For the assignment of bidentate or monodentate coordination of our complexes we have also taken into consideration the position of the symmetric stretching band of the carboxylato group, as this band is directly connected with the oxygen atom certainly linked to the metal ion. Values of $\nu(OCO)_s$ at the same or lower energies than those found for the alkali metal salts are considered indicative of the presence of "symmetric" or "asymmetric" bidentate coordination of the carboxylato group, while values greater than 1410 cm^{-1} may be associated with a bridging bidentate behaviour of the carboxylato group, as has been experimentally found in some polynuclear complexes.[10] This also agrees with a greater double bond character of the symmetric CO bond when the carboxylato group links two metal ions, acting as "bridging" bidentate ligand, than when it links one metal ion, acting as a simple bidentate ligand.

By considering the $\Delta\nu$ values and the $\nu(OCO)_s$ position we may suggest the presence of "bridging" bidentate carboxylato groups in the $Cu(AcLeu)_2 \cdot pid$ complex and "asymmetric" bidentate groups in all the other complexes. These conclusions are also in agreement with the EPR and electronic results, and confirm the presence of an essentially CuO_2N_2 chromophore in the amine adducts.

The coordination of the amines is confirmed by the shift to lower frequencies of the $\nu(NH)_B$ (Table 3), with respect to the free amines,[15,16] in the saturated heterocyclic amine adducts, and by the shifts of the bands in the 800—500 cm^{-1} region, with respect to the free amines,[17–19] in the aromatic amine adducts.

The Authors are grateful to the Centro Strumenti of the University of Modena for the recording of the IR spectra and to the Consiglio Nazionale delle Ricerche of Italy for a financial support.

Super Exchange in Copper(II) Dimers. II. Synthesis, Characterization and Magnetic Properties of Binuclear Adducts of Copper(II) Halides with 1,2-Benzoquinone Dioximes. Ligand-induced Ferromagnetic Exchange Coupling

Michel Megnamisi BÉLOMBÉ†

Department of Physics, Stanford University, Stanford, California 94305, U. S. A.

(Received April 26, 1979)

Various 1,2-benzoquinone dioximes (bqdH) have been combined with $CuCl_2$ or $CuBr_2$ to afford the following new dimeric adducts: di-μ-chlorobis[chloro(1,2-benzoquinone dioxime)copper(II)], $[CuCl_2(bqdH)]_2$; di-μ-chlorobis[chloro(4-chloro-1,2-benzoquinone dioxime)copper(II)], $[CuCl_2(ClbqdH)]_2$; di-μ-chlorobis[chloro(4-methyl-1,2-benzoquinone dioxime)copper(II)], $[CuCl_2(MebqdH)]_2$; di-μ-chlorobis[chloro(4,5-dimethyl-1,2-benzoquinone dioxime)copper(II)], $[CuCl_2(Me_2bqdH)]_2$; di-μ-bromobis[bromo(1,2-benzoquinone dioxime)-copper(II)], $[CuBr_2(bqdH)]_2$; di-μ-bromobis[bromo(4-chloro-1,2-benzoquinone dioxime)copper(II)], $[CuBr_2$-$(ClbqdH)]_2$; di-μ-bromobis[bromo(4,5-dimethyl-1,2-benzoquinone dioxime)copper(II)], $[CuBr_2(Me_2bqdH)]_2$. These brown solids were characterized by variable-temperature magnetic susceptibility measured within 4.2—300 K, as well as by room temperature near infrared and electron spin resonance spectra from which the dimeric structure of the compounds was inferred. The intradimer magnetic exchange interaction was found to occur by a super exchange mechanism mediated by the valence p wave functions of the bridging halide ions. It was observed that the electrophilic character of the benzoquinonoid ligands affects the magnetic exchange *via* backbonding and through mesomeric π electron delocalization. It was found, most interestingly, that the tendency to ferro-magnetic exchange interaction within a dimer is the stronger, the more electrophilic the bqdH ligands can be made.

We present here part II of our investigations of magnetic super exchange in di-μ-halobridged copper(II) dimers. In part I[1] we showed that this category of magnetic clusters provides the simplest solids that appear to be best suited for reliable studies of magnetic exchange effects within the frame of the molecular field approximation or Heisenberg-Dirac-Van Vleck (HDVV) model.[2] To test the existing theoretical models,[2,3] new materials with possibly flexible properties are needed.[4] We therefore focus our efforts primarily on the development of novel synthetic routes aimed at establishing a means for bringing about desirable changes in the magnetic properties of solids by a systematic chemical modification of the constituent molecules. Thus, part I of this research series dealt with the isomorphous dimers,[5,6] $[CuX_2(dmgH)]_2$, where $X=Cl^-$ or Br^-, and dmgH=dimethylglyoxime (or 2,3-butanedione dioxime). The results obtained there had revealed that the substantial difference noted in the super exchange effects of the two dimers ought to be linked to the nature of the halogen atom involved in the bridges, a result which is, in fact, quite consistent with a general trend.[7]

In the present work as well as in a recent note,[8] we have employed a series of 1,2-benzoquinone dioxime (bqdH) ligands (Fig. 1) instead of dimethylglyoxime (dmgH). The purpose is to check that the reported nephelauxetic effect[9] induced at the central metal site by the electrophilic benzoquinonoid ligands is likely to affect the intradimer exchange coupling. This ligand-induced nephelauxetic effect was first observed while searching for new Krogmann type one-dimensional conductors,[9–11] of interest in the study of high temperature superconductivity according to the hypothetical excitonic model of Little.[12] It was shown that the effect arises because the electrophilicity of the partially oxidized aromatic ligands couples more or less to the d-shell electron density of the central metal ions by means of backbonding[13] and mesomeric delocalization

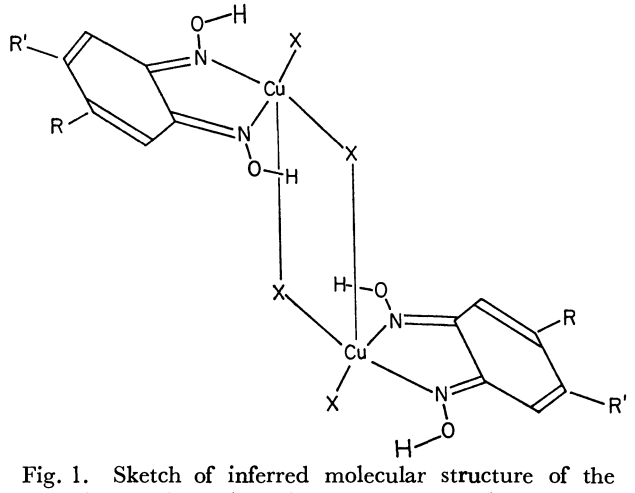

Fig. 1. Sketch of inferred molecular structure of the $[CuX_2(RR'bpdH)]_2$ dimers, with the planes of the individual molecules nearly perpendicular to the plane of the drawing. The *molecular planes* and the *intermolecular Cu–X bond direction* are taken roughly as the perpendicular ($\perp$) and parallel (//) orientations, respectively.[8]

f)	R=Cl, R'=H	$[CuBr_2(ClbpdH)]_2$
g)	R=R'=Me	$[CuBr_2(Me_2bpdH)]_2$

† Present address: Department of Chemistry, University of Ife, Ile-Ife, Nigeria.

of π electrons.[9] The effect is reminiscent of the through-bond phenomenon developed by Hoffmann.[14] Thus, the coupling between metal d-shell and ligand π-system provides a mechanism for d-shell "electron clouds" to be delocalized on to the spheres of the electrophilic benzoquinonoid rings. The degree of delocalization may be enhanced or reduced by appropriate substitution of these rings with electron withdrawing or electron releasing groups.

The objective of the present contribution, therefore, is three-fold: first to describe the synthesis of new di-μ-halobridged copper(II) dimers, second to examine the role of the bridging halide ion, third and most importantly, to check the impact of the ligand-induced nephelauxetic effect upon the super exchange coupling.

Experimental

Preparation of Materials. *The Reactants*: The commercially available anhydrous $CuBr_2$ crystals (Baker Analyzed Reagents, 99.4%) were used without further purification. $CuCl_2 \cdot 2H_2O$ crystals (90%+) from the same source were recrystallized from 99.5% acetone, finely ground and dehydrated at 105 °C over three consecutive nights to yield a dark-brown powder. The 1,2-benzoquinone dioxime ligands used were of analytical grade.[9]

Synthesis of the Compounds: The complexes listed in Table 1 were prepared according to the method reported earlier.[8] A general trend, however, was observed in the reaction yield which was found to be highest for the derivatives with less electrophilic bqdH ligands. The compounds decompose when heated above 200 °C.

Spectroscopic Experiments and Magnetic Susceptibility Measurements. The molar magnetic susceptibility data were collected at 36 closely spaced temperature points in the range 4.2—300 K, and near infrared and X-band electron spin resonance spectra were recorded at room temperature with the techniques described earlier.[1,15] A non-linear least-squares fitting procedure with a double-precision computer program[1,16] was employed to fit the susceptibility data to the conventional singlet-triplet Heisenberg equation.

Results

The Compounds. All the complexes listed in Table 1 crystallize as shiny, dark-brown tiny prisms or flakes. The ease of complex formation is apparently determined by the electrophilic character of the benzoquinonoid rings involved, since the reaction yield decreases noticeably with increasing electrophilic character of these rings (87% for the derivatives with methyl-substituted, and about 54% for those with chloro-substituted bqdH ligands). The stability of the complexes decreases in the same sense, particularly in the case of bromine-containing derivatives whose decomposition is obvious after a few weeks of exposure to air and light. The black body that results from this decomposition very probably consists of molecules with the Cu ions chelated by the quasi-coplanar 1,2-benzoquinone dioximate ligands, much like in $Cu(bqd)_2$[17] or in $Cu(dmg)_2$.[18] Note that the dimeric clusters reported here are very stable in vacuum or in a nitrogen atmosphere at room temperature. In solution, however, the likelihood of their decomposition increases considerably, especially at temperatures appreciably above ambient. For this reason, it is recommended that the syntheses be carried out at room temperature or lower.

In general the new materials are poorly soluble in the cold, even in water or in acetone and similar organic solvents. When a powdered sample of $[CuCl_2(bqdH)]_2$, for instance, is stirred for a while in H_2O at room temperature, it is rather transformed into the equally sparingly soluble $Cu(bqd)_2$ complex, presumably according to the reaction

$$[CuCl_2(bpdH)]_2 \xrightarrow{(2H_2O)} Cu(bpd)_2 + CuCl_2 \cdot 2H_2O + 2HCl,$$

as the resulting greenish-brown solution is strongly acidic. In hot acetone, the solubility is substantially higher, but the likelihood of chemical decomposition at that temperature is increased as well. The chemical decomposition taking place in the solution is recognizable by the formation of tear-causing bromoacetone in the case of the bromine-based derivatives. This suggests a redox reaction similar to the one noted previously on the related $[CuX_2(dmgH)]_2$ dimers.[1] The occurrence of this reaction is also indicated by the change in color of the solution which turns from dark-brown to light yellow-green after a few days. The true nature of this

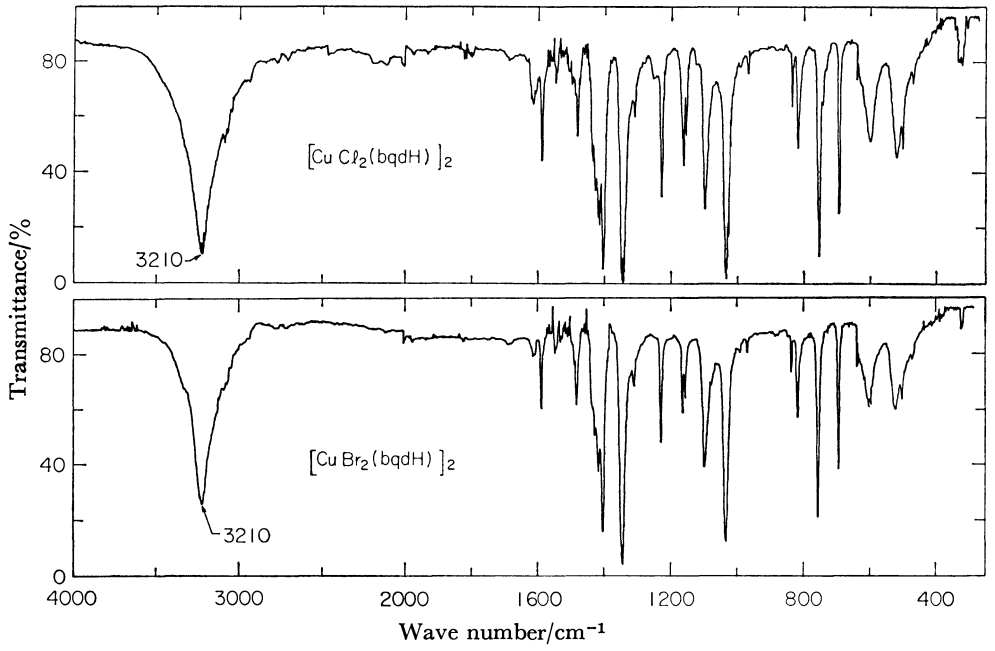

Fig. 2. Virtually identical near infrared spectra of $[CuCl_2(bpdH)]_2$ and $[CuBr_2(bpdH)]_2$ reflecting the matching structures of the compounds.

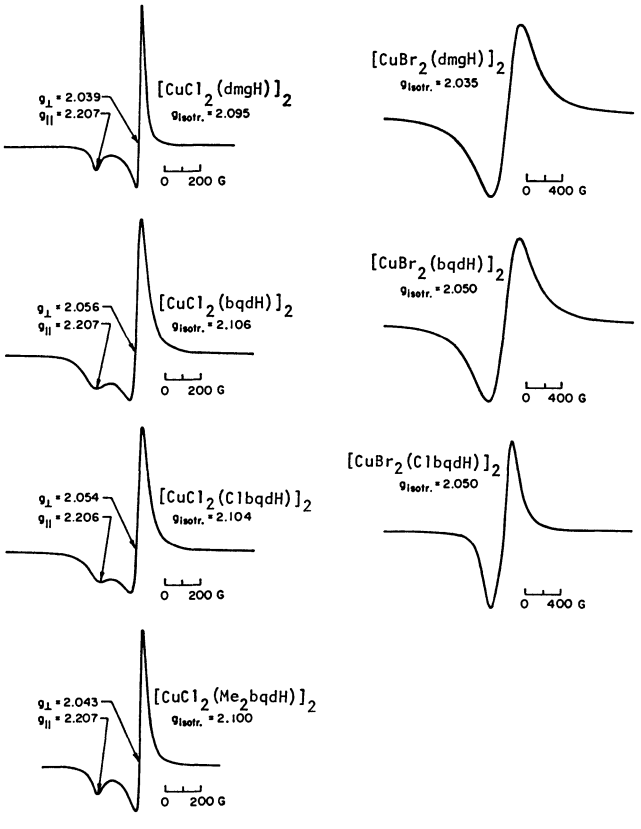

Fig. 3. *Row on the left*: Polycrystalline X-band ESR spectra of three representative chloro dimers, $[CuCl_2(RR'bpdH)]_2$, recorded at room temperature. The striking resemblance with the spectrum of the well-characterized dimer,[6] $[CuCl_2(dmgH)]_2$ (top of the row), reflects the dimeric structural similarity.
Row on the right: ESR spectra of two representative bromo dimers, $[CuBr_2(RR'bpdH)]$ demonstating their structural analogy to the well-characterized $[CuBr_2(dmgH)]_2$ dimer[1,5] (top of the row).

chemical process has not been established as yet.

Spectroscopic Results. Figure 2 shows the near infrared spectra[19] of $[CuCl_2(bqdH)]_2$ and $[CuBr_2(bqdH)]_2$, which exhibit a striking resemblance reminiscent of that observed previously on the $[CuX_2(dmgH)]_2$ dimers.[1] Nevertheless, the doublet splitting of the O–H stretching absorption band characteristic of the latter is not observed in the former pair of dimers.

In Fig. 3 are displayed the ESR spectra of both the $[CuX_2(dmgH)]_2$ and the $[CuX_2(RR'bqdH)]_2$ dimeric clusters. The absorption lines of four chloro compounds are presented in the row on the left, and the lines of three bromo derivatives in the row on the right side of the figure. In either case, the line shapes are characterized by their remarkable similarity. For the chloro compounds, the anisotropy of the $\boldsymbol{g}$ tensor is well-resolved into the parallel ($g_{//}$) and the perpendicular ($g_{\perp}$) components. Note, in particular, that $g_{//}$ remains equal to 2.207 as the ligand is varied from compound to compound, whereas $g_{\perp}$ does change markedly. The line shapes of the bromo derivatives, on the other hand, exhibit no obvious evidence for such a resolution of the $\boldsymbol{g}$ tensor which appears rather isotropic with the lines being considerably broader. In both categories of the $[CuX_2(RR'bqdH)]_2$ dimers, however, a significant narrowing of the lines is observed. This is obviously the result of substituent effects induced at the benzoquinonoid rings. Hence, the linewidth for the perpendicular absorption varies, *e.g.*, from $\Delta H_{\perp}=70$ G in $[CuCl_2(bqdH)]_2$ to $\Delta H_{\perp}=50$ G in $[CuCl_2(Me_2bqdH)]_2$. Likewise the width decreases from $\Delta H_{isotr}=330$ G in $[CuBr_2(bqdH]_2$ to $\Delta H_{isotr}=230$ G in $[CuBr_2(ClbqdH)]_2$.

atoms were used to correct for the diamagnetism of the ligands.

The corrected molar susceptibility data, χ_m, and the corresponding effective moments, μ_{eff}/Cu(II), of three representative dimers are listed in Tables 3, 4, and 5. The magnetic behavior of all three compounds is very similar over the temperature range examined. No maximum susceptibility is observed above 4.2 K, suggesting small J values in these materials. The trend in μ_{eff} data, on the contrary, is noticeably different. Whereas the effective moment per Cu(II) ion in $[CuCl_2(bqdH)]_2$ and in $[CuBr_2(bqdH)]_2$ remains virtually unchanged and close to the spin 1/2 value throughout the temperature range, the μ_{eff}/Cu(II) of $[CuBr_2(ClbqdH)]_2$ drops rather sharply in the lowest temperature region. A similar, though less dramatic, dropoff was observed in $[CuCl_2(ClbqdH)]_2$ as well. In all three cases, plots of inverse molar susceptibilities, $1/\chi_m$, *versus* temperature yielded nearly straight lines. From the slopes of these lines, the Curie constants of 0.804 for $[CuBr_2(ClbqdH)]_2$, 0.761 for $[CuBr_2(bqdH)]_2$,

TABLE 6. ROOM TEMPERATURE PARAMAGNETIC MASS SUSCEPTIBILITY, χ_g, AS A FUNCTION OF THE APPLIED FIELD, H FOR THE $[CuCl_2(bqdH)]_2$ DIMER

H/kG	$10^{-6}\chi_g$/emu g^{-1}
2.10	4.36
3.13	4.20
4.11	4.16
5.12	4.19
6.12	4.17
7.13	4.36
8.10	4.24

and 0.754 for $[CuCl_2(bqdH)]_2$ were calculated.

Table 6 shows the field-dependence of the mass susceptibility, χ_g, for $[CuCl_2(bqdH)]_2$ at room temperature.[19] It is clearly seen that the magnetic susceptibility is independent of the applied field, H.

Discussion

By analogy to the previously well-characterized $[CuX_2(dmgH)]_2$ dimers,[1,5,6] the spectroscopic results of this study reflect conclusive evidences for a closely related dimeric structure of the present $[CuX_2(RR'bqdH)]_2$ clusters sketched in Fig. 1.[8]

The observations of a constant parallel g value in the ESR spectra of all chloro-bridged dimers (Fig. 3, row on the left) may be taken as good grounds to believe that the axial Cu–X bonds (which coincide roughly with the molecular parallel orientation) do not vary in character, no matter how radically the organic ligands lying in the horizontal direction (perpendicular orientation of the molecule) may be chemically modified. In other words, the structural element defined by the CuXCuX quadrangle in Fig. 1 remains virtually the same for all the dimers. From the well-known structure of $[CuCl_2(dmgH)]_2$ dimer,[6] therefore, it is reasonable to conclude that the present chlorobridged clusters have fairly the same structure, the specific difference residing merely in the replacement of the dmgH by the RR'bqdH ligands.

Likewise the ESR spectra of the bromobridged dimers (Fig. 3, row on the right) suggest that the structure of these derivatives is analogous to that of $[CuBr_2(dmgH)]_2$ (top of the row) which, in turn, has been shown to be isomorphous with the $[CuCl_2(dmgH)]_2$ dimer.[1,5,6]

Just as was found in that pair of dimers, it is demonstrated here that the new pair, $[CuCl_2(bqdH)]_2$ and $[CuBr_2(bqdH)]_2$, exhibit quasi-identical infrared spectra (Fig. 2). Yet, the doublet splitting of the O–H stretching absorption band characteristic of the former pair is not observed in the latter pair of dimers, thus suggesting that in the latter case, the hydroxyimino hydroxyl groups of the bqdH ligands find themselves in crystallographically equivalent positions. On the basis of these matching spectroscopic results, the dimeric structure of the new clusters is most reasonably assumed to be as sketched in Fig. 1, with the bridging angle CuXCu approximately 85°—88°.

Bearing in mind this structural similarity, it appears interesting next to examine the role of the halogen ligands in the super exchange effect. Considering, again, the pair of dimers, $[CuCl_2(bqdH)]_2$ and $[CuBr_2(bqdH)]_2$ (which differ only in their halogen ligands), it is seen that the variation of the exchange parameter, J, between the two compounds follows consistently the trend observed previously on the pair, $[CuCl_2(dmgH)]_2$ and $[CuBr_2(dmgH)]_2$.[1] For either dimer pair, the exchange coupling in the bromo derivative turns out to be antiferromagnetic ($J=-1.51$ cm^{-1} for the dmgH-based dimer, $J=-0.11$ cm^{-1} for the bqdH-based dimer), whilst in the chloro derivative it is found to be ferromagnetic ($J=+0.31$ cm^{-1} for the dmgH-based dimer, $J=+0.14$ cm^{-1} for the bqdH-based dimer). These observations indicate that, at least for the particular dimeric structure sketched in Fig. 1, bromo ligands are more likely to induce antiferromagnetic exchange coupling, while chloro ligands tend to drive a ferromagnetic coupling of the single electron spins at very low temperatures.

When, however, the ligand-induced nephelauxetic effect introduced above is modulated by appropriate substitutions of the benzoquinonoid rings, remarkable variations in the value of the exchange parameter result.[8] Considering the following dimers: $[CuCl_2(MebqdH)]_2$, $[CuCl_2(bqdH)]_2$, $[CuCl_2(ClbqdH)]_2$, where the electrophilic character of the benzoquinonoid rings is progressively enhanced in the same order, the corresponding J values of -3.32 cm^{-1}, $+0.14$ cm^{-1} and $+0.38$ cm^{-1} are observed. For $[CuBr_2(bqdH)]_2$ and $[CuBr_2(ClbqdH)]_2$ likewise, the exchange coupling constant changes from $J=-0.11$ cm^{-1} to $J=+4.63$ cm^{-1}, respectively. Clearly, electron releasing groups such as Me (methyl) at the bqdH moities are likely to induce antiferromagnetic exchange coupling, whereas electron withdrawing substituents such as Cl definitely drive the exchange process towards a ferromagnetic ordering of the intradimer single electron spins. In other words, the more electrophilic the bqdH ligands can be made, the more ferromagnetic the exchange coupling at lowest temperatures is expected to be. This finding constitutes the innovation of central interest in the present research.

The overall magnetic behavior of the binuclear Cu(II) clusters studied here is very much alike for the temperature region appreciably above 4.2 K. In particular the μ_{eff}/Cu(II) for $[CuCl_2(bqdH)]_2$ and $[CuBr_2(bqdH)]_2$ remains comparable to the spin 1/2 value over the temperature range considered. This indicates Curie-like behavior and agrees well with the small J values observed on these derivatives. The μ_{eff}/Cu(II) for $[CuBr_2(ClbqdH)]_2$, by contrast, departs markedly from this behavior at lowest temperatures, which is consistent with the larger J value found for this compound. Thus, it turns out that when the effect of the bridging halogen and the ligand-induced nephelauxetic effect are considered together with respect to their impact upon the exchange interaction within a dimer, the latter effect dominates overwhelmingly.

Although the dmgH-based copper(II) dimers on the one hand, and the bqdH-based dimers on the other hand, exhibit very similar magnetic and hence analogous structural features, the colors of the two compound classes differ radically. The blue-green crystals of the first class exhibit a color that is common to and characteristic of copper(II) derivatives of this type. The dark-brown color of the second class of compounds, by contrast, is rather unusual for such copper(II) derivatives.

The observed narrowing of the ESR lines upon substitution of the bqdH ring may be interpreted as a tangible manifestation of the ligand-induced nephelauxetic effect acting at the microscopic level. These observations indicate that there is a finite degree of involvement of the paramagnetic electrons in the phenomenon of ligand-induced nephelauxetic effect.

As a novel aspect of scientific interest, one may view the experimental evidence gained here on the basis of this nephelauxetic effect as a potential input to guide new developments in the field of magnetism. It is hoped that such developments might lead to the derivation of a model generally valid for predicting the occurrence of ferromagnetism in magnetic coordination compounds. Other effects such as the degree of coplanarity of the individual molecules, the magnitude of the bridging angle, the degree of the copper-halogen bondings, as well as the extent of the Cu–Cu contacts, considered together or separately, may play a non-negligible role in the intradimer exchange interactions. Detailed structural analyses, however, must be awaited in order to assess the importance of these factors. For more accurate and quantitative correlations of anisotropic spin-lattice relaxation processes, magnetic measurements on single crystals—possibly supplemented by neutron diffraction studies— are needed.

This work was supported by the National Science Foundation through Grant No. DMR-76-28087-A01.

I am indebted to Professor W. A. Little under whose auspices the work was done. I am grateful to Dr. E. J. Laskowski and M. A. Novotny for their invaluable experimental assistance. I wish to thank Professor R. H. Holm for the use of his magnetic susceptibility and ESR equipments, and Professor H. Taube for the use of his infrared instrument. Very useful conversations with Professors R. Hoffmann of Cornell and Z. G. Soos of Princeton are sincerely appreciated.

Studies on Xanthylium Salts. Behaviour of 9-Vinylidenexanthenes in Acid Media

Nadia Fouad ABDUL-MALIK, Sami Bassili AWAD, and Alfy Badie SAKLA*

Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

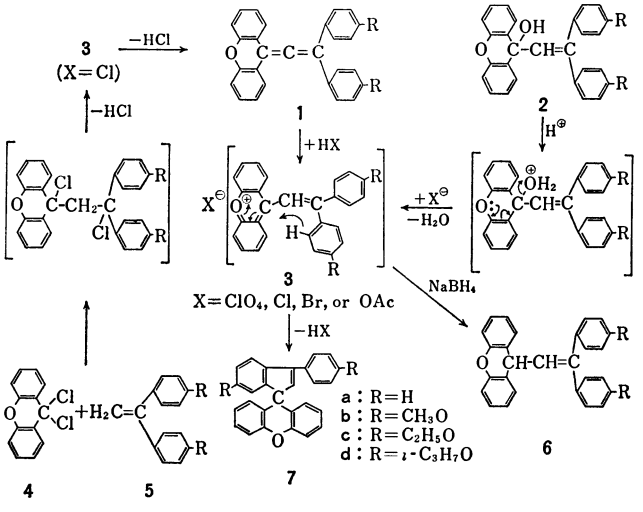
(Received June 5, 1978)

Unsymmetrical allenes namely, 1,1-diaryl-2-(9′-xanthenylidene)ethylenes (**1**) reacted readily with perchloric acid, hydrogen chloride, and acetic acid to give the corresponding highly coloured 9-vinylxanthylium salts (**3**). The latter derivatives (**3**) thermally rearranged in acid media to give spiro[indene-1,9′-xanthene]s (**7**). Structures of compounds **3** and **7** were established from chemical and spectral evidences. A new route for synthesis of allenes (**1**) was reported.

Orientation of polar addition of acids to substituted allenes to give carbonium ions has been shown to be controlled by the nature of substituents present.[1,2] A study is now reported on the behaviour of unsymmetrical allenes[3,4] (**1**) namely, 1,1-diaryl-2-(9′-xanthenylidene)ethylenes in acid media. These allenes (**1**, R=H, CH_3O, C_2H_5O, or *i*-C_3H_7O) added perchloric acid (in either acetic acid or methanol) to give crystalline, deeply coloured mono-perchlorate derivatives namely, 9′-[2,2-bis(*p*-substituted phenyl)vinyl]xanthylium perchlorates (**3**, R=H, CH_3O, C_2H_5O, or *i*-C_3H_7O; X=ClO_4). The structure of **3** (X=ClO_4) was established from analytical data and from the following findings: (i) The perchlorate **3** (R=H; X=ClO_4), derived from the corresponding allene (**1**, R=H), was identical with an authentic sample prepared by treatment of 1,1-diphenyl-2-(9′-hydroxy-9′-xanthenyl)ethylene (**2**, R=H) with perchloric acid in methanol at −5 °C; (ii) Reduction of perchlorate **3** (R=C_2H_5O; X=ClO_4) with sodium borohydride gave mainly 1,1-bis(*p*-ethoxyphenyl)-2-(9′-xanthenyl)ethylene (**6**, R=C_2H_5O); (iii) NMR spectrum of the *p*-alkoxy perchlorate **3** (R=*i*-C_3H_7O; X=ClO_4) revealed the equivalency of the 2,2-diaryl residues.

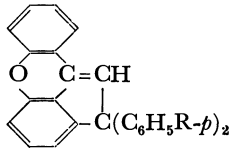
Allene **1** (R=H) added hydrogen chloride to yield deep red crystals of 9-(2,2-diphenylvinyl)xanthylium chloride (**3**, R=H; X=Cl). Synthesis of an authentic sample of **3** (R=H; X=Cl) was achieved by adding 9,9-dichloroxanthene (**4**) to 2,2-diphenylethylene (**5**, R=H). The reaction likely proceeded *via* an intermediate (scheme) which spontaneously eliminated hydrogen chloride on heating. The latter addition reaction was extended to prepare allenes **1** (R=H, CH_3O, C_2H_5O, or *i*-C_3H_7O) by using the appropriate ethylene (**5**, R=H, CH_3O, C_2H_5O, or *i*-C_3H_7O), and treatment of the intermediate products, without being isolated, with pyridine.

Electrophilic addition of hydrogen halides to substituted allenes has been reported to give monohalogenated products that were probably derived from vinylic cations formed by protonation of central carbon atom of these allenes.[1,2,5] Selective addition of acids to π bond attached to xanthene residue of allenes (**1**) seemed to take place initially *via* a similar mechanism that followed by cyclic conjugation[6] to give xanthylium derivatives (**3**). The deep colour of such perchlorates or chlorides (**3**, X=ClO_4 or Cl) in crystalline form or in solution might account for such conjugation. A similar chromophoric effect was noticed when colourless allenes (**1**) were dissolved in acetic acid (deep red, R=H, and bluish violet, R=alkoxy). This was probably due to similar type of protonation to give xanthylium acetate derivatives (**3**, X=OAc). UV spectra for both perchlorates (**3**, X=ClO_4) and acetates (**3**, X=OAc) were consistent with this observation.



Allenes **1** (R=H, CH_3O, C_2H_5O, or *i*-C_3H_7O) rearranged in boiling acetic acid to afford colourless crystalline products namely, 6-substituted-3-(*p*-substituted phenyl)spiro[indene-1,9′-xanthene]s (**7**, R=H or alkoxy). This rearrangement could also be brought about by heating a solution of allene **1** (R=H, CH_3O or C_2H_5O) in either ethanol containing hydrochloric acid or in ether saturated with hydrogen bromide. The reaction pathway for this rearrangement would require an initial formation of xanthylium ion intermediate (**3**, X=OAc, Cl, or Br) that cyclized through an internal electrophilic substitution[7,8] of one of the 2,2-diaryl residues to give spiroindene (**7**). This was evidenced by: (i) the perchlorate **3** (R=H or C_2H_5O; X=ClO_4) converted in boiling acetic acid to yield typical indene **7** (R=H or C_2H_5O); (ii) 1,1-diphenyl-2-(9′-hydroxy-9′-xanthenyl)ethylene (**2**, R=H) cyclized in acid medium to give indene **7** (R=H), and (iii) NMR of *p*-alkoxy indenes (**7**, R=alkoxy) revealed the nonequivalency of the two *p*-alkoxyphenyl residues, and that one of them became trisubstituted. For example, the methoxyl groups of **7** (R=CH_3O) appeared as two singlets (δ, 3.71 and 3.53, each 3H), whereas the same groups were

shown as overlapped singlet in the spectrum of each of the parent allene (**1**, R=CH_3O, δ, 3.90, 6H) and of 1,1-bis(*p*-methoxyphenyl)ethylene (**5**, R=CH_3O, δ, 3.75, s, 6H). The above findings were also in support of structure **7** for indenes rather than the alternative structure **8**. Furthermore, the latter **8**, by analogy with the behaviour of 9-xanthenylidene derivatives,[9,10] might be expected to add acids to give the corresponding xanthylium salt. This was not the case with our indenes; they failed to add acetic acid or perchloric acid and recovered mainly unchanged. Further relevant evidence was obtained from UV measurements in methanol or in acid medium (in acetic acid or in acetic acid/perchloric acid). Indene **7** (R=H) showed the same single absorption maximum at λ_{max} 290 nm in either solvent, whereas 9-benzylidenexanthene, as a reference example, showed: λ_{max} (CH_3OH) 341 nm; and λ_{max} (AcOH) 288, 336 nm; and λ_{max} (AcOH/$HClO_4$) 296, 384, 474, and 500 (shoulder) nm.



8

Experimental

NMR spectra were measured with a Varian T 60 instrument and mass spectra with an A.E.I. MS9 spectrometer, and UV spectra with a Beckman DK-1 spectrophotometer. The infrared spectra were recorded with a Pye-Unicam SP 1000 spectrometer. All melting points were determined in open capillary tubes.

*9,9-Dichloroxanthene (**4**).* This was prepared by refluxing a solution of xanthone (2 g) in excess of thionyl chloride (10 ml) for 5 h. Excess thionyl chloride was recovered by distillation under reduced pressure. The residue obtained was mixed with 10 ml of petroleum ether (bp 60—80 °C), and the solvent was again removed under reduced pressure. The procedure was repeated for 5 times. All the processes were carried out under complete protection of moisture, and the final residue kept under dry conditions, mp 101—103 °C (lit, mp[11] 103 °C).[11]

*1,1-Diaryl-2-(9-xanthenylidene)ethylene (**1a—d**).* A mixture of 9,9-dichloroxanthene (prepared from 2 g xanthone) and 1,1-diphenylethylene (1.8 g) was heated on a steam bath for 2 h. The mixture was further heated in benzene for 15 min and filtered. The insoluble reddish-brown material, mp 155—157 °C (dec) showed no depression in mp when admixed with an authentic sample. The sample was prepared by passing hydrogen chloride for 10 min into a solution of 1,1-diphenyl(9-xanthenylidene)ethylene (**1a**, 0.5 g) in benzene (15 ml) and the deep red crystals formed were collected by filtration to give **3a** (X=Cl), mp 157 °C.

After a solution of **3a** (0.5 g) in pyridine (10 ml) had been refluxed for 10 min, water was added to the reaction mixture and worked up in the usual way. The product was recrystallized from methanol to give **1a**, mp and mixed mp[3] 205 °C in *ca.* 50% overall yield.

In the case of a mixture of 1,1-bis(*p*-alkoxyphenyl)ethylene (0.01 mol) and 9,9-dichloroxanthene (0.01 mol), extensive evolution of hydrogen chloride was observed on heating, and the reaction mixture was directly treated with pyridine and worked up to give 1,1-bis(*p*-alkoxyphenyl)-2-(9-xanthylidene)-ethylene (**1**): **1b**, mp and mixed mp[3] 125 °C; **1c**, mp and mixed mp[3] 125 °C; and **1d**, mp and mixed mp[3] 147 °C in *ca.* 40% yield. IR spectra of these allenes were superimposable with that of authentic samples. UV and visible spectra measurements which performed in glacial acetic acid showed for **1a**: λ_{max}: 515, 371, 346, 330, 257 nm and for **1b**: λ_{max}: 628, 478, 373, 355, 277 nm.

*9-(2,2-Diarylvinyl)xanthylium Perchlorates (**3a—d**).* Perchloric acid (2 ml, 70%) was added gradually to a stirred solution of 1,1-diaryl-2-(9-xanthenylidene)ethylene **1** (1.0 g) in either acetic acid or methanol (25 ml) and the mixture was further stirred for 30 min. The mixture diluted with ether and cooled to give the corresponding perchlorates **3a—d**, which separated as highly coloured crystals in *ca.* 90% yield. Thus were obtained: **3a**, mp 181 °C, λ_{max} (AcOH): 533, 380, 278 nm; Found: Cl, 7.8%. Calcd for $C_{27}H_{19}ClO_5$: Cl, 7.73%. This perchlorate (**3a**) could be prepared by adding perchloric acid (0.5 ml) to a cold solution (−5 °C) of compound (**2a**) (0.2 g) in methanol (25 ml). The mixture was stirred for 10 min and the red crystals deposited were collected by filtration, mp and mixed mp 181 °C.

3b, mp 170 °C, λ_{max} (AcOH): 612, 497, 367, 271 nm; Found: Cl, 6.9%. Calcd for $C_{29}H_{23}ClO_7$: Cl, 6.83%.

3c, mp 172 °C, λ_{max} (AcOH): 619, 490, 367, 271 nm; Found: Cl, 6.6%. Calcd for $C_{31}H_{27}ClO_7$: Cl, 6.48%.

3d, mp 157 °C, Found: Cl, 6.2%. Calcd for $C_{33}H_{31}ClO_7$ Cl, 6.17%.

*Reduction of 9-(2,2-Diarylvinyl)xanthylium Perchlorates (**3a, c**).* To a cold stirred suspension of each of the title compound (0.5 g) in methanol (10 ml), sodium borohydride (0.2 g) was added at once. The deep colour (red or blue violet) disappeared immediately and colourless crystals deposited. After stirring for 15 min, the mixture diluted with water (2 ml) was cooled and the solid precipitated was collected by filtration. It was crystallized from methanol to give the corresponding 1,1-diaryl-2-(9′-xanthenyl)ethylene (**6**) in *ca.* 90% yield. Thus were obtained: **6a**, mp and mixed mp[3] 164 °C and **6c**, mp and mixed mp[3] 115 °C.

*Action of Pyridine on 9′-(2,2-Diarylvinyl)xanthylium Perchlorates (**3**).* A solution of the perchlorate **3a—d** (1.0 g) in pyridine (10 ml) was heated to boiling for 10 min. The mixture diluted with water was extracted with ether. The ether phase was washed thoroughly with water, separated, dried ($MgSO_4$), and the solvent was distilled off. The residue crystallized from methanol, from which the allene (**1**) separated as colourless crystals in *ca.* 90% yield. Thus were obtained: **1a**, mp and mixed mp[3] 205 °C; **1b**, mp and mixed mp[3] 125 °C; **1c**, mp and mixed mp[3] 125 °C; and **1d**, mp and mixed mp[3] 147 °C.

*6-Substituted-3-(p-substituted phenyl)spiro[indene-1,9′-xanthene]s (**7**).* These compounds were obtained as follows: A solution of 1,1-diaryl-2-(9′-xanthenylidene)ethylene (0.5 g) in acetic acid (20 ml) was heated to boiling until the deep colour developed on dissolution (red in case of **1a**, and blue violet with **1b—d**) almost discharged (*ca.* 4 h). The solution was cooled, diluted with water and extracted with ether. The extract was washed successively with water, sodium carbonate solution (5%), and water and dried ($MgSO_4$). The residue obtained by evaporation of the solvent was crystallized from methanol to give colourless crystals of compound **7** in *ca.* 90% yield. Thus were obtained: **7a**, mp 174 °C, δ (CCl_4) 7.07 (s, C_6H_5) superimposed on 7.51—6.61 (m, 8H, of xanthene plus 3H, indene), *m/e* 358 (M^+); Found: C, 90.5; H, 5.1%. Calcd for $C_{27}H_{18}O$: C, 90.47; H, 5.06%. λ_{max} 290 nm (AcOH/Ac_2O, 9: 1, v/v) or in AcOH/Ac_2O/$HClO_4$ (70%) (9: 0.9: 0.1, v/v/v).

7b, mp 174 °C;[13] δ (CCl_4) 7.67—6.42 (m, 15H, Ar), 6.35 (s, 1H, indene H-2) and 3.71, 3.53 (2s, 6H, $2CH_3O$); *m/e* 418 (M^+); Found: C, 83.3; H, 5.4%. Calcd for $C_{29}H_{22}O_3$: C, 83.23; H, 5.30%.

7c, mp 157 °C; δ (CCl_4) 7.58—6.46 (m, 15H, Ar), 6.41 (s, 1H, indene H-2), 3.94, 3.78 (2 overlapped q, J=8 Hz, each 2H of C_2H_5O), 1.38 and 1.24 (2 overlapped t, J=8 Hz, each 3H of C_2H_5O); *m/e* 446 (M^+); Found: C, 83.4; H, 5.8%. Calcd for $C_{31}H_{26}O_3$: C, 83.38; H, 5.87%.

7d, mp 122 °C, *m/e* 474 (M^+); Found: C, 83.4; H, 6.4%. Calcd for $C_{33}H_{30}O_3$: C, 83.51; H, 6.37%.

When a solution of **3a** or **3c** (0.5 g) in acetic acid (20 ml) heated to boiling for 5 h and worked up as above, spiroindenes **7a**, mp and mixed mp 174 °C and **7c**, mp and mixed mp 157 °C were obtained respectively in *ca.* 80% yield.

To each solution of **1a** or **1c** (0.5 g) in ethanol (10 ml) concentrated hydrochloric acid (2 ml) was added. Each mixture was heated to boiling for 10 h. The colourless crystals separated on cooling the mixture were collected by filtration and were recrystallized from methanol to give the corresponding indenes **7a** and **7c**, mp and mixed mp 174 and 157 °C respectively.

Hydrogen bromide was bubbled in a cold ethereal solution of **1b** (0.5 g in 15 ml ether) until no more absorption of gas was observed. The mixture was refluxed for 30 min and left overnight. The solvent was recovered and the residue obtained was recrystallized from methanol to give **7b**, mp and mixed mp 174 °C.

9-Benzylxanthylium Perchlorate. To a cold solution of 9-benzylidenexanthene (0.5 g) in a mixture of acetic acid (4 ml)/acetic anhydride (1 ml), perchloric acid (70%, 0.5 ml) was added. The mixture was left for 30 min at room temperature and then was diluted with ether. The deep yellow crystals precipitated were collected by filtration and were washed with ether. They had mp 226 °C which showed no depression when admixed with an authentic sample of 9-benzylxanthylium perchlorate prepared from 9-benzyl-9-hydroxyanthene according to the procedure reported by Conant *et al.*;[13] λ_{max} 288, 336 nm ($AcOH/Ac_2O$, 9: 1 v/v) and λ_{max} 296, 384, 474, and 500 (shoulder) nm ($AcOH/Ac_2O/HClO_4$, 8.9: 1: 0.1 v/v/v) were shown in the spectra of 9-benzylidenexanthene. The same absorption maxima in acetic acid perchloric acid, were obtained when 9-benzylxanthylium perchlorate was measured in acetic acid.

We are indebted to Dr. R. S. Atkinson, Department of Chemistry, University of Leicester, England, for his help to carry out mass and NMR spectra.

Synthesis of *cis*-Aryl Cyclopropyl Sulfones

T. BALAJI and D. Bhaskar REDDY*

Department of Chemistry, Sri Venkateswara University, Tirupati 517502, India

(Received March 17, 1979)

Some new *cis*-1-(arylsulfonyl)-2-phenylcyclopropanes have been synthesized by the addition of arylthiocarbenes to styrene in presence of excess potassium *t*-butoxide at low temperatures. The (arylthio)cyclopropanes thus obtained are subsequently oxidized with 30% hydrogen peroxide in acetic acid to corresponding sulfones. The IR and PMR spectra of all these compounds were recorded. Their IR spectra displayed bands in the region 1033—1008 cm^{-1} which are considered to be the most characteristic of the cyclopropane ring. They have also exhibited bands in the region 850—820 cm^{-1} characteristic of *cis*-configuration. The PMR spectra gave complex multiplets in the region 1.4—3.1 ppm. A study of these chemical shifts for ring protons and other substituents reveals that all the substituents tend to cause protons *cis*-to them to appear at higher fields than those *trans*-to them. Thus the differences of the chemical shifts can be used as a criterion to distinguish between *cis*- and *trans*-1-(arylsulfonyl)-2-phenylcyclopropanes.

One of the important methods[1] of preparing cyclopropanes is by the utility of dimethylsulfoxonium methylide (I) and dimethylsulfonium methylide (II).[2] A wide variety of Michael acceptors have been explored with I and II. α,β-Unsaturated ketones, nitriles, isocyanides and nitro compounds gave good to excellent yields for the preparation of cyclopropanes.[3] The utility of II as a co-reactant with α,β-unsaturated sulfones for the synthesis of cyclopropyl sulfones[4–8] seemed to be stereoselective and the cyclopropane derivatives thus obtained appeared to have *trans*-configuration.

The reaction of carbenes, derivatives of bivalent carbon with carbon-carbon multiple bonds provides one of the important methods for the preparation of cyclopropane compounds. Schoellkopf *et al.*[9–13] reported the preparation of cyclopropanes by treating olefins with chloromethyl phenyl ether ($PhOCH_2Cl$) and chloromethyl phenyl sulfide ($PhSCH_2Cl$) through phenoxycarbene and phenylthiocarbene intermediates respectively. These reactions were considered to proceed stereospecifically *cis*.

Although the synthesis and study of quite a number of *trans*-1-(arylsulfonyl)-2-arylcyclopropanes are known,[4–8] there are no reports about the synthesis and study of corresponding *cis*-compounds in the literature except *cis*-1-(phenylsulfonyl)-2-phenylcyclopropane.[4] It was therefore felt that the preparation of *cis*-1-(arylsulfonyl)-2-arylcyclopropanes would be of quite interest and of significance.

Results and Discussion

The first synthesis[14] of cyclopropyl sulfones was reported by α,γ-dehydrohalogenation of 3-chloropropyl sulfones. A few more cyclopropyl sulfones were reported according to various methods.[4,9,15,16] The synthesis of *cis*- and *trans*-1-(phenylsulfonyl)-2-phenylcyclopropane was reported first, by Truce and Badiger[4] in 1964.

A series of new *cis*-1-(arylsulfonyl)-2-phenylcyclopropanes (see Table 1) were synthesized by the addition of different aryl chloromethyl sulfides to excess of styrene at low temperature (−5 to −10 °C) in presence of excess potassium *t*-butoxide. The *cis*-1-(arylthio)-2-phenylcyclopropanes thus formed were subsequently oxidized with 30% hydrogen peroxide in acetic acid to obtain *cis*-1-(arylsulfonyl)-2-phenylcyclopropanes. Fairly high yields of *cis*-1-(arylsulfonyl)-2-phenylcyclopropanes have been obtained by refluxing for longer periods during the oxidation.

The IR spectra of most of these compounds showed medium to weak intensity bands in the region 1033—1008 cm^{-1} (see Table 2) which were considered to be the most characteristic of the cyclopropane deformation mode of the ring.[8,17–20] These compounds also displayed two high frequency bands in the region 3085—3060 cm^{-1} (ν CH_2 symmetric) and 3025—3000 cm^{-1} (ν CH_2 asymmetric) which in addition to the 1033—1008 cm^{-1} bands confirm the presence of cyclopropane ring system. All these compounds exhibited strong to medium intensity bands in the region 852—820 cm^{-1}, characteristic of *cis*-1-(arylsulfonyl)-2-phenylcyclopropanes.[21] These compounds have also exhibited very strong peaks characteristic of sulfonyl groups[22–25] in the regions 1342—1300 cm^{-1} and 1150—1136 cm^{-1}.

The PMR spectra of the compounds under present investigation exhibited complex multiplets in the region 1.40 to 2.45 ppm (methylene) and 2.36 to 3.12 ppm (methine) (see Table 3). The phenyl and arylsulfonyl groups showed signals in the regions 6.96 to 8.20 ppm. The chemical shifts data have been used[26–28] for the structural problems of cyclopropane derivatives. A study of the chemical shifts for ring protons and other substituent groups in cyclopropanes has indicated generally that all substituents tend to cause protons *cis*-to them to appear at higher fields than those *trans*-to them.

In the structure III both H_A and H_B are having substituents *cis*-to them. Hence H_A and H_B resonate at higher frequency with a small difference of chemical shifts between them, as is observed[7] in *trans*-1-(2-thienylsulfonyl)-2-phenylcyclopropane (H_A 1.50 ppm; H_B 1.89 ppm; H_C 2.77 ppm; H_D 2.89 ppm). Fig. 1. 100 MHz ^1H NMR spectrum of **3** in the high field region (measured in $CDCl_3$).

as in IV H_A has substituents *cis*-to it but H_B is not having likewise. As a result of this, the chemical shift of H_A is observed at higher fields. There is a marked difference between chemical shifts of H_A and H_B in IV in comparison to III.

A representative spectra of these compounds in high field region in $CDCl_3$ is given in Fig. 1. Thus the chemical shifts data of ring protons of cyclopropane derivatives discussed above may be used as a criterion for the configurational assignments of *cis*- and *trans*-1-(arylsulfonyl)-2-phenylcyclopropanes.

The stereospecific synthesis adopted for these aryl cyclopropyl sulfones, IR and PMR spectral data, confirm that all these compounds are *cis*-isomers.

Experimental

All melting points were determined on a Mel-Temp apparatus and are uncorrected. The elemental analyses were performed by Dr. R. D. MacDonald, Australian Micro Analytical Service. The IR spectra were recorded on Perkin-Elmer model 257 in KBr discs. The PMR spectra were obtained at 100 MHz and on a Varian XL-100 spectrometer in deuteriochloroform using TMS as an internal reference. Chemical shifts were recorded in parts per million downfield from tetramethylsilane and IR frequencies in cm^{-1}.

Starting Materials. Styrene is obtained commercially and purified by distillation under reduced pressure.

Thiophenols. The arenesulfonyl chlorides were obtained by the chlorosulfonylation of the corresponding hydrocarbons as described by Huntress and Carten.[30] The arenesulfonyl chlorides were reduced to the corresponding thiophenols with zinc dust and dilute sulfuric acid. The procedure adopted was a modification of the method described by Vogel.[31] To a mixture of crushed ice and concentrated sulfuric acid the arenesulfonyl chloride was added with stirring. The zinc dust was added in portions as rapidly as possible to the cooled mixture without allowing the temperature to rise above 10 °C. The distillate obtained after the steam distillation of the mixture was extracted with ether. The product obtained after evaporation of ether was purified. Thiophenol: bp 168—169 °C, *p*-chlorothiophenol: mp 52—53 °C, *p*-bromothiophenol: mp 74—76 °C, *p*-thiocresol: bp 195—196 °C, *p*-methoxythiophenol: bp 225—227 °C, 3,4-dichlorothiophenol: bp 80—81 °C/8 mmHg. The *p*-nitrothiophenol: mp 73—74 °C, was prepared according to the procedure of Price and Stacy.[32]

Aryl Chloromethyl Sulfides: The aryl chloromethyl sulfides were prepared following the procedure of Francher.[33] A mixture of paraformaldehyde and benzene was taken in a conical flask and to this, concentrated hydrochloric acid was added rapidly with stirring. After a while, the mixture was kept at 40 °C and the appropriate thiol in benzene was added slowly. The resulting mixture was maintained slightly above 40 °C for 2 h. After removing the solvent the products were purified by distillation under reduced pressure. Phenyl chloromethyl sulfide: bp 109—110 °C/11 mmHg, *p*-chlorophenyl chloromethyl sulfide: bp 131—132 °C/12 mmHg, *p*-bromophenyl chloromethyl sulfide: bp 164—165 °C/18 mmHg, *p*-methoxyphenyl chloromethyl sulfide: bp 175—176 °C/20 mmHg, *p*-nitrophenyl chloromethyl sulfide: mp 54—55 °C, 3,4-dichlorophenyl chloromethyl sulfide: bp 144—145 °C/8 mmHg.

General Procedure for the Preparation of cis-*1-(Arylsulfonyl)-2-phenylcyclopropanes*: In a 250 ml three necked flask equipped with magnetic stirrer and fitted with a dropping funnel and calcium chloride guard tube was placed 25 ml of styrene. Small portions of potassium *t*-butoxide (5 g, 20% excess than 0.025 mol) was added with stirring to styrene at −5 to −10 °C. The aryl chloromethyl sulfide was added dropwise to the above mixture. After the complete addition the reaction mixture was stirred for 3 h and was diluted with water. The oily layer was separated and dried over anhydrous calcium chloride. It was then subjected to fractional distillation under reduced pressure and the product *cis*-1-(arylthio)-2-phenylcyclopropane was collected.

The sulfide (2.0 g) was dissolved in 20 ml of glacial acetic acid and 9 ml of 30% hydrogen peroxide was added to the mixture at ice-cold temperature. The mixture was refluxed for 25 to 48 h. It was then poured on to crushed ice and the solid separated was filtered off and dried. The product *cis*-1-(arylsulfonyl)-2-phenylcyclopropane was recrystallized from 2-propanol. The relevant data on the compounds synthesized are given in Table 1.

One of the authors (T.B.) is thankful to CSIR, India, for awarding him a Junior Research Fellowship.

Stereochemistry of Diels-Alder Reactions at High Pressure. II. Influence of High Pressure on Asymmetric Induction in Condensation of (−)-Di-(*R*)-menthyl Fumarate with Butadiene and Isoprene[1)]

Janusz Jurczak

Institute of Organic Chemistry, Polish Academy of Sciences, 01-224 Warszawa, Poland

(Received December 18, 1978)

The high-pressure Diels-Alder condensation of (−)-di-(*R*)-menthyl fumarate with butadiene and isoprene, followed by reduction of the adducts with lithium aluminium hydride, produced (1*S*,2*S*)-(+)-4-cyclohexene-1,2-dimethanol and (1*S*,2*S*)-(+)-4-methyl-4-cyclohexene-1,2-dimethanol in 6.2—12.8% optical yield, depending on the pressure applied. Results of asymmetric synthesis were discussed in light of the concept of parallel transition states. An interpretation of the thermal and Lewis-acid-catalyzed asymmetric Diels-Alder condensations using (−)-di-(*R*)-menthyl fumarate was proposed.

The Diels-Alder reaction is one of the best known organic reactions.[2)] In recent years the effect of pressure on the course of the (2+4) cycloaddition reaction has been widely studied.[3)] Cycloaddition reactions are characterized by negative values of activation volume ΔV^{*} defined as the difference between the volume occupied by the transition state and that occupied by the reactants. The large negative activation volume means that the reaction ought to be accelerated by an increase in pressure. Although this concept is very clear and simple from the theoretical standpoint, there are so far few studies dealing with the utilization of high pressure in organic synthesis.[4—6)] This is due to the relative inaccessibility of high-pressure equipment permitting work on a preparative scale.

High-pressure kinetics are much more frequently studied.[3,7,8)] High-pressure kinetics in solution permit observation of the activation volume ΔV^{*} whose changes are a convenient tool for interpretation of the mechanism of the reaction.

$$\Delta V^{*} = -RT(\partial \ln k/\partial P)_T$$

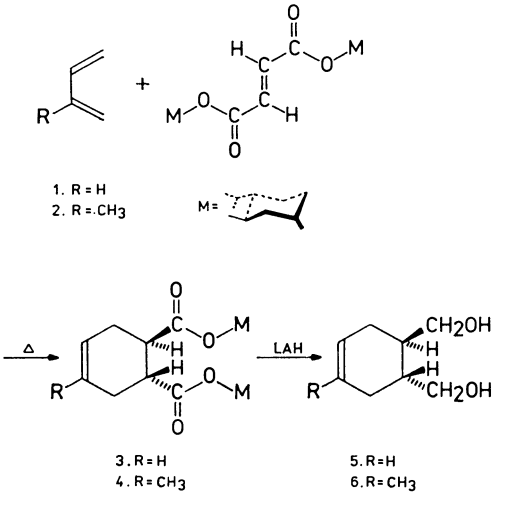
McCabe and Eckert[7)] have shown that the mechanism of the Diels-Alder reaction is of the nature of a concerted process, according to Woodward and Hoffmann.[9)] The (2+4) cycloaddition reaction is characterized by a large negative activation volume, and in some cases the activation volume is more negative than the volume change of reaction, ΔV_r ($\Delta V_r = V_{\text{products}} - V_{\text{reactants}}$). That is, in this case, the transition state is actually more compact than the product, probably due to the occurance of secondary π interactions in the transition state.[10)]

Recently we have observed an effect, heretofore unreported, of high pressure on the direction and magnitude of asymmetric induction in the Diels-Alder condensation of 1-methoxy-1,3-butadiene with (*R*)-(−)-menthyl glyoxylate.[1)] Satisfactory results of these preliminary investigations led us to undertake systematic studies on the effect of high pressure on the stereochemistry of the Diels-Alder reaction, especially on asymmetric induction.

In the present study we report the reaction between butadiene or isoprene and (−)-di-(*R*)-menthyl fumarate. Historically, this is the system for which Korolev and Mur[11)] first demonstrated the possibility of asymmetric induction in diene synthesis in 1948.

Results

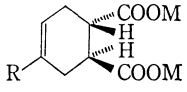
The pioneering work of Korolev and Mur[11)] was repeated and extended by Walborsky *et al.*[12)] who studied the effect of a Lewis acid catalyst on asymmetric induction. Thermal condensation of butadiene or isoprene with (−)-di-(*R*)-menthyl fumarate was carried out by these authors at 25—180 °C in benzene as solvent (Scheme 1).

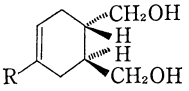


Scheme 1.

Optical yield and the direction of asymmetric induction were studied by measurements of the optical rotation of glycols **5** and **6** whose absolute configurations were established to be (−)-(1*R*,2*R*) by chemical correlations. Specific rotations of pure enantiomers were for **5** $[\alpha]_{589}^{22}$ −70.4° (*c* 3.0, in chloroform) and for **6** $[\alpha]_{589}^{25}$ −78.8° (*c* 3.4, in chloroform). In non-catalyzed reactions carried out at room temperature the products showed no induced optical activity. Elevation of temperature brought about formation of optically active products (0.8% optical yield at 65 °C and 3% at 180 °C), with predominance of the adduct with a 1*R*,2*R* configuration. Longer reaction time increased the total yield of the product, without changing the optical yield. The effect of solvent on the optical yield was slight. Reactions carried out in the presence of Lewis acids afforded predominantly

Table 1. Condensations of butadiene (**1**) and/or isoprene (**2**) with (−)-di-(*R*)-menthyl fumarate in different solvents under high pressure at 25 °C





Diene	Solvent	ΔP/kbar	Yield/%	$[\alpha]_{589}^{20}$ in $CHCl_3$	c	Abs. conf.	Optical yield/%
1	$C_6H_5CH_3$	6.9	100	+9.0°	3.14	1*S*,2*S*	12.8
1	CH_2Cl_2	6.9	100	+5.2°	3.22	1*S*,2*S*	7.4

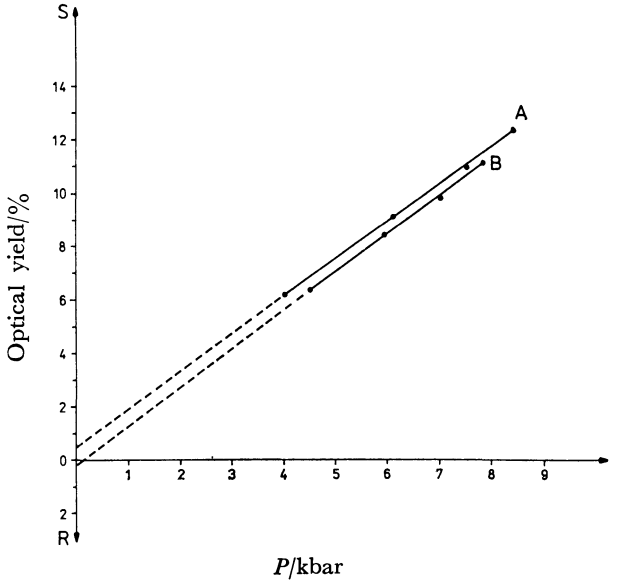

Fig. 1. Dependence of optical yield on pressure in the reactions between isoprene and (−)-di-(*R*)-menthyl fumarate carried out in toluene (A) and dichloromethane (B).

the adducts with opposite absolute configuration, 1*S*,2*S*; optical yields of the asymmetric synthesis were very high—about 75%.

For high-pressure studies of the stereochemistry of the Diels-Alder reaction, earlier observations[13] and preliminary experiments showed that the optimal conditions for the reactions of (−)-di-(*R*)-menthyl fumarate with dienes is at 25 °C and about 7 kbar for 20 h, which afforded a $\sqrt{100}$% yield of the product. These conditions were accepted for all high-pressure reactions presented in this study.

In the present studies toluene and dichloromethane were employed as solvents (solidification pressures at room temperature are about 8.8 kbar and about 8 kbar, respectively). We selected these two solvents also because previous work[14] showed that there is a change in the direction of asymmetric induction in the Diels-Alder reaction of 1-methoxy-1,3-butadiene with (*R*)-(−)-menthyl glyoxylate upon changing from an aromatic solvent to dichloromethane or chloroform. Results are presented in the Table showing the yields of adducts **3** or **4**, optical yields and configurations at C-1 and C-2.

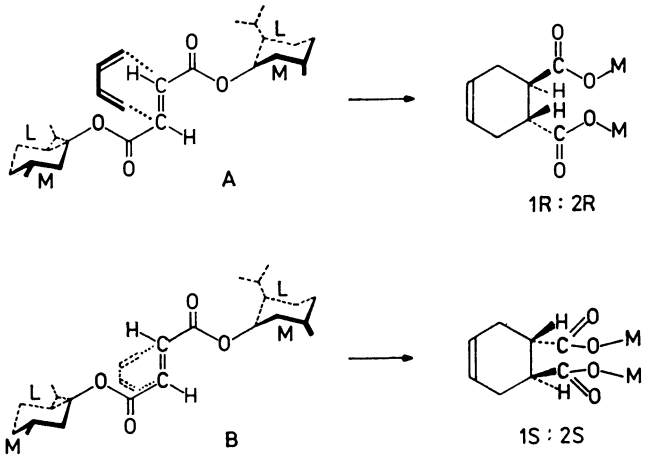
The reaction of butadiene (**1**) with (−)-di-(*R*)-menthyl fumarate in toluene or dichloromethane at approximately 7 kbar gives adduct **3** in a quantitative yield. In all cases *S* configuration is induced at C-1 and C-2; the optical yield is higher in toluene than in dichloromethane. For systematic studies of the effect of pressure on the optical yield of the reaction, isoprene (**2**) was selected as a solvent. In all four reactions carried out in toluene (4.0—8.4 kbar), we obtained product **4** with predominance of the diastereomer of 1*S*,2*S* configuration. The optical yield increased from 6.2% at 4.0 kbar to 12.4% at 8.4 kbar. Similar results were obtained in reactions carried out in dichloromethane. Comparison of the dependence of optical yield on pressure in both solvents is presented graphically in Fig. 1.

The plots clearly testify to the same linear nature of the dependence of optical yield on pressure for both solvents; under the same pressure, optical yields are somewhat higher in toluene than in dichloromethane.

Discussion

Walborsky[12] has accepted the conformational model of Prelog[15] for (−)-di-(*R*)-menthyl fumarate as well as the concept of a rigid transition state in the Diels-Alder reaction[2] (Scheme 2).

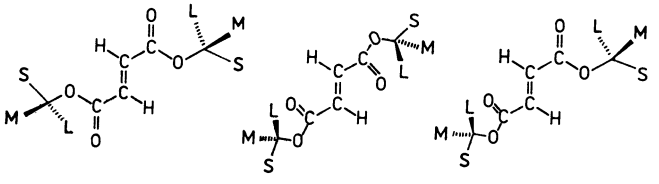
The dienophile and diene approach each other in parallel planes, which results in two possible transition states of the reaction: "A", in which the diene is situated above the dienophile plane from the side of the smaller substituent M, giving an adduct of 1*R*,2*R* configuration, and "B", in which the diene is situated



Scheme 2.

under the dienophile plane, from the side of larger substituent L, giving an adduct of 1*S*,2*S* configuration. The optical activity of the product is due to the difference in the steric ease of mutual approach of the reactants from one or the other side.

Conformational analysis of dienophile leads to the conclusion that three low-energy conformations are prefered: *s-trans*, *s-trans* (**7**), *s-cis*, *s-cis* (**8**), and *s-trans*, *s-cis* (**9**) (Scheme 3). Transoid-transoid conformation **7** prefers the approach of diene "from above," yielding the 1*R*,2*R* product. Cisoid-cisoid conformation **8** brings about formation of the 1*S*,2*S* product. In case of the transoid-cisoid conformation **9**, no asymmetric induction can be expected in reactions with symmetric dienes (*e.g.* butadiene).

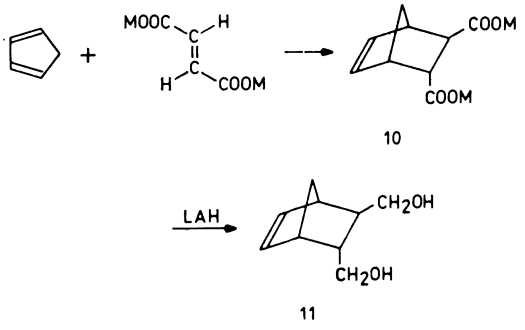


Scheme 3.

Acceptance of the concept of parallel transition states, as proposed by us,[14] permits elucidation of the stereochemical course of asymmetric diene synthesis, without severe deviation from the rules of Prelog[15] and Cram.[16]

For interpretation of the present results of condensations at room temperature, we assume that the optical yield is the result of the population of conformers **7** and **8** in the ground state. It is intuitively obvious that the probabilities of formation of transition states with the participation of conformers **7** and **8** are almost the same, and thus the difference between the activation energies of both transition states is only slight. Therefore, asymmetric induction should depend on the population of conformers **7** and **8**, which at constant temperature ought to be affected by the solvent used. Indeed, we found differences between the absolute configuration and optical yields of the products of the reaction of isoprene with (−)-di-(*R*)-menthyl fumarate run in toluene (2*S*,6*S*, 0.6%) and in dichloromethane (2*R*,6*R*, 0.4%);[17] this seems to confirm the accepted assumption.

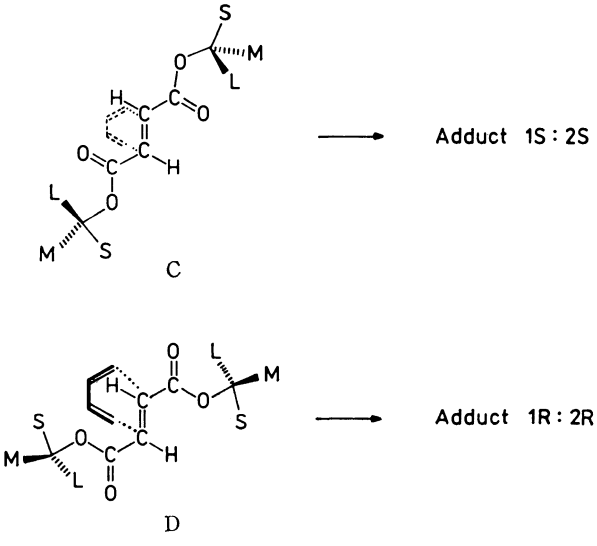
Similar results have been obtained by Sauer and Kredel[18] in reactions of cyclopentadiene with (−)-di-(*R*)-menthyl fumarate (Scheme 4), carried out at 35 °C in several solvents. Using acetone and dioxane, these authors have obtained product **10** with optical yields of 2.8% and 1.5%, respectively; the resulting glycols **11** were dextrorotatory. Upon use of dichloromethane, the optical yield was 3.6%, and the resulting glycol was levorotatory.



Scheme 4.

Results of the high-temperature condensations of Walborsky[12] can be interpreted using the above concept. Elevation of temperature changes the conformational equilibrium of the dienophile, in this case in favor of transoid, transoid form **7**, which is responsible for the formation of the adduct of 1*R*,2*R* configuration. The tendency for an increase in optical yield with elevation of temperature[12] confirms our interpretative approach.

In high-pressure reactions we obtained, irrespective of the solvent, adducts of 1*S*,2*S* configuration, with optical yields much higher as compared with atmospheric-pressure reactions carried out at the same temperature. Optical yields increase distinctly with an increase in pressure. We shall consider these facts in light of the concept of parallel transition states[14] (Scheme 5).



Scheme 5.

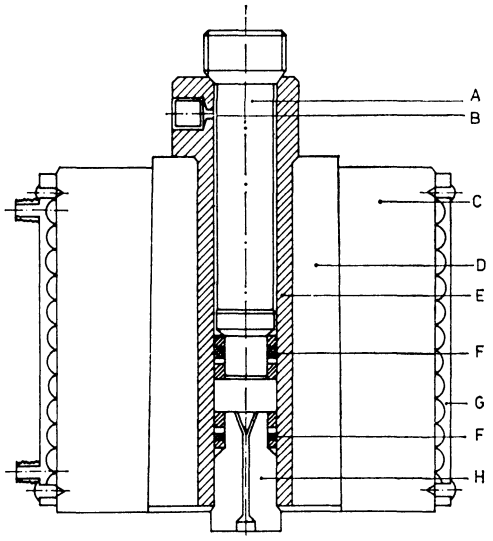


Fig. 2. Sketch of high-pressure apparatus.

Induction of the 1*S*,2*S* configuration in the high-pressure reaction indicates clearly that the active complex of the "C" type is favored, which suggests that it is more compact than "D". The probability of formation of active complex "C" increases with increasing pressure which is in practice the sole parameter determining the optical yield.

The direction of asymmetric induction in high-pressure reactions is identical to that in the reactions catalyzed by Lewis acids; in either case adducts of absolute 1*S*,2*S* configuration are formed. This may suggest that in both cases transition states of a similar type, *i.e.* with a cisoid-cisoid conformation of the dienophile, are preferred.

This conclusion is supported by high-pressure studies of the catalyzed Diels-Alder reaction between 2,3-dimethyl-1,3-butadiene and butyl acrylate, carried out by Poling and Eckert.[19] According to these authors, the activation volume for the reaction catalyzed by $AlCl_3$ is $\Delta V^{\neq} = -25.7$ cm^3/mol and for the non-catalyzed reaction it is $\Delta V^{\neq} = -28.6$ cm^3/mol. Comparison of these two values clearly points to similarities in the structures of the transition states of both reactions.

Experimental

Bps refer to air-bath temperatures. Mps (uncorrected) were determined on a Kofler block. Polarimetric measurements were performed with a Perkin-Elmer 141 automatic polarimeter. Silica gel G Merck was used for TLC, and silica gel 100—200 mesh Macherey-Nagel for column chromatography. All reactions and chromatographic separations were monitored in TLC. All high-pressure reactions were carried out in a piston-cylinder type apparatus. Initial working volume was about 10 ml. The details of this apparatus, previously applied to various investigations on the metal-hydrogen system,[20,21] are presented in the Fig. 2. The internal part (E) consisted of a beryllium brass vessel supported by two external steel rings (C,D). A jacket (G) supplied by flowing water served thermostatic conditions. It could be maintained within ±1 °C. The electrical leads for pressure and temperature measurements (manganine manometer, thermocouple) were led through a conical electrode placed in the stopper (H) of beryllium brass. The mobile piston (A) was made of special steel composition with an ending of beryllium brass. The sealing (F) of the mobile piston and the stopper was conventional character (O-ring and metallic Bridgeman type sealing) as described previously[22]. The reaction can be done under any gaseous atmosphere. The gas was introduced into the working volume through the capillary inlet (B), being initially compressed to 1—1.5 kbar in a separate multiplier.[21] The pressure inside the working volume was measured by a calibrated manganine coil with accuracy ±0.1 kbar.

Butadiene and isoprene were redistilled commercial (Fluka) reagents. (—)-Di-(*R*)-menthyl fumarate was prepared according to earlier procedure,[11] mp 59—60 °C, $[\alpha]_{589}^{20}$ −103.1° (*c* 1.55, in chloroform).

Condensations of butadiene and/or isoprene with (—)-di-(*R*)-menthyl fumarate.

Partial asymmetric synthesis of *trans*-4-cyclohexene-1,2-dimethanol (**5**) and *trans*-4-methyl-4-cyclohexene-1,2-dimethanol (**6**) was effected using both the atmospheric- and high-pressure methods.

Procedure A; *Atmospheric-pressure Method.* To a solution of 1.96 g (5 mmol) (—)-di-(*R*)-menthyl fumarate and 10 mg hydroquinone in 20 ml of toluene, 0.68 g (10 mmol) isoprene was added and the mixture was left at room temperature for 300 h. Solvent was removed and residue was dissolved in anhydrous ether and added to a refluxing slurry of 2.2 g (6 mmol) lithium aluminium hydride in 100 ml anhydrous ether. The reaction mixture was dried ($MgSO_4$) and filtered. The solvent was evaporated and the product isolated by column chromatography. Menthol was eluted using a mixture of ligroin and ether (9 : 1, v/v) and the glycol **6** was eluted using a mixture of ligroin and ether (7 : 3, v/v). After removal of the solvents the residue was distilled to give **6** (70%), bp 128—130 °C/0.2, mp 54—57 °C (from ether).

Procedure B; *High-pressure Method.* The high-pressure apparatus, closed on the bottom with a stopper, was filled with the reaction mixture (2.5 mmol (—)-di-(*R*)-menthyl fumarate, 5 mmol butadiene and 5 mg hydroquinone in 10 ml of dichloromethane) and a mobile piston was inserted. Then the whole assembly was placed between the pistons of a hydraulic press and the pressure was elevated up to 7.3 kbar. After stabilization of the pressure the heater was switched on, whereupon the temperature was raised to 25 °C and pressure to 7.4 kbar. The reaction mixture was kept under these conditions for 20 h. Pressure was released and the solvent was evaporated. The residue (100% yield of adduct **3**) was treated with 1 g (2.7 mmol) of lithium aluminium hydride in anhydrous ether for 12 h and the glycol **5** isolated (78%), bp 103—105 °C/0.2. The glycol **5** solidified on standing, mp 49—53 °C.

The author is very indebted to Professors B. Baranowski and A. Zamojski for stimulating interest and helpful discussions and to Mrs. M. Zajaczkowska and Mr. M. Tkacz for fruitful cooperation. This work was supported by grants from the Polish Academy of Sciences (MR I-12.1.1.1 and 03.10.7.01.01).

SO_2-Produced Acidic Hydroxyl Groups and the Catalytic Activities of Alkaline Earth X Zeolites

Kiyoshi Otsuka,* Yuji Wada, Kimiaki Tanaka, and Akira Morikawa

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 30, 1979)

Synopsis. The generation of Brönsted acid sites by SO_2-adsorption on alkaline earth X zeolites has been examined by infrared spectroscopy. The SO_2-induced catalytic activities of the zeolites in the double-bond isomerization of butenes can be ascribed to both the increase in the number of acidic hydroxyl groups and the enhancement in the catalytic activities of the groups after the SO_2 adsorption.

The kinetic studies of the SO_2-induced isomerization of 2-butene over various cation-exchanged X zeolites have been reported in the previous paper.[1,2] It was inferred that the promoting action of SO_2 on the rate of double-bond isomerization of butenes is caused by the generation of acidic hydroxyl groups. The formation of acidic hydroxyl groups by the adsorption of NO_2, SO_2, or Cl_2 has been confirmed on CaY zeolites, and the induced catalytic acitivity of the zeolite in dehydration of 2-propanol by these inorganic gases has been attributed to the formation of the acidic hydroxyl groups.[3] The object of the present work is to examine these suggestions by studying the generation of the Brönsted acid sites after SO_2-adsorption by infrared spectroscopy.

Experimental

The alkaline earth X zeolites used were prepared by a conventional ion exchange of a NaX zeolite (13X from Linde) with aqueous solution of the appropriate chlorides. The percentages of cation exchange, expressed by 100 ([Al]—[Na])/[Al], were as follows: MgX (78), CaX (78), SrX (94), and BaX (93).

The apparatus and the materials used and the analysis of butene isomers were described elsewhere.[1]

Prior to every run, the catalyst in the reactor was degassed under vacuum for 2 h at the required temperature. After the adsorption of SO_2 at 25 °C for 30 min, the isomerization was started at the same temperature by feeding *cis*-2-butene (1.29×10^{-3} mol) and circulating the gas through the catalyst bed.

Infrared-spectra measurements were made with the zeolite in the form of a self-supporting wafer (3—4 mg/cm^2). The sample wafer was calcined in dried oxygen at 400 °C in the IR-cell and degassed in a vacuum at the same temperature for 1 h. The wafer was then brought into contact with 15 Torr of D_2O vapor for 1 h at 200 °C to exchange OH by OD groups, because the broad OH stretching band around 3600 cm^{-1}, probably due to adsorbed water molecules on the zeolites, makes it difficult to identify the different kinds of OH groups. After this treatment, the wafer was outgassed again in a vacuum for 1 h at 400 °C. The spectra of the wafer were recorded, before and after a required amount of SO_2 was adsorbed at 100 °C, using a Shimadzu IR-430 grating spectrometer. It was confirmed that all the SO_2 introduced was adsorbed on the zeolites under the experimental conditions applied here.

Results and Discussion

Figure 1 shows the infrared spectra of the zeolites at the region of OD-stretching vibration, taken before and after the adsorption of SO_2. For all the zeolites, the intensities of the bands for OD groups around 2695 cm^{-1}, corresponding to the band at ≈3640 cm^{-1} due to acidic OH groups in the super cage for the undeuterated alkaline earth faujasites,[4-6] increased after the adsorption of SO_2. The shift in the frequency of the acidic OD band to a lower frequency of about 4 cm^{-1} has been confirmed by repeated experiments for the infrared spectra of the MgX zeolite. This shift caused by SO_2 was not clear within experimental error (±2 cm^{-1}) for the other three zeolites.

The increase in the absorbance of the acidic OD band at the maximum caused by the SO_2-adsorption and the rate of SO_2-induced double-bond isomerization of *cis*-2-butene have been plotted in Fig. 2 as functions of the amount of SO_2 on the zeolites. The dotted-lines or curve for the rate of the isomerization were from the data for the zeolites pretreated at 500 °C in the previous work.[2] For the CaX zeolite pretreated

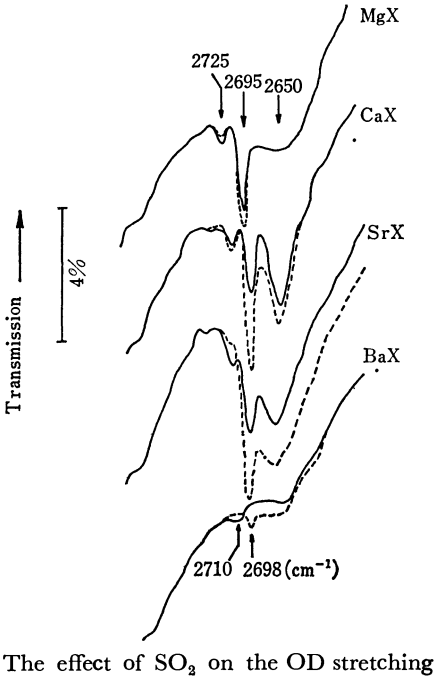

Fig. 1. The effect of SO_2 on the OD stretching bands of the alkaline earth zeolites: ——, without adsorbed SO_2; ----, after the addition of SO_2. The amount of SO_2 adsorbed (10^{-4} mol g^{-1}): MgX, 1.3; CaX, 1.5; SrX, 3.2; BaX, 1.3.

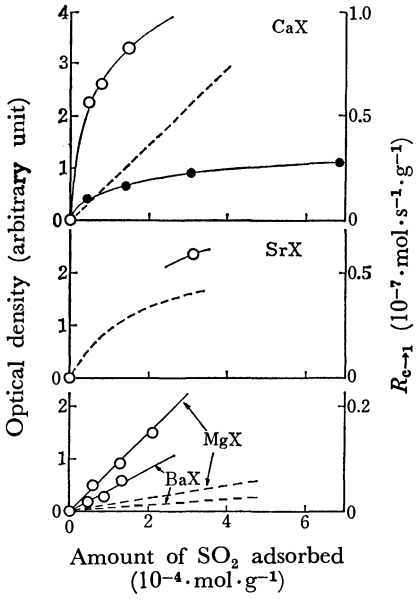

Fig. 2. The optical density of the acidic OD band generated by SO_2 and the rate of the double-bond isomerization as a function of the amount of pre-adsorbed SO_2: ○, optical density of the SO_2-induced acidic OD band; ●, the rate of double-bond conversion, $R_{c\rightarrow 1}$, over the CaX pretreated at 400 °C; ----, $R_{c\rightarrow 1}$ obtained for the zeolites pretreated at 500 °C.

at 400 °C, the catalytic activity in the isomerization increases with a rise in the concentration of SO_2 adsorbed in the similar way as that of the increase for the absorbance of acidic OD groups. Although the pretreatment temperatures for MgX, SrX, and BaX zeolites are different in the experiments of activity test and infrared spectra measurement, the identical order observed in the SO_2-induced activities among the four zeolites, *i.e.*, CaX≃SrX>MgX>BaX, has been confirmed in the generation of acidic OD groups.

The schemes proposed for the formation of Brönsted acid sites are as follows:[2,3]

$$M^{2+}(H_2O)_x + SO_2 \longrightarrow M^{2+}[SO_3]^{2-} + 2H^+ + (H_2O)_{x-1} \quad (1)$$

or

$$M^{2+}(OH)^- + SO_2 \longrightarrow M^+\text{-}O\text{-}S(=O)\text{-}O^- + H^+ \quad (2)$$

where, $M^{2+}(H_2O)_x$ is the divalent cation coordinated by water, and $M^{2+}(OH)^-$ is the basic hydroxyl groups formed through the following reaction:[5,7]

$$M^{2+} + H_2O \rightleftharpoons M^{2+}(OH)^- + H^+ \quad (3)$$

Mirodatos, Pichat, and Barthomeuf have suggested that the OH band at 3685 (MgY) (2710 cm^{-1} in the case of the corresponding OD band) or 3675 cm^{-1} (CaY) should be attributed to the basic OH group of M^{2+}-$(OH)^-$ which is responsible for the generation of acidic OH group after CO_2 addition.[8] The OD bands at 2725—2710 cm^{-1} shown in Fig. 1 correspond to the band due to the basic OD groups. In fact, for MgX, SrX, and BaX, the intensities of these OD bands decreased after the introduction of SO_2, accompanying the increase in intensities of acidic OD groups at ≈2695 cm^{-1} as shown in Fig. 1. However, the relatively greater increase in the intensities of the latter bands compared to the decrease in the former bands suggests that the generation of acidic OH groups cannot be attributed only to the reaction of Scheme 2. We believe that Scheme 1 is also important for the generation of the acid sites.

The spectra in Fig. 1 demonstrate the presence of OD groups at ≈2695 cm^{-1} even in the absence of SO_2 on MgX, CaX, and SrX. These OD groups, however, do not catalyse the isomerization of *cis*-2-butene at 100 °C. The reactivity of the acidic OH group at ≈3640 cm^{-1} with *cis*-2-butene has been examined at 100 °C for MgX before and after the adsorption of SO_2. In the absence of SO_2, the intensity of the OH band did not change by the addition of *cis*-2-butene. On the other hand, the intensity of the band decreased considerably with time in the presence of SO_2. These results suggest that the reactivity of the acidic OH group at ≈3640 cm^{-1} or of the OD group at ≈2695 cm^{-1} increases after the addition of SO_2. Hence, the favorable action of SO_2 on the catalytic activities of the zeolites can be ascribed not only to the increase in the number of acidic hydroxyl groups but also to the enhancement in the catalytic activities of the groups. The little or no change in the frequency of the OD band after the adsorption of SO_2 does not give us any information about the difference in the nature of the OD groups in the presence and absence of SO_2. A possible explanation for the increase in the reactivities of OD groups is that the acidic strength of the OD groups has been totally enhanced through the inductive effect of SO_2 adsorbed on the surface. An alternative explanation is that SO_2 may release the OD or OH groups which had been inhibited in regard to catalysis by the basic $M^{2+}(OD)^-$ or $M^{2+}(OH)^-$ species (Eq. 3).[9] Further studies are needed to clarify these points.

Addition of SO_2 onto alkaline earth hydroxides, such as $Mg(OH)_2$, $Ca(OH)_2$, and $Sr(OH)_2$, which contain a large number of basic hydroxyl groups and water molecules, causes neither the catalytic activities of these compounds in the double-bond isomerization of butene nor the generation of new hydroxyl groups. These tests have been carried out at 25 °C on the hydroxides pretreated at various temperatures between 100 and 400 °C. These results indicate that the reactions of Schemes 1 and 2 are found specifically on zeolites. A strong electrostatic field in the zeolite cavity must play an important role for the generation of the acidic OH groups.

(Received April 10, 1979)

Synopsis. Activity coefficients and molar conductivities of biguanide salts (Bg·HX) in aqueous solutions were determined at 25 °C. The values of mean activity coefficients of these salts were relatively low and lay in the order Bg·HOAc>Bg·HCl>Bg·HBr>ButylBg·HCl. These results were discussed in terms of the ion-ion interactions and the concomitant structural change of water.

Biguanide is a condensed compound of two molecules of guanidine and its salts are known to induce a significant change of conformation of protein in aqueous solutions.[1] Some of its alkyl and arylalkyl derivatives have been used clinically as hypoglycemic agents.

In a previous paper,[2] we reported that there was a close relation between $\gamma_\pm$ values and the denaturation abilities of various guanidinium salts with different counter anions, that is, the lower the $\gamma_\pm$ values are, the stronger the denaturation abilities are. The minimum concentration of a biguanide salt to produce the denaturation of BSA is about a half of that of the guanidinium salt.[3] On the basis of the similarities of functional group and the molecular structure between these two kinds of salts, the denaturation mechanism of biguanide salts seems to be similar to that of the guanidinium salts. As for the protein denaturation, the structure breaking action of the guanidinium salt is considered to be the most important factor. From these points of view, we determined the osmotic and activity coefficients of some biguanide salts and discussed their effects on the structure of water by using the cosphere overlap model of Desnoyers.[4]

Experimental

Materials. Biguanide hydrochloride, hydrobromide, and acetate were prepared from biguanide sulfate monohydrate obtained from Aldrich Chemical Co., Ltd. The crude compounds were recrystallized twice or more from ethanol. Butylbiguanide hydrochloride was obtained from Sankyo Co., Ltd. and used without further purification. The purities of these salts were described elsewhere.[3] These salts were dissolved in redistilled and deionized water.

Methods. Osmotic and activity coefficients were determined at 25±0.02 °C by the isopiestic comparison method described elsewhere.[3] From the osmotic coefficient (ϕ), mean activity coefficient ($\gamma_\pm$) was calculated from Eq. 1.

$$\ln \gamma_\pm = (\phi - 1) + 2\int_0^{\sqrt{m}} \frac{\phi - 1}{\sqrt{m}} d\sqrt{m} \qquad (1)$$

where m is the molality of salt. Buoyancy corrections were made for biguanide salts using the densities of solid salts reported previously.[3] For the determination of isopiestic molality, buoyancy correction was also made to the aqueous solution on the assumption that the densities of aqueous solutions were all unity. The isopiestic molalities of aqueous solutions of potassium chloride (reference solute) and the biguanide salts are shown in Table 1. The experimental determination of isopiestic concentrations is precise to ±0.2%. Conductance was measured by the universal bridge manufactured by Yokogawa-Hewlet-Packard Co., Ltd. at 25± 0.05 °C. The conductance of the solution was obtained by subtracting the experimental value of conductance of water from that of the solution to avoid the effect of CO_2 dissolved in water. The molar conductivity at infinite dilution was obtained graphically by using the Fuoss-Onsager equation.[5]

Results and Discussion

The values of ϕ and $\gamma_\pm$ are shown in Table 2. The values of log $\gamma_\pm$ *vs.* $\sqrt{m}$(mol kg^{-1})$^{1/2}$ curves for various biguanide salts approach the Debye-Hückel limiting line (DHL-L) from above at low concentration, indicating the absence of such ion pairs as seen in the case of cadmium sulfate. The relatively low values of log $\gamma_\pm$ for Bg·HOAc, Bg·HCl, and Bg·HBr as compared with the alkali metal salts with the same counter anions, may be attributed to the nature of structure breaking of the biguanide ion. The values of log $\gamma_\pm$ for three biguanide salts lie in the same order ($OAc^- > Cl^- > Br^-$) as the guanidinium salts with the corresponding counter anions.[2] The values of log $\gamma_\pm$ for Bg·HCl and Bg·HBr are smaller than those of guanidinium chloride and bromide respectively, while the value of log $\gamma_\pm$ of Bg·HOAc is larger than that of guanidinium acetate. The order of log $\gamma_\pm$ is consistent with the order predicted by the cosphere overlap model on the assumption that the biguanide ion is a structure breaker and cation-anion interaction predominate over the other interactions. The differences of log $\gamma_\pm$ values between biguanide and guanidinium salts imply that the biguanide ion breaks water structure more significantly than the guanidinium ion does. Butyl Bg·HCl shows the lowest value among the four salts. On the basis of the cosphere overlap model, this result can be attributed to the hydrophobic cation-cation interaction. As the concentration increases and two butylbiguanide ions approach each other, the water-structure-enforced ion pairing would occur to compensate the decrease of the entropy based on the hydrophobic hydration, leading to the decrease of $\gamma_\pm$ value. Therefore cation-cation interaction is the most predominant factor for the decrease of $\gamma_\pm$ value of butylbiguanide hydrochloride, while cation-anion interactions for the other three salts.

The molar conductivities of biguanide salts and ions at infinite dilution are shown in Table 3. Using the Λ° values in Table 3, the Stokes' radius (γ_s) of

each biguanide ion and butylbiguanide ion calculated from Eq. 2 were 2.57 and 3.52 Å.

$$\gamma_s = \frac{0.82|z|}{\Lambda^\circ \eta_0} \qquad (2)$$

where z and η_0 are the valency of ion and the viscosity of water, respectively. Partial molar volumes at infinite dilution of biguanide ion and butylbiguanide ion were 69.8 and 137.1 cm^3/mol at 25 °C, respectively.[3] Assuming that these ions are spherical, the ionic radii of biguanide ion and butylbiguanide ion

Table 3. Molar conductivities of biguanide ions and salts at 25 °C

Salts or ions	Λ° / cm^2 Ω^{-1} mol^{-1}
Bg·HCl	112.4
Bg·HBr	114.3
Bg·HOAc	76.2
ButylBg·HCl	102.5
Bg·H$^+$	35.8
ButylBg·H$^+$	26.2

are calculated to be 2.55 and 3.20 Å, respectively. The ionic radius of the biguanide ion obtained from the partial molar volume is almost the same as that obtained from Eq. 2. But as for the butylbiguanide ion, the former is smaller than the latter indicating the hydrophobic hydration of butyl group.

The denaturation abilities for the three biguanide salts lie in the order $Br^- > Cl^- > OAc^-$, which is the reverse order of $\gamma_\pm$ values. This fact supports that the structure breaking actions of the biguanide salts contribute to the denaturation of protein in aqueous solutions. As reported previously,[3] butyl Bg·HCl has the strongest denaturation ability, but the denaturation mechanism may be different from the other three salts on the basis of the consideration of the mean activity coefficients. In other word, the hydrophobic interaction between the butyl group of butylbiguanide and the hydrophobic moiety of protein may play an important role as observed in the interaction of tetraalkylammonium salts and DNA.[6]

From the analysis of viscosity B-coefficients, the biguanide ion was concluded to be neither a structure maker nor a structure breaker.[3] But thermodynamically the biguanide ion should be a structure breaker. We have no idea to account for the discrepancy at the present stage. Now we are planning NMR study for solving this problem.

Resonance Energy Stabilization in Crystalline Ion Radical Salts

Yôichi IDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 20, 1979)

Synopsis. In solid ion radical salts, the ion radical molecules form a segregated stacking into columns, and the charge-transfer interaction occurs between ion radicals. The resonance energy stabilization due to the charge-transfer interaction was estimated for non-alternant one-dimensional system of solid ion radical salts.

The prominent magnetic, electrical, and optical properties of solid ion (cation or anion) radical salts have been the subject of many theoretical and experimental investigations over the past seventeen years.[1-5] In such solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into columns so as to make a large overlap between their half-occupied molecular orbitals.[2,3] In this case, any individual radical molecule interacts through charge transfer most strongly with other neighboring radicals, and the electronic and magnetic properties of the solid salts differ distinctly from those of ion radical monomer. In previous papers,[4,5] we applied half-filled Hubbard Hamiltonian to one-dimensional system of ion radical molecules, and explained the optical and magnetic properties of solid ion radical salts in terms of such a model. In the present paper, by using the same model, we examine the magnitude of the resonance energy stabilization due to the charge-transfer interaction in one-dimensional system of solid ion radical salts and apply this approach to certain crystalline ion radical salt such as Würster's Blue perchlorate cation radical salt.

Since every ion radical salt belongs to a kind of ionic crystals, Madelung energy is the most important factor for the cohesive energy. However, in contrast to typical ionic crystals such as alkali halides, resonance energy stabilization due to intermolecular charge-transfer interaction between ion radical molecules is the next important factor for the total cohesive energy in solid ion radical salts. In other words, because of half-occupied molecular orbital of the ion radical, there acts intermolecular covalent bonding between the ion radicals along infinite one-dimensional column. Calculation of the Madelung energy of solid ion radical salt is rather difficult, but we have found a way to estimate the magnitude of the resonance energy stabilization on the basis of a many-body problem. For this purpose, we consider only one-dimensional column of ion radicals in simple ion radical salt, where each ion radical carries one unpaired electron. The half-occupied molecular orbital of unpaired electron is taken for one site of ion radical molecule. We assume a model of non-alternant one-dimensional system composed of infinite number of such sites and neglect the effect of intramolecular electronic transitions of ion radical. In this model, each ion radical site has one identical molecular orbital with equal energy level, and there is one electron per each site. Along such one-dimensional column, an unpaired electron transfers from one site to another site, but a strong repulsive potential will take place when an electron happens to come onto a site which is already occupied by another electron with opposite spin. Let us denote the intra-site Coulomb repulsive energy as I, and consider a system of electrons described by the following Hamiltonian, which is often called the Hubbard Hamiltonian,[6]

$$\mathscr{H} = \sum_{i,j,\sigma} T_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \tag{1}$$

where $n_{i\sigma} = C_{i\sigma}^{+} C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where T_{ij} is the transfer matrix element between the i-th and j-th sites, and the repulsive potential, I, appears only when two electrons with up and down spins are at the same site. Since each ion radical has identical molecular orbital with equal energy level, we put $T_{ii}=0$ without loss of generality. In the case of non-alternant one-dimensional model, we further assume that the transfer matrix elements exist only between nearest neighbor sites, and the value of this transfer matrix element is denoted by T (<0).

It is rather difficult to obtain the ground state energy of Eq. 1 in general case. However, Takahashi showed that, in the case of half-filled Hubbard model with $I \gg |T|$, the Hamiltonian of Eq. 1 becomes equivalent to the following effective Hamiltonian,[7]

$$\mathscr{H}_{\text{eff}} = \frac{4T^2}{I} \sum_{i} \left(\boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1} - \frac{1}{4} \right) + 0\left(\frac{T^3}{I^2} \right), \tag{2}$$

where $\boldsymbol{S}_i$, ($S=1/2$), is the spin operator of an electron at the i-th site. In other words, in the limit of $I/|T| = \infty$, we can neglect such higher terms as $0(T^3/I^2)$, and the one-dimensional half-filled Hubbard model is reduced to one-dimensional Heisenberg antiferromagnetic model with exchange interaction, $J=2T^2/I$. Hereafter, we denote the number of sites in one-dimensional system as N. If we know the ground-state energy of the following non-alternant one-dimensional Heisenberg antiferromagnet,

$$\mathscr{H}' = 2J \sum_{i} \boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1}, \qquad (J = 2T^2/I > 0), \tag{3}$$

we can obtain the value of the ground-state energy of Eq. 2 in the limit of $I/|T| = \infty$. It is well known that the exact ground-state energy of Eq. 3, as indicated by E', was obtained by Bethe and Hulthén.[8] For infinite number of sites, the value of E' is given by

$$E' = -2NJ \ln 2 + \frac{1}{2} NJ. \tag{4}$$

Therefore, if in the limit of $I/|T| = \infty$ we denote the exact ground-state energy of Eq. 2 as E, we can obtain

$$E = E' - \frac{1}{2}J\sum_{i} 1 = E' - \frac{1}{2}NJ$$
$$= -2NJ\ln 2 = -4N\frac{T^2}{I}\ln 2. \quad (5)$$

When we go back to our original system of ion radicals, we can see that the magnitude of E in Eq. 5 corresponds to the resonance energy stabilization due to charge-transfer interaction between ion radicals in one-dimensional system of solid ion radical salts and that the value of $E/N=-4(T^2/I)\ln 2$ is the resonance energy per one site of ion radical molecule. Obviously, if $T=0$, that is, if no electron transfer occurs between ion radical molecules, we have $E=0$ in Eq. 5, and no resonance energy stabilization takes place in such a system.

In the following, we shall estimate the magnitudes of E and E/N for certain system of solid ion radical salt. For example, we apply the present method to the high-temperature phase of Würster's Blue perchlorate crystal, which is one of stable cation radical salts derived from *N,N,N',N'*-tetramethyl-*p*-phenylenediamine. Although a solid-state phase transition occurs at 186 K,[3,9] the crystal structure of the high-temperature (room-temperature) phase of Würster's Blue perchlorate is known to be orthorhombic and to be built up from non-alternant one-dimensional columns composed of segregated stacking of equivalent Würster's Blue cation radicals along the a-axis, the intermolecular spacing between nearest neighbor cation radicals being 3.550 Å.[3] In a previous paper,[5] we examined the electronic state of the system of the cation radicals on the basis of the above-mentioned non-alternant one-dimensional Hubbard model. We could well understand the optical and magnetic properties of this Würster's Blue perchlorate salt in terms of the parameter values of $I=11900$ cm^{-1} and $T=-650$ cm^{-1}. In this case, since the magnitude of $I/|T|=18.3$ is much larger than unity, we can apply, in place of Eq. 1, the effective Hamiltonian of Eq. 2 to the one-dimensional system of Würster's Blue cation radicals. Then, in the approximation of $I/|T|=\infty$ limit, the magnitude of E in Eq. 5 was estimated by using the $I=11900$ cm^{-1} and $T=-650$ cm^{-1} values. The calculated resonance energy of the high-temperature phase of Würster's Blue perchlorate was $E=-277$ cal/mol or $E/N=-97$ cm^{-1} per one site of the cation radical. On the other hand, for this salt, Metzger performed calculation of Madelung energy by using Ewald's method in order to clarify the mechanism of the phase transition at 186 K.[10] Although the Madelung energy is rather sensitive to details in the atomic charge distribution, he estimated the Madelung energy for the 300 K (high-temperature phase) Würster's Blue perchlorate crystal to be -94550 ± 690 cal/mol. Therefore, the total cohesive energy is found to be -94827 ± 690 cal/mol by summing the Madelung energy and the resonance energy. Although the resonance energy is very small compared to the Madelung energy and is only 0.29% of the total cohesive energy in Würster's Blue perchlorate, it is important to note that the resonance energy stabilization does not take place in usual ionic crystals but only takes place in solid ion radical salts.

Photolysis of Water on Illuminated Strontium Titanium Trioxide

Hiroshi YONEYAMA,* Masashi KOIZUMI, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 17, 1979)

Synopsis. The photolysis of water was demonstrated in an illuminated strontium titanium trioxide suspension. Electrochemical mechanism takes place in the decomposition reaction.

The photolysis of water by the use of light from a xenon lamp was accomplished by Fujishima and Honda in a photoelectrochemical cell using a semiconducting titanium dioxide photoanode.[1] It was found that the photolysis occurs at illuminated titanium dioxide suspended in an aqueous solutions.[2] Schrauser and Guth[3] reported the quantitative photodecomposition of chemisorbed water on titanium dioxide.

It has been revealed from electrochemical studies on photocatalysis of n-type semiconductors[4–11] that electrochemical mechanisms are occasionally involved in heterogeneous photocatalytic reactions using semiconductor catalysts. In these cases, the photocatalytic reaction consists of a photosensitized oxidation process coupled with a reduction process thermodynamically regulated, the onset potential of the photosensitized oxidation being more negative than that of the reduction process. The coupled processes proceed spontaneously on an illuminated n-type semiconductor accompanied by local cell action. This principle is basically the same as that for construction of photoelectrochemical cells.[12]

If such a mechanism prevail in photolysis of water at illuminated n-type semiconductor catalysts, the following reaction schemes are established for pure water.

photosensitized oxidation

$$H_2O + 2p^+ \longrightarrow 1/2O_2 + 2H^+ \quad (1)$$

reduction

$$2H_2O + 2e^- \longrightarrow H_2 + 2OH^- \quad (2)$$

overall

$$H_2O \longrightarrow H_2 + 1/2O_2 \quad (3)$$

where p^+ and e^- represent a positive hole in the valence band and an electron in the conduction band, respectively. The oxidation of water (Reaction 1) should then occur at potentials negative to the reversible hydrogen electrode potential (RHE).

It is well known in semiconductor electrochemistry[12–14] that photosensitized oxidation on a semiconductor electrode sets on at its flat-band potential. Thus, photodecomposition of water is expected if a semiconductor having a flat-band potential more negative than RHE is used as a photocatalyst. Strontium titanium trioxide (Strontium titanate) satisfies this prerequisite for the flat-band potential.[14–16]

Experimental

The decomposition experiments were carried out in an air-tight cell made of pyrex glass, with gas inlet and outlet, a flat window (dia. 30 mm) and a mouth in a tubular form for sampling the gas. The mouth was sealed in the lower portion with silicone rubber packing (dia. 5 mm, height 8 mm), water being filled on the packing (height 10 mm) in order to make a perfect seal during the course of gas sampling.

Strontium titanium trioxide powder, purity 99.9%, was reduced by hydrogen at 900 °C for 3 h, giving the surface area 0.67 m^2/g, and stored in a desiccator under humid nitrogen for a week. 1 g was suspended in 20 cm^3 of distilled water and the suspension was magnetically stirred overnight in the cell into which prepurified nitrogen was continuously bubbled. Stop cocks of the gas inlet and outlet were then closed, and the light from an 1 kW xenon lamp was illuminated on the suspension. The light was so focused as to fit with the cell window, its intensity being *ca.* 3 W as measured by a laser power meter (Coherent Radiation, model 201). The gas was analyzed at intervals with a gas chromatograph using a molecular sieve 5A coloum.

A strontium titanium trioxide single crystal (Nakazumi Crystal Co., Ltd.) was used as an electrode in order to confirm govering of photodecomposition by the electrochemical processes given by Eqs. 1 and 2. The electrode was prepared in the same way as reported by Watanabe *et al.*[15] The effective area of the electrode was 0.3 cm^2.

Results and Discussion

Figure 1 shows the evolution of gases as a function of illumination time. With no illumination, no gas evolution took place. Illumination without strontium titanium trioxide caused no decomposition. The results (Fig. 1) satisfy the stoichiometry of the decomposition reaction. However, the rate of the decomposition showed a tendency to diminish with illumination time.

The cause of the decline in the evolution rate is not clear. This may reflect some change in the surface condition of the catalyst. However, judging from the volume ratio of the evolved gases, the reduction of the catalyst surface does not seem probable. It might

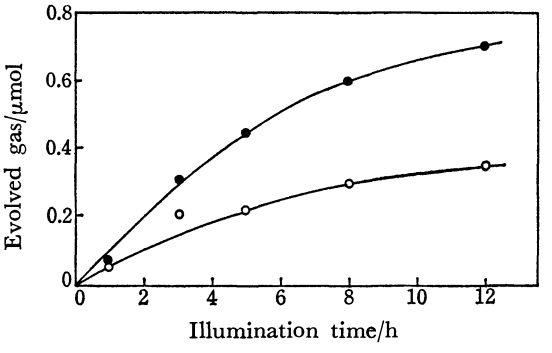

Fig. 1. Amount of oxygen and hydrogen evolved as a function of illumination time. —●—: H_2, —○—: O_2.

—●—: Anodic curve under illumination, —○—: cathodic curve in the dark, O.C.P.: open circuit potential under illumination. Illumination: 1 kW xenon lamp.

be postulated that the mode of reaction changed from water decomposition to a cycled reaction of oxygen evolution and reduction of the evolved oxygen. However, this does not seem to be the case. From Henry's law, the amount of evolved oxygen seems to be too small to dissolve into water in an appreciable amount.

Figure 2 shows polarization curves of the single crystal electrode in 0.5 mol·dm^{-3} Na_2SO_4. The anodic curve obtained under illumination (a) is related to the oxygen evolution reaction.[14,15] On the other hand, the cathodic curve in the dark (b) seems to be due to the hydrogen evolution reaction, since small bubbles were observed to stick on the electrode surface when a relatively high cathodic polarization was made. The open circuit potential of the illuminated strontium titanium trioxide electrode shown by arrow was in the potential region where the hydrogen evolution is thermodynamically feasible. Although these polarization curves were obtained in the solution of pH=6.3 and not in the pure water, almost the same situation should take place in pure water. The flat-band potential at which the oxidation of water sets on has the same pH dependency as RHE.

The decomposition rate is 0.03—0.05 μA/cm^2 (Fig. 2), corresponding to the water photolysis of 0.001 μmol/h per unit surface area of the catalyst at most. Since light was concentrated into a cell window of *ca.* 7 cm^2, the decomposition rate of 0.007 μmol/h can be expected for a single crystal having an area equal to that of the cell window. However, the rate estimated is low, suggesting that the quantum yield of water photolysis is too low to be significant. The potential at which the photolysis proceeds is near the flat-band potential, resulting in a weak field strength to anihilate photo-generated carriers.[13]

The surface area can be increased greatly with use of powder catalyst. However, attempts to increase the surface area do not always bring about a proportional increase in the photodecomposition rate. The decomposition rate of 0.1 μmol/h was observed in the initial stage of the experiment (Fig. 1). This gives only fourteen times the value estimated above for the single crystal catalyst having the area of the cell window. The increase in the surface area can in principle enhances the cathodic process, but the anodic process is usually controlled by the number of incident photons rather than by the surface area. Thus, the result seems to be reasonable.

This suggests that the photolysis of water can be carried out on illuminated n-type semiconductors having flat-band potentials more negative than RHE, if they are stable against both anodic and cathodic decomposition.

Photoisomerization of Bis(*t*-butyl isocyanide)dichlorobis-(triphenylphosphine)ruthenium(II)

Tamotsu TSUIHIJI, Takeo AKIYAMA, and Akira SUGIMORI*

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102

(Received March 24, 1979)

Synopsis. UV-irradiation of bis(*t*-butyl isocyanide)-dichlorobis(triphenylphosphine)ruthenium(II) brings about isomerization. The composition of the photo-stationary state is wavelength-dependent. A mechanism *via* the photo-elimination of triphenylphosphine is proposed.

Photochemical redox and ligand substitution reactions of ruthenium complexes have been extensively investigated.[1,2] However, only a few studies have been done on the photoisomerization. Jeffery and Mawby observed the isomerization of dicarbonyldiiodobis(triphenylphosphine)ruthenium(II) by sunlight.[3] We report here the photochemical mutual conversion of bis(*t*-butyl isocyanide)dichlorobis(triphenylphosphine)-ruthenium(II) isomers with light from 254 to 436 nm.

Experimental

Materials. *af*-Bis(*t*-butyl isocyanide)-*bd*-dichloro-*ce*-bis(triphenylphosphine)ruthenium(II) (**1**) was prepared by the reaction of dichlorotris(triphenylphosphine)ruthenium-(II) with *t*-butyl isocyanide. *ad*-Bis(*t*-butyl isocyanide)-*bf*-dichloro-*ce*-bis(triphenylphosphine)ruthenium(II) (**2**) was prepared by refluxing **1** in benzene for 2 days according to the preparation of corresponding ethyl isocyanide complex.[4] Elemental analyses: **1**, Found: C, 63.85; H, 5.65; N, 3.34%. **2**, Found: C, 63.75; H, 5.50; N, 3.00%. Calcd for $C_{46}H_{48}Cl_2N_2P_2Ru$: C, 64.03; H, 5.61; N, 3.25%. The structures of **1** and **2** were established from the comparison of their IR spectra and color with those of dichlorobis(ethyl isocyanide)bis(triphenylphospine)ruthenium(II).[4] **1**, Yellow; IR: 2110 (ν_{NC}) and 320 cm^{-1} (ν_{RuCl}). **2**, Colorless; IR: 2135 and 2090 cm^{-1} (ν_{NC}); no absorption of ν_{RuCl} was observed above 300 cm^{-1}. Ruthenium(II) complexes in which two chlorine atoms are situated in *trans*-position have an IR band above 300 cm^{-1} and those in which two chlorine atoms are in *cis*-position have two IR absorption bands below 300 cm^{-1}.[4,5]

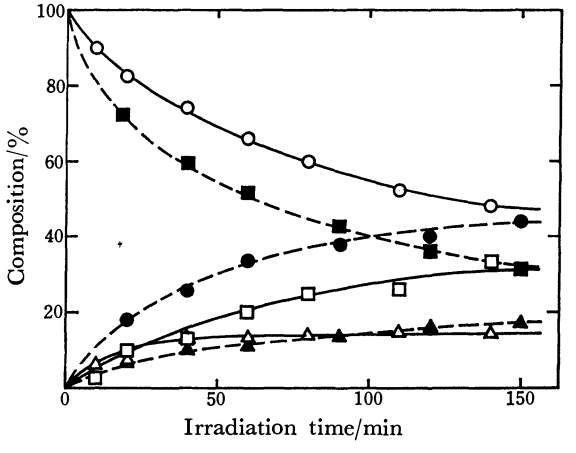

Fig. 1. Dependence of the composition of products on irradiation time (Irradiated with 254 nm).
Products in the irradiation of **1** —○—, **1**; —□—, **2**; —△—, **X**. Products in the irradiation of **2** —●—, **1**; —■—, **2**, —▲—, **X**.

Photoreaction. The photoreaction was followed by the change of NMR spectra. Solutions containing 5.8—8.5 mmol dm^{-3} of **1** or **2** in CD_2Cl_2 in quartz NMR sample tubes were irradiated with UV-light. For the irradiation with 254 nm, a low pressure mercury lamp was employed. For the irradiation with 313, 365, and 436 nm, the light from a high pressure mercury lamp was filtered with interference filters M-313, M-365, and M-436 of Karl Zeiss Co., respectively.

After the irradiation, five proton NMR peaks were observed. The peak at $\delta=7.75$—8.06 (multiplet) is assigned to the *o*-proton of coordinated triphenylphosphine (PPh_3), and the peak at $\delta=7.29$—7.57 (multiplet) to *m*- and *p*-protons of coordinated and *o*-, *m*-, and *p*-protons of free PPh_3. The peaks at $\delta=0.76$ (singlet) and 1.04 (singlet) are due to *t*-butyl of **2** and **1**, respectively. The peak at $\delta=1.34$ is ascribed to *t*-butyl of an unidentified product (**X**).

Results and Discussion

UV-irradiation of bis(*t*-butyl isocyanide)dichlorobis-(triphenylphosphine)ruthenium(II) isomers brings about the mutual isomerization and the formation of a complex **X**. No reaction occurs in the dark at room temperature. Over the wide range of the wavelength of the irradiating light (254—436 nm), almost no other photoproducts are formed.

Complex **X** which has an NMR peak at $\delta=1.34$ can be assigned to a dimer of the five-coordinate complex **3** or **4**, which is formed by the photochemical elimination of a molecule of PPh_3 from **1** or **2**. The area of the NMR absorption ascribed to *t*-butyl of **X** corresponds well with the increase in the area ascribed to the free PPh_3. The shift of the *t*-butyl peak to lower field can be explained by the increase in the positive charge of the central metal caused by the elimination of a PPh_3 molecule.

The change in the composition of the products with the irradiation time is shown in Fig. 1, as exemplified by the 254 nm irradiation. The prolonged irradiation gives photo-stationary mixtures, the composition of which depends on the wavelength of the irradiating light. Results are summarized in Table 1.

Photochemical conversion of **X** to **1** and **2** is suggested, because the quantity of **X** showed a maximum or saturation at the earlier stage of the photoreaction. The mechanism shown in Scheme 1 is proposed. The intermediacy of the five-coordinate complexes (**3** and **4**) is supported by the suppression of the formation of **X** by the addition of excess PPh_3. Similar five-coordinate complexes have been postulated in the

Table 1. Photoreactions of bis(*t*-butyl isocyanide)-dichlorobis(triphenylphosphine)ruthenium(II)

Wavelength nm	$\varepsilon_2/\varepsilon_1$	Starting complex	Additive	Composition at photo-stationary state $[1]_s/[2]_s$	Composition at photo-stationary state $[X]_s/([1]_s+[2]_s+[X]_s)$
254	1.3	**1**		1.3	0.17
		2		1.5	0.22
		1	PPh_3[a)]	1.5	0.07
313	0.85	**1**		0.11	0.04
		2		0.05	0.03
365	6.7	**1**		5.4	0.11
		2		3.0	0.06

a) $[PPh_3]/[1]=10$.

photoisomerization of tetracarbonylbis(triphenylphosphine)molybdenum(0).[6] The fact that the addition of PPh_3 does not retard the photoisomerization of the ruthenium complex indicates that the conversion between **3** and **4** occurs efficiently.

If the reaction giving the dimer is neglected, we can obtain an approximate equation for the composition at the photo-stationary state as

$$\frac{[1]_s}{[2]_s}=\frac{k_2k_5k_{-7}\,(k_3+k_1)}{k_1k_6k_7\,(k_4+k_2)}\,\frac{\varepsilon_2}{\varepsilon_1}$$

where suffix s represents the stationary state, the k's are rate constants of the specified reactions in Scheme 1, and ε_1 and ε_2 are the molar absorption coefficients of **1** and **2**, respectively. In the equation, $[1]_s/[2]_s$ is independent on the concentration of free PPh_3. The fact that the addition of PPh_3 does not change the value supports the mechanism in Scheme 1.

Complex **1** has three electronic absorption bands at 268 (ε=26900 $dm^3\,mol^{-1}\,cm^{-1}$), 315 (ε=3200 $dm^3\,mol^{-1}\,cm^{-1}$), and 439 nm (ε=165 $dm^3\,mol^{-1}\,cm^{-1}$), which could be assigned to the excitations of coordinated PPh_3, CT, and d-d, respectively. For **2** the separation of CT and d-d bands is not enough, and **2** has no absorption in the visible region.

The value $[1]_s/[2]_s$ does not follow the ratio of molar absorption coefficients. Especially, in the irradiation with 313 nm, the isomerization from **1** to **2** occurs efficiently, whereas almost no reverse reaction occurs. This suggests that the irradiation with different wavelength produces different excited states, and each excited state has different efficiency of the elimination of PPh_3. For 254 nm irradiation, by which **1** and **2** are brought to excited states of a similar character (the excitation of coordinated PPh_3), $[1]_s/[2]_s$ is almost equal to $\varepsilon_2/\varepsilon_1$. This indicates that the overall efficiency from **1** to **2** is equal to that from **2** to **1** in the photoisomerization with 254 nm light.

The pK_a Value and Volume Change for the Neutralization of [Co(edda)($H_2NCH_2CH_2OH$)]$^+$

Yoichi KITAMURA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received January 16, 1979)

Synopsis. The pK_a value of [Co(edda)($H_2NCH_2CH_2OH$)]$^+$at 25 °C has been determined spectrophotometrically to be 5.01±0.05. The volume change for the equilibrium: [Co(edda)($H_2NCH_2CH_2OH$)]$^+$+OH^-=[Co(edda)($H_2NCH_2CH_2O$)]^0+H_2O has been found to be 16.9±0.7 cm^3/mol at 25 °C at an ionic strength of *ca.* 5 mM (1 mM $=10^{-3}$ mol dm^{-3}).

The volume change (ΔV) for the neutralization equilibrium of a complex ion is essential for the interpretation of the activation volume for a reaction of a complex ion, proceeding *via* the S_N1 CB mechanism.[1,2] Values of ΔV for three such equilibria of trivalent complex ions are known:

$$[Co(NH_3)_5H_2O]^{3+} + OH^- = [Co(NH_3)_5OH]^{2+} + H_2O \quad (1)$$

ΔV_1=20.6 cm^3/mol at 30 °C;[3]

$$[Cr(H_2O)_6]^{3+} + OH^- = [Cr(H_2O)_5OH]^{2+} + H_2O \quad (2)$$

ΔV_2=18.3 cm^3/mol at 25 °C;[4]

$$[Fe(H_2O)_6]^{3+} + OH^- = [Fe(H_2O)_5OH]^{2+} + H_2O \quad (3)$$

ΔV_3=20.9 cm^3/mol.[5]

A value of ΔV for the analogous equilibrium of a univalent complex ion is however not known and is of interest with respect to the charge effect on the magnitude of ΔV.

α-*cis*-Ethylenediamine-*N*,*N*′-diacetato(2-aminoethanol)cobalt(III) perchlorate, α-*cis*-[Co(edda)(Hame)]ClO_4 was obtained by Kuroda.[6] The aqueous solution of this complex gives a low pH value (3.94 in a 2.5 mM solution) and the indication is that in water there exists an acid dissociation equilibrium:[6]

$$[Co(edda)(Hame)]^+ = [Co(edda)(ame)]^0 + H^+, \quad (4)$$

where Hame=$H_2NCH_2CH_2OH$ and ame=$H_2NCH_2CH_2O^-$.

The determination of the pK_a value of 4 is significant *per se*, since the pK_a values of Co(III) complex ions are known only for ones with the aqua ligand so far.[7] The volume change (ΔV_5) for the equilibrium:

$$[Co(edda)(Hame)]^+ + OH^- = [Co(edda)(ame)]^0 + H_2O \quad (5)$$

has been measured in relation to the interpretation of the activation volume for the base hydrolysis reactions of α-, β-*cis*-[Co(edda)(NH_3)$_2$]$^+$.[8]

Experimental

α-*cis*-[Co(edda)(Hame)]ClO_4 was obtained by the standard method and identified by the visible absorption spectrum of a 5 mM aqueous solution.[6] The λ_{max} (ε_{max}) values were 536 nm(89.2), 380 nm(84.4) which compare to the values reported by Kuroda of 535 nm(90.3), 377 nm(85.1) respectively. A Hitachi-Horiba M-5 pH meter was used and a Carlsberg dilatometer for the measurement of the volume change. The procedures were essentially the same as those described by Spiro *et al.*[3] Two liquids separated by kerosene were mixed and the volume change obtained from the change of the kerosene level in the capillary. 10 min was required for the establishment of the thermal equilibrium. In some experiments slow linearly time-dependent variations of the kerosene level were observed before and after mixing. The dilatometer readings were extrapolated to the time of mixing. The radius of the capillary was calibrated with mercury (0.0202±0.0003 cm) and the kerosene level read by a cathetometer. The thermostat was maintained at 25.02±0.02 °C with a variation of less than 0.002 °C. Boiled out water was used. The kerosene was purified.

Results and Discussion

The color of a solution of [Co(edda)(Hame)]ClO_4 in 0.01 M HCl is reddish pink and in 0.01 M KOH it is pale blue violet (1 M=1 mol dm^{-3}). The color changes instantaneously and reversibly by the addition of an acid or an alkali, which indicates that the color change is caused by a shift of the chemical equilibrium. The absorption spectrum is illustrated in Fig. 1. The absorption maxima (*ca.* 570 and 384 nm) of [Co(edda)(ame)]^0 (in 0.01 M KOH) lie at longer wavelengths relative to those (536 and 380 nm) of [Co(edda)(Hame)]$^+$ (in 0.01 M HCl). This tendency is analogous to the relative position of bands of the complexes with a hydroxo ligand to those of the corresponding complexes with an aqua ligand. In pure water the spectrum is similar to that in 0.01 M HCl and the complex exists mostly in the acid form, [Co(edda)(Hame)]$^+$.

The pK_a value was determined from the optical densities (OD) at 300 nm in a 1 mM solution of the complex in acetate buffers (Table 1). The absorption coefficients at 300 nm of [Co(edda)(Hame)]$^+$ and [Co-

a) CH_3COOH(mM)/CH_3COONa(mM). b) Measured at 25 °C.

(edda)(ame)]^0 are 290 and 842 l mol^{-1} cm^{-1}, respectively. The activity coefficients of H^+ may be estimated according to the method of Davies.[9)] The magnitude of pK_a 5.01±0.05 is small compared with those of a Co(III) complex with an aqua ligand.[7)]

An aqueous solution of [Co(edda)(Hame)]ClO_4 (25 cm^3) was mixed with 0.035 M KOH (10 cm^3). Values of the volume change were [given as the initial concentration of the complex/mM, volume change/μl]: 5.21, 2.31; 5.13, 2.10; 5.20, 2.25; and 5.14, 2.18. Heat was evolved in the mixing. As a blank test, water (25 cm^3) was mixed with 0.035 M KOH (10 cm^3) and the volume change found to be negligibly small (0.00±0.11 μl, average for five runs). Thus, a value of 17.1±0.7 cm^3/mol is obtained for $\alpha\Delta V(H_2O)+(1-\alpha)\Delta V_5$, where $\Delta V(H_2O)$ is the volume change (22.07 cm^3/mol at 25 °C) for the equilibrium, $H^+ + OH^- = H_2O$ and α is the degree of dissociation (0.04) of [Co(edda)(Hame)]$^+$ in the 5.2 mM solution.[10)] Thus, ΔV_5 at 25 °C is evaluated as 16.9± 0.7 cm^3/mol. The magnitude of ΔV_5 is comparable to those of ΔV_1, ΔV_2, and ΔV_3, which indicates that the difference between the molar volume of water and the partial molar volume of OH^- (*ca.* 1.4 cm^3/mol) is the major contribution for the volume changes.[11)] The intrinsic volumes of the complex ions would be little affected by protonation and hence the somewhat smaller magnitude of ΔV_5 compared to those of ΔV_1, ΔV_2, and ΔV_3 may be qualitatively explained by the smaller contribution of the electrostrictive volume change (ΔV_{el}) of the complex in Equilibrium 5. To a first approximation, neglecting the compressibility of the complex ion[5)] and the dielectric saturation of water,[12)] the electrostrictive volume (V_{el}) for an ion of radius r and charge Ze in water is given by; $V_{el}=-(NZ^2e^2)(dD/dP)/(2rD^2)$, where N and D represent Avogadro's number and the bulk dielectric constant for water, respectively.[5)] Hence, ΔV_{el} in Equilibria 1, 2, and 3 ($\Delta Z^2=-5$) is larger than that in Equilibrium 5 ($\Delta Z^2=-1$). This difference in ΔV_{el} is evaluated as 5.5 cm^3/mol for $r=3$ Å, using the value of $(1/D^2)(dD/dP)$ at 1 bar (6.0×10^{-7} bar^{-1}).[13)] The water molecules around the ion however are under high pressure due to the electrostriction and this pressure is higher for ions of higher valency.[5)] Thus, values of $(1/D^2)(dD/dP)$ at high pressures must be used. Since, $(1/D^2)(dD/dP)$ decreases with increase in pressure, the difference in ΔV_{el} would be smaller than as simply estimated above.[13)]

The author would like to thank Professor Kashiro Kuroda of Ehime University for his continuous interest in the present work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (11), 3455—3456 (1979)

Preparation of a Rare Earth Ion Selective Electrode

Yoshihiro TAKASAKA† and Yasuo SUZUKI*

Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Ikuta, Tama-ku, Kawasaki 214

(Received May 9, 1979)

Synopsis. A new rare earth-ion selective electrode with a cerium(IV) oxide membrane has been prepared. The electrode was selective for the trivalent rare earths with a slope as great as 58 mV. The electrode was less selective for bi- and quadrivalent cations.

The conventional cation-selective electrodes with solid-state membranes have been prepared from insoluble salts, the iron(III)-selective electrode with a chalcogenide glass membrane[1] being the only exception. The fluoride-selective electrodes, containing lanthanum fluoride as the membrane, are possibly sensitive to lanthanum(III) ion,[2] but are of little analytical importance because of a small slope of 20 mV. The solid-membrane electrodes containing either a quadri- or bivalent rare-earth compound are possible sensors for the rare earths(III), with a slope as great as 59 mV. The present work includes the preparation and properties of the cerium(IV) oxide membrane electrodes as rare-earth(III) sensors. Since the trivalent rare earths behave similarly in aqueous solutions, the new electrodes should have identical selectivity for any of the rare earths.

Experimental

All the rare-earth oxides of 99.9% or higher purity were supplied by Shin-etsu Chemical Industries Co., Ltd. The solutions of rare-earth(III) nitrates were prepared by dissolving the respective oxides with nitric acid. Cerium(III) perchlorate and nitrate solutions were prepared from the corresponding salts of I. C. N. Pharmaceuticals Inc. Other reagent solutions were prepared from reagent-grade chemicals.

The electromotive force measurements were performed on a Beckman Model 3500 pH meter with an Orion 90-02 double junction reference electrode. The pH measurements were made by a Denki Kagaku Keiki Model HG-3 pH meter. Electric resistances of the membranes were measured by a Yokokawa Denki Model L-6B insulation-resistance tester.

The appropriate amounts of cerium(IV) oxide and Rapid Araldite, an epoxy adhesive from Ciba-Geigy, were mixed homogeneously, and coated on the copper plate of the electrode body, as shown in Fig. 1. All the electrode behaviors were studied at 25.0°C with an electrode system of: CeO_2 electrode|Solution X|Salt bridge|Ag–AgCl reference electrode.

Results and Discussion

The values of the activity coefficients of the rare-earth ions were selected[3,4] assuming that the mean activity coefficients of the rare-earth ions do not vary appreciably from ion to ion under identical conditions.

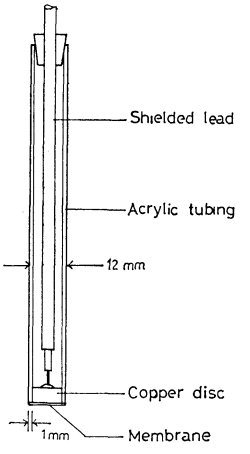

Fig. 1. A cerium(IV) oxide membrane electrode.

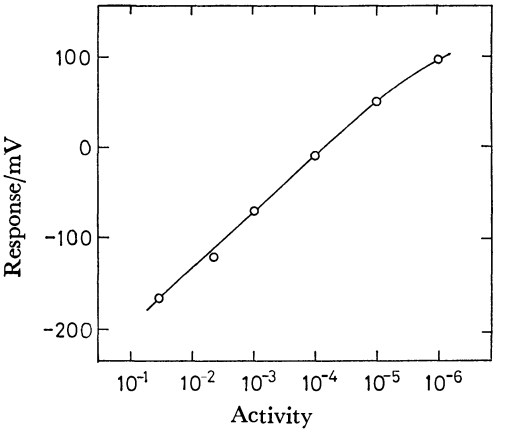

Fig. 2. Response of cerium(IV)-oxide electrode to the cerium(III) activity.

Of the electrodes having membranes of various cerium(IV) oxide concentrations, the ones containing 55% oxide and 45% adhesive in weight exhibited the closest response to the Nernstian theory. The slope of the electrode for cerium(III)-ion concentration ranged from 43 to 58 mV within a concentration range of 10^{-1} to 10^{-6} mol dm^{-3}, while the linear relationship between the response and concentration held only in a range of 10^{-3} to 10^{-5} mol dm^{-3} with a slope of 58 mV. By taking the activity scale, however, the linearity extended from 10^{-1} to 10^{-5}, as shown in Fig. 2. Considering the overall properties studied, the 55-% electrode was found to be superior to the other electrodes of 30—70%, and has thus been used in subsequent work.

The response time of the electrode was determined for several cerium(III) concentrations as 5 to 10 min.

† Present address: Japan Scientific Instrument Co., Ltd., Ichiban-cho, Chiyoda-ku, Tokyo 102.

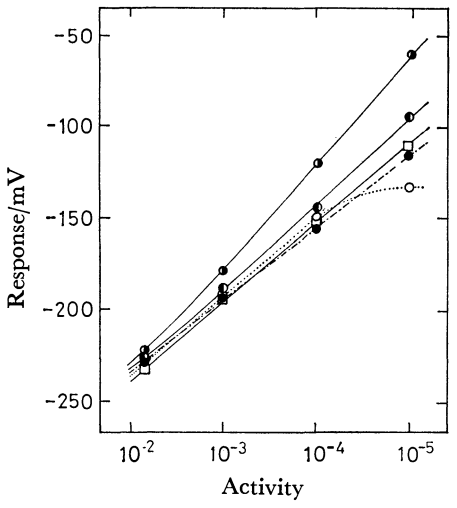

Fig. 3. Response curves of cerium(IV)-oxide electrode for some rare-earth(III) ions.
●: Lanthanum, ○: praseodymium, □: dysprosium, ◐: lutetium, ◑: yttrium.

The effect of the membrane thickness at 55-% cerium(IV) oxide concentration was also examined, and an electrode having a 0.100 g membrane, *i.e.* a 0.13 g cm^{-2} thickness, exhibited the optimum response. The electric resistance of the membrane ranged from 0.2 to 9 MΩ. No appreciable variation in the response behavior was observed within several months of repeated use.

The response behavior of the electrode against five trivalent rare-earth ions, including lanthanum, praseodymium, dysprosium, lutetium, and yttrium, were investigated, and the activity-response relations are shown in Fig. 3. It is remarkable that lanthanum and praseodymium, both adjacent elements to cerium, exhibited lower responses than the heavy rare earths, while yttrium exhibited the highest response among the rare earths examined.

The effect of pH was studied within the pH range of 2 to 9, where it was shown that the electrode could be useful in solutions of pH 3 to 5.5. Both higher hydrogen-ion concentrations and hydroxide precipitation apparently interfere in the measurements in solutions of pH less than 2 and above 6, respectively.

The selectivity coefficients for several cations, determined by separate and mixed solution methods,[5-9] are shown in Table 1. As might be expected, the rare-earth(III) ions exhibited selectivity coefficients as great as unity. Though barium(II) and zirconium(IV) ions did not interfere appreciably, the alkali metals, such as sodium and potassium, did interfere considerably. The latter fact is apparently not desirable when using the electrode in determining stability constants of the rare-earth complexes, where the solutions usually contain appreciable amounts of alkali metal salts, such as potassium nitrate, as the supporting electrolyte.

Though the present results are not sufficient for elucidating the response mechanism, it is probable that the oxidation-reduction reaction of cerium in the membrane and in solution predominates, at least in the case of cerium(III) solutions.

Table 1. Selectivity coefficients for several cations at 10^{-3} M

Cation	Selectivity coefficients	
	Separate solution method	Mixed solution method
Na(I)	1.0×10^{-2}	0.44
K(I)	2.5×10^{-2}	0.10
Ba(II)	0.11	3.5×10^{-3}
Fe(III)	0.20	1.4×10^{-2}
Zr(IV)	—	1.4×10^{-3}
La(III)	1.0	—
Ce(III)	1.0	—
Pr(III)	1.0	—
Dy(III)	1.0	—
Lu(III)	1.0	—
Y(III)	1.0	—

The cerium(IV) oxide-membrane electrode may thus be used as a sensor for the rare-earth(III) ions, with further possible improvements. The current work also includes research on the application of quadri- and bivalent rare-earth compounds as sensing materials, which would account for the response mechanism of the electrodes of the present type.

The authors wish to express their thanks to Shinetsu Chemical Industries Co., Ltd. for supplying the rare-earth oxides, to Dr. Kazuo Hiiro, Government Industrial Research Institute, Osaka, for his helpful advice, and to Mr. Hiroshi Itoh, Department of Electrical Engineering, Meiji University, for his assistance in the measurements of membrane resistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Institute of Science and Technology, Meiji University.

(Received May 25, 1979)

Synopsis. The title salts were synthesized. Segregated columnar structures of the salts are suggested from their electronic spectra and electrical resistivities; 10^4—10^5 Ω cm range at 25 °C with activation energies of 0.24—0.33 eV as compact samples.

In a previous paper, a report was given on the preparation and electrical resistivity of simple and complex salts formed by the reaction between bis(dialkyldithiocarbamato)gold(III) cations and $TCNQ^-$ radical anion; $[Au(S_2CNR_2)_2]^+TCNQ^-$ (R=Me, Et, *n*-Pr, *n*-Bu, *n*-C_6H_{13}, *n*-C_8H_{17}, and $CH_2C_6H_5$), $[Au(S_2CN(CH_2C_6H_5)_2)_2]^+(TCNQ)_2^-$, and $[Au(S_2CN(CH_2C_6H_5)_2)_2]^+(TCNQ)_2^-\cdot MeCN$, all of which showed semiconducting behavior.[1] This paper describes the preparation, electronic spectra, and electrical resistivity of some bis(dialkyldithiocarbamato)copper(III) cation–TCNQ radical anion and –bis(1,2-dicyano-1,2-ethylenedithiolato)nickel(III) anion simple salts; $[Cu(S_2CNR_2)_2]^+TCNQ^-$ and $[Cu(S_2CNR_2)_2]^+[Ni(S_2C_2(CN)_2)_2]^-$ (R=Et, *n*-Pr, and *n*-Bu).

Experimental

Bis(dialkyldithiocarbamato)copper(III) perchlorates, $[Cu(S_2CNR_2)_2]^+ClO_4^-$ (R=Et, *n*-Pr, and *n*-Bu),[2] and tetraethylammonium bis(1,2-dicyano-1,2-ethylenedithiolato)-nickelate(III), $[Et_4N]^+[Ni(S_2C_2(CN)_2)_2]^-$,[3] were prepared by the methods reported.

*Bis(dialkyldithiocarbamato)copper(III)–TCNQ, $[Cu(S_2CNR_2)_2]^+TCNQ^-$ (R=Et (**1**), n-Pr (**2**), and n-Bu (**3**)).* To a boiling ethanol (30 ml) solution of Li^+TCNQ^- (0.39 g, 1.8 mmol) was added a hot acetonitrile (40 ml) solution of $[Cu(S_2CNEt_2)_2]^+ClO_4^-$ (0.82 g, 1.8 mmol). The mixture was allowed to stand in a refrigerator overnight to afford dark green needles of **1** in a 60% yield. **2** and **3** were similarly obtained both as dark green needles in 58 and 55% yields, respectively, by the equimolar reaction of $TCNQ^-$ in ethanol with the appropriate bis(dialkyldithiocarbamato)copper(III) cations in acetonitrile.

No complex salt was obtained by the reaction of **1**—**3** with neutral TCNQ in acetonitrile, only the starting materials being recovered.

*Bis(dialkyldithiocarbamato)copper(III) Bis(1,2-dicayno-1,2-ethylenedithiolato)nickelate(III), $[Cu(S_2CNR_2)_2]^+[Ni(S_2C_2(CN)_2)_2]^-$ (R=Et (**4**), n-Pr (**5**), and n-Bu (**6**)).* To an acetone (50 ml) solution of $[Cu(S_2CNEt_2)_2]^+ClO_4^-$ (0.67 g, 1.5 mmol) was added $[Et_4N]^+[Ni(S_2C_2(CN)_2)_2]^-$ (0.68 g, 1.5 mmol) in acetone (30 ml). After being stirred for 1 h, the mixture was concentrated to about half the volume under reduced pressure, followed by cooling to *ca.* 5 °C to give dark brown microcrystals of **4** in a 80% yield. Two analogues with R=*n*-Pr and *n*-Bu were similarly prepared as black and dark brown microcrystals in 71 and 85% yields, respectively.

Physical Measurements. Electrical resistivities, electronic spectra, and magnetic susceptibilities were measured as described previously.[1]

Results and Discussion

Linearity holds between log ρ (ρ: electrical resistivity) and $1/T$ for all the salts in the range 293—373 K (Table 1), indicating semiconducting behavior. Figure 1 shows the electronic absorption spectra of **1** and **4** in the solid state and **4** in acetonitrile; solid **1** exhibits three absorption maxima at 8800, 14800, and 24500 cm^{-1}. Similar spectra were observed in **2** and **3**. The spectral patterns of **1**—**3** closely resemble those of gold analogues, $[Au(S_2CN(n\text{-}Bu)_2)_2]^+TCNQ^-$ (λ_{max}: 8900, 13900, and 22400 cm^{-1}) and $[Au(S_2CN(n\text{-}C_8H_{17})_2)_2]^+TCNQ^-$ (λ_{max}: 10800, 14500, and 25100 cm^{-1}), both of which have been reported to involve dimeric $(TCNQ)_2^{2-}$.[1] The existence of the $(TCNQ)_2^{2-}$ dimer in **1**—**3** is supported by their diamagnetic properties at room temperature. Thus, **1**—**3** seem to have a segregated columnar stacking of $TCNQ^-$ radical anion in the crystalline state. This is in line with the ρ values of these salts in the order of 10^4 Ω cm. The columnar structure of **1** and **2** is in contrast to the corresponding gold salts, $[Au(S_2CNR_2)_2]^+TCNQ^-$ (R=Et and *n*-Pr), in which the cation and the anion are stacked alternatively: $D^+A^-D^+A^-\cdots$.[1]

The electronic spectrum of solid **4** shows absorption maxima at 8000, 13500, 16800, 22600, and 30200 cm^{-1}, of which the 22600 cm^{-1} band is due to the $[Cu(S_2CNEt_2)_2]^+$ cation and the remaining four bands to the $[Ni(S_2C_2(CN)_2)_2]^-$ anion. Thus, the solid state spectrum of **4** coincides with a superimposition of the spectra of the cation and anion moieties, indicating

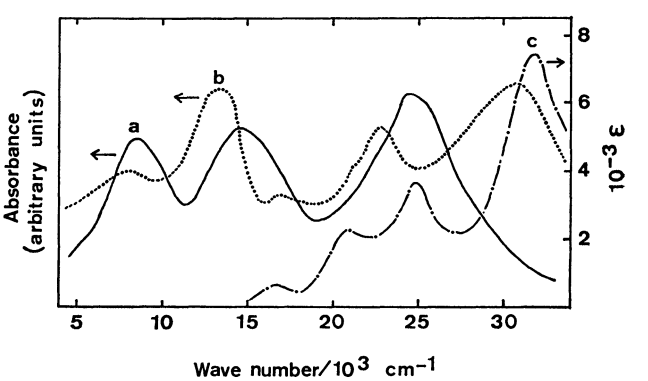

Fig. 1. Electronic absorption spectra of **1** (a) and **4** (b) in Nujol mulls, and **4** in acetonitrile (c).

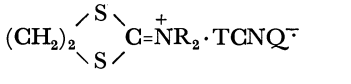
Table 1. Analytical data, electrical resistivity (ρ), and activation energy (E_a) of the salts[a)]

No.	Salt	%C Found (Calcd)	%H Found (Calcd)	%N Found (Calcd)	$\rho_{25\,°C}$ / Ω cm	E_a [b)] / eV
1	$[Cu(S_2CNEt_2)_2]^+TCNQ^-$	47.11 (46.83)	4.15 (4.29)	14.66 (14.89)	4.6×10^4	0.24
2	$[Cu(S_2CN(n\text{-}Pr)_2)_2]^+TCNQ^-$	50.05 (50.34)	5.17 (5.20)	13.70 (13.55)	7.1×10^4	0.28
3	$[Cu(S_2CN(n\text{-}Bu)_2)_2]^+TCNQ^-$	53.08 (53.26)	5.80 (5.96)	12.30 (12.42)	8.5×10^4	0.30
4	$[Cu(S_2CNEt_2)_2]^+[Ni(S_2C_2(CN)_2)_2]^-$	30.59 (30.92)	2.86 (2.88)	11.61 (12.02)	3.1×10^5	0.31
5	$[Cu(S_2CN(n\text{-}Pr)_2)_2]^+[Ni(S_2C_2(CN)_2)_2]^-$	34.88 (34.99)	3.69 (3.74)	11.09 (11.13)	4.0×10^5	0.31
6	$[Cu(S_2CN(n\text{-}Bu)_2)_2]^+[Ni(S_2C_2(CN)_2)_2]^-$	38.20 (38.49)	4.20 (4.47)	10.17 (10.36)	8.9×10^5	0.33

a) Mp (dec) >300 °C for all the salts. b) Calculated by the equation $\rho=\rho_0\exp(E_a/kT)$.

that in the solid state the anion and the cation are segregated from each other. This is supported by the fact that **4** in acetonitrile exhibits an additional band at 25000 cm^{-1} (Fig. 1), which may be due to an anion-cation interaction. The interaction of this type has been reported in some double complex salts, such as $[Pt(CNR)_4]^{2+}[Pt(CN)_4]^{2-}$ (R=Me, Et, and *t*-Bu), in solution.[4)] Segregation between the anion and the cation is suggested also for solids **5** and **6** on the basis of their electronic spectra. Some bis(1,2-dithiolato)nickel(III) salts such as $[Et_4N]^+[Ni(S_2C_2(CN)_2)_2]^-$ ($\rho=3.5\times10^5$ and 4.9×10^7 Ω cm for two crystalline forms) have been reported to adopt a segregated columnar structure.[5)] Such a structure can be assumed in the crystals of **4**—**6**, since the ρ values (Table 1) are of the same orders as or smaller than those of $[Et_4N]^+$ salts.

In both series **1**—**3** and **4**—**6**, the ρ and E_a values trend to increase to some extent as the alkyl substituents on the carbamato nitrogen atom become bulky. A similar trend has been reported for a series of *N,N*-dialkyl-1,3-dithiolan-2-iminium–$TCNQ^-$ simple salts.[6)]



(R=Me, *n*-Pr, *n*-C_6H_{13}, and *n*-C_8H_{17})

The interplanar distance between the cation moieties in segregated columnar structures significantly influences electrical conduction, where the cation behaves as a matrix for the arrangement or packing of the planar anion moieties.[7)] It can be concluded that bulky substituents on the nitrogen atom of the cationic moieties increase the interplanar distances not only between the cation moieties but also between the anion moieties, raising electrical resistivity of the present salts.

The authors wish to express their thanks to the Central Research Institute, Matsushita Electric Industrial Co., Ltd. for supplying a sample of TCNQ. This work was carried out with a Grant-in-Aid for Scientific Research No. 347066 from the Ministry of Education, Science and Culture.

Synthesis and Magnetism of Cobalt(II)–Manganese(II)–Cobalt(II) Trinuclear Complexes with *N,N'*-Disalicylidenealkanediamines

Visit KASEMPIMOLPORN, Hisashi OKAWA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 31, 1979)

Synopsis. Cobalt(II)–manganese(II)–cobalt(II) trinuclear complexes were synthesized by reacting *N,N'*-disalicylidenealkanediaminatocobalt(II) and manganese(II) halide in a 2:1 mole ratio. Cryomagnetic measurements indicated an antiferromagnetic spin-exchange interaction operating between the low-spin cobalt(II) and the high-spin manganese(II) ions, exchange integrals being estimated at -8——-12 cm^{-1}.

Recently we have reported the preparation and the characterization of the mixed-spin trinuclear cobalt(II) complexes with *N,N'*-disalicylideneethylenediamine and its homologues.[1] A considerably strong antiferromagnetic spin-exchange interaction ($J=-10$——-14 cm^{-1}) in these complexes prompted us to synthesize new trinuclear complexes of Co(II)($s=1/2$)–Mn(II)($s=5/2$)–Co(II)($s=1/2$) system in order to obtain further informations of spin-exchange in polynuclear complexes containing low-spin cobalt(II) ion.

N,N'-Disalicylidenealkanediamines are abbreviated as $H_2(R_1,R_2\text{-L})$ (R_1,R_2=H, CH_3; L=en, pn), where R_1 and R_2 denote the substituents attached to the 5- and the α-positions of salicylaldehyde moiety, respectively, and L is the chain connecting two imino-nitrogens.

Experimental

Syntheses. Mononuclear cobalt(II) complexes were obtained by the method of Bailes and Calvin.[2] Syntheses of the trinuclear complexes are practically the same and exemplified by $[Co(H,H\text{-en})]_2MnBr_2$. A mixture of Co(H,H-en) (500 mg) and manganese(II) bromide tetrahydrate (287 mg) in ethanol (80 ml) was stirred for 3 h under reflux in an atmosphere of nitrogen and allowed to stand overnight. Orange crystals which separated were collected by suction, washed with ethanol and dried.

Elemental analyses of the complexes are given in Table 1.

Measurements. Electronic spectra of powder samples were measured with a Shimadzu multipurpose spectrophotometer Model MSP-5000. Infrared spectra were measured with a Hitachi grating infrared spectrophotometer Model 215 in the region 4000—650 cm^{-1} on a KBr disk. Magnetic susceptibilities were measured by the Faraday method over the range from liquid nitrogen temperature to room temperature. Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828(\chi_M \cdot T)^{1/2}$, where χ_M is the molar magnetic susceptibility corrected for diamagnetisms using Pascal's constants.

TABLE 1. ELEMENTAL ANALYSES OF COMPLEXES

$[Co(H,Me\text{-en})]_2MnCl_4$	51.74	4.49	6.60	14.76	6.55	51.94	4.35	6.73	14.16	6.60
$[Co(Me,Me\text{-en})]_2MnCl_4$	53.50	4.96	6.17	12.82	6.23	54.07	4.99	6.30	13.26	6.18
$[Co(H,H\text{-pn})]_2MnBr_4$	45.43	3.53	6.19	13.70	6.40	45.71	3.61	6.27	13.19	6.15

Results and Discussion

Infrared spectra of the complexes display a skeletal vibration around 1530—1545 cm^{-1}, which is higher in frequency compared with that of the mononuclear cobalt(II) complexes. The high-frequency shift of this band has been utilized as a diagnosis of the bridging mode of the phenolic oxygen.[3] The similarity in infrared spectrum between $[Co(R_1,R_2\text{-L})]_2MnX_2$ and $[Co(R_1,R_2\text{-L})]_2CoX_2$[1] are indicative of the same structure between them. Since two molecules of $Co(R_1, R_2\text{-L})$ can not coordinate to a metal in a square plane because of the steric requirement of the molecule,[1,4,5] the most likely structure of the trinuclear complexes is *cis*-octahedral around the central manganese(II) ion (Fig. 1).

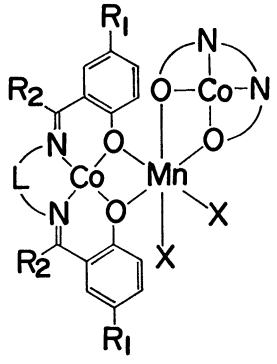

Fig. 1. Probable structure of $[Co(R_1,R_2\text{-L})]_2MnX_2$.

Powder reflectance spectra of the trinuclear complexes are nearly the same as those of the mononuclear cobalt(II) complexes except for Co(H,H-en), showing d-d bands at 8000 and 19000 cm^{-1}. Monomeric square-planar[6] and dimeric square-pyramidal[7] modifications are known for Co(H,H-en), and the electronic spectra of the present complexes are substantially the same as that of monomeric Co(H,H-en).[8] Since high-spin manganese(II) complexes show no spin-allowed d-d bands, the electronic spectra indicate that the electronic configuration of the low-spin cobalt(II) in $[Co(R_1,R_2\text{-L})]_2MnX_2$ is identical with that of Co(H,H-en), whose $(d_{x^2-y^2})^2(d_{yz})^1$ ground state electronic configuration was already demonstrated.[9,10]

Magnetic moments of the trinuclear complexes depend upon temperature (Table 2). This fact can be attributed to an antiferromagnetic spin-exchange interaction between the cobalt(II) and the manganese(II) ions. Molar magnetic susceptibility for the Co(II)($s=1/2$)–Mn(II)($s=5/2$)–Co(II)($s=1/2$) system is given by

$$\chi_M = \frac{Ng^2\beta^2}{4kT} \times \frac{35+10\exp(-7J/kT)+35\exp(-2J/kT)+84\exp(5J/kT)}{3+2\exp(-7J/kT)+3\exp(-2J/kT)+4\exp(5J/kT)} + N\alpha,$$ [11]

where J is the exchange integral between the low-spin cobalt(II) and the high-spin manganese(II) ions and other symbols have their usual meanings. This expression is applicable to the present complexes. Agreement between the theoretical and the experimental χ_M *versus* T curves is satisfactory. An example of this is shown in Fig. 2. The magnetic parameters, g and J, were determined by the best fit technique on estimating the temperature-independent paramagnetism, $N\alpha$, at 120×10^{-6} c.g.s./mol. The results are as follows. $[Co(H,H\text{-}en)]_2MnBr_2$: $g=2.13$, $J=-10$; $[Co(H,Me\text{-}en)]_2MnCl_2$: $g=2.12$, $J=-12$; $[Co(Me,Me\text{-}en)]_2MnCl_2$: $g=2.14$, $J=-8$; $[Co(H,H\text{-}pn)]_2MnBr_2$: $g=2.13$, $J=-11$ cm^{-1}.

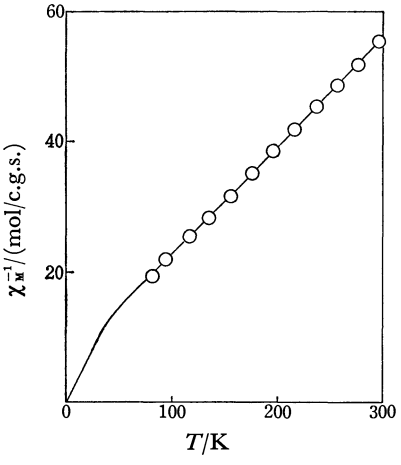

Fig. 2. Temperature variation of inverse molar magnetic susceptibility of $[Co(H,H\text{-}en)]_2MnBr_2$. The solid line represents the theoretical inverse susceptibility with $J=-10$ cm^{-1}, $g=2.13$ and $N\alpha=120\times10^{-6}$ c.g.s./mol.

The present complexes quite differ from the cobalt(II)–manganese(II) complexes, $CoMn(fsaR)(py)_3$,[12] in magnetic property (where H_4fsaR represents *N,N'*-bis(3-carboxysalicylidene)alkanediamines). In $CoMn(fsaR)(py)_3$ the low-spin cobalt(II) ion possesses an unpaired electron in its d_{z^2} orbital and no spin-exchange interaction is operating between the metal ions. Thus, we may conclude that an antiferromagnetic spin-exchange interaction in the present complexes results from the π-superpathway of $d_\pi(Co)$-$p_\pi(O)$-$d_\pi(Mn)$ overlapping.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (11), 3461—3462 (1979)

A Catalytic Effect of Amines on the Reaction of α-Toluenethiol with *N,N'*-Thiodiphthalimide[1]

Yasuo ABE,* Toyokazu HORII, Shun-ichi KAWAMURA, and Takeshige NAKABAYASHI
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai 593

(Received March 5, 1979)

Synopsis. In the presence of catalytic amounts of several amines, *N,N'*-thiodiphthalimide has been allowed to react with α-toluenethiol in benzene and dichloromethane giving *N*-(benzyldithio)phthalimide. *N*-(Benzyldithio)-phthalimide has been obtained in excellent yields with 2,4- or 2,6-lutidine as the catalyst in benzene.

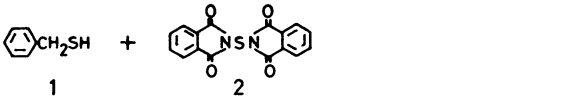
Harpp *et al.*[2] prepared the *N*-(alkyldithio)- and *N*-(aryldithio)phthalimides in good yields by the reaction of thiols with *N,N'*-thiodiphthalimide(**2**) in refluxing benzene. In a previous paper,[3] it was shown that a catalytic amount of imidazole markedly accelerates Harpp's reaction in dichloromethane. This has lead to the present examination as to whether amines act as catalysts in the present reaction.

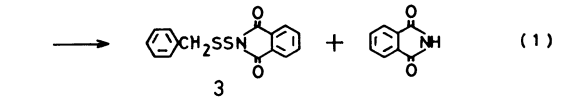
A mixture of α-toluenethiol (**1**) (5 mmol), **2** (5 mmol), and amine (0.5 mmol) was refluxed for 30 min in benzene (100 ml). The starting material **2** was not sufficiently soluble in hot benzene, but the product, *N*-(benzyldithio)phthalimide (**3**), and phthalimide were soluble. Consequently, the dissolution of **2** promotes the reaction. The product **3** was isolated from the reaction mixture by fractional dissolution in cold benzene and cold ethanol, and weighed. The remaining reaction mixture was subjected to column chromatography. The eluate obtained gave a mixture of the unchanged thiol and a by-product, dibenzyl trisulfide (**4**), which were identified and evaluated from NMR analysis,[4] the results of which are summarized in Table 1. As shown in the material balance of the benzyl group in Table 1, the compounds stemming from **1** collected exceeded 90% with few exceptions.

The unchanged thiol (93%) was recovered in the absence of amine in the reaction mixture (Run 1). Regardless of the functional group, *i.e.*, primary, secondary, or tertiary, all amines accelerated the present reaction. The product distribution varied with the amine employed, the results of which are given in Table 1. The results can be classified into three categories: (1) the thiol remaining practically unchanged (Runs 1—5); (2) the thiol being quantitatively changed into **3** (Runs 6—10); (3) the thiol being consumed to give mainly **3** but the remaining (over 20%) was changed into **4** (Runs 11—16). The variety in product distribution appears directly related to the pK_a value of the amine used. With the amine having a pK_a value of 5.06 or less, the unchanged thiol was recovered in over 25% of the initially charged amount. When 2,6- or 2,4-lutidine having a pK_a value of 6.75 or 6.79, respectively, was applied to the reaction system, **3** was obtained almost quantitatively. A pK_a value of 6.95 or greater caused a decrease in the yield of **3**. The yield of **4** increased with an increase in the pK_a value of the amine.[5]

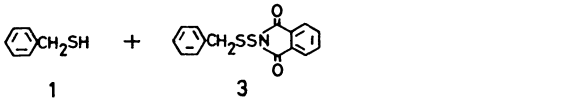
Recently, Yamabe *et al.*[6] reported that 1 : 1 S–H–N type hydrogen bonding is formed between 1-propanethiol and several amines, and that the strength of the hydrogen bonding enhances with increase in the pK_a value of the amine. Therefore, the present reaction is expected to proceed rapidly to give **3** in a good yield since the nucleophilicity of the thiol toward **2** would increase in the presence of a strongly basic amine.

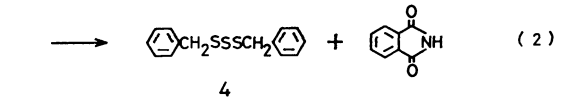
Table 1 shows that, in spite of the reaction of **2** with one equivalent of **1**, an undesirable trisulfide **4** was produced. This suggests that the thiol reacted competitively with the starting material **2** and product **3** (Eqs. 1 and 2). The thiol predominantly reacted





(1)





(2)

with **2** to give **3** when the nucleophilicity was suitable; this corresponds to a pK_a value of the amine of approximately 6.7 (Runs 7 and 8). As the nucleophilicity of the thiol increases, the two reactions occur giving both **3** and **4**. A second interpretation in formation of **4** is as follows. The starting material **2** does not dissolve adequately in hot benzene, and consequently the reaction rate of the thiol having a large nucleophilicity toward **2** may be limited by the rate of solution **2** into the benzene, and thus the reaction with **3** will increase giving **4**. The formation of **4** in the case of weak amines (Runs 2—6) is impossible to explain completely by the above reaction mechanisms. Amines having large pK_a values abstract protons from arylalkyl hydrodisulfide but amines having small pK_a values attack the sulfur atoms of the compound.[7] There is a possibility in the present reaction that the amine having a small pK_a value attacks the electron-deficient sulfur atom of **2** and **3** as a nucleophile but the actual reaction mechanism remains obscure.[8]

In order to increase the yield of **3** but to decrease that of **4**, a mixture of **1** and **2** was refluxed for 20

Table 1. Reactions of **1** with **2** in the presence of amines[a]

Run	Amine	pK_a	Solvent	Recovered **1** (mmol)	Products **3** (mmol)[b]	Products **4** (mmol)	Material Balance of benzyl group[c]

20	Triethylamine	10.67	Dichloromethane	0	3.60 (72)	0.70	5.00
21	Piperidine	11.22	Dichloromethane	0	2.96 (59)	0.81	4.58

a) All the reactions were performed by the use of **1** (5 mmol), **2** (5 mmol), amine (0.5 mmol) in a solvent (100 ml) at boiling point for 30 min in benzene and 20 min in dichloromethane. b) Values in parentheses show the yield based on **2** used. c) Summation of mmol of recovered **1** and **3** and two-fold mmol of **4**. The Theoretical value is 5.00. d) The pK_a value of phenol group is 9.71. e) The product unidentified was detected other than listed. f) The value includes dibenzyl polysulfide besides trisulfide.

min in dichloromethane which is able to dissolve **2** completely. It is expected that the nucleophilicity of the thiol in polar solvents increases because the hydrogen bonding between thiol and amine is enhanced by the polar solvent.[6] As seen in Run 17 of Table 1, the reaction without amine proceeded hardly as in benzene. Even with amines possesing small pK_a values, the reaction was significantly accelerated and gave **3** in good yield (Run 18). The formation of the by-product **4** was not sufficiently depressed by use of this reaction system.

Nucleophilic Substitution on Dialkoxy Disulfides. II.[1] Reactions with Hydrazine Derivatives

Hiroaki KAGAMI and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 12, 1979)

Synopsis. Diethoxy disulfide (**1**) reacted with arylhydrazines to give arylbenzenes, diaryl sulfides, and aryl ethoxy tetrasulfides. The reaction of **1** with hydrazobenzenes gave azobenzenes in quantitative yields. The treatment of **1** with 1,5-diphenylthiocarbonohydrazide or 1,5-diarylthiocarbazones afforded 2,3-diaryltetrazolium-5-thiolates.

Dialkoxy disulfides (**1**) are reactive toward some nucleophilic reagents.[2,3] Previously, we have also found that the alkoxyl group of **1** is readily displaced by secondary amines,[1] thiols,[1] or thiocarboxylic acids[4] to give several unsymmetrical polysulfides. Further, the reaction of primary amines with **1** afforded *N*-thiosulfinylamine (**2a**) by the intramolecular elimination of alcohol (Scheme 1).[1] We have now studied the reaction of **1** with hydrazine derivatives, and found that not only the substitution of the alkoxyl group, but also the elimination of sulfur and nitrogen, takes place.

Scheme 1.

4-Nitrophenylhydrazine was allowed to react with **1** in refluxing benzene. Ethanol was eliminated, and 4-nitrobiphenyl, ethoxy 4-nitrophenyl tetrasulfide, and bis(4-nitrophenyl) disulfide were obtained. The other monosubstituted hydrazines reacted similarly. The results are shown in Table 1. Considering the formation of the thiosulfinyl compound (**2a**) from **1** and primary amines, it seems reasonable to assume that the reaction of **1** with hydrazines proceed *via* a thiosulfinyl intermediate (**2b**) in the following way: arylhydrazines and **1** initially afford **2b**, followed by the transfer of a proton to give an azo intermediate (**3**).

Scheme 2.

Table 1. Reaction of diethoxy disulfide (**1**) with monosubstituted hydrazine

Hydrazine ($ArNHNH_2$) Ar	Benzene refluxing time / h	Products Isolated yield/% Ar-C_6H_5	Ar-S_4-OEt	Ar-S_x-Ar
4-$NO_2C_6H_4$	10	21	29	13 (x=2)[a]
2-ClC_6H_4	30	27	10	48 (x=4)
4-BrC_6H_4	20	0[b]	5[b]	39 (x=4)[a]
C_6H_5	12	8[b]	0[b]	37 (x=4)
4-$CH_3C_6H_4$	15	20	0[b]	31 (x=4)
2-$C_{10}H_7$	15	5[b]	0[b]	47 (x=4)

a) Diaryl tetrasulfides are relatively unstable compounds, and especially careful handling is necessary for bis(4-bromophenyl) tetrasulfide to prevent its thermal decomposition to the disulfide during recrystallization. Presumably, the formation of bis(4-nitrophenyl) disulfide is due to the elimination of sulfur from the tetrasulfide during the operation. b) In these cases, the complete separation of the products by chromatography is extremely difficult. The low yields of the biphenyl and aryl ethoxy tetrasulfide are mainly the result of the loss of these products during the operation.

The azo intermediate (**3**) then replaces the ethoxyl group in **1** to give the intermediate arylazo ethoxy tetrasulfide (**4**) (Scheme 2). The formation of the aryl radical by the decomposition of diazonium salts is well known.[5] Therefore, the intermediate, **4**, presumably decomposes to the aryl radical with the evolution of nitrogen, and the resulting radical reacts immediately with benzene (solvent) or the ethoxy tetrasulfanyl radical to give biphenyl or aryl ethoxy tetrasulfides respectively. Symmetrical diaryl sulfides would be formed by the thermal decomposition of aryl ethoxy tetrasulfides.

On the other hand, hydrazobenzene reacted with **1** to give azobenzene in a quantitative yield, with the elimination of ethanol and sulfur. 2,2′-Dibromohydrazobenzene reacted similarly. It can be assumed that hydrazobenzene reacts with **1** to give a cyclic disulfide (**5**), followed by the elimination of sulfur to form azobenzene (Scheme 3). In these reactions, the sulfur of **1** serves as an oxidizing agent, whereas divalent sulfur compounds such as dialkyl sulfoxylates

$$\mathrm{Ar\text{-}\underset{\mathrm{H}}{\underset{|}{N}}\text{-}\underset{\mathrm{H}}{\underset{|}{N}}\text{-}Ar} \xrightarrow[-\mathrm{EtOH}]{\mathrm{EtOSSOEt\ (1)}} \left[\mathrm{Ar\text{-}\underset{\mathrm{H}}{\underset{|}{N}}\text{-}\underset{\mathrm{H\ S\text{-}S\text{-}OEt}}{\underset{|}{N}}\text{-}Ar}\right] \xrightarrow[-\mathrm{EtOH}]{}$$

$$\left[\underset{\mathbf{5}}{\mathrm{Ar\text{-}\underset{\mathrm{S\text{-}S}}{\underset{|}{N}}\text{-}\underset{\mathrm{S\text{-}S}}{\underset{|}{N}}\text{-}Ar}}\right] \xrightarrow[-\mathrm{S}]{} \mathrm{Ar\text{-}N{=}N\text{-}Ar}$$

Ar: C_6H_5, 2-BrC_6H_4

Scheme 3.

are known as reducing agents.[6,7] Such conflicting dual properties of sulfur compounds has aroused interest.

In contrast to hydrazobenzene or phenylhydrazine, 1,1-diphenylhydrazine and **1** gave diphenylamine with ethanol and sulfur. However, the mechanism of the reaction has not yet been elucidated.

A related compound of hydrazine 1,5-diphenylthiocarbonohydrazide (**6a**) reacted with 2 mols of **1** to give 2,3-diphenyltetrazolium-5-thiolate (**9a**).[8] Similarly, 1,5-diphenylthiocarbazone (**7a**) or 1,5-di-2-naphthylthiocarbazone (**7b**) reacted readily with **1** to give **9a** or 2,3-di-2-naphthyltetrazolium-5-thiolate (**9b**). It is considered that these reactions proceed *via* azo compounds (**7**,**8**), much like the formation of azobenzene from hydrazobenzene.

Scheme 4.

Experimental

The IR spectra were measured with a Hitachi 260-10 spectrometer. The NMR spectra were determined in a $CDCl_3$ solution with a JEOL JNM-PMX-60 spectrometer. The mass spectra were obtained on a Hitachi RMU-7 M at 70 eV. Diethoxy disulfide (**1**)[3] and 2,2′-dibromohydrazobenzene[9] were prepared by the method of the literature.

Reaction of ***1*** *with Arylhydrazine.* A solution of arylhydrazine (0.02 mol) and **1** (0.04 mol) in 50 cm³ of benzene was refluxed for 10—30 h. The reaction mixture was then evaporated, and the residue was chromatographed on silica gel, using hexane or benzene–hexane (1:2) as an eluent, to give arylbenzene, aryl ethoxy tetrasulfide, and diaryl sulfide. Ethoxy 4-nitrophenyl tetrasulfide: light yellow liq.; NMR ($CDCl_3$) δ 1.32 (m, 3H), 3.93 (m, 2H), 7.36—8.40 (aromatic, 4H); MS *m/e* 295 (M^+). Found: N, 4.80; S, 43.74%. Calcd for $C_8H_9NO_3S_4$: N, 4.74; S, 43.41%. Bis(4-nitrophenyl) disulfide, mp 180 °C. Found: C, 46.90; H, 2.68%. Calcd for $C_{12}H_8N_2O_4S_2$: C, 46.74; H, 2.62%. 2-Chlorophenyl ethoxy tetrasulfide; light yellow liq., NMR ($CDCl_3$) δ 1.28 (m, 3H), 3.98 (m, 2H), 7.03—8.00 (aromatic, 4H). Found: C, 33.48; H, 2.92%. Calcd for $C_8H_9OClS_4$: C, 33.73; H, 3.18%. Bis(2-chlorophenyl) tetrasulfide, light yellow liq. Found: C, 41.10; H, 2.50%. Calcd for $C_{12}H_8Cl_2S_4$: C, 41.02; H, 2.30%. 4-Bromophenyl ethoxy tetrasulfide; light yellow liq., NMR ($CDCl_3$) δ 1.30 (m, 3H), 3.95 (m, 2H), 7.20—7.67 (aromatic, 4H). Found: C, 28.92; H, 2.52%. Calcd for $C_8H_9OBrS_4$: C, 29.18; H, 2.75%. Bis(4-bromophenyl) tetrasulfide, light yellow liq. Found: C, 32.95; H, 2.01%. Calcd for $C_{12}H_8Br_2S_4$: C, 32.74; H, 1.83%. Diphenyl tetrasulfide, light yellow liq. Found: C, 50.88; H, 3.66%. Calcd for $C_{12}H_{10}S_4$: C, 51.03; H, 3.57%. Ditolyl tetrasulfide, light yellow liq. Found: C, 54.03; H, 4.32%. Calcd for $C_{14}H_{14}S_4$: C, 54.15; H, 4.55%. Dinaphthyl tetrasulfide, light yellow liq. Found: C, 62.56; H, 3.41%. Calcd for $C_{20}H_{14}S_4$: C, 62.79; H, 3.69%.

