors (K. Y.) should like to express his sincere gratitude to Dr. Elliot Charney of the National Institutes of Health, Bethesda, Md. (USA) for his encouragement. The CD measurements were carried out in his laboratory in the summer of 1973 and 1975.

An Estimation of the Thermodynamic Properties of Organic Compounds in the Ideal Gas State. I. Acyclic Compounds and Cyclic Compounds with a Ring of Cyclopentane, Cyclohexane, Benzene, or Naphthalene**

Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 6, 1978)

A new group-contribution method for estimating the standard enthalpy of formation, the standard absolute entropy, and the standard molar heat of organic compounds in the ideal gas state is proposed with tables of the contribution values. This method (the ABWY method) is a completely revised and enlarged version of the Anderson, Bayer, and Watson method, and it can be used with regard to a more diverse variety of compounds with a higher reliability. The neighboring effects in group-contribution methods are introduced to obtain better estimated values. The substitutions of various functional groups on aromatic rings are discriminated. Type-number corrections of the functional groups and multiple-substitution effects of halogens are also introduced; thus even heterofunctional compounds can be processed. A new concept, the quality of contribution values, is proposed to designate the qualitative reliability of the estimated physical properties. The manual procedures and tables of contribution values are given for estimating the thermodynamic properties of the compounds, as mentioned in the title, composed of C, H, O, halogens, S, and N. This method was critically compared with the Benson method in versatility and reliability.

In spite of the tremendous efforts of many scientists, the *observed* values of the fundamental properties of organic compounds, such as the heat of formation in the ideal gas state, are unexpectedly scarce; only around 1600 are known among several million compounds. As for the observed data of IR, already nearly two hundred thousand spectra have been collected by chemists. If we take into account the difficulty in the measurement of thermochemical and thermodynamic data as compared to that of the IR spectra, *e.g.*, the necessary purity of the specimens and the skill in measurement, one can hardly expect rapid increase of the former data within the next few years.

Thus, many investigators have published various methods of estimating the thermodynamic properties of organic compounds in the ideal gas state.[1-2] All of the estimation methods employ the principle of the group contribution; the target molecules are decomposed into atom groups, or functional groups, and the sum of the contributions of these groups makes the estimated values.

Among the group-contribution methods for estimating the standard enthalpy of formation, the standard absolute entropy, and the standard molar heat, the Anderson, Bayer, and Watson method (the ABW method)[3] and the Benson method[4] have been rated as two of the best.[2] The present author has already presented an extended method (the ABWY method)[5] modified from the ABW method. In this paper, a further improved version of the ABWY method and updated tables of contribution values will be reported. The functional groups and correlations due to multiple bonds were much diversified in this version; the concept of quality, or reliability, of the contribution values was also introduced.

The present ABWY method was originally intended to be implemented in computer program packages, EMPRIC[5] and EROICA,[6] the outline of which has been published earlier. These programs permit the CHEMO inputs, *i.e.*, the linear notations of rational formulas also proposed by the present author,[5,6] to accept information on organic compounds. The contribution values were statistically selected from the observed properties with the aid of the method of the least squares with a computer program, THEDES.

In this paper the method is presented for estimating acyclic compounds and cyclic compounds that have only one of four ring compounds, cyclopentane, cyclohexane, benzene and naphthalene, both composed of C, H, O, halogens, N, and S. Even the *heterofunctional* compounds, *i.e.*, compounds with plural kinds of functional groups, can be processed, not to mention the *monofunctional* or the *homofunctional* ones. The estimation method for complex compounds, excluded in this report, will be published in forthcoming papers.

This group-contribution method may be applicable in principle even to properties other than those in the ideal gas state if the properties can be so ingeneously converted that the linear additivity holds in them. The methods of estimating the critical properties, the vapor pressure, the heat of vaporization, and the normal boiling point, as well as the thermodynamic properties in the liquid phase, will also be reported in the forthcoming papers.

Theoretical

Since the thermodynamic properties covered in this paper are those of *ideal gas*, intermolecular forces can play no part in their estimation. Also, by the same reasoning, the law of corresponding states, used so widely in the estimation of other properties such as vapor pressure, is inapplicable. All methods of estimating enthalpy, entropy, and molar heat involve some form of group-contribution method based on the structure of the molecule.[4]

Benson[4] and Benson and Buss[7] pointed out a hierarchy of such methods, in the order of the additivi-

** CHEMOGRAM, a Computer Program Package for Chemical Logic, Part 3.

ties of (i) atom properties, (ii) bond properties, and (iii) group properties. The present author has described the hierarchy in another way.[5] The most successful method assigns the contribution to common groups, for example, $-CH_3$, $-OH$, or $-COO-$; by simple additivity, one can then estimate the ideal-gas properties from tables of the group-contribution values.

Neighboring Effects in Estimation. Allowance is made at least for the next-nearest neighbors to this group in order to proceed to a more complicated and usually more accurate method. In principle, there is no limit to the extension of the neighborhood-environmental concept, although the effect of neighboring groups separated by more than one atom usually becomes so small as to be insignificant. Some exceptions would be the effects of the *cis-trans* isomerism of olefin and the positional isomerism of polysubstituted ring compounds, and the influence of aromaticity; these effects are due to interaction between groups separated by two or more atoms.

Hence, the following classification and nomenclature of neighboring effects are given:

(1) Nearest-neighboring effect: effect from directly bonded atoms.

(2) Geminal effect: effect from atoms separated by one atom.

(3) Vicinal effect: effect from atoms separated by two atoms.

(4) Global effect: effect from atoms separated by more than two atoms.

Examples of these hierarchial effects will be given later.

Definition of Groups. In the ABWY method, a *group* is defined as follows:

(1) Base groups, *i.e.*, methane and ring compounds such as benzene, cyclohexane or naphthalene. Exceptions are the methyl radical, cation, and anion.

(2) Functional groups including $CH_n(n=0—3)$, but excluding H(hydrogen atom). Functional groups usually consist of an atom or an ensemble of atoms. Even when a complicated functional group could be decomposed into simpler or smaller functional groups, the original one should be adopted as a group when its contribution value is available, because complex groups include neighboring effects of a higher order; for example, the chloroformyl group, $-COCl$, should be adopted instead of carbonyl and chlorine. The only two exceptions to this rule are the formyl group, or aldehyde, $-CHO$, and the carbonyl group, $-CO-$, which should be decomposed into carbon and the oxo group, $=O$, as a heritage from the ABW method. Thus, the ligancy of groups may be from one to four, in contrast to two or more in the case of the Benson method.[4]

Linear Additivity of Thermodynamic Properties. The thermodynamic properties[7a] of organic compounds in the ideal gas state can be empirically represented as the sum of group contributions by virtue of the absence of any intermolecular interaction:

$$\Delta H^\circ_{f,298.15}(g)/\text{kcal mol}^{-1} = \sum_j n_{ij}\Delta(\Delta H)_j \quad (1)$$

$$S^\circ_{298.15}(g)/\text{cal mol}^{-1}\,\text{K}^{-1} = \sum_j n_{ij}\Delta S_j \quad (2)$$

$$C_p^\circ(g,T)/\text{cal mol}^{-1}\,\text{K}^{-1} = a + 10^{-3}bT + 10^{-6}cT^2 \quad (3)$$

$$a = \sum_j n_{ij}\Delta a_j,\ b = \sum_j n_{ij}\Delta b_j,\ \text{and}\ c = \sum_j n_{ij}\Delta c_j \quad (4)$$

where $\Delta(\Delta H)_j$, ΔS_j and Δa_j, Δb_j, and Δc_j are the group-contribution values of the j-th group for the standard enthalpy of formation, the standard absolute entropy, and their coefficients of the three-term molar heat equation respectively, where n_{ij} is the contribution count of the j-th contribution in the i-th compound, and where T is temperature in K.

Thermodynamic Properties of Hydrocarbons. In the ABMY method, molecules with hetero atoms are processed by *replacing* CH_n groups in the chain structure of a parent hydrocarbon with functional groups. Hence, the first step is the estimation of the properties of saturated hydrocarbon skeletons. Each compound is considered to be composed of a base group, *i.e.*, methane, or a cyclic compound, which is modified by the *substitution* of the other groups for the atoms composing it. For example, all paraffinic hydrocarbons are considered to be derived from methane by the successive substitution of CH_3 groups for hydrogen atoms. Similarly, any benzene derivatives are regarded as derived from a base group, benzene.

Primary Methyl Substitution: The contributions resulting from the primary substitution of a methyl group for a hydrogen atom in any one of the base groups are the specified ones for the groups concerned. In the cases of ring compounds as base groups, successive substitutions for the different hydrogen atoms on the ring involve different contributions depending on the number and position owing to geminal, vicinal, or global effects.

Secondary Methyl Substitution: A secondary methyl substitution is the substitution of a methyl group with a hydrogen in the methyl group derived by the primary substitution or in recursively substituted methyl groups. Contributions from the secondary substitution depend empirically on the types of both the nearest-neighboring atom and the geminal atoms. The carbon-atom types are defined, on the basis of the number of non-hydrogen atoms attached, as follows:

Type	1	$-CH_3$
	2	$-\overset{\vert}{C}H_2$
	3	$-\overset{\vert}{\underset{\vert}{C}}H$
	4	$-\overset{\vert}{\underset{\vert}{\overset{\vert}{\underset{\vert}{C}}}}-$
	9	C atom in aromatic rings.

Branched hydrocarbons are usually more stable than straight-chain isomers, except for highly branched ones, which suffer from steric hindrance. Hence, the contributions of the secondary substitutions are naturally classified according to A, the type number of the carbon atom on which the substitution is made (the nearest-neighboring effect), and B, the highest type number among adjacent atoms (the geminal effect). The type number 9 of an aromatic ring indicates the strongest geminal effect among them. In the present estimation method, an aromatic ring is limited to a benzene ring or one of the benzene rings in fused-ring compounds.

Multiple Bonds and Corrections due to Their Context: After the properties of saturated-hydrocarbon chain-structure are estimated, some of the single bonds may be replaced with multiple bonds, if any. Contributions for this replacement are classified according to the type numbers of the carbon atoms connected by the multiple bonds. Corrections due to conjugated multiple bonds, conjugation with an aromatic ring, and cumulative double bonds may be added.

Replacement of CH_n Groups with Functional Groups. The implementation of functional groups are made by the *replacement* of CH_n groups with functional groups; three kinds of contribution values, *i.e.*, the *fundamental*, *type-number correction*, and *multiple-substitution correction*, will be described below.

Fundamental Contribution : When one of the CH_n groups is replaced, a fundamental contribution is added. Table 1 shows examples of fundamental contributions, where the global effect of the aromaticity is significant. Therefore, the discriminated values must be given to groups directly connected to aromatic rings. The divalent or trivalent functional groups, such as –O–, –NH–, –N<, or –COO–, have different values from those of the monovalent parent groups, like –OH, $-NH_2$, or –COOH.

Table 1. Global effect of aromatic ring on fundamental contribution values of functional groups.

Replacement of CH_3 with functional group	Change by replacement[a]	
	$\Delta H^\circ_{f,298.15}$ / kcal mol^{-1}	$S^\circ_{298.15}$ / cal mol^{-1} K^{-1}
CH_3-CH_3→CH_3-NH_2	14.74	3.13
C_6H_5-CH_3→C_6H_5-NH_2	8.81	0.36
CH_3-CH_3→CH_3-OH	−27.84	2.44
C_6H_5-CH_3→C_6H_5-OH	−34.98	−1.21

a) 1 cal=4.184 J. Data from SWS.[8]

Type-number Correction for Functional Groups : The geminal effect for functional groups generally may be enhanced by the superconjugation between unshared electrons in functional groups and pseudo-π-orbitals in geminal methyl groups. Table 2 shows the reasonings for the type-number correction. Columns 3 and 6 give, respectively, the increases caused by the replacement in the enthalpy of formation and in entropy, both at the standard state. The fundamental contributions being estimated as −0.39 and 1.19 respectively (line 1), deviations solely due to the geminal effect are seen in Columns 4 and 7. On the other hand, t in Column 2, which is equal to (A-1), denotes the number of geminal methyl groups relative to the chloro group; therefore, the type-number corrections for enthalpy and entropy are derived to be −1.18 and 0.69 respectively, on the assumption that the geminal effect is simply additive regardless of the number of geminal atoms. Finally, Columns 5 and 8 show the calculated geminal effects, which are in good agreement with those observed.

Functional groups directly bonded to aromatic rings have no type-number corrections because these fundamental contributions already include the global effect. The groups directly bonded to non-aromatic rings, however, require the appropriate type-number corrections according to the type number of the methyl-substituted carbon atom in the ring; for example, the twofold corrections to chlorocyclohexane are necessary because the type number, A, of the carbon atom in the ring is three.

Multiple-substitution Correction for Functional Groups: The polar groups bonded to one carbon atom may interact with each other, probably because of electrostatic repulsion or steric hindrance. Therefore, the multiple-substitution correction may be added. Table 3 shows an example of this correction. The quantities in Columns 2, 4, and 7 are the same as the corresponding notations in Table 2. Columns 5 and 8 are the remainders of enthalpy and entropy respectively, after type-number correction by the use of t. The notation m in Column 3 implies the number of geminal Cl–C–Cl effects; its sum is ten. By the use of the averaged correction values of 5.04 and −1.66 derived from the totals in Columns 5 and 8 respectively, the values in Columns 6 and 9 are calculated; again, they are in good agreement with the observed values. The mixed substitutions such as F–C–Cl can be corrected similarly.

Preparation of Contribution Values

Sources of Observed Data. The newest observed values of the standard enthalpy of formation, the absolute entropy at 25 °C, and the molar heat at temperatures from 273 to 1000 K were selected from three major sources: SWS,[8] API,[9] and TRC;[10] the estimated, or correlated, values described very often in the sources were carefully excluded. The observed data thus selected (the molar heats were converted into three coefficients of Eq. 3) were stored in a database, the EROICA database,[6] together with their contribution counts, as prepared by a computer program rigorously following the estimation procedures to be described in the next chapter.

Besides these three sources, three other data sources, PRN[11], BCG,[12] and LBT1,[13] were utilized suplementarily in order to obtain the contribution values of functional groups which could not be retrieved from the former three. The PRN, which was recently published, complies the observed data of enthalpy reported up to early 1976, along with their uncertainties, but this is not yet implemented into the EROICA database. In BCG, Benson *et al.*[8] estimated the enthalpies of formation in the gaseous phase of a wide variety of compounds from those in the liquid phase (even in the solid phase in rare cases) by assuming the heat of evaporation.[14] These estimated values were adopted only when unavoidable. The data of molar heats at temperatures were adopted also from LBT1, which is also not implemented.

Preparation of Contribution Values from the Database. Most of the contribution values were prepared with the aid of a computer program, THEDES, written in FORTRAN IV, on a HITAC 8800/8700 of the University of Tokyo.

Contribution Values in Tables A1 through A4 : Table A1 in the Appendix was prepared from the observed data themselves.

First, all of the paraffins except methane were retrieved from the database, and simultaneous equations of Eqs. 1, 2, and/or 4 were prepared with given contribution counts, n_{ij}'s, as independent variables and observed values minus that of methane as dependent variables; then the parameters, $\Delta(\Delta H)_j$, ΔS_j, and Δa_j, Δb_j, and Δc_j, were calculated by the method of the least squares. The primary substitution to methane in Table A2 and secondary substitutions, except for those related with aromatic rings in Table A3, were thus prepared.

Second, all of the olefins, diolefins and acetylenes were retrieved, and, after the elimination of contributions due to primary and secondary substitutions, multiple-bond contributions and their corrections in acyclic compounds were calculated by the same method; the results are given in Table A4.

Third, all of the hydrocarbon derivatives of cyclopentane and cyclohexane were retrieved, and primary substitutions to these two cycloalkane base groups were estimated; these results are shown in Table A3.

Finally, hydrocarbon derivatives of benzene and naphthalene were processed to estimate the primary substitutions to these two aromatic base groups (Table A2), the secondary substitutions related with the aromatic rings (Table A3), and the conjugation effects of multiple bonds with aromatic rings (Table 4).

Contribution Values in Tables A5 and A6: The fundamental values, type-number corrections, and multiple-substitution corrections were calculated at the same time with the aid of the same procedure, after eliminating the contributions already given in Tables A1 through A4. In practice, compounds with hetero atoms derived from methane or the above-mentioned four cyclic base groups were subdivided, so that compounds containing a specified hetero atom besides carbon and hydrogen were processed to calculate the contribution values for functional groups containing the above-mentioned hetero atom. Following this sequence, the majority of the values in Tables A5 and A6 were statistically estimated.

Illustrations for Tables A1 through A8. In Table A2, several primary methyl substitutions are possible for ring compounds, while only one primary substitution is possible for methane. Each line corresponds to one methyl substitution on the base group; hence the primary methyl substitutions to form 1,2,3-trimethylbenzene, for example, are composed of the first primary (line 23) and two of the second primary substitutions, *i.e.*, 1,2 (line 24) and 1,2,3 (line 27). As for the cyclopentane and cyclohexane derivatives, *cis* or *trans* configuration must be discriminated in polymethyl derivatives, although averaged values without the *cis-trans* notation may be used for an equilibrium mixture. The values designated as *unspecified* may be used to form derivatives which require additive substitutions; 1,2,3,4-tetramethylbenzene may be estimated by adding the unspecified values (line 30) to those of 1,2,3-trimethylbenzene.

In Table A4, the unspecified 2=2 contribution implies that of an equilibrium mixture of *cis* and *trans* configurational isomers. An additional correction to multiple-bond arrangements may be present in lines 12 to 17.

The fundamental contributions of the functional group in Table A5 are arranged in the order of O, F, Cl, Br, I, S, and N. Two single bonds and one double bond should be discriminated; the values of –NH–, secondary amine, should not be used instead of those of =NH, imine. The contribution of functional groups directly connected to an aromatic ring (denoted by @) should be discriminated from the others. The observed values of *o*-difluorobenzene deviate slightly from the ordinarily estimated values because of the vicinal effect.

Corrections due to type numbers are given in lines with one functional-group notation in Table A6. Topologically non-symmetric multivalent groups such as –C(=O)–O– should have two kinds of type-number corrections, for which a percent mark(%) is given to indicate the direction of the bonds to be considered. Corrections due to multiple substitutions are given in lines where two functional-group notations are described.

In addition, Table A7 lists simple substances and Table A8 lists inorganic compounds and a few organic compounds whose properties can not be estimated by the present method, for the convenience of users in calculating the change of properties in reaction, *etc.*

Quality of Contribution Values. The reliability of contribution values given in these tables depends on the reliability and plentifulness of the observed thermochemical and thermodynamic data from which the contribution values are derived. Since the compounds in Table A1 are key compounds, the observed values are highly reliable. The contribution values in Tables A2 to A4, which are employed to form various hydrocarbons, are usually of a high quality because the reliable observed data are available for diversified kinds of hydrocarbons; some minor corrections for the context concerned with multiple bonds are, however, less reliable because of the scarcity of observed data of a high quality. The contribution values for some functional groups are less reliable, because often only one set of observed data even with a low accuracy is available. The assumed contribution values, which could not be otherwise determined because of the lack of observed data, may much diversify the range of organic compounds to be handled, but these assumed values are undoubtedly of less reliability.

Thus, the *quality* given in Table 4 was assigned to each of the contribution values in parentheses following values. The qualities in Table 4 range from 1 (the most reliable) to 6. The reliability of a physical property obtained as a sum of the contribution values may be designated by the worst quality of the contributions.

The uncertainty for quality 1 may be evaluated as 0.5 kcal/mol, except for fluorides and chlorides, for the enthalpies of formation judged from the standard deviations discussed in Results and Discussion, while that for quality 4 may be more than 1 kcal/mol; properties with quality 5 or quality 6 must be used at the

Table 4. Quality of contribution values

Quality	Remarks
1	Calculated values from reliable observed data
2	Approximated values correlated from very similar contributions
3	(Reserved for observed data)
4	Calculated values from less reliable observed data—in the present version, those from observed data rated 'C' in SWS[8]
5	Assumed values by correlation with less reliability
6	Assumed values by decomposing functional groups into their fragments

user's risk.

Contribution Values Manually Selected. In Tables Al through A6 of the Appendix, the values with quality 2 were determined manually, although those from the reliable data in PRN are rated 1; the procedures of estimation are given in the corresponding footnotes of the tables.

As for some primary methyl substitutions (Table A2), the contribution values were assumed from those of the relevant substitutions. The values of the relevant combination of type numbers were also used in place in the secondary methyl substitutions (Table A3). Properties in the gaseous phase were estimated from those in the liquid or even solid phases when the former was unavailable;[12] these values were rated 5.

Fundamental Contribution Values for Functional Groups : It is surprising that no data are available for the entropy and the molar heat of any aromatic ether, a popular homolog, with which the chemical equilibria of its formation at temperatures may be calculated. The contribution values of aromatic ether (@O–) may be assumed by subtraction : $\Delta(@OH)+\{\Delta(-O-)-\Delta(-OH)\}$, where the contributions in the formula stand for phenol, ether, and alcohol, whose values have already been calculated. Supposedly, the entropy and molar heat may be not so seriously affected by the bond to an aromatic ring as enthalpy,[15] because the former is affected by the curvature of the potential surface, whereas the latter is determined by the bond energy itself. Hence, the application of this method to a fundamental contribution was restricted only for entropy and molar heat, although no data is available to verify the above discussion, even for the latter two properties. These methods may give less reliable values, so they were rated 5.

In the cases where the fundamental values of the functional groups could not be estimated by means of any method given above, some of them were assumed by decomposing a group into small fragments. An example is the entropy and molar heat for –COBr, which was decomposed as consisting of –C(=O)– and Br.[16] Table 5 shows the effects of decomposing groups whose contribution values were obtained beforehand from observed data. As regards the entropy and molar heat, the estimation by decomposition may not give bad values, although the agreement between values for enthalpy is untolerably poor; hence, a few values only for the former two properties were estimated by this method, and they were rated 6.

Minor Corrections for Functional Groups : As for the minor corrections in Table A6, the subtraction method was employed even for enthalpy because of their small magnitude. In some cases, values were assumed from those of similar functional groups. One example is that the difference between the values for @COF and –COF is assumed to be equal to that between the values for corresponding COCl groups. Assumption that the type correction of %–COO– is equal to that of –COOH is another example. Some type correction values for the entropy and molar heat, which could not be correlated by these methods, were assumed to be zero because they are usually small; they were rated 5.

Sequence of Manual Operations in Estimation

The following features have been changed from the original ABW method : (1) base groups are limited to methane and ring compounds; (2) functional groups substituted to aromatic rings are discriminated from those substituted to non-aromatic fragments; (3) type corrections are given throughout functional groups; (4) multiple-substitution corrections are also given to some of the functional group; (5) corrections due to the context of multiple bonds are expanded, (6) the *quality* of estimated values is made available in order to make it possible to recognize their reliability, and (7) minor corrections due to the chain length as well as the enlargement of the cyclohexane ring are abolished.

Manual Operation. The suggested sequence of operations in estimating the properties of a complex compound is as follows :

Step 1: Select the base group, and determine its properties from Table A1. In an acyclic compound, yan one of the terminal atom groups may be selected

Table 5. Effects of decomposing functional groups into fragments on their fundamental contribution values

Functional group		Fundamental group-contribution values[a]				
		$\Delta(\Delta H)$	ΔS	Δa	Δb	Δc
-COCl	from observed data	−38.06	12.89	5.41	−5.63	−0.58
	-CO- and -Cl	−32.58	17.07	5.19	−7.29	1.37
$-NHNH_2$	from observed data	40.64	11.76	—	—	—
	-NH- and NH_2	29.13	13.27	—	—	—

a) The units are the same as those given in Table A5.

as the base group. In the case of a cyclic compound, a ring compound should be selected as the base group.

Step 2: Make all the *primary substitutions* before starting the *secondary substitutions*, where *substitution* means an exchange of a hydrogen atom with a methyl group. In the case of methane, only one primary substitution is possible. With ring structures, one primary substitution (the *first* primary substitution) is possible for each hydrogen atom of the base group. If two or more primary substitutions (*second* primary substitutions) are to be made on a base ring, the two substitutions closest together should be made first. If more than one substitution is to be made on a specific carbon atom in the base ring, such additional substitutions are to be treated in the same way. The unspecified contributions may be assigned for substitutions other than those clearly indicated, Table A2 is used to evaluate the group contributions resulting from primary substitutions.

Step 3: Complete the carbon skeleton of the compound by making a series of secondary substitutions, and use Table A3 to obtain the values of group contributions for such substitutions. Each of the multivalent functional groups, *e.g.*, –COO– or –N<, should be regarded as a CH_n group of the carbon skeleton. In order to have the results conform with the procedures used in developing the tables, the following rules should be observed, although the deviations are usually small even if they are violated:

(a) The longest straight chain should be fully developed before any side chains are added.

(b) Side chains are added in the order of their length. However, if the carbon atom with the longest side chain is to have a second side chain, this second side chain should be added before additions are made to other carbon atoms of the straight chain.

Step 4: Make additional secondary methyl substitutions for monovalent functional groups. Allowance for such substitution is made from Table A3. For *multibonded* functional groups in Steps 3 and 4, *e.g.*, =O or =N–, *additional* secondary methyl substitutions should be made; *one* additional substitution for *double* bonds and *two* for *triple* bonds.

Step 5: Add multiple bonds and obtain from Table A4 the contributions resulting from such additions. If required, make the additional corrections indicated by Table A4 for correlations between bonds.

Step 6: Replace CH_n groups by the substitution groups listed in Table A5.

(a) First, add the *fundamental* contributions given in Table A5.

(b) Second, check the types of connecting atom groups, and add contributions for the *type-number correction* from Table A6. In counting the type, assume that all of the functional group(s) were replaced *beforehand*.

(c) Third, check the other substituting groups to the group to which the present group is connected (the geminal effect). Add contributions for *multiple-substitution corrections* from Table A6. Repetition from each substituent should be allowed.

Step 7: Find out the maximum of *quality* associated with the contribution values. This gives the user a measure of the reliability of the estimated values.

Examples of Estimation. Four examples will be illustrated in order to make clear the above-mentioned sequence of manual operations.

Example 1. Enthalpy, Entropy, and Molar Heat of 2-Methyl-1,3-butadiene (Isoprene): The replacement of two single bonds with two double bonds in 2-methylbutane makes this compound. Methane is selected as the base group (Step 1); then a hydrogen atom is substituted by a methyl group as the primary methyl substitution to make ethane (Step 2). The carbon skeleton is completed by the successive secondary substitutions, with consideration paid to the type numbers of the atoms concerned (Step 3). Finally the contribution values due to double bonds as well as the correction for the conjugated double bonds are added to make the given compound (Step 5). The numerals will be given below:

	$\Delta(\Delta H)$ / kcal mol^{-1}	$\Delta(S)$ / cal mol^{-1} K^{-1}
(1) Base group:		
Methane	−17.89 (1)[a]	44.50 (1)[a]
(2) Primary substitution:		
CH_3CH_3	−2.35 (1)	10.35 (1)
(3) Secondary substitutions:		
$CH_3CH_2CH_3$ (1,1)[b]	−5.04 (1)	10.44 (1)
$CH_3CH_2CH_2CH_3$ (1,2)	−4.92 (1)	9.29 (1)
	(−30.20)[c]	(74.58)[c]
$CH_3CH(CH_3)CH_2CH_3$ (2,2)	−6.35 (1)	6.53 (1)
(5) Multiple bonds:		
1=3	27.94 (1)	0.17 (1)
1=2	30.15 (1)	−1.43 (1)
Conjugated double bonds	−3.66 (1)	−4.06 (1)
Total	17.88 (1)	75.79 (1)

where the superscripts a, b, and c indicate the quality, type numbers, and subtotals respectively. The observed values[8] are 18.10 for $\Delta H^\circ_{f,298.15}$ and 75.44 for $S^\circ_{298.15}$, and the quality of the estimates is 1. The molar heats at 298 K and 1000 K were estimated similarly to be 25.43 cal mol^{-1} and 52.68 respectively, while the observed values[9] are 25.00 and 52.90. The agreement among these observed and estimated values is surprisingly good in this case.

The group contributions by the Benson method are composed of $2\times[(C_d\text{-}(H)_2]+[C_d\text{-}(C_d)_2]+[C_d\text{-}(C_d)(H)]+[C\text{-}(C)(H)_3]$; this gives the estimate of enthalpy of 13.7 in the same unit.

Example 2. Enthalpy and Entropy of 2-Butanone: The replacement of two methyl groups with an oxo (=O) group will make this compound. First, 2,2-dimethylbutane will be prepared by Steps 1 through 4; second, two methyl groups will be replaced by a substitution group with the twofold type-number corrections, because the 2-carbon atom *after* substitution is tertiary (Step 6).

	$\Delta(\Delta H)$ / kcal mol^{-1}	$\Delta(S)$ / cal mol^{-1} K^{-1}
(1-3) Methyl substitutions:		
$CH_3CH_2CH_2CH_3$	−30.20 (1)	74.58 (1)

(4) Additional substitutions for functional groups:		
$CH_3CH(CH_3)CH_2CH_3$ (2,2)	−6.35 (1)	6.53 (1)
$CH_3C(CH_3)_2CH_2CH_3$ (3,2)	−6.84 (1)	4.30 (1)
(6) Replacement by functional group:		
$CH_3COCH_2CH_3$		
Fundamental	−7.09 (1)	−20.19 (1)
Type number	−3.30 (1) ×2	7.39 (1) ×2
Total	−57.08 (1)	80.00 (1)

The observed values[9] are −56.97 and 80.81 respectively, whereas the Benson method gives a fairly good value of enthalpy of −56.56.

Example 3. Enthalpy and Entropy of Perfluoroethane: Since fluorine atoms are substituted to ethane by replacing a methyl group for each fluorine atom, the hydrocarbon molecule *before* replacement is 2,2,3,3-tetramethylbutane, as estimated in Steps 1 through 4. In Step 6, the fundamental contributions of fluorine to non-aromatic fragments are added six times at first. As for the type-number correction, threefold corrections for each fluorine atom are necessary because the 2- and 3-carbon atoms are quaternary; hence, altogether 18 corrections are added. Besides, the multiple-substitution corrections must be added six times, because each of the two trifluoromethyl groups has a threefold correction in it.

	$\Delta(\Delta H)$ / kcal mol^{-1}	$\Delta(S)$ / cal mol^{-1} K^{-1}
(1-4) Methyl substitutions:		
$CH_3C(CH_3)_2$-$C(CH_3)_2CH_3$	−53.99 (1)	93.07 (1)
(6) Functional groups:		
(a) Fundamental	−221.10 (1) (−36.85×6)	−23.82 (1) (−3.97×6)
(b) Type number	−26.46 (1) (−1.47×3×6)	17.82 (1) (0.99×3×6)
(c) Multiple substitution	−22.02 (1) (−3.67×3×2)	−5.46 (1) (−0.91×3×2)
Total	−323.57	81.61 (1)

The agreement between the estimated and observed values,[8] −321.00 and 79.37, shall be rated as excellent in the case of rather large numerals. The estimate of enthalpy by the Benson method is −316.8.

Example 4. Enthalpy and Entropy of 1,2,3,4-Tetramethylbenzene: As a matter of course, benzene is selected as the base group (Step 1). The first- and second-primary substitutions will be processed by exactly following the descriptions in Step 2, as is shown below:

	$\Delta(\Delta H)$ / kcal mol^{-1}	$\Delta(S)$ / cal mol^{-1} K^{-1}
(1) Base group:		
Benzene	19.82 (1)	64.34 (1)
(2) Primary substitutions:		
(a) First primary	−8.48 (1)	11.45 (1)
(b) Second primary		
To make 1,2-	−6.64 (1)	8.70 (1)
To make 1,2,3-	−7.26 (1)	10.24 (1)
Unspecified (to make 1,2,3,4-)	−7.61 (1)	4.94 (1)
Total	−10.17 (1)	99.67 (1)

The agreement between the estimated and observed values,[9] −10.02 and 99.55, is again excellent. If one employs the second primary substitution to make 1,2,4- instead of the above one to make 1,2,3-, he may obtain the estimates of −10.19 and 99.85, which are slightly poorer values than the above ones, presumably because of less enhancement of the ortho effect among methyl groups. The contributions by the Benson method, composed of $2\times[C_B\text{-}(C)]+4\times[C_B\text{-}(H)]+4\times[C$-

a) Number of compounds employed in calculation. b) Number of contribution values calculated. c) Number of error $=\sum|\text{obsd}-\text{calcd}|/(N_d-N_s)$; kcal mol^{-1} for H, and percentage error for S and C_p. e) Standard deviation; f) For classification of compounds, see text. g) Mean.

(C)(H)$_3$]+3×[ortho correction], give −10.45.

Results and Discussion

In the evaluation of the estimation methods by the use of the correlation of the physical properties of organic compounds, it may be worthwhile to discuss the following four items.

Accuracy or Reliability of the Estimated Values. Table 6 shows the average errors and the standard deviations derived from the differences between the observed data and the calculated data by the use of contribution values; these tables were prepared during the statistical calculations using the program, THEDES.

The errors as well as the number of compounds, N_d, employed for the calculation, the number of contributions, N_c, whose values were found during the calculation, and the number of compounds which contain the unique contributions, N_s, are given for each classification of compounds.

The degree of freedom used for the calculation of errors should not be the number of samples, N_d, but N_d-N_s. Sometimes, it is necessary to determine the value for a specified contribution from one compound, that is, a compound which has a *unique* contribution; for example, the contribution due to the replacement of a single bond in ethane with a triple bond to form acetylene, or Δ(1≡1) in Table A4, is derived solely from the observed value of acetylene. In these cases, the differences between observed and calculated data should be null *by definition*. Hence, the true accuracy must be estimated by excluding the null differences; this consideration suggests the use of N_d-N_s, instead of N_d, for the actual degree of freedom. A high accuracy, including many nulls by definition, in the estimation of thermodynamic values has been reported by the use of group-contribution values, supposedly derived not statistically but by the mere subtraction method;[17] nevertheless, such an unthinkably high accuracy can not be expected throughout a wide variety of compounds other than those cited in their report.

The average errors shown in Table 6 are usually small enough for practical purposes. The standard deviations described there give us the statistical reliability of the estimated values; 95% of the population has a deviation not larger than 2σ, 70% of it, one not larger than σ, and 40% of it, one not larger than $\sigma/2$.

During the processing, however, a number of compounds were excluded because of the poor agreement between the estimated and the observed values, although these compounds very often had observed values measured many years ago and, hence, with less reliability.

A certain monograph[18] presents a comparison between the estimated and the observed values of 29 organic compounds obtained by several methods. The average errors in enthalpy are obtained by excluding the compounds which are outside the scope of each method or which have unique contributions; for the Benson and the ABWY methods, the four compounds described in Examples are added. The average errors are :

Benson: 35.70/27=1.3 kcal mol^{-1}; Verma and Doraiswamy:[19] 50.71/19=2.7; Franklin:[20] 42.28/20=2.1; ABW:[3] 82.8/23=3.6; ABWY: 21.06/27=0.8, where the numerator and the denominator are the sum of errors and the degree of freedom defined above respectively. In conclusion, the ABWY method may exceed the existing methods in accuracy or in the reliability of the estimated values.

Every effort should be made to improve further the reliability of the estimated values; one of such effort may be the experimental determination of the properties of the *key* compounds which contain contributions with poor quality in Table A2 through A6. The endeavors of thermochemists are particularly waited for.

Soundness of the Empirical Rules and Formulations. As has been mentioned earlier, it has been empirically guaranteed that the additivity rule holds for the estimation of the thermodynamic properties of organic compounds in the ideal gas state. Therefore, the soundness of the method may be criticized for its way of incorporating a variety of neighboring effects, especially the global effect. In the present method, the geminal effects includes even the multiple-substitution contributions between different halogen atoms, and the type-number corrections are also incorporated as one of the vicinal effects. The contributions of functional groups to aromatic rings are, as a global effect, discriminated from those to non-aromatic fragments.

The *symmetry number* has been taken into account in the Benson method in order to estimate the values of entropy. In our method, the symmetry number due to the three-dimensional geometry of compounds seems to be implicitly incorporated by adopting the secondary methyl substitution, discriminated from the primary one, which produces the propane skeleton with a higher symmetry number from the ethane skeleton. As for the case of more complicated compounds, the rather small correction due to the symmetry or the existence of optical isomers may be negligible as com-

			C_p°			
			e[d]		σ[e]

compounds having a unique contribution. d) Average kcal mol^{-1} for H, and percentage error for S and C_p.

pared with the inevitable errors generally associated with the empirical methods.

Variety of Estimable Compounds. The variety of estimable compounds can be judged by the kinds of fundamental, type-number, and multiple-substitution correction contributions and the combinations of them; the present method exceeds others in this respect, because more recent data have been adopted in this method.

The concepts of both the type number and the multiple substitution have been implicitly incorporated in the Benson method. For example, altogether four kinds of carbon atoms are given in the contribution of bromine, although six kinds are logically necessary to process every variety of bromide derivative of paraffinic compounds. The kind of contribution in their method should, however, be surprisingly increased in order to cover mixed halides such as –CFClBr and haloolefins like $=CBr_2$ in contrast to the limited kinds of contributions in the present method. It may be additionally remarked that no compound consisting of one carbon such as CFClBrI can, by definition, be treated with the Benson method.

It should be mentioned, however, that hydrogen is not a functional group in the present method, so HCOOH is not derived from =COOH or HCOO–. Also, compounds that are composed only of functional groups can not be treated; thus, for example, the estimation of oxalic acid, HOOC–COOH, by the ABWY method gives an enthalpy of -193.5 kcal mol^{-1} as compared with the observed value of -174.86.[11] The compounds which are otherwise not processed are listed in Table A8 for convenience.

In conclusion, the ABWY method may be evaluated as having a higher potentiality for estimating a much wider variety of compounds than the existing methods.

Applicability for Computation with the Aid of Computers. As was described in the opening paragraphs, the present method has been already implemented in computer programs including the whole logic. The symmetry number, a stereochemical concept, cannot be determined without the knowledge of the whole geometry of a compound, while the geometry can be estimated with only highly sophisticated computer programs such as a program, STERIC,[5] also prepared by the present author. A logic which requires no symmetry number for estimation may be rated higher for implementation into computer programs.

The author's thanks are due to Dr. Makoto Misono for his helpful discussions. A part of the research expenses was defrayed from the Grant-in-Aid for a Special Project Research, "Chemical Research in the Development and Utilization of Nitrogen-Organic Resources," of the Ministry of Education, Science, and Culture. The clerical work of Miss Masako Oya and the technical aid of Mr. Kiyoshi Arai are highly appreciated.

Appendix

Tables of Contribution Values for the Thermodynamic Properties of Organic Compounds in the Ideal Gas State, A1 through A8. Unit of standard enthalpy of formation(H) in kcal mol^{-1}; unit of standard entropy(S) and three coefficients of molar heat (a, b, and c) in cal mol^{-1} K^{-1}. 1 cal=4.184 J. The abbreviations for the contribution values of the functional groups are: Δ_f: fundamental; Δ_t: type-number correction; Δ_m: multiple substitution correction; @: aromatic ring directly connected; %: direction of extending chain in which the type number may be counted. 'Single data source' in the footnotes implies that the contribution value was derived only from a compound (or a pair of compounds for the contribution of functional groups having type-number correction).

The molar heats can be calculated from three coefficients at 273 through 1000 K.

Table A1. Thermodynamic properties of base groups in ideal gas state

Line	Base group	$\Delta H^\circ_{f,298.15}$	$S^\circ_{298.15}$	a	b	c
1	Methane	−17.89 (1)	44.50 (1)	3.99 (1)	15.68	−2.38

Electrical Properties of a One-dimensional Conductor, $Na_xV_2O_5$

Hayao KOBAYASHI

Department of Chemistry, Faculty of Science, Toho University, Chiba 274

(Received October 9, 1978)

The resistivity measurement, DTA analysis, refinement of the crystal structure, and examination of the X-ray diffuse scattering have been carried out on the β-phase of the sodium vanadium bronze. A resistivity minimum was observed around 200 K. The peak position of the logarithmic derivative of the resistance and an anomaly in the DTA curvature indicate that a metal-insulator transition occurs at about 130 K. The X-ray diffuse scattering shows a tendency of the sodium atoms toward cluster formation. It is concluded that the β-phase of sodium vanadium bronze is neither a simple one-dimensional metal nor a simple semiconductor, but can behave partly as a one-dimensional metal and partly as an anisotropic semiconductor.

Since the 1960's many investigations have been undertaken by solid state chemists in the field of vanadium oxide bronzes ($M_xV_2O_5$; M=Li, Na, K, Cu, ···). It was at first commonly accepted that the materials lie near the critical donor concentration range required in the Mott theory for semiconductor-metal transitions and that the metal-metal spacing is approximately equal to the critical distance predicted by Goodenough for electron delocalization *via* d-orbital overlap.[1] The early works seemed to established that the charge transfer in vanadium bronzes is realized *via* the auto-localized electrons (polarons).[2,3] However, it has recently suggested that the β-phase vanadium bronzes should be considered as quasi-one-dimensional conductors.[4] Evidence for this view comes from (1) conductivity measurements which show that the anisotropy ($\sigma_{\parallel}/\sigma_{\perp}$) is 130 at room temperature ($\sigma_{\parallel(\perp)}$ is the conductivity parallel (perpendicular) to the b axis) and rises as high as 400 at 125 K;[4] (2) ESR measurements where the lineshape is asymmetric when the electric-field vector is parallel to the b axis, but Lorentzian for $E \perp b$,[5] and (3) optical reflectivity measurements which give a metallic plasma edge with light polarized along the b axis, but a featureless behaviour for perpendicular polarization.[6] In addition, recent investigation by Gunning *et al.*,[7] has shown that the dielectric constant is highly anisotropic and very large parallel to the b axis. This new view appears to conflict with the localization picture of the electron-conduction mechanism.

In this paper, we wish to present the results on our electrical conductivity, DTA measurements, structure refinement, and examination of the X-ray diffuse scatterings of the β-phase of the sodium vanadium bronze (β-NaVB).

Experimental

Preparation of Samples. The samples of the sodium vanadium bronze were prepared in a quartz boat. A 6 : 1 mixture of V_2O_5 and Na_2CO_3 or a 1 : 1 mixture of $NaVO_3$ and V_2O_5 was heated for 17 h at 700 °C in an air atomosphere and then cooled at a rate of 6 °C/h.[1,8] The black needle-shaped crystals were pried out of the quartz boat. Examination by X-ray diffraction revealed that the crystals are monoclinic with the Wadsley β-type structure.[8]

Refinement and Brief Description of the Crystal Structure. The crystal structure of β-NaVB was determined in the 1950's by Wadsley[8] and by Ozerov *et al.*[9] Considering the fundamental significance of the Wadsley β-structure[2] and the relatively large R index (the R indices for $h0l$ and $0kl$ are 0.17 and 0.13 respectively[8]), the crystal structure refinement would be desirable. Since our measurements were made before the publication of the works of Wallis *et al*[4] and [Kaplan and Zylbersztejn,[6] which have first suggested a "one-dimensional metallic character" of this compound, our observation seemed to be inconsistent with the semiconducting behavior previously accepted. At first sight, this discrepancy appears to be attributable to a slight change in the crystalline state, one which might be introduced in the stage of the sample preparation, because our samples were prepared in quartz boats, whereas the other authers used platinum boats or platinum dishes. The purpose of the structure refinement was partly to examine this possibility.

The lattice constants were determined using a computer-controlled four-circle diffractometer. The crystal data are: monoclinic, space group C2/m,[10] $a=16.435(16)$ Å, $b=3.612(1)$, $c=10.086(10)$, $\beta=109.61(15)°$, $D_x=3.55$ gcm^{-3}, $Z=6$ ($Na_xV_2O_5$; $x=0.287$ (see Appendix)).

Some details of the structure refinements, the atomic coordinates, and the bond lengths and angles around the vanadium atoms are given in Appendix. There is no serious difference between the newly refined structure and the previously determined one.

The crystal structure is shown in Fig. 1. The unit cell contains three crystallographycally independent vanadium sites. As was pointed out by Wadsley,[8] the coordination of vanadium is of two kinds. V(1) and V(2) are each linked to six oxygens disposed at the corners of strongly distorted octahedra. The octahedra are associated in pairs, with a shared edge which unites with similar pairs above and below to form a zigzag ribbon extending along the b axis (Fig. 2a). On the other hand, V(3) has five bonds to oxygen to form trigonal bipyramids, which are associated in pairs to form a double chain by each having an edge in common with each V(3) neighbour (Fig. 2b). The short distance between the vanadium ions (Figs. 1 and 2) appears to allow the formation of delocalized states arranged in linear chains along the b axis.[5] The sodium atoms lie at random in two rows in the tunnels formed by the vanadium and oxygen atoms as a whole (Fig. 3). The distance between two sodium sites is only 1.95 Å. With an increase in the sodium content ($Na_xV_2O_5$; $0.2<x<0.33$), the sodium sites are gradually filled; the occupancy probability is 50% if $x=1/3$. Because of the Coulomb interaction, sodium ions will tend to be arrayed regularly. In fact, a tendency for the regular arrangement of sodium atoms has been revealed by the examination of oscillation photographs, which will be described later.

Resistivity Measurements. The d.c. electrical resistivities were measured over the temperature range of 78 K—

600 K for several specimens along the needle axis (the b axis) of the crystals using a four-probe method. The crystals were washed with aqueous NH_3. Gold wires 0.025 mm in diameter were bonded to the crystals by silver conducting paint (Shoei 4895). Then the crystals were annealed for about 30 min at about 300 °C. The sample dimensions and probe separations were measured with a microscope. Because of the uncertainty in determining the exact probe separation and sample dimensions, the estimated error in the resistivities is about 50%. The results are shown in Figs. 4 and 5. The room-temperature resistivityis $6.0\pm 3.0\times 10^{-3}\,\Omega$ cm. The logarithmic derivative of the resistance, $-(\mathrm{d}\ln R/\mathrm{d}T)$, *versus* the temperature is also shown in Fig. 4. In a one-dimensional conductor, a metal-insulator (M-I) transition temperature is defined by the peak posotion of $-(\mathrm{d}\ln R/\mathrm{d}T)$ *versus* T.[11,12] The inset of Fig. 4 shows a peak around 130 K.

DTA Experiments. A quasi-one-dimensional conductor exhibits a specific heat anomaly in the temperature range around the M-I transition temperature.[13,14] Judging from the anisotropy of the electric conductivity and the optical reflectivity, the peak of the $\mathrm{d}\ln R/\mathrm{d}T$ *vs.* T curveture around 130 K (Fig. 4) can be considered to be an indication of the occurrence of a M-I transition. The DTA measurements were made to obtain further evidence.

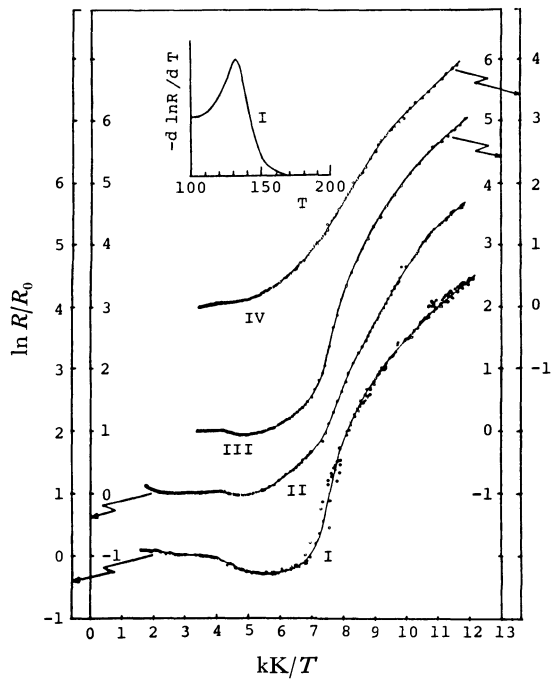

Fig. 4. Logarithm of normalized resistivity *versus* inverse temperature. The inset shows $-(\mathrm{d}\ln R/\mathrm{d}T)$ *versus* T. Curvetures I—IV indicate the resistivities of four different samples.

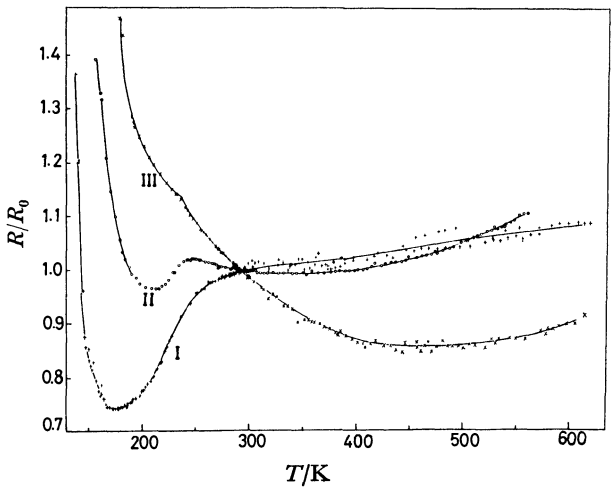

Fig. 5. The temperature dependence of the normalized resistivity. Curvetures I, II, and III show the resistivities of the samples I, II, and IV in Fig. 4, respectively.

The crystals of β-NaVB were ground in a glass mortar and mixed thoroughly with an approximate amount of powdered almina. A copper-Constantan thermocouple was embedded in a quantity of the mixed powder placed in a hole (50 mm × 6 mmϕ) in a cylindrical copper block. The reference thermocouple and the thermocouple used for temperature measurements were in the other two holes, packed with powdered almina. The DTA measurements were made by warming or cooling the copper block. The rate of temperature change was controlled by raising or lowering a liquid-nitrogen vessel with respect to the copper block. Since a small anomaly was observed in the first run, the measurements were repeated eight times to confirm it. On the repeated runs, however,

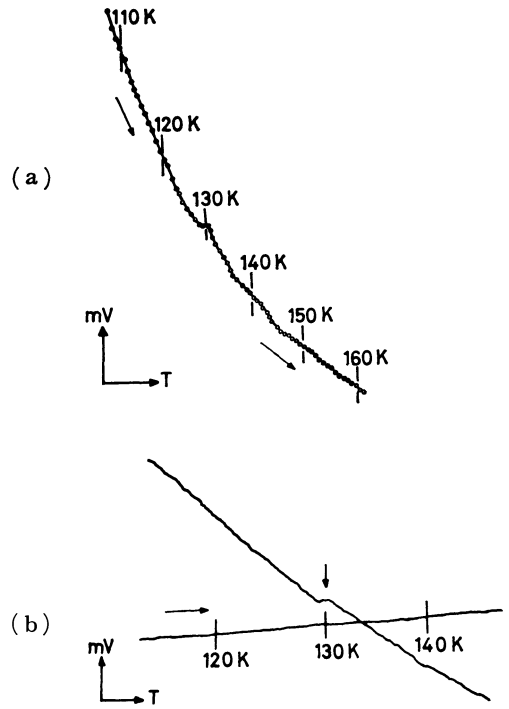

Fig. 6. (a) Averaged thermogram obtained from eight warming curves. (b) An example of the warming curves.

only the warming cycles were examined because of the facility of the temperature control. The voltage readings of the eight thermograms were then added. The dependence on the temperature is shown in Fig. 6a. An anomaly was observed at about 130 K. The measurements were repeated on another sample in order to confirm the reproducibility of the anomaly (Fig. 6b). The heat of transition was roughly estimated to be 10—20 cal/mol by reference to the thermograms of NH_4Cl(T_c=242.8 K, 0.20 kcal/mol) and $NH_4H_2PO_4$ (T_c=148 K, 0.15 kcal/mol).

X-Ray Diffuse Scatterings. X-Ray diffuse scatterings associated with the one-dimensional charge-density waves are among the most direct indications of the metallic state of a system. Besides this, another type of X-ray diffuse scattering can also be expected in β-NaVB. Although crystal-structure analysis shows that the sodium atoms are randomly distributed in two rows in the tunnels, a short-range order among the sodium atoms, which gives rise to X-ray diffuse scatterings, also exists.

Oscillation photographs around the b axis were taken at room temperature using Ni-filtered Cu $K\alpha$ radiation. The exposure times were about 100 h. An example of the photographs is shown in Fig. 7. Weak and broad scatterings are observed between strong layer lines. The existence of the diffuse scatterings was confirmed by comparing the photograph with one taken without mounting a crystal on a glass capillary.

The X-ray diffuse scattering associated with a one-dimensional distortion or a Kohn anomaly generally consists of diffuse, narrow streaks[15] and is inconsistent with the breadth of the observed diffuse scattering. The diffuse scatterings in the middle of the sharp layer lines indicates a tendency of the doubling of the lattice spacing along the b axis. Wadsley has suggested that sodium atoms in a tunnel alternately occupy one of the two possible sites to form a staggered string.[8] If this suggestion were true, the lattice spacing would be doubled along the b axis. Actually, the mode of

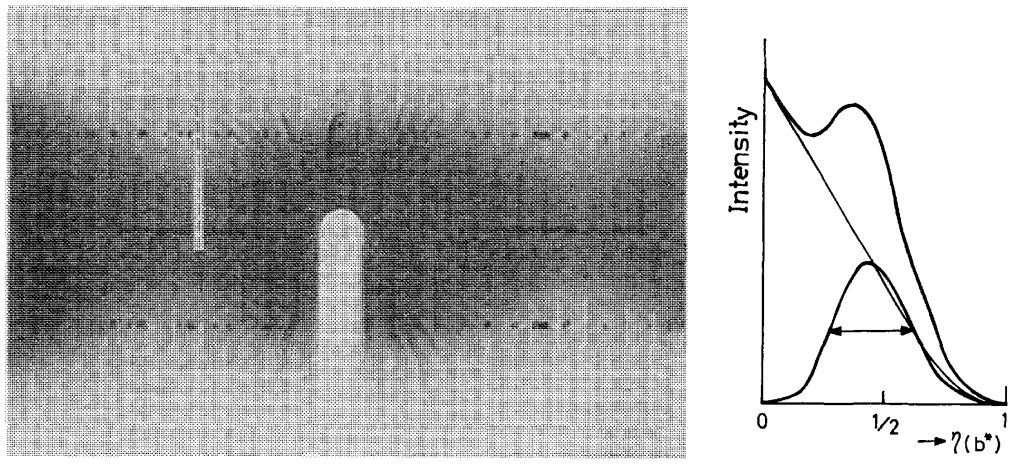

Fig. 7. Oscillation photograph around the **b** axis and the scattering intensity along the dashed line.

the arrangement of sodium atoms is even more complicated because of the nonstoichiometry of the sodium content. The staggered strings may be interrupted. Consequently, the diffuse scatterings may be attributable to existence of "imperfect staggered strings." The constant scattering intensity along the direction perpendicular to ***b*** implies that the correlation between sodium atoms belonging to different tunnels is weak. If the "correlation length ξ" can be estimated by $\xi \approx 2/\Gamma$[16] (Γ is the full width at a half maximum of the diffuse scatterings), it is of the order of 20 Å for the b direction (the width of the "diffuse belt" is about 0.35 b*).

Discussion

The room-temperature conductivity of 200 ± 100 $(\Omega\,\mathrm{cm})^{-1}$ agrees with those values reported by Sienko and Sohn (230 $(\Omega\,\mathrm{cm})^{-1}$)[17] and Wallis, Sol, and Zylbersztejn ($110(\Omega\,\mathrm{cm})^{-1}$);[4] it is also of the same order as that of the well-known one-dimensional metal $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ (≈ 500 $(\Omega\,\mathrm{cm})^{-1}$).[18] In addition, it is compatible with the optical conductivity along the b axis (250 $(\Omega\,\mathrm{cm})^{-1}$) as calculated from $\sigma_{opt}=\omega_p{}^2\tau/4\pi$ using the plasma frequency ($\omega_p=1.44\times10^{15}\,\mathrm{s}^{-1}$) and the electronic relaxation time ($\tau=1.35\times10^{-15}$ s) reported by Kaplan and Zylbersztejn.[6] Needless to say, this agreement does not necessarily support a "simplified one-dimensional metal picture" of this compound. Some crystals show small, but distinct, resistivity minima around 200 K, and the other crystals give an indication of resistivity minima by means of their concave curvatures (Figs. 4 and 5). This is the first observation of the resistivity minimum. However, similar resistivity-*vs.*-temperature behaviour can also be found in papers previousely reported: (1) $\log\sigma$ plotted against $1/T$ of Wallis *et al.*[4] shows a distinct concave curve upwards around 180 K, implying a latent conductivity maximum. (2) Despite the small number of the datum points, a deviation from the smooth curve of resistivity *versus* the inverse temperature around 200 K can be found reported in the paper of Sienko and Sohn.[17]

The existence of the relatively sharp minimum (Fig. 5) shows the non-semiconductive character of the compound. When the resistivity minimum is sharp, the logarithmic derivative of the resistance *versus* temperature gives a well-defined peak at about

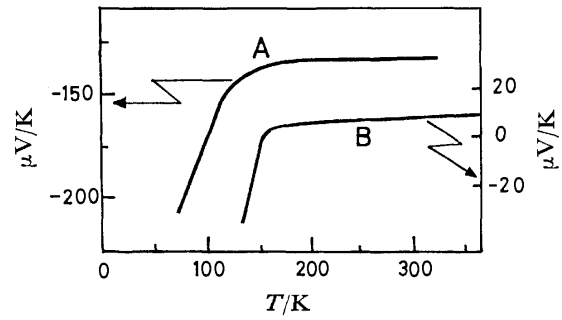

Fig. 8. Seebeck coefficient *versus* temperature of β-NaVB (A) (Ref. 1) and that of one-dimensional conductor, $(TTF)_{12}(SCN)_7$ around its M-I transition temperature ($T_c=169$ K) (B) (Ref. 12).

130 K, which suggests that the phase transition observed by DTA measurements is a M-I transition. The ratio of the low-temperature activation energy to the M-I transition temperature, Δ/T_c. is approximately constant in one-dimenstional systems ($\Delta/T_c=5\pm1$). Wallis *et al*[4] reported that the conductivity shows a simple activated behaviour between 80 K and 125 K, the activation energy being 61 m eV (=708 K). The Δ/T_c ratio is 5.5. Some observations indicating a phase transition can also be seen in the literature: (1) The Seebeck coefficient is almost constant when $T>150$ K and decreases abruptly when $T<110$ K: that is, the temperature dependence changes around $T_c(\approx130\,\mathrm{K})$ (Fig. 8).[1] (2) The susceptibility follows a Curie-Weiss law from 150 K to 450 K, but its temperature dependence becomes more complicated when $T<T_c$.[19] (3) The anisotropy of the conductivity reaches a maximum ($\sigma_\parallel/\sigma_\perp\approx400$) at 125 K ($\approx T_c$).

Thus, the occurrence of the M-I transition appears to be confirmed. On the other hand, on the basis of an examination of the temperature dependence and the anisotropy of electric conductivity, Wallis *et al.* have shown that a variable-range hopping model is applicable at low temperatures ($T<80$ K) and have proposed an interrupted strand model.[4] ESR study by Friederich *et al.* has suggested that the sodium ions are clustered rather than being distributed randomly among

possible sites in the tunnel structure, and that a crystal is separated into regions where the electron concentration is fixed at the value corresponding to $x=1/3$.[19] This picture provides a basis for the interrupted strand model of the electronic-transport mechanism. As has been described above, the observation of diffuse X-ray scattering gives more direct evidence for the "cluster formation" of sodium atoms.

Thus, β-NaVB can be regarded as neither a simple metal nor a simple semiconductor; rather, it has the following two aspects: (1) a one-dimensional metallic character originating from the delocalization states arranged in a linear chain along the b axis,[5] and (2) a semiconductive nature due to the localization of the electron.

On the basis of this information, the temperature variation in Seebeck coefficient will now be interpreted. The room-temperature Seebeck coefficient of $M_xV_2O_5$ (M=Na, Cu, Ag; $0.2<x<0.6$) has been explained by Goodenough in terms of a small polaron formula.[2] Since a Seebeck coefficient, α, is generally small in a metallic state, the large room-temperature value of 135 μV/K (Fig. 8)[1] appears to be inconsistent with the observation of matallic behaviour around room temperature. However, if α includes the sum of α_A (the contribution from the "metallic part"), and α_B (the contribution from the "semiconductive part"), the large room-temperature value can be attributed to α_B. When a one-dimensional metal undergoes a M-I transition, the magnitude of the Seebeck coefficient (α_A) increases abruptly (Fig. 8).[12,20] Thus, the temperature variation of α can be explained.

Figure 9 shows a typical example of the resistivity behaviour of a one-dimensional metal around the M-I transition temperature (A) and that of a variable-range hopping mechanism in a disordered semiconducting system (B).[4,21] The sample dependence of the resistivity (Fig. 5) can be interpreted by the superposition of A and B, if the contribution of A (R_A) and B(R_B) to the resistivity vary from sample to sample ($R=R_A+R_B$). Below the M-I transition temperature, R_A increases exponentially with a decrease in the temperature. Therefore, the magnitude of the resistivity can be mainly determined by the variable-range hopping process ($R\approx R_B$). In fact, Wallis *et al.* have pointed out that the activation energy decreases smoothly below 80 K. On the other hand, at high temperatures R is approximately equal to R_A and the "metallic conductivity" may be observed.

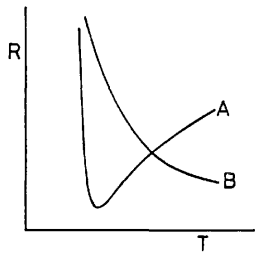

Fig. 9. Schematic illustration of the resistivity *versus* temkerature curve of a one-dimensional metal around the M-I transition temperature (A) and that by one-dimensional variable range hopping conduction (B).

It is well-known that small amounts of disorder and defects in a crystal have a great influence on the electrical conductivity and frequently smear out the M-I transition.[12,22] Kapuskin *et al.* have reported that the lattice parameters of $M_xV_2O_5$ (M=Li, Na, K) are changed slightly by the evolution of oxygen on heating to 730—780 K.[23] Although no more than 0.7 atoms of oxygen are evolved from one elementary cell of bronze, a drastic change in electronic properties is produced. As has been mentioned before, the crystals of β-NaVB were prepared at about 700 °C and then cooled at a rate of 6 °C/h. Since the reaction temperature is higher than 730—780 K, it may be possible that a slight modification is made in the crystalline state, which then gives rise to a sample dependence of the electrical resistivity.

In conclusion, β-NaVB appears to be a non-stoichiometric compound which can behave partly as a one-dimensional metal and partly as an anisotropic semiconductor. The chain-like structure of vanadium and oxygen atoms and a tendency towards the formation of disordered strings of sodium atoms accomondated in the tunnels provide a structural background for this picture of the compound.

Appendix

Refinement of the Crystal Structure. The intensity data were collected with a Rigaku automated four-circle diffractometer using Mo $K\alpha$ radiation. There are 1180 independent reflections ($|F_o|>3\sigma(|F_o|)$) up to $2\theta\leqq 70°$. The systematic abscences indicate the space group to be C2/m, Cm, or C2. The $N(z)$ test and the statistical intensity distribution of $|E|(hkl)$ favoured the centrosymmetrical group; the space group was, therefore, assumed to be C2/m.[10] The atomic parameters and the occupancy probability of the sodium site were refined by a full-matrix least-squares method. The final R-factor is 0.038. The occupancy probability becomes 43% ($Na_xV_2O_5$; $x=0.287$) for the crystal subjected to this structure refinement. The positional and thermal parameters are given in Table 1. The structure

Solubilities and Rates of Dissolution of Diaspore in NaOH Aqueous Solutions

Byong-Tae CHANG,* Li-Hye PAK, and Yu-Suk LI
Department of Chemistry, Korea University, Kodaira, Tokyo 187

(Received October 13, 1978)

The solubility of diaspore(α-$Al_2O_3 \cdot H_2O$ or α-AlOOH) has been measured in NaOH aqueous solutions from 523.15 K to 598.15 K, and at concentrations of Na_2O up to 150.7 g/l. In order to evaluate the equilibrium constant, $K_2^\circ = (a_{AlO_2^-} \cdot a_{H_2O})/a_{OH^-}$, for the dissolution equilibrium of diaspore $AlOOH(s) + OH^-(l) = AlO_2(l) + H_2O(l)$, two methods have been applied to the solubility data. In the first method, analogous to the method previously applied to the dissolution equilibria of gibbsite, bayerite and beohmite, the values of K_2 at relatively low concentrations of NaOH were extrapolated to zero NaOH concentrations. The temperature dependence of K_2° was expressed as $\log K_2^\circ = -(2500/T) + 4.45$. The second method was based on the extended Debye-Hückel theory for the variation in the activity coefficients of AlO_2^-, OH^-, and H^+ ions with ionic strength at any temperature, that is, the value of the solubility product, $K_1^\circ = a_{H^+} \cdot a_{AlO_2^-}$, was obtained at a given temperature by extrapolating values of K_1, equal to $(m_{H^+} m_{AlO_2^-})$, to zero ionic strength. According to the second method, K_2° was expressed as a function of the temperature: $\log K_2^\circ = -(1600/T) + 2.52$ when $A = 2.0$ or $\log K_2^\circ = -(1550/T) + 2.48$ when $A = 1.5$, where A is a parameter. From kinetic analysis of the dissolution rate of diaspore in NaOH solution, the rate constants per unit surface area of diaspore were found to be 0.31, 0.45, and 0.68 $m^{-2}\,h^{-1}$ at 548.15, 573.15, and 598.15 K, respectively.

The dissolution of alumina hydrates in aqueous NaOH solutions is well known, and serves as a key step in the extractive metallurgy of aluminium (the Bayer process). The solubilities of alumina hydrates in NaOH solutions have been measured by Russell, Edward and Taylor.[1] The solubilities of gibbsite, bayerite and boehmite in NaOH solutions from 313.15 K to 473.15 K were reported, and equilibrium constants for the reaction in which alumina hydrates react with OH^- ion to form AlO_2^- ion were presented. The solubility of gibbsite was precisely determined in order to calculate the free energy of formation and to clarify the structures of the aluminate ions in solution at high pH.[2-5] Bernshtein and Matsenok reported the solubilities of boehmite[6] and diaspore[7] at high temperatures between 532.15 and 573.15 K. The data on the solubilities of diaspore, however, appear to be insufficient for discussion of the thermodynamic properties of diaspore in NaOH solutions.

The purpose of this work is to determine the solubilities of diaspore in NaOH solutions and to clarify the thermodynamic and kinetic properties of the dissolution process.

Experimental

Diaspore samples were prepared by the hydrothermal treatment of boehmite in 0.5 M NaOH solution, to which 10 wt % of natural diaspore was added as seed crystals (623 K, 170 atm for two weeks).[8,9] In order to increase the purity of the diaspore samples, the hydrothermal treatment was repeated several times, using the synthesized diaspore as seed crystals. The results of chemical analysis of the samples are listed in Table 1. X-Ray diffraction analysis showed the presence of only diaspore. Furthermore, DTA analysis indicated an endothermic peak from 623 K to 873 K, corresponding to the transformation of diaspore into α-alumina. The above results confirmed the purity of the diaspore to be higher than 99%.

Measurements of the solubility of diaspore were as follows: a sample (0.40 g) and NaOH solution (5 ml) were laid in a Morey-type reactor which was made of Hastelloy with Ag packing. Heat was supplied and the temperature was kept constant in an electric furnace for the attainment of equilibrium. Quenching to room temperature, treatment with hot hydrochloric acid removed the aluminium hydroxide precipitated. Experimentally it was confirmed that the amounts of diaspore dissolved in the hot HCl solution were negligible. The concentrations of alumina dissolved in the NaOH solution, $m_{AlO_2^-}$, were calculated from the differences in the weights of the diaspore before and after dissolution. The concentrations of the OH^- ion at equilibrium, m_{OH^-}, were calculated from the differences between the initial concentration of NaOH, $(m_{OH^-})_0$, and that of $m_{AlO_2^-}$, *i.e.*, $m_{OH^-} = (m_{OH^-})_0 - m_{AlO_2^-}$.

Results and Discussion

Solubility of Diaspore. In Table 2 are shown the results of solubility measurements for diaspore (No. 1) in NaOH solution up to 4.83 M from 523.15 K to 598.15 K. The dissolution process for diaspore in NaOH solution may be expressed as follows;

$$Al_2O_3 \cdot H_2O(s) + 2OH^-(1) = 2AlO_2^-(1) + 2H_2O(1) \quad (1)$$

or

$$AlOOH(s) + OH^-(1) = AlO_2^-(1) + H_2O(1). \quad (2)$$

The equivalent ratio of the AlO_2^- ion to the OH^- ion, α, may be used as a measure of the solubility of diaspore, *i.e.*, as the solubility increases, α approaches unity. As shown in Fig. 1, the values of α shifted to unity not only with increase in the dissolution temperature but also with the initial concentrations of NaOH solution. Bernshtein and Matsenok[7] also observed

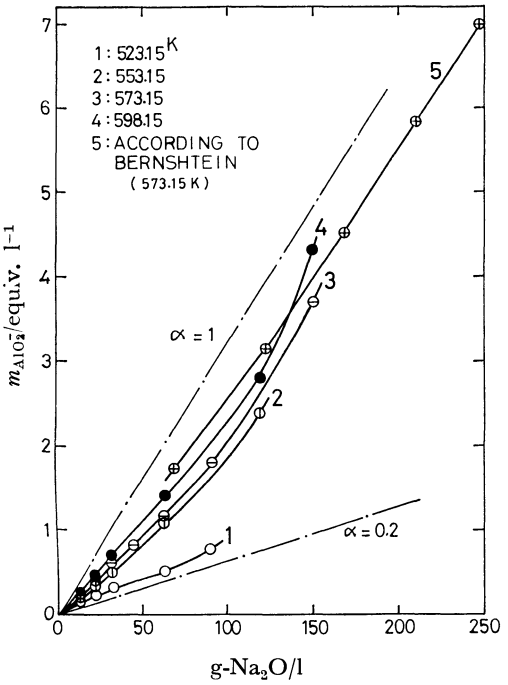

Fig. 1. Solubilities of diaspore in NaOH solutions from 523.15 K to 598.15 K.

similar results in the solubility of diaspore. The values of α for diaspore in this work, however, are lower.

In Fig. 2, the values of α for diaspore are compared with those of α-alumina for approx. equal concentrations of NaOH.[10] At 626 K the two curves intersected which agrees with the transformation temperature of diaspore into α-alumina under 100 atm in the phase diagram of Al_2O_3–H_2O system.[8,9] It is readily seen from Fig. 2 that the temperature dependancy of the solubility of diaspore was much larger

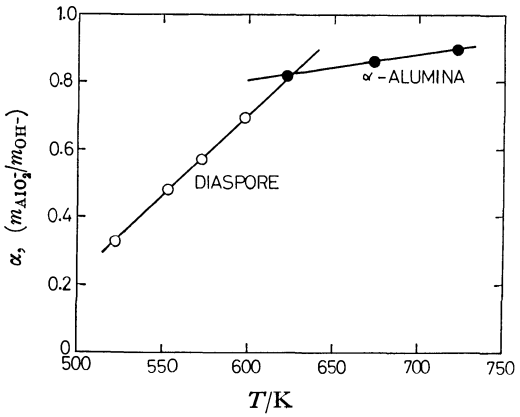

Fig. 2. Comparison of the solubilities of diaspore with those of α-alumina in about 1 M NaOH solution.

than that of α-alumina.

Equilibrium Constants of Dissolution. In order to discuss the dissolution process of diaspore, three equilibrium constants were used as follows:

$$AlOOH(s) = AlO_2^-(1) + H^+(1) \quad (3)$$

$$K_1^\circ = a_{AlO_2^-} \cdot a_{H^+} \quad (4)$$

$$AlOOH(s) + OH^-(1) = AlO_2^-(1) + H_2O(1) \quad (5)$$

$$K_2^\circ = a_{AlO_2^-} \cdot a_{H_2O}/a_{OH^-} \quad (6)$$

$$H_2O(1) = H^+(1) + OH^-(1) \quad (7)$$

$$K_w = a_{H^+} \cdot a_{OH^-}/a_{H_2O} \quad (8)$$

where

$$K_1^\circ = K_2^\circ \cdot K_w. \quad (9)$$

Russell *et al.*[1] derived equilibrium constants, K_2°, at various temperatures by extrapolating $K_2 = m_{AlO_2^-} \cdot m_{H_2O}/m_{OH^-}$ to zero NaOH concentration, assuming that the activity coefficients of the OH^- and AlO_2^- ions are equal and using values of the activity of water in NaOH solutions at 298.15 K. The values of K_2° for diaspore obtained by Russell's method are given in Table 2 and Fig. 3 where the values of K_2° have been neglected at very low NaOH concentration because of large deviations. From the linear relationship between $\log K_2^\circ$ and $1/T$, K_2° was found to be a function of the temperature by the following equation:

$$\log K_2^\circ = -2500/T + 4.45. \quad (10)$$

In Table 3 the equilibrium constants and thermodynamic quantities for the dissolution equilibrium (5) obtained from K_2°, Eq. 10 and the thermodynamic relationships are given. The solubility product of $HAlO_2$, K_1°, was found to be 1.13×10^{-13} at 573.15 K, which was approx. six times greater than at 298.15 K (2×10^{-13}).[1]

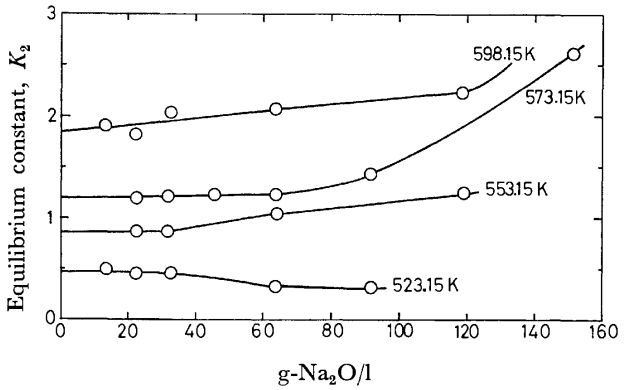

Fig. 3. Equilibrium constants (K_2) obtained by the Russel's method for the dissolution of diaspore in NaOH solutions.

Several assumptions are made in the detremination of equilibrium constants by Russell's method. Firstly, the activity coefficients of AlO_2^- and OH^- ions are assumed to be equal, neglecting the difference in ion size. Secondly, the values of a_{H_2O} at 298.15 K were used at high temperatures without any correction (up to 598.15 K). Thirdly, it is not appropriate to mix units in an equilibrium constants expression by multiplying the activity of water on the mole fraction scale together with the activities of AlO_2^- and OH^- ions on the normality scale.

As described above, generally the value of α at a given temperature becomes larger with increase in the concentration of NaOH solution. The addition of salts such as NaCl, Na_2SO_4, and $NaNO_3$ to the NaOH solution increased the solubility of the alumina hydrates.[4] In the case of diaspore, it was experimentally confirmed that the solubility in a mixed solution containing 1 M NaOH and 1 M NaCl was one and a half times larger than in 1 M NaOH solution at 573.15 K. This indicates that the increase in NaOH concentration raises the solubility of diaspore not only through an increase in the OH^- ion concentration but also through an increase in the ionic strength of the solution. Marshall *et al.* discussed the effect of ionic strength on the solubilities of $CaSO_4$ and its hydrates, and $Ca(OH)_2$ by applying the extended Debye-Hückel theory to high temperature aqueous solution sup to the critical temperature of water.[12,13]

According to Marshall's method, the solubility products are given as follows:

$$K_1^\circ = m_{H^+} \cdot m_{AlO_2^-} \cdot \gamma_{H^+} \cdot \gamma_{AlO_2^-} \quad (11)$$

$$= K_1 \cdot \gamma_\pm^2 \quad (12)$$

where

$$K_1 = m_{H^+} m_{AlO_2^-}. \quad (13)$$

According to the extended Debye-Hückel theory,

$$\log \gamma_\pm = -S_T I^{1/2}/(1 + baI^{1/2})$$
$$= -S_T I^{1/2}/(1 + AI^{1/2}) \quad (14)$$

where S_T is the limiting Debye-Hückel slope, b is a function of temperature and dielectric constant, a is an "ion size parameter," and $A = ba$. From Eqs. 12 and 14,

$$\log K_1^\circ = \log K_1 + 2S_T I^{1/2}/(1 + AI^{1/2}). \quad (15)$$

The ionic strengths, I, are equal to the initial concentrations of NaOH solution expressed as molality, *i.e.*,

Table 3. Equilibrium constants obtained by Russel's method and thermodynamic quantities for the dissolution equilibrium

T (K)	Equilibrium constants			ΔG (kJ)	ΔH (kJ)	ΔS (J/deg)
	K_1°	K_2	K_w[a]

553.15	8.70×10^{-12}	0.87	1.00×10^{-11}	0.63	47.8	85
573.15	1.13×10^{-11}	1.24	9.12×10^{-12}	−1.0	47.8	85
598.15	1.29×10^{-11}	1.82	7.08×10^{-12}	−3.0	47.8	85

a) From Ref. 11.

$$I = (m_{AlO_2^-} + m_{OH^-} + m_{Na^+})/2 \quad (16)$$

$$= (m_{NaOH})_0. \quad (17)$$

Figures 4 and 5 presnet the experimental data for the solubilities of diaspore plotted as $\log K_1$ against the Debye-Hückel function, $I^{1/2}/(1+AI^{1/2})$. The values of $A=1.5$ and 2.0 used correspond to $a=3.2$ and4.3 Å

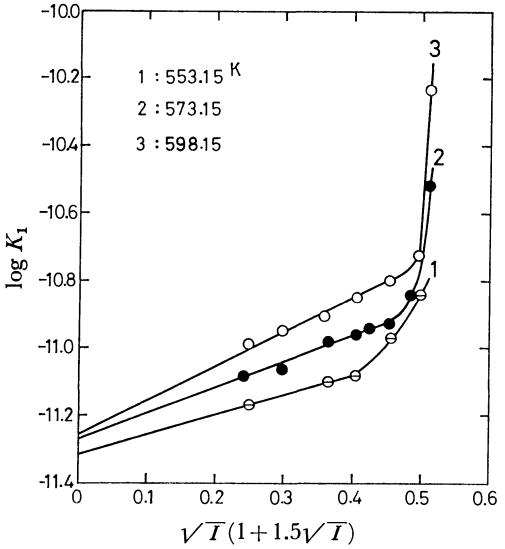

Fig. 4. Logarithm of solubility products (K_1) of diaspore in NaOH solutions *vs.* $I^{1/2}/(1+1.5I^{1/2})$.

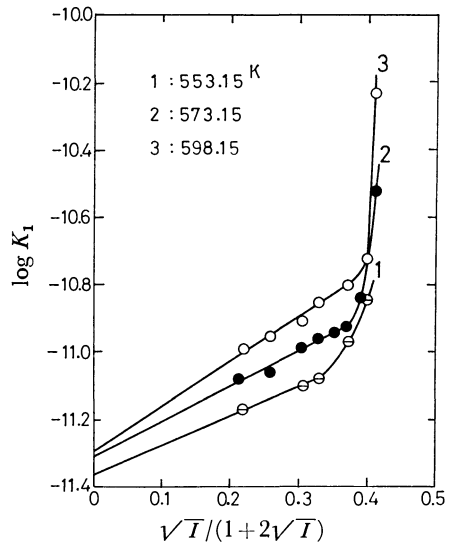

Fig. 5. Logarithm of solubility products(K_1) of diaspore in NaOH solutions *vs.* $I^{1/2}/(1+2I^{1/2})$.

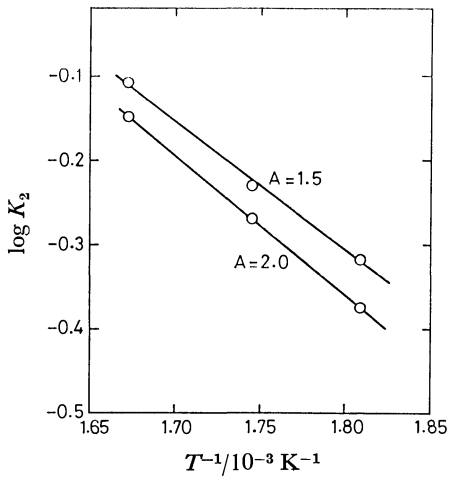

Fig. 6. Temperature dependencies of equilibrium constant K_2 obtained by the Marshall's method.

at 573.15 K, respectively. In the range of relatively low ionic strengths $\log K_1$ changed linearly with the Debye-Hückel function at three temperatures except 523.15 K. The slopes correspond to $2S_T$ in Eq. 15 with the extrapolated values at zero ionic strength corresponding to $\log K_1^\circ$. Figure 6 shows an almost linear relationship between $\log K_2^\circ$ and $1/T$, *i.e.*,

$$\log K_2^\circ = -1550/T + 2.48 \quad (A=1.5) \quad (18)$$

$$\log K_2^\circ = -1600/T + 2.52 \quad (A=2.0). \quad (19)$$

In Table 4 the equilibrium constants and the thermodynamic quantities are listed for Reaction 5 which have been calculated using Eqs. 18 and 19, and thermodynamic relationships. The magnitudes of K_2° were smaller than those obtained by Russell's method. Although the values of S_T were about half the calculated values according to the Debye-Hückel theory, the values of K_2° obtained by Marshall's method may be more reasonable due to the improved extrapolation. As shown in Figs. 4 and 5, $\log K_1^\circ$ deviated from linearity largely at high ionic strength, which may be a direct consequence of ion-solvent interactions[14] and/or the formation of a new solid phase(s) such as $Na_2O \cdot Al_2O_3 \cdot 2.5H_2O$, $3Na_2O \cdot Al_2O_3 \cdot 6H_2O$, *etc.*[15]

Rate of Dissolution of Diaspore. In Fig. 7, the amounts of dissolved diaspore (No. 2) have been plotted as $m_{AlO_2^-}$ against reaction time, t, at three temperatures (548.15, 573.15, and 598.15 K) with a constant initial NaOH concentration of 0.970 M. The times required for the dissolution equilibrium to be

	573.15	4.9×10^{-12}	0.54	9.12×10^{-12}	2.9	30.6	48	0.52
	598.15	5.0×10^{-12}	0.71	7.08×10^{-12}	1.7	30.6	48	0.67

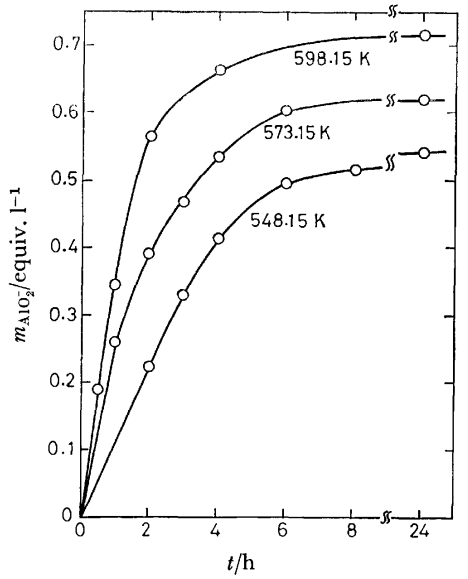

Fig. 7. Dissolution curves of diaspore in 0.970 M NaOH solution at three temperatures.

attained were 40 h(548.15 K), and 24 h(573.15 and 598.15 K). The diaspore sample of No. 2 had a special surface area of 3.40 m^2/g(BET).

Assuming that the chemical reaction of AlOOH with OH^- ions on the surface of the diaspore is the rate-determining step, the rate of dissolution may be expressed as follows:

$$d(m_{AlO_2^-}/m_{OH^-})/dt = kS[(m_{AlO_2^-}/m_{OH^-})_e - (m_{AlO_2^-}/m_{OH^-})] \quad (20)$$

where k is the rate constant per unit of surface area of the sample, S is the total surface area of undissolved diaspore at time t and $(m_{AlO_2^-}/m_{OH^-})$ is the concentration ratio of AlO_2^- to OH^- ions at equilibrium.

In terms of a new variable, x, Eq. 20 becomes

$$dx/dt = kS(x_e - x) \quad (21)$$

where

$$x = m_{AlO_2^-}/m_{OH^-}. \quad (22)$$

From the experimental data, x_e equals 0.59 at 548.15 K, 0.64 at 573.15 K, and 0.74 at 598.15 K, respectively.

The value of S is also a function of x. Introducing the mean size of the diaspore particles, r, S, and the weight of the undissolved diaspore, W, may be expressed as follows:

$$S(r) = a_1 r^2 \quad (23)$$

$$W(r) = a_2 r^3 \quad (24)$$

$$S(r)/S(r_0) = (r/r_0) = [W(r)/W(r_0)]^{2/3} \quad (25)$$

where a_1 and a_2 are proportionality constants and r_0 is the initial mean size. From the mass balance for the diaspore sample,

$$W(r_0) - W(r) = (m_{AlO_2^-} \cdot G \cdot V)/1000. \quad (26)$$

In this equation, G is the gram equivalent of diaspore equal to 60 and V is the volume of the solution. Substituting V=5 ml and G=60,

$$W(r_0) - W(r) = 0.030 m_{AlO_2^-}. \quad (27)$$

Furthermore, since $W(r_0)$=0.40 g and (m_{OH^-})=0.970 M, S may be expressed as a function of x as follows:

$$S(x)/S_0 = [(1+0.27x)/(1+x)]^{2/3} \quad (28)$$

where S_0 is the initial total surface area and equal to 1.36 m^2 when $W(r_0)$=0.40 g. Substituting Eq. 28 into Eq. 20:

$$dx/dt = kS_0[(1+0.27x)/(1+x)]^{2/3}(x_e - x). \quad (29)$$

This differencial equation may be solved as follows:

$$[f(1) - f(y)]/(BS_0) = kt \quad (30)$$

where

$$y = [(1+0.27x)/(1+x)]^{1/3} \quad (31)$$

$$f(y) = n^2\left[\ln(y-m) - \frac{1}{2}\ln(y^2+my+m^2) + 3^{1/2}\tan^{-1}\left(\frac{2y+m}{\sqrt{3}}\right)\right] - m^2\left[\ln(y-n) - \frac{1}{2}\ln(y^2+ny+n^2) + 3^{1/2}\tan^{-1}\left(\frac{2y+n}{\sqrt{3}}\right)\right] \quad (32)$$

$$B = 1.38m^2n^2(m^3-n^2)(1+x_e) \quad (33)$$

$$m = [(1+0.27x_e)/(1+x_e)]^{1/3} \quad (34)$$

$$n = (0.27)^{1/3} = 0.65. \quad (35)$$

Figure 8 shows the linear relationship between t and $[f(1)-f(y)]/(BS_0)$. From the slopes of the straight lines, the values of k were obtained as follows:

$$k = 0.31 \text{ m}^{-2}\cdot\text{h}^{-1} \quad (548.15 \text{ K}) \quad (36)$$

$$= 0.45 \quad (573.15 \text{ K}) \quad (37)$$

$$= 0.68. \quad (598.15 \text{ K}). \quad (38)$$

From the Arrhenius plot between $\log k$ and $(1/T)$, the activation energy for the dissolution of diaspore in NaOH solution was found to be 44 kJ.

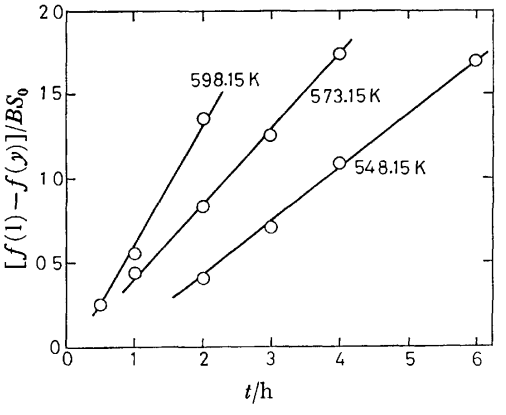

Fig. 8. $f(1)-f(y)/(BS_0)$ *vs.* dissolution time.

Polymer Effects under Pressure. III. Hydrolysis of Normal Alkyl Acetate Catalyzed by Dodecyl Hydrogensulfate Micelle

Yoshihiro TANIGUCHI,* Osamu INOUE, and Keizo SUZUKI

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto, 603

(Received November 6, 1978)

Measurements of the rates of hydrolysis of methyl, ethyl, propyl, and butyl acetates have been made to 2 kbar in water catalyzed by dodecyl hydrogensulfate (DSA) micelle at 40 °C. The rate of hydrolysis decreases with compression up to approximately 1 kbar and then increases above 1 kbar; methyl acetate differs in these respects. The inversion phenomenon under pressure has been explained by the incorporation of both the H_3O^+ ion and ester molecules into the micellar phase. The observed value of the over all activation volume at 1 atm ΔV^* is -5.3 ± 1 cm³/mol for methyl, 0.40 ± 1 cm³/mol for ethyl, 9.7 ± 1 cm³/mol for propyl, and 20 ± 1 cm³/mol for butyl acetate, respectively. From the activation volumes of HCl and DSA micellar catalysts, the volume change accompanying the incorporation of the esters into the micellar phase $\Delta\Delta V_{micelle}$, has been estimated to be 4.0 ± 1 cm³/mol for methyl, 9.8 ± 1 cm³/mol for ethyl, 18.7 ± 1 cm³/mol for propyl, and 27.9 ± 1 cm³/mol for butyl acetate, respectively. The values above have been explained in terms of the contribution to the hydrophobic interaction between the ester molecule and the micelle.

Recently, there have been a large number of publications dealing with the enzyme and enzyme-model reactions as polymer and micellar effects;[1-3] the micellar catalyzed reaction being one of the polymer effects. The incorporation of substrates into the micellar phase is brought about by secondary forces such as the electrostatic and hydrophobic interactions between substrates and micelles. The rate of hydrolysis of esters is recognized to be markedly accelerated above the critical micelle concentration (CMC) and is expected to be retarded under pressure since the volume change accompanying each bond formation is positive. In a previous study,[4] the rate of hydrolysis of alkyl acetates catalyzed by sulfonated polystyrene (PSS) accompanying the hydrophobic incorporation of esters into the polymer domain was shown to be retarded by compression up to about 2 kbar.

It is well documented that hydrophobic interactions participate in micelle formation[5] and a maximum appears in the CMC *vs.* pressure plots at about 1 kbar.[6-13] In the present study, we measured the rate of the hydrolysis of methyl ethyl, propyl, and butyl acetates by dodecyl hydrogensulfate micelle as an acid catalyst up to 2 kbar. The reaction mechanism under pressure is discussed from the activation volume ΔV^* for the micellar catalyzed reaction.

Experimental

Materials. Sodium dodecyl sulfate (SDS) was prepared by the reaction of chlorosulfuric acid and 1-dodecanol, which was fractionally distilled three times and analyzed by gas chromatography. The reaction mixture was neutralized with sodium hydroxide. The crude SDS was extracted three times with petroleum ether in a Soxhlet apparatus for 50 h, and finally recrystallized from methanol. The CMC value of 8.3×10^{-3} mol/kg agrees with those of Hamann[6] and Kaneshina *et al.*[10] A DSA solution was prepared from the SDS solution using an ion exchange resin (Amberlite IR-120). The CMC value was 1.8×10^{-3} mol/kg at atmospheric pressure and 40 °C. An ester was distilled prior to use.

Apparatus and Procedures. The high pressure apparatus for measuring the hydrolysis of the ester has been described in detail elsewhere.[4] Under these experimetal conditions, the rate of hydrolysis of DSA was negligibly smaller than that of the alkyl acetates from the blank test for 3 h, which was compared with the data of Kurz.[14] Analysis of the acetic acid formed was conducted by titration using 1/20 M NaOH solution. The rate constant k_a was obtained by dividing the first-order rate constant by the concentration of acid at atmospheric pressure and 40 °C.

Results

At atmospheric pressure, the catalytic effects of the DSA micelle were greater than that of HCl as shown in Fig. 1. The k_a values for the HCl catalyst are almost identical for all esters, however, those for the micellar catalyst increase with increasing carbon number, *i.e.*, the hydrophobicity of the esters. For example the rates are 2.57, 4.31, 6.87, and 10.2×10^{-2} M^{-1} min^{-1} for methyl, ethyl, propyl, and butyl acetate at 40 °C, respectively. The accelerating effect is similar to that previously reported for PSS catalysts.[4]

Under high pressure, as shown in Fig. 2, the rates showed a minima at approximately 1 kbar, the ex-

a) Ref. 4.

ception being methyl acetate, and the pressure effects were larger with longer esters. The inversion phenomena corresponded to the appearance of the maximum of the CMC of DSA at 1 kbar.[12] The observed activation volume ΔV^* is defined by

$$(\partial \ln (k_p/k_1)/\partial P)_T = -\Delta V^*/RT, \quad (1)$$

where R is the gas constant and T the absolute temperature. From the initial slope of the plot of log (k_p/k_1) *vs.* pressure, the ΔV^* values determined graphically have been summarized in Table 1, and compared with previous data for HCl,[4] in addition to the data of propyl acetate catalyzed by HCl.

Discussion

The acid-catalyzed reaction of carboxylic esters in water is generally accepted to occur by an A-2 mechanism,[15,16]

$$H_3O^+ + RCOOR' \overset{K}{\rightleftharpoons} \overset{+}{R}COOHR' + H_2O \quad (2)$$

$$\overset{+}{R}COOHR' + H_2O \xrightarrow{k} R'OH + \overset{+}{R}COOH_2 \quad (3)$$

$$\overset{+}{R}COOH_2 + H_2O \xrightarrow{\text{fast}} RCOOH + H_3O^+ \quad (4)$$

at dilute ester concentration. The rate is given by the equation:

$$(\text{rate})_{HCl} = K\cdot k\cdot C_{ester}\cdot C_{H_3O^+} \quad (5)$$

where C_{ester} and $C_{H_3O^+}$ are the ester and H_3O^+ concentrations. In the micelle catalyst, $C_{H_3O^+}$ is not uniform throught out the solution but is higher near the micellar anion and C_{ester} is also concentrated in the micellar region through hydrophobic interaction. Assuming that $K\cdot k$ in Eq. 5 is approximately independent of the electric field, the rate of acid hydrolysis in the micelle is given by

$$(\text{rate})_{micelle} = K\cdot k\langle C_{ester}\cdot C_{H_3O^+}\rangle, \quad (6)$$

where $\langle C_{ester}\cdot C_{H_3O^+}\rangle$ are the concentrations of the ester and H_3O^+ incorporated into the micellar phase.

A strong acid such as DSA is completely ionized and the counterions are distributed closely to the micellar anion by electrostatic interaction. The effect of added salts on the CMC of SDS surfactants at high pressure was reported by Kaneshina *et al.*,[10] where it was suggested that the ratio of the number of counterions to surfactant in micelles decreases initially with an increase in pressure and then slightly increases with pressure *via* a minimum at 1.5 kbar. This suggests that compression at low pressure causes dissociation of the counterions from the micelle and that compression at higher pressure causes association of the ions to the micelle. If this tendency is the same as for the DSA micelle, the incorporation of the H_3O^+ ion into the micellar phase would show a minimum at approximately 1 to 1.5 kbar independent of the carbon number of the ester.

The driving force of the incorporation of the ester molecules into the micellar phase is expected to be a hydrophobic from Fig. 1. That the rate catalyzed by the DSA micelle increases with increasing carbon number in the ester, indicates a great degree of incorporation of the longer alkyl chain esters into the micellar phase. The methyl acetate, however, would be poorly incorporated into the micelle since the rate catalyzed by DSA is approximately the same as that of the HCl catalyst. Therefore, the rate of methyl acetate catalyzed by DSA micelle under pressure may be expected to increase linearly independently of the behaviour of the micelle under pressure in a similar manner of HCl. The behaviour of the mixed micelle of DSA and ester molecules would be similar to that of the DSA micelle under pressure. From a study of the pressure effect on the CMC of SDS and dodecyltrimethylammonium bromide (DTAB) in water–organic solvent mixtures,[17] the maximum in the CMC–pressure plots gradually shifts to higher values as the alcohol content of the solvent increases, and the effect of 1-butanol is larger than that of methanol. This agrees with the minimum pressure on the rate of hydrolysis for esters having longer alkyl chains under pressure which increase (Fig. 2). Therefore, the inversion phenomena in the rate of hydrolysis for esters having long alkyl chain under pressure has been attributed to the joint effects of the incorporation of the H_3O^+ ion and ester molecules into the micellar phase under pressure in Eq. 6.

Table 2 shows the micellar effects on ΔV^*, $\Delta\Delta V_{micelle}$

Table 2. Micellar effect on ΔV^* for ester hydrolysis compared with PSS polymer effect at 40 °C

Catalyst	CH_3COO-R, $\Delta\Delta V_{micelle}$ ±1.0 cm³/mol			
	-CH_3	-C_2H_5	-n-C_3H_7	-n-C_4H_9
DSA	4.0	9.8	18.7	27.9

PSS(60)[a]	6.6	12.5		15.5

a) Ref. 4.

compared with the PSS polymer effect. The increase of $\Delta\Delta V_{micelle}$ with increase in the carbon number of the esters needs consideration. The results correspond to the order of the incorporation of the esters into the micelle, and may be explained by the volume increase accompanying rupture of the hydrophobic hydration around the hydrocarbon part of the esters. It has been reported that the volume change for the formation of hydrophobic interaction is 1, 5, and 8 cm³/mol for methyl, ethyl, and propyl groups, respectively.[18] The value of 1—2 cm³/mol per methyl group accompanying the breaking down of hydrophobic hydration is supported by Noguchi,[19] Kaneshina *et al.*,[10] Corkill *et al.*,[20] and Friedman *et al.*[21] For butyl acetate the expected value accompanying the hydrophobic incorporation of ester molecules into the micelle is approximately half the $\Delta\Delta V_{micelle}$ suggesting additional contributions to $\Delta\Delta V_{micelle}$ accompanying a strong hydrophobic atmosphere *e.g.*, the dehydration of H_2O molecules from the carbonyl oxygen atom of the esters for hydrophobic incorporation, which accompanies a positive volume change of 5 to 7 cm³/mol.[22–25] Also, the exclusion of water molecules by strong hydrophobic atmosphere may change the A-2 mechanism into an A-1 mechanism in the *t*-butyl acetate system. Assuming such a development, the ΔV_{HCl} in Eq. 1 becomes small and positive or zero.[26] The $\Delta\Delta V_{micelle}$ for the butyl acetate system is 20 cm³/mol, which is a reasonable value. Further studies are necessary to confirm the A-1 mechanism in the micelle.

(Received November 8, 1978)

Partially sulfonated poly(1,4-piperazinediylterephthaloyl) microcapsules were found to undergo disintegration by the action of poly(diallyldimethylammonium) ions if the polycation concentration exceeded a certain value. The polycation concentration at which disintegration started was dependent on the degree of sulfonation of the microcapsules and pH of the medium. Exact electrical equivalence of the polyions involved was shown to be a necessary condition for disintegration of the microcapsules to take place. Disintegration of the microcapsules resulted in a formation of coacervate-like liquid drops. This formation of coacervate-like liquid was accelerated by mechanical and thermal agitation. Crosslinking among the polymers constituting the microcapsules prevented disintegration from occurring.

In a previous paper[1] the disintegration phenomenon of poly(N^{α},N^{ε}-L-lysinediylterephthaloyl) microcapsules by poly(diallyldimethylammonium chloride) was reported. The cationic polyelectrolyte caused disintegration of the microcapsules if its concentration exceeded a certain value which was dependent on the pH of the medium while it acted on the microcapsules to bring about their aggregation at lower concentrations. In any case where disintegration was observed, exact electrical equivalence of the polyions involved was found to exist. The physical process of disintegration was indicated to be a formation of coacervate-like liquid.

As this way of the use of a polycation should be useful to probe the stability and exchangeability of the components of a coacervate film it will be worth while to extend our work to see if the mechanism established for the above system also works in other systems. In view of this, the present paper deals with disintegration of partially sulfonated poly(1,4-piperazinediylphthaloyl) microcapsules by poly(diallyldimethylammonium chloride) in terms of the degree of sulfonation of the polymer and the pH and ionic strength of the medium. The effect of crosslinking of the polymers constituting the microcapsules on disintegration will also be discussed.

Experimental

Preparation of Microcapsules. Sulfonated poly(1,4-piperazinediylterephthaloyl) microcapsules (SPP microcapsules) were prepared in a manner similar to that described in an earlier paper.[2] This way, SPP microcapsules with different degrees of sulfonation were prepared using mixtures of piperazine(Pip) and 4,4′-diaminostilbene-2,2′-disulfonic acid(DASSA) in varying ratios as water-soluble monomers in the interfacial polycondensation reaction between diamine and diacid dichloride, and named SPP-2, -3, and -5 microcapsules, respectively, according to the mixing ratio given in Table 1.

To 7.5 cm³ of aqueous 1% polyethylene glycol(degree of polymerization 4000) solution in a 1 liter round bottom flask surrounded by ice was added an equal volume of 0.4 M solution of a mixture of Pip and DASSA in aqueous 0.45 M sodium carbonate solution containing 1% polyethylene glycol.

To this solution was added 75 cm³ of the mixed solvent (chloroform–cyclohexane 1 : 3, v/v, containing 10% sorbitan trioleate as an emulsifier). The mixture was then mechanically emulsified with a constant speed stirrer for 5 min to yield a water-in-oil emulsion. The alkali served to neutralize hydrogen chloride formed during the polycondensation reaction. Without stopping the stirring, 75 cm³ of terephthaloyl dichloride solution were quickly added to the emulsion, and the stirring was continued for further 3 min. The terephthaloyl dichloride solution was prepared just before use by adding 0.6 g of pure terephthaloyl dichloride to 75 cm³ of the mixed solvent. SPP microcapsules thus obtained were separated from the organic phase by centrifugation at 1000 rpm for 3 min and washed with the mixed solvent containing no emulsifier on the centrifuge at least three times to remove the emulsifier. Then, the washed SPP microcapsules were transferred to aqueous phase with the aid of poly(oxyethylene) sorbitan monolaurate, washed repeatedly with deionized water on the centrifuge, and dialyzed in a Visking tube against distilled water for a week.

Table 1. Molar mixing ratios of Pip to DASSA in diamine mixtures used for preparation of SPP microcapsules and sulfur contents in SPP microcapsules

Microcapsule	Molar mixing ratio Pip : DASSA	Sulfur content %
SPP-2	2 : 1	3.82
SPP-3	3 : 1	3.53
SPP-5	5 : 1	2.89

Microscopic Observation of Microcapsule Disintegration. To the dialyzed suspension of each of SPP-2, -3, and -5 microcapsules in test tubes was added an equal volume of a series of various concentrations of aqueous poly(diallyldimethylammonium chloride)(PDADMA) solution. The pH and ionic strength of the medium were adjusted by the addition of HCl or NaOH and NaCl, respectively. The mixtures were allowed to stand for 1 h with occasional shaking in a thermostated bath kept at 30 °C. At the end of this period, a small portion of each of the mixtures was withdrawn by a capillary tube and placed on a slide glass to observe the state of the SPP microcapsules under an optical microscope. In some cases, the microcapsules were photographed.

Preparation of Dried Samples of SPP Microcapsule Membranes for Adsorption Experiments. Each of SPP-2, -3, and -5 microcapsules in the organic phase was washed repeatedly with the mixed solvent containing no emulsifier, thoroughly dried *in vacuo*, and ground down into fine powder in a porcelain mortar. The powdered samples were stored in a desic-

cator until the time of use.

Measurements of Adsorption of PDADMA to SPP Microcapsule Membranes. To 0.05 g of the powdered samples of SPP microcapsule membranes was added 50 cm³ of various concentrations of aqueous PDADMA solution at different pH(7.0, 4.0, and 2.0) and ionic strengths (0.1 and 0.2). The pH and ionic strength of the medium were adjusted by the addition of HCl or NaOH and NaCl, respectively. The mixtures were permitted to stand for 1 h with continuous stirring in a thermostat maintained at 30 °C to ensure complete dispersion of the samples. At the end of this period, the mixtures were centrifuged at 2000 rpm for 5 min to settle the floating particles. Then, 10 cm³ each of the supernatant solutions was withdrawn by a pipet and titrated with a standardized solution of potassium poly(vinylsulfonate) using toluidine blue as an indicator.[3] The end point of titration could easily be detected visually by the metachromatic color change from blue to purple of the indicator.

Measurements of Electrophoretic Mobility of SPP Microcapsules. To a dialyzed suspension of each of SPP-2, -3, and -5 microcapsules in test tubes was added an equal volume of a series of various concentrations of PDADMA solution. The mixtures were allowed to stand for 1 h with occasional shaking in a thermostated water bath kept at 30 °C. The pH and ionic strength of the medium were adjusted by the addition of the acid or alkali and the salt, respectively, as before.

At the end of this period, nondisintegrated microcapsules were separated from the mixtures by centrifugation at 2000 rpm for 3 min. A small portion of the separated SPP microcapsules as the top layer in the centrifuge tube was withdrawn by a capillary tube and put into a 10^{-3} M NaCl solution. The resulted suspension was used for electrophoresis measurement.

Electrophoretic mobility measurements of the SPP microcapsules were carried out at 30 °C using a microelectrophoresis apparatus(Rank Brothers Co., Ltd., England). For each measurement, at least 20 microcapsules were timed in each direction to eliminate the polarization effect of the electrodes. The mobility of the microcapsules thus obtained was converted into the zeta potential by the Smoluchowski equation.

A portion of disintegrated SPP microcapsules settled in the bottom of the centrifuge tube was also withdrawn by a capillary tube and put into a 10^{-3} M NaCl solution. The mobility of disintegrated SPP microcapsules was converted into the zeta potential in the same way as for nondisintegrated SPP microcapsules.

Preparation of Coacervate-like Liquid Drops from SPP Microcapsules and PDADMA and Measurements of Their Electrophoretic Mobility. On the basis of the microscopic observations of disintegration of SPP microcapsules described later, coacervate-like liquid drops were prepared from SPP-2 and -5 microcapsules and PDADMA under two extreme conditions, *i.e.*, the most favorable and unfavorable conditions for disintegration. In the case of SPP-2 microcapsules, equal volumes of microcapsule suspension and 1.73×10^{-1} N PDADMA solution at pH 7.0 and ionic strength 0.1 were mixed in a 100 cm³ Erlenmeyer flask immersed in a thermostated water bath kept at 30 °C and the mixture was allowed to stand for 1 h. The mixture was then transferred to a 200 cm³ beaker in a water bath at 40 °C, stirred for 30 min, and centrifuged at 2000 rpm for 5 min to sediment coacervate-like liquid.

A small portion of the bottom layer in the centrifuge tube was withdrawn by a microspatula and put into 100 cm³ of 10^{-3}M NaCl solution. The electrophoretic mobility of the drops was measured in the same way as before. A similar procedure was employed to prepare coacervate-like liquid drops from SPP-5 microcapsules and 1.73×10^{-3} M solution of PDADMA. In this case, the pH and ionic strength of the medium were 2.0 and 0.2, respectively.

Treatment of SPP Microcapsules with Glutaraldehyde. The terminal amino groups of the constituent polymers of SPP-2 microcapsules were crosslinked with glutaraldehyde in the following way. Dialyzed suspension of SPP-2 microcapsules and 0.1 M NaCl solution were mixed in a 30 cm³ Erlenmeyer flask. Then, the pH of the resultant suspension was adjusted to about 10 by dropwise addition of 0.1 M NaOH solution to ensure complete deprotonation of the terminal amino groups. Twenty five grams of 25% aqueous glutaraldehyde solution was added to the suspension in the flask and the mixture was kept at 30 °C for 1 h during which the flask was gently shaken. After this treatment, the mixture was centrifuged and the separated SPP-2 microcapsules were redispersed in a medium of pH 7.0 and ionic strength 0.1 containing 1.73×10^{-1} N PDADMA to observe if the polycations would cause disintegration of the aldehyde-treated microcapsules.

Results

Microscopic Observations. In Fig. 1 are shown photomicrographs of intact SPP microcapsules. They were all spherical in shape and well-dispersed in the medium.

Disintegration of SPP microcapsules by PDADMA was found to depend strongly on the polycation concentration, moderately on the pH of the medium, and slightly on the ionic strength of the medium. In Table 2 is shown the dependency of the disintegration phenomenon on the three variables.

At any pH and ionic strength of the medium, disintegration of SPP microcapsules was observed only when the polycation concentration exceeded a certain value though the polycations caused aggregation of the microcapsules at lower concentrations. It was also observed that large microcapsules are readily ruptured by the action of the polycations as compared with small ones.

On the other hand, disintegration was apparently affected by the degree of sulfonation of SPP microcapsules since the pH dependence of the minimum PDADMA concentration required for the microcapsules to undergo disintegration varied with the degree of sulfonation as shown in Table 2. That is to say, disintegration of SPP-5 microcapsules with the lowest degree of sulfonation was prevented at low pH while SPP-2 microcapsules of the highest degree of sulfonation were ruptured independently of the pH of the medium above a certain polycation concentration.

Although the influence of the ionic strength of the medium on disintegration of SPP microcapsules was generally insignificant, it was appreciable in the case of SPP microcapsules of low degree of sulfonation at low pH.

Figure 2 gives the process of disintegration of SPP-2 microcapsules under the most favorable condition for disintegration in the present work, *i.e.*, at pH 7.0 and ionic strength 0.1 when the PDADMA concentration is increased.

At first, a low concentration of PDADMA caused

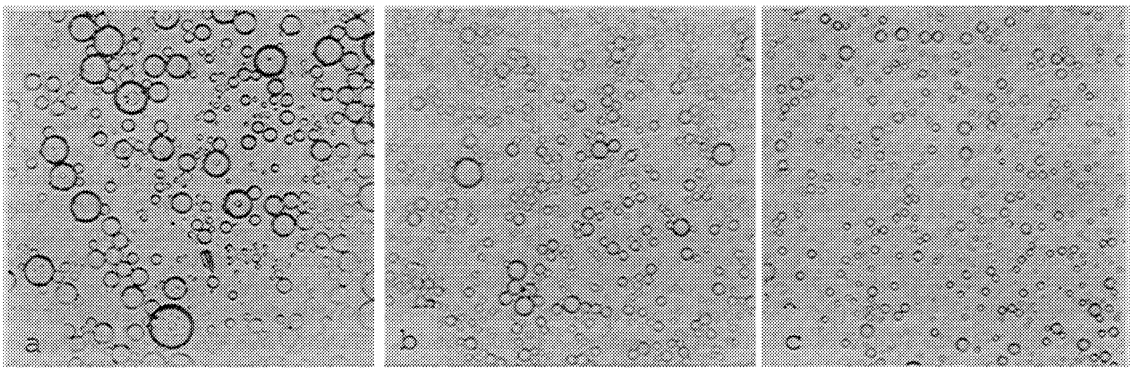

Fig. 1. Photomicrographs of intact SPP-2 (a), -3 (b), and -5 (c) microcapsules (×150).

Table 2. Disintegration of SPP microcapsules by PDADMA

		0.2	−	−	−	−	+

−: Aggregation alone; ±: very slight disintegration; +: slight disintegration; ++: moderate disintegration.

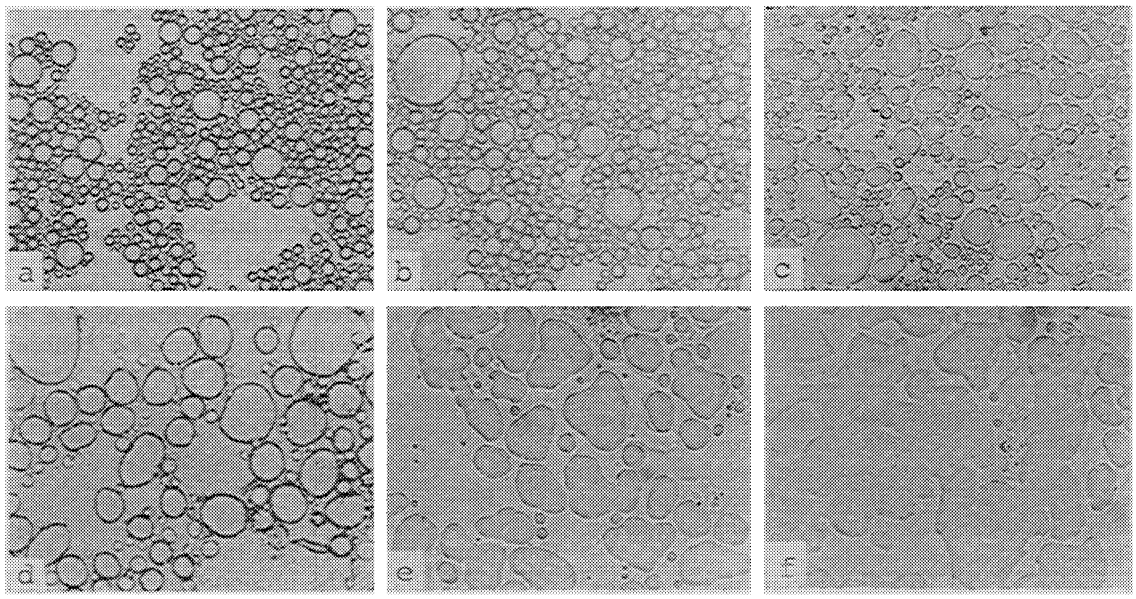

Fig. 2. A series of photomicrographs showing the process of disintegration of SPP-2 microcapsules by PDADMA at pH 7.0 and ionic strength 0.1. PDADMA concentration increases in the alphabetical order of the photos.

aggregation of the microcapsules(a); fusion among the aggregated microcapsules began here and there as the polycation concentration increased, large capsules having been liable to be the centers of fusion(b); the number of the centers from which fusion spread increased rapidly with further increase in the polycation concentration(c); the fusion developed further and large coacervate-like drops were formed(d); coalescence among the large drops proceeded(e); and finally, the microcapsule membranes were almost completely broken to the extent that their original form could not be seen.

Adsorption of PDADMA to SPP Microcapsule Membrane. In Fig. 3 is shown the effect of the degree of sulfonation on the adsorption of PDADMA upon SPP microcapsule membranes at pH 7.0 and ionic strength 0.1. The abscissa represents the logarithm of the initial PDADMA concentration.

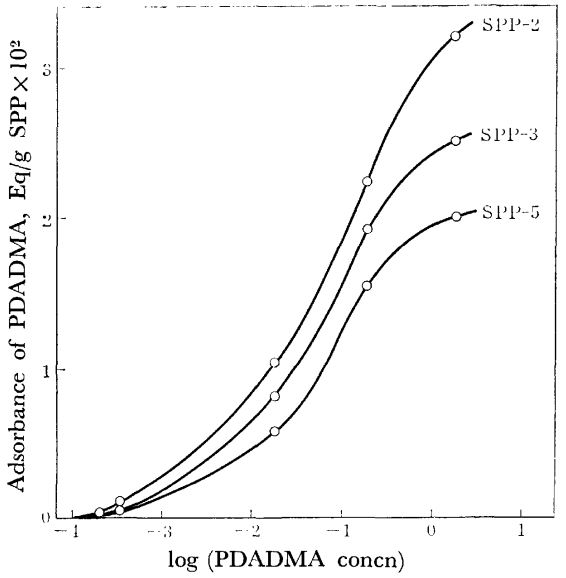

Fig. 3. Adsorption isotherms of PDADMA on SPP microcapsule membranes in a medium of pH 7.0 and ionic strength of 0.1 at 30 °C.

In any case, the PDADMA adsorption increased steeply first and then showed a tendency to saturate as the polycation concentration increased beyond 1.73×10^{-1} N. The adsorption was strongly dependent on the degree of sulfonation. Namely, it increased with increasing degree of sulfonation at all polycation concentrations. Variations in the pH and ionic strength of the medium did not alter this trend though not given here.

The effects of the pH and ionic strength of the medium on the polycation adsorption are illustrated in Fig. 4 for SPP-3 microcapsules.

As the pH was increased the adsorption rose remarkably. An increase in the ionic strength brought about a decrease in the adsorption. The adsorption decrease became less pronounced when the pH was lowered. Similar results were obtained with SPP-2 and -5 microcapsules.

Electrophoretic Behavior of SPP Microcapsules in the Presence of PDADMA. Figure 5 shows the zeta potential of nondisintegrated SPP-3 microcapsules as a function of the polycation concentration and the pH and ionic strength of the medium. The values of these variables are those employed in the preparation of the samples for electrophoresis experiment.

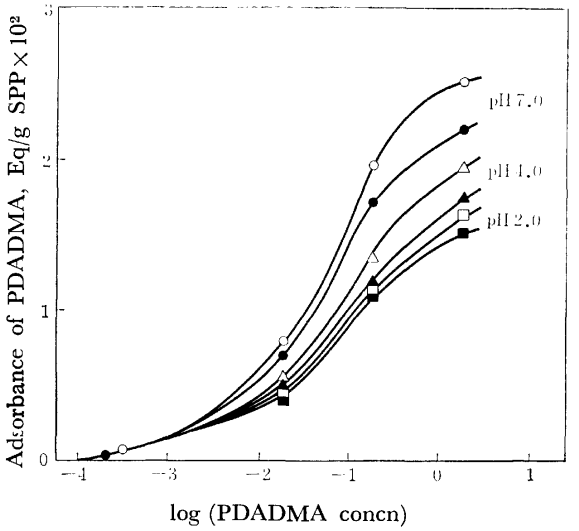

Fig. 4. Adsorption isotherms of PDADMA on SPP-3 microcapsule membranes at 30 °C. Ionic strength: 0.1 (open symbols) and 0.2 (closed symbols).

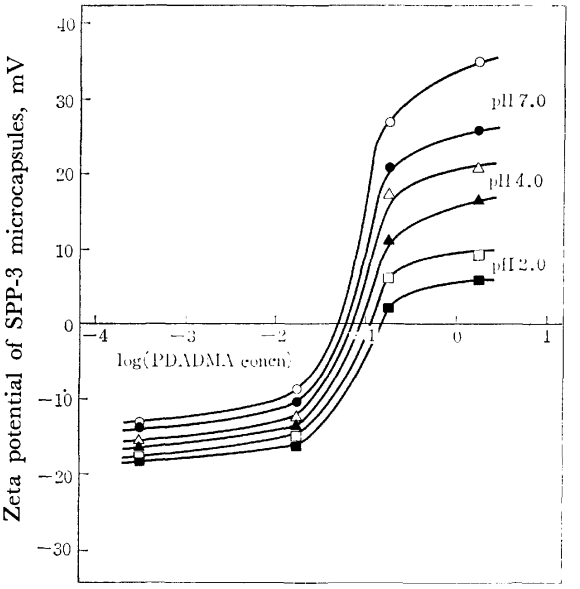

Fig. 5. Zeta potential of SPP-3 microcapsules at 30 °C as a function of PDADMA concentration, pH, and ionic strength. Ionic strength: 0.1 (open symbols) and 0.2 (closed symbols).

In all cases, the zeta potential changed its sign when the polycation concentration attained a value between 1.65×10^{-2} and 1.73×10^{-1} N. The polycation concentration at which the zeta potential reversed its sign shifted downward as the hydrogen ion concentration and ionic strength of the medium were reduced. A decrease in the degree of sulfonation gave rise to an increase in the polycation concentration required to cause reversal of the sign of the zeta potential.

The zeta potential of disintegrated SPP-3 microcap-

sules is shown in Fig. 6 as a function of the polycation concentration and the pH and ionic strength of the medium used for the preparation of the samples for electrophoresis.

Reversal of the sign of the zeta potential was observed as the polycation concentration increased beyond 1.65×10^{-2} N as in the case of nondisintegrated SPP microcapsules. The positive zeta potential after the sign reversal was at most as high as 7 mV and insensitive to changes in the pH and ionic strength of the medium.

Electrophoretic Behavior of Coacervate-like Liquid Drops Prepared from SPP Microcapsules and PDADMA. In Fig. 7 is given a photomicrograph of coacervate-like liquid drops prepared from SPP-2 microcapsules and PDADMA.

The zeta potentials of coacervate-like liquid drops prepared from SPP-2 and -5 microcapsules and PDADMA were almost zero or slightly positive, being indicative of a very low, if any, electric charge of the drops and they were almost independent of the degree of sulfonation and pH and ionic strength of the medium at which the drops were prepared.

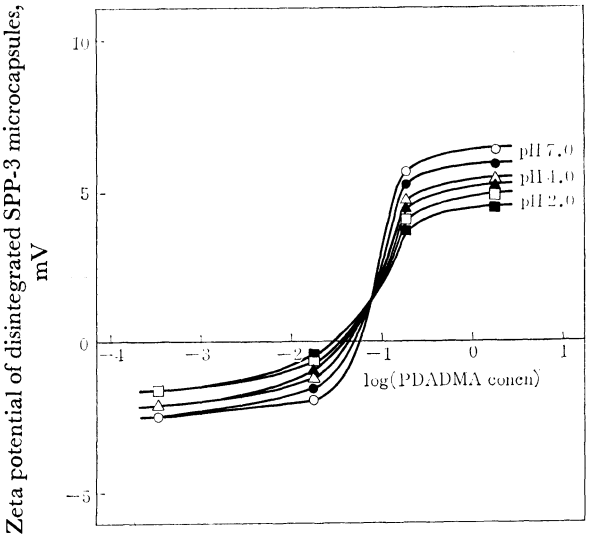

Fig. 6. Zeta potential of disintegrated SPP-3 microcapsules at 30 °C as a function of PDADMA concentration, pH, and ionic strength. Ionic strength: 0.1 (open symbols) and 0.2 (closed symbols).

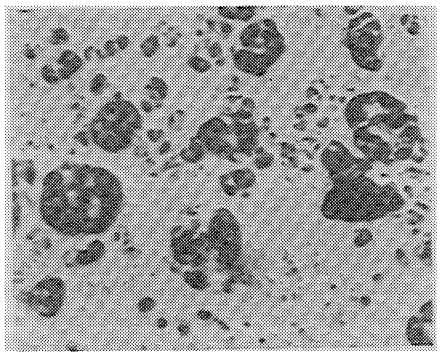

Fig. 7. Photomicrograph of coacervate-like liquid drops prepared from SPP-2 microcapsules and PDADMA.

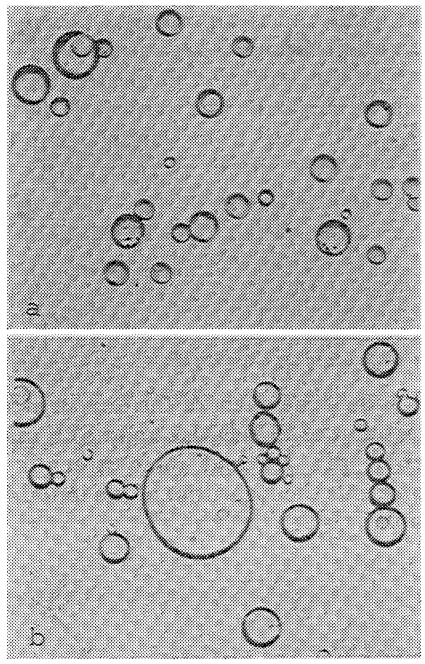

Fig. 8. Photomicrographs of glutaraldehyde-treated SPP-2 microcapsules taken in the absence (a) and presence (b) of PDADMA (×150).

Effect of Glutaraldehyde Treatment on Disintegration of SPP Microcapsules. As described already, SPP-2 microcapsules were appreciably ruptured in 1 h at pH 7.0 and ionic strength 0.1 when the polycation concentration was 1.73×10^{-1} N. On the contrary, glutaraldehyde-treated SPP-2 microcapsules were hardly disintegrated by the action of PDADMA under the same condition. Photomicrographs of glutaraldehyde-treated SPP-2 microcapsules taken in the absence(a) and presence(b) of PDADMA are shown in Fig. 8.

Discussion

As is apparent from the polycondensation reaction utilized in the preparation, SPP microcapsules have a number of sulfonato groups on their constituent polymer molecules as the ionizable group. Disintegration of the microcapsules is clearly caused by the electrostatic interaction between the negatively charged microcapsules and the oppositely charged polycations in the aqueous medium. Namely, it is a prerequisite for disintegration of the microcapsules that PDADMA ions are adsorbed on the sulfonato groups of the microcapsules. However, there seems to be a minimum number of sulfonato groups on the microcapsules for their disintegration to occur because SPP-5 microcapsules are not disintegrated at the PDADMA concentration of 1.73×10^{-1} N when the pH is low though this concentration produces disintegration of the microcapsules with higher degrees of sulfonation at the same pH(Table 2). It is reasonable that the pH effect on disintegration is less significant for SPP microcapsules than for PPL†† microcapsules which have carboxyl groups as the ionizable group since $-SO_3H$ group has

†† Abbreviation for poly(N^{α},N^{ε}-L-lysinediylterephthaloyl).

Table 3. Numbers of quarternary ammonium groups of PDADMA ions adsorbed on SPP microcapsules

Micro-capsule	pH	Ionic strength	PDADMA concn (N)

a lower pK value than –COOH group.

The disintegration phenomenon, polycation adsorption, and zeta potential of SPP microcapsules are closely interrelated. When the PDADMA concentration exceeds a value of 1.65×10^{-2} N the polycation adsorption to the microcapsules begins to increase abruptly (Figs. 3 and 4), disintegration of the microcapsules starts, and the zeta potential of the microcapsules reverses its sign (Fig. 5). In order to give this interrelationship a quantitative basis on which it rests, the numbers of sulfonato groups per unit weight of SPP-2, -3, and -5 microcapsules were first calculated from the sulfur contents. They were 7.08, 6.64, and 5.40×10^{21}, respectively. Secondly, calculations were made of the numbers of quarternary ammonium groups of the PDADMA ions adsorbed on unit weight of the microcapsules based on the adsorption data. The results are given in Table 3.

Interestingly enough, the number of sulfonato groups on the constituent polymers of the microcapsules and that of quarternary ammonium groups on the adsorbed polycations are nearly equal to each other in the polycation concentration region where the disintegration phenomenon is observed. This means that there exists an exact or nearly exact electrical equivalence between the polyanions and the polycations involved in disintegration. In fact, as mentioned before, coacervate-like liquid drops prepared from the microcapsules and the polycations under the conditions favorable to disintegration to occur bear no or little electrical charge, indicating that the electrical equivalence holds in these cases.

Inspection of Fig. 6 seems to give a clue to elucidate the mechanism of disintegration of the microcapsules. Disintegrated SPP microcapsules still have positive zeta potentials though not so high in the polycation concentration region in which coacervate-like liquid drops carry no or little electrical charge. This can be interpreted as showing that interminglement of the polyanions and the polycations is not sufficient and the latter component is still more abundant than the former in the surface layer of the disintegrated microcapsules, thus giving them positive zeta potentials though both components exist on the whole in approximately equivalent amounts in the capsules. Application of thermal and mechanical agitations to the disintegrated capsules should bring about a complete interminglement of the polyion components and this really happens in the preparation of coacervate-like liquid drops. If there are crosslinks among the constituent polymers of the microcapsules random mixing of the polyanions of the microcapsules and the polycations must be prevented and therefore no disintegration is observed.

Interaction between a strongly acidic polyanion and strongly basic polycation in aqueous solution usually yields a colloidal precipitate rather than a gelatinous coacervate.[4,5] The reason why coacervate-like liquid drops were formed in the present work instead of colloidal precipitates as a result of the interaction between SPP polymers and PDADMA polycations both of which are strong polyelectrolytes would presumably be due to a very low charge density of the former as compared with the latter.

It is obvious from the way in which the foregoing argument has been developed that PDADMA ions adsorb on the surface of SPP microcapsules to interact electrostatically with sulfonato groups on the constituent polymers of the microcapsules, causing disintegration of the microcapsules which leads to a complex coacervation under favorable conditions. The electrical equivalence holds in the coacervation and the effects of the degree of sulfonation and the pH and ionic strength of the medium on the disintegration phenomenon can be explained in terms of the effects of these variables

on the electrostatic interaction between the polyions involved. The effect of the molecular sizes of the components is left to be studied in future because there is no way of obtaining samples of the polyanions and the polycations of definite molecular dimensions at present.

Deuteration Kinetics of Tyrosine by Means of Fluorescence Measurement

Mamoru NAKANISHI and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 2, 1978)

When tyrosine was rapidly transferred from water into deuterium oxide medium by means of a stopped-flow device, a time-dependent change in the fluorescence intensity at 305 nm (excited at 275 nm) has been observed. The rate constant (k_e) was found to be 116 s^{-1} at pH 5.8 and 14 °C. This k_e value has been attributed to the rate constant of the $O^1H \rightarrow O^2H$ reaction of the phenolic OH group, on the basis of similar fluorescence examinations on phenol, anisole, glycyl-L-tyrosine, and N^{α}-acetyl-*N*-methyl-L-tyrosinamide as well as on the basis of a stopped-flow ultraviolet absorption study of tyrosine. The stopped-flow fluorometry has been applied to a study of tyrosine residues in yeast 3-phosphoglycerate kinase.

Deuteration kinetics can, in general, be a sensitive means of detecting differences in the intramolecular environment of a given functional group in a biological macromolecular system. We have recently shown that an ultraviolet absorption measurement in combination with a stopped-flow device provides a useful method for tracing a rapid deuteration process of tryptophan or tyrosine residues in a protein in an aqueous solution.[1,2] It is known, however, that a fluorescence measurement often provides a greater sensitivity and selectivity than an ultraviolet absorption measurement for an examination of the same chromophore. We, therefore, started a development of "stopped-flow fluorometry," with a possibility in mind that this may be a more useful method for deuteration kinetics.

In general, the isotope effect on fluorescence intensity is not a simple problem.[3,4] There can be a number of possible mechanisms for the occurrence of such an effect, and the intensity does not always reflect the extent of deuteration of the chromophore (or the fluorophore) in question. Indeed, the fluorescence increase of tryptophan on bringing it from ^1H_2O into ^2H_2O medium is attributable to the deuteration of the α-ammonium ($-NH_3^+$) group, but not to that of the imino group of the indole ring.[5,6] For tyrosine, however, the fluorescence increase on bringing it from ^1H_2O into ^2H_2O medium seems to be caused simply by the $O^1H \rightarrow O^2H$ change at its phenolic hydroxyl group. This is shown in this paper, with an example which suggests a possible application to a protein study.

Experimental

Phenol, anisole, L-tyrosine, and glycyl-L-tyrosine were obtained from commercial sources, and were used without further purification. Acetyl-L-tyrosine-*N*-methylamide (N^{α}-acetyl-*N*-methyl-L-tyrosinamide) was prepared by the Protein Research Foundation, Osaka, Japan, and was placed at our disposal by the courtesy of Dr. Y. Koyama, Kansei Gakuin University. Its purity was confirmed by an examination of its proton magnetic resonance. The sample of 3-phosphoglycerate kinase of yeast was purchased from Boeringer, Mannheim. The solvents ^1H_2O and ^2H_2O were used after being distilled. Emission spectra were observed by the use of a Hitachi MPF-4 fluorometer.

The time dependence of the fluorescence intensity or of the ultraviolet absorbance was observed by the use of a Union Giken stopped-flow spectrophotometer RA-401. This is equipped with a rapid-mixing device of dead time 500 μs, and with an ultraviolet monochromator of focal length 25 cm. For stopped-flow fluorometry, a 200 W deuterium discharge lamp was placed at the entrance of the monochromator, and at its exit a cell with optical path length of 2 mm was placed. The solution, after rapid mixing, is led into this cell, and when the flow is stopped the time dependent fluorescence change (if any) should start. The fluorescence is excited by monochromatic light, and is observed through a Hoya UV 30 filter, which allows the emitted light of wavelength longer than 300 nm to come into the detector. For a stopped-flow ultraviolet absorption study, the same deuterium discharge lamp and the same cell were used with the same monochromator as above. Only the location of the photomultiplier was changed. The fluorescence intensity *versus* time curve or the absorbance *versus* time curve was obtained by the use of a Union Giken data processor RA-450, a monitorscope, and an XY recorder.

Results and Discussion

Fluorescence of Tyrosine and Its Change on Deuteration. The observed emission spectra are reproduced in Fig. 1. The fluorescence peaks are found at 296 nm for phenol and at 295 nm for anisole. On transfering from ^1H_2O to $^2H_2O+^1H_2O$, the peak intensity increases by 22% for phenol, but only 2% for anisole. L-Tyrosine, glycyl-L-tyrosine, and N^{α}-acetyl-*N*-methyl-L-tyrosinamide show their fluorescence maxima at 303 nm. On changing the solvent from ^1H_2O to $^2H_2O+^1H_2O$, the intensity increases of 18, 13, and 16% are found, respectively, for these three compounds. Of the total 13% fluorescence increase for L-tyrosine, 9% takes place rapidly within 1 ms, while the remaining 4% increase takes place more slowly, in a period of about 20 ms (see Fig. 2(c)). A re-plot of such a fluorescence intensity on a logarithmic scale against time indicates that the process is apparently a single first order process. The rate constant is found to be 116 s^{-1} at pH 5.8 and 14 °C. This is exactly equal to the rate constant value obtained by a stopped-flow ultraviolet absorption measurement at 285 nm as described in our previous paper[2] (see also the curve given at the bottom of Fig. 2, (c)). This rate constant was assigned to that of the deuteration reaction $O^1H \rightarrow O^2H$ of the phenolic hydroxyl group of tyrosine.[2]

A similar fluorescence increase takes place with nearly equal rate for phenol (Fig. 2, (a)), but not at all for anisole (Fig. 2, (b)). In contrast with glycyl-L-tryptophan, which shows no time-dependent fluorescence increase when it is transferred from ^1H_2O into ^2H_2O medium,[6] glycyl-L-tyrosine shows an increase with nearly an equal rate constant to that for tyrosine (Fig. 2, (d)). All of these facts support the idea that

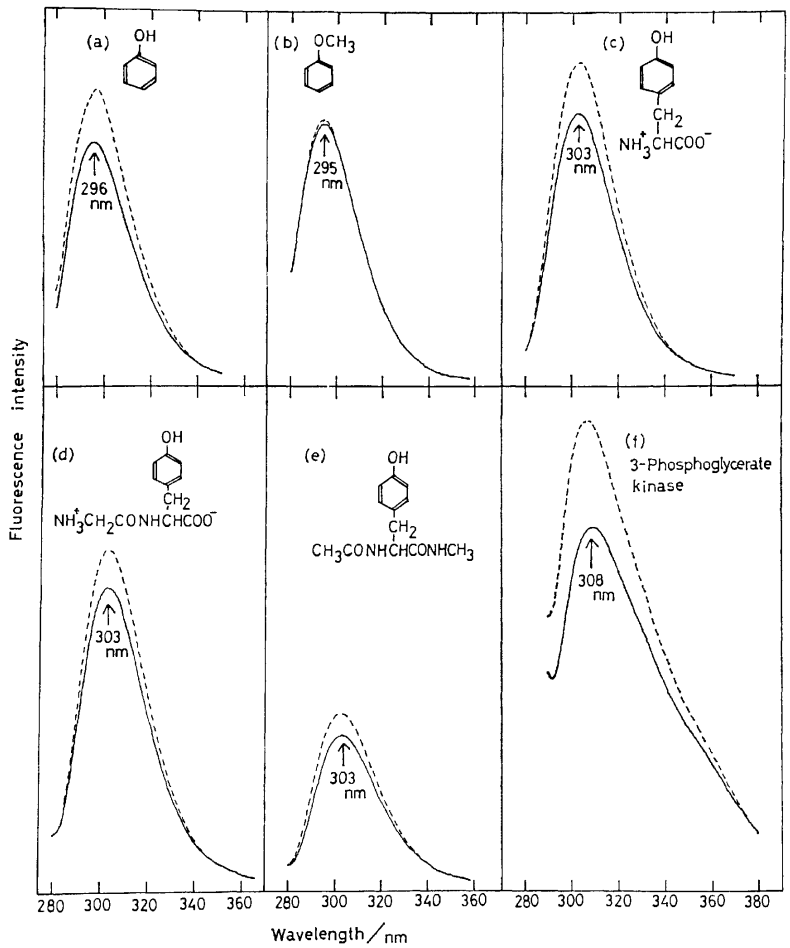

Fig. 1. Emission spectra in ^1H_2O (full line) and in $^2H_2O+^1H_2O$ (broken line), at pH 5.8 and at 14 °C.
(a) Phenol, excited at 270 nm. (b) Anisole, excited at 270 nm. (c) L-Tyrosine (0.15 mM), excited at 275 nm. (d) Glycyl-L-tyrosine, excited at 275 nm. (e) N^{α}-Acetyl-N-methyl-L-tyrosinamide, excited at 275 nm. (f) Yeast 3-phosphoglycerate kinase (0.01%), excited at 280 nm.

the time-dependent fluorescence increase in question is caused by the $O^1H \rightarrow O^2H$ process of the phenolic hydroxyl group.

The amount and the rate of fluorescence increase for N^{α}-acetyl-N-methyl-L-tyrosinamide is also nearly equal (Fig. 2(e)) to those of L-tyrosine or to phenol. Such a rate constant value is to be used as a standard (k_e) value in estimating the attenuation factor $\gamma_j = k_j/k_e$ of a given tyrosine group (j) in a protein molecule whose rate constant value is k_j.

Application to a Protein Study. 3-Phosphoglycerate kinase (EC 2.7.2.3) from yeast contains two tryptophan and eight tyrosine residues per molecule.[7] Nojima *et al.*[8] has found that, in its emission spectrum, a fluorescence maximum is present at 308 nm if excited at 280 nm, while at 329 nm if excited at 295 nm. The former (308 nm) is considered to be caused by the tyrosine residues, and the latter (329 nm) by the tryptophan residues. The emission spectrum of this protein excited at 280 nm is shown in Fig. 1, (f). As may be seen here the fluorescence intensity increases by 28% on bringing it from ^1H_2O to $^2H_2O+^1H_2O$. The same amount (27.5%) of total fluorescence increase was observed when an ^1H_2O solution of this protein is rapidly mixed with the same volume of ^2H_2O by means of the stopped-flow fluorometry technique. Of this total 27.5% increase, 22% takes place within the dead time of the stopped-flow equipment, and the remaining 5% increase takes place very slowly (see Fig. 3). The rate of this slow process was found to be 3.9 s^{-1} at pH 5.9 and at 29 °C. At this pH and at this temperature, k_e of tyrosine is estimated to be 350 s^{-1}, and therefore the attenuation factor $\gamma_i = 3.9/350 = 1/90$. It may be interpreted that the tyrosine residue (or residues) now in question is rather rigidly fixed inside of the protein molecule, and that the chance of its being exposed to the solvent is only 1/90.

In a protein molecule an energy transfer takes place often from tyrosine to tryptophan, and even when a tyrosine residue is excited the fluorescence comes often from the tryptophan residue instead of the tyrosine residue itself.[9] If a protein containing both tyrosine and tryptophan residues gives a tyrosine fluorescence, such a tyrosine residue is considered to be firmly fixed at a particular orientation in the protein molecule, so that no energy transfer takes place between the tyrosine residue now in question and any of the tryptophan residues in the same molecule. Because 3-

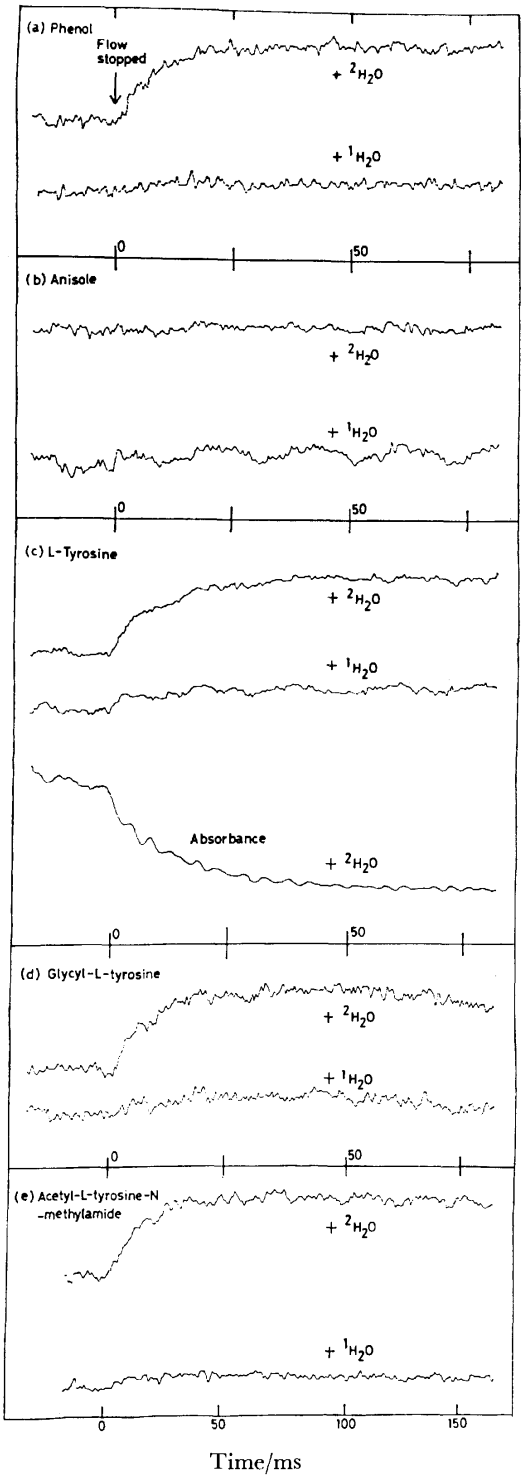

Fig. 2. The time dependence of the fluorescence intensity observed when an ^1H_2O solution of each compound indicated is rapidly mixed with the same volume of ^2H_2O, so that the solvent of the final solution is 1 : 1 $^1H_2O+^2H_2O$. For each compound, a curve recorded in a control experiment in which the same ^1H_2O solution was mixed with ^1H_2O instead of ^2H_2O is also shown.

(a) Phenol (pH 5.3, at 15 °C), excited at 255 nm. (b) Anisole, (pH 5.5, at 15 °C), excited at 255 nm. (c) L-Tyrosine (final concentration 1.2 mM, pH 5.8, at 12.5 °C), excited at 275 nm. The curve at the bottom is the time dependence of the ultraviolet absorbance recorded at 285 nm when an L-tyrosine in ^1H_2O solution was mixed with the same volume of ^2H_2O, so that the final concentration was 1.2 mM, pH 5.8, at 12.5 °C. (d) Glycyl-L-tyrosine, pH 5.5, at 17 °C, excited at 275 nm. (e) N^{α}-Acetyl-N-methyl-L-tyrosinamide pH 5.5, at 17 °C, excited at 275 nm.

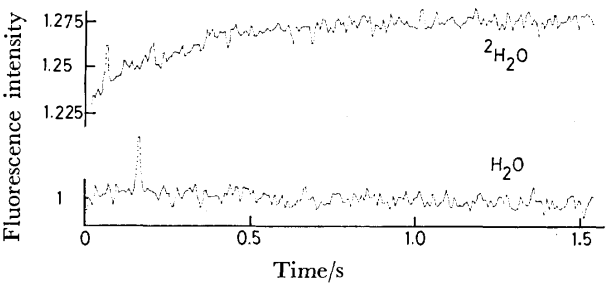

Fig. 3. Change in time of fluorescence intensity at 308 nm (excited at 280 nm) is observed for yeast 3-phosphoglycerate kinase in ^1H_2O upon mixture with ^2H_2O (1 : 1 in volume; final concentration of the protein is 0.05%, pH 5.9) at 29 °C.

phosphoglycerate kinase has both the tyrosine and tryptophan residues, the tyrosine fluorescence (at 309 nm) we have observed is attributed to such a tyrosine residue (or tyrosine residues) rigidly fixed in a special orientation. The fact that the hydrogen-deuterium exchange reaction between this tyrosine residue and the solvent ^2H_2O is 90 times as slow as the tyrosine exposed to the solvent is therefore understandable.

On the Normal Modes of Vibration in the Uracil Residue — The Use of ^{15}N-Isotope Effects

Yoshifumi NISHIMURA, Hideyuki HARUYAMA, Kimiko NOMURA, Akiko Y. HIRAKAWA, and Masamichi TSUBOI*

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 2,1978)

β-Uridine-5′-phosphoric acid-$^{15}N_2$ has been prepared from ^{15}N-RNA of baker's yeast which was grown in $(^{15}NH_4)_2SO_4$ as the sole nitrogen source. Its Raman spectrum has been observed both in ^1H_2O and ^2H_2O solutions. On the basis of the observed ^{15}N isotope effects on the Raman spectra and on the basis of other data previously obtained, normal modes of vibration have been discussed for six Raman bands of the uracil residue that are considered to be in resonance with its electronic transition at 260 nm. The result has led to a conclusion that $C^5=C^6$ is longer and C^4-C^5 is shorter in the excited electronic state $\tilde{A}$ (260 nm) than those in the ground electronic state $\tilde{X}$.

Resonance Raman spectroscopy may sometimes be useful as a tool for exploring the excited state geometry of a molecule.[1,2] Let us suppose that our present aim is to ellucidate the geometrical structure of the electronic excited state of the uracil residue corresponding to its 260 nm absorption band. For this aim we first need to examine which Raman lines of the uracil residue are in resonance with the 260 nm electronic transition ($\tilde{A}$-$\tilde{X}$),[3] and secondly we need to find the normal modes of vibration that are to be assigned to these particular Raman lines. We can then predict that, on going from the ground ($\tilde{X}$) to the excited ($\tilde{A}$) state, a distortion of the molecular conformation takes place along such a normal coordinate or along a linear combination of such normal coordinates. This prediction is based upon a theory which is valid only in a certain approximation.[1,2] In combination with other data, however, this approach often leads to a useful piece of information on the excited state geometry.

In our present study we have used a set of ^{15}N isotope shifts in the vibrational frequencies of the uracil residue, as a data for fixing normal modes, in addition to the usual data obtained by an examination of deuterated products. In our normal coordinate treatment, it has been found that a fixing of the force constant values corresponding to interactions of two bond-stretching motions in the six-membered ring is critical. In this respect, a recent work on the force field in benzene[5] was found to be helpful. On the basis of these data, the normal modes of vibration of the six Raman bands, which were previously found[3,4] to be in resonance with the electronic transition at 260 nm, have now been determined with a considerable reliability.

Experimental

Preparation of ^{15}N RNA. Baker's yeast was grown in a medium in which $(^{15}NH_4)_2SO_4$ is the sole nitrogen source. This part of our experiment was made in collabotation with Dr. Masatsune Kainosho in the Central Research Laboratory, Ajinomoto Company, Ltd. 400 g of wet cells of such yeast were placed in 1 litre of 0.0125 M phosphate buffer (pH 6.8) with 2% sodium dodecyl sulfate and 4.5% ethanol. The suspension was incubated at 95 °C for 5 min, rapidly cooled with dry ice plus methyl cellosolve, and then centrifuged at 4000 rpm for 5 min. From the supernatant, crude RNA was precipitated by adding 2 litre ethanol. The precipitate was washed with 70% ethanol and then with 80% ethanol overnight. The precipitate was dissolved again in 500 ml of 5 mM phosphate buffer, and centrifuged at 4000 rpm for 5 min. RNA was precipitated from the supernatant with 1 M NaCl plus ethanol. This was dissolved in 500 ml of 2.5 mM phosphate buffer and dialyzed against 1 mM phosphate buffer. By an ethanol precipitation, 3.3 g purified ^{15}N RNA was obtained.

Preparation of β-Uridine-5′-phosphoric acid-$^{15}N_2$ (5′-UMP-$^{15}N_2$). ^{15}N-RNA was dissolved in phosphate buffer (pH 5.2) and incubated with nuclease P_1 (kindly provided by Dr. A. Kuninaka, The Research Laboratory of Yamasa Shoyu Co., Ltd., Chyoshi Japan) at 37 °C overnight. After the pH of the digested solution was adjusted to 7.2, the solution was subjected to a Dowex 1X2 column chromatography, where the formic acid form of 200—400 mesh was placed in a 20×1000 mm tube. For elusion, HCOOH gradient (from 0 to 3 M) was used, and 5′CMP, 5′AMP, 5′GMP, and finally 5′UMP came out. 5′UMP-$^{15}N_2$ was recrystallized with ethanol and water. This gave only one spot in a thin-layer chromatography. Its isotopic purity was judged from the isotopic purities determined of 5′AMP-$^{15}N_5$ and 5′-CMP-$^{15}N_3$, prepared from the same batch of ^{15}N-RNA with that for 5′-UMP-$^{15}N_2$. The isotopic purity of each of these two nucleotides was examined by mass-spectrometry of ammonia produced by a micro-Kjeldahl procedure from the nucleotide sample. The ^{15}N content was found to be 89% of the total nitrogen both for 5′-AMP and for 5′-CMP. Because the biosynthesis process is similar for cytosine residue to that for uracil residue, the ^{15}N content of our 5′UMP is considered to be also 89% of its total nitrogen.

Raman Spectroscopic Measurement. Raman spectra of 5′-UMP-$^{14}N_2$ and 5′-UMP-$^{15}N_2$ were examined in neutral ^1H_2O and ^2H_2O solutions. The measurements were made by the use of a JEOL (Japan Electron Optics Laboratory Co.) JRS-Ul spectrophotometer with 514.5 nm line of a Coherent Radiation model 52 GA argon ion laser. The ^{15}N isotope shift was examined for each Raman line by repeating a short-range scan for 5′-UMP-$^{14}N_2$ and for 5′-UMP-$^{15}N_2$ alternately many times by keeping the conditions of the instrument as steady as possible.

Results and Discussions

^{15}N Isotope Effects on the Raman Spectra. In Figs. 1 and 2 are given the observed Raman spectra, observed Raman frequencies (in cm^{-1}), and the amounts of ^{15}N-shifts determined for 5′-UMP, both in ^1H_2O and in ^2H_2O (pH 7.2). In

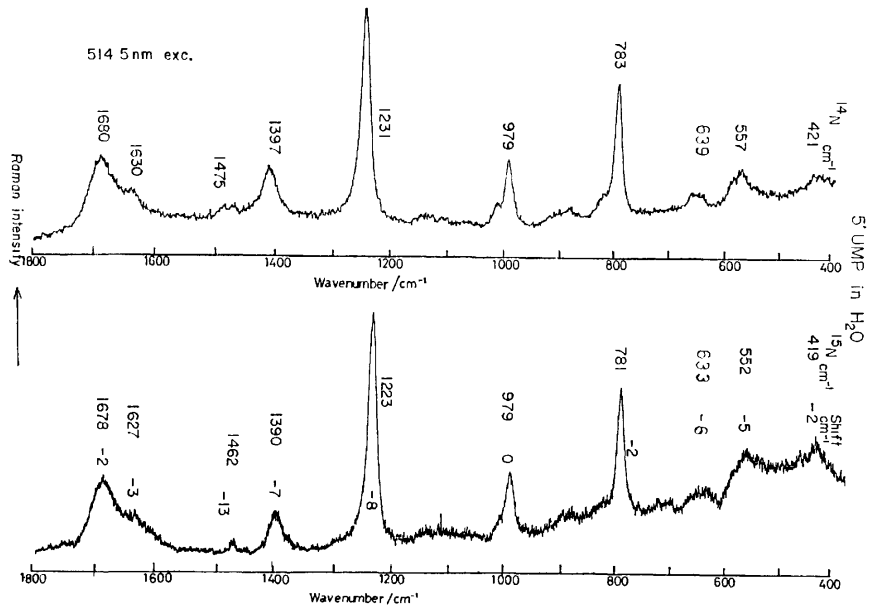

Fig. 1. Raman spectra of β-uridine-5′-phosphoric acid (5′-UMP-$^{14}N_2$ and 5′-UMP-$^{15}N_2$) in ^1H_2O, pH 7.2 at room temperature, concentation 10%. Excited by 514.5 nm line of an Ar^+ laser.

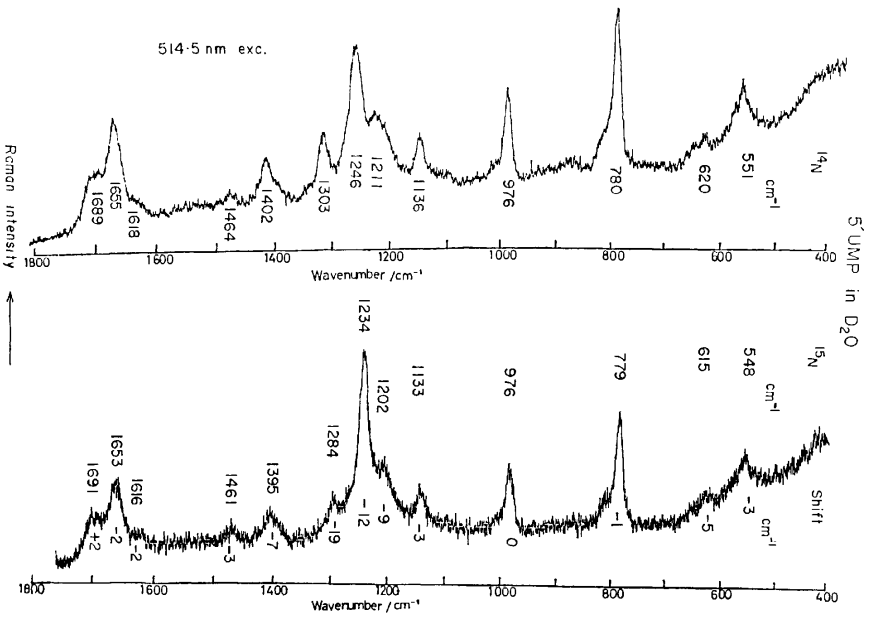

Fig. 2. Raman spectra of β-uridine-5′-phosphoric acid (5′-UMP-$^{14}N_2$ and 5′-UMP-$^{15}N_2$) in ^2H_2O, pH 7.2 at room temperature, concentration 10%. Excited by 514.5 nm line of an Ar^+ laser.

^2H_2O, the NH group at position 3 is deuterated (ND) (for numbering of the positions, see Table 1). As may be seen in Figs. 1 and 2, most of the Raman lines assignable to the uracil residue show appreciable ^{15}N-shifts, while the line at 979 cm^{-1} assignable to the phosphate group[6] shows no shift at all. The observed amounts of ^{15}N-shifts form a useful set of data for determining the force constants and normal modes of vibration of the uracil residue. These are discussed later in this paper. Here, a comment is added as for an interesting isotope effect on the Raman scattering intensity. As may be seen in Fig. 2, the relative intensity of the 1246 cm^{-1} line of 5′-UMP-d_3 is appreciably raised on ^{15}N substitution. This Raman line (let us call its mode "V") is one of the characteristic lines of pyrimidine bases. This is isolated and strong when it is located at about 1235 cm^{-1} or lower frequency (*e.g.*, in uracil residue, and uracil residue-d_1, $^{15}N_2$). On the other hand, it is weaker and has a few satellite lines when it is located at a frequency higher than 1240 cm^{-1} (*e.g.*, in deprotonated uracil residue, deuterated uracil residue, and cytosine residue). This is the strongest Raman line in the uracil residue and shows the greatest intensity enhancement on bringing the exciting wavelength from 514.5 nm to 351.1 nm. The ^{15}N-isotope effect on the intensity of this line may be ascribed to a change in the vibrational mode "V" in the electronic excited state $\tilde{A}$ (260 nm) rather than that in the electronic ground state $\tilde{X}$. It may be explained, in other words, by taking a Duschinsky effect into account.

Thus, it is not improbable that, in the first excited state $\tilde{A}$ (260 nm) of the uracil residue, the $C^5=C^6$ bond order is very low so that its intrinsic stretching frequency is as low as 1234 cm^{-1}. If so, "mode II" (mainly $C^5=C^6$ stretching) and "mode V" have nearly equal frequencies to each other in the upper $\tilde{A}$ state; while, in the ground electronic state, "mode II" (mainly $C^5=C^6$ stretching, at about 1600 cm^{-1}) and "mode V" (1234 cm^{-1}) are orthogonal to each other. In such a situation, the Franck-Condon overlap integrals that cause the Raman scattering of the "V-vibration" may have an appreciable value. If the "V-frequency" is exactly 1234 cm^{-1} (as that for 5′-UMP-$^{15}N_2$, d_3), then the vibrational coupling in $\tilde{A}$ would be very strong and the "V-Raman line" would be strong. If, on the other hand, the "V-frequency" is slightly higher than 1234 cm^{-1} (as that for 5′-UMP-$^{14}N_2$, d_3) the vibrational coupling in $\tilde{A}$ would be weaker and the "V-Raman line" would be weaker.

The Raman Lines That are in Resonance with the 260 nm Electronic Transition. Raman spectra of β-uridine-5′-phosphoric acid (5′-UMP) in neutral aqueous solution were examined with excitation at 647.1, 514.5, 488.0, 457.9, 363.8, and 351.1 nm (Fig. 3). By the use of the 979 cm^{-1} Raman line (PO_3^{2-} symmetric stretching) as an internal intensity standard, the Raman intensity *versus* excitation frequency relation (excitation profile) has been examined for each of the Raman lines of the uracil residue. From a comparison of such an observed excitation profile with theoretical ones, it was shown[4] (i) that the Raman lines at 1231, 1394, and 1475 cm^{-1} are primarily associated with the absorption band at 260 nm, (ii) that, to the 1680, 1630, and 783 cm^{-1} Raman lines, there are appreciable amounts of contribution from the 260 nm absorption band, but contribution from the 210 nm band or from other bands of shorter wavelengths should also be taken into account, and (iii) that the contribution of the 260 nm transition to the 560 cm^{-1} Raman line is rather small.

A rigorous resonance Raman effect of 5′-UMP was examined with 257 nm excitation[3] (see Fig. 3(e)). It became

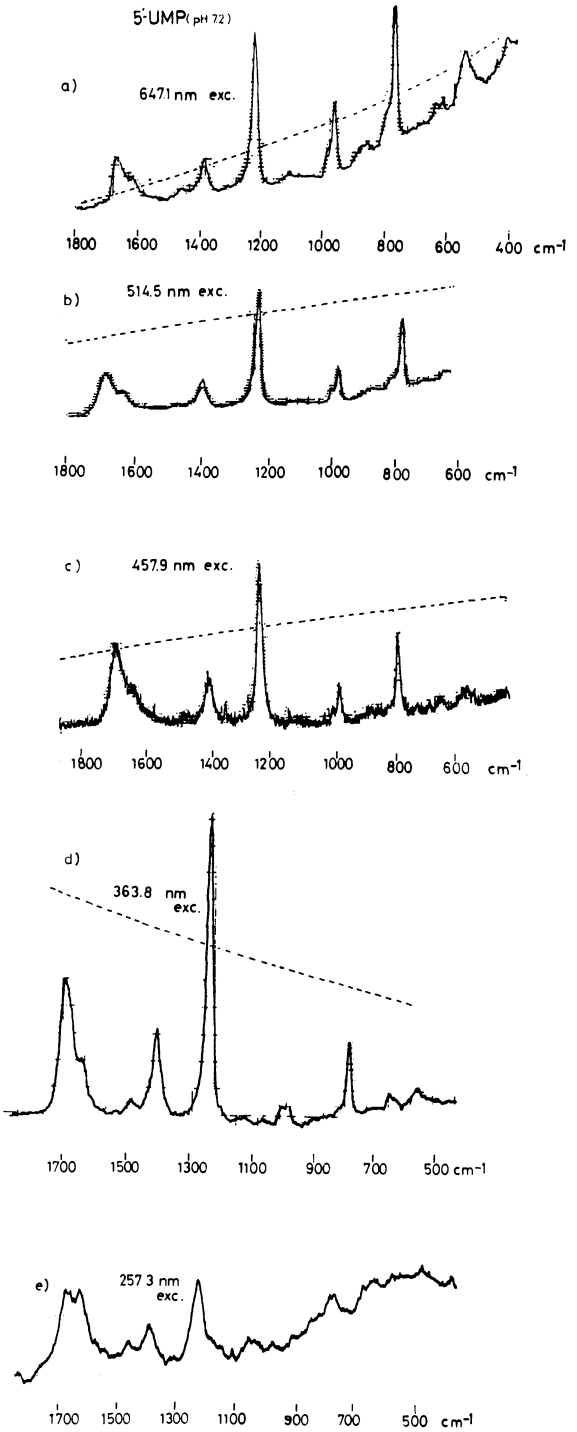

Fig. 3. Raman spectra of 5′-UMP in neutral aqueous solution. Excited by (a) 647.1 nm (Kr), (b) 514.5 nm (Ar), (c) 457.9 nm (Ar), (d) 363.8 nm (Ar), and (e) 257.3 nm (Ar ion laser plus a frequency doubler) lines. Broken lines indicate the spectral sensitivity of the monochromator and detector system.

evident that the six Raman lines at 1680, 1630, 1475, 1395, 1231, and 787 cm^{-1} of the uracil residue are caused by the electronic excited state at 260 nm. Let us call these six Raman lines UrI, UrII, UrIII, UrIV, UrV, and UrVI, respectively.

Characterization of the On-resonance Raman Lines. Pre-resonance and resonance Raman spectra were observed[4] of various related compounds which are considered to be

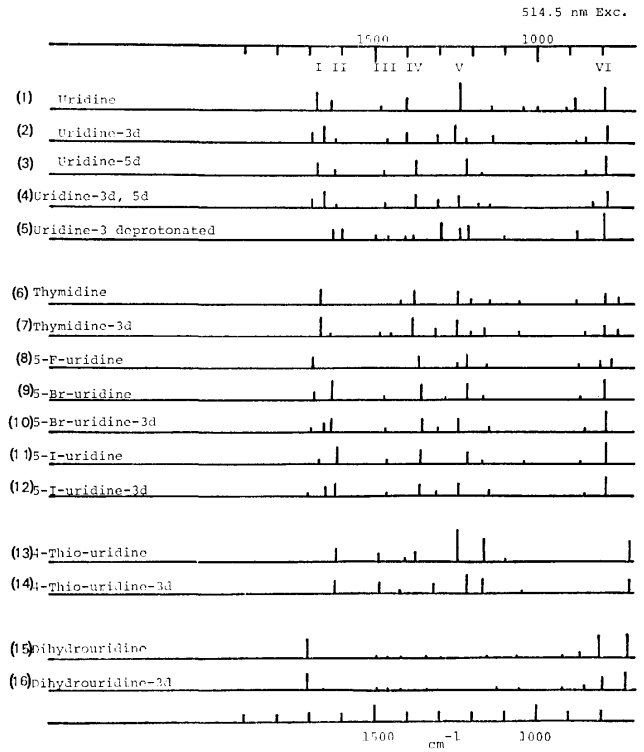

Fig. 4. Raman lines observed for uridine and its derivatives. ^1H is replaced by ^2H at the position indicated.

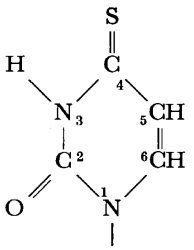
relevant to the interpretation of the Raman spectrum of the uracil residue. Observed Raman lines of uridine and some uridine derivatives are shown in Fig. 4. On the basis of these data, a detailed discussion were given on the Raman lines of the uracil residue in our previous article.[4] Some of the results and conclusions are briefly summerized below:

a) All of the six Raman lines, UrI to UrVI, are in the skeletal-stretching frequency region. All of these Raman lines, except UrIII, are strong in off-resonance condition. In addition, neither position-3 deuteration nor position-5 deuteration causes a wavenumber shift greater than 100 cm^{-1} for any of these Raman lines. Therefore, all of these are assignable primarily to in-plane skeletal bond-stretching vibrations of the neutral uracil residue.

b) The 787 cm^{-1} line is assignable to a vibration in which all eight skeletal stretching motions take place in-phase (ring breathing).[7,8] It is understandable that, while the relative intensity of this line is very strong in an off-resonance Raman spectrum (see Fig. 3(a)), it is very weak in a rigorous resonance Raman spectrum (Fig. 3(e)) excited in the longest wavelength (260 nm) absorption band ($\tilde{A} \leftarrow \tilde{X}$). The distortion of the uracil residue does not take place along such a ring breathing coordinate on going from $\tilde{X}$ to $\tilde{A}$ states.

(c) In the 1600 to 1700 cm^{-1} region there are three skeletal stretching vibrations expected, because of the three double bonds, $C^2=O$, $C^4=O$, and $C^5=C^6$. Actually there are observed three Raman lines (and three infrared bands) for the position-3 deuterated uracil residues (see Fig. 4; (2), (4), (10), and (12)). In each of the Raman spectra of undeuterated uracil residues (Fig. 4; (1), (3), (9), and (11)), however, one of these three is missing. The missing vibration here must be at 1710 cm^{-1}, because the undeuterated uracil residue gives a strong infrared absorption band at 1710 cm^{-1}.[8] This is assignable to the $C^2=O$ stretching vibration.[9] Thus, the UrI and UrII are probably assignable to a coupled pair of the $C^4=O$ stretching and the $C^5=C^6$ stretching vibrations.

(d) An additional support to the assignments of the UrI and UrII Raman lines is obtained from an examination of the Raman spectrum of 4-thiouridine. This is a derivative of uridine in which the position-4 carbonyl is replaced by thiocarbonyl, so that it has residue. In a resonance condition,



this shows six strong Raman lines at 1619, 1482, 1372, 1243, 1160, and 709 cm^{-1}. In the 1600—1700 cm^{-1} region only one Raman line (assignable to UrII) is observed as is expected. The $C^2=O$ stretching line is missing as it is for the uracil residue, and $C^4=O$ is absent here. Instead, there are two strong Raman lines observed at 1167 and 709 cm^{-1}, which are assignable to the two vibrations caused by a strong coupling of the $C^4=S$ stretching and the ring breathing motions. The three lines at 1482, 1372, and 1243 cm^{-1} are considered to correspond to the UrIII, UrIV, and UrV lines of the uracil residue, respectively.

(e) The Raman lines corresponding to the UrIII and UrIV are found at about 1470 and 1400 cm^{-1}, respectively, for all of the uridine derivatives examined (see Fig. 4) except for dihydrouridine. UrV Raman line is also found for all of the uridine derivatives with high intensities. Deuteration at position-3 causes a slight higher frequency shift of this line and at the same time an appearance of a few satellite lines (see Fig. 4; (2), (4), (7), (10), and (12)). A similar effect is caused also by the position-3 deprotonation (Fig. 4, (5)). Position-5 deuteration, on the other hand, causes a slight lower frequency shift of UrV line (Fig. 4, (3)). This is caused also by the position-5 substitution with bromine or iodine (Fig. 4, (9) and (11)).

(f) Dihydrouridine shows a completely different Raman spectrum (Fig. 4, (15) and (16)) from those of the uridine derivatives with $C^5=C^6$ double bond. Here, no strong Raman lines are found in the 900 to 1500 cm^{-1} region. It is clear that the $C^5=C^6$ double bond, which makes the whole six-membered ring nearly conjugated, is essential for giving rise to the UrI—UrV Raman lines (the $C^5=C^6$ double bond is also essential for the 260 nm absorption band).

Normal Modes of Vibration for the On-resonance Raman Lines. A normal coordinate treatment was made for in-plane vibrations of 1-methyl uracil. Here, every hydrogen atom (except that of the methyl group) was taken as a dynamical unit, while the methyl group was assumed as one dynamical unit. The bond lengths and bond angles in the uracil residue were assumed to be equal to those given by a crystallographic study of 1-cyclohexyluracil (Dr. T. Katsura, personal communication). The calculation was carried out using a HITAC 8800/8700 in the Computer Center at the University of Tokyo, and the programs, BGLZ, and LSMA, written by Shimanouchi and his collaborators.[10] In the calculation, a general valence force field was assumed, where all the bond-stretch bond-stretch interaction terms were taken into consideration. The force constants were determined by a trial and error method so that the calculated frequencies were in the best agreement with the observed frequencies. The adjustment of the force constant values was guided by the Jacobian matrix which was

calculated for each trial set of force constants. The adjustment was made by taking the following items into account:

(a) The calculated ^{15}N-shifts should be in the best agreement with the observed shifts (see Table 2).

(b) The observed effects of the position-3 deuteration and position-5 deuteration on the vibrational frequencies should be well reproduced by the calculation. This was achieved by a proper adjustment of the bending force constant values, so as to bring the N^3H in-plane bending vibration to about 1416 cm^{-1},[11] and the C^5H in-plane bending vibration to about 1100 cm^{-1}.

(c) Not only the Raman frequencies of the uracil residue observed in the aqueous solutions of uridine and its derivatives, but also Raman[12,13] and infrared[11] frequencies observed for powder 1-methyluracil are to be taken as a set of data.

(d) Not only the bond-stretch bond-stretch cross terms for adjacent two bonds (let us call "ortho"), but also those for two bonds "next door but one" from each other (meta) and for two bonds two doors away from each other (para) should have appreciable values. Such force constant values were not found to be negligible in a conjugated double-bond system such as benzene.[5]

The final set of force constant values are given in Table 1, and the calculated vibrational frequencies for the undeuterated and deuterated (at position-3) uracil residues are given in Table 2. The agreement between the observed frequencies (also given in Table 2) and the calculated ones are satisfactory. The agreement between the observed and calculated ^{15}N-isotope shifts are also good except for the 1397 (UrIV) line of the undeuterated uracil residue and for the 1689 (C^2=O), 1464 (UrIII), and 1402 cm^{-1} (UrIV) lines of the deuterated uracil residue . In the actually observed ^{15}N shifts, there must be some factors involved, such as anharmonicity, Fermi resonance, and vibrational couplings with the solvent molecules, which were not taken into consideration in our present calculation. It may also be pointed out here that the amount of the ^{15}N-shift of each vibration is extremely sensitive to the amount of the contribution of the N–H in-plane deformation motion to the vibration now in question. This is, however, not always be properly estimated in our present calculation on the basis of a simple harmonic potential function.

In Fig. 5, are depicted the normal modes of vibration calculated on the basis of the set of force constants given in Table 1. This forms one of the main conclusions of our present study. The modes of the UrI—UrVI vibrations now in question may be characterized as follows:

UrI(1680 cm^{-1}). C^4=O stretching and C^5=C^6 stretching vibrations take place in-phase.

UrII (1630 cm^{-1}). C^4=O stretching and C^5=C^6 stretching vibrations take place with 180° phase difference.

UrIII (1475 cm^{-1}). A skeletal stretching vibration which has a similarity to one of the e_{2g} stretching vibrations of benzene at 1584 cm^{-1}.

UrIV (1397 cm^{-1}). A skeletal stretcing vibration which has a similarity to one of the e_{1u} stretching vibrations of benzene at 1485 cm^{-1}.

UrV (1231 cm^{-1}). A skeletal stretching vibration which has a similarity to the b_{2u} vibration of benzene at 1309 cm^{-1} (Kekulé vibration).

UrVI (783 cm^{-1}). All of the eight bonds, C=C, C–C, C–N, and C=O, stretch and contract in-phase (ring breathing vibration).

Excited State Geometry for the 260 nm Band. Among the six on-resonance Raman lines of the uracil residue, three at 1475 (UrIII), 1397 (UrIV), and 1231 cm^{-1} (UrV) are considered to be most intimately associated to the excited electronic state $\tilde{A}$ corresponding to the 260 nm absorption band. Among the vibrational modes for these three Raman lines, a motion in which the C^4–C^5 stretching and C^5=C^6 stretching take place with 180° phase difference is commonly predominant (see Fig. 5). Therefore, it is probable that, on going from the electronic ground state $\tilde{X}$ to the excited state $\tilde{A}$, a distortion of the molecualr conformation takes place along this coordinate; as shown in Fig. 6, the C^5=C^6 bond is probably longer in $\tilde{A}$ than in $\tilde{X}$, while C^4–C^5 is shorter in $\tilde{A}$ than in $\tilde{X}$. This is another main conclusion of our present study.

The conclusion just reached by our Raman spectroscopic investigation is in an agreement with an expectation from

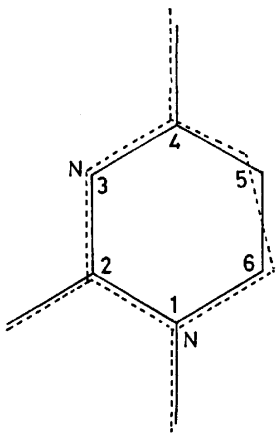

Fig. 6. A schematic drawing to show a possible change in the molecular conformation of the uracil residue on going from the electronic ground state $\tilde{X}$ (shown by full line) to the electronic excited state $\tilde{A}$ (shown by broken line).

theoretical studies on the electronic structure of the uracil residue. Thus, Nagata *et al.*[14] made a semiempirical Pariser-Parr-Pople calculation for the π-electron system of this base residue. This calculation shows that, on going from the highest occupied to the lowest vacant π-orbital, C^5=C^6 bond should change dramatically from *bonding* to *antibonding*, and C^4–C^5 bond should change from *antibonding* to *bonding*, while all other bonds should change only very slightly from *bonding* to *antibonding*. This means that, on going from $\tilde{X}$ to $\tilde{A}$, the bond order of the C^5=C^6 should appreciably decrease, that of the C^4–C^5 should appreciably increase, and those of other bonds should only slightly decrease (see also reference[4]).

Hug and Tinoco[15] made an all-valence electron MO-CI calculation for uracil. It was shown that a marked localization of the monopoles of transitions $\tilde{A}\leftarrow\tilde{X}$ and $\tilde{B}\leftarrow\tilde{X}$ along the acrolein-like fragment O=C^4–C^5=C^6 is expected to take place. For the $\tilde{A}\leftarrow\tilde{X}$ transition, the above view based upon the result of the calculation of Nagata *et al.*[14] is supported by this more elaborate treatment.

We wish to express our thanks to Dr. C. Nagata, National Cancer Center Research Institute, Tokyo, for his kindness in showing an unpublished part of the results of his caluculation and allowing us to use them, and to Dr. S. Nishimura, National Cancer Center Research Institute for his kind instruction in our preparation of ^{15}N-RNA.

(Received December 18, 1978)

The triplet-triplet absorption spectra of [2.2]paracyclophane and related cyclophanes (naphthalenophane, pyrenophane, and anthracenophane) were measured. Cyclophanes in which two component subunits fully overlap, show new bands together with monomer-like bands. The electronic structures of triplet states of these cyclophanes were studied theoretically by the "molecules in molecule" method, special attention being paid to the correlations of the electronic structures of cyclophanes with those of corresponding monomers and also to the dependences of the charge transfer interaction upon the overlapping between the component subunits and upon the molecular size.

[2.2]Paracyclophane and other cyclophanes have the conjugated aromatic rings faced to each other and are of particular importance because of the transannular interaction. [2.2]Paracyclophane is regarded as a model of a benzene dimer; especially in the excited state it is a model of a benzene excimer. Thus the electronic structure of this molecule has been studied by several authors.[1)]

Previously, we investigated the singlet states of [2.2]paracyclophane from both experimental and theoretical points of view.[2)] The near and vacuum ultraviolet absorption spectra were well analyzed by considering the configuration interaction (CI) among the ground, locally excited, and charge transfer configurations.

Hausser *et al.* showed in their ODMR (optical detection of magnetic resonance) and ESR studies that in the lowest triplet state, T_1, of cyclophanes which contain two same aromatic molecules two unpaired electrons are rather localized in either ring.[3)] In other words, the charge transfer character is not significant in the lowest triplet state.

In this paper, we have studied the triplet-triplet ($T_n \leftarrow T_1$) absorption spectra of several cyclophanes in order to elucidate the character of the lowest triplet state and higher triplet states, T_n, and also the dependences of the charge transfer interaction upon the ring overlapping and upon the molecular size.

Experimental

Cyclophanes studied here are shown in Fig. 1: [2.2]paracyclophane (PC), *anti*-[2.2](1,4)naphthalenophane (*anti*-NP), *syn*-[2.2](1,4)naphthalenophane (*syn*-NP), [2.2](2,7)-pyrenophane (PyP), *anti*-[2.2](1,4)anthracenophane (*anti*-AP), [2.2](1,4)(9,10)anthracenophane ((1,4)(9,10)-AP), and *syn*-[2.2](1,4)anthracenophane (*syn*-AP). [2.2]Paracyclophane (the Aldrich Chemical Company) was purified by column chromatography and vacuum sublimation. The preparation and purification of other cyclophanes were described previously.[4)]

The $T_n \leftarrow T_1$ absorption spectra of PC, *anti*-NP, *syn*-NP, and PyP were observed at 77 K in 2-methyltetrahydrofuran by an improved "parallel beam method"[5)] in which the exciting light and the monitoring light was set to pass a sample through the same optical path by the use of two sectors synchronized by stepping motors. By setting up the double beam system, the S/N ratio was much improved. Consequently, we could measure the transient spectra with the absorbance less than 0.01. The polarized $T_n \leftarrow T_1$ spectrum of PC was measured by the photoselection method,[6)] two polarizer films being used.

The sensitization method was used for excitation to the triplet states of anthracenophanes since the quantum yields were low for the direct excitation. Biacetyl was added into the sample solution as a triplet sensitizer. Biacetyl was excited with a dye laser pumped with a nitrogen laser at room temperature. Through the energy transfer from triplet biacetyl, anthracenophanes were populated in their T_1 states, and their $T_n \leftarrow T_1$ absorption spectra were measured. The details of the excitation and detection systems used for the measurement were described previously.[7)]

Theoretical

The "molecules in molecule" method was used for the calculation of the energy levels of triplet states of PC in a similar way as for the calculation of singlet states.[2a)]

The energies of the locally excited (LE) configurations for PC were taken to be equal to the observed values of benzene:[8)]

$$E(^3B_{1u}^+) = 3.9\,\text{eV},\ E(^3E_{1u}^\pm) = 4.7\,\text{eV},\ E(^3B_{2u}^-) = 5.6\,\text{eV},$$
$$E(^3E_{2g}^+) = 6.8\,\text{eV},\ E(^3E_{2g}^-) = 9.3\,\text{eV}.$$

The energies of the CT configurations were calculated by the usual method.[9)] The energy, $E_{CT}(i \rightarrow j)$, for the configuration in which one electron transfers from the i-th occupied orbital of one benzene ring to the j-th vacant orbital of the other is given by the following equation:

$$E_{CT}(i \rightarrow j) = I_i - A_j - C_{ij}^{I,II}. \quad (1)$$

Here I_i and A_j are the ionization potential for the i-th orbital and the electron affinity for the j-th orbital, respectively. The Coulombic interaction term, $C_{ij}^{I,II}$, was evaluated with the aid of the Nishimoto-Mataga approximation.[10)]

In actual calculation, I_i and A_j were evaluated by the following equations for the cyclophanes except

‡ Present address: The Institute for Molecular Science, Myodaiji, Okazaki, Aichi 444.

for PC.

$$I_i = I + E_i^+ \quad (2)$$

$$A_j = A - E_j^- \quad (3)$$

Here I and A are the first ionization potential and the electron affinity of an appropriate neutral molecule (naphthalene for naphthalenophane), respectively. E_i^+ and E_j^- are the excitation energies of the corresponding cation and anion determined experimentally,[11] respectively. Since the assignment of spectra has some ambiguity for the benzene cation and anion, Eqs. 2 and 3 are not applicable to PC. Therefore we evaluated I_i and A_j by the following equations:

$$I_i = I + (\varepsilon_{HO} - \varepsilon_i), \quad (4)$$

$$A_j = A - (\varepsilon_j - \varepsilon_{LV}). \quad (5)$$

Here ε_{HO}, ε_{LV}, ε_i, and ε_j are the orbital energies for the highest occupied, lowest vacant, i-th, and j-th orbitals, respectively. They were calculated with the Pariser-Parr-Pople method.[12]

The molecules of *syn*-series, namely, PC, *syn*-NP, PyP, and *syn*-AP belong to the D_{2h} symmetry, and other cyclophanes to the C_{2h} symmetry. The coordinate systems are shown in Fig. 1. In all cyclophanes that belong to D_{2h}, the symmetry of T_1 is $^3B_{2g}$ and the allowed transitions are $^3B_{1u} \leftarrow {}^3B_{2g}$ (x-polarization), $^3A_u \leftarrow {}^3B_{2g}$ (y-polarization), and $^3B_{3u} \leftarrow {}^3B_{2g}$ (z-polarization). In the case of C_{2h}, T_1 is ^3B_g, and the allowed transitions are $^3A_u \leftarrow {}^3B_g$(x,y-polarization) and $^3B_u \leftarrow {}^3B_g$ (z-polarization).

The semi-empirical SCF MO-CI calculation was also made, using MO's calculated by the Pariser-Parr-Pople method.

Results and Discussion

[2.2]*Paracyclophane (PC).* Figure 2 shows the $T_n \leftarrow T_1$ absorption spectrum and its polarization of PC. We found a very weak band at 550 nm and a broad strong band around 330—400 nm. The polarization experiment using the 313 nm light for excitation shows that the strong band consists of two transitions with the polarizations perpendicular to each other. Therefore, three distinct $T_n \leftarrow T_1$ absorption bands were observed for PC. On the other hand, benzene has only two weak $T_n \leftarrow T_1$ transition bands at 430 nm ($^3E_{2g}^+ \leftarrow {}^3B_{1u}^+$)[8b] and at 280 nm ($^3E_{2g}^- \leftarrow {}^3B_{1u}^+$).[8c] The difference in the $T_n \leftarrow T_1$ absorption spectrum between benzene and PC is clearly due to the transannular interaction in the excited triplet states of PC.

In order to analyze the $T_n \leftarrow T_1$ absorption spectra, we performed the semi-empirical SCF MO-CI calculation and the "molecules in molecule" calculation. Figure 3 shows the calculated ("molecules in molecule" method) and observed energy levels of the triplet

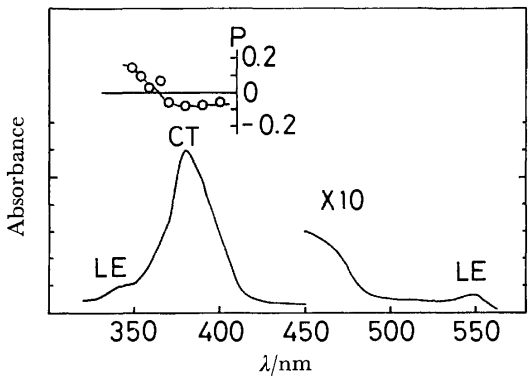

Fig. 2. The $T_n \leftarrow T_1$ absorption spectrum of PC and the polarization, P.

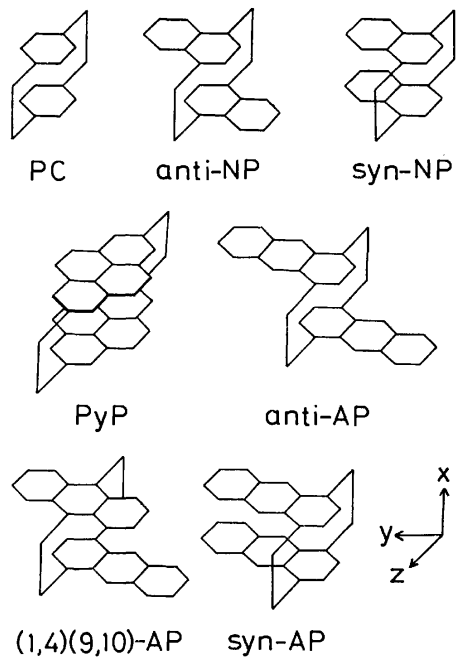

Fig. 1. The molecular structures of PC, *anti*-NP, *syn*-NP, PyP, *anti*-AP, (1,4)(9,10)-AP, and *syn*-AP.

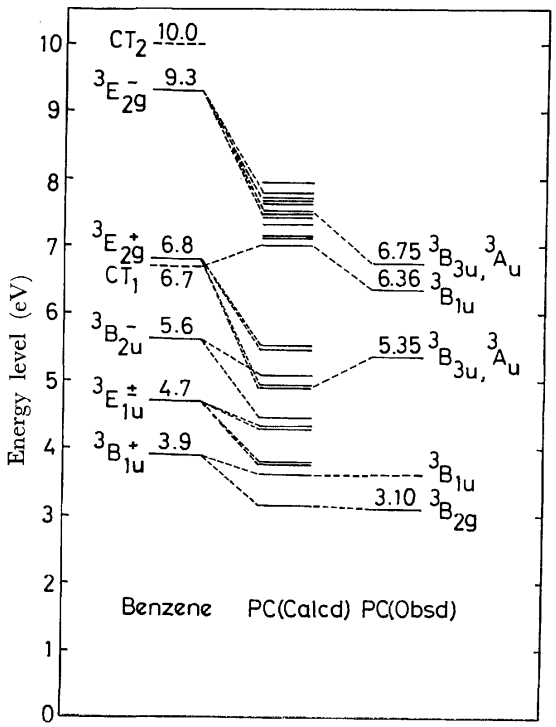

Fig. 3. Observed and calculated energy levels of the triplet states of PC and observed levels of benzene.

states of PC, together with the observed levels of benzene. The zeroth-order LE levels of $^3B_{1u}^-$, $^3E_{1u}^+$, and $^3B_{1u}^+$ of benzene strongly interact with the CT_1 level, and those of $^3E_{2g}^+$ and $^3E_{2g}^-$ with CT_2.

We can see from Fig. 3 that the lowest triplet state of benzene ($^3B_{1u}^+$) is split into two states, $^3B_{2g}$ and $^3B_{1u}$ in PC. The $^3B_{2g}$ state is slightly lower than the $^3B_{1u}$ state and is of the neutral exciton nature. The weight of $^3B_{1u}^+$ of benzene in the T_1 state of PC is more than 80%. Hausser *et al.* recently showed that the zero-field splitting parameter, *D*, of PC is reduced only by 15% with respect to the corresponding monomer, *p*-xylene.[3b] This is consistent with the present result. The present result is also consistent with the result calculated by Hillier *et al.*[1c]

Contrary to the T_1 state, there are no previous studies on higher triplet states. From theoretical consideration we can see that the transitions from the $^3B_{2g}$ state to the $^3B_{3u}$ and ^3A_u states (polarized parallel to the ring), and to the $^3B_{1u}$ state (polarized perpendicularly to the ring) are allowed. These states are shown in Fig. 3. The $^3B_{1u}$ state located at about 7 eV in the column of PC (calcd) is mainly of the CT character. As is clearly seen in this figure, the theoretical study predicts that three bands appear in the observed wavelength region. This prediction agrees well with the experimental result. The semi-empirical SCF MO-CI calculation shows that the intensity ratio of the $T_n \leftarrow T_1$ absorption spectrum is 1 : 0.38 : 0.03 for the $^3B_{1u} \leftarrow {}^3B_{2g}$, ($2^3B_{3u} \leftarrow {}^3B_{2g} + 2^3A_u \leftarrow {}^3B_{2g}$), and ($1^3B_{3u} \leftarrow {}^3B_{2g} + 1^3A_u \leftarrow {}^3B_{2g}$) transitions. With the aid of this intensity ratio together with the calculated and observed transition energies, the three $T_n \leftarrow T_1$ absorption bands are assigned as follows. The most intense band at 380 nm is the CT band ($^3B_{1u} \leftarrow {}^3B_{2g}$) characteristic of the transannular interaction. The band around 340 nm which is polarized perpendicularly to the above CT band, is assigned to the LE band ($2^3B_{3u} \leftarrow {}^3B_{2g} + 2^3A_u \leftarrow {}^3B_{2g}$) and the parentage of this transition is the $^3E_{2g}^- \leftarrow {}^3B_{1u}^+$ transition of benzene. The weak band at 550 nm is ascribed to the LE band ($1^3B_{3u} \leftarrow {}^3B_{2g} + 1^3A_u \leftarrow {}^3B_{2g}$) which comes from the forbidden transition ($^3E_{2g}^+ \leftarrow {}^3B_{1u}^+$) of benzene.

The polarization of the absorption of PC at 313 nm (the excitation wavelength for the measurement of the $T_n \leftarrow T_1$ absorption spectrum of PC) is not clear, since the absorption band in this region consisting of two forbidden transitions, $^1B_{1g} \leftarrow {}^1A_g$ and $^1B_{2g} \leftarrow {}^1A_g$,[2a,13] is only vibrationally allowed. By the polarized absorption spectra of PC crystal measured on the ac plane, the absorbance at 313 nm of the c// spectrum is about twice larger than that of the a// spectrum.[2a] The c axis is parallel to the long axis of the molecule. On the basis of this, the present experiment of the $T_n \leftarrow T_1$ absorption is explained as follows. The degree of polarization, P, is expected to be 1/2 when the $T_n \leftarrow T_1$ transition is polarized parallel to the $S_n \leftarrow S_0$ transition used for excitation, and −1/3 when it is polarized perpendicularly. The band around 380 nm shows the negative value of P. This is consistent with our assignment that the band is the CT band the polarization of which is perpendicular to the benzene plane. In the $T_n \leftarrow T_1$ absorption band around 340 nm, P becomes positive. This indicates that the transition parallel to the $S_n \leftarrow S_0$ excitation is involved in this region.

It is interesting that the CT band was more distinctly observed in the $T_n \leftarrow T_1$ absorption spectrum than in the usual $S_n \leftarrow S_0$ absorption spectrum. This may be because of the weak $T_n \leftarrow T_1$ transition of the component molecule, benzene; that is, the transition localized in one ring is rather weak in the case of PC, and therefore the transition over two rings (CT transition) is observed clearly without the hindrance of LE bands.

anti- *and* syn-*NP*. Figure 4 shows the $T_n \leftarrow T_1$ absorption spectra of *anti*- and *syn*-NP together with that of naphthalene. In the case of naphthalene, the very strong $T_n \leftarrow T_1$ absorption is observed in the visible and ultraviolet regions. The most intense band at 417 nm is known to be polarized parallel to the long axis of the molecule and is assigned to the $^3B_{3g}^- \leftarrow {}^3B_{1u}^+$ transition.[14] The band in the shorter wavelength side is regarded as a vibrational structure. In the $T_n \leftarrow T_1$ absorption spectrum of *anti*-NP, a distinct peak at 447.5 nm was observed but the vibrational structure was not clear. We could not find other bands in the longer wavelength region up to 900 nm. In the spectrum of *syn*-NP, a peak was observed at 465 nm. This is similar to the band of *anti*-NP. In addition, a new broad band was observed around 612.5 nm.

In order to interpret these spectra, the LE and CT levels were also analyzed with the "molecules in molecule" method. The lowest triplet states of *anti*- and *syn*-NP's have mainly a character of T_1 ($^3B_{1u}^+$) of naphthalene. Froines and Hagerman showed that the phosphorescence bands of *anti*- and *syn*-NP shifted

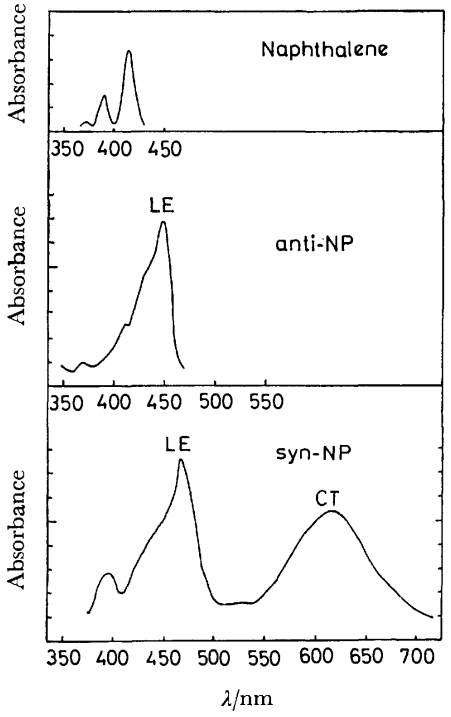

Fig. 4. The $T_n \leftarrow T_1$ absorption spectra of naphthalene, *anti*-NP, and *syn*-NP.

by 1700 cm^{-1} and 2700 cm^{-1}, respectively, to the longer wavelength side from the monomer, 1,4-dimethylnaphthalene, and that the vibrational structures in the phosphorescence spectra of *anti-* and *syn*-NP were rather similar to the monomer's.[15] According to Hausser *et al.* the *D* value of *anti*-NP is reduced by $\approx 10\%$ with respect to 1,4-dimethylnaphthalene.[3a] Therefore, it is concluded that the CT character of T_1 state of NP is small.

Because of the similarity of the spectral shapes, both the $T_n \leftarrow T_1$ absorption bands of *anti*-NP at 447.5 nm and of *syn*-NP at 465 nm are attributed to the LE transitions polarized parallel to the long axes of the molecules. Their parentage is the $^3B_{3g}^- \leftarrow {}^3B_{1u}^+$ transition of naphthalene. On the other hand, we attributed the new band of *syn*-NP around 612.5 nm to the CT band ($^3B_{1u} \leftarrow {}^3B_{2g}$) polarized perpendicularly to the ring plane. The calculated energy levels of the zeroth-order CT states clearly shows that the CT band appears in the longer wavelength side of the LE band at 465 nm. The next problem is why the $T_n \leftarrow T_1$ CT band can be observed in *syn*-NP but not in *anti*-NP. The spacial overlapping of two rings is larger for *syn*-NP than for *anti*-NP. Because of this difference in the overlapping, it is expected that the interaction between the zeroth-order CT level and the zeroth-order lowest triplet LE level is larger for *syn*-NP than for *anti*-NP. This means that absorption intensity of the CT band is larger for *syn*-NP than for *anti*-NP.

Very recently, Subudhi and Lim observed the $T_n \leftarrow T_1$ absorptions of the intramolecular excimers from fluid solutions of di(1-naphthyl)alkanes.[16] The transient absorption spectrum of 1,2-di(1-naphthyl)-ethane observed 150 μs after excitation has a broad band around 470 nm , and the band is continuing up to 600 nm. The band around 470 nm may correspond to our "LE band" observed with *anti-* and *syn*-NP's. Since the LE bands are conceivably rather insensitive to the geometry of the molecule, they are observed at similar positions for *anti-* and *syn*-NP's and also for di(1-naphthyl)alkanes.

Pyrenophane (PyP). The $T_n \leftarrow T_1$ absorption spectra of PyP and pyrene are shown in Fig. 5. In pyrene, the $T_n \leftarrow T_1$ spectrum has a sharp band at 413 nm polarized parallel to the long axis ($^3A_g^- \leftarrow {}^3B_{1u}^+$) and another band at 518 nm polarized parallel to the short axis ($^3B_{3g}^- \leftarrow {}^3B_{1u}^+$).[17] On the other hand, the $T_n \leftarrow T_1$ absorption spectrum of PyP has three bands: a sharp band at 380 nm, a weak band at 480 nm, and a strong band at 625 nm. From the consideration of the spectral shape, the sharp band of PyP can be clearly assigned to the LE band ($^3B_{3u} \leftarrow {}^3B_{2g}$) corresponding to the 413 nm band of pyrene ($^3A_g^- \leftarrow {}^3B_{1u}^+$).

The energy separation between the two absorption peaks of pyrene is about 5000 cm^{-1}, and the separation between the sharp band and the weak band of PyP is 5400 cm^{-1}. Because of this similarity the weak band at 480 nm was assigned to the LE band ($^3A_u \leftarrow {}^3B_{2g}$) corresponding to the 518 nm band of pyrene ($^3B_{3g}^- \leftarrow {}^3B_{1u}^+$). The strong band in the red region can be assigned to the CT transition ($^3B_{1u} \leftarrow {}^3B_{2g}$). It is interesting that the CT band was clearly observed

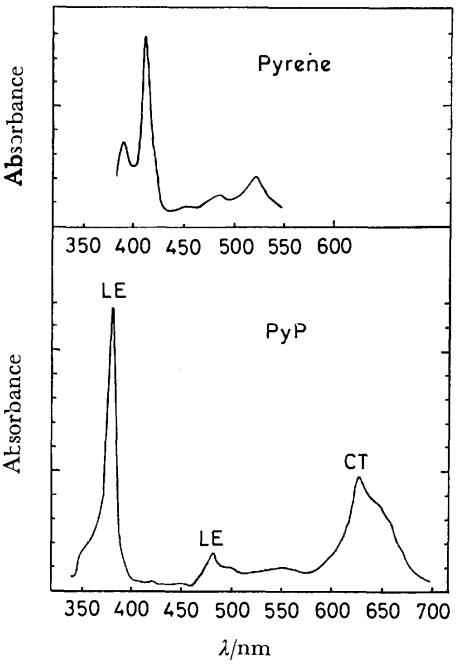

Fig. 5. The $T_n \leftarrow T_1$ absorption spectra of pyrene and PyP.

for PyP as well as for *syn*-NP. This may be due to the whole overlapping of two component subunits.

anti-, *(1,4)(9,10)-, and* syn-*AP.* We measured the $T_n \leftarrow T_1$ absorption spectra of *anti-*, (1,4)(9,10)-, and *syn*-AP by the sensitization method as mentioned in experimental section. The transient spectra observed by the method are confirmed to be the $T_n \leftarrow T_1$ spectra of AP's, since the spectra are quenched by oxygen and the observed rise times of the spectra are

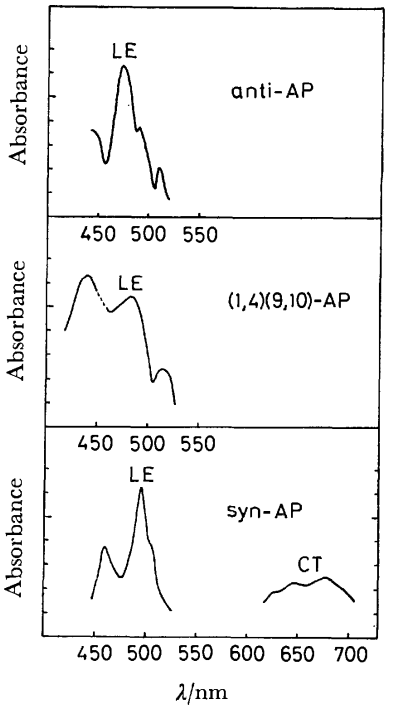

Fig. 6. The $T_n \leftarrow T_1$ absorption spectra of *anti-*, (1,4)-(9,10)-, and *syn*-AP.

well explained in terms of the fact that the related energy transfer process is diffusion controlled. The $T_n \leftarrow T_1$ absorption spectra of *anti*-, (1,4)(9,10)-, and *syn*-AP are shown in Fig. 6. $T_n \leftarrow T_1$ absorption spectra could not be observed for *anti*- and *syn*-AP in the shorter wavelength region than 450 nm, because of the ground state absorption and of scattering of the exciting light.

Anthracene shows the strong $T_n \leftarrow T_1$ absorption band at 425 nm with the polarization parallel to the long axis of the molecule ($^3B_{3g}^- \leftarrow {}^3B_{1u}^+$).[14] Contrary to the cases of NP and PyP, the $T_n \leftarrow T_1$ absorption spectra of AP cannot be interpreted from a simple analogy with the monomer. In *syn*-AP, we found a new band in the red region.

Although it is difficult to assign clearly the bands observed with the three AP's, the strong bands around 500 nm may be due to the LE transition of anthracene, in view of their positions and intensities.

From the calculation of the zeroth-order CT energy level, the CT band is expected to appear for *syn*-AP in the longer wavelength region than the LE band around 500 nm in consistence with the experimental result. The reason why the CT band is observed for *syn*-NP but not for *anti*-NP can be applied to the cases of AP's.

Trend in syn-*Series.* In order to elucidate the dependence of the CT interaction upon the molecular size, the spectra of *syn*-series should be compared. Figure 7 shows the correlation of triplet energy levels of *syn*-series and corresponding monomers. The lower zeroth-order CT levels presented in the columns of monomers interact with the $T_1(^3B_{1u})$ states, and the higher CT with the higher LE ($^3E_{2g}$, $^3B_{3g}$, and ^3A_g). The energy separation between T_1 and CT_1 levels are almost the same in naphthalene, pyrene, and anthracene. In fact, in all of *syn*-NP, PyP, and *syn*-AP spectra the new CT bands are found around 600 nm.

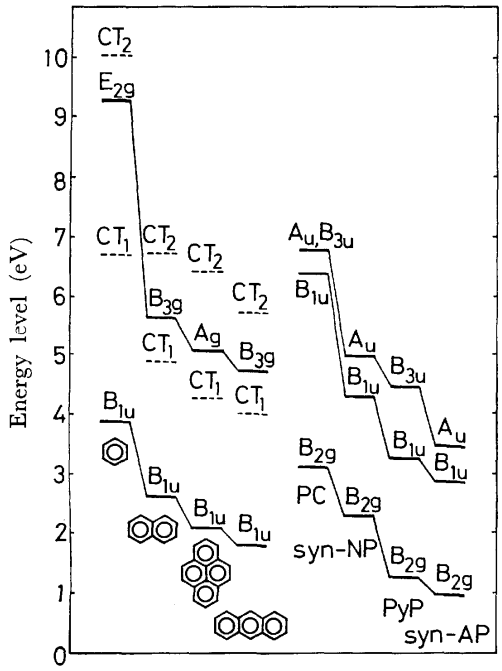

Fig. 7. Energy levels of triplet states of benzene, naphthalene, pyrene, anthracene, PC, *syn*-NP, PyP, and *syn*-AP. The zeroth-order CT levels are also presented in the columns of monomers.

Conclusion

(1) The T_1 states of PC and related compounds are the neutral exciton states.
(2) Higher triplet levels of cyclophanes are well analyzed in terms of the interaction among the zeroth-order LE and CT levels.
(3) CT bands are observed for the *syn*-series : PC, *syn*-NP, PyP, and *syn*-AP in which overlapping between the aromatic rings is large.

The authors should like to express their sincere thanks to Dr. Toshihiko Hoshi, Aoyama Gakuin University, for his kind advice in preparing the polarizer film.

Studies of Inorganic Ion Exchangers. III.[1] Ion Exchange Properties of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ to Alkali Metal and Ammonium Ions

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received April 28, 1978)

In order to develop an inorganic ion exchanger for industrial use, the ion exchange behaviour of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ with alkali metal and ammonium ions has been investigated. The ion exchange capacities of $Ti(HPO_4)_2 \cdot 1/2H_2O$ (hemihydrate) have been determined by forward and backward titration. The saturation ion exchange capacities (Q^A) of the hemihydrate to Li, Na, K, Cs, and NH_4 (M) ions by the forward titration method were 1.9, 3.2, 4.1, 2.5, and 3.7 meq/g at pH 4.5, respectively. The ion exchange capacities (Q°) of the hemihydrate from 0.1 M MCl were 0.31, 1.84, 2.31, 0.21, and 1.01 meq/g to each of the ions. The selectivity quotients (K_H^M) estimated from the Q^A and Q° were 0.028, 3.77, 15.7 0.008, and 0.255 to each of the ions, and the selectivities of the hemihydrate increased in the order $Cs^+ < Li^+ < NH_4^+ < Na^+ < K^+$. The empirical formula of the 50% ion exchange products derived from the hemihydrate may be represented by $TiMH(PO_4)_2 \cdot 0—1/2H_2O$, (where, M=Na, K, and NH_4). The ion exchange of Li and Cs ions did not take place completely however to give a 50% ion exchanger, and the hemihydrate was then converted into a non-stoichiometric compound.

Certain metal oxides, hydroxides, acid salts, heteropolyacids, insoluble hexacyanoferrate (II), and zeolite have been known as inorganic ion exchangers.[2] Zirconium phosphate, as an acid salt of a multivalent metal is useful as an ion exchanger in analytical chemistry.[3] In order to develop an ion exchanger for industrial use, the ion exchange behavior of various phosphates has been investigated.[4,5] Titanium phosphate as an ion exchanger appears promising because of the stability and low price of the raw material. The titanium(IV) bis(hydrogenphosphate) hemihydrate ($Ti(HPO_4)_2 \cdot 1/2H_2O$) has been synthesized by refluxing amorphous titanium(IV) phosphate (ATP) with concentrated phosphoric acid.[6] The X-ray diffraction pattern of the hemihydrate was entirely different from that of the titanium(IV) bis(hydrogenphosphate) monohydrate ($Ti(HPO_4)_2 \cdot H_2O$), known already.[7] It has been reported[6] that the hemihydrate has an ion exchangeability with ions of relatively large ionic radius, such as potassium and cesium. Further, $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ has also been prepared by refluxing a phosphoric acid and a sulfuric acid solution of $TiOSO_4$, which is the intermediate in the industrial process of titanium(IV) dioxide.[1] In the present work, the ion exchange properties of the hemihydrate toward Li, Na, K, Cs, and NH_4 ions have been investigated. Alberti *et al.*[7] examined the ion exchange properties of $Ti(HPO_4)_2 \cdot H_2O$ with Li, Na, and K ions, and Takaguchi and Tomita[8,9] reported the ion exchange behaviour of the monohydrate with Li and Na ions by forward and backward titration. However, no data of the ion exchange reactions of the hemihydrate exist except for the Na, K, and Cs ions as determined previously by the forward titration.[6] Ion exchange characteristics, such as selectivity quotient, degree of absorption and distribution coefficient for the hemihydrate do not exist. The ion exchange behaviour of the hemihydrate towards Li, Na, K, Cs, and NH_4 ions has been observed by forward and backward titration, and the saturation and equilibrium capacities determined. Ion exchange characteristics have been introduced from the relationship between the capacities. The ion exchange characteristics of the monohydrate have also been estimated and contrasted with the hemihydrate. Moreover, the apparently 50%, 100%, and the 50% →H ion exchange products have been examined by X-ray diffraction and chemical analysis.

Experimental

Preparation of Ion Exchanger. Titanium(IV) bis(hydrogenphosphate) were prepared by the methods described previously,[1,6] the conditions for the monohydrate and hemihydrate and the analytical results being summarized in Table 1.

Analysis. Product components, such as P_2O_5, TiO_2, and H_2O were determined by methods previously reported.[6] The M_2O (M=Li, Na, K, Cs) content was derived from the following equation.

$$100\% - (P_2O_5\% + TiO\% + H_2O\%) = M_2O\%$$

The NH_3 content was determined by Kjeldahl's method. The X-ray diffraction patterns were obtained under the conditions reported previously.[6]

pH *Titration Curves.* *Forward Reaction*: The product (Nos. 1 and 2) (0.100 g)portion was placed in a 20 ml stoppered test tube, and the solutions in the proper ratio of 0.1 M MCl to 0.1 M MOH added (10 ml). The contents in the test tube were shaken periodically and the pH of the supernatant liquid measured after 48 h. The forward titration curve was drawn from the relation between the pH and the ion exchange capacity estimated from the mixed ratio of 0.1 M MCl to 0.1 M MOH.

Backward Reaction: 0.5 M MOH solution (40 ml) was gradually added to the product (0.01 mol)(Nos. 1, 2, and 3); the neutralized product was separated from the mother liquor after 48 h, washed with water, and vacuum-dried over phosphorus pentoxide for 24 h. A portion (0.100 g) of the apparently 100% ion exchange product thus obtained was placed in a (10 ml) stoppered test tube, and the solution 10 ml, mixed in the proper ratio of 0.1 M MCl to 0.1 M HCl added. The contents in the test tube were shaken periodically and the pH of the supernatant liquid measured after 48 h. The backward pH titration curve was then drawn from the relation between the pH and the ion exchange capacity.

Dissolution of Ion Exchanger. A portion of the above supernatant liquid (5.00 ml) was taken, and the phosphorus dissolved determined colorimetrically as phosphomolybdenum blue.

Saturation Capacity at pH 4.5 *(Q°, meq/g).* Titanium(IV) bis(hydrogenphosphate) as an ion exchanger is stable

in an acidic aqueous solution up to a pH of 4.5. Therefore, the ion exchange capacity at pH 4.5 on the forward titration curve was determined as the saturation ion exchange capacity.

The Equilibrium Capacity at pH *4.5 (Q^A, meq/g).* The ion exchanger (0.500 g) was mixed with 0.1 M MCl (25 ml) solution in a 50 ml stoppered Erlenmeyer flask and the contents in the flask periodically shaken. After equilibration, a portion of the supernatant liquid(10.00 ml) was titrated potentiometrically with 0.1 M NaOH using a recording auto titrator (Hiranuma Sangyo Co.). The relation between the pH and the volume of 0.1 M NaOH was drawn as the titration curve. In the titration curve, the ion exchange capacity, corresponding to a volume of 0.1 M NaOH consumed at pH 4.5, was determined as the equilibrium ion exchange capacity.

Selectivity Quotient (K_H^M). This was derived as follows.

$$K_H^M = \frac{(M^+)i}{(H^+)i} \cdot \frac{(H^+)s}{(M^+)s} = \frac{Q^A}{Q^\circ - Q^A} \cdot \frac{Q^A}{C - Q^A},$$

where C is the initial amount (2.5 meq) of 0.1 M MCl used for the determination of the equilibrium ion exchange capacity.

Absorption Quantity (A). This was obtained as follows.

$$Q^A/C \cdot 100 = A(\%).$$

Distribution Coefficient (K_D, ml/g). This was obtained from the expression,

$$\{A/(100-A)\} \cdot S/I = K_D,$$

where S is the volume (25 ml) of 0.1 M MCl used for the determination of the equilibrium ion exchange capacity, and I, the weight (0.500 g) of ion exchanger used.

Results and Discussion

The Ion Exchange Behavior of Titanium(IV) Bis(hydrogenphosphate) Dissolution. The ion exchange titration curves of the hemihydrate to alkali metal (Li, Na, K, Cs) and ammonium ions and solubility curves are shown in Figs. 1, 3, 4, 5, and 6.

Lithium Ion: As shown by the forward titration curve in Fig. 1, the ion exchange capacities of the hemihydrate with Li^+ were 1.9 and 3.9 meq/g at pH 4.5 and 7.0, respectively, and these increased linearly

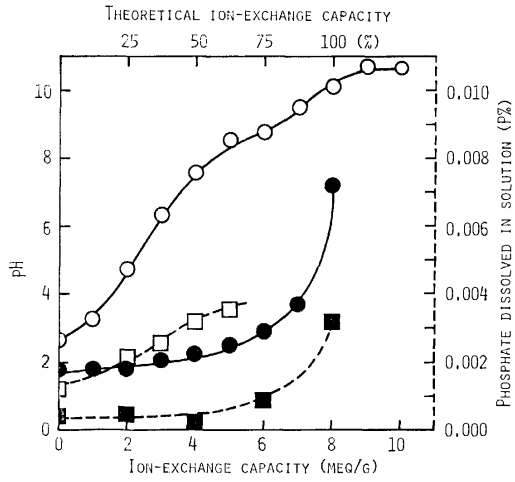

Fig. 1. Li ion-exchange titration curve of and dissolution curve of $Ti(HPO_4)_2 \cdot 1/2H_2O$.

in the pH range 2.6—7. The P dissolved in the aqueous solution from the ion exchanger was 0.001—0.005% at pH 1—5. The forward and backward titration curves showed a hysteresis loop, and it is thought that the apparently 100% Li product used for the backward titration did not sufficiently absorb the Li^+. In the backward titration, the dissolved P was smaller than in the forward titration.

The ion exchange titration curve and the solubility curve of the monohydrate with Li^+ have been reported.[7,8] In contrast to the hemihydrate, the results of re-examination with regard to the monohydrate are shown in Fig. 2. The ion exchange behavior in the forward titration agrees with the previous reports.[7,8] The capacities of the monohydrate were 1.9 and 7.0 meq/g at pH 4.5 and 7.0, respectively. In the range of ion exchange capacities 1—6 meq/g, the pH of the

solution was 4.5—5.0, and then the change of pH slacked up entirely. The P dissolved in the solution at pH 3.8—7.0 was from 0.001—0.006% and the backward titration curve did not agree with the forward titration curve, the P dissolved in the backward titration being about 0.0025%. As reported above, the pH of the solution equilibrated with the hemihydrate for the forward titration increased with an increase in the ion exchange capacity. The pH in the case of the monohydrate did not change as much in the range of ion exchange capacities 0—6 meq/g. The ion exchange capacities of the hemihydrate and monohydrate at pH 5 were 3.5 and 6.0 meq/g, respectively. It is unreasonable that the ion exchange capacity of the hemihydrate, which provides the large spacings recognized by the X-ray diffraction pattern, should be less than that of the monohydrate which provides the small spacings. The explanation may be that an inorganic ion exchanger can absorb the metal ion, excluding part of the water molecules from the hydrated ion at the cavities and then the ion exchange reaction takes place. When the monohydrate is used as the ion exchanger for Li^+, this explanation is reasonable. Approximately 84% of H^+ in the monohydrate exchanged with Li^+. It is well documented that the size of the alkali metal ions is in the order of $Li^+ < Na^+ < K^+ < Cs^+$, though the degree of hydration is the order of $Cs^+ < K^+ < Na^+ < Li^+$, and the Li^+ is hydrated particularly in neutral and alkaline solutions. It is the hemihydrate which provides the cavities through which large ion particles can pass and when it is used

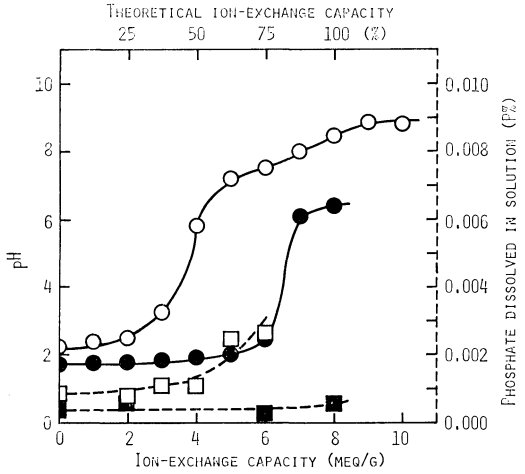

Fig. 6. NH_4 ion-exchange titration curve and dissolution curve of $Ti(HPO_4)_2 \cdot 1/2H_2O$.

as the ion exchanger for Li^+, the fully hydrated Li^+ is adsorbed. Consequently the H^+ in the exchanger largely remains further ion exchange is restricted.

Sodium Ion: The forward titration curve in Fig. 3, indicates the ion exchange capacities of the hemihydrate with Na^+ as 3.2 and 6.6 meq/g at pH 4.5 and 7.0, respectively. The P dissolved in the solution was 0.0015—0.003% in the pH range 2.0—6.5. The behavior of the backward titration curve did not agree with that of the forward titration curve. Therefore, it is assumed that the apparently 100% Na product used as the starting material for the backward titration is in reality an 85% ion exchange product. The P dissolved in the backward titration solution was about 0.0005%, the same as with Li^+ and the ion exchange capacities of the hemihydrate with Na^+ were less than those of the monohydrate (5.8, 7.6 meq/g from Fig. 4 in a previous report[6]) at pH 4.5 and 7.0. This may be explained in terms of the adsorption of hydrated ions as mentioned above.

Potassium Ion: In the forward titration curve in Fig. 4 the ion exchange capacities of the hemihydrate to K^+ were 4.1 and 6.7 meq/g at pH 4.5 and 7.0, respectively. The P dissolved in the solution was about 0.0015% in a pH range 2.0—3.7, and then was increased rapidly at higher pH. A 50% K product corresponding to a composition of $TiKH(PO_4)_2 \cdot 1/2H_2O$ was formed from the aqueous solution at pH 4.5, and was stable in weakly acidic solution. The backward titration curve was similar to that of the forward titration curve. The P dissolved in the solution of backward titration was about 0.0007% below pH 4.5.

Cesium Ion: In the forward titration curve in Fig. 5, the ion exchange capacities of the hemihydrate with Cs^+ were 2.5 and 3.3 meq/g at pH 4.5 and 7.0, respectively. The P dissolved in the solution was 0.001—0.002% in the pH range 2.7—3.5, and the dissolubility of the ion exchanger markedly increased above pH 3.5. The backward titration curve was at a considerable distance from the forward titration curve, the explanation being that an apparently 87% Cs product adsorbs Cs^+ to 35% of the theoretical ion exchange capacity of $Ti(HPO_4)_2 \cdot 1/2H_2O$. Also damage is caused to the exchanger by the alkaline aqueous solution.

Ammonium Ion: In the forward titration curve in Fig. 6, the ion exchange capacities of the hemihydrate to NH_4^+ were 3.7 and 4.8 meq/g at pH 4.5 and 7.0, respectively. The P dissolved in the solution was about 0.001%. An apparently 100% NH_4 product was in reality about 50% ion exchanger. Consequently, the backward titration curve, drawn using this product, was at a considerable distance from the forward titration curve. As seen in the X-ray diffraction pattern of Fig. 9, the apparently 100% NH_4 product changed to an amorphous product by the ammoniacal solution. The hemihydrate however provides wide spacings which can adsorb ions of large ionic radii, such as NH_4^+. Therefore, it may be anticipated that the hemihydrate with prove useful for the exclusion of NH_4^+ in a solution below pH 4.5.

The ion exchange properties of the monohydrate with NH_4^+ have not been investigated, since, the behaviors of ion exchange are examined, and shown in Fig. 7. The radius of the NH_4^+ is larger than that of the Li^+ and Na^+. Therefore, the monohydrate, which provides narrow spacings, does not show ion exchangeability with NH_4^+. Part of the ion exchanger dissolved in the ammoniacal solution, and a considerable change in the structure was observed.