Reaction of ***1*** *with Hydrazobenzene.* A solution of 9.2 g (0.05 mol) of hydrazobenzene and 7.7 g (0.05 mol) of **1** in 50 cm³ of benzene was refluxed for 20 h. The color of the solution turned red. The reaction mixture was then evaporated, and 60 cm³ of hexane was added. The precipitated sulfur (2.3 g) was filtered off, and the filtrate was evaporated. The residue was chromatographed on silica gel, using hexane as an eluent, to give 9.03 g (99%) of azobenzene (mp 67—68 °C) and 0.2 g of sulfur. A total of 2.5 g (78%) of sulfur was obtained. Similarly, 2,2′-dibromohydrazobenzene (3.42 g, 0.01 mol) and **1** (1.54 g, 0.01 mol) gave 2,2′-dibromoazobenzene (3.35 g, 99%) by column chromatography. 2,2′-Dibromoazobenzene; mp 131—132 °C; reddish orange needles from ethanol. A total of 0.63 g (98%) of sulfur was obtained.

Reaction of ***1*** *with 1,1-Diphenylhydrazine.* To a suspension of 2.21 g (0.01 mol) of 1,1-diphenylhydrazine hydrochloride in 30 cm³ of benzene, a solution of 1.51 g (0.01 mol) of triethylamine was added. After that, a solution of 1.54 g (0.01 mol) of **1** in 10 cm³ of benzene was added to the reaction mixture and the mixture was refluxed for 3 h. Triethylamine hydrochloride was then filtered off, and the filtrate was evaporated. The residue was chromatographed on silica gel, using benzene–hexane (1:2) as an eluent, to give 1.36 g (80%) of diphenylamine; mp 52 °C.

Reaction of ***1*** *with 1,5-Diphenylthiocarbonohydrazide (**6a**).* A suspension of 2.58 g (0.01 mol) of **6a** and 3.08 g (0.02 mol) of **1** in 50 cm³ of benzene was refluxed for 3 h. The color of the solution gradually turned reddish brown. Upon cooling to room temperature, a red solid precipitated from the solution. This red solid was collected and was recrystallized from ethanol to give 2.1 g (83%) of **9a** as red needles; mp 180 °C dec (lit,[8] 180 °C); MS *m/e* 254 (M^+, 18), 226 (M^+-N_2, 18), 167 (11), 105 (25), 77 (100); IR (KBr) 1320 cm^{-1} (very strong). Found: C, 61.25; H, 4.01%. Calcd for $C_{13}H_{10}N_4S$: C, 61.40; H, 3.96%.

Reaction of ***1*** *with 1,5-Diphenylthiocarbazone (**7a**).* A suspension of 2.56 g (0.01 mol) of **7a** and 1.54 g (0.01 mol) of **1** in 50 cm³ of benzene was refluxed for 0.5 h. The color of the suspension immediately turned from dark green to red. A red solid was collected and recrystallized to give 2.38 g (94%) of **9a**. Similarly, 1,5-di-2-naphtylthiocarbazone (**7b**) (1.1 g, 0.003 mol) and **1** (0.48 g, 0.003 mol) gave **9b** (0.8 g, 73%); red prisms from ethanol; mp 167—168 °C dec; MS *m/e* 354 (M^+, 11), 326 (M^+-N_2, 18), 267 (15), 131 (18), 127 (100); IR (KBr) 1310 cm^{-1} (very strong). Found: C, 71.33; H, 4.14; N, 15.66%. Calcd for $C_{21}H_{14}N_4S$: C, 71.16; H, 3.98%; N, 15.81%.

Photochemical Ethoxycarbonylmethylation of Anisole with Ethyl Chloroacetate in the Presence of Zinc Chloride

Yasuji IZAWA,* Hideo TOMIOKA, Masato KUTSUNA, and Yasuo TOYAMA

Chemistry Department of Industry and Resources, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received April 5, 1979)

Synopsis. Irradiation of ethyl acetate solution of anisole and ethyl chloroacetate in the presence of $ZnCl_2$ gave ethyl *o*-, *m*-, and *p*-methoxyphenylacetates (**3**) (28.6—48%). The similar ethoxycarbonylmethylation in anisole–ethyl acetate (9:1) resulted in higher yields (80—81%) of **3**. The results on the positional and substrate selectivities imply that $ZnCl_2$-participated attacking species would play an important role in the present ethoxycarbonylmethylation.

It has been well known that in the Friedel-Crafts reactions of ordinary carboxylic acids or their esters with aromatic compounds a carboxymethylation or alkoxycarbonylmethylation is difficult. In previous studies,[1] however, we reported that the photochemical ethoxycarbonylmethylation of benzene with ethyl chloroacetate in the presence of metallic halides, such as $SbCl_3$, $AlCl_3$, $ZnCl_2$, and $FeCl_3$, was possible and gave ethyl phenylacetate (2.3—24.4%) as a sole product. We assumed that the reaction might proceed *via* an electrophilic aromatic substitution by such a C-T exciplex as $(MCl^-_{n+1}\cdots\cdots{}^+CH_2CO_2Et)^*$. If this is the case, the similar reaction of anisole, one of electron rich benzenes, could occur more efficiently and show a high positional selectivity. Thus, it was hoped that this reaction would provide greater mechanistic insight into the course of the photochemical ethoxycarbonylmethylation of aromatic compounds with ethyl chloroacetate in the presence of metallic halides. Herein we wish to report the results of our study on the photochemical ethoxycarbonylmethylation of anisole with ethyl chloroacetate in the presence of $ZnCl_2$ and discuss a probable mechanism.

Reaction Products. Irradiation of ethyl acetate solution of anisole (**1**) and ethyl chloroacetate (**2**) in the presence of $ZnCl_2$ with an unfiltered low pressure mercury lamp at room temperature for 37 h gave isomeric ethyl methoxyphenylacetates (28.6—48.1% yield) (**3**) accompanied by a trace of diethyl succinate (**4**). As shown in Table 1, addition of $ZnCl_2$ to the reaction significantly increases the yield of ethyl methoxyphenylacetates (**3**), which increases as the concentration of $ZnCl_2$ increases, and at the same time produces noticeable change in the isomer distribution. No photochemical interconversion between each methoxyphenylacetate was observed. The similar ethoxycarbonylmethylation was performed in anisole–ethyl acetate (9 : 1). This resulted in higher yields (80—81%) of methoxyphenylacetates (**3**) and no detection of **4** which eliminates the participation of ethoxycarbonylmethyl radicals. In absence of $ZnCl_2$ **4** was detected, but only in a trace.

Positional and Substrate Selectivities. Data of Table 1 show the effect of $ZnCl_2$ on positional selectivity (as shown with isomer distributions). The isomer distributions did not show any measurable change during irradiation from 3 to 37 h. Thus, the positional selectivity is safely shown with the isomer distribution. Addition of ethyl vinyl ether as a radical scavenger to the reaction without $ZnCl_2$ gave no detectable amounts of **3**. This result, together with the formation of **4** derived from ethoxycarbonylmethyl radicals and results for related reaction,[2] suggests the radical nature of the reaction without $ZnCl_2$. Thus, the relative high proportion of meta isomer in the absence of $ZnCl_2$ may be attributed to a radical substitution by the ethoxycarbonylmethyl radicals.

As shown in Table 2, striking is the significant increase in the values for the Selectivity Factor (S_f), as defined by Brown and Smoot,[3] in the reactions with $ZnCl_2$, when compared with those in the absence of $ZnCl_2$. From the S_f values it is possible to say that the reactions in the presence of $ZnCl_2$ proceed *via* competitive radical and non-radical mechanisms, the relative contributions of which depend on the concentration of $ZnCl_2$. The $k_{anisole}/k_{benzene}$ rate ratio ($=k_a/k_b$) in the presence of $ZnCl_2$ is found to be 5.9 from the competitive method. The lower substrate selectivity in the form of low k_a/k_b suggests the reaction to be an electrophilic aromatic substitution involving strongly electrophilic reagent.[4] These results on the positional and substrate selectivities imply that in the non-radical mechanism the carbon atom undergoing attack develops a partial positive charge and may have considerable carbonium ion charactor. Thus, $ZnCl_2$-participated attacking species, as expected previously,[1] would play an important role in the present reaction.

Fluorescence Quenching of Anisole by Ethyl Chloroacetate. In order to examine whether the reactions are induced by energy transfer from singlet anisole to **2**, fluorescence quenchings of **1** by **2** were carried out in cyclohexane and cyclohexane–ethyl acetate (1:1) containing $ZnCl_2$. Both solutions showed structureless fluorescence spectra

with a maximum at 296 nm. The fluorescences of **1** in cyclohexane and cyclohexane–ethyl acetate containing $ZnCl_2$ are quenched by **2** to give linear Stern-Volmer plots, whose slopes are 18[5] and 7.0 M^{-1} at 13 °C, respectively. The fluorescence quenching with the different efficiency cannot be inferred from the different viscosities of the solutions. The lower efficiency in the presence of $ZnCl_2$ may be attributed to weak interaction between $ZnCl_2$ and **2** in the ground state, although it has been shown that the basicity of ethyl acetate is higher than that of **2**.[6] No fluorescence quenching by only $ZnCl_2$ was observed. Thus, it seems likely that the present reactions are induced by energy transfer from singlet anisole to **2** or that interacting weakly with $ZnCl_2$.[7]

Reaction Schemes. Prior to discussing the reaction schemes, the UV spectra of ethyl acetate solutions of anisole in the presence of $ZnCl_2$ were measured. The results show that the spectra do not change by addition of $ZnCl_2$. This implies that there is no interaction between a ground state anisole and $ZnCl_2$ in ethyl acetate. On the basis of the facts mentioned above and before, the possible reaction schemes are outlined as follows:

: without $ZnCl_2$:

$$\text{Anisole} \xrightarrow{h\nu} (\mathbf{1})^S$$

$$(\mathbf{1})^S + \mathbf{2} \longrightarrow (\mathbf{2})^S \longrightarrow Cl\cdot + \cdot CH_2CO_2Et \longrightarrow$$

$$\text{radical aromatic substitution}$$

$$(\mathbf{2})^T$$

: with $ZnCl_2$:

$$\mathbf{2}^*_{S \text{ or } T} \longrightarrow Cl\cdot + \cdot CH_2CO_2Et \longrightarrow \text{radical substitution}$$

$$(\mathbf{1})^S + (ZnCl_2\cdots ClCH_2CO_2Et) \longrightarrow$$

ground state

$$(\overset{\delta-}{Z}nCl_2\cdots Cl\cdots \overset{\delta+}{C}H_2CO_2Et)^*$$

2a

$$\longrightarrow \text{electrophilic aromatic substitution}$$

Thus, in the presence of $ZnCl_2$, an electrophilic aromatic substitution by electronically excited attacking species (**2a**) having considerable carbonium ion charactor may compete with a radical substitution by ethoxycarbonylmethyl radicals. **2a** can be produced by an energy transfer from singlet anisole to **2** interacting weakly with $ZnCl_2$, assuming that the low-lying reactive excited state for **2** is n,π^*.[8]

Experimental

Materials. Ethyl chloroacetate (**2**), bp 142—143 °C, and authentic diethyl succinate, bp 108—108.5 °C/19 Torr, were prepared as previously described.[1a] Authentic ethyl *p*-methoxyphenylacetate was prepared by the conventional esterification of *p*-methoxyphenylacetic acid: bp 136—139 °C/9.5 Torr. *p*-Methoxyphenylacetic acid, mp 85—86 °C (lit, 84; 87 °C[9]) was prepared by hydrolysis of *p*-methoxybenzyl cyanide obtained by cyanation of *p*-methoxybenzyl chloride. Authentic ethyl *o*- and *m*-methoxyphenylacetates were similarly prepared: ethyl *o*-methoxyphenylacetate, bp 137 °C/14 Torr; ethyl *m*-methoxyphenylacetate, bp 135—138 °C/7 Torr. The *o*- and *m*-methoxybenzyl chlorides were prepared by crossed Cannizzaro reaction between the corresponding anisaldehydes and formaldehyde followed by chlorination with hydrochloric acid.

Irradiation for Analytical Purposes. The irradiations were conducted using a Halos 30 W low-pressure mercury lamp without filter. The solutions (5 mL) outlined in Table 1 were placed in 12 mm o.d. quartz tubes, and these were capped with polyethylene-stopples after flushing with nitrogen for about 5 min, then irradiated at 13—23 °C for 37 h. After irradiation, analysis of the reaction mixtures was performed by means of GC.

Fluorescence Quenching of ***1***. A stock solution of **1** in cyclohexane was prepared and varying amounts of **2** were added to aliquots of the stock: [**1**]=30 mM, [**2**]=3.8—30 mM. Five solutions were used for the quenching experiment. The fluorescence spectra were recorded at about 13 °C and the relative intensities (I_0/I) at 296 nm in the absence and presence of **2** were plotted with concentration of **2**. A linear Stern-Volmer plot was obtained. Similarly, fluorescence quenching of **1** by **2** containing $ZnCl_2$ (molar ratio= 1:1) was carried out in cyclohexane–ethyl acetate (1:1).

The BF_3 Catalyzed Decomposition of Diazo Compounds in the Presence of Carbonyl Compounds

Toshikazu IBATA,* Kazuo MIYAUCHI, and Seiji NAKATA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received April 9, 1979)

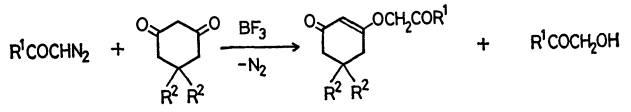
Synopsis The BF_3 catalyzed decomposition of diazo compounds such as α-diazoacetophenones, ethyl diazoacetate, and diphenyldiazomethane in the presence of cyclic β-diketones gave the corresponding enol ether. Used as a substrate, cyclohexanone gave the ring expanded homologation product.

The reactions of diazo compounds with carboxylic acids have been extensively studied as a preparative method for esters.[1] Few papers have however been published on the Lewis acid catalyzed reaction of diazo compounds with carbonyl compounds. For example, the BF_3 catalyzed decomposition of ethyl diazoacetate in carbonyl compounds was reported to give homologation products (**1**).[2-5]

$$\text{R-C(=O)-R} + N_2CHCOOC_2H_5 \xrightarrow[-N_2]{BF_3} \text{R-C(=O)-CH(COOC}_2\text{H}_5\text{)-R}$$

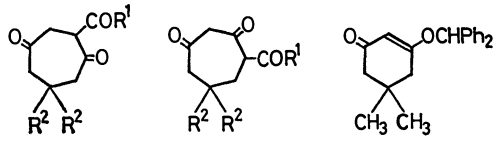
(**1**)

In this paper a further type of reaction observed in the BF_3 catalyzed decomposition of diazo compounds in the presence of β-diketones such as dimedone (5,5-dimethyl-1,3-cyclohexanedione) and 1,3-cyclohexanedione will be reported. A catalytic amount of BF_3 etherate when added to a solution of α-diazoacetophenone and dimedone (1 : 3 molar ratio) in benzene at 60 °C gave a vigorous evolution of nitrogen gas. Column chromatography (silica gel–benzene) of the reaction mixture gave two products. The first fraction was identified as α-hydroxyacetophenone (**3a**, 28%) by comparison of the IR and NMR spectra with those of authentic samples prepared by the decomposition of the diazoacetophenone in dilute sulfuric acid. The second product was characterized as 5,5-dimethyl-3-phenacyloxy-2-cyclohexene-1-one (**2a**: R^1=Ph, R^2=CH_3, 63%) on the basis of the results of elemental analysis and spectral properties. The IR spectrum shows the carbonyl band of the benzoyl group at 1700 cm^{-1} and bands of the enone group at 1650 and 1600 cm^{-1}. The NMR spectrum exhibits a singlet of the vinyl proton at δ 5.22 and three methylenes at 5.12, 2.43, and 2.22 ppm besides two methyl signals and a phenyl signal. Similar results were observed in the reactions of substituted diazoacetophenones with dimedone or 1,3-cyclohexanedione (Table 1, Runs a—f and h—j). Ethyl diazoacetate gave the corresponding enol ethers (**2g** and **2k**: R^1=OC_2H_5) in the reactions with dimedone and 1,3-cyclohexanedione.



(**2**) (**3**)

In these reactions, no ring expanded homologation product, *e.g.*, **4** or **5** was found in detectable amounts despite detailed inspection of the reaction mixture by column chromatography.



(**4**) (**5**) (**10**)

An excess of BF_3 etherate,[6] did not give the homologation product. In these cases **2** and **3** were accompanied by α-ethoxyacetophenone (**9**) which is thought formed by attack of the reaction intermediate (**6**) on diethyl ether through betaine (**8**). An increase in the amount of BF_3 etherate used caused a decrease in the yields of **2** and **3** an increase in the yield of **9**. The use of a five molar amount of BF_3 etherate gave only one product **9**, (69%), **2** and **3** were not detected.

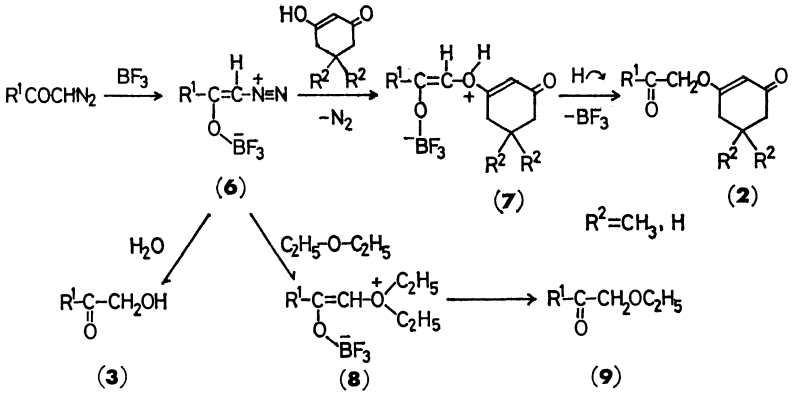
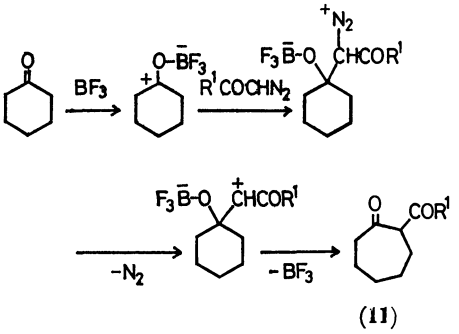


Scheme 1.



Scheme 2.

The reactions are explained in terms of the attack of the diazonium ion type intermediate (**6**) on the enol oxygen of the β-diketones to give the intermediate **7** which by the elimination of BF_3 and hydrogen migration gives the product **2**. An alternative mechanism which can not be excluded is the attack by **6** on the carbonyl oxygen of the keto form of the β-diketones. The formation of α-hydroxyacetophenones (**3**) may be explained by the attack of **6** on the water contained in the reaction system. Diphenyldiazomethane also gave the corresponding enol ether (**10**, 44%) in a similar reaction accompanying benzhydryl alcohol and tetraphenylethylene. Cyclohexanone however changes the mode of the reaction. The decomposition of *p*-methoxydiazoacetophenone in cyclohexanone in the presence of catalytic amounts of BF_3 occurs vigorously even at temperatures as low as 0 °C, affording the homologation product (**11**: R^1=*p*-$CH_3OC_6H_4$, 92%). A small broad singlet at 16.6 ppm in the NMR spectrum shows the partial existence of the enol form in **11**. This reaction may be initiated by the attack of BF_3 on the oxygen of cyclohexanone as shown in the following Scheme 2.

The difference in reaction between cyclohexanone and the cyclic β-diketones may be attributed to differences in affinity of these ketones to BF_3. The affinity appears to be in the order: cyclohexanone> diazoacetophenone>dimedone≈1,3-cyclohexanedione.

Experimental

All melting points are not corrected. The IR spectra were measured on a Hitachi Spectrometer Model 215. The ^{1}H-NMR spectra were recorded in $CDCl_3$ solution at 60 MHz on a Varian Spectrometer Model EM-360 using TMS as an internal standard.

Materials. All diazo compounds were prepared by the methods described in the literature.[7,8]

General Procedure of the BF_3 Catalyzed Decomposition of Diazoacetophenones in the Presence of Cyclic β-Diketones. To a benzene solution (50 ml) of diazoacetophenone (5 mmol) and the carbonyl compound (15 mmol) a catalytic amount of BF_3 etherate (20 mg) was added under magnetic stirring at 60°C. Vigorous evolution of N_2 occurred and the reaction mixture changed from yellow to dark red. The reaction mixture was added to water (50 ml) and the benzene layer washed with H_2O (10 ml), dried over Na_2SO_4, and column chromatographed on silica gel.

The BF_3 Catalyzed Decomposition of Diphenyldiazomethane in the Presence of Dimedone. To a benzene solution (50 ml) of diphenyldiazomethane (0.51 g, 2.6 mmol) and dimedone (0.63 g, 4.5 mmol) two drops of BF_3 etherate were added and the mixture stirred at room temperature. After the evolution of N_2 ceased, the reaction mixture was treated as described above. Column chromatography of the reaction mixture gave three products. Benzhydryl alcohol (35%) and tetraphenylethylene (8%) were characterized by direct comparison with authentic samples. Enol ether (**10**): colorless crystals; yield 44%; mp 57—58°C; IR (KBr) 1650, 1600 cm^{-1} (enone); NMR ($CDCl_3$) δ 1.03 (s, 6H, CH_3), 2.17 (s, 2H, CH_2), 2.45 (s, 2H, CH_2), 5.41 (s, 1H, =CH), 6.17 (s, 1H, OCH), and 7.33 ppm (s, 10H, Ph). Found: C, 82.10; H, 7.31%. Calcd for $C_{21}H_{22}O_2$: C, 82,37; H, 7.24%.

Reaction of p-*Methoxydiazoacetophenone with Cyclohexanone.* To a solution of *p*-methoxydiazoacetophenone (0.53 g, 3 mmol) in cyclohexanone (5 ml) three drops of BF_3 etherate were added. After the usual workup, 2-(*p*-anisoyl)cycloheptanone (**11**: R^1=*p*-$CH_3OC_6H_4$) was obtained; yield 92%, colorless needles; mp 125.0—126.5°C; IR (KBr) 1700, 1670 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.2—2.9 (m, 10H, CH_2), 3.85 (s, 3H, OCH_3), 4.5 (broad t, 1H, CH), 6.95, 7.97 (ABq, 4H, Ar), and 16.6 ppm (broad s, 0.1H, enol-H). Found: C, 72.94; H, 7.32%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%.

Reaction of Thiobenzamides with Arylmagnesium Bromides

Takayuki KARAKASA, Takashi HANZAWA, and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received April 12, 1979)

Synopsis. Reactions of thiobenzamide, *p*-methylthiobenzamide, *p*-methoxythiobenzamide, and *p*-chlorothiobenzamide with 4 equivalents of phenyl-, *p*-tolyl-, *p*-methoxyphenyl-, and *p*-chlorophenylmagnesium bromides gave the corresponding diphenylmethyleneamine and thiobenzophenone as 1,2-addition produsts in good yields.

Thiones, thioesters, and dithioesters are known to react with organometallic reagents to give thioethers and their derivatives.[1] However little is known of reactions of thioamides with organometallic reagents.[2] *N*-Phenyl-2,2-diphenylthioacetamide does not react with excess ethylmagnesium bromide.[2a] However, highly basic carbanions such as phenyllithium react with *N*,*N*-dimethylthiobenzamide to give *N*,*N*-dimethyltriphenylmethylamine, triphenylmethanol, and a small amount of benzophenone.[2b] *N*,*N*-Dialkyl-α,β-unsaturated thioamides undergo the 1,4-addition reaction with organolithium and magnesium compounds.[2c] We were interested in the reaction of thioamides with Grignard reagents as part of our study on thiocarbonyl compounds.[3]

Treatment of *N*-substituted thioamide such as *N*-morpholino(thiobenzamide) or *N*-methyl(thiobenzamide) with excess phenylmagnesium bromide in ether at room temperature resulted in the recovery of unchanged thioamide. In contrast, the reaction of primary thioamides with arylmagnesium bromides proceeded readily under the same conditions. When thiobenzamide was allowed to react with 4 equivalents of phenylmagnesium bromide, diphenylmethyleneamine (**5a**) and thiobenzophenone (**6a**) were obtained. Hydrogen sulfide was evolved after being hydrolyzed with aqueous ammonium chloride. The results are summarized in Table 1.

The formation of **5** and **6** can be explained by the following mechanisms.

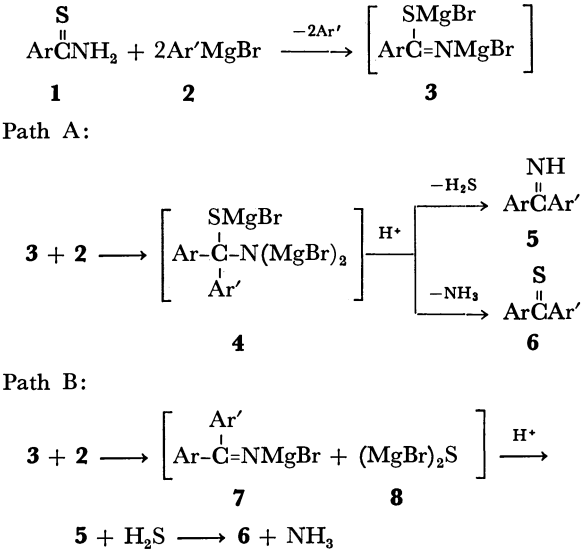
When thiobenzamide was treated with 2 equivalents of phenylmagnesium bromide, unchanged thioamide was recovered. This indicates that the reaction proceeds *via* an initial dimetallation of the thioamide affording an intermediate (**3**).[4a] The reaction of **3** with **2** would give the intermediates (**4**) and/or (**7**)[4b,4c] (Scheme 1).

Path A involves the addition of **2** to the carbon–nitrogen double bond of **3** to give an intermediate (**4**) which cleaves to afford **5** and **6** by hydrolysis.

Alternative path B involves the replacement of the sulfur moiety of **3** by the aryl group of **2** to give **7** and **8** which afford **5** and hydrogen sulfide by hydrolysis. In this pathway, **6** may be formed by the reaction of **5** with hydrogen sulfide.[5]

If the reaction proceeds along either path A or B, the ratio of the products (Imine/Thione) in run **b** (or **c**) is approximately equal to that in run **e** (or **f**) since both runs **b** and **e** (**c** and **f**) give rise to the formation of an identical intermediate. However, the actual ratios are quite different as shown in Table 1.

An explanation is given by assuming that the reaction proceeds *via* both pathway A and B. The ratio of the products (Imine/Thione) from the intermediate **4** would not be the same as that from the intermediate **7**, the formation ratio of **4** and **7** depending on the nucleophilicity of the Grignard reagents.



Scheme 1. Reaction route.

Experimental

Thiobenzamide (**1a—d**)[6] and *N*-morpholino(thiobenzamide)[7] were synthesized by the methods reported. *N*-Methyl(thiobenzamide) was prepared by the reaction of methyl isothiocyanate with phenylmagnesium bromide.[4]

A Typical Procedure for the Reaction of Thiobenzamides with Arylmagnesium Bromides. Thiobenzamide (0.1 mol) was added gradually to a solution of phenylmagnesium bromide (0.4 mol) in 300 cm^3 dry ether at room temperature under nitrogen atmosphere. After being allowed to stand overnight, the reaction mixture was quenched with saturated aqueous ammonium chloride at −10 °C and filtered, the solvent then being evaporated. The deep blue residue was dissolved in 150 cm^3 petroleum ether. Dry hydrogen chloride was bubbled into the solution until precipitation was complete. Precipitated diphenylmethyleneamine hydrochloride (13.56 g)(sublimed at 230—270 °C (230—250 °C)[8b]) was filtered off and the filtrate was evaporated. The deep blue residue was distilled to give thiobenzophenone (2.97 g) (120 °C/1 Torr (120—125 °C/1 Torr)[8a]).

The products (Table 1) were identified by comparing their boiling points, IR spectra, and/or GLC (Silicone Gum SE-30) with those of authentic compunds.[8]

Studies on the Configuration of *N*-Cyclohexylideneanilines with ^{13}C-NMR Spectroscopy

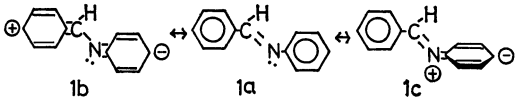
Masato YOSHIDA and Michio KOBAYASHI*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received May 1, 1979)

Synopsis. ^{13}C-NMR chemical shifts and the rates of thermal *E*-*Z* isomerizations of *N*-cyclohexylideneanilines have been determined and the substituent effects discussed.

In a previous paper the existence of two types of conjugation[1] in *N*-benzylideneanilines (**1a**) was reported. One is conjugation between the π-electrons of the carbon-nitrogen double bond and aromatic ring (**1b**), and the other is conjugation between the lone pair electrons of the nitrogen and aromatic ring (**1c**).

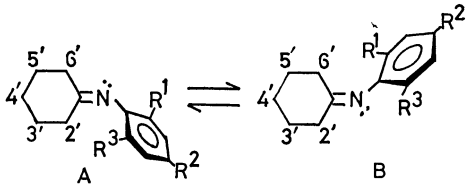


1b 1a 1c

There is no type **1c** conjugation when the dihedral angle between the >C=N– plane and imino benzene ring is 0°, whereas an angle of 90° represents the optimum conditions. *N*-Cyclohexylideneanilines appear to be suitable compounds to study this type of conjugation since the imino benzene rings are known to rotate by about 90° out of the >C=N– plane.[2] The ^{13}C-NMR spectra of substituted *N*-cyclohexylideneanilines (**2**—**6**) have been studied at several temperatures and the substituent effects discussed in connection with the thermal isomerism between the *E* and *Z* forms.

Results and Discussion

Thermal isomerization between the *E* and *Z* forms of the *N*-benzylideneanilines is known to readily occur. In *N*-cyclohexylideneaniline, thermal isomerization between the forms **A** and **B** shown below is expected.



A B

	2	**3**	**4**	**5**	**6**
R^1	H	H	H	H	Me
R^2	NO_2	COOEt	H	OMe	NO_2
R^3	H	H	H	H	Me

The ^{13}C-NMR spectra of **2**—**5** were measured at room temperature in $CDCl_3$, and the δ_C values for **2**—**5** are given in Table 1. The differences in value of $\delta_{C-2'}$ and $\delta_{C-6'}$ (or $\delta_{C-3'}$ and $\delta_{C-5'}$) for **2**—**5** indicates that the configurations of **2**—**5** are fixed within the NMR time scale at room temperature. As shown in Fig. 1b the ^{13}C-NMR of C-2′-6′ of compound **6** could not be observed as a set of five signals. Five ^{13}C-NMR signals of each C-2′-6′ were observed at −50 °C, while at 100 °C the signals of C-2′ and C-6′ (also C-3′ and C-5′) coalesced and the ^{13}C-NMR signals of C-2′-6′ appeared as three signals. This indicates that the thermal isomerization between **6A** and **6B** is slower at −50 °C and faster at 100 °C than the

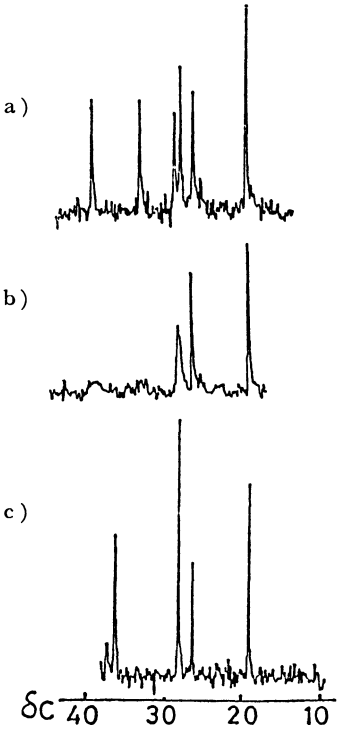


Fig. 1. ^{13}C-NMR spectra of compound **6** at a) −50 °C in $CDCl_3$, b) at room temperature in $CDCl_3$, and c) at 100 °C in DMSO-d_6.

TABLE 1. CARBON-13 CHEMICAL SHIFTS OF **2**—**6** AT ROOM TEMPERATURE

	2	**3**	**4**	**5**	**6**[a]

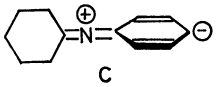
Table 2. Coalescence temperatures (T_c) of $C_{2'}$, $C_{6'}$ and ΔG^* values for **2**—**6**[a]

	$\nu C_{2'}-\nu C_{6'}$	T_c/K[b]	ΔG^*/kcal mol^{-1}
2	106.20	348	16.7
3	109.86	398	19.2
4	118.14	>413	>19.7
5	124.51	>413	>19.7
6	92.77	328	15.7

a) Solv. DMSO-d_6 for **2**—**5** and $CDCl_3$ for **6**. b) Accuracy: ±5 K.

NMR time scale. Consequently, at elevated temperatures, the thermal isomerizations in **2**—**5** are expected to be observable by NMR. The ^{13}C-NMR spectra of **2**—**6** were measured at several temperatures, and the coalescence temperatures (T_c) for C-2′ and C-6′ signals determined, and the ΔG^* values calculated. The results are summarized in Table 2.

Type **1b** conjugation should not be possible when the imino benzene ring is rotated out of the >C=N– plane by approximately 90°. Interaction between the *N*-lone pair and imino benzene ring however becomes important. Table 1 shows that $\delta_{C-1'}$ is very little affected by the substituents of the aromatic ring in comparison with $\delta_{C-\alpha}$ of *N*-benzylideneanilines (PhCH=N–C_6H_4–R-*p*) whose imino benzene rings are rotated approximately 50°.[3] This suggests that the substituents of the aromatic ring do not affect the electron density on the carbon atom of >C=N– when the imino benzene ring is rotated out of the >C=N– plane by approximately 90°. As shown in Table 2, the ΔG^* of **2** and **3** having electron-withdrawing groups are smaller than those of **4** and **5**. This can be explained by assuming a linear transition state **C** for the thermal isomerization between forms **A** and **B**.[4]



C

In this transition state, the hybridization of the N atom is of the sp type. The transition state (**C**) should be stabilized by the electron-withdrawing substituent on the imino benzene ring to a greater extent than in the ground state, since the delocalization of the *N*-lone pair into the imino benzene ring will be easier with a linear structure. Electron-withdrawing substituents on the imino benzene ring will assist this delocalization and decrease ΔG^*.

Experimental

N-Cyclohexylideneanilines[2] were prepared by condensation between the corresponding anilines and cyclohexanone diethyl acetal:[5] bp (mp): **2**; 176 °C/6 mmHg, **3**; 187 °C/5 mmHg, **4**; 140 °C/18 mmHg, (lit,[2] 156 °C/30 mmHg), **5**; 76—77 °C (mp), **6**; 57—58 °C (mp).

^{13}C-NMR chemical shifts were determined at room temperature in $CDCl_3$ with a JEOL Fx-60 FT spectrometer. The accuracies of chemical shifts were approximately 0.1 ppm (data points; 4096, sampling time; 900 ms, pulse flipping angle; 45°). The coalescence temperatures were determined in DMSO-d_6 well-dried with molecular sieves, and the values of the activation free energy calculated using the following equation,[6]

$$k = \pi\nu_{ab}/\sqrt{2} = (KT/h)\exp(-\Delta G^*/RT).$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (11), 3473—3474 (1979)

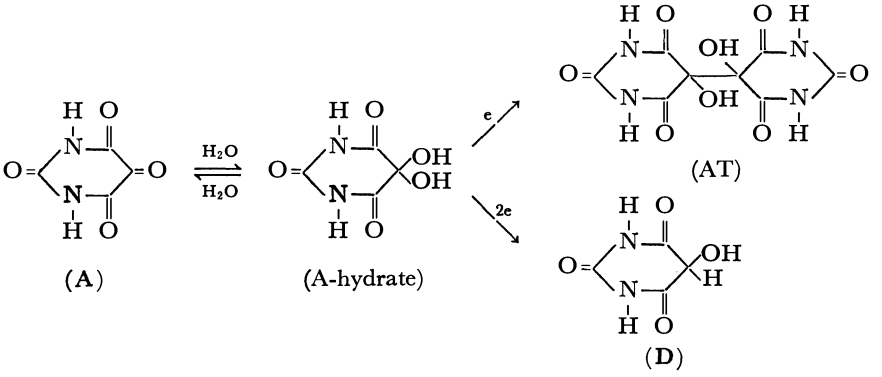
Reduction of Alloxan by Cyanide Ion. Isolation of Alloxan Radical Anion Salts and Alloxantin

Takeshi ENDO,* Akira KUDO, and Makoto OKAWARA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received May 2, 1979)

Synopsis. Potassium or pyridinium salts of alloxan radical anion were isolated by the one-electron reduction of alloxan monohydrate with potassium cyanide or 1-benzyl-4-cyano-1,4-dihydronicotinamide at room temperature, respectively.

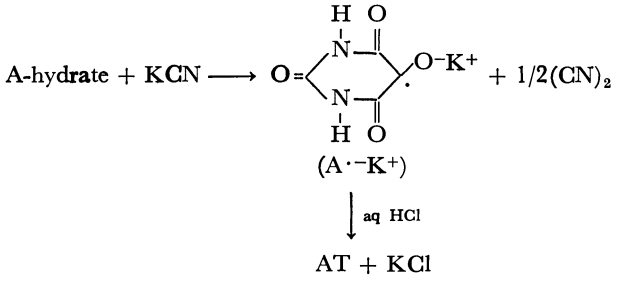
Alloxan(A) is known as one of vicinal tricarbonyl compounds, of which central carbonyl group activated by adjacent two carbonyl groups is so reactive that easily combines one mole of water to form hydrate (A-hydrate).[1] It has been also reported that A-hydrate can be easily reduced by hydrogen sulfide[2] or 1-alkyl-1,4-dihydronicotinamide[3] (NADH model) to obtain AT and dialuric acid(D) by one-electron or two-electron reduction of A-hydrate, respectively.



A is also known as one of "reductones" as same as ascorbic acid which plays important roles in the biological oxidation-reduction system.

In this paper, we wish to report the isolation of alloxan radical anion salts obtained by the reduction of A-hydrate with potassium cyanide and 1-benzyl-1,4-dihydronicotinamide.

Reduction of A-Hydrate by Potassium Cyanide. The reduction of nitro compounds[4] and sulfoxides[5] by cyanide ion have been reported. We found that A-hydrate could be reduced by potassium cyanide in water (pH 6.8) at room temperature to give a yellow precipitate in good yield. The esr spectrum of the precipitate in bulk showed the broad singlet line at 25 °C, as shown in Fig. 1. The precipitate was shown to be the 1 : 1 salt of potassium ion and alloxan radical anion by elemental analyses. Upon treating the precipitate with aq hydrochloric acid, AT was obtained in excellent yield. Based on the results described above, the reasonable structure of the precipitate is considered to the salt ($A^{\cdot-}$ K^+) of potassium ion and alloxan radical anion.



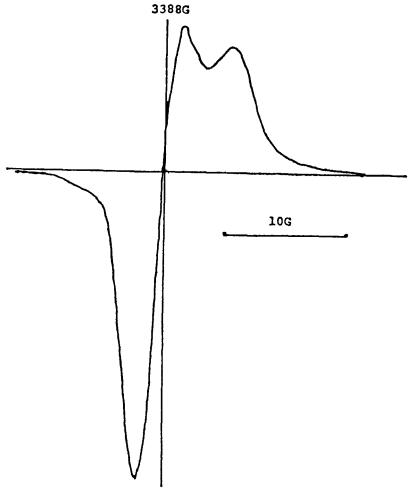


Fig. 1. ESR spectrum of potassium salt ($A^{\cdot-}K^+$) of alloxan radical anion (bulk, 25 °C).

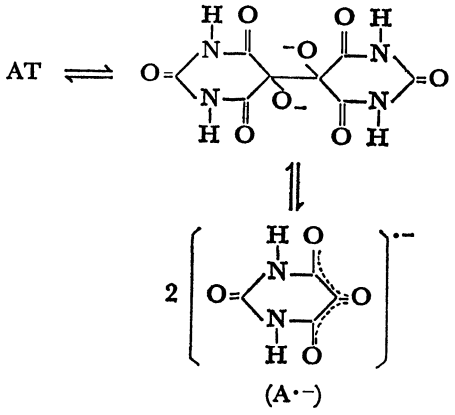
Cyanogen (bp −21.2 °C, mp −27.9 °C[6]) could be also detected by IR (2200 cm^{-1}) qualitatively by trapping in ethanol by bubbling nitrogen gas into the reaction mixture during the reaction.

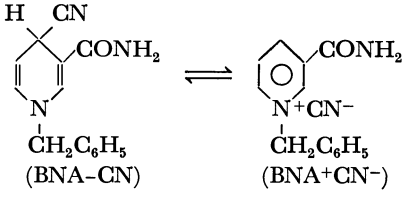
The formation of alloxan radical anion ($A^{\cdot-}$) has been observed by the reduction of A-hydrate with sodium dithionite in water or methylsulfinylmethanide ($CH_3SOCH_2^-$) in dimethyl sulfoxide (DMSO), and the esr was analyzed in detail. Further, $A^{\cdot-}$ was effectively produced by the dissociation of AT in DMSO.[7]



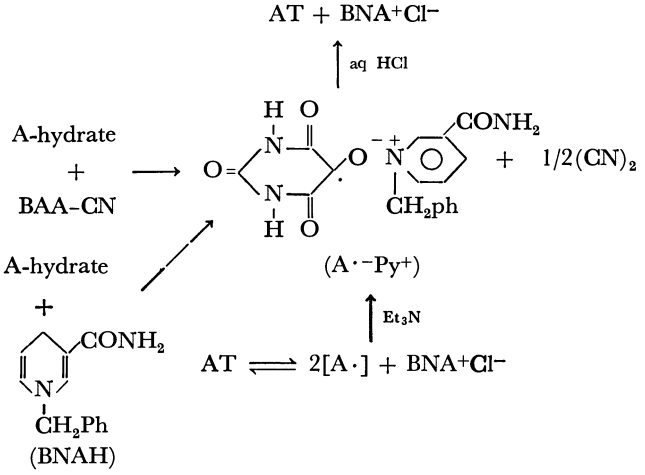
A·⁻ K⁺ was also prepared by treating AT with triethylamine in the presence of excess potassium chloride.

$$AT \rightleftharpoons 2[A\cdot] + 2KCl \xrightarrow{Et_3N} 2A\cdot^{-}K^{+} + 2Et_3N\cdot HCl$$

Reduction of A-Hydrate by 1-Benzyl-4-cyano-1,4-dihydronicotinamide. Whereas 1-benzyl-4-cyano-1,4-dihydronicotinamide (BNA–CN) shows the absorption maximum at 333—337 nm (dihydro form) in acetonitrile or dichloromethane, it exhibits both 337 (BNA–CN) and 265 nm (BNA⁺CN⁻) bands in methanol or ethanol, indicating the presence of equilibrium between BNA–CN and BNA⁺CN⁻.



The reaction of A-hydrate and BNA–CN was tried in ethanol at room temperature to yield a yellow precipitate in a good yield. The yellow precipitate was found to be the pyridinium salt (A·⁻Py⁺) of alloxan radical anion which was obtained by the reduction of A-hydrate with 1-benzyl-1,4-dihydronicotinamide (BNAH) or the reaction of AT and 1-benzyl-3-carbamoylpyridinium chloride (BNA⁺Cl⁻) in the presence of triethylamine.[3] The production of cyanogen during the reaction was also detected by IR spectrum qualitatively. A·⁻Py⁺ was treated with aq. HCl to give and BNA⁺Cl⁻ in excellent yields. A·⁻K⁺ and A·⁻Py⁺ are insensitive to oxygen in solid state, but they are easily oxidized in solution to give alloxan.



Experimental

Materials. Alloxan monohydrate(A-hydrate) (mp 253 °C (dec)) was prepared by the oxidation of barbituric acid with chromium trioxide.[8] Alloxantin(AT) (mp 230—231 °C) used in this study was prepared by the reduction of A-hydrate with hydrogen sulfide.[9] 1-Benzyl-3-carbamoylpyridinium chloride (BNA⁺Cl⁻) (mp 230—232 °C)[10] was synthesized by the reaction of benzyl chloride and nicotinamide in *N,N*-dimethylformamide. 1-Benzyl-4-cyano-1,4-dihydronicotinamide (BNA–CN) was prepared by the reaction of BNA⁺Cl⁻ and potassium cyanide in water and recrystallized from acetonitrile. Mp 113—133 °C (dec).[11]

The Reaction of A-Hydrate and Potassium Cyanide. To a solution of 0.8 g (5 mmol) of A-hydrate in 30 ml of water (buffer solution; pH 6.8), was added a solution of potassium cyanide (0.39 g, 6 mmol) in 10 ml of distilled water with stirring at room temperature to yield a precipitate immediately. After stirring for 2 h, the precipitate was filtered off and dried in vacuo to give alloxan radical anion salt (A·⁻K⁺) in 65% yield. Mp 270—273 °C (dec). IR (KBr, cm^{-1}): 3250 (N–H), 1670 (C=O). Found: C, 26.31; H, 1.61; N, 15.26%. Calcd for $C_4H_2O_4N_2K_1$: C, 26.50; H, 1.67; N, 15.46%.

AT (mp 229—231 °C) was also isolated from the filtrate in 15% yield.

The Reaction of AT and Potassium Chloride in the Presence of Triethylamine. To a solution of 1.6 g (5 mmol) of AT and 1.8 g (25 mmol) of potassium chloride in 100 ml of water, was added a solution of 1 g (10 mmol) of triethylamine dropwise with stirring at room temperature to obtain A·⁻K⁺ (5.6 g, 70%).

The Reaction of A-Hydrate and BNA–CN. To a solution of 0.8 g (5 mmol) of A-hydrate in 20 ml of ethanol, was added a solution of 1.2 g (5 mmol) of BNA–CN in 20 ml of ethanol in the atmosphere of nitrogen at room temperature to give 1.1 g (70%) of pyridinium salt (A·⁻Py⁺) of alloxan radical anion. IR (KBr, cm^{-1}): 3350, 3180 (N–H), 1700, 1590 (C=O). Found: C, 57.30; H, 4.57; N, 15.72%. Calcd for $C_{17}H_{15}O_5N_2$: C, 57.25; H, 4.52; N, 15.46%.

^{17}O Nuclear Magnetic Resonance Studies. V.[1] ^{17}O Shieldings of Some Substituted Anisoles

Morimatsu KATOH, Tadashi SUGAWARA, Yuzo KAWADA, and Hiizu IWAMURA*

Division of Applied Molecular Science, Institute for Molecular Science, Myodaiji, Okazaki 444

(Received June 4, 1979)

Synopsis. Fourier transform ^{17}O NMR spectra have been measured for a number of meta and para substituted anisoles in natural abundance at 10.8 MHz. The shielding of the methoxyl oxygen nucleus decreases as the electron-withdrawing substituents are introduced to the ring. A good linear correlation is obtained for a plot of the ^{17}O shifts *versus* the Hammett σ^- constants.

Proton nuclear magnetic resonance studies have shown that methoxyl proton shifts are linearly related to the Hammett σ parameter.[2] A similar but only a slight dependence of methoxyl ^{13}C shifts on the nuclear substitution has been reported.[3] In order to investigate the effects of nuclear substitution on the methoxyl oxygen shielding, we have now measured the ^{17}O NMR shifts of a series of sixteen anisoles.

It is apparent from the observed data collected in Table 1 that the oxygen shifts are highly sensitive to meta and para substitution on the ring; they cover a rather wide total range of 30 ppm. It is easily expected that electron-withdrawing groups on the ring decrease the shielding at the oxygen nucleus, since the conjugative electron release from the oxygen will be enhanced. This general trend is exactly what was observed for the ^{17}O chemical shifts of anisoles. A plot of the methoxyl oxygen shifts *versus* the Hammett σ^- values reveals a good linear correlation between the two parameters ($\rho=16.2$ ppm, correlation coefficient r of 0.963). Analyses of the data according to the Yukawa-Tsuno equation, $\Delta\delta=\rho\{\sigma^\circ+\gamma(\sigma^- -\sigma^\circ)\}$, give the following values: $\rho=17.2$ ppm and $\gamma=0.881$.[4] A quantitative measure of the resonance interaction of the methoxyl group with para substituents is thus obtained. These results may be compared with the Hammett σ dependence of the methoxyl hydrogen ($\rho=0.24$ ppm)[2] and carbon chemical shifts.[3]

TABLE 1. ^{17}O NMR SHIFTS OF *p*- AND *m*-SUBSTITUTED ANISOLES

Substituent	$\delta^{17}O$/ppm	π-Bond order $\times 10^2$	π-Electron density
p-NH_2	139[a]	4.03	1.905
p-OCH_3	141	4.16	1.902
p-$C(CH_3)_3$	147		
p-CH_3	147	4.32	1.899
p-F	148	4.27	1.900
H	151	4.36	1.898
p-Cl	151		
p-Br	154		
p-CF_3	157		
p-CN	163	4.49	1.894
p-NO_2	170	4.72	1.888
m-NH_2	149		
m-Cl	154		
m-Br	155		
m-F	156		
m-NO_2	166		

a) Subtract 103 ppm from the shift values to convert them into the data referenced to external H_2O.

Theoretical reasoning of the shielding pattern observed here is not so easy as it would be understood intuitively. The diamagnetic electric current about the nucleus which is directly affected by polar substituents play a major role in governing the chemical shifts of ^1H NMR, but not of ^{13}C and ^{17}O nuclei. The paramagnetic screening is considered to dominate the chemical shifts of the latter nuclei. Decrease of shielding with the increasing electron-withdrawal should be explained by increase in the mean inverse cube of the 2p electron radius $\langle r^{-3}\rangle_{\text{oxygen}}$ and/or in the orbital terms $[Q_{AA}+\Sigma Q_{AB}]$ in the Karplus-Pople expression of the paramagnetic screening (Eq. 1).[5]

$$\sigma_p^A = -\frac{e^2\hbar^2\langle r^{-3}\rangle}{2m^2c^2(\Delta E)}[Q_{AA}+\sum_{A\neq B}(Q_{AB})] \quad (1)$$

Decreasing charge density at the oxygen is expected to lead to a contraction of the 2p orbitals and thereby an increase in the paramagnetic screening. The good linear correlations were obtained between the observed ^{17}O chemical shifts on the one hand and the π-electron densities at the oxygen (2040 ppm/π-electron, $r=0.993$) or the π-bond orders between the oxygen and the aromatic carbon attached to it (4770 ppm/π-bond order, $r=0.974$) calculated by the CNDO/2 methods on the other.[6]

The trend observed here for the anisoles is just the opposite to that of the oxygen nuclei of the aliphatic ethers in which the more electron-donating tertiary alkyl ethers are deshielded compared to less electron-donating primary alkyl ethers.[7] Whereas the change in the effective excitation energy ΔE in Eq. 1 was a dominant factor in the paramagnetic screening there,[7] both the n- and π^*-levels would be affected simultaneously by the ring substituents in the anisoles, leaving the effect of ΔE term less obvious.

We conclude that one of the most direct experimental evidence for the dependence of the electron density about the methoxyl oxygen nucleus on the ring substituents was obtained by the ^{17}O NMR shifts.

Experimental

Pulsed Fourier transform spectra were obtained on a Varian FT-80A spectrometer at 10.8 MHz. A pulse width

of 35 μs with an acquisition time of 0.02 s was employed with a spectral width of 8000 Hz. Anywhere between 3×10^6 and 4×10^7 transients were accumulated depending on the sample. Chemical shifts were read as frequency shifts from the synthesizer setting (8.53200 MHz), expressed in ppm, and judged to be accurate to ±1 ppm (the Fourier number was at 1,6384). The spectra were run at 80 °C on pure, natural-abundance samples (1.0—1.4 g) dissolved in chloroform-*d* (0.9—1.2 ml) which also provided an internal deuterium lock signal.

p-*t*-Butyl- and *m*-chloroanisoles were prepared from the corresponding phenols by the standard methylation with dimethyl sulfate. The others were commercial samples of reliable grade and were used directly.

The π-electron densities and π-bond orders were calculated by the CNDO/2 methods with the aid of the program No. 141 of QCPE on a HITAC M-180 system of this institute. Molecular geometries employed for the framework of anisoles were basically those reported for 4,4′-anisoin[8] and the standard bond lengths and angles[6] were used otherwise.

Calculation of the H_4 Potential Energy Surface by a Semi-empirical Method

Noboru TANAKA

Department of Chemistry, Hachinohe Institute of Technology, Hachinohe 031

(Received December 27, 1978)

A semi-empirical method recently proposed for the calculation of the potential energy surface of the H_3 system is extended to a larger polyatomic H_4 system. The energy formula is based on the valence-bond formulation and is expressed as functions of many multiple exchange integrals. These integrals can be decomposed into "diatomic" contributions by using the Mulliken approximation. The diatomic contributions are estimated from accurate values of the H_2 molecule. Calculations of the H_4 potential energy for the symmetric linear, linear equidistant, and square planar configurations are presented. The present method is of use for dynamical studies of the H_2+D_2 exchange reaction.

In a previous paper, the author has proposed a new semi-empirical method for the calculation of the H_3 potential surface,[1] and has shown that this simple method yields a satisfactory and useful surface when compared with Liu's detailed *ab initio* calculation of the H_3 system.[2] It is interesting to extend the method to the case of larger polyatomic systems. In the present note the application to the H_4 potential surface calculation is presented.

There have been many *ab initio* calculations of the H_4 system at its special configurations, and the results have been discussed in connection with the mechanism of the $H_2+D_2\rightarrow 2HD$ exchange reaction. Experimental results for this reaction have often been interpreted in terms of a vibrational excitation mechanism,[3] which assumes a four-center H_4 transition state. The recent extensive *ab initio* calculation of Silver and Stevens (SS)[4] yielded potential barriers for the four-center transition state larger than the H_2 dissociation energy, which is in disagreement with the experimental activation energy, 42 kcal/mol.[3] Thus we are very much interested in the reaction dynamics study of the H_2+D_2 reaction, in order to examine the effect of vibrational activation on the reaction cross section. For such a study, we must have a complete reliable potential surface of the H_4 system. The author believes that the present note provides a practically useful method of calculating the surface, since it requires less computer time than *ab initio* calculations.

In the following section, we proceed in much the same way as the case of H_3.[1] By making use of the Mulliken approximation,[5] Slater's energy formula[6] is shown to be expressed in terms of "diatomic" contributions, *i.e.*, diatomic Coulomb (Q_i), exchange (α_i), and overlap (S_i) integrals. Hence we obtain the energy formula involving several empirical parameters. The surface thus calculated is compared with the results of the *ab initio* calculations of the H_4 surface,[4,7] in the last section.

Theoretical

Slater's energy formula[6] for the four-orbital four-electron system corresponding to H_4 is

$$E_{\pm} = (1/C_1)[-C_2 \pm (C_2^2 - C_1C_3)^{1/2}]. \tag{1}$$

The quantities C_1, C_2, C_3 are expressed in terms of the matrix elements:

$$\begin{aligned} C_1 &= (\mathrm{I}|\mathrm{I})(\mathrm{II}|\mathrm{II}) - (\mathrm{I}|\mathrm{II})^2, \\ C_2 &= (\mathrm{I}|H|\mathrm{II})(\mathrm{I}|\mathrm{II}) - \frac{1}{2}\{(\mathrm{I}|H|\mathrm{I})(\mathrm{II}|\mathrm{II}) \\ &\quad - (\mathrm{II}|H|\mathrm{II})(\mathrm{I}|\mathrm{I})\}, \\ C_3 &= (\mathrm{I}|H|\mathrm{I})(\mathrm{II}|H|\mathrm{II}) - (\mathrm{I}|H|\mathrm{II}), \end{aligned} \tag{2}$$

where the bond functions Ψ_{I} and Ψ_{II} correspond to the bonding schemes (a—b, c—d) and (a—d, b—c) respectively, and H is the Hamiltonian of the system,

$$H = \sum_{i=1}^{4}\left(-\frac{1}{2}\nabla_i^2 - \sum_{\nu=1}^{4}\frac{1}{r_{i\nu}} + \sum_{j>i}\frac{1}{r_{ij}}\right) + \sum_{\kappa=1}^{6}\frac{1}{R_\kappa}. \tag{3}$$

The subscripts i, j refer to the electrons, ν=a, b, c, d represent the four hydrogen nuclei, and R_1, R_2, R_3, R_4, R_5, and R_6 are the a—b, a—c, a—d, b—c, b—d, and c—d internuclear distances respectively. In terms of the functions Ψ_{I} and Ψ_{II}, the matrix elements can be written as

$$\begin{aligned} (\mathrm{I}|H|\mathrm{I}) &= 4Q + 2(2\alpha_1' - \alpha_2' - \alpha_3' - \alpha_4' - \alpha_5' + 2\alpha_6') \\ &\quad + 4(\beta_{25}+\beta_{34}+\beta_{16}) - 4(\gamma_{214}+\gamma_{153}+\gamma_{326}+\gamma_{465}) \\ &\quad + 4(\delta_{2543}+\delta_{3425}) - 2(\delta_{1526}+\delta_{2165}+\delta_{3146}-\delta_{1463}), \\ (\mathrm{II}|H|\mathrm{II}) &= 4Q - 2(\alpha_1' + \alpha_2' - 2\alpha_3' - 2\alpha_4' + \alpha_5' + \alpha_6') \\ &\quad + 4(\beta_{16}+\beta_{25}+\beta_{34}) - 4(\gamma_{214}+\gamma_{465}+\gamma_{153}+\gamma_{326}) \\ &\quad + 4(\delta_{2165}+\delta_{1526}) - 2(\delta_{2543}+\delta_{3425}+\delta_{3146}+\delta_{1463}), \\ (\mathrm{II}|H|\mathrm{I}) &= -2Q - 2(\alpha_1' - 2\alpha_2' + \alpha_3' + \alpha_4' - 2\alpha_5' + \alpha_6') \\ &\quad - 2(\beta_{16}+\beta_{34}+\beta_{25}) + 2(\gamma_{465}+2\gamma_{153}+\gamma_{326}+\gamma_{214} \\ &\quad -\gamma_{315}-\gamma_{546}) + 2(2\delta_{3146}+\delta_{1463}-\delta_{2165}-\delta_{1526} \\ &\quad -\delta_{2543}-\delta_{3425}), \\ (\mathrm{I}|\mathrm{I}) &= 2\{(1-S_2^2)(1-S_5^2) + (1-S_3^2)(1-S_4^2) \\ &\quad + (S_1S_6-S_3S_4)^2 - 2(S_1-S_3S_5)(S_2S_4-S_1) \\ &\quad + (S_1S_6-S_2S_5)^2 - 2(S_6-S_2S_3)(S_4S_5-S_6)\}, \\ (\mathrm{II}|\mathrm{II}) &= 2\{(1-S_1^2)(1-S_6^2) + (1-S_2^2)(1-S_5^2) \\ &\quad + (S_3S_4-S_2S_5)^2 - 2(S_4-S_1S_2)(S_5S_6-S_4) \\ &\quad + (S_1S_6-S_3S_4)^2 - 2(S_3-S_2S_6)(S_1S_5-S_3)\}, \\ (\mathrm{I}|\mathrm{II}) &= 2\{(S_4-S_1S_2)(S_5S_6-S_4) + (S_3-S_1S_5)(S_2S_6-S_3) \\ &\quad + (S_1-S_3S_5)(S_2S_4-S_1) + (S_6-S_2S_3)(S_4S_5-S_6) \\ &\quad - (S_2-S_1S_4)(S_3S_6-S_2) - (S_5-S_4S_6)(S_1S_3-S_5) \\ &\quad - (S_1S_6-S_3S_4)^2 - (1-S_2^2)(1-S_5^2)\}, \end{aligned} \tag{4}$$

where Q is the Coulomb integral, α_i' are single-exchange integrals, β_{ij} are double-exchange integrals, γ_{ijk} are triple-exchange integrals, δ_{ijkm} are quadruple-exchange

integrals, and S_i are overlap integrals. These are defined by the relations,

$$\begin{aligned}
&Q = (\mathrm{abcd}|H|\mathrm{abcd}),\\
&\alpha_1' = (\mathrm{abcd}|H|\mathrm{bacd}), \quad S_1 = (\mathrm{a}|\mathrm{b}),\\
&\alpha_2' = (\mathrm{abcd}|H|\mathrm{cbad}), \quad S_2 = (\mathrm{a}|\mathrm{c}),\\
&\alpha_3' = (\mathrm{abcd}|H|\mathrm{dbca}), \quad S_3 = (\mathrm{a}|\mathrm{d}),\\
&\alpha_4' = (\mathrm{abcd}|H|\mathrm{acbd}), \quad S_4 = (\mathrm{b}|\mathrm{c}),\\
&\alpha_5' = (\mathrm{abcd}|H|\mathrm{adcb}), \quad S_5 = (\mathrm{b}|\mathrm{d}),\\
&\alpha_6' = (\mathrm{abcd}|H|\mathrm{abdc}), \quad S_6 = (\mathrm{c}|\mathrm{d}),\\
&\beta_{16} = (\mathrm{abcd}|H|\mathrm{badc}),\\
&\beta_{25} = (\mathrm{abcd}|H|\mathrm{cdab}),\\
&\beta_{34} = (\mathrm{abcd}|H|\mathrm{dcba}),\\
&\gamma_{142} = (\mathrm{abcd}|H|\mathrm{bcad}) = \gamma_{214},\\
&\gamma_{153} = (\mathrm{abcd}|H|\mathrm{bdca}),\\
&\gamma_{263} = (\mathrm{abcd}|H|\mathrm{cbda}) = \gamma_{326},\\
&\gamma_{315} = (\mathrm{abcd}|H|\mathrm{dacb}),\\
&\gamma_{465} = (\mathrm{abcd}|H|\mathrm{acdb}) = \gamma_{546},\\
&\delta_{2165} = (\mathrm{abcd}|H|\mathrm{cadb}) = \delta_{1526},\\
&\delta_{1463} = (\mathrm{abcd}|H|\mathrm{bcda}) = \delta_{3146},\\
&\delta_{2543} = (\mathrm{abcd}|H|\mathrm{cdba}) = \delta_{3425}.
\end{aligned} \tag{6}$$

The Coulomb integral Q is written as a sum of the diatomic Coulombic contributions Q_i:

$$Q = 4E_{\mathrm{H}} + \sum_{i=1}^{6} Q_i, \tag{7}$$

where E_{H} represents the energy of a hydrogen atom.

The exchange integrals α_i', β_{ij}, γ_{ijk}, and δ_{ijkm} can also be decomposed into "diatomic" contributions Q_i, α_i, and S_i by using the Mulliken approximation:[5]

$$\begin{aligned}
&\alpha_i' \simeq \alpha_i + S_i^2(Q-Q_i),\\
&\beta_{ij} \simeq S_i^2S_j^2\{\alpha_i/S_i^2+\alpha_j/S_j^2+(Q-Q_i-Q_j)\},\\
&\gamma_{ijk} \simeq \frac{1}{2}S_iS_jS_k\{\alpha_i/S_i^2+\alpha_j/S_j^2+\alpha_k/S_k^2+2Q\\
&\qquad -(Q_i+Q_j+Q_k)\},\\
&\delta_{ijkm} \simeq \frac{1}{2}S_iS_jS_kS_m\{\alpha_i/S_i^2+\alpha_j/S_j^2+\alpha_k/S_k^2+\alpha_m/S_m^2\\
&\qquad +2Q-(Q_i+Q_j+Q_k+Q_m)\}.
\end{aligned} \tag{8}$$

Eventually, the energy, Eq. 1, is evaluated in terms of the diatomic integrals Q_i, α_i, and S_i. Following Porter and Karplus,[8] we write the Q_i, α_i, and S_i as

$$\begin{aligned}
Q_i &= [(E^1+E^3)+S_i^2(E^1-E^3)]/2,\\
\alpha_i &= [(E^1-E^3)+S_i^2(E^1+E^3)]/2,
\end{aligned} \tag{9}$$

where

$$\begin{aligned}
E^1 &= D_1\{\exp[-2\alpha(R_i-R_e)]-2\exp[-\alpha(R_i-R_e)]\},\\
E^3 &= D_3\{\exp[-2\beta(R_i-R_e)]+\exp[-\beta(R_i-R_e)]\},
\end{aligned} \tag{10}$$

and

$$S_i = (1+\zeta_iR_i+\zeta_i^2R_i^2/3)\exp(-\zeta_iR_i), \tag{11a}$$

where

$$\zeta_i = 1.0 + \kappa\exp(-\lambda R_i). \tag{11b}$$

Results and Discussion

The parameters D_1, D_3, α, β, and R_e in Eqs. 10 have been determined from the results of the accurate *ab initio* calculation on H_2 by Kołos and Wolniewicz[9] (see Ref. 1 for details). The screening parameter ζ_i appearing in Eq. 11a for the overlap integral S_i is given as a function of the internuclear distance R_i by Eq. 11b, which involves two parameters κ and λ. In their calculation of the H_3 system, Porter and Karplus[8] determined the values of κ and λ from early calculations of the H_2 molecule by Wang and Rosen.[10] In the present paper, however, κ and λ have been determined by fitting Eq. 1 to the *ab initio* calculations on the linear symmetric H_4 by Bender and Schaefer III (BS).[7] The values of the parameters thus determined are shown in Table 1. The values of the screening parameter ζ_i determined by Eq. 11b with the values of κ and λ in Table 1 are slightly higher than the values of ζ_i by Porter and Karplus (Table 2). This difference of the two sets of ζ_i values seems to be due to the difference

Table 1. The parameters used to calculate the H_4 potential energy[a]

D_1=0.174475 a.u.	κ=1.00
D_3=0.072900 a.u.	λ=0.40
α=1.050000 a.u.$^{-1}$	
β=1.036000 a.u.$^{-1}$	
R_e=1.401000 a.u.

in the methods by which the values of κ and λ have been determined (see above).

In the case of linear symmetric and linear equidistant configurations, the results obtained here are compared with those of BS[7] in Figs. 1 and 2: The agreement is satisfactory. A similar calculation for square planar configuration is shown in Fig. 3, where we compare the results with those of SS.[4] The agreement is not so good as in the case of Figs. 1 and 2. It should be remembered that the values of κ and λ have been adjusted for the linear symmetric H_4. However it does not seem worthwhile to try to improve the above disagreement by readjusting the values of κ and λ for the square H_4, because the precision of the SS calculation is not as high as that of the BS calculation. In fact, it has been pointed out that the SS energies can be lowered by more than 0.025 hartrees by extending the orbital basis and by optimizing the orbital exponents.[4]

The author wishes to thank Professor T. Nakamura of Hokkaido University for many helpful discussions and suggestions. The numerical calculations were performed on the FACOM 230-75 computer at the Hokkaido University Computing Center.

On the Magnetic Susceptibility of Interacting Spin-pair Systems

Hiroaki OHYA-NISHIGUCHI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received February 8, 1979)

Modifying a general theory of antiferromagnetism proposed by Oguchi, the parallel and perpendicular magnetic susceptibilities ($\chi_{//}$ and $\chi_{\perp}$ respectively) of antiferromagnetically interacting spin-pair systems have been formulated. As the parameter of the equations, $\kappa=z|J'|/|J|$, approaches zero, both of them coincide with a familiar equation of isolated spin-pairs. In the $0<\kappa\leq 1$ range the maximum susceptibility and the Weiss constant are compared with those estimated exactly by the alternating antiferromagnetic linear-chain model. For $1<\kappa\leq 2$, they can be characterized by a broad maximum and a transition to the antiferromagnetically ordered state. For $\kappa>2$, $\chi_{//}$ and $\chi_{\perp}$ show curves similar to those of a typical three-dimensional antiferromagnet. The $\chi_{//a}$ and $\chi_{\perp a}$ of the 2,2-diphenyl-1-picrylhydrazyl–benzene (1 : 1) complex have been examined based on the theoretical results for $\kappa=1.3$. The magnetic susceptibilities of the other organic free radicals have been compared with the results calculated in the $0\leq\kappa<1$ range.

Since the first observation of two-spin clusters in $Cu(CH_3COO)_2$ by means of electron paramagnetic resonance (EPR) and magnetic susceptibility (χ) measurements, many examples of such spin-pair systems in organic and inorganic materials have been studied by a number of investigators.[1] The χ or the EPR intensity has usually been characterized by a familiar equation:

$$\chi = \frac{N(g\mu)^2S(S+1)}{2kT[3+\exp(2|J|/kT)]} \tag{1}$$

where J is the interaction between two spins coupled antiferromagnetically; μ, the Bohr magneton, and g, the Lande g-factor, and where the other notations have the usual meanings. This equation, however, cannot be applied to systems with comparatively large inter-pair interactions. In 1955 Oguchi[2] developed a general theory of ferromagnetism and antiferromagnetism, based on the Heisenberg model of two-spin clusters. Modifying this theory, one can calculate analytically and tractably the susceptibility of interacting spin-pair systems. In this paper this theory will be extended to antiferromagnetically interacting spin-pair systems in order to understand qualitatively their physical behavior by relatively simple formulations. Based on the theoretical results thus derived, first we will examine the magnetic susceptibility of 2,2-diphenyl-1-picrylhydrazyl–benzene (1 : 1) complex (DPPH–Bz) measured by Fujito.[3] Recently it was shown for the complex that none of the isolated spin-pair, linear chain, or quadratic net Heisenberg models give a satisfactory agreement with the experimental results.[4] The main object of applying our model to DPPH–Bz, therefore, is to examine its magnetic property in relation to spin-cluster models. Secondly, the χ values of some organic free radicals with small or intermediate inter-pair interactions are compared with the theoretical results obtained by our model and the alternating linear-chain model developed by Duffy and Barr.[5]

Theoretical

We treat here a spin-pair, whose spin operators are denoted by $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$, interacting with each other with a negative exchange interaction $-|J|$. For the sake of simplicity, it is assumed hereafter that g is isotropic and S is 1/2. Such assumptions can reasonably be accepted in spin systems consisting of usual organic free radicals. In addition to J inter-pair exchange interaction, $J'(|J'|<|J|)$, is introduced in the system. Then, the Hamiltonian can be written as

$$\mathcal{H} = 2|J|(\boldsymbol{S}_i\cdot\boldsymbol{S}_j) + 2|J'|[\sum_k(\boldsymbol{S}_i\cdot\boldsymbol{S}_k)+\sum_l(\boldsymbol{S}_j\cdot\boldsymbol{S}_l)] + g\mu H^z(S_i^z+S_j^z), \tag{2}$$

where the sums k and l go over the nearest neighbors of the i-spin except for the j-spin, and of the j-spin except for the i-spin, respectively. Here, the last term is the Zeeman energy of the system with an external magnetic field, H^z, along the easy axis, hereafter denoted as the z-axis. According to the usual molecular field approximation, $\boldsymbol{S}_k$ and $\boldsymbol{S}_l$ are replaced by their thermal mean expectation values, $-\bar{S}$ and $+\bar{S}$, respectively, which change to $\mp\bar{S}+\delta\bar{S}^z$ by the application of the magnetic field along the z-axis. Thus, the Hamiltonian can simply be written as

$$\mathcal{H} = 2|J|(\boldsymbol{S}_i\cdot\boldsymbol{S}_j) + aS_i^z + bS_j^z, \tag{3}$$

where

$$\begin{aligned} a &= 2|J'|z(-\bar{S}+\delta S^z) - g\mu H^z, \\ b &= 2|J'|z(+\bar{S}+\delta S^z) - g\mu H^z, \end{aligned} \tag{4}$$

and where z is the number of the nearest neighbors of the i-spin, excluding the j-spin. Next, we define a new parameter, $\kappa=z|J'|/|J|$, which means the strength of the molecular field. For simplicity in the description, we adopt the exchange interaction, $|J|$, as the unit of the energy. Then,

$$\mathcal{H} = 2(\boldsymbol{S}_i\cdot\boldsymbol{S}_j) + [2\kappa(-\bar{S}+\delta S^z)-h]S_i^z + [2\kappa(\bar{S}+\delta S^z)-h]S_j^z, \tag{3'}$$

where $h=g\mu H/|J|$. Using the spin states $\alpha_i\alpha_j$, $(1/\sqrt{2})(\alpha_i\beta_j+\beta_i\alpha_j)$, $\beta_i\beta_j$ and $(1/\sqrt{2})(\alpha_i\beta_j-\beta_i\alpha_j)$, the eigen values of Eq. 3′ are derived as

$$\begin{aligned} E_1 &= (1+4\kappa\delta S^z-2h)/2, \\ E_2 &= (-1/2) + R, \\ E_3 &= (1-4\kappa\delta S^z+2h)/2, \\ E_4 &= (-1/2) - R, \end{aligned} \tag{5}$$

where

$$R = (1+4\kappa^2\bar{S}^2)^{1/2}. \tag{6}$$

Now the magnetization in the external magnetic field along z-axis is defined self-consistently as

$$\bar{S} + \delta S^z = \mathrm{Tr}\, S^z e^{-\beta\mathcal{H}} / \mathrm{Tr}\, e^{-\beta\mathcal{H}} \tag{7}$$

where $\beta = 1/t = |J|/kT$. By substituting Eq. 5 into Eq. 7, we obtain

$$\bar{S} + \delta S^z = \frac{1}{2} \cdot \frac{\frac{2\kappa}{R}\bar{S}e^{\beta}\sinh\beta R + \sinh(h - 2\kappa\delta S^z)}{\cosh(h - 2\kappa\delta S^z) + e^{\beta}\cosh\beta R}. \tag{8}$$

As the terms containing h and S^z are small quantities of the first order, one can divide Eq. 8 into two parts. The zeroth-order term is

$$\bar{S} = \frac{\kappa\bar{S}\sinh\beta R}{R(e^{-\beta} + \cosh\beta R)} \tag{9}$$

which leads to the non-zero solution of $\bar{S}$. At the limit of $R=1$, the Néel temperature, $T_N = |J|/k\beta_N$, can be calculated from:

$$e^{-\beta_N} + \cosh\beta_N = \kappa\sinh\beta_N \tag{10}$$

As a function of κ, the solution of this equation is shown in Fig. 1. The lower part of the solid line of the figure is the antiferromagnetically ordered state, denoted as AF, while its upper part is the paramagnetic region (P). It should be noted here that in the $0 \leq \kappa < 1$ range no antiferromagnetic transition occurs.[6]

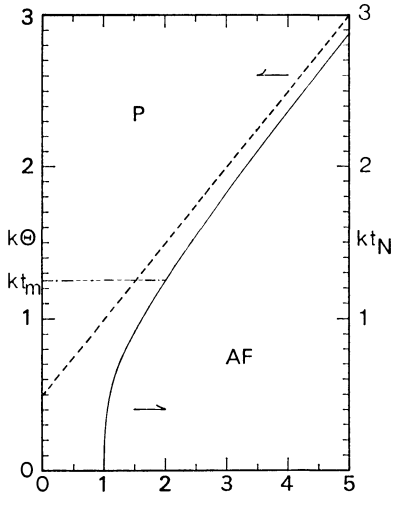

Fig. 1. The reduced Néel temperature (t_N: solid line), Weiss temperature (Θ: broken line), and temperature showing broad maximum of the susceptibility (t_m: dotted broken line) *versus* the molecular field parameter κ. AF: Antiferromagnetic state, P: Paramagnetic state.

From the first-order term of Eq. 8:

$$\chi_{\parallel} = Ng\mu\left(\frac{\delta S^z}{\delta H}\right)_{H=0} = \frac{1}{2}\,\frac{N(g\mu)^2\beta}{\kappa\beta + 1 + e^{\beta}\cosh\beta R}. \tag{11}$$

By a manner similar to that used with $\chi_{/\!/}$, the magnetic susceptibility perpendicular to the z-axis ($\chi_{\perp}$) is given as:

$$\chi_{\perp} = \frac{(R-1)^2 e^{\beta}\cosh\beta R + 2R - (R^2+1)e^{\beta(1-R)}}{\{2\kappa[(R-1)^2 e^{\beta}\cosh\beta R + 2R(R^2+1)e^{\beta(1-R)}] + 2R(R^2-1)(1+e^{\beta}\cosh\beta R)\}}. \tag{12}$$

In the paramagnetic region ($\bar{S}=0$), Eq. 12 coincides with Eq. 11 if we take the limit of $R = 1+\delta$ as δ approaches 0. Furthermore, for $\kappa=0$ Eqs. 11 and 12 coincide with Eq. 1 for $S=1/2$. In Fig. 2 the powder susceptibilities $\chi = (\chi_{/\!/} + 2\chi_{\perp})/3$, are shown as functions of the reduced temperature, t. The numbers in the figure are the values of κ.

We will now show some typical cases of Eqs. 11 and 12. At high temperatures ($t \gg 1/k$), χ becomes a simple form:

$$\chi = \frac{N(g\mu)^2}{4k} \cdot \frac{1}{t - (-\Theta)}, \tag{13}$$

where $\Theta(=(\kappa+1)/2k)$ is called the Weiss temperature. The dependence of Θ on κ is also shown in Fig. 1 by a broken line which coincides with the asymptote of the solid line.

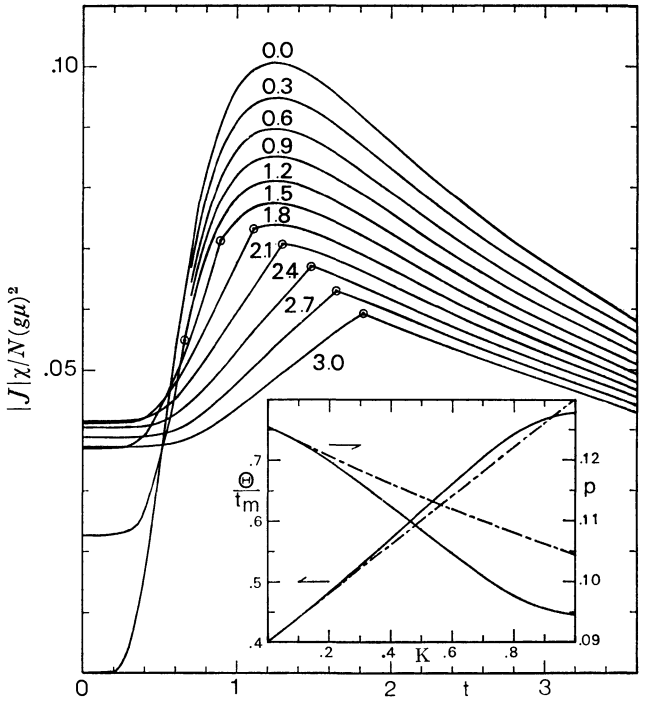

Fig. 2. The powder magnetic susceptibility *versus* the reduced temperature for $\kappa=0.0$ to 3.0. The Néel temperatures are indicated by the circles in the figure. The inset shows the Weiss temperature divided by t_m and the product of maximum susceptibility times t_m, $p = \chi_m k t_m / Ng^2\mu^2$, *versus* the molecular field parameter κ (broken line) compared with the alternating linear chain model (solid line) (Ref. 5).

At moderate temperatures comparable to $|J|/k$, χ depends sensitively on κ. For $0 \leq \kappa < 1$, Θ shows a broad maximum at a constant temperature, $t_m(=1.2473/k)$, without any phase transition. The inset in Fig. 2 shows the variations in the dimensionless Θ/t_m and of

$$p = \chi_m k t_m / N(g\mu)^2 \tag{14}$$

as functions of κ. In this range of κ for $z=1$, our results can be compared with the magnetic susceptibility of the alternating linear chain calculated exactly by Duffy and Barr.[5] Also shown by the solid line in the inset of Fig. 2 are the results of their theoretical calculations. Θ/t_m is in good agreement with their value, while p deviates upward as κ increases, the deviation being

about 10% at $\kappa=1$. For $\kappa<0.3$, however, our susceptibility calculations agree well with those by Duffy and Barr with the deviation of only 2%. The deviation of p for κ values larger than 0.3 in the inset is mainly due to the energy separation between the singlet ground state and the excited triplet states (Δ). In our model, Δ can be derived from Eq. 5 for $h=0$ and $R=1$ as $\Delta=2$ in units of $|J|$. This constant value of Δ in the paramagnetic state is one of the features of our simple model. For a more quantitative analysis of χ, it is desirable that Δ be explicitly expressed as a function of J' or κ, as will be discussed later. In the case of the alternating linear-chain model, on the other hand, Δ for $h=0$ depends on the continuous-energy spectrum, which is expressed as $\Delta(k)=2-\kappa\cos k$.[5]

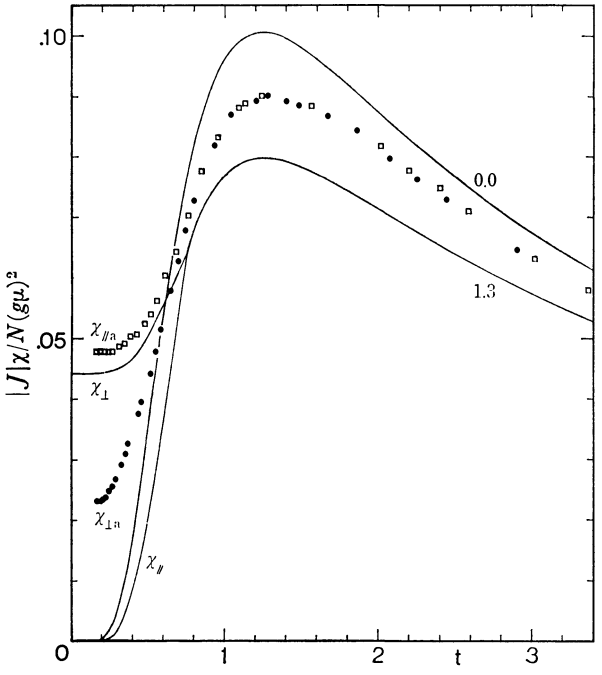

Fig. 3. The magnetic susceptibilities of the DPPH–Bz complex along a-axis (square) and perpendicular to a-axis (full circle) *versus* the reduced temperature t for $|J|/k=0.54$ K. Solid lines are the theoretical calculations by Eqs. 11 and 12 for $\kappa=0.0$ and 1.3.

In the antiferromagnetic region ($t>t_N$, $R>1$) $\chi_{//}$ decreases rapidly with a decrease in the temperature, while $\chi_\perp$ gives a constant value near absolute zero. Its magnitude depends approximately on κ as follows:

$$\chi_\perp(0) \fallingdotseq (\kappa-1)/4\kappa^2 \qquad (15)$$

As an illustrative example, the calculated $\chi_{//}$ and $\chi_\perp$ values for $\kappa=1.3$ are shown in Fig. 3 as functions of t. Such special susceptibilities can be experimentally visualized by a stable free radical, DPPH–Bz, as will be shown in the following section. In the antiferromagnetic region, Eq. 5 explicitly includes J', even for $h=0$. Therefore, our model is considered to be a good approximation compared with the case in the paramagnetic region mentioned above.

By a comparison of Eqs. 11 and 12 with the experimental results, one can estimate J' in addition to J, provided that z can be derived crystallographically. It should be noted, however, that the estimated J' is fundamentally not the real value, because, in the approximation treated here, we use a mean value of the molecular field produced by the neighbors.

Comparison with Experiments

Magnetic Susceptibility of DPPH–Bz Single Crystal. We will examine here the magnetic susceptibilities along the a-axis and perpendicular to the a-axis of the DPPH–Bz complex, hereafter denoted as $\chi_{//a}$ and $\chi_{\perp a}$ respectively.[3] In a previous paper[7] the powder susceptibility of DPPH–Bz at temperatures lower than 1.7 K, which were measured by a bridge method in a zero static field, were fitted to the value at 1.7 K measured by a force method in the field of 0.829 T. By this procedure, however, the values below 1.7 K were overestimated, because the $\chi_{//}$(also $\chi_\perp$) values of spin-pair systems with a singlet ground state depends on the applied magnetic field. In the paramagnetic region ($R=0$), for example, one can simply derive the χ as a function of the external field from Eq. 8 as

$$\frac{|J|\chi(t,h')}{N(g\mu)^2} = \frac{\beta j 2}{1+\kappa\beta+e^{\beta}\cosh\beta/\cosh\beta h'} \qquad (16)$$

where $h'=h-2\kappa\delta S^z$ is the effective field including the contribution from the induced magnetization. At temperatures higher than $|J|/k$, this contribution can be neglected ($h'=h$). $|J|/k$ was estimated to be 0.54 ± 0.02 K from the temperature (T_m) at which χ reached χ_m. By substituting this value into Eq. 16, the χ of DPPH–Bz at 1.7 K in 0.829 T is estimated to be 10% larger than that in the zero field. The experimental data in Fig. 3, measured by the bridge method were, therefore, calibrated by the value measured by the force method at 4.22 K which was corrected using Eq. 16. The anisotropy of the susceptibility ($\chi_{//a}-\chi_{\perp a}$) appeared at around 0.42 K at which the low-field EPR absorption line disappeared.[3] This behavior coincided with that which occurs around the Néel temperature of antiferromagnetic materials.[8] Therefore, we tentatively adopted 0.42 K as the T_N of DPPH–Bz. The ratio of T_m to T_N, 1.62, was used to determine the value of κ. The theoretical susceptibilities calculated for $|J|/k=0.54$ K and $\kappa=1.3$ are compared with $\chi_{\perp a}$ and $\chi_{//a}$ in Fig. 3. $\chi_\perp$ reproduces well the temperature dependence of $\chi_{//a}$. $\chi_{\perp a}$ also shows a value similar to $\chi_{//a}$ at t near t_N, but approaches a finite value as the temperature decreases. This is probably due to the lack of coincidence of the observed axis with the easy axis of the crystal.

Above t_N, on the other hand, the experimental values in Fig. 3 are just in the middle between those for $\kappa=0$ and 1.3. Such a deviation from our theoretical calculations for $\kappa=1.3$ in the paramagnetic region may indicate: 1) a cooperative phenomenon caused by J' and similar to those in the magnetic linear-chain and quadratic net Heisenberg models, or 2) the energy splittings of the degenerate triplet states by J', even in the range of the paramagnetic state. Recently Duffy, Strandburg and Deck[4] reported the susceptibility and

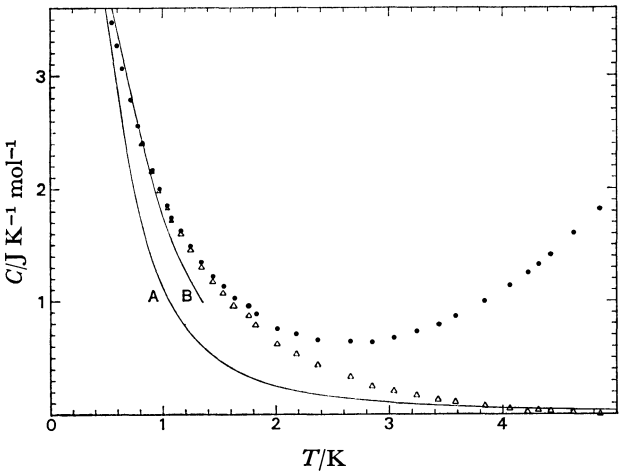

Fig. 4. Comparison of theoretical calculations of heat capacity with experimental data of DPPH–Bz measured by Duffy *et al.* (Ref. 4). A: Eq. 17, B: Two-spin-pair model calculated by Duffy and Barr (Ref. 5), ●: total heat capacity, △ magnetic part of the heat capacity.

the heat capacity (C_v) of DPPH–Bz from 0.4 K to room temperature, with which neither the linear-chain nor the quadratic net Heisenberg model gives satisfactory agreement. Therefore, the latter possibility described above may contribute to the deviation from the theoretical values.

Their heat-capacity data, shown in Fig. 4, are helpful in understanding the magnetic interactions of DPPH–Bz. Using Eq. 5, C_v of our model can be derived as

$$C_v = 6kN\beta^2|J|^2/(3e^{-\beta|J|}+e^{\beta|J|})^2 \qquad (17)$$

which coincides with the C_v of the isolated spin-pair systems, because in the paramagnetic state the energy levels under consideration are equal to those of the isolated spin-pair systems. A in Fig. 4 is calculated by means of Eq. 17 for $|J|=0.54\,k$. As has already been pointed out for the susceptibility data, the experimental data of C_v also deviate upward from A. For the linear-chain model, the magnitude of the theoretical heat capacity and the $\chi_m T_m$ values are quite low.[4] One of the possible ways to interpret both the susceptibility and heat capacity is to include J' in Eq. 5 explicitly, even in the paramagnetic region. Dufly and Barr[5] calculated the C_v of an alternative four-membered ring with $J'=0.8\,J$, a kind of two-spin-pair model, which is also shown in Fig. 4 as B for the sake of comparison. The agreement of B with the experimental results is better than that of A. The two-spin-pair model, therefore, is an improvement of the model for DPPH–Bz. Thus, one can conclude that our simple model well explains the appearance of t_N in addition to the temperature dependence of the magnetic susceptibilities of DPPH–Bz if we adopt 0.42 K as the T_N of DPPH–Bz. For the quantitative agreement of the susceptibilities, however, it is desirable to take into account the energy splittings in the triplet states. Some formulations according to such a modification are now in progress.

Examples of Other Organic Free Radicals. In order to show the applicability of our model, the χ values of other compounds are compared with those calculated by means of Eq. 11. Table 1 summarizes the compounds with the values of $\kappa<1$. We can also derive the values of the parameter from Θ, but this method is not so reliable because of the large experimental errors. The $|J|$ values were estimated from T_m. It has been concluded that the sulfite and the DPPH-free are mostly isolated spin-pairs, while the others have comparatively large inter-pair interactions. For comparison with the experimental results on 2,2-bis(*p*-nitrophenyl)-1-picrylhydrazyl ($D(NO_2)_2$), Duffy and Barr estimated the alternation parameter (a) of the alternating linear-chain model as $a=0.6$, which corresponds to our value of $\kappa=0.9$ in the inset of Fig. 2. Thus, the molecular-field approximation of interacting spin-pair systems is useful for a physical understanding of complicated organic free radicals.

Polarized Two-photon Absorption Spectra of Naphthalene in Durene Single Crystal with Two Synchronized Tunable Dye Lasers

Naohiko MIKAMI*,† and Hwai-Kwan HONG

Department of Chemistry and Radiation Laboratory, University of Notre Dame, Notre Dame, Indiana 46556, U.S.A.††

(Received February 15, 1979)

Polarized two-photon absorption spectra of naphthalene in a single crystal of durene were observed with one and two beams of tunable dye lasers. Diagonal elements of the two-photon transition tensor were determined by one beam experiments with different incident polarizations on different faces of an oriented single crystal. The off-diagonal elements of the two-photon transition tensor were determined with two synchronized beams of different wavelengths and polarizations on the same sample. It was found that most of the vibronic states have large σ_{LL} consistent with an overall vibronic A_g symmetry and a long axis polarized $^1B_{2u}$ intermediate state. The intermediate states of the two-photon process of the strongest vibronic origin have been discussed on the basis of the observed values of the two-photon transition tensor elements. The band also has a small but non-vanishing off-diagonal tensor element (σ_{LM}). A crystal field perturbation due to reduced site symmetry by a B_{3g} two-photon allowed state is postulated.

Two-photon spectroscopic measurements of polyatomic molecules have become popular for observing new states inaccessible to the usual one-photon spectroscopy. A considerable amount of work has been done on the lowest singlet state of benzene.[1-7] The two-photon excitation spectra of a benzene crystal at very low temperature and of benzene vapor reveal new vibronic structures identified as u-type vibrations in the electronically two-photon forbidden state. In order to determine the symmetry species of these vibrations in the excited state, polarization measurements in the gas phase were performed with high resolution. Unlike one-photon spectroscopy, two-photon spectroscopy has the advantage that the polarization effects can be measured in isotropic media such as gases, since a molecule interacts with two photons simultaneously. Assignments of the vibronic transition in benzene vapor *via* polarization measurements have been carried out by several groups.[4-7]

Similarly, polarization measurements of two-photon spectra in crystals provide us direct and detailed information concerning tensors of two-photon transition amplitudes for crystals or molecules in the crystals. The tensor is composed of nine elements. Each element in the tensor can be determined uniquely by polarization measurements on crystals.[8,9] Studies on the polarized two-photon spectra have been made for crystals of aromatic molecules such as naphthalene,[10] pyrazine[14] and biphenyl.[15] However, the experiments were carried out by using only one exciting beam. Hochstrasser and Sung[12] utilized crystal birefringence to obtain two beams of identical photon energies but different polarizations inside the crystal and were able for the first time to obtain information on both the diagonal and off-diagonal elements of the two-photon transition tensors. If the diagonal elements of the tensor for a particular transition are large as compared with the off-diagonal elements, the two-photon signals are dominated by the absorption of the two photons of the same polarization. The determination of a small off-diagonal contribution due to the absorption of two photons of different polarizations becomes difficult. Thus, a two beam experiment with independent photons in frequencies and polarizations is particularly suitable for the detection of off-diagonal elements of the two-photon transition tensors. The frequencies of the two beams should be so chosen that neither $2\nu_1$ and $2\nu_2$ are in resonance with the transition but $\nu_1+\nu_2$ is. This requires sharp transitions and clear window area. Only mixed crystals at low temperatures such as naphthalene in durene reported here are amenable.

The only experiment using two different light sources on an unisotropic crystal was carried out by Froehlich and Mahr on the single crystal of anthracene.[16] The two beam experiment of the two-photon transition of benzene vapor was carried out by Hampf, Neusser and Schlag.[17]

We have measured polarized two-photon excitation spectra of the lowest singlet excited state of naphthalene in a durene single crystal at very low temperature by using two exciting light beams of different wavelength and polarization. The two-photon spectra of naphthalene in this spectral region has been thoroughly studied in the gas phase[18] and crystalline phase at low temperature.[12,13] The strongest false origin is known to be vibronically induced by a u-type vibration of b_{2u} symmetry in the excited state, all experimental evidence being consistent with this assignment. However, there is some uncertainty as to the mechanism for the appearence of the false origin. Careful polarization measurements of both the single crystals of naphthalene and naphthalene in a durene single crystal by Hochstrasser and Sung[12] shed some light on the nature of intermediate states, crystal field mixing and vibronic coupling in these systems. Our two beam experiment is complimentary to their one beam experiments. The polarization measurements include not only all the possible crystal faces but also new results with two synchronized dye laser beams of different wavelength and polarization. It is thus possible to obtain information on the relative ratio of the individual elements of

the two-photon transition tensor. We will discuss the intermediate states of the two-photon process of the strongest vibronic origin and also the crystal field perturbation on two-photon states based on our results for the two-photon transition tensor.

Experimental

Apparatus for the two-photon excitation spectra with two beams of parallel incidence is shown in Fig. 1. Two dye lasers were pumped simultaneously by a nitrogen laser (Molectron UV-1000) with a beam splitter, reflection-transmission ratio being *ca.* 2:3. A home-made dye laser (laser 1) of almost the same design as Molectron DL-200 generated a lasing line with a fixed wavelength. After passing through a 90° prism and an iris, the output beam (beam 1) was polarized horizontally by a Glan-Thompson prism (P_1). A halfwave plate (H) made of thin mica was used in order to change the polarization of beam 1. Suitable selection of the angle between the axis of the plate and the horizontal axis afforded a horizontally or vertically polarized beam without any beam walk-off. A neutral density filter N_1 was used to control the light intensity. Beam 2, frequency of which was tuned continuously and which exits from dye laser 2 (Molectron DL-200), was polarized vertically by another Glan-Thompson prism (P_2). The two beams were adjusted close to each other, the distance between centers being *ca.* 7 mm, and kept parallel to each other by a mirror M_2. Mirrors M_1 and M_2 constitute an optical delay line to synchronize the two light pulses. The two beams were focused onto a sample by a spherical mirror M_3 of 300 mm focal length, spatial matching between the two beams also being accomplished at the same time. As long as the angle between the axis of the incident beam and the normal axis of the mirror is small ($<5°$), good focusing can be achieved. Polarization of the two beams was carefully checked at the point where the dewar was to be placed. No scrambling of polarization was observed. The sample was held on a rotatable holder and suspended in a sample compartment of a variable temperature cryostat (Cryogenic Associate CT-72) which was cooled by thermal conduction of cool helium gas down to *ca.* 5 K.

The optical arrangement using two beams with 90 degree incidence is shown in Fig. 2. The crystal should be carefully placed at the exact position where the two beams cross each other since only in this small area do we have sufficient intensities in both beams to observe two-photon signals.

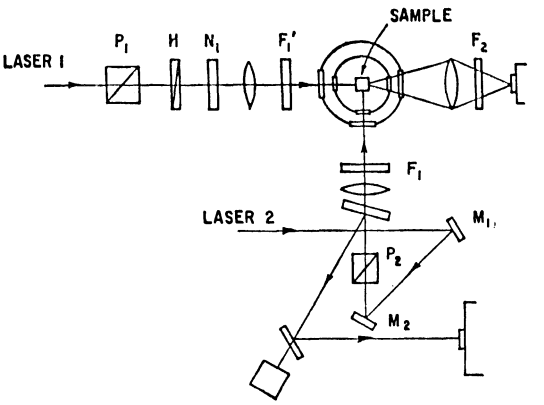

Fig. 2. Optical arrangement for two-photon excitation spectra by two beams with 90 degree incidence.

The fluorescence from the sample was focused onto a small monochromator (Bausch and Lomb) and detected with a photomultiplier (EMI 9635QB) connected to a boxcar integrator (PAR 162). A UV cut-off filter (F_1; Schott GG-22) and a visible cut-off filter (F_2; Corning 7-54) were used to eliminate undesirable photons. The output intensity of beam 2 was monitored by a biplanar photodiode (ITT FW114 with S-20 spectral response). Wavelength of the lasing line was calibrated by a monochromator (Spex 1402).

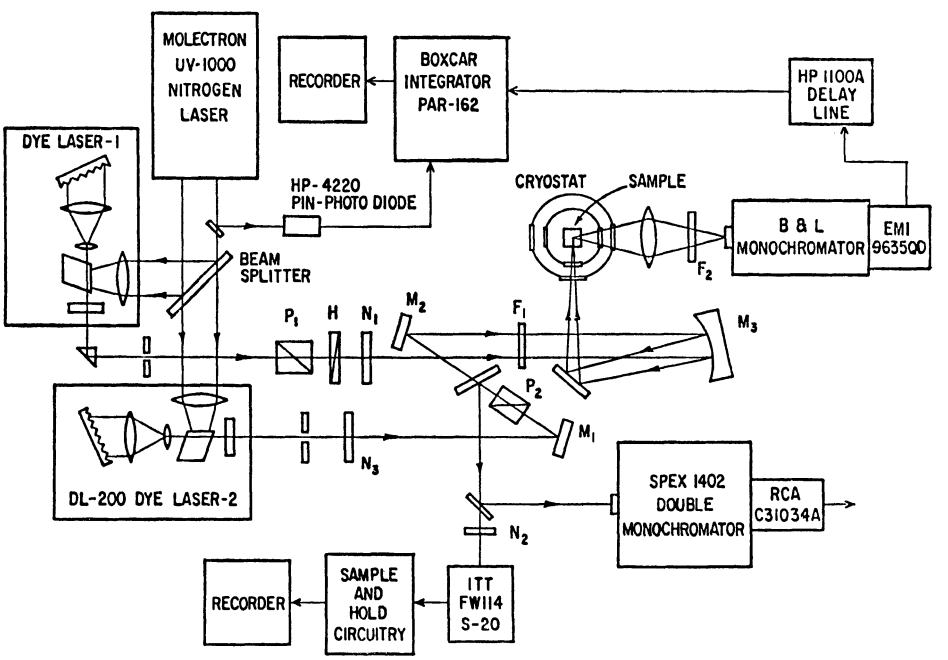

Fig. 1. Experimental set-up for two-photon excitation spectra by two synchronized tunable dye lasers with parallel beam incidence. Notice that the laser beams actually enter the cryostat from the bottom window. The last mirror reflects the beam propagation vector from horizontal to vertical.

Dye solutions were as follows: Cresyl violet perchlorate +Rhodamine-B in EtOH 6600—6200 Å, Rhodamine-B in EtOH 6450—5900 Å, Rhodamine-6G in EtOH 6050—5700 Å. Line width of dye laser 1 in these spectral region was 0.5—0.7 Å, that of laser 2 being less than 0.5 Å.

Naphthalene was purified by fusion with sodium followed by zone refining. Durene (1,2,4,5-tetramethylbenzene) was also purified by the zone melting method. Mixed crystals of durene with *ca.* 1% of naphthalene were grown by the simple Bridgman method. The actual concentration of naphthalene in durene is presumed to be less than 10^{-2} mol/mol. The (ab) crystal plane of durene was cleaved easily. Extinction directions on the (ab) plane were observed under a polarizing microscope. A cube of the crystal with edges parallel to the two extinction axes in the (ab) face (a and b axes) was cut with a razor blade. Examination of the conoscopic pattern of a small flake of the plane showed axis a to differ from axis b. All the directions along the edges of the crystal cube were therefore identified as a, b, and c′ (perpendicular to (ab) face) axes. The X-ray diffraction pattern in precession photographs along each axis confirmed the optical determination of these axes.

One of the principal axes denoted by X is almost parallel to axis a (the angle between it and axis X is known to be −0°54′ in Robertson's axis choice).[19,20] Since axis b coincides with the optical axis Y, all the three crystallographic axes a, b and c′, parallel to the edges of the crystal cube in this work, are parallel to the optical axes X, Y, and Z, respectively. We were able to use the crystallographic axes as reference axes for the polarization experiments.

Results

One Beam Experiment. The two-photon fluorescence excitation spectra of naphthalene in durene crystal with one laser beam was first observed by Hochstrasser, Sung, and Wessel.[10] We have observed almost the same spectra (Figs. 3 and 4). The relative intensities of these absorption peaks are not normalized with respect to the intensity distribution of the dye laser output, since the polarization ratios of the partially polarized laser output varied considerably in the tuning range. The 0-0 transition in this spectral region was

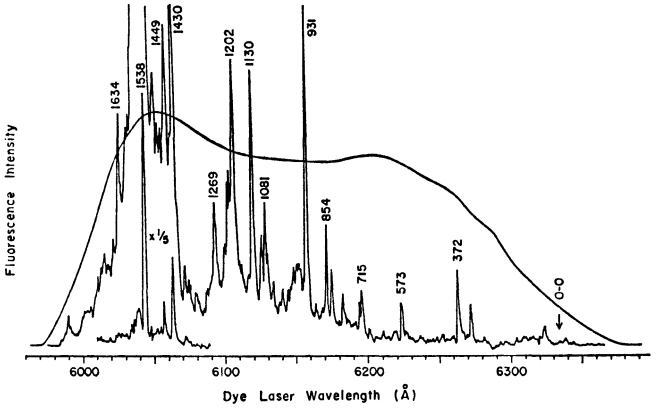

Fig. 3. Unpolarized two-photon excitation spectrum of naphthalene on the (bc′) face of durene crystal at 5 K taken with one laser beam. The smooth curve indicates the intensity distribution of the dye laser (rhodamine-B). The arrow indicates the position of the 0-0 transition.

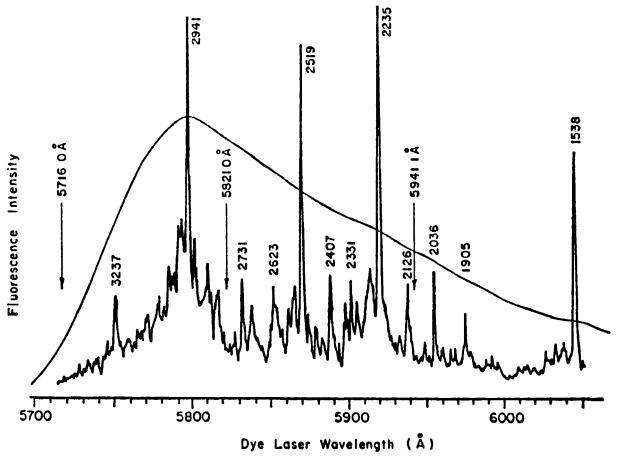

Fig. 4. Unpolarized two-photon excitation spectrum of naphthalene on the (bc′) face of durene crystal at 5 K by using one laser beam. The smooth curve indicates the intensity distribution of the dye laser (rhodamine 6G). The arrows indicate the frequency of the high energy photon in two beam experiments.

measured at 31554 cm^{-1} by McClure.[21] The arrow in Fig. 3 shows the position of the 0-0 transition forbidden in two-photon transition. Energy differences of the main bands from the 0-0 band are summarized in Table 1. Many bands observed in the lower energy side of the strongest false origin at 0+1538 cm^{-1} can be attributed to vibronic bands induced by non-totally symmetric vibrations of u-type. Most bands at the higher energy side of the false origin can be attributed to combinations of u-vibrations and totally symmetric vibrations in the excited state.

The polarized excitation spectra with one beam (Figs. 5—7) are essentially the same as those observed by Hochstrasser and Sung.[12] Due to the wavelength dependence of the polarization of the laser output, the spectra had to be taken in four sections separately for comparison of the two spectra. Usually, one polarized component of the dye laser output is attenuated with respect to the other so that the two polarizations have comparable intensities. The attenuation ratio changes from one spectral section to another, so that one should not compare the intensities of two peaks from different spectral sections. Figure 5 shows a part of the polarized spectra of the strongest vibronic origin at 0+1538 cm^{-1} and a band at 0+1430 cm^{-1} taken on the three principal crystal faces of durene. In the spectra on the (ab) face in which the propagation vector of the incident light is parallel to the c′ axis ($k//c'$), the peak intensity of the a-polarized spectrum ($E//a$) of 1538 cm^{-1} is as intense as that of the b-polarized component ($E//b$). However, in the (ac′) spectra the a-component of the band is more than twice as intense as the c′-component. On the other hand, the 1430 cm^{-1} band is the opposite of that of the 1538 cm^{-1} band in polarization behavior, being predominantly polarized along the c′ axis. Similar characteristics of the polarization spectra in the lower energy regions than the 1430 cm^{-1} band can be seen in Figs. 6 and 7. The polarization ratios are given in Table 2.

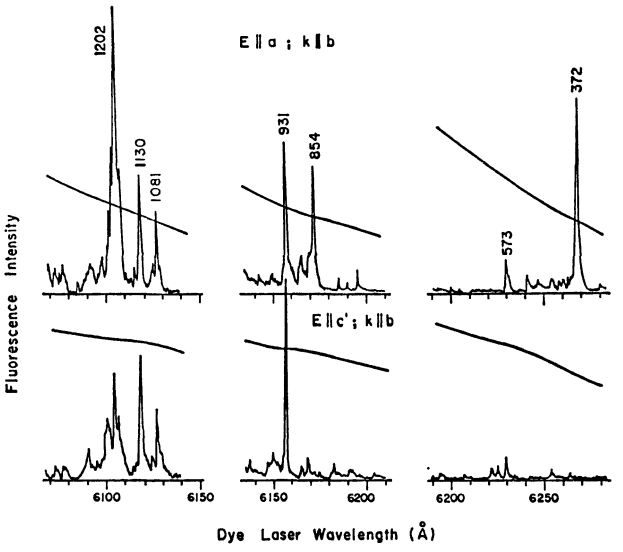

Fig. 6. A part of polarized two-photon excitation spectra in the (ac′) face of durene. Smooth curves indicate dye laser intensity distributions. One cannot compare the relative intensities in different spectral regions.

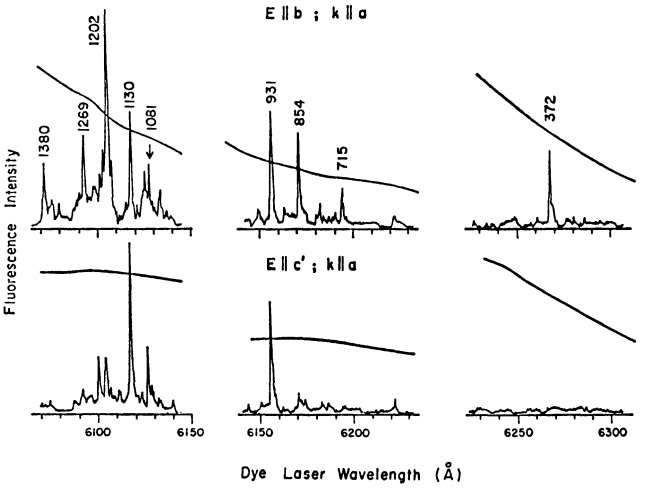

Fig. 7. A part of the polarized two-photon excitation spectra in the (bc′) face of durene. Smooth curves indicate dye laser intensity distributions. One cannot compare the relative intensities in different spectral regions.

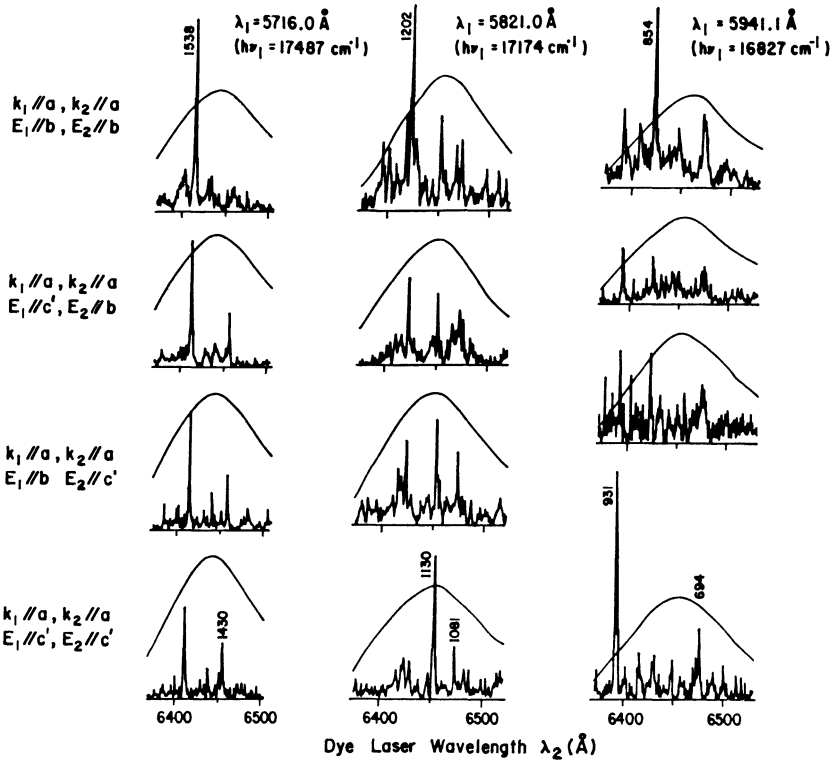

Fig. 8. A part of the polarized two-photon excitation spectra with two dye lasers of different frequencies and different polarizations and parallel beam incidence. The spectra were taken on the (bc′) face of durene at 5 K. k_1, E_1, and λ_1 indicate the k-vector, the polarization and the wavelength of the incident photon with higher energy, respectively. k_2, E_2, λ_2 indicate those of the lower energy photon. One cannot compare the relative intensities in different spectral regions. Smooth curves indicate intensity distributions of dye laser with lower-energy (Cresyl violet+ Rhodamine-B).

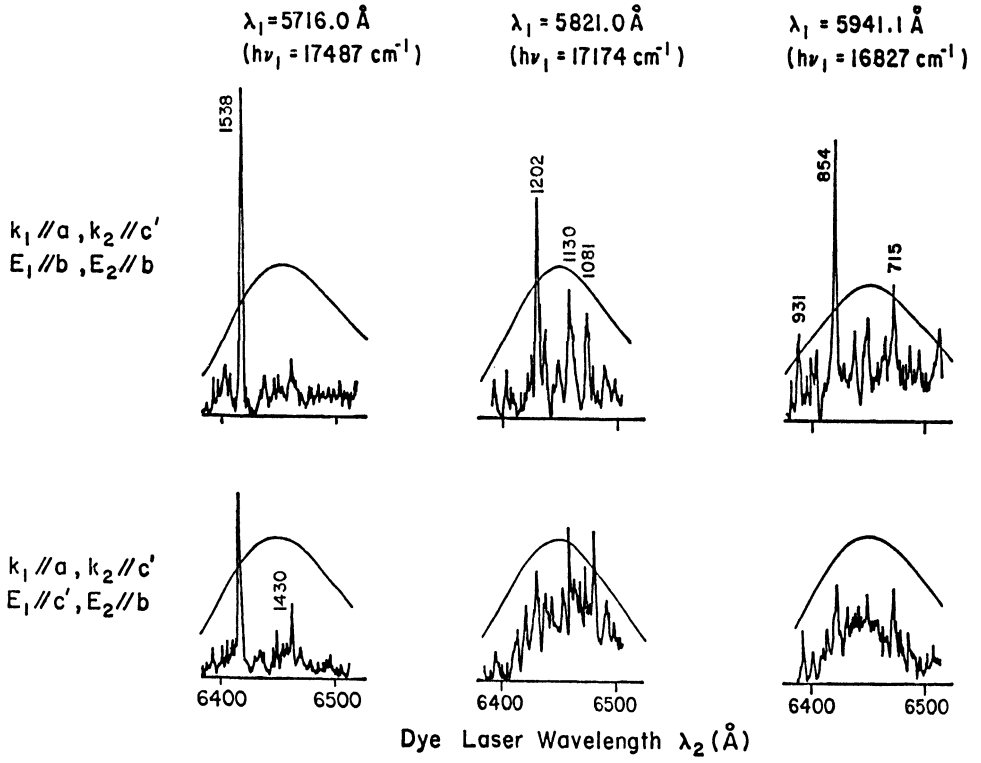

Fig. 9. A part of the polarized two-photon excitation spectra using two beams with 90 degree incidence. k_1, k_2 indicate k-vectors of the high energy photon λ_1 with the polarization E_1 and the lower energy photon λ_2 with the polarization E_2 respectively.

We can distiguish at least three kinds of bands with different polarization behavior (Figs. 5—7). The vibronic bands at 372, 715, 854, 1202, and 1269 cm^{-1} (type I) are polarized predominantly along the a-component on the (ac') spectra and also along the b-component on the (bc') spectra. Another group including 931, 1130, and 1430 cm^{-1} (type III) are apparently polarized along the c'-component in the (ac') or (bc') spectra. The strongest false origin at 1538 cm^{-1} and a band at 1081 cm^{-1} (type II) which are polarized weakly along the a axis in the (ac') plane and also along the b axis in the (bc') plane.

Two Beam Experiment. The excitation spectra taken with two beams of different frequencies and polarizations are shown in Figs. 8 and 9. λ_1 refers to the wavelength of the laser beam with higher energy and λ_2 to that of lower energy photons (Fig. 1). The sum of the frequencies of these two lights should coincide with the excitation energy of the transition. Since the lower frequency photon (λ_2) was tuned in the range where the molecule was not excited by the absorption of the two quanta of λ_2, the two-photon energy of λ_1 should always be higher than the transition energy. Thus, λ_1 beam necessarily induces a constant background on the excitation spectra. However, we were able to find suitable wavelengths of λ_1 to minimize the background (the wavelength λ_1 is indicated by arrow in Fig. 4).

Figure 8 shows the observed spectra using two beams of parallel incidence. The top two spectra in each

a) Value taken from one beam experiment. b) Value taken from two beam experiment.

column were taken by simply changing the polarization of beam 1 without disturbing the optics or changing the sensitivity of the detection system. The lower two spectra were taken after a 90° rotation of the crystal along the axis of incident beams (the incident beams enter the cryostat from the bottom window, see Fig. 1). Thus we can directly measure the ratio for an individual band, $I(\mathrm{bc}')/I(\mathrm{bb})$, by using the normarized peak of the upper two spectra and also $I(\mathrm{c'b})/I(\mathrm{c'c'})$ by using the lower two spectra in Fig. 8. We can assume that the middle two spectra, *i.e.* $I(\mathrm{bc}')$ and $I(\mathrm{c'b})$, are identical when the frequency difference between the photons λ_1 and λ_2 is so small that the asymmetric property of the two-photon transition tensor can be neglected. We can then obtain the polarization ratio $I(\mathrm{bb})/I(\mathrm{c'c'})$ with two beams on the (bc') plane. Observed polarization ratios in the two beam experiment are summarized in Table 2 together with the ratios in the one beam experiments. The reproduced intensity ratios $I(\mathrm{bb})/I(\mathrm{c'c'})$ or $I(\mathrm{aa})/I(\mathrm{c'c'})$ for the two beam experiments are in line with those measured directly from the one beam experiment.

A part of the polarized spectra using two beams with 90 degree incidence is shown in Fig. 9. Each spectrum is similar to its counterpart in Fig. 8. It can be concluded that the polarized spectra do not depend on the direction of propagation of the incident laser beams.

Discussion

Estimation of the Two-photon Transition Tensor. Polarization dependence of two-photon transition can be expressed in terms of a 3×3 tensor. Consider the probability of a two-photon transition i→f. A component of the matrix element of the two-photon transition is expressed as follows:

$$(\sigma^{\mathrm{if}})_{\mathrm{AB}} = \sum_{\mathrm{e}}\left\{\frac{\langle \mathrm{i}|\vec{\mathrm{p}}\cdot\hat{\mathrm{e}}_{\mathrm{A}}|\mathrm{e}\rangle\langle \mathrm{e}|\vec{\mathrm{p}}\cdot\hat{\mathrm{e}}_{\mathrm{B}}|\mathrm{f}\rangle}{\Delta E_{\mathrm{ie}}-\hbar\omega_{\mathrm{A}}+i\Gamma_{\mathrm{e}}} + \frac{\langle \mathrm{i}|\vec{\mathrm{p}}\cdot\hat{\mathrm{e}}_{\mathrm{B}}|\mathrm{e}\rangle\langle \mathrm{e}|\vec{\mathrm{p}}\cdot\hat{\mathrm{e}}_{\mathrm{A}}|\mathrm{f}\rangle}{\Delta E_{\mathrm{ie}}-\hbar\omega_{\mathrm{B}}+i\Gamma_{\mathrm{e}}}\right\}, \tag{1}$$

where $|\mathrm{e}\rangle$ is an intermediate state for the two-photon process with its excitation energy ΔE_{ie} and a line width Γ_{e}. A and B denote the polarization of the incident photons with energy $\hbar\omega_{\mathrm{A}}$ and $\hbar\omega_{\mathrm{B}}$, respectively. The complete form of the tensor can be expressed by using molecular symmetric axes (L, M, N) as basis axes. We have

$$\sigma^{\mathrm{if}} \equiv \begin{bmatrix} \sigma_{\mathrm{LL}} & \sigma_{\mathrm{LM}} & \sigma_{\mathrm{LN}} \\ \sigma_{\mathrm{ML}} & \sigma_{\mathrm{MM}} & \sigma_{\mathrm{MN}} \\ \sigma_{\mathrm{NL}} & \sigma_{\mathrm{NM}} & \sigma_{\mathrm{NN}} \end{bmatrix}_{\mathrm{if}} \tag{2}$$

Generally, σ^{if} is an asymmetric tensor. It can be split into two parts,[8] symmetric and antisymmetric:

$$\sigma^{\mathrm{if}} = \sigma_{\mathrm{s}}^{\mathrm{if}} + \sigma_{\mathrm{a}}^{\mathrm{if}}$$

$$\sigma_{\mathrm{s}}^{\mathrm{if}} = \begin{bmatrix} \sigma_{\mathrm{LL}} & \frac{(\sigma_{\mathrm{LM}}+\sigma_{\mathrm{ML}})}{2} & \frac{(\sigma_{\mathrm{LN}}+\sigma_{\mathrm{NL}})}{2} \\ \frac{(\sigma_{\mathrm{ML}}+\sigma_{\mathrm{LM}})}{2} & \sigma_{\mathrm{MM}} & \frac{(\sigma_{\mathrm{MN}}+\sigma_{\mathrm{NM}})}{2} \\ \frac{(\sigma_{\mathrm{NL}}+\sigma_{\mathrm{LN}})}{2} & \frac{(\sigma_{\mathrm{NM}}+\sigma_{\mathrm{MN}})}{2} & \sigma_{\mathrm{NN}} \end{bmatrix}_{\mathrm{if}}, \tag{3}$$

$$\sigma_{\mathrm{a}}^{\mathrm{if}} = \begin{bmatrix} 0 & \frac{(\sigma_{\mathrm{LM}}-\sigma_{\mathrm{ML}})}{2} & \frac{(\sigma_{\mathrm{LN}}-\sigma_{\mathrm{NL}})}{2} \\ \frac{(\sigma_{\mathrm{ML}}-\sigma_{\mathrm{LM}})}{2} & 0 & \frac{(\sigma_{\mathrm{MN}}-\sigma_{\mathrm{NM}})}{2} \\ \frac{(\sigma_{\mathrm{NL}}-\sigma_{\mathrm{LN}})}{2} & \frac{(\sigma_{\mathrm{NM}}-\sigma_{\mathrm{MN}})}{2} & 0 \end{bmatrix}_{\mathrm{if}} \tag{4}$$

If the energy separation between the initial state and the intermediate state ΔE_{ie} is large as compared with the incident photon energies, *i.e.* off-resonance condition or energy difference between the two photons $\hbar\omega_{\mathrm{A}}$ and $\hbar\omega_{\mathrm{B}}$ is negligible as compared with the ΔE_{ie}, $\sigma_{\mathrm{a}}^{\mathrm{if}}$ can be neglected. Therefore, σ^{if} will be adequately approximated by the symmetric form $\sigma_{\mathrm{s}}^{\mathrm{if}}$. We assume that the transition tensor is symmetric even in the case of the two beam experiment with different photon energies, because the difference of these photon energies is very small as compared with the ΔE_{ie}.

The electronic state in the crystal can be described in terms of molecular states in the crystal lattice, *i.e.* the oriented gas model. Knowing the direction cosines of the molecular axes in the crystal, we can express the polarization characteristics of the two-photon transition in an oriented crystal in terms of the molecular two-photon transition tensor. The intensity ratio between the two polarized spectra $I(\alpha\beta)$ and $I(\gamma\delta)$ can be written as

$$\frac{I(\alpha\beta)}{I(\gamma\delta)} = \frac{|\sum_{\mathrm{AB}}\sigma_{\mathrm{AB}}\cos\theta_{\alpha}^{\mathrm{A}}\cos\theta_{\beta}^{\mathrm{B}}|^2}{|\sum_{\mathrm{AB}}\sigma_{\mathrm{AB}}\cos\theta_{\gamma}^{\mathrm{A}}\cos\theta_{\delta}^{\mathrm{B}}|^2}, \tag{5}$$

where α, β, or γ, δ denote the crystal axes, and A and B the molecular axes. σ_{AB} denotes the AB elements of molecular tensor of the two-photon transition amplitude in Eq. 2, $\cos\theta_{\alpha}^{\mathrm{A}}$ being the direction cosine between the crystal axis α and molecular axis A. Orientational factor of the two-photon transition of naphthalene in durene crystal can be easily obtained since the guest molecules are known to be embedded substitutionally in the lattice. L and M indicate the molecular long and short axes, respectively, in the molecular plane of naphthalene. a, b, and c' indicate the crystal axes of durene which are very close to the optical axes. Since the projection of axis N, which is perpendicular to the molecular plane, are very similar to those of axis L, we cannot distinguish their contributions. However, the contribution from axis N can be safely neglected since there are no dipole allowed transitions along it for the low-lying electronic states of the molecule. Under these conditions, we can easily find a leading term of the molecular tensor component in the two-photon spectra. As an example,

$$\begin{aligned} I(\mathrm{bb}) &= C\cdot(0.317)\sigma_{\mathrm{LL}}^2 \\ I(\mathrm{c'c'}) &= C\cdot(0.972)\sigma_{\mathrm{MM}}^2 \\ I(\mathrm{c'b}) &= I(\mathrm{bc}') = C\cdot(0.555)\{\sigma_{\mathrm{LM}}^2+\sigma_{\mathrm{ML}}^2\} \\ I(\mathrm{aa}) &= C\cdot(0.184)\sigma_{\mathrm{LL}}^2 \\ I(\mathrm{ab}) &= I(\mathrm{ba}) = C\cdot(0.241)\sigma_{\mathrm{LL}}^2 \\ I(\mathrm{ac}') &= I(\mathrm{c'a}) = C\cdot(0.423)\{\sigma_{\mathrm{LM}}^2+\sigma_{\mathrm{ML}}^2\} \end{aligned} \tag{6}$$

where C is a constant.

We can estimate the relative magnitudes of the squared elements of the tensor in the first approxima-

tion. If the relative signs of the elements are known, iterations using Eq. 5 can be employed to obtain more precise values. However, our experimental values are not sufficiently accurate to do so and the signs of the elements are not known. Corrections on the first approximation cannot exceed 10% of the original values and are thus ignored. The relative magnitude of the squared molecular two-photon transition amplitudes are given in Table 3.

Table 3. Relative magnitude of the tensor elements for two-photon transitions

$\Delta\tilde{\nu}$ / cm^{-1}	$\left\|\frac{\sigma_{MM}}{\sigma_{LL}}\right\|^2$	$\left\|\frac{\sigma_{LM}}{\sigma_{LL}}\right\|^2$	Type
715	0.04	0.14	I
854	0.02	0.08	I
931	0.78	0.23	III
1081	0.22	0.25	II
1130	0.42	0.23	III
1202	0.07	0.12	I
1269	0.02	0.04	I
1430	0.86	0.77	III
1538	0.16	0.18	II

We can draw the following conclusions: (1) The gross features of the polarization measurements indicate that σ_{LL} is the predominant tensor element. This might be due to the fact that most intense low-lying transitions of naphthalene are long-axis polarized. Since two-photon transition should gain intensity from one-photon transitions, the behavior is not unexpected. (2) Type I bands can be associated with the smallest σ_{MM}; type II with slightly larger σ_{MM} and type III with even larger σ_{MM}, with respect to σ_{LL}. The naphthalene guest molecules are so oriented that even a small σ_{MM} gives rise to a large $I(c'c')$. (3) The relatively large σ_{LM} is somewhat unexpected. For type I and II bands, all the assignments so far are in line with a b_{2u} vibration in a $^1B_{2u}$ electronic state to yield an overall A_g vibronic state. No σ_{LM} is expected within the oriented gas model. We can either relax the symmetry selection rules by introducing the crystal field perturbations or assume higher order radiation field-molecule coupling schemes. It appears that the former interpretation is more reasonable. (4) Type III bands can be interpreted as either a (LL+MM) mechanism of an A_g vibronic symmetry or LM mechanism of a B_{3g} vibronic symmetry. The crystal field perturbation could be operating here also with the net effect that polarization behavior becomes less distinct.

Assignments for Prominent Lines Based on the Dominant Tensor Elements. Assignments have been made by Hochstrasser and Sung[12] and by Mikami and Ito[13] for the individual vibronic transitions of naphthalene based on polarization experiments on crystals and by Boesel *et al.*[18] for the spectrum in vapor. Let us discuss these assignments (Table 3).

(1) 1538 cm^{-1}: This is the strongest vibronic origin of the spectrum. The dominant tensor element is σ_{LL} of an A_g two-photon tensor, which confirms the results reported by the others 1538 cm^{-1} in this work corresponds to 1540 cm^{-1} in durene crystal and 1542 cm^{-1} in neat crystal given by Hochstrasser and Sung, to 1535 cm^{-1} in pure crystal given by Mikami and Ito, and to 1559 cm^{-1} in vapor spectrum given by Boesel *et al.* The vibrational assignment of this band seems to be well established, *i.e.* 1538 cm^{-1} in the excited state has been assigned to a b_{2u} species which corresponds to 1375 cm^{-1} (ν_{14}) of a b_{2u} type vibration in the ground state. Although this is polarized strongly along the LL-component in the neat crystal, we have observed a non-vanishing amount of MM-component (σ_{MM}) in the durene crystal. In the study by Hochstrasser and Sung the same characteristics have been observed (*cf.* Ref. 12, Table IV) while the ratio of σ_{MM} to σ_{LL} in the neat crystal should be much less than the ratio in durene (*cf.* Ref. 12, Table V). Another remarkable point is existence of the unexpected off-diagonal two-photon tensor element σ_{LM}. This would not be the case on the basis of the assignment described above.

(2) 1430 cm^{-1}: Two-photon tensor shows mixed polarization. Like other type III bands, assignment of this band could not be made unequivocally. This could be attributed to LM-polarization, characteristic of a B_{3g} tensor with a b_{1u} vibration. Hochstrasser and Sung assigned their 1433 cm^{-1} band to a b_{2u} vibration with a dominant MM-component of an A_g tensor. No corresponding band was observed in the gas phase.

(3) 1269 cm^{-1}: This is polarized dominantly in LL-component which means an A_g tensor with a b_{2u} vibration. This agrees with the assignment by Hochstrasser and Sung for their 1276 cm^{-1} band. No corresponding band was observed in vapor.

(4) 1202 cm^{-1}: This polarized in the LL-component of an A_g tensor although an unnegligible amount of LM-component was observed. This corresponds to 1207 cm^{-1} by Hochstrasser and Sung and 1206 cm^{-1} in vapor by Boesel *et al.*, which have also been assigned as an A_g vibronic transition with a b_{2u} vibration.

(5) 1130 cm^{-1}: Mixed components were observed. The polarization characteristics of this band are similar to those of 1430 cm^{-1}. This could be assigned as LM-mechanism of a B_{3g} vibronic state, although an A_g tensor with mixed components (LL+MM) are also possible. Hochstrasser and Sung also observed 1140 cm^{-1} band with a similar polarization behavior to their 1433 cm^{-1}. They pointed out that the appropriate tensor is an A_g type on the basis of polarization in the neat crystal.

(6) 1081 cm^{-1}: The tensor pattern is similar to that of 1538 cm^{-1}. No corresponding band was observed by others.

(7) 931 cm^{-1}: Mixed polarization was observed. The tensor pattern is similar to that of 1430 cm^{-1}. We assigned this to A_g with mixed polarization (LL+MM) confirming the assignment for their 941 cm^{-1} by Hochstrasser and Sung. Boesel *et al.* assigned their 940 cm^{-1} band in vapor spectrum to a B_{3g} vibronic band induced by b_{1u} vibration, and Mikami and Ito also assigned their 901 cm^{-1} band in neat crystal to a B_{3g} state. The discrepancy might be due to the complicated tensor pattern of this band which cannot be clarified by simple one beam experiments.

TABLE 4. ASSIGNMENTS AND MECHANISMS OF TWO-PHOTON TRANSITIONS OF THE MAIN VIBRONIC BANDS (in cm^{-1})

Hochstrasser and Sung[a] (in durene)	Mikami and Ito[b] (in pure crystal)	Boesl, Neusser and Schlag[c] (in gas)	This work (in durene)
390(b_{1u})	365(b_{1u})	355(b_{1u})	372
		592(b_{2u})	573
			715(b_{2u}) LL
863(b_{3u})	847(b_{2u})	865(b_{3u})	854(b_{2u}) LL
941(b_{2u})	901(b_{1u})	940(b_{1u})	931(b_{2u}) LL+MM
	1029(b_{2u})		
1102			1081(b_{2u}) LL
1140(b_{1u})	1107(b_{2u})		1130(b_{2u} or b_{1u}) LL+MM or LM
1194(b_{1u})			
1207(b_{2u})	1203(b_{2u})	1206(b_{2u})	1202(b_{2u}) LL
1276(b_{1u})			1269(b_{2u}) LL

1506(b_{1u})			
1540(b_{2u})	1535(b_{2u})	1559(b_{2u})	1538(b_{2u}) LL

a) Ref. 12. b) Ref. 13. c) Ref. 18.

(8) 854 cm^{-1}: This band is polarized dominantly along LL-component which corresponds to an A_g tensor, if we assume that the contribution from the N axis of the molecule can be neglected. Hochstrasser and Sung assigned their 863 cm^{-1} in durene to a B_{1g} vibronic band on the basis of the anisotropy of the two-photon signal of the corresponding bands 853 and 857 cm^{-1} in the neat crystal. Boesel *et al.* also assigned their 865 cm^{-1} in vapor spectrum to a B_{1g} state induced by b_{3g} vibration in the excited state. In our analysis we cannot distinguish the difference in polarization characteristics of LL and NN, because of the orientation of the molecule in durene crystal.

(9) 715 cm^{-1}: This is polarized along LL-component. This band might correspond to 727 cm^{-1} in the neat crystal spectra by Hochstrasser and Sung. No corresponding band was observed in vapor.

(10) 372, 573 cm^{-1} and Other Weak Bands: No two beam experiments was carried out on these bands because of weakness of their two-photon signal. The results are summarized in Table 4.

Intermediate States of the Two-photon Processes in the 1538 cm^{-1} Band. The strongest false origin at 1538 cm^{-1} in the spectrum is one of the key bands which characterize the two-photon spectrum in the lowest excited singlet state ($^1B_{2u}$) of naphthalene. The mechanism of the vibronic coupling for this band has been discussed in detail based on the polarization experiment of the neat crystal. It was emphasized that the vibronic coupling between the excited state and the ground state through the b_{2u} vibration of 1538 cm^{-1} is involved.[13] Let us consider the intermediate states for the two-photon transition processes of the band. From Eq. 1 we get the following expressions of the matrix element for the two-photon transition.

$$(\sigma^{gf})_{LL} = \sum_L \left\{ \frac{\vec{\mu}_{gL}^{(1)} \cdot \vec{\mu}_{Lf}^{(2)}}{\Delta E_{gL} - \hbar\omega_1 + i\Gamma_L} + \frac{\vec{\mu}_{gL}^{(2)} \cdot \vec{\mu}_{Lf}^{(1)}}{\Delta E_{gL} - \hbar\omega_2 + i\Gamma_L} \right\}$$
$$(\sigma^{gf})_{MM} = \sum_M \left\{ \frac{\vec{\mu}_{gM}^{(1)} \cdot \vec{\mu}_{Mf}^{(2)}}{\Delta E_{gM} - \hbar\omega_1 + i\Gamma_M} + \frac{\vec{\mu}_{gM}^{(2)} \cdot \vec{\mu}_{Mf}^{(1)}}{\Delta E_{gM} - \hbar\omega_2 + i\Gamma_M} \right\} \quad (7)$$

Where $\vec{\mu}_{gL}^{(1)} \equiv \langle g|\vec{r}\cdot\hat{e}_1|L\rangle$, $\vec{\mu}_{Mf}^{(2)} \equiv \langle M|\vec{r}\cdot\hat{e}_2|f\rangle$ *etc.* L denotes an intermediate state of the two-photon process with B_{2u} symmetry and M a state with B_{1u} symmetry. $\vec{\mu}_{Lf}$, $\vec{\mu}_{Mf}$ denote the transition moment from the intermediate states to the final vibronic level at 1538 cm^{-1} above the origin of the lowest singlet state. We do not known the values of $\vec{\mu}_{Lf}$ or $\vec{\mu}_{Mf}$. However, we adopt the vibronic coupling involving the ground state described above. The transition moment can be estimated from the known values of $\vec{\mu}_{gL}$ or $\vec{\mu}_{gM}$ which are the transition moments from the ground state to the L or M states. The electronic wave function of the vibronic state in the first excited state can be expressed by a linear combination of the zeroth order wave function of the state and that of the ground state with the coupling constant of Herzberg-Teller type along the normal coordinate of the b_{2u} vibration. Transition moment from a higher electronic excited state L or M to the vibronic state expressed by such an approximation can be split into two terms, the transition moment from L or M to the zeroth order first excited state, and that from L or M to the ground state multiplied by a Herzberg-Teller coupling constant. Since the L or M state is an optically allowed state from the ground state and should have an *ungerade* symmetry, the former term in the transition moment would vanish in the framework of approximation. The second term contributes to the transition moment $\vec{\mu}_{Lf}$ or $\vec{\mu}_{Mf}$. We can safely assume that the transition moments from a higher electronic excited state L or M to the vibronic state are proportional to the transition moments from the L or M state to the ground state. Neglecting the difference between $\hbar\omega_1$ and $\hbar\omega_2$ in Eq. 7, we have the following expressions for the two-photon tensor elements:

$$(\sigma^{gf})_{LL} = 2\sum_L \left\{ \left(\frac{H'_{ge}}{\Delta E_{ge}} \right) \cdot \left(\frac{\vec{\mu}_{gL} \cdot \vec{\mu}_{Lg}}{\Delta E_{gL} - \hbar\omega + i\Gamma_L} \right) \right\}$$
$$(\sigma^{gf})_{MM} = 2\sum_M \left\{ \left(\frac{H'_{ge}}{\Delta E_{ge}} \right) \cdot \left(\frac{\vec{\mu}_{gM} \cdot \vec{\mu}_{Mg}}{\Delta E_{gM} - \hbar\omega + i\Gamma_M} \right) \right\} \quad (8)$$

where H'_{ge} denotes the matrix element of the Herzberg-Teller coupling.

By means of the expressions we can estimate $(\sigma_{MM}/\sigma_{LL})^2$ by using the observed values of the oscillator strength f and the excitation energies of the low-lying π-π^* excited states. The values are as follows[22]

$S_1(^1B_{2u}$: L-polarization) $f=0.002$ $\Delta E=32200\ cm^{-1}$
$S_2(^1B_{1u}$: M-polarization) $f=0.18$ $\Delta E=35000$
$S_3(^1B_{2u}$: L-polarization) $f=1.70$ $\Delta E=45300$
$S_4(^1B_{2u}$: L-polarization) $f\approx0.2$ $\Delta E=52500$
$S_5(^1B_{1u}$: M-polarization) $f\approx0.6$ $\Delta E=59800$

Taking 16500 cm^{-1} as the photon energy of the incident photon $\hbar\omega$ and neglecting the line width Γ's, we have 1.7×10^{-8} cm^2 for the $(\sigma)^2_{LL}$ with unit Herzberg-Teller constant. The contribution to the two-photon tensor element arises mainly from S_3 and S_4 with constructive sum. For the MM-component the constructive sum of the contributions from the two M-polarized excited states S_2 and S_5 has also been considered, $(\sigma)^2_{MM}$ being found to be 2.2×10^{-9} cm^2 with the same unit. The calculated ratio $(\sigma_{MM}/\sigma_{LL})^2$ is then 0.13, the value observed being 0.16. In spite of the simple estimation agreement between the estimate and observed values is fairly good. The ratio calculated with a contribution from a single excited state to each component turns out too large or too small as compared with the value obtained. The destructive interference between the contributions in each tensor component from any two excited states can be neglected because neither excited state is below the energy of the incident photon. From the results we conclude that all the low-lying electronic states contribute as the intermediate states for the two-photon transition to the 1538 cm^{-1} vibronic state in the lowest singlet state. This seems to be reasonable since the energies of both incident photons ω_1 and ω_2 in this experiment are far from the excitation energies of the intermediate states, *viz.*, the off-resonance condition in the two-photon absorption processes. In the off-resonance condition all the low-lying electronic states should contribute to the two-photon processes, as in the case of the off-resonance condition in Raman processes.

Crystal Field Effects on the Two-photon Transition. If we assume the oriented gas model for two-photon spectra in the crystal, we should have no off-diagonal matrix element σ_{LM} (and σ_{ML}) of the molecular two-photon tensor of A_g type. However, as shown in Table 3, a considerable amount of off-diagonal component was observed even in A_g vibronic states. For example, the 1538 cm^{-1} band has already been assigned to the A_g vibronic state composed of b_{2u} vibration in the $^1B_{2u}$ electronic state from both crystal and vapor spectra. For the sake of confirmation we have carried out detailed polarization measurement of the band using two beams on the three different crystal faces of durene. The ratios of intensities of different polarizations as compared to the strongest component I(ab) are given in Table 5, together with calculated ratios using the estimated values of the squared ratio of the two-photon tensor elements (Table 3); $\sigma_{LL}=1.00$, $\sigma_{MM}=0.16$, $\sigma_{LM}=0.18$. We see that the estimated values of the squared tensor elements reproduce the polarization ratios for different crystal faces fairly well. The predicted behavior and that of observed polarization of the vibronic states are more or less in agreement.

Table 5. Relative intensities of the strongest false origin at 1538 cm^{-1} in the polarized spectra of different crystal faces

	I(aa)	I(bb)	I(c'c')	I(ab)	I(bc')	I(ac')
Obsd ratio	0.97	0.65	0.38	1.00	0.41	0.68
Calcd ratio	0.38	0.66	0.32	1.00	0.41	0.32

In order to understand the strange polarization effect of the two-photon transition in the crystal, we should take into account the crystal field effect on the molecular states. Group-theoretically the tensor of the molecule embedded in the site of the durene crystal is no longer diagonal since the site symmetry of the crystal is C_i and all the g molecular states fall into A_g symmetry in the C_i site group. In this case three different crystal field mixing processes of the states in the crystal can be considered. (1) Mixing of the normal modes of the molecular vibrations in the crystal due to molecular deformation. For example, the vibrational mode mixing between b_{2u} vibration and b_{1g} vibration causes mixing of the two-photon states of A_g symmetry and of B_{3g} symmetry. In this process, redistribution of the two-photon intensity among all the vibronic states of the same electronic state would take place. This is not very likely since no intense bands with a σ_{LM} component can be identified that can share σ_{LM} with the A_g vibronic state. (2) Mixing among the intermediate states of the two-photon processes is possible. One intermediate state with B_{2u} symmetry (L-polarization), for example, will interact with the other intermediate state with B_{1u} symmetry (M-polarization) in the presence of the crystal field or due to the molecular deformation in the crystal. In this case, the apparent LM-component of the tensor due to the crystal field perturbation V_c can be expressed as

$$(\sigma^{gf})_{LM}=2\sum_L\left\{\frac{\vec{\mu}_{gL}\cdot\sum_M(\lambda_{LM}\cdot\vec{\mu}_{Mf})}{\Delta E_{gL}-\hbar\omega+i\Gamma_L}\right\}+2\sum_M\left\{\frac{\vec{\mu}_{gM}\cdot\sum_L(\lambda_{ML}\cdot\vec{\mu}_{Lf})}{\Delta E_{gM}-\hbar\omega+i\Gamma_M}\right\} \quad (9)$$

where $\lambda_{LM}=\langle L|V_c|M\rangle/\Delta E_{LM}$ stands for the interaction between the intermediate states L and M. Using the same assumption and oscillator strengths for the L or M states employed in the preceding section, we require a very large value of λ_{LM} (more than unity) for any pair of the states L and M to reproduce the observed ratio $(\sigma_{LM}/\sigma_{LL})^2$. Such a large coupling is not likely. (3) The third process is interstate coupling between the vibronic state and other two-photon allowed electronic state with g symmetry. At least two g-electronic states in near UV region have been observed.[11,23] The lower one has been assigned to a B_{3g} electronic state in consideration of theoretical calculations. The other state has been assigned to an A_g electronic state. We can expect the mixing of wave

functions of the vibronic state A_g with that of the electronic B_{3g} and/or of the electronic A_g states. Such a mixing could provide a mechanism for the appearance of σ_{LM} in an A_g vibronic state. The perturbed wave function of the vibronic A_g state in the B_{2u} state (with a reduced symmetry of A) can be found by application of perturbation theory using the crystal flield perturbation V_c and the perturbing electronic state B which has originally a B_{3g} symmetry. Two-photon transition tensor of the true crystalline state of the vibronic A state can be expressed as

$$\begin{bmatrix} \sigma_{LL} & \sigma_{LM} \\ \sigma_{ML} & \sigma_{MM} \end{bmatrix}^{A}_{crystal} = \begin{bmatrix} \sigma_{LL} & 0 \\ 0 & \sigma_{MM} \end{bmatrix}^{A_g}_{mol} + \frac{\langle A|V_c|B\rangle}{\Delta E_{AB}} \begin{bmatrix} 0 & \sigma_{LM} \\ \sigma_{ML} & 0 \end{bmatrix}^{A_{3g}}_{mol} \quad (10)$$

where the perturbation on the ground state is neglected and contributions from axis N are omitted. From Table 3, the ratio of the $|\sigma_{LM}|^2$ to $|\sigma(\text{total})|^2 (=|\sigma_{LL}|^2+2\cdot|\sigma_{LM}|^2+|\sigma_{MM}|^2)$ is found to be 0.12. The strength of the two-photon transition to the B_{3g} electronic state (located at about 44400 cm^{-1}) is about ten times that of the A_g vibronic state.[11] The mixing coefficient, $\langle A|V_c|B\rangle/\Delta E_{AB}$, is therefore estimated to be 0.11 or less. If we take the energy separation between the vibronic state and the B_{3g} state as $\Delta E_{AB}=9300$ cm^{-1}, the interaction energy $\langle A|V_c|B\rangle$ due to the crystal field is estimated to be about 990 cm^{-1}.

In order to ascertain the possibility of the crystal field mixing mechanism (3), there are no other suitable physical quantities in the excited state of the molecule which is directly related to the perturbation. However, if we assume that the stabilization energy of the excited molecular state in the crystal is almost of the same order of magnitude as that of the ground state, we can estimate the order of magnitude of the crystal field effect in the excited state. The total energy of an excited molecule A in a crystal can be written as

$$E_A(\text{crystal}) = E_A(\text{gas}) + \langle A|V_c|A\rangle + \sum_B \frac{|\langle A|V_c|B\rangle|^2}{\Delta E_{AB}}, \quad (11)$$

if we regard the $[E_A(\text{crystal})-E_A(\text{gas})]$ as the heat of sublimation of naphthalene (or durene). We have 6×10^3 cm^{-1}/ molecule for the stabilization energy of a molecule in crystal from the gas phase.[24] Since excited states are generally more polarizable, the value probably represents a lower limit of the stabilization energy of an excited molecule in the crystal. Actually the polarizability of the lowest singlet excited state of naphthalene is slightly larger than that of the ground state.[25,26] Considering only one perturbing state B and taking the value 990 cm^{-1} for $\langle A|V_c|B\rangle$, we have 105 cm^{-1}/ molecule for the second order polarization energy term in Eq. 11, which is one or two orders of magnitude less than the total stabilization energy in the crystal. Although it is not known what percentage of stabilization energy is due to the second order contribution in Eq. 11, the estimated value may not exceed the total second order polarization energy. Our estimate of the strength of crystal field perturbation on the guest molecules appears to be reasonable.

In the absorption study of the first singlet excited state of naphthalene in durene, McClure[27] reported an unexpected polarization behavior of many vibronic bands. Crystal field mixing on the one-photon spectra causes only reduction in the polarization ratios. In order to confirm the effect, very accurate measurements on the relative intensities of the spectra are required. On the other hand, in the two-photon experiments we have more degrees of experimental freedom on the polarization measurements than in the case of one-photon spectra. It is easy to find out the crystal field effects from the unexpected polarization. Two-photon transition tensors depend on more precise electron distributions in the ground and excited states than the one-photon transition dipoles. Crystal perturbation on the molecular wave function will give rise to more effects on the two-photon tensors.

Possibility of Optical Kerr Effect. Another possible cause for the unexpected off-diagonal component of the two-photon transition tensor in the crystal can be attributed to the occurrence of electric field-induced birefringence by optical light beam, *i.e.*, optical Kerr effect.[28] A strong polarized monochromatic laser beam at frequency ν_1 induces birefringence change in a medium so that the other polarized light beam at frequency ν_2 becomes partially depolarized when the two beams pass through the medium simultaneously. Resonance enhancement of the Kerr effect can efficiently depolarize the beam originally polarized. The resonance effect occurs when the photon energy $2\nu_1$, $2\nu_2$, $|\nu_1-\nu_2|$, or $\nu_1+\nu_2$ coincides with the proper molecular transitions. In the case of Raman resonance, *i.e.*, when $|\nu_1-\nu_2|$ corresponds to the molecular vibrational energy of a Raman active mode, this resonance enhancement of the optical Kerr effect has been observed and is known as Raman-induced Kerr effect.[29]. We can expect a similar enhancement effect on the two-photon resonance, when $\nu_1+\nu_2$ matches the energy of a strong two-photon allowed molecular transition. If this is the case, //b-polarization of ν_1 photon produces //b-polarization of ν_2 polarized originally along $\perp$b. As a result, apparent signal $I(//b, \perp b)$ is nearly a mixture of $I(//b, //b)$ and $I(\perp b, \perp b)$ factorized by the ratio of the generated light intensity divided by the original intensity. Since the factor is supposed to be very small, the anomalous polarization observed is too large to be explained completely as a result of the effect.

One of the authors (N. M.) wishes to thank Professor M. Ito, Tohoku University, for his encouragement.

The Activities of Methyl Orange and Homologs in Aqueous Solutions

Masaru MITSUISHI* and Yuzoh YAMAGUCHI

Faculty of Textile Science and Technology, Shinshu University, Tokida, Ueda-shi 386

(Received March 18, 1979)

The mean activity coefficients of Methyl Orange (MO), Ethyl Orange (EO), Propyl Orange (PO), and Butyl Orange (BO) in aqueous solutions ranging in concentration from 10^{-3} to 10^{-2} mol kg^{-1} have been determined by means of isopiestic measurements at 50 and 60 °C respectively. It has been found that the mean activity coefficients of MO being the largest, and those of BO, the smallest. The coefficients have been found to decrease with an increase in the dye concentration. The examination of the results by Milicéivic treatment suggests that MO, EO, and PO are present as a monomer or a dimer, while BO exists as a trimer at 60 °C.

Most of the anionic dyes are sodium salts of aromatic sulfonic acids. In aqueous solutions, they have been known to be dissociated completely and to be capable of intermolecular interactions through the hydrophobic groups of the dyes.[1-3] Consequently, the mean activity coefficients of such dyes in aqueous solutions may be governed by the hydrophobic groups in the dye anions.

Since there have been few reports on the mean activity coefficients from the above-mentioned point of view, it seemed that it might be worthwhile to examine the mean activity coefficients of the dyes with various alkyl groups in the dye molecules.

In this paper, the mean activity coefficients of Methyl Orange and its homologs, such as Ethyl Orange, Propyl Orange, and Butyl Orange, in aqueous solutions will be determined by means of isopiestic measurements, and the results will be examined by Milicéivic treatment.

Experimental

Materials. Methyl Orange (MO), Ethyl Orange (EO), Propyl Orange (PO), and Butyl Orange (BO) were used in this experiment. The MO was prepared by coupling diazotized sulfanilic acid with *N*,*N*-dimethylaniline in a weakly acetic acid solution; it was recrystallized three times from water. The EO, supplied by the British Drug House Co., was of a reagent grade; it was isolated by column chromatography on activated alumina and then further purified by recrystallization from ethanol. The PO was synthesized from sulfanilic acid and *N*,*N*-di-*n*-propylaniline by procedures similar to those used for MO; it was then purified in a manner similar to that used for EO. The BO, supplied by the Eastman Kodak Co., was also of a reagent grade; it was purified by procedures to those used for EO.

Vapor-pressure Osmotic Measurements. The vapor-pressure osmometry may also be applicable to the examination of the physical properties of such electrolyte solutions as a dye solution. All the vapor-pressure osmotic measurements were carried out at 50 and 60±0.1 °C[4] using a Hitachi molecular-weight apparatus, Model 115. The difference in electrical resistance of a pair of matched thermistors is measured when a drop of a dye solution on one thermistor and a drop of water on the other thermistor evaporate isothermally in a closed compartment saturated with water vapor. From this value, the resistance difference when water drops are placed on both thermistors is subtracted; the resulting value, ΔR, is known to be dependent linearly upon the osmotic concentration of the dye solution:[5,6]

$$\Delta Rk = -\ln(p/p_0) = \nu\phi m_2/m_1 \quad (1)$$

where k is a constant dependent on the temperature of the solution and the instrumental characteristics; p and p_0 are the partial pressures of the solvent over the solution and over the pure solvent; ν is the number of the particles into which the solute dissociates; ϕ is the osmotic coefficient, and m_2 and m_1 are the solute and solvent molarities respectively. Urea was used in order to determine the numerical values of k,[7,8] so the ϕ values could be obtained by means of Eq. 1.

The evaluation of the mean activity coefficient of an electrolyte can be made as follows.[9] The Gibbs-Duhem equation is applied to the derivation of the interrelation between the osmotic coefficient and the mean activity coefficient, $\gamma_\pm$.

$$\mathrm{d}\ln\gamma_\pm = \mathrm{d}\phi + (\phi-1)\mathrm{d}\ln m_2 \quad (2)$$

$$\ln\gamma_\pm = (\phi-1) + \int_0^m (\phi-1)\mathrm{d}\ln m_2 \quad (3)$$

The integration can be carried out graphically from the plot of $(1-\phi)m_2^{-1}$ *vs.* m_2.

Table 1 gives the measured resistance differences, ΔR, of urea solutions at 50 and 60 °C respectively. The numerical values of k are also shown in Table 1.

Table 1. Measured resistance differences, ΔR, and constants, k, of urea solutions at 50 and 60 °C

$10^{-3}\,m_2$ / mol kg^{-1}	50 °C		60 °C	
	ΔR / Ω	$10^{-6}k$ / Ω^{-1}	ΔR / Ω	$10^{-6}k$ / Ω^{-1}

4.0	9.9	7.27	7.6	9.47
6.0	15.2	7.10	11.4	9.47
8.0	19.6	7.34	14.9	9.67
10.0	24.7	7.28	18.4	9.77
Mean		7.18		9.67

Results and Discussion

Measured Resistance Differences. The measured resistance differences, ΔR, of MO, EO, PO, and BO solutions at 50 and 60 °C are plotted against m_2 in Figs. 1 and 2 respectively. From Figs. 1 and 2 it may be seen that the plots of urea solutions are almost linear, while the plots of the dye solutions display slight downward curvatures. It is noteworthy that the ΔR values of MO solutions are the largest, while those of BO solutions are the smallest. All of the ΔR values of the dye solutions are smaller than twice the ΔR values of urea solutions.

Osmotic Coefficients. The osmotic coefficients, ϕ, of MO, EO, PO, and BO solutions ranging in concentration from 10^{-3} to 10^{-2} mol kg^{-1} were obtained from the ΔR values given in Figs. 1 and 2 by means of Eq. 1;

they are shown in Table 2. All of the ϕ values of the four dyes are seen to be much smaller than unity. The ϕ values of the MO solution are the largest, while those of the BO solution are the smallest. These results strongly suggest that the aqueous solutions of these dyes deviate from the ideal.

Determination of Mean Activity Coefficients. The

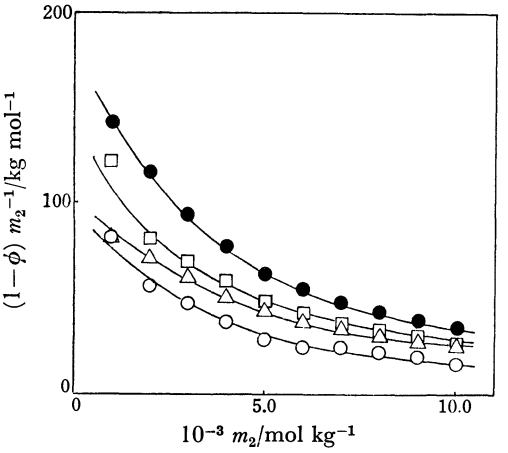

Fig. 3. Plots of $(1-\phi)m_2^{-1}$ against m_2.
○: Methyl Orange, △: Ethyl Orange, □: Propyl Orange, ●: Butyl Orange.

determination of the mean activity coefficients, $\gamma_\pm$, was made as follows. The $(1-\phi)m^{-1}$ at 50 °C was plotted against m_2 as is shown in Fig. 3. After the plot has been extrapolated to zero concentration, the area under the curve was measured and the $\gamma_\pm$ values were calculated according to Eq. 3. The $\gamma_\pm$ values of MO, EO, PO, and BO at 50 and 60 °C are shown in Table 3. These values are comparable to those of C. I. Direct Blue 1.[10,11] In Table 3 it may be seen that the $\gamma_\pm$ values are much smaller than unity and decrease with an increase in the chain length of the alkyl groups in the dye molecules. These results strongly suggest that the mean activity coefficients are influenced by the hydrophobic parts of the dye molecules: *i.e.*, the differences in the $\gamma_\pm$ values among these four dyes are attributable to the association of the dye anions.

Examinations of Results by Milicëivic Treatment. Since these dyes are known to dissociate completely in aqueous solutions, and since the ionic strengths of these solutions are small, the Debye-Hückel limiting law may be supposed to hold. The relation between the mean activity, $a_\pm$, and the mean association number of the dye anions, n, can be derived from the Debye-Hückel limiting law:[12]

$$\log a_\pm = \log m_2 - \frac{1}{n+1}\log n - Anm_2\sqrt{\frac{1+n}{2}} \qquad (4)$$

where;

$$a_\pm = \gamma_\pm m_2 \qquad (5)$$

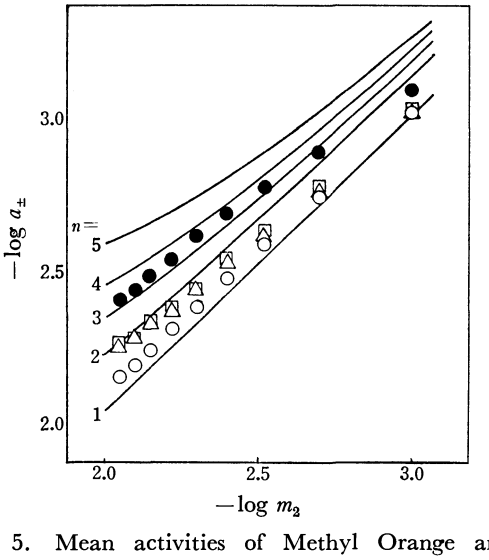

Fig. 5. Mean activities of Methyl Orange and its homologs at 60 °C.
○: Methyl Orange, △: Ethyl Orange, □: Propyl Orange, ●: Butyl Orange.

Also, if the electronic charge and the gas constant are taken as 4.80×10^{-10} esu and 8.31×10^{-7} erg °C mol^{-1} (1 erg$=1\times10^{-7}$ J) respectively,

$$A = 1.825\times10^{6}\left(\frac{\rho_0}{D_0^3T^3}\right)^{1/2} \qquad (6)$$

where D_0 and ρ_0 are the dielectric constant and the density of the solvent at a temperature, T, respectively.

The mean activities of MO, EO, PO, and BO at 50 and 60 °C are plotted against log m_2 in Figs. 4 and 5 respectively. The solid lines in Figs. 4 and 5 are theoretical lines drawn according to Eq. 4. In Fig. 4, the plots for MO and EO are seen to be close to the dimer line ($n=2$), the plots for PO, close to the trimer line ($n=3$), and the plots for close to the tetramer line ($n=4$). These results indicate that the MO and EO dye anions are present as dimers, the PO anions, as trimers, and the BO dye anions, as tetramers, on the average, at 50 °C. From Fig. 5, MO, EO, and PO are seen to exist as monomers or dimers, and BO, as trimers, at 60 °C.

Simultaneous Measurement of Photoacoustic and Excitation Spectra for the Evaluation of Quantum Efficiencies of Uranium-mica Type Compounds

Yoshinori SUGITANI* and Kenji KATO†

Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

(Received April 3, 1979)

A new method of estimating the absolute quantum efficiency of a phosphor material based on the simultaneous measurement of photoacoustic and fluorescent excitation spectra is presented. The method is distinguishable from previous methods in that a reference material is not required. The method has been successfully applied to uranium-mica compounds. The transition rate constants for the radiative and non-radiative processes have been obtained on the basis of the quantum efficiency and fluorescence life time data.

The determination of the absolute quantum efficiency of fluorescence may be achieved either by determination of a defined fraction of the fluorescent radiation, or by the measurement of the complementary part of the non-radiative process by calorimetry.[1] The former optical method appears to be more popular due to the relatively sensitive detection of the fluorescent radiation, which is more sensitive than thermal detection. Electronic units and components are also readily available. The actual determination of quantum efficiency, however, consists of various processes and the necessary corrections, and results are generally of low accuracy.

Determination with the aid of photoacoustic spectrometry belongs to the latter case. Lahmann and Ludewig[2] compared the photoacoustic signal of the sample solution of rhodamine 6G with that of a reference solution of $K_2Cr_2O_7$ which is nonfluorescent but has comparable absorption coefficients. Adams *et al.*[3] determined the quantum efficiency of quinine bisulfate in aqueous solution utilizing the quenching effect of fluorescence by halide ions.

A study of photoacoustic spectra combined with fluorescence spectra enables the flow of the relaxed energy passing through both processes, radiative and non-radiative, to be traced.[4] Simultaneous detection of the photoacoustic and excitation signals as a function of the wave length of the exciting light enables the determination of the absolute quantum efficiencies of fluorescence, as discussed on the uranium-mica type compounds in the present study.

Experimental

Apparatus. The system for the simultaneous measurement of photoacoustic and excitation spectra is shown in Fig. 1, where the system for measuring emission spectra and luminescence life times is also shown. The exciting light from the xenon lamp (300 W) is chopped (CHI) at 80 Hz and monochromated at SPI(JASCO, CT-25N) and irradiated on the sample cell (PFC), the details of which are reported in this journal.[5] The photoacoustic signal is detected by a microphone (SONY, Electlet condenser type, FET buffer included, parts number 8-814-196-50) attatched on the cell, amplified at P1, introduced to a lock-in amplifier L2 (NF Circuit Design Block, LI-574) and recorded on R2. The optical signal is filtered at SP2, detected by a photomultiplier (PM), amplified (P3 and L1) and recorded on R1.

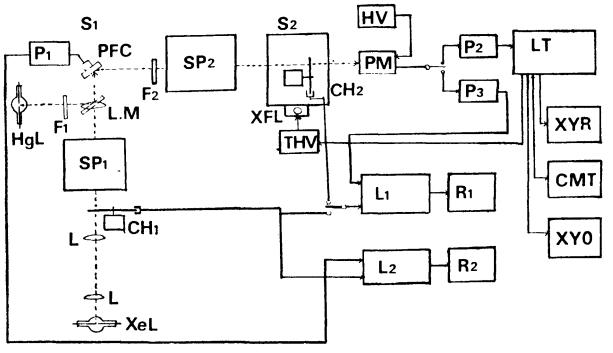

Fig. 1. Block diagram showing the system for simultaneous measurement of photoacoustic and fluorescent excitation spectra. The system for measuring emission spectra and fluorescent life time are also shown. XeL: Xenon arc lamp, L: lenses, CH1 and CH2: light choppers, HgL: mercury lamp, F1 and F2: filters, PFC: sample cell, S1 and S2: sample position, THV: trigger circuit and power supply for xenon flash lamp, XFL: xenon flash lamp, PM: photomultiplier, P1, P2, and P3: preamplifiers, L1 and L2: lock-in amplifiers, R1 and R2: recorders, LT: signal processor unit with a microcomputer, XYR: XY-recorder, CMT: magnetic cassette tape, XYO: XY-oscilloscope, SP1 and SP2: spectrometers.

In the measurement of emission spectra, the sample is irradiated with UV light (365 nm) from a mercury lamp (HgL) and the fluorescent emission is monochromated by the spectrometer SP2 (NIKON, P-250), chopped (CH2), and detected by the photomultiplier PM. With the luminescence life time measurement, the sample specimen is placed in the S2 position instead of the S1 position and, is excited by a xenon flash lamp XFL. The fluorescent signal is detected (PM), amplified (P2), and introduced to the life time measuring system LT, the details of which will be published elsewhere.[6]

All measurements in the present study were taken at room temperature.

Samples. The samples used in the present study are the same as those described previously.[7,8]

Results and Discussion

Procedure for Determining Quantum Efficiency. In a system which is not chemically reactive to visible light

† Present address: National Chemical Laboratory for Industry, 1-1 Yatabe-cho Higashi, Tsukuba-gun, Ibaraki 305.

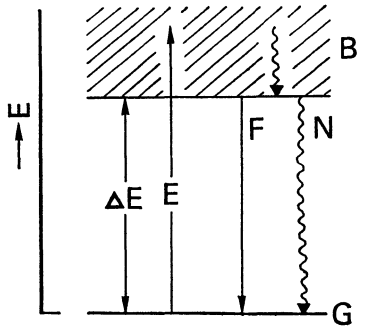

Fig. 2. An energy diagram tentatively given for derivating the relations of quantum efficiency calculation. F: Radiative process, N: non-radiative process.

irradiation, photoacoustic spectrometry provides a complementary system to fluorescent spectrometry which deals with the radiative process. A method of estimating the absolute quantum efficiency of fluorescence Q_F is presented in Fig. 2, based on a simple model of energy diagram where the ground state G and the excited state B of a broad band is given with a separation of ΔE. Assuming the system absorbs light energy E larger than ΔE, the system will release heat energy and will return to the bottom of the band, from which the system will relax to the ground state G by a radiative (F) and/or non-radiative (N) transition. The intensity of the fluorescent emission $I_F(E)$ caused by the excitation of light with energy E is given by

$$I_F(E) = k \cdot \beta(E) \cdot Q_F \cdot I_{EX}(E), \tag{1}$$

where k is a measuring constant, $\beta(E)$ is an absorption coefficient for the light energy E, and $I_{EX}(E)$ is the intensity of the exciting light at energy E. The photoacoustic signal is proportional to the output of thermal energy, which is given as the sum of the excess energy, $E-\Delta E$, and the energy released in the non-radiative process N. Thus the photoacoustic intensity $I_P(E)$ is given by

$$\begin{aligned} I_P(E) &= l \cdot \beta(E) \cdot I_{EX}(E) \cdot [(E-\Delta E)+\Delta E(1-Q_F)] \\ &= l \cdot \beta(E) \cdot I_{EX}(E) \cdot (E-\Delta E \cdot Q_F), \end{aligned} \tag{2}$$

where l is a measuring constant. Supposing that $\beta(E)$ and $I_{EX}(E)$ are taken as invariant, the $I_F(E)$ and $I_P(E)$ will be given as functions of the energy E as in Fig. 3. Taking the ratio of $I_P(E)$ and $I_F(E)$, the $\beta(E)$ and $I_{EX}(E)$ terms vanish giving:

$$\frac{I_P(E)}{I_F(E)} = \frac{1}{k} \cdot \frac{E-\Delta E \cdot Q_F}{Q_F}. \tag{3}$$

The $I_P(E)/I_F(E)$ ratio will be directly related to E as shown in Fig. 3c. Extrapolation leads to an energy of E_0 as in the following;

$$\frac{I_P(E)}{I_F(E)} = 0 = \frac{1}{k} \cdot \frac{E_0-\Delta E \cdot Q_F}{Q_F}, \tag{4}$$

i.e.,

$$E_0 = \Delta E \cdot Q_F. \tag{5}$$

The quantum efficiency will be given as

$$Q_F = E_0/\Delta E. \tag{6}$$

Experimentally, the E_0 value will be obtained as a crossing point on the E axis in the extropolation of the plots of $I_P(E)/I_F(E)$ *versus* E, and the ΔE value will be obtained as the center of the gravity of the emission spectra.

The method of estimating the quantum efficiency presented here is an improvement of those reported to date,[2,3] in that reference materials and quenched samples are not required. In addition, the simultaneous measurement followed by the plotting of intensity ratios of both spectra removes the need for corrections for the power spectrum and the drift of the exciting light.

Quantum Efficiencies of Uranium-micas. A series of uranium-mica type compounds containing uranyl ions as fluorescent centers may be considered as one of those which have an energy diagram similar to that discussed above. Figure 4 shows an energy level diagram for the uranyl(VI) ion based on the paper of Bell and Biggers[9] which appears to be the most widely accepted diagram for uranyl salts. The totally symmetric singlet ground state $^1\Sigma_g^+$ is split into five sublevels due to symmetric

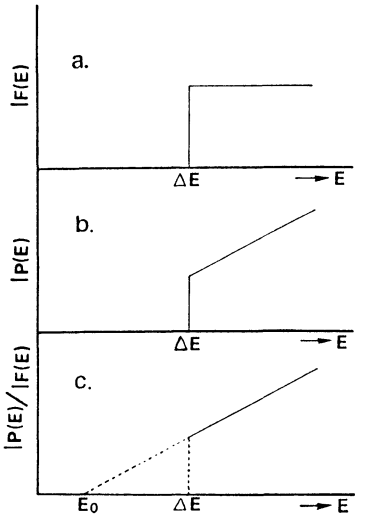

Fig. 3. Expected intensities of fluorescent (a) and photoacoustic (b) output based on the diagram of Fig. 2, and their ratios (c) as a function of the exciting energy E.

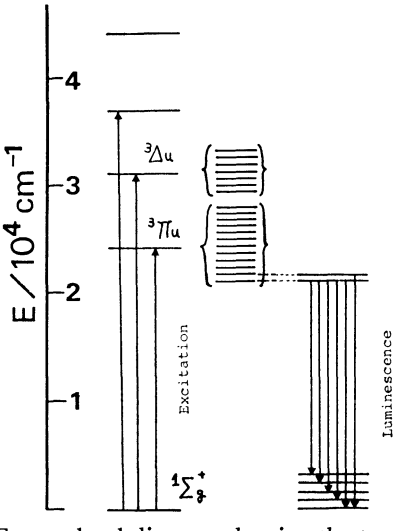

Fig. 4. Energy level diagram showing the transitions of excitation and fluorescent process for uranyl(VI) ion.[9]

stretching in the ground state, while the lowest excited state $^3\Pi_u$ and the second lowest excited state $^3\Delta_u$ are also split into the twelve and seven sublevels, respectively, due to the symmetric stretching in the excited state. The average spacings of the sublevels are approximately 750—860 cm^{-1} depending on the respective sample.[10-12] The luminescence appears to occur from the lowest one or two sublevels to the ground state sublevels showing six emission peaks. The emission peak at the shortest wavelength has a relatively small intensity of about 1/30 of the total intensity suggesting that the contribution to the emission from the second lowest sublevel is negligibly small.

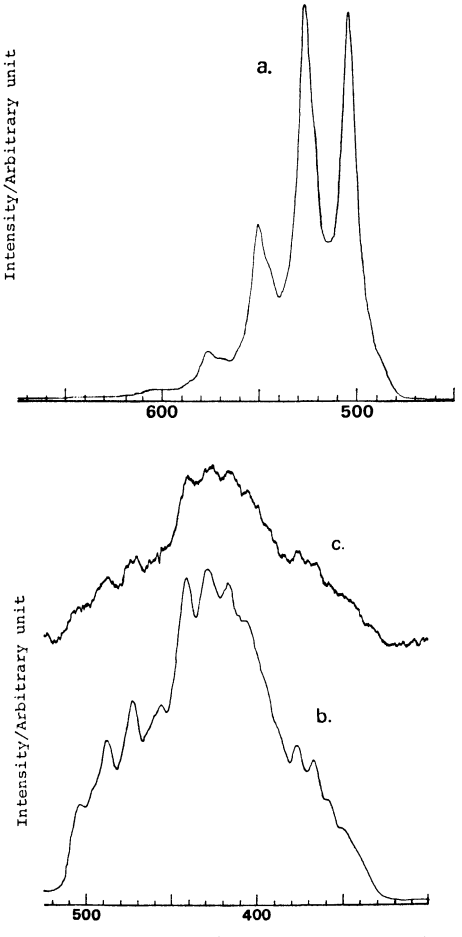

Fig. 5. Fluorescent emission spectra (a), fluorescent excitation spectra (b), and photoacoustic spectra (c) of $Ba(UO_2)_2(PO_4)_2 \cdot nH_2O$. The latter two spectra was simultaneously measured.

The emission spectra of $Ba(UO_2)_2(PO_4)_2 \cdot nH_2O$, one of the prepared uranium-mica samples, are also shown in Fig. 5. The main features of the three spectra for other uranium-mica samples are very similar except for shifts in the peak values of approximately 5 nm in the respective spectra.

Plots of the $I_P(E)/I_F(E)$ ratios *versus* the exciting energy E for the case of Ba-containing uranium-mica samples are given in Fig. 6, where the six points in the lower energy region fall on a straight line giving the experimental E_0 value on the abscissa. The experimental

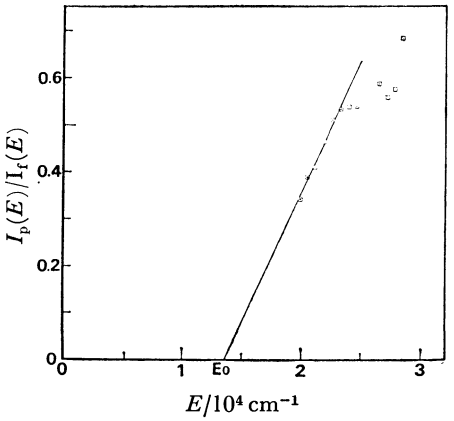

Fig. 6. Plots of the intensity ratios of photoacoustic and fluorescent excitation signals as a function of the exciting energy E.

ΔE value has been tentatively evaluated as 1.92×10^4 cm^{-1} (520 nm) from the peak position of the envelope curve of the emission spectra (Fig. 5a). The value of the quantum efficiency, calculated from Eq. 6 is 0.7. The value of quantum efficiency obtained using similar procedures for the other uranium-micas are given in Table 1. The E_0 value of 1.92×10^4 cm^{-1} has been constantly applied in the estimation of quantum efficiencies of other uranium-micas. The error from this approximation is estimated as $\pm 4\%$. Table 1 includes the fluorescence life times and the transition rate constants which will be discussed later.

In Fig. 6, some of the data in the higher energy region deviate from linearity. This deviation was also found in other unanium micas, where the number of points falling on the line ranges from 4 to 7 out of fifteen.

The reason of the observed deviation appears to be due to the grain size δ of the sample powder. For a photoacoustic signal Ps from a solid sample,[11] Ps varies as a rather complex function of the parameters concerning the sample and/or experimental conditions such as absorption coefficient β, thermal conductivity, grain size δ, chopping frequency ω, *etc.* For the samples studied here the relation between δ and the optical penetration distance, μ, which is defined as $1/\beta$, appears to be responsible for the deviation.

In the situation that μ is larger than δ, the acoustic signal Ps is proportional to β, whereas if μ is comparable to or smaller than δ, the acoustic signal Ps remains constant and independent of β. This indicates that in the energy region with a relatively large β around 400—450 nm, the optical penetration distance μ is equal to or smaller than δ, so that the intensity of the photoacoustic signal will be reduced to some extent, resulting in deviation from linearity. The plots in the higher energy region appear closer to the line than those in the middle energy region which appears to correspond to a lower β value in this region. Samples having a large grain size such as $Mg(UO_2)_2(PO_4)_2 \cdot nH_2O$: Mn (0.03 mol%) show large deviations, while fine grain samples such as $Zn(UO_2)_2(PO_4)_2 \cdot nH_2O$: Cu (0.01 mol%) do not show deviations. It may be concluded

TABLE 1. DATA OF QUANTUM EFFICIENCY Q_F, FLUORESCENCE LIFE TIME τ, AND TRANSITION RATE CONSTANTS k_f AND k_n OF THE RESPECTIVE RADIATIVE AND NON-RADIATIVE PROCESSES, FOR A SERIES OF URANIUM-MICA COMPOUNDS $M(UO_2)_2(XO_4)_2 \cdot nH_2O$

* less reliable data

that a sample with a smaller grain size gives greater linearity and thus more reliable results in terms of estimation of the quantum efficiency.

Transition Rate Constants k_f and k_n for the Radiative and Non-radiative Processes. The combination of the values of quantum efficiency Q_F and the fluorescence life time allows the transition rate k_f for the radiative process and k_n for the non-radiative process to be evaluated. The values are related in the following equations;

$$\tau = 1/(k_f + k_n) \quad (7)$$

$$Q_F = k_f/(k_f + k_n), \quad (8)$$

which may be rewritten:

$$k_f = Q_F/\tau \quad (9)$$

$$k_n = (1 - Q_F)/\tau. \quad (10)$$

The results calculated from Eqs. 9 and 10 are given in Table 1. The life time data in Table 1 have been measured in this study, and are slightly different from those previously reported.[8] The difference is considered to be within experimental error so far as the room temperature data are concerned. As seen in Table 1, the phosphate samples have Q_F, k_f, and k_n values of approximately 80%, $3 \times 10^3\ s^{-1}$, and $0.5—1.0 \times 10^3\ s^{-1}$, respectively. The arsenate samples have a shorter τ, a slightly larger Q_F, and a larger k_f value than in the phosphate samples. The k_n values are comparable for the phosphate and arsenate samples. This suggests that the fast radiative process (large k_f) makes the life time short for the samples without the quencher ions such as Cr and Mn. The sample with quencher ion $Mg(UO_2)_2(PO_4)_2 \cdot nH_2O$: Mn (0.03 mol%), however, has a shorter τ and lower Q_F leading to a larger value of k_n. It is considered that the effect of the doping ion Mn^{2+} receives part of the excited energy of the UO_2^{2+} ion making the τ value shorter as well as making the Q_F value lower. The effect of the doping ion Cu^{2+}, as seem in Table 1, is to decrease the value of Q_F without changing the life time data. This indicates that the Cu^{2+} ions absorb almost all the excited energy of the nearest UO_2^{2+} ions making the Q_F value low, while the other UO_2^{2+} ions which are free from the Cu^{2+} neighbors decay within their own relaxation mechanism.

The authors wish to express their thanks to Professor Kozo Nagashima for his kind support and encouragement during this work.

The Rate Constants for H and D-Atom Additions to O_2, NO, Acetylene, and 1,3-Butadiene

Yo-ichi ISHIKAWA, Ko-ichi SUGAWARA, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 15, 1979)

Pulse radiolysis has been combined with Lyman-α absorption spectroscopy for the measurement of absolute rate constants for the addition reactions of H and D-atoms to oxygen, nitrogen monoxide, acetylene-d_0 and -d_2, and 1,3-butadiene at room temperature. The rate constants obtained with O_2 and NO were in good agreement with the results previously reported and no H/D isotope effect was found. With acetylenes and 1,3-butadiene, the following rate constants were obtained (units of cm^3 $molecule^{-1}$ s^{-1}): $(3.8\pm0.4)\times10^{-13}$ for $H+C_2H_2$; $(2.6\pm0.2)\times10^{-13}$ for $D+C_2H_2$; $(3.8\pm0.2)\times10^{-13}$ for $H+C_2D_2$; $(2.5\pm0.2)\times10^{-13}$ for $D+C_2D_2$; $(8.5\pm1.5)\times10^{-12}$ for $H+1,3\text{-}C_4H_6$; $(7.5\pm0.6)\times10^{-12}$ for $D+1,3\text{-}C_4H_6$. These results are compared to previous studies, and the H/D isotope effect discussed.

In previous papers the absolute rate constants for the addition reactions of H and D-atoms to seven mono-olefins were reported.[1,2] The technique used for the measurement can readily be extended to the reactions with other reactants. This paper describes the results obtained with oxygen, nitrogen monoxide, acetylene-d_0 and -d_2, and 1,3-butadiene.

Experimental

The apparatus and procedures used in this study are the same as those previously described for the reactions of hydrogen and deuterium atoms with olefins.[1,2]

Research grade oxygen, nitrogen monoxide, acetylene-d_0, and 1,3-butadiene (Takachiho Shoji Co.) were used without further purification. Acetylene-d_2 was synthesized by the reaction of D_2O (99.99% up; Merck Co.) with CaC_2 (Tokyo Kasei Co.), which was heated at approximately 500 °C for 70 h in vacuum prior to use. The acetylene-d_2 thus obtained was introduced into a flask containing sulfuric acid and shaken for 1 h to remove hydrogen sulfide, ammonia, and phosphine. The mass and infrared spectra showed that the purity of acetylene-d_2 was better than 99%.

Results and Discussion

Reaction with Oxygen. Figure 1 shows the oscillogram for the time dependence of the concentration of H-atoms obtained with 747 Torr (1 Torr ≃133.322 Pa) hydrogen containing 0.93 Torr oxygen, and the first order decay rates thus obtained are plotted as functions of the initial pressures of hydrogen and oxygen in Figs. 2 and 3, respectively. The linear relationships obtained are consistent with the widely accepted reaction mechanism, *i.e.*, a third order combination reaction of hydrogen atoms with oxygen:

$$H + O_2 + H_2 \longrightarrow HO_2 + H_2$$

The rate constant was calculated to be $(3.0\pm0.6)\times10^{-32}$ cm^6 $molecule^{-2}$ s^{-1}, a value somewhat smaller than that reported by Hikida *et al.*, $(4.7\pm1.1)\times10^{-32}$ cm^6 $molecule^{-2}$ s^{-1}.[3]

A similar experiment employing deuterium in place of hydrogen gave a rate constant for the reaction,

$$D + O_2 + D_2 \longrightarrow DO_2 + D_2$$

as $(2.9\pm1.3)\times10^{-32}$ cm^6 $molecule^{-2}$ s^{-1}. No H/D isotope effect was found.

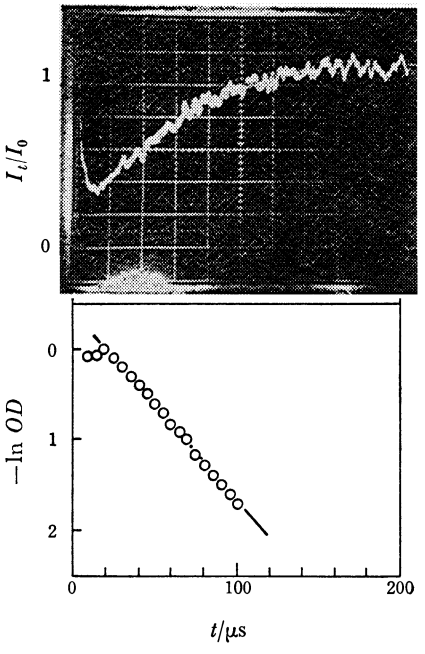

Fig. 1. The decay curve of hydrogen atoms due to the reaction of $H+O_2+H_2\rightarrow HO_2+H_2$, and the first order plot of this decay curve. Temperature is 298 K. The pressure of hydrogen is 747 Torr; pressure of oxygen 0.93 Torr.

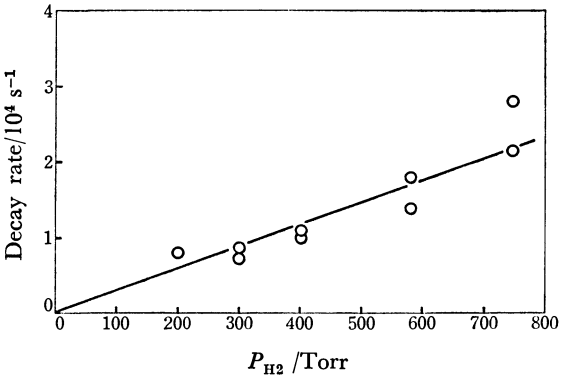

Fig. 2. The decay rate as a function of the pressure of hydrogen. The pressure of oxygen is 0.95±0.02 Torr.

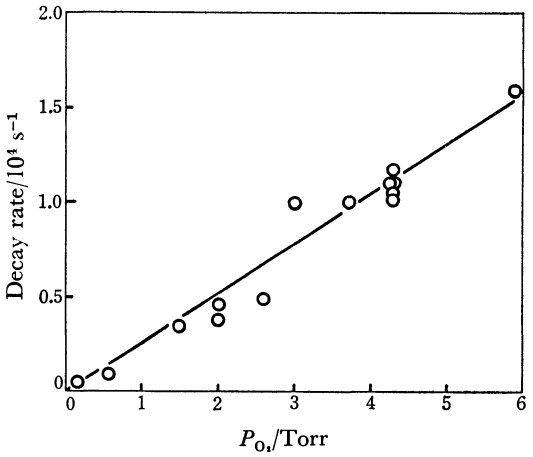

Fig. 3. The decay rate as a function of the pressure of oxygen. The pressure of hydrogen is 750±4 Torr.

Reaction with Nitrogen Monoxide. This is a well documented third order reaction. Thirty measurements, in which the hydrogen and deuterium pressures were changed from 100 to 900 Torr and the nitrogen monoxide pressure from 0.05 to 0.85 Torr, gave the following rate constant: $(4.6\pm0.6)\times10^{-32}$ cm^6 molecule^{-2} s^{-1} for the reaction:

$$H + NO + H_2 \longrightarrow HNO + H_2$$

and $(4.4\pm1.0)\times10^{-32}$ cm^6 molecule^{-2} s^{-1} for the reaction:

$$D + NO + D_2 \longrightarrow DNO + D_2.$$

Again no isotope effect could be observed. Table 1 compares previous studies for this reaction where it can be seen that agreement is within experimental error.

Reaction with Acetylene. Figure 4 shows the oscillogram for the time-dependence of hydrogen atom concentration obtained with 752 Torr hydrogen containing 47 mTorr acetylene after irradiation of pulsed electrons, and the first order plot for the optical density, from which the decay rate of hydrogen atoms was estimated. The decay rates thus obtained with various pressures of hydrogen, from 300 to 1200 Torr, and with a constant pressure, 73 mTorr, of acetylene are plotted in Fig. 5. The decay rate appears to be independent of hydrogen pressure in the range studied.

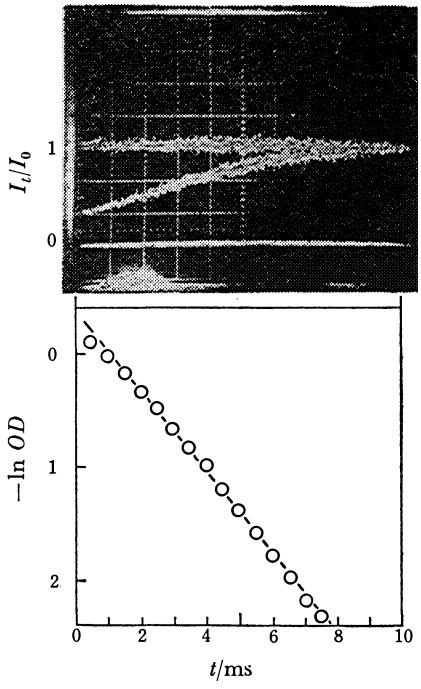

Fig. 4. The decay curve of hydrogen atoms due to the reaction of $H+C_2H_2\rightarrow C_2H_3$, and the first order plot of this decay curve. Temperature is 298 K. The pressure of hydrogen is 752 Torr; pressure of acetylene 47 mTorr.

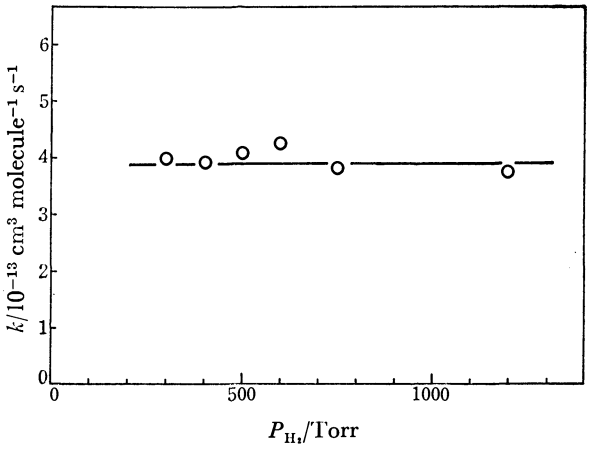

Fig. 5. The rate constant of reaction of hydrogen atoms with acetylene as a function of the pressure of hydrogen. The pressure of acetylene is 73 mTorr.

It is known that the apparent decay rate of hydrogen atoms in the reaction with acetylene is pressure dependent at low total pressure, because the reverse reaction: $C_2H_3^*\rightarrow H+C_2H_2$ cannot be ignored.[4] The present result suggests that such a reverse reaction becomes important only below 300 Torr in hydrogen. Unfortunately, the present method cannot be applied to low pressures, since the amount of hydrogen atoms produced by pulse irradiation is proportional to the total pressure and the concentration obtained below 300 Torr is too small for decay measurement.

Figures 6 and 7 show the decay rates of H and D-atoms as functions of the pressure of acetylene-d_0 and

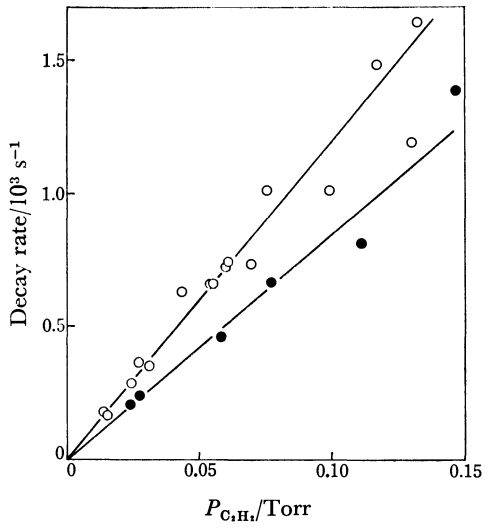

Fig. 6. The decay rates of hydrogen (○) and deuterium (●) atoms as a function of the pressure of acetylene-d_0.

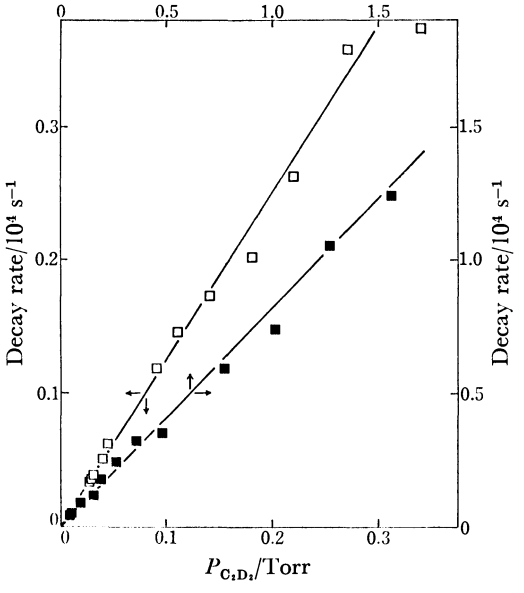

Fig. 7. The decay rates of hydrogen (□) and deuterium (■) atoms as a function of the pressure of acetylene-d_2.

-d_2, where the pressure of hydrogen and deuterium is approximately 750 and 600 Torr respectively. It should be noted here that in the reaction of $D+C_2D_2$, the acetylene-d_2 pressure could be raised to 1.56 Torr, which is approximately 10 times that used in the other three reactions. The absorption coefficient of acetylene-d_2 appears to be very small at the resonance line of D-atoms.

The rate constant for the reaction of hydrogen atoms with acetylene is one order of magnitude smaller than those obtained with olefins. Consequently it was presumed that the vinyl radicals produced in the reaction of hydrogen atoms with acetylene participate in the decay of hydrogen atoms.[1] However, the fact that a linear relationship between the decay rate of D-atoms and the C_2D_2 pressure exists up to 1.56 Torr of acetylene-d_2, suggests that the decay rates observed in the present experiments do correspond to the reactions of H or D-atoms with acetylene-d_0 or -d_2.

Table 2 summarizes the rate constants obtained in the present experiments, and Table 3 compares some previous studies in the reaction of $H+C_2H_2$. Most previous measurements were conducted using the discharge flow system under low pressures, where the reverse reaction, *i.e.*, the decomposition of excited vinyl radicals reproducing hydrogen atoms, may be important. Therefore, the value obtained here must be compared with those obtained by extrapolation to infinite pressure.

In a previous paper,[1] the rate constant in the reaction of $H+C_2H_4$ was reported and compared with previous studies. The value reported by Payne and Stief was in very good agreement with that of the present authors. The value for $H+C_2H_2$ obtained by Payne and Stief however, was less than a half. No proper interpretation for this discrepancy has been found.

Reaction with 1,3-Butadiene. The rate constants of hydrogen and deuterium atoms with 1,3-butadiene at room temperature were measured by an analogous method. The hydrogen pressure was 500 to 600 Torr and the 1,3-butadiene pressure from 0.02 to 0.09 Torr. The decay rates of hydrogen and deuterium atoms were found to be linearly proportional to the pressure of 1,3-butadiene. The rate constants obtained were as follows (units of cm³ molecule⁻¹ s⁻¹):

$$k(\mathrm{H}+1,3\text{-butadiene}) = (8.5\pm1.5)\times10^{-12}$$

$$k(\mathrm{D}+1\text{-}3\text{-butadiene}) = (7.5\pm0.6)\times10^{-12}$$

These results are in fair agreement with those reported by Daby *et al.*, $(8.3\pm1.1)\times10^{-12}$ for the reaction of H +1,3-butadiene and $(5.3\pm1.1)\times10^{-12}$ for D+1,3-butadiene.[5] Daby *et al.* used a discharge flow system combined with a mass spectrometer. This agreement suggests that vibrationally excited radicals formed by the addition reaction do not release a hydrogen atom under low total pressure.

The Thermal Gas-phase Decomposition of Vinyl Bromide

Ko SAITO,* Teiji YOKUBO, Tohru FUSE, Hiroyuki TAHARA, Osamu KONDO, Tetsuo HIGASHIHARA, and Ichiro MURAKAMI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Senda-machi, Hiroshima 730

(Received June 1, 1979)

The thermal gas-phase decomposition of vinyl bromide in Ar has been studied behind reflected shock waves over the temperature range between 1300 and 2000 K and the density range of $5.2\times10^{-6}-3.8\times10^{-5}$ mol cm^{-3} by monitoring the UV absorption of C_2H_3Br and the IR emission of HBr. The decomposition proceeds *via* the molecular elimination of HBr, and the unimolecular process is in the low-pressure region under the present experimental conditions. The low-pressure-limit rate constant was obtained as

$$k_{2nd} = 10^{13.98\pm0.21}\exp\{-(41.5\pm1.6\text{ kcal mol}^{-1})/RT\}\text{ cm}^3\text{ mol}^{-1}\text{ s}^{-1}.$$

The collision efficiency factor, β_c, was obtained as about 2×10^{-4}, considerably lower than that of vinyl chloride.

The thermal decomposition of vinyl fluoride was investigated in a single-pulse shock tube over the temperature range of 1174—1353 K.[1] The reaction proceeded *via* HF elimination, and the unimolecular process was in the high-pressure region in the total density range of $(3.7—4.8)\times10^{-5}$ mol cm^{-3}. The decomposition of vinyl chloride was measured by means of a time-resolved UV absorption method behind reflected shock waves over the range of 1350—1900 K.[2] The reaction proceeded *via* HCl elimination and was in the fall-off region in the density range between 7×10^{-7} and 1.6×10^{-3} mol cm^{-3}.

In the case of vinyl bromide, the following two channels are probable for the initiation reaction:

$$C_2H_3Br(+M) \longrightarrow C_2H_2 + HBr(+M)$$
$$\Delta H^\circ_{r298} = 26.5\text{ kcal mol}^{-1} \quad (1)$$

$$C_2H_3Br(+M) \longrightarrow C_2H_3 + Br(+M)$$
$$\Delta H^\circ_{r298} = 76.7\text{ kcal mol}^{-1}. \quad (2)$$

From the large difference in the heat of reaction, Reaction 1 seems preferable for the initiation reaction, although its preexponential factor is relatively small because of the four-center reaction. An estimation based on the semiempirical method of Benson and Haugen[3] suggests that the HBr elimination is much faster than the C–Br bond fission. However, it is not certain whether or not all alkenyl halides decompose *via* molecular elimination, since the difference in the heat of reaction between the two channels becomes small as the halogen changes from F to Br. Thus, at high temperatures, the simple bond fission becomes important as the initiation reaction.

In this work, we measured the concentration profiles of the reactant and HBr produced in order to determine the overall decomposition rate of C_2H_3Br and the production rate of HBr.

Experimental

The experiments were performed in a shock tube made of stainless steel (SUS-304). The test section was 4.52 m long and 9.4 cm in inner diameter, and it was evacuated to less than 5×10^{-6} Torr (1 Torr = 133.322 Pa) by means of a 6-inch oil-diffusion pump. The leak and outgassing rate of this section in the stage just before the run was about 2×10^{-7} Torr l/s. The driver section (1.8 m long and 8.5 cm in inner diameter) was evacuated to about 1×10^{-2} Torr. Hydrogen was used as the driver gas at pressures of 2—6 atm (1 atm = 101325 Pa). Tetoron sheets of 100, 75, 50, and 25 μm were used as diaphragms to separate the two sections. Shock waves were generated by bursting the diaphragm with a needle driven by a solenoid.

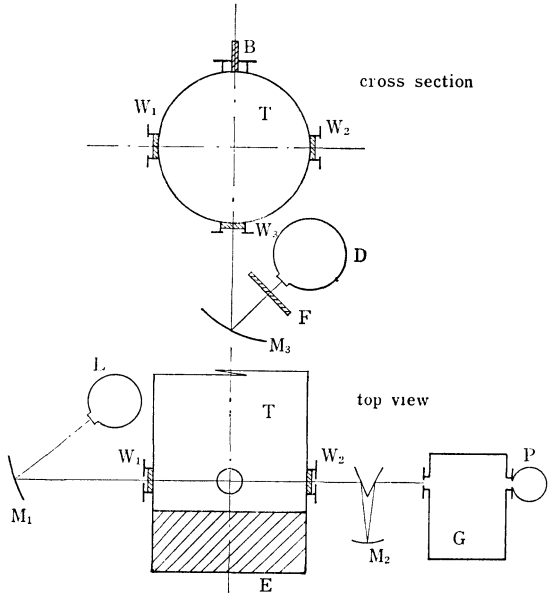

Fig. 1. Experimental arrangement. T: Shock tube, E: end plate, B: pressure gauge, L: deuterium lamp, G: grating monochromator, P: photomultiplier, M_1—M_3: concave mirrors, F: filter, D: InSb detector, W_1: quartz window, W_2 and W_3: CaF_2 windows.

At a distance of 4.44 m from the diaphragm, two sets of windows were mounted in the tube in order to observe the physical properties of the shocked gas. Figure 1 shows the experimental arragement for the absorption and emission experiments. Light from a deuterium lamp (HTV, L544) was focussed on the center of the tube through an inlet slit (4 mm wide and 8 mm high), and the light from an outlet slit (2 mm wide and 8 mm high) was focussed again on the entrance slit (1 mm wide) of a monochromator (Jarrell-Ash, 0.25 M). The average width of the light beam in the tube was 3 mm, while the hight was 8 mm. The light passed through the exit slit (1 mm wide) of the monochromator was detected by a photomultiplier (HTV, R106UH) supplied with a voltage of −800 V. The output signal was fed into a pre-amplifier (IWATSU, DA-2A) and then to a wave-memory (Kawasaki Electronica, M-50E), which was connected to an

oscilloscope and a pen-recorder. The response time of the optical-electrical system was less than 10 μs enough for the present study. The IR emission was detected by an InSb photo-voltaic element (HTV, P839A) at 77 K through a filter of 3.9 ± 0.05 μm. The signal-recording system was the same as in the absorption experiment. The response time of this system was about 10 μs. Measurements of the incident shock velocity were performed by counting the time intervals of shock-arrival signals between two pressure gauges mounted on the walls, 32 cm apart from each other, with a universal counter (Takeda Riken, TR-5104G) having an accuracy of 0.1 μs. The attenuation in the shock velocities was estimated to be less than 1% per meter of travel. The measured incident shock velocities were then used to compute the non-reaction conditions behind the reflected shock.

Liquid C_2H_3Br (99.5% stated minimum purity) was purified by trap-to-trap distillations. Ar (99.998%) was used as the diluent, without any further purification. Several mixture (0.03—3.0 mol% C_2H_3Br in Ar) were prepared in a 30-l glass flask. They were allowed to stand for more than 12 h before use.

Results

The experiments were performed behind reflected shock waves over the temperature range between 1300 and 2000 K and the density range of 5.2×10^{-6}—3.8×10^{-5} mol cm^{-3}. Vinyl bromide has an absorption spectrum in the vacuum ultraviolet region with a maximum at 52200 cm^{-1}.[4] At the high temperatures available in shock waves, the absorption may be detected at higher wavelengths. In this work, the absorption experiment was performed at 250 nm with FWHM= 1.7 nm. The absorption coefficient at this wavelength was in the range of $(1—2)\times10^5$ cm^2 mol^{-1} over the temperature range studied, and Lambert-Beer's law was ascertained to hold. Figure 2 shows typical UV absorption (a) and IR emission (b) profiles obtained simultaneously in one experimental run. The absorption profile clearly reveals a decay of the reactant with the time, and the emission profile shows an increase of a product immediately behind the reflected shock front. The polyacetylenes which may be produced in the later part of the reaction have an absorption at this wavelength.[5] However, it is likely that at low temperatures the decay curve does not involve the absorption of products. At high temperatures the effect of the products was seen as a very slow increase in the absorption after a large consumption of the reactant. The decay rate of the reactant was first-order in $[C_2H_3Br]$ up to at least 25% decrease in the reactant. Thus, the first-order rate constant, k_{1st}, was obtained by means of this definition: $k_{1st}=-\mathrm{d}(\ln D)/\mathrm{d}t$, where $D=[C_2H_3Br]\times\varepsilon\times L$, ε=absorption coefficient, and L= inner diameter of the shock tube. Figure 3 shows an

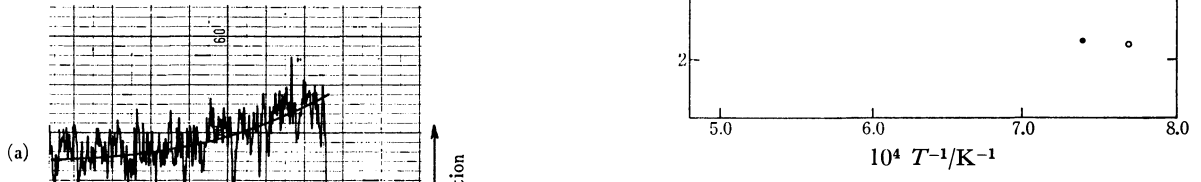

Fig. 2. Typical absorption and emission record in the same experimental run. 1.5 mol % C_2H_3Br in Ar, Temperature=1430 K, Pressure=2.10 atm, $k_{1st}=7.78\times10^2$ s^{-1}, $k_{ir}=2.75\times10^3$ s^{-1}.

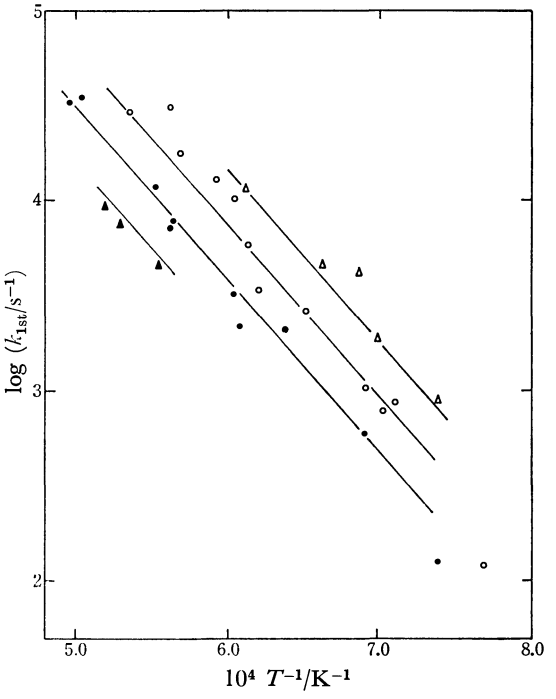

Fig. 3. Arrhenius plot of the first order rate constant k_{1st}. Total density (mol cm^{-3}): ▲$=5.2\times10^{-6}$, ●$=1.0\times10^{-5}$, ○$=1.9\times10^{-5}$, △$=3.6\times10^{-5}$. Straight lines denote the precise change of k_{1st} with the density (relative) assuming that k_{1st} is proportional to the total density.

Arrhenius plot of k_{1st} for four different total densities. It appears that the first-order rate constant depends on the total density and that the data corresponding to each constant density are parallel to, but apart from, each other because of the density change. Thus, the apparent decomposition rate is expressed as

$$-\mathrm{d}[C_2H_3Br]/\mathrm{d}t = k_{2nd}[C_2H_3Br][M].$$

Figure 4 shows an Arrhenius plot of the second-order rate constant, k_{2nd}. The best-fitting line gives an Arrhenius expression as

$$k_{2nd}=10^{13.98\pm0.21}\exp\{-(41.5\pm1.6\ \mathrm{kcal\ mol^{-1}})/RT\}\ \mathrm{cm^3\ mol^{-1}\ s^{-1}},$$

where the error limits denote the standard deviations.

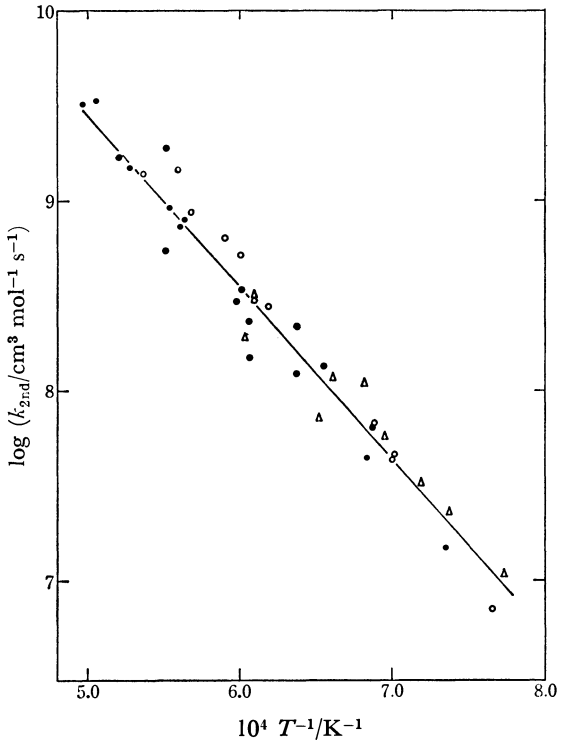

Fig. 4. Arrhenius plot of the second order rate constant. Straight line is the least square evaluation.

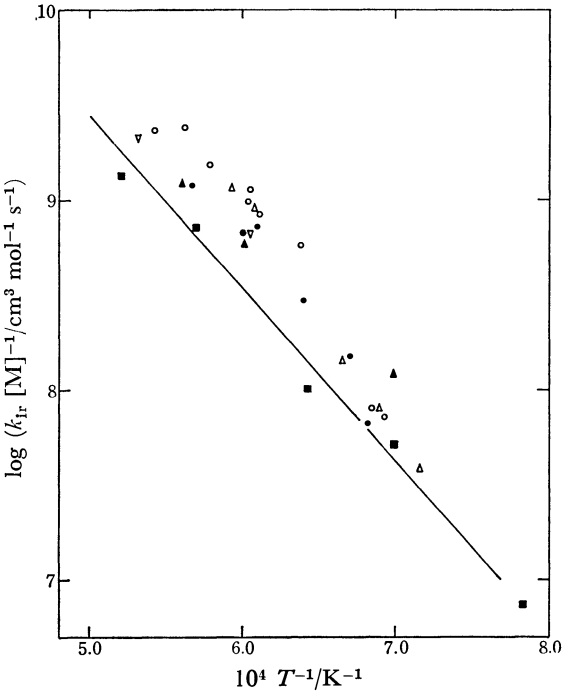

Fig. 5. Arrhenius plot of the second order rate constant k_{1r}/[M] obtained from IR profiles. ▽=3.0%, ▲=1.5 %, ○=0.5%, △=0.25%, ●=0.1%, ■=0.03%. Straight line denotes the least square evaluation of k_{2nd} shown in Fig. 4.

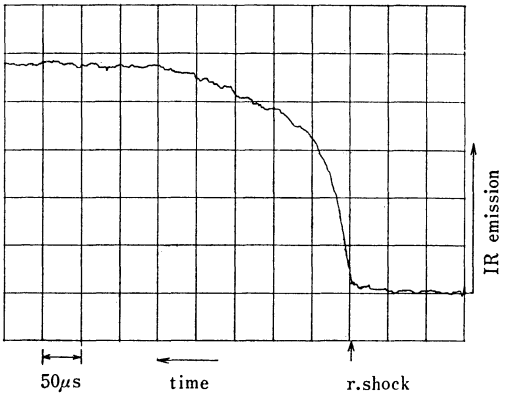

Fig. 6. Typical IR emission profile for the mixture of 0.03% C_2H_3Br in Ar. Temperature=1760 K, total density=1.99×10^{-5} mol cm^{-3}, k_{1r}/[M]=7.2×10^8 cm^3 mol^{-1} s^{-1}.

The IR emission intensity at 3.9 μm is assumed to be proportional to the HBr concentration, since, at this wavelength, there exists no emission by possible products other than HBr. If HBr is produced only by Reaction 1 and does not react subsequently, the time history of the intensity may be expressed as: $I=I_{t=\infty}\{1-\exp(-k_{1r}t)\}$. At first sight, the emission profile seems to follow the above relation. Figure 5 shows the values of k_{1r}/[M] obtained for the various mixtures studied. It may be seen from Fig. 4 that the values of k_{1r}/[M] for mixtures of 0.1—3.0 mol % C_2H_3Br are somewhat larger than those of k_{2nd} (straight line), especially at high temperatures. This implies that, at the later part of the reaction, the dissociation of HBr by secondary reactions cannot be neglected in these relatively high concentration mixtures. That is, the concentration of HBr, $[HBr]_t$, cannot be described by the simple relation: $[HBr]_t=[C_2H_3Br]_0-[C_2H_3Br]_t$ when there is much decomposition. Thus, in order to control the secondary reactions, further experiments were performed for a highly diluted mixture (0.03 mol % C_2H_3Br in Ar). In these additional experiments, the apparatus for the IR observation was modified so as to detect a weak emission. That is, the emission intensity was increased by setting a concave mirror on the opposite side of the tube so as to focus the light on the slit at the detecting side. The emission profile for this mixture is shown in Fig. 6, which is essentially the same as those for the high C_2H_3Br mixtures (Fig. 2(b)). The values of k_{1r}/[M] were obtained again for this series, as plotted in Fig. 5, they show a good agreement with the absorption data (straight line). This suggests that, in highly diluted mixtures such as $[C_2H_3Br]/[Ar]\simeq3\times10^{-4}$, the consumption of HBr by the secondary reactions is negligibly small, even after long reaction times.

Discussion

The initial decomposition rate of vinyl bromide was expressed as first-order in $[C_2H_3Br]$ and first-order in the total density. From the absorption profile, it seems that the decomposition of C_2H_3Br is not so complicated as the chain process, even for mixtures involving a relatively high C_2H_3Br concentration. Also, the fact that the initial rate of the C_2H_3Br consumption is just equal to the HBr production rate for the highly diluted

mixture means that the decomposition at the early stage of the reaction occurs *via* a simple reaction. Thus, the following discussion will be made on the basis of the assumption that the decomposition rate constant, k_{2nd}, corresponds to the unimolecular low-pressure-limit rate constant of the primary reaction.

According to the Arrhenius parameters of k_{2nd}, the value of the preexponential factor is somewhat low if the initial process is a single-bond fission, in this respect, the activation energy is much lower than the bond dissociation energy of C–Br, which is the weakest bond in this molecule. This discrepancy (about 35 kcal mol^{-1}) between the activation energy and the bond dissociation energy is too large to be explained by the lower-limit unimolecular process of Reaction 2. If Reaction 2 is the main initiation step, a sequence of rapid consecutive reactions may be expected to occur:

$$C_2H_3(+M) \longrightarrow C_2H_2 + H(+M) \quad (3)$$

$$C_2H_3Br + H \longrightarrow C_2H_3 + HBr \quad (4)$$

$$C_2H_3Br + Br \longrightarrow C_2H_2Br + HBr \quad (5)$$

$$C_2H_2Br(+M) \longrightarrow C_2H_2 + Br(+M). \quad (6)$$

These consecutive reactions would compose a chain cycle and would give rise to an acceleration of the vinyl bromide consumption as the reaction proceeded. In some experiments, such an acceleration was observed in the absorption and emission records at long reaction times and at low temperatures. However, in such cases no unique correlation of the acceleration with the C_2H_3Br concentration could be detected. Therefore, although the possibility of the above reaction scheme (Reactions 2—6) cannot be rejected completely, from the fact that the decomposition rate constant, k_{2nd}, is not changed by the variation in the mixture composition the contribution of the above reactions to the initial decomposition rate may be considered to be negligible under the present conditions. Thus, Reaction 2 is not important as the initiation step.

For Reaction 1 an activation energy much higher than ΔH_r may be expected, as is the case for other well-known four-center reactions. In this case, possible subsequent reactions are the decompositions of acetylene and hydrogen bromide. The unimolecular dissociation of HBr below 2000 K is negligibly small,[6] though, and thus it is not important as the secondary reaction. The decomposition of acetylene has a very high activation energy (124 kcal mol^{-1}),[7] therefore, the effect of the C_2H_2 decomposition is also negligible.

A theoretical calculation of the low-pressure-limit rate constant was performed by using a refinement of the equation of the RRKM theory presented by Troe[8] (Eq. 2.11 in Ref. 8). The molecular constants of C_2H_3Br were taken from Ref. 9, while the parameters appearing in the equation were calculated as in Ref. 10. To obtain the threshold energy, E_0, of the initiation reaction, we first assumed that the collision efficiency, β_c, was constant regardless of the temperature. Thus, we obtained $E_0=55.5$ kcal mol^{-1} when $\beta_c=1.6\times10^{-4}$. This value is the lower limit of E_0, because β_c has a slightly negative temperature dependence.[11] An estimate for the reverse reaction of Reaction 1 according to the semiempirical method by Benson and Haugen[3] leads to 59.5 kcal mol^{-1} for the high-pressure activation energy, $E_{a\infty}$, of Reaction 1 at 1600 K, the middle temperature of the present experiment. Thus, the value of E_0 (55.5 kcal mol^{-1}) obtained as the lower limit seems to be reasonable compared with the value of $E_{a\infty}$. By using this relation: $E_{a0}=E_{a\infty}-(S_{eff}+0.5)RT$, E_{a0} is calculated to be 41.0 kcal mol^{-1} at 1600 K, where S_{eff}, the number of the effective vibration, is 6.31 at 1600 K. This value of E_{a0} is very close to the experimentally obtained activation energy (41.5 kcal mol^{-1}).

The value of β_c (1.6×10^{-4}) is unexpectedly low compared with that of vinyl chloride ($\beta_c=0.04$).[2] It is recongnized that the unimolecular process of vinyl halides tends toward the low-pressure region as the halogen changes from F to Br under similar conditions, as has been shown by previous experiments[1,2] and also in this work. The fact that the decomposition process of C_2H_3Br is in the low-pressure region is probably the result of the low efficiency of the energy transfer per collision. Nevertheless, at the present time, we cannot explain why, for the C_2H_3Br decomposition, the collision efficiency is extremely small compared with similar reactions.

Pressure and Solvent Shifts of Charge Transfer Absorption Band of Iodine Complexes

Seiji SAWAMURA, Yoshihiro TANIGUCHI, and Keizo SUZUKI*

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received June 6, 1979)

Absorption spectra of the CT band of I_2 complexes were observed in several nonpolar solvents at 1 bar, and in heptane up to 4400 bar. All solvent shifts were red with an increase in $(n^2-1)/(2n^2+1)$, the refractive index (n) function of solvents, consistent with the solvent shift theory. On the other hand pressure caused a variety of shifts, that is, red shifts in benzene–, toluene–, and mesitylene–I_2 complexes, an inversion shift from red to blue in HMB–I_2 complex, and blue shifts in Et_3N–, n-Pr_3N–, and n-Bu_3N–I_2 complexes, though increase in pressure invariably raises the $(n^2-1)/(2n^2+1)$ value of solvent. The pressure shifts of I_2 complexes seem to be interpreted by a sum of two effects. One is the increased polarity of the solvent, which causes a red shift. The other is the decrease in the bond distance between a donor and an acceptor, which contributes to a blue shift in a strong CT complex and to a red shift in a week one. The pressure and solvent shifts of I_2 complexes were compared with those of π-donor–TCNE complexes.

Recently, we found the pressure shifts of charge transfer (CT) absorption band of n-donor (diethyl sulfide (Et_2S) and diethyl selenide (Et_2Se))–iodine (I_2) complexes in heptane, changing from red to blue at *ca.* 2500 bar.[1] Such an inversion shift is known only in the π-π complex between hexamethylbenzene (HMB) and tetracyanoethylene (TCNE).[2-4] The other CT bands of π-π complexes[2-5] and π-donor–I_2 complexes[6,7] in solution shifted only to red.

In the present work we have found blue shifts of well-defined CT band of amine–I_2 complexes in heptane. In polymer matrix the blue shift of CT band was reported by Offen and Nakashima[8] in two π-π complexes between *trans*-stilbene and phenanthrene as donors and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) as an acceptor. However, it seems to be obscured by a strong overlap with another absorption band.

The red shift of CT band has been interpreted by an increase in the polarity of the solvent with increase in pressure.[6,9,10] Two different interpretations have been proposed for the blue shift: (1) Offen and Nakashima[8] tried to explain the blue shift of DDQ complexes by a decrease in the bond distance between a donor and an acceptor. (2) Nakayama *et al.*[4] ascribed the blue shift of HMB–TCNE complex to an increase in the polarity of solvent caused by pressure, the relevance of the interpretation being examined by a comparison of the pressure shift of CT band with the solvent shift.

In the present work we measured the pressure shifts of CT bands of I_2 complexes with several π- and n-donors up to 4400 bar. In order to interpret them, the observed pressure shifts, red, red to blue, or blue, were compared with the solvent shifts.

Experimental

I_2 was sublimed from a mixture of I_2, calcium oxide, and potassium iodide, and then was done under nitrogen atmosphere. TCNE was sublimed under reduced pressure (10 mmHg). The purification of diethyl ether (Et_2O), Et_2S, and Et_2Se was reported.[1] HMB was recrystallized twice from ethanol. Triethylamine (Et_3N), tripropylamine (n-Pr_3N), and tributylamine (n-Bu_3N) were shaken with acetic anhydride, dried over potassium hydroxide and sodium metal successively, and distilled over sodium metal (under reduced pressure for the last two amines, 34—36 °C/6 mmHg and 51—52 °C/2 mmHg, respectively). The other donors (benzene, toluene, and mesitylene) and the solvents (pentane, heptane, cyclohexane, carbon tetrachloride, decalin, and carbon disulfide) were purified by the usual method.[11] The method of measuring the absorption spectra under high pressure was reported[1]

Results

Solvent Shift. The dielectric constant or refractive index (n) of solvent has been often used as a measure of the property of solvent for interpretation of the solvent shift of the electronic spectrum. Theories given by Ooshika[12] and McRae[13] on solvent shift predicted that the wavenumber at absorption maximum ($\bar{\nu}_{max}$) of electronic spectrum depends linearly on the value of $(n^2-1)/(2n^2+1)$ of nonpolar solvents. The linear relation between $\bar{\nu}_{max}$ of CT band and $(n^2-1)/(2n^2+1)$ has been reported for several π-donor–TCNE[14,15] and π-donor–I_2[6] complexes. Pressure shifts to red in the latter complexes were interpreted by Ham[6] in comparison with the solvent shifts using the function of $(n^2-1)/(2n^2+1)$.

The $\bar{\nu}_{max}$ values of I_2 complexes in several nonpolar solvents at 1 bar are plotted as a function of $(n^2-1)/(2n^2+1)$ of solvents, including that of HMB–TCNE complex, in Figs. 1 and 2. All CT bands shift linearly to red with increase in the $(n^2-1)/(2n^2+1)$ values of solvents. The red shift in HMB–TCNE complex observed by Voigt[14] was confirmed. The $\bar{\nu}_{max}$ values of mesitylene–, and Et_2S–I_2 complexes in gaseous state fit the lines. The values of the slopes (Figs. 1 and 2) are given in Table 1 as C_{solv}, together with the data of π-donor–TCNE complexes. For the I_2 complexes with a series of π-donors (Table 1-A) the values of C_{solv} increase with an increase in the bond energy ($-\Delta H$). A similar trend is seen for n-donor–I_2 and π-donor–TCNE (Table 1-B and C, respectively) but not so marked in the latter.

Pressure Shift. Absorption spectra of the CT band of n-Bu_3N–I_2 complex under various pressures are shown in Fig. 3. The absorption maximum shifts toward blue with increase in pressure. Similar well-defined

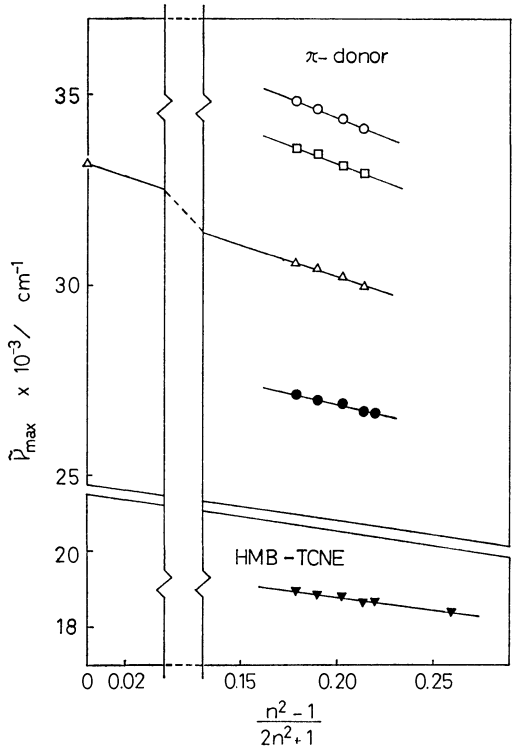

Fig. 1. Solvent shifts on CT absorption maxima of the I_2 complexes with π-donors, including HMB–TCNE complex. Donors are, ○: benzene, □: toluene, △: mesitylene, and ●: HMB in I_2 complexes. Solvents are pentane ($(n^2-1)/(2n^2+1)=0.179$), heptane (0.190), cyclohexane (0.203), carbon tetrachloride (0.214), decalin (0.220), and carbon disulfide (0.261), adding the data in gaseous state (0.000) of Ref. 16 for mesitylene–I_2 complex. The values of n of solvents were cited from Ref. 11.

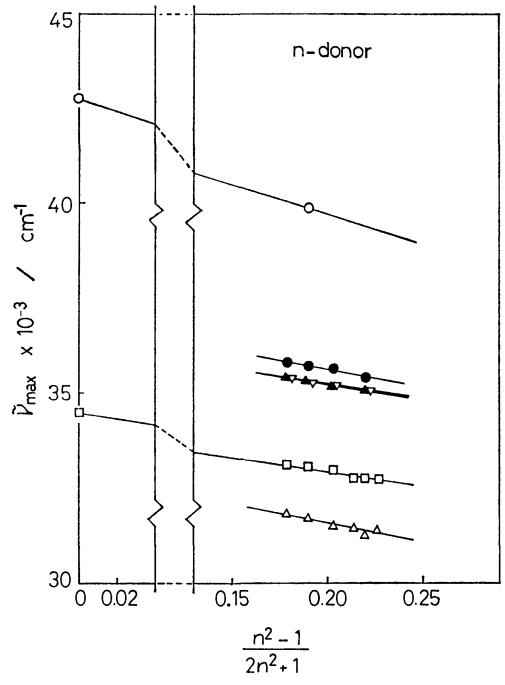

Fig. 2. Solvent shifts on CT absorption maxima of the I_2 complexes with n-donors. Donors are, ○: Et_2O, □: Et_2S, △: Et_2Se, ●: Et_3N, ▲: n-Pr_3N, and ▽: n-Bu_3N. Solvents are the same as Fig. 1, adding benzene (0.227) instead of carbon disulfide. Gaseous data for Et_2O– and Et_2S–I_2 complexes are cited from Refs. 16 and 17, respectively.

absorption spectra were also observed in Et_3N– and n-Pr_3N–I_2 complexes, causing blue shifts.

Figures 4 and 5 show the pressure shifts of absorption maxima of several I_2 complexes as a function of $(n^2-1)/(2n^2+1)$ of heptane. Various pressure shifts were observed: red shifts in benzene–, toluene–, mesitylene–, and Et_2O–I_2 complexes, inversion shifts from red to blue in HMB–, Et_2S–, and Et_2Se–I_2 complexes, and blue shifts in Et_3N–, n-Pr_3N–, and n-Bu_3N–I_2 complexes. The values of the initial slope in Figs. 4 and 5 are given in Table 1 as C_{press}, with the values of π-donor–TCNE complexes given by Nakayama *et al.*[4]

In I_2 or TCNE complexes with benzene, toluene, and mesitylene (Table 1), each slope estimated from the pressure shift (C_{press}) is smaller than that estimated from the solvent shift (C_{solv}). The reverse is found in other CT complexes, except in the case of comparable values in Et_2O–I_2 complex. In the series of π-donor–I_2 complexes, C_{press} becomes large accompanied by an increase in the bond energy ($-\Delta H$). A similar relation between C_{press} and $-\Delta H$ is found in n-donor–I_2 complexes and π-donor–TCNE complexes, though less explicit in the former.

Table 1. Slopes of solvent (C_{solv}) and pressure (C_{press}) shift and the bond energy ($-\Delta H$) of several CT bands

Complex	C_{solv} / 10^3 cm^{-1}	C_{press} [a] / 10^3 cm^{-1}	$-\Delta H$ / kJ mol^{-1}
(A) π-Donor–I_2			
Benzene–I_2	−20±2	−29±3	6[b]
Toluene–I_2	−19±2	−24±2	8[c]
Mesitylene–I_2	−16±2	−22±3	12[b]
HMB–I_2	−12±2	−8±2	16[b]
(B) n-Donor–I_2			
Et_2O–I_2	−16±2	−17±4	18[d]

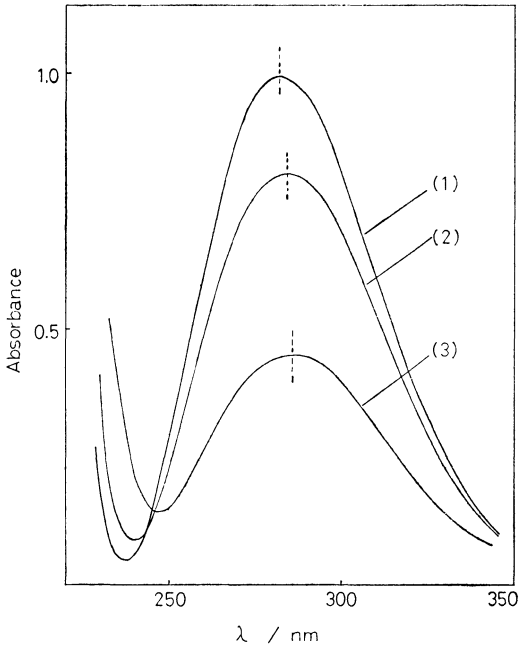

Fig. 3. Absorption spectra of CT band of n-Bu_3N–I_2 complex in heptane. n-Bu_3N: 5×10^{-4} mol dm^{-3}, I_2: 3.5×10^{-5} mol dm^{-3}. (1) 4.4 kbar, (2) 2.2 kbar, (3) 1 bar. Dotted lines show the absorption maxima at each pressure.

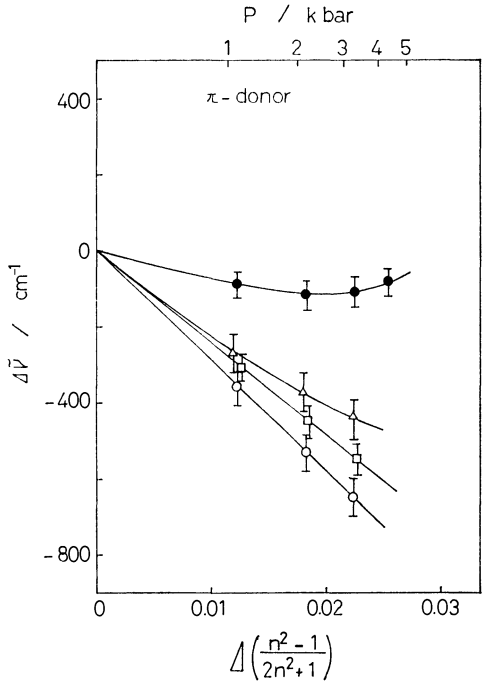

Fig. 4. Pressure shifts of CT absorption maxima of the I_2 complexes with π-donors in heptane. The marks of π-donors are the same as in Fig. 1. $\Delta\bar{\nu}=\bar{\nu}_{max}$ (at P bar) $-\bar{\nu}_{max}$ (at 1 bar). The value of n of heptane under high pressure was cited from the dielectric constant (ε) of heptane in Ref. 25 using the relation of Maxwell ($\varepsilon=n^2$). $\Delta[(n^2-1)/(2n^2+1)]=(n_P^2-1)/(2n_P^2+1)-(n_1^2-1)/(2n_1^2+1)$.

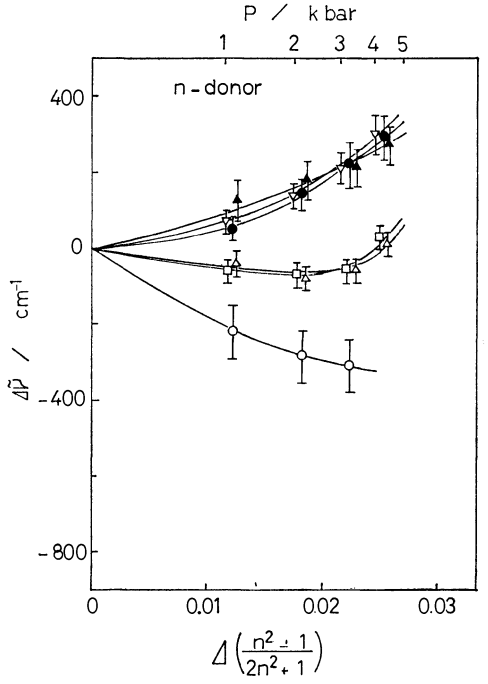

Fig. 5. Pressure shifts of CT absorption maxima of the I_2 complexes with n-donors in heptane. The marks are the same as in Fig. 2. $\Delta\bar{\nu}$ and $\Delta[(n^2-1)/(2n^2+1)]$ are defined in Fig. 4. The data of Et_2O–, Et_2S–, and Et_2Se–I_2 complexes are cited from Ref. 1.

Discussion

Linear red shift of CT bands in Figs. 1 and 2 are in line with the solvent shift theory as in the case of π-donor–TCNE[14,15] and π-donor–I_2[6] complexes. The result that C_{solv} values (Table 1-A, B, and C) increase accompanied by an increase in $-\Delta H$ would be interpreted by the solvent shift theory regarding $-\Delta H$ as a measure of the CT interaction, since the excited state of CT band becomes less polar and the dipole moment of the ground state increases with increasing CT interaction.[26,27]

In Figs. 4 and 5 the values of $(n^2-1)/(2n^2+1)$ of heptane are 0.190 at 1 bar 0.216 at 4400 bar. The values are covered by those in Figs. 1 and 2, *viz.*, 0.179 for pentane to 0.261 for carbon disulfide. If the pressure shifts of CT bands are attributed to only the increasing polarity of solvent, red shifts similar to those given in Figs. 1 and 2 can be expected in Figs. 4 and 5, respectively. In HMB–, Et_2S–, and Et_2Se–I_2 complexes, however, the observed inversion shifts differ from the expected ones, the blue shifts of Et_3N–, n-Pr_3N–, and n-Bu_3N–I_2 complexes (Fig. 5) being a striking contrast to the red shifts (Fig. 2). The solvent shift of HMB–TCNE complex (Fig. 1) is not in line with the inversion shift caused by increase in pressure. Though the increasing polarity of the solvent caused by compression may contribute to a red shift, another effect causing a blue shift should participate in at least HMB–, Et_2S–, Et_2Se–, Et_3N–, n-Pr_3N–, and n-Bu_3N–I_2 complexes, and HMB–TCNE complex.

As a plausible effect causing a blue shift, a decrease

in the bond distance (R_{DA}) between a donor and an acceptor proposed by Offen and Nakashima[8] may be taken into account. The effect is interpreted by means of the Mulliken's equation[27] for the CT transition energy $hc\tilde{\nu}_{CT}$:

$$hc\tilde{\nu}_{CT} = \frac{\sqrt{4\beta_0\beta_1+\Delta^2}}{1-S_{01}^2} \quad (1)$$

$$\beta_0 = W_{01} - W_0S_{01}$$
$$\beta_1 = W_{01} - W_1S_{01} \quad (2)$$
$$\Delta = W_1 - W_0$$

where W_0 and W_1 are the energy of no-bond and dative structure, respectively, and W_{01} is the interaction matrix which is approximately proportional to the overlap integral S_{01}. $|\beta_0|$ and $|\beta_1|$ increase with increase in S_{01}. When R_{DA} decreases by compression, S_{01} increases and so $\beta_0\beta_1$ does. Δ is the energy accompanied by the transfer of an electron from a donor to an acceptor. It is approximately expressed as follows, decreasing with reduction in R_{DA}.

$$\Delta \approx I_D - E_A - \frac{e^2}{R_{DA}} \quad (3)$$

where I_D is the ionization potential of a donor, E_A the electron affinity of an acceptor, and e the charge of an electron. The denominator $(1-S_{01}^2)$ and the first term in the square root $(4\beta_0\beta_1)$ in Eq. 1 might contribute to a blue shift and the second term in the square root (Δ^2) to a red shift with increasing pressure, the shifts overlapping the red shift caused by an increase in the polarity of the solvent.

Table 2. Reasonable values of $4\beta_0\beta_1$ and Δ^2 for I_2 complexes

Complex	$4\beta_0\beta_1$[a] / eV^2	Δ^2 / eV^2
Et_3N–I_2[b]	12—42	0—1
Benzene–I_2[c]	1—7	13—21

a) $4\beta_0\beta_1 = 4\beta_0(\beta_0 - \Delta S_{01})$, deduced from Eq. 2. b) Mulliken's "Reasonable Values"[28] are $S_{01}=0.4$—0.5, $(I_D-\Delta)=6.5$—7.5 eV, and $-\beta_0=1.7$—3 eV. $I_D=7.50$ eV.[29] c) Mulliken's "Reasonable Values"[28] are $S_{01}=0$—0.15, $(I_D-\Delta)=4.7$—5.7 eV, and $-\beta_0=0.5$—1.0 eV. $I_D=9.24$ eV.[30]

In a strong CT complex of a large $-\Delta H$ value such as Et_3N–I_2 complex, the value of $4\beta_0\beta_1$ should be large as compared with Δ^2 in view of the CT theory.[27] The reverse holds for a weak CT complex such as benzene–I_2. The values of $4\beta_0\beta_1$ and Δ^2 given in Table 2 are roughly estimated from the values of I_D and Mulliken's "Reasonable Values" for S_{01}, $I_D-\Delta$, and β_0 of the I_2 complexes from Eq. 2. In Et_3N–I_2 complex Δ^2 is negligible as compared with $4\beta_0\beta_1$. Thus in a strong CT complex the contribution to a blue shift by the term of $4\beta_0\beta_1$ with reducing R_{DA} is expected to be effective. The observed blue shift may be attributed to this effect. On the other hand, in a weak CT complex a decrease in R_{DA} may contribute to a red shift since $4\beta_0\beta_1$ is small or negligible as compared with Δ^2. The excessive red shift caused by pressure as compared with the solvent shift in I_2 or TCNE complexes with benzene, toluene, and mesitylene, may be due to such a contribution of Δ^2.

In conclusion, the observed pressure shifts of CT bands could be interpreted by a sum of two effects, the increased polarity of the solvent causing a red shift, and the decrease in R_{DA} contributing to a blue shift in a strong CT complex and to a red shift in a weak one.

We wish to thank Mr. Hisashi Mizuno for his assistance in the experiments.

Molecular Force Field of Dialkyl Selenides

Hiroatsu MATSUURA* and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 14, 1979)

The molecular force field in terms of the local symmetry coordinates was determined for unbranched dialkyl selenides. Twenty-six important force constants associated with the selenium part were adjusted by using about two hundred observed vibrational wave numbers for a total of twelve conformational isomers of ethyl methyl selenide, diethyl selenide, methyl propyl selenide, butyl methyl selenide, and ethyl propyl selenide. Remaining force constants of the selenides were assumed to be equivalent to those for unbranched dialkyl sulfides and alkanes. The least-squares calculation gave an overall root-mean-square deviation of 6.7 cm^{-1} between the observed and calculated wave numbers. The force constants and the results of the normal coordinate treatment are given in this paper.

The molecular force field of molecules is fundamentally important for studying various problems in chemistry and physics. To establish the force field, vibrational spectra have been extensively investigated for a number of compounds. The force constants deduced from the experimental data were, however, reliable only, in general, for relatively small molecules. To conquer the difficulty in determining the molecular force field of larger molecules, various attempts have been made.[1-4] One of the approaches is to assume the transferability of the force constants for similar atomic groups in different molecules.[5] This assumption allows ones to reduce the number of force constants to determine. In this model, the symmetry coordinates in each of the atomic groups, namely the local symmetry coordinates, are used to express the molecular force field, as most of organic molecules, which we are interested in, give characteristic group vibrations.

Recent systematic studies[6-15] on the vibrational spectra of unbranched organic compounds made possible to determine the force constants, in terms of the local symmetry force field, for alkanes, dialkyl ethers, dialkyl sulfides, halogenoalkanes, and alkylsilanes.[16,17] In the present study, the molecular force field of unbranched dialkyl selenides was treated by utilizing the experimental data which have been accumulated in our laboratory.[18] The force constants thus obtained are reported in this paper and are discussed in comparison with those for related compounds. A preliminary result of the normal coordinate treatment has been reported previously.[19]

Calculation of Normal Coordinates

The calculation of the normal coordinates for unbranched dialkyl selenides was carried out by a program system MVIB[20] with a HITAC 8700 computing system at Hiroshima University. The force field adopted in the MVIB system is the local symmetry force field which has been successfully applied to a number of unbranched organic compounds.[16,17]

Initial values of the force constants for the selenium part and for the alkyl parts next to the selenium atom were transferred or estimated from the results for the sulfides.[16] The force constants for the unbranched alkyl part, not directly associated with the selenium atom, were the same as those obtained for the alkanes.[16] Some of the important force constants for the selenium and neighboring parts were adjusted by a least-squares procedure by utilizing the observed vibrational wave numbers for the *trans* and *gauche* isomers of ethyl methyl selenide $CH_3SeCH_2CH_3$, the *trans-trans*, *trans-gauche*, and *gauche-gauche* isomers of diethyl selenide $CH_3CH_2SeCH_2CH_3$, and the *trans-trans*, *trans-gauche*, *gauche-trans*, and *gauche-gauche* isomers of methyl propyl selenide $CH_3SeCH_2CH_2CH_3$.[18]

The force field thus obtained was applied to butyl methyl selenide $CH_3SeCH_2CH_2CH_2CH_3$ and ethyl propyl selenide $CH_3CH_2SeCH_2CH_2CH_3$ to study the rotational isomerism. The force field was then refined by using the additional observed data for the *gauche-gauche-trans* isomer of butyl methyl selenide and the *gauche-gauche-trans* and *gauche-gauche-gauche* isomers of ethyl propyl selenide,[18] which have been shown to exist in the solid state.[19] At the final stage of the calculation, twenty-six important force constants

TABLE 1. ATOMIC MASSES AND STRUCTURAL PARAMETERS USED IN THE CALCULATION

Property	Quantity
Atomic masses, u	
Hydrogen (H)	1.007825
Carbon (C)	12.011
Selenium (Se)	78.96
Bond lengths, Å	
r(C–H)	1.100[a]
r(C–C)	1.539[a]
r(C–Se)	1.943[b]
Bond angles, degree	
∠(C–C–C)	112.2[a]
∠(C–C–Se)	113.6[c]
∠(C–Se–C)	96.18[b]
∠(C–C–H)	110.4[a]
∠(Se–C–H)	108.8[d]
Dihedral angles of molecular skeleton, degree	
trans conformation	180
gauche$^+$ conformation	60
gauche$^-$ conformation	−60

a) Ref. 16. b) Taken from dimethyl selenide (Ref. 21). c) Assumed to be equal to ∠(C–C–S) (Ref. 16). d) Assumed to be equal to ∠(S–C–H) (Ref. 16). This value is close to an average value, 108.2°, of two unequivalent ∠(Se–C–H) of dimethyl selenide (Ref. 21).

TABLE 2. DEFINITION AND SYMBOLISM OF ATOMIC GROUPS AND LOCAL SYMMETRY COORDINATES

Atomic group		Local symmetry coordinate		
Description	Symbol	Description	Symbol	Definition[a,b]
CH_3–(X)	1	CH_3 symmetrical stretching	1	$(\Delta r_1+\Delta r_2+\Delta r_3)/\sqrt{3}$
		CH_3 symmetrical deformation	2	$a(\Delta\alpha_{23}+\Delta\alpha_{31}+\Delta\alpha_{12})-b(\Delta\beta_1+\Delta\beta_2+\Delta\beta_3)$
		CH_3 degenerate stretching (in-plane)	3	$(2\Delta r_1-\Delta r_2-\Delta r_3)/\sqrt{6}$
		CH_3 degenerate deformation (in-plane)	4	$(2\Delta\alpha_{23}-\Delta\alpha_{31}-\Delta\alpha_{12})/\sqrt{6}$
		CH_3 rocking (in-plane)	5	$(2\Delta\beta_1-\Delta\beta_2-\Delta\beta_3)/\sqrt{6}$
		CH_3 degenerate stretching (out-of-plane)	6	$(\Delta r_2-\Delta r_3)/\sqrt{2}$
		CH_3 degenerate deformation (out-of-plane)	7	$(\Delta\alpha_{31}-\Delta\alpha_{12})/\sqrt{2}$
		CH_3 rocking (out-of-plane)	8	$(\Delta\beta_2-\Delta\beta_3)/\sqrt{2}$
(X)–CH_2–(Y)	2	CH_2 symmetrical stretching	1	$(\Delta r_1+\Delta r_2)/\sqrt{2}$
		CH_2 scissoring	2	$c\Delta\alpha-d(\Delta\beta_{1X}+\Delta\beta_{2X})-e(\Delta\beta_{1Y}+\Delta\beta_{2Y})$
		CH_2 antisymmetrical stretching[c]	3	$(\Delta r_1-\Delta r_2)/\sqrt{2}$
		CH_2 rocking[c]	4	$(\Delta\beta_{1X}-\Delta\beta_{2X}+\Delta\beta_{1Y}-\Delta\beta_{2Y})/2$
		CH_2 wagging[c]	5	$f(\Delta\beta_{1X}+\Delta\beta_{2X})-g(\Delta\beta_{1Y}+\Delta\beta_{2Y})/2$
		CH_2 twisting	6	$(\Delta\beta_{1X}-\Delta\beta_{2X}-\Delta\beta_{1Y}+\Delta\beta_{2Y})/2$
		X–C–Y deformation	D	$h\Delta\gamma-i\Delta\alpha-j(\Delta\beta_{1X}+\Delta\beta_{2X})-k(\Delta\beta_{1Y}+\Delta\beta_{2Y})$
(X)–Se–(Y)	W	X–Se–Y bending	B	$\Delta\gamma$
Skeleton –(X)–(Y)–	—	Stretching	S	Δr_{XY}
		Torsion[d]	T	Δt_{XY}

a) a=0.403003 and b=0.413427 for X=Se. c=0.908651, d=0.211232, e=0.206297, f=0.494055, g=0.505875, h=0.896458, i=0.185032, j=0.203690, and k=0.198931 for X=C and Y=Se. b) *Definition of the internal coordinates of the methyl group.* The hydrogen atoms in the CH_3–(X)–(Y) group are numbered in the following way (Refs. 16 and 22). The hydrogen atom located at the *trans* position relative to Y is numbered as 1. The atoms numbered 2 and 3 are defined in the clockwise direction, viewing the atoms along the bond X–C with the atom X nearer to the observer (see Fig. 1 of Ref. 16). $r_1=r(C\text{–}H_1)$, $r_2=r(C\text{–}H_2)$, $r_3=r(C\text{–}H_3)$, $\alpha_{12}=\angle(H_1\text{–}C\text{–}H_2)$, $\alpha_{23}=\angle(H_2\text{–}C\text{–}H_3)$, $\alpha_{31}=\angle(H_3\text{–}C\text{–}H_1)$, $\beta_1=\angle(H_1\text{–}C\text{–}X)$, $\beta_2=\angle(H_2\text{–}C\text{–}X)$, and $\beta_3=\angle(H_3\text{–}C\text{–}X)$. *Definition of the internal coordinates of the methylene group.* The hydrogen atoms in the (X)–CH_2–(Y) group are numbered in the following way (Ref. 16). Viewing the (X)–CH_2–(Y) group from the direction perpendicular to the HCH plane with the atom X nearer to the observer, the hydrogen atoms located at the ten o'clock and two o'clock positions (or, for example, at the four o'clock and eight o'clock positions, respectively) are numbered as 1 and 2, respectively (see Fig. 1 of Ref. 16). $r_1=r(C\text{–}H_1)$, $r_2=r(C\text{–}H_2)$, $\alpha=\angle(H_1\text{–}C\text{–}H_2)$, $\beta_{1X}=\angle(H_1\text{–}C\text{–}X)$, $\beta_{2X}=\angle(H_2\text{–}C\text{–}X)$, $\beta_{1Y}=\angle(H_1\text{–}C\text{–}Y)$, $\beta_{2Y}=\angle(H_2\text{–}C\text{–}Y)$, and $\gamma=\angle(X\text{–}C\text{–}Y)$. c) The signs of the CH_2 antisymmetrical stretching, rocking, and wagging coordinates of the (Y)–CH_2–(X) group (viewing the atomic group from the direction perpendicular to the HCH plane with the atom Y nearer to the observer) are opposite to those of the corresponding coordinates of the (X)–CH_2–(Y) group (viewing the atomic group with the atom X nearer to the observer) (Refs. 16 and 22). The signs of the other coordinates in this table are invariable with the viewing direction. d) For the definition of the torsional coordinate, see Refs. 22 and 23.

associated with the selenium and neighboring parts were determined from a total of 196 observed wave numbers with non-zero weights for the twelve conformers of the five compounds.

In the normal coordinate calculation, the observed wave numbers in the liquid phase were used, so that the origin of the experimental data for any one isomer is consistent with that for any other.

The atomic masses and structural parameters used in the calculation are listed in Table 1. The structural data for the selenium part were taken from a microwave study on dimethyl selenide.[21]

Local Symmetry Coordinates. The local symmetry coordinates defined in Table 2 were used as basis coordinates in the normal coordinate treatment. The deformation coordinates for the methyl or methylene group were constructed in accordance with the bond angles, given in Table 1, around a central carbon atom, so that the redundant coordinate was properly eliminated from the coordinate system. The definition of the local symmetry coordinates adopted in this study for the methyl and methylene groups is in accord with the conventions recommended by IUPAC.[22] The coordinates for the methyl group with a neighboring carbon atom, CH_3–(C), and the methylene group with neighboring carbon atoms, (C)–CH_2–(C), have been defined previously[16] on the basis of $\angle$(C–C–C) and $\angle$(C–C–H) values given in Table 1.

According to the coordinate definition mentioned above, the signs of the CH_2 antisymmetrical stretching, rocking, and wagging coordinates for the (X)–CH_2–(Y) group are opposite to those of the corresponding coordinates for the (Y)–CH_2–(X) group. The signs of other coordinates given in Table 2 are invariable with the direction of ordering the atomic groups. One must be careful in defining the coordinates, since the signs of the off-diagonal force constants in terms of these coordinates depend directly upon the signs of the coordinates concerned.

Force Constants. The force constants in the local symmetry force field are expressed on the basis of the local symmetry coordinates.[5] In a series of studies on the local symmetry force field,[16,17] force constants have been denoted by symbols, which are suitable for com-

Table 3. Force constants for unbranched dialkyl selenides[a)]

a) Only the force constants with non-zero values are given in this table. Force constants not found in the table have zero values. The atomic-group symbol "4" denotes –Se–. b) Values for the intergroup force constants for the g$^-$ (*gauche*$^-$) conformation are the same as those for the corresponding force constants for the g$^+$ (*gauche*$^+$) conformation, unless they are marked with *. For those marked with *, the absolute values for the g$^+$ and g$^-$ force constants are the same but their signs are opposite to each other. For example, 222W-6D-g$^+$ = −222W-6D-g$^-$. For those force constants marked with †, their signs are reversed if they are defined by ordering the atomic groups in an opposite direction. For example, 012W-84 = −W210-48. c) Units are mdyn Å^{-1} for the diagonal stretching and off-diagonal sretching-stretching constants, mdyn for the off-diagonal stretching-bending constants, and mdyn Å for the diagonal bending, off-diagonal bending-bending, and diagonal torsional constants.

puter input and output, under a systematic nomenclature rule. Details of the force constant symbols have been described previously.[16] Only fundamental aspects are quoted here with some examples for dialkyl selenides. The symbols for dialkyl selenides are found to be analogous to those for dialkyl sulfides or ethers.

The symbol for the intragroup force constant on the diagonal has a general form *abc-d* and that on the off-diagonal *abc-de*, where *a*, *b*, and *c* are symbols for the atomic groups, *b* being the group in question and *a* and *c* the two adjacent groups, and *d* and *e* are symbols for the local symmetry coordinates in question. The symbols for the atomic groups and the local symmetry coordinates applicable to dialkyl selenides are given in Table 2. In cases where the atomic group in question is a terminal group (for example, methyl group), a nonexistent adjacent group is denoted by 0.

The symbols for the intergroup force constant on the diagonal has a general form *fghi-j* and that on the off-diagonal *fghi-jk* or *fghi-jk-l*, where *f*, *g*, *h*, and *i* are symbols for the atomic groups, *g* and *h* being the two groups in question and *f* and *i* their adjacent groups, and *j* and *k* are symbols for the local symmetry coordinates in question. The coordinates *j* and *k* belong, respectively, to the atomic groups *g* and *h*. The symbol *l*, if any, denotes the conformation of the molecular skeleton given by the atomic groups *f*, *g*, *h*, and *i*. Possible symbols for *l* are t (for *trans* conformation), g$^+$ (*gauche*$^+$), g$^-$ (*gauche*$^-$), c (*cis*), s$^+$ (*skew*$^+$), and s$^-$ (*skew*$^-$).

Some examples of the symbols for dialkyl selenides are given below.

01W-2: the diagonal force constant for the CH_3 symmetrical deformation in the CH_3 group of the CH_3Se– part.

22W-46: the off-diagonal force constant for the CH_2 rocking and twisting within the C^bH_2 group of the $-C^aH_2C^bH_2Se$– part.

2W2-SS: the off-diagonal force constant for the C^a–Se stretching and the Se–C^b stretching of the $-C^aH_2SeC^bH_2$– part.

01W2-S: the diagonal force constant for the C^a–Se stretching of the $C^aH_3SeC^bH_2$– part.

12W2-5S: the off-diagonal force constant for the C^bH_2 wagging and the C^b–Se stretching of the $C^aH_3C^bH_2SeC^cH_2$– part.

22W2-SB: the off-diagonal force constant for the C^b–Se stretching and the C^bSeC^c bending of the $-C^aH_2C^bH_2SeC^cH_2$– part.

222W-46-g$^+$: the off-diagonal force constant for the C^bH_2 rocking and the C^cH_2 twisting of the $-C^aH_2C^bH_2C^cH_2Se$– part in the *gauche*$^+$ skeletal conformation.

The coordinates *d*, *e*, *j*, and *k* are defined so that their signs are positive when one views the successive atomic groups from *a* to *c* for the intragroup force constant or from *f* to *i* for the intergroup force constant. It should be noticed that the signs of some of the force constants are reversed if the force constants are defined

by ordering the atomic groups in a different direction. These force constants are indicated in Table 2.

Results of the Normal Coordinate Treatment

The force constants for unbranched dialkyl selenides are given in Table 3. In this table only the force constants with non-zero values are given and force constants not found in the table have zero values. Most of the force constants have been assumed to be equivalent to those for unbranched dialkyl sulfides and alkanes, and only twenty-six important force constants have been determined by a least-squares procedure. Results of the normal coordinate calculation for ethyl methyl selenide, diethyl selenide, and methyl propyl selenide are given in Tables 4—6. In these tables, only the vibrations below 800 cm^{-1}, which are more important in examining the rotational isomerism than those with higher wave numbers, are listed in comparison with the observed ones. Assignments of the vibrations are given on the basis of the calculated potential-energy distributions.

The calculation gave an overall root-mean-square deviation of 6.69 cm^{-1} between the observed wave numbers $\tilde{\nu}_{obsd}$ and the calculated wave numbers $\tilde{\nu}_{calcd}$ for 196 experimental data. Distribution of the wave number differences $\tilde{\nu}_{obsd}-\tilde{\nu}_{calcd}$ is shown in Fig. 1. The result indicates that 134 calculated wave numbers (68% of the total number 196) are within ± 5 cm^{-1} of the observed values and 173 (88%) are within ± 10 cm^{-1}.

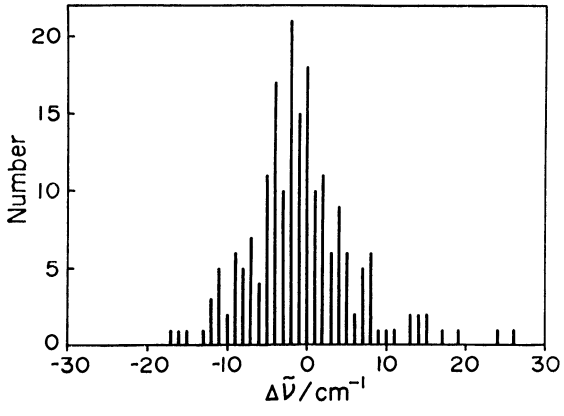

Fig. 1. Distribution of the wave number differences $\Delta\tilde{\nu}=\tilde{\nu}_{obsd}-\tilde{\nu}_{calcd}$ for the unbranched dialkyl selenides.

Discussion

In this study, the local symmetry force field for unbranched dialkyl selenides has been deduced from experimental data for the fundamental selenide molecules. The force constants listed in Table 3 fully cover any dialkyl selenide compound consisting of the following molecular fragments: CH_3CH_2Se–, CH_3SeCH_2–, –CH_2CH_2Se–, and –CH_2SeCH_2–. The present experience in studying the molecular force field indicates that most of the off-diagonal force constants for the dialkyl selenides and the dialkyl sulfides have similar values to each other. Common values have been, in fact, assumed for many constants for these compounds (Table 3). According to the previous[16] and present results, the difference of the force field is more significant between the sulfides and the ethers than between the sulfides and the selenides. This must be related to a closer resemblance of the chemical nature between sulfur and selenium atoms than between sulfur and oxygen atoms.

The diagonal force constants, which have been determined by the least-squares method, show a systematic variation of the values going from the ethers to the sulfides and the selenides. Their values have been compared and discussed in a previous letter.[19]

A comparison is made between the force constants for the dialkyl selenides and the bromoalkanes[24] and between those for the dialkyl sulfides and the chloroalkanes.[24] The methylene deformation diagonal constants (in units of mdyn Å) for the (C)–CH_2–(X) groups are as follows. CH_2 scissoring: 0.549, 0.535, 0.551, and 0.537 for X=Se, Br, S, and Cl, respectively; CH_2 rocking: 0.754, 0.700, 0.804, and 0.756; CH_2 wagging: 0.582, 0.621, 0.607, and 0.662; CH_2 twisting: 0.596, 0.613, 0.626, and 0.649; CCX deformation: 0.891, 0.977, 0.846, and 0.984. These data show that the values for the Group VI and Group VII compounds are not necessarily similar to each other, though the structural parameters and atomic masses are close. It is interesting to note that for the scissoring and rocking constants, the values for Se or S are larger than those for Br or Cl, while for the wagging, twisting, and CCX deformation constants, the values for Br or Cl are larger than those for Se or S. On the other hand, the diagonal C–X stretching force constants are 2.621, 2.609, 2.959, and 2.983 mdyn $Å^{-1}$ for X=Se, Br, S, and Cl, respectively, indicating that the values for Se and Br coincide and those for S and Cl coincide within errors in the values.

The present set of the force constants reproduced about two hundred observed wave numbers for the dialkyl selenides with a root-mean-square deviation of 6.7 cm^{-1}. This accuracy of the normal coordinate calculation is good enough to analyze the observed spectra and to study the rotational isomerism. The distribution of wave number differences $\tilde{\nu}_{obsd}-\tilde{\nu}_{calcd}$ (Fig. 1) is close to the normal distribution. This means that the least-squares calculation has been made on the basis of the proper vibrational assignments of the observed spectra and that the force field obtained has high validity in the normal vibration study.

The authors wish to thank Dr. Keiichi Ohno of Hiroshima University for his helpful discussions.

The Molecular and Crystal Structure of the Green Form of Bis(*N*-cyclohexylsalicylideneaminato)copper(II)

Hatsue TAMURA, Kazuhide OGAWA,* Akira TAKEUCHI, and Shoichiro YAMADA

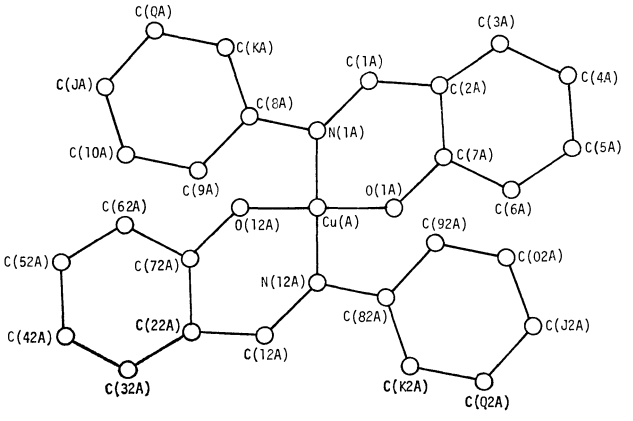
College of General Education, Osaka University, Toyonaka, Osaka 560

(Received January, 16, 1979)

Bis(*N*-cyclohexylsalicylideneaminato)copper(II) crystallizes in two forms: one is a brown crystal (Form I), and the other is a green one (Form II). The crystal structure of Form II has been determined by X-ray analysis. The green crystals are monoclinic; space group, $P2_1/n$. The cell dimensions are $a=23.134(6)$, $b=9.525(3)$, $c=21.472(8)$ Å, $\beta=99.42(1)°$, and $Z=8$. The structure was deduced by the heavy-atom method and was refined to a final R value of 0.082 for 1883 observed reflections by the block-diagonal least-squares method. The molecular structure in Form II is dimeric, in contrast with the case of Form I, which is composed of a monomeric molecule. The two monomeric halves are joined by two Cu–O bonds with distances of 2.60(1) and 2.64(1) Å. Each copper(II) ion is penta-coordinated in a distorted square-pyramidal configuration. The molecular structures in Form I and II have been compared with those of the related Cu(II) compounds.

Among the crystal structures of various kinds of copper(II) complexes with *N*-substituted derivatives of salicylideneaminates (abbreviated as Cu(*N*-R, salim)$_2$ hereafter) so far determined, the following derivatives have been reported to have polymorphic crystals: the polymorphs of α-[1] and γ-forms[2] of bis(*N*-methylsalicylideneaminato)copper(II) (Cu(*N*-Me, salim)$_2$) have a relation of the monomer and the dimer, while the polymorphism of bis(*N*-ethylsalicylideneaminato)-copper(II), which has monoclinic[3] and orthorhombic forms,[4] is due to the different coordination geometry. It seems to be significant to examine related copper(II) complexes with isopropyl and cyclohexyl groups, which are bulkier than methyl and ethyl groups.

Two of the present authors (A.T. and S.Y.) previously synthesized the green(low-temperature form) and the brown(high-temperature form) complexes of bis(*N*-isopropyl-3-methoxysalicylideneaminato)copper(II) (Cu(*N*-*i*-Pr, 3-CH_3O-salim)$_2$) and reported their structures on the basis of the absorption spectra, thermal, and X-ray data.[5] Recently two modifications of bis(*N*-cyclohexylsalicylideneaminato)copper(II) (Cu(*N*-Ch, salim)$_2$) were also obtained by the two authors (A.T. and S.Y.); one is brown, and the other, green. Hereafter, the former and the latter will be designated as Form I and Form II respectively. With a rise in the temperature, the brown crystal melts at 165—166 °C and crystallizes in the green Form II, which melts at 176—177 °C. Crystals of Form II are also obtained by the slow evaporation of a chloroform solution of Form I. The crystals of Form II obtained by this method gave the same X-ray diffraction pattern as that of crystal obtained by heating crystals of Form I on an oil-bath at 170—180 °C. The crystal structure of Form I was reported previously.[6] In the present work, the crystal structure of Form II has been determined and compared with that of Form I.



Atom numbering scheme of the one half ([Cu(A)]) of the dimer. The same atom numbering as [Cu(A)] was used for [Cu(B)], and the distinction between the atoms in [Cu(A)] and those in [Cu(B)] was made by the letters A and B.

Experimental

The green crystals of Cu(*N*-Ch, salim)$_2$ were obtained by the slow evaporation of a chloroform solution of Form I at a temperature below 10 °C. The crystal and experimental data of Form II are listed in Table 1 and compared with those of Form I. The X-ray intensity data were measured on a Rigaku-Denki four-circle diffractometer with Zr-filtered

Mo $K\alpha$ radiation. Of 3231 independent reflections collected by the 2θ-θ scan technique, 1348 reflections with $|F_o|<3\sigma(|F_o|)$ were not used in the subsequent calculation. The data were corrected for Lorentz and polarization effects, but not for absorption. The crystal size was $0.15\times0.20\times0.30$ mm.

Structure Determination. The crystal structure was solved by the heavy-atom technique, and the refinement was performed by a block-diagonal least-squares calculation. The function minimized was $\sum w(F_o-|F_c|)^2$, with $w=1.0$ for all reflections. All the atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[7] The computations were carried out on a NEAC 2200-700 computer at Osaka University. The computer programs used in the calculations were RSSFR-5,[8] HBLS-V,[9] and DAPH[10]

in the UNICS. The final R value was 0.032. A list of observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7938).

Results and Discussion

Table 2 lists the final atomic and thermal parameters, along with the estimated standard deviations. The bond distances and angles are also listed in Table 3.

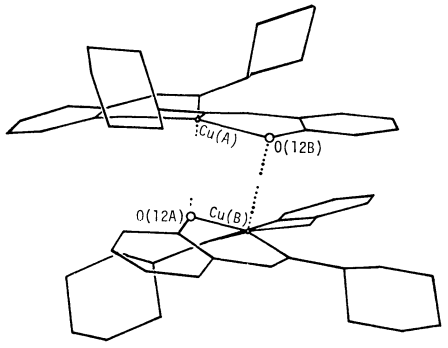

Fig. 1. Dimeric structure.

The molecular structure is shown in Fig. 1. The two crystallographically independent Cu(*N*-Ch, salim)$_2$ molecules are joined by two Cu–O bonds, with distances of 2.60 and 2.64 Å, forming a dimer. Hereafter, the two halves of the dimer will be denoted by [Cu(A)] and [Cu(B)]. Each copper(II) ion in [Cu(A)] or [Cu(B)] is penta-coordinated in a distorted square-pyramidal configuration. The basal plane of the pyramid is tetrahedrally distorted; the angle between the plane through Cu(A), O(1A), N(1A), and the plane through Cu(A), O(12A), N(12A) in [Cu(A)] is 26°, and the corresponding angle in [Cu(B)] is 32°. The coordination geometry is different from that in Form I: the Cu(II) ion in Form I has a planar coordination and the molecule is bent or stepped, so that the distance (step height) between the salicylideneamine planes is 1.28 Å. [Cu(A)] has almost the same structure as [Cu(B)]. The equations of the best planes through the three selected sets of atoms in each salicylideneamine moiety are given in Table 4(a). The displacements of the atoms from these planes and the dihedral angles between them are given in Tables 4(b) and 4(c) respectively. The dihedral angle between Plane(II) of the salicylideneamine moiety and the plane through the copper, oxygen, and nitrogen atoms ranges from 165° to 167°. (The corresponding angle in Form I is 153.5°). As may be seen in Fig. 1, the cyclohexyl groups lie outside the basal planes so as to avoid the non-bonded repulsion between the groups in one Cu(*N*-Ch, salim)$_2$ moiety and the atoms of the opposite moiety. The bond distances and angles in Form II are almost in complete agreement with those in Form I, within the limits of experimental accuracy.

The crystal structure is shown in Fig. 2. There are no

TABLE 5. STEP-HEIGHTS IN SQUARE-PLANAR Cu(*N*-R, salim)$_2$

R	Step-height(l/Å)	Ref.
Me(α-form)	0	1
H	0.29	13
Propyl	0.32	14
Butyl	0.74	15
Phenyl	0.89	16
Ch(Form I)	1.28	6

intermolecular distances less than 3.65 Å in the crystal structure.

Most of the monomeric Cu(*N*-R, salim)$_2$-type complexes whose coordination geometry is square-planar are bent or stepped. Table 5 lists the step heights in a series of square-planar salicylideneaminato complexes. The bulkier the *N*-substituents (R) are, the larger the step heights are, except for the case of Cu(*N*-H, salim)$_2$. The large step height (1.28 Å) in Form I probably results from the interligand interaction between the bulky cyclohexyl substituent and the opposite ligand. The dimerization of the two Cu(*N*-Ch, salim)$_2$ molecules of Form I occurs by means of the formation of the Cu–O bands. Of the two ligands in a monomeric molecule, the O atom of one ligand (Type i) participates in the Cu–O bond, but that of the other ligand (Type ii) does not. In the Type i ligand the bond formation gives rise to an approach of the salicylideneamine portion to the opposite molecule, while the *N*-cyclohexane portion becomes somewhat distant from the opposite one because of the non-bonded repulsion. Consequently, the Cu$\langle^{N}_{O}$ plane of the Type i ligand slants against that of the Type ii ligand in each monomeric unit, and the disposition of the donor atoms become tetrahedral.

The dimeric molecular structure of Form II is similar to that of the γ-form of Cu(*N*-Me, salim)$_2$, but the configuration of atoms at the basal plane in Form II is much more distorted tetrahedrally than that in the γ-form of Cu(*N*-Me, salim)$_2$, because the *N*-substituents of Form II are bulkier than those of the γ-form of Cu(*N*-Me, salim)$_2$: the angle between the plane through Cu(A), O(1A), N(1A) and the plane through Cu(A), O(12A), N(12A) in [Cu(A)] is 26°, and the corresponding angle in [Cu(B)] is 32°, as has been described above; on the other hand, the corresponding angles in the γ-form of Cu(*N*-Me, salim)$_2$ are 11 and 12°.

The polymorphism in Cu(*N*-Ch, salim)$_2$ is caused by such a chemical change. On the other hand, in the case of Cu(*N*-*i*-Pr, 3-CH_3O-salim)$_2$, which has two crystal forms—the green complex (low-temperature form)[11] and the brown one(high-temperature form),[12] it has become apparent that its polymorphism is not due to dimerization, but to the difference between the coordination configurations about the Cu(II) ions(the dihedral angle between Cu, O, N planes in the low-temperature form is 47.4° and the corresponding angle in the high-temperature one is 57.9°), and also to the difference between the molecular geometry (twisted-umbrella shape in the low-temperature form and twisted-stepped shape in the high-temperature one).

The authors wish to express their thanks to Dr. N. Kamijo of the Government Industrial Research Institute, Osaka, for the use of the Rigaku-Denki automatic diffractometer.

The Synthesis of Crystalline Zirconium Phosphate with Large Particle Size by the Direct-precipitation Method

Yasushi INOUE and Yoshimune YAMADA*

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received January 23, 1979)

The direct-precipitation method was studied as a possible way to synthesize crystalline zirconium phosphate of a large and uniform crystal size. The yield and the crystal size were examined as functions of the initial hydrofluoric-acid and phosphoric-acid concentrations and the warming temperature. The conditions for preparing the largest crystal were: $ZrOCl_2 \cdot 8H_2O$, 0.13 M; hydrofluoric acid concentration, 0.715 M; phosphoric acid concentration, 5 M; temperature, 50 °C. Those for preparing the material with uniform crystal-size distribution and a possibly large-mean crystal size were: $ZrOCl_2 \cdot 8H_2O$, 0.13 M; hydrofluoric acid concentration, 0.715 M; phosphoric acid concentration, 9 M; temperature, 60 °C. The product was confirmed to be crystalline $Zr(HPO_4)_2 \cdot H_2O$ by means of chemical, thermal, and X-ray analyses, and by an examination of the titration curve.

The crystalline zirconium phosphate (ZP) cation exchanger has been extensively studied since the work of Clearfield and Stynes,[1] who first prepared the material by refluxing amorphous zirconium phosphate for a long time in a phosphoric acid solution. The investigation of ion-exchange kinetics, however, has just started, and only a little information[2-9] is available to date. The present authors intend to carry out kinetic studies for elucidating the ion-exchange mechanism of ZP. To accomplish this purpose, it is necessary to prepare a material which has not only a high degree of crystallinity, but also a large and uniform size and an excellent yield. Horsley and Nowell[10] have compared four alternative methods for preparing ZP: (A) the reflux method proposed by Clearfield and Stynes;[1] (B) the direct precipitation method proposed by Alberti and Torracca;[11] (C) the rapid precipitation method, which is a modification of (B), and (D) the method of direct precipitation in the presence of oxalic acid. They concluded that Method (C) was the best, mainly because the crystallinity of its products was the best. However, no detailed investigations from the point of view of the crystal-size distribution of the products have yet been reported. The present authors have attempted to establish a good procedure for obtaining material with a large and uniform crystal size. A preliminary experiment suggested that Method (B) above was most promising, for it provided crystals larger than those obtained by the other methods.

This report will describe the results of the investigation undertaken to establish the best conditions for the synthesis based on Method (B) by varying such factors as the concentrations of hydrofluoric acid and of phosphoric acid and the temperature of precipitation.

Experimental

Procedure for the Preparation of ZP. Five and a half grams of $ZrOCl_2 \cdot 8H_2O$ were dissolved in distilled water in a polyethylene beaker (5.5 cm in inside diameter, 6.7 cm high). The desired amounts of hydrofluoric acid as a complexing agent for zirconium and of phosphoric acid were added successively with vigorous stirring, to make the total volume 130 cm^3. The solution thus prepared was then allowed to warm in a thermostatic water bath for longer than 100 h in order to decompose the fluoro-complex of zirconium. The volume of the solution gradually decreased during the warming and reached about 70 cm^3 under the recommended conditions: hydrofluoric acid concentration; 0.13 M, phosphoric acid concentration; 9 M, temperature; 60 °C (see below). The white flaky product was separated centrifugally, washed with distilled water until the pH of the filtrate became about 5, and stored over P_2O_5 for two weeks. The yield was calculated on the basis of the zirconium recovery.

Measurement of Crystal Size. The flaky product was observed to be composed of many crystals of rectangular platelets, 50—450 μm in length and 8—90 μm in width. About a hundred well-shaped crystals were randomly selected from them, and their cross sections were measured by means of an optical microscope.

Analysis. Zirconium was precipitated by cupferron from a dil hydrofluoric acid solution in which 0.5 g of ZP had been dissolved, and was determined by ignition to the oxide.[12] The phosphate ion was precipitated as ammonium molybdophosphate from the above filtrate, reprecipitated as ammonium magnesium phosphate, and determined by ignition to $Mg_2P_2O_7$.[13] The water content was calculated from the weight loss on ignition.

Titration Curve. A half gram of ZP was immersed in 100 cm^3 of a solution (ionic strength 0.1 M, (1 M=1 mol/dm^3)) for a week at a room temperature, followed by the pH measurement and by the chemical analysis of the solution. To obtain a titration curve, this procedure was undertaken for various solutions which had been prepared by the desired combinations of 0.1 M NaOH and 0.1 M NaCl (forward titration) or of 0.1 M HCl and 0.1 M NaCl (backward titration). The amount of ion taken up by the exchanger was evaluated from the difference between the initial and the final concentrations of the Na^+ ions present in the solution. The Na^+ ions were converted to the corresponding pure chlorides and indirectly determined by titrating Cl^- ions by means of Fajans' method.

Apparatus. The thermal analysis was undertaken with a Shimadzu micro thermal analyzer, Model DT-20B, connected to a thermal balance, Model TGC-20H, for thermogravimetric analysis (TGA), and a high-temperature sample-holder, Model MDH-20, for differential thermal analysis (DTA). α-Alumina was used as the standard for DTA. The measurement was carried out in air at a heating rate of 5 °C/min. X-Ray diffraction patterns were taken using Ni-filtered Cu $K\alpha$ radiation.

Results and Discussion

In the direct precipitation method, there is a lower limit of the molar ratio of F/Zr in the mixed solution

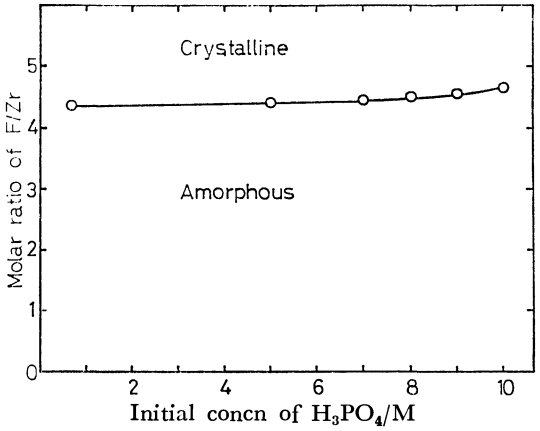

Fig. 1. Dependence of lower limit of F/Zr molar ratio on the concentration of H_3PO_4.

for obtaining crystalline material. When the F/Zr was lower than this limit, amorphous zirconium phosphate was precipitated. Figure 1 indicates that the limit depended slightly on the concentration of phosphoric acid. If the ratio is higher than 4.5, the crystalline form will be precipitated, irrespective of any other factors.

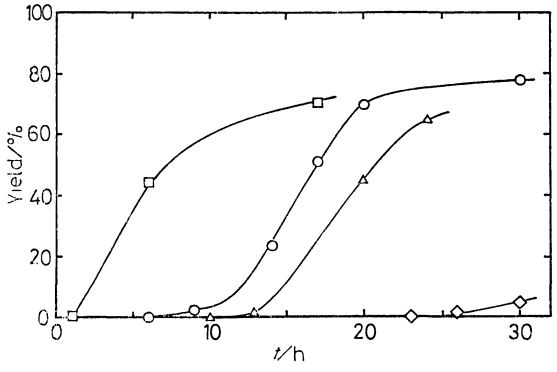

Fig. 2. Effect of F/Zr ratio on the rate of precipitation.
Conditions: T, 70 °C; concn of H_3PO_4, 5 M. F/Zr, □: 4.8, ○: 5.5, △: 6.8, ◇: 11.9.

The effect of the F/Zr ratio on the rate of precipitation was measured at an initial phosphoric acid concentration of 5 M and at 70 °C. Figure 2 indicates that the time needed for the first appearance of the precipitate (induction period) tended to become longer with the increase in the F/Zr ratio, while the progress of the precipitation, once it set in, was independent of the F/Zr ratio in the 4.8—6.8 region. From these results, a F/Zr ratio of 5.5 was selected by taking into account the margin for producing crystalline material and the rapidity of the procedure.

The dependence of the initial concentration of phosphoric acid on the formation rate of precipitate was investigated; the results are shown in Fig. 3. The progress of precipitation was little affected by the phosphoric acid concentration, but the induction period became longer with a decrease in the initial concentration of phosphoric acid.

As to the effect of the temperature, Fig. 4 reveals

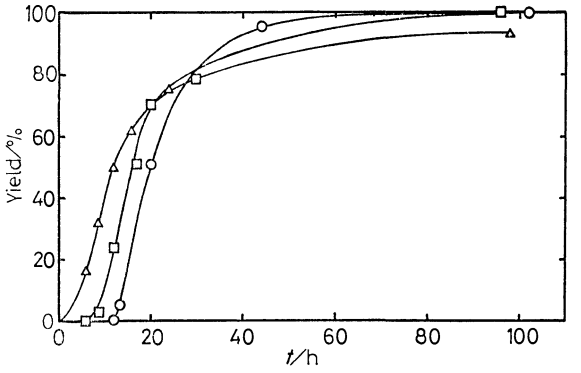

Fig. 3. Dependence of the initial concentration of H_3PO_4 on the formation rate of precipitate.
Conditions: F/Zr, 5.5; T, 70 °C. Concn of H_3PO_4, ○: 1 M, □: 5 M, △: 10 M.

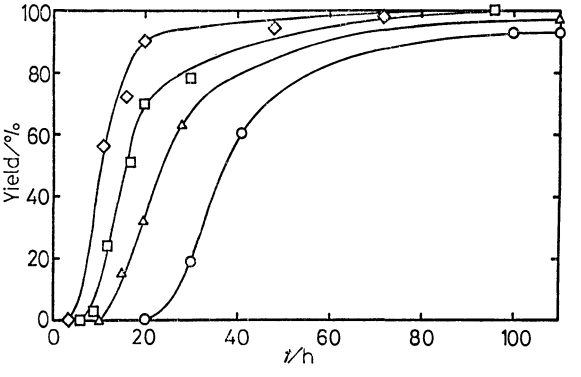

Fig. 4. Effect of temperature on the formation rate of precipitate.
Conditions: F/Zr, 5.5; concn of H_3PO_4, 5 M.
T, ○: 50 °C, △: 60 °C, □: 70 °C, ◇: 80 °C.

that, in addition to the shortening in the induction period, the progress of precipitation became faster as temperatures became warmer. These results suggest that, among the three factors examined, only the increasing temperature governs the progress of precipitation, while the concentrations of both hydrofluoric

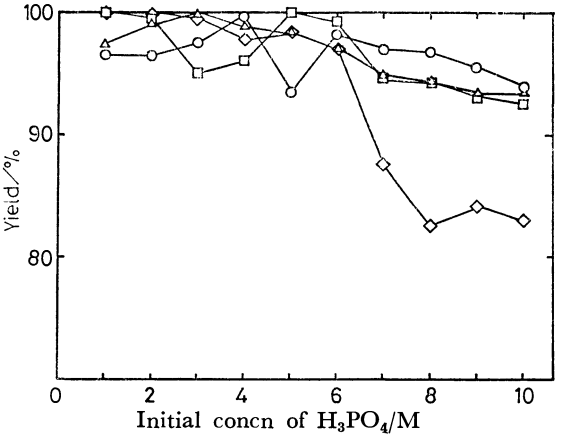

Fig. 5. Yield as functions of H_3PO_4 concentration and temperature.
F/Zr, 5.5.
T, ○: 50 °C, △: 60 °C, □: 70 °C, ◇: 80 °C.

acid and phosphoric acid affect only the length of the induction period. Furthermore, it is obvious from Figs. 3 and 4 that the precipitation reaction was completed within 100 h, whatever the conditions. Therefore, the yield after warming for longer than 100 h was measured as functions of the phosphoric acid concentration and the temperature. Figure 5 shows that the yield decreased a little with the concentration of phosphoric acid, but that it was higher than 90% under any conditions except in the case of 80 °C, where the yield decreased considerably when the concentration of phosphoric acid exceeded 7 M. Thus, the temperature should be fixed below 80 °C.

On the other hand, it is very important to ascertain the effect of the preparative conditions on the crystal size of the precipitate. The mean size of the crystals is plotted as a function of the initial concentration of phosphoric acid at different temperatures in Fig. 6, while its standard deviations under several representative conditions are shown in Table 1. The mean

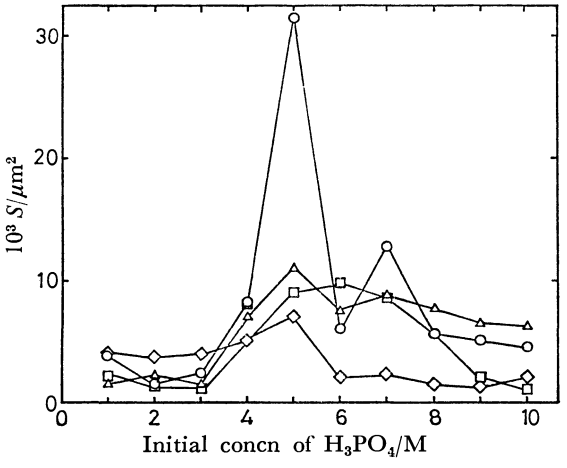

Fig. 6. Mean size of the crystals as functions of H_3PO_4 concentration and temperature.

1	1.4	0.7
5[a)]	31.5	18.1
5	10.1	4.9
9	6.5	2.3
10	6.3	3.1

Conditions of synthesis: F/Zr; 5.5, T; 60 °C except for a). a) F/Zr; 5.5, T; 50 °C.

crystal size was at its maximum near 5 M phosphoric acid. When we compared the two sides of the maximum, the mean crystal size was larger for the higher than for the lower concentrations of phosphoric acid. Furthermore, it decreased as the temperature rose. A comparison of the mean crystal size and its standard deviation shows that, in the case of 5 M phosphoric acid, though the mean crystal size was the largest, the uniformity of the crystals was poor, but in other cases it was comparatively good.

These observations can be understood as follows. The precipitate did not appear until the concentration of phosphoric acid approached about 8—9 M by the evaporation of water with hydrofluoric acid. This observation seems to reflect the length of the induction period. As the precipitation results from the decomposition of fluoro-complex of zirconium, the fact that the progress of precipitation depends only on the warming temperature, and not on the initial hydrofluoric acid and the phosphoric acid concentrations, can be understood if free hydrofluoric acid is considered to be expelled during the induction period. As a natural consequence, the lower the initial concentration of phosphoric acid, the higher the concentration of zirconium at the stage of precipitation. This fact makes it possible to interpret the slight decrease in the yield with the increase in the initial concentration of phosphoric acid. The higher rate of the generation of the free zirconium ion at the stage of precipitation—this corresponds to the conditions of a lower initial concentration of phosphoric acid and a higher temperature—facilitates the formation of many nuclei of the precipitate and leads to the small crystals. This argument is compatible with the observations of the mean crystal size except for the occurrence of the maximum in Fig. 6. Further investigations should be carried out to learn the reason for this important irregularity.

On the basis of these results, the conditions for the synthesis which provides the largest crystals are found to be; phosphoric acid concentration, 5 M; warming temperature, 50 °C. If the uniformity of the crystal size is required in addition to the large size of the crystals, the most favorable conditions are; phosphoric acid concentration, 9 M; warming temperature, 60 °C.

The following fact is worth noticing. The ZP thus prepared was in the form of flakes consisting of crystals of various sizes which adhered closely together. When converted to the sodium form, the flakes were broken down into fine particles. The ZP flakes, as prepared, were coverted to the sodium form by treating them with a mixture of 0.1 M NaCl and 0.1 M NaOH solutions (pH=11 at equilibrium). The particle-size distribution of the sodium-form exchangers thus prepared was examined by sieving, as is shown in Table 2. It is

TABLE 2. PARTICLE-SIZE DISTRIBUTION OF SODIUM-FORM EXCHANGERS

Mesh size	>70	70—100	100—145	145—200	200—280	280>
(1)[a)]	1	4	13	22	20	40
(2)[b)]	0	3	9	31	35	22

Conditions of synthesis: a) F/Zr, 5.5; concn of H_3PO_4, 5 M; T, 50 °C; b) F/Zr, 5.5; concn of H_3PO_4, 9 M; T, 60 °C.

evident from this table that (2) possessed a better uniformity in particle size than (1), though there existed very few particles larger than 100 mesh. Moreover, (2) contained fine powder, which cannot be used for column operation, only a half as much as (1). This particle-size distribution corresponds roughly to that of the crystals in the hydrogen form. Further breaking was not observed by reconversion to the hydrogen form or by repeated regeneration cycles. This phenomenon may be due to the separation of crystals by the stress exerted by the change in the interlayer distance in the structure of ZP by conversion.

Chemical, thermal, and X-ray analyses were performed in order to characterize the materials which had been prepared by the procedures recommended above.

The composition of the product was independent of the conditions for synthesis and was found to be $Zr(HPO_4)_2 \cdot H_2O$. (Found: ZrO_2, 41.23; P_2O_5, 47.27; H_2O, 11.88%).

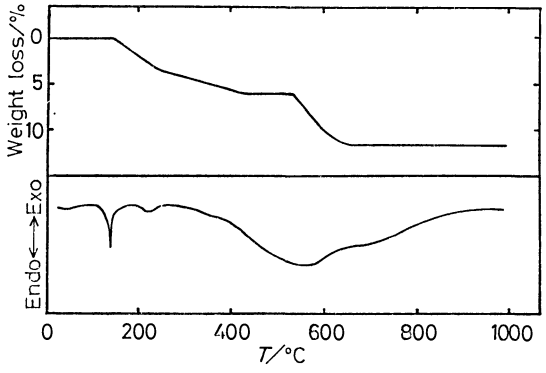

Fig. 7. TGA and DTA curves of ZP. Heating rate: 5 °C/min.

Figure 7 shows the TGA and DTA curves of the product. The TGA curve indicates that the product lost weight rapidly up to about 200 °C and then gradually up to 400 °C, where the weight became constant. The weight loss in this stage corresponds to one mole of water for each mole of ZP. Further heating to 650 °C gave rise to the release of a second mole of water, which resulted in the formation of pyrophosphate. In the DTA curve, there appeared a large and sharp endothermic peak at 150 °C, which was considered to correspond to the release of water. An exothermic peak attributed to the recrystallization by Clearfield and Stynes[1] did not appear. These curves closely resemble those of Sample (B) prepared by Horsley and Nowell.[10]

The results of X-ray analysis agreed well with the published data of α-ZP reported by Clearfield and Stynes.[1]

Forward and backward titration curves of ZP with sodium ion were constructed, as is shown in Fig. 8. The titration curves show two reversible exchange stages.

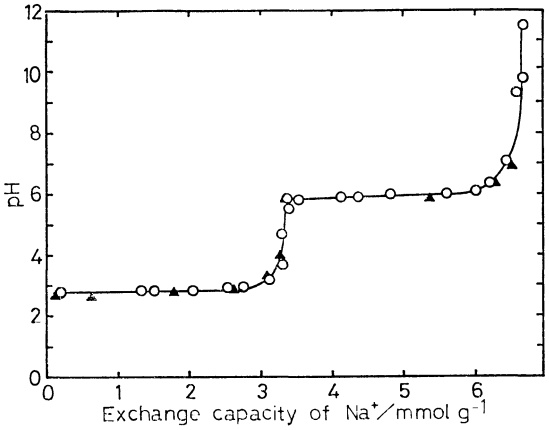

Fig. 8. Titration curves of ZP with sodium ion. ○: Forward titration, 0.1 M (NaOH+NaCl); ▲: Backward titration, 0.1 M (HCl+NaCl).

On the contrary, Clearfield *et al.*[14] reported that the titration curves exhibited a hysteresis loop, which resulted from the presence of different phases in the forward and backward titrations. These differences in titration and DTA curves can be explained by assuming that the crystallinity of the present product is better than that of Clearfield's.

Kinetics and Mechanism of the Oxidation Reactions of Dialkyldithiocarbamatocopper(I) Tetramer and -silver(I) Hexamer with Tetraalkylthiuram Disulfide

Hidetoshi KITA, Shin-ichi MIYAKE, Koji TANAKA, and Toshio TANAKA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 19 1979)

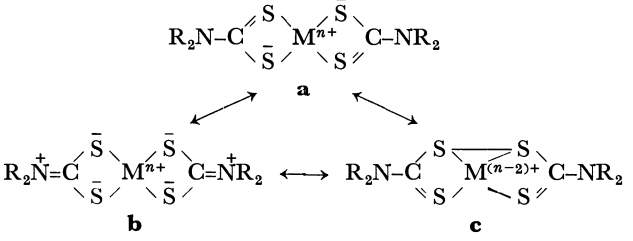
Kinetics of the oxidations of dialkyldithiocarbamatocopper(I), $[\{Cu(S_2CNR_2)\}_4]$ (R=Et, *n*-Pr), and -silver(I), $[\{Ag(S_2CNR_2)\}_6]$ (R=Et, *n*-Pr, *i*-Pr), with the corresponding tetraalkylthiuram disulfide, $[(R_2NC(S)S\}_2]$, were investigated in dichloromethane employing a stopped-flow technique. The reactions are interpreted to proceed by a mechanism involving a rapid equilibration (**i**) (the multi-step equilibrium constant=K_0) to form adduct,

$$[\{M(S_2CNR_2)\}_x] \overset{+[(R_2NC(S)S\}_2]}{\rightleftharpoons} [M(S_2CNR_2)\{(R_2NC(S)S\}_2\}] + [\{M(S_2CNR_2)\}_{x-1}] \overset{+[(R_2NC(S)S\}_2]}{\rightleftharpoons} \cdots\cdots \quad (\mathbf{i})$$

(M=Cu, x=4; M=Ag, x=6)

$[M(S_2CNR_2)\{(R_2NC(S)S\}_2\}]$, which are decomposed in a rate-determining step (the rate constant=k) yielding the final products, $[M(S_2CNR_2)_2]$. According to this mechanism, the rate law in the presence of excess $[(R_2NC(S)S\}_2]$ is expressed as $v=K_0k[[(R_2NC(S)S\}_2]][[\{M(S_2CNR_2)\}_x]]/(1+K_0[[(R_2NC(S)S\}_2]])$, where K_0k(25 °C)=1.17×10^4 (Et), 5.70×10^3 (*n*-Pr) $M^{-1}s^{-1}$ (M=mol dm^{-3}) for the copper system, and K_0(25 °C)=28.2 (Et), 49.1 (*n*-Pr), 86.7 (*i*-Pr) M^{-1} and k(25 °C)=2.17 (Et), 1.50 (*n*-Pr), 6.56 (*i*-Pr) s^{-1} for the silver system. The activation parameters also were determined and the nature of transition states is discussed.

The dithiocarbamate ligand can stabilize transition metal ions in unusually high formal oxidation states by delocalization of electronic charges[1] and S–S interligand interactions,[2] as shown in the canonical structures of **b** and **c**, respectively.



This interesting property seems to facilitate a number of studies[3-9] on the reaction of dithiocarbamato complexes of metals in the normal oxidation state with oxidizing agents such as halogens, boron trifluoride *etc*. All the works reported in this field, however, had been of a preparative nature until recently. Thus, we have reported the kinetics and mechanism of the oxidation reactions of dithiocarbamato complexes of tin(IV),[10] zinc(II),[11] and gold(I)[12] with halogens. These reactions have well been described to proceed *via* a charge-transfer complex formed by electrophilic attack of halogen on the sulfur atom of the dithiocarbamate ligand. As an extension of these studies to more complicated systems, the present paper reports kinetic and mechanistic studies on the oxidation reactions of dialkyldithiocarbamatocopper(I) tetramer and -silver(I) hexamer with tetraalkylthiuram disulfide, giving bis(dialkyldithiocarbamato)copper(II) and -silver(II), respectively.

Experimental

Materials. Dialkyldithiocarbamatocopper(I), $[\{Cu(S_2CNR_2)\}_4]$ (R=Et and *n*-Pr),[13] dialkyldithiocarbamatosilver(I), $[\{Ag(S_2CNR_2)\}_6]$ (R=Et, *n*-Pr, and *i*-Pr),[14] and tetraalkylthiuram disulfide, $[(R_2NC(S)S\}_2]$ (R=Et, *n*-Pr, and *i*-Pr),[14] were prepared according to the literature methods. Analytical data for these complexes (C, H, N) were satisfactory. Dichloromethane used as a solvent was purified as described previously.[12]

Spectra and Kinetics. Electronic spectra were recorded on a Hitachi 124 spectrophotometer. Rapid scanning spectra were measured with a Union RA-413 stopped-flow rapid scanning spectrophotometer equipped with a 2 mm quartz cell in a cell holder thermostated within ±0.2 °C. The rate of reaction was followed by monitoring the absorbance at a fixed wavelength in the electronic spectra of the reaction mixture under pseudo-first-order conditions, using at least a ten-fold excess of tetraalkylthiuram disulfide. Absorbance-time data were accumulated at least five times on a Union System-71 data processor and average absorbance-time curves were recorded on a National VP-6421A X-Y recorder. Pseudo-first-order rate constants, k_{obsd}, were calculated from the slope of a linear part of the $\ln(A_\infty - A_t)$ *vs.* time plots by the least-squares method, where A_∞ and A_t are absorbances at the end of reaction and at a time t, respectively.

Results and Discussion

Reaction of $[\{Cu(S_2CNR_2)\}_4]$ *with* $[(R_2NC(S)S\}_2]$. The reaction of $[\{Cu(S_2CNR_2)\}_4]$ with $[(R_2NC(S)S\}_2]$ rapidly proceeds to give bis(dialkyldithiocarbamato)-copper(II), $[Cu(S_2CNR_2)_2]$, in quantitative yields.[15] The stoichiometry of reaction can, therefore, be expressed as Eq. 1.

$$\frac{1}{4}[\{Cu(S_2CNR_2)\}_4] + \frac{1}{2}[(R_2NC(S)S\}_2] \longrightarrow [Cu(S_2CNR_2)_2] \quad (1)$$

A typical rapid scanning spectrum after mixing the reactant solutions is shown in Fig. 1. An absorption maximum at 303 nm observed immediately after mixing is identical in wavenumber with that of the

reactant $[\{Cu(S_2CNR_2)\}_4]$ ($\lambda_{max}=303$ nm, $\varepsilon_{max}=4.5\times10^4$ M^{-1} cm^{-1} ($M=$mol dm^{-3}) in CH_2Cl_2). The final spectrum with three absorption peaks at 270, 290, and 435 nm is assigned to $[Cu(S_2CNR_2)_2]$ ($\varepsilon_{max}=3.1\times10^4$, 1.8×10^4, and 1.2×10^4 M^{-1} cm^{-1} in CH_2Cl_2, respectively).[15-18] Half-lives of these absorption bands were almost identical with one another, and isosbestic points are found at 295 and 370 nm.

The rate data of reaction 1 (R=Et and *n*-Pr) were obtained from increase of the absorbance at 435 nm after mixing $[\{Cu(S_2CNR_2)\}_4]$ with excess $[(R_2NC(S)S\}_2]$. Figure 2 shows a typical example of $\ln(A_\infty-A_t)$ *vs.* time plots. Except for the period of initial several milliseconds, a good linear relation between them is obtained for at least 80% completion of the reaction. The linear part of plots was used to determine the values of pseudo-first-order rate constants. Table 1 lists the rate data at various concentrations of $[\{Cu(S_2CNR_2)\}_4]$ and $[(R_2NC(S)S\}_2]$. All the plots of k_{obsd} *vs.* the concentration of $[(R_2NC(S)S\}_2]$ at each temperature yielded straight lines with zero intercepts. This result may be interpreted by assuming the reaction pathways of 2 to 4.

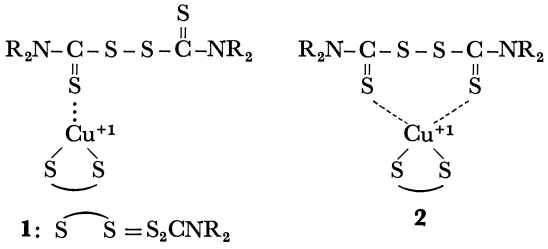
$$[\{Cu(S_2CNR_2)\}_4] \overset{+[(R_2NC(S)S\}_2]}{\rightleftharpoons} [Cu(S_2CNR_2)\{(R_2NC(S)S\}_2] + [\{Cu(S_2CNR_2)\}_3]$$

$$\overset{+[(R_2NC(S)S\}_2]}{\rightleftharpoons} \cdots\cdots \quad K_0, \quad (2)$$

$$[Cu(S_2CNR_2)\{(R_2NC(S)S\}_2] \overset{k}{\longrightarrow} [Cu(S_2CNR_2)_2] + [R_2NCS_2\cdot] \quad (3)$$

$$2[R_2NCS_2\cdot] \overset{\text{fast}}{\longrightarrow} [(R_2NC(S)S\}_2] \quad (4)$$

Equation 2 consists of multi-step equilibrium reactions, where the tetrameric compound $[\{Cu(S_2CNR_2)\}_4]$ dissociates by the attack of $[(R_2NC(S)S\}_2]$ to form an adduct $[Cu(S_2CNR_2)\{(R_2NC(S)S\}_2]$ and a trimer $[\{Cu(S_2CNR_2)\}_3]$, the latter of which successively reacts with $[(R_2NC(S)S\}_2]$ to give the adduct in a similar manner. The initial curvature of $\ln(A_\infty-A_t)$ *vs.* time plots (Fig. 2) may correspond to a preequilibrium immediately after mixing, where the concentration of the adduct does not reach a steady state. The formation of the adduct as an intermediate may be supported by the fact that several metal complexes of thiuram disulfide have been isolated,[19-21] although there is no direct evidence in the present study. Thus, two possible structures, **1** and **2**, are proposed for the adduct formed between the copper(I) complex and thiuram disulfide.



In either structure the adduct may be decomposed in a rate-determining step (Eq. 3), which involves homolytic cleavage of the S–S bond of tetraalkylthiuram disulfide to give the oxidized copper(II) product, $[Cu(S_2CNR_2)_2]$, and the $[R_2NCS_2\cdot]$ radical. The resulting radical may rapidly dimerize to regenerate tetraalkylthiuram disulfide as reported by Cauquis and Lachenal,[22] who have estimated the rate constant of dimerization for R=Et to be 2×10^5 M^{-1} s^{-1} in acetonitrile.

According to the pathways of 2—4, the k_{obsd} value in the presence of excess tetraalkylthiuram disulfide is expressed by Eq. 5,

$$k_{obsd}=\frac{K_0k[[(R_2NC(S)S\}_2]]}{1+K_0[[(R_2NC(S)S\}_2]]}, \quad (5)$$

where K_0 stands for the multi-step equilibrium constant in Eq. 2. If one assumes $K_0[[(R_2NC(S)S\}_2]]\ll1$, Eq. 5 can be reduced to Eq. 6,

$$k_{obsd}=K_0k[[(R_2NC(S)S\}_2]] \quad (6)$$

which predicts a linear relationship between k_{obsd} and the concentration of $[(R_2NC(S)S\}_2]$ with the slope of K_0k and the zero intercept. This is consistent with the observed rate profile. Table 2 lists the K_0k value and activation parameters determined from the Arrhenius plot of $\ln(K_0k)$ *vs.* $1/T$.

Reaction of $[\{Ag(S_2CNR_2)\}_6]$ *with* $[(R_2NC(S)S\}_2]$. The addition of a dichloromethane solution of $[(R_2NC(S)\}_2]$ to $[\{Ag(S_2CNR_2)\}_6]$ in dichloromethane immediately causes a blue color, which becomes more intense as more $[(R_2NC(S)S\}_2]$ is added. The electronic spectrum of the blue solution displayed an

absorption maximum at *ca.* 600 nm, which has been assigned to the $[Ag(S_2CNR_2)_2]$ complex.[15,18] Thus, stoichiometry for the reaction of $[\{Ag(S_2CNR_2)\}_6]$ with $[(R_2NC(S)S\}_2]$ (R=Et, *n*-Pr, and *i*-Pr) is expressed as Eq. 7. The equilibrium constants K in

$$\frac{1}{6}[\{Ag(S_2CNR_2)\}_6] + \frac{1}{2}[(R_2NC(S)S\}_2] \overset{K}{\rightleftharpoons} [Ag(S_2CNR_2)_2] \quad (7)$$

chloroform at 20 °C (see Table 3) were determined spectrophotometrically by Åkerström.[15] We determined the K value in dichloromethane at four different temperatures by the same method (Table 3). Plots of $\ln K$ *vs.* $1/T$ for each system gave a linear relation, from which thermodynamic parameters of the reaction 7 were obtained. The results are given in Table 3, which indicates that the equilibrium lies so far to the left. The fact that the K value for R=*i*-Pr is larger than those for R=*n*-Pr and Et may be due to a larger inductive effect of the isopropyl group than the propyl and ethyl groups of the dithiocarbamate ligands, resulting in increasing stability of $[Ag(S_2CNR_2)_2]$ by delocalization of electronic charges from the dithiocarbamate ligand to Ag(II).

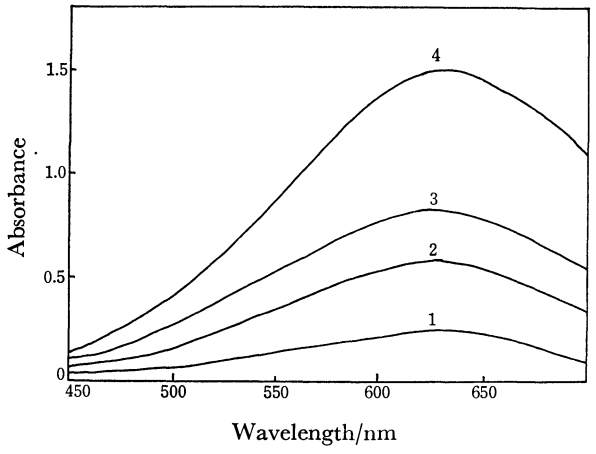

Fig. 3. Rapid scanning spectra after mixing $[\{Ag(S_2CN\text{-}i\text{-}Pr_2)\}_6]$ (5.0×10^{-4} M) with $[(i\text{-}Pr_2NC(S)S\}_2]$ (5.0×10^{-2} M) in CH_2Cl_2 at 25 °C; cell length=2 mm. 1: 0.1 s, 2: 0.2 s, 3: 0.3 s, 4: 1.0 s.

A typical change of electronic spectra in the visible region after mixing of the reactants is depicted in Fig. 3, which clearly shows the formation of $[Ag(S_2CN\text{-}i\text{-}Pr_2)_2]$ (λ_{max}=620 nm, $\varepsilon_{max}=1.3\times10^4$ M^{-1} cm^{-1} in CH_2Cl_2; lit,[15] λ_{max}=620 nm in $CHCl_3$). The rate of reaction was, therefore, followed by measuring the absorbance at 620 nm (R=*i*-Pr) or 600 nm (R=Et and *n*-Pr). Plots of $\ln(A_\infty-A_t)$ *vs.* time were found to be linear to at least 80% completion except for the initial short period after mixing, as in the case of copper complexes (Fig. 2). Pseudo-first-order rate constants obtained from a linear region of the plots are listed in Table 4. Plots of k_{obsd} *vs.* the concentration of $[(R_2NC(S)S\}_2]$ showed pronounced curvature at high concentrations of $[(R_2NC(S)S\}_2]$. A typical example is shown in Fig. 4, which is in contrast with the linear relationship for the

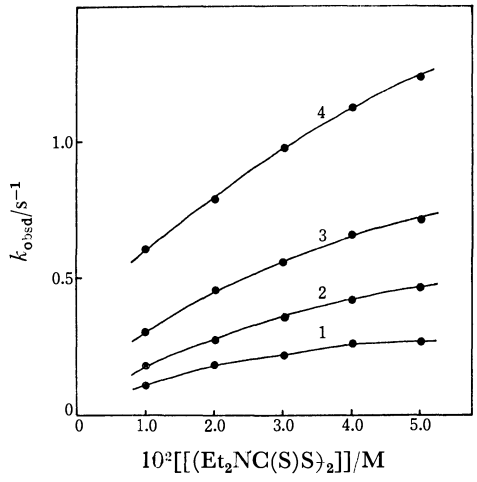

Fig. 4. Plots of k_{obsd} *vs.* $[[(Et_2NC(S)S\}_2]]$ for the reaction of $[\{Ag(S_2CNEt_2)\}_6]$ with $[(Et_2NC(S)S\}_2]$ in CH_2Cl_2; $[[\{Ag(S_2CNEt_2)\}_6]]=5.0\times10^{-4}$ M. 1: 10.6 °C, 2: 15.2 °C, 3: 20.3 °C, 4: 25.0 °C.

copper system. This notable difference can be explained by the assumption that the multi-step equilibrium constant K_0 appearing in Eq. 5 is larger in the silver system than in the copper system.

The mechanism proposed above for the copper complexes is, therefore, applicable to the silver complexes; the reaction pathways can be postulated as Eqs. 8 and 9, followed by dimerization of the $[R_2NCS_2\cdot]$

$$[\{Ag(S_2CNR_2)\}_6] \overset{+[(R_2NC(S)S\}_2]}{\rightleftharpoons} [Ag(S_2CNR_2)\{(R_2NC(S)S\}_2\}] + [\{Ag(S_2CNR_2)\}_5] \overset{+[(R_2NC(S)S\}_2]}{\rightleftharpoons} \cdots\cdots \quad K_0, \quad (8)$$

$$[Ag(S_2CNR_2)\{(R_2NC(S)S\}_2\}] \overset{k}{\longrightarrow} [Ag(S_2CNR_2)_2] + [R_2NCS_2\cdot] \quad (9)$$

radical (Eq. 4). Moreover, the bivalent silver complex, $[Ag(S_2CNR_2)_2]$, formed by Eq. 9 is expected to degrade because of its instability around room temperature. Similar instability has been reported for bis(diethylthiocarbamato)copper(II),[23] which rapidly rearranges into a hexameric univalent copper complex according to Eq. 10. By analogy with this, $[Ag(S_2CNR_2)_2]$ is suggested to rearrange as shown in Eq. 11. Equation 11 displays a unimolecular rearrangement of the

$$[Cu(SOCNEt_2)_2] \longrightarrow \frac{1}{6}[\{Cu(SOCNEt_2)\}_6] + \frac{1}{2}[(Et_2NC(O)S\}_2] \quad (10)$$

$$[Ag(S_2CNR_2)_2] \overset{k'}{\longrightarrow} \frac{1}{6}[\{Ag(S_2CNR_2)\}_6] + \frac{1}{2}[(R_2NC(S)S\}_2] \quad (11)$$

Ag(II) complex into the hexameric Ag(I) complex and tetraalkylthiuram disulfide with the rate constant of k', though the mechanism has not been clarified in the present work. The Ag(II) complex is possible also to react with the dialkyldithiocarbamato radical produced by Eq. 9, bimolecularily with the rate constant of k'', affording the Ag(I) hexamer, as shown

in Eq. 12. It is not obvious, however, which of Eqs. 11

$$[Ag(S_2CNR_2)_2] + [R_2NCS_2\cdot] \xrightarrow{k''} \frac{1}{6}[\{Ag(S_2CNR_2)\}_6] + [(R_2NC(S)S\}_2] \quad (12)$$

and 12 is predominant in the silver system. If one assumes $k \gg k'$ and/or k'', then k_{obsd} in the presence of excess $[(R_2NC(S)S\}_2]$ also is given by Eq. 5. It is apparent from Eq. 5 that the plots of k_{obsd} *vs.* the concentration of $[(R_2NC(S)S\}_2]$ show a curvature at so high concentrations of $[(R_2NC(S)S\}_2]$ as $K_0[[(R_2NC(S)S\}_2]]$ can not be neglected against unity. This is consistent with the observed kinetics (Fig. 4). Equation 5 can be transformed to Eq. 13, which predicts that there should be a

$$\frac{1}{k_{obsd}} = \frac{1}{K_0k[[(R_2NC(S)S\}_2]]} + \frac{1}{k}, \quad (13)$$

linear relationship between $1/k_{obsd}$ *vs.* $1/[[(R_2NC(S)S\}_2]]$, with the intercept of $1/k$ and the slope of $1/K_0k$. As an example of the plots is depicted in Fig. 5,

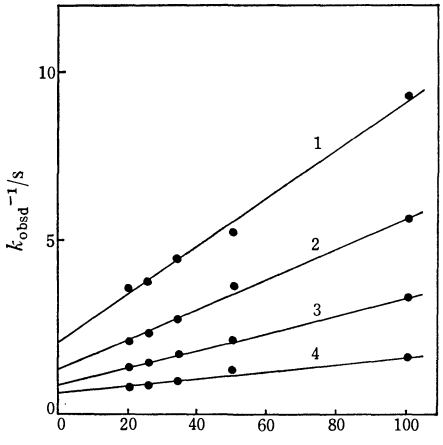

Fig. 5. Plots of $1/k_{obsd}$ *vs.* $1/[[(Et_2NC(S)S\}_2]]$ for the reaction of $[\{Ag(S_2CNEt_2)\}_6]$ with $[(Et_2NC(S)S\}_2]$ in CH_2Cl_2; $[[\{Ag(S_2CNEt_2)\}_6]]=5.0\times10^{-4}$ M. 1: 10.6 °C, 2: 15.2 °C, 3: 20.3 °C, 4: 25.0 °C.

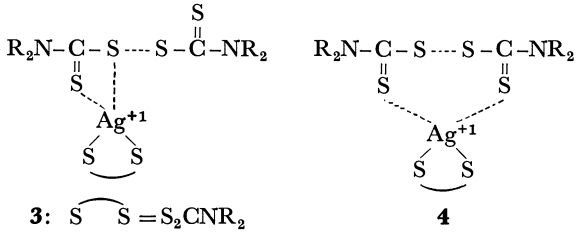
which shows a linear relation over the observed range of $[(R_2NC(S)S\}_2]$ concentrations. The rate and equilibrium constants for the $[\{Ag(S_2CNR_2)\}_6]$–$[(R_2NC(S)S\}_2]$ system are summarized in Table 5.

Thermodynamic and activation parameters calculated from K_0 and k at four different temperatures (Table 5) are listed in Table 6, which reveals that the $\Delta H^\circ_{(K_0)}$ values are near to zero. The $\Delta S^\circ_{(K_0)}$ term is, therefore, a dominant factor to cause the reaction 8. The positive $\Delta S^\circ_{(K_0)}$ values are consistent with the stepwise dissociation of $[\{Ag(S_2CNR_2)\}_6]$ by the attack of $[(R_2NC(S)S\}_2]$. The small negative $\Delta S^{\ddagger}_{(k)}$ values suggest that the configuration of the adduct formed between monomeric $[Ag(S_2CNR_2)]$ and thiuram disulfide, as shown in **3** or **4**, is essentially maintained in the transition state of reaction 9.



Finally, it should be mentioned that the K_0k values for the copper system are about two orders greater than those for the silver system under similar experimental conditions (Tables 2 and 5). In addition, a linear dependence of k_{obsd} on the concentration of thiuram disulfide observed for the copper system predicts that the K_0 value is not so large as that for the silver system, as described above. Thus, the k values for the copper system must be more than two orders greater than those for the silver system. This is in agreement with the fact that the oxidation to a bivalent state is easier in Cu(I) complexes than in Ag(I) complexes.[24]

An X-Ray Diffraction Study on the Structures of Bis- and Tris-(ethylenediamine)zinc(II) Complexes in Solution

Tadao FUJITA, Toshio YAMAGUCHI, and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 30, 1979)

An X-ray diffraction study has been carried out at 25 °C for aqueous ethylenediamine(en) solutions of zinc(II) nitrate, the mole ratios, en/Zn, in the solutions being 2.252 and 3.204. In the former solution bis(ethylenediamine)-zinc(II) complex existed as the main species, while in the latter tris(ethylenediamine)zinc(II) complex was predominant. The X-ray scattering data of the solution containing the bis-complex showed that four nitrogen atoms within the two ethylenediamine molecules were tetrahedrally coordinated to the zinc(II) ion at a distance of 2.131 (9) Å. The nonbonding Zn···C distance was also determined to be 2.89(2) Å. In the tris-complex in which the zinc(II) ion was coordinated with the six nitrogen atoms, the Zn–N and Zn···C distances were 2.276(5) Å and 3.00(1) Å, respectively. Raman spectra of the solutions supported the structures of the complexes.

X-Ray diffraction studies on complexes in solution have been markedly developed in these years, and the structural data of metal complexes with various unidentate ligands, such as halide and hydroxide ions and water and ammonia molecules, have been accumulated to provide the most fundamental knowledge on elucidating behavior of metal complexes in solution. Recent progresses in techniques and apparatus for X-ray diffraction analysis allow to investigate structures of polynuclear complexes containing relatively heavy metals. However, structures of metal chelates in solution have never been examined by the X-ray diffraction method.

In the present work, as a first step of investigation of structures of metal chelates, we choose ethylenediamine complexes of zinc(II) ion, because ethylenediamine is one of the simplest chelating agents. To find the structural difference, if it presents, of the complexes with varying numbers of the ligand coordinated is another aim of this investigation, since no crystallographic study of these complexes has been made so far.

Raman spectroscopic measurements have been employed to provide a supplement to the structural determination of the complexes.

Experimental

Preparation and Analysis of Sample Solutions. Anhydrous ethylenediamine of guaranteed reagent grade was obtained from Tokyo Kasei Co., Ltd. and was purified by refluxing and distilling over sodium (bp 167 °C). Zinc(II) nitrate of reagent grade was purchased from Wako Pure Chemical Co., Osaka and was recrystallized twice from water. The samples were prepared by dissolving zinc nitrate into aqueous ethylenediamine solutions.

The concentration of zinc(II) ions in the test solutions was determined by EDTA titration and gravimetry as $ZnNH_4PO_4$. The results of the two independent methods agreed each other within 0.2%.

The concentration of the nitrate ion was determined from the stoichiometry of the zinc(II) nitrate.

TABLE 1. THE COMPOSITION (g-atom/dm³) AND THE STOICHIOMETRIC VOLUME V PER ZINC ATOM IN THE SOLUTIONS

	Solutions	
	A	B
Zn	1.846	1.295
N	15.52	8.422
C	11.83	5.832
O	47.11	49.28
H	119.4	106.4
en/Zn	3.204	2.252
V/Å³	899.5	1282
Density/g cm⁻³	1.239	1.171

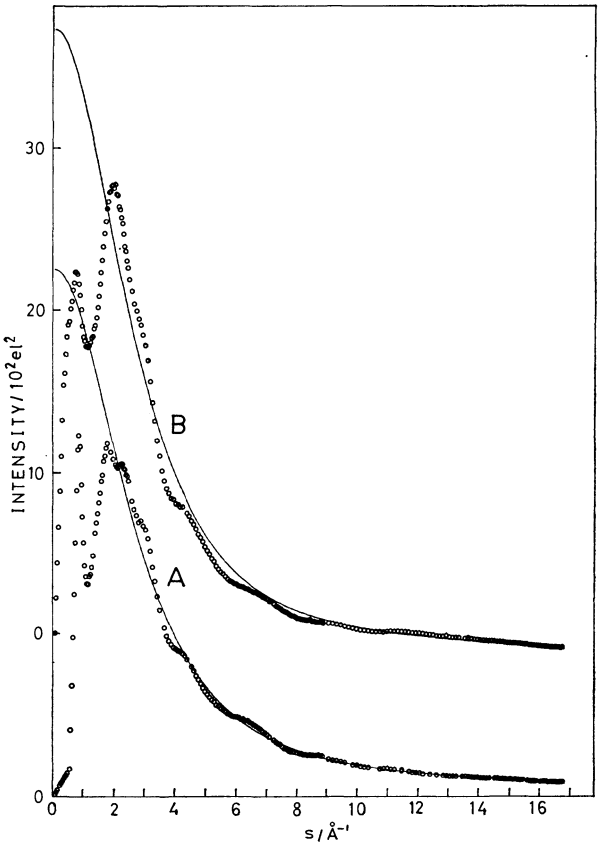

Fig. 1. Coherent scattering intensities of the sample solutions A and B. Experimentally obtained intensities I^{coh} are shown by circles and calculated independent scattering intensities by solid lines.

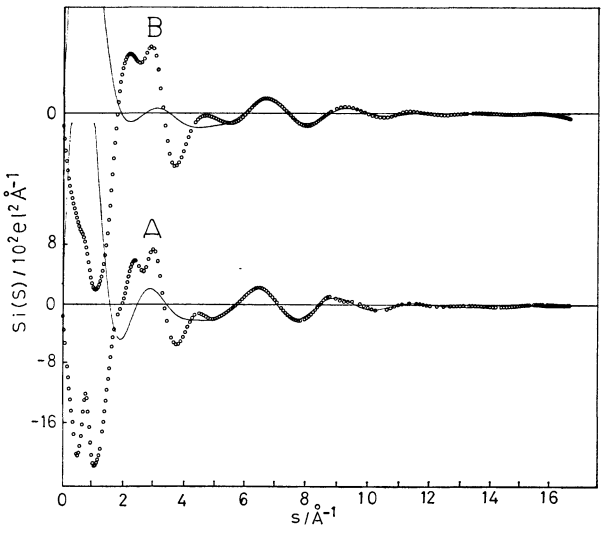

Fig. 2. The reduced intensities multiplied by s for solutions A and B. Open circles indicated experimentally obtained $s \cdot i(s)$ values and full lines are calculated ones by using parmeter values finally proposed.

The density of the test solutions was measured pycnometrically.

The composition of the test solutions is given in Table 1.

Method of Measurements and Treatment of X-Ray Scattering Data. The method of measurements and the apparatus used were essentially the same as those in previous papers.[1] Coherent and reduced intensities of the test solutions are given in Figs. 1 and 2, respectively. The radial distribution function $D(r)$ was calculated by the following equation:

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{s_{max}} s \cdot i(s) \cdot M(s) \cdot \sin(rs)\mathrm{d}s, \quad (1)$$

where ρ_0 is the average scattering density in the stoichiometric volume V of the solution per Zn atom, and s_{max} denotes the maximum s-value attained in the measurements ($s_{max}=16.7$ Å). $M(s)$ represents the modification function[2] and the reduced intensities $i(s)$ are given by

$$i(s) = I^{coh}(s) - \sum n_i\{(f_i(s)+\Delta f_i')^2+(\Delta f_i'')^2\}, \quad (2)$$

where n_i is the number of atom i and $f_i(s)$ denotes the scattering factor of atom i at s. $\Delta f_i'$ represents the real part of the anormalous dispersion, whereas $\Delta f_i''$ is the imaginary one.[3] The radial distribution curves $D(r)$ of the solutions were drawn after the Fourier transform of the reduced intensities which had been smoothed by the method described previously.[1]

The theoretical scattering intensities due to atom pairs of all possible combinations in the system were given as follows:

$$i_{calcd}(s) = \sum_{i}\sum_{i\neq j} n_{ij}\{(f_i(s)+\Delta f_i')(f_j(s)+\Delta f_j') + (\Delta f_i'')(\Delta f_j'')\} \cdot \frac{\sin(r_{ij}s)}{(r_{ij}s)} \cdot \exp(-b_{ij}s^2), \quad (3)$$

where r_{ij}, b_{ij}, and n_{ij} denote the distance, the temperature factor, and the frequency factor of an atom pair i-j, respectively.

All calculations were performed with the aid of electronic computers M 160 and M 180 by means of KURVLR program.[4]

Raman Spectroscopic Measurements. A JEOL JRS-S1 Raman spectrometer was employed with the use of the 4880 Å excitation line of Ar^+ laser.

Results and Discussion

Since no formation constants of the complexes has been reported in the literature in such concentrated solutions examined here, distributions of the zinc(II)–ethylenediamine complexes in the solutions were not estimated in advance of the X-ray measurements. However, we can approximately evaluate the formation constants of the ethylenediamine zinc(II) complexes in the solutions used in the present work by simply extrapolating the literature values.[5] The extrapolated values, as well as the literature values obtained in relatively low ionic strengths, suggested that both bis- and tris(ethylenediamine)zinc(II) complexes may coexist in each solution. In solution A the tris-complex may be the main species, whereas the bis-complex may be

(c) The theoretical peak shapes for the Zn–N, Zn···C, and N···N pairs within the $Zn(en)_2^{2+}$ complex. (d) The theoretical peak shapes for the Zn–N, Zn···C, and N···N pairs within the $Zn(en)_3^{2+}$ complex. (e) The corresponding $(D(r)-4\pi r^2\rho_0)$ curve to the $D(r)$ in (a). The dotted lines in (a) and (e) show the residual radial and residual differential radial distribution curves, respectively, after subtraction of these theoretical peaks.

predominant in solution B. In the analyses of the radial distribution curves of solutions A and B, the both complexes were taken into consideration at the same time in the following manner; at a first approximation the $D(r)$ curve of solution A was analyzed by assuming that the only tris-complex was contained. The parameter values for the structure of the complex thus estimated was used for analyzing the $D(r)$ curve of solution B in order to determine the structural parameters of the bis-complex so as to obtain a smooth background of the $D(r)$ curve. The parameter values thus obtained for the bis-complex were turned back to the calculation of the $D(r)$ curve of solution A in order to evaluate better parameter values of the tris-complex. The improved values of the tris-complex were again used for analyzing the $D(r)$ curve of solution B. The successive approach of the analysis was continued until no appreciable peak was left in the background of the radial distribution curves of both solutions A and B.

The parameter values, the bond distance(r), temperature factor(b), and frequency factor(n) of the models used for calculations of intensities due to intramolecular interactions were refined by using the data at high angle regions of the $s \cdot i(s)$ curves of solutions A and B. The refinements were carried out so as to obtain an error-square sum $U=\sum s^2\{i_{\mathrm{obsd}}(s)-i_{\mathrm{calcd}}(s)\}^2$ to be a minimum. The lower s limit in the calculation was varied in order to avoid introduction of errors to the refined parameters from intermolecular interactions. The least-squares calculations were performed by using the NLPLSQ program.[1]

Solution A. The radial distribution curve of solution A showed four major peaks over the range $r=$ 1—5 Å (Fig. 3a). A small peak at about 1.3 Å is composed of peaks due to the O–H bond within water, the N–H, C–H, C–C, and C–N bonds within ethylenediamine molecules and the N–O bond within nitrate ions (Fig. 3b). The second peak appearing at around 2.2 Å may be attributed to the interactions between zinc(II) ion and the nitrogen atoms of the ethylenediamine molecules coordinated to the central metal ion (Fig. 3, c and d). The distances corresponding to the nonbonding C···N pair in ethylenediamine molecules and the O···O contact within NO_3^- ion may also partly contribute to the peak. The third peak at 2.95—3.05 Å may be mainly ascribed to the nonbonded interactions of zinc(II) ion with the carbon atoms within ethylenediamine molecules coordinated. The broad peak at around 4—5 Å may include contributions among the complexes, free ligand and solvent molecules, which we will not discuss in this paper.

We assumed that the bond lengths of the N–H, C–H, C–C, C–N and C···N pairs within the ethylenediamine molecules are practically the same as those within free ligand molecules in the gas phase.[6] The structural parameters of nitrate ion were taken from the work by Maeda, *et al.*[7] and Caminiti, *at al.*[8] The values used in this work are summarized in Table 2. The Zn–N and Zn···C distances within the bis- (Fig. 3c) and tris-complexes (Fig. 3d) were estimated from the radial distribution curve of solution A. Successive approaches for the estimation have been employed as mentioned previously. The Zn–N and Zn···C bond lengths within the tris-complex were thus estimated to be 2.28 and 3.02 Å, respectively. The temperature factor of the former was determined to be 0.003 Å^2, while that of the latter was 0.006 Å^2. The area under the peak at 2.28 Å corresponded to six Zn–N bonds (see Fig. 3d), which were expected from the composition of the tris-complex. Subtraction of the peaks due to Zn–N and Zn···C interactions from the residual radial distribution curve led to a smooth background having no appreciable peak over the range $r<4$ Å, except for the peak at about 2.9 Å which was ascribed to the adjacent O···O interactions in the bulk water and hydrated nitrate ions[8] (Fig. 3, a and e).

The parameter values thus estimated from the analysis of the radial distribution curve were refined by the least-squares method for the intensity curve

Table 2. Bond distances (r) and temperature factors (b) for water and ethylenediamine molecules and nitrate ions

		r/Å	b/Å^2

	n	6.2(1)	6[b]
N···N[a]	r	3.16(6)	3.16(6)
Zn···C	r	3.00(1)	3.00(1)
	b	0.0053(6)	0.0053(6)
	n	6.1(2)	6[b]

a) The temperature factor of this interaction is estimated to be 0.01, quoted from Ref. 6. b) Fixed.

(Fig. 2). Two types of refinement (A-1 and A-2) were performed for solution A.

In type A-1, all the twelve parameters listed in Table 3 were allowed to change independently, a tetrahedral structure of the bis-complex being assumed. The frequency factors of the Zn–N bond and the nonbonding Zn···C interaction were close to six as expected in all the sets of data examined over the different s-regions from 5.0, 6.0, and 7.0 to 16.7 Å^{-1}.

In type A-2, an octahedral structure of the tris-complex as the main species was also assumed and the distances and the temperature factors of the Zn–N and nonbonding Zn···C interactions were refined. Since no appreciable difference was found in the results of the two calculations, the octahedral structure of the tris-complex having the parameter values given in Table 3 was concluded.

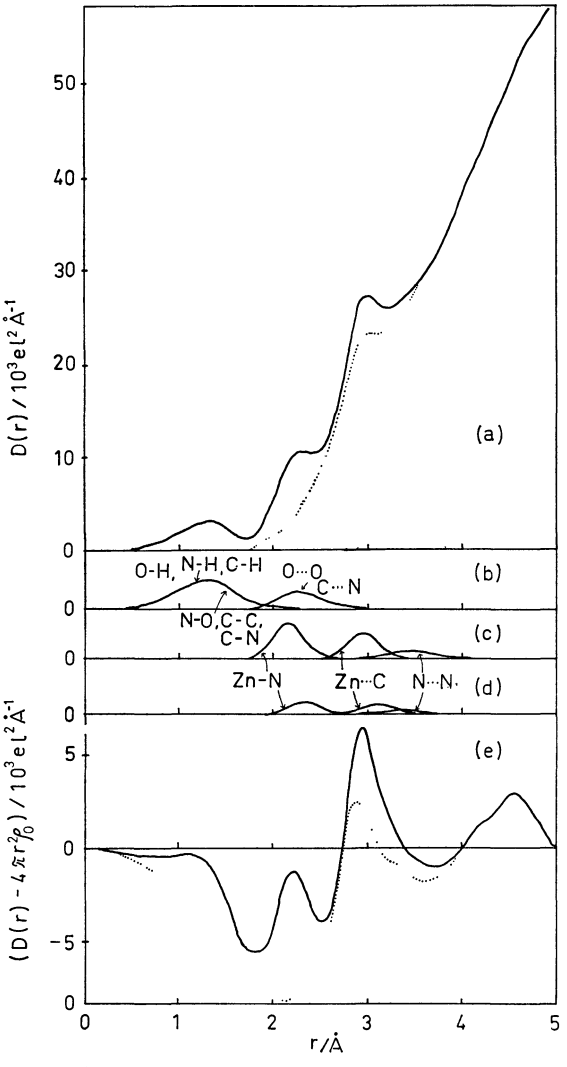

Fig. 4. (a) The radial distribution curve for solution B. (b) The theoretical peak shapes for the O–H bond within water, the N–H, C–H, C–C, C–N, and C···N pairs within ethylenediamine molecule, and the N–O and O···O contacts within nitrate ion. (c) The theoretical peak shapes for the Zn–N and Zn···C and N···N pairs within the $Zn(en)_2^{2+}$ complex. (d) The theoretical peak shapes for the Zn–N, Zn···C, and N···N pairs within the $Zn(en)_3^{2+}$ complex. (e) The corresponding $(D(r)-4\pi r^2\rho_0)$ curve to the $D(r)$ in (a). The dotted lines in (a) and (e) show the residual radial and residual differential radial distribution curves, respectively, after subtraction of these theoretical peaks.

Solution B. The essentially same procedure as that used for solution A was employed for analyzing the radial distribution curve of solution B. The contribution of the tris-complex coexisting to the curve was taken into account in the analysis. The structural parameters of the N–H, C–H, C–C, C–N, and C···N bonds within ethylenediamine molecules in the complexes were the same as those used in the previous section. The peaks due to the Zn–N and Zn···C distances within the tris-complex were eliminated from the radial distribution curve by the trial-and-error method.

The Zn–N and Zn···C distances within the biscomplex were evaluated as 2.14 and 2.93 Å, respectively, from the analysis of the radial distribution curve (Fig. 4). The area under the peak at 2.14 Å showed the four-coordinated zinc atom. A peak still remained at about 2.9 Å in the radial distribution curve (dotted lines in Fig. 4, a and e) was attributed to the structure of the bulk water and hydrated nitrate ions[8] as has been discussed in the previous section.

TABLE 4. RESULTS OF THE LEAST-SQUARES REFINEMENTS OF SOLUTION B

The refined parameters of the bond distance (r), temperature factor (b), and frequency factor (n) are obtained from the reduced intensity curve. The units of r and b are Å and Å^2, respectively. Standard deviations are given in parentheses.

Interaction	Parameter	B-1	B-2	B-3
O···O(NO_3^-)	r	2.20(2)	2.18(2)	2.18(2)
C···N(en)	r	2.31(5)	2.37(5)	2.29(6)
Bis-complex				
Zn–N	r	2.113(7)	2.134(7)	2.131(9)
	b	0.0035(4)	0.0027(4)	0.0026(5)
	n	4.10(8)	4.09(8)	4[b]
N···N[a]	r	3.9(2)	4.0(2)	3.8(2)
Zn···C	r	2.90(1)	2.90(2)	2.89(2)
	b	0.0057(6)	0.006[b]	0.006[b]
	n	4.7(2)	4[b]	4[b]

a) The temperature factor of this interaction is estimated to be 0.01, quoted from Ref. 6. b) Fixed.

The least-squares refinements were carried out for the parameter values of the bis-complex in order to obtain the best-fit curve to the experimentally obtained $s\cdot i(s)$ curve. In the case of solution B, three types of refinement (B-1, B-2, and B-3) were examined. In type B-1, all the nine parameters given in Table 4 were changed simultaneously. The frequency factor of the Zn–N bond of the bis-complex was always close to four in the various sets with lower s limits of 5.0, 6.0, and 7.0 Å^{-1}. In type B-2, the temperature and frequency factors of the nonbonding Zn···C interaction were held constant and the parameters for the Zn–N bond were refined because the frequency factor was strongly correlated to the temperature factor in the nonbonding Zn···C interaction. The possibility of the existence of $Zn(en)_2(H_2O)_2^{2+}$ as the bis-complex instead of $Zn(en)_2^{2+}$ could also be checked by this treatment; if the former

complex were formed, the frequency factor of the Zn–N in the calculation of B-2 would be six, because no distinction between Zn–O and Zn–N bonds was possible in the calculation. In type B-3, a tetrahedral structure of the bis-complex was assumed and the distances and temperature factors for the Zn–N and nonbonding Zn···C interactions were refined. The refined parameter values in the B-3 set were almost the same as those in the B-2 set.

The observed intensities are compared with the calculated ones (Eq. 3) by using the parameter values in Tables 3 (A-2) and 4 (B-3) (see Fig. 2). The agreement between the two curves is satisfactory except at the low-angle part of the curves where the intermolecular interactions significantly contribute to the $s \cdot i(s)$ curves. From the independent refinements of the parameter values for solutions A and B, the bis- and tris-complexes were confirmed to be tetrahedrally and octahedrally constructed in aqueous solution.

The Zn–N bond within the bis-complex was shorter than that within the tris-complex. The results are consistent with those reported in the literature[9] that the crystal ionic radius of a zinc(II) ion having the coordination number of 4 is smaller than that of a zinc(II) ion of the six-coordination.

Raman Spectra of Solutions A and B. Raman spectra of the tris(ethylenediamine)zinc(II) complex in aqueous solution have been studied by Krishnan and Plane.[10] They reported that the line at 423 cm^{-1} was due to the totally symmetric Zn–N stretching vibration of the tris-complex. In solution A of the present work (Fig. 5) we also found the line at 427 cm^{-1}. Since the line is strongly polarized, it is distinguishable from the skeletal deformation vibration band of free ethylenediamine of the *trans*-conformation which would appear at 475 cm^{-1} in solution.[11] Another strong line was observed at 883 cm^{-1}, for which Krishnan and Plane gave no assignment (in their work the line appeared at 878 cm^{-1}). The line may be ascribed to the rocking vibration of the $-CH_2-$ groups[11] within the ethylenediamine molecules. The band at 722 cm^{-1} was assignable to the ν_4-band of the nitrate ion. In the low frequency region of 170—300 cm^{-1}, some Raman lines were observed. However, no reasonable assignments to the lines were given.