Ion Exchange Characters. The titration curves drawn for the estimation of the equilibrium ion exchange capacity are shown in Fig. 8. The various ion exchange characters of titanium(IV) bis(hydrogenphosphate) to the alkali metals and ammonium ions are summarized in Table 2.

The equilibrium ion exchange capacities (Q^A) of

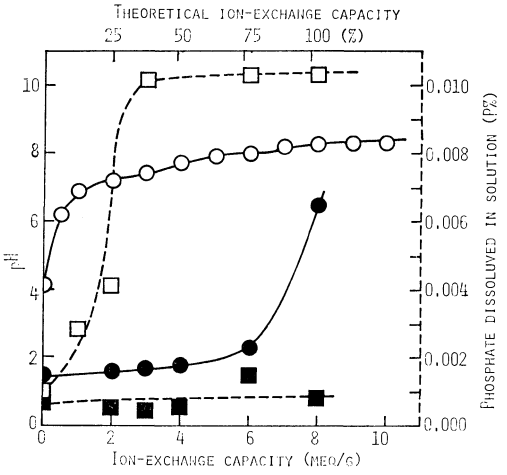

Fig. 7. NH_4 ion-exchange titration curve and dissolution curve of $Ti(HPO_4)_2 \cdot H_2O$.
○: Forward titration, ●: backward titration, □: P released to the external solution on the forward titration, ■: P released to the external solution on the backward titration.

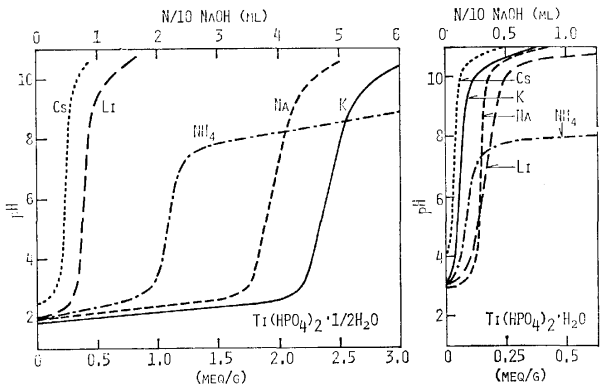

Fig. 8. Titration curves for equilibrium solution of titanium hydrogen phosphate with alkali metal and ammonium chlorides.

the monohydrate with Li^+, Na^+, K^+, Cs^+, and NH_4^+ were 0.025—0.12 meq/g, *i.e.*, the monohydrate hardly adsorbed the above ions in acidic solution at equilibrium. The Q^A of the hemihydrate to NH_4^+, Na^+, and K^+, except for Li^+ and Cs^+, were 1.0, 1.8, and 2.3 meq/g, respectively.

Generally, titanium(IV) bis(hydrogenphosphate) is stable in acid solution below pH 4.5. The saturation ion exchange capacity ($Q°$) of the monohydrate with Na^+ was 5.8 meq/g at pH 4.5. With other ions however, the $Q°$ of the monohydrate was less than 0.6 meq/g. The $Q°$ of the hemihydrate with Li^+, Na^+, K^+, Cs^+, and NH_4^+ was between 1.9—4.1 meq/g.

The selectivity quotients (K_H^M) of the hemihydrate, estimated from the values of Q^A and $Q°$, were 3.77 for Na^+ and 15.7 for K^+. It is thought that the values of K_H^M are significant for the separation of sodium and potassium ions.

The adsorption quantities (A) of the monohydrate for the alkali metal and ammonium ions were less than 5%. However, the A of the hemihydrate increased in the order of $Cs^+<Li^+<NH_4^+<Na^+<K^+$, and exhibited a remarkably high value of 92.4% for K^+.

The distribution coefficients (K_D) of the hemihydrate with Na^+ and K^+ showed remarkably large values. The K_D of K^+ was about 4 times that of K_D for Na^+. Therefore, $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ may be considered as an ion exchanger for the recovery of potassium in sea water and brine.

X-Ray Diffraction Patterns. *Li^+ Exchangers*: A diffraction line of 11.6 Å, which characterized the hemihydrate, disappeared in the pattern of a 50% Li product. Where some lines appeared split in the pattern of the hemihydrate, this disappeared from the pattern of the 50% Li product; *i.e.*, half the diffraction lines decreased. In a previous report,[1] $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ was thought to consist of at least two species and not just one crystallite. The X-ray diffraction pattern of a 50%→H product returned to that of the initial H form. The X-ray diffraction data of an apparently 100% Li product was approximately the same as the 50% Li product, a fact subsequently proved by analysis.

Na^+ Exchanger: The diffraction lines of the hemihydrate at 11.6 and 9.21 Å diasppeared in the 50% Na product. A single diffraction line at 10.2 Å appeared in the 50% Na product. Several lines appeared (in pairs) in the X-ray diffraction pattern of the hemihydrate, but disappeared from the 50% Na product. Therefore, it is assumed that the 50% Na product is a single crystallite. In the 50% Na→H product, the diffraction line at 11.2 Å appeared, and the number of diffraction lines that decreased was greater than in the case of the hemihydrate. The X-ray diffraction data of an apparently 100% Na product was very similar to that of the 50% Na product. The 85% ion exchanger was attacked by the alkaline solution and the intensities of the X-ray diffraction

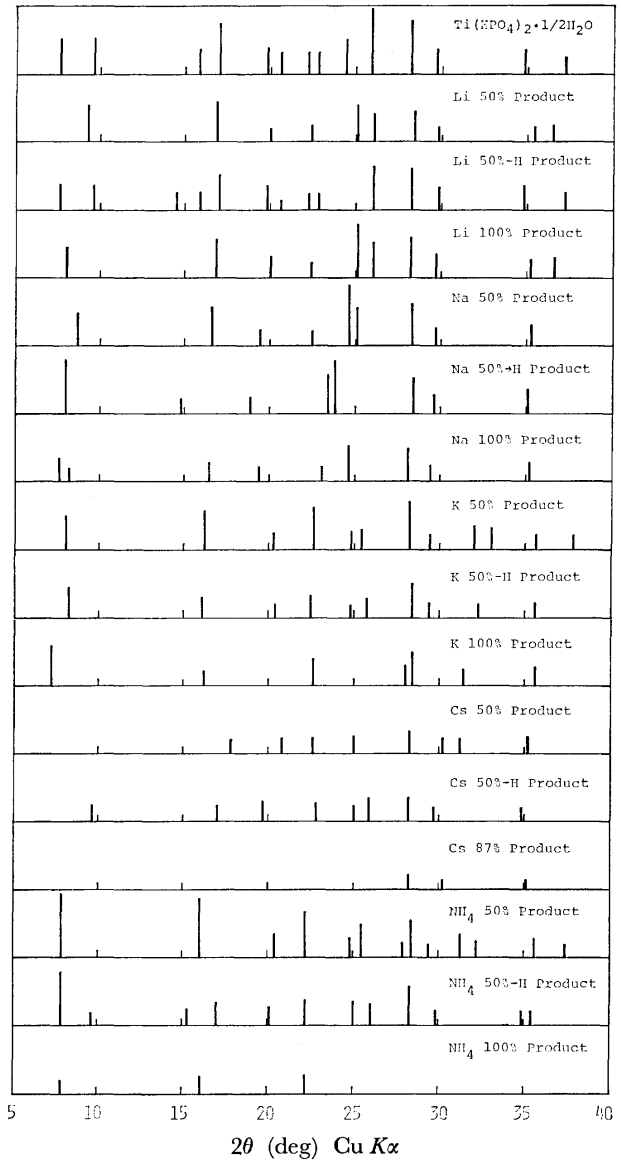

Fig. 9. X-Ray diffraction patterns of titanium hydrogen phosphate and its ion exchange products.

pattern decreased.

K^+ Exchanger: The X-ray diffraction lines at 11.6 and 9.21 Å, which characterized the hemihydrate, disappeared in the X-ray diffraction pattern of the 50% K product. The number of diffraction lines was reduced by a half in contrast with that in the case of the hemihydrate. The diffraction intensities however were increased considirably. As seen in Fig. 4, the 50% K product was in a state of equilibrium with the aqueous solution at pH 4.5. Thus, it is assumed that the composition of this product agrees with that of $TiKH(PO_4)_2 \cdot 0—1/2H_2O$. The X-ray diffraction pattern of a 50% K→H product did not change so much with that of the 50% K product. In an apparently 100% K product, the diffraction line at 12.3 Å reappeared and the intensity of all the diffraction lines increased. As seen in Fig. 4, the apparently 100% K product was in a state of equilibrium with the aqueous solution at pH 7.5. Therefore, it is assumed that the composition of the product agrees with that of $TiK_2(PO_4)_2 \cdot 0—1/2H_2O$.

Cs^+ Exchanger: The 50% Cs product was attacked by the CsOH aqueous solution, and the intensity of the X-ray diffraction pattern decreased. With an apparently 87% Cs product, the ion exchange reaction was not completed, being converted into an amorphous substance.

NH_4^+ Exchanger: In the 50% NH_4 product, the diffraction line at 11.3 Å appeared, and the intensity of all diffraction lines was relatively high. It is assumed from the forward titration curve in Fig. 6 that the product $TiNH_4H(PO_4)_2 \cdot 0—1/2H_2O$, is formed. The diffraction lines at 9.21, 5.21, and 3.42 Å, which characterize the hemihydrate, reappeared in the diffraction pattern of the 50% NH_4→H product. There is the possibility that the product was reconverted to the hemihydrate. The apparently 100% NH_4 product was attacked by the ammoniacal solution, and converted into an amorphous substance.

Composition of the Apparently 50% Ion Exchangers. From the view point of stability, $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ possibly underwent ion exchange to become $TiMH(PO_4)_2 \cdot 0—1/2H_2O$. The conditions for preparation of the 50% products and their analytical results are summarized in Table 4.

From these results, the compositions of the 50% products were estimated as follows; $TiLi_{0.6}H_{1.4}(PO_4)_2 \cdot 1/2H_2O$, $TiNaH(PO_4)_2 \cdot 0.17H_2O$, $TiKH(PO_4)_2 \cdot 0.31H_2O$, $TiNH_4H(PO_4)_2 \cdot 1/2H_2O$, and $Ti_{0.8}Cs_{0.6}H_{2.3}(PO_4)_2 \cdot 0.11H_2O$. As described above, the products of $TiMH(PO_4)_2 \cdot 0—1/2H_2O$ readily obtained by the ion exchange of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ with Na, K, and NH_4 ions respectively. Ion exchange of the hemihydrate with Li or Cs ions, however, brought about conversion of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ to a non-stoichio-

Studies of Inorganic Ion Exchangers. IV.[1] Ion Exchange Equilibrium between Titanium(IV) Bis(hydrogenphosphate) and NaCl–KCl Aqueous Solution

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received July 27, 1978)

In order to develop an inorganic ion exchanger, ion exchange equilibriums between titanium(IV) bis(hydrogenphosphate) and NaCl–KCl aqueous solution have been investigated together with the possibility of separation of Na and K ions. A suitable quantity of $Ti(HPO_4)_2 \cdot H_2O$ (monohydrate), or $Ti(HPO_4)_2$ (anhydrate) was added to a fixed volume of the mixed solution of 0.1 M NaCl with 0.1 M KCl at various ratios. The Na and K ions in the equilibrium solution were determined, and the mole fractions of the ions distributed in the liquid and solid phases estimated. When 0.1 or 0.5 g of the monohydrate were added to 10 ml of each initial solution, the sum of the ion exchange capacities for Na and K ions was approx. 0.1—0.3 meq/g. When 0.1 g of the anhydrate were added to 10 ml of each of the initial solutions, the pH of the final solutions showed values in the range of 1.6—1.9. With the mole fractions of KCl/(NaCl+KCl) above 0.5 in the initial solution, only 2.5—3.5 meq/g of the K ion adsorbed. With an excess (0.5 g exchanger to 10 ml soln) of the anhydrate, all K ions and a part of Na ions were removed together from the solution with the mole fractions of KCl/(NaCl+KCl) being in a range of 0—0.8. The K ion could be effectively separated, when a suitable amount of the anhydrate was added to a solution containing approx. an equimole of NaCl and KCl; however, the elution of K ion with HCl could not be eased by this static method.

Titanium phosphate has been of recent interest as an inorganic ion exchanger similar to zirconium phosphate.[2] In order to develop an ion exchanger for industrial use, titanium(IV) bis(hydrogenphosphate) hemihydrate ($Ti(HPO_4)_2 \cdot 1/2H_2O$) has been synthesized by refluxing amorphous titanium(IV) phosphate with concentrated phosphoric acid.[3] The X-ray diffraction pattern of the hemihydrate differs from that of the titanium(IV) bis(hydrogenphosphate) monohydrate ($Ti(HPO_4)_2 \cdot H_2O$), known already.[4] It has been observed that the hemihydrate has an ion exchangeability toward ions of large size, such as the potassium ion. Further more, $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ was prepared[5] by refluxing concentrated phosphoric acid with a sulfuric acid solution of $TiOSO_4$, the intermediate in the production process of titanium(IV) oxide. In a previous work,[1] the ion exchange properties of the hemihydrate towards alkali metals and ammonium ions have been reported where it was found that the equilibrium ion exchange capacities (Q^A) of the hemihydrate towards Na and K ions were larger than those of the monohydrate, and that the selectivity quotient (K_H^M) and distribution coefficient (K_D) increased in the order $Cs^+ < Li^+ < NH_4^+ < Na^+ < K^+$. This result will aid in the separation of the Na and K ions. In the present work, the ion exchange equilibria between titanium(IV) bis(hydrogenphosphate) and NaCl–KCl aqueous solutions have been examined under various conditions. It has been confirmed that the K ion can be selectively separated from an aqueous solution containing approx. equivalent moles of Na and K ions. In this paper, the experimental data derived will be presented.

Experimental

Preparation of Ion Exchangers. Titanium(IV) bis(hydrogenphosphate) were prepared by the refluxing methods described in previous reports.[3,5] The composition of the monohydrate and hemihydrate, were found as follows: TiO_2, 31.1%; P_2O_5, 54.6%; H_2O, 14.4%; giving an empirical formula of $Ti(HPO_4)_2 \cdot H_2O$. For the hemihydrate: TiO_2, 33.1%; P_2O_5, 58.8%; H_2O, 7.7%; giving the formula as the anhydrous salt, $Ti(HPO_4)_2$.

Ion Exchange Equilibrium and Analysis of Na and K Ions. The ion exchanger (0.100 g) was placed in a 20 ml stoppered test tube, and the initial solution (10 ml), varying in volume ratio of 0.1 M NaCl and 0.1 M KCl added. The contents were shaken periodically and the pH of the supernatant liquid measured after 48 h. A portion of the supernatant liquid (5.00 ml) was taken, and diluted with distilled water to 1000 ml and the Na and K ions determined using a flame photometer at 589 and 768 nm, respectively.

Separation of K Ion from NaCl–KCl Aqueous Solution. The solution mixed in the proper ratio of 0.1 M NaCl and 0.1 M KCl (100 ml) was placed in a 300 ml stoppered Erlenmeyer flask, and to this $Ti(HPO_4)_2$ (2.00 g) was added. The contents of the flask were periodically shaken and the pH of the supernatant liquid and the concentration of Na and K ions determined after 48 h. The ion exchanger was separated from the mother liquor using a centrifugal separator. The adsorbed Na and K ions in the solid phase were eluted with 0.1, 0.5, 1, and 5 M HCl (100 ml) respectively. The K ion in the effluent was determined by flame photometry.

Results and Discussion

Ion Exchange Equilibrium between Titanium(IV) Bis(hydrogenphosphate) and NaCl–KCl Aqueous Solution. When the powder of titanium(IV) bis(hydrogenphosphate) was added to the initial solution varying ratio in volume of 0.1 M NaCl with 0.1 M KCl, the mole fractions of Na and K ions, estimated from the analytical data, are shown in Figs. 1—4.

In No. 1 (Fig. 1), the monohydrate (0.1 g) as ion exchanger was added to the initial solution (10 ml). Consequently, the mole fraction ratios of the Na and K ions in the final solutions were approx. the same as those of the mole fraction of 0.1 M NaCl and 0.1 M KCl in the initial solution at all times and this is indicated by the straight line dividing the L–Na^+ and L–K^+ areas, as seen in Fig. 1. The sum of the mole fractions of the Na and K ions in the solid phase was

0.03—0.04, a value equivalent to the mole fraction of the H^+ in the final solution, corresponding to an ion exchange capacity of 0.3—0.4 meq/g, *i.e.* the ion exchange capacity of the monohydrate was considerably smaller in weakly acid solution (pH 2.2—2.7). In the mole ratio range 1.0—0.8 (NaCl to NaCl+KCl), the Na ion was absorbed together with the K ion in the solid phase. In the mole ratio 0.8—0.0 (NaCl to NaCl+KCl), only the K ion was adsorbed. However, the ion exchange capacity was small as mentioned above.

In No. 2 (Fig. 2), the monohydrate (0.5 g) was added to the initial solution (10 ml). In this case, the sum of the mole fractions of Na and K ions adsorbed in the solid phase was 0.05—0.08. The ion exchange capacity however was 0.10—0.16 meq/g, and decreased more than No. 1. Both Na and K ions were adsorbed in the solid phase regardless of the mole ratio of NaCl with KCl in the initial solution, *i.e.* neither ion could be separated.

In No. 3 (Fig. 3), the anhydrate (0.1 g) as ion exchanger was added to the initial solution (10 ml). The pH of the final solution showed values in the range 1.6—1.9, and this value decreased gradually with increasing mole fraction of potassium chloride in the final solution. The sum of the mole fractions of Na and K ions adsorbed in the solid phase was 0.18—0.38 corresponding to an ion exchange capacity of 1.8—3.8 meq/g, *i.e.* the ion exchange capacity of the anhydrate was 3.6—4.7 times higher than that of the monohydrate. With a mole ratio of NaCl to NaCl+KCl in the initial solution in the range 0.0—0.5, the ion exchange capacities were 2.5—3.8 meq/g and only the K ion was adsorbed. The above results show that the Na and K ions remained considerably in the final solution, although the anhydrate exhibited selective adsorptive behaviour towards the K ion. Consequently, five times the anhydrate in No.4 (Fig. 4) was used compared to No.3. The sum of the mole fractions of Na and K ions in the solid phase was 0.49—0.89, 2.5 times greater than the sum in No. 3. but the ion exchange capacities derived from the mole fractions were 0.98—1.78 meq/g. When the mole ratio of NaCl to NaCl+KCl was 1.0—0.2, all K ions contained in the solution were adsorbed completely. However, at all points of the mole ratio of NaCl to NaCl+KCl, both the Na and K ions were adsorbed into the solid phase,

i.e. it was impossible to separate them. This is the manner in which an excess of ion exchanger is employed toward both ions in the initial solution. Thus, it may be expected from experiments Nos. 3 and 4 that the selective adsorption of the anhydrate towards the K ion is achieved.

Effects of pH *on Ion Exchange Equilibrium.* Generally, the ion exchange capacity of an acid salt as an ion exchanger increased with a rise in pH of the aqueous solution. In a previous work,[1] the equilibrium ion exchange capacities of titanium(IV) bis(hydrogenphosphate) with the alkali metal and ammonium chlorides, and the saturation ion exchange capacities have been estimated. As a direct consequence of this the values of the latter at pH 4.5 were larger than those of the former measured in the acid liberated from the ion exchange. In the present study, the ion exchange equilibrium between $Ti(HPO_4)_2$ and a weak acid-neutral aqueous solution containing the Na and K ions has been examined, the results of which are given in Table 1.

In No. 5 (Table 1), the mole ratio of the sodium and potassium chlorides with the sodium and potassium hydroxides in the initial solution was adjusted to 6 : 4 and consequently the pH values of the initial solutions were about 12.7. On adding the anhydrate to the alkaline aqueous solutions, an ion exchange reaction took place and consequently the pH of the solution dropped to betweeen 4.0 and 5.5. The ion exchange capacities of the anhydrate toward the Na and K ions were 3.4 and 4.2 meq/g at pH 5.5 and 4.0, respectively. The ion exchange capacity toward the K ion did not greatly increase in comparison with that estimated in the acid aqueous solutions of No. 3 (3.8 meq/g).

In No. 6 (Table 1), the mole ratio of the chloride and hydroxide was adjusted to 2 : 8 in the initial solution. The pH values of the initial solutions were about 13.0. When anhydrate was added to the alkaline aqueous solutions, the pH of the solution changed, lying in the range 7.4—8.1. The ion exchange capacities of the anhydrate toward Na and K ions were 6.4 and 5.8 meq/g, respectively. In the presence of both Na and K ions the sum of the ion exchange capacities for both ions was about 6 meq/g in all cases. In that case neither ion could be separated despite the ratio of the Na and K ions in the initial solution.

The ion exchange isotherms for the Na and K ions in Nos. 3, 5, and 6 are shown in Fig. 5.

As reported earlier in No.3, the solutions were acidified by the ion exchange reaction. K ions were adsorbed on the ion exchanger when fractions of K ion in the final solution were in the range of 0.33—1.00 as shown by the isotherm. The ion exchange capacities increased as the pH of the final solution increased. However, it is clear from the isotherms in Nos. 5 and 6 that the separation of Na and K ions using the anhydrate may be progressively more difficult with the increase in pH of the final solution.

Separation of Na^+ with K^+ and Elution of K^+ from Ion Exchanger. From the above results the separation of K ion from a NaCl–KCl solution, such as sea water which contains a small quantity of KCl to NaCl, is

TABLE 2. THE SEPARATION OF Na WITH K IONS FROM THE NaCl-KCl MIXED SOLUTION AND THE ELUTION OF POTASSIUM ION

difficult. However, K ions can be separated in high yield from an aqueous solution containing approx. an equivalent mole of NaCl and KCl, using an appropriate amount of ion exchanger. The separation of both ions using $Ti(HPO_4)_2$ and the elution of K ion are summarized in Table 2.

These experiments confirm that the K ion can be adsorbed in the solid pahse and that most of the Na ions remain in the liquid phase. With hydrochloric acid as the eluate in the static method, the adsorbed K ions were not released completely from the ion exchanger since the selectivity quotient (K_H^M) of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ toward K ion is larger than that of the hemihydrate toward other ions as reported in a previous paper.[1] When $Ti(HPO_4)_2$ was used as the ion exchanger for the separation of K ion, the release of K ion was not smooth. The granulation of $Ti(HPO_4)_2$ and the recovery of K ion by the column method need further study.

(Received July 17, 1978)

Tris(1,3-diphenyl-1,3-propanedionato)germanium(IV) $[Ge(bzbz)_3]^+$ was prepared as crystalline perchlorate, and resolved by the crystallization of its salt with hydrogen (*R,R*)-*O,O*-dibenzoyltartrate. The patterns of UV and circular dichroism spectra are very similar to those of $[Si(bzbz)_3]ClO_4$. The racemization of the *Δ*-$[Ge(bzbz)_3]ClO_4$ was studied kinetically in acetonitrile at 40—60 °C to find the rate law: Rate$=k_{rac}$[complex], where $k_{rac}=9.86\times10^{-5}$ s^{-1} at 50 °C. The activation parameters ($\Delta H^*=99\pm2$ kJ mol^{-1} and $\Delta S^*=-17\pm2$ J K^{-1} mol^{-1}) are very similar to those of tris(acetylacetonato)germanium(IV) complex. Compared with the rate of ligand isotopic exchange, the racemization should proceed *via* intramolecular mechanism. The steric effect coming from the substituents on the chelate ring should play an important role in determining the racemization rate.

We had studied the kinetics of racemization and ligand isotopic exchange of tris(acetylacetonato)germanium(IV) $[Ge(acac)_3]^+$.[1,2] With aims of understanding the detailed processes of the intramolecular racemization of tris(*β*-diketonato)germanium(IV) complex, our study has been extended to tris(1,3-diphenyl-1,3-propanedionato)germanium(IV) $[Ge(bzbz)_3]^+$. The pK_a value (K_a; acid dissociation constant) of 1,3-diphenyl-1,3-propanedione (Hbzbz) is greater by ten times than that of acetylacetone, and different electronic and steric effects are expected. This paper deals with the synthesis, the resolution and the kinetics of racemization in acetonitrile of this new complex.

Experimental

Materials. Preparation of $[Ge(bzbz)_3]ClO_4$ and $[Ge(bzbz)_3]Cl$: $[Ge(acac)_3]ClO_4$ was synthesized by the reported procedure.[1] An acetonitrile solution (80 cm^3) of $[Ge(acac)_3]ClO_4$ (2.8 g, 6.0×10^{-3} mol) and Hbzbz (14.8 g, 6.6×10^{-2} mol) was refluxed with stirring at *ca.* 110 °C for *ca.* 120 h, and poured into diethyl ether (500 cm^3). The yellow precipitates were filtered off and recrystallized from acetonitrile by adding diethyl ether. Pale-yellow needles melted at 289 °C with decomposition, and are soluble in acetonitrile, chloroform, acetone, nitromethane and glacial acetic acid. Found: C, 64.10; H, 4.21; Ge (as GeO_2 in ash), 8.85%. Calcd for $C_{45}H_{33}O_{10}ClGe$: C, 64.19; H, 3.95; Ge, 8.62%. The UV absorption spectra in acetonitrile are shown in Fig. 1. The IR absorption pattern in KBr disc is very similar to that of $[Si(bzbz)_3]ClO_4$. ^{1}H-NMR spectra in CD_3CN show phenyl peaks at 8.1—8.2(*ortho*), 7.65(*meta*), 7.5(*para*) ppm and a methine peak at 7.75 ppm *vs.* tetramethylsilane (TMS).

$[Ge(bzbz)_3]Cl$ was prepared by treating $[Ge(bzbz)_3]ClO_4$ with the anion exchange resin Amberlyst A-26 (Cl^--type) in acetonitrile, and crystallized by adding diethyl ether.

Optical Resolution: $[Ge(bzbz)_3]Cl$ (320 mg, 8.5×10^{-4} mol) was dissolved in 56 cm^3 of acetonitrile-acetone (5 : 2), and treated with sodium hydrogen (*R,R*)-*O,O*-dibenzoyltartrate (340 mg, 8.5×10^{-4} mol) in 24 cm^3 of aqueous acetone (5 : 1). Two hundred cm^3 of water was dripped to the solution at a rate of 3 cm^3 per minute with stirring at room temperature to give oily precipitates, which were recrystallized from acetonitrile by adding diethyl ether. A solution of this diastereoisomer (0.8 g, 7.2×10^{-4} mol) and magnesium perchlorate (1.0 g, 4.5×10^{-3} mol) in 60 cm^3 of glacial acetic acid was poured into diethyl ether to give partially resolved, optically active $[Ge(bzbz)_3]ClO_4$, which was collected by filtration. The product was fractionally crystallized from chloroform solution by adding diethyl ether. (yield *ca.* 10%) Circular dichroism spectrum of the partially resolved complex is shown in Fig. 1. (The optical resolution seems to be *ca.* 6% in this case.)

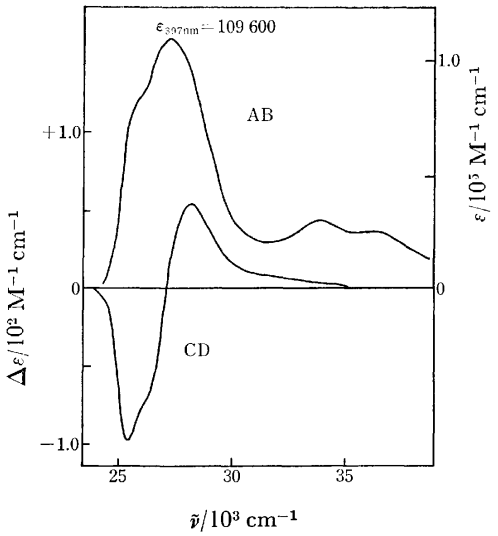

Fig. 1. Ultraviolet absorption (AB) and circular dichroism (CD) spectra of $(-)_{589}$-$[Ge(bzbz)_3]ClO_4$ in acetonitrile.

Other Reagents: Acetonitrile, trichloroacetic acid, pyridine, and tetraethylammonium perchlorate were purified by the ordinary methods. The labelled Hbzbz(Hbzbz[^{14}C]) was prepared by the Claisen condensation between ethyl benzoate[^{14}C] and acetophenone, and purified by recrystallization from ethanol (specific radioactivity; 19.1 mCi/g).

Kinetic Procedure. Racemization: Acetonitrile solution containing the optically active $[Ge(bzbz)_3]ClO_4$, and other reagents whenever necessary, was kept in a thermostatted cell at 40 to 60 °C (±0.1 °C), and the progress of racemization was followed by observing the CD strength at a proper wavelength in the range from 390 to 414 nm. The UV spectra of the reaction mixtures were also recorded before and after the kinetic runs. The water content in the complex solution was determined by Karl Fischer titration.

Isotopic Exchange: The complex and Hbzbz[^{14}C] were dissolved in acetonitrile. Aliquots were sealed in pyrex-glass tubes and placed in a thermostat (60 and 90 °C). The ampoules were chilled one by one at proper time intervals, and the contents were poured into cold diethyl ether. Precipitated $[Ge(bzbz)_3]ClO_4$ was filtered off, dried *in vacuo*, and dissolved in acetonitrile. The solution was divided into two portions. One portion was mixed with *p*-bis(5-phenyl-2-oxazolyl)benzene(POPOP) solution in toluene and the β-activity was counted with a liquid scintillation counter. Another portion was diluted with acetonitrile and the extinction was measured at 377 nm to find the concentration of the complex. The rate of isotopic exchange was calculated on the basis of the change of specific activities of the complex by McKay's formula.[5]

Apparatus. Hitachi 323 Spectrophotometer and JASCO model J-40 Spectropolarimeter were used for recording the UV absorption and CD spectra respectively. The β-activity of ^{14}C was recorded with a Nuclear Chicago Unilux II-A Liquid Scintillation Counter.

Results

The Kinetics of Racemization in Acetonitrile. The logarithm of CD strength decreased linearly with the reaction time. The extinction of UV spectra remained unchanged during several half-lives, and the decrease in CD strength should be due to intrinsic racemization of the complex. The rate was proportional to the complex concentration (5×10^{-6} to 5×10^{-3}M) (Fig. 2), and expressed by the rate law

$$\text{Rate} = k_{obsd}[\text{complex}] = 2k_{rac}[\text{complex}]. \quad (1)$$

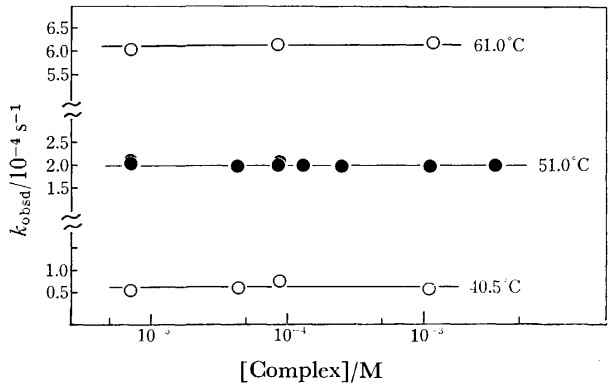

Fig. 2. Influence of the complex concentration upon k_{obsd} in acetonitrile.

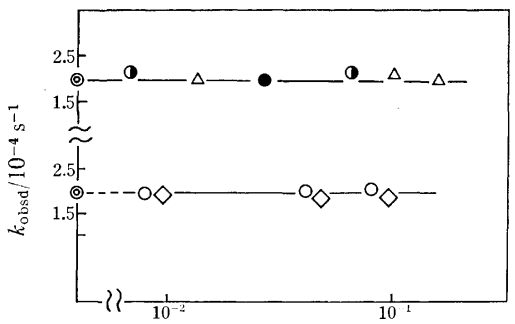

Fig. 3. Influence of water, acid, pyridine, free ligand, and tetraethylammonium perchlorate concentration upon the racemization rate in acetonitrile at 51 °C. △: Water, ◇: trichloroacetic acid, ○: pyridine, ●: dibenzoylmethane, ◑: tetraethylammonium perchlorate, and ◎: without any reagent.

Water (10^{-3} to 10^{-1}M) gave no influence on the racemization rate. (Fig. 3.) Neither did free Hbzbz, trichloroacetic acid, and pyridine in the concentration ranges given in Fig. 3. The rate is insensitive to the ionic strength ($<6.5\times10^{-2}$ mol dm^{-3} by tetraethylammonium perchlorate.) The rate constants and activation parameters are shown in Table 1.

Ligand Isotopic Exchange. Experimental conditions were as follow: $[Ge(bzbz)_3ClO_4]=3.95\times10^{-3}$ M, $[Hbzbz\text{-}^{14}C]=4.97\times10^{-2}$ M, $[H_2O]=3.17\times10^{-2}$ M. No exchange was observed at 60 °C within 1500 min. However, at 90 °C, the ligand exchange was observed and the following rate law was obtained.

$$\text{Rate} = k_{obsd}[\text{complex}],\ k_{obsd} = 2.18\times10^{-8}\ \text{s}^{-1} \quad (2)$$

Discussion

Bond Rupture Mechanism. The results are summarized in Table 1 together with those of the related complexes. The $[Ge(bzbz)_3]^+$ racemizes faster but exchanges the ligand slower than $[Ge(acac)_3]^+$ does. Absence of solvolysis, hydrolysis and ligand isotopic exchange at 40 to 60 °C under the given conditions indicates that the racemization proceeds *via* an intramolecular mechanism. Absence of influence of the concentrations of the complex and the free ligand on the rate also supports this mechanism. The rate

Table 1. Rate constants and activation parameters for the racemization and the ligand isotopic exchange in acetonitrile

was not influenced by water, trichloroacetic acid, pyridine and tetraethylammonium perchlorate. These facts might appear to be consistent with the twist mechanism without bond break throughout the racemization. However, we tend to think that the present racemization proceeds *via* bond break mechanism, by comparing the activation parameters with those of related compounds. Racemization of $[Ge(acac)_3]^+$ was claimed to involve a solvent assisted break of Ge–O bond, on the basis of solvent effect (*i.e.* linear correlation between the racemization rate and the nucleophilicity of the solvents[1]). The ΔH^* and ΔS^* values of the present racemization are very similar to those for the $[Ge(acac)_3]^+$ complex.

Jones and Fay studied the geometrical isomerization of dihalobis(β-diketonato)germanium(IV) in an equimolar mixture of diphenylmethane and 1,3-dimethoxybenzene by the nmr line broadening technique and proposed an intramolecular mechanism involving the break of one Ge–O bond. The activation enthalpy and entropy are respectively 103±6 kJ mol^{-1}, −5±13 J mol^{-1} K^{-1} for $[GeCl_2(dpm)_2]$ (dpm; enolate anion of 2,2,6,6-tetramethyl-3,5-heptanedione). These values are also very similar to ours, and provide support to the postulation that the racemization involves one Ge–O bond break as rate determining step.

$[Ge(bzbz)_3]^+$ with a more basic ligand racemizes faster than $[Ge(acac)_3]^+$. If the racemization rate were governed by the ease of bond break alone, the rate should depend directly on the pK_a of the free ligand. Hence, some other factors must be encountered. The proposed mechanism is visualized in Fig. 4. We studied the racemization kinetics of some tris (β-diketonato)silicon(IV) complexes[3], and found that the $[Si(meacac)_3]^+$(meacac; enolate anion of

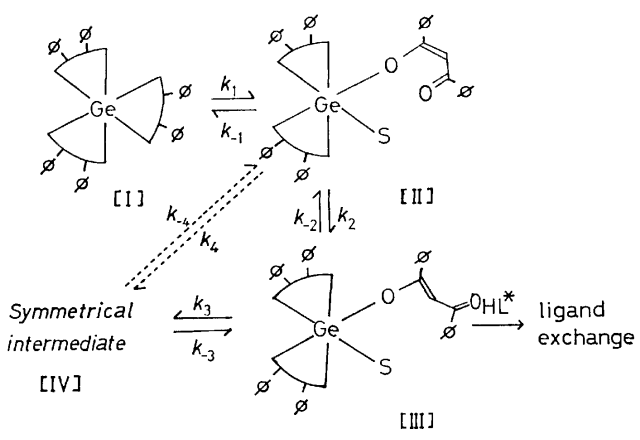

Fig. 4. Racemization mechanism of $[Ge(bzbz)_3]^+$ in acetonitrile.
S; Solvent molecule (acetonitrile). The present kinetics was studied only in acetonitrile because of the solubility, and the role of solvent molecules was not examined. From the analogy to the racemization mechanism of $[Ge(acac)_3]^+$, however, the vacant coordination site formed by the break of one Ge–O bond is likely to be occupied by an acetonitrile molecule (donor number 14.1).[8] HL*; labelled Hbzbz.

3-methyl-2,4-pentanedione)racemizes faster in acetonitrile than $[Si(acac)_3]^+$ does, despite of the larger pK_a of Hmeacac than Hacac. This observation was interpreted by Eq. 3 by considering a mechanism similar to Fig. 4.

$$k_{rac} = k_1 \frac{k_2}{k_{-1}+k_2} \frac{k_3}{k_{-2}+k_3}, \quad (3)$$

where k_1, k_{-1}, k_2, k_{-2}, and k_3 are the rates of Si–O bond break, ring closure, isomerizations of the unidentate ligand (from *cis* to *trans* and *vice versa*) and twist around Si(IV) respectively. The branching ratio $k_2k_3/(k_{-1}+k_2)(k_{-2}+k_3)$ for the meacac complex was considered to be greater than that for the acac complex on the basis of large steric interaction among the methyl groups in the state coresponding to II. A similar interpretation would be applicable to the present racemization, if the branching ratio were greater for the bzbz complex than for the acac complex. This assumption does not seem inadequate because molecular model studies disclose that more repulsive interaction is expected in II around the methine proton for the bzbz complex than for acac complex. However, there remains a possibility that the symmetrical transition state (IV) might be formed directly from II, so that the branching ratio is modified to $k_4/(k_4+k_{-1})$. Nevertheless a steric factor coming from the terminal group must be responsible for the faster racemization of $[Ge(bzbz)_3]^+$ than $[Ge(acac)_3]^+$.

On the other hand, the ligand isotopic exchange of $[Ge(bzbz)_3]^+$ is slower by *ca.* 300 times than of $[Ge(acac)_3]^+$ at 90 °C. On the basis of the ΔS^* value and the deuterium isotopic effect,[2] the isotopic exchange was claimed to be mostly governed by the ease of proton transfer from Hacac* to acac$^-$ in an intermediate of the form $[Ge(O,O\text{-acac})_2(O\text{-acac})(O\text{-acac*}\ H)]^+$. If this mechanism commonly operates in the ligand isotopic exchange of $[Ge(bzbz)_3]^+$, increase in bulkiness of the terminal groups in the ligand will decrease the ease of proton transfer to result in slower isotopic exchange.

The authors wish to thank the Ministry of Education for the Great-in-Aid.

Precise Coulometric Titration of the Potassium Hydrogen Phthalate (NBS-SRM 84d). The Use of the Faraday Constant as an International Standard†

Takayoshi YOSHIMORI* and Tatsuhiko TANAKA

Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 28, 1978)

The purity of the potassium hydrogen phthalate (NBS SRM 84d) was determined by precise coulometric titration. The purity obtained was 99.995±0.002% (standard deviation: 0.003%), and was in excellent agreement with the purities of the same SRM determined already in three laboratories in U.S.A. These results support the recommendation on the use of the Faraday constant as an international standard for titrimetric analysis.

In 1974, the Commission V.5 of the Analytical Chemistry Division of IUPAC recommended the use of the Faraday constant as an international standard for chemical analysis.[1] This recommendation has been partly supported by Yoshimori.[2] He discussed on the relationship between the results of chemical analysis and the basic SI units, and pointed out that the Faraday constant should be used as the international standard for titrimetric analysis. The results of gravimetric analysis are obtainable as the mass fraction by using the masses of a sample and of a precipitate, and usually the atomic weights or the molar masses of the elements concerned should be used. Therefore, the results of gravimetric analysis can directly be referred to the system of SI units (including the values of international atomic weights). There is no opportunity to use the Faraday constant as the standard for gravimetry.

On the other hand, a standard solution in a titrimetric analysis plays only the role which relates the elementary entities in a weighed portion of a standard reference material (SRM) to those of the material to be determined in a sample. Actually, an SRM of 100% purity is not obtainable, and it is nearly impossible to weigh an SRM without any contamination.[2] Therefore, the concentration of a standard solution and the results obtained by using the solution always include, as a factor, the purity of the SRM which was utilized for the standardization.

The SRMs for titrimetric analysis are now produced and certified individually in many countries. Therefore, the results of titrimetric analysis are internationally not unified yet. Thus, the Faraday constant becomes an excellent standard when it is used as the standard for titrimetric analysis.[2] Since 1973, the Faraday constant has been defined as the electricity of one mole of electrons (or protons).[3] Therefore, the purities (as mass fraction) of the SRMs for titrimetric analysis determined by a precise coulometric titration are obtainable from both the values of molar masses and the physical measurements (weight of sample and electricity consumed), and provide the fundamentals of the system of the SI units. Thus, the results of the titrimetric analysis obtained by using the standard solutions which were standardized with such SRMs, may also be referred to the system of the SI units.

† Presented at the 26th International Congress of Pure and Applied Chemistry, Tokyo, Japan, September 1977.

In order to use the Faraday constant as an international standard for titrimetric analysis, the experimental proof is not enough to get the international concensus, though the opinion has theoretically excellent fundamentals. One of the methods to support the use of the constant is to determine the purity of the same and important SRM for titrimetric analysis in collaboration with many laboratories in various countries by the precise coulometry. This paper presents one of such results, namely, the purity of the potassium hydrogen phthalate given by the National Bureau of Standards (SRM 84d) which was already assayed in three laboratories in U.S.A. by the precise coulometric titration.

Experimental

The instruments for the constant-current coulometric generation of hydroxide ion were similar to those shown previously.[4,5] From the certified values of the measuring devices, it is expected that the standard deviation in the measurement of the generating current was not greater than 0.005%. A 50 Hz electronic oscillator based on the frequency of a quartz crystal and a cycle counter were used to measure the time interval of the electrolysis. All weights were corrected against absolute weights. The other apparatus and reagents were the same as those of the previous paper.[5]

The sample was gently crushed in an agate mortar to about 100 mesh, dried at 120 °C for 2 h and cooled in a desiccator containing magnesium perchlorate before weighing. The procedure for the coulometric titration was the same as that of the previous paper.[5] The following values

were used for calculating the results; Faraday constant: 96484.6 C mol^{-1}, molar mass of potassium hydrogen phthalate: 204.223 g mol^{-1}, density of the reagent: 1.64 g cm^{-3}.

Results and Discussion

The results obtained by this investigation on the NBS SRM-84d are given in Table 1. The SRM was first assayed in NBS in 1957[6] by titrimetry based on the purity of the single crystal of benzoic acid, then by the precise coulometric titration in 1959.[7] Eckfeldt and Shaffer[8] and more recently Knoeck and Diehl[9] also analyzed the same sample by the precise coulometry. These laboratories are in U.S.A. and based on the same system of prototypes and standards. Their results are summarized in Table 2 in comparison with the results given in Table 1. The purities shown previously were recalculated by using the latest values of the Faraday constant and the molar masses in 1977 (shown above). The recalculated results are in excellent agreement with the purity obtained by this investigation, though they were based on the different prototypes of weight and electricity between Japan and U.S.A. Therefore, the results in Table 2 can be the fundamental data which support the recommendation on the use of the Faraday constant as an international standard for titrimetric analysis.

The authors express their sincere thanks to Dr. John K. Taylor (U.S. National Bureau of Standards) who supplied them the SRM.

Phase Relation in the System PbO–$PbGeO_3$

Kazushi HIROTA* and Toshimori SEKINE

National Institute for Researches in Inorganic Materials, Sakura-mura, Ibaraki 300-31

(Received August 9, 1978)

Phase relations in the system PbO–$PbGeO_3$ were determined using both the quenching and DTA techniques. Two new lead germanate phases Pb_5GeO_7 and $Pb_{11}Ge_3O_{17}$ were found to be stable. It was found that the Pb_5GeO_7 melts incongruently at 738 °C to PbO plus liquid, whereas the $Pb_{11}Ge_3O_{17}$ decomposes into Pb_5GeO_7 plus Pb_3GeO_5 at 728 °C. The compounds Pb_3GeO_5, $Pb_5Ge_3O_{11}$, and $PbGeO_3$ were identified as congruently melting compounds, in accordance with previous investigations. Some other compounds, such as Pb_6GeO_8, Pb_4GeO_6, and $Pb_3Ge_2O_7$, which have been reported previously could not be confirmed as stable phases.

The PbO–GeO_2 binary system has been studied by Speranskaya,[1] Phillips and Scroger,[2] and Gouju *et al.*[3] There is an almost total disagreement regarding intermediate phases. Speranskaya reports Pb_6GeO_8, Pb_3GeO_5, $Pb_5Ge_3O_{11}$, $PbGeO_3$, and $PbGe_3O_7$ as stable compounds, while Phillips and Scroger list Pb_4GeO_6, $Pb_3Ge_2O_7$, $PbGeO_3$, $PbGe_2O_5$, and $PbGe_4O_9$. Only the compound $PbGeO_3$ is common to the two diagrams. Gouju *et al.* report Pb_3GeO_5, $Pb_3Ge_2O_7$, $PbGeO_3$, and $PbGe_4O_9$ in their phase diagram.

Sugii, *et al.*[4] grew crystals of $PbGeO_3$, and $Pb_5Ge_3O_{11}$ successfully by means of the Czochralski method, but were unable to confirm the existence of $Pb_3Ge_2O_7$. Zwicker *et al.*[5,6] also grew crystals of $Pb_5Ge_3O_{11}$ by the Czochralski method. The prototype structures of $Pb_5Ge_3O_{11}$ and Pb_3GeO_5 were described by Newnham *et al.*[7] and Neurgaonkar *et al.*[8] respectively. These studies on single crystals of $Pb_5Ge_3O_{11}$ and Pb_3GeO_5 agree with Speranskaya's data, but disagree with those of Phillips *et al.* and Gouju *et al.* Contrary to Speranskaya's phase diagram, Pentegova *et al.*[9] have concluded that the $Pb_3Ge_2O_7$ is a stable phase.

The aim of the present study is to examine the discrepancies among these phase diagrams and to establish the phase relations of intermediate compounds in the system PbO–$PbGeO_3$.

Experimental

General Procedure. Two different experimental methods were used in the present investigation: quenching and differential thermal analysis (DTA). In the quenching method, samples were heated at given temperatures until an equilibrium was attained among stable phases. The samples were then quenched rapidly to room temperature and the phases present were determined by electron probe microanalysis, X-ray diffraction, and microscopic examination.

Melting and crystallization temperatures were obtained by means of DTA. Melting temperature of each compound obtained was also ascertained by the quenching method.

Starting Materials. Commercial GeO_2 of purity 99.99% and a purified PbO were used as starting materials. The PbO was prepared from basic lead carbonate. A raw basic lead carbonate was brought into a lead nitrate solution by treating with an equivalent nitric acid. The solution was added with aqueous ammonia to form a small amount of lead hydroxide precipitate. After standing in a water bath for about 10 h, the solution was filtered. The solution was then heated again in a water bath, and an equivalent sulfuric acid was added to it. The precipitate with its mother liquid was heated in a water bath for a day and the volume of the precipitate was allowed to decrease. The precipitate was filtered, washed, and mixed with an excess of ammonium carbonate to bring the precipitate into lead carbonate. The mixture was heated overnight in a water bath, filtered, and washed. The washed precipitate was treated with nitric acid to bring the carbonate into a solution of lead nitrate. The solution was kept again in a water bath for a day and filtered. After that, lead nitrate crystals were allowed to deposit from the filtrate. The lead nitrate was heated at 420 °C in air, and PbO was obtained as product. Only about 10 ppm of Al and Ni were detected in the PbO by means of spectroscopic analysis.

Furnace and Temperature Control. A vertical-tube quench furnace with three heating zones was used for the equilibration runs. About 10 cm length of even heating zone reduced the total variation of temperature of the sample to less than ±0.5 °C. The actual temperature in the furnace was measured with a Pt–PtRh (13%) thermocouple which was calibrated against the melting point of gold. Frequent calibration was necessary because a decrease in emf of the thermocouple was found after a series of runs.

Checking of Equilibration and Quenching Procedures. The approach to equilibrium was studied by X-ray diffraction and microscopy. The quenched samples in the equilibration runs were examined as a function of time. Starting from a mixture of PbO and GeO_2, a complex mixture of more than 3 phases of intermediate compounds was obtained for short runs. Two phases or a single phase was found at equilibrium. The equilibrium was approached closely, for example, after several hundred hours of reaction poriod at about 650 °C. Starting from glasses, metastable crystalline phases were found after short runs.

Liquids of high PbO concentrations could not be quenched to glasses. The presence of a liquid phase, therefore, was evidenced by meniscus formation from the powdered compound in question.

Differential Thermal Analysis. About 2 g of PbO and GeO_2 were mixed and enclosed by welding in a platinum capsule, 6 mm in diameter and 35 mm long. The platinum capsule was mounted in a silver block and heated. The use of the silver block, which resulted in a long zone of even heating, reduced the total variation of temperature within the lead germanate sample to less than 2 °C.

Electron Probe Microanalysis. A mixture of PbO and GeO_2, mixed thoroughly in an agate mortar, was enclosed in a platinum tube by welding and kept at 800 °C for several hours in a vertical tube furnace, and allowed to fall into chilled water. Three kinds of glasses thus obtained and the two pure oxides were used as standards of known compositions to determine the correction factor. The oxide binary has been known to have the following linear relationship for C/K *vs.* C:

$$C/K = \alpha + (1-\alpha)C,$$

where C is the concentration of oxide in weight, K is the background-corrected intensity of characteristic radiation relative to that of the element in the pure oxide, and α is the constant introduced by Bence and Albee.[10] Under the present experimental conditions, *i.e.*, 20 kV accelerating potential and 40° take-off angle, the correction factor α was determined as follows: $\alpha^{Pb}_{GeO_2}=1.50$ and $\alpha^{Ge}_{PbO}=1.54$. Relative deviations of the analysis were determined by replicate analysis and are within ±2% for PbO and GeO_2 respectively.

Results and Discussion

Identification of Phases. The phases present in quenched samples were identified by X-ray diffraction and electron probe microanalysis. Selected results are summarized in Table 1.

Four phases with intermediate compositions were detected between PbO and $PbGeO_3$. These compositions of intermediate phases can be represented approximately by the following formulae: Pb_5GeO_7, $Pb_{11}Ge_3O_{17}$, Pb_3GeO_5, and $Pb_5Ge_3O_{11}$. The latter two, Pb_3GeO_5 and $Pb_5Ge_3O_{11}$ have been reported by Speranskaya. But the former two phases, Pb_5GeO_7 and $Pb_{11}Ge_3O_{17}$, have not been reported yet.

Equilibrium relations are illustrated in Fig. 1. The Pb_5GeO_7 was determined to be stable only between 738 °C and 632±7 °C. The composition of this phase was determined to be 4.9±0.2 in atomic ratio of Pb/Ge. The crystal structure determined by Kato indicates that the site ratio of Pb to Ge in the crystal lattice is equal to 5.[11] These results are consistent with each other within the experimental errors.

The phase $Pb_{11}Ge_3O_{17}$ seems the same compound as "Pb_4GeO_6" reported by Phillips and Scroger. X-Ray diffraction data on Pb_4GeO_6 shown by them could be indexed assuming that the sample was mainly $Pb_{11}Ge_3O_{17}$ mixed with a small amount of Pb_5GeO_7.

The analytical results of this phase ranged from 79.3 to 77.4 mol % PbO; this variation is considered to be within analytical errors. This phase is not regarded as a solid solution but as a compound with a constant composition. Preliminary study of the crystal structure of this compound indicates that there are 14 metal sites in a subunit cell, after Kato.[14] The average atomic ratio Pb/Ge=3.62 and the number of metal sites for this compound indicate the formula of $Pb_{11}Ge_3O_{17}$ (Pb/Ge=3.67) to be the compound with the simplest integral ratio.

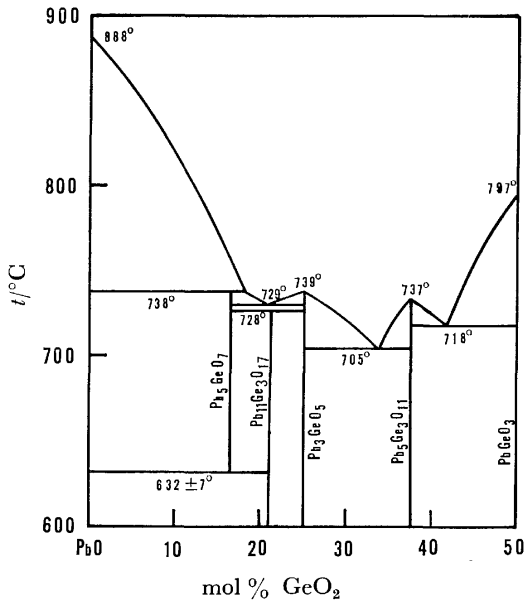

Fig. 1. Phase relations in the system PbO–$PbGeO_3$.

Not Substantiated Compounds. No evidence for the existence of the compounds Pb_6GeO_8 and Pb_2GeO_4 was obtained in this work. Speranskaya has reported Pb_6GeO_8 as stable. It is difficult to determine the chemical composition by means of DTA only, when a compound melts incongruently. The phase Pb_5GeO_7, found in the present investigation, melts incongruently at 738±2 °C, while the Pb_6GeO_8 also has been reported to melt incongruently at 740 °C. It is noteworthy that the temperatures of incongruent melting of the two are in good agreement with each other within experimental errors. The methods adopted to determine the chemical composition of the phase Pb_6GeO_8 were not given.

The phase Pb_2GeO_4 has been reported by Merker *et al.*[12] An X-ray diffraction pattern has been given. But Hasegawa *et al.*[13] have pointed out that this diffraction pattern can be completely indexed by as-

suming that the phase is a mixture of $Pb_5Ge_3O_{11}$ and Pb_3GeO_5.

The stability of a $Pb_3Ge_2O_{11}$ compound could not be substantiated at the temperature range in our experiment. The result is in accordance with Zwicker *et al.* and Sugii *et al.* The congruently melting phase in question is not $Pb_3Ge_2O_7$ but $Pb_5Ge_3O_{11}$. Hasegawa *et al.* have reported that $Pb_3Ge_2O_7$ crystallized from a glass at lower temperatures and transformed to $Pb_5Ge_3O_{11}$ at 489 °C. In the present investigation the presence of a phase with composition $Pb_3Ge_2O_7$ could not be verified at 600 °C, the lowest temperature in our experiment; the product after 1600 h of reaction period was a mixture of $Pb_5Ge_3O_{11}$ and $PbGeO_3$.

It may seem surprising that the three published phase diagrams in the system $PbO-GeO_2$ disagree with one another, and that the existence of compounds such as $Pb_5Ge_3O_{11}$ or Pb_3GeO_5 has been questioned several times. One of the reasons for this is probably due to the presence of metastable phases. Slow cooling of melts tried by Pentegova *et al.*, is not necessarily adequate to investigate the phase relations in the system $PbO-GeO_2$. For example, Zwicker *et al.* have shown that, in the system $PbO-GeO_2$, slow cooling can substantially bring about super-cooling of the melt, and rapid crystallization may form metastable crystalline phases.

In order to assure the equilibrium state in this system, therefore, it is essential to keep the sample at constant temperature and composition for a sufficiently long time, this was tried in the present investigation.

Preparations and Characterization of Cycloruthenated Complexes Derived from 1-Phenylpyrazole, 2-Phenylpyridine, and Benzo[*h*]quinoline

Katsuma HIRAKI,* Yayoi OBAYASHI,† and Yoko OKI

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki, 852

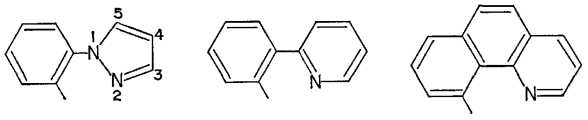
(Received September, 1, 1978)

A pale yellow solution, prepared from $RuCl_3 \cdot 3H_2O$ and carbon monoxide in 2-methoxyethanol, reacted with 1-phenylpyrazole (Hphpz), 2-phenylpyridine (Hphpy), and benzo[*h*]quinoline (Hbzqn) to give new chloro-bridging dinuclear cycloruthenated complexes, $[\{RuCl(C\sim N)(CO)_2\}_2]$ (C∼N=cycloruthenated moiety). These complexes reacted with Tl(acac) (acac=acetylacetonato ligand), γ-picoline (pic), and triphenylphosphine resulting in the break-down of the chloro-bridging bond of the complexes, and afforded new mononuclear cycloruthenated complexes, $[Ru(acac)(C\sim N)(CO)_2]$, $[RuCl(C\sim N)(CO)_2(pic)]$, and $[RuCl(C\sim N)(CO)_n(PPh_3)_{3-n}]$ (n=2 for phpz, and n=1 for phpy and bzqn), respectively. The complexes prepared in this study were characterized by IR, ^{1}H-NMR, and mass spectroscopies.

Recently, cyclometallation reactions have become of interest in view of the stabilization of transition metal–carbon σ bonds[1–3] and of availabilities for the syntheses of heterocycles.[3] Several investigations have been reported concerning cycloruthenation reactions of azobenzene,[2,4–7] polyhaloazobenzene,[2,6] benzo[*h*]quinoline,[8] Schiff bases derived from benzaldehyde,[9] triphenylphosphite,[2,7,10] triphenylphosphine[2,7] and 1,3-di-*p*-tolylimidazolidin-2-ylidene group.[11] These cycloruthenation reactions in most cases were carried out using activated ruthenium species, such as $[\{RuCl_2(CO)_3\}_2]$,[4,9] or alkyl-,[6,7] hydrido-,[10] or zerovalent[5,8,9] ruthenium complexes.

This paper deals with direct and convenient cycloruthenation reactions of 1-phenylpyrazole (Hphpz), 2-phenylpyridine (Hphpy), and benzo[*h*]quinoline (Hbzqn) yielding new chloro-bridging dinuclear cycloruthenated complexes, and with some mononuclear complexes prepared by the bridge-splitting reactions of the dinuclear complexes with thallium acetylacetonate [Tl(acac)], γ-picoline (pic), and triphenylphosphine (PPh_3).

Cyclometallated complexes of Hphpz and Hphpy have been obtained with palladium and rhodium,[1–3] whereas those of Hbzqn have been reported for several transition metals.[1,2]



phpz phpy bzqn

Experimental

Materials. Commercial grade ruthenium(III) chloride trihydrate ($RuCl_3 \cdot 3H_2O$), benzo[*h*]quinoline, and γ-picoline were used without further purification. 1-Phenylpyrazole,[12] 2-phenylpyridine,[13] and Tl(acac)[14] were prepared according to the methods described in the literature. Solvents were dried by usual procedures and distilled.

General Procedures. IR spectra were obtained using a Hitachi 285 grating spectrometer. ^{1}H- and ^{31}P-NMR spectra were run on JEOL model-JNM-MH-100 and -FX-100 spectrometers, respectively. Molecular weights were determined using a JEOL model MS-01SG double-focussing mass spectrometer, referring to parent ion peaks. Melting points were determined on a Yanagimoto MP-S3 microstage apparatus and are uncorrected. All preparative operations were performed in an atmosphere of dry dinitrogen.

Cycloruthenation Reactions of Hphpz, Hphpy, and Hbzqn. Carbon monoxide was bubbled into a 2-methoxyethanol solution (30 ml) of $RuCl_3 \cdot 3H_2O$ (1 g) under refluxing for 6 h to give a yellow solution. An excess amount of Hphpz (2.6 g) was added to the yellow solution, and the mixture was refluxed for 3.5 h. A yellow precipitate was separated and washed with diethyl ether and benzene to afford di-μ-chloro-tetracarbonylbis{2-(1′-pyrazolyl)phenyl-1-*C*,2′-*N*}-diruthenium(II) (**1**) in 60% yield. 2-Phenylpyridine and benzo[*h*]quinoline reacted similarly with the yellow solution to yield $[\{RuCl(phpy)(CO)_2\}_2]$ (**2**) and $[\{RuCl(bzqn)(CO)_2\}_2]$ (**3**), respectively.

*Reactions of **1**, **2**, and **3** with Tl(acac).* Thallium acetylacetonate (0.6 mmol) and **1** (0.3 mmol) in 40 ml of dichloromethane were stirred under refluxing for 7 h and then at ambient temperature for 98 h. After the reaction mixture was filtered and concentrated, hexane was added to the resulting solution. A pale reddish gray solid precipitated and was washed with hexane to give mononuclear acetylacetonatodicarbonyl{2-(1′-pyrazolyl)phenyl(1-*C*,2′-*N*)}ruthenium(II) (**4**) in 45.9% yield.

Complexes **2** and **3** also reacted similarly with Tl(acac) to afford $[Ru(acac)(phpy)(CO)_2]$ (**5**) and $[Ru(acac)(bzqn)(CO)_2]$ (**6**), respectively.

*Reactions of **1**, **2**, and **3** with Triphenylphosphine.* A dichloromethane suspension containing **1** (0.4 mmol) and triphenylphosphine (2.0 mmol) was stirred at room temperature for 22 h. The resulting solution was concentrated, and diethyl ether was added. On standing overnight at 5—6 °C, the mixture yielded a white crystal, which was separated and washed with diethyl ether to give mononuclear dicarbonylchloro{2-(1′-pyrazolyl)phenyl(1-*C*,2′-*N*)}triphenylphosphineruthenium(II)-diethyl ether(2/1) (**7**) in 87.4% yield.

Complexes **2** and **3** also reacted analogously with triphenylphosphine to yield $[RuCl(phpy)(CO)(PPh_3)_2]$ (**8**) and $[RuCl(bzqn)(CO)(PPh_3)_2]$ (**9**), respectively.

*Reactions of **1**, **2**, and **3** with γ-Picoline.* A dichloromethane suspension (40 ml) involving **1** (0.4 mmol) and γ-picoline (2.4 mmol) was stirred at room temperature for 3.5 h. After the concentration of the resultant solution, followed by addition of hexane, an off-white powder precipitated. Recrystallization of the off-white powder from dichloromethane gave a mother liquor and a white granule,

† Present address: Sagamidai-jutaku 3-101, Iwase 531, Matsudo 271,

The evaporation to dryness of the mother liquor, followed by recrystallization from dichloromethane-hexane, afforded a pale gray solid, dicarbonylchloro(γ-picoline){2-(1′-pyrazolyl)phenyl-1-*C*,2′-*N*}ruthenium(II) (**10a**) in 46.9% yield. Three times recrystallizations of the white granule from dichloromethane yielded **10b** (2.9% yield), which was ascribed to an isomer of **10a** by elemental analysis, IR, and ^{1}H-NMR data.

Complex **2** reacted similarly with 4-picoline and gave [RuCl(phpy)(CO)$_2$(pic)] (**11a**) and a slight amount of a mixture consisting of **11a** and a by-product. Attempts to separate the mixture into the components were unsuccessful.

A dichloromethane suspension (25 ml) containing **3** (0.27 mmol) and γ-picoline (0.73 mmol) was refluxed for 4 h and stirred at ambient temperature for 14 h. After the concentration of the resulting solution, addition of hexane yielded a dark yellow microcrystal and a mother liquor. A silica-gel chromatography of a dichloromethane solution of the microcrystal afforded a yellow solid [RuCl(bzqn)(CO)$_2$(pic)] (**12a**). An orange-yellow powder, formed gradually from the mother liquor on cooling, produced an orange yellow solid [{RuCl(bzqn)(CO)(pic)}$_2$] (**12b**) with recrystallization from dichloromethane-hexane.

Results and Discussion

Cycloruthenation Reactions of Hphpz, Hphpy, and Hbzqn. Chatt *et al.*[15] reported that the 2-methoxyethanol solution of $RuCl_3 \cdot 3H_2O$ was refluxed under bubbling carbon monoxide to yield the yellow solution, in which a main ruthenium species was represented by [RuCl$_m$(CO)$_n$].[16] This solution reacted easily with tertiary phosphine or arsine resulting in the formation of complexes, [RuCl$_2$(CO)$_2$L$_2$] (L=a neutral donor ligand).[15] In the present study, the yellow solution reacted also with Hphpz, Hphpy, and Hbzqn under reflux to give the cycloruthenated dinuclear complexes, [{RuCl(C∼N)(CO)$_2$}$_2$] (C∼N=cycloruthenated moiety), **1**, **2**, and **3**, respectively (*vide infra* as for configurations). On the other hand, the preparation of a more carbonylated ruthenium complex, [{RuCl$_2$(CO)$_3$}$_2$], needs higher pressure of carbon monoxide than 10 atm.[17] In consideration of these facts, it seems certain that the main ruthenium species in the yellow solution bears two carbonyl groups, and has a divalent state, not the initial trivalent one, judging from the π-back bonding character of the carbonyl groups. Accordingly, the main ruthenium species is represented by [RuCl$_2$(CO)$_2$S$_2$], where S means a solvent molecule or a chloro ligand. The cycloruthenation reactions are shown by the following equation:

$$[RuCl_2(CO)_2S_2] + 2H(C\sim N) \longrightarrow 1/2[\{RuCl(C\sim N)(CO)_2\}_2] + H_2(C\sim N)\cdot Cl + 2S.$$

These reactions proceed fairly smoothly, and seem to provide a convenient route for the syntheses of the cycloruthenated complexes of the aryl-substituted heterocycles. Driving forces for these reactions are possibly associated both with a basicity of the heterocycles and with a structural factor of the aryl-substituted heterocycles susceptible to the cyclometallation.[1-3,8] Tables 1—3 summarize yields, elemental analyses, and some properties of **1**, **2**, and **3** and their derivatives.

Complexes **1**, **2**, and **3** are stable and insoluble in common organic solvents. Each of these complexes contains terminal carbonyls as shown by IR spectra (Table 2), and has one chlorine atom and four other coordination sites per ruthenium atom, as indicated clearly by the elemental analyses (Table 1). It has been well known that most of divalent ruthenium complexes have a six-coordinated structure,[4,8,9,15,17] and that chlorine atoms serve as bridging ligands to form a dinuclear structure in chlororuthenium(II) complexes.[4,17] On the basis of these considerations, of the high insolubilities, and of reactivities towards a few reagents as stated later, each of **1**, **2**, and **3** was assigned to the dinuclear structure having the chlorine bridges, similarly to [{RuCl(azb)(CO)$_2$}$_2$], (Hazb=azobenzene).[4]

Acetylacetonato and Triphenylphosphine Complexes. The dinuclear complexes **1**, **2**, and **3** reacted with Tl(acac) to afford the mononuclear acetylacetonatoruthenium(II) complexes **4**, **5**, and **6**, respectively.

a) In chloroform solution, unless noted elsewhere. b) In KBr disc. c) Calculated value corresponding to ^{102}Ru is given in parentheses.

Triphenylphosphine also cleaved the chloro-bridging bonds of the dinuclear complexes, giving mononuclear complexes **7**, **8**, and **9**. These complexes are stable in a solid state and soluble in dichloromethane and chloroform. The acetylacetonato complexes decompose slowly in the solution, whereas the triphenylphosphine complexes are stable in the solution, too.

^{1}H-NMR spectrum of **4** (Table 3 and Fig. 1) shows two doublets at δ 7.41 (1H, 5′-H, J=2.5 Hz) and 8.09 (1H, 3′-H, J=2.5 Hz), one triplet at δ 6.49 (1H, 4′-H) and two multiplets at δ 7.6—7.75 (1H) and 6.9—7.4 (3H), in addition to signals characteristic of the acac group. The multiplets differ completely from that of Hphpz, and are due to an *o*-phenylene group of the phpz moiety. As for mass spectrum of **4**, peaks of *m/e* corresponding to ^{102}Ru appeared at 400, 372, 344, 301, 273 and 245, which were ascribable to a parent peak [Ru(acac)(phpz)$(CO)_2$]$^+$, and fragment

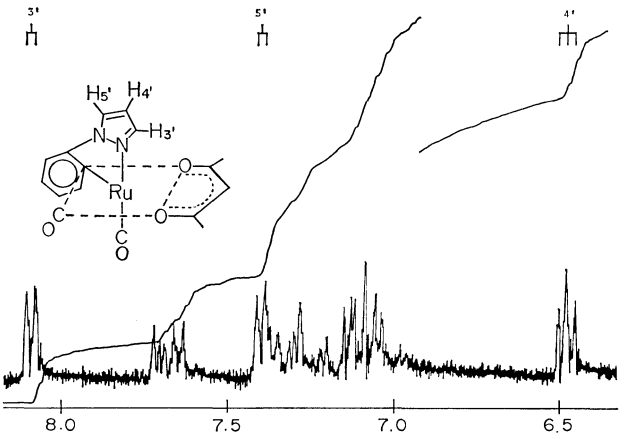

Fig. 1. ^{1}H-NMR spectrum of **4** in CD_2Cl_2 solution (δ-value from TMS).

peaks [Ru(acac)(phpz)(CO)]$^+$, [Ru(acac)(phpz)]$^+$, [Ru(phpz)$(CO)_2$]$^+$, [Ru(phpz)(CO)]$^+$, and [Ru(phpz)]$^+$, respectively. These evidences elucidated unambiguously the cycloruthenated structure of the phpz moiety in **4**. Mass spectrum of **5** gave also a very similar pattern to that of **4**, to which the phpy moiety corresponded in place of the phpz one. This fact and the aromatic proton resonances[18] in ^{1}H-NMR spectrum of **5** indicate analogously the cycloruthenated structure of the phpy moiety in **5**. Complex **6** was similarly ascribed to the cycloruthenated structure on the basis of the ^{1}H-NMR spectrum.[19]

It is noted that **8** and **9** bear two triphenylphosphine ligands and one carbonyl group, while **7** has one triphenylphosphine ligand and two carbonyl groups, similarly to [RuCl(azb)$(CO)_2(PPh_3)$].[4] It is certain that both the phpy and bzqn moieties have a more conjugated skeleton than the phpz and azb moieties. The difference of the skeletal conjugation is probably responsible for that of the substitution of the carbonyl group with triphenylphosphine in these complexes. A proton-decoupled ^{31}P-NMR spectrum of **9** in dichloromethane showed a sharp singlet at 105.20 ppm to upper field from trimethyl phosphite (external standard). This fact proves undoubtedly that two triphenyl-

a) In CD_2Cl_2, unless noted elsewhere. Abbreviations used: s=singlet, d=doublet, t=triplet, q=quartet. b) Acac group. c) Pic group. d) See the text about the *o*-phenylene protons. e) Confirmed by a measurement in $CDCl_3$ solution. f) See the notes 18, 19, and 21 about the aromatic protons of **5**, **6**, and **10b**, respectively. g) In $CDCl_3$. h) Containing CH_2[δ 3.58(q, J=7.0 Hz, 2H)] and CH_3[δ 1.25(t, 3H)] resonances of diethyl ether. i) Overlapping with the *o*-phenylene protons.

phosphine ligands in **9** are located at *trans* positions to each other, but not at *cis* positions, because the two triphenylphosphine ligands at the latter positions would be magnetically unequivalent and result in two ^{31}P resonances. The *trans* configuration of the ligands is presumably due to a steric interaction among the two triphenylphosphine ligands and the chelating bzqn moiety.

Accordingly, two isomers A and B are possible for **9**, as demonstrated in Fig. 2. IR spectrum of this complex exhibits a comparatively low frequency of ν(CO) band. Low stretching frequencies of carbonyl group have been observed for $[RuCl_2(CO)(pyridine)_3]$[20] and $[Ru(azb)(pz_3BH)(CO)]$ (pz=1-pyrazolyl),[4] possessing the carbonyl group *trans* to a nitrogen donor ligand. In consideration of these facts, **9** was ascribed to configuration A, in which the nitrogen donor site was situated at a *trans* position to the carbonyl group. Complex **8** was also associated with the configuration A, from the similarity of the composition and the ν(CO) frequency.

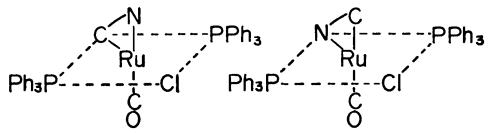

Fig. 2. Possible configurations of the bis(triphenylphosphine) complexes. C∼N=the cycloruthenated moiety.

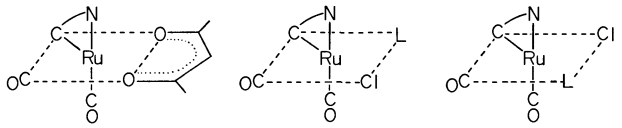

Fig. 3. Possible configurations of the dicarbonyl complexes. L=triphenylphosphine or γ-picoline.

Complexes **4**, **5**, **6**, and **7** show two strong ν(CO) bands near 1978 and 2040 cm^{-1}, revealing a *cis* coordination of the two carbonyl groups. One of the two carbonyl groups is presumably situated at a *trans* position to the nitrogen donor site, analogously to the cases of **8** and **9**, since the coordinations of these ligands are likely to be unaffected by the splitting reactions of the chlorobridging bonds of **1**, **2**, and **3** with Tl(acac) or triphenylphosphine. These discussions lead to proposals that **4**, **5**, and **6** are assignable to configuration C, and that **7** is to configuration D or E (Fig. 3).

γ-Picoline Complexes. γ-Picoline also reacted with **1**, **2**, and **3** to yield corresponding derivatives **10**, **11**, and **12**, respectively. Each of **10** and **12** was separated into a major product **a** and a minor one **b** by means of the repeated recrystallizations. These complexes are stable in a solid state and soluble in dichloromethane and chloroform.

Mononuclear complexes **10a**, **11a**, and **12a** showed very similar ν(CO) bands to those of **4**, **5**, **6**, and **7**, suggesting a similarity among the configurations of these complexes. ^{1}H-NMR spectrum of **10a** contains two multiplets at δ 7.0—7.4 (3H) and 7.7—7.9 (1H) assignable to the *o*-phenylene protons, in addition to γ-picoline and pyrazolyl proton resonances (Table 3), indicating the cycloruthenated structure of the phpz moiety in **10a**. Moreover, ^{1}H-NMR spectrum of **10b**[21] showed lower field γ-picoline proton resonances than that of **10a** did. It is expected that all the protons of γ-picoline *trans* to a carbonyl group are deshielded more strongly owing to a π-back bonding character of the carbonyl group than those of γ-picoline *trans* to the aryl carbon. On the basis of these discussions, **10b** was assigned to configuration D, whereas **10a**, **11a**, and **12a** to configuration E.

Complex **12b** exhibited a medium ν(CO) band at 1923 cm^{-1}, accompanied by very weak bands at 1950, 1975, and 2040 cm^{-1}. Elemental analysis of **12b** reveals that this complex is not an isomer of the main product **12a**, but has one chlorine atom and four other coordination sites per ruthenium atom, similarly to **3**. These data are consistent with a dimeric structure of **12b**, retained even during the reaction of **3** with γ-picoline, although γ-picoline has been regarded as a typical bridge-splitting reagent. Complex **12b** was probably formed by a substitution of two carbonyl groups in **3** with two γ-picoline ligands, in place of the chlorine-bridge splitting reaction. However, further characterization of **12b** was impossible, since its yield was low and irreproducible.

Dinuclear Complexes. All the mononuclear complexes derived from the dinuclear ones **1**, **2**, and **3** had one or two carbonyl ligands, but not more than three. In addition, all the mononuclear dicarbonyl complexes exhibited two strong ν(CO) bands. These facts indicate that each ruthenium atom in the dinuclear complexes is coordinated with two carbonyl groups in a *cis* form, but not in a *trans* form. Accordingly, one of the two carbonyl groups is necessarily located at a *cis* position to the two bridging chlorine atoms. On the basis of these discussions and the conclusion that the nitrogen donor site of the cycloruthenated moiety was situated at the *trans* position to one of the carbonyl groups, as stated above, four isomers are

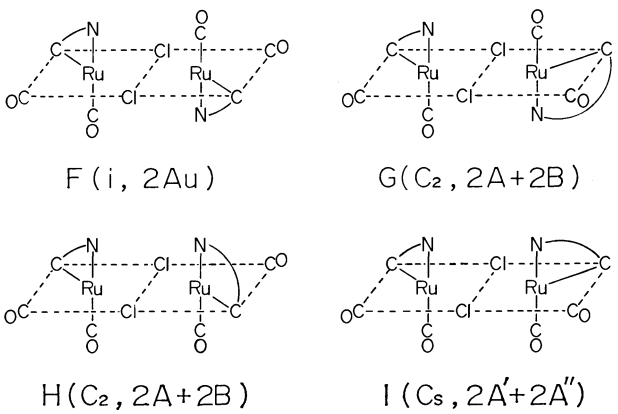

Fig. 4. Possible configurations of the dinuclear complexes. The symmetry and the infrared active mode for the ν(CO) vibrations are given in parenthesis. The cycloruthenated moiety is represented by C∼N.

possible for each of **1**, **2**, and **3**, as depicted in Fig. 4. In Fig. 4, symmetry and an infrared active mode for the carbonyl stretching vibrations are given for each somer.

IR spectrum of **1**, **2**, or **3** shows three strong ν(CO) bands and a few weak ones. In consideration of the steric interaction between the two cycloruthenated moieties, it appears that each of these dinuclear complexes consists of two isomers, F and G. This proposal is reasonable, since all the mononuclear complexes investigated in the present study can be derived by a substitution of the bridging chlorine atoms, and by an additional substitution of one carbonyl group only in the cases of **8** and **9**, from F or G without any rearrangement of the other ligands.

We wish to express our gratitude to Mrs. Hisako Mazume and Miss Yumi Kojima of Nagasaki University for their technical assistances and also to Mr. Toru Hinomoto of Japan Electron Optics Laboratory for the ^{31}P-NMR measurement.

The Absolute Configuration and Circular Dichroism of $(+)_{240}^{CD}$-[(2*S*,7*S*)-2,7-Dimethyl-3,6-diazaoctane-1,8-diamine]platinum(II) Chloride Dihydrate

Yasuji NAKAYAMA, Shun'ichiro OOI,* and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received September 11, 1978)

The title compound was synthesized and characterized by means of absorption, circular dichroism, and its NMR spectra as well as X-ray structure analysis. The crystals are monoclinic, with a $P2_1$ space group, a=9.175(3), b=12.423(5), c=7.434(3) Å, β=108.1(4)°, and Z=2. The structure was determined from the diffractometer data and refined by a least-squares method to R=0.041 for 1732 observed reflections. The Pt atom has an essentially planar coordination with 4 N atoms. The disposition of the four donor atoms is not rectangular, but trapezoidal; it is, moreover, slightly tetrahedral. The quadridentate ligand forms three 5-membered chelate rings with the Pt atom. The two terminal rings are of a δ asymmetric envelope conformation, while the middle ring has a λ symmetric skew conformation. Both of the secondary N atoms possess a R configuration. The complex ion has a pseudo-two-fold axis by which the two terminal rings are related to each other. The circular dichroism spectrum reflects mainly the conformations of the 5-membered chelate rings. The features of the absorption and circular dichroism spectra are discussed on the basis of the geometry of the PtN_4 chromophore.

This work has been undertaken as a part of the investigation into the interrelation between structure and circular dichroism (CD) in the Pt(II) complexes. For the title complex there are three possible isomers, as is shown in Fig. 1, where *RR*, *RS*, and *SS* denote the configurations of the asymmetric nitrogens in each isomer. The information from the PMR spectrum is that the synthesized compound is not a mixture of these isomers, but contains either the *RR*- or the *SS*-isomer. The CD spectrum suggests that the compound consists of the *RR*-isomer, but this is not decisive. Therefore, a single-crystal structure analysis has been performed on the title complex.

Experimental

Preparation of the Compound. The (2*S*,7*S*)-2,7-dimethyl-3,6-diazaoctane-1,8-diamine (=3*S*,8*S*-dimetrien, NH_2CH_2-C*H(CH_3)NH(CH_2)$_2$NHC*H(CH_3)CH_2NH_2) hydrochloride was prepared according to the method described in the literature.[1]

$K_2[PtCl_4]$(3.8 g) and 3*S*,8*S*-dimetrien·4HCl (2.0 g) were dissolved in 50 cm³ of water. The solution was heated at 80 °C, and then a KOH solution (1.4 g in 10 cm³ of water) was added, drop by drop. The precipitate was washed with water and found by analysis to be [Pt(dimetrien)]-[$PtCl_4$].

Found: C, 13.59; H, 3.13; N, 8.01%. Calcd for [Pt-($C_8H_{22}N_4$)][$PtCl_4$]: C, 13.60; H, 3.12; N, 7.93%.

The Magnus-type salt (2.0 g) was dissolved in 2 dm³ of an aqueous $HClO_4$ solution (pH≈3). The resulting solution was passed through an anion-exchange column (Dowex 1X-8) in the chloride form, and the effluent was rotary-evaporated. The single crystals of [Pt(3*S*,8*S*-dimetrien)]Cl_2·$2H_2O$ were subsequently obtained by recrystallization from water–acetone.

Found: C, 20.23; H, 5.57; N, 12.07%. Calcd for [Pt-($C_8H_{22}N_4$)]Cl_2·$2H_2O$: C, 20.16; H, 5.46; N, 11.76%.

Spectral Measurements. The PMR spectrum was recorded at 60 MHz on a JEOL-C-60HL Spectrometer, using DSS as the internal reference. The FT ^{13}C NMR spectrum was obtained at 15.04 MHz with broad-band proton decoupling. Dioxane was used as the internal reference. The values of the chemical shifts in the text have been converted to the TMS scale. The absorption spectrum was measured using a Hitachi EPS-3T Spectrophotometer, while the CD spectrum was recorded on a JASCO J-20 Automatic Recording Spectrometer. In order to protect the asymmetric nitrogens from inversion, samples were dissolved in a 0.01 M DCl solution in the NMR measurements, whereas a 0.03 M HCl solution was used in the absorption and CD measurements.

X-Ray Data Measurement. Crystal Data: C_8Cl_2-$H_{26}N_4O_2Pt$, *F.W.*=476.1, Monoclinic, a=9.175(3), b=12.423(5), c=7.434(3) Å, β=108.1(4)°, U=805.4(5) Å³, D_m=1.93, D_c=1.96 g/cm³, Z=2, μ(Mo $K\alpha$)=94.8 cm^{-1}. The Laue symmetry and approximate unit-cell dimensions were determined from Weissenberg and precission photographs. The unit-cell dimensions were refined by a least-squares analysis of 28 θ values measured on a Philips PW1100 diffractometer.

Data Collection: A unique data set in the $2\theta \leq 55°$ range was collected by a conventional ω-2θ scan method using graphite-monochromated Mo $K\alpha$ radiation. The crystal size was 0.16×0.17×0.19 mm. The scan speed and scan width in ω were 0.017° s^{-1} and (1.0+0.2 tan θ)° respectively. The background was counted for 20 s at each end of the scan range. No significant variations were found in the intensities of three standard reflections menitored every 3 h. A total of 1732 intensities with $I_t - 2\sqrt{I_t} > I_b$ were collected and used for the structure analysis (I_t, intensity at the peak of reflection; I_b, mean background count obtained from preliminary background measurements for 5 s at each side of the peak). Intensity data were corrected for the Lp factors.[2] A spherical absorption correction (r=0.085 mm) was applied.

Structure Determination and Refinement. The crystal structure was solved by the heavy atom method. The positional and thermal parameters were refined by a block-diagonal least-squares method. The minimized function was $\sum w(F_o - |F_c|)^2$. The weighting scheme, w=1.0 for $F_o \leq 96.0$ and $w=(96.0/F_o)^2$ for $F_o > 96.0$, was found to be optimum in order to make $w\Delta F_o^2$ relatively constant over the ranges of F_o. The final R value was 0.041. In the final cycle of refinement all the parameter shifts were less than 0.2σ. The positional and thermal parameters are listed in Table 1.

The atomic scattering factors for all atoms were taken from Ref. 3, with corrections for anomalous scattering for Pt^0 and Cl^-. The absolute crystal structure was determined on the basis of the configuration (*S*) of asymmetric carbons.

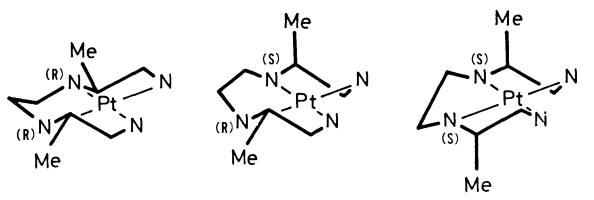
The observed and calculated structure factors are available at the Chemical Society of Japan (Document No. 7916). All the computations were carried out using programs in the UNICS.[4]

Results and Discussion

As is illustrated in Fig. 1, the complex ion may exist in three isomers. In the *RR*-isomer two terminal rings assume a δ conformation, while the middle ring is of a λ conformation, both methyl groups being equatorial with respect to the chelate ring. The *SS*-isomer has a δ middle ring and two λ terminal rings with axial methyl groups. In the *RS*-isomer the middle ring has an envelope conformation, but one of the terminal rings is of a λ conformation and the other is of a δ one. Of the two methyl groups, one is axial, whereas the other is equatorial. Although the *RR*-isomer with equatorial methyl groups seems to be the most probable of the three, the *RS*- and *SS*-isomers should not be left out of account, since, in the planar complex, the methyl group is not always constrained in the equatorial disposition.[5] The *RR*- and *SS*-isomers have a two-fold axis, but the *RS*-isomer has no symmetry.

The PMR spectrum showed one prominent methyl doublet at 1.19 ppm, while four carbon signals appeared at 12.73, 54.94, 56.76, and 61.24 ppm in the ^{13}C NMR spectrum. These observations indicate that the prepared compound is not a mixture of the isomers, but is, rather composed of either the *RR*- or the *SS*-isomer. Since the CD spectrum did not offer data decisive for distinguishing between these isomers, an X-ray structure analysis was performed.



RR *RS* *SS*

Fig. 1. Possible isomers for $(+)^{CD}_{240}$-[Pt(3*S*,8*S*-dimetrien)]$^{2+}$.

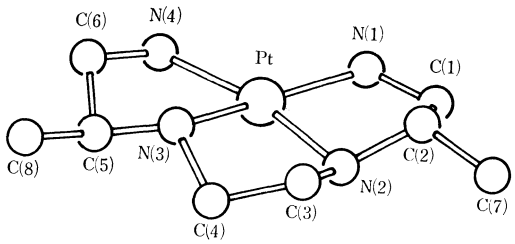


Fig. 2. Structure of $(+)^{CD}_{240}$-[Pt(3*S*,8*S*-dimetrien)]$^{2+}$.

Figure 2 shows a perspective drawing of the complex ion. This structure corresponds to the *RR*-isomer. The ion has an approximate two-fold axis which runs through the Pt atom and bisects the N(1)–Pt–N(4) bond angle. The molecular parameters (Table 2) related by this axis are in good agreement, within the limit of experimental error. In each of the three 5-membered rings, the middle ring is of a symmetric λ skew conformation, while the two terminal rings have an asymmetric δ envelope conformation.

The projection of the complex ion is shown in Fig. 3. The disposition of the 4 N atoms is not square or rectangular, but trapezoidal. Moreover, these atoms are disposed in a slightly tetrahedral configuration around the Pt atom, as may be seen in Fig. 3, where the deviations of atoms from the coordination plane defined by N(1)–N(4) are given in parentheses. Such a trapezoidal disposition of four ligators is usual in the metal chelates of triethylenetetramine (=trien) and its substituted derivatives.[6,7] Although the N(1)–Pt–N(4) angle is considerably larger than 90°, it is comparable to the corresponding angle (104°) in [Pd(trien)] $(PF_6)_2 \cdot KPF_6$.[8] An examination of the scaled model of the complex ion indicates that the slightly tetrahedral disposition of the 4 N atoms results from the conformation of the 3*S*,8*S*-dimetrien ligand, in which both C(*S*)–CH_3 groups are constrained equa-

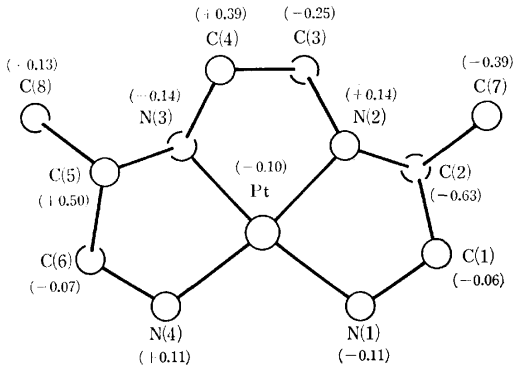

Fig. 3. Projection of $(+)_{240}^{CD}$-[Pt(3*S*,8*S*-dimetrien)]$^{2+}$ on the coordination plane defined by four nitrogen atoms. The deviations (Å) of atoms from the plane are given in parentheses.

torially. Such a disposition seems to be characteristic of the *RR*-isomer. This view is supported by the similar configuration of the 4 N atoms in $(-)_{589}$-*trans*-[Co$(NO_2)_2$(3*S*,8*S*-dimetrien)]ClO_4,[6] in which the dimetrien ligand has the same conformation as the present complex ion.

The Pt–N(secondary) distance seems to be shorter than the Pt–N(primary) distance. Such a tendency was also found in the Pd–N(secondary) and Pd–N(primary) bond lengths in the Pd(II) chelate of trien cited above for comparison. The C(2)–N(2)–C(3) and C(4)–N(3)–C(5) bond angles are significantly larger than the tetrahedral angle. This may be caused by the planar coordination of the quadridentate ligand. The other bond lengths and angles are normal.

Figure 4 shows the crystal structure viewed along the b axis. All amino H atoms participate in the

Roman-numeral superscripts refer to atoms in the following equivalent positions:
I x, y, z; II $1+x, (1/2)+y, z$; III $1+x, (1/2)+y, 1+z$; IV $x, (1/2)+y, z$; V $x, -(1/2)+y, z$; VI $-1+x, y, z$; VII $1+x, -1+y, z$; VIII $x, -(1/2)+y, 1+z$

a) The positions of the H atoms in the NH_2 groups were calculated on the assumption that the N-H distance is 1.03 Å.

N–H···Cl^- or N–H···O(H_2O) hydrogen bonding, the data of which are presented in Table 3.

The absorption and CD spectra are presented in Fig. 5. The electronic spectrum shows three bands, at 35000, 41000, and 44200 cm^{-1}. The peak positions are very similar to those in [Pt$(NH_3)_2$ (*RR*-chxn or *R*-pn)]Cl_2 and in [Pt(*RR*-chxn or *R*-pn)$_2$]Cl_2;[9] hence these peaks can be assigned to the $^1A_1 \rightarrow {}^3A_2$ and ^3E, $^1A_1 \rightarrow {}^1A_2$, and $^1A_1 \rightarrow {}^1E$ transitions (D_4 symmetry), respectively (*RR*-chxn = (1*R*,2*R*)-1,2-cyclohexanediamine; *R*-pn = (*R*)-1,2-propanediamine). However, the absorption is generally more intense than those in the chxn and pn complexes. Similarly, the absorption intensity in [Pd(trien)]$^{2+}$ was found to be about three times as intense as that in [Pd(*R*-pn)$_2$]$^{2+}$.[8] The disposition of the 4 N donor atoms is rectangular in [Pt(*R*-pn)$_2$]$^{2+}$;[5] this may also be the case in [Pd(*R*-pn)$_2$]$^{2+}$ and in the Pt(II) chelates of chxn, whereas the disposition is trapezoidal in the 3*S*,8*S*-dimetrien and trien complexes. The PtN_4 and PdN_4 chromophores in the last two complexes lack a center of symmetry, which may be responsible for the enhancement of the absorp-

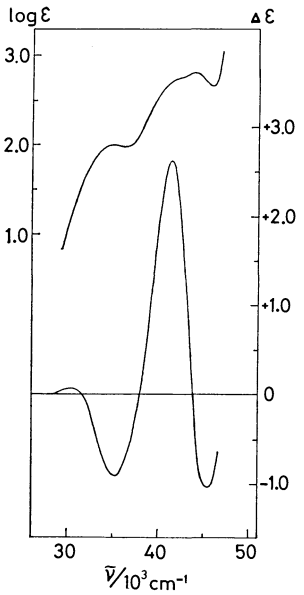

Fig. 5. Absorption (top) and CD (bottom) spectra of $(+)^{CD}_{240}$-[Pt(3*S*,8*S*-dimetrien)]$Cl_2 \cdot 2H_2O$

tion intensity. The enhancement is largest in the $^1A_1 \rightarrow {}^1A_2$ ($d_{xy} \rightarrow d_{x^2-y^2}$) transition. This is compatible with the interpretation of the intensity enhancement, because the electronic transition within the coordination plane should be the most sensitive to the disposition of donor atoms in the plane.

The d→d optical activity of the present complex could be regarded as composed of the contributions from the vicinal effects of the dissymmetric 5-membered rings and that of the asymmetric secondary nitrogen. The second effect may be small in magnitude, since the local effective symmetry around the secondary nitrogen can be taken as C_s. Then, the *RR*-isomer can be anticipated to show a CD pattern similar to that of $[Pt(NH_3)_2(SS\text{-chxn})]^{2+}$,[9] with one δ ring. Indeed, the CD signs of the ^3E and ^1E bands in the present complex are the same as those in the *SS*-chxn complex, but there is a remarkable difference between the CD spectra of these complexes; the $^1A_2$ CD band which appears at 41000 cm^{-1} in the former complex (Fig. 5) is not found in the latter complex. Similarly, the $^1A_2$ band is not observed in the CD spectra of $[Pt(NH_3)_2(S\text{-pn})]^{2+}$ and $[Pt(SS\text{-chxn or } S\text{-pn})_2]^{2+}$.[9] As has been described above, the increase in the electric-dipole transition moment is largest for the $^1A_2$ transition; this is responsible for the emergence of the intense $^1A_2$ CD band in the former. The CD sign of this band is compatible with that of the $^1A_2$ band in *trans*-$[CoCl_2(3S,8S\text{-dimetrien})]^+$.[10] The intensities of the other CD bands are also larger than those in $[Pt(NH_3)_2(SS\text{-chxn})]^{2+}$; this increase is mainly attributable to the increase in the transition moments.

Kinetic Studies of the Electron Transfer Reaction in Iron(II) and Iron(III) Systems. VIII. The Effect of Hexamethylphosphoric Triamide on the Electron Transfer Reaction in Aqueous Solution

Goro WADA,* Sayuri NAKAGO, and Yuriko ABE

Department of Chemistry, Nara Women's University, Nara 630

(Received September 14, 1978)

The kinetics and mechanism of the electron transfer reaction between Fe(II) and Fe(III) in mixed solvents of water and hexamethylphosphoric triamide (HMPA) were studied. The apparent rate constant k varies depending upon [HMPA] and [H^+]; k exhibits a minimum value at [HMPA]=1.5 M at constant [H^+] and increases linearly with respect to [H^+]$^{-1}$ at constant [HMPA]. Judging from the basicity constant of HMPA, the complex formation constant of Fe(hmpa)$^{3+}$, and the absorption spectra of aqueous solutions containing Fe(II), Fe(III), HMPA, and $HClO_4$, the existing species in the reaction systems are mostly Fe^{2+}_{aq}, Fe^{3+}_{aq}, $Fe(OH)^{2+}$, Fe(hmpa)$^{3+}$, and Fe(hmpa)$(OH)^{2+}$ at low concentrations of HMPA. Therefore, the probable reaction paths are Fe^{2+}–Fe^{3+}, (k_0); Fe^{2+}–$Fe(OH)^{2+}$, (k_H); Fe^{2+}–Fe(hmpa)$^{3+}$, (k_L); and Fe^{2+}–Fe(hmpa)$(OH)^{2+}$, (k_{HL}) at the concentration range of [HMPA]=0—1 M and [$HClO_4$]=0.03—0.2 M. The occurrence of a minimum value of k *vs.* [HMPA] is reasonably understood by taking the complex formation between Fe(III) and HMPA into account in reaction rate equation. If the hydrolysis constants of both $Fe(OH)^{2+}$ and Fe(hmpa)$(OH)^{2+}$ are considered to be nearly of the same order, the value of k_H are approximately ten times larger than that of k_{HL}. At higher concentrations of HMPA, the higher Fe(III)-complexes with HMPA might take part in the electron transfer reaction.

The electron transfer reaction between iron(II) and iron(III) in aqueous media, Fe(II)+*Fe(III)→Fe(III)+*Fe(II), has been studied since the radioactive tracer method by use of ^{59}Fe was first established by Silvermann and Dodson,[1] and it is now well-known that, in case that no catalytic ligand exists, the reaction in aqueous media proceeds predominantly through a hydrogen atom transfer mechanism along the extended chains of the hydrogen bonds between a certain number of water molecules connecting the two reacting species.[2,3] Therefore, in aqueous solvents mixed with aprotic organic substances, such as acetone,[4] nitromethane,[5] and dimethyl sulfoxide,[6] the rate of the electron transfer reaction *via* the hydrogen atom transfer mechanism is made smaller than that in pure water, because of the partial breakdown of the hydrogen bondings by such aprotic molecules.

In this investigation, hexamethylphosphoric triamide (abbreviated HMPA) is adopted as another aprotic substance, since HMPA has come into notice on account of a recent finding that the life time of solvated electrons in this medium is surprisingly long, as compared with those of hydrated electrons or other usual solvated ones.[7] In this connection, it looks to be very interesting to study how the effect of HMPA appears on the electron transfer reaction mechanism of iron(II) and iron(III) system.

Experimental

Materials. The commercially obtained HMPA of guaranteed reagent grade was refined as follows: after it was refluxed over barium oxide at 85—90 °C under a reduced pressure of nitrogen of 5 mmHg for 2 h and the first portion of the distillate was taken out, the rest of the liquid was distilled with iron(II) chloride at 80 °C under reduced pressure of nitrogen, and then the middle portion of the distillate was collected and immediately used for the experiments. Since HMPA had a slight tendency to form a kind of peroxide with time which would perturb our present experiments, iron(II) chloride was adopted for reducing it under nitrogen atmosphere.

The purification of other materials such as $Fe(ClO_4)_2$, $Fe(ClO_4)_3$, $NaClO_4$, and water and the preparation of iron(III) tracer labeled by radioisotope ^{59}Fe were already described elsewhere.[8,9] $NaClO_4$ was used for maintaining the ionic strength of the reaction media at μ=0.2 M.

Procedure of Measurements. For the purpose of determining the basicity constant of HMPA in water, the spectrophotometric indicator method was adopted, using thymol blue as an indicator and a Hitachi-Perkin-Elmer UV-VIS spectrophotometer Model 139 for the observation. The detailed procedure is shown in the literature.[10]

For the determination of formation constant of Fe(hmpa)$^{3+}$, Job's continuous variation method was applied using the same spectrophotometer.[11]

The method to determine the rate constants of the electron transfer reaction was also the same as that described in the literature,[8,9] except that the concentration of iron(III) in the reaction solution was initially kept much lower than those in the cases in other media, because a small amount of iron(II) was inevitably oxidized to iron(III) by the peroxide in HMPA which happened to be formed even during the careful experimental procedure.

Results and Discussion

Basicity Constant of HMPA. Prior to the kinetic observations, the basicity constant of HMPA in water was needed to be known in order to make clear in what form HMPA exists in acidic media. The basicity constant of HMPA is defined as K_a=[HMPA] [H^+]/[HMPA·H^+]. Hence, the optical absorbance of a solution containing thymol blue and $HClO_4$ at a certain wavelength, A, is expressed as follows:[10]

$$A = \frac{\varepsilon_a[H^+]+\varepsilon_b K_{HIn}}{[H^+]+K_{HIn}}[HIn]_0 \quad (1)$$

where ε_a and ε_b stand for the molar absorptivities of thymol blue (HIn) in acid and base forms respectively, $[HIn]_0$ the total concentration of thymol blue, and K_{HIn} the dissociation constant of thymol blue as K_{HIn}=[H^+] [In^-]/[HIn]. When HMPA is added at the total

concentration $[HMPA]_0$ to the initial solution of thymol blue and $HClO_4$, the hydrogen ion concentration and the absorbance would alter as much as $\Delta[H^+]$ and ΔA respectively, in a relation expressed by the following equation.

$$\Delta A = \frac{(\varepsilon_a-\varepsilon_b)K_{HIn}\Delta[H^+]}{([H^+]+\Delta[H^+]+K_{HIn})([H^+]+K_{HIn})}[HIn]_0 \quad (2)$$

Since $\Delta[H^+]$ is equal to $[HMPA.H^+]$, K_a can be calculated by using $\Delta[H^+]$ which is obtained from Eq. 2.[10]

$$K_a = \frac{([HMPA]_0-\Delta[H^+])([HClO_4]_0-\Delta[H^+])}{\Delta[H^+]} \quad (3)$$

Thus, the value of K_a was given $K_a=0.71\pm0.16$ M as the mean value of thirty-one observations at $[HMPA]_0=0.23$—1.15 M, $[HClO_4]_0=0.01$—0.02 M and 25 °C at wavelengths 420, 440, 520, and 540 nm, where HMPA exhibits no absorption.[12] This value corresponds to $pK_a=0.15$, indicating that HMPA is a very weak base although it is a little more basic than *N,N*-dimethylformamide, $pK_a(DMF)=-0.19$[13] and dimethyl sulfoxide, $pK_a(DMSO)=-0.67$.[10] According to the Gutmann's donor numbers, D_{SbCl_5}, the sequence of the basic nature as Lewis bases agrees with the present results, HMPA>DMF>DMSO.[14]

Formation Constant of Fe(hmpa)$^{3+}$. In aqueous solution of iron(III) perchlorate, optical absorbance increases at the shorter wavelengths than 450 nm with decreasing concentration of perchloric acid from 1.0 M to 0.01 M due to the partial hydrolysis of $Fe^{3+}{}_{aq}$ with the hydrolysis constant $K_H=[Fe(OH)^{2+}][H^+]/[Fe^{3+}]=2.2\times10^{-3}$ M at 25 °C.[15] In order to determine the formation constant of $Fe(hmpa)^{3+}$ defined as $K_L=[Fe(hmpa)^{3+}]/[Fe^{3+}][HMPA]$, it is desirable that the acid concentration is chosen to be high enough to be able to avoid the partial hydrolysis of Fe^{3+}, although too high acid concentration would give rise to the protonation of HMPA due to $K_a=0.71$ M, as described above.

Thus, the formation constant K_L was determined under a carefully considered condition of $[HClO_4]_0=1.0$ M by Job's continuous variation method.[11] In Fig. 1, are drawn two Job's curves of $[Fe^{3+}]_0+[HMPA]_0=0.1$ and 0.08 M at 350 nm, where Y is defined by the following relation, in which ε_0 and ε_1 are the molar absorptivities of Fe^{3+} and $Fe(hmpa)^{3+}$ respectively.

$$Y = \varepsilon_0[Fe^{3+}] + \varepsilon_1[Fe(hmpa)^{3+}] - \varepsilon_0[Fe^{3+}]_0$$
$$= (\varepsilon_1-\varepsilon_0)[Fe(hmpa)^{3+}] \quad (4)$$

The curves exhibit maxima both at $x=[Fe^{3+}]_0/([Fe^{3+}]_0+[HMPA]_0)=0.5$ indicating that the predominant species is a 1 : 1 complex between Fe^{3+} and HMPA at these concentration ranges, and give $K_L=1.46\pm0.22$ M^{-1} as a result.[11]

At higher concentrations of HMPA than 0.1 M, higher complexes such as $Fe(hmpa)_n{}^{3+}$ ($n\geqq2$) might be formed.

Effect of Concentration of HMPA on Rates of the Electron Transfer Reaction. The process of the electron transfer reaction between iron(II) and iron(III) obeys the following McKay's relationship, as has been commonly recognized in any exchange reactions;

$$\ln\left(1-\frac{x}{x_\infty}\right) = -([Fe(II)] + [Fe(III)])kt \quad (5)$$

in which x and x_∞ represent the specific radioactivity of Fe(II) species at reaction time t and at equilibrium, respectively. Therefore, the apparent second-order rate constant, k, is expressed by use of half-time period of the reaction, $t_{1/2}$, which is obtained from the linear plot of $\ln(x_\infty-x)$ *vs.* t.

$$k = \frac{0.693}{([Fe(II)]+[Fe(III)])t_{1/2}} \quad (6)$$

When $[H^+]$ is maintained constant, k is affected by addition of HMPA; at a low concentration range of HMPA, k is lowered by HMPA and after passing the minimum point at about $[HMPA]_0=1.5$ M, k increases with increasing $[HMPA]_0$. The variation of k with $[HMPA]_0$ are shown in Fig. 2. Similar

phenomena have been recognized in water–DMSO systems, with the minimum value of k appearing at the mole fraction of DMSO 0.2—0.3 ([DMSO] =6.5—8.0 M) when $[HClO_4]=5\times10^{-2}$ M,[8] and in water–DMF systems, with the minimum value of k appearing at $[H_2O]=2$ M (namely [DMF]=12.5 M) when $[HClO_4]=1\times10^{-2}$ M.[16]

Dependence of Rate Constants upon Acid Concentration. The apparent rate constant k is also dependent upon $[H^+]$ at constant [HMPA], becoming smaller as $[H^+]$ becomes larger. When k is plotted against the reciprocal $[H^+]$, straight lines are obtained at respectively constant concentration of HMPA, as is reproduced in Fig. 3, at the concentration range of $[HMPA]_0=0$—3 M and $[H^+]=0.03$—0.2 M. Therefore, k is apparently expressed by the following equation at constant [HMPA];

$$k = k_A + \frac{k_B}{[H^+]} \tag{7}$$

where k_A and k_B are the intercept and the slope of an

empirically observed straight line respectively in Fig. 3; k_A's are very small at every $[HMPA]_0$, while k_B varies with $[HMPA]_0$ and exhibits a minimum again at $[HMPA]_0=1.5$ M, as is shown in Fig. 4.

Mechanism. According to the absorption spectra of aqueous solutions containing Fe^{3+}, HMPA, and $HClO_4$ at various concentrations at a wavelength range of 270—500 nm, the following results are observed : in the ultraviolet region, the absorbance increases with increasing [HMPA] and decreasing $[HClO_4]$, whereas in the visible region, it increases with increasing both [HMPA] and $[HClO_4]$, and approximate isosbestic phenomena occur in the vicinity of 340—350 nm among spectra of different $[HClO_4]$ at individually constant [HMPA]. These observed facts are caused by the hydrolysis of iron(III) species and the complex formation between iron(III) and HMPA. Consequently, it can be deduced that in the mixed solvents of water and HMPA, predominant part of iron(III) exists in the forms such as Fe^{3+}, $Fe(OH)^{2+}$, $Fe(hmpa)^{3+}$, and $Fe(OH)(hmpa)^{2+}$, and the rest part is in the forms of some higher complexes of HMPA. Since the pK_a value of HMPA is comparatively small, the occurrence of the protonated species of $Fe(hmpa)^{3+}$ is not probable. In regard to iron(II) species, both the hydrolysis and the complex formation with HMPA would be weak.

Thence, the important reaction paths of the electron transfer would be expressed by the following equations, having the activated complexes composed of $[Fe^{2+}, Fe^{3+}]$, $[Fe^{2+}, OH^-, Fe^{3+}]$, $[Fe^{2+}, HMPA, Fe^{3+}]$, and $[Fe^{2+}, OH^-, HMPA, Fe^{3+}]$ respectively. The asterisked Fe in the equations stands for the labeled species by tracer radioisotope:

$$Fe^{2+} + {}^*Fe^{3+} \rightarrow Fe^{3+} + {}^*Fe^{2+} \quad (k_0) \tag{8}$$

$$Fe^{2+} + {}^*Fe(OH)^{2+} \rightarrow Fe(OH)^{2+} + {}^*Fe^{2+} \quad (k_H) \tag{9}$$

$$Fe^{2+} + {}^*Fe(hmpa)^{3+} \rightarrow Fe(hmpa)^{3+} + {}^*Fe^{2+} \quad (k_L) \tag{10}$$

$$Fe^{2+} + {}^*Fe(OH)(hmpa)^{2+} \rightarrow Fe(OH)(hmpa)^{2+} + {}^*Fe^{2+} \quad (k_{HL}) \tag{11}$$

When the respective rate constants of Reactions 8—11 are denoted by k_0, k_H, k_L, and k_{HL}, the formation constant of $Fe(hmpa)^{3+}$ by K_L, and the hydrolysis constants of $Fe(OH)^{2+}$ and $Fe(OH)(hmpa)^{2+}$ by K_H and K_{HL} respectively, the apparent rate constant k is given by the following equation.

$$k = \frac{k_0 + k_H K_H [H^+]^{-1} + k_L K_L [HMPA] + k_{HL} K_L K_{HL} [HMPA][H^+]^{-1}}{1 + K_H [H^+]^{-1} + K_L [HMPA] + K_L K_{HL} [HMPA][H^+]^{-1}} \tag{12}$$

Since HMPA is slightly basic in aqueous solutions, the concentration of free HMPA, [HMPA], appearing in Eq. 12, has to be strictly expressed by the following equation.

$$[HMPA] = \frac{[HMPA]_0}{1 + K_a^{-1}[H^+] + K_L [Fe^{3+}] + K_L K_{HL} [Fe^{3+}][H^+]^{-1}} \tag{13}$$

By using the values $K_a=0.71$ and $K_L=1.46$ and supposing that K_{HL} would be approximately as small as 10^{-3} of the same order as K_H, the value of the denomi-

nator of Eq. 13 can be regarded as unity at low but not extremely low acid concentrations, and therefore, $[HMPA]_0$ may be plausibly used in place of [HMPA] in Eq. 12.

On the other hand, among the three terms in the denominator of Eq. 12, only $K_L[HMPA]$ is no longer negligible as compared with unity, according to the numerical consideration. Therefore, Eq. 12 can be simplified as follows:

$$k(1+K_L[HMPA]) = (k_0+k_LK_L[HMPA]) + (k_HK_H+k_{HL}K_LK_{HL}[HMPA])[H^+]^{-1} \quad (14)$$

Comparing Eq. 14 with Eq. 7, more accurate straight lines will be obtained when $k(1+K_L[HMPA])$, instead of the mere k, is plotted against $[H^+]^{-1}$, as are shown in Fig. 5, with the intercept k_A' and the slope k_B' of respective straight lines.

$$k_A' = k_0 + k_LK_L[HMPA] \quad (15)$$

$$k_B' = k_HK_H + k_{HL}K_LK_{HL}[HMPA] \quad (16)$$

The values of k_A' as obtained from the extrapolation of the straight lines are small and inaccurate to determine the value, while k_B' is accurately determined and found to increase with the increasing [HMPA], although it is not linear against the expectation from Eq. 16. The variation of k_B' with the function of [HMPA] is shown in Fig. 6, where any minimum phenomenon is no longer observed, which has been observed in the case of plotting k_B *vs.* [HMPA] in Fig. 4.

In both cases of mixed solvents of water–*N*-methylacetamide (NMA) and water–*N*,*N*-dimethylacetamide (DMA),[17] the linear relationship corresponding to Eq. 14 with the same physical meanings of k_A' and k_B' as the present case, was found to hold, and another

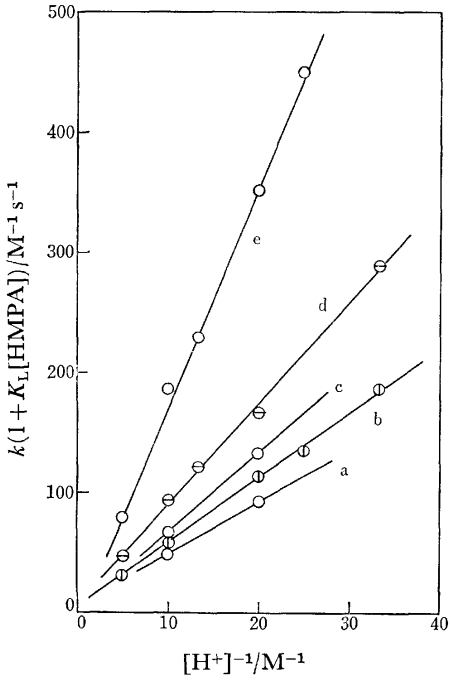

Fig. 5. Linear relationships of $k(1+K_L[HMPA])$ with $[H^+]^{-1}$ at $\mu=0.2$ M and 25 °C.
a, b, c, d, and e: Respectively the same as in Fig. 3.

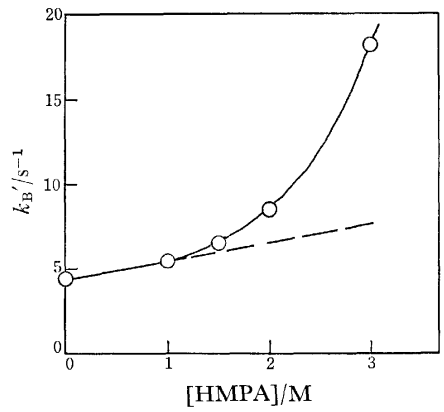

Fig. 6. Variation of k_B' with [HMPA] at $\mu=0.2$ M and 25 °C.

linear relationship of k_B' with [NMA] or [DMA] as represented by Eq. 16 was also noticed, giving reasonable values of k_HK_H and $k_{HL}K_LK_{HL}$.

Both of the observed facts that k exhibits a minimum value as a function of $[HMPA]_0$ as in Fig. 2 and that k_B also shows a minimum at the same $[HMPA]_0$ as in Fig. 4 may result from a same cause and reflect on the failure of k_B' from the linearity with respect to [HMPA] as in Fig. 6.

The abrupt increment of k_B' failing from the linearity in Fig. 6 may indicate a probability that the higher complexes of $Fe(hmpa)_n^{3+}$ ($n\geqq 2$) participate in the total reaction at higher HMPA concentration. From the limiting slope of the curve at $[HMPA]\rightarrow 0$, the value of $k_{HL}K_LK_{HL}$ may be given to be 1.2 $M^{-1}s^{-1}$, which may lead to a further estimation of $k_{HL}=3.7\times10^2$ M^{-1} s^{-1}. Since $k_H=2.7\times10^3 M^{-1}s^{-1}$ at 25 °C,[15] the reaction path (11) is supposed to be about ten times slower than the reaction path (9). The existence of HMPA molecule in coordinate sphere of the iron(III) complex may interfere with the hydrogen atom transfer mechanism of the electron transfer, probably due to both the larger geometrical dimension of an HMPA molecule, and the poorer possibility of hydrogen bonding of an HMPA molecule which is surrounded with as many as six methyl groups towards the outside of the complex, than that of a water molecule.

Synthetic Inorganic Ion-exchange Materials. XX. Ion-exchange Properties of Crystalline Antimonic(V) Acid with Alkaline Earth Metal Ions

Mitsuo ABE

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 17, 1978)

A stoichiometrical ion-exchange was observed for all the systems of Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} with H^+ in the crystalline antimonic(V) acid as a cation exchanger. The selectivity sequence, $Mg^{2+}<Ba^{2+}<Sr^{2+}<Ca^{2+}$, has been found for the ion-exchange reactions in 0.1 M nitrate salt solutions of different alkaline earth metals. Breakthrough and further elution studies were carried out in order to test the reversibility of the ion-exchange reactions. X-Ray analysis indicates that a solid solution forms for the ion-exchange system of the alkaline earth metal ions in the crystalline antimonic(V) acid.

Antimonic acid, $Sb_2O_5 \cdot 4H_2O$, has been of interest during last two decades because of its high ion-exchange capacity.[1] Various antimonic acid materials have been obtained with different chemical compositions and ion-exchange properties, depending on the method of preparation as well as on aging.[2] The species can be classified into three groups-crystalline, amorphous, and glassy. Among three different antimonic acids, crystalline antimonic(V) acid, C-SbA, shows an unusual selectivity for alkali metal ions as compared with the strong acid-type cation-exchange resins. The increasing selectivity shows: $Li^+<K^+<Cs^+<Rb^+<Na^+$ for microquantities of alkali metal ions in a nitric acid solution.[3,4] Similar unusual selectivity has been observed for polyantimonic acid[5] and hydrated antimony pentoxide.[6] These materials can be applied to the effective separation of sodium ion from certain elements.[3,4,6,7]

An unusual selectivity has been found in the ion-exchange system for microquantities of alkaline earth metal ions in a nitric acid solution.[8] An increasing order of selectivity is: $Mg^{2+}<Ba^{2+}<Ca^{2+}<Sr^{2+}$. A large difference in the distribution coefficients has been observed for the pairs of Mg^{2+}-Ba^{2+}, Ba^{2+}-Sr^{2+}, and Cs^+-Sr^{2+}. Effective separations can be achieved for these pairs.[8] Slightly different selectivities have been found for polyantimonic acid (PAA): $Mg^{2+}<Ca^{2+}<Sr^{2+}<Ba^{2+}$.[9]

In general, the selectivities of the inorganic ion-exchangers vary not only with the solution media, but also with exchange loading as a function of the concentration of the elements.

In this paper, the ion-exchange properties of C-SbA with macroquantities of alkaline earth metal ions will be reported.

Experimental

Reagents. The antimony pentachloride (Yotsuhata Chemical Co., Ltd.) was used without further purification. The other reagents used were all of an analytical grade.

Preparation of C-SbA as an Ion-exchange Material. C-SbA was prepared as has been described previously:[2] the precipitate obtained by the hydrolysis of antimony pentachloride was kept in the mother solution at 40 °C for over 20 days, and then washed with cold demineralized water with the aid of a centrifuge (about 10000 rpm) until it was free from chloride ions. After drying, the product was ground and sieved (100—200 mesh size). The collected sample was rewashed with demineralized water in order to obtain a clear supernatant solution following batch equilibrium experiments and to improve the elution-flow rate.

The Stoichiometry of Ion-exchange. Equilibrations were carried out by the batch technique as follows: a 0.25 g portion of the C-SbA was immersed in 25 ml of a 0.1 M nitrate salt solution of different alkaline earth metals at 30±0.1 °C with intermittent shaking. The amounts of metal ions adsorbed were determined from the changes in the concentrations of the alkaline earth metal ions and hydrogen ions relative to the initial concentration of the solution after equilibration. The emf titration method was employed for determining the hydrogen-ion concentration by means of a standard sodium hydroxide solution.

Breakthrough Curves. A column, 2.3 long and 0.4 cm i.d., containing 0.40 g of C-SbA in hydrogen ion-form, was employed, with a flow rate of 0.3 ml/min. The concentrations of hydrogen ions liberated by the ion-exchange reaction were titrated with a standard sodium hydroxide solution, using methyl red as an indicator.

Elution Curves of Alkaline Earth Metal Ions. A nitric acid solution at different concentrations was passed through the C-SbA column saturated with alkaline earth metal ions with a flow rate of about 0.3 ml/min.

Composition of the Ion-exchanged C-SbA with Different Alkaline Earth Metal Ions. The ion-exchanged C-SbA of a weighed amount (0.1 g) was dissolved by heating in a mixed solution of 25 ml of a 12 M HCl solution and 10 ml of a 0.5 M KI solution. After cooling, a 10 ml portion of a 10% tartaric acid solution was added in order to avoid the hydrolysis of Sb(III) and a 50 mg portion of L-ascorbic acid was added to reduce of the I_3^- formed as a result of the reaction of oxidation-reduction from Sb(V) to Sb(III). The concentrations of the alkaline earth metals and of antimony in the solutions were determined by using a Varian-Techtron 1100 atomic-absorption spectrometer. The water content of the ion-exchanged C-SbA was calculated by subtracting the weights of the corresponding metal oxides from the initial weight.

X-Ray Power-diffraction Analysis. The X-ray data for the ion-exchanged C-SbA were determined by using a JEOL X-ray diffraction meter Model, JDX-7E with, Ni-filtered Cu $K\alpha$ radiation.

Results and Discussion

The results of the TGA, DTA, and X-ray studies of C-SbA in the hydrogen-ion form showed a good

TABLE 1. STOICHIOMETRY OF THE ION-EXCHANGE REACTION OF ALKALINE EARTH METAL IONS ON C-SbA

Ion-exchange system	Amounts meq/g			
	Mg^{2+}/H^+	Ca^{2+}/H^+	Sr^{2+}/H^+	Ba^{2+}/H^+
Adsorbed metal ions	0.61±0.02	3.37±0.02	3.15±0.02	2.55±0.02
Liberated hydrogen ions	0.60±0.05	3.40±0.05	3.10±0.02	2.50±0.05

agreement with our earlier works.[2,10]

Batch Equilibration. The equilibrium for macroquantities of alkaline earth metal ions was attained within 3 months from our preliminary studies. For microquantities of Ca^{2+} and Sr^{2+}, previous work indicated that the exchange equilibrium would be attained in about 6 months. These phenomena may be explained by the presence of limited numbers of sites favorable to Ca^{2+} and Sr^{2+} making for a very tight network structure of the C-SbA. Thus no difference in the adsorbed amounts was observed within the limits of experimental error, although a further uptake of very small amounts occurred for a few consecutive months.

The relation between the liberated hydrogen ions and the adsorbed alkaline earth metal ions indicates a stoichiometry of the ion-exchange reaction for the systems studied (Table 1). The affinity sequence for macroquantities was found to be in this increasing order:

$$Mg^{2+} < Ba^{2+} < Sr^{2+} < Ca^{2+}$$

which was slightly different from the sequence for microquantities presented above. This may suggest that the selectivity sequence varys with the loading of the alkaline earth metal ions in C-SbA, as has been found for the ion-exchange systems of alkali metal ions–hydrogen ions on the C-SbA.[10] A definite selectivity sequence has been reported for both micro- and macroquantities of the same system on PAA by Baetsle and Huys.[5] However, no equilibrium time required has been reported in the literature. The rate of the adsorption of Ca^{2+} and Sr^{2+} was extremely slow, and the same sequence observed on PAA was found at the initial stage of the adsorption within a few weeks.

Breakthrough Curves. The breakthrough curves showed that hydrogen ions are liberated quantitatively for the equivalent uptake of alkaline earth metal ions by the ion-exchange reaction. The elution of the hydrogen ions by the ion-exchange proceeded rapidly at first, but they were still being liberated even after the passage of a relatively large volume of a 0.05 M nitrate salt solution of different alkaline earth metals, except in the case of the 0.05 M $Ba(NO_3)_2$ solution (Fig. 1). The breakthrough curve obtained for Ba^{2+}/H^+ exchange was steeper than those obtained for other systems. This can be explained by the fast rate of the adsorption for Ba^{2+} and the slow rate for the other alkaline earth metal ions, as was to be expected from a previous report.[8] The breakthrough capacities were determined by the analysis of alkaline earth metal and antimony after decomposing the exchanged C-SbA, because the determination from the liberated

hydrogen ions may lead to large experimental error because of long tailing.

Elution of the Alkaline Earth Metal Ions Adsorbed on the C-SbA. Individual elution peaks with a sharp front and a tailing rear were observed for the elution of Mg^{2+}, Ca^{2+}, and Sr^{2+} (Figs. 2 and 3). Incomplete regenerations were achieved for the systems of Ca^{2+}/H^+ and Sr^{2+}/H^+, even if a 10 M nitric acid was used as an eluant. These phenomena may be due to the slow rate of desorption and the highly adsorptive ability on the C-SbA for Ca^{2+} and Sr^{2+}.

The adsorbed Ba^{2+} were eluted easily with a relatively small volume of a 1 M HNO_3 as an eluant. The results of the breakthrough and the elution are summarized in Table 2. The breakthrough capacities are found to be in the following increased order: $Mg^{2+}<Ca^{2+}<Ba^{2+}<Sr^{2+}$. The lower value of the breakthrough capacity than the uptake by batch equilibration for Ca^{2+} may be due to the slow rate of adsorption. A complete regeneration was achieved for the Ba^{2+}-exchanged C-SbA. Elutions of 79%, 31% and 43% for the adsorbed metal ions were achieved for Mg^{2+}, Ca^{2+} and Sr^{2+} respectively under the above experimental conditions.

different alkaline earth metal ions decrease with an increase in the amounts of the metal ions adsorbed and also with an increase in the crystal ionic radii of the metals, except in the case of Ba^{2+}. This indicates that the net transfer of some water molecules from the solid phase to the solution phase occurs with the ion-exchange of the alkaline earth metal ions on the C-SbA in hydrogen-ion form.

X-Ray Analysis. The X-ray diffraction data of the ion-exchanged C-SbA with different alkaline earth metal ions are summarized in Table 3.

There are changes in the lattice constant of up to a few percent with the cations adsorbed, but no change in the space group, Fd3m. Similar behavior is established for C-SbA and various zeolites on the ion-exchange systems of the alkali metal ions.[10,11] This may be due to the fact that C-SbA does not undergo remarkably any dimensional change with the ion-exchange because of its three-dimensional framework structure, like that of zeolite. In contrast, clay mineral and crystalline zirconium phosphate, possessing two dimensional structure, may undergo swelling or shrinking and may also be converted to two immiscible phases during the ion-exchange of some metal ions.[11,12] All of the X-ray diffraction patterns determined belong to Fd3m, and no immiscible phase was found over the entire range of systems studied. A remarkable decrease in the diffraction intensities of the (111) and (311) planes was observed with an increase in the crystal ionic radii of the adsorbed metal ions, while the (222) plane increased.

The calculated values of the lattice constant of the ion-exchanged C-SbA are plotted against the effective ionic radii of the metal ions in Fig. 4, the data of the C-SbA exchanged with alkali metal ions being included for comparison. The effective ionic radii can be found from the Shannon and Prewitt Table by assuming that the metal ion has six-coordinated

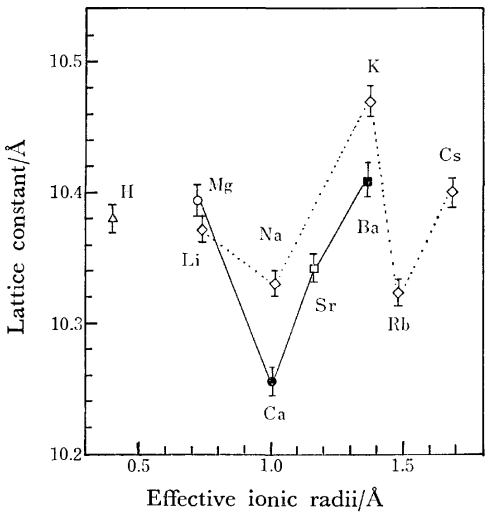

Fig. 4. Changes in the lattice constant of the C-SbA ion-exchanged with alkaline earth metal ions.
△: H-form, ○: (1), ●: (3), □: (5), ■: (7), A numeral in parenthesis indicates batch number.

radii.[13] A strong dependence on the effective ionic radii was noticed for the changes in the lattice constant, although it may be very difficult to explain its relationship quantitatively because of the metal ions adsorbed in different amounts in the C-SbA. When the exchanging cation, Na^+ or Ca^{2+}, has an ionic radii of about 1.0 Å, the lattice constant decreases markedly, as compared with that of the C-SbA in the hydrogen-ion form. Increased lattice constants are observed for the adsorption of a metal ion with effective ionic radii of about 1.3 Å (in the case of K^+ and Ba^{2+}).

Our work indicates that C-SbA has interstitial-(free) water with the chemically bonded water combined as Sb–OH.[14] The shrinking of the crystal lattice makes it progressively easier to exclude some

$\bar{a}$: Mean lattice constant.

of the water molecules of the solid phase by the ion-exchanging metal ions. In contrast, the swelling may cause some of the water molecules to be retained with the exchanging metal ions. If the dimension of the crystal lattice remain constant during the ion-exchange, the net transfer of some of the water molecules from the solid phase to the solution phase are probably caused by the adsorption of the metal ion with large effective ionic radii. The differences in the water content in the C-SbA exchanged with Ba^{2+} and with Ca^{2+} can be explained by the swelling and the shrinking.

The X-ray diffraction data of the C-SbA regenerated by different nitric acid solutions are summarized in Table 4. The X-ray data for the regenerated sample (Batch No.8) show that the conversion from the Ba^{2+}-exchanged C-SbA to the C-SbA in the hydrogen-ion form is indeed reversible within the limit of experimental error. In the other system, the X-ray patterns show intermediate profiles between the fully exchanged C-SbA and the C-SbA in hydrogen-ion form in the diffraction intensities and in values of the lattice constant.

The apparent irreversibility for the ion-exchange systems of Ca^{2+}/H^+ and Sr^{2+}/H^+ may be due to the extremely slow rate of adsorption and desorption in addition to the extremely high adsorptive ability of C-SbA for Ca^{2+} and Sr^{2+}.

Only a single phase is noticed over the entire range of C-SbA ion-exchanged with different alkaline earth metal ions. This indicates that a solid solution forms for the ion-exchange system of the metal ions in the C-SbA.

Synthesis, Absorption and CD Spectra of [Co(amino alcohol)$(N)_2(O)_2$]-type Complexes

Kenichi Okazaki and Muraji Shibata*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received October 19, 1978)

Complexes of the [Co(amOH)$(N)_2(O)_2$]-type, where amOH represents 2-aminoethanol or (*S*)-2-amino-1-propanol and $(N)_2(O)_2$ represents $(gly)_2$, $(\beta\text{-ala})_2$, (ox)(en) or (ox)$(NH_3)_2$, have been prepared and characterized on the basis of absorption and PMR spectra. Splitting of the T_{2g} band has been observed in the solution spectra of certain isomers of the [Co$(gly)_2$(eta)], [Co$(gly)_2$(*S*-pra)], or [Co$(\beta\text{-ala})_2$(eta)] complex. Using the crystal spectral data of the isomers of [Co$(gly)_2$(eta)], the σ- and π-antibonding parameters for the ligating alcoholate O atom have been estimated and it has been found that each parameter shows a higher value than the corresponding parameters for the other ligating N and O atoms. The CD spectrum, in the T_{2g} region, of *fac*-[Co$(gly)_2$(eta)] has shown an intense peak at *ca.* 25000 cm^{-1}, and the vicinal effect curve of each isomer of the [Co$(gly)_2$(*S*-pra)] complex has shown an intense peak at the same frequency.

The mixed ligand complex of cobalt(III) containing 2-aminoethanol (Heta) and ethylenediamine, $[Co(en)_2(Heta)]^{3+}$, was first prepared by Buckingham *et al.*[1] Later, Ogino *et al.*[2] prepared optically active complexes such as $[Co(en)_2(S\text{-Hpra})]^{3+}$ (*S*-Hpra denotes (*S*)-2-amino-1-propanol), $[Co(en)_2(Heta)]^{3+}$ and $[Co(NH_3)_4(S\text{-Hpra})]^{3+}$ and reported that dissociation of the hydroxyl protons resulted in changes in the absorption and circular dichroism (CD) spectra; in the spectra of the deprotonated $[Co(eta)(en)_2]^{2+}$ and $[Co(S\text{-pra})(en)_2]^{2+}$ complexes, a shoulder and maximum are observed in the second absorption (T_{2g}) region. In the CD spectra of $[Co(S\text{-pra})(en)_2]^{2+}$ and $[Co(S\text{-pra})(NH_3)_4]^{2+}$ complexes, the vicinal effect curve shows of medium intensity peaks not only in the first absorption (T_{1g}) region but also at the shoulder of the split T_{2g} band. These observations are of interest since, in general, splitting of the T_{2g} band and an intense CD peak in the T_{2g} region are both rare. Nishide *et al.*[3] prepared [Co(amOH)$(N)_4$]-type complexes using a variety of amino alcohols (amOH) and studied the vicinal effect due to the chelated amino alcohols. There is however no study of other complexes which differ from the above in chromophore.

The present work was undertaken to prepare mixed ligand complexes of [Co(amOH)$(N)_2(O)_2$]-type, in which amOH denotes 2-aminoethanol or optically active (*S*)-2-amino-1-propanol and the $(N)_2(O)_2$ moiety denotes two glycinate ions, two β-alaninate ions, ethylenediamine and oxalate ion, or two ammonia and oxalate ions. The complexes obtained exhibited remarked different absorption and CD spectra, and splitting of the second absorption band was observed. In order to clarify the splitting of the T_{1g} and T_{2g} bands, polarized crystal spectra were measured, and from the spectral data, the σ- and π-antibonding parameters of the N and O donor atoms of the 2-aminoethanolate ion evaluated using the Angular Overlap Model.[4]

Experimental

Preparation. *a) (2-Aminoethanol)bis(glycinato)cobalt(III) Perchlorate, [Co(gly)$_2$(Heta)]ClO_4:* To a slurry of K[Co$(CO_3)(gly)_2]\cdot H_2O$ (9.7 g, 0.03 mol)[5] in water (25 cm^3) was added sufficient 3 M $HClO_4$ (M=mol dm^{-3}) to acid-hydrolyze the carbonato complex species. After removal of the precipitated $KClO_4$ by filtration, 2-aminoethanol (1.8 g, 0.03 mol) was added to the filtrate. The solution was stirred at 50 °C for 40 min, during which the pH of the solution was maintained at *ca.* 8.5 by the addition of an aqueous KOH solution. The resulting solution was adjusted to pH *ca.* 2, and the precipitated material filtered off. The filtrate was charged on a column containing 100—200 mesh Dowex 50W-X8 resin (Na^+ form, 5×20 cm). The red violet band held on the top of the column was eluted with 0.3 M NaCl solution and the band separated into four bands, the second and third bands being the desired species. Both eluates were concentrated to a small volume below 35 °C under reduced pressure and the concentrate poured into a column of the same resin (5×45 cm). By elution with water, the concentrate from the second band gave a violet band which was the parent species and a dark blue band which was the desired species (labeled A-1). The concentrate from the third band gave three bands, dark violet, red violet and red bands, of the desired species labeled A-2, A-3, and A-4 respectively. Acidification of the eluates with $HClO_4$ to pH *ca.* 3 brought about a change in colour, A-1, A-2, and A-3 to red violet and A-4 to rose. After concentration of the acidified solutions to small volumes, the A-1 and A-4 concentrates were kept in a refrigerator overnight, A-2 being kept in a refrigerator after the addition of a mixture of ethanol and ether (1 : 1). With respect to A-3, red violet crystals deposited during concentration. The yields of A-1, A-2, A-3, and A-4 were approximately 0.1, 0.2, 2.3, and 0.4 g, respectively.

b) (2-Aminoethanol)(ethylenediamine)(oxalato)cobalt(III) Perchlorate, [Co(ox)(en)(Heta)]ClO_4: To a green solution of tricarbonatocobaltate(III) ($Co(NO_3)_2\cdot 6H_2O$, 0.1 mol)[6] was added the solid material (17 g), prepared previously from ethylenediamine and oxalic acid. The mixture was stirred at 40 °C for 1.5 h, the resulting solution carefully acidified with $HClO_4$ under ice-cold conditions and filtered to remove any material precipitated. To this filtrate was added 2-aminoethanol (6 g, 0.1 mol), and the mixture stirred at 60 °C for 1 h, during which time the pH of the mixture was maintained at *ca.* 8.5 by the addition of an aqueous solution of KOH. The resulting solution was acidified to pH *ca.* 6 and concentrated. After the insoluble material had been filtered off, the filtrate was poured into a column of 100—200 mesh Dowex 50W-X8 resin (Na^+ form, 7×20 cm). Elution with water produced two bands, one dark violet and the other red (B-1 and B-2). Both eluates were adjusted to pH *ca.* 3 and concentrated. The crystals formed were recrystallized several times from aque-

ous solution (pH 2 adjusted with $HClO_4$).

c) (2-Aminoethanol)diamine(oxalato)cobalt(III) Perchlorate and Bis(2-aminoethanol)ammine(oxalato)cobalt(III) Bromide, [Co(ox)-$(NH_3)_2$(Heta)]ClO_4 and [Co(ox)(NH_3)(Heta)$_2$]Br: In the same manner as in a), $K[Co(CO_3)(ox)(NH_3)_2]\cdot H_2O$ (12 g, 0.04 mol)[7] was acid-hydrolyzed with 3 M $HClO_4$ and 2-aminoethanol (2.4 g, 0.04 mol) and ammonium oxalate (0.7 g) added to the solution. After the mixture had been stirred for 40 min at 60 °C, the pH being maintained at 8.5, the solution was acidified to pH *ca.* 6 and concentrated. The material precipitated was filtered off and the filtrate charged on a column of the same resin (Na^+ form, 7×20 cm). Elution with water produced three bands consisting of an anionic species, non-charged dark violet species and a red species. The final eluate (C-1) was further acidified to pH *ca.* 3 with aqueous $HClO_4$, concentrated and kept in a refrigerator overnight. The dark-violet eluate was made pH 2, whereupon the color turned violet. This solution was charged on a column of the same cation exchanger (4.5× 12 cm). Elution with a 0.3 M $NaClO_4$ solution, produced two violet bands (C-2 and C-3). The eluates were adjusted to pH *ca.* 2 and concentrated under reduced pressure, whereby pure violet crystals were obtained with respect to C-3. Crystals of C-2 were obtained as follows; to the concentrate was added a mixture of ethanol and ether (1 : 3), whereby a tarry material separated out. This material was dissolved in a small amount of water and an ethanol–HBr (47%) mixture (4 : 1) and ether added to the solution. The violet crystals (C-2) thus obtained were recrystallized from water by adding the same mixture of ethanol–HBr as above.

d) Bis(β-alaninato)(2-aminoethanol)cobalt(III) Perchlorate and Iodide, [Co(β-ala)$_2$(Heta)]X (X=ClO_4 or I): To a solution of tricarbonatocobaltate(III) ($Co(NO_3)_2\cdot 6H_2O$, 0.05 mol scale)[6] was added β-alanine (10.7 g, 0.12 mol), and the mixture stirred at 50 °C for 3 h. To the resulting solution 2-aminoethanol (3.5 g, 0.05 mol) neutralized previously with aqueous $HClO_4$ and activated charcoal (4 g) were added, and the solution stirred at 50 °C for 30 min. After the activated charcoal had been removed, the solution was neutralized and concentrated. The concentrate was poured into a column of the same resin as above (Na^+ form, 7× 20 cm), and eluted with water. A violet band and some overlapped bands descended after some bands of the anionic species had been eluted. For the sake of convenience, the violet band eluate has been named E-1, and the overlapped ones combined and named E-2. Each fraction was brought to pH 2 and charged on a column containing the same resin as above (5×22 cm). Elution with a 0.3 M $NaClO_4$ solution at pH 2, enabled each band held at the top of the column to be separated into four bands colored red or violet, numbered Nos. 1—4 according to the order of elution. The eluates No. 1 and No. 2 of the E-1 and No. 2 of the E-2, were subsequently concentrated. After the addition of a mixture of ethanol and ether (2 : 1), the concentrates were kept in a refrigerator overnight and the deposited crystals were recrystallized from water. With respect to eluate No. 4 of E-1, the addition of an ethanol–ether mixture (1 : 3) to the concentrate induced immediate crystallization. The crystals thus obtained sparingly recrystallized from aqueous solution due to the ready isomerized to an other species identical to No. 1 of E-1. The No. 1 eluate of E-2 was concentrated until red crystals were found and the crystals recrystallized from aqueous $HClO_4$. The addition of ethanol–ether mixture (1 : 5) to No. 3 of E-2, resulted in a red tarry material separating from the aqueous phase, this being dissolved in a minimum amount of water. To this solution a small amount of NaI and followed by an ethanol–ether mixture were added. On standing in the refrigerator overnight, red crystals deposited. No recrystallization was conducted due to the poor yield of product. The eluates of No. 3 of E-1 and No. 4 of E-2 were too small in quantity for crystals to be obtained.

e) (S)-2-Amino-1-propanolbis(glycinato)cobalt(III) Perchlorate, [Co(gly)$_2$(S-Hpra)]ClO_4: Four fractions were obtained in the same way as in a), except that (*S*)-2-amino-1-propanol (1.5 g, 0.02 mol) was used instead of 2-aminoethanol and that a longer time was necessary for reaction (1 h). The fractions were conveniently named A-1—A-4. The following description concerns the separation of the diastereoisomers for each geometrical isomer: Eluate A-1, adjusted to pH 2 with aqueous $HClO_4$ was charged on a column of the same cation exchanger (3×35 cm). The red violet band held at the top of the column was eluted first with a 0.2 M aqueous solution of sodium $(+)_{589}$-bis(tartrato)diantimonate(III), the pH being controlled to 3.5 with aqueous $HClO_4$, until the band clearly separated into two, and secondly eluted with a 0.3 M aqueous solution of $NaClO_4$. A-2 gave two bands in chromatographic elution conducted in a similar manner to that in A-1, using a 0.3 M $NaClO_4$ solution as the cluent. The effluents were concentrated and ethanol added. The products of the diastereoisomeric pairs were recrystallized from water by the addition of ethanol. The diastereoisomers for A-3 were isolated in the following manner; the eluate containing non-charged species was concentrated and charged on a column of the same resin (5×45 cm). Elution was conducted with water by means of a fraction collector. Frontal fractions, where the intensity ratios of the $\Delta\varepsilon$ values at 530 nm and the ε values at 550 nm were smaller than −0.033 and the rear fractions where the intensity ratios of the $\Delta\varepsilon$ values at 581 nm and the ε values at 550 nm were larger than 0.015 were collected and labeled A-3(−) and A-3(+), respectively. The collected eluates were adjusted to pH *ca.* 3 and evaporated. The violet crystals of A-3(−) separated out during concentration and the crystals of A-3(+) were obtained by adding an ethanol–ether mixture (1 : 1). Recrystallization was repeated until the $\Delta\varepsilon$ of the main CD peak attained a constant value. One of the diastereoisomers of A-4 was obtained as red crystals from the concentrate adjusted to pH *ca.* 3; the crystals were recrystallized repeatedly until the $\Delta\varepsilon$ value remained constant. The solution containing the other diastereoisomer was charged on a column containing the same resin (3×35 cm) and the band held at the top of the column eluted with a 0.3 M $NaClO_4$ solution. The rear fractions exhibiting a (−) CD sign were collected together and concentrated. A mixture of ethanol and ether (1 : 1) was added and the solution kept in a refrigerator until crystals separated. The crystals thus obtained were recrystallized until the $\Delta\varepsilon$ value remained constant.

The elemental analyses are summarized in Table 1.

Resolution. The A-1 and A-3 Isomers of [Co(gly)$_2$-(Heta)]$^+$: In an aqueous, warm solution (*ca.* 40 °C) of the perchlorate (0.76 g, 0.002 mol) was dissolved $(-)_{589}Na[Co(ox)_2(en)]$ (0.34 g, 0.001 mol),[8] whereupon the less soluble diastereoisomeric salt crystallized. The crystals were dissolved in water (100 cm^3) containing some $NaHCO_3$ in order to assist dissolution. The resulting alkaline solution was adjusted to pH 2 with aqueous $HClO_4$ and concentrated until crystallization, after which recrystallization was repeated.

The A-4 Isomer of [Co(gly)$_2$(Heta)]$^+$: The chloride which is more soluble than the perchlorate was prepared in the following manner; the red effluent (A-4) described in a) was acidified with an aqueous HCl solution and concentrated and methanol added to precipitate the chloride. The chlo-

( ): Calcd.

ride (2 g, 0.0065 mol) was dissolved in warm water (*ca.* 15 cm^3, *ca.* 40 °C), and $(-)_{589}Na[Co(ox)_2(en)]$ (1 g, 0.003 mol)[8] added. The addition of ethanol gave red, needle-like crystals. Which was followed by recrystallization from warm water (*ca.* 40 °C).

The elemental analyses are summarized in Table 1.

Measurements. The absorption spectra were measured with a Hitachi 323 recording spectrophotometer, the absorption spectra of single crystals being measured by a micro-spectrophotometer constructed in this laboratory.[9] The CD spectra were recorded with a JASCO Model ORD/UV-5 spectrometer with CD attachments. Proton magnetic resonance (PMR) spectra were conducted with JEOL Model JNM-PS-100 spectrometer (100 MHz) at *ca.* 24 °C. The values of the chemical shifts were measured in relation to sodium 2,2,3,3-tetradeuterio-3-(trimethylsilyl)propionate (TMSP) as the internal reference. The acid dissociation constants of the complexes were determined by pH titration at 25 °C and the ionic strength 0.1 adjusted by $NaClO_4$.

The absorption and CD spectra were measured in acid (pH 2) or alkaline solutions (pH 8). For the PMR spectra, all of the protons of $-NH_2$ of the isomeric complexes of $[Co(gly)_2(Heta)]^+$ were deuterized in alkaline D_2O solution and the chlorides of the isomers used for the samples in acid solutions (DCl). The PMR spectra of the C-2 and C-3 were measured in D_2O–D_2SO_4 (30%) solutions.

Results and Discussion

Characterization of Complexes. The possible geometrical isomers of a $[Co(Heta)(N)_2(O)_2]$-type complex are illustrated in Fig. 1, where *trans(O)*, *cis·cis*, and *trans(N)* isomers are *mer* isomers with respect to the three N donor atoms. Assuming the $(N)_2(O)_2$ moiety consists of two glycinate or two β-alaninate ions, *i.e.* $(N)_2(O)_2=(gly)_2$ or $(\beta\text{-ala})_2$, then the four isomers are possible. When the moiety consists of (ox)(en), two isomers, *cis·cis* and *fac*, are possible; $(ox)(NH_3)_2$ as the moiety gives, *cis·cis*, *trans(N)* and *fac* isomers.

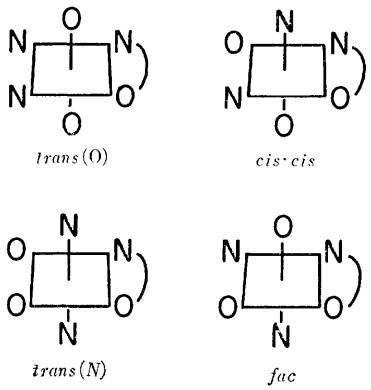

Fig. 1. Possible geometrical isomers of $[Co(Heta)(N)_2(O)_2]$. N–O denotes Heta.

From the absorption spectra of whole complexes, some of which are shown in Figs. 2 and 3, a *fac* isomer is readily distinguishable from the corresponding *mer* isomer, but the *mer* isomers cannot be distinguished from each other despite the fact that there are remarkable differences in the spectra for deprotonated isomers.

Yoneda *et al.*[10] explained theoretically the "through-cobalt effect" which had been found experimentally,[11] and on this basis assigned the signals of a number of complexes in the PMR spectra. The "through-cobalt effect" has been applied to the PMR data of the *mer*-$[Co(gly)_2(eta)]$ isomers and to the C-2 and C-3 isomers for characterization.

The PMR spectra, in alkaline solutions, of the $[Co(gly)_2(eta)]$ isomers are shown in Fig. 4, in which the signals of the methylene groups of the glycinate ions may be distinguished from the multiplets due to the methylene groups of the chelated eta, since the glycinate protons undoubtedly exhibit either a singlet or a doublet. No significant difference in chemical

ppm, *vs.* TMSP

Fig. 4. PMR spectra of; a—d) $[Co(gly)_2(eta)]$ (deprotonated form), a'—d') $[Co(gly)_2(Heta)]^+$ (protonated form), a, a') *trans(O)* (A-1), b, b') *cis·cis* (A-2), c, c') *trans(N)* (A-3), d, d') *fac* (A-4).

shift between the two glycinate groups of the *trans(N)* isomer is expected because of the symmetric situations of the two N atoms in the glycinate ions. Thus the spectrum of A-3, which possesses two singlets around 3.6 ppm, has been assumed to be the *trans(N)* isomer. Concerning the signals eminating from the chelated 2-aminoethanol, the multiplet of the CH_2 protons adjacent to the oxygen is thought to appear at lower field than that of the CH_2 protons adjacent to the nitrogen because of the stronger electron-withdrawing effect due to oxygen. The spectrum of the A-1 isomer shows two multiplets at approximately 3.2 and 2.8 ppm, whereas the spectrum of A-2 shows a multiplet around 2.8 ppm, the integrated intensity of which corresponds to the four hydrogens of the 2-aminoethanol, *i.e.*, the protons adjacent to the oxygen induce the signals at approximately 3.2 ppm in the A-1 isomer and at approximately 2.8 ppm in the A-2 isomer. Thus the A-1 isomer may be identified as the *trans(O)*, and the A-2 as the *cis·cis*. The results[12] of X-ray analysis of a crystal of the A-2 isomer supports this.

The PMR spectra of the protonated $[Co(gly)_2(Heta)]^+$ isomers are also shown in Fig. 4. The resonance signals of the protonated and deprotonated forms of the $[Co(gly)_2(Heta)]^+$ isomers may be assigned in the same manner as above, the results of which are summarized in Table 2.

With respect to the C-2 and C-3 isomers, the PMR spectra measured in D_2O–D_2SO_4 (30%) solution are shown in Fig. 5. There are five signals in the C-3 spectrum; the signal at 5.94 ppm is due to the NH_2 protons of the chelated 2-aminoethanol (Deta), where the hydroxyl group is deuterated, and the signals due to the two NH_3 groups are at 4.40 and 3.72 ppm. The other two signals due to the methylene groups of the Deta are at *ca.* 3.6 and 2.9 ppm as multiplets. Since the spectrum indicates the existence of two non-equivalent NH_3 groups, the C-3 isomer is regarded as the *cis·cis* form. Furthermore, from the "through-cobalt effect" the NH_3 proton signal at low field is due to the NH_3 trans to the N atom of the chelated Deta. From elemental analysis and PMR data it is thought that the C-2 isomer is $[Co(ox)(NH_3)(Heta)_2]^+$, in which one of the Heta molecules acts as a bidentate ligand and another as a unidentate ligand. The PMR spectrum of the C-2 isomer is more intricate than C-3; there are two broad signals at 5.9 and 4.4 ppm and multiplets around 3.7 and 2.8 ppm, the integrated ratio

a) The ε values were not obtained because of a lack of elemental analyses.

of the four signals being estimated as 2 : 5 : 4 : 4 (from lower to higher field). The multiplets are due to the methylene groups of the two Deta, while one of the broad signals at 5.9 ppm is assignable to the NH_2 protons of the chelated Deta from a comparison with the spectrum of the C-3 isomer. With respect to the broad signal at 4.4 ppm, it is considered from the integrated ratio that the two types of signal due to the NH_3 and the NH_2 of the unidentately bound amino alcohol overlap. Comparing the signals due to NH_3 and NH_2 in the C-2 isomer spectrum (4.4 and 5.9 ppm) with those in the C-3, *cis*·*cis* configuration with NH_3 in the trans position of the N of the chelated Deta is assumed to this isomer. The remaining isomer for the [Co(ox)$(NH_3)_2$(Heta)]$^+$ complex should be *trans*(*N*), but no band corresponding to such a species has been observed in the chromatographic separation.

The absorption spectra in alkaline solutions for the *cis*·*cis* isomers (A-2, B-1, C-2, and C-3) are similar. The No. 4 isomer of E-1 which exhibits a similar spectrum to those of the *cis*·*cis* isomers has been assigned *cis*·*cis*. On the basis of the similarity of spectra, the No. 1 isomer of E-1 and the No. 2 isomer of E-2 have been assigned *trans*(*O*) and the No. 2 isomer of E-1 *trans*(*N*).

The crystals of the No. 1 isomer of E-2 have been identified as *fac*-[Co(*β*-ala)$_3$]·$(HClO_4)_2$·0.5H_2O from elemental analysis, the absorption spectrum,[13] and the acid-base titration (see below). The complex species in acidified aqueous solution was adsorbed on the cation exchanger and the crystals contained perchloric acid of crystallization, both of which are of interest.

The No. 1 isomer of E-1 and the No. 2 isomer of E-2 have been identified as the same isomer since both species exhibit identical absorption spectra in acidic and basic solution and possess the same pK_a values as seen from Table 4.

Ogino *et al.*[2] assigned the absolute configurations of the [Co(en)$_2$(Heta)]$^{3+}$ and [Co(en)$_2$(*S*-Hpra)]$^{3+}$ complexes by a comparison of the CD spectra with those of the [Co(gly)(en)$_2$]$^{2+}$ and [Co(L-ala)(en)$_2$]$^{2+}$ complexes. Each CD spectrum of the *mer* and *fac* isomers of the present [Co(gly)$_2$(amOH)]$^+$ (amOH=Heta, *S*-Hpra) complexes exhibits a major CD peak in the T_{1g} region, similarly to those of the *mer* and *fac* isomers of [Co(am)$_3$] (am=gly, L-ala)[14,15] complexes, respectively. Thus, the sbaolute configuration of an isomer of [Co(gly)$_2$(amOH)]$^+$, which exhibits (+) CD sign at *ca.* 19000 cm^{-1}, is assignable to *Λ*, and hence, the other isomer to *Δ*. The structures thus assigned are summarized in Table 3.

pK_a *Values.* Nishide *et al.*[3] have reported that the pK_a values of the [Co$(NH_3)_4$(amOH)]$^{3+}$, [Co$(en)_2$-(amOH)]$^{3+}$ and [Co(*R*-chxn)$_2$(amOH)]$^{3+}$ complexes are *ca.* 3.6, 3.2, and 3.2, respectively. From the pK_a values of the present complexes summarized in Table 4, it is seen that the *cis*·*cis* and *trans*(*N*) isomers exhibit lowerer pK_a values (*ca.* 4.2) compare to the *trans*(*O*) and *fac* isomers (*ca.* 5.2). This indicates that the pK_a value of amOH, where the O atom is situated trans to the other O atom, shows *ca.* 4.2, while the value of amOH, where the O atom is situated trans to the N atom, shows *ca.* 5.2. This difference may be due to reduced electron density on the former hydroxyl O atom.

The No. 1 isomer of E-2, which has been assigned as [Co(*β*-ala)$_3$] from the absorption spectrum,[13] behaves as a strong and dibasic acid in titration, this being additional evidence that the chemical formula is [Co(*β*-ala)$_3$]·$(HClO_4)_2$.

Absorption Spectra. A spectra of [Co(gly)$_2$(*S*-Hpra)]$^+$ isomers show great similarity to the spectrum of the corresponding [Co(gly)$_2$(Heta)]$^+$ isomer. The numerical data for all the absorption spectra for the protonated and deprotonated isomers are summarized in Table 3. The spectrum of the *fac*-[Co(gly)$_2$(Heta)]$^+$

a) No. 1 (E-1) and No. 2 (E-2) complexes.

complex is similar to that of *fac*-[Co(gly)$_3$],[16] suggesting that amino alcohol in the protonated form and the glycinate ion are situated in close positions in the spectrochemical series.[17] For the *mer* isomers of [Co(*β*-ala)$_2$(Hpta)]$^+$, having two six-membered chelate rings, the spectra of the *cis·cis* and *trans*(*N*) isomers exhibit a remarkable degree of splitting in the T_{1g} region, while no splitting has been observed in the spectrum of the *trans*(*O*) isomer. Among the *cis·cis* and *trans*(*N*) isomers of the [Co(gly)$_2$(Heta)]$^+$, [Co(gly)$_2$(*S*-Hpra)]$^+$ and [Co(ox)(Heta)(N)$_2$]$^+$-type complexes, the spectra are similar and show a little splitting; however, no splittings have been observed in the spectra of the *trans*(*O*) isomers in the T_{1g} region.

Each of the deprotonated complexes exhibits quite a different spectrum from the corresponding protonated complex. The *trans*(*O*), *cis·cis*, *trans*(*N*) and *fac* isomers exhibit remarkedly different spectra. The T_{1g} band for each *trans*(*O*) isomer is clearly split into two and the separation between the maxima is in the range 3200—3800 cm^{-1}; the T_{2g} band for each *trans*(*O*) isomer shows a sharp band. For the *cis·cis* isomers, the T_{1g} bands are not split as clearly as the *trans*(*O*) isomers, but each has a noticeable shoulder at lower wave-number, the T_{2g} band exhibiting a broad maximum generally splitting. The exceptions are the *cis·cis* isomers of B-1, C-2, and C-3, which contain no N–O chelate rings beyond eta, which show only sharp bands in the T_{2g} region. For the *trans*(*N*) isomers, recognizable splittings in the T_{2g} region and sharp bands in the T_{1g} region have been observed in contrast to the *trans*(*O*) isomers. The remaining isomers of *fac* give sharp and red-shifted bands in both the T_{1g} and T_{2g} regions. The complexes are, however, shifted to the blue end.

As seen in Fig. 3, there is a remarkable difference between the shapes of the T_{2g} bands for the *trans*(*N*) isomers of the [Co(gly)$_2$(eta)] and [Co(*β*-ala)$_2$(eta)] complexes, both of which have an identical chromophore *trans*(*N*)-[Co(eta)(N)$_2$(O)$_2$]. The same differences in the T_{2g} bands have been observed between the *cis·cis*-[Co(ox)(eta)(N)$_2$] isomer and each *cis·cis* isomer of the [Co(gly)$_2$(eta)] and [Co(*β*-ala)$_2$(eta)] complexes as well as between the *fac* isomers of the [Co(ox)(eta)(N)$_2$] complex and the [Co(gly)$_2$(eta)] and [Co(*β*-ala)$_2$(eta)] complexes. These differences may be related to the manner of chelation of the ligands forming the (N)$_2$(O)$_2$ moiety.

Three possible transitions for the T_{1g} band have been revealed in the polarized crystal spectra of the *trans*(*O*) and *cis·cis* isomers of the [Co(gly)$_2$(eta)] complex, and the polarized crystal spectra of the *cis·cis* and *trans*(*N*) isomers provides clearer splitting of the T_{2g} band (Fig. 6). The *trans*(*O*) isomer shows a large splitting of the T_{1g} band and this together with the X-ray analysis of the *cis·cis* isomer[12] allows assignment of the three bands. The paths of the polarized light are schematically shown in Fig. 7. In the ∥ polarized spectra, a maximum at 15900 cm^{-1} for the *trans*(*O*) isomer and two maxima at 20200 and 16400 cm^{-1} for the *cis·cis* isomer have been assigned to the transitions from the d_{zx} orbital for the *trans*(*O*) and from the d_{yz} and d_{zx} orbitals for the *cis·cis* isomer,

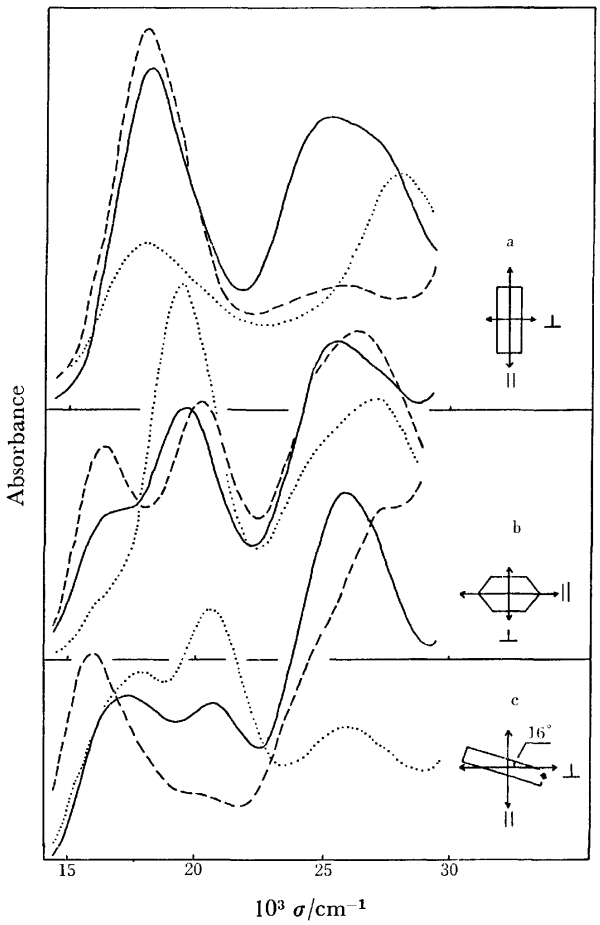

Fig. 6. Absorption spectra of [Co(gly)$_2$(eta)]; a) *trans*(*N*), b) *cis·cis*, and c) *trans*(*O*) (—— solution, —— ∥, ····· ⊥).

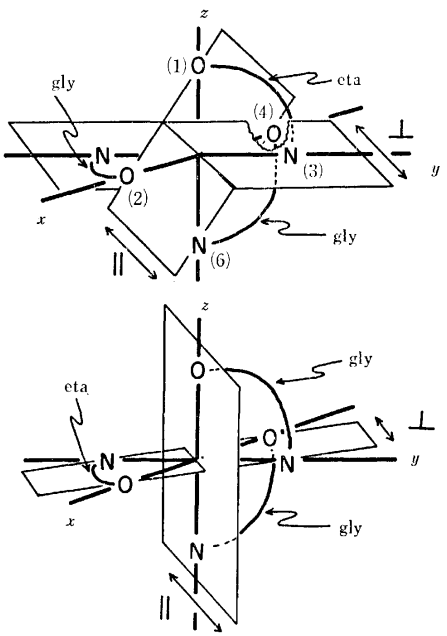

Fig. 7. The arrangements of the donor atoms and the paths of the polarized lights; *trans*(*O*)-[Co(gly)$_2$(eta)] (upper) and *cis·cis*-[Co(gly)$_2$(eta)] (lower).

respectively (Fig. 7). In the spectra with ⊥ polarization two maxima at 20600 and 17800 cm^{-1} for the *trans(O)* and a maximum at 19500 cm^{-1} for the *cis·cis* isomer have been assigned to the transitions from d_{yz} and d_{xy} for the former and from d_{xy} for the latter isomer, respectively. Using the Angular Overlap Model[4] (Appendix), the antibonding parameters, e_σ and e_π, may be obtained from the above data assuming that the $e_\sigma(N)$ parameters of the amino alcoholate and glycinate ions are equal. Assuming $C=4B$ and $B=450$ cm^{-1} (C and B denote the Racah parameters), the most reasonable values are shown in Table 5. Both the e_σ and the e_π values for the alcoholate O atom are large which are comparable with those for the OH^- ligand. The e_σ and e_π values for the OH^- ligand have been reported as 8500 and 2100 cm^{-1}, respectively, for the *trans*-$[Cr(OH)_2(NH_3)_4]^+$ isomer.[18]

CD Spectra. The CD spectra of the protonated and deprotonated forms of the resolved three isomers of the $[Co(gly)_2(Heta)]^+$ complex are shown in Fig. 8, and the configurational and vicinal effect curves, calculated from the CD spectra of the protonated and deprotonated isomers of the $[Co(gly)_2(S\text{-Hpra})]^+$ complex are shown in Fig. 9. The configurational curves show striking resemblances to the CD spectra, in both acidic and basic solutions of the corresponding isomers of the $[Co(gly)_2(Heta)]^+$ complex indicating the additivity of the configurational and vicinal effects in both the $[Co(gly)_2(S\text{-Hpra})]^+$ and $[Co(gly)_2(S\text{-pra})]$

complexes. The T_{2g} transitions are magnetic-dipole-forbidden, but nevertheless the configurational effect curve for the *fac*-[Co(gly)$_2$(eta)] isomer exhibits a sharp peak at *ca.* 25000 cm^{-1}.

With respect to the [Co(N)$_5$(O)]-type complexes, Nishide *et al.*[3] reported that all vicinal effect curves for the deprotonated [Co(*S*-pra)(en)$_2$]$^{2+}$ and [Co(*S*-pra)(NH$_3$)$_4$]$^{2+}$ complexes showed a weak positive and an intense negative CD peak in the T_{1g} region and a moderately intense positive CD peak in the T_{2g} region (*ca.* 25000 cm^{-1}). In the [Co(N)$_3$(O)$_3$]-type complexes, all the vicinal effect curves of the deprotonated isomers exhibit a strong negative CD band on the high-frequency-side in the T_{1g} region and a strong positive CD band at *ca.* 25000 cm^{-1} in the T_{2g} region. It is interesting that the strong positive CD peaks in the T_{2g} region for both the [Co(N)$_5$(O)]- and [Co(N)$_3$(O)$_3$]-type have been observed at the same frequency of 25000 cm^{-1}. Among the *mer* isomers the half-width of each T_{1g} band decreases in the order: *trans*(*O*), *cis*·*cis* and *trans*(*N*). In this order each major peak in the vicinal effect shifts to the lower-energy-side, while the minor (+) peak at a lower-energy gradually enhances in intensity.

The authors wish to express sincere thanks to Dr. T. Nishide and Prof. K. Saito, Tohoku University, for the aid in the preparation of the (*S*)-2-amino-1-propanol ligand, and also to Dr. H. Miyamae and Prof. Y. Saito, Tokyo University, for the X-ray analysis of the *cis*·*cis*-[Co(gly)$_2$(eta)] complex.

Appendix

Energy Matrices. For the *trans*(*O*) isomer, the arrangement of gly$^-$ and eta$^-$ is defined as in Fig. 7; all the ligating atoms are placed on the x, y, and z axes, and the lone pairs of the alcoholate ion interact with only the d_{xz} and d_{yz} orbitals. The π orbitals of the chelating carboxylate ions at (2) and (4) in Fig. 7 interact with only d_{xz} and d_{xy}, respectively. Based on these assumptions, the antibonding parameters have been defined as follows:

σ_N=a σ-antibonding parameter for the N donor atom of gly$^-$ or eta$^-$=e_σ(N)

σ=a σ-antibonding parameter for the O donor atom of gly$^-$=e_σ(O)

σ'=a σ-antibonding parameter for the O donor atom of eta$^-$=e_σ(O′)

π=a π-antibonding parameter for the O donor atom of gly$^-$=e_π(O)

π'=a π-antibonding parameter for the O donor atom of eta$^-$ related with the d_{xz} orbital=$e_{\pi 1}$(O′)

π''=a π-antibonding parameter for the O donor atom of

eta⁻ related with the d_{yz} orbital=$e_{\pi_2}(O')$.
The antibonding energies with non-vanishing values are;

$$\langle z^2|\mathbf{A}|z^2\rangle = \frac{3}{2}\sigma_N + \frac{1}{2}\sigma + \sigma'$$
$$\langle yz|\mathbf{A}|yz\rangle = \pi''$$
$$\langle zx|\mathbf{A}|zx\rangle = \pi + \pi'$$
$$\langle xy|\mathbf{A}|xy\rangle = \pi$$
$$\langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle = \frac{3}{2}\sigma_N + \frac{3}{2}\sigma$$
$$\langle x^2-y^2|\mathbf{A}|z^2\rangle = \frac{\sqrt{3}}{2}[\sigma_N-\sigma].$$

Using the above relations, the energy matrix for the *trans(O)* isomer may be obtained.

On the assumption that the N and O donor atoms for the *cis·cis* isomer are arranged as in Fig. 7, the energy matrix can be obtained similarly to that for the *trans(O)* isomer.

Evaluation of Parameters. The three transitions assigned are for the *trans(O)* isomer,

$$E(d_{y^2-z^2} \longleftarrow d_{yz}) = 20600\ cm^{-1}$$
$$E(d_{z^2-x^2} \longleftarrow d_{zx}) = 15900\ cm^{-1}$$
$$E(d_{x^2-y^2} \longleftarrow d_{xy}) = 17800\ cm^{-1},$$

and for the *cis·cis* isomer,

$$E(d_{y^2-z^2} \longleftarrow d_{yz}) = 20200\ cm^{-1}$$
$$E(d_{z^2-x^2} \longleftarrow d_{zx}) = 16400\ cm^{-1}$$
$$E(d_{x^2-y^2} \longleftarrow d_{xy}) = 19500\ cm^{-1}.$$

Assuming the energy differences originating from the off-diagonal elements are negligibly small; the above relations may be rewritten in terms of the diagonal elements of T_{1g} transitions

$$\frac{3}{4}(3\sigma_N+\sigma') - \pi'' - C = 20600 \quad (1)$$
$$\frac{3}{4}(\sigma_N+2\sigma+\sigma') - \pi - \pi' - C = 15900 \quad (2)$$
$$\frac{3}{4}(\sigma_N+\sigma) - \pi - C = 17800 \quad (3)$$
$$\frac{3}{4}(3\sigma_N+\sigma) - C = 20200 \quad (4)$$
$$\frac{3}{4}(\sigma_N+2\sigma+\sigma') - \pi - \pi' - C = 16400 \quad (5)$$
$$\frac{3}{4}(2\sigma_N+\sigma+\sigma') - \pi - \pi'' - C = 19500 \quad (6)$$

The left-hand-sides of the equations are related as follows;
(1)+(3)=(4)+(6)
(2)=(5),
and t .us the six equations may be reduced to four. Assuming $C=4B$, the value of B may be estimated for the [Co(gly)$_2$(eta)] complex (450 cm^{-1}), since the values of B for the *fac*-[Co(gly)$_3$] and *fac*-[Co(eta)$_3$] isomers are equal to 470 and 430 cm^{-1}, respectively. Furthermore, the value of σ_N has been estimated as 7700 cm^{-1}, which is identical with the value of σ_N for the [Co(en)$_3$] complex.

Using these values of B and σ_N, the four independent equations, which have been arbitrarily chosen from the six equations, may be solved and eight groups of $\sigma,\sigma'-4\pi''/3$, π, and $\pi'-\pi''$ values obtained. The average values of each $\sigma,\sigma'-4\pi''/3$, π, and $\pi'-\pi''$ are 5800, 7200, 325, and 1600 cm^{-1}, respectively.

From the above relations, the energies of the diagonal elements of the T_{2g} transitions are expressed by the use of the parameters. By comparing the absorption spectra with the calculated energies of the T_{2g} transitions, the most reasonable value of π'' is 700 cm^{-1}. Consequently, the parameters of σ_N, σ, σ', π, π', and π'' have been evaluated as 7700, 5800, 8100, 325, 2300 and 700 cm^{-1}, respectively.

A Mössbauer Study of the Photolysis of Bis- and Tris-oxalato Iron(III) Complexes in a Solid, Solutions, and Frozen Solutions

Haruo SATO and Takeshi TOMINAGA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received October 31, 1978)

The photolytic reactions of bis- and tris-oxalato iron(III) complexes in a solid, solutions, and frozen solutions were studied by means of ^{57}Fe Mössbauer spectroscopy. An iron(II) species was observed as a metastable intermediate product in the photolysis of tris(oxalato)ferrate(III) in a solid and solutions. A mechanism with a sequence of iron(II) intermediates was tentatively proposed for the photolysis and subsequent reactions in this compound. The Mössbauer technique was also used to examine whether or not tris(oxalato)ferrate(III) was diluted uniformly with diamagnetic substances in the mixed crystals and frozen solutions.

It has been demonstrated in our earlier work that Mössbauer spectroscopy is a useful tool for detecting the changes in oxidation states and structures induced by radiolysis, photolysis, and pyrolysis in solid iron compounds.[1-6] Recently, we have investigated the photolysis of potassium tris(oxalato)ferrate(III) in a solid and solutions[7] and proposed the possible application of Mössbauer spectroscopy in the photochemistry of metal complexes in the liquid and frozen states.

The object of this article is to present a more complete report of our work concerning the photolysis of potassium tris(oxalato)ferrate(III) in a solid and solutions, together with our recent results on the photolysis of potassium diaquabis(oxalato)ferrate(III) in solutions. In addition, the Mössbauer technique has also been applied to the investigation of whether or not potassium tris(oxalato)ferrate(III) is diluted uniformly with diamagnetic substances in mixed crystals and in frozen solutions.

Experimental

Materials. *Potassium Tris(oxalato)ferrate(III) Trihydrate* $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$: An aqueous solution of a (1 : 3) mixture (by mole ratio) of iron(III) chloride and potassium oxalate was heated for 2 h at 80 °C; after the solution had been cooled, the precipitate was collected and recrystallized three times from water. Found: C, 14.6; H, 1.2%. Calcd for $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$: C, 14.7; H, 1.2%.

^{57}Fe-enriched Potassium Tris(oxalato)ferrate(III) Trihydrate $K_3[^{57}Fe(C_2O_4)_3]\cdot 3H_2O$: A 0.2 M potassium hydrogenoxalate solution was added to an excess of freshly precipitated $^{57}Fe_2O_3\cdot nH_2O$, after which the mixture was heated for 1 h at 70 °C (1 M=1 mol dm^{-3}). The resulting solution was filtered, and the filtrate was concentrated in a vacuum.[8] Found: C, 14.7; H, 1.0%. Calcd for $K_3[^{57}Fe(C_2O_4)_3]\cdot 3H_2O$: C, 14.6; H, 1.2%.

^{57}Fe-doped Potassium Tris(oxalato)cobaltate(III) Trihydrate $K_3[(^{57}Fe,Co)(C_2O_4)_3]\cdot 3H_2O$: An aqueous solution containing a (1 : 33) mixture (by weight) of ^{57}Fe-enriched potassium tris(oxalato)ferrate(III) trihydrate and potassium tris(oxalato)cobaltate(III) trihydrate was quenched quickly in liquid nitrogen, and then the frozen solution was condensed in a vacuum at −21 °C by pumping it through a liquid nitrogen trap.

^{57}Fe-enriched Potassium Diaquabis(oxalato)ferrate(III) ($K[^{57}Fe(C_2O_4)_2(H_2O)_2]$) Solutions: A (1 : 3) mixture (by mole ratio) of potassium oxalate and oxalic acid in an aqueous solution was added to an excess of freshly precipitated $^{57}Fe_2O_3\cdot nH_2O$; the solution was then filtered after having been heated for 1 h at 70 °C.

Potassium Diaquabis(oxalato)ferrate(II) $K_2[Fe(C_2O_4)_2(H_2O)_2]$: This compound was prepared according to the procedures described by Temperly *et al.*[9]

Potassium μ-Oxalato-bis[bis(oxalato)ferrate(II)] $K_6[Fe_2(C_2O_4)_5]$: This was prepared by heating potassium tris(oxalato)ferrate(III) for 15 min at 260 °C according to the method described by Bancroft *et al.*[10]

Photoirradiation. Samples were exposed either to a 500-W superhigh-pressure mercury lamp (spectral range: 300—600 nm) or to a 30-W low-pressure mercury lamp (253.7 nm). The solid samples were irradiated as crystals spread over a glass plate or adhesive tape, as film coated on an acrylic plate,[11] or as a disk in KCl.

A quartz cell with a 5-mm optical path was used for the irradiation of the solutions. Frozen solutions were irradiated as dipped directly in liquid nitrogen or as contained in acrylic or Teflon holders designed for Mössbauer measurements.

Freezing of Solutions. Both irradiated and unirradiated solutions were frozen quickly by one of the following procedures, A—D, prior to Mössbauer measurements:

A) The holder containing the solution was placed on Dry Ice.

B) The holder containing the solution was immersed in liquid nitrogen.

C) Droplets of the solution were added directly to liquid nitrogen.

D) A spatula precooled at 77 K was dipped into the solution so that a small amount was condensed on it, and then it was quickly put into liquid nitrogen. By repeating this procedure, small droplets of the frozen solution were collected in the liquid nitrogen.

By Procedures B—D, we may achieve freezing rates of 5—8 K/s, 10—40 K/s, and 100—250 K/s respectively.

Measurements of Mössbauer Spectra, Infrared Spectra, and Powder X-Ray Patterns. The Mössbauer spectra at 77 K and 293 K were measured by using a Hitachi AA-40 or a Shimadzu MEG-2 Mössbauer spectrometer against ^{57}Co in copper or rhodium foil. Acrylic or Teflon holders (32 mm in diameter) were used for the measurements of the solutions.

The curve-fitting of the spectra thus obtained was performed with a HITAC 8800/8700 computer, assuming that they were composed of absorption peaks in a Lorentzian line shape.

The infrared spectra were recorded on a Hitachi EPI-G2 spectrophotometer (400—4000 cm^{-1} region). The powder X-ray patterns of the (1 : 33) mixture of potassium tris(oxalato)ferrate(III) trihydrate with potassium tris(oxalato)cobaltate(III) trihydrate, and ^{57}Fe-doped potassium tris(oxalato)cobaltate(III) trihydrate were taken by using a Rigaku Denki Geigerflex and Fe $K\alpha$-radiation.

Results and Discussion

Photolysis of Potassium Tris(oxalato)ferrate(III) in the Solid Phase. The Mössbauer spectrum at 77 K of the unirradiated solid potassium tris(oxalato)-ferrate(III) (Product I) in Fig. 1a is composed of a single broad absorption indicative of an electronic spin relaxation effect.[12] After irradiation at 253.7 nm for 5 h at room temperature, the Mössbauer spectrum (Fig. 1b) represents two sets of quadrupole doublets for an iron(II) species (Product II) and an iron(III) species (Product III) in addition to the broad single absorption of the unreacted parent compound. After the prolonged standing of the photolyzed sample in air, however, the intensities of the iron(III) doublet peaks (Product III) had increased, while those of the iron(II) doublet (Product II) had decreased and the iron(II) doublet (Product II) had disappeared eventually (Fig. 1c).

When smaller amounts of ^{57}Fe-enriched potassium tris(oxalato)ferrate(III) were irradiated in a solid, in a disk, or on film, two iron(II) species (Products IV and V) other than Product II were obtained as photolysis products, depending on the irradiation conditions (period, temperature, and atmosphere) (Fig. 2).

Table 1 summarizes the Mössbauer parameters of the photolysis products from potassium tris(oxalato)-ferrate(III), together with the identities of those products tentatively deduced on the basis of the results reported previously for the pyrolysis and radiolysis of the same system.[9,10,13,14]

Among such products, Products V and VI[15] are fairly unstable intermediates which have not been observed in the earlier work. The Mössbauer parameters and infrared spectra (Fig. 3) reveal that both products, V and VI, cannot be identical with any of the known products, I to IV, nor with any tetrahedral species. Furthermore, from the conceivable structures for Products V and VI, we may rule out the following ones:

1) $[Fe(C_2O_4)_3]^{4-}$ and $[Fe(C_2O_4)_2(C_2O_4H)(H_2O)]^{3-}$ can be excluded for stoichiometric reasons.

2) $[Fe(H_2O)_6]^{2-}$ and $[Fe(C_2O_4)(H_2O)_4]$ are unlikely because Product VI is stable in solutions containing excess potassium oxalate.

3) Structures with bridging oxalates may also be eliminated because the infrared spectrum of Product

Table 1. Mössbauer parameters of the photolysis products from potassium tris(oxalato)ferrate(III)

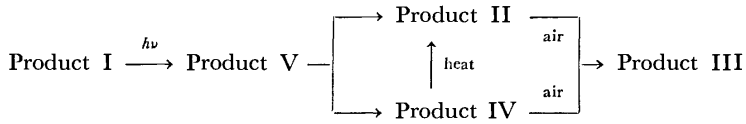
Product	77 K		293 K		Tentative assignment
	δ[a]	ΔE_Q	δ[a]	ΔE_Q	
	mm/s		mm/s		
Product I	0.44±0.02	—	0.33±0.02	—	Parent compound
Product II	1.26±0.02	4.09±0.08	1.16±0.02	3.89±0.08	$[Fe_2^{II}(C_2O_4)_5]^{6-}$
Product III	0.49±0.02	0.70±0.03	0.36±0.03	0.68±0.04	$[Fe^{III}(C_2O_4)_2(H_2O)_2]^-$
Product IV	1.34±0.02	3.27±0.04	1.22±0.02	2.53±0.04	$[Fe^{II}(C_2O_4)_2(H_2O)_2]^{2-}$
Product V	1.28±0.02	2.94±0.03	—	—	Metastable iron(II) species
Product VI	1.29±0.01	2.91±0.01	—	—	Metastable iron(II) species
Freeze drying (Product V)	1.29±0.02	2.94±0.02	—	—	Metastable iron(II) species

a) With respect to the centroid of the spectrum of iron foil at 293 K. Experimental errors are indicated of maximum deviations.

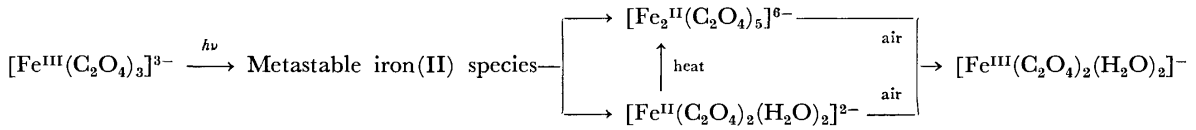
V shows no absorption band in the 1300—1400 cm^{-1} region (characteristic of the iron complexes with oxalate bridging, such as $FeC_2O_4 \cdot 2H_2O$ and $K_6[Fe_2(C_2O_4)_5]$).

Although further investigation will be necessary for determining the identities of Products V and VI, we may assume tentatively that a geometrical isomer of Product IV ($K_2[Fe(C_2O_4)_2(H_2O)_2]$) remains as one of the possible structures for Product V (and VI).

As has been mentioned above, the formation and subsequent conversion of Products II, III, IV, and V were governed mainly by the photoirradiation conditions. A brief irradiation at a lower temperature generally favors the initial formation of Product V. After prolonged standing, Product V is converted into Products IV and II, which are eventually converted into Product III by oxidation in air. Product II also appears on the heating of Product IV at 120 °C. Thus, the overall mechanism for the formation of such products can be generally accounted for by assuming the following sequence of photolytic and subsequent reactions:



or, in terms of tentative assignments;



Dilution of Potassium Tris(oxalato)ferrate(III) in Mixed Crystals and Frozen Solutions. As is shown in Fig. 4a, the Mössbauer spectrum of solid potassium tris(oxalato)ferrate(III) trihydrate consists of a remarkably broadened absorption peak, indicating an electronic spin relaxation effect.[12] If this compound is diluted uniformly with a diamagnetic substance (*e.g.*, potassium tris(oxalato)cobaltate(III) trihydrate or water), however, a resolved hyperfine structure is observed in the Mössbauer spectrum due to the developing relaxation effect. In fact, the Mössbauer spectrum of ^{57}Fe-doped potassium tris(oxalato)ferrate(III) trihydrate, $K_3[(^{57}Fe,Co)(C_2O_4)_3] \cdot 3H_2O$ (Fig. 4b), indicates a resolved magnetic hyperfine structure and suggests that potassium tris(oxalato)ferrate(III) trihydrate is diluted uniformly in solid potassium tris(oxalato)cobaltate(III) trihydrate. By comparing the powder X-ray pattern of the ^{57}Fe-doped potassium tris(oxalato)cobaltate(III) with that of a (1 : 33) mixture of potassium tris(oxalato)ferrate(III) trihydrate and potassium tris(oxalato)cobaltate(III) trihydrate, it may be presumed that the ^{57}Fe-doped potassium tris(oxalato)cobaltate(III) trihydrate is constituted of mixed crystals.

In frozen solutions containing uniformly dispersed iron(III) species, Mössbauer spectra have been reported to show similar hyperfine structures resulting from long spin-relaxation times.[16,17] Although we have, in this work, measured the Mössbauer spectra of frozen solutions (quenched by Procedure B) at various concentrations (0.002—1 M) of potassium tris(oxalato)ferrate(III), no significant difference was observed in their spectra over the concentration range studied. For example, the Mössbauer spectrum of the 0.005 M potassium tris(oxalato)ferrate(III) solution (Fig. 4c) quenched by Procedure B resembles that of the same compound in the solid state (Fig. 4a) and suggests that microcrystals of the solute were separated on freezing the solutions. However, the Mössbauer spectrum of the 0.005 M potassium tris(oxalato)ferrate(III) solution containing an excess of potassium hydrogenoxalate, frozen quickly by Procedure D

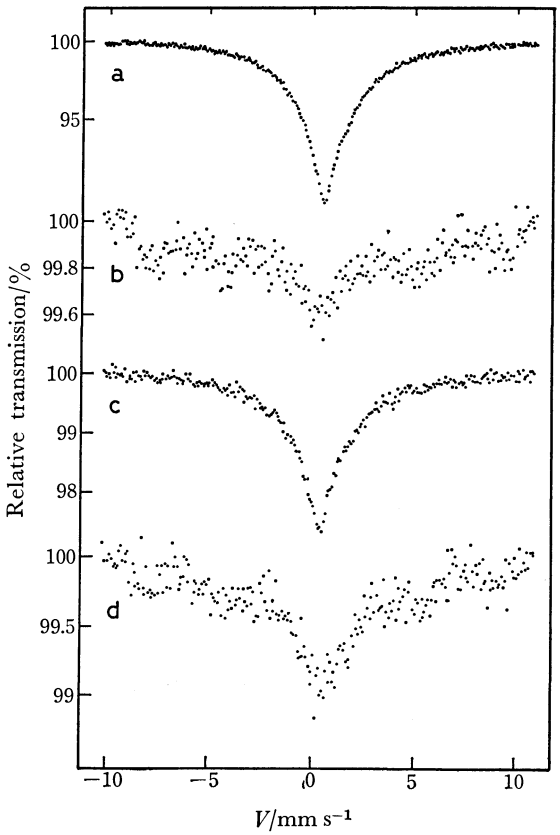


Fig. 4. Mössbauer spectra at 77 K of (a) solid $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$, (b) solid $K_3[(^{57}Fe,Co)(C_2O_4)_3]\cdot 3H_2O$, (c) a 0.005 M $K_3[^{57}Fe(C_2O_4)_3]$ solution quenched by procedure B, and (d) a 0.005 M $K_3[^{57}Fe(C_2O_4)_3]$ solution containing an excess of KHC_2O_4, quenched quickly by procedure D.

(Fig. 4d), shows the hyperfine structure characteristic of the relaxation effect. Accordingly, it is obvious that the solute is diluted more uniformly in this frozen solution. Thus, the Mössbauer technique can be used to examine whether or not solutes are uniformly diluted in quenched solutions.

Photolysis of Potassium Tris(oxalato)ferrate(III) in Aqueous Solutions and Frozen Aqueous Solutions. In Fig. 5 are illustrated the Mössbauer spectra of neutral

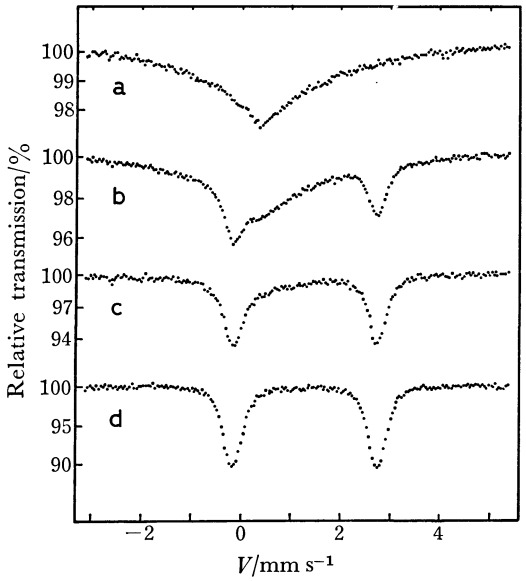

Fig. 5. Mössbauer spectra at 77 K of neutral aqueous solutions of $K_3[^{57}Fe(C_2O_4)_3]$ quenched by procedure B after photoirradiation for various periods. (a) Unirradiated, (b) 3-s irradiated, (c) 10-s irradiated, and (d) 120-s irradiated.

aqueous solutions of potassium tris(oxalato)ferrate(III) quenched by Procedure B after photoirradiation for 3, 10, and 120 s with a superhigh-pressure mercury lamp. The iron(III) single peak of the parent complex (Product I) tended to disappear, yet the iron(II) doublet (Product VI) became predominant with the increase in the irradiation period. Table 2 summarizes the Mössbauer parameters of the products obtained by the photoirradiation of the solutions, together with the percentage photoreduction for various irradiation periods.

The Mössbauer spectrum of the photoirradiated frozen solutions of potassium tris(oxalato)ferrate(III) also indicates the formation of Product VI (Fig. 6a). On 5-min standing at room temperature after 2-min exposure to the superhigh-pressure mercury lamp, iron(II) oxalate has already started precipitating in an aqueous solution of potassium tris(oxalato)-

Table 2. Mössbauer parameters at 77 K of the photolysis products of 0.02 M $K_3[^{57}Fe(C_2O_4)_3]$ aqueous solutions and the percentage photoreduction for various irradiation periods

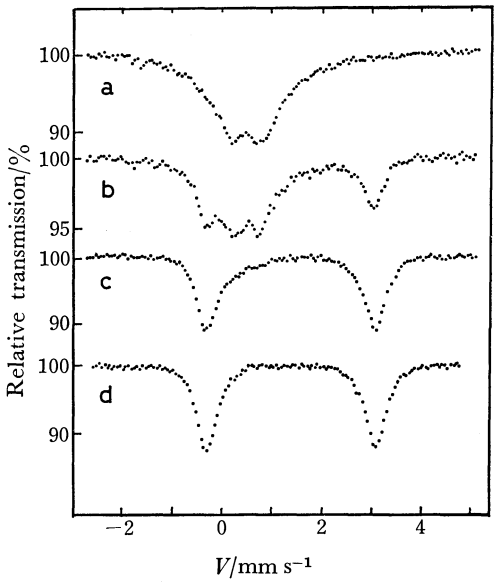

Fig. 7. Mössbauer spectra at 77 K of 0.05 M sulfuric acid solutions of $K_3[^{57}Fe(C_2O_4)_3]$ quenched by procedure A after photoirradiation for (b) 3 s, (c) 10 s, and (d) 60 s. (a): Unirradiated solution.

ferrate(III); Fig. 6b shows the spectrum of this solution quenched quickly. Although Product VI is at first converted into iron(II) oxalate, iron(II) oxalate is in turn oxidized after prolonged standing in air and is dissolved again. The Mössbauer spectrum of the iron(III) species resulting from the oxidation of iron(II) oxalate (Fig. 6c) reveals the formation of potassium diaquabis(oxalato)ferrate(III) and potassium tris(oxalato)ferrate(III).

The Mössbauer parameters and infrared spectra suggest that the product obtained from freeze-drying (at −21 °C) of Product VI may be identical with Product V.

Hence, the photolysis and subsequent reactions of potassium tris(oxalato)ferrate(III) in aqueous solutions presumably proceed as in the following sequence:

$$[Fe(C_2O_4)_3]^{3-} \xrightarrow{h\nu} \underset{\text{species (Product VI)}}{\text{Metastable iron(II)}} \longrightarrow \underset{\text{(precipitate)}}{FeC_2O_4\cdot 2H_2O} \xrightarrow{\text{air}} [Fe^{III}(C_2O_4)_2(H_2O)_2]^- \text{ or } [Fe^{III}(C_2O_4)_3]^{3-}$$

$$\downarrow \text{freeze-drying}$$

Product V

Photolysis of Potassium Tris(oxalato)ferrate(III) in Sulfuric Acid Solutions. Based on spectrophotometric measurements, Parker has reported that both monooxalato- and bisoxalato- iron(III) complexes are present in sulfuric acid solutions of potassium tris(oxalato)ferrate(III).[18]

The Mössbauer spectrum obtained in this work of a frozen 0.05 M sulfuric acid solution of potassium tris(oxalato)ferrate(III) reveals a broad singlet absorption of tris(oxalato)ferrate(III) ion in addition to the mono- and bis-oxalato complexes (Fig. 7a). The relative quantities of mono-, bis-, and tris-oxalato complexes in frozen solutions were found to depend on the freezing rate. Figures 7b—d illustrates the Mössbauer spectra of sulfuric acid solutions of potassium tris(oxalato)ferrate(III) frozen by Procedure A after having been irradiated with the superhigh-pressure mercury lamp for 3, 10, and 60 s. It is obvious that the parent complex was reduced to an iron(II) species (Product VII). The Mössbauer parameters of Product VII (δ=1.4 mm/s, ΔE_Q=3.2—3.4 mm/s) appear to change slightly with the change in the freezing rate. The percentage photoreduction to the iron(II) species was estimated as being about 30, 70, and 100% for 3-, 10-, and 60-s irradiations respectively. The percentage reduction determined spectrophotochemically by means of the *o*-phenanthroline method[19] was in good agreement with the Mössbauer data.

Since Product VII is unstable, iron(II) oxalate has already appeared in the solution after 120-s photoirradiation. When a frozen-sulfuric-acid solution of potassium tris(oxalato)ferrate(III) has been exposed to light, the Mössbauer spectrum also indicates the formation of Product VII.

Photolysis of Potassium Diaquabis(oxalato)ferrate(III) in Aqueous Solutions. Figure 8 demonstrates the Mössbauer spectra of aqueous solutions of potassium diaquabis(oxalato)ferrate(III) frozen by Procedure B after photoirradiation; the percentage photoreduction of the parent complex to iron(II) species increases with the increase in the photoirradiation period. Table

Table 3. Mössbauer parameters at 77 K of the photolysis products of 0.02 M $K[^{57}Fe(C_2O_4)_2(H_2O)_2]$ aqueous solutions for various irradiation periods

Product		Period of photoirradiation/s			
		0	3	10	60
Iron(III) species (parent)	δ[a]/(mm/s)	0.49	0.49	[b]	—
	ΔE_Q/(mm/s)	0.64	0.58	[b]	—

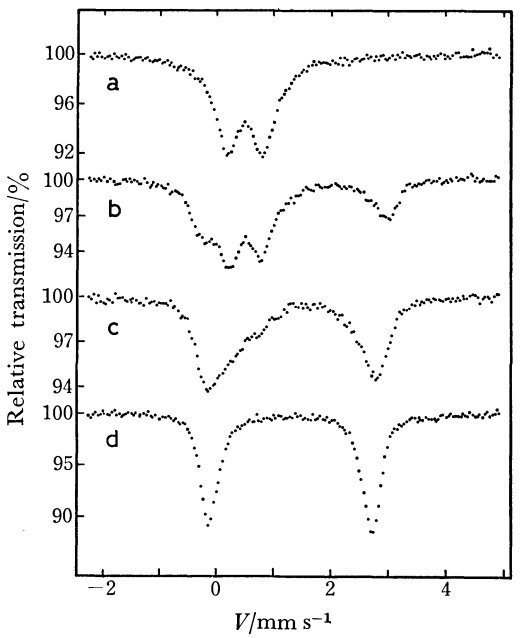

Fig. 8. Mössbauer spectra at 77 K of aqueous solutions of $K[^{57}Fe(C_2O_4)_2(H_2O)_2]$ quenched by procedure B after photoirradiation for (b) 3 s, (c) 10 s, and (d) 60 s. (a): Unirradiated solution.

3 summarizes the Mössbauer parameters obtained from curve-fitting by assuming a quadrupole doublet of the Lorentzian line-shape for the iron(II) species. While the isomer shift and quadrupole splitting of the iron(II) species are decreased with the increase in the irradiation period, the line-width shows anomalous behavior. Although the Mössbauer line-width is, in general, expected to increase with the concentration of iron species,[20] the line-width of the iron(II) species in Fig. 8 does not simply increase with the concentration in terms of the irradiation period; the widths are 0.48, 0.57, and 0.39 mm/s for 3-, 10-, and 60-s irradiations respectively. Such an anomaly can be explained tentatively by assuming that at least two iron(II) species with slightly different parameters are formed in photolysis; one of them is predominant after 3-s irradiation, while the other becomes predominant after 60-s irradiation. Both species can exist after 10-s irradiation. Unfortunately, the Mössbauer spectrum obtained after 10-s irradiation (Fig. 8c) cannot be resolved well by computer curve-fitting because of the broad overlapping absorption of tris(oxalato)ferrate(III), possibly formed by the combination of the parent complex with free oxalate ions.[21]

Further study will be necessary for a complete understanding of the mechanism of the photolysis of diaquabis(oxalato)ferrate(III) in aqueous solutions.

Preparation and Stereochemistry of Optical Isomers of the Tris-(3,3′-dimethyl-2,2′-bipyridyl *N,N′*-dioxide)chromium(III) Complex

Hideaki KANNO, Kazuo KASHIWABARA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received October 30, 1978)

A new ligand, (*R*)- and (*S*)-3,3′-dimethyl-2,2′-bipyridyl *N,N′*-dioxide(mbdo) forms three diastereomers(I, II, and III) of $[Cr(mbdo)_3]^{3+}$ by the reaction with $[Cr(H_2O)_6]^{3+}$ in water. (I) was assigned to a pair of enantiomers, $\Delta(RRR)$ and $\Lambda(SSS)$, and (II) and (III) to either a diastereomeric pair of $\Delta(RRS)$ and $\Lambda(SSR)$ or $\Delta(SSR)$ and $\Lambda(RRS)$. While the racemic (I) was resolved by SP-Sephadex column chromatography, (II) and (III) isomerized in water to each other (II$\rightleftarrows$III) by exposure to ultraviolet light, were resolved by the reaction of $[Cr(H_2O)_4$(*R* or *S*)-mbdo$]^{3+}$ with a stoichiometric amount of (*S* or *R*)-mbdo. The circular dichroism spectra of these optically active isomers were measured in aqueous solutions and compared with those of complexes of the $[CrO_6]$-type of known absolute configuration. The optically active free $(+)_{589}$- and $(-)_{589}$-mbdo were isolated by decomposing $\Lambda(SSS)$- and $\Delta(RRR)$-$[Cr(mbdo)_3]^{3+}$, respectively, with $edta^{4-}$. The active mbdo is optically stable even in boiling water.

2,2′-Bipyridyl *N,N′*-dioxide(bpdo) forms a skew seven-membered chelate ring upon coordination to a metal ion. Since the skew chelate ring is chiral (δ or λ), a tris-type complex of bpdo has four theoretically possible diastereomers, each of which has a pair of enantiomers (Δ and Λ).[1] By analogy with the stereoisomerism in $[Co(en)_3]^{3+}$(en=ethylenediamine),[2] these diastereomers can be designated as $lel_3(\Delta(\lambda\lambda\lambda), \Lambda(\delta\delta\delta))$, $lel_2ob(\Delta(\lambda\lambda\delta), \Lambda(\delta\delta\lambda))$, $lelob_2$ $(\Delta(\lambda\delta\delta), \Lambda(\delta\lambda\lambda))$, and $ob_3(\Delta(\delta\delta\delta), \Lambda(\lambda\lambda\lambda))$. However, we have reported that $[Cr(bpdo)_3]^{3+}$ forms only one pair of enantiomers which racemize spontaneously in water at room temperature.[3] This indicates that the bpdo chelate ring is flexible, changing its conformation ($\delta\rightleftarrows\lambda$) very easily. If the rotation around the bond between the 2 and 2′ carbons of bpdo is prohibited by replacing the 3 and 3′ hydrogens with some bulky substituents, such a conformational change is forbidden and the complex ion is expected to exist in some optically stable isomers. This paper deals with the preparation and stereochemistry of the tris-chromium(III) complex with a new chelate ligand, (*R*)- and (*S*)-3,3′-dimethyl-2,2′-bipyridyl *N,N′*-dioxide(mbdo)(Fig. 1).

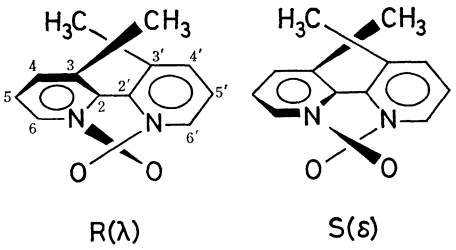

Fig. 1. A pair of enantiomers of mbdo.

Experimental

Preparation of Ligand. 3,3′-Dimethyl-2,2′-bipyridyl *N,N′*-dioxide(mbdo) was prepared from 3,3′-dimethyl-2,2′-bipyridyl[4] according to a method similar to that for 2,2′-bipyridyl *N,N′*-dioxide(bpdo).[5] An acetic acid solution(75 cm^3) of 3,3′-dimethyl-2,2′-bipyridyl(18 g, 0.1 mol) was mixed with 30% aqueous hydrogen peroxide(60 cm^3). The solution was refluxed for 4 h, then mixed with another 50 cm^3 of 30% aqueous hydrogen peroxide and refluxed for 3 h. The resulting pale yellow solution was evaporated under reduced pressure to give an oily residue. A small amount of ethanol was added to the residue and the mixture was evaporated. This procedure was repeated several times to remove water contained in the product. White precipitate was obtained upon addition of a small amount of acetone and then ether to the oily residue. The precipitate was filtered, washed with acetone and then ethanol, and air-dried. Recrystallization from a small amount of hot ethanol gave white cubic crystals. Yield: 12.3 g (60%), mp 212—214 °C (sublimation); IR(KBr disk) 1255 and 1242(ν_{N-O}) and 802 cm^{-1}(δ_{N-O}); ^{1}H-NMR(D_2O) δ=2.17 ppm(s, CH_3). The mbdo ligand exists in a pair of enantiomers. The optically active ligand was obtained by decomposing an optically active $[Cr(mbdo)_3]^{3+}$ complex (*vide post*).

Preparation of $[Cr(mbdo)_3]^{3+}$. A 10^{-2} mol/dm^3 hydrochloric acid solution (40 cm^3) containing $Cr(NO_3)_3\cdot 9H_2O$ (1.2 g, 3 mmol) and racemic mbdo(2.4 g, 11 mmol) was heated at 80 °C for 5 h. After cooling, sodium perchlorate (2 g, 16 mmol) was added to the solution to give green precipitate, which was filtered, washed with water and then ethanol, and recrystallized from warm water. Yield: 1.1 g (73%). This complex perchlorate consists of three pairs of diastereomers of $[Cr(mbdo)_3]^{3+}$.

Separation of Optical Isomers of $[Cr(mbdo)_3]^{3+}$. The $[Cr(mbdo)_3]^{3+}$ complex obtained above was dissolved in water, and the solution was poured on a column(ϕ2.7×130 cm) of SP-Sephadex C-25 resin in the Na^+ form. By eluting the adsorbed band with a 0.2 mol/dm^3 sodium $(+)_{589}$-tartratoantimonate(III) solution, the column gave three separate bands, Ia,Ib, and Ic in the order of elution (Fig. 2a). All the fractions of Ia and of Ib gave positive and negative, respectively, rotations at sodium D line, the CD patterns of Ia and Ib fractions being enantiomeric to each other. Thus, the Ia and Ib bands were assigned to a pair of enantiomers (diastereomer I(Ia, Ib)). The fractions of Ic band were collected and rechromatographed. The adsorbed complex on an SP-Sephadex column(ϕ2.7×130 cm) was eluted with a 0.15 mol/dm^3 Na_2SO_4 solution. Two separate bands (II and III) were obtained (Fig. 2b). The diastereomers in these bands isomerize to each other on exposure to light (II$\rightleftarrows$III), so that the chromatography should be carried out in the dark. The isomers Ia and Ib in solution are stable in the light. The diastereomers II and III were found to be partially resolved by column chromatography. The fractions of Ia, Ib, II, and III bands were collected separately, diluted several times with water, and poured on small columns of SP-Sephadex resin. The adsorbed isomers were eluted with a 2 mol/dm^3 NaCl solution, and the eluates

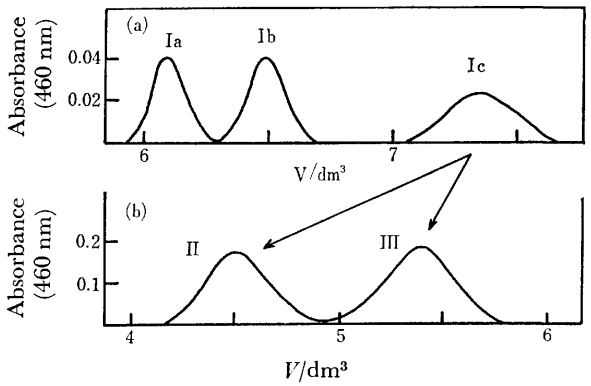

Fig. 2. (a) Elution curve of $[Cr(mbdo)_3]^{3+}$. Eluent: 0.2 mol/dm³ sodium $(+)_{589}$-tartratoantimonate(III). (b) Elution curve of Ic. Eluent: 0.15 mol/dm³ sodium sulfate.

were mixed with $NaClO_4$ to give green crystals, which were filtered, washed with a small amount of cold water, and air-dried. The formation ratio, I(Ia+Ib):II:III was 4 : 1 : 1.

Preparation of $Cr(mbdo)Cl_3 \cdot 5H_2O$. A 10^{-2} mol/dm³ hydrochloric acid solution(50 cm³) containing $Cr(NO_3)_3 \cdot 9H_2O$(0.8 g, 2.0 mmol) and racemic mbdo(0.5 g, 2.3 mmol) was heated at 70 °C for 3 h. After cooling, the resulting solution was poured on a column (ϕ 2.5×80 cm) of SP-Sephadex C-25 resin. The adsorbed product was eluted with a 0.5 mol/dm³ NaCl solution to give three separate bands. The last blue-green band was a mixture of the mono-mbdo complex and $[Cr(H_2O)_6]^{3+}$, which were separated by similar SP-Sephadex column chromatography using a 0.2 mol/dm³ Na_2SO_4 solution as an eluent. The green fraction of the mono-mbdo complex was again poured on a small column(ϕ 2.7×5 cm) of SP-Sephadex after dilution with water. The column was washed well with 10^{-2} mol/dm³ hydrochloric acid in order to replace Na^+ ions on the resin with H^+, and the adsorbed complex was eluted with 3 mol/dm³ hydrochloric acid. The eluate was evaporated to dryness in a vacuum desiccator over P_2O_5 and NaOH to give violet crystals. They were washed with ethanol and air-dried. Yield: 60%. This complex has the composition of $Cr(mbdo)Cl_3 \cdot 5H_2O$, and turns from violet to green in water, indicating that some chloride ions coordinate to the chromium(III) ion in the solid state. On heating an aqueous solution of the complex at 60 °C for a few hours, the absorption spectrum coincides with that of the green fraction ($(Cr(H_2O)_4(mbdo)]^{3+}$) separated by chromatography.

Resolution of mbdo. Optically active mbdo was obtained from the $(+)_{589}$-Ia or $(-)_{589}$-Ib isomer. To an aqueous solution (20 cm³) of the Ia or Ib isomer(50 mg, 0.05 mmol) was added $Na_2H_2edta \cdot 2H_2O$ (100 mg, 0.27 mmol) and the solution was heated at 70 °C for 10 h. During the course of heating, the color of the solution gradually turned from green to red violet. The resulting solution was diluted with 500 cm³ of water, adjusted to pH 9—10 with NaOH. The solution was passed through first a column of Dowex 1X8 anion exchange resin in the Cl^- form (ϕ 2.7×20 cm) to remove $[Cr(OH)(edta)]^{2-}$ produced and other anions, and then through a column of Dowex 50W cation exchange resin in the H^+ form (ϕ 2.7×10 cm) to remove cations such as Na^+ and the unreacted mbdo-chromium(III) complex. The solution was then evaporated to dryness under reduced pressure to give optically active mbdo. The $(+)_{589}$-Ia isomer gave $(+)_{589}$-mbdo ($[\alpha]_{589}^{23} = +10.6°$). The active mbdo is optically stable in solution.

Preparation of Optically Active $[Cr(H_2O)_4((+)_{589}$- *or* $(-)_{589}$-*mbdo)]^{3+}$. This complex was prepared from $[Cr(H_2O)_6]^{3+}$ and optically active mbdo by the method described for the racemic $[Cr(H_2O)_4(mbdo)]^{3+}$ complex. Its isolation was not achieved because of the small amount obtained. The quantitative circular dichroism(CD) spectrum of this complex was determined with the aid of the ε values of the racemate.

Preparation of Optical Isomers of $[Cr((+)_{589}$-*mbdo)*$_2((-)_{589}$-*mbdo)]*$^{3+}$. To an aqueous solution of $[Cr(H_2O)_4((-)_{589}$-mbdo)]$^{3+}$ was added twice the equivalent amount of $(+)_{589}$-mbdo. The solution was heated at 50 °C for 7 h and poured on an SP-Sephadex column (ϕ 2.0×50 cm). The adsorbed product was eluted with a 0.5 mol/dm³ NaCl solution in order to separate the tris-complex from the starting material. The fractions of the second band were collected and rechromatographed. By elution with a 0.2 mol/dm³ Na_2SO_4 solution, two bands(IIa and IIIa) were obtained, corresponding to enantiomers of diastereomers II and III, respectively, described for the racemic complex. Both isomers show positive rotation at 589 nm and epimerize to each other in the light (IIa$\rightleftarrows$IIIa) as observed for the racemic II and III. Diastereomer I was not formed, indicating that no disproportionation took place.

Analytical data of all the new compounds are given in Table 1.

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40 spectropolarimeter, respectively. Optical rotations were determined with a JASCO DIP-40 digital polarimeter.

Results and Discussion

A new ligand mbdo can exist in a pair of enantiomers, since free rotation around the common axis connecting the two rings is prohibited by the presence of the methyl and NO groups. The ligand molecule has no functional group to form diastereomers with resolving agents, but the optical resolution was achieved by forming optically active $[Cr(mbdo)_3]^{3+}$, the ligands

Table 1. Analytical data

		C/%		H/%		N/%

a) mbdo = $C_{12}H_{12}N_2O_2$.

in which have the same chirality (*vide infra*). The resolved mbdo is optically stable even in boiling water. The enantiomers are denoted by *R* and *S*,[6] as shown in Fig. 1. The *R*-(or *S*-) ligand forms a λ(or δ) skew chelate ring stereoselectively upon coordination. In this paper, the chilarity of the ligand is represented by the symbols δ and λ.

The $[Cr(mbdo)_3]^{3+}$ complex has eight theoretically possible optical isomers; $lel_3(\Delta(\lambda\lambda\lambda),\ \Lambda(\delta\delta\delta))$, $lel_2ob(\Delta(\lambda\lambda\delta),\ \Lambda(\delta\delta\lambda))$, $lelob_2(\Delta(\lambda\delta\delta),\ \Lambda(\delta\lambda\lambda))$, and ob_3 $(\Delta(\delta\delta\delta),\ \Lambda(\lambda\lambda\lambda))$. In the *lel* structure, the line joining the two nitrogen atoms of the mbdo ligand is nearly parallel to the C_3 axis of the complex ion, while in the *ob* structure, it is extremely oblique to the same axis so that the line and the axis are almost perpendicular to each other.

Of the four possible diastereomers, three (I, II, and III) were obtained by the reaction of $[Cr(H_2O)_6]^{3+}$ with racemic mbdo. No indication was found for the presence of more than three diastereomers by column chromatography. The isomers show absorption spectra differing from each other in the region of the first absorption band (Fig. 3). Diastereomer I is completely resolved into enantiomers Ia and Ib by SP-Sephadex column chromatography. The enantiomers are optically stable in solution. On the other hand, diastereomers II and III isomerize to each other in solution by exposure to ultraviolet light. Since the chirality of the ligand is retained in the complexes and no disproportionation takes place, the isomerization between II and III can be attributed to inversion in the arrangement of ligands around the metal ion ($\Delta \rightleftarrows \Lambda$, epimerization). Such epimerization will arise in the following two systems; (1) $lel_3 \rightleftarrows ob_3[\Delta(\lambda\lambda\lambda)(\text{or } \Lambda(\delta\delta\delta)) \rightleftarrows \Lambda(\lambda\lambda\lambda)(\text{or } \Delta(\delta\delta\delta))]$ and (2) $lel_2ob \rightleftarrows lelob_2$ $[\Delta(\lambda\lambda\delta)(\text{or } \Lambda(\delta\delta\lambda)) \rightleftarrows \Lambda(\lambda\lambda\delta)(\text{or } \Delta(\delta\delta\lambda))]$. Reaction (1) does not seem to take place, since molecular models show that the ob_3 isomer forms an extremely crowded structure, while reaction (2) appears to arise without difficulty from the studies of molecular models. Thus, diastereomer I which is stable in solution can be assigned to the lel_3 isomer, and diastereomers II and III to two isomers of the lel_2ob and $lelob_2$. The assignments are supported by the following experimental results. Diastereomer I assigned to the least crowded lel_3 structure is obtained in the largest amount (*vide ante*). The reaction of $[Cr(H_2O)_6]^{3+}$ with optically active mbdo obtained from the Ia (or Ib) enantiomer gives only the Ia (or Ib) enantiomer. Thus, the ligand recovered from Ia (or Ib) is proved to be optically pure, and diastereomer I should be the lel_3 isomer. On the other hand, the tris-complex prepared from $[Cr(H_2O)_4((-)_{589}\text{-mbdo})]^{3+}$ and $(+)_{589}$-mbdo consists of two optically active IIa and IIIa isomers, no diastereomer I being formed (see Experimental). Isomers IIa and IIIa thus formed should be enantiomers of diastereomers II and III, respectively, corresponding to either group of $\Delta(\delta\lambda\lambda)$ and $\Lambda(\delta\lambda\lambda)$ or $\Delta(\delta\delta\lambda)$ and $\Lambda(\delta\delta\lambda)$. The isomers isomerize (epimerize) to each other in solution by exposure to ultraviolet light, distributing in almost equal amounts at equilibrium. Thus, the equilibration study gives no information on the assignment of the structures of diastereomers II and III. In the column chromatography, diastereomer I(lel_3) eluates most quickly. If the elution order of the diastereomers is proportional to the number of the *lel* ligand, diastereomers II and III are assigned to the lel_2ob and $lelob_2$ isomers, respectively.

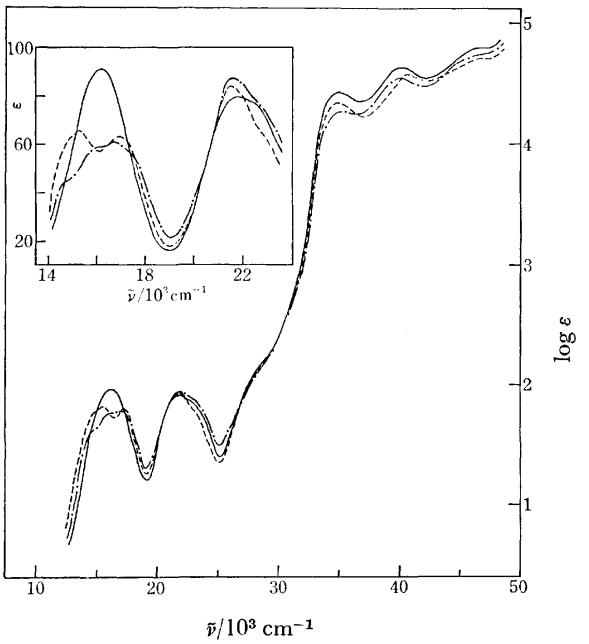

Fig. 3. Absorption spectra of three diastereomers of $[Cr(mbdo)_3]^{3+}$, Ia(——), II(----), and III(—·—).

Figure 3 shows the absorption spectra of diastereomers Ia, II, and III. Their spectral patterns in the region of the first absorption band differ remarkably, while those in the other region are similar to each other. The first absorption band of Ia is sharp and symmetrical, but those of II and III split into three components. All the diastereomers belong to the $[CrO_6]$-type in which the ligating oxygen atoms are the same kind. However, the actual symmetry of the lel_3 isomer will be D_3, and those of both lel_2ob and $lelob_2$ isomers will lower to C_2. In the fields of D_3 and C_2 symmetries, the first absorption band ($^4T_{2g}$) will split into two ($^4A_1$, ^4E) and three (2^4A, ^4B) components, respectively. Although diastereomer Ia shows no splitting in the first absorption band, the fact that diastereomers II and III exhibit the presence of three components in these bands supports the previous assignment for structures of these diastereomers. The absorption spectrum of diastereomer Ia is very similar to that of $[Cr(bpdo)_3]^{3+}$ over the whole region.[3] This indicates that the latter complex in which the ligands can easily change the conformation exists in the lel_3 form in solution. The spectral data are given in Table 2.

Figure 4 shows the CD spectra of $(+)_{589}$-$[Cr((+)_{589}\text{-mbdo})_3]^{3+}$ (Ia), $(+)_{589}$-$[Cr((+)_{589}\text{-mbdo})_2((-)_{589}\text{-mbdo})]^{3+}$(IIa), and $(+)_{589}$-$[Cr((+)_{589}\text{-mbdo})_2((-)_{589}\text{-mbdo})]^{3+}$(IIIa). The Ia isomer gives strong CD in the regions of the first and the ligand absorption bands. On the other hand, isomers IIa and IIIa show very similar spectra to each other over the whole

sh: shoulder.

region, although the strength of the former is somewhat larger. Both isomers consist of the same ligands, two $(+)_{589}$-mbdo and one $(-)_{589}$-mbdo. However, these isomers are antipodal to each other in the arrangement of the ligands around the metal ion. If one is Δ-configuration, the other is Λ-configuration. The similarity in the CD spectra suggests that the circular dichroism in these isomers is mainly caused by the contribution due to the vicinal effect of the chiral mbdo ligand (δ,λ) rather than to the configurational

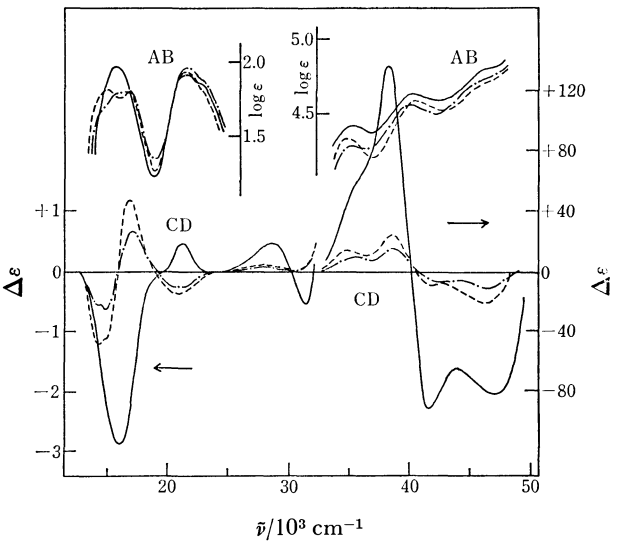

Fig. 4. Absorption(AB) and CD spectra of $(+)_{589}$-$[Cr((+)_{589}$-mbdo$)_3]^{3+}$ (Ia)(——), $(+)_{589}$-$[Cr((+)_{589}$-mbdo$)_2((-)_{589}$-mbdo$]^{3+}$ (IIa)(----), and $(+)_{589}$-$[Cr((+)_{589}$-mbdo$)_2((-)_{589}$-mbdo$)]^{3+}$ (IIIa)(—·—).