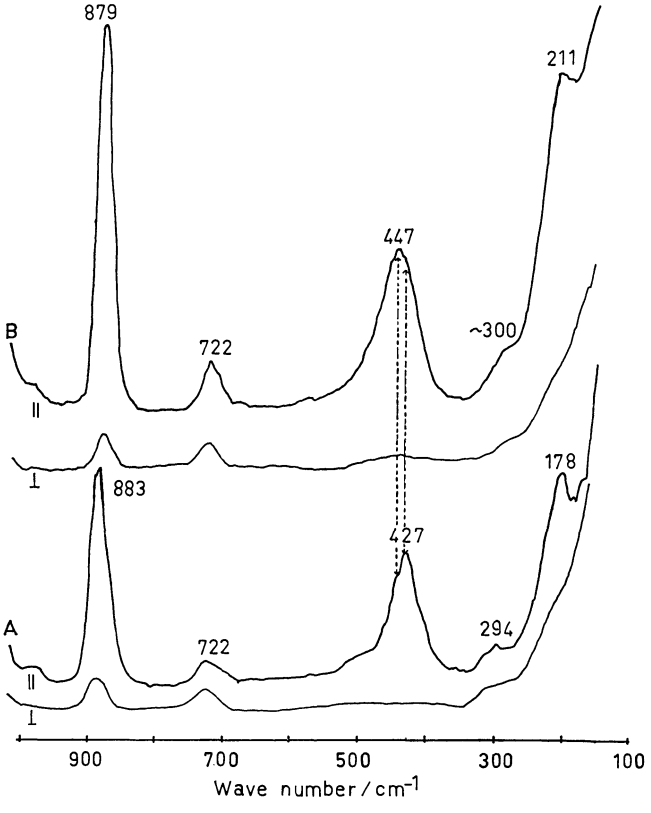

Fig. 5. Raman spectra of solutions A and B. The lines are the components parallel (∥) and perpendicular (⊥), respectively, to the direction of polarization of the incident light.

Krishnan and Plane have also measured the Raman spectrum of the bis-complex.[10] However, since their measurements were carried out in a very diluted solution (*ca.* 0.1 mol dm^{-3} for zinc(II) ion) and the test solution contained both bis- and tris-complexes to some extent, assignments of the bands observed for the bis-complex may be less reliable. Solution B in the present work contained the bis-complex with a relatively high concentration, which might be suitable for measuring the Raman spectrum of the bis-complex. The spectrum of solution B showed three major lines at 447, 722, and 879 cm^{-1} (Fig. 5B). The 722 and 879 cm^{-1} bands were readily assigned to the nitrate-ν_4 and CH_2-rocking vibrations, respectively, as have been described previously. The polarized line at 447 cm^{-1}, which was ascribed to the Zn–N sterching in the bis-complex, was in good agreement with the line found at about 450 cm^{-1} by Krishnan and Plane.[10] The frequency of the line was apparently higher than those of the corresponding lines of the tris-complex (427 or 423 cm^{-1} [10]) and the $Zn(NH_3)_4^{2+}$ complex (429[2] or 427 cm^{-1} [12]). These results indicated that the bis-complex has a stronger metal–nitrogen interaction than the other two complexes. This conclusion is supported by the fact that the bis-complex has a shorter Zn–N bond than the tris-complex. The Zn–N distance within the bis-complex is, however, longer than the Zn–NH_3 distance within the tetraammine-zinc(II) complex. The stronger interaction between zinc(II) ion and amino groups within the ethylenediamine molecules may be due to a greater basicity of the NH_2-groups in the ethylenediamine molecules by donating electrons from the CH_2 groups to the amino groups.

Kinetics of Ligand Exchange between Tris(acetylacetonato[2-^{14}C])cobalt(III) and Acetylacetone in Acetonitrile. Evidence for S_N1 Mechanism

Hiroaki KIDO* and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received May 1, 1979)

Tris(acetylacetonato[2-^{14}C])cobalt(III) undergoes ligand isotopic exchange with acetylacetone(Hacac) in acetonitrile at 85—100 °C without decomposition and solvolysis. The exchange rate is proportional to the complex concentration (0.002—0.007 M, 1 M=1 mol dm^{-3}), the first-order rate constant k_o being independent of [Hacac] (0.001—0.97 M). $k_o=1.6\times10^{-5}$ s^{-1} at 93.2 °C. The activation enthalpy and entropy are 38 ± 4 kcal mol^{-1} (1 cal=4.18 J) and 23 ± 8 cal K^{-1} mol^{-1}, respectively. Trichloroacetic acid (<0.02 M) gives acid catalysis. The rate-determining step should be the S_N1 Co–O cleavage in a chelate ring to give a five coordinate intermediate.

The complexes of Co(III) along with those of Cr(III) and Ni(II) have played an essential role for enabling us to understand the mechanism of octahedral substitution.[1,2] A number of kinetic studies were carried out on Co(III)N_5O type complexes represented by $[Co(NH_3)_5(H_2O)]^{3+}$.[3] However, little information is available concerning kinetics and mechanisms of ligand substitution processes of spin-paired Co(III) complexes containing Co(III)O_6 core. Kinetics of aquation of $[Co(ox)_3]^{3-}$ [4] and $[Co(mal)_3]^{3-}$ [5] (ox=oxalate, mal=malonate) are complicated for discussing the substitution mechanism around the metal ion. Water exchange[6] and the anation of chloride[7] for $[Co(H_2O)_6]^{3+}$ were kinetically studied only in the presence of $[Co(H_2O)_6]^{2+}$.

In a previous paper, we discussed the mechanism of the ligand exchange between Cr(acac[2-^{14}C])$_3$ and acetylacetone (Hacac) in acetonitrile.[8] The rates of the ligand exchange of the present complex in toluene, anisole, and chlorobenzene under conditions involving partial decomposition of the complex were observed.[9] We have found that the decomposition of Co(acac)$_3$ in acetonitrile subsides on elimination of dissolved oxygen, and have reinvestigated the ligand exchange kinetics to disclose the substitution mechanism at the low-spin Co(III)O_6 core.

Experimental

Materials. Acetylacetone[2-^{14}C] was prepared and purified as reported.[10] Acetylacetone was dehydrated with calcium sulfate and distilled. Co(acac[2-^{14}C])$_3$ and Co(acac)$_3$ were synthesized from the labelled and the commercial ligand, respectively, by the usual method,[11] and sublimed *in vacuo* at *ca.* 130 °C. Deuterium oxide (spectroscopic grade, E. Merck, 99.75%) was used without further purification. Trichloroacetic acid was sublimed *in vacuo*. Acetonitrile was distilled twice in the presence of phosphorus pentaoxide.

Kinetic Procedure. Two ml portions of acetonitrile solution containing Co(acac[2-^{14}C])$_3$ (0.0017 to 0.0070 M, 1 M=1 mol dm^{-3}), Hacac (0.001 to 0.97 M), and water (0.02 to 0.12 M), were degassed and sealed in 3—5 Pyrex glass tubes (diam. 10 mm, length 80 mm) *in vacuo* (10^{-3} mmHg). The tubes were simultaneously heated in a silicone oil bath at 85—101 °C, withdrawn one by one at appropriate time intervals and put into a cold water bath. Hacac, water and acetonitrile were collected individually from the 1 ml portions by distilling into small tubes in a liquid nitrogen bath *in vacuo* at room temperature to leave Co(acac)$_3$ in the original tubes. (Trichloroacetic acid, whenever present in the reaction mixture also remained in the original tubes.) Both Hacac and Co(acac)$_3$, quantitatively recovered and found to be spectroscopically pure, were separately dissolved in anisole containing 0.1% *p*-terphenyl and 0.04% *p*-bis(5-phenyl-2-oxazolyl)benzene(POPOP), the counting rate being measured with a Nuclear Chicago Unilux IIA Liquid Scintillation Counter. The specific counting rate was calculated from the counting rate and the original weight of the compounds. The water content of the reaction mixture was determined by the Karl Fischer titration before and after the kinetic run; it remained unchanged within experimental error.

Calculation of the Exchange Rate. The rates were calculated by the McKay equation

$$\text{Rate} = \frac{-3[\text{Co}][\text{Hacac}]}{3[\text{Co}]+[\text{Hacac}]}\,\frac{\ln(1-F)}{t},$$

where [Co] and [Hacac] stand for the concentrations of the complex and the free ligand, respectively, t is the lapse of time in seconds, and F the fraction of reaction which is expressed by $(x_0-x_t)/(x_0-x_\infty)$, x being the specific counting rate of the complex or the free ligand at the time indicated by subscript.

Hacac is in tautomeric equilibrium between enol and keto form, but the intercoversion rate is *ca.* 10—100 times as great as the exchange rate in the given temperature range. The total concentration of Hacac, therefore, was taken to be [Hacac].

Results

The absorption spectra of the reaction mixtures remained unchanged throughout the reaction. The McKay plots gave straight lines up to at least 75% completion of the exchange. The F values individually calculated from the measured specific counting rates of Hacac and Co(acac)$_3$ coincide with each other within experimental error. Thus no reactions other than the isotopic exchange

$$\text{Co}(\overset{*}{\text{acac}})_3 + \text{Hacac} \rightleftharpoons \text{Co}(\text{acac})_3 + \overset{*}{\text{Hacac}} \qquad (1)$$

took place during the course of heating. No significant zero time exchange was observed. The rate is proportional to the complex concentration (0.0017—0.0070 M) as shown in Table 1, and expressed by

$$\text{Rate} = k_o[\text{Co}], \qquad (2)$$

where k_o is the observed first-order rate constant. The k_o value is independent of the water (0.017—0.119 M, Table 1) and the free ligand concentrations (0.001—1 M, Fig. 1). Thus we have

TABLE 1. RATES AND OBSERVED FIRST-ORDER RATE CONSTANTS FOR THE ISOTOPIC EXCHANGE BETWEEN $Co(acac)_3$ AND Hacac IN ACETONITRILE AT 101.1 °C ([Hacac]$=9.75\times10^{-3}$ M)

[Co] / 10^{-3} M	[H_2O] / 10^{-3} M	R / 10^{-8} M s^{-1}	k_o / 10^{-5} s^{-1}
1.74	69	8.9±0.4	5.1±0.2
3.48	66	18 ±1	5.1±0.2
6.59	72	38 ±2	5.4±0.3
3.48	17	17 ±1	4.9±0.3
3.48	119	18 ±1	5.3±0.3

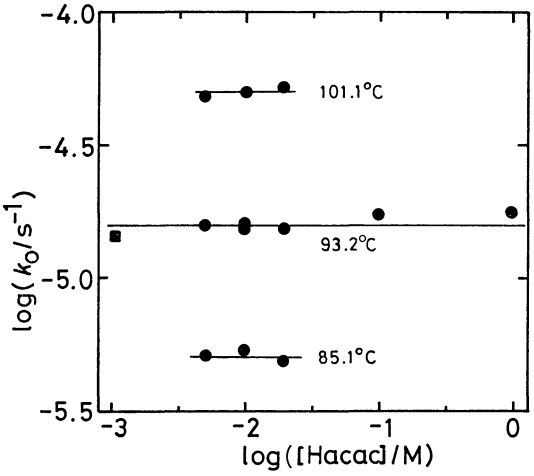

Fig. 1. Log-log plots of the observed rate constant k_o *vs.* the concentration of the free ligand, [Hacac], for the ligand exchange of $Co(acac[2\text{-}^{14}C])_3$ in acetonitrile. ([Co]$=3.5\times10^{-3}$ M (circles), 9.9×10^{-3} M (square). [H_2O]$=7\times10^{-2}$ M.)

$$k_o = k_i[\text{Hacac}]^0[H_2O]^0. \quad (3)$$

When D_2O was added to the reaction mixtures in place of H_2O, no change occured in k_o.

In the presence of trichloroacetic acid, the exchange proceeded apparently by 20—30% at zero time, which would be separation induced exchange. The k_o value depends on the acid concentration at given concentrations of the complex (0.0035 M), the free ligand (0.0097 M) and water (0.07 M) (Fig. 2). The solid lines have intercepts, which coincide with k_i values obtained in the absence of the acid. Thus we have

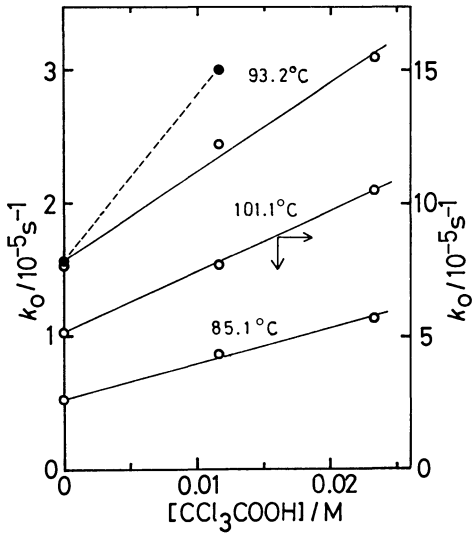

Fig. 2. Influence of trichloroacetic acid and deuterium oxide on the exchange rate. ([Co]$=3.5\times10^{-3}$ M, [Hacac]$=9.7\times10^{-3}$ M and [H_2O]$=7\times10^{-2}$ M for open circles. $D_2O(5\times10^{-2}$ M)+$H_2O(2\times10^{-2}$ M) as the original ingredients for full circles.)

$$k_o = k_i + k_a[CCl_3COOH]. \quad (4)$$

When D_2O was added to the reaction mixture in place of H_2O, k_o increased significantly in the presence of the acid (Fig. 2). Ratio of the rate constants (k(H)/k(D)) was calculated on the assumption that equilibrium was attained for all the dissociable protons and deuterons in the reaction system.

The rate constants are summarized in Table 2 together with the activation parameters and k(H)/k(D) values.

Discussion

Equation 4 indicates that the exchange (Eq. 1) proceeds by the two paths, k_i and k_a.

Rate-determining Steps of the k_i Path. Equations 2 and 3 indicate the participation of only the complex in the rate-determining step of the k_i path.

The k_i value is similar to that of the first-order rate constant k_{rac} of the racemization of $Co(acac)_3$ in chlorobenzene in a similar temperature region.[12] Their activation enthalpies and entropies are also very

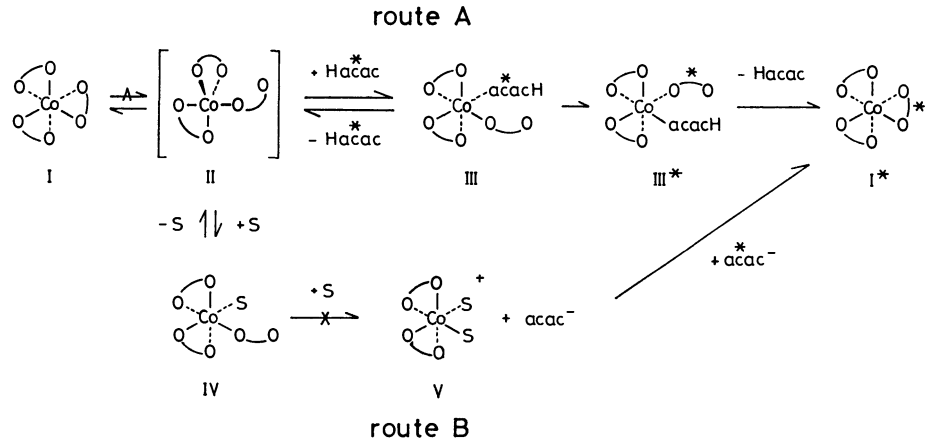

Fig. 3. Proposed mechanism for the ligand exchange of Co(acac[2-^{14}C])$_3$ in acetonitrile. (The structure of II is provisional. Asterisks denote ^{14}C labelling. Arcs and S represent acetylacetonate and acetonitrile or H_2O, respectively.)

similar (Table 2). This suggests a common rate-determining step for the reactions, despite the difference in solvent. The mechanism of the racemization has not been verified, but it is anticipated to be very similar to that of the racemization and the isomerization of *fac*- and *mer*-tris(benzoylacetonato)cobalt(III) (Co(bzac)$_3$) in chlorobenzene,[13] on the basis of similar values of ΔH^* and ΔS^*. Girgis and Fay verified that these reactions of Co(bzac)$_3$ proceed by an intramolecular mechanism and found that the rates are independent of solvents including chlorobenzene and acetonitrile. The racemization of Co(acac)$_3$ in these solvents might proceed similarly. The present k_i value was also insensitive to the variation of solvent, *e.g.* no change by use of acetylacetone as solvent.[14] Thus, there should be a common rate-determining step for these inter- and intra-molecular reactions. It should be the first cleavage of Co–O bond. The bond break would take place by the S_N1 mechanism, since the solvent-assisted S_N2-like path does not seem feasible in these reactions. Consequently, five-coordinate intermediate containing a unidentate acetylacetonate would be formed (I→II in Fig. 3).[15] The intermediate might have an achiral structure, *e.g.*, a trigonal bipyramid shown in Fig. 3.

Mechanism for k_i Path. After the rate-determining step, the k_i path can proceed *via* two possible routes A and B (Fig. 3). In route A, II interacts with free Hacac to form III containing both unidentates, acac$^-$ and Hacac, as ligands. III is converted into III* by a proton transfer process, and III* turns to I*. In route B, II loses one acac$^-$ to give V. The solvent molecule or water may occupy the vacant site. V can pick up acac$^-$. However, route B is unlikely. If the dissociation of the unidentate acac$^-$ proceeded fast, direct exchange of acac$^-$ between the complex molecules could take place at a measurable rate even in the absence of free Hacac. Such an interchange for Co(bzac)$_3$ was much slower than the isomerization.[13] The intermediate IV, even if it is formed, might be in equilibrium only with II as a dead end species. Therefore, the k_i path must proceed *via* route A. The exchange of the k_i path is understood to consist of the substitution processes (I→III and III*→I*) connected with a proton transfer process (III→III*). The substitution processes should be identical with each other, since reaction routes of exchange reactions are symmetrical.

The substitution process can be reckoned to proceed by the S_N1 mechanism. The mechanism is also in line with the observed activation parameters, a large positive value of ΔS^* and a rather large value of ΔH^*. It is thus demonstrated for the first time that a low-spin complex with Co(III)O$_6$ core undergoes ligand substitution by the S_N1 mechanism, as almost all other complexes with different ligating atoms.[1]

Structure of the Intermediate. The intermediate II seems stable towards the Co–O bond cleavage of the unidentate ligands. Even in the absence of free Hacac, II undergoes racemization but not dissociation. Such a stability may be attributed to the conjugated structure of the ligand. The Co–O bond may be stabilized by concentration of negative charge on the coordinated oxygen, which is partly neutralized with positive charge on the central metal ion. Hence, the structure Co–O–C(CH$_3$)=CH–C(CH$_3$)=O, is presumed for the unidentate in II, III, III*, and IV. This structure is found in *trans*-[Pt^{II}(C$_5$H$_7$O$_2$)$_2$(PEt$_3$)$_2$] in solution (CDCl$_3$) and crystals.[17]

The structure of the intermediates III and III* could not be determined exactly. The enol form of the incoming Hacac is more feasible than the keto form. Enol was found to be much more reactive over keto in the ligand exchange of Ti^{IV}(acac)$_3^+$ in acetonitrile.[18] The keto oxygen of enol Hacac could coordinate to Co(III). Coordination of enolic acetylacetone as a unidentate is found in crystals of Mn^{II}Br$_2$(Hacac)$_2$.[19,20]

The two unidentates in III (and III*) should be cis to each other, at least when the proton is exchanged. The presence of a trans isomer cannot be excluded, but it does not seem to play an important role in the ligand exchange reaction. It may be a dead end species, even if it is formed.

k_a Path. The exchange reaction (Eq. 1) is catalyzed by trichloroacetic acid (Eq. 4). A remarkable

deuterium isotope effect ($k(H)/k(D)=0.4$) was found for the acid catalyzed k_a path (Table 2). A $k(H)/k(D)$ value less than unity indicates the participation of a proton in a pre-equilibrium step.[21] A plausible mechanism is proposed in the following.

$$\underset{\text{I}}{\text{Co(acac)}_3} + \text{H}^+ \overset{\text{fast}}{\rightleftharpoons} \underset{\text{I}'}{\text{(acac)}_2\text{Co}\begin{array}{l}\diagup\text{OH}^+\\ \\ \diagdown\text{O}\end{array}} \qquad (5)$$

$$\underset{\text{I}'}{\text{(acac)}_2\text{Co}\begin{array}{l}\diagup\text{OH}^+\\ \\ \diagdown\text{O}\end{array}} \overset{\text{r.d.s.}}{\longrightarrow} \underset{\text{II}'}{\text{(acac)}_2\text{Co–O—OH}^+} \qquad (6)$$

where O–O$^-$ denotes acac$^-$, and II′ is a five-coordinated intermediate. The fate of II′ is considered to be similar to that of II in the k_i path (Fig. 3). The observed ΔH^* value for k_a slightly lower than that for k_i may be due to an easier cleavage of a Co–O bond with the aid of H$^+$.

Comparison with Cr(acac)$_3$. The ligand exchange of Cr(acac)$_3$ in acetonitrile in high [Hacac] (>0.1 M) region was considered to proceed *via* III type intermediate (Fig. 3) by the S_N2 attack of the free ligand, in view of the first-order dependency of k_o on [Hacac] and the values of the activation parameters.[8] However, the present k_i value did not change with the increase of [Hacac] up to 1 M (Fig. 1). This indicates that an S_N1 operates in the k_i path even in the high [Hacac] region. The difference in mechanism is in line with that in the general understanding of substitution mechanisms of these two kinds of metal complexes containing N_5O core (Cr(III): S_N2; Co(III): S_N1).[1]

The work was carried out with a Grant-in-Aid from the Ministry of Education.

Reaction Processes of Vanadium Dichloride Oxide and Vanadium Trichloride with Oxygen

Akimasa YAJIMA, Ryoko MATSUZAKI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received May 11, 1979)

The products formed by the heating of VCl_2O in an oxygen stream at various temperatures were examined by chemical and X-ray analysis. The reaction products between VCl_3 and oxygen were examined in the same manner. The reaction process between VCl_2O and oxygen may be represented as follows: VCl_2O reacts with oxygen above *ca.* 170 °C to form V_2O_5 and VCl_3O, $12VCl_2O(s)+3O_2(g)\rightarrow 2V_2O_5(s)+8VCl_3O(g)$, and this reaction is accompanied by the reaction, $4VCl_2O(s)+3O_2(g)\rightarrow 2V_2O_5(s)+4Cl_2(g)$. The reaction process between VCl_3 and oxygen may be represented as follows: VCl_3 reacts with oxygen above *ca.* 100 °C to form VCl_3O, $2VCl_3(s)+O_2(g)\rightarrow 2VCl_3O(g)$, and this reaction is accompanied by the reaction, $2VCl_3(s)+O_2(g)\rightarrow 2VCl_2O(s)+Cl_2(g)$.

Vanadium trichloride oxide (VCl_3O) which is dissolved in crude titanium tetrachloride ($TiCl_4$) prepared by the chlorination of titanium ores is commercially removed as a non-volatile vanadium-containing precipitate by bubbling hydrogen sulfide through the crude $TiCl_4$. The present authors[1] have previously reported that the vanadium-containing precipitate formed by the reaction between VCl_3O and hydrogen sulfide is a mixture of vanadium dichloride oxide (VCl_2O) and a small amount of vanadium trichloride (VCl_3). From the view point of waste reclamation, it is necessary to understand the chemical process for the preparation of divanadium pentaoxide (V_2O_5) and chlorine by the oxidation of the mixture of VCl_2O and VCl_3 with oxygen (air).

There has been no report on the reaction process between VCl_2O and oxygen. Regarding the reaction between VCl_3 and oxygen, Ruff and Lickfett[2] have reported that VCl_3O is formed by heating VCl_3 at *ca.* 500—600 °C in an oxygen stream. Lamprey and Forsyth[3] have briefly described that the reaction, $VCl_3+1/2O_2\rightarrow VCl_3O$, mainly occurs above 250 °C on heating VCl_3 in air. Pechkovskii and Vorob'ev[4] have reported that the reaction between VCl_3 and oxygen to form VCl_3O mainly occurs above 200 °C on heating VCl_3 in an oxygen stream, and that onyl a small part of the VCl_3 is oxidized to V_2O_5.

In this paper, the reaction processes of VCl_2O and VCl_3 with oxygen will be revealed.

Experimental

The VCl_2O used was prepared from VCl_3, divanadium trioxide (V_2O_3), and VCl_3O by the method based on the literature.[5] Chemical analysis of the VCl_2O obtained gave V, 37.0; Cl, 51.4% (Calcd for VCl_2O: V, 36.96; Cl, 51.44 %); it was confirmed to be VCl_2O[6] by X-ray analysis. VCl_3 was obtained by the thermal decomposition of VCl_4, which was prepared by the reaction between vanadium (V, 99.8% up) and chlorine at 500 °C,[7] at 180 °C in an argon atmosphere.[8] The chemical analysis gave V, 32.4; Cl, 67.6% (Calcd for VCl_3: V, 32.38; Cl, 67.62%); it was confirmed to be VCl_3[9] by X-ray analysis. The oxygen was dried by passing it through conc. sulfuric acid and over diphosphorous pentaoxide.

The sensitivity of the quartz helix used for thermogravimetry (TG) was approximately 67 mm/g. The sample (0.15 g) was heated at a rate of 2.5 °C/min and the flow-rate of argon or oxygen was maintained at 50 cm^3/min.

X-Ray analysis of the solid sample was performed using Ni-filtered Cu radiation. The sample chamber of the diffractometer was maintained under dry nitrogen atmosphere to prevent the contamination of the sample with moisture in air during the irradiation.

The products obtained by heating VCl_2O and VCl_3 in an oxygen stream at various temperatures were examined by the following procedures: The sample (1.0 g) in a quartz boat (60 mm length, 13 mm width, 7 mm depth) was placed in a straight reaction tube (16 mm i. d.) with a water-cooled condenser. Oxygen was introduced into the reaction tube at a flow-rate of 50 cm^3/min. The sample part was then placed in the centre of an electric furnace (300 mm in heating length) maintained at a specified temperature for a specified period. The temperature of the sample part was controlled to within ±2 °C.

The liquid product (VCl_3O) was collected in a trap cooled in solid carbon dioxide through the condenser. The chlorine formed was absorbed in KI solution through the trap and determined by iodometry. The total amount of chlorine formed during the reaction was determined by adding the above value and the amount of chlorine dissolved in the liquid product in the solid carbon dioxide trap.[10] The determination of the amount of chlorine dissolved in the liquid product will be described later.

Chemical analysis of the solid and liquid products was performed as follows: The vanadium content in the sample was determined by chelatometric titration,[11] while the chlorine content was gravimetrically determined as AgCl, after dissolving the sample in dilute nitric acid.

The amount of chlorine dissolved in the liquid product in the solid carbon dioxide trap was determined as follows: After the reaction was over, the liquid product was allowed to warm to room temperature in an argon atmosphere in order to liberate the chlorine from the liquid product. The liberated chlorine was absorbed in NaOH solution. A small amount of the liquid product which vaporized during the above procedure was also absorbed in the NaOH solution. The total amount of chlorine in the NaOH solution was gravimetrically determined as AgCl and the vanadium content in the NaOH solution was also determined by chelatometric titration. From the vanadium content, the amount of the liquid product absorbed in the NaOH solution was calculated. The amount of chlorine dissolved in the liquid product was calculated by subtracting the amount of chlorine corresponding to the liquid product absorbed in the NaOH solution from the total amount of chlorine in the NaOH solution.

The total amount of liquid product formed was corrected by adding the amount of liquid product absorbed in the NaOH solution to the amount of liquid product in the trap.

Throughout this work, the chlorides and chloride oxides of vanadium were handled in an argon atmosphere or *in vacuo* to prevent any contamination with moisture in air.

Results and Discussion

Reaction Process between Vanadium Dichloride Oxide and Oxygen. It has been reported that on heating VCl_2O in an inert atmosphere, the disproportionation occurs above 300 °C[12] or 330 °C,[4] according to the reaction, $2VCl_2O(s) \rightarrow VClO(s) + VCl_3O(g)$.

Prior to the examination of the reaction between VCl_2O and oxygen, the behavior of VCl_2O on heating in an argon stream was examined. The TG curve showed that VCl_2O lost weight continuously above *ca.* 295 °C and the weight reached a constant value at *ca.* 380 °C. The sample heated up to 380 °C was shown to be VClO[13] by X-ray analysis. The weight loss at 380 °C was 62.9%. This value was in good agreement with the calculated value, 62.86%, based on the disproportionation of VCl_2O. The gaseous product was confirmed to be VCl_3O by chemical analysis of the product obtained by heating VCl_2O (1.0 g) in an argon stream at 370 °C for 3 h. From these results, it is confirmed that VCl_2O disproportionates above *ca.* 295 °C according to the reaction, $2VCl_2O(s) \rightarrow VClO(s) + VCl_3O(g)$.

The TG curve of VCl_2O in an oxygen stream showed that VCl_2O reacted appreciably with oxygen above *ca.* 180 °C before disproportionating. To obtain more detailed information on the reaction between VCl_2O and oxygen, the products formed by heating VCl_2O at various temperatures for 0.5—3 h in an oxygen stream were examined by X-ray and chemical analysis.

At 160 °C, no reaction product was observed. The reaction products obtained at various temperatures above 170 °C and their weight percentages to the initial VCl_2O were determined by chemical and X-ray analysis.[6,14,15] The results are summarized in Table 1.

The most stable oxide phase of vanadium under the conditions of this work is V_2O_5.[16] Trivanadium heptaoxide (V_3O_7) was not formed below 240 °C as shown in Table 1, but a small amount of V_3O_7 was formed in addition to V_2O_5 above 260 °C. As shown in Table 1, the reaction between VCl_2O and oxygen proceeded markedly above 260 °C to form a large amount of gaseous VCl_3O. Consequently, the reaction between VCl_2O and oxygen has been thought to proceed under a low oxygen concentration to form V_3O_7 in addition to V_2O_5. The solid products obtained by heating VCl_2O (1.0 g) at 290 °C under various flow-rates of oxygen for 1 h were examined. The results are shown in Table 2.

Table 2. Solid products between VCl_2O and oxygen at various flow-rates of oxygen

O_2 flow-rate/ $cm^3\ min^{-1}$	Solid product/%		Unreacted VCl_2O/%
	V_2O_5	V_3O_7	
50	66	3	31
100	71	1	28
200	73	—	27

From the results, it was observed that V_3O_7 was not formed under a high flow-rate of oxygen. This confirms the above consideration on the formation of V_3O_7.

The experimental results for the reaction products between VCl_2O and oxygen at various temperatures, shown in Table 1, indicated that V_2O_5 and VCl_3O were the main products. This fact was considered to indicate that the main reaction on heating VCl_2O in an oxygen stream was the reaction,

$$12VCl_2O(s) + 3O_2(g) \longrightarrow 2V_2O_5(s) + 8VCl_3O(g). \quad (1)$$

The possible reactions giving the chlorine (in Table 1) were considered to be the reaction,

$$4VCl_2O(s) + 3O_2(g) \longrightarrow 2V_2O_5(s) + 4Cl_2(g), \quad (2)$$

and the reaction between gaseous VCl_3O formed by Reaction 1 and oxygen,

$$4VCl_3O(g) + 3O_2(g) \longrightarrow 2V_2O_5(s) + 6Cl_2(g). \quad (3)$$

As reported in the previous report,[17] Reaction 3 does not proceed below 400 °C. Consequently, the formation of a small amount of chlorine obtained by heating VCl_2O in an oxygen stream was considered to be due to Reaction 2.

Based on this assumption, the amount of V_2O_5 formed by Reaction 2 was calculated from the amount of chlorine formed (in Table 1). The molar ratio of the amount of VCl_3O to the amount of V_2O_5 obtained by subtracting the amount of V_2O_5 formed by Reaction 2 from the total amount of V_2O_5 formed was calculated to be approximately 4: 1. In this calculation, the amount of V_3O_7 formed was converted into that of V_2O_5 on the assumption that V_3O_7 was oxidized to V_2O_5. These results confirmed that the main reaction which occurred by heating VCl_2O in an oxygen stream was Reaction 1 and that this reaction was accompanied by Reaction 2.

The above-mentioned results reveal that VCl_2O reacts with oxygen above *ca.* 170 °C according to Reaction 1 and that this reaction is accompanied by Reaction 2. As a result, V_2O_5 (under a low oxygen concentration, V_3O_7 is formed in addition to V_2O_5), VCl_3O, and a small amount of chlorine are formed.

Reaction Process between Vanadium Trichloride and Oxygen. On heating VCl_3 in an argon stream, the VCl_3 disproportionates above *ca.* 350 °C according to the reaction, $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$, as previously reported by the present authors.[17]

The TG curve showed that VCl_3 reacted appreciably with oxygen above *ca.* 110 °C before disproportionating. To obtain more detailed information on the reaction between VCl_3 and oxygen, the products formed by heating VCl_3 at various temperatures for 1—6 h in an oxygen stream were examined.

At 90 °C, no reaction product was observed. The reaction products obtained at various temperatures above 100 °C and their weight percentages to the initial VCl_3 were determined by chemical and X-ray analysis.[6,9] The results are summarized in Table 3.

The experimental results shown in Table 3 indicated that VCl_3O was the main product by the reaction between VCl_3 and oxygen. This fact was considered to indicate that the main reaction on heating VCl_3 in an oxygen stream was the reaction,

$$2VCl_3(s) + O_2(g) \longrightarrow 2VCl_3O(g). \quad (4)$$

Small amounts of VCl_2O and chlorine were formed in addition to VCl_3O. The molar ratio of the amount of VCl_2O to the amount of chlorine was calculated to be approximately 2: 1. This fact was considered to indicate that the reaction,

$$2VCl_3(s) + O_2(g) \longrightarrow 2VCl_2O(s) + Cl_2(g), \quad (5)$$

occurred in addition to Reaction 4.

Based on the assumption that the formation of VCl_2O and chlorine was due to Reaction 5, the amount of VCl_3 consumed by Reaction 5 was calculated from the amount of chlorine formed (in Table 3). The molar ratio of the amount of VCl_3O formed to the amount of the reacted VCl_3 obtained by subtracting the amount of VCl_3 consumed by Reaction 5 from the total amount of the reacted VCl_3 was calculated to be approximately 1: 1. These results confirmed that the main reaction which occurred by heating VCl_3 in an oxygen stream was Reaction 4 and that this reaction was accompanied by Reaction 5.

The above-mentioned results reveal that VCl_3 reacts with oxygen above *ca.* 100 °C according to Reaction 4 and that this reaction is accompanied by Reaction 5. As a result, VCl_3O and small amounts of VCl_2O and chlorine are formed.

As mentioned above, Pechkovskii and Vorob'ev[4] have reported that on heating VCl_3 in an oxygen stream, a small part of the VCl_3 is oxidized to V_2O_5. From the results of this work, it is probable that the V_2O_5 is formed by the reaction of VCl_2O, formed by Reaction 5, with oxygen.

Circular Dichroism and Stereochemistry of Tetranuclear Cobalt(III) Complexes of Hexol Type. II.[1] Hexakis(ethylenediamine)-hexa-μ-hydroxo-tetracobalt(III) Ion, $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$

Tomikatsu KUDO* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 24, 1979)

The theoretically possible eight optical isomers of hexakis(ethylenediamine)-hexa-μ-hydroxo-tetracobalt(III) ion, $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$, were separated by column chromatography, absorption and circular dichroism spectra being measured in the visible and ultraviolet region in 0.01 mol dm^{-3} HCl and 0.15 mol dm^{-3} Na_2SeO_3 solutions. Absolute configurations were determined by means of circular dichroism spectra and the characterization of mononuclear cobalt(III) ions produced by decomposition of the tetranuclear isomers in an acid solution. The additivity of the two main circular dichroism contributions due to the chiral CoO_6 and CoN_4O_2 chromophores is discussed, and the configurational chirality of CoO_6 chromophore is expressed by summing up the contributions from three pairs of CoN_4O_2 chromophores as in the so-called ring-pairing method.

Hexakis(ethylenediamine)-hexa-μ-hydroxo-tetracobalt(III) complex salt was prepared by Werner for the first time.[2] For this tetranuclear hexol-type complex there are eight possible optically active isomers which then compose four racemic isomers. The structures of two of the four racemic isomers have been found by X-ray analysis of the salts of $\Delta(\Delta\Delta\Delta)/\Lambda(\Delta\Delta\Lambda)$ and $\Delta(\Lambda\Lambda\Lambda)/\Lambda(\Delta\Delta\Delta)$ isomers.[3-5] However, little success has been made concerning the optical resolution of this complex ion.[6,7] Kern and Wentworth reported that four of the eight possible optical isomers of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ are formed in solution, only two of them (a couple of enantiomers) being obtained in pure fractions.[6] They could not assign the configurations of the isomers. The present paper deals with successful separation of all the eight isomers and assignments of their configurations. Discussion is given on their circular dichroism (CD) spectra including CD change by ion-pairing with some oxoanions as compared with the spectra of the corresponding dodecaammine complex.[1]

Experimental

Preparation and Separation of the Isomers of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$. The complex was prepared by a modification of the method of Werner.[2] To 14.5 g of $Co(NO_3)_2\cdot 6H_2O$ in 15 cm^3 of water was slowly added 30 cm^3 of a 10% solution of ethylenediamine with stirring. The mixture was stirred vigorously by blowing compressed air on the surface for about one hour at room temperature, the remaining solid being filtered off and washed with a small amount of water. The filtrate and washings were poured into a column (5×120 cm) of strong-acid exchanger (SP Sephadex C-25, Na^+ form). After a broad pink-red band had been swept out with 0.1 M (1 M = 1 mol dm^{-3}) sodium *d*-tartrate solution, the adsorbed band was eluted with 0.3 M sodium *d*-tartrate solution. During the course of elution the column was cooled by flushing cold water of 5 °C. Eight brown bands eluted were numbered f-1, f-2, ···, and f-8 in the order of elution. At this stage, it was confirmed by measurements of CD spectra that each pair of isomers f-1 and f-2, f-3 and f-4, f-5 and f-6, and f-7 and f-8 represents a couple of enantiomers. Each eluate was concentrated in a vacuum rotatory evaporator at 20 °C, when necessary, and then a saturated aqueous sodium tetraphenylborate solution was added to the eluate to precipitate the desired product. The precipitate was collected by filtration and washed with cold water and then air-dried. The precipitate was dissolved in cold ethanol. The solution was filtered, and a cold ethanol solution of calcium nitrate was added to the filtrate. A voluminous pale-brown nitrate immediately precipitated was filtered off and washed with ethanol several times and then dried in the air. The product was dissolved in a small amount of water, and powdered sodium nitrate was added to the solution which was kept in a refrigerator overnight. Fine brown needle crystals which appeared were collected by filtration and recrystallized from a small amount of water by adding powdered sodium nitrate, and then dried in a vacuum desiccator over calcium chloride. Found for isomer f-3: C, 13.01; H, 5.35; N, 22.12%. Calcd for $[Co\{(OH)_2Co(en)_2\}_3](NO_3)_6\cdot 3H_2O = C_{12}H_{54}N_{18}O_{24}Co_4\cdot 3H_2O$: C, 12.82; H, 5.38; N, 22.42%. Found for isomer f-4: C, 12.96; H, 5.38; N, 22.26%. Calcd for $C_{12}H_{54}N_{18}O_{24}Co_4\cdot 3H_2O$: C, 12.82; H, 5.38; N, 22.42%. Found for isomer f-5: C, 12.91; H, 5.10; N, 22.72%. Calcd for $C_{12}H_{54}N_{18}O_{24}Co_4\cdot 1.5H_2O$: C, 13.13; H, 5.24; N, 22.97%. Found for isomer f-6: C, 12.96; H, 5.32; N, 22.36%. Calcd for $C_{12}H_{54}N_{18}O_{24}Co_4\cdot 3H_2O$: C, 12.82; H, 5.38; N, 22.42%. Found for isomer f-7: C, 12.49; H, 5.34; N, 22.03%. Calcd for $C_{12}H_{54}N_{18}O_{24}Co_4\cdot 3.5H_2O$: C, 12.72; H, 5.42; N, 22.24%. Found for isomer f-8: C, 12.76; H, 5.09; N, 22.94%. Calcd for $C_{12}H_{54}O_{24}Co_4\cdot 1.5H_2O\cdot 0.5NaNO_3$: C, 12.64; H, 5.04; N, 22.73%. Isomers f-1 and f-2 were not obtained as solid salt because of low yields, and partial overlapping of the chromatographic bands of f-1 and f-2 with those of the Λ and Δ isomers, respectively, of a by-product complex, $[Co(en)_3]^{3+}$.

Measurements. The visible and ultraviolet absorption spectra were measured with a Shimadzu UV-200 spectrophotometer. The CD spectra were recorded with a JASCO MOE-1 spectropolarimeter. Measurements were carried out at room temperature in 0.01 M HCl, 0.15 M Na_2SeO_3, and aqueous solutions.

Results and Discussion

Characterization of Isomers. The absorption and CD data of eight isomers are summarized in Table 1. It is evident that the isomer f-1 is enantiomeric to the isomer f-2, as is f-3 to f-4, f-5 to f-6, and f-7 to f-8. The CD curves of isomers f-1, f-3, f-5, and f-7, all of which have a positive CD band at about 16400 cm^{-1}, are shown in Fig. 1. Isomers f-1 and f-2 were not obtained as solid salt, their CD values being estimated on the

basis of the concentration calculated from the absorbance at 620 nm assuming the molar absorption coefficient $\varepsilon_{620}=113$ mol^{-1} dm^3 cm^{-1}; the absorption intensities of all the other isomers were almost equal to this value (Fig. 1 and Table 1). The absorption and CD spectra remained unchanged in 0.3 M sodium *d*-tartrate (eluting solution) at room temperature for about 24 h, being the same in 0.01 M HCl and in H_2O, in which the complex, except for isomer f-7, is considerably stable to mutarotation. Isomers f-3 and f-5 are considerably stable against mutarotation also in 0.15 M Na_2SeO_3 in a sharp contrast to the case of the dodecaammine complex, $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$, which undergoes mutarotation in 0.17 M Na_2SeO_3 and in H_2O.[1] Isomers f-7 undergoes mutarotation in 0.15 M Na_2SeO_3 and in H_2O, but it is considerably stable against mutarotation in 0.01 M HCl. Judging from the chromatographic band strech and the degree of coloration on the column, the yields of isomers are in the order f-3 (f-4)>f-5 (f-6)>f-7 (f-8)>f-1 (f-2). The isomers reported by Kern and Wentworth[6] and Mason and Wood[10] correspond to the present isomers f-5 and f-6.

Configuration of CoO_6 Chromophore. The hexakis-(ethylenediamine)-hexa-μ-hydroxo-tetracobalt(III) ion, $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$, is regarded as being composed of a $Co(OH)_6$ and three $Co(OH)_2(en)_2$ chromophores. In the following discussion the former chromophore is abbreviated to CoO_6, and the latter to CoN_4O_2. The CoO_6 chromophore has a configurational chirality, Δ or Λ, due to the tris-chelate type arrangement of three $Co(OH)_2Co$ four-membered rings. Each CoN_4O_2 chromophore also has a configurational chirality, Δ or Λ, due to the tris-chelate type arrangement of two ethylenediamine chelate rings and a $Co(OH)_2Co$ four-membered ring. Thus eight isomers are possible in

TABLE 1. THE ABSORPTION AND CD DATA OF $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ IN 0.01 M HCl UNLESS OTHERWISE STATED

Wave numbers are given in 10^3 cm^{-1} unit and log ε or $\Delta\varepsilon$ values (in parentheses) mol^{-1} dm^3 cm^{-1}.

a) In 0.15 M Na_2SeO_3.

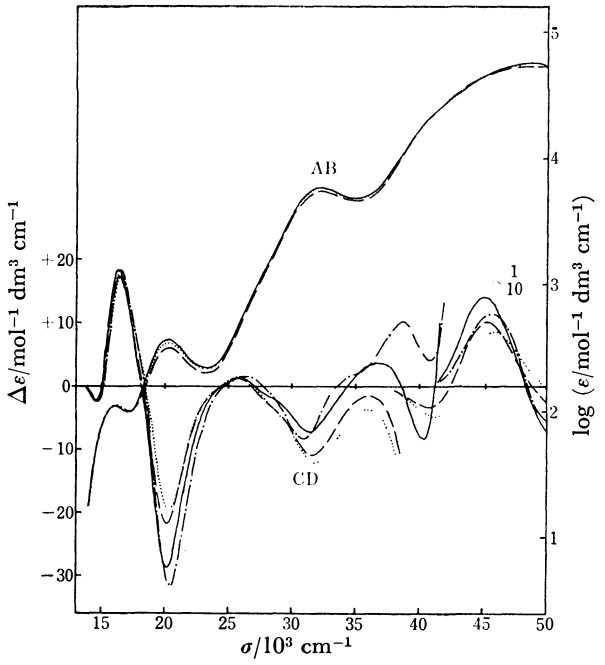

Fig. 1. Absorption (AB) and CD curves of isomer f-1 (—·—·—), f-3 (——), f-5 (– – –), and f-7 (····) of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ in 0.01 M HCl.

total: $\Delta(\Delta\Delta\Delta)$, $\Delta(\Delta\Delta\Lambda)$, $\Delta(\Delta\Lambda\Lambda)$, $\Delta(\Lambda\Lambda\Lambda)$, $\Lambda(\Delta\Delta\Delta)$, $\Lambda(\Delta\Delta\Lambda)$, $\Lambda(\Delta\Lambda\Lambda)$, and $\Lambda(\Lambda\Lambda\Lambda)$; the chirality symbols in parentheses denote the configurations of CoN_4O_2 chromophores. The eight isomers are classified into four geometrical isomers, since each of them finds its enantiomer in themselves.

Since the first and second d-d transition bands of $[Co(H_2O)_6]^{3+}$ are located at 16500 and 24700 cm^{-1}, respectively,[8] and those of *cis*-$[Co(en)_2(H_2O)_2]^{3+}$ at

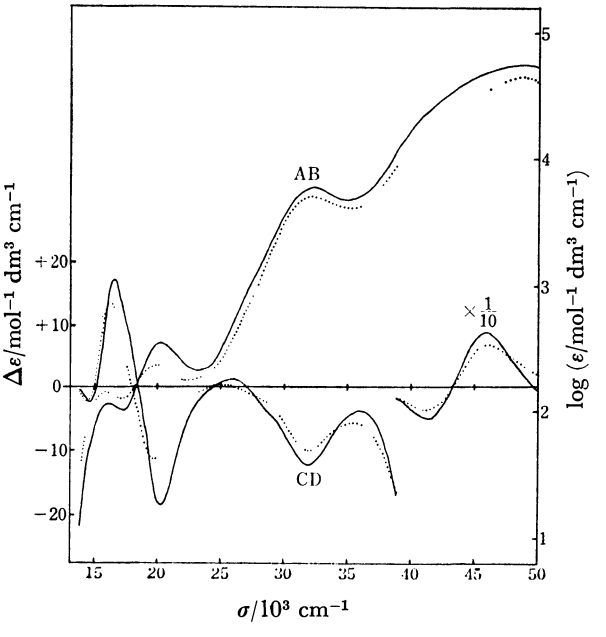

Fig. 2. Absorption (AB) and CD curves of isomer f-7 of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ (——) and Λ-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ (····) in 0.01 M HCl.

20200 and 27700 cm^{-1},[9] the absorption bands of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ at *ca.* 16100 and 20300 cm^{-1} are assigned to the first d-d transition bands of CoO_6 and CoN_4O_2 chromophores, respectively. The second d-d transition bands of both chromophores seem to be masked by an intense band at 32360 cm^{-1}, which is due to the charge transfer transition from the oxygen atom of the OH bridge groups to the central metal, $p_\pi(O)\rightarrow e_g(Co)$. The assignments are in line with those for those of similar hexa-μ-hydroxo-tetracobalt(III) type ions.[1,6,10,11] For all four geometrical isomers, the band positions and intensities are almost equal for the CoO_6 chromophore region, but not for the CoN_4O_2 chromophore region (Fig. 1 and Table 1).

Similarly the intensities of the longer or shorter wavelength CD peak of CoO_6 chromophore are almost equal for isomers f-1, f-3, f-5, and f-7: $\Delta\varepsilon_{ext}=-2.3$——$-3.0$ and $+17.1$——$+18.4$ mol^{-1} dm^3 cm^{-1}, respectively. The CD intensity of CoN_4O_2 chromophore band at about 20300 cm^{-1} varies widely: $\Delta\varepsilon_{ext}=-18.7$——$-33.0$ mol^{-1} dm^3 cm^{-1}. The CD patterns in the d-d transition region are similar to each other, while those in the charge transfer transition region differ. From the close similarity (Fig. 2) between the CD spectra of isomers f-1, f-3, f-5, and f-7 and spectrum of Λ-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ previously reported,[1] it is concluded that isomers f-1, f-3, f-5, and f-7 have Λ configuration and the remaining isomers f-2, f-4, f-6, and f-8 Δ configuration.

Configurations of CoN_4O_2 Chromophores. Acid hydrolysis of one mole of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ ion is expected to produce one mole of $[Co(H_2O)_6]^{2+}$ (*via* $[Co(H_2O)_6]^{3+}$) and 3 mol of mononuclear $[Co(en)_2(H_2O)_2]^{3+}$. While the former ion has no chirality, the latter has a configurational chirality, Δ or Λ, due to the bis-chelate type structure. The isomers $\Delta(\Delta\Delta\Delta)$ or $\Lambda(\Delta\Delta\Delta)$ will produce three Δ-$[Co(en)_2(H_2O)_2]^{3+}$ ions, $\Delta(\Delta\Delta\Lambda)$ or $\Lambda(\Delta\Delta\Lambda)$ two Δ and one Λ, $\Delta(\Delta\Lambda\Lambda)$ or $\Lambda(\Delta\Lambda\Lambda)$ one Δ and two Λ, and $\Delta(\Lambda\Lambda\Lambda)$ or $\Lambda(\Lambda\Lambda\Lambda)$ three Λ.

Table 2. The $\Delta\varepsilon_{488}$ values after decomposition by 6 M HCl ($\Delta\varepsilon$ values are given in mol^{-1} dm^3 cm^{-1} unit.)

Isomer	$\Delta\varepsilon_{488}$	Ratio	Assignment
f-1	(+1.5) [a]	(+2.0)	$(\Lambda\Lambda\Lambda)$
f-3	−2.2	−2.9	$(\Delta\Delta\Lambda)$
f-5	−0.8	−1.1	$(\Lambda\Delta\Lambda)$
f-7	+0.7	+0.9	$(\Lambda\Lambda\Delta)$

a) The original tetranuclear complex was not isolated in solid salt, but concentration was estimated from the absorbance at 620 nm.

The $\Delta\varepsilon$ values at 488 nm after decomposition in 6 M HCl solution are given in Table 2. Each isomer was dissolved in 6 M HCl and warmed on a water bath at 45 °C for two hours with stirring. The CD intensity of Λ-$[Co(en)_2(H_2O)_2]^{3+}$ was reported to be 1.0 mol^{-1} dm^3 cm^{-1} at 486 nm.[4] The observed $\Delta\varepsilon_{488}$ values as a whole are smaller than the reported value, which can be attributed to partial racemization, isomerization, and/or decomposition of the generated $[Co(en)_2(H_2O)_2]^{3+}$ in

presence of Co^{2+} ions. From the data in Table 2, the absolute configurations of isomers f-1, f-3, f-5, and f-7 are assigned to $\Lambda(\Lambda\Lambda\Lambda)$, $\Lambda(\Delta\Lambda\Lambda)$, $\Lambda(\Delta\Delta\Lambda)$, and $\Lambda(\Delta\Delta\Delta)$, respectively. Thus isomers f-2, f-4, f-6, and f-8 are assigned to the configurations, $\Delta(\Delta\Delta\Delta)$, $\Delta(\Lambda\Lambda\Lambda)$, $\Delta(\Delta\Lambda\Lambda)$, and $\Delta(\Delta\Delta\Lambda)$, respectively.

The CD spectra of Λ-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ might be expected to be more similar to those of the isomers $\Lambda(\Delta\Lambda\Lambda)$ and $\Lambda(\Delta\Lambda\Lambda)$ than to those of $\Lambda(\Delta\Delta\Lambda)$ and $\Lambda(\Delta\Delta\Delta)$. Isomers f-5 and f-7 show a similar CD pattern (−, −, and +) in the charge transfer transition region, which is similar to that of Λ-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ (Fig. 2). From the order of yields, $\Lambda(\Delta\Delta\Lambda) > \Lambda(\Delta\Lambda\Lambda) > \Lambda(\Delta\Lambda\Lambda) > \Lambda(\Lambda\Lambda\Lambda)$, the stability of isomers seems to decrease with increase in the number of Λ-configuration for CoN_4O_2 chromophore in the Λ series of CoO_6 chromophore. A molecular model examination shows that the Λ-configuration of CoN_4O_2 chromophore gives a slight repulsion between a proton of ethylenediamine chelate ring and an OH bridge group.

CD Change by Ion-pairing. The absorption peak of the CoO_6 chromophore of isomers f-3 and f-5 shifted to higher energy side in 0.15 M Na_2SeO_3 and then the intensity decreased, the shift being larger for f-3 than f-5. The peak of CoN_4O_2 chromophore shifted to lower energy side and the intensity increased. The intensity change is larger for f-3 than f-5. For the CD spectra, the longer wavelength extremum of CoO_6 chromophore shifted to higher energy side and the intensity increased for both isomers (Fig. 3 and Table 1). The intensity of the shorter wave-length CD extremum of CoO_6 chromophore decreased for both isomers. The CoN_4O_2 chromophore CD band (at 20160 cm^{-1} for both isomers) did not shift, the intensity increasing for f-3 and slightly decreasing for f-5. The difference in CD curves of 0.01 M HCl and 0.15 M Na_2SeO_3 (Fig. 4) show the ion-pairing effect of SeO_3^{2-} ion on the CD of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$. The curves have six extrema at *ca.* 14200, 16000, 19800, 22400, 24500, and 28000 cm^{-1} in the d-d transition region. The CD spectra of Λ-$[Co(en)_3]^{3+}$ with D_3 symmetry show strong ion-pairing effect[12–14] in the region of the first d-d absorption band when an oxoanion species such as PO_4^{3-} or SeO_3^{2-} is added to form the so-called Mason type ion-pair,[13–17] the CD intensity of E_a component of the first d-d transition decreasing and that of A_2 component increasing. Thus the first positive and next negative extrema, at 14200 and *ca.* 16000 cm^{-1}, correspond to the increment of the negative A_2 component and the decrement of the positive E_a component, respectively, of the first d-d transition of CoO_6 chromophore.

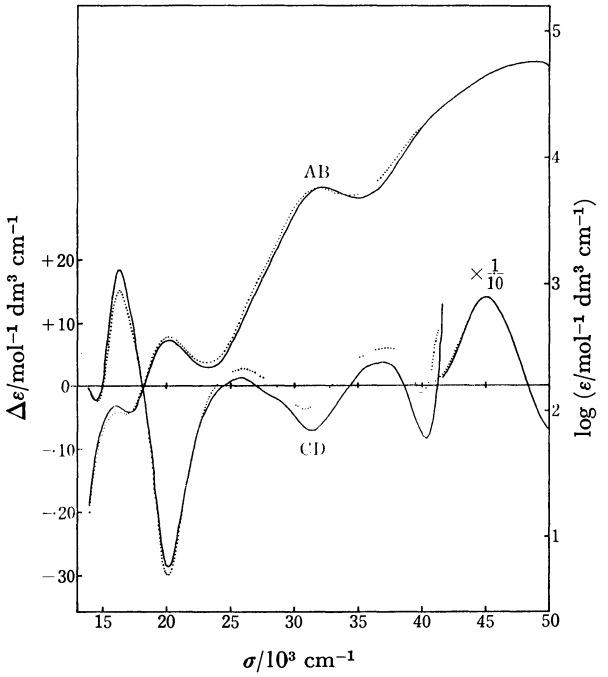

Fig. 3. Absorption (AB) and CD curves of isomer f-3 of $[Co\{(OH)_2Co(en)_{23}]^6\}^+$ in 0.01 M HCl (——) and in 0.15 M Na_2SeO_3 (····).

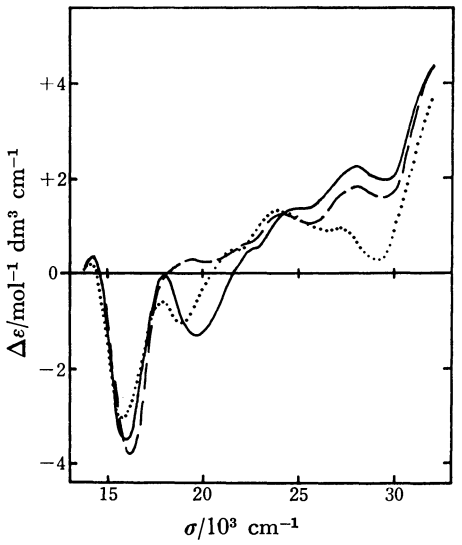

Fig. 4. The ion-pairing effect curves, $\{\Delta\varepsilon_{(In\ 0.15\ M\ Na_2SeO_3)} - \Delta\varepsilon_{(In\ 0.01\ M\ HCl)}\}$, of isomer f-3 (——) and f-5 (– – –) of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$, and Λ-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ (····) (in 0.17 M Na_2SeO_3).

In $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$, hydrogen bond formation occurs between SeO_3^{2-} and the OH bridge groups as for the corresponding dodecaammine complex.[1] The hydrogen bond formation may occur between the oxoanion and the coordinated $-NH_2$ groups of ethylenediamine of CoN_4O_2 chromophores. Thus chiral oxygen and nitrogen centers are stereospecifically produced by the ion-pair formation. The axial disposition of OH groups in the tetranuclear complex of Λ configuration of CoO_6 chromophore constrains an (*R*) chirality for the "asymmetric" oxygen atoms,[1] and the axial hydrogen bonding of the NH_2 groups in $\Lambda(\Delta\Delta\Lambda)$ configuration constrains an (*S*) chirality for the "asymmetric" nitrogen atoms. The ion-pairing effect curves in Fig. 4 are regarded as having their origin in the vicinal effect of chiral oxygen and/or nitrogen centers stereospecifically produced by the ion-pair formation. A molecular model consideration shows that in the isomer $\Lambda(\Delta\Delta\Lambda)$ a set of three OH groups is available each on the upper face and below the downward face (two A sites, 2×3 (*R*) oxygens) and six sets of one OH group and two amino groups (six B sites,

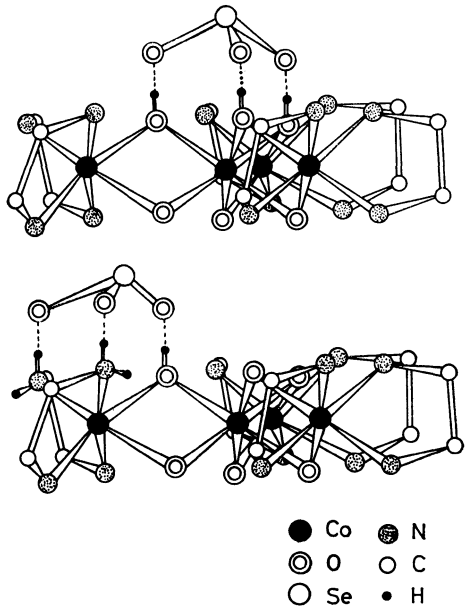

Fig. 5. The possible hydrogen bond formation site for the isomer $\Lambda(\Delta\Delta\Delta)$ with a selenite ion, A site (top) and B site (bottom), viewed normal to the C_3 axis of CoO_6 chromophore.

6×1 (R) oxygens and 6×2 (S) nitrogens) for hydrogen bond formation (Fig. 5). In the isomer $\Lambda(\Delta\Delta\Lambda)$, two A sites with 2×3 (R) oxygens and only four B sites with 4×1 (R) oxygens and 4×2 (S) nitrogens are available for hydrogen bonding. As shown in Fig. 4, the ion-pairing effect curve of isomers f-3, $\Lambda(\Delta\Delta\Lambda)$, shows a similar CD pattern to that of Λ-$[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ which has the origin of the effect only in the asymmetric oxygens, which show a negative extremum at *ca.* 19800 cm^{-1}. Thus the ion-pair formation in the present $\Lambda(\Delta\Delta\Lambda)$ complex occurs between SeO_3^{2-} and one or two A sites rather than B sites. The ion-pairing effect curve of isomer f-5, $\Lambda(\Delta\Lambda\Lambda)$, shows a positive extremum at 19400 cm^{-1} (Fig. 4). The B sites may play a role in this case of ion-pair formation.

Additivity of CD Contributions. If the observed CD curve of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ can be simply divided into the contributions of CoO_6 and CoN_4O_2 chiralities as has been established for configurational and vicinal chiralities of many other mononuclear cobalt(III) complexes,[18] the following relations are expected to hold:

$$\left.\begin{aligned} \Lambda(\Lambda\Lambda\Lambda) &= \Lambda + 3(\Lambda) \\ \Lambda(\Delta\Lambda\Lambda) &= \Lambda + 2(\Lambda) + (\Delta) = \Lambda + (\Lambda) \\ \Lambda(\Delta\Delta\Lambda) &= \Lambda + (\Lambda) + 2(\Delta) = \Lambda - (\Lambda) \\ \Lambda(\Delta\Delta\Delta) &= \Lambda + 3(\Delta) = \Lambda - 3(\Lambda) \end{aligned}\right\} \quad (1)$$

where Λ (or Δ) and (Λ) (or (Δ)) are CD contributions of CoO_6 and CoN_4O_2 chiralities, respectively, and $\Lambda = -\Delta$ and $(\Lambda) = -(\Delta)$. The individual Λ and (Λ) can be derived from the observed CD curves from the following relations:

$$\Lambda = [\Lambda(\Lambda\Lambda\Lambda) + \Lambda(\Delta\Delta\Delta)]/2,$$
$$\Lambda = [\Lambda(\Delta\Lambda\Lambda) + \Lambda(\Delta\Delta\Lambda)]/2,$$
$$(\Lambda) = [\Lambda(\Lambda\Lambda\Lambda) - \Lambda(\Delta\Delta\Delta)]/6, \text{ and}$$
$$(\Lambda) = [\Lambda(\Delta\Lambda\Lambda) - \Lambda(\Delta\Delta\Lambda)]/2.$$

However, the calculation (Fig. 6) shows that the separation of Λ and (Λ) (or (Δ)) contributions are very unsatisfactry and that Eq. 1 in this simple form is inadequate for evaluating the CD contributions.

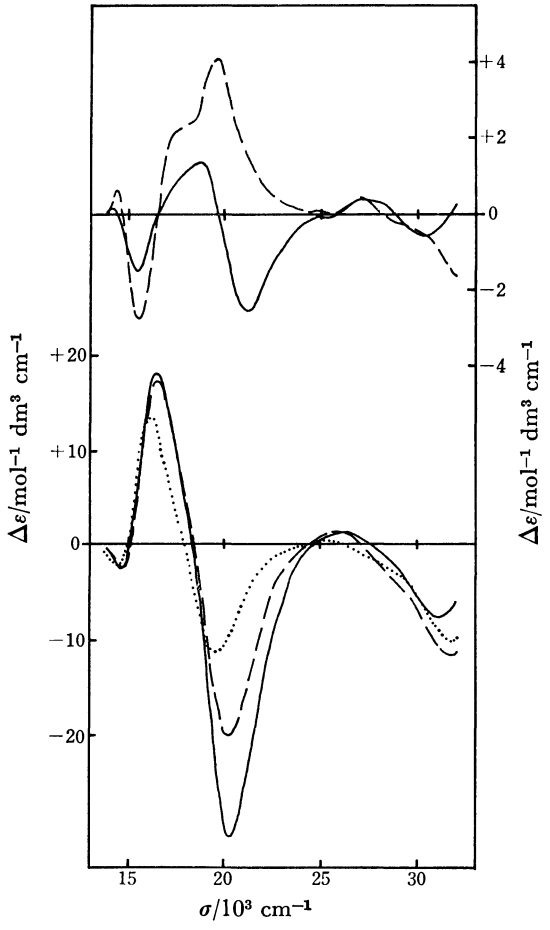

Fig. 6. Inadequacy of Eq. 1 is shown by the calculated curves of (Λ): $[\Lambda(\Lambda\Lambda\Lambda) - \Lambda(\Delta\Delta\Lambda)]/6$ (——) and $[\Lambda(\Delta\Lambda\Lambda) - \Lambda(\Delta\Delta\Lambda)]/2$ (– – –) (upper curves); and of Λ: $[\Lambda(\Lambda\Lambda\Lambda) + \Lambda(\Delta\Delta\Lambda)]/2$ (——) and $[\Lambda(\Delta\Lambda\Lambda) + \Lambda(\Delta\Delta\Lambda)]/2$ (– – –); and observed curve of Λ in the dodecaammine complex (• • • •) (lower curves).

As shown by X-ray analysis of the racemic salts of $\Lambda(\Delta\Lambda\Lambda)/\Lambda(\Delta\Lambda\Lambda)$[3,5] and $\Lambda(\Lambda\Lambda\Lambda)/\Lambda(\Delta\Lambda\Lambda)$[4] isomers, the four isomers of Λ series $\Lambda(\Delta\Delta\Lambda)$, $\Lambda(\Delta\Lambda\Lambda)$, $\Lambda(\Delta\Lambda\Lambda)$, and $\Lambda(\Lambda\Lambda\Lambda)$ have different dispositions of three CoN_4O_2 chromophores. The model of the isomer $\Lambda(\Delta\Delta\Lambda)$ is rather flat, the pseudo C_3 axes of tris-chelate type CoN_4O_2 chromophores being parallel (p) to the C_3 axis of the CoO_6 one; the structure of $\Lambda(\Delta\Delta\Lambda)$ isomer is thus written as $\Lambda(p_\Delta p_\Delta p_\Delta)$. The model of the isomer $\Lambda(\Lambda\Lambda\Lambda)$ is not flat but tall, the pseudo C_3 axes of CoN_4O_2 chromophores being oblique (q) to the C_3 axis of the CoO_6 one. The structure of $\Lambda(\Lambda\Lambda\Lambda)$ isomer is thus written as $\Lambda(q_\Lambda q_\Lambda q_\Lambda)$. The remaining two isomers $\Lambda(\Delta\Lambda\Lambda)$ and $\Lambda(\Delta\Lambda\Lambda)$ have a mixed structure, $\Lambda(p_\Delta p_\Delta q_\Lambda)$ and $\Lambda(p_\Delta q_\Lambda q_\Lambda)$, respectively. Kojima *et al.*[19] showed that the CD spectra of the mixed complexes $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ can be expressed by summing up the

contributions from three pairs of chelate rings, as has been made in the so-called ring-pairing method[20] (tn= trimethylenediamine and tmd=tetramethylenediamine). By this treatment, Eq. 1 can be rewritten as follows:

$$\left.\begin{aligned} A(\Lambda\Lambda\Lambda) &= A(q_\Lambda q_\Lambda q_\Lambda) = 3A_{qq} + 3(A) \\ A(\Delta\Lambda\Lambda) &= A(p_\Delta q_\Lambda q_\Lambda) = 2A_{pq} + A_{qq} + (A) \\ A(\Delta\Lambda\Delta) &= A(p_\Delta p_\Delta q_\Lambda) = A_{pp} + 2A_{pq} - (A) \\ A(\Delta\Delta\Delta) &= A(p_\Delta p_\Delta p_\Delta) = 3A_{pp} - 3(A) \end{aligned}\right\} \quad (2)$$

where A_{pp} *etc.* denote the CD contribution of a ring-pair of two p-oriented CoN_4O_2 chromophores *etc.*

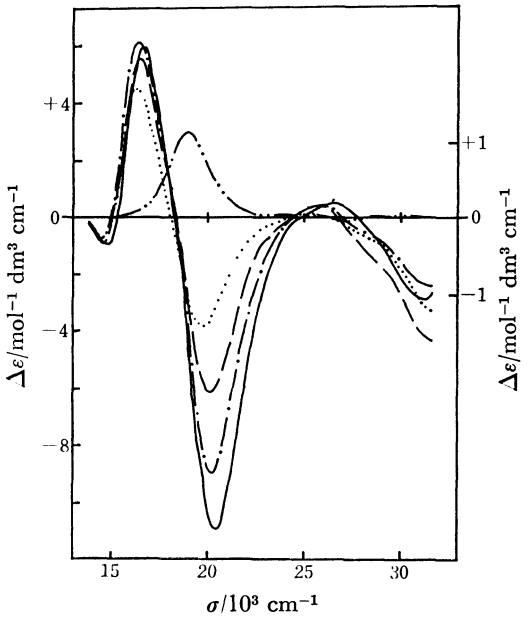

Fig. 7. Calculated curves of A_{qq} (——), A_{pq} (– – –), A_{pp} (–·–·–), and A_{aa} (·····), and observed curve of Λ-$[Co(TeO_6H_4)(en)_2]^+$ (–·····) (the right ordinate).

Equation 2 can be solved by assuming that the CD contribution (A) is equal to the observed CD of Λ-$[Co(TeO_6H_4)(en)_2]^+$.[21] The results are shown in Fig. 7. For the dodecaammine complex the CD contribution A is expressed by $3A_{aa}$ which denotes CD contributions of three ring-pairs of two CoN_4O_2 chromophores of tetraammine type. The calculated CD contributions of four kinds of ring-pairs A_{pp}, A_{pq}, A_{qq}, and A_{aa} differ from each other in the region of the first d-d absorption band of CoN_4O_2 chromophore. The absolute value of CD intensities in this region is in the order $A_{qq} > A_{pp} > A_{pq} > A_{aa}$. The A_{pq} contribution can be calculated in two ways from Eq. 2, one from the third formula of the equation (Fig. 7) and the other from the second formula. The results do not differ much, showing the adequacy of Eq. 2.

Kinetics of the Ligand Substitution Reactions of the Copper(II) Chelates of 1-(2-Pyridylazo)-2-naphthol Analogs with EDTA

Hiroko WADA* and Genkichi NAKAGAWA

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received June 13, 1979)

The rates of the substitution reactions of copper(II) chelates of metallochromic indicators such as 1-(2-pyridylazo)-2-naphthol (PAN, Hpan), 1-(2-thiazolylazo)-2-naphthol (TAN, Htan), 2-(2-pyridylazo)-4-methylphenol (PAC, Hpac), 2-(2-thiazolylazo)-4-methylphenol (TAC, Htac), 4-(2-pyridylazo)resorsinol (PAR, H_2par), and 4-(2-thiazolylazo)resorcinol (TAR, H_2tar) were determined. The rate laws can be written as $-\frac{d[CuL]}{dt}=k^{CuL}_{edta'}$ [CuL][edta'] for PAN, TAN, PAC, and TAC in the pH range of 4 to 6.5, and $-\frac{d[(CuL)']}{dt}=(k^{CuL}_{edta'}[CuL]+k^{CuHL}_{edta'}[CuHL])[edta']$, where $[(CuL)']=[CuL]+[CuHL]$, for PAR and TAR in the pH range of 3.5 to 6.5. In the pH range lower than 3.5 the laws are written as $-\frac{d[CuL]}{dt}=(k^{CuL}_{edta'}[edta']+k^{CuL}_{H}[H])[CuL]$ for PAN, and as $-\frac{d[CuHL]}{dt}=(k^{CuHL}_{edta'}[edta']+k^{CuHL}_{H}[H])$ [CuHL] for PAR and TAR. The rate constants (μ=0.1, 25 °C, dioxane 2 vol% or 5 vol% (PAN and TAN) ($dm^3\ mol^{-1}\ s^{-1}$)) are $k^{Cu(tan)}_{edta'}=2.8\times10^4$, $k^{Cu(pac)}_{edta'}=8.0\times10^4$, $k^{Cu(tac)}_{edta'}=4\times10^6$, $k^{Cu(par)}_{edta'}=2.0\times10^3$, $k^{Cu(tar)}_{edta'}=6.3\times10^4$, $k^{Cu(Hpar)}_{edta'}=1.2\times10^4$, $k^{Cu(Htar)}_{edta'}=7.9\times10^5$, $k^{Cu(pan)}_{H}=6.5\times10$, $k^{Cu(Hpar)}_{H}=6.6\times10^2$, and $k^{Cu(Htar)}_{H}=1.2\times10^4$. The rate constants, $k^{CuL}_{edta'}$, are inversely proportional to the basicities of the donor atoms of indicators. Thus, the rate of color change of thiazolylazo compound is larger than that of corresponding pyridylazo compound in the chelatometry of copper(II).

In the chelatometric titrations using metallochromic indicators, the rate of substitution reaction of the metal-indicator chelate with EDTA is one of the important factor in obtaining the sharp color change at the equivalence point.[1] Several papers have been published on the substitution reactions of metallochromic indicator chelates with complexans. The mechanisms of the substitution reactions of some metal chelates of 4-(2-pyridylazo)resorcinol with 1,2-bis(2-aminoethoxy)-ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid or 1,2-cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid have been elucidated by Tanaka and Funahashi.[2-4] In our previous work, the kinetics of the substitution reaction of copper(II)–1-(2-pyridylazo)-2-naphthol(PAN) chelate with EDTA was investigated.[5] The structure of indicator influences the rate of the color change in the chelatometric titrations. In the case of heterocyclic azophenols, the rate of color change of a pyridylazophenol indicator is slower than that of a thiazolylazophenol indicator. For example the rate of color change of 4-(2-pyridylazo)resorcinol is smaller than that of 4-(2-thiazolylazo)resorcinol in copper(II)–EDTA titrations.

In this work the rates of the substitution reactions of copper(II) chelates of the several 1-(2-pyridylazo)-2-naphthol derivatives with EDTA have been determined, and the reaction mechanisms and the influences of the indicator structure on the rate of the substitution reaction are discussed.

Experimental

Reagents. Copper(II) nitrate solution: Copper metal (99.99%) was dissolved in dilute nitric acid. Indicator solutions: TAN, PAC, TAC, PAR, and TAR synthesized and/or purified as described in previous papers[6-9] were dissolved in dioxane. Commercial Na_2H_2edta·$2H_2O$ was recrystallized. Dioxane was purified as described in the previous paper.[5] Buffers: 0.1 mol dm^{-3} $ClCH_2COOH$–$ClCH_2COOK$ (pH<4.5), and 0.1 mol dm^{-3} 2-morpholino-1-ethanesulfonicacid(MES)–KOH (pH 4.5—7) were used. Ionic strength was maintained at 0.1 with KNO_3. All experiments were carried out in 2 or 5 vol % dioxane–H_2O solutions at (25±1) °C.

Apparatus. A Union Giken Stopped-Flow Spectrophotometer Type RA-401 (dead time 3 ms), a Hitachi Rapid Scan Spectrophotometer Type TSP-2 (dead time 20 ms), and a Radiometer pH Meter Type 26 were used.

Results

Substitution Reactions of Copper(II) Chelates of TAN, PAC, and TAC with EDTA. When a small excess of the indicator compared with copper(II) ion is added, these indicators form the 1:1 chelates with copper(II) at pH values lower than 6.5. The rate of the substitution reaction of indicator chelate, CuL, with a large excess of EDTA was determined under the experimental conditions shown in Table 1. The rate law is expressed as (Charges are omitted for simplicity.)

$$-\frac{d[CuL]}{dt}=k_{obsd}[CuL], \quad (1)$$

where k_{obsd} is the conditional rate constant.[5] Decrease in the absorbance of CuL chelate was measured as a function of the reaction time. The pseudo first-order plots were obtained for at least 90% of the total reaction. In every case k_{obsd} was proportional to the total concentration of EDTA not combined with copper(II), [edta'], while no dependence on the concentration of excess indicator and hydrogen ion concentration was observed, the same result as in the case of PAN.[5] Hence the rate law can be written as

$$-\frac{d[CuL]}{dt}=k^{CuL}_{edta'}[edta'][CuL]. \quad (2)$$

TABLE 1. EXPERIMENTAL CONDITIONS EMPLOYED FOR THE DETERMINATION OF THE RATE CONSTANTS

	Wavelength / nm	$10^6 C_{Cu}$ / mol dm^{-3}	$10^5 C_L$ / mol dm^{-3}	$10^4 C_{EDTA}$ / mol dm^{-3}	pH range	Dioxane / vol%
PAN	550	5.0	0.5 —1.5	1.0 —2.0	2.5—5	5
TAN	575	4.0	0.48—0.78	0.40—1.0	4.5—5.2	5
PAC	570	10.0	1.5 —3.0	1.0 —1.4	4.4—5.1	2
TAC	605	5.0	0.75—1.5	0.50	4.0—4.6	2
PAR	542	10.0	1.5 —3.0	1.0 —2.0	2.8—6.5	2
TAR	557	10.0	1.5	1.0 —5.0	2.5—6.5	2

The rate constants obtained are summarized in Table 2.

In the case of TAC, since the substitution reaction was too fast to be measured accurately on the stopped-flow apparatus employed in this work, the value of the rate constant was roughly estimated.

Substitution Reactions of Copper(II) Chelates of PAR, and TAR with EDTA. In the cases of PAR and TAR, copper(II) forms a chelate, CuHL, with PAR at pH$<$4 and with TAR at pH$<$3.5. The protonation constants, K^H_{CuHL}, had been determined as $10^{5.07}$ for PAR[8] and $10^{4.37}$ for TAR[6] (dioxane 2 vol%, μ=0.1, 15 °C). The absorption maxima of Cu(Hpar) and Cu(par) are at 525 and 515 nm, respectively, and the isosbestic points appear at 440 and 542 nm. The absorption maxima of Cu(Htar) and Cu(tar) are at 560 and 520 nm, respectively, and the isosbestic points appear at 450 and 557 nm. The rates of the substitutions of copper(II) chelates of PAR or TAR with large excess of EDTA were determined in the pH range from 2.5 to 6.5 by measuring the decrease in the absorbance of the chelates at an isosbestic point as a function of reaction time under the conditions shown in Table 1.

To examine the influence of buffer, in the pH range from 3 to 4.5 both $ClCH_2COOH$–$ClCH_2COOK$ buffer and MES–KOH buffer were used. No difference in the rate of the reactions was observed.

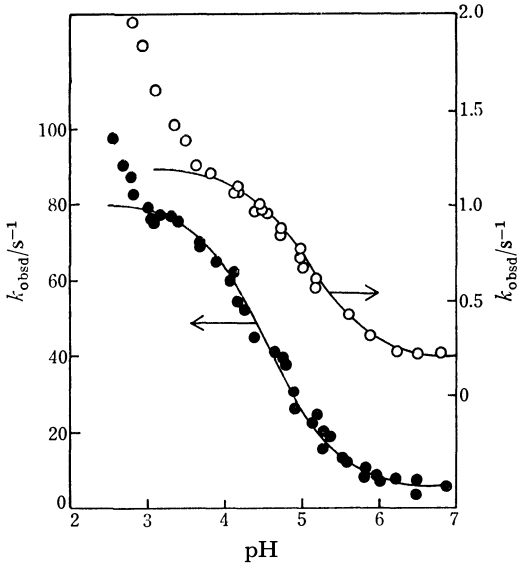

Fig. 1. Plots of k_{obsd} *vs.* pH for PAR and TAR.
○: PAR, ●: TAR.
k_{obsd} obtained at various concentrations of EDTA were converted to the values at 1.0×10^{-4} mol dm^{-3} C_{EDTA}. The lines are the theoretical curves calculated with the values obtained by curve fitting.

As seen from Fig. 1, the marked increases in the rates of the substitution reactions were observed with decreasing pH between pH 3.5 and 6. At the various pH values the conditional rate constants, k_{obsd}, were proportional to the concentration of EDTA, but independent of the concentration of PAR or TAR. As described above, the protonation equilibrium,

$$CuL + H^+ \rightleftarrows CuHL, \tag{3}$$

exists in the pH range from 4 to 6 for PAR or from 3.5 to 5.5 for TAR. Thus, the substitution reaction proceeds as

$$CuL + edta' \rightleftarrows Cu(edta) + L' \tag{4}$$

$$\uparrow\downarrow H^+$$

$$CuHL + edta' \rightleftarrows (Cuedta)' + L'. \tag{5}$$

If the total concentration of CuHL and CuL is expressed as [(CuL)'], the rate law is given by

$$-\frac{d[(CuL)']}{dt} = k_{obsd}[(CuL)']$$
$$= (k^{CuL}_{edta'}[CuL] + k^{CuHL}_{edta'}[CuHL])[edta']$$
$$= \left(k^{CuHL}_{edta'} + \frac{k^{CuL}_{edta'} - k^{CuHL}_{edta'}}{1+K^H_{CuHL}[H]}\right)[(CuL)'][edta'], \tag{6}$$

where

$$K^H_{CuHL} = \frac{[CuHL]}{[CuL][H]}. \tag{7}$$

The plot of k_{obsd} *vs.* pH in each case was compared with a family of normalized functions $y=p/(1+x)=f(\log x)$. As shown in Fig. 1, the plot fits well one of the theoretical curves. The values of $k^{CuL}_{edta'}$, and $k^{CuHL}_{edta'}$ are listed in Table 2.

As seen in Fig. 1 the rate of substitution reaction of CuHL further increased at pH values lower than 3.5 for PAR and 3.0 for TAR. In these pH ranges Cu-

TABLE 2. RATE CONSTANTS OF SUBSITUTION REACTIONS OF Cu(II) CHELATES WITH EDTA AT μ=0.1, AT 25 °C

	$k^{CuL}_{edta'}$ or $k^{CuHL}_{edta'}$ / dm^3 mol^{-1} s^{-1}	k^{CuL}_H or k^{CuHL}_H / dm^3 mol^{-1} s^{-1}
Cu(pan)	1.9×10^3	6.5×10
Cu(tan)	2.8×10^4	
Cu(pac)	8.0×10^4	
Cu(tac)	4×10^6	
Cu(par)	2.0×10^3	
Cu(Hpar)	1.2×10^4	6.6×10^2
Cu(tar)	6.3×10^4	
Cu(Htar)	7.9×10^5	1.2×10^4

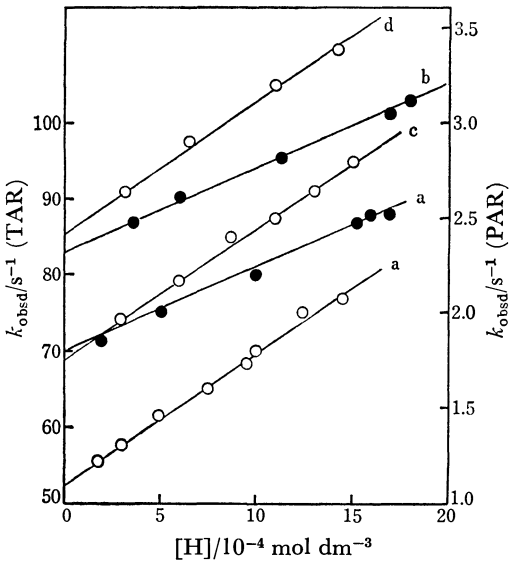

Fig. 2. Plots of log k_{obsd} *vs.* [H].
○: PAR, ●: TAR.
$C_{EDTA}=1.0\times10^{-4}$ (a), 1.2×10^{-4} (b), 1.5×10^{-4} (c), 2.0×10^{-4} mol dm^{-3} (d).

(Hpar) or Cu(Htar) is predominantly formed. Plots of k_{obsd} *vs.* the concentration of hydrogen ion yielded straight lines with intercepts on the y-axes. (Fig. 2). Thus the rate law can be expressed as

$$-\frac{d[CuHL]}{dt} = (k_{edta'}^{CuHL}[edta']+k_{H}^{CuHL}[H])[CuHL]. \quad (8)$$

The values of $k_{edta'}^{CuHL}$ and k_{H}^{CuHL} were obtained from the intercepts and the slopes of the straight lines, respectively:

$$k_{edta'}^{Cu(Hpar)} = 1.1\times10^{4}\ dm^3\ mol^{-1}\ s^{-1},$$
$$k_{edta'}^{Cu(Htar)} = 7.0\times10^{5}\ dm^3\ mol^{-1}\ s^{-1},$$
$$k_{H}^{Cu(Hpar)} = 6.6\times10^{2}\ dm^3\ mol^{-1}\ s^{-1},$$
$$k_{H}^{Cu(Htar)} = 1.2\times10^{4}\ dm^3\ mol^{-1}\ s^{-1}.$$

The values of $k_{edta'}^{CuHL}$ obtained were approximately equal to the values previously obtained by the curve fitting method.

Substitution Reaction of Copper(II) Chelate of PAN with EDTA. In our previous work,[5] the rate of the substitution reaction of Cu(pan) with EDTA was determined in the pH range from 5.0 to 6.3, in which PAN can be used as an indicator for the chelatometric titrations of copper(II). In this pH range, the substitution reaction is of first-order with respect to EDTA and Cu(pan), while there is no dependence on pH as in the cases of TAN, PAC, and TAC. In this study, in the lower pH range the rate of the substitution reaction of Cu(pan) with EDTA was examined. At pH lower than 4 the rate of the reaction gradually increased with decreasing pH, as in the cases of PAR and TAR. The conditional rate constants, k_{obsd}, depended on [H] and [edta'], hence the rate law can be written as

$$-\frac{d[Cu(pan)]}{dt} = (k_{edta'}^{Cu(pan)}[edta']+k_{H}^{Cu(pan)}[H])[Cu(pan)]. \quad (9)$$

The values of $k_{edta'}^{Cu(pan)}$ and $k_{H}^{Cu(pan)}$ obtained are shown in Table 2. The values of $k_{edta'}^{Cu(pan)}$ determined in this study agrees with that obtained in the previous study:[5]

$$k_{edta'}^{Cu(pan)} = 1.7\times10^{3}\ dm^3\ mol^{-1}\ s^{-1}.$$

Discussion

The constant rates were observed in the following pH ranges: pH 3.5—6.3 for Cu(pan), pH 4.5—5.2 for Cu(tan), pH 4.4—5.1 for Cu(pac), pH 4.0—4.6 for Cu(tac), pH 6—6.5 for Cu(par) and for Cu(tar), while the fraction of H_2edta, Hedta, and edta changes in these pH ranges. Cassatt and Wilkins reported that in the reaction of EDTA with nickel(II) ion Hedta is 10^2-fold more reactive than H_2edta.[10] From our results, however, no difference in the rate of substitution reaction with different protonated forms of EDTA was observed. Copper(II) chelates, CuL, of PAN, TAN, PAC, TAC, PAR, and TAR are substituted by EDTA in these pH regions according to the following mechanism, as proposed by Tanaka and Funahashi:

$$CuL + edta' \rightleftharpoons CuL(edta) \xrightarrow{r.d.s.} Cu(edta) + L'. \quad (10)$$

The values of log $k_{edta'}^{CuL}$ were plotted against the sum of the dissociation constants of protonated pyridine or thiazole and phenolic *o*-hydroxyl groups ($pk_{NH}+pk_{o\text{-}OH}$). (Fig. 3). A straight line was obtained. This

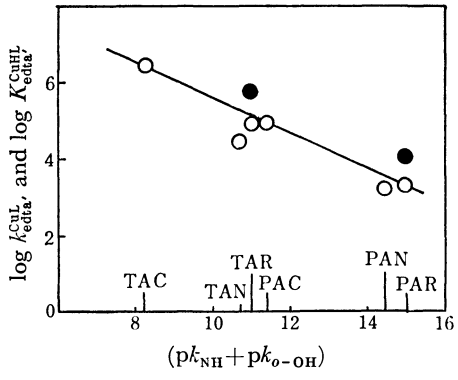

Fig. 3. Plots of log $k_{edta'}^{CuL}$, and log $K_{edta'}^{CuHL}$ *vs.* ($pk_{NH}+pk_{o\text{-}OH}$).
○: $k_{edta'}^{CuL}$, ●: $K_{edta'}^{CuHL}$.

result indicates that the rate of the substitution reaction of CuL chelate is inversely proportional to the basicities of the donor atoms of the leaving ligands. However, the values of log $k_{edta'}^{CuL}$ for Cu(pan) and Cu(tan) chelates are smaller than those of other indicators, probably due to the steric effect of the naphthalene ring in PAN or TAN. Since the basicities of donor atoms in the thiazolylazo compounds are weaker than those of corresponding pyridylazo compounds, the rate of the substitution reaction of copper(II) chelates of thiazolylazo compounds is, generally speaking, faster than that of corresponding pyridylazo compound chelates. Thus, as regards the rate of color change, the thiazolylazo compounds are more favorable for use as metallochromic indicators than the pyridylazo compounds.

The reaction rate of CuHL chelate with PAR or TAR is faster than that of CuL by one order. In the

chelatometric titrations of copper(II) with EDTA using TAR as an indicator, the optimum pH range is from 4 to 6. The large rate of the substitution reaction of Cu(Htar) chelate with EDTA gives a great advantage for the sharp color change of the indicator at the equivalence point.

Trimethylenediamine Complexes. VIII.[1] Some Cis-Trans Isomeric Pairs of the Bis(trimethylenediamine)chromium(III) Complexes

Mamoru NAKANO and Shinichi KAWAGUCHI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 28, 1979)

The cis-trans isomeric pairs of diisothiocyanato-, dinitrito-, diazido-, diaqua-, and aquahydroxo-bis(trimethylenediamine)chromium(III) complexes have been obtained as crystals and characterized by infrared and electronic absorption spectra. The cis isomers of diisothiocyanato and diazido complexes as well as $[Cr(N_3)_2(en)_2]ClO_4$ were resolved and the absolute configurations of $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$, $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$, and $(-)_{589}$-*cis*-$[Cr(N_3)_2(en)_2]ClO_4$ were all assigned to Δ.

Comparative Chemistry of the five-membered ethylenediamine (en) chelates and the six-membered trimethylenediamine (tn) chelates is interesting from both the structural and kinetic viewpoints. Absolute configurations of several optically active cobalt(III) complexes containing trimethylenediamine as a ligand have been established by X-ray analysis,[2] and the empirical criterion of McCaffery *et al.*[3] relating the absolute configuration to the CD-spectral feature in the first d-d band region has been shown to hold in these complexes. On the other hand, optically active chromium(III) trimethylenediamine complexes are rather few, and only four examples, $(-)_{589}$-$[Cr(tn)_3]^{3+}$,[4] $(+)_{589}$-*cis*-$[CrCl_2(tn)_2]ClO_4$,[5] $(+)_{589}$-$[Cr(acac)(tn)_2]I_2\cdot 0.5H_2O$,[1] and $(-)_{589}$-$[Cr(acac)_2(tn)]I\cdot H_2O$[1] have been reported so far, and further development in this field is desirable.

The aquation rates of *trans*-$[CoCl_2(tn)_2]^+$ and *trans*-$[CoBr_2(tn)_2]^+$ are extraordinarily large as compared with those of the corresponding ethylenediamine complexes,[6] but *trans*-$[CrCl_2(tn)_2]^+$ hydrolyzes in acid solution with a rate comparable to that of *trans*-$[CrCl_2(en)_2]^+$.[7] The cis isomer of $[CoCl_2(tn)_2]^+$ is unknown,[8] although *cis*-$[CoCl_2(en)_2]^+$ is easily prepared by heating the trans isomer in aqueous solution. On the other hand, *cis*-$[CrCl_2(tn)_2]ClO_4\cdot 0.5\,H_2O$ was obtained as violet crystals, although it is liable to isomerize to the *trans* form in solution.[5] Thus further comparison of the thermodynamic and kinetic ring-size effects in the chromium(III) and cobalt(III) complexes may be interesting.

In previous papers we have prepared and characterized several cis-trans isomeric pairs of dianionbis(trimethylenediamine)cobalt(III) complexes,[9] and compared the ligand substitution rates of some trimethylenediamine cobalt(III) complexes with those of the corresponding ethylenediamine complexes.[10] The present paper reports preparation and characterization of some bis(trimethylenediamine)chromium(III) complexes inclusive of the optically active *cis*-$[Cr(NCS)_2(tn)_2]^+$ and *cis*-$[Cr(N_3)_2(tn)_2]^+$ complexes.

Experimental

Preparation and Optical Resolution of Complexes. The starting compounds, *cis*-$[CrCl_2(tn)_2]Cl\cdot H_2O$ and *trans*-$[CrCl_2(tn)_2]Cl$ were prepared by the method of Pedersen.[5] Commercially available potassium antimony(III) (*R,R*)-tartrate was used without further purification. Another resolving agent, (*R,R*)-di-*O*-benzoyltartaric acid was prepared by the reaction between (*R,R*)-tartaric acid and benzoyl chloride[11] and used after partial neutralization with one-half equivalent of sodium hydroxide.

cis-*Diisothiocyanatobis(trimethylenediamine)chromium(III) Thiocyanate Hydrate*, cis-$[Cr(NCS)_2(tn)_2]SCN\cdot H_2O$: Aqueous solution (10 ml) of *cis*-$[CrCl_2(tn)_2]Cl\cdot H_2O$ (1.1 g) was heated at 70 °C on a water-bath for 10 min to result in a red-orange solution, to which was added sodium thiocyanate (1.6 g) and heating was continued for about 1 h to obtain an orange precipitate. After cooling to room temperature, another portion (1.0 g) of sodium thiocyanate was added to the mixture, which was then allowed to stand overnight. The crude product was filtered, washed with cold water and air-dried. The yield was 1.2 g (92.6%). Recrystallization from hot water gave orange needles.

trans-*Diisothiocyanatobis(trimethylenediamine)chromium(III) Thiocyanate*, trans-$[Cr(NCS)_2(tn)_2]SCN$: The reaction of *trans*-$[CrCl_2(tn)_2]Cl$ (1.0 g) with sodium thiocyanate was performed in a similar manner as above to obtain orange crystals in an 80.9% (1.0 g) yield. Recrystallization from hot water gave orange plates.

cis-*Diaquabis(trimethylenediamine)chromium(III) Nitrate*, cis-$[Cr(H_2O)_2(tn)_2](NO_3)_3$: A solution (5 ml) of silver nitrate (1.7 g) was added to an aqueous solution (10 ml) of *cis*-$[CrCl_2(tn)_2]Cl\cdot H_2O$ (1.1 g) and the mixture was stirred at room temperature for 1 h to complete the reaction. A precipitate of silver chloride was filtered. Concentrated nitric acid (20 ml) and ethanol (50 ml) were added to the combined washings and the solution was left in a refrigerator to deposit an orange precipitate in a 69.8% (1.0 g) yield. The crude product was dissolved in a minimum amount of water and a few drops of concentrated nitric acid was added to the solution. On cooling in ice orange plate precipitated.

cis-*Aquahydroxobis(trimethylenediamine)chromium(III) Nitrate Hemihydrate*, cis-$[CrOH(H_2O)(tn)_2](NO_3)_2\cdot 0.5H_2O$: To an aqueous solution (5 ml) of *cis*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (1.0 g) was added aqueous ammonia drop by drop to adjust pH to *ca.* 7, color of the solution changing from orange to red. Ethanol (50 ml) was poured into the solution to deposit a red precipitate. The yield was 0.8 g (94.0%). Recrystallization from water–ethanol gave red needles which are slightly hygroscopic.

trans-*Aquahydroxobis(trimethylenediamine)chromium(III) Nitrate*, trans-$[CrOH(H_2O)(tn)_2](NO_3)_2$: One gram of *trans*-$[CrCl_2(tn)_2]Cl$ was dissolved in hot water. A solution (5 ml) of silver nitrate (1.7 g) was added and the mixture was kept at 50 °C for 2 h to complete the reaction. After cooling to room temperature, silver chloride was filtered. On addition of aqueous ammonia dropwise to the combined washings to attain pH≈7 (solution turning red), red-brown thin crystals precipitated. The yield was 0.3 g (25.6%). After separation

of the product, concentrated nitric acid (20 ml) and ethanol (50 ml) were added to the filtrate and the mixture was kept in a refrigerator to deposit an orange precipitate, which was identified as *cis*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ on the basis of IR and electronic spectra. The yield of the *cis*-diaqua complex was 0.6 g (43.6%).

trans-*Diaquabis(trimethylenediamine)chromium(III) Nitrate*, trans-$[Cr(H_2O)_2(tn)_2](NO_3)_3$: The aquahydroxo complex *trans*-$[CrOH(H_2O)(tn)_2](NO_3)_2$ (1.0 g) was dissolved in *ca.* 8 M nitric acid (20 ml) and the solution was stirred for a while to separate out a red-brown precipitate in an 85.1% (1.1 g) yield. The crude product was dissolved in a minimum amount of water. After filtration, the solution was kept in ice and concentrated nitric acid was added dropwise to it to precipitate red-brown needles.

cis-*Dinitritobis(trimethylenediamine)chromium(III) Perchlorate*, cis-$[Cr(ONO)_2(tn)_2]ClO_4$: Sodium nitrite (0.5 g) was added to an aqueous solution (10 ml) of *cis*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (1.0 g) and the mixture was stirred for 10 min in an ice bath. After filtration, sodium perchlorate (2.0 g) was added to the filtrate and the solution was kept overnight in a refrigerator to deposit orange prisms. The yield was 0.74 g (79.8%). The product is slightly hygroscopic and was recrystallized from hot water. The compound is not so stable against light, but changes slightly to red on long standing.

trans-*Dinitritobis(trimethylenediamine)chromium(III) Perchlorate*, trans-$[Cr(ONO)_2(tn)_2]ClO_4$: The reaction of *trans*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (1.0 g) with sodium nitrite (0.5 g) was performed in the same manner as above to obtain orange crystals of the trans isomer in a 91.6% (0.85 g) yield. Orange plates were obtained by recrystallization from hot water.

cis-*Diazidobis(trimethylenediamine)chromium(III) Perchlorate*, cis-$[Cr(N_3)_2(tn)_2]ClO_4$: An excess amount (15.0 g) of sodium azide was added to a solution of *cis*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (15.0 g) in a mixture of acetic acid (10 ml) and water (30 ml) and the solution was heated at 50 °C for 10 min to turn deep violet. Sodium perchlorate (5.0 g) was added after cooling to room temperature and the mixture was kept in a refrigerator overnight to precipitate red plates. The yield was 4.8 g (35.2%). Recrystallization from acetone–ethanol gave red needles.

trans-*Diazidobis(trimethylenediamine)chromium(III) Perchlorate*, trans-$[Cr(N_3)_2(tn)_2]ClO_4$: Sodium azide (1.0 g) was added to an aqueous solution (10 ml) of *trans*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (1.0 g) and the mixture was heated at 50 °C for 5 min to afford a red solution, to which was added sodium perchlorate (2.0 g) and heated at 50 °C for further 1.5 h to turn violet. After cooling to room temperature, 60% perchloric acid was added to adjust pH to *ca.* 7 and the solution was kept in a refrigerator overnight to deposit violet needles. The yield was 0.2 g (22.0%). Recrystallization from hot water gave deep violet plates.

Caution: Synthesis of the azido complexes must be performed in a good hood, since gaseous hydrazoic acid is evolved.

$(+)_{589}$-cis-*Diisothiocyanatobis(trimethylenediamine)chromium(III) Thiocyanate*, $(+)_{589}$-cis-$[Cr(NCS)_2(tn)_2]SCN$: A solution (100 ml) of sodium hydrogen (*R,R*)-di-*O*-benzoyltartrate (1.2 g) was added slowly to an aqueous solution (100 ml) of *cis*-$[Cr(NCS)_2(tn)_2]SCN\cdot H_2O$ (1.2 g) with stirring at 50 °C. After cooling to room temperature, a pink precipitate was filtered, washed with water and air-dried. The yield was 0.8 g. Found: C, 44.90; H, 4.94; N, 11.95%. Calcd for $[Cr(NCS)_2(tn)_2][HC_{18}H_{12}O_8]\cdot H_2O = C_{26}H_{35}N_6O_9S_2Cr$: C, 45.14; H, 5.16; N, 12.14%. The diastereoisomer (0.8 g) was dissolved in a solution (10 ml) of sodium thiocyanate (2.0 g) and sodium hydroxide (0.1 g), and the mixture was stirred in an ice bath for 5 min. An orange precipitate was filtered, washed with water and air-dried. The yield was 0.4 g. Recrystallization from acetone–diethyl ether gave orange needles. In order to assure the optical purity, the resolution process was repeated. Molar rotations in methanol are $[M]_{589} = +312°$ and $[M]_{436} = +937°$.

$(-)_{589}$-cis-*Diisothiocyanatobis(trimethylenediamine)chromium(III) Thiocyanate*, $(-)_{589}$-cis-$[Cr(NCS)_2(tn)_2]SCN$: A solution (50 ml) of potassium antimony (*R,R*)-tartrate (0.8 g) was added to a solution of *cis*-$[Cr(NCS)_2(tn)_2]SCN\cdot H_2O$ (1.0 g) in a mixture of acetone (40 ml) and water (40 ml), and the solution was left standing in a refrigerator for two days. Orange needles of diastereoisomer were filtered, washed with a small amount of cold water and air-dried. The yield was 0.6 g. Found: C, 23.31; H, 4.23; N, 13.11%. Calcd for $[Cr(NCS)_2(tn)_2]SbC_4H_2O_6\cdot 2H_2O = C_{12}H_{26}N_6O_8S_2SbCr$: C, 23.24; H, 4.23; N, 13.55%. The diastereoisomer was added to a solution (5 ml) of sodium thiocyanate (2.0 g) and the mixture was stirred for 10 min to deposit orange and white precipitates, which were filtered, washed with cold water and air-dried. Acetone dissolved the orange precipitate, leaving the insoluble white one. Diethyl ether was added to the combined washings to precipitate the $(-)_{589}$ isomer (0.3 g). The resolution procedure was repeated once again to assure the optical purity. The observed values of molar rotation in methanol, $[M]_{589} = -314°$ and $[M]_{436} = -936°$, show an excellent coincidence with those of the $(+)_{589}$ isomer which was obtained above by the resolution with sodium hydrogen-(*R,R*)-di-*O*-benzoyltartrate.

$(+)_{589}$-cis-*Diisothiocyanatobis(ethylenediamine)chromium(III) Thiocyanate*, $(+)_{589}$-cis-$[Cr(NCS)_2(en)_2]SCN$: This complex has already been resolved by House,[12] and both of pure $(+)_{589}$ and $(-)_{589}$ isomers were isolated in solution. Now for comparison with the corresponding trimethylenediamine complex, the ethylenediamine complex was resolved by potassium antimony (*R,R*)-tartrate and isolated as crystals of which the molar rotations are $[M]_{589} = +22°$, $[M]_{546} = +402°$ and $[M]_{436} = -704°$ in methanol and $[M]_{589} = +100°$, $[M]_{546} = -434°$ and $[M]_{436} = -810°$ in water.

$(+)_{589}$-cis-*Diazidobis(trimethylenediamine)chromium(III) Perchlorate*, $(+)_{589}$-cis-$[Cr(N_3)_2(tn)_2]ClO_4$: A solution (200 ml) of sodium hydrogen (*R,R*)-di-*O*-benzoyltartrate (4.8 g) was added slowly to an aqueous solution (250 ml) of the racemic complex (4.8 g). A red precipitate, which deposited from the solution kept in an ice bath for 1 h, was filtered, washed with cold water and air-dried. The yield was 2.7 g. Found: C, 44.08; H, 5.09; N, 21.16%. Calcd for $[Cr(N_3)_2(tn)_2][HC_{18}H_{12}O_8]\cdot H_2O = C_{24}H_{35}N_{10}O_9Cr$: C, 43.70; H, 5.35; N, 21.24%. A mixture of the diastereoisomer (0.9 g) and silver acetate (0.4 g) was stirred in water (10 ml) for 5 min. Acetone (50 ml) was added to the solution to precipitate the silver salt of resolving agent. Sodium perchlorate (2.0 g) was dissolved in the filtrate and acetone was distilled away under reduced pressure to deposit a red precipitate (0.35 g). Repeated resolution assured the optical purity of the product, of which the molar rotations are $[M]_{589} = +76°$ and $[M]_{436} = +1590°$ in water.

$(-)_{589}$-cis-*Diazidobis(ethylenediamine)chromium(III) Perchlorate*, $(-)_{589}$-cis-$[Cr(N_3)_2(en)_2]ClO_4$: Racemic *cis*-$[Cr(N_3)_2(en)_2]ClO_4$ (2.0 g) prepared according to the literature[13] was resolved by sodium hydrogen (*R,R*)-di-*O*-benzoyltartrate and worked up to obtain the optically active perchlorate as red-violet plates (0.3 g). Repeated resolution assured the optical purity. The molar rotations are $[M]_{589} = -754°$ and $[M]_{436} = +710°$ in water.

Measurements. The electronic absorption spectra were measured by a Hitachi EPS-3T spectrophotometer, and the IR spectra by JASCO IR-E (4000—600 cm^{-1}) and Hitachi

EPI-L (700—200 cm^{-1}) spectrometers. The optical rotations were determined with a Yanagimoto OR-50 polarimeter, and the CD spectra with a JASCO J-20 recording spectrometer.

Results and Discussion

Several kinds of cis-trans isomeric pairs of the bis(trimethylenediamine)chromium(III) complexes were prepared by the ligand substitution reactions of *cis*- and *trans*-$[CrCl_2(tn)_2]^+$ in aqueous solution. Results of the elemental analysis for the products are collected in Table 1. The ligand substitution reactions of these chromium(III) complexes proceeded with steric retention except in one case. As was described in Experiment, the yield of *trans*-$[CrOH(H_2O)(tn)_2](NO_3)_2$ from *trans*-$[CrCl_2(tn)_2]Cl$ was as low as 25.6% and acidification of the mother liquor gave *cis*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ in a 43.6% yield. Thus the hydrolysis of *trans*-$[CrCl_2(tn)_2]^+$ induced by the silver ion resulted in *ca.* 50% isomerization under the synthetic conditions. For the sake of comparison, the reaction of *trans*-$[CrCl_2(en)_2]^+$ with silver nitrate was examined, and only *trans*-$[Cr(H_2O)_2(en)_2]^+$ was obtained.

The spontaneous solvolysis of dihalogenobis(diamine)chromium(III) complexes usually occurs with essentially complete retention of configuration.[14] However the secondary hydrolysis of *trans*-$[CrCl_2(tn)_2]^+$ was reported to be complicated by isomerization.[7] The silver(I)-induced aquation of the $[CrCl_2(tn)_2]^+$ complexes seems to proceed *via* the **D** mechanism by analogy with the mercury(II)-catalyzed aquation of $[CrX(H_2O)_5]^{2+}$ (X= F, Cl, Br, and I).[15] It is noteworthy and deserves detailed investigation that the silver(I)-assisted complete aquation of *cis*-$[CrCl_2(tn)_2]^+$ occurs stereoretentively under the present synthetic conditions, while *trans*-$[CrCl_2(tn)_2]^+$ gives a mixture of *cis*- and *trans*-diaqua complexes.

The *cis*- and *trans*-dinitritobis(ethylenediamine)chromium(III) complexes have been synthesized and characterized by Garner and his coworkers.[16] Now the trimethylenediamine analogues are reported. When excess sodium nitrite was used, *cis*- and *trans*-$[Cr(ONO)_2(tn)_2]NO_2$ were obtained as hemihydrate and anhydrous salt, respectively. The cis nitrite salt is even more unstable than the perchlorate. Thus the crude product was obtained as lustrous brown plates, but lost lustre on washing with alcohol, decomposing rapidly. Optical resolution of the *cis*-$[Cr(ONO)_2tn_2]^+$ salts by means of sodium hydrogen (*R,R*)-di-*O*-benzoyltartrate was unsuccessful because of instability of the complex.

Wendlandt prepared *cis*-$[Cr(NCS)_2(tn)_2]SCN$ by the thermal matrix reaction.[17] In the present study the *cis*-diisothiocyanato complex was obtained as a hydrate by the reaction in aqueous solution, but changed curiously to anhydrous salts after optical resolution. Resolution of *cis*-$[Cr(NCS)_2(en)_2]^+$ was successful only by means of the antimony (*R,R*)-tartrate, and the values of molar rotation in aqueous solution nearly coincide with those reported by House.[12] Rotations in methanol were also recorded for comparison with $(+)_{589}$- and $(-)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$ whose solubilities in water are very poor.

Both *cis*- and *trans*-$[Cr(N_3)_2(tn)_2]ClO_4$ were obtained although *trans*-$[Cr(N_3)_2(en)_2]^+$ has not yet been reported. Both isomers are rather stable and can be recrystallized from hot water. The optical rotation of $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]^+$ as well as that of $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]^+$ shows no change after leaving for one day in aqueous solution at room temperature.

Infrared Spectra. Infrared spectra of the dianionobis(diamine)metal complexes are useful for distinguishing linkage[18] and geometrical[19] isomers. *cis*- and *trans*-$[Cr(ONO)_2(tn)_2]ClO_4$ exhibit the ν(N=O) bands at 1500 and 1470 cm^{-1}, respectively and no band assignable to the $\rho_w(NO_2)$ vibration, although the ν(N–O) bands which are expected to appear around 1100 cm^{-1} are masked by the absorption of the perchlorate anion. Thus the NO_2^- ligand is considered to have the Cr–O linkage in both isomers as is known for all other chromium(III)–nitrite complexes. The Cr–N linkage of the thiocyanate ligand in *cis*- and *trans*-$[Cr(NCS)_2(tn)_2]SCN$ is also suggested by IR

Table 1. Analytical data for the bis(trimethylenediamine)chromium(III) complexes

Complex	Found, %			Calcd, %		
	C	H	N	C	H	N
cis-$[Cr(NCS)_2(tn)_2]SCN\cdot H_2O$	27.80	5.80	24.79	27.53	5.64	24.99

trans-$[Cr(N_3)_2(tn)_2]ClO_4$	18.45	5.29	36.10			
$(-)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$	13.76	4.42	39.00	13.51	4.53	39.38

spectra, the ν(C≡N) and δ(NCS) bands appearing at around 2090 and 480 cm^{-1}, respectively in either isomer.

Baldwin's criterion[20] to distinguish between geometrical isomers was successful for many dianionobis(trimethylenediamine)cobalt(III) complexes,[9,21] trans isomers exhibiting one peak and cis isomers two in the CH_2-rocking (880—900 cm^{-1}) region. However all of the present chromium(III) complexes except *trans*-$[Cr(ONO)_2(tn)_2]ClO_4$ have single peak in the 880—895 cm^{-1} region irrespective of the geometrical structure, invalidating the Baldwin's criterion.

Hughes and McWhinnie examined the IR spectra of eleven bis(ethylenediamine)chromium(III) complexes including four cis-trans couples, and found the clearest distinction in the band pattern in the 550—395 cm^{-1} region.[22] Figures 1 and 2 show the IR spectra in the lower frequency region of four isomeric pairs of bis(trimethylenediamine)chromium(III) complexes. The complexity in the band pattern for each cis isomer compared with that for the corresponding trans isomer is apparent in the 550—330 cm^{-1} region. Thus discrimination between cis and trans isomers seems possible in these cases if the couple is presented, whereas it will be quite difficult to assign the geometrical structure on the IR data when only one isomer is obtained.[23]

Absorption and CD Spectra. Table 2 collects the absorption data for the present complexes. The molar absorbance of each cis isomer in the first d-d band is a little larger than that of the trans isomer except for the diazido complexes. Similar trend has frequently been reported for bis(ethylenediamine)chromium(III) complexes.[24] It is noteworthy in the present complexes that the energy difference between the first and second bands is larger for the trans isomer than for the cis isomer (Table 2).

In the case of dianionobis(trimethylenediamine)-cobalt(III) complexes, the absorption maxima of the first band exist in appreciably lower energy region as compared with those of the corresponding ethylenediamine complexes, indicating the weak ligand field of trimethylenediamine relative to ethylenediamine.[9,21] In the case of chromium(III) complexes, the same trend is observed but the difference is quite small.

TABLE 2. ELECTRONIC ABSORPTION DATA FOR THE BIS(TRIMETHYLENEDIAMINE)CHROMIUM(III) COMPLEXES

Complex	Solvent	λ_{max} / nm	ε_{max} / $l \cdot mol^{-1} \cdot cm^{-1}$	$\Delta\nu_{12}$[a] / 10^3 cm^{-1}

a) Difference in wave numbers between the first and second absorption maxima.

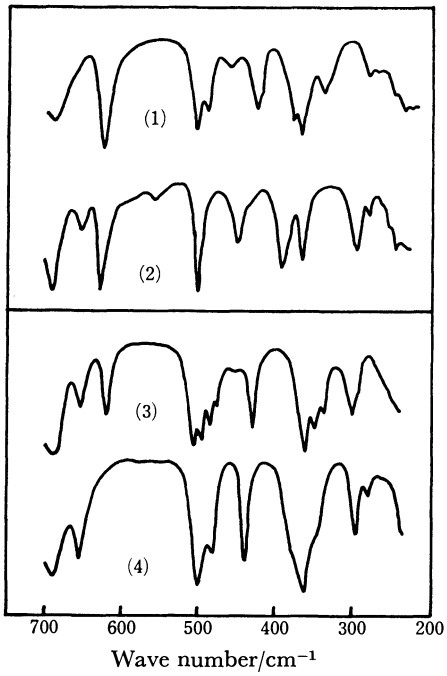

Fig. 1. Infrared spectra (700—200 cm^{-1}) in Nujol of *cis*-$[Cr(ONO)_2(tn)_2]ClO_4$ (1), *trans*-$[Cr(ONO)_2(tn)_2]ClO_4$ (2), *cis*-$[Cr(NCS)_2(tn)_2]SCN$ (3), and *trans*-$[Cr(NCS)_2(tn)_2]SCN$ (4).

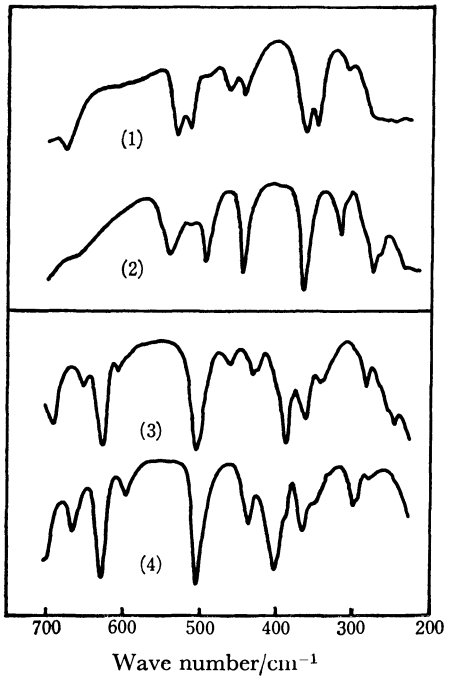

Fig. 2. Infrared spectra (700—200 cm^{-1}) in Nujol of *cis*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (1), *trans*-$[Cr(H_2O)_2(tn)_2](NO_3)_3$ (2), *cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ (3), and *trans*-$[Cr(N_3)_2(tn)_2]ClO_4$ (4).

Thus the largest value of difference in λ_{max} is 14 nm observed between *trans*-$[CrCl_2(tn)_2]Cl$ (590 nm) and *trans*-$[CrCl_2(en)_2]Cl$ (576 nm), and in the case of *cis*-diisothiocyanato and *cis*-diazido complexes depicted in Figs. 3 and 4, respectively, the difference is negligibly

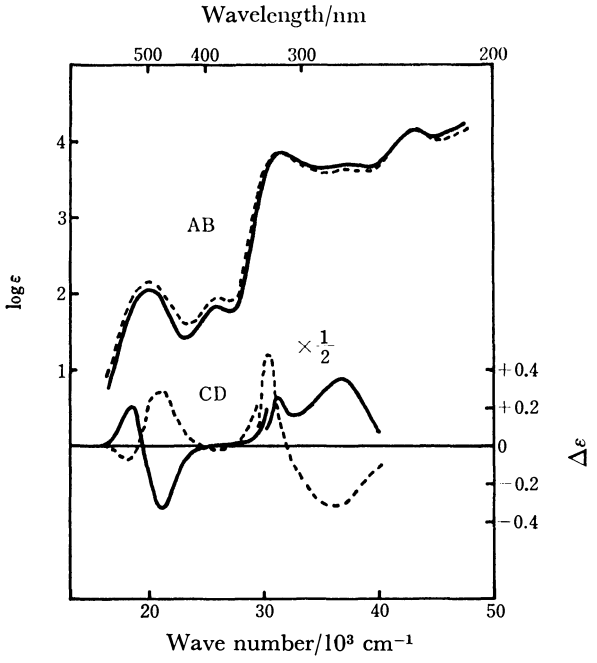

Fig. 3. Absorption and CD spectra of $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$ (——) and $(+)_{589}$-*cis*-$[Cr(NCS)_2(en)_2]SCN$ (- - -) in methanol.

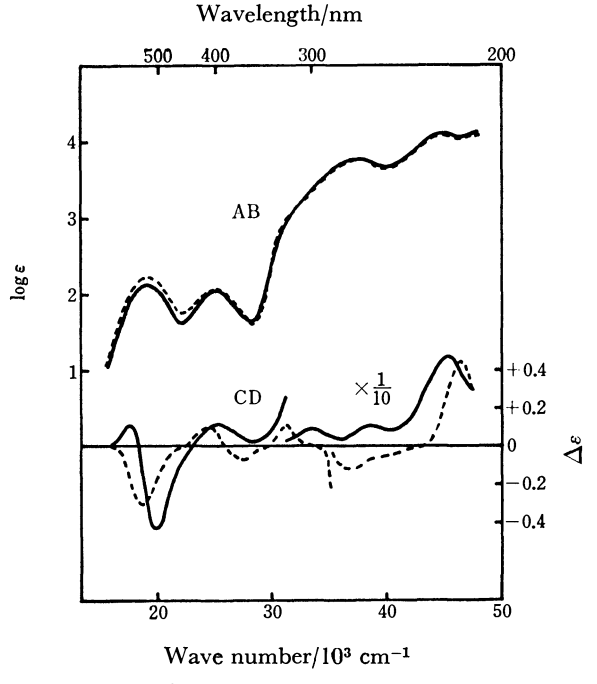

Fig. 4. Absorption and CD spectra of $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ (——) and $(-)_{589}$-*cis*-$[Cr(N_3)_2(en)_2]ClO_4$ (- - -) in water.

small (2 nm).

Figures 3 and 4 also compare the CD spectra of the diisothiocyanato- and diazido–bis(diamine) complexes. Although the intensity of the positive CD band of $(+)_{546}$-$[Cr(tn)_3](ClO_4)_3$ in the first d-d absorption band region ($\Delta\varepsilon = +0.34$ at 20.9×10^3 cm^{-1} in water) is remarkably smaller than that of $(+)_{546}$-$[Cr(en)_3](ClO_4)_3$ ($\Delta\varepsilon = +1.49$ at 21.9×10^3 cm^{-1} in water),[25] the intensities of CD bands in the same region of $(+)_{589}$-

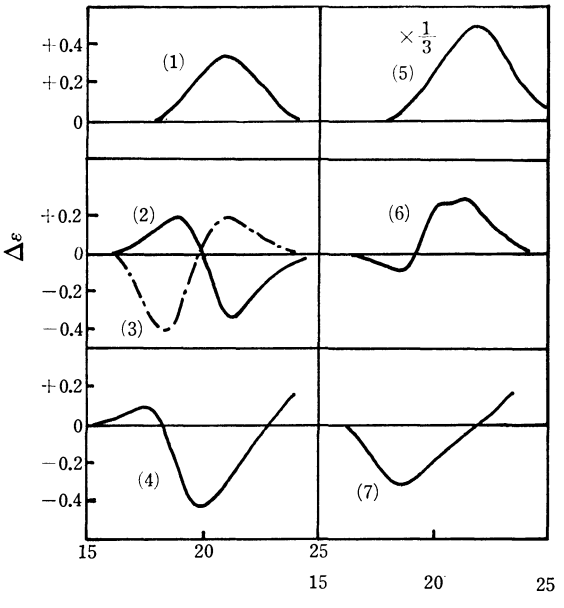

Fig. 5. CD bands in the first d-d absorption region of $(+)_{546}$-$[Cr(tn)_3](ClO_4)_3$ in water (1),[25] $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$ in methanol (2), *Λ*-$(-)_{589}$-*cis*-$[Co(NCS)_2(tn)_2]SCN$ in water (3),[9] $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ in water (4), $(+)_{546}$-$[Cr(en)_3](ClO_4)_3$ in water (5),[25] $(+)_{589}$-*cis*-$[Cr(NCS)_2(en)_2]SCN$ in methanol (6), and $(-)_{589}$-*cis*-$[Cr(N_3)_2(en)_2]ClO_4$ in water (7).

cis-$[Cr(NCS)_2(tn)_2]SCN$ and $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ are rather larger than those of the corresponding ethylenediamine complexes. Another feature to be noted is that $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ exhibits two CD components in this region, whereas $(-)_{589}$-*cis*-$[Cr(N_3)_2(en)_2]ClO_4$ only one.

Figure 5 compares the CD spectra of the bis(diamine) complexes in the first d-d absorption region with those of the tris(diamine) complexes. The CD pattern of $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$ is just opposite to that of $(-)_{589}$-*cis*-$[Co(NCS)_2(tn)_2]SCN$[9] which was confirmed by X-ray analysis to have the *Λ* configuration.[26] Thus the absolute configuration of $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$ is readily assigned to *Δ*. On the same reasoning $(+)_{589}$-*cis*-$[Cr(NCS)_2(en)_2]^+$ was concluded to be *Λ* by House.[12] The dominant CD band of this ethylenediamine complex is positive in accord with the CD band of *Λ*-$[Cr(en)_3](ClO_4)_3$ in this region.[25] On the contrary $(-)_{589}$-*cis*-$[Cr(N_3)_2(en)_2]ClO_4$ exhibits a negative band, suggesting the *Δ* configuration. The spectral pattern of $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ closely resembles that of $(+)_{589}$-*cis*-$[Cr(NCS)_2(tn)_2]SCN$, both having the dominant negative component in the higher energy region. Thus the absolute configuration of $(+)_{589}$-*cis*-$[Cr(N_3)_2(tn)_2]ClO_4$ is assigned to *Δ* in accordance with the *Δ* configuration of $(-)_{589}$-*cis*-$[Cr(N_3)_2(en)_2]ClO_4$.

The authors wish to thank Mr. J. Gohda for the elemental analyses. This work was supported in part by the Grant-in-Aid administered by the Ministry of Education.

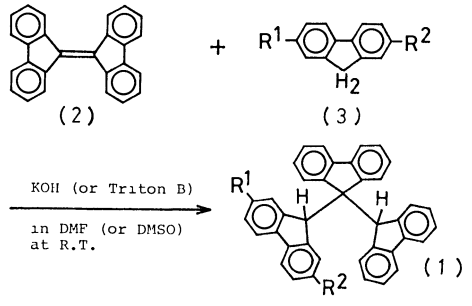
(Received September 8, 1978)

The conformations of 9,9-di(9-fluorenyl)fluorene derivatives (**1**) with substituents at the 2- or 2,7-positions in a terminal fluorene ring were illustrated by the *gauche-gauche* forms at room temperature. DNMR studies of **1** gave the values of about 85—88 kJ/mol for the free energy of activation ($\Delta G^{\ddagger}$) for the restricted rotation around the C(9)–C(9) bonds. The conformation of 9,9-di(9-fluorenyl)fluorene, the parent compound of **1**, was also shown to the only *gauche-gauche* ($+sc$, $+sc$ or $-sc$, $-sc$) form at room temperature.

We have recently reported[2] that the NMR signal of 9-(9-fluorenyl)-9-(2-methyl-9-fluorenyl)fluorene (**1a**) at room temperature showed the existence of two conformers which were caused by restricted rotation around the C(9)–C(9) bonds, and that both the conformations were illustrated by the more stable form, the *gauche-gauche* form. In this paper, we would like to describe the conformations of 9,9-di(9-fluorenyl)fluorene derivatives (**1**) with methyl, ethyl, methoxy, acetyl, and bromo substituents at the 2- or 2,7-positions in a terminal fluorene ring, and also the conformation of the parent 9,9-di(9-fluorenyl)fluorene (**4**).

The derivatives **1** were prepared from the Michael reactions[3] of 9,9′-bifluorenylidene (**2**) with 2(or 2,7-di)-substituted fluorene derivatives **3**, catalyzed by a base in DMF or DMSO at room temperature. The ^{1}H-NMR data of **1** are shown in Table 1.



The NMR spectra for the 2-substituents in **1** have shown the set of signals illustrated in Table 1, suggesting that the rotation around the C(9)–C(9) bonds in **1b**—**1g**, as well as in **1a**,[2] is frozen at room temperature on the NMR time scale. The restricted rotation around the C(9)–C(9) bonds of **1** was investigated by temperature-dependent NMR spectroscopy: some typical DNMR spectra of **1b** are shown in Fig. 1. The values of the free energy of activation ($\Delta G^{\ddagger}$) for the rotation around the bonds in **1** were obtained by means of the usual line-shape analysis[4] on their DNMR spectra of

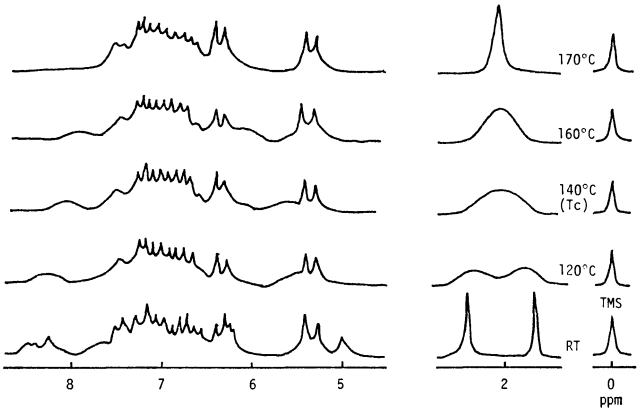


Fig. 1. Temperature dependence of ^{1}H-NMR spectra of **1b** (solvent: HCB).

TABLE 1. ^{1}H-NMR DATA OF **1** IN $CDCl_3$ (ppm)

1g	HCB	84.5 (140)

a) The estimated errors of $\Delta G^{\ddagger}$ are $\pm$1.3—1.7 kJ/mol.
b) *o*-DCB: *o*-dichlorobenzene. HCB: hexachlorobutadiene.

2-substituents, which did not directly hinder the rotation around the C(9)–C(9) bonds, as shown in Table 2.

Figure 2 shows two conformations, (**A**) (*ap*, +*sc*) and (**C**) (+*sc*, −*sc*), both of them *gauche-gauche* forms, and their interconversion process. The conformation **C** is derived from **A** *via* an unstable intermediate (**B**) (+*ac*, *sp*) by the rotation of the two C(9)–C(9) bonds in a conrotatory manner. In the conformation **A**, the substituent R^1 at the 2-position in the terminal fluorene ring **b** is located in a shielding zone of the central fluorene ring **a**. Thus, it is reasonable to assume that the R^1 gives the ^{1}H-NMR signal at a higher field than the R^2 at the 7-position, which is located in a deshielding zone of the two fluorene rings **a** and **c**. The same thing can also be said for the ^{1}H-NMR signals of R^1 and R^2 in the conformation **C** or **D** (enantiomer of **C**). Table 1 illustrates the assignments of the conformations **A** and **C** based on these ^{1}H-NMR signals, and also shows the equilibrium constants K (N_C/N_A) for the equilibria **A**⇌**C** of **1**.

Recently, Suzuki and Minabe reported that 9,9-di(9-fluorenyl)fluorene (**4**), the parent compound of **1**, has two conformational isomers occuring as a result of the restricted rotation around the C(9)–C(9) single bonds, and proposed, on the basis of the ^{1}H-NMR data at room temperature, that the two rotamers can exist in the *s-cis*, *s-cis* form (mp 291—293 °C) (corresponding to our *gauche-gauche* form) and the *s-cis*, *s-trans* form (mp 256—257 °C).[5)] However, we could not confirm any isomers of the above *s-cis*, *s-trans* type from **1**. Actually, the reaction of **2** with fluorene catalyzed by potassium hydroxide in DMF gave the sole product **4** (mp 291—293 °C).[3)] The DNMR spectra of **4** in HCB are shown in Fig. 3.

The spectrum of **4** is almost analogous to that of **1** (Fig. 1) except for the region of the substituents, supporting the *gauche-gauche* form as the stable conformation of **4** by analogy with **1**. The isomerization process between the +*sc*, +*sc* and −*sc*, −*sc* (enantiomer of +*sc*, +*sc*) forms of **4** can be well demonstrated in a manner similar to that described in the case of **1**. The $\Delta G^{\ddagger}$ value for the restricted rotation around the C(9)–C(9) bonds in **4** may also be about 85—88 kJ/mol, by analogy with that of **1**. Unfortunately, we could not find the *s-cis*, *s-trans* isomer[6)] which was reported by Suzuki and Minabe in these DNMR process.

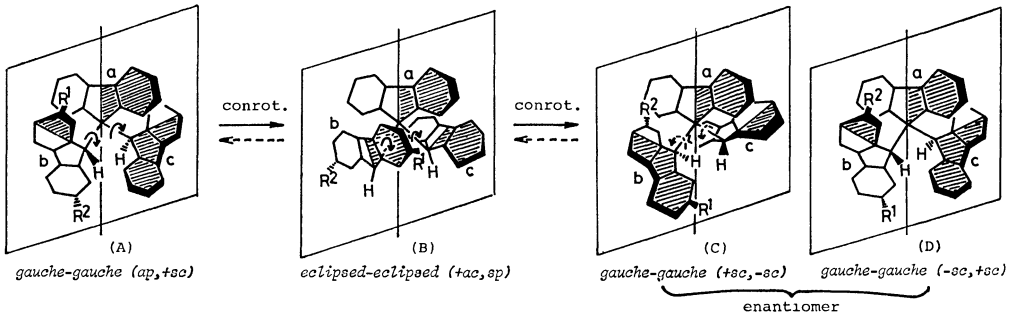

Fig. 2. The process for isomerization of **1** by rotation around the C(9)–C(9) bonds.

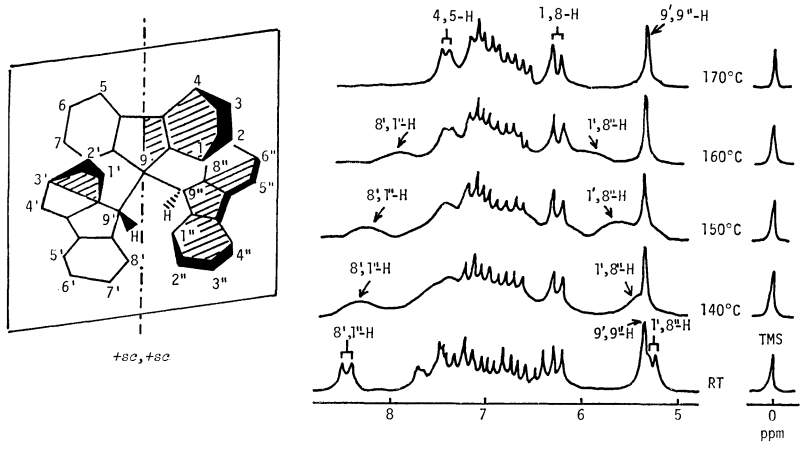

Fig. 3. Temperature dependence of ^{1}H-NMR spectra of **4** (solvent: HCB).

From the behavior of the DNMR spectra of **4**, the doublets of δ=5.22 (J=8 Hz) and δ=8.40 (J=8 Hz) at room temperature were identified as protons at the 1′,8″- and 8′,1″-positions, respectively. These two doublets are broadened, and are observed to approach each other gradually with an increase in the temperature, and are then hidden in the region of other aromatic protons at 165 °C. On the other hand, the doublets of δ=6.22 (J=8 Hz) and δ=7.44 (J=8 Hz) which are observed clearly at high temperatures are identified as protons at the 1,8- and 4,5-positions in the central fluorene ring, respectively. Then, 9,9-di(9-fluorenyl)-fluorene was prepared by the Michael addition of fluorene to **2** with sodium ethoxide in ethyl alcohol by the same method as that described by Suzuki and Minabe.[5] The two products, **4** (mp 291—293 °C) and **5** (mp 255—257 °C), were obtained just as has been described in the literature.

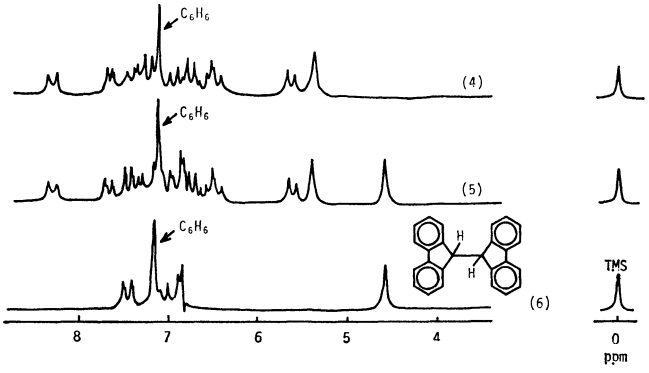

Fig. 4. ^{1}H-NMR spectra of **4**, **5**, and **6** at room temperature (solvent: C_6D_6).

The ^{1}H-NMR spectra of **4** and **5** in C_6D_6 at room temperature are shown in Fig. 4, together with that of 9,9′-bifluorenyl (**6**).[5] In this case, the shape of spectrum of **5** was in fair agreement with the overlapped shape of the spectrum of **4** with **6**. The chemical shift (4.60 ppm) in **5** is the same as that of methine protons in **6**, and the signal is amplified by the addition of **6**. The equimolar mixture of **4** and **6** was recrystallized from ethyl acetate to give crystals with the melting point of 255—257 °C; its ^{1}H-NMR spectrum was identical with that of **5**. Furthermore, the product **5** was confirmed to be an equimolar mixture of **4** and **6** by high-speed liquid-chromatographic analysis.

On the Michael reaction of **2** with fluorene, if alkoxide is used as a catalyst, **5** is obtained as the product. In this case, **6** should be produced along with **4** in the reaction mixture. That is, the alkoxide should act on **2** as a reductant. The reaction of **2** with fluorene using other bases (*e.g.*, KOH in DMF,[3] Triton B in DMSO, and KOH in pyridine[5]) instead of alkoxide gave **4** as the sole product. Actually, the reaction of **2** with sodium ethoxide in ethyl alcohol in a sealed tube gave **6** in a substantial yield.

It is known that, in the case of $\Delta G^{\ddagger}<96$ kJ/mol rotamers are unstable at room temperature.[7] If the $\Delta G^{\ddagger}$ value for **4** is estimated as 85—88 kJ/mol as in the case of **1**, we should not be able to isolate the *s-cis*, *s-trans* rotamer of **4** stably at room temperature.

Experimental

All the melting points are uncorrected. The NMR spectra were run on a JEOL-MH-100 spectrometer with a JEOL model JES-VT-3 variable-temperature controller. The chemical shifts are expressed in ppm, with tetramethylsilane as the internal standard. Signal-shape-analysis was done by matching the experimental spectra with the spectra calculated from the computer program given by Nakagawa.[8] High-speed liquid-chromatographic analysis was carried out on a Tōyō Sōda TSK-HLC-803 apparatus equipped with a UV monitor using an LS-410K (4 mm i.d. × 30 cm) column, with acetonitrile as the mobile phase, at room temperature.

Syntheses of ***1***. *A Typical Synthetic Procedure for* ***1***: The starting material, 2-acetyl-7-methoxyfluorene (**3f**), was prepared by the reaction of 2-methoxyfluorene with acetyl chloride, using $AlCl_3$ as the catalyst, by the procedure reported by Gray *et al.*;[9] mp 131—132 °C (lit, 134.5 °C); IR (KBr) 1670 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.60 (3H, s, $COCH_3$), 3.83 (2H, s, 9-methylene), 3.84 (3H, s, OCH_3), 6.70—8.20 (6H, m, aromatic protons).

To a mixture of **2** (1.6 g, 0.005 mol) and **3f** (1.2 g, 0.005 mol) in DMF (2 ml), we added Triton B (0.1 ml) at room temperature. The solution was stirred for 5 min, during which the color changed from red to dark brown, and was then poured into dil hydrochloric acid (10 ml). The precipitate thus obtained was filtered, washed with water, and recrystallized from acetone to give colorless crystals **1f**; 2.0 g (70%); mp 244—248 °C. Found: C, 89.43; H, 5.07%. Calcd for $C_{42}H_{30}O_2$: C, 89.02; H, 5.34%.

1d, mp 237—242 °C; Found: C, 91.82; H, 5.36%. Calcd for $C_{40}H_{28}O$: C, 91.57; H, 5.38%.

1e, mp 251—255 °C; Found: C, 91.51; H, 5.15%. Calcd for $C_{41}H_{28}O$: C, 91.76; H, 5.26%.

1g, mp 260—263 °C; Found: C, 79.24; H, 4.48%. Calcd for $C_{40}H_{27}OBr$: C, 79.60; H, 4.51%.

Reaction of ***2*** *with Sodium Ethoxide.* Metallic sodium (0.23 g, 0.01 g-atom) was treated with 20 ml of absolute ethanol, and then there was added 0.33 g (0.001 mol) of **2**. The mixture was heated in a sealed tube at 95—98 °C for 14 h. After cooling, the precipitate was filtered off and dissolved in benzene. The benzene solution was chromatographed on alumina. The eluent was evaporated to dryness under reduced pressure, and the residue was recrystallized from benzene–ethanol (1:1) to afford **6**: 0.20 g (61%); mp 246—247 °C. This compound was confirmed by direct comparison with an authentic sample. On the other hand, **2** was recovered unchanged from the red ethanolic solution; 0.05 g (15%).

We wish to express our thanks to Mr. Atsushi Aiura and Mr. Katsuyuki Tanaka, Tōyō Sōda Manufacturing Co., Ltd., for the high-speed liquid-chromatographic analysis.

Catalytic Efficiency of Cationic Micellar Catalysts Bearing a Mercapto Group as the Reaction Center†

Yukito MURAKAMI,* Akio NAKANO, Kiyoshi MATSUMOTO, and Kiyoshi IWAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 2, 1979)

In order to clarify micro-environmental effects on the reactivity of mercapto groups in enzymes, cationic surfactants bearing a mercapto group, *N*-hexadecyl-N^{α}-(3-trimethylammoniopropionyl)-L-cysteinamide bromide (CM·Cys-1) and *N*-dodecyl-N^{α}-(6-trimethylammoniohexanoyl)-L-cysteinamide bromide (CM·Cys-2), were synthesized and their kinetic behavior investigated. The surfactants above their critical micelle concentrations markedly catalyzed the decomposition of *p*-nitrophenyl hexanoate (PNPH) and acetate (PNPA), the concentration-rate profiles being found to be those for typical micelle-catalyzed reactions. The rate constants for the degradation of PNPH as catalyzed by CM·Cys-1 and -2 in the micellar phase are 0.482 and 0.197 s^{-1}, respectively, in 9.8% (v/v)-ethanol–1.0% (v/v)dioxane–1.0% (v/v)methanol–water at 30.0±0.1 °C, pH 8.65, and μ 0.10 (KCl). The difference in catalytic activity can be attributed partly to the micro-environmental effect on the pK_a value of the mercapto group lying at the reaction center. The rate constants for the thiolate anions (true reactive species) of CM·Cys-1 and -2 to react with PNPH were identical with each other irrespective of the nature of the surfactants. The electrostatic effect provided by the cationic charge in the Stern layer, which acts to reduce the pK_a value of the reactive mercapto group, seems to play a more important role than the desolvation effect on the thiolate anion by the hydrophobic field.

Functionalized surfactants involving a reactive group such as the imidazolyl,[1] carboxyl,[2] or hydroxyl group[3] have been developed as enzyme models. However, only a limited number of surfactants bearing a mercapto group have been synthesized; their catalytic activity for degradation of *p*-nitrophenyl carboxylates has been examined.[4] The active mercapto group of these surfactants seems to be located in the electrostatic Stern layer judging from their molecular structures. In spite of the fact that the catalytically active groups of enzymes are located in their hydrophobic pockets, no successful attempt has been made to locate the catalytic groups in the hydrophobic micellar core so as to simulate the function of an enzymatic reaction center. The anionic surfactants involving a L-cysteinyl residue as the reaction center markedly accelerate the degradation of *p*-nitrophenyl carboxylates below their critical micelle concentrations, the reactivity of the mercapto group being lost upon formation of the anionic micelles.[5] The surfactants show pronounced reactivity even in a neutral pH region when mixed with hexadecyltrimethylammonium bromide (CTAB) in the micellar phase. The electrostatic field effect provided by the cationic head of CTAB micelle enhances the nucleophilicity of the mercapto group in the mixed micelles for such reactions.

In order to develop novel surfactants which can incorporate the multi-functions provided by the comicelle constructed by CTAB and *N*-hexadecyl-N^{α}-glutaryl-L-cysteinamide, we have prepared cationic surfactants bearing a mercapto group, *N*-hexadecyl-N^{α}-(3-trimethylammoniopropionyl)-L-cysteinamide bromide (CM·Cys-1) and *N*-dodecyl-N^{α}-(6-trimethylammoniohexanoyl)-L-cysteinamide bromide (CM·Cys-2). The mercapto group is expected to be placed in a hydrophobic core of the micellar phase. The micro-environmental effect on the nucleophilicity of the mercapto group provided by the present cysteine-containing cationic surfactants has been investigated as regards the deacylation of *p*-nitrophenyl carboxylates. The synthetic procedure for CM·Cys-1 is shown in Scheme 1.

Scheme 1.

† Contribution No. 512 from this Department.

Experimental

Spectroscopic data were taken on a JASCO DS-403G grating IR spectrophotometer, a Varian A60 NMR spectrometer, and a Hitachi 124 spectrophotometer. pH-Measurements were carried out with a TOA HM-9A pH meter equipped with a TOA GC-125 combined electrode after calibration with a combination of appropriate aqueous standard buffers.

p-Nitrophenyl carboxylates were prepared by the reaction of the corresponding carbonyl chlorides with *p*-nitrophenol. The esters were identified by elemental analyses and spectroscopic measurements.[6] 2,2′-Dinitro-5,5′-dithiodibenzoic acid (DTNB, Nakarai Chemicals, bio-analytical grade) was used without further purification.

The synthetic procedure for *N*-hexadecyl-N^{α}-(3-trimethylammoniopropionyl)-L-cysteinamide bromide (CM·Cys-1) is outlined in Scheme 1. *N*-Hexadecyl-N^{α}-*t*-butoxycarbonyl-*S*-benzyl-L-cysteinamide (**1**) was prepared as described previously.[5]

*N-Hexadecyl-N$^{\alpha}$-(3-bromopropionyl)-S-benzyl-L-cysteinamide (**3**).* Trifluoroacetic acid (25.0 g) was added to a dichloromethane solution (17 ml) of **1** (2.4 g) and the mixture was stirred at room temperature for 1 h. Evaporation of excess trifluoroacetic acid *in vacuo* gave pale yellow oil (**2**); yield 2.5 g (quantitative). Elimination of the *t*-butoxycarbonyl group was confirmed by means of NMR spectrum. Amine component **2** (1.74 g) and triethylamine (0.97 g) were dissolved in dichloromethane (20 ml) and cooled down to 0 °C. 3-Bromopropionyl chloride (1.09 g) dissolved in dichloromethane (5 ml) was added to the solution in 10 min at this temperature. The mixture was stirred for 30 min at 0 °C and at room temperature for 2 h. The reaction mixture, after dichloromethane (50 ml) had been added, was washed with water (50 ml×3), 5% aqueous sodium hydrogencarbonate (50 ml×3), 5% aqueous citric acid (50 ml×3), and saturated aqueous sodium chloride (50 ml×3). After being dried over anhydrous sodium sulfate, the mixture was evaporated *in vacuo* at 40 °C to give a glassy solid of pale yellow; yield 1.65 g (99%), mp 86—88 °C. NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{14}CH_2$–), 1.25 (28H, s, $CH_3(C\underline{H}_2)_{14}CH_2$–), 2.65—2.95 (4H, m, $BrCH_2C\underline{H}_2CO$– and $-C\underline{H}_2SCH_2$-Ph), 3.22 (2H, broad t, $CH_3(CH_2)_{14}C\underline{H}_2NH$–), 3.65 (2H, t, $BrC\underline{H}_2CH_2CO$–), 3.80 (2H, s, $-CH_2SC\underline{H}_2Ph$), 4.55 (1H, broad t, $-C\underline{H}(CH_2SCH_2Ph)CO$–), and 7.37 (5H, s, phenyl H's).

*N-Hexadecyl-N$^{\alpha}$-(3-trimethylammoniopropionyl)-S-benzyl-L-cysteinamide Bromide (**4**).* Dry trimethylamine gas was introduced into a benzene solution (60 ml) of **3** (1.6 g) for 6 h, and the solution was stirred at room temperature for 14 h. After benzene had been evaporated off *in vacuo*, methanol was added to the residue and removed *in vacuo*. The treatment with methanol was repeated three times. A white solid was recovered and recrystallized from ethyl acetate–petroleum ether; yield 1.60 g (86%), mp 88—95 °C, Dragendorff positive. NMR (methanol-d_4, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{14}CH_2$–), 1.25 (28H, s, $CH_3(C\underline{H}_2)_{14}CH_2$–), 2.60—3.05 (4H, m, $(CH_3)_3\overset{+}{N}CH_2C\underline{H}_2CO$– and $-C\underline{H}_2SCH_2Ph$), 3.18 (9H, s, $(C\underline{H}_3)_3\overset{+}{N}$–), 3.04—3.41 (4H, m, $(CH_3)_3\overset{+}{N}C\underline{H}_2CH_2CO$– and $CH_3(CH_2)_{14}C\underline{H}_2NH$–), 3.80 (2H, s, $-CH_2SC\underline{H}_2Ph$), 4.55 (1H, broad t, $-C\underline{H}(CH_2SCH_2Ph)CO$–), and 7.35 (5H, s, phenyl H's).

N-Hexadecyl-N$^{\alpha}$-(3-trimethylammoniopropionyl)-L-cysteinamide Bromide (CM·Cys-1). Anisole (1.0 ml) and **4** (700 mg) were placed in a reaction vessel into which hydrogen fluoride (10 ml) was introduced. The mixture was stirred at 0 °C for 1 h, at 15 °C for 30 min, and then evaporated *in vacuo* to remove hydrogen fluoride completely. Methanol (30 ml) was added to the residue and white precipitates were recovered by filtration. After methanol had been evaporated off, 2-mercaptoethanol (5 ml) was added to the residue and the mixture was stirred at room temperature for 14 h. Methanol (10 ml) was added to the mixture and the product was purified by gel-filtration chromatography (Sephadex LH-20, methanol as eluant) to give a hygroscopic solid; yield 180 mg (30%), nitroprusside positive. IR (neat): 3240 (NH str.); 2900 and 2840 (CH str.); 1655 and 1545 cm^{-1} (C=O str.). NMR (methanol-d_4, TMS): δ 0.90 (3H, broad t, $C\underline{H}_3(CH_2)_{14}CH_2$–), 1.30 (28H, s, $CH_3(C\underline{H}_2)_{14}CH_2$–), 2.65—3.20 (6H, m, CH_3-$(CH_2)_{14}C\underline{H}_2NH$–, $-C\underline{H}_2SH$, and $(CH_3)_3\overset{+}{N}CH_2C\underline{H}_2CO$–), 3.18 (11H, s, $(C\underline{H}_3)_3\overset{+}{N}C\underline{H}_2CH_2CO$–), and 4.35 (1H, broad, $-C\underline{H}$-$(CH_2SH)CO$–). Found: C, 56.25; H, 9.46; N, 6.99%. Calcd for $C_{25}H_{52}BrN_3O_2S$: C, 55.79; H, 9.72; N, 7.80%.

N-Dodecyl-N^{α}-(6-trimethylammoniohexanoyl)-L-cysteinamide bromide (CM·Cys-2) was prepared in a manner similar to that described for CM·Cys-1.

N-Dodecyl-N$^{\alpha}$-t-butoxycarbonyl-S-benzyl-L-cysteinamide. Yield 51%, needles (recrystallized from ethyl acetate), mp 57—59 °C. NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{11}$–), 1.25 (20H, s, $CH_3(C\underline{H}_2)_{10}CH_2$–), 1.45 (9H, s, $(C\underline{H}_3)_3CO$–), 2.76 (2H, broad d, $-C\underline{H}_2SCH_2Ph$), 3.25 (2H, m, CH_3-$(CH_2)_{10}C\underline{H}_2$–), 3.75 (2H, s, $-CH_2SC\underline{H}_2Ph$), 4.21 (1H, broad t, $-C\underline{H}(CH_2SCH_2Ph)CO$–), and 7.37 (5H, s, phenyl H's).

N-Dodecyl-N$^{\alpha}$-(6-bromohexanoyl)-S-benzyl-L-cysteinamide. Yield 81%, pale yellow oil. IR (neat): 3250 (NH str.); 2900 and 2830 (CH str.); 1635 and 1535 cm^{-1} (C=O str.). NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{11}$–), 1.26 (20H, s, $CH_3(C\underline{H}_2)_{10}CH_2$–), 1.90 (6H, m, $BrCH_2(C\underline{H}_2)_3$-$CH_2CO$–), 2.50 (2H, broad t, $BrC\underline{H}_2(CH_2)_3CH_2CO$–), 2.78 (2H, d, $-C\underline{H}_2SCH_2Ph$), 3.19 (2H, broad t, $CH_3(CH_2)_{10}$-$C\underline{H}_2$–), 3.42 (2H, t, $BrC\underline{H}_2$–), 3.76 (2H, s, $-CH_2SC\underline{H}_2Ph$), 4.51 (1H, broad t, $-C\underline{H}(CH_2SCH_2Ph)CO$–), and 7.33 (5H, s, phenyl H's).

N-Dodecyl-N$^{\alpha}$-(6-trimethylammoniohexanoyl)-S-benzyl-L-cysteinamide Bromide. Yield 97%, hygroscopic glassy solid of pale yellow (recrystallized from ethyl acetate–petroleum ether), mp 68—75 °C, Dragendorff positive. IR (Nujol): 3260 (NH str.); 1630 and 1540 cm^{-1} (C=O str.). NMR (methanol-d_4, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{11}$–), 1.25 (20H, s, CH_3-$(C\underline{H}_2)_{10}CH_2$–), 2.00 (6H, m, $(CH_3)_3\overset{+}{N}CH_2(C\underline{H}_2)_3CH_2CO$–), 2.31 (2H, broad t, $(CH_3)_3\overset{+}{N}(CH_2)_4C\underline{H}_2CO$–), 2.75—3.20 (4H, m, $-C\underline{H}_2SCH_2Ph$ and $CH_3(CH_2)_{10}C\underline{H}_2NH$–), 3.40 (11H, s, $(C\underline{H}_3)_3\overset{+}{N}C\underline{H}_2$–), 3.75 (2H, s, $-CH_2SC\underline{H}_2Ph$), 4.60 (1H, broad, $-C\underline{H}(CH_2SCH_2Ph)CO$–), and 7.35 (5H, s, phenyl H's).

N-Dodecyl-N$^{\alpha}$-(6-trimethylammoniohexanoyl)-L-cysteinamide Bromide (CM·Cys-2). Yield 32%, glassy solid, mp 133—145 °C, nitroprusside positive. IR (Nujol): 3260 (NH str.); 1630 and 1530 cm^{-1} (C=O str.). NMR (methanol-d_4, TMS): δ 0.90 (3H, broad t, $C\underline{H}_3(CH_2)_{11}$–), 1.30 (20H, s, $CH_3(C\underline{H}_2)_{10}$-$CH_2$–), 1.10—2.00 (6H, m, $(CH_3)_3\overset{+}{N}CH_2(C\underline{H}_2)_3CH_2$–), 2.40 (2H, broad, $(CH_3)_3\overset{+}{N}(CH_2)_4C\underline{H}_2CO$–), 2.65—3.10 (4H, m, $-C\underline{H}_2SH$ and $CH_3(CH_2)_{10}C\underline{H}_2NH$–), 3.18 (11H, s, $(C\underline{H}_3)_3$-$\overset{+}{N}C\underline{H}_2$–), and 4.35 (1H, broad, $-C\underline{H}(CH_2SH)CO$–). Found: C, 55.23; H, 9.12; N, 7.08%. Calcd for $C_{24}H_{50}BrN_3O_2S$: C, 54.95; H, 9.61; N, 7.08%.

Kinetic Measurements. The concentration of free thiol for CM·Cys-1 and -2 was determined by using Ellman's reagent (DTNB)[7] before kinetic runs. Under the conditions employed, the reaction between surfactant and ester species

was fast enough to neglect oxidation of the mercapto group of the surfactants. Rates of *p*-nitrophenol liberation from *p*-nitrophenyl esters were measured at 400 nm with a Hitachi 124 spectrophotometer. Each run was initiated by adding a dry dioxane solution (30 μl) of a substrate ester to a mixture of a reaction medium (3.0 ml) and a dry methanol solution (30 μl) of a catalyst which was pre-equilibrated at 30.0±0.1 °C in a thermostatted cell set in the spectrophotometer. The reaction medium was prepared as follows: 10.0 ml of 1.0 M aqueous potassium chloride, 10.0 ml of an appropriate aqueous buffer, and 10.0 ml of dry ethanol were placed in a 100-ml volumetric flask; the flask was filled with deionized and distilled water. Aqueous buffer solutions adopted in the present study were prepared by combining 1/10 M potassium dihydrogenphosphate and 1/20 M sodium borate.

The mole fractions of CM·Cys-1 and -2, which bear the free mercapto group and were used for kinetic runs, were 0.63 and 0.67, respectively. Thus, all the rate data were corrected to a 100% content of the free mercapto group. In order to find the effect of disulfide content on kinetic behavior, the thiol surfactants involving the free mercapto group in the mole fraction range 0.33—0.67 were also examined for their catalytic activity. All the kinetic data thus obtained after correction for the disulfide content were identical regardless of disulfide content. The substrate-binding ability of the surfactants was not affected by the disulfide content.

Results and Discussion

Degradation of *p*-nitrophenyl carboxylates as catalyzed by CM·Cys-1 and -2 has been studied in 9.8%(v/v)ethanol–1.0%(v/v)dioxane–1.0%(v/v)methanol–water at 30.0±0.1 °C and μ 0.10 (KCl). Apparent first-order rate constants (k_{obsd}) were obtained by measuring the amount of liberated *p*-nitrophenol. The first-order kinetics was found to hold up to 90% conversion of the substrate for each kinetic run, no noticeable hydrolysis of the acylated thiol ester being observed.

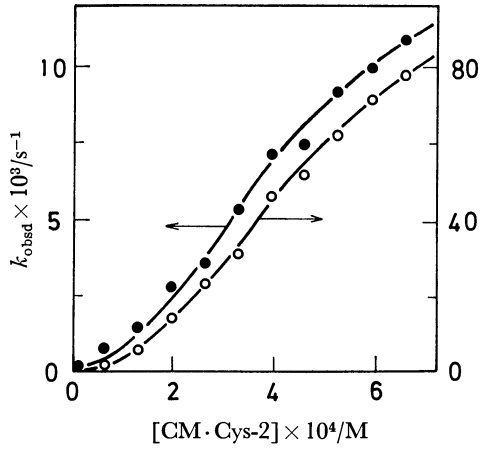

Fig. 1. Plots of apparent first-order rate constant *vs.* surfactant concentration (C_D) for the deacylation of *p*-nitrophenyl hexanoate (PNPH, ○) and acetate (PNPA, ●) as catalyzed by CM·Cys-2 in 9.8%(v/v)-ethanol–1.0% (v/v)dioxane–1.0% (v/v) methanol–water at 30.0±0.1 °C, pH 8.65, and μ 0.10 (KCl). Initial concentrations: PNPH, 0.992×10⁻⁵ M; PNPA, 0.990 ×10⁻⁵ M.

Rate(k_{obsd})-concentration profiles (Fig. 1) for the degradation of *p*-nitrophenyl hexanoate (PNPH) and acetate (PNPA) as catalyzed by CM·Cys-2 at pH 8.65 are typical for the micellar catalysis. The reaction pathway for the degradation of *p*-nitrophenyl carboxylates as catalyzed by the thiol surfactants is given by Scheme 2, where S denotes an ester substrate (PNPH or PNPA), M a micelle constructed by a thiol surfactant

$$\mathrm{M} + \mathrm{S} \overset{K_b}{\rightleftharpoons} \mathrm{MS} \xrightarrow{k_m} \mathrm{P}$$
$$\mathrm{MS} \xrightarrow{k_s} \mathrm{P'}$$

Scheme 2.

(CM·Cys-1 or -2), MS a complex formed with the micelle and the substrate, and P and P′ denote reaction products. The k_s and k_m values are defined as follows.

$$k_s = k_{hyd} + k_{SH}(\text{monomer}) \quad (1)$$

$$k_m = k_M^{OH} + k_{SH}(\text{micelle}) \quad (2)$$

where k_{hyd} denotes the rate constant for the alkaline hydrolysis, k_{SH}(monomer) that for the acyl transfer from a substrate to the mercapto group of a monomeric surfactant in the bulk phase, k_M^{OH} that for the alkaline hydrolysis by concentrated hydroxide ions in the Stern layer of the micelle, and k_{SH} (micelle) that for the acyl transfer from a bound substrate to the mercapto group of the micellar surfactant. The observed first-order rate constant (k_{obsd}) is given by the following equation on the basis of Scheme 2.[8]

$$k_{obsd} = \frac{k_s + K_b k_m [M]}{1 + K_b [M]} \quad (3)$$

This can be rearranged to give

$$\frac{1}{(k_{obsd} - k_s)} = \frac{1}{(k_m - k_s)} + \frac{N}{(k_m - k_s) K_b (C_D - CMC)} \quad (4)$$

where N denotes the aggregation number and C_D total concentration of the thiol surfactant. The critical micelle concentration (CMC) was kinetically estimated

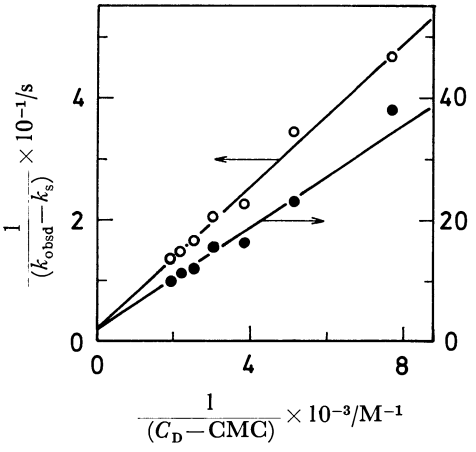

Fig. 2. Plots of $1/(k_{obsd}-k_s)$ *vs.* $1/(C_D-CMC)$ for the deacylation of PNPH (○) and PNPA (●) as catalyzed by CM·Cys-2 in 9.8%(v/v)ethanol–1.0%(v/v)dioxane–1.0%(v/v)methanol–water at 30.0±0.1 °C, pH 8.65, and μ 0.10 (KCl). Initial concentrations: PNPH, 0.992×10⁻⁵ M; PNPA, 0.990×10⁻⁵ M.

a) In 9.8 %(v/v)ethanol–1.0%(v/v)dioxane–1.0%(v/v)methanol–water at 30.0±0.1 °C, pH 8.65, and μ 0.10 (KCl). Initial concentrations: PNPH, 0.992×10^{-5} M; PNPA, 0.990×10^{-5} M. Apparent first-order rate constants for the alkaline hydrolysis: PNPH, 1.31×10^{-4} s^{-1}; PNPA, 1.56×10^{-4} s^{-1}. Approximate CMC's: CM·Cys-1, 4×10^{-5} M; CM·Cys-2, 9×10^{-5}M. 1 M=1 mol dm^{-3}. b) $k_{cat}=k_{obsd}^{max}/[\text{surfactant}]_{max}$; k_{obsd}^{max}, maximum observed rate constant under present conditions with a surfactant concentration, $[\text{surfactant}]_{max}$.

from the corresponding rate-concentration profile. The apparent first-order rate constants observed at the critical micelle concentrations were referred to the k_s values. Linearity holds between the left-hand side term of Eq. 4 and the reciprocal concentration of micellized surfactant (C_D—CMC) as shown in Fig. 2 for the CM·Cys-2 catalysis as an example. The kinetic parameters are summarized in Table 1. The k_s values for the reaction between thiol surfactants and ester substrates indicate that the reactivity of CM·Cys-1 is identical with that of CM·Cys-2 in the bulk phase. The pseudo-intramolecular rate constant (k_m) and the binding ability (K_b/N) reflect the catalytic activity of CM·Cys-1 and -2 in the micellar phase. In order to clarify the difference in catalytic activity, k_m and K_b/N values for the degradation of PNPH as catalyzed by CM·Cys-1 and -2 were evaluated at several pH's from the corresponding data of saturation kinetics (Fig. 3, CM·Cys-2 catalysis). The kinetic parameters obtained are given in Table 2. The pH-rate profiles (Fig. 4) suggest that the reactive species is the thiolate anion in the micellar phase as shown by

a) In 9.8%(v/v)ethanol–1.0% (v/v) dioxane–1.0%(v/v)-methanol–water at 30.0±0.1 °C and μ 0.10 (KCl). Initial concentrations: PNPH, 0.992×10^{-5} M; CM·-Cys-1, $(0.660—6.60)\times10^{-4}$ M; CM·Cys-2, $(0.664—6.64)\times10^{-4}$ M. Approximate CMC's: CM·Cys-1, 4×10^{-5} M; CM·Cys-2, 9×10^{-5} M.

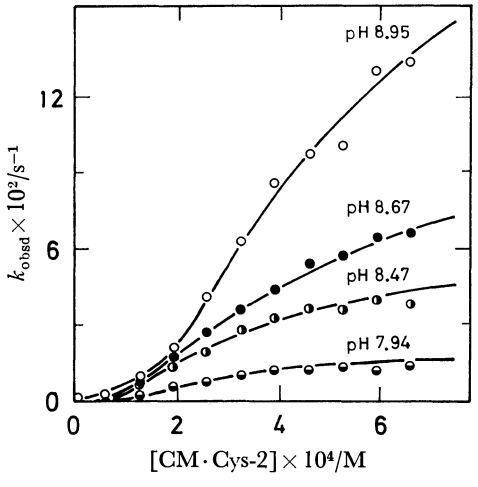

Fig. 3. Plots of apparent first-order rate constant *vs.* surfactant concentration (C_D) for the deacylation of PNPH as catalyzed by CM·Cys-2 in 9.8%(v/v)ethanol–1.0%(v/v) dioxane–1.0%(v/v) methanol–water at 30.0±0.1 °C and μ 0.10 (KCl); initial concentration of PNPH, 0.992×10^{-5} M.

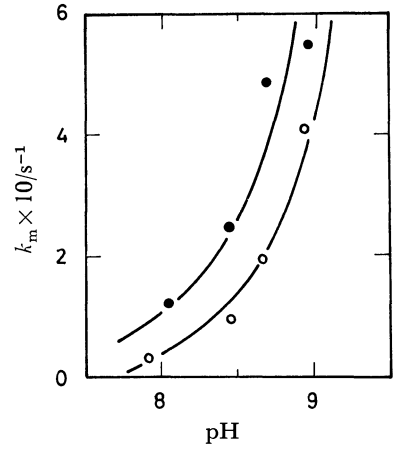

Fig. 4. pH-rate profiles for the deacylation of PNPH as catalyzed by CM·Cys-1 (●) and -2 (○) in 9.8%-(v/v)ethanol–1.0%(v/v)dioxane–1.0%(v/v)methanol–water at 30.0±0.1 °C and μ 0.10 (KCl); initial concentration of PNPH, 0.992×10^{-5} M.

$$S\cdot M(SH) \overset{K_a}{\rightleftharpoons} S\cdot M(S^-) \overset{k_m^*}{\longrightarrow} P$$

Scheme 3.

where M(SH) and M(S$^-$) denote micellar surfactants bearing neutral mercapto and anionic sulfido groups, respectively. The following relations are established.

$$k_m\{[S\cdot M(SH)] + [S\cdot M(S^-)]\} = k_m^*[S\cdot M(S^-)] \quad (5)$$

$$K_a = \frac{[S\cdot M(S^-)][H^+]}{[S\cdot M(SH)]} \quad (6)$$

By combination and rearrangement of Eqs. 5 and 6, we obtain the relation between the k_m and k_m^* values:

$$\frac{1}{k_m} = \frac{1}{k_m^*} + \frac{[H^+]}{k_m^* K_a} \quad (7)$$

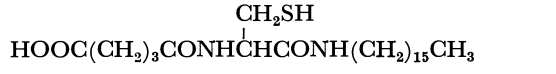
Plots of $1/k_m$ against [H$^+$] for the deacylation of PNPH as catalyzed by CM·Cys-1 and -2 provide k_m^* and pK_a values (Table 3).

Table 3. True rate constants (k_m^*) and kinetic pK_a values for the deacylation of *p*-nitrophenyl hexanoate as catalyzed by CM·Cys-1 and -2[a)]

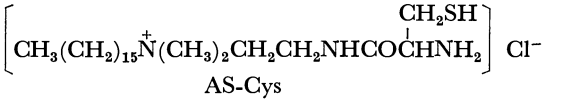
Surfactant	k_m^*/s^{-1}	pK_a
CM·Cys-1	1.36	9.09
CM·Cys-2	1.28	9.52

a) Calculated from data given in Table 2.