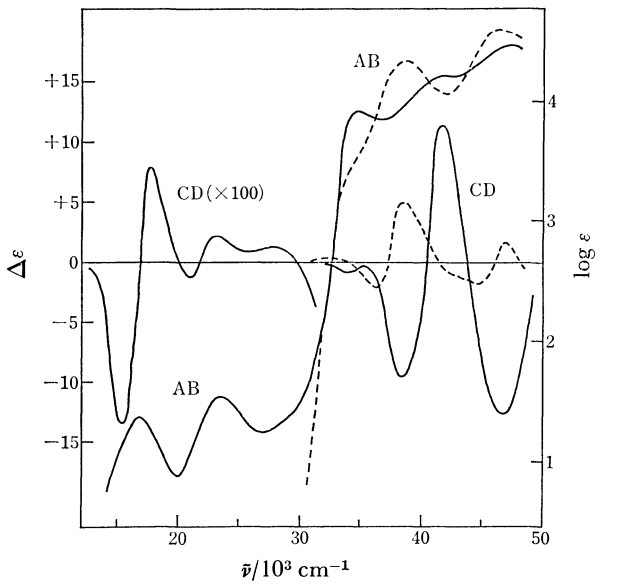

Fig. 5. Absorption(AB) and CD spectra of $[Cr(H_2O)_4$-$((+)_{589}$-mbdo$)]^{3+}$(——) and $(+)_{589}$-mbdo(----).

effect (Δ, Λ). Since these isomers contain two $(+)_{589}$-mbdo and one $(-)_{589}$-mbdo, the vicinal effect would come from one $(+)_{589}$-mbdo, if such effects of chiral ligands function additively. The $[Cr(H_2O)_4((+)_{589}$-mbdo$)]^{3+}$ complex of the $[CrO_6]$-type is a good example for knowing the vicinal effect of $(+)_{589}$-mbdo. However, as Fig. 5 shows, the CD spectrum of this complex is similar in pattern but much weaker in intensity than that of isomers IIa and IIIa, in the region of the first absorption band. In the ultraviolet region, its spectrum differs remarkably from that of the isomers. This indicates that the configurational and vicinal effects do not contribute additively to the CD spectra of these complexes. The additivity rule has been reported to hold for a number of five-membered chelate complexes.[7] The chiral conformation of the mbdo chelate ring does not cause inversion.

However, the chelate ring is large and would be flexible in a certain range. The most stable conformation of the ring may differ more or less from each other in each complex to minimize steric interactions among ligands. The different conformations would bring about different vicinal effects in CD spectra. The reason why the additive rule fails in the mbdo complexes can be attributed to such flexible conformation of the chelate ring. The free $(+)_{589}$-mbdo ligand which should be in a different conformation from those in the complexes exhibits a quite different CD spectrum in the ultraviolet region from that of the complexes. The absolute configurations of isomers IIa and IIIa can not be assigned from the CD spectra.

Isomer Ia, $(+)_{589}$-$[Cr((+)_{589}\text{-mbdo})_3]^{3+}$ shows a strong negative CD band in the region of the first absorption band. The $(+)_{589}$-$[Cr(bpdo)_3]^{3+}$ isomer which gives a similar CD pattern in this region was assigned to the *Λ*-configuration[3] from comparison of the CD patterns of a series of complexes, $[Cr(bpdo)_n(en)_{3-n}]^{3+}$. Figure 6 shows a comparison of the CD spectrum of Ia isomer with that of *Λ*-$[Cr(ox)_3]^{3-}$ (ox= oxalate ion)[8,9] and *Λ*-$[Cr(mal)_3]^{3-}$ (mal=malonate ion).[8,9] The spectral changes for these five-, six-, and seven-membered chelate complexes, are similar to those observed for a series of complexes, $[Co(NH_2(CH_2)_nNH_2)_3]^{3+}$ (n=2, 3, and 4).[10] In the ultraviolet region, the Ia (or Ib) isomer exhibits a characteristic CD pattern with strong intensity; a positive (or negative) and a negative (or positive) CD band from the smaller wavenumber side. The other complexes of mbdo show no such strong CD in this region. The CD bands in this region may be assigned to the $\pi\rightarrow\pi^*$ transitions of the ligand. Since the Ia isomer consists of ligands with the same chirality, $(+)_{589}$-mbdo, such strong CD might be caused by the exciton interaction among the ligands as observed for $[M(phen)_3]^{n+}$ (phen=1,10-phenanthroline).[11] Although the exciton CD for the system consisting of ligands with a twist conformation is unknown, the CD pattern of the Ia isomer resembles that of *Λ*-$[Cr(phen)_3]^{3+}$,[11,12] and the isomer can be assigned to the *Λ*-configuration. The assignment agrees with that based on the CD sign in the region of the first absorption band. If the isomer has the *Λ*-configuration, the $(+)_{589}$-mbdo ligand should be in the *δ*-skew conformation to form the lel_3 structure. Hence the $(+)_{589}$-mbdo can be assigned to the *S*-configuration.

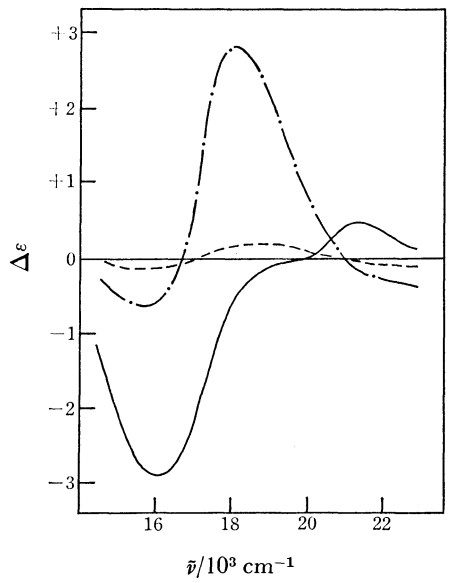

Fig. 6. CD spectra of $[CrO_6]$ complexes in the region of the first absorption band, $(+)_{589}$-$[Cr((+)_{589}\text{-mbdo})_3]^{3+}$ (Ia)(——), *Λ*-$[Cr(mal)_3]^{3-}$ (----), and *Λ*-$[Cr(ox)_3]^{3-}$ (—·—).

This work was carried out with Scientific Research Grant-in-Aid No. 243013 from the Ministry of Education and the Kurata Research Grant.

(Received November 29, 1978)

(*S*)-2-(Butylphenylphosphinomethyl)pyrrolidine(L) was prepared from (*S*)-proline *via* four main reaction steps. A pair of diastereomers of the $PdCl_2L$ complex, the isomerism of which comes from chiral configuration of the phosphorus atom, crystallized in different forms (needle and block), which were separated by hand picking. The molecular structure and absolute configuration of one(block) of the dichloro complexes was determined by X-ray analysis. Crystallographic data are: $P2_12_12_1$, $Z=4$, $a=13.576(4)$, $b=16.351(3)$, $c=8.041(2)$ Å, and $R=7.8\%$ for 1659 reflections. The Pd atom has a distorted square planar coordination of four donor atoms. The Pd–Cl bond distance *trans* to Pd–P, 2.367 Å, is longer than that *trans* to Pd–N, 2.296 Å. The absolute configuration of the coordinated phosphorus atom was determined to be *R* by assuming *S* configuration for the asymmetric carbon atom of the aminophosphine. The corresponding diastereomers of the dibromo complex were also prepared from each diastereomer of the chloro complex. The circular dichroism spectra of these diastereomers were compared with one another and with those of other related complexes, and the vicinal effects due to the chiral phosphorus atoms in these complexes were examined.

There has been much interest in asymmetric syntheses catalized by transition metal complexes, especially by rhodium(I) complexes containing chiral phosphines. These studies have extensively developed preparations[1-5] and optical resolutions[6] for a variety of chiral phosphines. Recently, some of optically active natural products have been used for precursors of chiral phosphines.[7-9] However, tedious procedures are often required for preparing optically active phosphines with a chiral phosphorus atom. The importance of a chiral center at a phosphorus atom has been pointed out for high efficiency of asymmetric hydrogenation.[10]

This paper reports the preparation of (*S*)-2-(butylphenylphosphinomethyl)pyrrolidine, which has three chiral centers at the carbon, nitrogen, and phosphorus atoms, and the isolation of a pair of diastereomers of its dichloro palladium(II) complex caused by a pair of the chiral phosphorus atoms. The chiral carbon atom has *S* configuration and the nitrogen one should yield the same *S* configuration stereoselectively upon coordination as seen in bis(*S*-prolinato)palladium(II).[11] The paper also describes the molecular structure and absolute configuration of one of the diastereomers determined by X-ray analysis.

So far little work has been reported concerning circular dichroism(CD) spectra of metal complexes containing chiral phosphines. The accumulation of CD data of chiral phosphine complexes will be necessary for investigating the stereochemistry of phosphine complexes catalyzing asymmetric syntheses. In this paper the CD spectra of diastereomers of the dichloro complex are compared with those of the related complexes and the vicinal effects due to the coordinated chiral phosphorus atoms are examined. A part of this study has been reported briefly.[12]

Experimental

All the preparations and handlings of the aminophosphines were carried out under an atmosphere of nitrogen or *in vacuo*. The palladium(II) complexes containing the aminophosphines can be handled in air. Absorption, CD, ^{1}H-NMR, and IR spectra were recorded on a HITACHI 323 spectrometer, a JASCO J-20 or J-40 spectropolarimeter, a JEOL PMX-60 spectrometer, and a HITACHI EPI-L 2 spectrometer, respectively.

Preparations. The following compounds were prepared according to the methods previously reported; (*S*)-2-(diphenylphosphinomethyl)pyrrolidine[8] and (*S*)-2-(aminomethyl)-pyrrolidine.[13]

(S)-2-(Phenylphosphinomethyl)pyrrolidine. To liquid ammonia (150 cm^3) in a 500 cm^3 round-bottom, three neck flask with a mechanical stirrer, a dropping funnel, and nitrogen inlet was added sodium metal(3.3 g) and then phenylphosphine(15 g) dropwise with vigorous stirring over 40 min at −78 °C (Dry Ice–methanol). After stirring for further 20 min, (*S*)-2-(bromomethyl)pyrrolidine hydrobromide[14] (17 g) was added in small portions and then the solution was stirred for 2 h at −78 °C. The liquid ammonia was evaporated off at room temperature and oxygen-free tetrahydrofuran(THF) was added on the residue. The undissolved material (sodium bromide) was filtered off and the filtrate was evaporated to remove THF. The oily residue was distilled under reduced pressure to yield colorless liquid. Yield: 7.4 g, bp 140.5—141 °C/933 Pa.

(S)-2-(Butylphenylphosphinomethyl)pyrrolidine. To a mixture of liquid ammonia (150 cm^3) and sodium metal (0.52 g) was added dropwise (*S*)-2-(phenylphosphinomethyl)-pyrrolidine(4.38 g) with vigorous stirring over 20 min at −78 °C. The solution changed from blue green to green. After stirring for 1 h, butylchloride (6 cm^3) was added dropwise to the solution. The color of the solution changed to deep red instantly and the stirring was continued until the color became light yellow. The liquid ammonia was evaporated off at room temperature and oxygen-free THF was added on the residue to extract the object. The undissolved material (sodium chloride) was filtered off and the filtrate was evaporated to give oily residue. It was distilled in vacuo to yield colorless liquid. Yield: 3.6 g, bp 135—136 °C/13.3 Pa.

*{(S)-2-(Butylphenylphosphinomethyl)pyrrolidine}dichloropalladium(II) (**1a** and **1b**).* To an acetonitrile solution (50 cm³) of $PdCl_2(CH_3CN)_2$[15] (198 mg) was added (*S*)-2-(butylphenylphosphinomethyl)pyrrolidine(190 mg). After stirring for 3 h at 50 °C, appropriate amounts of diethyl ether and then hexane were added to the resultant solution to yield yellow precipitate, which was filtered(250 mg). The product was dissolved in a small amount of chloroform and the solution was poured into a column (ϕ 1.2×10 cm) of acidic activated alumina. The adsorbed yellow band was eluted with a mixture of chloroform and ethanol(20 : 1). The yellow eluate was concentrated to a small volume(10 cm³) and mixed with ethanol(50 cm³). The ethanol solution was slowly concentrated at room temperature in air to yield two different crystal forms (total yield 77%), needle (**1a**) and block(**1b**), which were separated by hand picking. The crystals of each form were separately recrystallized from a mixture of chloroform and ethanol. Yield: *ca.* 15% for each isomer. Found for **1a**: C, 42.41; H, 5.66; N, 3.21%. Found for **1b**: C, 42.43; H, 5.68; N, 3.26%. Calcd for $PdCl_2(C_{15}H_{24}NP)$: C, 42.22; H, 5.68; N, 3.28%.

*{(S)-2-(Butylphenylphosphinomethyl)pyrrolidine}dibromopalladium(II) (**2a** and **2b**).* To the complex **1a** or **1b** (60 mg) in a mixture(30 cm³) of chloroform and ethanol (1 : 1) was added an ethanol solution (10 cm³) saturated with sodium bromide. After stirring for 3 h at room temperature, the solution was evaporated to dryness under reduced pressure and dichloromethane was added to the residue to extract the dibromo complex. To the extract was added diethyl ether to yield yellow precipitate, **2a** or **2b** from **1a** or **1b**, respectively. Yield: 50 mg. Found for **2a**: C, 34.65; H, 4.70; N, 2.32%. Found for **2b**: C, 34.77; H, 4.69; N, 2.50%. Calcd for $PdBr_2(C_{15}H_{24}NP)$: C, 34.94; H, 4.70; N, 2.32%.

*{(S)-2-(Diphenylphosphinomethyl)pyrrolidine}dichloropalladium(II) (**3**).* To a suspension of $PdCl_2(CH_3CN)_2$(328 mg) in chloroform(30 cm³) was added a chloroform solution (10 cm³) of (*S*)-2-(diphenylphosphinomethyl)pyrrolidine (341 mg). After stirring overnight, the solution was poured into a column (ϕ 1.5×10 cm) of acidic activated alumina and the adsorbed band was eluted with a mixture of chloroform and ethanol(5 : 1). Diethyl ether was added to the eluate to yield yellow crystals (**3**). Yield: *ca.* 30%. Found: C, 45.38; H, 4.50; N, 3.03%. Calcd for $PdCl_2(C_{17}H_{20}NP)$: C, 45.71; H, 4.52; N, 3.14%.

*{(S)-2-(Aminomethyl)pyrrolidine}dichloropalladium(II) (**4**).* To a chloroform solution(150 cm³) of $PdCl_2(CH_3CN)_2$ (1.1 g) was added a chloroform solution(70 cm³) of (*S*)-2-(aminomethyl)pyrrolidine (0.43 g) and the solution was stirred for 3 h at room temperature to give a precipitate gradually. The precipitate was filtered and dissolved in hot water containing a few drops of concd hydrochloric acid. The solution was concentrated and then potassium chloride was added to the concentrate to yield yellow crystals (**4**). Yield: 0.7 g. Found: C, 21.64; H, 4.37; N, 10.10%. Calcd for $PdCl_2(C_5H_{12}N_2)$: C, 21.39; H, 4.49; N, 10.09%.

*(2-N,N-Dimethylaminoethyldiphenylphosphine)dichloropalladium(II) (**5**).* This complex was prepared according to the method of Meek *et al.*[16]

*Structure Determination of **1b**.* The crystal data of **1b** are as follows: orthorhombic, $P2_12_12_1$, a=13.576(4), b=16.351(3), c=8.041(2)Å, D_m=1.60, D_x=1.588 g cm⁻³, Z=4, and μ(Mo $K\alpha$)=14.1 cm⁻¹. The intensity data were collected on a Hilger & Watts automatic diffractometer using Zr-filtered Mo $K\alpha$ radiation. The crystal used for the data collections had the dimensions of 0.45×0.40×0.25 mm. Independent 1840 reflections with $2\theta \leq 50°$ were measured by the θ-2θ step scan technique, of which non-zero reflections were 1659. The intensity data were corrected for Lorentz and polarization effects. Absorption correction was also carried out by the Furnas's method.[17]

The structure was solved by the heavy atom method. The refinement was carried out by the block-diagonal least-squares method.[18] In the refinement, the weights $w=1/(\sigma^2(F)+a|F_o|+b|F_o|^2)$ for $|F_o|>0$, and $w=c$ for $|F_o|=0$ were assigned ,where $\sigma(F)$ is the standard deviation

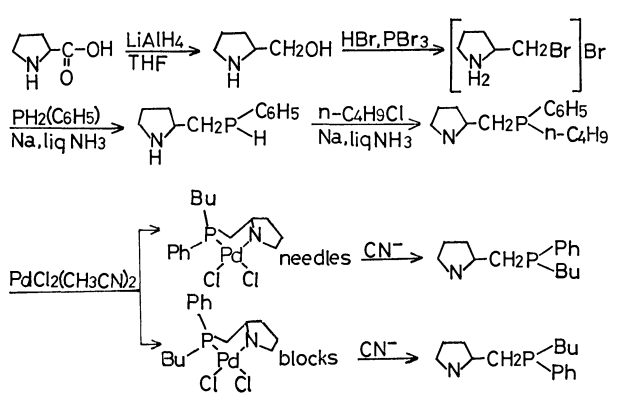
based on counting statistics. A disorder occurs at the butyl group. Both the C^{β} and C^{γ} atoms of the butyl group were located at two sites with occupancies of 0.5 each from the D-map. Finally the C^{β} atom converged into the resultant position, though its temperature factors are significantly larger than those of the other atoms. The H atoms were found on the D-map. However, those bonded to the C^{β}, C^{γ}, C^{δ} atoms of the butyl group were not found, and not included in the further refinement. The final *R* value is 9.9% ($a=-0.1777$, $b=0.0082$, and $c=0.2184$), while it is 7.8% for non-zero reflections.

The atomic scattering factors for the Pd^{2+}, Cl^-, P, N, C, and H were taken from International Tables for X-Ray Crystallography, Vol. IV.[19] Calculations were carried out on the FACOM 230-75 computers at Nagoya University. The final atomic parameters are listed in Tables 1 and 2.[20]

Results and Discussion

Preparation and Properties. Mislow[21] and Horner[22] prepared a number of chiral phosphines and phosphine oxides containing asymmetric phosphorus atoms. However, their methods are somewhat tedious. In the present study, a pair of diastereomers of (*S*)-2-(butylphenylphosphinomethyl)pyrrolidine was easily obtained by the following scheme:



The aminophosphine was prepared from (*S*)-proline by a method similar to those for 2-aminoethylphenylphosphine derivatives reported by Issleib.[23] The dichloro palladium(II) complex of the aminophosphine yields only two diastereomers arising from a pair of chiral phosphorus atoms. The nitrogen atom will have *S* configuration stereoselectively upon coordination as confirmed by X-ray analysis on [Pd(*S*-prol)$_2$].[11] The diastereomers (**1a** and **1b**) crystallize in different forms, needle and block, by slow evaporation of an ethanol solution, and can be separated by hand picking. They are stable in air and do not isomerize in boiling ethanol. The free chiral phosphines are easily liberated from the diastereomers by treating with sodium cyanide in water. The corresponding chiral dibromo complexes (**2a** and **2b**) were derived from each diastereomer of the dichloro complex.

Table 3. NMR spectral data of palladium complexes in $CDCl_3$
(δ/ppm from TMS)

Complex	$-CH_3$	$-CH_2-$	N–H	$-C_6H_5$
1a	0.83	1—4.2	7.0	7.5—8.3
1a[a]	0.93	1—4.0	6.6	7.5—8.3
1b	0.97	1—4.2	6.1	7.4—8.3
1b[a]	0.88	1—4.0	6.2	7.5—8.5
2a	0.85	1—3.9	6.5	7.5—8.3
2b	0.91	1—4.1	5.7	7.5—8.3
3	—	1—4.0	6.9	7.3—8.3

a) solvent: DMSO-d_6.

Table 3 shows the data of ^{1}H-NMR spectra of the aminophosphine complexes prepared. The peaks in the region 5.7—7.0 ppm can be assigned to the N–H protons, since these peaks disappear on deuteration. The N–H protons of **1b** and **2b** resonate at a considerably higher magnetic field than do those of **1a** and **2a** respectively. The chiral phosphorus atoms of **1a**, and **1b** have *S* and *R* configurations, respectively (*vide post*). In the *R* configuration(**1b**), the N–H proton and the phenyl group face each other on the same side of the complex plane. Therefore, the up-field shifts of the N–H protons of **1b** and **2b** indicate that the phenyl group causes the shielding effect to the N–H proton. In a previous paper,[12] such a phenyl group was considered to give the deshielding effect to the N–H proton, hence the absolute configuration of **1b** was assigned reversely. The chemical shifts of these N–H protons seem to be sensitive to environment such as the kinds of ligating halide ions and solvents (Table 3). The complex **3**, which has the phenyl group in the same arrangement as **1b** shows the N–H resonance at nearly the same field, 6.9 ppm as that of **1a**.

In the far IR spectra, all the dichloro-aminophosphine complexes show absorption bands around 280 and 330 cm^{-1}. These bands can be assigned to the ν(Pd–Cl), since the corresponding dibromo complexes show no band in this region. The dichloro-diamine complex (**4**) exhibits two strong bands at 301 and 337 cm^{-1} which may be correspond to the ν(Pd–Cl) of 306 and

327 cm^{-1} observed for *cis*-$[PdCl_2(NH_3)_2]$.[24] The IR spectra of the present complexes are too complicated to be assigned.

Molecular Structure of ***1b*** The stereoscopic view of **1b** (block crystal) drawn by ORTEP II[25] is shown in Fig. 1. The absolute configuration of the phosphorus atom in **1b** becomes *R*, when the asymmetric carbon atom of the pyrrolidine ring is assumed to be *S* configuration. Therefore the phosphorus atom of **1a** (needle crystal) has *S* configuration. The bond lengths and angles concerning non-hydrogen atoms are shown in Fig. 2. The e.s.d.'s are; 0.02—0.03 Å for bond lengths except for Pd–X(0.005—0.014 Å) and C(14)–X(0.05 Å), and 0.7—1.6° for bond angles except for X–Pd–X(0.2—0.4°) and C(13)–C(14)–C(15) (5°). The equations of the best planes and the related data are given in Table 4.

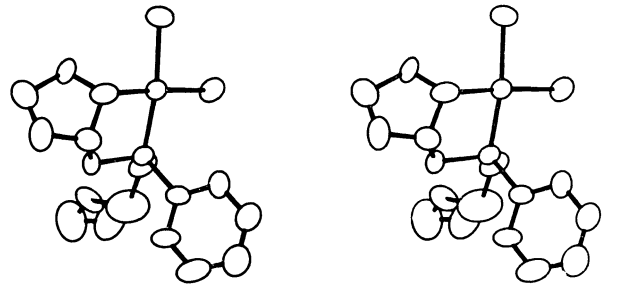


Fig. 1. The stereoscopic view of **1b**.

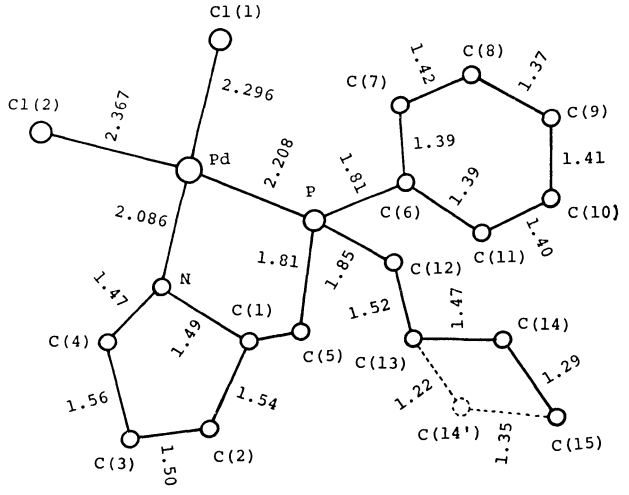

Fig. 2.(a) The bond lengths(Å) of **1b**.

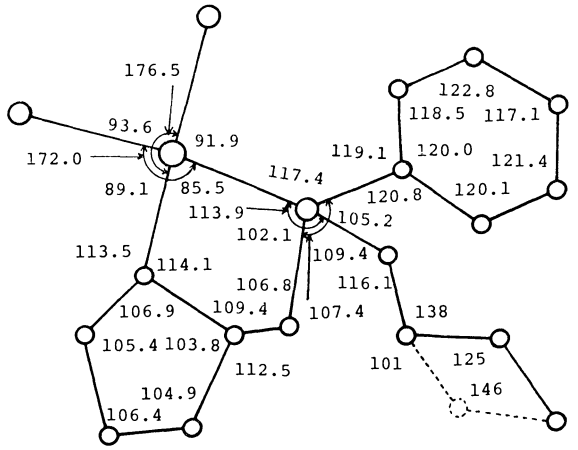

Fig. 2(b). The bond angles (°) of **1b**.

The Pd(II) ion forms a distorted square plane with four donor atoms. The dihedral angle between the plane of Pd, Cl(1), and Cl(2), and that of Pd, P, and N is 174.0°. The P atom deviates by 0.27 Å from the best plane formed with Pd, Cl(1), Cl(2), and N. However, the planarity is rather better than that in $[PdCl_2\{N,N$-dimethyl-α-methyl-*o*-(butylphenylphosphino)benzylamine$\}]$ (BENZYL),[26] in which the N

Pd	0	N	−1	P	3
Cl(1)	0	C(2)	1	C(6)	−3
Cl(2)	0	C(3)	−3	C(7)	1
P*	22	C(4)	3	C(8)	−1
N*	−6	C(1)*	52	C(9)	2
		C(5)*	204	C(10)	0
		Pd*	94	C(11)	−2

atom deviates by 0.423 Å from the best plane of Pd, Cl(1), Cl(2), and P. The Pd–Cl(2) (*trans* to Pd–P) length of 2.367 Å is longer than the Pd–Cl(1) (*trans* to Pd–N) length of 2.296 Å. The same trend in the Pd–Cl lengths is seen in BENZYL (2.386 and 2.285 Å). The elongation of Pd–Cl(2) bond may be attributed to the stronger *trans* effect of P than that of N. The Pd–P length of 2.208 Å is significantly short as compared with those of 2.241 Å in BENZYL and of 2.286 Å in [PdCl{(*S*)-isopropyl-*t*-butylphenylphosphine}{(*R*)-*N*,*N*-dimethyl-α-(2-naphthyl) ethylamine-3*C*,*N*}] (NAPHTHYL).[6] The Pd–N length of 2.086 Å is also shorter than those in BENZYL (2.134 Å) and NAPHTHYL (2.167 Å).

The five-membered chelate ring is fairly puckered to form a δ conformation. The torsion angles concerning the ring are: Pd–N–C(1)–C(5), −40.9°; N–C(1)–C(5)–P, 49.7°; C(1)–C(5)–P–Pd, −35.7°; C(5)–P–Pd–N, 11.9°; P–Pd–N–C(1), 13.7°. The deviations of C(1) and C(5) from the plane of Pd, P, and N are 0.32 Å (to the direction to C(6) (phenyl group)) and 0.37 Å(to the direction to C(12) (butyl group)), respectively. The N–Pd–P angle is 85.5°, while that of the six-membered chelate ring in BENZYL is 94.0°. On the contrary, the Cl–Pd–Cl angle (93.6°) is larger than that in BENZYL (88.12°).

The coordinated N atom of the pyrrolidine ring has *S* configuration. The torsion angles of the pyrrolidine ring are; χ_1=32.2, χ_2=−16.8, χ_3=−4.7, and χ_4=25.1°. The C^{α} (=C(1)) atom is puckered out by 0.52 Å in the pyrrolidine ring, while C^{δ} puckering is observed for [Pd(*S*-prol)$_2$].[11]

The disorder occurs at the location of C(14). Therefore the abnormal bond lengths and angles concerning this atom are observed. However, the distance between C(13) and C(15), 2.49 Å is rather normal.

Absorption and CD Spectra. The absorption and CD spectra of the dichloro (**1a** and **1b**) and the dibromo (**2a** and **2b**) complexes are shown in Figs. 3 and 4, respectively. The numerical data are given in Table 5 together with those of the other related complexes. The absorption spectra of a pair of diastereomers quite resemble each other, while the CD spectra are nearly enantiomeric to each other. The diastereoisomerism arises from a pair of enantiomeric configurations of the phosphorus atom, the other chiral centers at the carbon and nitrogen atoms being all *S* configurations. If it is assumed that the vicinal effects due to these three chiral atoms contribute additively to the CD, the vicinal effects of the chiral phosphorus atoms (*S* configuration) in the dichloro and dibromo complexes can be estimated by the following equations, respectively; [Δε(**1a**)−Δε(**1b**)]/2 and [Δε(**2a**)−Δε(**2b**)]/2. (Fig. 5) The calculated curves are very similar in the pattern between the dichloro and dibromo complexes, although the curve of the latter complex shifts to the smaller wavenumber side according to the spectrochemical series. From these curves, it is concluded that the coordinated (*S*)-phosphorus atom shows a positive main CD band in the region of the absorption band of the smallest wavenumbers. On the other hand, the curve of the combined vicinal effect due to both chiral atoms of the carbon and nitrogen can be derived by the equation, [Δε(**1a**)+Δε(**1b**)]/2. The derived curve is shown in Fig. 6 together with the absorption and CD spectra of the related complexes. The curve closely resemble the CD spectrum of **3** in the region of the smallest wavenumber absorption band. The complex **3** has two chiral centers at the carbon and nitrogen atoms with the same *S* chirality as **1a** and **1b**. The curve of the same vicinal effect calculated from **2a** and **2b** also show a pattern similar to that of the dichloro complex. These results indicate that the vicinal effects of the three different chiral atoms are additive in the CD spectra

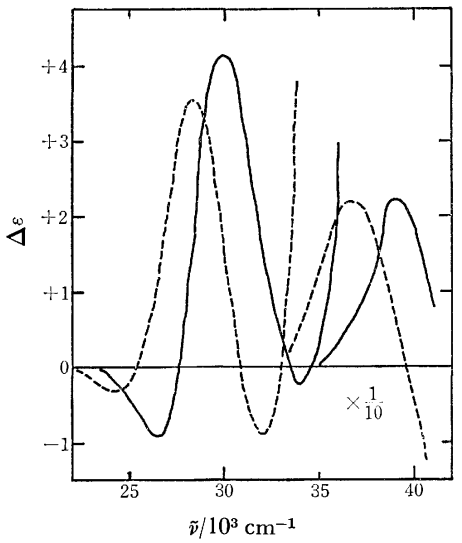

Fig. 5. CD curves calculated from (1/2)[$\Delta\varepsilon$(**1a**)−$\Delta\varepsilon$(**1b**)](——) and (1/2)[$\Delta\varepsilon$(**2a**)−$\Delta\varepsilon$(**2b**)](----).

of the present complexes. The diamine complex (**4**) which has the same chiral atoms as **3** also gives a CD pattern similar to that of **3** in the same region, although the CD intensity of the negative band is very weak.

Meek *et al.*[16] reported that the complex **5** gives absorption bands due to the d-d transitions at *ca.* 21000 cm^{-1}. However, all of the aminophosphine complexes prepared here shows neither absorptions nor

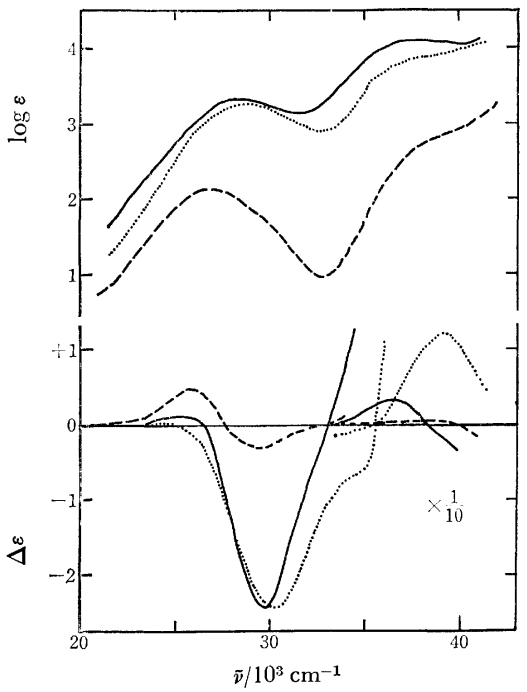

Fig. 6. Absoprtion and CD spectra of [(*S*)-2-(diphenylphosphinomethyl)pyrrolidine]dichloropalladium(II), **3** (——) and [(*S*)-2-(aminomethyl)pyrrolidine]dichloropalladium(II), **4** (----), and CD curve calculated from (1/2)[$\Delta\varepsilon$(**1a**)+$\Delta\varepsilon$(**1b**)] (……).

CD in this region. Therefore, the fairly strong bands at 28000 cm^{-1} of the aminophosphine complexes may be assigned to those associated with the d-d transitions. This assignment will be supported by the fact that the dichloro(diamine)Pd(II) complexes[27] including **4** exhibit similar absorption bands at nearly the same wavenumbers. The nitrogen and phosphorus atoms are known to stand at nearly the same position in the spectrochemical series.[28]

The authors express their thanks to Professor J. Tanaka of Nagoya University, who kindly allowed them to use the diffractometer in his laboratory. The authors also wish to thank the Ministry of Education for Scientific Research Grant-in-Aid No. 243013.

Temperature Dependence of the Optical Resolution and Solubility Isotherm of Bis(ethylenediamine)oxalatocobalt(III) (1*R*,3*S*,4*S*,7*R*)-3-Bromocamphor-9-sulfonate

Akira FUYUHIRO,* Kazuaki YAMANARI, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 27, 1978)

The determination of solubility isotherm of a ternary system, *Λ*-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)–*Λ*-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)–H_2O, between 5 and 25 °C, revealed that the resolving agent (1*R*,3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate ion is applicable to the optical resolution of the $[Co(ox)(en)_2]^+$ ion below 19 °C from the viewpoint of solubility in water, in spite of the formation of a pseudo racemic compound, *Λ*-[Co(ox)(en)$_2$]·*Λ*-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3)_2\cdot 2H_2O$.

Some useful informations on optical resolutions have been given from the studies of solubility isotherms for a multi-component system containing a pair of diastereomeric salts of metal complexes[1,2] or organic substances.[3] The previous investigations showed that the formation of a pseudo racemate[1] or solid solutions[3] causes an unsuccessful or difficult optical resolution; for example, the resolving agent, (1*R*, 3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate(1−) ion (abbreviated to *d*-bcs$^-$), is not applicable to the optical resolution of $[Co(ox)(en)_2]^+$ ion at 25 °C because of the formation of the pseudo racemate, *Λ*-[Co(ox)(en)$_2$]·*Λ*-[Co(ox)(en)$_2$](*d*-bcs)$_2\cdot 2H_2O$.[1] Successive study to determine the isotherms of the *d*-bcs salts at other temperatures revealed that the optical resolution becomes possible below 19 °C in spite of the formation of the pseudo racemate. Thus the solubility isotherm of the ternary system, *Λ*-[Co(ox)(en)$_2$](*d*-bcs)–*Λ*-[Co(ox)(en)$_2$](*d*-bcs)–H_2O, at 5 °C and the temperature dependence of two invariant points in a region of 5—25 °C are presented here; a short letter of the results was presented elsewhere.[4]

Experimental

Materials. *[Co(ox)(en)$_2$](d-bcs)*: The *Λ*- and *Δ*-diastereomers, and the pseudo racemate were prepared by the method previously reported[1]; ε(497 nm)=120 for each complex, and $\Delta\varepsilon$(523 nm)=+2.71, −2.71, and 0 for the *Λ*- and *Δ*-diastereomers, and the pseudo racemate, respectively. Found: C, 32.47; H, 5.48; N, 9.41%. Calcd for *Λ*-[Co(ox)(en)$_2$](*d*-bcs)·H_2O: C, 32.29; H, 5.42; N, 9.41%. Found: C, 31.93; H, 5.56; N, 9.35%. Calcd for *Λ*-[Co(ox)(en)$_2$](*d*-bcs)·1.5H_2O: C, 31.80; H, 5.50; N, 9.27%. Found: C, 32.30; H, 5.42; N, 9.40%. Calcd for *rac*-[Co(ox)(en)$_2$](*d*-bcs)·H_2O: C, 32.29; H, 5.42; N, 9.41%. The analytical values of the *Λ*-diastereomer corresponded to those of neither tetrahydrate nor 2.5-hydrate[1] but 1.5-hydrate.

Measurements. The solubilities of complexes in water were determined in molality in the same way as previously reported.[2] The solid phases were identified from the elemental analyses, the absorption and CD spectra, and so on. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

The solubility data obtained are given in Table 1, and Figs. 1 and 2, where any saturated solution is expressed as a point defined by summing up the position vectors of the solubilities of the one or two component salt(s) contained.[2]

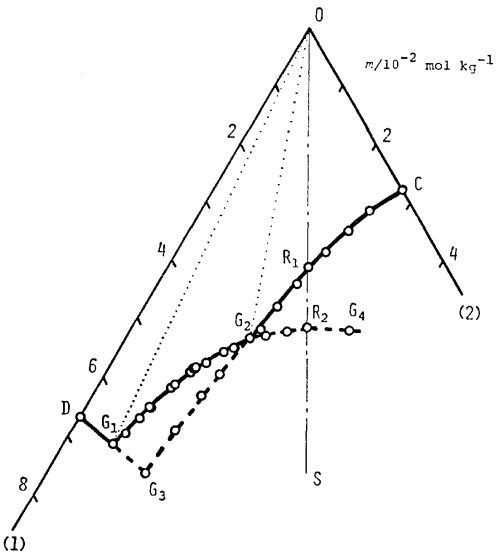

Fig. 1. Solubility isotherm of the ternary system, *Λ*-[Co(ox)(en)$_2$](*d*-bcs)–*Λ*-[Co(ox)(en)$_2$](*d*-bcs)–H_2O, at 5 °C. Solubility is presented in molality *m* of anhydrous salt; *Λ*-[Co(ox)(en)$_2$](*d*-bcs) (1) and *Λ*-[Co(ox)(en)$_2$](*d*-bcs) (2).

Solubility Isotherm of Λ-*[Co(ox)(en)$_2$](d-bcs)*-Δ-*[Co(ox)(en)$_2$](d-bcs)–H_2O at 5 °C.* Figure 1 shows the solubility isotherm of the ternary system, *Λ*-[Co(ox)(en)$_2$](*d*-bcs)–*Λ*-[Co(ox)(en)$_2$](*d*-bcs)–H_2O, at 5 °C. The pseudo racemate, *Λ*-[Co(ox)(en)$_2$]·*Λ*-[Co(ox)(en)$_2$](*d*-bcs)$_2\cdot 2H_2O$, exists in the region G_1G_2 at 5 °C as in the case of 25 °C.[1] At 25 °C the invariant points, G_1 and G_2, appear on the left and the right hand sides of the "racemic line" OS, respectively (see Fig. 2). On the contrary, at 5 °C, both points appear on the left hand side of the "racemic line". Therefore, the isotherms at 5 °C represents the first case that the optical resolution becomes possible in spite of existence of the pseudo racemic compound.

If an aqueous solution of *rac*-[Co(ox)(en)$_2$](*d*-bcs) is concentrated at the constant temperature 5 °C, in other words, if the solution whose composition is on the line OR_1 in Fig. 1 is concentrated, the less soluble diastereomer *Λ*-[Co(ox)(en)$_2$](*d*-bcs)·4H_2O will appear in the solid phase at the point R_1, and then

TABLE 1. EQUILIBRIUM OF THE SYSTEM, Λ-[Co(ox)(en)$_2$](d-bcs)-Λ-[Co(ox)(en)$_2$](d-bcs)-H_2O, AT 5 AND 25 °C, AND THE TEMPERATURE DEPENDENCE OF THE TWO INVARIANT POINTS, G_1 AND G_2

In liquid phase, solubility is presented in molality m of anhydrous salt. Abbreviations are as follows: Λ-[Co(ox)(en)$_2$](d-bcs)·H_2O=Λ, Δ-[Co(ox)(en)$_2$](d-bcs)·$4H_2O$=Δ, and Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$=*rac*; *, metastable state.

a) Positions of the points in Figs. 1 and 2. In these expressions, $G_1 \leftrightarrow G_2$, for example, does not contain the points G_1 and G_2. b) The values in parentheses are estimated errors and were calculated from twice the standard deviations of the experimental measurements, which were repeated 3—11 times.

the point of the saturated solution will move along the curve R_1G_2. After the liquid phase composition reaches the point G_2, the less soluble diastereomer will gradually disappear with precipitating the pseudo racemate, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$, while the liquid phase composition will remain unaltered. Finally, only the solid pseudo racemate will remain. When the solid less soluble diastereomer is removed from the system just before reaching G_2 on the curve R_1G_2, the yield of the diastereomer will be 49% of Δ-[Co(ox)(en)$_2$]$^+$ (25% of the racemic one). Further evaporation will change the composition of the liquid phase from G_2 to G_1 and the second solid, *rac*-[Co(ox)(en)$_2$](d-bcs)·H_2O, will precipitate till the solution composition reaches the point G_1. By separating and re-dissolving this pseudo racemate, successive optical resolution will become possible.

If the initial solution composition is in the region OR_1C in Fig. 1, the isothermal concentration of this solution will also cause the first precipitation of Δ-[Co(ox)(en)$_2$](d-bcs)·$4H_2O$. When the solution composition reaches the point G_2, the second solid,

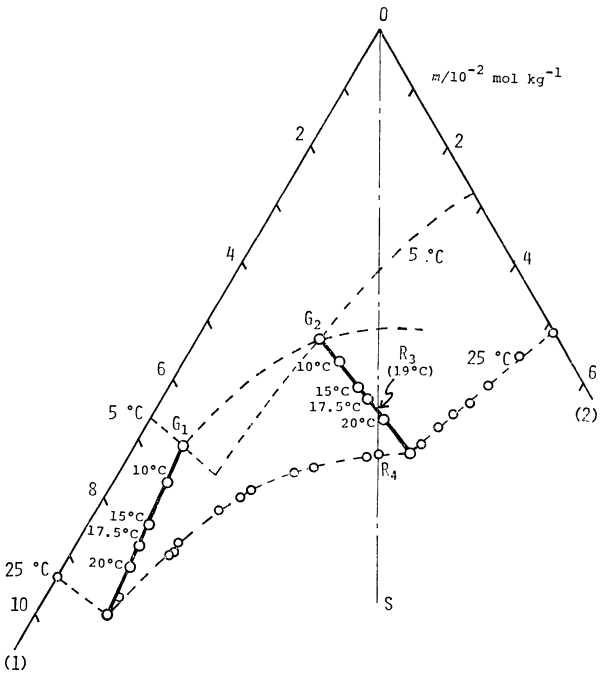

Fig. 2. Temperature dependence of the two invariant points, G_1 and G_2, of the ternary system, *Λ*-[Co(ox)-(en)$_2$](*d*-bcs)–*Λ*-[Co(ox)(en)$_2$](*d*-bcs)–H_2O, at 5—25 °C. Solubility is presented in molality *m* of anhydrous salt; *Λ*-[Co(ox)(en)$_2$](*d*-bcs) (1) and *Λ*-[Co(ox)-(en)$_2$](*d*-bcs) (2).

Λ-[Co(ox)(en)$_2$]·*Λ*-[Co(ox)(en)$_2$](*d*-bcs)$_2$·2H_2O, will begin to precipitate, but the first solid will not completely disappear and both solids will remain to the last. If the initial solution composition is in the region OG_2R_1, the first and the second solids will deposit similarly, and then the solution composition will begin to move along the curve G_2G_1 as soon as all the first solid dissolve in the liquid phase. When the solution composition reaches G_1, the third solid, *Λ*-[Co(ox)(en)$_2$](*d*-bcs)·H_2O, will appear in the system. At last, only the second and the third solids will remain.

Therefore the point G_2 is a kind of "pseudo invariant point", and corresponds to the final liquid phase composition of the right hand region in Fig. 1. Only when the liquid phase composition is in the region OG_1G_2 or on the line OG_2, the pseudo racemic compound, *Λ*-[Co(ox)(en)$_2$]·*Λ*-[Co(ox)(en)$_2$](*d*-bcs)$_2$·2H_2O, deposits as the first precipitation in this system at 5 °C. Thus the pseudo recemate shows the incongruent solubility in water at 5 °C and can be recrystallized at this temperature without decomposition only from an aqueous solution containing an appropriate amount of *Λ*-[Co(ox)(en)$_2$](*d*-bcs) salt.

Certain metastable states which were maintained at least for several hours were observed at 5 °C. On the curve $G_2R_2G_4$ in Fig. 1, the solution is in metastable equilibrium with the solid phase, *Λ*-[Co(ox)(en)$_2$]·*Λ*-[Co(ox)(en)$_2$](*d*-bcs)$_2$·2H_2O, and the point R_2 represents the metastable solubility of the pseudo racemate. The point G_3 corresponds to the metastable invariant point, where both solids, *Λ*-[Co(ox)-(en)$_2$](*d*-bcs)·H_2O and *Λ*-[Co(ox)(en)$_2$](*d*-bcs)·4H_2O, coexist. If the solution composition moves along the curve $R_1G_2G_3$ in an optical resolution, the yield of the *Λ*-diastereomer will increase.

Solubilities of Λ-[*Co(ox)(en)*$_2$](d-*bcs*)–Δ-[*Co(ox)(en)*$_2$]-(d-*bcs*)–H_2O *between 5 and 25 °C.* Figure 2 represents the temperature dependence (5—25 °C) of the two invariant points, G_1 and G_2. The curve of the temperature dependence of G_2 intersects the "racemic line" OS at 19 °C (point R_3). Therefore, the optical resolution using this ternary system becomes possible at temperatures lower than 19 °C. Futhermore, it was found that the solubility data reported previously for *rac*-[Co(ox)(en)$_2$](*d*-bcs)·H_2O at 5, 10, and 15 °C[1] are of metastable states and its value at 5 °C corresponds to the point R_2 in Fig. 1.

The solubility isotherm of the present system at 25 °C has somewhat changed from that previously reported,[1] in which some errors are included with regard to the solubilities of *Λ*-[Co(ox)(en)$_2$](*d*-bcs)·4H_2O, though the principal feature has not altered. Since the phase change in crystals of the *Λ*-diastereomer from the 1.5- or 2.5-hydrate to the tetrahydrate required about half a day with considerable deviations, it seems that the true tetrahydrate was not realized in some determinations of the previous experiment.[1] The corrected data are also given in Table 1.

Prefered Orientation and π-Bonding of the Hydroxyl Group in 1,2-Benzocycloalken-3-ols

Nobuo Mori,* Shin-ichi Kasuya, Hitoshi Miyazaki, and Toshiyuki Takezawa
Department of Chemistry, Science University of Tokyo, Shinjuku-ku, Tokyo 162
(Received July 22, 1978)

The various values of ν_{OH} of 1,2-benzocycloalken-3-ols observed in dilute CCl_4 solutions have been explained in terms of the inclination angle of the C–O bond to the plane of the benzene ring (θ) and the conformational isomerism of the OH group with respect to the C–O bond. The ν_{OH} shift caused by OH···π bonding is angle-dependent, *i.e.*, 9 cm^{-1} if θ=50—90°, or 17 cm^{-1} if θ=38—45°.

Intramolecular OH···π bondings have been extensively investigated by IR spectroscopy and have accepted successful application to the conformational and structural elucidation of various systems containing both hydroxyl group and π-source.[1] Oki, Iwamura, *et al.* found the geometry dependence of the π-bonded ν_{OH} or π-bond shift ($\Delta\nu_{OH}$) in biphenyl-2-ols,[2] alkenols,[3] and 2-phenylalkanols.[4] Such dependence has not however been reported in 1-phenylalkanols. The axial and equatorial OH groups of 1,2-benzocyclohexen-3-ols however show π-bonded ν_{OH}'s of 3618 and 3600 cm^{-1} respectively.[4,5]

In the present work, the angular dependence of $\Delta\nu_{OH}$ in a series of 1,2-benzocycloalken-3-ols having different inclination angles between the C–O bond and the plane of the benzene ring (θ's) have been studied. The range of θ has been from 10 to 82°. Table 1 gives the compounds examined and the relevant θ's for the axial and equatorial† C–O bonds (θ_a and θ_e), as measured using Dreiding models. In this work, the cyclopentene, cyclohexene, and cycloheptene rings have been assumed to take the envelope,[6–8] half-chair,[9] and chair conformations,[10–12] respectively. The cyclopentadiene rings of **5**'s have been assumed to be coplanar with the benzene rings.

Results and Discussion

Table 2 gives the ν_{OH} data observed in CCl_4, in which each alcohol exhibits at least one maximum at 3600, 3607, 3616, 3620, or 3626 cm^{-1}. The last ν_{OH} is characteristic of monomeric secondary alcohols[13] and the remaining ν_{OH}'s will be assigned later.

In each compound, the prefered orientation of the C–O bond is determined by at least one of the following factors: (1) the interaction between the equatorial hydroxyl group and the *peri*-substituent (*peri*-interaction), (2) 1,3-diaxial and/or other steric interactions, and (3) OH···π bonding. A previous IR study of **2a** and **2b**[5] indicated that an axial orientation, free from factor (1), is prefered. In the IR and NMR studies of substituted 1-tetralols and analogs by Hanaya, *et al.*[14] factor (1) was found to predominate over (2) with a few exceptions. The same will not always apply to the **1**'s and **3**'s, however, since the substituent arrangements in space are different. In the **1**'s where the equatorial hydroxyl and the *peri*-substituent are less eclipsed than in the **2**'s, the *peri*-interaction will be less. In the **3**'s, with the substituents in a more eclipsed position, the *peri*- and also the 1,3-diaxial interactions will be greater. Nevertheless, the prefered orientation will be decided by examining the *peri*-substituent effects on the relative absorption intensities.

The strongest OH bands of **1a** and **1b** appear at 3601 and 3607 cm^{-1} respectively. The shift to higher frequency in **1b** is due to the steric effects of the *peri*-methyl substituent which are expected to cause changes in the population of the OH conformers around the C–O bond and/or conversion of the prefered orientation of the C–O bond. If the former is true and if the most favoured OH conformer of **1a** is that of Type II (see Table 4), this conformer would convert to Type

† In the text, "axial" and "equatorial" mean "quasi-axial" and "quasi-equatorial," respectively.

4b	5.25, dd(J: 4.5, 9.5 Hz)	—

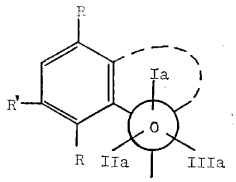
a) δ of H(1) is concentration-dependent. b) Saturated solution. c) The unresolved multiplet has a width of 12 Hz at the half height and a double intensity at the center relative to the side signals. d) The unresolved multiplet has a width of 12 Hz at the half height.

I by *peri*-methyl substitution, relieving the resulting interaction between the OH hydrogen and *peri*-methyl. This conversion, however, can not explain the observed ν_{OH} shift to higher frequency, since the ν_{OH} of Type I should be lower than that of Type II.[13] Conversion of Type I to II is unlikely. It appears reasonable to assume that **1a** prefers the equatorial C–O orientation (ν_{OH}: 3601 cm^{-1}), not taking into account the question of the prefered OH conformer. The orientation is converted to the axial form (ν_{OH}: 3607 cm^{-1}) by the introduction of the *peri*-methyl group, which relieves the resulting interaction between the equatorial hydroxyl and *peri*-methyl. Both **2a** and **2b** prefer an axial orientation.[4,5] In the case of **3a** and **3b**, the single 3620 cm^{-1} band is practically unchanged by the introduction of the *peri*-methyl group and thus the axial orientation seems to be exclusively prefered.

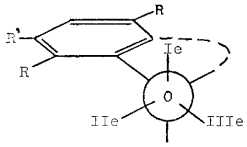
A comparison of the relative intensities of the axial and equatorial OH bands indicates that the axial orientation is increasingly prefered in the sequence from **1a** to **3a** or with a decrease in θ_e and exclusively prefered in **1b** to **3b**. This result is consistent with the ^1H NMR results (Table 3). Indeed, the J-coupling data for the H(1) of **1a** to **3a** in $CDCl_3$, which are similar to those in CCl_4, suggest the preference for axial orientation in **2a** and **3a** but not in **1a**.[15] The $J_{1,2}$ values for **1b** to **3b** are of a magnitude expected from the Karplus relationship and are very similar to those observed for analogs with equatorial H(1).[8,11,12,16] It appears that the prefered axial orientation is caused predominantly by the *peri*-interaction which becomes greater with decreasing θ_e and increasing size of the *peri*-substituent ($H<CH_3$).

The π-bondings of the axial and the equatorial OH species assigned above may be expected from the considerably low values of ν_{OH}. In fact, the nitro substituent in **1c** and **2c** increases the relative intensity of the free OH band, indicating at least one of the OH species to be π-bonded. Iwamura and Hanaya[4] assigned the 3618 and 3600 cm^{-1} bands of 1,2-benzocyclohexen-3-ols to the axial and equatorial π-bonded OH species, respectively, by taking account of the usual conformational and π-bonding effects on ν_{OH} and expected the π-bond shifts to be 9 and 18 cm^{-1}. On a similar base, the ν_{OH} values in Table 2 may be assigned to Types I, II, and III of the OH conformers,

TABLE 4. TYPES OF OH CONFORMERS AND ASSIGNMENTS OF THE MAXIMUM ν_{OH} BANDS



Axial C–O orientation



Equatorial C–O orientation

Type of OH conformer	Free ν_{OH} assumed[18]	Compounds **1a—1c**			Compounds **2a—2c**			Compounds **3a, 3b**		
		ν_{OH} observed	$\Delta\nu_{OH}$	$\theta°$	ν_{OH} observed	$\Delta\nu_{OH}$	$\theta°$	ν_{OH} observed	$\Delta\nu_{OH}$	$\theta°$
Ia	3618	3607	11	75	—		82	—		50
IIa	3627	3616sh	11		3618	9		3620	7	
IIIa	3627	3626	1		3626sh	1		—		
Ie	3618	3600	18	45	3602	16	38	—		10
IIe	3627	—			—			—		
IIIe	3627	3626			3626sh	1		—		

as given in Table 4. In each type of conformer, the O–H is assumed to be staggered between the opposing bonds. OH···π bonding occurs in Types I and II in which the OH hydrogen is directed towards the π-cloud. In **1a** to **3a**, Type Ia, in which the O–H is pointing inside the cycloalkene ring, may be sterically unfavorable, since repulsion operates between the OH hydrogen and one or two axial hydrogens on the cycloalkene ring which are in close proximity.[17] In Type IIe also, the OH hydrogen is close to the *peri*-hydrogen. Thus, Types IIa and Ie, in which no overcrowding of the OH hydrogen may be expected, are probably prefered and may largely contribute to the axial and equatorial OH absorptions at 3618 and 3600 cm,$^{-1}$ respectively. The shifts from the free ν_{OH} values ($\Delta\nu_{OH}$)[18] are 7—11 and 16—18 cm^{-1}, respectively, which are ascribable to OH···π bonding.

In **1b** to **3b**, Type IIa may contain an additional interaction between the OH hydrogen and *peri*-methyl. With a decrease of θ_a or in moving from **3b** to **1b**, this interaction will increase and Type IIa becomes less possible, whereas the crowding in Type Ia will be relieved. Thus, the prefered conformer will be IIa in **3b** and **2b** (ν_{OH}: 3620 cm^{-1}; $\Delta\nu_{OH}$: 7 cm^{-1}), but it will be Ia in **1b** (ν_{OH}: 3607 cm^{-1}; $\Delta\nu_{OH}$: 11 cm^{-1}). The weak absorptions at 3610 and 3615 cm^{-1} which **2b** and **1b** exhibit may be assigned to Ia and IIa, respectively, as the less prefered conformers. Benzyl alcohols with θ=90°[19] show π-bonded ν_{OH} (3617 cm^{-1})[13,20] which may be assigned to Type II, so that $\Delta\nu_{OH}$ is 10 cm^{-1}. These results indicate the angular dependence of the π-bond shift: $\Delta\nu_{OH}$ is *ca.* 9 cm^{-1} if θ=50—90°, or *ca.* 17 cm^{-1} if θ=38—45°. **5a** and **5b** (θ=60°) exhibit intense bands at 3600 cm^{-1} which may be assigned to Type I, so that $\Delta\nu_{OH}$ is 18 cm^{-1}. This shift is larger than expected from the above relationship, probably because the OH may be π-bonded with the two benzene rings. The weak 3620 cm^{-1} band of **5a** is probably due to an OH species π-bonded with one benzene ring, so that $\Delta\nu_{OH}$ is 8 cm^{-1}, as expected. The IR and NMR data of **4a** and **4b** are similar to those of **3a** and **3b**. It thus appears that the cyclooctene ring[21] is not as flexible as expected from molecular models.[22] The above relationship between θ and $\Delta\nu_{OH}$ predicts that the C–O bond is axial ($\Delta\nu_{OH}$: 7 or 12 cm^{-1}).

Experimental

Samples. Most of the compounds examined are known substances. 5-Nitroindan-1-ol (**1c**) was prepared from the corresponding ketone by $NaBH_4$ reduction and purified by recrystallization; mp 82.1—82.9 °C; Found: C, 60.43; H, 5.07; N, 7.75%. Calcd for $C_9H_9NO_3$: C, 60.33; H, 5.06; N, 7.82%.

Measurements. IR spectra were recorded on a JASCO DS-403G grating spectrometer. The solvent was CCl_4 distilled over P_2O_5 before use and the concentration selected was *ca.* 0.003 mol/l or less, so as to avoid intermolecular association (cell length: 50 mm). The spectral slit width was 1.5 cm^{-1} at 3600 cm^{-1}.

^{1}H NMR spectra were measured using a JEOL JNM4H-100 spectrometer operating at 100 MHz for *ca.* 10 w/v% solutions in CCl_4 or $CDCl_3$ with TMS as an internal reference. All measurements were carried out at ambient temperature (20—25 °C).

The Regioselective *C*-Hydroxyalkylation of 1,3-Diphenyl-1,3-propanedione with Halo Alcohols, Involving Intramolecular Alcoholysis: the Synthesis of Oxoalkyl Esters†

Hideo Tsutsumi, Kimio Inoue, and Yoshiharu Ishido*

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

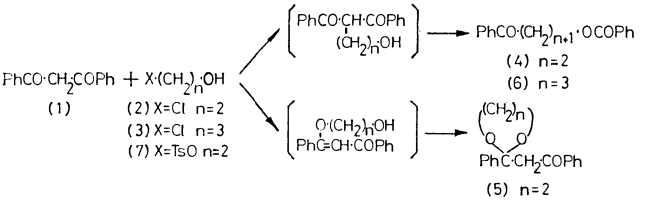
(Received July 17, 1978)

The reaction of 1,3-diphenyl-1,3-propanedione (**1**) with 2-chloroethanol (**2**) or 3-chloro-1-propanol (**3**) was performed in the presence of potassium carbonate and sodium iodide as an improved procedure for regioselective *C*-hydroxyalkylation, involving intramolecular alcoholysis; the effects of the solvents, the temperature, and the amounts of potassium carbonate and sodium iodide were also investigated. The reaction with **2** afforded 3-benzoylpropyl benzoate (**4**) (*ca.* 70% yield), together with 2-benzoylmethyl-2-phenyl-1,3-dioxolane (**5**) (*ca.* 15% yield). The reaction with **3**, on the other hand, gave 4-benzoylbutyl benzoate (92—94% yield); the corresponding 1,3-dioxane derivative was detected only in a trace. Moreover, the reaction of **1** with 2-hydroxyethyl tosylate was similarly performed, but the yields of both **4** and **5** were unexpectedly low.

The *C*-hydroxyalkylation of 1,3-dicarbonyl compounds was first demonstrated by the reaction of 2,4-pentanedionatosodium with ethylene oxide in ethanol at 0 °C; this gave 3-(2-hydroxyethyl)-2,4-pentanedione (20% yield).[1] On the other hand, the synthesis of methyl ketones has been accomplished by the *C*-alkylation of 2,4-pentanedione with benzyl halides in ethanol in the presence of potassium carbonate, involving simultaneous ethanolysis.[2] Based on these facts, a novel synthetic route to 4-oxoalkanols has been established ; *i.e.*, the reaction of 2,4-pentanedione with 1,2-epoxyoctane in the presence of potassium carbonate and sodium iodide in ethanol under reflux gave a 28% yield of 5-hydroxy-2-undecanone.[3] There have recently been reported the syntheses of some eleven-membered cyclic ketolactones by the *C*-alkylation of 2-substituted dimedones with 4-chloro-2-butenyl acetate in the presence of potassium *t*-butoxide and potassium iodide, followed by the hydrolysis of the esters and intramolecular alcoholysis.[4] On the other hand, we recently demonstrated that the sodium iodide-catalyzed reactions of ethylene carbonate with some active methylene compounds, which are assumed to proceed *via* 2-iodoethanol, afforded the corresponding 4-oxoalkyl esters as predominant products.[5] In view of the mechanism of these reactions, therefore, we set out to develop an improved procedure for a more-highly regioselective and effective *C*-hydroxyaltion of 1,3-dicarbonyl compounds involving intramolecular alcoholysis by the use of 1,3-diphenyl-1,3-propanedione (**1**) and 2-chloroethanol (**2**) or 3-chloro-1-propanol (**3**); we wish now to report our results.

Results and Discussion

Although ethanol has usually been used as a solvent in the alkylation of 1,3-dicarbonyl compounds, we examined a series of solvents for the reaction; a mixture of **1** (10 mmol), **2** (45 mmol), potassium carbonate (10 mmol), and sodium iodide (13 mmol) in a solvent



Scheme 1.

a) All the reactions were performed by the use of **1** (10 mmol), **2** (45 mmol), K_2CO_3 (10 mmol), and NaI (13 mmol) in a solvent (50 ml). b) This reaction was performed without NaI.

was stirred for 2 days in an autoclave under the conditions given in Table 1. As expected, the products obtained were the same as those formed in the reaction of ethylene carbonate;[5] we obtained small amounts of acetophenone and 2-chloroethyl benzoate in addi-

† This paper was partly presented at 26th International Congress of Pure and Applied Chemistry, Tokyo, Japan, September 4—10, 1977; the Abstract p. 999.

tion to the main products of the corresponding 4-oxoalkyl ester and ethylene acetal derivative, namely, 3-benzoylpropyl benzoate (**4**) and 2-benzoylmethyl-2-phenyl-1,3-dioxolane (**5**). When hexane, benzene, chloroform, diethyl ether, and 1,4-dioxane were used, scarcely none of the benzoate, **4**, was obtained, and the starting material, **1**, was recovered in the yields shown in the table. In contrast with these, ethyl acetate, acetonitrile, 1,2-dimethoxyethane, and acetone were effective for the coupling reaction, giving **4** in 41, 40, 59, and 50% yields respectively, together with traces of **5**. On the increasing polarity of solvents in turn from *N*,*N*-dimethylformamide up to dimethyl sulfoxide and hexamethylphosphoric triamide, however, we obtained **4** (39, 28, and 29% yields respectively) and **5** (7, 14, and 47% yields respectively), in addition to the recoveries of **1** seen in the table. The last entry clearly demonstrated the importance of the addition of sodium iodide to the reaction system, resulting in the formation of **4** in only an 8% yield.

In order to check if an elevated temperature brings about any improvement in the reaction, we performed some of the reactions in acetone, 1,2-dimethoxyethane, acetonitrile, and ethyl acetate at 150 °C. However, no improved results were obtained, giving **4** (49, 28, 21, and 27% yields respectively) and **5** (trace, trace, 9% yield, and trace respectively)(see Table 2). Judging from the yield of **4** and the easy of handling the solvents, it was concluded that it is more advantageous to perform the reaction at around 90 °C in acetone.

Subsequently, the molar proportions of **2** and potassium carbonate in the reaction were examined; the conditions used and the results thus obtained are summarized in Table 3. The results led us to the conclusion that the reaction gives the desired compound, **4**, in 60—71% yields, provided the proportions of **2** and potassium carbonate were 3.75 : 1—1.5 : 1.

The utilization of an excess amount of **2** (75 mmol) in relation to potassium carbonate (2 mmol), however, gave no product at all. This may arise from the predominant reaction of **2** with potassium carbonate, by which the surface of potassium carbonate was covered with the resultant potassium chloride; this may make the potassium carbonate ineffective in the objective reaction. As may be seen from the third entry, the elongation of the reaction time was not fruitful; a 4 day-elongation improved the yield by only 11%. For reference, the reaction in ethyl acetate was checked by the use of 1.5 : 1 **2**–potassium carbonate as is shown in the last entry; this gave **4** (33% yield) in parallel with the results shown in Table 2.

Consequently, the reaction system for a highly regioselective *C*-hydroxyalkylation has been furhter investigated in terms of the reaction involving **3** in

Table 2. The reaction of **1** with **2** in some solvents at an elevated temperature[a]

Entry	Solvent	Yield of product **4** (%)	Yield of product **5** (%)	Recovery of **1** (%)
1	Acetone	49	trace	41

place of **2** under the conditions summarized in Table 4. In this case, the reaction was almost regiospecifically induced on the methylene carbon of **1** to give a 92% yield of 4-benzoylbutyl benzoate (**6**) as is shown in the fifth entry. In addition, it should be noticed that this reaction could also be performed in acetone under reflux, giving **6** in a 94% yield together with a trace amount of a by-product which was barely confirmed as 2-benzoylmethyl-2-phenyl-1,3-dioxane by PMR spectroscopy. The sixth entry shows that an elevated temperature is also inadequate for this reaction. Moreover, the reaction in 1,2-dimethoxyethane (Entry 7) also gave **6** in an 80% yield. The mechanism of these reactions is conceivably similar to that proposed in the sodium iodide-catalyzed reaction of ethylene carbonate with **1**[5)] as follows: the chloro-substituent of **2** or **3** may first be replaced by the iodide ion to give the corresponding iodoalkanols, which are then subjected to the coupling reaction with **1** in the presence of potassium carbonate to give the corresponding intermediary 3,3- or 4,4-dibenzoyl-1-alkanol. Subsequently, the resulting dibenzoylalkanols may undergo intramolecular alcoholysis to give **4** or **6** as is depicted in Scheme 1.

Finally, we performed the reaction of 2-hydroxyethyl tosylate (**7**), in place of **2**, with **1** in order to compare it with the above reactions, since **7** seems to behave similarly to **2**, judging from the nucleofugacity of the tosyloxy function. The conditions and the results thus obtained are summarized in Table 5. We observed a similar trend in the yields of **4**, although they were inferior to those obtained in the reactions of **2** with **1**.

Experimental

The PMR spectra were recorded on a Varian T-60 instrument in deuteriochloroform with tetramethylsilane (TMS) as the internal standard. The IR spectra were recorded on a Hitachi 285 spectrophotometer. The column chromatographic separations were performed by the use of Wakogel C-300 (Wako Pure Chemicals, Japan), and TLC, by the use of Merck silica gel 60 F_{254} precoated plates (thickness, 0.25 mm); spots were detected with a UV lamp (S. L. Light, Tokyo Machinery Co., Ltd. 253.7 and 365 nm).

Materials. We purchased commercially 2-chloroethanol (**2**) and 3-chloro-1-propanol (**3**) (Aldrich Chemical Co., Inc.). 1,3-Diphenyl-1,3-propanedione (**1**) was prepared from 1,3-diphenyl-2-propene-1-one according to the method of Allen *et al.*;[6)] mp 77—78 °C (from MeOH) (lit,[6)] 77—78 °C). 2-Hydroxyethyl tosylate (**7**) was prepared according to the method of Rompuy *et al.*;[7)] the PMR spectrum of the product was identical with that of an authetic specimen.

*Examination of the Solvent Effect on the Reaction of **1** with **2**.* A mixture of **1** (2.24 g, 10 mmol), **2** (3 ml, 45 mmol), potassium carbonate (1.40 g, 10 mmol), and sodium iodide (2.0 g, 13 mmol) in a solvent (50 ml) was stirred in an autoclave at 90 °C for 2 days. The resulting mixture was evaporated *in vacuo*, and the residue was triturated with chloroform (50 ml). The supernatant was filtered and evaporated. When DMSO, DMF, or HMPT was used as the solvent, the resulting mixture was made weakly acidific by the use of 1 M (=1 mol dm^{-3}) hydrochloric acid and then extracted with chloroform (20 ml×3). The extracts were combined and evaporated, after drying over anhydrous magnesium sulfate. The syrups thus obtained were subjected to chromatographic separation on a column of silica gel by the use of 1 : 1 v/v benzene-cyclohexane to give 1,3-diphenyl-1,3-propanedione (**1**), 3-benzoylpropyl benzoate (**4**), and 2-benzoylmethyl-2-phenyl-1,3-dioxolane (**5**) in turn. The PMR spectra of these products were superimposable with those of the corresponding authentic specimen.[5)] The results thus obtained are summarized in Table 1.

The Reaction at 150 °C. The products were similarly chromatographed on a column of the silica gel after stirring a mixture of **1** (448 mg, 2 mmol), **2** (1 ml, 15 mmol), K_2CO_3 (280 mg, 2 mmol), and NaI (400 mg, 2.7 mmol) in a solvent at 150 °C for 1 day. The results thus obtained are summarized in Table 2.

*Examination of Appropriate Amounts of **2** and K_2CO_3 in the Reaction.* In acetone, a mixture of the agents as described above with various proportions of **2** and K_2CO_3 was treated in the same way as above; the results thus obtained are summarized in Table 3.

*The Reactions of **1** with **3** in the Presence of K_2CO_3 and NaI.* A mixture of **1** (448 mg, 2 mmol), **3** (2.3—12 mmol), K_2CO_3 (280 mg, 2 mmol), and NaI (400 mg, 2.7 mmol) in a solvent (20 ml) was stirred under reflux, at 90 °C or at 150 °C for 15 h, 2 days, or 4 days in an autoclave. The purification of the products thus obtained was performed in the same way as described above to give **1** and 4-benzoylbutyl benzoate (**6**); IR (NaCl): 1720, 1680, 1270, and 1110 cm^{-1}; PMR ($CDCl_3$-TMS) : δ1.7—2.1 (4H, m, C-CH_2CH_2-C), 3.03* (2H, PhCO-CH_2-), 4.36* (2H, O-CH_2-), and 7.2—8.2 (10 H, m, aromatic). The *J*-values with an asterisk could not be determined by the first-order analysis because of virtual coupling. Found: C, 76.48; H, 6.39%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%. The results thus obtained are summarized in Table 4.

The Reaction of ***1*** *with* ***7*** *in the Presence of* K_2CO_3 *and NaI.* A mixture of **1** (448 mg, 2 mmol), **7** (2.1 or 4.2 mmol), K_2CO_3 (4 or 8 mmol), and NaI (400 mg, 2.7 mmol) in acetone (20 ml) was treated under reflux or at 90 °C in an autoclave with stirring for 2 days; the solvent was then evaporated after the addition of some water to dissolve the insoluble crystals. The resulting aqueous residue was weakly acidified with 1 M hydrochloric acid, followed by extraction with chloroform (10 ml×3). After the organic layer had been dried over anhydrous sodium sulfate, the filtrate was evaporated; the residue was subjected to chromatographic separation on a column of silica gel. The results thus obtained are summarized in Table 5.

The authors wish to thank the members of the Laboratory of Organic Analysis, Tokyo Institute of Technology, for the elemental analyses, and the Ministry of Education, Japanese Government, for their Scientific Research Grant-in-Aid (No. 947038).

Phosphinyl- and Phosphinothioylamino Acids and Peptides. IV. Further Examples of Use of the Diphenylphosphinothioyl Group for the Protection of Amino Acids

Shigeru IKEDA, Fumio TONEGAWA, Etsuro SHIKANO, Kozo SHINOZAKI, and Masaaki UEKI*

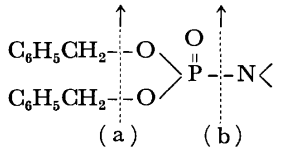
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 31, 1978)

The preparation and purification of diphenylphosphinothioyl(Ppt)-amino acids were studied. The side-chain functional groups of tyrosine and cysteine were found to react also with diphenylphosphinothioyl chloride to form *O*-Ppt and *S*-Ppt derivatives. Acidic reagents for the removal of *N*-Ppt group were examined by using *N,O*-bis-Ppt-tyrosine ethyl ester (III) as the most difficult model, HCl in HCO_2H–CH_2Cl_2 being found to be most preferable. The *O*- and *S*-Ppt bonds were stable during the course of acidic treatments, but could be removed by alkaline hydrolysis. An application of Ppt-amino acids to the solid phase peptide synthesis is given.

Selection of the α-amino protecting group is important in working out peptide synthesis because an *N*-terminal elongation strategy is generally favored. Urethane groups such as benzyloxycarbonyl(Z)[1] and *t*-butoxycarbonyl(Boc)[2] have been used since they are superior in selectivity for the removal and prevention of racemization. However, complete prevention of side-reactions by carbonium ions formed during the course of deprotection seems difficult. We have investigated a new series of amino protecting groups not producing such an active species by cleavage.

The phosphazo method[3] is well-known as regards its utilization of the reactivity of trivalent phosphorus-nitrogen compounds with carboxylic acids. The acid lability of P–N bonds decreases in the oxidated state of phosphorus. In fact, the bis(benzyloxy)phosphinylidyne $(C_6H_5CH_2O)_2P(O)$– group has been used as an amino protecting group in the syntheses of amino sugars[4] and peptides.[5] The group can be removed, as in the case of the Z group, by catalytic hydrogenation or hydrogen bromide in acetic acid. In the latter case of deprotection, it is not clear which bond, C–O (a) or P–N (b), is cleaved initially. Recently



we have used monofunctional phosphinyl, RR'P(O)–, and phosphinothioyl, RR'P(S)–, groups as amino protecting groups and found that they can be removed not only by HBr in acetic acid but also by HCl reagents usually used for the removal of the Boc groups.[6,7] Among various kinds of phosphinyl and phosphinothioyl groups examined the diphenylphosphinothioyl (Ppt) group was thought to be the most useful since diphenylphosphinothioyl chloride can be easily prepared both in laboratories and on an industrial scale starting from benzene and thiophosphoryl chloride by the Friedel-Crafts reaction.[8] This paper gives further examples of the use of the Ppt group for the protection of amino acids.

$$2C_6H_6(\text{benzene}) + S{=}PCl_3 \xrightarrow{AlCl_3} (C_6H_5)_2P(S)\text{-}Cl \quad (\text{Ppt-Cl})$$

$$\text{Ppt-Cl} + H_2N\text{-}CHR\text{-}CO_2R' \xrightarrow{N(C_2H_5)_3} \text{Ppt-NH-CHR-}CO_2R'$$

$$\text{Ppt-NH-CHR-}CO_2R' \xrightarrow[2)\ H^+]{1)\ OH^-} \text{Ppt-NH-CHR-}CO_2H$$

$$\text{Ppt-Cl} + H_2N\text{-}CHR\text{-}CO_2^- \xrightarrow[2)\ H^+]{1)\ OH^-} \text{Ppt-NH-CHR-}CO_2H$$

Ppt-amino acids were prepared by alkaline hydrolysis of Ppt-amino acid esters obtained from Ppt–Cl and amino acid esters.[6] Difficulties in the alkaline hydrolysis of *N*-diisopropoxyphosphinylidyne- and *N*-diphenoxyphosphinylidyneamino acid esters were reported.[9,10] However, no such steric hindrance was encountered in the case of Ppt derivatives. Importance of the Ppt group exists in the direct synthesis of Ppt-amino acids from amino acid betaines.

Phosphinothioyl chlorides are surprisingly resistant to hydrolysis as compared with phosphinyl chlorides.[11] The rate of hydrolysis was accelerated by the addition of a suitable solvent such as dioxane (Fig. 1). Addition of dioxane up to the same volume of water is admissible.

The synthesis of Ppt-amino acids was studied by Schotten-Baumann type reactions in water or aqueous dioxane. An amino acid was dissolved in a 2 M (1 M=1 mol dm^{-3}) NaOH solution and Ppt–Cl was added in one portion. The mixture was stirred vigorously to initiate a rapid reaction within several minutes. Then, 2 M NaOH solution was added, the pH of the solution being kept in the desired range. An 8.5—9.5 pH range was recommended,[6] but yields from

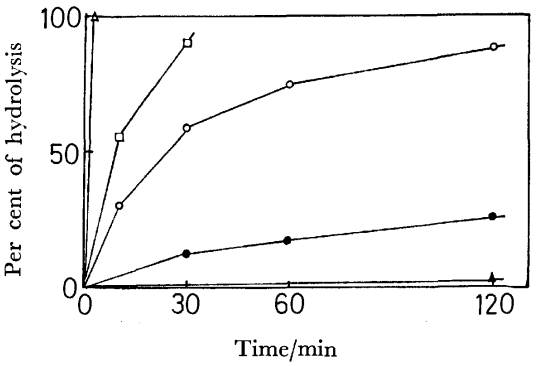


Fig. 1. Rate of hydrolysis of Ppt-Cl in dioxane–water (△: 2/1, □: 1/1, ○: 1/2, ●: 1/5) and in water (▲) at pH 9.5.

reactions in this range were later found to be sometimes poor. This could be attributed to the second reaction of the Ppt-amino acid salt with Ppt–Cl to give the Ppt-amino acid diphenylphosphinothioic anhydride,[12] since better yields were obtained by reactions at higher pH. This was confirmed by isolation of a small amount of dicyclohexylamine salt of Ppt–Gly–Gly–OH, Mp 187—192 °C, Found: C, 63.52; H, 7.46; N, 7.99; P, 5.45%. Calcd for $C_{28}H_{40}N_3O_3PS$: C, 63.53; H, 7.56; N, 7.93; P, 5.85%, from the mother liquor of recrystallization of Ppt–Gly–OH.

Most of the Ppt-amino acids were obtained as free acids which could be easily purified by recrystallization. Complete removal of contaminating diphenylphosphinothioic acid(Ppt–OH) was difficult in the case of oily substances. However, the presence of a small amount of Ppt–OH does not seem to hinder peptide synthesis by the dicyclohexylcarbodiimide (DCC) method since Ppt–OH reacts very rapidly with DCC to produce a stable 1 : 1 adduct.[13] Pure samples of Ppt-amino acids were obtained by utilizing the difference of acid strength of Ppt-amino acids and Ppt–OH. Ppt-amino acids, which are weaker as an acid and more lipophilic than Ppt–OH, can be extracted preferentially by organic solvents from slightly acidic aqueous solution. A considerable amount of dicyclohexylamine(DCHA) salt of Ppt–OH remained without being made free after the usual treatment to regenerate a free Ppt-amino acid from its DCHA salt by shaking with ethyl acetate and 5% aqueous citric acid solution. Ppt-glutamine could be purified by recrystallization from ethyl acetate or by column chromatography on silica gel. When a solution of crude Ppt–Gln–OH in ether saturated with water was passed through a silica gel column, Ppt–Gln–OH was absorbed completely, only Ppt–OH being eluted out. Pure Ppt–Gln–OH was then obtained by eluting with methanol.

In the case of γ-benzyl glutamate and ε-Z-lysine only hydrolysis of Ppt–Cl occurred under the conditions described above. Various conditions were tested; Ppt–Glu(OBzl)–OH can be prepared by using 50% aqueous dioxane as a solvent and triethylamine as a base and isolated in 32% yield as the *t*-butylamine salt.

The reactions of Ppt–Cl with side-chain functional groups were investigated. Alcoholic hydroxyl groups of serine and threonine were not affected by Ppt–Cl since Ppt–Ser–OH and Ppt–Thr–OH were obtained as DCHA salts in 66 and 47% yields, respectively, by the Schotten-Baumann type reactions. Ppt–Ser–OH can be benzylated with benzyl bromide and sodium hydride[14] to give Ppt-*O*-benzyl-serine in 61% yield as the DCHA salt. When tyrosine was treated with 2 molar equiv. of Ppt–Cl under the conditions described above, a mixture of two phosphinothioylated tyrosines was obtained. The mixture was separated by silica gel column chromatography to give *N*-Ppt-tyrosine (I), which was isolated as the DCHA salt, and *N*,*O*-bis-Ppt-tyrosine (II), Mp 117—124 °C, in 6 and 30% yields, respectively. Ethyl tyrosinate also reacted with Ppt–Cl in the presence of triethylamine to give *N*,*O*-bis-Ppt-tyrosine ethyl ester (III) contaminated with *N*-Ppt-tyrosine ethyl ester. When III was hydrolyzed by 1 M NaOH at room temperature for 48 h, both carboxylate ester and phosphinothioate ester bonds were cleaved to afford I in 80% yield. The *O*-Ppt group could also be cleaved slowly by hydrazinolysis.

$$\text{H-Tyr-OH} \xrightarrow[\text{OH}^-]{\text{2 Ppt-Cl}} \underset{\text{(I)}}{\text{Ppt-Tyr-OH}} + \underset{\text{(II)}}{\text{Ppt-Tyr(Ppt)-OH}}$$

$$\text{H-Tyr-OEt} \xrightarrow[\text{N}(C_2H_5)_3]{\text{2 Ppt-Cl}} \underset{\text{(III)}}{\text{Ppt-Tyr-OEt}} + \text{Ppt-Tyr(Ppt)-OEt}$$

The *N*-Ppt group of compound III was found to be unexpectedly slow in cleavage by acidic reagents. Hydrogen bromide in acetic acid could remove the *N*-Ppt group within 5 min, but it took 4 days for complete removal by trifluoroacetic acid–dichloromethane (1/1). Hydrogen chloride in dioxane or acetic acid and triphenylphosphine dihydrochloride solution in dichloromethane[15] were also so impotent that it took more than 2—3 h for complete deprotection. The most preferable reagent for removal of the *N*-Ppt group was HCl in formic acid. When compound III was dissolved in dichloromethane and the same volume of 0.6 M HCl in formic acid was added, complete deprotection took place within 20 min to give *O*-Ppt-tyrosine ethyl ester hydrochloride (IV). These conditions are generally applicable to the removal of *N*-Ppt groups. The *O*-Ppt group was quite stable during the course of acidic treatment since no Pauly positive spot[16] was detected by TLC. The results suggest the possible use of the *O*-Ppt group for the protection of the OH function of tyrosine. This was exemplified in the following synthesis. IV was coupled in the presence of triethylamine with Z–Ser(Bu^t)–OH by DCC to give Z–Ser(Bu^t)–Tyr(Ppt)–OEt(V) in 91% yield. Alternative cleavage of the two *O*-protecting groups was accomplished by alkaline hydrolysis for the *O*-Ppt group and by treatment with trifluoroacetic acid for the *O*-Bu^t group.

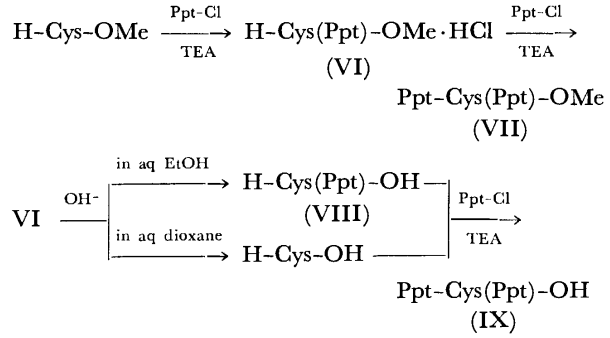
$$\text{III} \xrightarrow{0.3\text{M HCl/HCO}_2\text{H-CH}_2\text{Cl}_2(1/1)} \underset{\text{(IV)}}{\text{H-Tyr(Ppt)-OEt}\cdot\text{HCl}}$$

$$\text{Z-Ser(Bu}^t\text{)-OH} + \text{IV} \xrightarrow{\text{DCC}} \underset{\text{(V)}}{\text{Z-Ser(Bu}^t\text{)-Tyr(Ppt)-OEt}}$$

$$\text{V} \begin{cases} \xrightarrow{\text{OH}^-} \text{Z-Ser(Bu}^t\text{)-Tyr-OH} \\ \xrightarrow{F_3CCO_2H} \text{Z-Ser-Tyr(Ppt)-OEt} \end{cases}$$

The SH function of cysteine was more reactive than the amino function with Ppt–Cl. When cysteine methyl ester was treated with equimolar amounts of Ppt–Cl in the presence of triethylamine, *S*-Ppt-cysteine methyl ester hydrochloride (VI) was obtained as the main product. When 2 molar equiv. of the reagent was used, the α-amino group of VI was also phosphinothioylated to give *N*,*S*-bis-Ppt-cysteine methyl ester (VII) in 79% yield. When VI was hydrolyzed by 1 M NaOH in ethanol, selective removal of the methyl ester occurred to give *S*-Ppt-cysteine (VIII) in 61% yield. Stability of the *S*-Ppt group changed

with solvent. When aqueous dioxane was used as a solvent the phosphinothioate ester bond also underwent hydrolysis. However, *N*,*S*-bis-Ppt-cysteine (IX) could be obtained in 12% yield when VIII or cysteine itself was reacted for a short time with Ppt–Cl in aqueous dioxane in the presence of triethylamine. Since the *S*-Ppt group was also stable under the acidic conditions, IX would be useful for the synthesis of cysteine containing peptides.



TEA: triethylamine

Arginine reacted very rapidly with Ppt–Cl, but no useful Ppt derivative was obtained probably because of the lactam formation.[17] Since Ppt–Cl is unreactive toward the indole moiety of tryptophan, tryptophan reacted with Ppt–Cl to give Ppt-tryptophan as a sole product. Pure acid was obtained as crystals containing 1 mol of ethanol by recrystallization from ethanol.

The physical properties of Ppt-amino acids prepared in the present experiments are summarized in Table 1.

Coupling of the Ppt-amino acids was successful[6] with use of DCC, mixed anhydride and the oxidation-reduction condensation[18] methods. No steric hindrance was observed in the coupling of the Ppt-amino acids contrary to the case of *N*-trityl-amino acids.[19]

Ppt-amino acids can be used for the solid phase synthesis of peptides.[20] Ppt-glycine was esterified *via* caesium salt[21] to a chloromethylated resin. Deprotection was performed by treatment with 1 M HCl in HCO_2H–CH_2Cl_2(2/1) for 30 min, carried out twice. Couplings were mediated with oxidation-reduction condensation. After incorporation of Ppt–Leu followed by Ppt–Pro, the protected tripeptide

was removed from the resin by transesterification[22] to give Ppt–Pro–Leu–Gly–OMe in 95% yield. No undesirable product, Ppt–Leu–Gly–OMe, was detected by TLC.

Experimental

Diphenylphosphinothioyl chloride (Wako Pure Chemical Ind. Ltd.) was distilled before use.

N-Diphenylphosphinothioylamino acids were prepared by the reaction of diphenylphosphinothioyl chloride and α-amino acids (or α-amino acids bearing a protected side-chain functional group) in aqueous alkaline solution or in aqueous dioxane containing triethylamine. The diphenylphosphinothioylamino acids thus prepared were isolated either as free acids (procedures *A*, *B*, and *C*) or in the form of dicyclohexylamine(DCHA), cyclohexylamine(CHA) or *t*-butylamine(TBA) salt (procedures *D*, *E*, and *F*). They are listed in Table 1.

A. The amino acid (0.85 mol) was dissolved in 400 ml of 2 M NaOH solution. Diphenylphosphinothioyl chloride (214 g, 0.85 mol) was added in one portion and the mixture was stirred vigorously to initiate a rapid reaction within several minutes. 2 M NaOH solution was added at a rate to keep the pH of the solution in the range 9.5—10.0. After the pH change had ended the reaction mixture was diluted with 1 l of water and the remaining chloride was removed by extraction with ethyl acetate. The aqueous layer was acidified to pH 6 with solid citric acid, saturated with NaCl and extracted 3 times with ethyl acetate. Combined ethyl acetate extracts were washed successively with saturated $NaHCO_3$ solution, 5% citric acid solution and saturated NaCl solution, dried over anhydrous Na_2SO_4 and evaporated to give a pasty mass. This was crystallized by trituration with petroleum ether. The crude products were recrystallized from ethyl acetate, ethyl acetate–hexane or benzene–hexane.

B. The amino acid was treated with diphenylphosphinothioyl chloride as described in procedure *A*. The solution was acidified with 5% citric acid solution, ether being added. The resulting precipitate was collected by filtration and washed thoroughly with water and then with ether and dried. In the case of tyrosine, a mixture of *N*,*O*-bis-Ppt-L-tyrosine (II) and *N*-Ppt-L-tyrosine (I) was obtained. The mixture was dissolved in dichloromethane and applied to a silica gel column. II was obtained by elution with the same solvent. Following elution with ether gave I.

C. After synthesis and extraction as described in procedure *A*, dicyclohexylamine was added to the ethyl acetate extracts, the corresponding salt separating out. Sometimes, addition of the same volume of ether was necessary. The product was filtered off and washed with ethyl acetate or ether. The crude salt was shaken vigorously in a separatory funnel with a mixture of ethyl acetate and 5% citric acid solution. After removal of insoluble substance, mainly DCHA salt of diphenylphosphinothioic acid, by filtration, the aqueous layer was separated and extracted twice with ethyl acetate. The combined ethyl acetate extracts were washed with 5% citric acid solution and satu-

rated NaCl solution, dried and evaporated to dryness. Ppt-L-leucine was crystallized as a monohydrate by addition of water and recrystallized from methanol–water.

D. The Ppt-amino acid obtained as in procedure *C* was converted again into the corresponding DCHA salt.

E. After synthesis and extraction as in procedure *A*, cyclohexylamine or dicyclohexylamine was added to the ethyl acetate extracts, the corresponding salt separating out. The product was filtered off, washed with ethyl acetate and recrystallized from methanol or ethanol.

F. The amino acid (0.30 mol) was dissolved in a mixture of 425 ml of water and 425 ml of dioxane by addition of 56 ml (0.4 mol) of triethylamine with vigorous stirring under ice cooling. 90.7 g(0.36 mol) of diphenylphosphinothioyl chloride and 36.4 ml (0.26 mol) of triethylamine in 150 ml of 50% aqueous dioxane were added separately in one portion. Within 5 min a clear solution resulted and was extracted twice with ether. The ether extracts were back extracted with 5% $NaHCO_3$ solution. The combined aqueous solution was acidified to pH 4—5 with 5% citric acid solution and extracted 3 times with ethyl acetate. The ethyl acetate extracts were washed successively with 5% $NaHCO_3$ solution, two portions of 30 ml of 1% $NaHCO_3$ solution, three portions of 150 ml of 5% citric acid solution, two portions of 300 ml of water and saturated NaCl solution. The ethyl acetate layer was dried and concentrated to dryness. The oily residue was dissolved in dichloromethane, applied to a silica gel column (3×40 cm) and eluted with the same solvent (about 1.5 l). After evaporation of the eluate the product was dissolved in ether, the amine shown in Table 1 being added to give the corresponding salt.

Ppt-L-Tyr(Ppt)-OEt (III) and Ppt-L-Tyr-OEt. Ppt-Cl(5.05 g, 20 mmol) was added to a suspension of L-Tyr-OEt·HCl(2.48 g, 10 mmol) in 20 ml of chloroform and 4.2 ml (30 mmol) of triethylamine. After being stirred at room temperature for a day the solution was successively washed with water, 5% citric acid, water, 5% $NaHCO_3$, and water. The chloroform layer was dried and concentrated to dryness. The oily residue was dissolved in benzene, applied to a silica gel column (1.5×30 cm) and eluted with 150 ml of benzene to give III as amorphous white powder; 3.93 g (61%). It was homogeneous chromatographically. $[\alpha]_D$ −10.0° (*c* 1, EtOH); Found: C, 65.81; H, 5.04; N, 2.28%. Calcd for $C_{35}H_{33}NO_3P_2S_2$: C, 65.54; H, 5.14; N, 2.18%. Further elution with CH_2Cl_2 gave Ppt-L-Tyr-OEt; 0.86 g (20%). Mp 93—98 °C; $[\alpha]_D$ −32.5° (*c* 1, EtOH); Found: C, 64.92; H, 5.75; N, 2.90%. Calcd for $C_{23}H_{24}NO_3PS$: C, 64.96; H, 5.64; N, 3.29%.

H-L-Tyr(Ppt)-OEt·HCl (IV). III(0.64 g, 1 mmol) was dissolved in 10 ml of 0.3 M HCl/HCO_2H–CH_2Cl_2(2/1). After being left to stand at room temperature for 30 min the solution was evaporated *in vacuo*, the residue being distributed between water and ether. The layers were separated and the ether layer was extracted with 1 M hydrochloric acid (×5). The combined aqueous extracts were concentrated and dried under reduced pressure over NaOH pellets. The product was triturated with ether to give IV as white crystals; 0.42 g (93%). Mp 137—141 °C; $[\alpha]_D$ +22.5° (*c* 1, EtOH); Found: C, 58.37; H, 5.48; N, 3.07%. Calcd for $C_{23}H_{25}NO_3PSCl\cdot 1/2H_2O$: C, 58.68; H, 5.25; N, 2.97%.

Z-L-Ser(Bu^t)-L-Tyr(Ppt)-OEt (V). IV(0.23 g, 0.5 mmol), Z-L-Ser(Bu^t)-OH(0.15 g, 0.5 mmol) and triethylamine(0.07 ml, 0.5 mmol) were dissolved in 1 ml of chloroform. Dicyclohexylcarbodiimide (0.11 g, 0.5 mmol) was added under stirring at 0 °C. Stirring was continued at 0 °C for 30 min and at room temperature for 12 h. After the usual work-up the product was separated and purified by silica gel preparative layer chromatography to give an oil; 0.33 g (91%). $[\alpha]_D$ +30.0° (*c* 1, EtOH); Found: C, 64.91; H, 6.31; N, 3.86%. Calcd for $C_{38}H_{43}N_2O_7PS$: C, 64.97; H, 6.12; N, 3.99%.

Z-L-Ser-L-Tyr(Ppt)-OEt. V(0.18 g, 0.25 mmol) was treated with anhydrous trifluoroacetic acid(0.25 ml) at 0 °C for 20 min and at room temperature for 2 h. After the removal of trifluoroacetic acid by evaporation *in vacuo* the product was separated and purified by silica gel preparative layer chromatography to give an oil; 0.15 g (91%). $[\alpha]_D$ −5.0° (*c* 1, EtOH); Found: C, 62.71; H, 5.46; N, 4.13%. Calcd for $C_{34}H_{35}N_2O_7PS$: C, 63.17; H, 5.41; N, 4.33%.

Z-L-Ser(Bu^t)-L-Tyr-OH. A solution of 0.14 g (0.2 mmol) of V in 3 ml of ethanol and 0.66 ml of 1 M sodium hydroxide was stirred at room temperature for 3 h. After removal of ethanol *in vacuo* the aqueous solution was extracted with ethyl acetate and acidified to pH 4 with 5% citric acid. The acidified solution was extracted with ethyl acetate. The ethyl acetate extracts were washed with water, dried and concentrated. The oily residue was dissolved in methanol and purified by gel filtration on Sephadex LH-20 (1.7×17 cm) to give a chromatographically homogeneous oil; 0.073 g (80%). $[\alpha]_D$ +40.0° (*c* 1, EtOH); Found: C, 62.04; H, 6.74; N, 6.16%. Calcd for $C_{24}H_{30}N_2O_7\cdot 1/2H_2O$: C, 61.69; H, 6.63; N, 5.99%.

Solid Phase Synthesis of Ppt-L-Pro-L-Leu-Gly-OMe. Chloromethyl resin, prepared by chloromethylating the Bio-Beads S-X1 (Bio-Rad Laboratories), was esterified with Ppt-glycine by means of the caesium salt method(Gly content 0.43 mmol/g). One gram of the ester resin was placed in the reaction vessel of the Beckman model 990 peptide synthesizer. The machine was programmed to perform the following steps automatically: (1) washing three times with CH_2Cl_2, (2) pre-washing with 1 M HCl in HCO_2H–CH_2Cl_2 (2/1), (3) deprotection twice with 1 M HCl in HCO_2-H–CH_2Cl_2 (2/1) for 30 min, (4) washing three times each with CH_2Cl_2, EtOH, and again CH_2Cl_2, (5) neutralization three times with 10% triethylamine in CH_2Cl_2 for 5 min, (6) washing three times with CH_2Cl_2, (7) successive addition of 1.29 mmol each of Ppt-amino acid, tris(*p*-methoxyphenyl)-phosphine and 2,2′-dithiodipyridine in CH_2Cl_2, (8) coupling for 60 min, (9) washing three times with CH_2Cl_2, (10) repetition of steps 7, 8, and 9, (11) washing twice each with *N,N*-dimethylformamide and EtOH. After the completion of coupling the protected peptide was removed from the resin by transesterification with use of 1 M triethylamine in MeOH for 12 h four times. The combined filtrates and washings were evaporated *in vacuo* and the residue was dissolved in ethyl acetate. The solution was washed with water, dried and concentrated to give a pasty mass. This was crystallized slowly by triturating with ether; 0.21 g (95%). Mp 143—144 °C; $[\alpha]_D$ −70.0° (*c* 0.5, EtOH); Found: C, 60.38; H, 6.61; N, 7.89; P, 5.98%. Calcd for $C_{23}H_{34}N_3O_4PS$: C, 60.59; H, 6.59; N, 8.15; P, 6.01%.

Synthesis of 3-Ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]azepine

Masaru KIMURA* and Shiro MOROSAWA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

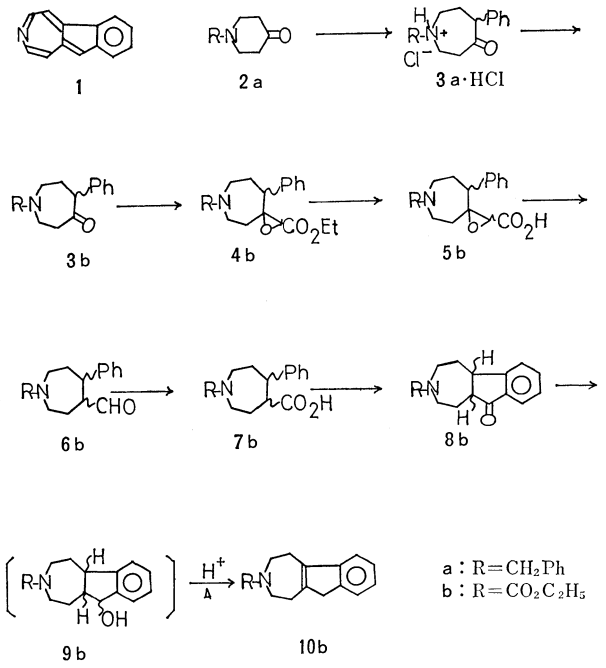
(Received August 14, 1978)

3-Ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]azepine (**10b**) was synthesized from 1-benzylpiperidin-4-one and 1-benzyl-4-[*o*-(hydroxymethyl)phenyl]hexahydroazepin-4-ol. Compound **10b** is of particular interest as an intermediate for the preparation of the hitherto unknown indeno[1,2-*d*]azepine. It was found that 1-ethoxycarbonyl-4-[*o*-(hydroxymethyl)phenyl]hexahydroazepin-4-ol and 1-ethoxycarbonyl-4-[*o*-(hydroxymethyl)-phenyl]piperidin-4-ol (**16b**) give 1-ethoxycarbonylspiro[azepin-4,1′(3*H*′)-isobenzofuran] and 1-ethoxycarbonyl-spiro[3*H*-isobenzofuran-1,4′-piperidine] (**17b**), respectively. Treatment of **16b** with 88% formic acid gave **17b** and 2-ethoxycarbonyl-2,3,4,9-tetrahydro-1*H*-indeno[2,1-*c*]pyridine.

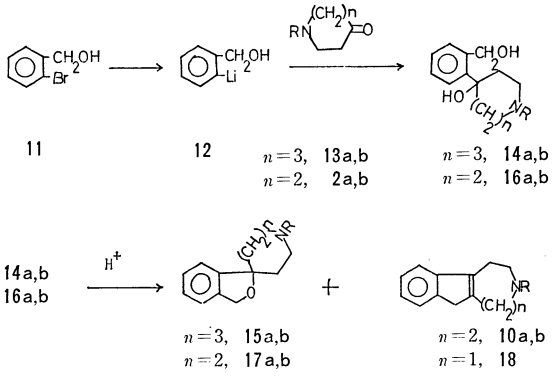
Although several benzazazulenes have been extensively studied in recent years,[1-6] indeno[1,2-*d*]azepine (**1**, 7-azabenz[*a*]azulene) does not seem to have been reported. As the only example of this ring system, 1,2,3,4,5,5a,10,10a-octahydroindeno[1,2-*d*]azepine was reported by Boyakchan *et al.*[6] We wish to report two independent methods A and B for the preparation of the title compound **10a** which might be converted into compound **1** by dehydrogenation.

Method A is characterized by use of **3a**·HCl, the structure of which was determined by X-ray analysis.[7] The structure of the final product **10a** was established as 3-ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]azepine. The method required 8 steps from **2a**, the overall yield being only 4% on the basis of **2a**. It thus became necessary to develop another facile method for obtaining **10b**.

Recently, Parham *et al.* found that 1-[*o*-(hydroxymethyl)phenyl]cycloheptan-1-ol gives the corresponding 5,6,7,8,9,10-hexahydrobenz[*a*]azulene.[8] We investigated the possibility of preparing **10b** from **14a** according to method B, and attempted application of this method to the preparation of indenopyridine (**18b**, Scheme 2).



Scheme 1.



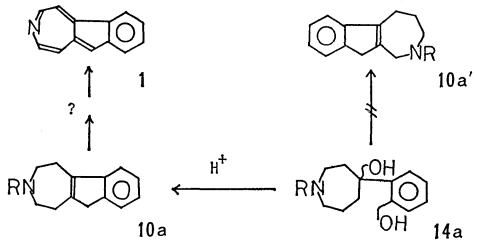
Scheme 2.

Results and Discussion

*Method A. Synthesis of 3-Ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]azepine (**10b**) from 1-Benzylpiperidin-4-one (**2a**).* 1-Benzyl-5-phenylhexahydroazepin-4-one (**3a**) was obtained by ring expansion of **2a** with ethyl *N*-nitrosobenzylcarbamate in 21% yield. Treatment of **3a**·HCl with ethyl chloroformate gave 1-ethoxycarbonyl-5-phenylhexahydroazepin-4-one (**3b**) quantitatively. Condensation of **3b** with ethyl chloroacetate in the presence of potassium *t*-butoxide by Darzen's method,[10] followed by hydrolysis with KOH in methanol gave the corresponding glycidic acid (**5b**) in 55% yield. When the reaction was stopped in the first step, the corresponding glycidic ester (**4b**) was isolated in 96% yield. Decarboxylation of **5a** at 150—155 °C without a solvent gave 1-ethoxycarbonyl-4-formyl-5-phenylhexahydroazepine (**6b**) in 64% yield. Oxidation of **6a** with silver oxide generated *in situ* gave 1-ethoxycarbonyl-4-phenylhexahydroazepin-5-carboxylic acid (**7b**) in 49% yield. Cyclization of **7b** by the Friedel-Crafts reaction (PCl_5, $SnCl_4$) resulted in the formation of 3-ethoxycarbonyl-1,2,3,4,5,5a,10,10a-octahydroindeno-[1,2-*d*]azepin-10-one (**8b**) in 83% yield. Further transformation of **8b** by hydrogenation ($LiAlH_4$, MeOH), followed by heating with a trace of hydrochloric acid without a solvent at 215 °C gave the indeno-[1,2-*d*]azepine (**10b**, title compound) in 86% yield; the structure of **10b** was deduced by the NMR and IR data and analytical result. The final step from **8b** to **10b** can be explained by acid catalyzed indene formation *via* a transient intermediate **9b** under the above conditions. Indenoazepines, such as **8b** and

10b, are of particular interest as an intermediate in the preparation of the hitherto unknown indeno-[1,2-*d*]azepine (**1**).

Method B. Synthesis of ***10b*** *from 1-Benzyl-4-[o-(hydroxymethyl)phenyl]hexahydroazepin-4-ol (**14a**).* 1-Benzyl- and 1-ethoxycarbonyl-4-[*o*-(hydroxymethyl)-phenyl]hexahydroazepin-4-ol (**14a** and **14b**), and 1-benzyl- and 1-ethoxycarbonyl-4-[*o*-(hydroxymethyl)-phenyl]piperidin-4-ol (**16a** and **16b**) were prepared in a similar way to that employed by Parham and Egberg,[11] as follows. The lithium derivative (**12**) of *o*-bromobenzyl alcohol (**11**) was allowed to react with 1-benzyl- or 1-ethoxycarbonylhexahydroazepin-4-one (**13a** or **13b**), and 1-benzyl- or 1-ethoxycarbonylpiperidin-4-one (**2a** or **2b**) at −40 °C. The usual work-up gave **14a**, **14b**, **16a**, and **16b** in 80, 48, 56, and 31%,[8b] respectively.



Scheme 3.

The reaction of **14a** in the presence of boron trifluoride etherate in refluxing benzene for 10 h gave indenoazepine (**10a** or **10a'**, Scheme 3) in 10% yield accompanied by 1-benzylspiro[azepine-4,1'(3*H*')-isobenzofuran] (**15a**) in 42% yield. The structure of this indene has two possibilities, since there are two ways to form the indene ring *via* the elimination of water from **14a** as shown in Scheme 3. For the confirmation of the structure, the indene (**10a** or **10a'**) was treated with ethyl chloroformate in refluxing benzene. The expected 1-ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]azepine (**10b**, title compound) was obtained in 83% yield. **10b** was identified by comparison with the NMR and IR data of the authentic sample obtained by method A. Method B from **14a** requires much shorter steps than method A from **2a**.

On the other hand, the reaction of **14b** and **16b** gave only 1-ethoxycarbonylspiro[azepine-4,1'(3*H*')-isobenzofuran](**15b**) and **17b** in 89 and 49% yields, respectively, under the same conditions as in the case of **14a**. However, the reaction of **16b** in 88% formic acid at 100 °C for 90 min gave 1'-ethoxycarbonylspiro[isobenzofuran-1(3*H*), 4'-piperidine] (**17b**) and the other expected 2-ethoxycarbonyl-2,3,4,9-tetrahydro-1*H*-indeno[2,1-*c*]pyridine (**18b**) in 23 and 30% yields, respectively. **16a** which gave only the corresponding spiro compound (**17a**)[8b] afforded no corresponding indene (**18a**) even in the formic acid at 100 °C.

Experimental

The structures of all the new compounds were confirmed by NMR, IR, and analytical data. All melting points and boiling points are uncorrected. IR (Nujol) spectra were determined on a JASCO IRA-1 grating infrared spectrometer. NMR ($CDCl_3$/TMS, Hitachi-Perkin Elmer R-20) spectra were obtained at 60 MHz. The chemical shifts are represented in terms of δ values. Column chromatography and TLC were performed using Wakogel C-200 and Kieselgel 60F 254, respectively. **2a**, **2b**, **13a**, and **13b** were prepared by the method developed by one of us (S. M).[9]

*HCl Salt of 1-Benzyl-5-phenylhexahydroazepin-4-one (**3a**·HCl).* Ethyl *N*-nitrosobenzyl carbamate (19.8 g, 0.095 mol) was added over a period of 1.5 h to a stirred mixture of freshly distilled 1-benzyl-1-azacyclohexan-4-one (**2a**, 15.5 g, 0.082 mol), finely powdered potassium carbonate (14.5 g) and absolute methanol (8 ml), the reaction temperature being maintained at 25 °C by means of an ice–water bath. The dark red reaction mixture was then allowed to stand at room temperature until the evolution of nitrogen gas ceased (48 h). Ether (50 ml) and water (30 ml) were added to the mixture. After shaking, the two layers were separated. The ethereal solution was washed with saturated aqueous NaCl solution. A white solid appearing in the aqueous layer was collected, washed with a small amount of water and dried in a desiccator (soild KOH). The solid was recrystallized from ethanol to give colorless prisms (**3a**·HCl, 4.5 g, 21%): mp 225 °C (dec); IR 2540, 1710, 760, 740, 700 cm^{-1}; NMR (CCl_4, free **3a**, mp 72 °C) 1.80—3.30 (9H, m), 3.61 (2H, s, $-C\underline{H}_2Ph$), 7.20 (5H, m, aromatic H), 7.28 (5H, m, aromatic H). Found: C, 71.96; H, 6.74; N, 4.62%. Calcd for $C_{19}H_{21}NO$·HCl: C, 72.25; H, 7.02; N, 4.44%.

*1-Ethoxycarbonyl-5-phenylhexahydroazepin-4-one (**3b**).* A mixture of **3a**·HCl (21.76 g, 0.078 mol) and ethyl chloroformate (19.0 g, 0.172 mol) was stirred for 4 h at 140 °C (bath temp). After being cooled to room temperature, excess formate was removed by a rotary evaporator at 50 °C. Benzyl chloride was then distilled at 70—80 °C/20 Torr (9.6 g). Distillation of the residue gave a colorless viscous oil (**3b**, 19.3 g, 95%, bp 171 °C/0.15 Torr): IR (neat) 1700 cm^{-1}(broad); NMR 1.24 (3H, t, J=7Hz), 2.00 (2H, m), 2.70 (2H, m), 2.90—3.65 (2H, m), 3.70—4.40 (3H, m), 4.15 (2H, q, J=7 Hz), 7.28 (5H, m, aromatic H). Found: C, 68.87; H, 7.48; N, 5.16%. Calcd for $C_{15}H_{19}NO_3$: C, 68.94; H, 7.33; N, 5.36%.

*1-Ethoxycarbonyl-5-phenyl-1,2,3,5,6,7-hexahydrospiro[azepine-4(4H),2'-oxirane]-3'-carboxylic Acid (**5b**).* A flask flame-dried at reduced pressure was charged with freshly distilled ethyl chloroacetate (3.07 g, 2.65 mmol) and **3b** (6.98 g, 2.50 mmol). A solution of potassium *t*-butyrate in *t*-butyl alcohol (50 ml, 2.6 mmol) was added from a dropping funnel over a period of *ca.* 30 min to the flask with stirring, the temperature of the reaction mixture being maintained at 10—15 °C on an ice bath. The mixture was stirred for 1—1.5 h at *ca.* 10 °C. Most of the *t*-butyl alcohol was removed by distillation. The oily residue was taken up in ether. The ether solution was washed with water, then with saturated aqueous sodium chloride solution, and was finally dried over anhydrous sodium sulfate. The residue obtained on evaporation of the ether was distilled to give colorless glycidic ester (**4b**, 8.8 g, 96.2%, 195—200 °C/0.2 Torr), ethyl 1-ethoxycarbonyl-5-phenyl-1,2,3,5,6,7-hexahydrospiro[4*H*-azepine-4,2'-oxirane]-3'-carboxylate. IR (neat) 1760 (sh), 1700, 1220, 770, 705 cm^{-1}. No analytical sample could be prepared, since it was partially decomposed during the course of vacuum distillation.

Crude **4b** (8.8 g, 2.5 mmol) was dissolved in a solution of potassium hydroxide (2.65 g, 6.1 mmol) in absolute ethanol (29 ml), and the resulting solution was kept at room temperature under nitrogen atmosphere for 40 min. The mixture was then warmed on a water bath (60 °C) for 7 h, the solvent being evaporated under reduced pressure. The

residue was dissolved in 50 ml of water and extracted with benzene (50 ml). The water layer was acidified with aqueous 10% sulfuric acid, and extracted twice with ether (50 ml portions). After the separation, the ether layer was dried over $MgSO_4$, the solvent being distilled off. A dark-red crude product (**5b**, 6.1 g, 75%) was obtained and crystallized from benzene to give pure **5b** (4.1 g, 56.8%, dec 153 °C): IR 1730, 1630 cm^{-1}; NMR 1.25 (3H, t, J=7 Hz), 1.51—2.28 (4H, m), 2.99—3.95 (5H, m), 4.17 (2H, q, J=7Hz), 7.24(5H, m), 8.45 (1H, bs, COOH). Found: (dried for 3 h at 130 °C): C, 64.20; H, 6.93; N, 4.38%. Calcd for $C_{17}H_{21}NO_5$: C, 63.94; H, 6.63; N, 4.39%.

*1-Ethoxycarbonyl-4-formyl-5-phenylhexahydroazepine (**6b**).* **5b** (2.8 g, 1.0 mmol) was heated on an oil bath (at 150—155 °C) under nitrogen for 4 h. Ether (20 ml) was added. Drying and evaporation of the ether solution gave tan oil. The oil was mixed with 10% sulfuric acid (10 ml) and dioxane (14 ml). The solution was heated under reflux for 14 h. The solution was evaporated under reduced pressure, and the usual work-up gave a reddish residue. The residue was distilled to give **6b** (1.76 g, 64%, 180—183 °C/0 .1 Torr): IR(neat) 1710, 1690 cm^{-1}; NMR 1.24 (3H, t, J=7Hz), 1.59—2.35 (4H, m), 2.59—3.08 (4H, m), 4.14 (2H, q, J=7 Hz), 7.18 (5H, m), 10.29 (1H, s, CHO). Found: C, 69.96; H, 7.86; N, 5.13%. Calcd for $C_{16}H_{21}NO_3$: C, 69.79; H, 7.69; N, 5.09%.

*1-Ethoxycarbonyl-4-phenylhexahydroazepine-5-carboxylic Acid (**7b**).* To a solution of **6b** (2.8 g, 1.1 mmol) and sodium hydroxide (0.79 g, 1.75 mmol) in a mixed solvent (50 ml, ethanol: water=3 : 2) cooled on an ice bath was added a solution of silver nitrate in water (20 ml) in small portions with stirring. The oxidation was complete in *ca.* 5 min after the last addition. The black silver suspension was removed by filtration and washed with several portions of hot water. The cold combined filtrate and washing were acidified with concd hydrochloric acid, a white powder being precipitated out. Recrystallization of this powder from water gave **7b** (2.6 g, 82%, mp 146—147 °C): IR 1720, 1640, 705, 690 cm^{-1}; NMR 1.24 (3H, t, J=7 Hz), 1.60—2.30(4H, b), 2.50—3.10 (2H, b), 3.20—3.90 (4H, b), 4.14 (2H, q, J=7 Hz), 7.18 (5H, s), 10.30 (1H, s, COOH). Found: C, 65.99; H, 6.88; N, 4.54%. Calcd for $C_{16}H_{21}NO_4$: C, 65.96; H, 7.27; N, 4.81%.

*7-Ethoxycarbonyl-4a,5,6,7,8,9,9a,10-octahydro-7-azabenz[a]azulen-10-one (**8b**).* To a suspension of **7b** (1.5 g, 0.55 mmol) in 30 ml of benzene (dried over sodium) was added powdered phosphorus pentachloride (1.14 g, 0.55 mmol) in portions with swirling and cooling on an ice-water bath. After evolution of hydrogen chloride had ceased by the vigorous reaction at 80 °C, all the volatile substances were distilled under reduced pressure at 100 °C. Aluminum chloride (0.5 g, 0.4 mmol) was added to a stirred solution of the residual oily acid chloride in 30 ml of dry benzene at room temperature over a period of 1.5 h. The mixture was then heated at 80 °C for 1.5 h. After being cooled to room temperature, the mixture was poured onto ice and hydrochloric acid, and ether (10 ml) was added for the separation of the layers. The ether layer was concentrated and the product was purified by distillation (**8b**, 1.14 g, 82.6%, bp 180—195 °C/0.1 Torr); IR (neat) 1720, 1680, 770 cm^{-1}; NMR 1.26 (3h, t, J=7Hz), 1.50—3.35 (6H, b), 3.35—3.89 (4H, b), 4.17 (2H, q, J=7 Hz), 7.18—7.91 (4H, m). (the oxime of **8b**, mp 181 °C): Found: C, 66.49; H, 6.99; N, 9.71%. Calcd for $C_{16}H_{20}N_2O_3$: C, 66.65; H, 6.99; N, 9.71%.

*3-Ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-d]azepine (**10b**).* A three-necked flask was charged with 1% aqueous sodium hydroxide (4 ml) and sodium borohydride (0.39 g, 1 mmol) and the system was purged with nitrogen. A solution of the indanone (**8b**, 4.8 g, 1.8 mmol) in methanol (70 ml) was added dropwise over a period of 10—20 min. After addition was complete, the mixture was carefully reheated to reflux for 2 h. The mixture was then cooled on an ice bath, and a sufficient amount of 3 M aqueous hydrochloric acid (50 ml) was carefully added dropwise to decompose excess sodium borohydride. The acidified solution was worked up immediately by extraction with benzene. The benzene extract was washed with saturated aqueous sodium hydrogencarbonate. The benzene solution was dried over anhydrous sodium sulfate, the benzene being removed. The residue was distilled and pressure reduced to give the indene **10b** (4.1 g, 85.4%, bp 215—216 °C/0.23 Torr): IR (neat) 1690, 1600, 760, 720 cm^{-1}; NMR (CCl_4) 1.25(3H, t, J=7Hz, $-CH_3$), 2.50—2.90(4H, b, aliphatic CH_2), 3.25 (2H, s, CH_2 in indene system), 3.45—3.81 (4H, b, aliphatic CH_2N), 4.15 (2H, q, J=7 Hz, CH_2CH_3), 7.02—7.22 (4H, m, aromatic H). Found: C, 74.21; H, 7.51; N, 5.64%. Calcd for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44; N, 5.44%.

*Reaction of o-Bromobenzyl Alcohol (**11**). Typical Procedure. 1-Benzyl-4-[o-(hydroxymethyl)phenyl]hexahydroazepin-4-ol (**14a**).* Butyllithium (12.2 ml, 3.2 mmol, 2.45 M in hexane) was added to a cold (−40 °C) mixture of **11** (1.3 g, 1.6 mmol) in THF (15 ml) and hexane (10 ml). The mixture was stirred for 5 min at −40 °C and 1-benzylhexahydroazepin-4-one (**13a**, 1.7 g, 0.8 mmol) was added at a rate such that the temperature was maintained at −40 °C for 30 min. The mixture was poured into a large volume of saturated aq NH_4Cl, and extracted with ether. The extract was washed with water, and dried (Na_2SO_4). Removal of the solvent gave a practically pure product. Product **14a** was purified by column chromatography on silica gel eluting with petroleum ether–ethyl acetate (1 : 1): yield 1.83 g (80%); IR (neat) 3360 (OH, hydrogen bonding), and 720 cm^{-1}; NMR (DMSO-d_6) 1.60—2.90 (10 H, two broad peaks, aliphatic CH_2), 3.51 (2H, s, benzylic CH_2N), 4.72 (2H, s, benzylic CH_2O), 4.55—5.32 (2H, bs, alcohol OH), 7.00—7.62 (9H, m, aromatic H). Found: C, 76.83; H, 8.07; N, 4.88%. Calcd for $C_{20}H_{23}NO_2$: C, 77.13; H, 8.09; N, 4.50%.

*1-Ethoxycarbonyl-4-[o-(hydroxymethyl)phenyl]hexahydroazepin-4-ol (**14b**).* The reaction was carried out as described for **14a**. The crude product was purified by preparative TLC (using 50% ethyl acetate in benzene as eluent): **14b**, 47.6%; IR (neat) 3400, 750 cm^{-1}; NMR 1.18 (3H, t, J=7 Hz), 1.50—2.60 (6H, b), 3.00—3.70 (4H, b), 4.06 (2H, q, J=7Hz), 4.30—5.00 (2H, bs, OH), 4.80 (2H, s), 7.10—7.20 (4H, m, aromatic H). Found: C, 65.60; H, 7.82; N, 4.89%. Calcd for $C_{16}H_{23}NO_4$; C, 65.51; H, 7.90; N, 4.78%.

*1-Benzyl-4-[o-(hydroxymethyl)phenyl]piperidin-4-ol (**16a**)* was prepared by the method described in the literature.[8b]

*1-Ethoxycarbonyl-4-[o-(hydroxymethyl)phenyl]piperidin-4-ol (**16b**).* The crude product, obtained in a similar way to that used for **14a**, was crystallized from ethyl acetate to give **16a**: 31.3% yield, mp 113—114 °C; IR 3400, 1670, 750 cm^{-1}; NMR 1.22(3H, t, J=7 Hz), 1.55—3.68 (8H, two broad peaks), 3.95 (2H, s), 4.40 (2H, q), 4.20—5.01 (2H, bs, OH), 7.18—7.28 (4H, m). Found: C, 64.20; H, 7.82; N, 4.91%. Calcd for $C_{15}H_{21}NO_4$: C, 64.49; H, 7.58; N, 5.01%.

*Reaction of **14a**, **14b**, **16a**, and **16b** with Boron Trifluoride Etherate.* 1-Benzylspiro[azepine-4,1′(3*H*′)-isobenzofuran] (**15a**) and 1-benzyl-1,2,3,4,5,10-1*H*-indeno[1,2-*d*]azepine (**10a**). Boron trifluoride etherate (2.0 g, 1.4 mmol) was

added to the benzene (50 ml) solution of **14a** (1.96 g, 0.66 mmol). The reaction mixture was heated to reflux for 2 h. The reaction mixture was poured into a large amount of ice water. The layers were separated and the benzene layer was washed with saturated aqueous sodium hydrogencarbonate followed by water, and dried over $MgSO_4$. The solvent was removed to yield an oil. The oil was chromatographed on silica gel by elution with a mixed solvent (10% ethyl acetate in benzene). From fraction Nos. 17—27, a pale yellow oil (160 mg) was collected . The oil was distilled under reduced pressure to give **10a**: 10% yield, 140—150 °C/0.14 Torr; IR (neat) 1600, 750, 720, 690 cm^{-1}; NMR 2.15—3.10 (8H, two broad peaks), 3.12—3.35 (2H, bs, CH_2 in indene system), 3.76 (2H, s, benzylic CH_2N), 7.00—7.30 (4H, m, aromatic H), 7.32 (5H, m, aromatic H). When **10a** was treated with ethyl chloroformate in refluxing benzene, the less labile oil **10b** was obtained in 83% yield. **10b** was identified by comparison with the sample obtained from **2a** by method A.

*1-Ethoxycarbonylspiro[azepine-4,1'(3H')-isobenzofuran] (**15b**).* The reaction of **14b** was carried out as described for **10a**. The product was purified by preparative TLC (20% ethyl acetate in benzene as eluent). **15b** (R_f=0.38): 89% yield; IR 1690, 1040, 755 cm^{-1}; NMR 1.22(3H, t, J=7 Hz), 1.60—2.50 (6H, b), 2.80—3.90 (4H, b), 4.10 (2H, q, J=7 Hz), 4.98 (2H, s), 6.90—7.30 (4H, m). Found: C, 69.35; H, 7.92; N, 5.03%. Calcd for $C_{16}H_{21}NO_3$: C, 69.79; H, 7.69; N, 5.09%.

*1-Ethoxycarbonylspiro[isobenzofuran-1(3H),4'-piperidine] (**17b**).* The reaction of **16b** was carried out as described for **10a**. The product was purified by preparative TLC (50% chloroform in benzene as eluent). **17b** (R_f=0.4): 43% yield; IR 1700, 1035, 750 cm^{-1}; NMR (CCl_4) 1.24 (3H, t, J=7 Hz), 1.50—1.90 (4H, b), 2.70—4.30 (4H, two broad peaks), 4.10 (2H, q, J=7 Hz), 5.01 (2H, s), 7.00—7.30 (4H, m). Found: C, 69.42; H, 6.63; N, 5.41%. Calcd for $C_{15}H_{17}NO_3$: C, 69.48; H, 6.61; N, 5.40%. The reaction of **16a** was carried out as described for **10a**. When the labile product (**17a**) was treated with ethyl chloroformate in refluxing benzene, **17b** was obtained in 65% yield based on **16a**.

*2-Ethoxycarbonyl-2,3,4,9-tetrahydro-1H-indeno[2,1-c]pyridine (**18b**).* **16b** (0.3 g, 0.11 mmol) was added to 2 ml of 88% formic acid and heated at the reflux temperature for 1.5 h. The reaction mixture was added with stirring to a large amount of ice water and resulting mixture was extracted with benzene. After the usual work-up, the solvent of the extract was removed to give a yellow oil (0.23 g). The crude oil was subjected to preparative TLC on silica gel with 20% ethyl acetate in benzene as eluent. From the first band (R_f=0.55), **18b** was collected: 80 mg, 30% yield; IR (neat) 1695. 1605, 760 cm^{-1}; NMR(CCl_4) 1.26 (3H, t, J=7 Hz), 2.50—3.00 (2H, bt, J=*ca.* 5Hz), 3.24 (2H, bs), 3.40—3.80 (2H, bt, J=*ca.* 5 Hz), 4.24 (2H, q, J=7 Hz), 7.00—7.40 (4H, m). Found: C, 73.92; H, 7.04; N, 5.76%. Calcd for $C_{15}H_{17}NO_2$: C, 74.05; H, 7.04; N, 5.76%. From the second band, **17b** (R_f=0.38) was collected in 23% yield.

When a solution of **16a** in formic acid was refluxed for 1.5 h, only **17a** was obtained. Treatment of **17a** with ethyl chloroformate in refluxing benzene gave **17b** in 90% yield based on **16a**.

S_N2 Reactions in Dipolar Aprotic Solvents. VIII.[1] Chlorine Isotopic Exchange Reaction of (Arylsulfonyl)chloromethanes, (Arylsulfinyl)chloromethanes, and 2-Chloro-1-arylethanones in Acetonitrile. A Role of the Nucleophile-substrate Interaction in the Finkelstein Reaction

Jun-ichi HAYAMI,*[2] Tohru KOYANAGI, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received August 22, 1978)

Chlorine isotopic exchange reactions of substituted chloromethanes [(arylsulfonyl)chloromethanes (**1**), (arylsulfinyl)chloromethanes (**2**), and 2-chloro-1-arylethanones (**4**)] with tetraethylammonium chloride-^{36}Cl were studied in acetonitrile. This study enabled, for the first time, the accurate rate study of the former two classes of compounds (**1** and **2**) of extremely low reactivity. Both the large enthalpies of activation and the positive entropies of activation were the characteristics for these two substrates (**1**-*p*-NO_2 and **2**-*p*-NO_2). High reactivity of 2-chloro-1-phenylethanone was substantiated, and was not associated with the significant secondary kinetic deuterium isotope effect. A nucleophile-substrate association that proceeds the reaction was suggested and the possible role of such an interaction was examined in the light of the intermediary of the nucleophile-substrate complex in the Finkelstein reaction.

The present authors have been investigating the symmetrical Finkelstein reaction between the substituted chloromethanes and radioactive chloride ion in dipolar aprotic solvent.[3] Through the Hammett type analysis of the reaction rates, two factors were pointed out to govern the reactivity of this reaction system: One is the approach of the nucleophile to the substrate, and the other is the electron-donating stabilization of the incipient electro-positive reaction center at the transition state. These findings were accomodated in the framework of the traditional S_N2 reactions.[4]

However, in a recent work, the authors confirmed the presence of an 1 : 1 complex between the substrate and the anionic nucleophile in the Finkelstein reaction mixture. This complex shows many characteristics of the approach of a nucleophile in the S_N2 reactions.[5]

In a separate study, secondary kinetic deuterium isotope effect at the α-hydrogen of the S_N2 reaction center was substantiated for S_N2 substrates of high reactivity.[6] Inverse equilibrium deuterium isotope effects were also found for the substrate-nucleophile association, suggesting that the secondarty isotope effects are explained in terms of the intervention of the complex as the direct precursor of the Finkelstein reaction and in terms of the operation of the electron-donating conjugation at the loose transition state of the unimolecualr scrambling of the complex.[7]

In the present work, chlorine isotopic exchange reactions of (arylsulfonyl)chloromethanes (**1**), (arylsulfinyl)chloromethanes (**2**), and 2-chloro-1-arylethanones (**4**) with tetracthylammonium chloride-^{36}Cl were studied in acetonitrile to get an insight of the rate-controlling factors of the S_N2 reactions.

Results and Discussion

In dry acetonitrile as the solvent, substituted chloromethanes were treated with tetraethylammonium chloride-^{36}Cl as are shown in Scheme 1.

Good second-order kinetics was followed for this isotopic exchange reaction in the every instance. Good

linear free energy relationships held for Hammett σ in each classes of substrates, giving positive ρ values. The accurate rate study for the substrates of diminished reactivity, (arylsulfonyl) and (arylsulfinyl)chloromethanes (**1** and **2**) was achieved for the first time.[8] Results are shown in Table 1.

In Table 2, the second-order rate constants for the substituted chloromethanes with unsubstituted phenyl ring are collected to show the effect of the functional group adjacent to the S_N2 reaction center. Substituent effects on the phenyl moiety are also shown by the Hammett $\rho\sigma$ relationship.

As is shown in Table 2, reactivity spreads in wide range (10^{10}) between the most reactive compound [(phenoxy)chloromethane] and the least reactive one [(phenylsulfonyl)chloromethane]. In 2-chloro-1-arylethanones (**4**), which are about 10^9 times as reactive

as (arylsulfonyl)chloromethanes (**1**), electron-withdrawing groups on the phenyl ring facilitate the isotope exchange raection. While in all the other reactive substrates studied [especially in (arylthio)chloromethanes (**3**) and (aryloxy)chloromethanes] the effect of the substituent on the phenyl ring is reversed. Therefore, a quite different accelerating factor seems to be operative in the reaction of the halo ketone **4**.

Reaction of 2-Chloro-1-Arylethanone (4). A marked reactivity was shown by 2-chloro-1-arylethanones, which were about 10^7—10^9 times more reactive than (arylsulfinyl)chloromethanes, and (arylsulfonyl)-chloromethanes.

The enhanced reactivity of an α-halo carbonyl compound is often cited[9] and is a matter of controversy considering the presence of the carbonyl group which is an electron-withdrawing group as effective as the sulfinyl and sulfonyl groups.[10]

To get the insight of the reactivity of the 2-chloro-1-arylethanones **4**, substrate–nucleophile interaction was examined first, as the importance of the approach of the nucleophile was implicated by the positive ρ_{obsd}.

On the addition of nucleophile, chloride ion, to the solution of 2-chloro-1-arylethanone in acetonitrile, a significant PMR shift was observed.[5b] As are shown in the left side column of Table 3 for 2-chloro-1-phenylethanone (**4**-H), the representative compound of the class, the enthalpy of formation of the complex ($\Delta H°$) was the most negative among the substrates studied, implicating some interaction other than hydrogen bonding.[11] However, this stabilization (deactivation) is counterbalanced by the extensive decrease in the entropy of formation of the complex ($\Delta S°$) giving rise a fairly small formation constant for the nucleophile-substrate association (Tables 4 and 5).[5b]

A study on the proton spin-lattice relaxation time (T_1) suggested that such a large decrease of the entropy

** k_2 is the second-order rate constant corrected for the decrease in the concentration of both the free nucleophile and the free substrate on the formation of complex. Such correction gave essentially no effect on the Arrhenius parameters.

on complexing was accompanied by the extensive freezing of the intramolecular rotation in the substrate.[11] The examination of the limiting PMR shift and of the thermodynamic parameters of the association equilibria pointed out the possibility that the nucleophilic anion interacts with the carbonyl group, as well as with the α-methylene protons.[11]

Another indication of such an interaction was obtained by the ^{13}C-NMR study. Carbon-13 NMR (CMR) spectra were obtained for 2-chloro-1-phenylethanone-1-^{13}C (C_6H_5–^{13}CO–CH_2Cl), with phenylchloromethane-1-^{13}C (C_6H_5–$^{13}CH_2Cl$) as the reference compound. As are shown in Table 4, α-methylene carbon of phenylchloromethane, carbon at the potential reaction center, showed no significant CMR shift (about 0.1 ppm or less) by the addition of chloride ion.

Table 4. ^{13}C-NMR shift induced by the formation of complex

Ph–Y–CH_2Cl + $(C_2H_5)_4NCl$[a]

Y	δ [b] ppm	δ [c] ppm	δ_c [d] ppm
NONE (Ph–$^{13}CH_2Cl$)	47.2	47.3	(<0.5)
CO (Ph–^{13}CO–CH_2Cl)	192.2	193.3	8.3

a) At 25 °C, in acetonitrile-d_3. b) δ from TMS. 0.1 M standard solution. c) δ from TMS. TEA-Cl (1.0 M) is added to the standard solution. d) $\delta_c=\delta/f$; "f" is the fraction of the complexed substrate. K/M^{-1} (25 °C); 0.132 (Ph–$^{13}CH_2Cl$), 0.157 (Ph–^{13}CO–CH_2Cl).

On the other hand, carbonyl carbon of 2-chloro-1-phenylethanone, located at α-position to the reaction center, gave the low field shift, amounting to 1.1 ppm, on the addition of tetraethylammonium chloride (1.0 M). The amount of the shift is evidently larger than the errors inherent in the present CMR measurements (±0.1 ppm).[12]

When correction is made of the fraction of the complex in the equilibrium, with the due assumption that the equilibration is rapid for the time scale of the NMR spectroscopy, the limiting shift of the complex of 8.3 ppm is obtained for 2-chloro-1-phenylethanone. In PMR spectra, α-methylene proton of this substrate showed limiting complexing shift of −1.52 ppm, indicating the attacking nucleophile resides in the proximity of the methylene protons, at the site of the potential S_N2 displacement.[5b]

These results suggest that, preceding the isotopic exchange reaction, a nucleophilic anion coordinates to both α-methylene protons and the carbonyl group. Hindrance of the internal rotation thus sets in, as reflected on the sharp decrease in ΔS° and the increase in the rotational correlation time (τ_c) of the substrate in the complex.[5b]

Thus, a quite similar structure to that of the transition state of the nucleophilic displacement reaction accompanying "orbital overlap" is suggested for the nucleophile-substrate complex of **4**. In this complex, a coordination of the nucleophile is already accomplished and the "entropy activation", necessary for the S_N2 reaction to take place, is essentially attained.[9a,13]

There seems to be no reason to suppose that such a complex should dissociate to the free components to enter the classical "S_N2" displacement. Possible intermediary of such an association complex was already discussed.[8,9]

As a second approach, the measurement of the secondary α-deuterium isotope effect (α-d effect) using 2-chloro-1-phenylethanone-2-d_2 (**4**-H-d_2) was undertaken to present a clue to the nature of the transition state of the displacement reaction of this chloro ketone. The results are shown in Table 5 along with the results of another reactive substrate, **3**-p-NO_2.

Table 5. α-Deuterium isotope effect of the Finkelstein reaction system in acetonitrile

Substrate	k_2^H/k_2^D	K^H/K^D	k_1^H/k_1^D
Ph–CO–CH_2Cl (0 °C)	0.96_2 [a]	0.94_2 [b]	1.02_1
p-NO_2–C_6H_4–S–CH_2Cl (20 °C)	1.11_9 [c]	0.97_6 [c]	1.14_7 [c]

a) k_2/M^{-1} min^{-1}: 1.50×10^{-1} (for Ph–CO–CH_2Cl), 1.62×10^{-1} (for Ph–CO–CD_2Cl). b) K/M^{-1}: 0.307 (for Ph–CO–CH_2Cl), 0.326 (Ph–CO–CHDCl). c) Ref. 7.

In the symmetrical Finkelstein reaction, the chloro ketone **4**-H gave an inverse α-d effect ($k_2^H/k_2^D=0.96_2$) for the second order rate coefficient.

Such an inverse kinetic isotope effect seems to be too large for a reaction that proceeds through a symmetrical transition state. In a symmetrical S_N2 reaction, Seltzer suggested an operation of a normal isotope effect or an isotope effect of close to unity when the nucleophilicities of the incoming and leaving nucleophile are equal.[14] Interestingly, PMR experiments showed that the α-d effect on the complex formation equilibrium for **4**-H is appreciable and inverse ($K^H/K^D=0.94_2$).

Now an explanation in terms of the operation of an association-scramble mechanism, which was applied to accomodate the kinetic isotope effect of the reactive substrates,[7] is worth trying.

This mechanism postulates an intervention of the nucleophile-substrate association complex as a direct precursor of the rate-determining (unimolecular) scrambling and is depicted in Scheme 2.[5]

As expressed in Scheme 2, α-d effect (k_2^H/k_2^D), kinetic parameters ($\Delta H^\ddagger_{obsd}$, $\Delta S^\ddagger_{obsd}$), and ρ_{obsd} values can be separated into those parameters, both for the complex-forming step and for the unimolecular-scrambling step.

When one postulates the operation of the association-scramble mechanism, α-d effect ascribable to the rate-determining scrambling step of this halo ketone is calculated to be normal and is very close to unity, suggesting a very tight transition state[16] (Table 5).

For the chloro ketone **4**, there is no intramolecular functionality among the substrate itself to stabilize the incipient electropositive center developing in the course of the S_N2 reaction. This is in contrast to the

$$\begin{array}{ccc} X\text{-}C_6H_4\text{-}Y\text{-}CH_2Cl + {}^*Cl^- & & X\text{-}C_6H_4\text{-}Y\text{-}CH_2{}^*Cl + Cl^- \\ K \updownarrow \uparrow\downarrow (rapid) & & (rapid) \uparrow\downarrow K \\ [X\text{-}C_6H_4\text{-}Y\text{-}CH_2Cl\cdot{}^*Cl^-] & \xrightarrow[(slow)]{k_1} & [X\text{-}C_6H_4\text{-}Y\text{-}CH_2{}^*Cl\cdot Cl^-] \end{array}$$

K: Equilibrium constant of the complex formation.
k_1: Rate coefficient of the (unimolecular) scrambling in the complex.

$$K = \frac{[\text{Complex}]}{[\text{Substrate}]\,[\text{Nucleophile}]}$$

$$\text{Rate} = k_1\cdot[\text{Complex}] = K\cdot k_1\,[\text{Substrate}]\,[\text{Nucleophile}]^{15)}$$

$k_2 = K\cdot k_1$
$k_2^H/k_2^D = (K^H/K^D)(k_1^H/k_1^D)$
$\Delta H^*_{obsd} = \Delta H^\circ + \Delta H_1^*$
$\Delta S^*_{obsd} = \Delta S^\circ + \Delta S_1^*$
$\rho_{obsd} = \rho^\circ + \rho_1$
(*Cf.* Table 3, footnote)

Scheme 2. Association-scramble mechanism.

cases of the chloromethyl sulfide **3** and other reactive compounds.

However, it is conceivable that the incoming chloride ion which resides at a position close enough to perturb the carbonyl group keeps interacting in the course of the rate-determining scrambling. This sort of an interaction could energetically be favored by the "orbital overlap" among the π-orbital of the carbonyl group, the incipient p-orbital of the reaction center, and the p-orbital of the nucleophile.[9a)]

Thus a kind of the attraction-dissociation process is feasible. In fact, very small α-d effect can be reasonably interpreted assuming a tight transition state where no significant charge separation around the reaction center is expected.[17)] Positive ρ_1 value in Table 3(a) also are in accord with the above explanation, since the electron-withdrawing group on the phenyl ring facilitates the attraction of the nucleophile.

Effect of the Sulfur-containing Functional Group on the Finkelstein Reactions. As shown in Table 2, marked retardation in reaction was observed for (arylsulfonyl)- and (arylsulfinyl)chloromethanes (**1** and **2**), in contrast to the appreciable rate acceleration in (arylthio)-chloromethanes (**3**). In the present study, the reactivity gap between **2** and **3** was significantly larger than that reported earlier by Bordwell and coworkers.[8)]

For (*p*-nitrophenylsulfonyl)chloromethane (**1**-*p*-NO_2) and for (*p*-nitrophenylsulfinyl)chloromethane (**2**-*p*-NO_2), as the representatives for these classes of the substrates, activation parameters were evaluated. In Table 6, these parameters are given with those for (*p*-nitrophenylthio)chloromethane (**3**-*p*-NO_2) as the reference substrate.

The observed enthalpies of activation (ΔH^*_{obsd}) increase in the order of **3**-*p*-NO_2<**2**-*p*-NO_2<**1**-*p*-NO_2, reflecting the relative reactivities of these substrates. As to the observed entropies of activation (ΔS^*_{obsd}) incontestable positive values were obtained for **1**-*p*-NO_2 and **2**-*p*-NO_2.

This is quite a contrast with the Bordwell's experiment. They found large negative entropies of activation in the reaction of **2** and potassium iodide in acetone. They also claimed only a small difference in the enthalpies of activation between **2** and **3**.[8)]

These findings led Bordwell to accomodate the rate retardation in terms of the steric hindrance (and of the electrostatic repulsion) by sulfinyl (and possibly by sulfonyl) group.[8)] A similar explanation was made of the ring opening of the episulfonium ion, under the nucleophilic attack by chloride ion, substituted with alkylsulfonyl group.[18)]

However, positive entropy of activation obtained in the present study cannot be accomodated in terms of increased steric restriction in the transition state. Thus the cause of the rate retardation other than the steric hindrance must be sought for the least reactive substrates **1** and **2**.

There is a possibility that an isokinetic relationship holds for the symmetrical exchange reaction of **1**, **2**, and **3**, although the apparent linear relationship found can probably be fallacious. If the present observation is not fortuitous in nature, an operation of a common mechanism should be postulated among the three classes of compounds.[19)] This implies a possible intervention of the nucleophile-substrate complex playing a role of the direct precursor of the rate-determining step, as behaviors of the chloromethyl sulfide **3** were better accomodated in the frame work of this mechanism.[7)]

In Table 3(b), there are also shown kinetic and thermodynamic parameters which are obtained by taking into account the intervention of the complex.

Interestingly, an isokinetic relationship about ΔH_1^*-ΔS_1^* suggests a different interaction between chloro ketone **4** and the three classes of the sulfur-containing substrates, while ΔH^*_{obsd}-ΔS^*_{obsd} relationship suggests a single interaction among those four classes of the substrates.

The postulation of the association-scramble mechanism suggests a more comprehensive picture. The effect of a facilitated approach of a nucleophile is separated from k_{obsd} into K, thus the rate retardation observed in **1** and **2** could be an outcome of the lack of the electron-donating capacity of both the sulfinyl and the sulfonyl groups to the reaction center in the

[*Cf.* Ref. 3a.]

(unimolecular) scrambling step of the nucleophilic displacement reaction. There are examples of the difference in the electron-donating capacity of these three sulfur-containing groups.[20]

A conceivable presence of the isokinetic relationship(s) among the nucleophilic displacement reactions studied, suggests a prevailing positive entropy of activation for substrates with extremely high activation enthalpy. However, no indication is obtained from this reasoning about the physical meaning of the positive entropy of activation where a tight transition state can plausibly be ascribed.[21]

At present, the postulation of the intermediary of the nucleophile-substrate complex remains as a proposal. Further studies to support (or disprove) the role of such a complex are necessary to help clarify the situation on the possibility of the intermediary in the Finkelstein reaction system.

Experimental

Preparative gas chromatography was performed on a Varian Model-920 gas chromatograph. The CMR spectra were obtained on a JEOL JNM-FX60 spectrometer. The mass spectra were recorded on a Hitachi M-52 spectrometer. The radioactivity was measured with a Nuclear Chicago Model-6801 liquid scintillation counter.

Materials. Substituted chloromethanes were synthesized according to the standard procedures.[3,8]

2-Chloro-1-phenylethanone-1-^{13}C: (a) Benzoic-*carboxy*-^{13}C Acid:[22] A Grignard solution was prepared from 480 mg (20 mmol) of magnesium turning and 3.1 g (20 mmol) of bromobenzene in absolute ether (20 ml). Phenylmagnesium bromide was carbonated with carbon-^{13}C dioxide liberated from 1 g (5 mmol) of barium carbonate-^{13}C (isotopic enrichment 90%, Prochem). Following hydrolysis with aqueous ammonium chloride, the ethereal solution was extracted repeatedly (5 ml×5) with saturated aqueous sodium hydrogencarbonate solution. Then the alkaline solution was washed with ether, acidified and extracted with a small amount of saturated aqueous sodium hydrogencarbonate solution. The hot aqueous solution was acidified with hydrochloric acid, and cooled to precipitate the product, yield 556 mg (91%). (b) Benzoyl-*carbonyl*-^{13}C Chloride. A mixture of 556 mg (4.6 mmol) of benzoic acid and 4 ml (30 mmol) of purified thionyl chloride was refluxed for 1 h and the excess thionyl chloride was removed under reduced pressure. The residual liquid was used without further purification. (c) 2-Diazo-1-phenylethanone-^{13}C: To a stirred and ice-cooled ethereal solution of diazomethane (65 ml) [from 10.8 g (50 mmol) of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide] was added dropwise a solution of crude benzoyl chloride in 20 ml of absolute ether. The mixture was stirred for 15 min at 0 °C and for additional 2 h at room temperature. The product was used for the following process without further purification. (d) 2-Chloro-1-phenylethanone-1-^{13}C; Into a stirred dry ethereal solution (20 ml) containing 2-diazo-1-phenylethanone was introduced anhydrous hydrogen chloride for 1 h at 0 °C. Then the solution was concentrated, and the resulting crude material was recrystallized from ethanol, to give a pure product, 506 mg, 72% based on the benzoic acid. Mass; 156 (M^+) (isotopic enrichment 90%).

2-Chloro-1-phenylethanone-2-d_2: To a stirred and ice-cooled solution of 2-diazo-1-phenylethanone (400 mg, 2.7 mmol) in dry ether (20 ml) was bubbled anhydrous deuterium chloride, generated by the reaction between phosphorus pentachloride (24 g, 0.1 mol) and deuterium oxide (2 g, 0.1 mol). The mixture was stirred for 1 h at 0 °C, then concentrated to give the crude material. Recrystallization from ethanol gave a pure product, 407 mg, 82% based on the 2-diazo-1-phenylethanone. Mass; 157 (M^+) (isotopic enrichment 99.7%).

Benzyl-α-^{13}C Chloride: (a) Methyl Benzoate-*carbonyl*-^{13}C; An ethereal solution (10 ml) of 500 mg (4.0 mmol) of benzoic-^{13}CO acid was treated with a cold ethereal solution (65 ml) of diazomethane prepared from 10.8 g (50 mmol) of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide. The solution was concentrated under reduced pressure, and used for the following step without further purification. (b) Phenylmethanol-1-^{13}C; An ethereal solution (3 ml) of the ester was added dropwise to a stirred ethereal solution (15 ml) of 455 mg (1.2 mmol) of lithium aluminum hydride. The mixture was then refluxed for 2 h, cooled with ice bath, and acidified with dilute hydrochloric acid. The aqueous layer was separated, and extracted with several portions of ether. The ether layer and the extracts were combined and the combined solution was dried over anhydrous magnesium sulfate. Concentration of the solution gave the cited compound as an almost colorless liquid. This product was used without further purification. The yield was essentially quantitative. (c) Benzyl-α-^{13}C chloride; To the crude benzyl alcohol, was added slowly 5 ml (25 mmol) of purified thionyl chloride, and the mixture was refluxed for 1 h. The excess thionyl chloride was distilled off, and the product was purified by preparative gas chromatography. The yield was 370 mg, 71% based on the benzoic acid. Mass; 127 (M^+) (isotopic enrichment, 90%).

Kinetic Measurements. Batch method was employed for kinetic measurements. Procedures were almost similar as previously reported.[3] At the appropriate intervals, the reaction mixture was quenched by cooling and dilution with cold (−78 °C) toluene, while tetraethylammonium chloride was extracted in water. Chlorine-36 radioactivity was measured by liquid scintillation counter. In the measurement of the less reactive substrate, tetraethylammonium chloride-^{36}Cl with high specific activity (10 μCi/mmol) was utilized. In such cases, to avoid the experimental error caused by the contamination of unreacted tetraethylammonium chloride-^{36}Cl to the organic layer, the organic layer was washed repeatedly with water (at least six times) until the radioactivity of the aqueous layer was reduced to that of the natural backgound.

The tracer experiments were carried out at the Radioisotope Research Center of Kyoto University. The authors are grateful to the staffs of this institution. The present work was supported by the Grant-in-Aid for Scientific Research from the Ministry of Education (No. 83151, 84076) and by the grants kindly given from Saneyoshi Shogakukai and from Ito Kagaku Shinkokai. Special thanks are due to the donors of these grants.

12) Besides the change in electron density, one should also take into account the electrostatic perturbation by the anion that results in the downfield shift of CMR. This effect should have happened for the case of phenylchloromethane. The absence of complex shift on CMR of this substrate suggests that the chloride ion that makes van der Waals contact with the α-hydrogen locates fairly far from the carbon in question, or that there occurs a fortuitous compensation of up- and downfield shift. The latter possibility seems to be less feasible, as is suggested from the work of Hagen and Roberts. The downfield shift of CMR spectra by the electrostatic perturbation was reported for the carboxylic acids on the ionization of a carboxyl group to a carboxylate anion. The present result suggests that the chloride ion resides in a proximity of the carbonyl group to perturb the CMR shift. *Cf.*, R. Hagen and J. D. Roberts, *J. Am. Chem. Soc.*, **91**, 4504 (1969).

15) a) Heavy atom isotope effect for both the leaving and the incoming chlorine is ignored. *Cf.*, C. J. Collins and N. S. Bowman, Ed., "Isotope Effects in Chemical Reactions," Van Nostrand-Reinhold, New York, 1970; b) In the isotopic exchange reaction, the (total) chemical concentrations of both the substrate and the nucleophile remain unchanged throughout the reaction. However, formation of the complex causes a decrease in the concentration of the free substrate and the free nucleophile. Thus the corrections must be made for the rate constants, even if the association complex is in merely parasitic equilibrium with the free substrate and the free nucleophile.

For the sake of simplicity and to show the experimental results, rate data in Tables 1 through 2 are not corrected. As is exemplified in the footnote of Table 3, the due correction is often close to 20% for the substrates with a high K. However, as are given in the footnote of Table 3, $\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$ (also $\Delta H_{obsd}^{\ddagger}$ and $\Delta S_{obsd}^{\ddagger}$) are affected little by the due correction of the decrease in the concentrations of the reactants and, accordingly, of the rate constants on the complex formation.

21) There is, at least in principle, no guarantee that the bimolecular nucleophilic displacement reaction is a "single interaction reaction". Accordingly, scattered entropy-enthalpy plot can be a sign of the presence of a host of different isokinetic relationships that show different isokinetic temperatures. Thus, with the isokinetic temperature(s) of 300—400 K, available data can predict a positive entropy of activation even for a reasonable activation enthalpy of 25—30 kcal/mol. Isokinetic temperatures calculated from $\Delta H_1^{\ddagger}$-$\Delta S_1^{\ddagger}$ in Table 3 is 926 K, while that from $\Delta H_{obsd}^{\ddagger}$-$\Delta S_{obsd}^{\ddagger}$ is 771 K.

Michael Addition of 4*H*-Cyclopenta[*def*]phenanthrene to 9,9′-Bifluorenylidene and the Related Reactions

Takao KIMURA,*,† Masahiro MINABE, and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

(Received August 28, 1978)

The compound 9-(4*H*-cyclopenta[*def*]phenanthren-4-yl)-9,9′-bifluorene was synthesized by the Michael addition of 4*H*-cyclopenta[*def*]phenanthrene to 9,9′-bifluorenylidene and also by other reactions. In addition, five kinds of trimers which consisted of 4*H*-cyclopenta[*def*]phenanthrene and fluorene were obtained by the same reactions. The conformation of these trimers is assigned to be the *gauche-gauche* form.

The Michael addition of fluorene (**1**) to 9,9′-bifluorenylidene (**2**) has been reported in detail.[1] In our previous publication,[2] the ring expansions on the active methylene of 4*H*-cyclopenta[*def*]phenanthrene (**3**) were shown to have a property similar to that of **1**. The acidities of methylene protons of hydrocarbons **1** and **3** have been investigated closely, with their analogues, by determination of the dissociation constant in some solvents.[3]

The present paper deals with the Michael additions of **3** and **1** to some fulvalenes in order to compare with additions of **1** to **2**, and also to clarify the conformations of the resulting trimers.

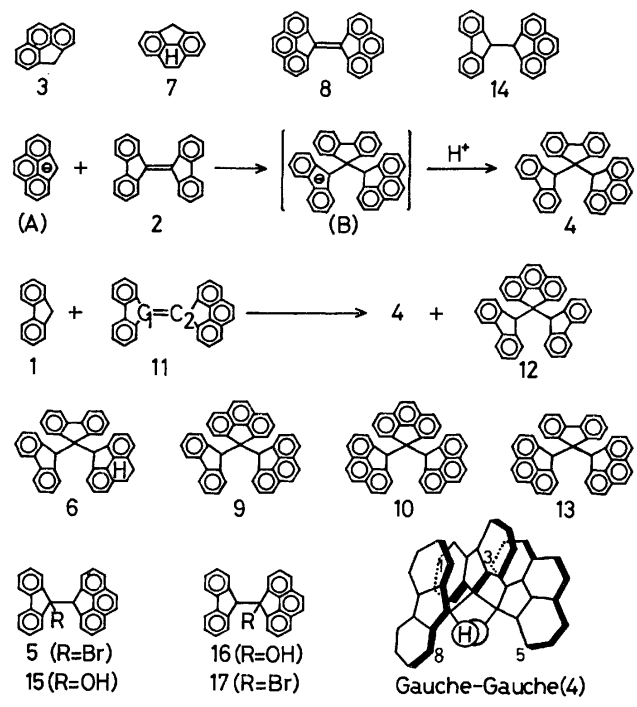
Results and Discussion

The Michael addition of **3** to **2** gave 9-(4*H*-cyclopenta[*def*]phenanthren-4-yl)-9,9′-bifluorene (**4**); the yield of **4** increased (10—35%) with the increase of base concentration (2—10% of sodium ethoxide). This reaction proceeded rapidly under a potassium hydroxide–aqueous pyridine system to give **4** in a reasonable yield. The addition can be explained by the nucleophilic attack of carbanion (A) on the highly-polarized acceptor **2** to form carbanion (B) followed by protonation to give **4** (Scheme 1).

Compound **4** was also prepared by the reaction of 9-lithiofluorene with bromide **5**, and also by dehydrogenation of 9-(8,9-dihydro-4*H*-cyclopenta[*def*]-phenanthren-4-yl)-9,9′-bifluorene (**6**), which was obtained by the addition of hydrocarbon **7**[4] to **2**.

The Michael reactions of fulvalene **8**[5] with **1** and with **3** yielded 4-(9-fluorenyl)-4,4′-bi(4*H*-cyclopenta-[*def*]phenanthrene) (**9**) and 4,4′ : 4′,4″-ter(4*H*-cyclopenta[*def*]phenanthrene) (**10**), respectively. The addition of **1** to unsymmetrical ethylene **11**[5] afforded isomeric **4** and 4,4-di(9-fluorenyl)-4*H*-cyclopenta[*def*]-phenanthrene (**12**) in a ratio of 75 to 25. Furthermore, the reaction of **3** with **11** gave 9,9-di(4*H*-cyclopenta[*def*]phenanthren-4-yl)fluorene (**13**) (73%) and **9** (27%).

The methine protons in the NMR spectrum of hydrocarbon **14** appear as two doublets about 0.3 ppm apart. In addition, the methine signals of alcohol **15** and bromide **5** shift to lower fields than those of alcohol **16** and bromide **17**, respectively. These findings may be explained as due to the difference of



Scheme 1.

the acidities between the methylene protons of fragmental hydrocarbons **1** and **3**.[3] Also, this presumption would be extended reasonably to the reactivity of fulvalene **11**: the electron distribution on the central double bond of **11** lies to the **3** moiety. Therefore, the carbanion preferentially attacks the C_1 atom rather than the C_2 atom on **11**.

The assignment of the methine protons in the NMR spectra of the trimers was confirmed by comparison[6] with the corresponding deuterated compounds, as summarized in Table 1. The methine protons of **6** are observed as a two-proton singlet, which suggests that the electronic property of a methine proton on the **7** moiety of **6** is equivalent to that of a **1** segment. The two methine protons of the unsymmetrical trimers, such as **4** and **9**, are observed as two separate singlets, which may be regarded as the case of **14**. The two methine protons of **4** and **9** are assigned so that the methine on the leaflet of **3** corresponds to the peak in lower field and the methine on the leaflet of **1** to the one in higher field.

The compound **4** would be symmetrical with respect to the central fluorenylidene plane as in the analogues, **10**, **12**, and **13**, whose methine proton NMR

TABLE 1. PROTON NMR SPECTRA OF THE MICHAEL ADDUCTS IN PYRIDINE-d_5

Compd	Methine (δ)	Aromatic (δ)
4	5.65 (1H, s), 5.93 (1H, s)	5.68 (2H, d, J=7.2 Hz), 6.46—8.78 (22H, m)
6[a]	5.35 (2H, s)	2.94 (4H, s, $-CH_2-CH_2-$), 4.87 (1H, d, J=7.8 Hz), 5.24 (1H, d, J=7.8 Hz), 6.18—8.70 (20H, m)
9	5.89 (1H, s), 6.18 (1H, s)	5.36 (1H, d, J=6.6 Hz), 5.48 (1H, d, J=6.6 Hz), 6.10—8.83 (22H, m)
10	6.41 (2H, s)	5.45 (2H, d, J=7.2 Hz), 6.52—8.90 (22H, m)
12	5.73 (2H, s)	5.44 (2H, d, J=7.8 Hz), 6.08—8.83 (22H, m)
13	6.14 (2H, s)	5.74 (2H, d, J=7.2 Hz), 6.54—8.86 (22H, m)

a) Measured in DMSO-d_6.

spectra showed a two-proton singlet. An examination of molecular scale models of **4** suggests that the *gauche-gauche* form is more appropriate to the conformation of **4** at the ground state than the *anti-anti* form, due to the steric interaction of the bulky aromatic rings.

The anomalous spread of the aromatic signal zone in the spectrum of **4** is probably attributable to the torsional conformation.[1] The signals at higher fields would be assigned to be the 1-proton of the outside 9-fluorenyl plane and the 3-proton of the 4*H*-cyclopenta[*def*]phenanthren-4-yl plane, because of being located in the shielding zone of the adjacent central aromatic ring,[1,7,8] as simulated in Scheme 1. On the contrary, the peaks at lower fields are due to the 8-proton of the 9-fluorenyl plane and the 5-proton of the 4*H*-cyclopenta[*def*]phenanthren-4-yl plane. The broad aromatic zone on the spectrum of **4** is observed to become narrower with the elevation of temperature. At a high temperature, the central sp^3-sp^3 single bonds may be released from the torsion, which would increase the probability of the *eclipsed-eclipsed* form. Therefore, the shielding effect of the central aromatic ring decreases and results in some reducing of the signal zone. A similar view can be applied to the other analogues: **6**, **9**, **10**, **12**, and **13**.

Experimental

All the melting points are uncorrected. The melting points of deuterated compounds in this series are identical with those of the parent hydrocarbons.

The IR spectra were obtained as KBr disks using a IR-G spectrophotometer (JASCO). The mass spectra were measured with a RMU-6E apparatus (Hitachi). The proton NMR spectra were recorded with a JNM-C-60HL (60 MHz) spectrometer (JEOL) using TMS as an internal reference. The deuterium incorporation was determined from the average value of five peaks on the NMR spectra.

*Michael Reaction of 9,9'-Bifluorenylidene (**2**) with 4H-Cyclopenta[def]phenanthrene (**3**).* To a soln of KOH (0.05 g) in H_2O (1 ml) and pyridine (9 ml), there was added 492 mg (1.5 mmol) of **2** and 285 mg (1.5 mmol) of **3**. The mixture was stirred for 1 h at room temperature under an atmosphere of nitrogen.

The reaction mixture was then poured into HCl (2%, 150 ml) and extracted with benzene (150 ml). The organic layer was dried over Na_2SO_4 and evaporated to dryness, and the residual materials were separated by means of silica-gel column chromatography (2.0×50 cm) in cyclohexane. The first and second eluates gave 34 mg of **3** (mp 114—116 °C) and 72 mg of **2** (mp 185—187 °C), respectively.

The third eluate was evaporated off and the residue was recrystallized from EtOAc to afford 554 mg (71%) of **4**: mp 259—260 °C (dec); MS, *m/e*, 518 (M^+), 353, and 329. Found: C, 94.91; H, 4.94%. Calcd for $C_{41}H_{26}$: C, 94.95; H, 5.05%.

*Michael Reaction between **2** and 8,9-Dihydro-4H-cyclopenta[def]phenanthrene (**7**).* A mixture of **2** (492 mg, 1.5 mmol), **7** (288 mg, 1.5 mmol), and aq K_2CO_3 (1.1 g in 2 ml) in pyridine (8 ml) was heated in a sealed tube at 95—98 °C for 24 h. The reaction mixture was treated in a manner similar to the above to yield 273 mg (35%) of **6**: mp 253—254 °C (dec); MS, *m/e*, 520 (M^+) and 494. Found: C, 94.65; H, 5.46%. Calcd for $C_{41}H_{28}$: C, 94.58; H, 5.42%.

*Michael Addition of **1** to 4,4'-Bi(4H-cyclopenta[def]phenanthren-4-ylidene) (**8**).* A mixture of **1** (249 mg, 1.5 mmol), **8** (564 mg, 1.5 mmol), and aq KOH (0.3 g in 1 ml) in pyridine (9 ml) was refluxed for 8 h under an atmosphere of nitrogen to give 520 mg (64%) of **9**: mp 319—320 °C (dec); MS, *m/e*, 542 (M^+) and 353. Found: C, 95.16; H, 4.67%. Calcd for $C_{43}H_{26}$: C, 95.17; H, 4.83%.

*Addition of **3** to **8**.* To a soln of $NaOPr^n$ prepared from metallic sodium (0.3 g) and *n*-PrOH (13 ml), there were added 564 mg (1.5 mmol) of **8** and 285 mg (1.5 mmol) of **3**. The resulting mixture was refluxed for 8 h under an atmosphere of nitrogen to yield 738 mg (87%) of **10**: mp 327—328 °C (dec); MS, *m/e*, 566 (M^+). Found: C, 95.11; H, 4.30%. Calcd for $C_{45}H_{26}$: C, 95.37; H, 4.63%.

*Michael Reaction of 4-(9-Fluorenylidene)-4H-cyclopenta[def]phenanthrene (**11**) with **1**.* A mixture of **11** (528 mg, 1.5 mmol) and **1** (249 mg, 1.5 mmol) in EtOH (10 ml) containing NaOEt (1.0 g) was heated in a sealed tube at 95—98 °C for 8 h. After cooling, the precipitates were collected and separated by silica-gel column chromatography to afford 381 mg (49%) of the mixture, which consisted of **4** (75% by NMR) and **12** (25%).

*Michael Addition of **3** to **11**.* A mixture of **3** (285 mg) and **11** (528 mg) was allowed to react under the conditions similar to those of **1** and **11** to yield the products (545 mg, 67%), which consisted of **13** (73% by NMR) and **9** (27%).

*9-(4H-Cyclopenta[def]phenanthren-4-yl)-9,9'-bifluorene (**4**).*

a): A soln of 9-lithiofluorene (prepared from 870 mg of **1** according to the procedure described elsewhere[9]) was added dropwise to a soln of bromide **5** (1.00 g, 2.3 mmol) in benzene–xylene (1 : 1, 60 ml) at 0 °C with stirring for 10 min. After being boiled for an additional 2 h, the reaction mixture was treated with aq NH_4Cl (5%, 50 ml), dried over Na_2SO_4, and then evaporated to dryness *in vacuo*. The residue was recrystallized from cyclohexane to afford 550 mg (46%) of **4**, which was identical in all respects with the specimen obtained by the Michael addition of **3** to **2**.

b): A soln of **6** (281 mg, 0.54 mmol) in 10 ml of *p*-cymene was refluxed with Pd–C (5%, 50 mg) for 40 h. The reaction

mixture was filtered and the filtrate was then steam distilled. The residue was chromatographed in cyclohexane on a silica-gel column to give 99 mg (35%) of **4**: mp 259—260 °C (dec).

*4,4-Di(9-fluorenyl)-4*H*-cyclopenta*[def]*phenanthrene* (**12**). A mixture of 9-lithiofluorene and bromide **17** was treated in a manner similar to that used for **4**, giving **12** in a yield of 50%: mp 286—287 °C (dec); MS, *m/e*, 518 (M^+), 353, and 165. Found: C, 94.73; H, 5.06%. Calcd for $C_{41}H_{26}$: C, 94.95; H, 5.05%.

*9,9-Di(4*H*-cyclopenta*[def]*phenanthren-4-yl)fluorene* (**13**). Compound **13** was prepared by the reaction of **3** with **5** according to a procedure similar to the above: yield 42%; mp 308—309 °C (dec); MS, *m/e*, 542 (M^+), 353, and 189. Found: C, 95.08; H, 4.89%. Calcd for $C_{43}H_{26}$: C, 95.17; H, 4.83%.

*9-(4*H*-Cyclopenta*[def]*phenanthren-4-yl)-9-fluorenol* (**15**).[5] A soln of fluorenone (5.4 g, 30 mmol) in xylene (60 ml) was allowed to react with 4-lithio-4*H*-cyclopenta[*def*]phenanthrene[10] (prepared from 5.7 g of **3** with $LiBu^n$ in xylene) at 0 °C. The resulting mixture was refluxed for 1 h to afford 9.85 g (89%) of **15**: mp 188—189 °C (lit,[5] 188—189 °C); IR: 3310 cm^{-1} (–OH); MS, *m/e*, 370 (M^+); NMR (benzene-d_6): δ 1.94 (1H, s, –OH), 5.27 (1H, s, >CH–), and 6.50—7.65 (16H, m, Ar–H).

*4-(9-Fluorenyl)-4*H*-cyclopenta*[def]*phenanthren-4-ol* (**16**). To a soln of 4*H*-cyclopenta[*def*]phenanthren-4-one (3.0 g, 14.7 mmol) in benzene–xylene (1 : 1, 80 ml), there was added dropwise a soln of 9-lithiofluorene (prepared from 2.5 g of **1**) at 0 °C with stirring for 10 min. The mixture was boiled for an additional 2 h to yield 2.77 g (51%) of **16**: mp 202—203 °C; IR, 3275 cm^{-1} (–OH); MS, *m/e*, 370 (M^+); NMR (benzene-d_6): δ 1.98 (1H, s, –OH), 4.96 (1H, s, >CH–), and 6.60—7.50 (16H, m, Ar–H). Found: C, 90.80; H, 4.90%. Calcd for $C_{28}H_{18}O$: C, 90.78; H, 4.90%.

*4-(9-Fluorenylidene)-4*H*-cyclopenta*[def]*phenanthrene* (**11**).[5] A soln of **15** (0.8 g, 2.2 mmol) in AcOH (30 ml) containing concd HCl (0.2 ml) was refluxed for 1 h to give 500 mg (66%) of **11**: mp 197—198 °C (dec) (lit,[5] mp 196 °C, dec); MS, *m/e*, 352 (M^+).

Compound **16** was also converted into **11** in a 68% yield.

*4-(9-Fluorenyl)-4*H*-cyclopenta*[def]*phenanthrene* (**14**). A mixture of **11** (100 mg, 0.28 mmol), Zn powder (1 g), and concd HCl (1 ml) in AcOH (30 ml) was refluxed for 1.5 h to give 97 mg (96%) of **14**: mp 208—209 °C (from EtOAc); MS, *m/e*, 354 (M^+), 189, and 165; NMR (benzene-d_6): δ 5.04 (1H, d, J=4.2 Hz), 5.35 (1H, d), and 6.85—7.79 (16H, m). Found: C, 94.60; H, 5.01%. Calcd for $C_{28}H_{18}$: C, 94.88; H, 5.12%.

*9-Bromo-9-(4*H*-cyclopenta*[def]*phenanthren-4-yl)fluorene* (**5**). Dry HBr was bubbled into a soln of **15** (3.7 g, 10 mmol) in AcOH (135 ml) for 1 h. The reaction mixture was allowed to stand overnight and the precipitate was filtered, dried, and then recrystallized from benzene–cyclohexane (1 : 1) to afford 3.73 g (86%) of **5**: mp 185—187 °C (dec); MS, *m/e*, 434, 432 (M^+), 354, and 352; NMR (benzene-d_6) δ 5.53 (1H, s, >CH–) and 6.46—7.66 (16H, m, Ar–H). Found: C, 77.39; H, 3.74%. Calcd for $C_{28}H_{17}Br$: C, 77.60; H, 3.95%.

*4-Bromo-4-(9-fluorenyl)-4*H*-cyclopenta*[def]*phenanthrene* (**17**). Compound **17** was produced from **16** by a method similar to the above in a 78% yield: mp 171—172 °C (dec); MS, *m/e*, 434, 432 (M^+), 354, and 352; NMR (benzene-d_6): δ 5.24 (1H, s, >CH–) and 6.60—7.60 (16H, m, Ar–H). Found: C, 77.90; H, 3.96%. Calcd for $C_{28}H_{17}Br$: C, 77.60; H, 3.95%.

Syntheses of Deuterated Compounds. Hydrocarbon **3** was deuterated by the method applied in **1**[11] to give 4,4-dideuterio **3** (**3**-4,4-d_2) in a 92% yield. The deuterium incorporation was calculated to be 97% by NMR.

Also, **7**-4,4-d_2 was obtained in a 93% yield (deuterium incorporation, 97%).

Deuterated compounds of **4**, **6**, **9**, **10**, **12**, and **13** were prepared by the Michael reaction using corresponding substrates in a NaOEt–EtOD or NaOD–D_2O–pyridine system. The deuterium contents of these compounds were found to be *ca.* 100% at the methine protons.

The Total Synthesis of (+)-Totarol and (+)-Podototarin

Takashi MATSUMOTO* and Akira SUETSUGU

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received August 28, 1978)

The Grignard reaction of 7-methoxyphthalide with methylmagnesium iodide, followed by acetylation and dehydration, gave 3-acetoxymethyl-2-isopropenylanisole which, on catalytic hydrogenation, afforded 3-acetoxymethyl-2-isopropylanisole. This was then converted into (2-isopropyl-3-methoxybenzyl)triphenylphosphonium chloride (**8**) *via* 3-hydroxymethyl-2-isopropylanisole and 3-chloromethyl-2-isopropylanisole. The Wittig reaction of (*R*)-(−)-α-cyclocitral with **8** in the presence of butyllithium afforded the corresponding styryl derivative, which was converted into the dihydro compound (**19**) by partial catalytic hydrogenation. The intramolecular cyclization of **19** gave (+)-totaryl methyl ether (**20**) along with its *cis*-isomer. The methyl ether **20** was finally demethylated with boron tribromide to give (+)-totarol (**1**), which was further characterized as its acetate. Since the conversion of (+)-**1** into (+)-podototarin has already been reported, the present work can be regarded as the total synthesis of natural (+)-podototarin.

Totarol, a rare tricyclic diterpene phenol possessing an isopropyl group at the C-14 position, was first isolated as a major constituent of the heartwood of *Podocarpus totara* G. Benn. *ex.* D. Don by Easterfield and McDowell.[1] On the basis of chemical and spectroscopic studies, Short and his coworkers[2] deduced the structure of totarol to be **1**; this was confirmed by the synthesis of the racemate by Barltrop and Rogers.[3] The absolute configuration of totarol was determined by ORD measurements and by direct correlation with dehydroabietic acid by Chow and Erdtman.[4] Podototarin (**2**), a novel bisditerpene, was also isolated from the heartwood of P. *totara* by Brandt and Thomas[5] and Cambie and Mander.[6] The structure of podototarin was determined by the synthesis[7–9] of **2** from natural (+)-totarol. However, no investigation on the total synthesis of optically active totarol has hitherto been reported. It is thus still necessary to synthesize the optically active totarol to complete the total synthesis of natural podototarin. This paper describes the simple syntheses of (+)-totarol (**1**) and, consequently, of (+)-podototarin (**2**).

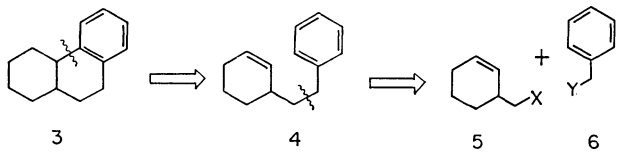
2

Our basic strategy for the synthesis of optically active octahydrophenanthrene backbone (**3**) is shown in Scheme 1. Since there are many precedents for the intramolecular cyclization of phenethylcyclohexene derivatives, the synthetic target is the optically active 3-phenethyl-1-cyclohexene derivative (**4**), which might be constructed by the condensation of optically active cyclohexenylmethyl derivative (**5**) and benzyl derivative (**6**).

In the present study, (*R*)-(−)-α-cyclocitral (**7**)[10,11] and (2-isopropyl-3-methoxybenzyl)triphenylphosphonium chloride (**8**) were chosen as the compounds



3 4 5 6

Scheme 1.

corresponding to **5** and **6**. Thus, the first synthetic goal was to prepare the phosphonium salt **8**. This was successfully achieved in the following manner. The Grignard reaction of 7-methoxyphthalide (**9**)[12] in tetrahydrofuran with methylmagnesium iodide in ether afforded the corresponding diol (**10**), which was converted into a monoacetate (**11**). The treatment of **11** with *p*-toluenesulfonic acid in hot benzene gave a mixture of the desired 3-acetoxymethyl-2-isopropenylanisole (**12**) and 7-methoxy-1,1-dimethyl-1,3-dihydroisobenzofuran (**13**) in a ratio of *ca.* 2 : 1. Since the separation of **12** and **13** was somewhat difficult, the mixture was directly oxidized with Jones reagent and then purified by column chromatography on silica gel to afford **12** and 4-methoxy-3,3-dimethylphthalide (**14**), which was easily converted into **10** by reduction with lithium aluminium hydride. The catalytic hydrogenation of **12** in ethanol over PtO_2 gave 3-acetoxymethyl-2-isopropylanisole (**15**) which, on reduction with lithium aluminium hydride, afforded 3-hydroxymethyl-2-isopropylanisole (**16**). The alcohol **16** was treated at room temperature with thionyl chloride in ether and the resulting benzyl chloride derivative (**17**), without purification, was converted into the phosphonium salt **8**, by treatment with triphenylphosphine in refluxing benzene. The Wittig reaction of **7** with **8** in benzene in the presence of butyllithium gave 6-(2-isopropyl-3-methoxystyryl)-1,5,5-trimethylcyclohexene (**18**). The NMR spectrum of **18** showed signals at δ 5.63 (dd, J=9 and 15 Hz) and 6.68 ppm (d, J=15 Hz) due to the newly formed olefinic protons. These vicinal coupling constants (J=15 Hz) suggested the presence of a *trans*-disubstituted double bond in **18**. The compound **18** in ethanol was submitted to partial catalytic hydrogenation over Pd–C to afford the corresponding phenethyl derivative (**19**). The intramolecular cyclization of **19** with anhydrous aluminium chloride in dichloro-

methane afforded (+)-totaryl methyl ether (**20**), $[\alpha]_D$ +23.3°(EtOH), as the major product and its *cis*-isomer (**21**), $[\alpha]_D$ −44.3°(EtOH), as the minor one. The *cis*-configuration of the A/B ring junction in **21** was supported by its NMR spectrum, which showed a high field signal, δ 0.41 ppm, due to the $C_{4\beta}$ methyl group and the shielding effect of the aromatic ring. Since the optical rotation of **20** was somewhat lower than that of the natural derivative,[6] it was further purified by crystallization to give the optically pure compound, $[\alpha]_D$ +40.6°(EtOH). The demethylation of **20** with boron tribromide in dichloromethane gave (+)-totarol (**1**), which was characterized as its acetate (**22**).

As has been described above, the partial synthesis of (+)-podototarin from (+)-totarol has already been reported.[7-9] Consequently, the present synthesis of (+)-totarol can be regarded as the total synthesis of (+)-podototarin.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as the internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, dd: double doublet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

*3-Hydroxymethyl-2-(1-hydroxy-1-methylethyl)anisole (**10**).* A solution of 7-methoxyphthalide (**9**)[12] (mp 108—109 °C, 3.347 g) in dry tetrahydrofuran (60 ml) was added dropwise to a stirred solution of methylmagnesium iodide prepared from magnesium (1.239 g) and methyl iodide (3.80 ml) in dry ether (20 ml), with cooling in an ice–water bath. The mixture was stirred at room temperature for 4 h, poured into aqueous ammonium chloride, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and water, dried over sodium sulfate, and evaporated to give an oil. The crude product was purified by column chromatography on silica gel (100 g) using ether–chloroform (3 : 97) as the eluent to give **10** (2.058 g: 52%), which was recrystallized from hexane–ether: mp 63—64 °C; IR: 3607, 3386 cm^{-1}; NMR: 1.60 (6H, s, $-\overset{|}{C}(CH_3)_2$), 3.78 (3H, s, $-OCH_3$), 4.68 (2H, s, $-CH_2OH$). Found: C, 67.26; H, 8.23%. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

*3-Acetoxymethyl-2-(1-hydroxy-1-methylethyl)anisole (**11**).* A solution of **10** (345 mg), acetic anhydride (0.4 ml), and pyridine (0.2 ml) was allowed to stand at room temperature for 15 h and diluted with ether. The ether solution was washed successively with dilute hydrochloric acid, aqueous sodium hydrogencarbonate, and water. After drying over sodium sulfate, the solvent was evaporated to dryness and the residue was chromatographed on silica gel (20 g) using ether–benzene (1 : 9) as the eluent to give a monoacetate (**11**) (352 mg: 84%) which was then recrystallized from petroleum benzin; mp 61—62 °C; IR: 3585, 3511, 1733 cm^{-1}; NMR: 1.63 (6H, s, $-\overset{|}{C}(CH_3)_2$), 2.02 (3H, s, $-OCOCH_3$), 3.00 (1H, bs, –OH), 3.82 (3H, s, $-OCH_3$), 5.48 (2H, s, $-CH_2O-$). Found: C, 65.61; H, 7.58%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

*3-Acetoxymethyl-2-isopropenylanisole (**12**) and 4-Methoxy-3,3-dimethylphthalide (**14**).* A solution of **11** (1.880 g) and *p*-toluenesulfonic acid (200 mg) in dry benzene (20 ml) was heated at 60 °C for 10 min, cooled to room temperature, and then diluted with ether. The solution was washed with aqueous sodium hydrogencarbonate and water, dried over sodium sulfate, and evaporated *in vacuo* to give an oil (1.812 g), whose NMR spectrum suggested the presence of the isopropenyl compound (**12**) and 7-methoxy-1,1-dimethyl-1,3-dihydroisobenzofuran (**13**); NMR: 1.47 (6H, s, $-\overset{|}{C}(CH_3)_2$), 3.83 (3H, s, $-OCH_3$), 4.94 (2H, s, $-OCH_2-$). Since the separation of **12** and **13** was unsuccessful, the above crude oil (1.812 g) was immediately oxidized with Jones reagent (8 N, 3.0 ml) in acetone (8.0 ml) at 16 °C for 1 h. The reaction mixture was diluted with ether, washed with water, and then dried over sodium sulfate. After the solvent had been evaporated, the residue was purified by column chromatography on silica gel (60 g) using benzene as the eluent to give **12** (764 mg: 44%) as an oil. IR: 1731, 1642 cm^{-1}; NMR: 2.00 (6H, s, $=\overset{|}{C}CH_3$ and $-OCOCH_3$), 3.78 (3H, s, $-OCH_3$), 4.79 and 5.23 (each 1H and bs, $-\overset{|}{C}=CH_2$), 5.01 (2H, s, $-CH_2O-$). Found: C, 70.84; H, 7.47%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

Further elution with ether–benzene (1 : 9) gave a phthalide (**14**) (323 mg: 21%) which was recrystallized from hexane: mp 88—89 °C; IR: 1751 cm^{-1}; NMR: 1.65 (6H, s, $-\overset{|}{C}(CH_3)_2$), 3.95 (3H, s, $-OCH_3$). Found: C, 68.90; H, 6.35%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

*Conversion of the Phthalide (**14**) into the Diol (**10**).* A mixture of **14** (1.020 g), lithium aluminium hydride (302 mg), and dry tetrahydrofuran (35 ml) was refluxed for 3 h. The reaction mixture was decomposed with aqueous ammonium chloride, extracted with ether, and the extract was washed with water. After drying over sodium sulfate, the solvent was evaporated *in vacuo* to give the diol (**10**) (968 mg: 93%) as a solid. The IR and NMR spectra were identical with those of the above authentic diol (**10**).

*3-Acetoxymethyl-2-isopropylanisole (**15**).* A mixture of **12** (2.988 g) and PtO_2 (170 mg) in ethanol (10 ml) was subjected to catalytic hydrogenation at room temperature for *ca.* 25 min. After the usual work-up, the crude product was purifi-

ed by column chromatography on silica gel (50 g) using benzene as the eluent to give **15** (2.733 g: 91%), which was recrystallized from methanol: mp 31.5—32 °C; IR: 1731 cm^{-1}; NMR: 1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.99 (3H, s, $-OCOCH_3$), 3.18 (1H, m, $-C\underline{H}(CH_3)_2$), 3.80 (3H, s, $-OCH_3$), 5.05 (2H, s, $-CH_2O-$). Found: C, 70.48; H, 8.25%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

*3-Hydroxymethyl-2-isopropylanisole (**16**).* A mixture of **15** (2.544 g), lithium aluminium hydride (434 mg), and dry ether (40 ml) was stirred at room temperature for 1.5 h, and then decomposed with aqueous ammonium chloride. The mixture was extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and then evaporated to give an alcohol (**16**) (2.036 g: 99%), which was used directly in the subsequent reaction. For microanalysis an aliquot of the crude product (157 mg) was purified by column chromatography on silica gel (20 g) using ether–benzene (5 : 95) as the eluent to give the pure alcohol (147 mg). IR: 3618, 3415 cm^{-1}; NMR: 1.30 (6H, d, J= 7 Hz, $-CH(C\underline{H}_3)_2$), 1.95 (1H, bs, –OH), 3.29 (1H, m, $-C\underline{H}-(CH_3)_2$), 3.80 (3H, s, $-OCH_3$), 4.51 (2H, s, $-CH_2O-$). Found: C, 73.45; H, 9.02%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

*3-Chloromethyl-2-isopropylanisole (**17**).* A solution of **16** (2.156 g) and thionyl chloride (1.7 ml) in dry ether (5.0 ml) was stirred at room temperature for 2 h, and then evaporated *in vacuo*. The residue was dissolved in dry benzene and the solution was evaporated *in vacuo* to afford **17** (2.278 g: 96%) which, without purification, was used in the next reaction. NMR: 1.36 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.22 (1H, m, $-C\underline{H}(CH_3)_2$), 3.82 (3H, s, $-OCH_3$), 4.53 (2H, s, $-CH_2-$).

*(2-Isopropyl-3-methoxybenzyl)triphenylphosphonium Chloride (**8**).* A solution of **17** (2.595 g) and triphenylphosphine (3.444 g) in dry benzene (10 ml) was refluxed for 16 h. The precipitates (**8**) (2.627 g, mp 239—241 °C) were filtered and washed with dry benzene. The filtrate was further refluxed for 14 h to give an additional salt (2.299 g, mp 239—242 °C).

*(−)-6-(2-Isopropyl-3-methoxystyryl)-1,5,5-trimethylcyclohexene (**18**).* A solution of butyllithium in hexane (15%; 4.5 ml) was added at room temperature to a stirred suspension of **8** (4.16 g) in dry benzene (25 ml) in a stream of nitrogen. The mixture was stirred at room temperature for 1.5 h and a solution of (*R*)-(−)-α-cyclocitral (**7**)[10,11] (860 mg), $[\alpha]_D$ −710° (EtOH), in dry benzene (5.0 ml) was added. After stirring at room temperature for 4 h, the reaction mixture was poured into a mixture of ice and aqueous ammonium chloride, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated. The residue was triturated with hexane and the precipitated triphenylphosphine oxide was removed by filtration. The filtrate was evaporated and the residue was purified by column chromatography on silica gel (100 g) using hexane–benzene (9 : 1) as the eluent to give **18** (733 mg: 44%) as an oil. $[\alpha]_D$ −248°; NMR: 0.92 and 0.96 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.30 (6H, d, J= 7 Hz, $-CH(C\underline{H}_3)_2$), 1.68 (3H, bs, $=\dot{C}CH_3$), 3.38 (1H, m, $-C\underline{H}(CH_3)_2$), 3.80 (3H, s, $-OCH_3$), 5.43 (1H, m, $-CH=\dot{C}-$), 5.63 (1H, dd, J=9 and 15 Hz, $-\dot{C}H-C\underline{H}=CH-$), 6.68 (1H, d, J=15 Hz, $-\dot{C}H-CH=C\underline{H}-$). Found: C, 84.72; H, 10.16%. Calcd for $C_{21}H_{30}O$: C, 84.51; H, 10.13%.

*(−)-2-(2,6,6-Trimethyl-2-cyclohexenyl)-1-(2-isopropyl-3-methoxyphenyl)ethane (**19**).* A suspension of **18** (1.550 g) and 5% Pd–C (700 mg) in ethanol (6.0 ml) was stirred at room temperature in an atmosphere of hydrogen. After one mole equivalent of hydrogen had been absorbed (*ca.* 80 min), the mixture was filtered. The filtrate was evaporated and the residue was purified by column chromatography on silica gel (150 g) using hexane and then hexane–benzene (7 : 3) as the eluents to give the dihydro compound (**19**) (1.253 g: 80%) as an oil. $[\alpha]_D$ −99.7°; NMR: 0.91 and 1.01 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.33 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.73 (3H, bs, $=\dot{C}CH_3$), 3.18 (1H, m, $-C\underline{H}-(CH_3)_2$), 3.78 (3H, s, $-OCH_3$), 5.29 (1H, m, $-CH=\dot{C}-$). Found: C, 84.24; H, 10.79%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

*Intramolecular Cyclization of **19**.* Anhydrous aluminium chloride (450 mg) was added at 35 °C to a solution of **19** (1.015 g) in dichloromethane (10 ml). The reaction mixture was stirred at 35 °C for 20 min, poured into ice–water, and then extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and evaporated to dryness. The crude product was chromatographed on silica gel (120 g) using hexane as the eluent to give the *cis*-isomer (**21**) (305 mg: 30%). $[\alpha]_D$ −44.3° (EtOH); NMR ($CDCl_3$): 0.41 (3H, s, $C_{4\beta}-CH_3$), 0.94 (3H, s, $C_{4\alpha}-CH_3$), 1.15 (3H, s, $C_{10}-CH_3$), 1.24 and 1.33 (each 3H, d, and J=7 Hz, $-CH-(C\underline{H}_3)_2$), 3.42 (1H, m, $-C\underline{H}(CH_3)_2$), 3.79 (3H, s, $-OCH_3$), 6.70 and 7.13 (each 1H, d, and J=9 Hz, $C_{11}-H$ and $C_{12}-H$). Found: C, 83.86; H, 10.74%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

Further elution gave the *trans*-isomer (**20**) (565 mg: 56%), $[\alpha]_D$ +23.3° (EtOH), which was recrystallized from ethanol to give pure totaryl methyl ether. Mp 91—93 °C; $[\alpha]_D$ +40.6° (EtOH) [lit,[6] mp 91—92 °C, $[\alpha]_D$+42° (EtOH)]; NMR ($CDCl_3$): 0.94 (6H, s, $-\dot{C}(CH_3)_2$), 1.20 (3H, s, $C_{10}-CH_3$), 1.31 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.29 (1H, m, $-C\underline{H}(CH_3)_2$), 3.77 (3H, s, $-OCH_3$), 6.72 and 7.12 (each 1H, d, and J=9 Hz, $C_{11}-H$ and $C_{12}-H$). Found: C, 83.72; H, 10.80%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

*(+)-Totarol (**1**).* A mixture of **20** (45 mg) and boron tribromide (0.04 ml) in dichloromethane (1.5 ml) was stirred at 0—5 °C for 15 min and then at room temperature for 2 h. The reaction mixture was poured into ice–water and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and then evaporated to dryness. The crude product was purified by column chromatography on silica gel (10 g) using hexane–benzene (3 : 7) as the eluent to afford totarol (**1**) (38 mg: 88%) which was recrystallized from petroleum ether: mp 132—133 °C; $[\alpha]_D$+41.5° (lit,[13] mp 131—132 °C, $[\alpha]_D$+42°); IR: 3608, 3352 cm^{-1}; NMR ($CDCl_3$): 0.93 and 0.95 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.18 (3H, s, $C_{10}-CH_3$), 1.33 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 4.50 (1H, bs, –OH), 6.49 and 7.01 (each 1H, d, and J=9 Hz, $C_{11}-H$ and $C_{12}-H$). Found: C, 83.71; H, 10.63%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

*(+)-Totaryl Acetate (**22**).* A solution of **1** (60 mg), acetic anhydride (0.2 ml), and pyridine (0.8 ml) was heated at 75—80 °C for 2 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (10 g) using hexane–benzene (1 : 1) as the eluent to give the acetate (**22**) (56 mg: 82%) which was recrystallized from ethanol: mp 122—124 °C (lit,[6] mp 122—124 °C); $[\alpha]_D$+46.0°; IR: 1751 cm^{-1}; NMR: 0.95 (6H, s, $-\dot{C}(CH_3)_2$), 1.20 (3H, s, $C_{10}-CH_3$), 1.21 and 1.24 (each 3H, d, and J= 7 Hz, $-CH(C\underline{H}_3)_2$), 2.21 (3H, s, $-OCOCH_3$), 3.21 (1H, m, $-C\underline{H}(CH_3)_2$), 6.65 and 7.05 (each 1H, d, and J=9 Hz, $C_{11}-H$ and $C_{12}-H$). Found: C, 80.64; H, 9.89%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%.

Improvement of Acetone Yield in the Oxidation of Propylene

Mamoru Ai* and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received September 1, 1978)

The outstanding property of the SnO_2–MoO_3 catalyst in the oxidation of propylene to acetone was confirmed by tests of various oxide catalysts supported on pumice. The optimum composition was found to be SnO_2-70/MoO_3-30 mol % for the oxidation at from 170 to 260 °C. It was also found that this pumice-supported catalyst is sufficiently selective for the acetone formation even at a high temperature of 260 °C, and that it gives a high yield of acetone while keeping its high selectivity. The selectivity increases up to 90 mol % with an increase in the partial pressure of water vapor and with a decrease in the oxygen partial pressure. On the basis of such information, it can be said that a high yield of acetone can be obtained by the divided introduction of oxygen.

It has been shown that propylene can be oxidized to acetone in the presence of water vapor on molybdenum-containing catalysts,[1–5] whereas the acetone yields attained in the previous works were limited because of low conversion at low temperatures or because of low selectivity at higher temperatures.[2–5] Thus, further study is required to improve the acetone yield.

Experimental

Catalysts. A number of mixed oxide catalysts were prepared by the procedures described in previous papers.[6–8] That is, an aqueous solution or slurry containing the required quantity of metal compounds was mixed with 10—20 mesh pumice in a fixed ratio of one g-atom metal per 500 ml of pumice (in apparent volume), followed by evaporation to dryness with vigorous stirring and calcination in a stream of air at 500 °C for 4—5 h.

Procedures. The catalytic reactions were carried out in a conventional continuous-flow system. The reactor was made of a steel tube coated with aluminum, 50 cm in length and 1.8 cm i.d., which was mounted vertically and immersed in a lead bath. The reactant gas was fed from the top of the reactor, with water or isopropyl alcohol (IPA) being introduced into a preheater section by means of an injection syringe pump.

The amount of catalyst in the propylene oxidation was 20, 30, or 40 g, and the feed rates of the reactants in a standard run were as follows: propylene-20/air-20/water vapor-76 ml (volume at 25 °C)/min. The effluent gas from the reactor was led successively into three chilled water-scrubbers to recover the water-soluble compounds. At the end of a 1-h run, the contents of the scrubbers (about 50 ml) were collected and analyzed by gas chromatography. The inlet and exit gases were intermittently analyzed.

The reaction of IPA was carried out at a fixed concentration of IPA (1.65 mol% in air) and a fixed total flow rate (1.5 l/min), changing the amount of catalyst in the range from 5 to 20 g.

Results and Discussion

Catalyst Screening. Acetone-forming Activities of Various Composite Oxide Catalysts: It seems apparent from the previous studies[8–11] that the propylene oxidation to acetone proceeds through an alcoholic intermediate, requiring two different functions for the catalyst: the hydration of olefin and the oxidative dehydrogenation of the alcoholic intermediate. It can, accordingly, be expected that information regarding the two functions will be helpful in the exploration of an effective catalyst. Since the hydration activity may be expected to run parallel with the activity for the dehydration of IPA, the catalytic activity for the dehydration and dehydrogenation of IPA in the presence of an excess of air would be relevant as measures of the two functions.

Since the first function is generally accepted to be associated with acid catalysts, various binary or ternary mixed oxide catalysts of an acidic property were tested for the ability to form acetone from propylene. The amount of catalyst used was 20 g, and the standard feed rates of the reactants were adopted. The results are summarized in Tables 1 and 2.

Another series of experiments were carried out with each catalyst using a mixture of IPA and air as the reactant. The rates of IPA dehydration, r_p, and dehydrogenation, r_a (mol/h·g-catalyst), were measured at 175 °C. They are also shown in Tables 1 and 2.

The results in Tables 1 and 2 may be summarized as follows.

(i) Acetone is obtained, more or less, with every V_2O_5- or MoO_3-containing catalyst, at least at a low temperature. The acetone yields is likely to increase with an increase in r_p, which can be regarded as a measure of the acidity.[6–8]

(ii) Although it gives a strikingly high value of r_p, WO_3–P_2O_5 does not convert IPA to acetone; thus, it is inactive for the propylene oxidation to actone.

(iii) The SnO_2–MoO_3 catalyst gives a strikingly high yield of acetone. It should be noted that both r_p and r_a are larger on this catalyst than on other catalysts. It is also notable that the high selectivity to acetone is retained at temperatures as high as 220 °C.

(iv) The Sn-60/V-40 is the second best catalyst.

Effect of the SnO_2–MoO_3 Composition on the Yield of Acetone: Five SnO_2–MoO_3 catalysts of different compositions were tested for the yield of acetone as well as for r_p and r_a, where the feed rate of air was twice as large as in the standard condition. The yields of acetone at 175, 190, 210, and 240 °C are plotted in Fig. 1, together with the values of r_p and r_a obtained at 140 °C.

Although the highest yield of acetone is obtained at around 30 atom % Mo at each temperature, it is noticeable that the effect of the temperature increase on the acetone yield is more marked with the catalysts

with a lower Mo content, suggesting that the rate-limiting step may be different depending on the Mo content. In fact, r_p is much larger than r_a on the 40% Mo catalyst, while r_a is much larger than r_p on the 20% Mo catalyst. If r_p and r_a represent the two functions required, the rate-limiting step on the 40% Mo catalyst would be the oxidation of the alcoholic intermediate. The less extensive effect of the temperature would be reasonable, because the equilibrium concentration of the alcoholic intermediate should decrease with an increase in the temperature. On the other hand, the rate-limiting step on the 20% Mo catalyst would be the hydration to form the alcoholic intermediate; this is in agreement with the more marked effect of the temperature. Thus, r_p and r_a can be regarded as parameters for the two functions.

Effect of the Third Components Added to Sn-70/Mo-30: The effect of the third component to improve the ace-

tone yield was tested with P_2O_5, SO_3, V_2O_5, U_3O_8, TiO_2, Al_2O_3, Fe_2O_3, and SiO_2 by adding 2—10 atom% to Sn-70/Mo-30, whereas none of then showed any improvement.

Effect of the Reaction Conditions on the Yield of Acetone. Since the Sn-70/Mo-30 catalyst proved to be the best, the effect of the reaction conditions were investigated on this catalyst.

Effect of the Reaction Temperature: The effects of the reaction temperature on the selectivity to acetone and on the yield were tested using different amounts of the catalyst. The results are shown in Figs. 2 and 3. At the acetone yield of around 35 mol%, almost all of the oxygen fed in was consumed.

The results may be summarized as follows:

(i) The yield of acetone increases with an increase in the temperature up to about 260 °C provided the oxygen is not completely consumed.

(ii) The selectivity largely depends on the conversion of propylene (Fig. 3), the effect of the temperature being less marked.

Effect of the Feed Rate of Oxygen and Nitrogen: Two series of runs were performed, changing the feed rate of oxygen or nitrogen. The results are shown in Table 3. Except for Run 56, the conversion of oxygen was very close to 100%, so that the total conversion of propylene increased with the flow rate of oxygen.

The results in Table 3 may be summarized as follows:

(i) The selectivity to acetone decreased as the inlet oxygen concentration increases, so that there is an optimum value in the oxygen-flow rate to give the highest yield of acetone for a fixed flow rate of propylene. An acetone yield of 43 mol % was achieved with a selectivity of 78 mol %.

(ii) The selectivity to acetone can be improved by dilution with nitrogen, suggesting a suppression of complete oxidation in the presence of nitrogen.

Effect of the Feed Rate of Water Vapor: The acetone-synthesis runs were carried out at different concentrations of water vapor. The results, shown in Table 4, indicate that the selectivity increases markedly with an increase in the water-vapor pressure. In the absence of water vapor, the catalytic activity was seriously impaired by the deposit of nonvolatile materials, while the catalyst was easily regenerated by air treatment at 500 °C. This suggests that the water vapor serves to prevent catalyst poisoning as well as to suppress complete oxidation.

a) Catalyst=SnO_2-70/MoO_3-30, amount of catalyst used=20 g (Reactor 1) and 20 g (Reactor 2), feed rate of propylene=20 ml/min, feed rate of water vapor for each reactor=76 ml/min. b) 100×(acetone)/(total). c) Calculated as acetic acid. d) Sum of acetone, acid, CO, and CO_2.

Improvement of the Acetone Yield. Although a high selectivity to acetone can be obtained by lowering the concentration of oxygen, the yield is limited by the oxygen feed. Thus, the reaction was performed successively in two reactor, with additional air or oxygen supplied to the second reactor. As is shown in Table 5, the yield is markedly improved by such a divided introduction of oxygen, while retaining the high selectivity. In this way, an acetone yield of 48—50 mol % is achieved with a selectivity of about 85 mol %. Although a retardation of acetone formation by product acetone was previously reported[12], the above result shows that the retardation by acetone is not strong.

Conclusion

The selective oxidation of propylene to acetone can be performed on SnO_2–MoO_3/pumice, particularly with a composition of 30% Mo; a high water partial pressure and a low oxygen partial pressure are requisites in improving the acetone yield. The superior performance of the SnO_2–MoO_3 catalyst is understood in terms of two functions: the hydration of propylene and the oxidative dehydrogenation of IPA. When the Mo content is varied, both functions, indicated by r_p and r_a, attain maxima at around 20 to 30% Mo, thus giving rise to an optimum composition of 30% Mo.

The Total Synthesis of (+)-Taxoquinone, (−)-7α-Acetoxyroyleanone, (−)-Dehydroroyleanone, (−)-Horminone, (−)-7-Oxoroyleanone, and (+)-Inuroyleanol

Takashi MATSUMOTO* and Shogo HARADA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received September 4, 1978)

Methylation of 12-benzoyloxyabieta-8,11,13-trien-11-ol with methyl iodide afforded 11-benzoyloxy-12-methoxyabieta- and 12-benzoyloxy-11-methoxyabieta-8,11,13-triene (**9**). Oxidation of the latter product with chromium trioxide, followed by sodium borohydride reduction and acetylation, gave 7β-acetoxy-12-benzoyloxy-11-methoxyabieta-8,11,13-triene (**17**) and its 7α-acetoxy isomer (**18**) in a ratio of *ca.* 5 : 1. On the other hand, treatment of **9** with lead tetraacetate produced **17** and **18** in a ratio of *ca.* 1 : 2. The 7β-acetate (**17**) was then oxidized with chromium trioxide and the resulting *p*-quinone derivative was hydrolyzed with aqueous sodium hydroxide to give taxoquinone (**1**), which on dehydration gave dehydroroyleanone. Similarly, the 7α-acetate (**18**) was converted into horminone (**4**) *via* the *p*-quinone derivative, which was treated with aqueous sodium hydrogencarbonate to give 7α-acetoxyroyleanone. Oxidation of **4** with manganese dioxide afforded 7-oxoroyleanone. Methylation of **1** with diazomethane, followed by oxidation with a chromium trioxide–pyridine complex, afforded 12-methoxyabieta-8,12-diene-7,11,14-trione, which on reduction with sodium dithionite gave inuroyleanol.

There have been reports on the isolation and structural elucidation of many naturally-occurring highly-oxygenated tricyclic diterpenes possessing an oxygen function at the C-11 position. In previous papers,[1,2] we reported the successful oxidation of the C-11 position in the tricyclic C ring-aromatized diterpenes with benzoyl peroxide. As an extension of that work, our efforts were further directed toward the syntheses of highly-oxygenated tricyclic diterpenes possessing an abietane skeleton. This paper[3] describes the syntheses of (+)-taxoquinone (**1**),[4,5] (−)-7α-acetoxyroyleanone (**2**),[6,7] (−)-dehydroroyleanone (**3**),[5,6,8,9] (−)-horminone (**4**),[5,10] (−)-7-oxoroyleanone (**5**),[5,7] and (+)-inuroyleanol (**6**),[7] all starting from (+)-ferruginol (**7**). Since the total synthesis of optically active ferruginol[11] has recently been accomplished in our laboratory, the present work constitutes the total syntheses of all the above natural diterpenes (**1**—**6**).

The oxidation of ferruginol (**7**) with benzoyl peroxide in chloroform afforded 12-benzoyloxyabieta-8,11,13-trien-11-ol (**8**)[2] which was methylated with methyl iodide and anhydrous potassium carbonate in refluxing ethyl methyl ketone to give the two monomethyl ethers, **9** and **10**, in a ratio of *ca.* 3 : 2. In order to elucidate the structures of these two products, the minor product (**10**) was reduced with lithium aluminium hydride in ether to yield a phenol (**11**) which responded positively to the Gibbs test,[12] suggesting the presence of an aromatic proton para to a phenolic hydroxyl group. Therefore, the structure of **10** was determined as 11-benzoyloxy-12-methoxyabieta-8,11,13-triene.[13] This structure was further confirmed by the following conversion. The oxidation of **10** with chromium trioxide in acetic acid produced the corresponding 7-oxo compound (**12**), which on alkaline hydrolysis gave cryptojaponol (**13**).[2,14] The major product (**9**) was then hydrolyzed with aqueous sodium hydroxide in refluxing methanol to give another phenol (**14**) which, in contrast with **11**, showed a negative Gibbs test,[12] suggesting the presence of a substituent para to a phenolic hydroxyl group. Therefore, the structure of **9** was assigned as 12-benzoyloxy-11-methoxyabieta-8,11,13-triene. The compound **9** was also oxidized with chromium trioxide in acetic acid to give the corresponding 7-oxo compound (**15**) together with the *p*-benzoquinone derivative, which was identical with 12-benzoyloxyabieta-8,12-diene-11,14-dione (**16**)[2] prepared from **8** by oxidation with *m*-chloroperbenzoic acid. The reduction of **15** with sodium borohydride in methanol at 0 °C followed by acetylation of the resulting mixture of epimeric alcohols with acetic anhydride in pyridine at room temperature produced a mixture of 7β-acetoxy-12-benzoyloxy-11-methoxyabieta-8,11,13-triene (**17**) and its 7α-acetoxy isomer (**18**) in a ratio of *ca.* 5 : 1. The stereochemistry of the acetoxyl group was established on the basis of the C-7 proton signals with half-height width of 15 Hz at δ 5.93 ppm in **17** and 5 Hz at δ 5.86 ppm in **18** in their NMR spectra. This reaction procedure leading to the 7-acetoxy compounds (**17** and **18**) is

suitable for the synthesis of taxoquinone (**1**) possessing a 7β-hydroxyl group. However, for the syntheses of 7α-acetoxyroyleanone (**2**) and horminone (**4**) it is necessary to prepare **18** predominantly. For this purpose, the direct acetoxylation on the C-7 position in **9** was carried out with lead tetraacetate in refluxing acetic acid in a stream of nitrogen. The chromatographic purification of the crude porduct on silica gel afforded a mixture of **17** and **18** in a ratio of *ca.* 1 : 2. The 7β-acetate (**17**) was then oxidized with chromium trioxide in acetic acid at room temperature to yield 7β-acetoxy-12-benzoyloxyabieta-8,12-diene-11,14-dione (**19**) along with the 7-oxo compound (**15**). The hydrolysis of **19** with aqueous sodium hydroxide in refluxing methanol, followed by treatment with dilute hydrochloric acid, afforded taxoquinone (**1**). This was dehydrated[5] with *p*-toluenesulfonic acid in refluxing benzene to give dehydroroyleanone (**3**) and also methylated[5] with diazomethane to give 7β-hydroxy-12-methoxyabieta-8,12-diene-11,14-dione (**20**). Similarly, the 7α-acetate (**18**) was oxidized with chromium trioxide in acetic acid to give 7α-acetoxy-12-benzoyloxyabieta-8,12-diene-11,14-dione (**21**) along with the 7-oxo compound (**15**). The treatment of **21** first with aqueous sodium hydroxide in refluxing methanol, followed with dilute hydrochloric acid, produced horminone (**4**) which on oxidation[5] with manganese dioxide in dioxane afforded 7-oxoroyleanone (**5**). On the other hand, when **21** was hydrolyzed with aqueous sodium hydrogencarbonate in refluxing methanol, 7α-acetoxyroyleanone (**2**) was obtained. The hydroxyquinone (**20**) was then oxidized with a chromium trioxide–pyridine complex to give 12-methoxyabieta-8,12-diene-7,11,14-trione (**22**), which was reduced at 95 °C with sodium dithionite in acetic acid to afford inuroyleanol (**6**).

Experimental

All melting points are uncorrected. The IR and UV spectra were taken in chloroform and ethanol, respectively. The NMR spectra were obtained in carbon tetrachloride at 60 MHz with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. The optical rotations were measured in chloroform using a Yanaco OR-50D. Column chromatography was performed using Merck silica gel (0.063 mm).

Methylation of 12-Benzoyloxyabieta-8,11,13-trien-11-ol (8). A mixture of **8**[2] (10.00 g), methyl iodide (16.0 ml), and anhydrous potassium carbonate (40.0 g) in ethyl methyl ketone (50 ml) was refluxed for 8 h. The mixture was cooled to room temperature, poured into water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (300 g) using benzene as the eluent to give 12-benzoyloxy-11-methoxyabieta-8,11,13-triene (**9**) (6.25 g: 60%) which was recrystallized from ether–methanol: mp 125—126 °C; $[\alpha]_D$+76.4°; IR: 1735 cm^{-1}; NMR: 0.95 (6H, s, $-\underset{|}{C}(CH_3)_2$), 1.15 and 1.17 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (3H, s, C_{10}–CH_3), 3.68 (3H, s, $-OCH_3$), 6.67 (1H, s, C_{14}–H), 7.3—8.3 (5H, m, aromatic protons). Found: C, 80.03; H, 8.45%. Calcd for $C_{28}H_{36}O_3$: C, 79.96; H, 8.63%.

Further elution gave 11-benzoyloxy-12-methoxyabieta-8,11,13-triene (**10**) (3.95 g: 38%) which was recrystallized from chloroform–acetone: mp 183.5—184.5 °C; $[\alpha]_D$+76.5°; IR: 1735 cm^{-1}; NMR: 0.91 and 0.96 (each 3H and s, $-\underset{|}{C}-(CH_3)_2$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.39 (3H, s, C_{10}–CH_3), 3.52 and 3.57 (each *ca.* 1.5 H and s, $-OCH_3$),[15] 6.74 (1H, s, C_{14}–H), 7.3—8.4 (5H, m, aromatic protons). Found: C, 80.24; H, 8.55%. Calcd for $C_{28}H_{36}O_3$: C, 79.96; H, 8.63%.

12-Methoxyabieta-8,11,13-trien-11-ol (11). A mixture of **10** (208 mg) and lithium aluminium hydride (300 mg) in dry ether (15 ml) was refluxed for 2 h. The mixture was poured into ice–dilute hydrochloric acid and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (15 g) using benzene as the eluent to give **11** (126 mg: 80%) which responded positively to the Gibbs test.[12] Mp 94—94.5 °C (from methanol); $[\alpha]_D$+67.2°; IR: 3510 cm^{-1}; NMR : 0.94(6H, s, $-\underset{|}{C}(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (3H, s, C_{10}–CH_3), 3.70 (3H, s, $-OCH_3$), 5.79 (1H, s, C_{11}–OH), 6.25 (1H, s, C_{14}–H). Found: C, 79.92; H, 10.21%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

11-Benzoyloxy-12-methoxyabieta-8,11,13-trien-7-one (12). A mixture of **10** (2.00 g) and chromium trioxide (2.00 g) in acetic acid (60 ml) was allowed to stand at room temperature for 24 h. The mixture was poured into ether–aqueous sodium hydrogencarbonate and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was chromatographed on silica gel (200 g) using ether–benzene (5 : 95) as the eluent to give **12**[14] (1.24 g: 60%) which was recrystallized from chlroroform–ether : mp 197—198 °C; $[\alpha]_D$+68.9°; IR: 1739, 1676 cm^{-1}; NMR: 0.97 (6H, s, $-\underset{|}{C}(CH_3)_2$), 1.25(3H, s, C_{10}–CH_3), 1.26 and 1.39 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.56 (2H, bd, J=7 Hz, $-CH_2CO-$), 3.61 and 3.65 (each *ca.* 1.5 H and s, $-OCH_3$),[14] 7.85 (1H, s, C_{14}–H), 7.3—8.3 (5H, m, aromatic protons). Found: C, 77.10; H, 7.85%. Calcd for $C_{28}H_{34}O_4$: C, 77.39; H, 7.89%.

Cryptojaponol (13). A mixture of **12** (600 mg) and 10% aqueous sodium hydroxide (5.0 ml) in methanol (35 ml)

was refluxed for 1 h and then evaporated *in vacuo*. The residue was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine. The dried solution was then evaporated *in vacuo* to afford a solid which was recrystallized from methanol, giving **13** (180 mg), mp 205—207 °C. Found: C, 76.21; H, 9.08%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%. The mother liquor of crystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (20 g) using ether–benzene (1 : 99) as the eluent to give an additional **13** (106 mg). The IR and NMR spectra of **13** were identical with those of authentic cryptojaponol.[2]

11-Methoxyabieta-8,11,13-trien-12-ol (14). A mixture of **9** (171 mg) and 10% aqueous sodium hydroxide (1.5 ml) in methanol (10 ml) was refluxed for 1 h. After the same work-up as described for the preparation of **13**, the crude product was chromatographed on silica gel (15 g) using benzene as the eluent to give **14** (124 mg: 80%) which responded negatively to the Gibbs test.[12] Mp 114.5—115 °C (from methanol); $[\alpha]_D$+67.5°; IR: 3545, 3340 cm^{-1}; NMR: 0.95 (6H, s, $-\dot{C}(CH_3)_2$), 1.20 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (3H, s, $C_{10}-CH_3$), 3.74 (3H, s, $-OCH_3$), 5.18 (1H, s, $C_{12}-OH$), 6.48 (1H, s, $C_{14}-H$). Found: C, 79.98; H, 10.21%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

Oxidation of 9 with Chromium Trioxide. Chromium trioxide (6.0 g) was added to a stirred solution of **9** (5.959 g) in acetic acid (80 ml) over a 1 h period. The mixture was further stirred at room temperature for 5 h and then allowed to stand for 18 h. The mixture was poured into water and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine. After drying over sodium sulfate, the solvent was evaporated *in vacuo* and the residue was chromatographed on silica gel (300 g) using benzene as the eluent to give 12-benzoyloxyabieta-8,12-diene-11,14-dione (**16**) (1.630 g: 27%) which was recrystallized from ethanol: mp 196—197 °C. Found: C, 76.97; H, 7.89%. Calcd for $C_{27}H_{32}O_4$: C, 77.11; H, 7.67%. The IR and NMR spectra of **16** were identical with those of authentic royleanone benzoate.[2] Further elution with ether–benzene (1 : 9) afforded 12-benzoyloxy-11-methoxyabieta-8,11,13-trien-7-one (**15**) (2.731 g: 44%) which was recrystallized from methanol: mp 163—163.5 °C; $[\alpha]_D$+38.0°; IR: 1740, 1678, 1600 cm^{-1}; NMR: 0.99 (6H, s, $-\dot{C}(CH_3)_2$), 1.22 and 1.27 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.40 (3H, s, $C_{10}-CH_3$), 3.70(3H, s, $-OCH_3$), 7.76 (1H, s, $C_{14}-H$), 7.3—8.4 (5H, m, aromatic protons). Found: C, 77.57; H, 7.83%. Calcd for $C_{28}H_{34}O_4$: C, 77.39; H, 7.89%.

7β-Acetoxy-12-benzoyloxy-11-methoxyabieta-8,11,13-triene (17) and Its 7α-Acetoxy Isomer (18). From the Methyl Ether (9): A mixture of **9** (1.00 g) and lead tetraacetate (3.00 g) in acetic acid (30 ml) was refluxed for 40 min with stirring in a stream of nitrogen. The mixture was cooled to room temperature and ethylene glycol (1.0 ml) was added. The mixture was further stirred at room temperature for 30 min, poured into water, and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine. After drying over sodium sulfate, the solvent was evaporated *in vacuo*. The residue was chromatographed on silica gel (120 g) using ether–benzene (2 : 98) as the eluent to give a mixture of **17** and **18** (647 mg: 57%) whose NMR spectrum showed the presence of **17** and **18** in a ratio of *ca.* 1 : 2 from the intensities of the C-14 proton signals. The crystallization of the mixture from methanol gave **18** (290 mg): mp 176—177 °C; $[\alpha]_D$+75.2°; IR: 1735 sh, 1725 cm^{-1}; NMR: 0.94 (6H, s, $-\dot{C}(CH_3)_2$), 1.19 and 1.21 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (3H, s, $C_{10}-CH_3$), 2.04 (3H, s, $-OCOCH_3$), 3.72 (3H, s, $-OCH_3$), 5.86 (1H, m, $W_{1/2}$=5 Hz, $C_{7\beta}-H$), 6.88 (1H, s, $C_{14}-H$), 7.3—8.4 (5H, m, aromatic protons). Found: C, 75.15; H, 7.94%. Calcd for $C_{30}H_{38}O_5$: C, 75.28; H, 8.00%.

The isolation of the pure 7β-acetate (**17**) was difficult; it showed the following NMR spectrum: 0.95 and 1.00 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.18 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.37(3H, s, $C_{10}-CH_3$), 2.09 (3H, s, $-OCOCH_3$), 3.70 (3H, s, $-OCH_3$), 5.93 (1H, m, $W_{1/2}$=15 Hz, $C_{7\alpha}-H$), 6.85 (1H, s, $C_{14}-H$), 7.3—8.4 (5H, m, aromatic protons).

From the Ketone (15): Sodium borohydride (600 mg) was added at 0—5 °C to a stirred solution of **15** (1.469 g) in methanol (20 ml). The mixture was further stirred at this temperature for 3 h, acidified with dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo* to give a mixture of alcohols (1.17 g). IR: 3590, 3350, 1740 cm^{-1}; NMR: 0.95 (6H, s, $-\dot{C}(CH_3)_2$), 1.28 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.33 (3H, s, $C_{10}-CH_3$), 3.70 (3H, s, $-OCH_3$), 4.3—4.8 (1H, m, C_7-H), 7.25 (1H, s, $C_{14}-H$), 7.3—8.3 (5H, m, aromatic protons).

An aliquot of the above mixture (880 mg) was dissolved in acetic anhydride (15 ml) and pyridine (1.5 ml), allowed to stand at room temperature for 24 h, and then diluted with ether. The ether solution was washed successively with dilute hydrochloric acid and water, dried over sodium sulfate, and evaporated *in vacuo* to give an oil (861 mg) whose NMR spectrum showed the presence of **17** and **18** in a ratio of *ca.* 5 : 1.