Catalytic Efficiency of the Micellar Thiol Surfactants. The more effective micellar catalyst was provided by CM·Cys-1, the k_m value for the deacylation of PNPH being 3680 times as large as the corresponding k_{hyd} value (Table 1). The remarkable efficiency of CM·Cys-1 is comparable to that of the mixed micelle formed with CTAB and *N*-hexadecyl-*N*$^\alpha$-glutaryl-L-cysteinamide (AM·Cys-1); k_m/k_{hyd}, 3080.[5)] For the degradation of



AM·Cys-1



AS-Cys

PNPA, CM·Cys-1 shows large catalytic efficiency as compared with [2-(cysteinylamino)ethyl]hexadecyldimethylammonium chloride (AS-Cys) reported by Moss and his coworkers (k_{cat}, 26.0).[4b)] The catalytic efficiency (k_m) of CM·Cys-1 for the degradation of PNPH is larger than that of CM·Cys-2 by 2.44-fold at pH 8.65. Nevertheless, both micelles show similar reactivity toward the substrate in terms of k_m^* (Table 3). The result suggests that the reactivity of the thiolate anion of these surfactants does not depend on the depth of its location in a hydrophobic micellar core. On the contrary, the pK_a value for the mercapto group of CM·Cys-2 increases by 0.5 pK_a unit relative to that for CM·Cys-1. Moss and his coworkers reported pK_a for the dissociation of the thiol proton of AS-Cys (at 2×10^{-4} M) as 8.9.[4c)] The mercapto group of AS-Cys is presumably located in the cationic Stern layer. The results suggest that the pK_a value is affected by the depth of the active group in the micellar phase and its micro-environment is subject to the electrostatic field effect as well as to the hydrophobic effect. The difference of the catalytic efficiency among CM·Cys-1 and -2 at pH 8.65 for the deacylation of PNPH can be explained by the pK_a effect. On the other hand, the catalytic efficiency of CM·Cys-1 is nearly comparable to that of CM·Cys-2 for the deacylation of PNPA. The catalytic efficiency of these surfactants for the deacylation of PNPA seems to be affected by its orientation behavior in the micellar phase which is different from that of PNPH. PNPH would be so arranged in the micellar phase that an attack of the mercapto group on it is facilitated in the hydrophobic core, PNPA being incorporated into the electrostatic Stern layer as shown in Fig. 5. This is in line with the results reported by Brown and Schofield.[9)] They indicated that hexane is solubilized in the micellar interior, enforcing tighter packing and reduced mobility, while benzene and 1-pentanol disrupt the micellar structure by binding close to the Stern layer.

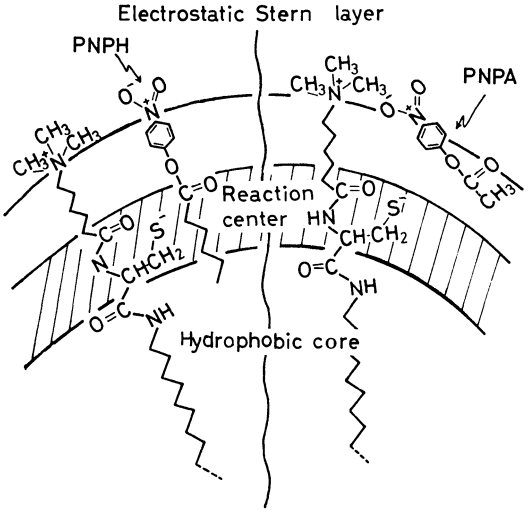


Fig. 5. Schematic representation for the orientation of ester substrates (PNPH and PNPA) in the CM·Cys-2 micelle.

Substrate-binding Ability of the Micellar Thiol Surfactants. The K_b/N values (Table 1) indicate that both micelles have stronger binding ability for PNPH than for PNPA, and that CM·Cys-1 has stronger binding ability for both substrates than CM·Cys-2. The result suggests that the bulky side chain (mercaptomethyl group) located in the hydrophobic micellar core disturbs the micelle structure; *i.e.*, the hydrophobicity of micelles. The binding ability due to the hydrophobic interaction between the substrate and the micelle seems to be affected by the depth of the bulky branched group along the hydrophobic alkyl chain of the surfactant molecule. The K_b/N value decreases with increasing pH of the medium (Table 2). Thus, the binding ability decreases with increasing the fraction of the anionic sulfido group, indicating that the ionic charge on the hydrophobic chain perturbs the structure of micellar

core so as to reduce the hydrophobic micro-environmental effect. The critical micelle concentration of these surfactants is practically not affected by pH under the present conditions.

Conclusion. Both CM·Cys-1 and -2 show profound catalytic efficiency for the degradation of carboxylic esters to an extent comparable to that of the CTAB–AM·Cys-1 comicelle.[5] The large efficiency of CM·Cys-1 and -2 in the micellar phase is due to the electrostatic field effect provided by the cationic charge placed in the Stern layer which acts to stabilize the anionic transition state and to reduce pK_a of the mercapto group. An anionic nucleophile in general would be subjected to the desolvation effect in the hydrophobic micellar core. However, the reactivity of the anionic sulfido group of CM·Cys-1 is comparable to that of CM·Cys-2 in the micellar phase. This indicates that the desolvation effect does not play a primary role for the development of the thiol reactivity. Being a soft nucleophile, the thiolate anion would not sustain the solvation effect by water molecule as effectively as a hard nucleophile, such as the carboxylate anion.

Studies on 2-Aziridinecarboxylic Acid. II.[1] A Novel Synthesis of Threonine *O*-Peptide Derivatives *via* (2*S*,3*S*)-3-Methyl-2-aziridinecarboxylic Acid

Takumi TANAKA, Kiichiro NAKAJIMA, Toru MAEDA, Akihiro NAKAMURA, Noboru HAYASHI, and Kenji OKAWA*

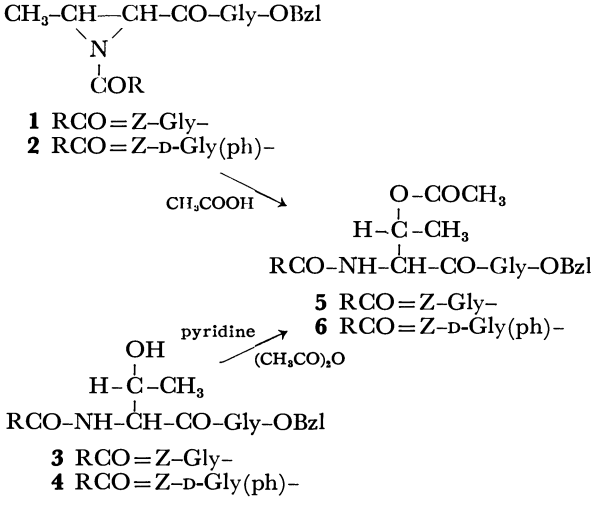
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received March 23, 1979)

A new synthesis of threonine *O*-peptides *via* the ring opening reaction of aziridine peptide with carboxylic acid has been investigated. Benzyl (2*S*,3*S*)-1-[*N*-(benzyloxycarbonyl)glycyl]-3-methyl-2-aziridinecarbonylglycinate was treated with several *N*-protected amino acids or dipeptides at their mixed melting point, and the corresponding *O*-aminoacyl or dipeptidyl esters of L-threonine peptide derivative were obtained in good yields without racemization.

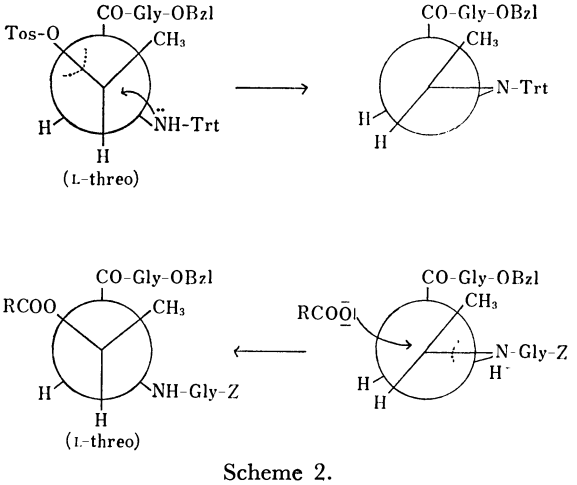
Depsipeptide represents a major part of the biological active cyclic peptides. Many studies on an effective synthetic method of these peptides have been carried out. So far total synthesis, except in some cases, has been accomplished by the usual cyclization under peptide bond formation after performance of ester linkage at the first step in the synthetic procedure. Synthetic approaches in this field are limited. It is therefore desirable to establish a convenient synthetic method for *O*-peptide without racemization.

In a previous paper,[2] it was reported that *N*-tosyl-*O*-acetyl-L-threoninanilide is obtained quantitatively *via* the ring opening reaction of (2*S*,3*S*)-1-tosyl-3-methyl-2-aziridinecarboxanilide by the action of acetic acid in the presence of BF_3.



Scheme 1.

The method was applied to aziridine peptides such as Z–Gly–3-Me–Azy–Gly–OBzl (**1**) and Z–D-Gly(ph)–3-Me–Azy–Gly–OBzl (**2**).[3] The corresponding *O*-acetylthreonine peptide derivatives (**5**, **6**) were easily obtained in the absence of any catalyst as shown in Scheme 1 and Table 1. On the other hand, authentic samples of **5** and **6** were prepared from Z–Gly(or D-Gly(ph))–L-Thr–Gly–OBzl (**3**, **4**) according to the usual *O*-acetylation procedure. The yields of the *O*-acetylthreonine peptide derivatives were equally good, no remarkable differences being observed between the two methods. The configuration of β-carbon atom of threonine residue was retained in its original threo form, double inversion being encountered through the formation and cleavage reaction of the aziridine ring (Scheme 2).



Scheme 2.

The above results prompted us to attempt effective preparation of *O*-peptides which might be used as an important intermediate of depsipeptide synthesis. A preliminary test using Z–Gly–OH to Z–Gly–3-Me–Azy–Gly–OBzl (**1**) with BF_3 in CH_2Cl_2 at 25 °C, gave low yield (about 20%). The aziridine ring showed unexpected resistance against Z–Gly–OH. However, the reaction proceeded with greater facility under drastic

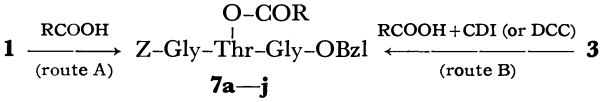

Scheme 3.

conditions, *i.e.*, at the mixed melting point of the two reactants in the absence of catalyst or solvent as shown in Scheme 3 (*via* route A). Several *N*-protected amino acids and dipeptides were used as the carboxylic acid component. All the reactions through the ring opening (*via* route A) were accomplished in a short time (2—4 h), threonine *O*-peptide derivatives (**7a—j**) being obtained in good yields. The yields and physical characteristics of **7a—j** are given in Table 2.

Special attention was paid to racemization during the course of heating, but none was observed: **7i** (*via* route A); $[\alpha]_D^{23}$ −26.8° (*c* 0.91, MeOH), ($[\alpha]_D^{23}$ −27.4° (*c* 0.9, MeOH)).[4] Partial racemization might occur by the usual method (*via* route B), using activating reagent (CDI or DCC), during the course of direct introduction of *N*-protected dipeptide.

From the results, it was concluded that the new method would become a convenient means for the synthesis of biological active depsipeptides.

Experimental

All the melting points are uncorrected. The optical rotations were measured on a Parkin-Elmer 141 Polarimeter. Purity of the synthetic compounds was confirmed by thin layer chromatography on silica gel G.

Synthesis of O*-Acetylthreonine Peptide Derivatives. Z–Gly–*L*-Thr(OAc)–Gly–OBzl (5).* *From 1*: Z–Gly–3-Me–Azy–Gly–OBzl (**1**)[3b] (220 mg, 0.5 mmol) was dissolved in acetic acid (5 ml) and the solution was left to stand at room temperature for 3 days. After removal of acetic acid, the crystals obtained were collected and recrystallized from ethyl acetate–ether–hexane (206 mg). Found: C, 59.78; H, 5.36; N, 8.39%. Calcd for $C_{25}H_{29}O_8N_3$: C, 60.11; H, 5.85; N, 8.41%.

From 3: Acetic anhydride (708 mg, 4 mmol) was added with stirring to a solution of Z–Gly–L-Thr–Gly–OBzl (**3**)[5] (458 mg, 1 mmol) in pyridine (5 ml) at 0 °C. After being stirred for 12 h, the reaction mixture was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with 10% citric acid, 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residual product was crystallized from ethyl acetate–ether–hexane (428 mg). Found: C, 59.96; H, 5.73; N, 8.36%. The results are summarized in Table 1.

*Z–*D*-Gly(ph)–*L*-Thr(OAc)–Gly–OBzl (6).* *From 2*: Compound **6** was obtained in the same way as described above from Z–D-Gly(ph)–3-Me–Azy–Gly–OBzl (**2**)[3b] (515 mg, 1 mmol) and acetic acid (3 ml). Compound **6** was crystallized from ethyl acetate (511 mg). Found: C, 63.09; H, 5.86; N, 7.16%. Calcd for $C_{31}H_{33}O_8N_3 \cdot H_2O$: C, 62.72; H, 5.94; N, 7.08%.

From 4: Compound **6** was obtained in the same way as described above from Z–D-Gly(ph)–L-Thr–Gly–OBzl (**4**)[6] (267 mg, 0.5 mmol) and acetic anhydride (100 mg, 1 mmol) in pyridine (3 ml). Compound **6** was crystallized from ethyl acetate–ether (231 mg). Found: C, 62.67; H, 5.87; N, 7.01 %. The results are summarized in Table 1.

Z–Gly–
Synthesis of Threonine O*-Peptide Derivatives. Z–Gly–*L*-Thr–Gly–OBzl (7a).* Via *Route A*: A mixture of **1** (45 mg, 0.1 mmol) and Z–Gly–OH (45 mg, 0.22 mmol) was heated at 110 °C in an oil bath. After being heated for 2 h, the reaction mixture was dissolved in ethyl acetate. The solution was washed with 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residual product was crystallized from ethyl acetate–ether–hexane (63 mg). Found: C, 61.07; H, 5.43; N, 8.52%. Calcd for $C_{33}H_{36}O_{10}N_4$: C, 61.10; H, 5.59; N, 8.64%.

Via *Route B*: CDI (194 mg, 1.2 mmol) was added with stirring to a solution of Z–Gly–OH (250 mg, 1.2 mmol) in THF (5 ml) at −10 °C. After 1 h, a solution of **3** (320 mg, 0.7 mmol) in dioxane (5 ml) was added to the reaction mixture with stirring at 0 °C. After being stirred for 4 h, the solvent was removed *in vacuo*. The residual product was dissolved in ethyl acetate and the solution was washed with 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residual product was purified by column chromatography on silica gel in benzene–ethyl acetate (1: 1 v/v). Compound **7a** was crystallized from ethyl acetate–ether–hexane (99 mg). Found: C, 60.95; H, 5.54; N, 8.54%. The results are summarized in Table 2.

*Boc–*L*-Leu–*
*Z–Gly–*L*-Thr–Gly–OBzl (7b).* Via *Route A*: A mixture of **1** (104 mg, 0.24 mmol) and Boc–L-Leu–OH (166 mg, 0.72 mmol) was heated at 85 °C for 2 h, and then worked up as described for **7a**. The residual oily product was purified by

column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (146 mg). Found: C, 59.97; H, 6.92; N, 8.31%. Calcd for $C_{36}H_{46}O_{10}N_4 \cdot H_2O$: C, 60.66; H, 6.79; N, 7.86%.

Via *Route B*: CDI (1.49 g, 9.20 mmol) was added with stirring to a solution of Boc-L-Leu-OH (1.94 g, 8.37 mmol) in THF (7 ml) at −10 °C. After 1 h, compound **3** (2.74 g, 6.0 mmol) in DMF (5 ml) was added to the reaction mixture with stirring at 0 °C. After being stirred for 3 days, it was worked up as described for **7a**. The residual product was purified by column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (646 mg). Found: C, 60.51; H, 7.13; N, 8.44%. The results are summarized in Table 2.

Boc-L-Pro—

Z-Gly-L-Thr-Gly-OBzl (7c). Via *Route A*: A mixture of **1** (659 mg, 1.5 mmol) and Boc-L-Pro-OH (1.29 mg, 6.0 mmol) was heated at 125 °C for 3 h, and then worked up as described for **7a**. The residual product was purified by column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (906 mg). Found: C, 59.66; H, 6.56; N, 8.19%. Calcd for $C_{33}H_{42}O_{10}N_4 \cdot 1/2H_2O$: C, 59.72; H, 6.53; N, 8.44%. The results are summarized in Table 2.

Boc-L-Phe—

Z-Gly-L-Thr-Gly-OBzl (7d). Via *Route A*: A mixture of **1** (220 mg, 0.5 mmol) and Boc-L-Phe-OH (531 mg, 2 mmol) was heated at 100 °C for 3 h, and then worked up as described for **7a**. Compound **7d** was crystallized from ethyl acetate–ether–hexane (260 mg). Found: C, 61.15; H, 6.35; N, 7.38 %. Calcd for $C_{37}H_{44}O_{10}N_4 \cdot H_2O$: C, 61.48; H, 6.42; N, 7.75 %. The results are summarized in Table 2.

Z-L-Ser—

Z-Gly-L-Thr-Gly-OBzl (7e). Via *Route A*: A mixture of **1** (800 mg, 1.82 mmol) and Z-L-Ser-OH (1.74 g, 7.28 mmol) was heated at 96 °C for 4 h, and then worked up as described for **7a**. Compound **7e** was crystallized from hot ethyl acetate (1.05 g). Found: C, 59.01; H, 5.64; N, 8.05%. Calcd for $C_{34}H_{38}O_{11}N_4 \cdot 1/2H_2O$: C, 59.36; H, 5.72; N, 8.51%. The results are summarized in Table 2.

Boc-L-Met(O)—

Z-Gly-L-Thr-Gly-OBzl (7f). Via *Route A*: A mixture of **1** (800 mg, 1.82 mmol) and Boc-L-Met(O)-OH (1.93 g, 7.28 mmol) was heated at 100 °C for 4 h, and then worked up as described for **7a**. The residual product was purified by column chromatography on silica gel in ethyl acetate–MeOH–$CHCl_3$ (1: 1: 8 v/v) to give an amorphous powder (1.22 g). Found: C, 55.11; H, 6.26; N, 7.73; S, 4.31%. Calcd for $C_{33}H_{43}O_{11}N_4S \cdot 1/2H_2O$: C, 55.53; H, 6.35; N, 7.85; S, 4.49%. The results are summarized in Table 2.

Boc-L-Glu(OBzl)—

Z-Gly-L-Thr-Gly-OBzl (7g). Via *Route A*: A mixture of **1** (300 mg, 0.68 mmol) and Boc-L-Glu(OBzl)-OH (922 mg, 2.73 mmol) was heated at 100 °C for 4 h, and then worked up as described for **7a**. The residual product was purified by column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (439 mg). Found: C, 61.72; H, 6.30; N, 7.35%. Calcd for $C_{40}H_{48}O_{12}N_4$: C, 61.84; H, 6.23; N, 7.21%. The results are summarized in Table 2.

Z-L-MeVal—

Z-Gly-L-Thr-Gly-OBzl (7h). Via *Route A*: A mixture of **1** (300 mg, 0.68 mmol) and Z-L-MeVal-OH (724 mg, 2.73 mmol) was heated at 110 °C for 4 h, and then worked up as described for **7a**. Compound **7h** was crystallized from ethyl acetate–ether–hexane (446 mg). Found: C, 63.11; H, 6.85; N, 8.02%. Calcd for $C_{37}H_{44}O_{10}N_4$: C, 63.05; H, 6.29; N, 7.95%. The results are summarized in Table 2.

Boc-L-Leu-L-Leu—

Z-Gly-L-Thr-Gly-OBzl (7i). Via *Route A*: A mixture of **1** (300 mg, 0.68 mmol) and Boc-L-Leu-L-Leu-OH (941 mg, 2.73 mmol) was heated at 115 °C for 4 h, and then worked up as described for **7a**. The residual product was purified by column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (426 mg). Found: C, 60.70; H, 7.50; N, 8.30%. Calcd for $C_{40}H_{57}O_{11}N_5 \cdot 1/2H_2O$: C, 60.59; H, 7.37; N, 8.83%.

Via *Route B*: CDI (135 mg, 0.83 mmol) was added with stirring to a solution of Boc-L-Leu-L-Leu-OH (236 mg, 0.69 mmol) in THF (3 ml) at −10 °C. After 95 min, compound **3** (158 mg, 0.35 mmol) in THF (3 ml) was added to the reaction mixture with stirring at 0 °C. After 7 days, it was worked up as described for **7a**. The residual product was purified by column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (48 mg). Found: C, 61.12; H, 7.67; N, 8.87%. Calcd for $C_{40}H_{57}O_{11}N_5$: C, 61.28; H, 7.33; N, 8.93%.

Via *Route B*: Compound **3** (915 mg, 2 mmol) and Boc-L-Leu-L-Leu-OH (689 mg, 2 mmol) were combined with DCC (413 mg, 2.2 mmol) in absolute pyridine (8 ml) at −10 °C for 3 days. Isolation and washing procedure gave an oil, which was purified by column chromatography on silica gel in $CHCl_3$–ethyl acetate (1: 1 v/v) to give an amorphous powder (23.6 mg). Found: C, 58.67; H, 7.12; N, 7.74%. Calcd for $C_{40}H_{57}O_{11}N_5 \cdot H_2O$: C, 59.91; H, 7.42; N, 8.73%. The results are summarized in Table 2.

Boc-L-Pro-Sar—

Z-Gly-L-Thr-Gly-OBzl (7j). Via *Route A*: A mixture of **1** (55 mg, 0.13 mmol) and Boc-L-Pro-Sar-OH (143 mg, 0.5 mmol) was heated at 85 °C for 4 h, and then worked up as described for **7a**. Compound **7j** was crystallized from $CHCl_3$–ether–hexane (83.3 mg). Found: C, 58.27; H, 6.50; N, 9.15%. Calcd for $C_{36}H_{47}O_{11}N_5 \cdot H_2O$: C, 58.27; H, 6.64; N, 9.42%. The results are summarized in Table 2.

Reaction of Diazo Ketones in the Presence of Metal Chelates. VII. 1,3-Dipolar Cycloaddition of 1-Methoxybenzo[*c*]pyrylium-4-olate with Acetylenic Dipolarophiles

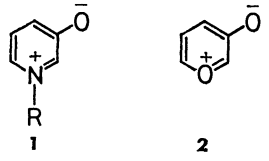
Toshikazu IBATA* and Kimiko JITSUHIRO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received March 28, 1979)

The $Cu(acac)_2$ catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**3**) in the presence of acetylenic dipolarophiles gave cycloadducts of the dipolarophiles with 1-methoxybenzo[*c*]pyrylium-4-olate generated by the intramolecular carbene-carbonyl reaction of the corresponding carbene. The direction of the cycloadditions of unsymmetrically substituted acetylenes has been determined on the basis of the NMR coupling pattern and chemical shift of the bridgehead methine protons of the adducts. Treatment of **3** with strong dipolarophiles such as dibenzoylacetylene or dimethyl acetylenedicarboxylate gave spiro pyrazoles by the direct cycloaddition of **3** and acetylenes followed by the elimination of methanol.

The 1,3-dipolar cycloaddition of pyridinium-3-olates (**1**) have recently been extensively studied by Katritzky *et al.*[1] Only a few papers exist however on the reaction of pyrylium-3-olates (**2**),[2] having isoelectronic structures with pyridinium-3-olate, due to the low stability and difficulty formation of **2**. The reported methods for the formation of pyrylium-3-olates were the thermal and photochemical cleavage of the corresponding epoxides.[2] In the previous paper the formation of benzo[*c*]-pyrylium-4-olate (**5**) was reported in which the contribution of the carbonyl ylide type resonance formula (**5b**), in the copper chelate-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**3**) *via* intramolecular carbene-carbonyl reaction.[3] In this paper the cycloaddition of the carbonyl ylide with acetylenic dipolarophiles will be described.

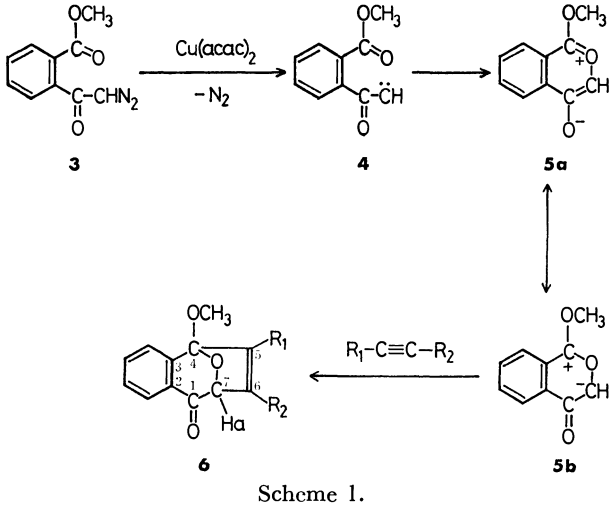


1 **2**

Results and Discussion

The $Cu(acac)_2$ catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**3**) in benzene at 80 °C in the presence of 1.2 mol equivalents of dibenzoylacetylene gave two products. The main product (66% yield) was assigned as 5,6-dibenzoyl-4-methoxy-4,7-epoxy-2,3-benzo-2,5-cycloheptadien-1-one (**6a**) on the basis of the spectral and analytical data. The IR spectrum of **6a** shows carbonyl bands of cyclic ketone and benzoyl groups at 1710 and 1660 cm^{-1}, respectively, together with an ethylenic band at 1630 cm^{-1}. The NMR spectrum of **6a** has a singlet signal of the methoxyl group at δ 3.73 and that of a bridgehead proton at δ 5.75 together with the multiplet signal of the aromatic protons.

The formation of **6a** is reasonably explained by the 1,3-dipolar cycloaddition of dibenzoylacetylene with 1-methoxybenzo[*c*]pyrylium-4-olate (**5**) which is derived by the intramolecular carbene-carbonyl reaction of the *o*-methoxycarbonylbenzoylcarbene intermediate (**4**) generated by the $Cu(acac)_2$ catalyzed decomposition of **3**

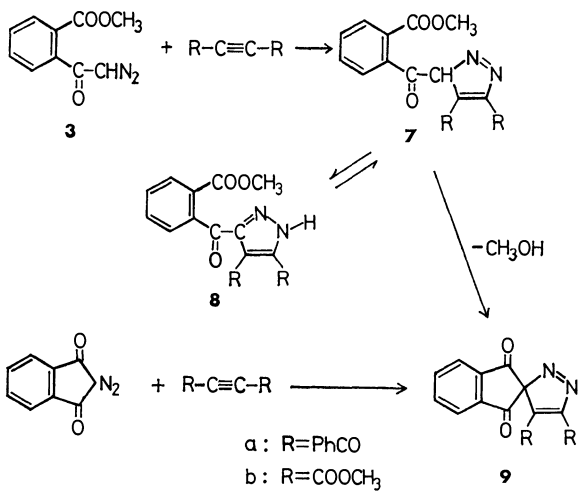


3 **4** **5a** **5b** **6**

Scheme 1.

(Scheme 1).

The other product contains nitrogen and has a molecular formula $C_{25}H_{14}O_4N_2$ which corresponds to the compound obtained by the elimination of CH_3OH from a 1 : 1 adduct of the diazo ketone and dibenzoylacetylene. The absence of methoxyl and methine signals in the NMR spectrum agrees with the molecular formula. The IR spectrum shows strained carbonyl and benzoyl bands at 1748 and 1680 cm^{-1} respectively and also shows an ethylenic band at 1650 cm^{-1}. Heating of the 1 : 1 mixture of the diazo ketone and dibenzoylacetylene in xylene at 120 °C without $Cu(acac)_2$ catalyst gave the same product in high yield. The nitrogen containing product was assigned as 4′,5′-dibenzoylspiro[indan-2,3′-[3*H*]pyrazole]-1,3-dione (**9a**) on the following basis. The cycloaddition of diazo ketones toward electron-deficient acetylenes has been reported to give pyrazoles.[4] The cycloaddition of the diazo ketone (**3**) towards dibenzoylacetylene gives pyrazole (**7a**) which may be in equilibrium with pyrazole (**8a**) by a 1,3-proton shift. The intramolecular elimination of methanol from the pyrazole (**7a**) may give 4′,5′-dibenzoylspiro[indan-2,3′-[3*H*]pyrazole]-1,3-dione (**9a**). The structure of the spiro pyrazole (**9a**) was confirmed by comparison of the spectral properties with an authentic sample prepared by the cycloaddition of 2-diazo-1,3-indandione with dibenzoylacetylene.[5] In



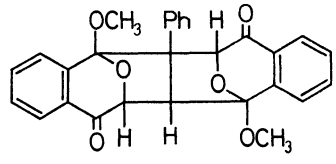
Scheme 2.

order to ascertain the intermediacy of the pyrazole **7a** and **8a**, an absolute benzene solution of equimolar amounts of the diazo ketone (**3**) and dibenzoylacetylene was heated at 60 °C for 6 h. In the IR spectrum of the reaction mixture (after evaporation of benzene under reduced pressure below 50 °C) the characteristic absorption of the diazo group at 2150 cm^{-1} disappeared. The carbonyl bands at 1710 and 1660 cm^{-1} (broad) remained unchanged and a broad band appeared at 3270 cm^{-1}. The NMR spectrum exhibited a singlet of the methoxyl methyl group at δ 3.70 together with a multiplet of aromatic protons. Column chromatography of the reaction mixture on silica gel did not isolate the intermediate **7a** or **8a** but gave the spiro pyrazole (**9a**) in high yield. Fractional recrystallization of the reaction mixture from a mixture of benzene–heptane below 60 °C gave colorless crystals, which were assigned to pyrazole (**8a**) on the basis of analytical and spectral data (see experimental section). Treatment of the pyrazole (**8a**) on silica gel or heating it at 110 °C for 5 h gave the spiro pyrazole (**9a**) quantitatively.

The reaction of **3** with dimethyl acetylenedicarboxylate with $Cu(acac)_2$ catalyst gave a small amount (4%) of the corresponding spiro pyrazole (**9a**) together with cycloadduct (**6b**; 73%) of the benzopyrylium-4-olate (**5**). The spiro pyrazole (**9b**) was also confirmed by comparison with an authentic sample prepared by a similar method as cited above.

In the reactions with asymmetric acetylenes there exist two possibilities in the direction of the cycloaddition giving two isomers. Methyl propiolate however gave only one adduct (**6c**: R_1=$COOCH_3$, R_2=H) in 44% yield despite a detailed inspection of the reaction mixture by column chromatography. The structure of **6c** was characterized by the NMR coupling pattern of two methine protons of the adduct. Both bridgehead methine protons (H_a) and vinyl protons (H_b) show doublet signals coupled with one another (J=2.8 Hz) at δ 5.16 and 7.21 ppm, respectively. This indicates that H_a and H_b are located in vicinal positions (C-7 and C-6).[6]

Phenylacetylene gave two adducts (**6d**: R_1=Ph, R_2=H and **6e**: R_1=H, R_2=Ph) in 45% and 13% yields respectively, together with isochroman-1,4-dione (**10**; 8%) and a 1:2 adduct (**11**; in 5% yield). The structure of the major adduct **6d** was assigned on the basis of the coupling pattern of the methine protons similar to that with **6c** (Table 1). The minor adduct **6e** showed singlet methine proton signals at δ 5.61 and 6.80 ppm indicating that the vinyl proton is located on C-5 and consequently the phenyl group is attached to C-6. The 1:2 adduct is tentatively assigned as **11** on the basis of the elemental analysis and spectroscopic data. The NMR spectrum shows the chemical shifts of two methoxyl groups at δ 3.86 (s) and 3.53 (s) and those of methine protons at δ 6.50 (d), 5.38 (d), and 5.27 (s) and a singlet signal of phenyl protons at δ 7.23 except for a multiplet of aromatic protons. The value of the coupling constant, J=2.4 Hz, for the two doublet methine protons indicates that the two vicinal protons are in a trans configuration.[7] The precise configuration of the 1:2 adduct has however not been determined.



11

Methyl phenylpropiolate gave a small amount (6%) of an adduct (**6f**) and isochromandione (**10**, 58%) in

Table 1. Yields and ^{1}H-NMR data of 1,3-dipolar cycloadducts (**6**)

Adduct	R_1	R_2	Yield/%	NMR (δ/ppm, in $CDCl_3$)					
				OCH_3	OCH_3	H_a	H_b(=R_2)	H_c(=R_1)	J_{ab}/Hz
6a	PhCO	PhCO	66	3.73	—	5.75 (s)	—	—	—
6b	$COOCH_3$	$COOCH_3$	73	3.83	3.67	5.46 (s)	—	—	—
6c	$COOCH_3$	H	44	3.70	3.53	5.16 (d)	7.21 (d)	—	2.8
6d	Ph	H	9(45)[a]	3.49	—	5.21 (d)	6.68 (d)	—	2.6

6g	Ph	$COOCH_3$	0(9)[a]	3.72	3.40	5.48 (s)	—	—	—
6h[b]	COOH	Ph		3.74[c]	—	5.67 (s)[c]	—	—	—

a) Neat dipolarophile was used as the solvent instead of benzene. b) **6h** was obtained by the hydrolysis of **6f**.
c) The NMR spectrum was measured in $CDCl_3$–pyridine solution.

the reaction according to the general procedure (in benzene). When the decomposition was conducted in neat methyl phenylpropiolate (large excess), the yield of the adduct (**6f**) was improved (39%) and the yield of **10** decreased (7%). Moreover, another isomer (**6g**) was obtained in 9% yield. In the previously cited adducts (**6a**—**6g**), the chemical shifts of the bridgehead protons (H_a) are revealed to be affected by the substituents on C-6. The deshielding effect of the C-6 substituent on the chemical shift of H_a decreases in the following order, phenyl (**6e**, 5.61 ppm), methoxycarbonyl (**6b**, 5.46), hydrogen (**6c**, 5.16; **6d**, 5.12). The major adduct (**6f**) shows the chemical shift of H_a at 5.55 ppm which is closer to the value for **6e** than **6b**. The value of the minor adduct (**6g**) corresponds to that of **6b** (5.46 ppm) which has a methoxycarbonyl group on C-6 indicating that the methoxycarbonyl group is on C-6 in the minor adduct (**6g**). These assignments were confirmed by means of conversion of the major adduct (**6f**) into **6e** *via* hydrolysis followed by the decarboxylation.

The reactions when conducted in benzene solution as is shown in the general procedure, the yields of the adducts of these acetylenic dipolarophiles decrease in the order: dimethyl acetylenedicarboxylate>dibenzoylacetylene>methyl propiolate>methyl phenylpropiolate ≈phenylacetylene>diphenylacetylene (no reaction). The order of the reactivities of the dipolarophiles are consistent with their reactivities toward 3-methyl-2,4-diphenyloxazolium-5-olate having an azomethine ylide system.[8] The intermediate benzopyrylium-4-olate (**5**) reacts competitively with the dipolarophile or water (a contaminant in the reaction system) affording the adduct or isochromandione due to the low dipolarophilicity of methyl phenylpropiolate and phenylacetylene.

The preferential formation of the cycloadduct (**6c**) in the reaction of methyl propiolate is reasonably explained by the dipolar interaction between the dipole and the dipolarophile considering the dipolar structure, $H\overset{\delta+}{-}C\equiv\overset{\delta-}{C}-COOCH_3$, of methyl propiolate and a resonance formula **5b** for benzopyrylium-4-olate. The regioselectivity of the reaction of phenylacetylene and methyl phenylpropiolate with **5** is difficult to explain only on the basis of the dipolar interaction as cited above. 3-Phenylphthalazinium-1-olate, having an isoelectronic system with benzopyrylium-4-olate (**5**), has been reported to give two cycloadducts in the reaction with phenylacetylene.[9] The steric factor and π-π interaction[10] between the substituents of the dipole (**5**) and dipolarophiles may also effect the direction of cycloaddition.

Experimental

All melting points were taken with a Yanagimoto Melting Point Apparatus and are uncorrected. The IR spectra were measured on a Hitachi Infrared Spectrometer model EPI-S2. Unless otherwise indicated ^{1}H-NMR spectra were recorded in $CDCl_3$ solution at 60 MHz on a Varian Spectrometer model A-60 or EM-360 using tetramethylsilane as an internal standard.

Materials. *o*-Methoxycarbonyl-α-diazoacetophenone (**3**) was prepared by the method of Hudson;[11] mp 62.0—62.5 °C.

Dipolarophiles. Dibenzoylacetylene,[12] dimethyl acetylenedicarboxylate,[13] and methyl phenylpropiolate[14] were prepared by procedures described in the literature. Methyl propiolate, phenylacetylene, and diphenylacetylene were used after purification of commercial reagents by distillation or recrystallization.

General Procedure of the $Cu(acac)_2$ Catalyzed Decomposition of o-Methoxycarbonyl-α-diazoacetophenone (3) in the Presence of Acetylenic Dipolarophiles. To an absolute benzene solution (50 ml) containing a catalytic amount of $Cu(acac)_2$ and a 1.2—2.0 molar amount of the dipolarophile was added a benzene solution (20 ml) of the diazo ketone (**3**) with magnetic stirring at 80 °C. Almost quantitative amounts of nitrogen gas were evolved and the reaction mixture turned colorless. After heating for 2 h the benzene was removed under reduced pressure, and the residue fractionated by column chromatography (silica gel–benzene).

Decomposition of 3 in the Presence of Dibenzoylacetylene by General Procedure: In the reaction of **3** (2.0 g, 9.8 mmol) and dibenzoylacetylene (2.75 g, 12 mmol) two products were obtained.

Cycloadduct (6a): Colorless crystals; yield 2.65 g (66%); mp 146—148 °C; IR (KBr) 1710, 1660 (C=O), 1630 cm^{-1} (C=C). Found: C, 75.90; H, 4.28%. Calcd for $C_{26}H_{18}O_5$: C, 76.09; H, 4.42%.

Spiro Pyrazole (9a): Pale yellow crystals; yield 0.38 g (10%); mp 234—235 °C; IR (KBr) 1748, 1680 (C=O), 1650 cm^{-1} (C=C). Found: C, 73.56; H, 3.48; N, 6.89%. Calcd for $C_{25}H_{14}O_4N_2$: C, 73.88; H, 3.47; N, 6.90%.

Reaction of 3 with Dibenzoylacetylene at High Temperature Without Catalyst: A xylene solution of **3** (0.21 g, 1 mmol) and dibenzoylacetylene (0.24 g, 1 mmol) was heated at 120 °C for 7 h. Evaporation of xylene under reduced pressure and recrystallization gave **9a** in 95% yield.

Reaction of 3 with Dibenzoylacetylene at Low Temperature Without Catalyst: A benzene solution of **3** (0.21 g, 1 mmol) and dibenzoylacetylene (0.24 g, 1 mmol) was heated at 60 °C for 6 h. Two careful recrystallizations of the product from a mixture of benzene–heptane below 60 °C gave colorless crystals (**8a**); yield 0.328 g (81%); mp 67.5—68.5 °C; IR (KBr) 3270 (NH), 1710 (ester C=O), 1660 cm^{-1} (C=O); NMR (in $CDCl_3$) δ 3.73 (s, 3H, OCH_3), 7.3—7.7 (m, 14H, aromatic), and 12.2 ppm (broad s, 1H, NH). Found: C, 71.11; H, 4.16; N, 6.63%. Calcd for $C_{26}H_{18}O_5N_2$: C, 71.22; H, 4.14; N, 6.39%.

Thermal Decomposition of 8a: Treatment of **8a** (0.086 g, 0.2 mmol) at 110 °C for 5 h yielded spiro pyrazole (**9a**) in quantitative yield after the evaporation of the solvent under reduced pressure.

Reaction of 2-Diazo-1,3-indandione with Dibenzoylacetylene: A mixed solution of 2-diazo-1,3-indandione (0.344 g, 2 mmol) and dibenzoylacetylene (0.468 g, 2 mmol) in xylene was heated at 140 °C for 5 h. Evaporation of the solvent gave a pale yellow crystalline product in quantitative yield. The IR spectrum of the product was identical to that of **9a** obtained in the reaction of **3** and dibenzoylacetylene.

Decomposition of 3 in the Presence of Dimethyl Acetylenedicarboxylate by General Procedure: The reaction of **3** (2.0 g, 9.8 mmol) and dimethyl acetylenedicarboxylate (1.7 g, 12 mmol) gave two products.

Cycloadduct (6b): Yield 2.0 g (73%); mp 79—80 °C; IR (KBr) 1720 (broad, ester and ring C=O), 1650 cm^{-1} (C=C). Found: C, 60.24; H, 4.34%. Calcd for $C_{16}H_{14}O_7$: C, 60.38; H, 4.43%.

Spiro Pyrazole (9b): Yield 0.12 g (4%); mp 187.5—188.5 °C; IR (KBr) 1745 (broad, ester and indandione C=O), 1675 cm^{-1} (C=C); NMR (in $CDCl_3$) δ 4.05 (s, 3H, OCH_3), 4.09 (s, 3H, OCH_3), 7.1—8.2 ppm (m, 4H, aromatic). Found:

C, 57.13; H, 3.40; N, 8.87%. Calcd for $C_{15}H_{10}O_6N_2$: C, 57.33; H, 3.21; N, 8.92%.

Reaction of 2-Diazo-1,3-indandione with Dimethyl Acetylenedicarboxylate: A xylene solution of 2-diazo-1,3-indandione (0.344 g, 2 mmol) and dimethyl acetylenedicarboxylate (0.31 g, 2.2 mmol) was heated at 140 °C for 6 h. Evaporation of the solvent under reduced pressure gave a crystalline product (0.540 g, 85%) which showed no mixed melting point depression with **9b** obtained in the reaction of **3** and dimethyl acetylenedicarboxylate.

*Decomposition of **3** in the Presence of Methyl Propiolate by General Procedure*: Reaction of **3** (0.284 g, 1.4 mmol) and methyl propiolate (0.22 g, 2.5 mmol) gave an adduct (**6c**); yield 0.160 g (44%); mp 87—88 °C; IR (KBr) 1710 (C=O), 1630 cm^{-1} (C=C). Found: C, 64.57; H, 4.63%. Calcd for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65%.

*Decomposition of **3** in the Presence of Phenylacetylene by General Procedure*: Reaction of **3** (0.61 g, 3 mmol) and phenylacetylene (0.61 g, 6 mmol) gave cycloadduct (**6d**) together with isochroman-1,4-dione (**10**, 0.10 g, 20%) and unidentified intractable products.

*Cycloadduct (**6d**)*: Yield 0.070 g (9%); colorless oil; IR (liquid film) 1705 cm^{-1} (C=O). Found: C, 77.53; H, 5.24%. Calcd for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07%. Isochromandione (**10**) was characterized by comparison of the IR spectrum with that of an authentic sample.[3)]

*The $Cu(acac)_2$ Catalyzed Decomposition of **3** in Neat Phenylacetylene (Large Excess)*: The diazo ketone **3** (0.408 g, 2 mmol) was decomposed at 80 °C in a large excess of phenylacetylene (5 g, 50 mmol) and a catalytic amount of $Cu(acac)_2$. Column chromatography of the reaction mixture gave another cycloadduct (**6e**) and a 1:2 adduct (**11**) together with **6d** (45%) and **10** (8%).

*Cycloadduct (**6e**)*: Yield 0.070 g (13%); colorless oil; IR (liquid film) 1705 cm^{-1} (C=O). Although the elemental analysis of **6e** did not show a satisfactory result, the structure was confirmed by the similarity of the IR spectrum with that of an isomeric cycloadduct (**6d**). The NMR spectrum also supported the structure.

*1:2 Adduct (**11**)*: Yield 0.045 g (10%); mp 244—246 °C; IR (KBr) 1710 cm^{-1} (C=O); NMR (in $CDCl_3$) δ 3.53 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), 5.27 (s, 1H, methine), 5.38 (d, J=2.4 Hz, 1H, methine), 6.50 (d, J=2.4 Hz, 1H, methine), 7.23 (s, 5H, Ph) and 7.0—8.0 ppm (m, 8H, aromatic). Found: C, 74.19; H, 4.92%. Calcd for $C_{28}H_{22}O_6$: C, 74.00; H, 4.88%.

*Decomposition of **3** in the Presence of Methyl Phenylpropiolate by General Procedure*: Two products were obtained in the reaction of **3** (0.61 g, 3 mmol) and methyl phenylpropiolate (0.64 g, 4 mmol). The main product was confirmed to be isochromandione (**10**, 0.28 g, 58%).

*Cycloadduct (**6f**)*: Yield 0.097 g (9%); mp 112—113 °C; IR (KBr) 1710 (C=O), 1640 cm^{-1} (C=C). Found: C, 71.37; H, 4.79%. Calcd for $C_{20}H_{16}O_5$: C, 71.42; H, 4.80%.

*The $Cu(acac)_2$ Catalyzed Decomposition of **3** in Neat Methyl Phenylpropiolate (Large Excess)*: The diazo ketone (**3**) (0.408 g, 2 mmol) was decomposed in neat methyl phenylpropiolate (1.28 g, 8 mmol) in the presence of a catalytic amount of $Cu(acac)_2$ at 80 °C. Column chromatography of the reaction mixture isolated three products, isochromandione (**10**, 0.022 g, 7%), the cycloadduct (**6f**, 0.261 g, 39%), and an isomeric cycloadduct (**6g**): yield 0.058 g (9%); colorless crystals; mp 124—127 °C; IR (KBr) 1710 (C=O), 1640 cm^{-1} (C=C). Elemental analysis of **6g** did not show a satisfactory result.

*Hydrolysis of **6f***: The cycloadduct **6f** (0.103 g, 0.3 mmol) was hydrolyzed in EtOH (2 ml) and 40% aqueous NaOH solution (2 ml) at room temperature with vigorous stirring for 5 h. Acidification of the reaction mixture with 3 M HCl after evaporation of EtOH gave colorless crystals (**6h**): yield 0.090 g, (93%); mp 260—262 °C (from EtOH–H_2O); IR (KBr) 3450, 3000, 2500, 1690, 930 (COOH), 1710 (C=O), 1640 cm^{-1} (C=C). Found: C, 70.55; H, 4.32%. Calcd for $C_{19}H_{14}O_5$: C, 70.80; H, 4.38%.

*Decarboxylation of **6h***: A quinoline solution (10 ml) of **6h** (0.040 g, 0.12 mmol) was heated at 200—210 °C for 5 h with a suspension of copper powder (0.10 g). After cooling the reaction mixture was poured into water (50 ml) and acidified with 3 M HCl in order to dissolve the quinoline. Column chromatography of the ether extract gave 0.010 g (27%) of **6d**, which was identified on the basis of the IR and NMR spectra.

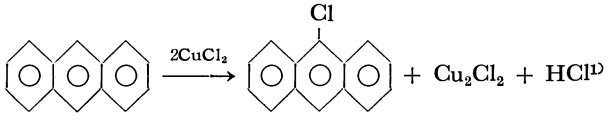
(Received April 6, 1979)

Anthracene is selectively chlorinated with solid copper(II) chloride to give a quantitative yield of 9-chloroanthracene. The tentative reaction mechanisms so far proposed fail to explain the nonreactivity of some other hydrocarbon homologues, *e.g.* naphthalene and phenanthrene, toward copper(II) chloride. The present study revealed that the oxidative half-wave potentials ($E_{1/2ox}$) of all reactive hydrocarbon homologues were less than 1.26 V. On the basis of this finding we postulate a reaction mechanism involving one electron transfer from hydrocarbon to copper(II) chloride.

Solid copper(II) chloride has been used to regio- and chemospecific synthesis of 9-chloroanthracene from anthracene. This binary phase chlorination which is performed under heterogeneous conditions gives a high yield of the regiospecific product:



While solid copper(II) chloride is effective also for chlorination of pyrene,[2] the reagent was found to be entirely nonreactive toward some of other homologous hydrocarbons, *e.g.* naphthalene and phenanthrene. Furthermore, a solution of copper(II) chloride in acetone or in acetonitrile failed to react with those hydrocarbons which react under the binary phase conditions. Such an outstanding contrast has not been fully explained by tentatively proposed mechanisms, *e.g.* ionic[3] or ligand transfer[4] mechanisms.

The present work deals with the binary phase chlorination of a wide variety of aromatic hydrocarbons by solid copper(II) chloride. The results evidently showed that their reactivities were closely related with their oxidative half-wave potentials ($E_{1/2ox}$), but for some substituted anthracenes steric effects were a dominant factor controlling the reactivity.

Results and Discussion

Reactivities of Aromatic Hydrocarbons toward Solid Copper(II) Chloride. In a typical procedure, aromatic hydrocarbon (5×10^{-4} mol) was refluxed with pulverized copper(II) chloride (1×10^{-3} mol) in chlorobenzene. The reaction proceeds under heterogeneous binary phase conditions. The chlorination was followed by means of gas chromatograph and the products were identified by elemental analysis, MS and NMR. The chlorination products obtained are summarized in Table 1. In general, single product was obtained in a high yield under the conditions. Active and inactive hydrocarbons toward solid copper(II) chloride are tabulated in Table 2 together with their $E_{1/2ox}$ values.

Voltammetric Measurement of $E_{1/2ox}$ of Aromatic Hydrocarbons. To investigate a correlation between $E_{1/2ox}$ and the reactivity of hydrocarbons toward solid copper(II) chloride, $E_{1/2ox}$ measurements of aromatic hydrocarbons were carried out in an acetonitrile solution containing tetraethylammonium perchlorate (TEAP), using a rotatory platinum disk electrode (2000 rpm). The voltage sweep rate was 0.2 V/min. The data are summarized in Table 2. The correlation between $E_{1/2ox}$ and the reactivity of an aromatic hydrocarbon for solid copper(II) chloride, if any, is not immediately clear, but it should be emphasized that of the aromatic hydrocarbons examined only those with $E_{1/2ox}$ below *ca.* 1.26 V were reactive toward solid copper(II) chloride. $E_{1/2ox}$ correlates linearly with the ionization potential (IP) of aromatic hydrocarbons as proposed by Pysh and co-workers,[5] and $E_{1/2ox}$ value of 1.26 V corresponds to 7.68 eV of IP value, which is in a close agreement with that obtained by photoelectroscopy (*ca.* 7.5 eV).[6] This fact suggests that initial one electron transfer from aromatic π-system to solid copper(II) chloride is a key step required for the initiation of the reaction. The electron transfer may trigger off the reaction. The oxidation potential is obviously lowered by the introduction of electron-donating methyl group to aromatic ring.

It is known that anhydrous solid copper(II) chloride is in covalent state and consists of planar $CuCl_4$ groups.[7] In the binary phase chlorination performed in a non-

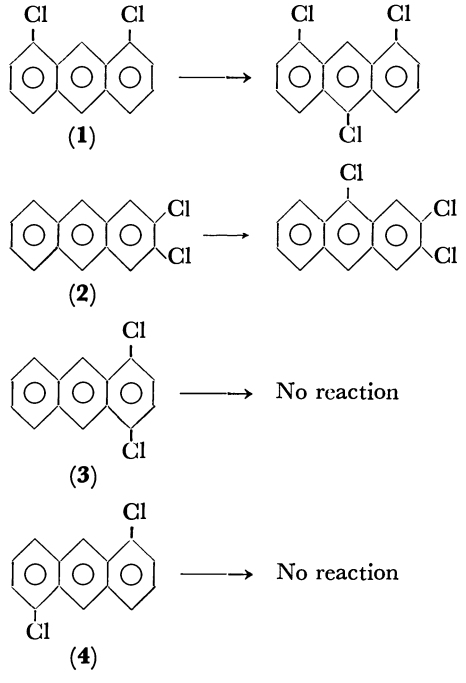
a) Solvent: acetonitrile. Supporting electrolyte : 0.1 M tetraethylammoniumperchlorate. Working electrode: rotatory platinum disk electrode (2000 rpm). Voltage sweep rate: 0.2 V/min.

polar solvent, the planar chloro ligands of anhydrous copper(II) chloride presumably occupies a favorable position for one electron transfer from hydrocarbons to copper(II) clusters. The plane of aromatic ring could approach to solid copper(II) chloride in the fashion parallel with the $CuCl_4$ surface, and the electron transfer from the approaching hydrocarbon could occur at a critical distance where the aromatic ring plane would come in a close contact with the acceptor orbital of copper(II) chloride. Although $E_{1/2ox}$ of 7- and 12-methylbenz[*a*]anthracene were 1.26 and 1.22 V (*vs.* SCE), respectively, they were hardly reactive toward solid copper(II) chloride. Presumably, steric repulsion due to rotating methyl group could prevent the molecule from closely approaching to copper(II) chloride surface in the transition state.

Competitive halogenation of anthracene gives us a further insight of the reacting aspect. Halogenation of anthracene (3.8×10^{-4} mol) by solid copper(II) bromide (7.6×10^{-4} mol) in the presence of tetraethylammonium chloride (3.8×10^{-4} mol) dissolved in chlorobenzene (30 ml) afforded 9-bromoanthracene nearly as a sole product, whereas the halogenation using an equimolar mixture of solid copper(II) chloride and bromide gave a higher yield of 9-chloroanthracene than 9-bromoanthracene (11: 1). These facts will readily suggest that the binary phase halogenation proceeds in a closely contacted state of reacting substrate with the surface of solid copper(II) halide.

Chlorination of substituted anthracenes with methyl or chloro groups by solid copper(II) chloride in chlorobenzene resulted in the formation of chlorinated products. The yields and structures of the products together with their ^{1}H-NMR data are summarized in Table 3 and 4.

From the results of chlorination of substituted anthracenes it is concluded that the rate of chlorination is enhanced by methyl substituent, but in contrary, chloro substituent retarded it. Since the electron-donating substituents lower the oxidation potential of aromatic hydrocarbons, the observation supports the view mentioned above that the reaction is initiated by an electron transfer. In addition, steric effect of the substituents controlls the product. Though the monochlorination of substituted anthracenes occurs at 9- or 10-position, less hindered position is more favorable for the chlorination; *e.g.* 1-methyl or 1-chloroanthracene was chlorinated at 10-position. Chlorination of dichloroanthracenes provides a good example to show both steric and electronic effects are operating together. Since $E_{1/2ox}$ values of 1,8- (1.48 V) (**1**), 2,3- (1.40 V)



(**2**), 1,4- (1.48 V) (**3**), and 1,5-dichloroanthracene (1.40 V) (**4**) were comparable, they are expected to be similarly reactive toward solid copper(II) chloride. However, **1** and **2** were reactive, but **3** and **4** were not. These results clearly indicates that chlorine atom occupying peri position against 9- or 10-position of anthracene affects a strong steric inhibition on the chlorination.

Hydrogen Abstraction by Solid Copper(II) Chloride. Diphenylmethane, xanthene, tetrahydronaphthalene, and cumene were recovered after refluxing for 14 h with solid copper(II) chloride in cyclohexane, whereas anthracene was chlorinated under the same reaction conditions (Table 5). It is noteworthy that under the present reaction conditions no hydrogen abstraction occurred with those hydrocarbons which allow, in general, an easy hydrogen abstraction by a radical,

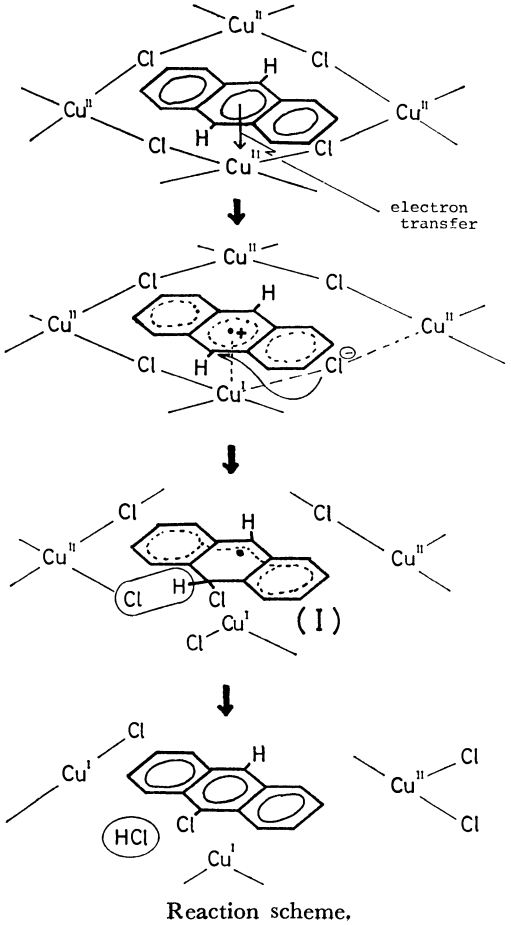
Reaction time: a) 10 min, b) 14 h. Product: c) naphthalene (yield 90%), d) anthracene (yield 65%). Solvent: cyclohexane 10 ml; reaction temp: 80 °C; compound: 2.5×10^{-3} mol; $CuCl_2$: 5×10^{-3} mol.

although 1,2-dihydronaphthalene or 9,10-dihydroanthracene reacted under the same conditions, yielding naphthalene or anthracene together with evolution of hydrogen chloride.

Reaction Scheme. As has been shown above, hydrocarbons with IP value lower than *ca.* 7.5 eV were reactive for solid copper(II) chloride chlorination. 7- and 12-Methylbenz[*a*]anthracene, both nonreactive, may be the borderline case, where spatial repulsive effect due to the methyl group presumably inhibits the initial electron transfer from the hydrocarbons to copper(II) chloride. The electron transfer will trigger the chlorination. This is strongly supported by the above-mentioned electronic effect of methyl and chloro substituents. Once an electron is transferred to copper(II) chloride from a hydrocarbon, the resulting cation radical of the aromatic hydrocarbon could be immediately attacked by chloride anion at the less hindered, but the highest positively charged position to give (I). Although copper(II) chloride is a typical ligand-transfer oxidation reagent toward a radical, under the present reaction conditions the reagent may abstract a hydrogen atom from the radical (I) and convert it into the stable chlorinated aromatic molecule (see Reaction scheme).



Reaction scheme.

Experimental

Melting points were measured on a micro hot-stage manufactured by Mitamura Riken Kogyo Inc. and were uncorrected. ^{1}H-NMR spectra were recorded on a JEOL MH-100 spectrometer with Me_4Si as an internal standard. GLC analyses were carried out on a JEOL Model JGC-1100 using a 1 m column packed with Apiezone L grease 3 wt % on Celite 545 NAW. HPLC analyses were performed on a Shimadzu liquid chromatograph Model LC-2F equipped with a Shimadzu-Du Pont Permaphase ODS column. Voltammetry was carried out in an acetonitrile solution on a Yanagimoto Model P-8 polarograph. The working electrode was a rotatory platinum disk electrode (2000 rpm). An aqueous saturated calomel electrode (SCE) and a platinum electrode were used as a reference and a counter electrode, respectively. Voltage sweep rate was 0.2 V/min. Tetraethylammonium perchlorate (Eastman) was used as supporting electrolyte (0.1 M).

Materials. Anhydrous copper(II) chloride was prepared by heating copper(II) chloride dihydrate in an oven at 110 °C for 20 h. 1,2-Dihydronaphthalene (Aldrich) was used without further purification.

The following substrates were prepared according to the procedure described in literature.

1-Methylanthracene:[8)] Mp 85 °C (lit, mp 86 °C); NMR (CCl_4) δ=2.80 (3H, s, 1-Me), 7.20—7.50 (2-, 3-, 6-, and 7-H, m), 7.6—8.1 (4-, 5-, and 8-H, m), 8.28 (10-H, s) and 8.39 (9-H, s).

1,4-Dimethylanthracene:[8)] Mp 73—74 °C (lit, mp 74 °C); NMR (CCl_4) δ=2.79 (6H, s, 1- and 4-Me), 7.03 (2- and 3-H, s), 7.30 (6- and 7-H, dd, J=8 and 2 Hz), 7.85 (5- and 8-H, dd, J=8 and 2 Hz) and 8.34 (9- and 10-H, s).

1-Chloroanthracene:[9)] Mp 84—85 °C (lit, mp 81—82 °C); NMR (CCl_4) δ=7.18—7.58 (2-, 3-, 6-, and 7-H, m), 7.76—8.12 (4-, 5-, and 8-H, m), 8.32 (10-H, s) and 8.77 (9-H, s).

2-Chloroanthracene:[9)] Mp 223 °C (lit, mp[10)] 223 °C); NMR (CCl_4) δ=7.28—7.60 (3-, 6-, and 7-H, m), 7.80—8.05 (1-, 4-, 5-, and 8-H, m), 8.28 (9-H, s) and 8.36 (10-H, s).

1,4-Dichloroanthracene:[11)] Mp 179—181 °C (lit, mp 180 °C); NMR (CCl_4) δ=7.44 (2- and 3-H, s), 7.50 (6- and 7-H, dd, J=8 and 2 Hz), 8.04 (5- and 8-H, dd, J=8 and 2 Hz) and 8.81 (9- and 10-H, s).

1,5-Dichloroanthracene:[9)] Mp 181—182 °C (lit, mp 185 °C); NMR (CCl_4) δ=7.32 (3- and 7-H, t, J=8 Hz), 7.55 (2- and 6-H, d, J=8 Hz), 7.93 (4- and 8-H, d, J=8 Hz) and 8.76 (9- and 10-H, s).

1,8-Dichloroanthracene:[9)] Mp 151—153 °C (lit, mp 156 °C); NMR (CCl_4) δ=7.35 (3- and 6-H, t, J=8 Hz), 7.59 (2- and 7-H, d, J=8 Hz), 7.87 (4- and 5-H, d, J=8 Hz), 8.38 (10-H, s) and 9.24 (9-H, s).

2,3-Dichloroanthracene:[11)] Mp 265—265.5 °C (lit, mp 261 °C); NMR (CCl_4) δ=7.3—7.58 (6- and 7-H, m), 7.94 (5- and 8-H, dd, J=8 and 2 Hz), 8.06 (1- and 4-H, s) and 8.25 (9- and 10-H, s).

7-Methylbenz[a]*anthracene*:[12)] Mp 138.5—139.5 °C (lit, mp[13)]

140.5—141.5 °C).

12-Methylbenz[a]*anthracene*:[12] Mp 136—137 °C (lit, mp 138—139 °C).

1,5-Dimethyl- (5) and 1,4,5-Trimethylanthracene (6): Synthesis of **6** was performed as follows. 3,6-Dimethylphthalic anhydride (**7**) was obtained from maleic anhydride and 2,5-dimethylfuran.[14] The reaction of **7** and 2-methylphenylmagnesium bromide afforded 2-(2-methylbenzoyl)-3,6-dimethylbenzoic acid (**8**) by a similar procedure described for 2-benzoyl-3-methylbenzoic acid.[15] By the heating of **8** and concentrated sulfuric acid for 1.5 h in a steam bath, 1,4,5-trimethylanthraquinone (**9**) (mp 142—147 °C, lit, mp[16] 143 °C) was obtained. The reduction of **9** by zinc dust and aqueous ammonia afforded **6**. 1,5-Dimethylanthracene was prepared by a similar method. **5**: mp 139—140 °C (lit, mp[17] 139—140 °C); NMR (CCl_4) δ=2.84 (6H, s, 2Me), 7.12—7.30 (2-, 3-, 6-, and 7-H, m), 7.78 (4- and 8-H, dd, J=8 and 2 Hz) and 8.38 (9- and 10-H, s). **6**: mp 107.5—108.5 °C; NMR (CCl_4) δ=2.82 (6H, s, 2Me), 2.85 (3H, s, 1Me), 7.07 (2- and 3-H, s), 7.18—7.32 (6- and 7-H, m), 7.76 (8-H, dd, J=8 and 2 Hz), 8.37 (9-H, s) and 8.46 (10-H, s). Found: C, 92.83; H, 7.38%; M$^+$, 220. Calcd for $C_{17}H_{16}$: C, 92.68; H, 7.32%; M 220.

General Reaction Procedures. Anhydrous copper(II) chloride (2.2 or 4.4 mmol) and aromatic hydrocarbons (1 mmol) was refluxed with stirring in 10 ml of chlorobenzene for appropriate reaction time. The reaction was stopped when the yield of product, which was followed by GLC, reached to a maximum. The reaction of azulene was followed by HPLC, in which methanol–water was used as the eluent at a rate of 1 ml/min. After usual work-up the crude product was dissolved in benzene and eluted by petroleum ether on a Florisil column.

Identification of Products. *9-Chloroanthracene*: Mp 103 °C (lit, mp[18] 105.2—107 °C); NMR (CCl_4) δ=7.3—7.6(2-, 3-, 6-, and 7-H, m), 7.87 (4- and 5-H, dd, J=8 and 2 Hz), 8.24 (10-H, s) and 8.38 (1- and 8-H, dd, J=8 and 2 Hz). (Found: C, 79.20; H, 4.32%).

9,10-Dichloroanthracene: Mp 210 °C (lit, mp[19] 209 °C) NMR (CCl_4) δ=7.5 (2-, 3-, 6-, and 7-H, dd, J=8 and 2 Hz) and 8.41 (1-, 4-, 5-, and 8-H, dd, J=8 and 2 Hz). (Found: C, 67.88; H, 3.11%).

1-Chloropyrene: Mp 116—118 °C (lit, mp[20] 119 °C). (Found: C, 80.71; H, 3.69%; M$^+$ 236).

6-Chlorobenz[a]*pyrene*: Mp 212 °C (lit, mp[21] 210 °C). (Found: C, 83.17; H, 3.71%; M$^+$ 286).

Chloroperylene: Mp 243—246 °C. (Found: C, 80.96; H, 3.65%. Calcd for $C_{20}H_{11}Cl$: C, 83.77; H, 3.87%).

Dichloroperylene: Mp 222—226 °C.[22] (Found: C, 73.97; H, 3.04%. Calcd for $C_{20}H_{10}Cl_2$: C, 74.74; H, 3.14%).

5,11-Dichloronaphthacene: Mp 227—228 °C (lit, mp[23] 220 °C); NMR ($CDCl_3$) δ=7.4—7.7 (2-, 3-, 8- and 9-H, m), 8.10 (1- and 7-H, d, J=8 Hz), 8.50 (4- and 10-H, d, J=8 Hz) and 9.12 (6- and 12-H, s). (Found: C, 72.70; H, 3.25%).

1,3-Dichloroazulene: Mp 93—94 °C; NMR (CCl_4) δ=7.13 (5- and 7-H, t, J=10 Hz). Found: C, 61.02; H, 2.95%; M$^+$, 197. Calcd for $C_{10}H_6Cl_2$: C, 60.95; H, 3.07%; M, 197.

1,10-Dichloroanthracene: Mp 126—127 °C (lit, mp[24] 127—128 °C has been reported as the mp of 1,9- or 1,10-dichloroanthracene); NMR (CCl_4) δ=7.32—7.68 (2-, 3-, 6-, and 7-H, m), 8.02 (8-H, dd, J=8 and 2 Hz), 8.42 (4- and 5-H, dd, J=8 and 2 Hz) and 8.76 (9-H, s). Found: C, 68.20; H, 3.29%; M$^+$, 246. Calcd for $C_{14}H_8Cl_2$: C, 68.04; H, 3.26%; M, 246.

2,10-Dichloroanthracene: Mp 115—116 °C; NMR (CCl_4) δ=7.3—7.7 (3-, 6- and 7-H, m), 7.78—7.96 (1- and 8-H, m), 8.22 (9-H, s), 8.3—8.5 (4- and 5-H, m). Close examination of NMR data showed that the sharp peak due to 1-H at δ=*ca.* 8.5 was characteristic of 2,9-dichloro substituted anthracenes. Accordingly, the lack of this peak necessarily indicates that the present product is 2,10-dichloroanthracene. Found: C, 68.24; H, 3.33%; M$^+$, 246. Calcd for $C_{14}H_8Cl_2$: C, 68.04; H, 3.26%; M, 246.

2,9,10-Trichloroanthracene: Mp 181—182 °C (lit, mp[24] 178 °C); NMR (CCl_4) δ=7.5—7.7 (3-, 6-, and 7-H, m), 8.4—8.55 (4-, 5-, and 8-H, m) and 8.48 (1-H, s).

1,8,10-Trichloroanthracene: Mp 191—192 °C (lit, mp[25] 194 °C); NMR (CCl_4) δ=7.4—7.7 (2-, 3-, 6-, and 7-H, m), 8.40 (4- and 5-H, d, J=8 Hz) and 9.24 (9-H, s).

2,3,9-Trichloroanthracene: Mp 172—173 °C; NMR (CCl_4) δ=7.4—7.7 (6- and 7-H, m), 7.86 (5-H, dd, J=8 and 2 Hz), 7.95 (4-H, s), 8.08 (10-H, s), 8.36 (8-H, dd, J=8 and 2 Hz) and 8.48 (1-H, s). Found: C, 59.84; H, 2.52%; M$^+$, 281. Calcd for $C_{14}H_7Cl_3$: C, 59.72; H, 2.51%; M, 281.

9-Chloro-10-methylanthracene: Mp 177—178 °C; NMR (CCl_4) δ=3.06 (3H, s, 10-Me), 7.3—7.6 (2-, 3-, 6-, and 7-H, m), 8.15 (4- and 5-H, dd, J=8 and 2 Hz) and 8.42 (1- and 8-H, dd, J=8 and 2 Hz). Found: C, 79.20; H, 5.12%; M$^+$, 226. Calcd for $C_{15}H_{11}Cl$: C, 79.47; H, 4.89%; M, 226.

9-Chloro-4-methylanthracene: Mp 66—68 °C; NMR (CCl_4 δ=2.81 (3H, s, 4-Me), 7.15—7.60 (2-, 3-, 6-, and 7-H, m), 7.96 (5-H, dd, J=8 and 2 Hz), 8.32 and 8.50 (1- and 8-H, dd, J=8 and 2 Hz) and 8.46 (10-H, s). Found: C, 79.25; H, 5.08%; M$^+$, 226. Calcd for $C_{15}H_{11}Cl$: C, 79.47; H, 4.89%; M, 226.

9,10-Dichloro-1-methylanthracene: Mp 132—134 °C; NMR (CCl_4) δ=3.22 (3H, s, 1-Me), 7.2—7.64 (2-, 3-, 6-, and 7-H, m) and 8.3—8.6 (4-, 5-, and 8-H, m). Found: C, 69.89; H, 3.70%; M$^+$, 260. Calcd for $C_{15}H_{10}Cl_2$: C, 68.99; H, 3.86%; M, 260.

9-Chloro-1,4-dimethylanthracene: Mp 41.5—44.0 °C; NMR (CCl_4) δ=2.70 (3H, s, 4-Me), 3.14 (3H, s, 1-Me), 7.04 (2- and 3-H, s), 7.3—7.56 (6- and 7-H, m), 7.8 (5-H, dd, J=8 and 2 Hz), 8.26 (10-H, s) and 8.45 (8-H, d, J=8 Hz). Found: C, 79.45; H, 5.40%; M$^+$, 240. Calcd for $C_{16}H_{13}Cl$: C, 79.83; H, 5.44%; M, 240.

9-Chloro-1,5-dimethylanthracene: Mp 111—114 °C; NMR (CCl_4) δ=2.70 (3H, s, 5-Me), 3.14 (3H, s, 1-Me), 7.1—7.4 (2-, 3-, 6-, and 7-H, m), 7.5—7.7 (4-H, m), 8.18 (10-H, s) and 8.32 (8-H, d, J=8 Hz). Found: C, 80.12; H, 5.48%; M$^+$, 240. Calcd for $C_{16}H_{13}Cl$: C, 79.83; H, 5.44%; M, 240.

9,10-Dichloro-1,5-dimethylanthracene: Mp 154—156 °C; NMR (CCl_4) δ=3.14 (6H, s, 1- and 5-Me), 7.2—7.40 (2-, 3-, 6-, and 7-H, m) and 8.3—8.5 (4- and 8-H, m). Found: C, 70.18; H, 4.63%; M$^+$, 274. Calcd for $C_{16}H_{12}Cl_2$: C, 69.84; H, 4.40%; M, 274.

9-Chloro-1,4,5-trimethylanthracene: Mp 120—122 °C; NMR (CCl_4) δ=2.76 (3H, s, Me), 2.82 (3H, s, Me), 3.16 (3H, s, 1-Me), 7.1 (2- and 3-H, s), 7.1—7.5 (6- and 7-H, m), 8.4 (8-H, d, J=8 Hz) and 8.46 (10-H, s). Found: C, 80.40; H, 6.10%; M$^+$, 254. Calcd for $C_{17}H_{15}Cl$: C, 80.15; H, 5.94%; M, 254.

The present work was partially supported by a Research Grant from Kyoto Women's University.

Reaction of *N,N*-Dialkylanilines with Palladium(II) Compounds

Tsutomu SAKAKIBARA,* Yoko DOGOMORI, and Yuichiro TSUZUKI

Institute of Chemistry, College of Liberal Arts, Kagoshima University, Korimoto, Kagoshima 890

(Received April 20, 1979)

The reaction of *N,N*-dialkylaniline with palladium(II) acetate or di-μ-acetato-bis[α-(dimethylamino)-*o*-tolyl]-dipalladium (**B**) gave 4,4′-bis(dialkylamino)diphenylmethane as a major product. It was elucidated that the origin of $-CH_2-$ in the product might be methyl group of palladium acetate and the primary reaction product might be *N,N*-dialkyltoluidine. The absorption spectra of the initial reaction mixture of *N,N*-dimethylaniline with **B** in acetic acid at room temperature showed the absorption maximum at 470 nm and at 750 nm. The latter peak was tentatively assigned to *N,N*-dimethylaniline radical cation–palladium(I) acetate complex, which was suggested as a key-intermediate for the formation of diarylmethanes.

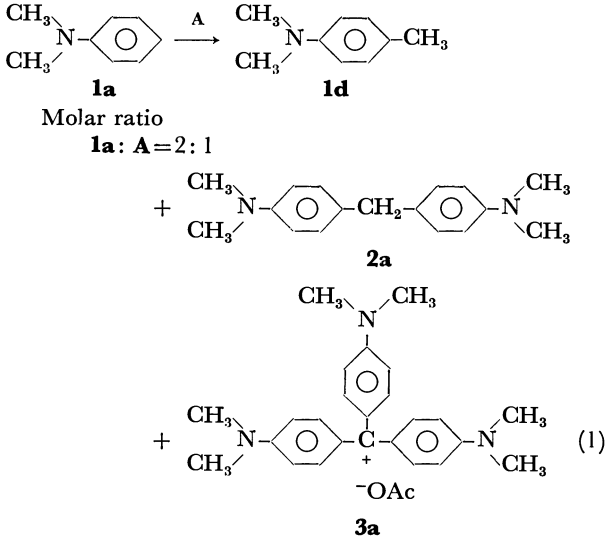
A large number of studies on the reactions of many aromatic compounds with palladium(II) salts have been actively done,[1] since van Helden and Verberg presented the oxidative coupling of aromatic rings with palladium(II) chloride.[2] In exploring the synthetic utility of palladium-assisted aromatic substitution, two types of investigation have been carried out. One is concerned with substitution of vinylic hydrogen by aryl groups,[3,4] and another is on the functionalization of aromatic rings by other nucleophiles.[5] In both studies, various monosubstituted aromatic compounds have been used as reactants. However, to our knowledge, no information on the reaction of aniline derivatives with palladium(II) salts have been presented so far.[6]

N,N-Dialkylanilines have relatively low ionization potential. For example, those of *N,N*-dimethylaniline and *N,N*-diethylaniline are 7.12 and 6.99 eV, respectively.[7] These values are much smaller than the ionization potentials of other aromatic compounds such as nitrobenzene (9.92 eV), methyl benzoate (9.35), benzene (9.24), chlorobenzene (9.07), toluene (8.82), anisole (8.21), and so on. Thus, we might expect some different reactivity of aniline derivatives for palladium(II) salts.

We have already communicated that *N,N*-dialkylanilines react with palladium(II) acetate to give diarylmethanes as a major product.[8] The reaction was quite different from generally known aromatic oxidative coupling or aromatic functionalization with palladium(II) salts. The reaction involves some novel reaction paths such as aromatic methylation and benzylic arylation.[9] Therefore, further investigation was carried out on the reactions of *N,N*-dimethylanilines with some palladium(II) compounds. In this report, the detailed information and the spectroscopic data will be presented and some reaction intermediates will be also suggested.

Results and Discussion

N,N-Dimethylaniline (**1a**) reacted with a half equimolecular palladium(II) acetate (**A**) in acetic acid at 80 °C to give *p*-toluidine (**1d**) (trace), 4,4′-bis(dimethylamino)diphenylmethane (**2a**) (72.1%), and Crystal Violet (**3a**) (16.8%). **A** was quantitatively reduced to metallic palladium and all of **1a** was consumed. However, no *N,N,N′,N′*-tetramethylbenzidine was detected on GLC of the organic product mixture. Although a mixture of **1a** (0.02 mol) and acetic acid (1.0 mol) was heated in the absence of **A** at 80 °C for 5 h under nitrogen atmosphere, none of **2a** was obtained and 96% of the used **1a** was recovered. The results of reactions of *N,N*-dialkylanilines with **A** are summarized in Table 1.



(1)

In acetonitrile or dioxane, the reaction of **1a** with **A** proceeded similarly to that in acetic acid to give diarylmethane (**2a**) as a major product. However, it can be seen in Table 1 that the reaction in aprotic solvent is relatively slower than in acetic acid. Furthermore, the yield of some by-products such as *N,N,N′,N′*-teramethylbenzidine (**6**) or dimethylaminobenzoic acid (**7**) somewhat increased in aprotic solvents (14.7% and 2.15%, respectively).

These results clearly show that formation of diarylmethane is the major path in the reaction of *N,N*-dialkylanilines with palladium(II) acetate (**A**), and that the charactor of solvents has some influence on the reaction sequences.

The conversion of **1a** to **2a** has been reported in the electrochemical oxidation at high concentration of **1a** in acetonitrile,[10] in which the origin of $-CH_2-$ in **2a** has been explained to be *N*-methyl group of **1a**, since the yields of **2a** never exceeded 50%.

In the present reaction, the yield of **2a** was usually higher than 50% (Table 1). Moreover, the reaction of **1b** with **A** gave **2b**, although in relatively low yield due to the accompanied dealkylation.[8] These facts suggest that the origin of $-CH_2-$ group in **2a** is not the

Table 1. The reaction of *N,N*-dialkylanilines with **A**

Reactant[a]	Sovlent	Reaction time/h	Conversion[b] of **1**/%	Products, (yield/%)[c]
1a	Acetic acid	5	100	**1d** (trace), **2a** (72.1), **3a** (16.3)

N-methyl group of the reactant (**1a**), but methyl group of palladium(II) acetate (**A**). As the formation of **1d** or **1e** was always observed in the reactions of **1a** or **1b**, the aromatic methylation by **A**, followed by further arylation of the product (**1d** or **1e**), might occur to give **2a** or **2b**. Thus, the reaction of a mixture of **1a** and **1d** with **A** was carried out, in order to know the possibility of the further arylation of **1d**. Namely, a 1 : 1 mixture of **1a** and **1d** in acetic acid was heated in the presence of **A** at 80 °C for 5 h, and the yields of produced diarylmethane (**2a**) were calculated according to both Eqs. 2 and 3 as in Table 2. The yields of **2a** were higher than quantitative yield based on Eq. 1, which meant that Eq. 2 is at least partly operative. Thus, **1d** should be one of reactants for the formation of **2a**.

(2)

(3)

Further supporting evidences for benzylic arylation are that the reaction of **1d** with **A** in acetic acid gave diarylmethane (**2d**), along with cyclic dimer (**4**) and that **1c** yielded **2c** together with **3c** (Table 1).

Consequently, it is likely that the first product in the reaction of *N,N*-dialkylaniline (**1a** or **1b**) with **A** should be *N,N*-dialkyltoluidine (**1d** or **1e**). **1d** or **1e** might be furthermore oxidized by **A** to give diarylmethane (**2a** or **2b**), followed by reoxidation into Crystal Violet (**3a** or **3b**). However, another problem remains since the stoichiometry of **1a** shows that a formation of 1 mol of **2a** from **1a** should result in a reduction of 1 mol of **A** to metallic palladium (Table 1). The successive oxidation mechanism might possibly consume 2 mol of **A** for a formation of 1 mol of **2a**.

Di-μ-acetato-bis[α-(dimethylamino)-o-tolyl]dipalladium (**B**) can also oxidize **1a** in acetic acid under mild conditions. Even at room temperature, **B** was gradually decomposed to give diarylmethane (**2a**). The results of reactions in various conditions at 80 °C are summarized in Table 3. It clearly elucidates that the

(4)

5

reaction of **1a** with **B** undergoes remarkably large effect of proton on the reaction rate. Namely, in aprotic solvents such as *N,N*-dimethylaniline, dioxane, or tetrahydrofuran the reaction never went on even at 96 °C. However, in the presence of proton, the oxida-

Table 2. Oxidation of mixed **1a** and **1d** with **A**

Reactants/mol[a)]	Yield of **2a**[b)]/%	
	Based on Eq. 2	Based on Eq. 3
1a (0.01), **1d** (0.01)	109.8	54.9
1a (0.02), **1d** (0.02)	99.3	49.4
1a (0.05), **1d** (0.05)	116.6	58.3

a) The reaction of the reactants with **A** (0.02 mol) in acetic acid (1.0 mol) was carried out at 80 °C under nitrogen atmosphere. b) The yields are based on the reacted **1a**.

tion completely proceeded to give **2a** in good yields. The poor yield of **3a** might possibly be expalined by steric hindrance in the contact between **2a** and palladium complex by benzylamine ligand. Therefore, the result suggests that the oxidation of **1a** with **B** may proceed *via* similar reaction sequences to the case of **A**.

The UV spectrum of **1a** in acetic acid shows a long-wavelength absorption maximum at 290 nm (ε 2.0×10^2), while palladium complex (**B**) has it at 330 nm (ε 1.0×10^3) (Fig. 1). These compounds have no absorption maximum in the longer wave region.

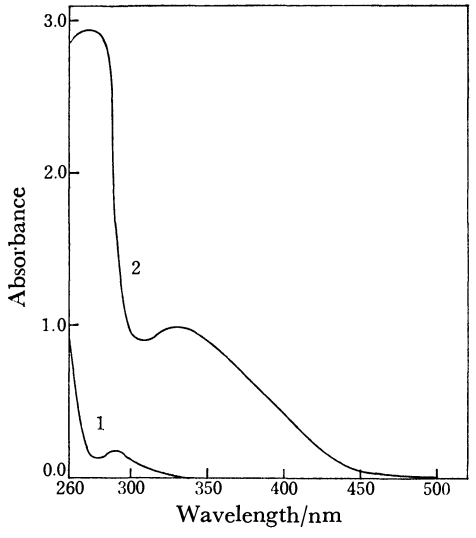

Fig. 1. Absorption spectra of **1a** (1) and **B** (2). The spectra were measured in 1.0×10^{-3} M acetic acid solution at room temperature. (1 M=1 mol dm^{-3}).

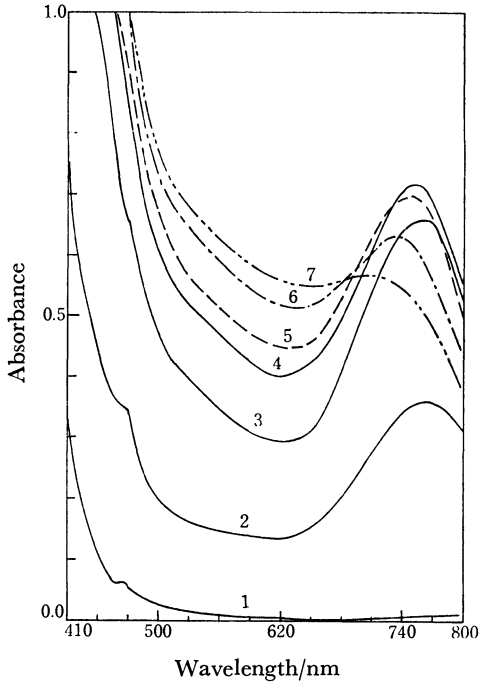

Fig. 2. Spectral change of reaction mixture of **1a** and **B** in acetic acid at room temperature under nitrogen atmosphere. Reaction time (min); 1: 0.5, 2: 10, 3: 30, 4: 50, 5: 60, 6: 80 7: 100.

However, when **B** and **1a** were mixed at room temperature (23 °C) in acetic acid under nitrogen atmosphere, a new absorption appeared at 470 nm, which could not be observed after about 50 min due to strong absorption enhancement in shorter wave region. Furthermore, another strong peak in a visible region appeared about 10 min after mixing. The visible spectra of a mixture of **1a** and **B** in acetic acid are shown in Fig. 2. The spectra indicate a clear appearance of new absorption maximum at 750 nm. Figure 3 shows the time dependent change of the 750 nm peak. The absorption had maximum in 48 min under measurement conditions and afterwards gradually decayed.

The peak at 470 nm appears immediately after mixing of **1a** and **B**, and its intensity looks relatively weak. Therefore, the formation rate of the intermediate related with 470 nm peak might be relatively rapid.

Table 3. The solvent effect on the reaction of **1a** with **B**[a)]

Solvents	Reaction temp/°C	Recovered **B**/%	Product yields/%		
			2a[a)]	**3a**[b)]	**5**[c)]
Acetic acid (1.0)	80	8	43	3	60

Dioxane (1.0)	80	100	0	0	0
Dioxane (1.0)	96	98	0	0	0

a) **B** (0.01 mol as the dimeric form) and **1a** (0.04 mol) were used, if not indicated in the table. b) Isolated yields based on the reacted **1a**. c) Yields based on the reacted **B**. They were determined by NMR analyses of reaction mixture. d) 5 ml of 12 M HCl was used.

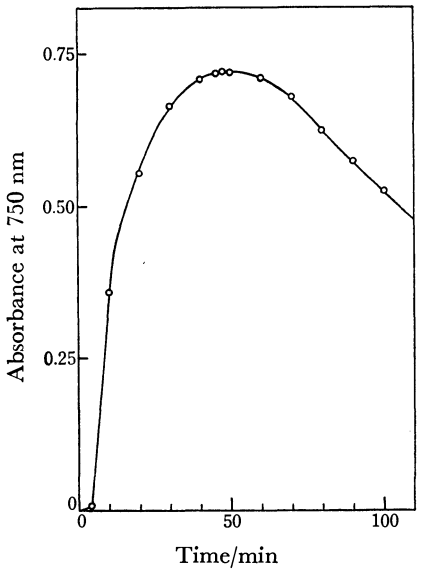

Fig. 3. Time dependence of the absorbance at 750 nm.

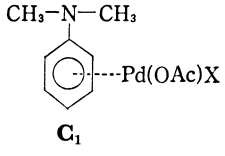
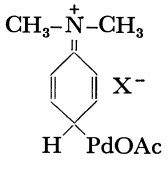
The well-known primary intermediates in the reaction of aromatic compounds with palladium(II) salt are π- or σ-complexes between aromatics and palladium, which are readily formed in a rapid process.[2] Thus, the origin of 470 nm peak might be tentatively assigned to the complex $\mathbf{C_1}$ or $\mathbf{C_2}$. However, another possibility can not be completely eliminated that the absorption at 470 nm[12] might be concerned with a radical cation intermediate, in relation to the assignment of 750 nm peak.



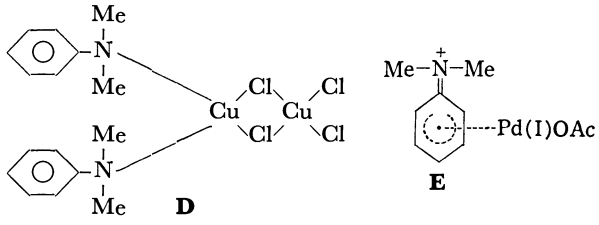
$\mathbf{C_1}$



$\mathbf{C_2}$

The second peak at 750 nm has appeared after some induction period and has some life time. It is noteworthy that the absorption was in a remarkably long wave region and the intensity was considerably strong. The analogous peak has also been observed in the reaction of **1a** under different conditions; first, electrochemical study of **1a** in acetic acid showed the absorption peaks at 469 nm and at 750 nm, which were assigned to oxidized *N,N,N′,N′*-tetramethylbenzidine (TMBOx) and 2:1 **1a**: TMBOx adduct, respectively.[15] Second, the oxidation of **1a** with copper(II) chloride in ethanol showed λ_{max} at 472 nm and 740 nm, in which the latter peak was assigned to the 1:1 **1a**: copper(II) chloride complex (**D**).[16]

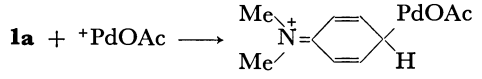
In the present reaction in acetic acid, *N,N,N′,N′*-tetramethylbenzidine (**6**) was never a product. It is also unlikely that a similar palladium(II) complex to **D** may have such a long-wavelength absorption. Therefore, we would suggest the formation of a radical cation–palladium(I) complex (**E**) and tentatively assign the peak at 750 nm to the complex (**E**).[17]



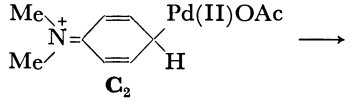
D **E**

The radical cation complex (**E**) could be formed *via* σ-complex ($\mathbf{C_2}$) because of a low ionization potential of *N,N*-dialkylaniline (Eqs. 5, 6, and 7).

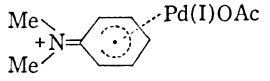
$$\underset{\textbf{A or B}}{\text{X–Pd–OAc}} + \text{H}^+ \longrightarrow {}^+\text{PdOAc} + \text{HX} \qquad (5)$$



(6)



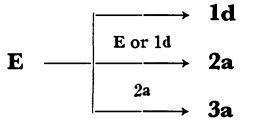
$\mathbf{C_2}$



(7)

E

In conclusion, the complex (**E**) is suggested to be a key-intermediate to the products (**1d**, **2a**, and **3a**).



Experimental

Materials. Palladium(II) acetate (**A**) and di-μ-acetato-bis[α-(dimethylamino)-*o*-tolyl]dipalladium (**B**) were prepared according to the methods of Stephenson *et al.*[18] and R. Heck *et al.*,[19] respectively. Commercially available *N,N*-dialkylanilines were used after distillation under a reduced pressure and drying on anhydrous sodium sulfate before use.

TABLE 4. ^{1}H NMR DATA OF ISOLATED PRODUCTS

Compound	τ-Value			
	N-CH_3 (or C_2H_5)	Other-CH_3	$-CH_2-$	Aroma-H
2a	7.06 (s, 12H)		6.11 (s, 2H)	2.94 (q, 8H)

a) Measured in $CDCl_3$ using TMS as internal standard.

Measurements. UV and visible spectra were measured by Shimadzu multipurpose MPS-50L spectrophotometer. IR and PMR measurements were carried out by JASCO IRA-I and JEOL JNM60 apparatus, respectively. The NMR data of obtained products are summarized in Table 4.

The spectral change of the reaction of **1a** with **B** was recorded at an appropriate time after adding 15.18 mg of **1a** to 25 ml of 1.0×10^{-3} M acetic acid solution of **B** under nitrogen atmosphere at room temperature (23 °C). The scan time (410—800 nm) was 1.5 min.

Reaction of N,N-*Dimethylaniline (1a) with Palladium(II) Acetate (A).* A stirred mixture of **1a** (2.4 g, 0.02 mol) and **A** (2.2 g, 0.01 mol) in acetic acid (60 g, 1.0 mol) was heated at 80 °C for 5 h under nitrogen atmosphere. A filtration of the reaction mixture gave metallic palladium (1.1 g, 0.01 mol). The filtrate was evaporated to remove the solvent. It was confirmed by TLC and GLC of the evaporated residue that all of used **1a** was consumed and that trace of *N,N*-dimethyl-*p*-toluidine (**1d**) was obtained. The residue was column-chromatographed using 90 g of Wacogel. The elution by benzene gave 1.83 g of 4,4′-bis(dimethylamino)diphenylmethane (**2a**) (72.1%), which was recrystallized from benzene–petroleum ether: plates, mp 86.5—87.0 °C (lit,[16] mp 89.5—90.5 °C), UV; λ_{max}^{EtOH} 261.8 nm (ε 3.04×10^4), Mass (*m/e*); 254 (M^+-Me_2), 134. The elementary analyses for C, H, and N were correctly analyzed. Further elution by a mixed solvent of ethyl ether and ethanol gave 0.483 g of Crystal Violet (acetate salt) (**3a**): UV; $\lambda_{max}^{CHCl_3}$ 596.2 nm (lit, as chloride salt,[20] 590 nm), IR (KBr disk, in cm^{-1}); 1660—1550 (br, aromatic C=C and CH_3COO^-). The reactions of *N,N*-dialkylaniline with **A** or **B** in various solvents were similarly treated as described above. The yields of **2a** in the reactions of **1a** and **1d** mixture with **A** were determined by GLC analysis using SE 30 on chromosorb (270 °C, carrier gas H_2) and using the identified **2a** sample as an authentic material. **6** and **7** were identical with their specimen on IR and NMR spectra and GLC.

Reaction of N,N-*Dimethyl*-p-*toluidine (1d) with A.* A stirred mixture of **1d** (2.7 g, 0.02 mol) and **A** (2.2 g, 0.01 mol) in acetic acid (60 g, 1.0 mol) was heated at 80 °C for 5 h under nitrogen atmosphere. The filtration of the reaction mixture gave metallic palladium (1.1 g, 0.01 mol). The filtrate was distilled under a reduced pressure to remove the solvent and the unreacted toluidine. The distillate contained 0.84 g of unreacted **1d**, from the result of GLC analysis. The distilled residue was column-chromatographically separated using 300 g of Wacogel. The elution by a mixed solvent of petroleum ether (50%) and chloroform (50%) gave 44 mg of the solid which was recrystallized from dichloromethane. It was identified with dibenzodiazocine derivative (**4**) from following data: mp 147.0—147.5 °C, Mass (*m/e*); 266 (M^+), 254 (M^+-CH_3), 146, 134.

Found: C; 81.27, H; 8.39, N; 10.39%. Calcd for $C_{18}H_{22}N_2$: C; 81.20. H; 8.27, N; 10.53%. The NMR data are shown in Table 3. Further elution by petroleum ether (30%) and chloroform (70%) gave 86 mg of diarylmethane (**2d**) (8.2%), followed by 86 mg of *N*, *p*-dimethylacetoanilide (3.8%) which were identified with authentic materials by GLC, IR, and NMR.

The authors wish to thank Professor T. Hase of Kagoshima University for his various supports throughout the study. They are also grateful to Professor Y. Odaira and his laboratory-staffs of Osaka University for mass and elemental analyses.

The Acid Catalyzed Decomposition of Diazo Compounds. I. Synthesis of Oxazoles in the BF_3 Catalyzed Reaction of Diazo Carbonyl Compounds with Nitriles

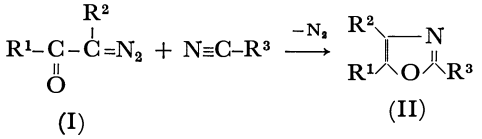
Toshikazu IBATA* and Ryohei SATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received April 23, 1979)

The BF_3-catalyzed decomposition of diazo carbonyl compounds in nitriles have afforded the corresponding oxazoles in high yields. This method is applicable to diazo carbonyl compounds such as *m*- and *p*-substituted diazoacetophenones, ethyl diazoacetate, 1,2-diphenyl-2-diazoethanone, dibenzoyldiazomethane, and dimethyl diazomalonate. Bis(diazo ketone)s such as terminal bis(diazoacetylated) alkanes (III_{1-4}: $n=6$, 8, 10, 12) and *m*- and *p*-bis(diazoacetyl)benzenes also gave the corresponding bisoxazoles in a similar reaction. The reaction has been interpreted in terms of a stepwise mechanism *via* betaine intermediates initiated by the attack of BF_3 on the carbonyl oxygen of diazo carbonyl compounds. The emission spectra of oxazoles are described.

The synthesis of oxazoles has been the subject of numerous studies in connection with the pharmaceutical properties of oxazole derivatives.[1] Most of the methods reported however are not satisfactory as a general method for the synthesis of oxazoles because of the low yield of oxazoles and the difficulties in obtaining the starting materials.



(I) (II)

The 1,3-dipolar cycloaddition of carbonylcarbene to the carbon-nitrogen triple bond of the cyano group was first proposed by Huisgen *et al.* to give oxazoles (II) having arbitrary substituents on C-2, C-4, and C-5 positions.[2] In accordance with this working hypothesis, the thermal,[2,3] phtochemical,[4] and transition metal catalyzed[2,3] decomposition of diazo carbonyl compounds in nitriles were studied. The yields of oxazoles were not high even though the use of copper[2,3a] and π-allylic palladium[5] catalysts which were employed to prevent the Wolff rearrangement of the diazo carbonyl compound. Nozaki *et al.* improved the yield (up to 66%) using WCl_6 as a catalyst.[6] The by-product formation of α-chlorinated ketones was not inevitable in this reaction. Recently Doyle *et al.* reported the $AlCl_3$-catalyzed reaction of α-unsubstituted diazo ketones and nitriles giving oxazoles in high yields.[7] In a previous paper in this series the BF_3-catalyzed decomposition of diazo carbonyl compounds in nitriles to give oxazoles in high yields was reported.[8] In this paper this method has been employed to the synthesis of several substituted oxazoles.

Results and Discussion

The BF_3-catalyzed decomposition of α-diazoacetophenone in an excess of acetonitrile proceeded with vigorous evolution of nitrogen and gave 2-methyl-5-phenyloxazole (II_1) in 94% yield. This method is applicable to other nitriles. Propionitrile, isobutyronitrile, phenylacetonitrile, benzonitrile, *p*-methoxybenzonitrile, cinnamonitrile, and chloroacetonitrile gave oxazoles in high yields. (Phenylthio)acetonitrile afforded *N*-phenacyl-α-(phenylthio)acetamide (12%) together with 2-phenylthiomethyl-5-phenyloxazole (II_9). Under these circumstances neither the expected cyanomethylphenylsulfonium phenacylide nor the (cyanomethyl)phenacylphenyl sulfonium salt was obtained despite a detailed inspection of the reaction mixture by column chromatography.[9] This indicates the higher reactivity of the cyano group towards the diazonium type intermediate (VII) than that of the sulfur atom. Methyl cyanoacetate yielded oxazole (II_{10}) in moderate yields with accompanying intractable oily products. The electron attracting substituent on the nitrile lowered the yield of oxazole, *e.g.*, *p*-nitrobenzonitrile gave the oxazole (II_7) in lower yield than in the cases of benzonitrile and *p*-methoxybenzonitrile.

The *m*- and *p*-substituted α-diazoacetophenones, 12-cyano-1-diazo-2-dodecan-2-one, ethyl diazoacetate, and 1,2-diphenyl-2-diazoethanone also gave 5-aryl-2-methyloxazoles (II_{12-23}), 5-(*p*-methoxyphenyl)-2-ethyloxazole (II_{24}), 5-(ω-cyanodecyl)-2-methyloxazole (II_{25}), 5-ethoxy-2-methyloxazole (II_{26}), and 3,5-diphenyl-2-methyloxazole (II_{27}) respectively. Both the electron-attracting and electron-releasing substituents on a benzene ring of diazoacetophenones do not effect the yield of the oxazoles and the rate of the reaction. A benzoyl group or a methoxycarbonyl group attached to a diazomethyl carbon atom however suppressed the reaction and consequently elevated temperatures were necessary for completion of the reaction. Some dimethyl diazomalonate was recovered even after prolonged heating of the reaction mixture (80 °C, 50 h) and caused a low yield of oxazole (II_{29}).

The NMR data shows that the chemical shift of the oxazole ring proton (C_4–H) is effected by the substituent on C_5 rather than that on C_2 (Table 1). Electron-attracting groups on the benzene ring attached to C_5 deshielded the C_4–H and an alkyl group on C_5 shielded the C_4–H.

Bis(diazo ketone)s such as α,ω-bis(diazoacetyl)alkanes (III_{1-4}: $n=6$, 8, 10, 12) and *m*- and *p*-bis(diazoacetyl)-benzenes ($V_{1,2}$) gave bisoxazolyl compounds (IV_{1-4}) and ($VI_{1,2}$: R=CH_3; VI_3: R=Ph) in the reaction with acetonitrile or benzonitrile.

In the experimental work conducted here an excess of BF_3 was used although a catalytic amount of BF_3 is

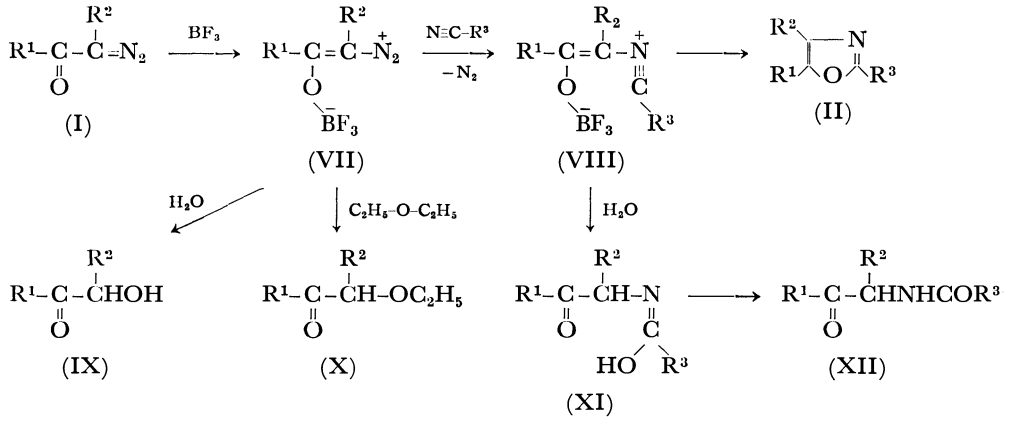
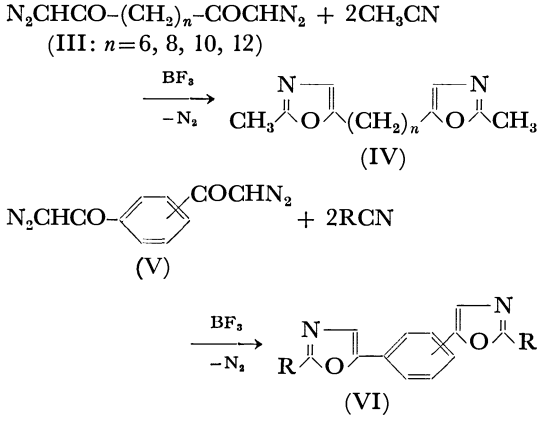
sufficient for completion of the reaction. The reaction is reasonably explained by a stepwise mechanism *via* betaine intermediates, unlike the 1,3-dipolar cycloaddition of carbonylcarbene towards the carbon-nitrogen triple bond of nitrile proposed for the thermal and transition metal catalyzed reactions.[2,3] The reaction is initiated by the attack of BF_3 on the carbonyl-oxygen of the diazo carbonyl compound affording a diazonium type intermediate (VII).[9] The intermediacy of VII was supported by the facts that α-hydroxy or α-ethoxy ketones (IX, X) were obtained when the reaction was conducted in the presence of water or diethyl ether.[10,11] The electrophilic attack of the intermediate (VII) on the nitrogen atom of the nitrile may form a betaine intermediate (VIII) with the elimination of nitrogen. The electron-attracting substituent on the nitrile may retard this step and subsequently lower the yield of oxazole (Table 1 run 7). The reaction conducted in



Scheme 1.



acetonitrile containing a trace amount of H_2O gave *N*-(aroylmethyl)acetamide (XII: R^1=Ar, R^2=H, R^3=CH_3) together with oxazole and α-hydroxyacetophenone (IX). The formation of XII supports the existence of an intermediate (VIII) as shown in Scheme 1. The attack of VIII on a water molecule competes with the intramolecular cyclization of VIII which gives the oxazole.

Several oxazole derivatives have been found to exhibit fluorescence properties and have been used as liquid scintillators.[1b] The bisoxazolyl compound, 1,4-bis(5-phenyl-2-oxazolyl)benzene (VI_3), is an isomer of the well known scintillator POPOP, 1,4-bis(2-phenyl-5-oxazolyl)benzene, and shows strong emission bands at 405 nm. The UV and fluorescence spectral data of oxazoles are listed in Table 3.

Table 3. UV and emission data of oxazoles

Experimental

All melting points were taken with a Yanagimoto Melting Point Apparatus and are uncorrected. The IR spectra were measured on a Hitachi Infrared Spectrometer model 215. The ^{1}H-NMR spectra were recorded in $CDCl_3$ solution at 60 MHz on a Varian Spectrometer model EM-360 using TMS as an internal standard. UV spectra were measured on a Hitachi Spectrometer model 323 in ethanol solution. Emission spectra were recorded on Hitachi Emission Spectrometer model MPE-2A in ethanol solution ($1—5\times10^{-6}$ mol/l).

Materials. Diazoacetophenones,[12] ethyl diazoacetate,[13] 1,2-diphenyl-2-diazoethanone,[14] dibenzoyldiazomethane,[15] and dimethyl diazomalonate[16] were synthesized by the methods described in the literature. Liquid nitriles were purified by distillation of commercial reagents after refluxing over P_2O_5. *p*-Methoxybenzonitrile and *p*-nitrobenzonitrile were purified by recrystallization.

General Procedure of the BF_3 Catalyzed Reaction of Diazo Carbonyl Compounds in Acetonitrile. A solution of the diazo carbonyl compound (3 mmol) in acetonitrile (3 ml) was added dropwise to acetonitrile (10 ml) containing BF_3–etherate (1.0 ml) under magnetic stirring at temperatures described in the Tables. After the vigorous evolution of N_2 ceased the reac-

tion mixture was poured into H_2O (50 ml) and ether (50 ml). The ether layer was extracted twice with 3 M HCl and the combined aqueous solution made basic with $NaHCO_3$. The separated oxazole was extracted with ether and purified by recrystallization.

General Procedure of the BF_3 Catalyzed Reaction of Diazo Carbonyl Compounds in Liquid Nitriles. The Diazo carbonyl compound (3 mmol) was treated in the similar manner described above in an excess of liquid nitrile. The oxazoles ($R^3 \neq CH_3$) could not be extracted with 3 M HCl and therefore the reaction mixture was treated with H_2O and extracted twice with ether (2×20 ml) after the solution was made basic with $NaHCO_3$. The ether extract was dried over Na_2SO_4, the ether evaporated, and column chromatographed over silica gel.

Reaction with Solid Nitriles. A five molar equivalent of the nitrile was reacted with α-diazoacetophenone in dried benzene (20 ml). The reaction mixture was separated by column chromatography after the usual work up.

Reaction of m-Chloro-α-diazoacetophenone in Water Containing Acetonitrile. *m*-Chloro-α-diazoacetophenone (1 mmol) was decomposed in water containing acetonitrile[17] (20 ml) at 5 °C. Column chromatography of the reaction mixture gave three products: 5-(*m*-chlorophenyl)-2-methyloxazole (II_{20}, 55 %), α-hydroxy-*m*-chloroacetophenone (12%), and *N*-(*m*-chlorophenacyl) acetamide (XII: R^1=*m*-ClC_6H_4, R^2=H, R^3=CH_3): colorless crystals; mp 118—119 °C; yield 0.057 g, 27 %; IR (KBr) 1690 (C=O), 1650, 3280 cm^{-1} (amide); NMR ($CDCl_3$) δ 2.41 (s, 3H, CH_3), 4.97 (d, 2H, CH_2), 6.8 (broad s, 1H, NH), 7.4—8.2 ppm (m, 4H, Ar). Found: C, 56.66; H, 4.80; N, 6.63%. Calcd for $C_{10}H_{10}O_2NCl$: C, 56.75; H, 4.76; N, 6.62%.

We are indebted to Professor S. Kato and Dr. A. Yoshimura of this Institute for their valuable suggestions and discussion concerning the measurement of emission spectra of the oxazoles.

Diversity in the Base-induced Photoreactions of Thiolane-2,4-dione and Derivatives. Reductive Ring Cleavage and Novel Rearrangements of the Carbon Skeleton[1)]

Kimitoshi SAITO† and Tadashi SATO*

Department of Applied Chemistry, Waseda University, Ookubo, Shinjuku-ku, Tokyo 160

(Received May 11, 1979)

The irradiation of thiolane-2,4-dione (thiotetronic acid) and its derivatives, **1a**—**1d**, in methanol in the presence of bases induced the reductive ring cleavage to give β,β'-diketo esters. The base-induced reductive ring cleavage was also observed in aprotic solvents, such as acetonitrile or acetone, although the products were obtained as β,β'-diketo amides in these cases. On the other hand, the irradiation of **1a**—**1d** in water in the presence of bases induced a rearrangement of the carbon skeleton to give succinic thioanhydrides, γ-keto amides or succinamides, along with the reduction products. When pyridine was used as a base in the photolysis in water, two 3-acetyl derivatives, **1a** and **1b**, gave γ-keto thiols and the corresponding disulfides, resulted from another type of rearrangement of the carbon skeleton. Conceivable reaction mechanisms were discussed.

It has previously been reported that the photoreactions of sulfur-containing carbonyl compounds depend on the relative positions of the sulfur and carbonyl groups.[2)] Previous investigations have shown that the UV spectra of cyclic keto sulfides are substantially different from those of alkyl or aryl ketones or acyclic keto sulfides, and this difference has been attributed to the transannular interaction of a lone pair of electrons on sulfur with the carbonyl group, the coupling being strongly dependent on the orientation of the two groups.[3)] Several types of photoreactions—rearrangement of the ring system,[4)] ring contraction,[5)] fragmentation,[6)] and some others[7)]—have been known for cyclic β- or γ-keto sulfides, and these reactions have been interpreted as involving different degrees of interaction between sulfur and carbonyl groups.

It is well known that photoreactions in the presence of an amine proceed through a charge-transfer complex to form reduction products. Previously, we reported on the reductive cleavage of the isoxazole ring by irradiation in the presence of triethylamine.[8)] We have now undertaken the photoreactions of thiolane-2,4-dione (thiotetronic acid) and its derivatives, **1a**—**1d**, in the presence of bases, expecting an unusual photoreaction caused by the intramolecular charge-transfer interaction of the two chromophores and also the intermolecular interaction of **1a**—**1d** with the bases.

Results and Discussion

When methanol solutions of 3-acetylthiolane-2,4-dione (**1a**) and its derivatives, **1b**—**1d**, containing an equal amount of such bases as piperidine, triethylamine, or sodium hydroxide (10% aqueous solution) were irradiated with Pyrex-filtered light for 8—12 h, methyl 2-acetylacetoacetate (**2a**) and its derivatives, **2b**—**2d**, were obtained. When pyridine was used as a base in the reaction of **1a**, deacetylation occurred and methyl acetoacetate (**2c**) was identified as a product along with **2a**. The corresponding ethyl ester was obtained in a 29% yield upon the irradiation of **1a** in ethanol in the presence of piperidine. The base-induced reductive ring cleavage was also observed in aprotic solvents, such as acetonitrile or acetone, although the products were obtained as amides, **3**, in these cases. The details are shown in Table 1. It should be noted that diethylamine and triethylamine gave an identical product, *N,N*-diethyl-2-acetylacetamide (**3aD**), upon the irradiation of **1a** in acetonitrile. The deethylation could proceed as is shown in **4**, a similar type of deethylation having been speculated about in the photolysis of 3,5-dimethylisoxazole in the presence of triethylamine.[8)] The presence of the bases is essential for these reactions to proceed; the starting materials are recovered under the irradiation in the absence of bases, except in the case of **1c**, in which **2c** was obtained in a 22% yield as well as the main product, 4-methoxy-2-oxo-2,5-dihydrothiophene (**5c**), under irradiation in methanol.

The compounds **1a**—**1d** have enolizable protons and are acidic. Actually, **1a** formed a stable crystalline salt with piperidine, and the salt, when irradiated in methanol or in acetonitrile, afforded **2a** (24% in methanol) or piperidyl 2-acetylacetoacetamide (**3aP**, 10% in acetonitrile). It might be considered that the present reaction proceeds from the anion forms of **1a**—**1d**, but it was confirmed that the presence of an enolizable proton is not necessary because the 3,3-dimethylthiolane-2,4-dione (**6**) also afforded the corresponding reductive ring-cleavage products, as a mixture of methyl 2,2-dimethylacetoacetate (**7R**, 27%) and piperidyl 2,2-dimethylacetoacetamide (**7P**, 25%), when irradiated in methanol in the presence of piperidine.

In contrast to the reductive ring cleavage in the organic solvents described above, the reaction in an aqueous solution proceeded in a different way. The irradiation of **1a** in water containing three equivalents of piperidine gave 2-acetylsuccinic thioanhydride (**8a**) and piperidyl levulinamide (**9aP**) along with the reduction product, **3aP**. Similarly, the methyl derivative **1b** gave the corresponding products, **8b** and **9bP**. The piperidine-induced photolysis of **1c** and **1d**, on the other hand, gave two derivatives of succinamide, **10cP** and **10dP**, as well as the corresponding succinic thioanhydrides, **8c** and **8d**. It is evident from the results shown in Table 1 that the products **9** and **10** are secondary products from **8**, since the yields of **9** and **10**

a) Yields for 4 h. b) Yields in an acetone solution.

increased at the expense of those of **8** upon the 12 h irradiation as compared with the 4 h irradiation. Actually, **9aP** and **9bP** were obtained from **8a** and **8b** in 86% and 72% yields respectively, upon irradiation in water in the presence of piperidine for 8 h. Similarly, **10cP** and **10dP** were obtained from **8c** and **8d** in 31% and 36% yields respectively under the same conditions.

The solubility of **1a** in water is low, and three equivalents of the base were necessary to prepare homogeneous aqueous solutions. When the amount of piperidine was increased tenfold, the reductive ring-cleavage product, **3aP** (33%), was obtained in preference to the rearrangement product, **9aP** (22%).

When pyridine was used as a base in the photolysis in water (1 : 1 by volume), **1a** and **1b** gave γ-ketobutanethiol (**12**) and the corresponding disulfide, **13**, instead of **8** and **9**. The same reaction was also observed in the irradiation of **1a** in a 10% aqueous sodium hydroxide solution, but the reaction was slow in this case. No abnormality of pyridine was, however, observed in the reactions of **1c** and **1d**, and the corresponding succinic acid derivatives, **10cO** and **10dO**, were obtained.

The reactions in aqueous solutions are notable in that the products have a carbon skeleton which was not present in the starting materials. In our preliminary report,[1] we proposed two mechanistic paths for the carbon skeleton rearrangement. One mechanism involved the radical fission (a or b; see Scheme 1) of the ring, followed by the elimination of CSO or CO to give observed products, **9** and **12**, *via* cyclopropanone, **17**, or thietanone, **18**, intermediates, respectively. This mechanism is analogous to that reported by Kooi and Wynberg in the ring contraction of non-enolizable α-diketo sulfides.[9] More recently, Yates and Toong[6] reported the formation of disulfides by the photoreaction of tetrahydrothiophene-3-one through a radical cleavage of the ring. The other mechanism involved thiophene-type transposition reactions, assuming **1** to be thiophenediol, **19**, as is shown in Scheme 2. It was

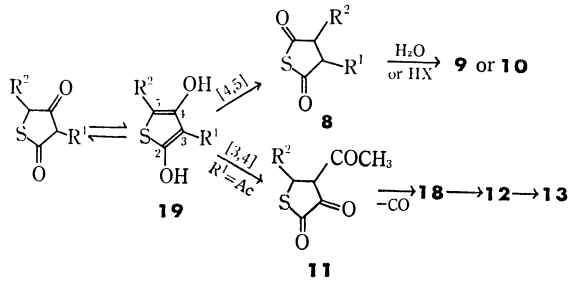


Scheme 2.

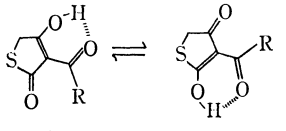
considered that the piperidine-induced reactions leading to **9** proceeded through the intermediacy of **8**, which, in turn, might have been formed through 4,5-transposition of **1**, while the pyridine-induced reactions leading to **12** and **13** could be explained in terms of involving 4-acetylthiolane-2,3-dione, **11**, as intermediates, resulting through the 3,4-transposition of **1**. This mechanism now seems preferable to the radical mechanism because (i) **8a** and **8b** were actually identified as intermediates in the reactions of **1a** and **1b**, and (ii) the formation of **10c** and **10d** from **1c** and **1d** respectively could not be explained by the radical mechanism.

When primary amines, such as aniline, cyclohexylamine, and butylamine, were used as the base in the reaction of **1a** in methanol or acetonitrile, the condensation products, **14**, became the major products and no reduction products or rearrangement products were identified at all. In an aqueous solution, however, appreciable amounts of the reduction products (**3aC**, **3aB**) and the rearrangement products (**9aB**, **9aC**) were identified, as well as the condensation products (**14B**, **14C**) and a fission product, **15C**. Since the condensation product, **14A**, was intact under the present reaction conditions, the reduction and rearrangement are considered to have proceeded prior to the condensation.

In contrast to the base-induced reductive ring cleavage in organic solvents, where the presence of enolizable proton was unnecessary, it was concluded that the base-induced reactions in an aqueous solution required the presence of the enolizable proton, because the dimethyl derivative, **6**, underwent fragmentation to afford *N*-formylpiperidine, without giving any reduction product or rearrangement product. Most of the starting material, **6**, was recovered in pyridine–water.

It is presumable that the reductive ring cleavage proceeds *via* a charge-transfer complex in organic solvents, while the carbon-skeleton rearrangements proceed through the excitation of the anion form of the substrate, which is predominant only in an aqueous solution.

The irradiation of 3-benzoyl and 3-ethoxycarbonyl derivatives (**1e** and **1f**) in the presence of piperidine or pyridine resulted in the recovery of the starting materials (62—81%) in water, methanol, or acetonitrile. Previously we demonstrated that unsymmetrical cyclic β,β'-diketo esters such as **1** may generally exist in "external" tautomers (A⇌B) in solution, as is shown in Scheme 3.[10] The presence of the "external"



Scheme 3.

tautomers in 3-acylthiolane-2,4-dione (**1a**—**1b**) was evident in view of the presence of two singlets of the ring methylene protons in their PMR spectra:[11] A: B=24: 76 for **1a** and A: B=28: 72 for **1b**. On the contrary, it was confirmed that **1e** and **1f** exist exclusively in Form A, as revealed by the single methylene signal in their PMR spectra. It is assumed that the lack of the reactivity of **1e** and **1f** might be attributable to a fixation of the tautomeric system to the Form A through the interaction of 3-benzoyl or 3-ethoxycarbonyl groups. In addition, 3-acetyl-5-benzylidenethiolane-2,4-dione (**16**) and **14A**, which have an exo-double bond on the ring, were also recovered unreacted under the same irradiation conditions. Presumably, the difficulty in attaining the thiophene chromophore might deprive these compounds of the photoreactivity.

Experimental

The mass spectra were obtained with a Hitachi RMS-4 spectrometer; the IR spectra, with a Hitachi 215 spectrometer; the PMR spectra, with a JEOL MH-60 (60 MHz) or PS-100 (100 MHz) spectrometer (with Me_4Si as the internal standard), and the CMR spectra, with a JEOL FX-10 spectrometer operated at 25.1 MHz.

The starting materials, **1a**,[12] **1b**—**1d**,[13] **1e**,[12] **1f**,[13] and **16**,[14] were prepared according to the procedures described in the literature cited.

General Procedure for the Photolysis. Unless otherwise noted, a solution (3—5 mmol, 0.033 M) of the starting material containing a base (one equivalent in the cases of the reactions in organic solvents, three equivalents in the cases of the reactions in aqueous solutions) was irradiated in Pyrex test tube by means of a high-pressure mercury lamp [Ushio UM 452 (450 W)] for 4—12 h. After the irradiation, the solution was poured into water, acidified with 6 M hydrochloric acid, and then extracted with chloroform (Procedure A). In some cases, the irradiated solution was concentrated *in vacuo*, and the crude residue, after having been dissolved in chloroform, was washed with dilute aqueous hydrochloric acid (Procedure B). The chloroform solution after Procedure A or B was dried over sodium sulfate and evaporated *in vacuo*. The residue was treated as indicated below.

Photolysis of 1a. In Alcohols: The crude material obtained by Procedure A was placed in a silica-gel column and then eluted with chloroform. Upon removing the solvent *in vacuo*

from the eluate, **2a** (in methanol) or the corresponding ethyl ester (in ethanol) was isolated; the **2a** was further purified by vacuum distillation. **2a**; Bp, 47—48 °C (3 mmHg). MS, *m/e* 158 (M), 126, 98 (base peak), and 85. IR (CCl_4), 1700 and 1550 cm^{-1}. PMR (CCl_4), δ 2.32 (s, 6H), 3.74 (s, 3H), and 18.5 (bs, 1H). CMR ($CDCl_3$), δ 26.0, 51.5, 108.3, 167.5, and 196.8. Found: C, 51.20; H, 6.48%. Calcd for $C_7H_{10}O_4$: C, 52.14; H, 6.37%. The IR and PMR spectra of the ethyl ester were identical with those of an authentic sample.[15]

In Acetone or Acetonitrile in the Presence of Piperidine, Morpholine, Diethylamine, or Triethylamine: The viscous residue obtained by Procedure B was purified on a preparative TLC (silica gel, 10% methanol in chloroform). **3aP**, **3aM**, and **3aD** were isolated depending on the bases used. **3aP**: IR (CCl_4), 1630 cm^{-1}. PMR (CCl_4), δ 1.4—1.6 (b, 6H), 1.95 (s, 6H), 3.2—3.8 (b, 4H), and 16.8 (bs, 1H). **3aM**: IR (CCl_4), 1635 cm^{-1}. PMR (CCl_4), δ 1.98 (s, 6H), 3.3—3.6 (b, 4H), and 16.8 (bs, 1H). CMR ($CDCl_3$), δ 23.2, 44.2, 47.3, 66.6, 66.7, 110.5, 166.5, and 189.1. **3aD**: IR (CCl_4), 1630 cm^{-1}. PMR (CCl_4), δ 0.98 (t, J=8 Hz, 3H), 1.06 (t, J=8 Hz, 3H), 1.98 (s, 6H), 3.19 (q, J=8 Hz, 2H), 3.24 (q, J=8 Hz, 2H), and 16.6 (bs, 1H). CMR ($CDCl_3$), δ 14.1, 14.2, 23.1, 40.2, 41.8, 107.3, 109.5, and 188.8. The amide-type structure of **3aP** was also confirmed by hydrolyzing it with a 10% aqueous potassium hydroxide solution to acetylacetone and piperidine.

In Acetonitrile in the Presence of Aniline, Cyclohexylamine, or Butylamine: After the irradiation, the solvent was removed *in vacuo*. In an aniline-induced reaction, **14A** was obtained when the crude solid was washed with carbon tetrachloride. In a cyclohexylamine-induced reaction, **14C** and **15C** were isolated by preparative TLC (silica gel, 2% methanol in chloroform). In a butylamine-induced reaction, the crude oil obtained was placed in a silica-gel column and then eluted with chloroform. Upon removing the solvent *in vacuo* from the eluate, a colorless oil of **14B** was isolated in a pure state. The spectra of **14A** and **15C** were identical with those of authentic samples.[14] **14B**: IR (CCl_4), 1680, 1600, and 1135 cm^{-1}. PMR (CCl_4), δ 0.95 (t, J=7 Hz, 3H), 1.2—1.6 (m, 4H), 2.38 (s, 3H), 3.2—3.5 (m, 4H), 3.42 and 3.36 (s, s, 2H), and 11.05 and 11.95 (bs, bs, 1H). **14C**: IR (CCl_4), 1685, 1600, and 1360 cm^{-1}. PMR (CCl_4), δ 1.2—2.0 (m, 10H), 2.46 (s, 3H), 3.42 and 3.50 (s, s, 2H), 3.4—3.6 (m, 1H), and 11.2 and 12.2 (bs, bs, 1H). The PMR analysis indicated that Compounds **14A**, **14B**, and **14C** existed as mixtures of external tautomers, as shown in Scheme 3; the A form/B form ratio was calculated to be 0.35 for **14A**, 0.43 for **14B**, and 0.33 for **14C**.

In Water in the Presence of Piperidine, Morpholine, Diethylamine, or Triethylamine: After the irradiation, the solution was shaken with chloroform (Extract A). The aqueous solution was acidified with 6 M hydrochloric acid and further shaken with chloroform (Extract B). Extract B, after the evaporation of the solvent, was purified by preparative TLC (silica gel, 10% methanol in chloroform). **3aP**, **3aM**, and **3aD** were thus obtained along with **8a** and the unreacted starting material. Extract A, after purification by preparartive TLC (10% methanol in chloroform), gave **9aP**, **9aM**, and **9aD**. **8a**: Mp 35—37 °C. MS, *m/e* 158 (M), 98 (base peak), 75, 70, and 43. IR (CCl_4), 1740, 1715, 1625, and 1600 cm^{-1}. PMR (CCl_4), δ 1.95 (s, 3H) 3.52 (s, 2H), and 12.3 (bs, 1H). The IR and PMR spectra of **9aP** and **9aD** were identical with those of authentic samples.[16] **9aM**: MS, *m/e* 185 (M), 99, 98, 86 (base peak), 84, and 69. IR (CCl_4), 1720 and 1630 cm^{-1}. PMR (CCl_4), δ 2.0—2.3 (m, 4H), 2.12 (s, 3H), 3.3—3.6 (m, 4H), and 3.62 (s, 4H).

In Water in the Presence of Aniline, Cyclohexylamine, or Butylamine: After irradiation, the solution was shaken with chloroform (Extract A). The aqueous solution was acidified with 6 M hydrochloric acid and further shaken with chloroform (Extract B). When Extract A was purified by preparative TLC (silica gel, 10% methanol in chloroform), **3aB** and **3aC** were isolated. From Extract B, **15B**, **15C**, **9aB**, and **9aC** were obtained, along with the condensation products, **14B** and **14C**. **3aB**: IR (CCl_4), 1630 and 1590 cm^{-1}. PMR (CCl_4), δ 0.97 (t, J=7 Hz, 3H), 1.2—1.6 (m, 4H), 2.09 (s, 6H), 3.29 (q, J=7 Hz, 4H), 7.52 (bs, 1H), and 10.58 (bs, 1H). **3aC**: IR (CCl_4), 1630 and 1590 cm^{-1}. PMR ($CDCl_3$), δ 1.2—2.0 (m, 10H), 2.04 (s, 6H), 3.3—3.4 (m, 1H), and 7.4 (bs, 1H). **9aB**: IR (CCl_4), 1670 and 1630 cm^{-1}. PMR (CCl_4), δ 0.97 (t, J=7 Hz, 3H), 1.2—1.6 (m, 4H), 2.30 (s, 3H), 2.0—2.15 (m, 4H), 2.95—3.05 (m, 2H), and 7.4 (bs, 1H). **9aC**: IR (CCl_4), 1670 and 1630 cm^{-1}. PMR ($CDCl_3$), δ 1.2—2.0 (m, 10H), 2.11 (s, 3H), 2.0—2.2 (m, 4H), 3.3—3.4 (m, 1H), and 6.8 (bs, 1H).

In Pyridine–Water: A solution of **1a** in pyridine–water (1:1 by volume) was irradiated for 12 h. When the viscous residue obtained by Procedure B was chromatographed on preparative TLC (silica gel, 5% methanol in chloroform), **12a** and **13a** were isolated; **13a** was further purified by vacuum distillation at 50—55 °C (3 mmHg). The IR and PMR spectra of **12a** and **13a** were identical with those of authentic samples.[17]

Preparation and Photolysis of 3-Acetylthiotetronic Acid Piperidinium Salt. When 0.17 g (2 mmol) of piperidine was added to a stirred solution of 0.16 g (1 mmol) of **1a** in 30 ml of dry benzene at room temperature, a white solid crystallized out in 1—2 h. The solid was filtered and recrystallized from benzene to give 3-acetylthiotetronic acid piperidinium salt; yield 175 mg (72%); Mp 98—100 °C, IR (KBr), 3400, 1680, and 1590 cm^{-1}. PMR ($CDCl_3$), δ 1.7 (b, 6H), 2.28 (s, 3H), 3.3 (b, 4H), 3.42 (s, 2H), and 7.6 (b, 2H).

A solution of the salt in methanol or in acetonitrile was irradiated for 12 h. After the irradiation, the solvent was removed *in vacuo*. The formation and yield of **2a** (42% in methanol) or **3aP** (10% in acetonitrile) were determined by means of their PMR spectra (tetrachloroethane was used as the internal standard).

Photolysis of 1b. In Methanol or Acetonitrile: When the viscous residue obtained by Procedure B was purified by preparative TLC (silica gel, chloroform), **2b** and **3bP** were isolated. **3bP** was isolated as a single product when the irradiation was carried out in acetonitrile. **2b**: IR (CCl_4), 1715 and 1550 cm^{-1}. PMR (CCl_4), δ 1.12 (t, J=7.5 Hz, 3H), 2.02 (s, 3H), 3.35 (q, J=7.5 Hz, 2H), 3.65 (s, 3H); no enolic proton could be observed. **3bP**: IR (CCl_4), 1635 cm^{-1}. PMR ($CDCl_3$), δ 1.15 (t, J=8 Hz, 3H), 1.4—1.6 (b, 6H), 2.20 (s, 3H), 2.44 (q, J=8 Hz, 2H), 3.2—3.8 (b, 4H), and 16.5 (bs, 1H).

In Water: The crude product obtained by Procedure A was purified by preparative TLC (silica gel, chloroform). **9bP** and **9bM** were obtained, along with **8b**. **8b**: IR (CCl_4), 1730, 1705, 1640, 1595, and 1220 cm^{-1}. The PMR analysis indicated that the compound existed as a mixture of 24% of the keto form and 76% of the enol form in carbon tetrachloride. PMR (CCl_4), for the keto form, δ 1.32 (d, J=7 Hz, 3H), 2.40 (s, 3H), 3.94 (q, J=7 Hz, 1H), for the enol form, δ 1.44 (d, J=7 Hz, 3H), 2.02 (s, 3H), 3.64 (q, J=7 Hz, 1H) and 12.6 (bs, 1H). **9bP**: IR ($CHCl_3$), 1717, 1640, and 1470 cm^{-1}. PMR ($CDCl_3$), δ 0.97 (d, J=7 Hz, 3H), 1.35—1.80 (m, 6H), 2.00 (s, 3H), 2.06—3.06 (m, 3H), and 3.15—3.18 (m, 4H). **9bM**: IR ($CHCl_3$), 1720, 1645, and 1550 cm^{-1}. PMR ($CDCl_3$), δ 1.03 (d, J=7 Hz, 3H), 2.06 (s, 3H), 2.15—3.21 (m, 3H), and 3.49—3.79 (m, 8H).

In Pyridine–Water: When a solution of **1b** in pyridine–water (1:1 by volume) was irradiated for 12 h, a solid was obtained

upon the removal of the solvent *in vacuo*. The crude residue was purified by preparative TLC (silica gel, chloroform) to give **13b**, along with an unreacted material. **13b**: IR ($CHCl_3$), 1720, 1635, and 1155 cm^{-1}. PMR ($CDCl_3$), δ 1.24 (d, J=7 Hz, 6H), 2.10 (s, 6H), and 2.30—3.55 (m, 6H).

Photolysis of ***1c*** *or* ***1d***. *In Methanol*: The crude solid obtained by Procedure B were purified by preparartive TLC (silica gel, 5% methanol in chloroform). **3cP** or **3dP** was isolated. A by-product, **5d**, was also isolated in the case of the reaction of **1d**. The IR and PMR spectra of **3cP** and **3dP** were identical with those of authentic samples. When the reaction was carried out in acetonitrile, the same products (**3cP** and **3dP**) were obtained.

In Water in the Presence of Piperidine: The oil obtained from **1c** by Procedure A gave white crystals of **8c** and a pale yellow oil of **10cP** upon vacuum distillation. The IR and PMR spectra of **8c** corresponded to those previously reported.[18] **10cP**: IR (CCl_4), 1640, 1440, and 950 cm^{-1}. PMR ($CDCl_3$), δ 1.6 (b, 12H), 2.48 (s, 4H), and 3.5 (m, 8H).

The crude material obtained from **1d** by Procedure A was placed in a silica-gel column and then eluted with chloroform. Upon removing the solvent *in vacuo* from the first eluate, an oil, **8d**, was isolated. Similarly, crystals of **10dP** were obtained from the second eluate. **8d**: IR (CCl_4), 1700 cm^{-1}. PMR (CCl_4), δ 1.42 (d, J=7 Hz, 3H), 2.56 (ABq, 1H), 3.18 (ABq, 1H), and 3.12 (m, 1H). **10dP**: IR (CCl_4), 1640 and 1440 cm^{-1}. PMR (CCl_4), δ 0.95 (d, J=7 Hz, 3H), 1.6—1.8 (b, 12H), 2.1—2.5 (m, 3H), and 3.4—3.6 (b, 8H).

In Pyridine-Water: A solution of **1c** and **1d** in pyridine–water (1: 1 by volume) was irradiated for 12 h. After the irradiation, the solution was evaporated *in vacuo*. The residue was dissolved in dry methanol containing a few drops of concd hydrochloric acid, and then refluxed for 4 h. The reaction mixture was poured into water and extracted with chloroform to afford **10cR** and **10dR**. The IR and PMR spectra of **10cR** and **10dR** corresponded to those previously reported.[19]

Preparation of ***6***. A mixture of 1.02 g (10 mmol) of **1c**, 3.0 g (20 mmol) of methyl iodide, 1.40 g of anhydrous potassium carbonate, and 50 ml of dry acetone was heated under reflux for 20 h and then allowed to cool. The insoluble material was removed by filtration and washed with acetone. The combined filtrate and acetone washings were evaporated *in vacuo*. The residue was chromatographed on a silica-gel column. The subsequent elution of the column with chloroform afforded 0.48 g of pale yellow crude oil, which was further purified by vacuum distillation to give **6** in the pure state; 0.6 g (42%), Bp 78—80 °C (3 mmHg). PMR ($CDCl_3$), δ 1.21 (s, 6H) and 3.94 (s, 2H).

Photolysis of ***6***. *In Methanol*: The reaction mixture obtained by Procedure A was chromatographed on a preparative TLC plate. Subsequent elution with 10% methanol–chloroform afforded **7R** (27%) and **7P** (25%). **7R**: IR (CCl_4), 1725 and 1630 cm^{-1}. PMR (CCl_4), δ 1.48 (s, 6H), 2.30 (s. 3H), and 3.66 (s, 3H). **7P**: IR (CCl_4), 1630 and 1610 cm^{-1}. PMR (CCl_4), δ 1.38 (s, 6H), 2.07 (s, 3H), and 3.4—3.6 (b, 4H).

In Water in the Presence of Piperidine: The brown oil obtained by Procedure A was chromatographed on a preparative TLC (silica gel, 5% methanol in chloroform). The removal of the solvent from the upper band afforded a pale yellow oil, whose IR and PMR spectra indicated it to be *N*-formylpiperidine.

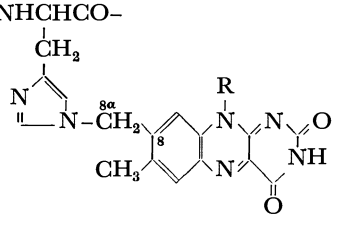
Enhanced Reactivity of a Flavin Bound to Quaternized Poly(4-vinylpyridine) *via* 8-Position. A Model System of a Flavin Coenzyme Covalently-linked to Enzymes†

Seiji SHINKAI,* Kenji MORI, Yumiko KUSANO, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received May 15, 1979)

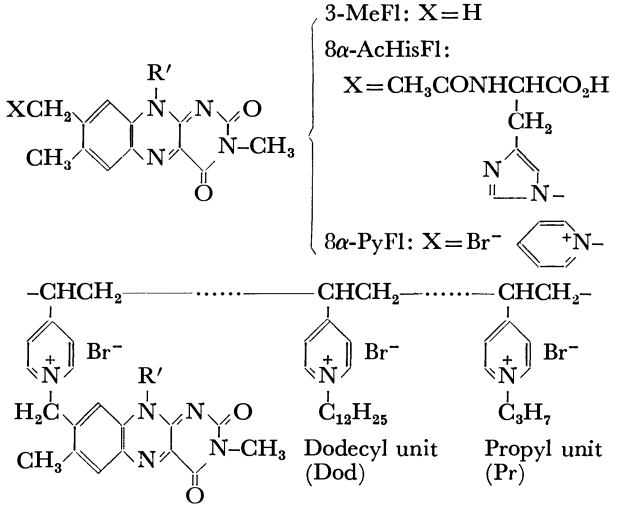
The rate constants for the reaction of the title flavin and the monomeric analogues with 1-benzyl-1,4-dihydronicotinamide (BzlNH), 1-nitroethanide ion, glutathione (GSH), and thiophenol (PhSH) were determined at 30 °C. Although the reactivity of 8α-AcHisFl is slightly improved as compared with that of unmodified flavin, the rate constants for 8α-PyFl which is expected to mimic the reactivity of protonated 8α-AcHisFl were significantly increased. The rate constants for the oxidation of anionic reductants(1-nitroethanide ion, GSH, and PhSH) were further increased by immobilization of the 8α-PyFl structure in quaternized 4VP polymers. The kinetic results implicate that (1) with regard to the action of a flavin covalently-linked to enzymes *via* histidine residue, the flavin must be more reactive in acidic pH region due to protonation of the histidine than in basic pH region, (2) the cationic polyelectrolyte environment accelerates selectively the oxidation of anionic reductants, and (3) the title flavin serves as a strong, selective oxidizing agent under ambient reaction conditions.

Suggestion has been made that a fourth flavin exists in nature in addition to riboflavin, FMN, and FAD. In 1955, Kearney and Singer[1] presented unequivocal evidence that succinate dehydrogenase contains covalently-linked FAD which is not extracted from tissues by the conventional denaturation methods. The claim has been further supported by their subsequent studies.[2–4] In the last five years, it has been established that no less than ten flavoenzymes contain the covalently-linked flavin in the active sites and that the covalent linkage occurs in most cases at $C^{8\alpha}$ position, *e.g.*, *via* the imidazole group of the histidine residue of the enzymes.[5]



The influence of 8-substituents on the reactivity of the isoalloxazine ring has been estimated in detail by several groups,[6–10] but studies on 8α-substitution are very limited. Edmondson *et al.*[11,12] reported, on the basis of flash photolysis and oxidation-reduction potentials, that 8α-substitution by histidine or cysteine gives rise to the electron-withdrawing influence on the isoalloxazine ring system. Except for their study, little is known with certainty about the influence of 8α-substitution on the reactivity of flavin despite its importance in connection with the behavior of covalently-linked flavin.

The rate constant for the reaction of sulfite ion with 8α-(N_1-histidinyl)flavin is greater by a factor of only 1.4 than that with unmodified flavin.[12] This suggests that the 8α-(N_1-histidinyl) group may slightly affect the reactivity of the isoalloxazine ring. However, two important effects, reaction environment and protonation of the imidazole group, remain to be clarified in order to generalize the conclusion with respect to the covalently-linked flavin systems. Both effects should cause a significant change in the reactivity of covalently-linked flavin. With these objects in view, we have synthesized the following flavins and estimated the oxidative reactivity toward 1-benzyl-1,4-dihydronicotinamide (BzlNH), 1-nitroethanide ion ($CH_3\bar{C}HNO_2$), glutathione (GSH), and thiophenol (PhSH) (R′=tetra-*O*-acetylribityl group).



Flavin unit (Fl)

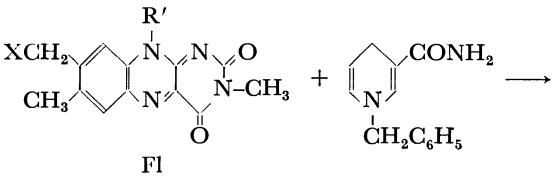
4VP-Fl-Dod-0: Fl, 6 mol%; Dod, 0 mol%; Pr, 88 mol%.
4VP-Fl-Dod-20: Fl, 6 mol%; Dod, 20 mol%; Pr, 67 mol%.

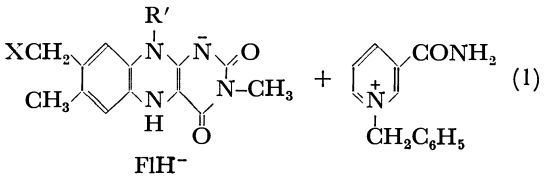
Results

Oxidation of 1-Benzyl-1,4-dihydronicotinamide. Flavin oxidation of BzlNH (Eq. 1) is a typical model

† Coenzyme Models 22. Abbreviations employed are: GSH, glutathione; PhSH, thiophenol; BzlNH, 1-benzyl-1,4-dihydronicotinamide; 3-MeFl, 3-methyltetra-*O*-acetylriboflavin; 8α-AcHiFl, 3-methyl-8α-[N_α-acetyl-(N_1-histidinyl)]-tetra-*O*-acetylriboflavin; 8α-PyFl, 3-methyl-8α-(1-pyridinio)-tetra-*O*-acetylriboflavin bromide; FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; NADH, reduced form of nicotinamide adenine dinucleotide; 4VP, 4-vinylpyridine.

reaction for the inter-coenzyme hydrogen transfer between NADH and flavin, the rate constants being in line with the polarographic half-wave potentials of flavins.[13,14] The second-order rate constant (k_2) for





(1)

the oxidation by 8α-AcHisFl is 1.5 times greater than that by unmodified flavin, 3-MeFl (Table 1). The small rate augmentation is in line with the observation of Edmondson *et al.*[12] that the 8α-(N_1-histidinyl) group behaves as a weak electron-withdrawing substituent.

Table 1. Rate constants for the oxidation by monomeric and polymer-bound flavins

Flavin	k_2/M^{-1} s^{-1}		k_3'/M^{-2} s^{-1}	
	BzlNH[a]	$CH_3\bar{C}HNO_2$[b]	GSH[c]	PhSH[b]
3-MeFl	32.4	($<10^{-7}$)	1.98	(<1)
8α-AcHisFl	48.1	($<10^{-7}$)	2.59	(<1)
8α-PyFl	363	4.8×10^{-4}	4.29	152
4VP-Fl-Dod-0	277	0.642	9500	31100

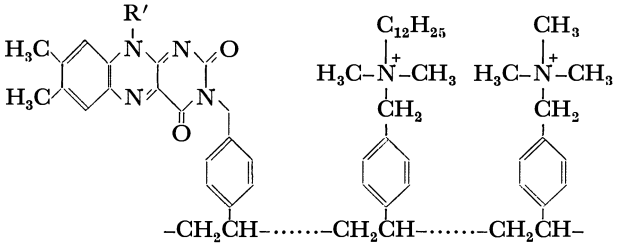

Scheme 1.

NADH analogues decompose rapidly into tetrahydronicotinamides in acidic pH region where imidazole is protonated,[15] making it impossible to evaluate directly the rate constant for the reaction of BzlNH with protonated 8α-AcHisFl. We thus employed 8α-PyFl as an analogue of protonated 8α-AcHisFl. 8α-PyFl oxidizes BzlNH 11.2 times faster than 3-MeFl. On the other hand, immobilization of the 8α-PyFl unit in the quaternized 4VP polymers is insignificant as regards the enhancement of the oxidative reactivity of flavin toward BzlNH. The reaction is presumably accelerated by protonation of 8α-histidyl group and almost unaffected by polyelectrolyte reaction environments.

Oxidation of 1-Nitroethanide Ion. Although D-amino acid oxidase (flavoenzyme) rapidly oxidizes 1-nitro-1-alkanide ion to the corresponding aldehydes and nitrite ion (Eq. 2),[16] no corresponding nonenzymatic reaction is considered to occur under ambient reaction conditions.[6] Neither 3-MeFl nor 8α-AcHisFl can oxidize

$$Fl + CH_3\bar{C}HNO_2 \xrightarrow{OH^-} FlH^- + CH_3CHO + NO_2^- \quad (2)$$

1-nitroethanide ion under the present reaction conditions, the second-order rate constant being presumed to be smaller than 10^{-7} M^{-1} s^{-1} (Table 1). On the other hand, oxidation of 1-nitroethanide ion by 8α-PyFl was easily detected under the same reaction conditions, the rate constant being augmented by more than three orders of magnitude relative to that of 3-MeFl. Yokoe and Bruice[6] reported that 3,10-dimethyl-8-cyanoisoalloxazine, an electron-deficient isoalloxazine with a positively-shifted poralographic half-wave potential, is able to oxidize 1-nitro-1-alkanide ion with $k_2=(2—5)\times10^{-3}$ M^{-1} s^{-1}. The k_2 value for 8α-PyFl (4.8×10^{-4} M^{-1} s^{-1}) is thus smaller by only one order of magnitude than that for 3,10-dimethyl-8-cyanoisoalloxazine.

The second-order rate constants were further enhanced by immobilization of the 8α-PyFl unit in the quaternized 4VP polymers. For example, the k_2 value for 4VP-Fl-Dod-20 is augmentated by 10^7 fold and 3×10^3 fold in comparison to those of 3-MeFl and 8α-PyFl, respectively, exceeding even that of 3,10-dimethyl-8-cyanoisoalloxazine by two to three orders of magnitude. The result is in contrast to the trend observed in flavin oxidation of BzlNH. Since the reaction rate for polymer-bound flavin was first-order in flavin and 1-nitroethanide ion under the employed reaction conditions (footnotes, Table 1), the reaction route is not apparently changed by immobilization of the 8α-PyFl unit in the cationic polymers.

Oxidation of Thiols. The oxidation of thiols by the conventional flavins (Eq. 3) is first-order in flavin and second-order in thiols.[6,17] The reaction of the

$$Fl + 2RSH \xrightarrow{-H^+} FlH^- + RSSR \quad (3)$$

monomeric flavins with GSH was confirmed to be of second-order in GSH (Fig. 1), the apparent third-order rate constants ($k_3'=v_{obsd}/[\text{flavin}][RSH]^2_{total}$) increasing in the order, 3-MeFl<8α-AcHisFl<8α-PyFl. Although aliphatic thiols such as GSH and 2-mercaptoethanol are slowly oxidized by flavin, thiophenol is not oxidized under ambient reaction conditions unless the electron-deficient isoalloxazine is employed.[6] As expected, oxidation of PhSH by 3-MeFl and 8α-AcHisFl could not be detected under the present reaction conditions, but that by 8α-PyFl was detected accurately to give $k_3'=152$ M^{-2} s^{-1}. The k_3' value for 3,10-dimethyl-8-cyanoisoalloxazine determined under the comparable reaction conditions is 5×10^4 M^{-2} s^{-1},[6] so that the k_3' value for 8α-PyFl is smaller by about two orders of magnitude than that for the electron-deficient iso-

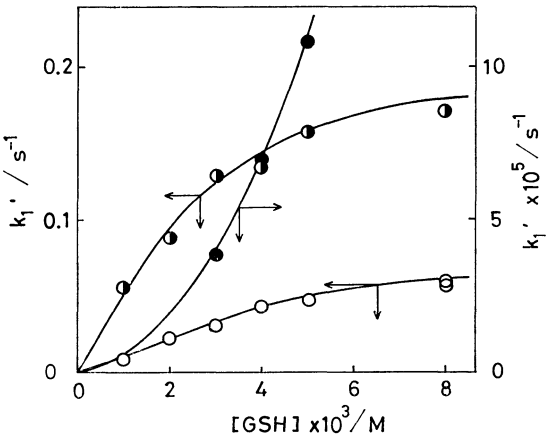

Fig. 1. Plots of k_1' as a function of GSH concentration. (●) 8α-PyFl; (○) 4VP-Dod-0; (◑) 4VP-Fl-Dod-20.

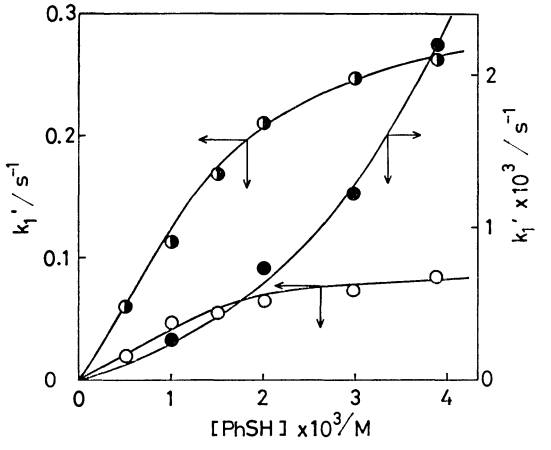

Fig. 2. Plots of k_1' as a function of PhSH concentration. (●) 8α-PyFl; (○) 4VP-Fl-Dod-0; (◑) 4VP-Fl-Dod-20.

alloxazine with an 8-cyano group.

Plots of pseudo first-order rate constant ($k_1'=v_{obsd}$/[flavin]) *vs.* thiol concentration are given in Figs. 1 and 2. In contrast to the second-order dependence of conventional flavin on thiol concentrations, the pseudo first-order rate constants (k_1') for 4VP-Fl-Dod-0 and 4VP-Fl-Dod-20 showed a saturation phenomenon which is essentially approximated by sigmoid curves. The result indicates that the oxidation by polymer-bound flavins (polymer-Fl) proceeds *via* complexation as shown by

$$\text{polymer-Fl} + 2\text{RSH} \underset{K_m}{\rightleftharpoons} \text{polymer-Fl}\cdot(\text{RSH})_2 \xrightarrow[k_{cat}]{} \text{polymer-FlH}^- + \text{RSSR} \quad (4)$$

where K_m is the equilibrium constant for dissociation of polymer-Fl·RSH_2 complex ($=$[polymer-Fl][RSH]$^2_{total}$/[polymer-Fl·$(RSH)_2$]) and k_{cat} the first-order intra-complex reaction rate constant. If we assume that [flavin]$\ll$[RSH]$_{total}$, the corresponding rate equation can be expressed by

$$v_{obsd} = k_1'[\text{polymer-Fl}] = \frac{k_{cat}[\text{polymer-Fl}][\text{RSH}]^2_{total}}{K_m + [\text{RSH}]^2_{total}} \quad (5)$$

The theoretical plot of k_1' *vs.* [RSH]$_{total}$ gives a sigmoid curve. Following the derivation of the Lineweaver-Burk equation from the Michaelis-Menten equation, Eq. 5 can be re-written as follows which gives the linear relation between $1/k_1'$ and $1/[\text{RSH}]^2$.

$$\frac{1}{k_1'} = \frac{1}{k_{cat}} + \frac{K_m}{k_{cat}} \cdot \frac{1}{[\text{RSH}]^2_{total}} \quad (6)$$

The plots (Figs. 3 and 4) show fairly good linearity ($r<0.98$). The slope (K_m/k_{cat}) and the intercept ($1/k_{cat}$) were determined by least-squares computation. The k_{cat} and K_m values are summarized in Table 2. The apparent third-order rate constants ($k_3'=v_{obsd}$/[Polymer-Fl][RSH]$^2_{total}$) at [RSH]$_{total}=1.00\times10^{-3}$M are given in Table 1.

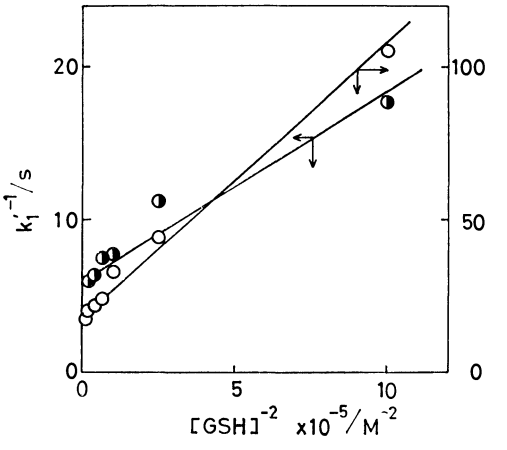

Fig. 3. Plots of $k_1'^{-1}$ *versus* $[GSH]^{-2}$. (○) 4VP-Fl-Dod-0; (◑) 4VP-Fl-Dod-20.

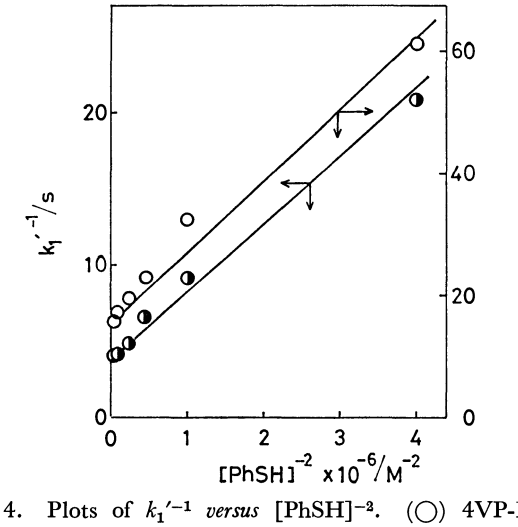

Fig. 4. Plots of $k_1'^{-1}$ *versus* $[PhSH]^{-2}$. (○) 4VP-Fl-Dod-0; (◑) 4VP-Fl-Dod-20.

Examination of the apparent third-order rate constant (k_3') reveals that (1) the rate augmentation of 10^3—10^4 fold is achieved by immobilization of 8α-PyFl unit in the quaternized 4VP polymers and (2) the rate constants increase with increase in the dodecyl group content.

Flavin immobilized in the quaternized 4VP polymers

Table 2. Kinetic parameters for the oxidation of GSH and PhSH by polymer-bound flavins

Flavin	GSH			PhSH

via 8α-position gives rate constants greater than flavin immobilized in cationic polystyrene *via* 3-position.[18] Since oxidation of GSH and PhSH by flavin immobilized in cationic polystyrene shows a simple second-order dependence upon GSH and PhSH under the comparable reaction conditions,[18,19] the improved reactivity of 8α-PyFl unit in 4VP polymers should be rationalized in terms of the efficient complexation with thiol substrates. Kinetic parameters (Table 2) indicate that 4VP-Fl-Dod-20 which is classified as a more hydrophobic polymer possesses k_{cat} values greater than 4VP-Fl-Dod-0 by factors of 3—4. On the other hand, no significant difference could be found for K_m values. This suggests that the hydrophobicity of 4VP polymer is related to the efficiency of intra-complex reaction and not to the binding efficiency.

Discussion

The oxidative reactivity of flavin was not largely improved by introduction of histidine into 8α-position.[12] The present study established that 8α-PyFl employed as an analogue of protonated 8α-AcHisFl exhibits enhanced reactivities toward several substrates. This indicates that the reactivity of flavin covalently-linked to enzymes *via* the histidine residue can also be enhanced in acidic pH region (pK_a of histidine linked to the 8α-position is estimated to be 6.9).[20]

Shinkai *et al.* reported the micellar effects on flavin oxidation.[21-23] In general, the reaction of flavin and NADH analogue is affected to a smaller extent by surfactant micelles,[21] whereas flavin oxidation of anionic species such as carbanions and thiolates is remarkably facilitated by cationic micelles.[22,23] The marked rate acceleration is rationalized in terms of enhanced local concentration of anions by interaction with micellar cationic surface and activation of anions by desolvation in micellar hydrophobic environment.[24,25] The results (Table 1) indicate that oxidation of 1-nitroethanide ion, GSH, and PhSH is facilitated considerably by immobilization of 8α-PyFl structure in the cationic 4VP polymer, the k_2 value for flavin oxidation of BzlNH being hardly improved. The trend is in line with the micellar effects. The marked rate acceleration might be caused by the high cationic charge density along the polymer chain which concentrates anionic reactant species and by polymeric hydrophobic environment.

Cationic polystyrene polymers which immobilize flavin *via* 3-position were synthesized (Scheme 1).[26] The reaction of NADH (polyanionic species) with the immobilized flavin proceeded according to Michaelis-Menten kinetics.[26] However, oxidation of 1-nitroethanide ion, GSH, and PhSH showed no saturation phenomenon.[18,19,27] This indicates that the reaction proceeds according to a simple second-order path, or the dissociation constant (K_m) is greater than the employed reactant concentrations even if the reaction occurs *via* complexation. In contrast, oxidation of GSH and PhSH by flavin immobilized in the cationic 4VP polymers gave distinct saturation curves under comparable reaction conditions (Figs. 1 and 2). It is not clear why quaternized 4VP polymers adsorb GSH and PhSH more efficiently than cationic polystyrene polymers. A possible explanation is that the flavin unit in the 4VP polymers is immobilized as a cationic unit and that in the polystyrene polymers as a neutral unit. The flavin unit in cationic polystyrenes may exist, due to the hydrophobicity, in a hydrophobic domain of the polymer which is isolated from a cationic, substrate-binding site, the enhanced substrate concentration at the cationic site thus not being reflected advantageously by the subsequent flavin oxidation process.

The results can be summarized as follows: (1) the reactivity of isoalloxazine ring is enhanced by protonation of 8α-(N_1-histidinyl) group, (2) the oxidation of carbanion and thiols is facilitated by cationic polymer environment, and (3) as a result of combination of (1) and (2), flavin immobilized in cationic 4VP polymers *via* 8α-position acts as an excellent oxidizing agent for anionic species.

Experimental

Materials. Preparation of BzlNH and 3-MeFl was reported.[26] 8-Methyl group of 3-MeFl was brominated according to the method of Walker *et al.*[20] The content of 3-methyl-8α-bromotetra-*O*-acetylriboflavin was estimated from the decrease of the C(8)–CH_3 peak in the NMR spectrum[20] (δ=2.58 ppm in $CDCl_3$) to be 64%. The mixture was used without further purification for the preparation of 8α-PyFl, 8α-AcHisFl, and 4VP-bound flavins.

In a 100 ml flask covered with aluminium foil were placed 0.3 g of brominated flavin mixture containing 3.2×10^{-4} mol of 3-methyl-8α-bromotetra-*O*-acetylriboflavin and 0.4 ml (4.8×10^{-4} mol) of pyridine which were dissolved in 60 ml of ethanol. The mixture was then heated under reflux and the progress of the reaction was monitored by TLC method (silica gel and ethyl acetate). The spot for 3-methyl-8α-bromotetra-*O*-acetylriboflavin(R_f=0.20) disappeared and a new spot attributed to 8α-PyFl appeared at the origin. After 6 h, the spot for 3-methyl-8α-bromotetra-*O*-acetylriboflavin became undetectable. Solvent ethanol was evaporated *in vacuo*, and the yellow residue was recrystallized three times

from ethanol–diisopropyl ether; mp 85—97 °C (hygroscopic), yield 0.3 g. NMR (Me_2SO-d_6): $COCH_3$, 1.60 ppm (3H), 2.40 ppm (3H), 2.20 ppm (6H); 7-CH_3, 2.52 ppm, 3H; N(3)–CH_3, 3.39 ppm, 3H; N(10)–CH_2, 4.40 ppm, 2H; CH_2 in ribityl group, 4.95 ppm, 2H; CH in ribityl group, around 5.4 ppm, 3H; 8-CH_2, 6.24 ppm, 2H; 6-H, 7.78 ppm, 1H; 9-H, 8.14 ppm, 1H; pyridine, 8.3—9.2 ppm, 5H. Found: C, 48.50; H, 4.98; N, 9.02%. Calcd for $C_{31}H_{34}N_5O_{10}Br$: 2.84 H_2O: C, 48.50; H, 4.84; N, 9.12%.

The preparation of 8α-AcHisFl was carried out according to the method of Walker *et al.*[20] 0.20 g (1.0×10^{-3} mol) of N_α-acetyl-L-histidine, and 1.28 g of brominated flavin mixture containing 1.3×10^{-3} mol of 3-methyl-8α-bromotetra-*O*-acetylriboflavin were dissolved in 30 mol of *N,N*-dimethylformamide, and the mixture was stirred at 50 °C in the presence of 1.38 g (1.0×10^{-2} mol) of powdered potassium carbonate. The progress of the reaction was monitored by TLC method (silica gel and ethyl acetate). The spot of 3-methyl-8α-bromotetra-*O*-acetylriboflavin became undetectable after 48 h. The solvent was evaporated *in vacuo*, the orange residue being taken with 100 ml of chloroform. The chloroform layer separated was washed with 50 ml of 0.5 M phosphate buffer solution to extract 8α-AcHisFl and unreacted N_α-acetyl-L-histidine. The aqueous layer was then adjusted to pH 4 with acetic acid, saturated with ammonium sulfate, and then extracted four times with 100 ml of 1-butanol. The 1-butanol solution was dried over sodium sulfate for one day. The solvent was evaporated *in vavuo*, the residue being recrystallized twice from ethanol–diisopropyl ether; mp 244—247 °C, yield 0.45 g. Found: C, 49.97; H, 5.43; N, 12.02%. Calcd for $C_{34}H_{39}N_7O_9\cdot3H_2O$: C, 50.62; H, 5.25; N, 12.15%.

Polymer-bound flavins (4VP-Fl-Dod-0 and 4VP-Fl-Dod-20) were prepared from 3-methyl-8α-bromotetra-*O*-acetylriboflavin and poly(4-vinylpyridine) (MW 100000; Ko-ei Kagaku Kogyo Co.). Two grams of poly(4-vinylpyridine) were dissolved in 10 ml of *N,N*-dimethylformamide and mixed with 1.8 g of brominated flavin mixture containing 1.9×10^{-3} mol of 3-methyl-8α-bromotetra-*O*-acetylriboflavin. The reaction mixture was heated under reflux for 4 h and then poured into diisopropyl ether. The recovered polymer became orange plates when dried under reduced pressure. The composition of flavin unit was determined by the absorption spectrum method, assuming that the molar absorbancy index is equal to that of 8α-PyFl($\varepsilon=10040$ in *N,N*-dimethylformamide). The flavin content thus determined was 6 mol %. The polymer was further quaternized by propyl bromide and dodecyl bromide according to the method employed for the preparation of polysoaps.[28] The quaternized polymers were purified by extensive dialysis and the composition was estimated by means of NMR for the dodecyl unit[28] and potentiometric titration for the propyl unit. The results are given in terms of the structure of polymer-bound flavins.

Kinetics. The rates for flavin oxidation of BzlNH were estimated under aerobic conditions by following the decrease in the absorption band of BzlNH at 357 nm. The other flavin oxidation reactions were performed under anaerobic (N_2) conditions by following that of flavins at *ca.* 445 nm. Details of the methods were described in previous papers.[18,26,27] All the reactions were carried out at 30 °C (Tables 1 and 2).

As reported earlier,[6,13,22,26] flavin oxidation of BzlNH and 1-nitroethanide ion is first-order in flavin and substrate, while that of GSH and PhSH is second-order in thiol.[18] On the other hand, plots of oxidation rate *versus* thiol concentration for 4VP polymer-bound flavins show sigmoidal curves (Figs. 1 and 2).

Ring-opening Reaction of Oxiranes, Oxetanes, and Tetrahydropyran by Mercury(II) Salts and Alkyl Halides

Nanao WATANABE,** Sakae UEMURA, and Masaya OKANO*

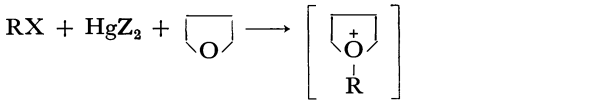
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

***Koei Chemical Co., Ltd., Joto-ku, Osaka 536*

(Received May 18, 1979)

The reaction of primary and secondary alkyl halides with mercury(II) acetate in oxiranes, oxetanes, and tetrahydropyran results in ring-opening to give the corresponding alkoxyalkyl acetates. Similar reactions with mercury(II) thiocyanate in oxetanes afford alkoxyalkyl isothiocyanate and thiocyanate, $ROCH_2C(R')_2CH_2NCS$ and $ROCH_2C(R')_2CH_2SCN$, where the isomer ratios (N/S ratios) are 82—96/4—18. It is suggested that the reactions involve the initial formation of a three-, four-, or six-membered *O*-alkyloxonium ion intermediate and subsequent attack by $XHgZ_2^-$.

It has been established that primary and secondary alkyl halides react with mercury(II) thiocyanate, acetate, and chloride in tetrahydrofuran (THF) to give the THF-incorporated compounds, $R[O(CH_2)_4]_nZ$ (n=1, 2; Z=SCN, NCS, OAc, Cl). The reaction was thought to proceed through an *O*-alkyltetrahydrofuranium ion intermediate as shown in Scheme 1.[1,2] In the case of mercury(II) thiocyanate the products were

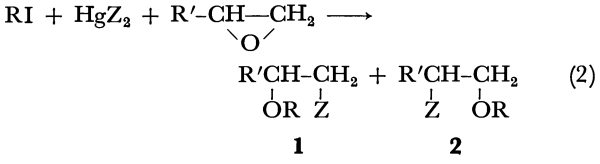


$$\longrightarrow R[O(CH_2)_4]_nZ \quad (1)$$

the isomeric alkyl thiocyanate and isothiocyanate, the results revealing the ambident reactivity of the mercury salt.[1] It is of interest to ascertain whether similar reactions occur with three-, four-, and six-membered ring cyclic ethers and how the ambident character of thiocyanate ion is reflected in the products. The results of the reactions of several alkyl halides with several mercury(II) salts in oxiranes, oxetanes, and tetrahydropyran will be described.

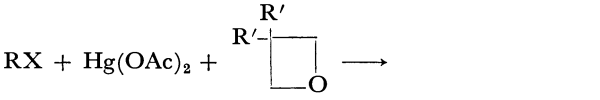
Results and Discussion

The reaction of alkyl iodides with mercury(II) acetate or chloride in several oxiranes afforded the isomeric ring-opening products (**1** and **2**) in a good to moderate yield (Scheme 2). In the cases of 1,2-epoxypropane (R'=Me) and 1,2-epoxybutane (R'=Et) the yields of **1** and **2** were nearly equal, while **1** was the sole product in the case of epichlorohydrine (R'=$ClCH_2$). From the reaction of cyclohexene oxide only *trans*-product was formed. Typical results are summarized in Table 1.



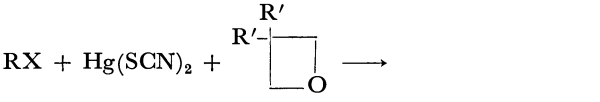
$$\mathbf{1} \qquad \mathbf{2} \quad (2)$$

Treatment of alkyl halide with mercury(II) acetate in several oxetanes afforded the oxetane-incorporated compounds (**3**) as shown in Scheme 3. Such ring-opening reaction also occurred with mercury(II)



$$ROCH_2C(R')_2CH_2OAc \quad (3)$$
$$\mathbf{3}$$

thiocyanate to give the isomeric oxetane-incorporated alkoxyalkyl isothiocyanate (**4**) and thiocyanate (**5**) (Scheme 4), and the isomer ratio (N: S=82—96: 4—18) differed very much from that of the products obtained in THF solvent (N: S=*ca.* 1: 1).[1] Typical results are shown in Table 2.



$$\mathbf{4} \qquad \mathbf{5} \quad (4)$$

The reaction in tetrahydropyran gave similar ring-opening compounds such as **6**, **7**, and **8** in low yields

Table 1. Reaction of alkyl iodide with mercury(II) salt in oxirane

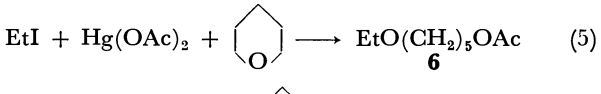
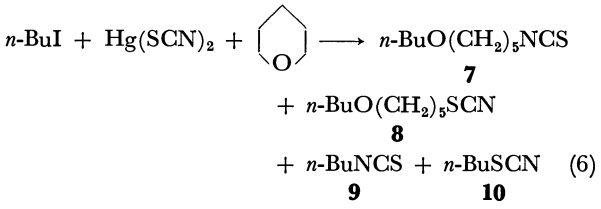
a) Determined by GLC analysis.