Oxidation of the 7α-Acetate (18). Chromium trioxide (900 mg) was added to a stirred solution of **18** (900 mg) in acetic acid (15 ml). The mixture was further stirred at room temperature for 20 h, poured into water, and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and water. After drying over sodium sulfate, the solvent was evaporated *in vacuo*. The residue was recrystallized from methanol to give 7α-acetoxy-12-benzoyloxyabieta-8,12-diene-11,14-dione (**21**)[16] (210 mg: 23%). Mp 261—262 °C; $[\alpha]_D$+42.0°; IR: 1738, 1664, 1655 sh cm^{-1}; MNR ($CDCl_3$): 0.89 (6H, s, $-\dot{C}(CH_3)_2$), 1.23 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (3H, s, $C_{10}-CH_3$), 2.06 (3H, s, $-OCOCH_3$), 5.99 (1H, m, $W_{1/2}$=5 Hz, $C_{7\beta}-H$), 7.4—8.3 (5H, m, aromatic protons). The mother liquor of crystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (40 g) using ether–benzene (1 : 99) as the eluent to give **15** (354 mg).

Oxidation of the 7β-Acetate (17). A solution of **17** (900 mg) containing a small amount of **18** was oxidized with chromium trioxide (900 mg) at room temperature for 20 h. After the same work-up as described for the preparation of **21**, the crude product was recrystallized from methanol to afford **21** (40 mg). The mother liquor of crystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (40 g) using ether–benzene (1 : 99) as the eluent to give a quinone fraction (400 mg) which was recrystallized from methanol to give 7β-acetoxy-12-benzoyloxyabieta-8,12-diene-11,14-dione (**19**)[16] (140 mg). Mp 125—127 °C and 155—160 °C; $[\alpha]_D$+30.0°; IR: 1737, 1663, 1653 sh cm^{-1}; NMR ($CDCl_3$): 0.90 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.20 and 1.26 (each 3H, d, and J= 7 Hz, $-CH(C\underline{H}_3)_2$), 1.39 (3H, s, $C_{10}-CH_3$), 2.08 (3H, s, $-OCOCH_3$), 6.02 (1H, t, J=8.5 Hz, $W_{1/2}$=17 Hz, $C_{7\alpha}-H$),

7.4—8.4 (5H, m, aromatic protons). Further elution gave **15** (68 mg). The mother liquor of the above crystallization was chromatographed on silica gel to afford some additional **15** (201 mg).

Taxoquinone (1). A mixture of **19** (103 mg) and 10% aqueous sodium hydroxide (4.0 ml) in methanol (15 ml) was refluxed for 30 min. After the addition of methanol (5.0 ml) and 10% hydrochloric acid (8.0 ml), the mixture was further refluxed for 5 min, cooled to room temperature, and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g) using ether–benzene (2 : 98) as the eluent to give taxoquinone (**1**) (49 mg: 68%) which was recrystallized from ether: mp 206—207 °C; $[\alpha]_D$+344° (lit,[4] mp 212—214 °C, $[\alpha]_D$+340°); IR: 3548, 3378, 1671, 1647, 1623, 1597 cm^{-1}; NMR ($CDCl_3$): 0.93 (6H, s, $-\dot{C}(CH_3)_2$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.35 (3H, s, C_{10}–CH_3), 3.84 (1H, d, J=2 Hz, $C_{7\beta}$–OH), 4.84 (1H, m, $W_{1/2}$=20 Hz, $C_{7\alpha}$–H), 7.33 (1H, s, C_{12}–OH). Found: C, 72.04; H, 8.60%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%. The synthetic **1** was shown to be identical with natural taxoquinone by mixed melting point determination and IR and NMR spectral comparisons.

Dehydroroyleanone (3). A mixture of **1** (36.1 mg) and *p*-toluenesulfonic acid (40 mg) in dry benzene (10 ml) was refluxed for 30 min. The mixture was cooled to room temperature, stirred with sodium hydrogencarbonate for 30 min, and then filtered. The filtrate was evaporated *in vacuo* and the residue was chromatographed on silica gel (15 g) using ether–benzene (2 : 98) as the eluent to give dehydroroyleanone (**3**) (12.5 mg: 37%) which was recrystallized from petroleum ether: mp 166—167 °C; $[\alpha]_D$−609° (lit,[6] mp 166—168.5 °C, $[\alpha]_D$−620°); IR: 3363, 1665, 1635, 1610 cm^{-1}; UV λ_{max} nm (ε): 247sh (8600), 333 (7100), 459 (610); NMR ($CDCl_3$): 0.98, 1.02, and 1.04 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}–CH_3), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.14 (1H, t, J=3 Hz, C_5–H), 6.45 (1H, dd, J=3 and 10 Hz, C_6–H), 6.81 (1H, dd, J=3 and 10 Hz, C_7–H), 7.32 (1H, s, C_{12}–OH). Found: C, 76.52; H, 8.52%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%. The IR and NMR spectra of **3** were identical with those of natural dehydroroyleanone.

Further elution gave the recovered **1** (20.0 mg).

7α-Acetoxyroyleanone (2). A mixture of **21** (41.9 mg) in methanol (30 ml) and 5% aqueous sodium hydrogencarbonate (4.0 ml) was refluxed for 45 min and evaporated *in vacuo*. The residue was acidified with dilute hydrochloric acid, refluxed for 5 min, cooled to room temperature, and then extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and water, dried over sodium sulfate, and evaporated *in vacuo*. The residue (31.8 mg) was recrystallized from ethanol to give 7α-acetoxyroyleanone (**2**) (11.9 mg: 36%). Mp 212—214 °C; $[\alpha]_D$−7° (lit,[6] mp 212—214.5 °C, $[\alpha]_D$−14°); IR: 3390, 1736, 1671, 1642, 1608 cm^{-1}; UV λ_{max} nm (ε): 272 (12,400), 410 (760); NMR ($CDCl_3$): 0.84 (6H, s, $-\dot{C}(CH_3)_2$), 1.19 and 1.22 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.24 (3H, s, C_{10}–CH_3), 2.02 (3H, s, $-OCOCH_3$), 5.94 (1H, m, $W_{1/2}$=6 Hz, $C_{7\beta}$–H), 7.13 (1H, s, C_{12}–OH). Found: C, 70.75; H, 8.23%. Calcd for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08%. The synthetic **2** was shown to be identical with natural 7α-acetoxyroyleanone by mixed melting point determination and IR and NMR spectral comparisons.

Horminone (4). A mixture of **21** (105 mg) and 10% aqueous sodium hydroxide (4.0 ml) in methanol (20 ml) was refluxed for 30 min, acidified with 10% hydrochloric acid, and further refluxed for 5 min. After the same work-up as described for the preparation of **1**, the crude product (88.3 mg) was recrystallized from ether–petroleum ether to give horminone (**4**) (39.3 mg: 54%). Mp 176—178 °C; $[\alpha]_D$−120° (lit,[6] mp 172.5—174.5 °C, $[\alpha]_D$−132°); IR: 3570, 3380, 1671, 1647, 1627, 1601 cm^{-1}; NMR ($CDCl_3$): 0.91 and 0.99 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.22 (3H, s, C_{10}–CH_3), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 4.75 (1H, m, $W_{1/2}$=9 Hz, $C_{7\beta}$–H), 3.05 and 7.27 (each 1H and s, 2-OH). Found: C, 72.11; H, 8.38%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%. The synthetic **4** was shown to be identical with natural horminone by mixed melting point determination and IR and NMR spectral comparisons.

7-Oxoroyleanone (5). According to the method of Eugster *et al.*,[5] a mixture of **4** (160 mg) and active manganese dioxide (1.80 g) in dioxane (25 ml) was stirred at 75—80 °C for 44 h. The crude product was chromatographed on silica gel (20 g) using ether–benzene (3 : 97) as the eluent to give the recovered **4** (107 mg). Further elution with ether–benzene (1 : 9) afforded 7-oxoroyleanone (**5**) (13.0 mg) which was recrystallized from methanol: mp 202—203 °C dec (lit,[7] mp 204—205 °C); IR: 3400, 1695, 1663, 1645, 1575 cm^{-1}; NMR ($CDCl_3$): 0.93 and 0.96 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.36 (3H, s, C_{10}–CH_3), 6.98 (1H, s, C_{12}–OH). The IR and NMR spectra of **5** were identical with those of natural 7-oxoroyleanone.

12-Methoxyabieta-8,12-diene-7,11,14-trione (22). A solution of **1** (110 mg) in ether was methylated at 0—5 °C with diazomethane to give 7β-hydroxy-12-methoxyabieta-8,12-diene-11,14-dione (**20**) (110 mg). The crude ether (**20**) was dissolved in pyridine (2.0 ml) and chromium trioxide (120 mg) was added at 0—5 °C. The mixture was stirred at room temperature for 45 h, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g) using ether–benzene (3 : 97) as the eluent to give **22** (26 mg) which was recrystallized from petroleum ether: mp 90—92 °C (lit,[7] mp 88—91 °C); IR: 1700, 1663, 1625, 1577 cm^{-1}; NMR ($CDCl_3$): 0.92 and 0.96 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.19 and 1.21 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.42 (3H, s, C_{10}–CH_3), 3.90 (3H, s, $-OCH_3$).

Inuroyleanol (6). A solution of sodium dithionite (300 mg) in water (1.0 ml) was added at 95—100 °C to a solution of **22** (42.0 mg) in acetic acid (1.5 ml). The mixture was stirred at this temperature for *ca.* 2 min, cooled to room temperature, and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine. After drying over sodium sulfate, the solvent was evaporated *in vacuo* and the residue was recrystallized from methanol to give inuroylcanol (**6**) (29.4 mg: 70%). Mp 185—186 °C; $[\alpha]_D$+106° (lit,[7] mp 185—187 °C, $[\alpha]_D$+113.9°); IR: 3520, 1620 cm^{-1}; NMR ($CDCl_3$): 0.96 (6H, s, $-\dot{C}(CH_3)_2$), 1.37 (3H, s, C_{10}–CH_3), 1.39 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.80 (3H, s, $-OCH_3$), 5.72 (1H, s, C_{11}–OH), 13.30 (1H, s, C_{14}–OH). Found: C, 72.77; H, 8.85%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

The authors are grateful to Arakawa Chemical Co., Ltd. for a generous gift of rosin. Thanks are also due to Professors S. Morris Kupchan, C. H. Eugster, and O. E. Edwards for their kind supply of the natural samples and spectral copies.

(Received September 21, 1978)

Solvent extracts of Athabasca tar sand were analyzed by the Brown-Ladner method, the Takeya *et al.* method, and the Speight method on the basis of the ^{1}H-NMR data and by ^{13}C-NMR spectroscopy. The structural characteristics of Athabasca tar sand derivatives were also compared with those of coal-hydrogenolysis products. The results show that the structural characteristics of hexane solubles, monomers consisting of one aromatic ring substituted highly with C_6 aliphatic chains, resemble those of the oil fraction produced during the initial stage of the hydrogenolysis of Taiheiyo coal. However, the structural characteristics of the hexane insoluble-benzene solubles, oligomers consisting of 2 aromatic rings substituted highly with C_{4-5} aliphatic chains, are different from those of any coal-hydrogenolysis products. In addition, the close agreement between the f_a value obtained by the Brown-Ladner method and ^{13}C-NMR may indicate that, for solvent extracts of Athabasca tar sand, the assumption in the Brown-Ladner method that the atomic H/C ratio of aliphatic structures is 2 is proper.

From the standpoint of developing alternative resources to petroleum, studies of the chemical structures of coal, tar sand bitumen, and shale oil have been carried out with the view of utilizing these materials as raw material for energy. Studies of the chemical structure of tar sand bitumen have been carried out by the Speight method[2-5] using the data of ultimate analysis, ^{1}H-NMR, and molecular weight. The present authors have previously studied coal-hydrogenolysis products[6-9] using the Brown-Ladner method[10] and the Takeya *et al.* method,[11] which determined the structural parameters for structural units from the data of ultimate analysis and ^{1}H-NMR. Therefore, in the present investigation solvent extracts of Athabasca tar sand were analyzed by the Brown-Ladner method and the Takeya *et al.* method, and the results were compared with the chemical structures of coal-hydrogenolysis products. The aromaticity (f_a) determined by ^{13}C-NMR analysis was compared with the value obtained on the basis of the Brown-Ladner method. The Speight method is also discussed.

Experimental

Solvent Separation. As solvents, hexane and benzene used in the separation of coal-hydrogenolysis products[8,9] were adopted. A portion of about 10—20 g of tar sand was weighed accurately and they extracted with 5 vol of hexane per weight of tar sand. The solution was filtered after it had been stirred for 1 h at room temperature. The residue was again extracted with hexane in the same manner as the first extraction. The yield of hexane solubles (oil) was defined as the sum of the yields of the two hexane extractions. The hexane-insoluble residue was extracted with benzene in the same manner as in the hexane extraction. The yield of the hexane insoluble-benzene solubles (asphaltene) was obtained as the sum of two benzene extractions. Bitumen prepared from tar sand at the Research Council of Alberta was also separated in the same manner as the tar sand.

Analysis of the Hexane Solubles and the Hexane Insoluble-Benzene Solubles. The ultimate analysis,[8,9] ^{1}H-NMR analysis (solvent:$CDCl_3$),[8,9] ^{13}C-NMR analysis(solvent:$CDCl_3$),[12] molecular-weight determination (solvent:$CHCl_3$),[8,9] GPC (solvent:THF),[8] and determination of the hydroxyl-group content by trimethylsilylation[13] were carried out on both fractions in the manners previously reported.[8,9,12,13]

Results and Discussion

The yields of the hexane solubles and the hexane insoluble-benzene solubles are 9.5—10.3% and 2.0—2.2% respectively on the basis of tar sand, and the yield of bitumen is 11.5—12.5%. Consequently, the yields of the hexane solubles and the hexane insoluble-benzene solubles are 82.4—82.6% and 17.4—17.6% respectively on the basis of bitumen. The yield of benzene-insoluble matter, namely sand, is 87.6—88.5% on the basis of tar sand. The ash content of tar sand determined by high-temperature ashing techniques (815 °C) is 87.2%, which is almost equal to the yield of benzene-insoluble matter. These results indicate that the sand obtained here does not contain any organic matter. This fact was confirmed by the TGA of the benzene-insoluble matter. The weight loss of benzene-insoluble matter up to 800 °C is 0.2%.

The data on the ultimate analysis of hexane solubles and the hexane insoluble-benzene solubles are shown in Table 1, along with the data for the coal-hydrogen-

Table 1. Elementary analysis (%)

	C	H	O	N	S
Tar sand

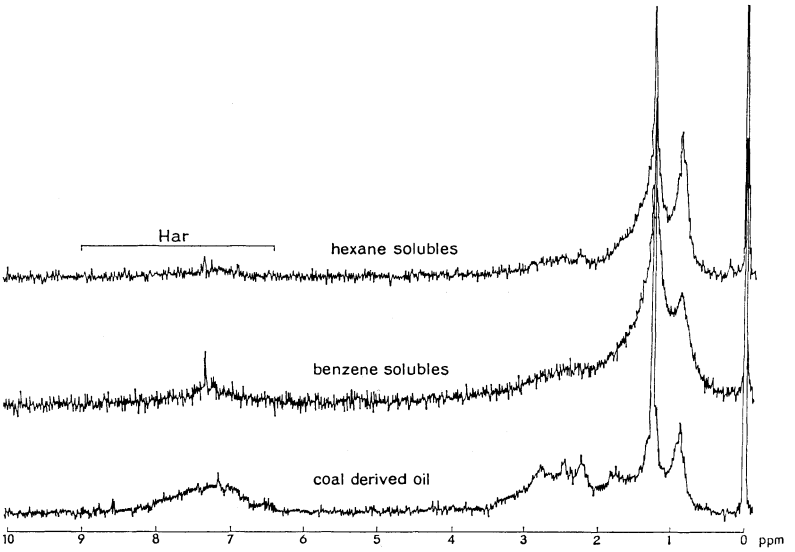

Fig. 1 ^{1}H-NMR spectra of tar sand extracts and coal-hydrogenolysis product.

olysis products. For both fractions of tar sand, the carbon content is lower and the hydrogen content is higher than those of the coal-hydrogenolysis products. The most remarkable differences in ultimate composition between the tar-sand derivatives and the coal-hydrogenloysis products is that the oxygen content of the coal-hydrogenolysis products is higher, while the sulfur content of the tar-sand derivatives is higher. The hydroxyl oxygen content of tar-sand bitumen is 0.3%, lower than that of the coal-hydrogenolysis products(1.1—3.3%).[8] In Figs. 1 and 2 the spectra of the ^{1}H-NMR and ^{13}C-NMR of tar-sand derivatives are compared with those of coal-hydrogenolysis products. In Table 2 the hydrogen distributions determined by means of ^{1}H-NMR, the structural parameters calculated on the basis of the Brown-Ladner method and ^{13}C-NMR, the weights of the average structural units calculated from the values of the

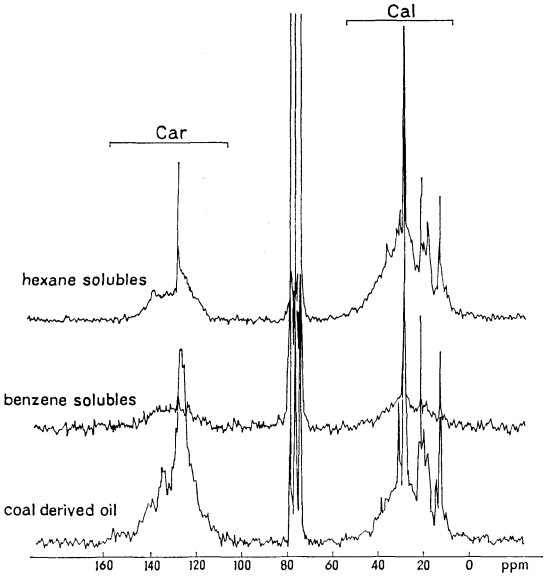

Fig. 2. ^{13}C-NMR spectra of tar sand extracts and coal-hydrogenolysis product.

structural parameters(M_n), and the molecular weights determined by the vapor-pressure osmometry(M_v) of tar-sand derivatives are compared with those of coal-hydrogenolysis products. Regarding the hexane solubles, the aromaticity(f_a) is low, and the f_a values based on the Brown-Ladner method and on ^{13}C-NMR agree closely. The measure of the substitution of the aromatic system(σ) is high, the size of the aromatic rings in the structural unit is 1 ring (H_{au}/C_a : 1.07), and the measure of the aliphatic chain length (H_o/H_α) is about 5, which means that the length of the aliphatic chain is C_6. The molecular weight(M_v) is 410—440, and the degree of polymerization(M_v/M_n) is 1.2—1.4. This shows that hexane solubles consist mostly of monomers. These structural characteristics resemble those of Oil(S_1) from Taiheiyo coal. They are however, different from those of Oil(S_1) from Oyubari coal(C:85.6%), which is of a higher rank than Taiheiyo coal(C : 76.9%), from those of Oil(S_2), and from those of benzene solubles, Asphaltene(R). The following reaction scheme for coal hydrogenolysis has been proposed:[14,15]

$$\text{Coal} \begin{cases} \nearrow \text{Oil}(S_1) \\ \searrow \text{Asphaltene(R)} \longrightarrow \text{Oil}(S_2) \end{cases}$$

Oil(S_1) is the product produced during the initial stage of coal hydrogenolysis. Oil(S_2) is the product produced through the reaction of Coal→Asphaltene(R)→Oil(S_2). Regarding the hexane insoluble-benzene solubles, f_a is higher than for hexane solubles, while the f_a values based on the Brown-Ladner method and on ^{13}C-NMR agree closely. The size of the aromatic rings is larger(about 2 rings, H_{au}/C_a: 0.76—0.86), H_o/H_α is smaller, and M_v and M_v/M_n are much larger than those for the hexane solubles. This is also obvious from the GPC chromatogram in Fig. 3. The structural unit of this fraction resembles Oil(S_1) from Oyubari coal as to f_a and H_{au}/C_a, but compared with Oil(S_2) and Asphaltene(R) f_a is much lower and H_o/H_α is much larger. M_v and M_v/M_n are much larger than those of coal-hydrogenolysis products.

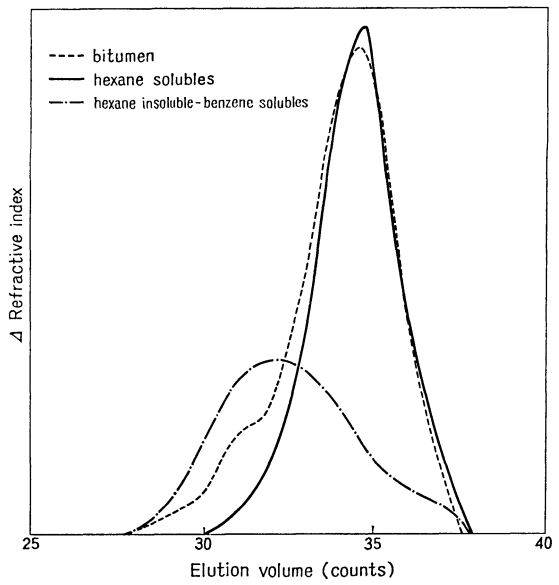

Fig. 3. GPC chromatograms of tar-sand extracts.

This fraction is an oligomer(M_v/M_n: 6.3—6.7) consisting of 2 aromatic rings substituted highly with the C_{4-5} aliphatic chain. In Table 3, a comparison of the results obtained by the Speight method with the results obtained by the Brown-Ladner method is shown. Theoretically, R_a, C_{sa}/C_p, C_s/C_{sa}, and C_p/C_a in the Speight method have the same meaning as R_a'(aromatic rings per molecule, they can be calculated from the values of H_{au}/C_a and M_v/M_n), σ, H_o/H_α, and H_{au}/C_a respectively. Comparing the analytical results obtained by the two methods, R_a and R_a', and C_s/C_{sa} and H_o/H_α, agree precisely, but C_{sa}/C_p and σ, and C_p/C_a and H_{au}/C_a, differ slightly. This may be due to the lack of consideration of heteroatoms in the Speight method. Comparing the present data with Speight's data[2] obtained by the Speight method for the hexane solubles, similar values for molecular weight and R_a are obtained. However, for the hexane insoluble-benzene solubles the molecular weights are remarkably different from each other. There is also a large difference between the values of R_a. The present data on the molecular weight of the hexane insoluble-benzene solubles(2130—2250) agree closely with the data of Boyd *et al.*(2492).[16] The value of R_a in the Speight method varies with the value of the molecular weight according to $R_a=(C_i+1)/2$, where C_i is a function of the molecular weight. In addition, the close agreement between the f_a values obtained by the Brown-Ladner method and by ^{13}C-NMR may indicate that, for Athabasca tar-sand derivatives, the assumption in the Brown-Ladner method of 2 for the atomic H/C ratio of aliphatic structures is correct.

The authors are grateful to Dr. Yosuke Maekawa of the Government Industrial Development Laboratory, Hokkaido, for samples, and would like to thank Prof. D. M. Bodily of the University of Utah for his helpful discussion.

Stereochemical Studies of the Hydrogenation with Asymmetrically Modified Nickel Catalysts; The Hydrogenation of Methyl 2-Alkyl-3-oxobutyrate

Akira TAI,* Hiroshi WATANABE, and Tadao HARADA

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received September 25, 1978)

The hydrogenation of methyl 2-methyl-3-oxobutyrate (I) to methyl 3-hydroxy-2-methylbutyrate (III) was carried out with various types of asymmetrically modified nickel catalysts (MNi). The use of MNi always resulted in the deviation of the ratio, **2S/2R**=((2*S*,3*R*)-III+(2*S*,3*S*)-III)/((2*R*,3*R*)-III+(2*R*,3*S*)-III), from 1/1, in spite of the use of racemic I. A catalyst giving a larger **2S/2R** value always gave a larger **3R/3S** value. These results led to the conclusion that the configurations at the C-2 and C-3 positions of the product were determined in the process of the formation of the complex between the substrate and the modifying reagent (the absorption step), not at the step of the hydrogen addition to the adsorbed substrate (the rate-determining step). The best optical yield and the highest ratio of *erythro*-III/*threo*-III were obtained when (*R*,*R*)-tartaric acid–MNi was used as a catalyst. The amounts of the isomers produced were in the following order: 2*S*,3*R*≫2*R*,3*R*≈2*R*,3*S*>2*S*,3*S*. Stereochemical models are proposed to account for the formation of the 2*S*,3*R*-isomer in a large excess.

The comparative study of the rate and the optical yield of methyl acetoacetate (MAA) over an asymmetrically modified Raney nickel catalyst has revealed that the enantioface-differentiating step of the substrate took place elsewhere than in the step of the hydrogen addition to the adsorbed substrate (the rate-determining step).[1] Although the kinetic study has suggested that the modifying reagent differentiated the enantioface of the substrate by making a complex with the substrate at the adsorption step, the mode of the differentiation has not yet been made clear.

In the hydrogenation of methyl 2-methyl-3-oxobutyrate (I) to *threo*- and *erythro*-methyl 3-hydroxy-2-methylbutyrate (III) over a modified nickel catalyst (MNi), it has been noticed that the function of the modifying reagent is not only to differentiate the enantioface of the substrate, but also to determine the ratio of the diastereomers produced.[2]

The readily interconvertible chiral center at the C-2 position of I may serve as an internal probe for the detection of the substrate-modifying reagent interaction. In this respect, the stereochemical investigation of the hydrogenation of I was expected to give useful information about the mode of the enantio-differentiation.

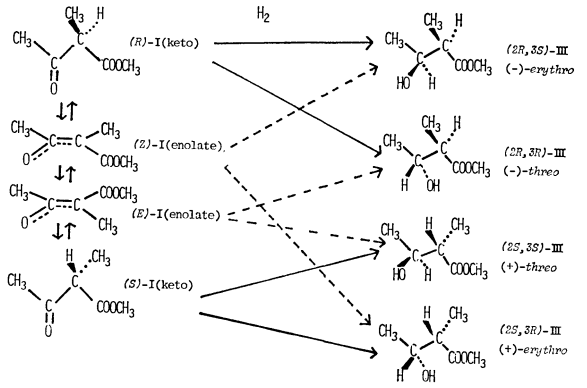
In this paper, we will present an account of the mode of the enantio-differentiation and evidence which may support the conclusion of our kinetic study with respect to the enantio-differentiating step.

Results and Discussion

The stereochemical relationship between the substrate and the products in the hydrogenation of I is shown in Scheme 1.

The results of the hydrogenations of I as well as of methyl 2-ethyl-3-oxobutyrate (II) and MAA over various sorts of modified nickel catalysts are summarized in Table 1.

The amounts of the four stereoisomers, calculated from the data of Table 1, are listed in Table 2, together with following values: **2R**=(2*R*,3*R*)-III+(2*R*,3*S*)-III, **2S**=(2*S*,3*R*)-III+(2*S*,3*S*)-III, **3R**=(2*R*,3*R*)-III+(2*S*,3*R*)-III, **3S**=(2*R*,3*S*)-III+(2*S*,3*S*)-III, configuration excess at the C-2 position: |**2R**−**2S**|/(**2R**+**2S**), and configuration excess at the C-3 position: |**3R**−**3S**|/(**3R**+**3S**).



Scheme 1.

The activated nickel powders prepared either by the thermal decomposition of nickel formate (DNi) or by the hydrogenolysis of nickel oxide (HNi), gave better optical yields than did Raney nickel (RNi). As for modifying reagents, the enantio-differentiating abilities were in the order of tartaric acid≫valine≈glutamic acid. These greneal features were the same as those found in the hydrogenation of MAA[3].

Enantio-differentiating Step. The preliminary experiment indicated that an authentic IIIe or IIIt was not epimerized nor racemized under the conditions used for the hydrogenation of I to III.

Therefore, in the course of the reaction, the configuration of the product is determined before the addition of hydrogen to the substrate. Thus, the distribution of stereoisomers in the product directly reflects the equilibrium situation of the substrate, as is shown in Scheme 1.

If the distribution of stereoisomers is different between the modified and unmodified catalysts, the difference indicates the interaction between the substrate and the modifying reagent prior to the step of the hydrogen addition.

As may be seen in Tables 1 and 2, with asymmetrically modified catalysts the values of |**2R**−**2S**|/(**2R**+**2S**) always deviated from zero despite the use of racemic

Table 1. Hydrogenation of the β-keto ester with a modified nickel catalyst

I, and the ratio of *erthro*-III/*threo*-III was also changed from the value obtained with an unmodified catalyst.

Thus, it is evident that the relative amounts of (*S*)-I (keto) and (*R*)-I(keto), or of (*Z*)-I (enolate) and (*E*)-I (enolate), are changed by the modifying reagent. The present results clearly show the existence of an interaction between the substrate and the modifying reagent before the hydrogenation of the adsorbed substrate took place. In Tables 1 and 2 it can also be seen that the catalyst giving a larger $|\mathbf{2S}-\mathbf{2R}|/(\mathbf{2S}+\mathbf{2R})$ value always gave a larger $|\mathbf{3R}-\mathbf{3S}|/(\mathbf{3R}+\mathbf{3S})$ value. In connection with this relation, the increase in *erythro*-III resulted in an increase in the optical purity of both *erythro*- and *threo*-III. These facts strongly suggest that the configurations at both the C-2 and C-3 positions of III were determined by the same process involving the formation of a substrate-modifying reagent complex. Therefore, the stereochemistry of the product is considered to be fixed at the adsorption step of the substrate.

This conclusion is very compatible with that obtained from our kinetic study.[1]

Mode of Enantio-differentiation. The use of (*R*,*R*)-tartaric acid–MHNi gave the best results with respect to the optical yield and the diastereomer excess. The amounts of stereoisomers produced were in the order of 2*S*,3*R*≫2*R*,3*R*≈2*R*,3*S*>2*S*,3*S*. According to the physicochemical studies, tartaric acid is adsorbed on the catalyst with one of its carboxyl groups; the other carboxyl group and two hydroxyl groups are essentially free from the catalyst surface.[4] The two hydroxyl groups of tartaric acid are expected to play an important role in interacting with the substrate.[5] The excellent enantio-differentiation obtained in the combination of tartaric acid and I as well as MAA can be attributed to the two-point interaction with hydrogen bondings between the modifying reagent and the substrate.

When the substrate takes a keto form, the co-adsorbed species with the best-fitting interaction between I and tartaric acid on the catalyst surface gives the complex shown in Fig. 1, in which the carbonyl group to be hydrogenated faces the catalyst with its *si*-face and the configuration at the C-2 position is *S*, so that the methyl group at the C-2 position is remote from the catalyst. The large deviation of the $|\mathbf{2R}-\mathbf{2S}|/(\mathbf{2R}+\mathbf{2S})$ value from zero indicates that the substrate originally having the 2*R* configuration is converted to the 2*S* configuration in order to make this favorable complex. The addition of hydrogen to this complex gives (2*S*,3*R*)-III.

When the substrate takes an enolate form, the complex of (*Z*)-enolate with (*R*,*R*)-tartaric acid shown in Fig. 2 is the best fitting one. This complex also gives (2*S*,3*R*)-III.

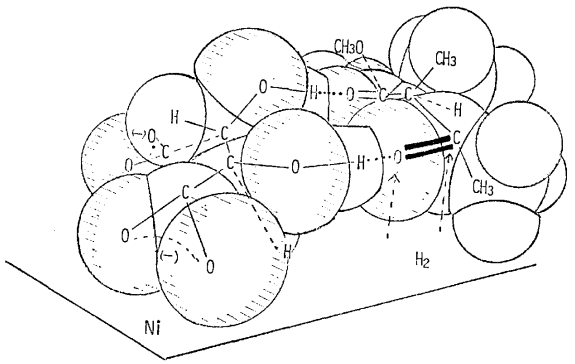

Fig. 1. Schematic representation of the complex between I(keto form) and (*R*,*R*)-tartaric acid on the MNi catalyst. The complex gives (2*S*,3*R*)-III by the attack of hydrogen from the catalyst-side (*si*-face attack)

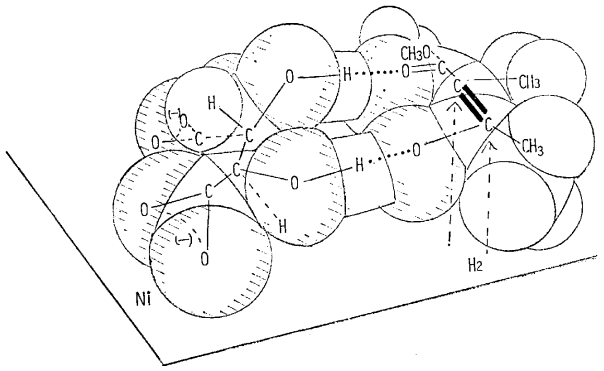

Fig. 2. Schematic representation of the complex between I(enolate) and (*R*,*R*)-tartaric acid on the MNi catalyst. The complex gives (2*S*,3*R*)-III by the attack of hydrogen from the catalyst-side (*si*-face attack).

Thus, the predominant formation of (2*S*,3*R*)-III may be well explained by both of the models. Although it is not clear whether the substrate is hydrogenated in a keto or an enolate form, the mode of the differentiation was found to be well understood without specifying the form of the substrate to be hydrogenated.

The quantitative discussion of the amounts of minor isomers is difficult at present, since the distribution of stereoisomers depends on the relative amount of the unmodified part of the catalyst.[1b] The difference in the results with MRNi and MHNi may be expected to arise in part from the difference in the unmodified part of the catalyst.

The use of (*R*,*R*)-tartaric acid–MNi always gave the 3*R*-isomer in a large excess in the hydrogenation of I as well as those of II and MAA (entries 8 and 9 in Table 2). Thus, it seems that the same mode of interaction between the substrates and the modifying reagent is involved in the enantio-differentiating hydrogenation of β-keto esters with tartaric acid–MNi.

Experimental

The analytical GLC was carried out with a Shimadzu GC-4A-PF gas chromatograph using a 3 m, 5 mm o.d. glass column packed with 15% Ucon 50-HB-2000 on Chromosorb W at the stated temperature. The preparative GLC was carried out with a Shimadzu GC-3HA instrument using a 6 m, 8 mm o.d. stainless column packed with the same packing.

The ^{1}H-NMR spectra were taken with a JEOL-FX-100 spectrometer.

The optical rotations were measured with a Perkin Elmer 241 polarimeter.

Substrate. Methyl 2-methyl-3-oxobutyrate (I) was prepared from methyl acetoacetate and methyl iodide in the presence of sodium methoxide. A slight excess of methyl acetoacetate was used in order to minimize the formation of methyl 2,2-dimethyl-3-oxobutyrate. From 850 g of methyl acetoacetate and 993 g of methyl iodide, 752 g of crude I containing 8% of methyl acetoacetate and 5% of methyl 2,2-dimethyl-3-oxobutyrate was obtained. To 750 g of crude I, 50 g of freshly prepared $Ni(OH)_2$ was added, after which the mixture was stirred for 5 days at room temperature. After removing the insoluble matter by filtration, the filtrate was mixed with 10 g of Raney nickel and allowed to stand overnight at room temperature. After the solid had been removed, the resulting liquid was dried over magnesium sulfate and then distilled under reduced pressure to give 680 g of purified I; bp 88—90 °C/20 mmHg. A GLC (at 90 °C) analysis indicated 95% purity. Also, there were 4% of methyl 2,2-dimethyl-3-oxobutyrate and 1% of methyl acetoacetate.

Methyl 2-ethyl-3-oxobutyrate (III) (bp 75—80 °C/20 mmHg was prepared by the same procedure except for the use of ethyl bromide instead of methyl iodide.

Catalyst. The catalyst from nickel formate (DNi): Well-dried nickel formate prepared from nickel chloride and sodium formate was thermally decomposed at 250—300 °C under a pressure of 20—25 mmHg for 1 h. Reduced nickel oxide (HNi): This was obtained by the reduction of nickel oxide with hydrogen at 350 °C for 1 h. The nickel oxide used for this work was obtained by the dehydration (at 500 °C for 4 h) of nickel hydroxide prepared from nickel nitrate and sodium hydroxide. No active catalyst was obtained from nickel oxide of a commercial grade. Raney nickel (RNi): Raney alloy (Kawaken Fine Chemical Co., Ni 40% Al 60%) was leached with sodium hydroxide in the way previously reported.[1]

Modification of the Catalyst. Each catalyst was soaked in a 1% solution of a modifying reagent adjusted to pH 4.1 with 1 M sodium hydroxide at 85 °C for 1 h. The amount of the modifying solution used was 120 ml per gram of the catalyst.

After the removal of the solution by decantation, the modified catalyst was washed successively with a 60 ml/(g catalyst) portion of water, two 300 ml/(g catalyst) portions of methanol, and a 60 ml/(g catalyst) portion of THF.

Solvent. THF was used as a solvent of the hydrogenation. Commercial THF was dried over NaH overnight and was then distilled under a nitrogen atmosphere.

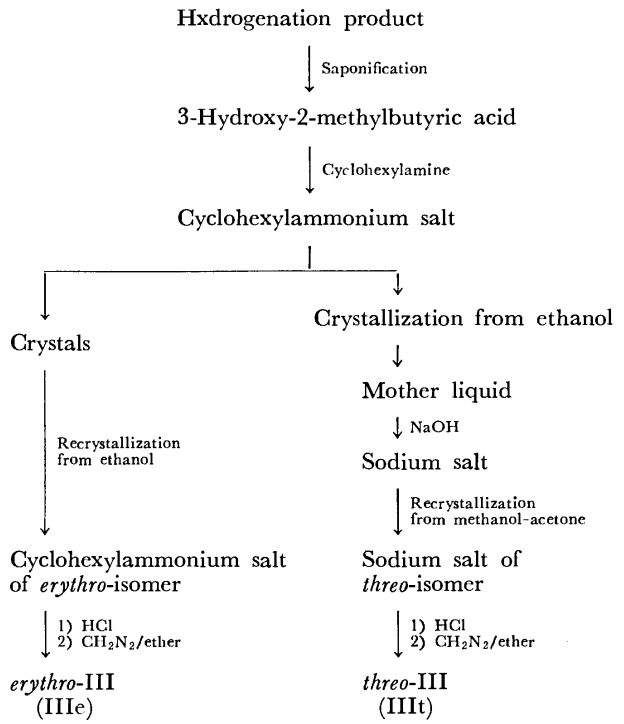
Hydrogenation of I. In an autoclave (1000 ml capacity), I (100 g) in 300 ml of THF with 1.5 g of acetic acid was hydrogenated over 8 g of a modified catalyst under an initial hydrogen pressure of 110 kg/cm^2 at 120 °C until no more consumption of hydrogen was observed. After the removal of the catalyst, the product was subjected to flash distillation under reduced pressure.

Determination of Stereoisomers in the Hydrogenation Product of I. The flash-distilled hydrogenation product essentially consisted of two components, *erythro*-III (IIIe) and *threo*-III (IIIt), accompanied by less than 5% of an unidentified impurity. The relative amounts of the *erythro* isomer; D_e=

$\frac{\text{IIIe}}{\text{IIIe}+\text{IIIt}}$, and the threo isomer; $D_t=\frac{\text{IIIt}}{\text{IIIe}+\text{IIIt}}$, were determined from the peak area of the analytical GLC (115 °C). The retention times of IIIt and IIIe were 21.6 min and 23.4 min respectively.

The separation of IIIe and IIIt in the reaction product was carried out by the method reported in our previous paper.[6]

The process of separation is illustrated in Scheme 2.



Scheme 2.

The isolated IIIe and IIIt were subjected to the polarimetric determination of their optical purity $(OY)_e=[2S3R-2R3S/(2S3R+2R3S)]\times 100$ and $(OY)_t=[2R3R-2S3S/(2R3R+2S3S)]\times 100$ as a methanol solution (c 5). The values were calculated based on the reported values: $[\alpha]_D^{20}$, (2*S*,3*S*)+36.80° (c 5, methanol) and (2*S*,3*R*), +14.32° (c 5, methanol).[6]

The distribution of each stereoisomer in the reaction product was calculated as follows:

$$2S3R(\%) = D_e \times \left(\frac{100+(OY)_e}{2}\right)$$

$$2R3S(\%) = D_e \times \left(\frac{100-(OY)_e}{2}\right)$$

$$2R3R(\%) = D_t \times \left(\frac{100+(OY)_t}{2}\right)$$

$$2S3S(\%) = D_t \times \left(\frac{100-(OY)_t}{2}\right)$$

The recrystallizations of the authentic sodium *threo*-3-hydroxy-2-methylbutyrate and cyclohexylammonium *erythro*-3-hydroxy-2-methylbutyrate with this separation process under the same conditions resulted in no change in the optical rotations. Thus, the optical purity of diastereomers in the hydrogenation product was proved to be the same as that of the isolated diastereomers.

The Stereochemical Stability of IIIe and IIIt in the Presence of a Catalyst and Hydrogen. An authentic optically active IIIe or IIIt was shaken with MNi under a hydrogen pressure of 100 kg/cm² at 100 °C for one day. The subsequent GLC and polarimetric determination of the recovered IIIe or IIIt indicated that no epimerization and racemization took place on this treatment.

Hydrogenation of II. In an autoclave (100 ml capacity), II (12.5 g) in 25 ml of THF and 1.5 g of acetic acid were hydrogenated over 1 g of the modified catalyst in the way described above.

Determination of Stereoisomers in the Hydrogenation of II. The analytical GLC (140 °C) of the product showed two peaks at the retention times of 7.4 min and 8.8 min.

The two components were isolated by the preparative GLC. The compound with a shorter retention time (7.2 min) in the analytical GLC (140 °C) showed the NMR ($CDCl_3$, TMS) assigned to $\underset{(b)}{CH_3}-\underset{(e)}{\underset{|}{C}}(\underset{(g)}{H})(\underset{(d)}{H})-\underset{(c)}{\underset{|}{C}}(\underset{(a)}{CH_2CH_3})-\underset{(f)}{COOCH_3}$; δ, 0.93 (3H, t, J=7.1 Hz, (a)), 1.23 (3H, d, J=6.3 Hz, (b)), 1.64 (2H, m, (c)), 2.33 (1H, m, (d)), 2.45 (1H, d (broad), (e)), 3.73 (3H, s, (f)), 3.91 (1H, m, (g)).

The compound with a longer retention time (8.8 min) in the analytical GLC (140 °C) showed NMR ($CDCl_3$, TMS) δ, 0.91 (3H, t, J=7.1 Hz (a)), 1.19 (3H, d, J=6.4 Hz, (b)), 1.66 (2H, m, (c)), 2.35 (2H, overlapped two signals, (d) and (e)), 3.72 (3H, s, (f)), 3.90 (1H, broad, (g)).

The compound with a shorter retention time was determined to be *threo*-IV (IVt) by the comparisons of its retention time with that of IIIt[6] or ethyl *threo*-3-hydroxy-2-propylbutyrate[7] and of its NMR spectra with those of ethyl *threo*- and *erythro*-3-hydroxy-2-propylbutyrate.[7]

The ratio in the amounts of *threo*-IV: D_t and *erythro*-IV: D_e was determined by the analytical GLC.

The NMR spectra of IVe and IVt taken in the presence of Eu(hfmc)$_3$ showed two signals of H(f), which correspond to those of the enantiomers. Thus, the enantiomer excess (*e.e.*) of each diastereomer was determined from the relative peak area of the H(f) signals of the solution containing 10 mg of IVe or IVt and 25 mg Eu(hfmc)$_3$ in 500 μl of $CDCl_3$.

The absolute configuration at C-3 of IVe with the low-field H(f) signal and that of IVt with the high-field H(f) signal was assigned to the S-configuration by the use of Horeau's method.[6,8]

When the enantiomer excess of each diastereomer is expressed by *e.e.*(%)=[peak area (high-field)−peak area (low-field)]/peak area (high-field+low-field)×100, the distribution of each stereoisomer is calculated as follows:

$$2R3R(\%) = D_t \times \left(\frac{100+(e.e.)_t}{2}\right)$$

$$2S3S(\%) = D_t \times \left(\frac{100-(e.e.)_t}{2}\right)$$

$$2S3R(\%) = D_e \times \left(\frac{100-(e.e.)_e}{2}\right)$$

$$2R3S(\%) = D_e \times \left(\frac{100+(e.e.)_e}{2}\right)$$

The authors wish to express their gratitude to Professor Yoshiharu Izumi, Osaka University, for his many helpful discussions and suggestions in the course of this work. The work was supported partially by a Grant-in-Aid from the Ministry of Education (No. 203522).

Kinetics of the Reaction of α-Chloro Aliphatic Acids with Aqueous Ammonia[1)]

Yoshiro OGATA,* Atsushi KAWASAKI, Yasuhiko SAWAKI, and Yuya YAMAUCHI
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received November 30, 1978)

The kinetics of the reaction of α-chloro aliphatic acids (CAA's) with aqueous ammonia to form the corresponding α-amino acids and α-hydroxy acids have been studied by measuring the produced chloride ion. The observed rate for CAA's having COOH on a *s*-C (*s*-CAA's) is expressed as: $v=(k_1+k_2[NH_3]_{ex})[CAA]$, while the rate for CAA having COOH on a *t*-C (*t*-CAA): $v=k_1[CAA]$. These results together with previous observations indicate that the mechanism changes with substrate, *i.e.*, pure S_N2 type for chloroacetic acid to pure S_N1 type for α-chloroisobutyric acid. The exclusion of α-lactone mechanism and the effect of carboxylato group are discussed. The reactivity of ammonia toward α-chloro aliphatic acids is as twice as that of hydroxide ion.

The ammonolysis of α-halo aliphatic acids is an important method for preparation of α-amino acids.[2-4)] Generally, α-chloro aliphatic acids (**1**) are treated with a large excess of aqueous ammonia to give α-amino acids (**2**) accompanied by α-hydroxy acids (**3**). (See Eq. 1.)

Cheronis and Spitzmuller[5)] have reported the effect of molar ratio, temperature, and pH on the yields for this ammonolysis, but not the kinetics and mechanism. We have reported the kinetics for the ammonolysis of chloroacetic acid, where the rate law was: $v=k[NH_3][ClCH_2CO_2H]$, suggesting S_N2 mechanism.[6)] But this nucleophilic mechanism may vary with the change of branching at α-position from primary to tertiary.

The present study was undertaken to obtain some information on the kinetics of the reaction of α-chloro aliphatic acids having COOH on *s*-C and *t*-C (abbreviated as *s*-CAA and *t*-CAA, respectively) with aqueous ammonia, and the change of mechanism with structure. The role of carboxylate ion is discussed.

Results and Discussion

Ammonolysis was conducted at 60 °C in aqueous ammonia, and the produced chloride ion was measured to follow the rate of reaction. The reaction gave α-amino acids (**2**) along with α-hydroxy acids (**3**). The products ratios are shown in Table 1.

$$\underset{\text{(1)}}{R^1R^2CCO_2H\ (Cl)} + \text{aq } NH_3 \longrightarrow \underset{\text{(2)}}{R^1R^2CCO_2H\ (NH_2)} + \underset{\text{(3)}}{R^1R^2CCO_2H\ (OH)} \quad (1)$$

General Kinetics of the Ammonolysis. α-Chloro aliphatic acids were treated with over tenfold excess of ammonia. The rate of ammonolysis was first-order in the acid. For the determination of the order with respect to ammonia, the rate constant was measured at constant concentration of α-chloro aliphatic acid and various concentrations of ammonia. The observed rate constants are in Table 2. The plot of the observed rate constants against the initial concentrations of ammonia gave a straight line with an intercept at $[NH_3]_{ex}=0$. Therefore, the rate equation consists of first- and second-order terms, where $[\ ]_{ex}$ means excess concentration to that of CAA.

$$\frac{d}{dt}[Cl^-] = (k_1+k_2[NH_3]_{ex})[CAA] \quad (2)$$

Here, k_1 was evaluated from the intercept of the plot and k_2 from the slope. The results are shown in Table 3. The α-amino acids and α-hydroxy acids produced in the reaction show that the ammonolysis and hydrolysis occur competitively.

Table 1. Product ratio for ammonolysis of α-chloro aliphatic acids (**1**) (See Eq. 1)

	R^1	R^2	$[CAA]_0=0.1$ M $[NH_3]_{ex}=5.1$ M
1a	H	Me	**2a** : **3a** = 83 : 17
1b	H	Et	**2b** : **3b** = 73 : 27
1c	H	*i*-Pr	**2c** : **3c** = 39 : 61
1d	Me	Me	**2d** : **3d** = 14 : 86

s-CAA's. The rate equation for *s*-CAA's (**1a**, **1b**, and **1c**) can be expressed as Eq. 2. (Table 3.) The second-order rate constants decrease in the order; R^2: Me>Et≫*i*-Pr.

The order is due to inductive effect as well as steric effect. Especially, the steric effect is important for the reaction of 2-chloro-3-methylbutyric acid (**1c**). The transition state, crowded with leaving chloride ion, attacking ammonia, and carboxylato and isopropyl groups, reduced the second-order rate constants (k_2).

The accompanying hydrolysis was confirmed by the isolation of α-hydroxy acids. The rate of hydrolysis for α-chloropropionic acid (**1a**) was measured. The rate equation was expressed as

$$v = (0.35+0.76[OH^-])[CH_3CH(Cl)CO_2H]\times 10^{-5} \quad \text{at 60 °C.} \quad (3)$$

Therefore, ammonolysis of secondary α-chloro aliphatic acids is a "border line case" between S_N2 and S_N1.

t-CAA. In contrast to *s*-CAA's, *t*-CAA, α-chloroisobutyric acid (**1d**), has a rate independent of the concentration of nucleophiles.

$$\frac{d}{dt}[Cl^-] = k_1[(CH_3)_2C(Cl)CO_2H] \quad (4)$$

The first-order rate constant is greater than that for analogous secondary substrates. α-Amino acid (**2a**) is the main product of the reaction of α-chloro-

a) k'_1: hydrolysis rate constants for α-chloro carboxylates.

propionic acid (**1a**) with aqueous ammonia, while α-hydroxy acid (**3d**) is the main product from α-chloroisobutyric acid (**1d**) with only a little α-aminoisobutyric acid (**2d**) (Table 1).

The activation parameters were calculated from k_1's at 60 and 30 °C. The energy of activation is 27.9 kcal mol^{-1} and the entropy of activation +9.3 e.u. This consistent with S_N1 mechanism, while the entropy of activation for ammonolysis of chloroacetic acid, where S_N2 mechanism operates, is −16 e.u.[6]

Grunwald and *et al.*[7] suggested α-lactone mechansim for the hydrolysis of α-bromopropionic acid on the basis of the first-order rate equation, the retention of configuration, common ion effect, and a small solvent effect. Hence, solvent effect was studied with our α-chloroisobutyric acid to examine the intermediacy of α-lactone. The results expressed as Grunwald-Winstein equation,[8] $\log(k/k_0)=mY$, are shown in Table 4.

The observed m value for the ammonolysis of α-

80 vol % MeOH	0.381	0.19

chloroisobutyric acid (m=0.27) is three times larger than that for the hydrolysis of α-bromopropionic acid (m=0.095); *i.e.*, the former reaction is more susceptible to solvent effect than the latter.[7]

Gripenberg *et al.*[9] proposed that a methyl group increased the unimolecular rate by a factor of 10^4 and a carboxylato group by a factor of about 10^3. Based on these values, we can expect a decrease of the unimolecular rate by a factor of 10 by substitution of carboxylato group for methyl group. Contrary to this expectation, the unimolecular rate constant for the methanolysis of α-bromopropionic acid (5.12×10^{-5} s^{-1} at 64.5 °C)[7] was found to be much larger than that of isopropyl bromide (5.0×10^{-8} s^{-1} at 64.5 °C).[7] This would be ascribed to the neighboring group participation of carboxylate ion in spite of the inductive rate-retarding effect of carboxylate ion. [The comparison of rate constants alone may not be appropriate to judge the participation].

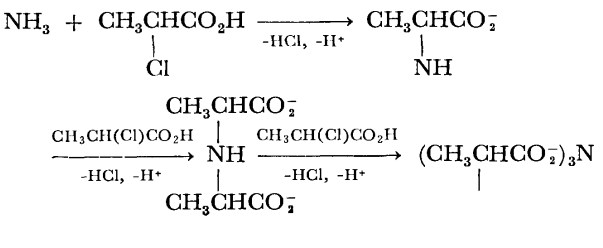
On the other hand, the observed first-order rate constant for the ammonolysis of α-chloroisobutyric acid (1.4×10^{-5} s^{-1} at 30 °C) was much lower than the reported value for the hydrolysis of *t*-butyl chloride (3.3×10^{-2} s^{-1} at 25 °C).[8] Thus, no acceleration by neighboring carboxylate ion was observed; hence the α-lactone mechanism is excluded for the present reaction. Namely, the ammonolysis of α-chloroisobutyric acid proceeds by S_N1 mechanism, *i.e.*, rate-determing dissociation of Cl$^-$ forming zwitter ion $Me_2\overset{+}{C}COO^-$, where carboxylate ion acts as a weaker electron-releasing group than methyl group. The change of mechanism to S_N1 in isobutyric acid may be ascribed to the high stabilization of carbonium ion by the presence of two Me and a solvated COO$^-$.

Subsequent Reaction of α-Chloropropionic Acid with Ammonia. Ammonolysis of α-chloropropionic acid is a consecutive reaction. The kinetics for the reaction of α-chloropropionic acid with α-aminopropionate or α,α′-iminodipropionate ion were studied. The rate constants are listed in Table 5.

Table 5. Rate constants for the reaction of α-chloropropionic acid with α-aminopropionate and α,α′-iminodipropionate ions in aqueous solution at 60±0.1 °C

$v=(k_1+k_2[\text{Amino compound}])$ **[1a]**

Amino compound	$k_1\times10^5$ (s^{-1})	$k_2\times10^5$ (M^{-1} s^{-1})
NH_3	0.68	0.94
$CH_3\underset{\underset{NH_2}{\vert}}{C}HCO_2^-$	0.12	3.1
$(CH_3\underset{\underset{\vert}{}}{C}HCO_2^-)_2NH$	0.33	1.7



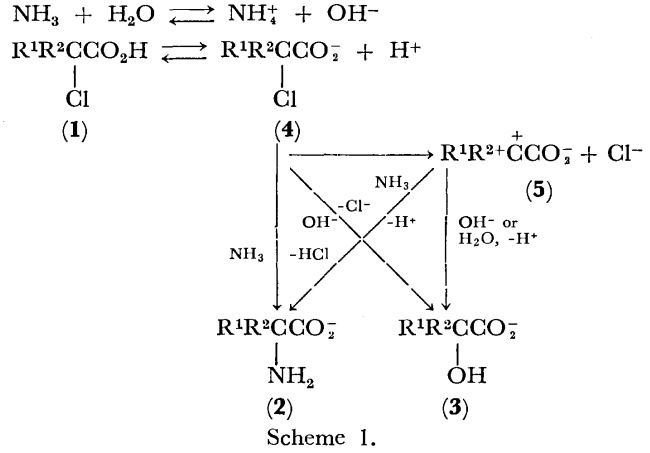
α-Aminopropionate ion having an α-carboxylatoethyl group ($CH_3\underset{\underset{\vert}{}}{C}HCO_2^-$) is about three times as reactive as ammonia in k_2, while α,α′-iminodipropionate ion is no more so stronger nucleophile than ammonia in spite of the presence of two α-carboxylatoethyl groups:

$$CH_3\underset{\underset{NH_2}{\vert}}{C}HCO_2^- \gtrsim (CH_3\underset{\underset{\vert}{}}{C}HCO_2^-)_2NH \gtrsim NH_3$$

We reported that the reactivity toward chloroacetic acid was in the order: $NH_2CH_2CO_2^-\simeq NH(CH_2CO_2^-)_2>NH_3$ in which the steric effect caused a slight decrease in the rate for iminodiacetate ion, compared with the rate for aminoacetate ion.[6] Similarly, a small reactivity of α,α′-iminodipropionate ion is due to the steric effect, because α-carboxylatoethyl group is much bulkier than carboxylatomethyl group.

In aqueous solution, the hydrolysis of α-chloropropionic acid is not negligible. (Eq. 3.) The rate constant for the hydrolysis of chloroacetic acid in an aqueous solution at 60 °C (7.67×10^{-5} s^{-1} M^{-1}) was reported to be *ca.*1/2 of that for the ammonolysis (15.0×10^{-5} s^{-1} M^{-1}).[10] We obtained the rate constants for hydrolysis (0.76×10^{-5} s^{-1} M^{-1}) and for ammonolysis (0.94×10^{-5} s^{-1} M^{-1}) of α-chloropropionic acid in an aqueous solution at 60 °C. Hence, the nucleophilicity of ammonia toward alkyl chloride is *ca.* 1.6 fold higher than that of hydroxide ion. But the relative nucleophilicity of OH$^-$ and NH_3 may depend on the structure of RX and the solvent. Though the Swain-Scott nucleophilicity parameter for ammonia is unavailable, aniline (n=4.49) is twice as reactive as hydroxide ion (n=4.20).[11] Ammonia seems to have the same reactivity as aniline.

Mechanism. The above observations suggest a following scheme for the reaction in an aqueous solution.



Scheme 1.

The primary reaction is a competition between ammonia and hydroxide ion for α-chloro aliphatic acid. In the ammonolysis of α-chloropropionic acid, a fall of pH by addition of ammonium chloride decreased the formation of lactic acid, which suggests that the hydrolysis proceeds by an attack of hydroxide ion.

The mechanism changes from S_N2 to S_N1, as the alkyl group varies from primary to tertiary. This result agrees with the earlier observation in the sol-

TABLE 6. CHANGE OF MECHAMISM WITH STRUCTURE

R^1	R^2	Mechanism
H	H	S_N2
H	Me	S_N2 + S_N1
H	Et	S_N2 + S_N1
H	*i*-Pr	S_N2 + S_N1
Me	Me	S_N1

volysis of alkyl halides.[12] The hydrolysis occurs competitively, and thus the yields of α-amino acids were lowered. The yields of α-amino acids decreased in the order: **2a>2b>2c>2d**. The results also support this mechanism. The hydrolysis can be suppressed on addition of ammonium chloride as was observed. In these reactions, the carboxylato group acts as a weaker electron-releasing group, but exerts no anchimeric assistance.

Experimental

Melting points were measured by a Yanagimoto micro-melting point apparatus and were corrected. Boiling points were uncorrected. IR spectra were recorded on a Perkin-Elmer 337 grating spectrophotometer, and NMR spectra on a Hitachi R-24B spectrometer.

Materials. Aqueous ammonia, nitric acid, hydrochloric acid, sodium hydroxide, ammonium chloride, α-aminoisobutyric acid, and alanine used were of guaranteed reagent grade. α-Chloropropionic acid was redistilled under vacuum before use: bp 92—93 °C/15 Torr (lit,[13] 82.5—83.5 °C/12 Torr; NMR (CCl_4) δ 1.70 (d, 3H, CH_3), 4.35 (q, 1H, CH).

Preparation of the Other α-Chloro Aliphatic Acids. 2-Chloro-3-methylbutyric, α-chlorobutyric, and α-chloroisobutyric acids were prepared by α-chlorination[14] of the corresponding acids. The corresponding aliphatic acid was reacted with a gaseous mixture of Cl_2–O_2 gas in a molar ratio of 1/2 in the presence of chlorosulfuric acid and chloranil at 120 °C for 6 h. The product was then extracted with ether, the organic layer being distilled to obtain α-chloro aliphatic acid. α-Chlorobutyric acid: bp 101—111 °C/27 Torr (lit,[15] 98 °C/10.5 Torr); NMR(CCl_4) δ 4.2 (t, 1H, CH), 2.5—2.0 (m, 2H, CH_2), 1.1 (t, 3H, CH_3); IR (neat) 1730 cm^{-1} (C=O), 625 (C–Cl). α-Chloroisobutyric acid: bp 97—99 °C/27 Torr; mp 29—30 °C (lit,[16] mp 28—30 °C); NMR (CCl_4) δ 1.75 (s); IR (neat) 1720 cm^{-1} (C=O), 615 (C–Cl). α-Chloroisovaleric acid: bp 108—109 °C/15 Torr (lit,[17] 125—126 °C/32 Torr); NMR (CCl_4) δ 4.05 (d, 1H, CH), 2.5—1.8 (m, 1H, CH), 1.10 (d, 6H, CH_3); IR (neat) 1720 cm^{-1} (C=O), 620 (C–Cl).

Preparation of α-Amino Acid. A mixture of α-chloro aliphatic acids (0.01 mol) and aqueous ammonia (5.2 M, 50 ml) was heated, in the case of α-chloropropionic and α-chlorobutyric acids. A mixture of 2-chloro-3-methylbutyric acid and aqueous ammonia 50 ml (28%) was reacted at room temperature for 3 weeks. The solution was evaporated under vacuum, and α-amino acids were recrystallized from aqueous methanol. The yields of isolated products were based on α-chloro aliphatic acids. Alanine: Yield 55%; NMR (D_2O/DSS) δ 4.2—3.8 (q, 1H, CH), 1.75 (d, 3H, CH); IR (KBr) 3200—3000 cm^{-1}, 2250 (NH_2), 1600 (CO_2^-). α-Aminobutyric acid: Yield 39%; NMR (D_2O/DSS) δ 4.15 (t, 1H, CH), 2.4—2.2 (m, 2H, CH_2), 1.5 (t, 3H, CH_3); IR(KBr) 3200—3000 cm^{-1} (NH_2), 1600 (CO_2^-). Valine: Yield 17%; NMR (D_2O/DSS) δ 3.55 (d, 1H, CH), 2.2—1.9 (m, 1H, CH), 1.0 (dd, 6H, CH_3); IR (KBr) 3200—3000 cm^{-1} (NH_2), 1600 (CO_2^-).

Preparation of α-Hydroxy Aliphatic Acid. An aqueous solution of α-chloro aliphatic acid (0.01 mol) and the equivalent amount of NaOH was refluxed for 24 h. The solution was acidified with HCl and extracted with ether (20 ml). The solution was evaporated to obtain α-hydroxy aliphatic acid. In the case of α-chloropropionic and α-chloroisobutyric acids, the solution was dried without acidification and α-hydroxy aliphatic acid sodium salts were obtained. Sodium lactate: NMR (D_2O/DSS) δ 4.2 (q, 1H, CH), 1.5 (d, 3H, CH_3). α-Hydroxybutyric acid: NMR (CCl_4) δ 7.10 (s, 1H, OH), 4.15 (t, 1H, CH), 2.2—1.9 (m, 2H, CH_2), 1.0 (t, 3H, CH_3); IR (KBr) 3450 cm^{-1} (OH), 1720 (C=O). 2-Hydroxy-3-methylbutyric acid: NMR (CCl_4) δ 7.15 (s, 1H, OH), 4.1 (d, 1H, CH), 2.2—2.0 (m, 1H, CH), 0.9 (dd, 6H, CH_3); IR (KBr) 3420 cm^{-1} (OH), 1720 (C=O). Sodium α-hydroxyisobutyrate: NMR (D_2O/DSS) δ 1.80 (s, CH_3); IR (KBr) 3440 cm^{-1} (OH), 1610 (CO_2^-).

The products were identified similarly by means of NMR in comparison with the authentic samples. The ratio of products of ammonolysis of α-chloropropionic and α-chloroisobutyric acids was estimated by NMR spectra of the reaction mixture after evaporation of the solvent. In the case of α-chlorobutyric and 2-chloro-3-methylbutyric acids, the reaction mixture of α-chloro aliphatic acids and aqueous ammonia was acidified with aqueous HCl and extracted with ether. After evaporation of the solvent the molar ratio of α-amino acids to DMSO was estimated by NMR spectra of the residue of the aqueous layer. Similarly, the ratio's of α-hydroxy aliphatic acids to DMSO were estimated by that of the ether extract. Then, the ratio of products of ammonolysis of α-chlorobutyric and 2-chloro-3-methylbutyric acids was obtained in this way.

Preparation of α,α′-Iminodipropionic Acid. Alanine (25 g, 0.3 mol), 100 ml of aqueous NaOH (24 g, 0.6 mol), and 50 ml of aqueous α-chloropropionic acid (32 g, 0.3 mol) were mixed in a flask equipped with a reflux condenser at room temperature. The solution was refluxed for 24 h. Then, the aqueous solution was acidified with HCl and was washed with ether (50 ml×3) to extract lactic acid. After evaporation of aqueous layer in vacuum to dryness, α,α′-iminodipropionic acid was extracted with ethanol (1.5 l), the ethanol solution being condensed in vacuum and cooled. α,α′-Iminodipropionic acid was slowly crystallized, filtered, washed with cold ethanol, and recrystallized from water-ethanol-ether (1 : 2 : 1). 5.0 g of colorless crystals of α,α′-iminodipropionic acid was obtained: mp 236—238 °C (lit,[18] 238 °C); NMR (D_2O/DSS) δ 3.90 (q, d, 2H, CH), 1.55 (d,d, 6H, CH_3); IR (KBr) 3400 cm^{-1} (NH), 1720 (C=O), 1600 (CO_2^-). Found: C, 43.07; H, 6.45; N, 8.35%. Calcd for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

Kinetics. A solution of α-chloro aliphatic acid (5 ml) was added to an aqueous solution of amino compound (45 ml) in a glass-stoppered flask, which had reached thermal equilibrium in a thermostat. Aliquots (5 ml) were pipetted out at regular intervals of time and cold dilute nitric acid was added to stop the reaction. The chloride ion concentration was determined by the Volhard method.[19]

The rate constants for the reaction of α,α′-iminodipropionate ion and α-chloropropionic acid was rather inaccurate (±10%) because of the lower initial concentration of α,α′-iminodipropionate ion and a small amount of impurity (NaCl), which could not completely be eliminated, but the content of NaCl was determined and subtracted. The initial first-order rate constants (up to 20% conversion) were calculated by the least square method (r>0.98). The

% conversion of the reaction of NH_3 or OH^- was 30—50%. Probable error in rate constants was ±5%.

(Received October 7, 1978)

Solvolysis of a series of ring substituted *threo*-1-methyl-2-phenylpropyl brosylates has been carried out in *N,N*-dimethylacetamide (DMA) as solvent. Hammett treatment of the rate data indicated that the DMA solvolysis of the unsubstituted brosylate (**1c**) falls into the category of k_s pathway (100%). In order to gain further information of the nature of the k_s pathway, the DMA solvolysis of **1c** or **1c**-2-*d* (labeled at C(2)) has been conducted. The product distribution, effect of water content on it, the composition and deuterium distribution of recovered brosylate, kinetic isotope effect, and the deuterium distribution of product have been investigated. The products consisted of the olefins ((*E*)- and (*Z*)-2-phenyl-2-butenes, and 2- and 3-phenyl-1-butenes), and, in the presence of water in DMA, the carboxylates (*erythro*- and *threo*-1-methyl-2-phenylpropyl acetates) and the small amount of diastereomeric alcohols. The major product was (*Z*)-2-phenyl-2-butene, indicating the occurrence of *anti*-*E*1 process. The deuterium was substantially scrambled in each product. These findings suggest that the reaction proceeds through tight ion-pair and subsequent processes such as *anti*-*E*1, 2,1-phenyl and -hydride shifts, solvent capture, and *threo-erythro* interconversion take place competitively. In view of a substantial extent of intervention of such rearrangement, the involvement of nucleophilic solvent assistance is thought to be less probable in this k_s process.

The β-phenyl participation in solvolytic reactions has been one of interesting subjects in organic reaction mechanism for more than twenty years.[2] Cram has first proposed the phenonium ion as intermediate in the acetolysis of optically active *threo*- and *erythro*-1-methyl-2-phenylpropyl tosylates to account for the remarkable stereospecificity of the reaction.[3] For example, the acetolysis of the *threo*-substrate gave acetate (53% yield) with 94% retention of configuration, accompanied with the olefin formation (35%).[3]

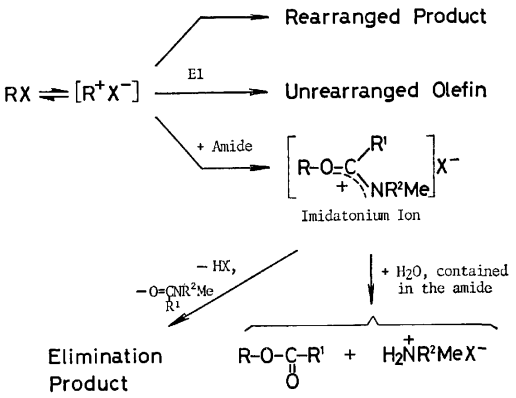
Winstein *et al.*[4] have shown, however, that the rate enhancement expected for the β-phenyl participation is generally quite small. In fact, when titrimetric rate is compared, the rate of the acetolysis of *threo*-1-methyl-2-phenylpropyl tosylate was 0.6 times the rate of *s*-butyl tosylate under the same conditions.[4]

Such an apparent discrepancy between rate data and stereospecificity of product has made it difficult to clarify the role of β-phenyl group in solvolytic reactions and, therefore, was the starting point of the current controversy.[2,5-13]

Schleyer and his collaborators[6] have recently suggested that the solvolysis of β-arylalkyl systems proceeds through discrete aryl-assisted (k_Δ) and/or aryl-unassisted (k_s) pathways. They have developed the method for the dissection of the observed rate constant (k_t) into its Fk_Δ and k_s components by the use of Hammett correlation.[6a]

The application of this approach[6a] to 2-aryl-1-methylpropyl system has been performed by Brown and Kim.[5e] They conducted the acetolysis of a series of ring substituted *threo*-1-methyl-2-phenylpropyl brosylates and found the existence of an excellent rate-product correlation, when $100Fk_\Delta/k_t$ value was compared with the yield of retained acetate. However, since the rate ratio (k_Δ/k_s) of 12 for the unsubstituted derivative (**1c**) was too small to be ascribed to the mechanism involving the simultaneous formation of open and bridged ions,[6] they have proposed a mechanism involving an open tight ion-pair as a common intermediate to which both the aryl-assisted and the aryl-unassisted pathways compete,[5e,f] employing the original formulation of Shiner[14] and Sneen.[15]

In a series of our investigations with respect to the nature of carboxamide solvolysis for typical secondary cycloalkyl systems, 4-*t*-butylcyclohexyl,[16] 7β-methylbicyclo[3.3.1]non-3β-yl,[17] and *exo*-2-norbornyl[1] systems, it has been revealed that the reactions proceed through an initially formed tight ion-pair intermediate [R^+X^-] (classical) which undergoes various subsequent processes such as *E*1 reaction, solvent capture (formation of imidatonium ion), or rearrangements, as is outlined in Scheme 1.



R^1, R^2=H or Me

Scheme 1.

As a principal characteristic of the carboxamide solvolysis, it has been demonstrated that the carboxamides suppress the formation of rearranged products even when the substrate has a structure prone to rearrangement and, in addition, they accelerate *syn*-*E*1 process in the cyclic substrates[1,16,17] to result in an increase in the yield of unrearranged olefin. Based on such trends observed in the previous studies,[1,16,17] it was anticipated that a fraction of the k_Δ pathway

for **1c** might be suppressed in the carboxamide solvolysis as compared with that in the acetolysis.[5e] It appeared also of interest to examine whether the rate-product correlation, observed in the acetolysis,[5e] is observed or not in carboxamide solvolysis of such system.

In this paper, we report on a) the Hammett treatment of rate data for the DMA solvolysis of a series of ring substituted *threo*-1-methyl-2-phenylpropyl brosylates (**1a**—**g**), b) the products of the DMA solvolysis of the unsubstituted derivative **1c** in the presence of various amounts of water, c) the composition and deuterium distribution of the unchanged brosylate recovered from half-life reaction of C(2)-deuterated substrate **1c**-2-*d* in DMA solvent, d) deuterium distribution of the products produced from the DMA solvolysis of **1c**-2-*d*, and e) kinetic isotope effect for **1c**-2-*d* solvolysis in four carboxamide solvents, *i.e.*, *N*-methylformamide (NMF), *N*-methylacetamide (NMA), *N*,*N*-dimethylformamide (DMF), and *N*,*N*-dimethylacetamide (DMA). We also discuss the generality of the mechanism (Scheme 1) and the mechanistic problem[2,5-13] of 2-aryl-1-methylpropyl solvolysis, especially on the nature of the k_s process.

Results

Rate Study and Hammett Correlation for the DMA Solvolysis of ***1a***—***g***. The rates of solvolysis of **1a**—**g** in DMA solvent were determined titrimetrically in the same manner as reported.[1] All the kinetic runs exhibited first-order behavior over two to three half lives. Pyridine, added to neutralize liberated *p*-bromobenzenesulfonic acid, did not alter the rate, presumably indicating that the reaction proceeds through typical *E*1 or S_N1 mechanism. The rate constants and activation parameters are tabulated in Table 1. The Hammett plot for the rates of **1a**—**g** at 75 °C is shown in Fig. 1, together with that for the acetolysis[5e] for the purpose of comparison.

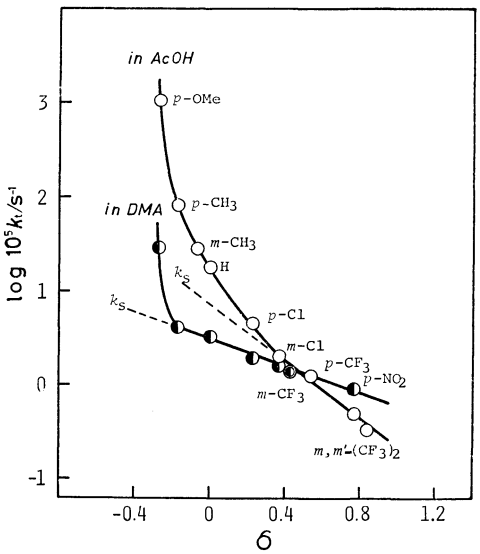

Fig. 1. Plot of $\log k_t$ (*thero*-2-aryl-1-methylpropyl brosylate) for the DMA solvolysis and acetolysis (Ref. 5e) *vs.* σ at 75 °C; ρ-value and correlation coefficient for the DMA line are −0.72 and 0.991, respectively.

A satisfactory linear relation was observed for all the substrates except for *p*-methoxyphenyl derivative **1a**. The k_s line was determined by a least-squares treatment to obtain the ρ-value of −0.72.[18] Unlike the acetolysis,[5e] the k_Δ pathway was suppressed in DMA solvent for *p*-tolyl derivative **1b** as well as the parent phenyl derivative **1c**. Thus the DMA solvolysis of **1c** turned out to be the case of 100% k_s solvolysis. This result is quite notable as compared with previously known solvolyses of unsubstituted phenyl derivatives in the system such as 2-aryl-1-methylpropyl,[5e] 2-aryl-1-methylethyl,[6a-c,19] or *trans*-2-arylcyclopentyl[5f] because these reactions are known to proceed more or less through the k_Δ pathway.

Product Distribution and Effect of Water Content for the DMA Solvolysis of **1c**. In the light of the results mentioned above, it is pertinent to investigate the nature of k_s pathway by the use of the DMA solvolysis of **1c**. The product distribution for such reaction was determined by the combined use of gas chromatography and ^1H NMR spectroscopy. As illustrated in Scheme 1, the carboxylates can be formed by rapid hydrolysis of the imidatonium ion. The stereochemistry of solvent capture on initial carbonium ion intermediate could be disclosed by efficient trapping of the imidatonium ion with water. This method has been successfully utilized in the previous works.[1,17] Thus the effect of water content in DMA solvent on the product distribution was examined and the results are summarized in Table 2 and illustrated in Fig. 2.

Similarly to the trends observed for cycloalkyl systems,[1,17] the olefins, (*Z*)-2-phenyl-2-butene (**7**), its (*E*)-isomer (**8**), 2-phenyl-1-butene (**9**), and 3-phenyl-1-butene (**10**), were produced in completley dried DMA. Among them, the (*Z*)-butene **7** was a major product (≈66%). The carboxylates, *erythro*-1-methyl-2-phenylpropyl acetate (**11**) and its *threo*-isomer (**12**), were obtained only in the presence of water and they should stem from the reaction of water and the imidatonium ions, [*erythro*-R-DMA]$^+$OBs$^-$ (**4**) or [*threo*-R-DMA]$^+$OBs$^-$ (**5**), respectively (*vide infra*). These imidatonium ions can be derived from the tight ion-pair intermediate (**2**) by solvent capture (Scheme 3, *vide infra*).

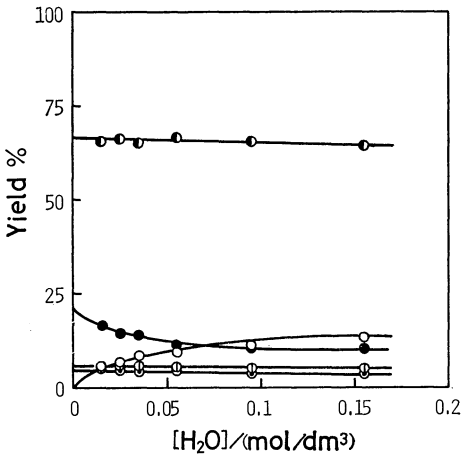

Fig. 2. Effect of water content of DMA on the formation of (*Z*)-olefin **7** (◐), (*E*)-olefin **8** (●), 2-phenyl-1-butene **9** (⊙), 3-phenyl-1-butene **10** (◫), and *erythro*-acetate **11** (○) at 75.0 °C.

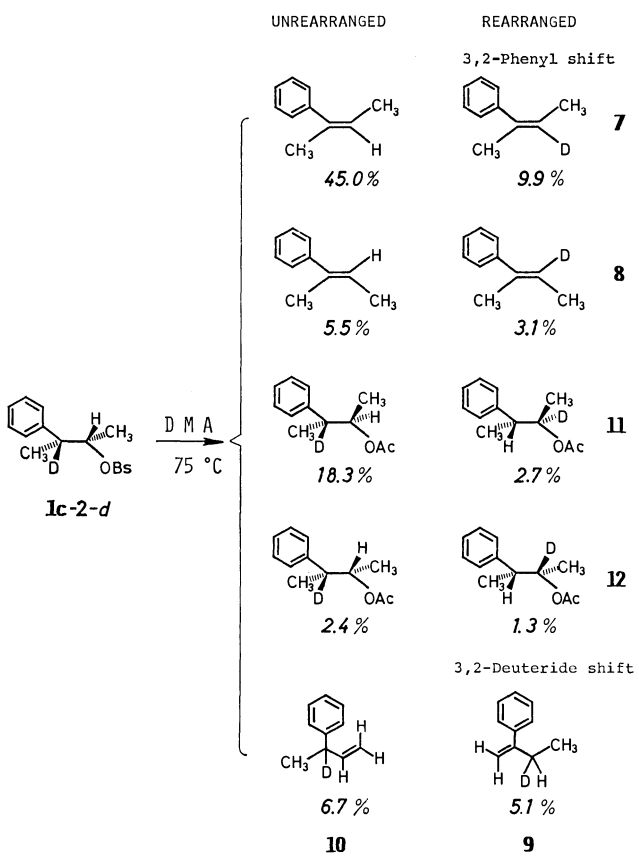

Scheme 2.

Deuterium Distribution in the Products for DMA Solvolysis and for Acetolysis of **1c**-2-d. In the investigation of the product composition, the occurrence of 2,1-hydride shift in the tight ion-pair **2** is disclosed in view of the formation of 2-phenyl-1-butene **9**. However, 2,1-phenyl shift, if any, is impossible to be proved, unless the substrate labeled at C(2). Thus, by the use of **1c**-2-*d*, the extent of phenyl migration can be estimated from the deuterium distributions in the phenylbutenes, **7**, **8**, and **10**, and also in *erythro*- and *threo*-1-methyl-2-phenylpropyl acetates, **11** and **12**.

The DMA solvolysis of **1c**-2-*d* has been carried out at 75.0 °C, and for the purpose of comparison the acetolysis of **1c**-2-*d* was also conducted at the same temperature. The isotopic distribution was measured by means of ^1H NMR spectroscopy in the Fourier transform mode for all the products, which were separated by the use of column chromatography, preparative gas chromatography, and/or an appropriate chemical transformation. The extent of rearrangement, *i.e.*, 2,1-hydride shift and 2,1-phenyl shift, was calculated from the product composition and the deuterium distribution in the each product. The results are summarized in Table 3 and illustrated in Scheme 2.

Partial Solvolysis and the Analysis of Unchanged Brosylate for the DMA Solvolysis of ***1c*** *and* ***1c***-2-d. Previously, we have demonstrated that 4-*t*-butylcyclohexyl tosylate undergoes rearrangement of the type *cis*⇄*trans* during the solvolysis in phenol–benzene,[20] acetic acid,[21] 60% (v/v) acetone–water,[21] and NMA solvent.[16] From these results, it is anticipated that the rearrangement of **1c** from *threo* to *erythro* configuration may also occur during the DMA solvolysis. Accordingly, the half-life solvolysis of **1c** or **1c**-2-*d* has been carried out in the absence and the presence of added pyridinium brosylate at 75.0 °C and then the unchanged brosylate was isolated. The recovered brosylate was converted into the corresponding alcohol keeping the stereochemical integrity by the use of sodium–naphthalene reagent in tetrahydrofuran at −78 °C. The alcohol was analyzed to determine its isomer composition and/or deuterium distribution by means of gas chromatography and ^1H NMR spectroscopy. As expected, it was disclosed that *threo* brosylate **1c** rearranges to *erythro* brosylate (**13**) during the solvolysis. The results are summarized in Table 4.

Kinetic Isotope Effect. In order to obtain information on the transition-state structure for the DMA solvolysis of **1c**, the isotope effect on the DMA solvolysis rate of **1c** by deuteration of C(2) position was examined at 75.0 °C. Such examination has been also made on the other carboxamide solvolyses in DMA, NMA, and NMF. These results are tabulated in Table 5 together with data pertinent to appropriate systems. The β-effect ($k_H/k_{\beta\text{-}D}$) of 1.93 (DMA solvolysis) appears to be comparable to the values reported for solvolyses of the systems[22–24] with the tertiary β-hydrogen.

Table 5. Summary of isotope effect for solvolysis of secondary alkyl sulfonates bearing tertiary β-hydrogen[a)]

Substrate	Solvent (T/°C)	$k_H/k_{\beta-D}$	Olefin Yield %[b)]	Ref.

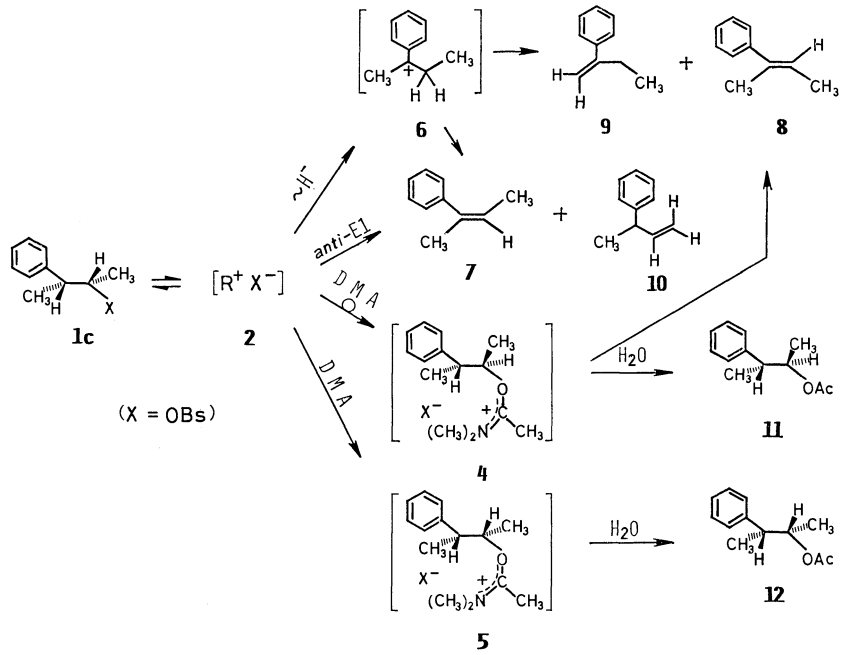
Discussion

Possible Reaction Scheme Drawn on the Basis of the Product Distribution and Effect of Water Content on It for DMA Solvolysis of ***1c***. The yields of the (*Z*)-2-olefin **7** and 1-butenes, **9** and **10**, are virtually unchanged even with the increase in the water content (Fig. 2). In contrast, the yield, though much less, of (*E*)-2-butene **8** decreases with the increase in water content, but becomes actually invariant at the water concentration higher than 0.15 mol/dm³. On the other hand, the yield of the *erythro*-acetate **11** increases complementing the decrease in the yield of (*E*)-2-butene **8**, and it also becomes constant (Fig. 2), although the increase in the acetate **11** yield can not completely compensate the (*E*)-olefin **8** yield.

From these features of the yield variation caused by increase in water content, the following reaction pathway can be depicted as one of the simplest reaction schemes: a) the (*Z*)-olefin **7** and 1-butene **10** are formed from the tight ion-pair **2**, b) the *erythro*-acetate **11** can be produced by the reaction of water with *erythro*-imidatonium ion **4**, partially compensating the decrease in the yield of the (*E*)-2-butene **8**, c) thus the (*E*)-2-butene **8** comes actually from the *erythro*-imidatonium ion **4**, but a part of it can be formed through a rearranged cation (**6**) which is formed after 2,1-hydride shift of the tight ion-pair 2, d) the 1-butene **9** can also be produced from the rearranged cation **6**, and e) the *threo*-acetate **12**, although in very low yield, is derived from the *threo*-imidatonium ion **5**. These pathways are illustrated in Scheme 3, which are essentially the same as those depicted in Scheme 1.

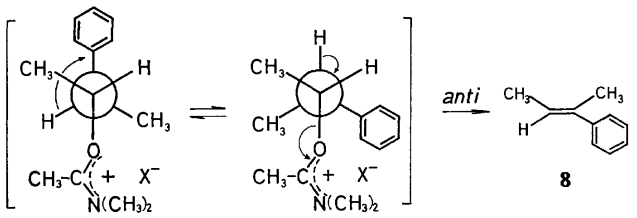
The formation of conjugated terminal olefin **9** suggests the occurrence of 2,1-hydride shift to produce tertiary benzylic cation **6**. Cram and Sahyun[25)] have demonstrated that the acetolysis of a tertiary benzylic system, *i.e.*, 1-methyl-1-phenylpropyl chloride, affords the olefins in 94% yield which consist of (*Z*)-olefin **7**, (*E*)-olefin **8**, and 1-butene **9** in the ratio 9 : 68 : 23. If the same ratio for Saytzeff orientation could be expected on the reaction of benzylic cation **6** in the solvolysis of **1c** in DMA containing 0.155 mol/dm³ of water, the yields of **7** and **8** can be predicted to be 1.4% and 10.6%, respectively, based



Scheme 3.

on the observed yield (3.6%) of **9** (Table 2; $[H_2O]=0.155$ mol/dm^3). Since the observed yield of (*E*)-olefin **8** (10.1%) is in line with the predicted value (10.6%), most of the (*E*)-olefin **8** should be derived from the benzylic cation **6** (Scheme 3). Obviously, most of (*Z*)-olefin **7** stems from the tight ion-pair **2**, since the yield of **7** is far greater than the expected value (1.4%) from the cation **6**.

Stereochemistry of E1 Reaction. When stereochemistry of the *E*1 reaction was compared with the cyclic systems, in which elimination takes place in *syn*-fashion,[1,16,17] the remarkable contrast was observed. Namely, the formation of (*Z*)-olefin **7** should be ascribed to *anti*-*E*1 reaction from the tight ion-pair **2**; the (*E*)-olefin formation from the imidatonium ion **4** should also be attributed to *anti*-elimination (Scheme 4).



Scheme 4.

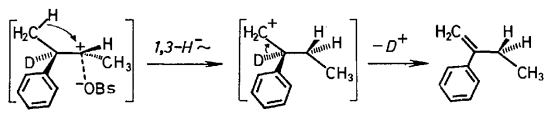
In the solvolysis of cyclic substrates,[1,17] which bear no β-hydrogens antiperiplanar to the leaving group, the *syn*-elimination was predominant. However, the tight ion-pair derived from open-chain compound **1c** can rotate easily to afford the conformers capable of both *syn*- and *anti*-eliminations. In the case of solvolysis of 1-methylpropyl-2-*d* tosylate in a dipolar aprotic solvent, *i.e.*, nitrobenzene, Skell and Hall[26] have demonstrated that it gives predominantly *syn*-elimination product. In contrast, the DMA solvolysis of **1c** afforded overwhelmingly *anti*-elimination product **7**. Thus, this feature seems to be characteristic of DMA solvolysis of the open-chain system. Further scrutinies are required to explain such contrasting stereochemical results.

Occurrence of 2,1-Phenyl Shift in the Tight Ion-pair 2. Appearance of the label at C(3) positions of the olefins **7** and **8**, or at C(1) positions of the acetates **11** and **12** (Table 3 or Scheme 2) clearly indicates that 2,1-phenyl shift occurs not only during the acetolysis with k_Δ process, but also actually *in the DMA solvolysis of 100% k_s process.*

It is notable that the isotopic scrambling in the retained acetate **12** is far from complete equilibration (Table 3) for the DMA solvolysis. Consequently, the formation of this product can not be ascribed to intervention of a symmetrical intermediate expected for the phenonium ion pathway. Although Harris *et al.*[6a] have suggested that even the deactivated substrates of a series of ring substituted 2-phenylethyl system undergo a small, almost undetectable amount of aryl participation (Fk_Δ), the present result rules out such a possibility so far as the DMA solvolysis of **1c** is concerned.

Based on the dual mechanism ($k_\Delta+k_s$) of solvolysis of β-arylalkyl system,[6] the inverted acetate should be produced by k_s pathway without any scrambling, unless the starting material has first undergone the k_Δ ionization at first and subsequently internal return to give a scrambled substrate. The DMA solvolysis of **1c** has already turned out to have no k_Δ process but 100% k_s pathway as is shown in Fig. 1 and mentioned above. Therefore, the scrambling of the isotope in the inverted acetate **11** can not be compatible with the previously proposed k_s process without the scrambling.[6]

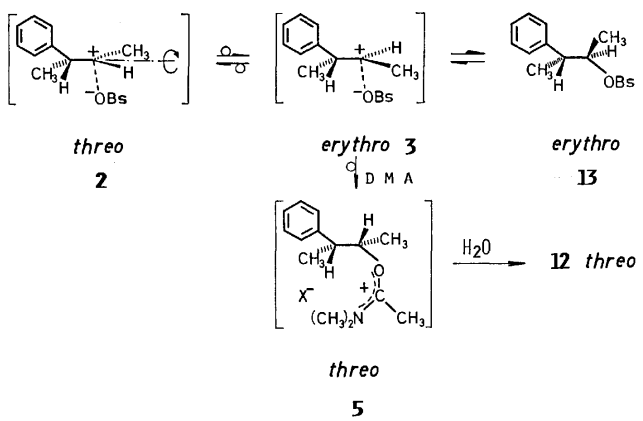
The extent of rearrangement of the DMA solvolysis and the acetolysis was calculated from the data in Table 3 and Scheme 2, to be 22% and 47%, respectively. Thus, DMA solvent much more suppresses the rearrangement accompanied the solvolytic reaction of the brosylate **1c**-2-*d* than does acetic acid as solvent. For the formation of 2-phenyl-1-butene **9**-3-H_2 (Table 3), 3,1-hydride shift and the subsequent deuteron elimination is conceivable (Scheme 5).



Scheme 5.

Possible Double Inversion Course for the Formation of Retained Acetate 12. As is shown in Table 4, it was revealed that *threo* brosylate **1c** rearranges to *erythro* brosylate (**13**) to a substantial extent (5.9%) during the half-life solvolysis of **1c** in DMA solvent. Furthermore, when the similar analysis has been conducted for the solvolysis in the presence of two-fold excess of pyridinium brosylate, the essentially same result was obtained (Table 4), indicating that the *threo-erythro* interconversion is caused intramolecularly by the rotation of C(1)–C(2) bond at the stage of the tight ion-pair intermediate **2** (Scheme 6). Such crossover by an internal rotation in the tight ion-pair has also been suggested by Cram and Knight[27] and by Collins *et al.*[28]

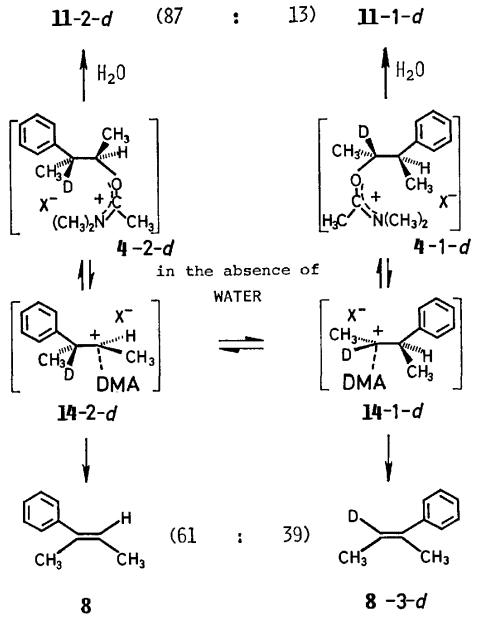
On the basis of Scheme 6, it is deduced that the formation of the retained acetate **12** in the DMA solvolysis of **1c** should be ascribed, at least partly,



Scheme 6.

to the double inversion course; *erythro*-type ion-pair intermediate (**3**) should intervene between *threo*-type ion pair intermediate **2** and *threo*-type imidatonium ion **5** (Scheme 3).

The Formation of (E)-Olefin 8 from [erythro-*R-DMA*]$^+$-*OBs*$^-$. As mentioned in the foregoing section (Scheme 4), in completely dried DMA, [*erythro*-R-DMA]$^+$OBs$^-$ **4** undergoes *anti*-elimination to give the (*E*)-olefin **8**. The yield of the (*E*)-olefin **8** (8.6% in the wet solvolysis (Table 3)) was increased to 26.7% in the dry solvolysis (Table 3), whereas *erythro*-acetate **11** was reduced from 21% to trace amount under dried conditions. The amounts of the (*E*)-olefin **8** arising from [*erythro*-R-DMA]$^+$OBs$^-$ **4**, therefore, can be calculated to be 18.1%(=26.7—8.6%). If [*erythro*-R-DMA]$^+$OBs$^-$ **4** undergoes *anti*-elimination keeping the same isotopic distribution as that in the *erythro*-acetate **11** (Table 3), the deuterium content at C(3) position of (*E*)-olefin **8** produced can be estimated to be about 20%.[29] However, as is indicated in Table 3, it actually amounts to 38%. This result suggests that [*erythro*-R-DMA]$^+$OBs$^-$ **4** must undergo further 2,1-phenyl shift before it is transformed to (*E*)-olefin **8**. The following scheme can be drawn to account for the situation (Scheme 7), and this scheme appears to be essentially the same as that proposed previously to explain the observed chemical behavior of imidatonium ion derived from *exo*-2-norbornyl cation.[30]



Scheme 7.

Nature of the k_s Pathway. Brown and Kim[5e] have made a detailed comparison of the characteristics of the k_s pathway in secondary β-arylalkyl solvolysis with the corresponding characteristics of primary β-arylalkyl solvolysis in terms of ΔS^*, secondary isotope effect, ρ-value, lyate ion effect, or hydride shift. They have noted on the basis of these features that no evidence for strong nucleophilic solvent participation in the secondary k_s process could be detected and these were considered to lend support to an S_N1 mechanism. The present findings as regards ΔS^* value (Table 1), ρ-value (Fig. 1), the cocurrences of 2,1-hydride as well as 2,1-phenyl shift and of intramolecular *threo-erythro* interconversion of the brosylate **1c** (Table 4), or no effect of added pyridine on the rate (*vide supra*), are in line with the implications pointed out by Brown and Kim.[5e]

An additional mechanistic aspect could be drawn on closer inspection of the data for the kinetic isotope effects (Table 5) and the product distributions (Tables 2 and 3), as in the following. First, the olefins arising from the process involving 2,1-hydride shift are not in large amount (Tables 2 and 3), probably suggesting that the relatively large β-deuterium isotope effect for the DMA solvolysis of **1c** (Table 5) can not be ascribed to hydrogen participation.[23,24] Secondly, although the olefins arising from *anti*-elimination is predominant, its yield is not sufficiently reduced by C(2)-deuteration, clearly indicating that the intervention of *E*2 process can be eliminated from the present reaction: the yield of (*Z*)-olefin **7** is 64.7% for **1c** and is 54.6% for **1c**-2-*d* (Tables 2 and 3). Thus the isotope effect for the DMA solvolysis of **1c** should be predominently associated with a specific transition-state structure of the reaction. Thirdly, when the isotope effects for the solvolysis of **1c**-2-*d* in the four carboxamide solvents (NMF, NMA, DMF, and DMA) are compared with the yields of (*Z*)-olefin **7** in the corresponding reactions (Table 6), the larger isotope effect is accompanied with the increased yield of the (*Z*)-olefin **7**. This may indicate that the magnitude of kinetic isotope effect for the carboxamide solvolysis of **1c** could be correlated to the degree of hyperconjugative stabilization[14,22] of the transition state with antiperiplanar conformation, from which (*Z*)-2-phenyl-2-butene **7** is formed. The larger isotope effect probably means the more stabilization of antiperiplanar transition state which, in turn, results in the more (*Z*)-olefin **7**.

As regards the relatively high β-deuterium isotope effect in the acetolysis of *cis*-2-phenylcyclopentyl tosylate (Table 5), Kim and Brown[22] have recently suggested that it may be the result of the combined effects of hyperconjugative destabilization of the transition state, leading to tight ion-pair intermediate, and of destabilization of the subsequent transition state, leading to tertiary benzylic cation, by the difficulty

Table 6. Comparison between kinetic isotope effect and amount of *anti*-elimination product for the carboxamide solvolyses of **1c**-2-*d* at 75 °C

Amide	$k_H/k_{\beta-D}$[a]	Yield % of (*Z*)-olefin **7**[b]
DMA	1.93±0.01	54.9
DMF	1.67±0.01	43.5
NMA	1.63±0.02	43.0
NMF	1.41±0.01	35.5

a) The k_H values for DMF, NMA, and NMF solvolyses were 4.79, 18.1, and 38.5 (10^{-5} s^{-1}), respectively; for the DMA solvolysis, see Table 1. b) Data for the labeled substrate,

of loosening a C–D bond compared to a C–H bond.

In conclusion, all the results presented above can be explained by the mechanism involving the tight ion-pair intermediate **2** which undergores intramolecular processes, such as *anti-E*1 reaction, phenyl or hydride shift, and *threo-erythro* interconversion, competitively with the solvent capture leading to the imidatonium ion **4**. These rearrangements require that the site of the carbonium center opposite to the leaving group should not be shielded by solvent molecule at the stage of the tight ion-pair intermediate **2**, and this, in turn, suggests that the reaction may proceed without any kinetically significant involvement of nucleophilic solvent assistence.[6h]

Experimental

Melting points determined on a Yamato Model MP-1 apparatus were uncorrected. NMR spectra were recorded in $CDCl_3$ at 60 MHz on a Hitachi R-24 spectrometer or at 100 MHz on a JEOL JNM-MH 100 or JEOL JNM-FX 100 instrument. Infrared spectra were taken on a Hitachi EPI-S2 spectrometer. Both analytical and preparative GLC's were performed on a Hitachi K-53 gas chromatograph equipped with a thermal conductivity detector. The following columns were used: A, 3 m×3 mm 5% Benton 34+5% DIDP on 60—80 mesh Neopak 1A; B, 3 m×3 mm 10% PEG 6000 on 60—80 mesh Chromosorb W (NAW). Silicic acid powder (Wakogel C-200) was employed for column chromatography. For the alumina column, Merck neutral alumina (activity 1) was used.

Materials and Solvents. *N,N*-Dimethylacetamide (DMA) of commercial grade was purified in the same manner as described in the previous paper.[1] $NaBD_4$ (97.0 D-atom %) was supplied from CEA. Ether, diglyme, THF, and pentane used for reaction medium or recrystallization were distilled over sodium–benzophenone ketyl before use. Boron trifluoride etherate was distilled over CaH_2. Pyridine was distilled over BaO. All other solvents and reagents were of reagent grade and liquid materials were distilled before use.

(E)-2-Aryl-2-butenes. These olefins were prepared in the same manner as reported by Brown and Kim.[5e] Treatment of 2-butanone with arylmagnesium bromide (except for *p*-nitrophenyl derivative) gave 2-aryl-2-butanol which was dehydrated to a mixture of (*Z*)- and (*E*)-2-aryl-2-butenes and 2-aryl-1-butene according to the procedure of Garbisch[31] except for *p*-methoxyphenyl derivative for which dehydration was carried out by the use of $POCl_3$–pyridine mixture (0 °C—room temp, 24 h). The olefin mixture was subjected to fractional distillation by the use of a spinning band column and fractions containing gas chromatographically pure (*E*)-2-aryl-2-butene component were collected.

threo-*3-Aryl-2-butanols.* Various *threo*-3-aryl-2-butanols were prepared from corresponding (*E*)-2-aryl-2-butenes by hydroboration-oxidation reaction following the reported method.[5e]

threo-*2-Aryl-1-methylpropyl Brosylates.* These substrates were synthesized from the corresponding alcohols in the usual manner.[32] The melting points of the various brosylates were 100—101 (**1a**), 97—98 (**1b**), 94—95 (**1c**), 91—93 (**1d**), 69.5—71.5 (**1e**), and 50—51 °C (**1f**) (lit, 97.5—98.5 (**1a**),[33] 97—98 (**1b**),[5e] 93—93 (**1c**),[3] 94—95 (**1c**),[5e] 68.5—69.5 (**1d**),[5e,34] 91.5—92.5 (**1e**),[5e,34] and 50—51 °C (**1f**)[5e]).

threo-*3-(p-Nitrophenyl)-2-butanol and Its Brosylate.* *threo*-3-(*p*-Nitrophenyl)-2-butanol was prepared from the parent phenyl derivative similarly to the method reported for the preparation of *cis*-2-(*p*-nitrophenyl)cyclopentanol;[22] *threo*-3-Phenyl-2-butanol (3.1 g, 20.6 mmo) was treated with acetic anhydride (24 cm^3) and pyridine (48 cm^3) at room temp overnight. Workup gave acetate in 95% yield. The acetate was dissolved in a mixture of acetic acid (7 cm^3) and acetic anhydride (10 cm^3) and the resulting solution was cooled to 0 °C. To the solution was added a solution of 90% nitric acid (2 cm^3) in acetic acid (5 cm^3) under stirring at 0 °C and the mixture was stirred for 2 h at 0 °C and overnight at room temp. The mixture was poured on ice–water (100 cm^3) and extracted several times with ether. The ether solutions were washed successively with 10% K_2CO_3 and water, and dried (Na_2SO_4). Evaporation of the ether gave *threo*-1-methyl-2-(*p*-nitrophenyl)propyl acetate in 70% yield (3.3 g). The acetate was dissolved in methanol containing 0.5 mol/dm^3 HCl (43 cm^3) and the resulting solution was heated under reflux for 8 h. After workup, *threo*-3-(*p*-nitrophenyl)-2-butanol was distilled to afford practically pure sample (2.7 g, 98% yield).

The brosylate **1g** was synthesized from this alcohol in the usual manner.[32] **1g**: mp 104—105 °C; NMR (60 MHz) δ=1.25 (d, 3H, CH_3), 1.32 (d, 3H, CH_3), 3.0 (quintet, 1H, C(2)–H), 4.74 (quintet, 1H, C(1)–H), 7.4 (d, 2H, Ar–H), 7.5 (s, 4H, Ar–H), and 8.0 ppm (d, 2H, Ar–H); IR (KBr); 1520 (NO_2), 1350 (SO_2), 1185, and 1170 cm^{-1} (SO_2).

Found: C, 46.50; H, 3.71%. Calcd for $C_{16}H_{16}O_5NSBr$: C, 46.39; H, 3.89%.

threo-*3-Phenyl-2-butan-3-d-2-ol and Its Brosylate* ***1c***-*2*-d. Deuterium at C(2) position was introduced by deuterioboration of (*E*)-2-phenyl-2-butene. Deuterioboration–oxidation was carried out according to the standard procedure.[35] Diborane-d_6 was generated externally from $NaBD_4$ and borontrifluoride etherate in diglyme and was supplied into THF solution of the olefin. After workup, the labeled alcohol was purified by column chromatography (alumina) to give pure alcohol in 90% yield.

Brosylate **1c**-2-*d* was prepared from this alcohol in the usual manner.[32] **1c**-2-*d*: mp 93—94 °C (lit,[5e] 93—94 °C for unlabeled sample). ^1H (100 MHz) and ^{13}C (25 MHz) NMR spectra of **1c**-2-*d* indicated an isotopic purity of 97% and the absence of deuterium scrambling throughout its synthesis.

Product Analysis. A reaction mixture for product study was prepared by the same method as described in the previous paper:[1] [ROBs]=0.075 mol/dm^3; [C_5H_5N]=0.077 mol/dm^3 (in an ampoule). The sealed ampoule was then kept at desired temperature for ten half-lives. The contents of the ampoule were poured on ice-water and extracted with pentane–ether mixture. The pentane–ether solution was washed several times with water, dried ($MgSO_4$), and condensed to 1—2 cm^3 by the use of 30-cm distillation column packed with glass helices. The condensed solution was subjected to GLC on column A. An excellent separation was effected on the column for all the products except for (*Z*)-2-phenyl-2-butene **7** and 3-phenyl-1-butene **10** which were identical in their retention times. The yields of (**7**+**10**), **8**, **9**, **11**, **12**, *erythro*-3-phenyl-2-butanol, and *threo*-3-phenyl-2-butanol were calculated from GLC's peak areas, calibrating based on molar response ratios. The mixture of (**7**+**10**) was isolated by means of preparative GLC and their composition was analyzed from the integral intensities of NMR (100 MHz in the Fourier transform mode) signals of methyl protons for the respective olefins **7** and **10**.

Partial Solvolysis and Isolation of Unchanged Brosylate. The brosylate recovered from half-life solvolysis of **1c** or **1c**-2-*d* in DMA solvent was isolated from the reaction mixture by

repeated recrystallization at −50 °C (ether–pentane). Colorless crystalline brosylate was obtained easily in 98% yield based on the theoretical amount. The brosylate was kept under high vacuum (0.05 mmHg) at room temperature overnight. ^{1}H NMR spectrum (100 MHz) of the sample exhibited no sign of contamination with the solvolysis products.

Cleavage Reaction of the Recovered Brosylate with Sodium–Naphthalene.[36] A mixture of naphthalene (0.49 g, 3.67 mmol), sodium (0.088 g, 3.67 mmol) cut in small pieces, and THF (12.5 cm^3) was stirred at room temp for 2 h to result in a dark-green solution of sodium–naphthalene anion radical, and then, was cooled to −78 °C. To this solution was added the brosylate (0.226 g, 0.61 mmol), recovered from half-life solvolysis of **1c**-2-*d* in DMA solvent, in THF (3 cm^3) by the use of a syringe through a septum. Within a minute, a critical color changeocc urred (from dark green to reddish black). The excess of reagent was quenched by the addition of THF–water (1 : 1, 5 cm^3). Workup followed by column chromatography (silicic acid, 20 g) afforded a diastereomeric mixture of 3-phenyl-2-butanol in 80% yield: column was eluted successively with benzene and CH_2Cl_2, and the mixture was collected from the fractions eluted with CH_2Cl_2. The mixture was subjected to preparative GLC (column B) which provided *threo*- and *erythro*-3-phenyl-2-butanols without mutual contamination. Deuterium distribution in each alcohol was determined by means of ^{1}H NMR spectroscopy as described below.

Isotopic Distribution Analysis. The deuterium distribution analysis of the solvolysis products was carried out by means of ^{1}H NMR spectroscopy (100 MHz) in the Fourier transform mode. A sample for NMR assay was prepared under dry nitrogen in order to avoid contamination with moisture. The combined use of column chromatography and preparative GLC, and, in some cases, an appropriate chemical transformation, provided the compounds that meet the purpose of the determination of isotopic distribution.

Although the separation of the (*Z*)-olefin **7** and nonconjugated terminal olefin **10** could not be effected on GLC, all the NMR signals due to the both olefins **7** and **10** were advantageously well-resolved. The isotopic distribution in **7** and **10** was, therefore, determined from the NMR spectrum of the mixture which was isolated by means of preparative GLC. For the (*Z*)-olefin **7** a decrease in the integral intensity of the olefinic proton signal was measured. The partial labeling at C(3) position was easily verified by the observation that the C(4)-protons (methyl) gave clean doublet and singlet signals when C(1)-protons (methyl) were irradiated.

As for the 3-phenyl-1-butene **10**, integral intensities of the benzylic proton and internal vinylic proton were measured and a relative intensity of the respective signals to that of methyl protons was calculated. The methyl proton signal, consisted of doublet and triplet, and complicated multiplet of the terminal vinylic proton signals indicated that deuterium was situated at both C(2) and C(3) positions of the olefin **10**.

With regard to 2-phenyl-1-butene **9**, relative integral intensity of the methylene protons (C(3)) to that of methyl or olefinic protons was determined. The methyl signal consisted of "doublet of sharp triplets" and clean triplet. The former is considered to be due to the presence of adjoining –CHD– group to which the methyl protons are coupled and the latter undoubtedly indicates that the methyl protons are involved in spin-spin coupling with the adjoining $-CH_2-$ group. The integral intensity ratio for the olefinic proton *cis* to phenyl, that *trans* to phenyl, and the methyl protons was strictly 1 : 1 : 3. These findings clearly demonstrated that partial deuteron loss, though in small amount, actually occurred during the formation of the olefin **9**.

The deuterium content at C(3) position of the (*E*)-olefin **8** was determined similarly to that described above for the (*Z*)-olefin **7**.

The mixture of diastereomeric acetates **11** and **12** was isolated by column chromatography (silicic acid) and was hydrogenolyzed ($LiAlH_4$) into a mixture of *threo*- and *erythro*-3-phenyl-2-butanols from which each isomer was separated by preparative GLC. Deuterium distribution was determined by measuring the relative integral intensity between the C(2)–H and C(3)–H signals. The partial labeling at both positions was easily observed in splitting pattern of the two methyl signals.

The deuterium distribution in each isomer of the diastereomeric 3-phenyl-2-butanol obtained from the cleavage reaction of the recovered brosylate (*vide supra*) was also determined similarly to the method mentioned above.

The operating parameters employed in ^{1}H NMR spectroscopy in the Fourier transform mode were a spectral width of 1000 Hz, a 45° pulse, pulse repetition of 10 s, and an appropriate number of pulses to provide spectra with almost same S/N ratio for each sample. The integral intensity of each observed nuclei was directly computed on a JEOL 980B computer with SYSTEM Q/D PROGRAM FAFT08/11. The spectra of each unlabeled sample were recorded by the use of above-mentioned parameters and were used in order to calibrate the integral intensity obtained for each labeled sample.

Kinetic Measurements. The procedure was described in the previous paper.[1] In determining the kinetic isotope effect, simultaneous rate measurements of two compounds, the parent and C(2)-deuterated compounds **1c** and **1c**-2-*d*, were carried out. Three individual set of such determinations were conducted.

New Ring Opening Reactions of Oxiranes with Aryl Carboxylates

Kazutoshi FUNAHASHI

Central Research Institute, Teijin Ltd., Asahigaoka, Hino, Tokyo 191

(Received October 13, 1978)

Oxiranes reacted with aryl esters in the presence of base. The reactions of aryl carboxylates with alkyloxiranes afforded almost exclusively 1-alkyl-2-(aryloxy)ethyl carboxylates, whereas the reactions with aryloxiranes gave a mixture of 1-aryl-2-(aryloxy)ethyl carboxylates and 2-aryl-2-(aryloxy)ethyl carboxylates. Similar results were also obtained in the reaction with *S*-aryl thiocarboxylates and diaryl carbonates. The rate of reaction between phenyl acetate and phenoxymethyloxirane (PMO) in the presence of tributylamine (n-Bu_3N) as a catalyst has been determined in the temperature range 110 to 130 °C and may be expressed by $-d[PMO]/dt=k_2[n\text{-}Bu_3N]\cdot[PMO]$. The apparent activation energy calculated from the Arrhenius plots is 85.8 kJ/mol. The reaction catalyzed by tributylamine is assumed to proceed through zwitter ions, n-$Bu_3\overset{+}{N}CH_2CH(R)O^-$ and n-$Bu_3\overset{+}{N}CH(R)CH_2O^-$, which attack aryl carboxylate.

Oxiranes have drawn much attention recently as starting compounds in chemical syntheses. Reports[1] have been published on the addition reactions of oxiranes, but not on the addition reactions of aryl carboxylates to oxiranes. In this paper it will be reported that an aryl carboxylate adds to an oxirane to give addition products, **1** and **2**, as shown in Scheme 1. The reaction is catalyzed by bases such as pyridine, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), tributylamine, and potassium *t*-butoxide. When the substituent R^2 on the oxirane is an electron donating group, *e.g.* methyl or phenoxymethyl, cleavage of the oxirane occurs almost exclusively at the β-position, yielding **1** as the product. When R^2 is an aryl group, a mixture of **1** and **2** is obtained. When aryl carbonates or *S*-aryl thiocarboxylates are employed as aryl esters, similar results are observed.

The reaction rate has been determined in the reaction of phenoxymethyloxirane (abbreviated to PMO hereafter) with phenyl acetate in the presence of tributylamine as the catalyst. A probable reaction mechanism has been proposed.

Results and Discussion

The reaction between an aryl carboxylate and alkyloxirane in the presence of a base produced almost exclusive β-cleavage of the oxirane to form aryl carboxylate adducts **1a—g**, as shown in Scheme 1.

Scheme 1.

In several reactions, a very small amount of compound resulting from α-cleavage was found in the products. The structure of the products has been confirmed by a comparison of the isolated reaction products with authentic samples prepared by other routes, the results of which are shown in Table 1. For example, the compound isolated from the reaction product of phenyl acetate with methyloxirane has been identified as 1-methyl-2-phenoxyethyl acetate by comparison with an authentic sample of **1b**, synthesized through other routes.[2] In the case of $R^2=CH_2OC_6H_5$ in Scheme 1, the reaction product was similarly compared with an authentic sample of **1c** synthesized separately[5] and found to be pure **1c**.

The reaction between a phenyl carboxylate and phenyloxirane however caused both α- and β-cleavage of the oxirane to form a mixture of the phenyl carboxylate adducts **1** and **2**. For example, the reaction of phenyloxirane with phenyl acetate produced 2-phenoxy-1-phenylethyl acetate **1h** and β-phenoxyphenethyl acetate **2h**, which were identified by comparison with authentic samples derived from 2-phenoxy-1-phenylethanol and 2-phenoxy-2-phenylethanol, each synthesized by Guss's procedure.[3] The ratio of **1** to **2** formed in the reaction has been determined by gas chromatography, the results of which are shown in Table 2.

A similar reaction occurred when diphenyl carbonate was used as an aryl ester.

a) The molar ratio of substrates: phenyl ester/phenyloxirane/catalyst=1/1/0.015. b) Total isolated yield.

For example, diphenyl carbonate reacted with methyloxirane to give a mixture of **3b**, **4b**, and **5b**, the proportion of **3b** being more than 91% in the product, which was determined by integration of the NMR peak. Product **3b** was identified by comparison with an authentic sample prepared by the reaction of phosgene with 1-phenoxy-2-propanol.

The reaction of *S*-phenyl thiobenzoate with oxirane was conducted in order to determine the reaction mechanism and was found to proceed as follows.

$$PhCOSPh + \overset{\diagdown\!\diagup}{O} \longrightarrow PhCO_2CH_2CH_2SPh$$

6

Product **6** was identified by comparison with an authentic sample prepared by the benzoylation of 2-(phenylthio)ethanol. No other products, for example, *S*-(2-phenoxyethyl) thiobenzoate, were detected. The reaction proved therefore that the aryl ether oxygen of the product came from the aryloxyl group in the aryl carboxylate.

Reaction Rates. The reaction rate was investigated as follows. PMO was chosen as the oxirane and allowed to react with phenyl acetate in nitrobenzene in the presence of tributylamine. The reaction rate was determined by measurement of the unchanged PMO.

Reaction Rate and Catalyst Concentration and Reaction Temperature. The rate of reaction was found to be in linearly related to the PMO concentration as shown in Figs. 1 and 2, *i.e.*,

$$-d[PMO]/dt = k_1[PMO] \quad (1)$$

where k_1 is the first order rate constant and [PMO] is the concentration of PMO.

The reaction rate was also determined at various [PMO]/[Phenyl acetate] ratios and was found to be first order with respect to [PMO] and zero order with respect to [Phenyl acetate] as may be seen in Fig. 1.

The relation between k_1 and catalyst concentration was determined by changing the concentration of n-Bu_3N. A linear relationship passing through the origin was established as shown in Fig. 3.

Eq. 1 may be rewritten:

$$-d[PMO]/dt = k_2[cat][PMO] \quad (2)$$

where k_2 is the second order rate constant and [cat] is the concentration of catalyst. k_2 is equal to $k_1/[cat]$.

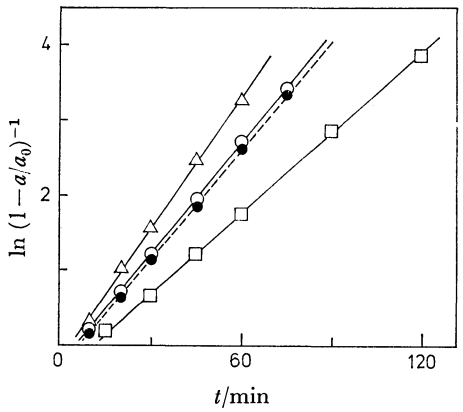

Fig. 1. First-order decrease of [PMO] in the reaction of AcOPh with PMO. The reactions were carried out at various temperatures, △; 130 °C, ○; 120 °C, □; 110 °C, in the reaction system containing AcOPh (1.6 mol), PMO (1.6 mol), *n*-Bu_3N (0.08 mol), and $PhNO_2$ with which the total weight of the system was adjusted to 1 kg. ●; Instead of using 1.6 mol of AcOPh in the system, 3.2 mol was used at 120 °C. a_0; $[PMO]_{initial}$, a; $[PMO]_{decreased}$.

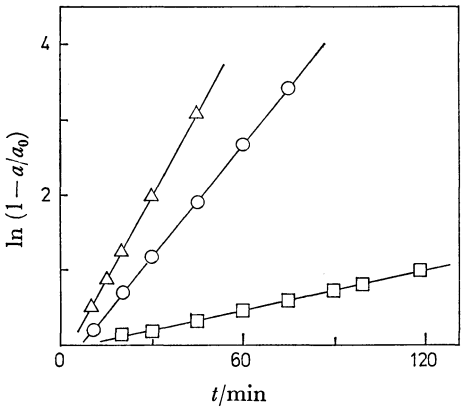

Fig. 2. First-order decrease of [PMO] in the reaction of AcOPh with PMO at 120 °C. The reactions were carried out in the reaction system containing AcOPh (1.6 mol) and PMO (1.6 mol) and various amounts of *n*-Bu_3N, △; 0.12 mol, ○; 0.08 mol, □; 0.016 mol.

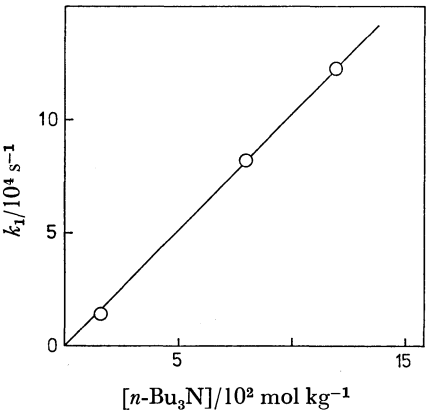

Fig. 3. The relation between the first order rate constant (k_1) and the concentration of *n*-Bu_3N at 120 °C. The reactions were carried out in the reaction system containing AcOPh (1.6 mol), PMO (1.6 mol), and various amounts of *n*-Bu_3N.

TABLE 3. RELATION OF REACTION TEMPERATURES TO k_1 AND k_2 IN THE REACTION SYSTEM CONTAINING AcOPh (1.60 mol), PMO (1.60 mol), *n*-Bu_3N (0.08 mol), AND $PhNO_2$ (TOTAL WEIGHT OF 1 kg)

	110 °C	120 °C	130 °C
10^4k_1 (s^{-1})	6.048	8.222	10.60
10^2k_2 ($l\,mol^{-1}\,s^{-1}$)[a]	0.713	0.979	1.274

a) Converted by the density of the reaction system.

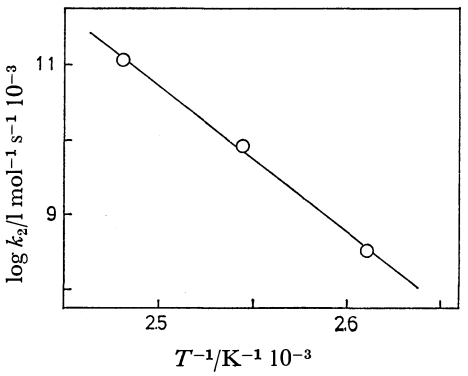

Fig. 4. Arrhenius plots of the second order rate constants.

Values of k_1 and k_2 are given in Table 3.

The Apparent Activation Energy. The Arrhenius plots based on k_2 are shown in Fig. 4 and the apparent activation energy has been estimated as 85.8 kJ/mol in the temperature range 110—130 °C.

The Reaction Mechanism. 1) In the presence of tributylamine and nitrobenzene as catalyst and solvent respectively, the rate of the reaction shown in Scheme 1, may be expressed as follows:

$$-d[PMO]/dt = k_2[n\text{-}Bu_3N][PMO]$$

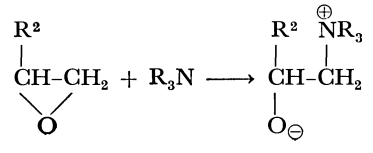
and is of zero order with respect to the concentration of aryl ester.

2) In the reactions of Scheme 1, with methyloxirane and PMO as oxiranes the reaction products were produced almost exclusively by selective β-cleavage of the oxiranes, *i.e.*, **1b**, and **1c**. This shows that a nucleophile attacks the primary carbon of the oxirane.

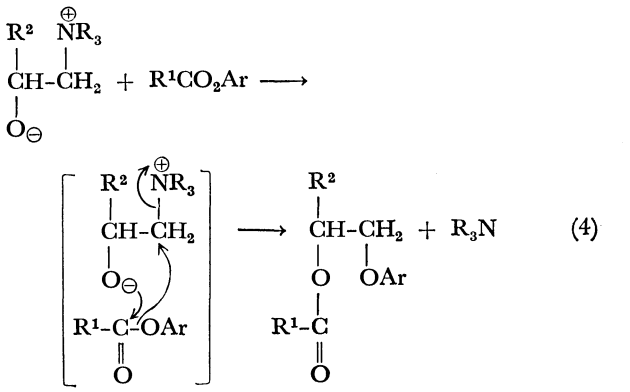
3) The formation of **6** in the reaction between *S*-phenyl thiobenzoate and oxirane suggests that the addition of an aryl ester to an oxirane occurs *via* C–O bond cleavage between the carbonyl carbon and the aryloxyl group of an aryl ester.

4) Laird and Parker[4] assumed that the reaction of oxirane with an alcohol in the presence of triethylamine as catalyst formed a intermediate zwitter ion, $Et_3\overset{+}{N}CH_2CH_2O^-$.

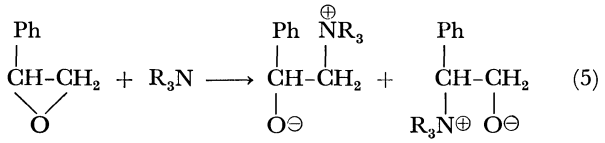
On the basis of the above evidence, the reaction of alkyloxirane, catalyzed by a tertiary amine is assumed to proceed as follows. The rate determining step is Eq. 3.



(3)



In the reaction of phenyloxirane with a phenyl carboxylate, it appears that the tertiary amine attacks competitively on both the primary and secondary carbons in the oxirane. This is due to inductive and steric effects of the phenyl group in the oxirane, as shown in Eq. 5. Thus, a mixture of **1** and **2** was formed.



Experimental

All boiling and melting points are uncorrected. The IR and NMR spectra were recorded on a Hitachi EPI-G and JEOL-PS-100/PET-100A spectrometer respectively. Mass spectra (MS) were obtained on a Shimadzu LKB-9000 mass spectrometer at 70 eV.

Reaction between Phenyl Acetate and Methyloxirane. Phenyl acetate (2.72 g, 20 mmol), methyloxirane (1.28 g, 22 mol) and tributylamine (0.11 g, 0.6 mmol) in THF (15 ml) were placed in an autoclave and stirred at 170 °C for 3 h. The reaction mixture was distilled under reduced pressure giving 3.26 g (84%) of **1b**; bp 141 °C/3.1 kPa; IR(neat) 3040(=C–H), 2970(CH_3), 2920(CH_2), and 1740 (C=O) cm^{-1}; MS (70 eV) *m/e* (rel intensity) 194(2), 134(2), 101(46), 77(13), and 43(100); NMR ($CDCl_3$) δ (ppm from TMS) 1.32 (3H, d, J=7.1 Hz, C–C$\underline{H}_3$), 2.01(3H, s, OCOC$\underline{H}_3$), 3.95(2H, d, J=5.2 Hz, C$\underline{H}_2$–OPh), and 5.22(1H, m, CH_3CO_2–C$\underline{H}$). Found: C, 68.21; H, 7.37%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

The product was identified as **1b** by comparison with an authentic sample of **1b** prepared by another route.

Reaction between Phenyl Acetate and Phenyloxirane. Phenyl acetate (6.8 g, 50 mmol), phenyloxirane (6.0 g, 50 mmol) and potassium *t*-butoxide (0.090 g, 0.8 mmol) were heated at 170 °C for 3 h. The reaction mixture was dissolved in ether and the ethereal solution washed with water, and distilled under reduced pressure, giving 11.6 g (91%) of a mixture of **1h** and **2h**; bp 154—157 °C/0.53 kPa; IR (neat) 1747(C=O) cm^{-1}; Found: C, 75,27; H, 6.37%. Calcd for $C_{16}H_{16}O_3$: C, 75.00; H, 6.29%.

The product was found by means of gas chromatography to be a mixture of **1h** and **2h** (1m column of SE-30 on Celite). The products were identified by comparison with authentic samples prepared separately. The proportion of **1h** in the mixture was 68.2% determined by gas chromatography.

Reaction between S-Phenyl Thiobenzoate and Oxirane. *S*-Phenyl thiobenzoate (4.3 g, 20 mmol), oxirane (1.8 g, 41 mmol) and potassium *t*-butoxide (0.06 g, 0.53 mmol) were heated at 180 °C for 6 h to give 3.7 g (71.6%) of **6**: bp 161—162 °C/0.27 kPa; IR (neat) 3050(=C–H), 2920(CH_2), and 1715(C=O) cm^{-1}; NMR ($CDCl_3$) δ 3.24(2H, t, J=6.8 Hz, PhSC$\underline{H}_2$), and 4.45(2H, t, J=6.8 Hz, $CH_3CO_2C\underline{H}_2$). Found: C, 69.49; H, 5.25%. Calcd for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%. The product was identified as **6** by comparison with an authentic sample prepared by another route.

Reaction of Diphenyl Carbonate with Methyloxirane. Diphenyl carbonate (3.2 g, 15 mmol), methyloxirane (2.6 g, 45 mmol) and potassium *t*-butoxide (0.09 g, 0.8 mmol) were heated at 170 °C for 4 h to give 3.7 g(75.0%) of a mixture of **3b**, **4b**, and **5b**: bp 182—186 °C/0.27 kPa; IR (neat) 2960(CH_3) and 1735(C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.39 (d, J=6.8 Hz, C$\underline{H}_3$), 3.98(d, J=4.8 Hz, PhOC$\underline{H}_2$), 4.23(d, J=7.9 Hz, $CO_2C\underline{H}_2$), 4.58(m, PhOC$\underline{H}$), and 5.10(m, CO_2-C$\underline{H}$). Found: C, 69.35; H, 6.89%. Calcd for $C_{19}H_{22}O_5$: C, 69.07; H, 6.71%. The proportion of **3b** in the product was more than 82% determined by integration of the NMR absorption area.

Syntheses of Authentic Samples. ***1b***, ***2b***, ***1g***, *and* ***2g***: 1-Phenoxy-2-propanol and 2-phenoxy-1-propanol were prepared by Sexton's procedure[2] and acetylated or benzoylated by Schotten-Baumann's reaction.

1b: Bp 140—142 °C/3.2 kPa. Found: C, 68.09; H, 7.36%.

2b: Bp 134—136 °C/3.3 kPa; NMR ($CDCl_3$) δ 1.30(3H, d, J=6.0 Hz, CHC$\underline{H}_3$), 2.02(3H, s, C$\underline{H}_3$CO), 4.18(2H, m, C$\underline{H}_2$), and 4.58(1H, m, C$\underline{H}$). Found: C 68.16; H, 7.35%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

1g: Bp 135—137 °C/0.2 kPa; NMR ($CDCl_3$) δ 1.47(3H, d, J=6.8 Hz, C$\underline{H}_3$), 4.10(2H, m, C$\underline{H}_2$), and 5.48(1H, m, C$\underline{H}$). Found: C, 74.88; H, 6.27%.

2g: Bp 131—133 °C/0.2 kPa; NMR ($CDCl_3$) δ 1.40(3H, d, J=6.8 Hz, C$\underline{H}_3$), 4.39(2H, m, C$\underline{H}_2$), and 4.72(1H, m, C$\underline{H}$). Found: C, 74.90; H, 6.21%. Calcd for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29%.

1c. **1c** was prepared by Fairbourne's procedure:[5] bp 143—146 °C/0.27 kPa; MS (70 eV) *m/e* 286(M^+); NMR ($CDCl_3$) δ 2.00(3H, s, C$\underline{H}_3$), 4.10(4H, d, J=4.8 Hz, 2 C$\underline{H}_2$), and 5.35(1H, m, C$\underline{H}$).

3b. **3b** was prepared by the reaction of 1-phenoxy-2-propanol with phosgene in pyridine: bp 185—186 °C/0.27 kPa; NMR($CDCl_3$) δ 1.39(6H, d, J=6.8 Hz, 2C$\underline{H}_3$), 3.98(4H, d, J=4.8 Hz, 2C$\underline{H}_2$OPh), and 5.10(2H, m, $2CO_2$-C$\underline{H}$). Found: C, 69.21; H, 6.77%. Calcd for $C_{19}H_{22}O_5$: C, 69.07; H, 6.71%.

1h, ***1i***, ***2h***, *and* ***2i***. 2-Phenoxy-1-phenylethanol and 2-phenoxy-2-phenylethanol were prepared by Guss's procedure[3] and the products acetylated or benzoylated by Schotten-Baumann's reaction.

1h: Bp 148—151 °C/0.4 kPa; MS(12 eV), *m/e* 256(M^+), and 196. Found: C, 75.15; H, 6.17%.

2h: Bp 141—143 °C/0.4 kPa; MS(12 eV), *m/e* 256(M^+), and 183. Found: C, 75.21; H, 6.21%. Calcd for $C_{16}H_{16}O_3$: C, 75.00; H, 6.29%.

1i: Bp 205—208 °C/0.4 kPa; MS(70 eV), *m/e* 318(M^+), and 196. Found: C, 79.29; H, 5.59%.

2i: Bp 200—205 °C/0.4 kPa; MS(70 eV), *m/e* 225($M^+ - C_6H_5O$), and 183. Found: C, 79.34; H, 5.63%. Calcd for $C_{21}H_{18}O_3$: C, 79.22; H, 5.70%.

6. **6** was prepared by benzoylation of 2-(phenylthio)ethanol by Schotten-Baumann's reaction.

6: Bp 162 °C/0.27 kPa. Found: C, 69.83; H, 5.30%. Calcd for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%.

Measurement of Reaction Rates. The rate of the reaction between PMO and phenyl acetate in the presence of tributylamine catalyst was determined.

Samples: PMO was prepared from phenol and epichloro-

hydrin by conventional means. The purity was determined according to Stenmark[6] and was greater than 98.1%. Phenyl acetate, and tributylamine were purified by conventional means. Nitrobenzene solvent was a commercially available product which was further purified.

Determination: PMO, phenyl acetate and tributylamine were mixed in the appropriate amounts and nitrobenzene added until the total amount was 2.5 g. The mixture was charged into a sealed glass tube of 0.8 cm inner diameter and 8 cm length. The sealed glass tube was vigorously agitated in a thermostat bath maintained at a specific temperature. After a specified reaction period the sealed tube was taken out of the bath and quenched. Unchanged PMO in the reaction mixture was determined by Stenmark's procedure.[6]

The author wishes to express his thanks to Prof. Takeshi Matsumoto, Faculty of Science, Hokkaido University, for helpful discussions. Thanks are also given to Dr. Takeo Shima for his encouragement and support.

Reaction of Coordinated Phosphines. IV. Mechanism of Carbon-Phosphorus Bond Cleavage in Triarylphosphines and Trialkylphosphines by Palladium(II) Acetate

Kiyoshi KIKUKAWA, Makoto TAKAGI, and Tsutomu MATSUDA*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received October 19, 1978)

Reaction of triphenylphosphine with an equimolar amount of $Pd(OAc)_2$ in acetic acid at room temperature in the presence of styrene gave *trans*-stilbene(94%), H_3PO_4(0.8%), $PhP(O)(OH)_2$(40%), $Ph_2P(O)(OH)$(19%), and $Ph_3P{=}O$(35%). Reactions of tributyl- and trioctylphosphine with $Pd(OAc)_2$ in acetic acid at 90 °C yielded butene(20%) and octene(1-; 22%, 2-; 17%), respectively, as main products. The phenylation of some olefins with triphenylphosphine in acetic acid-*d*, as well as other features of the reaction lead to the conclusion that nucleophilic attack on coordinated phosphorus atom is the most probable pathway for the formation of the phenylation agent (phenylpalladium species) in the reaction system among the others, *ortho*-metallation and oxidative addition.

Tertiary phosphines have been used as versatile and useful ligands in various phases of the chemistry and reactions of transtion-metal complexes, and are considered to bear carbon-phosphorus bond being stable under usual reaction conditions. Only a few has been known about the reaction of tertiary phosphines coordinated to transition metals,[2] except for *ortho*-metallation to arylphosphines and metallation of carbon-hydrogen bond in alkylphosphines which leads to five membered metal cycles.[3] Thus, degradation of the phosphines themselves in the metal complexes has hitherto been ignored or overlooked as a minor side reaction. Recent studies, however, indicated that the degradation of such ligands can take place under suitable conditions with surprising ease.[1,2] These findings suggest that detailed informations of this type of degradation would not only serve for a full understanding of the chemical transformation of transition-metal complexes in general, but also may shed light on a specific problem such as the mechanism of catalyst decay where the transformationof the ligands may result in a significant loss of its activity after repeated reaction cycles.

Previously, we reported that $Pd(OAc)_2(PPh_3)_n$ (n=1 or 2) served as an arylating reagent of various kinds of olefins, and proposed a tentative mechanism involving a facile cleavage of the carbon-phosphorus bond assisted by nucleophilic attack to the phosphorus with acetate ion, mostly based on the effect of *p*-substituents in the aryl groups and the nature of the products.[4] Moreover, a related C–A bond fission in APh_n–PdX_2 system (A=As, Sb, Bi, Se, or Te, n=2 or 3, X=OAc or halogen) evidenced that the behavior of PPh_3–$Pd(OAc)_2$ system was clearly different from those containing Bi, Sb, (or Hg), which proceeded *via* a simple electrophilic attack by bivalent palladium (or metal exchange) without the assistance of acetate ion.[1] Present paper deals with the studies on a stoichiometry of the phosphorus compound and deuterium labeling to substantiate the mechanistic features of the arylation. An analogous carbon-phosphorus bond cleavage of some trialkylphosphines assisted by $Pd(OAc)_2$ is also presented.

Results and Discussion

Reaction of Triphenylphosphine with $Pd(OAc)_2$. A mixture of triphenylphosphine and 1 or 4 equivalents of $Pd(OAc)_2$ in acetic acid was allowed to react at room temperature in the presence of excess styrene. After removal of organic compounds except for phosphorus containing compounds, chromatography of the chloroform extract from aqueous phase afforded triphenylphosphine oxide and the other phosphorus compounds (Reaction 1 and Table 1).

$$PPh_3 + Pd(OAc)_2 + CH_2{=}CHPh \xrightarrow{\text{AcOH, room temp, 48 h}} PhCH{=}CHPh(\mathbf{1}) + PhCH{=}CHOAc(\mathbf{2}) + Ph_3P{=}O(\mathbf{3}) + Ph_2P(O)OH(\mathbf{4}) + PhP(O)(OH)_2(\mathbf{5}) + H_3PO_4(\mathbf{6}) \quad (1)$$

In view of the results that in the absence of $Pd(OAc)_2$ most of triphenylphosphine was recovered unchanged except for oxidation to its oxide, the formation of these compounds are reasonably understood in terms of aerobic oxidation and hydrolysis of probable intermediates acetoxyphenylphosphines, $Ph_n(OAc)_{3-n}P$ (n=3—1), in the treatment. It is to be noted that despite of the recovery of some amount of triphenylphosphine (as its oxide), much of the products was obtained as phenylphosphonic acid, especially in the presence

TABLE 1. REACTION OF TRIPHENYLPHOSPHINE WITH $Pd(OAc)_2$ IN THE PRESENCE OF STYRENE IN ACETIC ACID[a]

Run	Molar ratio	Yield(%) based on PPh_3[b]					Yield(%) based on Pd
	PPh_3 : $Pd(OAc)_2$: Styrene	**1**	**3**	**4**	**5**	**6**	**2**[c]
1	1 : 1 : 4	94	35	19	40	0.8	trace
2	1 : 4 : 16	200	14	8	70	2.0	30

a) At room temp for 2 days. b) Moles of product per moles of PPh_3 utilized. c) The product is contaminated with a small amount of acetophenone and other carbonyl compounds.

of excess $Pd(OAc)_2$. The results in Table 1 indicate that two of the three phenyl groups (and some of the third one) are effectively utilized in the phenylation, and the diphenylphosphine intermediate is more reactive than triphenylphosphine in the present phenyl transfer. The marked depression of the amount of acetoxylated product(**2**) may be explained in terms of decrease of associated palladium(II) species in the presence of the phosphine ligand by considering the recent mechanistic study[5] on olefin-acetoxylation describing that dimeric palladium acetate was the most reactive species. The specific role of $Pd(OAc)_2$ is supported by the observations that none of the phenylated olefins or biphenyl was produced in the reactions of triphenylphosphine with $PdCl_2$ or other transition metal salts, $RhCl_3 \cdot 3H_2O$, $RuCl_3$, $CoCl_2$, $NiCl_2$, and $Ni(OAc)_2 \cdot 4H_2O$, but the systems of $PdCl_2$–NaOAc or $RhCl_3 \cdot 3H_2O$–AgOAc with PPh_3 gave rise to phenylated olefins (54% and a trace amount, respectively, based on PPh_3).

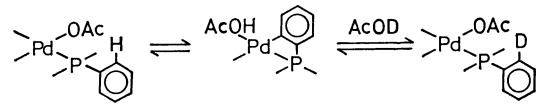
Reaction of Trialkylphosphine with $Pd(OAc)_2$. Although an attempted alkylation of styrene with some trialkylphosphines in place of triphenylphosphine failed under the same conditions described above and even at temperature up to 50 °C, heating of an equimolar mixture of $Pd(OAc)_2$ and tributyl- or trioctylphosphine in acetic acid at 90 °C gave a considerable amount of olefins and a small amount of oxidation product (Reactions 2 and 3) accompanied by precipitation of a considerable amount of palladium black.

$$P(n\text{-Bu})_3 + Pd(OAc)_2 \xrightarrow{\text{AcOH, 90 °C, 3 h}} \text{1-butene(20\%)} + \text{2-butanone(2.5\%)} + \text{2-butenes(traces)} + \text{butane(trace)} \quad (2)$$

$$P(n\text{-}C_8H_{17})_3 + Pd(OAc) \xrightarrow{\text{AcOH, 90 °C, 20 h}} \text{1-octene(22\%)} + \text{2-octene(17\%)} + \text{octane(0.2\%)} + \text{2-octanone(2.2\%)} + \text{octenyl acetates(2.1\%)} \quad (3)$$

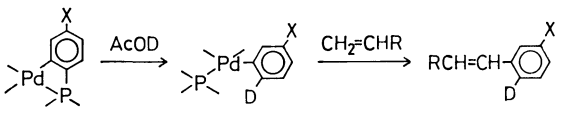
Carbon-phosphorus bond cleavage could not be found in the absence of $Pd(OAc)_2$ under the same reaction conditions. Only traces of cyclohexene and cyclohexanone were formed from tricyclohexylphosphine. The formation of the olefins could be explained in terms of alkyl transfer from phosphorus to palladium to form an alkylpalladium species which decomposed to the olefins and palladium hydrides. The low reactivity of the alkylphosphines for the carbon-phosphorus bond cleavage can be understood by considering larger electron donating ability of the alkyl groups as compared to phenyl group and steric effect, especially for tricyclohexylphosphine, if one assumes that nucleophilic attack of acetate ion on the coordinated phosphine is operative in the reaction as proposed previously.[1,4]

Reaction of Triphenylphosphine or Triphenylphosphine-d_{15} with $Pd(OAc)_2$ in Acetic Acid-d. *ortho*-Metallation to coordinated triarylphosphines has been widely observed in transition-metal complexes.[2a,3,6] Furthermore, Nyholm *et al.*[7] reported that in the reaction with osmium carbonyl cluster complex triphenylphosphine was subjected to cleavage of carbon-phosphorus bond to produce a benzyne complex as one of the products. When a solution of $Pd(OAc)_2(PPh_3)_2$ in acetic-d_3 acid-*d* was allowed to stand at room temperature for 11 days, the NMR spectrum showed that 1.2 hydrogens per mole of triphenylphosphine were exchanged. The exchange can be reasonably interpreted by the process which involves the formation of an *ortho*-metallated intermediate as delineated in Reaction 4. This observation led us to inquire the mechanistic relation between the arylation and the *ortho*-metallation.

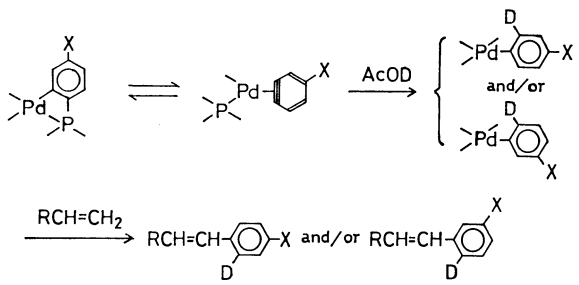


(4)

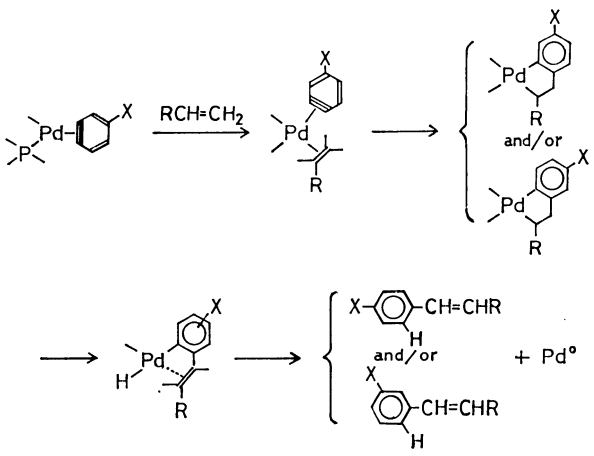
If the *ortho*-metallation were operative as a crucial step in the formation of a phenylpalladium species, either directly or through a benzyne complex, the arylation with *p*-substituted triphenylphosphine would give rise to the product carrying the substituent(X) at a *meta* position or a mixture of phenylated olefins with *meta* and *para* substituent, as formally shown in Reactions 5, 6, and 7. Similarly *meta*-substituted triphenylphosphine would give rise to a mixture of *ortho*, *meta*, and *para* substituted products.



(5)



(6)



(7)

However, this was not the case for the current arylation, and only *p*-substituted products were obtained in the reactions with several *p*-substituted triphenyl-

Table 2. Phenylation of 1-octene and styrene by PPh_3 or PPh_3-d_{15} with $Pd(OAc)_2$ in acetic acid-d

Run	Phosphine and ratio to $Pd(OAc)_2$		Olefin	Conditions: temp (°C)	Conditions: t (h)	Deuterium content in phenylated olefin[a]

8	PPh_3	1	Styrene	r.t.	2	Stilbene-$d_{0.0}$
9	PPh_3-d_{15}	1	Styrene	r.t.	2	Stilbene-$d_{5.08}$

a) Deuterium content was estimated by MS measurement for Runs 6, 7, and 8, and by NMR measurement for Run 9.

phosphines.[4] The regiospecificity of the position where olefin is introduced was further evidenced by the fact that only ethyl *m*-methylcinnamate was formed in the reaction of tri-*m*-tolylphosphine with $Pd(OAc)_2$ in the presence of excess ethyl acrylate. In order to obtain further information relating to the role of the *ortho*-metallation, phenylation of olefins with triphenylphosphine and $Pd(OAc)_2$ in acetic acid-*d* was carried out. The reaction with triphenylphosphine-d_{15} in the same solvent was also conducted to differentiate between the usual route *via* phenylpalladium and the other which might occur through the benzyne intermediate, if it formed (Reactions 6 and 7). As shown in Table 2, when one equivalent of triphenylphosphine or triphenylphosphine-d_{15} was utilized, the phenyl group in the starting phosphines transferred as such without being subjected to any H–D exchange. On the other hand, the presence of another mole of triphenylphosphine gave rise to incorporation of deuterium in the products, though it is to a small extent. It is to be mentioned here that the ratio of triphenylphosphine to $Pd(OAc)_2$ affects the rate of the phenylation as shown in Fig. 1. The reverse relationship between the rate of phenylation and the extent of the H–D exchange strongly suggests that the exchange became recognized only because of the decrease of the phenylation rate and that the *ortho*-metallation (Reaction 4) does not contribute to the formation of the phenylpalladium species for phenylation of olefins.

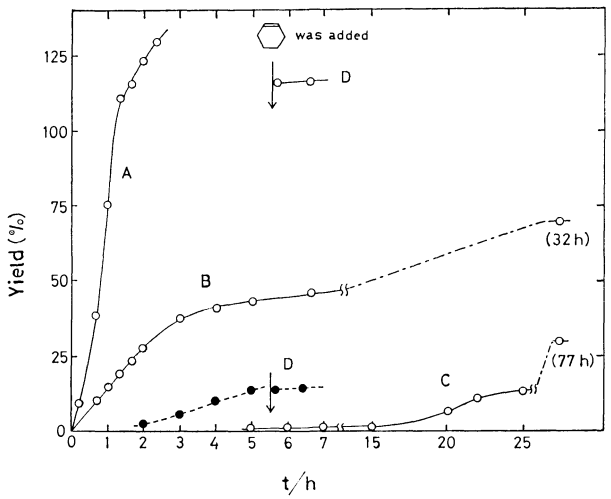

Fig. 1 Time course of phenylation of cyclohexene in acetonitrile. $[Pd(OAc)_2]=0.1$ M, $[PPh_3]=0.05$ M (A), 0.1 M (B), 0.2 M (C), 0.05 M (D), $\left[\bigcirc\right]=$ 0.2 M. Temp: 25.0 °C (A and D), 30.0 °C (B and C). Yields are based on PPh_3.

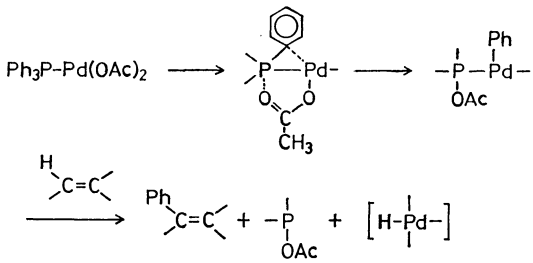
Mechanism of the Arylation. Previously we proposed the tentative mechanism for the facile carbon-phosphorus bond cleavage, which involved an initiatory nucleophilic attack on the coordinated phosphorus atom by acetate ion leading to phenyl transfer to palladium.[4]



(8)

Recently, Fahey and Mahan[8] have described reversible oxidative addition of triphenylphosphine to zero-valent nickel and palladium complexes (Reaction 9).

$$C_6F_5\text{-}PPh_2 + Pd(0) \longrightarrow C_6F_5\text{-}Pd(II)\text{-}PPh_2 \quad (9)$$

This fact introduces an alternative pathway to be considered for the formation of the phenylpalladium species in the present phenylation, since the reaction proceeds with accompanied formation of zero-valent palladium. If the oxidative addition route is operative in the present system the phenylation should be expected to proceed more favorably under nitrogen atmosphere than under aerobic conditions. The effect of the atmosphere examined in the reaction of $Pd(OAc)_2(PPh_3)_2$ with 1-octene (Table 3) shows that under nitrogen the yield of phenylated olefins decreased remarkably, whereas the addition of an oxidizing agent, $Cu(OAc)_2\cdot 2H_2O$, increases the yield even under nitrogen. Since the phenylation in the system of phenylmercury(II) acetate–$Pd(OAc)_2$ is known to be little affected by the atmosphere,[9] the results can be considered to indicate that the atmosphere influences the step of the formation of the phenylpalladium species, and divalent palladium is principally responsible for the present carbon-phosphorus bond cleavage.

Another feature of the current phenylation is the marked effect of the ratio of triphenylphosphine to $Pd(OAc)_2$ on the reaction rate (Fig. 1). The increase in triphenylphosphine/Pd ratio depressed both the rate and yield of the phenylation. Particularly, the use of double moles of triphenylphosphine to $Pd(OAc)_2$ introduced a long induction period (curve C), and the presence of excess triphenylphosphine substantially

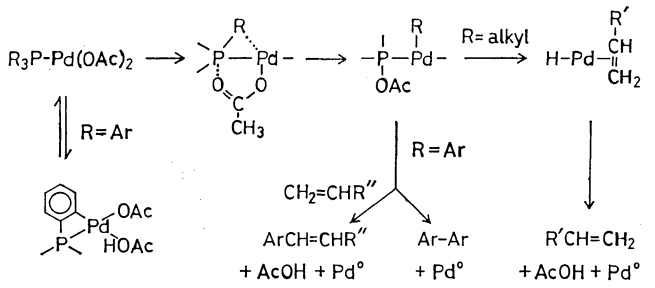
Table 3. The effect of atmosphere on the phenylation of 1-octene by $Pd(OAc)_2(PPh_3)_2$ in acetic acid

Run	Atmosphere	Additive	Conditions t (h), (temp, °C)		Phenylated olefins (%)[a]	Acetoxylated olefins (%)[b]
3	air	—	9	(50)	97	3
4	nitrogen	—	70	(50)	35	5
5	nitrogen	$Cu(OAc)_2 \cdot 2H_2O$	22	(50)	113	2

a) 1- and 2-Phenyl-1-octenes and -2-octenes. Yields are based on the Pd complex. b) A mixture of isomeric octenyl acetates and octan-2-one. Yields are the sum of those of the acetates and the ketones.

inhibited the reaction.[4] It would be unreasonable to consider that the rate of the oxidative addition (Reaction 9) reduces in such a manner as shown in Fig. 1 even in the presence of one or two equivalents of triphenylphosphine. It is most probable that coordination of two phosphine molecules to $Pd(OAc)_2$ somehow prevents the phenyl migration from phosphorus to palladium (Reaction 8). Under aerobic conditions the phosphine is extruded from the coordination sphere by oxidation to the phosphine oxide, thus leaving a vacant site in the palladium complex which serves for the phenyl migration to take place. Under nitrogen atmosphere, such process obviously is not available, and cupric acetate is needed as oxidant or more probably as carrier of the "excess" triphenylphosphine. The reasoning for the formation of the phenylpalladium species directly from $Pd(OAc)_2$ and triphenylphosphine was further evidenced by the following experiment. The reactions A and D in Fig. 1 were carried out under the same conditions except for the mode of addition of cyclohexene. In the reaction A, the olefin was applied to a solution of $Pd(OAc)_2$ just before the addition of triphenylphosphine. When a mixture of triphenylphosphine and $Pd(OAc)_2$ in acetonitrile was allowed to react for 5.5 h, a small amount of biphenyl was detected before the addition of cyclohexene (Reaction D). On addition of the olefin to the mixture, the formation of phenylcyclohexenes took place very rapidly and was completed within 5 min. Nevertheless, the yield (120 %) was comparable to those under the condition A. The results strongly supports the conclusion that the phenylpalladium species are formed to a considerable extent even in the absence of olefins and the presence of zero-valent palladium species is unnecessary for the production of phenylating agent in the present reaction system.

All of the observations are consistent with the following reaction scheme which involves an nucleophilic attack by acetate on the coordinated phosphorus atom. The similar mechanism could be applied for the migration of the second and the third phenyl groups from phosphorus to palladium, though no direct evidence is available at present.



Scheme.

Experimental

Materials. Palladium acetate and bis(triphenylphosphine)palladium(II) acetate were prepared by the method of Wilkinson *et al.*[10] Triphenylphosphine and tributylphosphine were of commercial origin and were used without further purification. Triphenylphosphine-d_{15} was prepared from pentadeuterophenyl magnesium bromide and phosphorus trichloride.[11] Trioctylphosphine was prepared by the similar method described above; bp 183—187 °C/1 mmHg (lit,[12] 173—178 °C/0.3 mmHg). Olefins and solvents were of commercial origin and were used after distillation. Acetic acid was refluxed with potassium permanganate before distillation.

Reaction of Trialkylphosphine with $Pd(OAc)_2$. The solution of trialkylphosphine(5 mmol) and $Pd(OAc)_2$(5 mmol) in acetic acid (20 ml) was heated at 90 °C under stirring for 3 to 20 h. Evolution of gas (24 ml at 15 °C) was observed for tributyl phosphine. The gas was consisted of 1-butene(98%), 2-butene(1%) and butane(1%) according to the analysis with GLC (20% dibenzyl ether on Celite 545). Palladium black deposited was removed by filtration and organic products in the reaction mixture were extracted with ether, neutralized with aq sodium hydrogencarbonate, washed three times with aq sodium chloride and dried. The products were identified by comparison with those of authentic samples and with decane as an internal standard on GLC. The peak assigned to ketones disappeared by the treatment of the ethereal solution with 2,4-dinitrophenylhydrazine.

Reaction of Triphenylphosphine with $Pd(OAc)_2$ in the Presence of Styrene. In a 100 ml flask were placed 1.31 g(5 mmol) of triphenylphosphine, 1.12 g(5 mmol) of $Pd(OAc)_2$, 2.08 g (20 mmol) of styrene and 10 ml of acetic acid. The mixture was stirred at room temperature for 48 h. Excess styrene and acetic acid were evaporated under vacuum at room temperature, and then styrene derivatives were steam-distilled from the residue. The distillate was extracted with ether. Stilbene, acetoxylated styrene and acetophenone in the extract was separated by column chromatography on silica gel (Wakogel, C-100). The residue was extracted with chloroform, and the chloroform layer gave triphenylphosphine oxide and diphenylphosphinic acid after chromatography on silica gel. $Ph_2P(O)OH$, mp 188—192 °C(lit,[13] 194—195 °C). Phenylphosphonic acid was obtained from the aq layer, mp 145—150 °C(without purification, lit,[14]

158—161 °C). A small portion of aq layer was used for the analysis of phosphoric acid.[15] All the phosphorus compounds obtained in the present reaction were identified by comparison of the IR with those of authentic samples except for phosphoric acid. The assignment of the phenylated and acetoxylated products was described previously.[4,16]

*Reaction of Tri-*m*-tolylphosphine with Pd(OAc)$_2$ in the Presence of Ethyl Acrylate.* To a mixture of Pd(OAc)$_2$(5 mmol) and ethyl acrylate(20 mmol) in acetonitrile(30 ml) was added tri-*m*-tolylphosphine at room temperature and stirred for 12 h. Palladium metal deposited was removed by filtration and a distillation of the filtrate gave 0.60 g of ethyl *m*-methylcinnamate(bp 120 °C/5 mmHg). The structure of the product was identified by comparison of IR, NMR, and the retention time on GLC (Reoplex 400, 1.5 m, 140 °C) with an authentic sample. The IR and GLC analysis excluded the formation of ethyl *p*-methylcinnamate.

*Phenylation in Acetic Acid-*d. Reaction procedure in acetic acid-*d* was similar to that in acetic acid except for the protection from the moisture by a calcium chloride tube. *trans*-1-Phenyl-1-octene was separated by preparative GLC as described previously[4] and was analyzed by MS: *m/e*, 188(M^+), relative intensities of isotope peaks; M+1=35.7 (%), M+2=7.15(%) (values from lit[17] for $C_{14}H_{20}$, M+1=15.45, M+2=1.11). Stilbene was isolated in the same way as described above. The relative intensities were as follows. Run 7: *m/e*, 180(M^+); M+1=30.92, M+2=5.01. Run 8: M+1=15.27. Run 9: M+1=15.0 (values from lit,[17] for $C_{14}H_{12}$, M+1=15.32, M+2=1.09). Stilbene from the run 9 was hydrogenated over Pd/$BaCO_3$ to 1,2-diphenylethane. PMR of the product showed two singlets placed at δ 2.86(methylene protons) and 7.12(aromatic protons). The ratio of the peak area of the aromatic to aliphatic protons was 1.23(an average from five measurements) which showed the presence of 5.08 of deuterium in a molecule. The deuterium calcd from MS was 4.83.

Determination of Time Course of Phenylation. Runs A and B: To a solution of Pd(OAc)$_2$(0.5 mmol) in acetonitrile containing an internal standard (diethyleneglycol dibutyl ether), cyclohexene (1.0 mmol) triphenylphosphine (0.25 or 0.5 mmol) were added and stirred in a thermostated cell. Samples were withdrawn at appropriate time intervals by a microsyringe and directly analyzed on GLC equipped with flame ionization detector. Rection procedure for Runs C and D was similar to the above except for the way of addition of cyclohexene and triphenylphosphine. Thus, in Run C, bis(triphenylphosphine)palladium acetate was used and in Run D, triphenylphosphine was allowed to react with Pd(OAc)$_2$ for 5.5 h before the addition of cyclohexene.

A Simple MO Treatment on the Nucleophilic Substitution Reactions of Six-membered Aza-aromatic Compounds

Minoru HIROTA,* Hideyuki MASUDA, Yoshiki HAMADA,** and Isao TAKEUCHI**

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 232

***Department of Pharmacy, Meijo University, Tempaku-ku, Nagoya 468*

(Received October 30, 1978)

Nucleophilic substitution reactions of monoaza- and diaza-naphthalenes and -phenanthrenes were discussed on the basis of an HMO calculation taking the nature of the reagent into consideration. Results were compared with the orientation of some nucleophilic substitution reactions, *i.e.* Chichibabin amination, phenylation by phenyllithium, and methylation by methylsulfinylmethanide ion. The nature of the reagent was explicitly taken into account as the difference in the coulomb integrals and the reagent-dependent orientation of these reactions were explained theoretically.

In recent decades, molecular orbital theory has been applied to many organic reactions and, in most instances, succeeded in interpreting the reactions. In the field of heteroaromatic chemistry, many applications of MO theory were also reported.[1] In an earlier stage the reactivity indices were calculated and shown to reproduce the orientations of substitution reactions.[2-5] However, several heteroaromatic compounds exhibit different orientations depending on the nature of nucleophiles (or electrophiles), which prevents the use of common reactivity indices throughout all kinds of nucleophilic (or electrophilic) reactions. For example, quinoline, a typical of the six-membered aza-aromatics, reacts with amide anion in liquid ammonia to produce 2-aminoquinoline,[6] while it is methylated to produce 4-methylquinoline by methylsulfinylmethanide ion (dimsyl anion) in DMSO.[7] Both reactions are caused by the attack of nucleophile, being usually classified as nucleophilic substitution reactions. The results are embarrassing when the reactions were predicted in terms of reactivity indices. On the other hand, the reactivity indices themselves are also inconsistent, predicting the different sites of reaction depending upon the kinds of the indices. Brown[8] has classified the reactivity indices from the theoretical consideration on the transition states of the reactions and has given a general guideline to select the proper index as follows: When the reagent or the substrate is reactive, orientation of the reaction is determined by localization energy (L_r) or superdelocalizability (S_r), while the orientation is determined by electron density (q_r) or polarizability (π_{rr}) in the case contrary. The classification is rationalized afterwords by several authors by considering the orbital energies of the reagents (and also of the substrates). Klopman[9] has developed a generalized poly-electronic perturbation theory (GE theory) in which the energies of the unoccupied MO's of electrophile (acceptor) and of the occupied MO's of nucleophile (donor) were both taken into accounts and succeeded in explaining the different orientation of the nucleophilic substitution reactions of pyridinium salts. Simonetta[10] has proposed a π-electronic model for the transition state of aromatic substitution reaction in which the AO's of the tetra-valent carbon and the leaving and the substituting groups were treated analogous to the case of hyperconjugation in order to separate the π-orbitals from the σ-orbitals. The reactivity is discussed on the basis of the π-part of MO's alone. Chalvet and Daudel[11-13] have developed a theory for the treatment of the transition state of aromatic substitution, in which, again, π-MO's of the interacting system were solely considered to predict the orientation of the reaction as a function of the HOMO-energies of the attacking nucleophile.

In practice, substituted benzenes are resistant to nucleophilic aromatic substitutions and react only at the ipso position of the nucleophilically activated halogen or alkoxyl substituent. On the contrary, nucleophilic substitution reaction is quite common with so-called π-electron-deficient aza-aromatic compounds,[6,7,14-22] and the orientations of the reactions are dependent on the nature of the attacking nucleophiles. The present authors have reported the nucleophilic substitutions of several monoaza- and diaza-naphthalenes, -phenanthrenes, and -anthracenes,[23-25] and found remarkable differences in orientations depending upon the nature of the nucleophiles. In this paper, the different orientation observed in some nucleophilic reactions will be discussed according to the above mentioned theory developed by Chalvet and Daudel.

Theoretical

In order to predict the orientations of the substitution reactions on the heteroaromatic compounds, the relative MO energies of the transition states leading to variously oriented substituted products were estimated by a method similar to the unified treatment of transition state proposed by Chalvet *et al.* In this theory, a transition state is treated as a heteroaromatic π-system (substrate) with extension of delocalization by reagent, and the MO Φ of the transition state is formed in terms of the linear combination of the reagent atomic orbital (or group orbital) γ and the substrate molecular orbitals ϕ^σ and ϕ^π.

$$\Phi = \lambda\gamma + \sum C_i\phi_i^\sigma + \sum C_j\phi_j^\pi$$
$$= \lambda\gamma + \sum C_m\chi_m^\sigma + \sum C_n\chi_n^\pi$$

As the reagent (X) attacks the periphery of the π-electron cloud of the substrate aromatic molecule, the overlap between the ϕ^σ and γ will be small and can be neglected. Thus,

$$\langle\gamma|\phi^\sigma\rangle = \langle\gamma|\chi_r^\sigma\rangle = 0$$

and

$$\langle\gamma|\boldsymbol{h}|\phi^{\sigma}\rangle = \langle\gamma|\boldsymbol{h}|\chi_{r}^{\sigma}\rangle = 0$$

where r refers to the site of the nucleophilic (or electrophilic) attack in the substrate molecule. This means that the relative energies of the transition state can be estimated by considering solely the following π-MO's.

$$\Phi^{\pi} = \lambda\gamma + \sum C_{n}\chi_{n}^{\pi}$$

The calculation of the Φ^{π}'s can be carried out within the framework of the Hückel MO approximation if the following integrals are properly evaluated.

$$\alpha_{x} = \langle\gamma|\boldsymbol{h}|\gamma\rangle$$

$$\beta_{rx} = \langle\gamma|\boldsymbol{h}|\chi_{r}^{\pi}\rangle$$

These integrals can be evaluated by the following way. The perturbation energy caused by the interaction with the reagent has been shown to increase monotonously as the increase of β_{rx} without significant crossings of the energies within the range of $\beta_{rx}=0$—2.0.[12] Thus the resonance integrals β_{rx} are simply evaluated to be 0.5 after Chalvet *et al.*

The coulomb integrals α_{x} are evaluated with reference to the Mulliken's electronegativities[26,27] of the attacking nucleophiles. Discussions in this paper are confined to the following three reactions; (i) phenylation with phenyllithium, (ii) methylation by dimsyl anion, and (iii) Chichibabin amination. The phenylation with phenyllithium is assumed to be induced by the initial attack of phenyl carbanion. The anion has been proved to be a sigma anion carrying the unshared electron pair in an sp^2 non-bonding AO. The anion is stabilized by the aromatic sextet of electrons as is in the parent hydrocarbon. Methylation of the six-membered aza-aromatic compounds by dimsyl anion is rather complex in the mechanistic point of view, involving an initial addition of the nucleophile and subsequent elimination in some cases. However, the orientation of the reaction is determined by the initial attack of dimsyl anion towards the heteroaromatic nucleus. The transition state energies of this initial process can be properly evaluated by the method mentioned above. The dimsyl anion is a carbanion in conjugation with sulfinyl group, and its anionic center is supposed to be planar. Thus, the unshared electron pair of this anion should occupy a p-AO. Chichibabin amination reactions are carried out in liquid ammonia, and the effective nucleophile is amide anion. The anion is generally supposed to take an angular conformation. However, the hybridization state of its nitrogen atom is not known in details, since the exact geometry of the anion has not been determined. Anyhow the nitrogen atom has a non-bonding AO of which s-character is ranging from 0 to 50%. In other words, the AO has an intermediate character between pure p and sp-hybridized.

Ionization potentials I, electron affinities A, and Mulliken's electronegativities χ_{M} for these AO's are given, together with the estimated α_{x} values, in Table 1. Ionization potentials, electron affinities, and other properties have been correlated with coulomb integrals by many authors.[26,28–31] Nevertheless, coulomb and other integrals for HMO calculations have been assigned in a qualitative manner with reference to these properties

Table 1. The electronegativities and the coulomb integrals of carbon and nitrogen atoms of various valence states

Atom	AO	I/eV	A/eV	χ_{M}	h_{x}
C(sp^2)	2p(π)	11.16	0.03	5.60	−0.5
	tr(σ)	15.62	1.95	8.79	+2.0
N[a]	2p	13.94	0.84	7.39	
N(sp^2)	2p	14.12	1.78	7.95	+1.5
N(sp)	2p	14.11	2.14	8.13	

a) Unhybridized N atom.

in most instances, and such integrals are also employed to formulate the Hückel determinant of the substrate heteroaromatic molecules in this investigation. Thus, the α_{x}'s are also evaluated by taking the following factors into account. Firstly, as the β_{rx} is *a priori* assigned to be 0.5 which corresponds to a rather weak interaction, the effect of electronegativity should be a little exaggerated in the α_{x} integrals to compensate the smaller β_{rx}. Secondly, the coulomb integrals for anionic centers should be shallower than those for the neutral atoms of similar electronic states. Thirdly, the electronegativities of the anionic centers of the reagents increase in the order; dimsyl anion<amide anion<phenyl anion, even though there exists some ambiguity in the χ_{M} value of the nitrogen atom in amide anion. Thence, h_{C}(dimsyl)<h_{N}(amide)<h_{C}-(phenyl). In conclusion, the integrals given in Table 1 were employed in the calculations. These values are carefully adjusted so as to be consistent with other integrals in the substrate heteroaromatic molecules.

Results and Discussion

By performing the MO calculations described in the theoretical part, total π-energies of the models for the transition states were obtained. The total π-energy E_{π}(r) is dependent on the site (r) of reaction in a molecule concerned, and the one with the lowest π-energy corresponds to the transition state for the most feasible reaction path, which should be realized in practice. The relative π-energies for the various reaction sites in the heteroaromatic molecules 1 to 13 are shown graphically in Fig. 1(a)—(n) as a function of the coulomb integral ($\alpha_{x}=\alpha+h_{x}\beta$) of the attacking nucleophiles. In these figures, the "transition state" with the lowest π-energy at $h_{x}=-3$ is chosen as the reference(s) and the energy difference E_{π}(r)−E_{π}(s) in β unit are plotted as a function of h_{x}. Then, the relative "transition state" energy for the site chosen as the reference is given by the straight line E_{π}(s)=0 (which superposed on the abscissa). When the energy curves for other "transition states" do not intersect the abscissa, the relative energies of them are always higher than E_{π}(s), and the heteroaromatic molecule is expected to react at the same site (s) irrespective of the nature of the attacking nucleophiles. When the energy curve(s) of other "transition states" crosses the abscissa, the lowest energy one is replaced as the change in h_{x}. Therefore, the site of the nucleophilic attack is predicted to be altered as the change in the

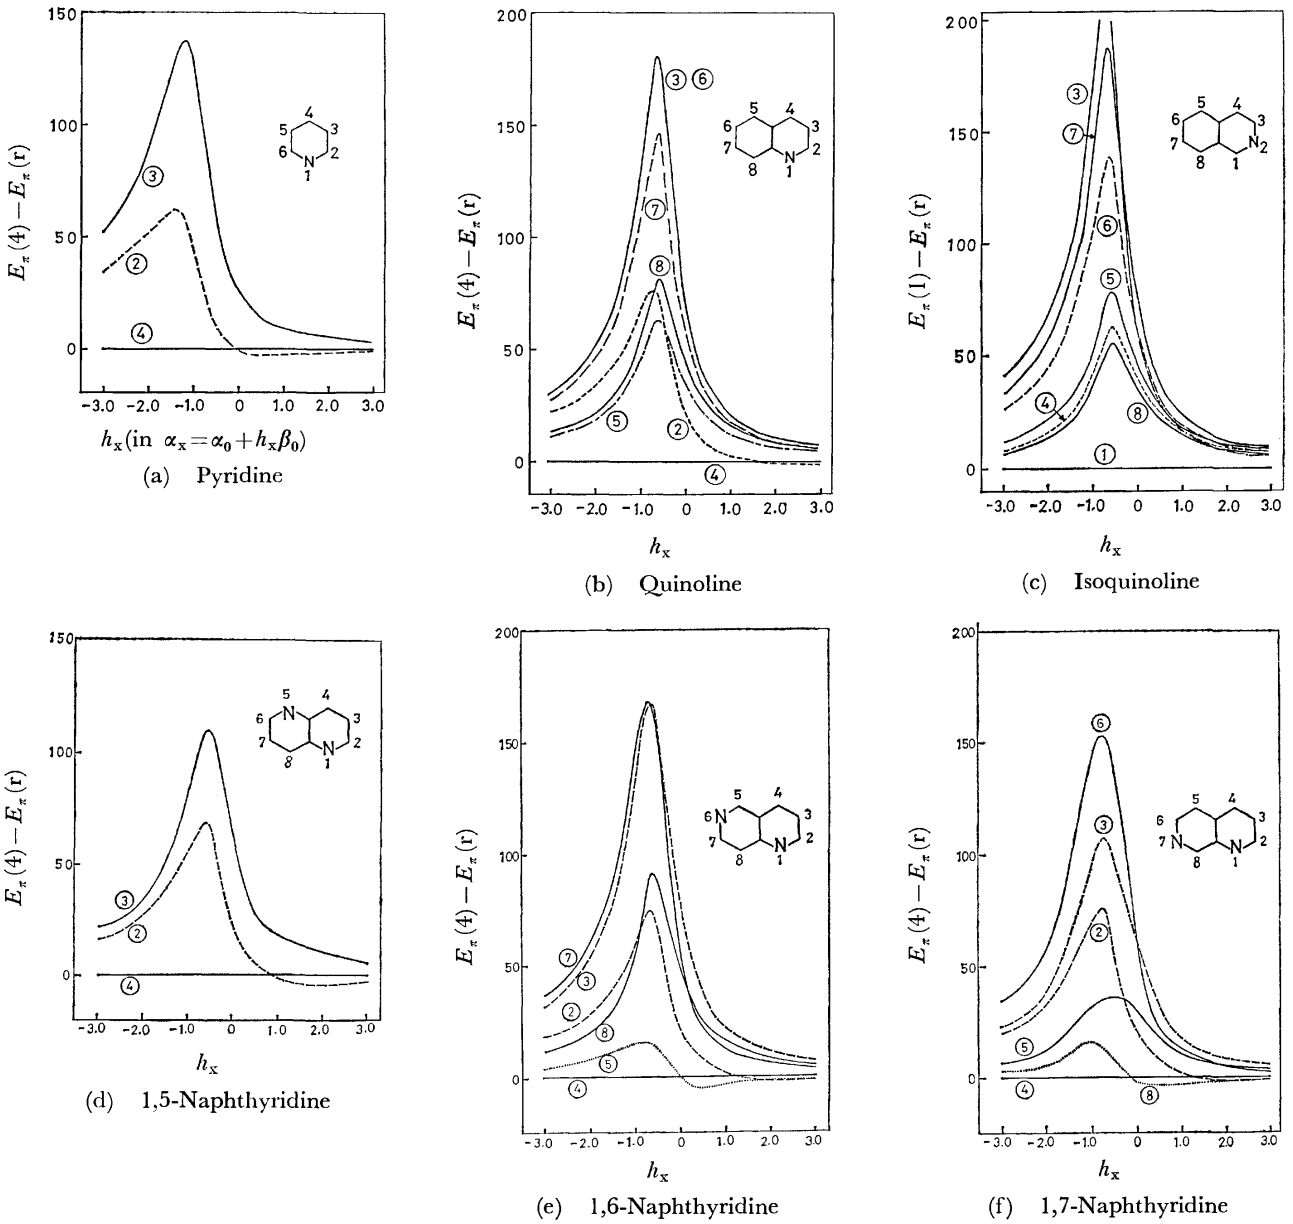

Fig. 1. Relative π-energies for the transition states of various reaction sites (in β units$\times 10^3$).

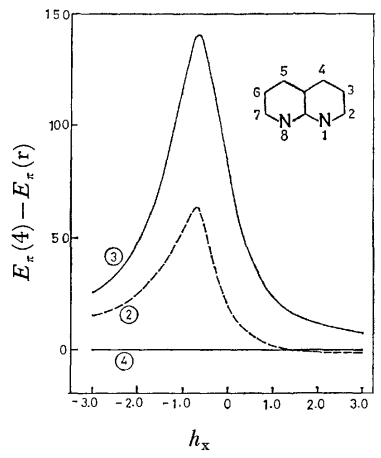
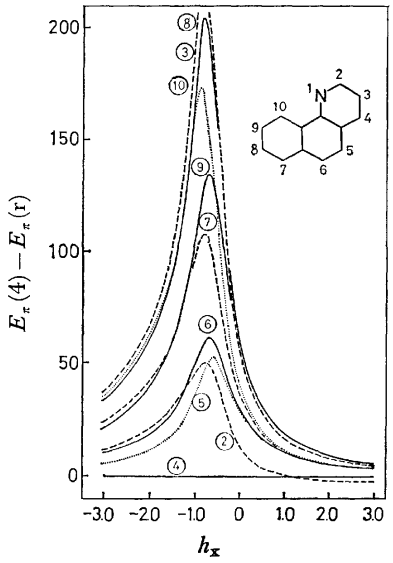
nucleophilicity of the reagent.

Of all the heterocycles investigated, isoquinoline (**3**), 5-azaphenanthrene (**10**), 4,6-diazaphenanthrene (**12**), acridine (**13**), and 1,10-diazaanthracene (**14**) belong to the former cases. Nucleophilic substitution reactions of these nitrogen heterocycles have been extensively investigated by several authors. Since the first report on pyridine and related substances by Chichibabin and Zeide,[6] the amination by alkali amide in liquid ammonia has been applied to a variety of the six-membered aza-aromatic compounds and called Chichibabin reaction. This modification of amination on a series of naphthyridines have been studied in details by Paudler and Kress,[17] and further extended to the benzo analogs of naphthyridines by the present authors.[23-25] The reaction on 1,5-naphthyridine had been reported to give the 2-amino derivative initially,[17] but the 4-amino derivative was identified as the product of the amination recently.[18,23]

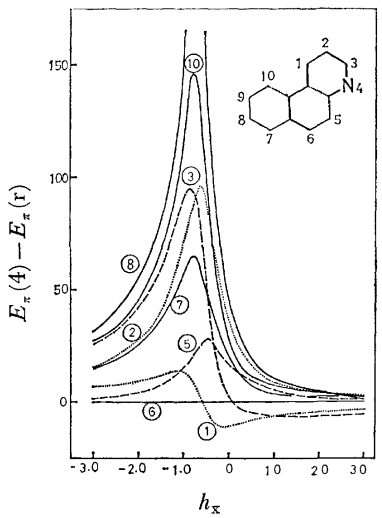
Phenylation by phenyllithium in ether or hydrocarbon medium is also a well-known reaction, and the substitution occurs predominantly on the carbon atom ortho to the ring nitrogen atom in almost all cases reported.[14-16,32] The present authors[25] have investigated on the orientation of the phenylation of 1,*x*-naphthyridines and shown that the main product is the 2-phenyl derivative in the reactions of all isomeric heterocycles. Methylation of these aza-aromatic compounds were first reported by Russel and Weiner.[7] They carried out the reaction on pyridine and several of its benzo analogs and, though pyridine is unreactive to dimsyl anion, showed that the ortho or para-substituted derivatives were produced *via* addition-elimination mechanism. The methylation was applied to diazanaphthalenes and diazaphenanthrenes by the present authors.[24,25] The products of these reactions were summarized in Table 2 together with the orientations predicted from Fig. 1 by assuming the coulomb



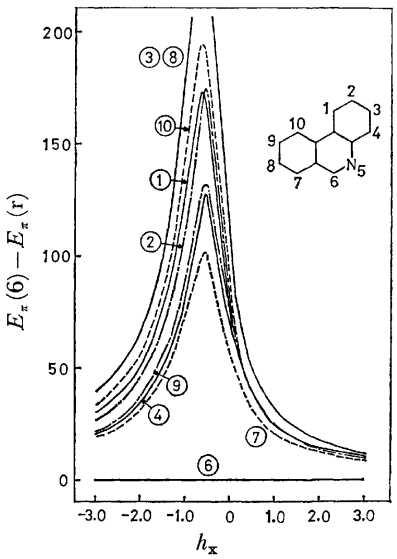
(g) 1,8-Naphthyridine



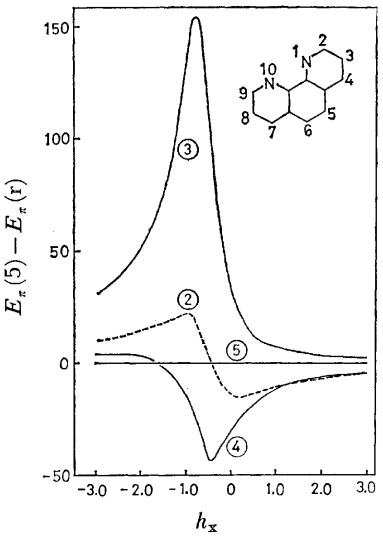
(h) 1-Azaphenanthrene



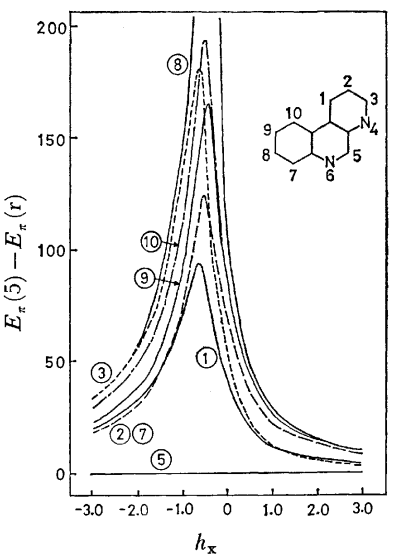
(i) 4-Azaphenanthrene



(j) 5-Azaphenanthrene



(k) 1,10-Diazaphenanthrene



(l) 4,6-Diazaphenanthrene

Fig. 1

integrals of the reagents as given in Table 1.

The orientations of the compounds **3**, **10**, **12**, **13**, and **14** are invariable throughout all three kinds of nucleophilic reaction, and the prediction from Fig. 1 is shown to be consistent with the experimental results. With other heterocycles, the orientation alters with the change in reagents in accord with the crossing of the π-energy curve in Fig. 1. 1,5-Naphthyridine (**4**), for example, produce 2-phenyl-, 2- or 4-amino-, and 4,8-dimethyl-naphthyridines by the above mentioned reactions, and the difference in orientation is properly explained by the crossing of the transition state π-energy curve for the 2 (and 6)-position with abscissa which corresponds to that for the 4(and 8)-position. Thus, the reagent of which h_x is larger than 1 (crossing point) is predicted to attack toward 2 (and 6)-position. The compounds **1**, **2**, **5**, **6**, **7**, **8**, **9**, and **11** also have some similar crossings with abscissa in their "transition state" π-energy curve and expected to behave differently toward the attack of various nucleophiles in orientation. The difference in orientation is verified with all the compounds investigated experimentally (**2**, **5**, **6**, **7**, **8**, and **9**). Phenylation and amination have not yet been carried out on 1,10-diazaphenanthrene (**11**), lacking the evidence for the different orientation, and pyridine (**1**) is unreactive toward dimsyl anion even if it is expected to react at the 4-position.[33] After all the comparison with the experimental consequence illustrates that the method is quite trustworthy and widely applicable to the qualitative prediction of the orientation.

The results are compared with the orientations predicted from reactivity indices. Among various reactivity indices, electron density q_r, as well as superdelocalizability $S_r^{(-)}$ and frontier electron density $f_r^{(-)}$ for nucleophilic reactions, is suitable for this discussion, being given in Table 3. With the heterocycles of which reaction site toward nucleophile is

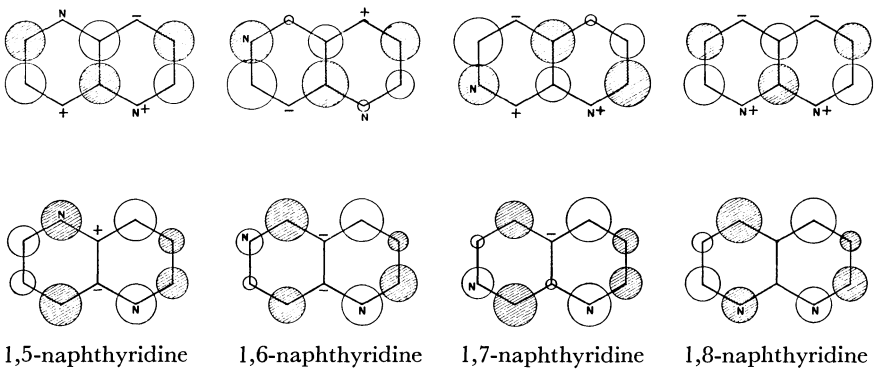
indifferent with varying h_x values (**3**, **10**, **12**, **13**, and **14**), their reactivity indices also foresee the same site for nucleophilic reactions. The predicted sites (indicated by bold letters in Table 3) are always consistent with those from the transition state π-energy curves in Fig. 1.

The reactivity indices for other compounds investigated are apparently inconsistent among them, predicting different sites of nucleophilic reaction for a compound. All of these compounds have crossings with abscissa in the transition state π-energy curves in Fig. 1, and the reagent dependent orientation has been rationalized. As expected by the frontier electron theory, frontier electron density is the most suitable index to predict the site of the attack by dimsyl anion of which HOMO energy is high ($h_x=-0.5$) and close to that of the LUMO of the heteroaromatic compounds reacting as substrates (Fig. 2). The orientations of the methylation agrees with those predicted from $f_r^{(-)}$'s in most instances. Hence, the methylation is frontier-controlled. Only one exception is the case of 1,10-diazaphenanthrene. The 5,6-bonds of azaphenanthrenes usually have higher double bond character than the other bonds in the same molecule, and the bond alter-



1,5-naphthyridine 1,6-naphthyridine 1,7-naphthyridine 1,8-naphthyridine

Fig. 2. The LUMO's and the next LUMO's of naphthyridines. In this figure, magnitudes of the AO coefficients (c_{ir}'s) are proportional to the radii of circles, and the hatched circles correspond to the coefficients with negative signs. Only the signs of c_{ir}'s are given when they are too small to be illustrated by circles.

nation is significant in the ring annelated by two benzene nuclei. Since both the reactivity indices (Table 3) and the transition state π-energy curves (Fig. 1) are calculated by assuming identical β-values to all C–C and C–N bonds in the rings, the results become less trustworthy by the increase in bond alternation. A variable β-calculation will improve them considerably.

On the other hand, the orientations of the amination and the phenylation are predicted by the electron densities. In these reactions, the HOMO's of the nucleophiles are estimated to be considerably lower than the LUMO's of substrates, being charge-controlled.[34]

Similar quantities for the delocalized π-model of the transition states were also obtained by the perturbational calculations on the PPP-SCF wave functions of these heterocycles.[35] However, the results agree with the experiments only fairly, and no further improvement is expected by the calculations on the basis of more sophisticated MO.

These calculations were carried out using the HITAC 8250 computer of Yokohama National University and the HITAC 8700 computer of the University of Tokyo Computer Center.

The authors thank to Mr. K. Hisada and Mr. N. Hyodo for their assistance in calculations. Double Diels-Alder Reactions of Coumalic Acid with 1,3-Dienes

Takeshi IMAGAWA, Tsunefumi NAKAGAWA, Mituyosi KAWANISI, and Keiiti SISIDO

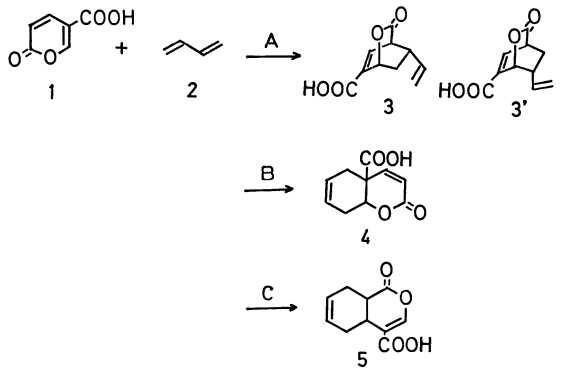
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 9, 1978)

Thermal reaction of coumalic acid with 1,3-butadienes gave after diazomethane treatment dimethyl tricyclo[3.2.1.$0^{2,7}$]oct-3-ene-2,4-dicarboxylate *via* double Diels-Alder reaction. This represents the simplest synthesis of such a tricyclic system. The reaction with cyclopentadiene was also studied.

Diels-Alder reaction of 2-pyrone and esters of some 2-pyronecarboxylic acids are well documented.[1] With acetylenes as dienophile the reaction provided the benzene derivatives by loss of carbon dioxide from the intermediary adduct. With olefinic dienophiles, a decarboxylative double diene synthesis occurred to afford a bicyclo[2.2.2]oct-2-ene system, and with electron-rich dienophiles the so-called Diels-Alder reaction with inverse electron-demand[2] was effected with high regiospecificity.

In view of these facts, the reaction in the combination of coumalic acid (**1**) and 1,3-butadienes (**2**) seems most probably to follow the path A (Scheme 1).



1 2 3 3' 4 5

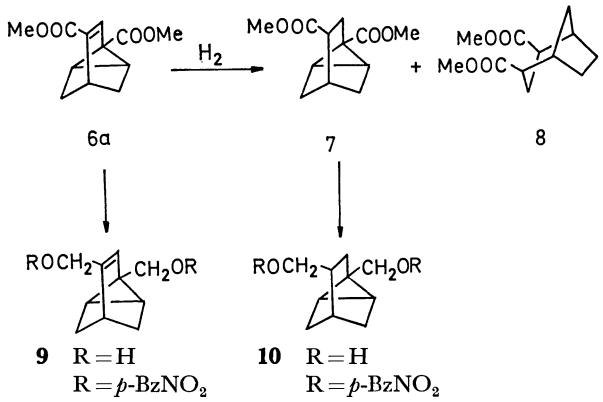
Scheme 1.

Meanwhile, taking the properties of 1,3-butadienes as a good diene part in Diels-Alder reaction as well as the lesser electron-withdrawing nature of the carboxylic acid **1** than that of the ester in consideration, we are intrigued by the possibility of the reaction path B[3] or C, the product **5** in the latter reaction path being a potential intermediate for the synthesis of natural products.[4]

Evidences to be presented gave the precedence to the reaction path A and the structural investigation and the fate of the adduct **3** will be described in detail in this report.[5]

Results and Discussion

The reaction of **1** with excess of butadiene (**2a**) in anhydrous methanolic solution at 100 °C for 6 h in a pressure bottle gave after treatment with ethereal diazomethane colorless needles **6a**, mp 101—102 °C, in 70% yield. This product was analyzed for C_8H_8-$(COOMe)_2$ by elemental analysis and mass spectrometry. The presence of a saturated ester function and an α,β-unsaturated ester moiety was apparent from the intense IR absorptions at 1735, 1710, and 1620 cm^{-1}. In UV spectrum a maximum at 243 nm (log ε 4.08) was interpreted to show the presence of a



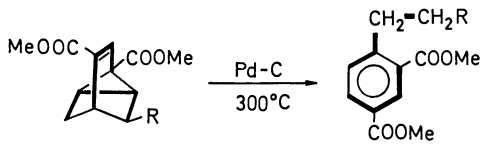
9 R=H, R=*p*-$BzNO_2$ **10** R=H, R=*p*-$BzNO_2$

Scheme 2.

β-cyclopropylacrylic ester chromophore[6] where the arrangement of the cyclopropane ring attains the maximum conjugation with the double bond, *i.e.*, the "bisected" conformation. Catalytic hydrogenation over Raney-Ni resulted in the uptake of one equivalent of hydrogen to yield the saturated ester **7**, but the hydrogenation over Pd–C gave a mixture of **7** and another product **8** resulting from the uptake of two equivalents; this fact clearly suggests the coexistence of a cyclopropane ring and a double bond. The structure of **8** was later deduced from the consideration of the reaction path and the symmetry confirmed by seven signals in its ^{13}C-NMR spectrum.

Lithium aluminum hydride reduction of **6a** and **7**, followed by treatment with *p*-nitrobenzoyl chloride gave the di-*p*-nitrobenzoates **9** and **10**, respectively. Although the NMR spectrum of **9** showed two singlets in the region of acyloxymethyl protons, **10** showed a singlet and a doublet of 6.6 Hz spacing. These facts indicate that **6a** has a carboxyl group on a tertiary carbon atom and an α,β-unsaturated ester group having no hydrogen at the α-position.

The fact that thermal treatment of **6a** over Pd–C at 300 °C gave an aromatic isomer, dimethyl 4-ethylisophthalate (**11**), especially combined with the fact that similar treatment of the 1,3-pentadiene adduct **6d** gave dimethyl 4-propylisophthalate (**12**), implicates the retention of a 1,3-dicarboxylate moiety and a butadiene moiety in **6a** without rearrangement or



6a R=H **11** R=H

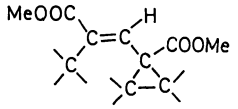
Scheme 3.

cleavage as shown by bold lines in Scheme 3. These results, taken together, require the partial structure i in **6a**.



i

Formula 1.

Further structural evidences were obtained from its NMR spectrum which showed five well-separated multiplets for eight ring-protons as well as the two singlets due to the ester methyl protons, indicating the inherent symmetry of the molecule (Fig. 1); its ^{13}C-NMR spectrum confirmed this symmetry. The large coupling constant between H_a and H_b (12.3 Hz) may be ascribed to the geminal coupling of the methylene protons. In view of the observed spin-spin couplings between H_a (2H) and H_b (2H), and H_c (2H) and H_d (1H) (4.8 Hz), these five protons must constitute the partial structure ii, in which the coupling J_{ad} is nearly

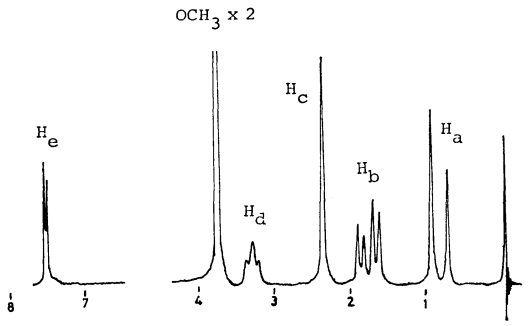


Fig. 1. ^{1}H-NMR spectrum of **6a** (60 MHz).

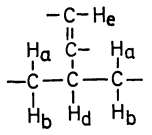
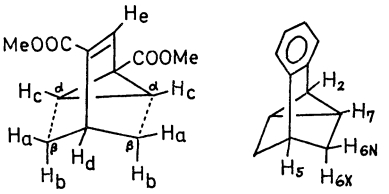


ii

Formula 2.

0 Hz. The triplet signals of H_d are further spin-splitted by the long-range coupling (1.7 Hz) with the olefinic proton H_e; this fact allows us to link the partial structures i and ii. Taking the total number of carbons and hydrogens into account, the other two protons (H_c) causing the 2H singlet may be divided into a cyclopropane ring as shown in the structure iii from consideration of the molecular symmetry. The bonding of C_α and C_β leads to a structure iii.



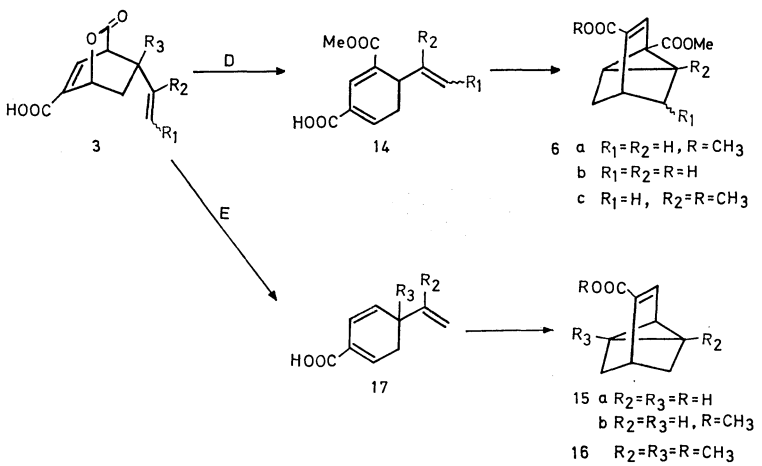
iii **13**

Formula 3.

At this stage, it was helpful to consider the NMR spectral features of the reported tricyclo[3.2.1.0^{2,7}]oct-3-ene system,[7] particularly of benzo[3,4]tricyclo[3.2.1.0^{2,7}]oct-3-ene (**13**).[7a] The cyclopropyl protons of **13** form a doublet due to the coupling with the other cyclopropyl proton H_2, but that of **6a** a singlet. The other coupling feature of the methylene protons is very similar in both compounds. It is well established[7] that, since the dihedral angles of *endo*-H_6–C_6–C_5–H_5 and *endo*-H_6–C_6–C_7–H_7 are close to 80°, little, if any, splitting is expected for these protons.

The reaction of **1** and butadiene **2a** under the same conditions described above gave, without diazomethane treatment, a half-ester **6b**. The structure of **6b** follows from the NMR spectrum which showed a similar pattern of the ring protons to that of **6a** except one ester methyl group. Its IR spectrum displayed strong carbonyl absorptions at 1740 and 1680 cm^{-1}: these bands are characteristic for a saturated ester and an α,β-unsaturated carboxylic acid. Therefore, to the half-ester **6b** is assigned the structure shown. Treatment of **6b** with diazomethane gave **6a** quantitatively.

These findings lead to the conclusion that **6b** is best explained as a result of two sequential Diels-Alder reactions. That is, the thermal [4+2]cycloaddition



Scheme 4.

reaction between the diene moiety of **1** and the ene part of **2** as the dienophile with inverse electron-demand would generate the bicyclic lactone **3**, which could then undergo methanolysis-dehydration to produce the half-ester of vinylcyclohexadienedicarboxylic acid **14**. The succeeding intramolecular Diels-Alder reaction also takes place with inverse electron-demand, giving the product **6b**. This [4+2]cycloaddition step leading to the cyclopropane ring formation has rather ample analogy.[8] Since the reaction step D in Scheme 4 without added acid-catalyst is unprecedent, the intermediate **3** was trapped to disclose the reaction mechanism. The reaction at lower temperature (80 °C) and in aprotic solvent (benzene) gave the lactone **3**. Thus obtained **3** reacted in anhydrous methanol only very sluggishly at 100 °C and gave at 150 °C **6b** and **15a** in a ratio of 1 : 3. The reaction temperature and course are different from those of the reaction of **1** and **2a**. This difference may be ascribed to the absence or presence of acid catalysis of **1** itself.[9]

The reaction of **1** with isoprene at 100 °C for 20 h gave after diazomethane treatment **6c** in 23% yield. The location of the methyl substitution is clearly demonstrated by consideration of the coupling pattern in the NMR spectrum. In this case, the coupling constant between the cyclopropyl proton H_7 and *endo*-methylene proton H_{6N} was observed as 2.3 Hz.

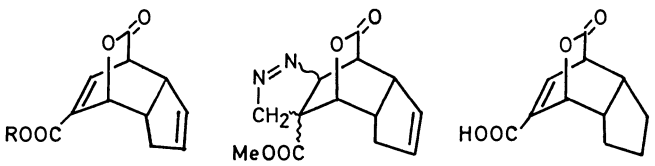
The reaction of **1** with 1,3-pentadiene at 100 °C for 20 h gave **6d** in 20% yield after diazomethane treatment.

In sharp contrast to the aforementioned case, the reaction of **1** with 2,3-dimethylbutadiene at 100 °C for 30 h gave chiefly a crystalline decarboxylated adduct **15b**. The structure of **15b** follows from its spectral characteristics. Treatment with diazomethane gave an oily ester **16**, which was identical with the tricyclic adduct obtained by the reaction of methyl coumalate with 2,3-dimethylbutadiene.[3]

This fact implies that with the change of the substituent(s) on the butadiene component, the construction of the ene-diene moiety necessary for the posterior Diels-Alder reaction of the primary cycloadduct was achieved by an alternative route E, *i.e.*, a simple decarboxylative step into **17**. Although the concurrent route E is supposed to be the reason for the low yield of **6c** and **6d**, inspection of the fore-run of distillation was fruitless since so many components were included.

We believe that the reaction presented herewith represents the simplest synthesis of the tricyclo[3.2.1.$0^{2,7}$]oct-3-ene system yet reported.[10]

The reaction of **1** with cyclopentadiene in boiling methanol for 3 h gave **18** in 48% yield. Elemental analysis showed it to be an undecarboxylated 1 : 1 adduct and its NMR spectrum revealed a marked similarity to that of the product **19** obtained by the reaction of methyl coumalate with cyclopentadiene. The identity of the skeletal structures of **18** and **19** was established by the fact that both gave the same 1,3-dipolar cycloadduct of the methyl ester **20** by the treatment with excess of ethereal diazomethane. Half hydrogenated product **21** of the adduct **18** showed in its NMR spectrum three well separated, mutually coupled pairs of doublet of doublets in the lower field



18 R=H
19 R=CH_3

20 **21**

Formula 4.

region (δ 3.97, 5.73, and 7.57): this reinforces the assignment of the signals in the spectrum of **18**.

It should be emphasized that even cyclopentadiene can behave mainly as a dienophile in this type of reaction.

Experimental

All the melting points were determined on a Yanagimoto hot-stage apparatus and are uncorrected. IR spectra were recorded on a Shimadzu IR 27-G spectrometer, and UV spectra on a Hitachi EPS-2 spectrophotometer. Mass spectra (MS) were obtained with a Hitachi RMS-4 spectrometer (70 eV). NMR spectra were measured on a JEOL C-60HL spectrometer using TMS as an internal standard. We are grateful to Dr. S. Kojima for the courtesy that made possible the use of this instrument. ^{13}C-NMR spectra were obtained with a Varian CFT-20 spectrometer at 20 MHz in $CDCl_3$ solution using TMS as an internal standard. Microanalyses were performed by Mrs. K. Fujimoto using a Yanagimoto C.H.N. Corder MT-1. GLC was performed with a Shimadzu GC-4AIT with a 3 mm×3 m column packed with 10% High Vacuum Silicone Grease on Chromosorb W (80—100 mesh).

*Reaction of **1** with Butadiene.* (a) A suspension of **1**[9] (7.0 g) and excess of butadiene (20 ml) in methanol (35 ml) was heated in a pressure bottle at 100—110 °C for 5 h. After removal of the solvent, treatment with ethereal diazomethane, concentration, and distillation gave with a small amount of fore-run, a fraction of bp 172 °C/15 Torr, which crystallized immediately (mp 97—98 °C). Recrystallization from diisopropyl ether or methanol gave **6a** (2.2 g; 70%) as colorless needles: mp 101—102 °C; IR and UV (EtOH): see text; MS, *m/e*(rel intensity) 222(M^+, 44), 207 (16), 191(25), 190(20), 163(100), 131(44), 119(20), 103 (37), 91(26), 77(22), 59(45); NMR (CCl_4): δ 0.84 (2H, d, 12.3 Hz, H_{6N} and H_{8N}), 1.74(2H, dd, 4.9 and 12.3 Hz, H_{6X} and H_{8X}), 2.28(2H, bs, H_1 and H_7), 3.27 (1H, bt, 4.9 and 1.8 Hz, H_5), 7.36(1H, d, 1.8 Hz, H_3), and 3.70 and 3.73(3H each, s, COOMe); ^{13}C-NMR: δ 28.3(t, C_6 and C_8), 29.4(d, C_1 and C_7), 29.7(s, C_2), 31.1(d, C_5), 51.4 and 52.0 (q, OMe), 131.1(s, C_4), 132.4(d, C_3), 164.9 (C=C-C=O), 171.5(s, C=O). Found: C, 65.05; H, 6.38%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

(b) A similar reaction using 2.00 g of **1** afforded without diazomethane treatment 0.89 g (30%) of **6b**, on standing for many days after removal of the solvent: mp 178—178.5 °C (MeOH); IR(Nujol): see text; NMR ($CDCl_3$): δ 0.88 (2H, d, 12.3 Hz, H_{6N} and H_{8N}), 1.82(2H, dd, 12.3 and 4.8 Hz, H_{6X} and H_{8X}), 2.43(2H, bs, H_1 and H_7), 3.32(1H, bt, 4.8 Hz, H_5), 7.70(1H, d, 1.8 Hz, H_3), 3.76 (3H, s, COOMe). Found: C, 63.18; H, 5.65%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

(c) A suspension of **1** (500 mg) and excess of butadiene (1 ml) in benzene (20 ml) with a trace amount of hydroquinone was heated in a pressure bottle at 150 °C for 20 h.

After removal of the solvent, distillation gave a fraction of bp 160—180 °C/25 Torr (381 mg; 71%), which crystallized soon (mp 107—110 °C). Recrystallization from ether gave an analytically pure **15a**: mp 117—118 °C; IR(Nujol): 1660, 1600 cm^{-1}; NMR ($CDCl_3$), δ 0.75(2H, d, 12.0 Hz, H_{6N} and H_{8N}), 1.5—2.0(3H, cm, H_1, H_2, and H_7), 3.23(1H, bt, H_5), 7.24(1H, dd, 5.4 and 2.0 Hz, H_3). Found: C, 71.97; H, 6.65%. Calcd for $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

(d) A similar mixture from 310 mg of **1** was heated at 80 °C for 6 days. After removal of the solvent, preparative TLC separation gave 109 mg of **3a** as thermally very labile oil; NMR($CDCl_3$): δ 1.53 (1H, ddd, 14, 4, and 2 Hz, H_{5N}), 2.52(1H, ddd, 14, 10, and 4 Hz, H_{5X}), 2.90(1H, m, H_4), 3.80(1H, dd, 6.4 and 2.8 Hz, H_3), 5.0—6.0(4H, complex m, H_6 and vinyl H), 7.48(1H, dd, 6.4 and 2.4 Hz, H_2).

The adduct **3a** (72 mg) in anhydrous methanol was heated at 100 °C for 6 h to result in only small conversion. Heating further at 150 °C for 4 h gave a mixture of **6b** and **15a** in a ratio of 1 : 3 (by NMR analysis).

*Catalytic Hydrogenation of **6a**.* A solution of **6a** (111 mg) in methanol (30 ml) was hydrogenated over Raney-Ni, resulting in one equivalent H_2 uptake. Filtration and solvent removal gave oily **7** (110 mg) which showed only one peak on GLC analysis. Analytical sample of **7** had bp 142—143.5 °C/5 Torr: $n_D^{24.8}$ 1.4924; IR(neat): 1750, 1720, 1625 cm^{-1}; MS: *m/e* 224(M^+, 20), 193(35), 192(100), 164 (76), 137(28), 132(49), 105(77), 79(23), 77(22), 59(26): NMR($CDCl_3$): δ 1.4—2.7(10H, m), 3.67 and 3.72(3H each, s, $COOCH_3$); ^{13}C-NMR: δ 19.3(t), 23.1(s), 27.0(t), 27.7(d), 27.6(d), 32.4(t), 32.7(d), 41.8(d), 51.6(q), 51.7(q), 174.7(s), 175.1(s). Found: C, 64.39; H, 7.17%. Calcd for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19%.

A solution of **6a** (444 mg) in ethanol (30 ml) was hydrogenated over 5% Pd–C (400 mg), resulting in 74 ml (1.65 eq) of H_2 uptake. Removal of the catalyst and the solvent gave an oily mixture, which was shown by GLC analysis to consist of two components **7** and **8** in the ratio of 5.9 : 1. After preparative GLC separation, the major component was identified to be **7** by spectral comparison. The minor component **8** had bp 140—145 °C(bath)/5 Torr; NMR ($CDCl_3$): δ 1.4—2.7 (12H, m), 3.78(6H, s, $COOCH_3$); ^{13}C-NMR: δ 21.9(t), 28.8(t×2), 32.5(t), 36.4(d×2), 44.8 (d×2), 51.6(q×2), 175.3(s×2); MS: *m/e* 226 (M^+, 5), 195(23), 194(59), 167(30), 166(100), 162(20), 160(20), 135(31), 134(31), 107(61), 80(31), 79(55), 67(23). Found: C, 63.98; H, 8.06%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*Di-p-nitrobenzoate **9**.* A solution of **6a** (222 mg) in ether (30 ml) was added dropwise to $LiAlH_4$ (100 mg) suspended in dry ether (30 ml). The mixture was stirred for 2 h and excess of hydride was decomposed by addition of ethyl acetate and then satd. Rochelle salt solution (50 ml). The ethereal solution was dried (Na_2SO_4) and evaporated to give diol (227 mg). The diol without purification was dissolved in pyridine–CH_2Cl_2, and *p*-nitrobenzoyl chloride (371 mg) was added. After standing overnight at room temperature the mixture was poured onto ice water, and extracted with CH_2Cl_2. The organic solution was washed successively with dil HCl, satd. $NaHCO_3$, and water. The solution was dried and evaporated, and digestion of the residue with ethanol and several recrystallizations gave **9**: mp 91—92 °C; IR(Nujol): 1720, 1528, and 1350 cm^{-1}; NMR ($CDCl_3$): δ 0.95 (2H, d, 14 Hz, H_{6N} and H_{8N}), 1.66(2H, bs, H_1 and H_7), 1.7(2H, m, H_{6X} and H_{8X}), 2.76(1H, bt, H_5), 6.17(1H, bs, H_3), 4.47(2H, s, $-OCH_2$), 4.88(2H, s, $-OCH_2$), 8.28(8H, s, Ar-H). Found: C, 61.88; H, 4.23; N, 5.75%. Calcd for $C_{24}H_{20}N_2O_8$: C, 62.06; H, 4.34; N, 6.03%.

*Di-p-nitrobenzoate **10**.* Similarly to the above, the dihydro ester **7** (254 mg) was reduced by $LiAlH_4$ (110 mg). After usual work-up, the resulting diol without purification was treated with 400 mg of *p*-nitrobenzoyl chloride, giving **10**, mp 143—144 °C (EtOH); IR(Nujol): 1722(with shoulder), 1528, 1355 cm^{-1}; NMR($CDCl_3$): δ 1.4—2.3(10H, m), 5.88 (2H, s, $-O-CH_2$), 5.76(2H, d, 6.6 Hz, $-OCH_2$), 8.25(8H, s, Ar-H). Found: C, 61.56; H, 4.78; N, 5.75%. Calcd for $C_{24}H_{22}N_2O_8$: C, 61.80; H, 4.75; N, 6.01%.

*Isomerization of **6a** with Pd–C.* A suspension of 10% Pd–C (500 mg) in **6a** (1.0 g) was heated in a test tube at 300—310 °C for 2 h. Ethereal extract of the reaction mixture was evaporated to give crude oil (802 mg), which showed a single peak on GLC analysis. Distillation gave diemthyl 4-ethylisophthalate[12] (**11**) (591 mg): bp 142—146 °C/5 Torr; $n_D^{26.0}$ 1.5202; IR(neat): 1738(with shoulder), 1614 cm^{-1}; NMR(CCl_4): δ 1.24(3H, t, 7.5 Hz, $CH_2\underline{CH}_3$), 3.04 (2H, q, 7.5 Hz, $\underline{CH}_2CH_3$), 7.27(1H, d, 8.6 Hz, H_5), 8.01 (1H, dd, 8.6 and 2.0 Hz, H_6), 8.44(1H, d, 2.0 Hz, H_2), 3.93(6H, s, $COOCH_3$). (Found: C, 64.94; H, 6.38%).

For comparison, when **6a** (500 mg) was heated without addition of Pd-C at 300—310 °C for 3 h, **6a** (200 mg) was recovered after distillation: mp 98—110 °C.

*Reaction of **1** with Isoprene.* A suspension of **1** (2.0 g) and isoprene (6 ml) in methanol (50 ml) was heated at 100—110 °C for 24 h in a pressure bottle. Removal of the solvent, treatment with ethereal diazomethane and subsequent evaporation gave an oily mixture. Fractional distillation with a Vigreux column gave a fore-run (bp 120—160 °C/15 Torr: 1.01 g) and **6c** (761 mg: 23%); bp 160—165 °C/15 Torr. The fore-run showed on GLC analysis at least six peaks and the structures were not further investigated. Analytically pure **6c** had bp 132—136 °C/5 Torr; IR(neat): 1740 (with shoulder), 1620 cm^{-1}; NMR(CCl_4): δ 0.85(2H, d, 12.3 Hz, H_{6N} and H_{8N}), 1.43 (3H, s, C_1-CH_3), 1.65 (1H, dd, 12.3 and 5.0 Hz, H_{8X}), 1.82(1H, ddd, 12.3, 5.0, and 2.3 Hz, H_{6X}), 2.26(1H, bd, 2 Hz, H_7), 3.22(1H, bt, H_5), 7.32(1H, d, 1.7 Hz, H_3), 3.67 and 3.73(3H each, s, $COOCH_3$). Found: C, 65.91; H, 7.06%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

*Reaction of **1** with 1,3-Pentadiene.* A suspension of **1** (2.0 g) and 1,3-pentadiene (*cis/trans* mixture: 4 ml) in methanol (50 ml) was heated at 110 °C for 9 h. After diazomethane treatment and solvent removal, the residue was fractionally distilled at 4 Torr with a 10 cm Vigreux column, giving four fractions; A: 85—95 °C (470 mg); B: 95—118 °C (837 mg); C: 128—140 °C (725 mg); D: 140—155 °C (249 mg). From the fractions B, C, and D, crystalline **6d** (286 mg) was obtained: mp 98.5—99.5 °C. Column chromatography (Al_2O_3: PhH) of the mother liquid (B,C,D) gave further crop of crystals (415 mg: total 21%); IR(Nujol): 1740 (with shoulder), 1620 cm^{-1}; MS: *m/e* 326(M^+, 77), 221(29), 205(44), 204(60), 177(100), 163(33), 145(61), 117(40), 105(36), 91(31), 59(37); NMR(CCl_4): δ 0.61(3H, d, 7.2 Hz, *endo*-CH_3-C_6), 0.90(1H, d, 12.2 Hz, H_{8N}), 1.87 (1H, ddd, 12.2, 2.0, and 4.8 Hz, H_{8X}), 2.1(1H, ddd lower half was obscured by overlapping, 7.3, 3.7, and 2 Hz, H_{6X}), 2.18 and 2.28 (1H each, AB q with further splitting, 5.4 and 2 Hz, H_1 and H_7), 3.16(1H, bt, H_5), 7.67(1H, d, 2.0 Hz, H_3), 3.76(6H, s, 2×$COOCH_3$). Found: C, 65.96; H, 6.75%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

*Pd–C Treatment of **6d**.* A sample of **6d** (200 mg) was heated with Pd–C at 300—310 °C as described before. Work-up and distillation gave a single substance **12**: bp 150 °C (bath)/5 Torr; IR(neat): 1735 (with shoulder), 1610 cm^{-1}; MS: *m/e* 236 (M^+, 37), 205(100), 189(57); NMR(CCl_4):

δ 1.02(3H, t, 7.0 Hz, CH_3), 1.57(2H, m, $CH_2\underline{CH_2}CH_3$), 2.99 (2H, t, 8.2 Hz, $\underline{CH_2}CH_2CH_3$), 7.31(1H, d, 8.2 Hz, H_6), 8.07 (1H, dd, 8.2 and 1.8 Hz, H_5), 8.53(1H, d, 1.8 Hz, H_2), 3.92(6H, s, $2\times COOCH_3$). Found: C, 66.12; H, 6.91%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Reaction of ***1*** *with 2,3-Dimethylbutadiene.* A suspension of **1** (2.0 g) and 2,3-dimethylbutadiene (2 ml) in methanol (50 ml) was heated at 100—110 °C for 30 h. Removal of the solvent and distillation gave an oily mixture (2.156 g): bp 150—180 °C/20 Torr. Upon standing **15b** crystallized (378 mg): mp 191—192 °C(CH_2Cl_2); IR(Nujol): 3400—2400, 1670, 1608 cm^{-1}; MS: *m/e* 178(M^+, 82), 163(29), 133(100), 119(26), 117(27), 105(70), 93(33), 91(71), 79(34); NMR ($CDCl_3$): δ 0.82(2H, d, H_{6N} and H_{8N}), 1.63(2H, dd, 12.3 and 3.4 Hz, H_{6X} and H_{8X}), 3.11(1H, bt, H_5), 7.40(1H, dd, 7 and 2 Hz, H_3), 1.28(6H, s, CH_3-C_1 and CH_3-C_7), 1.3 (1H, d, H_2). Found: C, 74.30; H, 7.99%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

The acid **15b** was esterified with CH_2N_2 giving in a quantitative yield the ester **16** which was identical in all respects with an authentic sample.[3]

Reaction of ***1*** *with Cyclopentadiene.* A solution of **1** (2.0 g) and freshly prepared cyclopentadiene (2.5 g) in methanol (80 ml) was heated under reflux for 3 h. Removal of the solvent and dicyclopentadiene gave a crystalline residue. Recrystallization from ethanol gave **17** (1.397 g: 47.5%): mp 198—199 °C(dec); IR($CHCl_3$): 3400—2400, 1738, 1688, 1630 cm^{-1}; NMR($CDCl_3+CF_3COOH$): δ 1.90(1H, d with further splittings, 17.2 Hz, H_{1N}), 2.57(1H, dd, with further splittings, 17.2 and 9.2 Hz, H_{1X}), 3.2(1H, m, H_{7a}), 3.4(1H, m, H_{3a}), 3.93(1H, dd, 6.3 and 2.9 Hz, H_4), 5.38 and 5.58(1H each, AB q with further splittings, 6.8 Hz, H_3 and H_2), 5.67 (1H, dd, H_7), 7.32(1H, dd, 6.3 and 2.3 Hz, H_5). Found: C, 63.82; H, 4.87%. Calcd for $C_{11}H_{10}O_4$: C, 64.07; H, 4.89%.

Partial Hydrogenation of ***18****.* A solution of **18** (1.0 g) in ethanol (100 ml) was hydrogenated over 5% Pd–C (0.5 g) until about one equivalent (120 ml) of H_2-uptake resulted. Immediate removal of the catalyst and the solvent, followed by several recrystallizations from ethanol gave **21** (525 mg): mp 160—161 °C (dec with frothing); IR(Nujol): 1716, 1760(shoulder), 1628 cm^{-1}; NMR ($CDCl_3+CF_3COOH$): δ 0.8—2.2(6H, m, $3\times CH_2$), 2.4—3.2(2H, m, $2\times CH$), 3.97(1H, dd, 6.9 and 3.0 Hz, H_4), 5.73(1H, dd, 4.2 and 2.6 Hz, H_7), 7.57(1H, dd, 6.9 and 2.6 Hz, H_5). Found: C, 63.40; H, 5.69%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

1,3-Dipolar Cycloaddition of Diazomethane. A solution of **19** (650 mg) in CH_2Cl_2 was treated with excess of CH_2N_2. After standing for 4 h, AcOH was added until the faint yellow color of CH_2N_2 was disappeared. Solvent removal followed by recrystallization (MeOH) gave **20** (694 mg): mp[12] 146—147 °C(dec with frothing); IR ($CHCl_3$): 1765, 1746 cm^{-1}; MS: *m/e* 234(M^+, small), 190(20), 175(61), 169(50), 131(100), 129(27), 116(27), 115(30), 91(45), 66(41), 44(93); NMR($CDCl_3$): δ 2.3—2.8(2H, m, CH_2), 2.7—3.5 (4H, m, CH), 4.82 and 4.92(1H each, AB q, NCH_2), 5.6—5.8(2H, m, olefinic H), 3.85(3H, s, $COOCH_3$). Found: C, 59.29; H, 5.32; N, 10.77%. Calcd for $C_{13}H_{14}N_2O_4$: C, 59.53; H, 5.38; N, 10.68%.

A solution of **18** (500 mg) in methanol was treated with CH_2N_2 as described above. The obtained crystals had mp[12] 146—147 °C. The spectral characteristics were consistent with those of the product described above.

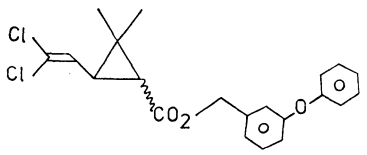
Studies on Chrysanthemate Derivatives. VI.[1] A Stereoselective Synthesis of *trans*-3-(2,2-Dichlorovinyl)-2,2-dimethyl-1-cyclopropanecarboxylic Acid and Related Compounds

Yasuo NAKADA,* Rokuro ENDO, Shigeki MURAMATSU, Junya IDE, and Yasuo YURA[2]
Central Research Laboratories, Sankyo Co., Ltd. 1-2-58 Hiromachi, Shinagawa-ku, Tokyo 140

(Received October 7, 1978)

A new method is described for the stereoselective synthesis of *trans*-3-(2,2-dichlorovinyl)-2,2-dimethyl-1-cyclopropanecarboxylic acid (**2t**) *via* ethyl 3,3-dimethyl-4,6,6,6-tetrachlorohexanoate (**3a**) as a key intermediate. The key intermediate (**3a**) was obtained by addition of carbon tetrachloride to ethyl 3,3-dimethyl-4-pentenoate, prepared by condensation of 3-methyl-2-buten-1-ol and triethyl orthoacetate followed by Claisen rearrangement. Treatment of **3a** with sodium *t*-pentyloxide in benzene gave ethyl *trans*-2,2-dimethyl-3-(2,2,2-trichloroethyl)-1-cyclopropanecarboxylate (**6t**) in good yield. Dehydrochlorination and hydrolysis of **6t** using potassium hydroxide in ethanol afforded **2t** in high yield.

Natural pyrethrins and related synthetic pyrethroids, which consist mainly of furylmethyl and cyclopentenyl derivatives as alcohol moieties and chrysanthemic acid as acid moiety, are unstable in air and light.[3] This property restricts their use, particularly against agricultural pests, in spite of their outstanding potency against many insect species and low mammalian toxicity. 3-Phenoxybenzyl alcohol was discovered by the Sumitomo group to be useful as an alcohol moiety of pyrethroids and the benzyl chrysanthemate (phenothrin) had been known to be relatively resistant to photo-irradiation.[4] Its stability, however, has been assessed to be still insufficient for agricultural use. Recently, Elliott and his coworkers have found a new pyrethroid, 3-phenoxybenzyl 3-(2,2-dichlorovinyl)-2,2-dimethyl-1-cyclopropanecarboxylate (**1**; permethrin) which showed adequate stability in light and air, prominent insecticidal activity, and low mammalian toxicity.[5] This breakthrough focused attention on the potential of synthetic pyrethroids in agricultural pest control. Further detailed investigation on permethrin (**1**) has clarified that the *trans*-isomer of **1** was much less toxic to mammals than the *cis*-isomer.[6]

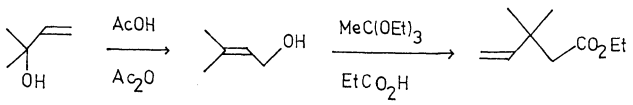


Permethrin (**1**)

The acid moiety of permethrin (**1**), 3-(2,2-dichlorovinyl)-2,2-dimethyl-1-cyclopropanecarboxylic acid (**2**; dichlorovinylchrysanthemic acid), was originally synthesized by Farkas *et al.*[7] by cyclopropanation of 1,1-dichloro-4-methyl-1,3-pentadiene with ethyl diazoacetate. Alternatively, the acid (**2**) was prepared by ozonolysis of the parent chrysanthemate followed by condensation of the resulting 2,2-dimethyl-3-formyl-1-cyclopropanecarboxylate with dichloromethylenetriphenylphosphorane.[8]

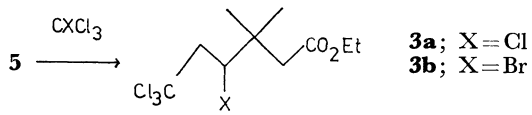
These methods, however, provide less satisfactory results from an industrial point of view concerning yield, stereoselectivity of the cyclopropanecarboxylate formation, and cost. Under these considerations, the stereoselective synthesis of **2** deserves high priority.[9] In this report, we describe a new stereoselective synthesis of the *trans*-isomer (**2t**)[10] *via* ethyl 3,3-dimethyl-4,6,6,6-tetrachlorohexanoate (**3a**) as a key intermediate.[11]

3-Methyl-2-buten-1-ol (**4**) was prepared by allylic rearrangement of 2-methyl-3-buten-2-ol in the presence of acetic acid and acetic anhydride followed by hydrolysis with aqueous sodium hydroxide in good yield. Condensation of **4** and triethyl orthoacetate followed by Claisen rearrangement under catalysis of propionic acid gave ethyl 3,3-dimethyl-4-pentenoate (**5**) in 54% yield according to the procedure of Johnson *et al.*[12]



4 **5**

Addition reaction of haloalkanes such as carbon tetrahalides and haloforms to olefins using transition metal halides as catalysts was applied to elongation of the vinyl chain in **5** by trichloromethyl group.[13] In addition of carbon tetrachloride to **5**, the combination of iron(III) chloride and benzoin gave the ester **3a** in satisfactory yield. Addition of bromotrichloromethane to **5** occurred at lower temperature under the same catalyst to give ethyl 4-bromo-3,3-dimethyl-6,6,6-trichlorohexanoate (**3b**) in moderate yield.



3a; X=Cl
3b; X=Br

The mass spectrum of the adduct (**3a**) showed molecular peaks at *m/e* (relative intensity): 314 (1), 312 (4), 310(9), and 308 (7) suggesting a 1 : 1 adduct between **5** and carbon tetrachloride. The NMR spectrum of **3a** showed two doublets at 2.28 (1H; J=15.1 Hz) and 2.53 ppm (1H; J=15.1 Hz) assignable to nonequivalent methylene protons adjacent to the carboxyl group, and three doubleting doublets at 3.08 (1H; J=6.3 and 16.2 Hz), 3.22 (1H; J=2.8 and 16.2 Hz), and 4.40 ppm (1H; J=2.8 and 6.3 Hz) assignable to nonequivalent two methylene protons and the chloromethine proton, respectively.

Cyclization of **3a** was conducted with the use of a variety of bases (Table 1). The distribution of reaction products substantially depends on the employed bases: sodium *t*-pentyloxide in *t*-pentyl alcohol

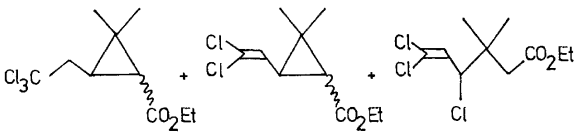
Table 1. Cyclization of ethyl 3,3-dimethyl-4,6,6,6-tetrachlorohexanoate (**3a**) with various bases

Run No	Base (2 mmol)	Solvent	Time (h)[a]	Yield (%) 6 *cis*	6 *trans*	7 *cis*	7 *trans*	8
1	EtONa[b]	EtOH	16	>1	1	>1	2	14
2	t-$C_5H_{11}ONa$	t-$C_5H_{11}OH$	2	24	41	2	5	—
3	NaH[c]	DMF	4	5	10	>1	>1	>1
4	$NaNH_2$[d]	DMF	4	1	8	>1	>1	48
5	DBU	THF	16	—	—	—	—	75

a) Reaction temperature: room temperature. b) The starting material (**3a**) was recovered in 67% yield. c) A complex mixture which was not separated was obtained in about 60% yield. d) An unidentified product was obtained in about 20% yield.

gave the cyclized products in good yield, *i.e.*, ethyl 2,2-dimethyl-3-(2,2,2-trichloroethyl)-1-cyclopropanecarboxylate (**6**) as a main product and ethyl dichlorovinylchrysanthemate (**7**), the product of further elimination, as a minor one, whereas the reaction with sodium ethoxide, sodium amide, and 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) in the solvents listed in Table 1 only resulted in the formation of the dehydrochlorinated compound, ethyl 3,3-dimethyl-4,6,6-trichloro-5-hexenoate (**8**).

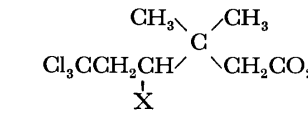
3a ⟶



6 **7** **8**

Furthermore scrutiny of cyclization of **3a** and **3b** was made with various solvents using sodium t-pentyloxide as a base (Table 2). In cyclization of the chloride (**3a**), the use of benzene, a less polar aprotic solvent, furnished stereoselectively *trans*-cyclization products (**6t** and **7t**), whereas the use of polar solvents such as dioxane, ether, and tetrahydrofuran (THF) increased the amount of *cis*-cyclization products (**6c** and **7c**). In particular the use of THF as a solvent gave predominantly the products of further elimination (**7c** and **7t**) and the total ratio of *cis*/*trans* (**6c**+**7c**/**6t**+**7t**) was nearly 1 : 1. Eventually combination of inverse addition of the base and controlled reaction temperature provided the maximal ratio of *trans*- and *cis*-isomer (Run 2). However, the cyclization of the bromide (**3b**), even in a less polar aprotic solvent such as benzene, proved to be less stereoselective, resulting in a ratio of 3 : 5 (**6c** and **6t**). The results suggest that the *cis*/*trans* ratio of the product (**6**) depends to a great extent on both the polarity of the solvents and the leaving groups (Cl or Br). Presumably in a less polar aprotic solvent the cyclization of the chloride (**3a**) may proceed by bimolecular 1,3-elimination reaction (E2), prefering *anti*-parallel elimination to *syn*-elimination. On the other hand, in a polar solvent it may proceed by unimolecular 1,3-elimination reaction (E1), leading to a mixture of *cis*- and *trans*-isomers. There would be three conformers (**A**, **B**, and **C**) in the chloride **3a**, among which, however, the conformer **C** would be unfavorable because of nonbonded dipole-dipole interaction between the carbonyl

Table 2. Cyclization of ethyl 3,3-dimethyl-4-halo-6,6,6-trichlorohexanoate (**3a**) and (**3b**) with sodium t-pentyloxide in various solvents



3a: X=Cl, **3b**: X=Br

a) Reaction conditions: room temperature for 2 h. b) Inverse addition of the base and reaction at 15—20 °C for 5 h.

group and the chlorine atom. Of the conformers **A** and **B**, the conformer **A** undergoes cyclization smoothly by bimolecular *anti*-parallel 1,3-elimination of hydrogen chloride in a less polar aprotic solvent to lead to the *trans*-isomer, while the conformer **B** does not cyclize in a such manner because of its having no hydrogen *anti*-parallel to the chlorine atom. The *cis*-isomer would be formed by *syn*-1,3-elimination of the conformer **A** and/or unimolecular 1,3-elimination, which is likely in polar aprotic solvents. Under the same conditions as the case of the chloride (**3a**), the bromide (**3b**) tended to increase the *cis*-isomer. Since the reactivity of the bromine atom as a leaving group is much higher than that of the chlorine atom, the unimolecular reaction may significantly compete with the bimolecular *anti*-parallel 1,3-elimination even in a less polar aprotic solvent such as benzene.

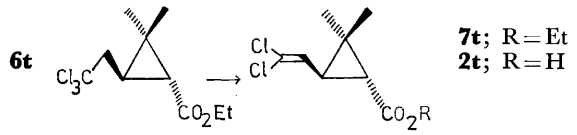
Table 3. Dehydrochlorination of ethyl *trans*-2,2-dimethyl-3-(2,2,2-trichloroethyl)-1-cyclopropanecarboxylate (**6t**)[a]

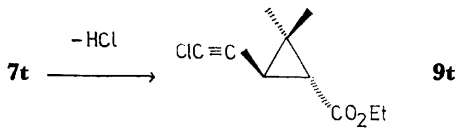
Run No	Reagent (mmol)	Solvent (ml)	Reaction conditions	Product	Yield (%)
1	KOH (25)	EtOH (30)	55 °C, 20 h	**2t**	92
2	DBU (10)	—	90 °C, 15 min	**7t**	96
3	$ZnCl_2$ (0.5)	—	120 °C, 2 h	**7t**	38

a) Compound **6t** (5 mmol) was used.

The *cis*- and *trans*-isomers of **6** were successfully separated by high pressure liquid chromatography (see Experimental part). In the NMR spectrum (100 MHz), the methine proton adjacent to the carboxyl group on the cyclopropane ring of the *cis*-isomer showed a doublet at 1.66 ppm with a coupling constant of J=8.4 Hz, and the corresponding proton of the *trans*-isomer was observed at 1.36 ppm with a coupling constant of J=5.4 Hz. The fact that the methine proton of the *trans*-isomer appeared at higher field than the *cis*-isomer may be due to the shielding effect of the trichloroethyl group in the same side. Furthermore these assignments are consistent with the values of the coupling constants in *cis*- and *trans*-protons on cyclopropane rings.[14]



Dehydrochlorination of *trans*-isomer of the ester (**6t**) was examined with several dehydrohalogenation reagents (Table 3). Treatment of **6t** with potassium hydroxide in ethanol and DBU gave the *trans*-acid (**2t**) and the ester (**7t**) respectively in excellent yield. The elimination from **6t** was also effected by zinc chloride to afford **7t** in moderate yield. Under the reaction conditions employed above, no isomerization from *trans*-isomers to *cis*-isomers was observed.



Treatment of **7t** with potassium *t*-butoxide in THF gave ethyl *trans*-3-(2-chloroethynyl)-2,2-dimethyl-1-cyclopropanecarboxylate (**9t**) in good yield.

Experimental

IR spectra were measured on a JASCO IR-A2 Spectrometer. NMR spectra were obtained in a Varian High Resolution NMR Spectrometer A-60 or HA-100 using tetramethylsilane as an internal standard. Chemical shifts are expressed in ppm. Mass spectra were recorded on a Japan Electron Optics Lab. Spectrometer JMS-01SG. All melting and boiling points are uncorrected.

*3-Methyl-2-buten-1-ol (**4**).* To a solution of acetic acid (500 ml), acetic anhydride (200 ml), and *p*-toluenesulfonic acid (20 g) was added dropwise a solution of 2-methyl-3-buten-2-ol (88 g) in acetic acid (100 ml) at 20 °C. After stirring for 15 min at room temperature, the mixture was poured into ice-water, neutralized with 10% aqueous potassium hydroxide, and extracted with ether. The extracts were washed successively with 5% aqueous potassium hydroxide and aqueous sodium chloride and dried over anhydrous sodium sulfate. Distillation gave 79 g of 3-methyl-2-butenyl acetate, bp 69—75 °C/53 mmHg (lit,[15] bp 40—44 °C/15 mmHg). The acetate was hydrolyzed by sodium hydroxide in aqueous methanol to give **4** in 70% yield, bp 65—68 °C/38 mmHg (lit,[15] bp 45—52 °C/15 mmHg).

*Ethyl 3,3-Dimethyl-4-pentenoate (**5**).* The pentenoate **5** was prepared according to the procedure of Johnson *et al.*[12] A solution of the alcohol **4** (8.6 g), triethyl orthoacetate (81 g), and propionic acid (0.45 g) was stirred at 130—140 °C for 4 h under removing of the resulting ethanol. After cooling, the reaction mixture was washed with saturated aqueous solution of sodium hydrogencarbonate and then with that of sodium chloride, and dried over anhydrous magnesium sulfate. The organic fraction was carefully distilled to give 5.3 g of **5**;[16] bp 81—83 °C/47 mmHg (lit,[16a] bp 35—45 °C/0.10 mmHg), IR, ν_{max}^{film} cm^{-1}: 1740, 1645, 1230, and 915, NMR ($CDCl_3$): 1.15 (s, 6H, $2CH_3$), 1.24 (t, 3H; J=7.1 Hz, $OCH_2\underline{CH_3}$), 2.31 (s, 2H, $\underline{CH_2}CO_2$), 4.16 (q, 2H; J=7.1 Hz, $O\underline{CH_2}CH_3$), 5.01 (dd, 1H; J=1.5 and 10.4 Hz, CH=C$\underline{H}$H), 5.03 (dd, 1H; J=1.5 and 18.3 Hz, CH=CH$\underline{H}$), and 6.02 (dd, 1H; J=10.4 and 18.3 Hz, $\underline{CH}$=CHH).

*Addition of Tetrahalomethane to **5**.* A mixture of **5** (0.1 mol), carbon tetrachloride (0.3 mol), isopropyl alcohol (0.2 mol), iron(III) chloride (0.01 mol), benzoin (0.01 mol), and diethylamine hydrochloride (0.015 mol) was heated under nitrogen at 70—80 °C for 8 h. After cooling, the mixture was diluted with 1% hydrochloric acid and extracted with chloroform. The extracts were dried over anhydrous magnesium sulfate and evaporated *in vacuo* to give a residue, which was distilled to afford the 1 : 1 adduct, ethyl 3,3-dimethyl-4,6,6,6-tetrachlorohexanoate (**3a**) in 82% yield, bp 112—117 °C/0.6 mmHg, IR, ν_{max}^{film} cm^{-1}: 1730 and 1200, NMR (CCl_4): 1.10 (s, 3H, CH_3), 1.18 (s, 3H, CH_3), 1.23 (t, 3H; J=7.0 Hz, $OCH_2\underline{CH_3}$), 2.28 (d, 1H; J=15.1 Hz, C$\underline{H}$HHCO$_2$), 2.53 (d, 1H; J=15.1 Hz, CH$\underline{H}$HCO$_2$), 3.08 (dd, 1H; J=6.3 and 16.2 Hz, ClCHC$\underline{H}$H), 3.22 (dd, 1H; J=2.8 and 16.2 Hz, ClCHC$\underline{H}$H), 4.11 (q, 2H; J=7.0 Hz, $O\underline{CH_2}CH_3$), 4.40 (dd, 1H; J=2.8 and 6.3 Hz, ClC$\underline{H}$CHH), MS, *m/e* (relative intensity) for $C_{10}H_{16}O_2{}^{35}Cl_4$: 314 (1), 312 (4), 310 (9), and 308 (M^+, 7). With the same catalyst as the case of the addition of carbon tetrachloride, bromotrichloromethane and **5** were heated at 35—45 °C for 5 h to give ethyl 4-bromo-6,6,6-trichlorohexanoate (**3b**) in 33% yield, IR, ν_{max}^{film} cm^{-1}: 1730, 1150, and 650, NMR ($CDCl_3$): 1.17 (s, 3H, CH_3), 1.26 (s, 3H, CH_3), 1.27 (t, 3H; J=7.2 Hz, $OCH_2\underline{CH_3}$), 2.37 (d, 1H; J=15.1 Hz, C$\underline{H}$HCO$_2$), 2.65 (d, 1H; J=15.1 Hz, CH$\underline{H}$CO$_2$), 3.31 (d, 1H; J=5.0 Hz, BrCHC$\underline{H}$H), 3.32 (d, 1H; J=3.5 Hz, BrCHCH$\underline{H}$), 4.15 (q, 2H; J=7.2 Hz, $O\underline{CH_2}CH_3$), and 4.55 (dd, 1H; J=3.5 and 5.0 Hz, BrC$\underline{H}$CHH). Found: C, 33.90; H, 4.52; Br, 22.60; Cl, 30.11. Calcd for $C_{10}H_{16}O_2BrCl_3$: C, 33.88; H, 4.54; Br, 22.54; Cl, 30.00%.

*Cyclization of **3a** and **3b**.* A solution of **3a** or **3b** (1 mmol) in any one of solvents (1 ml) as listed in Tables 1 and 2 was added dropwise to a solution or suspension of various bases (2—5 mmol) in the same solvent (2—5 ml) at room temperature, with the exception of run 2 in Table 2. In run 2 a solution of sodium *t*-pentyloxide (1.5 mmol) in benzene was added to a solution of **3a** at 10—15 °C. After stirring under the reaction conditions as shown in Tables 1 and 2, the mixture was diluted with ice-water and extracted

with ethyl acetate. The extracts were washed with saturated water solution of sodium chloride and dried over anhydrous magnesium sulfate. Evaporation of the solvent *in vacuo* gave a residue, from which yields were determined by analytical GLC (PEG 20 M, 125 °C). *Cis*- and *trans*-isomers of ethyl 2,2-dimethyl-3-(2,2,2-trichloroethyl)-1-cyclopropanecarboxylate (**6**) were separated by high pressure liquid chromatography on a μ-porasil column (Waters Associates Inc.,) using hexane as the eluent; **6t**, IR, ν_{max}^{film} cm^{-1}: 1729 and 1179, NMR ($CDCl_3$) at 100 MHz: 1.21 (s, 3H, CH_3), 1.25 (s, 3H, CH_3), 1.26 (t, 3H; J=7.2 Hz, OCH_2CH_3), 1.36 (d, 1H; J=5.4 Hz, $CHCHCO_2$), 1.73 (broad q, 1H; J=5.8 Hz, $CHHCHCH$), 2.72 (dd, 1H; J=6.0 and 15.0 Hz, $CHHCH$), 2.77 (dd, 1H, J=6.3 and 15.0 Hz, $CHHCH$), 4.08 (q, 2H; J=7.2 Hz, OCH_2CH_3), MS, *m/e* (relative intensity) for $C_{10}H_{15}O_2{}^{35}Cl_3$: 278 (1), 276 (5.3), 274 (17.1), and 272 (M^+, 12.8) and **6c**, IR, ν_{max}^{film} cm^{-1}: 1725 and 1180, NMR ($CDCl_3$) at 100 MHz: 1.22 (s, 6H, $2CH_3$), 1.23 (t, 3H; J=7.0 Hz, OCH_2CH_3), 1.48 (dt, 1H; J=5.5 and 8.4 Hz, $CHHCHCH$), 1.66 (d, 1H; J=8.4 Hz, $CHCHCO_2$), 3.01 (dd, 1H; J=5.5 and 15.2 Hz, $CHHCH$), 3.13 (dd, 1H; J=5.5 and 15.2 Hz, $CHHCH$), and 4.11 (q, 2H; J=7.0 Hz, OCH_2CH_3), MS, *m/e* (relative intensity): 278 (1), 276 (3.5), 274 (11.0), and 272 (M^+, 9.7). The mixture of *cis*- and *trans*-ethyl dichlorovinylchrysanthemate (**7**) was separated by column chromatography (silica gel-silver nitrate, hexane/ethyl acetate=100/3); **7t**[7], IR, ν_{max}^{film} cm^{-1}: 1730, 1620, and 1180, NMR (CCl_4): 1.20 (s, 3H, CH_3), 1.27 (t, 3H; J=7.2 Hz, OCH_2CH_3), 1.29 (s, 3H, CH_3), 1.53 (d, 1H; J=5.2 Hz, $CHCHCO_2$), 2.19 (dd, 1H; J=5.2 and 8.3 Hz, $=CHCHCH$), 4.12 (q, 2H; J=7.2 Hz, OCH_2CH_3), and 5.63 (d, 1H; J=8.3 Hz, $=CHCH$) and **7c**[7], IR, ν_{max}^{film} cm^{-1}: 1725, 1620, and 1190, NMR ($CDCl_3$): 1.26 (s, 6H, $2CH_3$), 1.27 (t, 3H; J=7.1 Hz, OCH_2CH_3), 1.83 (dd, 1H; J=1.0 and 8.0 Hz, $=CHCHCHCO_2$), 2.02 (t, 1H; J=8.0 Hz, $=CHCHCH$), 4.11 (q, 2H; J=7.1 Hz, OCH_2CH_3), and 6.28 (dd, 1H; J=1.0 and 8.0 Hz, $=CHCHCH$). Ethyl 3,3-dimethyl-4,6,6-trichloro-5-hexenoate (**8**) was purified by column chromatography on silica gel (hexane/benzene=1/1), IR, ν_{max}^{film} cm^{-1}: 1730, 1612, and 1150, NMR ($CDCl_3$): 1.15 (s, 6H, $2CH_3$), 1.28 (t, 3H; J=7.1 Hz, OCH_2CH_3), 2.35 (d, 1H; J=14.5 Hz, $CHHCO_2$), 2.51 (d, 1H; J=14.5 Hz, $CHHCO_2$), 4.21 (q, 2H; J=7.1 Hz, OCH_2CH_3), 4.98 (d, 1H; J=10.5 Hz, $=CHCHCl$), and 6.13 (d, 1H; J=10.5 Hz, $=CHCHCl$), MS, *m/e* (relative intensity) for $C_{10}H_{15}O_2{}^{35}Cl_3$: 278 (1), 276 (7.0), 274 (20.3), and 272 (M^+, 20.4).

Dehydrochlorination of ***6t***. Compound **6t** (5 mmol) was heated with a variety of reagents such as zinc chloride (0.5 mmol), DBU (10 mmol), and potassium hydroxide (25 mmol) under reaction conditions described in Table 3. After the usual work-up, the crude products were chromatographed on silica gel, using benzene and benzene–ethyl acetate (3/1) as eluents for **7t** and **2t**, respectively. Following spectral data were obtained for **2t**, mp 96—97 °C (lit,[7] mp 95—96.5 °C), IR, ν_{max}^{Nujol} cm^{-1}: 2700, 1680, and 1620, NMR (CCl_4): 1.23 (s, 3H, CH_3), 1.35 (s, 3H, CH_3), 1.57 (d, 1H; J=5.6 Hz, $CHCHCO_2$), 2.25 (dd, 1H; J=5.6 and 8.5 Hz, $=CHCH-CHCO_2$), 5.61 (d, 1H; J=8.5 Hz, $=CHCH$), and 11.97 (broad s, 1H, CO_2H).

Ethyl trans*-3-(2-Chloroethynyl)-2,2-dimethyl-1-cyclopropanecarboxylate* ***(9t)***. A solution of **7t** (0.21 g) in THF (2 ml) was added dropwise to a slurry of potassium *t*-butoxide (0.22 g) in THF (5 ml) at room temperature. After stirring for 6 hr, the reaction mixture was poured into ice-water and extracted with ether. The extracts were washed with saturated aqueous sodium chloride and dried over anhydrous sodium sulfate. Evaporation of the solvent *in vacuo* gave a residue, which was chromatographed on silica gel (hexane/benzene=1/1) to afford 0.11 g of **9t**, IR, ν_{max}^{film} cm^{-1}: 2220, 1730, and 1175, NMR (CCl_4): 1.20 (s, 3H, CH_3), 1.27 (t, 3H; J=7.1 Hz, OCH_2CH_3), 1.29 (s, 3H, CH_3), 1.59 (d, 1H; J=5.6 Hz, $CHCHCO_2$), 1.85 (d, 1H; J=5.6 Hz, $CHCHCO_2$), and 4.12 (q, 2H; J=7.1 Hz, OCH_2CH_3), MS, *m/e* (relative intensity) for $C_{10}H_{13}O_2{}^{35}Cl$: 202 (1) and 200 (M^+, 2.7).

The authors wish to express their thanks to Dr. K. Murayama for his encouragement and advice and to Dr. N. Soma for his valuable discussion.

Layered Compounds. LIX.[1] Facile Syntheses and Spectral Properties of [3.3]Cyclophanes and Related Cyclophanes

Tetsuo Otsubo, Masashi Kitasawa, and Soichi Misumi*

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received December 18, 1978)

A simple synthetic method of [3.3]cyclophanes *via* dithia[4.4]cyclophanes is presented. The spectra of a variety of cyclophanes were examined and compared to those of [2.2]analogues. It was concluded from the absorption spectra that the transannular π-π interactions of the cyclophanes were strongly dependent on both ring-to-ring distance and overlapping mode. From the emission spectra, it was described that cyclophanes of parallel sandwich type formed easily normal excimers, whereas [2.2]metacyclophane and [2.2]- and [3.3]metaparacyclophanes formed strained excimers showing marked red shifts of fluorescence bands.

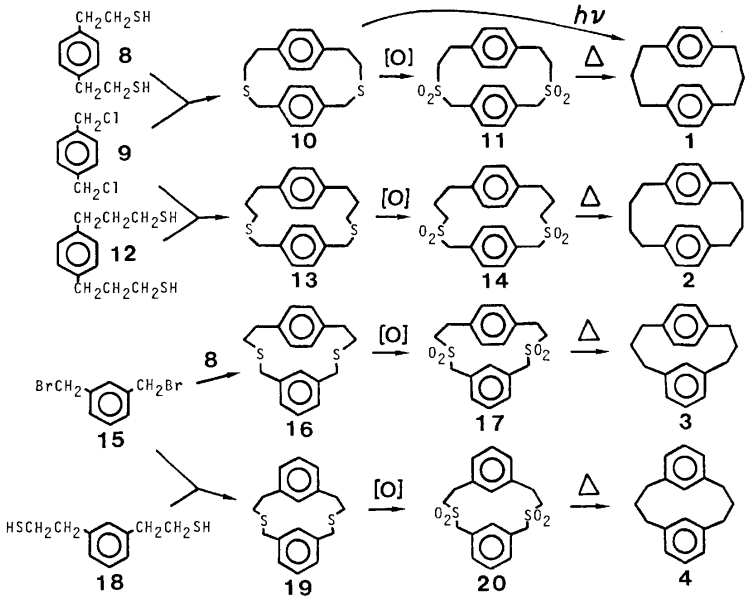
Cram and his coworkers reported the first synthesis of [3.3]paracyclophane **1** in the study of a series of [*m.n*]paracyclophanes and pointed out its unique properties, *e.g.*, the formation of a rather stronger tetracyanoethylene complex than [2.2]paracyclophane **31** in spite of longer ring-to-ring distance.[2] In this regard, an investigation was undertaken for comparing the strength of intramolecular charge-transfer interaction in a series of donor-acceptor [*n.n*]paracyclophanes, of which the [3.3]system was expected to provide the most stable intramolecular complex.[3]

It has been well known that [3.3]paracyclophane **1** might be the most suitable system for the transannular electronic interaction because **1** has a parallel sandwich structure of the two benzene rings with considerably short ring-to-ring distance and without severe ring strain.[4] However, further extensive study of **1** has been limited owing to tedius route in the initial synthesis. Although a few synthetic methods of **1** were developed by means of ring expansion of [2.2]paracyclophane,[5] 1,8-cycloaddition,[6] and condensation of malonic ester,[7] a general method has been expected for applying to a variety of [3.3]cyclophanes such as multibridged and multilayered types and donor-acceptor type.

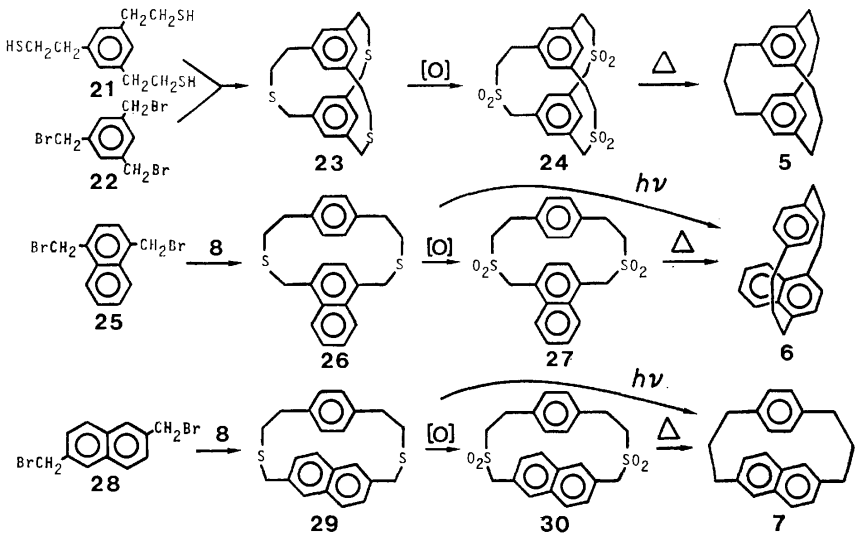
The synthesis of [2.2]cyclophanes by sulfur elimination from dithia[3.3]cyclophanes has proved to be very useful as a general method of [2.2]cyclophanes.[8] This successful approach results from a facile extrusion of sulfur atom bonded to two benzyl groups forming relatively stable radicals in desulfurization, in contrast to stubborn sulfur atom bonded to alkyl groups. When bonded to phenethyl or longer phenylalkyl groups, elimination of sulfur atom was difficult due to predominant decomposition. Recently we found that when either of two interposing groups was benzyl group, a similar extrusion of sulfur smoothly proceeded, and a series of [*n*]cyclophanes was prepared by desulfurization of such type of dithiacyclophanes.[9] Furthermore, this method made it possible to extend to the syntheses of higher homologues of [*n.n*]paracyclophanes. Here we present a general method for syntheses of [3.3]- and [4.4]paracyclophanes **1** and **2** and the application to a variety of [3.3]- and related cyclophanes **3**—**7**.[10] Their absorption and emission spectra are discussed together with those of [2.2]-analogues from view points of transannular electronic interaction and excimer formation.

Results and Discussion

Syntheses: All the starting materials required in



Scheme 1.



Scheme 2.

the general synthesis of cyclic thia compounds were prepared according to the literatures or conventional methods, except commercially available **9** and **15**.[11] Cyclic thia compounds **10**, **13**, **16**, **19**, **23**, **26**, and **29** were obtained in high yields (60—90%) by the corresponding coupling reactions of these precursors under high dilution conditions. [3.3]Paracyclophane **1** was produced by irradiation of 2,13-dithia[4.4]-paracyclophane **10** in triethyl phosphite with a high pressure mercury lamp for one week in 24% yield or with a low pressure mercury lamp for 15 h in 20% yield. As an alternative route, **10** was oxidized with hydrogen peroxide (95% yield) or *m*-chloroperbenzoic acid (81% yield) to disulfone **11**, and the subsequent pyrolysis of **11** gave **1** in 75% yield (flash pyrolysis) or in 33% yield (flow system pyrolysis).[12] [4.4]-Paracyclophane **2**[13] was similarly prepared by oxidation (97% yield) of 2,15-dithia[5.5]paracyclophane **13**, followed by pyrolysis (76% yield) of disulfone **14**. In this case, the direct photodesulfurization of **13** to **2** was unsuccessful. The pyrolytic method is widely applicable to the syntheses of all the other [3.3]-cyclophanes, *i.e.*, [3.3]metaparacyclophane **3** (40% yield), [3.3]metacyclophane **4**[7] (52%), [3.3.3](1,3,5)-cyclophane **5**[14] (16%), [3.3]paracyclo(1,4)naphthalenophane **6** (37%), and [3.3]paracyclo(2,6)naphthalenophane **7** (13%). The photochemical method was also applied with success for the synthesis of **6** (5.6%) and **7** (12%), but not for **3**, **4**, and **5**. All the new compounds were characterized by NMR and mass spectra and elemental analyses.

Electronic Absorption Spectra: Cram *et al.* reported that the electronic spectra of [*m.n*]paracyclophanes showed bathochromic shift and broadening of absorption bands due to an increasing transannular π-electronic interaction between the two benzenes as the number of *n* and *m* decreased.[2] As seen in the spectra of [2.2]- and [3.3]paracyclophanes (Fig. 1), these anoma-

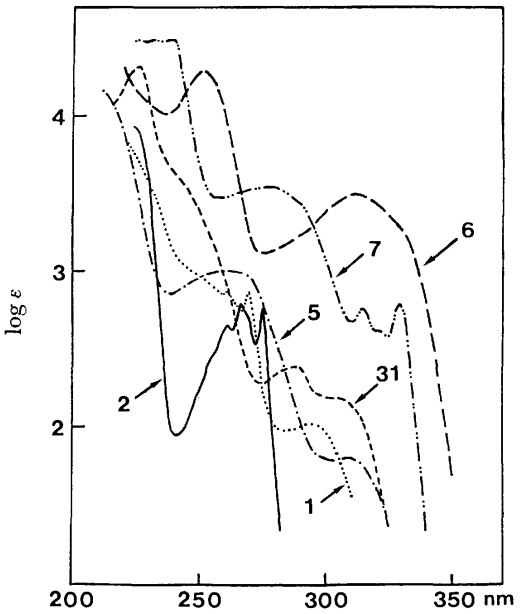

Fig. 1. Electronic spectra of cyclophanes **1**, **2**, **5**, **6**, **7**, and **31** in tetrahydrofuran.

lous phenomena become marked when the two benzene rings were more closely fixed within van der Waals contact.[4,15] It should be noted that the interaction depends not only on ring-to-ring distance but also on overlapping mode. Thus, the two benzenes of [2.2]paracyclophane **31** are well superposed on each other,[15] whereas those of [3.3]paracyclophane **1** are stacked with a little parallel displacement, so that the pπ-pπ overlap somewhat diminishes.[4] The overlapping in [3.3.3](1,3,5)cyclophane **5** is very similar as in **31**, though the ring-to-ring distance is the almost same as that of **1**. If the ring-to-ring distance is main factor for the spectral anomalousness of cyclophanes, **5** should show a spectrum similar to that of **1**. In practice, however, it showed considerable red shift of the longest wavelength band compared to that of **1**, and its maxima (λ_{max} 261 and 310 nm) are, interestingly, quite similar to those (λ_{max} 258 and 312 nm) of the lower homologue, *i.e.*, [2.2.2]-(1,3,5)cyclophane **34**.[16] This result clearly indicates the significance of the overlapping mode rather than the ring-to-ring distance. The spectra of the two paracyclonaphthalenophanes **6** and **7** also reflect the difference in the overlapping mode. According to molecular model examination, the benzene ring of [3.3]paracyclo(2,6)naphthalenophane **7** is stacked above the center of the faced naphthalene ring, but pπ-pπ overlapping may be less effective than that of [3.3]paracyclo(1,4)naphthalenophane **6**. In fact, the longest wavelength band (L_b transition) of **7** shows only a small red shift by *ca.* 5 nm as compared to that of 2,6-dimethylnaphthalene and retains a fine structure, while that of **6** shows a striking red shift by *ca.* 25—30 nm as compared to that of 1,4-dimethylnaphthalene.

[2.2]Metaparacyclophane **32** and [2.2]metacyclophane **33** exhibit weak transannular interaction due to partial overlapping of two benzene rings in the spectra (Fig. 2). [3.3]Metaparacyclophane **3** no longer

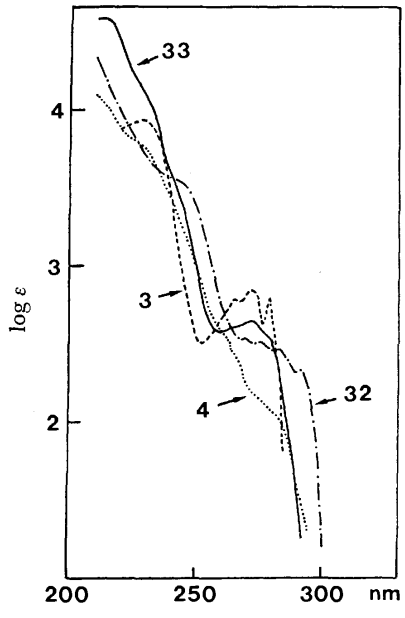

Fig. 2. Electronic spectra of cyclophanes **3** and **4** in tetrahydrofuran and **32** and **33** in cyclohexane.

demonstrates such an effect because the two benzene rings are far apart beyond van der Waals contact. However, [3.3]metacyclophane **4** is not the case, in spite of longer distance between the two benzene rings. Its absorption bands are more broad than that of the lower homologue **33**. This can be explained by a conformational flipping between syn and anti forms, which occurs much easily than the corresponding [2.2] system **33**. Thus, **33** exists only as the anti form,[17] which is hardly interconvertible to syn form, whereas **4** favors the syn form **35** over the anti form **36**, according to molecular model examination. In other words, the increased overlapping of the two benzene rings in the syn form seems to be responsible for the marked interaction in [3.3]system.

Emission Spectra: The emission spectra of paracyclophanes have been studied as a model for examining the structure of benzene excimer, *i.e.*, dimolecular associate in excited state.[18] For example, Vala *et al.* observed the excimer emissions of [2.2]- and [4.4]-paracyclophanes **31** and **2**, indicating that an excimer was formed when two benzene rings were stacked in parallel.[19] Study on the emission spectrum of [3.3]-paracyclophane, in which two benzenes are stacked with little strain, is expected to give further information about the excimer structure. Excimer fluorescences are readily distinguishable from the normal monomer fluorescences, because the former is characterized by large Stokes shifts, broadening, and weak intensity of emission bands.

Table 1 summarizes the emission data of the present cyclophanes measured at 77 K and room temperature (RT). [2.2]- And [3.3]paracyclophanes **31** and **1** and [3.3.3]cyclophane **5** exhibit excimer emissions at both temperatures, although their maxima appear at somewhat longer wavelength due to benzene ring warping than that (*ca.* 330 nm) of ordinary benzene excimer.[20] [4.4]Paracyclophane **4** shows an excimer emission at RT, but a monomer emission at 77 K. These results obviously indicate that the structures of **31** and **1** are favorable for strong π-π interaction even at the ground state, whereas **2** requires a conformational change to bring the two benzene rings close to a certain distance equal to or less than van der Waals contact for the excimer formation.[21]

Shizuka *et al.* reported that **33**, which is consisted of anti form alone in the ground state, exhibited an excimer fluorescence together with a normal fluorescence at RT but no excimer fluorescence at 77 K, and the excimer fluorescence was resulted from its syn form[22] A similar conversion of anti form to syn form in the excited state was observed with [2.2]-(1,3)pyrenophane **38**.[23] The fact that **33** exhibits excimer emission only at RT implies considerable activation energy for syn-anti conversion. In addition, significant red shift of the emission band (392 nm) reflects the severe strain in the syn form. On the other hand, [3.3]metacyclophane, which favors syn form in the ground state in contrast to anti form for **33**, emits an excimer fluorescence characteristic of less strained system even at 77 K.

[2.2]- and [3.3]metaparacyclophanes **32** and **3** exhibit both monomer and excimer emissions at RT and

	RT	346 (monomer)[b]	

a) Broad. b) Fine structure.

only monomer emission at 77 K. The maxima of their excimer bands lie at a wavelength comparable to that of **33**. The emission spectra suggest their structures to be of sandwich type with severe strain such as **39** and **40**, in which the two benzene rings are stacked with remarkably different mode compared to the syn form of **33**.

The orientation dependence of excimer formation was found in the case of paracyclonaphthalenophanes **6** and **7**. The 1,4-isomer **6** exhibits an excimer emission at RT and 77 K, whereas the 2,6-isomer **7** a monomer emission at both temperatures. Evidently, $p\pi$-$p\pi$ interaction is also an important factor for excimer formation.

Experimental

Melting points are uncorrected. All solvents are of reagent grade. NMR measurements were made with a Hitachi Perkin-Elmer R-20 spectrometer (60 MHz) or a JEOL JNM-FX100 in deuteriochloroform using tetramethylsilane as an internal standard. Mass spectra were determined on a Hitachi RMU-7 spectrometer at 70 eV using direct insertion technique. UV spectra were recorded on a Hitachi EPS-3T spectrophotometer. Emission spectra were taken on a Hitachi MPF-2A spectrophotometer attached with a HTV R-446F photomultiplier in EPA (ethyl ether–isopentane–ethanol of 5 : 5 : 2 volume ratio). A solution of about 1×10^{-3} M was prepared and degassed by freeze-pump-thaw method. Emission spectra were uncorrected.

1,4-Bis(2-mercaptoethyl)benzene ***8***. A mixture of 1,4-bis(2-bromoethyl)benzene[24] (19.70 g, 0.068 mol) and thiourea (12.32 g, 0.162 mol) in 200 ml of 95% ethanol was refluxed with stirring for 2.5 h. After evaporation of the solvent, the residue was refluxed with potassium hydroxide (80 g) in 400 ml of water for 7 h under nitrogen. The mixture was cooled in an ice bath and acidified with 1 : 1 of concd sulfuric acid–water. The resulting oil was extracted with benzene. The extract was washed with water, dried over anhyd magnesium sulfate, and evaporated to give a colorless oil, 12.83 g (96%), bp 125—127 °C/1 Torr.

NMR ($CDCl_3$, 60 MHz) δ=1.39(m, 2H, SH), 2.4—3.0 (m, 8H, CH_2), 7.14 ppm(s, 4H, ArH). Found: C, 60.29; H, 6.82; S, 32.14%. Calcd for $C_{10}H_{14}S_2$: C, 60.55; H, 7.11; S, 32.33%.

1,4-Bis(3-mercaptopropyl)benzene ***12***. Dithiol **12** was obtained in 97% yield from 1,4-bis(3-bromopropyl)benzene[25] in a similar manner as described in dithiol **8**; colorless oil, bp 165—167 °C/2 Torr.

NMR ($CDCl_3$, 60 MHz) δ=1.34(t, 2H, J=8 Hz, SH), 1.89(quint, 4H, J=7 Hz, CH_2), 2.48(t, 4H, J=7 Hz, CH_2S), 2.71(t, 4H, J=7 Hz, $ArCH_2$), and 7.09 ppm(s, 4H, ArH). Found: C, 63.81; H, 7.95; S, 28.13%. Calcd for $C_{12}H_{18}S_2$: C, 63.66; H, 8.01; S, 28.32%.

1,4-Bis(2-mercaptoethyl)benzene ***18***. Dithiol **18** was led from 1,3-bis(ethoxycarbonylmethyl)benzene[26] as described below.

A solution of 1,3-bis(ethoxycarbonylmethyl)benzene(1.65 g, 6.6 mmol) in 15 ml of dry tetrahydrofuran was slowly added into a suspension of lithium aluminium hydride (0.53g, 13.9 mmol) in 25 ml of dry THF over a period of 30 min at room temperature. After 30 min of reflux, a small amount of ethyl acetate, water, and dil hydrochloric acid were added successively. The mixture was saturated with sodium chloride and extracted with ethyl ether. The extract was washed with satd. aq NaCl solution and dried over magnesium sulfate. Evaporation gave a colorless oil of 1,3-bis(2-hydroxyethyl)benzene, 1.05 g (96%).

NMR ($CDCl_3$, 100 MHz) δ=2.75(t, 4H, J=6.7 Hz, $ArCH_2$), 3.27(bs, 2H, OH), 3.71(t, 4H, J=6.7 Hz, CH_2O), and 6.9—7.3 ppm(m, 4H, ArH).

The above 1,3-bis(2-hydroxyethyl)benzene (1.48 g, 8.9 mmol) was mixed with 100 ml of 48% hydrobromic acid and 6 ml of concd sulfuric acid. The mixture was refluxed for 1.5 h, cooled to room temperature, and extracted with benzene. The extract was washed with water and dried over anhyd magnesium sulfate. Evaporation gave a colorless oil of 1,3-bis(2-bromoethyl)benzene, 3.2 g (84%), bp 141 °C/2 Torr.

NMR ($CDCl_3$, 100 MHz) δ=3.12(A_2B_2m, 4H, $ArCH_2$), 3.53(A_2B_2m, 4H, CH_2Br), and 7.0—7.3 ppm(m, 4H, ArH).

The above dibromide was converted to 1,3-bis(2-mercaptoethyl)benzene **18** in 81% yield as described in the para analogue **8**; colorless oil, bp 115 °C/10 Torr.

NMR ($CDCl_3$, 60 MHz) δ=1.37(m, 2H, SH), 2.5—3.1 (m, 8H, CH_2), and 7.0—7.3 ppm(m, 4H, ArH). Found: C, 60.28; H, 6.81; S, 32.12%. Calcd for $C_{10}H_{14}S_2$: C, 60.55; H, 7.11; S, 32.33%.

General Method of Coupling Reaction. A solution of the corresponding thiol (0.01 mol) and halide (0.01 mol) in 100 ml of benzene was added dropwise into a refluxed ethanol solution (1 l) containing potassium hydroxide (1.78 g) in a nitrogen atmosphere. The addition was complete in 12 h. The mixture was refluxed an additional 12 h and then concentrated. The residue was taken up in benzene and chromatographed over silica gel with benzene–hexane (1 : 1) to give a crystalline solid of the desired cyclic dithia compound from the main fraction of eluates.

2,13-Dithia[4.4]paracyclophane ***10***. Yield 62%, colorless plates from benzene, mp 183—185 °C.

NMR ($CDCl_3$, 60 MHz) δ=2.75(A_2B_2m, 8H, CH_2), 3.39(s, 4H, CH_2), and 6.80 ppm(s, 8H, ArH). MS *m/e* 300(M^+). Found: C, 71.75; H, 6.57; S, 21.11%. Calcd for $C_{18}H_{20}S_2$: C, 71.95; H, 6.71; S, 21.34%.

2,15-Dithia[5.5]paracyclophane ***13***. Yield 91%, colorless scales from benzene–hexane, mp 153—153.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=1.85(m, 8H, CH_2), 2.60 (m, 4H, $ArCH_2$), 3.55(s, 4H, $ArCH_2S$), 6.87(s, 4H, ArH), and 7.03 ppm (s, 4H, ArH). MS *m/e* 328(M^+). Found: C, 72.94; H, 7.36; S, 19.30%. Calcd for $C_{20}H_{24}S_2$: C, 73.12; H, 7.36; S, 19.52%.

3,12-Dithia[4.4]metaparacyclophane ***16***. Yield 76%, colorless needles from benzene–hexane, mp 81—82 °C.

NMR ($CDCl_3$, 60 MHz) δ=2.83(bs, 8H, CH_2), 3.46(s, 4H, $ArCH_2S$), 6.40(bs, 1H, meta ArH), 6.88(s, 4H, para ArH), and 6.98 ppm(bs, 3H, meta ArH). MS *m/e* 300(M^+). Found: C, 71.78; H, 6.53; S, 21.61%. Calcd for $C_{18}H_{20}S_2$: C, 71.95; H, 6.71; S, 21.34%.

2,13-Dithia[4.4]metacyclophane ***19***. Yield 79%, colorless prisms from benzene–hexane, mp 109—109.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=2.74(A_2B_2m, 8H, CH_2), 3.65(s, 4H, $ArCH_2S$), 6.67(bs, 1H, ArH), 7.0—7.2(m, 3H, ArH), and 7.39 ppm(bs, 4H, ArH). MS *m/e* 300(M^+). Found: C, 72.06; H, 6.52; S, 29.49%. Calcd for $C_{18}H_{20}S_2$: C, 71.95; H, 6.71; S, 21.34%.

2,13,22-Trithia[4.4.4](1,3,5)cyclophane ***23***. Yield 65%, colorless plates from benzene–hexane, mp 251—252 °C.

NMR ($CDCl_3$, 100 MHz) δ=2.71(A_2B_2m, 12H, CH_2), 3.31(s, 6H, $ArCH_2S$), 6.56(s, 3H, ArH), and 6.62 ppm (s, 3H, ArH). MS *m/e* 372 (M^+). Found: C, 67.87; H, 6.65; S, 25.57%. Calcd for $C_{21}H_{24}S_3$: C, 67.69; H, 6.49; S, 25.82%.

2,13-Dithia[4.4]paracyclo(1,4)naphthalenophane ***26***. Yield 63%, colorless columns from benzene–hexane, mp 187—188 °C.

NMR ($CDCl_3$, 60 MHz) δ=2.3—3.1(A_2B_2m, 8H, CH_2), 3.86(s, 4H, $ArCH_2S$), 6.45(s, 4H, ArH), 6.72(s, 2H, ArH), 7.53(A_2B_2dd, 2H, J=7 and 3 Hz, ArH), and 8.02 ppm (A_2B_2dd, 2H, J=7 and 3 Hz, ArH). MS *m/e* 350(M^+). Found: C, 75.65; H, 6.17; S, 18.04%. Calcd for $C_{22}H_{22}S_2$: C, 75.38; H, 6.33; S, 18.29%.

2,13-Dithia[4.4]paracyclo(2,6)naphthalenophane ***29***. Yield 89%, colorless plates from benzene–hexane, mp 198—200 °C.

NMR ($CDCl_3$, 60 MHz) δ=2.2—2.8(m, 8H, CH_2), 3.77 (s, 4H, $ArCH_2S$), 6.41(s, 4H, ArH), 7.26(ABd, 2H, J=8 Hz, ArH), 7.36(bs, 2H, ArH), and 7.53 ppm(ABd, 2H, J=8 Hz, ArH). Found: C, 75.52; H, 6.19; S, 18.51%. Calcd for $C_{22}H_{22}S_2$: C, 75.38; H, 6.33; S, 18.29%.

General Synthetic Method of Disulfone. A) With Hydrogen Peroxide: Cyclic disulfide (4 mmol) was mixed with 8 ml of acetic acid and 2.4 ml of 35% hydrogen peroxide, and heated at 100 °C with stirring for 6 h. The mixture was cooled in an ice bath, and the resulting white crystalline solid of disulfone was filtered, washed, and dried.

B) With m-Chloroperbenzoic Acid: A mixture of cyclic disulfide (1 mmol) and *m*-chloroperbenzoic acid (1.1 g, 6 mmol as 85% active) in 20 ml of dichloromethane was stirred at room temperature for 2 d. After some milliliters of dichloromethane was added to dissolve the resulting precipitate, the solution was washed successively with 3M NaOH solution and water, dried, and concentrated to give a white powder of disulfone. Disulfones thus obtained were essentially pure and used in the following pyrolysis without further purification.

2,13-Dithia[4.4]paracyclophane 2,2,13,13-tetraoxide **11**, yield 95%(method A) and 81%(method B), dec 330—340 °C. 2,15-Dithia[5.5]paracyclophane 2,2,15,15-tetraoxide **14**, yield 97%(by A), dec 310—320 °C. 3,12-Dithia[4.4]-metaparacyclophane 3,3,12,12-tetraoxide **17**, yield 90% (by A) and 67%(by B), mp 283—285 °C. 3,12-Dithia-[4.4]metacyclophane 3,3,12,12-tetraoxide **20**, yield 72% (by B), dec 320—325 °C with melting. 2,13,22-Trithia-[4.4.4](1,3,5)cyclophane 2,2,13,13,22,22-hexaoxide **24**, yield 83%(by A), dec 350 °C. 2,13-Dithia[4.4]paracyclo(1,4)-naphthalenophane 2,2,13,13-tetraoxide **27**, yield 82% (by B), dec 240 °C. 2,13-Dithia[4.4]paracyclo(2,6)naphthalenophane 2,2,13,13-tetraoxide **30**, yield 96%(by A), dec 320—330 °C.

General Synthetic Method of [3.3]-, [4.4]-, and [3.3.3]Cyclophanes. A)Flash Pyrolysis: Sulfone (100—500 mg) was packed in a Pyrex tube sealed at one end. The open end was connected to a rotary pump and the system was maintained under 0.1—0.5 Torr. The tube was placed in a furnace (15 cm in length, preheated to 650 °C) in such a way as the middle of the tube could be heated. The sample part was slidden smoothly inside the furnace. As soon as pyrolysis started, an oily product condensed at the opposite cool end. Column chromatography of the product on silica gel with hexane led to the isolation of the desired cyclophane as white crystals.

B) Flow System Pyrolysis: Sulfone (100 mg) was placed in a pyrolytic flow system modelled after that of Boekelheide *et al.*[27] The first furnace was set at 300 °C and the second at 600 °C. The whole system was maintained under 0.1 Torr. The pyrolysis was complete in a few hours. The resulting cyclophane was trapped in the cold finger and purified by column chromatography.

C) Photodesulfurization: Cyclic dithia compound (100 mg) was dissolved in 10 ml of benzene and 5 ml of triethyl phosphite in a quartz tube. The solution was irradiated with a high pressure mercury lamp in a nitrogen atmosphere (one week for [3.3]paracyclophane and 3 h for [3.3]paracyclonaphthalenophane). After removal of the solvent, the residue was chromatographed on silica gel to give white crystals of the desired product.

[3.3]Paracyclophane ***1***. Yield 75% (method A), 33% (method B), and 24%(method C), colorless plates from methanol, mp 103—104 °C (lit[2]), mp 104.3—105.3 °C).

NMR ($CDCl_3$, 60 MHz) δ=2.03(m, 4H, CH_2), 2.72 (t, 8H, CH_2), and 6.66 ppm(s, 8H, ArH). MS *m/e* 236 (M^+).

[4.4]Paracyclophane ***2***. Yield 76%(by A), colorless

plates from ethanol, mp 147.5—149 °C (lit,[13] mp 146.2—147.3 °C).

NMR ($CDCl_3$, 60 MHz) δ=1.6(m, 4H, CH_2), 2.3(m, 4H, $ArCH_2$), and 6.68 ppm(s, 8H, ArH). MS *m/e* 264 (M^+).

[3.3]Metaparacyclophane **3**. Yield 40% (by A), 20% (by B), colorless plates from hexane, mp 90—91 °C.

NMR ($CDCl_3$, 60 MHz) δ=1.9—2.9(m, 8H, CH_2), 2.71(t, 4H, J=6 Hz, CH_2), 5.55(bs, 1H, meta ArH), 6.63 (s, 4H, para ArH), and 6.6—7.2 ppm (m, 3H, meta ArH). MS *m/e* 236(M^+). Found: C, 91.25; H, 8.30%. Calcd for $C_{18}H_{20}$: C, 91.47; H, 8.53%.

[3.3]Metacyclophane **4**. Yield 52% (by A), 2.7% (by B), colorless plates from ethanol, mp 81—82 °C (lit,[7] 79—80 °C).

NMR ($CDCl_3$, 100 MHz) δ=1.92—2.15(m, 4H, CH_2), 2.74(t, 8H, J=5.8 Hz, $ArCH_2$), 6.54—6.84 (A_2B_2m, 6H, outer ArH), and 6.84 ppm(bs, 2H, inner ArH). MS *m/e* 236(M^+).

[3.3.3](1,3,5)Cyclophane **5**. Yiled 16% (by A), colorless plates from pentane, mp 134—135.5 °C (lit,[14] mp 140 °C).

NMR ($CDCl_3$, 100 MHz) δ=2.18(m, 6H, CH_2), 2.75 (t, 12H, J=5.8 Hz, $ArCH_2$), and 6.52 ppm(s, 6H, ArH). MS *m/e* 276 (M^+).

[3.3]Paracyclo(1,4)naphthalenophane **6**. Yield 13% (by A), 12% (by C), colorless fine crystals from pentane, mp 106—107 °C.

NMR ($CDCl_3$, 60 MHz) δ=2.0—3.0(m, 10H, CH_2), 3.4—3.8(m, 2H, CH_2), 5.95(bs, 2H, ArH), 6.70(s, 2H, ArH), 6.76(bs, 2H, ArH), 7.43(A_2B_2dd, 2H, J=7 and 3 Hz, ArH), and 7.94 ppm(A_2B_2dd, 2H, J=7 and 3 Hz, ArH). MS *m/e* 286(M^+). Found: C, 91.82; H, 7.32%. Calcd for $C_{22}H_{22}$: C, 92.26; H, 7.74%.

[3.3]Paracyclo(2,6)naphthalenophane **7**. Yield 37% (by A), 5.6% (by C), colorless plates from benzene-hexane, mp 160—161 °C.

NMR ($CDCl_3$, 60 MHz) δ=1.8—3.0(m, 12H, CH_2), 6.04(s, 4H, ArH), 7.01(bs, 2H, ArH), and 7.13 ppm(bs, 2H, ArH). MS *m/e* 286(M^+).

Found: C, 92.31; H, 7.51%. Calcd for $C_{22}H_{22}$: C, 92.26; H, 7.74%.

Photochemical Reduction of Di-*t*-butyl Thioketone

Atsuyoshi OHNO,* Misao UOHAMA, Kaoru NAKAMURA, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received December 4, 1978)

Synopsis. Photochemical reduction of the title compound has been studied and the result is compared with that from the reaction with thiobenzophenone, an aromatic thioketone.

In a previous communication, we reported the result from the photoreaction of di-*t*-butyl thioketone (**1**) in the n,π^* triplet state (T_1, E_T=43—45 kcal/mol) with various olefins.[1] The thioketone **1** reacted with electron-rich olefins affording open-chain photo-adducts instead of cycloadducts. This is a marked contrast between **1** and other thioketones such as thiobenzophenone and adamantanethione.[2]

It is known that thiobenzophenone in the n,π^* triplet state abstracts a hydrogen from various hydrogen-donors yielding the corresponding thiol or disulfide.[2,3] Hydrogen-abstraction by aliphatic thioketones are scarcely studied,[2,4] and we now wish to report some interesting observation in the photohydrogen-abstraction of **1** from various hydrogen-donors.

Results and Discussion

The photo-irradiation was continued until the color of **1**(λ_{max}=540 nm) disappeared. The reaction is summarized in Table 1. Since hydrogen-donors presently employed for the reaction have no absorption above 300 nm, there is no doubt that the reaction takes place through the excitation of **1** into the n,π^* singlet state (S_1) with the lights of 550 and 580 nm.[5] Namely, it has been confirmed that the reaction of tetraphenylethylene with thiobenzophenone under the irradiation for 60 days with the light of 589 nm from sodium lamps (8×60 W)[6] yields 9,10-diphenylphenanthrene. The photoreaction of 9,10-dihydroanthracene with thiobenzophenone has already been reported.[7] Although we did not study the reaction quantitatively, existence of self-quenching, that is, the retardation of reaction by the increase of the concentration of **1**, suggests that the T_1 state of **1** is responsible to the reaction.[2,8]

Table 1 reveals a remarkable reactivity of excited (S_1 or T_1) **1** toward the hydrogen-abstraction; generally, the reactivity of 2-propanol is larger than, or at least comparable to, that of toluene toward hydrogen-abstraction,[9,10] whereas toluene and even tetraphenylethylene are much better hydrogen-donors than aliphatic alcohols and ethers in the present photo-reduction. The large reactivity of aromatic compound can be corelated with their ionization potentials[11] and seems to imply the formation of a charge-transfer-type complex between **1** (in S_1 or T_1) and a hydrogen-donor. Similar process has been suggested for the photo-reductions of benzophenone,[12] α,α,α-trifluoroacetophenone,[13] and thiobenzophenone.[7] The intermediacy of the charge-transfer-type complex is also witnessed by facile reaction with amines.[3a,14] That is, the photo-excited **1** does not abstract a hydrogen from ethanol, whereas it does in the presence of aniline, an electron-donor.

TABLE 1. PHOTOREDUCTION OF DI-*t*-BUTYL THIOKETONE

Hydrogen-donor	Reaction time, day	Yield of Bu^t_2CHSH, %
$PhBH_3$	28	72
 /in C_6H_6 (400 mg) (10 ml)	21	85[a]
$Ph_2C{=}CPh_2$/in C_6H_6 or $CHCl_3$ (800 mg) (10 ml)	14	70[b]
$PhCH_2OH$	6	82[c]
EtOH	≈60	0[d]
i-PrOH	≈60	0[d]
Et_3N	2	80
i-$BuNH_2$	7	27[e]
$PhNH_2$/in EtOH (5 ml) (10 ml)	28	24[f]
Et_2O	≈60	0[d]
	≈60	0[d]

a) Anthracene was isolated in 90% yield. b) 9,10-Diphenylphenanthrene was isolated in 70% yield. c) Benzaldehyde was detected on VPC. d) No reaction took place. **1** was recovered quantitatively. e) **1** was recovered in 49% yield. f) **1** was recovered in 61% yield.

It is noteworthy that the excitation of **1** into the π,π^* state results in completely different reactivity from **1** in the n,π^* state.[15] It is also interesting to compare the reactivity of **1** with that of thiobenzophenone, an aromatic thioketone, by the following two sets of reactions.[3a,12,16]

$$\left\{\begin{array}{l} Ph_2C{=}S + EtOH \xrightarrow{h\nu} Ph_2\dot{C}SH + Me\dot{C}HOH \\ \qquad\qquad \longrightarrow Ph_2CHSH \xrightarrow{h\nu} Ph_2CHSSCHPh_2 \\ Bu^t_2C{=}S + EtOH \xrightarrow{h\nu} \text{no reaction} \end{array}\right.$$

$$\left\{\begin{array}{l} Ph_2C{=}S + PhCH_3 \overset{h\nu}{\rightleftharpoons} Ph_2CSH + PhCH_2\cdot \\ \qquad\qquad\qquad\qquad \longrightarrow \text{no reaction} \\ Bu^t_2C{=}S + PhCH_3 \xrightarrow{h\nu} Bu^t_2CSH + PhCH_2\cdot \\ \qquad\qquad\qquad \xrightarrow{PhCH_3} Bu^t_2CHSH + PhCH_2CH_2Ph \end{array}\right.$$

The results clearly suggest that, in their biradical-type excited states, thiobenophenone has more radical-character on sulfur than on thiocarbonyl-carbon, and the reverse is true for **1**. That is, the electronic configuration of thiocarbonyl group is much affected by the substituent. This is also true for their ground-state chemistry.[17]

Experimental

Materials. Di-*t*-butyl thioketone (**1**) and thiobenzophenone were prepared as previously mentioned.[6,18] Solvents were dried and distilled prior to the use.

Procedure. As a standard procedure, 300 mg of **1** in 10 ml of a hydrogen-donor solvent was sealed in a Pyrex tube (10 mmϕ) under an atmosphere of nitrogen. The mixture was irradiated with a 500 W high-pressure mercury lamp at a temperature of running water. After the reaction, the solvent was evaporated under a reduced pressure and the residual oil was subjected to column chromatography on silica gel with an eluent of hexane–benzene (4 : 1 v/v) mixture. The product isolated was identified to be 2,2,4,4-tetramethyl-3-pentanethiol by comparing the spectral data with those of the authentic sample.

(Received September 21, 1978)

Synopsis. The optical and magnetic properties of solid cation radical salts derived from 9,10-dimethylanthracene and 9,10-dichloroanthracene were explained in terms of one-dimensional Hubbard model composed of equivalent sites of the cation radicals, while those of perylene cation radical salt, in terms of Hubbard model of cation radical dimer.

There have been made extensive investigations concerning the optical and magnetic properties of a number of crystalline ion radical salts.[1-10] On one hand, a deviation from the Curie or Curie-Weiss law has often been found in the temperature dependence of their magnetic susceptibilities, and this deviation has been explained in terms of an existence of spin exchange interaction between ion radicals.[1-3] On the other hand, the electronic spectrum of such solid ion radical salt is found to be different from the monomer spectrum of the corresponding ion radical molecule, but shows a charge-transfer transition between ion radicals in the low-energy region.[3-5]

In most solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into one-dimensional columns.[5] In this respect, the intermolecular charge-transfer interaction between ion radical molecules is important for the solid-state properties of ion radical salts. In order to understand this situation in more detail, we have applied half-filled Hubbard model to the segregated stack of ion radical molecules and investigated the optical and magnetic properties characteristic of solid ion radical salts.[6-10] Earlier, Sato *et al.* examined the optical absorptions and the magnetic susceptibilities of crystalline cation radical salts of 9,10-dimethylanthracene (DMA), 9,10-dichloroanthracene (DCA) and perylene (P) with antimony pentachloride and perchlorate anions.[3] In the present paper, we shall explain their experimental results in terms of our Hubbard model and understand the electronic states of those crystalline cation radical salts.

A compound of DMA–$SbCl_5$ was obtained as chemically stable cation radical salt. Its solid-state spectrum showed a band peak at 14400 cm^{-1} and a shoulder around 11600 cm^{-1}.[3] The high-energy peak at 14400 cm^{-1} corresponds to the monomer absorption of the 9,10-dimethylanthracene cation radical at 14800 cm^{-1}. The shoulder in the lower-energy region is characteristic of the solid salt and was assigned to the charge-transfer transition between the 9,10-dimethylanthracene cation radicals.[3] On the other hand, the temperature dependence of the paramagnetic susceptibility of DMA–$SbCl_5$ showed a broad maximum at approximately 80 K. The observed magnetic properties could be well explained in terms of antiferromagnetic linear Ising model with exchange coupling constant $J=56$ cm^{-1}.[3] In order to understand those optical and magnetic properties, we consider a system of non-alternant one-dimensional stack of 9,10-dimethylanthracene cation radicals in terms of Hubbard Hamiltonian, which can be written by

$$\mathscr{H} = \sum_{i,j,\sigma} T_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \tag{1}$$

where $n_{i\sigma}=C_{i\sigma}^{+}C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where $T_{ij}(<0)$ is the transfer matrix element between the i-th and j-th sites. The Coulomb repulsion potential, I, appears only when two electrons with up and down spins are at the same site. For non-alternant one-dimensional column of the 9,10-dimethylanthracene cation radicals, we consider the half-occupied molecular orbital of the unpaired electron as one site of cation radical molecule, and take into account only the transfer matrix element between the nearest neighbor sites. Hereafter, it is simply denoted by $T(<0)$. The shape of the intermolecular charge-transfer absorption spectrum of this system, $\sigma(\omega)$, is then given by[6]

$$\sigma(\omega) \propto \frac{e^2}{4} \frac{I^2}{\omega^2 \sqrt{\omega^2 - I^2}} \sqrt{4T^2 - \omega^2 + I^2}. \tag{2}$$

Here, a δ-function was assumed for each elementary transition in which the spin and the wave vector of an electron are conserved. The charge-transfer absorption of Eq. 2 has a sharp divergent peak at $\omega=I$ and has a band width of $\sqrt{I^2+4T^2}-I$ in the region $\omega>I$. On the other hand, for the magnetic properties of the same system, the Hubbard model leads to, in a region of small $|T|$ limit, a non-alternant one-dimensional antiferromagnet with an exchange interaction $J \approx 2T^2/I$.[8,9] Therefore, if we combine the experimental data on the peak energy of the observed charge-transfer absorption and the exchange interaction parameter, we can uniquely determine the magnitudes of I and T of Eq. 1. For the cation radical salt of DMA–$SbCl_5$, the observed peak energy of the charge-transfer absorption, 11600 cm^{-1}, thus corresponds to $I=11600$ cm^{-1}. As for the antiferromagnetic exchange interaction, rigorously speaking, the J value of Heisenberg model should correspond to $2T^2/I$, but only the J value estimated with linear Ising model is available at the present time. Therefore, we approximately use the estimated $J=56$ cm^{-1} value as $J \approx 2T^2/I$. By putting the $I=11600$ cm^{-1} value into this relation, we obtain $T \approx -570$ cm^{-1} for the one-dimensional system of the DMA–$SbCl_5$ salt.

The optical and magnetic properties of DCA–

$SbCl_5$ salt can be understood in quite a similar way. Sato *et al.* observed a weak charge-transfer absorption at 11200 cm^{-1}.[3] The observed temperature dependence of the magnetic susceptibility was again analyzed in terms of antiferromagnetic linear Ising model with exchange coupling constant $J=56$ cm^{-1}. Then, the application of non-alternant one-dimensional Hubbard model gives $I=11200$ cm^{-1} and $T\approx-560$ cm^{-1} for the cation radical salt of DCA–$SbCl_5$.

Next, we consider the electronic state of P–ClO_4 salt. Its magnetic susceptibility was weakly paramagnetic and the intrinsic paramagnetism decreased with decrease of temperature. The observed magnetic susceptibility *versus* temperature curve fitted closely to the curve calculated from the singlet-triplet model, where the excited triplet state lies 1370 cm^{-1} above the ground singlet state.[3] Therefore, the perylene cation radicals appear to form dimers in the solid state. In contrast to the DMA–$SbCl_5$ and DCA–$SbCl_5$ salts, the electronic spectrum of the solid P–ClO_4 salt showed a strong low-energy absorption at 7700 cm^{-1}, which was attributable to the charge-transfer absorption of the dimer of the perylene cation radicals.[3] We consider the above optical and magnetic properties of the P–ClO_4 salt in terms of the dimer model of Hubbard Hamiltonian, which can be written by

$$\mathscr{H} = \sum_{\sigma} T(C_{1\sigma}^{+}C_{2\sigma}+C_{2\sigma}^{+}C_{1\sigma}) + I(n_{1\downarrow}n_{1\uparrow}+n_{2\downarrow}n_{2\uparrow}), \quad (3)$$

where the notations are common to those in Eq. 1. The suffixes, 1 and 2, denote two sites of perylene cation radicals in a dimer, and $T(<0)$ is the transfer matrix element between the cation radicals in the dimer. If we again take the half-occupied molecular orbital of the cation radical for each site, there are six bases of the wave functions for the dimer. After solving the eigenvalue problem, we have three singlet states and one triplet state. A detail of the wave functions and the energy levels are described in a previous paper.[8] The energy of the charge-transfer absorption, $h\nu_{CT}$, and the singlet-triplet energy separation, δ, are given by

$$h\nu_{CT} = \{(I/2)^2+(2T)^2\}^{1/2} + I/2, \quad (4)$$

$$\delta = \{(I/2)^2+(2T)^2\}^{1/2} - I/2. \quad (5)$$

This dimer model was then applied to the above optical and magnetic properties of the P–ClO_4 salt. By putting the observed values of $h\nu_{CT}=7700$ cm^{-1} and $\delta=1370$ cm^{-1} into Eqs. 4 and 5, we obtain $I=h\nu_{CT}-\delta=6330$ cm^{-1} and $T=-1630$ cm^{-1}, respectively.

The transfer matrix elements thus estimated are considered as a measure of the intermolecular interaction between cation radicals in the solid state. In this respect, the intermolecular interaction in the dimer of the perylene cation radicals of the P–ClO_4 salt should be strongest, while the intermolecular interactions between the 9,10-dimethylanthracene cation radicals in the DMA–$SbCl_5$ salt and between the 9,10-dichloroanthracene cation radicals in the DCA–$SbCl_5$ salt will be of the same order but will be much weaker than that of the P–ClO_4 system. Sato *et al.* noted that the intensity of the charge-transfer band observed in solid spectrum was correlated to the magnitude of exchange coupling constant.[3] In fact, solid P–ClO_4 shows the large values both in exchange coupling constant and intensity of the charge-transfer band, while DMA–$SbCl_5$ and DCA–$SbCl_5$ have weak charge-transfer absorptions and small exchange coupling constants. Although their suggestion was qualitative, we can verify quantitatively their idea on the basis of our Hubbard model. According to our theoretical work,[10] in the region of small $|T|$ limit, the intensity of the intermolecular charge-transfer absorption in non-alternant one-dimensional system of ion radicals is given by CT^2/I, where C is a constant including electric charge, unit cell length and number of sites of the system. On the other hand, the absorption intensity in the dimer model is expressed by $C'T^2/I$,[8] where the constant C' is somewhat different from C. Regardless of this minor difference, the intensity of charge-transfer absorption is predominantly governed by the magnitude of T^2/I. If we take into consideration the T and I values estimated above, the charge-transfer absorption intensity of the P–ClO_4 salt will be ten times or more stronger than those of the DMA–$SbCl_5$ and DCA–$SbCl_5$ salts. Moreover, we have found that, since the antiferromagnetic exchange coupling constant is given by $J\approx 2T^2/I$, the charge-transfer absorption intensity is approximately proportional to the magnitude of J.[10] In this respect, Sato's suggestion that the observed charge-transfer absorption intensity in solid spectrum may be greatly dependent on the magnitude of J receives strong evidence from our Hubbard model.

An INDO-MO Study of Peroxyacetyl Nitrate Formation

Katsutoshi OHKUBO* and Hiroyuki SATO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received September 29, 1978)

Synopsis. The process of peroxyacetyl nitrate (PAN) formation has been disscussed on the basis of INDO calculations. The acetylperoxy radical (APR) has been found to be more reactive towards nitrogen monoxide than towards nitrogen dioxide. The bond strength of the O–O linkage in $CH_3C(=O)OONO$, however, is weaker than that of PAN or H_2O_2.

Peroxyacetyl nitrate (PAN) is a major class of eye irritant (lachrymators) in photochemical smog,[1–9] exhibiting toxicity in the inactivation of enzymes such as hemoglobin, papain, reduced ribonuclease and glutathione, and coenzyme A by the oxidation of the susceptible mercapto groups.[8,10,11] PAN has hitherto been considered to be formed in two distinct ways:

$$CH_3C{=}O \xrightarrow{O_2} CH_3C(=O)O_2 \xrightarrow{NO_2} CH_3C(=O)O_2NO_2 \quad \text{(Stephens's mechanism[2,6,8])} \quad (1)$$

$$[CH_3C(=O)O_2NO] \xrightarrow{-NO_2} [CH_3C(=O)O] \xrightarrow{NO_3} CH_3C(=O)O_2NO_2 \quad \text{(Hanst's mechanism[4])} \quad (2)$$

where the acetyl radical is produced by the photochemical decomposition of ketones or the oxidation of olefins and aldehydes in smog.[7] Louw *et al.*[6] and Cox *et al.*[12] recently supported Stephens's mechanism, but suggested the presence of a competitive reaction between $CH_3C(=O)O_2$ (APR) and NO.[12] Although there are some IR spectroscopic studies of PAN,[1,3,13] PAN has hitherto been the object of only limited investigation in terms of the molecular orbital treatment. The present MO study deals with the process of PAN formation.

Method of Calculation

Conformational optimizations were performed on $CH_3C{=}O$ $CH_3C(=O)O_2$, $CH_3C(=O)O_2NO$, and $CH_3C(=O)O_2NO_2$ by means of the INDO method[14] which is reliable for bond angles but less so for bond lengths.[14,15] The optimization, by means of a repeated SCF-procedure for the minimization of the total energy of a molecule, was conducted by changing the geometric parameters in turn until the optimum conformations of identical bond length and angle (within ±0.01 Å and 1°) were reached, the parameters of which are shown in Fig. 1.

Results and Discussion

The σ-type acetyl radical undergoes a rapid reaction with O_2 in air to form the acetylperoxy radical (APR) *via* the overlapping between the singly-occupied (SO), sp^2-like hybridized carbon orbital (spin density=0.62) on $CH_3C{=}O$ and the SO π_g-orbital of O_2 with a binding energy of 180.6 kcal/mol. APR

$$CH_3C{=}O \xrightarrow{O_2} CH_3\text{-}C(=O)\text{-}O\text{-}O^{\bullet} \text{ or } CH_3\text{-}C(=O)\text{-}O^{\bullet}\text{-}O \quad (3)$$

(I) (II)

corresponds to I which is energetically more stable than II by 1.03 kcal/mol (rotational barrier around the C–O bond=4.86 kcal/mol). The SO orbital (located at −0.504 a.u.) on the terminal oxygen (spin density=0.819) in APR, which expands perpendicularly to the C(=O)–O–O plane, is capable of coupling with the nitrogen SO orbital (at −0.489 a.u.) on the NO_2 (spin density=0.383) or with that (at −0.454 a.u.) on the NO (spin density=0.468). The minimized energetic process of the above coupling reaction was followed by the optimization of the geometric parameters of $CH_3C(=O)O_2$–NO or $CH_3C(=O)O_2$–NO_2 along the O–N bond. As can be seen from Table 1, the APR–NO_2 reaction is more energetically favored than the APR–NO_2 reaction. The most stable $CH_3C(=O)O_2NO$ and $CH_3C(=O)$-O_2NO_2 are obtained at an O–N distance of 1.28 and 1.31 Å respectively. The nuclear-electron attraction (E_I) makes the APR–NO_2 reaction more favorable than the APR–NO reaction, but the increase in the internuclear and interelectron repulsions (E_N and E_{II} respectively) in the reaction is more remarkable in the APR–NO_2 reaction. That the APR–NO reaction predominates the APR–NO_2 reaction agrees with the priority of $CH_3C(=O)O_2NO$ formation in the following competitive reactions:

$$\text{APR} \left\{ \begin{array}{ll} \xrightarrow[k]{NO} & CH_3C(=O)O_2NO \quad (4a) \\ \xrightarrow[k']{NO_2} & CH_3C(=O)O_2NO_2 \quad (4b) \end{array} \right. \qquad (k/k' \simeq 1.7^{12})$$

The relatively small amount of NO as compared with that of NO_2 in air ([NO]/[NO_2]=0.1(daytime)—1.0(night) in towns[12]), however, does not make Reaction 4a predominate over Reaction 4b in photochemical smog. The calculated binding energy of

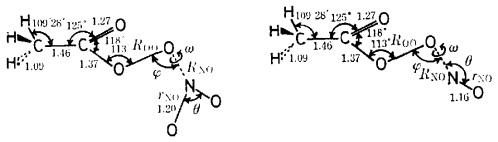
ΔE/a.u.[b]	0.0 (0.0)	0.135 (0.122)	−0.058 (−0.069)	−0.213 (−0.230)	−0.292 (−0.319)	(−0.324)

Values in parentheses are those for the APP-NO system. a) $\omega=0°$ in the following conformations. b) $\Delta E=E_{total}$(APR-NO_2 or APR-NO)$-E_{total}$(APR)$-E_{total}$(NO_2 or NO).



(HC-C(=O)-OO fragment is in the same plane).

the weakest O–O bond in $CH_3C(=O)OONO$ (249 kcal/mol) is less than that of the same bond in H_2O_2 (281 kcal/mol). Consequently, $CH_3C(=O)O_2NO$ undergoes thermal decomposition through the following reaction.

$$CH_3C(=O)O_2NO \xrightarrow{\Delta} CH_3C(=O)O + NO_2 \quad (5)$$

PAN formed by Reaction 4b has many rotational isomers (Fig. 2). The rotational barrier around the $O–NO_2$ bond was found to be 10.2 kcal/mol, around the O–O bond 1.66 kcal/mol, and around the C–O bond 11.9 kcal/mol. The bond strength of the O–O linkage (binding energy=273 kcal/mol) in PAN

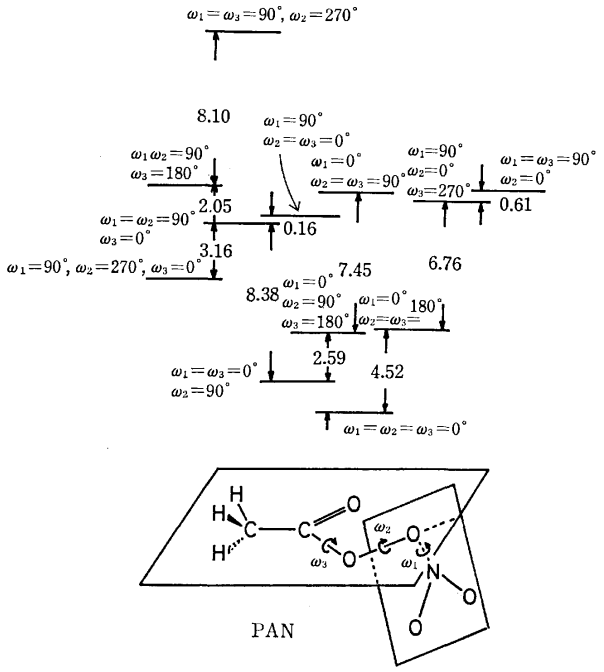


Fig. 2. Relative stability of the rotamers of PAN (energy difference: kcal/mol. $\omega_1=\omega_2=\omega_3=0$ and dihedral angle of the two planes=90° in the above energetically most stable conformation of PAN).

is of the same magnitude as that of H_2O_2, so that PAN is also thermally decomposed in the following way:[7]

$$PAN \xrightarrow{\Delta} [CH_3C(=O)O\text{-}\text{-}ONO_2] \longrightarrow$$

$$[CH_3\text{-}\text{-}C(=O)O] + ONO_2 \longrightarrow CH_3ONO_2 + CO_2 \quad (6)$$

where the binding energy of the C–C bond in CH_3-C(=O)O has been calculated as 249 kcal/mol. The photo-irradiation of PAN in the daytime, however, may bring about [n→π^*] type electron excitation on the carbonyl group (calculated excitation energy =227 kcal/mol). Such an electron excitation on the carbonyl group results in a weakening of the neighboring acyl bond in addition to that of the C=O bond *per se*; the excitation decreased the overlap population of the acyl bond by more than 10% with respect to the same bond in the ground state. Thus, the decomposition of PAN in the daytime may be expressed as follows:[7]

$$PAN \xrightarrow{h\nu} CH_3C{=}O + O_2NO_2 \xrightarrow{H_2O}$$

$$CH_3ONO_2 + CH_4 + CH_3OH + HCO_2H + NO_2 + O_2. \quad (7)$$

The radicals formed through the photochemical decomposition of PAN possibly abstract hydrogen from the SH group of the enzymes, thereby inactivating the enzymes *via* the formation of disulfides which are unobtainable from the *S*-acetyl group oxidation by PAN (or by H_2O_2).[11]

Lifetime Measurement of HO_2 Radical

Soji Tsuchiya* and Tomiji Nakamura

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received October 25, 1978)

Synopsis. The formation and dissipation kinetics of HO_2 radical was investigated by means of UV absorption measurement in a gas mixture, H_2+*ca.* 1% O_2+a trace of Hg vapor which was irradiated by a 253.7 nm light pulse. The rate constant of the reaction $2HO_2 \rightarrow H_2O_2+O_2$ was determined to be $(2.8\pm0.3)\times10^{12}$ cm^3 mol^{-1} s^{-1}.

The reported values of the reaction rate constants of HO_2 which is relevant to photochemical pollution are not in very good agreement with each other.[1] This may be attributed partly to lack of a reliable recombination rate constant of HO_2, since in most reactions the rate constants are determined relative to that of the recombination reaction. However, because of the difficulty in observing accurately the absolute concentration of HO_2, the recombination rate constants determined in different reaction systems show a relatively large scatter.[2-4]

In this note, the direct lifetime measurement as well as the determination of its absolute concentration are described. The method of HO_2 formation is based on the association reaction of H and O_2, the former of which is produced by the Hg photo-sensitized decomposition of H_2. The method is essentially similar to the one employed by Hunziker and Wendt who observed the near IR absorption spectrum of HO_2.[5]

The experimental apparatus is schematically shown in Fig. 1. The H_2 gas containing *ca.* 1% O_2 with a trace of Hg vapor is passed through a quartz cell, whose diameter and length are 3 and 30 cm, respectively, its flow rate being controlled to be several tens cm^3 s^{-1} at 1 atm and at room temperature. The cell was surrounded by six low pressure Hg lamps which were turned on periodically with a pulse width of *ca.* 20 ms and with a repetition frequency of several Hz. A d.c. source for the lamps was controlled by power transistors whose base current was supplied from a pulse generator. Thus, the Hg resonant light pulse with a rise time of 30 μs and variable pulse width was obtained. The UV light beam from a D_2 discharge lamp was passed through the cell, and fed into a monochromator. In order to measure a very weak absorption, the signal from the monochromator was digitized and accumulated to obtain the averaged signal of repeated light pulses. This made it possible to observe a change of transmittance as small as 5×10^{-5}. When a signal change Δ is obtained with the original light intensity of I_0, the optical density of the absorption is defined by

$$D \equiv \ln [I_0/(I_0-\Delta)] = \Delta/I_0 = \beta l[HO_2], \quad (1)$$

where β is the absorption coefficient of HO_2 and l is an optical pathlength.

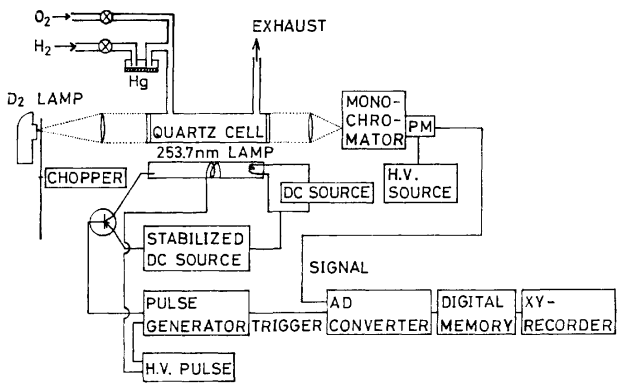

Fig. 1. Block diagram of the apparatus.

A transmittance change following the irradiation of the 253.7 nm light and its recovery after termination of the irradiation were found in the wavelength range of 200—250 nm as shown in Fig. 2. The absorption, which has a maximum intensity around 205 nm, is assigned to that of HO_2 since the absorption disappears with reduction of the O_2 content even if its fraction in H_2 is less than 10^{-2}. HO_2 must be formed by the reaction mechanism:

$$Hg + h\nu\ (253.7\ nm) \longrightarrow Hg^*, \quad (R1)$$

$$Hg^* + H_2 \longrightarrow Hg + 2H, \quad (R2)$$

$$H + O_2 + H_2 \longrightarrow HO_2 + H_2. \quad (R3)$$

A large Hg* quenching cross section of H_2 leads to the instantaneous formation of H atoms by irradiation of the Hg resonant light pulse. In Fig. 2, the transmission of the 205 nm light begins to decrease at the onset of the 253.7 nm light pulse approaching gradually a stationary value. After termination of the light pulse, the transmission recovers to some extent, and for com-

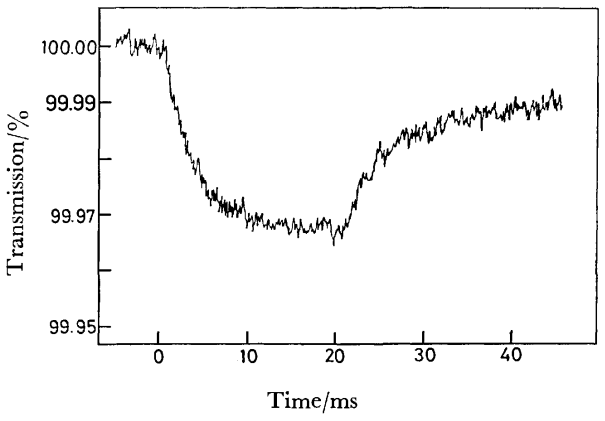

Fig. 2. An example of the observed transmittance change at 205 nm. The flow rates of H_2 and O_2 are 500 and 5 cm^3 min^{-1}, respectively, and the 253.7 nm light pulse width is 20 ms with its repetition frequency of 4 Hz. Number of data accumulated is 256.

plete recovery a fairly long time, during which the cell is refilled with fresh gas, is necessary.

Referring to the table of the reaction rate constants of HO_2,[1] the most probable reactions for the dissipation of HO_2 must be as follows:

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2, \quad (R4)$$

$$HO_2 + H \longrightarrow H_2 + O_2. \quad (R5)$$

Reaction R5 is excluded because $[HO_2]$ is at most on the order of 10^{-11} mol cm^{-3} in comparison with *ca.* 10^{-7} mol cm^{-3} of the O_2 concentration. Thus, H atoms react with O_2 rather than with HO_2. Hence, the following kinetic relation is derived;

$$d[HO_2]/dt = \alpha I - 2k_5[HO_2]^2, \quad (2)$$

where I represents the 253.7 nm radiation intensity per unit volume and time and α is a constant to describe the conversion of the absorbed light quantum to moles of HO_2. After termination of the light pulse, Eq. 2 is integrated to give the relation

$$(1/[HO_2]_t) - (1/[HO_2]_{t=\tau}) = 2k_5(t-\tau), \quad (3)$$

where τ is the duration of the light pulse. This equation is modified by substituting Eq. 1 as

$$(1/D_t) - (1/D_{t=\tau}) = 2(k_5/\beta l)(t-\tau). \quad (4)$$

Thus, the absorption coefficient must be known in order to determine the relevant reaction rate.

Inspecting the data of Fig. 2, it is found that a stationary concentration of HO_2 is not realized strictly during the irradiation of 253.7 nm light, and that the UV light does not recover its original intensity long after the termination of the light pulse. These facts may be attributed to the formation of H_2O_2 which absorbs the UV light with an absorption coefficient smaller than that of HO_2. Hence, Eq. 1 should be corrected to

$$D = \beta l[HO_2] + \beta' l[H_2O_2], \quad (5)$$

where β' is the absorption coefficient of H_2O_2. On the beginning of the irradiation, the increase of absorption intensity can be assumed to be solely due to the formation of HO_2, *i.e.*,

$$(dD/dt)_{t=0} = \beta l(d[HO_2]/dt)_{t=0} = \beta l\alpha I. \quad (6)$$

Since the absorption at the final stage should originate from H_2O_2, that is the end product, the stoichiometric relation

$$D_{t=\infty} = \beta' l[H_2O_2]_{t=\infty} = \beta' l\alpha I\tau/2_2 \quad (7)$$

is satisfied. Substituting Eq. 7 into Eq. 6, the absorption coefficient β may be determined by the use of the equation

$$2D_{t=\infty}/(dD/dt)_{t=0}\tau = \beta'/\beta, \quad (8)$$

where β' is known accurately.[6] The absorption coefficient thus determined is $(1.80\pm0.14)\times10^6$ cm^2 mol^{-1} at 205 nm in good agreement with the value reported.[4]

If we deal with the behavior of HO_2 after termination of the light pulse, the following stoichiometric relation is obtained:

$$[HO_2]_t + 2[H_2O_2]_t = 2[H_2O_2]_{t=\infty}, \quad (9)$$

where $t \geq \tau$. Then, $[HO_2]_t$ may be determined by the equation

$$[HO_2]_t = [D(t) - D(t=\infty)]/l(\beta - 0.5\beta'). \quad (10)$$

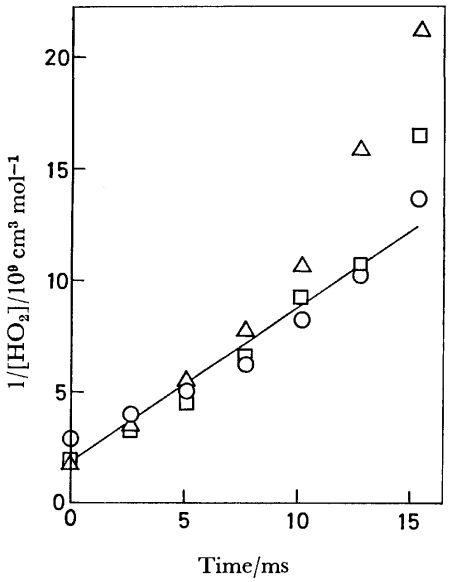

Fig. 3. Plots of $[HO_2]^{-1}$ *vs.* time after the termination of the light pulse. △: 1% O_2 in H_2, ○: 2%O_2, □: 0.5% O_2.

Table 1. Rate constant of $2HO_2 \rightarrow H_2O_2 + O_2$

Investigator	$k_5/10^{12}$ cm^3 mol^{-1} s^{-1}
Foner & Hudson[2]	*ca.* 1.8
Hochanadel *et al.*[4]	5.7±0.5
Paukert & Jonston[3]	2.2±0.3
This work	2.8±0.3

The reciprocals of the obtained values of $[HO_2]_t$ are plotted in Fig. 3 as a function of time lapse after termination of the light pulse, $(t-\tau)$. According to Eq. 3 the initial slope gives the relevant rate constant. A good linearity is found for the initial decay of $[HO_2]$ supporting the second order reaction of the HO_2 dissipation. However, in a later stage, the bimolecular process becomes a minor one since atomic hydrogen or impurity molecules may react with HO_2, so that the plots of $[HO_2]^{-1}$ *vs.* $(t-\tau)$ deviate significantly from the linear line, although the quantity of HO_2 which reacts in non-bimolecular processes is fairly small, probably less than 10% of the original $[HO_2]$. The rate constant obtained is given in Table 1 together with the literature values.

Matrix Representation of an Olefinic Reference Structure for Monocyclic Conjugated Compounds

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 13, 1978)

Synopsis. A reference polynomial which represents an olefinic reference structure of a monocyclic conjugated system can be expressed in the form of a Hermitian matrix. Some interesting features of the reference structure have been deduced from it.

The author has developed a graph theory of aromaticity,[1,2] in which the resonance energy due to aromaticity is given as the difference between the total π-electron energy of a conjugated compound and that of its olefinic reference structure. The reference energy of a conjugated hydrocarbon, *i.e.*, the total π-electron energy of its reference structure, has been defined by the following reference polynomial:[1]

$$R(X) = X^N + \sum_{r=1}^{[N/2]} (-1)^r p(r) X^{N-2r}, \quad (1)$$

where N is the number of sp^2-carbon atoms in a conjugated system, $[N/2]$ is the maximum integer not exceeding $N/2$, and $p(r)$ is the number of ways of choosing r disjoint π bonds from the conjugated system.[3] The reference energy is given as twice the sum of the larger $[N/2]$ roots of the equation

$$R(X) = 0. \quad (2)$$

A matrix representation of such a reference polynomial is possible for any monocyclic conjugated system, and is discussed below.

Consider a monocyclic conjugated hydrocarbon with N sp^2-carbon atoms, M of which constitute a closed π ring. The other carbon atoms, if any, belong to the substituent(s). Let an adjacency matrix[4] for this conjugated system be denoted by A and the elements by a_{ij}. The matrix element a_{ij} is therein equal to unity if there is a π bond between the atoms i-j. All the other matrix elements are zero. The eigenvalues of this matrix represent the orbital energies of a conjugated system.

The elements of the matrix A are then changed as follows. If matrix element a_{ij} corresponds to one of the M π bonds forming a π ring, it is weighted with a factor $\exp(i\eta_{ij}\theta)$, where the numerical value of θ is $\pi/(2M)$, and

$$\eta_{ij} = \begin{cases} +1 & \text{if atoms i}\rightarrow\text{j are arranged clockwise in a } \pi \text{ ring of a conjugated system, and} \\ -1 & \text{if not.} \end{cases}$$

The remaining matrix elements are left unchanged. The resulting matrix is denoted by B and the elements by b_{ij}. Matrix B is thus a weighted adjacency matrix.

Next, consider a secular determinant defined by

$$Q(X) = (-1)^N \det|B - EX|, \quad (4)$$

where E is a unit $N \times N$ matrix. On expansion, $Q(X)$ leads to a polynomial in X, the coefficients all being expressible in terms of the closed cyclic products of the type $b_{ij}b_{jk}\cdots b_{pq}b_{qi}$.[5] Such products of more than two matrix elements represent a cyclic array of π bonds, *i.e.*, a π ring, in a conjugated system. These products, however, vanish in the present case since

$$b_{ij}b_{jk}\cdots b_{pq}b_{qi} + b_{ji}b_{kj}\cdots b_{qp}b_{iq} = 2\cos\left(\frac{\pi}{2}\right) = 0. \quad (5)$$

The non-zero cyclic product is represented by

$$b_{ij}b_{ji} = \exp(0) = 1 \quad (6)$$

for each π bond. Then, apply an extended version of Sachs' graph-theoretical theorem[5] to the secular determinant $Q(X)$ with Eqs. 5 and 6 in mind, and the determinant will necessarily be expanded into the same polynomial as the reference polynomial for the same conjugated system, namely,

$$R(X) \equiv Q(X). \quad (7)$$

It has thus been proved that a reference polynomial for a monocyclic conjugated system can be expressed in the form of Eq. 4. Since matrix B is a Hermitian matrix, the eigenvalues of the matrix, *i.e.*, the roots of the equation $Q(X)=0$, are all real.

For example, matrix B for styrene in Fig. 1 is

$$B = \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & z & 0 & 0 & 0 & z^* \\ 0 & 0 & z^* & 0 & z & 0 & 0 & 0 \\ 0 & 0 & 0 & z^* & 0 & z & 0 & 0 \\ 0 & 0 & 0 & 0 & z^* & 0 & z & 0 \\ 0 & 0 & 0 & 0 & 0 & z^* & 0 & z \\ 0 & 0 & z & 0 & 0 & 0 & z^* & 0 \end{pmatrix}, \quad (8)$$

where

$$z = \exp\left(\frac{\pi}{12}\,\mathrm{i}\right). \quad (9)$$

This matrix leads to the same polynomial as $R(X)$ for this compound, *i.e.*,

$$Q(X) = R(X) = X^8 - 8X^6 + 19X^4 - 14X^2 + 2. \quad (10)$$

From the present definition of matrix B, the following

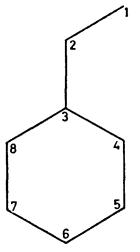

Fig. 1. A conjugated system of styrene.

equalities have been clarified for monocyclic conjugated hydrocarbons:

$$\mathrm{Tr}\, B = \mathrm{Tr}\, A = 0, \tag{11}$$

$$\mathrm{Tr}\, B^2 = \mathrm{Tr}\, A^2 = 2H, \tag{12}$$

where H is the number of π bonds in an entire conjugated system. Note that the trace of a matrix is the sum of the eigenvalues. Equation 11 indicates that the sum of the orbital energies vanishes both for a conjugated system and its reference structure. Equation 12 indicates that the sum of the orbital energies squared for a conjugated system is equal to that for its reference structure. According to extensive numerical analysis, these equalities appear to hold true for polycyclic conjugated hydrocarbons without exception. Since the sum of the orbital energies squared is preserved in the reference structure, it can be deduced that some of the occupied orbitals in a conjugated system must be energetically higher than the corresponding orbitals in its reference structure[6] even if the conjugated system is aromatic with positive resonance energy.

A reference polynomial for a monocyclic heterocyclic conjugated system can also be derived from the secular determinant simply by weighting the matrix elements with the same factors $\exp(i\eta_{ij}\theta)$ as in the case of monocyclic conjugated hydrocarbons. It is interesting to note that, if $\theta=\pi/M$, matrix B represents a Möbius conjugated system, *i.e.*, a singly twisted conjugated system.[7]

Determination of Self-diffusion Coefficient of Nickel in Nickel Sulfide

Kazuo KOTANI,** Kenichiro OTA,* Takemi AIZAWA,*** and Kazuo FUEKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 2, 1978)

Synopsis. The self-diffusion coefficient of nickel in nonstoichiometric nickel sulfide, $Ni_{1-\delta}S$, was measured as a function of δ, using ^{63}Ni in the temperature range of 550—750 °C. At $\delta=0.028$, the self-diffusion coefficient, D^*_{Ni}, was expressed by the following equation:

$$D^*_{Ni} = 3.3 \times 10^{-7} \exp\left(-\frac{73.2\pm9.2/\text{kJ mol}^{-1}}{RT}\right) \text{m}^2\,\text{s}^{-1}.$$

At 550 °C and 650 °C, D^*_{Ni} increased with an increase in δ from 0 to 0.04 and tended to reach the saturation point above $\delta=0.04$.

Generally, the self-diffusion in inorganic crystals takes place *via* point defects, so it is necessary to know the relation between the self-diffusion coefficient and the defect concentration in order to elucidate the diffusion mechanism. There have, however, been only a few studies which have determined the self-diffusion coefficient as a function of the defect concentration. $Ni_{1-\delta}S$ has a wide nonstoichiometric region, δ.[1-3] The purpose of the present study is to determine the self-diffusion coefficient of nickel in $Ni_{1-\delta}S$ as a function of δ at 550—750 °C.

Experimental

Specimen. The nickel sulfide was prepared by sulfidizing electrolytic nickel powder (99.99% purity) with sulfur purified by distillation *in vacuo*.

They were reacted in a Vycor reaction tube, first at 400 °C for a week and then at 900 °C for 4 days to complete the sulfidization. A single crystal of nickel sulfide, 5 mm in diameter and 50 mm long, was grown by the Bridgeman method. The crystal orientation was determined by the Laue method. Disks, 2 mm in thickness, were cut perpendicular to the c-axis from the single crystal by means of a crystal cutter and polished with polishing paper.

Controlling of δ. A sulfide specimen and sulfur were sealed in an evacuated Vycor tube and placed in an electric furnace which had two different temperature zones. The specimen was set in the high-temperature zone (700 °C), while the sulfur was placed in the low-temperature zone. The specimen was then annealed for 4 days in sulfur vapor, whose vapor pressure was controlled by the lowest temperature of the tube. The δ was determined using the relation between the sulfur pressure and δ,[2] and doubly checked by means of the lattice constant using Laffitte's results.[3]

Diffusion Annealing. About 10 μCi of ^{63}Ni was applied to one end of the disk specimen, after which the specimen was placed in a Vycor tube, evacuated, and sealed. Then the tube was placed in an electric furnace kept at a desired temperature for diffusion annealing. In order to avoid any change in composition resulting from the decomposition of sulfide, the volume of the reaction tube was minimized to about 3 cm^3.

Measurement of the Self-diffusion Coefficient. After the diffusion-annealing the specimen was taken out and sectioned by successive grinding by means of a grinding machine which has been described elsewhere.[5] The thickness of each layer was 5—10 μm, as determined from the weight decrease in the specimen after grinding.

The radioactivity of ^{63}Ni on the polishing paper was counted by the liquid-scintillator-method, since β-rays from ^{63}Ni are too weak for the radioactivity to be measured by the use of a Geiger-Muller counter, especially at low radioactivity. Polishing paper smeared with sulfide powder was immersed in the liquid scintillator, and photons activated by β-rays were measured by means of a photomultiplier.

Results and Discussion

Figure 1 shows the Arrhenius plot for the self-diffusion coefficient, D^*_{Ni}, in $Ni_{1-\delta}S$ at $\delta=0.028$. The D^*_{Ni} value obtained by Klotsman at $\delta=0.03$ is also shown in the same figure for the sake of comparison. There is a good agreement between the two results. The present result at $\delta=0.028$ can be expressed by the following equation:

$$D^*_{Ni} = 3.3 \times 10^{-7} \exp\left(-\frac{73.2\pm9.2/\text{kJ mol}^{-1}}{RT}\right) \text{m}^2\,\text{s}^{-1}$$

Since δ is constant, the activation energy, 73.2 kJ mol^{-1}, indicates the enthalpy of activation for the migration of nickel in $Ni_{1-\delta}S$.

Figure 2 shows the relation between D^*_{Ni} and δ at 550 °C and 650 °C. D^*_{Ni} increases with an increase in δ from 0 to 0.04 at both temperatures. However,

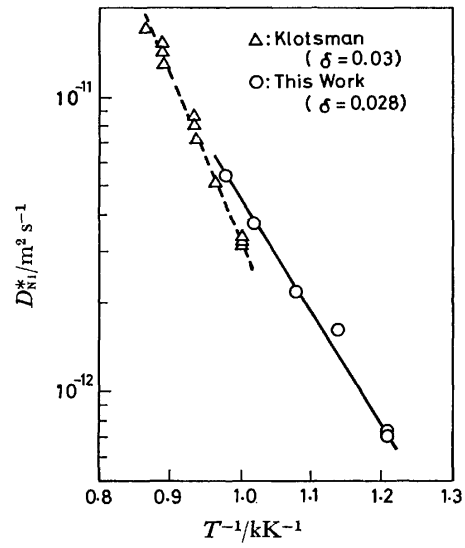

Fig. 1. Arrhenius plot of D^*_{Ni} in $Ni_{1-\delta}S$.

**Present address: National Institute for Researches in Inorganic Materials, Sakura-mura, Ibaragi.

***Present address: Onoda Cement Co., Ltd., Fujiwara-cho, Mie.

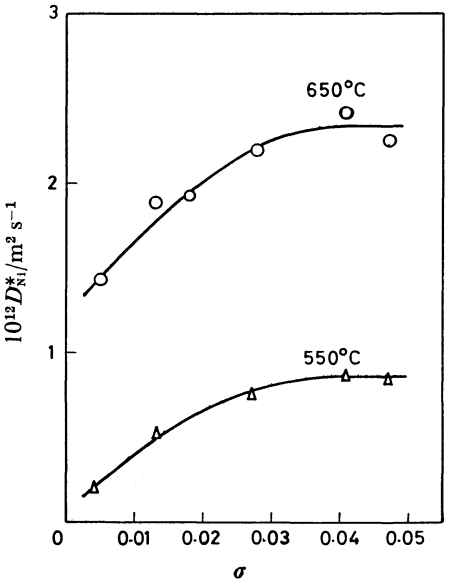

Fig. 2. Relation between D^*_{Ni} and δ in $Ni_{1-\delta}S$.

D^*_{Ni} is not linearly related to δ and tends to reach the saturation point above $\delta=0.04$. A simple defect model would thus appear to be inappropriate for $Ni_{1-\delta}S$.

The same tendencies for the D^*_{Fe} in $Fe_{1-\delta}S$, which has the same Ni–As type of crystal structure,[6] and also for D^*_{Fe} in $Fe_{1-\delta}O$[7] have been reported. The dependence of the D^*_{Fe} in $Fe_{1-\delta}O$ on δ was explained by the formation of clusters of iron vacancies.[7] If the defect clusters are formed in $Ni_{1-\delta}S$, the concentration of free vacancies that are responsible for the diffusion process would not be expected to be linearly related to the deviation from stoichiometry. To ascertain the defect structure of $Ni_{1-\delta}S$, detailed studies, for example, neutron and X-ray diffraction studies, are necessary.

The authors wish to thank Dr. Koichi Kitazawa for his helpful discussions.

1,3,5-Triarylpyrazoles as Phosphorescing Impurities in 1,3,5-Triaryl-2-prazolines

Hiroyoshi YAMAMOTO, Yumiko SANO, Yasuhiko SHIROTA,* Hajime SEKI,** and Hiroshi MIKAWA

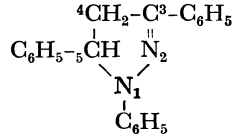
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

***IBM Research Laboratory, San Jose, California 95193*

(Received December 5, 1978)

Synopsis. The origin of the phosphorescence observed for 1,3,5-triphenyl-2-pyrazoline and its substituted derivatives was investigated. Unlike the previously accepted conclusion, our conclusion is that the phosphorescence originates from the corresponding pyrazoles formed from the pyrazolines by the action of light.

Numerous studies have been made of the electronic absorption and emission spectra of 1,3,5-triphenyl-2-pyrazoline (TPP) and its derivatives. These compounds exhibit three absorption bands, *i.e.*, two intense bands in the wavelength regions at around 230—260 nm and 350—420 nm, and a less intense one appearing frequently in the form of an inflection at the 300—330 nm region.[1,2] On excitation in the longest wavelength absorption band, an intense fluorescence with a quantum yield of close to unity appears in nonpolar solvents, no phosphorescence being observed.[3,4] It has been reported, however, that a weak, long-lived green phosphorescence is observed with TPP and some of its derivatives on excitation in the shorter wavelength absorption band by the light of 313 nm, and the phosphorescence has been ascribed as due to the 5-aryl group that constitutes an independent set of singlet and triplet levels from the conjugated π-electron system Ar–N–N=C–Ar in the pyrazoline ring which is responsible for the characteristic spectral features of TPP and its derivatives.[2] This conclusion has been cited also in a recent publication by an independent researcher.[5]



TPP

As a part of our studies on the physical and chemical properties of TPP and its derivatives,[6] we have reinvestigated the origin of the phosphorescence emission observed for TPP and its derivatives. Three compounds, *i.e.*, TPP, 1,5-diphenyl-3-(*p*-methoxyphenyl)-2-pyrazoline (MTPP), and 1,5-diphenyl-3-(*p*-dimethylaminophenyl)-2-pyrazoline (DMATPP), were examined in the present study. The use of the amino-substituted TPP has made the assignment of the phosphorescence emission easy and successful. As shown in Fig. 1, TPP and MTPP purified by repeated recrystallizations exhibit a very weak phosphorescence in the wavelength region of 400 to 500 nm on excitation by the light of 300 to 320 nm, whereas only intense fluorescence appears in the wavelength region of 400 to 500 nm on excitation in the long-wavelength absorption band of these compounds. The phosphorescence was so weak that it was detected under conditions of the maximum sensitivity of the instrument with a wide slit width. On the other hand, DMATPP purified by repeated recrystallizations shows a much more intense phosphorescence in the wavelength region of 440 to 550 nm on excitation by the light of 300 to 340 nm (Fig. 2d), whereas on excitation in the long-wavelength absorption band, only intense fluorescence of DMATPP appears in the wavelength region of 400 to 500 nm (Fig. 2a). It was also found that, in the total emission spectrum (Fig. 2c), the appearance of the phosphorescence is accompanied by the appearance of a new fluorescence at around 350 to over 400 nm. The excitation spectra for the phosphorescence and the new fluorescence were found to be the same with each other, but different from that for the DMATPP fluorescence at the 400 to 500 nm region which corresponds to the absorption spectrum of DMATPP.

These results indicate that the phosphorescence and the new fluorescence (in the case of DMATPP) observed on excitation by the light of 300 to 340 nm do not result from the singlet and triplet levels of the 5-phenyl group in the pyrazoline ring as has been stated in the literature. Emitting impurities conceivable to be incorporated into the pyrazoline compounds during the synthetic process were examined, but their emission spectra did not agree with those shown in Figs. 1 and 2. It was found that the intensity of the phosphorescence and the new fluorescence observed for DMATPP increases when a sample solution was left to stand as it is for long days or after spectral measurements were repeated, and that these emissions are extremely weak with respect to a virgin sample prepared in the dark throughout the processes of purification, drying, and preparation of a solution (Fig. 2b). These

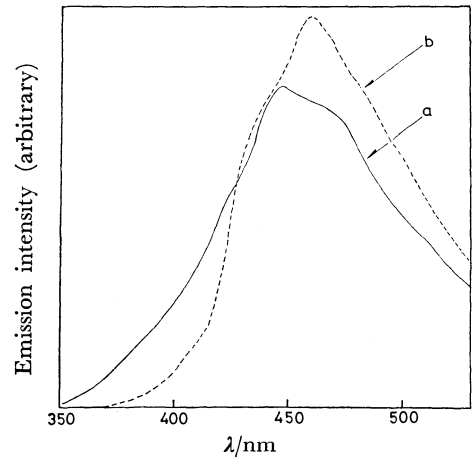


Fig. 1. Corrected phosphorescence spectra observed for TPP (a) and MTPP (b) on excitation by the light of 320 nm in MTHF at 77 K.

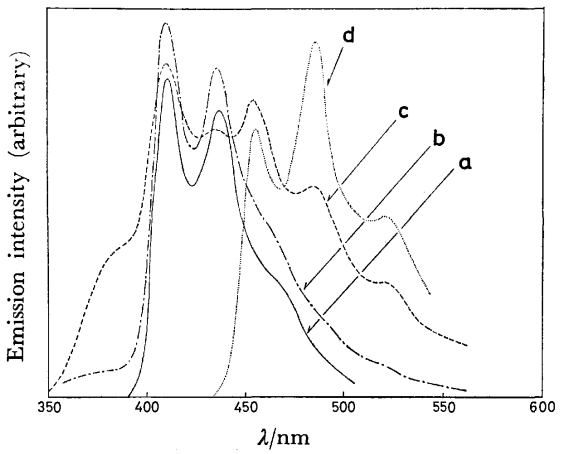

Fig. 2. Corrected emission spectra observed for DMATPP in MTHF at 77 K.
a, b, and c: Total emission spectra; d: delayed emission spectrum.
a: Fluorescence spectrum inherent to DMATPP observed on excitation by the light of 370 nm. b: Emission spectrum observed for a virgin smaple prepared in the dark on excitation by the light of 320 nm. c: Emission spectrum observed on excitation by the light of 320 nm. d: Phosphorescence spectrum observed on excitation by the light of 320 nm.

results indicate that the impurity which is responsible for these emissions is derived from the pyrazoline compound probably by the action of light such as sunlight, light from fluorescent room lamps, and the light employed for spectral measurements. Confirmation for this conjecture was obtained from the result that the intensity of the new emissions for DMA-TPP increases gradually on illuminating a sample solution by the light of 366 nm using a 500 W high pressure mercury lamp, while the intensity of the DMATPP fluorescence decreases with an isoemissive point at 396 nm.[7]

The phosphorescence and the new fluorescence observed for DMATPP on excitation in the ostensible shorter wavelength absorption band were identified as the ones originating from the excitation of 1,5-diphenyl-3-(*p*-dimethylaminophenyl)pyrazole (DMATPPzole) based on the identity of the shape and position of the emission bands, the excitation spectra, and the lifetimes of the emissions with those of the authentic DMATPPzole (τ_f=7.2 ns at room temp, τ_p=0.97 s at 77 K, in a degassed solution of 2-methyltetrahydrofuran). Likewise, the phosphorescences observed for TPP and MTPP were found to be identical with those of the corresponding pyrazoles, although the resolution of the vibrational structure of the phosphorescence bands shown in Fig. 1 is lower as compared with the phosphorescence bands of the authentic 1,3,5-triphenylpyrazole (TPPzole) and 1,5-diphenyl-3-(*p*-methoxyphenyl)pyrazole (MTPPzole). The major reason why the emission due to the impurity pyrazole is much more intense for DMATPP as compared with TPP and MTPP is that DMATPPzole absorbs the light of 300 to 340 nm much more strongly than TPPzole and MTPPzole (λ_{max}(log ε) in MTHF at room temp: 257 nm(4.46) for TPPzole; 261 nm (4.51) for MTPPzole: 290 nm(4.54) for DMATPPzole).

Although the photochemical conversion of TPP and its derivatives into the corresponding pyrazoles has been known,[8] the present sudy of the measurement of the emission spectra has revealed that these compounds are very sensitive to light. The phenomena observed in the emission spectra seem to be general with many other derivatives of TPP which undergo photodehydrogenation. TPP and its derivatives have found applications for practical use, *e.g.*, as fluorescent whitening agents,[9] and as material for electrophotography.[10] The chemical properties described above should be taken into account in evaluating the function of these materials.

Experimental

Materials. TPP (mp 141—2 °C), MTPP (mp 140.5—141.5 °C) were prepared according to the known procedure,[11] purified by repeated recrystallizations from EtOH and dried *in vacuo*. DMATPP (mp 199.5—201 °C) was synthesized in a similar manner by the reaction of phenylhydrazine with 1-(*p*-dimethylaminophenyl)-3-phenyl-2-propenone which was obtained by the reaction of *p*-dimethylaminoacetophenone with benzaldehyde, purified by repeated recrystallizations from EtOH and dried *in vacuo*. TPPzole (mp 138—138.5 °C), MTPPzole (mp 141—142 °C), and DMATPPzole (149—149.5 °C) were prepared from the corresponding pyrazolines by the dehydrogenation reaction with chloranil in refluxing xylene, followed by column chromatography over neutral alumina, recrystallized several times from EtOH, and dried *in vacuo*.

Spectral Measurement. The electronic absorption spectra were recorded with a Hitachi 124 spectrophotometer. The emission and excitation spectra were recorded with a Hitachi MPF-3 spectrofluorometer fitted with a R446 photomultiplier. The concentration of the solution was *ca.* 2×10^{-5} mol/l. The fluorescence lifetime was measured by means of a pulsed N_2 laser with a pulse width of *ca.* 2 ns and repetition of *ca.* 3 Hz.

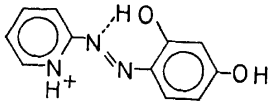
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received July 26, 1978)

Synopsis. The kinetics of complex formation of Tl(III) with PAR (LH_3^+) was studied in aqueous solution at 25 °C, $[H^+]=0.1$—1.0 mol dm^{-3}, and ionic strength $I=2.0$ mol dm^{-3} ($NaClO_4$). The formation rate constants k_1 and k_2 assigned to the reactions of Tl^{3+} and $TlOH^{2+}$ with LH_3^+ were determined to be 4.1×10^4 and 1.8×10^5 mol^{-1} dm^3 s^{-1}, respectively. The rate data were discussed in comparison with those for Tl(III)-Semi-Xylenol Orange system.

Thallium(III) has been reported to form colored complexes with some *o*-hydroxy azo multidentate ligands as PAR and its analogs even in acidic media.[1,2] However, no kinetic studies have been reported so far except for our early work on the complex formation of Tl(III) with Semi-Xylenol Orange, SXO, which gives the rate constant 3×10^5 mol^{-1} dm^3 s^{-1} for the reaction of $TlOH^{2+}$ and a neutral species of SXO, H_4SXO^0.[3,4] In the present paper we report the kinetic data for the complex formation of Tl(III) with PAR, in order to compare the rate constants with those for the reaction of Tl(III) with SXO.



PAR (LH_3^+)

In the proton concentrations 0.1—1.0 mol dm^{-3} the formation of 1 : 1 Tl(III)–PAR complex was confirmed by means of the method of continuous variation at 520 nm, the absorption maximum of the complex.[5] For the kinetic measurements the total concentration of Tl(III) was kept at least in tenfold excess over the PAR concentration. The change in the absorbance at 560 nm, a shoulder of the absorption spectrum of 1 : 1 complex, was followed by stopped-flow technique. This wavelength was adopted for the measurements in order to avoid the influence of the absorbance of the free ligand. Under the experimental conditions the value of the pseudo-first-order rate constants, k_{obsd}, did not depend on the total concentrations of PAR.

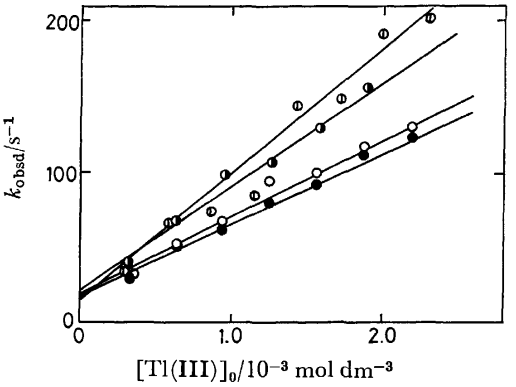


Fig. 1. Dependence of rate constants, k_{obsd}, on total concentrations of Tl(III) at various proton concentrations. $[H^+]=0.2$ (◑), 0.3 (◑), 0.5 (○), and 0.6 mol dm^{-3} (●). $[PAR]_0=2.49\times10^{-5}$ mol dm^{-3}. $I=2.0$ mol dm^{-3} ($NaClO_4$-$HClO_4$) and 25 °C.

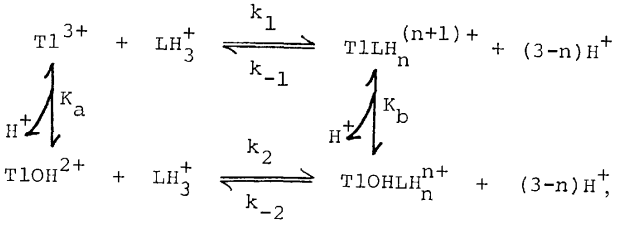
Figure 1 shows the dependence of the pseudo-first-order rate constants, k_{obsd}, on the total concentration of Tl(III), $[Tl(III)]_0$, at various proton concentrations. The slopes and the intercepts of the straight lines give the overall rate constants, k_f and k_d, for the formation and dissociation of 1 : 1 complexes, respectively.

The acid-dissociation constants of PAR, $K_c=[LH_2]\times[H^+]/[LH_3^+]=10^{-3.1}$ mol dm^{-3},[1] suggests that the protonated species of PAR, LH_3^+, should be the main species responsible for the complex formation in the acidic region as $[H^+]=0.1$—1.0 mol dm^{-3}.

According to the following scheme with due considerations on the contribution of a base-catalyzed path and the equilibria for very fast protolytic reactions



the formation rate constant k_f can be expressed as follows,

$$k_f = \frac{k_1[H^+] + k_2K_a}{[H^+] + K_a}$$

or

$$k_f([H^+]+K_a) = k_1[H^+] + k_2K_a.$$

The plot of $k_f([H^+]+K_a)$ against $[H^+]$ gives a straight line as shown in Fig. 2.[6] From the slope and the intercept the rate constants were determined to be $k_1=4.1\times10^4$ and $k_2=1.8\times10^5$ mol^{-1} dm^3 s^{-1}, respectively.

The value of k_2 was in the same order of magnitude as the formation rate constant for the reaction of $TlOH^{2+}$ and H_4SXO^0. For the completion of the complex formation between Tl(III) and multidentate ligand SXO, the cleavage of the hydrogen-bond

† Presented at the 1978 Winter Meeting in Hokkaido of the Chemical Socity of Japan and the Japan Society for Analytical Chemistry, Sapporo, February 2, 1978.

†† Present address: Hitachi, Ltd., Hitachi 317.

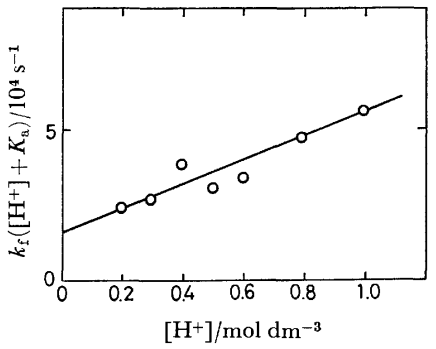


Fig. 2. Plots of $k_f([H^+]+K_a)$ *versus* $[H^+]$ at 25 °C and $I=2.0$ mol dm^{-3} ($NaClO_4$-$HClO_4$). $K_a=10^{-1.14}$ mol dm^{-3}.[10]

between the *o*-hydroxyl group and the nitrogen of iminodiacetate group should necessarily be involved. As regards the first step of the complex formation of PAR with Tl(III) two reaction paths are possible, namely, the first attack of metal ion on the protonated pyridyl nitrogen or the first attack of metal ion on the intramolecular hydrogen-bond between the *o*-hydroxyl group and the azo nitrogen. However, the attack at the protonated unipositive pyridyl group of PAR is very unlikely as reported in the case of the Co(II)–PAR[7] and the Ni(II)–PAR system.[8] Furthermore, it is surprising that the rate constant for the complex formation of Tl(III) with PAR is in the same order of magnitude as that of Tl(III)–SXO despite the differences in the structure, charge type, and the donor atoms between these two ligands. This fact suggests the control of the reaction rate by the step of dissociation of the coordinated water molecule from aqua Tl(III) ion. It is likely that the first attack of Tl(III) ion occurs on the hydrogen-bond between the *o*-hydroxyl group and azo nitrogen of PAR to form the complex.[9]

Experimental

Measurements. All measurements were carried out at 25.0±0.2 °C and ionic strength 2.0 ($NaClO_4$–$HClO_4$). The kinetic measurements were carried out with a stopped-flow spectrometer Yanagimoto SPS-1. The absorption spectra were measured with a Hitachi recording spectrophotometer EPS-3T.

Materials. All reagents are of analytical grade, unless otherwise specified. Water was deionized and distilled. A stock solution of Tl(III) perchlorate was prepared by anodic oxidation of Tl(I) perchlorate in 2 mol dm^{-3} perchloric acid.[10] The concentration of Tl(III) was determined titrimetrically with EDTA using XO as an indicator.[11] The stock solution was stored in the dark. The monohydrate of monosodium salt of PAR was synthesized and purified by repeating recrystallization from ethanol.[2] The purity was confirmed by elemental analysis.[7]

Kinetics of the Substitution of Acetonitrile in (Acetonitrile)chlorobis(triphenylphosphine)rhodium(I) by Triphenylphosphine

Yoshimi OHTANI, Akihiko YAMAGISHI, and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 7, 1978)

Synopsis. The substitution of coordinated acetonitrile in (acetonitrile)chlorobis(triphenylphosphine)rhodium(I) by triphenylphosphine was studied in benzene by the stopped-flow method under anaerobic conditions. The reaction was found to proceed through both an associative and a dissociative path to yield chlorotris(triphenylphosphine)rhodium(I).

The catalytic activity of Wilkinson's complex, $RhClL_3$ ($L=PPh_3$), in homogeneous hydrogenations strongly depends on the nature of the solvent. The highest activities are usually observed in weakly coordinating solvents.[1] Hydrogenation is practically inhibited in a strongly coordinating solvent such as acetonitrile.[2,3] Since kinetic data on coordination of the solvent molecule to the rhodium catalyst are limited,[4,5] we have carried out a kinetic study on the coordination of an acetonitrile molecule to the Wilkinson's complex:

$$RhClL_3 + CH_3CN \underset{}{\overset{K}{\rightleftharpoons}} RhCl(NCCH_3)L_2 + L. \quad (1)$$

Since the direct measurement of the reaction between $RhClL_3$ and CH_3CN was difficult because of the small equilibrium constant K and partial dimerization of $RhClL_3$, $2RhClL_3 \rightleftharpoons (RhClL_2)_2 + 2L$, we measured the reverse reaction observed upon addition of PPh_3 to $RhCl(NCCH_3)L_2$ in benzene.

Equilibria. When a solution of PPh_3 is added to a solution of $RhCl(NCCH_3)L_2$, the absorption spectrum of the latter changes to that of $RhClL_3$. The equilibrium constant for Reaction 1 is expressed as follows:

$$K = \frac{[RhCl(NCCH_3)L_2][L]}{[RhClL_3][CH_3CN]} \simeq \frac{(A_\infty - A)[L]_{add}}{(A - A_0)[CH_3CN]}, \quad (2)$$

where A, A_0, A_∞, and $[L]_{add}$ denote the absorbance at equilibrium, the initial absorbance, the limiting absorbance at high $[PPh_3]$, and the concentration of PPh_3 added, respectively. Figure 1 shows a typical change in absorbance at 500 nm at $[CH_3CN]=1.9$ mol dm^{-3}. The solid line is reproduced by assuming $K=1.0\times10^{-3}$, $A_0=0.077$, and $A_\infty=0.330$ in Eq. 2, the result showing good agreement with experimental values.

At $[CH_3CN]=1.0$ and 3.8 mol dm^{-3}, the value of K was calculated to be 1.3×10^{-3} and 0.9×10^{-3}, respectively, giving the average equilibrium constant $K_{av}=1.1\times10^{-3}$.

Kinetics. The rate of substitution of CH_3CN in $RhCl(NCCH_3)L_2$ by PPh_3 was measured at 500 nm using a single exponential change observed upon addition of a solution of PPh_3 to a solution of $RhCl(NCCH_3)L_2$. Observed rate constants, k_{obsd}, were proportional to $[PPh_3]$ at constant $[CH_3CN]$ (Fig. 2). The dependence of k_{obsd} on $[CH_3CN]$ at constant

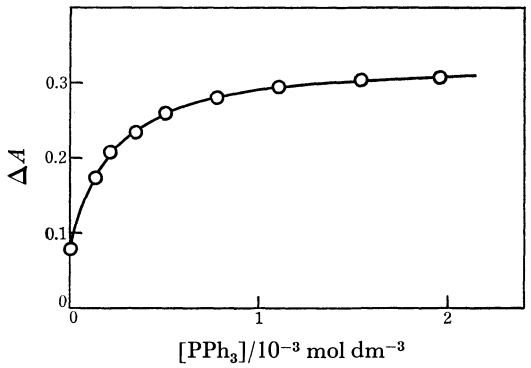

Fig. 1. Change in absorbance of the solution of $RhCl(NCCH_3)(PPh_3)_2$ by the addition of PPh_3 at 500 nm. Solid line is reproduced by assuming Eq. 2 with $K=1.0\times10^{-3}$, $A_0=0.077$, and $A=0.330$. $[RhCl(NCCH_3)(PPh_3)_2]_0=5.4\times10^{-4}$ mol dm^{-3}.

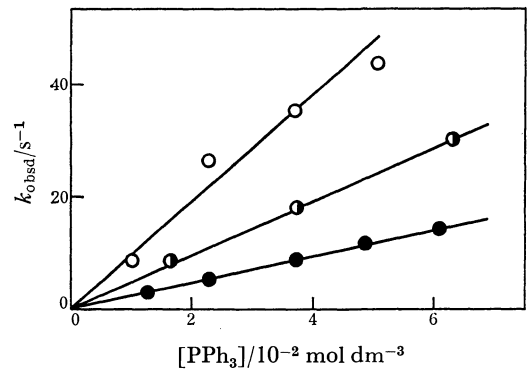

Fig. 2. The dependence of k_{obsd} on the concentration of PPh_3; $[RhCl(NCCH_3)(PPh_3)_2]_0=3.9\times10^{-4}$ mol dm^{-3} and $[CH_3CN]=0.50$ (○), 1.0 (◑), and 2.9 (●) mol dm^{-3}.

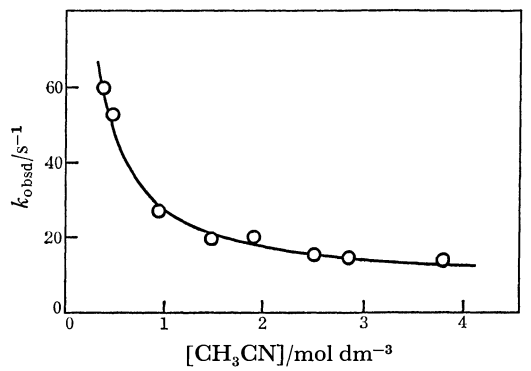

Fig. 3. The dependence of k_{obsd} on the concentration of CH_3CN. $[RhCl(NCCH_3)(PPh_3)_2]_0=4.0\times10^{-4}$ and $[PPh_3]=3.7\times10^{-2}$ mol dm^{-3}.

[PPh_3] is shown in Fig. 3. From Figs. 2 and 3 the observed rate constant is given by

$$k_{obsd} = \left\{k + k' \frac{1}{[CH_3CN]}\right\}[L]. \quad (3)$$

The following reaction mechanism is postulated for the interpretation of the above relationship:

$$\begin{array}{ccc} RhClL_3 + CH_3CN & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & RhCl(NCCH_3)L_3 \\ k_3 \downarrow\uparrow k_{-3} & & k_4 \downarrow\uparrow k_{-4} \\ RhClL_2 + CH_3CN & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & RhCl(NCCH_3)L_2. \\ +L & & +L \end{array} \quad (4)$$

By applying the steady-state approximation to the intermediate species, $RhClL_2$ and $RhCl(NCCH_3)L_3$, we obtain

$$k_{obsd} = \frac{k_1k_4[CH_3CN] + k_{-1}k_{-4}[L]}{k_{-1} + k_4} + \frac{k_2k_3[CH_3CN] + k_{-2}k_{-3}[L]}{k_2[CH_3CN] + k_{-3}[L]}. \quad (5)$$

The rate terms for the reaction between $RhClL_3$ and CH_3CN, $k_1k_4[CH_3CN]$ and $k_2k_3[CH_3CN]$, can be neglected, since Equilibrium 1 lies far to the left-hand side under the reaction conditions. If $k_{-3}[L]$ is small as compared with $k_2[CH_3CN]$, *viz.*, the step $RhCl(NCCH_3)L_2 \rightleftharpoons RhClL_2 + CH_3CN$ is pre-equilibrated, Eq. 5 is modified as

$$k_{obsd} = \left\{\frac{k_{-1}k_{-4}}{k_{-1} + k_4} + \frac{k_{-3}}{K_2} \cdot \frac{1}{[CH_3CN]}\right\}[L]. \quad (6)$$

The equation was found to fit the kinetic data for the values, $k_{-1}k_{-4}/(k_{-1}+k_4) = 2.4 \times 10^2$ mol^{-1} dm^3 s^{-1} and $k_{-3}/k_2 = 3.5 \times 10^2$ s^{-1}. The value of k_3 is calculated to be 0.39 s^{-1} from the overall equilibrium constant $K = K_2k_3/k_{-3} = 1.1 \times 10^{-3}$. The value of k_3 agrees with the value 0.4 s^{-1} obtained from the experiment on the substitution of a coordinated PPh_3 in $RhClL_3$ by C_2H_4,[6] even when an experimental error (about 20%) is taken into consideration. The results indicate that both the associative and dissociative paths exist.

Schrock and Osborn suggested that an acetonitrile should compete with an olefin for coordination site on the central metal.[5] Thus, it is expected that an olefin cannot coordinate to $RhCl(NCCH_3)L_2$ without prior dissociation of CH_3CN (Eq. 7) as observed in the case of $RhClL_3$ (Eq. 8).[6] Actually, ethylene cannot coordinate to $RhCl(NCCH_3)L_2$ without dissociation of CH_3CN.[7]

$$RhCl(NCCH_3)L_2 + Ol \overset{K'}{\rightleftharpoons} RhCl(ol)L_2 + CH_3CN \quad (7)$$

$$RhClL_3 + Ol \overset{K''}{\rightleftharpoons} RhCl(ol)L_2 + L, \quad (8)$$

where Ol denotes olefin. In the case of cyclohexene, K'' is too small to be determined by the spectrophotometric method; styrene has an even smaller K'' (2.4×10^{-4})[8] than K for acetonitrile. Thus, Reaction 7 in the solution containing a considerable amount of acetonitrile lies far to the left-hand side under the conditions of hydrogenation. The coordination of CH_3CN suppresses the formation of olefin complexes, $RhCl(ol)L_2$ and $RhClH_2(ol)L_2$, the rate of hydrogenation of the olefins being lowered in acetonitrile.

Experimental

$RhCl(C_2H_4)(PPh_3)_2$ was prepared according to Osborn *et al.*[2] A solution of $RhCl(NCCH_3)(PPh_3)_2$ was prepared by dissolving $RhCl(C_2H_4)(PPh_3)_2$ in benzene containing an appropriate amount of CH_3CN, the coordinated C_2H_4 being easily replaced by CH_3CN.[9] Benzene and acetonitrile were distilled. Distilled acetonitrile contained 0.06 mol dm^{-3} of water, which affected neither the spectrum nor the reaction rate. All the measurements were carried out at 20±0.2 °C in oxygen-free benzene. Equilibrium measurements were carried out *in vacuo* with a Hitachi EPS-3T spectrophotometer. The rate of substitution of the coordinated CH_3CN in $RhCl(NCCH_3)(PPh_3)_2$ by PPh_3 was measured with a Union Giken RA-1300 stopped-flow apparatus under nitrogen atmosphere.

Studies on Unusual Amino Acids and Their Peptides. X. The Convenient Synthesis of *t*-Leucine and the Optical Resolution of the *N*-Benzyloxycarbonyl Derivative[1)]

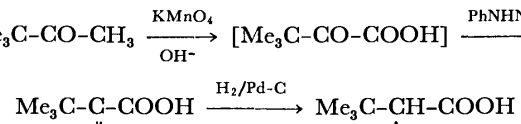
Toshifumi MIYAZAWA, Katsumi TAKASHIMA, Yoshikazu MITSUDA,** Takashi YAMADA, Shigeru KUWATA, and Hiroshi WATANABE*

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kobe 658

(Received March 28, 1978)

Synopsis. *t*-Leucine has been conveniently prepared on a large scale from the phenylhydrazone of trimethylpyruvic acid, which was readily obtained as a precipitate from the oxidation of pinacolone. The *N*-benzyloxycarbonyl derivative of DL-*t*-leucine has been resolved with quinine and quinidine in ethanol.

In the course of investigation,[2)] it has been necessary to prepare optically active *t*-leucine on a large scale. For this purpose the route shown in Scheme was chosen.



Scheme.

Pinacolone has been oxidized with aqueous alkaline permanganate to trimethylpyruvic acid.[3)] This keto acid has been converted, without isolation, into the insoluble phenylhydrazone (I) and separated by filtration. Hydrogenation of I in the presence of palladium on carbon gave *t*-leucine (II) in good yield.

N-Z-DL-*t*-Leucine (III) has been resolved with quinine and quinidine in ethanol, and the optical purities of the resolved isomers confirmed by gas chromatographic analysis[4)] after conversion to the *N*-pivaloyl-*t*-leucyl-L-valine methyl ester.

Experimental

All melting points are uncorrected. Optical rotations have been measured by Yanagimoto OR-10 and JASCO DIP-4 polarimeters.

Phenylhydrazone of Trimethylpyruvic Acid (I). Pinacolone (50 g) was oxidized with alkaline potassium permanganate (160 g) by Knoop's method.[3)] To the filtrate of the reaction mixture (*ca.* 5.5 l), after neutralization with HCl, was added phenylhydrazine (65 g) dissolved in acetic acid (250 ml) and the mixture allowed to stand at room temperature overnight. The resulting precipitates were separated by filtration, dried, and recrystallized from 70% ethanol, affording pale yellow needles (84 g, 76%) of mp 157—158 °C (lit,[5)] mp 157—158 °C).

Hydrogenation of the Phenylhydrazone (I). The phenylhydrazone (I) (100 g) was dissolved in a mixture of ethanol and water (510 ml EtOH+75 ml H_2O), and hydrogenated with 5% Pd–C (20 g) at 70 °C under an initial pressure of 50—140 kg/cm². The resulting solution was removed from the catalyst and evaporated to dryness under reduced pressure. The residue was dried sufficiently and washed repeatedly with dry benzene. The crude DL-*t*-leucine (II) (53.7 g; mp 248—251 °C (sublime)) was recrystallized from aqueous acetone; yield, 41.6 g (70%); mp 250—251 °C (sublime) (lit,[6,7)] mp 250 °C (sublime)).

Optical Resolution of N-*Z*-DL-t-*Leucine(III).* Thirty-eight mmol of III[8)] and quinine (or quinidine) were dissolved in hot ethanol (90 ml), and the precipitated white crystals recrystallized from ethanol four times. The purified salt was suspended in ethyl acetate, and shaken with 2 M HCl to remove the base, and subjected to the usual work-up. The optically active *t*-leucine was obtained by hydrogenation of the corresponding *N*-Z-derivative.

N-Z-D-*t*-Leucine quinine salt: mp 166—167 °C, $[\alpha]_D^{20}$ −106.5° (*c* 1.0, MeOH). Found: C, 69.46; H, 7.47; N, 7.12%. Calcd for $C_{34}H_{43}N_3O_6$: C, 69.24; H, 7.35; N, 7.13%.

N-Z-D-*t*-Leucine: syrup, $[\alpha]_D^{20}$ +5.9° (*c* 1.0, MeOH).

N-Z-D-*t*-Leucine dicyclohexylamine (DCHA) salt: mp 165.5—166 °C (from EtOH–Et_2O), $[\alpha]_D^{20}$ +8.5° (*c* 1.0, MeOH). Found: C, 69.90; H, 9.56; N, 6.04%. Calcd for $C_{26}H_{42}N_2O_4$: C, 69.92; H, 9.48; N, 6.27%.

D-*t*-Leucine: mp 250—252 °C (sublime), $[\alpha]_D^{21}$ +10.5° (*c* 1.0, H_2O), $[\alpha]_D^{20}$ −29.1° (*c* 1.0, AcOH) (lit,[9)] $[\alpha]_D^{20}$ +10.01° (*c* 5.19, H_2O) (*cf.* Refs. 3 and 10)). Found: C, 54.74; H, 9.87; N, 10.35%.

N-Z-L-*t*-Leucine quinidine salt: mp 134—136 °C (*ca.* 98 °C sinter), $[\alpha]_D^{20}$ +127.7° (*c* 1.0, MeOH).

N-Z-L-*t*-Leucine: syrup, $[\alpha]_D^{20}$ −6.0° (*c* 1.0, MeOH).

N-Z-L-*t*-Leucine DCHA salt: mp 166—166.5 °C (from EtOH–Et_2O), $[\alpha]_D^{20}$ −8.7° (*c* 1.0, MeOH) (lit,[11)] mp 165—168 °C, $[\alpha]_D$ −8.4° (*c* 0.59, MeOH)). Found: C, 69.79; H, 9.35; N, 5.98%.

L-*t*-Leucine: mp 250—252 °C (sublime), $[\alpha]_D^{21}$ −10.9° (*c* 1.0, H_2O), $[\alpha]_D^{26}$ +30.0° (*c* 1.0, AcOH) (lit, mp 250 °C (sublime),[12)] $[\alpha]_D^{28.5}$ −10.15° (*c* 4.63, H_2O)[9)] (*cf.* Refs. 3, 10, and 13), $[\alpha]_D^{25}$ +36.0° (*c* 2, AcOH)[3)]). Found: C, 54.77; H, 9.91; N, 10.35%.

Synopsis. *N*-Imidoyliminotriphenylphosphoranes **2** have been prepared by the reaction of triphenylphosphine with *N*-chloroamidines followed by treatment with base. **2** can react readily with hydrochloric acid or methyl iodide to give the corresponding salts. Treatment of **2** with carbon disulfide gave *N*-(thioacyl)iminotriphenylphosphoranes together with isothiocyanates.

In a previous paper[1] the reaction of imidoyltriphenylphosphonium methylides **1** with carbon disulfide was reported. The products were a result of the attack on either the ylide carbon atom or the imidoyl nitrogen atom.

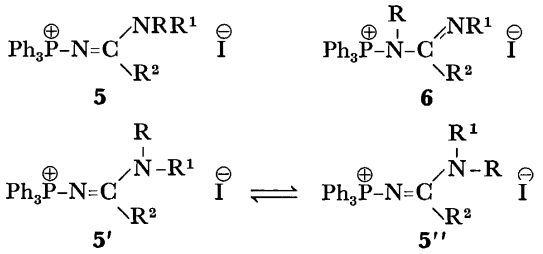
Iminophosphoranes show similar chemical properties to those of phosphonium methylides.[2] In this paper the reaction of *N*-imidoyliminotriphenylphosphoranes **2** with carbon disulfide and halides will be reported.

Iminophosphoranes **2** have been prepared by the reaction of *N*-(1-chloro-2,2-diphenylvinyl)iminophosphorane, prepared from chlorodiphenylacetonitrile and triphenylphosphine, with aromatic amines[3] or the reaction of *N*-chlorobenzamidines with triphenylphosphine followed by treatment with base.[4] In the reports however, no information of the nature of the compounds **2** was reported. Based on the second route, several iminophosphoranes **2** have been synthesized to give moderate yields, the results of which are given in Table 1. The hydrochloric acid salts of **2** (R^1=aryl, R^2=$CHPh_2$), prepared by the reaction of **2** with hydrochloric acid, have been found to be **3**(R^1=aryl, R^2=$CHPh_2$)[3] [protonation on imidoyl nitrogen] not **4** [protonation on the nitrogen atom of iminophosphorane].

The structure of **3** has been elucidated by NMR analysis of the N–C=NH proton,[3] which shows a down field shift due to the electron withdrawing group R^1.[3] The NH protons in **3** (R^1=*p*-$Me_2NC_6H_4$, R^2=$CHPh_2$) and **3** (R^1=*p*-$NO_2C_6H_4$, R^2=$CHPh_2$) appear at δ 11.4 and 12.8 in $CDCl_3$, respectively.

Elucidation of the structure of the hydrochloric acid salts of **2a—i** posed difficulties. The salt of **2h**, however, was confirmed as **3h** and not **4h** on the basis of the NMR studies. The NMe protons of **2h** appear at δ 3.23 as a doublet due to coupling with phosphorous ($^5J_{PNCNCH}$=2 Hz). The NMe protons of the hydrochloride of **2h** in $CDCl_3$ appear at δ 3.36 as a doublet (J=5 Hz). The addition of D_2O to the solution disappeared the splitting indicating that the splitting is due to HNCH interaction not PNCNCH.

The reaction of **2** with methyl iodide was conducted at room temperature to give **5** (R=Me). The structures of the products were elucidated on the basis of the NMR results (Table 3). The NMe protons of



5 show no coupling with phosphorus, indicating that methylation of the nitrogen atom in the imidoyl group occurs, since $^3J_{PNCH}$=10—12 Hz[5] has been reported for compounds of the type $Ph_3\overset{\oplus}{P}NCH_3$.

The NMR spectra of **5** derived from **2h** with ethyl iodide and **2i** with methyl iodide showed two groups of peaks of the same intensity (Table 3), indicating the presence of two isomers **5′** and **5″**,[6] especially in the case of sterically hindered compounds **5e, f, h, i**.

The reaction of *N*-alkyl or aryl iminotriphenylphosphoranes with carbon disulfide has been shown to give phosphine sulfide and isothiocyanates.[2] In contrast, it was found here that iminophosphorane **2**

a) A mixture of two crystalline compounds.

readily reacted with carbon disulfide to give *N*-(thioacyl)iminophosphorane **6** and isothiocyanate:

$$Ph_3P{=}NC(=NR^1)R^2 \; (\mathbf{2}) + CS_2 \longrightarrow Ph_3P{=}NC(=S)R^2 \; (\mathbf{6}) + R^1NCS$$

Iminophosphoranes **6** have been considered as intermediates in the reaction of thiobenzoyl azide (phenyl thiatriazole) with triphenylphosphine,[7] giving benzonitrile and phosphine sulfide. In the thermolysis of the phosphonium salts **7** (R=Me, *t*-Bu), the isolation of **6** have not been successful.[3,7] The structure of **6** has been confirmed on the basis of NMR, IR, and MS.[8]

$$Ph_3\overset{\oplus}{P}{-}N{=}C(CHPh_2)SR \; \overset{\ominus}{Cl} \quad \mathbf{7}$$

Experimental

Preparation of **2**. As a typical experiment the preparation of **2a** will be given. *N*-Phenyl-*N'*-chlorobenzamidine was prepared according to the literature[9] and used without purification. To a stirred solution of *N*-phenyl-*N'*-chlorobenzamidine(0.01 mol) in dry benzene(30 ml) was added a solution of triphenylphosphine(0.01 mol) in dry ether(20 ml), the temperature being kept below 10 °C. After 2 h the oily precipitate was separated and dissolved in EtOH (20 ml). To the solution was added in one step a solution of KOH (0.03 mol) in EtOH(10 ml) and the solution stirred vigorously. After 3 min the mixture was quenched with water (60 ml) and extracted with $CHCl_3$(50 ml). The extract was dried over Na_2CO_3 and concentrated *in vacuo* to give a crystalline material. Crystallization from $CHCl_3$–petroleum ether gave **2a** in 37% yield, the results of which are shown in Table 1.

Preparation of the Hydrochloric Acid Salts of **2**. To a solution of **2a**(5 mmol) in $CHCl_3$(20 ml) was added concd HCl(1 ml) in one portion. The mixture was stirred and the organic layer separated. Concentration of the solution *in vacuo* gave white crystalline substance **3a** quantitatively (Table 2).

Alkylation of **2** *with Alkyl Iodide*. To a solution of **2a** (5 mmol) in $CHCl_3$(20 ml) was added MeI(0.5 ml) in one portion. The mixture was left at room temperature for 24 h. Concentration of the solution *in vacuo* gave a white resin **5a**(R=Me)quantitatively.

The Reaction of **2** *with Carbon Disulfide*. A solution of **2a** (10 mmol) and CS_2(100 mmol) in $CHCl_3$(30 ml) was left to stand for 3 days at room temperature. The mixture was dried *in vacuo* and extracted with petroleum ether. On crystallization from AcOEt the extracts gave **6a** in 96% yield. The mother liqour was found to be *p*-tolyl isothiocyanate by comparison of the IR spectrum with that of authentic sample. The yield was determined by VPC (Silicone Grease 20% on celite) using mesitylene as an internal standard.

The Formation of 3,4,5-Tris(substituted phenyl)-4,5-dihydro-1,2-oxazole *N*-Oxides in the Oxidations of (Substituted phenyl)nitromethanide Anions with Silver Nitrate or Peroxodisulfate

Kimitoshi FUKUNAGA,* Kenji HAMANAKA, and Makoto KIMURA

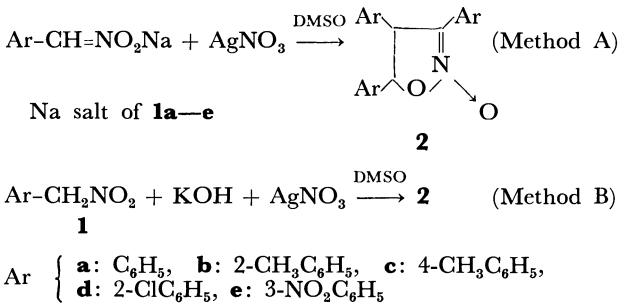
(Received May 11, 1978)

Synopsis. The reaction of an alkali metal salt of (substituted phenyl)nitromethane (**1**) with silver nitrate or peroxodisulfates in dimethyl sulfoxide (DMSO) gives 3,4,5-tris(substituted phenyl)-4,5-dihydro-1,2-oxazole *N*-oxides (**2**) in a good yield.

The oxidations of an alkali metal salt of primary nitroalkane with peroxodisulfates[1-3] or silver ions[1,3,4] have been known to be a general method for the formation of vicinal dinitro compounds. Particularly, the oxidation of the alkali metal salt of α-arylnitroalkane with silver nitrate in aqueous dimethyl sulfoxide (DMSO) or acetonitrile has been recognized as one of the most convenient methods for the formation of vicinal dinitro compounds.[4] Little information is, however, available about the formation of 4,5-dihydro-1,2-oxazole *N*-oxides in the oxidation of an alkali metal salt of nitroalkane under similar reaction conditions to those described above. Shechter and Kaplan[1] have reported that the reaction of nitroethane with peroxodisulfate in alkaline medium gives 3,4,5-trimethyl-1,2-oxazole in a 25% yield. Nenitzescu[5] has reported that anodic oxidation of an aqueous solution of sodium salt of phenylnitromethane (**1a**) gives 3,4,5-triphenyl-1,2-oxazole (**4a**). The mechanism of these reactions has not been discussed but it should involve the intermediate 4,5-dihydro-1,2-oxazole *N*-oxide ring formation. Recent studies by Pagano and Shechter have shown that the sodium salt of **1a** reacts with ammonium peroxodisulfate in aqueous sodium hydroxide to give 3,4,5-triphenyl-4,5-dihydro-1,2-oxazole *N*-oxide (**2a**) in a 1.3% isolated yield together with other products.[3] We describe here the reactions of alkali metal salts of (substituted phenyl)nitromethanes (**1a**—**e**) with peroxodisulfates or silver nitrate[6] in DMSO to give 3,4,5-tris(substituted phenyl)-4,5-dihydro-1,2-oxazole *N*-oxides (**2a**—**e**) without concomitant formation of the corresponding vicinal dinitro compounds (**3a**—**e**).

Alkali metal salts of **1a**—**e** were allowed to react with an equimolar amount of silver nitrate in DMSO according to methods A and B, and the corresponding **2a**—**e** were obtained in good yields, as shown in Scheme 1. The structures of **2a**—**e** were confirmed by the analytical and spectral data reported in Ref. 6.



Scheme 1.

The reaction of the sodium salt of **1a** with silver nitrate in *N*,*N*-dimethylformamide (DMF) or acetonitrile, however, gave yellow (*E*)-α-nitrostilbene (**5a**) as the main product. When a mixture of the sodium salt of **1a** and peroxodisulfate was stirred in DMSO at room temperature for 1 h, only **2a** was obtained. The reaction also took place in other solvents such as DMF and acetonitrile, but it was slower and the yield of **2a** was lower than that in DMSO. Typical results are summarized in Tables 1 and 2. The reason for the ineffectiveness of silver nitrate or peroxodisulfate

a) All the reactions were carried out using 3.98 g (25 mmol) of sodium salt of **1a** and 1.05 g (12.5 mmol) of sodium hydrogencarbonate at room temperature. The amounts of peroxodisulfates and solvents are given in parentheses. b) Yields were based upon **1a**, and referred to isolated ones.

in DMF or acetonitrile seems to be the low solubility of the sodium salt of **1a** in these cases. Two possible mechanisms for this reaction may be considered. The first mechanism is an ionic pathway postulated originally by Pagano and Shechter[3] for the reaction of the sodium salt of **1a** with ammonium peroxodisulfate. The second possible mechanism involves both $S_{RN}1$ and $E_{RC}1$ reactions, as shown in Scheme 2. This Scheme is based on the observation that the reaction of α-bromophenylnitromethane with the sodium salt of **1a** in DMSO gives also **2a**.[6,8] The exclusive formation of **2** can be well explained by S_{RN} and E_{RC} processes, but there is no experimental evidence for excluding an ionic pathway.

Scheme 2.

The only alternative route to **2a** is the reaction of **5a** with **1a**,[7] but the present reaction seems to provide a more convenient one-step method for preparation of **2**, because readily available **1** is the only starting material.

Experimental

Materials. Silver nitrate, potassium peroxodisulfate, ammonium peroxodisulfate, and sodium hydrogencarbonate were commercial reagent-grade. Commercial DMSO, DMF, and acetonitrile were distilled prior to use. (Substituted phenyl)nitromethanes (**1a—d**) were prepared from the corresponding arylacetonitriles[9] according to the method of Black and Bakers.[10] 3-Nitrophenylnitromethane (**1e**) was prepared by nitration of **1a** with fuming nitric acid.[11] The sodium salts of **1a—e** were prepared by addition of methanol solution of **1a—e** to an equivalent amount of sodium methoxide in methanol.

General Procedure for Reaction of 1 with Silver Nitrate. General Procedure by Method A. A sodium salt of **1** (0.05 mol) was added in portions to a stirred solution of silver nitrate (0.06 mol) in DMSO (150 ml) at room temperature. The mixture was stirred at the same temperature for 2 h, and then the silver deposited was removed by filtration, and washed with small amounts of DMSO. The filtrate and washings were poured into cold water to give a pale yellow precipitate, which was collected by filtration, washed with water, and dried. Crystallization from acetic acid or ethanol gave **2** as colorless needles.

General Procedure by Method B. A mixture of **1** (0.05 mol), water (20 ml), and potassium hydroxide (0.05 mol) was added rapidly to a solution of silver nitrate (0.06 mol) in DMSO (150 ml) with stirring. The mixture was stirred at room temperature for 2 h and work-up was carried out as described under Method A.

General Procedure for Reaction of the Sodium Salt of 1a with Peroxodisulfates. To a stirred mixture of potassium peroxodisulfate (0.015 mol) and sodium hydrogencarbonate (0.0125 mol) in DMSO (30 ml), the sodium salt of **1a** (0.025 mol) was added in portions and the mixture was stirred at room temperature for 12 h. The solution was then poured into cold water to give slightly yellow precipitates, which were collected, washed with water, and dried. Crystallization from acetic acid gave **2a**.

The Glow-discharge Reactions of Amines

Hideki ASADA, Masakatsu NOMURA, and Shōichi KIKKAWA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita 565

(Received July 10, 1978)

Synopsis. The glow-discharge reactions of propylamine, dipropylamine, and *N*,*N*-dimethyl-2-methyl-1-propenylamine were studied. The results show that the primary amines yield RN=CHR′ and $RNHCH_2CN$, and that the secondary amines produce R(R′)NCH(R″)CN. *N*,*N*-Dimethyl-2-methyl-1-propenylamine produces a series of imine and nitrile.

We have already reported that the glow-discharge reactions of butylamine, pyrrolidine, and pyrrole[1] gave characteristic products. In this note, propylamine, dipropylamine, and *N*,*N*-dimethyl-2-methyl-1-propenylamine, whose double bond may be supposed to stabilize the active species produced by a C–N fission, were chosen as the starting materials in order to clarify the glow-discharge reactions of amine derivatives. Their glow-discharge reactions were discussed principally on the basis of detailed product analyses.

Propylamine gave such products as could be deduced from the reaction of butylamine, while dipropylamine gave the same kind of products that could be deduced from the products of pyrrolidine, considered as a typical secondary amine, so it has become apparent that primary and secondary amines gave characteristic products in the discharge field.

N,*N*-Dimethyl-2-methyl-1-propenylamine was prepared by the dehydration of dimethylamine with isobutylaldehyde. From the product analyses, the double bond of enamine may be supposed to stabilize the N-radical produced by the cleavage of the weakest C–N bond in the discharge field, accordingly, several characteristic products were produced. These results will be reported in this note.

Experimental

The propylamine and dipropylamine were obtained from Wako Pure Chemical Industries, Ltd., and were used without further purification. *N*,*N*-Dimethyl-2-methyl-1-propenylamine, which was composed of a fraction with a bp of 87—88 °C/760 mmHg, was prepared according to the ordinary method.[2] The apparatus was a fast-flow system which has been previously described,[3] it was operated in a similar way. The rate of the reactants was adjusted by being controlled the heating of their reservoir. The reaction products were collected in the liquid nitrogen trap.

The principal liquid products were isolated from an appropriate fraction using preparative gas chromatography (Shimadzu GC-2C, Silicone DC 550, 4.5 m, H_2), and were identified by the analyses of their NMR spectra, IR spectra, and mass spectra obtained using GC-MS, and by comparing their retention times with those of the authentic samples in the gas chromatogram. The quantitative analyses of the liquid products were undertaken by comparing the area of the chromatogram using a Shimadzu GC-4BPTF apparatus (4.4 m×3 mm column packed with 10% and 20% SE-30 on Chromosorb W and Uniport B respectively; oven temp: 30—270 °C; program rate: 10 °C/min; H_2 was used as the carrier gas).

Results and Discussion

N-Propylidenepropylamine, *N*-ethylidenepropylamine, and (propylamino)acetonitrile were produced by the glow-discharge reaction of propylamine. *N*-Propylidenepropylamine and *N*-ethylidenepropylamine are assumed to be formed by the attack of the propyl and ethyl radicals upon the N-atom of propylamine, followed by dehydrogenation. (Propylamino)acetonitrile is supposed to be produced by the reaction of $\dot{C}H_2CN$ with propylamine. It is obvious that these compounds correspond to the reaction products of butylamine.

The results of both reactions under similar conditions are cited in Table 1 in an attempt to deduce a general rule with regard to the behavior of primary aliphatic amines under the influence of the glow discharge. The glow-discharge reactions of $CH_3(CH_3)CHCH_2NH_2$ and $CH_3CH_2(CH_3)CHNH_2$ also gave the products deduced from the above results.

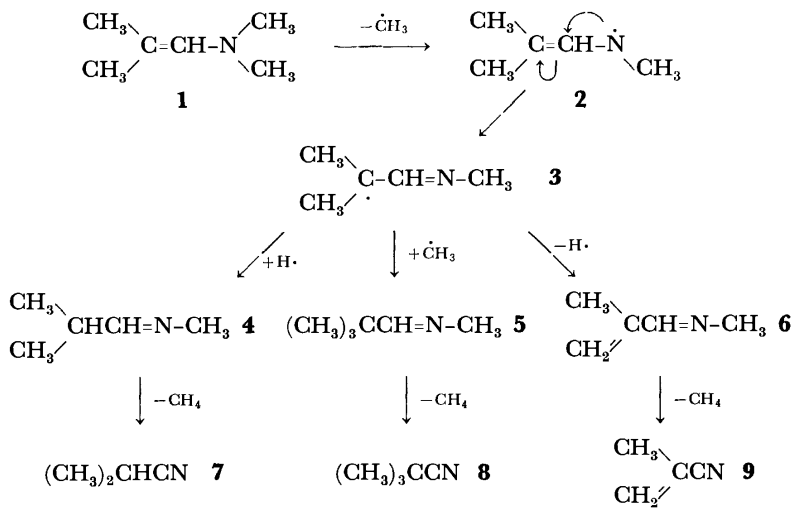
Table 1. General products of primary amines

	(%)[a]		(%)[a]
n-$PrNH_2$	25.9	*n*-$BuNH_2$	38.8
n-PrN=CHR	(35.1)	*n*-BuN=CHR	(22.3)
R=CH_3	30.5	R=CH_3	21.0
R=CH_2CH_3	4.6	R=CH_2CH_3	tr
		R=$CH_2CH_2CH_3$	1.3
n-$PrNHCH_2CN$	34.3	*n*-$BuNHCH_2CN$	27.7

a) Ratio in the liquid products.

Concerning the cleavage of the secondary amines obtained in the mass spectra, β-fission is very important; also, in the discharge field, the $CH_3CH_2CH_2NH\dot{C}H_2$ formed according to the β-fission of dipropylamine is considered to rearrange to $CH_3CH_2\dot{C}HCN$ accompanying dehydrogenation. The α-fission of dipropylamine formed $CH_3\dot{C}HCN$, and the double β-fission of dipropylamine yielded $\dot{C}H_2CN$. The reactions of these radicals with dipropylamine were supposed to lead to 2-aminonitriles. As the process caused by β-fission is supposed to be a main one, it seems probable that the amount of 2-(dipropylamino)propionitrile is less than that of 2-(dipropylamino)butyronitrile.

The discharge reaction of pyrrolidine also gave a series of 2-(1-pyrrolidinyl)nitrile as the main products; therefore, the formation of such products seems to be a general feature in the glow-discharge reactions of secondary aliphatic amines (see Table 2).



Scheme 1.

Table 2. General products of secondary amines

	(%) [a]		(%) [a]
$(n\text{-Pr})_2NH$	25.4	NH	19.9
$(n\text{-Pr})_2NCH(R)CN$	(40.8)	NCH(R)CN	(47.8)
R=H	17.7	R=H	20.4
$R=CH_3$	4.7	$R=CH_3$	16.0
$R=CH_2CH_3$	18.4	$R=CH_2CH_3$	11.4

a) Ratio in the liquid products.

Thus, the glow-discharge reactions of primary amines gave RN=CHR′ and $RNHCH_2CN$, while that of secondary amines gave R(R′)NCH(R″)CN.

Table 3 shows the results of the glow-discharge reaction of *N,N*-dimethyl-2-methyl-1-propenylamine. This table indicates the formation of many kinds of nitrile and imine under the present experimental conditions. The process leading to these products could be reasonably deduced in the following way (see Scheme 1). According to the evaluation of the bond energy of *N,N*-dimethyl-2-methyl-1-propenylamine on the basis of the data of Egger and Cocks,[4] the (a) bond in $C=C-N^{(a)}-C$ is believed to be the weakest in the molecule. The largest fragment in the mass spectrum of *N,N*-dimethyl-2-methyl-1-propenylamine is also M—Me. The N-radical produced by a cleavage of the N–Me bond in the discharge field attacked the neighboring sp^2-carbon, forming an imine, and produced a relatively stable tertiary radical at the β-position. Supposing the existence of this radical in the middle of the way, we can explain the formation of **4**, **5**, and **6**. The doubly-occurring cleavage of the N–Me bonds in the starting enamine, followed by the elimination of hydrogen, leads to **7**, **8**, and **9**. The formation of other identified products, such as propionitrile, acrylonitrile, and hydrogen cyanide, are attributed to the further decomposition of **7**, **8**, and **9**.

Another feature of the discharge reaction of *N,N*-dimethyl-2-methyl-1-propenylamine is the formation of *N,N*-dimethyl-1-cyano-2-methyl-1-propylamine, produced by HCN addition to the enamine, which occurred during the warming up of the reaction mixture in the trap to room temperature.

Table 3. Experimental conditions and yields of the liquid products for the glow-discharge reaction of *N,N*-dimethyl-2-methyl-1-propenylamine

Reaction condition	Run No. 1	2	3
Anodic current of discharge (mA)	50	65	80

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (5), 1547—1548 (1979)

The Crystal and Molecular Structure of an Isomer of Dibromoperylenes[1)]

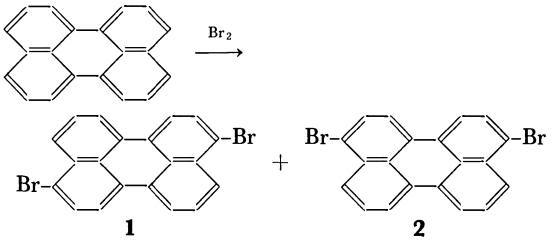
Tokiko UCHIDA,* Kozo KOZAWA, Yukinori NAGAO, and Takahisa MISONOO

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda, Chiba 278

(Received August 10, 1978)

Synopsis. Of two isomers of dibromoperylene, the one possessing the higher melting point has been determined to be 3,9-dibromoperylene from the X-ray diffractometer data. The crystals are monoclinic, with a space group of $P2_1/a$, $a=15.238$, $b=11.826$, $c=3.928$ Å, $\beta=95.53°$, $D_m=1.90$, $D_x=1.94$ g cm^{-3}, and $Z=2$. The structure was solved by the heavy-atom method. The final R value was 0.090 for 931 reflections.

As early as 1925, Zinke *et al.*[2)] obtained two kinds of dibromoperylene, **1** and **2**, by adding bromine to perylene. They presumed the one with the lower melting point, **2**, to be 3,10-dibromoperylene, since it was oxidized in sulfuric acid to produce 3,10-perylenequinone. However, the other dibromoperylene, **1**, has remained ambiguous as to the positions of its substituted bromine atoms. From the view point of our systematically synthetic study of perylene derivatives, the above-mentioned ambiguity is not permissible. Therefore, we have now determined the crystal and molecular structure of **1** from the three-dimensional X-ray data.



Experimental

Materials. Perylene (2.5 g) was dissolved in benzene (375 ml) at 80 °C; the solution was then cooled and the temperature kept at 35 °C with stirring. After adding bromine (7.5 g) to it in a drop-by-drop manner for about 10 min, the mixture was cooled and 3.9 g of solid products were separated. Then, the reaction products were fractionated into two parts, **1** and **2**, with aniline–nitrobenzene (1/1 v/v), the fractionation being done on the basis of the difference in their solubility.

The **1** portion was purified by repeated recrystallizations from aniline–nitrobenzene (1/1 v/v). Yield, 0.51 g; mp 289—293 °C. Found: C, 58.96; H, 2.28%. Calcd for $C_{20}H_{10}Br_2$: C, 58.57; H, 2.46%. **2** was obtained similarly by recrystallization from aniline–toluene (5/3 v/v). Yield, 0.71 g; mp 218—223 °C.[3)] Found: C, 58.16; H, 2.34%. Calcd for $C_{20}H_{10}Br_2$: C, 58.57; H, 2.46%.[4)]

Procedures. A c-elongated needle crystal of **1**, $0.05\times0.1\times0.5$ mm, was grown in a benzene solution. The reflection intensities and cell parameters were determined with a Rigaku four-circle diffractometer at the University of Tokyo with LiF-monochromatized Mo $K\alpha$ radiation ($\lambda=0.7107$ Å). The data were collected by the 2θ-ω scan method up to $2\theta\leqq55°$. Lorentz and polarization corrections were applied, but no absorption correction was made. The profiles of the reflection peaks showed that the crystal was rather poor in quality. Of the 1845 independent measured reflections, 931 (with $|F_o|>3\sigma(F)$) were used in the analysis.

Crystal Data. $C_{20}H_{10}Br_2$, $M_r=410.11$, monoclinic, space group $P2_1/a$, $a=15.238(3)$, $b=11.826(3)$, $c=3.928(3)$ Å, $\beta=95.53(2)°$, $U=704.5$ Å^3, $D_m=1.90$ (flotation), $D_x=1.94$ g cm^{-3}, $Z=2$, $\mu=59.8$ cm^{-1} (Mo $K\alpha$).

Structure Determination and Discussion

The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares procedure. The discrepancy index, R, was finally reduced to 0.090 with the anisotropic thermal parameters for non-hydrogen atoms, a constant isotropic thermal parameter (4.0 Å^2) for hydrogen atoms, and an anomalous dispersion correction for the bromine atom. The atomic scattering factors were adopted from the International Tables for X-Ray Crystallography, Vol. IV.[5)] All the computations were performed at the Computer Centre of the University of Tokyo, using the UNICS program system.[6)]

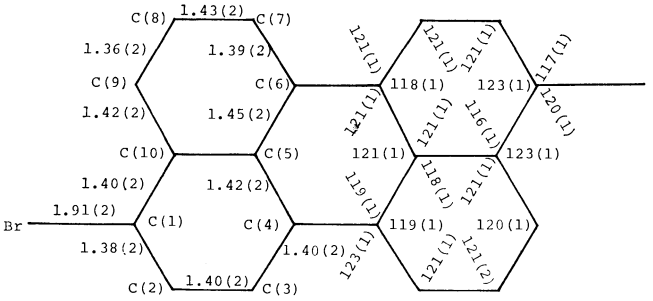


Fig. 1. Bond distances (Å) and angles(°). Estimated standard deviations are shown in parentheses.

The structure analysis indicates that the molecule has a center of symmetry and is 3,9-dibromoperylene. Table 1 gives the positional and thermal parameters,[7)] while the bond distances and angles are shown in Fig. 1. Though the relatively high value of the estimated standard deviations (esd's) prevents any precise discussion of the results, the structure of the perylene skeleton is not affected by the substituted bromine atoms.[8,9)] These large esd's might due to the poor crystallinity, as has been mentioned above.

The molecule makes the following least-squares plane:

$$0.3524X - 0.1280Y + 0.9270Z = 0$$

where X, Y, and Z are coordinates (in Å) referred to the a, b, and c* crystal axes respectively. The largest atomic deviation from this plane is 0.02 Å for C(7).

The dibromoperylene molecules stack to form a

TABLE 1. THE FINAL ATOMIC PARAMETERS ($\times 10^4$), WITH THEIR ESTIMATED STANDARD DEVIATIONS
The anisotropic thermal parameters are of the form: $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$

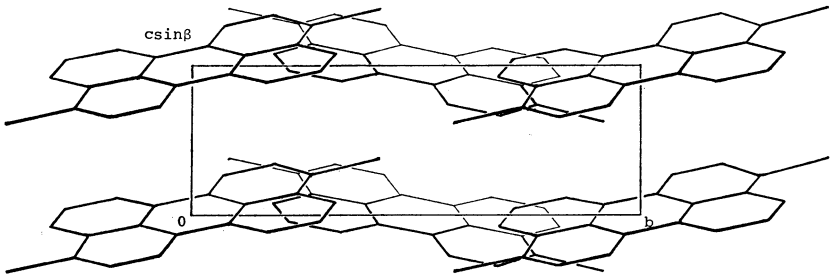

Fig. 2. The structure viewed along the a axis.

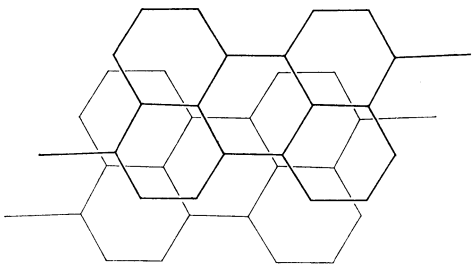

Fig. 3. Molecular overlap projected to the best plane.

column parallel to the c axis, as is shown in Fig. 2. Figure 3 gives the overlapping scheme of two adjacent molecules in a column projected on the molecular plane. The ovelapping manner of the perylene skeleton is very similar to that in the α-form crystal of perylene.[9] All the intermolecular Br···H distances exceed 3.0 Å. Since the sum of the van der Waals radii of Br and H is 3.12 Å, there might well not be any special interaction between intercolumnar atoms.

The authors wish to thank Dr. Maki Sato of the University of Tokyo for his help in the data collection.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (5), 1549—1550 (1979)

New Azulene Derivatives Obtained by the Sulfur Dehydrogenation of Guaiene: 3,6,9-Trimethylazuleno[4,5-*b*]thiophene and 2-Methylthioguaiazulene[1)]

Kazuko KOHARA,* Hojun TACHIBANA, Yukio MASUYAMA, and Yasushi OTANI
Konan Chemical Industry, Co. Ltd., 5-21, Nakagawa-cho, Takatsuki, Osaka 569

(Received October 2, 1978)

Synopsis. Two new azulene derivatives, 2-methylthioguaiazulene and 3,6,9-trimethylazuleno[4,5-*b*]thiophene, have been obtained and characterized, along with known 3,5,8-trimethylazuleno[6,5-*b*]thiophene and 2,2′-biguaiazulenyl, by the sulfur dehydrogenation of guaiene.

Guaiazulene[2)] is a well-known azulene derivative and is readily accessible as a major product of the sulfur dehydrogenation of guaiene. In our factory, guaiazulene was produced in large quantities as a precursor for sodium salt of guaiazulene-3-sulfonic acid. During the production of the guaiazulene, several products retaining an azulene skeleton were obtained as minor ingredients. This paper will deal with the isolation and structural elucidation of these minor products.

Experimental

All the melting points are uncorrected. The infrared spectra were determined with a Hitachi Model EPI-G2 spectrometer. The proton nuclear magnetic resonance spectra were recorded as a solution in chloroform-*d*, with internal tetramethylsilane, on a Varian T-60, a Varian A-60D, or a Varian XL-100-15 spectrometer. The mass spectra were measured at 70 eV. The guaiene was prepared by the dehydration of guaiol with formic acid.[3)]

The dehydrogenation of guaiene was performed with sulfur at 200—260 °C for 2—3 h. After the separation of guaiazulene by extraction with sulfuric acid, followed by distillation, the mother liquor of the recrystallization of guaiazulene from methanol was extracted again with 55% sulfuric acid. The extract was diluted with water, and the products were taken into benzene and washed with an aqueous solution of sodium carbonate. The solvent was removed by distillation, and the residue was subjected to fractional vacuum distillation. Seven fractions; i) bp 155 °C/3.5 Torr, ii) bp 155—160 °C/3.5 Torr, iii) bp 160—170 °C/3.5 Torr, iv) bp 170—185 °C/3.5 Torr, v) bp 185—190 °C/3.5 Torr, vi) bp 190—195 °C/3.5 Torr, vii) bp 195—203 °C/3.5 Torr, were thus obtained. Fractions i, ii, and iii contain mainly guaiazulene. From the latter fractions, four kinds of crystalline products were obtained through repeated column chromatography on alumina and/or silica gel as follows:

Product ***A***: Fraction iii was dissolved in hexane and they allowed to stand in a refrigerator. The crystals thus separated were recrystallized from hexane and benzene (10 : 1) to give purple crystals; mp 116—117 °C (≈1%).[4)] Found: C, 79.34; H, 6.14%. Calcd for $C_{15}H_{14}S$: C, 79.60; H, 6.23%.

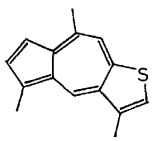
Product ***B***: After the separation of a small quantity of Product **A** from Fraction vii, the residue was extracted with 40% sulfuric acid. The usual work-up of the extract afforded blue crystals with a mp of 73—74 °C (recrystallized from hexane) in a 0.3% yield.[4)] $\lambda_{max}^{c\text{-hexane}}$ nm (log ε) 235 (4.24), 259 (4.46), 300 (sh, 4.18), 321 (4.37), 335 (4.34), 365 (3.52), 383 (3.58), 403 (3.12), 622 (2.72), 650 (sh, 2.67), 683 (2.59), 725 (sh, 2.28). Found: C, 79.54; H, 6.21%. Calcd for $C_{15}H_{14}S$: C, 79.60; H, 6.23%.

Product ***C***: Products **A** and **B** were removed from Fraction v in the usual manner, and the residue was dissolved in hexane and allowed to stand in a refrigerator. The crystals thus separated were purified by repeated column chromatography on silica gel containing 3% of water eluted with hexane. Product **C** was thus obtained as blue crystals with a mp of 58.5—59 °C in a 0.1% yield.[4)] $\lambda_{max}^{c\text{-hexane}}$ nm (log ε) 254 (4.28), 307 (4.70), 316 (4.74), 348 (3.45), 365 (3.66), 383 (3.89), 403 (4.03), 570 (2.60), 605 (2.58), 670 (sh, 2.18). Found: C, 78.63; H, 8.24; S, 12.74%. Calcd for $C_{16}H_{20}S$: C, 78.63; H, 8.25; S, 13.12%.

Product ***D***: This product was separated from Fraction vii through repeated column chromatography on alumina with hexane. Pure Product **D** was obtained as blue crystals with a mp of 176 °C (recrystallized from hexane) in a ≈0.05% yield.[4)]

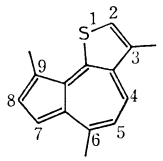
Results and Discussion

Product **A** was easily identified as 3,5,8-trimethylazuleno[6,5-*b*]thiophene (**1**) on the basis of a comparison of its melting point and ^{1}H-NMR spectrum with those of the authentic sample reported by Hayashi *et al.*[5)]

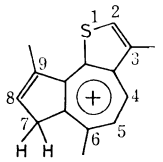


1

The structure of Product **B** was unambiguously established by an examination of its ^{1}H-NMR spectrum, which exhibited two sets of AB-quartets at δ 6.94 and 7.68 (J=11 Hz) and 7.29 and 7.57 (J=4.5 Hz), indicating the presence of vicinal hydrogens on both seven- and five-membered rings. Along with the resonance of two methyl groups at δ 2.88 (6H, s), a signal at δ 2.42 (3H, d, J=1.5 Hz) and a broad singlet at δ 7.07 (1H, bs) indicate that the condensed thiophene ring is substituted with the methyl group at the β-position.[6)] In trifluoroacetic acid, Product **B** exists as its conjugate acid (**2′**), showing three methyl groups at δ 2.92 (3H, d, J=1.0 Hz, 3-CH_3), 3.04 (3H, q, J=1.5 Hz, 9-CH_3), and 3.22 (3H, s, 6-CH_3), a two-proton multiplet at δ 4.15 (7,7′-H), a one-proton multiplet at δ 7.85 (8-H), a one-proton broad singlet at δ 8.65 (2-H), and an AB-quartet at δ 8.58 and 9.11 (J=10.5 Hz, 5-, 4-H). These NMR data are fully consistent with the formulation of Product **B** as 3,6,9-trimethylazuleno[4,5-*b*]thiophene (**2**). To the best of



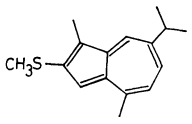
2



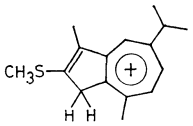
2′

our knowledge, Compound **2** is the second example of an azulene derivative in which a thiophene ring is annulated to the seven-membered ring of an azulene skeleton.

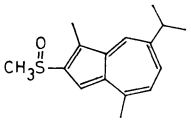
The fact that Product **C** retained a guaiazulene structure was confirmed by the absorption in the ^{1}H-NMR spectrum at δ 1.33 (6H, d, J=7 Hz, $-CH(\mathbf{CH_3})_2$), 3.07 (1H, septet, J=7 Hz, $-\mathbf{CH}(CH_3)_2$), 2.76 (3H, s, 4-CH_3), and 2.63 (3H, s, 1-CH_3). Furthermore, seven-membered ring protons appeared as a doublet at 7.97 (1H, d, J=2.0 Hz, 8-H) and AB-quartet, with further small doublet splittings in the lower-field half of the signals at 6.98 (1H, d, J=10.0 Hz, 5-H), 7.26 (1H, dd, J=10.0, 2.0 Hz, 6-H). In addition, a one-proton singlet attributable to 3-H appeared at δ 6.99. Since the methyl protons characteristic of the methylthio group were observed at δ 2.49 as a singlet,[7] it may be concluded that Product **C** is to be identified as 2-methylthioguaiazulene (**3**). Further support for the structure of **3** was obtained from the sodium periodate oxidation of **3**. The sulfoxide (**4**) was easily obtained in a pure form by chromatography on alumina eluted with benzene as a blue oil. The 4-CH_3 hydrogen resonance in the NMR spectrum of **4** appeared as a



3



3′



4

singlet at δ 2.68 which is comparable to that of **3**. As expected, 1-CH_3, S-CH_3, and 3-H resonated at δ 2.89 (6H, bs) and 7.72 (1H, s) respectively, points lower than those for the corresponding signals of **3**. The spectrum of **3** taken in trifluoroacetic acid can also be interpreted as supporting the assignment as a conjugate acid (**3′**) of **3**.

Product **D** was identified as 2,2′-biguaiazulenyl since its physical and spectral data are identical with those of the reported values for 2,2′-biguaiazulenyl.[8]

The Reaction of Methylferrocene with Manganese(III) Acetate

Taeko IZUMI, Yoshibumi SATOU, Yoshio YOSHIDA, and Akira KASAHARA*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received October 24, 1978)

Synopsis. The oxidation of methylferrocene with manganese(III) acetate in acetic acid yielded three products which arose from the ferrocenylmethylation of methylferrocene. The reaction of methylferrocene with manganese(III) acetate in presence of styrene was also examined.

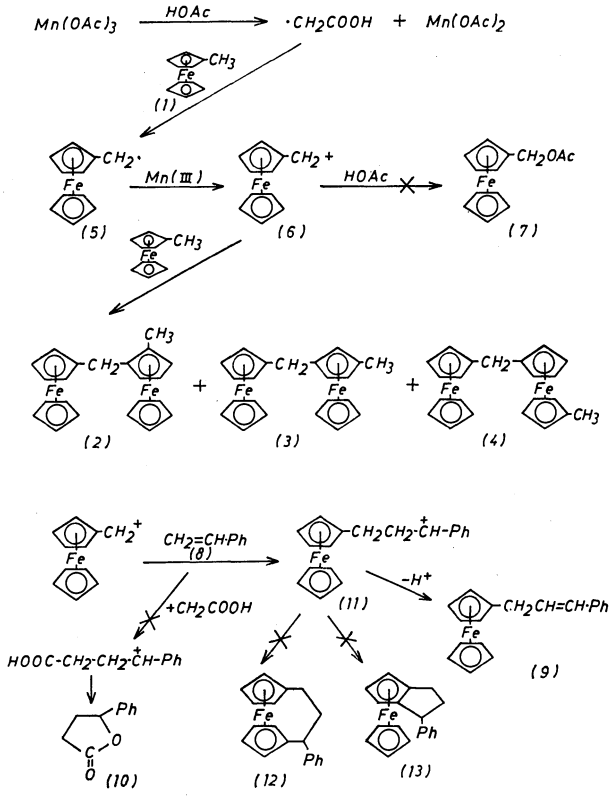
Previously, Heiba *et al.*[1] have reported the oxidation of aromatic hydrocarbons by manganese(III) acetate in acetic acid; they suggested that a free radical mechanism involving the selective generation and oxidation of organic free radicals is present. For example, the reaction of toluene with manganese(III) acetate led to the formation of a mixture of benzyl acetate, methylbenzyl acetate, and tolylacetic acid. The present investigation deals with the manganese(III) acetate oxidation of methylferrocene (**1**).

Results and Discussion

In a solution of acetic acid containing manganese(III) acetate and anhydrous potassium acetate, **1** was heated at 120 °C until the dark brown color of Mn(III) ion disappeared. Ferrocenyl(2-methylferrocenyl)methane (**2**), ferrocenyl(3-methylferrocenyl)methane (**3**), and ferrocenyl(1′-methylferrocenyl)methane (**4**) were obtained as the products.

In general, the thermolysis of manganese(III) acetate leads almost exclusively to the formation of $\cdot CH_2COOH$ radicals.[1,2] On the other hand, ferrocene does not appear to be particularly susceptible to attack by free radicals.[3] Consequently, in the reaction of **1** with manganese(III) acetate, the attack by the $\cdot CH_2COOH$ radical most likely occurs at the methyl group of **1**; this mechanism is shown in Scheme 1. Kochi *et al.*[4] suggested that the $\cdot CH_2COOH$ radical is oxidized relatively slowly to the correposnding carbonium ion, in contrast to the benzylic radical. In the oxidation of **1** with manganese(III) acetate, the formation of **2**, **3**, and **4** indicates therefore that the $\cdot CH_2COOH$ radical reacts more rapidly with **1** than the radical is oxidized by Mn(III) and the ferrocenylmethyl radical (**5**) is oxidized somewhat more rapidly to the corresponding carbonium ion (**6**) than the $\cdot CH_2COOH$ radical is oxidized by Mn(III). Furthermore, the absence of the formation of ferrocenylmethyl acetate (**7**), which is an expected side product in this reaction, indicated that the **6** carbonium ion reacts more rapidly with **1** than with acetic acid.

Heiba and Dessau[5] described a reaction of olefins with aromatic ketones such as acetophenone in the presence of manganese(III) acetate, leading to the formation of cyclized ketones together with noncyclized products. We have now found that the reaction of **1** with manganese(III) acetate in the presence of



styrene (**8**) led to the formation of a noncyclized product (**9**), together with **2**, **3**, and **4**. The formation of **9** and the absence of γ-lactone (**10**), which is an expected product in the reaction, indicate that the **6** carbonium ion adds to the olefin more quickly than the $\cdot CH_2COOH$ radical adds to the olefin and that the H^+ abstraction from an intermediate (**11**) is faster than the intramolecular cyclization of **11** to **12** or **13**.

Experimental

Materials. All the melting points are uncorrected. The IR and mass spectra were measured using a Hitachi 215 spectrophotometer and a Model RMU-6M mass spectrometer at 70 eV. The NMR spectra were obtained on a Hitachi Model R-22 (90 MHz), using TMS as an internal standard.

The preparation of the following compounds has already been reported: methylferrocene (**1**)[6] and manganese(III) acetate dihydrate.[1]

*The Reaction of Methylferrocene (**1**) with Manganese(III) Acetate.* A mixture of **1** (3.0 g, 15 mmol) and anhydrous potassium acetate (7.4 g) in 75 ml of acetic acid was heated at 120 °C under nitrogen with manganese(III) acetate dihydrate (4.0 g, 15 mmol) until the brown color of Mn(III) ion disappeared (14 h). The reaction mixture was diluted with water and extracted several times with ether. The ether extracts were then dried over anhydrous magnesium sulfate

and evaporated. The residue was chromatographed on silica gel with hexane as the eluent.

The first elution with hexane gave 1.82 g of the starting material (**1**).

The second elution with hexane–benzene (1 : 1) gave 0.38 g (6.4%[7]) of **2**, mp 95—97 °C (ethanol). Found: C, 66.21; H, 5.43%. Calcd for $C_{22}H_{22}Fe_2$: C, 66.37; H, 5.56%; mol wt, 398. IR: 3090, 2980, 2920, 1100, 1000, and 910 cm^{-1}. NMR ($CDCl_3$): δ 1.90 (3H, s, CH_3), 3.33 (2H, s, CH_2), 3.97, 4.01, and 4.05 ppm (17H, m, Cy protons). MS: *m/e* 398 (M^+ for $C_{22}H_{22}Fe_2$). The physical constants and IR and NMR spectra were identical with those of ferrocenyl(2-methylferrocenyl)methane (**2**), which was prepared by the reduction with $LiAlH_4$–$AlCl_3$ of ferrocenyl 2-methylferrocenyl ketone (mp 102—103 °C).

The third elution with benzene–hexane (1 : 1) gave 0.47 g (7.8%) of **3**, mp 83—85 °C (ethanol). Found: C, 66.22; H, 5.45%. Calcd for $C_{22}H_{22}Fe_2$: C, 66.37; H, 5.56%, mol wt, 398. IR: 3090, 2980, 2920, 1100, 1000, 920, and 910 cm^{-1}. NMR ($CDCl_3$): δ 1.87 (3H, s, CH_3), 3.28 (2H, s, CH_2), 3.96, 4.03, and 4.07 ppm (17H, m, Cy protons). MS: *m/e* 398 (M^+ for $C_{22}H_{22}Fe_2$). The **3** compound is identical in all respects with ferrocenyl(3-methylferrocenyl)-methane, which was prepared by the reduction of ferrocenyl 3-methylferrocenyl ketone (mp 90—92 °C) with $LiAlH_4$–$AlCl_3$.

The following elution with benzene–hexane (1 : 1) gave 0.43 g (7.0%) of **4**, mp 85—97 °C (ethanol). Found: C, 66.31; H, 5.48%. Calcd for $C_{22}H_{22}Fe_2$: C, 66.37; H, 5.56%; mol wt, 398. IR: 3090, 2980, 2920, 1100, 1000, and 910 cm^{-1}. NMR ($CDCl_3$): δ 1.91 (3H, s, CH_3), 3.36 (2H, s, CH_2), 3.97, 4.02, and 4.07 ppm (17H, m, Cy protons). MS: *m/e* 398 (M^+ for $C_{22}H_{22}Fe_2$). The **4** compound is identical in all respects with ferrocenyl(1′-methylferrocenyl)-methane, which was prepared by the reduction of ferrocenyl 1′-methoxycarbonylferrocenyl ketone (mp 180—182 °C)[8] with $LiAlH_4$–$AlCl_3$.

*The Reaction of Methylferrocene (**1**) with Manganese(III) Acetate in the Presence of Styrene.* A mixture of **1** (3.0 g, 15 mmol), styrene (1.54 g, 15 mmol), and anhydrous potassium acetate was heated at 120 °C under nitrogen with manganese(III) acetate dihydrate (4.0 g, 15 mmol) until the brown color of Mn(III) ion disappeared (10 h). The isolation of the products in the same manner as was used for the oxidation of **1** with manganese(III) acetate gave **2** (mp 95—97 °C, 0.35 g, 6.0%), **3** (mp 83—85 °C, 0.41 g, 7.0%), **4** (mp 85—87 °C, 0.38 g, 6.3%), and **9** (mp 68—70 °C, 0.52 g, 11.5%).

The **9** compound is identical in all respects with 3-ferrocenyl-1-phenyl-1-propene, which was prepared by the reduction of cinnamoylferrocene (mp 139—140 °C)[9] with $LiAlH_4$–$AlCl_3$. Found: C, 75.38; H, 5.83%. Calcd for $C_{19}H_{18}Fe$: C, 75.51; H, 6.00%; mol wt, 3.02. IR: 3090, 2980, 2920, 1100, 1000, 905, and 960 cm^{-1} (trans –CH=CH–). NMR ($CDCl_3$): δ 3.21 (2H, t, CH_2), 4.10 (5H, s, Cy protons), 4.16 (4H, br-s, Cy protons), 6.40 (1H, m, J=15 Hz, –CH=C–Ph), and 7.20—7.40 ppm (6H, m, –C=CH–Ph+Ph protons). MS: *m/e* 302 (M^+ for $C_{19}H_{18}Fe$).

A Novel Approach to *cis*-Jasmone and Dihydrojasmone from 2-(2-Benzothiazolylthio)-2-(3-oxobutyl)oct-5-en(or -an)oic Acid by Electrolytic Procedure

Sigeru Torii,* Hideo Tanaka, Yuichi Kobayasi, Junzo Nokami,** and Mikio Kawata**

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

***Okayama University of Science, Ridai, Okayama 700*

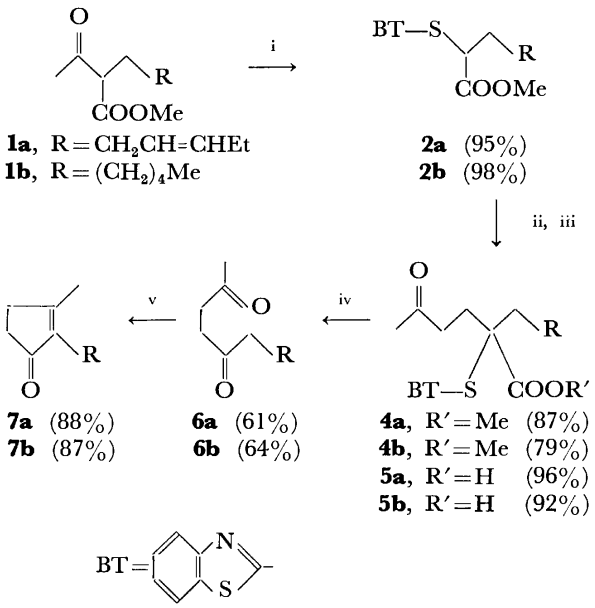
(Received November 21, 1978)

Synopsis. *cis*-Jasmone (**7a**) and dihydrojasmone (**7b**) have been synthesized by facile five-step processes starting from methyl acetoacetate involving electrolysis procedure. Methyl 2-(2-benzothiazolylthio)oct-5-en(or -an)oate, prepared from methyl 2-acetyloct-5-en(or -an)oate (**1**) by the reaction with the *N*-(2-benzothiazolylthio)morpholine, were allowed to react with methyl vinyl ketone, leading to the Michael adducts **4**. After hydrolysis of **4**, the corresponding acids **5** were electrolyzed to afford the desired 1,4-diketone **6** in 45—48% overall yields (based on **1**), whose base-catalyzed cyclization gave **7** smoothly.

As part of our program to investigate the electrochemical functionalization of carboxylates, we examined the conversion of the carboxylates bearing 2-benzothiazolylthio group in the α-position into the corresponding oxo compounds by electrolysis. Our efforts to utilize 2-(2-benzothiazolylthio)-2-(3-oxobutyl)oct-5-en(or -an)oic acid (**4**) in such a reaction led successfully to the expected 1,4-diketone **6**,[1] important precursors of *cis*-jasmone (**7a**) and dihydrojasmone (**7b**).

Methyl 2-(2-benzothiazolylthio)oct-5-en(or -an)oate (**2**) was smoothly prepared by treatment of methyl 2-acetyloct-5-en(or -an)oate (**1**) with *N*-(2-benzothiazolylthio)morpholine (**3**)[2] in methanol under refluxing for *ca.* 16 h.[3] The reaction of **2** with methyl vinyl ketone was carried out successfully in refluxing acetone using excess amounts of potassium carbonate for 12 h in the presence of a trace of 2,5-di-*t*-butylhydroquinone as a polymerisation inhibitor. This afforded **4a** in 87% yield and **4b** in 79% yield. Hydrolysis of Michael adducts **4** in aqueous methanol in the presence of potassium carbonate at 45—55 °C for 14 h afforded the corresponding acids **5** in 92—96% yields.

The electrolysis of **5a** using carbon rod electrodes in acetic acid–*t*-butyl alcohol–triethylamine (6/3/0.2, v/v) at a current of 20 mA/cm² (applied voltage 18—25 V) at 45—55 °C for 2.5 h gave **6a** in 61% yield. Similarly, the electrolysis of **5a** could be carried out using platinum electrodes in methanol–triethylamine (10/0.2, v/v) at a current of 30 mA/cm² (applied voltage 18—22 V) at 45—50 °C for 2.5 h, giving **6a** in 54% yield. On the other hand, the acid **5b** favored the electrolysis in the two-phase system, consisting of water and hexane (extracting solvent) layers as described in the preceeding paper.[4] Thus, an aqueous solution of **5b** and sodium hydroxide was electrolyzed using an undivided cell fitted with two platinum electrodes under a current of 30 mA/cm² (applied voltage 7—9 V) at 46—50 °C for 4 h, giving the desired **6b** in 64% after evaporation of the organic layer.



The carbonyl group of **6** seems to be formed by electrolytic decarboxylation of **5** followed by hydroxylation (methoxylation, acetoxylation), leading to intermediate (A), and subsequent elimination of 2-benzothiazolylthio group.[5]

The base-catalyzed cyclization of the 1,4-diketones **6** afforded *cis*-jasmone (**7a**) and dihydrojasmone (**7b**), respectively.[1]

Y=H, Me, or Ac

Experimental

All boiling points were uncorrected, the boiling points indicated being air-bath temperatures. IR spectra were determined with a JASCO Model IRA-1 spectrophotometer

with a grating. ^{1}H NMR spectra were obtained with Hitachi R-24 and/or JEOL MH-100 spectrometers. Elemental analyses were carried out in this laboratory.

*Methyl (Z)-2-Acetyl-5-octenoate (**1a**).* A suspension of methyl acetoacetate (540 mg, 4.65 mmol), (*Z*)-3-hexenyl bromide (836 mg, 5.13 mmol), K_2CO_3 (2.57 g, 18.6 mmol), and KI (1.07 g, 6.45 mmol) in acetone (20 ml) was heated to reflux for 6 h. Insoluble materials were filtered off and the filtrate was concentrated. The residue was chromatographed (SiO_2, benzene/AcOEt, 30/1) to give **1a** (840 mg, 91%): bp 94—98 °C/9 Torr; IR (neat) 1745 (ester C=O), 1717 (C=O), 1649 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.98 (t, 3, J=7 Hz, CH_3), 1.55—2.34 (m, 9), 3.34 (t, 1, J=7 Hz, CH), 3.70 (s, 3, CH_3O), 4.89—5.66 (m, 2, HC=CH). Found: C, 66.56; H, 9.14%. Calcd for $C_{11}H_{18}O_3$: C, 66.44; H, 9.15%.

*Methyl (Z)-2-(2-Benzothiazolylthio)-5-octenoate (**2a**).* A solution of **1a** (619 mg, 3.12 mmol) and *N*-(2-benzothiazolylthio)morpholine[2] (**3**, 886 mg, 3.51 mmol) in MeOH (7 ml) was heated to reflux for 15 h. After evaporation of the solvent, the residue was chromatographed (SiO_2, benzene/hexane/AcOEt, 20/10/1) to give **2a** (955 mg, 95%): bp 120—124 °C/0.01 Torr; IR (neat) 3056 (HC=C), 1734 cm^{-1} (C=O); ^{1}H NMR (CCl_4) δ 0.93 (t, 3, J=7 Hz, CH_3), 1.72—2.30 (m, 6, CH_2), 3.70 (s, 3, CH_3O), 4.68 (t, 1, J=7 Hz, CH), 5.22—5.57 (m, 2, HC=CH), 7.02—7.92 (m, 4, HC=C). Found: C, 59.61; H, 6.11%. Calcd for $C_{16}H_{19}NO_2S_2$: C, 59.78; H, 5.96%.

Similarly, *methyl 2-(2-benzothiazolylthio)octanoate (**2b**)* was obtained in 98% yield, bp 120—123 °C/0.004 Torr (lit,[3] bp 123—126 °C/0.005 Torr).

*Methyl (Z)-2-(2-Benzothiazolylthio)-2-(3-oxobutyl)-5-octenoate (**4a**).* A mixture of **2a** (515 mg, 1.60 mmol), methyl vinyl ketone (562 mg, 8.01 mmol), K_2CO_3 (443 mg, 3.21 mmol), and 2,5-di-*t*-butylhydroquinone (7 mg) in acetone (7 ml) was heated to reflux for 12 h. The insoluble materials were filtered off and the filtrate was concentrated. The residue was chromatographed (SiO_2, benzene/AcOEt, 15/1) to give **4a** (547 mg, 87%): bp 150—154 °C/0.005 Torr; IR (neat) 3061 (HC=C), 1729 (ester C=O), 1717 cm^{-1} (C=O); ^{1}H NMR (CCl_4) δ 0.92 (t, 3, J=7 Hz, CH_3), 1.68—2.85 (m, 13), 3.69 (s, 3, CH_3O), 5.12—5.50 (m, 2, HC=CH), 7.10—8.00 (m, 4, HC=C). Found: C, 61.43; H, 6.69%. Calcd for $C_{20}H_{25}NO_3S_2$: C, 61.35; H, 6.44%.

Similarly, *methyl 2-(2-benzothiazolylthio)-2-(3-oxobutyl)-octanoate (**4b**)* was obtained in 79% yield, bp 152—155 °C/0.01 Torr; IR (neat) 3058 (HC=C), 1731 (ester C=O), 1716 cm^{-1} (C=O); ^{1}H NMR (CCl_4) δ 0.62—1.04 (m, 3, CH_3), 1.04—2.81 (m, 17), 3.71 (s, 3, CH_3O), 7.08—8.02 (m, 4, HC=C). Found: C, 60.95; H, 7.04%. Calcd for $C_{20}H_{27}NO_3S_2$: C, 61.04; H, 6.92%.

*(Z)-2-(2-Benzothiazolylthio)-2-(3-oxobutyl)-5-octenoic Acid (**5a**).* A solution of **4a** (950 mg, 2.43 mmol) and K_2CO_3 (1.01 g, 7.31 mmol) in MeOH (20 ml) containing water (5 ml) was stirred at 45—55 °C for 14 h. The solution was concentrated to *ca.* 5 ml of total volume, diluted with brine, acidified with aqueous 10% HCl, and extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4) and concentrated. The residue was chromatographed (SiO_2, benzene/AcOEt/MeOH, 30/3/1) to give **5a** (882 mg, 96%): IR (neat) 3650—2200 (COOH), 1713 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 0.86 (t, 3, J=7 Hz, CH_3), 1.69—2.95 (m, 15), 5.14—5.54 (m, 2, HC=CH), 7.20—8.08 (m, 4, HC=C), 10.41 (s, 1, COOH). Found: C, 60.40; H, 6.13%. Calcd for $C_{19}H_{23}NO_3S_2$: C, 60.45; H, 6.14%.

Similarly, hydrolysis of **4b** afforded **5b** in 92% yield, IR (Nujol) 2996 (COOH), 1713 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 0.86 (t, 3, J=6 Hz, CH_3), 1.02—2.96 (m, 17), 7.22—8.07 (m, 4, HC=C), 12.10 (s, 1, COOH). Found: C, 60.34; H, 6.64%. Calcd for $C_{19}H_{25}NO_3S_2$: C, 60.13; H, 6.64%.

*Electrolytic Decarboxylation of **5**. Method A*: A solution of **5a** (51 mg, 0.14 mmol) in AcOH (6 ml), *t*-BuOH (3 ml), and Et_3N (0.2 ml) was electrolyzed under a constant current of 20 mA/cm^2 (applied voltage 18—25 V) at 42 °C using two carbon electrodes (1.5×2 cm^2) for 2.5 h. Evaporation of the solvents followed by column chromatography (SiO_2, benzene/AcOEt, 10/1) gave **6a** (15 mg, 61%), whose IR and NMR spectra were identical with those of reported one.[1]

Method B: The electrolysis of **5a** (48 mg, 0.13 mmol) in MeOH (10 ml) and Et_3N (0.2 ml) at 30 mA/cm^2, 18—22 V, at 45—55 °C using platinum electrodes (1.5×2 cm^2) for 2.5 h gave **6a** (12.5 mg, 54%). Similarly, the electrolysis of **5b** gave **6b** in 54% yield.

Method C: The electrolysis of **5b** (101 mg, 0.27 mmol) in aqueous 0.025 M NaOH (20 ml) covered with hexane (10 ml) using platinum electrodes (1.5×2 cm^2) at 30 mA/cm^2, 7—9 V, at 46—50 °C for 4 h gave **6b** (31 mg, 64%) after evaporation of the organic layer (upper layer). Extractive workup of the aqueous alkaline solution gave **5b** (7 mg, 5%).

*cis-Jasmone (**7a**) and Dihydrojasmone (**7b**).* According to the reported procedure,[1a] a solution of **6a** (15 mg, 0.08 mmol) in aqueous 2% KOH was heated to reflux for 3 h. Extractive workup of the solution gave **7a** (12 mg, 89%). Similarly, **7b** was obtained in 87% yield. Their spectral data were identical with those of reported ones.[1]

The Crystal and Molecular Structure of Perylene-2,5-Dibromo-3,6-dichloro-*p*-benzoquinone Complex

Kozo Kozawa* and Tokiko Uchida

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received June 14, 1978)

Crystals of the 1 : 1 molecular complex of perylene–2,5-dibromo-3,6-dichloro-*p*-benzoquinone are triclinic, with $a=8.669$, $b=9.697$, $c=7.321$ Å, $\alpha=103.20$, $\beta=110.92$, $\gamma=64.60°$, space group $P\bar{1}$, $Z=1$. The structure has been determined from diffractometer data by the heavy atom method and refined using the full-matrix least-squares method to R 0.069 for 2241 independent reflections. Stacks, with alternating donor and acceptor molecules, extend along the **c** direction. The acceptor molecule assumes two orientations, with a population ratio 1 : 1. A small degree of correlative change in the C–C bond lengths has been found in the perylene molecule on complex formation. The geometry of the quinonoid skeleton of the acceptor is similar to those of the anils and their complexes.

Perylene is a characteristic electron donor among polycyclic aromatic hydrocarbons. The perylene-iodine possesses the lowest electrical resistivity among hydrocarbon-iodine complexes.[1] And the perylene-antimony pentachloride is highly conductive in complexes which include antimony pentachloride as an electron acceptor.[2] Recently, perylene and 7,7,8,8-tetracyanoquinodimethane (TCNQ) were found to form a new type of complex, composed of three perylene molecules and one TCNQ moiety.[3,4] It is very rare in TCNQ complexes that more than two molecules of donor adduct to an acceptor molecule.

Tetrahalobenzoquinones are very useful electron acceptors, forming mainly π-π type donor-acceptor complexes. Their high electron affinity often gives complexes of ionic ground states.[5]

In this paper, the crystal structure of the 1 : 1 complex of perylene and 2,5-dibromo-3,6-dichloro-*p*-benzoquinone (BCQ) will be reported.

Experimental

Dark blue prismatic crystals of perylene-BCQ complex have been grown in a toluene solution. The crystal ($2.0\times0.5\times0.2$ mm^3) was mounted with the c axis parallel to the ϕ axis of a Rigaku four-circle automated diffractometer. The cell parameters and intensity data were obtained with LiF-monochromatized Mo $K\alpha$ radiation ($\lambda=0.7107$ Å). The intensities of the 2916 unique reflections were collected by the 2θ-ω scan technique with a scan speed of 1° min^{-1} in 2θ in the range $2\theta\leq60°$, 2241 reflections ($F_o\geq3\sigma(F)$) were used in the calculations. The scan range for each reflection was $(1+0.45\tan\theta)°$, and the background measurements were made 15 s at the extremeties of the scan range. Four reflections were monitored every 50 measurements and the fluctuations in the intensities of the monitored reflections were within ±2 %. Lorentz and polarization corrections were made, but no absorption correction was applied.

Crystal Data. $C_{20}H_{12}\cdot C_6Br_2Cl_2O_2$, *F.W.* =587.1; Triclinic, $a=8.669(3)$, $b=9.697(3)$, $c=7.321(3)$ Å, $\alpha=103.20(2)$, $\beta=110.92(2)$, $\gamma=64.60(1)°$, $V=517.2$ Å^3; $D_m=1.87$, $D_x=1.885$ g cm^{-3}, $Z=1$, μ(Mo $K\alpha$)=43.9 cm^{-1}, $F(000)=288$. Space group $P\bar{1}$.

The density was measured by the flotation method in an aqueous solution of K_2HgI_4. Structure determination was conducted assuming the space group $P\bar{1}$, and the possibility of P1 was excluded at the refinement step.

Structure Determination

The structure was solved by the heavy atom method. Several block-diagonal, least-squares calculation cycles for non-hydrogen atoms gave convergence at a residual index $R=0.176$. At this stage, the electron densities about the Br and Cl atoms, both in the Fourier and difference Fourier maps, suggested the existence of orientational disorder in the BCQ molecule. Subsequent full-matrix, least-squares refinements were performed with two sets of Br and Cl atoms positionally overlapping, based on the assumption that the two kinds of overlapping halogen atoms had equal probability of occupancy (0.5 : 0.5). The anomalous dispersion corrections for the Br and Cl atoms, reduced the value of R to 0.074. The positional parameters of the six hydrogen atoms attached to perylene, were estimated, assuming a C–H bond distance of 1.08 Å. The next refinement including the hydrogen atoms with an isotropic temperature factor of 4.5 Å^2 converged at $R=0.069$. In the final cycle, the average parameter shift/e.s.d. for non-hydrogen atoms was 0.26.

The final difference map showed maxima about 1.3 e Å^{-3} and only around the halogen atoms. This may be due to systematic error arising from the Br and Cl atoms being located at almost the same positions.

The quantity minimized in the refinement was $\sum w(|F_o|-k|F_c|)^2$, $w=1.0$. The numerical calculations were carried out on a HITAC 8800/8700 computer at the Computer Centre of the University of Tokyo with UNICS program[6] and XRAY system.[7] The atomic scattering factors and anomalous dispersion factors were taken from "International Tables for X-Ray Crystallography" (1974).[8] The final atomic parameters are shown in Tables 1 and 2 and the F_o-F_c data is kept as Document No. 7918 at the Bulletin.

Results and Discussion

Figure 1 shows the molecular packing in the crystal and the numbering of the atoms. Each molecule occupies a center of symmetry. As is common to π-π complexes, the donor and the acceptor molecules alternately stack in a plane-to-plane manner along the c axis, forming columns. The molecular overlapping

Table 1. The final atomic parameters ($\times 10^4$) for non-hydrogen atoms

The anisotropic thermal parameters are of the form:
$\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+2B_{12}hk+2B_{13}hl+2B_{23}kl)]$.

manner of BCQ onto perylene, shown in Fig. 2, is the same as that in the perylene-fluoranil complex.[9] The perylene and the BCQ molecules are planar within standard deviations except for the halogen atoms. The shifts of Br(1) (0.074 Å) and Cl(2) (0.151 Å) from the least-squares BCQ plane are nine and eight times as large as the e.s.d.'s, but the existence of disorder qualifies the significance of these values. The equations of the

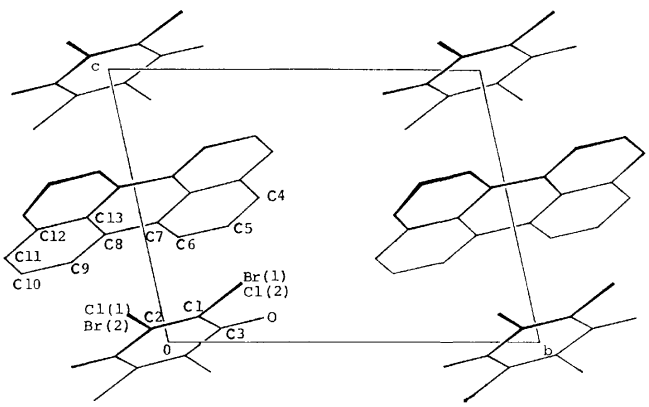

Fig. 1. Projection of the molecular arrangement onto the (100) plane.

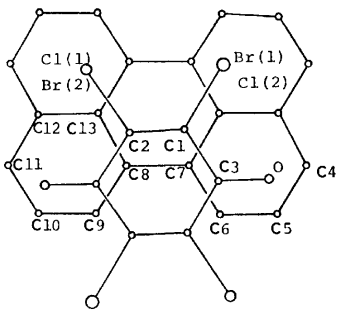

Fig. 2. Two overlapping molecules, viewed along normal to least-squares plane of a perylene molecule.

least-squares planes of the perylene and the BCQ molecules (calculated without hydrogen and halogen atoms) are

$0.7345X + 0.0132Y - 0.6784Z = -3.270$ and

$0.6752X + 0.0292Y - 0.7370Z = 0.0$ respectively,

where X, Y, and Z are orthogonal coordinates (in Å) given by the following equation.

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \begin{pmatrix} a & b\cos\gamma & c\cos\beta \\ 0 & b\sin\gamma & -c\sin\beta\cos\alpha^* \\ 0 & 0 & c\sin\beta\sin\alpha^* \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}$$

The mean separation between the two planes (in the region of overlap) is 3.35 Å and the angle between the plane normals is 4.9°. The values are larger than those of the perylene-fluoranil complex (3.23 Å, 1.8°),[9] which may be explained in terms of the difference between the van der Waals radii of the halogen atoms. The minimum interatomic distances between the overlapping molecules are 3.334 Å for O′–C(10), 3.350 Å for C(3′)–C(9), 3.371 Å for C(3′)–C(8), 3.376 Å for C(3)–C(6), 3.378 Å for C(3)–C(7), and 3.395 Å for O–C(5).

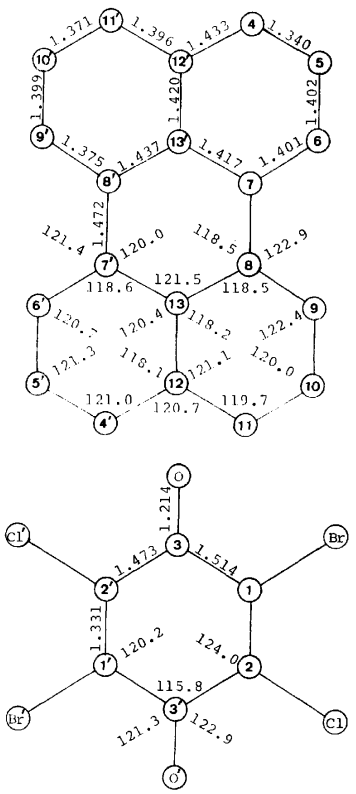

Fig. 3. Bond lengths (Å) and bond angles (°).
(a) Perylene; mean e.s.d.'s are 0.011 Å and 0.7° respectively.
(b) BCQ (quinonoid skeleton); mean e.s.d.'s are 0.010 Å and 0.7° respectively.

The bond distances and angles of the constituent molecules are shown in Fig. 3, in which the thermal vibrational motion has not been corrected for. The largest difference in the chemically equivalent bonds in the perylene skeleton is 0.037 Å between C(4)–C(12′) and C(11)–C(12) (2.2σ). Thus, in the perylene skeleton, all C–C lengths do not differ from the chemically equivalent bonds within experimental error. The geometry of the perylene molecule is similar to that of perylene itself (α-form)[10] or the complexes.[9,11–14]

Table 3 shows the bond lengths of the perylene skeleton together with six references.[9–14] The seven perylene skeletons show the following trends: (1) the longest bond length, C(7)–C(8), is close to a single bond as expected, and the lengths of C(4)–C(5) and C(10)–C(11) are the shortest within the same skeleton, (2) shortening of the C(7)–C(8) bond is accompanied by elongations of the C(8)–C(13), C(7)–C(13′), C(8)–C(9), and C(6)–C(7) bonds, (3) the chemically equivalent bond lengths slightly deviate from each other when the acceptors on both sides of the perylene are symmetrically situated about the molecular axis through C(12) and C(12′). The deviations become relatively large when the acceptors are not symmetrically situated about the axis.

Figure 3b shows the geometry of the quinonoid skeleton in BCQ. Although it is similar to that of other anils and their complexes,[9,15–30] the positional and thermal parameters of the halogen atoms are little reliable and the lengths of C–X bonds are not standard because of disorder. The bond lengths of C(1)–Br(1), C(2)–Br(2), C(2)–Cl(1), and C(1)–Cl(2) are 1.814, 1.820, 1.786, and 1.870 Å respectively. A similar effect, caused by disorder, was reported for benzo[*c*]phenanthrene and 2,3-dichloro-5,6-dicyanobenzoquinone.[31]

The authors would like to thank Mr. Teruyuki Kodama of the University of Tokyo for his help in the data collection and also to Mr. M. Kaneko and Mr. N. Edeh for their co-operation in this work as undergraduate students.