(Schemes 5 and 6). In the reaction with mercury(II) thiocyanate the main products were **9** and **10** and the yields of the tetrahydropyran-incorporated compounds (**7** and **8**) were *ca.* one-fifth of those of **9** and **10**. The



$$EtI + Hg(OAc)_2 + \text{oxetane} \longrightarrow \underset{\mathbf{6}}{EtO(CH_2)_5OAc} \quad (5)$$



$$n\text{-BuI} + Hg(SCN)_2 + \text{oxetane} \longrightarrow \underset{\mathbf{7}}{n\text{-BuO}(CH_2)_5NCS} + \underset{\mathbf{8}}{n\text{-BuO}(CH_2)_5SCN} + \underset{\mathbf{9}}{n\text{-BuNCS}} + \underset{\mathbf{10}}{n\text{-BuSCN}} \quad (6)$$

N/S ratios of **7** and **8** was almost the same as that of the products obtained in THF solvent.

For reactions in oxiranes, the isomer ratios of **1** and **2** are consistent with the directions of ring-opening in the addition of alcohol to such oxiranes in acidic conditions,[3] where reaction proceeds through the formation of a protonated oxirane followed by either direct attack by a nucleophile or nucleophilic attack on a carbonium ion after ring-opening.[4] The basicity of oxygen of oxiranes is known to be lower than that of THF.[5] Nevertheless the presence of the *O*-alkyloxonium ion of ethylene oxide has been confirmed by ^{1}H-NMR[6] and also assumed in the case of its acid-catalyzed polymerization.[4] The following pathways are thus conceivable

Table 3. Boiling points and analytical data of the products

Compound	Bp °C/mmHg	Found (Calcd), % C	H	N

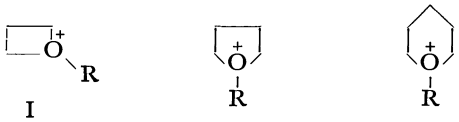
(neutral or slightly acidic condition); (a) the initial formation of an *O*-alkyloxonium ion intermediate, followed by the S_N2-like attack by $XHgZ_2^-$ as has been proposed in the reaction in THF,[1] and (b) the S_N1-like reaction of the oxonium ion with $XHgZ_2^-$ (a more carbonium ion-like mechanism than (a)). Both pathways (a) and (b) occurred concurrently in the cases of 1,2-epoxypropane and 1,2-epoxybutane, while pathway (a) predominated in the case of epichlorohydrine.

The reactions in oxetanes and tetrahydropyran appear to proceed *via* an *O*-alkyloxonium ion intermediate (I, III) as in the case of the reaction in THF, since the basicity of oxygen in these cyclic ethers is known to be similar.[5] The difference of the N/S isomer ratio of the products obtained in oxetanes with that obtained in THF may reflect the stability differences between the intermediate oxonium ions. In the reaction of alkyl halides with mercury(II) thiocyanate, it was found that the N/S ratio of the isomeric products became larger as the S_N1 reactivity of the alkyl halide increased: *i.e.*, N/S=21/79 for *n*-Bu, 85/15 for *i*-Pr, and 99/1 for PhCH(Me).[7] By comparing the stability of I, II, and III, it may be seen that I is the most unstable



I II III

and apt to react *via* a S_N1-like pathway, resulting in the preferred formation of alkyl isothiocyanate. The almost similar N/S ratio in the products obtained in THF and tetrahydropyran may reflect a similar stability of II and III. That the N/S ratios in the products obtained in the reactions of mercury(II) thiocyanate with 4-alkoxybutyl bromide and 5-ethoxypentyl bromide (*via* II and III respectively)[1] were almost the same supports this consideration.

Experimental

The isomer ratios in the products were determined by GLC. The GLC analyses were conducted on a Shimadzu 4BMPF and Yanagimoto G800-T apparatus, using SE-30(1 m), DEGS (1 m), PEG-6000 (2 m), TEA (3 m), and EGSS-X (1 m) columns (carrier gas, H_2 and N_2 respectively). The ^{1}H-NMR spectra were recorded with a JEOL MH-100 (100 MHz) and a Hitachi R-24 (60 MHz) spectrometer in CCl_4, using TMS as the internal standard.

Materials. All the organic substances were used after distillation. The commercial mercury(II) salts were used without further purification. Oxetane (bp 47—48 °C),[8] 3,3-dimethyloxetane (bp 79—80 °C),[9] and 3,3-bis(chloromethyl)-oxetane (bp 80 °C/10.5 mmHg)[10] were prepared from 3-chloropropyl acetate, 2,2-dimethyl-1,3-propanediol, and 3-chloro-2,2-bis(chloromethyl)propyl acetate, respectively, by the reported methods. All compounds except **1** and **2** (R′=Me, R=Et, Z=OAc or Cl), *trans*-1-acetoxy-2-ethoxycyclohexane, **3** (R′=H, R=Et), and **6** are new and were isolated by distillation or preparartive GLC; the boiling points and analytical data of the new compounds are shown in Table 3. The ^{1}H-NMR spectra for all compounds supported each structure.

Reaction of Alkyl Halide with Mercury(II) Acetate in Oxirane or Oxetane. The following example shows a typical procedure. A suspension of $Hg(OAc)_2$(1.62 g, 5.1 mmol) and ethyl iodide (0.78 g, 5.0 mmol) in 1,2-epoxybutane (10 ml) was stirred at 55—60 °C for 15 h, and the mixture subsequently treated as described in a previous report.[1] Distillation afforded a mixture of **1** and **2** (R′=Et, R=Et, Z=OAc) which was analyzed by ^{1}H-NMR spectroscopy. The proton signals of $-CH_2OAc$ at δ 3.88—4.14 and those of $-\overset{|}{C}HOAc$ at δ 4.70—4.96 were characteristic for **1** and **2**, respectively. GLC analysis of the crude reaction mixture using triethanolamine (TEA) column (3 m) revealed the isomer ratio of **1**: **2** to be 55: 45 and that using SE-30 column (1 m) (this column did not separate the two products) with 4-ethoxybutyl acetate as the internal standard showed the combined yield of products to be 74% (3.68 mmol) based on ethyl iodide charged.

Reaction of Alkyl Iodide with Mercury(II) Thiocyanate in Oxetane. The following example shows a typical procedure. To a suspension of $Hg(SCN)_2$(1.58 g, 4.97 mmol) in 3,3-dimethyloxetane (10 ml) was added ethyl iodide (0.87 g, 5.54 mmol) at 73—75 °C and the resulting homogeneous solution stirred for 5 h. After the work-up as described above, GLC analysis of the ether extract using PEG 6000 (2 m) column with diphenyl ether as the internal standard revealed the presence of **4** and **5** (R′=Me, R=Et) (0.27 g, 1.58 mmol, 29% yield, **4**: **5**=96: 4). Analytically pure **4** and **5** were obtained by simple distillation and determined by ^{1}H-NMR spectroscopy.

Authentic samples of **4** and **5** (R′=Me, R=Et) and **4** and **5** (R′=$ClCH_2$, R=Et) for GLC analysis were prepared as follows. A mixture of ethyl iodide (4 g, 25 mmol), $HgBr_2$ (9 g, 25 mmol), and 3,3-dimethyloxetane (2.2 g, 25 mmol) in 1,2-dichloroethane (10 ml) was maintained at 70—75 °C for 4 h with stirring. After the work-up described above, distillation gave 3-ethoxy-2,2-dimethylpropyl bromide (0.8 g 4.1 mmol, 16% yield) which reacted with KSCN (25 mmol) in DMF (5 ml) at 75—80 °C for 30 h to give two products, the retention times of which were identical with those of **4** and **5** (R′=Me, R=Et) on several different columns (**4**: **5** =17: 83). A similar procedure using 3,3-bis(chloromethyl)-oxetane afforded 1-bromo-2,2-bis(chloromethyl)-3-ethoxypropane (23% isolated yield) which then reacted with KSCN to give **4** and **5** (R′=$ClCH_2$, R=Et) (**4**: **5**=1: 99).

Reaction of Alkyl Iodide with Mercury(II) Salt in Tetrahydropyran. Treatment of ethyl iodide (5 mmol) and $Hg(OAc)_2$ (5 mmol) in tetrahydropyran (10 ml) at reflux temperature for 24 h afforded **6** in 30% isolated yield. Similarly, the reaction of butyl iodide (40 mmol) with $Hg(SCN)_2$ (40 mmol) in tetrahydropyran (15 ml) at 85—90 °C for 2 h gave **7** and **8** (7% isolated yield, **7**: **8**=49: 51) and **9** and **10** (39% isolated yield, **9**: **10**=38: 62).

Chemistry of *N*-Thiosulfinylanilines. IV.[1] Reactions of *N*-Thiosulfinylanilines with Electrophilic Reagents

Yoshio INAGAKI, Renji OKAZAKI, and Naoki INAMOTO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

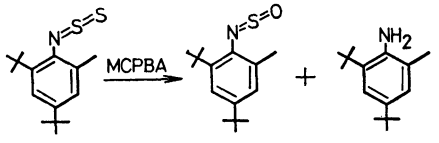
(Received May 24, 1979)

Reaction of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**1**) with *m*-chloroperbenzoic acid (MCPBA) afforded the corresponding aniline and *N*-sulfinylaniline. Reaction of MCPBA with 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo-[4.3.0]nona-2,4,9-triene equilibrated with 2,4,6-tri-*t*-butyl-*N*-thiosulfinylaniline gave 2,4,*r*-6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene *t*-7-oxide (**12**), 4,6-di-*t*-butyl-3*H*-1,2,3-benzodithiazole 2-oxide (**13**), and 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**14**). The oxide **13** was considered to be produced *via* a primary product 2,4,*r*-6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene *t*-8-oxide which was found to be unstable above −30 °C. Thermolysis of **12** affording **13**, **14**, and 2,4,6-tri-*t*-butylaniline demonstrated oxygen or sulfur migration in the thiosulfinate type compound. Bromine reacted with **1** to give bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide probably *via* a thionitroso intermediate. Neither trimethyloxonium tetrafluoroborate nor trimethylsilyl chloride reacted with **1**.

The synthesis of stable thiosulfinylamino compounds containing a new functional group (–N=S=S) has recently been reported by Barton's group[2] and us,[3] and the thermal[2,3] and photochemical behavior[3] has been delineated. Since the reactivity of thiosulfinylamino group towards electrophilic reagents has not been explored except for acid hydrolysis,[2] we investigated the reaction of stable *N*-thiosulfinylanilines with *m*-chloroperbenzoic acid, bromine, and other electrophiles, which is the subject of this paper.[4]

Results and Discussion

Reaction with m-*Chloroperbenzoic Acid (MCPBA).* Reaction of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**1**) with an equimolar amount of MCPBA afforded 2,4-di-*t*-butyl-6-methyl-*N*-sulfinylaniline (**2**) and 2,4-di-*t*-butyl-6-methylaniline (**3**) in 30.8 and 41.3% yields, respectively, along with recovered **1** (14.9%).

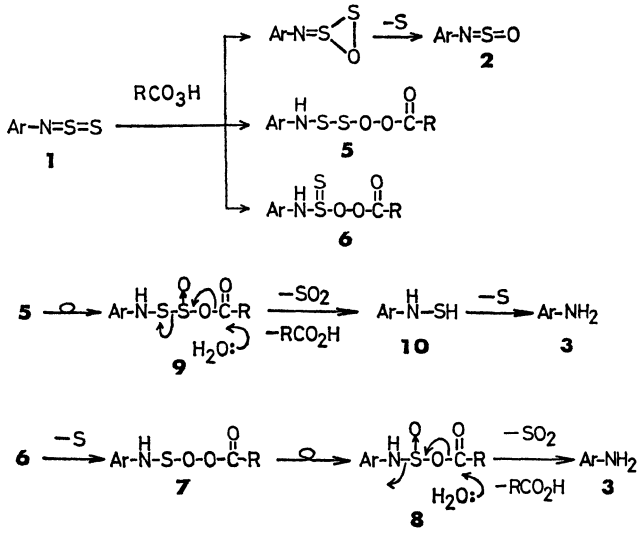


1 **2** **3**

Probable mechanism of formation of **2** and **3** is depicted in Scheme 1.

The reaction of aniline **3** with MCPBA has been reported to give 2,4-di-*t*-butyl-6-methylnitrosobenzene (**4**).[5] Therefore, the absence of **4** in the products suggests that **3** did not exist in the reaction mixture but was produced during the work-up procedure (probably hydrolysis of **8** or **9** with aqueous sodium hydrogencarbonate, see Experimental). The sulfinylaniline (**2**) was stable under the work-up conditions not to be hydrolyzed to the aniline (**3**).

Since a peroxy acid is known to attack sulfur atom of a thioketone,[6] the initial formation of **5** seems probable. The intermediate **5** would rearrange into **9**, which is considered to be hydrolyzed to give thiohydroxylamine (**10**), sulfur dioxide, and *m*-chlorobenzoic acid in analogy to acid hydrolysis of an acid anhydride. As

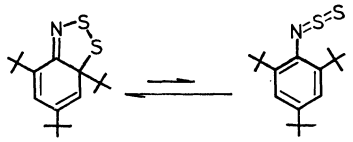


Ar=2,4-di-*t*-butyl-6-methylphenyl
R =*m*-chlorophenyl

Scheme 1.

thiohydroxylamine (**10**) has been reported to be unstable to give the corresponding amine and sulfur,[7] **10** would produce **3** as a final product. Since a peroxycarboxylic acid is a relatively strong nucleophile as to add to organic isocyanate,[8] nucleophilic attack on **1** to give **6** seems also reasonable. The intermediate **6** would lose one sulfur atom to give **7**.[9] Here also **7** probably rearranges into **8**, whose hydrolysis would give **3**, sulfur dioxide, and *m*-chlorobenzoic acid. We think that both mechanisms are plausible and have no experimental evidence at present to determine which is correct.

As the compound **11a** exists as a tautomeric mixture with *N*-thiosulfinylaniline (**11b**) as the minor component,[3] products arising from **11b** as well as **11a** are expected to be obtained in this case.

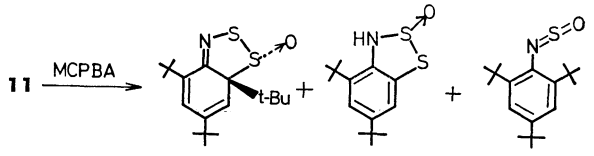


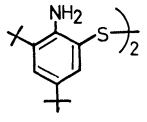
11a **11b**

Table 1. Yields of the products

Temp °C	Time min	Conversion %	Yield/% 12	13	14	13/12
39	3	92	44.8	43.9	1.3	0.98
22	30	91	36.3	44.0	5.8	1.21
0	20	98.5	34.3	42.9	6.2	1.25
−23	20	99.5	36.7	50.6	5.8	1.38
−78	40	94.3	20.6	62.2	2.9	3.02

Treatment of the dithiazole (**11**) with slightly deficient amount of MCPBA in dichloromethane gave **12**, **13**, and **14**. Yields and reaction conditions are shown in Table 1.

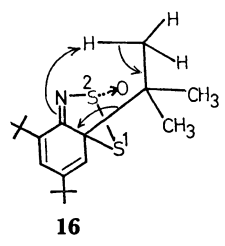




15

The structure of a new type of thiosulfinate (**12**) was determined by X-ray crystallographic analysis,[10] because conclusive evidence for that could not be obtained by spectroscopic and chemical behavior. The identity of **13** was established by the spectral data and by alkaline hydrolysis affording **15**.[11,14] The *N*-sulfinylaniline (**14**) was identified by comparison of the spectral data with those of an authentic sample obtained by the reaction of 2,4,6-tri-*t*-butylaniline with thionyl chloride. Formation of **14** is most likely attributable to the oxidation of **11b** because **1** was found to be oxidized by MCPBA under similar conditions to give the corresponding *N*-sulfinylaniline (*vide supra*). The major products **12** and **13** obviously result from the oxidation of the cyclized form **11a**. Although **11a** is the major component in the tautomeric mixture (*e.g.*, [**11a**]/[**11b**]=14.2 in CD_2Cl_2 at 35 °C),[3] much higher yields of **12** and **13** than that of **14** suggest that the reactivity of *N*-thiosulfinylaniline (**11b**) towards MCPBA is lower than that of **11a**.

As the compound **12** is stable in refluxing dichloromethane even in the presence of *m*-chlorobenzoic acid, **13** cannot be formed *via* **12** under the reaction conditions. Since the peroxy acid would attack **11a** also on the sulfur S^2 to give **16**, it is likely that **13** was produced *via* **16** which was unstable under the reaction conditions towards fast retro-ene type decomposition. Direct evidence for intermediacy of **16** was provided by monitoring the reaction spectroscopically: NMR spectrum of a mixture of **11** and MCPBA in CD_2Cl_2 at −50——40 °C showed a set of signals which seemed to be due to **16**[12] [δ 0.87 (s, 9H), 1.20 (s, 9H), 1.42 (s, 9H), 6.11 (d, J=2 Hz, 1H), and 6.98 (d, J=2 Hz, 1H)] besides two sets of signals due to **11** and **12** (the molar ratio; **11**: **12**: **16**=1: 0.67: 0.8). Upon raising the temperature, decomposition of **16** into **13** and 2-methylpropene started at −30 °C, and the intensity of the NMR signals due to **16** gradually decreased with concomitant increase in intensity of the signals due to **13** and 2-methylpropene. Finally, at 34 °C, the signals of **16** were completely replaced by those of **13** and 2-methylpropene.

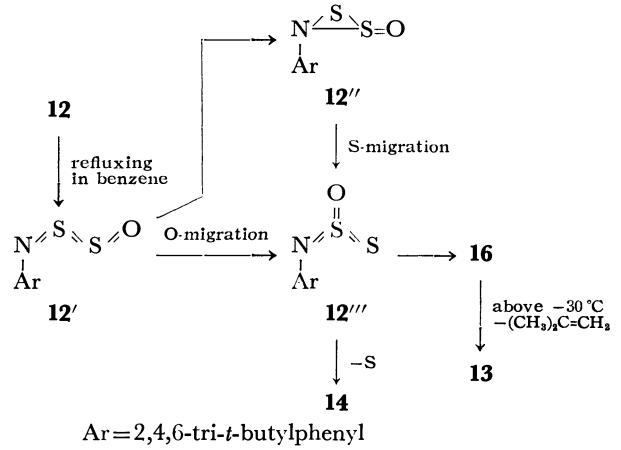


16

This unusual instability of **16** with respect to retro-ene reaction is in marked contrast with the stability exhibited by related compounds **11** and **12**.[13]

Under forced conditions (in refluxing benzene for 3.5 h), **12** gave **13** (11.6%), **14** (24.4%), and 2,4,6-tri-*t*-butylaniline (28.7%) along with recovered **12** (14.1%). Formation of **13** and **14** is noteworthy, because it indicates the occurrence of oxygen migration from S^1 to S^2 during the thermolysis. Thermal behavior of a thiosulfinate has recently attracted considerable attention because of its intriguing decomposition mode and the conclusion has been drawn from Block's extensive studies that *S*-alkyl thiosulfinates do not undergo oxygen migration like RS(O)SR′⇄RSS(O)R′.[15]

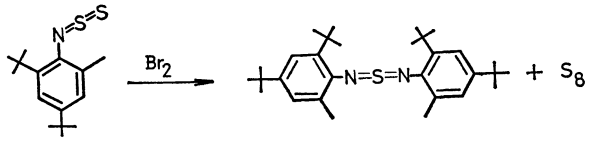
In view of this conclusion and the reversible cyclization between **11a** and **11b**,[3] the most attracting route to **13** and **14** is that involving cycloreversion of **12** to **12′** as shown in Scheme 2,[16] the driving force of which is aromatization. There still remain, however, other possibilities, because **12** is not a simple *S*-alkyl thiosulfinate for which the above conclusion by Block was obtained.[17] For example, isomerization of **12′** to **12‴** is also possible *via* **12″**, which proceeds through sulfur migration.[18] We have no experimental evidence to conclude which mechanism is actually operative. In any case, however, this reaction represents a new mode of isomerization in thiosulfinate type compounds.



Ar=2,4,6-tri-*t*-butylphenyl

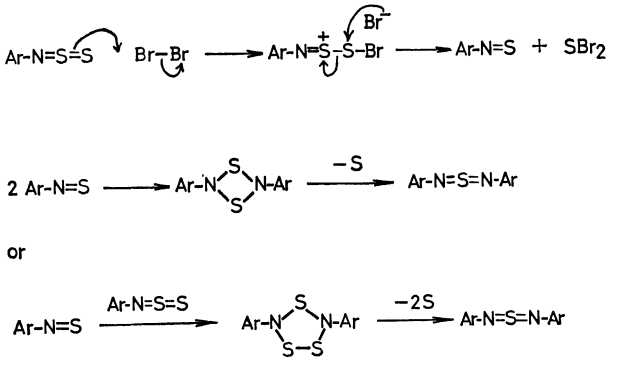
Scheme 2.

Reactions with Bromine and Other Electrophiles. Reaction of **1** with an equimolar amount of bromine afforded *N,N'*-bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide (**17**) in 64.4% yield and sulfur in 17.2% yield. Considering the formation of a sulfur diimide *via* a



1 **17**

thionitroso intermediate demonstrated in the reaction of *N*-thiosulfinylanilines with triphenylphosphine,[19] the reaction mechanism (Scheme 3) starting with electrophilic attack of bromine on the terminal sulfur atom seems probable.



Ar=2,4-di-*t*-bulyl-6-methylphenyl

Scheme 3.

In contrast to the above reactions, electrophilic reagents such as trimethylsilyl chloride or trimethyloxonium tetrafluoroborate did not react with **1** at room temperature.

Experimental

All melting points were uncorrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and EPS-3 spectrophotometers, respectively. The NMR spectra were measured with a Hitachi R-20B (60 MHz) spectrometer using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer (70 eV). Chromatographic separations were carried out using dry column chromatography (Woelm silica gel for dry column chromatography).

Reactions of N-*Thiosulfinylanilines with* m-*Chloroperbenzoic Acid (MCPBA).* In each of the following reactions, a slightly deficient amount of MCPBA was used assuming the purity of MCPBA as 80%.

*1) Reaction of 2,4-Di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (1):* To a dichloromethane solution (15 ml) of **1** (503 mg, 1.79 mmol),[3] was added dropwise at 0 °C a dichloromethane solution (8 ml) of MCPBA (395 mg) cooled to *ca.* 0 °C. After being stirred for 1.5 h at 0 °C and 1.5 h at room temperature, the reaction mixture was shaken with aq $NaHCO_3$, washed with water, and dried over $MgSO_4$. Removal of the solvent followed by dry column chromatography (DCC, silica gel, hexane) gave 75 mg (14.9%) of **1**, 146 mg (30.8%) of **2**, and 162 mg (41.3%) of **3**. These products were identified by comparison of the IR and NMR with those of authentic samples.

*2) Oxidation of 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]-nona-2,4,9-triene (11a):* Reaction at 22 °C was described below as a typical example and the reactions at other temperatures were carried out similarly. To a dichloromethane solution (20 ml) of **11a** (496 mg, 1.53 mmol)[3] was added MCPBA (280 mg) in the same solvent. The mixture was stirred for 30 min, shaken with aq $NaHCO_3$, washed with water, and dried over $MgSO_4$. After removal of the solvent, the residue was treated with hexane to give 166 mg of 4,6-di-*t*-butyl-3*H*-1,2,3-benzodithiazole 2-oxide (**13**) as colorless crystals, which showed IR and NMR spectra identical with those of an authentic sample obtained by thermolysis of **11a**.[14] The hexane-soluble part was subjected to DCC (silica gel, hexane) and three fractions (a brownish yellow fraction with the highest R_f value, an orange fraction and a yellow fraction) were obtained. From the brownish yellow fraction was recovered 44.8 mg (9.0%) of **11a**. The orange fraction gave 25 mg (5.8% based on consumed **11a**) of **14**, which was identified by comparing the IR and NMR spectra with those of an authentic sample. The most polar yellow part was again chromatographed on silica gel with hexane–CH_2Cl_2 (1 : 4) as eluent and divided into two fractions. A yellow fraction gave 172 mg (36.3% based on consumed **11a**) of 2,4,*r*-6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene *t*-7-oxide (**12**) as pale yellow crystals, which were recrystallized three times from aq methanol, mp 124.7—125.7 °C; IR (KBr): 1080 cm^{-1} (ν_{SO}); NMR (CCl_4): δ 1.05 (s, 9H), 1.18 (s, 9H), 1.37 (s, 9H), 6.01 (d, J=1.5 Hz, 1H), and 6.22 (d, J=1.5 Hz, 1H); λ_{max}^{hexane} (ε): 233 (9490) and 345 nm (2030), the latter band was very broad (293—450 nm); *m/e*: 339 (M^+, 0.7%), 307 (0.4), 291 (30.7), 266 (100), and 250 (24.6).

Found: C, 63.46; H, 8.85; N, 3.90; S, 18.82%. Calcd for $C_{18}H_{29}NOS_2$: C, 63.67; H, 8.61; N, 4.13; S, 18.88%.

Another fraction gave 8 mg of **13**. Thus total yield of **13** was 174 mg (44.0% based on consumed **11a**).

Thermolysis of 12. A benzene solution (10 ml) of **13** (163 mg, 0.480 mmol) was refluxed for 3.5 h under nitrogen. Removal of the solvent followed by preparative TLC (silica gel, hexane–CH_2Cl_2 (3 : 7)) afforded four fractions. An orange fraction with the highest R_f value gave 88.0 mg of orange crystalline material, which was purified by preparative TLC (silica gel–hexane, followed by silica gel–CCl_4) to give 36 mg (24.4%) of **14** and 21 mg of 2,4,6-tri-*t*-butylaniline (**18**). A pale yellow fraction gave 15 mg of **18**. Thus total yield of **18** was 36 mg (28.7%). From another pale yellow fraction was recovered 23 mg (14.1%) of **12**. A colorless fraction with the lowest R_f value gave 16 mg (11.6%) of **13**.

*Examination of Stability of 2,4,*r*-6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene* t*-7-Oxide (12).* A solution of **12** (126 mg, 0.37 mmol) and *m*-chlorobenzoic acid (66 mg, 0.42 mmol) in dichloromethane (6 ml) was allowed to stand for 3 h at room temperature. At this point, **13** was not detected on TLC (silica gel, CH_2Cl_2). Although the reaction mixture was subsequently refluxed for 3 min, no **13** was detected on TLC. The reaction mixture was washed with aq $NaHCO_3$ and dried over $MgSO_4$. Removal of the solvent followed by preparative TLC (silica gel, CH_2Cl_2) afforded 120 mg (96%) of **12**, which was identified by the IR and NMR spectra.

Examination of Stability of 11a. A solution of **11a** (145 mg, 0.45 mmol) and *m*-chlorobenzoic acid (79 mg, 0.50 mmol) in dichloromethane (6 ml) was stirred for 1 h at room temperature. However, neither **13** nor **12** was detected on TLC.

Reaction of 1 with Bromine. To a solution of **1** (204

mg, 0.725 mmol) in carbon tetrachloride (10 ml) was added 0.8 ml of carbon tetrachloride solution of bromine (0.909 M). The mixture was stirred for 1.5 h at 0 °C. Removal of the solvent followed by treatment with preparative TLC (silica gel, CCl_4) afforded three fractions. The first fraction gave 8 mg of sulfur. The next orange fraction gave 109 mg (64.4 %) of **17**. The third fraction gave 214 mg of partly crystalline brown tar. Its crystallization from ethyl acetate afforded 23 mg of white crystals, which could not be identified.

New Methods for Synthesis of α,β-Unsaturated Carboxylic Esters from Carbonyl Compounds Using Monoanions of Dithiocarbonates, and Dianions of Ethyl Mercaptoacetate and Ethyl 2-Mercaptopropionate

Kazuhiko TANAKA,* Nobuyuki YAMAGISHI, Rikuhei TANIKAGA, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received May 29, 1979)

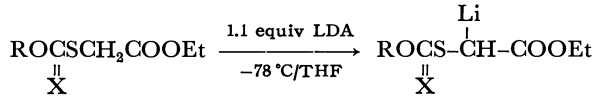
The lithium enolates of *O*-alkyl *S*-alkoxycarbonylmethyl dithiocarbonates and monothiocarbonates were found to be efficient reagents for the synthesis of α,β-unsaturated esters from carbonyl compounds by single-step procedure. The dianions of ethyl mercaptoacetate and ethyl 2-mercaptopropionate were successfully generated by treatment with 2.2 equivalents of lithium diisopropylamide (LDA) in the presence of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) at −78 °C in THF. The dianions so formed are highly reactive toward various electrophiles. The procedure leads to a novel one-pot synthesis of α,β-unsaturated carboxylic esters from carbonyl compounds.

Synthetic routes to α,β-unsaturated carboxylic esters have attracted considerable attention recently because of their importance as useful synthetic intermediates and the increase in the number of naturally occurring substances such as insect pheromones and pigments.[1,2] Ethoxycarbonylmethylenetriphenylphosphorane, an efficient reagent for the direct synthesis of α,β-unsaturated esters from carbonyl compounds, was introduced by Wittig and Haag in 1955.[3] Since then considerable efforts have been made to utilize the reagent.[2] Wadswarth and Emmons found that sodium enolate of diethyl ethoxycarbonylmethylphosphonate reacted with carbonyl compounds to give α,β-unsaturated esters in good yields.[4] Hartzell *et al.*[5] and Shimoji *et al.*[6] found a new method for the conversion of aldehydes or ketones into α,β-unsaturated esters utilizing lithium enolate of (trimethylsilyl)acetate.

We wish to report a novel and general method for the one-pot synthesis of α,β-unsaturated carboxylic esters using sulfur-stabilized carbanions and dianions.[7]

Results and Discussion

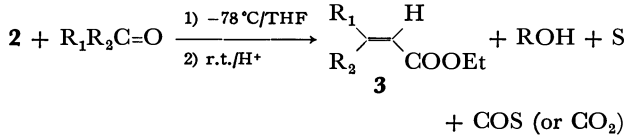
Lithium Enolates of Dithiocarbonates and Monothiocarbonates. A yellow solution of the carbanion **2a** is obtained by treatment of *O*-ethyl *S*-ethoxycarbonylmethyl dithiocarbonate (**1a**) with LDA at −78 °C in THF. It is stable at this temperature for several hours.



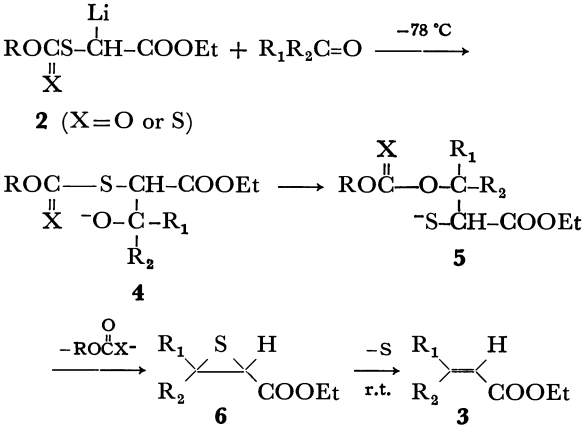
1a: R=Et; X=S
1b: R=Et; X=O
1c: R=*i*-Pr; X=S

2a: R=Et; X=S
2b: R=Et; X=O
2c: R=*i*-Pr; X=S

When the lithium enolate (**2a**) was allowed to react with a variety of carbonyl compounds, α,β-unsaturated esters (**3**) were obtained in good yields (Table 1). Since the starting materials are readily prepared from inexpensive commercial reagents, the sequence constitutes a useful one-pot synthesis of **3** from carbonyl compounds.

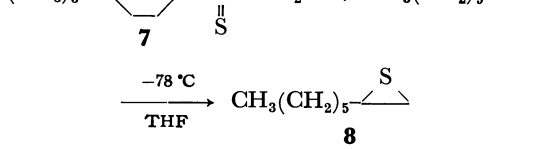


The structure of **3** was confirmed by its elemental analysis and spectral (IR, NMR) properties (see Experimental). No isomerized β,γ-unsaturated esters were detected by NMR analysis. The *E*/*Z* ratio of **3** was determined by GLC and NMR analysis; *e.g.*, the ratio of *E*-isomer to *Z*-isomer of ethyl 3-phenyl-2-butenoate (**3e**) determined by integration of the olefinic proton at δ 6.04 and δ 5.78, respectively, is 42: 58. Analysis of this material by GLC indicates a 43: 57 mixture of *E*-**3e** and *Z*-**3e**. The mechanism of this reaction consists of the intramolecular cyclization to



Scheme 1.

thiirane **6** as an intermediate, followed by spontaneous extrusion of sulfur to **3** (Scheme 1). Actually, an intermediate such as **6** could be isolated. Thus, treatment of lithium salt of *O-trans*-(4-*t*-butylcyclohexyl) *S*-methyl dithiocarbonate (**7**) with heptanal as described before gave 2-hexylthiirane (**8**) in 71% yield.[8]



Thiiranes containing strongly electron-attracting substituents such as alkoxycarbonyl or cyano groups readily extrude sulfur to afford olefins.[9]

When α-alkyl-substituted dithiocarbonates **1d** and **1e**

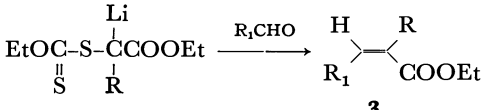
were allowed to react with LDA at −78 °C in THF, lithium enolates **2d** and **2e** were readily formed. These reagents also react with various aldehydes to produce **3** (Table 2).

1d: R=Me
1e: R=Et



3

2d: R=Me
2e: R=Et

The enolates **2d** and **2e** do not react with ketones, presumably due to steric hindrance or enolization of ketones.

Formation of Dianions and Their Synthetic Applications. We have found that the hitherto unknown dianion **10** derived from ethyl mercaptoacetate (**9**) can be generated, undergoing regioselective alkylation depending on electrophiles used. Treatment of **9** with 2.2 equiv of LDA in the presence of 2.2 equiv of TMEDA in THF at −78 °C gave soluble dianion **10**, stable at −78 °C for at least several hours. When a solution of **10** in THF was treated with an excess of alkylating agent, a facile reaction occurred both at carbon and at sulfur.

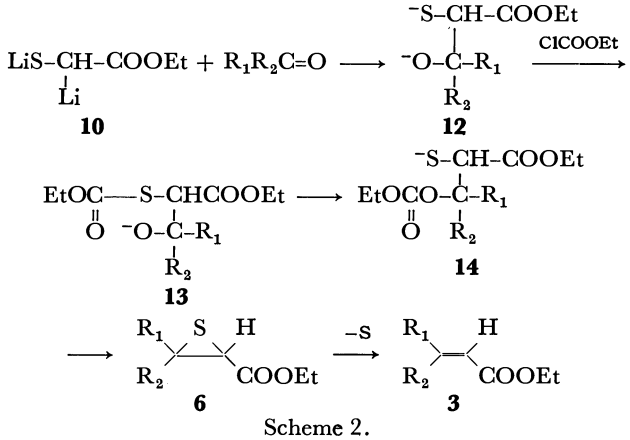
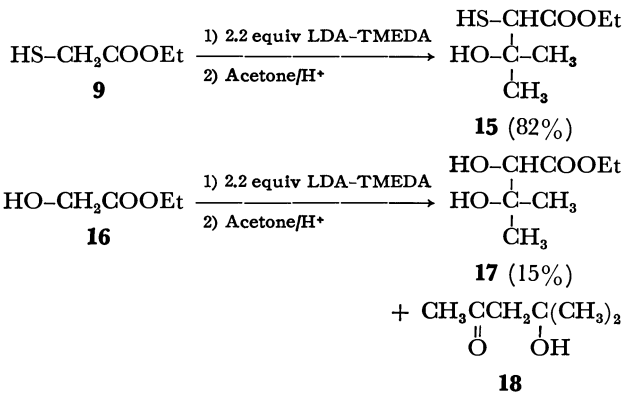
a) All reactions carried out at −78 °C on a 20 mmol scale. b) Isolated yields. c) Determined by ^{1}H-NMR and GLC. d) A mixture of THF and HMPA (8: 1 v/v) was used as a solvent.

Dianion **10** undergoes aldol-type reaction with carbonyl compounds. Thus, reaction of **10** with a variety of carbonyl compounds gave the adduct **12**, which, upon treatment with ethyl chloroformate at −78 °C, afforded **3** as the sole product in good yields after the usual work-up. Generality of this new methodology is apparent from the results summarized in Table 3. The use of ethyl chloroformate is important since no α,β-unsaturated esters can be isolated from the reaction of **10** and carbonyl compounds with *diethyl carbonate*. The low yields of monosubstituted propenoates, *i.e.*, **3u** and **3v**, are ascribed to the polymerization at the stage of thiirane formation.[10] The initial step of this reaction might be the formation of adduct **12** as shown in Scheme 2.

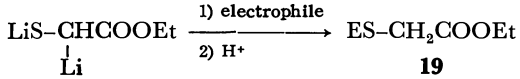


Scheme 2.

The adduct **12** should react with ethyl chloroformate to afford *S*-ethoxycarbonylated intermediate **13**, since a thiolate anion is a more powerful nucleophile than an alcoholate anion. Another intermediate such as **12** could be trapped when the reaction mixture of **10** and acetone was quenched with aqueous NH_4Cl solution at −78 °C.



In contrast, no such selective reaction of **10** was observed for oxygen analogue. The reaction of ethyl glycolate (**16**) with a base gives the addition product only in 15% yield along with the condensation product of acetone and some other unidentified products. The intermediacy of **13** in Scheme 2 is in line with the fact that lithium enolate of dithiocarbonate **2b** gives **4** (=**13**) on treatment with carbonyl compound. The regioselectivity of **10** depends upon the electrophiles used. Thus, the reaction of **10** with 1 equiv of alkyl halides afforded *S*-alkylated products in good yields, whereas **10** reacted with carbonyl compounds on α-carbon of dianion as described before.



Electrophile	E	Yield of **19**
MeI	Me	89% (**19a**)
EtBr	Et	81% (**19b**)
Propylene oxide	MeCHCH$_2$– OH	49% (**19c**)

In order to clarify the mechanism, we have investigated the effects of reaction time, temperature, and solvents in the case of 6-methyl-5-hepten-2-one. The results (Tables 4, 5, and 6) indicate that the reaction of dianion **10** is kinetically controlled process since there is no obvious effect on the *E*/*Z* ratio of **3q**. Dianion is highly reactive toward carbonyl compounds since even the α-methylsubstituted dianion **21** reacts with various ketones (Table 7), in contrast to monoanion **2d**.

Table 4. Effect of reaction time on the *E*/*Z* ratio of **3q**

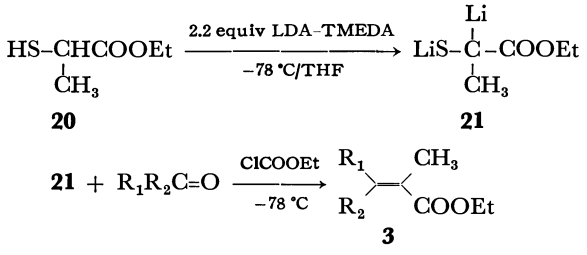
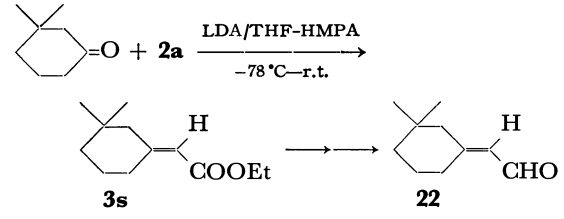
a) Reaction carried out in THF.



The methodology employed here is particularly useful synthetically since the conversion of ketones into trisubstituted propenoates is difficult.[11] In order to demonstrate the utility of our novel reactions, we have carried out the synthesis of the key intermediates for insect pheromones such as boll weevil sex pheromone (**22**), and a component of ant mandibular gland secretions (**23**).



Treatment of 3,3-dimethylcyclohexanone with **2a** at −78 °C gave the key intermediate for sex pheromones in 84% yield. Separation of *Z*-**3s** and *E*-**3s**, and conversion into the target pheromones have been established.[12] Utilizing the dianion **21**, α,β-unsaturated ester **3B** was isolated in 67% yield. The *E*- and *Z*-isomers of **3B** were separated by GLC in 98% and 95%

purity, respectively, exhibiting NMR and IR spectra identical to the reported data.[13] Hydrolysis of *E*-**3B** to the desired ant mandibular gland secretion has been reported.[13]

Experimental

General. Infrared spectra were determined on a Hitachi Model-215 spectrophotometer. Nuclear magnetic resonance spectra were determined on a JEOLCO PS-100 spectrometer. Chemical shifts are given in δ units, parts per million relative to tetramethylsilane as an internal standard. Gas chromatograms were obtained using a Varian Aerograph Model 920 instrument with a 0.15 cm × 120 cm glass column (20% Silicone DC-550 on Celite 545). Tetrahydrofuran (THF) was dried by distillation calcium hydride and by subsequent distillation from lithium aluminum hydride. Hexamethylphosphoric triamide (HMPA), diisopropylamine, and *N,N,N',N'*-tetramethylethylenediamine (TMEDA) were distilled from calcium hydride and stored over molecular sieves. All reactions were performed under a nitrogen atmosphere.

General Procedure. Reaction of Carbanion ***2a*** *with Carbonyl Compounds*: A solution of 20 mmol of **1a** in 3 ml of THF was added to a stirred solution of 22 mmol of LDA in 40 ml of THF at −78 °C. After the yellow solution had been stirred at −78 °C for 30 min, 24 mmol of carbonyl compound in 2 ml of THF was added over a 5 min period. Stirring was continued at −78 °C for 1 h and at room temperature for 1 h before it was quenched with aqueous NH_4Cl (10 ml). The mixture was poured into dilute HCl and extracted four times with ether, the combined organic layer being washed twice with brine, dried (anhydrous Na_2SO_4), and concentrated under reduced pressure. Distillation gave α,β-unsaturated esters (**3**).

Reaction of Dianion ***10*** *with Carbonyl Compounds.* To a mixture of LDA (44 mmol) and TMEDA (44 mmol) in 40 ml of THF was added a solution of 2.4 g (20 mmol) of ethyl mercaptoacetate (**9**) in 7 ml of THF at −78 °C. After being stirred for 1 h, a solution of 22 mmol of carbonyl compounds in 5 ml of THF was added and the reaction mixture was stirred at −78 °C for 2 h. Ethyl chloroformate (20 mmol) in 5 ml of THF was then added portionwise to the above solution with stirring and the mixture was kept at −78 °C for 30 min and at room temperature for 1 h before it was quenched with aqueous NH_4Cl (10 ml). The reaction mixture was poured into dilute HCl and extracted four times with ether, the combined organic layer being washed twice with brine, dried (anhydrous Na_2SO_4), and concentrated under reduced pressure. Distillation of the resulting oil gave **3**. The following α,β-unsaturated esters were prepared in a similar manner.

*Physical Properties. Ethyl 2-Pentenoate (**3a**)*: Bp 86—87 °C/70 Torr. ^{1}H-NMR (CCl_4); δ 6.86 (m, 1H, CH=C), 5.68 (m, 1H, CH=C), 4.08 (q, J=7 Hz, 3H, CH_2), 2.22 (m 2H, CH_2), 1.24 (t, J=7 Hz, 3H, CH_3), 1.10 (t, J=7 Hz, 3H, CH_3). IR (neat); 1650 cm^{-1} (C=C).

*Ethyl 3-Methyl-2-butenoate (**3b**)*: Bp 90—92 °C/100 Torr. ^{1}H-NMR (CCl_4); δ 5.52 (m, 1H, CH=C), 4.00 (q, J=7 Hz, 2H, CH_2), 2.08 (s, 1H, CH_3), 1.78 (s, 1H, CH_3), 1.16 (t, J=7 Hz, 3H, CH_3). IR (neat); 1675 cm^{-1} (C=C). Spectral data were identical with those of an authentic sample prepared from 3-methyl-2-butenoic acid and ethyl bromide in the presence of DBU in benzene.[14]

*Ethyl 3-Methyl-2-pentenoate (**3c**)*: Bp 93—97 °C/60 Torr. ^{1}H-NMR (CCl_4); δ 5.50 (m, CH=C), 4.04 (q, J=7 Hz, 2H, CH_2), 2.60 (q, J=8 Hz, CH_2 for *Z*-isomer), 2.14 (q, J=8 Hz, CH_2 for *E*-isomer), 2.06 (m, CH_3 for *E*-isomer), 1.84 (m, CH_3 for *Z*-isomer), 1.24 (t, J=7 Hz, 3H, CH_3), 1.04 (t, J=8 Hz, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 67.40; H, 10.15%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%.

*Ethyl 3-Ethyl-2-pentenoate (**3d**)*: Bp 84 °C/22 Torr. ^{1}H-NMR (CCl_4); δ 5.58 (bs, 1H, CH=C), 4.03 (q, J=7 Hz, 2H, CH_2), 2.56 (q, J=8 Hz, 2H, CH_2), 2.14 (q, J=8 Hz, 2H, CH_2), 0.9—1.3 (m, 9H, $3CH_3$). IR (neat); 1640 cm^{-1} (C=C). Found: C, 68.91; H, 10.50%. Calcd for $C_9H_{16}O_2$: C, 69.20; H, 10.32%.

*Ethyl 3-Phenyl-2-butenoate (**3e**)*: Bp 132 °C/12 Torr. ^{1}H-NMR (CCl_4); δ 7.24 (m, 5H, aromatic), 6.04 (m, CH=C for *E*-isomer), 5.78 (m, CH=C for *Z*-isomer), 4.10 (q, J=7 Hz, CH_2 for *E*-isomer), 3.88 (q, J=7 Hz, CH_2 for *Z*-isomer), 2.50 (brs, CH_3 for *E*-isomer), 2.05 (brs, CH_3 for *Z*-isomer), 1.24 (brs, CH_3 for *E*-isomer), 1.00 (brs, CH_3 for *Z*-isomer). IR

(neat); 1625 cm^{-1} (C=C). Found: C, 75.76; H, 7.42%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.52%.

*Ethyl Cyclopentylideneacetate (**3f**)*: Bp 93—96 °C/20 Torr. ^{1}H-NMR (CCl_4); δ 5.70 (m, 1H, CH=C), 4.04 (q, J=7 Hz, 2H, CH_2), 2.74 (m, 2H, CH_2), 2.40 (m, 2H, CH_2), 1.68 (m, 4H, $2CH_2$), 1.24 (t, J=7 Hz, 3H, CH_3). IR (neat); 1645 cm^{-1} (C=C). Found: C, 70.33; H, 9.23%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

*Ethyl Cyclohexylideneacetate (**3g**)*: Bp 110—112 °C/20 Torr. ^{1}H-NMR (CCl_4); δ 5.50 (brs, 1H, CH=C), 4.05 (q, J=7 Hz, 2H, CH_2), 2.84 (m, 2H, CH_2), 1.62 (m, 6H, $3CH_2$), 1.24 (t, J=7 Hz, 3H, CH_3). IR (neat); 1620 cm^{-1} (C=C). Found: C, 71.61; H, 9.44%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

*Ethyl 4-Methylcyclohexylideneacetate (**3h**)*: Bp 123—125 °C/23 Torr. ^{1}H-NMR (CCl_4); δ 5.54 (brs, 1H, CH=C), 4.05 (q, J=7 Hz, 2H, CH_2), 3.80 (m, 1H, CH), 0.8—2.4 (m, 8H, $4CH_2$), 1.25 (t, J=7 Hz, 3H, CH_3), 0.94 (d, J=6 Hz, 3H, CH_3). IR (neat); 1645 cm^{-1} (C=C). Found: C, 72.76; H, 10.13%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

*Ethyl 2-Methyl-3-phenyl-2-propenoate (**3i**)*: Bp 115—117 °C/12 Torr. ^{1}H-NMR (CCl_4); δ 7.62 (brs, CH=C for *E*-isomer), 7.26 (m, 5H, aromatic), 6.60 (brs, CH=C for *Z*-isomer), 4.18 (q, J=7 Hz, CH_2 for *E*-isomer), 4.00 (q, J=7 Hz, CH_2 for *Z*-isomer), 2.04 (s, 3H, CH_3), 1.28 (t, J=7 Hz, CH_3 for *E*-isomer), 1.02 (t, J=7 Hz, CH_3 for *Z*-isomer). IR (neat); 1635 cm^{-1} (C=C). Found: C, 75.95; H, 7.54%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

*Ethyl 2-Ethyl-3-phenyl-2-propenoate (**3j**)*: Bp 135—137 °C/11 Torr. ^{1}H-NMR (CCl_4); δ 7.52 (s, CH=C for *E*-isomer), 7.15 (m, 5H, aromatic), 6.48 (brs, CH=C for *Z*-isomer), 4.16 (q, J=7 Hz, CH_2 for *E*-isomer), 4.00 (q, J=7 Hz, CH_2 for *Z*-isomer), 2.40 (m, 2H, CH_2), 1.10 (m, 6H, $2CH_3$). IR (neat); 1640 cm^{-1} (C=C). Found: C, 76.28; H, 7.90%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

*Ethyl 2,4-Dimethyl-2-pentenoate (**3k**)*:[15] Bp 90—97 °C/55 Torr. ^{1}H-NMR (CCl_4); δ 6.45 (dq, CH=C for *E*-isomer), 5.60 (dq, CH=C for *Z*-isomer), 4.10 (m, 2H, CH_2), 3.24 (m, CH for *Z*-isomer), 2.60 (m, CH for *E*-isomer), 1.80 (m, 3H, CH_3), 1.28 (t, J=7 Hz, 3H, CH_3), 1.00 (t, J=7 Hz, 6H, $2CH_3$).

*Ethyl 2-Ethyl-4-methyl-2-pentenoate (**3l**)*: Bp 94—100 °C/63 Torr. ^{1}H-NMR (CCl_4); δ 6.44 (m, CH=C for *E*-isomer), 5.54 (m, CH=C for *Z*-isomer), 4.14 (m, 2H, CH_2), 3.12 (m, CH for *Z*-isomer), 2.64 (m, CH for *E*-isomer), 2.24 (m, 2H, CH_2), 1.28 (t, J=7 Hz, 3H, CH_3), 1.00 (m, 9H, $3CH_3$). IR (neat); 1620 cm^{-1} (C=C). Found: C, 70.51; H, 10.58%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65%.

*Ethyl 3-Phenyl-2-pentenoate (**3m**)*: Bp 98 °C/1.5 Torr. ^{1}H-NMR (CCl_4); δ 7.2—7.5 (m, 5H, aromatic), 5.96 (s, 1H, CH=C), 4.15 (q, J=7 Hz, 2H, CH_2), 3.11 (q, J=7 Hz, 2H, CH_2), 1.30 (t, J=7 Hz, 3H, CH_3), 1.08 (t, J=7 Hz, 3H, CH_2). IR (neat); 1620 cm^{-1} (C=C).

*Ethyl 3-Methyl-2-hexenoate (**3n**)*: Bp 75—76 °C/17 Torr. ^{1}H-NMR (CCl_4); δ 5.61 (brs, 1H, CH=C), 4.09 (q, J=7 Hz, 2H, CH_2), 1.88—2.62 (m, 5H, CH_2 and CH_3), 1.3—1.7 (m, 2H, CH_2), 1.25 (t, J=7 Hz, 3H, CH_3), 0.96 (m, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 69.04; H, 10.32%. Calcd for $C_9H_{16}O_2$: C, 69.20; H, 10.32%.

*Ethyl 3-Methyl-2-heptenoate (**3o**)*: Bp 97—98 °C/13 Torr. ^{1}H-NMR (CCl_4); δ 5.40 (brs, 1H, CH=C), 3.95 (q, J=7 Hz, 2H, CH_2), 1.03—2.32 (m, 5H, CH_2 and CH_3), 1.2—1.6 (m, 4H, $2CH_2$), 1.22 (t, J=7 Hz, 3H, CH_3), 0.92 (m, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 70.66; H, 10.68%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

*Ethyl 3-Cyclohexyl-2-butenoate (**3p**)*: Bp 121—123 °C/18 Torr. ^{1}H-NMR (CCl_4); δ 5.54 (m, 1H, CH=C), 4.06 (q, J=7 Hz, 2H, CH_2), 3.4—3.7 (m, 1H, CH), 1.0—2.1 (m, 13H, CH_2 and CH_3), 1.24 (t, J=7 Hz, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C).

*Ethyl 3,7-Dimethyl-2,6-octadienoate (**3q**)*: Bp 75—80 °C/2.3 Torr. ^{1}H-NMR (CCl_4); δ 5.52 (m, 1H, CH=C), 4.9—5.2 (m, 1H, CH=C), 4.03 (q, J=7 Hz, 2H, CH_2), 1.86—2.58 (m, 7H, $2CH_2$ and CH_3), 1.68 (s, 3H, CH_3), 1.61 (s, 3H, CH_3), 1.24 (t, J=7 Hz, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 73.43; H, 10.11%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

*Ethyl 3,5-Dimethyl-2,4-hexadienoate (**3r**)*: Bp 90 °C/23 Torr. *E*-isomer: ^{1}H-NMR (CCl_4); δ 5.64 (m, 1H, CH=C), 5.52 (m, 1H, CH=C), 4.07 (q, J=7 Hz, 2H, CH_2), 2.19 (s, 3H, CH_3), 1.83 (m, 6H, $2CH_3$), 1.25 (t, J=7 Hz, 3H, CH_3). IR (neat); 1625 cm^{-1} (C=C). *Z*-isomer: ^{1}H-NMR (CCl_4); δ 6.42 (brs, 1H, CH=C), 5.52 (brs, 1H, CH=C), 4.02 (q, J=7 Hz, 2H, CH_2), 2.00 (s, 3H, CH_3), 1.85 (s, 3H, CH_3), 1.73 (s, 3H, CH_3), 1.22 (t, J=7 Hz, 3H, CH_3). IR (neat); 1630 cm^{-1} (C=C).

*Ethyl 3,3-Dimethylcyclohexylideneacetate (**3s**)*: A solution of LDA (22 mmol) in a mixture of 40 ml of THF and 5 ml of HMPA was stirred under nitrogen at −78 °C and 20 mmol of *O*-ethyl *S*-ethoxycarbonylmethyl dithiocarbonate (**1a**) in 3 ml of THF was added dropwise. After the yellow solution had been stirred for 30 min, 2.78 g (20 mmol) of 3,3-dimethylcyclohexanone in 2 ml of THF was added over a 5 min period. The mixture was stirred at −78 °C for 1 h and at room temperature for 1 h. The usual work-up and distillation gave **3s** in 84% yield. Bp 113 °C/23 Torr. ^{1}H-NMR (CCl_4); δ 5.52 (m, 1H, CH=C), 4.06 (q, J=7 Hz, 2H, CH_2), 1.2—2.8 (m, 8H, $4CH_2$), 1.24 (t, J=7 Hz, 3H, CH_3), 0.92 (m, 6H, $2CH_3$). MS (20 eV) *m/e* 196 (M^+). IR (neat); 1645 cm^{-1} (C=C).

*Ethyl (*E*)-3-Phenyl-2-propenoate (**3t**)*: Bp 86 °C/0.7 Torr. ^{1}H-NMR (CCl_4); δ 7.64 (d, J=16 Hz, 1H, CH=C), 7.2—7.6 (m, 5H, aromatic), 6.36 (d, J=16 Hz, 1H, CH=C), 4.20 (q, J=7 Hz, 2H, CH_2), 1.32 (t, J=7 Hz, 3H, CH_3). IR (neat); 1630 cm^{-1} (C=C). Found: C, 74.86; H, 7.03%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%.

*Ethyl (*E*)-2-Hexenoate (**3u**)*: Bp 61 °C/17 Torr. ^{1}H-NMR (CCl_4); δ 6.80 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.72 (d, J=16 Hz, 1H, CH=C), 4.11 (q, J=7 Hz, 2H, CH_2), 2.20 (m, 2H, CH_2), 1.4—1.8 (m, 2H, CH_2), 1.28 (t, J=7 Hz, 3H, CH_3), 0.98 (t, J=7 Hz, CH_3). IR (neat); 1650 cm^{-1} (C=C).

*Ethyl 2-Nonenoate (**3v**)*: Bp 50 °C/1 Torr. ^{1}H-NMR (CCl_4); δ 6.88 (dt, J=7 Hz, 16 Hz, CH=C), 5.72 (d, J=16 Hz, 1H, CH=C), 4.12 (q, J=7 Hz, 2H, CH_2), 2.0—2.2 (m, 2H, CH_2), 1.1—1.8 (m, 8H, $4CH_2$), 0.9 (m, 3H, CH_3). IR (neat); 1645 cm^{-1} (C=C).

*Ethyl 2,3-Dimethyl-2-butenoate (**3w**)*: Bp 105—106 °C/100 Torr. ^{1}H-NMR (CCl_4); δ 4.10 (q, J=7 Hz, 2H, CH_2), 1.8—2.0 (m, 9H, $3CH_3$), 1.28 (t, J=7 Hz, 3H, CH_3). IR (neat); 1635 cm^{-1} (C=C).

*Ethyl 2,3-Dimethyl-2-pentenoate (**3x**)*: Bp 67—72 °C/14 Torr. ^{1}H-NMR (CCl_4); δ 4.15 (q, J=7 Hz, 2H, CH_2), 2.28 (m, 2H, CH_2), 1.93 (m, 6H, $2CH_3$), 1.28 (t, J=7 Hz, 3H, CH_3), 1.04 (t, J=7 Hz, 3H, CH_3). IR (neat); 1630 cm^{-1} (C=C).

*Ethyl 2,3-Dimethyl-2-heptenoate (**3y**)*: Bp 90—94 °C/13 Torr. *E*-isomer: ^{1}H-NMR (CCl_4); δ 4.02 (q, J=7 Hz, 2H, CH_2), 2.09 (m, 2H, CH_2), 1.93 (m, 3H, CH_3), 1.80 (m, 3H, CH_3), 1.2—1.6 (m, 4H, $2CH_2$), 1.26 (t, J=7 Hz, 3H, CH_3), 0.93 (m, 3H, CH_3). IR (neat); 1630 cm^{-1} (C=C). *Z*-isomer: ^{1}H-NMR (CCl_4); δ 4.03 (q, J=7 Hz, 2H, CH_2), 2.30 (m, 2H, CH_2), 1.74 (m, 6H, $2CH_3$), 1.2—1.6 (m, 4H, $2CH_2$), 1.25 (t, J=7 Hz, 3H, CH_3), 0.91 (m, 3H, CH_3). IR (neat); 1630 cm^{-1} (C=C). Found: C, 71.72; H, 11.00%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%.

*Ethyl 2-Cyclohexylidenepropionate (**3z**)*: Bp 104—107 °C/10 Torr. ^{1}H-NMR (CCl_4); δ 4.10 (q, 2H, CH_2), 2.0—2.6 (m, 4H, $2CH_2$), 1.80 (s, 3H, CH_3), 1.58 (m, 6H, $3CH_2$), 1.26 (t, J=7 Hz, 3H, CH_3). IR (neat); 1625 cm^{-1} (C=C).

*Ethyl 2-Methyl-2-nonenoate (**3A**)*: Bp 109—114 °C/14 Torr. IR (neat); 1650 cm^{-1} (C=C). *E*-isomer: ^{1}H-NMR (CCl_4); δ 6.64 (m, 1H, CH=C), 4.10 (q, J=7 Hz, 2H, CH_2), 2.16 (m, 2H, CH_2), 1.98 (s, 3H, CH_3), 1.1—1.6 (m, 11H, CH_2 and CH_3), 0.89 (m, 3H, CH_3). *Z*-isomer: ^{1}H-NMR (CCl_4); δ 5.83 (m, 1H, CH=C), 4.12 (q, J=7 Hz, 2H, CH_2), 2.42 (m, 2H, CH_2), 1.86 (s, 3H, CH_3), 1.0—1.6 (m, 11H, CH_2 and CH_3), 0.90 (m, 3H, CH_3).

*Ethyl 2,4-Dimethyl-2-hexanoate (**3B**)*: A solution of ethyl 2-mercaptopropionate (**20**) (20 mmol) in 3 ml of THF was added dropwise to a magnetically stirred solution of LDA (44 mmol) and TMEDA (44 mmol) at −78 °C. After the mixture had been stirred at this temperature for 1 h, a solution of 2-methylbutyraldehyde (24 mmol) in 3 ml of THF was added and the resulting pale yellow mixture was maintained at −78 °C for 2 h. After the addition of a solution of ethyl chloroformate (20 mmol) in 5 ml of THF was complete, the reaction mixture was stirred at −78 °C for 30 min and then at room temperature for 1 h. Work-up and distillation gave a mixture of *E*- and *Z*-isomers of **3B** in 67% yield, which was readily separated by GLC. Bp 110—115 °C/68 Torr. IR (neat); 1645 cm^{-1} (C=C). *E*-isomer: ^{1}H-NMR (CCl_4); δ 6.36 (m, 1H, CH=C), 4.08 (q, J=7 Hz, 2H, CH_2), 2.37 (m, 1H, CH), 1.76 (s, 3H, CH_3), 1.25 (m, 5H, CH_2 and CH_3), 0.98 (d, J=7 Hz, 3H, CH_3), 0.86 (t, 3H, CH_3). *Z*-isomer: ^{1}H-NMR (CCl_4); δ 5.52 (m, 2H, CH_2), 4.10 (q, 2H, CH_2), 3.00 (m, 1H, CH), 1.86 (s, 3H, CH_3), 1.29 (m, 5H, CH_2 and CH_3), 0.7—1.0 (m, 6H, $2CH_3$). Found: C, 70.42; H, 10.79%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65%.

Alkylation of Dianion. A solution of alkyl halide (80 mmol for dialkylation; 20 mmol for monoalkylation) was added dropwise to a solution of dianion (20 mmol) generated at −78 °C in THF in the same way as described above. After the solution had been stirred at −78 °C for 30 min and at room temperature for 1 h, the mixture was quenched with 10 ml of aqueous solution of NH_4Cl. The product was purified by distillation.

*Ethyl 2-Methylthiopropionate (**11a**)*: Bp 66—68 °C/15 Torr. ^{1}H-NMR (CCl_4); δ 4.12 (q, J=7 Hz, 2H, CH_2), 3.18 (q, J=7 Hz, 1H, CH), 2.10 (s, 3H, CH_3), 1.2—1.4 (m, 6H, $2CH_3$). IR (neat); 1725 cm^{-1} (COO). Found: C, 48.70; H, 8.36; S, 21.61%. Calcd for $C_6H_{12}O_2S$: C, 48.62; H, 8.16; S, 21.63%.

*Ethyl 2-Ethylthiobutanoate (**11b**)*: Bp 91—92.5 °C/14 Torr. ^{1}H-NMR (CCl_4); δ 4.09 (q, J=7 Hz, 2H, CH_2), 3.00 (t, J=7 Hz, 1H, CH), 2.55 (q, J=7 Hz, 2H, CH_2), 1.6—2.0 (m, 2H, CH_2), 1.1—1.4 (m, 6H, $2CH_3$), 0.97 (t, J=7 Hz, 3H, CH_3). IR (neat); 1720 cm^{-1} (COO).

*Ethyl 2-Allylthio-4-pentenoate (**11c**)*: Bp 115 °C/16 Torr. ^{1}H-NMR (CCl_4); δ 5.40—5.90 (m, 2H, CH=C), 5.05 (m, 4H, $2CH_2$=C), 4.09 (q, 2H, CH_2), 3.00—3.30 (m, 3H, CH_2 and CH), 2.2—2.8 (m, 2H, CH_2), 1.27 (t, J=7 Hz, 3H, CH_3). IR (neat); 1720 (COO), 1635 cm^{-1} (C=C).

*Ethyl 3-Hydroxy-2-mercapto-3-methylbutanoate (**15**)*: Bp 115 °C/27 Torr. ^{1}H-NMR (CCl_4); δ 4.22 (q, J=7 Hz, 2H, CH_2), 3.00—3.20 (m, 2H, OH and CH), 2.22 (d, J=9 Hz, 1H, SH), 1.0—1.4 (m, 9H, $3CH_3$). Found: C, 47.36; H, 8.01; S, 17.76%. Calcd for $C_7H_{14}O_3S$: C, 47.17; H, 7.91; S, 17.99%. IR (neat); 3500 (OH), 2550 (SH), 1710 cm^{-1} (COO).

*Ethyl 2,3-Dihydroxy-3-methylbutanoate (**17**)*: ^{1}H-NMR (CCl_4); δ 4.26 (q, J=7 Hz, 2H, CH_2), 3.83 (s, 1H, CH), 3.0—3.3 (m, 2H, 2OH), 1.34 (t, J=7 Hz, 3H, CH_3), 1.24 (s, 3H, CH_3), 1.16 (s, 3H, CH_3). IR (neat); 3400 (OH), 1720 cm^{-1} (COO).

*Ethyl (Methylthio)acetate (**19a**)*: Bp 111 °C/20 Torr. ^{1}H-NMR (CCl_4); δ 4.10 (q, J=7 Hz, 2H, CH_2), 3.06 (s, 2H, CH_2), 2.19 (s, 3H, SCH_3), 1.29 (t, J=7 Hz, 3H, CH_3). IR (neat); 1730 cm^{-1} (COO).

A Synthesis of Neamine

Akihiko HARAYAMA, Tsutomu TSUCHIYA, and Sumio UMEZAWA*

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

(Received May 31, 1979)

Neamine and its position isomer were synthesized from 3,4-di-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-α-D-glucopyranosyl bromide and racemic 5,6(4,5)-*O*-cyclohexylidene-2-deoxy-1,3-bis-*N*-(ethoxycarbonyl)streptamine. Influence of the *N*-protecting groups of 2-deoxystreptamine derivatives for glycosylation was discussed. The unusual $\Delta[M]_{TACu}$ value of the position isomer of neamine was ascribed to the interaction between the 6′-amino group and other groups.

Neamine[1] isolated from *Streptomyces cultures* is a constituent of several aminoglycoside antibiotics including neomycins, kanamycin B and butirosins. Its first synthesis starting from paromamine[2] was reported by Umezawa *et al.*[3] Kohno *et al.*[4] also reported a synthesis of neamine from a protected 2,6-diamino-2,6-dideoxy-α-D-glucopyranosyl bromide and a blocked deoxystreptamine derivative, using the 2,4-dinitrophenyl group as a non-participating group at C-2 of the glycosyl bromide. Interest in neamine synthesis lies in the efficient and stereocontrolled synthesis of α-glycoside having an amino group at C-2 of the glycosyl portion. This paper reports another total synthesis of neamine with the use of a glycosyl bromide carrying a *p*-methoxybenzylidene group (Schiff base) at C-2 as a non-participating group.

We used 3,4-di-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-α-D-glucopyranosyl bromide[5] (**1**) and racemic 5,6(4,5)-*O*-cyclohexylidene-2-deoxy-1,3-bis-*N*-(ethoxycarbonyl)streptamine[6] (**5**). Condensation of **1** and **5** in the presence of mercury(II) cyanide and Drierite in benzene–dioxane followed by treatment of the condensation product with dilute sulfuric acid and reaction with ethyl chloroformate gave a mixture of two α-glycosides, *viz.*, 4-*O*-[3,4-di-*O*-acetyl-2-deoxy-2-(ethoxycarbonylamino)-6-*O*-tosyl-α-D-glucopyranosyl]-2-deoxy-1,3-bis-*N*-(ethoxycarbonyl)streptamine (**6**) and its 6-*O*-isomer (**6′**) in 47% yield based on **5**.

Treatment of the above mixture with sodium azide gave a mixture of 6′-azido derivative (**7**, **7′**). Hydrolysis with sodium hydroxide gave a mixture of **8** and **8′**, which, by catalytic hydrogenation followed by chromatographic separation, afforded neamine (**9**) and its 6-*O*-isomer (**9′**). Separation of **8** and **8′** was troblesome. However, they were separated in low yields for the structural determination of **9** and **9′**. α-Anomeric configurations of **8** and **8′** were confirmed by means of the PMR spectrum ($J_{1,2}$=3.5 Hz each). The physical properties of **9** were identical with those of natural neamine. The synthetic neamine (**9**) also gave an antibacterial spectrum identical with that of natural neamine, the isomer (**9′**) showing very weak antibacterial activity. The azido derivatives (**8** and **8′**) showed no antibacterial activities.

In order to confirm the structure of **9** and **9′**, rotations of **9** and **9′** in TACu[7] were measured. Neamine and synthetic **9** gave expected $\Delta[M]_{TACu}$ values (≈−200°), indicating copper-complexing between 1-NH_2 and 6-OH and between 2′-NH_2 and 3′-OH, respectively. The contributions of both rotations are approximately equal in magnitude and opposite in sign, thus cancelling the values. However, **9′** gave $\Delta[M]_{TACu}$ −990° and not the expected value (−1800°). An explanation is that the copper-complexing between 3-NH_2 and 4-OH is disturbed by the presence of the 6′-NH_2 group. For the sake of confirmation the $\Delta[M]_{TACu}$ values of **8** and **8′** were measured. Since **8** and **8′** have no 6′-NH_2 group, they should give the expected $\Delta[M]_{TACu}$ values which were found to be −190° and −1820°, respectively, as expected, showing that **8** and **8′** are 4-*O*- and 6-*O*-glycosyl isomers of 2-deoxystreptamine, respectively.

Discussion

Use of the *p*-methoxybenzylidene group as a non-participating group at the C-2 amino group of glycosyl halide is based on the fact that a Schiff base derivative gives α-glycosides in the synthesis of paromamine[6] in an excellent yield.

We have examined the influence of several *N*-blocking groups of the 2-deoxystreptamine (aglycon) on the glycosidation. Condensation of 1,3-bis-*N*-(benzyloxycarbonyl)-4,5(5,6)-*O*-cyclohexylidene-2-deoxystreptamine[8] (**2**) with **1** under similar conditions gave the condensation product in a smaller yield (≈30%) which was also led to neamine.[9] 1,3-Bis-*N*-(allyloxycarbonyl)-4,5(5,6)-*O*-cyclohexylidene-2-deoxystreptamine (**4**) was prepared from 2-deoxystreptamine by the reaction with allyl chloroformate and subsequent cyclohexylidenation. Condensation of **4** with **1**, however, did not proceed satisfactorily (condensation yield, *ca.* 30%). The *N*-ethoxycarbonyl group was thus found to give the best condensation yield among the protecting groups tested.

Experimental

Thin-layer chromatography (TLC) was carried out on Wakogel B-5 with sulfuric acid spray for detection. For column chromatography, silica gel (Wakogel C-200) was used. Paper chromatography (PPC) was performed on Toyo-Roshi No. 50 with 1-butanol–pyridine–water–acetic acid (6:4:3:1) and spots were visualized by spraying 0.5% ninhydrin in pyridine. PMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer.

*1,3-Bis-*N*-(allyloxycarbonyl)-2-deoxystreptamine (**3**).* Allyl chloroformate (3 ml) was added dropwise under stirring to an ice-cold suspension of 2-deoxystreptamine dihydrochloride (2.0 g) and anhydrous sodium carbonate (5.2 g) in aqueous acetone (1:1, 40 ml). The mixture was stirred for 3 h at room temperature. The reaction mixture was concentrated and the residue extracted with hot dioxane. The dioxane solution was then concentrated, the residue being washed with ether to give a solid (2.4 g). Recrystallization from water gave needles, 1.8 g (65%), mp 223—224 °C; IR (KBr): 1700 (*ν* NHCOO), 1650 (sh, *ν* C=C), 1550 (amide II), 990 (*δ* CH=) cm^{-1}. PMR (pyridine-d_5): *δ* 1.95 (1H q, J=12 Hz, H-2_{ax}), 2.83 (1H double t, J=4.5, 4.5 and 12 Hz, H-2_{eq}), 4.6—4.8 (4H m, $CH_2CH{=}CH_2$), 5.0—5.5 (4H m, $CH_2CH{=}CH_2$), 5.98 (2H double quintet,[10] $CH_2{-}CH{=}CH_2$), 8.12 (2H d, J≈7 Hz, NH; disappeared on deuteration).

Found: C, 51.01; H, 6.66; N, 8.35%. Calcd for $C_{14}H_{22}N_2O_7$: C, 50.90; H, 6.71; N, 8.48%.

*Racemic 1,3-Bis-*N*-(allyloxycarbonyl)-4,5(5,6)-*O*-cyclohexylidene-2-deoxystreptamine (**4**).* A mixture of **3** (2.0 g), 1,1-dimethoxycyclohexane (1.3 ml) and *p*-toluenesulfonic acid (200 mg) was refluxed for a while, half the volume of the solvent then being distilled. The distillate was treated with Molecular Sieves 5A in order to remove methanol co-distilled, and then returned to the reaction vessel. The reaction mixture was treated likewise twice. After addition of triethylamine (4 ml), the mixture was concentrated to give a syrup. The syrup was dissolved in chloroform, washed with water, dried over sodium sulfate, and concentrated to give a solid. Recrystallization of the solid from acetone–hexane gave granular crystals, 1.66 g (67%), mp 106—108 °C: PMR (pyridine-d_5): *δ* 1.1—2.2 (11H, cyclohexylidene and H-2_{ax}), 2.80 (1H double t, H-2_{eq}); 4.6—4.8 (4H), 5.0—5.45 (4H) and 5.7—6.2 (2H) (allyl); 8.25 (1H d) and 8.48 (1H d) (NH; disappeared on addition of D_2O).

Found: C, 58.28; H, 7.42; N, 6.55%. Calcd for $C_{20}H_{30}N_2O_7$: C, 58.52; H, 7.37; N, 6.82%.

*4-O- and 6-O-[3,4-Di-O-acetyl-2-deoxy-2-(ethoxycarbonylamino)-6-O-tosyl-α-D-glucopyranosyl]-2-deoxy-1,3-bis-N-(ethoxycarbonyl)-streptamine (**6** and **6′**).* A mixture of **1** (991 mg, 1.66 mmol), **5** (400 mg, 1.04 mmol), mercury(II) cyanide (757 mg), and calcium sulfate (Drierite, 600 mg) in dry benzene–dioxane (2:1, 4 ml) was stirred at room temperature overnight. Mercury(II) cyanide (300 mg) was added and the mixture was stirred for 20 h. The mixture was centrifuged, the insoluble matter being washed with dioxane. The organic solution combined was concentrated to give a syrup which was washed with water to give a pale-yellow solid (1.35 g). The solid, on TLC with benzene–acetone (5:1), showed major spots at R_f 0.42 and 0.49, and weak spots at R_f 0.22 (**5**) and 0.77 (**1**).

0.5 M sulfuric acid (≈2 ml) was added (pH≈2) to a solution of the solid in acetone (27 ml), and the resulting suspension was stirred at room temperature overnight. The cyclohexylidene and the *p*-methoxybenzylidene groups of the condensation products were removed by this procedure. The reaction mixture was concentrated and the residue was washed with ether to give a solid (TLC, R_f 0). To a suspension of the solid in aqueous acetone (1:1) were added ethyl chloroformate (0.22 ml) and anhydrous sodium carbonate (240 mg) and the mixture was stirred at room temperature overnight. The resulting mixture was concentrated and the residue was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate, and concentrated to give a syrup. Addition of benzene to the syrup gave a precipitate which was removed by centrifugation. Concentration of the benzene solution gave a syrup (927 mg). The syrup on TLC with benzene–acetone (1:1) gave spots of R_f 0.51 and 0.45 (**6**, **6′**) and 0.34 (slight) and 0.26 (slight). The syrup was chromatographed with benzene–acetone (2:1) to give the syrup of a mixture of **6** and **6′**, 376 mg (47% based on **5**). IR (KBr): 1750 (*ν* CH_3CO), 1710 (*ν* NHCOO–), 1530 (amide II), 1240 (*ν* CH_3CO), 1180 (ν_s SO_2) cm^{-1}; PMR ($CDCl_3$): triplet-like signals centered at *δ* 1.23 (9H, J≈8 Hz, $COCH_2CH_3$); *δ* 1.84 (1.5 H), 1.90 (1.5 H) and 1.98 (3H) (each s, Ac), 2.47 (3H s, $CH_3C_6H_4SO_2$).

Found: C, 49.29; H, 5.87; N, 5.24; S, 3.83%. Calcd for $C_{32}H_{47}N_3O_{17}S$: C, 49.42; H, 6.09; N, 5.40; S, 4.12%.

*4-O- and 6-O-[3,4-Di-O-acetyl-6-azido-2,6-dideoxy-2-(ethoxycarbonylamino)-α-D-glucopyranosyl]-2-deoxy-1,3-bis-N-(ethoxycarbonyl)streptamine (**7**, **7′**).* Sodium azide (290 mg) was added to a solution of a mixture of **6** and **6′** (350 mg) in DMF (7 ml), and the mixture was stirred at 80 °C for 3 h. The solution on TLC with benzene–acetone (1:1) gave a single spot at R_f 0.47. Concentration gave a syrup which was dissolved in chloroform. The solution was washed with a saturated sodium chloride solution, then with water, dried over sodium sulfate, and concentrated to give a syrup. The syrup was dissolved again in benzene–ethyl acetate (3:1, 40 ml) and the solution was washed with water, dried (sodium sulfate), and concentrated to give a syrup, 234 mg (80%). IR (KBr): 2100 (N_3), 1740, 1700, 1530, 1240 cm^{-1}; PMR ($CDCl_3$): *δ* 1.27 (9H t, J=7 Hz, $CO_2CH_2CH_3$), 2.05 (6H m, half-height width is 4.5 Hz, Ac).

Found: C, 46.54; H, 6.12; N, 12.69%. Calcd for $C_{25}H_{40}N_6O_{14}$: C, 46.29; H, 6.22; N, 12.96%.

*4-O- and 6-O-(2-Amino-6-azido-2,6-dideoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**8**, **8′**).* A suspension of a mixture of **7** and **7′** (91.6 mg) in 1 M sodium hydroxide solution (5 ml)

was refluxed. The resulting clear solution after 15 min was refluxed for further 2 h. Dowex 50 WX 2 (H^+ form) resin was added until the solution became neutral and the mixture was poured into a column containing the same resin (NH_4^+ form, ≈1 ml). The column after being washed with water (100 ml) was treated with 0.5 M aqueous ammonia. The fractions containing ninhydrin-positive products were collected and concentrated to give a pale-brown syrup (42 mg). The syrup on PPC gave two spots at R_f 0.20 and 0.18 and a faint spot at 0.32. The syrup was charged on a column of CM-Sephadex C-25 (NH_4^+ form, 6 ml) and the column was washed with water. A ninhydrin-positive syrup (9.1 mg) was obtained from the washings. Its absorption spectrum (IR, 1640 cm^{-1}) indicated the product to be a 1,3-ureylene derivative.[11] The column was then treated with aqueous ammonia with gradual increase in concentration (0→0.15 M) to give a colorless syrup of **8** and **8′**, 28.1 mg (52%).

The syrup (59.3 mg) was charged again on a column of CM-Sephadex C-25 (NH_4^+ form, 23 ml) and eluted with aqueous ammonia (0→0.1 M). The elution was checked by PPC. Compound **8** (R_f 0.18) was eluted between 170—180 ml, **8′** (R_f 0.20) between 190—200 ml and the mixture of **8**, **8′** between 180—190 ml. Concentration of the respective fractions gave syrups of **8** (15.7 mg), **8′** (16.0 mg) and a mixture of both (23.4 mg).

8: $[\alpha]_D^{25}$ +71° (*c* 1, water), $\Delta[M]^{436}_{TACu\text{-}NH_3}$† −190°. IR (KBr): 2100 (N_3), 1590 (broad, δ NH_2) cm^{-1}. PMR (D_2O +ND_3): δ 1.18 (1H q, J=12 Hz, H-2_{ax}), 1.97 (1H double t, J=4.5, 4.5 and 12 Hz, H-2_{eq}), 2.5—3.1 (3H m, H-1, 3,2′), 5.23 (1H d, J=3.5 Hz, H-1′). Irradiation at δ 2.8 turned the doublet of H-1′ into a singlet.

Found: C, 39.36; H, 6.50; N, 21.37%. Calcd for $C_{12}H_{24}N_6O_6\cdot 1/2H_2CO_3$: C, 39.58; H, 6.64; N, 22.15%.

8′: $[\alpha]_D^{25}$ +85° (*c* 1, water), $\Delta[M]^{436}_{TACu\text{-}NH_3}$ −1820°. IR (KBr): 2100, 1590 cm^{-1}. PMR (D_2O+ND_3): δ 1.24 (1H q, J=12 Hz, H-2_{ax}), 1.98 (1H double t, J=4.5, 4.5 and 12 Hz, H-2_{eq}), 2.5—3.1 (3H m, H-1, 3,2′), 5.13 (1H d, J=3.5 Hz, H-1′). Irradiation at δ 2.8 turned the doublet of H-1′ into a singlet.

Found: C, 39.44; H, 6.53; N, 21.56%. Calcd for $C_{12}H_{24}N_6O_6\cdot 1/2H_2CO_3$: C, 39.58; H, 6.64; N, 22.15%.

*Neamine(**9**)(4-O-(2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl)-2-deoxystreptamine) and Its Isomer(**9′**)(6-O-(2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl)-2-deoxystreptamine).* A few drops of acetic acid were added to an aqueous solution (7 ml) of a mixture of **8** and **8′** (67.2 mg) obtained after the first Sephadex column treatment. The solution (pH≈3) was then treated with hydrogen at atmospheric pressure for 30 min in the presence of palladium black. The solution on TLC (DC-Fertigplatten Kieselgel 60, E. Merck, Darmstadt) with 1-butanol–ethanol–chloroform–17% aqueous ammonia=4: 7: 2: 7 showed two major spots at R_f 0.17 (**9′**) and 0.28 (**9**), and minor spots at R_f 0.66, 0.72 and 0.82. The spots corresponding to **8** and **8′** (R_f 0.51 and 0.48, respectively) completely disappeared. Concentration of the solution gave a syrup, which, by chromatography on a CM-Sephadex C-25 (NH_4^+ form) column with aqueous ammonia (0→0.25 M), gave **9** (25 mg, 36%) and **9′** (23 mg, 34%) which were eluted in this order.

9: $[\alpha]_D^{25}$ +69° (*c* 0.8, water), $\Delta[M]^{436}_{TACu\text{-}NH_3}$ −180° (natural neamine, −210°). PMR (D_2O+ND_3): δ 1.22 (1H q, J=12 Hz, H-2_{ax}), 2.01 (1H double t, J≈4.5, ≈4.5 and 12 Hz, H-2_{eq}), 2.5—3.1 (5H, H-1, 3, 2′, 6′, 6′?), 5.33 (1H d, J=3.5 Hz, H-1′). All signals were superimposable on those of natural neamine carbonate.

Found: C, 40.68; H, 7.21; N, 14.24%. Calcd for $C_{12}H_{26}N_4O_6\cdot H_2CO_3$: C, 40.62; H, 7.34; N, 14.58%.

9′: $[\alpha]_D^{25}$ +71° (*c* 0.6, water), $\Delta[M]^{436}_{TACu\text{-}NH_3}$ −990°. PMR (D_2O+ND_3): δ 1.27 (1H q, J=12 Hz, H-2_{ax}), 1.98 (1H q, J≈4.5, ≈4.5, and 12 Hz, H-2_{eq}), 2.5—3.2 (5H), 5.17 (1H d, J=3.5 Hz).

Elimination Reactions of Halohydrin Derivatives with a Palladium(0) Complex

Toshio SUGITA,* Yoshimi SHIRAIWA, Masayuki HASEGAWA, and Katsuhiko ICHIKAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 1, 1979)

Stilbene bromohydrin derivatives (Ph–CHBr–CHY–Ph: Y=OAc, OSO_2CH_3, OCH_3, SCH_3) and stilbene dibromide underwent β-elimination reaction with tetrakis(triphenylphosphine)palladium(0) to give stilbene. The stereochemistry of eliminations is nonselective except in the case of dibromide, where *anti*-selectivity is observed. A coupling reaction occurred favorably in the case of Y=OCH_3.

Organometallic compounds substituted by oxygen groups at the β-position have well been known as oxymetallation adducts when the metals are heavy ones such as mercury and thallium, and it is clear that the acid-catalyzed deoxymercuration proceeds in *anti* fashion. In the case of palladium, oxypalladation adducts of olefins have been postulated as intermediates of the Wacker oxidation of ethylene to acetaldehyde and many other palladium(II)-catalyzed reactions of olefins. Although unusually stable alkoxypalladation adducts of ethylene have been isolated,[1] the oxypalladation adducts are usually not isolable except for some atypical examples, in which the complexes are stabilized by the chelation of intramolecular double bonds,[2] because of their propensity to undergo elimination.

Previously, we reported that *syn*-elimination was favored when bromohydrin derivatives were treated with butyllithium, and that, particularly, 1-bromo-2-methoxy-1,2-diphenylethane (**5**) gave a stereospecific *syn*-elimination product in nonpolar solvents. In this reaction, we postulated a β-methoxylithium compound as a transient intermediate.[3]

Phosphine complexes of palladium(0) undergo oxidative addition reaction with alkyl halides, making a carbon–palladium σ-bond. If bromohydrin derivatives undergo oxidative addition to palladium complexes, the oxypalladation compounds should be produced. In this paper, we wish to report the results of the reactions of stilbene bromohydrin derivatives and dibromide with a palladium(0) complex.

Results and Discussion

The reactions of stilbene dibromide (**2**) and bromohydrin derivatives, 1-bromo-2-acetoxy-1,2-diphenylethane (**3**), 1-bromo-2-methylsulfonyloxy-1,2-diphenylethane (**4**), 1-bromo-2-methoxy-1,2-diphenylethane (**5**), and 1-bromo-2-methylthio-1,2-diphenylethane (**6**), with tetrakis(triphenylphosphine)palladium(0) (**1**) in degassed benzene produced only stilbene (**7**) in good yields, except in the case of **5**. In the case of **5**, a coupling product, 1,4-dimethoxy-1,2,3,4-tetraphenylbutane (**8**), was the primary product, accompanied by a small amount of *trans*-**7**. The structure of **8** was identified by means of its analytical and spectral data. As the NMR spectrum is simple, the **8** obtained seems to be diastereomerically not so complex, but its stereochemical structure has not yet been confirmed.

Oxypalladation adducts of olefins almost without exception eliminate palladium, accompanied by β-hydrogen, to produce olefins on which the oxygen groups remain. Only one report on the deoxypalladation-type eliminations has, to our knowledge, been made by Heck.[4] In contrast with the usual behavior of oxypalladation adducts, stilbene was the only elimination product, and no vinyl ether, esters, or other products derived from them were detected in the present case. If the reactions occurred by a series of steps, the oxidative addition of substrates to the palladium(0) complex to produce β-oxypalladium intermediates and the subse-

quent elimination of palladium from these intermediates, stilbene should be formed by the elimination of the palladium and the β-substituents.

Whether the present elimination proceeds *via* β-oxypalladium intermediates or by another mechanism, *e.g.*, the palladium-catalyzed synchronous elimination of the bromine and the heteroatom groups, is yet uncertain. When the leaving group is methoxyl, however, a coupling reaction takes place, together with elimination. Stille and Lau reported that the oxidative additions of 9-bromofluorene and α-bromophenylacetate to **1** gave, as the coupling products, 9,9′-bifluorenyl and ethyl 2,3-diphenylsuccinate respectively.[5] They concluded that these coupling products were attributable to the decomposition of transient alkylpalladium intermediates. An analogous reaction can be expected in the case of methoxy bromide (**5**), which undergoes oxidative addition to **1** to give the coupling product (**8**) and dibromobis(triphenylphosphine)palladium(II). Since methoxyl group is a poor leaving group, the coupling reaction is favored over the elimination. In the reactions of the other substrates, only the elimination reaction takes place, because the acetoxyl, methylsulfonyloxy, and methylthio groups as well as bromide are better leaving groups.

From these considerations, it is plausible to consider that the β-oxy- and β-thio-substituted bromides undergo oxidative addition to the palladium(0) complex to afford the β-oxy- and β-thiopalladium(II) complexes, which then eliminate the palladium accompanied by the β-substituents. As the palladium of the palladium-complex intermediates is coordinatively saturated by a strong phosphine ligand in the present case, it is considered to be difficult to abstract the β-hydrogen as a hydride, and so deoxypalladation-type elimination occurs.

Since both *erythro* and *threo* isomers of the bromohydrin derivatives gave only *trans*-**7**, the eliminations are considered to proceed nonstereoselectively. Stille and his co-workers reported that the oxidative addition of optically active phenethyl bromides to palladium(0) complexes proceeded with inversion of configuration at the carbon bearing bromine,[6] and that the decomposition of the oxidative addition products in the coupling reactions proceeded *via* a radical mechanism.[5] The loss of stereoselectivity in the elimination reactions of the bromohydrin derivatives with **1** can be consistently explained. The β-oxy- and β-thiopalladium complexes formed with inversion of configuration at the carbon bearing bromine eliminate the palladium *via* a radical mechanism, though no CIDNP could be observed, and the stereoselectivity is lost during the process of decomposition of the palladium complexes.

As contrasted with the other substrates, *dl*-**2** underwent a elimination reaction with **1** to give *cis*-**7** in a 20% yield. The fact that the thermodynamically very unstable *cis*-**7** was obtained from the *dl*-isomer as well as the fact that *meso*-**2** gave only *trans*-**7** indicates that the reaction proceeds with *anti* stereoselectivity. Since bromide is a better leaving group, the reaction seems to proceed more concertedly. An analogous result was obtained from the reaction of **2** with butyllithium.[3]

Experimental

The substrates were prepared as previously reported.[3] Tetrakis(triphenylphosphine)palladium(0) (**1**) was prepared by the reduction of dichlorobis(triphenylphosphine)palladium-(II) with hydrazine.[7]

General Procedure of the Elimination Reactions. A solution of 0.300 g (0.88 mmol) of *dl*-**2** and 1.032 g (0.89 mmol) of **1** in 100 ml of degassed anhydrous benzene was heated at 80 °C under argon for 2 h. The mixture was cooled and poured into water, and then extracted with ether. The ether extract was dried over magnesium sulfate, and a yellow complex precipitated was removed by filtration. GLPC analysis (150 °C, 5% Silicone SE-30 on Chromosorb W, 1 m) of the concentrated filtrate showed the presence of *cis*- and *trans*-**7**. The concentrated filtrate was dissolved in warm hexane, the undissolved crystal was filtered off, from which 33 mg of triphenylphosphine oxide was isolated. The filtrate was again concentrated and chromatographed by means of a silica-gel (Wakogel C-200) column, using hexane as an eluant; 32.1 mg (20%) of *cis*- and 95.4 mg (60%) of *trans*-**7** were isolated, their identities were confirmed by GLPC and NMR.

Reaction of 1-Bromo-2-methoxy-1,2-diphenylethane (5) with 1. Formation of 1,4-Dimethoxy-1,2,3,4-tetraphenylbutane (8). (a) A 2.67 g (9.17 mmol) sample of *erythro*-**5** was allowed to react with 10.58 g (9.15 mmol) of **1** in 400 ml of degassed anhydrous benzene at 70 °C under argon for 4 h. The reaction mixture was then worked up as described above. GLPC analysis (150 and 250 °C, SE-30 on Chromosorb W, 1 m) indicated that several components were present in the hexane-soluble product (0.96 g). *trans*-Stilbene and biphenyl were confirmed by the retention-time comparisons with authentic samples. The main peak, appearing at a longer retention time, was isolated as follows: the hexane-soluble product was chromatographed by means of a silica-gel (Wakogel C-200) column using mixed elutants the compositions of which were gradually changed from pure hexane to pure benzene. The fractions eluted with mixtures of benzene: hexane=7: 3 and 9: 1 were combined and concentrated. The product was purified twice more by means of the column chromatograph and finally by recrystallization with hexane to give **8**, mp 139—139.5 °C, yield 85.5 mg. Found: C, 85.48; H, 7.06%. Calcd for $C_{30}H_{30}O_2$: C, 85.27; H, 7.16%. IR ($CHCl_3$) 1600, 1490, 1450, 1100, 695, 585 cm^{-1}. NMR ($CDCl_3$) δ=7.20—6.67 (m, 20, C_6H_5), 4.45 (d, 2, J=6 Hz, CH–OR), 3.65 (d, 2, J=6 Hz, CH–Ph), 3.15 (s, 6, OCH_3). MS (75 eV), *m/e* (relative intensity), 422 (M^+, 0.03), 407 (0.02), 390 (0.03), 389 (0.03), 375 (0.01), 358 (0.7), 301 (0.3), 300 (0.3), 270 (1), 211 (17), 179 (43), 165 (26), 122 (78), 121 (98), 105 (59), 91 (100), 77 (93).

(b) To 100 ml of a degassed benzene solution of 2.03 g (1.76 mmol) of **1** was added 0.512 g (1.76 mmol) of *erythro*-**5**. The solution was allowed to stand at an ambient temperature under argon. After 30 h, an orange-red crystalline precipitate, dibromobis(triphenylphosphine)palladium(II), was isolated by filtration, mp 283 °C (dec) (lit,[5] mp 230—250 °C dec), Found: C, 54.68; H, 3.88%. Calcd for $C_{36}H_{30}Br_2P_2Pd$: C, 54.66; H, 3.82%.

The filtrate was concentrated to give a mixture of crystalline solids, which were then taken up in hexane. The undissolved substance was filtered off, and the filtrate was concentrated. The residue was taken up in ether and washed with water. The ether solution was passed through a short alumina column, bis(2-ethylhexyl) phthalate was added as an internal standard, and then it was submitted to GLPC analysis (230 °C, 5% SE-30 on Chromosorb W, 1 m). The

analysis showed the presence of *trans*-**7** (a small amount) and **8** (20% yield).

Alkylation of Bromocyclopropanes and Bromoarenes by Means of Dibutylcopperlithium and Alkyl Halides

Tamejiro HIYAMA,* Hajime YAMAMOTO, Koji NISHIO, Katuzi KITATANI, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received June 6, 1979)

Treatment of bromocyclopropanes with excess dibutylcopperlithium in tetrahydrofuran at −48 °C gives the respective organocopper intermediates which upon quenching with excess alkyl halides afford alkylated cyclopropanes with retention of the configuration. This process is applied to the synthesis of methyl cascarillate. Bromoarenes are also reduced with dibutylcopperlithium and allylarenes are prepared therefrom.

Organocopper reagents are widely used for C–C bond formation including addition reaction to unsaturated compounds[1] and coupling reaction with organic halides, tosylates, acetates and epoxides.[2] Synthetically versatile is the alkylation reaction of organocuprates (dialkylcoppermetals). Stereochemical studies have stimulated arguments on the mechanism of alkylation,[2] *i.e.* S_N2 like alkyl transfer pathway or oxidative addition followed by reductive coupling pathway. In both cases the ligand of the copper reagent and organic residue of substrates combine to give the alkylated products. The third mechanism is transmetallation suggested earlier by Whitesides *et al.*[3] for the reaction of dialkylcopperlithium (R_2CuLi) and aryl haldies (ArX), wherein a mixed homocuprate (ArCuRLi) is initially formed which subsequently gives an equilibrium mixture (Ar_2CuLi, ArCuRLi, R_2CuLi) of cuprates.[2] Therefore this process has been of no synthetic value. However, the synthetic utility of the transmetallation is suggested recently in the *gem*-dialkylation of 1,1-dibromocyclopropanes with dialkylcopperlithium.[4] This process involving a cyclopropylcopper intermediate is now proved to be general and useful especially for the stereocontrolled synthesis of substituted cyclopropanes.[5]

Bromocyclopropanes **1a**—**1h** were stereoselectively prepared by protonating or alkylating the carbenoid derived from the corresponding *gem*-dibromide.[6] When bromocyclopropane **1** was treated with 4 to 5 equivalents of dibutylcopperlithium in tetrahydrofuran (THF) at −48 °C to 0 °C, the starting bromide was all consumed. Quenching with excess allyl bromide (or methyl iodide) at the same temperature afforded allylcyclopropane **2** (or methylcyclopropane **3**) in good yield. The results are summarized in Table 1. In sharp contrast to the

conventional alkylation of organic halides with dibutylcopperlithium, no trace of butylated products were formed in the present reaction.

The salient features of this alkylation process are:

(1) The net retention of configuration is observed in the allylation of **1a** and **1b** furnishing **2a** and **2b** respectively as the sole product.

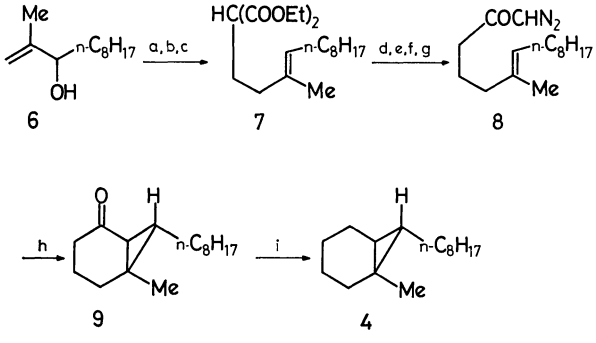
(2) Even tertiary halides (*e.g.* **1c** and **1g**) are alkylated to give the *gem*-dialkylated cyclopropanes. Thus, the two different alkyl groups are introduced both as electrophiles in contrast to the previous method.[4]

(3) The reaction reported here is sometimes more efficient than that which employs bromine-lithium exchange reaction.[7] Treating **1a** with *t*-butyllithium and then with excess allyl bromide gave only a 23% yield of **2a**. The *exo*-bromonorcarane derivative **1h** did not afford **2h** in the organolithium reaction.

(4) As the bromocyclopropanes are not reduced in ether, the highly coordinating THF is indispensable for the reaction.

(5) Control experiments using **1h** as the substrate revealed that at least 3.5 mol of dibutylcopperlithium is required for the complete consumption of **1h**. All attempts to reduce **1a** with *n*-Bu(PhS)CuLi (2 mol), *n*-Bu(*i*-Pr_2N)CuLi (2 mol) or *t*-Bu_2CuLi (4 mol) failed and the recovery of the starting bromide was observed. Although an excess of dibutylcopperlithium (generally 4 to 5 mol) is required for the bromocyclopropanes and the excess cuprate also reacts with alkyl halides, such by-products are fortunately removed readily by simple distillation or chromatography.

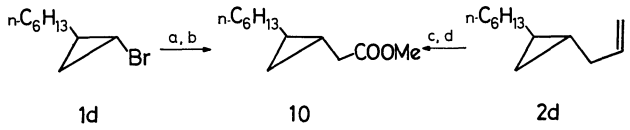
(6) Alkylation of **1h** by use of an unactivated bromide such as octyl bromide turned out rather sluggish. The yield was somewhat improved by adding hexamethylphosphoric triamide (HMPA) as the cosolvent. The stereochemistry of the product was unambiguously determined by the synthesis of the authentic specimen as shown in Scheme 1.



a: CH_2I_2, Zn–CuCl; b: 48% HBr: c: $NaCH(COOEt)_2$; d: OH^-; e: AcOH; f: $SOCl_2$; g: CH_2N_2; h: $CuSO_4$–Cu, Δ; i: N_2H_4, KOH.

Scheme 1.

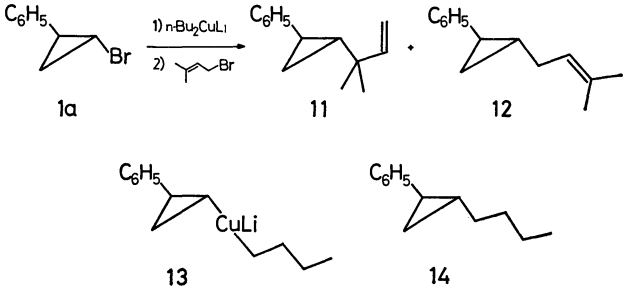
(7) Dibutylcopperlithium treatment of **1d** followed by alkylation with methyl bromoacetate gave methyl cascarillate (**10**),[8] a component of an essential oil of *Croton eluteria* Benett. This compound was alternatively obtained by permanganate-periodate oxidation of **2d** followed by esterification. The resulting ester was completely identical with the authentic sample spectrometrically and chromatographically.



a: *n*-Bu_2CuLi; b: $BrCH_2COOMe$; c: $KMnO_4$–$NaIO_4$; d: CH_2N_2.

(8) Alkylation by means of vinyl bromide was very slow and this reaction turned out futile practically.

Following experiments serve to give insight of the reaction intermediates. Metallation of **1a** and quenching with 3-methyl-2-butenyl bromide gave an S_N2' coupling product **11** mainly. Treatment with benzoyl chloride yielded *trans*-1-benzoyl-2-phenylcyclopropane (95%)and the reaction with methyl propiolate gave methyl *trans*-3-(2-phenylcyclopropyl)acrylate (46%), whereas attempted reaction with benzaldehyde gave only a 26% yield of the adduct and the one with acetone failed to succeed. Decomposition of the intermediary species occurred at 60 °C to give phenylcyclopropane (56%), while oxidation with air yielded *trans*-1-butyl-2-phenylcyclopropane (**14**)[9] (60%). These results favor a mixed homocuprate **13** as an intermediate which is ascribed to the C–Cu bond formation with retention of configuration. Such bromine-copper exchange reaction is not unprecedented.[3] However, it should be noted that butyl-cyclopropyl coupling is almost completely suppressed in **13**. Discrete existence of such mixed cuprate



is suggested recently in the reaction of propargyl acetate with dimethylcopperlithium at low temperature.[10]

The reaction of *cis*-1-chloro-2-phenylcyclopropane with dibutylcopperlithium took 4 days at room temperature, and the product proved to be **14**. GLC monitoring revealed that chlorine was directly substituted with butyl group in sharp contrast to the reaction of **1a**. It is noteworthy that the substitution occurs under inversion.

Bromoarenes underwent the Br–Cu exchange reaction under the same conditions in sharp contrast to the results by Whitesides *et al.*[3] who used ether as the solvent. Upon quenching with allyl bromide allylarenes were produced in good yields. For example, bromobenzene was treated successively with dibutylcopperlithium and allyl bromide to give allylbenzene in 64% isolated yield. Some results are listed in Table 2. HMPA cosolvent improved somewhat the yield of the allylated products. Again butylbenzene was not produced to any extent, and **15** and **16** were produced

Table 2. Allylation of bromoarenes[a]

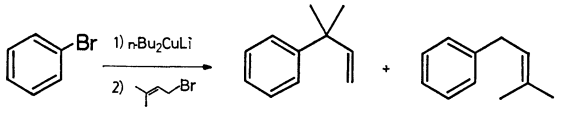
in the reaction with 3-methyl-2-butenyl bromide, the S_N2' product **15** being the major one. Thus the mixed cuprate of type ArCu(*n*-Bu)Li apparently is an intermediate responsible for the observed reactivity. The s character of C–Br bond is the key for the Br–Cu exchange reaction.



15 16

Experimental

All the reactions were carried out under an argon atmosphere and the temperatures are uncorrected. The cold bath of −48 °C was prepared by mixing Dry Ice with *m*-xylene. The IR spectra were recorded on a Shimadzu spectrometer 27-G, MS on a Hitachi RMU-6L, and PMR on a JEOL JNM-PMX 60 or Varian EM 390 spectrometer. Butyllithium was purchased from Aldrich Chemical Co. Ltd. Tetrahydrofuran (THF) was dried on benzophenone ketyl and freshly distilled before use.

Standard Procedure for Dibutylcopperlithium Reduction of Cyclopropyl Bromides and Alkylation. Butyllithium hexane solution (1.65 M, 7.2 ml, 12.0 mmol) was added over 5 min period at −48 °C to a suspension of copper(I) iodide (1.13 g, 6.0 mmol) in THF (20 ml) under an argon atmosphere. After 10 min cyclopropyl bromide (1.5 mmol) in THF (2 ml) was added to the resulting black solution of dibutylcopperlithium, and the reaction mixture was stirred further for 30 min, then treated with excess of an electrophile. After 30 min the reaction mixture was quenched at −48 °C with methanol (1 ml), diluted with aq sat. ammonium chloride and extracted with ether. Product was purified by preparartive TLC.

trans-*1-Allyl-2-phenylcyclopropane (**2a**)*: Bp 55—60 °C (bath temp)/15 Torr. PMR (CCl_4): δ 0.6—1.5 (m, 3H), 1.5—1.9 (m, 1H), 2.0—2.4 (m, 2H), 4.9—6.3 (m, 3H), 6.8—7.4 (m, 5H); IR (neat): 1639, 1605, 1030, 995, 913, 790, 756, 700 cm^{-1}; MS *m/e* (rel intensity): 156 (M^+, 6), 117 (100), 104 (36), 91 (35). Found: C, 90.84; H, 9.01%. Calcd for $C_{12}H_{14}$: C, 91.08; H, 8.92%.

cis-*1-Allyl-2-phenylcyclopropane (**2b**)*: Bp 70—75 °C (bath temp)/20 Torr; PMR (CCl_4): δ 0.5—2.4 (m, 6H), 4.7—6.0 (m, 3H), 7.10 (s, 5H); IR (neat): 1640, 1605, 1501, 1026, 990, 910 cm^{-1}; MS *m/e* (rel intensity): 158 (M^+, 4), 117 (83), 115 (100), 104 (35), 91 (23). Found: C, 90.80; H, 9.15%. Calcd for $C_{12}H_{14}$: C, 91.08; H, 8.92%.

r-*1-Allyl-1-methyl*-t-*2-phenylcyclopropane (**2c**)*: Bp 60—63 °C (bath temp)/14 Torr; PMR (CCl_4): δ 0.7—0.9 (m+s (δ 0.75), 5H), 1.7—2.3 (m, 3H), 4.8—5.3 (m, 2H), 5.5—6.3 (m, 1H), 7.12 (s, 5H); IR (neat): 3060, 1640, 1604, 1500, 1068, 1022, 992, 912, 790, 700 cm^{-1}; MS *m/e* (rel intensity): 172 (M^+, 1), 131 (100), 104 (17), 91 (39). Found: C, 90.34; H, 9.52%. Calcd for $C_{13}H_{16}$: C, 90.64; H, 9.36%.

trans-*1-Allyl-2-hexylcyclopropane (**2d**)*. A THF (2 ml) solution of **1d** and its cis isomer[6] (83: 17 as assayed by GLC) (411 mg, 2.0 mmol) was added to dibutylcopperlithium (10 mmol) in THF (30 ml) at −48 °C. After 30 min allyl bromide (1 ml) was added, and 30 min thereafter the reaction mixture was worked up. Preparative TLC (silica gel, hexane, R_f 0.7—0.9) of the crude product gave a mixture of **2d** and its cis isomer (84: 16 as revealed by GLC) (319 mg, 96% yield). Each product was separated and characterized. **2d**: bp 70—75 °C (bath temp)/20 Torr; PMR (CCl_4): δ 0.0—0.6 (m, 4H), 0.6—1.7 (m, 13H), 1.93 (t, J=5 Hz, 2H), 4.7—5.2 (m, 2H), 5.4—6.1 (m, 1H). IR (neat): 3060, 1638, 1022, 994, 912 cm^{-1}; MS *m/e* (rel intensity): 166 (M^+, 0.9), 138 (11), 125 (11), 124 (11), 96 (24), 95 (23), 81 (50), 69 (80), 67 (93), 56 (97), 54 (87), 41 (100). Found: C, 86.92; H, 13.43 %. Calcd for $C_{12}H_{22}$: C, 86.66; H, 13.34%.

cis-*1-Allyl-2-hexylcyclopropane*. This compound was characterized by spectrometric data: PMR (CCl_4): δ −0.2—0.0 (m, 1H), 0.6—1.8 (m, 16H), 1.8—2.3 (m, 2H), 4.8—5.3 (m, 2H), 5.6—6.1 (m, 1H). IR (neat): 3060, 1640, 1024, 995, 913 cm^{-1}; MS *m/e* (rel intensity): 166 (M^+, 0.4), 96 (24), 95 (21), 81 (50), 67 (91), 55 (86), 54 (78), 41 (100).

trans-*1-Allyl-2-(benzyloxymethyl)cyclopropane (**2e**)*: Bp 80—85 °C (bath temp)/15 Torr; PMR (CCl_4): δ 0.2—1.1 (m, 4H), 2.00 (t, J=6 Hz, 2H), 3.2—3.4 (2H, ABM), 4.43 (s, 2H), 4.8—5.4 (m, 2H), 5.5—6.2 (m, 1H), 7.23 (s, 5H); IR (neat): 3080, 1638, 1496, 1095, 1028, 996, 914, 740, 703 cm^{-1}; MS *m/e* (rel intensity): 202 (M^+, 0), 173 (1), 117 (7), 107 (8), 91 (100). Found: C, 82.98; H, 8.99%. Calcd for $C_{14}H_{18}O$: C, 83.17; H, 8.97%.

7-exo-*Allylnorcarane (**2f**)*: Bp 52—55 °C (bath temp)/18 Torr; PMR (CCl_4): δ 0.2—0.9 (m, 3H), 0.9—2.3 (m, 10H), 4.8—5.3 (m, 2H), 5.6—6.3 (m, 1H); IR (neat): 3080, 1635, 990, 910 cm^{-1}; MS *m/e* (rel intensity): 136 (M^+, 8), 121 (13), 107 (18), 95 (76), 79 (47), 67 (100). Found: C, 88.02; H, 11.99%. Calcd for $C_{10}H_{16}$: C, 88.16; H, 11.84%.

7-endo-*Allyl*-7-exo-*methylnorcarane (**3g**)*. To a THF (10 ml) solution of dibutylcopperlithium (5.0 mmol) at −48 °C was added **1g** (217 mg, 1.0 mmol) dissolved in THF (2 ml). After stirring at −48 °C for 30 min and at 0 °C for 30 min methyl iodide (1 ml) was added. Fifteen min thereafter the reaction was stopped by usual work-up. TLC purification (silica gel, hexane) gave **3g** (R_f 0.8—0.9, 145 mg, 96%). Bp 65—72 °C (bath temp)/22 Torr; PMR (CCl_4): δ 0.4—2.2 (m+s (δ 1.88), 15H), 4.5—6.0 (m, 3H); IR (neat): 3050, 1635, 995, 910 cm^{-1}. MS *m/e* (rel intensity): 150 (M^+, 0.9), 135 (13), 109 (96), 67 (100). Found: C, 87.95; H, 12.36%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%.

7-exo-*Allyl-1-methylnorcarane (**2h**)*: Bp 70—75 °C (bath temp)/20 Torr; PMR (CCl_4): δ 0.2—0.7 (m, 2H), 0.7—2.3 (m+s (δ 1.03), 13H), 4.7—5.2 (m, 2H), 5.5—6.2 (m, 1H); IR (neat): 1635, 990, 905 cm^{-1}; MS *m/e* (rel intensity): 150 (M^+, 4), 121 (9), 109 (61), 96 (87), 81 (80), 67 (100). Found: C, 88.13; H, 12.20%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%.

*Methyl Cascarillate (**10**)*. A THF (2 ml) solution of **1d** (stereochemically pure) (208 mg, 1.0 mmol) was added to a THF (10 ml) solution of dibutylcopperlithium (5.0 mmol) at −48 °C. After stirring at −48 °C for 30 min and at 0 °C for 5 min methyl bromoacetate (1.5 ml) was added all at once, and the reaction mixture was allowed to warm to room temperature in 20 h. Preparative TLC (silica gel,

hexane) of the crude product gave **10** (R_f 0.6—0.7, 151 mg, 75% yield). IR (neat): 3060, 1740, 1168, 1013 cm^{-1}; PMR ($CDCl_3$): δ 0.1—1.7 (m, 17H), 2.15 (d, J=6 Hz, 2H), 3.57 (s, 3H); MS *m/e*: 198 (M^+).

*Alternative Synthesis of Methyl Cascarillate (**10**).* To a well-stirred mixture of **2d** (and its cis isomer, 84: 16) (63 mg, 0.38 mmol), potassium carbonate (20 mg) in *t*-butyl alcohol (6 ml) and water (4 ml) was added an aqueous solution (10 ml) of sodium metaperiodate (550 mg) and potassium permanganate (20 mg). The resulting mixture was vigorously stirred for 3 h at room temperature, and then extracted with chloroform. Concentration of the chloroform extract gave an oil which was dissolved in ether (10 ml) and mixed with excess diazomethane ether solution. Usual work-up and purification (preparative TLC, silica gel, hexane–dichloromethane 3: 1, R_f 0.2—0.3) gave a mixture of **10** and its cis isomer (85: 15) (53 mg, 67% yield). Each product was separated by preparative GLC and compared with the authentic sample.[8]

trans-*1-(1,1-Dimethyl-2-propenyl)-2-phenylcyclopropane (**11**) and* trans-*1-(3-methyl-2-butenyl)-2-phenylcyclopropane (**12**).* To dibutylcopperlithium (6.0 mmol) solution prepared as above was added **2a** (294 mg, 1.5 mmol) dissolved in THF (2 ml) at −48 °C. After 30 min 3-methyl-2-butenyl bromide (1 ml) was added and the reaction mixture was stirred for 30 min and worked up. Preparative TLC (silica gel, hexane, R_f 0.4—0.5) gave a mixture (7: 3) of **11** and **12** (269 mg, 97% yield). Each product was separated by preparative GLC (Apiezon L, 10% on Celite 545, 3 m, 180 °C). **11**: bp 55—60 °C (bath temp)/14 Torr; PMR (CCl_4): δ 0.6—1.5 (m+s (δ 1.03), 9H), 1.65 (t, J=6 Hz, 2H), 4.7—5.2 (m, 2H), 5.75 (dd, J=18, 10 Hz, 1H), 6.8—7.3 (m, 5H); IR (neat): 1635, 1605, 1004, 914 cm^{-1}; MS *m/e* (rel intensity): 186 (M^+, 3), 143 (9), 132 (21), 117 (72), 115 (44), 104 (100), 91 (72), 82 (88), 41 (78). Found: C, 90.19; H, 9.88%. Calcd for $C_{14}H_{18}$: C, 90.26; H, 9.74%. **12**: bp 55—60 °C (bath temp)/14 Torr; PMR (CCl_4): δ 0.5—1.8 (m+2s (δ 1.60, 1.70), 11H), 2.07 (t, J=6 Hz, 2H), 5.17 (t, J=6 Hz, 1H), 6.7—7.3 (m, 5H); IR (neat): 1670, 1605, 1500, 1030 cm^{-1}; MS *m/e* (rel intensity): 186 (M^+, 4), 171 (3), 145 (21), 130 (27), 117 (100), 115 (39), 104 (40), 95 (38), 91 (48). Found: C, 90.23; H, 9.99%. Calcd for $C_{14}H_{18}$: C, 90.26; H, 9.74%.

*1-Methyl-7-*exo*-octylnorcarane (**4**).* A THF (2 ml) solution of **1h** (152 mg, 0.80 mmol) was added dropwise at −48 °C to dibutylcopperlithium (5.0 mmol) in THF (10 ml). After stirring for 10 min at −48 °C and 2 h at 0 °C octyl bromide (1 ml) in HMPA (1 ml) was added to the reaction mixture which was stirred at 0 °C for 1 h and then worked up. As the crude product was contaminated with the recovered bromide, dodecane and hexadecane, the yield of **4** (50%) was estimated by GLC. Preparative GLC gave a pure sample to **4** completely identical with the authentic specimen. PMR (CCl_4): δ 0.2—0.4 (m, 2H), 0.7—2.1 (m+s (δ 1.01), 28H); IR (neat): 2920, 2850, 1463, 1370 cm^{-1}; MS *m/e* (rel intensity): 222 (M^+, 18), 123 (15), 109 (72), 96 (68), 81 (100), 67 (74), 55 (64).

*Synthesis of Authentic Specimen of **4**.* Octylmagnesium bromide was prepared from octyl bromide (58 g, 0.30 mol) and magnesium (8.0 g, 0.33 mol) in ether (150 ml). The magnesium reagent was cooled to 0 °C and methacrylaldehyde (14.0 g, 0.20 mol) dissolved in ether (20 ml) was added dropwise over 30 min. After the addition was completed the reaction mixture was stirred at room temperature for 1 h, heated to reflux for 1 h, then cooled to room temperature and worked up. Distillation of the product at 83—84 °C/1.1 Torr gave **6** (35.0 g, 94% yield). PMR (CCl_4): δ 1.70 (s, 3H), 3.8—4.2 (m, 1H), 4.6—4.9 (m, 2H); IR (neat): 3350, 1660, 898 cm^{-1}. Found: C, 78.49; H, 13.36%. Calcd for $C_{12}O_{24}O$: C, 78.19; H, 13.13%.

A mixture of **6** (18.4 g, 0.10 mol), copper(I) chloride (4.95 g, 0.05 mol) and zinc powder (32.7 g, 0.50 mol) and ether (80 ml) was heated for 30 min, mixed with diiodomethane (67.0 g, 0.25 mol) and again heated to reflux overnight. Filtration and concentration gave a crude cyclopropylmethyl alcohol derivative which was added to 48% hydrobromic acid (100 ml) cooled at 0 °C in 3 min, and the mixture was vigorously stirred for 7 min. Extractive work-up with ether and distillation at 90—92 °C/0.06 Torr gave an unstable homoallyl bromide (5.65 g, 22% yield).

The homoallyl bromide dissolved in ethanol (6 ml) was added at 0 °C to diethyl sodiomalonate (prepared from diethyl malonate (4.80 g, 0.030 mol) and sodium ethoxide (0.030 mol) in ethanol (20 ml)). After stirring at 0 °C for 30 min and at reflux temperature for 4 h, the solvent was evaporated *in vacuo*. The residue was triturated with water and extracted with ether. Purification of the crude product gave **7** (3.27 g, 44% yield). Bp 130—133 °C/1 Torr. PMR (CCl_4): δ 0.7—2.2 (m+br s (δ 1.60), 30H), 3.0—3.2 (m, 1H), 4.13 (q, J=7 Hz, 4H), 5.10 (t, J=7 Hz, 1H); IR (neat): 1730, 1250, 1145, 1030 cm^{-1}. MS *m/e* (rel intensity): 295 (M^+−OEt, 11), 249 (14), 173 (100), 160 (93), 133 (43), 95 (45), 81 (88), 68 (84), 55 (70), 40 (59). Found: C, 70.50; H, 10.75%. Calcd for $C_{20}H_{36}O_4$: C, 70.54; H, 10.66%.

The malonate **7** (3.27 g) in 95% ethanol (13 ml) was mixed with potassium hydroxide (3.0 g) and heated at reflux temperature for 3 h, and then the solvent was evaporated *in vacuo*. To the residue was added acetic acid and the mixture was heated to reflux for 2 days. Work-up was performed by adding water, extracting with ether 4 times, washing the ethereal extracts with brine, drying the organic phase with sodium sulfate and by concentrating under reduced pressure. Distillation gave the corresponding monocarboxylic acid (1.47 g, 57%), bp 130—140 °C (bath temp)/0.03 Torr; PMR (CCl_4): δ 0.7—2.4 (m+s (δ 1.58), 26H), 5.10 (t, J=7 Hz), 11.7 (br s, 1H); IR (neat): 3600—2400, 1705 cm^{-1}. Found: C, 75.21; H, 12.01%. Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

Thionyl chloride (0.82 g, 6.9 mmol) was added to the carboxylic acid obtained as above and dissolved in benzene (8 ml), and the solution was heated to reflux for 1 h. Subsequent distillation gave the corresponding acid chloride (1.06 g, 74% yield). Bp 125 °C (bath temp)/0.05 Torr. The acid chloride was allowed to react with excess diazomethane ether solution at 0 °C overnight. Concentration *in vacuo* gave a crude diazo ketone **8** which was dissolved in cyclohexane (24 ml) and this solution was added over 1 h to the suspension of copper powder (110 mg) and copper(II) sulfate (7 mg) in cyclohexane (9 ml) heated at the reflux temperature. After 2 h the reaction mixture was cooled and filtered. Concentration of the filtrate and preparative TLC of the residue gave the norcaran-2-one derivative **9** (166 mg, 19% yield from the acid chloride). Bp 70—73 °C (bath temp)/1 Torr. IR (neat): 1678 cm^{-1}; MS *m/e*: 236 (M^+).

The ketone **9** (160 mg, 0.68 mmol) was mixed with 80% hydrazine hydrate (2.82 g, 45 mmol), hydrazine hydrochloride (577 mg, 5.5 mmol) and triethylene glycol (15.3 g). The mixture was heated at 130 °C for 2.5 h, mixed with potassium hydroxide (842 mg) and further heated at 210 °C for 2.5 h, while volatile compounds were distilled off. The residue and the distillate were mixed with water and extracted with ether. Concentration of the organic phase and subsequent preparative TLC gave **4** (82 mg, 54% yield). This compound was completely identical with the product obtained from **1h**. Bp 100—105 °C (bath temp)/13 Torr. Found: C, 86.18; H,

13.90%. Calcd for $C_{16}H_{30}$: C, 86.40; H, 13.60%.

Thermal Decomposition of the Intermediate ***13***. To dibutylcopperlithium (4.0 mmol) in THF (10 ml) was added **1a** (193 mg, 1.0 mmol) dissolved in THF (2 ml) at −48 °C. The reaction mixture was stirred at −48 °C for 30 min and subsequently heated to reflux for 1 h. Usual work-up and preparative TLC (silica gel, hexane–ether 10: 1, R_f 0.8) gave phenylcyclopropane (65 mg, 56%) characterized spectrometrically.

Air Oxidation of the Intermediate ***13***. Dibutylcopperlithium (4.0 mmol) and **1a** (199 mg, 1.0 mmol) were mixed at −48 °C as above and after 30 min dry air was bubbled into the reaction mixture for 1 h. The initially black solution gradually turned to green, when the reaction mixture was quenched with methanol. Work-up and TLC analysis showed 7 UV sensitive products which were separated by preparative TLC. Three of them were characterized: *trans*-1-butyl-2-phenylcyclopropane (**14**)[9] (R_f 0.5—0.65, 106 mg, 60%), *trans*-1-iodo-2-phenylcyclopropane (R_f 0.45, 21 mg, 12% yield) and 2,2′-diphenyl-1,1′-bicyclopropane (R_f 0.25, 9.2 mg, 8%). The last compound showed bp 110—115 °C (bath temp)/0.05 Torr; PMR (CCl_4): δ 0.6—1.9 (m, 8H), 6.7—7.3 (m, 10H); IR (neat): 3070, 3030, 3000, 1605, 1502, 1030, 905, 755, 700 cm^{-1}; MS *m/e* (rel intensity): 234 (M^+, 1.6), 180 (18), 143 (100), 128 (53), 115 (34), 91 (34). Found: C, 92.33; H, 7.79%. Calcd for $C_{18}H_{18}$: C, 92.26; H, 7.74%.

Th Reaction of the Intermediate ***13*** *with Methyl Propiolate*. To the intermediate **13** prepared by the standard procedure from **1a** (196 mg, 1.0 mmol) and dibutylcopperlithium (4.0 mmol) at −48 °C was added methyl propiolate (0.8 ml). The reaction mixture was stirred at −48 °C for 2 h, and then worked up. Preparative TLC (silica gel, hexane–ether 20: 3) gave phenylcyclopropane (R_f 0.7—0.8, 17 mg, 14%) and methyl *trans*-3-(2-phenylcyclopropyl)acrylate (R_f 0.3—0.4, 93 mg, 46%) which showed bp 110—115 °C (bath temp)/2 Torr; PMR (CCl_4): δ 1.1—2.3 (m, 4H), 3.61 (s, 3H), 5.80 (d, J=16 Hz, 1H), 6.48 (dd, J=9, 16 Hz, 1H), 6.8—7.3 (m, 5H); IR (neat): 1710, 1638, 1605, 1503, 1250, 1142, 978, 753, 700 cm^{-1}; MS *m/e* (rel intensity): 202 (M^+, 9), 169 (13), 142 (98), 128 (84), 111 (100), 98 (71), 91 (35). Found: C, 77.44; H, 6.98%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%.

The Reaction of the Intermediate ***13*** *with Benzaldehyde*. Benzaldehyde (0.81 ml, 8.0 mmol) was added to the intermediate **13** prepared from **1a** (196 mg, 1.0 mmol) and dibutylcopperlithium (4.0 mmol). After 30 min the reaction mixture was worked up. Preparative TLC purification (silica gel, hexane–ether 3: 1) gave phenylcyclopropane (R_f 0.7—0.8, 41 mg, 35%), and an adduct (R_f 0.1—0.2, 57 mg, 26%). The adduct was a mixture of two diastereomers, each isomer being separated by preparartive TLC (silica gel hexane–ether 1: 1). The one of R_f 0.5—0.6 (11 mg) showed following properties: bp 140—145 °C (bath temp)/0.07 Torr; PMR (CCl_4): δ 0.6—1.6 (m, 3H), 1.6—2.1 (m, 1H), 2.20 (br s, 1H), 4.31 (d, J=6 Hz, 1H), 6.7—7.5 (m, 10H); IR (neat): 3350, 3060, 3030, 1605, 1500, 1031, 765, 700 cm^{-1}; MS *m/e* (rel intensity): 206 (M^+-H_2O, 12), 120 (100), 107 (33), 91 (38), 79 (35), 77 (25). Found: C, 85.95; H, 7.44%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%. The second diastereomer (R_f 0.4—0.5, 39 mg) gave bp 138—141 °C (bath temp)/0.05 Torr; PMR (CCl_4): δ 0.6—1.7 (m, 3H), 1.7—2.1 (m, 2H), 4.15 (d, J=7 Hz, 1H), 6.8—7.4 (m, 10H); IR (neat): 3350, 3040, 1603; 1505, 1018, 760, 700 cm^{-1}; MS *m/e* (rel intensity): 206 (M^+-H_2O, 25), 120 (100), 107 (38), 91 (44), 79 (38), 77 (31). Found: C, 85.83; H, 7.19%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%. Stereochemical assignment was not accomplished.

Quenching the Intermediate ***13*** *with Benzoyl Chloride*. Benzoyl chloride (0.93 ml, 8.0 mmol) was added to **13** prepared from **1a** (192 mg, 1.0 mmol) and dibutylcopperlithium (4.0 mmol) at −48 °C, and the mixture was stirred at −48 °C for 30 min. Usual work-up and preparative TLC (silica gel, hexane–ether 20: 3, double development) gave 1-phenylbutanone (R_f 0.5—0.7, 802 mg, 5.0 mmol) and 1-benzoyl-2-phenylcyclopropane (R_f 0.4—0.5, 220 mg, 95% pure, 95% yield) which exhibited mp 43.5—44.0 °C; PMR (CCl_4): δ 1.2—1.6 (m, 1H), 1.6—2.0 (m, 1H), 2.3—2.9 (m, 1H), 7.03 (s, 5H), 7.2—7.5 (m, 3H), 7.6—8.1 (m, 2H); IR (Nujol): 3100, 1660, 1601, 1593, 1578, 1502, 1215, 1028, 985, 779, 766, 746, 700 cm^{-1}; MS *m/e*: 222 (M^+).

Attempted Reaction of ***13*** *with Vinyl Bromide*. Dibutylcopperlithium (6.0 mmol) prepared from copper(I) iodide (1.14 g, 6.0 mmol) and butyllithium (2.01 M hexane solution, 6.0 ml, 12 mmol) in THF (20 ml) was mixed with a THF (2 ml) solution of **1a** (299 mg, 1.5 mmol) at −48 °C. After 30 min vinyl bromide (1 ml) and 1 h thereafter HMPA (1 ml) were added, and the reaction mixture was allowed to warm to room temperature over 20 h. Work-up followed by preparative TLC (silica gel, hexane) gave **14** (R_f 0.6—0.65, 35 mg, 13%), 1-phenyl-2-vinylcyclopropane (R_f 0.4—0.5, 38 mg, 18%), and 2,2′-diphenyl-1,1′-bicyclopropane (R_f 0.2—0.3, 79 mg, 45%).

Alkylation of Bromobenzene with 3-Methyl-3-butenyl Bromide. Bromobenzene (158 mg, 1.0 mmol) dissolved in THF (2 ml) was added to dibutylcopperlithium (4.0 mmol) at −48 °C, and the mixture was stirred for 30 min at −48 °C, then warmed to 0°C, treated with 3-methyl-2-butenyl bromide (1 ml) and allowed to react for 40 min. Usual work-up followed by column chromatography on silica gel gave an oil (100 mg, 68%) consisted of **15** and **16**. The ratio (73: 27) was estimated by PMR. **15** showed singlet at δ 1.37, vinylic absorption at δ 4.7—6.3, and **16** broad singlet at δ 1.70 and doublet at δ 3.23.

1-Allylnaphthalene. A Typical Procedure of Allylation of Bromoarenes. Under an argon atmosphere at −48 °C butyllithium (1.8 M hexane solution, 4.4 ml, 8.0 mmol) was added to THF (10 ml) suspension of copper(I) iodide (760 mg, 4.0 mmol). After 15 min 1-bromonaphthalene (200 mg, 0.97 mmol) was added, and the reaction mixture was warmed to 0 °C and stirred for 2 h until the bromide was all consumed. Then allyl bromide (970 mg) dissolved in HMPA (2 ml) and THF (3 ml) was added and the reaction mixture was stirred for 2 h. Work-up was effected by adding water (10 ml) and aq sat ammonium chloride (15 ml), filtering the mixture through Celite pad and by extracting with ether. The organic phase was dried (Na_2SO_4), concentrated and purified by column chromatography (silica gel, 75% yield). Bp 138—150 °C (bath temp)/27 Torr. PMR (CCl_4): δ 3.72 (d, J=6 Hz, 2H), 4.7—6.4 (m, 3H), 6.8—8.1 (m, 7H); IR (neat): 1595, 1506, 990, 910 cm^{-1}; MS *m/e*: 168 (M^+).

Kinetic Study for the Reaction of (Arylthio)trimethylstannane with Benzoyl Chloride Giving *S*-Aryl Thiobenzoate.

Seizi KOZUKA* and Ikuya NARIBAYASHI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi, Osaka 558

(Received June 14, 1979)

A kinetic study has been conducted on the reaction of (arylthio)trimethylstannane with benzoyl chloride giving chlorotrimethylstannane and *S*-aryl thiobenzoate. The reaction has been found to obey a second order kinetic equation. A mechanism involving bimolecular nucleophilic attack of the sulfur atom on the acyl carbon has been suggested for the reaction based on the substituent effects of arylthio and benzoyl moieties.

Several different mechanisms are conceivable for the cleavage reactions of group IVb–VIb bonds with various reagents as expressed by the following general formula. Namely, the IVb element can form a coordinated

$$\equiv M\text{–}Y\text{–} + E\text{–}Nu \longrightarrow \equiv M\text{–}Nu + E\text{–}Y\text{–}$$

M = Si, Ge, Sn *etc.*, Y = O, S, Se *etc.*
E–Nu = H_2O, ROH, RCOOH, RX, RCOX, RS(O)X *etc.*

intermediate and the complex has been suggested as the reaction intermediate in the reactions of silyl ether hydrolysis,[1] acetoxysilane[2] and thiosilane[3] with carboxylic acids on the basis of kinetic results. Assuming the nucleophilicity of the VIb element

$$R_3'SiOCOCH_3 \text{ (or } R_3'SiSR'') + RCOOH \rightleftharpoons \left[CH_3\overset{O}{\overset{\|}{C}}OSi^-(R_3')O\overset{+OH}{\overset{\|}{C}}R\right] \overset{\text{slow}}{\longrightarrow} \left[CH_3\overset{+OH}{\overset{\|}{C}}OSi^-(R_3')O\overset{O}{\overset{\|}{C}}R\right] \rightleftharpoons R_3'SiOCOR + CH_3COOH \text{ (or } R''SH)$$

played an important role in the course of reaction, a nucleophilic reaction involving an onium intermediate would result instead of the 5-coordination of the IVb element. The reaction of thiostannane with haloalkane is a typical reaction of this type.[4]

$$R_3'SnSR'' + RX \overset{\text{slow}}{\longrightarrow} [R_3'SnS^+(R'')R\ X^-] \longrightarrow R_3'SnX + RSR''$$

Another possible mechanism for the reaction is a 4-centered cyclic process.[5] Thus, different mechanisms would be expected for individual reactions based on the coordination ability of the group IVb element, nucleophilicity of the group VIb atom and also the nature of the reactant, E–Nu. In this paper, the mechanism of the reaction of (arylthio)trimethylstannane with benzoyl chloride will be reported.

Results and Discussion

Product Analysis. The reactions of (arylthio)-trimethylstannanes with benzoyl chlorides have been found to give *S*-aryl thiobenzoate and chlorotrimethylstannane quantitatively. No other product in the reaction mixture was found by NMR analysis. The products were isolated and identified. The reaction

$$Me_3SnSC_6H_4\text{–}X\text{-}p + p\text{-}Y\text{–}C_6H_4COCl \longrightarrow Y\text{–}C_6H_4COSC_6H_4\text{–}X + Me_3SnCl$$

X, Y = H, CH_3, Cl, OCH_3

thus appeared to be similar to analogous reactions of this type.[6] This reaction provides a novel route to prepare thiocarboxylic acid *S*-esters.

Kinetics and Mechanism. Rate of reaction of (arylthio)trimethylstannanes with benzoyl chlorides in carbon tetrachloride solutions were measured by monitoring the relative ratio of ^{1}H-NMR trimethyl signals of the thiostannane (δ 0.33—0.38 ppm) and chlorostannane (δ 0.63 ppm) with time. Second order rate constants were obtained with good reproducibility, the results of which are summarized in Table 1.

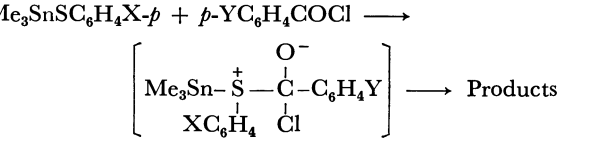
Table 1. Rate constants for the reaction of p-$XC_6H_4SSnMe_3$ (0.48 mol/dm^3) with p-YC_6H_4COCl (0.57 mol/dm^3) in CCl_4

Substituent X	Substituent Y	Temp °C	$k_2 \times 10^5$ dm^3 mol^{-1} s^{-1}	Remarks
MeO	H	34.0	6.6±0.2	$\rho_{X(\sigma)} = -1.6$
Me	H	34.0	4.5±0.1	$\gamma = 0.999$
H	H	34.0	2.3±0.1	
Cl	H	34.0	1.2±0.02	
H	H	42.9	5.2±0.4	$\Delta H^{\neq} = 14.0$ kcal/mol
H	H	50.7	10 ±0.1	$\Delta S^{\neq} = -34.0$ e.u.
H	H	61.9	20 ±2.0	
H	MeO	34.0	1.3±0.05	$\rho_{Y(\sigma)} = +1.1$
H	Me	34.0	1.5±0.1	$\gamma = 0.996$
H	Cl	34.0	4.6±0.1	

The large negative entropy value observed in the present study is in accordance with those of reactions of this type.[2-5a] This may be recognized in terms of an ionic reaction which is conducted in a nonpolar solvent, rather than pπ-dπ bonding[1] since the large negative value observed for the reaction of thiostannane with haloalkane in a nonpolar solvent has been shown to fall in a normal magnitude for a bimolecular reaction when conducted in a polar solvent.[4]

The Hammett plot of the rates of reaction of substituted arylthiostannanes (substituent X) gave a straight line with a negative ρ value which is reasonable in magnitude for a reaction involving sulfonium ion formation positioned α- to the phenyl ring bearing the substituent.[7] A quite comparable ρ value was also observed for the reaction of the same thiostannane with haloalkane and the reaction has been suggested to proceed *via* a sulfonium intermediate.[4] As an analogy, the mechanism of the reaction of the thiostannane with

acyl halide can be formulated as following, involving a nucleophilic attack of the sulfur atom on the acyl



carbon. The positive and smaller ρ value due to the substituent Y on the benzoyl moiety is consistent with the mechanism since the negative charge in the intermediate is localized in the β-position to the aryl ring bearing the substituent.

Experimental

Materials. Preparation of the thiostannanes have previously been reported.[4] All solvents and benzoyl chlorides were purified prior to use.

Product Analysis. Trimethyl(phenylthio)stannane (1.40 g) and benzoyl chloride (0.70 g) were dissolved in CCl_4 (10 cm^3) and heated at 60 °C for 16 h in a sealed tube. NMR analysis confirmed the presence of only chlorotrimethylstannane and *S*-phenyl thiobenzoate. Chlorotrimethylstannane was obtained by distillation (65%, bp 59 °C/18 mmHg; 1 mmHg=133.322 Pa) and *S*-phenyl thiobenzoate was isolated from the residue by recrystallization (72%, mp 55 °C from $CHCl_3$–C_6H_{14}, lit,[8] 56 °C, IR $\nu_{C=O}$ 1662 cm^{-1}). Other thiol esters were isolated similarly: $C_6H_5COSC_6H_4Cl$-*p*, 70%, mp 75—76 °C, lit,[8] 74—75 °C; *p*-$ClC_6H_4COSC_6H_5$, 72%, mp 80—82 °C, lit,[9] 81.5—83 °C; $C_6H_5COSC_6H_4OCH_3$-*p*, 66%, mp 93—94 °C, lit,[9] 93—95 °C; *p*-$CH_3OC_6H_4COSC_6H_5$, 75 %, mp 99—100 °C, lit,[8] 99—100 °C. All the yields are based on the isolated compound in pure form.

Kinetic Procedure. The procedure is essentially the same as that employed for the acyloxy exchange reaction of acetoxysilane.[2] Trimethyl(phenylthio)stannane (40 mm^3, 59 mg) and benzoyl chloride (30 mm^3, 36 mg) were dissolved in CCl_4 (370 mm^3) and the reaction monitored by following the ^1H-NMR trimethyl signals of the starting material and the product with time. The second order rate constant was obtained with an experimental error of 5%.

Synthesis and Properties of *o*-Thioquinone Methides Having Ketene Aminal, Ketene Acetal, Ketene Monothioacetal, or Ketene Dithioacetal Group

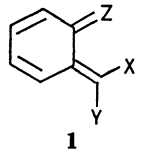
Kyung-Tae KANG, Renji OKAZAKI, and Naoki INAMOTO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 15, 1979)

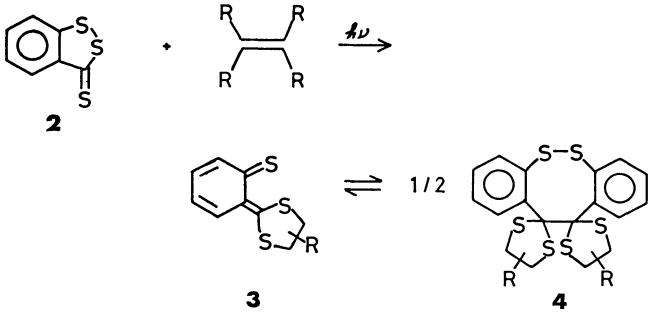
Reaction of 1,2-benzodithiole-3-thione with *N,N'*-dialkyl-1,2-ethanediamine afforded *o*-thioquinone methides with a ketene aminal group (**6**) in high yields. Two similar thionaphthoquinone methides were also prepared. *o*-Thioquinone methide derived from *N,N'*-dimethyl-*o*-phenylenediamine was prepared from 3-chloro-1,2-benzodithiol-3-ylium chloride (**10**). These compounds were found to exist as a monomer of a considerable betaine nature. Reactions of **6a** (*N,N'*-dimethyl derivative) with dimethyl acetylenedicarboxylate and dibenzoylacetylene led to [4+2] adducts. *o*-Thioquinone methides with a ketene acetal group were obtained from desulfurization of spiro[1,3-benzodioxole-2,3'-[1,2]benzodithiole] with trimethyl phosphite, which are equilibrated with two kinds of aggregates; one is a dimer and the other is a trimer or a higher oligomer. Reactions of **10** with *o*-mercaptophenol and 1,2-benzenedithiols gave spiro[1,2-benzodithiole-3,2'-[1,3]benzoxathiole] (**29**) and spiro[1,2-benzodithiole-3,2'-[1,3]benzodithiole] (**39** and **40**), respectively. *o*-Thioquinone methide with a ketene monothioacetal group (**30**) was prepared by desulfurization of **29**. The violet compound **30** is equilibrated with a colorless dimer. This *o*-thioquinone methide reacted with olefins and an acetylene having electron-withdrawing groups to give 1,4-cycloaddition products. Similar desulfurization of **39** and **40** gave *o*-thioquinone methides with dithioacetal group. Their properties were very similar to those of *o*-thioquinone methides with dithioacetal group prepared by the photoreaction of **2** with olefins.

Chemistry of *o*-quinonoid compounds (**1**) has been a subject of increasing interest in recent years because of their interesting, chemical and physical properties and synthetic applications.[1,2] For thioquinone methide (**1**, Z=S), however, there has been only a few reports which demonstrated its existence as a transient species.[3]



1

Recently, de Mayo[4] and we[5] described the synthesis of stable *o*-thioquinone methides with a ketene dithioacetal group (**3**) from the photoreaction of 1,2-benzodithiole-3-thione (**2**) with olefins, **3** being equilibrated with a colorless head-to-head [4+4] dimer (**4**).



2 **3** **4**

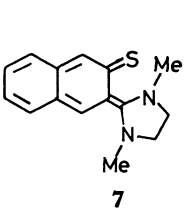
In this paper we report the synthesis and properties of other types of *o*-thioquinone methides (**1**, Z=S) which have a ketene aminal (**1**, X, Y=NR_2), a ketene acetal (**1**, X, Y=OR) or a ketene monothioacetal group (**1**, X=OR, Y=SR). *o*-Thioquinone methides of type **3** (**1**, X=Y=SR) derived from 1,2-benzenedithiols are also described. These *o*-thioquinone methides were found to show significantly different properties from one another.[6]

Results and Discussion

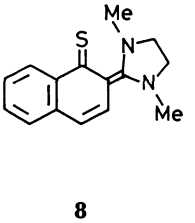
o-Thioquinone Methides with a Ketene Aminal Group. Reaction of 1,2-benzodithiole-3-thione (**2**) with *N,N'*-dialkyl-1,2-ethanediamine (**5**) in ethanol afforded **6** in high yields.[7] In the reaction of **2** with **5a**, the formation of hydrogen sulfide (91% as PbS) and sulfur (94%) was also confirmed.

	5	6		
a:	R=Me	99%	91%	94%
b:	R=Et	64%		
c:	R=*n*-Pr	61%		
d:	R=*i*-Pr	78%		
e:	R=*n*-Bu	72%		
f:	R=*n*-C_6H_{13}	56%		

o-Thioquinone methides (**7** (78%) and **8** (85%)) were also prepared in a similar way from 3*H*-naphtho[1,2-*c*]-[1,2]dithiole-3-thione and 3*H*-naphtho[2,3-*c*][1,2]-dithiole-3-thione, respectively.[8]



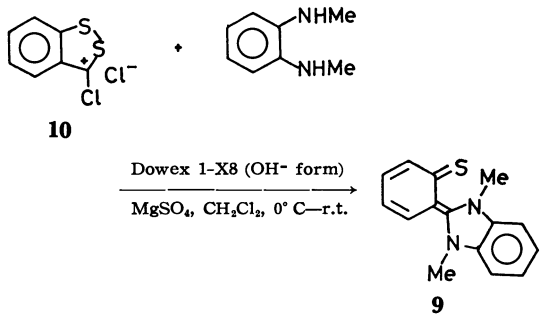
7



8

Compound **9** (69%) was synthesized by the reaction of the more reactive 3-chloro-1,2-benzodithiol-3-ylium chloride (**10**)[9] with *N,N'*-dimethyl-*o*-phenylenediamine[10] using ion exchange resin as a base. The use

of the resin made the isolation of the water soluble **9** easier.



10 **9**

These thioquinone methides (**6**—**9**) were not developed on silica gel even if ether was used as an eluent, suggesting their polar nature. The color of the solution of **6** is pale yellow or colorless, depending on the solvent. The electronic spectra of **6b** in benzene and ethanol showed no concentration dependence, indicating that it exists as a monomer in solution. This is in marked contrast with **3** which is in equilibrium with the dimer. The NMR spectra of **6**—**9** are very similar to one another, implying that other thioquinone methides synthesized here are also monomeric in solution.

Table 1. NMR spectra (δ) of **6**—**9**, **11**, and **13** in methanol-d_4

Compound	*N*-Alkyl	Ethylene	Aromatic
6a	2.91(s)	4.00(s)	6.9—7.4
6b	1.18(t) 3.27(q)	4.04(s)	6.9—7.6

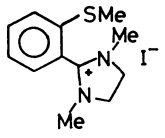
a) SMe protons. b) Methine proton.

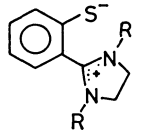
Table 2. Electronic spectra of **6b** in various solvents

Solvent	λ_{max}/nm	log ε
Water	252	4.00
Acetic acid	263	3.57
Ethanol	278	4.18
Acetonitrile	299	4.26
N,*N*-Dimethylformamide	303	4.18
Dichloromethane	299	4.06
Benzene	307	4.27

In the NMR spectra (CD_3OD) of **6a**, **7**, **8**, and **9**, the *N*-methyl protons exhibit very far downfield shift (Table 1). These chemical shifts are almost the same as that of **11** prepared from **6a** and methyl iodide, indicating the large contribution of an ionic canonical structure (*e.g.*, **12** for **6**). This is reflected in the



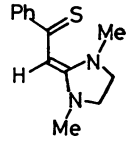
11



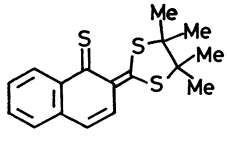
12

solubility of these compounds; for example, **6a** is very soluble in water and alcohols, but only slightly soluble in chloroform and benzene. The importance of the ionic contribution (**12**) to the ground state of **6** was also shown by the solvent effect of the UV spectra of **6b** (Table 2). The more polar the solvent, the shorter the absorption maximum, which indicates the stabilization of the ionic ground state by polar solvents. Here again, these *o*-thioquinone methides are quite different from those with a ketene dithioacetal group (**3**) whose electronic spectra show no essential solvent dependence.[5d]

In the NMR spectra of **6a**, the ethylene protons of the imidazolidine ring appear as a sharp singlet at δ 4.00. At −80 °C it becomes broad but no coalescence occurs, which shows that the imidazolidine ring is rotating freely at this temperature. On the other hand, the ethylene protons of **13** prepared from the reaction of 5-phenyl-1,2-dithiole-3-thione[11] with **5a** appear as AA'BB' multiplet centered at δ 3.62 and 3.91, suggesting the higher double bond nature of the *exo* methylene bond of the imidazolidine.



13



14

In the case of **6**, when R is bulkier than the *n*-propyl group (*i.e.*, **6c**—**6f**), the ethylene protons appear as a broad singlet. In the isopropyl derivative (**6d**), the methyl and ethylene protons appear as a broad singlet at δ 3.96 and a doublet of doublet at δ 1.12 and 1.34 in methanol-d_4, respectively. In 1-chloronaphthalene, however, the ethylene protons appear as AA'BB' multiplet centered at δ 2.72 and 2.98, indicating that the imidazolidine ring is not rotated on NMR time scale. The most reasonable explanation of these observations is that the ring is perpendicular to the benzene ring. In this conformation, the two methyl groups of the isopropyl group are magnetically nonequivalent if the rotation is restricted. The methyl protons of **14**, prepared from the photoreaction of 3*H*-naphtho[1,2-*c*]-[1,2]dithiole-3-thione with 2,3-dimethyl-2-butene in benzene,[12] appear as two singlets at δ 1.56 and 1.62.

Since this type of *o*-thioquinone methide is known to exist as a monomer,[13] the observation of the two singlets indicates the restricted rotation of the dithiole ring. This is in sharp contrast to the fact that the imidazolidine ring in **8** is freely rotating and we regard this as another demonstration of the higher betaine nature of the *o*-thioquinone methides with a ketene aminal group.

Of particular interest is the isolation and stability of **7**, since compounds with 2,3-naphthoquinone structure are usually very unstable[2g,14] and can be isolated only in special cases.[15]

The *o*-thioquinone methides (**6**) are strong enophiles and react with acetylenes having electron-withdrawing groups at room temperature to afford 1,4-cycloaddition products. The reaction of **6a** with dimethyl acetylenedicarboxylate and dibenzoylacetylene gave **15** (76%) and **16** (53%), respectively, and that with *N*-phenylmaleimide afforded rapidly **17** (80%) at 7—8 °C in benzene. The structure of **17** was tentatively assigned by the spectral data; the NMR spectrum showed the *N*-methyl protons as a singlet at δ 3.02 and a broad peak due to six methylene protons at δ 4.0, two protons of which disappeared upon addition of D_2O.

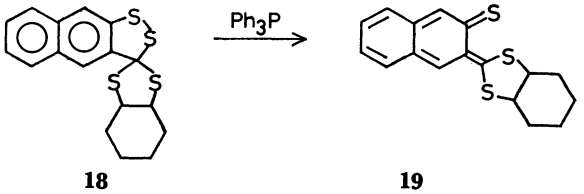
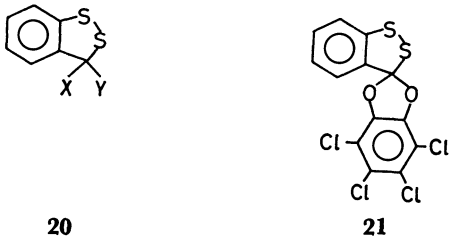
17

o-*Thioquinone Methides with a Ketene Acetal Group.* We considered that 3,3-disubstituted 3*H*-1,2-benzodithiole would be a suitable precursor of *o*-thioquinone methides (**1**, Z=S) with hetero atoms X and Y, because we previously found[12] that desulfurization of spiro compound (**18**) with trivalent phosphorus compound gave in a high yield *o*-thioquinone methide (**19**) which actually exists as a dimer. The only reported example of a compound with a general formula (**20**; X, Y= hetero atom) is **21** which was prepared by the reaction of **2** with *o*-chloranil.[16]



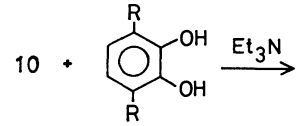
18 **19**

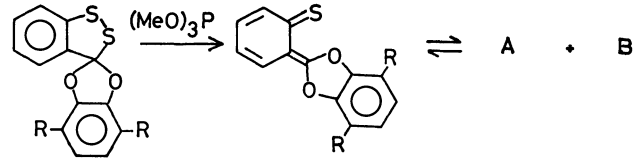


20 **21**

Reaction of the dithiolium salt (**10**) with pyrocatechols gave spiro compounds (**22** and **23**). This reaction has also been applied successfully to the synthesis of spiro compounds, **29**, **39**, and **40** (*vide infra*).

The spiro compounds (**22** and **23**) reacted rapidly with trimethyl phosphite in benzene at room temperature to give white crystals, **24A** and **25A**, respectively. When the filtrate was evaporated and the residue was left for some time, other white crystals (**24B** and **25B**, respectively) were formed.





22: R=H 83% **24**: R=H **24A** 88% **24B** 3%
23: R=Me 53% **25**: R=Me **25A** 50% **25B** 28%

The NMR spectra, melting points, and reactivity of **A** and **B** were different from each other both for **24** and **25**; however, the same 1,4-cycloadducts (*i.e.*, **26** and **27**) were obtained by the reaction with *N*-phenylmaleimide irrespective of whether the starting material was **A** or **B**. Their UV spectra depend upon the concentration, indicating that these aggregates, **A** and **B**, are equilibrated with the monomer **24** and **25** in both cases.

	From **A**	From **B**
26: R=H	85%	91%
27: R=Me	85%	79%

On the basis of molecular weight determination by vapor pressure osmometry in benzene (Found 440, Calcd 456), it was found that the aggregate **24B** was a dimer. High resolution mass spectrum of **24B** also showed the parent peak as a dimer at *m/e* 456.0509 (Calcd for $C_{26}H_{16}O_4S_2$: 456.0491).

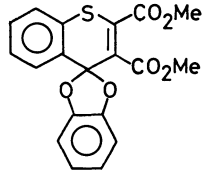
Since the aggregates **24A** and **25A** decomposed in benzene at room temperature, the correct molecular weight could not be determined. For example, the molecular weight of **24A** was observed to be 662 at the beginning of the measurement but it decreased gradually by decomposition. Since it takes some time to make a sample for the measurement and **24A** might decompose during this time, we infer that **24A** is a trimer or a higher oligomer.

The NMR spectrum ($CDCl_3$) of **25B** showed its methyl signal at δ 2.30 as a singlet. However, **25A** showed a sharp and weak singlet at δ 2.30 and a broad and strong singlet at δ 2.07 in the methyl region at the

beginning of measurement, but the spectral pattern changed very rapidly; the intensity of the peak at δ 2.30 increased and that of the peak at δ 2.07 decreased. After several hours the NMR pattern of **25A** became very similar to that to **25B**, suggesting the occurrence of the change **25A**→**25B** probably *via* the monomer.

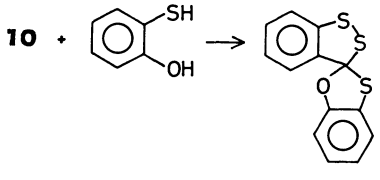
The existence of two types of aggregates is an interesting phenomenon, although their structures could not be determined exactly. However, it is clear that the equilibrium between the aggregate **A** and the monomer is more favorable toward the monomer than the equilibrium for the aggregate **B**, because the afore-mentioned reaction with *N*-phenylmaleimide proceeds much more rapidly for **A** (1 h for **A** *vs.* 20 h for **B** in refluxing benzene) and it is reasonably assumed that the monomer, not the aggregates, reacts with *N*-phenylmaleimide.

The reaction of **24A** with dimethyl acetylenedicarboxylate in refluxing benzene for 5 h gave **28** in 80% yield. The formation of these [4+2] adduct clearly indicates the presence of the monomer in solution, but we could not find any spectroscopic evidence for it.

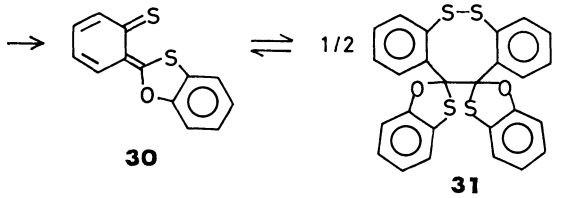


28

o-*Thioquinone Methides with a Monothioacetal Group.* Spiro compound **29**, prepared from **10** and *o*-mercaptophenol, reacted with trimethyl phosphite at room temperature to afford **31** in 92% yield. The structure of **31** was established by its cycloaddition leading to [4+2] adduct (*vide infra*), as in the case with all other *o*-thioquinone methides.



29

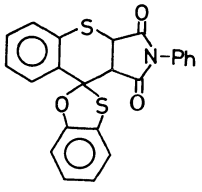


30 **31**

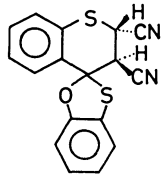
The color of the solution of **31** depends on solvent and temperature. For example, **31** shows violet in dichloromethane or benzene at room temperature, but the cyclohexane solution is almost colorless. Recrystallization of **31** from benzene–ethanol afforded white crystals but the dissolution of the crystals in an appropriate solvent (*e.g.*, dichloromethane) led to a violet solution. The colorless cyclohexane solution turned violet when heated, but the violet color was discharged when the solution was left at room temperature. These facts and the dependence of UV spectrum of **31** on the concentration suggest that the colorless aggregate **31** is also equilibrated with a monomer **30**. The molecular weight determination (vapor pressure osmometry) indicates that the aggregate is a dimer (Found 480, Calcd 488). Although we do not have any experimental evidence for the structure of the dimer, we infer that **31** is a head-to-head dimer by analogy with the equilibrium between **3** and **4**.[5]

The *o*-thioquinone methide **30** also reacted with *N*-phenylmaleimide, fumaronitrile and dimethyl acetylenedicarboxylate to afford **32**, **33**, and **34** in 99, 81, and 85% yields, respectively.

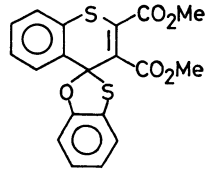
Two methine protons α to the cyano group in **33** appeared as two sets of doublet of doublet of AX type in the NMR spectra of the crude product. The intensity ratio of the two was about 5 : 1 (J_{AX}=6.6 Hz for the major one and J_{AX}=7.8 Hz for the minor one). In the light of the reported value[5c,d] for **35a** (J_{AX}=3.4 Hz) and **35b** (J_{AX}=9.1 Hz), the coupling constants observed for **33** imply that it is a *trans* adduct, suggesting the stereoselectivity of the cycloaddition, although the results for reaction of **30** with maleonitrile is necessary for definite conclusion. The two sets of the doublets of



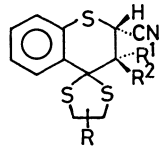
32



33



34



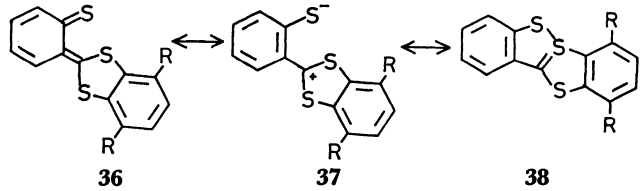
a: R^1=CN, R^2=H

b: R^1=H, R^2=CN

35

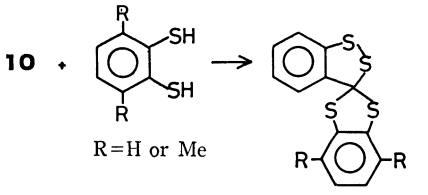
doublet observed for **35** are considered to correspond to two isomers with respect to the direction of the oxygen and sulfur atoms of the thioxolane ring.

o-*Thioquinone Methides Derived from 1,2-Benzenedithiols.* *o*-Thioquinone methides (**36**) derived from 1,2-benzenedithiols were prepared with an expectation that they might exist as **38** because of the large contribution of the canonical structure of 18π system as in the case of trithiapentalene systems.[18] There was also another anticipation that there might be a large contribution from the ionic canonical structure (**37**) which would favor the equilibrium between the monomer and the dimer, like **3**⇌**4**, for the monomer.

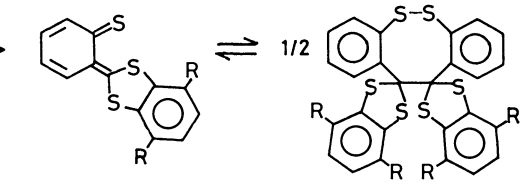


36 **37** **38**

Reaction of the dithiolium salt (**10**) with 1,2-benzenedithiols gave new spiro compounds **39** and **40**. Desulfurization of **39** and **40** with trimethyl phosphite gave **41** and **42**, respectively, in high yields.



39 R=H 55%
40 R=Me 62%

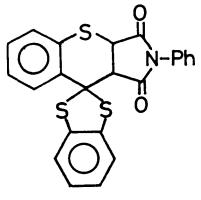


41 R=H 91%
42 R=Me 96%

43 R=H
44 R=Me

Contrary to the above expectations, the properties of **41** and **42** were found to be very similar to those of **3**, and both **41** and **42** exist as an equilibrium mixture between the monomer and the dimer. The structure of the dimers **43** and **44** was assigned a head-to-head dimer by analogy with the case of **3**.[5]

o-Thioquinone methide (**41**) reacted with *N*-phenylmaleimide to give a [4+2] cycloadduct (**45**).



45

Experimental

NMR spectra were recorded with a Hitachi R-20B or R-24B spectrometer, using tetramethylsilane as an internal standard unless otherwise stated. UV and IR spectra were recorded on Hitachi ESP-3 and EPI G-2 spectrometers, respectively. Mass spectra were determined on a Hitachi RMU-6L mass spectrometer (70 eV). High resolution and chemical ionization mass spectra were taken with a JEOL JMS-D300. Molecular weights were measured with a Hitachi 117 Molecular Weight Apparatus (vapor pressure osmometry in benzene at 40 °C). All the melting points were not corrected.

Preparation of o-*Thioquinone Methides (6—8).* An ethanol solution (4 ml) of **2**[19] (567 mg, 3.08 mmol) and *N,N'*-dimethyl-1,2-ethanediamine (320 mg, 3.64 mmol) was refluxed for 4 h. Concentration of the reaction mixture followed by addition of benzene and cooling yielded **6a** (621 mg, 99%) as yellow solid, which was recrystallized from benzene–ethanol; mp 153—155 °C; MS: *m/e* 206 (M^+, 100%), 173 (39), and 135 (16). Found: C, 63.94; H, 7.14; N, 13.39; S, 15.88%. Calcd for $C_{11}H_{14}N_2S$: C, 64.04; H, 6.84; N, 13.58; S, 15.54%.

Thioquinone methides **6b**, **6c**, **6e**, **6f**, **7**, and **8** were also prepared in a similar way from the corresponding dithiolethiones, the yield being 64, 61, 72, 56, 78, and 85%, respectively. In the case of **6d**, it was necessary to heat at 160 °C for 30 h in a sealed tube (78% yield). These *o*-thioquinone methides were purified by recrystallization from benzene–ethanol. Since **6c**, **6e**, and **6f** could not be obtained as crystals, the resultant oils were purified by washing with benzene–hexane.

6b: mp 148—149 °C; MS: *m/e* 234 (M^+, 100%), 201 (87), and 135 (55). Found: C, 66.45; H, 8.00; N, 11.84; S, 13.86%. Calcd for $C_{13}H_{18}N_2S$: C, 66.63; H, 7.74; N, 11.95; S, 13.68%. **6d**: NMR (1-chloronaphthalene): δ (hexamethyldisiloxane) 0.25 (6H, d, J=6.6 Hz), 0.90 (6H, d, J=6.6 Hz), 2.6—2.85 (2H, m), 2.85—3.10 (2H, m), and 3.60 (2H, sept, J=6.6 Hz); MS: *m/e* 262 (M^+, 100%), 230 (98), 220 (43), and 188 (43). **7**: mp 230—232 °C; UV_{max} (EtOH) (log ε): 218 (4.82), 262 (4.58), and 314 nm (4.31); MS: *m/e* 256 (M^+, 100%), 233 (70), and 200 (12). Found: C, 65.63; H, 6.68; N, 10.17; S, 11.71%. Calcd for $C_{15}H_{16}N_2S \cdot H_2O$: C, 65.66; H, 6.61; N, 10.21; S, 11.68%. **8**: mp 204—206.5 °C; UV_{max} (EtOH) (log ε): 223 (4.78), 245 (sh) (4.44), and 348 nm (4.11); MS: *m/e* 256 (M^+, 92%), 233 (100), 200 (12), and 185 (21). Found: C, 70.02; H, 6.32; N, 10.71; S, 12.77%. Calcd for $C_{15}H_{16}N_2S$: C, 70.28; H, 6.29; N, 10.93; S, 12.51%.

Preparation of **9**. To a cold (0 °C), stirred mixture of *N,N'*-dimethyl-*o*-phenylenediamine (594 mg, 4.37 mmol), ion exchange resin (Dowex 1-X8 OH^- form, 10 g), anhydrous magnesium sulfate (638 mg) in dichloromethane (30 ml), was added the dithiolium salt (**10**) (792 mg, 3.55 mmol) in small portions for 1 h and the mixture was stirred at room temperature for 11 h. The resins were collected by filtration and washed with ethanol thoroughly. After removal of the ethanol, the residue was triturated with ethyl acetate to afford **9** (620 mg, 69%); mp 221.5—223 °C; MS: *m/e* 254 (M^+, 41%) and 239 (100).

Preparation of **11**. An acetone solution (7 ml) of **6a** (207 mg, 1.01 mmol) and methyl iodide (1.58 g, 11 mmol) was refluxed for 1.5 h. Evaporation of the solvent gave a crystalline material (329 mg, 94%) whose purity was confirmed by the NMR spectrum. Mp 178.5—180 °C (C_6H_6–EtOH); NMR ($CDCl_3$): δ 2.57 (3H, s), 2.93 (6H, s), 4.13 (2H, m), 4.52 (2H, m), 7.3—7.7 (3H, m), and 8.05—8.22 (1H, m); UV_{max} (EtOH) (log ε): 217 (4.52), 247 (4.21), and 297 (sh) nm (3.29). Found: C, 41.34; H, 5.02; N, 7.95; S, 9.69; I, 36.25%. Calcd for $C_{12}H_{17}N_2SI$: C, 41.39; H, 4.92; N, 8.04; S, 9.21; I, 36.44%.

Preparation of **13**. An ethanol solution (10 ml) of 5-phenyl-1,2-dithiole-3-thione (597 mg, 3.01 mmol) and **5a** (293 mg, 3.33 mmol) was refluxed for 4 h. After removal of the solvent, the residue was recrystallized from benzene–ethanol (430 mg, 62%). A specimen for elemental analysis was obtained by recrystallization from methanol; mp 186—187.5 °C; UV_{max} (EtOH) (log ε): 235 (3.98) and 351 nm (4.36); MS: *m/e* 232 (M^+, 100%) and 200 (28). Found: C, 67.52; H, 7.10; N, 11.93; S, 14.28%. Calcd for $C_{12}H_{16}N_2S$: C, 67.20; H, 6.94; N, 12.06; S, 13.80%.

Reaction of **6a** *with Dimethyl Acetylenedicarboxylate.* An acetonitrile solution (10 ml) of **6a** (207 mg, 1.00 mmol) and dimethyl acetylenedicarboxylate (148 mg, 1.04 mmol) was stood for 10 h at room temperature. After removal of the solvent, the crystalline residue was recrystallized from benzene–hexane to give **15** (264 mg, 76%); mp 148.5—150 °C; NMR ($CDCl_3$); δ 2.31 (6H, s), 3.1—3.4 (4H, m), 3.89 (3H, s), 3.95 (3H, s), and 7.23 (4H, s); MS: *m/e* 348 (M^+, 6%), 290 (100), and 206 (70). Found: C, 58.79; H, 5.91;

N, 8.11; S, 9.57%. Calcd for $C_{17}H_{20}N_2O_4S$: C, 58.60; H, 5.79; N, 8.04; S, 9.20%.