Effect of Etching on Intrinsic and Dye-sensitized Photocurrents in Zinc Oxide Electrodes

Michio MATSUMURA, Yoichi NOMURA, and Hiroshi TSUBOMURA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 7, 1978)

The photoelectrochemical behavior of sintered zinc oxide electrodes was studied. The intrinsic photocurrent, generated by ultraviolet illumination of the zinc oxide electrode, significantly diminished by grinding the electrode surface with an abrasive, and was restored by etching in 2 M(M= mol dm^{-3})HCl for *ca.* 120 s. The dye-sensitized photocurrent caused by rose bengal was also lowered by grinding, but the effect was not as large as in the case of the intrinsic photocurrent, and the photocurrent was restored in a much shorter time of etching. The dye-sensitized photocurrent for an insufficiently etched electrode was enhanced by addition of a reducing agent, *e.g.*, hydroquinone or allylthiourea. However, no enhancement was observed for a well etched electrode. The results, together with the luminescence and reflection spectra of zinc oxide, were discussed by means of models for the semiconductor electronic bands.

Many studies have been carried out on electrochemical solar cells each comprising a semiconductor electrode such as ZnO, TiO_2, or CdS, an electrolyte solution, and a metal counter electrode.[1-6] In these cells, the photocurrent generally arises by the band gap excitation of the semiconductor. The photocurrent is referred to as intrinsic photocurrent, i_{int}, of the semiconductor electrode.

The dye-sensitized photocurrents in the semiconductor electrodes, i_{dye}, have also been studied.[7-11] The dye-sensitized photocurrents are caused by the dye adsorbed on the electrode, but not by those dissolved in the solution.[11-13] Stationary photocurrents can be obtained only when reducing agents are added to the solution.[12,14] Relatively high photocurrents have been obtained by use of rose bengal as a sensitizer and a porous zinc oxide electrode.[15,16] In this paper, further results on some fundamental aspects of the dye-sensitization effects are reported.

Experimental

Zinc oxide sintered disks were prepared by heating compressed zinc oxide powder at 1300 °C in the air for 1 h. The dye adsorptivity on the disk varies a great deal with the source of zinc oxide powder. This seems to be due to impurities such as $ZnCO_3$ present in a small amount. In the present experiment, the powder (Kanto Chemical Co.) was used without further purification. The sinter made from this material has low adsorptivity, giving a reproducible photocurrent. The density of the sinter is almost equal to that of a single crystal. The scanning electron micrograph shows a very compact array of crystalline grains and no visible pore (Fig. 1). The sinter has low electric resistivity $\approx 10\ \Omega$ cm. The shape of the electrode is the same as that described previously.[15] All the other chemicals were of reagent grade and used without further purification.

The photocurrents were measured under potentiostatic conditions with a Hokutodenko HA-101 potentiostat and a saturated calomel electrode (SCE). A 500 W xenon lamp (Ushio Electric, Inc.) was used as the light source. The light was monochromatized by use of a Japan-Jarrell Ash 0.25 m Ebert type monochromator. The light intensity was measured with an Eppley bismuth-silver thermopile. The dye-sensitized photocurrents were studied in aqueous solutions of rose bengal and 0.2 M (mol dm^{-3}) potassium nitrate, the pH of the solution being 6.1. For the measurements of intrinsic photocurrents,

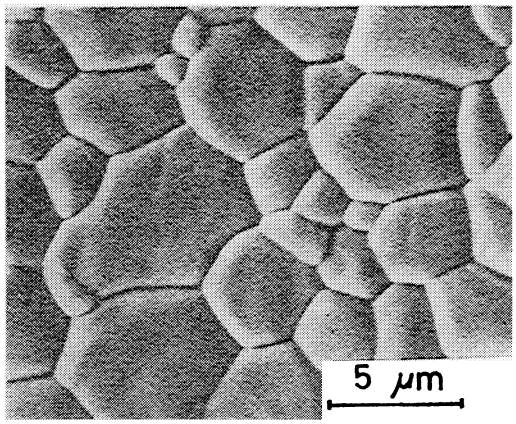

Fig. 1. The scanning electron micrograph of the zinc oxide sinter.

the pH of the solution was adjusted to 7.8 with a borate buffer. Dissolved oxygen was removed by bubbling the solution with high purity nitrogen. In many cases, the zinc oxide sinter was ground with a silicon carbide abrasive (No. 2000), etched in 2 M hydrochloric acid, washed with water and dried.

The luminescence intensity of zinc oxide sinter excited by the same light source as above was measured by use of an RCA 1P28 photomultiplier equipped with Toshiba B46 and 052 glass filters. The luminescence spectra were measured with an Aminco-Bowman spectrofluorimeter. The absorption spectra and the diffuse reflectance spectra were measured with a Shimadzu MPS-50L spectrophotometer. The ZnO sinter was colored slightly after dipping in the dye solution. The amount of the dye adsorbed on the electrode was estimated from the diffuse reflectance spectra of the ZnO sinter taken out of the dye solution, the residual solution on the sinter being soaked with a filter paper.

The differential capacitance at the semiconductor-electrolyte interface was measured with a Yokogawa Hewlett-Packard 4265B universal bridge at a frequency of 1 kHz.

Results

The dye-sensitized photocurrent under steady illumination decayed exponentially during the first several seconds (curve 1, Fig. 2). The initial value of the dye-sensitized photocurrent, i°_{dye}, was determined by extrapolating the curve to zero time of the illumination. When the dye solution contained a reducing agent such

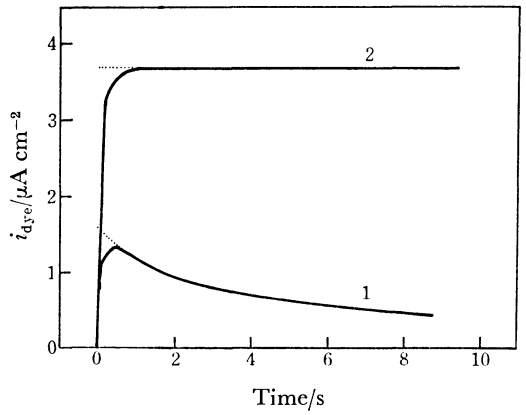

Fig. 2. Change of photocurrent *vs.* time for un-etched electrodes in a solution of 2×10^{-5} M Rose Bengal at potential of 0.4 V (*vs.* SCE). Curve 1, without hydroquinone. Curve 2, with 1.6×10^{-3} M hydroquinone.

as hydroquinone, allylthiourea, or potassium iodide, the decay was suppressed. In some cases the initial value of the photocurrent was enhanced as shown by curve 2 for the case of hydroquinone as a reducing agent. The decay of i_{dye} was suppressed by addition of hydroquinone or allylthiourea at a concentration as low as 5×10^{-5} M, while the increase of i°_{dye} was small at such a low concentration and reached saturation at *ca.* 1×10^{-3} M. In the case of iodide ion, the decay of i_{dye} was not prevented at concentrations below 5×10^{-2} M, and the increase of i°_{dye} could not be observed even at 1.0 M. The difference seems to arise from the weaker electron donor strength of the iodide ion than hydroquinone or allylthiourea. On the other hand, the intrinsic photocurrent did not decay even when the electrolyte solution contained no reducing agent, nor was it affected by the reducing agent.

The photocurrent-potential curves of both i_{int} and i°_{dye} for electrodes etched for various periods of time are shown in Fig. 3. The photocurrents are proportional to the illumination intensity, the shapes of the photocurrent-potential curves not being changed by decrease in the illumination intensity to 1/7. The apparent quantum efficiency of i_{int}, defined as the number of electrons flowing per the number of incident photons on the electrode, is *ca.* 80% for the electrode etched for more than 120 s and polarized at a higher electrode potential than 0.3 V (*vs.* SCE). The onset potentials of the photocurrents did not change with etching. The flat band potentials of ZnO electrodes in the solutions used for the measurements of i_{int} and i_{dye} as determined by the Mott-Schottky plots of the differential capacitance are *ca.* −0.48 and −0.32 V (*vs.* SCE), respectively, agreeing nearly with the onset potentials of photocurrents. The donor densities were determined to be in the range 4.9×10^{22}—7.1×10^{22} m^{-3} by assuming the roughness factor of 2 for the electrode surface.

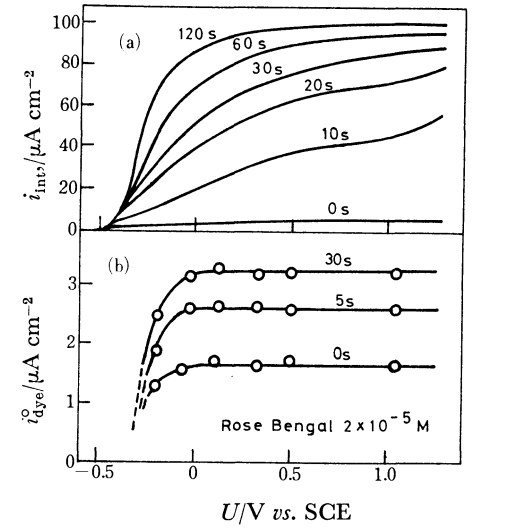

Fig. 3. Current-potential curves of (a) intrinsic photocurrents (excited at λ 360 nm) and (b) the initial values of dye-sensitized photocurrents (λ 562 nm) of ZnO electrode etched for various periods of time.

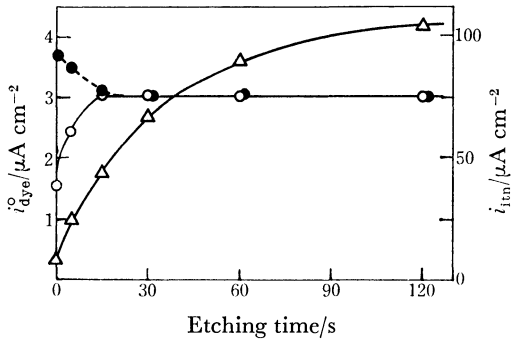

Fig. 4. The photocurrent (at 0.4 V *vs.* SCE) *vs.* etching time in the electrode ground with an abrasive.
○: Initial values of dye-sensitized photocurrent (λ 562 nm) in the presence of 2×10^{-5} M Rose Bengal, ●: the dye-sensitized photocurrent obtained by addition of 1.6×10^{-3} M hydroquinone into the solution; △: the intrinsic photocurrent (λ 360 nm).

The photocurrents observed at the electrode potential of 0.4 V (*vs.* SCE) are plotted against the etching time in Fig. 4. The i°_{dye} value becomes constant at an etching time much shorter than that for the i_{int}. The enhancement of i°_{dye} by hydroquinone occurs only at an etching times less than 15 s. The addition of hydroquinone up to the concentration of 10^{-2} M did not affect the adsorptivity of dye. The amount of the dye adsorbed on the electrode changed slightly by etching, being approximately proportional to the i_{dye} observed in the presence of hydroquinone. This might be due to the change of the surface area caused by etching.

The ZnO sinter emits luminescence when exposed to ultraviolet light. The emission band lies in the range 400—750 nm with a maximum near 530 nm (Fig. 5). The luminescence intensity was quenched drastically by grinding the sinter, but was gradually restored with etching. By etching for 150 s, the luminescence intensity returned to the value before grinding. Figure 6 shows the luminescence intensity at various electrode potentials. The luminescence intensity falls near the onset potential of the photocurrents, decreasing nearly to zero at potentials where the i_{int} value is saturated.

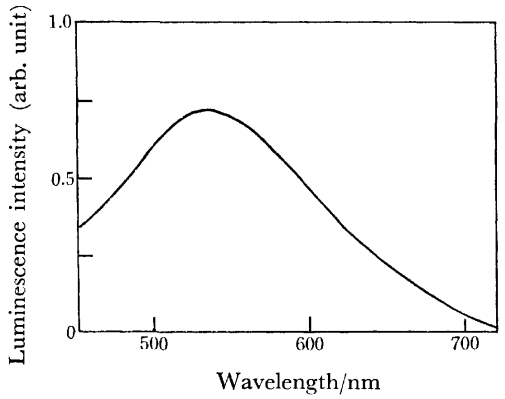

Fig. 5. The luminescence spectrum of ZnO sinter excited at 360 nm.

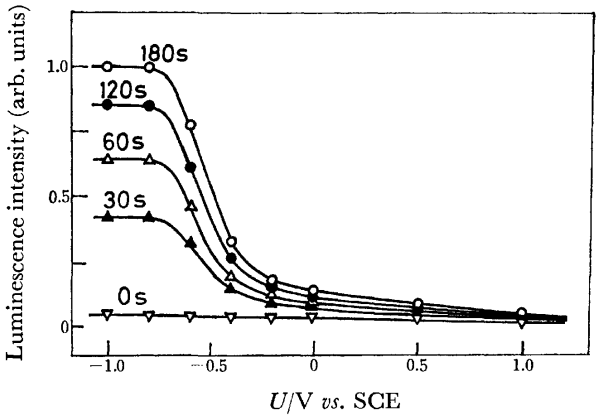

Fig. 6. The luminescence intensity of zinc oxide electrode etched for various periods of time *vs.* electrode potential. The luminescence was excited at 360 nm.

By measuring the weight loss of the ZnO sinter etched in 2 M HCl, the average thickness of the ZnO sinter dissolved by the solution was determined to be 4.3 μm min^{-1}.

Discussion

Our results have revealed that there are fundamental differences between the behavior of the intrinsic photocurrent (i_{int}) and that of the dye-sensitized photocurrent (i_{dye}):

1. The i_{int} is weakened to a greater extent than i_{dye} by grinding the electrode.
2. The increase in i_{dye} with etching reaches saturation when etching time is *ca.* 15 s. The i_{int} value increaes much more slowly by etching, reaching saturation at *ca.* 120 s.
3. The i_{int} value for an insufficiently etched electrode rises gradually as the electrode becomes anodically polarized up to quite high voltages, whereas i_{dye} rises sharply and is saturated at 0.0 V (Fig. 3).
4. By addition of reducing agents to the solution, the decay of i_{dye} is suppressed. Sometimes i°_{dye} increases, whereas i_{int} is hardly affected.

Based on these results, we shall discuss the mechanism of these photocurrents.

Intrinsic Photocurrent. The mechanism of the generation of i_{int} is shown in Fig. 7a. When an n-type semiconductor immersed in an electrolyte is polarized anodically, a potential gradient develops in the space charge layer. By the band gap excitation, the electrons in the valence band are excited to the conduction band. The electron-hole pairs thus generated in the space charge layer are separated efficiently by the electric field.

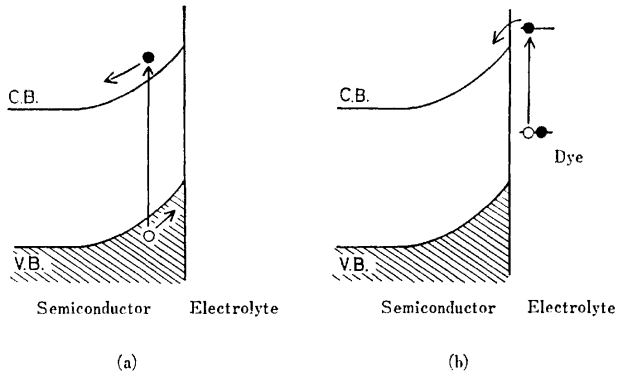

Fig. 7. The energy level diagrams of the semiconductor illustrating the mechanisms of the intrinsic photocurrent (a) and dye-sensitized photocurrent (b).

The i_{int} value of a well etched electrode reaches saturation at the electrode potential of *ca.* 0.3 V (Fig. 3). The quantum efficiency of the saturated i_{int} is regarded to be almost 100% if the reflection of the incident light at the surface is taken into account.

The depth of the space charge layer, L, is approximately given by[17]

$$L = \sqrt{2(U - U_{fb})\varepsilon\varepsilon_0/N_d e} \quad (1)$$

where U is the electrode potential in the bulk, U_{fb} the flat band potential, ε the dielectric constant, ε_0 the permittivity of vacuum, and e the elementary electric charge. The value of L is calculated to be 110 nm at the electrode potential of 0.3 V, at which i_{int} of a well-etched electrode reaches saturation, by substituting $U_{fb} = -0.48$ V, $\varepsilon = 8.5$, $N_d = 6 \times 10^{22}$ m^{-3} (the mean value of the observed donor density) into Eq. 1. On the other hand, the penetration depth of the incident light (λ 360 nm) in ZnO, l, defined as the distance at which the light intensity becomes 5%, is calculated to be *ca.* 100 nm from the absorption constant of *ca.* 3×10^7 m^{-1},[18] in good agreement with the above derived L value. The result suggests that the recombination is negligible in the space charge layer of a well-etched electrode.

On the other hand, the i_{int} value for an insufficiently etched electrode did not reach saturation even when the electrode potential was raised to 5 V (*vs.* SCE). This cannot be explained by the relation between the penetration depth of the light and the depth of the space charge layer, but by taking into account the recombination center of electron-hole pair in the space charge layer generated by the grinding. At a higher anodic polarization, the electric field strength near the surface of the electrode increases and the electrons and holes are separated more rapidly, leading to a higher photocurrent.

This mechanism is supported by the measurements of luminescence from ZnO. The luminescence drops sharply at around −0.5 V (*vs.* SCE) to the more positive region where i_{int} begins to rise (Figs. 3 and 6). This is reasonable since the luminescence is caused by a recombination of the electron-hole pairs. The figures also indicate that non-radiative recombination centers are generated by grinding the electrode, since both the luminescence and i_{int} are weak when the etching time is short, increasing in a similar way with longer etching.

Dye-sensitized Photocurrent. It is generally admitted that the dye sensitized photocurrent (i_{dye}) is caused by an electron injection from the excited dye into the conduction band, the electrons being driven inward by the electric field in the space charge layer (Fig. 7b). In the case of i_{dye}, free holes do not exist in the valence band, and, therefore, the recombination process does not take place even though defects are present in the space charge layer. This can explain i_{dye} being less affected than i_{int} by grinding of the electrode.

The effect of grinding on i°_{dye} can be explained by assuming the formation of electron traps near the surface which capture electrons injected from the dye and send them back to the dye. The fact that the photocurrent at sufficiently high anodic polarization became constant by etching for 15 s indicates that the density of the traps is high in the region very close to the surface (Fig. 4).

Sintered ZnO, normally slight yellow, turns deep yellow on grinding. The increase in absorbance of the sinter from 380 to 650 nm thus produced can be measured by diffuse reflectance spectroscopy. This can be removed by etching for *ca.* 15 s, which is comparable to that necessary to make i°_{dye} reach saturation. The increased absorbance seems to be due to the surface defects, which trap the injected electrons.

The Effect of Reducing Agents on i_{dye}. There are two features of the effect of reducing agents on i_{dye},[12] the increase of i°_{dye} and the prevention of decay of i_{dye}.

Hydroquinone increases i°_{dye} for an electrode etched for less than 15 s, but not for a sufficiently etched electrode (Fig. 4). This can be explained by assuming the presence of surface traps (Fig. 8). Without a reducing agent, a part of the injected electrons are capturated by the surface traps, returning to the dyes which have injected these electrons. Such a backward movement of electrons is prevented by a rapid electron supply from the reducing agent, increasing i°_{dye}.

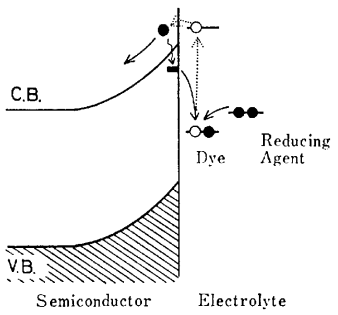

Fig. 8. The energy level diagrams explaining the influence of the surface defect and the reducing agent on the dye-sensitized photocurrent.

Some authors pointed out that the effect of reducing agents on i_{dye} is attributable to either an electron transfer from the reducing agent to the dye in excited state or an exciplex formation between the dye and the reducing agent. In the present case, however, the results are explained in terms of the electron transfer from the reducing agents to the photo-oxidized dye. There seems to be no general "super sensitization" effect of the reducing agents.

From the present study, the dye-sensitized photocurrent has been proved to be less sensitive to the defects in the electrode than the intrinsic photocurrent, especially when the solution contains reducing agents. This is one of the advantages of the dye-sensitized photocurrent as regards utilization of imperfect solid specimens for electrochemical photocells.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 911504).

Association and Photolysis of 1-Benzyl-4-methoxycarbonylpyridinyls

Yusaku IKEGAMI,* Shozo KUBOTA, and Hidetoshi WATANABE[1)]

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai 980

(Received August 31, 1978)

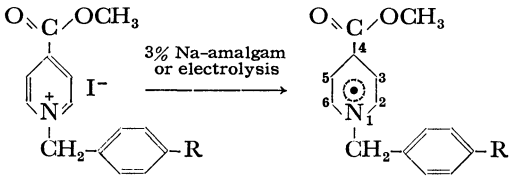
1-Benzyl- and 1-(4-methylbenzyl)-4-methoxycarbonylpyridinyl radicals have been prepared by reducing the corresponding pyridinium iodides with sodium amalgam. Hyperfine structures of the ESR spectra were analyzed. The radicals were decomposed photochemically with visible light in the region 380—440 nm in order to generate the intermediate benzyl radicals which were identified spectroscopically at 77 K. Association of each radical at low temperature forms a diamagnetic radical dimer, which is transformed by irradiating the solution with 440—470 nm light into the triplet dimer with zero-field parameters, $D=ca.$ 0.017 cm^{-1} and $E\approx 0$. Another radical, 1-(4-nitrobenzyl)-4-methoxycarbonylpyridinyl, is unstable at room temperature.

Pyridinyl radicals play an important role in studies on radical structure, radical reactions and radical association since the radicals are stable, neutral, and aromatic.[2)] One peculiar property of pyridinyls is the association to form both the diamagnetic singlet (A_S) and paramagnetic triplet (A_T) dimers at low temperature. Another triplet species (B_T) is generated from A_S by irradiating the radical solution with visible light.[3,4)] 1-Benzyl-4-methoxycarbonylpyridinyl (**1**) was prepared in order to investigate the effect of *N*-substituent on stability and association.[5)] In the course of the study, an unexpected sensitivity of the radical to light was observed. The photosensitivity as well as the association were examined for the radical and its derivatives.

Results and Discussion

Preparation. Generation of radicals **1**—**3** for preliminary study was performed by electrolytic reduction of the corresponding pyridinium iodides in degassed acetonitrile or *N*,*N*-dimethylformamide using tetrapropylammonium perchlorate as the supporting electrolyte. Each radical was generated in a stable form, exhibiting the expected ESR spectrum.

Treatment of 1-benzyl-4-methoxycarbonylpyridinium iodide with 3% sodium amalgam in degassed acetonitrile under ice-cooling in the dark afforded a green solution. Removal of the solvent gave blue crystals composed of **1** and NaI. The radical is slightly soluble



1: R=H
2: R=CH_3
3: R=NO_2

in hydrocarbons, soluble in ethereal and aprotic polar solvents, and not distillable in a vacuum. In solution it is stable for a long period at room temperature in the dark, but decomposes gradually in the light and rapidly in contact with alcohols, water, or air. Yield of the radical in preparation, based on spectroscopic titration, was over 85%. The 4-methylbenzyl derivative **2** prepared in a similar manner to the above showed

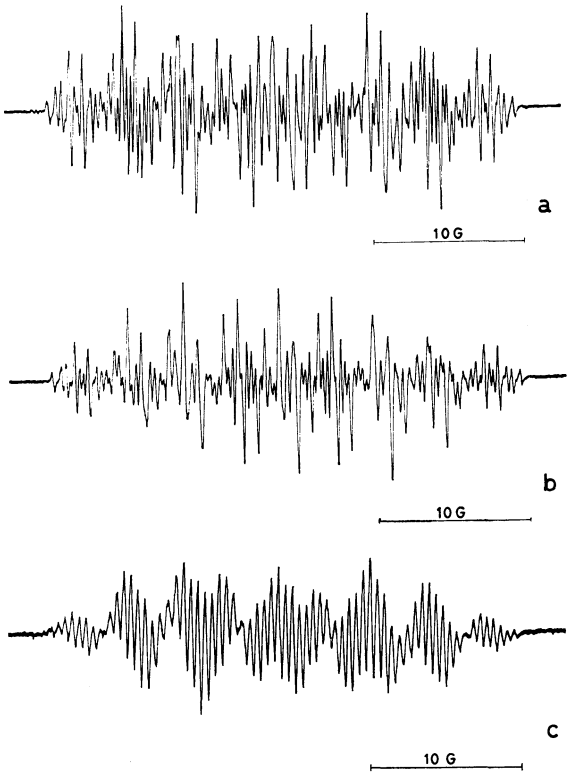


Fig. 1. ESR spectra of 1-benzyl- (a), 1-(4-methylbenzyl)- (b), and 1-(4-nitrobenzyl)-4-methoxycarbonylpyridinyls (c) in acetonitrile at room temperature. The 4-nitrobenzyl derivative was generated electrolytically.

similar properties. On the other hand, the 4-nitrobenzyl derivative **3** was not so stable as **1** and **2**. The deep blue color of **3** turned gradually yellow even in the dark. Approximate half-life for the decomposition, estimated by the ESR signal intensity, was *ca.* 15 min in acetonitrile at 20 °C. Because of the instability, spectroscopic examination of **3** was not carried out.

ESR spectra of radicals **1**—**3** in acetonitrile at room temperature are shown in Fig. 1. The hyperfine structure of each spectrum is interpreted as arising from the radical structure with six splitting constants. The constants observed in two solvents are summarized in Table 1, the assignments being given tentatively according to the type of splitting and by comparing them with the assignments to the constants of 1-methyl-4-methoxycarbonylpyridinyl.[6)] The coplanarity of the carbonyl

TABLE 1. HYPERFINE SPLITTING CONSTANTS FOR RADICALS **1**—**3** AT ROOM TEMPERATURE

Assignment	Splitting constant, *G*				
	1 (R=H)		**2** (R=CH_3)		**3** (R=NO_2)
	In CH_3CN	In MTHF	In CH_3CN	In MTHF	In CH_3CN

$-CH_2-$	3.56	3.56	3.59	3.60	3.51

group with pyridinyl ring is clearly seen in the nonequivalence of the constants at positions 2 and 6.

The radical concentration of the solution of **1** or **2** for spectroscopic studies was determined spectroscopically by the following electron-transfer reaction.

1 (or **2**) + 1,1′-Dimethyl-4,4′-bipyridinium (MB^{2+})
$\longrightarrow$ $\mathbf{1}^{+}$ (or $\mathbf{2}^{+}$) + MB^{+}

The reaction of a dilute solution of the radical (concn$<5\times10^{-3}$ M) with an excess of solid 1,1′-dimethyl-4,4′-bipyridinium (MB^{2+}) dichloride in acetonitrile in the dark proceeded rapidly to form the corresponding radical cation (MB^{+}) (Paraquat radical cation). The absorption intensity of the resulting cation at 605 nm ($\varepsilon=10060$)[7] was used to calculate the radical concentration.

TABLE 2. ABSORPTION MAXIMA OF RADICALS **1** AND **2** IN ACETONITRILE (23 °C)

Radical	λ_{max} (ε)

A 500 W xenon lamp equipped with a Toshiba filter UV-39 was used for the irradiation.

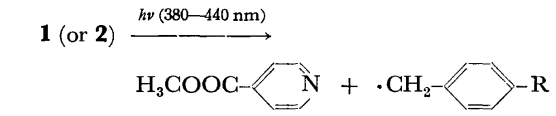
Spectra and Photolysis. Radical **1** shows absorption maxima given in Table 2 with features similar to 1-alkyl homologs.[8–10] Irradiation of the solution with visible light caused the disappearance of the three longer bands as a result of photolysis; the dispersed weak light in the spectrometer caused no photolysis. The effect of irradiation on the spectrum is shown in Fig. 2; the same phenomenon is observed in MTHF at room temperature. The photolysis occurred also in MTHF glass at 77 K, leading to the spectral change shown in Fig. 3, in which the disappearance of strong bands at 286, 372, and 616 nm on irradiation is accompanied by the appearance of new bands at 260, 306, and 319 nm. The new bands coincide in their wavelengths with those of the benzyl radical generated in 2-methylpentane at 77 K.[11] Irradiation of radical **2** also led to its substantial loss. The absorption bands at 267, 300, 311, and 323 nm

(Fig. 4) correspond to those of the 4-methylbenzyl radical.[11] Thus, the photolysis is interpreted to be the following C–N bond cleavage.



The photolysis occurred with 380—440 nm wavelengths. Strong irradiation of the solution with light of wavelength shorter than 350 nm from a 500 W mercury lamp led to further photoreaction showing a complex spectral change with time. Photolytic change was also observed in the ESR spectrum of a dilute solution at 77 K, an example of which is shown in Fig. 5 for radical **2**. The hyperfine structure appearing on irradiation is ascribed to the 4-methylbenzyl radical. Irradiation of **1** in a similar way resulted in appearance of hyperfine structure in the ESR spectrum differing from that in Fig. 5.

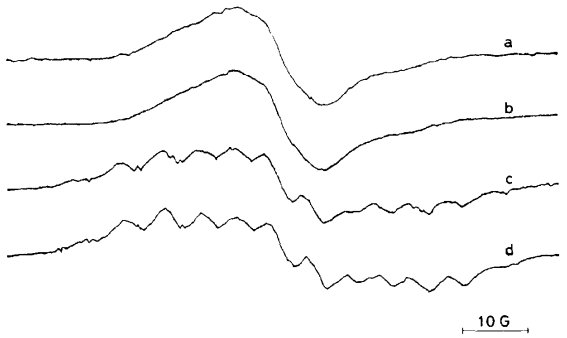


Fig. 5. The ESR spectral change observed by irradiating the dilute solution of **2** in MTHF at 77 K: (a) 1.2×10^{-4} M before irradiation; (b) after 10 min irradiation of (a) with a 500 W xenon lamp using a Toshiba filter VY-50; (c) after 1 min irradiation of (b) using a Toshiba filter VY-42; (d) after further 9 min irradiation of (c).

Since 1-alkylpyridinyls are not sensitive to visible light, the photolysis should be interpreted in terms of a photochemical interaction between the arene ring and the pyridinyl ring. One possible explanation is that excitation of the pyridinyl radical leads to the formation of an intramolecular exciplex *via* electron transfer to the aryl ring, followed by dissociation to an unstable free radical and a stable molecule, methyl isonicotinate.[12] If this is the case, the instability of the 4-nitrobenzyl derivative (**3**) can be explained by a thermal mechanism analogous to the photochemical one, as Mochida *et al.*[13] recently substantiated a general formulation, originally put forth by Kosower,[14] that electron-transfer processes resulting from charge-transfer interaction can share common photochemical and thermal pathways.

Radical Association and Associated Triplet State. The absorption spectrum of **1** at low temperature (Fig. 3a) has an intense band at 616 nm, while the absorption in this region at room temperature (Fig. 2a′) is very weak. The strong absorption is due to the radical dimer denoted by π-mer.[15] Since the solution contains a considerable amount of sodium iodide, the strong intensity might be partially due to the complex formation of the radical with sodium iodide. Complex formation can account for the hypsochromic shifts of the bands at 300 and 391 nm to 286 and 372 nm, respectively, on lowering the temperature in MTHF.[16] The spectrum of **2** can be interpreted similarly (Fig. 4a).

The radical association is also observed as conspicuous decrease in the ESR signal intensity with fall in temperature. The decrease in intensity for the solution of **1** at −150 °C is less than 2% of that at room temperature. (Fig. 6). This can be ascribed to the formation of the diamagnetic radical dimer at low temperature.

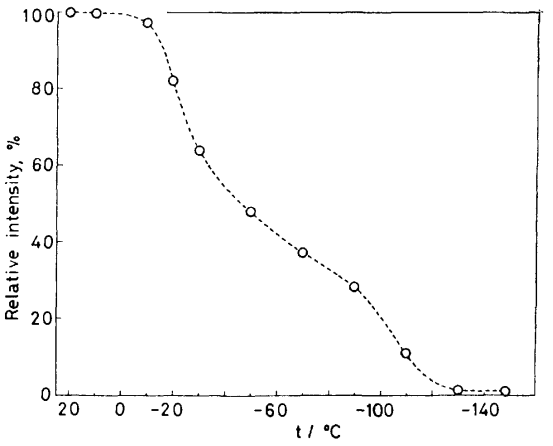

Fig. 6. Decrease of the ESR signal intensity with lowering temperature for the radical **1** in MTHF at the concentration, 4.0×10^{-2} M.

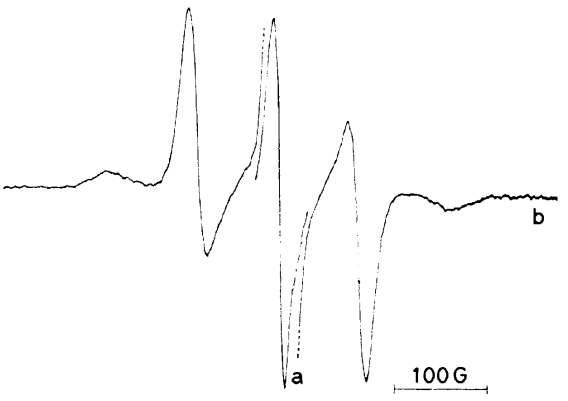

Fig. 7. ESR spectrum of **1** in MTHF at 77 K. 2.5×10^{-2} M. (a) Before irradiation; (b) after 20 min irradiation with a 500 W xenon lamp using a Toshiba filter VY-46. (a) was recorded with 1/2.5 gain amplitude of that for (b).

It has been demonstrated for 1-alkyl-4-methoxycarbonylpyridinyls that the diamagnetic dimer (A_S) is convertible into the triplet dimer (B_T) by light irradiation.[3,4] The same phenomenon is observed for the radicals. Radicals **1** in MTHF at 77 K shows a very weak signal corresponding to the central line in Fig. 7. Irradiation of the solution with light of wavelength longer than 440 nm added a new triplet signal to the ESR spectrum, with no significant change in the central

line. Appearance of the $\Delta M=2$ transition in the ESR spectrum at around 1650 G confirms the triplet. The zero-field parameters estimated roughly are $D=0.0174$ cm^{-1} and $E\approx0$, with $2D=372$ G. The D value is consistent with a spin-spin dipolar interaction for an average separation of 5.3 Å, using the relation $D=-(3/2)g^2\beta^2r^{-3}$.[17] A similar triplet spectrum was obtained for radical **2**, the zero-field parameters, $D=0.0166$ cm^{-1} and $E\approx0$ with $2D=356$ G, corresponding to the spin-spin interaction for an average separation of 5.4 Å. These D values for the association of **1** and **2** are close to those of 1-methyl- and 1-ethyl-4-methoxycarbonylpyridinyls. This indicates that the *N*-substituent has no significant influence upon the structure of the triplet dimer formed by an access of pyridinyl rings.

No spectral change was observed by irradiation with light of wavelength longer 470 nm. The singlet-triplet transformation occurred with visible light in the region 440—470 nm, which differs from both the light specific to the photolysis and the light corresponding to the long-wavelength charge-transfer absorption of π-mer at *ca.* 620 nm. Since no strong absorption was observed in the 440—470 nm region (Figs. 3 and 4), excitation expected in this region, corresponding to the band at 437 nm observed before irradiation for pure 1-methyl-4-methoxycarbonylpyridinyl in MTHF at 77 K,[4] might cause the dynamic reorientation of the radicals in a dimer to the positions capable of triplet transition.

Experimental

Solvents. Acetonitrile (guaranteed reagent, Kanto Chemical Co.) was passed through an alumina (Woelm, neutral) column and distilled. After being degassed by at least five freezing-pumping cycles, the solvent was treated with 1-methyl-4-methoxycarbonylpyridinyl radical, prepared by the reaction of the pyridinium iodide with sodium amalgam, to remove radical-reactive impurities. The solvent was distilled again in a vacuum system at low temperature and left to stand over previously degassed molecular sieves (4A) in a storage vessel. 2-Methyltetrahydrofuran (MTHF) (Eastman Organic) was refluxed over sodium for 3 days and then distilled. The solvent was degassed and then distilled onto sodium and anthracene in a storage vessel. Solvents were transferred, when needed, by distillation into the apparatus using a vacuum system.

Salts. 1-Benzyl-4-methoxycarbonylpyridinium iodide was prepared by the method of Craig *et al.* through the chloride.[18] Mp 163—164 °C. 1-(4-Methylbenzyl)-4-methoxycarbonylpyridinium iodide was prepared as follows. A solution of 4-methylbenzyl chloride (0.04 mol) in acetone (50 ml) was refluxed with an excess of sodium iodide (0.05 mol) under nitrogen for 2 h. The sodium chloride produced was filtered off. Methyl isonicotinate was added to the solution, the temperature being maintained at 50 °C for 2 h, the solution allowed to cool overnight, then left at 0 °C for 40 h. The yellow crystals were filtered off and recrystallized from ethanol and then from methanol. Mp 151—152 °C. Found: C, 49.12; H, 4.34; N, 3.97%. Calcd for $C_{15}H_{16}NO_2I$: C, 48.80; H, 4.37, N, 3.79%. 1-(4-Nitrobenzyl)-4-methoxycarbonylpyridinium iodide was prepared by the method of Kosower *et al.*[19] as orange red crystals, mp 152 °C. 1,1′-Dimethyl-4,4′-bipyridinium dichloride (Wako Chemical Co.) was recrystallized from ethanol, and then dried thoroughly.

Radicals. Pyridinyl radicals were prepared using the apparatus shown in Fig. 8. A pyridinium iodide (0.001 mol), 3 % sodium amalgam, and a magnetic stirrer were put into A and the apparatus was evacuated with an oil diffusion pump to 2×10^{-6} Torr. After the addition of solvent acetonitrile into A by distillation, the mixture was stirred under ice-cooling (1—2 h) until a clear green color was obtained. The solution was filtered in order to remove insoluble substance and the filtrate was put into three tubes (B, C, and D), which were subjected to determination of radical concentration and spectral measurements.

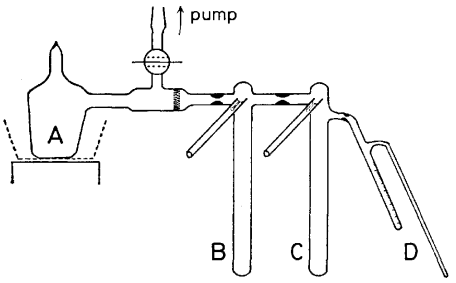

Fig. 8. Apparatus for radical preparation.

Spectral Measurements. A Cary 14 spectrophotometer was used to record absorption spectra. A specially constructed glass Dewar vessel[20] was used to measure the spectra at 77 K. ESR spectra were measured with a Varian E-4 ESR spectrometer. Electrolytic generation of radicals was carried out in the cavity of the spectrometer using acetonitrile or *N,N*-dimethylformamide as the solvent and tetrapropylammonium perchlorate as the supporting electrolyte. A JEOL spectrum computer, JEC-5, was used for spectral simulation.

The investigation was supported by the Asahi Glass Technological Foundation. We thank Prof. Shuichi Seto for his advice and Mr. Takashi Muramatsu for the preparation of pyridinium salts.

Hydrogen Atom Abstraction of *p*-Chloranil Triplet in 1,4-Dioxane in the Presence and Absence of Tetrachlorohydroquinone

Harumichi KOBASHI,* Yasunaka TOMIOKA, and Toshifumi MORITA

Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received September 7, 1978)

Mechanisms of hydrogen atom abstraction by triplet *p*-chloranil [CA(T)] from 1,4-dioxane (DOH) and tetrachlorohydroquinone (CAH_2) were studied in detail by means of nanosecond laser flash photolysis. A broad band around 740 nm in the transient absorption spectrum of CA in DOH was assigned to the charge-transfer band of the triplet EDA complex between CA and DOH. Efficiencies for the hydrogen atom abstraction from DOH and CAH_2 were determined to be 0.13 and 0.58, respectively. The former value indicates that the hydrogen atom abstraction from DOH is less effective than a physical process in deactivation of the triplet complex. From the latter value together with the measured value of the quenching rate constant (1.7×10^9 dm^3 mol^{-1} s^{-1}) of the triplet by CAH_2, it is inferred that the hydrogen atom abstraction of CA(T) from CAH_2 takes place competing with an efficient radiationless deactivation *via* the triplet exciplex between CA(T) and CAH_2 as a common intermediate.

In a previous work a report was given on the interaction of *p*-chloranil triplet with several vinyl monomers and solvents.[1] It was found that the hydrogen atom abstraction by CA(T) depends remarkably on the charge-transfer (CT) interaction between CA(T) and the hydrogen donors, and that CAH_2 added quenches CA(T) efficiently in company with simultaneous formation of *p*-chloranil semiquinone radical (CAH·) through the CA(T)$+CAH_2\rightarrow$2CAH· reaction. We have carried out an extended study on the mechanism, especially on the possible existence of exciplex as an intermediate for the hydrogen atom transfer. In general, the intersystem crossing (ISC) can be enhanced as in EDA system,[2] when a remarkable CT interaction occurs. Deactivation of CA(T) may thus be considered to proceed through the triplet exciplex as a common intermediate for the hydrogen atom transfer from CAH_2 competing with physical quenching leading to the ground state. In order to confirm this the determination of efficiency of CAH· formation due to hydrogen atom transfer might be valuable. This work deals with the nanosecond laser flash photolysis of CA in DOH and the addition effect of CAH_2 on the efficiency of CAH· formation.

Experimental

The nanosecond flash photolysis at 347 nm by a ruby laser was carried out at room temperature with use of the apparatus described previously.[1] Photomultipliers HTV-1P28 and HTV-R106 were used for analysis in the wavelength ranges of $\leq$650 nm and 650—1000 nm, respectively, according to the low noise operation technique developed by Hunt and Thomas.[3] The intensity of the laser pulse was measured with a photodiode (HP 4220), the output being recorded digitally on a hand-made peak-hold meter[4] calibrated with a thermopile (TRG, Model 107) and a pulse generator (Anritsu, MG 411B). When the laser intensity was too high the decay of the triplet chloranil showed a considerably nonexponential feature at the initial stage owing to the triplet-triplet annihilation. In order to reduce this effect the energy of the excitation pulse was attenuated to less than 25 mJ/pulse by glass plates.

p-Chloranil (CA), tetrachlorohydroquinone (CAH_2), and benzophenone were the same as used previously.[1] 1,4-Dioxane (DOH, the letter H is used separately from others in order to emphasize a hydrogen atom which is abstracted) and benzene (Dotite spectrograde) were used without purification. The benzophenone solution in benzene was used as a reference for the determination of the extinction coefficient of CA(T). The concentrations of CA and CAH_2 were 2.5×10^{-3} mol dm^{-3} and $\leq2.5\times10^{-3}$ mol dm^{-3}, respectively. The sample solutions subjected to photolysis were degassed by freeze-pump-thaw cycles. Fresh solutions were used separately for time resolved spectral measurements, determination of efficiencies of CAH· formation, and measurement of extinction coefficient of CA(T), respectively.

Results and Discussion

CA–DOH System. Figure 1a shows the ground state absorption spectrum of CA in DOH. The absorption with a maximum at *ca.* 335 nm can be assigned to the CT band of the EDA complex between CA and DOH according to the linear relationship[2] between the CT band energies and ionization potentials of donors. The intensity of the CT absorption band at 347 nm is considerably higher than that of the absorption of CA in non-interacting solvent such as 1,2-dichloroethane (DCE) (Fig. 1b). The laser light for excitation is thus absorbed pracically only by the EDA complex between CA and DOH.

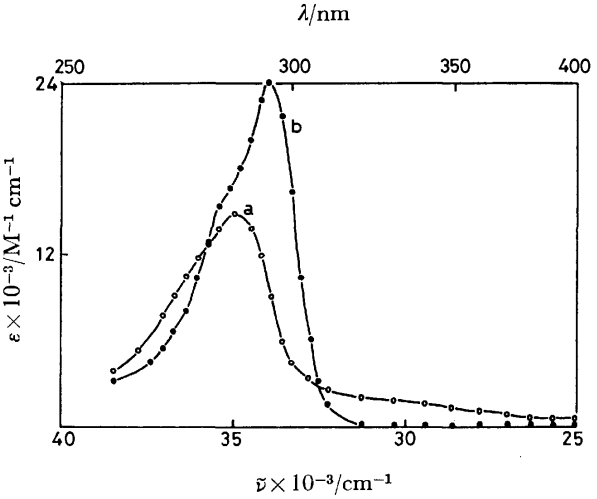

Fig. 1. Electronic absorption spectra of *p*-chloranil in 1,4-dioxane (a) and 1,2-dichloroethane (b).

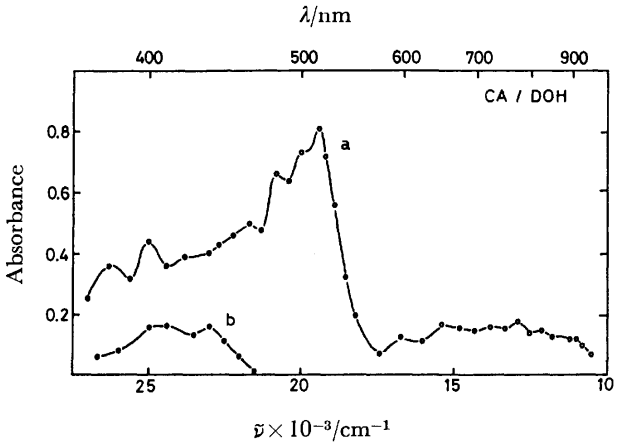

Fig. 2. Transient spectra from laser photolysis of degassed solution of CA (2.5×10^{-3} mol dm^{-3}) in DOH taken at different time after the end of excitation pulse: (a) $t=0$ and (b) $t=8$ μs.

The transient absorption spectra obtained by laser photolysis are shown in Fig. 2. The spectrum immediately after excitation (Fig. 2a) consists of a strong band with a maximum at 515 nm and a weak, broad band in the region 600—900 nm. The spectrum in the wavelength region less than 400 nm has only a qualitative significance since the ground state absorption of CA considerably overlaps in this region and the transient absorption is distorted by the recovery of CA after the photolysis. Concerning the identification of the spectrum (Fig. 2a), the following observations are noted. (1) The strong absorption band around 515 nm is very similar in wavelength position and shape to that of CA(T) in other solvent systems.[1] The decay time of this band which obeys pseudo-first order kinetics in the time range from just after pulsing to 10 μs is obtained to be 3.4 μs. (2) The absorption in the long wavelength region has a maximum at *ca.* 740 nm, its decay profile being almost the same as that of the 515 nm band. (3) By addition of CAH_2 to the solution, the two bands were quenched efficiently, decaying with an identical time constant. (4) The transient absorption spectrum obtained on photolysis of an aerated solution of CA resembles very closely that shown in Fig. 2a. It decays rapidly keeping its whole spectral feature, no new bands appearing after complete decay.

We identified the spectrum immediately after excitation (Fig. 2a) as the one attributable to the triplet EDA complex between CA and DOH, although the band due to CA(T) free from the CT interaction with the solvent would be superposed a little. Thus, the band located around 515 nm can be assigned to the local triplet-triplet absorption in CA moiety. On the other hand, the band in the longer wavelength region may be assigned to the CT transition from DOH to CA(T) for the following reasons. Ionization potentials, 9.13 eV,[5] of 1,4-dioxane is comparable with 9.245 eV[5] of benzene. Both of the CT bands of CA complexes with 1,4-dioxane and benzene in the ground state are located closely together in energy *i.e.*, 3.7 and 3.6 eV,[6] respectively. Since benzene forms a triplet complex with CA having the CT absorption band beyond 550 nm,[7] it is expected that the triplet complex of CA–DOH also has the corresponding absorption in a similar wavelength region. By the same consideration as given by Kawai *et al.*,[7] the CT band of the complex between CA(T) and DOH can be roughly estimated by

$$E_{CT}^{T} = E_{CT}^{G} - E_{T}$$

where E_{CT}^{T} and E_{CT}^{G} are the CT transition energies of the complex in the triplet and the ground state, respectively, and E_T is the energy of CA(T) above the ground state. When we take 3.7 eV for E_{CT}^{G} and 2.1 eV[8] for E_T, E_{CT}^{T} is calculated to be 1.6 eV (=770 nm), in agreement with the experimental value, 1.68 eV (=740 nm). The assignment for the long wavelength band seems to be reasonable.

After the disappearance of the 515 and 740 nm bands, the relatively weak absorption with maximum at 435 nm still remains. Figure 2b shows the absorption at 8 μs after the end of the excitation pulse, the band shape resembling that of CAH· in CA–DCE system.[1] The absorption also resembles that of CAH· produced through the $CA(T)+CAH_2\rightarrow 2CAH\cdot$ reaction. The decay of this long-lived transient was approximately of the second order. We thus identify, the transient spectrum as that of CAH·. Wong *et al.*[9] identified the corresponding transient in the same system as CAH· which decays by the disproportionation with a second order rate as observed by means of electron spin resonance spectroscopy. It is obvious that the CAH· has been produced through the interaction of CA(T) with the solvent, since no absorption around 435 nm could be detected by the addition of a quenching species for CA(T) as in styrene[1] or air.

If the intersystem crossing of CA from S_1 to T_1 proceeds with unit efficiency ($\Phi_{ISC}=1$) as is the case for duroquinone,[10] the extinction coefficient of CA(T), $\varepsilon_{CA(T)}$, interacting with DOH can be determined by comparison with that of benzophenone triplet.[1] The value of $\varepsilon_{CA(T)}$ at 515 nm was found to be $(5.8\pm0.1)\times10^3$ dm^3 mol^{-1} cm^{-1}. The extinction coefficient of CAH· in DOH, $\varepsilon_{CAH\cdot}$, is known to be 7.7×10^3 dm^3 mol^{-1} cm^{-1} at 435 nm.[9] Using these values, we can estimate the yield (Φ_r^0) of CAH· produced from CA(T) in DOH by

$$\Phi_r^0 = \frac{D_{CAH\cdot}(435)/\varepsilon_{CAH\cdot}(435)}{D_0(515)/\varepsilon_{CA(T)}(515)}$$

where $D_0(515)$ is the absorbance at 515 nm just after the cessation of the pulse and $D_{CAH\cdot}(435)$ is the residual absorbance at 435 nm at the time when CA(T) disappeared completely. A small amount of CAH· absorption decayed before this was neglected because the cecay of CAH· is considerably slower than that of CA(T). Φ_r^0 was estimated to be 0.13 ± 0.03 by five runs. The error indicated is the maximum deviation from the mean. Since CAH· is considered to be produced through the reaction sequence, $CA(S_0)\cdots DOH \xrightarrow{h\nu} CA(S_1)\cdots DOH \xrightarrow{ISC} CA(T)\cdots DOH \rightarrow CAH\cdot + DO\cdot$, the efficiency ($\phi_r^0$) of CAH· formation from CA(T) interacting directly with solvent DOH is related to Φ_r^0 by $\Phi_r^0=\Phi_{ISC}\phi_r^0$ where $\Phi_{ISC}=1$. We then have $\phi_r^0=0.13$. This indicates that the hydrogen atom abstraction from the solvent contributes to deactivation of CA(T) to a smaller

extent than the physical quenching process. The first order rate constants of CAH· formation (k_r^0) and another deactivation process (k_d^0) of CA(T) are evaluated to be 3.8×10^4 s^{-1} by use of $k_r^0=\phi_r^0/\tau_T^0$ and 2.6×10^5 s^{-1} by use of $k_d^0=(1-\phi_r)/\tau_T^0$, respectively, where τ_T^0 is the lifetime of CA(T). Thus, the deactivation processes of CA(T) interacting with DOH [CA(T)···DOH] are expressed as follows:

$$\mathrm{CA(T)\cdots DOH} \longrightarrow \mathrm{CAH\cdot + DO\cdot}, \quad k_r^0 = 3.8\times10^4\ \mathrm{s^{-1}} \qquad (1)$$

$$\mathrm{CA(T)\cdots DOH} \longrightarrow \mathrm{CA\cdots DOH}, \quad k_d^0 = 2.6\times10^5\ \mathrm{s^{-1}} \qquad (2)$$

CA–CAH$_2$–DOH System. The ground state absorption spectrum in CA–CAH$_2$–DOH system, which is not illustrated here, was exactly the same as that constracted by the superposition of individual spectrum of CA and CAH$_2$ in DOH up to the maximum concentration of CAH$_2$. No spectral evidence of complexation was obtained between CA and CAH$_2$ in the ground state at room temperature.

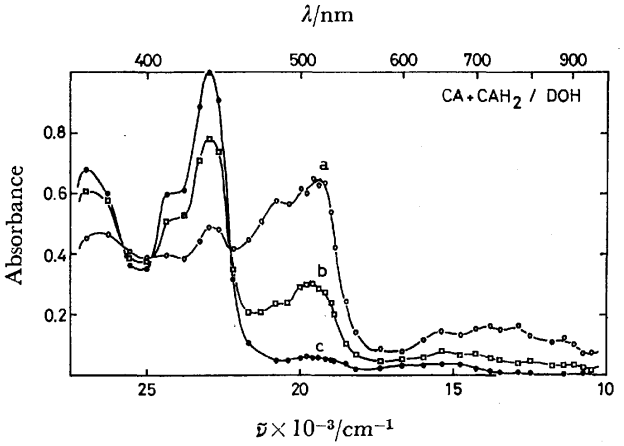

Fig. 3. Transient spectra observed in CA (2.5×10^{-3} mol dm^{-3})–CAH$_2$ (2.5×10^{-3} mol dm^{-3})–DOH system: (a) $t=0$, (b) $t=200$, and (c) $t=600$ ns after pulsing.

Figure 3 shows the transient spectra in CA–CAH$_2$–DOH system at an equal concentration of CA and CAH$_2$, 2.5×10^{-3} mol dm^{-3}. The spectrum obtained immediately after pulsing is very similar to that shown in Fig. 2a except for a small increase around the 435 nm band. With the lapse of time the triplet absorption beyond 500 nm decays rapidly and the 435 nm band grows remarkably. It is apparent that the band around 435 nm is attributed to the characteristic band of CAH· produced by the CA(T)···DOH+CAH$_2$→2CAH· reaction. This is also confirmed by the simultaneous increase of another characteristic band of CAH· at *ca.* 370 nm. There are isosbestic points at 22.3×10^3, 24.8×10^3, and 25.8×10^3 cm^{-1}. This indicates that the growing-up of CAH· absorption around 435 nm is not disturbed by any transient species formed by processes other than the CA(T)···DOH+CAH$_2$→2CAH· reaction. The CAH· absorption decays exactly according to the second order kinetics after reaching the maximum. The decay rate constant (k_t) obtained is 4.5×10^8 dm^3 mol^{-1} s^{-1}, in good agreement with the reported value, 4.1×10^8 dm^3 mol^{-1} s^{-1}. [9]

The small peak at 435 nm (Fig. 3a) may be assumed to be due to absorption of CAH· produced within the time of excitation pulse width. This is understandable on the basis of the following observations. The 435 and 515 nm-band intensities immediately after pulsing show dependence upon the concentrations of CAH$_2$ added; increase of CAH$_2$ concentration makes the 515 nm band decrease and the 435 nm band increase. This shows that the small peak at 435 nm immediately after pulsing is due to CAH· produced within the pulse width. This is also supported by the kinetic analysis at 435 nm. After subtraction of the 435 nm absorbance presumed to be due to CAH· produced within laser excitation and the absorbance due to CA(T) contributing to 435 nm from the observed absorbance, the remaining absorbance which corresponds to that of CAH· produced gradually by the reaction between CA(T)···DOH and CAH$_2$ gives a rise time approximately equal to the decay time of the triplet monitored at 515 nm. The kinetic behavior of 435 nm absorption can thus be analyzed. Production of CAH· from the excited singlet state of CA would be rare if occurring at all. The finite difference between the 435 nm absorbances (Figs. 2a and 3a) does not indicate the existence of the triplet exciplex between CA(T) and CAH$_2$.

In general, the quenching processes of CA(T) interacting with DOH by CAH$_2$ can be represented by

$$\mathrm{CA(T)\cdots DOH + CAH_2} \longrightarrow \mathrm{2CAH\cdot + DOH}, \quad k_r \qquad (3)$$

$$\mathrm{CA(T)\cdots DOH + CAH_2} \longrightarrow \mathrm{CA\cdots DOH + CAH_2}. \quad k_d \qquad (4)$$

Reaction 3 represents the hydrogen atom abstraction from CAH$_2$ and Reaction 4 the physical quenching. The relation between the yield (Φ_r) of CAH· generated after the cessation of pulsing and the efficiency (ϕ_r) of CAH· formation through the interaction between the triplet and CAH$_2$, is expressed by

$$\Phi_r = \frac{\phi_r^0(k_r^0+k_d^0)+2\phi_r k_q[\mathrm{CAH_2}]}{(k_r^0+k_d^0)+k_q[\mathrm{CAH_2}]} = \{(\phi_r^0/\tau_T^0)+2\phi_r k_q[\mathrm{CAH_2}]\}\tau_T, \qquad (5)$$

where, τ_T and τ_T^0 are lifetimes of CA(T) in the presence and absence of CAH$_2$, respectively, ϕ_r^0 is the efficiency of CAH· formation by the interaction with solvent (DOH in this case), $k_q(=k_r+k_d)$ is the quenching rate constant of CA(T)···DOH by CAH$_2$, and [CAH$_2$] is the molar concentration of CAH$_2$. The value of k_q was determined to be 1.7×10^9 dm^3 mol^{-1} s^{-1} from the plot corresponding to the $1/\tau_T=1/\tau_T^0+k_q[\mathrm{CAH_2}]$ equation. Since k_q is so high as to be close to the value for diffusion control, when CAH$_2$ of adequate concentration is present, Eq. 5 can be simplified to

$$\Phi_r = 2\phi_r(1-\tau_T/\tau_T^0) \qquad (6)$$

for the case of $\phi_r^0/\tau_T^0 \ll 2\phi_r k_q[\mathrm{CAH_2}]$, or

$$\Phi_r = 2\phi_r \qquad (7)$$

for the case of $\tau_T \ll \tau_T^0$. When CAH$_2$ is absent, Eq. 5 becomes $\Phi_r=\phi_r^0$ in accordance with Φ_r^0. On the other

hand, Φ_r is obtained experimentally from absorbance changes:

$$\Phi_r = \frac{\{D_{max}(435) - \Delta D_0(435)\}/\varepsilon_{CAH\cdot}(435)}{D_0(515)/\varepsilon_{CA(T)}(515)} \quad (8)$$

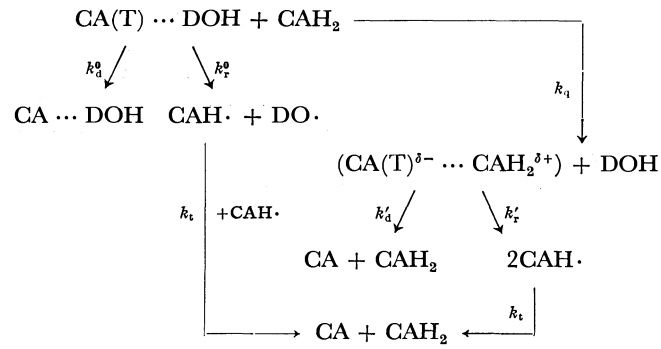
where $D_0(515)$ is the absorbance at 515 nm immediately after pulsing, $D_{max}(435)$ the maximum absorbance at 435 nm, and $\Delta D_0(435)$ the absorbance at 435 nm of CAH· formed within laser excitation. $\varepsilon_{CA(T)}(515)$ and $\varepsilon_{CAH\cdot}(435)$ are as noted before. Hence, $\phi_r(=k_r/(k_r+k_q)=k_r/k_q)$ can be calculated by combining Eq. 5 with Eq. 8. The average value of ϕ_r was found to be 0.58 ± 0.05[11] from 15 different observations for three different concentrations of CAH_2, 2.5×10^{-3}, 2.0×10^{-3}, and 1.5×10^{-3} mol cm^{-3}. The error indicated is the standard deviation. The results are summarized in Table 1.

Table 1. Rate parameters and the extinction coefficient obtained by laser flash spectroscopy in CA–DOH and CA–CAH_2–DOH systems

CA(T)···DOH	CA(T)···DOH+CAH_2
$\phi_r^0=0.13$	$\phi_r=0.58$
$\tau_T^0=3.4$ μs	$k_q=1.7\times10^9$ dm^3 mol^{-1} s^{-1}
$k_r^0=0.4\times10^5$ s^{-1}	$k_r=1.0\times10^9$ dm^3 mol^{-1} s^{-1}
$k_d^0=2.5\times10^5$ s^{-1}	$k_d=0.7\times10^9$ dm^3 mol^{-1} s^{-1}
$\varepsilon_{CA(T)}(515)=5.8\times10^3$ cm^3 mol^{-1} cm^{-1}	$k_t=4.5\times10^8$ dm^3 mol^{-1} s^{-1}

In the absence of CAH_2, CA(T)···DOH decays by the hydrogen atom abstraction from DOH but mainly by the physical process of deactivation. This is similar to the previous result in DCE or acrylonitrile.[1] It is evident from k_r and k_d values that Reaction 4 is present competing with Reaction 3 in the efficient quenching (see k_q value) of CA(T)···DOH by CAH_2 and the two processes take place with almost the same probability, indicating that ISC of CA(T) is enhanced by the interaction with CAH_2. This is often observed in the excited singlet[12] and the triplet state[13] in electron transfer or charge-transfer quenching. Recently, Steiner and Winter elucidated the mechanism of the physical quenching of thionine triplet competing with radical formation by halogenated anilines.[14] Their result is explained in terms of a heavy atom effect on ISC (occurring after nearly complete electron transfer) in a triplet exciplex. In the present hydrogen atom abstraction, the existence of such an enhanced ISC also seems to favor an exciplex as an intermediate. Results suggesting the existence of exciplex are as follows. (1) A study[15] on the solvent effect of CAH· formation yield strongly suggests the CT nature of the intermediate in question; the efficiency of the hydrogen atom abstraction increases with solvent polarity. (2) In fluid media no CT band is found in the CA and CAH_2 system nor in the duroquinone and durohydroquinone system.[16] However, DOH solution of the former system shows pink coloration in the frozen state at liquid nitrogen temperature. Even *p*-benzoquinones substituted by very bulky groups such as chlorine or methyl form the quinhydrone type complexes[17] with hydroquinone in the solid state.[18] The above finding seems to be attributed to the same type of complex under restricted conditions. In the triplet state the electron affinity of CA becomes greater than in the ground state. Thus, even in fluid media, CA(T) might form a quinhydrone type complex with CAH_2 by the aid of the CT force surpassing the steric hindrance caused by bulky chlorine atoms. We may assume that the triplet exciplex between CA(T) and CAH_2 exists as a precursor for the hydrogen atom abstraction. This is essentially the same as suggested by Amouyal and Bensasson for duroquinone triplet reduction by durohydroquinone.[10]

From an unified point of view, deactivation processes of CA(T)···DOH in the absence and presence of CAH_2 are as follows:



where the ground state CA is the same as CA···DOH in the DOH solvent, $(CA(T)^{\delta-}\cdots CAH_2^{\delta+})$ represents the triplet exciplex with some charge-transfer interaction between CA(T) and CAH_2, k_d' and k_r' are the first order rate constants for the ISC and the semiquinone radical formation in the exciplex, respectively, and other rate constants having their usual meanings. If we define the quenching probability per collision as γ, k_q is replaced by γk_D where k_D is the diffusion controlled rate constant calculated by $8RT/(3000\,\eta)$. The value of γ is obtained as 0.34 in DOH at 24 °C. In other solvents γ values were found to be of the same order of magnitude.[19] The quenching reaction can be considered as a diffusion controlled reaction. The parameters given in Table 1 are related to the rate parameters in this scheme:

$$k_q = \gamma k_D$$
$$k_r = \gamma k_D \cdot k_r'/(k_r'+k_d')$$
$$k_d = \gamma k_D \cdot k_d'/(k_r'+k_d')$$
$$\phi_r = k_r'/(k_r'+k_d')$$

The values of k_r' and k_d' would be so large that no exciplex absorption could be observed.

Although no absorption spectrum due to exciplex could be detected, the existence of the triplet exciplex from which the hydrogen atom abstraction takes place competing with the intersystem crossing to the ground state may be postulated in order to understand the mechanism of the hydrogen atom abstraction by CA(T) from CAH_2.

Anodic Oxidation of *N,N*-Dimethyl-*m*-toluidine at a Platinum Electrode in an Acetonitrile Solution

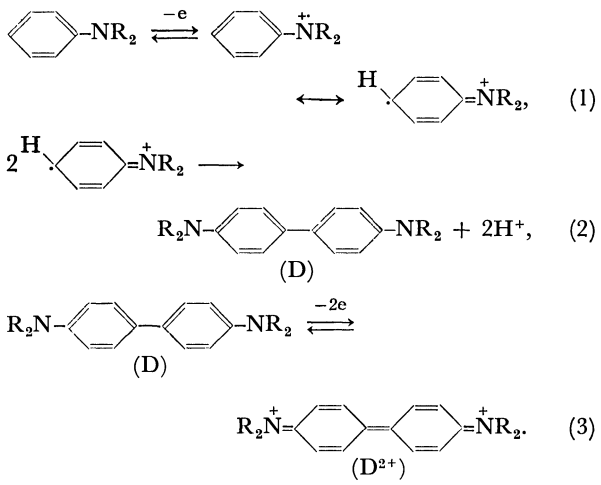
Kazuo YASUKOUCHI, Isao TANIGUCHI,* Hiroko YAMAGUCHI, and Tatsuya TANOUE

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, 2-39-1, Kurokami, Kumamoto 860

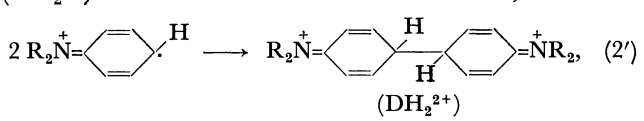
(Received September 9, 1978)

The electrochemical behavior of *N,N*-dimethyl-*m*-toluidine (DMMT) in an acetonitrile solution at a Pt electrode was investigated. By controlled-potential oxidation at 0.65 V (*vs.* Ag/0.01 mol dm^{-3} $AgClO_4$), the dihydro compound (**I-a**), which had been considered to be an intermediate in the reaction forming benzidine, was probably obtained. **I-a** was gradually converted to *N,N,N',N'*-tetramethyl-2,2'-dimethylbenzidine (TMMB) in the solution within several hours. **I-a** was easily converted to TMMB by the cathodic re-reduction at −0.9 V or by adding either pyridine or water; this reaction pathway is useful for the synthesis of TMMB. Preliminary mechanistic information on the anodic oxidation of DMMT is also given by cyclic and ring-disk electrode voltammetry, current-reversal chronopotentiometry, and controlled-potential coulometry. The proposed reactions are: A$-$e$\rightarrow$A$^+$, A$^+$+A$\xrightarrow{k}$A-A$^+$, and A-A$^+-$e$\rightarrow DH_2^{2+}$, where A and A$^+$ are, respectively, DMMT and its cation radical, DH_2^{2+} is the dihydro compound (**I-a**), and k is the rate constant of the coupling reaction (*ca.* 5×10^3 dm^3 mol^{-1} s^{-1}). TMMB is formed by: DH_2^{2+}+2e(or 2Py)$\rightarrow$D+H_2(or 2PyH$^+$), where D is TMMB and Py is pyridine.

N,N-dialkyl-substituted aromatic amines show very similar behavior to each other on the anodic oxidation in a nonaqueous solution. In the case of *N,N*-dimethylaniline (DMA),[1] the primary electrode reaction is a one-electron transfer to form a cation radical which then couples to form *N,N,N',N'*-tetramethylbenzidine (TMB) with simultaneous loss of protons. TMB thus formed is more readily oxidized than the starting amine and is converted to the diquinoid structure (TMB^{2+}). Thus, a general reaction scheme is



In the coupling reaction (Eq. 2), the dihydro compound (DH_2^{2+}) is considered to be an intermediate,[2]



and D is formed by loss of protons from DH_2^{2+}.

The same reactions as Eqs. 1—3 were proposed for DMA also in $AlCl_3$–NaCl melts.[3] However, an intermediate such as DH_2^{2+} is usually unstable and has not yet been isolated. Furthermore, some coupling reactions other than Eq. 2 are possible, but the mechanism has usually not been clarified.

The aims of this paper are to describe the interesting fact that a DH_2^{2+}-like compound was formed by the anodic oxidation of *N,N*-dimethyl-*m*-toluidine (DMMT), to give preliminary information on the mechanism of this electrode reaction, and also to describe the fact that *N,N,N',N'*-tetramethyl-2,2'-dimethylbenzidine (TMMB) was easily synthesized by the re-reduction of the oxidation product of DMMT or by adding a base to the product.

DMMT was adopted for the present study because (i) the ring-substituted methyl group makes the cation radical stable, and thus the coupling reaction may be easily examined, (ii) the low basicity of DMMT[4] compared to its isomers may decrease the complication of the oxidation pathway due to protonation of the parent molecule, and (iii) no study has been reported on the anodic oxidation of DMMT in a nonaqueous solution.

Experimental

DMMT (analytical GR grade) was used as received. Sodium perchlorate (analytical EP grade) was recrystallized twice from ethanol, dried overnight under a reduced pressure (3 mmHg, 1 mmHg≈133.3 Pa), and stored over silica gel. Acetonitrile (MeCN) was purified by distillation from P_2O_5, from K_2CO_3, and then three times by slow fractional distillation. The water content of the MeCN (0.18 wt %) was determined by the Karl-Fischer titration.

Cyclic voltammograms were measured at a Pt disk electrode (1.96×10^{-3} cm^2) sealed in a soft glass using a set of Yanaco P8 polarographs. The working electrode was polished with an oilstone before each measurement. The counter electrode was an Hg pool (*ca.* 3 cm^2). A Ag/0.01 mol dm^{-3} $AgClO_4$ couple in MeCN, which was connected to the test solution with a 1 mol dm^{-3} $NaClO_4$ agar bridge, was used as a reference electrode. All potentials appearing in this paper are referred to this electrode (whose potential was 0.19 V *vs.* SCE).

Macro-scale electrolyses were carried out using a Nikko Keisoku NPGS 301 potentiostat. A two-compartment cell with a fine glass frit was used. The anode electrolyte was usually 200 ml in volume. The working and the counter electrodes were planar Pt. During electrolysis, cyclic voltammograms of the solution were measured at suitable times to check the changes of the composition of the solution. Low concentrations of DMMT (<10 mmol dm^{-3}) were used

because a benzidine-type product was generally formed predominantly at a low concentration of a starting amine.[5] After exhaustive oxidation at 0.65 V (*vs.* Ag/Ag^+), the product I was obtained as follows: After evaporation of the solvent and then addition of 100 ml of aqueous 0.2 mol dm^{-3} $HClO_4$ to remove the supporting electrolyte, I was extracted with benzene and was obtained by evaporation of the benzene. When the supporting electrolyte was removed by water with no perchloric acid, the same product as II described below was obtained. Since the product I was gradually converted to product II in the test solution within several hours and its stability depended sensitively upon the concentration of water contained in the solution, repeated trials for obtaining I were made to get reproducible data. The product II, which was produced by re-reduction at −0.9 V of the solution obtained by exhaustive oxidation at 0.65 V, was obtained by the same method as that used for the product I except for the use of water to remove the supporting electrolyte. To check the purity of the products, they were chromatographed on both an alumina (Wako B-10F) and a silica gel (Wako B-10) with benzene, and the chromatograms obtained were developed with iodine. For both products, three spots due to products I and II, and DMMT which remained unreacted, were detected. Thus, I obtained here contained II (typically about 10—20 %) and a small amount (less than 5 %) of DMMT, while II obtained here contained only a small amount of DMMT and a trace amount of I. For both products I and II without further purification, IR (in KBr wafer using a Hitachi 125 G spectrophotometer), NMR (in $CDCl_3$ using a Hitachi R-24 at 60 MHz), and mass (at 75 eV using a JOEL JMS D-100) spectra were measured. A UV spectrum of the test solution was measured by a Hitachi 200-10 spectrophotometer.

Other electrochemical measurements for rotating ring-disk electrode (RRDE) voltammetry and current-reversal chronopotentiometry (CRC) were carried out by using commercially available apparatuses constructed by Nikko Keisoku. All experiments were carried out at 25±0.3 °C.

Results and Discussion

The cyclic voltammogram of DMMT exhibited one anodic wave (Ia) having a peak potential (E_p) of 0.45 V (Fig. 1a), and no other appreciable wave was observed near this peak. To obtain the oxidation product, controlled-potential electrolysis at 0.65 V was carried out. During electrolysis the height of the wave Ia decreased and a new irreversible reduction wave (IIc) appeared at $E_p = -0.83$ V (Fig. 1b). Since no wave was observed at the potential near 0.45 V, TMMB was not produced because TMMB, if formed, must be oxidized at a somewhat less anodic potential than that for the wave of DMMT. The vicinity of the anode was colored pink, which might be due to the formation of the cation radical of DMMT, and the bulk solution became green. By coulometry for a 5 mmol dm^{-3} DMMT solution, 0.97 electrons/molecule of DMMT were consumed and the product I was obtained.

Controlled-potential re-reduction at −0.9 V was carried out consecutively after exhaustive oxidation at 0.65 V. 0.9 electrons/molecule of DMMT were consumed to make the reduction wave IIc on the voltammogram of the solution disappear; the solution turned dark brown and this color no longer changed to green by the anodic re-oxidation. The cyclic voltammogram of the solution obtained by the re-reduction showed one reversible wave (IIIa/IIIc) at a somewhat less anodic ($E_p = 0.42$ V for IIIa) potential than that for DMMT (Fig. 1c). This suggests that TMMB is produced by the re-reduction of the product I. In confirmation of this consideration product II was isolated after exhaustive re-reduction of I. Both products I and II thus obtained were analyzed to determine their structures, and the characteristics of the analytical data are summarized in

Table 1. Analytical data on the products (I and II) and DMMT

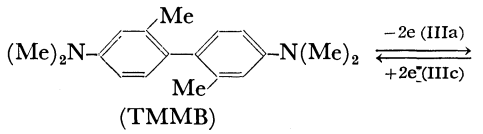
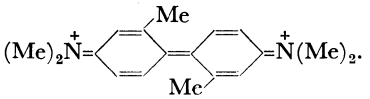
a) Before controlled-potential electrolysis, b) after exhaustive oxidation at 0.65 V, and c) after exhaustive re-reduction at −0.9 V.

Table 1.

Re-reduction Product II. Comparing the analytical data on II with those on DMMT, we easily find that II is TMMB, as was suggested by the cyclic voltammetric behavior. The reasons for the conclusion that II is identical with TMMB are as follows. a) The IR data on II show that (i) C–N stretching absorption of the tertiary aromatic amine at 1350 cm^{-1} remains and (ii) absorption due to C–H bending of the 1,3-substituted aromatic ring at 692 and 767 cm^{-1} observed for DMMT changes to those of the 1,2,4-substituted one at 808, 815, and 832 cm^{-1}. b) The NMR data on II indicate that (i) since the peak of methyl protons on the ring shifts to a higher field (δ=2.04 for II and δ=2.30 for DMMT), a shift which probably results from the ring-current effect, the methyl group is not coplanar to the ring and thus a 2,2′-dimethylbiphenyl-type structure is suggested, and (ii) the number of aromatic protons reduces to three-fourths of that of DMMT. c) In the mass spectrum, the parent ion peak of TMMB is observed (Found: *m/e* 268.5, Calcd for TMMB: M, 268.4) and the fragmentation is also reasonably explained. d) The UV spectrum of II is similar to that of 2,2′-dimethylbenzidine[6] (the red-shift of λ_{max} for II is explained in terms of the replacement of H atoms on nitrogen with methyl groups). e) The electrochemical data are also consistent with the conclusion of the formation of TMMB, and the reaction for the wave IIIa/IIIc is



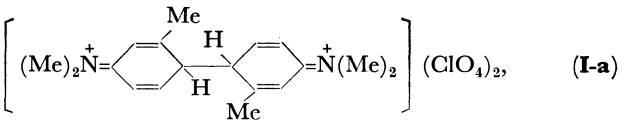
(TMMB)



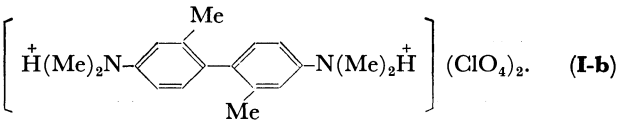
(TMMB^{2+}) (4)

Furthermore, anodic oxidation of II gave a blue solution having absorption maxima at 378 and 680 nm, a result which is similar to that reported for the oxidation of 3,3′-dimethylbenzidine.[7] Thus, TMMB was formed either by the re-reduction or by adding a base after exhaustive oxidation of DMMT in MeCN. This simple method is useful for the synthesis of TMMB in the yield of 80—90%.

Oxidation Product I. Some remarkable differences in the analytical data on I from those on DMMT and TMMB are observed. However, since TMMB is easily produced by the reduction of I or by adding pyridine (or a base) to I, the structure of I must be similar to that of II. The strong absorption at 1120 cm^{-1} in the IR spectrum shows that I forms a salt with a perchlorate anion; the NMR data also support this conclusion because the electron density near *N,N*-dimethyl protons of I (δ=3.08) is lower than those of DMMT (δ=2.83) and TMMB (δ=2.92). The methyl-proton peak of I shifts to a higher field (δ=2.08) than that of DMMT (δ=2.30), as is observed for TMMB (δ=2.04), a fact which indicates that the structure of I is similar to that of TMMB. These results and the fact that no strong UV absorption of I was observed suggest the following two possible structures:



(I-a)

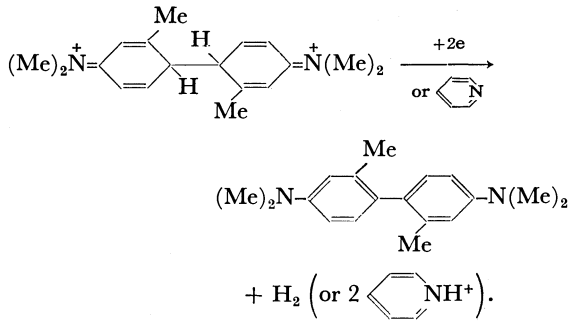


(I-b)

Thus, to determine the structure of I, we tried to distinguish between **I-a** and **I-b** by measuring the number of aromatic protons by integration of the NMR spectrum, but no reproducible result was obtained (the number of protons was 3—4). No appreciable absorption was observed for an N–H proton. However, the structure **I-b** is rejected because (i) in the IR spectrum of I, the C=C ring stretching absorption at 1491 and 1607 cm^{-1} is reduced and the C=N stretching absorption at 1687 cm^{-1} appears, and (ii) in the mass spectrum of I, the peaks at *m/e*=134 and 135 have larger intensity than that of the parent ion peak, a fact which shows that I has an unstable structure which can be split easily into two halves. On the other hand, the largest-intensity peak of **I-b** may be the parent ion peak, as is observed for TMMB. Thus, product I is determined to be the dihydro compound (**I-a**).

I-a was easily converted, as is expected from its

structure, to TMMB by cathodic reduction or by adding pyridine (or a base):



(5)

Oxidation Mechanism. To obtain mechanistic information on the formation of the dihydro compound (**I-a**), some preliminary experiments were carried out. By cyclic voltammetry, the ratio of the anodic peak current of the wave Ia to the square root of the scan rate, $i_{pa}/v^{1/2}$, decreased with increasing scan rate, and the ratio of the cathodic reversal current (i_{pc}) to i_{pa}, i_{pc}/i_{pa}, decreased with an increase in the concentration of DMMT (Table 2). These results are explained in terms of the reactions in which a second-order chemical reaction is involved between two charge-transfer reactions (so-called an ECE mechanism). Usually two possible types of coupling reactions are considered. One is dimerization of intermediates and the other is the coupling of an intermediate with a parent molecule. These two mechanisms are distinguishable by both RRDE voltammetry[8,9] and CRC.[10] Thus, RRDE voltammetry was first applied to obtain precise information. On the basis of Bard's method, the kinetic collection efficiency, $N_k(=-i_r/i_d$ where i_r and i_d are the ring and the disk currents, respectively), was measured as a function of the disk current, CONI ($=i_d/i_{d,l}$ where $i_{d,l}$ is a limiting disk current for the oxidation of DMMT). The N_k values decreased with increasing 1-CONI (Fig. 2). This trend shows[8] that the intermediate generated by the first charge-transfer reacts with the parent molecule and is further oxidized to form the dimer:

$$A - e \rightleftarrows A^+, \quad (6)$$

$$A^+ + A \xrightarrow{k} A\text{-}A^+, \quad (7)$$

$$A\text{-}A^+ - e \rightleftarrows DH_2^{2+}, \quad (8)$$

where A and A^+ are DMMT and its cation radical and DH_2^{2+} is the dihydro compound (**I-a**).

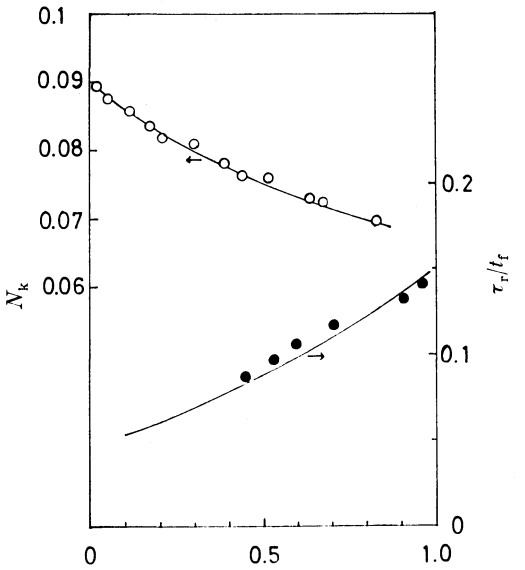

Fig. 2. Collection efficiency (N_k) *vs.* 1-CONI and τ_r/t_f *vs.* t_f/τ_r for oxidation of 1 mM DMMT in MeCN–0.1 M $NaClO_4$. Points are experimental data. For RRDE voltammetry the ring electrode was maintained at 0 V and the rotation rate of the electrode was 105 rad s^{-1}. For CRC the ratio of reverse to forward currents was 1/2 and $t_f=1.0$ s. Solid lines are simulated results corresponding to the rate constant of 5×10^3 M^{-1} s^{-1} (for RRDE) and 7×10^3 M^{-1} s^{-1} (for CRC) for Eqs. 6—8.

To give further support for this mechanism, CRC using the method developed by Evans[10] was also applied. The plots of τ_r/t_f *vs.* t_f/τ_f, where τ_f and τ_r are the forward and the reverse transition times, respectively, and t_f is the forward electrolysis time, showed an upward trend in τ_r/t_f values with increasing t_f/τ_f (Fig. 2); this trend also indicates[10] the above reaction pathway (Eqs. 6—8). By using a digital simulation method the rate constant for the coupling reaction (Eq. 7) was estimated to be approximately 5×10^3 dm^3 mol^{-1} s^{-1} (Fig. 2). To obtain an accurate value of k and more precise mechanistic information, the details of the kinetics of the reaction are being investigated by CRC and RRDE voltammetry and will be reported later.

This work was partially supported by the Asahi Glass Foundation for the Contribution to Industrial Technology. Mass spectra associated with this work were measured at the Japan Atomic Energy Research Institute at Tokai. The authors would like to thank Mr. Ichiro Tsuji for his help in the experiment.

Clustering Reactions of the Protonated Nitrogen N_2H^+ with Hydrogen Molecule in the Gas Phase

Kenzo HIRAOKA

Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received September 28, 1978)

Clustering reactions of the protonated nitrogen N_2H^+ with hydrogen molecule, $N_2H^+(H_2)_{n-1}+H_2=N_2H^+(H_2)_n$ $(n-1, n)$, were studied in a pulsed electron beam mass spectrometer with a high-pressure ion source. The values of enthalpy change $-\Delta H_{n-1,n}$(kcal/mol) and the entropy change $-\Delta S_{n-1,n}$(e.u.) obtained from the van't Hoff plots of equilibrium constants were (0, 1) 7.2, 22.6, (1, 2) 1.5, 14.0. No cluster ions larger than $N_2H^+(H_2)_2$ were observed even at −187 °C. The relatively low values of enthalpy change for the clustering reactions (0, 1) and (1, 2) suggest that the positive charge in N_2H^+ is delocalized, the N_2H^+ ion very weakly interacting with additional hydrogen molecules electrophilicly. The calculated entropy change also suggests that hydrogen molecules in $N_2H^+(H_2)_n$ are weakly bound to the core ion N_2H^+, having considerable freedom of motion in the cluster ion. The thermochemical study proves that the cluster ion $N_2H^+(H_2)_2$ does not have the structure of the protonated hydrazine $N_2H_5^+$.

Studies of ion-solvent molecule interactions in solution date back to the beginning of physical chemistry. However, it is only 10 years since a systematic study of ion-solvent molecule interactions in the gas phase was begun. Studies of ion-solvent clustering reactions in the gas phase provide direct indication of the preferred coordination of ions by solvent molecules and the energy relations between solvated species in the gas phase containing different numbers of coordinated solvent molecules.

A merit of studies in the gas phase by means of mass spectrometry is that the stoichiometry of detectable species can be deduced exactly. The mass spectrometric method also permits measurements of gas phase ion equilibria and their temperature dependence. These data in turn lead to enthalpies, entropies and free energies for ionic reactions. These thermochemical data often give information on the structure of ionic species.

A mass spectrometric study of the ions present in the air at near atmospheric pressures (≈100 Torr) led to the incidental observation[1,2] of the proton hydrates $H^+(H_2O)_n$ formed by ion-molecule reactions involving a trace of water vapor. The observation of clusters such as $NH_4^+(NH_3)_m(H_2O)_n$ and $H^+(CH_3OH)_n$ in ammonia, methanol and other gases led to the systematic study of ion-solvent molecule interactions and ion equilibria in the gas phase.[3] Because of hydrogen bonding, bond energies are very large in the water. Since the charge is very efficiently dispersed by hydrogen bonding, the relative stability difference between the favorable and the unfavorable structures is small.

Recently, Hiraoka and Kebarle investigated two clustering reactions, $H_3^+(H_2)_{n-1}+H_2=H_3^+(H_2)_n$ and $CH_5^+(CH_4)_{n-1}+CH_4=CH_5^+(CH_4)_n$.[4,5] From the thermochemical data obtained, they predicted the structure of H_3^+, CH_5^+ and of cluster ions $H_3^+(H_2)_n$ and $CH_5^+(CH_4)_n$. In both systems, the positive charge is not so well dispersed in the cluster ions as in the case of water system, because hydrogen and methane have no hydrogen bonding ability. Since the charge is not efficiently dispersed in the cluster ions, the relative stability differences between the favorable and the unfavorable structures are larger, thus making it easier to predict the structure of cluster ions.

In this investigation, the clustering reactions of the protonated nitrogen N_2H^+ with hydrogen molecule were studied. Since the protonated molecule and the solvent molecule are different, new information was expected.

Experimental

The ion-molecule reaction ion source and the mass spectrometer were described;[6] only a brief description of the procedures is given herewith.

The H_2 gas(Linde UHP) was purified by passing through a liquid nitrogen cooled trap containing molecular sieve 5 Å at atmospheric pressure. Downstream of this trap, the H_2 gas passed through a variable needle valve in order to reduce the pressure to 1—6 Torr, flowing in and out of the ion source. The H_2 gas thus prepared contains no impurities except a trace amount of nitrogen.[7]

Ionization is produced by a short pulse of 2 keV electrons which enters the sourse through a small slit (12 μm×2 mm, razor blade edges) of the field free ion source. The electron beam is pulsed "on" for 10 μs and "off" for 5 ms. Each pulse contains some 10^6 electrons. The primary ions H_2^+ and H^+ are rapidly converted by ion-molecule reactions into H_3^+. This species reacts further giving H_5^+, H_7^+, *etc.* The reaction occurs due to proton transfer from H_3^+ and H_5^+ to impurity N_2 leading to N_2H^+ and its hydrogen clusters. The vast majority of ions are ultimately destroyed by diffusion towards the wall. Some ions diffuse to the vicinity of an ion exit slit (12 μm×3 mm, razor blade edges) and escape into an evacuated region where they are accelerated, magnetically mass analyzed and detected with counting equipments attached to a multichannel analyser. Collection of some 10^4 pulses at a given m/e gave a satisfactory temporal profile of the ion with a channel dwell time of 20—30 μs.

The equilibrium constants for the clustering reactions $(n-1, n)$ were calculated by

$$K_{n-1,n} = I_n/I_{n-1} \times P_s$$

where I_n/I_{n-1} is the stationary intensity ratios of the corresponding cluster ions and P_s is the solvent (hydrogen) pressure.

Results and Discussion

General. The solvation of ions by neutral molecules is an exothermic process. Since the solvated

ions may fall apart or be collisionally dissociated to reform the original reactants, it is possible that thermodynamic equilibrium can be achieved under conditions where the complex can undergo sufficient collisions to remove the heat of reaction. By the rule of thumb the achievement of equilibrium can be determined by the rate of the slow reaction, which has a rate constant $k \approx 10^{-29}$ cm^6 molecule^{-2} s^{-1}. With this value one can calculate the half-life for the clustering reaction at 3 Torr of H_2 as 2×10^{-6} s or less. The subsequent steps in the clustering sequence require considerably shorter time since their rate constants are considerably higher. Thus, thermodynamic information about the clustering reactions can be obtained from equilibrium constants. At equilibrium we have

$$-RT \ln K = \Delta G = \Delta H - T\Delta S \qquad (1)$$

The enthalpy of reaction can be obtained from the slope of a van't Hoff plot. We can evaluate ΔS if ΔG and ΔH are known.

Results. Figure 1 shows the temperature and pressure ranges for the (0, 1) equilibrium. The equilibrium constant is independent of the hydrogen pressure. Figure 2 gives the van't Hoff plots of the

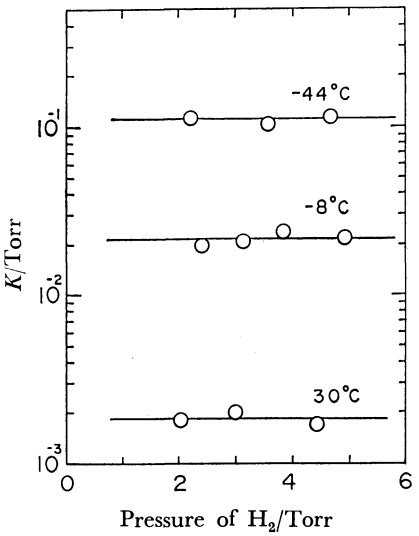

Fig. 1. Equilibrium constant $K_{0,1}$ for the reaction $N_2H^+ + H_2 = N_2H^+(H_2)$ at 3 temperatures plotted *vs.* hydrogen pressure. Standard state for K as given in these plots is 1 Torr.

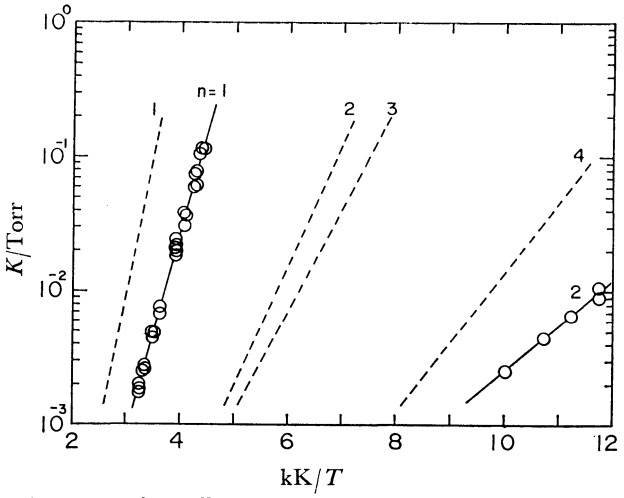

Fig. 2. van't Hoff plots for the reactions $N_2H^+(H_2)_{n-1} + H_2 = N_2H^+(H_2)_n (n-1, n)$. (----) plots for the reactions $H_3^+(H_2)_{n-1} + H_2 = H_3^+(H_2)_n$ $(n-1, n)$, Ref. 4.

clustering reactions of N_2H^+ with hydrogen molecule. For the sake of comparison the results of the clustering reactions of H_3^+ with hydrogen molecule[4] are given in Fig. 2. The thermochemical values obtained are given in Table 1 together with the results of H_2 solvation reaction of HCO^+.[8] The solvent molecule is hydrogen for all the reactions.

Free Energy and Enthalpy Change. Decrease in $\Delta H_{n,n-1}$ ($\Delta H_{n,n-1} = -\Delta H_{n-1,n}$) with n is observed as is always the case for ion clusters. The decrease is expected because of gradual charge dispersal with the addition of new clustering molecules. The irregularity of the van't Hoff plots for the clustering reactions of H_3^+ with H_2 shown in Fig. 2 was discussed.[4] In the hydrogen experiment, cluster ions $H_3^+(H_2)_n$ for $n=1$ to 4 were observed as major ions between room temperature and -170 °C. However, in the present experiment, the ion $N_2H^+(H_2)_2$ $(n=2)$ was the largest cluster observed at low temperatures, no higher clusters $(n>2)$ being observed even at -187 °C; N_2H^+ has much lower hydrogen molecule affinity than H_3^+. The vertical distance between two adjacent van't Hoff plots taken at a constant $1/T$ corresponds to $(\Delta G_{n+1,n} - \Delta G_{n,n-1})(1/2 \cdot 3RT)$, being proportional to the free energy difference at a certain temperature T. A big gap between two van't Hoff plots thus indicates a big drop of stability

toward dissociation of one molecule. We see from Fig. 2 that there is a very big gap between plots $n=1$ and 2 (Reactions 1 and 2, Table 1), indicating that (a) the first incoming H_2 molecule interacts with reasonable strength with N_2H^+, but the second molecule experiences very weak interactions with $N_2H^+(H_2)$, and (b) the stability of $N_2H^+(H_2)_2$ is remarkably lower than that of $H_3^+(H_2)_2$.

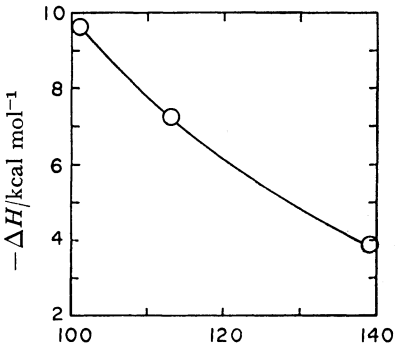

Fig. 3. Relationsflip between $-\Delta H_{0,1}$ for the reaction $BH^+ + H_2 = BH^+(H_2)$ and proton affinity for molecule B as H_2, N_2 and CO. See text.

The values of enthalpy change $\Delta H_{1,0}$ (Table 1) give the order $\Delta H(H_3^+\cdots H_2) > \Delta H(N_2H^+\cdots H_2) > \Delta H(HCO^+\cdots H_2)$, *i.e.*, the order of the hydrogen molecule affinity for each protonated species is $H_3^+ > N_2H^+ > HCO^+$. The order is opposite that of proton affinities of H_2, N_2, and CO, which are 101.0, 113.7, and 139.1 kcal/mol, respectively.[9] The relationship between proton affinities and $-\Delta H_{0,1}$ is shown in Fig. 3. For all Reactions 1, 3, and 7, the solvent molecule is hydrogen which interacts nucleophilicly with each protonated molecule. If the positive charge is more delocalized in the protonated species, the interaction of the solvent molecule with the ion should be weaker, and *vice versa*. The larger proton affinity indicates that the positive charge is more dispersed in the protonated species, and the following clustering step should be less favorable (Fig. 3). This is also the case for polar molecules which have a strong tendency to hydrogen bonding. Water has been known as the best solvent for proton. However, the proton affinity of water is the lowest among all other oxygen containing hydrocarbons.[10]

The Structure of $N_2H^+(H_2)$ and $N_2H^+(H_2)_2$. The characteristic enthalpy changes for Reactions 3—6 led to the prediction of the structure of $H_3^+(H_2)_n$.[4] For the present clustering Reactions 1 and 2, the big drop of $-\Delta H_{n-1,n}$ seems somewhat unusual. A theoretical calculation predicts that N_2H^+ has a linear equilibrium geometry.[11] However, no theoretical work has been carried out on the structure of $N_2H^+(H_2)_n$ for $n=1$. Tentatively two possible structures are suggested (Fig. 4), a solvent hydrogen molecule interacting with the terminal hydrogen atom in structure(a), and with the central nitrogen atom in structure(b). From the large electronegativity of a nitrogen atom and the relatively low proton affinity of a nitrogen molecule, an appreciable amount of positive charge is considered to be on the hydrogen atom in N_2H^+. Because of the smaller size of the hydrogen atom, the nucleophilic interaction between a solvent hydrogen molecule and the terminal hydrogen atom may be stronger than that between a solvent hydrogen molecule and the central nitrogen atom. We would like to suggest that the cluster ion(a) would be the most stable isomer of the cluster ion $N_2H^+(H_2)$. In (a), the proton is sandwiched between N_2 and H_2 molecules. In such a structure, the potential energy curve for the proton may have double potential minima.[12] Since the proton affinity of nitrogen is larger than that of hydrogen, the proton in $N_2H^+(H_2)$ should be closer to the nitrogen molecule (Fig. 4(a)).

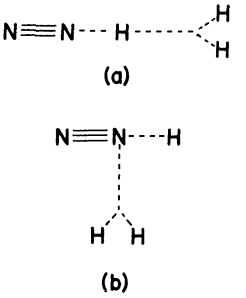

Fig. 4. Possible structures of cluster $N_2H^+(H_2)$,

When the cluster ion $N_2H^+(H_2)$ has structure(a), the second incoming hydrogen molecule would interact either with the central hydrogen atom or the nitrogen atom adjacent to the central hydrogen atom. In either case, the nucleophilic interaction would be much weaker than that for the first clustering step, since the positive charge is already dispersed in $N_2H^+(H_2)$. This might explain the big drop of the enthalpy changes for Reactions 1 and 2.

$N_2H^+(H_2)_2$ has the same chemical formula as the protonated hydrazine, $N_2H_5^+$. From a comparison of heat of formation of $N_2H^+(H_2)_2$ and $N_2H_5^+$, it can easily be shown that the cluster ion $N_2H^+(H_2)_2$ does not have the structure of protonated hydrazine. The heat of formation of $N_2H^+(H_2)_2$ can be obtained from the proton affinity of N_2 and the enthalpy changes of Reactions 1 and 2 as 244.6 kcal/mol. So far no proton affinity of hydrazine has been measured. The proton affinity of hydrazine is considered to be equal or larger than that of ammonia (202 kcal/mol) because of the inductive effect of $-NH_2$ group. Thus the heat of formation of the protonated hydrazine should be $\leqq$187.8 kcal/mol. The difference between these two values is large enough to conclude that $N_2H^+(H_2)_2$ and $N_2H_5^+$ are structural isomers. Although the reaction of the formation of protonated hydrazine, $N_2H^+(H_2) + H_2 = N_2H_5^+$, is highly exothermic ($\approx$60 kcal/mol), it must have a large free energy barrier, *i.e.*, an activation energy barrier as well as an entropy barrier, since the reaction sould undergo the rearrangement of atoms.

Entropy Change. The entropy of a molecule in the gas phase is given by

$$S = S_t + S_r + S_v + S_e \qquad (2)$$

where S_t, S_r, S_v, and S_e are translational, rotational, vibrational and electronic entropy, respectively. The

contribution of the electronic entropy S_e is usually negligible at normal temperatures. The translational entropy is evaluated by

$$S_t = \frac{3}{2}R\ln M + \frac{5}{2}R\ln T - R\ln P - 2.315 \quad (3)$$

where R, M, T, and P are gas constant, molecular weight in atomic unit, temperature, and gas pressure in atmospheric pressure unit, respectively. The rotational entropy for a linear molecule and that for a non-linear molecule are respectively given by the equations

$$S_r = R\ln I + R\ln T - R\ln\sigma + 177.671 \quad (4)$$

$$S_r = \frac{R}{2}\ln I_A I_B I_C + \frac{3}{2}R\ln T - R\ln\sigma + 267.644 \quad (5)$$

where I and σ are the moment of inertia and the symmetry number of the molecule, respectively. The vibrational entropy is given by

$$S_v = R\sum_i\left[-\ln(1-\exp(-h\nu_i/kT)) + \frac{h\nu_i/kT}{\exp(-h\nu_i/kT)-1}\right] \quad (6)$$

where ν_i is the frequency of the i-th fundamental vibration.

The translational entropy change which is by far the most important term is readily evaluated for Reaction 1 by means of the Sackur-Tetrode equation

$$\Delta S_t = \frac{3}{2}R\ln\frac{M_3}{M_1\cdot M_2} - \frac{5}{2}R\ln T + R\ln P + 2.315 \quad (7)$$

where M_1, M_2, and M_3 are the molecular weights of N_2H^+, H_2, and $N_2H^+(H_2)$, respectively. Substituting 265 K for T, we obtain $\Delta S_t = -27.3$ e.u. The temperature 265 K corresponds to the average in the temperature range of the van't Hoff plot from which $\Delta H_{0,1}$ and also $\Delta S_{0,1}$ were obtained (Fig. 2).

In order to evaluate the rotational entropy change, we should know the structure of N_2H^+ and $N_2H^+(H_2)$. The linear structure of N_2H^+[11] theoretically predicted leads to the moment of inertia of $N\equiv N\cdots H^+$ of 1.74×10^{-39} g·cm². The following assumptions will be made for the possible structures of $N_2H^+(H_2)$ shown in Fig. 4. Since the $N_2H^+\cdots H_2$ ion consists of weakly bonded N_2H^+ and H_2, the vibrational modes in H_2 and N_2H^+ would be essentially preserved in $N_2H^+\cdots H_2$. The distance between H atom and H_2 in structure(a), and N atom and H_2 in structure(b) is 1.9 Å. This value is adopted on the basis of the theoretical calculation done by Yamabe, Hirao and Kitaura.[13] They predicted the bond distance $H_3^+\cdots H_2$ of 1.857 Å. Since the bond energy of $H_3^+\cdots H_2$ (9.6 kcal/mol) is of the same order as that of $N_2H^+\cdots H_2$ (7.2 kcal/mol), the predicted value would not be in large error. Actually, the calculated rotational entropy changes are rather insensitive to a small change in the molecular structure. Substitution of these values in Eqs. 4 and 5 leads to $\Delta S_r = 1.3$ e.u. for the cluster ion(a) and $\Delta S_r = 4.2$ e.u. for the cluster ion(b). The total entropy change $\Delta S_{0,1}$ experimentally determined is -22.6 e.u., indicating that $\Delta S_v \approx 3$ e.u. for the formation of the cluster ion(a) and $\Delta S_v \approx 1$ e.u. for that of the cluster ion(b). The new vibrational modes in $N_2H^+(H_2)$ can be represented by a rocking motion with ω_1 in which alternately one end of H_2 and then the other swings toward N_2H^+, a nearly free internal rotation with ω_2 of H_2 around the bond $N_2H^+\cdots H_2$, a bond stretching vibration ω_3, and two normal bending vibrations ω_4 and ω_5. Salmon and Poshusta[14] have estimated $\omega_1\approx\omega_2\approx 200$ cm^{-1} and $\omega_4\approx\omega_5\approx 50$ cm^{-1} for $H_3^+\cdots H_2$. Frequencies of 50 and 200 cm^{-1} lead to vibrational entropy changes of -1.8 and -2.44 e.u. at 265 K, respectively. If the values are used for vibrations in $N_2H^+\cdots H_2$, the four vibrations lead to $\Delta S_v = -8.5$ e.u. Evidently the actual vibrations in $N_2H^+\cdots H_2$ should be considerably milder than the predicted vibrations in $H_3^+\cdots H_2$. Certain vibrations with the frequency of 30 cm^{-1} ($\Delta S_v \approx 1.6$ e.u) or less and the near free internal rotation of H_2 ($\Delta S_v \approx 2$ e.u.) should be taken into consideration in order to explain the estimated ΔS_v.

A number of assumptions would be required for the evaluation of the entropy change for Reaction 2. The translational entropy change $\Delta S_{1,2}$ calculated by Eq. 7 is -21.9 e.u. at 90 K. The temperature 90 K corresponds to the average in the temperature range of the van't Hoff plot for Reaction 2. The total entropy change $\Delta S_{1,2}$ experimentally determined is -14.0 e.u., indicating that $\Delta S_r + \Delta S_v = 7.9$ e.u. We obtain $\Delta S_r \approx 1$ e.u. by assuming several structures of $N_2H^+(H_2)_2$ in which an additional hydrogen molecule interacts with clusters(a) and (b) with the bond length of 2 Å. This value leads to the value of 7 e.u. for ΔS_v. The large positive value of the predicted vibrational entropy change strongly suggests that bonds in $N_2H^+(H_2)_2$ are very loose, additional hydrogen molecules having a large freedom of motion in the cluster ion.

The author is greatly indebted to Professor P. Kebarle for valuable discussions and for the use of the high pressure mass spectrometer.

An Empirical Relation between the Quenching Cross-sections of Metastable Argon and the Molecular Diameter of the Quenchers

Kazuhiro MATSUBARA, Yoshitsugu OONO,* Shoichi KAI,** and Yukio NISHIMURA

Research Institute of Industrial Science, Kyushu University, Fukuoka 812

***Department of Electronics, Kyushu University, Fukuoka 812*

(Received October 4, 1978)

For polyatomic quenchers there is a fairly accurate linear relation between $\sigma_Q^{1/2}$ and r, where σ_Q is the quenching cross-section of rare gas metastables (especially $Ar(^3P_2)$) and r, the effective radius of the quencher.

The quenching process for metastable rare gas atoms by neutral molecules is one of the simplest and most elementary chemical reactions. So far many workers have studied the quenching cross-sections, σ_Q (esp. for metastable argon), and also discussed the quenching mechanism.[1-5] However, as will be summarized in the next section, there seems to have been no definite conclusion as to the quenching mechanism. All the theoretical approaches are also unsuccessful.[6] Therefore, what we should do first is to study the existing experimental data systematically and to search for empirical laws. As will be mentioned in the next section, some attempts of this kind have already been done, but the empirical laws they have proposed are not sufficiently quantitative.

The purpose of the present paper is to give a much more quantitative empirical law than has ever been reported: a linear relation between $\sigma_Q^{1/2}$ (esp. for metastable argon) and the effective diameter of the quencher. Empirical laws of this type for several gaseous processes have already been given in a previous paper.[7] Our study shows that diatomic quenchers and polyatomic quenchers are rather clearly different. All the quenching cross-sections cited in this paper are those obtained from $k/\bar{v}$, where k is the rate constant and $\bar{v}$, the mean velocity of the colliding particles.

Summary of the Present View on the Quenching Mechanism

Bourène and Calvé suggested that the ionization potential, I, is relevant to σ_Q from the fact that there is a rough inverse relation between σ_Q and I. As will be discussed later, this suggestion does not hold. Moreover, there is an experiment[8] showing that the ionization process does not contribute to the quenching process of $Ar(^3P_2)$. Bourène and Calvé[3] also suggested that the dispersion force is relevant and obtained a rough linear relation between σ_Q and the polarizability, α_Q, of the quencher. We reexamined this plot and obtained an approximate relation, $\sigma_Q \propto \alpha_Q^{2/3}$ (Fig. 1). However, if α_Q governs σ_Q, a dimensional analysis asserts that $\sigma_Q \propto \alpha_Q^{1/3}$. Hence, their second suggestion is also doubtful. Later we will see that the empirical relation just mentioned is one derivable from other empirical relations which appear more fundamental.

Setser *et al.*[1,2,8] have been studying the quenching

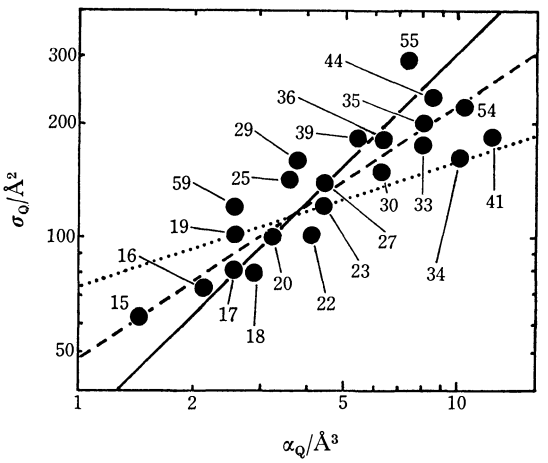

Fig. 1. The relation between σ_Q for $Ar(^3P_2)$ and the polarizability α_Q of quenchers. The slope of the lines are: ——1,– – –2/3,·····1/3. Thus the line with the slope 1/3 (which is suggested by a dimensional analysis or quantum mechanical considerations) does not fit the data, which are taken from Ref. 3. The line with the slope 2/3 best fits the data. The data for α_Q are taken from Ref. 11. All the numbers correspond to those in Table 1.

process extensively; they have also considered quenching mechanisms. Their conclusions thus far are summarized in Ref. 6. They plotted log σ_Q *vs.* log C_6, where C_6 is the van der Waals coefficient, and obtained a linear relation with a unit slope. Their experiments showed that the nature of the product channel is irrelevant to σ_Q. Therefore, they suggested that σ_Q is determined by the long-range forces in the entrance channel. Hereafter we will interpret the long-range interaction as the interaction which does not include the direct repulsive interaction due to the molecular core, *i.e.*, the overlap of electron clouds. As is the case of σ_Q *vs.* α_Q, however, the slope of the log σ_Q *vs.* log C_6 plot apparently contradicts the mechanism suggested (a dimensional analysis shows $\sigma_Q \propto C_6^{1/3}$). King and Setser[6] suggested that this contradiction is either because the long-range forces are not properly represented by C_6, or because the probability of quenching increases in a systematic way, making the slope larger than 1/3. Thus, they seem to assert that the relevant mechanism is due to long-range interactions (esp. dipole-dipole interaction). However, apart from the *ad hoc* nature of their explanation of the value of the slope, the long-range-force mechanism contradicts the facts that σ_Q for $Ar(^3P_2)$ and that for $Ar(^1P_1)$ have the same order of magnitude and that permanent dipoles are irrelevant to σ_Q, as will be shown below (Fig. 6).

Thus, we may conclude that there is no conclusive view on the quenching mechanism of metastable rare gas atoms.

Phenomenological Survey of the Quenching Process

As was discussed in the introductory part of this paper, the $\sigma_Q \propto \alpha_Q^x$ ($x \approx 2/3$) and $\sigma_Q \propto C_6^y$ ($y \approx 1$) relations afford universal phenomenological relations independent of the detailed nature of the quenchers. However, these relations are not sufficiently quantitative.

It has been shown[7] that the effective hard-core radius of the molecule, r, appearing in the statistical mechanics of liquids can be successfully used as the representative length of the molecules in gaseous reactions. Therefore, it is natural to try to find the relation between r and σ_Q. It is known that r is a good measure of the radius of the repulsive core of molecules, *i.e.*, a good measure of the effective radius of the electron cloud of molecules. A dimensional analysis suggests a linear relation between $\sigma_Q^{1/2}$ and r. As a convenient measure of r, we adopted $r_w = (3V_w/4\pi N)^{1/3}$, where V_w is the van der Waals volume of the quencher, which is calculated by using the tables of Bondi,[9] and N, the Avogadro constant. A linear relation holds between r and r_w, as has been shown in Ref. 10. First, we will consider $Ar(^3P_2)$.

Figure 2 shows the linear relation for polyatomic molecules involving only atoms belonging to the first and second periods of the periodic table. The linear relation is much more accurate than any previously reported. Note that the plot is not a log-log one, in contrast to the relations previously obtained. This linear relation, however, does not hold accurately for quenchers containing sulfur, bromine, *etc.* Still, we can

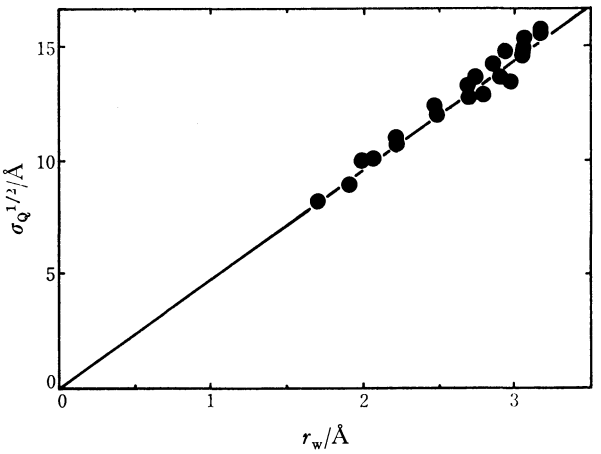

Fig. 2. The linear relation between r_w (see the text) and $\sigma_Q^{1/2}$ for polyatomic quenchers consisting of atoms belonging to the first and second periods of the periodic table. The data are taken from Ref. 4.

get a universal linear law similar to it. For this purpose we systematically modify the van der Waals volumes allotted to the larger atoms as follows: for the atoms belonging to the $(n+2)$-th ($n>0$) period of the periodic table, the modified van der Waals volume, V_w', is related to that of Bondi[9] as $V_w' = (1.7)^n V_w$. This modification seems to reflect the extension of the outermost shell of atoms, but we cannot give a clear physical meaning for it. At any rate, by this modification of the van der Waals volume allotted to the larger atoms, we get the linear relation shown in Fig. 3 for all polyatomic quenchers except those containing fluorin atoms. The accuracy of the linear relation is excellent. The effect of the modification of the van der Waals volumes is shown in Fig. 4. As may clearly be seen from Fig. 5, the diatomic quenchers and the polyatomic quenchers

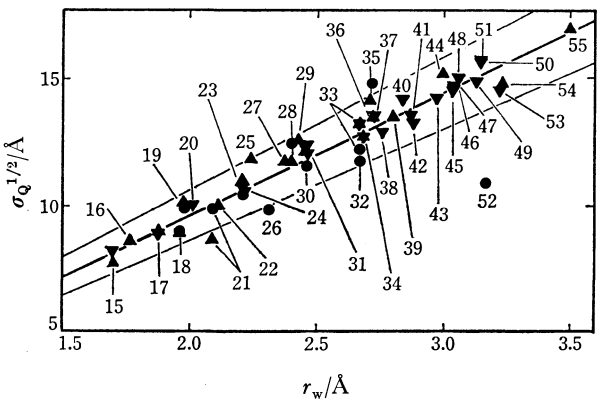

Fig. 3. The linear relation between r_w and $\sigma_Q^{1/2}$. r_w is calculated from the modified van der Waals volumes in the text. The line denotes $\sigma_Q^{1/2} = 4.80\, r_w$. The thin lines show $\sigma_Q^{1/2} = (4.80 \pm 0.48)\, r_w$. Thus our empirical relation is very accurate than those so far obtained. All the numbers in the figure correspond to those in Table 1. The data are taken from Refs. 1, 2 (●), Ref. 3 (▲), and Ref. 4 (▼). The quenchers containing fluorine atoms deviate from the linear law wildly. This suggests that the quenching mechanism for these compounds are different from other quenchers.

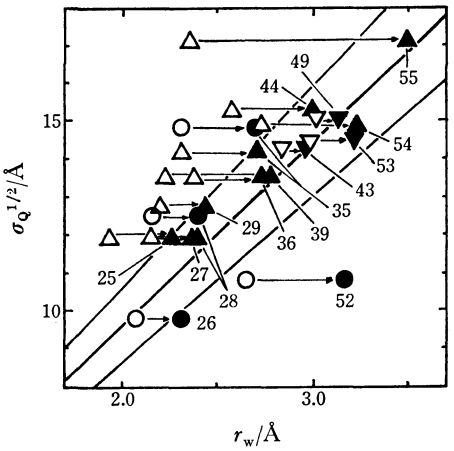

Fig. 4. The effect of the modification of the van der Waals volumes. Open symbols show the $\sigma_Q^{1/2}$ *vs.* r_w relation before the modification of the van der Waals volumes and solid symbols show that after the modification. All the numbers correspond to those in Table 1. Triangles and circles correspond to those in Fig. 3.

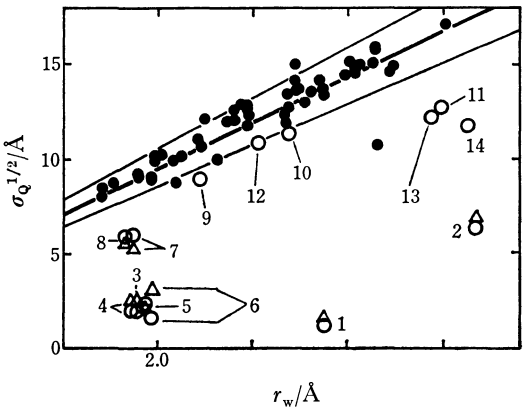

Fig. 5. The $\sigma_Q^{1/2}$ *vs.* r_w relation for mono- and diatomic quenchers. The σ_Q of these quenchers are systematically smaller than those of polyatomic quenchers (denoted by solid symbols). All the numbers correspond to those in Table 1.

Table 2. Irrelevance of the polarizability α_Q (Å^3) to whether or not $\sigma_Q^{1/2} \propto r_w$ holds

Although King and Setser[6] suggested that the quenchers with smaller α_Q values are different from other quenchers, their suggestion does not hold. In the table, the numbers in parentheses show the α_Q values in Å^3.

Mono- and diatomic quenchers		Polyatomic quenchers	
O_2	(1.57)		
N_2	(1.74)	H_2O	(1.45)
NO	(1.70)		
CO	(1.94)	NH_3	(2.16)
Kr	(2.48)	CO_2	(2.59)
HCl	(2.58)	CH_4	(2.56)
HBr	(3.49)	H_2S	(3.61)
		SO_2	(3.78)
		CH_3OH	(3.25)

are different. This difference could not be found, though, as long as we had only the rough empirical laws mentioned above.

The difference cannot be ascribed to that of the number of (valence) electrons nor to that of the ionization potential (see also the next section). Furthermore, although the magnitude of the polarizability may seem relevant, as has been suggested by Setser *et al.*, α_Q has no direct effect on whether $\sigma_Q^{1/2} \propto r$ holds or not (Table 2). Therefore, in so far as we base our conclusions on the existing data, the most natural conclusion is that the number of nuclei in the quencher is relevant to the quenching process (mechanism). This further suggests that the number of vibrational degrees of freedom of the quencher is relevant.

Irrelevance of Other Quantities

The irrelevance of other quantities, such as the permanent dipole moment, the ionization potential, *etc.*, to the quenching mechanism can be seen as follows. Possible relevant quantities, other than r, may include the reduced mass, μ, of colliding particles; the de Broglie wave length, λ; the permanent dipole moment, D; the ionization potential, I; the initial relative velocity, $v(=(3kT/\mu)^{1/2})$, and the initial kinetic energy, $E(=3kT/2)$. A dimensional analysis implies the following functional relation:

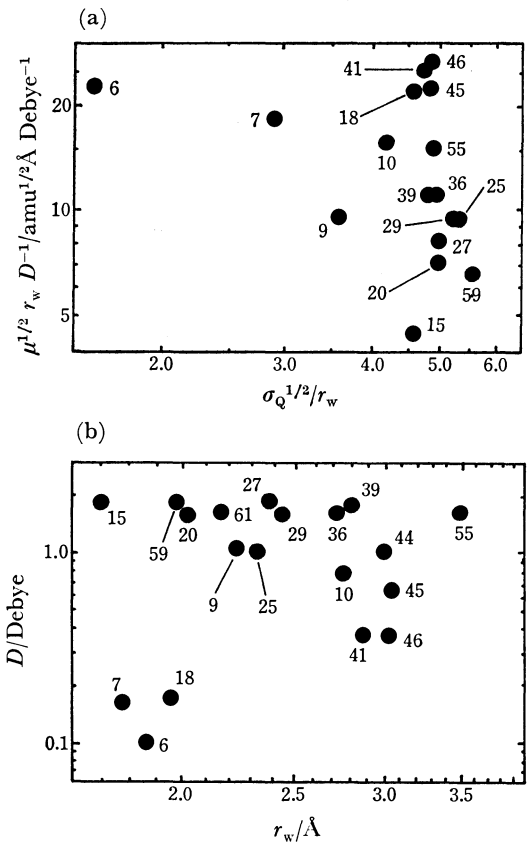

Fig. 6. Irrelevance of dipole moment D of quenchers. (a) Shows that there is no direct relation between D and σ_Q. (b) Shows, furthermore, that D is irrelevant to r_w. Therefore there is no indirect relation between D and σ_Q either.

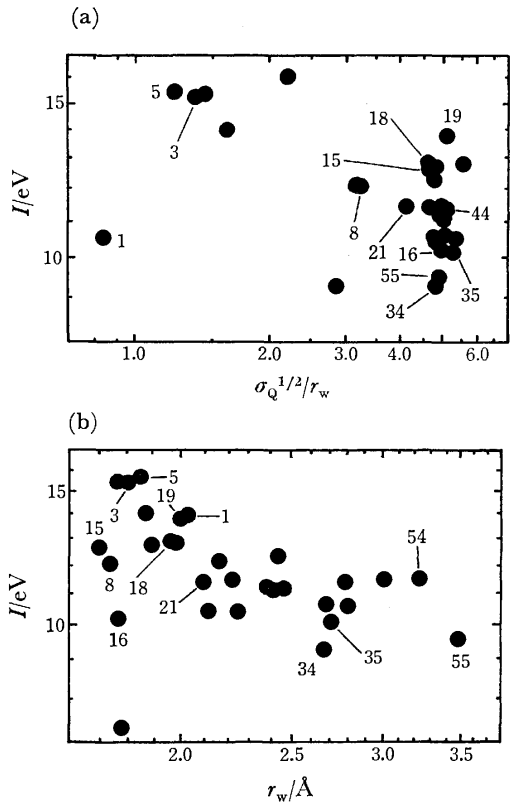

Fig. 7. Irrelevance of the ionization potential I of quenchers. (a) Shows that there is no direct relation between I and σ_Q. Although (b) shows a vague correlation between r_w and I (this is the reason why Bourène and Calvé suggested the relevance of I), but (a) and (b) show that I is substantially irrelevant to σ_Q. All the numbers correspond to those in Table 1. The data for I are taken from Ref. 2.

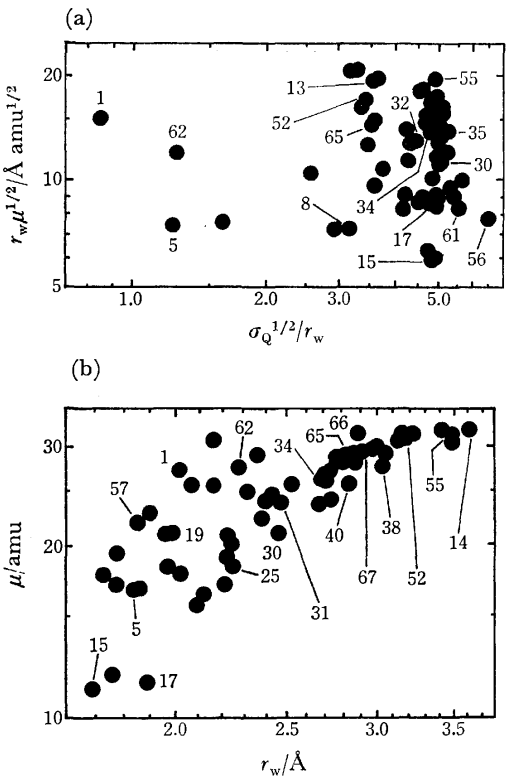

Fig. 8. Irrelevance of the reduced mass μ or the de Broglie wavelength of quenchers. (a) Shows that there is no direct relation between μ and σ_Q. Of course, as is shown in (b), there is a positive correlation between μ and r_w, but the comparison of the scattered distribution of points in (b) and fairly compact distribution of points in (a) implies that reduced mass (and de Broglie wave length) are irrelevant to σ_Q. All the numbers correspond to those in Table 1.

$$\sigma_Q^{1/2} = rf(\lambda/r,\ I,\ D^{1/2}/\mu^{1/2}r,\ \cdots)$$

where constant dimensional quantities are suppressed. All the existing data are obtained from experiments performed under almost the same E (or T). Figures 6—8 show that all the quantities other than r have no direct relevance to σ_Q. The irrelevance of the permanent dipole moment is evidence that the interaction due to the so-called long-range forces has no direct effect on σ_Q, as we suggested at the beginning of this paper.

Discussion

It may seem quite curious that the number of nuclei in the quencher is relevant. There is a possibility that the relevance is explained by the relation between the stochasticity of the motion of a nonlinear oscillator and its number of degrees of freedom. The stochasticity of the internal motion of the quencher enhances its quenching ability. Diatomic quenchers never exhibit stochastic internal motion, so that the quenching cross-section is smaller than would be expected from the empirical law for polyatomic molecules. This explanation is mere speculation, but it is fascinating because there is a growing interest in the chaos appearing in dynamical systems with even a small number of degrees of freedom.

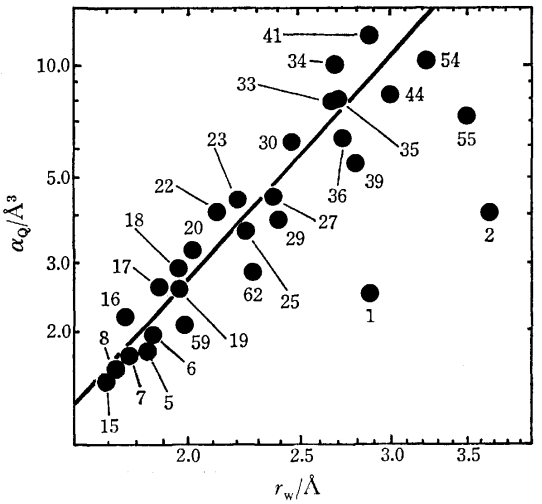

Fig. 9. The relation between modified r_w and the polarizability α_Q. The slope of the line is 3, *i.e.*, $\alpha_Q \propto r_w^3$. α_Q are taken from Ref. 11. All the numbers correspond to those in Table 1.

A close examination of σ_Q suggests that there is some effect of the shape of the quencher. For the series of quenchers with the same van der Waals volume, we have the order of: butane>isobutane and *p*-xylene>

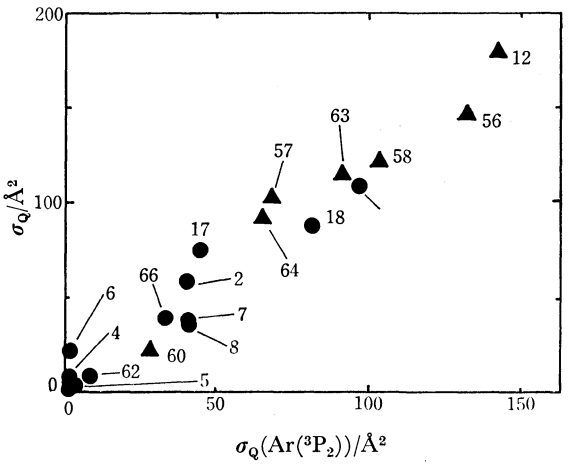

Fig. 10. The relation between the quenching cross sections of $Ar(^3P_2)$ and $Ar(^3P_0)$[1] (●) or Kr $(^3P_2)$[2] (▲). All the numbers correspond to those in Table 1.

m-xylene>*o*-xylene. Thus, the deviation from the spherical shape increases σ_Q slightly. These deviations are, however, very small, and the main feature is that σ_Q is governed by the effective radius of the quencher.

The empirical relation, $\sigma_Q \propto \alpha_Q^{2/3}$, mentioned earlier is derived from $\sigma_Q^{1/2} \propto r_w$ and the empirical relation $\alpha_Q \propto r_w^3$ shown in Fig. 9.

Figure 10 suggests that the quenching mechanisms for $Ar(^3P_2)$ and $Ar(^3P_0)$ or $Kr(^3P_2)$ are the same. However, since only a few results are known for $Kr(^3P_2)$ for polyatomic quenchers, we cannot make a $\sigma_Q^{1/2}$ *vs.* r_w plot. It seems that the same conclusion can be drawn for $Xe(^3P_2)$, but there are not sufficient data in this case, either. For $He(2^1S)$, as was shown in a previous paper,[7] no universal relation between σ_Q and r was found.

One of the authors (Y. O.) is grateful to Dr. M. Tsuji for informing him of Ref. 1—3. He would also like to thank Professor K. Hirakawa and Professor T. Oyama for their stimulating discussions and encouragement.

The Electronic Spectra and Nonaqueous Oxidation and Reduction Potentials of Azoxybenzenes, and Their Mutual Correlation

Tanekazu KUBOTA,* Hiroshi MIYAZAKI, Masumi YAMAKAWA, Kiyoshi EZUMI, and Yoshiko YAMAMOTO

Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka 553

(Received October 20, 1978)

The near-ultraviolet absorption spectra of various *p,p'*- and *m,m'*-disubstituted azoxybenzenes were recorded in aprotic and protic solvents. The PPP-SCFMO-CI calculation was used in analyzing the spectra and the solvent effect on them. The π-π^* bands of azoxybenzene could be well interpreted on the basis of the electronic structure of benzaldehyde *N*-phenyl oxime (a nitrone). In addition, the half-wave potentials of reduction ($E_{1/2}^{red}$) and oxidation ($E_{1/2}^{oxd}$) were also measured in nonaqueous solvents. These electrochemical data and the above spectral data satisfied a good linear relation: $(E_{1/2}^{oxd}-E_{1/2}^{red})=k_1\cdot E_{ho\to lu}^{UV}+k_2$, this equation having been previously proposed by us. In the Appendix, we have discussed the physical meaning of the constant term, k_2, from the quantitative standpoint, using a series of alternant hydrocarbons as a typical example. Finally, a good linear relation between the $E_{1/2}^{red}$ or $E_{1/2}^{oxd}$ values and the substituent constants was demonstrated and discussed in azoxybenzenes.

So far the electronic spectra and the electronic states of multifarious aromatic amine oxides have been extensively studied experimentally and theoretically in singlet, doublet, and triplet states.[1] Various kinds of experimental techniques have also been used in the studies.[1] However, as far as we know, there have been only a few discussions of the electronic state of azoxybenzenes (AOB's),[2-6] which are classified as one of the aromatic amine oxides. In this report, the electronic spectra and the half-wave potentials of the oxidation ($E_{1/2}^{oxd}$) and reduction ($E_{1/2}^{red}$) of various substituted AOB's have been systematically examined from the viewpoint of experimental and theoretical treatments. For the $E_{1/2}^{oxd}$ and $E_{1/2}^{red}$ values, the interrelation of the half-wave potentials and the electronic spectra is also discussed.[7]

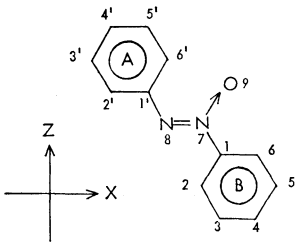
a) The compounds designated by A, B, and C were synthesized according to Refs. 10, 11, and 12 in the text respectively. The others were commercially available. b) The melting points are uncorrected. The values in parentheses were taken from the literature in the text. c) Measured at 25 °C in dioxane.[13] The values in parentheses were taken from Refs. 14a (1.57: 27 °C, benzene) and 14b (1.72: 22 °C, benzene). d) R: Recrystallized from ethanol except for *m,m'*-$(CN)_2$ and 4,4'-$[N(CH_3)_2]_2$, where benzene and chloroform were suitable as the solvents respectively. T: Purified by preparative thin-layer chromatography. For 4,4'-Cl_2 it was developed with heptane and then recrystallized from ethanol. For 3,3'-$(NO_2)_2$, benzene was used for both the development and the recrystallization. AC: Alumina column chromatography was used for 4,4'-$(CN)_2$. Elution was made first with benzene and then with a benzene(1)–ether(1) mixture, the latter portion being recrystallized from ethanol. TR: Although purification was tried repeatedly by thin-layer chromatography (TLC) and by recrystallization for this compound, its purity was not sufficient judging from the TLC and the elemental analyses. Its purity, however, may be about 95%. e) See text and Ref. 50.

spectra were recorded in the usual manner with a Beckman DK-2A Far-UV spectrometer at room temperature. The organic solvents used were CCl_4, CH_2Cl_2, CH_3CN, heptane, ethanol, and methanol, all of which were spectrograde in purity. They were desiccated sufficiently with a suitable drying agent, such as $CaCl_2$, Na, or Mg ribbon, and then carefully rectified.[1b,d] The electrochemical data were obtained using the polarographic technique, whose details have been described in a previous paper.[7a] The DC and AC polarograms were measured with a Yanagimoto polarograph, Model P8-AP (three-electrode system), a saturated calomel electrode (SCE) being used as the reference electrode. The capillary used for the dropping mercury electrode to yield the $E_{1/2}^{red}$ was: $m=0.855$ mg/s and $t=5.17$ s at $h=70$ cm in distilled water at an open circuit. Alternatively, the $E_{1/2}^{oxd}$ values were obtained with a rotating platinum electrode, the type and the manipulation of which are exactly the same as in our previous report.[7a] All the experiments were carried out at 25 ± 0.1 °C in *N*,*N*-dimethylformamide (DMF) or CH_3CN containing 0.1 mol dm^{-3} terapropylammonium perchlorate (TNPAP). The method used in the purification of DMF, CH_3CN, and TNPAP was also the same as in our references.[7a,8,9]

Samples. The substances employed here are listed in Table 1 along with their synthetic and purification methods and the melting points. The compounds whose preparation method and physical constants have not yet been reported were synthesized and purified by applying the methods of similar substances known already (see Table 1). The structure and purity of the samples were checked by means of TLC, IR, UV, dipole moment, and elemental analyses. A good agreement was obtained between the calculated and experimental values of elemental analyses except for the 4,4′-dinitroazoxybenzene, the purity of which is less than the others. The structure of the AOB's synthesized here is well known to be the *trans*-in plane-form, just like [I].



[I]

For the *m*,*m*′-derivatives, however, we could not determine any accurate configuration[50] except for the dinitro derivative, whose NO_2 groups are judged to be in the 3 and 3′ positions from a comparison of the observed (see Table 1) and calculated dipole moments. The latter value is 5.31D, as the vector sum of 1.93D (AOB, whose moment is assumed to be in the direction of the N→O σ moment) and the NO_2 group moment (3.98D)[15] at the 3 and 3′ positions. If two NO_2 groups are in the 5 and 5′ positions, the calculated value is 8.62D.

Results and Discussion

Electronic Spectra of Azoxybenzene Derivatives. As a typical example, the spectrum of AOB is shown in Fig. 1 and compared with that of benzaldehyde *N*-phenyl oxime (BANO: a kind of nitrone),[16] since these are isoelectronic in π-electron systems. It can easily be understood from the figure that the spectra of AOB and BANO are quite similar to each other, especially

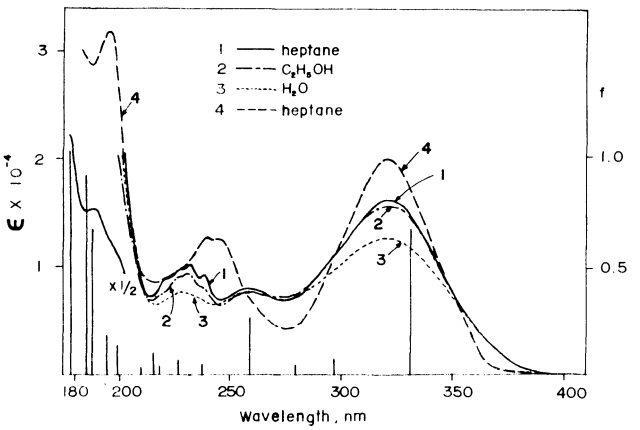


Fig. 1. Electronic spectra of azoxybenzene in aprotic (curve 1) and protic (curves 2 and 3) solvents and of benzaldehyde *N*-phenyl oxime (curve 4) in heptane.

for the characteristic strong π-π^* band appearing in the longest wavelength region, although the bands in the 275—217 nm region is more clearly separated for AOB. This spectral behaviour is very reasonable, as the molecules are the *trans*-in plane-form for both the benzene rings,[17] and suggests that the electronic spectra and the electronic structures of AOB's can be interpreted on the basis of those of BANO previously reported (*vide infra*).[3,16] In the spectra of various substituted AOB's, the spectral pattern of the compounds with electron-donating or electron-accepting substituents at the *p*,*p*′-positions is quite similar to that of AOB, as may be seen in Fig. 2 for 4,4′-bis(dimethylamino)-AOB.

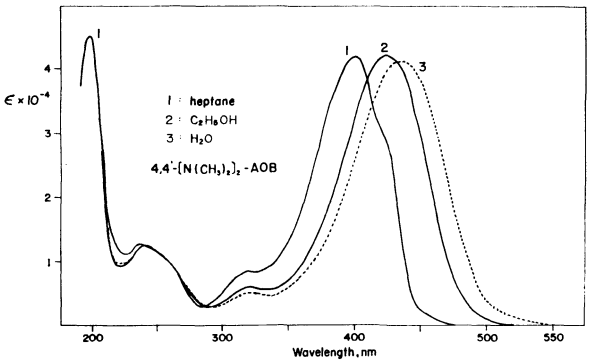

Fig. 2. Electronic spectra of 4,4′-bis(dimethylamino)-azoxybenzene in aprotic (curve 1) and protic (curves 2 and 3) solvents.

For the case of *m*,*m*′-substituents, the weak electron-donating groups like CH_3 and Cl lead also to spectra analogous to that of AOB. On the other hand, if the groups showing quite a large substituent effect are introduced in the *m*,*m*′-positions of AOB, the spectral patterns become very different from that of AOB, as may be understood from Fig. 3. The spectral data are collected in Table 2. Alternatively, the main difference in the spectral behaviour of AOB and BANO is that the well-known blue-shift phenomena found in protic solvents on aromatic amine *N*-oxides including nitrones and nitrile *N*-oxides[18] could not be generally observed

a) Data in heptane. b) Data *vs.* S.C.E. c) $\Delta\tilde{\nu}=\tilde{\nu}$ (heptane) − (ethanol). d) Obtained with a dropping mercury electrode in DMF. e) Obtained with a rotating platinum electrode ($\phi=1$ mm, 600 rpm) in CH_3CN. f) Values in CH_3CN. g) Taken from Refs. 7a, 8, 45, and 46 given in the text. h) The symmetry of this absorption curve is bad. The 350 nm is the weighted mean wavelength (center of gravity) of the curve, but the peak is 345.4 nm. i) This is a σ^- value (Jaffé's σ^*) cited from Ref. 47. j) See text and Ref. 50.

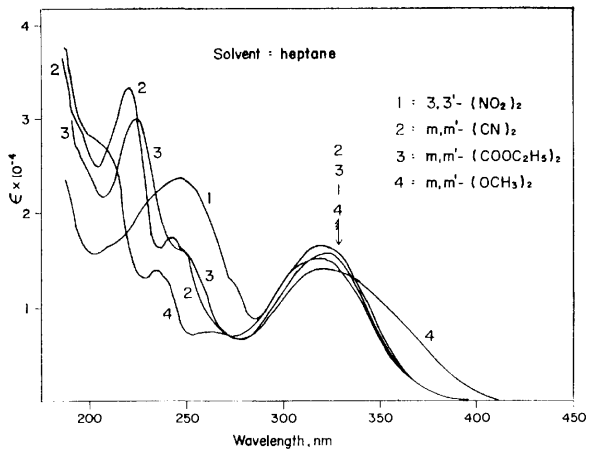

Fig. 3. Electronic spectra of azoxybenzenes substituted at *m,m′*-positions with the groups showing quite a large substituent effect.

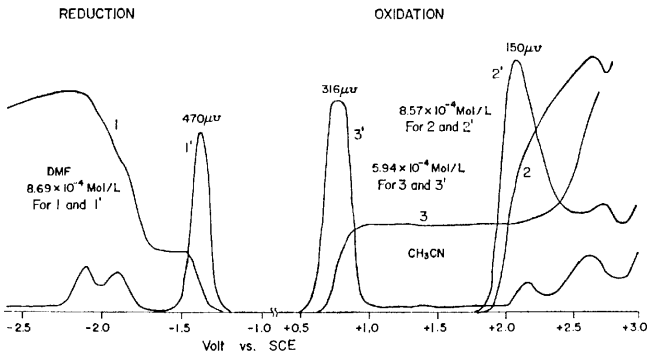

Fig. 4. DC(1) and AC(1′) reduction polarograms in DMF and DC(2) and AC(2′) oxidation voltammograms in CH_3CN of azoxybenzene respectively. Curves 3 and 3′ are DC and AC voltammograms of 4,4′-bis-(dimethylamino)azoxybenzene respectively. The absolute value of current is taken at the ordinate for the conveniences's sake.

for AOB and its derivatives. The red shift, rather than the blue shift, of the strong π-π^* band in the longest-wavelength region was observed in protic solvents in the case of substituted AOB's. This red shift is especially large for the AOB's with 4,4′-$[N(CH_3)_2]_2$ (2003 cm^{-1}), 4,4′-$(OC_2H_5)_2$ (976 cm^{-1}), and 4,4′-$(OCH_3)_2$ (949 cm^{-1}): the values in parentheses are the red shift from heptane to aqueous ethanol (C_2H_5OH: H_2O=3: 2). The spectral change with protic solvents is illustrated in Fig. 2 for the AOB substituted with 4,4′-$[N(CH_3)_2]_2$. The mechanism of the effect of protic solvents on the π-π^* band seems to be more or less different between –N=N→O and –C=N→O groups, the former having two active sites for intermolecular hydrogen-bonding interaction.

Nonaqueous Polarograms and Half-wave Potentials of Reduction and Oxidation. In Fig. 4 are illustrated the reduction polarogram in DMF and the oxidation voltammogram in CH_3CN on AOB as an example. The first reduction wave in Fig. 4 is due to the formation of the corresponding anion radical in the reversible process. This was inferred from the high value (541 $\mu\mho/mol\ m^{-3}$) of the AC wave, and directly verified by recording the ESR spectrum at the potential of the first limiting current. The same circumstances as the above

can be applied to the substituted AOB's, the first wave of which is quite a bit similar to that of AOB in showing a high AC wave. Almost the same reduction DC and AC waves which were obtained with a dropping Hg electrode were also yielded with a rotating Pt electrode. These first waves may be attributed to the anion radical formation. The data are listed in Table 2. On the other hand, the first oxidation wave of AOB, depicted in Fig. 4, seems not only to be overlapped with the next waves, but also the reversibility is less[19] than in the case of the reduction wave. The AC waveheight (175 μC/mol m^{-3}) is considerably smaller than that (*vide supra*) of the reduction wave. Of the AOB derivatives, 4,4'-bis(dimethylamino)-AOB showed a typical oxidation wave. The ESR measurement at the oxidation wave of the compound has ravealed a well-resolved spectrum due to the cation redical. Although the reversibility of the first oxidation wave of all the other AOB's is less than that of 4,4'-bis(dimethylamino)-AOB mentioned above, the $E_{1/2}^{oxd}$ values were determined by the wave analysis as reasonably as possible. All the data are included in Table 2.

Molecular Orbital (MO) Calculation and the Character of the Electronic Spectra. Some qualitative discussions of the excited states of AOB's have previously been reported,[2-6] but there have been no systematic considerations of their electronic states. In order to interpret the electronic spectra and their correlation with the $E_{1/2}^{red}$ and $E_{1/2}^{oxd}$ values, we have carried out the so-called PPP-SCFMO-CI calculations of the AOB's. As has been discussed in the "Electronic Spectra" section, the spectrum of AOB is quite similar to that of BANO (a nitrone). Since the electronic structures of nitrones including BANO were previously studied in detail,[16] the electronic states of AOB's may reasonably be understood by replacing the carbon atom in the bridge part of nitrones with a nitrogen atom, whose valence-state ionization potential (I_P: 14.51) and electron affinity (E_A: 1.20) are taken for the π electron in sp^2 hybridization.[20] The substituents employed in the calculations are the CH_3, Cl, OCH_3, and $N(CH_3)_2$ groups, the I_P, E_A, and core resonance energy (β_{XY}^{core}) of which are the same as those reported in a foregoing paper.[1d] The benzene ring in AOB was assumed to be a regular hexagon with the distance of 1.384 Å, cited from the X-ray analysis data of substituted AOB's.[17a]

The β_{XY}^{core} values in the bridge part, *i.e.*, β_{C-N}^{core} and $\beta_{N=N}^{core}$, were evaluated as follows. The β_{CN}^{core} was estimated by applying the Nishimoto and Forster equation,[21] $\beta_{CN}^{core}=-0.53P_{CN}-2.24$, where the bond order, P_{CN}, was calculated from the $R_{CN}=1.451-0.18P_{CN}$ relation and where the observed CN distance, $R_{CN}=1.496$ Å.[17a] The obtained value is $\beta_{CN}^{core}=-2.108$ eV. Alternatively, the value of $\beta_{N=N}^{core}$ tentavively estimated by employing the various equations connecting the $\beta_{\mu\nu}^{core}$, $S_{\mu\nu}$, valence state I_P, *etc.* led to the conclusion

that the $\beta_{N=N}^{core}$ is in the range 2.00—3.00 eV. With this result in mind, the $\beta_{N=N}^{core}$=2.75 eV was the most suitable for reproducing the observed UV spectra and dipole moments of AOB's.[22] The N atoms in the –N=N(O)– bridge group are assumed to be in sp^2 hybridization, so that the angles of ∠CNN and ∠CNO are 120° in the *trans*-form, as is shown in [I]. Here, one-electron transitions alone were taken into account in the UV spectral calculation. The excited-state energies of AOB are illustrated in Fig. 1 as stick diagram, while all the calculated and experimental spectral data on it are collected in Table 3, where the corresponding data of BANO are included for the sake of comparison. The orbital electron densities pertinent to the UV spectra are also shown in Fig. 5 for AOB and BANO. It is clear from Table 3 that the strong band of AOB (≈321.5 nm) and that (≈321.1 nm) of BANO appearing in the longest-wavelength region are mainly contributed by the HOMO→LUMO transition. This conclusion is the same as that reported hitherto by other workers;[2-6] their discussions were, however, in the framework of HOMO, without any CI treatment. The tentative assignment of the other bands of AOB and BANO is indicated in Table 3. Quite a good similarity is observed between the two calculations, which may suggest that the two bands recorded at 256.8 and ≈232.1 nm on AOB are coagulated into one band (263—224 nm) for BANO. The orbital-charge distribution (25.4%) on the *N*-oxide group oxygen atom in the HOMO of AOB is much less than that (43.6%) of BANO, so the charge-transfer (CT) character[24] from the above oxygen atom to the π-residual system is also smaller for AOB than in BANO for the case of the HOMO→LUMO transition (the strong band at ≈322 nm). For AOB, this transition is, rather, considered to be an intramolecular CT from the A ring to the bridge N=N(O) group and to the B ring (see Fig. 5 and [I]).[26]

Let us now focus our attention on the substituent effect on the spectrum of AOB. As may be seen in Table 2 and Fig. 6, the first strong π-π^* band is quite sensitive to the 4,4'-substituents with an electron-donor nature, and shows a red shift which is particularly large for the $N(CH_3)_2$ group. This result was confirmed by the present MO calculation, as Fig. 7 shows. The calculation indicates that the first strong π-π^* band observed on the 4,4'-substituted AOB's is also contributed mainly by the HOMO→LUMO transition. On the other hand, the shift of the first strong π-π^* band is small for the case of *m,m'*-substitution of AOB. The results, listed in Table 2, may be explained qualitatively as follows. The MO coefficients of AOB at the *m,m'*-positions are quite small (see Fig. 5) for the HOMO and LUMO, which contribute greatly to the above π-π^* band. Therefore, the small perturbation of these orbitals can be expected from the introduction of *m,m'*-substituents, leading to the small spectral shift. The red shift of the spectra of AOB's due to the solvent change from heptane to protic solvents was described in the foregoing section. The general rule pertaining to the blue-shift phenomena[27] caused by the solvent effect on the electronic spectra of aromatic tertiary amine *N*-oxides seems not to hold for AOB's.[28] That the first strong π-π^* band of AOB is somewhat different in CT

nature from that of BANO has already been discussed. This tendency increases with, for example, an increasing electron-donor nature of the substituents introduced at 4,4′-positions. For 4,4′-$(OCH_3)_2$ or 4,4′-$[N(CH_3)_2]_2$, the electron densities on the *N*-oxide-group oxygen atom are quite small at HOMO (14.36 and 6.33% for the former and the latter respectively), so there is almost no CT from the oxygen atom to the π-residual system in the case of the HOMO→LUMO transition. On the other hand, the electron densities at the N(8) atom (see [I]) always increased upon the HOMO→LUMO transition. These circumstances would be favorable to the red shift of the π-π^* band in protic solvents; that is, such intermolecular interactions as hydrogen bonding with protic solvents would become more or less stronger in the excited π-π^* state than in the ground state.

The Correlation of the Electronic Spectra and Half-wave Potentials. The fact that the first strong π-π^* band of substituted AOB's at the 4,4′-positions is mainly contributed by the HOMO→LUMO transition has been shown in the previous chapter. The linear relation written as Eq. 1 can thus be expected for the AOB's:

$$(E^{oxd}_{1/2} - E^{red}_{1/2}) = k_1 \cdot {}^1E^{UV}_{ho\to lu} + k_2 \qquad (1)$$

Here, ${}^1E^{UV}_{ho\to lu}$ is the singlet electronic transition energy, in which the HOMO→LUMO transition is the main configuration.[30] Of course, if the configuration of triplet excited states (${}^3E^{UV}_{ho\to lu}$) is localized mainly in the HOMO→LUMO transition, Eq. 2 can also be expected:

$$(E^{oxd}_{1/2} - E^{red}_{1/2}) = k_1 \cdot {}^3E^{UV}_{ho\to lu} + k_3 \qquad (2)$$

This relation was recently observed by Loutfy and Loutfy.[31] Figure 8 gives the correlation of Eq. 1, each of the experimental data being taken from Table 2. A good linear relation is found there for 4,4′-substituents, as is to be expected from the MO calculation.[32] The observed k_1 value is 1.27, which is near the theoretical value, 1. Alternatively, the k_2 value of −1.44 was obtained. In the case of the *m*,*m*′-substituents, the shift of the UV spectra is insensitive even to the groups of a stronger electron-donor or -acceptor, as may be seen in Fig. 3 so that the correlation of Eq. 1 was not obtained. The character of the absorption bands for these substances seems to be somewhat different from those of 4,4′-substituents. For the physical meaning of the k_2 and k_3 terms in Eq. 1 or 2, see the Appendix.

Substituent Effect on the $E^{oxd}_{1/2}$ and $E^{red}_{1/2}$ values. In a previous paper we have already pointed out that, in the electrode oxidation process, the σ^+ substituent constant is the better parameter to explain the substituent effect on the $E^{oxd}_{1/2}$ values.[7a] On the other hand, the usual σ or σ^- scales afford a better description of the substituent effect on the $E^{red}_{1/2}$ values.[8,33] In the series of AOB's these same relationships have also been observed. The plotting of the $E^{oxd}_{1/2}$ values against the $2\sigma^+$ gave a nice linear relation, as is indicated in Fig. 9.[34] In the case of the $E^{red}_{1/2}$ values, the good linearity shown in Fig. 10 was also found for 2σ and partly $2\sigma^-$ parameters; σ^- values were adopted for 4,4′-$(NO_2)_2$, 4,4′-$(CN)_2$, and 4,4′-$(COOC_2H_5)_2$, because the electron-accepting ability in the transition state is large for these. The above fact indicates that the treatment of a linear free-energy approximation can safely be applied to the half-wave potentials of AOB's in nonaqueous media, and that

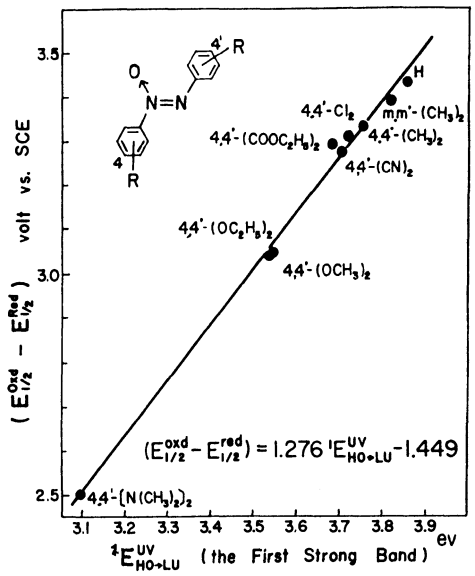

Fig. 8. The relationship between $(E^{oxd}_{1/2} - E^{red}_{1/2})$ values and the first strong π-π^* band energies for 4,4′-disubstituted azoxybenzenes.

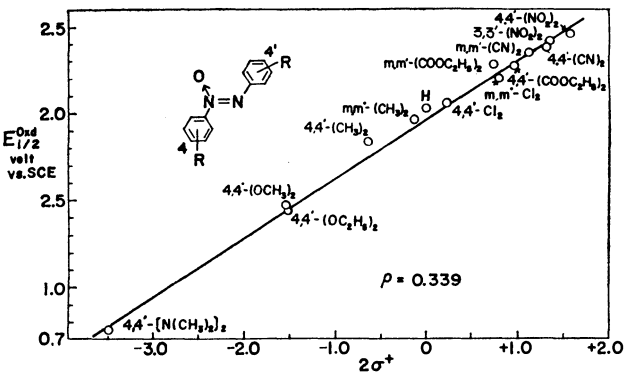

Fig. 9. Linear relationship between the σ^+ values (see Table 2) and the first $E^{oxd}_{1/2}$ values for substituted azoxybenzenes.

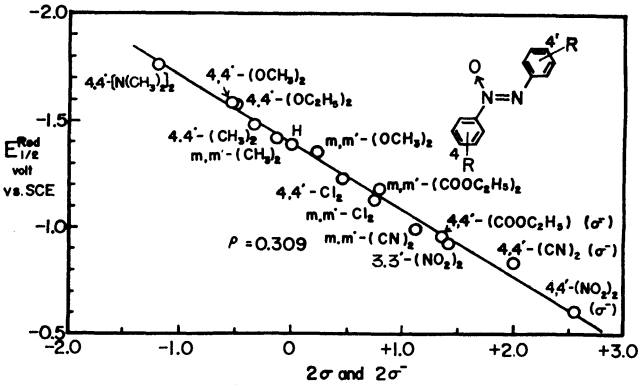

Fig. 10. Linear relationship between the σ and σ^- values (see Table 2) and the first $E^{red}_{1/2}$ values for substituted azoxybenzenes.

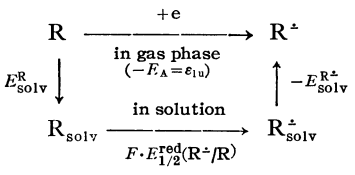
the above-mentioned linear relations make it easy to predict the $E_{1/2}^{red}$ and $E_{1/2}^{oxd}$ of substituted AOB's.

Appendix

In our previous papers[7] we did not discuss quantitatively the physical meaning of the constant terms, k_2 and k_3, in Eqs. 1 and 2 respectively. Here an interpretation of the k_2 and k_3 terms will be given. Let us now consider a reversible system of anion-radical formation, such as $R+e \rightleftarrows R^{\pm}$, so that the k_1 value of Eqs. 1 and 2 becomes 1 when the electron volt (eV) is adopted as the energy unit.[36] Applying the Born-Haber-type[35] thermochemical cycle given in Scheme 1 for anion-radical formation in solution, the $E_{1/2}^{red}(R^{\pm}/R)$ can be written by Eq. 3 in eV units, where the energy zero level is placed *in vacuo*:[31,37]

$$E_{1/2}^{red}(R^{\pm}/R) = \Delta G^{\circ} - \varepsilon_{lu} - \Delta E_{solv}^{\pm} \quad (3)$$



Scheme 1.

$\Delta E_{solv}^{\pm}$ is the solvation energy difference of the anion radical and neutral species; $\Delta E_{solv}^{\pm} = E_{solv}^{R\pm} - E_{solv}^{R}$. The contribution from the $E_{solv}^{R\pm}$ term is predominant. The absorolute potential of the reference electrode is expressed as ΔG°, which is -4.70 eV in the case of the (Ag/Ag^{+}) electrode in acetonitrile (0.01 mol dm^{-3} $AgClO_4$, 0.1 mol dm^{-3} $Et_4N^{+}ClO_4^{-}$).[37] Similarly the $E_{1/2}^{oxd}(R^{+}/R)$ is given by:

$$E_{1/2}^{oxd}(R^{+}/R) = \Delta G^{\circ} - \varepsilon_{ho} + \Delta E_{solv}^{+} \quad (4)$$

The ΔE_{solv}^{R+} equals $(E_{solv}^{+} - E_{solv}^{R})$. Taking account of the difference between Eqs. 3 and 4, Eq. 5 is obtained under the same experimental conditions, *i.e.*, the ΔG° term is cancelled out:[38]

$$(E_{1/2}^{oxd} - E_{1/2}^{red}) = \varepsilon_{lu} - \varepsilon_{ho} + \Delta E_{solv}^{+} + \Delta E_{solv}^{\pm} \quad (5)$$

Note that the $(E_{1/2}^{oxd} + E_{1/2}^{red})/2 \approx E^{\circ}(R^{\pm}/R^{+})$ may become $(-\varepsilon_{ho} - \varepsilon_{lu})/2 + \Delta G^{\circ} = (I_P + E_A)/2 + \Delta G^{\circ}$ when we use Eqs. 3 and 4 and $\Delta E_{solv}^{\pm} = \Delta E_{solv}^{+}$. This relation was employed by Senda and Takahashi to determine the standard electrode potential in nonaqueous solvents.[37b,49] We will now combine Eq.5 with this relation: $^1E_{ho\to lu}^{UV} = \varepsilon_{lu} - \varepsilon_{ho} - J_{ho\cdot lu} + 2K_{ho\cdot lu} + {}^1E_{CI}$, where the small contribution from the CI energy ($^1E_{CI}$) is postulated.[7] Thus, the k_2 value in Eq. 1 is given by Eq. 6 in eV units for a completely reversible system:

$$k_2 = J_{ho\cdot lu} - 2K_{ho\cdot lu} - {}^1E_{CI} + \Delta E_{solv}^{\pm} + \Delta E_{solv}^{+}$$
$$\approx J_{ho\cdot lu} - 2K_{ho\cdot lu} - {}^1E_{CI} + 2\Delta E_{solv}^{\pm} \quad (6)$$

Similarly, the k_3 value in Eq. 2 is given by

$$k_3 = J_{ho\cdot lu} - {}^3E_{CI} + \Delta E_{solv}^{\pm} + \Delta E_{solv}^{+}$$
$$\approx J_{ho\cdot lu} - {}^3E_{CI} + 2\Delta E_{solv}^{\pm} \quad (7)$$

Recently Loutfy and Loutfy discussed the meaning of the k_2 and k_3 values.[31] However, they completely neglected the term of $(\Delta E_{solv}^{\pm} + \Delta E_{solv}^{+})$. In addition, their MO's participating in the UV transition, which they interpreted as the "molecular orbital in solution" of neutral species, should rather be ascribed to those of the anion and cation radicals ($^2\Gamma$ state) generated by electrolysis. Also, they used the $E_{1/2}^{red}$ and $E_{1/2}^{oxd}$ values obtained in different solvents (CH_3CN and DMF) for plotting Eqs. 1 and 2 in the case of AH hydrocarbons, so the $(\Delta G_{CH_3CN}^{\circ} - \Delta G_{DMF}^{\circ})$ term should appear in Eq. 5. They did not take care in this point. Their discussions, therefore, are erroneous.

In the case of the AH hydrocarbons there are some experimental data by which to estimate the k_2 and k_3 values. In addition, the fact that the k_1 value of Eq. 1 is experimentally almost 1 has already been reported.[7] The $\Delta E_{solv}^{\pm}$ and ΔE_{solv}^{+} values can be estimated from Eqs. 3 and 4 respectively by adopting the experimentally determined I_P, E_A, $E_{1/2}^{red}$, and $E_{1/2}^{oxd}$ values.[37] In turn, the value of $(J_{ho\cdot lu} - 2K_{ho\cdot lu} - {}^1E_{CI})$ can be experimentally derived from the evaluation of the $(I_P - E_A - {}^1E_{ho\to lu}^{UV})$ value. The ^1L_a bands of AH's correspond to the $^1E_{ho\to lu}^{UV}$ value.[7] Here note that, in the foregoing papers,[7] we discussed how the value of the $(J_{ho\cdot lu} - 2K_{ho\cdot lu} - {}^1E_{CI})$ term becomes nearly constant from the standpoint of the PPP-SCFMO-CI calculation in a series of similar com-

a) Taken from Ref. 37a. b) Taken from Refs. 37a, 37b, and 40. c) Taken from Refs. 37b and 41. d) Taken from Refs. 7b and 42. e) Taken from Ref. 43. f) Taken from Ref. 44. g) The constant term in Eq. 1 in the test. h) The constant term in Eq. 2 in the text. i) The k_2 or k_3 value listed for each compound was obtained by averaging the values derived from the two different I_p's.

pounds such as AH's or aromatic *N*-oxides.[48] The same treatment as the above leads to the evaluation of the ($J_{ho\cdot lu} - {}^3E_{CI}$) term, which is obtained from the calculation of ($I_P - E_A - {}^3E^{UV}_{ho\to lu}$). Here, ${}^3E^{UV}_{ho\to lu}$ is for the ${}^3L_a$ bands. We can now obtain the k_2 and k_3 values in Eqs. 6 and 7 respectively from the experimental values alone. The results thus obtained are listed in Table 4, from which it may be understood that the k_2 value is $\approx$0.04 eV and quite small, while the k_3 value is $\approx$1.55 eV. The $E^{red}_{1/2}$ and $E^{oxd}_{1/2}$ values in Table 4 are those reported under the same conditions as were used for the determination of $\Delta G^\circ = -4.70$ eV,[37] so these are the best values for the evaluation of k_2 and k_3. The plotting of Eqs. 1 and 2 was as follows: $(E^{oxd}_{1/2} - E^{red}_{1/2}) = 1.011\ {}^1L_a - 0.001$ with $n=6$, $s=0.094$, $r=0.980$, and $(E^{oxd}_{1/2} - E^{red}_{1/2}) = 1.018\ {}^3L_a + 1.496$ with $n=6$, $s=0.067$, $r=0.990$.[39] Note that our previously reported result[7b,c] was $(E^{oxd}_{1/2} - E^{red}_{1/2}) = 0.941\ {}^1L_a + 0.092$. The values of the constant term given above seem to be in good agreement with the ones estimated theoretically in the order of magnitude and in the approximation adopted. For AOB's we did not attempt to evaluate the k_2 term in Eq. 1 because of the lack of experimental data and because of the smaller reversibility of the $E^{red}_{1/2}$ and, especially, $E^{oxd}_{1/2}$ values.

Thermodynamic Study on the Adsorption of Dioctadecyl Ether at Hexane/Water Interface

Norihiro MATUBAYASI,† Masatake DOHZONO, Makoto ARATONO, Kinsi MOTOMURA, and Ryohei MATUURA*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

(Received October 27, 1978)

The adsorption of dioctadecyl ether was studied at hexane/water interface, as functions of temperature, pressure, and mole fraction of dioctadecyl ether in hexane. The phase transition between expanded and condensed films was observed with decreasing temperature and increasing pressure and concentration. The thermodynamic quantities associated with the adsorption such as entropy, volume, and energy change were evaluated and comparison was made with the adsorbed films of 1-octadecanol at the same interface in which phase transition takes place. It is found that the dioctadecyl ether shows small negative discontinuous changes of the thermodynamic quantities with the transition from the expanded to the condensed films.

It is of great importance from the viewpoint of surface chemistry to clarify the structure and properties of adsorbed films at interface. In recent papers, we have shown that it can be achieved by applying the thermodynamic treatment developed previously.[1,2] Further we have revealed that the adsorbed film of 1-octadecanol at hexane/water interface shows a phase transition from an expanded to a condensed one and this phase transition is characterized by large negative discontinuous changes of the thermodynamic quantities associated with the adsorption.[3]

As an extension of this study, measurements are made for the adsorbed film of dioctadecyl ether at the same interface, in which the phase trandition takes place.

Experimental

Dioctadecyl ether was purified by repeated recrystallization. The purity was checked by the gas-liquid chromatography. Only one peak was obtained. Hexane used in this study was dehydrated and the impurity was removed by passing through an activated alumina column. Water distilled thrice from alkaline permanganate solution was used. The purity of hexane and water was always checked by the value of the interfacial tension between them.

The interfacial tension was measured by the pendant drop method. Detailed description of the apparatus and the method was given previously.[2,4]

Results

According to the phase rule the state of the system under consideration is completely specified by three independent variables and the structure and properties of interface are speculated by the thermodynamic quantities.[1,2] Then, the interfacial tension γ is measured as functions of temperature T and pressure p at the constant mole fraction of dioctadecyl ether in hexane x_1^0. Plots of γ against T under atmospheric pressure are shown in Fig. 1. At low concentrations the interfacial tension decreases linearly with increasing temperature. At higher concentrations, on the other hand, it increases. At intermadiate concentrations, the γ *vs.* T curve appeares to have a break point. This behavior is

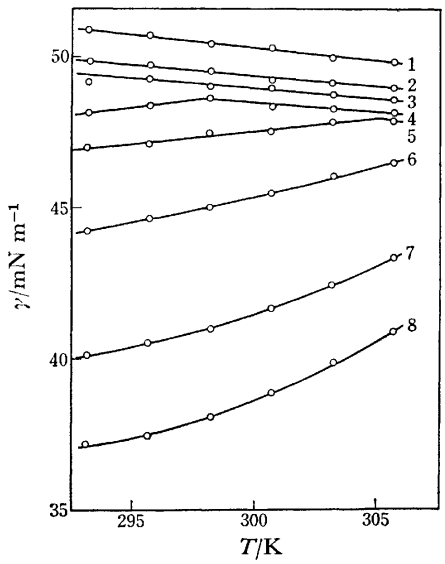

Fig. 1. Interfacial tension *vs.* temperature curves at various concentrations under 0.1 MPa.
1) $x_1^0=0$; 2) 7.88×10^{-5}; 3) 2.66×10^{-4}; 4) 3.11×10^{-4}; 5) 3.35×10^{-4}; 6) 4.00×10^{-4}; 7) 5.46×10^{-4}; 8) 7.19×10^{-4}.

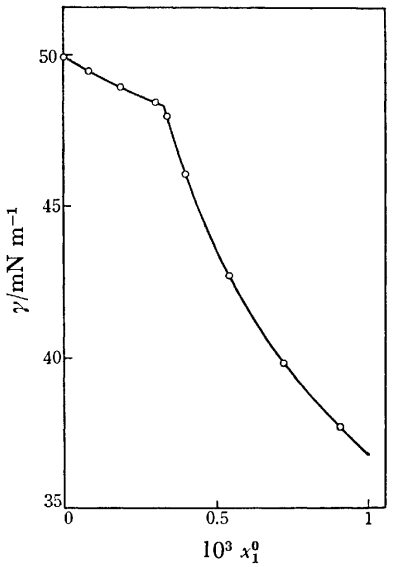

Fig. 2. Interfacial tension *vs.* mole fraction of dioctadecyl ether in hexane curve at 303.15 K under 0.1 MPa.

† Present address: Fuculty of Fisheries, Nagasaki University, Bunkyo-cho, Nagasaki 852.

similar to that of the adsorption of 1-octadecanol at hexane/water interface.[3] However, the break point is limited within a very narrow concentration range, *i.e.* between 2.7×10^{-4} and 3.6×10^{-4} of x_1^0 in this work. In Fig. 2 the interfacial tension *vs.* composition curve at 303.15 K is drawn which is prepared from Fig. 1. It has a sharp break point. In the study of the adsorption of 1-octadecanol, we observed that the first order phase transition is reflected on the γ *vs.* x_1^0 curves as a break point.[3] It is, therefore, conceivable that in the adsorbed film of dioctadecyl ether a similar phase transition takes place. Further, it is observed that at concentrations corresponding to the expanded state γ reaches rapidly its equilibrium value and at concentrations corresponding to the condensed state γ decreases gradually to an equilibrium value.

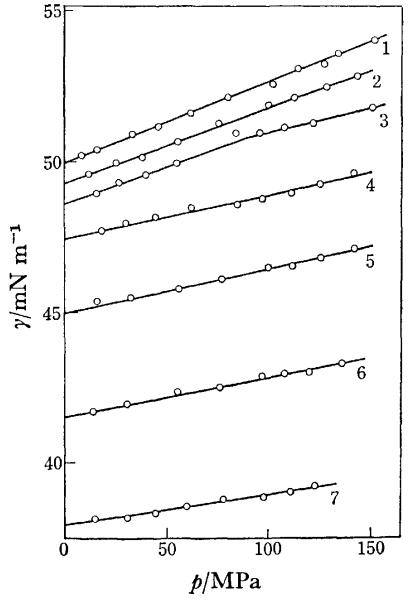

Fig. 3. Interfacial tension *vs.* pressure curves at various concentrations at 303.15 K.
1) $x_1^0=0$; 2) 1.02×10^{-4}; 3) 1.77×10^{-4}; 4) 3.54×10^{-4}; 5) 4.25×10^{-4}; 6) 6.04×10^{-4}; 7) 8.66×10^{-4}.

In Fig. 3 the interfacial tension is plotted against the pressure at various concentrations. The slope of γ *vs.* p curve is linear and positive except the curve at $x_1^0=1.77\times10^{-4}$ which has the break point at about 90 MPa. This figure is considerably different from that of 1-octadecanol.

Discussion

Taking into account that the mutual solubility of hexane and water is in fact negligible and dioctadecyl ether is soluble only in hexane, the thermodynamic quantities associated with the adsorption are estimated by applying the treatment developed previously.[1] The measurements being made on the solution of solute mole fraction below 1.0×10^{-3}, the solution is assumed to be ideal. Thus the interfacial density of surface active solute Γ_1^{H} is calculated by

$$\Gamma_1^{\mathrm{H}} = -(x_1^0/RT)(\partial\gamma/\partial x_1^0)_{T,p} \qquad (1)$$

and other thermodynamic quantities are given as the derivatives of γ with T and p, that is

$$\Delta s = -(\partial\gamma/\partial T)_{p,x_1^0} \qquad (2)$$

$$\Delta v = (\partial\gamma/\partial p)_{T,x_1^0} \qquad (3)$$

and

$$\Delta u = \gamma - T(\partial\gamma/\partial T)_{p,x_1^0} - p(\partial\gamma/\partial p)_{T,x_1^0}, \qquad (4)$$

where Δs, Δv, and Δu are the entropy, volume, and energy changes associated with the adsorption, respectively.

First Γ_1^{H} was calculated by Eq. 1 at various temperatures and pressures. Its value increases with concentration and pressure and decreases with temperature. An abrupt change is seen on the Γ_1^{H} *vs.* x_1^0 curve at the break point at which the expanded and condensed films coexist in equilibrium. Its values of the expanded and condensed states are 0.410 and 4.43 μmol m^{-2}, respectively. This significant behavior of dioctadecyl ether in the interface is revealed more clearly by drawing the interfacial pressure π *vs.* area per molecule A curve on the assumption that the adsorbed film is monomolecular. The π *vs.* A curve at 303.15 K and at 80 MPa is shown in Fig. 4 in which the curve of 1-octadecanol is

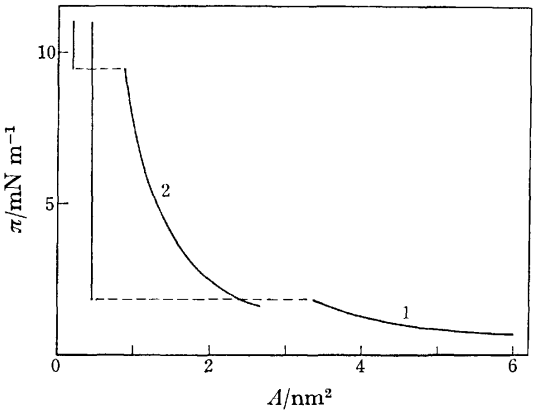

Fig. 4. Interfacial pressure *vs.* area curves at 303.15 K under 80 MPa. 1) Dioctadecyl ether; 2) 1-octadecanol.

also drawn. Although they seem somewhat different in shape, they are essentially identical with each other. In the condensed state the value of A of dioctadecyl ether is almost twice that of 1-octadecanol. Then it can be expected that the molecule adsorbes at the interface in such a way that its polar part is directed to the water phase and its two hydrocarbon chains are perpendicular to the interface. This restricted conformation might be related to the fact that the time dependence of interfacial tension is pronounced for the concentrated solutions.

It is now interesting to compare the entropy change of the adsorption on dioctadecyl ether and that of 1-octadecanol. The value of Δs evaluated by Eq. 2 is shown grafically as a function of x_1^0 at 303.15 K under atmospheric pressure in Fig. 5. The corresponding one of 1-octadecanol is also shown in this figure. It is seen apparently that dioctadecyl ether has a larger value than 1-octadecanol in the expanded state although

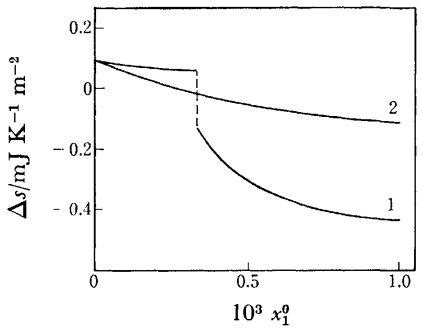

Fig. 5. Entropy change *vs.* concentration curves at 303.15 K under 0.1 MPa. 1) Dioctadecyl ether; 2) 1-octadecanol.

dioctadecyl ether has a more restricted conformation. We notice here that in such a comparison the difference between their interfacial densities is ignored. In Fig. 7A, Δs is plotted against Γ_1^H. As expected, the value of Δs of dioctadecyl ether is smaller than that of 1-octadecanol when compared at the same value of Γ_1^H. Thus we may say that the dioctadecyl ether molecule makes more negative contribution to Δs than 1-octadecanol molecule. It is also found that the entropy change associated with the phase transition, $\Delta s^c - \Delta s^e$, in which the superscripts c and e represent the condensed and expanded states, respectively, has a significantly small negative value compared with that of 1-octadecanol, *i.e.*, -1.4 mJ K^{-1} m^{-2} at 303.15 K and at 80 MPa. This small negative value might be ascribed in part to a loosely packed structure of the condensed film.

It is worthwhile to note that the fact that the break point on the γ *vs.* T curve is observed in a limited range of the concentration is related closely to a small difference between Δs^c and Δs^e. The variation of the equilibrium interfacial tension γ^{eq} between the expanded and condensed phases with temperature is given by[3]

$$(\partial\gamma^{eq}/\partial T)_p = -(\Delta s^c/\Gamma_1^{H,c} - \Delta s^e/\Gamma_1^{H,e})/(1/\Gamma_1^{H,c} - 1/\Gamma_1^{H,e}). \quad (6)$$

The left side of Eq. 6 is given by the slope of the locus of break points in Fig. 1; its value estimated roughly is *ca.* -0.12 mN m^{-1} K^{-1}. On the other hand, the numerical value of the right side, calculated from the experimental results of Figs. 3 and 5, is -0.087 mJ K^{-1} m^{-2} (mN m^{-1} K^{-1}). Taking account of some uncertainty in accuracy, the agreement of these numerical values is not unsatisfactory.

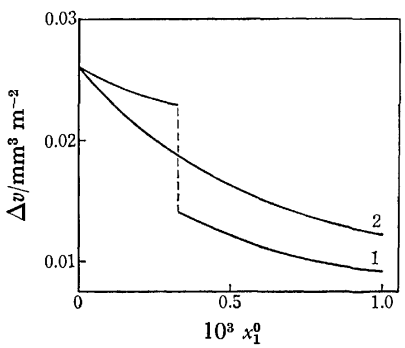

Fig. 6. Volume change *vs.* concentration curves at 303.15 K under 0.1 MPa. 1) Dioctadecyl ether; 2) 1-octadecanol.

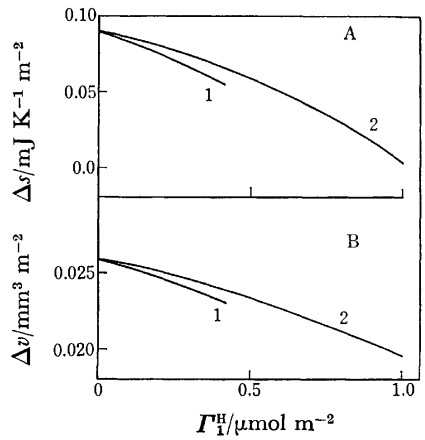

Fig. 7. A) Variation of entropy change with interfacial density at 303.15 K under 0.1 MPa.
B) Variation of volume change with interfacial density at 303.15 K under 0.1 MPa. 1) Dioctadecyl ether; 2) 1-octadecanol.

Lutton *et al.*[5] measured the interfacial tension as a function of temperature for the systems of monoglyceride and diglyceride solutions in cotton seed oil and water. Although the data are not complete, it is found that the difference in the slope of γ *vs.* T curve at the break point obtained for diglyceride is fairly smaller than that obtained for monoglyceride. Their data seem to support our observation that the phase transition of dioctadecyl ether is characterized by the small difference in Δs.

By use of Eq. 3 the value of Δv was evaluated from Fig. 3. The comparison of Δv *vs.* x_1^0 curves between dioctadecyl ether and 1-octadecanol is also made in Fig. 6. This figure is quite similar in appearance to Fig. 5. Further, a figure analogous to Fig. 7A is obtained when Δv is plotted against Γ_1^H (Fig. 7B). This fact indicates that the change in entropy associated with the adsorption is interrelated to the changes in volume. It is also explicable by the corresponding equation to Eq. 6 that the break point in the γ *vs.* p curve is observed only in a limited range of concentration as seen in Fig. 3.

Let us now calculate the energy of interface formation Δu by applying Eq. 4 to the above data. In Fig. 8, the

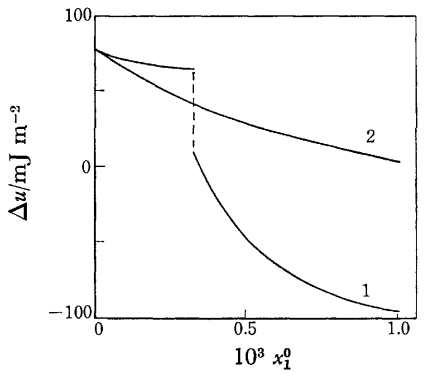

Fig. 8. Energy change *vs.* concentration curves at 303.15 K under 0.1 MPa. 1) Dioctadecyl ether; 2) 1-octadecanol.

value of Δu is plotted against x_1^0 at 303.15 K under atmospheric pressure. It varies with x_1^0 in a similar manner as Δs and Δv do. In the condensed state, however, its decrease with increase in x_1^0 is found to be relatively steep. This might reflect a gradual change of the structure of dioctadecyl ether film at the hexane/water interface with the concentration.

Excited-state Electronic Interaction of *m*-Aminoacetophenone with Aliphatic Alcohols

Yoshifumi TANIMOTO,* Kenji INOUE, Yoshihiko FURUKAWA, Yoko SEGAWA, and Michiya ITOH

Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920

(Received November 1, 1978)

The electronic interaction of both ground-state and excited-state *m*-aminoacetophenone (MAAP) with several aliphatic alcohols in nonpolar viscous solvent was investigated by steady-state and nanosecond fluorescence spectroscopies. Concentration dependence of several alcohols in liquid paraffin-hexane (LPH) mixed solvent upon fluorescence and absorption spectra suggests a complex formation of MAAP with aliphatic alcohols in the ground state. In the typical LPH solution of MAAP containing high concentration of alcohol, the complex fluorescence exhibits two-component decay and a longer wavelength fluorescence than the complex fluorescence exhibits a rise and decay. The results demonstrate that the complex in the excited state further associates with alcohol to make an exciplex including an alcohol molecule.

The fluorescence properties of many aromatic molecules strongly depend on the solvent system; fluorescence maximum, fluorescence quantum yield, and lifetime remarkably change from nonpolar to polar solvent. In most cases, these changes have been explained in terms of "the solvent effect," which usually involves dispersion force of solvent, and dipole-dipole and dipole-induced dipole interactions between solute and solvent.[1] However, the possibility of a new type of the electronic interaction was reported by Lumry and his coworkers;[2] they suggested the importance of the excited-state solute-solvent complex (exciplex) formation in the polar solvent. Actually, they investigated the fluorescence of indole and indole derivatives in the mixed systems of nonpolar-polar solvents (mainly in pentane–alcohol systems), and showed that an excited-state solute-solvent complex is responsible to a large red shift and loss of vibrational structure in the fluorescence spectra of indole and indole derivatives in the polar solvents. However, since the possibility of the ground state solute-solvent complex was not strictly excluded and since they did not show any dynamical experimental evidence, their explanation does not seem to be generally accepted. On the other hand, Ware and his coworkers[3] investigated the problem of the origin and nature of the temperature-dependent spectral shift characteristic of aminophthalimides in alcoholic solvents by the aid of nanosecond time-resolved emission techniques. They showed that at least two relaxation times characterize the phenomenon. One relaxation time was observed to be subnanosecond in character and may be associated with the exciplex that presumably is present in the system. The other relaxation time was presumably associated with the nonspecific dipolar reorientation. Recently, the interaction of 2-anilinonaphthalene with ethyl alcohol and glycerol in the excited state was studied by DeToma and Brand.[4] They showed a direct kinetic evidence that 2-anilinonaphthalene undergoes a specific reversible association with ethyl alcohol and glycerol in the excited state.

In the previous paper,[5,6] we have clarified that *m*-aminoacetophenone (MAAP) makes a complex with *t*-pentyl alcohol in the ground state and that the complex further associates with alcohol in the excited state (*i.e.*, the complex in the excited state makes an exciplex with alcohol). However, *t*-pentyl alcohol may be not so popular as ethyl alcohol in spectroscopic studies, and the results look some special case. Therefore, we have extended the study to other alkanols. This paper describes the excited-state complex formation (exciplex formation) of MAAP with several alcohols, and the results clearly suggest the general importance in studying the fluorescence properties of polar aromatic molecules in the alcoholic solvents.

Experimental and Kinetic Analysis

MAAP (Nakarai EP Grade) was recrystallized twice from ethyl alcohol, followed by vacuum sublimation. *t*-Butyl alcohol, butyl alcohol (both Nakarai EP Grade) were dried with molecular sieve and thereafter distilled. Isopropyl alcohol (Merck Uvasol) and ethyl alcohol (Nakarai Spectro Grade) were used as supplied. Liquid paraffin and hexane (both Nakarai Spectro Grade) were also used as supplied. The mixture of them (9: 1 volume ratio) was used as a viscous nonpolar solvent. Solutions for lifetime measurements were degassed with the freeze-thaw technique.

Absorption and fluorescence spectra were measured on Hitachi 323 and MPF-4 spectrophotometers at room temperature unless denoted. Fluorescence lifetimes were measured with a similar method described in a previous paper.[5] Observed lifetimes were analyzed by a nonlinear least-squares method including the exciting pulse shape.[7]

For the fluorescence quantum yield measurements,[8] the spectral response of the observed system was corrected by using the fluorescence of quinine sulfate in 0.5 M sulfuric acid as a standard. Fluorescence spectra of both ethyl alcohol solutions of MAAP and quinine sulfate standard solution were measured successively, and after correcting absorbances and refractive indices, the quantum yield of ethyl alcohol solution of MAAP was determined. Here, the quantum yield of quinine sulfate solution was assumed to be 0.55, and solutions were excited by the 360 nm light. The yields of other solutions were then determined by using the ethyl alcohol solutions of MAAP as a second standard and by correcting similarly.

The experimental results are shown to be consistent with the kinetic scheme given below.[9]

$$\mathrm{MAAP} + \mathrm{A} \underset{}{\overset{K}{\rightleftharpoons}} \mathrm{C} \qquad (1)$$

$$\mathrm{C} \xrightarrow{h\nu} \mathrm{C}^* + \mathrm{A} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \mathrm{E}^* \qquad (2)$$

$$\mathrm{C}^* \xrightarrow{k_1} \mathrm{C} + h\nu' \qquad \mathrm{C}^* \xrightarrow{k_2} \mathrm{C} \qquad \mathrm{E}^* \xrightarrow{k_5} \mathrm{C} + \mathrm{A} + h\nu'' \qquad \mathrm{E}^* \xrightarrow{k_6} \mathrm{C} + \mathrm{A}$$

where A, C, C*, and E* are alcohol, the complex, the complex in the excited state, and excited-state complex (exciplex) generated from C* and A, respectively; K is equilibrium constant of the complex formation in the ground state, and k's are rate constants of respective processes.

Under photostationary state, the process 2 gives the following equations;

$$[C]/F_C = c'\{k_3(k_5+k_6)[A]/(k_4+k_5+k_6)+k_1+k_2\} \quad (3)$$

$$F_E/F_C = c''k_3k_5[A]/\{k_1(k_4+k_5+k_6)\} \quad (4)$$

$$\phi = \{(k_4+k_5+k_6)k_1+k_3k_5[A]\}/\{(k_1+k_2+k_3[A]) \times (k_4+k_5+k_6)-k_3k_4[A]\} \quad (5)$$

In Eqs. 3, 4, and 5, F_C and F_E are the fluorescence intensities of C* and E*, respectively; [A] and [C] are the concentrations of the alcohol and the complex, respectively, ϕ is the fluorescence quantum yield of total emission, and c' and c'' are proportional constants.

For the pulse excitation, following equations are also obtained.

$$[C^*] = c_1 \exp(-\lambda_1 t) + c_2 \exp(-\lambda_2 t) \quad (6)$$

$$[E^*] = c_3\{\exp(-\lambda_1 t)-\exp(-\lambda_2 t)\} \quad (7)$$

where

$$\lambda_{1,2} = 1/2[k_1+k_2+k_3[A]+k_4+k_5+k_6 \mp \{(k_4+k_5+k_6 -k_1-k_2-k_3[A])^2+4k_3k_4[A]\}^{1/2}]$$

$$c_1 = [(\lambda_2-X)/(\lambda_2-\lambda_1)][C^*]_0$$

$$c_2 = [(X-\lambda_1)/(\lambda_2-\lambda_1)][C^*]_0$$

$$c_3 = k_3[A][C^*]_0/(\lambda_2-\lambda_1)$$

$$X = k_1 + k_2 + k_3[A]$$

and

$$\lambda_1 + \lambda_2 = k_1 + k_2 + k_3[A] + k_4 + k_5 + k_6 \quad (8)$$

Results and Discussion

Absorption and Fluorescence Spectra of MAAP. Figure 1 shows the absorption and fluorescence spectra of MAAP in several solvents. In hexane, absorption maximum appears at 325 nm and no fluorescence band is practically observed. In 2-methyltetrahydrofuran (MTHF), the absorption maximum of MAAP shifts to the longer wavelength (λ_{max} 340 nm), while a strong fluorescence band appears at ≈420 nm. The absorption maxima of this compound in tetrahydrofuran, MTHF, and several alcohols appear in similar wavelength region each other, while the fluorescence in alcohols remarkably shifts to 490—510 nm. The Stokes shifts in alcoholic solvents are about 9000—10000 cm^{-1}, though about 5600 cm^{-1} in MTHF. The unusually large Stokes shift seems to suggest some specific interaction between MAAP and alcohols. Since general feature of the absorption and fluorescence spectra was common in all systems reported here (*i.e.*, MAAP–*t*-butyl alcohol, MAAP–butyl alcohol, MAAP–isopropyl alcohol, and MAAP–ethyl alcohol), the results on the MAAP–*t*-butyl alcohol in liquid paraffin–hexane mixed system (abbreviated to LPH hereafter) were mainly described in this paper. Figure 2 shows the concentration dependence of *t*-butyl alcohol (TBA) in the LPH solution of MAAP upon fluorescence spectra. Although MAAP is practically non-fluorescent in LPH, the fluorescence with a short lifetime appears at ≈430 nm by adding a small amount of TBA, and the band increases in intensity with increasing the concentration of TBA (<0.2 M) (1 M=1 mol dm^{-3}). Furthermore, including a small red shift, a new band with a long lifetime appears at ≈490 nm, and increases in intensity with further increasing the concentration of the alcohol (>0.2 M).

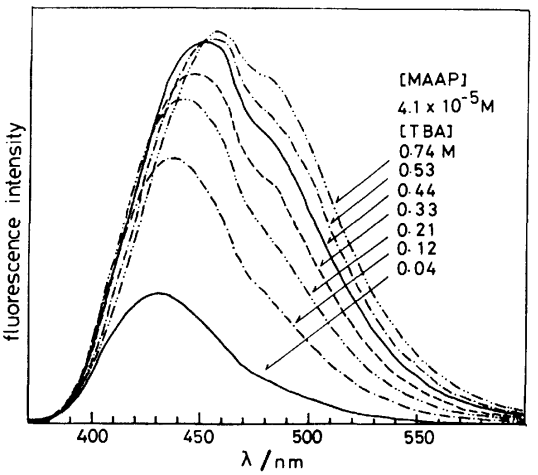

Fig. 2. Fluorescence spectra of MAAP in LPH containing several concentrations of TBA. The excitation wavelength is 360 nm.

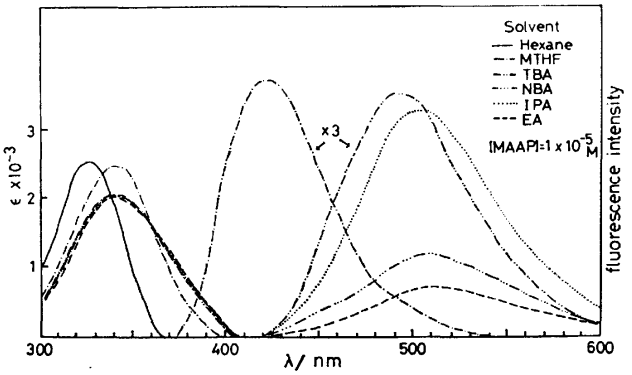

Fig. 1. Absorption and fluorescence spectra of MAAP in various solvents; MTHF, 2-methyltetrahydrofuran; TBA, *t*-butyl alcohol; BA, butyl alcohol: EA, ethyl alcohol. The excitation wavelength is 360 nm.

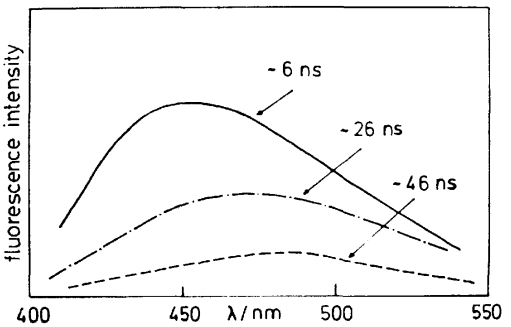

Fig. 3. Time-resolved fluorescence spectra of MAAP (1.4 $\times 10^{-5}$ M) in LPH containing TBA (1×10^{-1} M). Times indicated are after a peak of an exciting laser pulse.

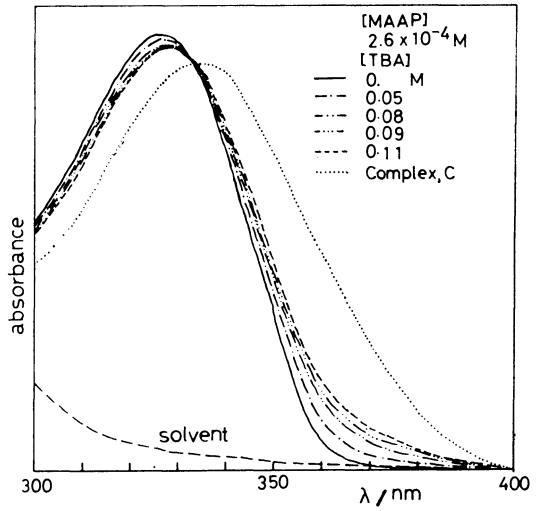

Fig. 4. Absorption spectra of MAAP in LPH, containing several concentrations of TBA. Absorption spectrum of the complex, C, was depicted from K and concentrations of MAAP and TBA.

Time-resolved fluorescence spectra in Fig. 3 exhibit these two kinds of fluorescence bands. Since it can be expected that MAAP and TBA make a hydrogen-bonding complex in the ground state, the shorter wavelength band, which is predominant in the low concentration of TBA, is most probably due to the hydrogen-bonding complex. Figure 4 shows the effect of TBA concentration upon the absorption spectra of MAAP in LPH. A new band appears at ≈360 nm and gradually increases in intensity with increasing the concentration of TBA (an isosbestic point at 334 nm). Therefore, assuming the complex formation in the ground state, the spectra were analyzed in terms of an ordinary 1 : 1 complex formation, shown in Eq. 1.[6] Figure 5 shows the Scott plots of absorption intensity of the new band (I_C) *vs.* [TBA]. The plots exhibit linear relationship, as is clear from Fig. 5, affording an equilibrium constant of 4.6 M^{-1}. Fluorescence intensity of the shorter wavelength band (F_C) was also analyzed in the same manner by assuming that the intensity is proportional to the absorption intensity of the new band. Figure 6 shows the plots of $[TBA]/F_C$ *vs.* [TBA], which afford the equilibrium constant of 3.4 M^{-1}. Both results agree each other within experimental errors.

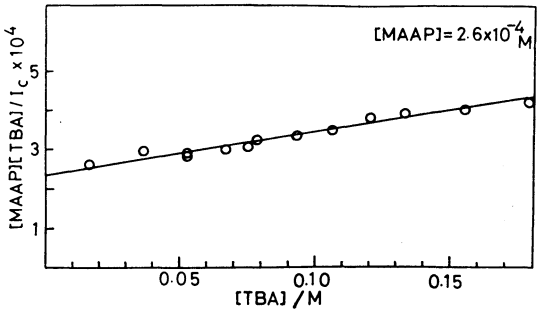

Fig. 5. Plots of $[MAAP][TBA]/I_C$ *vs.* [TBA]. Absorption intensities (I_C) were monitored at 370 nm.

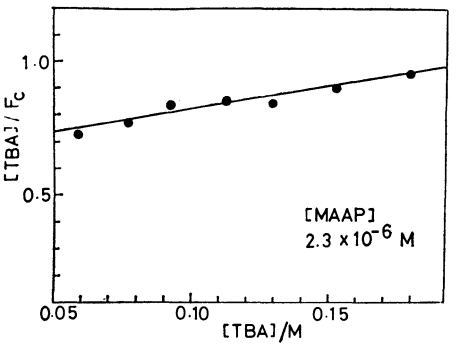

Fig. 6. Plots of $[TBA]/F_C$ *vs.* [TBA]. Fluorescence intensities (F_C) were monitored at 430 nm. In the range of TBA concentration (0.05—0.2 M), spectral shift of the fluorescence was small.

Now, let us examine the longer wavelength fluorescence which appears at rather concentrated solution of TBA. The excitation spectrum monitored at 530 nm (*i.e.*, at the longer wavelength band) is identical with that at 430 nm (*i.e.*, at the shorter wavelength band). Fluorescence intensity of the longer wavelength band increases with increasing the concentration of TBA, as mentioned above. Figures 7 and 8 show the plots of

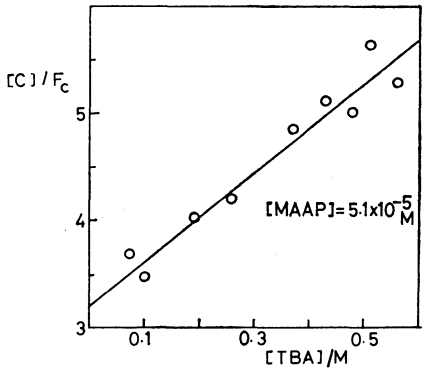

Fig. 7. Plots of $[C]/F_C$ *vs.* [TBA]. Fluorescence intensities (F_C) were monitored at 430 nm. Concentrations of C in the plots were evaluated from K, [MAAP] and [TBA].

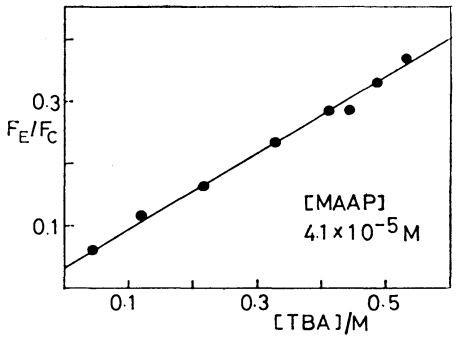

Fig. 8. Plots of F_E/F_C *vs.* [TBA]. Fluorescence intensities, (F_C and F_E) were monitored at 430 nm and at 530 nm, respectively.

[C]/F_C *vs.* [TBA], and F_E/F_C *vs.* [TBA], respectively. They show the linear relationships expected from Eqs. 3 and 4, respectively, though fluorescence intensities, F_C and F_E, may include the spectral shift owing to the change of solvent polarity. With these findings and time evolution of the fluorescence intensities which will be mentioned later, the longer wavelength fluorescence is tentatively ascribed to the exciplex (E*) formed between the complex in the excited state (C*) and TBA.

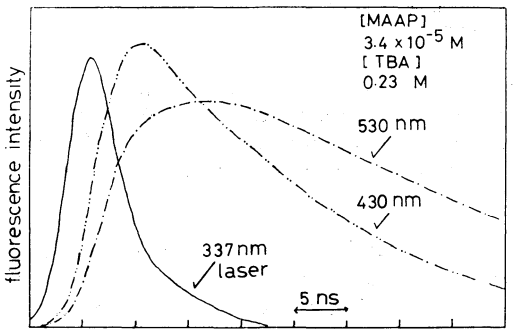

Fig. 9. Time evolution of the fluorescence intensities of MAAP in LPH.

The Time Evolution of Fluorescence and the Estimation of Kinetic Parameters. From Eq. 1, one can expect a simple two-component decay for [C*] and a growth and decay for [E*]. Figure 9 shows the typical time evolutions of the fluorescence of [C*] and [E*], in the MAAP–TBA–LPH system. The shorter wavelength band (C*) exhibits typical two-component decay, and the longer one (E*) shows a growth and decay as expected. The λ_1 and λ_2 obtained from both fluorescence bands coincide with each other within experimental errors. Therefore, these findings provide an evidence that the longer wavelength fluorescence (F_E) is ascribed to the exciplex, E*, generated from C* and TBA.

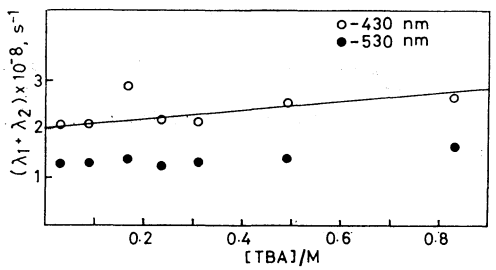

Fig. 10. Plots of $\lambda_1+\lambda_2$ *vs.* [TBA]. Fluorescence intensities were monitored both at 430 nm and at 530 nm. The fluorescence intensities at 530 nm was analyzed as a superposition of the fluorescence of both C* and E*, since both spectra partly overlapped each other in this region. Concentration of MAAP is 3.4×10^{-5} M.

Equation 8 gives k_3 from the plots of $\lambda_1+\lambda_2$ *vs.* [TBA]. As [TBA]$\longrightarrow$0,

$$\lambda_1 \longrightarrow k_1 + k_2$$

$$\lambda_2 \longrightarrow k_4 + k_5 + k_6$$

Thus k_3, k_1+k_2, and $k_4+k_5+k_6$ can be obtained (see Fig. 10). The results were shown in Table 1. Then combining Eq. 4 and the above values obtained, k_4 and k_5+k_6 can be calculated separately (see Fig. 7). If one may calculate the fluorescence quantum yields of more than two TBA concentrations of the solution, one may solve Eq. 5 to estimate k_1 and k_5. From this analysis, the radiative and nonradiative rate constants of respective states, C* and E*, were estimated to be of nearly the same order of magnitude. Furthermore, if only the exciplex formation is an activation process, the energy barrier may be obtained from the plots of F_E/F_C *vs.* $1/T$ (T: temperature, K), assuming that only k_3 in Eq. 4 is temperature dependent.[10] Figure 11 shows this relationship and the activation energy was obtained to be 7 kcal mol^{-1}.

Table 1. KINETICAL PARAMETERS OF THE MAAP–ALCOHOL SYSTEMS IN LPH AT ROOM TEMPERATURE

Alcohol	TBA	BA	IPA	EA
ε[a]	12.5	17.5	19.9	24.5
ϕ[b]	0.56	0.08	0.19	0.05
K, M^{-1} [c]	4.6	5.7	5.6	12.2
$k_3\times10^{-9}$, M^{-1} s^{-1}	0.09	0.31	0.19	0.68
$(k_1+k_2)\times10^{-8}$, s^{-1}	0.58	0.49	0.52	0.69
$(k_4+k_5+k_6)\times10^{-9}$, s^{-1}	0.17	0.15	0.14	0.35

a) Dielectric constant of alcohol. b) Total fluorescence quantum yield (see text). c) Equilibrium constant of the complex formation at room temperature.
TBA, *t*-butyl alcohol; BA, butyl alcohol; IPA, isopropyl alcohol; EA, ethyl alcohol.

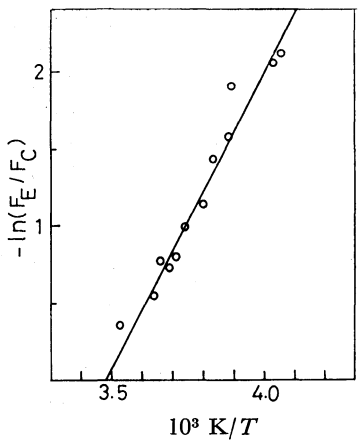

Fig. 11. Plots of $-\ln(F_E/F_C)$ *vs.* $1/T$. Fluorescence intensities, F_C and F_E, were monitored at 430 nm and at 530 nm, respectively. Concentrations of MAAP and TBA are 3.4×10^{-5} M and 0.82 M, respectively.

Fluorescence behavior of the MAAP–butyl alcohol, MAAP–isopropyl alcohol, and MAAP–ethyl alcohol in LPH is essentially parallel to that of MAAP–TBA mentioned above, and observed data in these systems were analyzed in the same procedure as mentioned above. Unfortunately, the activation energy of these systems could not be obtained, because of lack of the solubility of the alcohols at low temperature. The results obtained were listed in Table 1. From the Table,

equilibrium constants of the complex formation seem to increase with increasing strength of the dielectric constant of the alcohols. The rate constants of the exciplex formation, k_3, also seem to increase with the dielectric constant of the alcohols.

Generally, unusually large spectral change observed in the high concentration of TBA (>0.2 M) (see Fig. 2) might be explained in terms of following mechanisms; 1) the internal rotation of MAAP leading to the intramolecular CT interaction in MAAP, 2) the general solvent effect, 3) the reorientation of alcohols around MAAP, and 4) the exciplex formation with the solvent molecules. As for the mechanism 1, the process may be expected to occur very fast in the order of some picoseconds, which is inconsistent with our observation. The mechanism 2 means that the long-range intermolecular interaction between solute and solvent molecules such as dispersion force, dipole-dipole interaction, *etc.*[1] In this mechanism, the effect of alcohol upon the fluorescence band shape may be considered to be small, and wavelength-independent decay in a certain fluorescence spectrum may be expected. However, these are in contradiction to the observation reported here, since Figs. 2, 3, and also 9 show the drastic change of fluorescence band with increasing the TBA concentration, and the time-resolved fluorescence spectra including two different fluorescent species. Then, the mechanism 3 may be ruled out as follows. If MAAP molecule may be surrounded by TBA molecules by adding small amount of TBA in the LPH solution, it is unlikely that there are the two different fluorescent states stable in the excited state of MAAP surrounded by unspecified alcohol molecules. The rate for the reorientation of surrounding molecules may be of the order of picosecond. However, if the alcohol molecule may diffuse to make an interaction with MAAP in LPH, the rate may be of the order of some nanosecond. The diffusion rate constant in LPH is approximately estimated to be of the order of 10^8 M^{-1} s^{-1} from the viscosity of LPH ($\approx$100 cp). With this mechanism, observations shown in Figs. 2, 3, and 9 may be qualitatively explained. Figure 8 shows a linear relationship of F_E/F_C *vs.* [TBA], and may strongly suggest the stochiometric complex formation in the excited state. The mechanism 4 may suggest the specific intermolecular interaction between the complex and another alcohol molecule (*i.e.*, stochiometric excited-state complex formation). As already shown, all the observations have been quantitatively explained with this mechanism. The mechanism 4 seems to be most reasonable in the interpretation of the results observed in this paper.

Preliminary results on the fluorescence of *m*-dimethylaminoacetophenone[11,12] (DMAAP) show essentially the similar fluorescence property to that of MAAP. Although the weak fluorescence band appears at $\approx$405 nm in LPH, a new fluorescence band appears at $\approx$430 nm by adding a small amount of TBA, and increases in intensity with increasing the TBA concentration (<0.15 M). Furthermore, with further increasing the TBA concentration, another new fluorescence band appears at $\approx$490 nm (>0.15 M). The LPH solution of DMAAP containing high concentration of TBA exhibits the two-component decay of the shorter wavelength (at 440 nm), and the rise and decay of the longer wavelength fluorescence (at 530 nm). The similar kinetic analysis suggests that DMAAP makes the 1:1 complex with TBA in the ground state (K=4—10 M^{-1}), and the complex in the excited state (C*) further associate with the alcohol molecule ($k_3=0.08\times10^9$ M^{-1} s^{-1}, $k_1+k_2=0.4\times10^8$ s^{-1}, and $k_4+k_5+k_6=0.1\times10^9$ s^{-1}). Here, if the complex formation in the ground state might be tentatively attributable to a kind of the hydrogen-bonding with alcohol, the interaction between carbonyl of MAAP and hydroxylic hydrogen of alcohol seems to be most reasonable to the complex formation in the ground state. Furthermore, it is likely that the exciplex may be stabilized by the weak electronic interaction such as charge-transfer between C* and alcohol molecule, as already discussed in indole fluorescence by Lumry and his coworkers.[2] However, this is not obvious at this stage.

The authors wish to thank Dr. Kiyokazu Fuke for his help in the analysis of fluorescence lifetimes by a nonlinear least-squares fit, and for valuable discussions.

6) In Ref. 5, the 1:2 complex formation of the ground-state MAAP with *t*-pentyl alcohol was presented. The discrepancy between the previous and present results may be explained by the following two possibilities. The difference might be attributable to the nature of *t*-pentyl alcohol somewhat different from others, since the dielectric constant of *t*-pentyl alcohol (ε: 5.8) is much smaller than that of alcohols used in the present work. Otherwise, the spectral changes observed in the previous system may exhibit the 1:2 complex formation in appearence, since the equilibrium constant of the 1:1 complex of MAAP with *t*-pentyl alcohol may be very small.

Anharmonic Potential Functions of Simple Molecules. III. Computation of Vibration-Rotation Energies of XYZ and X_2Y_2 Type Linear Molecules through Direct Numerical Diagonalization: Application to the N_2O Molecule

Isao SUZUKI

Institute of Information Sciences, University of Tsukuba, Sakuramura, Niihari-gun, Ibaraki 300-31

(Received December 9, 1978)

A formalism has been developed for the calulation of vibration-rotation energy levels of linear XYZ and X_2Y_2 type molecules through direct numerical diagonalization of vibration hamiltonian matrix. The procedure of evaluating vibration as well as vibration-rotation energies can be described mostly in matrix algebra and thus easily converted to computer languages. The N_2O molecule was chosen as an example of numerical treatment. Several approaches have been checked in evaluating B_v and D_v and they are discussed from the view point of accuracy and efficiency in computations. It is found that the variational approach of computing B_v^r, contribution of rotational hamiltonian to B_v, is very efficient and accurate. Some peculiar features of the molecular potential of the X_2Y_2 type molecule are discussed in connection with their adaptation on the direct numerical diagonalization method.

There has been an increasing number of studies on the direct numerical diagonalization method of vibrational hamiltonian matrix in terms of a large number of harmonic oscillator basis wave functions.[1-7] The major advantages of reducing the vibrational hamiltonian numerically to fit the observed spectroscopic quantities are threefold. (1) Accidental degeneracies, which require special and somewhat cumbersome treatments in conventional perturbation method, are automatically taken care of. (2) Higher order terms in vibrational potential as well as in expansions of moment of inertial tensor are incorporated without changing the general scheme of computations. (3) Orthonormal vibrational wave functions are readily available through diagonalization as linear combinations of basis harmonic oscillator wave functions. These wave functions may be used to compute any average molecular properties in a given vibrational state.

It is also possible, at least in principle, to apply this method to individual vibration-rotation energy levels. The Coriolis coupling terms in the hamiltonian, however, interact the ro-vibrational states with $\Delta l=\pm 1$ in linear polyatomic molecules, and the factorization is no longer possible for the vibration-rotation states with $J\neq 0$. Therefore, an entire vibration-rotation hamiltonian matrix (unfactorized) must be solved at a time, which forces to use a huge number of basis wave functions (usually products of harmonic oscillator wave function and symmetric rotor type wave function). Since the vibration-rotation coupling constants are as important as the vibrational wavenumbers themselves in the determination of molecular force field, several less rigorous methods have been proposed to calculate vibration-rotation levels. Recent studies of Whiffen *et al.*[6,7] on the OCS molecule have made a significant contribution to this field.

This is our third report on the above subject and the method previously reported (hereafter referred to as I and II) has been extended to include the XYZ and X_2Y_2 type linear molecules. It is shown that the rotational and Coriolis parts of the vibration-rotation hamiltonian are reduced to almost identical forms for these two types of molecule. Several methods have been tested for the evaluation of vibration rotation levels and in each case these levels are converted to the corresponding rotational constant (B_v) and the centrifugal distortion constant (D_v). The results are compared from the view point of accuracy and efficiency in computations.

Extensive numerical calculations have been made on the N_2O molecule and the results are given in the present paper. This molecule is of particular interest, for we plan to apply the resultant vibrational wave functions to the intensity problem for N_2O. In some cases we also used the OCS molecule so that the direct comparison is possible for the results of Whiffen *et al.*[6,7]

The X_2Y_2 type molecule requires some extra handling since it has two degenerate modes and individual l_4 and l_5 are no longer "good" quantum numbers. The proper treatment in direct diagonalization procedure has also been discussed.

Hamiltonian

The general form of the vibration-rotation hamiltonian of a polyatomic molecule given by Goldsmith, Amat, and Nielsen[8] is reduced to a much simpler form for a linear molecule.[9,10] It is conveniently expressed as the sum of the vibrational, rotational, and Coriolis hamiltonians:

$$\mathbf{H} = \mathbf{H}_{vib} + \mathbf{H}_{rot} + \mathbf{H}_{Cor}, \quad (1)$$

$$\mathbf{H}_{vib} = V_h(q_s^2, j_s^2) + V_{anh}(q_s) + \mathbf{H}'_{vib}, \quad (2)$$

$$\mathbf{H}'_{vib} = B(j_x^2 + j_y^2) = (B/2)(j_+j_- + j_-j_+), \quad (3)$$

$$\mathbf{H}_{rot} = B(J_x^2 + J_y^2) = (B/2)(J_+J_- + J_-J_+), \quad (4)$$

$$\mathbf{H}_{Cor} = -2B(j_xJ_x + j_yJ_y) = -B(j_+J_- + j_-J_+). \quad (5)$$

The definitions for symbols appearing in Eqs. 1—5 are summarized in Table 1. All the operators are dimensionless, hamiltonains and other constants are given in cm^{-1} as in I and II. The reduced moment of inertia, I', can be expressed in the following form.[9,10]

$$I' = I_e[1 + \gamma_1 q_1 + \gamma_s q_s]^2. \quad (6)$$

For the molecules of current interest, the expansion coefficients, γ's, are given as

Table 1. Listings of symbols to describe vibration-rotation hamiltonians

q_s	Dimensionless normal coordinate
j_s	Dimensionless vibrational momentum conjugated to q_s $[j_s=p_s/\hbar=\hbar^{-1}(\partial T/\partial \dot{q}_s)]$
V_h	Harmonic part of vibrational potential
V_{anh}	Anharmonic part of vibrational potential
j_x, j_y	x,y-Components of vibrational angular momenta $(j_x=p_x/\hbar, j_y=p_y/\hbar)$
j_+, j_-	Ladder operators for vibrational angular momenta $(j_\pm=j_x\pm ij_y)$
J_x, J_y	Dimensionless total angular momenta $(J_x=P_x/\hbar, J_y=P_y/\hbar)$
J_+, J_-	Ladder operators for total angular momenta $(J_\pm=J_x\pm iJ_y)$
I_e	Equilibrium moment of inertia
B_e	Equilibrium rotational constant $\hbar=/(4\pi cI_e)$
I'	Instantaneous moment of inertia with correction of Coriolis effect
B	Instantaneous rotational constant defined as $\hbar/(4\pi cI')$

a) The molecular axis coincides with the z-axis.

XY_2: $\gamma_1 = (2B_e/\omega_1)^{1/2}$ $s=3$ $\gamma_3=0$

XYZ: $\gamma_1 = (2B_e/\omega_1)^{1/2}|\zeta_{23}{}^x|$ $s=3$ $\gamma_3=(2B_e/\omega_3)^{1/2}|\zeta_{21}{}^x|$

X_2Y_2: $\gamma_1 = (2B_e/\omega_1)^{1/2}|\zeta_{42}{}^x|$ $s=2$ $\gamma_2=(2B_e/\omega_2)^{1/2}|\zeta_{41}{}^x|$

This is the results from the fact that only $a_1{}^{xx}=a_1{}^{yy}$ and $a_s{}^{xx}=a_s{}^{yy}$ are nonvanishing among the derivatives of moment of inertia with respect to normal coordinate: *i.e.* $a_{s\sigma}^{\alpha\beta}=(\partial I^{\alpha\beta}/\partial Q_{s\sigma})$. See, for example, Eq. 17 of Ref. 10. The phases of normal coordinates q_1 and q_s are taken so that the coefficients $a_1{}^{xx}$ and $a_s{}^{xx}$, and thus γ_1 and γ_s, are positive. Taking the reciprocal of I' and expanding it in terms of the related normal coordinates, B is given as

$$B = B_e\sum_{k=0}(-1)^k(k+1)(\gamma_1q_1+\gamma_sq_s)^k$$
$$= B_e[1+\sum_{k=1}(-1)^k(k+1)(\gamma_1q_1+\gamma_sq_s)^k]. \quad (7)$$

Equation 7 reflects the vibrational effects on rotational constants through the changes in moment of inertia. Coupling between the vibrational and rotational angular momenta also affects vibration-rotation energies. Vibrational angular momentum operators $j_\pm$ are given as the sum of

$$j_\pm = \sum_{i=1}^{m} j_\pm^{(s_i,d_i)}, \quad (8)$$

where m is a number of nonvanishing Coriolis coupling constants, s_i and d_i denote nondegenerate and degenerate dimensionless normal coordinates associated with the Coriolis coupling constant. Each term in summation is given as

$$j_\pm^{(s,d)} = \pm i\cdot\zeta_{ds}{}^x[(\omega_d/\omega_s)q_sp_\pm-(\omega_s/\omega_d)j_sq_\pm], \quad (9)$$

where $q_\pm=q_{dx}\pm iq_{dy}$ and $p_\pm=j_{dx}\pm ij_{dy}$ and the suffix i for the coordinate is dropped in Eq. 9. For the present case, the relevant indeces are:

XY_2: $m=1$ $(s_1=3, d_1=2)$,

XYZ: $m=2$ $(s_1=1, d_1=2)$ and $(s_2=3, d_2=2)$,

X_2Y_2: $m=3$ $(s_1=1, d_1=4)$, $(s_2=2, d_2=4)$, and $(s_3=3, d_3=5)$

Substitutions of $j_\pm$ into Eqs. 3 and 5 yield the final forms of hamiltonians in terms of dimensionless normal coordinates and their conjugate momenta.

Energy Levels

Vibrational Energy and Its Matrix Representation. Pure vibrational energies are determined from harmonic and anharmonic potential as well as from squared angular vibrational momenta designated as $\mathbf{H}'_{vib}$ in Eq. 3. The number of nonvanishing force constants are

Table 2. Non-vanishing force constants in general quartic force field

	Quadratic[a]	Cubic	Quartic	Total
XY_2	3	3	6	12
XYZ	4	6	9	19
X_2Y_2	6	11	23	40

a) This column corresponds to the sum of harmonic frequencies and independent Coriolis coupling constant(s) in normal coordinate space. Because of the Coriolis sum rule, only one Coriolis coupling constant is independent in XYZ and X_2Y_2 type molecules. (None in XY_2 type)

tabulated in Table 2 for the three types of linear molecules. As in II, the force constants in curvilinear internal coordinates are transformed into normal coordinate space. It is also convenient to set up the vibrational hamiltonian matrix as the sum of its component matrices for individual force constants.

$$\boldsymbol{H}_v = \sum_{i=1}^{f+1} k^{(i)}\boldsymbol{Z}^{(i)}, \quad (10)$$

where f is a total number of force constants, $k^{(i)}$ could be either ω_s, $k_{ss's''}$ or $k_{ss's''s'''}$. The matrix element $Z_{nn'}^{(i)}$ is defined as

$$Z_{nn'}^{(i)} = \langle n|U^{(i)}(q)|n'\rangle \quad (11)$$

If $k^{(a)}=k_{111}$, for example, $U^{(a)}=q_1{}^3$, and if $k^{(b)}=k_{1122}$, then $U^{(b)}=q_1{}^2q_2{}^2$, $|n\rangle$ represents harmonic oscillator wave function. To be more precise it is either $|n\rangle=|n_1, n_2, l_2, n_3\rangle$ or $|n_1, n_2, n_3, n_4, l_4, n_5, l_5\rangle$. It is convenient to include the term arising from $\mathbf{H}'_{vib}$ in $\boldsymbol{Z}^{(i)}$ and treat as if it were the $(f+1)$th force constant, *i.e.* $k^{(f+1)}=B_e$ and $Z_{nn'}^{(f+1)}=(1/2)\langle n|j_+j_-+j_-j_+|n'\rangle$+higher terms. By selecting a proper set of basis functions, $\boldsymbol{H}_v$ is divided into a desired number of symmetry manifolds (σ, π, δ, $\cdots$), each of which may be treated seperately. Then the eigenvalue problem is solved which yields a diagonal eigen value matrix $\boldsymbol{W}_v$ and the eigen vector matrix $\boldsymbol{A}_v$, the n-th column corresponds to the eigenvector of the n-th eigenvalue.

$$\boldsymbol{H}_v\boldsymbol{A}_v = \boldsymbol{A}_v\boldsymbol{W}_v \quad (12)$$

As described in I and II, only a limited number of lower eigenvalues, which is of immediate interest to us, is usually obtained by a modified Givens-Housholder method for symmetric matrices.[11] Therefore, $\boldsymbol{A}_v$ is not necessarily a square matrix but may be considered as a rectangular matrix. A set of orthonormal vibrational wave functions is readily obtained as a linear combination of the harmonic oscillator wave functions:

$$|v\rangle = \sum_n a_{vn}|n\rangle, \tag{13}$$

where a_{vn} is a corresponding element of $\boldsymbol{A}_v$.

Vibration-rotation Energy. The contributions from $\mathbf{H}_{rot}$ as well as from $\mathbf{H}_{Cor}$ must be considered to obtain the rotational energies of a given vibrational state. The basis function is usually in the form of $|n,J\rangle=|n\rangle\cdot|J\rangle$, the latter being a symmetric rotor type wave function. Since the matrix elements are diagonal with respect to J, the vibration-rotation hamiltonian matrix may be set for any required value of J. Since the operators $J_x^2+J_y^2$ can be replaced by $[J(J+1)-l^2]$ for practical purposes, the effect of $\mathbf{H}_{rot}$ is most conveniently treated as the $(f+2)$th component of $\boldsymbol{Z}$:

$$\boldsymbol{H}_r(J) = k^{(f+2)}\boldsymbol{Z}^{(f+2)}, \tag{14}$$

$$k^{(f+2)} = B_e[J(J+1)-l^2], \tag{15}$$

$$Z_{nn'}^{(f+2)} = \sum_{k=0}(-1)^k(k+1)[\sum_{m=0}^{k} {}_kC_m\gamma_1^{k-m}\gamma_s^m \times\langle n|q_1^{k-m}q_s^m|n'\rangle| \tag{16}$$

The γ's are given in Eq. 6 and ${}_kC_m=k!/[m!(k-m)!]$. The contribution from $\mathbf{H}_{rot}$ may be obtained either by diagonalizing directly $\boldsymbol{H}_{vr}(J)$

$$\boldsymbol{H}_{vr}(J) = \boldsymbol{H}_v + \boldsymbol{H}_r(J) = \sum_{i=1}^{f+2} k^{(i)}\boldsymbol{Z}^{(i)},$$

$$\boldsymbol{H}_{vr}(J)\boldsymbol{A}_{vr}(J) = \boldsymbol{A}_{vr}(J)\boldsymbol{W}_{vr}(J) \tag{17}$$

or by using a variation method: $\boldsymbol{Z}^{(f+2)}$ is transformed by $\boldsymbol{A}_v$ in Eq. 12 and the diagonal elements are taken to represent the rotational contribution.

$$\boldsymbol{W}_{vr}(J) \cong \boldsymbol{W}_v + k^{(f+2)}[\tilde{\boldsymbol{A}}_v\boldsymbol{Z}^{(f+2)}\boldsymbol{A}_v]_{diagonal} \tag{18}$$

In either case we define $\boldsymbol{W}_v^r(J)$ as the contribution from $\mathbf{H}_{rot}$ to the energy specified by J and v.

$$\boldsymbol{W}_v^r(J) = \boldsymbol{W}_{vr}(J) - \boldsymbol{W}_v = \boldsymbol{W}_{vr}(J) - \boldsymbol{W}_{vr}(0) \tag{19}$$

The Coriolis hamiltonian, $\mathbf{H}_{Cor}$, consists essentially of the products of the total and vibrational angular momentum operators and thus has no diagonal matrix elements with respect to vibrational quantum numbers. The total hamiltonian matrix with an arbitary nonzero J is schematically shown in Fig. 1, where each small square represents the submatrix of the size up to 200 by 200 and a superscript l specifies symmetry manifold. Let this total hamiltonian matrix be $\boldsymbol{H}(J)=\boldsymbol{H}_{vrc}(J)$, then the ultimate purpose of our calculation is to obtain $\boldsymbol{W}(J)$ in Eq. 20,

$$\boldsymbol{H}(J)\boldsymbol{A}(J) = \boldsymbol{A}(J)\boldsymbol{W}(J) \tag{20}$$

We may also define $\boldsymbol{W}_v^c(J)$ as the contribution from $\mathbf{H}_{Cor}$,

$$\boldsymbol{W}_v^c(J) = \boldsymbol{W}(J) - \boldsymbol{W}_{vr}(J) = \boldsymbol{W}_{vrc}(J) - \boldsymbol{W}_{vr}(J) \tag{21}$$

However, the total hamiltonian matrix for the states with $|l|\leq 3$ is well over one thousand. This total hamiltonian matrix may be divided into two blocks (so called c- and d-states) by taking symmetric and antisymmetric combinations of the basis functions with respect to $\pm l$, which seperates the l-type doublets (see Fig. 2). Still the size of the matrices is beyond the present practical limit and introduction of a certain approximation is inevitable. The second-order perturbation theory was used in II to calculate the Coriolis effects, however, this method requires summation over the third vibrational states and takes considerable computing time. A double diagonalization method is employed in the present case, which is almost equivalent to the perturbation method, but is much simpler to handle in computer since each step is described by matrix algebra. First, we start with $\boldsymbol{A}_{vr}^l(J)$ in Eq. 17, which is rectangular in most cases, a superscript being added again to specify the symmetry manifold. The original $\boldsymbol{H}_c^{ll'}$ matrices are successively transformed by using the related $\boldsymbol{A}_{vr}^l$ and $\boldsymbol{A}_{vr}^{l'}$, where $l'=l\pm 1$. Finally an assembly of the transformed matrices is diagonalized again to yield (approximate) solutions, $\boldsymbol{W}(J)$. The total process is schematically shown in Fig. 3.

The rotational levels in the n-th vibrational state are given for linear molecules as

$$E_v(J) = \nu_0(v) + B_v[J(J+1)-l^2] - D_v[J(J+1)-l^2]^2 + \cdots \tag{22}$$

where B_v and D_v are the rotational and centrifugal

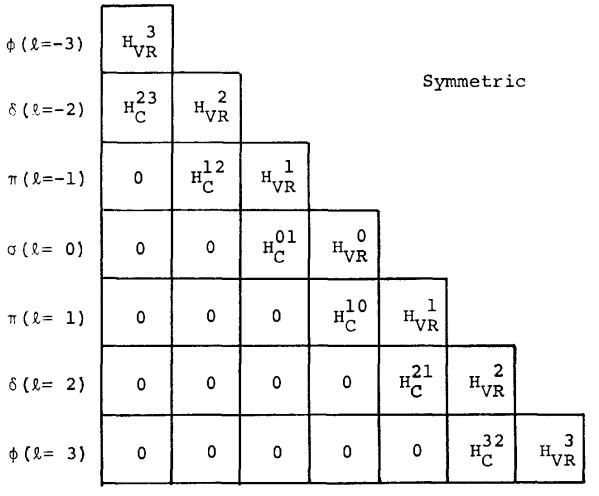

Fig. 1. A full vibration-rotation hamiltonian matrix with $|l|\leq 3$. Each square represents the matrix of size up to 200 by 200. The Coriolis hamiltoniam matrix $\boldsymbol{H}_C$ is off-diagonal with respect to l. For rotationless state ($J=0$), $\boldsymbol{H}_C$ vanishes and each $\boldsymbol{H}_{VR}$ matrix can be treated separately.

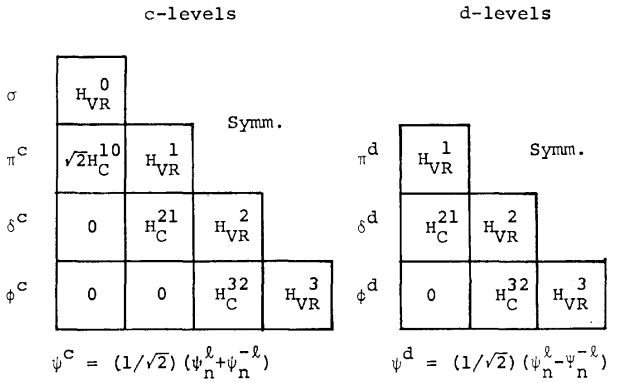

Fig. 2. The seperation of c- and d-states which causes l-type doubling. It is easily seen from the figure that π-states are most strongly affected.

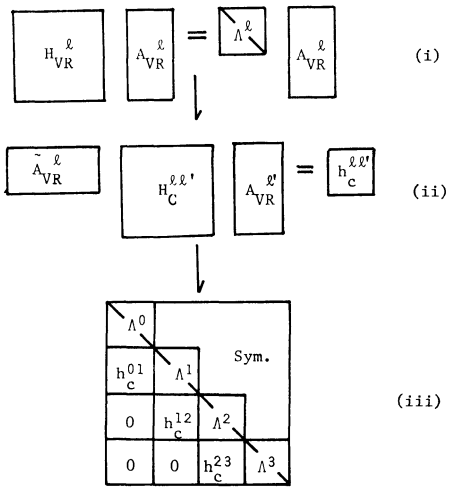

Fig. 3. Schematic representation of double diagonalization procedure. (i) The first diagonalization of $\boldsymbol{H}^{l}_{\mathrm{VR}}$ (The matrix size is usually 200 by 200, and $l=0, 1, 2, \cdots$) The lowest fortv eigenvalues are obtained: $\boldsymbol{\Lambda}^{l}$ is a diagonal matrix of 40 by 40 and $\boldsymbol{A}^{l}_{\mathrm{VR}}$ is an eigen vector matrix of 40 by 200. (ii) Transformation of $\boldsymbol{H}^{ll'}_{\mathrm{C}}$ matrix (iii) Reassembled matrix which is subjected to the second diagonalization to yield (approximate) solutions to $W(J)$ in Eq. 20.

distortion constants, respectively. They are usually determined from the observed transitions experimentally. Theoretical values of B_{v} and D_{v} are obtained by solving Eq. 12 first, then Eq. 20 for two different nonzero J's, say 5 and 10. The contributions from $\mathbf{H}_{\mathrm{rot}}$ and $\mathbf{H}_{\mathrm{Cor}}$ to B_{v} and D_{v} may be written as

$$B_{\mathrm{v}} = B_{\mathrm{e}} + B_{\mathrm{v}}^{\mathrm{r}} + B_{\mathrm{v}}^{\mathrm{c}} \tag{23}$$

and

$$D_{\mathrm{v}} = D_{\mathrm{e}} + D_{\mathrm{v}}^{\mathrm{r}} + D_{\mathrm{v}}^{\mathrm{c}} \tag{24}$$

Each term in Eqs. 23 and 24 gives a good measure for the effect of $\mathbf{H}_{\mathrm{rot}}$ or $\mathbf{H}_{\mathrm{Cor}}$ and can easily be obtained from $W_{\mathrm{v}}^{\mathrm{r}}(J)$ and $W_{\mathrm{v}}^{\mathrm{c}}(J)$. The calculated values of $B_{\mathrm{v}}^{\mathrm{r}}$ and $B_{\mathrm{v}}^{\mathrm{c}}$ are used to compare the results of different approaches and approximations.

The variational method given in Eq. 18 for evaluation of $B_{\mathrm{v}}^{\mathrm{r}}$ and the analytical method of Foord, Smith, and Whiffen (hereafter referred to as FSW method[6]) have also been tested. The latter uses the analytical expressions derived from the second-order perturbation theory, however, the vibrational quantum numbers in the expression are replaced by the "averaged" quantum numbers obtained from the perturbed wave functions. Their formula can easily be extended to cover X_2Y_2 type molecules and it is in the following form,

$$B_{\mathrm{v}}^{e} = \sum_{i=1}^{m} (\zeta_{\mathrm{ds}}^{x})^2 \left[2f(\omega_{\mathrm{s}}, \omega_{\mathrm{d}}) \left(\hat{n}_{\mathrm{s}} + \frac{1}{2} \right) + f(\omega_{\mathrm{d}}, \omega_{\mathrm{s}})(\hat{n}_{\mathrm{d}} + 1) \right], \tag{25}$$

where $f(x,y)=(3x^2+y^2)/[x(x^2-y^2)]$, $\hat{n}_{\mathrm{s}}$ and $\hat{n}_{\mathrm{d}}$ are averaged contributions of n_{s} and n_{d} to a particular vibrational level. Their values are readily obtained from the corresponding $a_{\mathrm{v}n}$'s. Although this treatment ignores certain off-diagonal effects, it is nonetheless an attractive approximation if it works reasonably well, since this approach requires only $\boldsymbol{A}_{\mathrm{v}}$ in Eq. 12 and the second diagonalization process may be skipped altogether.

Computational Procedures

Most of numerical computations have been carried out by a Hitac 8800/8700 system in Computer Centre in the University of Tokyo. As described in II the harmonic oscillator basis functions are specified either by a set of four integers corresponding to n_1, n_2, n_3, and l_2 for XYZ or by a set of seven integers corresponding to n_1 through n_5, l_4 and l_5 for X_2Y_2. A desired number of basis functions is systematically generated with the condition $\sum_{\mathrm{s}} n_{\mathrm{s}} \leq n_{\max}$ ($l_{\mathrm{t}}=n_{\mathrm{t}}, n_{\mathrm{t}}-2, \cdots 1$ or 0). For the case of N_2O, l_2 uniquely specifies the symmetry species, while the following simple rule applies for X_2Y_2.

(1) $n_3 + n_5$ (even, odd) (g, u)

(2) $l = l_4 + l_5$ (0, 1, 2, 3, $\cdots$) ($\sigma, \pi, \delta, \phi, \cdots$)

The generation of matrix elements was described in II in detail and it is not repeated here. As indicated in Eq. 8, the vibrational angular momentum operators $j_{\pm}$ have more than one term in the present case. The evaluation of $Z_{nn'}^{(f+1)}$ involves the product of operator $j_{+}^{(s_i,d_i)} \cdot j_{-}^{(s_j,d_j)}$ with $i \neq j$. Therefore, the treatment of $\mathbf{H}'_{\mathrm{vib}}$ has been modified to incorporate the cases mentioned above. A modified version of the Givens-Housholder method for real symmetric matrices, which allows to compute a limited number of either lowest or highest eigenvalues has been used as in II. Usually 200 basis functions are used for each symmetry species and the lowest 40 eigenvalues and eigenvectors are obtained; This saves considerable computing time and memories as compared with the case where a full set of eigenvalues and eigenvectors is forced to acquire.

Results and Discussion

The general quartic force field previously determined for the nitrous oxide molecule[12] has been used in the present calculation. These force constants are transformed into dimensionless normal coordinate space and their values are listed in Table 3. Within the framework of the second-order perturbation scheme three quartic force constants, k_{1113}, k_{1333}, and k_{1223} do not contribute to the vibrational energy and thus their values were not listed in the original paper,[12] however, they are all included in the present calculation. The bond lengths initially used were the same as those

Table 3. Force constants of N_2O in dimensionless normal coordinates (cm^{-1})

ω_1	1300.44	k_{1111}	2.96
ω_2	596.49	k_{1113}	−8.59
ω_3	2281.57	k_{1122}	−10.15
		k_{1133}	20.10
k_{111}	−59.72	k_{1223}	2.76
k_{113}	80.76	k_{1333}	1.66
k_{122}	54.40	k_{2222}	2.13
k_{133}	−226.60	k_{2233}	−30.40
k_{223}	51.06	k_{3333}	7.14
k_{333}	−64.82		

previously given.[12] Later the more recent values of $r_e(NN)=1.1282$ and $r_e(NO)=1.1843$ Å are used, which yield $B_e=0.4211312$ cm^{-1}. [13]

The requirement of $a_1^{xx}>0$ and $a_3^{xx}>0$ determines the phases of q_1 and q_3 uniquely. The transformation coefficients from mass-adjusted Cartesian to dimensionless normal coordinates (Nielsen's $l_{is\sigma}$[14]) are as follows.

$l_{is\sigma}$	z_1 (N)	z_2 (N)	z_3 (O)
q_1	−0.6184	−0.1952	0.7612
q_3	−0.5471	0.8023	−0.2387
	x_1 (y_1)	x_2 (y_2)	x_3 (y_3)
$q_{2x}(q_{2y})$	−0.4228	0.8247	−0.3760

a) $\nu(n)$ in cm^{-1}: obtained by solving $n\times n$ eigenvalue problem. b) $\Delta\nu(m)$ in 10^{-2} cm^{-1}: $\Delta\nu(m)=\nu(m)-\nu(200)$. c) Asterisks indicate negative coefficients. d) The basis functions are given as a set of three integers $(n_1n_2n_3)$, l_2 is omitted since it is constant in a given symmetry block.

The molecular axis coinsides with z-axis, the phases of q_{2x} and q_{2y} are chosen so that they go smoothly to the case of the XY_2 type molecules where ζ_{23}^x is taken to be +1.0.

Convergence Test. As described in I and II, the accuracy of the present treatment depends on the number of the basis functions used. Ten lowest wavenumbers of the σ- and π-species with 200 basis functions are listed in Table 4 along with the 15 and 20th wavenumbers for comparison. In this case n_{max} is about 13 which is smaller than the corresponding value of 19 for XY_2, because of lower symmetry. Calculation has also been made with 150 basis functions and the differences in wavenumbers are entered in the second column of Table 4. Also listed are some coefficients a_{vn}'s which contribute significantly to the vibrational levels in Table 4. Similar treatment has been done for the calculated values of B_v^r and the results are given in Table 5. The terms up to $k=4$ in Eq. 7 are retained in $\mathbf{H}_{rot}$. The accuracy of the computed B_v^c depends on the second factor, namely the number of eigenvalues and eigen-

$B_v=B_v(40/200)$, $B_v^r=B_v^r(40/200)$, and $B_v^c=B_v^c(40/200)$. (m/n) means that the value is calculated from an n by n eigenvalue problem, and the lowest m eigenvalues are obtained.

$\Delta B_v^r=B_v^r(40/150)-B_v^r$, $\Delta B_v^c(I)=B_v^c(40/150)-B_v^c$, $\Delta B_v^c(II)=B_v^c(30/200)-B_v^c$, and $\Delta B_v^c(III)=B_v^c(FSW)-B_v^c$, where $B_v^c(FSW)$ is estimated from Eq. 25.

vectors actually obtained. By varying this number with the fixed basis functions, another convergence test is performed for B_v^c. Only a leading term is retained in $\mathbf{H}_{Cor}$ so that direct comparison is possible for the FSW method in dealing $\mathbf{H}_{Cor}$. The last column in Table 5 shows the differences of B_v^c's computed by the two different methods.

The convergence test for wavenumbers and rotational constants has a markedly similar trend to that of CO_2. This result is in accordance with the earlier conclusion (II) that γ_s is a good measure for the convergence. The value $\gamma_1(N_2O)=0.025$ is very close to that of $\gamma_1(CO_2)=0.024$. The value of γ_3, which is zero for XY_2, is still very small (0.0036). It is gratifying to know that for most low-lying vibrational levels, the present method of the 200 basis functions with the 40 eigenvalues yields the wavenumbers and rotational constants free from the truncation effect of matrix sizes. It must be pointed out here, however, that the 10th lowest wavenumber of N_2O in the π-species, for example, is around 4000 cm^{-1} which is much lower than the corresponding value of 7000 cm^{-1} for the π_g-species of CO_2. A test run for the OCS molecule, of which γ_1 value is 0.021, has been attempted. This molecule shows much quicker convergence than N_2O.

As mentioned earlier, the quartic force constants k_{1333}, k_{1223}, and k_{1113}, do not contribute to the vibrational energies within the second-order perturbation theory. To see the actual effects of these force constants, the calculation is proceeded to drop these force constants one at a time. The results are summarized in Table 6, where only differences in 10^{-2} cm^{-1} are given. Table 6 shows in a way a limitation of the second order perturbation theory. The effect of k_{1113} is the largest, but this may be due to its relatively large value.

If we compare the present results with those calculated earlier by perturbation theory, discrepancies as large as 20 cm^{-1} are found for some levels involved in Fermi resonance. This has also been observed for the CO_2 molecule. More strictly, the quintic force constants, k_{11122}, k_{12222}, and k_{12233} must be considered to make the present calculation directly comparable with that of perturbation theory, since these quintic force constants were implicitly included as the parts of the third-order parameters in Fermi resonance.[12] This has not been tested, although the values of these force constants have become available recently.[15] The agreements of wavenumbers and rotational constants are much better for the levels which are relatively free from the effect of Fermi resonance. For example, discrepancies are within 0.6 cm^{-1} for the 001 and 002 levels located at 2223.7 and 4417.3 cm^{-1}, respectively.

Variational Method in Computing B_v^r. Off-diagonal matrix elements of transformed $\boldsymbol{Z}$ matrix were ignored in Eq. 18. This may be justified since the off-diagonal elements contribute mostly to higher order rotational terms: $[J(J+1)-l^2]^n$, where n is greater than one. The equation may be rewritten so as to give the explicit expression for B_v^r,

$$B_v^r = B_e[\tilde{\boldsymbol{A}}_v \boldsymbol{Z}^{(J+2)} \boldsymbol{A}_v]_{diagonal} \qquad (26)$$

The B_v^r values computed from Eq. 26 are found to agree almost exactly with those obtained by solving Eq. 17 successively with three J's (0, 5, 10) and then fitting the energies to Eq. 22. Discrepancies are less than 10^{-8} cm^{-1}. The agreements are less perfect ($\simeq 5\times10^{-6}$ cm^{-1}) if we drop the centrifugal term in Eq. 22 and fit the remaining two parameters from the results of $J=0$ and $J=5$, as has been done in II. In a way this is a numerical verification that Eq. 26 holds rigorously since B_v^r is a coefficient of $[J(J+1)-l^2]$, which is the leading term in the rotational energy expansion. It also implies that the consideration of centrifugal distortions is required to obtain an accurate value of rotational constant.

FSW Method in Evaluating B_v^c. Although the Coriolis coupling is considered as the second-order effect, the B_v^c values are far from negligible. On the average the $|B_v^c|$ value is smaller than the $|B_v^c|$ value, however, in some vibrational levels this tendency is reversed. The treatment of $\mathbf{H}_{Cor}$ may be the most cumbersome and time-consuming in the direct diagonalization procedure and this makes the FSW method mentioned earlier quite attractive. In the last column of Table 5 entered the calculated differences of B_v^c. The discrepancies are in the order of 10 to 15%. This was rather expected since Eq. 25 was derived by dropping some off-diagonal terms: Eq. 25 is independent of the sign of

Table 6. Effects of "Off-Diagonal" force constants to vibrational frequencies[a]

a) Only the differences are listed in 10^{-2} cm^{-1}: $\Delta\nu=\nu$(without k listed in column head) $-\nu(200)$.

ζ's, while sign dependent terms are expected as off-diagonal contribution.[7] However, the overall errors due to this are relatively small for the total computed value of B_v. In addition, this method is not affected by the second truncation problem discussed earlier. It is more robust and may give better approximation for higher vibrational levels.

If only wavenumbers and rotational constants are to be computed, the logical approach is to solve pure vibrational hamiltonian, Eq. 12, and then to apply Eqs. 25 and 26 to obtain B_v^r and B_v^c, respectively. This is particularly useful in the refinement process in which a number of cycles of calculations should be carried out. The more exact method may be applied in the final stage of refinement.

Centrifugal Distortion and l-Type Doubling Constants. If the centrifugal distortion constants are also to be computed, the procedure given in Eq. 12 through Eq. 21 cannot be avoided. To obtain an accurate D_J value the third-order term $H_J[J(J+1)-l^2]^3$ should be added to Eq. 22 and the four parameters must be fit from four sets of calculations ($J=0$ and three nonzero J's). This has already been done by Whiffen for the OCS molecule.[7] The present calculation shows that the D_v^r values are almost constant and in the range of 35—40 (10^{-8} cm^{-1}). The variations of the D_v values seem to arise mostly from D_v^c, the contribution of $\mathbf{H}_{Cor}$ to D_v.

Table 7. Observed and calculated l-type doubling constants (q_v) for the π-species of N_2O in the unit of 10^{-6} cm^{-1}

a) Ref. 16. b) Ref. 17.

The l-type doubling constants are obtained by a procedure analogous to that given in II (see also Fig. 2). The comparison of experimental and calculated constants are listed in Table 7. Just in the cases of CO_2 and CS_2, the calculated values slightly exceed the observed values, but overall profile is well represented by the calculation.

The X_2Y_2 Type Molecule. Acetylene may be an only X_2Y_2 type molecule on which the general quartic force field has been studied in some detail.[18-20] Numerical computations were carried out by using a modified GVFF[19] to test an extended portion of the direct diagonalization procedure. However, the details of numerical computations are not given here. Acetylene has two CH stretching fundamentals over 3000 cm^{-1}, it seems necessary to use more than 200 basis functions because of slower convergence. Rotational expansion is also slow in convergence with $\gamma_2=0.033$. Peculiar features of the X_2Y_2 molecular potential and their treatment in the direct diagonalization method are briefly described here. This type of molecule has non-vanishing force constants k_{345} (k_{1345} and k_{2345} as well) and k'_{4455} which appear in V_{anh} as[21]

$$k_{345}q_3r_4r_5\cos(\chi_4-\chi_5) \text{ and } k'_{4455}r_4^2r_5^2\cos(2\chi_4-2\chi_5).$$

They have off-diagonal matrix elements with respect to individual l_s, although the final matrix elements are always diagonal with respect to $l=l_4+l_5$. These force constants cause the well-known vibrational l-type doubling or resonance. In the σ_g- and σ_u-species, it is possible to reduce the size of hamiltonian matrices by taking linear combinations such as $|1^1 1^{-1}\rangle \pm |1^{-1}1^1\rangle$. However, the merit of taking similar combinations diminishes in the states with $l \neq 0$. In the present calculation no attempts have been made to separate + and − states. They are mixed in the σ_g- or σ_u-species, but their symmetries are obvious from the corresponding signs of a_{vn}'s.

The angular parts as well as the radial parts of degenerate normal coordinates have to be considered in evaluating the matrix elements associated with the above force constants, the subroutine OPERR is modified to allow this type of operations.

Concluding Remarks. A general algorithm for the direct diagonalization method of vibrational hamiltonian matrix has been extended to the XYZ and X_2Y_2 type linear molecules. The use of matrix algebra makes it easily adaptable to the computer programs. Some improvements have been made on the treatment of vibration-rotation energies. As pointed out in II, the present method yields an improved set of orthonormal vibrational wave functions, which may be used to evaluate an expectation value of any physical property P for a given vibrational level, where P is a function of normal coordinates.

$$\bar{P}_v = \langle v|P(q)|v\rangle = \sum_{n,m} a_{vn}a_{vm}\langle n|P(q)|m\rangle \qquad (27)$$

Formula for the transition moment has been given in II and extensive studies have been done on the dipole moment functions of the CO_2 and N_2O molecules and the vibrational wave functions obtained here are very useful, the details will be given elsewhere.[22]

A part of this work was done while the author was visiting the University of Minnesota. The author expresses his gratitude to Prof. John Overend for his hospitality and fruitful discussions, particularly on the phases of normal coordinates and vibrational wave functions.

HeI and HeII Photoelectron Study of N_2O_4

Katsunori NOMOTO, Yohji ACHIBA, and Katsumi KIMURA*

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received December 11, 1978)

A 304 Å HeII photoelectron spectrum of N_2O_4 in the gaseous phase has been deduced in the region up to 29 eV from a HeII spectrum of NO_2–N_2O_4 mixture obtained with a nozzle beam technique, indicating three new maxima in the region between 20 and 29 eV. A 584 Å HeI spectrum of N_2O_4 was also obtained here. From a comparison of the HeI and HeII spectra of N_2O_4 below 20 eV, it was confirmed that two ionization bands exist at 16.5 and 18.2 eV which appear as shoulders in the HeII spectrum. At least fourteen ionization bands have been identified from the HeII spectrum in the region studied. The thirteen bands below 24 eV have been assigned on the basis of a recent Green's function study of von Niessen *et al.*

It is well known that there exists a monomer-dimer equilibrium between NO_2 and N_2O_4 ($N_2O_4 \rightleftharpoons 2NO_2$) in the gaseous phase. Its thermodynamic properties have been studied extensively by Hisatsune.[1] Anomalous geometric features such as an unusually long N–N distance (1.78 Å) and planar structure for N_2O_4 have been found from a gas-phase electron diffraction study by Hedberg *et al.*[2] Furthermore a relatively high barrier to internal rotation (2.9 kcal mol^{-1}) and a relatively small heat of dissociation (12.7 kcal mol^{-1}) have been reported for N_2O_4 by Snyder and Hisatsune.[3] Because of such anomalous features, N_2O_4 has been received much attention in molecular structure and electronic structure from both experimental and theoretical points of views.

Vacuum UV photoelectron (PE) spectroscopy provides ionization energy data useful for studying valence electron orbitals.[4] HeI and HeII PE spectra of the NO_2 monomer have well been studied by Edqvist *et al.*[5] and Brundle *et al.*[6] For its bonded dimer (N_2O_4), however, there is some difficulty in obtaining PE spectra for N_2O_4 with a conventional PE spectrometer, because of its rapid dissociation in the ionization chamber in which the sample pressure is normally the order of 10^{-3} Torr. In order to overcome this difficulty, special gas inlet systems have recently been used to measure HeI PE spectra for mixtures of NO_2 and N_2O_4 by Ames and Turner,[7] Yamazaki and Kimura,[8] Frost *et al.*,[9] and Gan *et al.*[10] Ames and Turner[7] have used a nozzle inlet system in which rapid expansion of gas takes place by a large pressure difference through a pinhole with a nozzle pressure of about 1 atm. In a previous work in our laboratory, Yamazaki and Kimura[8] have used a long-path cooling inlet system in which the gas sample is cooled to −60 °C. Frost *et al.*[9] have used two kinds of gas samples one of which is a vapor from a frozen N_2O_4 sample condensed in the inlet system and the other is a continuous rapid flow of a cold NO_2 gas (−30—−50 °C). In those works of Ames and Turner[7] and Frost *et al.*,[9] the effused gas in the ionization chamber has been pumped out by an additional pumping system to increase the mole fraction of N_2O_4 up to 60—70%. Gan *et al.*[10] have also used a nozzle inlet system with a pressure near 1 atm.

In each of those PE studies,[7–10] the HeI spectrum of N_2O_4 has been deduced from that of the NO_2–N_2O_4 mixture by subtracting the NO_2 component in an appropriate manner. Spectral assignments already reported on the HeI spectra however differ largely from one another, although they are based on *ab initio* MO calculations. A number of theoretical studies on molecular orbitals of N_2O_4 have been published, employing *ab initio* methods[11–14] and many kinds of semiempirical methods.[15] Very recently, von Niessen *et al.*[16] have carried out *ab initio* many-body Green's function calculations on the photoionization of N_2O_4.

In order to obtain a further information about the photoionization of N_2O_4, in the present work we considered it important to compare HeI and HeII PE spectra with each other in spectral shape and intensity, as well as to find new PE bands in the region above 21 eV.

Experimental

PE measurement by HeI (584 Å) and HeII (304 Å) resonance radiations were carried out with our PE spectrometer with some improvements in the gas inlet system and a data accumulation system. The spectrometer is essentially the same as used previously,[17,18] containing a hemispherical electrostatic analyzer of 10 cm in diameter. The resolution is about 25—30 meV as measured for Ar using 584 Å radiation. The improvements of the gas inlet system and the data accumulation system are the following.

The gas inlet system used here is shown schematically in Fig. 1. Gas sample was introduced into the ionization chamber through a pinhole of a glass tube connected to a 2-litre gas reservoir in which the sample was contained at about 600

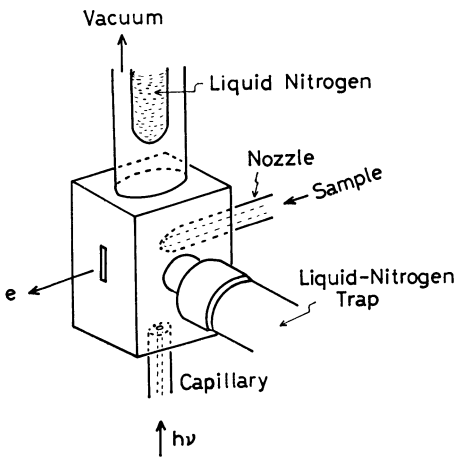

Fig. 1. Schematic drawing of the ionization chamber, the gas inlet system and the cold traps.

Torr. The nozzle pinhole was formed by discharge with a Tesla coil and then appropriately expanded by slowly dissolving in an aqueous HF solution so as to keep the pressure of the ionization chamber in the order of 1×10^{-3} Torr. (The diameter of the pinhole is approximately 50—60 μm.) In order to prevent accumulation of a static charge, the glass nozzle was covered with a brass cap coated by Aquaduck. The effused gas in the ionization chamber was pumped out with two additional diffusion pumps (2″ and 6″) as well as a liquid nitrogen trap, since N_2O_4 rapidly decomposes upon wall collision.

The data accumulating and processing system used consists of a multichannel analyzer (16 bit, 4 K memory) and a computer (YHP 2105-A). The PE spectrum was repeatedly measured, stored in the multichannel analyzer. After improved in signal-to-noise ratio by numerous numbers of repetitions, the data were transferred from the multichannel analyzer to the computer for data analysis. HeI and HeII spectra of pure NO_2 monomer were also measured in order to subtract them from those of the mixture. The procedure of extracting the dimer component is the following. (1) The spectra of both the monomer and the mixture were corrected in intensity for electron collecting efficiency on the basis of the intensity data of N_2, O_2 and CO_2 reported by Gardner and Samson.[19] (2) All the HeI and HeII spectra were smoothed by a moving average method[20] with which five successive points were averaged making each point. The number of points to be averaged was selected as it does not affect spectral resolution seriously. (3) Finally, HeI and HeII spectra of N_2O_4 were obtained from those of NO_2–N_2O_4 mixture by substracting the NO_2 component. Before each substraction, a slight correction for PE kinetic energy was also carried out for the NO_2 spectrum, since the abscissa of the spectrum depends slightly on the sample pressure.[21] (The spectra of NO_2–N_2O_4 mixture and pure NO_2 were observed under different pressure conditions.)

A relatively intense DC-discharge lamp which has recently been designed and constructed in our laboratory[22] was used for measurements of HeII spectra. With this HeII lamp, the PE count rate obtained as a test for the first ionization peak of N_2 was 400 cps under discharge conditions of 500 V, 100 mA and 0.7 Torr He pressure. Under such conditions, count rates of about 70 and 50 cps were obtained at highest peaks for the pure NO_2 and NO_2–N_2O_4 mixed samples.

Results

The HeI PE spectra obtained here for pure NO_2 and a mixture of NO_2 and N_2O_4 are shown in Fig. 2 (a and b, respectively) already corrected for analyzer transmission. The spectrum of pure NO_2 in Fig. 2a was obtained with an ordinary gas inlet system, while the spectrum of NO_2–N_2O_4 mixture in Fig. 2b was obtained with the pinhole nozzle. The spectrum of N_2O_4 in Fig. 2c

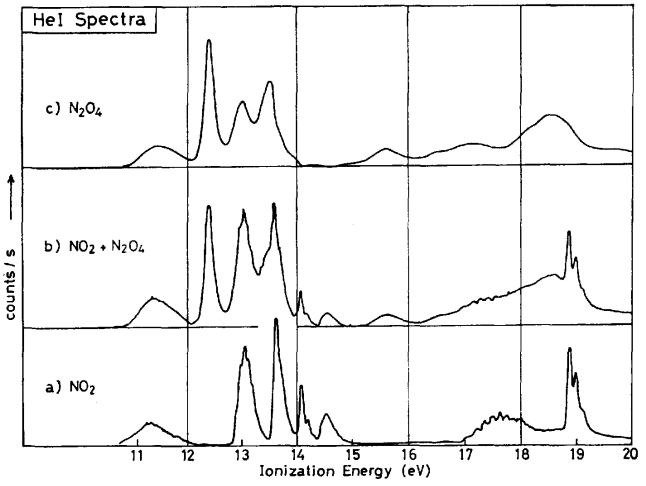

Fig. 2. HeI PE spectra corrected for analyzer transmission. (a) Spectrum of pure NO_2, obtained with a normal inlet system. (b) Spectrum of NO_2–N_2O_4 mixture, obtained with a nozzle inlet system at a total pressure of 600 Torr. (c) Spectrum of N_2O_4, deduced by subtraction of Spectrum a from Spectrum b. Spectra a and b are those already smoothed by a moving averaged method.

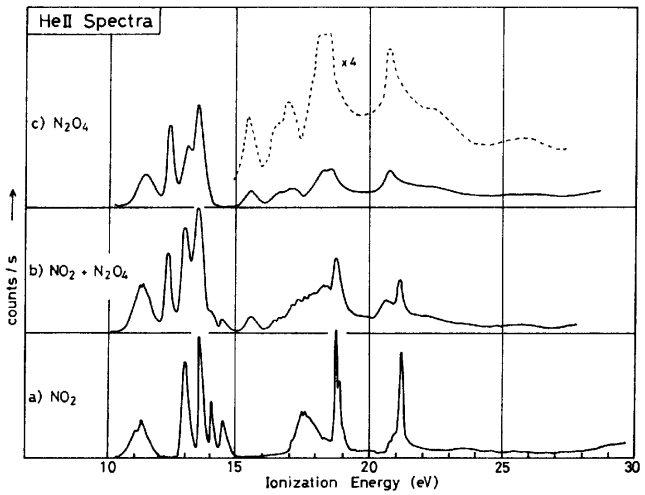

Fig. 3. HeII PE spectra corrected for analyzer transmission. (a) Spectrum of pure NO_2, obtained with a normal inlet system. (b) Spectrum of NO_2–N_2O_4 mixture, obtained with a nozzle inlet system at a total pressure of 450 Torr. (c) Spectrum of N_2O_4, deduced by subtraction of Spectrum a from Spectrum b. Spectra a and b are those already smoothed by a moving averaged method.

was obtained by subtracting a from b. Essentially no NO_2 peaks remain in the subtracted spectrum shown in Fig. 2c.

Similarly, HeII PE spectra obtained here for the monomer and dimer of NO_2 and their mixture are shown in Fig. 3 (a, c, and b, respectively). In the HeII spectrum of N_2O_4 in Fig. 3c, there appear three new maxima at 20.7, 22.5, and 25.9 eV. Results on ionization energies obtained here for N_2O_4 are summarized in Table 1, together with literature data for comparison. Relative intensities of the first five PE bands obtained from the HeI and HeII spectra of N_2O_4 are summarized in Table 2.

TABLE 2. EXPERIMENTAL RELATIVE INTENSITIES (BAND AREAS) IN THE TRANSMISSION-CORRECTED HeI AND HeII SPECTRA OF N_2O_4

Band maximum (eV)	Relative band area	
	HeI	HeII
11.4_5	0.71	1.13
12.39	1.00	1.00
13.0_5	0.8	2.4
13.5_5	1.2	
15.6	0.36	0.49

Discussion

The mole fraction of N_2O_4 in the reservoir behind the nozzle was 65% in the HeI PE measurements, while it was 58% in the HeII measurements. However, the mole fraction in the ionization chamber is not the same as that in the reservoir. The HeI spectrum of the mixture (Fig. 2b) indicates that the N_2O_4 mole fraction in our HeI measurements is very close to that in the work of Gan *et al.*,[10] and considerably higher than those in the works of Ames and Turner[7] and Frost *et al.*[9] The peak height ratio of the 12.39 eV band to the 13.0_5 eV band is about 1 : 1 in our intensity-corrected HeI spectrum, while it is 0.8 : 1 in the spectrum of Ames and Turner[7] and 0.6 : 1 in the spectrum of Frost *et al.*[9]

The reported HeI spectra of N_2O_4 more or less differ in band shape from one another, and there are some discrepancies in the number of PE bands.[7,9,10] It should be mentioned that the HeI spectrum of N_2O_4 shown in Fig. 2c is most close in spectral shape to that reported by Gan *et al.*[10] For HeII spectra of N_2O_4, no reports have been published so far. From the present HeII spectrum of N_2O_4, two interesting facts may be pointed out, one of which is the fact that three broad maxima appear in the region beyond 20 eV, and the other is that the HeI and HeII spectra below 20 eV considerably differ from each other in spectral shape and relative intensity.

Region below 14 eV. The HeI and HeII spectra below 14 eV, showing four maxima, largely differ in the relative intensity from each other. In the previous HeI studies[7–10] there have been large discrepancies in spectral interpretation in this region. Ames and Turner[7] have assigned the 12.39 eV band as a serious overlap of two ionization bands. Frost *et al.*[9] have considered that each of the maxima corresponds to a single ionization. Gan *et al.*[10] have interpreted that two ionization bands exist very closely at 13.4 and 13.5 eV to form apparently one maximum.

If Koopmans' theorem[23] is assumed, the first five ionic states are given in the order of $(6a_g)^{-1}<(1a_u)^{-1}<(1b_{1g})^{-1}<(4b_{2g})^{-1}<(4b_{3u})^{-1}$ with increasing ionization energy on the basis of *ab initio* MO calculations.[11–13] Such Koopmans' theorem assignment has been used in the previous PE studies except that of Gan *et al.*[10] who have proposed the following order on the basis of relative band intensities as well as orbital interactions between two NO_2 moieties: $(6a_g)^{-1}<(4b_{2g})^{-1}<(1a_u)^{-1}<(1b_{1g})^{-1}<(4b_{3u})^{-1}$. This PE assignment of Gan *et al.*[10] that differs from the Koopmans' theorem assignment has been supported by the recent Green's function study of von Niessen *et al.*[16]

In Fig. 4 the HeII spectrum obtained from the present work is compared with a theoretical ionization spectrum obtained by von Niessen *et al.*[16] If the Green's function calculation of von Niessen *et al.*[16] is correct, the three maxima in the 12—14 eV region should correspond to four rather than three ionized states. Considering the fact that the 13.5 eV band is highest in intensity in the HeII spectrum, there may be a large possibility that this band is due to two ionizations. Such interpretation of the 13.5_5 eV band supports the spectral assignment of Gan *et al.*[10] At the present stage, however, it is difficult to interpret unambiguously the HeI and HeII spectra in the 12—14 eV region in terms of the Green's function results. The relative intensity data given in Table 2 will give a clue to solve this question in future theoretical studies.

Region from 14 to 20 eV. In this region, the HeI and HeII spectra considerably resemble each other in spectral shape except that a bump is observed at 18.2 eV

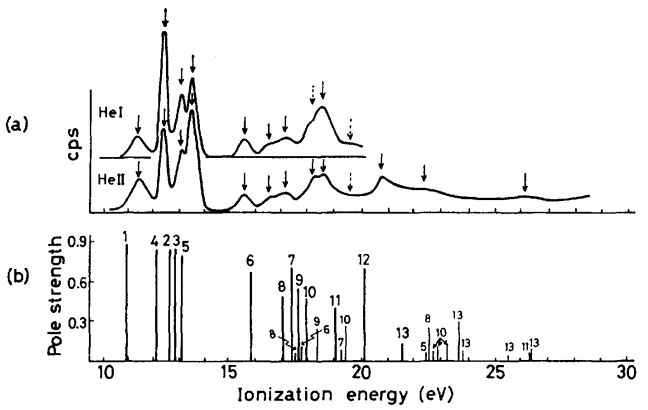

Fig. 4. Comparison of (a) the PE spectra and (b) the theoretical spectrum of von Niessen *et al.* (Ref. 16) in which lines with pole strengths larger than 0.05 are shown and the numbers indicate the following ionized states: $1=(6a_g)^{-1}$, $2=(1a_u)^{-1}$, $3=(1b_{1g})^{-1}$, $4=(4b_{2g})^{-1}$, $5=(4b_{3u})^{-1}$, $6=(5b_{1u})^{-1}$, $7=(3b_{2g})^{-1}$, $8=(1b_{3g})^{-1}$, $9=(2b_{3u})^{-1}$, $10=(1b_{2u})^{-1}$, $11=(5a_g)^{-1}$, $12=(4b_{1u})^{-1}$, $13=(4a_g)^{-1}$.

in the latter. As can be seen from Fig. 3c, two band maxima are clearly observed at 15.6 and 17.2 in the HeII spectrum.

The 15.6 eV band has previously been assigned to the $(5b_{1u})^{-1}$ ionization by Ames and Turner[7] and Gan *et al.*[10] This assignment has also been supported by the Green's function calculation of von Niessen *et al.*[16]

The shoulder appearing at 16.5 eV in the HeI spectrum has been neglected in the previous PE studies in which, for instance, Gan *et al.*[10] have assigned it to a HeI β (537 Å) band of the 18.6 eV peak. However, this 16.5 eV shoulder has been confirmed to appear also in the HeII spectrum, so that there should be at least one ionization band around here. Gan *et al.*[10] have mentioned that there are two ionization bands at 19.0 and 19.7 eV in the HeI spectrum. In the present work, however, we have not been able to identify any shoulder at 19.0 eV from the HeII as well as the HeI spectra. A slight shoulder may be seen at about 19.5 eV in the HeI spectrum, although there is no such shoulder in the HeII spectrum. From the HeI and HeII spectra, it may be considered that there is at least one ionization band in the 19—20 eV region. From their HeI spectra Gan *et al.*[10] have taken a total of six ionization energies, 15.6, 17.1, 18.1, 18.6, 19.0, 19.7 eV in the 14—20 eV region. In the present work, however, we have selected a different set of six ionization energies (15.6, 16.5, 17.2, 18.2, 18.6, 19.5 eV) in this region.

As shown in the theoretical spectrum of von Niessen *et al.*[16] in Fig. 4b, there are several main ionization lines in the 14—20 eV together with many satellite lines due to strong correlation effects. In this region, the main lines (6—11) are located in the order of the Koopmans' theorem assignment except that two lines 7 and 8 are reversed. Taking these theoretical results into account, we may point out a possibility that the six maxima or shoulders in the 14—20 eV correspond to theoretical lines 6, 8, 7, 9, 10, and 11 in this order, besides the satellite lines.

Region above 20 eV. The HeII spectrum obtained here shows three additional maxima at 20.7, 22.5, and 25.9 eV. There are no available spectra for comparison in this region. From the *ab initio* MO calculations,[11–13,16] it has been known that the first thirteen valence MO's are located between −12 and −30 eV in orbital energy and the remaining four valence MO's of oxygen 2s-type are between −40 and −50 eV. If Koopmans' theorem is assumed, thirteen PE bands would be observed below about 30 eV. However, according to the Green's function study of von Niessen *et al.*,[16] thirteen main ionizations occur below about 22 eV and the last two main lines (12 and 13) appear with a separation of about 1.5 eV in the region 20—22 eV, as shown in Fig. 4b. Therefore, it may be possible to correspond the two main theoretical lines (12 and 13) to the two PE maxima observed at 20.7 and 22.5 eV with a separation of 1.8 eV. The remaining broad maximum appearing at 25.9 eV may be due to a contour of many satellite lines.

Finally it may also be pointed out that the minima of the HeII spectrum above 17 eV are considerably lifted upwards from the base line, this suggesting the existence of many satellite ionizations indicated by von Niessen *et al.*[16] According to von Niessen *et al.*,[16] there are many satellite lines with considerably strong intensities even in the higher-energy region up to 50 eV. In the present work we were unable to deduce any HeII spectrum above 29 eV for N_2O_4 owing to a serious overlap of the HeI spectrum. A further experimental study on such higher-energy region is quite interesting in testing a validity of the Green's function calculations.

On the Phase Transitions in Hydrazinium(2+) Sulfate

Takeo OKAMOTO,† Nobuo NAKAMURA, and Hideaki CHIHARA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received January 10, 1979)

The existence of a "diffuse" phase transition below room temperature has been confirmed in $N_2H_6SO_4$ crystal by powder X-ray and DTA experiments. The transition temperature is very sensitive to the grain size. This size effect was discussed on the basis of the thermodynamic nucleation theory taking into account the interfacial energy between the high and the low temperature phases. The diffuse nature of the transition was interpreted by a theory proposed by Tobolsky *et al.* The spin-lattice relaxation times of ^1H were redetermined and the nature of the cationic motion in each phase was discussed.

Hydrazinium(2+) sulfate ($N_2H_6SO_4$) crystallizes in two modifications at room temperature, one orthorhombic and the other monoclinic.[1] The orthorhombic form has been studied extensively by the X-ray and neutron diffraction methods.[2-4] Its crystal structure is described by the space group D_2^4-$P2_12_12_1$ with four formula units in the unit cell; the crystal is ionic and contains distorted $N_2H_6^{2+}$ and SO_4^{2-} ions. The N–H bond distances in one of the two NH_3-groups, NH_3(I), in an $N_2H_6^{2+}$ ion distribute between 0.965 and 0.981 Å and those in the other NH_3-group (NH_3(II)) between 1.048 and 1.061 Å, the latter seems to form stronger hydrogen bonds with SO_4^{2-} groups than the former. The proton spin-lattice relaxation time T_1 was measured by Harrell and Howell in 1972 and there was found a first order phase transition at 481 K.[5] More recently Harrell and Peterson measured the spin-lattice relaxation time in the rotating frame, $T_{1\rho}$, in $N_2H_6SO_4$ as well as the line shapes of the deuteron resonance in $N_2D_6SO_4$.[6] They ascribed each of the two minima obserbed in both $T_{1\rho}$ and T_1 in the room temperature phase to the reorientation of the NH_3-groups about the N–N axis and to the 180°-flips of $N_2H_6^{2+}$ cation as a whole. They explained the steep decrease in $T_{1\rho}$ above the transition point in terms of translational diffusion of $N_2H_6^{2+}$.

Raman spectra were studied with regard to the distortion of the ionic species and the existence of the high temperature phase change at about 200 °C was also reported in Ref. 7. While these NMR and Raman studies failed to "see" any phase transition below room temperature, there is a report on the existence of a phase transition at −50 °C.[8] This phase transition was recognized by Power *et al.* in the process of their neutron diffraction experiment[4] and later examined in detail by Caville by Raman measurements.[9,10] Caville pointed out that the lowest temperature phase could exist in a metastable state even at room temperature.

We were interested in the nature of the lower phase transition and undertook a differential thermal analysis (DTA) and X-ray measurements on powdered specimens of $N_2H_6SO_4$ as well as remeasurements of proton spin-lattice relaxation time T_1. This paper reports the results of these experiments; an interesting grain-size dependence of the transition temperature will be described. A possible interpretation for the mechanism of the phase transition will be presented.

† Present address: The Institute for Solid State Physics, University of Tokyo, Roppongi, Tokyo 106.

Experimental

Polycrystalline specimens were obtained by recrystallization from an aqueous solution of $N_2H_6SO_4$ (Reagent Grade), followed by desiccation over 4 days. The crystals were ground to fine powders for X-ray, NMR, and DTA measurements. The grain-size effect on the lower phase transition was examined on the specimens which were divided into four parts by use of three sieves of different mesh dimensions. X-Ray powder patterns were obtained with a diffractometer (Rigaku Denki Kogyo Co.) at room temperature (≈18 °C). Proton magnetic relaxation times were determined by the saturation-90°method with a homemade pulsed spectrometer at 10 MHz. The exponential recovery of the magnetization was confirmed over the entire temperature range of the experiments. The details of the NMR measurements have been published elsewhere.[11] DTA experiments were carried out by use of a homemade DTA apparatus with about 1 g of specimen for each experiment. Chromel-*p*-constantan thermocouples (Driver and Harris Co., Ltd.) were used as the thermal sensors. Errors in the temperature measurements were within ±1 °C.

Results and Discussion

X-Ray Powder Diffraction. Figure 1 shows the X-ray powder patterns obtained at room temperature. Sample I in this figure is a specimen grown from an aqueous solution; the diffraction peaks of this sample were indexed consistently by use of the reported cell dimensions, $a=8.232$, $b=9.145$, and $c=5.535$ Å[4] together with the intensity data.[3] Samples II and III were obtained by cooling Sample I down to 189 and 77 K, respectively, kept at each temperature for a few minutes, and warmed up to the room temperature. One may see that Sample III gives a different powder pattern from that of Sample I, suggesting that the original orthorhombic crystals (hereafter referred to as Phase II) have transformed almost completely into the lowest temperature phase by cooling down to 77 K. Sample II, on the other hand, gives a powder pattern which is a superposition of those of Samples I and III. Therefore, one may understand that the phase transition occurred only in part by cooling down to 189 K. Annealing Sample III at 381 K for 2 h gave the pattern of Sample IV in which the majority of the crystal is transformed back to Phase II but some part still remains as a metastable phase even after the annealing.

Differential Thermal Analysis. A unique behavior of this material as mentioned above was also evidenced by a DTA experiment as shown in Fig. 2. When the

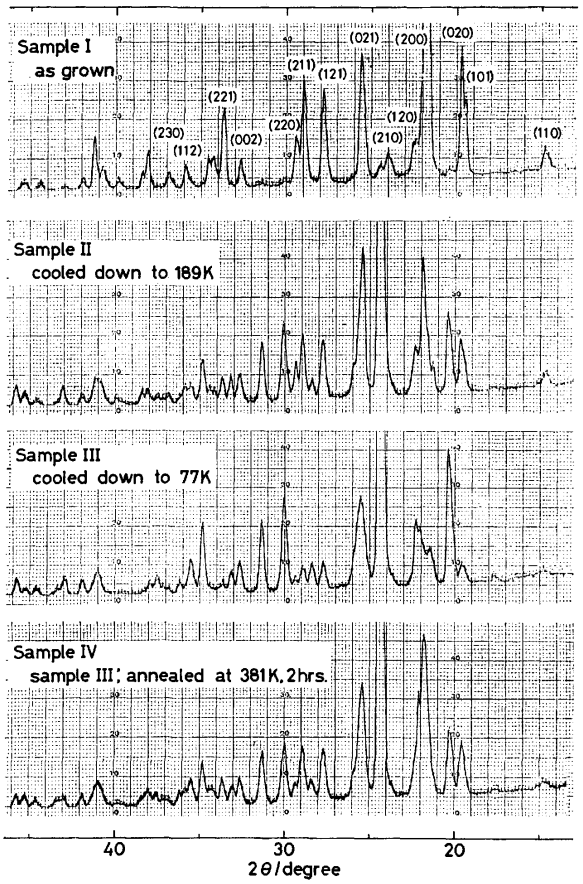

Fig. 1. X-Ray powder diffraction patterns of $N_2H_6SO_4$ at room temperature.

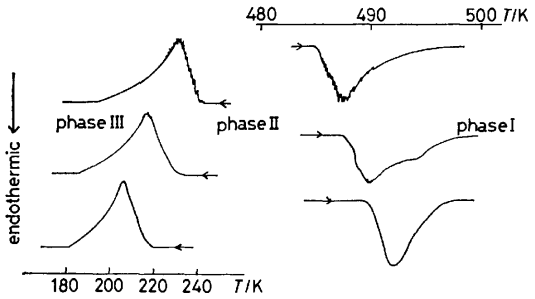

Fig. 2. DTA curves of $N_2H_6SO_4$ obtained by recrystallization (upper curves); after experienced the II→III transition once (middle) and twice (lower).

polycrystalline sample obtained by recrystallization (Phase II) was heated it transformed into Phase I, the highest temperature phase, at 485 K, but the DTA peak associated with this transition had some fine structure. Upon cooling, Phase I transformed into Phase II at 474 K, showing obvious thermal hysteresis as had been observed in Ref. 5. By further cooling a thermal anomaly with fine structure was observed between 242 and 200 K, indicating the transition from Phase II to III. Phase III did not give significant endothermic effect up to 488 K where there is a heat absorption corresponding to the transition from Phase II to I.[12] This fact suggests that Phase III can exist as a metastable state at least up to room temperature as evidenced in the X-ray study and can be transformed very gradually to Phase II at higher temperatures in such a way as to show no discernible DTA peaks.

The occurrence of this gradual transition was confirmed by the following experiments: First, after Phase III is heated up to 420 K a small peak was observed on cooling at 234 K, corresponding to the partial transition from Phase II to Phase III. Secondly, when Phase III had been annealed at about 380 K for 12 h it gave an anomaly on cooling at about 230 K as shown in Fig. 2 corresponding to the transition from Phase II to III; thus we concluded that Phase III had been transformed into Phase II during the annealing period.

The feature of the transition from Phase II to III will be summarized as follows: 1) This transition occurs over a very wide temperature range, namely 40 K, 2) the temperature at which the anomaly begins becomes displaced to a successively lower temperature after repeated thermal cycling, and 3) the fine structure in the DTA peak disappears gradually by repeating the thermal cycle. The shift of the transition point as well as disappearance of the fine structure of the DTA peak was also observed at the higher transition from Phase II to I, though only after the material had experienced the lower transition.

Grain-size Effect on the II—III Transition Point. Among the three characteristics of the II—III transition mentioned above, 2) and 3) may directly be interpreted in terms of a "size effect." The shattering of the crystal upon cooling down through the lower transition has been recognized by Caville.[9] Let us assume that the specimen with a smaller grain size undergoes the transition from Phase II to III at a lower temperature and that each grain shatters to finer ones as it passes its transition point. It follows then that the apparent transition point should be shifted to a lower temperature after each successive thermal cycle. If there is an

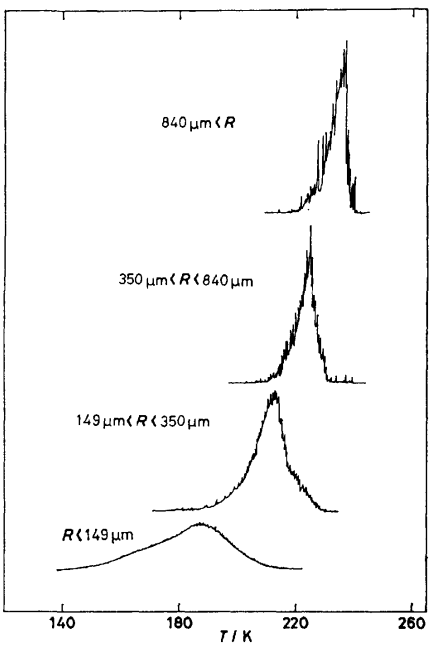

Fig. 3. DTA peaks of II→III transition in specimens with different grain sizes.

ultimate grain size obtained by such thermal cyclings, the specimen would have a homogeneous distribution in grain size and show a single, not composite, DTA peak with no fine structure.

In order to confirm the suggested size effect on the transition point we carried out the DTA on specimens with reasonably defined grain sizes. The results are shown in Fig. 3, which clearly demonstrate that the transition point becomes higher for larger grains. Also the structure of the peak is more prominent for larger grains whereas the transition region spreads broader for smaller grains. By plotting the temperature T_c at which the transition begins to occur against the reciprocal of the average grain size R a linear relation

$$T_0 - T_c = c/R \tag{1}$$

was obtained as given in Fig. 4, with c=2.36 mm K and T_0=237.5 K (the bulk transition point).

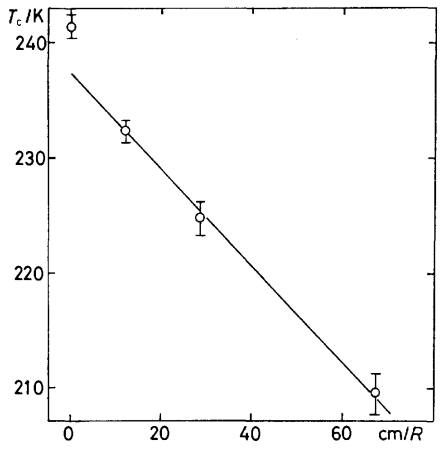

Fig. 4. The II→III transition temperature plotted against the reciprocal of the grain size.

Equation 1 has the form that has been derived for the first order phase transition from thermodynamic cosiderations which take into account the interfacial energy $\gamma_{\alpha\beta}$ between the high temperature parent modification (α-form) and the low temperature β-form.[13] There the coefficient depends totally on the "model" of the α-β interface: In the case of the liquid-to-solid phase change c is shown related to γ_{sl}, the interfacial energy between the solid and the liquid through

$$c = 2T_0\gamma_{sl}/L\rho_s \tag{2}$$

by assuming that a spherical nucleus of solid is in equilibrium with the surrounding bulk liquid phase,[14] where L is the latent heat of fusion and ρ_s the density of the solid. On the other hand the relation for the reverse (melting) transition

$$c = (2T_0/L\rho_s)\{\gamma_{sl} + (1-\rho_s/\rho_l)\gamma_l\} \tag{3}$$

was derived on the assumption that a crystallite can melt below the bulk melting point by the formation of a liquid skin which covers the entire crystal surface so as to make full use of the surface energy of the particle.[15] In this case T_0 is the "skin melting temperature." In Eq. 3 γ_l denotes the surface tension of the liquid and ρ_l the density of the liquid.

Validity of Eqs. 2 and 3 as well as of some other theoretical models was recently examined in relation to experiments on the melting transition of small lead particles. For the melting of lead particles Eqs. 2 and 3 predicted c=360 and 270 nm K, respectively, latter being found close to the experimental results.[13]

The value of c in our present study of II→III solid-solid transition of $N_2H_6SO_4$ is surprisingly large in comparison with that for the melting transition of lead (by a factor of 10^4). Although a value of c can not be estimated theoretically for $N_2H_6SO_4$ because of the lack of the knowledge of the interfacial energies, it seems that not only the interfacial energy but also some other factors will contribute to the large supercooling phenomenon. These factors are, *e.g.*, the large molecular misfit across the boundary of the two phases,[16] and the facility with which the nucleus of the new phase is formed in the mother crystal.[17]

In the case of the phase transition from Phase II to I the DTA peak is displaced to the higher temperature side as the grains become finer. This tendency is opposite to that in the II→III transition. If one is to apply Eq. 3 for the II→I transition, the surface tension of Phase I, γ_I, must be larger than $\gamma_{I,II}/(\rho_{II}/\rho_I - 1)$. Since ρ_{II} could be larger than ρ_I no more than 10%, this would mean that $\gamma_I > 10\gamma_{I,II}$ which is very questionable. Therefore, there will be other reason or reasons for the shift of the transition point in the II→I transition.

Diffuseness of the II—III Transition. As is pointed out in a previous section the phase transition between Phases II and III occurs gradually over a wide range. The possible origin of such a sluggish or diffuse phase transition was examined by Tobolsky *et al*:[18] They developed an *a posteriori* theory for the diffuse phase transition which is by nature the transition of the first order but actually occurs over a wide temperature range. They postulated the existence of a boundary phase K between two different phases A and B which are stable at high and low temperatures, respectively.

By solving for eigenvalues of an Ising matrix of molecular partition functions f_A, f_B, and f_K they obtained an expression for the number n_A or the number fraction x_A of molecules in the phase A as

$$x_A = \frac{n_A}{n_0} = \frac{1-y+(\varepsilon y)^{1/2}+[(1-y)^2+4(\varepsilon y)^{1/2}]^{1/2}}{(1-y)^2+4(\varepsilon y)^{1/2}+(1+y)[(1-y)^2+4(\varepsilon y)^{1/2}]^{1/2}} \tag{4}$$

where

$$y = \exp(-\Delta G_t/RT) \tag{5}$$

and

$$\varepsilon = \exp(-2\Delta G_K/RT). \tag{6}$$

Here ΔG_t and ΔG_k are changes of the molar Gibbs functions associated with A-to-B and A-to-K transitions, respectively, the latter being taken as infinite for an infinitely sharp transition. The expressions of x_B and x_K has also been given in Ref. 18. The anomalous part $\Delta C_p(T)$ of the heat capacity at a temperature T is written as

$$\Delta C_p(T) = -\{(\Delta H_t)^2/RT^2\}y(dx_A/dy) \tag{7}$$

where ΔH_t is the molar enthalpy change in the transition.

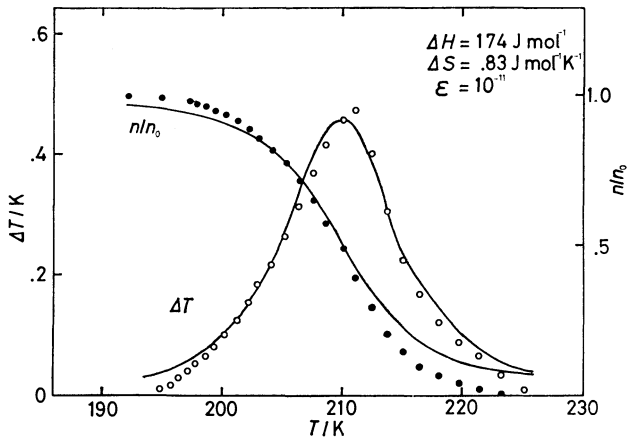

Fig. 5. The DTA curve (open circles) and the fraction of molecules in Phase III (filled circles) in II→III transition of the specimen with 149 μm $<R<$ 350 μm.

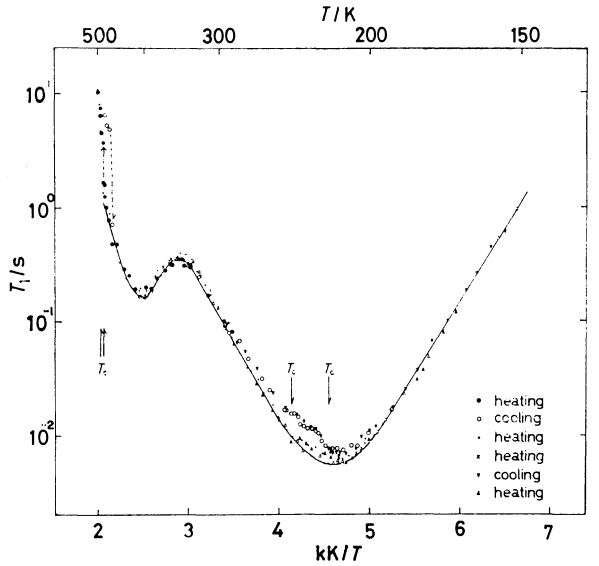

Fig. 6. T_1 of ^1H in polycrystalline $N_2H_6SO_4$ at 10 MHz. The two pairs of arrows indicate the transition regions. The solid curve is calculated with Eqs. 8 and 9. For the illustration of the symbols see in text.

Tobolsky *et al.* applied the theory to the heat capacity anomaly in several materials in detail and found that the heat capacity curve can be described using only one numerical parameter, ε or ΔG_k. In the present case of $N_2H_6SO_4$ no heat capacity data are available. But the shape of the anomaly in the DTA curve reasonably represents what one would expect for the anomalous part of the heat capacity curve. Thus, as an example, the DTA curve in the cooling direction for the specimen of the size 149 μm $<R<$ 350 μm in Fig. 3 was then fitted to Eqs. 4 and 7, the result being shown in Fig. 5. In this figure the fraction of the low temperature phase n/n_0 at each temperature was obtained by integrating the DTA thermogram (the height of which stands for ΔT, the temperature difference between the reference material and the sample under investigation).

Such a fitting gave the thermodynamic functions for the transition the values, $\Delta H_t=174$ J mol^{-1}, $\Delta S_t=0.83$ J mol^{-1} K^{-1}, and $\varepsilon=10^{-11}$, corresponding to $2\Delta G_k\approx 44$ kJ mol^{-1}. ΔG_k, the Gibbs energy of formation of a boundary phase K from Phase II, is not too large to neglect the formation of the phase K in the transition from Phase II to III. The disappearance of the reverse phase transition in the heating run as mentioned in the preceding section can also be accounted for if $\varepsilon>10^{-7}$ is assumed for the formation of phase K from Phase III. In such a case the theoretical curve becomes so flat that one can hardly "observe" any evidence of the phase transition.

The postulate of the boundary phase K has no direct bearing with the particle size effect but it certainly will be one form of manifestation of the significance of the interface energy. Unfortunately it is not possible to relate the value of ΔG_k derived here to any realistic structural model of the transition.

Spin-lattice Relaxation Time. Since the general nature of the phase transitions in $N_2H_6SO_4$ has been understood in the X-ray and the DTA experiments, we proceed to the results of measurements of the spin-lattice relaxation time T_1 on a polycrystalline sample in order to shed some light on the type of motion that $N_2H_6^{2+}$ cations undergo in each phase.

The results are shown in Fig. 6. On heating the specimen obtained by recrystallization from room temperature upwards the T_1 behavior was very similar to that reported by Harrell and Howell[5] as shown by filled circles in Fig. 6. However, on initial cooling of Phase II, the values of T_1 longer than those given in Ref. 5 were obtained (open circles); we also observed a significantly irregular behavior of T_1 in the transition region between about 210 and 250 K as will be described in the following. On heating, Phase III gave T_1 value shorter than those in Phase II, the former being shown by dots and open triangles.

Our values of T_1 for Phase III agree with the Harrell and Howell's results, indicating that what they were looking at was Phase III without being aware of the occurrence of the II—III transition when they cooled their specimen. As one sees in Fig. 6 the difference in T_1 between Phases II and III becomes smaller with increase in temperature and converges to zero somewhere around 300 K. This fact suggests that the transition from Phase III to II proceeds continuously during the T_1 measurements.

The T_1 data were interpreted according to the BPP type of formulation for the dipole-dipole interaction between protons in the form[19]

$$T_1^{-1} = K\{\tau_c/(1+\omega_0^2\tau_c^2) + 4\tau_c/(1+4\omega_0^2\tau_c^2)\} \quad (8)$$

where ω_0 is the Larmor frequency of the nuclear spin, τ_c the correlation time of a specified motion, and K a factor representing reduction of the strength of dipolar interaction due to that motion. If the two crystallographically nonequivalent NH_3-groups rotate about their figure axes (C_3-rotation) with different correlation times (τ_{ci}), the relaxation rate can be written as

$$T_1^{-1} = 1/2\sum_i K_i\{\tau_{ci}/(1+\omega_0^2\tau_{ci}^2)+4\tau_{ci}/(1+4\omega_0^2\tau_{ci}^2)\}, \quad i=1,2. \quad (9)$$

By fitting Eq. 9 to the experimental T_1^{-1} curve in Phase III as shown in Fig. 6 by solid line the activation

Table 1. The activation parameters for the motion of $N_2H_6^{2+}$ cations

Phase	Mode of Motion	$K/10^8$ s^{-1}	E_a/kJ mol^{-1}	$\tau_0/10^{-15}$ s
I	Translational diffusion[a]	—	184	—
II	C_3-rotation of NH_3-group	—	24.9	—
	180°-flip of $N_2H_6^{2+}$	2.5	54.0	1.0
	180°-flip of $N_2H_6^{2+}$[a]	1.9	40.5	166
III	C_3-rotation of NH_3(I)	104	24.9	7.9
	C_3-rotation of NH_3(II)	66	27.8	3.9
	C_3-rotation of NH_3[b]	—	26.2	6.0

a) Ref. 6. b) Ref. 6. A single correlation time was assumed for the motion of two kinds of NH_3-groups.

energies and τ_{0i}'s were obtained for the C_3-rotation as listed in Table 1. Here the Arrhenius activation process was assumed for the motion:

$$\tau_{ci} = \tau_{0i} \exp(E_{ai}/RT). \quad (10)$$

Of the two sets of values for activation parameters for Phase III, the one with the smaller E_a and the larger K may be assigned to NH_3(I) and the other set to NH_3(II). This is because NH_3(II) forms stronger hydrogen bonding with the surrounding SO_4^{2-} groups than NH_3(I) does.

Only the average activation energy was calculated for the C_3-rotation in Phase II from the slope of ln T_1 *vs.* $1/T$ between 250 and 295 K by assuming $\omega_0\tau_c \ll 1$ (see in Table 1). The activation parameters for the 180°-flip of $N_2H_6^{2+}$ were obtained by fitting Eq. 8 to the observed T_1^{-1} by assuming that the correlation time of this motion is so large in comparison with τ_c of C_3-rotation that the two modes of motion can be treated independently. The analysis gave E_a and τ_0 in Table 1 and the solid line in Fig. 6.

The activation energy and τ_0 for the 180°-flip of $N_2H_6^{2+}$ in the present work are significantly different from those in Ref. 6 which have been deduced from the $T_{1\rho}$ data. Such a discrepancy may have come from the ambiguity in fitting the theoretical T_1 curve to the experimental one in a rather narrow temperature range.

It is interesting to note, however, that the free energy of formation of a boundary phase K between Phases II and III is comparable to the activation energy for the 180°-flip of $N_2H_6^{2+}$, suggesting some rearrangement of $N_2H_6^{2+}$ cations takes place in the phase change process.

We are grateful to Mr. Takechika Iida for his assistance in the DTA measurements. Acknowledgment is made to the Mitsubishi Foundation for financial support of this research.

Wheland Polynomial. I. Graph-theoretical Analysis of the Contribution of the Excited Resonance Structures to the Ground State of Acyclic Polyenes

Noriko OHKAMI and Haruo HOSOYA*

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo 112

(Received January 30, 1979)

The Wheland polynomials, the set of the numbers, $w(G,j)$, of the j-th excited resonance structures, for a number of acyclic polyenes were calculated. The relations of $w(G,j)$ with the non-adjacent numbers, $p(G,k)$, topological index, Z_G, and the total π-electronic energy, E_π, were analyzed in detail for linear polyenes. For branched polyenes similar results were obtained, and it was found and proved that E_π is linearly related with the number of Dewar (singly excited)structures. Method for the numbering of atoms to generate the canonical resonance structures was discussed.

Recently a number of interesting relations between the Hückel molecular orbital (MO) and resonance or valence bond (VB) theories have been found and/or reinterpreted by the application of the graph theory (GT) and combinatorial theory to the electronic structures of conjugated molecules.[1-7] The essence of these lines of studies does not lie in the accurate prediction of certain properties of molecules by the use of many sophisticated parameters and approximations but in the physical interpretation of the empirical relations and also in the analysis of the mathematical structures of the theories which have been proposed.

Enumeration of the resonance structures of conjugated hydrocarbons is one of the revived problems, yielding abundant crops.[1,3,8-13] Although it has long been pointed out that as the size of the conjugated molecule increases the weight of the contribution of the Kekulé structures in the ground state rapidly decreases, the total π-electronic energy E_π of conjugated hydrocarbons is shown to be closely related to the number of the Kekulé structures, K.[2,3,7] From quite a different point of view one of the present authors has proposed the non-adjacent numbers $p(G,k)$ and topological index for characterizing the topological structure of a graph,[14] and found the relations of the $p(G,k)$ numbers with K and D, the number of the (singly excited) Dewar structures.[5] Further, the topological index Z_G, namely, the sum of the $p(G,k)$ numbers, for a tree graph is known to be closely related to the E_π value of the corresponding hydrocarbon molecule.[15] Then there must be also some useful relations between E_π and the numbers of higher excited resonance structures.

However, very few studies have been done on the analysis of the excited resonance structures. An effective method (hereinafter called as Wheland polynomial) for enumerating the set of numbers of the canonical resonance structures was proposed by Wheland[8] in 1935 but has been overlooked ever since.[16] The aims of the present paper are to generate the Wheland polynomials for a number of tree graphs, *i.e.*, the carbon atom skeletons of acyclic conjugated hydrocarbons, to find out the relations among these quantities of different origins, *i.e.*, of VB, MO, and GT, and to analyze these relations.

Definitions and Calculations[8]

Consider $N(=2n)$ circularly arranged and numbered points representing the carbon-atom skeleton of either an annulene or a linear polyene, and draw n non-crossing bonds. We get $C_n=(2n)!/\{n!(n+1)!\}$[17] patterns as exemplified in Fig. 1a for the case with $N=6$. When each pattern is projected back onto the σ-bond skeleton of the structural formula of the conjugated molecule concerned, a resonance structure is obtained. The degree of excitation of each resonance structure is defined as the number of "ineffective" or long bonds. The $(2n)!/\{n!(n+1)!\}$ resonance structures thus obtained form a set of the canonical structures.

The Wheland polynomial $W_G(x)$ is defined as

$$W_G(x) = \sum_{k=0}^{m} w(G,k)x^k \qquad (1)$$

where $w(G,k)$ is the number of the k-th excited structures for a given set of the canonical structures of graph G. Given any graph with N numbered points, a set of the canonical structures are automatically obtained by the above procedure (see Fig. 1b). All the $w(G,k)$ numbers in this paper were obtained by computers.[18] Note that the set of $w(G,k)$ numbers, or the Wheland polynomial $W_G(x)$ depends on the numbering of points, or atoms, as shown in Fig. 1c. Among a set of various $W_G(x)$ expressions for a given graph, let the highest priority be given to the one which would be the first entry when aligned in the "dictionary order." Such $W_G(x)$ may have the property that, if a proper value δ is chosen such that $0<\delta\ll 1$, the value of $W_G(\delta)$ is the largest among the set of the possible numberings. In Appendix some discussion on the numbering will be given.

Results and Discussion

In order to clarify the relation between the Wheland polynomial and the π-electronic energy of conjugated hydrocarbons, first the results of the linear polyenes will be analyzed in detail, and the effect of the branching will be discussed later.

Linear Polyene. Let us denote a linear polyene with n double bonds, or $2n(=N)$ sp^2 carbon atoms, by $\bar{n}$.[19] The Wheland polynomials for smaller members

of the series are given in Table 1, from which the general expressions are derived,

$$W_{\bar{n}}(x) = \sum_{j=0}^{n-1} w(\bar{n}, j)x^j \qquad (n>0) \tag{1'}$$

$$w(\bar{n}, j) = \frac{n!(n-1)!}{j!(j+1)!(n-j)!(n-j-1)!} = \frac{1}{n}\binom{n}{j}\binom{n}{j+1}. \tag{2}$$

By definition $W_{\bar{0}}(x)=1$.

The following relations have been known.[8]

$$W_{\bar{n}}(x) = W_{\overline{n-1}}(x) + x\sum_{j=1}^{n-1} W_{\bar{j}}(x)W_{\overline{n-j-1}}(x), \tag{3}$$

$$W_{\bar{n}}(1) = \sum_{j=0}^{n-1} w(\bar{n}, j) = \frac{(2n)!}{n!(n+1)!}, \tag{4}$$

or

$$\frac{1}{n}\sum_{j=0}^{n-1}\binom{n}{j}\binom{n}{j+1} = \frac{(2n)!}{n!(n+1)!}. \tag{4'}$$

The non-adjacent number $p(G,k)$, *i.e.*, the number of ways for choosing k disjoint lines, for linear polyene $\bar{n}$ is given by[14]

$$p(\bar{n}, k) = \binom{2n-k}{k}, \tag{5}$$

or

$$p(\bar{n}, n-k) = \binom{n+k}{n-k}. \tag{6}$$

The topological index Z_G is defined as the sum of the $p(G,k)$'s for graph G,[14]

$$Z_G = \sum_{k=0}^{m} p(G, k). \tag{7}$$

For a linear polyene

$$Z_{\bar{n}} = \sum_{k=0}^{n} p(\bar{n}, k) = \sum_{k=0}^{n} p(\bar{n}, n-k). \tag{8}$$

These values are given in Table 2.

In order to get the relation between $w(G,k)$ and $p(G,k)$, try to take the summation of $w(G,k)$ with weight as

$$S = \frac{k!(k+1)!}{(2k)!}\sum_{j=0}^{k}\binom{n-j}{k-j}w(\bar{n}, j) = \frac{(k+1)!(n-1)!}{(2k)!(n-k)!}\sum_{j=0}^{k}\binom{n}{j+1}\binom{k}{k-j}. \tag{9}$$

By using the Vandermonde convolution formula[20]

$$\binom{n+p}{m} = \sum_{k=0}^{m}\binom{n}{m-k}\binom{p}{k}, \tag{10}$$

one gets

$$\sum_{j=0}^{k}\binom{n}{j+1}\binom{k}{k-j} = \binom{n+k}{k+1}, \tag{11}$$

which gives

$$S = \binom{n+k}{n-k}.$$

That is, Eqs. 6 and 9 are found to be equal,

$$p(\bar{n}, n-k) = \frac{k!(k+1)!}{(2k)!}\sum_{j=0}^{k}\binom{n-j}{k-j}w(\bar{n}, j). \tag{12}$$

This is the relation between the coefficients of the Wheland polynomial and the non-adjacent numbers for a linear polyene. Similarly we get

$$w(\bar{n}, j) = \sum_{k=0}^{k}(-1)^{j-k}\frac{(2k)!}{k!(k+1)!}\binom{n-k}{j-k}p(\bar{n}, n-k). \tag{13}$$

Specifically, the following relations for a linear polyene are to be noted:

$$w(\bar{n}, 0) = K \quad \text{(number of "Kekulé structures")} = p(\bar{n}, n) \tag{14}$$

$$w(\bar{n}, 1) = D \quad \text{(number of "Dewar structures")} = p(\bar{n}, n-1) - np(\bar{n}, n) \tag{15}$$

$$w(\bar{n}, 2) = D_2 \quad \text{(number of "double Dewar structures")} = 2p(\bar{n}, n-2) - (n-1)p(\bar{n}, n-1) + \frac{n(n-1)}{2}p(\bar{n}, n). \tag{16}$$

By substituting Eq. 12 into Eq. 8, followed by the substitution $k=j+i$, one gets the relation between the topological index and the coefficients of the Wheland polynomial for a linear polyene as

$$Z_{\bar{n}} = \sum_{k=0}^{n}\sum_{j=0}^{k}\frac{k!(k+1)!}{(2k)!}\binom{n-j}{k-j}w(\bar{n}, j) = \sum_{j=0}^{n} C(n, j)\,w(\bar{n}, j) \tag{17}$$

$$C(n, j) = \sum_{i=0}^{n-j}\frac{(j+i)!(j+i+1)!}{(2j+2i)!}\binom{n-j}{i}. \tag{18}$$

For an acyclic hydrocarbon, whose carbon atom skeleton is expressed as a tree graph, the total π-electronic energy E_π calculated by the Hückel molecular orbital method is known to be related to Z_G as[15]

$$E_\pi = A \ln Z_G \qquad (G \in \text{tree}), \tag{19}$$

which, by the substitution of Eq. 17, yields

Table 3. Weight of the coefficients of the Wheland polynomial in the π-electronic energy for linear polyenes

$$E_\pi = A \ln \sum_{j=0}^{n} C(n,j) w(\bar{n},j). \quad (20)$$

From this equation one can obtain the contribution or weight of each coefficient $w(\bar{n},j)$ of the Wheland polynomial to the total π-electronic energy.

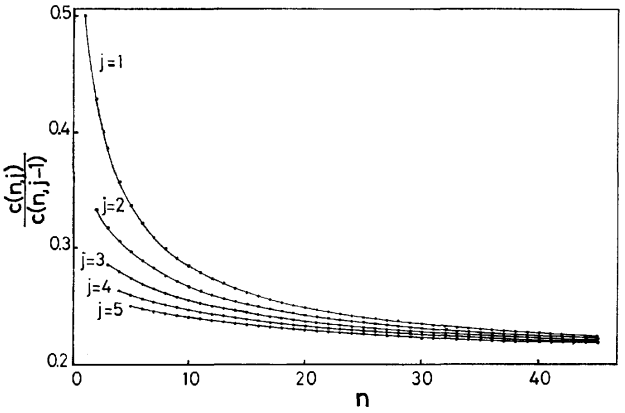

Fig. 2. Convergence of the ratio $C(n, j)/C(n, j-1)$ for larger polyenes. See also Table 3.

The values of $C(n,j)$ for smaller n and j's are given in Table 3, which shows a rapid decrease of $C(n,j)$ with the increase of j. Further, as seen in Fig. 2 the ratio of $C(n,j)$ to $C(n,j-1)$ converges to a certain value for larger n, or

$$C(n,j) \rightarrow C(n,0)\alpha^j, \quad (21)$$

with the value of α a little above 0.2.

By the substitution of Eq. 21 into Eq. 20, it turns out that E_π can approximately be expressed in terms of the Wheland polynomial,

$$E_\pi = A \ln \{C(n,0) W_{\bar{n}}(\alpha)\}, \quad (22)$$

or simply as

$$E_\pi = a \ln W_G(\alpha) + b \quad (\alpha=0.2). \quad (23)$$

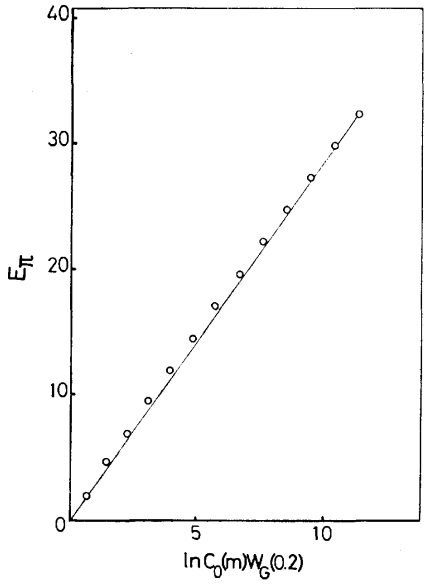

Fig. 3. Linearity between E_π and $\ln\{C_0(m) W_G(0.2)\}$. The straight line is drawn so as to pass the origin.

Although Eq. 22 has been derived for larger n, numerical calculation shows that this relation is also fairly valid even for smaller linear polyenes (Fig. 3). Later it will be shown that Eq. 23 can also be applied to branched polyenes.

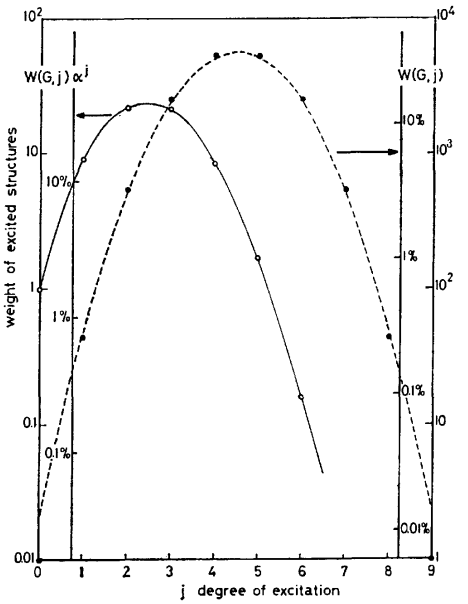

Fig. 4. Dependence of $w(G, j)$ and $w(G, j)\alpha^j$ on the degree of excitation for polyene $C_{20}H_{22}$.
—•—: $w(G, j)$.
——: Gaussian curve, $5600 \exp\{-0.392(j-4.5)^2\}$, to fit the $w(G, j)$ values.
—o—: $w(G, j)\alpha^j$.

Among the whole spectrum of the resonance structures scanned with the order of excitation, one can analyze what is the largest contribution to the energy of the ground state. The values of $w(G,j)$ and $w(G,j)\alpha^j$ with $\alpha=0.2$ for linear polyne $\overline{10}$ are plotted in Fig. 4, where two remarkable features are seen. Although a rigorous proof can not be obtained yet, the smoothed curve of $w(\bar{n},j)\alpha^j$ against j is symmetric with respect to $j=n/2$ and very close to that of the Gaussian curve, $\exp(-x^2)$ (see the broken line). Next the peak of the smoothed curve of $w(\bar{n},j)\alpha^j$ is found at about $j=0.3n$. This can be proved as follows.

For larger n the value of j at which the curve $w(\bar{n},j)\alpha^j$ is an extremum is the root of the following equation

$$\frac{1}{n}\binom{n}{j}\binom{n}{j+1}\alpha^j = \frac{1}{n}\binom{n}{j-1}\binom{n}{j}\alpha^{j-1},$$

and is found to be approximately as

$$j = \sqrt{\alpha}\, n/(\sqrt{\alpha}+1),$$

or

$$j/n = \sqrt{\alpha}/(\sqrt{\alpha}+1) = 0.309, \quad (24)$$

if α takes 0.2.

As has been pointed out earlier,[21] this result confirms that the contributions of the Kekulé structures and even of the lower excited structures get vanishingly small with the increase of the size of the molecule. However, it might still be possible that the numbers of the lower

excited structures are good indicators for E_π. This will be the case if the shape of the curve $w(G,j)\alpha^j$ does not appreciably change from isomer to isomer or does change somewhat systematically so that some cancellation occurs.

Branched Polyenes. Analysis on the relation between the Wheland polynomial and the electronic energy can be extended to branched polyenes in two different aspects, *i.e.*, difference among isomers and general properties within a series of branched hydrocarbons. Questions are: 1) does relation 23 hold for a group of isomers, and 2) does Eq. 12 or 13 hold for a series of branched polyenes?

The Wheland polynomials for smaller branched polyenes are given in Tables 4 and 5, where the $p(G,k)$ numbers, topological index, and the total π-electronic Hückel energy E_π are also given. Here the isomers are numbered according to the values of E_π. It is to be noted that with only one exception (between compounds 5-4 and 5-5) for each group of isomers with $n\leq 5$ this is just the order of decreasing the number of the first excited or Dewar structures, $w(G,1)=D$. For the group of isomers with the same D, the larger the number of the second excited or double Dewar structures, $w(G,2)=D_2$, the larger the E_π value.

To be more quantitative, the E_π values of the decapentaene isomers are plotted against the $\ln\{W_G(0.2)\}$ values in Fig. 5a (see also Table 5). The linearity is a little worse than the remarkably good plot of $E_\pi - \ln Z_G$ (Fig. 5c), but unexpectedly good in spite of the several assumptions and approximations we have made. Similar linearity, though a little more scattered than the smaller polyenes, was obtained for the twenty four isomers of dodecahexaenes. It was found, further, that the contributions of only the first and second excited structures, $\alpha D+\alpha^2 D_2$, can predict the order of E_π value as well as the $\ln\{W_G(\alpha)\}$ value with $\alpha=0.2$ (see Fig. 5b). Namely, for a group of isomers of acyclic polyenes, the E_π values are linearly related with the numbers of the

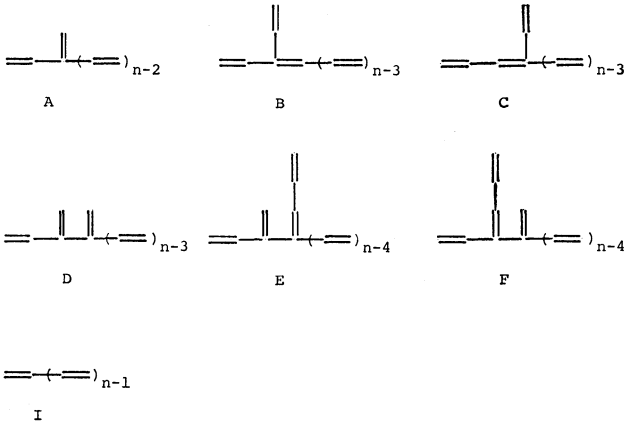

Chart 3.

first and second excited structures as

$$E_\pi \approx D + 0.2D_2. \tag{25}$$

This is also an unexpectedly good correlation, if one knows that the numbers of the Dewar structures for decapentaene and dodecahexaene isomers are, respectively, around 20 and 10% of the total number of the resonance structures.

In order to clarify the secret of this fortuitous result, the distributions of the $w(G,j)$ coefficients of the Wheland polynomial for the following six typical series of branched polyenes were studied (see Chart 3 and Table 6).

In Fig. 6 are plotted the $w(G,j)$ and $w(G,j)\alpha^j$ values against j for linear polyene 14 and one of its isomers. Although both the two curves of the isomer shift a little toward larger j values, the overall shapes are simulated fairly well by Gaussian functions. Both the $w(G,j)$ and $p(G,n-j)$ values for an isomer with n double bonds in each series studied are expressed by

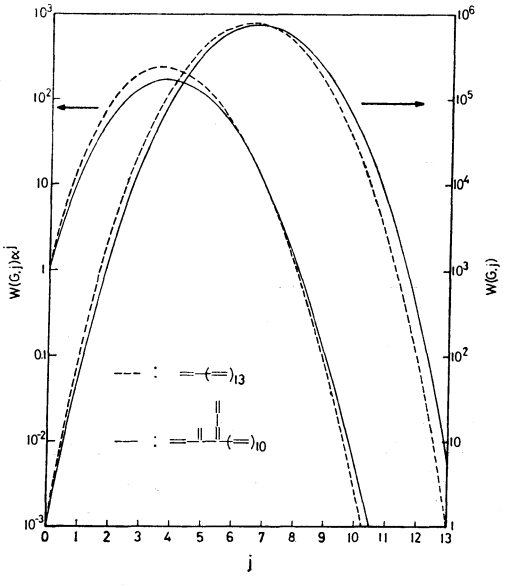

Fig. 6. Similar behaviors of $w(G,j)$ and $w(G,j)\alpha^j$ against j for $C_{28}H_{30}$ and one of its isomer.

polynomials of n with order $2j$. The results for smaller j values are given in Table 6. All these results confirm that the values of $w(G,j)$ and $w(G,j)\alpha^j$ for the isomers behave quite similarly with those for the linear polyene.

Try to expand the function below

$$\left(1+\frac{w_1\alpha}{n}\right)^n = 1 + w_1\alpha + \binom{n}{2}\left(\frac{w_1\alpha}{n}\right)^2 + \binom{n}{3}\left(\frac{w_1\alpha}{n}\right)^3 + \cdots$$

$$= 1 + w_1\alpha + \frac{n-1}{2n}\cdot w_1^2\alpha^2 + \frac{(n-1)(n-2)}{6n^2}\cdot w_1^3\alpha^3 + \cdots$$

$$= \sum_{j=0} A_j\alpha^j, \tag{26}$$

where w_1 is $w(\bar{n},1)$, or the number of the Dewar structures

of linear polyene $\bar{n}$. Note that the coefficient A_i to α^j is proportional to $w_1{}^j$ or to the $2j$-th power of n. Compare this expansion with the Wheland polynomial for $\bar{n}$ as

$$W_{\bar{n}}(\alpha) = \sum_{j=0} w(\bar{n}, j)\alpha^j, \tag{27}$$

whose coefficient $w(\bar{n},j)$ is also proportional to the $2j$-th power of n (see Eq. 2). Owing to the small value of α, $W_{\bar{n}}(\alpha)$ can be approximated, though not accurately but reasonably well, as expression 26, namely,

$$W_{\bar{n}}(\alpha) \sim \left(1+\frac{w_1\alpha}{n}\right)^n. \tag{28}$$

As inferred from the behavior of $w(\mathrm{G},j)$ observed above, we may also assume

$$W_{\mathrm{G}}(\alpha) \approx \left(1+\frac{w_1'\alpha}{n}\right)^n \tag{29}$$

for an isomer G with $w_1'=w(\mathrm{G},1)$. Then from Eq. 23 one gets

$$\begin{aligned}\Delta E_\pi &= E_\pi(\bar{n}) - E_\pi(\mathrm{G}) \\ &\approx \ln\{W_{\bar{n}}(\alpha)/W_{\mathrm{G}}(\alpha)\} \\ &\approx n \ln\left\{\left(1+\frac{w_1\alpha}{n}\right)\Big/\left(1+\frac{w_1'\alpha}{n}\right)\right\}.\end{aligned} \tag{30}$$

Since w_1 is equal to $n(n-1)/2$ (from Eq. 2), the value $w_1\alpha/n$ is smaller than unity for small n. Then ΔE_π can be approximated as

$$\Delta E_\pi \approx \alpha(w_1-w_1'). \tag{31}$$

This is a partial proof of relation 25. For larger n, however, the expression 31 would no longer be a good expansion of ΔE_π. In this case one has to expand $W_{\mathrm{G}}(\alpha)$ by the inclusion of higher $w(\mathrm{G},j)$ terms. This means that the larger the molecule the larger the weight of higher excited structures. However, for a group of moderate size of acyclic polyenes, the number of the Dewar structures is thus shown to be a good measure of the π-electronic energy.

Next the relation between $w(\mathrm{G},j)$ and $p(\mathrm{G},n-k)$ was studied. For $j,k\leq 1$ the results are the same as the case of linear polyenes. Namely, for polyene G with n double bonds,

$$K = w(\mathrm{G}, 0) = p(\mathrm{G}, n) \tag{14'}$$

and

$$D = w(\mathrm{G}, 1) = p(\mathrm{G}, n-1) - n\,p(\mathrm{G}, n). \tag{15'}$$

However, for larger values of j and k small correction should be introduced into relations 12 and 13.

Relation 14' is guaranteed by definition. Relation 15' has already been presented without proof by one of the present authors.[3,22] Since an acyclic polyene is an alternant hydrocarbon, namely, the corresponding graph is bipartite, the carbon atoms are grouped into starred and unstarred so that all the bonds are formed between atoms of different groups. As will be exemplified in Appendix, all the ineffective bonds in an excited canonical structure are also formed between atoms of different groups.

Suppose the C–C single bond skeleton of polyene G with n double bonds and choose $n-1$ disjoint bonds on which double bonds are to be drawn. There are $p(\mathrm{C},n-1)$ different ways. Since each double bond is so chosen as to span a couple of starred and unstarred atoms, there are left a couple of starred and unstarred atoms. Irrespective of the situation that they may or may not be adjacent, join them to form the n-th π bond. The resultant $p(\mathrm{G},n-1)$ graphs are the candidates for the set of the first excited canonical structures, or Dewar structures. It is obvious that no other candidate is possible. If the n-th π bond is formed between two adjacent atoms, the resultant graph is nothing else but the unexcited Kekulé structure to be deleted from the counting of $w(\mathrm{G},1)$ or D, and there are n such possible ways for each Kekulé structure. This completes the proof of Eq. 15'. Note that this relation is valid even for a graph with more than one Kekulé structures.

Let the difference between the right and left hand sides of Eq. 12 be defined as

$$\Delta p(\mathrm{G}, n-k) = p(\mathrm{G}, n-k) - \frac{k!(k+1)!}{(2k)!}\sum_{j=0}^{k}\binom{n-j}{k-j}w(\mathrm{G}, j) \tag{32}$$

which was shown to be always positive for $k\geq 2$ of all the series studied. In Table 6 are given the general expressions of the $\Delta p(\mathrm{G},n-2)$ and $\Delta p(\mathrm{G},n-3)$ for each series. It is seen from the expression of $p(\mathrm{G},n-k)$ and $\Delta p(\mathrm{G},n-k)$ that the relative correction is at most in the order of n^{-2} and negligible for larger polyenes. This is also the case with the higher values of k. Thus the number of the higher excited structures can be approximated by Eq. 13 for branched polyenes in terms of the set of the $p(\mathrm{G},k)$ numbers, which can systematically be obtained by the use of several recursion formulas.[14,23]

It is worth mentioning here that the quantities independently obtained from VB and GT are thus found to be closely related with each other through the quantity of MO. Work in these lines is in progress for the mathematical properties of the number of the resonance structures of polycyclic hydrocarbons.

Appendix

A Note on the Numbering of Atoms for Acyclic Polyenes. At present we are not yet in a position to state the unambiguous method for numbering the atoms to generate the Wheland polynominal of the highest priority for an arbitrary acyclic polyene. However, our experience on a number of examples has led to several empirical rules for the numbering of a polyene with a few branches.

Consider first the mapping procedure for generating the

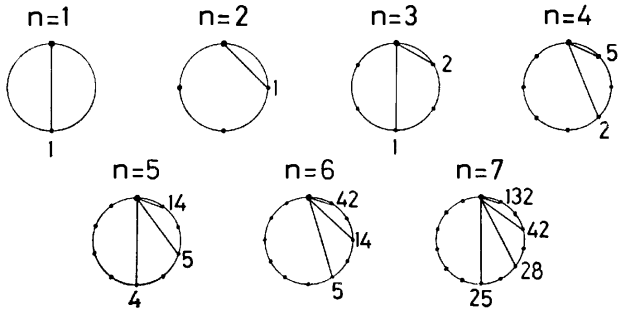

Fig. 7. Distribution of the numbers of the effective and ineffective bonds spanning from a pivot point among a set of C_n standard patterns. No bond is found between a pair of atoms of the same parity, and the distribution is symmetrical.

Wheland polynomial exemplified in Fig. 1. Draw $C_n=(2n)!/\{n!(n+1)!\}$ standard patterns for the set of circularly arranged and numbered $2n(=N)$ points. In each pattern n non-crossing lines are drawn. Choose a point as the pivot from the $2n$ points. Then for each member of the $2n-1$ points count the number of patterns in which it is connected with the pivot point. The results for smaller n's are shown in Fig. 7. Observe that no line is drawn between a pair of points of the same parity. Namely, an alternant hydrocarbon has no bond between a pair of starred atoms and also between a pair of unstarred atoms. The number of the effective bonds are the largest, and the number of the ineffective bonds rapidly decreases with the increase of the length. The sum of these numbers is C_n.

Recall that the set of the canonical resonance structures are obtained by mapping the given arbitrary numbered graph G (or the π-electron skeleton) onto each of the C_n standard patterns. The degree of excitation j for a resonance structure is the number of the ineffective bonds and $w(G, j)$ is the number of j-th excited structures for G. Then the total number of the effective bonds J in the set of the C_n resonance structures is given by

$$J = n \cdot C_n - \sum_{j=1} j \cdot w(G, j).$$

Note that the summation in the second term is equal to $W_G'(1)=(dW_G(x)/dx)_{x=1}$, where $W_G(x)$ is the Wheland polynomial $W_G(x)=\sum_{j=0} w(G, j)\cdot x^j$. The highest priority is given to such a $W_G(x)$ expression that has the top-heaviest set of the coefficients, which we are going to search. It is not sufficient but necessary for that expression to have the largest J value, or the smallest $W_G'(1)$ value.

For convenience's sake let us define the term "number difference", $d_{ij}=\min(|i-j|, 2n-|i-j|)$, for a pair of atoms i and j forming a bond. All the bonds are then classified into the following three types according to their d_{ij} value as,

α-type with $d_{ij}=1$

β-type with $d_{ij}=2, 4, 6, \cdots$

γ-type with $d_{ij}=3, 5, 7, \cdots$

Unless confusion may occur α, β, and γ stand also for the numbers of the bonds of the corresponding types. Then all the above observations and discussions lead to the following recipes for the numbering of atoms so as to give the largest J value, or the smallest $W_G'(1)$ value.

(1) Every bond should be composed of a pair of atoms of different parity, or $\beta=0$.

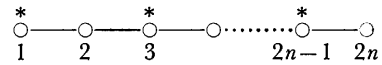
(2) The number of γ-type bonds should be minimized. There are several possible ways for satisfying the conditions (1) and (2). In these cases recipe (3) would be applied.

(3) The sum $D=\sum_{i<j} d_{ij}$ of the "number difference" for all the bonds should be minimized. Further, to the case where several numberings are still possible in which recipes (1)—(3) are obeyed we may apply.

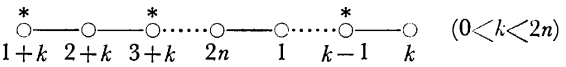
(4) The sizes of the polyene fragments obtained by excising the γ-(and also β-) type bonds should be as uniform as possible.

However, (3) and (4) should not necessarily be obeyed, and their relative priority seems to change from case to case.

Linear Polyene. Application of recipes (1) and (2) to a linear polyene assures that the following numbering gives the Wheland polynomial of the highest priority,



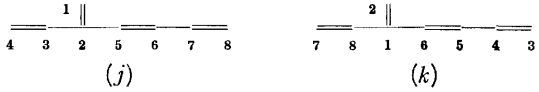
The cyclic change of numbering as



$(0<k<2n)$

gives the same result.

Polyene with One Branch. Three carbon chains, P_1, P_2, and P_3, emanate, from the carbon atom as the junction of the polyene with one branch, where P_1 is an odd chain, P_2 a shorter even chain, and P_3 longer even chain. Application of recipes (1) and (2) gives the numbering as shown in Chart 4a. For graph 4-3 in Chart 1 the following two numberings give the same result,



since they are related to each other by the formula

$$j + k = l \text{ or } l + 2n,$$

where j and k are the numberings given to the same atoms, respectively, by the numbering systems (j) and (k), and l is an arbitrary integer (here $l=3$).

Polyene with Two Branches. Consider first those polyenes with two branches, which are separated by one bond. There

Table 7. An example showing the factors for determining the coefficients of the Wheland polynomial

Numbering[a]	$W_G(x)$	$W_G'(1)$	β[b]	γ[c]	Fragment[d]
	$1+4x+8x^2+x^4$	24	0	1	4+4
	$1+4x+7x^2+2x^3$	24	0	1	1+7
	$1+3x+7x^2+3x^3$	26	1	0	2+6
	$1+2x+10x^2+x^4$	26	1	0	4+4

a) ——: α-type bond, −+−: β-type bond, ——: γ-type bond. b) Number of the β-type bond. c) Number of the γ-type bond. d) Indicates the sizes of the polyene chains obtained by excising the β- and γ-bonds.

are two cases depending that the central bond is single or double. For the former case the two numberings in Charts 4b and c are the candidates for the highest priority. Then compare the number differences at the central bridge bond, and the numbering giving the smaller value is chosen as the best.

In the case of the polyene with a central bridge double bond, the numbering with the highest priority can be chosen as the one having the smallest number difference at the bridge from the possible numberings of the types as in Chart 4d.

Table 7 shows how the Wheland polynomial depends on the recipes for the numbering given above.

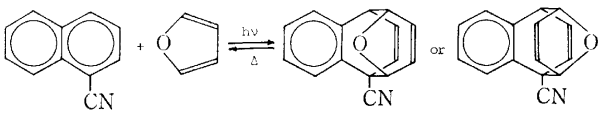
$C_{15}H_{11}ON$, *M.W.* 221.17, monoclinic, space group $P2_1/c$, $a=9.451(1)$, $b=8.267(1)$, $c=14.336(2)$ Å, $\beta=94.37(1)°$, $D_m=1.31$, $D_c=1.32$ g cm^{-3}, $Z=4$, $R=0.088$ for 1300 non-zero reflections. The molecule has an *endo*-configuration, and the furan ring has an envelope form.

Photoreaction between 1-naphthonitrile and furan gave a single cycloaddition product, although *endo*- and *exo*-isomers were expected to be formed.[1]



exo-form *endo*-form

In order to determine the stereochemistry of the cycloadduct, an X-ray analysis of the product has been carried out.

Experimental

For the data collection, a crystal with suitable size was mounted on a G.E. single crystal orienter equipped on a Rigaku SG-2 goniometer. Stationary crystal-stationary counter method was applied. During the data collection the intensity of the standard reflections decreased; as it did so uniformly with time, a linear correction factor was applied. 1397 unique data collected up to $2\theta=110°$ were then corrected for Lp effect but not for absorption [μ(Cu $K\alpha$)=6.70 cm^{-1}]. The structure was solved by the symbolic addition method.[2] Signs of 181 $|E|$'s ($|E|>1.4$) were determined, and all the non-hydrogen atoms

Results and Discussion

The molecular structure is shown in Fig. 1, which indicates that the cycloadduct has the *endo*-configuration. Bond lengths and bond angles are given in Fig. 2. The C(11)–C(24) and C(14)–C(21) bonds [1.633(8) and 1.588(8) Å, respectively] involved by the photocycloaddition are comparable with those observed in photodimers of anthracene [1.62(2) Å],[6] 2-methoxynaphthalene [1.610(5) Å][7] and 9-anthracenecarbaldehyde[1.61(1) Å],[8] which are longer than the usual $C(sp^2)$–$C(sp^3)$ bond length. The furan ring has an envelope form, the O atom is located by 0.58 Å out of the plane containing C(21) through C(24) atoms. The dihedral angle between the planes defined by O, C(21), and C(24) and C(21), C(22), C(23), and C(24) is 139.4°. The dihedral angle between C(1), C(6), C(11), and C(14) and C(11), C(12), C(13), and C(14) planes is 125.9° (Fig. 1).

The crystal structure is shown in Fig. 3. No close intermolecular atomic contact less than usual van der Waals distance can be observed.

The authors wish to express their deep thanks to Professor H. Sakurai and coworkers for crystals.

Properties and Structure of Alkali Aluminophosphate Glass

Akira KISHIOKA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received July 14, 1978)

Several series of alkali (sodium and potassium) aluminophosphate glasses were prepared with compositions of 32—63 mol % of P_2O_5 and the properties of these glasses were determined. In the glasses with a higher P_2O_5 content ($P_2O_5 \gtrsim 42.5$ mol % in the Na_2O–Al_2O_3–P_2O_5 glass and $P_2O_5 \gtrsim 45$ mol % in the K_2O–Al_2O_3–P_2O_5 glass), the density, refractive index, and chemical resistivity increased with increasing amounts of Al_2O_3. In the glasses with a lower P_2O_5 content ($P_2O_5 \lesssim 37.5$ mol % in the Na_2O glass and $P_2O_5 \approx 40$ mol % in the K_2O glass), however, almost no increase of the density was found by an increase of Al_2O_3; the increases in the refractive index and chemical resistivity were also smaller than those in the glasses with a higher P_2O_5 content. The infrared absorption spectra of the glasses varied also with the P_2O_5 content. These changes in the properties are due to a marked structural difference between the glasses with a higher P_2O_5 content and those with a lower P_2O_5 content, and are also associated closely with the structural role of Al^{3+} ions in the glass.

The structure and the role of Al^{3+} ions in aluminophosphate glasses are attracting the attention of many investigators because Al_2O_3 can be incorporated in fairly large quantities into phosphate glass and stabilizes the glass structure. Kreidl and Weyl[1] considered that the ($AlPO_4$) group was formed by AlO_4 and PO_4 tetrahedra in the glass structure. On the other hand, Sakka[2,3] has reported that there are two kinds of Al^{3+} ions with different coordination numbers in phosphate glass. The present authors[4] have investigated the formation of the glasses in the three-component diagram in alkali (sodium and potassium) aluminophosphate systems and found one Al_2O_3 peak in about 65 mol % of P_2O_5 and another peak in about 35 mol % of P_2O_5. We also reported the structural difference between the glasses with a higher P_2O_5 content and those with a lower P_2O_5 content. Reports concerning the fundamental properties such as density, refractive index, viscosity, *etc.* of aluminophosphate glass, however, are relatively few compared with those of aluminosilicate glass. Therefore, it may be interesting to investigate the changes of the properties of the glass with regard to the difference in glass structure.

In this investigation, the density, refractive index, and infrared absorption spectra and also the molar volume, volume per mole of oxygen, and molar refraction were determined for several series of the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 glasses with the same contents of P_2O_5, which ranged from 32 to 63 mol %. For Na_2O–Al_2O_3–P_2O_5 glass the chemical resistivity and solubility in water or hydrochloric acid were examined. From these results, the changes in the properties were discussed in connection with the glass structure.

Experimental

Preparation of Series of Glasses with the Same P_2O_5 Contents. The glass specimens containing 32.5—45 mol % of P_2O_5, as reported in the previous paper,[5] were used as the lower P_2O_5 alkali aluminophosphate glasses in this investigation. Furthermore, about fifty glass specimens containing more than 45 mol % of P_2O_5 were prepared in the glass-forming regions of the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems.[4] The materials used were reagent grade chemicals of sodium dihydrogenphosphate, potassium dihydrogenphosphate, aluminum oxide, and orthophosphoric acid (85 %). A batch (40-g) obtained by mixing appropriate amounts of the above chemicals was placed in Al_2O_3 crucible and heated in an electric furnace. After dehydration, the temperature of the batch was raised to 1350 °C and kept at this temperature for 1 h. The melt was poured out and quenched by pressing it with a copper plate cooled with water. All the quenched melts were obtained as transparent colorless glasses. The composition of these glasses were determined by chemical analyses and several series of glasses with the same P_2O_5 contents were selected and used in this experiment.

Determination of Al_2O_3. Glass powder containing about 0.1 g of Al_2O_3 was fused with 5—9 g of sodium carbonate and dissolved in 200 cm^3 of 1 mol/dm^3 hydrochloric acid. The Al^{3+} ion in the obtained solution was determined gravimetrically as $AlPO_4$.[6]

Determination of P_2O_5. Glass powder containing about 0.1 g of P_2O_5 was fused with about 3 g of sodium carbonate and dissolved in 100 cm^3 of 1 mol/dm^3 hydrochloric acid. The PO_4^{3-} ion in the solution was determined gravimetrically as $Mg_2P_2O_7$.[7]

Determination of H_2O. The H_2O content of the glass was determined gravimetrically by the method of Naruse *et al.*,[8] namely from the weight loss incurred by heating a mixture of the pulverized glass and preignited zinc oxide at 700 °C for 2 h.

Density and Volume of Glass. The density of the glass was determined pycnometrically using 1-butanol at 25 °C.

The molar volume and the volume per mole of oxygen of the glass were calculated by the following equations:[9]

$$V = \frac{W_f}{\rho} \tag{1}$$

and

$$V_0 = \frac{V}{N_0} \tag{2}$$

where V is the molar volume of the glass, V_0 is the volume per mole of oxygen, W_f is the gram formular weight of the glass based on the composition determined by chemical analyses, ρ is the density of the glass, and N_0 is the number of gram molecular weight of oxygen (32 g units) in the glass.

Refractive Index and Molar Refraction of Glass. The refractive index was estimated by the Becke oil immersion method.

The molar refraction of the glass was calculated by the following equation:[9]

$$R = \frac{n^2-1}{n^2+2}V \qquad (3)$$

where R is the molar refraction of the glass, n is the refractive index, and V is the molar volume.

Chemical Resistivity and Solubility of Glass. Glass grains (0.25—1 mm) of about 1 g were placed in a 100-cm^3 Erlenmeyer flask and 50 cm^3 of either water or hydrochloric acid were added into the flask. After shaking at a speed of 80 strokes per minute in the thermostat, the weight loss and the Al_2O_3/P_2O_5 (molar ratio) in the residual glass were determined. The experimental conditions: concentration of hydrochloric acid, temperature of the thermostat, and shaking time were selected so as to be suitable for the sample glass or the series of samples.

Infrared Spectra. The infrared absorption spectra ranging from 1500 to 600 cm^{-1} of the glasses were recorded by means of a Hitachi EPI-2G spectrophotometer, using the KBr pellet technique.

Results and Discussion

Composition of Glass. The analyses of the glasses with more than 45 mol % of P_2O_5 are given in Tables 1 and 2. The Na_2O or K_2O content was calculated by subtracting the Al_2O_3 and P_2O_5 contents from the weight of the sample. The H_2O content was in the range from 0.11 to 0.42 wt % in eight kinds of the glasses of two series of the Na_2O–Al_2O_3–P_2O_5 glass with 59—61 mol % of P_2O_5 and K_2O–Al_2O_3–P_2O_5 glass with 61—62 mol % of P_2O_5, and the H_2O content tended to decrease with an increase in the amount of Al_2O_3. Since the H_2O content was less than 0.42 wt % in the above glasses, even though they were prepared by adding a large amount of orthophosphoric acid, it is considered that the properties of the glass are not seriously effected by water.

△: 61—62 mol % P_2O_5, ▲: 55—56 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 45 mol % P_2O_5, ○: 40 mol % P_2O_5.

Density and Volume. The densities of these glasses are given in Figs. 1 and 2. In Fig. 1 the densities in the Na_2O–Al_2O_3–P_2O_5 glasses with the same P_2O_5 contents are plotted *vs.* the Al_2O_3 content; also in Fig. 2 those in the K_2O–Al_2O_3–P_2O_5 glasses are similarly plotted. The density of the Na_2O glass was larger than that of the K_2O glass in the same composition.

As shown in Figs. 1 and 2, a marked difference in the changes of the densities can be recognized between the glasses with a higher P_2O_5 content and those with a lower P_2O_5 content. The densities increased with an increase in the Al_2O_3 content in the glasses in the Na_2O–Al_2O_3–P_2O_5 system with 42.5 mol % of P_2O_5 or more and those in the K_2O–Al_2O_3–P_2O_5 system with 45 mol % of P_2O_5 or more. On the contrary, no increase of the densities was found in the glasses of 32.5, 37.5 (Na_2O system), and 40 mol % of P_2O_5 (K_2O system). Furthermore, the densities of the glasses

with a lower Al_2O_3 content in both systems decreased with an increase in the P_2O_5 content. In the glasses with 32.5, 37.5, and 40 mol % of P_2O_5, the P–O–P chain is changed to the P–O–Al chain by an increase in the Al_2O_3 content.[5] The density should tend to decrease rather than to increase because the Na_2O or K_2O content decreases with increasing amounts of Al_2O_3 and also because the P–O–Al chain formed is not very long in such a glass. On the other hand, the increase in the densities in the glasses with a higher P_2O_5 content may be interpreted from the assumption that most of the Al^{3+} ions do not form the chain and network consisting of P–O–Al linkages. The Al^{3+} ions outside the P–O–P chain should easily strengthen the glass structure because the ionic field strength $(Z_i/(r_i+r_0)^2$; where Z_i: charge of cation, r_i: radius of cation, r_0: radius of oxygen ion)[10] of the Al^{3+} ion is much larger than that of the Na^+ or K^+ ion. In addition, the decrease in the densities with an increase in the P_2O_5 content in the glasses with a lower Al_2O_3 content may be interpreted from the following facts: an increase of PO_4 groups having one nonbridging O^{2-} ion in each and decrease of Na^+ or K^+ ions tend to open the structure compared with that of the glass with a lower P_2O_5 content.

The molar volumes and the volumes per mole of oxygen in the Na_2O–Al_2O_3–P_2O_5 glass are given in Figs. 3(a) and 3(b) and those in the K_2O–Al_2O_3–P_2O_5 glass are given in Figs. 4(a) and 4(b). The molar volumes increased with an increase in the P_2O_5 content, while the volumes per mole of oxygen decreased. This indicates that the O^{2-} ions are packed more closely together as the Al_2O_3 and P_2O_5 contents increased. In

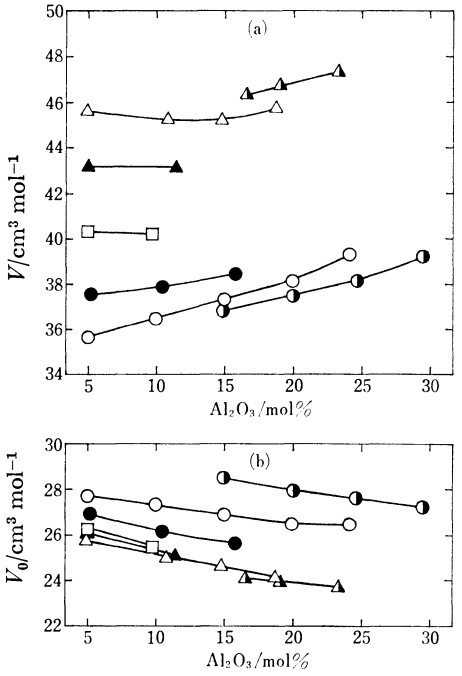

Fig. 3. (a) Molar volume (V) and (b) volume per mole of oxygen (V_0) of Na_2O–Al_2O_3–P_2O_5 glass.
▲: 63 mol % P_2O_5, △: 59—61 mol % P_2O_5, ▲: 55 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 42.5 mol % P_2O_5, ○: 37.5 mol % P_2O_5, ◑: 32.5 mol % P_2O_5.

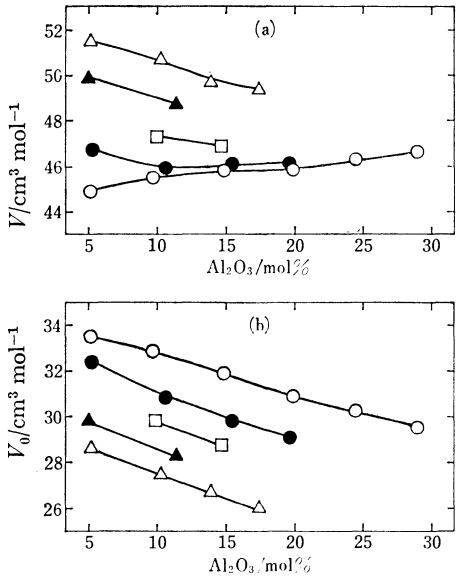

Fig. 4. (a) Molar volume (V) and (b) volume per mole of oxygen (V_0) of K_2O–Al_2O_3–P_2O_5 glass.
△: 61—62 mol % P_2O_5, ▲: 55—56 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 45 mol % P_2O_5, ○: 40 mol % P_2O_5.

the glasses with a lower P_2O_5 content in both systems the molar volumes exhibited the tendency to increase slightly with an increase in the Al_2O_3 content.

Refractive Index and Molar Refraction. The refractive indices of the Na_2O–Al_2O_3–P_2O_5 glass were in the range of 1.482—1.513 and those of the K_2O–Al_2O_3–P_2O_5 glass were 1.474—1.501. The values increased with increasing amounts of Al_2O_3 and P_2O_5, as shown in Figs. 5 and 6. The extent of the increase in the refractive indices with increasing amounts of Al_2O_3 in the glasses with a higher P_2O_5 content was much larger than that in the glasses with a lower P_2O_5

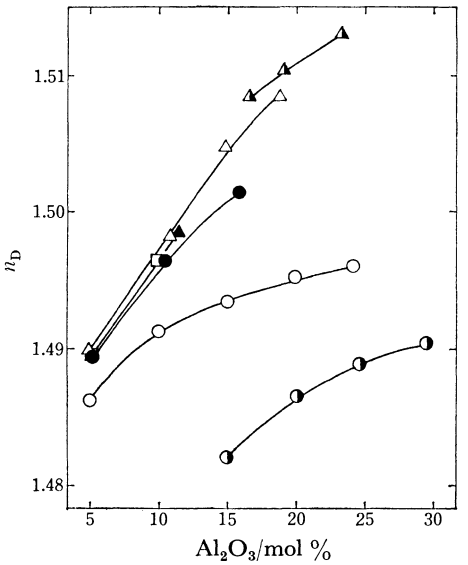

Fig. 5. Refractive index (n_D) of Na_2O–Al_2O_3–P_2O_5 glass.
▲: 63 mol % P_2O_5, △: 59—61 mol % P_2O_5, ▲: 55 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 42.5 mol % P_2O_5, ○: 37.5 mol % P_2O_5, ◑: 32.5 mol % P_2O_5.

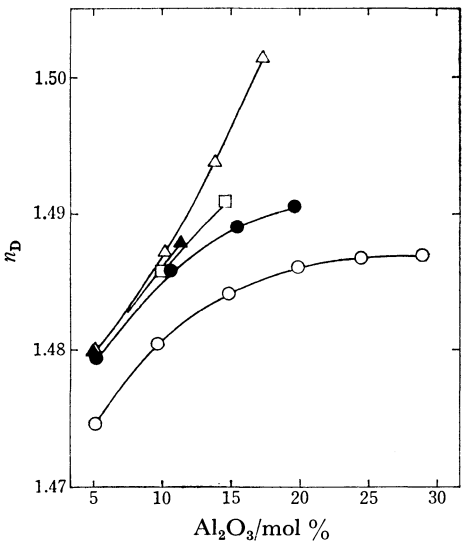

Fig. 6. Refractive index (n_D) of K_2O–Al_2O_3–P_2O_5 glass. △: 61—62 mol % P_2O_5, ▲: 55—56 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 45 mol % P_2O_5, ○: 40 mol % P_2O_5.

content. In the glasses with a lower Al_2O_3 content in both systems, however, the increase in the refractive indices with an increase in the P_2O_5 content was extremely small in the compositions with more than 42.5 mol % of P_2O_5 (Fig. 5) and 45 mol % of P_2O_5 (Fig. 6).

On the other hand, as shown in Figs. 7 and 8, the changes in the molar refractions *vs.* the Al_2O_3 content were almost the same as those in the molar volumes of the glasses in both systems (Figs. 3(a) and 4(a)).

From the measurements of the chemical shift of the Al $K\alpha$ line by X-ray emission spectroscopy, Sakka has reported that most of the Al^{3+} ions in the glasses with a higher P_2O_5 content (P/O≈0.33) are 6-fold coordinated, while those with a lower P_2O_5 content (P/O≲0.25) are 4-fold coordinated.[2,3] In the present investigation, the P/O ratios of the glasses with more than 42 mol % of P_2O_5 are in the range of 0.28—0.35 and those of the

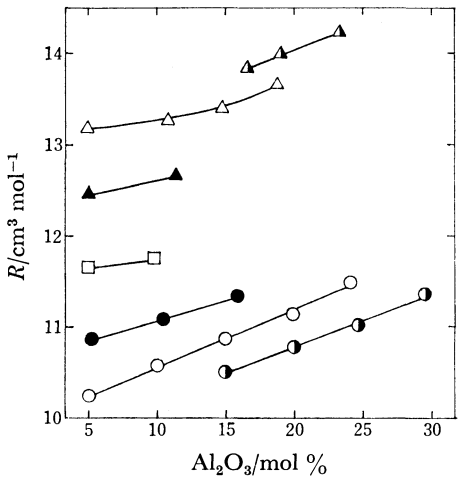

Fig. 7. Molar refraction (R) of Na_2O–Al_2O_3–P_2O_5 glass. ▲: 63 mol % P_2O_5, △: 59—61 mol % P_2O_5, ▲: 55 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 42.5 mol % P_2O_5, ○: 37.5 mol % P_2O_5, ◑: 32.5 mol % P_2O_5.

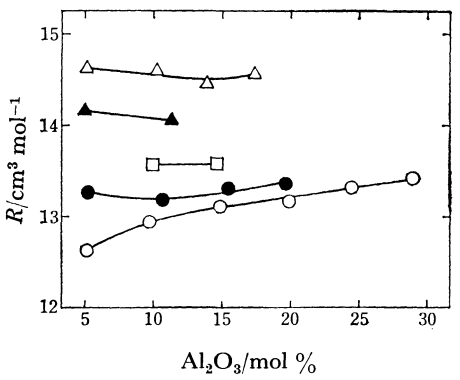

Fig. 8. Molar refraction (R) of K_2O–Al_2O_3–P_2O_5 glass. △: 61—62 mol % P_2O_5, ▲: 55—56 mol % P_2O_5, □: 49 mol % P_2O_5, ●: 45 mol % P_2O_5, ○: 40 mol % P_2O_5.

glasses with less than 42 mol % of P_2O_5 are 0.22—0.30. Therefore, the above results concerning the densities as well as the refractive indices can also be related with the difference in the coordination number of the Al^{3+} ion. From the changes in the densities and refractive indices with increasing amounts of Al_2O_3 shown in Figs. 1, 2, 5, and 6, it may be considered that the marked structural changes in the glasses with P_2O_5 content take place between 37.5 and 42.5 mol % of P_2O_5 in the Na_2O–Al_2O_3–P_2O_5 system and also between 40 and 45 mol % of P_2O_5 in the K_2O–Al_2O_3–P_2O_5 system. Therefore, in both systems the P_2O_5 content of 41—42 mol % may be taken as the boundary composition where the structural change occurs. This is associated closely with the above-mentioned change in the coordination number of Al^{3+} ion between the glasses with a higher P_2O_5 content and those with a lower P_2O_5 content.

Chemical Resistivity and Solubility of Glass. The chemical resistivities in hydrochloric acid in two series of the Na_2O–Al_2O_3–P_2O_5 glasses with 37.5 mol % and 59—61 mol % of P_2O_5 are given in Fig. 9. Although

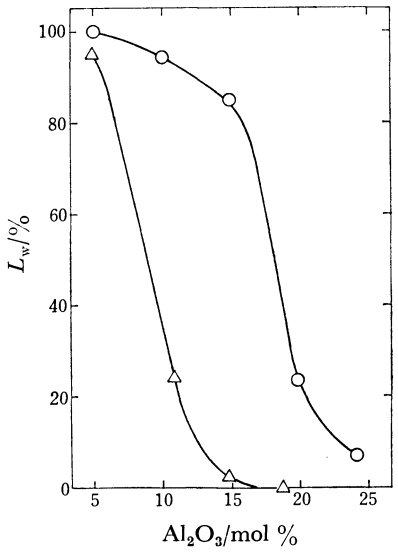

Fig. 9. Chemical resistivity of Na_2O–Al_2O_3–P_2O_5 glass in hydrochloric acid (L_w: weight loss).
○: 37.5 mol % P_2O_5, 1 mol/dm^3 HCl, 25 °C, 1 h, △: 59—61 mol % P_2O_5, concd HCl, 50 °C, 1 h.

the glasses of both series are strengthened chemically with an increase in the Al_2O_3 content, the resistivity of the glass with 59—61 mol % of P_2O_5 is very much larger than that of the glass with 37.5 mol % of P_2O_5. This indicates that the strengthening of the structure by the incorporation of Al_2O_3 is very effective in the glasses with a higher P_2O_5 content. This seems to be due to the tightening of the structure by the Al^{3+} ions outside the P–O–P network or chain in these glasses.

Table 3. Solubility of $52.5Na_2O \cdot 10Al_2O_3 \cdot 37.5P_2O_5$ glass in H_2O (25 °C)

t_s[b]/h	L_w[c]/%	Al_2O_3/P_2O_5[d]
0	—	0.27
1	14.51	0.28
3	38.99	0.29
5	59.30	0.29

b) t_s is the shaking time. c) L_w is the weight loss.
d) Molar ratio in the glass.

Table 4. Solubility of $42.5Na_2O \cdot 20Al_2O_3 \cdot 37.5P_2O_5$ glass in 0.5 mol/dm³ HCl (25 °C)

t_s[b]/h	L_w[c]/%	Al_2O_3/P_2O_5[d]
0	—	0.54
1	8.64	0.53
3	21.75	0.52
5	37.82	0.52
7	48.12	0.53

b) t_s is the shaking time. c) L_w is the weight loss.
d) Molar ratio in the glass.

Table 3 shows the solubility of the $52.5Na_2O \cdot 10Al_2O_3 \cdot 37.5P_2O_5$ glass in water and Table 4 shows that of the $42.5Na_2O \cdot 20Al_2O_3 \cdot 37.5P_2O_5$ glass in 0.5 mol/dm³ hydrochloric acid. The increase in the weight loss of each glass is approximately proportional to the shaking time. The molar ratio Al_2O_3/P_2O_5 in the residual glass is substantially the same value as that in the original glass. These facts indicate that a network consisting of PO_4 tetrahedra does not exist but short P–O–P or short P–O–Al chains exist in the glasses with a lower P_2O_5 content, and thus the structure of such a glass may be taken as "aggregates of molecules." This is an important result for the structure of the glasses with a lower P_2O_5 content.

Infrared Spectra. The infrared absorption spectra of the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 glasses are given in Figs. 10 and 11, respectively. Between the glasses with a higher P_2O_5 content ((1), (2), and (3) in Figs. 10 and 11) and those with a lower P_2O_5 content ((4), (5), and (6) in Fig. 10; (4) and (5) in Fig. 11), the following marked differences are found in the absorption bands: the absorptions in 1300 cm^{-1} (P=O stretching[8,11,12,13]) move to lower frequencies with decreasing P_2O_5 content and those in 900 cm^{-1} (P–O–P stretching[8,11,12,13]) to higher frequencies with increasing Al_2O_3 content, and also the absorptions in 1000 cm^{-1} (PO_4^{2-} group[8,11,12,13]) increase in intensity with increasing Al_2O_3 content in the glasses with a lower P_2O_5 content. These results show the structural changes

(3) $40.67K_2O \cdot 9.95Al_2O_3 \cdot 49.38P_2O_5$,
(4) $50K_2O \cdot 10Al_2O_3 \cdot 40P_2O_5$,
(5) $40K_2O \cdot 20Al_2O_3 \cdot 40P_2O_5$.

of the glasses corresponding to the variation of P_2O_5 and Al_2O_3 contents. Especially in the glasses with a lower P_2O_5 content the infrared spectra indicate the change of the short P–O–P chain to the short P–O–Al chain with increasing amounts of Al_2O_3.

From the changes in the properties described above and the coordination number of the Al^{3+} ion in phos-

phate glass,[2,3] the structure of alkali aluminophosphate glass may be considered to be as follows: the glasses with a higher P_2O_5 content consist of a network or long chain of PO_4 tetrahedra, Al^{3+}, and alkali metal ions, while those with a lower P_2O_5 content are formed from random aggregates of short P–O–P chains, Al^{3+}, and alkali metal ions (low Al_2O_3 glass) or random aggregates of short P–O–Al chains of PO_4 and AlO_4 tetrahedra and alkali metal ions (high Al_2O_3 glass).

The author wishes to thank Associate Professor Makio Kinoshita of Sophia University for his interest and encouragement.

Complexation Equilibria of Vanadium(V) with 8-Quinolinolate in Aqueous Solutions

Akio YUCHI, Shinkichi YAMADA, and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 25, 1979)

The complexation equilibria of vanadium(V) with 8-quinolinolate ion(ox^-) were investigated spectrophotometrically. Depending upon the acidity of the solution various 1:1 and 1:2 complexes are formed: VO_3ox^{2-}, VO_3Hox^-, VO_2ox, and $VO_2ox_2^-$. The formation and protonation constants of these complexes are discussed in terms of their structures.

Vanadium(V) reacts with 8-quinolinol(Hox) to give a black precipitate in weakly acidic solution. This complex has been identified to be $V_2O_3ox_4$ or $VO(OH)ox_2$ from the vanadium content.[1-5] This complex, reacting with alcohols (ROH), gives rise to a red complex, of which the structure has been established as $VO(OR)ox_2$ by X-ray study.[6] Furthermore, a yellow precipitate has also been isolated from nearly neutral solution, for which the composition $NaVO_2ox_2$ has been given according to the elemental analysis.[1,4,7] It seems interesting to make it clear why the protonation of $NaVO_2ox_2$ causes such a pronounced color change.

The solvent extraction of vanadium(V) with 8-quinolinol has also revealed the metal to ligand ratio of 1:2, from which the composition of $VO(OH)ox_2$ has been given to the black extracted species.[8,9] This extraction system has been utilized to determine the hydrolysis constants of dioxovanadium(V).[9,10] In these studies no complexed species being assumed in the aqueous phase, it is sometimes indispensable to take into account the formation of lower complexes especially in the extraction of multivalent metals.[11,12] Vanadium(V) itself tends to be hydrolyzed and is correspondingly expected to form various 1:1 and 1:2 complexes with 8-quinolinolate of various degree of hydrolysis. The complexation reactions of Mo(VI) and W(VI) with 8-quinolinolate were studied under limited conditions.[13] However, the stepwise complex formation of multivalent ions has been little studied.

In order to understand the complexation reaction and the extraction behavior of vanadium(V) with 8-quinolinol, we first study the complexation reaction of vanadium(V) with 8-quinolinolate under conditions where no black precipitate appears in the aqueous solution.

Experimental

Reagent. *Dioxovanadium(V) Perchlorate*: Ammonium metavanadate, recrystallized from isothermally distilled ammonia, was dissolved in sodium hydroxide solution. Then the solution was heated with nitrogen gas bubbling to expell ammonia. After cooling, perchloric acid was added to obtain dioxovanadium(V) perchlorate solution, which was standardized titrimetrically against a standard potassium permanganate solution.

8-Quinolinol: Reagent grade 8-quinolinol was recrystallized twice from aqueous acetone.

The method of preparation of sodium perchlorate and sodium hydroxide has been described previously.[11]

Measurement. All the experiments were carried out in a room thermostated at 25±0.5 °C. All the measurements were performed in a thermoelectric circulating bath thermostated at 25±0.1 °C. The ionic strength was maintained at 1.00 mol dm^{-3} with sodium perchlorate. Spectrophotometric measurements were performed on a UNION High Sens Spectrophotometer SM-401 with a thermostated cell compartment. Hydrogen ion concentration was determined by a Radiometer pH meter (PHM 22 type) with a Radiometer glass electrode (G 202 C type) and a calomel electrode filled with a saturated sodium chloride as an internal solution. A 1.00×10^{-2} mol dm^{-3} perchloric acid solution of ionic strength 1 mol dm^{-3} was used as a standard of hydrogen ion concentration: $-\log[H^+]=2.00$. The change of a liquid-junction potential was taken into account.[14]

In order to avoid the polymerization of vanadium(V),[15] it is indispensable to control the total concentration of vanadium(V), to observe the order of mixing various solutions, and to stir the solution vigorously. All the experiments have been carried out under conditions where no polymerized species occurs. The formation of polymers was always monitored by the near ultraviolet and visible spectra.

Results

Protonation Equilibria of 8-Quinolinolate Ion. The protonation equilibria of 8-quinolinolate are expressed by Eqs. 1 and 2:

$$ox^- + H^+ \overset{K_{Hox}}{\rightleftharpoons} Hox \quad (1)$$

$$Hox + H^+ \overset{K_{H_2ox}}{\rightleftharpoons} H_2ox^+ \quad (2)$$

The absorbance at 350 nm of the solution containing 3.91×10^{-4} mol dm^{-3} 8-quinolinol was plotted against $-\log[H^+]$. According to the plot we have two equilibria, which are separated enough to treat them as two independent steps. The plot was compared with a set of normalized curves; $X=\log x$, $Y=a/(1+x)$. The values of the protonation constants and the molar extinction coefficients obtained are as follows:

$$\log K_{H_2ox} = 5.36 \pm 0.02;\ \varepsilon_{H_2ox} = 1560;$$
$$\log K_{Hox} = 9.43 \pm 0.02;\ \varepsilon_{Hox} = 260;$$
$$\varepsilon_{ox} = 2710$$

at 25±0.1 °C and at an ionic strength of 1.0($NaClO_4$).

Protonation Equilibrium of Hydrogen Orthovanadate Ion. The protonation of hydrogen orthovanadate ion is expressed by Eq. 3:[16]

$$HVO_4^{2-} + H^+ \overset{K_{VO_3}}{\rightleftharpoons} VO_3^- \quad (3)$$

The ultraviolet spectra of the solutions containing about

5×10^{-4} mol dm^{-3} vanadium(V) were measured at various hydrogen ion concentrations. A distinct isosbestic point is observed at 290 nm over the range of $-\log[H^+]=7.6$—10. The deviation of the isosbestic point at $-\log[H^+]$ value lower than 7.6 was thought to be due to the formation of polymers. The absorbance change at 265 nm was plotted against $-\log[H^+]$ over the range of $-\log[H^+]=7.6$—10. The plot was compared with a normalized curve; $X=\log x$, $Y=a/(1+x)$ and we obtained $\log K_{VO_2}=8.07\pm0.06$. The value obtained by Schwarzenbach and Geier ($\log K_{VO_2}=8.04$ at 20 °C and 1 mol dm^{-3} KCl)[17] agrees with ours.

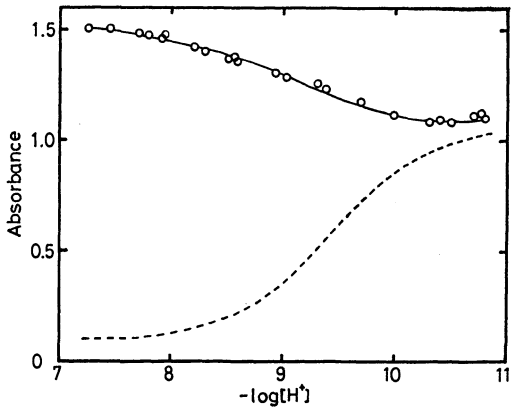

Fig. 1. Absorbance change at 350 nm as a function of $-\log[H^+]$. $C_V=1.39\times10^{-3}$ mol dm^{-3}, $C_{Hox}=3.93\times10^{-4}$ mol dm^{-3}. The solid line: the calculated curve with the constants obtained; the dotted line: data in the absence of vanadium(V).

Complexation Equilibria. The absorbance at 350 nm of the solution containing 1.39×10^{-3} mol dm^{-3} vanadium(V) and 3.93×10^{-4} mol dm^{-3} 8-quinolinol was plotted against $-\log[H^+]$ (Fig. 1). The absorbance change under the same conditions without vanadium(V) is also shown by the dotted line. Thus the difference between these two lines can be ascribed to the complex formation.

In the presence of an excess amount of vanadium(V), the formation of only 1 : 1 complex is anticipated and the equilibrium is generally expressed by Eq. 4:

$$HVO_4^{2-} + mH^+ + ox^- \overset{\beta_{1m1}}{\rightleftharpoons} VO_4H_{m+1}ox^{(3-m)-} \quad (4)$$

where m is the number of protons involved in the complexation reaction and β_{1m1} is the overall formation constant of the species formed. We have Eqs. 5 and 6:

$$\frac{A-A'}{\varepsilon_{1m1}C_{Hox}-A} = \beta_{1m1}\frac{[HVO_4^{2-}][H^+]^m}{\alpha_{ox}} \quad (5)$$

$$[HVO_4^{2-}] = \frac{1}{\alpha_{HVO_4}}\left(C_V - \frac{A-A'}{\varepsilon_{1m1}C_{Hox}-A'}\times C_{Hox}\right) \quad (6)$$

where A and A' are observed absorbances in the presence and in the absence of vanadium(V), respectively, C_{HOX} and C_V are the total concentration of 8-quinolinol and vanadium(V), respectively, and α_{OX} and α_{HVO_4} are the side reaction coefficients taking into account the protonation reaction of 8-quinolinolate ion and hydrogenorthovanadate ion, respectively. At 350 nm the molar extinction coefficients of the uncomplexed vanadium(V) species are negligibly small as compared with those of the complexes and the ligand. ($\log((A-A')/(\varepsilon_{1m1}C_{Hox}-A))-\log[HVO_4^{2-}]+\log\alpha_{ox}$) being plotted against $-\log[H^+]$, a straight line with a slope of m and an intercept of $\log\beta_{1m1}$ will be obtained, provided only one complex is involved in reaction given by Eq. 4.

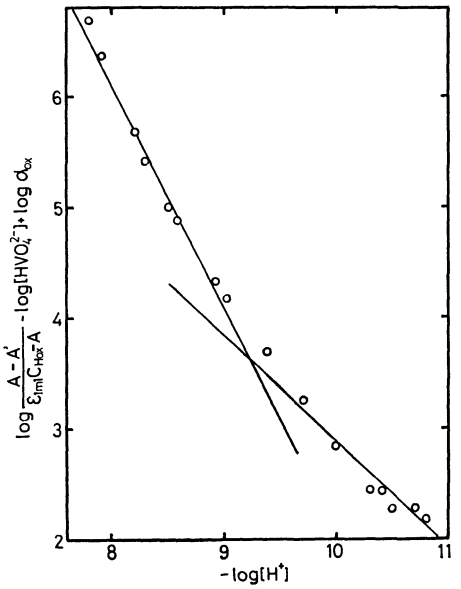

Fig. 2. Determination of the formation constants of vanadium(V)-8-quinolinolate complexes. Plot of $\log((A-A')/(\varepsilon_{1m1}C_{Hox}-A))-\log[HVO_4^{2-}]+\log\alpha_{ox}$ *vs.* $-\log[H^+]$.

The slope of the plot is close to 2 at lower value of $-\log[H^+]$, while at higher value of $-\log[H^+]$ it tends to be unity (Fig. 2). This points to the formation of two types of 1 : 1 complex, namely VO_3Hox^- and VO_3ox^{2-}. The complex is now described not to have more than 1 proton by the repeated elimination of two protons with one oxo group as one water (see Discussion). The overall formation constants and the molar extinction coefficients obtained by the graphical plot were refined with an electronic computer to have the following values:

$$\log\beta_{121} = 22.1\pm0.1;\ \varepsilon_{121} = \varepsilon_{VO_2Hox} = 3830\pm50;$$
$$\log\beta_{111} = 12.8\pm0.1;\ \varepsilon_{111} = \varepsilon_{VO_2ox} = 3650\pm100.$$

The data for the solution containing 1.48×10^{-4} mol dm^{-3} vanadium(V) and 7.82×10^{-5} mol dm^{-3} 8-quinolinol are also well interpreted with the above constants. This confirms the absence of polymerization under the present experimental conditions: the above results are regarded as reliable.

Equilibria in more acidic media were studied by decreasing the total concentrations of vanadium(V) and 8-quinolinol to 5.92×10^{-5} and 3.13×10^{-5} mol dm^{-3}, respectively, the polymerization of vanadium(V) being avoided. The absorbance of the solution at 400 nm was measured at various hydrogen ion concentration and plotted against $-\log[H^+]$ (Fig. 3). Under these conditions protonation equilibria of vanadium(V), Eqs. 7 and 8, must also be considered:[18]

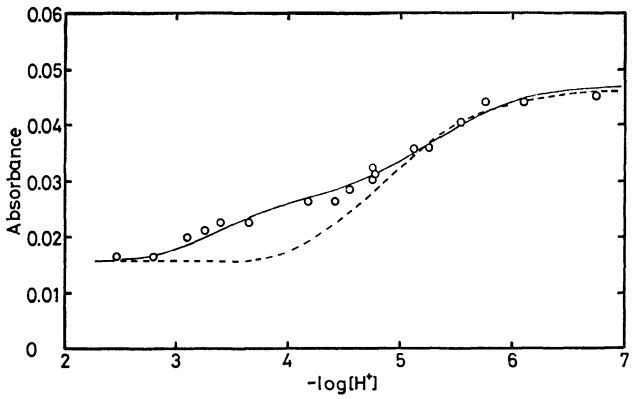

Fig. 3. Absorbance change at 400 nm as a function of $-\log[H^+]$. $C_V=5.92\times10^{-5}$ mol dm^{-3}, $C_{Hox}=3.13\times10^{-5}$ mol dm^{-3}. The solid line: the calculated curve with the constants obtained; the dotted line; the calculated curve without taking into account the formation of VO_2ox.

$$VO_3^- + H^+ \overset{K_{HVO_3}}{\rightleftarrows} HVO_3 \quad (7)$$

$$HVO_3 + H^+ \overset{K_{VO_2}}{\rightleftarrows} VO_2^+ \quad (8)$$

The assumption of VO_3Hox^- as a sole species leads to the deviation at lower value of $-\log[H^+]$ as shown by the dotted line in Fig. 3. This deviation points to the formation of a further protonated species, for example VO_2ox. The combination of the formation constants and the molar extinction coefficients of the above two protonated species, VO_3Hox^- and VO_2ox, leads to the best fit curve indicated by the full line in Fig. 3 with the following:

$$\log\beta_{131} = 27.5\pm0.1;\ \varepsilon_{131} = \varepsilon_{VO,ox} = 1100\pm50.$$

The absorbance at 350 nm of the solution containing 7.00×10^{-5} mol dm^{-3} vanadium(V) and 3.91×10^{-4} mol dm^{-3} 8-quinolinol was plotted against $-\log[H^+]$ (Fig. 4). In the presence of excess amounts of 8-quinolinol the formation of 1:2 complex is also anticipated:

$$HVO_4^{2-} + mH^+ + 2ox^- \overset{\beta_{1m2}}{\rightleftarrows} VO_4H_{m+1}ox_2^{(4-m)-} \quad (9)$$

It was revealed that in addition to 1:1 complexes only $VO_2ox_2^-$ with $m=3$ forms. The combination of the overall formation constant and the molar extinction coefficient giving a minimum error square sum is as follows:

$$\log\beta_{132} = 36.0\pm0.1;\ \varepsilon_{132} = \varepsilon_{VO,ox_2} = 7660\pm100.$$

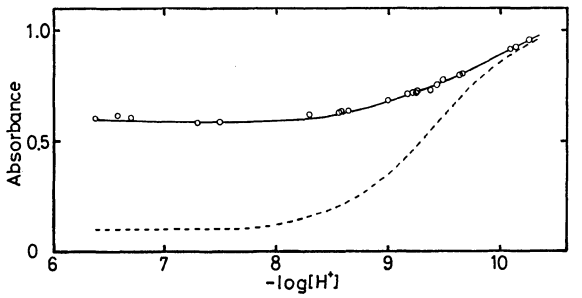

Fig. 4. Absorbance change at 350 nm as a function of $-\log[H^+]$. $C_V=7.00\times10^{-5}$ mol dm^{-3}, $C_{Hox}=2.91\times10^{-4}$ mol dm^{-3}. The solid line: the calculated curve with the constants obtained; the dotted line: data in the absence of vanadium(V).

Discussion

Species identified in this study are represented in Scheme 1 together with pK_a and logarithmic formation constants.[18,19]

In Scheme 1 the changes from left to right correspond to hydrolytic reactions and the changes from upper to lower complexation reactions. It can be seen that the complexation ability decreases with increasing degree of hydrolysis of vanadium(V): the formation constant of VO_3ox^{2-} is $10^{5.6}$ times as low as that of VO_3Hox^-. The same trend has been observed in the complexation of tungsten(VI) with 8-quinolinolate,[13] where the formation constant of WO_4Hox^{2-} is $10^{5.6}$ times as low as that of WO_3ox^-, as evident from the following scheme:

$$\begin{array}{ccccc} H_2WO_4 & \overset{3.5}{\rightleftarrows} & HWO_4^- & \overset{2.3}{\rightleftarrows} & WO_4^{2-} \\ \Big\updownarrow 14.2 & & \Big\updownarrow 8.6 & & \\ WO_3ox^- & \overset{9.1}{\rightleftarrows} & WO_4Hox^{2-} & & \end{array}$$

This difference is mainly attributable to the effect of charge and the number of oxo groups.

The formation constants of the dioxovanadium complexes with various ligands are summarized in Table 1, in which $\sum pK_a$, the summation of the loga-

Table 1. Formation constants of dioxovanadium complexes with various ligands at 25 °C

Number	Ligand	Ionic strength mol dm^{-3}	$\log\beta$	$\sum pK_a$	Reference

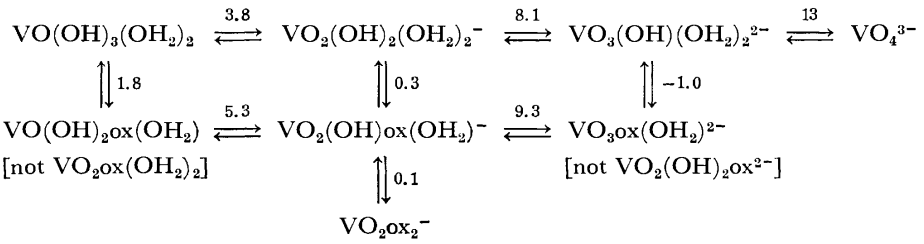
Scheme 1.



Scheme 2.

rithmic stepwise protonation constants for the donor atoms which actually coordinate to the central metal, is also listed. When the overall formation constant is plotted against $\sum pK_a$, a fairly good linear relationship is observed (Fig. 5).[22]

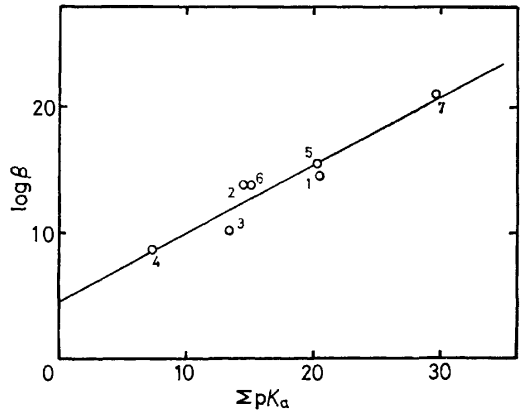


Fig. 5. Correlation of the overall formation constant of vanadium(V) complex with $\sum pK_a$ of the ligand. For the number Table 1 should be referred to.

In order to compare pK_a values Scheme 1 is rewritten as Scheme 2 with probable structures[23] and logarithmic constants. In Scheme 2 the species are arranged to have a same charge in a row. So the change from upper to lower is the substitution reaction of hydroxo group by 8-quinolinolate. VO_2ox and VO_3ox^{2-} have more than one possible structures.

The pK_a of a neutral acid of the formula H_aXO_{a+1}, which have one oxo group, lies in the range of 2—3 and increases by 4—5 for each successive proton dissociation with increase of oxo groups.[25,26] Vanadic acid belongs to this category and can be described as $VO(OH)_3(OH_2)_2$, which gives rise to $VO_2(OH)_2(OH_2)_2^-$ and $VO_3(OH)(OH_2)_2^{2-}$ upon proton dissociation. The formulation $VO(OH)_4(OH_2)^-$ for metavanadate ion[10] seems unlikely.

When pK_a values of complexes are compared with those of the corresponding vanadic acid, nearly the same difference is observed: 3.8 as compared to 5.3 for the first proton dissociation (difference of 1.5) and 8.1 as compared to 9.3 for the second proton dissociation (difference of 1.2). These differences may be ascribed to the difference in electron donating ability between hydroxide and 8-quinolinolate. Thus we may conclude that the change in the number of oxo groups during the hydrolysis of the complex is the same as in the proton dissociation of vanadic acid and that the skeleton of vanadium(V) species is retained during the complexation. Thus VO_2ox is $VO(OH)_2ox(OH_2)$ and not $VO_2ox(OH_2)_2$, and VO_3ox^{2-} is $VO_3ox(OH_2)^{2-}$ and not $VO_2(OH)_2ox^{2-}$.

Furthermore, this Scheme suggests that the constant of the substitution reaction of one hydroxide by 8-quinolinolate is largely affected by the number of coordinated oxo groups: 1.8 for $VO(OH)_2ox$, 0.3 for $VO_2(OH)ox^-$, and -1.0 for VO_3ox^{2-}. On the other hand, the coordinated 8-quinolinolate does not affect much the subsequent coordination of the same ligand: 0.3 for $VO_2(OH)ox^-$ as compared to 0.1 for $VO_2ox_2^-$ in Scheme 2.

The pK_a values are also available for *N*-methyliminodiacetato and 2,6-pyridinedicarboxylato complexes:[14,20]

$$VO_2(mida)(OH_2)^- \rightleftharpoons VO_2(mida)(OH)^{2-} + H^+ \qquad pK_a = 6.13 \pm 0.05$$

$$VO_2(pda)(OH_2)^- \rightleftharpoons VO_2(pda)(OH)^{2-} + H^+ \qquad pK_a = 5.87 \pm 0.02$$

However these reactions involving no increase of oxo groups, they can not be discussed on the same ground as in the present case.

Among the species which have been identified, VO_3ox^{2-}, VO_3Hox^-, and $VO_2ox_2^-$ have the absorption maximum at 363 nm. On the survey of ultraviolet and visible spectra of various metal 8-quinolinolate complexes, it is noticed that the absorption maximum depends upon the oxidation number of metal ions, *e.g.* 410—460 nm for Mox_2, 380—420 nm for Mox_3, 380 nm for Mox_4, and 360—370 nm for MO_2ox_2 (hexavalent).[27] Vanadium(V) complexes mentioned above are well lined up in this series, whereas the black complex has absorption maximum at 550 nm. On the other hand complexes with the dimeric $Mo_2O_3^{4+}$ unit have a fairly strong absorption maximum near 510 nm and monomeric species containing the same ligand do not.[28] This absorption maximum is attributable to the oxo bridged structure of molybdenum and the absorption maximum at 550 nm for the black vanadium(V) complexes also seems to be ascribed to the oxo bridged dimeric structure. The dimeric structure of black vanadium(V) 8-quinolinolate has recently been established by the solvent extraction in our laboratory. Details on this point will be shortly published elsewhere.

Circular Dichroism and Stereochemistry of Tetranuclear Cobalt(III) Complexes of Hexol Type. I. Dodecaammine-hexa-μ-hydroxo-tetracobalt(III) Ion, $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$

Tomikatsu KUDO* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 9, 1979)

From the circular dichroism spectra of optically active dodecaammine-hexa-μ-hydroxo-tetracobalt(III) ion, $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$, measured in the visible and ultraviolet region in several solvents such as 0.01M-HCl and 0.17M-Na_2SeO_3, the d-d transitions of the complex are assigned in consideration of the ion-pairing effect. The absolute configuration of $(+)_{589}$ isomer is assigned as Δ based upon a negative sign of the E_a component for the CoO_6 chromophore. The circular dichroism change by the ion-pairing is attributed to the vicinal effect of chiral oxygen centers stereospecifically produced by the ion-pair formation, and the importance of the oxygen chirality is discussed on the basis of the time-course of circular dichroism change in the solutions.

Dodecaammine-hexa-μ-hydroxo-tetracobalt(III) complex salt was firstly prepared by Jörgensen,[1] and was resolved into optical isomers as the first purely inorganic complex by Werner,[2] who named the complex "hexol" after the bridging ligands. The structure of the polynuclear cation has been established by an X-ray crystal structure analysis of the racemic chloride salt,[3] and there have been done several investigations concerning the optical activity of the resolved isomers and related hexa-μ-hydroxo-tetracobalt(III) type complex ions.[2,4-7] Heretofore there have been two different assignments for the absolute configuration of this type of complexes.[5,7] To solve the problem, a detailed CD investigation of the dodecaammine-hexa-μ-hydroxo-tetracobalt(III) ion, $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$, which is the most basic of this type of complexes, will be reported in the present paper; the absolute configuration will be determined mainly on the basis of the effect of ion-pairing on the CD spectra.

Experimental

Preparation and Optical Resolution. *(1)* $[Co\{(OH)_2Co(NH_3)_4\}_3]Cl_6\cdot 6H_2O$: The sulfate salt $[Co\{(OH)_2Co(NH_3)_4\}_3](SO_4)_3\cdot 4H_2O$ which was prepared by an established method[8] was converted into the chloride salt by treating with $BaCl_2$. Found: H, 6.13; N, 19.29; Cl, 25.05 %. Calcd for $H_{42}O_6N_{12}Cl_6Co_4\cdot 6H_2O$: H, 6.31; N, 19.48; Cl, 24.65%.

(2) $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3](ClO_4)_6\cdot 2.5H_2O\cdot 0.5NaClO_4$: The optical resolution was achieved by a modification of the procedure of Goodwin *et al.*,[4] which was for the corresponding ethylenediamine complex $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$. The racemic chloride hexahydrate (2.00 g, 2.32×10^{-3} mol) was dissolved in 200 cm^3 of cold water, and to this dark brown solution the first quarter of cold solution of $Na_2[Sb_2(d\text{-}C_4H_2O_6)_2]\cdot 2.5H_2O$ (2.18 g, 3.48×10^{-3} mol) in 160 cm^3 of water was added dropwise with stirring. During the reaction the vessel was cooled in an icebath. A voluminous pale-brown precipitate of the less soluble diastereoisomer deposited, which was filtered, washed with cold water, and air-dried. The filtrate was again cooled in an icebath, whereupon the second quarter of $[Sb_2(d\text{-}C_4H_2O_6)_2]^{2-}$ solution was added to it, and the second fraction of the diastereoisomer was obtained. The procedure was repeated 4 times in total. The time for the separation of each fraction did not exceed 20 min.

Each fraction was converted into the perchlorate as follows. A mixture of the less soluble diastereoisomer and solid $NaClO_4$ (*ca.* 2 g) was ground up finely in a mortar, and then to this mixture was added 7 cm^3 of ice-cold water which was in advance acidified to pH 5 with $HClO_4$. This mixture was rubbed with a pestle, the vessel being cooled in an ice bath. The resulting mixture was filtered, washed with an ethanol–water (2: 1) mixture, ethanol and then ether. The brown violet powdery crystals were dried in a vacuum desiccator over $CaCl_2$. The $\Delta\varepsilon_{614}$ values of the fractions were -13.5, -12.9, -6.23, and -1.35 in the order of precipitation. In other experiments the racemic compound was treated to yield 8 fractions or 16 fractions. But the $\Delta\varepsilon_{614}$ value of each the first fraction was same as that described above ($\Delta\varepsilon_{614}=-13.5$). Found: H, 3.78, N, 13.56 %. Calcd for $H_{42}O_{30}N_{12}Cl_6Co_4\cdot 2.5H_2O\cdot 0.5NaClO_4$: H, 3.80; N, 13.50 %.

Measurement. The visible and ultraviolet absorption measurements were made by a Shimadzu UV-200 spectrophotometer. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter. The time-course of CD change was followed at 614 and 505 nm in H_2O, 0.01M-HCl, 0.17M-Na_2SeO_3, 0.17M-Na_2tart, 0.17M-H_2tart, and NaOH aqueous solutions (pH 8.1 and 10.4) at 22 °C (tart stands for $(+)_{589}$-tartrate(2−) ion). The time-course of absorption change was followed at 625 and 505 nm in each case. The CD measurements in 0.17M-Na_2SeO_3 were made with the solutions prepared freshly every about 10 minutes, and the CD curve was obtained by extrapolating the spectra back to zero time.

Results and Discussion

The absorption and CD spectra are shown in Fig. 1 and the numerical data in Table 1. Since mutarotation of this complex was very fast in water, the CD spectra were measured in 0.01M-HCl solution, in which the complex is considerably stable for the mutarotation. The CD spectra in 0.17M-Na_2SeO_3 were obtained by extrapolating the observed $\Delta\varepsilon$ values back to zero time. The dodecaammine-hexa-μ-hydroxo-tetracobalt(III) ion, $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$, is regarded as composed of a $Co(OH)_6$ and three $Co(OH)_2(NH_3)_4$ chromophores. In the following discussion the former chromophore will be abbreviated to CoO_6 one, and the latter to CoN_4O_2 one. The CoO_6 chromophore has a configurational chirality, Δ or Λ, due to the tris-chelate type structure of the whole complex, while each the CoN_4O_2 chromo-

phore itself has no chirality.

The first and second d-d transition bands of $[Co(H_2O)_6]^{3+}$ are located at 16500 and 24700 cm^{-1}, respectively,[9] and those of *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ at 19900 and 28100 cm^{-1}. Therefore, the absorption bands of $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ at 15970 and 19860 cm^{-1} in 0.01M-HCl are assigned to the first d-d transition bands of CoO_6 and CoN_4O_2 chromophores, respectively. The second d-d transition bands of both chromophores seem to be masked by an intense band at 32210 cm^{-1}, which is due to the charge transfer transition from the OH bridge group to the central metal, $p_\pi(O)\rightarrow e_g(Co)$. These assignments of the absorption bands are consistent with earlier assignments for those of similar hexa-μ-hydroxo-tetracobalt(III) type ions.[5-7]

Upon going from in 0.01M-HCl to in 0.17M-Na_2SeO_3, the peak of the first d-d absorption band of CoO_6 chromophore shifted to higher energy side, while the peak of CoN_4O_2 chromophores to lower energy side. The charge transfer band shifted to lower energy side. For the CD spectra, the intensity of the longer wavelength extremum of CoO_6 chromophore increased with shifting to higher energy side, but the intensity of the shorter wavelength one of CoO_6 chromophore drastically decreased without shifting. The CD band of CoN_4O_2 chromophore shifted to lower energy side and the intensity increased slightly. Both CD bands at about 32000 and 41000 cm^{-1} shifted to lower energy side and their intensities decreased.

It has been well known that the CD spectra of *Λ*-$[Co(en)_3]^{3+}$ with D_3 symmetry show strong ion-pairing effect in the region of the first d-d absorption band when a kind of oxoanion species such as PO_4^{3-} or SeO_3^{2-} is added; the CD intensity of E_a component of the first d-d transition decreases, and those of A_2 component of the first d-d transition and E_b component of the second d-d transition increase.[10-12] Mason and Norman proposed that hydrogen bonds played an important role in the ion-pair formation between PO_4^{3-} and $[Co(en)_3]^{3+}$,[11] and this view has been supported by an X-ray crystal structure analysis of $[Co(en)_3]_2(HPO_4)_3\cdot 9H_2O$[13] and another CD study of $[Co\{1,1,1\text{-tris}(2\text{-aminoethylaminomethyl})\text{ethane}\}]^{3+}$.[14] In a similar way, hydrogen bonds may occur between SeO_3^{2-} and the OH bridge groups of $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$, because a set of three OH groups is available each on the upper face and below the downward face of the ion of D_3 symmetry. The CD intensities increased at the bands of 14500, 19800, and 25400 cm^{-1}, while decreased at the band of 16300 cm^{-1} (Fig. 1 and Table 1). Therefore, the bands at 14500 and 16300 cm^{-1} can be assigned to A_2 and E_a component of the CoO_6 chromophore respectively.

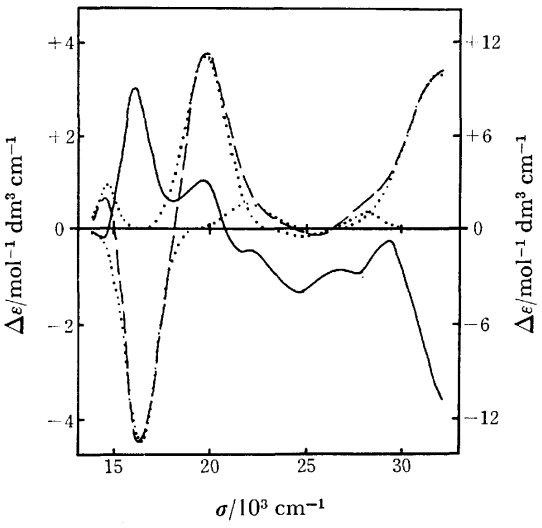

Fig. 2. The ion-pairing effect curve, $\{\Delta\varepsilon_{(in\ 0.17M\text{-}Na_2SeO_3)} - \Delta\varepsilon_{(in\ 0.01M\text{-}HCl)}\}$, (——) (the left ordinate), and CD curve of $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ in 0.01 M-HCl (----) and its component curves separated by curve analysis (……) (the right ordinate).

Figure 2 shows the difference CD curve between in 0.01M-HCl and in 0.17M-Na_2SeO_3; this presents the ion-pairing effect of SeO_3^{2-} ion on the CD of $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$. The curve have six extrema at 14200, 16000, 19600, 21600, 24600, and 27800 cm^{-1} in the d-d transition region. The first and next extrema, at 14200 and 16000 cm^{-1}, correspond to the increment of the positive A_2 component and the decrement of the negative E_a component, respectively, of the first d-d transition of CoO_6 chromophore. The extrema at 19600 and 21600 cm^{-1} correspond to the first d-d transition components of CoN_4O_2 chromophores, and it seems that the last two extrema, at 24600 and 27800 cm^{-1}, correspond to the second d-d transition components of CoO_6 or CoN_4O_2 chromophores. Since the second d-d transition CD bands have been observed at 24300 and 26500 cm^{-1} for Λ-$[Co(ox)_3]^{3-}$[15] and at 26500 and 29400 cm^{-1} for Λ-$[Co(en)_2(H_2O)_2]^{3+}$,[16] it seems that the extremum at 24600 cm^{-1} shows the increment due to the ion-pairing effect on the longer wavelength negative CD component of the second band of CoO_6 chromophore. The extremum at 27800 cm^{-1} corresponds to the longer wavelength CD component of the second band of CoN_4O_2 chromophore or the shorter wavelength CD component of the CoO_6 one. Gaussian curve analysis of the CD spectra measured in 0.01M-HCl showed six CD components at 14680 cm^{-1} ($\Delta\varepsilon=+3.00$), 16340 (-13.54), 19690 ($+11.10$), 21980 ($+1.65$), 24460 (-0.28), and 28120 ($+1.07$) (Fig. 2). These extremum positions are well close to the extrema on the ion-pairing effect curve.

As for the chirality of the hexol type ions, two different assignments of absolute configuration have been offered.[5,7] Both assignments based on the CD sign of E_a component of CoO_6 chromophore, the assignments of the E_a component being reversed. Mason and Wood[5] have assigned the E_a component from the intensity, because the E_a component is invariably stronger than the A_2 component in many trigonal cobalt(III) complexes. The major CD band of CoO_6 chromophore of the hexol type complexes situated at higher energy side than the minor band, and they assigned Λ-configuration to the complex which has a positive sign in the higher energy CD component. On the other hand, Masuda and Douglas[7] have assigned the E_a component on the basis of the CD extremum position, because the E_a component appears usually at lower energy side of the A_2 component for many trigonal cobalt(III) complexes. Thus they assigned the complex which has a positive sign in the lower energy CD band as having the absolute configuration Λ.

From the present study of the ion-pairing effect, it is shown that the intensity of the lower energy CD band of CoO_6 chromophore increases upon ion-pairing, while that of the higher energy CD band decreases. In consequence the higher energy band can be assigned to the E_a component; this suports the assignment of Mason and Wood. As a conclusion the $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ which shows a negative sign in the 16280 cm^{-1} CD band is assigned as having Λ-configuration.

Table 2 summarizes the rates of mutarotation, k, of the $(+)_{589}$ isomer determined from the time-course of CD change at 614 and 505 nm for the early reaction stage. The values of $\Delta\varepsilon_{614}$ and $\Delta\varepsilon_{505}$ are also presented, which were obtained by extrapolating the CD values back to zero time by using the rate constants k_{614} and k_{505}. In a NaOH solution of pH 8.1, $(+)_{589}$ isomer lost the optical activity completely within 3 min. In a NaOH solution of pH 10.4 the complex decomposed immediately. During the mutarotation, the absorption intensities at 625 and 505 nm did not change for more than 30 min in H_2O, for more than 120 min in 0.17M-H_2tart, 0.17M-Na_2tart, and 0.17M-Na_2SeO_3, for more than 2 days in 0.01M-HCl, and for more than 5 min in a NaOH solution of pH 8.1; in these periods the absorption spectra did not change in the d-d transition region.

As Table 2 shows, the $\Delta\varepsilon_{614}$ values in 0.01M-HCl and H_2O were -13.5 and -13.7, respectively; they are approximately equal. In 0.17M-Na_2SeO_3, 0.17M-Na_2tart, and 0.17M-H_2tart, they were -10.5, -12.4, and -12.2, respectively. On the other hand, the $\Delta\varepsilon_{505}$ values were almost equal for different solvents. The ion-pair formation affects strongly the $\Delta\varepsilon_{614}$ values, but not the $\Delta\varepsilon_{505}$ values. Thus the ion-pairing affects in a large extent the CoO_6 chromophore and less the CoN_4O_2 chromophores. This means that the hydrogen bonding between oxygen atoms of the counter ion and the OH bridge groups of the complex is more important than that between the counter ion and the ammonia ligands.

It may be worthwhile to consider the chirality of the oxygen atoms of the bridging OH groups, because they bonded directly to the cobalt(III) atoms and it is expected to produce rather strong vicinal effect on the CD bands of the CoO_6 and CoN_4O_2 chromophores. Since each oxygen atom of the six OH bridge groups has probably a pseudo-tetrahedral configuration of the three different attached groups and a lone pair of electrons, it must be asymmetric. For the complexes of Λ-configuration, axial disposition of the OH bond (parallel to

TABLE 2. RATES OF MUTAROTATION FOR THE EARLY STAGE AND THE INITIAL $\Delta\varepsilon$ VALUES AT 614 nm (16280 cm^{-1}) AND 505 nm (19780 cm^{-1}) ($\Delta\varepsilon$ values are given in mol^{-1} dm^3 cm^{-1} unit).

the C_3 axis) constraint (*S*) chirality for the asymmetric oxygen atom. Recently, Dixon *et al.*[17] made an X-ray crystal structure analysis of *rac*-$[Co\{(OH)_2Co(en)_2\}_3](SCN)_4(NO_3)_2\cdot 2H_2O$, and the two allowed (tetrahedral) positions were calculated for the hydrogen atoms of the OH bridge groups and the correct choice was made on the basis of difference maps, which revealed that all five but one of the six oxygen atoms take the axial disposition, only one OH group taking equatorial disposition. A molecular model consideration also shows that the axial orientation of the OH bridge groups may be more stable than the equatorial orientation because of some steric repulsion found in the latter case. It can therefore, be pressumed that the six asymmetric oxygen atoms of the *Δ*-$(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ complex have predominantly (*S*) configurations in the perchlorate crystals.

From absorption measurements during the time-course of CD change, other species expected for the original complex ion were not detected in the experimental time. Therefore the CD intensity decrease for the time-course can be ascribed to the racemization of *Δ*-$(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$. The origin of optical activity decrease of this complex is divided into the racemization of the chirality *Δ* for the CoO_6 chromophore and that of the chirality (*S*) for the asymmetric oxygen atoms. In an acid solution oxonium ions rapidly attack the lone-pair electrons enforcing the inversion of the oxygen chiral center, and the oxygen center may be regarded as being in an equilibrium (*R*)⇌(*S*) (this kind of configurational equilibrium is denoted by *E* in the following); thus the racemization in this case corresponds to the reaction *Δ*(*EEEEEE*)→*Λ*(*EEEEEE*). On the other hand, in the SeO_3^{2-} solution, the oxoanion enforces the OH groups to take the axial positions; then the racemization in this case corresponds predominantly to *Δ*(*SSSEEE*)→*Λ*(*RRREEE*) or *Δ*(*SSSSSS*)→*Λ*(*RRRRRR*), if 1:1 or 1:2 ion-pairing is assumed, respectively. Since the Na_2SeO_3 solution is alkaline (pH=10.4), the *k* value is much greater for the SeO_3^{2-} solution than for the HCl solution. Nevertheless the *k* value in SeO_3^{2-} solution is much less than that in NaOH solution of pH 10.4. Evidently the ion-pairing depressed the racemization. The *k* value in 0.17M-Na_2tart solution (pH=8.1) is about 10^{-1} min^{-1} and that in a NaOH solution of pH 8.1 about 2—3 min^{-1}. It has been well established that the $tart^{2-}$ ion is also capable of forming ion-pairs with several cobalt(III) complexes.[18-20] Therefore, the difference in the *k* values at equal pH is due to the ion-pairing between the OH bridge groups and the doubly charged tartrate anion in the 0.17M-Na_2tart solution. It may be expected that the *k* value is smaller in 0.17M-Na_2tart (pH 8.1) than in 0.17M-Na_2SeO_3 (pH 10.4) in terms of the pH values. However the *k* value in 0.17M-Na_2tart (about 5×10^{-4} s^{-1}) is larger than that in 0.17M-Na_2SeO_3 (about 3×10^{-4} s^{-1}) (Table 2). This is because the ion-pairing effect of Na_2SeO_3 is larger than that of Na_2tart, as can be seen from the comparison of the $\Delta\varepsilon_{614}$ values.

Some plots of $\ln|\Delta\varepsilon|$ *vs.* time (min) for the mutarotation of $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ were given in Figs. 3—5. The plots for the early stage gave a straight

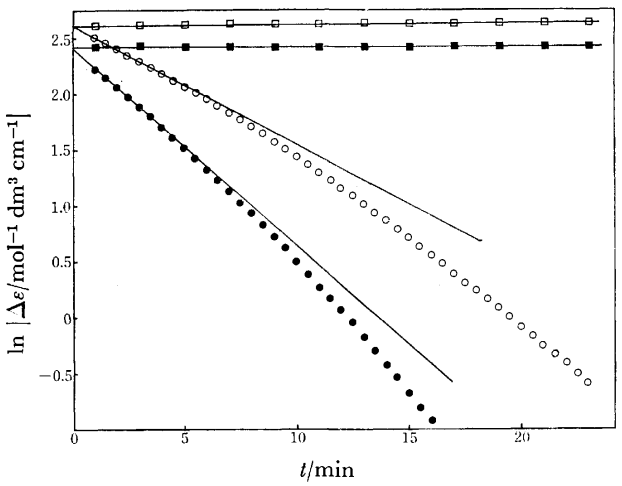

Fig. 3. Plots of $\ln|\Delta\varepsilon|$ *vs.* time for $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ in 0.01 M-HCl ($\Delta\varepsilon_{614}$; □, $\Delta\varepsilon_{505}$; ■) and in water ($\Delta\varepsilon_{614}$; ○, $\Delta\varepsilon_{505}$; ●).

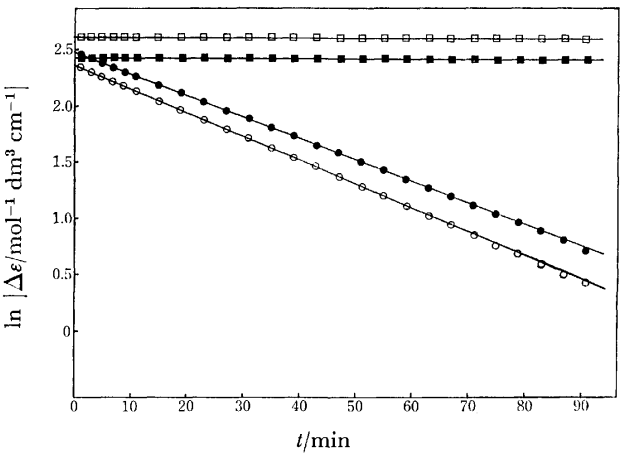

Fig. 4. Plots of $\ln|\Delta\varepsilon|$ *vs.* time for $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ in 0.01 M-HCl ($\Delta\varepsilon_{614}$; □, $\Delta\varepsilon_{505}$; ■) and in 0.17 M-Na_2SeO_3 ($\Delta\varepsilon_{614}$; ○, $\Delta\varepsilon_{505}$; ●).

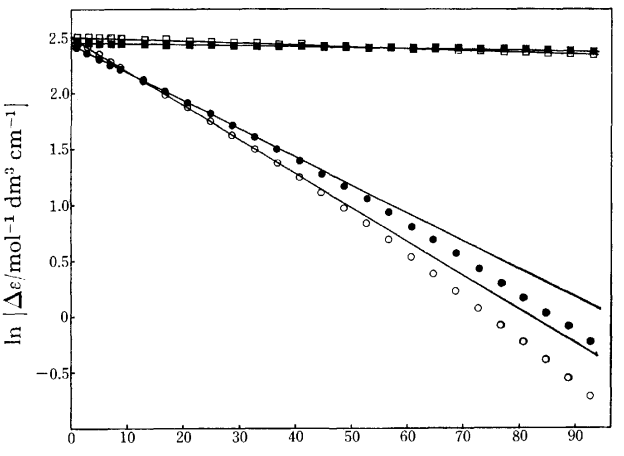

Fig. 5. Plots of $\ln|\Delta\varepsilon|$ *vs.* time for $(+)_{589}$-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ in 0.17 M-H_2tart ($\Delta\varepsilon_{614}$; □, $\Delta\varepsilon_{505}$; ■) and in 0.17 M-Na_2tart ($\Delta\varepsilon_{614}$; ○, $\Delta\varepsilon_{505}$; ●).

line; the lines in Figures were calculated by the least square method on the basis of the plots of initial stage. With elapse of time, a steep departure from the line was observed in H_2O (Fig. 3). In 0.17M-Na_2tart and 0.17M-Na_2SeO_3, with elapse of time, a slight departure from the line was observed (Figs. 4 and 5). While in 0.01M-HCl and 0.17M-H_2tart, only a slight departure from the line was observed (Figs. 4 and 5); the mutarotations in the latter two cases represent a true racemization $\Delta(EEEEEE) \rightarrow \Lambda(EEEEEE)$, $\Delta(SSSEEE) \rightarrow \Lambda(RRREEE)$, or $\Delta(SSSSSS) \rightarrow \Lambda(RRRRRR)$. It can be considered that the departure from a line, especially in the case in water, is due to a complicated configurational change due to the coexistence of different kinds of chiralities.

Sarneski and Ulbach[14] pointed out that the major source of CD change in the d-d transition region of Λ-$[Co(en)_3]^{3+}$–PO_4^{3-} ion-pair system may be the vicinal effect of chiral nitrogen centers stereospecifically produced at the primary amine donors by the ion-pair formation of Mason type. Similarly in the present polynuclear complex, the difference CD curve between in 0.01M-HCl and 0.17M-Na_2SeO_3 (Fig. 2) is regarded to have the origin in the vicinal effect of chiral oxygen centers stereospecifically produced by the ion-pair formation, because this curve corresponds to the difference $\Delta(SSSEEE) - \Delta(EEEEEE)$ or $\Delta(SSSSSS) - \Delta(EEEEEE)$. Thus the vicinal effect of the (*S*) oxygen atoms has a positive sign in the E_a component of the CoO_6 chromophore and this is in accord with the fact that the vicinal effect of (*R*) nitrogen center in the Λ-$[Co(en)_3]^{3+}$–PO_4^{3-} ion-pair system has a negative sign in the E_a component of the CoN_6 chromophore.

The authers are grateful to Dr. Takashi Komorita of Osaka University for his help in calculation of CD curve analysis.

Phase-transfer Reactions Catalyzed by Phosphoric Triamides Containing Hydrophobic Groups

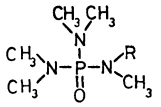
Masao TOMOI,* Takashi HASEGAWA, Manabu IKEDA, and Hiroshi KAKIUCHI

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Yokohama 232

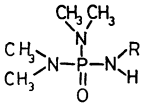
(Received July 4, 1978)

Aqueous organic two-phase reactions (halogen exchange, cyanation, and borohydride reduction) have been catalyzed by phosphoric triamides containing hydrophobic groups. The phosphoric triamides, which have a high cation binding ability, exibited high catalytic activity for the two-phase reactions. The catalytic activity of *N*-alkylteramethylphosphoric triamides (**1**) was higher than that of the corresponding pentamethyl derivatives and the difference has been explained in terms of the contribution of the dimeric species of **1** and/or hydrogen bonding between the NH of **1** and the anionic moieties of inorganic reagents.

Aqueous organic two-phase reactions are catalyzed by quaternary ammonium or phosphonium salts,[1] crown ethers,[2] cryptands,[3] and α-phosphoryl sulfoxides[4] and have found use in organic syntheses.[5] Recently, it was found that *N*-alkylpentamethylphosphoric triamides (**1**)[6] and *N*-alkyltetramethylphosphoric triamides (**2**) catalyzed two-phase reactions, the activity being dependent on the structure of the compounds.



1



2

In this report, the relationship between the structure and the catalytic activity will be discussed.

Experimental

Reagents. *N*-Alkylpentamethylphosphoric triamides (**1**) have been prepared by the reaction of the sodium salt of pentamethylphosphoric triamide[7] and the corresponding alkyl halides in toluene at 0 °C. *N*-Alkyltetramethylphosphoric triamides (**2**) have been synthesized by the reaction of bis(dimethylamino)chlorophosphine oxide[8] with the corresponding primary amine, in the presence of triethylamine, in refluxing benzene. **1** and **2** were purified by distillation under reduced pressure or recrystallization, and the structure confirmed by NMR, IR, and MS. The yields and physical properties are summarized in Table 1.

TABLE 1. YIELDS AND PHYSICAL PROPERTIES OF PHOSPHORIC TRIAMIDES

a) Commercial product. b) Hygroscopic. c) Uncorrected.

N-Benzylformamide,[9] tridecyl methyl sulfoxife,[10] 18-crown-6,[11] and benzo-18-crown-6[12] were prepared by the methods described in the literature. *N*-Dodecyl-2-pyrrolidone (Mitsubishi Petrochemical) was distilled under reduced pressure prior to use. Other organic reagents were obtained from commercial sources and distilled under reduced pressure prior to use. Inorganic reagents and quaternary ammonium salts were obtained commercially, and used without further purification.

Reaction Procedure. The two-phase reactions were conducted under standard phase-transfer conditions[2,3] and the yields determined by gas chromatography.

Measurements. The cation binding ability of the phosphoric triamides was evaluated by the procedure described by Smid *et al.*[13] and the degree of association measured cryoscopically in benzene.

Results

Halogen Exchange Reaction. Table 2 shows the results of the reaction of octyl bromide with potassium

iodide under phase-transfer conditions. Both hexamethylphosphoric triamide (**1a**) and pentamethylphosphoric triamide (**2a**) were not effective catalysts for the halogen exchange. *N*-Alkylpentamethylphosphoric triamides (**1b**—**1g**) and *N*-alkyltetramethylphosphoric triamides (**2b**, **2c**) containing higher aliphatic or arylalkyl groups were however found to catalyze the reaction. In particular, the tetramethylphosphoric triamide derivatives showed high catalytic activity.

Formamide, sulfoxide, and 2-pyrrolidone derivatives having hydrophobic groups in the molecules exibited low catalytic activity. Benzo-18-crown-6 was effective as a catalyst, while 18-crown-6 was not. Benzyltrimethylammonium chloride was also not effective. Hexadecyltrimethylammonium bromide (CTAB) showed the highest catalytic activity of all the catalysts used.

Table 3. Reaction of $C_8H_{17}Br$[a] with NaCN[b] under phase-transfer conditions[c]

Catalyst[d]	Time h	Yield[e] %
None	24	11

$C_{16}H_{33}N(CH_3)_3{}^+Br^-$	6	98[g]

a) No solvent was used for the substrate. b) 33 wt % aqueous solution, 1.5 mol equiv. c) Reaction temp, 80 °C; internal standard, naphthalene. d) 0.05 mol equiv. e) GLPC analysis. f) *N*-Dodecyl-2-pyrrolidone. g) Emulsified reaction.

Cyanation. Table 3 shows the results of the reaction of octyl bromide with sodium cyanide. The cyanation, as well as the halogen exchange reaction, was catalyzed by **1b**—**1e** and **2b**—**2c**, the catalytic activity of the latter being higher than that of the former. Benzo-18-crown-6 and CTAB showed high catalytic activity, but CTAB emulsified the system with increasing conversion of the reaction.

Reduction of Ketone. The results of the reduction of acetophenone and 2-octanone with sodium borohydride are shown in Table 4. The reduction proceeded very slowly in the absence of phosphoric triamide catalysts. This reaction, and the two reactions described above, were catalyzed by the phosphoric triamides, especially **2b** and **2c**.

Interaction between Phosphoric Triamides and Picrate Salts. The cation binding ability of the phosphoric triamides was investigated by the extraction method described by Smid *et al.*[13] and the results of the extraction of potassium picrate by the phosphoric triamides are shown in Table 5. The cation binding ability of **1a** and **2a** was very low. Tetramethylphosphoric triamides containing the benzyl (**2b**) or 1-naphthylmethyl (**2c**) group exibited high cation binding ability, compared with the other phosphoric triamides. Pentamethylphosphoric triamides possessing benzyl (**1b**), cinnamyl (**1c**), or 1-naphthylmethyl (**1e**) groups also proved efficient in the extraction of potassium picrate. The pentamethylphosphoric triamides having a dodecyl (**1f**) or hexadecyl (**1g**) group showed very low cation binding ability.

The cation binding ability of the phosphoric triamides was largely independent of the species of alkali cations,[6] in contrast with the observations on crown ethers.[13]

Association of Phosphoric Triamides. Table 6 shows the degree of association of the phosphoric triamides in benzene which for **2b** and **2c** was 1.2, and for **1b** and **1e** was 1.0. **1b** and **2b** were found to be present as monomeric forms in dioxane.

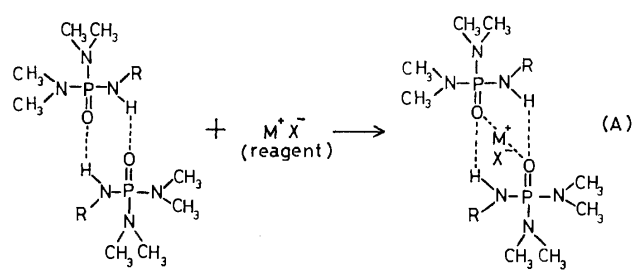
Discussion

It has been shown that the phosphoric triamides containing hydrophobic groups are effective as phase-transfer catalysts. The catalytic activity of some of the phosphoric triamides was comparable to that of benzo-18-crown-6, and somewhat lower than that of CTAB. The activity was considerably higher than that of formamide, sulfoxide, and pyrrolidone derivatives containing hydrophobic groups. The donor numbers of the corresponding compounds containing methyl, in place of the higher groups are as follows:[14] hexamethylphosphoric triamide, 38.8; *N,N*-dimethylformamide, 26.6; dimethyl sulfoxide, 29.8; *N*-methyl-2-pyrrolidone, 27.3. On the basis of this data, it is suggested that the phosphoric triamides containing hydrophobic groups interact strongly with the cationic moieties of inorganic reagents through pole-dipole interactions.

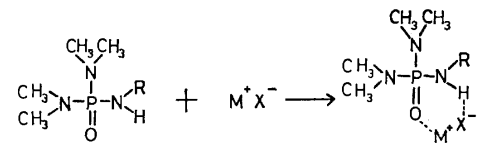
The mechanism of two-phase reactions catalyzed by ammonium or phosphonium salts was first proposed by Starks,[1] and supported by Herriot and Picker.[15] In the system, the onium salts are thought to extract the anionic reagent into the organic phase. In the reactions catalyzed phosphoric triamides, the compounds which were efficient extractors of potassium picrate from the aqueous to the organic phase (CH_2Cl_2), exibited high catalytic activity for the two-phase reactions (see Tables 2, 3, 4, and 5). These observations may be explained in terms of the mechanism proposed by Starks,[1] *i.e.*, the phosphoric triamides, and the onium salts, transfer the inorganic reagent from the aqueous phase to the organic phase, and thereby catalyze the two-phase reaction.

The catalytic activity of the phosphoric triamides was found to be dependent on the structure of the hydrophobic groups. In this study, the activity of the phosphoric triamides having arylalkyl groups such as benzyl or 1-naphthylmethyl groups was higher than those having alkyl groups such as dodecyl or hexadecyl.



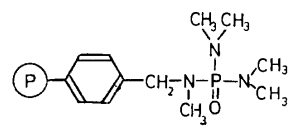
(A)

The catalytic activity of **2** is higher than that of **1**, although the electron-donating power of the dialkylamino group is stronger than that of the monoalkylamino group.[16] This result may be explained as follows; **2** slightly associates in benzene (Table 6) and the hydrogen of NH in **2** is weakly acidic (**2** reacts easily with NaH) suggesting the participation of a dimeric species. This is formed through hydrogen bonding, in the two-phase reaction (Scheme **A**).

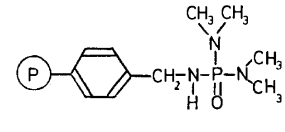


(B)

Moreover, it appears reasonable to assume that the anionic moiety (X^-) of the inorganic reagent (M^+X^-) may interact with the acidic hydrogen of **2** through hydrogen bonding (Scheme **B**). The enhanced interaction of **2** with M^+X^-, as described in schemes **A** and **B**, will result in an increase in the solubility of M^+X^- in the organic phase, and thereby an increase in the catalytic activity of **2**. In the case of **1** which does not contain an acidic hydrogen, the interaction of **1** with X^- is not expected.



3



4

Solid-phase catalysts (**3** and **4**), prepared by the reaction of chloromethylated polystyrene resin cross-linked with divinylbenzene and the sodium salts of pentamethylphosphoric triamide or tetramethylphosphoric triamide, were found to be effective for two-phase reactions.[17] In the tri-phase[18] and the two-phase system, the activity of the tetramethyl derivative **4** was higher than that of the pentamethyl derivative **3**. Such a difference between **3** and **4** may be interpreted by assuming a strong interaction of **4** with M^+X^- through hydrogen bonding as shown in scheme **B**, since the cooperative interaction of the phosphoric triamide groups, with M^+X^- as shown in scheme **A**, may be assumed to occur with difficulty in the immobilized system.[19]

α,β-Unsaturated Carboxylic Acid Derivatives. XVII. The Facile Synthesis of Ethyl α-Azido-α-alkenoates and Reduction to Ethyl α-Amino-α-alkenoates[1]

Chung-gi SHIN,* Yasuchika YONEZAWA, Kazuo UNOKI, and Juji YOSHIMURA**

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

***Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received July 25, 1978)

Several pathways leading to ethyl α-azido-α-alkenoates (**8**) by the β-elimination to ethyl α-azido-β-substituted (hydroxy-, acetoxy-, or mesyloxy)-alkanoates with NaN_3 or Et_3N have been examined. The optimized procedure, in combination with subsequent reduction provides a general synthetic route to α-amino-α-alkenoic acid esters (**9**). The configuration of **8** and **9** have been shown to be of (*Z*)-geometry.

α,β-Unsaturated α-amino acid (α-dehydroamino acid; DHA) or the α-imino form has been postulated as the intermediate in the biological epimerization of the L-α-amino acid into the enantiomer by the process of dehydrogenation-hydrogenation.[2] In addition, DHA is of great importance as a starting material for the incorporation and synthesis of dehydropeptides and peptide antibiotics.[2-5]

In previous papers,[6,7] the facile synthesis of ethyl 2-amino-2-alkenoates (**9**) by reduction of the corresponding 2-azido compounds (**8**) with aluminium-amalgam (Al–Hg) have been reported. Schmidt *et al.* reported the preparation of methyl 2-amino-2-alkenoates by the elimination of methanol from the corresponding α-methoxy α-amino acids[8] or the dehydrochlorination of α-chloro amino acid derivatives.[9]

The synthesis of **8** and the subsequent selective reduction of **8** into **9** will be reported in detail. The

Results and Discussion

The starting material, ethyl 2-bromo-3-hydroxyalkanoate (**2**) were readily prepared by treating ethyl (*E*)-2-alkenoates (**1**) with *N*-bromosuccinimide (NBS) or *N*-bromoacetamide (NBA) and water.[6]

The direct reaction of **2** with 3M NaN_3 in hexamethylphosphoric triamide (HMPA) gave **8** in low yield (Procedure A).

To effect β-elimination after azidation, **2** was converted into ethyl 3-acetoxy-2-bromo (**3**)- and 2-bromo-3-mesyloxyalkanoates (**4**) by conventional means, and subjected to a similar substitution-elimination. The

reaction of **4** in *N,N*-dimethylformamide (DMF) gave **8** in *ca.* 65% yield together with the direct β-elimination product, the ethyl 2-bromo-2-alkenoates (Procedure B-2). **3** was completed in HMPA in *ca.* 80% yield (Procedure B-1).

In subsequent experiment, **2** was firstly converted into ethyl 2-azido-3-hydroxyalkanoate (**5**), and subsequently into ethyl 3-acetoxy-2-azido (**6**)- and 2-azido-3-mesyloxyalkanoates (**7**) in good yields. The similar elimination reaction of **6** in HMPA in the presence of NaN_3 (Procedure C-1) and **7** in CH_2Cl_2 in the presence of Et_3N (Procedure C-2) proceeded more smoothly to give **8** in *ca.* 85 and 90% yields respectively. The reaction of **5** with mesyl chloride in CH_2Cl_2 in the presence of Et_3N was completed immediately to give **8** quantitatively (Procedure D).

Procedure D is the most satisfactory method for the preparation of **8** from **2** and is generally applicable for the conversion of α-hydroxy azides into the corresponding azido olefin, the results of which will be published elsewhere.

The reduction of **8** with Al–Hg in ether readily gave the expected **9** in *ca.* 80% yield.[7] In order to determine the geometric configuration of **9**, chloroacetylation was performed to give ethyl 2-(chloroacetylamino)-2-alkenoates (**10**). All physical constants and spectral data of **10** were in good agreement with the authentic samples of the (*Z*)-configuration.[10] Therefore, the structures of **8**, **9**, and **10** have been unambiguously assigned the (*Z*)-configuration.

The configuration of the addition products (**2**—**4**), have been the erythro-isomer from the observed $J_{2,3}$ values of over 7.0 Hz. Similarly, from the $J_{2,3}$ values (*ca.* 3.5 Hz), the configuration of **5**, **6**, and **7** has been assigned to the threo-isomer.

Consequently it is considered that the stereospecific *trans* addition to (***E***)-**1**[11] gave the erythro-isomer, which was converted into the threo-isomer by substitution and *trans* β-elimination of the two isomers above proceeded to give (***Z***)-**8**.

Experimental

All boiling and melting points are uncorrected. The IR and NMR spectra were recorded with Hitachi EPI-G3 and JNM-PS-100 Spectrometers with tetramethylsilane as the internal standard respectively.

Preparation of **2**. To a solution of **1** (0.5 mol) in H_2O (300 ml) and tetrahydrofuran (300 ml) was added portionwise NBS or NBA (0.6 mol) below 10 °C. After reaction at the same temperature for 12 h, the resulting solution was allowed to stand for 24 h at room temperature. The solution was extracted four times with ether (200 ml) and the ethereal extracts washed twice with water and dried over anhydrous $MgSO_4$. Evaporation of the ether gave a syrup, which was distilled under reduced pressure to give **2**.

Preparation of **5**. A mixture of **2** (0.1 mol) and NaN_3 (0.25 mol) in DMF (150 ml) was heated with stirring at 60—70 °C for 20 h. The reaction solution was poured into ice-

water (400 ml) and the aqueous solution extracted three times with benzene (100 ml). The combined benzene extracts were washed twice with water and dried over anhydrous $MgSO_4$. Evaporation of the solvent gave **5**.

Preparation of 3 and 6. Two drops of concentrated H_2SO_4 were added to a solution of **2** (0.1 mol) in acetic anhydride (0.15 mol). After stirring at 50—60 °C for 30 min, the reaction mixture was diluted with benzene (60 ml). The benzene solution was washed once with aqueous $NaHCO_3$ and twice with water and dried over anhydrous Na_2SO_4. Concentration of the benzene solution gave a syrupy residue, which was distilled under reduced pressure to give **3**. A similar reaction of **5** gave **6**.

Preparation of 4 and 7. To a solution of **2** (0.05 mol) and mesyl chloride (0.05 mol) in CH_2Cl_2 (50 ml) was added Et_3N (0.05 mol) under nitrogen at 0—3 °C. The chilled solution was allowed to stand at room temperature and the reaction solution continuously stirred at room temperature for 30 min. The reaction solution was washed three times with water and the solution dried over anhydrous Na_2SO_4 and evaporated. The syrup obtained was distilled under reduced pressure to give **4**. A similar reaction of **5** gave **7**.

Preparation of 8. Procedure A. A solution of **2** (0.05 mol) and NaN_3 (0.15 mol) in HMPA (70 ml) was stirred at 30—35 °C for 24 h. The reaction solution was poured into ice-water (300 ml) and the aqueous solution extracted three times with benzene (60 ml). The benzene extracts were washed twice with water, dried over anhydrous $MgSO_4$, and evaporated under reduced pressure. The syrupy residue obtained was purified on a silica gel column using a mixture of hexane and benzene (2: 1 v/v) as eluentent to give **8**.

Procedure B. B-1: A solution of **3** (0.05 mol) and NaN_3 (0.15 mol) in HMPA (70 ml) was stirred at room temperature for 20 h. The reaction solution was poured into ice-water (300 ml) and the aqueous solution similarly worked up to give **8**. *B-2*: Similarly, **4** (0.05 mol) was treated with NaN_3 in DMF (70 ml) at 40—45 °C for 48 h to give **8**.

Procedure C. C-1: Similarly, **6** (0.05 mol) and NaN_3 (0.1 mol) in HMPA (70 ml) was worked up for 12 h to give **8**. *C-2*: To a solution of **7** (0.05 mol) in CH_2Cl_2 (50 ml) was added dropwise Et_3N (0.08 mol) with stirring under nitrogen below 5 °C. After stirring at room temperature for 30 min, the reaction solution was washed once with 3 M HCl and three times with water and dried over anhydrous $MgSO_4$. A similar work-up of the residual syrup gave pure **8**.

Procedure D. To a solution of **5** (0.05 mol) and mesyl chloride (0.06 mol) in CH_2Cl_2 (50 ml) was added dropwise Et_3N (0.15 mol) with stirring under nitrogen below 3 °C. After stirring at room temperature for 40 min, the precipitated salt was filtered off and the filtrate washed once with 3 M HCl and three times with water and dried over anhydrous $MgSO_4$. Finally, a similar purification gave **8**.

Preparation of 9. A solution of **8** (0.05 mol) in ether (30 ml) was added dropwise to a suspension of Al-Hg (made from 4 g of Al) in ether (50 ml) with vigorous stirring at room temperature. After a few minutes, the ether began to reflux, and the refluxing was maintained by the addition of a few drops of water at 20 min intervals. After the addition of the solution was completed, stirring was continued for 3 h. The mixture was extracted several times with an ether-ethyl acetate mixture (1: 3 v/v). The combined extracts were evaporated and distilled under reduced pressure to give **9**.

Preparation of 10. To a solution of **9** (0.02 mol) and Et_3N (0.025 mol) in dry ether (20 ml) was added chloroacetyl chloride (0.025 mol) dropwise with stirring at room temperature. After stirring for 4 h, the salt separating out was filtered. The filtrate was washed once with 3 M HCl, once with aqueous $NaHCO_3$, and twice with water and dried over anhydrous Na_2SO_4. The ether solution was evaporated to give a viscous syrup, which was purified on a silica-gel column using a benzene-acetone mixture (8: 1 v/v) as the eluentent. The fraction obtained was concentrated under reduced pressure to give **10**.

Disproportionation of Propylene over MoO_3-SiO_2 Catalyst with Various Treatments

Toshiaki SODESAWA,*,** Eisuke OGATA, and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 25, 1978)

Disproportionation of propylene over MoO_3-SiO_2 (atomic ratio: Mo/Si=1/25) catalyst treated with HCl and aqueous ammonia was studied in the temperature range 350—600 °C under atmospheric pressure. The activity of MoO_3-SiO_2 catalyst extracted with aqueous ammonia remained for a long time, since most of free MoO_3 was removed from the MoO_3-SiO_2 surface. This gave rise to increase in the selectivity for disproportionation of propylene to ethylene and butenes and decrease in the selectivity for hydrogenation, isomerization and polymerization. When MoO_3-SiO_2 not subjected to treatment was pretreated by H_2 gas, it showed higher catalytic activity and lower selectivity for disproportionation than the one treated by N_2 gas.

In previous papers[1-4] we reported that MoO_3-Al_2O_3 shows high catalytic activity for the olefin disproportionation in the temperature range 100—200 °C and that Re_2O_7-Al_2O_3 has high catalytic activity even at ambient temperature. Ogasawara *et al.* reported that the pretreatment by H_2 gas makes active MoO_3-SiO_2 catalyst which has much free MoO_3 on its surface.[5] It is assumed that the free MoO_3 accompanies side reactions such as polymerization and hydrogenation which cause the catalytic degradation.[6] We have carried out disproportionation of propylene using MoO_3-SiO_2 catalyst treated with HCl and aqueous ammonia at relatively high temperatures.

The oxidation states of transition metal affect the catalytic activity of the disproportionation of olefins. It is known that MoO_3-Al_2O_3 catalyst is highly active even in hexa-valent state, and the lower the oxidation state of Mo, the greater the decrease in catalytic activity. It has been reported that the oxidation value of Mo over MoO_3-SiO_2 catalyst is lower than that over MoO_3-Al_2O_3.[7] We wish to consider the difference in oxidation state of Mo between the case of pretreatment of MoO_3-SiO_2 by H_2 and that by N_2.

Experimental

The MoO_3-SiO_2 catalyst was prepared by impregnating a $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ solution with silica which was evaporated to dryness "Snowtex" (Nissan Kagaku Co., Ltd.), and then by calcining in a flow of air at 550 °C for 5 h. The atomic ratio of Mo to Si was 1: 25, the same as that of Mo to Al, and Re to Al previously reported (A and B catalyst without treatment).[1-4]

The MoO_3-SiO_2 catalysts (C′, C″, C‴) were extracted with aqueous ammonia of various concentrations for 24 h. They were first filtered and washed with water, and then evaporated to dryness prior to calcination in a flow of air at 550 °C for 5 h. The catalysts (D′, D″) treated with HCl solution were evaporated to dryness in a flow of N_2 gas at 100 °C and then calcined at 550 °C for 1 h in a stream of air.

After pretreatment of the A catalyst with N_2 gas and the other catalysts with H_2 gas for 2 h, the reaction was carried out by the conventional fixed bed flow system with a U type reactor in the temperature range 350—600 °C. The reaction products were periodically analyzed by a gas chromatogram connected to the reaction system.

Results and Discussion

Effects of Various Treatments of MoO_3-SiO_2 on the Catalytic Activity. The profiles of the activity change of propylene disproportionation over MoO_3-SiO_2 catalyst with various treatments are shown in Fig. 1. In the initial reaction time, the catalytic activity for the disproportionation was in the order MoO_3-SiO_2 treated with HCl>MoO_3-SiO_2 without treatment>MoO_3-SiO_2 extracted with aqueous ammonia. The activity of catalysts extracted with aqueous ammonia differs greatly from that of catalysts not subjected to such treatment but treated with HCl solution. In the former case, the catalytic activity shows a maximum value at 25 min of the reaction time and then decreases gradually. Even after 20 h, its activity remains high. In the latter case

** Present address: Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260.

the catalytic activity decreases rapidly with the reaction time. The catalytic activity for hydrogenation over MoO_3–SiO_2 extracted with aqueous ammonia was suppressed and the disproportionation to ethylene and butenes was promoted.

Effects of Reaction Temperature. In the temperature range 350—6000 °C, the activity for the disproportionation and hydrogenation of propylene changes within 60 min (Figs. 2—4). At all temperatures examined, the activity of the catalyst extracted with aqueous ammonia for the disproportionation shows a maximum value at 25 min. The new active sites seem to be formed by the reduction of the catalyst with H_2 or aqueous ammonia. At 600 °C, the catalytic activity remains unchanged during the course of reaction. At temperatures below 400 °C, the activity for the disproportionation becomes much lower. This indicates that the suitable reaction temperatures for the disproportionation are above 450 °C.

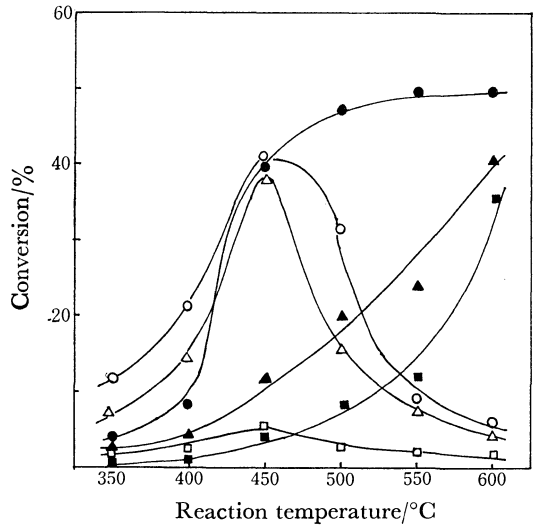

Fig. 2. Effect of temperature on the catalytic activity of MoO_3–SiO_2 without treatment in the gas phase disproportionation at GHSV=60 (h^{-1}).

Disproportionation; ●: 10 min, ▲: 25 min, ■: 60 min.
Hydrogenation; ○: 10 min, △: 25 min, □: 60 min.

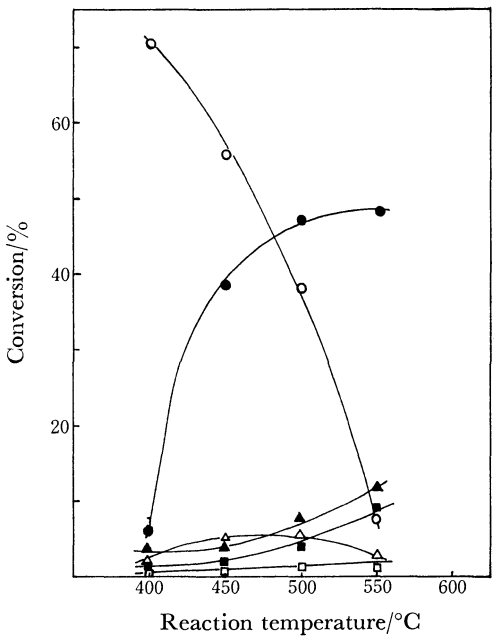

Fig. 4. Effect of temperature on the catalytic activity of MoO_3–SiO_2 treated with 5 % HCl solution in the gas phase disproportionation at GHSV=60 (h^{-1}).
Disproportionation; ●: 10 min, ▲: 25 min, ■: 60 min.
Hydrogenation; ○: 10 min, △: 25 min, □: 60 min.

The mode of activity change for hydrogenation reaction vary with catalyst. In the catalyst not subjected to treatment, the activity for the hydrogenation becomes maximum at 450 °C.

Effects of Concentration of Aqueous Ammonia. The initial activity of the catalyst extracted with various concentrations of aqueous ammonia is shown in Fig. 5.

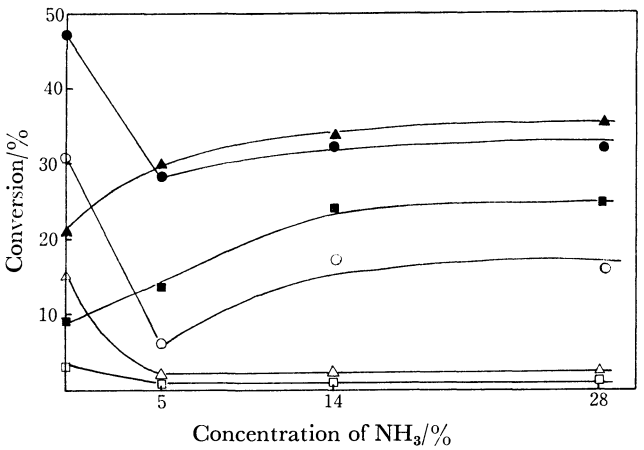

Fig. 5. Effect of concentration of aqueous ammonia on the catalytic activity of MoO_3–SiO_2 in the disproportionation of propylene at 500 °C and GHSV=60 (h^{-1}).
Disproportionation; ●: 10 min, ▲: 25 min, ■: 60 min.
Hydrogenation; ○: 10 min, △: 25 min, □: 60 min.

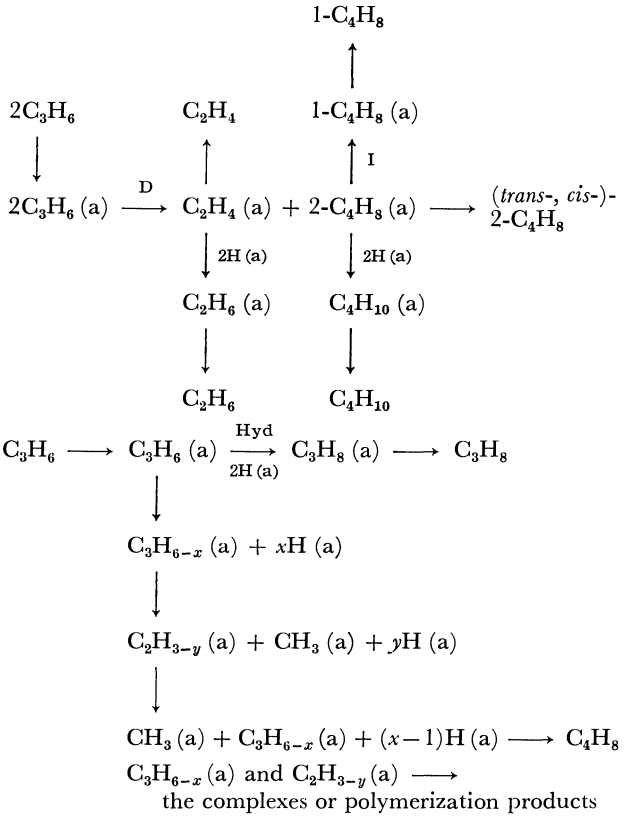
In each case, the catalytic activity after 10 min was lower than that not subjected to treatment. This seems to be due to the decrease of Mo metal by the extraction with aqueous ammonia. After 25 min the activity of the catalyst extracted with aqueous ammonia had higher value than that of the other catalysts. It seems that the hydrogenation over MoO_3–SiO_2 extracted with aqueous ammonia is suppressed, and the active sites for the disproportionation increase.

The hydrogenation decreased gradually with increase in reaction time. Yermakov *et al.* suggested that the oxidation state of Mo for the disproportionation or polymerization is +4, and that for hydrogenation is +2.[8] It seems that many active sites are formed for the disproportionation, the oxidation state of Mo being +4, but few for hydrogenation, the oxidation state of Mo being +2.

After removal of the free MoO_3 over MoO_3–SiO_2 catalyst by leaching with aqueous ammonia, the activity for the disproportionation remained unchanged as shown in Fig. 5. It is assumed that the increase in the acidity of the catalyst is due not to SiO_2 or MoO_3, but to the new acidic sites formed by the interaction of the two. The free MoO_3 can be extracted with aqueous ammonia. In the case of MoO_3–Al_2O_3 catalyst, 80% of free MoO_3 is removed from the catalyst surface, whereas in the MoO_3–SiO_2, 30% of free MoO_3 is taken off from the surface of MoO_3–SiO_2.[5] Vaghi *et al.* reported that the removal of polymolybdate by leaching with aqueous ammonia restores the activity in the tetrahedral Mo(VI) region, and the decomposition of the molybdosilicate anion occurs at pH 10.[9,10] From our results, it seems that leaching of MoO_3–SiO_2 with aqueous ammonia prefers the removal of free MoO_3 to the decomposition of Mo–O–Si bonds.

Product Distribution. An example of products distribution is given in Table 1. The catalysts extracted with aqueous ammonia (C′, C″, C‴) exhibit higher selectivity to ethylene and butenes as compared with the catalysts, the one without treatment and the other with treatment by HCl (D′, D″). On the other hand, the selectivity for hydrogenation of propylene to propane over MoO_3–SiO_2 extracted with aqueous ammonia is lower than that of the other catalysts. The isomerization of 2-butene to 1-butene produced *via* the disproportionation over the catalysts treated with aqueous ammonia decreases. This shows that the disproportionation over the catalysts subjected to aqueous ammonia extraction is promoted more selectively by suppression of self-hydrogenation or polymerization.[11,12]

The difference in products distribution between the catalyst pretreated by H_2 (A) and that by N_2 (B) shows that the oxidation state of Mo for each case is different. It may be assumed that the oxidation state of Mo in the case of H_2 becomes +4 according to Yermakov *et al.*[8]



D: Disproportionation, I: isomerization, Hyd: hydrogenation, (a): adsorbed species.

Reaction Scheme.

Table 1. Products distribution in the gas phase disproportionation of propylene over MoO_3–SiO_2 catalyst at 500 °C and GHSV=60 (after 25 min of reaction)

Catalyst	A[a]	B[b]	C′[c]	C″[c]	C‴[c]	D′[d]	D″[d]
Conversion for disproportionation (%)	17.3	6.23	29.0	32.8	35.7	7.63	6.51
(C_2+C_2'+C_4+C_4') selectivity (%)	60.5	80.7	92.2	92.4	90.0	58.5	62.2
(C_4+C_4')/(C_2+C_2') ratio	0.183	0.231	0.757	0.603	0.641	0.172	0.153
C_4'/C_2' ratio	0.380	0.675	0.807	0.660	0.711	0.391	0.373
$C_2/(C_2+C_2')$ (%)	53.0	68.0	7.62	9.93	11.8	60.5	63.3
$C_4/(C_4+C_4')$ (%)	15.5	6.74	1.59	1.42	2.10	10.2	10.6
$1\text{-}C_4'/C_4'$ (%)	46.8	47.2	31.0	39.9	42.5	39.6	47.2
trans-/*cis*- ratio in $2\text{-}C_4'$	1.33	1.31	1.30	1.34	1.35	1.30	1.31
Conversion for hydrogenation (%)	15.2	1.42	0.90	1.55	2.38	5.29	3.80
C_3 selectivity (%)	40.7	18.5	3.31	4.53	6.26	40.9	36.9

a) Pretreated with H_2. b) Pretreated with N_2. c) Extracted with 5% aqueous ammonia (C′), 14% aqueous ammonia (C″), and 28% aqueous ammonia (C‴). d) Treated with 5% HCl (D′) and 14% HCl solution (D″).

Since the ratio of (C_4+C_4') to (C_2+C_2') is lower than C_4'/C_2' and the ratio of C_2 to (C_2+C_2') is larger than that of C_4 to (C_4+C_4'), hydrogenation of ethylene to ethane proceeds more rapidly than that of butenes to butane during the course of disproportionation. The ratio of *trans-* to *cis-* in 2-butenes approximates to equilibrium value at each reaction temperature.

In the catalyst subjected to aqueous ammonia extraction, the molar ratios C_4'/C_2' and $(C_4+C_4')/(C_2+C_2')$ in the temperature range 400—600 °C decrease with increase in the reaction temperature (Fig. 6). At all temperatures, the values increase with reaction time. In the initial reaction periods, the desorption of C_4 and C_4' from the catalyst surface is more difficult than that of C_2 and C_2', the decomposition of C_4 and C_4' proceeding very rapidly at high temperature.