Reaction of ***6a*** *with Dibenzoylacetylene.* An acetonitrile solution (10 ml) of **6a** (281 mg, 1.37 mmol) and dibenzoylacetylene (358 mg, 1.53 mmol) was stood for 4 days at room temperature. After removal of the solvent, the oily residue was triturated with methanol to give **16** (316 mg, 53%) as yellow crystals. A pure specimen could not be obtained since this was partially decomposed by heating in ethanol. Mp 124—125.5 °C (EtOH); NMR ($CDCl_3$): δ 2.27 (6H, s), 2.93 (4H, s), and 7.0—8.0 (14H, m); MS: *m/e* 440 (M^+, trace), 335 (6%), 234 (37), and 206 (100); IR (KBr): 1730 and 1740 cm^{-1} (C=O).

Reaction of ***6a*** *with* N-*Phenylmaleimide.* To a cold (7—8 °C), stirred benzene solution (10 ml) of *N*-phenylmaleimide (154 mg, 0.89 mmol) was added **6a** (175 mg, 0.85 mmol) in portions over a period of 1 h to form red crystals. Stirring was continued at room temperature for 10 h to give **17** (265 mg, 80%). The purification was impossible since it decomposed to an unidentifiable material even when simply washed with ethanol, but the structure was tentatively established by the spectral data. Mp 131—135 °C (dec); NMR (DMSO-d_6): δ 3.02 (6H, s), 3.99 (6H, br s), and 6.6—7.7 (14H, m); MS: *m/e* 348 (2%), 289 (2), 206 (100), 205 (50), and 173 (54); IR (KBr); 1710 cm^{-1} (C=O).

Preparation of ***22*** *and* ***23.*** To a cold (0 °C) and stirred dichloromethane solution (20 ml) of pyrocatechol (1.02 g, 9.30 mmol) and triethylamine (5 ml) was added the salt **10** (1.68 g, 7.56 mmol) in small portions during 1 h, and the solution was stirred at room temperature for 4 h. The reaction mixture was washed with water and the dichloromethane layer was evaporated. The oily residue was subjected to dry column chromatography (DCC) (silica gel, CH_2Cl_2–CCl_4 (1:3)) to give 1.63 g (83%) of **22**; mp 140.5—141.5 °C (ethyl acetate); MS: *m/e* 260 (M^+, 66%) and 196 (100). Found: C, 60.11; H, 2.81; S, 24.53%. Calcd for $C_{13}H_8O_2S_2$: C, 59.98; H, 3.10; S, 24.63%.

Compound **23** was prepared similarly in 53% yield using 3,6-dimethyl-1,2-benzenediol.[20] DCC (silica gel, CH_2Cl_2–CCl_4 (1:9)), PLC (silica gel, ether–hexane (1:3)) and recrystallization from ethanol gave pure **23**; mp 119—120 °C; NMR ($CDCl_3$): δ 2.24 (6H, s), 6.73 (2H, s), and 7.2—7.6 (4H, m); MS: *m/e* 288 (M^+, 93%) and 224 (100). Found: C, 62.35; H, 4.06; S, 22.13%. Calcd for $C_{15}H_{12}O_2S_2$: C, 62.47; H, 4.20; S, 22.23%.

Preparation of ***24*** *and* ***25.*** A benzene solution (2 ml) of **22** (342 mg, 1.32 mmol) and trimethyl phosphite (168 mg, 1.35 mmol) was stirred at room temperature for 20 min. The color of the solution turned from yellow to colorless, and white precipitates were formed. Dry ether was added into this solution with stirring and the crystalline material (**24A**) was collected and washed with ether (264 mg, 88%). The filtrate was evaporated, and stood for some time to obtain another crystalline material, **24B** (8.0 mg, 3%). **24A**: mp 111.5—113 °C (benzene–ether); MS (CI): *m/e* 457 (dimer $+H^+$) and 485 (dimer$+C_2H_5^+$) were observed, but fragments higher than the dimer were not observed. Found: C, 68.30; H, 3.26; S, 13.89%. Calcd for $C_{13}H_8O_2S$: C, 68.40; H, 3.53; S, 14.05%. **24B**: mp 212—213 °C (ethyl acetate); MS (CI): *m/e* 456 (M^+, 5%), 365 (3), 231 (49), 229 (13), 197 (2), 153 (3), 137 (47), 123 (7), and 111 (100). Found: C, 67.84; H, 3.18; S, 14.20%. Calcd for $C_{13}H_8O_2S$: C, 68.40; H, 3.53; S, 14.05%.

Compounds **25A** and **25B** were prepared similarly in 50% and 28% yields, respectively. **25A**: mp 130—131 °C (C_6H_6–Et_2O); NMR ($CDCl_3$); δ 2.30 (s) and 2.07 (bs containing a sharp singlet at δ 2.14) (6H in total), and 6.3—8.0 (6H, m); MS: *m/e* 512 (trace) and 256 (100%). **25B**: mp 187.5—188 °C (AcOEt); NMR ($CDCl_3$): δ 2.30 (6H, s), 6.69 (2H, s), 7.14—7.33 (2H, m), and 7.5—7.8 (2H, m); MS: *m/e* 512 (trace) and 256 (100%).

Reactions of ***24*** *and* ***25*** *with* N-*Phenylmaleimide.* A benzene solution (1.5 ml) of **24A** (116 mg, 0.51 mmol as a monomer) and *N*-phenylmaleimide (97 mg, 0.56 mmol) was refluxed for 1 h under argon. Addition of ethanol to the cooled, stirring solution gave 173 mg (85%) of **26**, which was also prepared (91%) in a similar manner from **24B**, but in this case refluxing for 20 h was necessary. The identity of the adduct **26** from **24A** and **24B** was confirmed by the IR and NMR spectra. Mp 205 °C (dec); MS: *m/e* 401 (M^+, 47%), 292 (72), and 228 (100); IR (KBr): 1715 cm^{-1} (C=O); NMR (C_6D_6): δ 3.16 (1H, d, J=9.6 Hz), 3.83 (1H, d, J=9.6 Hz), 6.4—7.2 (12H, m), and 7.5—7.7 (1H, m).

27 was prepared from both **25A** (reflux for 1 h, 85%) and **25B** (reflux for 50 h, 79%). The adduct **27** from **25A** and **25B** was also confirmed to be the same by the spectral data (IR and NMR) and the fact that there was no depression of mixed melting point. Mp 208—209.5 °C (AcOEt–EtOH); NMR ($CDCl_3$): δ 2.18 (3H, s), 2.29 (3H, s), 3.95 (1H, d, J=9.6 Hz), 4.59 (1H, d, J=9.6 Hz), 6.63 (2H, s), and 6.9—7.9 (9H, m); IR (KBr): 1720 cm^{-1} (C=O); MS: *m/e* 429 (M^+, 31%), 292 (23), and 256 (100). Found: C, 70.12; H, 4.32; N, 3.08; S, 7.52%. Calcd for $C_{25}H_{19}NO_4S$: C, 69.91; H, 4.46; N, 3.26; S. 7.46%.

Reaction of ***24A*** *with Dimethyl Acetylenedicarboxylate.* A benzene solution (3 ml) of **24A** (204 mg, 0.89 mmol as a monomer) and dimethyl acetylenedicarboxylate (141 mg, 1.00 mmol) was refluxed for 5 h under argon. After removal of the solvent, the oily residue was triturated with methanol to give 264 mg (80%) of **28** as white crystals; mp 118—119 °C (EtOH); NMR ($CDCl_3$): δ 3.53 (3H, s), 3.79 (3H, s), and 6.7—7.8 (8H, m); MS: *m/e* 370 (M^+, 45%), 311 (100), and 228 (15); IR (KBr): 1745 cm^{-1} (C=O). Found: C, 61.72; H, 3.70; S, 8.81%. Calcd for $C_{19}H_{14}O_6S$: C, 61.62; H, 3.81; S, 8.66%.

Preparation of ***29.*** The dithiolium salt **10** (213 mg, 0.95 mmol) was added in portions at 0 °C to a stirred dichloromethane solution (5 ml) of *o*-mercaptophenol (140 mg, 1.11 mmol) and triethylamine (0.8 ml). Stirring was continued at room temperature for 3 h, after which the reaction mixture was washed with water. After removal of the solvent, the residue was subjected to PLC (silica gel, CH_2Cl_2–CCl_4 (1:3)) to give yellow crystals of **29** (159 mg, 61%); mp 134—135 °C (EtOAc); MS: *m/e* 276 (M^+, 100%), 244 (17), 212 (56), and 184 (53). Found: C, 56.77; H, 2.62; S, 34.39%. Calcd for $C_{13}H_8OS_3$: C, 56.49; H, 2.92; S, 34.80%.

Preparation of ***31.*** A benzene solution (2 ml) of **29** (563 mg, 2.04 mmol) and trimethyl phosphite (275 mg, 2.21 mmol) was stirred at room temperature for 20 min. The color of the solution turned from yellow to violet, and pale violet precipitates were formed. Ethanol was added to this solution with stirring and the crystalline material was collected (486 mg, 92%). Mp 117 °C (dec) (C_6H_6); MS: *m/e* 456 (M^+-S, 2%), 276 ($M^+/2+S$, 53), 244 ($M^+/2$, 100), 213 (32), and 184 (45).

Reaction of ***31*** *with* N-*Phenylmaleimide.* A mixture of **31** (116 mg, 0.24 mmol) and *N*-phenylmaleimide (88 mg, 0.51 mmol) in benzene (2 ml) was stirred at room temperature for 12 h. After removal of the solvent, the oily residue was triturated with ethanol to give **32** (193 mg, 99%), mp 193 °C (dec) (C_6H_6); NMR (C_6D_6): δ 3.58 (2H, s), 6.5—7.3 (12H, m), and 7.7—7.9 (1H, m); IR (KBr): 1720 cm^{-1} (C=O); MS: *m/e* 417 (M^+, 12%) and 244 (100). Found: C, 66.52; H, 3.49; N, 3.54; S, 15.02%. Calcd for

$C_{23}H_{15}NO_3S_2$: C, 66.17; H, 3.62; N, 3.55; S, 15.36%.

*Reaction of **31** with Fumaronitrile.* A mixture of **31** (248 mg, 0.51 mmol) and fumaronitrile (89 mg, 1.14 mmol) was refluxed in benzene (2 ml) for 40 min. After removal of the solvent, the NMR (in $CDCl_3$) of the residue was measured for the methine protons of the dihydrobenzothiopyran ring. The two methine protons appeared as two sets of AX type doublet of doublet whose intensity was 5: 1; the major one: δ 4.13, 4.24, 4.53, and 4.64 and the minor one: δ 3.88, 4.01, 4.53, and 4.64. In order to remove excess fumaronitrile the crude product was twice washed with ethanol giving **33** (280 mg, 85%). The major isomer was obtained by repeated recrystallization from ethanol; mp 138.5—140 °C (dec); NMR ($CDCl_3$): δ 4.18 (1H, d, J=6.6 Hz), 4.58 (1H, d, J=6.6 Hz), and 6.8—8.1 (8H, m); IR (KBr): 2250 cm^{-1} (C≡N); MS: *m/e* 322 (M^+, 37%) and 244 (100).

*Reaction of **31** with Dimethyl Acetylenedicarboxylate.* A benzene solution (2 ml) of **31** (123 mg, 0.25 mmol) and dimethyl acetylenedicarboxylate (87 mg, 0.62 mmol) was stirred at room temperature for 13 h and refluxed for 5 min. After removal of the solvent, the residue was subjected to PLC (silica gel, CH_2Cl_2–CCl_4 (1: 1)) to give **34** (158 mg, 81%), mp 140—141 °C (EtOH); NMR ($CDCl_3$): δ 3.76 (3H, s), 3.88 (3H, s), and 6.9—7.9 (8H, m); MS: *m/e* 386 (M^+, 21%) and 327 (M^+-CO_2Me, 100).

*Preparation of **39** and **40**.* To a cold (0 °C) and stirred dichloromethane solution (10 ml) of 1,2-benzenedithiol (332 mg, 2.33 mmol) and triethylamine (1.5 ml) was added the salt **10** (463 mg, 2.07 mmol) in portions over a period of 1 h and stirring was continued at room temperature for 4 h. The reaction mixture was washed with water and the organic layer was evaporated. The oily residue was subjected to PLC (silica gel, CH_2Cl_2–CCl_4 (1: 3)) to afford 335 mg (55%) of **39**; mp 144.5—146 °C (AcOEt); MS: *m/e* 292 (M^+, 98%) and 228 (100). Found: C, 53.80; H, 2.50; S, 43.30%. Calcd for $C_{13}H_8S_4$: C, 53.39; H, 2.76; S, 43.85%.

40 was prepared similarly in 62% yield using 3,6-dimethyl-1,2-benzenedithiol, which was synthesized by the same method as that of the unsubstituted derivative. Mp 117—117.5 °C (AcOEt); NMR ($CDCl_3$): δ 2.24 (6H, s), 6.91 (2H, s), 7.2—7.5 (3H, m), and 7.8—8.0 (1H, m); MS: *m/e* 320 (M^+, 91%), 288 (46), and 255 (100). Found: C, 56.33; H, 3.64; S, 39.60%. Calcd for $C_{15}H_{12}S_4$: C, 56.21; H, 3.78; S, 40.01%.

*Preparation of **43** and **44**.* A benzene solution (1.5ml) of **39** (203 mg, 0.69 mmol) and trimethyl phosphite (112 mg, 0.90 mmol) was stirred at room temperature for 1 h. The color of the solution turned rapidly from yellow to blue, and pale blue precipitates were formed. To this solution was added ethanol and the crystalline material **41** (probably mainly **43**) was collected by filtration (165 mg, 92%). Mp 184.5 °C (dec); MS: *m/e* 488 (M^+-S, 4%), 456 (M^+-2S, 2), 292 ($M^+/2+S$, 99), 260 ($M^+/2$, 20), and 238 ($M^+/2-S$, 100). Because the solubility of **43** was very low in any solvent, it could not be recrystallized, but the structure of **43** was confirmed by its cycloaddition with *N*-phenylmaleimide leading to [4+2] adduct, **45**.

44 was synthesized similarly in 96% yield; mp 196.5— 197 °C (C_6H_6–EtOH); NMR ($CDCl_3$): δ 2.66 (6H, s) and 6.7—7.4 (4H, m); MS: *m/e* 544 (M^+-S, 2%), 320 ($M^+/2+S$, 28), 288 ($M^+/2$, 100), and 273 ($M^+/2-CH_3$, 65). Found: C, 62.51; H, 4.05; S, 32.94%. Calcd for $C_{30}H_{24}S_6$: C, 62.46; H, 4.19; S, 33.34%.

*Reaction of **43** with N-Phenylmaleimide.* A toluene solution (10 ml) of **43** (131 mg, 0.25 mmol) and *N*-phenylmaleimide (88 mg, 0.51 mmol) was refluxed for 1.5 h. After removal of the solvent, the residue was recrystallized from ethanol–benzene to give **45** (177 mg, 82%), mp 178—179 °C; NMR ($CDCl_3$): δ 4.37 (1H, d, J=15 Hz), 4.84 (1H, d, J=15 Hz), and 6.8—8.2 (13H, m); IR (KBr): 1720 cm^{-1} (C=O); MS: *m/e* 433 (M^+, 15%) and 260 (100). Found: C, 63.79; H, 3.19; N, 3.25; S, 22.20%. Calcd for $C_{23}H_{15}NO_2S_3$: C, 63.72; H, 3.49; N, 3.23; S, 22.18%.

Catalytic Hydrolysis of *p*-Nitrophenyl Esters in the Presence of Representative Ammonium Aggregates. Specific Activation of a Cholesteryl Nucleophile Bound to a Dialkylammonium Bilayer Membrane[1)]

Yoshio OKAHATA, Reiko ANDO, and Toyoki KUNITAKE*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received June 16, 1979)

Catalytic hydrolysis of *p*-nitrophenyl esters (acetate and nonanoate) by hydroxamate and imidazole nucleophiles was studied at 30 °C in the presence of aqueous aggregates of single-chain (hexadecyl), double-chain (didodecyl and dioctadecyl) and triple-chain (trioctyl) ammonium amphiphiles. These three types of ammonium salts give rise to very different aggregate morphologies. The rate constant of ester cleavage by the nucleophiles was enhanced several hundred folds in the presence of these hydrophobic aggregates. Simple long-chain nucleophiles possessed esterolytic reactivities which reflect the hydrophobic microenvironment of the respective aggregates: single-chain<double-chain<triple-chain. On the other hand, the cholesteryl ester of imidazolecarboxylic acid showed an especially high reactivity when bound to the didodecylammonium bilayer. Cholic acid-derived nucleophiles showed normal reactivity patterns. Apparently, specific binding of the cholesterol derivative to the bilayer is responsible for the unusual catalytic behavior.

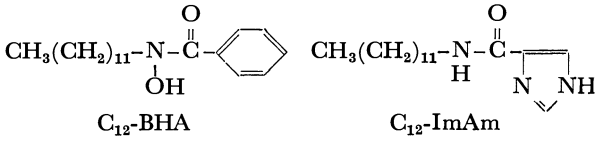
The reactivity of hydrophobic, anionic nucleophils toward *p*-nitrophenyl esters is greatly enhanced in the presence of cationic micelles of hexadecyltrimethylammonium bromide (CTAB).[2)] An additional rate-enhancing effect of *ca.* 100 fold has been observed with the aqueous aggregate of trioctylmethylammonium chloride.[3)] These results can be explained by the formation of *hydrophobic ion pairs* between anionic nucleophiles and cationic surfactants.[4,5)]

Recently we found that a series of dialkylammonium amphiphiles formed stable bilayer structures in dilute aqueous solution(10^{-2}—10^{-4} M)(1 M=1 mol dm^{-3}).[6-8)] According to the electron microscopic examination, these structures are quite similar to that of phospholipid membranes and further aggregation of the bilayer resulted in the vesicle and lamellar structures.

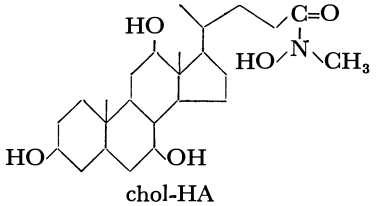
Thus, we have three distinct types of ammonium aggregates. An ammonium amphiphile which contains single, long alkyl chain (conventional surfactant) forms fluid, globular micelles at 10^{-2}—10^{-3} M. Alkylammonium salts with two long alkyl chains produce huge (10^6—10^7 daltons) aggregates with highly organized structure at 10^{-2}—10^{-4} M. An ammonium salt with three octyl chains forms fairly tight, small aggregates at 10^{-4}—10^{-5} M. Therefore, it is important to compare the influences of these ammonium aggregates on micelle-catalyzed reactions. In addition, the catalytic behavior in the ammonium bilayer would be interesting as a model of the action of membrane-bound enzymes.

In the present study, the catalytic hydrolysis of phenyl esters were examined in the presence of representative, aqueous aggregates. *p*-Nitrophenyl acetate (PNPA) and *p*-nitrophenyl nonanoate (PNPN) were used as substrate. Nucleophiles employed were *N*-dodecylbenzohydroxamic acid (C_{12}-BHA), *N*-dodecyl-4-imidazolecarboxamide (C_{12}-ImAm), *N*-methylcholohydroxamic acid (chol-HA), *N*-(4-imidazolylmethyl)-cholohydroxamic acid (chol-ImHA), *N*-[2-(4-imidazolyl)ethyl]cholamide(chol-His) and cholesteryl 4-imidazolecarboxylate(cholest-Im). The first two nucleophiles contain a long alkyl chain and the rest contain the steroidal skeleton. Their structures and abbreviations are shown below, together with those of substrates and surfactants.

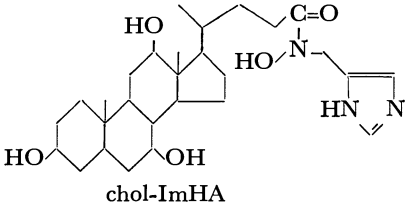
Nucleophile



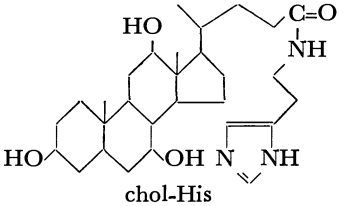
C_{12}-BHA C_{12}-ImAm



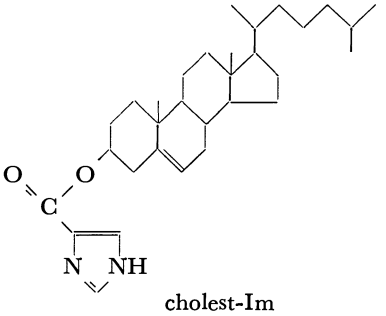
chol-HA



chol-ImHA

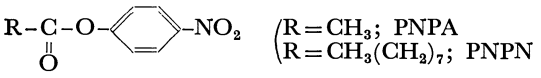


chol-His

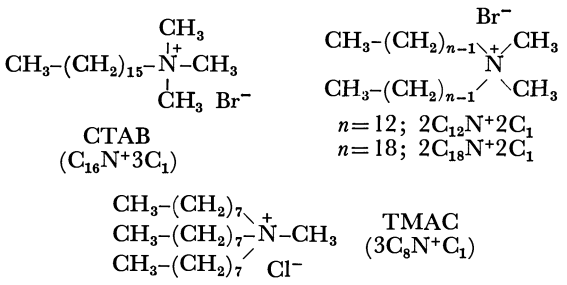


cholest-Im

Substrate



Ammonium salt



Experimental

N-Methylcholohydroxamic Acid (chol-HA). Cholic acid (4.09 g, 0.010 mol) was dissolved in a mixture of 80 ml of dry tetrahydrofuran (THF) and 20 ml of dry acetonitrile, and 1.38 g (0.012 mol) of *N*-hydroxysuccimide was added. To the resulting homogeneous solution were added dropwise 2.06 g (0.010 mol) of dicyclohexylcarbodiimide in 20 ml of dry THF at 10—15 °C. The mixture was stirred at room temperature for 2 h and the precipitates of *N,N'*-dicyclohexylurea were removed. Chloroform (300 ml) was added to the filtrate and the solution was washed with aqueous sodium carbonate (100 ml×2) and with water (100 ml×2) and dried over sodium sulfate. Chloroform was removed *in vacuo* and the white solid was recrystallized two times from a 1: 1 mixture of ethyl acetate and hexane: mp 119—120 °C, yield 2.50 g (55%). The product was confirmed by IR and NMR spectroscopies.

The succimide ester of cholic acid thus obtained (2.50 g, 0.005 mol) was dissolved in 50 ml of dry *N,N*-dimethylformamide (DMF) and added dropwise at 0 °C to 100 ml of dry DMF which contained 1.70 g (0.020 mol) of *N*-methylhydroxylamine hydrochloride and 2.0 g (0.020 mol) of triethylamine. Stirring was continued for 13 h at room temperature. The precipitates of triethylamine hydrochloride was separated and the solvent was removed *in vacuo*. The yellowish solid residue was recrystallized two times from a 1: 1 mixture of ethanol and water to give colorless needles: mp 215—216 °C, yield 1.8 g (41%). Found: C, 68.32; H, 10.04; N, 3.41%. Calcd for $C_{25}H_{43}O_5N$: C, 68.65; H, 9.84; N, 3.20%.

N-[2-(4-Imidazolyl)ethyl]cholamide (chol-His). This compound was prepared from the succimide ester of cholic acid and histamine dihydrochloride in the presence of triethylamine by a procedure similar to that mentioned above: colorless granules, yield 78%, mp 125—126 °C. Found: C, 69.49; H, 9.08; N, 8.48%. Calcd for $C_{29}H_{47}O_4N_3$: C, 69.46; H, 9.38; N, 8.38%. This procedure gave a better yield with higher purity than the previous method[9] in which methyl chloroformate was used as the condensation agent.

N-(4-Imidazolylmethyl)cholohydroxamic Acid (chol-ImHA). The succimide ester of cholic acid and *N*-(4-imidazolylmethyl)-*O*-benzylhydroxylamine dihydrochloride[10] was allowed to react similarly to give benzyl *N*-(4-imidazolylmethyl)cholohydroxamate, which was then hydrogenated over 5% Pd/$SrCO_3$ in ethanol. Colorless granules were obtained by recrystallizations (twice) from acetonitrile: mp 166—168 °C, yield 49%. Found: C, 66.52; H, 8.78; N, 8.14%. Calcd for $C_{28}H_{45}O_5N_3$: C, 66.80; H, 8.95; N, 8.35%.

Cholesteryl 4-Imidazolecarboxylate (cholest-Im). 4-Imidazolecarbonyl chloride[11] (2.8 g, 0.016 mol), 5.3 g (0.01 mol) of cholesterol and 6 g (0.06 mol) of triethylamine were added to 50 ml of chloroform and the mixture was refluxed for 4 h. Solvent was removed *in vacuo*, and the residual yellow solid was washed with a small amount of water and recrystallized three times from ethanol: pale yellow granules, mp 225—230 °C. Found: C, 76.68; H, 9.90; N, 6.00%. Calcd for $C_{31}H_{48}O_2N_2$: C, 76.86; H, 9.92; N, 6.08%.

Other Materials. *p*-Nitrophenyl acetate (PNPA) (mp 78 °C),[12] *p*-nitrophenyl nonanoate (PNPN) (bp 165 °C/0.3 mmHg (1 mmHg=133.322 Pa))[13] were prepared by the procedure reported before.

Commercial hexadecyltrimethylammonium bromide(CTAB) was recrystallized twice from water, and commercial trioctylmethylammonium chloride (TMAC) (Dojin Chemicals, Co.) was used without further purification. Didodecyldimethylammonium bromide ($2C_{12}N^+2C_1$) (Eastman Kodak) was recrystallized two times from ethyl acetate; mp 55—56 °C. Dioctadecyldimethylammonium bromide ($2C_{18}N^+2C_1$) was prepared by reaction of *N,N*-dimethyloctadecylamine and octadecyl bromide in refluxing ethanol in the presence of sodium carbonate and purified by repeated recrystallizations from ethyl acetate: colorless granules, mp 90—93 °C. Found: C, 70.04; H, 12.78; N, 2.18%. Calcd for $C_{38}H_{80}NBr\cdot H_2O$: C, 70.32; H, 12.73; N, 2.15%.

Kinetics. The hydrolysis was carried out mostly in 3 v/v % EtOH–H_2O at 30 °C, μ=0.01 (KCl), 0.01 M borate buffer (pH 7—10). The reaction rate was determined by using the absorbance of *p*-nitrophenolate at 401 nm (λ_{max}) with a Hitachi 200 UV-visible spectrophotometer. The pH value of the reaction medium varied less than 0.05 pH during the reaction (HM-10B digital pH meter, Toa Electronics).

Results

Dye Binding to Ammonium Aggregates. The absorption maximum of Methyl Orange shows hypsochromic shifts in less polar media: 465 nm in water and 420—430

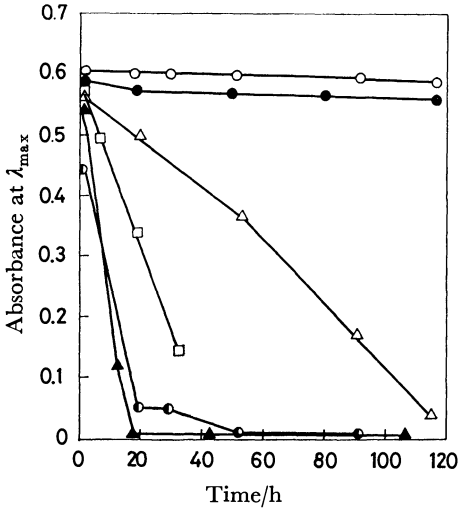


Fig. 1. Dialysis of Methyl Orange which are bound to ammonium aggregates.
pH 8.5, 0.01 M borate buffer, [Methyl Orange]=2×10^{-5} M.
▲: No ammonium salt, λ_{max}=465 nm. ○: $2C_{18}N^+2C_1$ (1×10^{-3} M), λ_{max}=410 nm. ◐: $2C_{18}N^+2C_1$(1×10^{-5} M), λ_{max}=450 nm. ●: $2C_{12}N^+2C_1$(1×10^{-3} M), λ_{max}=420 nm. △: CTAB(1×10^{-2} M), λ_{max}=430 nm. □: TMAC(2×10^{-4} M), λ_{max}=430 nm.

nm in organic media. Therefore, this compound has been used frequently for estimating the microscopic polarity of micelles[3] and polymers.[14,15] Methyl Orange (2×10^{-5} M) was dissolved in 10 ml of aqueous ammonium salts (10^{-3}—10^{-5} M) and these solutions in cellulose tubing (Visking Co.) were dialyzed against water. The residual Methyl Orange was determined at its absorption maximum.

As shown in Fig. 1, Methyl Orange is retained even after 120 h in the presence of 10^{-3} M of $2C_{12}N^+2C_1$ or $2C_{18}N^+2C_1$. Interestingly, however, Methyl Orange is rapidly lost in the presence of 1×10^{-5} M of $2C_{18}N^+2C_1$. Methyl Orange passes through the cellophane tube easily in the case of 2×10^{-4} M of TMAC, but the dialysis rate was slower in the presence of 10^{-2} M of CTAB.

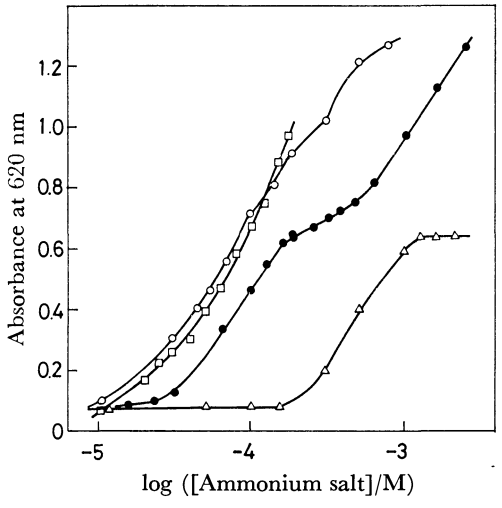

Fig. 2. Influence of hydrophobic ammonium salts on the dissociation of 2,6-dichlorophenolindophenol. 30 °C, 3 v/v % EtOH–H_2O, μ=0.01 (KCl), 1×10^{-4} M 2,6-dichlorophenolindophenol sodium salt, 3×10^{-4} M hydrochloric acid.
○: $2C_{18}N^+2C_1$. ●: $2C_{12}N^+2C_1$. □: TMAC. △: CTAB.

Dissociation of 2,6-dichlorophenolindophenol (*N*-(*p*-hydroxyphenyl)-2,6-dichloro-*p*-benzoquinone 4-imine) is often used for the measurement of the critical micelle concenctration (CMC) of cationic micelles:[3,16] λ_{max}= 500—520 nm for the undissociated species and λ_{max}= 600—650 nm for the dissociated species. Figure 2 shows the dependence of the absorbance at 620 nm, Abs_{620}, on the concentration of ammonium salts. In the case of CTAB, Abs_{620} starts to increase at *ca.* 5×10^{-4} M. The dissoication is facilitated at a lower concentration (5×10^{-5} M) of $2C_{12}N^+2C_1$. The effects of $2C_{18}N^+2C_1$ and TMAC are similar to each other, and Abs_{620} starts to increase at 1×10^{-5} M in both cases.

Alkaline(Spontaneous) Hydrolysis of p-*Nitrophenyl Esters.* The alkaline hydrolysis of *p*-nitrophenyl esters was studied at pH 10.0±0.1 in the presence of ammonium aggregates. The *p*-nitrophenol release obeyed the pseudo first order rate law for more than 90% completion. The logarithm of the pseudo first order rate constant, k_{spont}, was plotted against the logarithm of

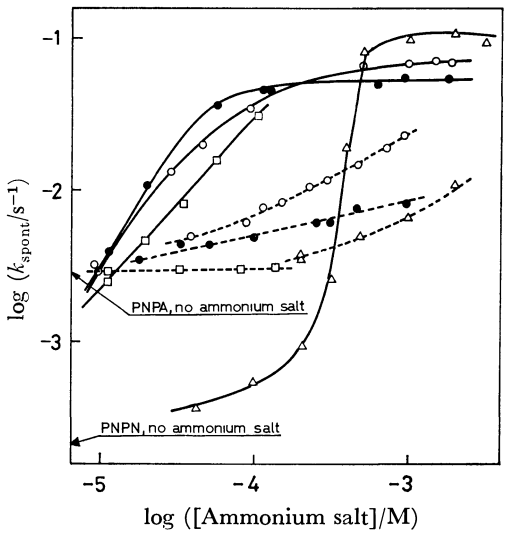

Fig. 3. Spontaneous (alkali) hydrolysis of *p*-nitrophenyl esters. 30 °C, pH 10.1±0.1, μ=0.01 (KCl), 3 v/v % EtOH–H_2O. ——: PNPN (2.00×10^{-5} M). ——:PNPA (2.00×10^{-5} M). ○: $2C_{18}N^+2C_1$. ●: $2C_{12}N^+2C_1$. △: CTAB. □: TMAC.

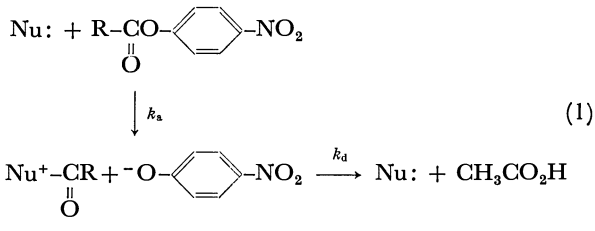
the ammonium concentration in Fig. 3. In the absence of ammonium salts, k_{spont} was 0.003 s^{-1} for PNPA and 0.00026 s^{-1} for PNPN. The TMAC aggregate did not affect the hydrolysis of PNPA, but micellar CTAB (1×10^{-3} M) increased the rate about two-fold. The bilayer aggregates of $2C_{12}N^+2C_1$ and $2C_{18}N^+2C_1$ accelerated the reaction by factors of 2.7 and 10 at the same concentration.

The rate enhancement was much greater with more hydrophobic PNPN substrate. k_{spont} increased by a factor of more than 100 fold upon micellization of CTAB. This must be due to efficient binding of PNPN to micellar CTAB and due to concentration of OH^- at the cationic micellar surface. The rate enhancement was observed at much lower concentrations ($<10^{-5}$ M) in the presence of other ammonium aggregates, but was saturated at 10^{-4} M. The rate saturation could not be confirmed with the TMAC aggregate because of its limited solubility.

The alkaline hydrolysis of PNPN was efficiently retarded by the increase in ionic strength: the rate decreased to 1/70 to 1/150 of the original value upon increase in ionic strength from 0.01 to 0.5 (KCl). The influence of ionic strength was larger in the bilayer systems than in the CTAB micelle.

Catalytic Hydrolysis of p-*Nitrophenyl Esters.* The catalytic hydrolysis by hydroxamate and imidazole nucleophiles proceeds *via* the acyl intermediate as in Eq. 1.



(1)

The apparent second-order rate constant of acylation is obtained by

$$k_{a,obsd} = \frac{k_{total} - k_{spont}}{[Nu]_T} \quad (2)$$

where k_{total} and k_{spont} are overall first order rate constants with and without catalyst, respectively. $[Nu]_T$ is the total concentration of nucleophile. The reaction obeyed the pseudo first order rate law for up to 90% completion. The rate constant of acyl transfer was obtained from these experiments, since excess catalyst was present in all cases relative to substrate molecules.

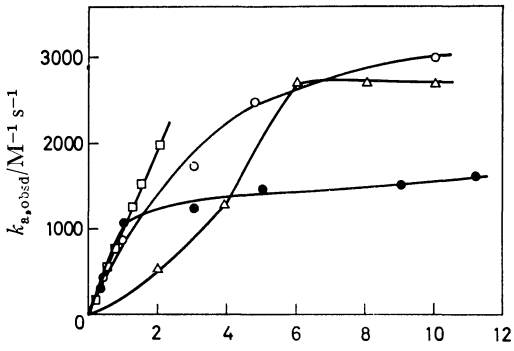


Fig. 4. Catalytic hydrolysis of PNPA by chol-HA in the presence of ammonium aggregates.
30 °C, 3 v/v % EtOH–H_2O, μ=0.01 (KCl), pH 8.9± 0.1, [PNPA]=3.79×10^{-6} M, [chol-HA]=3.02×10^{-5} M. ○: $2C_{18}N^+2C_1$. ●: $2C_{12}N^+2C_1$. △: CTAB. □: TMAC.

When chol-HA was used as nucleophilic catalyst $k_{a,obsd}$ increased in similar ways (100—300 fold) in the presence of all four ammonium aggregates as shown in Fig. 4. The rate enhanching effect is apparently related to the CMC, since efficient acceleration is noted at (2—6)$\times10^{-4}$ M for CTAB and at lower concentrations for the other ammonium salts. Similar trends were observed for other steroidal (chol-ImHA) and long-chain (C_{12}-BHA and C_{12}-ImAm) nucleophiles with rate enhancements of 100—300 fold.

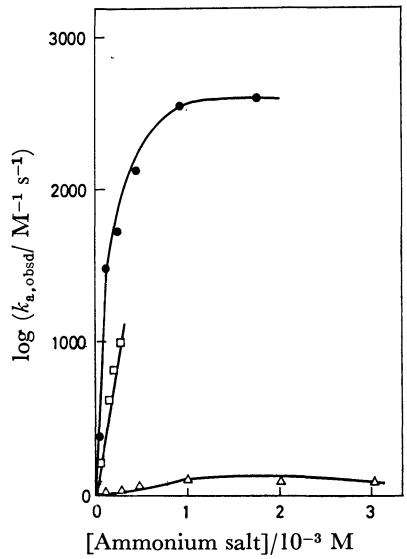

Fig. 5. Catalytic hydrolysis of PNPA by cholest-Im in the presence of ammonium aggregates.
30 °C, 3 v/v % EtOH–H_2O, μ=0.01 (KCl), pH 8.9± 0.1, [PNPA]=3.79×10^{-6} M, [cholest-Im]=3.10×10^{-5} M.
●: $2C_{12}N^+2C_1$. △: CTAB. □: TMAC

In contrast, the rate-enhancing effect for cholest-Im catalyst was more specific than those for the above-mentioned nucleophiles. As shown in Fig. 5, the nucleophilic reactivity of cholest-Im is much increased by the aggregate of TMAC and $2C_{12}N^+2C_1$, but the CTAB micelle produced a very small effect. It is interesting that cholest-Im could not be solubilized by the $2C_{18}N^+2C_1$ bilayer.

Chol-His catalyst could not be activated by any of the ammonium aggregates and $k_{a,obsd}$ was 6.5—9.2 $M^{-1}\,s^{-1}$ at pH 8.9 and 30 °C.

The $k_{a,obsd}$ values obtained for various nucleophiles in the presence of representative ammonium aggregates are collected in Table 1. The concentration of ammonium salt is 1×10^{-3} M except for TMAC in which case the concentration is 1×10^{-4} M because of its low solubility. The corresponding, less hydrophobic compounds were used to estimate $k_{a,obsd}$ in the absence

of the ammonium aggregate when hydrophobic nucleophiles were not soluble in water.

Figures 6 and 7 are pH-rate profiles for chol-HA and cholest-Im nucleophiles, respectively, in the presence and absence of some ammonium aggregates. In all cases, log $k_{a,obsd}$ increases linearly with slope of +1 in the low pH region and plateaus are observed at the high pH. Acid dissociation constants of nucleophile, K_a, and the true second-order rate constant of the anionic species, k_a, can be estimated by curve fitting of $k_{a,obsd}$ values to the following theoretical equation.

$$k_{a,obsd} = \frac{K_a}{a_H+K_a}\cdot k_a \quad (3)$$

$$k_{a,obsd} = \alpha\cdot k_a \quad (4)$$

where a_H is the activity of hydrogen ion and α is the fraction of the dissociated nucleophile species. Solid curves in Figs. 6 and 7 are obtained by using K_a and k_a values. The agreements between the calculated curves and the corresponding experimental plots are excellent.

Table 2 summarizes pK_a and k_a values thus obtained. In the presence of the ammonium aggregate, pK_a values are lowered and k_a values are enhanced by factors of 100 to 400. The k_a value for C_{12}-ImAm is similar in the CTAB micelle and in the $2C_{12}N^+2C_1$ bilayer; however, k_a for chol-HA is larger in CTAB than in $2C_{12}N^+2C_1$ and k_a for cholest-Im is some 20 times larger in $2C_{12}N^+2C_1$ than in CTAB. These results are suggestive of the specific interaction of nucleophiles and ammonium aggregates.

Discussion

Microenvironments of Ammonium Aggregates. As briefly mentioned in the Introduction, the three types of ammonium salts form quite different aggregates. Some of their physicochemical properties are summarized in Table 3. The critical micelle (aggregate) concentrations as determined by the surface tension measurement are in the range of 5×10^{-6} to 1×10^{-3} M, and decrease approximately with increasing carbon numbers. Therefore, the critical micelle concentration is predominantly determined by the hydrophobic-hydrophilic balance of a given ammonium salt without regard to the structural specificity. On the other hand, the mass of the ammonium aggregates is varied considerably, depending on their structural characteristics.

Table 2. Acidity and rate constants for hydroxamate and imidazole nucleophiles

Ammonium salts (1×10^{-3} M)	C_{12}-BHA		C_{12}-ImAm		chol-HA		cholest-Im	
	pK_a	k_a / M^{-1} s^{-1}	pK_a	k_a / M^{-1} s^{-1}	pK_a	k_a / M^{-1} s^{-1}	pK_a	k_a / M^{-1} s^{-1}
None	9.5[b]	20[b]	13[c]	12[c]	9.2	25	13[c]	12[c]

Table 3. Physicochemical properties of ammonium aggregates

Ammonium salts	Total carbon number	Aggregate morphology	10^4 CMC / M	10^{-4} Aggregate weight / dalton	Methyl Orange λ_{max}/nm
Single-chain					
CTAB ($C_{16}N^+3C_1Br^-$)	19	globular micelle	8	4	430(1×10^{-2} M)[a]
Double-chain					
$2C_{12}N^+2C_1Br^-$	26	bilayer	0.5[b]	100[d]	420(1×10^{-3} M)
$2C_{18}N^+2C_1Br^-$	38	bilayer	0.05[c]	1000[d]	410(1×10^{-3} M) 450(1×10^{-5} M)
Triple-chain					
TMAC($3C_8N^+C_1Cl^-$)	25	small, tight aggregate	*ca.* 0.3	<1	430(2×10^{-4} M)

a) λ_{max} is estimated at the ammonium concentration given in the parentheses. b) A. W. Ralston, D. N. Eggenberger, and P. L. DuBrow, *J. Am. Chem. Soc.*, **70**, 977 (1948). c) H. Kunieda and K. Shinoda, *J. Phys. Chem.*, **82**, 1710 (1978). The value for the chloride salt. d) Determined by the light scattering method: Union Giken Co., Ltd., Model LS-600.

The aggregate weight of TMAC is estimated to be less than 10^4 daltons and that of CTAB is 4×10^4 daltons. In contrast, the double-chain ammonium salts form huge aggregates of 1—10 million daltons. The hydrophobic nature of these aggregates can be estimated from λ_{max} of Methyl Orange. The λ_{max} values given in Table 1 correlate roughly with the total carbon numbers. However, λ_{max} was closer to that in water when 1×10^{-5} M of $2C_{18}N^+2C_1$ was present, probably due to incomplete formation of the stable aggregate.

The facilitated dissociation of 2,6-dichlorophenolindophenol appears to reflect the critical micelle concentration. Thus, Abs_{620} abruptly increased at *ca.* $(4—8)\times10^{-4}$ M of CTAB, but it increased at ammonium concentrations as low as 10^{-5} M in the case of other ammonium salts.

The dialysis experiments indicate that Methyl Orange is retained in the dialkylammonium bilayers most effectively as shown in Fig. 1. The CTAB micelle is much less effective and the TMAC micelle lacks in the retention capability almost completely. These trends can be correlated with the aggregate weight. Undoubtedly, the dialkylammonium aggregates can retain Methyl Orange very well because of their highly-organized, stable structures. This capacity is lost at concentrations close to the CMC, as shown by the data obtained in the presence of 1×10^{-5} M of $2C_{18}N^+2C_1$.

Specific Activation by Ammonium Bilayers. The spontaneous(alkali) hydrolysis of phenyl esters is accelerated in the presence of cationic micelles. This is usually explained by assuming that hydroxide ions concentrated in the Stern layer act on the phenyl ester bound to the micellar phase.[17] The results of Fig. 3 endorse this explanation. It is clear that PNPA is weakly bound to the ammonium aggregate in contrast to the tight binding for more hydrophobic PNPN, since acceleration of the spontaneous hydrolysis is 200—300 times for PNPN but is at most 10 times for PNPA.

As shown in Table 1, the catalytic hydrolysis of PNPA is remarkably accelerated in the presence of all the ammonium aggregates: 100—1000 times rate enhancements. The pK_a values of the hydroxamate and imidazole nucleophiles are lowered by 0.3—3 pK units when they are bound to any of the aggregates of the single-chain, double-chain and triple-chain ammonium salts. At the same time, their k_a values are enhanced by factors of several hundred (Table 2). These results violate the Brönsted relationship and is explained by the concept of "*hydrophobic ion pair*."[4,5,18]

According to this concept, prominent activation of some anionic nucleophiles is attributed to the formation of ion pairs between anionic nucleophiles and ammonium surfactants in the hydrophobic microenvironment, which usually results in pK_a lowering of the conjugate acid of the nucleophile (increase in the amount of the effective nucleophile) and the increased reactivity of the anionic nucleophile (k_a increase). The data of Table 2 clearly show that large enhancements of $k_{a,obsd}$ (Table 1) are derived from pK_a lowering and the increase in k_a. Chol-His nucleophile is not activated because it is not an anionic nucleophile under the reaction conditions used.

The extent of rate acceleration for long-chain hydroxamate and imidazole nucleophiles (C_{12}-BHA and C_{12}-ImAm) of Table 1 appears to be in general agreement with the trend of facilitated dissociation of 2,6-dichlorophenolindophenol: TMAC>$2C_{18}N^+2C_1$>$2C_{12}N^+2C_1$>CTAB. The rate-enhancing effect of the ammonium aggregate is somewhat different in the case of chol-HA, and the CTAB micelle is more effective than the $2C_{12}N^+2C_1$ bilayer. On the other hand, cholest-Im is *ca.* 40 time more activated in the $2C_{12}N^+2C_1$ bilayer than in the CTAB micelle. Furthermore, the bilayer-bound cholest-Im is more reactive than that bound to the TMAC aggregate. The reverse is true for other nucleophiles. These results cannot be explained by the hydrophobicity of the aggregate alone.

Aqueous solutions of the dialkylammonium aggregate can solubilize cholesterol, and the bilayer structure is retained in electron micrographs upon addition of one third molar cholesterol.[7] It is well known that cholesterol is an important ingredient of plasma membranes and affect the membrane fluidity.[19] Therefore, cholest-Im is conceivably bound to the ammonium bilayer in a specific manner. The specific nature of cholesterol binding may be related to the inability of the $2C_{18}N^+2C_1$ bilayer to solubilize cholesterol. On the other hand, cholic acid acts as a surfactant that disintegrates the phospholipid bilayer.[20] Similarly, the lamella structure

of the $2C_{18}N^{+}2C_1$ aggregate is destroyed when one third molar cholic acid is added.[21] Then, nucleophiles derived from cholic acid must be bound to the ammonium bilayer non-specifically.

The rate-enhancing effect of CTAB and TMAC aggregates appears to be determined predominantly by the hydrophobicity of nucleophiles and ammonium aggregates. Specific binding cannot be expected because of the fluid nature of these aggregates. In contrast, dialkylammonium salts form the stable bilayer structure similar to the phospholipid bilayer, and specific binding is quite conceivable. Why the conceivably specific binding of a cholesteric nucleophile produces better rate enhancement is not yet clear.

The Reactions of 1,2-Diphenyl-1-azaspiro[2.2]pentane and 2-Phenyl-1-azaspiro[2.2]pent-1-ene with *C,N*-Diarylnitrilimines[1)]

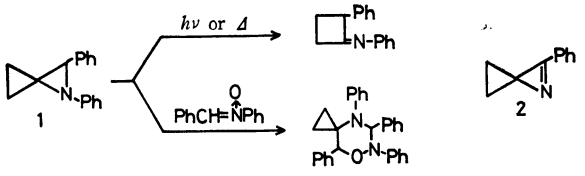
Otohiko Tsuge,* Hiroyuki Watanabe, and Yoko Kiryu

Research Institute of Industrial Science, Kyushu University 86, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 20, 1979)

The reactions of highly strained 1,2-diphenyl-1-azaspiro[2.2]pentane (**1**) and 2-phenyl-1-azaspiro[2.2]pent-1-ene (**2**) with *C,N*-diarylnitrilimines (**3**) were described. The reaction of **1** with **3** gave the corresponding 4,5,7,8-tetraphenyl-4,6,7-triazaspiro[2.5]oct-5-ene, 1,5,7,8-tetraphenyl-5,6,8-triazaspiro[3.4]oct-6-ene, 1,3,5-triphenyl-2-pyrazoline, 1,3,4-triphenyl-1,2,4-triazolin-5-one, and/or 1,3,4,6,8-pentaphenyl-1,2,4,6,7-pentaazaspiro[4.4]nona-2,7-diene, whose yields depended on the reaction conditions. The pathways for the formation of products are also postulated. The azaspiropentene **2** readily reacted with **3** to give the corresponding 1,2,4-triphenyl-2,3,5-triazabicyclo[4.2.0]octa-3,5-diene arising from the rearrangement of initial 1,3-cycloadduct.

It has been reported that highly strained 1,2-diphenyl-1-azaspiro[2.2]pentane (**1**) is susceptible to rupture of the peripheral C–N bond. Upon photolysis or pyrolysis the azaspiropentane **1** isomerizes to the (phenylimino)-cyclobutane,[2)] whereas the [3+3] cycloadduct is formed from the reaction in the presence of α,*N*-diphenylnitrone.[3)] On the other hand, 2-phenyl-1-azaspiro[2.2]pent-1-ene (**2**) exhibited high reactivity toward 1,3-dipoles such as nitrile ylide and nitrone.[4)]

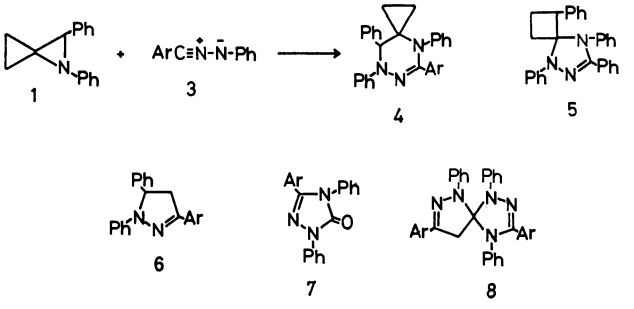


In the present paper we wish to report on the reactions of these highly strained heterocycles, **1** and **2**, with *C,N*-diarylnitrilimines, generated *in situ* from the corresponding *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazines and triethylamine.

Reaction of 1,2-Diphenyl-1-azaspiro[2.2]pentane (1). When the azaspiropentane **1** was allowed to react with 1 equivalent of *C,N*-diphenylnitrilimine (**3a**) in chloroform at room temperature for 60 h, a 1:1 adduct **4a** was obtained in 19.5% yield, together with small amounts of 1,3,5-triphenyl-2-pyrazoline (**6a**)[5)] and 1,3,4-triphenyl-1,2,4-triazolin-5-one (**7a**).[6)] However, the reaction employed 2 equivalents of **3a** in boiling chloroform for 1 h afforded a new 1:1 adduct **5a** and pyrazoline **6a** in 54 and 23% yields respectively.

Although purification of the 1:1 adduct **4a** was difficult, **4a** was deduced to be the expected [3+3] cycloadduct, 4,5,7,8-tetraphenyl-4,6,7-triazaspiro[2.5]-oct-5-ene, on the basis of its ^{1}H-NMR spectrum displaying signals at δ 0.50—1.85 (m, 4H) and 4.69 ppm (s, 1H) besides aromatic protons. On the other hand, the ^{1}H-NMR spectrum of the 1:1 adduct **5a** showed signals at δ 1.81—2.40 (m, 3H), 2.72—3.20 (m, 1H), and 4.54 ppm (t, 1H, J=12 Hz) besides aromatic protons. The adduct **5a** was thus assigned to be the 1,3-cycloadduct of **3a** to 1-phenyl-2-(phenylimino)-cyclobutane, 1,5,7,8-tetraphenyl-5,6,8-triazaspiro[3.4]-oct-6-ene[7)] (Scheme 1).

Next, the reaction of **1** with *C*-(*p*-chlorophenyl)-*N*-phenylnitrilimine (**3b**) was investigated in chloroform under various conditions. The results are summarized in Table 1. As shown in Table 1, the kinds and yields



a: Ar=Ph; **b**: Ar=p-ClC$_6$H$_4$

Scheme 1.

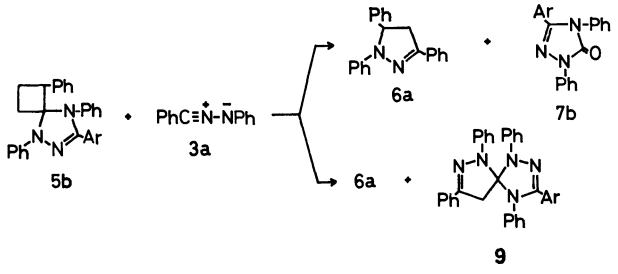
of products greatly depended on the reaction conditions. The reaction at room temperature gave the expected [3+3] cycloadduct **4b** as the major product, whereas the isomeric 1:1 adduct **5b** was formed as the sole product in the reaction under reflux. When excess of **3b** was employed, 3-(*p*-chlorophenyl)-1,5-diphenyl-2-pyrazoline (**6b**), 3-(*p*-chlorophenyl)-1,4-diphenyl-1,2,4-triazolin-5-one (**7b**), and/or a new product **8b** were formed together with 1:1 cycloadducts **4b** and/or **5b**. The structures of **6b** and **7b** were confirmed by the identification with authentic samples prepared from the 1,3-dipolar cycloadditions of **3b** to styrene and phenyl isocyanate respectively.

The molecular formula of **8b** agreed with that of the compound derived from a 1:2 adduct of **1** to **3b** with the elimination of styrene. The ^{1}H-NMR spectrum

Table 1. Reaction of azaspiropentane **1** with nitrilimine **3b** in chloroform

1/**3b** (mol/mol)	Reaction temp	Reaction time/h	Product yield/%				
			4b	**5b**	**6b**	**7b**	**8b**
1	r.t.	60	43	trace	—	—	—
1	reflux	1	—	21	—	—	—
1	reflux	4	—	38	—	—	—
1/2	reflux	2	29	17	3	7	—
1/3	reflux	6	10	—	60	—	8

of **8b** displayed two doublets (each 1H, J=20 Hz) at δ 3.20 and 3.78 ppm besides aromatic protons. On the basis of the above facts and of a consideration of the mode of formation, **8b** was deduced to be 3,8-bis(*p*-chlorophenyl)-1,4,6-triphenyl-1,2,4,6,7-pentaazaspiro-[4.4]nona-2,7-diene.

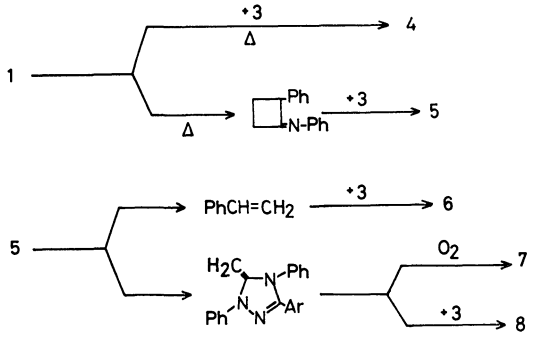


Ar=*p*-ClC$_6$H$_4$

Scheme 2.

The above results suggest that the products, **6**, **7**, and **8** might be arisen from the 1: 1 adduct **5**. In fact, when a chloroform solution of the 1: 1 adduct **5b** was heated with 1 equivalent of the nitrilimine **3a** for 4 h, the pyrazoline **6a** was formed in 23% yield along with a trace amount of the triazolinone **7b**. In the same reaction in degassed chloroform under nitrogen, however, **6a** and the pentaazaspiro[4.4]nonadiene **9** were obtained in 23 and 30% yields respectively (Scheme 2).

On the basis of the above facts, the pathways for the formation of products are outlined as depicted in Scheme 3. A species generated by the rupture of the peripheral C–N bond of the azaspiropentane **1** reacts with the nitrilimine **3** to give the [3+3] cycloadduct **4**, and/or isomerizes to the (phenylimino)cyclobutane. The nitrilimine **3** undergoes 1,3-dipolar cycloaddition to

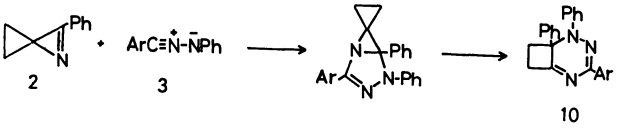


Scheme 3.

the (phenylimino)cyclobutane to yield the isomeric 1: 1 adduct **5**, which partially decomposes to styrene and methylenetriazoline. The 1,3-cycloaddition of **3** to styrene or methylenetriazoline gives the pyrazoline **6** or pentaazaspirononadiene **8** respectively. On the other hand, oxidation of the methylenetriazoline intermediate with oxygen leads to the formation of the triazolinone **7**. A similar oxidation of methylene group with oxygene has been reported by Woerner *et al.*[8]

Reaction of 2-Phenyl-1-azaspiro[2.2]pent-1-ene (2). Several 1,3-dipolar cycloadditions to 1-azirines have been investigated.[9] However, no studies on the cycloadditions of nitrilimine to 1-azirines seem to have been reported, although it is known that nitrilimines undergo cycloadditions to C=N bonds.[6]

The azaspiropentene **2** readily reacted with *C,N*-diarylnitrilimines, **3a** and **3b**, in benzene at room temperature, giving the corresponding 1: 1 adducts, **10a** and **10b**, in excellent yields respectively. On the basis of spectral data as well as of the chemical conversions, the 1: 1 adducts **10** were assigned to be the corresponding 1,2,4-triphenyl-2,3,5-triazabicyclo[4.2.0]octa-3,5-dienes which corresponded to the rearranged compounds of initial 1,3-cycloadducts (Scheme 4).



a: Ar=Ph; b: Ar=*p*-ClC$_6$H$_4$

Scheme 4

The ^{1}H-NMR spectra of **10a** and **10b** displayed four double double doublets (each 1H) indicating the presence of a cyclobutane ring. An inspection of the Dreiding models of **10** indicated that the fused cyclobutane ring in **10** is substantially fixed. On the basis of values of chemical shifts and coupling constants,[10] the protons of cyclobutane ring in **10** are assigned as shown in Table 2.

Reduction of **10a** with sodium borohydride in tetrahydrofuran gave the dihydro compound **11** in good yield. Structural elucidation of **11** was accomplished on the basis of spectral data. In addition, it was found that **10a** was converted to 2,4,5-triphenyl-1,3,4-triazabicyclo[3.3.0]oct-2-en-8-one (**12**) and 5-(2-benzoylethyl)-1,3-diphenyl-1,2,4-triazole (**13**) on treatment with silica gel or 1% aqueous acetic acid in benzene (Scheme 5).[11]

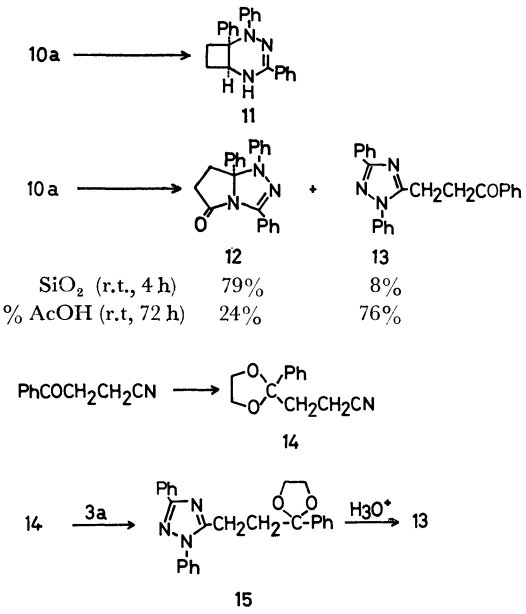
a) Measured in $CDCl_3$.



Scheme 5.

The structure of **12** was assigned on the basis of the spectral data, and **13** was confirmed by the identification with an authentic sample prepared by the route shown in Scheme 5.

Experimental

All melting points are uncorrected. IR, NMR, and mass spectra were obtained on a JASCO IRA-1 spectrometer, Hitachi R-40, JEOL SX-100 spectrometers, and a Hitachi RMS-4 spectrometer, respectively.

Reaction of Azaspiropentane ***1*** *with* C,N-*Diphenylnitrilimine (**3a**).* A solution of *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazine[6] (1.0 g, 4.34 mmol) in $CHCl_3$ (10 ml) was added, drop by drop, to a stirred solution of the azaspiropentane **1**[2] (0.89 g, 4.02 mmol) and NEt_3 (2.1 g, 20.8 mmol) in $CHCl_3$ (30 ml), under nitrogen, at room temperature. The reaction mixture was stirred at room temperature for 60 h, and then filtered to remove the formed triethylammonium chloride. The filtrate was concentrated *in vacuo*, and the residue was chromatographed on silica gel. From the fraction using hexane–benzene (1: 2) as eluent, 0.325 g (19.5%) of the [3+3] cycloadduct **4a**, mp *ca.* 100 °C, as yellow crystals, and 3 mg of 1,3,5-triphenyl-2-pyrazoline (**6a**), mp 137—138 °C (lit,[5] mp 137—138 °C), as colorless needles were obtained. The fraction using $CHCl_3$ as eluent gave 5 mg of 1,3,4-triphenyl-1,2,4-triazolin-5-one (**7a**), mp 224—225 °C (lit,[6] mp 223—224 °C), as colorless needles.

Recrystallization of **4a** was difficult. IR (KBr) 1560 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 0.50—1.85 (m, 4H), 4.69 (s, 1H), 6.25—7.75 ppm (m, 20H). MS *m/e* 415 (M^+).

The azaspiropentane **1** (0.89 g) reacted with the nitrilimine **3a**, generated from the chloride (2.0 g, 8.68 mmol) and NEt_3 (4.2 g, 41.6 mmol), in $CHCl_3$ (40 ml) under reflux for 1 h, giving 0.90 g (54%) of the isomeric 1: 1 adduct **5a** and 0.276 g (23%) of **6a**.

Recrystallization of **5a** from EtOH afforded yellow plates, mp 128—130 °C. IR (KBr) 1555 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 1.81—2.40 (m, 3H), 2.72—3.20 (m, 1H), 4.54 (t, 1H, J=12 Hz), 6.60—7.64 ppm (m, 20H). MS *m/e* 415 (M^+). Found: C, 83.82; H, 6.06; N, 10.11%. Calcd for $C_{29}H_{25}N_3$: C, 83.55; H, 6.04; N, 9.99%.

Reaction of Azaspiropentane ***1*** *with* C-(p-*Chlorophenyl*)-N-*phenylnitrilimine (**3b**).* The reaction of **1** with **3b**, generated from *N*-(α,*p*-dichlorobenzylidene)-*N'*-phenylhydrazine[12] and NEt_3, was carried out under various conditions. The reaction mixture was worked up in a similar manner as above. From the fraction using hexane–benzene (1: 2) as eluent the [3+3] cycloadduct **4b** and 3-(*p*-chlorophenyl)-1,5-diphenyl-2-pyrazoline (**6b**) were obtained. The second and third fractions using benzene and $CHCl_3$ as eluents afforded the isomeric 1: 1 adduct **5b**, and 3-(*p*-chlorophenyl)-1,4-diphenyl-1,2,4-triazolin-5-one (**7b**) and the pentaazaspirononadiene **8b** respectively. The results are summarized in Table 1.

The 1: 1 Cycloadduct ***4b***: Mp 203—204 °C as colorless prisms (from hexane). IR (KBr) 1560 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 0.50—2.05 (m, 4H), 4.69 (s, 1H), 6.21—7.52 ppm (m, 19H). MS *m/e* 451, 449 (M^+). Found: C, 77.70; H, 5.40; N, 9.32%. Calcd for $C_{29}H_{24}N_3Cl$: C, 77.40; H, 5.38; N, 9.34%.

The 1: 1 Adduct ***5b***: Mp 134—135 °C as yellow plates (from MeOH). IR (KBr) 1560 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 1.51—2.49 (m, 3H), 2.52 (m, 1H), 4.48 (m, 1H), 6.52—7.76 ppm (m, 19H). MS *m/e* 451, 449 (M^+), 347, 345 (M^+—$PhCH{=}CH_2$, base peak). Found: C, 77.36; H, 5.47; N, 9.41%. Calcd for $C_{29}H_{24}N_3Cl$: C, 77.40; H, 5.38; N, 9.34%.

The Pyrazoline ***6b***: Mp 150—151 °C as pale greenish needles (from EtOH). This compound was identical with an authetic sample prepared from the following method. A solution of styrene (1.0 g, 9.62 mmol) and *N*-(α,*p*-dichlorobenzylidene)-*N'*-phenylhydrazine (2.6 g, 9.81 mmol) in benzene (10 ml) was stirred with NEt_3 (4.3 g, 42.5 mmol) at 60 °C for 2 h. The reaction mixture was filtered to remove the formed triethylammonium chloride, and the filtrate was concentrated *in vacuo* to leave the residue. Recrystallization from MeOH gave 0.83 g (63%) of **6b**, mp 150—151 °C. IR (KBr) 1550 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 3.06, 3.78, 5.25 (each dd, 1H, J=7.5, 12.5, 17 Hz), 6.64—7.68 ppm (m, 14H). Found: C, 75.83; H, 5.05; N, 8.62%. Calcd for $C_{21}H_{17}N_2Cl$: C, 75.79; H, 5.11; N, 8.42%.

The Triazolinone ***7b***: Mp 185—186 °C as colorless needles (from EtOH). This compound was identical with an authentic sample prepared from the reaction of *N*-(α,*p*-dichlorobenzylidene)-*N'*-phenylhydrazine (1.0 g, 3.77 mmol) with phenyl isocyanate (0.5 g, 4.20 mmol) in the presence of aluminum oxide (0.3 g) according to the Huisgen's method.[6] IR (KBr) 1720 (C=O), 1580 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 7.08—7.58 (m, 12H), 7.90—8.16 ppm (m, 2H). Found: C, 68.89; H, 4.25; N, 12.13%. Calcd for $C_{20}H_{14}N_3OCl$: C, 69.06; H, 4.03; N, 12.08%.

The Pentaazaspirononadiene ***8b***: Mp 174—175 °C (dec) as colorless needles (from EtOH). IR (KBr) 1595 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 3.20, 3.78 (each d, 1H, J=20 Hz), 6.61—7.75 ppm (m, 23H). MS *m/e* 577, 575, 573 (M^+), 347, 345, 343 (M^+—$ArC{\equiv}\overset{+}{N}{-}\overset{-}{N}Ph$). Found: C, 70.86; H, 4.37; N, 11.99%. Calcd for $C_{34}H_{25}N_5Cl_2$: C, 71.08; H, 4.39; N, 12.19%.

Reaction of the 1: 1 Adduct ***5b*** *with the Nitrilimine* ***3a***. *i*): A solution of NEt_3 (0.1 ml, 0.69 mmol) in $CHCl_3$ (5 ml) was added, drop by drop, to a stirred solution of **5b** (0.3 g, 0.67 mmol) and *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazine (0.16 g, 0.69 mmol) in $CHCl_3$ (10 ml) at room temperature. The reaction mixture was then refluxed for 4 h, and concentrated *in vacuo* to leave the residue. Benzene was added to the residue, and the resultant mixture was filtered to remove the formed triethylammonium chloride. The filtrate was concentrated *in vacuo* and the residue was chromatographed on silica

gel using hexane–benzene (1: 1) and benzene as eluents, giving 46.3 mg (23%) of **6b** and 7 mg of **7b**.

ii): The same reaction was carried out in degassed $CHCl_3$ under nitrogen. After removal of triethylammonium chloride, the residue was triturated with EtOH to give 0.108 g (30%) of the pentaazaspirononadiene **9**. The EtOH solution was chromatographed on silica gel to give 31.9 mg (23%) of **6a**.

The Pentaazaspirononadiene 9: Mp 184—186 °C as colorless needles (from cyclohexane). IR (KBr) 1560 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 3.35, 3.86 (each d, 1H, J=20 Hz), 6.73—7.04 (m, 4H), 7.08—7.48 (m, 18H), 7.54—7.80 ppm (m, 2H). MS *m/e* 541, 539 (M^+), 347, 345 ($M^+ - PhC{\equiv}\overset{+}{N}-\bar{N}Ph$). Found: C, 75.53; H, 4.89; N, 13.03%. Calcd for $C_{34}H_{26}N_5Cl$: C, 75.64; H, 4.82; N, 12.97%.

Reaction of Azaspiropentane 2 with C,N-Diphenylnitrilimine (3a). A solution of *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazine (1.37 g, 5.94 mmol) in benzene (40 ml) was added, drop by drop, to a stirred solution of the azaspiropentene **2**[13] (0.85 g, 5.94 mmol) and NEt_3 (2.88 g, 28.4 mmol) in benzene (15 ml) under nitrogen at room temperature. The reaction mixture was then stirred for 24 h, and filtered to remove the formed triethylammonium chloride. The filtrate was concentrated *in vacuo* to leave the residue, which on recrystallization from hexane afforded 1.13 g (97%) of the triazabicyclooctadiene **10a**, mp 153—154 °C, as yellow needles. IR (KBr) 1675 cm^{-1} (C=N). ^{13}C-NMR ($CDCl_3$) δ 36.2, 38.5, 66.7, 116.2, 121.7, 125.5, 126.0, 127.9, 128.2, 128.5, 128.8, 129.0, 134.9, 136.3, 142.6, 146.0, 165.1. MS *m/e* 337 (M^+). Found: C, 81.85; H, 5.64; N, 12.46%. Calcd for $C_{23}H_{19}N_3$: C, 81.87; H, 5.18; N, 12.45%.

A similar reaction of **2** (0.37 g, 2.6 mmol) with the nitrilimine **3b**, generated from the corresponding chloride (0.68 g, 2.6 mmol) and NEt_3 (1.26 g, 13 mmol), in benzene (35 ml) afforded 0.89 g (94%) of the triazabicyclooctadiene **10b**, mp 178—180 °C (dec), as yellow needles. IR (KBr) 1673 cm^{-1}. ^{13}C-NMR ($CDCl_3$) δ 36.2, 38.5, 66.6, 116.3, 121.9, 125.9, 126.7, 127.9, 128.4, 128.8, 129.0, 133.4, 134.3, 136.1, 142.3, 145.1, 165.2. MS *m/e* 373, 371 (M^+). Found: C, 74.31; H, 4.83; N, 11.16%. Calcd for $C_{23}H_{18}N_3Cl$: C, 74.28; H, 4.88; N, 11.30%.

Reduction of 10a. After a solution of **10a** (0.1 g) in THF (2 ml) was stirred with $NaBH_4$ (26 mg) at room temperature for 5 h, water (5 ml) was added to the reaction mixture. The mixture was acidified with 1.8% HCl to give a solid, which on recrystallization from cyclohexane gave 96 mg (95%) of the dihydro compound **11**, mp 181—182 °C, as colorless needles. IR (KBr) 3470 (NH), 1630 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$) δ 1.4—2.75 (m, 4H), 3.85 (broad, 1H, after exchange with D_2O, the signal changed to a double doublet, J=7.0, 8.8 Hz), 4.95 (broad, 1H, exchanged with D_2O), 6.50—7.50 (m, 13H), 7.60—7.85 (m, 2H). ^{13}C-NMR ($CDCl_3$) δ 23.1, 29.2, 54.5, 61.8, 115.8, 118.3, 124.8, 125.6, 126.7, 128.1, 128.6, 134.9, 138.1, 142.7, 144.6. MS *m/e* 339 (M^+), 311 (base peak), 235, 219, 207, 180, 207, 180, 144, 104, 91. Found: C, 81.36; H, 6.33; N, 12.50%. Calcd for $C_{23}H_{21}N_3$: C, 81.38; H, 6.24; N, 12.38%.

Treatment of 10a with Silica Gel. A solution of **10a** (0.1 g) in benzene (2 ml) was stirred with silica gel (Wako-gel C-200, 0.5 g) at room temperature for 4 h. The mixture was filtered and the filtrate was concentrated *in vacuo* to leave a residue. The residue was chromatographed on silica gel using benzene as eluent to give 82.7 mg (79%) of the triazabicyclooctenone **12** and 8.4 mg (8%) of the 1,2,4-triazole **13**.

The Triazabicyclooctenone 12: Mp 96—97 °C as colorless prisms (from benzene). IR (KBr) 1735 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ 2.60—3.40 (m, 4H), 6.70—7.40 (m, 14H), 7.70—7.90 (m, 1H). ^{13}C-NMR ($CDCl_3$) δ 34.3, 35.4, 90.4, 114.4, 120.3, 125.5, 127.2, 127.8, 128.1, 128.2, 129.0, 129.7, 139.3, 140.9, 142.0, 174.5. MS *m/e* 353 (M^+), 298, 276, 194, 165, 103, 91. Found: C, 78.24; H, 5.43; N, 11.67%. Calcd for $C_{23}H_{19}N_3O$: C, 78.16; H, 5.42; N, 11.89%.

The 1,2,4-Triazole 13: Mp 115—116 °C as colorless needles (from EtOH). IR (KBr) 1682 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ 3.10—3.35 (m, 2H), 3.50—3.75 (m, 2H), 7.20—7.65 (m, 11H), 7.90—8.20 (m, 4H). ^{13}C-NMR ($CDCl_3$) δ 21.1, 36.1, 125.2, 126.4, 128.0, 128.5, 128.6, 128.9, 129.1, 130.8, 133.2, 136.5, 137.4, 155.8, 198.0. MS *m/e* 353 (M^+), 248 (M^+—PhCO, base peak), 105, 91. Found: C, 78.19; H, 5.34; N, 11.88%. Calcd for $C_{23}H_{19}N_3O$: C, 78.16; H, 5.42; N, 11.89%.

Treatment of 10a with 1% Aqueous AcOH. A solution of **10a** (40 mg) in benzene (2 ml) was stirred with 1% aqueous AcOH (1 ml) at room temperature for 4 days. The benzene solution was concentrated *in vacuo* to leave a residue. Chromatography of the residue on silica gel (benzene) afforded 10 mg (24%) of **12** and 32 mg (76%) of **13**.

Preparation of 5-(β-Benzoylethyl)-1,3-diphenyl-1,2,4-triazole (13). A mixture of β-benzoylpropionitrile[14] (4.0 g), ethylene glycol (6.0 g), and a catalytic amount of *p*-toluenesulfonic acid in benzene (70 ml) was boiled with azeotropic removal of water. After being boiled for 50 h, the reaction mixture was concentrated *in vacuo* to give 5.3 g (100%) of 2-(2-cyanoethyl)-2-phenyl-1,3-dioxolane (**14**) which on recrystallization from hexane afforded colorless needles, mp 62.5—63.5 °C. Found: C, 70.88; H, 6.54; N, 6.77%. Calcd $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45; N, 6.89%.

A solution of *N*-(α-chlorobenzylidene)-*N'*-phenylhydrazine (1.9 g, 8.24 mmol) in benzene (30 ml) was added, drop by drop, to a stirred solution of the above dioxolane **14** (1.7 g, 8.37 mmol) and NEt_3 (5.9 g, 83.4 mmol) in benzene (20 ml), under nitrigen, at room temperature. After being refluxed for 65 h, the reaction mixture was filtered, and the filtrate was concentrated *in vacuo* to leave a residue. The residue was chromatographed on silica gel using benzene as eluent to give 0.329 g (10%) of 2-[2-(1,3-diphenyl-1,2,4-triazol-5-yl)-ethyl]-2-phenyl-1,3-dioxolane (**15**), along with recovery of 1.5 g (88%) of **14**.

The Triazole 15: Mp 104—105 °C as colorless needles (from hexane). Found: C, 75.64; H, 5.87; N, 10.61%. Calcd for $C_{25}O_{23}N_3O_2$: C, 75.54; H, 5.83; N, 10.57%.

A suspension of the triazole **15** (50 mg) in 5% aqueous HCl (5 ml) was stirred at room temperature for 22 h. Filtration gave crystals which were washed with NH_4OH and water, and then recrystallized from EtOH to give 42.3 mg (95.5%) of **13**, mp 115—116 °C.

Effect of Alcohols on the Thermal Denaturation of Lysozyme as Measured by Differential Scanning Calorimetry

Yukihisa FUJITA,* Akihiko MIYANAGA, and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663

(Received June 30, 1979)

The thermal denaturation of lysozymc in aqueous alcohol solution has been investigated by differential scanning calorimetry. The alcohols employed were methanol, ethanol, isomeric propyl alcohols and butyl alcohols as monohydric alcohols, and ethylene glycol and glycerol as polyhydric alcohols. In monohydric alcohols, the temperature of denaturation, T_d, of lysozyme decreased linearly with increasing alcohol concentration, which became pronounced with an increasing in the hydrophobic character. The enthalpy of denaturation, ΔH_d, of lysozyme showed a complex dependence on the solvent composition; the ΔH_d first increased with increasing alcohol concentration and then started decreasing at different concentrations for each alcohol. The branching of the alkyl chain decreased the destabilizing effect of the alcohol on the native conformation of the protein. In polyhydric alcohols, both T_d and ΔH_d increased with increasing alcohol concentration. The polyhydric alcohols stabilized the native conformation of the protein in contrast with the monohydric alcohols. The results are discussed in terms of the hydrophobic and hydrophilic characters of the alcohols.

In an earlier work, the hydration, the ordering of the water molecules around the protein molecule, were reported to play an important role in the stabilizing the native structure of the globular protein.[1,2] The addition of alcohol to a protein solution is expected to affect the stability of the native structure of the protein due to alteration in the characteristic structure of water. The effect of alcohols on the stability of globular proteins have been extensively investigated by spectroscopic measurements.[3–5] The studies have revealed that the effectiveness of the alcohols as protein denaturants increased with increasing chain length or hydrocarbon content. Hamaguchi *et al.*[6,7] have, however, found that the CD and difference spectra of the lysozyme in aqueous alcohol solutions depend nonlinearly on the concentration of alcohol at a concentration below that required to unfold the protein. Moreover, Parodi *et al.*[8] have reported from different spectrophotometric and ORD studies of the thermal denaturation of lysozyme in aqueous alcohol solutions that the van't Hoff enthalpy of denaturation showed a complex dependence on alcohol concentration.

In this paper, the effect of mono- and polyhydric alcohols on the thermal denaturation of lysozyme as measured by differential scanning calorimetry (DSC) will be reported.

Experimental

Materials and Methods. The hen egg-white lysozyme used in the present study was a six-times recrystallized preparation obtained from Seikagaku Kogyo Co. The alcohols employed were methanol, ethanol, the isomeric propyl alcohols and butyl alcohols, ethylene glycol and glycerol. The alcohols employed were spectroscopic grade or analytical grade reagents and were used without further purification. The concentration of the stock solution of the lysozyme, which dissolved with the 0.1 M glycine–HCl buffer (pH 3), was determined spectrophotomerically using an extinction of $E^{1\%}_{1cm}=26.9$ at 280 nm. The sample solution were prepared by mixing suitable aliquots of stock solution with the alcohol.

Calorimetric measurements were conducted with a Rigaku Denki standard-type differential scanning calorimeter at a heating rate of 10 K/min and a concentration of 15—25 mg/cm^3. The molecular weight of lysozyme was taken as 14300.[9]

Results and Discussion

The thermal denaturation of lysozyme in aqueous alcohol solutions was measured with a differential scanning calorimeter. For each solution, a reproducible endothermic peak was observed occurring over a temperature range of 15—20 K. The temperature, T_d, and the enthalpy, ΔH_d, of denaturation were estimated from the peak temperature and the peak-area in the thermogram obtained.

The T_d and ΔH_d in solutions containing methanol, ethanol, 1-propanol, and 1-butanol are plotted as a function of the alcohol concentration in Figs. 1 and 2, respectively. The T_d decreased gradually with increasing alcohol concentration, which became more pronounced with an increase in length of the alkyl chain. A similar dependence of the T_d on the concentration and/or length of the alkyl chain of alcohols has been reported earlier for ribonuclease[3,10] and lysozyme[8,10] from spectroscopic studies of thermal denaturation. The ΔH_d showed a complex dependence on the solvent composition; the ΔH_d first increased with increasing

alcohol concentration and then started decreasing at a different concentration for each alcohol. The maximum in the values of ΔH_d occurred in the order of methanol, ethanol, 1-propanol, and 1-butanol, that is, increasing hydrophobic character of the alcohol added. Moreover, the maximum value of ΔH_d decreased with increasing length of the alkyl chain and all values of ΔH_d observed in aqueous 1-butanol solutions were smaller than that in the aqueous solution.

This observation was similar to that for van't Hoff enthalpies of denaturation obtained by Parodi *et al.*[8] from spectroscopic studies of lysozyme in aqueous alcohol solutions. Recently, Velicelebi and Sturtevant[11] have reported similar plots for the enthalpies of denaturation determined from high sensitivity calorimetric measurements of the thermal denaturation of lysozyme in similar alcohol–water mixtures at pH 2. The ΔH_d values obtained in our present work appear to be in fairly good agreement with those reported by Velicelebi and Sturtevant. The T_d values, however, in our work were considerably higher. The differences probably result from the large difference in the heating rate.

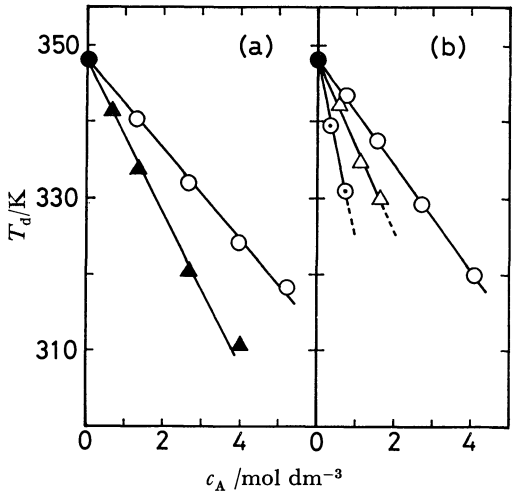

Fig. 3. The temperature of denaturation, T_d, of lysozyme as a function of the concentration, c_A. (a) Isomeric propyl alcohols, ●, water; ○, *i*-PrOH; ▲, *n*-PrOH. (b) Isomeric butyl alcohols, ●, water; ○, *t*-BuOH; △, *s*-BuOH; ⊙, *n*-BuOH.

The effect of branched-chain alcohols was also investigated and the results are showed in Figs. 3 and 4 together with the results of the corresponding straight-chain alcohols. The lowering of the T_d by the branched-chain alcohols was smaller than that by the corresponding straight-chain alcohols. The ΔH_d in the branched-chain alcohol solutions showed a complex dependence on the solvent composition, as found in the case of straight-chain alcohols. The maximum in the values of ΔH_d occurred at a higher alcohol concentration than that in the corresponding straight-chain alcohol. The results indicate that branching of the alkyl chain reduces the effectiveness of the alcohol as protein denaturants.

Aliphatic alcohols can be regarded either as hydrocarbons containing hydrophilic hydroxyl groups or as water in which one hydrogen atom has been replaced by a hydrophobic alkyl group. The effect of alcohols on the stability of the native structure of protein in terms of the hydrophobic, destabilizing, and hydrophilic, stabilizing, effects. In the monohydric alcohols the results indicate that the hydrophobic effect, which enhances with chain length of the alkyl groups, dominates the hydrophilic effect. The selective binding of alcohols to the nonpolar groups of protein in water–alcohol mixtures has been experimentally verified.[12] It is well documented that alcohols perturb the characteristic water structure around the protein molecule.[13] The binding of alcohols to the nonpolar side chains of proteins which become exposed during denaturation may reduce the ordering effect of the nonpolar side chains on the water molecules, simultaneously leading to the weakening hydrophobic interaction between the nonpolar side chains, which favors the denatured state. Therefore, the depression of T_d by the addition of alcohols which increases with increasing alcohol concentration and/or length of the alkyl chain appears to be

associated to a predominance of an increasing entropy of the denaturation. This result is in agreement with that of Schrier *et al.*[3] suggesting that the lowering of the denaturation temperature of ribonuclease by alcohols is largely entropy dependent.

The complex dependence of the ΔH_d on the alcohol concentration and/or length of the alkyl chain may also be discussed in terms of the hydrophobic effect of alcohols. At lower alcohol concentration, the alcohol molecules interact selectively with the nonpolar groups of protein, and thus the hydrophobic interaction between the nonpolar groups of protein is weakened. As suggested by Privalov,[14] rupture of the hydrophobic bond is accompanied by liberation rather than absorption of heat. It appears resonable to consider weakening of the hydrophobic bond by the addition of alcohol reduces the exothermic contribution of hydrophobic-bond rupture to the total ΔH_d. In addition, it has been experimentally shown that the secondary structure of polypeptide was stabilized more in water–alcohol mixtures than in water.[15] This suggestes that the disordering of the water molecules around the protein molecule due to the binding of alcohol to the nonpolar groups of protein enhances the stability of the secondary structure of protein which is created essentially by the interaction between the polar groups of protein. The addition of alcohol will lead to an increase in ΔH_d because the rupture of the polar interaction is an endothermic reaction. At higher alcohol concentration, however, alcohol may increase the ordering of water molecules, leading to not only stronger hydrophobic interaction but a weakening of the polar interaction. The rise in the temperature of maximum density of water by the addition of alcohol has been accounted for by the ordering of water molecules by alkyl groups.[16]

The T_d and ΔH_d in solutions containing ethylene glycol and glycerol are plotted as a function of the alcohol concentration in Fig. 5. In contrast with the case of monohydric alcohols, the T_d in the solutions of polyhydric alcohols increased with increasing alcohol concentration. The ΔH_d increased also with increasing alcohol concentration. The increase in the T_d and ΔH_d became more pronounced in the order: ethylene glycol, glycerol, that is, increasing the number of hydroxyl groups of the polyhydric alcohol added. It is apparent that polyhydric alcohols stabilize the native structure of protein; the hydrophilic effect of polyhydric alcohols dominate the hydrophobic effect. When the methylene group was present in equimolar quantities the polyhydric alcohol stabilized the native structure of protein in contrast to the monohydric alcohol. This is to be expected if the hydrophobic interaction between the nonpolar group of protein and the nonpolar part of the alcohol molecule is an important factor in destabilization. A higher degree of interaction exists between polyhydric alcohol and water than monohydric alcohol and water. Introduction of a second and third hydroxyl group into a monohydric alcohol increases the interaction with water, whereas the hydrophobic properties are less pronounced.

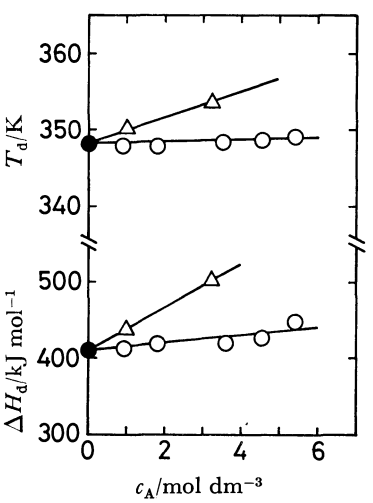

Fig. 5. The temperature, T_d, and the enthalpy, ΔH_d, of denaturation of lysozyme as a function of the alcohol concentration, c_A.

Gerlsma and Stuur[10] have suggested that there was no direct molecular interaction between protein and polyhydric alcohol from the studies on the thermal denaturation of ribonuclease and lysozyme in the present of polyhydric alcohols. This suggests that the hydrophilic effect of alcohols on the stability of protein appears mainly to be of an indirect kind, *viz.* either a strengthening of the polar interaction by a lowering of the dielectric constant, an increasing of the enthalpic change of denaturation, and/or an intensifying of the hydrophobic interaction of protein by altering the water structure, which principally is entropically controlled. The addition of polyhydric alcohol may lead to the strengthening of the polar interaction by reducing the interactions with water molecules and by lowering the dielectric constant of the medium. It is well known that hydrophobic interactions are intensified by an increase in temperature.[14] Therefore, it is also probable that the addition of polyhydric alcohol may enhance the hydrophobic interactions. The hydrophilic effect increases the hydrophobic contribution to the stabilizing of the native structure of protein. This may be induced not only by the hydrophilic groups of the added alcohols but the polar groups of the protein molecule itself will exert a similar effect on the surrounding water molecules.

Restricted Rotation Involving the Tetrahedral Carbon. XXVII. Rotamers of 9-(1-Cyano or 1-Methoxycarbonyl-1-methylethyl)triptycene Derivatives Carrying a Substituent in 1-Position[1)]

Soichi OTSUKA, Tsutomu MITSUHASHI, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received June 30, 1979)

The title compounds were prepared by the reaction between 9-(1-cyano or 1-methoxycarbonyl-1-methylethyl)-anthracene and substituted benzynes and their rotational isomers were isolated. The barriers to rotation of these compounds were found to be 35—36 kcal/mol and 32—34 kcal/mol for the processes *dl*→*meso* and *meso*→*dl*, respectively.

Triptycenes carrying a tertiary carbon in the 9-position are known to exhibit unusually high barriers to rotation about the C_9–C_{subst} bond.[2)] Thus various rotational isomers of this type have been isolated. The highest barrier to rotation has been realized with 9,9′-bitriptycyl derivatives (**1**).[3)] The second highest barrier known to date is that of 9,10-bis(1-cyano-1-methylethyl)triptycene (**2**).[4)] We have felt that it will be interesting to see whether triptycenes carrying a tertiary carbon in 9-position, one of which substituents is an sp^2 or sp hybridized carbon atom, exhibit high barriers to rotation in general. Since the barrier to rotation is the difference in energy between the ground and the transition states, the sp^2 or sp hybridized carbon might fit well in the triptycene skeleton to lower the ground state.

Syntheses

Syntheses of triptycenes are usually carried out by the Diels-Alder reaction of a substituted anthracene with a benzyne. The first problem, therefore, was to synthesize appropriately substituted anthracenes. This posed a problem, because this kind of compounds are usually prepared by the Grignard reaction with anthrone followed by dehydration. The electronegative groups such as cyano and methoxycarbonyl would not survive under the reaction conditions. Literature search indicated that, although there was a method to introduce a tertiary carbon carrying two electronegative groups to the 9-position of anthracene,[5)] there was no method to give the desired anthracenes. Various attempts were made, such as Reformatsky reaction, reaction of anthrone with the lithium derivative of isobutyronitrile, and methylation of 9-cyanomethylanthracene, but they all failed probably for steric reasons. Finally we were able to introduce 1-cyano- or 1-methoxycarbonyl-1-methylethyl group to the 10-position of anthrone by allowing the latter to react with azobisisobutyronitrile or dimethyl azobisisobutyrate under basic conditions.[6)] The substituted anthrone (**3**) was reduced with sodium borohydride and the product (**4**) was dehydrated with phosphorus pentaoxide. The 9-substituted anthracene (**5**) was treated with benzynes to give desired triptycenes

(**6**). Reactive benzynes such as tetrachlorobenzyne reacted to afford 1,4-addition products in addition to the desired 9,10-adducts. The former was found very difficult to remove from the latter. Thus the olefinic bond of the former was oxidized with performic acid and the resulted oxygenated compounds were removed by chromatography.

Experimental

10-(1-Cyano-1-methylethyl)anthrone (**3**, *Z=CN*). A solution of 3.07 g (15.8 mmol) of anthrone and 6.0 g (37 mmol) of azobisisobutyronitrile in 30 ml of pyridine–piperidine (2: 1) was heated at 90 °C for 6 h with stirring. The mixture was poured into excess of hydrochloric acid after cooling and the precipitate was collected. Tetramethylsuccinonitrile was removed by steam distillation of the precipitate and the residue taken up in dichloromethane. After drying, the solvent was evaporated and the residue was heated in vacuo until no sublimate was observed. The residue was chromatographed on alumina using hexane–benzene as an eluent. The desired product, mp 152 °C, was obtained as colorless crystals in 3.63 g (88%) yield. Found: C, 82.57; H, 5.79; N, 5.47%. Calcd for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36 %. ^{1}H NMR ($CDCl_3$, δ): 1.15 (6H, s), 4.27 (1H, s), 7.3—7.7 (6H, m), 8.1— 8.4 (2H, m). IR (KBr): 2235, 1675, 710 cm^{-1}.

9-(1-Methoxycarbonyl-1-methylethyl)anthrone (**3**, *Z=COOCH$_3$*), mp 89—90 °C, was similarly obtained in 62% yield from anthrone and dimethyl azobisisobutyrate. Found: C, 77.53; H, 6.16%. Calcd for $C_{19}H_{18}O_3$: C, 77.49; H, 6.14%. ^{1}H NMR ($CDCl_3$, δ): 0.89 (6H, s), 3.61 (3H, s), 4.52 (1H, s), 7.3—7.6 (6H, m), 8.0—8.3 (2H, m). IR (KBr): 1730, 1670, 1317, 705 cm^{-1}.

9-(1-Cyano-1-methylethyl)anthracene (**5**, *Z=CN*). A solution of 0.807 g (3.1 mmol) of **3** (Z=CN) in 15 ml of ethanol was refluxed for 2 h, while a solution of 0.9 g (24 mmol) of sodium borohydride in 10 ml of 90% ethanol was added in 10 min. Water was added and the mixture extracted with dichloromethane. After evaporation of the solvent, **4** (Z=CN) was obtained in 0.77 g yield as a roughly equimolar mixture of *cis* and *trans* isomers. The alcohol (**4**, Z=CN) in 20 ml of carbon tetrachloride was heated under reflux for 1 h with 5 g of phosphorus pentaoxide and the mixture was filtered. The solvent was evaporated from the filtrate and the residue was chromatographed on alumina. A small amount (*ca.* 4%) of anthracene was eluted first and then came 0.46 g (61%) of **5** (Z=CN), mp 138 °C (recrystallized from ethanol). Found: C, 87.83; H, 6.18; N, 5.69%. Calcd for $C_{18}H_{15}N$: C, 88.13; H, 6.16; N, 5.71%. ^{1}H NMR ($CDCl_3$, δ): 2.37 (6H, s), 7.3—7.6 (4H, m), 7.8—8.1 (2H, m), 8.40 (1H, s), 8.4—8.7 (2H, m). IR (KBr): 2230, 735 cm^{-1}.

9-(1-Methoxycarbonyl-1-methylethyl)anthracene (**5**, *Z=COOCH$_3$*), mp 123—125 °C, was similarly prepared in 41% yield. Found: C, 81.74; H, 6.46%. Calcd for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52%. ^{1}H NMR ($CDCl_3$, δ): 2.12 (6H, s), 3.46 (3H, s), 7.2—7.6 (4H, m), 7.8—8.3 (4H, m), 8.37 (1H, s). IR (KBr): 1715, 1258, 1143, 717 cm^{-1}.

9-(1-Carbamoyl-1-methylethyl)anthracene. A solution of 1.0 g of **5** (Z=CN) and 5.0 g of potassium hydroxide in 50 ml of 2-ethoxyethanol was heated under reflux for 3 h under a nitrogen atmosphere. The mixture was treated with dilute hydrochloric acid after cooling and the precipitate was taken up in benzene. Evaporation of the solvent and recrystallization of the residue from tetrahydrofuran–hexane gave the amide, mp 226—227 °C. Found: C, 82.11; H, 6.45; N, 5.38%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%. ^{1}H NMR ($CDCl_3$, δ): 2.13 (6H, s), 5.0 (2H, broad), 7.2—7.6 (4H, m), 7.7—8.1 (2H, m), 8.35 (1H, s), 8.1—8.5 (2H, m). IR (KBr): 3450, 3300, 3170, 1640, 735 cm^{-1}.

9-(1-Cyano-1-methylethyl)triptycene (**6**: *X=Y=H, Z=CN*). A solution of 2.00 g (8.16 mmol) of **5** (Z=CN) and 1.6 ml of isopentyl nitrite in 60 ml of dichloromethane was refluxed under a nitrogen atmosphere, while 1.45 g (10.6 mmol) of anthranilic acid in 40 ml of acetone was added in 50 min. The mixture was refluxed for further 30 min and the solvent was evaporated. The residue (2.40 g or 92% yield) was recrystallized to afford the desired material, mp 308—310 °C. Found: C, 89.42; H, 5.66; N, 4.26%. Calcd for $C_{24}H_{19}N$: C, 89.68; H, 5.96; N, 4.36%. ^{1}H NMR ($CDCl_3$, δ): 2.42 (6H, s), 5.30 (1H, s), 6.9—7.7 (10H, m), 7.8—8.0 (2H, m). IR (KBr): 2225 cm^{-1}.

9-(1-Methoxycarbonyl-1-methylethyl)triptycene (**6**: *X=Y=H, Z=COOCH$_3$*), mp 230—232 °C, was prepared similarly in 86% yield. Found: C, 84.75; H, 6.14%. Calcd for $C_{25}O_{22}O_2$: C, 84.71; H, 6.26%. ^{1}H NMR ($CDCl_3$, δ): 2.31 (6H, s), 3.75 (3H, s), 5.26 (1H, s), 6.8—7.5 (11H, m), 7.6—7.8 (1H, m). IR (KBr): 1740, 1715 cm^{-1}.

9-(1-Cyano-1-methylethyl)-1,2,3,4-tetrachlorotriptycene (**6**: *X=Y=Cl, Z=CN*). Similar treatment of 1.00 g of **5** (Z=CN) with tetrachloroanthranilic acid[7] afforded a mixture of products. The mixture was oxidized overnight with 1.75 ml of 30% hydrogen peroxide in 30 ml of formic acid at room temperature and diluted with water. The mixture was extracted with dichloromethane and the excess of peroxide was decomposed with iron(II) sulfate. Evaporation of the solvent followed by chromatography on alumina afforded the *dl* and the *meso* isomers of the desired compound in 0.407 g or 22% yield. The ratio *dl*/*meso* was *ca.* 11. The *dl* isomer was eluted first and was purified by recrystallization. The pure *meso* isomer was not obtained even though careful chromatographies were carried out.

The *dl* form, mp 289—291 °C. Found: C, 62.94; H, 3.02; N, 3.12; Cl, 30.72%. Calcd for $C_{24}H_{15}NCl_4$: C, 62.78; H, 3.29; N, 3.05; Cl, 30.88%. ^{1}H NMR ($CDCl_3$, δ): 2.43 (3H, s), 2.58 (3H, s), 6.08 (1H, s), 7.0—7.9 (7H, m), 8.3—8.5 (1H, m). IR (KBr): 2230 cm^{-1}.

The *meso* form exhibited the following signals in ^{1}H NMR spectrum, when those due to the *dl* form were subtracted from a spectrum of a *dl-meso* mixture ($CDCl_3$, δ): 2.71 (6H, s), 6.08 (1H, s), 7.0—7.6 (6H, m), 7.9—8.1 (2H, m).

9-(1-Methoxycarbonyl-1-methylethyl)-1,2,3,4-tetrachlorotriptycene (**6**: *X=Y=Cl, Z=COOCH$_3$*) was similarly prepared in 24% yield in total. The ratio *dl*/*meso* was 3.4.

The *dl* form, mp 286—288 °C. Found: C, 61.17; H, 3.74; Cl, 29.14%. Calcd for $C_{25}H_{18}O_2Cl_4$: C, 61.00; H, 3.69; Cl, 28.81%. ^{1}H NMR ($CDCl_3$, δ): 2.27 (3H, s), 2.48 (3H, s), 3.5—4.0 (3H, broad), 6.09 (1H, s), 6.9—7.6 (7H, m), 7.7—8.0 (1H, m). IR (KBr): 1740, 1720 cm^{-1}.

The *meso* form, mp 200—202 °C, solidified again on heating above the melting point and melted at the melting point of the *dl* form. High resolution MS: Found, M$^+$ 490.0001; Calcd for $C_{25}H_{18}O_2Cl_4$, 489.9943. ^{1}H NMR ($CDCl_3$, δ): 2.47 (6H, s), 3.70 (3H, s), 6.09 (1H, s), 6.9—7.6 (8H, m). IR (KBr): 1740, 1715 cm^{-1}.

9-(1-Cyano-1-methylethyl)-1,4-dimethyltriptycene (**6**: *X=CH$_3$, Y=H, Z=CN*) was similarly prepared from **5** (Z=CN) and 3,6-dimethylanthranilic acid[8,9] in 68% yield. The formation of the *meso* form was not detected by ^{1}H NMR spectra. Recrystallization of the product from tetrahydrofuran–hexane afforded pure *dl* form, mp 244—246 °C. Found: C, 89.66; H, 6.64; N, 4.04%. Calcd for $C_{26}H_{23}N$: C, 89.36; H, 6.63; N, 4.01%. ^{1}H NMR ($CDCl_3$, δ): 2.45 (3H, s), 2.47 (3H,

s), 2.51 (3H, s), 2.89 (3H, s), 5.61 (1H, s), 6.75 (2H, s), 6.9—7.7 (7H, m), 8.1—8.3 (1H, m). IR (KBr): 2225 cm^{-1}.

The *meso* form was obtained in the following way. The *dl* form (0.717 g) was dissolved in 50 ml of *o*-dichlorobenzene and the solution was refluxed overnight. The solvent was evaporated and the residue was chromatographed on alumina to afford 0.047 g (7%) of the *meso* form. Recrystallization from tetrahydrofuran–hexane gave a pure material, mp 256—257 °C. High resolution MS: Found, M^+ 349.1802; Calcd for $C_{26}H_{23}N$, 349.1776. ^1H NMR ($CDCl_3$, δ): 2.55 (3H, s), 2.61 (3H, s), 2.62 (6H, s), 5.64 (1H, s), 6.82 (2H, s), 6.9—7.5 (6H, m), 7.8—8.1 (2H, m). IR (KBr): 2220 cm^{-1}.

9-(1-Methoxycarbonyl-1-methylethyl)-1,4-dimethyltriptycene (**6**: $X=CH_3$. $Y=H$, $Z=COOCH_3$) was similarly prepared. For the purification, the oxidation with performic acid was applied. A mixture of *dl* and *meso* forms was obtained in 60% yield. The ratio *dl*/*meso* was 11.

The *dl* form, mp 264—265 °C. Found: C, 84.74; H, 6.84%. Calcd for $C_{27}H_{26}O_2$: C, 84.78; H, 6.85%. ^1H NMR ($CDCl_3$, δ): 2.29 (6H, s), 2.43 (3H, s), 2.52 (3H, s), 3.73 (3H, s), 5.62 (1H, s), 6.73 (2H, s), 6.8—7.5 (7H, m), 7.7—7.9 (1H, m). The signal at the highest field split into two in 1-chloronaphthalene at 70 °C. IR (KBr): 1740, 1710 cm^{-1}.

The *meso* form, mp 203—204 °C, was obtained by thin layer chromatography of a mixture which was rich in the *meso* form. The *meso* form resolidified at temperatures above the melting point and melted at the melting point of the *dl* form. High resolution MS: Found, M^+ 382.1853; Calcd for $C_{27}H_{26}O_2$, 382.1775. ^1H NMR ($CDCl_3$, δ): 2.40 (6H, s), 2.52 (3H, s), 2.65 (3H, s), 3.71 (3H, s), 5.61 (1H, s), 6.76 (2H, s), 6.8—7.5 (8H, m). IR (KBr): 1740, 1715 cm^{-1}.

Measurement of Spectra. ^1H NMR spectra were obtained with a Hitachi R-20B spectrometer, operating at 60 MHz. The temperature was 34 °C. IR spectra were obtained with a Hitachi EPI-G2 grating spectrophotometer and the wave numbers were calibrated with a polystyrene film. High resolution MS were obtained with a Hitachi RMH-1 spectrometer.

Measurement of Barries to Rotation and Equilibrium Constants. Isomerization of the stable rotamers were carried out by heating solutions of the rotamers in 1-chloronaphthalene by immersing the samples in appropriate baths. The temperature of the baths was controlled by using the boiling points of solvents. The solvents were dimethyl sulfoxide (189 °C), *o*-dichlorobenzene (179 °C), mesitylene (162 °C), and cumene (152 °C). Analyses of the isomers were performed by either ^1H NMR spectroscopy or high pressure liquid chromatography using benzophenone as an internal standard. The chromatography apparatus was a Waters M-6000A equipped with a UV detector. The rate constants were obtained as usual.[10] Some of the rate constants were obtained by using the rate constants of the forward reaction and the equilibrium constant from the relation $k_{-1}=k/K$. The kinetic parameters were obtained by both the Arrhenius plot and the Eyring plot and the thermodynamic parameters by the common practice.

Results and Discussion

Conformational Equilibria. The equilibrium constants of the rotamers at various temperatures are given in Table 1 and the thermodynamic parameters obtained from these results in Table 2. Clearly all the *dl* isomers are strongly favored over the *meso*. Since it is known that compounds, which do not have a substituent in the peri position, give values very close to 2 which is a statistical factor,[11,12] the equilibrium constants in Table 1 are unusual. The unusuality must be caused by the presence of the peri-substituent which is close to the substituent in the 9-position. The preference of the *dl* form must be attributed to the steric repulsion between the substituents in 1 and 9 positions, because methyl is a larger group than the sp^2 or sp moieties.[13]

Table 1. Equilibrium constants ($K=dl/meso$) of **6** at various temperatures in 1-chloronaphthalene

Substituents			Temp/°C			
Z	X	Y	189	179	162	152
CN	Cl	Cl	7.5	8.4	8.8	9.6
CN	CH_3	H	15	16	16	17
$COOCH_3$	Cl	Cl	21	26	29	28
$COOCH_3$	CH_3	H	8.4	14	16	14

Table 2. Thermodynamic parameters for equilibria (*meso* ⇌ *dl*) of rotamers of **6**

Z	X	Y	ΔH/kcal mol^{-1}	ΔS/eu
CN	Cl	Cl	−2.3	−1.0
CN	CH_3	H	−1.1	3.1
$COOCH_3$	Cl	Cl	−2.9	0.1
$COOCH_3$	CH_3	H	−4.9	−6.0

Close examination of the data in Table 1 discloses, however, an interesting point. Namely, the chloro group favors the *dl* form to a sizable extent relative to the methyl group in the methoxycarbonyl compounds. The tendency is reversed in the cyano compounds, however. Since the chloro group is smaller than the methyl in its size, the consideration of repulsive interactions predicts that the methyl group should disfavor the *meso* form relative to the chloro group. This is the case of the cyano compounds but, in the methoxycarbonyl compounds, the methyl group favors the *meso* form. The anomaly in the population ratio of the compound **6** (X=Y=Cl, Z=$COOCH_3$) may be at least partly attributed to atrractive interactions between the chloro group and the methoxycarbonyl group[14] which favor the *dl* form.

Barriers to Rotation. Rate constants of isomerization of the rotamers at 189 °C are summarized in Table 3 and activation parameters obtained from the rate constants at the 4 temperatures are shown in Table 4. Arrhenius parameters are added to facilitate the comparison of the data with those of **2**.

It is interesting to note that barriers to rotation of the compounds examined here are all lower than that of compound **2**. It is especially so in the case of the pro-

Table 3. Rate constants for isomerization of rotamers of **6** at 189 °C

Z	X	Y	k/s^{-1} (*dl*→*meso*)	k/s^{-1} (*meso*→*dl*)

cesses *meso*→*dl*. It is tempting to consider that the interaction between the peri-substituent and the methyl group in the 9-substituent is much larger than that involving the cyano or the methoxycarbonyl group. Thus the ground state is raised relative to the transition state for rotation to lower the barrier. The tendency is reverse with the case of 9-isopropyltriptycenes,[15] where the introduction of a larger substituent in the peri-position led to the increase in the barrier height. 9-Benzyltriptycenes exhibited higher barriers to rotation by introducing substituents in two peri positions.[16] The congestedness of the molecule in the ground state is evident from the molecular models and the fact that the rotational isomers are isolated. X-Ray analysis of 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene supports the idea: the molecule has unusual bond lengths and bond angles.[17] Therefore, relief of the steric strain to a small extent will lower the energy level of the ground state to a fair extent. This is reflected in the equilibrium constants discussed above. The higher barriers of the nitriles relative to the esters may be attributed to the lowering of the ground state also. A report by Anderson *et al.*[18] gives the similar explanation for the fact that the cyano group exhibited the highest barrier to rotation among compounds $(CH_3)_3C$–$C(CH_3)_2X$ where X was CN, CHO, CO_2H, CH_3CO, or $C(CH_3)$=CH_2.

Compound **6** (X=Y=Cl, Z=$COOCH_3$) was expected to show a higher barrier than others because the ground state is stabilized due to the attractive interaction between the chloro and the methoxycarbonyl groups. However, the barriers are by and large the same. Although the phenomenon must partly be attributed to the raise in the ground state due to steric reasons, other possibilities like solvation effects may not be ruled out. One notes that the frequency factors (and entropies of activation) and activation energies of compound **6** (X=CH_3, Y=H, Z=$COOCH_3$) are unusually small. The reasons for this phenomenon are not well understood at the present time.

It now seems to be necessary to remove the peri-substituents in order to raise the barriers to rotation of 9-(1-cyano or 1-methoxycarbonyl-1-methylethyl)triptycenes. A work along this line is in progress.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Restricted Rotation Involving the Tetrahedral Carbon. XXVIII. Barriers to Rotation about a C_{sp^3}–C(=O) Bond in 9-(1-Methoxycarbonyl-1-methylethyl)triptycenes[1,2]

Soichi OTSUKA, Hiroshi KIHARA, Tsutomu MITSUHASHI, and Michinori ŌKI*

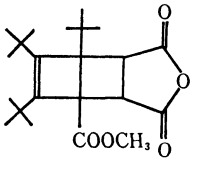
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received June 30, 1979)

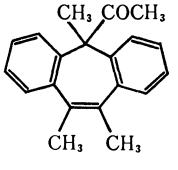
Restricted rotation about a C_{sp^3}–C(=O) bond in title compounds is found by ^1H NMR spectra of the *dl* forms. The barriers to rotation are obtained by the DNMR method to be *ca.* 15 kcal/mol. Infrared spectra which exhibit two conformations in the *dl* and the *meso* forms are also reported.

Rotational isomers of esters have been discussed with the use of vibrational spectra,[3] rotational spectra,[4] electron diffraction,[5] dipole moment,[6] and NMR spectra.[7] Infrared spectrum was a favorite technique for physical organic chemists and rotational isomerism about the C_{sp^3}–C(=O) bond of methyl chloroacetate was extensively studied by Josien.[8] The chloro group exerts large influences on the frequency and the intensity of the carbonyl stretching bands and makes it convenient to study by this method. Although the presence of two conformations of the ester group about a C_{sp^3}–C(=O) bond was deduced from the behaviors in the C–C–O stretching region of propionates and butyrates,[9] it has become possible to study the phenomenon from the C=O stretching region only recently.[10]

Since the rates of isomerization of rotamers are large, NMR spectra usually give information as a weighted mean of the possible rotamers. The rates of rotation may be made slow in the cases of sp^2-sp^2 bonds and there are numerous examples of this sort involving the carbonyl.[11] There had been only one example reported when we launched the project of synthesizing substituted 9-(1-methoxycarbonyl-1-methylethyl)triptycenes: Masamune *et al.* reported an exceptional case that a maleic anhydride adduct of methyl tri-*t*-butyl[4]-annulenecarboxylate (**1**) showed bifurcation of the methoxyl signal in ^1H NMR spectrum at −60 °C.[12] Although it is not an ester, restricted rotation about a C_{sp^3}–C(=O) bond has been found by NMR spectroscopy while our study has been in progress: Hart *et al.* concluded that the rotation of an acetyl group in compound **2** was frozen on the NMR time scale, because the two methyls in 4 and 5 positions of the cycloheptatriene system became nonequivalent at −12 °C.[13] Very recently, restricted rotation of bis(di-*t*-butylmethyl) ketone has been reported.[14]

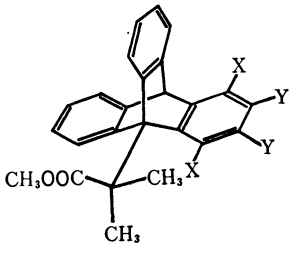


(1)

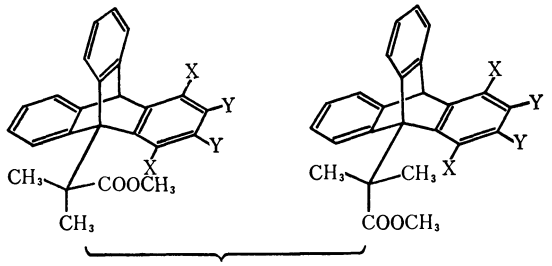


(2)

During the purification of 9-(1-methoxycarbonyl-1-methylethyl)-1,2,3,4-tetrachlorotriptycene (**3**, X=Y=Cl) we have encountered a phenomenon that the methoxyl signal of this compound in ^1H NMR spectrum operating at 60 MHz appears as a broad band, if it is the *dl* form. In this paper, we wish to report a detailed investigation of the restricted rotation about a C_{sp^3}–C(=O) bond, triggered by finding the broadened band for the methoxyl group.



(*meso*-**3**)



(*dl*-**3**)

Experimental

Materials. The preparation of materials in this study has been reported elsewhere.[1] Pure samples of respective rotamers after separation by chromatography were used for the measurements.

^1H NMR Spectra. The spectra were obtained on a Hitachi R-20B spectrometer with a temperature variation accessory, operating at 60 MHz, unless otherwise specified. Chloroform-*d* was used as a solvent for compounds which showed coalescence of signals at the higher temperature, whereas chloroform-*d*–carbon disulfide (1 : 1) was a solvent for those which required deep cooling. Temperature was calibrated using the chemical shifts of methanol and ethylene glycol at the lower and the higher temperatures, respectively.

Calculation of Spectra and Kinetic Parameters. The ^1H NMR spectra at various temperatures were calculated with the use of a modified Binsch program[15] and the best fit of the calculated spectra with the observed was determined by visual fitting. The rate constants thus obtained were put into the Eyring equation to obtain kinetic parameters. The populations which were necessary for the calculation of the spectra

were obtained by using the thermodynamic parameters derived from the populations at low temperatures.

Infrared Spectra. The spectra were obtained on either a JEOL JIR-03F FT-IR or a JASCO DS-403G spectrometer. The samples were dissolved in either carbon tetrachloride or chloroform to make up *ca.* 10^{-3} mol/l solutions.

Results and Discussion

Assignment of the Spectra. The ^{1}H NMR spectra of *dl*-**3** (X=Y=Cl) at three temperatures are shown in Fig. 1. At a low temperature the methoxyl signal which had been broad at 34 °C split into a pair of sharp singlets, whereas the signal for the methoxyl at a high temperature was a sharp singlet. Methyl signals which had been a pair of singlets at room temperature split into a pair of doublets at the low temperature as well.

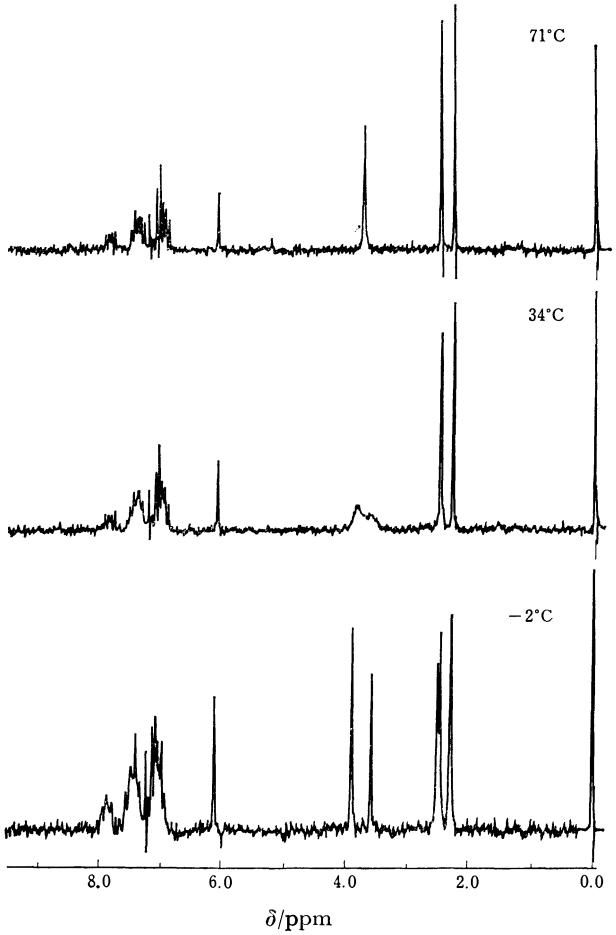


Fig. 1. ^{1}H NMR spectra of *dl*-**3** (X=Y=Cl) at three temperatures ($CDCl_3$, 60 MHz).

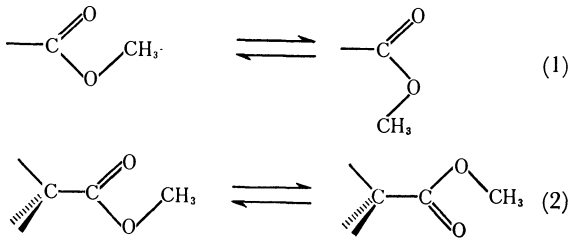
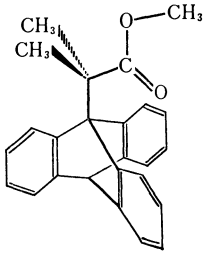
The temperature dependence of the spectra might be explained by two ways. One is to use the $Z \rightleftharpoons E$ conformational change (Eq. 1) and the other is the rotation about the C_{sp^3}–C(=O) bond (Eq. 2). The first possibility is unlikely, however. Esters are known to assume Z conformation in general and it is an exceptional case that the esters take E conformations. The E conformations are realized in esters which carry

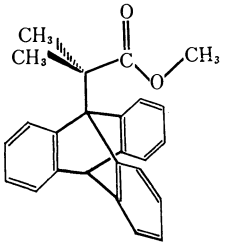


a small group as an acyl part and a large group as an alkoxyl part.[16] Since the compound in question carries a large acyl part and a small alkyl group, the possibility of the E conformation may be rejected.

Although the process is now said to be represented by Eq. 2, there remain minor problems to be discussed. Carbonyl groups are in general to be more stable if they assume conformations in which a carbonyl group eclipses one of the single bonds involving the adjacent carbon.[17] The conformations written in Eq. 2 do not necessarily conform to this generality. We justify the conformations from two points, however. The first is that there is a report which successfully interpreted the microwave absorption data of methyl acetate by assuming a C=O staggered conformation.[18] In addition, large groups associated with the α-carbon in this compound and the triptycyl group will make regular conformations, which are otherwise stable, unstable. We call the conformations represented by Eq. 2 as CH_3O-inside and CH_3O-outside in this paper.



CH_3O-outside



CH_3O-inside

Another problem is the assignment of the NMR signals to the respective conformations. We take advantage of the ring current effects[19] of the benzene ring for the assignment. Since the methoxyl signal of methyl acetate is at δ 3.67, one of the two signals of *dl*-**3** (X=Y=Cl) is at a higher field and the other is at a lower field than that of the methyl acetate. Thus the methoxyl signal at the higher field corresponds to the CH_3O-inside conformation and the other at the lower field to the CH_3O-outside.

dl-**3** ($X=CH_3$, Y=H) showed a similar phenomenon except that the splitting of the methoxyl signal occurred at a lower temperature. The coalescence temperature was −4 °C, while that of *dl*-**3** (X=Y=Cl) was 34 °C.

Any of the *meso* forms of these compounds and **3** (X=Y=H) failed to show splitting of the methoxyl signals, although the temperature was lowered to −80 °C. Since they all showed broadening of the signals, spectra of **3** (X=Y=H) were examined at 200 MHz. They did not show splitting at −50 °C, however.

Table 1. Thermodynamic parameters for the equilibria(CH_3O-outside$\rightleftharpoons CH_3O$-inside) of *dl*-**3** in $CDCl_3$

X	Y	ΔH/kcal mol^{-1}	ΔS/eu	ΔG/kcal mol^{-1} at 25 °C
Cl	Cl	−0.43	−1.9	0.15
CH_3	H	−0.34	−1.8	0.18

Populations and Thermodynamic Parameters. The ^{1}H NMR spectra of *dl*-**3** were obtained at various temperatures and, from the integration of the spectra, the populations of the CH_3O-inside and CH_3O-outside conformations were obtained. Usual treatment of the data afforded the thermodynamic parameters shown in Table 1. The free energy difference at 25 °C is also included in the Table. The data suggest that the CH_3O-inside conformation is favored in terms of enthalpy while it is disfavored by entropy factors. And, as a whole, the CH_3O-outside conformation is slightly favored at 25 °C.

Table 2. $\nu_{c=o}$ absorptions of **3**

X	Y	Form	$\nu_{max}(\varepsilon)$ in CCl_4	$\nu_{max}(\varepsilon)$ in $CHCl_3$
H	H	—	1747 (450)	1739 (340)
			1720 (360)	1712 (190)
Cl	Cl	*dl*	1743 (630)	1734 (370)
			1725 (480)	1718 (310)
		meso	1747 (510)	1741 (410)
			1720 (280)	1714 (240)
CH_3	H	*dl*	1746 (390)	1739 (330)
			1717 (370)	1712 (260)
		meso	1748 (270)	1740 (390)
			1717 (220)	1709 (210)

Infrared absorptions due to the C=O stretching are tabulated in Table 2. Each conformer possesses two absorptions. The possibility of the bifurcation due to the Fermi resonance may be ruled out because the shift due to the solvent change, from carbon tetrachloride to chloroform, is very similar with the case of methyl acetate.[20] Thus the results support the existence of the CH_3O-inside and CH_3O-outside conformations deduced by the NMR spectra. We tentatively assign the absorptions at higher frequencies to the CH_3O-outside conformations and those at lower frequencies to the CH_3O-inside conformations because of the correspondence between populations and intensities. Bond dipoles are known to affect the C=O stretching frequencies and intensities[21] but the effects seem small here. The separation of the two bands is abnormally large in these compounds, compared with the ordinary

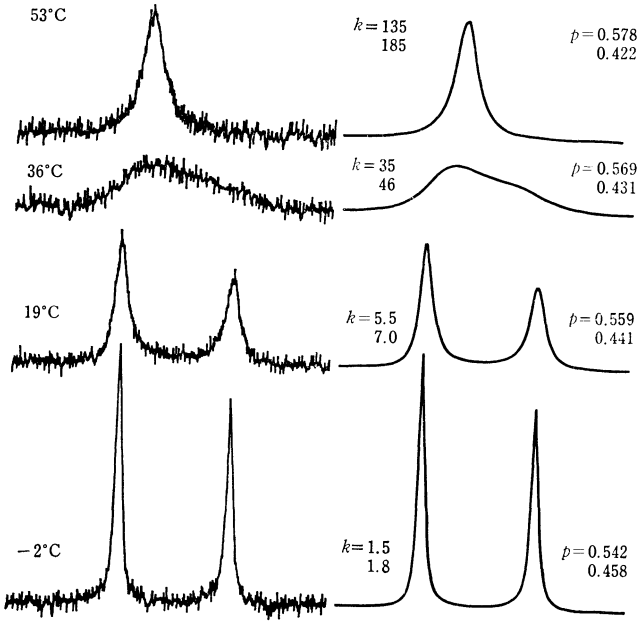


Fig. 2. Observed (left) and calculated (right) spectra of *dl*-**3** (X=Y=Cl) at four temperatures. The upper numbers of k's correspond to the rates of CH_3O-inside →CH_3O-outside processes and the lower the CH_3O-outside→CH_3O-inside. The upper numbers of p's correspond to populations of the CH_3O-outside conformation and the lower the CH_3O-inside conformation.

esters, probably due to the steric effect of the conformations concerned.

Barriers to Rotation. An example of the results of band shape simulations is shown in Fig. 2. The populations calculated by the thermodynamic values in Table 1 were used as constants and the rates of forward rotation were varied in the calculation. The rates of backward rotation are determined by the rates of forward rotation and the population automatically. The kinetic parameters obtained by this method are tabulated in Table 3.

The parent compound **3** (X=Y=H) and the *meso* forms of **3** failed to give split signals even at low temperatures. Therefore, it is not possible to perform the total line shape analysis. However, since the lines due to methoxyl and methyl groups show line broadening at low temperatures, it is possible to obtain rough estimates of barriers to rotation, by assuming the chemical shift differences. It may be argued that the chemical shift differences might be very small in these series, although the barriers are high. We rule out this possibility from the fact that *dl*-**3** (X=Y=Cl), δ 3.58 and 3.90, and *dl*-**3** (X=CH_3, Y=H), δ 3.58 and 3.89, give almost

Table 3. Kinetic parameters for rotation about the C_{sp^3}–C(=O) bond in *dl*-**3** in $CDCl_3$

X	Y	Process	$\Delta H^{\ddagger}$ kcal mol^{-1}	$\Delta S^{\ddagger}$ eu	$\Delta G^{\ddagger}$(25 °C) kcal mol^{-1}
Cl	Cl	CH_3O-out→CH_3O-in	13.7	−7.4	15.8
		CH_3O-in→CH_3O-out	14.1	−5.4	15.7
CH_3	H	CH_3O-out→CH_3O-in	10.9	−10.5	14.0
		CH_3O-in→CH_3O-out	11.2	−8.9	13.8

the same chemical shift differences. If the chemical shift difference were affected by the peri-substituents, the change in the peri-substituent would have resulted in a larger difference. Assuming that the chemical shift difference of the two forms of *meso*-**3** (X=Y=Cl) is the same with that of *dl*-**3** (X=Y=Cl) and that populations are 50: 50, we can use Eq. 3 for estimating the rates of rotation.[22]

$$k = \left\{\frac{\pi}{2}(\Delta\nu)\right\}^2 \Big/ \left(\frac{1}{T_2'} - \frac{1}{T_2}\right) \qquad (3)$$

where $1/T_2'$ is obtained from the line width at a given temperature and $1/T_2$ from that where exchange is fast. Thus $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta G^{\ddagger}$ at 25 °C were obtained as 4.2 kcal/mol, −21.8 eu, and 10.7 kcal/mol, respectively. *meso*-**3** (X=CH_3, Y=H) and **3** (X=Y=H) gave similar values. Although the reliability of these values is limited, these may be used as a first approximation in discussion.

The barriers obtained thus far indicate that, in order to exhibit high barriers to rotation, it is necessary to have a peri-substituent. Barriers to rotation are determined by the relative energies of the ground and the transition states. Since no special stabilization or destabilization of the ground state is apparent, the high barriers for the *dl* form may be attributed to the peri-substituent which gives a strong repulsion in the transition state of rotation to raise the transition state. Close examination of the data in Table 3 reveals that *dl*-**3** (X=Y=Cl) gives higher barriers to rotation than *dl*-**3** (X=CH_3, Y=H) in spite of the fact that the van der Waals radius of the methyl group is larger than the chloro. This may be ascribed to the attractive interaction between the carbonyl moiety and the chloro group[23] which are located closely with each other.

We wish to thank people in Brucker for the measurement of the ^1H NMR spectra at 200 MHz. Our thanks are also due to the Ministry of Education for a Grant-in-Aid for Scientific Research.

The Jacobsen Rearrengement of Tribromobenzenes

Masahiro NAKADA, Kiichiro ISHIBASHI, Sachio FUKUSHI, and Minoru HIROTA*,†

Chemical Laboratory, Chiba Institute of Technology, Narashino 275

† *Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240*

(Received February 3, 1979)

The Jacobsen rearrangement of tribromobenzenes was investigated at 110—180 °C in concentrated sulfuric acid. The reaction proceeds exclusively *via* the intramolecular 1,2-migration of the bromine atom, which is accelerated by the steric repulsion of the neighboring group. Sulfonation of both the reactant and the products occurs simultaneously with the rearrangement. The migration of bromine atoms in the sulfonic acids proceeds far more slowly, the rearranged products not being formed to any considerable extent by sulfonic acids.

The migration of alkyl groups and/or halogen atoms in alkylhalobenzenes and polyhalobenzenes, assumed to be modifications of the Jacobsen rearrangement, occurs under similar conditions. Alkyl migration has been extensively studied and its mechanism elucidated in detail.[1-3] On the other hand, only a few investigation have been reported on the migration of halogen atoms on the aromatic nuclei.[4-8]

At least in cases of alkyl migration, the rearrangements are supposed to be acid-catalyzed reactions, proceeding *via* protonated or SO_3H^+-added benzene derivatives, *i.e.* benzenium cations. However, no details of the halogen-migration have been confirmed so far.

During the course of investigations on the reactions, spectroscopic and chromatographic properties of polyhalogenated aromatic hydrocarbons,[9-11] we have studied the sulfuric acid-catalyzed rearrangements of polybromobenzenes as discussed the mechanism of the reaction.

Experimental

Materials. 1,2,3-Tribromobenzene was prepared by the method previously reported by Furuyama and Fukushi.[12] Dibromochloro- and bromodichloro-benzenes were prepared by the Sandmeyer reaction from the corresponding dihaloanilines. Other compounds were used after purification of the commercially available materials. All the polyhalobenzenes were identified by means of their melting and boiling points and spectral properties.

Reactions. The reactants polyhalobenzene (1.0×10^{-4} mol) and concentrated sulfuric acid (0.2 ml, special grade) were sealed in Pyrex tubes (6 mm dia.×50 mm length). A number of the sealed tubes thus prepared were heated in a thermostatic oil bath under efficient mixing with a magnetic vibrator. The polyhalobenzenes are sparingly soluble in sulfuric acid at room temperature, and are not completely miscible under the reaction conditions (at 110—180 °C). Thus, sufficient mixing should be carried out to avoid the effect of diffusion on the reaction rates. Absence of such effects under experimental conditions was confirmed by the fact that approximately the same apparent rate constants were observed for the decrease of the amount of reactant polyhalobenzenes in preliminary runs carried out with varying efficiency of mixing.

The reactions were carried out at 110—180 °C for 10—24 h. Each sealed tube was taken out at appropriate intervals of time, cooled immediately and quenched by pouring into an excess of water. The halogenated hydrocarbon component was extracted by cyclohexane and analyzed by gas chromatography.

Spectral and Chromatographic Measurements. The ^{1}H-NMR spectra were recorded on a JEOL JNM-C60H spectrometer operating at 60 MHz, the chemical shifts being given in terms of parts per million (ppm) upfield from the signal of internal $^1H_2SO_4$ reference. The infrared and mass spectra were measured with JASCO DS-402G and Hitachi RMU-6L spectrometers, respectively. Gas chromatographic analyses were carried out on a Shimadzu GC-6A apparatus equipped with a polyethylene glycol 20M column (3 mm×2 m).

Results and Discussion

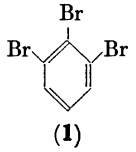
Formation of the Rearranged Products. Isomeric tribromobenzenes and their sulfonated products were obtained by the action of concentrated sulfuric acid on tribromobenzenes. However, the rates of reaction for the isomeric tribromobenzenes differ remarkably. The decrease in the reactant apparently shows first-order rate in each case (Table 1), 1,2,3-tribromobenzene (**1**)

Table 1. Apparent first order rate constants for the decrease of tribromobenzenes

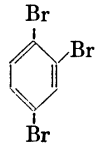
CH_3Br_3	Temp/°C	k_1/s^{-1}
1,2,3	160	2.94×10^{-4}
	180	9.00×10^{-4}
1,2,4	160	3.55×10^{-5}
	180	2.17×10^{-4}
1,3,5	160	—[a]
	180	4.4×10^{-6}

a) The reaction is very slow under these conditions.

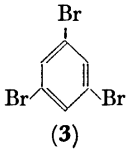
being most reactive. The amounts and proportions of tribromobenzene isomers present in the reaction system changed during the course of reaction. The relative amounts of three isomers **1**—**3** are given as a function of the reaction period in Fig. 1.



(**1**)



(**2**)



(**3**)

Formation of the sulfonic acids in the reaction medium causes loss in the total amount of tribromobenzenes. In the runs employing 1,2,3-tribromobenzene (**1**), the amount of the 1,2,4-isomer (**2**) produced increases

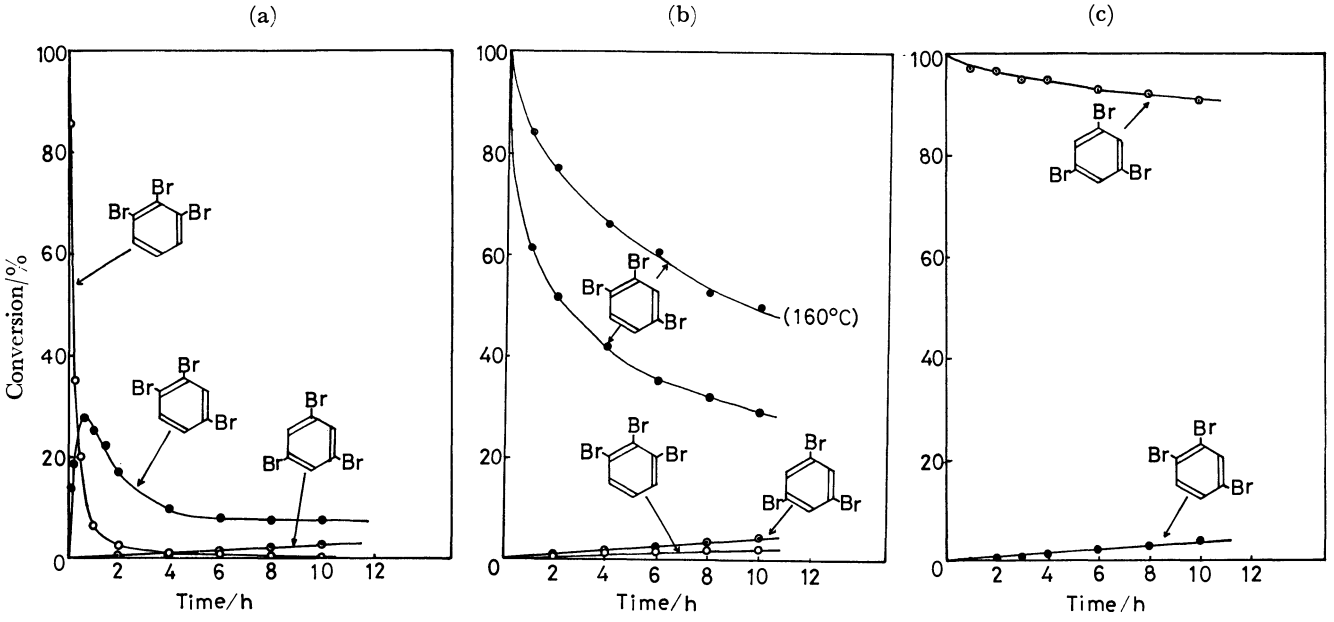


Fig. 1. Amounts of consumed and produced tribromobenzenes relative to the starting material (=100%) are plotted as a function of time with the runs starting from (a) 1,2,3-tribromobenzene (**1**), (b) 1,2,4-tribromobenzene (**2**), and (c) 1,3,5-tribromobenzene (**3**) and carried out at 180 °C (except the cases otherwise stated).

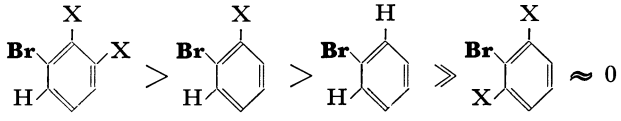
steeply in the earlier stage of the reaction process, decreasing gradually later (Fig. 1a). We see that very fast rearrangement from **1** to **2** is succeeded by considerably slower sulfonation of **2**.

In order to examine whether the rearrangement is intramolecular or intermolecular, crossover experiments with toluene, *m*-dichlorobenzene, trichlorobenzene, and naphthalene were carried out. No cross-products were obtained. This strongly suggests the intramolecular nature of the rearrangement. Another evidence in favor of intramolecularity of the rearrangement comes from the fact that the rate for consumption of the reactant, as well as that for the increases in the products, is linearly dependent on the initial concentration of the reactant. A quadratic relation is expected if the rearrangement is intermolecular.

1,2-Migration of the bromine substituent was found to occur exclusively in the rearrangement by the runs on bromodichloro- and dichlorobromo-benzenes (Table 2). No rearranged products were detected after 48 h reaction of 2,6-dichlorobromobenzene (**6**) at 180 °C. In contrast, 2,6-dibromochlorobenzene (**4**) rearranged nearly as fast as **1**, producing 2,5-dibromo- and 3,5-dibromo-chlorobenzenes. The proportion of products is similar to the case of **1**. The only reasonable explanation for the different behavior between **4** and **6** is that the migration of the chlorine substituent is negligible under the experimental conditions and that the migration of the bromine substituent in **6** is blocked by the chlorine atoms on the neighbor carbon atoms. In the case of 2,3-dichlorobromobenzene (**5**), the rearrangement to form 3,4-dichlorobromobenzene occurred with a rate slightly lower than that of **1**. However, the decrease in the rate of **5** is not remarkable, probably because the migration occurs considerably faster in bromobenzenes of 1,2,3-trihalosubstituted type than in that of 1,2-dihalo-substituted type. Migration of the chlorine substituent is not evident throughout the polyhalobenzenes (Table 2). This is also true in the case of 1,2,3-trichlorobenzene under similar conditions.

In conclusion, the rates of bromine migration decrease in the following order, the 1,2-migration being the only detectable pathway of the rearrangement.



Under more drastic conditions (above 250 °C in concentrated or fuming sulfuric acid), the intermolecular halogen migration to produce dibromo- and tetrabromobenzenes proceeds to a considerable extent.[7] However, the mechanism of these reactions evidently differs from that of the intramolecular rearrangement under discussion. In the runs carried out in phosphoric acid, polyphosphoric acid, selenic acid, concentrated hydrochloric acid, and fluorosulfuric acid[13] at temperatures 110—200 °C for 1—10 h, no rearranged products were detected. The results suggest the important role of sulfuric acid in the rearrangement.

Sulfonic Acids Formed During the Reaction and Their Possibility as Intermediates of the Rearrangement. In the reaction medium, considerable amounts of both the starting and the produced tribromobenzenes were sulfonated, resulting in a decrease in the total amount of tribromobenzene with the elapse of reaction period (Fig. 1). The sulfonic acids produced during the course of reaction were pursued by means of NMR and infrared spectroscopic methods. Figure 2a shows the NMR spectrum of a mixture of the produced sulfonic acids in the sulfuric acid layer of the reaction system separated from the organic layer after 1 h duration

(a) Sulfuric acid layer of the reaction mixture starting from 1,2,3-tribromobenzene (**1**) and separated after 1 h's reaction at 165 °C. The organic layer was separated off after the reaction period. (b) 2,3,4-Tribromobenzenesulfonic acid (**11**) in water and sulfuric acid. (c) 2,4,5-Tribromobenzenesulfonic acid (**13**) in sulfuric acid. (d) Spectrum measured after heating 2,3,4-tribromobenzenesulfonic acid (**11**) in sulfuric acid without the contact of the organic layer (tribromobenzenes). Isomerization to produce 3,4,5-tribromobenzenesulfonic acid alone was observed.

of the reaction at 165 °C. This is a typical example of the NMR spectra of the sulfonic acids in sulfuric acid, the signals being assigned by comparing them with those (Figs. 2b and 2c) of authentic tribromobenzenesulfonic acids. All the spectra (Figs. 2 and 3) were measured at 120 °C to avoid the crystallization of sulfonic acids. The NMR spectrum of 2,3,4-tribromobenzenesulfonic acid (**11**) shows an AB quartet (J=6.9 Hz) which can be assigned to the two hydrogen atoms on the adjacent carbon atoms. However, only a singlet was observed at 4.50 ppm upfield from the acidic ^1H signal of sulfuric acid when the spectrum of the same sulfonic acid was measured in concentrated sulfuric acid at 120 °C immediately after dissolution. This signal, corresponding to signal a in Fig. 2a, is assigned to **11**. The NMR spectrum of 2,4,5-tribromobenzenesulfonic acid (**13**) shows two signals at 4.08 and 3.87 ppm from the ^1H signal of H_2SO_4 (Fig. 2c), which correspond to signals b and c, respectively, in Fig. 2a. Signals observed in Fig. 2a were thus assigned to the sulfonic acids. However, much higher intensity of signal b than that of c indicates the overlap of another signal at 4.08 ppm. Prolonged heating (at 165 °C) of the sulfuric acid solution of **11** resulted in the appearance of a signal at 4.08 ppm in addition to signal a in its NMR spectrum. The new signal is located at 4.08 ppm, approximately the same frequency as the higher frequency signal of **13**, and assigned to 3,4,5-tribromobenzenesulfonic acid (**12**) for the following reasons. (i) Electrophilic substitution on 1,2,3-tribromobenzene usually occurs predominantly on the 4-carbon atom, when the reaction is kinetically controlled, to form **11** in the case of sulfonation. However, sulfonation at higher temperature is often reversible and the more stable isomer **12** is expected to become the major product gradually. (ii) Under the reaction conditions, formation of 1,2,4-tribromobenzene (**2**) after quenching and digestion of the reaction mixture was shown to be negligible, no measurable amount of sulfonated 1,2,4-tribromobenzene being expected to be present in the

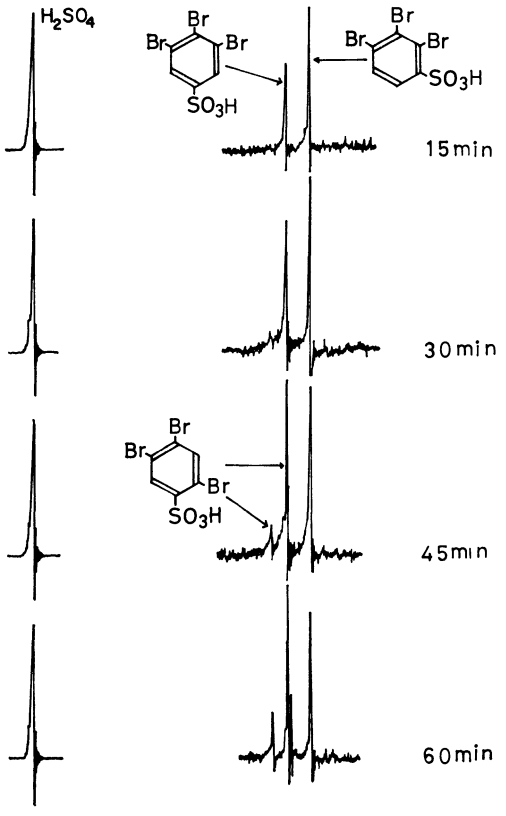

Fig. 3. Changes in NMR spectrum of the sulfuric acid layer during the process of the rearrangement of 1,2,3-tribromobenzene (**1**).

reaction mixture. No 2,4,6-tribromobenzenesulfonic acid was detected in either runs, and its formation from **1** is supposed to be a slow reaction.

The quantitative changes of these sulfonic acids during the course of reaction were determined by means of ^{1}H-NMR spectrometry.[14] When the reaction of **1** was carried out at 165 °C, the NMR spectrum of the sulfuric acid layer changed as a function of the reaction period (Fig. 3). As expected, sulfonic acid **11** was produced from **1** initially, amounts of sulfonic acids **12** and **13** increasing gradually. In the presence of tribromobenzenes, formation of **13** proceeds considerably faster than the isomerization to form **13** from the mixture of sulfonic acids **11** and **12**, which takes several hours to produce a detectable amount of **13** at the same reaction temperature. Thus, most of sulfonic acid **13** in the sulfuric acid layer is derived by sulfonation of the rearranged product **2**. Isomerization starting from 2,4,5-tribromobenzenesulfonic acid (**13**) also gave a mixture of sulfonic acids (**12**, **13**, and a small amount of 2,4,6-tribromobenzenesulfonic acid)[15] after heating for a longer period, the products being in slow equilibria in sulfuric acid solutions. Thus the migration of bromine atoms also proceeds with sulfonic acids, the rate being considerably lower than that of the runs in the presence of tribromobenzenes.

Actually the sulfonation to form **11**, **12**, and **13** proceeds simultaneously and/or successively with the rearrangement to form **2** and **3**, when **1** is treated with sulfuric acid. Thus the reaction of **1** at 180 °C was

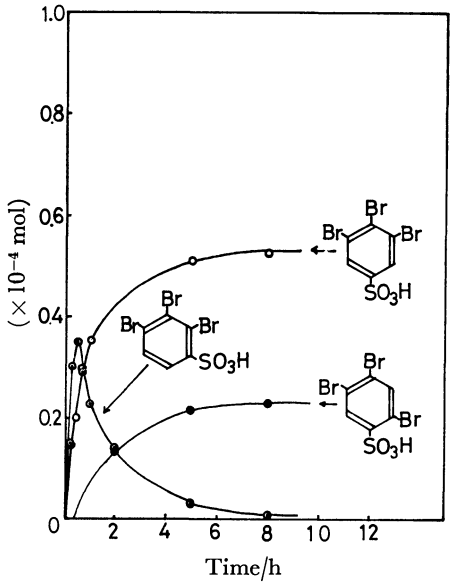

Fig. 4. Amounts of the produced sulfonic acids contained in the sulfuric acid layer are plotted as a function of time with the run starting from 1,2,3-tribromobenzene and carried out at 180 °C.

carefully reproduced and the sulfuric acid layer analyzed. The amounts of the sulfonic acids formed are plotted against the reaction period in Fig. 4. By comparing Fig. 4 with Fig. 1a, reactant **1** is supposed to undergo both sulfonation to **11** and isomerization to **2** and, to a less extent, to **3** initially, even if it is not certain whether compounds **1** and **11** are formed *via* a common intermediate or not.

The compositions of the sulfonic acids produced were determined also from the infrared spectra of the products in the sulfuric acid layer measured after their transformation into sodium salts. An example of the infrared spectra is shown in Fig. 5 together with the assignment of the bands to each sulfonic acid. Approximately the same results as in Fig. 4 were obtained from the changes in the infrared absorption intensities, leading to the same conclusion as obtained from the NMR spectra.

Mechanism of the Rearrangement. The rearrangement does not proceed in the presence of Brönsted acids other than sulfuric acid, and is not general-acid-catalyzed. Sulfonic acids **11**—**13** cannot be inter-

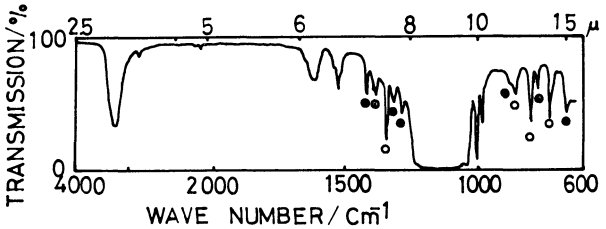

Fig. 5. Infrared spectrum of the mixture of sodium tribromobenzenesulfonates separated from the sulfuric acid layer after the reaction for 2 h at 180 °C. The absorption bands are assigned to 2,3,4-tribromobenzenesulfonate (⊙), 3,4,5-tribromobenzenesulfonate(○), and 2,4,5-tribromobenzenesulfonate (●) by comparing with the spectra of authentic samples.

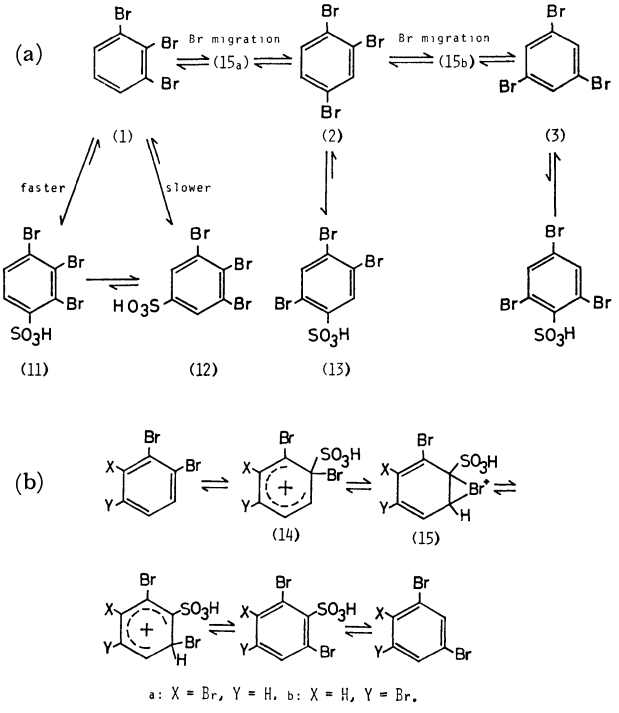

Fig. 6. (a) The whole reaction scheme including both isomerization and sulfonation. (b) Reaction mechanism for the bromine migration.

mediates of this rearrangement, since the isomerization to form bromine-migrated sulfonic acids is by far slower than the rearrangement itself. Moreover, the formation of tribromobenzenes from the sulfonic acids does not proceed to a considerable extent, probably because the equilibria among tribromobenzenes and the sulfonic acids are more favorable to the latter. Thus the possible intermediate or transition state for the reaction is a sulfonated benzenium cation (**14**) which is produced by the *ipso* attack of SO_3H^+, or more probably SO_3, and the subsequent formation of the three-membered ring containing bromine atom. The 1,2-shift proceeds more easily when the migrating bromine atom is sterically crowded. The formation of the bromonium cation might be assisted by the repulsion caused by the neighboring halogen atom. The repulsive force operating is of steric as well as electrostatic nature. The whole reaction is explained by the following scheme (Fig. 6). The desulfonation after rearrangement is expected to be a prompt reaction, since the sulfonic acid group is repelled sterically by the two bromine atoms on the neighboring carbon atoms. This is in line with the fact that it is difficult for 1,3,5-triboromobenzene to transform into the corresponding sulfonic acid and that 2,4,6-tribromobenzenesulfonic acid undergoes very fast desulfonation in sulfuric acid.

The rearrangement from **2** proceeds more slowly than that from **1**, giving **1** and **3**. The interconversion among the isomeric tribromobenzenes is reversible, thermodynamically controlled products being obtained after a very long period of reaction. Original Jacobsen rearrangements of polyalkylbenzenes tend to vicinal orientation, contrary to the rearrangements of polyhalobenzenes, and seem to proceed through a different mechanism.

The authors are grateful to Miss Hiroko Endo for her technical assistance in the measurements of the NMR and mass spectra.

13) When **1** was treated in fluorosulfuric acid medium under almost the same conditions, several products were isolated by gas chromatography from the hexane soluble part, neither of them being identical with $C_6H_{6-n}Br_n$'s. A run carried out at 100 °C in fluorosulfuric acid gave a slight but detectable amount of **2** after a longer period of reaction. From the time-conversion curve of this reaction, the formation of **2** is concluded to occur secondarily probably catalyzed by sulfuric acid produced in the process of reaction.
14) The amounts of sulfonic acids **11**, **12**, and **13** are easily estimated by the following equations, where I_a, I_b, I_c are the intensities of the NMR signals at 4.50, 4.08, and 3.87 ppm upfield from $^1H_2SO_4$ signal, respectively. $[\mathbf{11}]=k\cdot I_a$, $[\mathbf{12}]=k(I_b-I_c)$, and $[\mathbf{13}]=2k\cdot I_c$.
15) Since sulfonation is a reversible reaction, the bromine migration in the sulfonic acids is supposed to proceed through tribromobenzenes formed *in situ* by reverse desulfonation of the sulfonic acids in sulfuric acid. The electron withdrawing SO_3H group of the sulfonic acid might prevent the formation of benzenium cation (**14**) and subsequent bromonium cation (**15**) in Fig. 6. An evidence in favor of this hypothesis was obtained from the runs starting from mono- and di-bromonitrobenzenes. These compounds gave no rearranged products after being heated at 165 °C in sulfuric acid for several hours. The reactions at 180 °C and higher temperature caused decomposition of the starting materials, giving no rearranged products.

A Study of the Spin-Lattice Relaxation Time, T_1, of Coal-derived Oil

Tadashi YOSHIDA,* Yosuke MAEKAWA, Hiroyuki UCHINO,** and Susumu YOKOYAMA**

Government Industrial Development Laboratory, Hokkaido, Sapporo 061-01

***Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received June 14, 1979)

The spin-lattice relaxation time, T_1, of carbons was measured for various types of carbons in ring-type fractions separated from coal-derived oil. The T_1 for most carbons in the coal-derived oil was less than 2 s because of the existence of free radicals, while the T_1's of aromatic non-protonated carbons in the monocyclic and bicyclic aromatics fractions were approximately 12—15 s. The effects of a relaxation reagent on the T_1 were also discussed.

In recent years, ^{13}C-NMR spectrometry has been applied to the study of coal chemistry[1-7] and has proved to be a powerful tool for the investigation of the structure of coal-derived oil, since it makes the direct observation of the hydrocarbon skeleton possible.

The determination of various structural parameters for coal-derived oil requires a quantitative NMR spectrum. The peak intensity in the FT-NMR proton decoupling spectrum is generally affected by two factors, the nuclear Overhauser enhancement (NOE) and the spin-lattice relaxation time, T_1. The former, the NOE, can be fully suppressed by the gated-decoupling technique,[6-8] whereas the latter, T_1, can not be, since it is closely related to the structure and has a definite value for each carbon in the coal-derived oil.

The FT-NMR method requires a pulse repetition time much larger than T_1 in order to avoid the progressive saturation of signals. It is necessary, therefore, to have information on the T_1 of the sample prior to the NMR spectrum measurement. Unfortunately, however, there have not yet been any reports on the T_1 of coal-derived oil, as far as we know. In the present work, the T_1's of various types of carbons and other structural information of coal-derived oil have been obtained from the partially relaxed Fourier transform (PRFT) spectra.

Experimental

The coal sample used in the present work is from Akabira, Hokkaido. The sample was hydrogenated over an Adkins catalyst at 400 °C for 60 min under the initial hydrogen pressure of 100 kg/cm^2. The hydrogenated product was extracted with hexane in a Soxhlet extractor. The extracted coal-derived oil was separated into five fractions by liquid chromatography, a modification of the Bureau of Mines-API 60 method:[9] saturates (Fr-P), monocyclic aromatics (Fr-M), bicyclic aromatics (Fr-D), tri- and tetracyclic aromatics (Fr-T), and polycyclic aromatics and polar aromatics (Fr-PP).

The coal-derived oil and ring-type fractions (Fr-M, D, T, and PP) were used for the T_1 measurement. The samples were dissolved in deuteriochloroform, and the solution was

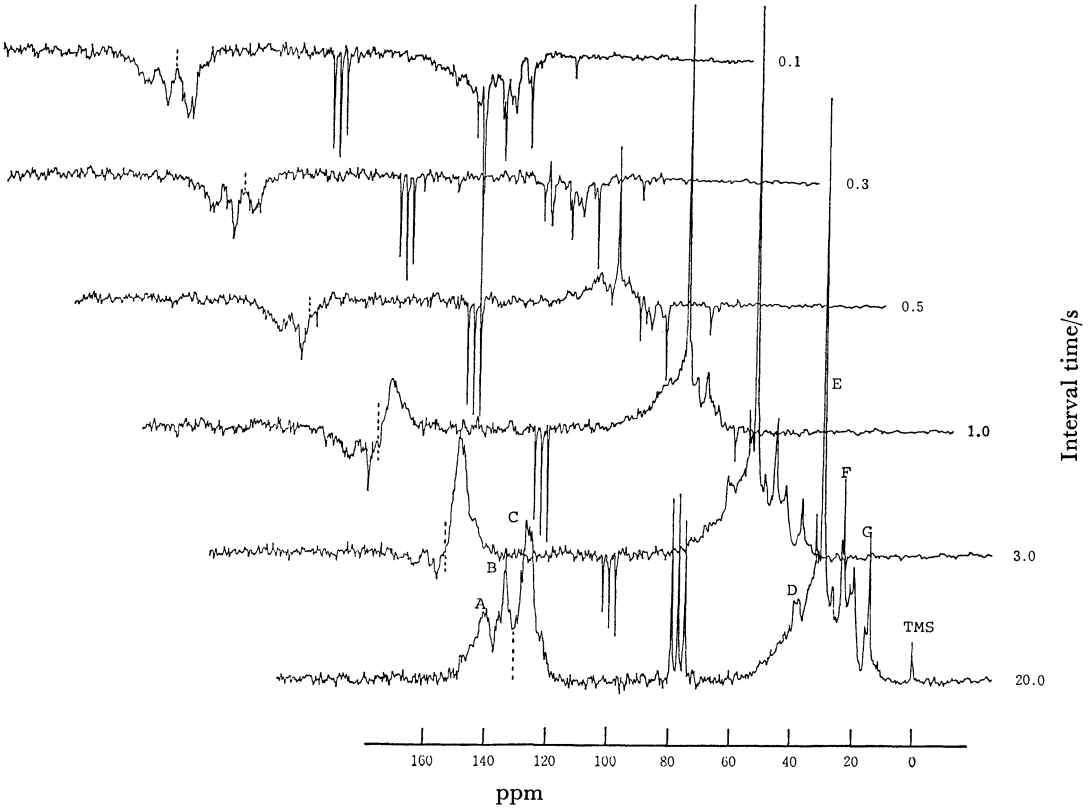

Fig. 1. Partially relaxed Fourier transform spectra for Fr-M.

not degassed. Tris(acetylacetonate)chromium(III)($Cr(acac)_3$) was used as the relaxation reagent.

The spectra were obtained with a JNM-FX60 Fourier transform spectrometer (JEOL Ltd.) and were measured over a range of 4000 Hz, with 8192 data points at 15 MHz. The T_1 measurement was performed using an inversion recovery pulse sequence $(180°\text{-}t\text{-}90°)_n$,[10] where t stands for the interval time between 180° and 90° pulses. The waiting time between pulse sequences was 20 s. The width of the 90° pulse was 16 μs. The NOE was fully suppressed by the gated decoupling technique.

Results and Discussion

In the ^{13}C-NMR method, the progressive saturation of signals should be avoided by making the excited spins completely relaxed. Therefore, a pulse-repetition time of at least five times the largest relaxation time, T_1, is needed. In general, the T_1 values for quarternary carbons of standard hydrocarbons are several decades of seconds, and the pulse-repetition time required for their quantitative spectra becomes extremely long. Fortunately, coal-derived oil contains an adequate amount of free radicals ($\approx 10^{18-19}$ spins/g),[11] and its T_1 turns out to be much smaller than those for standard chemicals. The PRFT spectra of the Fr-M fraction is shown in Fig. 1. The T_1 depends on the molecular size, the number of hydrogen atoms bonded to the carbon nucleus, the molecular motion, *etc.* Therefore, the difference in the relaxation rates of carbons can give structural information and the PRFT spectra are helpful for the assignment of signals. As can be seen in Fig. 1, the aromatic carbons are clearly divided at about 129 ppm into two groups of slowly relaxing nonprotonated and fast relaxing protonated carbons. On the other hand, the aliphatic carbons, though not conclusively, are also divided into two groups at about 22 ppm. The low-field group, for which the relaxation rate is fast, is assigned to cycloparaffinic, methylene bridge, and alkyl carbons except for the methyl and the terminal methyl groups. The T_1 values of these carbons are presumed to be relatively short because of their "rigid" structures. The high-field one is assigned to alkyl substituents (methyl, ethyl, and terminal methyl groups), and these carbons are presumed to have longer T_1 values because of their loose bondings. Thus, T_1 often provides information supplemental to the assignment of the signal.

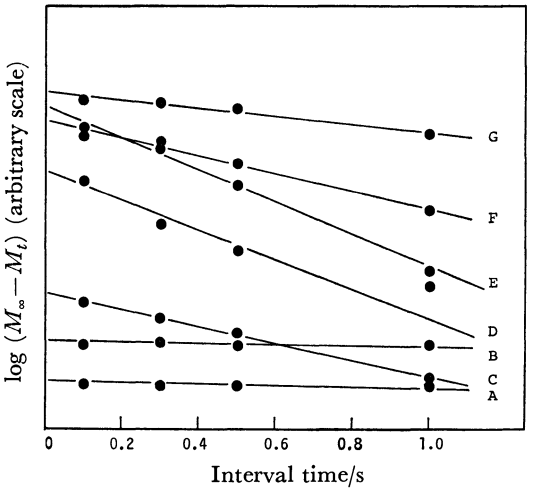

Fig. 2. Relationship between $\ln(M_\infty - M_t)$ and interval time.

T_1 is calculated by means of the following equation:

$$\ln (M_\infty - M_t) = \ln 2M_\infty - t/T_1$$

where M_∞ is the signal intensity when the carbon nucleus is completely relaxed. In the spectrum of a multi-component mixture such as coal-derived oil, the relation between $\ln(M_\infty - M_t)$ and the interval time generally has a tendency to deviate from a straight line, for each signal in the spectrum corresponds to some carbons with various T_1 values and the change in the signal intensity with the interval time may show the overall relaxation rates of these carbons. Therefore, the T_1 value calculated from the gradient of the straight line in Fig. 2 often varies the range of interval time

Table 2. Change in the aromaticity (f_a) of coal-derived oil with the pulse-repetition time

a) Amount of $Cr(acac)_3$ added to about 0.5 g of coal-derived oil in 0.53 ml of deuteriochloroform.

employed. We calculated the T_1 values from the gradient in the range of interval time from 0.1 to 1.0 s. The T_1 values of various types of carbons in the ring-type fractions of coal-derived oil are summarized in Table 1. The T_1 of aromatic non-protonated carbons is the longest among the T_1's of all the types of carbons. In particular, their T_1 values for the Fr-M,D fractions are much longer than those for Fr-T,PP. The great difference in the T_1 values of various types of carbons between the Fr-M,D and Fr-T,PP fractions may be attributed not only to their molecular sizes but also to the concentration of free radicals contained in the fractions. The components in the Fr-M,D fractions are presumed to be sufficiently hydrogenated compared with those in Fr-T,PP. The T_1 of coal-derived oil is nearly equal to that of the Fr-PP fraction. On the whole, the T_1 of coal-derived oil (hexane Soxhlet's extract) is moderately short, although some of the components have considerably long T_1 values. Table 1 shows that the pulse-repetition time required for the quantitative spectrum of coal-derived oil is approximately 5—6 s. This value is confirmed by the change in the aromaticity (f_a) of coal-derived oil with the pulse-repetition time, as is shown in Table 2. With a short pulse-repetition time, aromatic non-protonated carbons are not yet completely relaxed and f_a may have been underestimated because of the progressive saturation. Table 2 shows that the pulse-repetition time of 5—6 s is necessary to obtain a quantitative spectrum within the limits of experimental errors. This result is in good agreement with the T_1 data.

Thus, the quantitative spectrum for coal-derived oil requires a significantly long measurement time. Therefore, the addition of a relaxation reagent to samples is often used in time-effective measurements.[3,6-8] Table 3 shows the change in T_1 with the amount of relaxation reagent ($Cr(acac)_3$) added. The addition of $Cr(acac)_3$ shortens the T_1 values of all carbons considerably. With 20 mg of $Cr(acac)_3$, the T_1 of aromatic non-protonated carbons was nearly equal to those of other carbons. The addition of 10—20 mg of $Cr(acac)_3$ is found to be very effective for the reduction of T_1. However, more than 30 mg of $Cr(acac)_3$ should not be added, since such an addition will result in the broadening of the signals. In conclusion, the pulse-repetition time can be reduced from 5—6 s to about 2 s by the addition of a relaxation reagent, as can be seen in Table 3.

Finally, the NMR[12] and field desorption (FD) mass[13] spectrometric studies for the structural analysis of these ring-type fractions made it clear that alkylnaphtenomonocyclic aromatics were predominant for the Fr-M fraction; alkylnaphtenobicyclic aromatics, for the Fr-D fraction; alkylnaphtenotri- and tetracyclic aromatics, for the Fr-T fraction; and alkylpolycyclic aromatics, for the Fr-PP fraction. Thus, the Fr-M and D fractions have considerably saturated structures, that is, "mobile" structures, whereas the Fr-T and PPf ractions have "rigid" structures. The difference in ring size and chemical structure, as well as the concentration of free radicals present in the fractions, is considered to affect the T_1 values.

Synthesis of Some 3-Methylbut-2-enylated 1,3,5-Trihydroxyxanthones

Vinod GUJRAL and S. R. GUPTA*

Department of Chemistry, University of Delhi, Delhi-7, India

(Received October 9, 1978)

1,3,5-Trihydroxyxanthen-9-one reacts with 2-methylbut-3-en-2-ol in presence of a catalytic amount of BF_3-etherate to yield a mixture of 1,3,5-trihydroxy-2,4-bis-(3-methylbut-2-enyl)xanthen-9-one, in poor yield, identical with natural 8-desoxygartanin along with 1,3,5-trihydroxy-4-(3-methylbut-2-enyl)xanthen-9-one (**3**), in good yield, and 1,3,5-trihydroxy-2-(3-methylbut-2-enyl)xanthen-9-one (**4**) in poor yield. Compounds **3** and **4**, the probable biogenetic precursors of 6-desoxyisojacareubin and 6-desoxyjacareubin, have been reported to occur in nature as such but were characterised as their dimethyl ethers. Compounds **3** and **4** on oxidative cyclisation with DDQ gave 6-desoxyisojacareubin and 6-desoxyjacareubin respectively, completely identical with authentic natural samples.

8-Desoxygartanin, isolated from both fruit hulls and ripe fruits of *Garicinia mangostana* Linn.[1] and from the bark and heartwood of *Maclura pomifera*,[2] was assigned the structure (**2**) on the basis of its spectral data and its conversion to a bicyclo-derivative. 6-Desoxyisojacareubin and its possible biogenetic precursor, 1,3,5-trihydroxy-4-(3-methylbut-2-enyl)xanthen-9-one have very recently been isolated[3] from the heartwood of *Pentaphalangium solomonse* Warb. 6-Desoxyjacareubin, a linear isomer of 6-desoxyisojacareubin and its probable biogenetic precursor, 1,3,5-trihydroxy-2-(3-methylbut-2-enyl)xanthen-9-one, were reported[4] to occur in the heartwood of *Calophyllum scriblitifolium*. Both these probable biogenetic precursors were characterised as their dimethyl ethers and their structures were confirmed by comparison with the synthetic samples of the dimethyl ethers, prepared by indirect methods.