The molar ratios C_4'/C_2' and $(C_4+C_4')/(C_2+C_2')$ for the catalysts treated with aqueous ammonia are greater than those not subjected to such treatment but treated with HCl. It seems that the active sites for disproportionation are formed. In the reaction below 450 °C, the ratio C_4'/C_2' or $(C_4+C_4')/(C_2+C_2')$ after 25 min of the reaction is approximately 1.0, indicating the most selective disproportionation.

The molar ratios of 1-butene in all butenes are shown in Fig. 7. At temperatures below 550 °C, each ratio in the catalyst extracted with aqueous ammonia is the lowest among the catalysts subjected to various treatments. The ratio in the case of the catalyst treated with HCl is lower than that of the catalyst not subjected to treatment. Decrease in the ratio in aqueous ammonia shows that acid sites are necessary for the isomerization over MoO_3–SiO_2 catalyst. On the other hand,

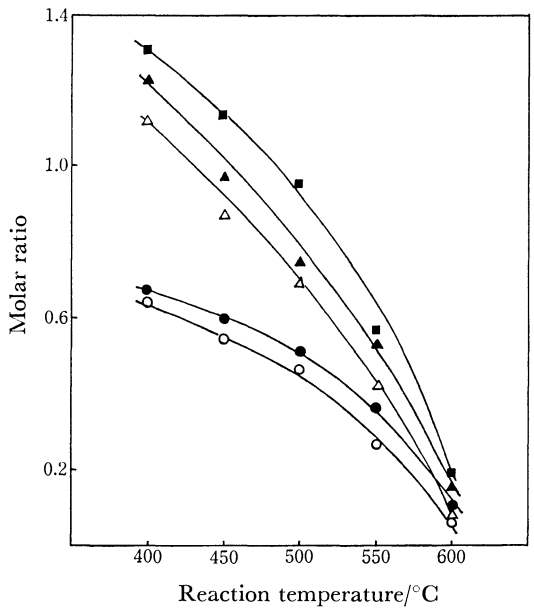


Fig. 6. Effect of temperature on C_4'/C_2' and $(C_4+C_4')/(C_2+C_2')$ molar ratio in the disproportionation of propylene over MoO_3–SiO_2 catalyst extracted with 5 % aqueous ammonia.
Reaction after 10 min; ●: C_4'/C_2', ○: $(C_4+C_4')/(C_2+C_2')$, 25 min; ▲: C_4'/C_2', △: $(C_4+C_4')/(C_2+C_2')$, 300 min; ■: C_4'/C_2'.

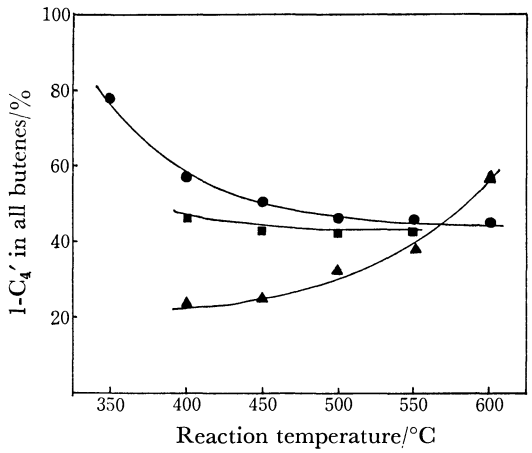

Fig. 7. Effect of temperature on molar ratio of 1-butene in all butenes in the gas phase disproportionation over MoO_3–SiO_2 catalyst at GHSV=60 (h^{-1}) after 25 minutes of reaction time.
●: MoO_3–SiO_2 catalyst. ▲: MoO_3–SiO_2 catalyst extracted with 5 % aqueous ammonia. ■: MoO_3–SiO_2 catalyst treated with 5 % HCl solution.

HCl which neutralizes basic sites is also effective for decreasing the isomerization activity of MoO_3–SiO_2 catalyst. This suggests that both acid and basic sites function effectively in isomerization of 2-butenes to 1-butene over MoO_3–SiO_2 catalyst.

The behavior of MoO_3–SiO_2 catalyst in the shift of the double bond from 2-butenes to 1-butene may be explained as follows.[13] The mechanism of this reaction involves the existence of an electron accepting (oxidative, *i.e.*, acid) center in the vicinity of the π-bond between carbons 2 and 3 and the presence of an electron donating (reducing, *i.e.*, basic) center in the vicinity of the σ-bond between carbons 1 and 2. The shift of the double bond is of a concerted type.

Syntheses of Several Muramyl Peptides in Relation to Chemical Structures of Less Immunoadjuvant Bacterial Cell Walls

Shoichi KUSUMOTO, Kazuhiro IKENAKA, and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received September 21, 1978)

Various structural analogs of *N*-acetylmuramyl-L-alanyl-D-isoglutamine, which had been shown to be the minimum structure required for the immunoadjuvant activity of bacterial cell walls, were synthesized in order to investigate in more detail the relationship between the activity and chemical structures. Particularly, the compounds of the structures corresponding to the cell walls of special bacteria without immunoadjuvant activity were prepared in this study. Several novel procedures including the preparation of a branched glutamyl peptide were newly exploited to accomplish the syntheses of muramyl peptides with complicated structures. As a result of this synthetic study, new informations were obtained on the structural requirement for the immunoadjucant activity.

Since *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MurNAc–L-Ala–D–Glu(OH)–NH_2)[1] (**1**) had been shown to be the minimum structure required for the immunoadjuvant activity of the bacterial cell walls,[2,3] investigations on the relationship between the structure and the adjuvant activity from the view point of synthetic approaches were much urged. In fact, we reconfirmed the more significance of the structure of MurNAc–L-Ala–D-Glu(OH)–NH_2 (**1**) by comparison with various synthetic analogs.[2]

Thereafter, we extended the study in the above line to the investigation on the structural relation of adjuvant inactive cell walls. According to the recent study of Kotani *et al.*,[4] there have been known quite a few bacteria whose cell walls do not show the immunoadjuvant activity, although usual bacteria possess the significant activities. It should be noted that most of inactive bacteria belong to plant pathogenic ones and are not familiar to mammals. Although MurNAc–L-Ala–D-Glu(OH)–NH_2 (**1**) mentioned above is the common structural unit in many bacterial peptidoglycan, a number of variations are often encountered especially in adjuvant inactive bacteria, for instance, replacement of L-Ala with Gly or L-Ser residue, or linkage of α-carboxyl group of D-Glu residue to the other amino acid.[5] In these respects, we synthesized now *N*-acetyl-

Table 1. Synthetic *N*-acetylmuramyl peptides

MurNAc-L-Ala-D-Glu(OH)–D-Ala–NH_2	(**8c**)	*Arthrobacter* sp. (NCIB 9423)
MurNAc-L-Ala-D-Glu(OH)–Gly–NH_2	(**9c**)	*Arthrobacter atrocyaneus*

a) These are prepared in our previous study. See Ref. 2b in the text. b) The names of the corresponding representative bacteria are given, that have the partial structure mentioned in each line. See Ref. 9. c) In the cell walls of these bacteria, the α-carboxyl group of glutamic acid does not exist actually as a simple amide but further links with a basic amino acid participating in a cross linkage.

muramyl peptides corresponding to the partial structures of inactive cell walls in order to investigate whether changes in rather small moieties are reflected in the inactivities of cell walls.

The *N*-acetylmuramyl peptides (**2c**—**9c**) prepared in this study are summarized in Table 1 together with the names of the representative bacteria in which the corresponding structures are involved. For the synthesis of these compounds, the same strategy was employed as described previously for the muramyl dipeptide (**1**).[2] Thus, peptide portions (**2a**—**9a**) were prepared in principle by conventional methods using Boc[1] and Bzl[1] groups for amino and carboxyl protections, respectively. After removal of the *N*-terminal Boc groups, the resulting peptide benzyl esters were coupled with protected muramic acid, *i.e.*, 1-α-*O*-benzyl-4,6-*O*-benzylidene-*N*-acetylmuramic acid (**10**), by means of the active ester method to give protected muramyl peptides (**2b**—**9b**), whose protecting groups were then removed simultaneously by catalytic hydrogenolysis. This procedure is illustrated for the preparation of **2c** in Fig. 1 for an example. In some syntheses, modifications were required as described below.

The first group of muramyl peptides (**2c**, **3c**, and **4c**) were synthesized in order to elucidate the role of the amino acid adjacent to the muramic acid moiety; the L-Ala residue in **1** was replaced with Gly or L-Ser as models of plant pathogenic and adjuvant-inactive cell walls and with D-Ala as non-natural peptidoglycan analog. Thus, the synthesis of MurNAc–L-Ser–D-Glu(OH)–NH_2 (**3c**) and MurNAc–D-Ala–D-Glu(OH)–NH_2 (**4c**) were performed in a similar manner to that illustrated for MurNAc–Gly–D-Glu(OH)–NH_2 (**2c**) (Fig. 1) except that the mixed anhydride method was used for the coupling of **10** with the peptide moieties.

In the another group of the analogs prepared so far, the α-carboxyl group of D-Glu is linked with an amino acid (**5c**, **6c**, and **7c**) or an amino acid amide (**8c** and **9c**) in place of ammonia in **1**. This type of variations has been mostly found also in adjuvant-inactive cell walls. For instance, the muramyl tri- and pentapeptides, *i.e.*, MurNAc–L-Ala–D-Glu(OH)–Gly–OH (**5c**) and MurNAc–L-Ala–D-Glu(L-Lys–D-Ala–OH)–Gly–OH (**6c**) are involved in the cell wall of *Micrococcus lysodeikticus* which shows exceptionally no adjuvant activity though this bacteria is familiar to human beings.

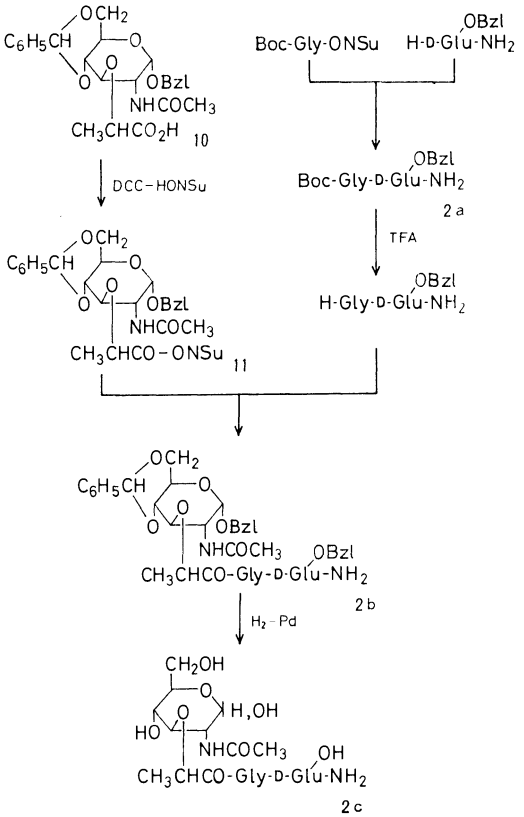

Fig. 1. Synthetic scheme for **2c**.

Though the compound **5c** was obtained according to usual series of reactions, some difficulty was encountered in the synthesis of muramyl pentapeptide (**6c**) particularly for a construction of the branched peptide structure at the D-Glu residue. Therefore, we improved a classical reaction of Boc-D-glutamic anhydride with H–Gly–OBzl to obtain the key intermediate Boc–D-Glu(OH)–Gly–OBzl (**13**) directly by a simple procedure. In this reaction, the isomeric γ-peptide, Boc–D-Glu(Gly–OBzl)–OH (**14**), formed simultaneously must be removed anyhow. LeQuesne and Young[6a] employed fractional extraction for this purpose, but their pro-

a) All these compounds were obtained by precipitation from abs ethanol–abs ether followed by lyophilization. See Ref. 18 in the text. b) In H_2O at 25—28 °C. c) At 19 °C. d) At 15 °C.

cedure was too tedious to be applied in a preparative scale.[6b] We improved the procedure as follows. Boc-D-glutamic anhydride was added to a solution of H–Gly–OBzl in THF and the resulting mixture of α- and γ-peptides (**13** and **14**) was dissolved in ethyl acetate. On addition of 1 equivalent of DCHA[1] to this solution, the desired α-peptide (**13**) was obtained as pure DCHA salt in 60% yield, where the γ-peptide (**14**) remained in the mother liquor. The idea came from the method of a selective precipitation of α-esters of *N*-protected glutamic acid,[7] but no one has yet applied it in direct peptide formation. The structure of the α-peptide obtained was checked after deprotection by amino acid analyzer and TLC in comparison with the authentic free dipeptides, *i.e.*, H–D-Glu(OH)–Gly–OH (**15**) and H–D-Glu(Gly–OH)–OH (**16**), which were obtained *via* unequivocal ways (see experimental). Meanwhile, we recognized a fact that the amount of α-peptide (**13**) decreased slightly in the presence of DCHA as compared to that in its absence at the stage of anhydride ring opening. The ratio of α- and γ-peptides was measured for the reaction mixture of Boc–D-glutamic anhydride and H–Gly–OBzl after deprotection by amino acid analyzer. That in the presence of DCHA was actually 2.0: 1.0 and in its absence 2.6: 1.0. These ratios did not change in a range of the reaction temperature between −70 and 20 °C. Furthermore, the same technique in our method was also applicable to the reaction of Z-D-glutamic anhydride with H–Gly–OBzl as described in the experimental section. In this case, the pure γ-peptide, *i.e.*, Z–D-Glu(Gly–OBzl)–OH, could be also isolated from the mother liquor, besides the crystalline α-peptide DCHA salt.

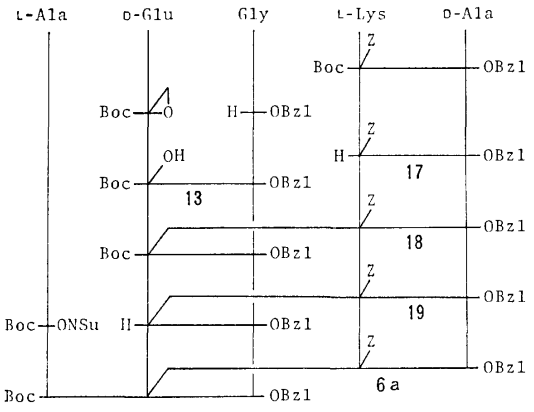

Fig. 2. Synthetic scheme for **6a**.

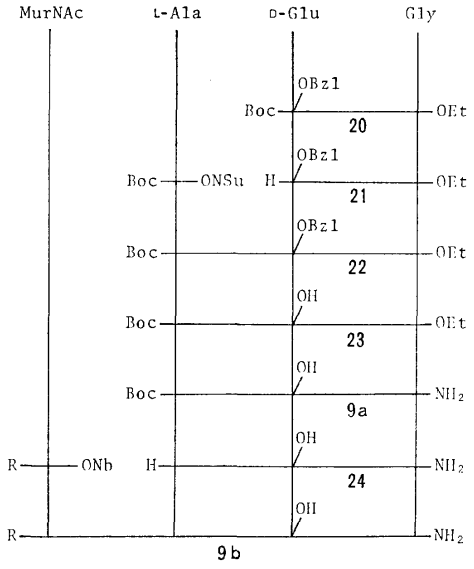
Concerning with the muramyl pentapeptide (**6c**), Boc–D-Glu(OH)–Gly–OBzl (**13**) was first condensed with H–L-Lys(Z)–D-Ala–OBzl (**17**) to give a branched tetrapeptide, *i.e.*, Boc–D-Glu(L-Lys(Z)–D-Ala–OBzl)–Gly–OBzl (**18**), whose Boc group was then selectively removed by treating with TFA (100 equivalents) at room temperature for 5 min.[8] The resulting H–D-Glu(L-Lys(Z)–D-Ala–OBzl)–Gly–OBzl (**19**) was successively coupled with Boc–L-Ala–OH. After removal of the Boc group, the product was condensed with the protected muramic acid 1-succinimidyl ester (**11**) to give the muramyl pentapeptide derivative (**6b**). Finally, hydrogenolysis of **6b** afforded MurNAc–L-Ala–D-Glu(L-Lys–D-Ala–OH)–Gly–OH (**6c**).

The muramyl tripeptide containing glycine, *i.e.*, MurNAc–Gly–D-Glu(OH)–Gly–OH (**7c**) was also prepared in a similar manner to that described above for **5c**.

Concerning with the syntheses of two muramyl tripeptides containing acid amide groups at their termini, *i.e.*, MurNAc–L-Ala–D-Glu(OH)–D-Ala–NH_2 (**8c**) and MurNAc–L-Ala–D-Glu(OH)–Gly–NH_2 (**9c**), the former (**8c**) could be prepared by conventional method starting from D-alanine amide, whereas a modified procedure should be used for the latter (**9c**) to avoid difficulties in experimental procedures due to high solubility of glycine amide derivatives in water. Thus, a tripeptide ester, *i.e.*, Boc–L-Ala–D-Glu(OBzl)–Gly–OEt (**22**), was first prepared by conventional method and its terminal ethyl ester was converted into amide function after selective removal of γ-benzyl ester group (Fig. 3). Other-



R = 1-α-*O*-benzyl-4,6-*O*-benzylidene

Fig. 3. Synthetic scheme for **9b**.

wise, α,γ-peptide migration would occur in the ammonolysis step. For the coupling of the protected muramic acid (**10**) with the ambient tripeptide, H–L-Ala–D-Glu(OH)–Gly–NH_2 (**24**) (Fig. 3), with less solubility in organic solvent and high solubility in aqueous media, we adopted HONb[1] ester method, particularly since this active ester has been known to afford relatively good yields in condensation in aqueous media.[9] In fact, the desired 1-α-*O*-benzyl-4,6-*O*-benzylidene-MurNAc-L-Ala-D-Glu(OH)-Gly-NH_2 (**9b**) was obtained in a satisfactory yield by this method. The product (**9b**) was then hydrogenolyzed to give the free *N*-acetylmuramyl tripeptide (**9c**). This advantageous method for the coupling of the active ester of muramic acid with a free peptide moiety was further utilized in our another synthesis of MurNAc–L-[U-^{14}C]Ala–D-Glu(OH)–NH_2 successfully.[10]

The immunoadjuvant activities of the muramyl pep-

tides (**2c**—**9c**) prepared above were measured by Kotani *et al.*[11,12] From these results, the relationship between the structure and the adjuvant activity had been already discussed.[11] For the reference, only the conclusion is now summarized as follows. i) The L-Ala residue in MurNAc–L-Ala–D-Glu(OH)–NH_2 (**1**) can be replaced with L-Ser without significant decrease in the activity. On the other hand, less activity is observed in the Gly analog and complete inactivity in the D-Ala analog. ii) Coupling of another amino acid residue at the α-carboxyl terminal of D-glutamic acid in **1** in place of the simple amide caused a remarkable decrease in the activity, while replacement with an amino acid amide kept the high activity. Therefore, the termination with an amide group in the molecule of muramyl peptide seems to be advisable in order to maintain the adjuvant activity in higher level.

Experimental

All melting points are uncorrected. Silica gel 60 (0.063—0.2 mm), Merck, was used for column chromatography and silica gel G, Merck, for thin layer chromatography. THF as solvent was purified by refluxing with $LiAlH_4$ followed by distillation and stored with Na-wire.

Boc–Gly–D-Glu(OBzl)–NH_2 (2a). Boc–Gly–ONSu (2.72 g, 10.0 mmol) was added to a mixture of H–D-Glu(OBzl)–NH_2·HCl (2.36 g, 8.7 mmol) and triethylamine (1.50 ml, 11.0 mmol) in THF (40 ml). After the usual work-up, the product was recrystallized from ethyl acetate–hexane; yield, 3.08 g (90%); mp 112—113 °C; $[\alpha]_D^{29}$ +4.95° (*c* 2.00, ethyl acetate).

Found: C, 57.76; H, 6.90; N, 10.64%. Calcd for $C_{19}H_{27}O_6N_3$: C, 58.00; H, 6.92; N, 10.68%.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-Gly-D-Glu(OBzl)–NH_2 (2b). Compound **2a** (2.36 g, 6.0 mmol) was dissolved in TFA (6 ml) and allowed to stand at room temperature for 1 h. On addition of abs ether and hexane, an oily layer separated. The supernatant was removed by decantation, the remaining oil was dissolved in THF, and then the solvent was removed *in vacuo*. The residue solidified by drying over KOH *in vacuo*. It was triturated with abs ether and filtered to give H–Gly–D-Glu(OBzl)–NH_2 TFA salt; yield, 2.08 g (85%).

A solution of 1-α-*O*-benzyl-4,6-*O*-benzylidene-MurNAc-ONSu[2b] (**11**) (0.57 g, 1.0 mmol) in DMF (10 ml) was added to a solution of the TFA salt obtained above (0.41 g, 1.0 mmol) and triethylamine (0.14 ml, 1.0 mmol) in THF (15 ml) with stirring. After the mixture had been kept at room temperature overnight, THF was evaporated *in vacuo* and ethyl acetate was added to the remaining mixture. The resulting gelatinous solid was filtered and recrystallized from dioxane–water; yield, 0.57 g (75%); mp 234 °C (dec); $[\alpha]_D^{28}$ +82° (*c* 0.95, DMF).

Found: C, 61.50; H, 6.24; N, 7.40%. Calcd for $C_{39}H_{46}O_{11}N_4 \cdot H_2O$: C, 61.24; H, 6.33; N, 7.33%.

MurNAc–Gly–D-Glu(OH)–NH_2 (2c). A solution of **2b** (0.30 g, 0.39 mmol) in acetic acid (20 ml) was hydrogenolyzed in the presence of palladium black catalyst. After removal of the catalyst, the filtrate was diluted with water and then evaporated *in vacuo*. The residue was crystallized from methanol; yield, 0.19 g (quantitative); mp 234 °C (dec); $[\alpha]_D^{28}$ +35° (after 5 min), +33° (after 24 h) (*c* 0.46, H_2O).

Found: C, 44.08; H, 6.32; N, 11.55%. Calcd for $C_{18}H_{30}O_{11}N_4 \cdot 1/2H_2O$: C, 44.35; H, 6.41; N, 11.49%.

Boc–L-Ser–D-Glu(OBzl)–NH_2 (3a). A mixture of Boc–L-Ser–OH (1.54 g, 7.5 mmol), H–D-Glu(OBzl)–NH_2·HCl (2.04 g, 7.5 mmol), and *N*-methylmorpholine (0.82 ml, 7.5 mmol) in THF was treated with DCC (1.70 g, 8.2 mmol) and HOBt[1] (1.01 g, 7.5 mmol) under ice-cooling. After the usual work-up, the product was recrystallized form ethyl acetate–hexane; yield, 3.13 g (98%); mp 73—75 °C; $[\alpha]_D^{29}$ +0.70° (*c* 2.98, ethyl acetate).

Found: C, 56.61; H, 7.02; N, 9.90%. Calcd for $C_{20}H_{29}O_7N_3$: C, 56.72; H, 6.90; N, 9.92%.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-L-Ser-D-Glu(OBzl)–NH_2 (3b). Compound **3a** (1.27 g, 3.0 mmol) was dissolved in TFA (3 ml) and set aside at room temperature for 35 min. Evaporation of TFA *in vacuo* afforded H–L-Ser–D-Glu(OBzl)–NH_2 TFA salt as a syrup, which was dried over KOH *in vacuo*. Ethyl chloroformate (0.29 ml, 3.0 mmol) was added to a solution of the protected *N*-acetylmuramic acid (**10**) (1.42 g, 3.0 mmol) and triethylamine (0.42 ml, 3.0 mmol) in THF (20 ml) at −19 °C. After being stirred at the same temperature for 15 min, a solution of the above TFA salt and triethylamine (0.42 ml, 3.0 mmol) in THF (15 ml) was added to the mixture, and stirring was continued overnight. Gelatinous solid obtained by addition of water was collected by filtration; yield, 1.95 g (82%). Recrystallization was effected from dioxane–water; mp 197 °C (dec); $[\alpha]_D^{28}$ +81.6° (*c* 1.12, DMF).

Found: C, 60.56; H, 6.19; N, 7.08%. Calcd for $C_{40}H_{48}O_{12}N_4 \cdot H_2O$: C, 60.44; H, 6.34; N, 7.05%.

MurNAc–L-Ser–D-Glu(OH)–NH_2 (3c). Compound **3b** (0.30 g, 0.38 mmol) was dissolved in acetic acid (35 ml) and hydrogenolyzed in the presence of palladium black catalyst. After addition of water, the solvent was evaporated *in vacuo* and the residue was precipitated from abs ethanol–abs ether to afford colorless hygroscopic solid. It was again dissolved in a small amount of water, and subjected to lyophilization;[13] yield, 0.11 g (55%); $[\alpha]_D^{28}$ +39° (after 5 min), $[\alpha]_D^{29}$ +35° (after 24 h) (*c* 0.49, H_2O).

Found: C, 44.29; H, 6.41; N, 10.91%. Calcd for $C_{19}H_{32}O_{12}N_4 \cdot 1/2H_2O$: C, 44.10; H, 6.43; H, 10.83%.

Boc–D-Ala–D-Glu(OBzl)–NH_2 (4a). This compound was prepared from Boc–D-Ala–OH (1.25 g, 6.6 mmol) and H–D-Glu(OBzl)–NH_2·HCl (1.79 g, 6.6 mmol) by means of the DCC–HONSu method in THF and recrystallized from ethyl acetate–hexane; yield, 2.33 g (87%); mp 130.5—131.5 °C; $[\alpha]_D^{29}$ +19.2° (*c* 1.88, ethyl acetate).

Found: C, 59.03; H, 7.20; N, 10.37%. Calcd for $C_{20}H_{29}O_5N_3$: C, 58.95; H, 7.17, N, 10.31%.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc–D-Ala-D-Glu(OBzl)–NH_2 (4b). Compound **4a** (1.22 g, 3.0 mmol) was treated with TFA (3 ml) and the resulting H–D-Ala–D-Glu(OBzl)–NH_2 was coupled with **10** (1.42 g, 3.0 mmol) by means of the mixed anhydride method as described for **3b**; yield, 1.69 g (73%). Recrystallization was effected from dioxane–water; mp 223 °C (dec); $[\alpha]_D^{28}$ +83.5° (*c* 1.09, DMF).

Found: C, 62.40; H, 6.39; N, 7.05%. Calcd for $C_{40}H_{48}O_{11}N_4 \cdot 1/2H_2O$: C, 62.40; H, 6.42; N, 7.28%.

MurNAc–D-Ala–D-Glu(OH)–NH_2 (4c) and Other MurNAc Peptides (5c—9c). These compounds were prepared by hydrogenolytic deprotection in acetic acid of **4b** and **5b**—**9b** whose syntheses are described below, followed by precipitation from abs ethanol–abs ether in a similar way to that for **3c**. The hygroscopic powders thus obtained were dissolved in water and lyophilized,[13] respectively. The yields, $[\alpha]_D$ values and the results of elemental analyses are summarized in Table 2.

Boc–D-Glu(OBzl)–Gly–OBzl (12). Boc–D-Glu(OBzl)–ONSu (8.69 g, 20.0 mmol) was added to a mixture of H–

Gly–OBzl·HCl (4.03 g, 20.0 mmol) and triethylamine (2.82 ml, 20.0 mmol) in THF (100 ml). After the usual work-up, the product was recrystallized from ethyl acetate–hexane; yield, 8.67 g (89%); mp 71—72 °C; $[\alpha]_D^{20}$ +6.99° (*c* 1.03, ethyl acetate).

Found: C, 64.07; H, 6.75; N, 5.83%. Calcd for $C_{26}H_{32}O_7N_2$: C, 64.45; H, 6.66; N, 5.78%.

*Boc–L-Ala–D-Glu(OBzl)–Gly–OBzl (**5a**).* The TFA salt of H–D-Glu(OBzl)–Gly–OBzl obtained from **12** (4.32 g, 8.9 mmol) was neutralized with triethylamine and then coupled with Boc–L-Ala–OH (1.70 g, 9.0 mmol) by means of DCC in a usual manner. The product was recrystallized from ethyl acetate–hexane; yield, 2.38 g (48%); mp 107 °C; $[\alpha]_D^{19}$ +6.5° (*c* 1.01, DMF).

Found: C, 62.68; H, 6.77; N, 7.63%. Calcd for $C_{29}H_{37}O_8N_3$: C, 62.69; H, 6.71; N, 7.56%.

*1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-L-Ala-D-Glu(OBzl)-Gly-OBzl (**5b**).* Compound **5a** (0.28 g, 0.50 mmol) was treated with TFA as described in the synthesis of **3b**. The syrupy H–L-Ala–D-Glu(OBzl)–Gly–OBzl TFA salt solidified on trituration with abs ether. It was filtered and dried over KOH *in vacuo*. A mixture of **10** (0.24 g, 0.51 mmol), HONSu (0.063 g, 0.55 mmol) and DCC (0.10 g, 0.49 mmol) in THF was stirred under ice-cooling for 4 h. After *N,N'*-dicyclohexylurea had been filtered off, the filtrate was again cooled in an ice bath, and a solution of the TFA salt and triethylamine (0.70 ml, 0.50 mmol) in a small amount of THF was added. The mixture was stirred overnight, and gelatinous solid was collected by filtration and then recrystallized from dioxane–water; yield, 0.28 g (63%); mp 220 °C (dec); $[\alpha]_D^{19}$ +68° (*c* 0.49, DMF).

Found: C, 64.48; H, 6.23; N, 6.26%. Calcd for $C_{49}H_{56}O_{13}N_4$: C, 64.74; H, 6.21; N, 6.16%.

*Boc–D-Glu(OH)–Gly–OBzl (**13**) DCHA Salt.* A mixture of H–Gly–OBzl·HCl (8.87 g, 44.0 mmol) and triethylamine (6.20 ml, 44.0 mmol) in THF (100 ml) was stirred at room temperature for 3 h, and then triethylamine hydrochloride was filtered off. The filtrate was cooled in an ice bath and Boc-D-glutamic anhydride (9.17 g, 40.0 mmol) was added with stirring. After being stirred in an ice bath for 6 h, the solvent was evaporated *in vacuo*. The residue was dissolved in ethyl acetate, washed with 1 M citric acid and water, and dried over Na_2SO_4. After addition of DCHA (8.0 ml, 40 mmol), the mixture was left stand at room temperature to afford crude crystalline material, which was collected by filtration (20.1 g). This was recrystallized from methanol–ethyl acetate–hexane; yield, 12.40 g (53%); mp 164—167 °C. The mother liquor of the recrystallization was condensed *in vacuo*, and the residue was shaken with ethyl acetate and 1 M citric acid. The organic layer was washed with water, dried and again treated with DCHA (2.0 ml, 10 mmol) to give an additional amount of the product; 1.46 g (6%); mp 165.5—167.5 °C.

Found: C, 64.30; H, 8.67; N, 7.04%. Calcd for $C_{31}H_{49}O_7N_3\cdot 1/4H_2O$: C, 64.17; H, 8.60; N, 7.24%.

Compound **13** was hydrogenolyzed in the presence of palladium black and then treated with TFA to give a free dipeptide, which was identified with the authentic specimen of H–D-Glu(OH)–Gly–OH (**15**) described below by means of TLC and amino acid analysis.

*Determination of the Ratio of **13** to **14**.* A solution of H–Gly–OBzl (0.11 g, 0.55 mmol) in THF (3 ml) was prepared as above and stirred at −70, 0, or 20 °C with or without addition of DCHA (0.10 ml, 0.50 mol). Boc-D-glutamic anhydride (0.11 g, 0.50 mmol) was added to the solution and the mixture was stirred overnight. After the solvent was removed *in vacuo*, the residue was dissolved in ethyl acetate and washed with 1 M citric acid and water. Hydrogenolysis with palladium black followed by treatment with TFA at room temperature afforded a mixture of free dipeptide **15** and **16**, whose ratio was determined by means of amino acid analyser. The standard color values for each substance were obtained using the pure authentic samples described below.

DCHA Salts of Z–D-Glu(OH)–Gly–OBzl and Z–D-Glu(Gly–OBzl)–OH. For the synthesis of these compounds, a similar procedure to that described for **13** was employed. A solution of *Z*-D-glutamic anhydride (0.53 g, 2.0 mmol) in THF (10 ml) was added to an ice-cooled solution of H–Gly–OBzl (2.2 mmol) in THF (8 ml). After being stirred overnight, the mixture was worked up as above and dissolved in ethyl acetate. After addition of DCHA (0.40 ml, 2.0 mmol), the mixture was left stand in a refrigerator for 4 days to afford Z–D-Glu(OH)–Gly–OBzl DCHA salt; yield, 0.57 g (48%); R_f on TLC, 0.60 ($CHCl_3$–acetone–acetic acid, 16:4:1). When the mother liquor was seeded with Z–D-Glu(Gly–OBzl)–OH DCHA salt and again left stand in a refrigerator for further 2 days, the γ-peptide DCHA salt was solidified; yield, 0.52 g (43%); R_f on TLC, 0.50.

*H–D-Glu(OH)–Gly–OH (**15**).* *i) TFA Salt as a Standard Sample*: Boc–D-Glu(OBzl)–Gly–OBzl (**12**) (0.70 g, 1.4 mmol) was deprotected by hydrogenolysis followed by action of TFA to afford white precipitate; yield, 0.43 g (94%); mp 139—140 °C (dec); R_f on TLC, 0.41 (1-butanol–acetic acid–water, 4:1:2).

ii) From Z–D-Glu(OH)–Gly–OBzl DCHA Salt: This salt (0.30 g, 0.50 mmol) was washed with aqueous citric acid and hydrogenolyzed in ethyl acetate with palladium black. The product was recrystallized from water–ethanol–ether; yield, 0.070 g (68%); mp 177.5—178.5 °C (dec).

Found: C, 40.74; H, 5.98; N, 13.66%. Calcd for $C_7H_{12}O_5N_2\cdot 1/8H_2O$: C, 40.72; H, 5.98; N, 13.57%.

*H–D-Glu(Gly–OH)–OH (**16**).* *i) TFA Salt as a Standard Sample*: Coupling of Boc–D-Glu(OH)–OBzl derived from its DCHA salt (2.60 g, 5.0 mmol) with H–Gly–OBzl *p*-toluenesulfonate (1.69 g, 5.0 mmol) by means of ethyl chloroformate afforded Boc–D-Glu(Gly–OBzl)–OBzl, which was recrystallized from ethyl acetate–hexane; mp 98—99 °C.

Found: C, 64.42; H, 6.63; N, 5.81%. Calcd for $C_{26}H_{32}O_7N_2$: C, 64.45; H, 6.66; N, 5.78%.

This dipeptide (0.23 g, 0.47 mmol) was deprotected as described in the preparation of **15** to afford **16** TFA salt; yield, 0.14 g (94%); mp 42 °C (dec); R_f on TLC, 0.29 (1-butanol–acetic acid–water, 4:1:2).

ii) From Z–D-Glu(Gly–OBzl)–OH DCHA Salt: A similar procedure to that described above for **15** afforded a product, which was recrystallized from water–ethanol–ether; mp 196—197 °C (dec).

Found: C, 40.55; H, 5.90; N, 13.53%. Calcd for $C_7H_{12}O_5N_2\cdot 1/8H_2O$: C, 40.72; H, 5.98; N, 13.57%.

*H–L-Lys(Z)–D-Ala–OBzl (**17**) HCl Salt.* A 2 M solution of dry HCl in ethyl acetate (60 ml, 120 mmol) was added to a solution of Boc–L-Lys(Z)–D-Ala–OBzl[2b] (8.21 g, 15.2 mmol) in ethyl acetate (70 ml) under ice-cooling. After the mixture had been kept at room temperature overnight, the crystalline product was filtered; yield, 7.00 g (95%); mp 142—144 °C.

Found: C, 59.51; H, 6.70; N, 8.73; Cl, 7.42%. Calcd for $C_{24}H_{32}O_5N_3Cl\cdot 1/4H_2O$: C, 59.74; H, 6.79; N, 8.71; Cl, 7.35%.

*Boc–D-Glu(L-Lys(Z)–D-Ala–OBzl)–Gly–OBzl (**18**).* A solution of **13** DCHA salt (1.20 g, 2.1 mmol) in $CHCl_3$ (30 ml) was shaken twice with 0.3 M citric acid solution, washed with water, dried over $MgSO_4$, and then added to a mixture of **17** HCl salt (1.00 g, 2.1 mmol) and triethylamine (0.29

ml, 2.1 mmol) in $CHCl_3$ (30 ml). To the total mixture was added DCC (0.50 g, 2.4 mmol) with stirring under ice-cooling. Stirring was continued at room temperature for 67 h with further addition of DCC (0.80 g, 3.9 mmol) during the first 48 h. After the usual work-up, the product was purified by silica gel column chromatography ($CHCl_3$–acetone, 1: 1), and then recrystallized successively from methanol–ether and ethanol–water; yield, 0.92 g (54%); mp 175.5—176 °C; $[\alpha]_D^{22}$ +1.9° (*c* 2.16, DMF).

Found: C, 62.92; H, 6.92; N, 8.69%. Calcd for $C_{43}H_{55}O_{11}N_5$: C, 63.14; H, 6.78; N, 8.56%.

Boc-L-Ala-D-Glu(L-Lys(Z)-D-Ala-OBzl)-Gly-OBzl (**6a**). Compound **18** (0.87 g, 1.1 mmol) was dissolved in TFA (8 ml). After 2.5 min at room temperature, abs ether and hexane were added to the mixture. The resulting gelatinous precipitate was crystallized from abs ethanol–ethyl acetate–hexane to give **19** TFA salt; yield, 0.86 g (98%).

To a suspension of **19** TFA salt (0.40 g, 0.48 mmol) obtained above in THF (20 ml) was added 1 M triethylamine in THF (0.48 ml, 0.48 mmol). The mixture was then cooled in an ice bath and Boc-L-Ala-ONSu (0.29 g, 1.0 mmol) was added. After being stirred overnight, the insoluble gelatinous solid was filtered and washed successively with acetone, water, acetone and then ether; yield, 0.29 g (67%); mp 173—174 °C (with softening at 167 °C); $[\alpha]_D^{26}$ +0.50° (*c* 1.99, DMF).

Found: C, 61.58; H, 6.82; N, 9.27%. Calcd for $C_{46}H_{60}O_{12}N_6$: C, 62.14; H, 6.80; N, 9.45%.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-L-Ala-D-Glu(L-Lys(Z)-D-Ala-OBzl)-Gly-OBzl (**6b**). Compound **6a** (0.30 g, 0.34 mmol) was dissolved in TFA(2.5 ml). After 2.5 min at room temperature, abs ether was added and the precipitate of the TFA salt was filtered. It was dissolved in DMF (30 ml), treated with 1 M triethylamine in THF (0.32 ml, 0.32 mmol), and then cooled in an ice bath. 1-α-*O*-Benzyl-4,6-*O*-benzylidene-MurNAc-ONSu (**11**) (0.28 g, 0.50 mmol) was added to the cooled solution, and the mixture was stirred overnight. The insoluble solid was filtered and washed with THF; yield, 0.22 g. An additional amount of the product (0.12 g) was recovered by condensation of the mother liquor *in vacuo* followed by removal of THF-soluble materials from the residue. The combined products were reprecipitated from dioxane–water; yield, 0.30 g (75%); mp 220 °C (dec); $[\alpha]_D^{25}$ + 56° (*c* 0.50, DMA).

Found: C, 63.37; H, 6.47; N, 7.70%. Calcd for $C_{66}H_{79}O_{17}N_7 \cdot 1/2H_2O$: C, 63.34; H, 6.44; N, 7.84%.

Boc-Gly-D-Glu(OBzl)-Gly-OBzl (**7a**). After removal of the Boc group in **12** (2.42 g, 5.0 mmol) with TFA (4 ml) in a usual way, the resulting TFA salt was dissolved in THF (30 ml). To the solution were added *N*-methylmorpholine (0.55 ml, 5.0 mmol), Boc-Gly-ONSu (1.50 g, 5.5 mmol) and K_2CO_3 (0.5 g) under ice-cooling. The mixture was worked up as usual and then subjected to silica gel column chromatography. Elution with benzene–ethyl acetate (3: 1) gave pure **7a** as a syrup; yield, 2.1 g (78%). The structure was confirmed by means of NMR spectrum.

H-Gly-D-Glu(OBzl)-Gly-OBzl. *i) HCl Salt*: Compound **7a** (80 mg, 0.15 mmol) was treated with 2 M dry HCl in ethyl acetate (1 ml) in a usual way and the product was recrystallized from methanol–ether; yield, 60 mg (84%); mp 133—134 °C; $[\alpha]_D^{30}$ +13.7° (*c* 1.74, methanol).

Found: C, 57.53; H, 5.88; N, 8.77; Cl, 7.38%. Calcd for $C_{23}H_{28}O_6N_3Cl$: C, 57.80; H, 5.91; N, 8.79; Cl, 7.42%.

ii) TFA Salt: Compound **7a** (80 mg, 0.15 mmol) was treated with TFA (1 ml), and the product was recrystallized from THF–abs ether; yield, 80 mg (97%); mp 84 °C (dec). This substance was identified with the HCl salt mentioned above on TLC.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-Gly-D-Glu(OBzl)-Gly-OBzl (**7b**). This compound was prepared in a similar manner to that described for **6b** from H-Gly-D-Glu(OBzl)-Gly-OBzl TFA salt (0.56 g, 1.0 mmol) and **11** (0.68 g, 1.2 mmol), and recrystallized from dioxane–water; yield, 0.70 g (78%); mp 203 °C.

Found: C, 63.94; H, 6.03; N, 6.23%. Calcd for $C_{48}H_{54}O_{13}N_4 \cdot 1/2H_2O$: C, 63.77; H, 6.13; N, 6.20%.

Boc-D-Glu(OBzl)-D-Ala-NH₂. This compound was prepared from Boc-D-Glu(OBzl)-ONSu (3.04 g, 7.0 mmol) and H-D-Ala-NH_2·HCl (0.93 g, 7.5 mmol) and recrystallized from ethyl acetate–hexane; yield, 2.57 g (90%); mp 139.5—140.5 °C.

Found: C, 58.94; H, 7.20; N, 10.19%. Calcd for $C_{20}H_{29}O_6N_3$: C, 58.95; H, 7.17; N, 10.31%.

Boc-L-Ala-D-Glu(OBzl)-D-Ala-NH₂ (**8a**). After removal of the Boc group in Boc-D-Glu(OBzl)-D-Ala-NH_2 (2.42 g, 5.9 mmol) with TFA (6 ml), the resulting TFA salt was treated with triethylamine (0.83 ml, 5.9 mmol) and Boc-L-Ala-ONSu (1.43 g, 5.0 mmol) in THF. The product was recrystallized from $CHCl_3$–hexane; yield, 2.35 g (98%); mp 182.5—183.5 °C (dec); $[\alpha]_D^{28}$ −4.98° (*c* 2.03, DMF).

Found: C, 57.73; H, 7.14; N, 11.61%. Calcd for $C_{23}H_{34}O_7N_4$: C, 57.72; H, 7.16; N, 11.71%.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-L-Ala-D-Glu(OBzl)-D-Ala-NH₂ (**8b**). Compound **8a** (0.57 g, 1.2 mmol) was treated with TFA (2 ml) in a usual manner, and the resulting TFA salt was neutralized with triethylamine and coupled with **11** (0.57 g, 1.0 mmol) in a mixture of DMF (8 ml) and THF (30 ml) overnight. Water was added to the mixture to afford gelatinous solid, which was filtered and then washed with 0.2 M citric acid and water. Reprecipitation was carried out from dioxane–water; yield, 0.60 g (72%); mp 275 °C (dec); $[\alpha]_D^{28}$ +83° (*c* 0.10, DMF).

Found: C, 61.77; H, 6.40; N, 8.31%. Calcd for $C_{43}H_{52}O_{12}N_5$: C, 62.28; H, 6.42; N, 8.42%.

Boc-D-Glu(OBzl)-Gly-OEt (**20**). This compound was prepared from H-Gly-OEt·HCl (1.66 g, 11.9 mmol) and Boc-D-Glu(OBzl)-ONSu (5.18 g, 11.9 mmol) in THF and was recrystallized from CH_2Cl_2–hexane; yield, 3.96 g (79%); mp 71—72 °C; $[\alpha]_D^{25}$ +6.20° (*c* 2.34, ethyl acetate).

Found: C, 59.79; H, 7.14; N, 6.59%. Calcd for $C_{21}H_{30}O_7N_2$: C, 59.70; H, 7.16; N, 6.63%.

Boc-L-Ala-D-Glu(OBzl)-Gly-OEt (**22**). Compound **20** (3.00 g, 7.1 mmol) was treated with 1 M dry HCl in ethyl acetate (50 ml), and the product was crystallized from $CHCl_3$–ether to give H-D-Glu(OBzl)-Gly-OEt (**21**) HCl salt (2.15 g, 84%). This salt (2.00 g, 5.6 mmol) was neutralized with triethylamine and coupled with Boc-L-Ala-ONSu (1.63 g, 5.7 mmol) in a usual manner. The product was recrystallized from ethyl acetate–hexane; yield, 2.55 g, (92%); mp 104—105 °C; $[\alpha]_D^{28}$ +7.19° (*c* 2.31, ethyl acetate).

Found: C, 58.37; H, 7.13; N, 8.45%. Calcd for $C_{24}H_{35}O_8N_3$: C, 58.40; H, 7.15; N, 8.51%.

Boc-L-Ala-D-Glu(OH)-Gly-OEt (**23**) *DCHA Salt.* Compound **22** (1.03 g, 2.1 mmol) was hydrogenolyzed in the presence of palladium black in ethanol (30 ml). The product was dissolved in ethyl acetate, and DCHA (0.42 ml, 2.1mmol) and ether were added to the solution to afford **23** DCHA salt as colorless crystals; yield, 1.04 g (83%); mp 138—139 °C; $[\alpha]_D^{26}$ +3.1° (*c* 2.06, methanol).

Found: C, 58.94; H, 9.05; N, 9.42%. Calcd for $C_{29}H_{52}O_8N_4 \cdot 1/2H_2O$: C, 58.66; H, 9.00; N, 9.44%.

Boc-L-Ala-D-Glu(OH)-Gly-NH₂ (**9a**) *DCHA Salt.* DCHA salt of **23** (0.29 g, 0.49 mmol) was dissolved in methanol (15 ml). The solution was saturated with NH_3 and left stand at room temperature in a pressure bottle for 3 days. After

removal of the solvent *in vacuo*, the residue was triturated with ether to afford **9a** DCHA salt; yield, 0.28 g (quantitative). Recrystallization was effected from ethanol–ethyl acetate–ether; mp 183 °C (dec); $[\alpha]_D^{25}$ −10.5° (*c* 1.99, methanol).

Found: C, 57.61; H, 8.78; N, 12.57%. Calcd for $C_{27}H_{49}O_7N_5 \cdot 1/2H_2O$: C, 57.42; H, 8.92; N, 12.40%.

1-α-O-Benzyl-4,6-O-benzylidene-MurNAc-L-Ala-D-Glu(OH)-Gly-NH₂ (9b). A solution of **9a** DCHA salt (0.56 g, 1.0 mmol) in water was passed through a column of Dowex 50 (H^+ form). The column was washed with water, and the combined eluate and washings was condensed *in vacuo*. The residue was twice dissolved in abs ethanol and the solvent was evaporated *in vacuo* to remove water completely. The final residue was dissolved in TFA (2 ml) and allowed to stand at room temperature for 20 min. Addition of abs ether to the solution afforded white precipitate of H–L-Ala–D-Glu(OH)–Gly–NH_2 (**24**) TFA salt (0.35 g, 0.90 mmol). An aqueous solution of this TFA salt was adjusted to pH 8 by addition of aqueous 1 M K_2CO_3 solution and mixed with a solution of 1-α-*O*-benzyl-4,6-*O*-benzylidene-MurNAc-ONb (0.44 g, 0.70 mmol) in THF (10 ml). The reaction mixture was stirred at room temperature for 4.5 h, and then brought to pH 3 by addition of 2 M HCl. Water was added to the mixture to afford gelatinous solid, which was collected by filtration; yield, 0.39 g (76%). Reprecipitation was effected from DMF–ethanol; mp 240 °C (dec); $[\alpha]_D^{25}$ +100° (*c* 0.95, DMF).

Found: C, 57.10; H, 6.28; N, 9.55%. Calcd for $C_{35}H_{45}O_{12}N_5 \cdot 1/2H_2O$: C, 57.05; H, 6.29; N, 9.51%.

Synthesis of a Protected Hexadecapeptide Corresponding to Positions 1—16 of Human Lysozyme

Shoko YOSHIMURA, Kunitatsu IZUMI, and Yasutsugu SHIMONISHI*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received September 22, 1978)

For a semi-synthesis of human lysozyme by coupling its natural fragment with synthetic peptides, a protected hexadecapeptide corresponding to positions 1—16 of the enzyme was constructed from three protected peptide fragments (V, IX, and XII) by the conventional method in pure state on the basis of analyses.

Lysozyme, isolated from the urine of patients with monocytic or monomyelocytic leukemia[1] and from human milk,[2] is a basic single-chain protein, 130 amino acid residues in length, cross-linked by four disulfide bridges.[3-5] The three dimensional structure[6] of human lysozyme shows considerable homology with that of hen egg-white lysozyme, in spite of the insertion of a glycine residue between positions 47 and 48 and the substitutions of about 40% of the amino acid residues of the latter. The enzyme can be unfolded by reduction with dithiothreitol, and the rapid refolding of the reduced disordered enzyme can be achieved in a high yield in the presence of oxidized and reduced glutathione,[7] as in the case of hen egg-white lysozyme. Recently,[8] investigation was made on the influence of anhydrous liquid hydrogen fluoride (HF) on human lysozyme. It was found that the original intact lysozyme can be recovered in fair yield from HF-solutions of native lysozyme and its derivative substituted by the 2-chlorobenzyloxycarbonyl group.

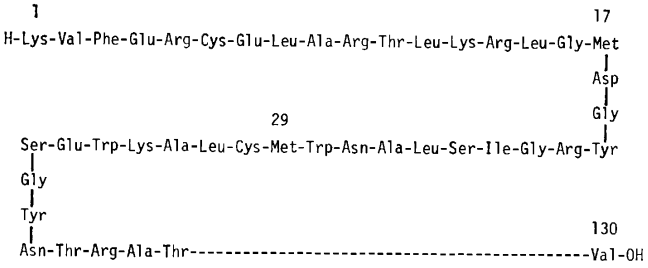

Fig. 1. N-Terminal region of human lysozyme.[3,4]

Human lysozyme contains two residues of methionine located in the N-terminal region of the peptide chain of the enzyme (Fig. 1). Cleavage by cyanogen bromide[9] of the methionyl bonds in the derivative[8] of the enzyme in which all the amino groups are substituted with 2-chlorobenzyloxycarbonyl group, followed by reductive alkylation[10] of the disulfide linkages gives a large fragment lacking the 29 amino acid residues at the N-terminal of the enzyne. The fragment seems to be a suitable material for a semi-synthesis[11,12] of the enzyme, because it has only one free amino group at the amino end. The coupling of the natural fragment with a synthetic peptide leads to the semi-synthesis of the enzyme. This prompted us to synthesize protected peptide fragments containing the N-terminal section of human lysozyme removed from the enzyme by cleavage with cyanogen bromide.

This paper describes the synthesis of a protected hexadecapeptide corresponding to positions 1—16 of human lysozyme. The procedure for synthesis of this peptide is outlined in Figs. 2—5. Figure 2 shows the synthesis of protected hexapeptide V with sqeuence [Lys[1]

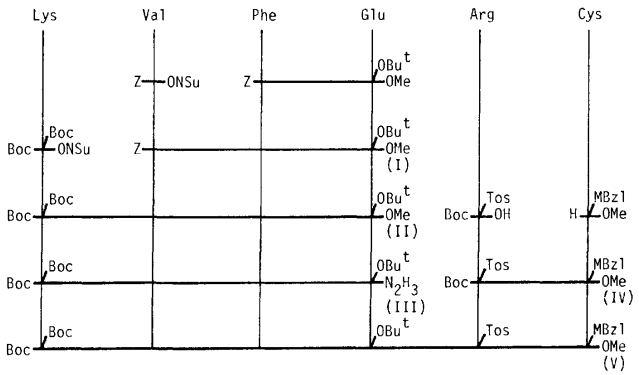

Fig. 2. Scheme for synthesis of sequence 1—6.

to Cys[6].[13] Namely, Z–Phe–Glu(OBu^t)–OMe[14] was subjected to catalytic hydrogenation and the peptide ester obtained was not isolated but allowed to react with Z–Val–ONSu[15] to give Z–Val–Phe–Glu(OBu^t)–OMe (I). The protecting group was removed by catalytic hydrogenation and the resulting tripeptide methyl ester was condensed with Boc–Lys(Boc)–ONSu[12] to yield Boc–Lys(Boc)–Val–Phe–Glu(OBu^t)–OMe (II). The tetrapeptide methyl ester was converted to the corresponding hydrazide (III). Boc–Lys(Boc)–Val–Phe–Glu(OBu^t)–N_3 prepared from compound III was not isolated, but allowed to react directly with H–Arg(Tos)–Cys(MBzl)–OMe prepared by removal of the Boc group from Boc–Arg(Tos)–Cys(MBzl)–OMe (IV) by trifluoracetic acid. In this way Boc–Lys(Boc)–Val–Phe–Glu(OBu^t)–Arg(Tos)–Cys(MBzl)–OMe (V) was obtained.

Figure 3 illustrates the synthesis of protected pentapeptide IX with sequence [Glu[7] to Thr[11]]. First, Z–Arg(Tos)–OH·CHA[16] was condensed with HCl·H–Thr–OEt in the presence of HOBt by DCC.[17] Z–Arg(Tos)–Thr–OEt (VI) thus obtained was hydrogenated catalytically and then coupled with Z–Ala–ONSu[15] to give Z–Ala–Arg(Tos)–Thr–OEt (VII). The protecting group was removed by catalytic hydrogenation and the resulting tripeptide ethyl ester was condensed with Z–Leu–ONSu[15] to give Z–Leu–Ala–Arg(Tos)–Thr–OEt (VIII). The Z group was cleaved by catalytic hydrogenation and the tetrapeptide ethyl ester thus obtained was coupled with Z–Glu(OBu^t)–ONSu[18] to yield Z–Glu(OBu^t)–Leu–Ala–Arg(Tos)–Thr–OEt (IX).

As shown in Fig. 4, protected pentapeptide XII with sequence [Leu[12] to Gly[16]] was constructed by stepwise elongation using Z–Leu–Gly–OEt[19] as starting material. The Z group was removed by catalytic hydrogenation, and the resulting peptide ester was coupled with Z–Arg(Tos)–OH[16] in the presence of HOBt by DCC. The protected tripeptide ester (X) was hydrogenated catalytically, the peptide chain being elongated by stepwise acylation with Z–Lys(Boc)–ONp[20] and Z–Leu–ONSu.[15] The pentapeptide derivative, Z–Leu–Lys(Boc)–Arg(Tos)–Leu–Gly–OEt (XII), was thus obtained.

Construction of the sequence [Lys[1] to Gly[16]] was carried out as illustrated in Fig. 5. Namely, the pentapeptide ethyl ester (IX) was converted to the corresponding hydrazide (XIII) by usual hydrazinolysis. The hydrazide (XIII) was converted to the corresponding azide by the method of Honzl and Rudinger[21] and coupled directly with pentapeptide ethyl ester, which was obtained by removal of the Z group of pentapeptide ethyl ester (XII) by catalytic hydrogenation. The decapeptide derivative (XIV) thus obtained was then hydrogenated over a palladium-catalyst in DMF and the resulting decapeptide ester was coupled with hexapeptide acid (XV) in the presence of HOBt by DCC[17] prepared from the corresponding methyl ester (V) by saponification. However, the resulting material could not be easily purified. Therefore, the decapeptide derivative (XIV) was hydrogenated over a palladium-catalyst in methanol, the catalyst was filtered off and the filtrate was mixed with DMF. Only the methanol in the mixture was evaporated under reduced pressure, and the remaining solution was mixed with hexapeptide acid (XV), and treated under the same conditions as those described above. Thus, a protected hexadecapeptide (XVI) corresponding to positions 1—16 of human lysozyme, Boc–Lys(Boc)–Val–Phe–Glu(OBu^t)–Arg(Tos)–Cys(MBzl)–Glu(OBu^t)–Leu–Ala–Arg(Tos)–Thr–Leu–Lys(Boc)–Arg(Tos)–Leu–Gly–OEt, could be prepared in pure form. Investigations toward a semisynthesis of the enzyme by coupling its natural fragment with synthetic peptides given in this and the following[22] papers are in progress.

Experimental

All melting points were measured by the capillary method and are uncorrected. Thin layer chromatography was performed on silica gel G (Merck) using the following solvent systems (volume ratios); $CHCl_3$: MeOH: AcOH (95: 5: 3), AcOEt: benzene (1: 1), 1-butanol: AcOH: H_2O (4: 1: 1), and $CHCl_3$: MeOH : AcOH : H_2O (10 : 10 : 1 : 10, lower phase). Peptide derivatives were hydrolyzed in 6 M HCl with phenol in sealed tubes at 105 °C for 24 or 48 h, and the hydrolysates were analyzed in a Hitachi KLA-5 analyzer by the method of Moore *et al.*[23] The purity of the peptide derivatives synthesized was confirmed by thin layer chromatography and by the ratio of their constituent amino acids measured in acid hydrolysates by amino acid analysis. Optical

rotations of the peptide derivatives synthesized were measured with a Perkin-Elmer Model 241 polarimeter. The chemicals used in this paper were of reagent grade and were used without further purification. All the amino acids used except glycine were of the L-configuration.

Z-Val-Phe-Glu(OBu^t)-OMe (I). Z-Phe-Glu(OBu^t)-OMe[14] (14.7 g, 29.5 mmol) was dissolved in MeOH (400 ml), and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to an oil *in vacuo*. The oil was dissolved with Z-Val-ONSu[15] (10.3 g, 29.5 mmol) in $CHCl_3$ (200 ml). The solution was stirred overnight at room temperature and mixed with *N,N*-dimethyl-1,3-propanediamine (3 ml). After 1 h the solution was diluted with $CHCl_3$ and then washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4, and the dried solution was concentrated to a solid *in vacuo*. The solid was collected with $CHCl_3$ and ether, and then recrystallized from $CHCl_3$ and hexane; wt 15.5 g (85.6%), mp 175—178 °C, $[\alpha]_D^{25}$ −40.6° (*c* 0.6, MeOH).

Found: C, 64.14; H, 7.29; N, 7.06%. Calcd for $C_{32}H_{43}O_8N_3$: C, 64.30; H, 7.25; N, 7.03%.

Boc-Lys(Boc)-Val-Phe-Glu(OBu^t)-OMe (II). Compound I (11.9 g, 19.9 mmol) was dissolved in MeOH (350 ml), and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to an oil *in vacuo*. The oil was dissolved with Boc-Lys(Boc)-ONSu[12] (8.85 g, 19.9 mmol) in DMF (100 ml) under cooling. The solution was stirred at room temperature for 2 days, and then concentrated to a syrup *in vacuo*. The syrup was dissolved in $CHCl_3$ and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4 and then concentrated *in vacuo* to an oil, which was repeatedly crystallized from EtOH and ether; wt 10.3 g (65.3%), mp 168—170 °C, $[\alpha]_D^{25}$ −43.5° (*c* 1.0, MeOH).

Found: C, 60.63; H, 8.30; N, 8.83%. Calcd for $C_{40}H_{65}O_{11}N_5$: C, 60.66; H, 8.27; N, 8.85%.

Boc-Lys(Boc)-Val-Phe-Glu(OBu^t)-N$_2$H$_3$ (III). Compound II (7.93 g, 10.0 mmol) was dissolved in DMF (56 ml) and mixed with 90% hydrazine hydrate (5.6 ml). The mixture was stirred at room temperature overnight, and concentrated *in vacuo* to a gelatinous residue, which was triturated with H_2O; wt 7.87 g (99.2%), mp 188.5—191 °C.

Found: C, 59.04; H, 8.32; N, 12.35%. Calcd for $C_{39}H_{65}O_{10}N_7$: C, 59.14; H, 8.27; N, 12.38%.

Boc-Arg(Tos)-Cys(MBzl)-OMe (IV). Boc-Arg(Tos)-OH[16] (4.14 g, 9.88 mmol) was added to a solution of HCl·H-Cys(MBzl)-OMe (3.50 g, 12.0 mmol) and TEA (1.68 ml) in DMF (50 ml), and cooled to −10 °C—−20 °C. HOBt (1.50 g, 11.1 mmol) and DCC (2.30 g, 11.2 mmol) were added to the cooled mixture. The mixture was stirred at the same temperature for 1 h and at 0 °C for 2 days. The precipitate formed was filtered off and the filtrate was concentrated to an oily residue *in vacuo*. The residue was dissolved in AcOEt and the solution was washed successively with 0.2 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4 and then concentrated to an oil *in vacuo*. The oil was purified on a column of silica gel using a solvent mixture of AcOEt and benzene (1: 1, v/v). A syrupy material was obtained; wt 5.85 g.

Boc-Lys(Boc)-Val-Phe-Glu(OBu^t)-Arg(Tos)-Cys(MBzl)-OMe (V). Compound III (2.38 g, 3.00 mmol) was dissolved in DMF (17 ml), cooled below −20 °C and mixed with 4.60 M HCl in dioxane (2.50 ml). The solution was mixed with isopentyl nitrite (0.37 g, 3.15 mmol) and stirred at the same temperature for 45 min, the solution was then mixed with a solution in DMF (10 ml) of the material prepared by treatment of compound IV (2.55 g, *ca.* 3.9 mmol) with trifluoracetic acid (10 ml) at 0 °C for 60 min. The solution was made slightly basic by adding TEA below −30 °C, and stirred at 0 °C for a day. The precipitate formed was filtered off and the filtrate was concentrated to half its volume *in vacuo*, and then diluted with $CHCl_3$ under cooling. The diluted solution was washed successively with 0.3 M HCl, 5% aqueous $NaHCO_3$ and H_2O, and dried over Na_2SO_4 and concentrated to an oil *in vacuo*. The oil was solidified in AcOEt and hexane; wt 3.83 g. The crude product was recrystallized from MeOH; wt 2.65 g (66.6%), mp 217—218 °C (dec), $[\alpha]_D^{20}$ −23.0° (*c* 1.0, DMF). Amino acid ratio in the acid hydrolysate: Glu, 1.00 (1); Cys, 0.49 (1); Val, 0.89 (1); Phe 1.00 (1); Lys, 0.91 (1); Arg, 1.06 (1).

Found: C, 57.15; H, 7.28; N, 10.24; S, 4.71%. Calcd for $C_{64}H_{96}O_{16}N_{10}S_2\cdot H_2O$: C, 57.21; H, 7.35; N, 10.43; S, 4.77%.

Z-Arg(Tos)-Thr-OEt (VI). A solution of HCl·H-Thr-OEt (14.7 g, 80.0 mmol) in tetrahydrofuran (100 ml) was added to a suspension of Z-Arg(Tos)-OH·CHA[16] (42.0 g, 75.0 mmol) in tetrahydrofuran (300 ml). The resulting solution was mixed with HOBt (10.8 g, 80.0 mmol), cooled to −10 °C and then mixed with a solution of DCC (16.5 g, 80.0 mmol) in tetrahydrofuran (100 ml). The mixture was stirred at −10 °C for 1 h and then overnight at room temperature. The precipitate thus formed was filtered off and the filtrate was concentrated to a syrup *in vacuo*. The syrup was dissolved in AcOEt and washed successively with 0.5 M HCl, 5% aqueous $NaHCO_3$ and H_2O. It was then dried over Na_2SO_4 and concentrated to an oily residue *in vacuo*. The oily residue was purified on a column of silica gel using a mixture of AcOEt and benzene (1: 1, v/v). The purified material was solidified in $CHCl_3$ and ether; wt 37.0 g (83.5%), mp 64—66 °C, $[\alpha]_D^{24}$ −6.4° (*c* 1.1, MeOH).

Found: C, 54.39; H, 6.42; N, 11.60; S, 5.21%. Calcd for $C_{27}H_{37}O_8N_5S$: C, 54.81; H, 6.30; N, 11.84; S, 5.40%.

Z-Ala-Arg(Tos)-Thr-OEt (VII). Compound VI (30.0 g, 50.0 mmol) was dissolved in MeOH (800 ml) and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to an oil under reduced pressure. The oil was dissolved with Z-Ala-ONSu[15] (19.2 g, 60.0 mmol) in DMF (50 ml). The mixture was stirred at room temperature for a day, and concentrated to a residue under reduced pressure. The residue was dissolved in AcOEt, and washed successively with 0.5 M HCl, 5% aqueous $NaHCO_3$ and H_2O, and dried over Na_2SO_4. The dried solution was concentrated *in vacuo* to a syrup, which was solidified in a mixture of $CHCl_3$ and ether. The crude product was reprecipitated from a mixture of $CHCl_3$, MeOH, and ether; wt 26.5 g (80.2%), mp 66 °C (sintered), $[\alpha]_D^{24}$ −25.1° (*c* 0.9, MeOH).

Found: C, 54.10; H, 6.52; N, 12.74; S, 5.23%. Calcd for $C_{30}H_{42}O_9N_6S$: C, 54.37; H, 6.39; N, 12.68; S, 4.83%.

Z-Leu-Ala-Arg(Tos)-Thr-OEt (VIII). Compound VII (19.9 g, 30.0 mmol) was dissolved in MeOH (500 ml) and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to an oil under reduced pressure. The oil was dissolved with Z-Leu-ONSu[15] (13.0 g, 36.0 mmol) in DMF (65 ml). The solution was stirred at room temperature for 24 h, and then concentrated to a residue under reduced pressure. The residue was dissolved in AcOEt and washed successively with 0.7 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The solution was dried over Na_2SO_4, and concentrated to a syrupy residue under reduced pressure. The residue was precipitated repeatedly with $CHCl_3$ and ether; wt 19.3 g

(82.6%), mp 80—85 °C, $[\alpha]_D^{24}$ −32.6° (*c* 1.0, MeOH).

Found: C, 54.44; H, 6.95; N, 12.48; S, 4.01%. Calcd for $C_{36}H_{53}O_{10}N_7S$: C, 54.46; H, 6.98; N, 12.35; S, 4.12%.

Z-Glu(OBu^t)-Leu-Ala-Arg(Tos)-Thr-OEt (IX). Compound VIII (15.5 g, 20.0 mmol) was dissolved in MeOH (350 ml) and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to a foaming residue *in vacuo*. The residue was dissolved with Z-Glu(OBu^t)-ONSu[18] (10.7 g, 24.0 mmol) in DMF (40 ml). The solution was stirred at room temperature for a day, and then concentrated to a residue *in vacuo*. The residue was dissolved in AcOEt, and washed successively with 0.5 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4 and then concentrated *in vacuo* to a syrup, which was precipitated from a mixture of AcOEt, EtOH, and ether. The crude product was reprecipitated from the same solvent mixture; wt 13.3 g (69.3%), mp 151—153 °C, $[\alpha]_D^{24}$ −37.6° (*c* 0.9, MeOH). Amino acid ratio in the acid hydrolysate: Thr, 0.89 (1); Glu, 1.02 (1); Ala, 1.00 (1); Leu, 1.00 (1); Arg, 1.07 (1).

Found: C, 55.73; H, 7.18; N, 11.30; S, 3.02%. Calcd for $C_{45}H_{68}O_{13}M_8S\cdot 1/2H_2O$: C, 55.71; H, 7.17; N, 11.55; S, 3.33%.

Z-Arg(Tos)-Leu-Gly-OEt (X). Z-Leu-Gly-OEt[19] (17.5 g, 50.0 mmol) was dissolved in MeOH (500 ml) and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to a gelatinous solid *in vacuo*. The solid was dissolved with Z-Arg(Tos)-OH obtained from Z-Arg(Tos)-OH·CHA[10] (28.1 g, 50.0 mmol), and HOBt (8.1 g, 60.0 mmol) in tetrahydrofuran (400 ml) at 0 °C. The solution was cooled to −10 °C and mixed with a solution of DCC (12.4 g, 60.0 mmol) in tetrahydrofuran (150 ml). The mixture was stirred at −10 °C for 4 h and overnight at room temperature. The precipitate formed was filtered off and the filtrate was concentrated to a syrup *in vacuo*. The syrup was dissolved in AcOEt, and washed successively with 0.5 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4, and concentrated to a syrup *in vacuo*. The syrup was purified by chromatography on a column of silica gel using a mixture of AcOEt and benzene (1: 1, v/v). The main fractions were collected and concentrated to a syrupy residue *in vacuo*. The residue was repeatedly precipitated from $CHCl_3$ and ether; wt 25.0 g (75.8%), mp 65—68 °C, $[\alpha]_D^{24}$ −24.8° (*c* 1.0, MeOH).

Found: C, 55.06; H, 6.62; N, 12.35; S, 4.77%. Calcd for $C_{31}H_{44}O_8N_6S\cdot H_2O$: C, 54.87; H, 6.83; N, 12.38; S, 4.84%.

Z-Lys(Boc)-Arg(Tos)-Leu-Gly-OEt (XI). Compound X (19.8 g, 30.0 mmol) was dissolved in MeOH (500 ml) and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to a syrup *in vacuo*. The syrup was dissolved with Z-Lys(Boc)-ONp[20] (16.5 g, 33.0 mmol) in DMF (100 ml). The solution was stirred at room temperature for a day and concentrated *in vacuo* to a syrupy residue, which was dissolved in AcOEt. The solution was washed successively with 1 M citric acid, 5% aqueous $NaHCO_3$ and H_2O, dried over Na_2SO_4, and concentrated *in vacuo* to a gelatinous solid, which was collected with a mixture of AcOEt, EtOH, and hexane. The crude material was recrystallized from the same mixture; wt 23.5 g (88.4%), mp 147—149 °C, $[\alpha]_D^{24}$ −20.4° (*c*, 1.0, DMF).

Found: C, 55.87; H, 7.24; N, 12.41; S, 3.52%. Calcd for $C_{42}H_{64}O_{11}N_8S\cdot 1/2H_2O$: C, 56.17; H, 7.30; N, 12.48; S, 3.60%.

Z-Leu-Lys(Boc)-Arg(Tos)-Leu-Gly-OEt (XII). Compound XI (17.8 g, 20.0 mmol) was dissolved in MeOH (500 ml) and hydrogenated at atmospheric pressure over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to a syrup *in vacuo*. The syrup was dissolved with Z-Leu-ONSu[15] (8.4 g, 22.0 mmol) in DMF (50 ml). The solution was stirred at room temperature for 36 h and concentrated to a syrup *in vacuo*. The syrup was dissolved in AcOEt, and washed successively with 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4, and concentrated to a solid *in vacuo*. The solid was dissolved in a mixture of AcOEt and EtOH and precipitated by adding a mixture of ether and hexane. The crude product was reprecipitated from a mixture of EtOH, hexane and ether; wt 16.0 g (80.8%), mp 159—161 °C, $[\alpha]_D^{27}$ −18.8° (*c* 1.0, DMF). Amino acid ratio in the acid hydrolysate: Gly, 1.00 (1); Leu, 1.96 (2); Lys, 1.00 (1); Arg, 0.98 (1).

Found: C, 56.32; H, 7.44; N, 12.32; S, 3.13%. Calcd for $C_{48}H_{75}O_{12}N_9S\cdot H_2O$: C, 56.50; H, 7.61; N, 12.36; S, 3.19%.

Z-Glu(OBu^t)-Leu-Ala-Arg(Tos)-Thr-N_2H_3 (XIII). Compound IX (19.2 g, 20.0 mmol) was dissolved in a mixture of EtOH (200 ml) and DMF (50 ml) by gentle heating. The solution was cooled to 0—5 °C and mixed with 90% hydrazine hydrate (60 ml). The mixture was stirred at room temperature for a day and concentrated to a residue *in vacuo*. The residue was collected with ether, and reprecipitated from EtOH and ether. The crude material was redissolved in a mixture of DMF and EtOH, and reprecipitated by adding a mixture of hexane and ether; wt 16.9 g (89.9%), mp 125—128 °C, $[\alpha]_D^{24}$ −22.0° (*c* 1.0, DMF).

Found: C, 53.80; H, 7.19; N, 14.84; S, 3.32%. Calcd for $C_{43}H_{66}O_{12}N_{10}S\cdot H_2O$: C, 53.51; H, 7.19; N, 14.51; S, 3.38%.

Z-Glu(OBu^t)-Leu-Ala-Arg(Tos)-Thr-Leu-Lys(Boc)-Arg(Tos)-Leu-Gly-OEt (XIV). Compound XII (3.00 g, 2.94 mmol) was dissolved in MeOH (300 ml) and hydrogenated over 5% palladium-charcoal catalyst in a water bath at 35 °C. The catalyst was filtered off and the filtrate was mixed with DMF (5 ml). Only the methanol in the filtrate was evaporated off under reduced pressure and the remaining solution was left to stand in a refrigerator. Meanwhile, compound XIII (3.13 g, 3.24 mmol) was dissolved in DMF (12 ml) by gentle heating, cooled to −20 °C——30 °C, and mixed with 3 M HCl in dioxane (6 ml) and isopentyl nitrite (0.48 ml, 3.7 mmol). The solution was stirred at the same temperature for 45 min and mixed with the solution obtained above and TEA (2.5 ml). The mixture was stirred at 0 °C for 10 days in a refrigerator. The precipitate formed was filtered off and the filtrate was concentrated to a syrup *in vacuo*. The syrup was triturated in cold 0.2 M HCl (250 ml), filtered and washed well with H_2O. The crude material was repeatedly crystallized from MeOH; wt 1.89 g (35.7%), mp 224—226 °C, $[\alpha]_D^{24}$ −20.3° (*c* 0.50, dimethyl sulfoxide). Amino acid ratio in the acid hydrolysate: Glu, 1.05 (1); Leu, 3.01 (3); Ala, 0.95 (1); Arg, 1.94 (2); Thr, 1.02 (1); Lys, 1.03 (1); Gly, 1.00 (1).

Found: C, 54.55; H, 7.48; N, 13.19; S, 3.69%. Calcd for $C_{83}H_{131}O_{22}N_{17}S_2\cdot 2H_2O$: C, 54.80; H, 7.48; N, 13.09; S, 3.52%.

Boc-Lys(Boc)-Val-Phe-Glu(OBu^t)-Arg(Tos)-Cys(MBzl)-OH (XV). Compound V (5.29 g, 3.94 mmol) was dissolved in a mixture of MeOH (100 ml) and DMF (20 ml), mixed with 1 M NaOH (8 ml) in an ice-bath under cooling and stirred at room temperature for 3 h. The solution was made neutral by adding 1 M HCl and concentrated to a syrupy residue under reduced pressure. The residue was triturated in cold 0.2 M HCl (300 ml), filtered and washed well with H_2O. The crude material was repeatedly crystallized from MeOH and ether; wt 4.27 g (81.5%), mp 234—236

°C, $[\alpha]_D^{24}$ −13.6° (*c* 0.51, dimethyl sulfoxide).

Found: C, 56.83; H, 7.29; N, 10.45; S, 4.95%. Calcd for $C_{63}H_{94}O_{16}N_{10}S_2 \cdot H_2O$: C, 56.91; H, 7.28; N, 10.54; S, 4.81%.

Boc–Lys(Boc)–Val–Phe–Glu(OBu^t)–Arg(Tos)–Cys(MBzl)–Glu(OBu^t)–Leu–Ala–Arg(Tos)–Thr–Leu–Lys(Boc)–Arg(Tos)–Leu–Gly–OEt (XVI). Compound XIV (0.89 g, 0.49 mmol) was dissolved in MeOH (200 ml) and hydrogenated over 5% palladium–charcoal catalyst at 35 °C for 3 h in a water-bath. The catalyst was filtered off and the filtrate was mixed with DMF (4 ml). Only the methanol in the filtrate was evaporated *in vacuo*. The remaining solution was mixed with HOBt (0.14 g, 1.0 mmol) and compound XV (0.79 g, 0.59 mmol), cooled below −20 °C and mixed with DCC (0.15 g, 0.7 mmol). The mixture was stirred at −20 °C for 50 min and at room temperature for 2 days. The gelatinous mixture formed during the course of reaction was made clear by adding a small volume of dimethyl sulfoxide. The precipitate formed was filtered off and the filtrate was concentrated to a residue under reduced pressure. The residue was precipitated from MeOH and ether; wt 0.85 g. The crude product was reprecipitated from acetonitrile and MeOH; wt 0.57 g (39.6%), mp 244 °C (dec), $[\alpha]_D^{24}$ −22.0° (*c* 0.49, dimethyl sulfoxide). Amino acid ratio in the acid hydrolysate: Lys, 1.85 (2); Val, 0.88 (1); Phe, 0.95 (1); Glu, 2.23 (2); Arg, 3.00 (3); Cys, not determined; Leu, 3.11 (3); Ala, 1.00 (1); Thr, 1.10 (1); Gly, 0.97 (1).

Found: C, 56.02; H, 7.42; N, 12.80; S, 4.31%. Calcd for $C_{138}H_{217}O_{35}N_{27}S_4$: C, 56.33; H, 7.43; N, 12.85; S, 4.35%.

Synthesis of a Protected Tridecapeptide Corresponding to Positions 17—29 of Human Lysozyme

Shoko YOSHIMURA and Yasutsugu SHIMONISHI*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received September 22, 1978)

For a semi-synthesis of human lysozyme by coupling its natural fragment with synthetic peptides, a protected tridecapeptide corresponding to positions 17—29 of the enzyme was prepared from three protected peptide fragments (II, VI, and XI) by the conventional method in pure form on the basis of analyses.

Human lysozyme[1] contains two residues of methionine at the positions 17 and 29 of the peptide chain of the enzyme.[2,3] Cleavage by cyanogen bromide[4] of the methionyl bonds in the enzyme followed by reductive alkylation[5] of the disulfide linkages give a fragment lacking the 29 amino acid residues at the N-terminus of the enzyme. The natural fragment is considered to be a suitable material for a semi-synthesis,[6,7] as described in the preceding paper.[8] Coupling of the natural fragment with synthetic peptides *via* the formation of peptide linkages will give a covalent semi-synthesis of human lysozyme. For the aim, we have attempted to isolate the natural fragment[5] and synthesize complementary peptide fragments. The peptide fragments refer to the N-terminal region corresponding to positions 1—29 of human lysozyme, which is liberated from the enzyme by treatment with cyanogen bromide. The N-terminal section of the enzyme was divided into two parts and synthesized; a hexadecapeptide[8] corresponding to positions 1—16 and a tridecapeptide corresponding to positions 17—29. This paper reports the synthesis of the latter peptide.

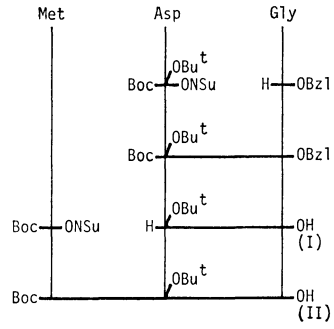

Fig. 1. Synthesis of sequence 17—19.

The peptide was constructed from three peptide fragments, Boc–Met–Asp(OBu^t)–Gly–OH (II),[9] Boc–Tyr–Arg(Tos)–Gly–Ile–Ser–OMe (VI), and Boc–Leu–Ala–Asn–Trp–Met–OMe (XI). The first fragment was synthesized by coupling Boc–Met–ONSu[10] with H–Asp–(OBu^t)–Gly–OH (I) (Fig. 1). The dipeptide (I) was obtained by the catalytic hydrogenation of the syrupy material, Z–Asp(OBu^t)–Gly–OBzl, which was prepared by condensing Z–Asp(OBu^t)–ONSu[11] with H–Gly–OBzl. The synthesis of the second fragment, Boc–Tyr–Arg(Tos)–Gly–Ile–Ser–OMe (VI), was started by coupling Z–Ile–ONp[12] with H–Ser–OMe (Fig. 2). Z–Ile–Ser–OMe (III) thus obtained was catalytically hydrogenated and the resulting dipeptide methyl ester was

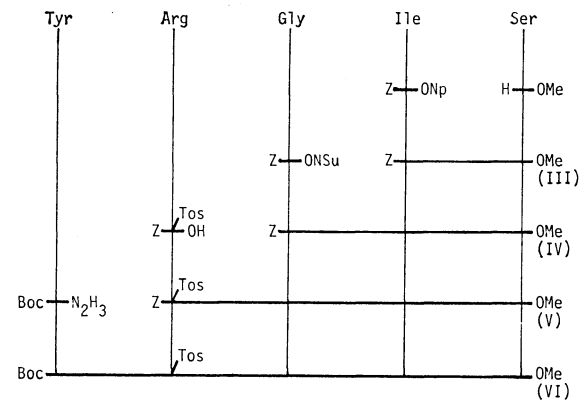

Fig. 2. Synthesis of sequence 20—24.

acylated with Z–Gly–ONSu[10] to give Z–Gly–Ile–Ser–OMe (IV). The tripeptide (IV) was catalytically hydrogenated and condensed with Z–Arg(Tos)–OH[13] by DCC in the presence of HOBt.[14] The resulting tetrapeptide, Z–Arg(Tos)–Gly–Ile–Ser–OMe (V), was catalytically hydrogenated. The tetrapeptide methyl ester was not isolated, but directly coupled with Boc–Tyr–N_3 prepared from the corresponding hydrazide,[15] to give Boc–Tyr–Arg(Tos)–Gly–Ile–Ser–OMe (VI).

For the synthesis of the last fragment, Boc–Leu–Ala–Asn–Trp–Met–OMe (XI), Boc–Asn–ONp[16] was first coupled with H–Trp–OMe. The resulting dipeptide, Boc–Asn–Trp–OMe (VII), was converted to the corresponding hydrazide (VIII) by usual hydrazinolysis. The hydrazide (VIII) was allowed to react with isopentyl nitrite by Rudinger's method,[17] the resulting

azide being condensed *in situ* with H–Met–OMe to give Boc–Asn–Trp–Met–OMe (IX). The tripeptide (IX) was treated with formic acid for removal of the Boc group, and elongated by two single-step reactions using Boc–Ala–ONSu[10] and Boc–Leu–ONSu[10] for acylation, the pentapeptide, Boc–Leu–Ala–Asn–Trp–Met–OMe (XI), thus being obtained (Fig. 3). Amino acid analysis of the acid hydrolysate of pentapeptide (XI) showed that the recovery of aspartic acid is low. The same phenomenon was observed on analyses of the acid hydrolysates of the peptides containing Asn–Trp linkage given in Table 1, which were synthesized separately (Table 2). In contrast, amino acid analyses of enzymatic[18] hydrolysates of the corresponding free peptides gave a theoretical recovery of asparagine. The results are summarized in Table 1.

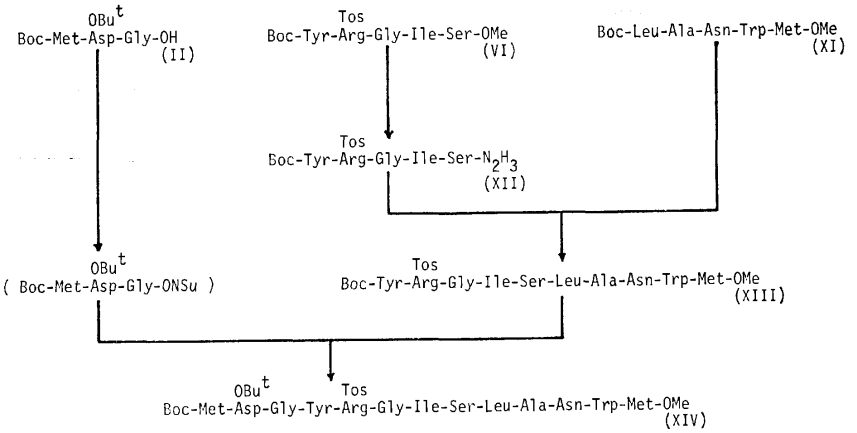

Fig. 4. Synthesis of the tridecapeptide corresponding to positions 17—29 of human lysozyme.

The tridecapeptide, Boc–Met–Asp(OBu^t)–Gly–Tyr–Arg(Tos)–Gly–Ile–Ser–Leu–Ala–Asn–Trp–Met–OMe (XIV), was obtained as shown in Fig. 4. First, the second fragment (VI) was combined with the third fragment (XI). The Boc group of the protected pentapeptide methyl ester (XI) was removed by treatment with formic acid in the presence of mercaptoacetic acid. The resulting pentapeptide with a free amino group was coupled with Boc–Tyr–Arg(Tos)–Gly–Ile–Ser–N_3, prepared from the corresponding hydrazide (XII) by the method of Honzl and Rudinger,[17] to give a decapeptide, Boc–Tyr–Arg(Tos)–Gly–Ile–Ser–Leu–Ala–Asn–Trp–Met–OMe (XIII). The decapeptide (XIII) thus obtained was treated with formic acid for removal of the Boc group and the resulting peptide was coupled with Boc–Met–Asp(OBu^t)–Gly–ONSu obtained from the first fragment (II) as an oily material and used without further purification. Thus, a protected tridecapeptide corresponding to positions 17—29 in the amino acid sequence of human lysozyme, Boc–Met–Asp(OBu^t)–Gly–Tyr–Arg(Tos)–Gly–Ile–Ser–Leu–Ala–Asn–Trp–Met–OMe (XIV), was obtained.

Experimental

The experimental and analytical methods are the same as described in the preceding paper.[8]

H–Asp(OBu^t)–Gly–OH (I). Z–Asp(OBu^t)–ONSu[11] (42.1 g, 0.1 mol) was added to a solution of TosOH·H–Gly–OBzl (33.7 g, 0.1 mol) and TEA (14.0 ml) in DMF (150 ml). The solution was stirred at room temperature for a day and then concentrated to an oily residue under reduced pressure. The residue was dissolved in AcOEt. The solution was washed successively with 0.5 M HCl, 5% aqueous $NaHCO_3$ and H_2O, and then dried over Na_2SO_4 and concentrated to an oil. The oil was dissolved in a mixture of EtOH (600 ml) and H_2O (150 ml), and hydrogenated over 5% palladium–charcoal catalyst under atmospheric pressure. The catalyst was filtered off and the filtrate was concentrated *in vacuo*. The residue was repeatedly flashed with benzene and then crystallized from MeOH and ether; wt 22.5 g (91.5%), mp 158—159 °C, $[\alpha]_D^{24}$ +18.5° (*c* 1.0, AcOH).

Found: C, 48.12; H, 7.45; N, 11.05%. Calcd for $C_{10}H_{18}O_5N_2$: C, 48.77; H, 7.37; N, 11.38%.

Boc–Met–Asp(OBu^t)–Gly–OH·DCHA (II). Boc–Met–ONSu[10] (24.2 g, 69.9 mmol) and TEA (8.4 ml) were added at 0 °C to a suspension of compound I (14.8 g, 60.1 mmol) in a mixture of DMF (200 ml) and H_2O (70 ml). The mixture was stirred at room temperature for 3.5 h to give a clear solution, which was concentrated to an oil under reduced pressure. The oil was redissolved in AcOEt and the solution was washed with 0.5 M HCl and H_2O, dried over Na_2SO_4, and concentrated to an oily residue *in vacuo*. The oil was dissolved in a mixture of ether (1 litre) and AcOEt (200 ml), and then mixed with DCHA (10.8 g). The resulting precipitate was filtered and recrystallized from EtOH, AcOEt, and hexane; wt 27.7 g (69.9%), mp 165—166 °C, $[\alpha]_D^{18}$ −19.4° (*c* 1.0, DMF).

Found: C, 58.08; H, 8.99; N, 8.41; S, 4.88%. Calcd for $C_{32}H_{58}O_8N_4S$: C, 58.33; H, 8.87; N, 8.50; S, 4.87%.

Z–Ile–Ser–OMe (III). Z–Ile–ONp[12] (38.6 g, 0.1 mol) was added to a solution of HCl·H–Ser–OMe (17.0 g, 0.11 mol) and TEA (15.4 ml) in DMF (100 ml). The solution was stirred at room temperature for 3 days, and then concentrated to an oily residue *in vacuo*. The residue was dissolved in AcOEt and H_2O. The AcOEt layer was separated, washed successively with 5% aqueous $NaHCO_3$, 0.7 M HCl and H_2O and dried over Na_2SO_4. The dried solution was concentrated to half its volume, and mixed with hexane and ether. Resulting crystals were separated and recrystallized from AcOEt; wt 31.1 g (85.0%), mp 179—181 °C, $[\alpha]_D^{18}$ +4.3° (*c* 1.0, DMF).

Found: C, 58.76; H, 7.11; N, 7.95%. Calcd for $C_{18}H_{26}O_6N_2$: C, 59.00; H, 7.15; N, 7.65%.

Z–Gly–Ile–Ser–OMe (IV). Compound III (22.0 g, 60.1 mmol) was dissolved in a mixture of MeOH (600 ml) and 4.74 M HCl in dioxane (14 ml), and then hydrogenated under atmospheric pressure over 5% palladium–charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to a solid residue *in vacuo*. The solid was dissolved in DMF (150 ml), and then mixed with TEA (8.4 ml) and Z–Gly–ONSu[10] (20.2 g, 66.0 mmol). The solution was stirred at room temperature for 2 days, and then concentrated to a syrup under reduced pressure. The syrup was dissolved in AcOEt, and washed successively with 0.7 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4, and then concentrated to a syrup *in vacuo*. The material was then crystallized from AcOEt and hexane, and recrystallized from AcOEt, ether and hexane; wt 23.0 g (90.6%), mp 137—139 °C, $[\alpha]_D^{18}$ −0.2° (*c* 1.0, DMF).

Found: C, 56.29; H, 6.97; N, 9.81%. Calcd for $C_{20}H_{29}O_7N_3$: C, 56.72; H, 6.90; N, 9.92%.

Z–Arg(Tos)–Gly–Ile–Ser–OMe (V). Compound IV (12.7 g, 30.0 mmol) was dissolved in MeOH (1 litre) and hydrogenated over 5% palladium–charcoal catalyst at atmospheric pressure in a water bath at 30—35 °C. The catalyst was filtered off and the filtrate was concentrated to a solid under reduced pressure. The solid was dissolved with Z–Arg(Tos)–OH, obtained from the corresponding cyclohexylammonium salt[13] (18.4 g, 32.7 mmol), and HOBt (8.1 g, 60.0 mmol) in a mixture of DMF (100 ml) and tetrahydrofuran (200 ml). The solution was cooled to −20 °C in a cold bath, and mixed with a solution of DCC (6.8 g, 33.0 mmol) in tetrahydrofuran (40 ml). The mixture was stirred at −10 °C for an hour and at room temperature overnight, and then concentrated to a solid residue under reduced pressure. The residue was suspended in AcOEt, the insoluble material being filtered off. The filtrate was washed successively with 0.7 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4, and then concentrated to an oily material *in vacuo*. The material was dissolved in a mixture of EtOH and AcOEt, and crystallized by adding hexane. The crude product was recrystallized from EtOH, AcOEt, and hexane; wt 18.8 g (85.5%), mp 138 °C (sintered) and 152 °C (melted), $[\alpha]_D^{18}$ −1.9° (*c* 1,1, DMF).

Found: C, 53.86; H, 6.52; N, 13.29; S, 4.58%. Calcd for $C_{33}H_{47}O_{10}N_7S$: C, 54.01; H, 6.46; N, 13.36; S, 4.37%.

Boc–Tyr–Arg(Tos)–Gly–Ile–Ser–OMe (VI). Compound V (14.7 g, 20.0 mmol) was dissolved in MeOH (350 ml) and hydrogenated over 5% palladium–charcoal catalyst under atmospheric pressure. The catalyst was filtered off and the filtrate was concentrated to a foaming residue *in vacuo*. Boc–Tyr–N_2H_3[15] (6.5 g, 22.0 mmol) was dissolved in DMF (80 ml). The solution was cooled below −20 °C in a cold bath and mixed with 4.74 M HCl in dioxane (21.6 ml) and then isopentyl nitrite (3.6 ml). The solution was stirred at the same temperature for 45 min and mixed with a solution of the foaming residue in DMF (20 ml) as described above and then with TEA (14.5 ml). The mixture was stirred at 0 °C for 5 days. The precipitate was then filtered off and the filtrate was concentrated to a small volume under reduced

pressure. The remaining solution was diluted with AcOEt, and washed successively with 0.4 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4 and then concentrated to a foaming residue under reduced pressure, the residue being solidified in a mixture of EtOH, AcOEt, and hexane. The crude material was repeatedly crystallized from a mixture of EtOH, AcOEt, and ether, and then a mixture of CH_3CN, AcOEt, and ether; wt 13.7 g (77.8%), mp 138 °C (sintered) and 142 °C (melted), $[\alpha]_D^{18}$ −4.8° (*c* 1.2, DMF). Amino acid ratio in the acid hydrolysate: Tyr, 0.99 (1); Arg, 0.96 (1); Gly, 1.00 (1); Ile, 0.96 (1); Ser, 0.91 (1).

Found: C, 53.38; H, 6.72; N, 12.52; S, 3.81%. Calcd for $C_{39}H_{58}O_{12}N_8S \cdot H_2O$: C, 53.17; H, 6.86; N, 12.72; S, 3.64%.

Boc-Asn-Trp-OMe (VII). H-Trp-OMe·HCl (22.8 g, 89.4 mmol) was dissolved in DMF (150 ml) and mixed with TEA (12.6 ml). Boc-Asn-ONp[16] (28.2 g, 79.9 mmol) was added to the solution which was stirred at room temperature for a day and then concentrated to a syrup *in vacuo*. The syrup was dissolved in AcOEt and washed successively with 5% aqueous $NaHCO_3$, 0.5 M HCl, and H_2O. The washed solution was dried over Na_2SO_4 with active charcoal, and then concentrated to a solid *in vacuo*. The solid was dissolved in a mixture of EtOH and AcOEt and crystallized by adding hexane. The crude material was recrystallized from the same solvent mixture; wt 30.2 g (86.5%), mp 132—133 °C, $[\alpha]_D^{24}$ +14.3° (*c* 1.0, DMF).

Found: C, 57.75; H, 6.53; N, 13.00%. Calcd for $C_{21}H_{28}O_6N_4 \cdot 1/4H_2O$: C, 57.72; H, 6.57; N, 12.82%.

Boc-Asn-Trp-N_2H_3 (VIII). Compound VII (30.2 g, 69.1 mmol) was dissolved in MeOH (350 ml) and cooled to 0 °C in an ice-bath. Then 90% hydrazine hydrate (100 ml) was added to the chilled solution. The solution was stirred at room temperature for 2 h, and concentrated to an oil *in vacuo*. The oil was triturated with cold water, and washed thoroughly with water. The crude product was crystallized from EtOH, ether, and hexane; wt 26.6 g (88.4%), mp 151—153 °C, $[\alpha]_D^{24}$ −24.6° (*c* 1.0, DMF).

Found: C, 55.09; H, 6.64; N, 18.93%. Calcd for $C_{20}H_{28}O_5N_6 \cdot 1/4H_2O$: C, 54.97; H, 6.58; N, 19.23%.

Boc-Asn-Trp-Met-OMe (IX). Compound VIII (21.6 g, 49.4 mmol) was dissolved in DMF (120 ml) and cooled below −20 °C in a cold bath and mixed with 4.74 M HCl in dioxane (33 ml) and then isopentyl nitrite (7.5 ml). The solution was stirred at −20 °C for 45 min, and then mixed with H-Met-OMe·HCl (12.0 g, 60.0 mmol) and TEA (30.4 ml) below −20 °C and stirred at 0 °C for a day. The precipitate was filtered off and the filtrate was concentrated to a small volume under reduced pressure. The remaining solution was diluted with AcOEt and washed successively with 0.3 M HCl, 5% aqueous $NaHCO_3$ and H_2O. The washed solution was dried over Na_2SO_4 with active charcoal. The dried solution was concentrated under reduced pressure to a solid, which was crystallized from AcOEt, EtOH, and hexane. The crude material was recrystallized from EtOH, hexane, and ether; wt 21.9 g (77.9%), mp 140—144 °C, $[\alpha]_D^{14}$ −39.0° (*c* 1.0, DMF).

Found: C, 54.99; H, 6.70; N, 12.29; S, 5.95%. Calcd for $C_{26}H_{37}O_7N_5S \cdot 1/4H_2O$: C, 54.96; H, 6.65; N, 12.33; S, 5.64%.

Boc-Ala-Asn-Trp-Met-OMe (X). Compound IX (16.9 g, 29.8 mmol) was mixed with 98% formic acid in an ice-bath, and the mixture was kept at room temperature overnight. The clear solution obtained was evaporated *in vacuo* and the residue was mixed with 2.5 M HCl in AcOEt under cooling. The mixture was concentrated to dryness *in vacuo*, and then triturated with ether. The powder was filtered and dried *in vacuo*. The dried powder was dissolved in DMF (60 ml) and mixed with TEA (4.2 ml) and Boc-Ala-ONSu[10] (9.5 g, 33.2 mmol). The mixture was stirred at room temperature for 2 days, and then concentrated to a syrupy residue *in vacuo*. The residue was dissolved in AcOEt and washed successively with 0.4 M HCl, 5% aqueous $NaHCO_3$, and H_2O. The washed solution was dried over Na_2SO_4, and concentrated *in vacuo* to a syrup, which was triturated in a mixture of AcOEt, EtOH, and hexane. The crude product was repeatedly crystallized from CH_3CN and ether; wt 15.8 g (83.2%), mp 134—136 °C, $[\alpha]_D^{24}$ −44.8° (*c* 1.0, DMF).

Found: C, 54.52; H, 6.72; N, 12.96; S, 5.07%. Calcd for $C_{29}H_{42}O_8N_6S \cdot 1/4H_2O$: C, 54.48; H, 6.70; N, 13.15; S, 5.02%.

Boc-Leu-Ala-Asn-Trp-Met-OMe (XI). Compound X (12.7 g, 19.9 mmol) was mixed with 98% formic acid (40 ml) containing mercaptoacetic acid (4 ml) under cooling, and the mixture was left to stand at room temperature overnight. The solvent was evaporated under reduced pressure, and the residue was mixed with 2.5 M HCl in AcOEt (20 ml) under cooling. The mixture was concentrated under reduced pressure to a solid, which was collected with ether. The solid was dissolved in DMF (50 ml) and mixed with TEA (2.8 ml) and Boc-Leu-ONSu[10] (7.2 g, 22.0 mmol). The mixture was stirred at room temperature for 6 days, and then concentrated to a syrup *in vacuo*. The syrup was dissolved in AcOEt containing a small amount of EtOH. The solution was washed successively with 0.3 M HCl, 5% aqueous $NaHCO_3$, and H_2O. The washed solution was dried over Na_2SO_4 and concentrated *in vacuo* to a syrup, which was crystallized from EtOH and hexane. The crude product was recrystallized from CH_3CN and ether; wt 8.0 g (53.3%), mp 173—175 °C. The material thus obtained was further purified by chromatography on silica gel, using a solvent mixture of $CHCl_3$ and MeOH (v/v, 5/1); wt 6.6 g (44.0%), mp 174—176 °C, $[\alpha]_D^{24}$ −41.0° (*c* 1.0, DMF). Amino acid ratio in the acid hydrolysate: Leu, 0.99 (1); Ala, 1.00 (1); Asp, 0.48 (1); Trp, not determined (1); Met, 0.56 (1).

Found: C, 55.87; H, 7.15; N, 12.57; S, 4.38%. Calcd for $C_{35}H_{53}O_9N_7S \cdot 1/4H_2O$: C, 55.87; H, 7.17; N, 13.03; S, 4.26%.

Boc-Tyr-Arg(Tos)-Gly-Ile-Ser-N_2H_3 (XII). Compound VI (25.9 g, 29.4 mmol) was dissolved in EtOH (250 ml) by gentle heating. The solution was cooled to 0 °C in an ice-bath and mixed with 90% hydrazine hydrate (70 ml). The mixture was stirred at room temperature for a day, and then concentrated and flashed repeatedly with benzene. The resulting solid was filtered with a mixture of AcOEt and EtOH. The solid was crystallized from DMF, EtOH, and ether; wt 23.8 g (92.0%), mp 156—158 °C, $[\alpha]_D^{18}$ −7.2° (*c* 1.1, DMF).

Found: C, 51.78; H, 6.95; N, 15.64; S, 3.70%. Calcd for $C_{38}H_{58}O_{11}N_{10}S \cdot H_2O$: C, 51.85; H, 6.87; N, 15.90; S, 3.63%.

Boc-Tyr-Arg(Tos)-Gly-Ile-Ser-Leu-Ala-Asn-Trp-Met-OMe (XIII). Compound XI (4.75 g, 6.31 mmol) was dissolved in 98% formic acid (60 ml) containing mercaptoacetic acid (0.5 ml). The solution was stirred at room temperature for 3.5 h, and then concentrated to a syrupy residue *in vacuo*. The residue was mixed for 1 min with 4 M HCl in dioxane (1.5 ml) under cooling and concentrated *in vacuo* to a syrup, which was triturated in ether. The powder was dried over NaOH *in vacuo*. Compound XII (3.74 g, 4.25 mmol) was dissolved in DMF (20 ml). The solution was cooled below −20 °C in a cold bath and mixed with 4 M HCl in dioxane (7 ml) and isopentyl nitrite (0.78 ml). The solution was stirred at the same temperature for 30 min and then mixed with the powder described above in dimethyl sulfoxide (15 ml), and *N*-methylmorpholine (4.0 ml), and stirred at 0 °C for

7 days. The precipitate formed was filtered off, and the filtrate was concentrated to a small volume under reduced pressure. The residual solution was poured into ice–water, and the precipitate formed was filtered, washed thoroughly with H_2O and dried over P_2O_5 *in vacuo*. The crude material was dissolved in a mixture of MeOH (300 ml) and $CHCl_3$ (200 ml), and insoluble material was filtered off. The filtrate was concentrated *in vacuo* to a residue, which was boiled in a mixture of MeOH (100 ml) and AcOEt (300 ml) and mixed with ether under cooling. The precipitated material was boiled in a mixture of CH_3CN (100 ml) and MeOH (20 ml), and reprecipitated with ether under cooling; wt 3.70 g (57.5%), mp 228—230 °C, $[\alpha]_D^{26}$ −21.2° (*c* 1.0, DMF). Amino acid ratio in the acid hydrolysate: Tyr, 0.95 (1); Arg, 1.08 (1); Gly, 1.01 (1); Ile, 0.93 (1); Ser, 0.83 (1); Leu 0.90 (1); Ala, 1.00 (1); Asp, 0.55 (1); Trp, 0.62 (1); Met, 0.66 (1).

Found: C, 53.84; H, 6.73; N, 13.71; S, 4.40%. Calcd for $C_{68}H_{99}O_{18}N_{15}S_2 \cdot 2H_2O$: C, 53.92; H, 6.85; N, 13.87; S, 4.23%.

Boc–Met–Asp(OBu^t)–Gly–Tyr–Arg(Tos)–Gly–Ile–Ser–Leu–Ala–Asn–Trp–Met–OMe (XIV). Compound II (2.70 g, 4.10 mmol) was suspended in AcOEt (150 ml), and washed with 1 M H_2SO_4 and then H_2O. The washed solution was dried over Na_2SO_4, and then concentrated to an oily material under reduced pressure. The oil was dissolved in a mixture of AcOEt (50 ml) and dioxane (30 ml). The solution was cooled to 0 °C in an ice bath, and mixed with HONSu (0.52 g, 4.5 mmol) and DCC (0.93 g, 4.5 mmol). The mixture was stirred at room temperature for a day. The precipitate formed was filtered off and the filtrate was concentrated to an oily material *in vacuo*.

Compound XIII (3.70 g, 2.44 mmol) was dissolved in 98% formic acid (50 ml). The solution was stirred at room temperature for 3 h and then concentrated to a residue *in vacuo*. The residue was stirred with 2.5 M HCl in AcOEt (5 ml) for 1 min in an ice bath, and then concentrated *in vacuo* to a syrup, which was solidified in ether and dried over NaOH under reduced pressure. The dried material was dissolved in a mixture of dimethyl sulfoxide (10 ml) and DMF (5 ml) with TEA (0.35 ml). The solution was mixed with the oily substance obtained as described above from compound II in DMF (5 ml). The mixture was stirred at room temperature for 4 days and then concentrated to a syrup *in vacuo*. The syrup was triturated in a mixture of AcOEt and ether, and the crude product was crystallized from MeOH. The crystallized material was repeatedly precipitated from a mixture of DMF and ether; wt 3.30 g (72.2%), mp 203 °C, $[\alpha]_D^{24}$ −28.1° (*c* 1.0, DMF). Amino acid ratio in the acid hydrolysate: Met, 1.33 (2); Asp, 1.54 (2); Gly, 1.88 (2); Tyr, 0.99 (1); Arg, 0.98 (1); Ile, 0.99 (1); Ser, 0.85 (1); Leu, 0.99 (1); Ala, 1.00 (1); Trp, not determined.

Found: C, 52.91; H, 6.83; N, 13.31; S, 4.80%. Calcd for $C_{83}H_{123}O_{23}N_{18}S_3 \cdot 2H_2O$: C, 53.19; H, 6.88; N, 13.45; S, 5.13%.

Restricted Rotation Involving the Tetrahedral Carbon. XXV. Barriers to Exchange between *dl* and *meso* Forms of 9-(Arylmethyl)triptycenes[1]

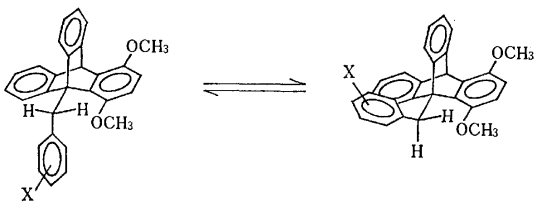
Motomichi KONO, Hiroshi KIHARA, Nobuo NAKAMURA, Fumio SUZUKI, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received November 17, 1978)

Barriers to exchange between *dl* and *meso* forms *via* rotation about the C_9–C_{subst} bond of 9-(arylmethyl)-1,4-dimethoxytriptycenes are obtained by the use of the methoxyl signals in the ^1H NMR spectra. It is found that, although the population ratios are affected by the substituent in the 9 position, the enthalpy of activation for the rotation is almost invariant at *ca.* 10 kcal/mol.

9-Substituted triptycenes constitute a unique system in that unusually high barriers are observed for rotation about the C_9–C_{subst} bond.[2] Thus freezing the rotation of even methyl groups on the NMR time scale has been realized[3] and stable rotational isomers isolated at room temperature.[4] Whereas barriers to rotation about the C_9–C_{subst} bond are known in the cases where the substituent is a tertiary alkyl,[5] an isopropyl,[6] or a methyl group,[3] barriers to rotation about the C_9–CH_2 bond have not been known except for one case, 9-(chloromethyl)triptycene, where signals due to ring protons[7] and ring carbons[8] have been used for the analysis.



dl-form *meso*-form

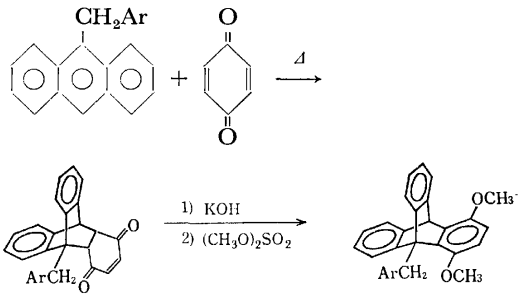
(1)

9-Benzyltriptycenes are interesting in that there is an attractive interaction between the 9-benzyl group and the benzo group of the triptycene skeleton:[9] the *dl* forms are unusually favored if there is an electron-attracting substituent in the benzyl group and the benzo group has a group of low ionization potential. The interaction should affect the enthalpy of activation for rotation if other conditions are the same. This paper describes the reinvestigation of the population ratios of the *dl* and the *meso* forms of 9-(arylmethyl)-1,4-dimethoxytriptycenes (**1**) using the FT NMR technique to obtain better data and the study of the barrier to exchange between the *dl* and the *meso* forms by internal rotation using the line shapes of the methoxyl signals in ^1H NMR spectra.

Experimental

Syntheses of Triptycenes. The substituted benzyltriptycenes were prepared by the Diels-Alder reaction between the corresponding 9-benzylanthracenes (**2**) and *p*-benzoquinone followed by enolization and methylation.

9-(m-Nitrobenzyl)anthracene. *m*-Nitrobenzylideneanthrone[10] (3 g) was heated under reflux with 10 ml of ethanol and 3 ml of water and 3 g of sodium borohydride was



(**1**)

added in small portions. The mixture was heated for 1 h and cooled. The insoluble material was removed by filtration and the mother liquor was concentrated. The residue was taken up in 200 ml of carbon tetrachloride and the solution was heated for 2 h with 20 g of phosphorus pentaoxide. The solution was decanted and evaporated. The residue was chromatographed on silica gel, using benzene as an eluent. The desired product was obtained in 70% yield and used directly for subsequent reactions.

9-(Arylmethyl)-1,4-dimethoxytriptycenes. These compounds were prepared by the following general procedure. The compounds were known unless otherwise stated and their physical properties agreed well with those reported.

A solution of 1.3 g (0.005 mol) of 9-benzylanthracene and 1.1 g (0.01 mol) of *p*-benzoquinone in 20 ml of acetonitrile was refluxed for 24 h and evaporated. The residue was chromatographed on silica gel and eluted with benzene–chloroform (10: 1). An adduct was obtained in over 90% yield. To a solution of the adduct (0.6 g) in 20 ml of dioxane was added 20 ml of 1 M aqueous potassium hydroxide in 10 min and the mixture was treated with 5 ml of dimethyl sulfate in small portions. The potassium hydroxide solution was added in small portions to the mixture until the addition caused no color change. After 10 min stirring, the precipitate was collected and purified by alumina chromatography using hexane–benzene (4: 1) as an eluent. The yield was over 90%.

1,4-Dimethoxy-9-(p-methylbenzyl)triptycene: Mp 223—224 °C. Found: C, 85.94; H, 6.25%. Calcd for $C_{30}H_{26}O_2$: C, 86.09; H, 6.26%. ^1H NMR ($CDCl_3$) δ=2.28 (CH_3), 3.21 (CH_3O), 3.80 (CH_3O), 4.64 (CH_2), 5.95 (bridgehead), 6.47 (AB quartet for dimethoxybenzo H's, J_{AB}=9.0 Hz, $\Delta\nu_{AB}$=6.3 Hz), 6.8—7.5 (aromatic H's).

1,4-Dimethoxy-9-(m-nitrobenzyl)triptycene: Mp 301—305 °C (dec). Found: C, 77.34; H, 4.95; N, 3.10%. Calcd for $C_{29}H_{23}NO_4$: C, 77.48; H, 5.16; N, 3.12%. ^1H NMR ($CDCl_3$–CS_2, integrated for 70 times) δ=3.19 (CH_3O), 3.85 (CH_3O), 4.70 (CH_2), 5.92 (bridgehead), 6.48 (AB quartet for dimethoxybenzo H's, J_{AB}=9.0 Hz, $\Delta\nu_{AB}$=11.0 Hz),

6.8—7.6 (aromatic H's).

^1H NMR Spectra. The spectra were obtained on a JEOL FX60 spectrometer equipped with FT facilities. The solvent was a 3:1 mixture of chloroform and carbon disulfide and sample tubes were of 10 mm diameter. In one case dichloromethane-d_2 was used as a solvent. The temperature was read by a thermocouple directly dipped into the mixed solvent placed in the probe. The error in reading the temperature was ± 0.6 °C. Pulses of 20 μs duration was used with 5 s intervals. The data were accumulated *ca.* 40 times except for the *m*-nitro derivative which required 400 time accumulation.

Total Line Shape Analysis. It was performed with the use of a modified Binsch program,[11] treating the spectra as a pair of uncoupled A⇄B exchanges. Populations were obtained as described in Results and Discussion and the rate constant (k_1) of the *meso*→*d* (or *l*) process was varied in the calculation, the rate constant (k_{-1}) of the reverse process being put outside of the consideration. Since there are two identical processes transforming the *meso* to the *dl* form, $2k_1[meso]=k_{-1}[d \text{ and } l]$ is obtained: namely $K(dl/meso)=2k_1/k_{-1}$. Thus the rate obtained by the computer simulation was divided by 2 to obtain k_1. Chemical shift differences were used as observed. T_2 was calculated from the half band width of the tetramethylsilane signal added as an internal standard.

The signal due to the 4-methoxyl group was always included in the calculation. *p*-Chloro and *m*-nitro compounds gave excellent results by this method. The presence of the *p*-methoxyl group in the *p*-methoxybenzyl compound gave a strong drawback to this method. Thus the line shape analysis was performed only at the higher field. The spectra of the *p*-methylbenzyl and the benzyl compounds were analyzed similarly. The calculated spectra were compared with the observed and the best fit spectra were chosen by visual fitting. The agreement between the observed and the calculated spectra was excellent.

Results and Discussion

Assignment of the Spectra. Fig. 1 shows ^1H NMR spectra of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene at three temperatures. Apparently the methoxyl and the methylene signals broaden on lowering the temperature. The latter splits into a quartet signal and a singlet. Assignments of the spectral peaks of the methylene part is straightforward: a quartet is due to the *dl* form and a singlet the *meso* form (see Newman projections). The former has two singlets which split into two large singlets and a small singlet at the lower temperature. The former two singlets are assigned to the *dl* forms and the latter to the *meso* form from the intensity considerations. The methoxyl groups of the *dl* form in 1- and 4-positions suffer from a large difference in magnetic environment because of the presence of the benzylic phenyl group in the proximity of the 1-position: the signal at the higher field is thus assigned to the 1-methoxyl group. In contrast, the two methoxyl groups of the meso form seem to be in similar magnetic environments.

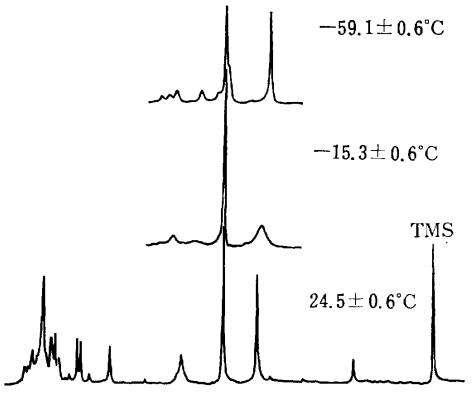


Fig. 1. ^1H NMR spectra of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene at three temperatures.

The aromatic region of the *p*-chloro compound showed temperature dependence in its spectrum but the change was too complicated to analyze.

Other compounds showed similar behavior in the ^1H NMR spectra at various temperatures. The assignments were performed similarly.

Populations of Rotamers. In principle, it should be possible to obtain population ratios at various temperatures by calculation, because the ratios can be used as variants in the total line shape analysis. In practice, however, it will add another uncertainty in the simulation. It was also hoped to reduce the number of parameters in simulations of the line shapes of the methylene part.[12] Thus we decided to obtain the ratios from other sources.

There are two signal pairs to be used for the population analysis. The methylene signals appear as an AB quartet and a singlet. Integration of these signals should produce the population ratio at a given temperature. However, in practice, there are some overlaps in the down-field part of the AB signal with that of the *meso* and in the up-field part of the AB signal with that of the methoxyl signal. The signal due to the methoxyl groups of the *meso* form heavily overlaps with that due to the 4-methoxyl of the *dl* form in the down-field. Thus integration of the methoxyl signals is less hopeful.

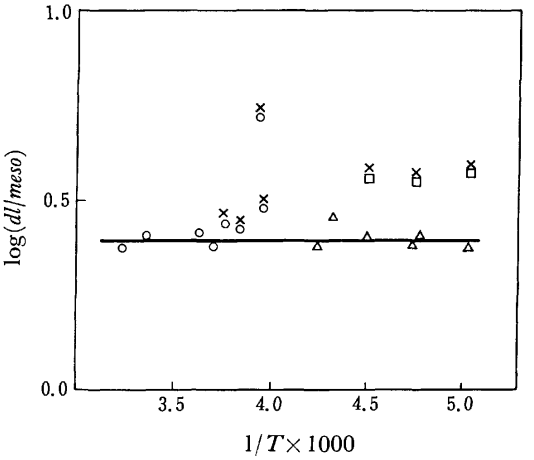

Fig. 2. Population ratios (*dl*/*meso*) of 9-(*p*-methylbenzyl)-1,4-dimethoxytriptycene at various temperatures: □ by integration of the methylene region, △ by integration of the methoxyl region, ○ by the drift in the chemical shift of the methoxyl signal after coalescence. Those with cross marks are rejected in drawing the straight line. See text for the reasons.

Table 1. Equilibrium constants and thermodynamic parameters pertaining to rotamers of 9-arylmethyl-1,4-dimethoxytriptycenes

Aryl	Representative K's (*dl*/*meso*) (Obsd)		$-\Delta H$ (kcal/mol)	ΔS (e.u.)
	−20 °C	−50 °C		
p-$CH_3OC_6H_4$	2.7±0.2	3.0±0.2	0.32±0.02	−1.5±0.5
p-$CH_3C_6H_4$	2.5±0.2	2.5±0.2	0.05±0.01	−1.1±0.2
C_6H_5	2.8±0.2	2.8±0.2	0.57±0.03	+0.3±0.1
p-ClC_6H_4	4.1±0.2	4.5±0.2	0.44±0.06	−1.6±0.1
m-$NO_2C_6H_4$	4.4±0.2	4.9±0.2	0.36±0.12	−0.7±0.1

To avoid these uncertainties, we decided to use the cross-check method of using both the methylene and the methoxyl signals. For the latter, both the integrated intensities and the chemical shift drift at temperatures higher than the coalescence were used. The results are shown in Fig. 2, taking the case of the *p*-methylbenzyl compound as an example. As is seen in the figure, the chemical shift method gives apparently absurd values at temperatures close to the coalescence, which are rejected as the unreliable. Those data obtained by integration of the AB signals were found to give apparently larger values in the cases where the population of the *meso* form was large. Therefore these were also abandoned in the least squares treatment.

The equilibrium constants and thermodynamic parameters thus obtained are tabulated in Table 1. The equilibrium data are in general accordance with those reported,[9] but we take the values reported here to be more reliable because of the better S/N ratios relative to the previously reported. The results confirm that the *dl* form is stabilized relative to the *meso* form and the stabilization is enhanced when the benzyl part carries an electronegative substituent.

Barriers to Exchange between the dl *and the* meso *Forms.* There are 6 rotational processes as depicted in Fig. 3. However, since we are looking at the signals due to the *dl* forms as a package, we can neglect the $d \rightleftharpoons l$ processes. Thus there remain 4 processes of which *meso*→*d* and *meso*→*l* are identical and so are the reverse processes, because *d* and *l* forms are not distinguishable.

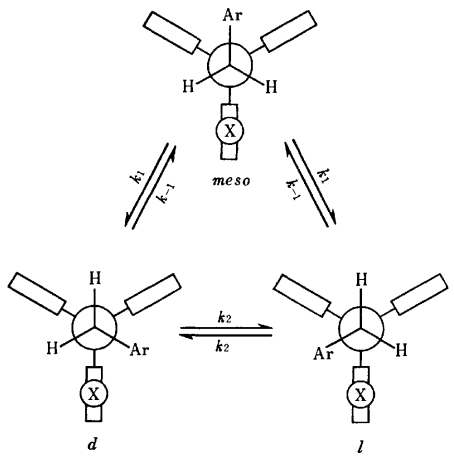

Fig. 3. Processes of mutual exchanges among *meso*, *d*, and *l* forms.

For the *m*-nitro compound, it is possible to take two conformations for the *meso* and the *dl* forms with respect to the nitrophenyl group, although that phenyl group will assume the conformation in which the π-system bisects the H–C–H angle of the α-methylene group.[9] They are NO_2-inside and NO_2-outside conformations. However, these species were not distinguishable by the present technique. We tentatively assume that the average processes are observed, although it is likely that the NO_2-inside conformations are unstable and we are observing processes which involve the NO_2-outside conformations.

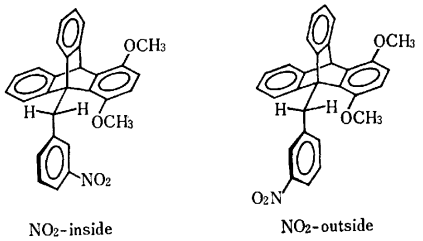

Fig. 4. NO_2-inside and NO_2-outside conformations of a *d* (or *l*) form.

Fig. 5. Computed and observed spectra of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene at various temperatures.

In Fig. 5 the results of computer simulation of the line shapes of the *p*-chloro compound are shown with the rate constants and compared with the observed spectra. These results were put into the Eyring's plot and excellent linear relationships were obtained. From the slopes and the intercepts, the activation parameters were obtained as shown in Table 2.

It is interesting to note that the ground state stabilities seen in the equilibrium constants K(*dl*/*meso*) is

Table 2. Activation parameters for the exchange between the *meso* and the *dl* forms of 9-arylmethyl-1,4-dimethoxytriptycenes in $CDCl_3$–CS_2 (3: 1)

not reflected in the $\Delta H^{\neq}$'s. All the compounds examined show almost the same $\Delta H^{\neq}$'s irrespective to the substituent. Since the ground state stability of the compounds with electronegative substituents is ascribable to the charge transfer interaction, it should be reflected in the $\Delta H^{\neq}$'s, if the other factors are the same. Although we must carefully discuss the entropy of activation derived by the total line shape analysis,[13] it is tempting to consider that in the transition state of rotation the *m*-nitro compound suffers from the decrease in entropy probably due to change in solvation which counterbalances the enthalpy factor in the ground state.

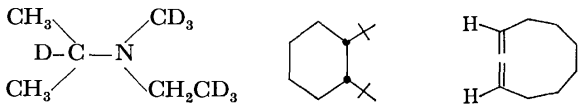
Restricted Rotation Involving the Tetrahedral Carbon. XXVI. Certainties and Uncertainties Involved in the Rates of Exchange among Three Sites as Obtained by Total Line Shape Analyses of ^{1}H NMR Spectra: The Case of Methylene Signals[1]

Michinori Ōki,* Motomichi Kono, Hiroshi Kihara, and Nobuo Nakamura
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113
(Received November 17, 1978)

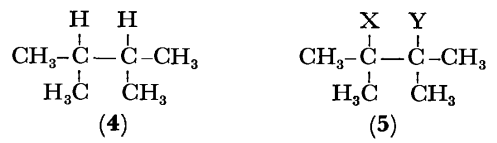
Benzyl methylene signals, which split into an AB quartet and a singlet and show temperature dependence, are obtained at various temperatures and are simulated with the use of two independent rates of rotation. Certain limitations of accuracy are found in this method. The uncertainty becomes less if additional data are provided from other sources, but never becomes negligible. Contribution of the slower process is found difficult to detect especially when the population involved in the process are the less.

The total line shape analysis of the NMR spectra is becoming increasingly popular due to the widespread utilization of high-speed computers and availability of the computing program.[2] The method furnishes the rate constants of 10^{-1}—10^5 s^{-1} easily and the data are favorably compared[3] with those obtained by other methods, when the exchanging sites are two, although there is a warning that the entropy of activation thus obtained may include a considerable error.[4]

As to the exchanging sites of more than two, there are some scattered reports which claim the rates of different processes are separately obtained. A typical example is a combination of internal rotation about the C-N bond and inversion with respect to the nitrogen atom of amines. Bushweller *et al.* succeeded in separating the two processes in a deuterated *N*-ethyl-*N*-methylisopropylamine (**1**) and obtained the rates of the respective process.[5] This method takes advantage of the fact that the rates of the two processes are so much different that the coalescence phenomena are found at two temperatures. The classical example of the carbon skeleton in this type of exchange was reported by Kessler *et al.* on *cis*-1,2-di-*t*-butylcyclohexane (**2**) in which rotation about the C_1–C_2 bond and ring inversion are observed at different temperatures.[6] A recent report by Anet and coworkers[7] on a 1,2-cyclononadiene (**3**) also falls into this category.



(**1**) (**2**) (**3**)



(**4**) (**5**)

Reports from this laboratory made use of the fact that *d* and *l* isomers are not distinguishable by ^{1}H NMR spectroscopy and treated many ethane derivatives, as if there were only two sites exchanging, although there are actually three sites.[8a] The use of ^{13}C NMR in the rate analysis of internal rotation[8b] also falls in this category. This type of treatment seems to be convenient when one barrier is high relative to others. Thus Lunazzi *et al.* treated the ^{13}C NMR spectra of 2,3-dimethylbutane (**4**) in this manner and good agreement between the observed and the calculated spectra was obtained.[9] By *ab initio* calculation barrier to gauche-to-gauche transformation is found to be *ca.* 8 kcal/mol, whereas the line shape analysis (4.3 kcal/mol) and *ab initio* calculation (4.6 kcal/mol) afforded barriers to gauche-to-trans transformation which are in good accordance. Bushweller *et al.* performed also total line shape analysis on 2,3-dimethylbutane derivatives (**5**) by assuming that the gauche-to-gauche barrier is high and the agreement between the observed and the calculated spectra was good.[10] The rotation of gauche-to-gauche seems to contribute little to the whole process.

The above cited cases are not general, of course. In the rotamer exchange, the barriers to rotation of gauche-to-gauche and gauche-to-trans are in general close to each other. Namely two processes of rotation compete in the general case. Then a question arises: to what extent can we rely upon the total line shape analysis in obtaining rate data when more than two independent processes are competing? To answer this question we have analyzed the line shape of benzyl methylene protons of 9-benzyltriptycenes (**6**) which exist as a mixture of *meso*, *d*, and *l* isomers, by taking all the processes

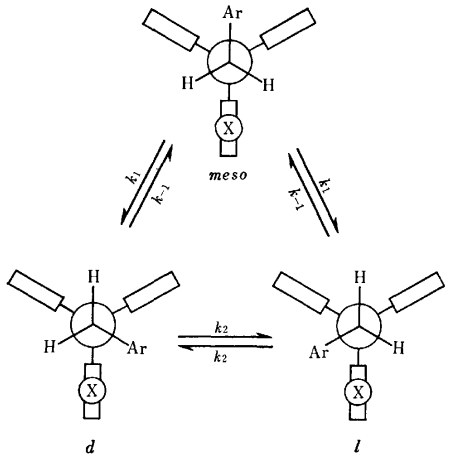


Fig. 1. Exchanging conformers and exchange processes.

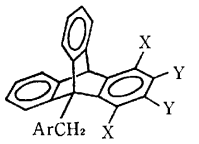

(6)

into consideration. In this case three back-and-forth processes are possible, but, due to the presence of a pair of enantiomers, the number of rate constants converges to three: k_1, k_{-1}, and k_2, as shown in Fig. 1.

In this paper we describe the results of the total line shape analysis and discuss uncertainties associated with the calculation.

Experimental and Data Processing

Materials. The syntheses of 9-arylmethyl-1,4-dimethoxytriptycene and 9-(*p*-chlorobenzyl)-1,2,3,4-tetrachlorotriptycene used in this study have been reported elsewhere.[1,11]

Measurement. The spectral measurement was performed on a JEOL FX 60 spectrometer equipped with FT facilities. The conditions of the measurements were the same as described in a previous paper.[1]

Total Line Shape Analysis. The benzyl methylene signals consisted of an AB quartet and a singlet due to the *dl* and the *meso* forms, respectively. The system was treated as the exchange of AB-BA-C_2 by the modified Binsch program.[12] The chemical shift difference and the coupling constant are used as observed. T_2 was calculated from the line width of TMS added as an internal standard. Population ratios derived in the previous paper were used for the calculation except for 9-(*p*-chlorobenzyl)-1,2,3,4-tetrachlorotriptycene, with which determination of the population ratio was straightforward because clear AB quartet and C_2 signals were observed owing to the absence of the methoxyl signals which prevented the accurate determination in the other compounds. Other pertinent considerations are described in the previous paper.

Results and Discussion

General Consideration. As a starting point, we discuss the limitation of the usefulness of the total line shape analysis. Shown in Fig. 2 are the computed spectra of various relative rates of the two processes using the chemical shift differences and the coupling constant of 9-benzyl-1,4-dimethoxytriptycene. The

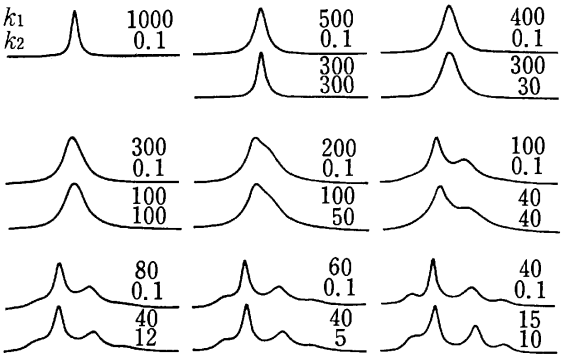

Fig. 2. Computed spectra with the use of various k_1's and k_2's taking other necessary data from those of 9-benzyl-1,4-dimethoxytriptycene.

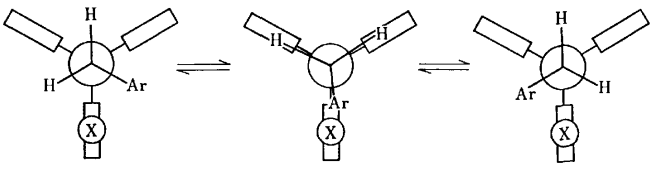
variables are limited to two because k_1 and k_{-1} are related by the equilibrium constant: $K(dl/meso)=2k_1/k_{-1}$. In our cases the population ratios are available from the integrated intensities and/or the chemical shifts as discussed in the previous paper.[1] We stick to the two independent variables because, although it is possible to obtain k_1 and k_{-1} independently in the computation of the spectra, increasing the number of the variables will increase the uncertainty in the obtained data. The used parameters were as follows: $\Delta\nu_{AB}$ 38.33 Hz, $\Delta\nu_{AC}$ 3.395 Hz, J_{AB} 17.46 Hz, T_2 0.318 s, molar fractions of the *meso* and the *d* (or *l*) forms 0.22 and 0.39, respectively.

In the rows 1, 3, and 5, are shown the line shapes computed with a constant k_2 of 0.1 s^{-1} and various k_1's from 1000 s^{-1} to 40 s^{-1}. The line shapes seem to be determined by the main process at the level of this slow process, because changing the k_2's to 0.01 s^{-1}, while using the k_1's of the same range as above, did not produce any significant change. It may be concluded that a process, the rate constant of which is less than 1/100 of that of a main process has no effect on the line shape of the NMR spectra.

In the rows 2, 4, and 6, are shown the line shapes computed using relatively large k_2 values. As is seen from the simpler spectra, it is clear that a unique combination of two rates cannot be obtained if the spectral shape is simple (compare for example, the shape of $k_1=300$ and $k_2=0.1$ s^{-1} with that of $k_1=100$ and $k_2=100$). Thus we may better exclude one-peaked spectra from the calculation as was pointed out previously.[3] In sharp contrast, the computed spectra with a constant k_2 of 0.1 s^{-1} can differentiate the k_1's of 80, 60, and 40 s^{-1} as shown in the row 5 and the rate of a slow process may be reflected if it becomes 1/10 of that of a fast process as is shown in the bottom row. It seems that, if the spectra are complex, there is a possibility that the rates of the two processes are uniquely determined by this method. Thus we will discuss the line shapes of considerable complexity in the following text to make the discussion more reliable. Another point worthy of note is that, if we neglect a process which does exist, the apparent rate constant of the main process is obtained larger than the real: if k_2 is practically neglected by putting the value of 0.1, the top right curve is simulated by using k_1 of 400 s^{-1}, whereas the curve may actually correspond to k_1 and k_2 of 300 and 30 s^{-1}, respectively (second from top, right curve). Therefore we should take the rate constant as a maximum value even though the main process could explain the line shape completely and the minor process is negligible.

If we assume that the transition state of rotation is a fully eclipsed form, the transition state of the highest energy is the one (**7**) in which the aryl group eclipses



d (or *l*) (**7**) *l* (or *d*)

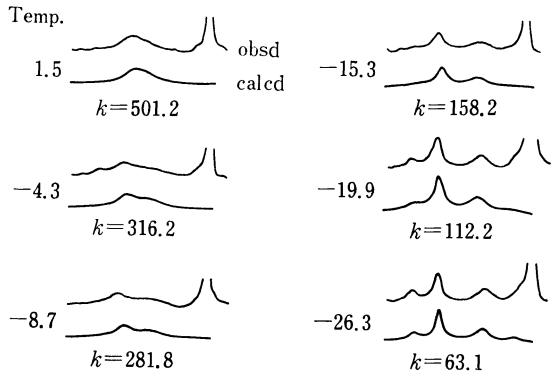


Fig. 3. Observed and calculated spectra of the methylene region of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene at various temperatures. The strong signal at the higher field corresponds to the methoxyl signal and is neglected in the computation.

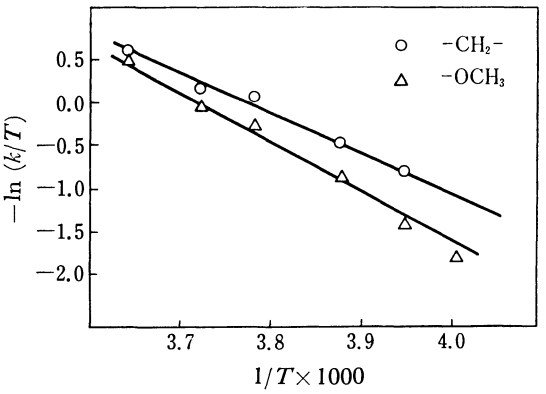

Fig. 4. Comparison of the Eyring's plots using k_1's obtained by the analysis of the methylene part and the methoxyl signals of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene.

the peri substituent. This transition state is realized when the rotation occurs from a *d* form to an *l* form or *vice versa* but never appears in the process of *meso*→*d* (or *l*). Therefore we can reasonably assume that k_1 and k_{-1} are larger than k_2.

Since the line shapes are affected by fast processes to a greater extent than slower processes, we may be able to obtain fairly good agreement between the real and the calculated rates which are obtained by neglecting the $d \rightleftarrows l$ process. Fig. 3 shows the observed spectra at the methylene and methoxyl region of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene at various temperatures and the computed spectra which were obtained by neglecting the $d \rightleftarrows l$ process and the methoxyl signal and were considered the best fit. The used parameters for computation were differences in chemical shifts of $\Delta\nu_{AB}$−40.52 Hz and $\Delta\nu_{AC}$ 2.148 Hz, coupling constant of 17.4 Hz, and T_2's and populations[1] at the respective temperatures. Fig. 4 shows the Eyring's plot using the rate constants thus obtained and compares the result with the straight line corresponding to the *meso*$\rightleftarrows$*d* (or *l*) process as obtained by the total line shape analysis of the methoxyl singnals.[1] Apparently this treatment gives higher rate values and a lower $\Delta H^{\ddagger}$, the difference amounting over 3 times of the standard deviation. Thus the results indicate that we should not overlook the process $d \rightleftarrows l$, although the rate may be small.

Aquisition of Two Independent Rate Constants by Calculation. We tried to evaluate the best k_1 and k_2 of the 9-(chlorobenzyl)-1,4-dimethoxytriptycene by using the computation only. For each spectrum, population ratio at that temperature, coupling constant, differences in chemical shifts, and T_2 are put as constants and k_1 and k_2 as variables. The rate constants are roughly changed by the scale of log *e* for the convenience of computation and an array of line shapes is made. From

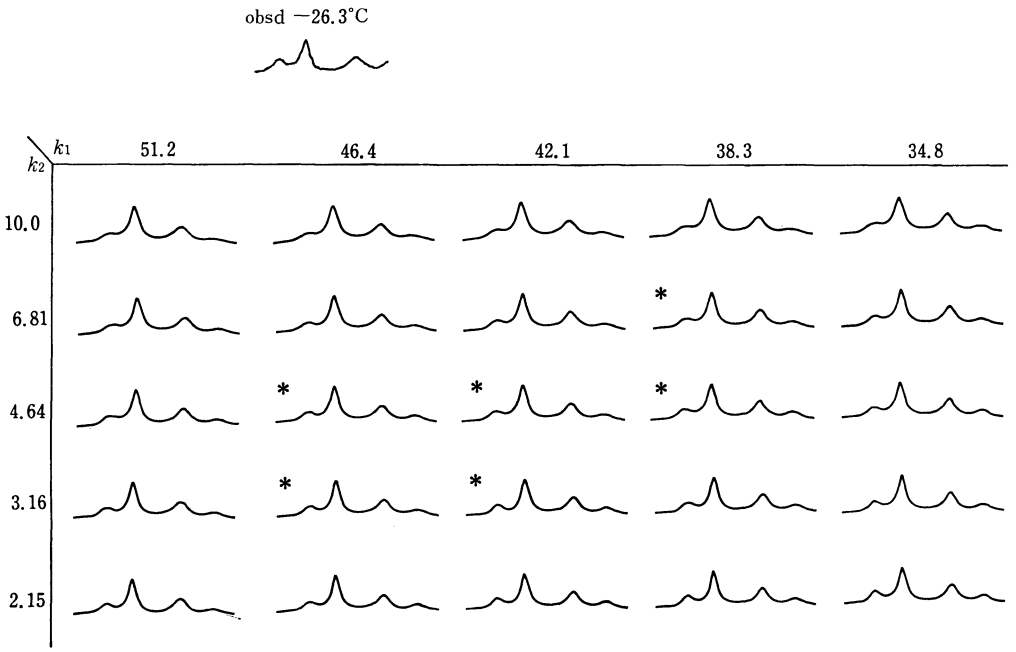

Fig. 5. Computed line shapes with various k_1's and k_2's using the data of *p*-(chlorobenzyl)-1,4-dimethoxytriptycene at −26.3 °C. Those marked with stars are the best fit spectra.

the array a seemingly best fit region is picked up and the portion is expanded with small variations in k_1 and k_2 to make a finer array. An example is shown in Fig. 5, taking the spectrum at −26.3 °C. By visual fitting, we cannot specify a single computed spectrum but can pick up 6 spectra which fit best. Thus it is possible to obtain k_1 and k_2 with certain ranges. Similarly at other temperatures, sets of 2 to 6 best fit spectra are obtained. The results are shown in Table 1.

TABLE 1. RATE CONSTANTS OBTAINED BY THE VISUAL FITTING OF THE COMPUTED SPECTRA WITH THE OBSERVED FOR 9-(*p*-CHLOROBENZYL)-1,4-DIMETHOXYTRIPTYCENE AT VARIOUS TEMPERATURES

Temperature (°C)	Rate constants (s^{-1})	
	k_1	k_2
−15.3	110—90.9	14.7—6.81
−19.9	75.0—48.6	14.7—4.64
−26.3	46.4—38.3	6.81—3.16
−31.1	21.5—19.6	6.81—4.64
−37.3	16.2—13.3	3.16—1.47

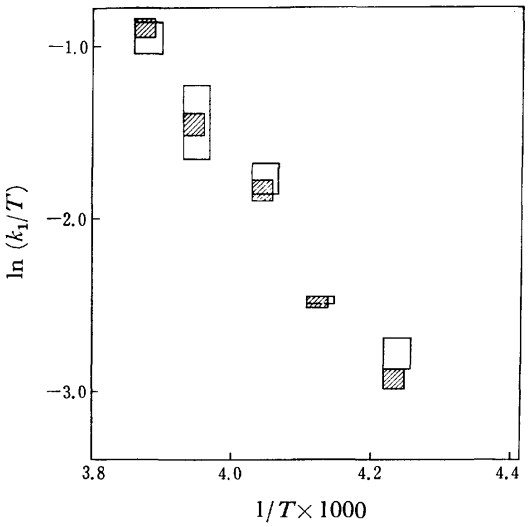

Fig. 6. Eyring's plot showing the ranges of possible errors for the process *meso*→*d*(or *l*) of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene. Open rectangles correspond to those obtained by computation only and hatched rectangles to those derived by the methoxyl signals, the temperature ranges of the latter being changed slightly for the convenience of comparison.

Figure 6 illustrates an Eyring's plot pertaining to the rate constants k_1 with probable error ranges indicated by the widths in the ordinate direction. The widths in the direction of abscissa is written by taking the error of temperature reading, which is ±0.6 °C, into consideration. Similarly Fig. 7 shows an Eyring's plot pertaining to the rate constants k_2. Although it is possible to obtain $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ as 10.2±0.6 kcal/mol and −9.6±2.3 e.u., respectively, for the process *meso*→*d* (or *l*) with a percent error of 5.6, it may contain errors derived by the ambiguity in the k_1's. It is difficult to draw a straight line in the case of k_2's.

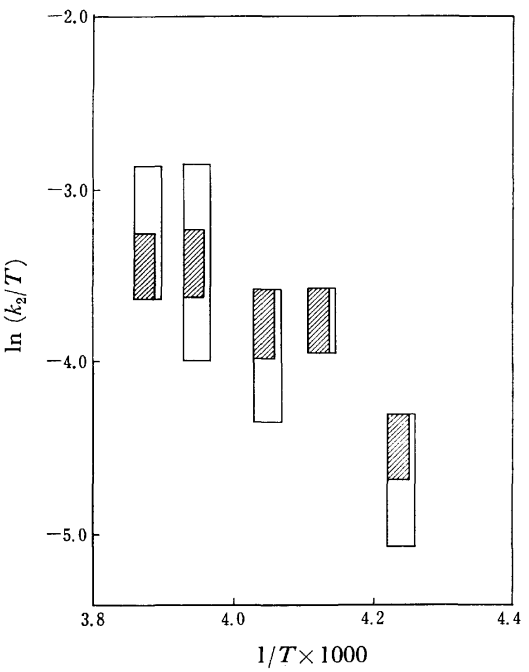

Fig. 7. Eyring's plot showing the ranges of possible errors for the process $d \rightleftharpoons l$ of 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene. Open rectangles correspond to those obtained by computation only and hatched rectangles to those derived by using k_1's obtained from the methoxyl signals. For the temperature ranges of the latter, see the caption of Fig. 6.

Barrier to the Minor Process. As pointed out in the previous paper, the rate constants k_1 may be obtained by analyzing the line shapes of the methoxyl signals. One may hope then that if we put these data to obtain the best fit spectra, we should be able to obtain k_2's of better quality. Indeed, the rate constants were obtained as follows at the temperatures where we have the methylene data, using the methoxyl signal shapes (units are s^{-1}): 106 (−15.3 °C), 59.5 (−19.9 °C), 39.8 (−26.3 °C), 19.9 (−31.1 °C), 12.6 (−37.3 °C). These data are also shown in Fig. 6, taking the error limit as ±5%, because we selected the best fit spectra by comparing the computed spectra of *ca.* 5% intervals of rates. The ranges of the k_2's can then be reduced and are shown in Fig. 7. Apparently the linear relation may not be claimed: although we can treat the data by the least squares method to draw a straight line, its percent error amounts to 20.7. Thus it is not practical to obtain the kinetic parameters for the $d \rightleftharpoons l$ process from these data.

It is noteworthy, however, that the calculated spectra suggest that k_2 is close to 1/10—2/10 of k_1. This corresponds to the difference of *ca.* 1 kcal/mol in the barriers to the two processes. Therefore we conclude that the $d \rightleftharpoons l$ process possesses a higher barrier to rotation than the *meso*→*d* (or *l*) process by *ca.* 1 kcal/mol.

The Case of 9-Benzyl-1,2,3,4-tetrachlorotriptycene. This compound is picked up as a model because it poses another problem: does lesser population have any influence on determing a rate constant? Variation of the temperature influenced the spectra of the methylene

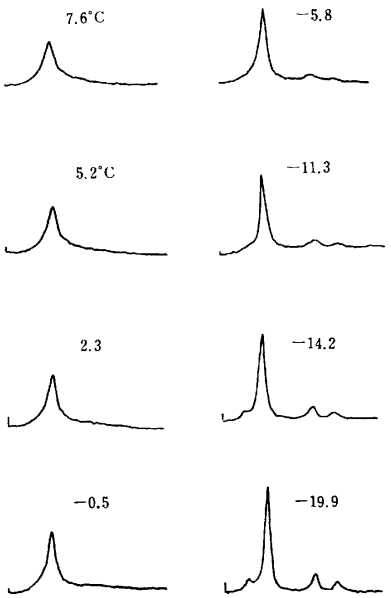

Fig. 8. Temperature dependent spectra of the methylene region of 9-benzyl-1,2,3,4-tetrachlorotriptycene.

Table 2. Populations of the *meso* and the *dl* forms and equilibrium constants of 9-benzyl-1,2,3,4-tetrachlorotriptycene at various temperatures

Temperature (°C)	Populations		K
	meso	*d* (or *l*)	(*dl*/*meso*)
7.6	0.63	0.18	0.58
5.2	0.62	0.19	0.59
2.3	0.62	0.19	0.61
−0.5	0.61	0.19	0.63
−5.8	0.60	0.20	0.66
−11.3	0.59	0.21	0.70
−14.2	0.58	0.21	0.73
−19.9	0.56	0.22	0.78

part as shown in Fig. 8. The population was *ca.* 6 to 4 (*meso*: *dl*). The temperature dependence of the population ratios was determined as shown in Table 2 and the thermodynamic parameters were obtained as follows: ΔH -2.3 ± 0.3 kcal/mol, ΔS -9.8 ± 1.4 e.u. Therefore this compound is a model which possesses less populations of which exchange corresponds to the slow process.

Typical calculated spectra are shown in Fig. 9, where the spectrum at −14.2 °C is taken as an example. Parameters used for the calculation were as follows: $\Delta\nu_{AB}$ −52.29 Hz; $\Delta\nu_{AC}$ 4.095 Hz; J_{AB} 18.6 Hz; populations, *meso* 0.58 and *d* (or *l*) 0.21. T_2's were observed at respective temperatures. As is seen in the figure, it is hardly possible to detect the effect of the slower process, although the rate constant was changed by a factor of almost 50. Thus we may be able to specify the rate constant of the faster process but not the slower one in this case: the line shapes are controlled by the faster process almost exclusively. We may obtain the rates of exchange *meso*⇌*d* (or *l*) independently by looking

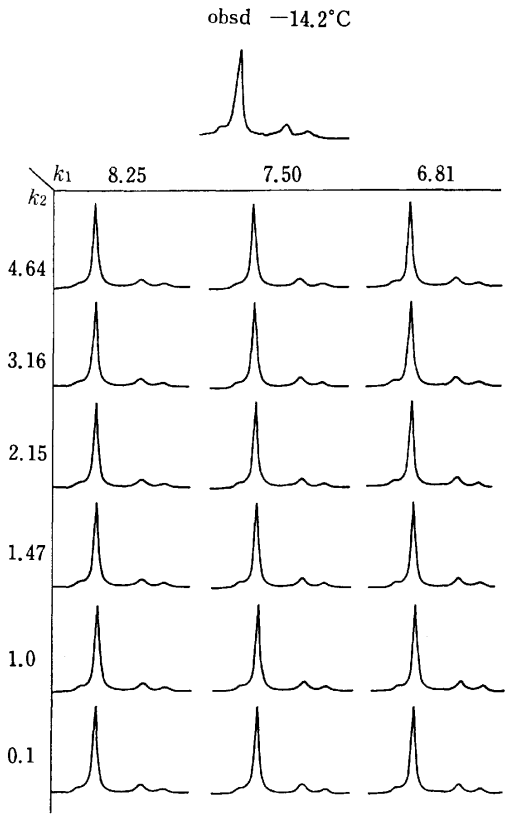

Fig. 9. Computed spectra of 9-benzyl-1,2,3,4-tetrachlorotriptycene at −14.2 °C using various k_1's and k_2's.

at the ^{13}C NMR line shape but the rates thus obtained do not help in obtaining the rates of the slower process.

The rate constants k_1's were obtained as follows (given in s^{-1}): 56.2 (7.6 °C), 46.4 (5.2 °C), 42.1 (2.3 °C), 26.1 (−0.5 °C), 14.7 (−5.8 °C), 12.1 (−11.3 °C), 7.50 (−14.2 °C), 4.64 (−19.9 °C). The Eyring's plot using these values affords ΔH^* 12.5 ± 0.3 kcal/mol and ΔS^* -6.0 ± 1.3 e.u. for the *meso*→*d* (or *l*) process. The activation parameters for the reverse process *d* (or *l*)→*meso* are then ΔH^* 14.0 ± 0.3 kcal/mol and ΔS^* 2.0 ± 0.2 e.u. We may have to expect that these values contain errors as large as 10% in addition to that of the least squares treatment.

Conclusion

We conclude that, in 9-benzyltriptycenes possessing a substituent in one of the peri positions which are close to the substituent, the barrier to rotation is *ca.* 13 kcal/mol. The activation parameters may be obtained by treating the rate constants obtained by the total line shape analysis of the methylene part in ^1H NMR spectra. However, the following should be kept in mind in discussing the data.

1) The process with a large rate constant plays a decisive role in determining the line shape, as was pointed out by Bushweller *et al.*[10] and the rate of the slow process, if obtained, includes a larger error.

2) If the rate constant of a slower process is less than a hundredth of that of a faster process, the former

cannot be detected by the visual fitting of calculated spectra with the obersved. The difference in free energies of activation for the two processes must be smaller than 2—3 kcal/mol to be detected.

3) It is extremely difficult to obtain accurate data for a slow process by comparison of the observed and the calculated spectra. Neglect of the slow process results in overestimation of a fast process, the enthalpy of activation of which is obtained smaller than the true.

4) The populations in the exchange sites have influence on the detectability of a slow process. The exchange between two sites with fewer populations contribute to the line shape too little to affect, if the rate is small.

5) The ambiguity in determining the rates of two exchanging processes is reduced to some extent by utilization of information obtained by other means. However, it was not possible to erase all the ambiguities in the present case.

Molecular Dynamics of the Inclusion Complexes of Cyclohexaamylose with Some Aromatic Amino Acids and Dipeptides

Yoshio INOUE,* Yukio KATÔNO, and Riichirô CHÛJÔ

Department of Polymer Chemistry, Tokyo Institute of Technology, O-okayama 2-12-1, Meguro-ku, Tokyo 152

(Received November 29, 1978)

The molecular dynamics of the inclusion complexes of cyclohexaamylose as a model of enzyme have been studied by means of carbon-13 NMR spectroscopy. As substrates we have chosen L-phenylalanine, L-tyrosine, L-tryptophan, glycyl-L-phenylalanine, and L-phenylalanyl-L-lysine. The molecular motion of both the cyclohexaamylose and the substrates in D_2O–DCl solutions have been investigated by dividing the spin-lattice relaxation time into two contributions, the overall molecular reorientation and the anisotropic internal rotation. Upon complex formation, the correlation times for the internal motion of the phenyl ring of phenylalanine residue increase by a factor of up to 8, while those for the overall reorientation increase by a factor of only 2. These results indicate that the complex formation of the substrate with the cyclohexaamylose are induced by the insertion of aromatic side chain into a cavity of cyclohexaamylose even in the aqueous solution. The overall correlation times of the substrates are about three to seven times shorter than those of the host molecule. Thus the forces which bind the host cyclohexaamylose and the substrate are relatively weak. It was observed that the tightness of the inclusion varies with the types of aromatic amino acids and dipeptides.

Cycloamylose (cyclodextrin, CD) is known to form inclusion complexes with various types of small molecules of appropriate size in solution as well as in the crystalline state.[1-3] Cyclohexaamylose (α-CD, cyclohexaglucopyranose) has the shape of a hollow truncated cone with 6 primary and 12 secondary hydroxyl groups crowning opposite ends of its torus. All the glucose units in CD are present in the Cl chair conformation, and the CH groups of carbons 3 and 5 of each unit compose the inside of the hollow torus, even in the aqueous solution.[1,2,4-6] Thus, the hollow space should be relatively hydrophobic.

Cycloamyloses have been used as models for enzymes[7] because their structures are well defined and because they can specifically bind substrates into their hydrophobic cavity. Cycloamyloses are especially good models at present for hydrolytic enzyme, chymotrypsin.[2-7] It is well known that chymotrypsin does not cleave all peptide bonds at a significant rate, and rather it is selective for peptide bonds on the carboxyl side of residues with aromatic side chains, tryptophan, tyrosine, and phenylalanine, and of large bulky hydrophobic residues such as methionine.[8] In these residues aromatic or bulky nonpolar side chains are assumed to be fitted neatly into a nonpolar pocket on chymotrypsin chain.

It is of great interest to investigate the molecular dynamics of inclusion complexes between CD and aromatic amino acids and peptide as models for enzyme-substrate specific binding. Interactions between phenylalanine and α-CD and β-CD (cycloheptaamylose) in aqueous solution have been studied using ^{1}H NMR.[5,6] It has been also studied the thermodynamics of binding of the aromatic guest molecules, including L-phenylalanine (Phe), L-tyrosine (Tyr), and L-tryptophan(Try), to α- and β-CD.[9] These studies have been providing the evidence for the inclusion nature of CD's complex formation with the aromatic side chain of amino acids. Since measurements of carbon-13 spin-lattice relaxation times are particularly useful for the investigation of molecular dynamics of CD inclusion complexes in detail,[10,11] we will study the molecular motion of both guest and host molecules in the inclusion complexes of α-CD with amino acids and dipeptides having aromatic side chain in aqueous solution by means of carbon-13 spin-lattice relaxation. As substrates we will chose Phe, Tyr, Trp, glycyl-L-phenylalanine(Gly–Phe), and N^{α}-(*N*-acetyl-L-phenylalanyl)-L-lysine methyl ester(Phe–Lys) for studying the effect of the types of aromatic ring and of the peptide sequence on the dynamics of the inclusion complex.

Experimental

Materials. α-CD, Phe, Tyr, Try, and Gly–Phe were purchased from Tokyo Kasei Kogyo Co., Ltd. Phe–Lys was supplied by the courtesy of Mr. M. Sakurai of our laboratory. D_2O (isotopic purity: 99.7 atom %D) and 38% (w/w) DCl solution in D_2O were used as solvents and the deuterium field-frequency lock signal in ^{13}C NMR measurement. These deuterated compounds were purchased from Merck Sharp and Dohme Canada Ltd.

Methods. ^{13}C spin-lattice relaxation times (^{13}C-T_1) were measured by the inversion-recoverly method using a 180°-*t*-90° pulse sequence as described by Freeman and Hill,[12] where *t* is time in seconds between the 180° and 90° pulses, on a JEOL JNM PS-100 spectrometer (25 MHz) equipped with a PFT-100 Fourier-transform system and a proton noise decoupler. Data were accumulated in a JEOL JEC-6 computer using 4000 Hz sweep widths in 4096 points (resolution: 2.0 Hz). The 90° pulse recycle times were chosen to be at least five times the longest ^{13}C-T_1 to be measured. The molar concentrations in D_2O–DCl solutions of both α-CD and the substrates for the ^{13}C NMR measurements were kept *ca.* 0.1 M, namely the molar ratio of α-CD to the substrate was 1:1 in the mixture. Samples in D_2O–DCl solutions were thoroughly deoxygenated with nitrogen in order to prevent from the paramagnetic effect of oxygen molecules on T_1 values, because ^{13}C-T_1 of protonated carbon nucleus obtained on such samples may be identical with those from samples degassed by repeated freeze-pump-thaw cycles.[13,14] In all experiments the decrease in amplitude of each resonance with increasing *t* followed an exponential curve characterized by a single T_1, and there was no evidence of heterogeneous relaxation times. The estimated error in T_1 was less than ±10%.

Ultraviolet absorption (UV) spectra were taken on a Beckman-25 spectrometer. For the UV measurements, the

molar concentrations of the aromatic substrates were kept *ca.* 5×10^{-5} M and those of α-CD were varied from zero to 10^{-2} M.

The pH values, read on a TOA pH meter HM-7A, of all samples were adjusted to *ca.* 2 unless otherwise stated. The temperature was kept at 32 ± 2 °C for all experiments.

Results and Discussion

Association Constants. The association constants (K_a) for the complexation of Phe, Tyr, and Trp with α-CD have been estimated by the UV spectral changes induced by the addition of α-CD.[15] The K_a values obtained by assuming the 1:1 complexation[5,6,9] were *ca.* $2\times10^2-6\times10^2$ M for these three α-CD-substrate systems. These values are comparable with those of closely related systems,[2,3,6,9] where the complexes are of the 1:1 inclusion types. Thus, in this paper, the values of ^{13}C-T_1 were analysed by assuming that the complexation of the substrates with α-CD are induced by the insertion of an aromatic side chain of the substrate into a cavity of α-CD.

Carbon-13 NMR Spectra. All peaks in the ^{13}C NMR spectra of both α-CD and the substrates have been assigned based on the assignments previously given by several authors.[16] The ^{13}C NMR spectrum of each α-CD-substrate system consists of only one set of peaks, indicating that only one type of complexation occur and/or the chemical exchange process expressed by Eq. 1 is rapid on the ^{13}C NMR time scale,

$$\alpha\text{-CD} + \text{S} \rightleftarrows [\alpha\text{-CD, S}] \qquad (1)$$

where S and [α-CD, S] are the substrate and α-CD-substrate complex, respectively. The ^{13}C chemical shifts induced in the spectra of α-CD by complexation with the substrates were less than 0.40 ppm of upper-field shifts, which could be attributed to the hydrophobic nature of the interaction between α-CD and the substrate.[11,17]

^{13}C Relaxation Times. In the limit of rapid exchange process of Eq. 1, one measures an average relaxation rate[18]

$$\frac{1}{T_1} = p_f\frac{1}{T_{1f}} + p_c\frac{1}{T_{1c}} \qquad (2)$$

where T_{1f} and T_{1c} are intramolecular spin-lattice relaxation times for a spin at the free and complex states, and p_f and p_c ($=1-p_f$) are the probabilities that α-CD or the substrate is found in the free and complex states, respectively. Eq. 2 is valid only if the relaxation times T_{1f} and T_{1c} are much larger than the life times in the free and complex states. Since the association-dissociation process between α-CD and the aromatic substrates in the aqueous solution is performed in the microsecond to millisecond range[3] and the observed values of ^{13}C-T_1 are in the order of 1—10^{-1} s (see below), the Eq. 2 is applicable to the present study.

For the reaction of Eq. 1, the probability p_c to find a α-CD or a substrate molecule in the complex state can be expressed by

$$p_c = \frac{1}{2}(1+k)\left\{1-\left[1-\frac{4K_a}{K_a+1}\cdot\frac{k}{(1+k)^2}\right]^{1/2}\right\} \qquad (3)$$

where k is the molar ratio of α-CD to substrate S (or converse). In the present case, $K_a\simeq10^2\gg1$ and $k=1$, hence $p_c\simeq1$. Eq. 2 can be, therefore, simplified as,

$$\frac{1}{T_1} \simeq \frac{1}{T_{1c}} \qquad (4)$$

that is, the ^{13}C-T_1 values observed in the present α-CD-substrate mixed system can be considered to be exclusively that of the complex state.

The values of ^{13}C relaxation time measured for the free substrates, free α-CD, and the complexes between them are listed in Table 1. From this table we shall analyse the molecular motions in the inclusion complexes.

For molecules of medium size whose motion is rapid on the ^{13}C NMR time scale, it is likely that the ^{13}C-T_1 value of the carbon atom directly linked at least one proton is governed by ^{13}C-^{1}H dipole-dipole relaxation brought about by a rotational motion.[19] In this case, if the overall molecular reorientation is isotropic, ^{13}C-T_1 is given by

$$\frac{1}{T_1} = \hbar^2\gamma_C^2\gamma_H^2 N r_{CH}^{-6}\tau_{eff} \qquad (5)$$

where τ_{eff} is the effective correlation time for overall molecular reorientation, r_{CH} is the carbon-hydrogen bond length, γ_H and γ_C are the gyromagnetic ratios of ^{1}H and ^{13}C nuclei, and N is the number of directly bonded proton. This τ_{eff} can be related to the isotropic rotational diffusion constant D, and according to the Brownian diffusion model[20-22]

$$\tau_{eff} = \frac{1}{6D} = \frac{8\pi\eta f_r r_0^3}{6kT} = \frac{V_m\eta f_r}{kT} \qquad (6)$$

where k is Boltzmann's constant, T is the absolute temperature, η is the viscosity of the solution in poise, f_r is a microviscosity factor, r_0 is the radius of a spherical solute molecule, and V_m is the molecular volume $V_m=4/3\pi r_0^3$. From Eqs. 5 and 6, a relationship between NT_1 value and the molecular volume is derived as follows

$$\frac{1}{NT_1} = \hbar^2\gamma_C^2\gamma_H^2 r_{CH}^{-6}\eta f_r V_m/kT. \qquad (7)$$

If α-CD is considered to be a spherical molecule of 7.31×10^{-10} m radius,[2,3] and the viscosity of the solution is assumed to be determined mainly by the solvent D_2O ($=1.04\times10^{-2}$ poise at 32 °C[24]), NT_1 values for the ring carbons of α-CD in the free states can be calculated from Eq. 7 using a value of f_r equal to unity[20] and the temperature equal to 305 K. We have 0.122 s for NT_1 value which agrees well with the observed mean value of 0.132 s for ring carbons C_{1-5} within experimental error. For the carbons of the free amino acids and dipeptides NT_1 values were calculated by a similar way. Here, the values of molecular volume of these molecules were calculated by the atomic increments method based on the van der Waals radii of the constituent atoms.[25] Since the molecules investigated here have the freedom of local internal rotation in the side chain and the backbone in addition to the overall motion, it is difficult to find the NT_1 value of the carbon which is determined mainly by the overall reorientation of the molecule. In general, the additional internal

	C_α(Lys)	0.39		

a) The molecular volume used for the calculation of NT_1 value, estimated by the atomic increments method.[25]

motion faster than the overall one makes the NT_1 value lengthen.[19] Therefore, we regarded the smallest NT_1 values as the representative of the measure of the overall reorientation. Agreements between the calculated and the observed NT_1 values are well as shown in Table 2, notwithstanding the values of molecular volume used in the calculation of NT_1 are only approximate. Thus we can use Eq. 5 for the analyses of the overall molecular reorientation of both α-CD and the substrates in the free states. Eq. 5 might be applicable, at least qualitatively, to the analyses of molecular motions of both α-CD and substrate molecules in the complex states.

For the group undergoing an additional internal motion, the NT_1 value of a protonated carbon with N directly bonded hydrogens is given by[19,26]

$$\frac{1}{NT_1} = \frac{\hbar^2\gamma_H^2\gamma_C^2}{r_{CH}^6}\tau_{eff}\left[A+B\frac{6\tau_G}{6\tau_G+\tau_{eff}}+C\frac{3\tau_G}{3\tau_G+2\tau_{eff}}\right] \quad (8)$$

where τ_G is the correlation time for internal motion and

$$A = 1/4(3\cos^2\theta-1)^2 \quad (9)$$

$$B = 3\sin^2\theta\cos^2\theta \quad (10)$$

$$C = 3/4\sin^4\theta. \quad (11)$$

Here θ is the angle between the C–H vector and the axis of internal rotation. In the case of rotation of a tetrahedral C–H bond about the C–C bond, $\theta=109°$, this yields $A=1/9$, $B=8/27$, and $C=16/27$. Similarly, in the case of a phenyl ring rotation about C_β–C_γ bond of the Phe residue, C_δ–H and C_ε–H vectors intersect with the rotational axis at $\theta=60°$ and 120°, respectively, and then $A=1/64$, $B=9/16$, and $C=27/64$.

From Eqs. 5 and 8, it is clear that the greater the NT_1 value, the more mobile is the ^{13}C moiety, and that the additional internal rotation faster than the overall one makes the NT_1 value lengthen as mentioned in the preceding paragraph.

As shown in Table 1, for α-CD in the free and the complex states, the NT_1 values for the ring carbons (C_{1-5}) are equal within experimental error in each system, indicating the absence of specific fast internal motion in the pyranose ring.[10] Thus the mean value $\langle T_1\rangle_{1-5}$ could be used to calculate the effective correlation times for overall molecular reorientation of α-CD. The NT_1 values show the existence of rapid internal rotation of the primary alcohol group of α-CD, the phenyl group of Phe and Tyr residues, and all the C_β-methylene groups even in the complex states. Definite increase is observed in NT_1 values in Lys residues when going from the α-carbon to the terminal ε-carbon. These results also show the existence of the internal motion.[27] In the case of Phe residue, the axis of rotation of the phenyl ring about C_β–C_γ bond coincides with the C_ζ–H bond. Therefore, the rotation about C_β–C_γ bond cannot affects the T_1 value of C_ζ, since $\theta=0$ and thus Eq. 8 is reduced to Eq. 5. Then we can estimate the τ_G value for the internal rotation of phenyl ring of Phe residue by using the τ_{eff} value for C_ζ. Since the phenyl ring of Tyr has no C–H bond on the prefered axis of internal rotation, we cannot estimate accurately the τ_G value. The results of calculation of the correlation times are shown in Table 3. Here the correlation time τ_{eff} for the substrate was calculated by adopting the smallest NT_1 value in each substrate as the representative of the overall molecular reorientation having no or a little contribution from the internal motion. Throughout these calculation we have assumed that all C–H bond lengths (r_{CH}) are 1.10×10^{-10} m.

Effect of Complex Formation on the Molecular Motion of α-CD and the Substrates. As can be seen in Tables 1 and 3, all the values of NT_1 (τ_{eff}, τ_G) for both α-CD and the substrates decrease (increase), namely, the motions of these molecules slow down by complexation between them. The reductions of NT_1 are qualitatively explainable as a consequence of the increases in apparent molecular volume by complexation as expected from Eq. 7. The change in molecular dimension induced by complexation is relatively small for α-CD and relatively large for substrates, namely the reduction in NT_1 value of the former is smaller than the latter. For the substrates, it is noticeable that the NT_1 values of aromatic groups show larger changes by complex formation than those of other groups. The effect of the complex formation on the molecular motion could be discussed quantitatively in terms of correlation time. Despite the lack of accurate C–H lengths, the results shown in Table 3 are giving some interesting facts.

Table 3. Rotational correlation time τ_{eff} and τ_G of α-CD, substrates, and molecular inclusion complexes between them[a]

Compd[b]	Correlation time (10^{-11} s)

[α-CD, Phe]	6.0(1.3)	19 (4.1)
[Tyr]	5.0	4.2[f]
[α-CD, Tyr]	7.2(1.4)	5.6(1.3)[f]
[Trp]	6.7	
[α-CD, Trp]	13 (1.9)	
[Gly–Phe]	6.6	5.6
[α-CD, Gly–Phe]	9.7(1.5)	13 (2.3)
[Phe–Lys]	13	9.0
[α-CD, Phe–Lys]	22 (1.7)	69 (7.7)

a) The values shown in parentheses are the ratios of the correlation times of the complexed to the free states. b) The calculated values correspond to the underlined species. c) Calculated by using the mean values of T_1 for C_{1-5}. d) Calculated by using the smallest NT_1 values shown in Table 1. e) The average T_1 values for $C_{\delta,\varepsilon}$ and for τ_{eff} for C_ζ were used for the calculation of τ_G. f) The values of τ_{eff} were shown, so these values could not compare directly with other τ_G values.

The correlation times for the internal motion of the phenyl ring are clearly showing the mechanism of complex formation. The values of τ_G for the free substrates are comparable or slightly smaller than those of τ_{eff}, indicating the existence of rapid internal rotation of the phenyl ring. Upon complex formation with α-CD, the internal motion of the phenyl ring slows down by a factor of up to *ca.* 8, while the reduction factor of the overall motion is only less than 2. These results support the assumption that the substrates investigated here form the complexes with α-CD by the insertion of an aromatic side chain into a cavity of α-CD even in the aqueous solution. The τ_G values of the phenyl ring in the inclusion complexes show still the existence of apprecia-

bly rapid internal rotation. The results that the NT_1 values of C_δ and C_ϵ in phenyl ring agree with each other and they are always larger than those of C_ζ indicate that α-CD favors the axial inclusion in which the internal rotational axis C_γ–C_ζ of the phenyl ring of the guest is parallel to the axis of the α-CD cavity. According to the space-filling models, the diameter of the cavity of α-CD is about 6.0×10^{-10} m.[3] The molecular diameter, including the van der Waals radii of the proton, of the benzene nucleus is about 6.8×10^{-10} m, thus the axial inclusion is the most natural mode of inclusion.[5]

For the substrates themselves the overall correlation time τ_{eff} increases in the order Phe<Tyr<Gly–Phe≃Trp<Phe–Lys, and this order is also valid after the complex formation. The τ_{eff} value of the three substrates Phe, Tyr, and Trp in the free states are about same and are in the range expected for a molecule of similar size. The Trp, however, shows the prominent increase in τ_{eff} by the formation of complex. The peculiarity of Trp should be a partly due to the difference of the inclusion mode and a partly due to the bulkiness of the indolyl group. In the most probable inclusion mode of the indolyl group, the long axis of the benzene ring $C_{\epsilon3}$–$C_{\zeta1}$ may crosses at about right angles with the axis of the α-CD cavity. This inclusion mode induces larger steric interactions between the indolyl group of Trp and the internal and peripheral group of the α-CD's cavity due to the bulkiness of indolyl group as compared with the axial inclusion of the monocyclic aromatic ring of Phe and Tyr. Thus the bulkiness and type of the aromatic side chain are important factors determining the tight packing of the substrate into the cavity.

Several mechanisms have been proposed for the formation of CD inclusion complex,[2,3,28] but the force driving complex formation and the mechanism of inclusion are still unclear and a matter of speculation.[28] A formation of hydrogen bond between α-CD and substrate may promote complex formation and stabilize resulting complex. It is generally accepted that many benzene derivatives and α-CD form 1 : 1 complexes with benzene ring inserted into the cavity from the secondary hydroxyl side.[3,6,15] According to this model several groups of the substrates investigated here have the hydrogen-bonding capabilities to the α-CD's hydroxyl groups located on the outside of the torus. The existence of hydrogen bond may be confirmable from an analyses of NT_1 values.[29,30] The hydroxyl group of Tyr has no noticeable influence, as compared to the other substrates, on the molecular motions of both α-CD and Tyr in the complexed state, indicating the absence of strong hydrogen bonding interaction between Tyr hydroxyl group and α-CD primary hydroxyl group. The NT_1 value of Gly–C_α in Gly–Phe, in spite of the adjoining carbon to the end group, reveals a significant decrease of motion by complex formation, while that in the free state indicates an evidence of appreciable internal motion. The reduction of Gly–C_α motion may be due to the anchoring effect of the hydrogen bond at the chain end on the molecular motion.[29]

Upon complex formation of Phe–Lys with α-CD, the NT_1 values of alkyl chain carbons of Lys residue show slightly larger reductions as compared with those of C_α and C_β of Phe and Lys residues of Phe–Lys, suggesting an existence of further weak interaction between alkyl chain of Lys residue and α-CD. In this case, two causes can be pointed out as the origin of interaction, *i.e.*, steric hindrance due to access of huge α-CD to Phe residue and $N_\epsilon H$ hydrogen bonding to α-CD. The changes of NT_1 values, however, are too small to clear the causes.

Phe dipeptide, Phe–Lys, in both free and complexed states shows the largest τ_{eff} and τ_G values among the corresponding values of all substrates. The magnitude of Phe–Lys's τ_{eff} is not unreasonable as compared with those of other substrates. However, Phe–Lys shows an unexpected increase in τ_G value of phenyl group by complex formation. Since, in the complex state, the phenyl τ_G value of Gly–Phe is shorter than that of Phe, a largeness of molecular volume or molecular weight of Phe–Lys is not a only reason for this unusual increase in τ_G value. From these results, we can say that the type of the amino acid residue adjoining to aromatic residue in peptide chain is also one of the factors for the tight packing of the substrate into the cavity.

It is noteworthy that, in the complexes, the overall correlation times of the five substrates are about three to seven times shorter than those of the host α-CD molecule. This result indicates the weakness of a dynamic coupling between α-CD and the substrates, namely the extensive independency of a overall motion between them. This result further suggests the shallowness of penetration of the aromatic ring of the substrates into the cavity of α-CD. If the penetration is deep, all motions of aromatic ring other than anisotropic internal rotation about C_β–C_γ bond are greatly restricted within narrow limits due to the steric hindrance. In this case, however, the NT_1 values of C_ζ of Phe residue are too large to explain because the internal rotation about C_β–C_γ bond cannot affects the T_1 values of C_ζ. Thus the penetration of the aromatic ring into the cavity may be an extent to allow the substrate a relatively rapid motion. The shallowness of the insertion is suggested by the absence of hydrogen bond between the hydroxyl group of Tyr and the primary hydroxyl group of α-CD. The results of ^1H NMR study also support the shallow insertion of phenyl ring of Phe into the α-CD cavity.[6] The inclusion of the phenyl ring of D- and L-Phe into the cavity is evident from the upperfield shift of the α-CD's H_3 resonances, but the H_5 resonances are not affected by complexation and furthermore the magnitude of the H_3 upperfield shift induced by complexation is only 0.10 ppm.[6] The three times larger shifts (0.31 ppm) of the H_3 resonances have been observed in the complex between α-CD and *p*-iodoaniline.[6] The strongest coupling between α-CD and the substrate overall motions is seen in [α-CD, Phe–Lys] system, where several intermolecular interaction may participate in the dynamic coupling.

In conclusion, the inclusion complexes between α-CD and the aromatic amino acids and dipeptides investigated here show some characteristics like general peculiarities of enzyme-substrate complex.[8] The host

α-CD has the cavity leading to substrate specifity and the shape matching between the cavity and the substrate is one of the factors determining the strong coupling between them. A nonpolar character of the host cavity and a intermolecular hydrogen bond enhance the binding of substrate and α-CD, but the forces which bind them are relatively weak. The strength of the dynamic coupling also depends on the types of dipeptides.

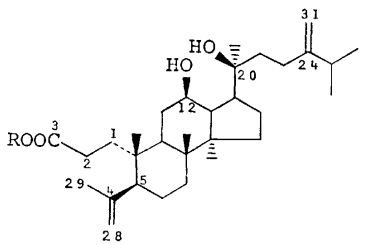
Structure of Alnustic Acid, a New Secodammarane-type Triterpenic Acid from *Alnus sieboldiana*

Takayuki SUGA,* Tadashi AOKI, Toshifumi HIRATA,
Keiko AOKI (*née* SUKEMIYA), and Yoshinori ASAKAWA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received December 4, 1979)

A novel C_{31} 3,4-secodammarane-type triterpenoid, alnustic acid, was isolated from the male flowers of *Alnus sieboldiana* Matsum. (Betulaceae). Its structure was elucidated to be (12*R*,20*S*)-12,20-dihydroxy-24-methylene-3,4-secodammar-4(28)-en-3-oic acid by a combination of chemical and spectroscopic methods.

The occurrence of only aromatic ring-containing compounds, such as phenyl propane derivatives, flavonoids, and stilbenes, in the male flowers of *Alnus sieboldiana* Matsum. (Betulaceae) was previously reported from our laboratory.[1-5] Ohmoto *et al.* also described the presence of a flavone glucoside in the pollens of this plant.[6] Our further investigation of the male flowers has newly led to the isolation of a novel C_{31} 3,4-secodammarane-type triterpenic acid, named alnustic acid, differing from the above-described group of compounds. We here wish to report evidence which led to the establishment of its structure.



1 R=H
2 R=CH_3

Results and Discussion

The male flowers of *Alnus sieboldiana* Matsum. were collected just before the flowering and immersed in benzene. The benzene extract was subjected to chromatography on a silica gel column and then to preparative thin layer chromatography to give alnustic acid.

Alnustic acid (**1**), $C_{31}H_{52}O_4$, showed the IR absorption bands due to a carboxyl and a hydroxyl group. Methylation of **1** with CH_2N_2 gave a methyl ester (**2**), which upon Jones oxidation yielded a keto alcohol (**3**). Acetylation of **2** with acetic anhydride under mild conditions gave a methyl ester monoacetate (**4**), which was found to possess another unaltered hydroxyl group from the IR spectrum. This inidcates that **1** possesses both a secondary and a tertiary hydroxyl group. The ORD curve pattern, as well as the CD curve, of **3** resembled to those of the previously-described dammaran-12-one derivatives,[7-9] implying the presence of the secondary hydroxyl group located at position 12 in the acid (**1**) and the similarity in surroundings of the newly-formed carbonyl chromophore in the keto alcohol (**3**). The presence of both the carboxyl group located at position 3 and the secondary hydroxyl group occupying the *R* position on C-12 (δ_c 70.6 ppm) was demonstrated by comparing the CMR chemical shifts (Table 1) with those of the corresponding carbon atoms of alnuseric acid (**5**) and the methyl ester (**6**)[10,11] and protopanaxadiol.[12] Simultaneously, the presence of an isopropenyl group on C-5 was shown by the CMR spectra (δ_c 147.3 and 113.6 ppm), as well as by the IR bands, the PMR signals, and the MS fragment. These findings indicate that alnustic acid is a 3,4-secodammarane-type derivative. On the other hand, the mass spectral fragmentation pattern (Scheme 1) indicated the presence of an

acyclic side chain. The presence of a terminal methylene and a tertiary hydroxyl group located, respectively, on C-24 and C-20 of the side chain was established by a combination of the IR bands, the PMR signals, the MS peaks (Scheme 1), and the CMR signals (Table 1). In addition, the comparison of these CMR chemical shifts with those of alnuserrudiolone (**7**),[8,9] alnuserrutriol,[9] and protopanaxadiol[12] demonstrated that the chirality at C-20 (δ_c 74.2 ppm) is *S*. This was supported by occurrence of both the free and the intramolecularly hydrogen-bonded hydroxyl bands between the 12-carbonyl and the 20-hydroxyl groups in **3**.[13] We here wish to propose structure **1** for alnustic acid. This proposed structure (**1**) possesses all the features necessary to explain all the spectral data of the acid.

The structure (**1**) was confirmed by its synthesis starting from alnuserrudiolone (**7**)[8,9] following the method established for ring-opening at the 3,4-position in ring A of β-amyrenone.[14] Acetylation of **7** gave a monoacetate, which was then transformed to the corresponding ketoxime, followed by treating with *p*-toluenesulfonyl chloride to yield an abnormal Beckmann rearrangement product (**8**). Hydrolysis of the product (**8**) with alkali under mild conditions gave (12*R*,20*S*)-12,20-dihydroxy-24-methylene-3,4-secodammar-4(28)-en-3-oic acid. Identity of an authentic sample of this acid with naturally occuring alnustic acid was established by direct comparison of a mixed melting point, thin layer chromatogram, and the infrared, mass, and nuclear magnetic resonance spectra.

Thus, the structure of alnustic acid (**1**) has been elucidated to be (12*R*,20*S*)-12,20-dihydroxy-24-methylene-3,4-secodammar-4(28)-en-3-oic acid.

Experimental

The mass spectral analyses were performed on a Hitachi RMS-4 mass spectrometer at 70 eV. The PMR spectra were taken on a Varian T-60 spectrometer using TMS as an internal standard. The CMR spectra were obtained on a JEOL JNM FX-100 spectrometer operating at 15.1 MHz ($\delta_{TMS}=0$).

Extraction and Isolation. The male flowers (95.0 kg) of *Alnus sieboldina* Matsum. naturally grown on a hill in suburbs of Hiroshima city were collected just before the flowering in March. After minced mechanically, the flowers were immersed in benzene at room temp for 2 months. The benzene extract was chromatographed on a silica gel column (Merck; type 60) with a hexane-EtOAc mixture with EtOAc increasing 0 to 100%. The eluate with 50% EtOAc in hexane, after removal of the solvent, was subjected to repeated preparative TLC (silica gel, Merck GF_{254}; EtOAc–$CHCl_3$–hexane (5: 1: 1, v/v); R_f 0.47) to give alnustic acid (577 mg), which was recrystallized from a hexane–EtOAc mixture to yield colorless needles.

*Alnustic Acid (**1**).* Mp 195—196 °C; $[\alpha]_D^{25}$ +27.8° (*c* 0.52, $CHCl_3$); IR (Nujol) ν_{max}3400—2800 and 1710 (COOH), 1640 and 892 cm^{-1} (>C=CH_2); PMR ($CDCl_3$) δ 0.88—1.19 (Me×6), 1.75 (3H, s, >C=C (CH_3)–), 3.60 (1H, br, >C<u>H</u>–OH), 4.71 and 4.87 (4H, br, >C=CH_2×2), 7.36 (1H, s, –COOH); MS, *m/e* (rel intensity), 470 ($(M-H_2O)^+$, 8), 445 (4), 427 (6), 391 (13), 387 (7), 330 (21), 141 (42), 123 (68), 43 (100), and 41 (71).

Found: C, 75.88; H, 10.56%. Calcd for $C_{31}H_{52}O_4$: C, 76.18; H, 10.72%.

*Methylation of **1**.* **1** (363 mg) was methylated with CH_2N_2, followed by purification with preparative TLC [silica gel; benzene–dioxane–acetic acid (90: 25: 4, v/v)], to give a methyl ester (**2**) (389 mg): mp 157—158 °C; $[\alpha]_D^{25}$ +42.7° (*c* 0.59, $CHCl_3$); IR (0.001 M, CCl_4) ν_{max} 3610 (free OH), 3435 (intramolecularly hydrogen-bonded OH), 1730 cm^{-1} (COOMe); PMR ($CDCl_3$) δ 0.98—1.18 (Me×6), 1.73 (3H, s, >C=C(CH_3)–), 3.60 (1H, br, >C<u>H</u>–OH), 3.65 (3H, s, –$COOCH_3$), 4.73 and 4.86 (4H, br, >C=CH_2×2).

Found: C, 76.20; H, 10.92%. Calcd for $C_{32}H_{54}O_4$: C, 76.44: H, 10.83%.

*Acetylation of **2**.* A mixture of **2** (380 mg), dry pyridine (4 ml), and acetic anhydride (8 ml) was allowed to stand overnight at room temp and the product, obtained on treatment of the reaction mixture in the usual method, was subjected to preparative TLC [silica gel; hexane–EtOAc (7: 3, v/v)] to give a methyl ester monoacetate (**4**) (376 mg): IR (Liquid) ν_{max} 3530 (OH), 1738 (C=O), 1642 and 900 cm^{-1} (>C=CH_2); PMR ($CDCl_3$) δ 0.85—1.10 (Me×6), 1.71 (3H, s, >C=C-(CH_3)–), 2.02 (3H, s, –$OCOCH_3$), 3.65 (3H, s, –$COOCH_3$), 4.67 (1H, br, >CH–OAc), 4.77 and 4.84 (4H, br, >C=CH_2×2).

*Oxidation of **2**.* A soln of **2** (58 mg) in dry pyridine (2 ml) was added to the CrO_3–pyridine complex prepared from 100 mg of CrO_3 and 4 ml of pyridine. The reaction mixture was stirred overnight to give a keto alcohol (**3**) (49 mg): IR (0.001 M, CCl_4) ν_{max} 3620 (free OH), 3450 (intramolecularly hydrogen-bonded OH), 1735 (COOMe), 1707 cm^{-1} (C=O); PMR ($CDCl_3$) δ 0.80—1.20 (Me×6), 1.72 (3H, s, >C=C (CH_3)–), 2.92 (2H, d, J=10 Hz, >CH–C<u>H_2</u>–CO–), 3.65 (3H, s, –COOMe), 4.70 and 4.88 (4H, br, >C=CH_2×2); ORD (*c* 0.75, dioxane) $[\Phi]_{600}$ +117°, $[\Phi]_{589}$ +117°, $[\Phi]_{309}$ −780°, $[\Phi]_{303}$ −552°, $[\Phi]_{300}$ −584°, $[\Phi]_{263}$ +1218°; CD (*c* 0.75, dioxane) $[\theta]_{312}$ 0, $[\theta]_{284}$ −244, $[\theta]_{250}$ 0.

*Synthesis of **1**.* *i) Acetylation of **7**:* A mixture of **7** (290 mg), dry pyridine (2 ml), and acetic anhydride (2.5 ml) was left overnight at room temp and, after treatment as usual method, the product obtained was subjected to preparative TLC [silica gel; hexane–EtOAc (7: 3, v/v)] to give a monoacetate (260 mg): IR (Nujol) ν_{max} 3550 (OH), 1730 (COOMe), 1710 (C=O); PMR ($CDCl_3$) δ 2.06 (3H, s, –COOMe).

*ii) Cleavage of Ring A of **7**:* According to the previously-described procedure,[14] a mixture of 12β-acetoxy-alnuserrudiolone oxime (145 mg) and *p*-toluenesulfonyl chloride (100 mg) in dry pyridine (4 ml) was kept for 24 h at room temp. After addition of a few drops of water, the reaction mixture

was further stirred for 30 min at room temp, acidified with 5% hydrochloric acid (15 ml), and extracted with ether to give a solid mass. This mass was subjected to preparative TLC to give (12*R*,20*S*)-12-*O*-acetoxy-3-cyano-20-hydroxy-24-methylene-3,4-secodammar-4(28)-ene (**8**) (16 mg): MS, *m/e* (rel intensity), 511 (M^+, 1), 414 (3), 311 (7), 141 (10), 123 (14), 43 (100), and 41 (72); IR (Nujol) ν_{max} 3550 (OH), 2250 (-C≡N), 1730 (OCOMe), 3077, 1638, and 888 cm^{-1} (>C=CH_2); PMR ($CDCl_3$) δ 2.05 (3H, s, -OCOMe), 4.73 and 4.90 (4H, br, >C=CH_2×2).

iii) Hydrolysis of 8: A soln of **8** (16 mg) in 20% KOH/MeOH (6 ml) was refluxed for 15 h. The reaction mixture, after acidification with 5% hydrochloric acid, was extracted with ether. The ether extract was subjected to preparative TLC [silica gel; EtOAc–benzene (7: 3, v/v)] to give (12*R*, 20*S*)-12,20-dihydroxy-24-methylene-3,4-secodammar-4(28)-en-3-oic acid (**1**) (14 mg): mp 195—196 °C; IR (Nujol) ν_{max} 3400—2800 and 1713 (COOH), 1638 and 890 cm^{-1} (>C=CH_2); PMR ($CDCl_3$) δ 0.88—1.18 (Me×6), 1.73 (3H, s, >C=C(CH_3)–), 3.58 (1H, br, >C<u>H</u>–OH), 4.73 and 4.90 (4H, br, >C=CH_2×2), 5.90 (1H, br, -COOH); MS, *m/e* (rel intensity), 470 ($(M-H_2O)^+$, 5), 445 (4), 427 (4), 391 (6), 387 (4), 330 (6), 141 (20), 123 (26), 43 (100), and 41 (82).

The authors thank JEOL Co., Ltd. for obtaining the ^{13}C-NMR spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research Nos. 234033 and 247027 (1977 and 1978, to T.S.) and No. 354189 (1978, to T.A.) from the Ministry of Education, Science, and Culture and Matsunaga Science Foundation in 1977 (to T.H.).

Syntheses of Cecropia Juvenile Hormones by Selective Side-chain Methylation of (*E,E*)-Farnesol[1)]

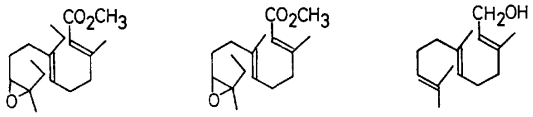
Arata YASUDA,*,† Shin TANAKA, Hisashi YAMAMOTO,†† and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received December 6, 1978)

The stereoselective route to the title insect hormones (JH-1 & JH-2) depends crucially on the epoxidation of allylic alcohols with *t*-butyl hydroperoxide in the presence of oxobis(2,4-pentanedionato-*O,O'*)vanadium(IV). The oxidation of 2-methyl-1-hepten-3-ol exclusively produces the (2*R**,3*S**) isomer of the diastereomeric epoxy alcohols. This is converted into (*Z*)-6-methyl-5-undecene by the sequence involving oxirane reaction with lithium dibutylcuprate(I) and the removal of both hydroxyl groups of the resulting 1,2-diol. Extension of the series of reactions to the mono- and bisoxirane derived from (*E,E*)-farnesol gives JH-2 and JH-1, respectively.

Since C_{18}-Cecropia juvenile hormone (**1**), now called JH-1, was first synthesized in a nonstereoselective manner, no less than ten syntheses of **1** and the lower homolog, JH-2 (**2**), have appeared.[2)]



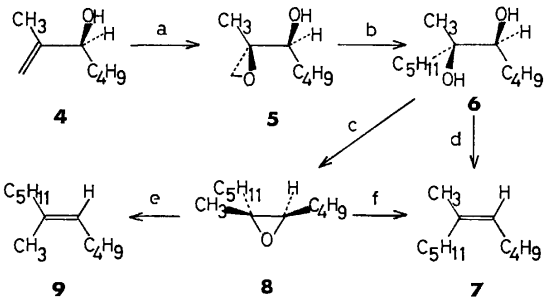
1 **2** **3**

Apparently of great interest are those routes which give only the required stereoisomer with the right configuration about each of the double bond. This paper presents a simple and efficient route starting from the readily available (*E,E*)-farnesol (**3**) and giving the desired products selectively.

The approach is based on a combination of catalyzed, stereoselective epoxidation of allylic alcohols and the transformation of the resulting glycidols into 3-alkylated 1,2-diols.

The principle is first illustrated with a simple example, then its application to syntheses of insect hormones being described.

Stereoselective Preparation of (Z)-6-Methyl-5-undecene (7) and Its Isomer (9). Sharpless *et al.* showed that catalytic epoxidation of cyclic allylic alcohols with *t*-butyl hydroperoxide proceeds with high degrees of stereoselectivity.[3)] The same technique can be successfully extended to a variety of acyclic allylic alcohols.[1)] Of special interest for the syntheses of **1** and **2** is the observation that epoxidation of the allylic alcohol **4** with $VO(acac)_2$-*t*-BuOOH reagent in benzene at room temperature produced (2*R**, 3*S**) epoxy alcohol **5** in 96% selectivity. This was improved (>99%) when the epoxidation was carried out in toluene at 0 °C. In contrast, *m*-chloroperbenzoic acid epoxidation of **4** gave a 62 : 38 mixture of (2*R**,3*S**) and (2*S**,3*S**) epoxy alcohols. The (2*R**,3*S**) structure of **5** was established, after acetylation, by GLPC comparison with the known data.[4,5)] Further study is required before stereochemical and mechanistic details can be understood.[6)] However, from the observation that cyclic allylic alcohols exhibit a strong preference for epoxidation *cis* to the hydroxyl group, we can assume that the preferred conformation of this allylic alcohol at the epoxidation transition state might be the one illustrated, close to that proposed in the case of cyclic allylic alcohols. The epoxy oxygen is then introduced on the same side as the hydroxyl group to give (2*R**,3*S**) epoxy alcohol **5**.[2,4,7)]



a) $VO(acac)_2$-*t*-BuOOH; b) Bu_2CuLi; c) BuLi, *p*-TsCl; d) $Me_2NCH(OMe)_2$, Ac_2O; e) NaI–AcOH, $SnCl_2$–$POCl_3$–C_5H_5N; f) $LiPPh_2$, MeI.

Treatment of the epoxy alcohol **5** with excess lithium dibutylcuprate(I) in ether at −26 °C for 2 h produced (5*R**,6*S**) diol **6** in 88% overall yield from **4**. As expected from earlier reports,[8)] dibutylcuprate-(I) exclusively attacked the unsubstituted carbon atom of the epoxide ring to furnish 1,2-diol as the sole product. Several methods for stereospecific deoxygenation of diols have been given;[9)] the one reported by Eastwood *et al.*[9c)] ($Me_2NCH(OMe)_2$, Ac_2O) afforded (*Z*)-6-methyl-5-undecene (**7**) in 80% yield. GLPC analysis of the olefin **7** displayed two peaks in the ratio 97 : 3. The major peak, having a shorter retention time, was ascribed to the *Z* isomer[10)] and this was supported by a vinyl methyl signal appearing at δ 1.65.[11)]

On the other hand, the geometrical isomer **9** was obtained from epoxide **8** by the Cornforth procedure[12)] in 80% yield, whose NMR spectrum supports the *E* configuration.[11)] The epoxide **8** was also converted into *Z* olefin **7** by treatment with lithium diphenylphosphide and then with methyl iodide (80% yield).[13)]

Stereospecific Synthesis of dl-*JH-2 (2).* Two methods of nonselective homologation of (*E,E*)-farnesol (**3**)

are known to afford a triene having the skeleton of JH-1 (**1**).[14,15] We now report a stereoselective route to hormones **1** and **2** which utilizes the series of reactions mentioned above.

The key intermediate in the synthesis of *dl*-JH-2 (**2**) is the allylic alcohol **13** prepared as follows. The epoxide **11**[16] was efficiently converted into bis-allylic alcohol **12** (90% yield) by reaction with diethyl-

aluminum 2,2,6,6-tetramethylpiperidide,[17] followed by tritylation of the primary hydroxyl group (88% yield). The trityl ether **13** was oxidized to the epoxy alcohol **14**[18] by the $VO(acac)_2$-*t*-BuOOH reagent and the resulting crude **14** was methylated to furnish the diol **15**[18] (81% yield after preparative TLC purification), which was found to be homogeneous upon TLC analysis. Application of the Eastwood procedure[9c] gave the triene trityl ether **16** stereospecifically in 55% yield. Removal of the protecting group by perchloric acid furnished the desired homofarnesol **17** almost quantitatively. The homogeneity of **17** was indicated by TLC analysis, its infrared and NMR spectra being identical with those obtained for homofarnesol.[19] The synthesis of JH-2 (**2**) from **17** has been reported.[19]

Synthesis of dl-*JH-1 (1).* (*E,E*)-Farnesol (**3**) was transformed by the van Tamelen-McCormick procedure[15] into the triene trityl ether **20**. The conversion of the intermediate **20** into the bishomofarnesol **24** was accomplished by the sequence of steps described above. The IR and NMR spectra of **24** were entirely analogous to those reported,[15,19] its structure and homogeneity being further confirmed, after acetylation, by TLC and GLPC comparison with an authentic sample of the acetate **25**.[21] The transformation of **24** into JH-1 (**1**) has been reported.[15,19]

Experimental

IR spectra were determined on a Shimadzu IR-27-G spectrometer, mass spectra on a Hitachi RMU-6L mass spectrometer, and NMR spectra on a Varian EM-360 or JEOL-C-60-H spectrometer; chemical shifts are given in δ with tetramethylsilane as an internal standard. Microanalyses were carried out at the Elemental Analyses Center of Kyoto University, and GLPC analyses on a Yanagimoto GCG-550F. All experiments were carried out under an atmosphere of dry nitrogen or argon, preparative thin layer chromatography on silica gel 60 PF_{254} (Merck, Art. 7747) plates, and preparative column chromatography on silica gel 60 (Merck, Art. 7734).

(2R,3S*)-2-Methyl-1,2-epoxyheptan-3-ol (5).* *t*-Butyl hydroperoxide (90%, 600 mg, 6.0 mmol) was added dropwise over a period of 10 min at room temperature to a solution of 2-methyl-1-hepten-3-ol (**4**) (512 mg, 4.0 mmol) and oxobis(2,4-pentanedionato-*O,O'*)vanadium(IV) (32 mg, 0.12 mmol) in benzene (15 ml). After being stirred at ambient temperature for 2 h, the resulting solution was poured into saturated aqueous sodium sulfite. The mixture was vigorously stirred for 20 min and extracted with ether. The ethereal phase was washed with water, dried (anhydrous sodium sulfate), and concentrated *in vacuo* to give the epoxy alcohol **5** as a pale yellow liquid: bp 80 °C (bath temp, 1 Torr); TLC, R_f 0.55 (3:1 hexane–ethyl acetate); IR (neat), 3400 (s), 1470 (m), and 1110 cm^{-1} (m); NMR (CCl_4), 1.28 (3H, s, CH_3–CO), 2.61 (2H, dd, CH_2–O), and 3.32—3.67 (1H, m, CH–OH).

A small aliquot was acetylated by stirring with acetic anhydride in pyridine. GLPC analysis (10% PEG 20 Mesh, 110 °C, 1.0 kg/cm^2) of the resulting acetates showed a peak at 6.5 min (96%), corresponding to the (2*R**,3*S**) epoxy acetate, and a small peak at 5.8 min (4%), corresponding to the (2*S**,3*S**) isomer: bp 80 °C (bath temp, 1 Torr); TLC, R_f 0.53 (1:1 hexane–ether); IR (neat), 1735(s), 1360 (m), 1230—1240(s), and 1110 cm^{-1}(m); NMR (CCl_4), 1.21 (3H, s, CH_3–CO), 1.91 (3H, s, CH_3–CO_2), 2.50 (2H, dd, CH_2–O), and 4.32 (1H, t, CH–O); MS (*m/e*), 186 (7), 156 (14), 144 (23), 127 (100), and 114 (52).

Found: C, 64.4; H, 9.5%. Calcd for $C_{10}H_{18}O_3$: C, 64.5; H, 9.7%.

(5R,6S*)-6-Methylundecane-5,6-diol (6).* Lithium dibutylcuprate(I) was prepared by the addition of 32.0 mmol (16.2 ml of 1.98 M hexane solution) of butyllithium to a vigorously stirred suspension of 3.04 g (16.0 mmol) of copper(I) iodide in 40 ml of ether at −26 °C. After being stirred at this temperature for 20 min, the crude epoxy alcohol **5** dissolved in 20 ml of ether was added at the same temperature. Stirring was continued for 2 h, then the product was isolated by quenching the reaction mixture in ether, filtering through a pad of Celite 545, extracting with ether, drying over sodium sulfate, and concentrating to give an

oil. Preparative TLC (3:1 hexane–ethyl acetate) afforded 663 mg (82% yield from **4**) of the (5*R**,6*S**) diol **6**, which showed a single spot of R_f 0.60 upon TLC analysis (3:1 hexane–ethyl acetate): bp 120 °C (bath temp, 1 Torr); IR (neat), 3450(s), 1470(m), and 1035 cm^{-1}(s); NMR ($CDCl_3$), 3.10—3.36 (1H, m, CH–OH); MS (*m/e*), 182 (18), 157 (36), 115 (36), 63 (100), and 57 (100).

Found: C, 71.2; H, 13.0%. Calcd for $C_{12}H_{26}O_2$: C, 71.2; H, 13.0%.

(Z)-6-Methyl-5-undecene (7). *A. From Diol 6*: A mixture of the (5*R**,6*S**) diol **6** (606 mg, 3.0 mmol) and *N,N*-dimethylformamide dimethyl acetal (3.0 ml) was stirred at room temperature for 17 h. After removal of the volatile material *in vacuo*, the resulting dioxolane derivative was heated in acetic anhydride (3.0 ml) at 130 °C for 17 h. The reaction mixture was allowed to cool to room temperature, poured into water, and the product was extracted with pentane. After being washed with saturated aqueous sodium hydrogencarbonate, saturated brine, and water, the organic phase was dried (Na_2SO_4), and concentrated. Column chromatography using pentane as an eluent gave (*Z*)-6-methyl-5-undecene (**7**) (403 mg, 80% yield) as a clear oil: bp 130 °C (bath temp, 24 Torr); TLC, R_f 0.80 (hexane); IR (neat), 1660—1675(w), 1385(m), and 840 cm^{-1}(w); NMR (CCl_4), 1.65 (3H, s, CH_3–C=), and 5.03 (1H, bt, CH=); MS (*m/e*), 168(12), 114(10), 94(31), 68(72), and 55(100).

Found: C, 85.8; H, 14.6%. Calcd for $C_{12}H_{24}$: C, 85.6; H, 14.4%.

B. From Oxirane 8: According to the procedure of Vedejs and Fuchs,[13] lithium diphenylphosphide in tetrahydrofuran (0.83 M) was prepared from chlorodiphenylphosphine (0.92 ml, 5.0 mmol) and lithium wire (140 mg, 20.0 mmol) in THF (5 ml). A solution of the oxirane **8** (184 mg, 1.0 mmol) in THF (5 ml) was added over a period of 5 min to the solution of lithium diphenylphosphide in THF (3.0 ml, 2.5 mmol) at ambient temperature. The resulting mixture was stirred at the same temperature for 17 h. Methyl iodide (0.27 ml, 4.3 mmol) was then added and the mixture was allowed to stand at room temperature for 1 h. After aqueous workup, the organic phase was dried (Na_2SO_4), and freed of the solvent. The residual liquid was subjected to column chromatography with pentane as an eluent to give pure olefin **7** (132 mg, 80% yield).

(E)-6-Methyl-5,6-epoxyundecane (8). A 1.83 M hexane solution of butyllithium was added dropwise at 0 °C to an ethereal solution (2 ml) of the diol **6** (202 mg, 1.0 mmol) containing a trace of 1,10-phenanthroline until the initially colorless solution turned orange. After 10 min, hexamethylphosphoric triamide (1 ml) and *p*-toluenesulfonyl chloride (229 mg, 1.2 mmol) were successively added and then the whole mixture was stirred at ambient temperature for 6 h. The crude product obtained on extractive workup was purified by preparative TLC (benzene) which furnished 166 mg (90% yield) of the oxirane **8**. GLPC analysis (10% PEG 20 Mesh, 90 °C, 1.0 kg/cm^2) showed the oxirane to be >97% pure: bp 86 °C (bath temp, 2 Torr); TLC, R_f 0.65 (benzene); IR (neat), 1470(s), 1376(m), and 1120 cm^{-1}(w); NMR ($CDCl_3$), 1.18 (3H, s, CH_3–CO), and 2.30—2.67 (1H, bt, CH–O); MS (*m/e*), 184(2), 155(6), 127(10), 114(18), and 58(100).

Found: C, 78.2; H, 13.3%. Calcd for $C_{12}H_{24}O$: C, 78.3; H, 13.0%.

(E)-6-Methyl-5-undecene (9). The oxirane **8** (80 mg, 0.44 mmol) was added to a cooled (−16 °C) solution of sodium iodide (150 mg, 1.0 mmol) and sodium acetate (15 mg, 0.18 mmol) in acetic acid (0.6 ml). After 1 h, the mixture was warmed to room temperature and poured into ether and aqueous sodium hydrogencarbonate. The ethereal solution was washed with a little sodium hydrogensulfite and water, dried (Na_2SO_4), and freed of the solvent. The resulting iodohydrin was added to a cooled (0 °C) solution of tin(II) chloride (230 mg, 1.21 mmol) in pyridine (0.9 ml). Phosphoryl chloride (0.06 ml, 0.40 mmol) in pyridine (0.2 ml) was then added with cooling, and the mixture was allowed to stand at room temperature overnight. After being diluted with hexane, the organic phase was washed with 1 M hydrochloric acid, and water, dried (Na_2SO_4), and concentrated. The crude product was subjected to column chromatography with hexane as an eluent. The olefin **9** (62 mg, 80% yield) was obtained as a colorless oil: bp 130 °C (bath temp, 24 Torr); TLC, R_f 0.80 (hexane); IR (neat), 1665—1675(w) and 840—860 cm^{-1}(sh); NMR (CCl_4), 1.59 (3H, s, CH_3–C=) and 5.05 (1H, bt, CH=); MS (*m/e*), 168 (16), 112(10), 96(30), 59(78), and 55(100).

Found: C, 85.7; H, 14.5%. Calcd for $C_{12}H_{24}$: C, 85.6; H, 14.4%.

(2E,6E)-3,7,12-Trimethyl-2,6,11-dodecatriene-1,10-diol (12). Diethylaluminum 2,2,6,6-tetramethylpiperidide was prepared *in situ* from diethylaluminum chloride (1.7 ml of 1.0 M benzene solution) and 1.68 mmol of lithium 2,2,6,6-tetramethylpiperidide in benzene (5 ml) at 0 °C for 30 min.[17] To this slurry was added dropwise the epoxy alcohol **11**[16] (80 mg, 0.34 mmol) dissolved in 4 ml of benzene at the same temperature. After being stirred for 2 h, 5 ml of 1 M hydrochloric acid was added. Ethereal extracts were dried (Na_2SO_4) and freed of the solvent. The remaining liquid was subjected to preparative TLC (5: 2 ether–hexane) to give pure **12** (71 mg, 90% yield); TLC, R_f 0.41 (2:1 ether–hexane); IR (neat), 3300—3420(s), 1650—1675(m), 1450 (m), 1000(m), and 895 cm^{-1}(m); NMR ($CDCl_3$), 1.59 (3H, s, CH_3–C= on C-3), 1.67 (3H, s, CH_3–C=, C-11), 3.86 (1H, bt, CH–OH), 3.97 (2H, d, CH_2–OH), 4.69 (2H, dd, CH_2=), and 4.82—5.40 (2H, m, CH=).

Microanalysis was performed after trimethylsilylation of both hydroxyl groups:

Found: C, 66.1; H, 11.2%. Calcd for $C_{21}H_{42}O_2Si_2$: C, 65.9; H, 11.1%.

(10R,11S*)-(2E,6E)-3,7,11-Trimethyl-1-trityloxy-2,6-tridecadiene-10,11-diol (15).* The diol **12** (71 mg, 0.31 mmol) was converted into the primary mono(trityl ether) **13** by reaction with trityl chloride (92 mg, 0.33 mmol) in 2 ml of pyridine at 50 °C for 2.5 h. Preparative TLC (1 : 1 hexane–ether) gave purified **13** (130 mg, 88% yield).

t-Butyl hydroperoxide (90%, 32 mg, 0.33 mmol) was added to a mixture of oxobis(2,4-pentanedionate-*O,O'*)-vanadium(IV) (11 mg, 0.04 mmol), the allylic alcohol **13** (130 mg, 0.27 mmol), and benzene (3 ml) as described above, yielding the epoxy alcohol **14** as a pale yellow liquid: TLC, R_f 0.68 (1 : 1 hexane–ether); NMR ($CDCl_3$), 1.23 (3H, s, CH_3–CO), 1.62 (3H, s, CH_3–C= on C-7), 1.95 (3H, s, CH_3–C=, C-3), 2.25—2.70 (2H, m, CH_2–O, C-12), 3.19 (1H, m, CH–O), 3.31—3.70 (2H, bd, CH_2–O, C-1), 5.03—5.52 (2H, m, CH=), and 7.00—7.40 (15 H, m, aromatic).

The crude epoxy alcohol **14** in ether (1 ml) was added at −26 °C to a solution of lithium dimethylcuprate(I) (0.56 mmol) in ether (3 ml) and the whole mixture was stirred at 0 °C for 12 h. According to the procedure described above, the trityl ether **15** (113 mg, 81% yield from **13**) was obtained as a pale yellow liquid after purification by preparative TLC (1 : 1 hexane–ether): TLC, R_f 0.54 (1 : 1 hexane–ether); IR (neat), 3410—3490(s), 1480(m), 1450 (s), 1380(m), and 1050 cm^{-1}(s); NMR ($CDCl_3$), 1.12 (3H, t, CH_3–CH_2), 1.45 (3H, s, CH_3–C= on C-7), 1.62 (3H, s,

CH_3–C= on C-3), 3.15—3.56 (1H, m, CH–OH), 4.94—5.53 (2H, m, CH=), and 7.05—7.45 (15H, m, aromatic).

Microanalysis was performed with the 10,11-*O*-isopropylidene-1-trimethylsilyl ether derivative:

Found: C, 69.1; H, 11.3%. Calcd for $C_{22}H_{42}O_3Si$: C, 69.1; H, 11.1%.

*(2E,6E,10Z)-3,7,11-Trimethyl-2,6,10-tridecatrien-1-ol (**17**).* The diol **15** (113 mg, 0.22 mmol) was transformed into the triene trityl ether **16** (56 mg, 55% yield) as described above for **7**: TLC, R_f 0.54 (3 : 1 petroleum ether–benzene); IR (neat), 1490(w), 1055(s), and 790 cm^{-1}(s); NMR ($CDCl_3$, 100 MHz), 0.95 (3H, t, J=8 Hz, CH_3–CH_2), 1.65 (6H, s, CH_3–C= on C-7 and C-11), 1.88—2.40 (12H, m, methylenes except C-1), 1.96 (3H, s, CH_3–C= on C-3), 3.60 (2H, d, J=7 Hz, CH_2–O), 5.09 (2H, bt, CH= on C-6, 10), 5.44 (1H, bt, CH= on C-2), and 7.16—7.68 (15H, m, aromatic).

The trityl ether **16** thus obtained was treated with 3 ml of 5% perchloric acid in tetrahydrofuran at 0 °C for 1.5 h. After being diluted with ether, the mixture was washed with water, saturated sodium hydrogencarbonate, and saturated brine, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel (1 : 1 hexane–ether) gave the purified homofarnesol **17** (28 mg, 99% yield) which exhibited appropriate physical properties:[19] TLC, R_f 0.41 (2 : 1 ether–hexane); IR (neat), 3250—3380(s), 1665(m), 1450(s), 1380(s), and 1000—1020 cm^{-1} (s); NMR ($CDCl_3$, 100 MHz), 0.95 (3H, t, J=7 Hz, CH_3–CH_2), 1.58 (3H, s, CH_3–C=, C-3), 1.65 (6H, s, CH_3–C=, C-7, 11), 1.85—2.16 (11H, m, methylenes except C-1 and OH), 4.05 (2H, d, J=7 Hz, CH_2–OH), 4.89—5.14 (2H, m, CH=, C-6, 10), and 5.35 (1H, bt, CH=, C-2); MS (*m/e*), 236(2), 218(2), 160(5), 83(71), and 55(100).

*(2E,6E,10Z)-7-Ethyl-3,11-dimethyl-2,6,10-tridecatrien-1-ol (**24**).* According to the same procedure as aforementioned, compound **24** was obtained in 25% overall yield from the diol **20**.[15] The bisoxirane **21**:[18] TLC, R_f 0.68 (ethyl acetate); NMR ($CDCl_3$), 1.23 (3H, s, CH_3–CO), 1.95 (3H, s, CH_3–C=), 2.25—2.80 (4H, m, CH_2–O, C-7, C-12), 3.19 (2H, m, CH–OH), 3.31—3.70 (2H, bd, CH_2–O, C-1), 5.13—5.52 (1H, bt, CH=), and 7.00—7.40 (15H, m, aromatic). The tetrol **22**: TLC, R_f 0.60 (ethyl acetate); NMR ($CDCl_3$), 1.65 (3H, s, CH_3–C=), 2.90—3.35 (2H, m, CH–OH), 3.60 (2H, d, CH_2–O, C-1), 5.46 (1H, bt, CH=), and 7.10—7.55 (15H, m, aromatic). The bishomofarnesol **24** so obtained was spectrometrically identical with the reported data:[14,17] TLC, R_f 0.54 (1 : 1 hexane–ether); IR(neat), 3280—3370(s), 1665(w), 1450(s), 1380(m), and 1000—1020 cm^{-1}(s); NMR ($CDCl_3$, 100 MHz), 0.95 (6H, t, J=7 Hz, CH_3–CH_2), 1.65 (3H, s, CH_3–C= on C-3), 1.90—2.35 (13H, m, methylenes except C-1 and OH), 4.12 (2H, d, J=7 Hz, CH_2–OH), 5.04 (2H, bt, CH=, C-6, 10), and 5.40 (1H, t, J=7 Hz, CH=, C-2); MS (*m/e*), 232(3), 203(3), 175(5), 149(12), 83(50). and 55(100).

The structure and homogeneity of the alcohol **24** were further confirmed, after acetylation, by TLC and GLPC comparison with an authentic sample of acetate **25**. TLC analysis showed a single spot of R_f 0.24 (3 : 1 hexane–ether). The substance was found to be >93% pure by GLPC analysis (10% PEG 20 Mesh, 165 °C, 45 ml/min, 14.1 min retention time).

The work was carried out with Grants-in-Aid 911506, 011010, 110309, 203014, and 303023 from the Ministry of Education.

18) Both the (10*R**,11*S**) configuration of **14**, and the (6*R**,7*S**,10*R**,11*S**) or (6*R**,7*S**,10*S**,11*R**) configuration of **21** were assumed on the stereochemical outcome of the previous example, as well as on the stereochemistry of the double bonds of the products **17** and **24**, since NMR analyses were not sufficiently effective. The stereochemical analysis of **21** was complicated by the fact that no stereochemical data were available allowing inference on the relative arrangement of the 6 and 10 positions in the MCPBA epoxidation step (**10**→**18**).

A Highly Stereospecific Isomerization of Oxiranes into Allylic Alcohols by Means of Organoaluminum Amides[1]

(Received December 6, 1978)

Organoaluminum reagents of type $R^1R^2NAlR_2$ allow highly stereospecific oxirane ring opening producing allylic alcohols under mild conditions. *trans*-Epoxycyclododecane is converted to (*E*)-2-cyclododecen-1-ol by reaction with diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP) in quantitative yield, while the *cis*-isomer gives only 8% yield of the same alcohol. Furthermore, this reagent enables us to perform the stereospecific isomerization of trisubstituted oxiranes: *c*-3-butyl-2-methyl-*r*-2-pentyloxirane is transformed into 2-pentyl-1-hepten-3-ol and the diastereomeric oxirane into (*E*)-6-methyl-6-undecen-5-ol, respectively. Such a rigorous stereospecificity is rationalized on the basis of a concerted syn elimination *via* the boat-like six membered ring imtermediary stage, in which the substituents of the oxirane ring should be arranged so as to minimize the severe nonbonded interactions.

A variety of synthetic methods have been developed to bring about the introduction of the allylic alcohol moiety.[2] Among them oxirane-allylic alcohol conversion by means of a strong base offers the advantage of wide spread applicability and experimental simplicity to a unique degree.[3–7] While lithium diethylamide has been widely used for this reaction, the rather vigorous conditions required decrease its practicability.[4–6] A further limitation arises in the reaction with unsymmetrical oxiranes and this reagent is rather nonspecific in the sense that the side chain methyl usually contributes proton to be removed. Accordingly the double bond of the resulting allylic alcohol is located rarely on the main chain. These facts led us to search for a new reagent allowing stereospecific isomerization of oxiranes into allylic alcohols under mild conditions which forms the subject of this paper.

Our attention has been focused on organoaluminum amides, since organoaluminum compounds in general are markedly strong Lewis acids and many of them are known to form stable 1 : 1 complexes with neutral bases such as amines or even ethers. In addition, the aluminum-nitrogen bond is cleaved readily by the attack of proton bearing base such as alcohol to leave aluminum-oxygen bond.[8] It was anticipated that an aluminum amide should be active with respect to both the oxirane ring and the proton to be removed simultaneously.

A series of dialkylaluminum *N,N*-dialkylamides were prepared *in situ* from (1) diethylaluminum chloride and lithium amides[9] obtained from secondary amines and butyllithium,[10] or from (2) diisobutylaluminum hydride and amines.[11] Reactions with *trans*-epoxycyclododecane (**1**)[7] under mild conditions (0 °C, 1 h) are summarized in Table 1. Best results were obtained upon the use of four equiv. of diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP) in benzene or hexane.[12] Other aluminum amides also gave (*E*)-2-cyclododecen-1-ol (**2**) as a sole product, however the rates of conversion were lower than that observed with DATMP. Thus the reactivity of alminum amides is apparently dependent on the structure of amine component.[13] Either benzene or hexane proved to be effective, as these do not solvate the aluminum species.[14]

TABLE 1. CONVERSION OF **1** TO **2** BY VARIOUS ALUMINUM AMIDES[a]

Aluminum amide[b]	Solvent	Yield (%)[c]
Et_2Al–TMP[d]	benzene	99
Et_2Al–TMP	hexane	99
Et_2Al–TMP	ether	76
Et_2Al–TMP	tetrahydrofuran	5
Et_2Al–N(*i*-Pr)$_2$[d]	benzene	65
Et_2Al–N(Cy)$_2$[d]	benzene	36
Et_2Al–NEt_2[d]	benzene	5
(*i*-Bu)$_2$Al–NPh_2[e]	benzene	48
(*i*-Bu)$_2$Al–NMePh[e]	benzene	69
(*i*-Bu)$_2$Al–N(*i*-Pr)$_2$[e]	benzene	30

a) For detailed reaction conditions, see Experimental part. b) Abbreviations used here are in accordance with those cited in Ref. 10. c) Yields are based on material isolated by preparative TLC. d) Prepared from diethylaluminum chloride and the corresponding lithium amide at 0 °C for 30 min. e) Prepared from diisobutylaluminum hydride and the corresponding amine.

Remarkably, the *cis* isomer **3** ($n=10$) reacted very reluctantly with DATMP under the same conditions (8 % yield of **2**). In addition, attempts to obtain allylic alcohols from medium ring-attached oxiranes **3** ($n=3$, 4, 5, and 6) were unsuccessful. Most of starting oxiranes were recovered unchanged.

A few examples illustrate the efficient conversion of oxiranes to allylic alcohols in the presence of DATMP.

† Present address: The Institute for Molecular Science, Myodaiji, Okazaki 444.

†† Present address: Department of Chemistry, University of Hawaii at Manoa, Honolulu, Hawaii 96822.

The oxirane **4** was smoothly converted to **5** in 92% yield, while in contrast the reaction with lithium amide yielded less than 5 % of **5**. Oxiranes **6**[7] and **8**[15] gave allylic alcohols **7** and **9** in 98 and 96% yield, respectively. Notably, none of cyclized byproducts was produced in these two cases.