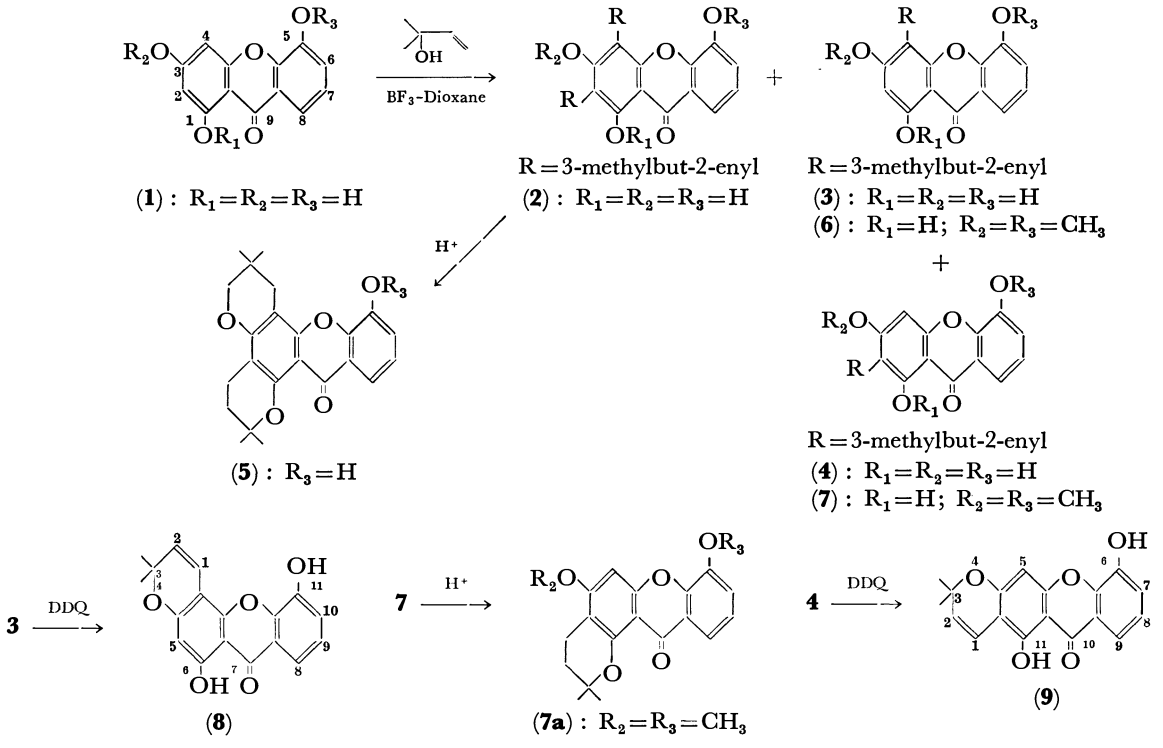
The synthesis of 4-(3-methylbut-2-enyl) and 2-(3-methylbut-2-enyl) derivatives of 1,3,5-trihydroxyxanthen-9-one have now been achieved for the first time with 2-methylbut-3-en-2-ol using catalytic amount of BF_3-etherate at room temperature.

1,3,5-Trihydroxyxanthen-9-one (**1**), prepared[5] from anhydrous phloroglucinol and 2,3-dihydroxy benzoic acid in the presence of phosphorous oxychloride and freshly fused zinc chloride, on condensation with 2-methylbut-3-en-2-ol using a catalytic amount of the Lewis acid boron trifluoride etherate in dry dioxane at room temperature gave a semi-solid mass. Thin layer chromatography indicated the formation of a number of products along with a large amount of unreacted xanthone (**1**). The major amount of unreacted xanthone was removed by extracting with 2% aq Na_2CO_3. The remaining mixture product on column chromatographic purification gave the following main fractions designated as compounds A, B, C, and D (unreacted xanthone).

Compound A, obtained in 2% yield, gave a green colour with alcoholic ferric chloride. Elemental and spectroscopic data confirmed it to be bis-*C*-(3-methylbut-2-enyl)xanthone. NMR($CDCl_3$) exhibited the resonance signals of two 3-methylbut-2-enyl groups along with the expected signals of other protons (see Experimental). It was established to be 2,4-bis-(3-methylbut-2-enyl) derivative (**2**) because its physical characteristics and spectral data was found to be in complete agreement with the data cited for natural 8-desoxygartanin.[1] On formic acid treatment it gave a bisdihydropyrano derivative (**5**), as indicated by its NMR which showed characteristic multiplets of four methylene protons at the expected chemical shifts (see Experimental) along with the signals for other protons. Other characteristics (mp and UV) were found to be in complete agreement with that of known bicycloderivative,[1] prepared from natural 8-desoxygartanin.

Compound B, obtained in nearly 8% yield, was soluble in dilute aq Na_2CO_3 and gave a green colour with alcoholic ferric chloride. Elemental analysis indicated the presence of one 3-methylbut-2-enyl group and its nuclear placement was indicated by the resonance signals shown in its NMR spectrum (see Experimental). It was methylated by using 2 mol of freshly distilled acid free dimethyl sulphate in acetone–potassium carbonate medium to give dimethoxy derivative (**6**) as indicated by its elemental data and confirmed by its NMR spectrum (2×s, δ 3.8 and 3.88). It gave a green colour with alcoholic ferric chloride. It did not undergo any change on formic acid treatment (indicated by TLC), confirming thereby, beyond doubt, the presence of a 3-methylbut-2-enyl group at 4-position in the dimethyl derivative (**6**) and hence in compound B. Further data was found to be completely identical (mmp; TLC and superimposable IR) with that of an authentic sample of dimethyl ether. Complete identity of these two dimethyl ethers confirmed, beyond doubt, the structure (**3**) for compound B.

Compound C, obtained in 3% yield, gave a green colour with alcoholic ferric chloride, was soluble in dilute aq Na_2CO_3. Elemental analysis indicated the entry of one 3-methylbut-2-enyl group into the xanthone nucleus which was confirmed by its NMR spectrum (see Experimental). On methylation with acid free freshly distilled dimethyl sulfate (2 mol) in acetone–potassium carbonate medium it gave a dimethoxy product (**7**), as indicated by its elemental analysis and confirmed by the two methoxyl singlets shown in its NMR spectrum (2×s, δ 3.98 and 4.12). It gave a positive alcoholic ferric chloride test. Its complete identity (mmp; TLC and co-TLC) with an authentic sample of dimethyl ether confirms the structure (**4**) assigned to compound C. Formic acid treatment yielded a product which did not give any colour change with alcoholic ferric chloride. It clearly in-



dicated the involvement of 1-hydroxyl in cyclisation with the 3-methylbut-2-enyl group, present at the 2-position. Therefore the 3-methylbut-2-enyl group in dimethyl ether and hence in compound C could only be present at the 2-position. This confirms the structure (**4**) for the compound C beyond any doubt.

Compound B (**3**) on oxidative cyclisation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in dry toluene afforded a product along with a very minute quantity of unreacted starting material. It was separated by preparative TLC and was identified as an angular mono-chromene as indicated by the two doublets for the olefinic protons shown in NMR (2×d, δ 5.70 and 6.78). Its structure (**8**), was confirmed by its complete identity (mp; UV; IR) with the natural 6-desoxyisojacareubin. Its formation has also served as an additional proof for the structure (**3**) of compound B.

Similarly, compound C (**4**) on refluxing with DDQ in dry toluene yielded a mixture, from which a chromenoxanthone, as a major product, was separated by preparative TLC. Its NMR spectrum showed two doublets for the olefinic protons of the chromene ring (2×d, δ 5.72 and 7.02) along with the signals for other protons. The complete agreement of its physical characteristics and spectroscopic data with that of natural 6-desoxyjacareubin[4] confirms its structure (**9**) which again confirms the structure (**4**) of compound C.

Experimental

Unless otherwise stated, all mps are uncorrected and were taken with a Kofler's mp apparatus; UV spectra were taken in MeOH; IR spectra were recorded using KBr disc and Perkin-Elmer infra-cord spectrophotometer and NMR in $CDCl_3$, CD_3COCD_3, CD_3COCD_3–$CDCl_3$ using 60 MHz spectrophotometer; silica gel 'Jai' was used for column chromatography and TLC was carried out on silica gel 'Jai' chromatoplates.

*3-Methylbut-2-enylation of 1,3,5-Trihydroxyxanthen-9-one (**1**) with 2-Methylbut-3-en-2-ol.* To a well stirred solution of 1,3,5-trihydroxyxanthen-9-one (**1**, 1 g) in dry dioxane (20 ml) was added boron trifluoride etherate (0.7 ml) and 2-methylbut-3-en-2-ol (0.430 g). The solution was stirred for 4 h at room temperature under anhydrous conditions. Moist ether was added and the ethereal solution stirred for 48 h at room temperature, then washed with water and dried over anhydrous $MgSO_4$. Removal of the solvent gave a solid which was extracted with 2% aq Na_2CO_3 to remove the large amount of unreacted xanthone. The remaining mixture was subjected to column chromatography over silica gel and the following three main fractions, designated as compound A, B, C, and D (unreacted xanthone), were obtained.

Compound A crystallised from benzene–petroleum ether mixture as a yellow powder (36 mg); mp 166—167 °C; green colour with alcoholic ferric chloride; λ_{max} 244, 261, 322, 375 nm; ν_{max} 1650 cm^{-1} (>C=O). Found: C, 72.4; H, 6.6%. Calcd for $C_{23}H_{24}O_5$: C, 72.6; H, 6.4%. NMR ($CDCl_3$): δ 1.68 and 1.80 (2×s, 12H, two $(CH_3)_2C<$), 3.50 (m, 4H, two $-CH_2-$), 5.22 (m, 2H, two $-CH=$), 7.32 (m, 2H, H-6 and H-7), 7.64 (q, J=6.5 Hz and 4 Hz, 1H, H-8). This agreed in all respects with the data cited for natural 8-desoxygartanin.[1] Compound A (**2**, 20 mg) in formic acid (1 ml) was heated on a steam bath for 30 min. The resulting pale yellow solution was poured over crushed ice, extracted with EtOAc and then dried and evaporated under reduced pressure. The solid so obtained crystallised from a benzene–hexane mixture as yellow needles (15 mg); mp 258—260 °C; λ_{max} 257, 310 nm; NMR ($CDCl_3$): δ 1.40 and 1.44 (2×s, 12H, two $(CH_3)_2C<$ of pyran rings), 1.84 and 2.82 (2×m, 8H, four $-CH_2-$ of two pyran rings), 7.22 (m, 2H, H-6, and H-7), 7.70 (q, J=6.5 Hz and 4 Hz, 1H, H-8). This data was found to be in complete agreement with that of bicyclo-8-desoxygartanin.[1] Thus the structure (**2**), as-

signed to compound A, is fully established.

Compound B crystallised from ethyl acetate–benzene mixture as a yellow fluffy powder (120 mg); mp 199—202 °C soluble in 5% aq Na_2CO_3 and giving green colour with alcoholic ferric chloride. λ_{max} 245, 285 nm; ν_{max} 1655 cm^{-1} (>C=O). Found: C, 68.8; H, 5.5%. Calcd for $C_{18}H_{16}O_5$: C, 69.2; H, 5.1%. NMR ($CD_3COCD_3+CDCl_3$): δ 1.66 and 1.74 (2×s, 3H each, $(CH_3)_2C<$), 3.47 (d, J= 7.5 Hz, 2H, $-CH_2-$), 3.66 (br s, 1H, 5-OH; exchangeable with D_2O), 5.20 (m, 1H, –CH=), 6.22 (s, 1H, H-2), 7.20 (m, 2H, H-6, and H-7), 7.72 (q, J=6.5 Hz and 4 Hz, 1H, H-8). An acetone solution of compound B (50 mg in 5 ml) containing freshly distilled acid free dimethyl sulphate (0.030 ml) and freshly ignited K_2CO_3 (nearly 200 mg) was refluxed for 4 h. The acetone was removed under reduced pressure, water added and the solid obtained was filtered. This solid was purified by repeated crystallisations from a ethyl acetate–benzene–hexane mixture to yield yellow needles(36 mg); mp 182—184 °C; λ_{max} 239, 242, 256, 312, and 368 nm; ν_{max} 1660 cm^{-1} (>C=O). Found: C, 70.1; H, 6.2%. Calcd for $C_{20}H_{20}O_5$: C, 70.6; H, 5.8%. NMR ($CDCl_3$): δ 1.62 1.78 (2×s, 6H, $(CH_3)_2C<$), 3.46 (d, J=7.5 Hz, 2H, $-CH_2-$), 3.8 and 3.88 (2×s, 3H each, $-OCH_3$ at 3- and 5-positions), 5.2 (m, 2H, H-6 and H-7), 7.68 (q, J=6.5 Hz, and 4 Hz, 1H, H-8). It was found to be identical in all respects (mmp; TLC and superimposable IR) with the sample of 1-hydroxy-3,5-dimethoxy-4-(3-methylbut-2-enyl)xanthen-9-one. On formic acid treatment, it did not undergo any change (as indicated by TLC). Thus the structure (**6**) could be assigned to above dimethyl ether and hence the structure (**3**) to compound B.

Compound C crystallised from a ethyl acetate–benzene–petroleum ether mixture as light yellow needles (46 mg); mp 182—184 °C; soluble in 5% aq Na_2CO_3; green colour with alcoholic ferric chloride; λ_{max} 242, 258, 300 nm; ν_{max} 1650 cm^{-1} (>C=O). Found: C, 69.4; H, 5.5%. Calcd for $C_{18}H_{16}O_5$: C, 69.2; H, 5.1%. NMR ($CD_3COCD_3+CDCl_3$): δ 1.78 (m, 6H, $(CH_3)_2C<$), 3.44 (d, J=7.5 Hz, 2H, $-CH_2-$), 3.65 (br s, 1H, 5-OH; exchangeable with D_2O), 5.24 (m, 1H, –CH=), 6.72 (s, 1H, H-4), 7.28 (m, 2H, H-6, and H-7), 7.94 (q, J=6.5 Hz and 4 Hz, 1H, H-8). Its dimethyl ether, prepared as above, crystallised from a ethyl acetate–benzene–petroleum ether mixture as a yellow powder (60%); mp 167—168 °C; insoluble in 5% aq Na_2CO_3; positive ferric reaction; λ_{max} 245, 258, 308 nm; ν_{max} 1660 cm^{-1} (>C=O). Found: C, 71.0; H, 5.9%. Calcd for $C_{20}H_{20}O_5$: C, 70.6; H, 5.8%. NMR ($CDCl_3$): δ 1.80 (m, 6H, $(CH_3)_2C<$), 3.46 (d, J=7.5 Hz, 2H, $-CH_2-$), 3.98 and 4.12 (2×s, 3H each, $-OCH_3$ at 3- and 5-positions), 5.35 (m, 1H, –CH=), 6.70 (s, 1H, H-4), 7.36 (m, 2H, H-6 and H-7), 7.92 (q, J=6.5 Hz and 4 Hz, 1H, H-8). It was found to be in complete agreement (mmp; TLC; co-TLC) with the sample of 1-hydroxy-3,5-dimethoxy-2-(3-methylbut-2-enyl)xanthen-9-one. This dimethyl ether (2 mg) in formic acid (3 drops) was heated on steam bath for 30 min. After working up as usual, the product obtained gave no colour change with alcoholic ferric chloride. Thus the 3-methylbut-2-enyl group in methyl ether is confirmed to be present at C-2, and involved in cyclisation with the 1-OH. Therefore the structure (**7**) could be assigned to methyl ether and hence the structure (**4**) to compound C. Compound D was recovered starting material (**1**, 878 mg).

*Oxidative Cyclisation of Compound B (**3**) and Compound C (**4**) with DDQ. 6-Desoxyisojacareubin (**8**)*: A solution of compound B (**3**, 20 mg) in dry toluene (1.5 ml) was refluxed with DDQ (3 mg) for 1 h. It was filtered hot and the residue (colourless hydroquinone) washed with toluene. The removal of solvent under reduced pressure from the filtrate gave a solid mass which was purified by preparative TLC (solvent; ethyl acetate: benzene (1 : 9)). The product, so obtained, crystallised from ethyl acetate–benzene–petroleum ether mixture as a light yellow powder (12 mg); mp 250—251 °C; λ_{max} 233, 250, 266, 310 nm; ν_{max} 1650 cm^{-1} (>C=O). Found: C, 69.3; H, 4.8%. Calcd for $C_{18}H_{14}O_5$: C, 69.6; H, 4.5%. NMR (CD_3COCD_3): δ 1.46 (s, 6H, $(CH_3)_2C<$), 3.60 (br s, 1H, 11 –OH; exchangeable with D_2O), 5.70 and 6.78 (2×d, J=10 Hz each, 1H each, –CH=CH–), 7.18 (m, 2H, H-9, and H-10), 7.62 (q, J=6.5 Hz and 4 Hz, 1H, H-8). This data was found to be in complete agreement with the data cited for natural 6-desoxyisojacareubin.[3]

*6-Desoxyjacareubin (**9**)*: Compound C (**4**, 18 mg) in dry toluene (1.5 ml) was refluxed with DDQ (3 mg) for 1 h. The progress of the reaction was checked with TLC. After working up as above it gave a product, which was purified by preparative TLC (solvent; ethyl acetate: benzene (1 : 9)). The compound, so obtained, crystallised from a ethyl acetate–benzene–petroleum ether mixture as a orange yellow solid (12 mg); mp 212—214 °C; λ_{max} 241, 272 sh, 288, 310 sh, 370 nm; ν_{max} 1650 cm^{-1} (>C=O). Found: C, 69.2; H, 4.9%. Calcd for $C_{18}H_{14}O_5$: C, 69.6; H, 4.5%. NMR(CD_3COCD_3): δ 1.47 (s, 6H, $(CH_3)_2C<$), 3.58 (br s, 1H, –OH; exchangeable with D_2O), 5.72 and 7.02 (2×d, J=10 Hz each, 1H each, –CH=CH–), 7.2 (m, 2H, H-7, and H-8), 7.68 (q, J=6.5 Hz and 4 Hz, 1H, H-9). This data agreed completely with the data cited for natural 6-desoxy-jacareubin.[4]

We express our very sincere thanks to Prof. F. Scheinmann for the authentic samples of 1-hydroxy-3,5-dimethoxy-4-(3-methylbut-2-enyl)xanthen-9-one and 1-hydroxy-3,5-dimethoxy-2-(3-methylbut-2-enyl)-xanthen-9-one.

Structural Studies of Commensurate Peierls State of $Rb_{1.67}[Pt(C_2O_4)_2]\cdot 1.5H_2O$

Akiko KOBAYASHI,* Yukiyoshi SASAKI, and Hayao KOBAYASHI**

Department of Chemistry, The Research Centre for Spectrochemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

***Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274*

(Received May 17, 1979)

X-Ray examination, chemical analyses and electrical conductivity measurements have been conducted on the partially oxidized platinum complex $Rb_{1.67}[Pt(C_2O_4)_2]\cdot 1.5H_2O$ (RbDOX). The cell constants are $a=12.690(10)$, $b=17.108(14)$, $c=11.357(3)$ Å; $\alpha=102.04(4)$, $\beta=115.17(3)$, $\gamma=43.58(4)°$, and the space group is $P\bar{1}$. The planar bis(oxalato)platinate ions stack along the crystallographic b axis and the Pt atoms form a sixfold distorted chain. RbDOX is the first example of a sixfold structure. Three independent Pt–Pt distances are 2.717(3), 2.830(3), and 3.015(3) Å. The Pt–Pt distance of 2.717 Å is the shortest spacing so far observed in partially oxidized platinate salts and shorter than the 2.77 Å interatomic separation in Pt metal itself. The oxalate ligands are staggered (46°, 55°, 80°) with respect to the ligands directly above and below them along the chain. Sixfold modulated superstructure of RbDOX is confirmed as the newly found commensurate Peierls structure based on agreement with the period of the Peierls distorted superlattice determined by the degree of partial oxidation. The calculation of Coulomb energy shows that RbDOX has a crystal lattice in which the interchain Coulomb energies are at a minimum indicating the strong tendency of the anti-phase ordering of the nearest-neighbour Pt chains.

In recent years there has been considerable interest in the partially oxidized quasi-one-dimensional cyanoplatinates and bis(oxalato)platinates because of their high, newly metallic electrical conductivities and they provide experimental results which greatly aid the development of the theory of the one-dimensional state. The prototype compounds of cyanoplatinates groups are the anion deficient derivatives, $K_2[Pt(CN)]_4Br_{0.3}\cdot 3.2H_2O$ referred to as KCP. Since the original discovery by Comès *et al.*[1] of X-ray diffuse scattering associated with the Peierls instability in KCP, the nature of the sinusoidal modulation of one-dimensional platinum chain has been studied by many authors.[2,3]

In one-dimensional metals, modulation waves (charge density waves: CDWs) have a wave vector $q=2k_F$ in the chain direction, where k_F is the Fermi wave vector, and in the insulating state, the CDWs are correlated to form a three-dimensional static Peierls distortion, that is, the lattice modulation waves give rise to a three-dimensional superstructure at low temperature.[4] The period of the lattice modulation wave in the Peierls phase is commensurate or incommensurate with the period in the high-temperature metallic phase.

There has been much research on KCP salts and TTF-TCNQ (tetrathiafulvalene–7,7,8,8-tetracyanoquinodimethane),[5] however, the crystal structure determination of the Peierls state of the one-dimensional conductors appears to be very limited. The modulated superstructure of $K_{1.81}[Pt(C_2O_4)_2]\cdot 2H_2O$ (γ-KDOX)[6,7] is the first example of the incommensurate Peierls state determined by X-ray analysis and it is attributed to the condensation of the $2k_F$ phonon of the one-dimensional metallic system. In the present work the sixfold modulated commensurate Peierls structure of a new salt $Rb_{1.67}[Pt(C_2O_4)_2]\cdot 1.5H_2O$ (RbDOX) will be reported.

Experimental

RbDOX was prepared from $Rb_2[Pt(C_2O_4)_2]$ and Rb_2PtCl_6 by a diffusion method. The solution was allowed to stand for a month and copper-colored needle-shaped crystals deposited. Many of the crystals were twinned, the twin axis being the needle axis. A suitable untwinned specimen was selected for data collection. The crystal needle axis was chosen as the axis for mounting and the crystallographic b axis. Oscillation photographs showed reciprocal lattice layers for which $k=6n$ were especially strong and all others were very weak. This feature clearly indicates the existence of a Pt chain with Pt atoms stacked $b/6$ apart.

Collection and Reduction of the Data. The crystal selected for data collection had dimensions of $0.28\times 0.10\times 0.038$ mm. The data were collected on a Rigaku automated diffractometer equipped with a graphite monochromator. A least-squares fit of the diffractometer angles obtained by automatically centering reflections in the range $30°<2\theta<40°$ (Mo $K\alpha$ radiation, $\lambda=0.71069$ Å) yielded the following crystal data: $a=12.690$ (10), $b=17.108$ (14), $c=11.357$ (3) Å, $\alpha=102.04$ (4), $\beta=115.17$ (3), $\gamma=43.58$ (4)°, $V=1518.6$ Å^3, $Z=6$, $d_{calcd}=3.549$ g cm^{-3}, μ(Mo $K\alpha$)$=230.6$ cm^{-1}.

Intensity data were collected with monochromatized Mo $K\alpha$ radiation by the ω-2θ scan technique up to $2\theta=60°$. Reflections were scanned at the rate of 4° per minute in 2θ. Background counts of 10s were taken at each end of the scan range. The diffracted intensity gradually decreased to 93% of the initial value during X-ray radiation. The data were corrected for deterioration, but no corrections were made for absorption owing to the irregularity of the crystal shape.

Solution and Refinement of the Structure. The structure was solved using a Patterson map. Space group $P\bar{1}$ was provisionally chosen and Pt(1) and Pt(4) were assigned to special positions at (0, 0, 0) and (0, 1/2, 0), while Pt(2) and Pt(3) were initially placed at general positions. The atomic parameters were refined by the block-diagonal least-squares method, using anisotropic temperature factors for Pt and Rb atoms and isotropic factors for O and C atoms. The final R values are $R_1=0.069$ for $F_o>3\sigma(F_o)$ and $R_2=0.084$. The agreement indices are defined as $R_1=\sum w||F_o|-|F_o||/\sum w|F_o|$, $R_2=\sum w||F_o|^2-|F_c|^2|/\sum w|F_o|^2$. The weighting schemes used were: $w=1/[a+b|F_o|+c|F_o|^2]$ for $|F_o|\geq 45.64$ (absolute scale), $a=91.28$, $b=1.0$, and $c=0.00289$; $w=0.1$ otherwise. As the exact Rb ion composition and those of the water molecules are uncertain, the multipliers were varied in one of the final refinements with the full matrix least-squares method. The multipliers converged to approximately 1.0 for

Rb ions indicating that the Rb ion sites are fully occupied. The exact H_2O content could not be determined from the X-ray crystal structure refinement. The ambiguity in the H_2O composition may be related to the deterioration of the crystal. Large R values and abnormal bond lengths and angles were obtained by the noncentrosymmetric refinement in P1 and thus $P\bar{1}$ was confirmed as the correct space group.

Positional and thermal parameters determined from the final least-squares cycle are presented in Tables 1 and 2. The atomic scattering factors and the values of $\Delta f'$, $\Delta f''$, were taken from International Tables for X-Ray Crystallography.[8] The F_o-F_c Tables are kept at the office of this

Bulletin as Document No. 7936. All calculations were performed on a HITAC 8700/8800 computer at the Computer Center, University of Tokyo using a local version of UNICS.[9]

Chemical Analyses. The selected crystals were subjected to chemical analyses. The contents of the Rb atom and Pt atom were determined with the aid of atomic emission spectrometry and atomic absorption spectrophotometry. Nitric acid was added to increase solubility. For the atomic absorption spectrophotometer, a Nippon-Jarrell Ash FLA 100 equipped with an air-acetylene flame and a carbon rod furnace was used. Jarrell Ash AA-1 MK-II was used for by atomic emission spectrometry. Carbon and hydrogen were analyzed by the usual procedure, the results of which are given in Table 3. The stoichiometry indicated by the formula $Rb_{1.66}[Pt(C_2O_4)_2]\cdot 1.5H_2O$ has been obtained for RbDOX. There will be some uncertainty in the water content.

contacts were made by four 0.025 mm gold wires attached with aquadag. RbDOX behaves as a semiconductor from 305 K to 83 K. The room temperature conductivity is 7×10^{-3} $(\Omega\,cm)^{-1}$ and the activation energy is 0.077 eV.

Results and Discussion

The intramolecular distances of the $Pt(C_2O_4)_2$ complexes are given in Table 4a and the intramolecular angles are listed in Table 4b. The distorted nonlinear sixfold Pt atom chain is formed along the crystallographic b axis and involves six bis(oxalate) groups in one repeating unit of 17.11(1) Å. There are four nonequivalent Pt atoms. Pt(1) and Pt(4) lie at the centres of symmetry (0,0,0) and (0,1/2,0), while Pt(2) and Pt(3) lie at the general positions (0.0021, 0.1582, 0.0033) and (0.0172, 0.3166, 0.0132). The stacking of $Pt(C_2O_4)_2$ complexes is shown in Fig. 1.

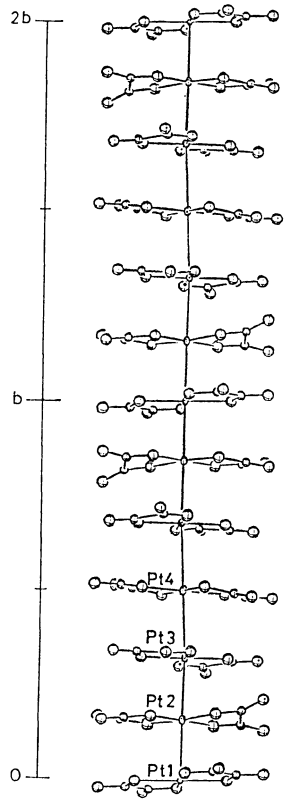

Fig. 1. The stacking of $Pt(C_2O_4)_2$ ions along the b axis. Two wavelengths of the Pt chain is shown.

The three independent Pt–Pt distances are Pt(1)–Pt(2)=2.717(3) Å, Pt(2)–Pt(3)=2.830(3) Å and Pt(3)–Pt(4)=3.015(3) Å. The Pt–Pt–Pt angles are Pt(1)–Pt(2)–Pt(3)=177.83(8)° and Pt(2)–Pt(3)–Pt(4)=174.23(5)°. The Pt–Pt distances in partially oxidized tetracyanoplatinate and bis(oxalato)platinate salts so far reported are shown in Table 5. The Pt–Pt distance of 2.717(3) Å found in RbDOX is the shortest spacing so far observed in partially oxidized platinate salts and shorter than the 2.77 Å interatomic separation in Pt metal itself. The Pt–O distances are 2.007(5) Å on average. Table 6 shows the averaged molecular structures of the four independent anions based on the assumption of D_{2h} symmetry. There appears to be a slight difference between the structure of the 3rd molecule and those of the others. Regarding the 3rd molecule, the O–Pt–O angle is 81.1(6)°, the C–O bond distance in the five membered ring is 1.27(2) Å and the C–C distance is on average 1.59(3) Å. This C–O bond is in the region of the C–O double bond. Regarding the other three molecules, the O–Pt–O angles are 85.0(4)° and the C–O distance is 1.35(1) Å. This bond length is close to that of the C–O single bond. The terminal C–O distances are in both cases 1.21(2) Å and 1.24(2) Å *i.e.*, those of normal double bonds. The structure of the third molecule is approximately equal to those of the molecules in $K_2[Pt(C_2O_4)_2]\cdot 2H_2O$,[20] $Co_{0.83}[Pt(C_2O_4)_2]\cdot 6H_2O$,[18] and $Mg_{0.82}[Pt(C_2O_4)_2]\cdot 5.3H_2O$.[17]

Figure 2 shows the mode of overlapping of platinate complex anions. The oxalate ligands are staggered with respect to the ligands directly above and below them along the chain. The staggered angles are approximately 46°, 55°, and 80°, while alternate ligands are eclipsed or staggered ≈90°. The 45° conformation has been found in the crystal of γ-KDOX. The 60° conformation has been observed in γ-KDOX and similar magnesium or cobalt defficient bis(oxalato)platinate complexes. It has been observed that these conforma-

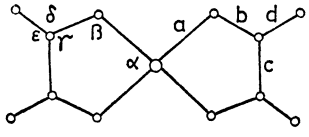

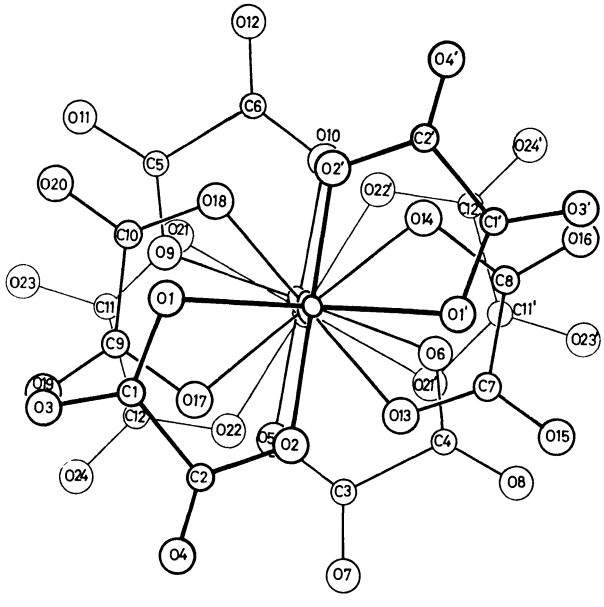

Fig. 2. The mode of overlapping of platinate complex anions.

tions are suitable for intermolecular stabilization due to the overlapping of the higher occupied molecular orbitals of one molecule and the lower unoccupied molecular orbitals of the neighbouring molecule. The importance of the charge transfer interactions in the stabilization of the molecular overlapping was first suggested in Miller's molecular back bonding theory.[21] The 80° conformation observed in this crystal is a new type conformation.

The equations of the best planes, perpendicular distances from these planes and the dihedral angles between these planes are listed in Tables 7a and 7b. The dihedral angles between the Pt(1), Pt(2), and Pt(3)

The Pt(1) plane is nearly planar but the Pt(2) plane is concave (Fig. 3). The Pt(2) atom is 0.11 Å shifted from the best plane toward the Pt(1) plane and the terminal oxygen atoms of the ligands O(16) and O(19) are 0.47 Å and 0.41 Å from the plane, respectively. The large deviation of these atoms from the plane is attributed mainly to the shortening of the Pt–Pt distance and partly to the interaction between the oxygen atoms of oxalate ligands and surrounding atoms. Figure 2 shows direct overlapping of the terminal oxygen atoms of the Pt(2) plane, O(16) and O(19), with O(3) and O(3′) atoms of the Pt(1) plane. The 46° staggered overlapping of the Pt(1) plane and the Pt(2) plane will be a very stable form considering the large intermolecular overlapping and the short interatomic distances within the chain. Many short interatomic contacts indicate that the charge transfer interactions between the ligands of the neighbouring molecules will have influence on the mode of overlapping. The Pt(3) plane is more planar than the Pt(2) plane but the terminal oxygen atoms of the ligands are shifted 0.11—0.22 Å from the plane. As to the Pt(4) plane, the oxygen atom in the five-membered ring shows a 0.19 Å deviation from the least-squares plane and the terminal oxygen atom is 0.12 Å distant from the plane. The Pt(4) plane has little overlapping with the molecules directly above and below. The inclination of the least-squares plane of the Pt(4) plane with respect to the other planes will be caused mainly by the longest Pt–Pt distance, small intermolecular overlapping and the interaction with Rb cations and the weak hydrogen bonding with water molecules. The short interatomic distances between

the terminal oxygen atoms of the Pt(4) plane and the Rb atoms or water molecules are as follows: O(23)··· $H_2O(2)$ 2.74 Å, O(23)···Rb(4) 3.01 Å and 3.09 Å, O(24)···Rb(4) 2.99 Å, O(24)···Rb(2) 2.89 Å. The crystal structure is shown in Fig. 4. The structure contains five independent Rb ions. Table 9 lists the interatomic distances within the coordination spheres to 3.3 Å around the Rb cations and the oxygen atoms of the water molecules. Rb(1), Rb(4) and Rb(5) are seven-coordinated ions, while Rb(2) and Rb(3) are eight-coordinated ones. Figures 5 and 6 show the c* axis and a* axis projections of the structure of RbDOX. The neighbouring Pt chains are not linked by hydrogen bonding of the water molecules but are linked by the coordinations of the terminal oxygen atoms to the Rb cations. The chain-chain interaction through Rb ions and water molecules do not appear to be so strong. Almost all the Rb^+···O distances exceed the Rb^+···O van der Waals sum (2.88 Å).

Peierls Distortion. A one-dimensional metallic system is unstable in the presence of changes in the crystal lattice period which split a partly filled band into completely filled and empty sub-bands. When the temperature is lowered, a one-dimensional metal should exhibit lattice distortions with a wave number equal to twice the Fermi momentum. The period of the Peierls distorted cell is determined by the degree of partial oxidation (DPO).[22]

Six Pt atoms and ten Rb atoms are found in the unit cell of RbDOX and the ratio of the content of Rb atoms to Pt atoms is 1.67, while the result of chemical analyses show that this ratio is 1.66. Thus the DPO of RbDOX is about 0.33. The possible period of the superlattice along the $Pt(C_2O_4)_2$ chain is $6nb_0(=2nb_0/\mathrm{DPO}; n=1,2,3\cdots)$, where b_0 is the average Pt–Pt distance. The case for $n=1$ ($\approx$17.1 Å) corresponds to the "$2k_F$-instability" of a one-dimensional metal. Thus the sixfold superstructure of RbDOX is confirmed as the structure of the commensurate Peierls state, produced by the condensation of $2k_F$ phonon, on the basis of the crystal structure determination, chemical analyses

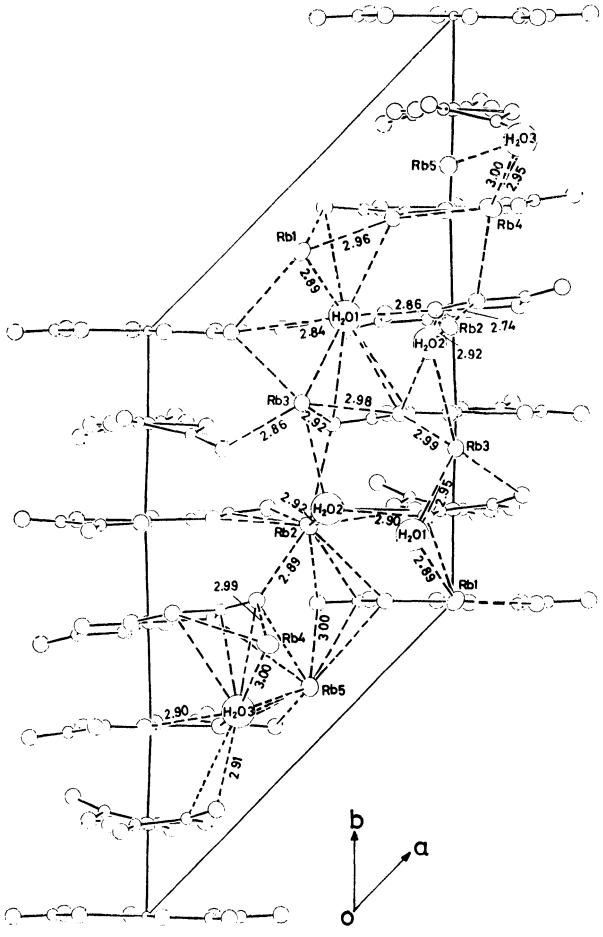

Fig. 5. The c* axis projection of the structure of RbDOX. Broken lines indicate some short interatomic contacts (<3.3 Å).

and the measurements of electrical conductivity. The longitudinal displacements of the Pt modulation wave from the point $[(0.0, n/6, 0.0); n=0, \cdots 5]$ are (0.0, 0.14, 0.16, 0.0, −0.16, −0.14 Å) respectively. These displacements can be approximately expressed in terms of the sinusoidal modulation wave. The amplitude of the modulation wave on the l-th platinum atomic position in the n-th cell $[n=(n_1,n_2,n_3)]$ is given by $0.17\sin\{(2\pi/6)-(l-1)+n_2\}(l=1,\cdots 6)$. The transverse displacements of the Pt atoms are (0.0, 0.04, 0.16, 0.0, −0.16, −0.04 Å). It is logical that the transverse displacements can not be described as a simple sinusoidal wave, considering that the longitudinal displacements will be mainly influenced by interchain interactions whereas the transverse displacements will be also influenced by interchain interactions. Table 10 shows a comparison of the modulation waves in γ-KDOX, RbDOX, and KCP. The amplitudes of the modulation waves in RbDOX and γ-KDOX are approximately 0.17 Å, *i.e.* seven times as large as that of KCP. The correlation of the phase of the lattice modulation waves on the different chain is incomplete in KCP, while the superstructures of bis(oxalato)platinate complexes indicate complete correlation.

In the Peierls phase, the charge density along the platinum chain varies periodically with the wave number of $2k_F$. In order to gain the stabilization energy, Peierls gap is developed at the Fermi level to involve two holes in one repeating unit of the Pt chain. Besides the simple Peierls structure with wavelike charge

amplitude	0.17Å (at R.T.)	0.17 Å (at R.T.) (0.20, −0.08, 0.11) Å	0.025 Å ($T<100$ K)
period	$6\times R_{Pt\cdots Pt}$(17.1 Å)	$10.5\times R_{Pt\cdots Pt}$(30.0 Å)	$6.5\times R_{Pt\cdots Pt}$ (18.8 Å)
Orderness of the chain distortion	Complete (sixfold superstructure)	Complete (superstructure)	Incomplete (fluctuation of the lattice distortion)

a) Refs. 6 and 7. b) Ref. 3.

distribution, a sixfold superstructure of mixed valence configuration may be supposed,[23] that is, $6Rb_{1.67}[Pt(C_2O_4)_2]\cdot 1.5H_2O = (Rb^+)_{10}(Pt^{2+})_5(Pt^{4+})(C_2O_4^{2-})_{12}\cdot 9H_2O$. This model is consistent with the fact that the Pt atom is apt to be in the Pt^{2+} and Pt^{4+} ionic states, but the mixed valence model of the superstructure is opposed to the structural characteristics of platinate complexes: 1. This model is inconsistent with the appearance of a incommensurate superstructure like γ-KDOX. 2. Pt^{4+} has an octahedral configuration and Pt^{2+} has a square planar configuration. Owing to the difference in these coordination types, the distortion of the Pt chain will be localized around the Pt^{4+} site assuming "the mixed valence model" is valid.

The displacements of the Pt atoms in RbDOX or γ-KDOX are in fact described as sinusoidal waves. Based on this reasoning, the mixed valence model is not suitable for RbDOX and γ-KDOX.

Coulomb Interaction between Pt Chains with Charge Density Waves. The lattice distortion waves give rise to a periodical variation of the charge density along the Pt chains.[24] Since the charge density wave thus produced on the Pt chains interact with each other, the phase of the periodical distortion wave is considered to be governed by the interchain Coulomb coupling between the charge density waves. The superstructure formation accompanied by successive phase transitions between 54 K and 37 K in TTF-TCNQ and the development of the diffuse-scattering at $(\pi/a, \pi/a, 2k_F)$ in the KCP salt with lowering of temperature indicate that the chains are anti-phase ordered so as to minimize the Coulomb energy.[25] Figure 5 is the c* axis projection of the structure of RbDOX. The interchain distance is 8.75 Å which is the shortest in all the interchain distances. Assuming that charge density waves or some periodical charge distribution exists along the sixfold Pt chains, the phase difference between the neighbouring positions on these two chains must be about 180°. The wave length of CDW is considered to be equal to the periodicity of the Pt chain ($6\times r_{Pt\cdots Pt}$) and the phase difference between the lattice points must be $2\pi n (n=0,1,2,\cdots)$. Figure 5 seems to indicate that the nearest-neighbour chains tend to be anti-phase ordered. Figure 6 is the a* axis projection of the structure and the interchain spacing is 11.1 Å. The phase difference between the neighbouring positions on two Pt chains is about 50°.

Coulomb interaction between two chains with charge density waves $\rho_i=\rho_0\cos\Phi_i$ may be estimated by the following equation;[26]

$$U_{int} = (1/4\varepsilon_\perp)\rho_0^2[2K_0(2k_F d)]\cos(\Phi_i-\Phi_j)$$
$$= (1/4\varepsilon_\perp)\rho_0^2\sqrt{\pi/2X}e^{-X}\cos(\Phi_i-\Phi_j) \quad X\gg 1$$

where $\varepsilon_\perp$ is the perpendicular static dielectric constant, $K_0(X)$ is the complete Elliptic Integral of the First Kind and d is the interchain spacing. Φ is the phase difference between the origin and the lattice point in the two dimensional lattice, the unit vectors of which are $\boldsymbol{a}_\perp$ and $\boldsymbol{c}_\perp$ which are perpendicular to the Pt chains (Fig. 7). Φ is expressed by the use of the phase parameters δ_a and δ_c, $\Phi_{n_1,n_2}=2\pi(\delta_a n_1+\delta_c n_2)$. The next examination was to establish whether the crystal lattice

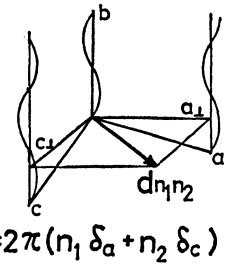

Fig. 7. The phase difference Φ between the platinum chains.

of RbDOX coincides with the structure which minimizes the Coulomb energy. The total Coulomb energy U_{tot} is proportional to

$$\sum_{n_1}\sum_{n_2}U(n_1,n_2) = \sum_{n_1}\sum_{n_2}\sqrt{1/X_{n_1,n_2}}e^{-X_{n_1,n_2}}\cos 2\pi\Phi_{n_1,n_2},$$
$$X_{n_1,n_2} = 2k_F d_{n_1,n_2},$$

where $d_{n_1,n_2}(=|n_1\boldsymbol{a}_\perp+n_2\boldsymbol{c}_\perp|)$ is the interchain distance between the origin (0,0) and the lattice point (n_1,n_2). In this calculation, the lattice constants a, b, c and the angle between $\boldsymbol{a}_\perp$ and $\boldsymbol{c}_\perp$ are fixed. The result of the calculation for several values of δ_a and δ_c are shown in Fig. 8. The point where the total energy is a minimum

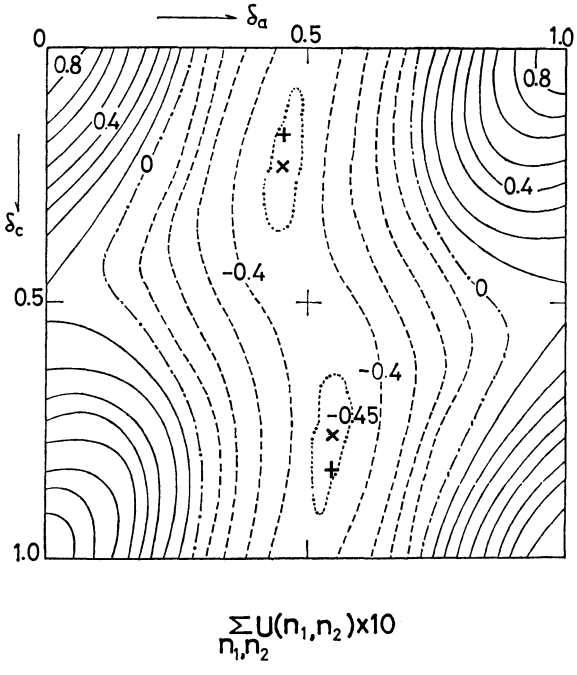

Fig. 8. Total Coulomb energies for various δ_a and δ_c. The point with the minimum total energy is indicated by a cross. Plus sign indicates the position of the parameters δ_a and δ_c derived from the lattice constants.

is indicated by a cross. A plus sign indicates the position of the parameters δ_a and δ_c derived from the lattice constants. The X-ray values of δ_a and δ_c can be calculated as (Fig. 9).

$$\delta_a = RA/OB = 0.537, \quad \delta_c = -R'C/OB = -0.138.$$

The agreement is satisfactory. A similar calculation

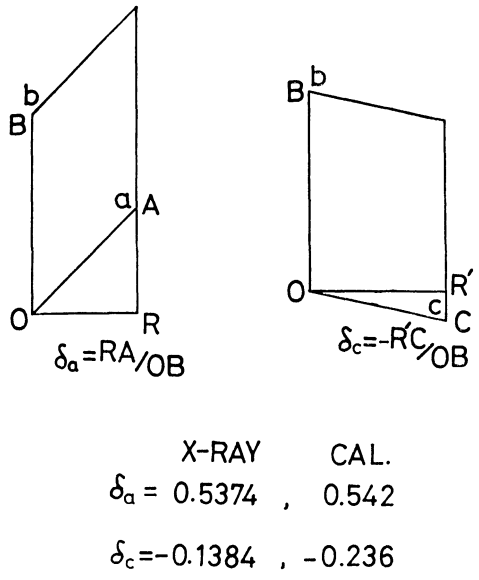

Fig. 9. The projection of the unit cell of RbDOX and the interchain phase differences δ_a and δ_c.

was made for γ-KDOX. The lattice of γ-KDOX is modulated by incommensurate distortion wave. The lattice constants of the fourfold fundamental structure of γ-KDOX are $a=9.749(9)$, $b=11.403(18)$, $c=10.694(8)$ Å, $\alpha=99.54(9)$, $\beta=115.81(9)$, $\gamma=102.32(17)°$. The modulation wave is described by $\boldsymbol{P}\sin(\boldsymbol{K}\cdot\boldsymbol{R})$, where $\boldsymbol{P}$ and $\boldsymbol{K}[=(2\pi\phi_1, 2\pi\phi_2, 2\pi\phi_3)]$ are the amplitude and the wave vector, respectively. The components of $\boldsymbol{K}/2$ along the reciprocal axes a*, b*, and c* are $\phi_1=0.30$, $\phi_2=-0.38$ and $\phi_3=0.05$. X-Ray values of δ_a and δ_c have two terms. $\delta_a=RA/OB+\phi_1=0.403$, $\delta_c=RC/OB+\phi_3=0.250$, ϕ_1 and ϕ_3 are the contributions from the sinusoidal modulation wave. The calculated values of δ_a, δ_c are $\delta_a=0.482$, $\delta_c=0.206$. Good agreement was again obtained. The calculations show that γ-KDOX and RbDOX have crystal lattices in which the interchain Coulomb energies are minimum. The total energy is almost independent of δ_c around the position of the energy minimum which indicates the strong tendency of the anti-phase ordering of the nearest-neighbour chains.

Selective Electrosyntheses on Chemically Modified Electrode. II. Anodic Chlorination of Anisole with Cyclodextrin on Electrode Surfaces and in Solution

Tomokazu MATSUE, Masamichi FUJIHIRA, and Tetsuo OSA*

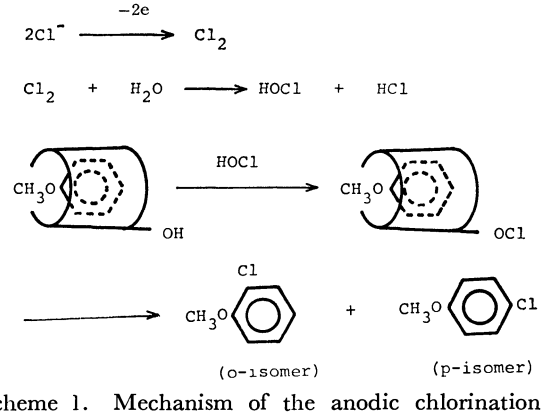
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980

(Received June 22, 1979)

The anodic chlorination of anisole on an α-cyclodextrin (α-CD) chemically modified electrode *via* ether linkage (α-CD-CME) and a naked graphite electrode with α-CD or β-CD in solution was studied. In the presence of CD, the *p*- to *o*-chloroanisole ratio, formed in the reaction, was higher than that in the absence of CD since *o*-positions of anisole included in CD are blocked by the inner wall of CD. Especially, α-CD had a profound effect on the *p*-isomer formation. Increasing the concentration of NaCl added as a supporting electrolyte in the presence of α-CD resulted in a decrease in the ratio because of the inhibition effect of chloride ion on the inclusion of anisole in α-CD, whereas such effect was small in the presence of β-CD. The ratio on α-CD-CME was slightly higher than that on the naked electrode. This indicates that α-CD was introduced on the graphite surface but the surface coverage of α-CD was low, which was in accord with the ESCA results of α-CD-CME.

Many studies of chemically modified electrodes (CMEs) have been developed in order to enhance or to change the characteristics of electrodes, but there have been only a few papers[1-4] on selective electrosyntheses with CMEs. Miller and his co-workers carried out asymmetric reductions[1,2] and asymmetric oxidations[2,3] with CMEs prepared by attaching optically active compounds on the electrode surfaces. However, the optical yields in their works were not high. In order to realize high selectivity in electrolysis with CME, it is necessary that the attached species strongly interact with the substrates as well as resist oxidation or reduction. Cyclodextrins (CDs) meet such requirements. These molecules are cyclic 1,4-linked D-glucopyranose oligomers containing several glucose units and can include various compounds in their cavities in aqueous solution.[5] Especially, α-CD (containing of 6 glucose units) and β-CD (containing of 7 glucose units) have cavities whose sizes are suitable for including benzene and naphthalene rings, respectively. Therefore, these compounds have been studied in various fields because of their catalytic abilities as enzyme models.[6,7] Taking advantage of the environment of α-CD's cavity, Breslow *et al.* carried out the selective chlorination in the presence of α-CD[8] and *O*-alkylated polymer of α-CD.[9]

Such selective chlorination would proceed in the anodic chlorination in the presence of CD (Scheme 1). Chloride ion is first oxidized at the anode to chlorine gas, and second, the nascent state of chlorine is reacted with H_2O to form hypochlorous acid (HOCl).[10] The HOCl formed attacks the anisole included in CD preferentially at the *p*-position because the *o*-positions of anisole are blocked by the inner wall of CD;[11] whereas free anisole is subject to substitution at the *o*-positions as well as at the *p*-position. Our preliminary results of the anodic chlorination of anisole with α-CD-CME (*via* ester linkage) showed that the chlorination occurred preferentially at the *p*-position.[4]



Scheme 1. Mechanism of the anodic chlorination of anisole in the presence of CD.

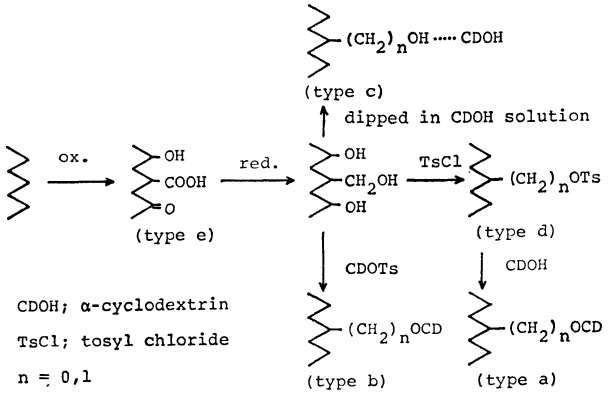
We report here the selective anodic chlorination of anisole on an α-CD-CME (*via* ether linkage) and a naked graphite electrode with α-CD or β-CD in solution in detail. In comparison with Breslow's method of homogeneous or heterogeneous reactions,[8,9] the anodic chlorination in this work has following merits. (1) No reagents such as HOCl difficult to handle are required because the reagent is formed quite easily by electrolysis of chloride salts added as a supporting electrolyte. (2) In a homogeneous reaction, a high concentration of CD is required to attain high selectivity. However, in the anodic chlorination with α-CD-CME, a certain selectivity is expected even in the absence of CD in solution, because the reaction proceeds at electrode surface on which α-CD is introduced by covalent bonding. (3) In Breslow's method with *O*-alkylated polymer of α-CD, an aqueous solution of HOCl should be passed through a column packed with the polymer which was loaded with anisole beforehand. However, in the present work, the above troublesome stepwise operation is omitted, because the reagent (HOCl) is produced electrochemically.

Experimental

A graphite plate (Tokai Carbon Co. G 2080) was cut into $30\times20\times2$ mm plates for electrolyses and $17\times5\times2$ mm plates for ESCA measurements. An AEI model ES 200 was used for ESCA measurements with a Mg anode under a vacuum of 10^{-8}—10^{-9} Torr. The binding energies were computed and corrected by the method reported.[12] All electrolyses were carried out with a Yanaco VE-8 controlled potential electrolyzer. The supporting electrolyte was NaCl, and the reference electrode was a saturated calomel electrode (SCE) inserted near the anode. The electrolysis cell was a divided

H-type with a graphite anode (30×20×2 mm) and a Pt gauze cathode. The anolyte consisted of anisole and NaCl dissolved in 50 ml of water (non-buffered), and was stirred with a magnetic bar. The cell was set in a thermostat kept at constant temperature. After electrolysis, the anolyte was extracted with ether three times and dried with Na_2SO_4 and then concentrated with an evaporator for gas chromatography (Shimadzu GC-6A). The injection and column temperatures of the gas chromatograph were 210 °C and 150 °C, respectively. The column was 2 m×3 ϕ SUS packed with 10% Carbowax 20 M on Chromosorb W. Quantitative analyses of the chloroanisoles formed were carried out by comparison with a calibration line of authentic samples. The ratios of *para*- to *ortho*-isomer (*p*-/*o*- ratios), the conversion of anisole, and the yields of monochloroanisoles of all products were determined using these gas chromatographic data.

Synthetic Procedure for α-CD-CME. The graphite plates were first dipped in water for 2 h to remove water soluble impurities on the surface and were then treated with a solution of 0.2 M $K_2Cr_2O_7$ in concd H_2SO_4 for 2 h to introduce the surface functional groups containing oxygen.[13] The oxidized electrodes were reduced electrochemically at −1.5 V *vs.* SCE in aqueous 0.5 M Na_2SO_4 solution to increase the hydroxyl groups on the graphite surface.[13] The reduced graphite electrodes were reacted with tosyl chloride (TsCl) in dry pyridine for several weeks and then treated with an aqueous solution of 0.1 M α-CD in 0.1 M KOH for 4 days. After the reaction, the electrodes were washed with water repeatedly to remove the adsorbed α-CD on the graphite surfaces. Another method for the modification of graphite electrodes with α-CD was as follows. Reduced graphite was reacted with α-CD tosylate[14] in 0.1 M KOH solution (pyridine: H_2O=30:70) for a week, followed by thorough washing with water. To compare these α-CD-CMEs with a physically adsorbed α-CD electrode, the reduced graphite electrode was dipped into 0.1 M KOH aqueous solution containing α-CD (0.1 M) for 10 h, and then washed with water (Scheme 2).



Scheme 2. Synthetic procedure for α-CD-CME and α-CD adsorbed electrode.

Results and Discussion

The potential range in the anodic chlorination must be carefully chosen because the substrate, anisole, is oxidized when the anode potential exceeds *ca.* 1.3 V *vs.* SCE in aqueous NaCl solution. At such a high potential, side reactions can also occur and *p*-/*o*- ratio or other values become inaccurate, and furthermore, the graphite electrode itself is oxidized. Consequently, it is desirable to set the anodic potential as low as possible. However, at low anodic potentials, the chlorination cannot occur or proceeds very slowly because chlorine generation starts at 0.9—1.0 V *vs.* SCE in aqueous NaCl solution, so that the anodic potential of 1.20 V *vs.* SCE was used.

In the Absence of CD. Increasing the concentration of anisole resulted in an increase in the *p*-/*o*- ratio and also an increase in the yields of chloroanisoles (Table 1, expts. 1 and 2). The *p*-/*o*- ratio was gradually decreased with increasing conversion of anisole during the electrolysis both on the untreated graphite (expts. 3, 4, and 5) and on the oxidized graphite (expts. 6 and 7). But a higher *p*-/*o*- ratio was observed on the untreated graphite electrode than the oxidized one. The yield of chloroanisoles was independent of the mode of preparation of the electrode, *i.e.* whether graphite electrode was oxidized or not. The influence of the concentration of NaCl added in the anolyte at low conversion of anisole was not great (expts. 2, 3, and 8). A slight tendency of the *p*-/*o*- ratio to increase was observed with a decrease in the concentration of NaCl. The temperature during electrolysis did not affect the *p*-/*o*- ratio in the temperature range 0—30 °C, but did affect the yield of chloroanisoles (expts. 8 and 9). It took *ca.* 10 min to convert 10% of anisole in the anolyte and the current efficiency was *ca.* 50%. The *p*-/*o*- ratios in the present work are a little lower than those in the previous report.[4] This might be attributed to the difference in the surface properties of the graphite plates used. The ratios on the oxidized electrodes in the present work, however, showed only slight deviations. After electrolysis (10% conversion of anisole), the pH

of the anolyte became 2.0 since hydrochloric acid was generated in the course of the electrolysis.

In the Presence of β-CD. The variations in *p*-/*o*- ratios and yields of chloroanisoles in the presence of β-CD, together with the percentages of included anisole in the β-CD solution, are shown in Table 2. The table shows a slight increase in the *p*-/*o*- ratio with increasing concentration of β-CD, which indicates that the *p*-isomer was formed preferentially in the presence of β-CD in solution (expts. 12, 13, and 14). This supports the idea described above that the reagent (HOCl) can scarcely attack the *o*-positions of anisole included in β-CD.[11] The temperature had some influence on the *p*-/*o*- ratio. When electrolysis was carried out at 0 °C, the ratio was 4.1 which was higher than the 3.5 value observed at 20 °C (expts. 12 and 15). This phenomenon may be a reflection of the thermodynamic nature in that CD includes substrate more easily at low temperatures.[15] The yield of monochloroanisoles was low at low temperature in a similar manner as in the absence of CD (Table 1, expts. 8 and 9). As the dissociation constant of β-CD–anisole complex is 1.9×10^{-2} M,[16] only 34% of the anisole is included in the 10^{-2} M β-CD solution which is almost the maximum concentration of β-CD in aqueous solution. This low complex formation of anisole with β-CD might be a cause for the low regioselectivity in the anodic chlorination of anisole in the presence of β-CD. The effect of the concentration of NaCl on the *p*-/*o*- ratios was small, but a slight tendency of the ratio to decrease with enhancement of the concentration of NaCl was observed (Table 2, expts. 10, 11, and 12).

In the Presence of α-CD. The results of the anodic chlorination of anisole in the presence of α-CD are given in Table 3. The electrolytic conditions were the same as those in the presence of β-CD. The *p*-/*o*- ratios became greater as the concentration of α-CD increased, *i.e.* the *p*-isomer was formed selectively at high concentrations of α-CD in solution. The yield of monochloroanisoles in the presence of α-CD was almost the same as that in the presence of β-CD, but selectivity of *p*-isomer formation was much higher. This is explained by the fact that α-CD binds anisole about 5 times stronger than β-CD. The dissociation constant of the α-CD–anisole complex is 3.75×10^{-3} M.[9] The table also shows that the *p*-/*o*- ratio increases significantly with decreasing NaCl concentration at a constant concentration of α-CD (Table 3, expts. 16, 18, and 22). This indicates that the inhibition effect of Cl^-[17] on the inclusion of anisole in α-CD is very great. On the other hand, the concentration of NaCl had only a small effect on the *p*-/*o*- ratios in the anodic chloriantion in the presence of β-CD (Table 2, expts. 10, 11, and 12), which is explained by the fact that Cl^- is not included in β-CD.[17] It is also shown that the selectivities in this work in the presence of α-CD are higher than those in the homogeneous reactions reported by Breslow and Campbell (Table 4).[8] The differences in *p*-/*o*- ratios (Table 3, expts. 16, 18, and 22) were greater than those expected from the percentages of included anisole in solution. These phenomena may reflect surface effects in which the concentrations of reagents on the graphite electrode surface are different from those in the bulk solution. The difference in the ratios in the presence of α-CD and in the presence of β-CD at the same percentage of included anisole in the bulk solution (*e.g.*, the difference between expt. 12, Table 2 and expt. 19, Table 3) may be accounted for by the following possi-

bilities.

(1) α-CD is more strongly adsorbed on the graphite surface than β-CD at this potential.

(2) Slight movement of the included anisole in β-CD is allowed since the size of the β-CD cavity is a little larger than that of the anisole molecule; whereas, the anisole included in α-CD is not free to move.

a) Obtained by the reaction between the tosylated graphite and α-CD. b) Obtained by the reaction between the reduced graphite and tosylated α-CD. c) Obtained by dipping the reduced graphite in α-CD aqueous solution followed by washing with water.

Anodic Chlorination with α-CD-CME. The results of the anodic chlorination with α-CD-CME (*via* ether linkage) obtained by the reaction between the tosylated graphite and α-CD (type a), by the reaction between the reduced graphite and tosylated α-CD (type b), and α-CD adsorbed graphite (type c) are given in Table 5. Type a shows a slight higher *p*-/*o*- ratio than the others, but its value is low compared with those in the presence of α-CD and on α-CD-CME (*via* ester linkage).[4] This indicates that the surface coverage of α-CD introduced by the chemical modification was low on type a. Type b showed no selectivity. The attachment of α-CD on the graphite surface by the reaction between the reduced graphite and α-CD tosylate was very difficult. The reaction may be hindered by the intra- or intermolecular reaction of tosylated α-CD. No selectivity was also obtained on type c. The adsorbed α-CD on the reduced graphite electrode was removed by washing with water. The yields of chloroanisoles formed in the anodic chlorination with the above three types of electrodes were the same as those with unmodified electrodes. When type a was treated with $K_2Cr_2O_7$ for 1 h to remove α-CD on type a, the *p*-/*o*- ratio became lower than that of the electrode of type a not subject to the treatment.

ESCA Results. Three types of electrodes, type a, the tosylated graphite (type d), and the oxidized graphite (type e), were examined by ESCA. Fig. 1 shows wide ESCA spectra obtained. There are strong peaks of O ls at 532 eV and C ls at 285 eV on type e, which are almost the same as those of glassy carbon baked in the air.[18] No peaks based either on Cr or on K of $K_2Cr_2O_7$ appears. The ESCA spectrum of type d shows small S 2s at 233 eV and S 2p at 170 eV in addition to the above peaks. These sulfur peaks originate from sulfur atoms in the tosyl group introduced on the graphite surface, and the peaks disappear with further modification with α-CD. This indicates that the tosyl group was removed by the reaction between the tosylated graphite (type d) and α-CD. Higher resolution ESCA spectra of O ls in type a and type e are shown in Fig. 2. The peak intensity of type a is larger than that of type e and the peak is shifted toward a higher binding energy compared with that of type e. It is, however, difficult to assign the chemical shift, since various types of oxygen atoms exist on the

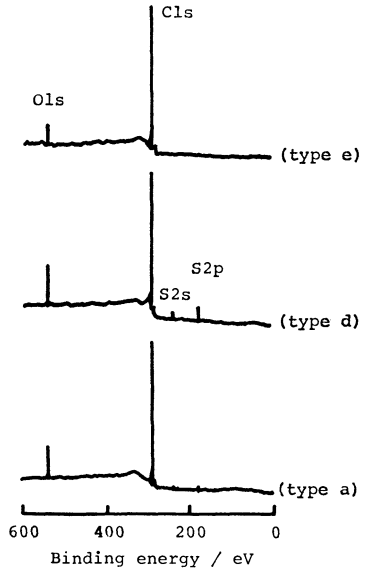

Fig. 1. ESCA spectra of the α-CD-CME (type a), the tosylated (type d), and the oxidized (type e) graphite electrodes.

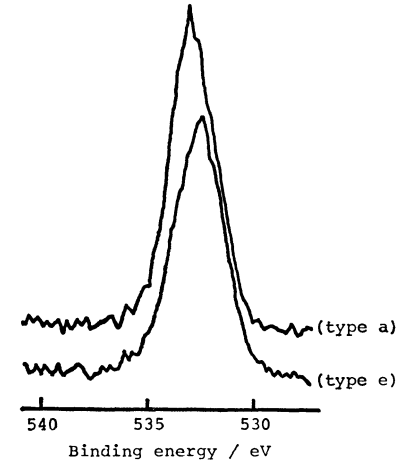

Fig. 2. O ls ESCA spectra of the α-CD-CME (type a) and the oxidized (type e) electrode.

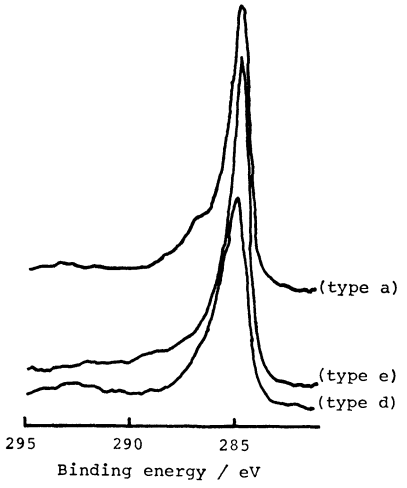

Fig. 3. C 1s ESCA spectra of the α-CD-CME (type a), the tosylated (type d), and the oxidized (type e) electrodes.

graphite surfaces. The changes in higher resolution ESCA spectra of C ls of types a, d, and e are shown in Fig. 3. By performing chemical modification with α-CD on the graphite surface, a shoulder at the higher binding energy side of the main peak at 285 eV appeared but its height was lower than that of the previous results.[4] This shoulder may be accounted for by consideration of the charge on the carbon atoms in α-CD. All carbon atoms in α-CD adjoin oxygen atoms which have a higher electronegativity compared with the carbon atoms.[19] The surface coverage by α-CD on type a is not large because the shoulder is small. The C ls of type d appeared at the same binding energy as type e and has no shoulder. These results also support the conclusion that the shoulder in the spectrum of type a is attributed to α-CD on the graphite surface. Fig. 4 shows S 2s ESCA spectra of types a, d, and e.

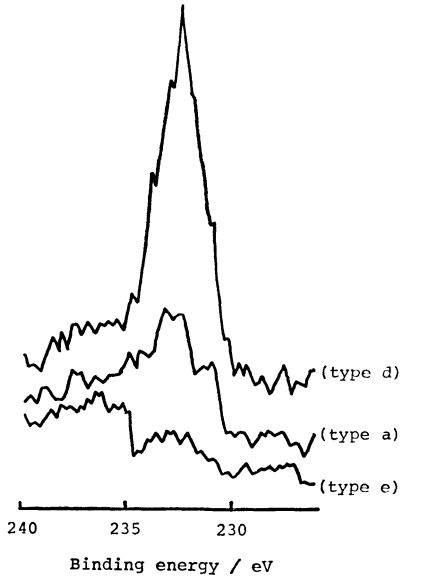

Fig. 4. S 2s ESCA spectra of the α-CD-CME (type a), the tosylated (type d), and the oxidized (type e) electrodes.

The peak of type d appeared at *ca.* 233 eV which is shifted toward the higher binding energy side compared with 229 eV, the binding energy of 2s electron in free sulfur.[20] The shift of the S 2s is in agreement with that of the S 2p of sulfonated compounds, *i.e.* the peaks of these compounds shift to a higher binding energy than those of the sulfide or disulfide compounds because the calculated charges on the sulfur atoms in sulfonated compounds are high.[19] On the other hand, the S 2s peak on type e could not be observed, which indicates that the surface is free from contamination by sulfur compounds on type e. On type a, small S 2s peak still remained. Most of tosyl group were removed by the reaction between the tosylated graphite (type d) and α-CD, but some unreacted tosyl groups remained on type a.

New Potassium and Ammonium Lead(II) Chromates with a Higher Lead Content and Iso-structural with Potassium Lead(II) Chromate, $K_2Pb(CrO_4)_2$

Tsutomu FUKASAWA* and Masaaki IWATSUKI

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received April 16, 1979)

An unknown yellow precipitate, similar to lead(II) chromate in appearance, has been reported. The precipitate was formed in the detection process of lead(II) ions using chromate ions by a classical qualitative analytical method. The present paper describes the elucidation of the unknown precipitate, and the presence of a series of new chromates iso-structural with the known potassium lead(II) chromate, $K_2Pb(CrO_4)_2$. The new chromates are explained as new stoichiometric chromates, $K_4Pb_4(CrO_4)_6$ and $(NH_4)_4Pb_4(CrO_4)_6$ [$=K_2Pb_2(CrO_4)_3$ and $(NH_4)_2Pb_2(CrO_4)_3$], and solid solutions (K, $NH_4)_{6-2z}Pb_{3+z}(CrO_4)_6$ ($z=+0.3$—$+1.2$) among the new stoichiometric chromates and the known chromates, $K_6Pb_3(CrO_4)_6$ and $(NH_4)_6Pb_3(CrO_4)_6$ [$=K_2Pb(CrO_4)_2$ and $(NH_4)_2Pb(CrO_4)_2$]. The compositions of the new chromates are dependant on the precipitating conditions. Relationships between compositions, lattice constants, and precipitating conditions are given together with indexed powder diffraction data for references to identification, and the results of thermal analyses.

It was described in a previous paper[1] that fine particles of an unknown yellow compound, similar to lead(II) chromate in appearance, precipitated under certain conditions in the reaction leading to the formation of lead(II) chromate, a substance used for the detection of lead(II) ions in classical qualitative analysis. The particles were unstable and changed into needle crystals of monoclinic lead(II) chromate when left in the mother liquor. In general, this unknown compound precipitated when a potassium chromate solution was added to a hot and dilute lead(II) solution containing a relatively large amount of ammonium acetate.

The present study was conducted to elucidate the unknown compound, and to obtain the powder X-ray diffraction data for identification. Precipitates were prepared by adding an ammonium chromate solution to an ammonium acetate solution of lead(II), or a potassium chromate solution to a potassium acetate solution of lead(II) at different concentrations and pH. X-Ray diffraction, chemical analysis, density measurement, and thermal analysis were conducted on the precipitates.

It was found that the unknown compound described was one of a series of new chromates, which were higher in lead content than the known potassium or ammonium lead(II) chromate $K_2Pb(CrO_4)_2$ or $(NH_4)_2Pb(CrO_4)_2$,[2] and iso-structural with known chromates. These new chromates have been expressed as $K_2Pb_2(CrO_4)_3$, $(NH_4)_2Pb_2(CrO_4)_3$, and $(K,NH_4)_{2+2y}Pb_{2-y}(CrO_4)_3$ ($y=-0.1$—$+0.3$) from the construction rule of chemical formulas and the analytical results, and as $(K,NH_4)_{2-2x}Pb_{1+x}(CrO_4)_2$ ($x=+0.1$—$+0.4$) when the conventional formula of the known chromate, $K_2Pb(CrO_4)_2$, was followed. The relationship between the new and known stoichiometric chromates is conveniently explained by the common formulas containing six chromate ions from the viewpoint of iso-structure: The new chromate are explained as new stoichiometric chromates, $K_4Pb_4(CrO_4)_6$ and $(NH_4)_4Pb_4(CrO_4)_6$, and solid solutions, $(K,NH_4)_{6-2z}Pb_{3+z}(CrO_4)_6$ ($z=+0.3$—$+1.2$), among the new stoichiometric chromates and the known chromates, $K_6Pb_3(CrO_4)_6$ and $(NH_4)_6Pb_3(CrO_4)_6$. The relationships between the compositions, lattice constants, and precipitating conditions of the new chromates are given with the indexed powder X-ray diffraction data, and the results of thermal analyses.

Experimental

Sample Preparation. Several differing lead(II) acetate solutions were prepared by the dissolution of appropriate quantities of lead(II) sulfate in ammonium or potassium acetate solutions of 1 to 6 M (1 M=1 mol dm^{-3}), followed by pH adjustment. The precipitates were prepared using each lead(II) acetate solution as follows: A small excess of a 1.5 M ammonium or potassium chromate solution was gradually added *via* a 5 cm^3 pipet to a lead(II) acetate solution in a 200 cm^3 or 1 dm^3 beaker at about 80 °C with stirring. The precipitate formed was filtered off, and dried at 105 °C in an electric oven.

All the precipitates prepared were yellow or yellow-orange, and fine particles smaller than 1 μm except that monoclinic lead(II) chromate occasionally precipitated in size of above 1 μm.

The precipitate samples used for the chemical analyses were identified by powder X-ray diffraction analysis.

Methods of Analysis. *Powder X-Ray Diffraction Analysis*: The X-ray diffraction analyses were conducted by use of an X-ray diffractometer (Rigaku) equipped with a copper-target tube and nickel filter. The sample was mounted in a standard aluminum specimen holder. The intensities were measured from the peak heights of the line profiles. The accurate diffraction angle for determination of the lattice constants was measured from the center of gravity of the line profile recorded at a low scanning speed. The diffraction angle was corrected by use of high-purity silicon powder as an internal standard.

Chemical Analysis: X-Ray fluorescence analysis and Nessler's test confirmed that the samples contained lead, chromium, potassium, and/or ammonium, but no sulfur. Lead, chromium, potassium, and ammonium were quantitatively determined as follows: For the determination of lead and potassium, the sample was dissolved in nitric acid (1+1), followed by dilution with water. Ascorbic acid was then added to reduce the chromate to chromium(III) ions. After an appropriate dilution, lead and potassium were determined

by the standard addition-atomic absorption method and by the standard addition-flame photometric method, respectively. For the determination of chromium, the sample was dissolved in nitric acid (1+1), and sodium hydroxide solution added until the solution became alkaline. The chromate ion was photometrically determined at 366 nm. The ammonium ion was determined by the micro-diffusion method.[3] The determination of each constituent was repeated at least twice and the average taken.

Density: "Observed density" was determined by use of a pycnometer with carbon tetrachloride. "Calculated density" was evaluated from lattice constants and the number of constituent ions in a unit cell.

Thermal Analysis: Thermal analysis was conducted by use of a thermobalance (Rigaku) with a differential thermal analyzer.

Results and Discussion

Chemical Composition and Crystallographic Consideration. Table 1 shows the results of chemical analyses of the representative samples prepared under different conditions, and chemical formulas obtained from the analytical results. The number of oxygens in the chemical formulas has been taken as 12, because the elemental ratio in the formula of sample K-0 was successfully expressed in the smallest integer when the conventional rule was applied to the construction of chemical formulas; the ratios in the formulas of the other samples were not successfully expressed in integers.

The lead contents of the prepared samples were higher than those of the known chromates, $K_2Pb(CrO_4)_2$ and $(NH_4)_2Pb(CrO_4)_2$. The chemical formulas of some samples were approximated to $K_2Pb_2(CrO_4)_3$ or $(NH_4)_2Pb_2(CrO_4)_3$. The other samples were nonstoichiometric, and have been expressed as $(K,NH_4)_{2+2y}Pb_{2-y}(CrO_4)_3$ ($y=-0.1$—$+0.3$). Some however have a slightly unbalanced charge. The charge unbalance in some formulas may be explained by the formation of nonstoichiometric compounds of lattice-defect type, and/or the presence of undetectable amounts of lead oxide which may be formed by heating lead hydroxide at 105 °C; the lead hydroxide may be produced together with the chromate in the precipitating process.

The X-ray powder patterns of the newly found chromates were similar to those of the known chromates (hexagonal), $K_2Pb(CrO_4)_2$, $(NH_4)_2Pb(CrO_4)_2$, *etc.*, and indexed successfully by the hexagonal system by use of the Bunn-Bjurström chart. Table 2 shows the X-ray diffraction data of the representative samples. It appears that the crystal structures of all the newly found chromates are iso-structural with the known chromates. The compounds previously expressed as $K_2Pb_2(CrO_4)_3$, $(NH_4)_2Pb_2(CrO_4)_3$, and $(K,NH_4)_{2+2y}Pb_{2-y}(CrO_4)_3$ may be expressed as $K_{1.33}Pb_{1.33}(CrO_4)_2$, $(NH_4)_{1.33}Pb_{1.33}(CrO_4)_2$, and $(K,NH_4)_{2-2x}Pb_{1+x}(CrO_4)_2$ assuming the conventional formulas of the known chromates are followed. The formulas $K_{1.33}Pb_{1.33}(CrO_4)_2$ and $(NH_4)_{1.33}Pb_{1.33}(CrO_4)_2$ do not however adhere to the construction rule of chemical formulas. The common formulas containing six chromate ions (oxygen=24) appear to fit both the new and known chromates which are stoichiometric and iso-structural with each other. The chromates $K_2Pb_2(CrO_4)_3$ and $(NH_4)_2Pb_2(CrO_4)_3$ are explained conveniently as the new stoichiometric chromates $K_4Pb_4(CrO_4)_6$ and $(NH_4)_4Pb_4(CrO_4)_6$ iso-structural with the known chromates $K_6Pb_3(CrO_4)_6$ and $(NH_4)_6Pb_3(CrO_4)_6$. The nonstoichiometric chromates expressed by $(K,NH_4)_{2+2y}Pb_{2-y}(CrO_4)_3$ are thought to be substitutional solid solutions lying between the new and known stoichiometric chromates, and are expressed by the general formula, $(K,NH_4)_{6-2z}Pb_{3+z}(CrO_4)_6$ ($z=+0.3$—$+1.2$). The latter formulas will be used in the subsequent discussion except for the thermal analysis.

Tables 3 and 4 show the precipitating conditions, lattice constants, chemical formulas, and densities of the representative compounds prepared; the lattice constants were calculated from accurate diffraction angles of appropriate lines and their assigned indices. The compositions of the compounds changed depending on the precipitating conditions; such changes were also supported by the differences in lattice constants. The relationships between the compounds formed and the precipitating conditions may be summarized as follows: (1) the lead content of the formed compound increased with decreasing concentration of ammonium or potassium acetate solution; (2) the lattice constant, a, of the compound increased with increasing lead content, while the lattice constant, c, decreased except in compounds obtained with potassium acetate solution; (3) monoclinic lead(II) chromate was preferentially formed when ammonium or potassium acetate solution of lower concentration was used; (4) the pH, and amounts of ammonium or potassium acetate solution per gram of lead(II) sulfate do not appear to affect the composition.

The number of chemical units in the unit cell, which was calculated from the observed density and lattice constants, was one for a series of the new chromates, $(K,NH_4)_{6-2z}Pb_{3+z}(CrO_4)_6$, as well as for the known chromates, $K_6Pb_3(CrO_4)_6$ and $(NH_4)_6Pb_3(CrO_4)_6$.

a) N.D.: Not detected. d_{calcd} was calculated with lattice constants measured in this work. b) Miller's indices are shown as one of hexagonal lattice.

Comparison of the lattice constants in Table 3 appears to indicate that the substitution of one Pb^{2+} ion for two NH_4^+ ions causes a slight decrease in c, and a slight increase in a, but no appreciable change in the volume of the unit cell. The Table 4 shows that the substitution of one Pb^{2+} ion for two K^+ ions has little effect on c, but causes a slight increase in a. In terms of the differences in number and size of the cations in their unit cells, the newly found chromates appear to be less compact in structure than the known chromates. The instability of the new chromates in their mother liquors may be explained by the less compact structures.

Thermal Analysis. Figure 1 shows the results of thermogravimetric (TGA) and differential thermal (DTA) analyses of sample NK-0. The endothermic

peak at approximately 205 °C, which was accompanied by a weight loss over the range 140 to 220 °C, was attributed to the evolution of ammonia; the evolution was confirmed by Nessler's test and the experimental and theoretical weight losses. The exothermic peak at approximately 245 °C, which was accompanied by a weight loss over the range 220 to 270 °C, may be attributable to the formation of water by the oxidation of ammonia, since, when the sample was heated to approximately 220 °C in a test tube attached with a conduit pipe, water drops were produced inside the pipe. High-temperature X-ray diffraction analysis showed a definite transition of sample NK-0 to monoclinic lead(II) chromate and the formation of an intermediate compound in the couse of this transition. Although this intermediate compound could not be identified, it appears to be a compound formed by the escape of ammonia from sample NK-0. The exothermic peak free from weight loss at approximately 405 °C appears due to a crystal transition. The transition could not, however, be detected by high-temperature X-ray diffraction analysis.

Several samples changed to known compounds with weight loss, when heated up to approximately 400 °C in an electric furnace, the results of which are summarized in Table 5. The residues obtained by heating

Table 5. The results of heating to 400 °C for some samples

Sample	Weight loss/%	Color of the residue	Crystalline phase in the residue

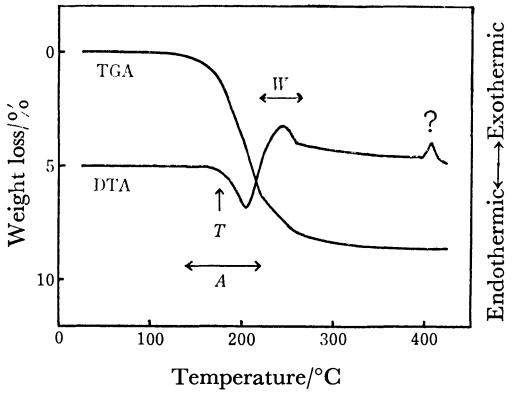

Fig. 1. Thermal analysis of $K_{0.2}(NH_4)_{2.0})Pb_{1.9}(CrO_4)_{3.0}$ (sample NK-0).
Heating rate: 3 °C/min; T: transition of sample NK-0 to $PbCrO_4$ (mon.); A: evolution of ammonia; W: evolution of water.

samples NK-0 and N-0 mainly consisted of monoclinic lead(II) chromate; small amounts of the known chromate, $K_2Pb(CrO_4)_2$, were also detected in the residue of sample NK-0 containing small amounts of potassium ions. Amorphous chromium(III) oxide appears to be present in both residues judging from the color (yellow-green). This chromium(III) oxide may be formed by the reduction of chromate ions by ammonia. Sample K-0 was decomposed by heat-treatment to known compounds, $K_2Pb(CrO_4)_2$, PbCrO-(mon.), $PbCrO_4 \cdot PbO$, *etc.*

The thermal analyses described above, together with the differences in X-ray diffraction patterns and lattice constants, also support the conclution that the compounds prepared here differ from the known chromates, $K_2Pb(CrO_4)_2$ and $(NH_4)_2Pb(CrO_4)_2$.

The authors are grateful to Professor Yoshihiko Saito of the University of Tokyo, Professor G. H. Morrison of Cornell University, and Dr. L. S. Birks of the Naval Research Laboratory for their advice. Acknowledgments are also due to Mr. Jun'ichi Ito of the Central Research Laboratory, Showa Denko K. K., for providing the facilities for thermal analysis, to Rigaku Denki K. K. for providing the facilities for high-temperature X-ray diffraction analysis, and to Mr. Shintaro Suzuki for assistance in the experimental work.

The Crystal Structures of $(+)_{589}$- and $(-)_{589}$-*trans*(*O*)-Ethylenediaminebis(glycinato)cobalt(III) Hydrogen-*d*-tartrates and Their Thermal Behavior

Masahiro KURAMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Hiroshima 730

(Received October 27, 1978)

The crystal structures of two diastereoisomeric salts, $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·3H$_2$O (**1**) and $(-)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·H$_2$O (**2**), have been determined by three-dimensional X-ray analysis. The less-soluble salt (**1**) is monoclinic; space group, $P2_1$; $Z=2$, $a=12.351(5)$, $b=7.671(3)$, $c=10.189(5)$ Å, and $\beta=110.71(4)°$ ($R=0.043$, 2241 reflections). The more-soluble salt (**2**) is monoclinic; space group, $P2_1$; $Z=2$, $a=11.135(4)$, $b=10.037(3)$, $c=7.716(3)$ Å, and $\beta=98.61(3)°$ ($R=0.064$, 2076 reflections). A comparison of the (unit cell volume)/Z values of the two crystals shows that the crystal **1** is more tightly packed than the crystal **2**. In both salts, adjacent complex cations form quite similar chain structures linked by (N–H···O) hydrogen bonds. The H-*d*-tart anions in **1** take a characteristic "head-to-tail" arrangement of an infinite chain of $\{$H-*d*-tart$\}_\infty$ along the b-axis. In contrast, this arrangement is not found in the more-soluble salt (**2**). From these findings, it can be considered that the discrimination of optical isomers in the H-*d*-tart system originates from the spiral chain structure of $\{$H-*d*-tart$\}_\infty$. The absolute configurations of $(+)_{589}$- and $(-)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]$^+$ are determined to be Λ-δ and Λ-λ respectively. TG and DSC measurements were carried out for both salts, and the ΔH values of the dehydration step were estimated to be 64.4 kJ mol^{-1} for **1** and 73.0 kJ mol^{-1} for **2**.

Optical resolutions of metal complex ions are performed mostly through fractional crystallization utilizing the difference in solubilities of diastereoisomeric salts. However, no general rule has yet been established to judge what sort of a resolving agent is most effective for a particular racemic complex. To approach this problem, the X-ray crystal analysis of a pair of diastereoisomeric salts is indispensable. A comparison of the crystal structures of the less- and more-soluble diastereoisomeric salt pair will give an important clue for elucidating the mechanism of optical resolution.

With this expectation, the crystal structures were investigated recently for a pair of a less-soluble salt, $(+)_{589}$-[Co(ox)en$_2$]H-*d*-tart·H$_2$O (**3**), and a more-soluble salt, $(-)_{589}$-[Co(ox)en$_2$]H-*d*-tart·2H$_2$O (**4**);[1,2] their thermal behavior was also examined. It was found that, in **3**, complex cations are locked tightly in a space formed by four spiral chains of H-*d*-tart(*d*-$C_4H_5O_6^-$, abbr. H-*d*-tart) anions related by a twofold screw axis, while in **4**, complex cations are packed loosely in the four chains of the H-*d*-tart anion formed by a translation operation.[2]

In the present study the crystal structures were determined for another pair of diastereoisomeric salts, $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·3H$_2$O (**1**) and $(-)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·H$_2$O (**2**). The complex, *trans*(*O*)-[Co(gly)$_2$en]$^+$, is actually resolved by way of these diastereoisomeric salts, both of which have been reported to be obtained easily as single crystals.[3] In addition, since *trans*(*O*)-[Co(gly)$_2$en]$^+$ and [Co(ox)en$_2$]$^+$ have the same chemical formula, $C_6H_{16}N_4O_4Co$, the volumes of both cations can be expected to be nearly equal. Thus, the present diastereoisomeric pair is considered to be one of the most suitable examples for clarifying the nature of discrimination by the H-*d*-tart anion.

Contrary to the diastereoisomeric salts, [Co(ox)en$_2$]-H-*d*-tart·*n*H$_2$O, the number of the water of crystallization of *trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·*n*H$_2$O is larger in the less-soluble salt than that in the more-soluble one. To see the role of the water of crystallization in their crystal packing, the thermal behavior of both crystals was investigated by means of TG and DSC measurements.

Experimental

*Preparation of Compound. (a) The Less-soluble Salt, $(+)_{589}$-*trans*(O)-[*Co(gly)$_2$en*]H-d-tart·3H$_2$O (1)*: The less-soluble salt (**1**) was prepared by the method of Dabrowiak and Cooke.[3]

Table 1. Crystal parameters of two diastereoisomeric pairs

Diastereoisomers	a/Å	b/Å	c/Å	β/°	Space group	D_m/g cm^{-3}	Z	D_c/g cm^{-3}	V/Å^3	V/Z/Å^3
$(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·3H$_2$O (**1**)	12.351(5)	7.671(3)	10.189(5)	110.71(4)	$P2_1$	1.72	2	1.73(1)	903.0(7)	451.5(4)
$(-)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·H$_2$O (**2**)	11.135(4)	10.037(3)	7.716(3)	98.61(3)	$P2_1$	1.67	2	1.69(1)	852.7(5)	426.4(3)
$(+)_{589}$-[Co(ox)en$_2$]H-*d*-tart·H$_2$O (**3**)[a]	8.256(3)	14.588(4)	7.009(1)	104.73(2)	$P2_1$	1.74	2	1.77(1)	816.4(4)	408.2(2)
$(-)_{589}$-[Co(ox)en$_2$]H-*d*-tart·2H$_2$O (**4**)[a]	16.583(5)	14.186(5)	7.403(2)	——	$P2_12_12$	1.72	4	1.73(1)	1741.5(10)	435.4(3)

1, **3**: The less-soluble salt. **2**, **4**: The more-soluble salt. a) The crystal data of **3** and **4** were remeasured in a manner similar to that used for **1** and **2**.

The crystals are hexagonal rods. Found: C, 25.52; H, 5.84; N, 11.80%. Calcd for $C_{10}H_{27}N_4O_{13}Co$: C, 25.54; H, 5.79; N, 11.91%.

(b) The More-soluble Salt, $(-)_{589}$-trans(O)-[Co(gly)$_2$en]H-d-tart·H_2O (2): After the removal of the precipitated crystals of the $(+)_{589}$-salt,[3] the filtrate was cooled in a refrigerator. The crystals **2** were thus separated out as rhombic plates. Found: C, 27.79; H, 5.40; N, 12.90%. Calcd for $C_{10}H_{23}N_4O_{11}Co$: C, 27.66; H, 5.33; N, 12.90%.

X-Ray Data Collection. Weissenberg photographs indicated a monoclinic unit cell with the systematic absence of $(0k0)$ when $k=2n+1$ for both **1** and **2**. Of the two possible space groups, $P2_1$ and $P2_1/m$, the latter was eliminated because of the optical activity of these compounds. The crystal sizes used for the cell constant and intensity measurements were $0.25\times0.50\times0.40$ mm^3 for **1** and $0.15\times0.20\times0.30$ mm^3 for **2**. All the cell constants were determined by a least-squares treatment of the setting of 15 reflections measured on a Syntex R3 computer-controlled four-circle diffractometer with Mo $K\alpha$ radiation ($\lambda=0.7107$ Å) monochromated by a graphite plate. All the cell constants are summarized in Table 1. The intensity data for **1** and **2** were collected by the ω-2θ scan technique to a maximum 2θ value of 55° at a scan rate of 3°/min. The intensities of 2366 and 2234 independent reflections were collected for **1** and **2** respectively. Reflections for which the intensities were less than three times their standard deviations were regarded as "unobserved" and were not included in subsequent calculations. Thus, 2241 and 2076 independent reflections were used for the structure determination for **1** and **2** respectively. Their intensities were corrected for Lorentz and polarization factors, but no absorption corrections were made since the μ-values (10.7 cm^{-1} for **1** and 11.2 cm^{-1} for **2**) were low.

Thermogravimetric Analysis (TG). The TG data were obtained with a Rigaku Thermal Analyzer (Model 8005). A heating rate of 3 K/min and a static air atmosphere were employed, and 7.65—11.13 mg samples were used in each run.

Differential Scanning Calorimetry (DSC). A Rigaku Differential Scanning Calorimeter (Model-8055Cl) was used to record the DSC curves. In order to determine the ΔH values of the dissociation of the water of crystallization for both diastereoisomers, the instrument was calibrated using the ΔH values of the fusion of pure indium, tin, and lead metals as standards. The weights of the samples were 9.20—13.75 mg. A heating rate of 10 K/min was used in each run. The dry nitrogen gas (25 ml/min) was used as the furnace atmosphere.

Determination and Refinement of Crystal Structures

The Less-soluble Salt, $(+)_{589}$-trans(O)-[Co(gly)$_2$en]H-d-tart·3H_2O (1). A three-dimensional Patterson function revealed the position of the cobalt atom. The remaining nonhydrogen atoms were located by an application of the Fourier method. Several cycles of block-diagonal least-squares refinement using isotropic thermal parameters reduced the R value (defined as $\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 0.118. Further refinement using both positional and anisotropic thermal parameters for the nonhydrogen atoms reduced the R value to 0.061. A difference map at this stage revealed the positions of all hydrogen atoms. The final refinement including the contribution of these hydrogen atoms with the fixed positions and isotropic temperature

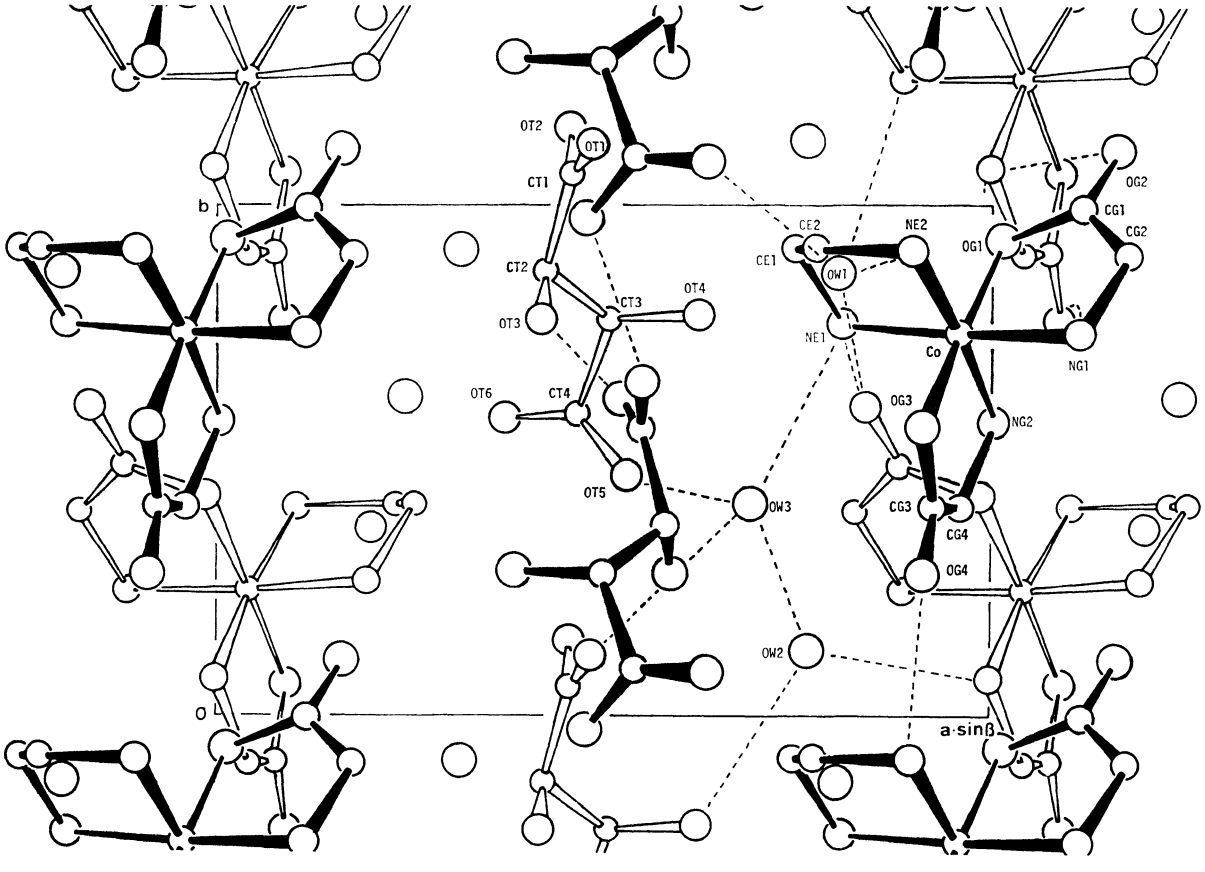

Fig. 1. Projection of the crystal structure along the c-axis of the less-soluble salt, $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·$3H_2O$. Possible hydrogen bonds are indicated by broken lines.

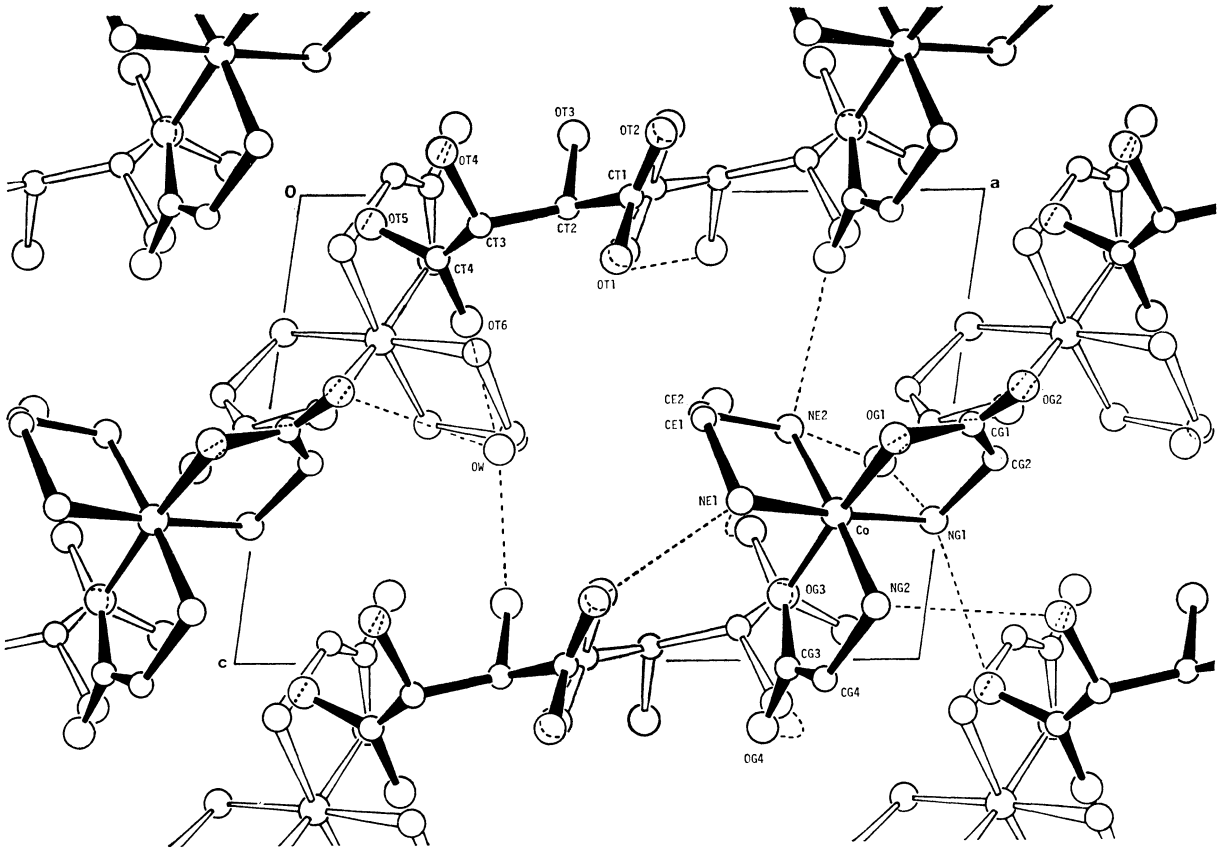

Fig. 2. Projection of the crystal structure along the b-axis of the more-soluble salt, $(-)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·H$_2$O. Possible hydrogen bonds are indicated by broken lines.

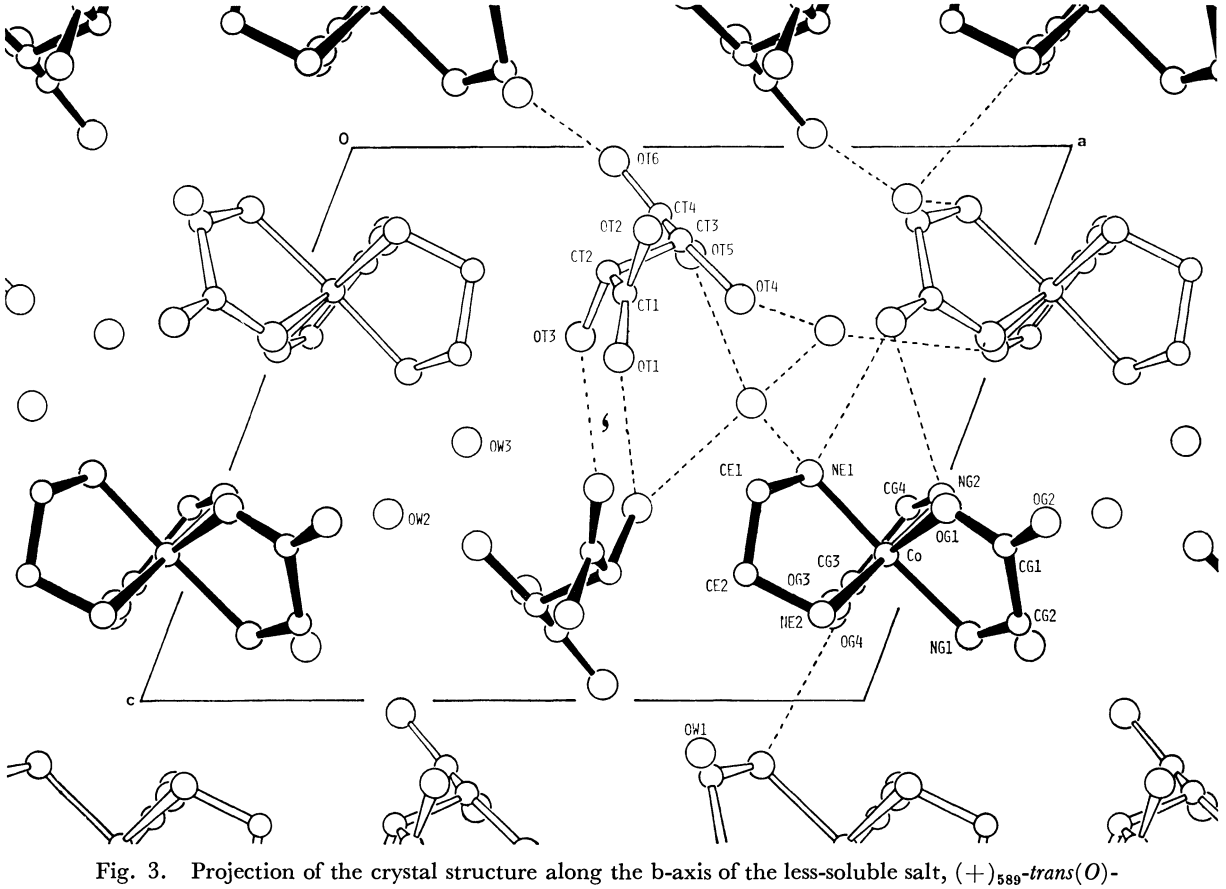

Fig. 3. Projection of the crystal structure along the b-axis of the less-soluble salt, $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·3H$_2$O. Possible hydrogen bonds are indicated by broken lines.

factors (B=4.0 Å^2) converged to R=0.043 (the refinement of the inverted structure gave R=0.045). A final difference map showed no peaks higher than 0.5 electron/Å^3. The quantity minimized was $w(|F_o|-k|F_c|)^2$. Cruickshank's weighting scheme[4] was used, where $w=1/(a+|F_o|+b|F_o|^2)$, with a=6.50 and b=0.019. The atomic scattering factors from the International Tables for X-Ray Crystallography[5] were used. The effect of the anomalous dispersion of the Co atom was included in the calculation: the values of $\Delta f'$=0.299 and $\Delta f''$=0.973 for Mo $K\alpha$ radiation were also taken from the International Tables for X-Ray Crystallography.[6]

The More-soluble Salt, (−)$_{589}$-trans(O)-[Co(gly)$_2$en]-H-d-tart·H$_2$O (2). The determination and the refinement of the structure were made in a way similar to those used for **1**. The final refinement converged to R=0.064 (the inverted structure gave R=0.067). A final difference map revealed no peaks higher than 0.4 electron/Å^3. A weighting scheme similar to that used in the case of **1** was used, with a=15.00 and b=0.016.

All the computations were carried out by a HITAC-8700 computer at the Hiroshima University Computer Center. The computer programs used were FOUR-2/M (Fourier synthesis)[7] and HBLS-IV (Least-square calculation), with a slight modification.[8] The final atomic parameters and temperature factors (with their estimated standard deviations) for both salts are listed in Tables 2—5. For both salts, complete lists of the $10|F_o|$ and $10|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 7937).

Results and Discussion

Geometry and Absolute Configuration of Cations. The bond distances and angles within the complex cation of the less- and more-soluble salts are listed in Tables 6 and 7. All the distances and angles are in good agreement with the reported values.[1,2,9-12]

The absolute configuration of the (+)$_{589}$-*trans*(*O*)-[Co(gly)$_2$en]$^+$ cation was identified as *Λ*-*δ*[13] on the basis of that of the hydrogen-*d*-tartrate used as an internal reference.[14,15] Similarly, that of the (−)$_{589}$-*trans*(*O*)-[Co(gly)$_2$en]$^+$ cation was identified as *Δ*-*λ*. These assignments are in accordance with those proposed

v $(1+x, y, 1+z)$,	vi $(1+x, y, z)$
vii $(1-x, -1/2+y, -z)$,	viii $(x, y, -1+z)$

a) D, hydrogen donor; A, hydrogen acceptor. b) Possible hydrogen bonds.

with the previously reported values.[1,2,16] The five nonhydrogen atoms of each α-hydroxycarboxylate moiety lie approximately on a plane. The angle between the planes of the two α-hydroxycarboxylate moieties in the less-soluble salt (**1**) is nearly equal to the corresponding angle of the H-*d*-tart anion in **3** (55.4° *vs.* 55.8°[1]). On the other hand, the corresponding value in the more-soluble salt (**2**) is 60.9° (61.3° for **4**[2]).

Crystal Packing. *(a) The Less-soluble Salt (1)*: The crystal structure consists of discrete $(+)_{589}$-*trans*(*O*)-$[Co(gly)_2en]^+$ cations, H-*d*-tart anions, and water molecules. Figures 1 and 3 show the projections of the crystal structure along the c- and b-axes respectively. The intermolecular distances and angles are summarized in Table 8.

In the crystal there are two distinct layers, as is shown in Figs. 1 and 3. The first layer is formed by H-*d*-tart anions. The H-*d*-tart anions are arranged to form a double-chain structure along the twofold screw axis at ($x=1/2$, $z=1/2$). Here, each component chain itself has a "head-to-tail" arrangement formed by a unit translation of the H-*d*-tart anion along the b-axis. The O(T2)···O(T5)^{iii} distance, 2.608 Å, is slightly longer than those in **3** and **4** (2.44 and 2.47 Å respectively).[1,2] The two-component chains, moreover, are linked to each other through the hydrogen bonds (O(T1)···O(T3)^x 2.906 Å) and are related by the twofold screw axis. These double-chain structures, then, are related to each other by the twofold screw axis at ($x=1/2$, $z=0$) to form the layer parallel to the bc plane.

The second layer is built up of the complex cations. The layer of the complex cation is constructed by the same symmetry operation as in the case of the H-*d*-tart anion, as is shown in Figs. 1 and 3.

The first and second layers are not only directly adjoined with each other by short contacts: N(E1)···O(T4) 3.235, O(G2)^{ii}···O(T4) 2.895, and N(G1)···O(T6)^{iv} 3.274 Å, but are also indirectly joined together by hydrogen bonds *via* the waters of crystallization: O(T6)···O(W1)···O(G2), O(T6)···O(W1)···N(E2), O(T6)···O(W1)···N(G1), O(T4)···O(W2)···N(G2), O(T3)···O(W3)···N(E1), and O(T5)···O(W3)···N(E1).

(b) The More-soluble Salt (2): Figures 2 and 4 show the projections of the crystal structure of **2** along the b- and

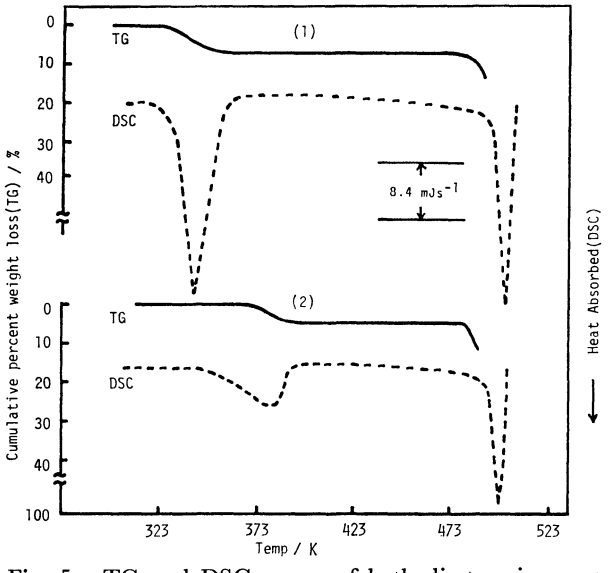

Fig. 5. TG and DSC curves of both diastereoisomers: (1) the less-soluble salt, $(+)_{589}$-*trans*(*O*)-$[Co(gly)_2en]$-H-*d*-tart·$3H_2O$; (2) the more-soluble salt, $(-)_{589}$-*trans*-(*O*)-$[Co(gly)_2en]$H-*d*-tart·H_2O.

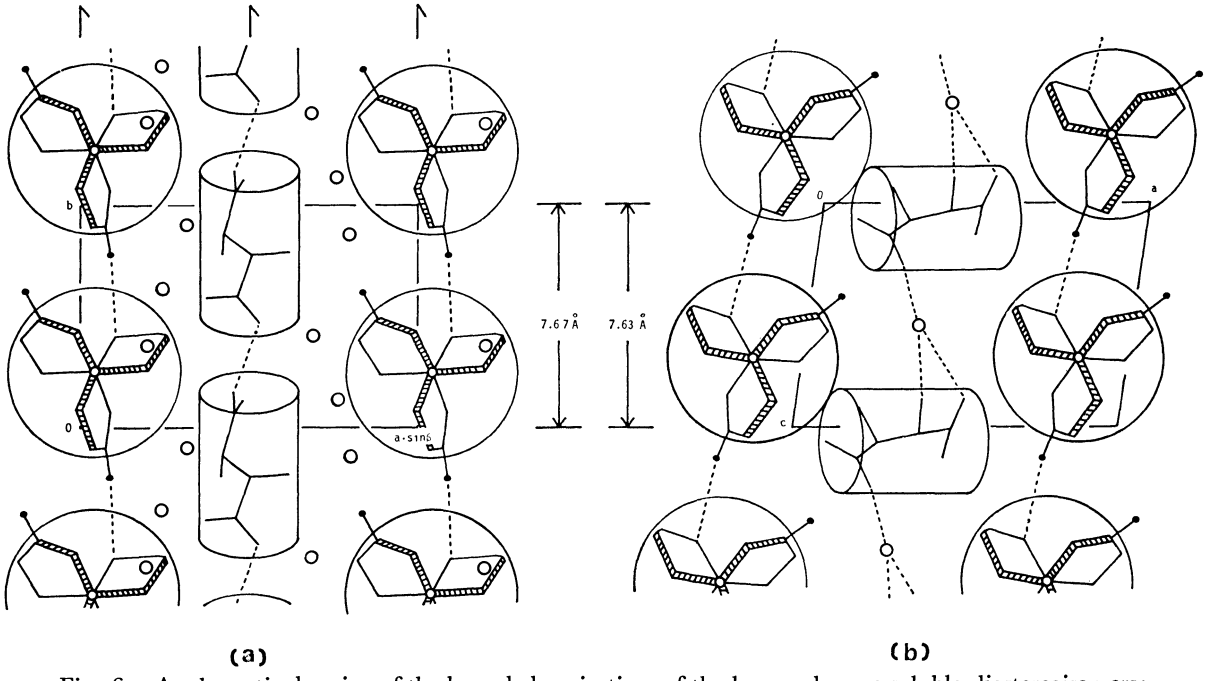

Fig. 6. A schematic drawing of the bounded projections of the less- and more-soluble diastereoisomers: (a) $(+)_{589}$-*trans*(*O*)-$[Co(gly)_2en]$H-*d*-tart·$3H_2O$(c-axis projection), (b) $(-)_{589}$-*trans*(*O*)-$[Co(gly)_2en]$-H-*d*-tart·H_2O(b-axis projection).
Broken lines denote hydrogen bonds and small circles indicate water molecules.

c-axes respectively. The structure consists of the discrete $(-)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]$^+$ cations, the H-*d*-tart anions, and the water molecules. The intermolecular distances and angles are listed in Table 9. In the crystal, the complex cations are stacked to form a chain by hydrogen bonds along the c-axis. The hydrogen bond distance, N(E2)···O(G4)^{viii}, is 2.867 Å. Along the c-axis, the H-*d*-tart anions do not form the "head-to-tail" chain structure, though they are connected to each other through the water of crystallization.

Thermal Behavior of the Water of Crystallization. The results of the TG and DSC measurements of both diastereoisomers are shown in Fig. 5. The crystals of the less-soluble salt (**1**) begin to release the water of crystallization at 327 K, and the dehydration ceases at 347 K. The weight loss accompanying this dehydration is found to be 9.7%. This value is very close to the value expected for the dehydration of 2.5H$_2$O (9.6%). The DSC peak is observed from 329 K to 354 K. The ΔH value for the dehydration is calculated to be 64.4 kJ mol^{-1}.

On the other hand, the more-soluble salt (**2**) loses 0.7 mol of the water of crystallization in the temperature range between 368 K and 382 K (TG curve). The DSC peak corresponding to this step is observed from 347 K to 389 K. The ΔH value for the dehydration step is found to be 73.0 kJ mol^{-1}, slightly larger than that of the less-soluble salt. The gradual decrease in both DSC curves in the range of about 420—470 K is probably due to the loss of the remaining water of crystallization (0.5H$_2$O for **1** and 0.3H$_2$O for **2**). The DSC peak was also found at about 500 K in both samples. While the TG measurement was being carried out, the samples got black and swelled above 490 K. The measurements was impossible above this temperature. It seems that the decomposition of both samples occurs at 490 K.

Thus, the less-soluble salt (**1**) (containing more water, trihydrate) has been proved to release water more easily than the more-soluble salt (**2**) (containing less water, monohydrate).

Comparison of the Packing Modes of the Less- and More-soluble Salts. The two crystal structures are shown schematically in Fig. 6, where the H-*d*-tart anions are depicted in a cylindrical form and the complex cations are represented as a large circle. There are some resemblances and differences between the packing modes of the two structures. The resemblances are: (1) The complex cations are stacked along the longitudinal axis in the figure, making a chain structure by the N–H···O hydrogen bonds in both crystals. (2) Unit translation along both longitudinal axes are quite similar; the distances are 7.67 Å for **1** and 7.63 ($c\times\sin\beta$) for **2**. The differences are: (1) In Fig. 6(a), the H-*d*-tart anions are linked with hydrogen bonds (–COOH···OOC–) just as the dry cells are arranged in a series circuit. In contrast, the H-*d*-tart anions in Fig. 6(b) are connected to each other *via* water molecules, COO···water $\cdots\begin{Bmatrix}\mathrm{OH}\\ \mathrm{COO}\end{Bmatrix}$, just as the dry cells are piled side by side in a parallel form. (2) A layer of water molecules exists in Fig. 6(a), but not in Fig. 6(b).

The crystal parameters of the two diastereoisomeric pairs are listed in Table 1. Since **2** and **3** have the same chemical formula, $C_{10}H_{23}N_4O_{11}Co$, the V/Z value of **2** should be nearly equal to that of **3**. However, the volume of **3** is 18.2 Å^3 smaller than that of **2**. The volume difference between **1** and **3** is 43.3 Å^3. This difference is nearly equal to twice the reported molecular volume of the water of crystallization (2×20.6 Å^3),[17] and can be attributed to the two excess water molecules in **1**. Hence, **1** is as dense as **3**. Consequently, in spite of the presence of more water of crystallization, the less-soluble salt (**1**) is more tightly packed than the more-soluble salt (**2**).

The situation is quite similar to the case in the diastereoisomeric pair of **3** and **4**. The volume difference between **3** and **4** is 27.2 Å^3. Since **4** has one more water molecule than **3**, this volume difference corresponds to the volume of one water molecule in **4**. The observed volume difference (27.2 Å^3) is 6.6 Å^3 larger than the expected volume for one water molecule.[17] Therefore, it may be inferred that **3** is more tightly packed than **4**.

The crystal structures of the less-soluble salts, **1** and **3**, contain the spiral chain of H-*d*-tart. In contrast, the more-soluble salts, **2** and **4**, do not have such spiral chains. Therefore, it can be considered that the tight packing in the less-soluble salt is caused by the existence of this spiral chain of H-*d*-tart. In other words, the existence of this spiral chain of H-*d*-tart plays a decisive role in the discrimination between Δ and Λ enantiomers. This conclusion is supported by the fact that several less-soluble salts of organic bases, (—)-adrenalinium H-*d*-tart,[16] (+)-[(—)-1-methyl-3-benzoylpiperidinium H-*d*-tart]H$_2$O,[18] and (—)-[(—)-1-methyl-3-ethyl-3-benzoylpiperidinium H-*d*-tart],[19] contain similar spiral chains of the H-*d*-tart anion in the crystal structures.

Additionally, a pitch of the spiral chain is considered important in the discrimination due to the H-*d*-tart anion. The observed length of the chain pitch (7.1—7.8 Å)* is nearly equal to the diameter of the complex cations, [Co(ox)en$_2$]$^+$ and [Co(gly)$_2$en]$^+$. These complex cations can themselves form a chain by hydrogen bonds (N–H···O) within the range of this pitch (7.1—7.8 Å). Other complex cations so far resolved by the H-*d*-tart anion are as follows: β-*cis*(*O*)-[Co(gly)$_2$en]$^+$,[3] *s*-*cis*-[Co(edda)(NH$_3$)$_2$]$^+$,[20] *trans*-[Co(edda)en]$^+$,[21] and *s*-*cis*-[Co(dmedda)(NH$_3$)$_2$]$^+$.[20],** The sizes and the skeletons of these complexes have a close resemblance to those of the [Co(ox)en$_2$]$^+$ and *trans*(*O*)-[Co(gly)$_2$en]$^+$ cations, as is shown in Fig. 7. The figure shows that the monovalent complex cation satisfying the following conditions has a great chance of optical resolution by way of the diastereoisomeric salt formation with the H-*d*-tart anion: (1) the complex cation has carboxyl and amino groups at the *trans* or *cis* positions of octahedral coordination, so that cations

* The chain pitches of the H-*d*-tart anion have values within 7.1—7.8 Å in Refs. 1, 2, 16, 18, and 19.

** The abbreviations used for the ligands are as follows: gly, glycinate anion; en, ethylenediamine; edda, ethylenediamine-*N*,*N*′-diacetate anion; dmedda, dimethylethylenediamine-*N*,*N*′-diacetate anion.

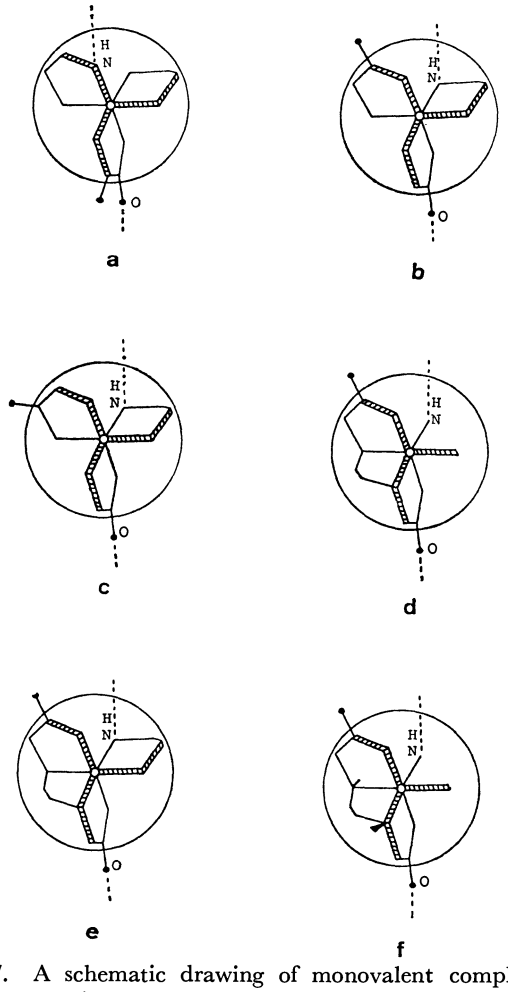

Fig. 7. A schematic drawing of monovalent complex cations having a structural resemblance to $(+)_{589}$-[Co(ox)en_2]$^+$ and $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]$^+$:
(a) $(+)_{589}$-[Co(ox)en_2]$^+$, (b) $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]$^+$, (c) *β-cis*(*O*)-[Co(gly)$_2$en]$^+$, (d) *s-cis*-[Co(edda)$(NH_3)_2$]$^+$, (e) *trans*-[Co(edda)en]$^+$, and (f) *s-cis*-[Co(dmedda)$(NH_3)_2$]$^+$.

can be linked with each other by N–H···O type hydrogen bonds, and (2) the complex cation is 7.1—7.8 Å in diameter, so that the complex cations can be arranged in a spiral chain with the same pitch as that of the H-*d*-tart spiral chain.

The author wishes to express his thanks to Professor Hayami Yoneda and Dr. Yoshihiko Kushi of Hiroshima University for their kind guidance and encouragement throughout this work, and also to Dr. Ushio Sakaguchi and to Dr. Katsuhiko Miyoshi for their stimulating discussion and helpful suggestions. The author is also grateful to Dr. Kozo Akabori, Hiroshima University, for the TG and DSC measurements and for his valuable suggestions; thanks are also due to the Hiroshima University Computer Center for a generous allocation of computer time.

The Synthesis of $Mg_3(PO_4)_2 \cdot 8H_2O$ and Its New Polymorphism

Takafumi KANAZAWA,* Takao UMEGAKI, and Masao SHIMIZU

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received February 2, 1979)

Bobierrite, $Mg_3(PO_4)_2 \cdot 8H_2O$, could be synthesized from mixed solutions of Na_2HPO_4 and $MgSO_4$ at an initial pH of 6.4—7.0 with the addition of $Ca(NO_3)_2$, $CuSO_4$, $NiSO_4$, gelatin, or agar, by heating at 80—90 °C for 2—48 h. X-Ray studies indicated the coexistence of two kinds of lattice in each synthetic $Mg_3(PO_4)_2 \cdot 8H_2O$ crystal. One phase (Phase 1) is monoclinic, space group $P2_1/m$ or $P2_1$, with $a=10.08(2)$, $b=27.86(3)$, $c=4.656(7)$ Å, and $\beta=105.0(2)°$. The other phase (Phase 2) is monoclinic, space group C2/m, C2, or Cm, with $a=10.07(2)$, $b=13.38(2)$, $c=4.656(7)$ Å, and $\beta=105.0(2)°$. If a centrosymmetric space group C2/m is assumed for the latter, Phase 2 may be considered to be a new polymorph of $Mg_3(PO_4)_2 \cdot 8H_2O$, one belonging to the vivianite series. Newberyite, $MgHPO_4 \cdot 3H_2O$, was also formed in the above synthetic procedure. This phosphate was precipitated under slightly more acidic conditions than those where $Mg_3(PO_4)_2 \cdot 8H_2O$ was obtained.

Bobierrite, $Mg_3(PO_4)_2 \cdot 8H_2O$ (TMP8), has been found chiefly in guano deposits as minute crystals, associated with newberyite, $MgHPO_4 \cdot 3H_2O$ (DMP3), and several magnesium ammonium orthophosphates. TMP8 was first described by Bobierre in 1868;[1] X-ray and optical studies of this mineral were made by Barth in 1937.[2] According to Barth's determinations, TMP8 belongs to a different space group from that of the vivianite series ($A_3(XO_4)_2 \cdot 8H_2O$; A=Fe, Co, Ni, Zn, Mg: X=P, As), and the b-axis of the unit cell is doubled compared with the $8H_2O$ family. However, the crystal structure of TMP8 has not yet been determined at present. Therefore, we have investigated the crystal growth of TMP8 and its X-ray diffraction data in order to clarify the crystallographical relation between TMP8 and the vivianite group.

The preparations of TMP8 have been reported by de Schulten (1903),[3] Bassett and Bedwell (1933),[4] Frazier *et al.* (1963),[5] and the present authors (1974, 1976).[6-8] However, we have seen no reference to the crystal growth of this mineral. The present paper will deal with a new method of synthesizing TMP8 from mixed solutions of $MgSO_4$ and Na_2HPO_4 in an initial pH of 6.4—7.0 at 80—90 °C for 2—48 h by using inorganic and organic additives, and then additionally preparing the crystals in a suitable size for the X-ray Weissenberg method. The X-ray oscillation and Weissenberg photographs have indicated the coexistence of two monoclinic lattices (Phase 1 and Phase 2) in each synthesized TMP8 crystal, as will be described below.

Experimental

Preparation. *Syntheses without Additives*: A mixed solution of 4.1—8.3 g of $MgSO_4 \cdot 7H_2O$ and 4.0—8.0 g of $Na_2HPO_4 \cdot 12H_2O$ in 1500 ml of water was prepared. In each run, $MgSO_4 \cdot 7H_2O$ and $Na_2HPO_4 \cdot 12H_2O$ were mixed in the ratios given in Table 1. The pH of the mixture was then adjusted to 6.0—7.0 by adding HCl (about 2%) or acetic acid (HAc) (2%). The mixture thus prepared was heated in a water bath with a reflux at 90 °C for 2 h. The precipitates thus formed were filtered, washed with water, and dried in air and then in a silica gel desiccator for several days. The run products of the synthetic experiments are summarized in Table 1.

Syntheses with Inorganic Additives: A mixed solution of 4.1 g of $MgSO_4 \cdot 7H_2O$ and 4.0 g of $Na_2HPO_4 \cdot 12H_2O$ in 1500 ml of water was prepared. The solution was adjusted with HCl or HAc to each pH value given in Table 2. To this mixture, each inorganic additive ($Ca(NO_3)_2 \cdot 4H_2O$, $CuSO_4 \cdot 5H_2O$, $NiSO_4 \cdot 6H_2O$, $CoSO_4 \cdot 7H_2O$, $MnSO_4 \cdot 4H_2O$, and $ZnSO_4 \cdot 7H_2O$) in a molar ratio to $MgSO_4$ of about 1: 100, was then added. The mixture thus prepared was heated in the same manner as in the syntheses without additives.

Syntheses with Gelatin: The same procedure as in the syntheses with inorganic additives was carried out except for the replacement of inorganic additives with 10—50 g of

a) HAc=acetic acid.

gelatin, the narrowing of an initial pH region from 6.4—7.0 to 6.6—6.8, and the extension of a heating time from 2 h to 4—24 h.

Syntheses with Agar: First, a solution of 4.0 g of $Na_2HPO_4 \cdot 12H_2O$ in 1200 ml of water was prepared, and then 5—10 g of agar were added to the solution. The solution was then heated up to about 80 °C until the agar was dissolved. To this, a solution of 4.1 g of $MgSO_4 \cdot 7H_2O$ in 300 ml of water, adjusted to an acidic condition by adding an appropriate amount of HCl or HAc, which had been determined by experiments, was then stirred in. The mixture thus prepared was set aside to gel for several hours. The agar gel solution was heated by the same procedure as in the above syntheses at 80—90 °C for 4—48 h. The crystals thus obtained were washed by boiling them mildly in water, and dried in air and then in a silica gel desiccator for several days.

Table 3. Chemical composition of synthetic TMP8[a]

	MgO (%)	P_2O_5 (%)	H_2O (%)	Mg/P[b]

			36.4[d]	
Calcd	29.7	34.9	35.4	1.5

a) Prepared by the addition of agar. b) Mole ratio. calculated by the use of this formula: $H_2O = 100 - (MgO + P_2O_5)$. d) Calculated from weight loss on heating.

Measurements. The run products were identified by X-ray powder diffractometry (Cu $K\alpha$, Ni filter), refractive index measurement (the immersion method), optical microscopy, and chemical analysis. Chemical analysis was performed on TMP8 grown in an agar-containing solution; the magnesium was determined by the chelatometric titration method; the phosphorus, by molybdovanadate colorimetry, and the water contents, as loss on ignition to about 800 °C. The chemical compositions of the synthetic TMP8 are shown in Table 3. The lattice constants of the synthetic TMP8 were obtained by the least-squares calculation on the basis of the results of the Weissenberg method (Cu $K\alpha$, Ni filter, and Si standard). Weissenberg photographs were taken with regard to zero-, first-, and second-layer lines about the c-axis, and the zero-layer line about the a- and b-axes.

Results and Discussion

General Remarks. As is shown in Table 1, no pure phase of TMP8 was precipitated on syntheses of this compound from a mixed solution of Na_2HPO_4 and $MgSO_4$ without additives. In this case, only a small amount of TMP8 appeared in the products. Under the syntheses without additives, it seemed rather diffcult to form. Therefore, we investigated tentatively the effects of inorganic and organic additives on the TMP8 formation, and then the influence of those additives on the size and morphology of the crystals. Inorganic additives ($Ca(NO_3)_2 \cdot 4H_2O$, $CuSO_4 \cdot 5H_2O$, or $NiSO_4 \cdot 6H_2O$) and organic additives (gelatin or agar) were found to be effective on the formation of TMP8. The habits of the synthetic TMP8 crystals obtained both with and without additives were plates, with (010) being the dominant forms and elongated along the c-axis. The size of the TMP8 crystals obtained inclined to increase as the initial pH of the mixture was lowered and as the heating temperature and time increased. The pH of the mixture was observed to be lowered after the precipitation of crystals.

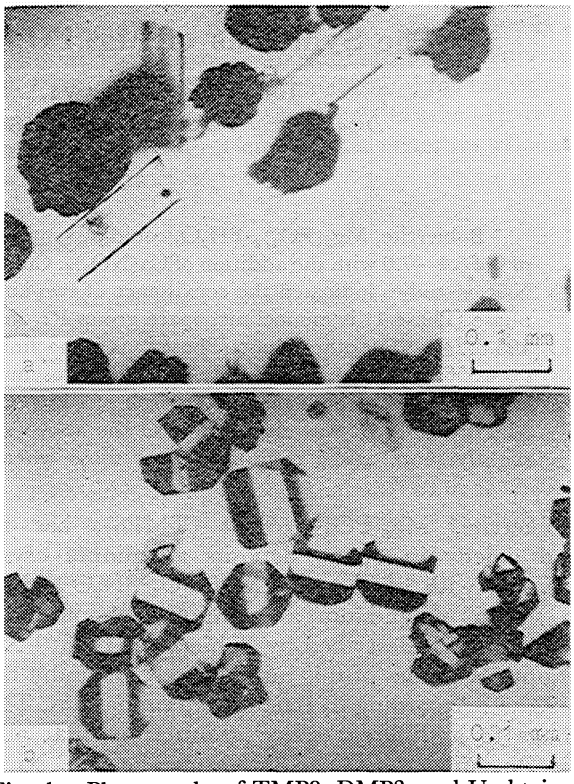

Fig. 1. Photographs of TMP8, DMP3, and U obtained without additives.
a) TMP8 and U obtained at initial pH 6.2 using HCl. TMP8=parallelepiped platy crystals. U=spherically aggregated materials. b) DMP3 obtained at initial pH 6.0.

Crystals from the Solution without Additives. In the syntheses without additives, TMP8 was found in only small amounts in the products at initial pH values of the mixture of 6.2—6.4, as is shown in Table 1. Figure 1-a shows TMP8 crystals coexisting with unidentified crystalline materials (U). Under slightly more acidic conditions, namely, at the initial pH 6.0, sometimes DMP3 (Fig. 1-b) containing U was obtained, while U was precipitated at the initial pH values of the mixture of 6.6—7.0.

Crystals from the Solutions with Inorganic Additives. The run data of the synthetic experiments with inorganic additives are given in Table 2. Below the initial pH value of 6.2, no precipitate was formed. Above each initial pH shown in Table 2, U tended to be precipitated predominantly.

The maximum size of the crystals obtained by the addition of $Ca(NO_3)_2 \cdot 4H_2O$ and $CuSO_4 \cdot 5H_2O$ were as large as 2.8 by 1.4 and 2.2 by 1.2 mm, respectively, while that of the crystals obtained by the addition of $NiSO_4 \cdot 6H_2O$ was relatively small (about 0.12 by 0.08 mm). The dimension in the direction of b-axis was usually below about 0.02 mm. The synthetic TMP8 crystals are shown in Figs. 2-a, b, and c. On the other hand, U was precipitated from the mixture to which $MnSO_4 \cdot 4H_2O$ or $ZnSO_4 \cdot 7H_2O$ had been added, under the synthetic conditions studied here, and both TMP8 and U were precipitated from a mixture to which

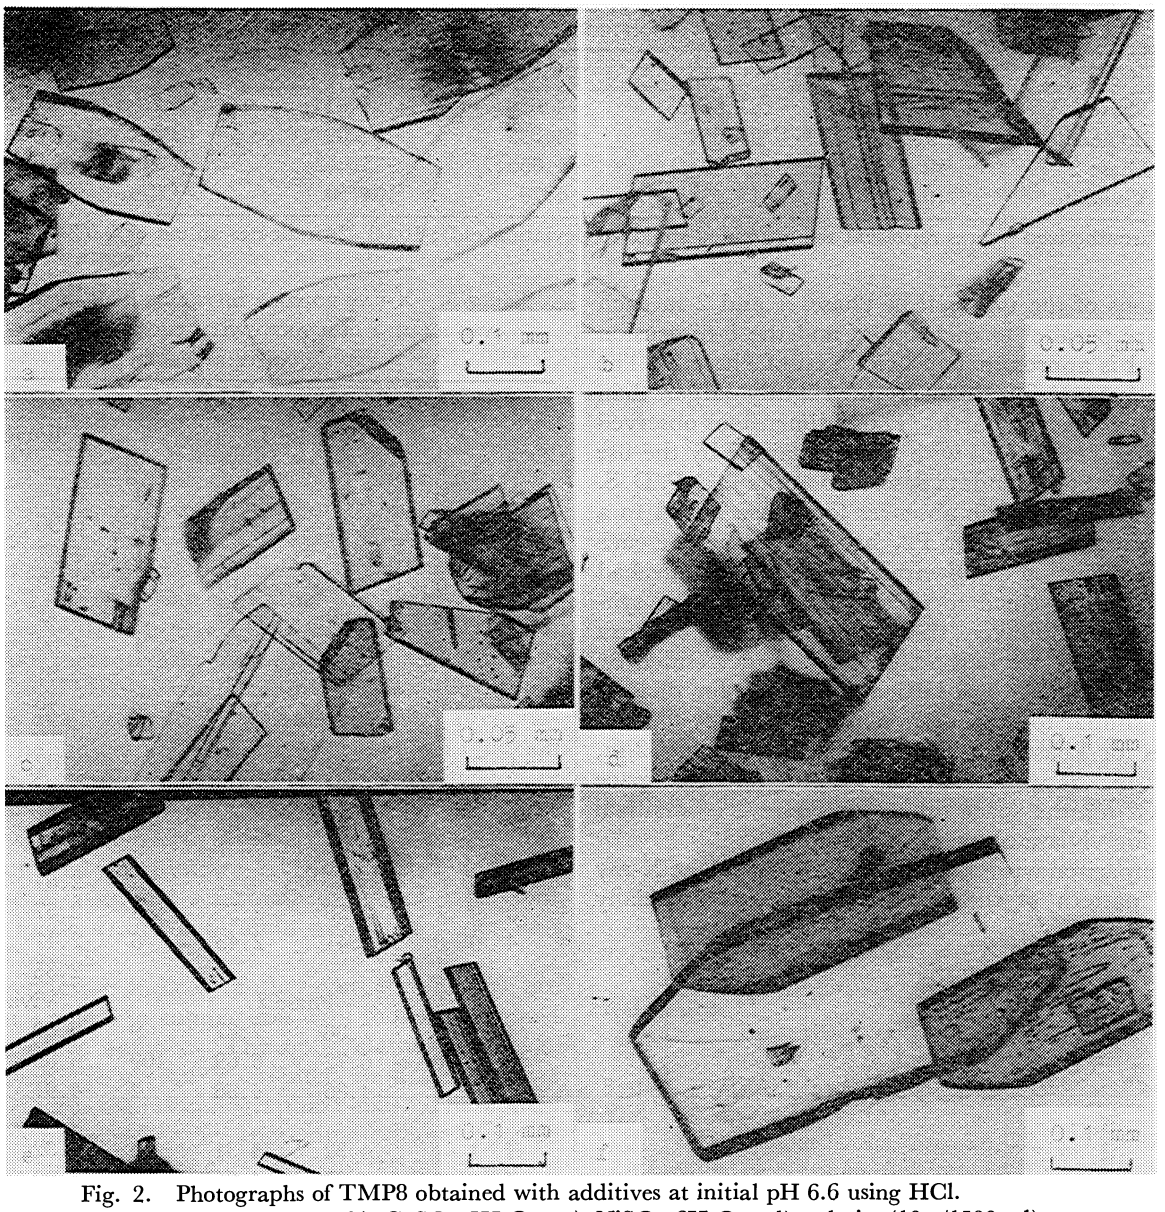

Fig. 2. Photographs of TMP8 obtained with additives at initial pH 6.6 using HCl.
a) $Ca(NO_3)_2 \cdot 4H_2O$, b) $CuSO_4 \cdot 5H_2O$, c) $NiSO_4 \cdot 6H_2O$, d) gelatin (10 g/1500 ml), e) gelatin (45 g/1500 ml), f) agar.

$CoSO_4 \cdot 7H_2O$ was added at an initial pH of about 6.4—6.6. These results might be interpreted as follows: since Mg ions in the TMP8 structure are inferred to be octahedrally coordinated in all their sites,[9] the presence of Cu^{2+} and Ni^{2+}, which tend to prefer octahedral coordination,[10] will be effective on the stabilization of those cation sites of TMP8 and, as a result, on the promotion of its nucleation and crystal growth.

Crystals from the Solutions with Organic Additives. The TMP8 crystals grown in the gelatin solution heated for 6 h were in the form of colorless and transparent fragments. The crystals were plates about 0.1 mm long as a maximum. When the heating time ranged to 24 h, the crystals with a maximum length of about 0.3—0.4 mm were obtained (Fig. 2-d). In this case, the smoothness of the surfaces of the crystals was generally inferior to that of the crystals obtained from the mixtures heated for 6 h described above. As the concentrations of gelatin were increased (40—50 g/1500 ml), the crystals obtained were more elongated along the c-axis and altered from a plate-like shape into a needle-like appearence (Fig. 2-e).

The crystals grown in the agar solution heated for 6 h were about 0.08 mm long as a maximum. Heat treatment for 24—48 h yielded crystals as large as $0.5 \times 0.25 \times 0.04$ mm in maximum size (Fig. 2-f). The surface smoothness of TMP8 crystals grown in the agar solution were, in general, superior to that of crystals in the gelatin solution microscopically. This is probably due to the difference in the stability of gel between the gelatin and agar solutions at 80—90 °C.

A New Crystal Phase of TMP8. Each crystal examined here showed the coexistence of two monoclinic lattices (Phase 1 and Phase 2), judging from the results of the oscillation and Weissenberg photographs. Table 4 shows the lattice constants and possible space groups of Phase 1 and Phase 2 in comparison with those of the natural TMP8 and vivianite, respectively. The axial

orientations of the unit cell of Phases 1 and 2 in each crystal are parallel to each other, and the b-dimension of Phase 1 is approximately twice that of Phase 2. The lattice constants for Phase 1 are slightly larger than those determined by Barth. Those dimensions observed by us agree rather well with those obtained by the use of the indexed powder data described in the J. C. P. D. S. File.[11] The systematic absences for Phase 1 lead to a space group of $P2_1/m$ or $P2_1$ because of the presence of a weak reflection of $h0l$ with both h and l odd, instead of the $P2_1/c$[1] assigned to natural TMP8. In this synthetic crystal, however, there are a number of extra extinctions that are beyond the criteria demanded by those space groups. The lattice dimensions for Phase 2 are very similar to those of vivianite, and the systematic absences for Phase 2 indicate a space group of C2/m, C2, or Cm. If we assume the centrosymmetric space group C2/m, the space group for Phase 2 is identical to that for vivianite series.

In comparison with the J. C.P. D. S. File,[11] the X-ray powder pattern of the synthetic TMP8 is especially

parameters shown in Table 4 and comparing the data with those of the Weissenberg photographs. The calculated and prominently observed interplaner spacings and indices of Phases 1 and 2 are shown in Table 5, compared with those of TMP8 and vivianite, respectively, in the J. C. P. D. S. File.[12] The reflexions of *h0l* in Phases 1 and 2 overlap each other completely. Therefore, the apparent intensities of the reflexions of each phase were measured on the basis of the X-ray diffraction data of TMP8, in which the intensities of the diffraction lines of Phase 1 or Phase 2 are relatively predominant. The indices and the intensities of each reflexion of Phase 2 correspond with those of each reflexion of vivianite. Phase 2 is considered to be a polymorph of TMP8 and is supposed to be isomorphous with vivianite. The calculated densities are 2.14 for Phase 1 and 2.23 for Phase 2, assuming a formula weight of 4 per unit cell for Phase 1 and a formula weight of 2 per unit cell for Phase 2.

The refractive indices of the synthetic TMP8 are shown in Table 6 in comparison with those determined by some other authors. The optic elasticity axis, Z, in the synthetic crystal is oriented in a direction of about 30° with the crystallographic c-axis. The optical properties measured by us approximate those reported by Barth, and Gruner *et al.*[1] The discrepancies among the refractive indices observed by us may be attributed to the coexistence of Phases 1 and 2 in each synthetic TMP8. The presence of two lattices in the crystal is probably due to the superposition of the thermodynamically stable regions of each phase and to the fact that there is hardly any difference in the potential energies between those phases.

Conclusion

From the studies of the synthetic conditions of $Mg_3(PO_4)_2 \cdot 8H_2O$ (TMP8) and the results of the X-ray single crystal method of the octahydrate, the following conclusions were obtained:

1) TMP8 was synthesized from the mixed solutions of Na_2HPO_4 and $MgSO_4$ at 80—90 °C for 2—24 h, in an initial pH of 6.4—7.0, with the addition of $Ca(NO_3)_2 \cdot 4H_2O$, $CuSO_4 \cdot 5H_2O$, $NiSO_4 \cdot 6H_2O$, gelatin, or agar.

2) Two phases (Phase 1 and Phase 2) of TMP8 were found by means of the X-ray Weissenberg technique to coexist in each synthesized crystal particle.

3) The above Phase 2 is considered to be a new polymorph of TMP8.

4) Newberyite, $MgHPO_4 \cdot 3H_2O$, was also formed in the synthetic procedure of TMP8. This phosphate was precipitated under slightly more acidic conditions than those where TMP8 was obtained.

The authors are indebted to Dr. Hideki Monma of the National Institute for Researches in Inorganic Materials, and to Mr. Hiroshi Kawazoe of Tokyo Metropolitan University, for their helpful suggestions with regard to synthetic procedures. Thanks are also due to Dr. Fujio Okamura of the National Institute for Researches in Inorganic Materials and to Dr. Kazuyori Urabe of the Tokyo Institute of Technology for their valuable advice with regard to X-ray studies.

Spectrophotometric Determination of Cadmium(II) with Dithizone and 1,10-Phenanthroline

Hideo AKAIWA,* Hiroshi KAWAMOTO, and Eiji YOSHIMATSU

Department of Applied Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received June 8, 1979)

Cadmium(II) has been quantitatively separated from zinc(II) by an ion-pair extraction system. An ion-pair consisting of cadmium(II) and 1,10-phenanthroline (phen) was found to be preferentially extracted into chloroform from an aqueous chloride solution containing zinc(II). The extracted species in chloroform reacted with dithizone (H_2Dz) to give the reddish mixed complex $Cd(HDz)_2(phen)$ having an absorption maximum at approximately 505 nm. The resulting calibration curve obeys Beer's law, the Sandell sensitivity being 0.0013 $\mu g\ cm^{-2}$. The effect of diverse ions has been examined, and a new highly selective method for the spectrophotometric determination of trace amounts of cadmium in metallic zinc established.

The spectrophotometric determination of cadmium(II) with dithiozone (H_2Dz) is well known as a highly sensitive method.[1] The separation of cadmium(II) from zinc(II) however remains a difficult problem. During the studies on the mutual separation of zinc(II) and cadmium(II) employing the synergistic extraction systems,[2-4] 1,10-phenanthroline (phen) was found to be the most suitable among several synergists. A new method of separation and determination of cadmium(II) was briefly reported.[5] In the preceding paper, it was stated that the species extracted with a mixture of dithizone and 1,10-phenanthroline at a pH of *ca.* 2 was a green complex. The reported procedure for the separation and determination of cadmium(II) is still feasible, however the previous observation concerning the extracted complex was found to be erroneous by additional detailed studies. Cadmium(II) is not extracted as a green complex but as a colorless ion-pair. This conclusion leads to the preferential and quantitative extraction of cadmium(II) using 1,10-phenanthroline alone, and in this case, zinc(II) was shown to remain in the aqueous phase. As a result, a highly selective method for the spectrophotometric determination of trace amounts of cadmium(II) with a mixture of dithizone and 1,10-phenanthroline has been established.

Experimental

Materials and Apparatus. ^{65}Zn and ^{115m}Cd were obtained from Nippon Isotope Kyokai. Dithizone and 1,10-phenanthroline were purchased from Wako Pure Chemicals and all organic solvents were of guaranteed grade.

The γ-ray activities of ^{65}Zn and ^{115m}Cd were measured with a γ-ray spectrometer consisting of a NaI(Tl) well crystal and a Hitachi RAH 403 type 400 channel pulse height analyser. The percent extraction (E) was obtained as a function of pH. The measurements of pH were conducted using a Hitachi-Horiba F-5 type pH meter. The absorbance of the organic phase was measured with a Hitachi 200-10 type spectrophotometer.

Extraction Procedure (A): The aqueous phase containing 0.01 mol dm^{-3} 1,10-phenanthroline, 0.1 mol dm^{-3} sodium chloride, 1.0×10^{-6} mol dm^{-3} metal ions, ^{65}Zn and ^{115m}Cd tracers was vigorously shaken for 10 min in a separatory funnel with an equal volume of the organic phase containing 0.002% dithizone. After the phases were allowed to separate, the γ-ray activity of each phase and the pH of the aqueous phase were measured.

Spectrophotometric Determination of Cadmium(II) (B): An aliquot of the sample solution containing less than 20 μg of cadmium(II) was taken in a separatory funnel, and 0.04 mol dm^{-3} 1,10-phenanthroline in water (5 cm^3) and 5 mol dm^{-3} sodium chloride (2 cm^3) added. The pH of the aqueous solution was adjusted to *ca.* 3 by the addition of hydrochloric acid or ammonia with Methyl Orange as the indicator. After the volume of the aqueous phase was adjusted to *ca.* 20 cm^3 with water, chloroform (10.0 cm^3) was added and the mixture shaken for 10 min. Each 5.00 cm^3 of the resulting organic phase and 0.002% dithizone in chloroform was transferred to another separatory funnel containing 5 mol dm^{-3} ammoniacal solution (20 cm^3), and the mixture shaken for 3 min. After the phases were allowed to separate, the absorbance of the organic phase was measured at 505 nm against the reagent blank.

Results and Discussion

Separation of Cadmium(II) from Zinc(II). Extraction curves for cadmium(II) and zinc(II) obtained according to procedure (A) are shown in Fig. 1, in which the selectivity for the separation of both elements

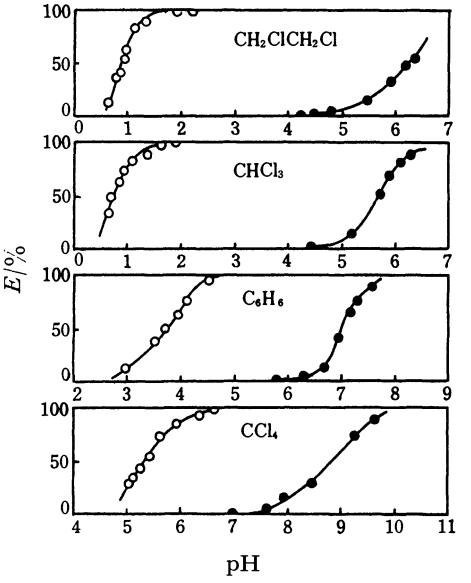

Fig. 1. Extraction curves, H_2Dz: 0.002%, phen: 0.1 mol dm^{-3}.
○: Cd(II), ●: Zn(II).

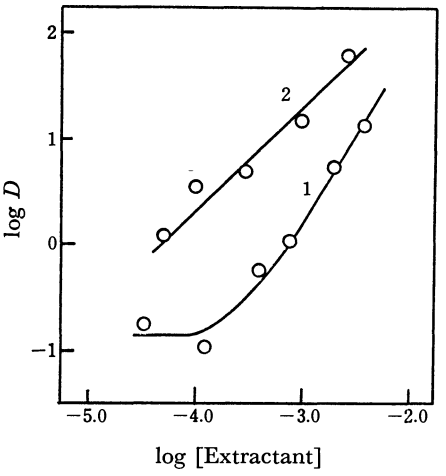

Fig. 2. Effects of dithizone and 1,10-phenanthroline concentrations on the extraction of cadmium(II).
1: log D *vs.* log[H_2O_2], phen: 1.0×10^{-3} mol dm^{-3}, pH: 2.1. 2: log D *vs.* log[phen], H_2Dz: 0.1%, pH: 2.1.

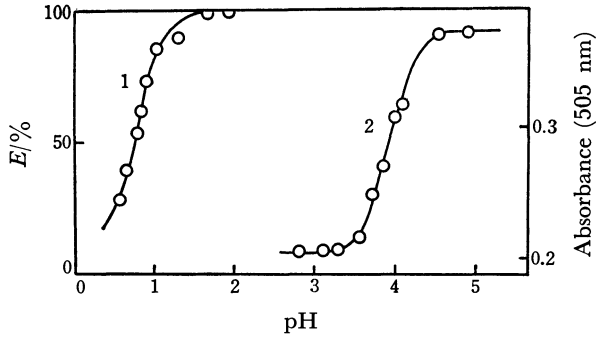

Fig. 3. Effect of pH on the extraction of cadmium(II).
1: E *vs.* pH, H_2Dz: 0.002%, phen: 0.1 mol dm^{-3}.
2: Absorbance *vs.* pH, H_2Dz: 0.001%, phen: 0.01 mol dm^{-3}.

is affected by the nature of the organic solvent. Chloroform and 1,2-dichloroethane both having relatively high polarities were the most suitable solvents for separation, based on the difference in the half extraction pH between cadmium(II) and zinc(II). By employing *e.g.* chloroform as a diluent, the quantitative separation of cadmium(II) from zinc(II) could be attained in the pH range of 2.0 to 4.0.

The Extracted Species of Cadmium(II). In order to examined the composition of cadmium(II) in chloroform, the logarithmic plots are given in Fig. 2, where D denotes the distribution ratio of cadmium(II). The slope analysis of the plots shows that $Cd(HDz)_2(phen)$ may be extracted at high concentration of dithizone. However, the extraction curve of ^{115m}Cd did not agree with that obtained by the spectrophotometric method, as is seen in Fig. 3. It is thought that a colorless species, *i.e.*, $Cd(phen)_3Cl_2$ is extracted at a pH of *ca.* 2.0, while the reddish $Cd(HDz)_2(phen)$ observed above pH 3.5. 1,10-phenanthroline itself extracts cadmium(II), leaving zinc(II) quantitatively in the aqueous phase. In addition, the optimum concentrations of sodium chloride and 1,10-phenanthroline for the determination of

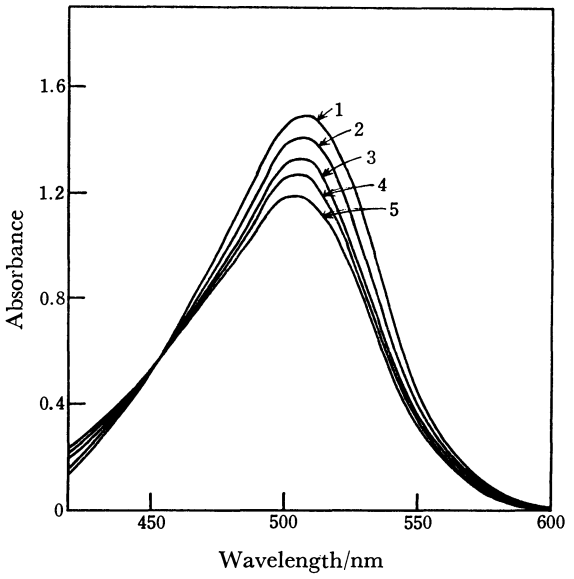

Fig. 4. Absorption spectra of the chloroform phase after shaking with 5 mol dm^{-3} ammoniacal solution. Cd(II): 50 μg, H_2Dz: 0.001%.
[phen]/mol dm^{-3} 1: none, 2: 1.0×10^{-5}, 3: 2.5×10^{-5}, 4: 7.5×10^{-5}, 5: 5.0×10^{-4}.

cadmium(II) according to procedure (B) were found to be greater than 0.4 mol dm^{-3} and 5.0×10^{-3} mol dm^{-3}, respectively.

The Absorption Spectra of the Extracts. The effect of the 1,10-phenanthroline concentration on the absorption spectrum of cadmium(II) dithizonate is shown in Fig. 4. An increase in the 1,10-phenanthroline concentration leads to a decrease in the absorbance at approximately 505 nm, and the isosbestic point appears at 455 nm, indicating that two colored species, namely $Cd(HDz)_2$ and $Cd(HDz)_2(phen)$ may exist in chloroform. Thus;

$$Cd(HDz)_{2,org} + phen_{org} \rightleftharpoons Cd(HDz)_2(phen)_{org} \quad (1)$$

and

$$\log\frac{A_1-A}{A-A_a} = \log K + \log[phen]_{org} \quad (2)$$

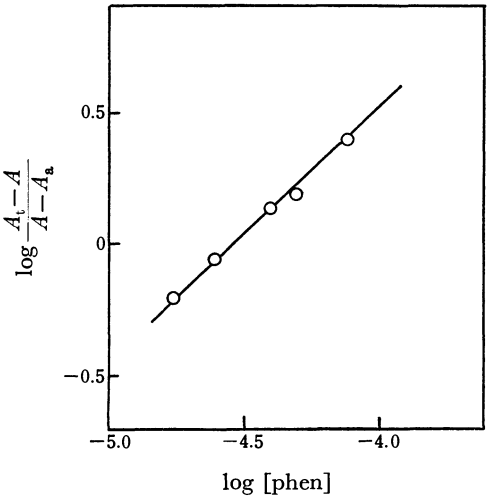

Fig. 5. Composition of the extracted species.

Table 1. Effects of diverse ions

Metal ions	Added as	Diverse ions added (μg)	Cd(II) found(μg)	Error (μg)

Zn^{2+}	Chloride	100mg[e)]	12.1	+0.1

12.0 μg of cadmium(II) was taken. a) 2 cm^3 of 1 mol dm^{-3} thiosulfate soln was added. b) 1 cm^3 of 1 mol dm^{-3} thiourea soln was added. c) 2 cm^3 of 1 mol dm^{-3} thiourea soln was added. d) The initial extraction of Cd(II) was performed in the presence of 0.1 mol dm^{-3} phen. soln. e) The initial extraction of Cd(II) was performed in the presence of 0.25 mol dm^{-3} phen. soln.

where the subscript org refers to the organic phase, K denotes the equilibrium constant for Eq. 1, A is the absorbance at 505 nm, and A_i and A_a represent the absorbances of $Cd(HDz)_2$ and $Cd(HDz)_2(phen)$ respectively. According to Eq. 2, a plot of the value of the left-hand side against log $[phen]_{org}$ should give a straight line having a slope of unity. As shown in Fig. 5, the above assumption is confirmed and the value of K has been calculated to be $10^{-4.54\pm0.02}$. Since no change in the spectrum of $Cd(HDz)_2(phen)$ was observed within one hour, $Cd(HDz)_2(phen)$ is considered to be useful for analytical purposes.

Calibration Curve. The calibration curve prepared according to procedure (B) was linear in the range of zero to 20 μg of cadmium(II), and passed through the origin. The molar absorptivity at 505 nm was shown to be 65000 $dm^3\ mol^{-1}\ cm^{-1}$, the Sandell sensitivity being 0.0013 μg cm^{-2}. The reproducibility test taking 12.0 μg of cadmium(II) gave an average absorbance of 0.361 from 7 determinations, the relative standard deviation being 0.0050.

Effect of Diverse Ions. The experimental results are summarized in Table 1. Each 100 μg of cobalt(II), iron(II, III), lead(II), manganese(II), nickel(II), and tin(II) did not interfere with the determination. Interferences caused by the presence of mercury(II) and copper(II) could be eliminated by the addition of thiosulfate and thiourea, respectively.

Analytical Result. The above procedure (B) was applied to the analysis of cadmium in a metallic zinc, which was found to contain 221±6 ppm as the average value of 5 determinations. The result agrees with the value obtained by the atomic absorption spectrometry (223 ppm).

The Modification of Porous Polymer Beads; Use Packing Material in Gas Chromatography

Yuzi TAKAYAMA

Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi, Aichi 440

(Received April 7, 1979)

A new method of the surface modification of a porous polymer has been developed and applied to packing materials for gas chromatography. The porous polymer was coated with a α,β-unsaturated polyester solid polymer, which had a high acid value and which was cross-linked on the porous polymer by polymerization. By using this in gas chromatography, formic acid peaks are completely separated from acetic acid and water peaks without any apparent tailing. This polyester layer was not extractable and could stably be used at 230 °C or higher. If the diallyl phthalate polymer is used instead of the α,β-unsaturated polyester, propionic acid and acrylic acid, which are very diffecult to separate, were resolved. The present method may be applicable to some components of composite materials.

It is well known that the quality of the packing material in gas chromatography depends sensitively upon its surface properties. Hence, the material, such as diatomaceous earth and porous polymer,[1] is treated with acids[2] or silylating agents[3] to modify its surface properties. Studies of the surface modification are very important not only in the field of gas chromatography but also in other regions, for instance, that of composite materials. In the present work, as a first step, studies were made of the modification of the surface properties of the porous copolymer of styrene divinylbenzene. Also its quality as a packing material in gas chromatography was studied.

Usually, surface acidity and polarity are introduced by adding the proper monomer raw materials of the polymer. This method, however, is very cumbersome, since the stability of the suspension polymerization sensitively depends upon the conditions of the liquid. Surface properties may also be modified by coating the surface low-molecular weight substances. However, such a coating material easily evaporates in gas chromatography and dissolves into the mobile phase in liquid chromatography or into the organic matrix of composite materials.

With these facts in mind, we used curable substances to coat the surface of the porous polymer beads and so modified their surface properties. By choosing the proper curable substances, we controlled the number of acid points and also obtained a neutral and polar surface. The beads thus obtained were highly suitable as the packing material for gas chromatography. The present method may be applied to the pretreatment of polymers for composite materials.

Experimental

Diaion HP 30 (manufactured by the Nippon Rensui Co., a subsidiary of Mitsubishi Chemical Industry) consists of nonpolar porous polymer beads, nominally made of styrene and divinylbenzene. It is supplied in a wet state. The wet polymer was air-dried at room temperature and further heated to a constant weight in nitrogen flow at 140 °C. About 210—220 g of dry polymer, in spherical form (30—50 mesh), were obtained from 1000 ml of the wet polymer. The apparent density of the dried polymer was 0.275 g/cm^3.

About 33 g of the α,β-unsaturated polyester solid polymer, Espol TVF-5704-0 (supplied by the Mitsubishi Gas Chemical Co.) were dissolved in 400 ml of benzene. This solution was then poured onto 150 g of the dried Diaion HP 30 in a flask of a rotary evaporator. Then, a 100-ml portion of a benzene solution containing 1 ml of *t*-butyl perbenzoate (TBPB) was added to this mixture. The benzene was evaporated to dryness under reduced pressure. This dried polymer was packed in a glass pipe (1 m length; 34 mm inside diameter) and heat-treated in about a 100 ml/min nitrogen flow at 140 °C for 5 h. Thus the polymer was modified by the polyester (PMP). In this process, care must be taken of the following point: beads sticking on the wall have unfavourable properties and must be discarded.

Results and Discussion

Gas Chromatography for Free Fatty Acid (FFA). PMP was packed in 1 m×3 mm i.d. stainless steel column and tested by means of a Shimadzu Model-3BT TCD gas chromatograph with a mixture of C_1-, C_2-acids and water, their peaks being efficiently separated by PMP without any serious tails. For comparison, dried Diaion HP 30 was tested in a similar way. Except for water, it gave peaks with long tails as is shown in Fig. 1(b).

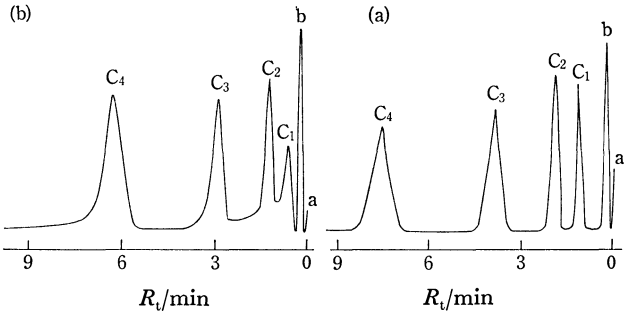

Fig. 1. Gas chromatograms of free fatty acids on (a) Diaion HP 30 modified by TVF 22.5% (see Table 2, Expt. No. 1) and (b) Diaion HP 30 unmodified. All packed in 1 m×3 mm i. d. stainless steel columns. Other conditions: (a) He flow-rate, 15 ml/min; column temperature, 150 °C; isothermal; sample load, 0.5 μl; recorder span, 4 mV. (b) He flow-rate, 16 ml/min; column temperature, 170 °C; isothermal; sample load, 2 μl; recorder span, 16 mV.
Peaks: a, air; b, water; C_1, formic acid; C_2, acetic acid; C_3, propionic acid; C_4, butyric acid.

Usually, an added tailing reducer reduces the retention volume, but this is not the case with Samples Nos. 1 and 2 rows in Table 2. The reason for this is that the TVF added in these present case is not a usual tailing reducer, but essentially changes the surface properties, that is, it increases the affinity to FFA and decreases the radius of the surface pores. The latter change may result in the decrease of the retention time of molecules with larger diameters such as C_4-acid.

Usable Maximum Temperature. The packed column with PMP was kept at 230 °C in a nitrogen flow for 24 h. After this treatment, the PMP was tested as has been described above. As a result, about a 5% shortening of the retention time was observed for all peaks, but there was no change in the peak shapes. Since a similar shortening was also observed in dried Diaion HP 30, the effect may be attributed to the shrinkage of Diaion HP 30. Furthermore, after the above test, the PMP could be taken out of the column smoothly, *i.e.* without any sticking to the column wall or to each other. Its color changed to a light yellowish brown from its original white yellow color. It may be concluded from these experimental results that the usable maximum temperature of PMP was about 230 °C.

Superiority of the α,β-Unsaturated Polyester Solid Polymer. It may be said, from our experience with diatomaceous earth, that the character of a packing material is primarily determined by the liquid phase on it. With this fact in mind, the porous polymer was similarly covered with acidic substances of a lower molecular weight, and its properties as a support were investigated. The favourable acid must satisfy the conditions that it does not destroy the base polymer and not be volatile, even at 240 °C. A small amount of added H_3PO_4 changed the color of Diaion HP 30 homologeneously to gray from the original white-yellow. Sebacic, stearic, and isophthalic acids did not change the color of the base polymer, but began to evaporate at temperatures below 200 °C. Thus, it is presumed that this shortcoming may be overcome by the use of polymer acids.

As for the α,β-unsaturated polyester, a method has been established for controlling the amount of carboxylic acid in it. We can obtain, by polymerizing this polyester on the beads, a film with a large number of acid points and a higher molecular weight; the film is stable even at 230 °C or so. For the present purpose, however, the polyester used must be as pure as possible. The commercially available, in the form of a liquid, contains 40—50% of the styrene monomer, and its acid values range between 5 and 16. If one uses such an impure polyester, the film obtained is inferior in its character, that is, it is thermally unstable and gives a peaks with some tailing. Hence, it is highly advisable to use a so-called solid (crystal) polymer with a high acid value. Solid polymers, TVF-5704-0 and Espol MG-1012, were chosen as modifiers in the present work. The specifications of these materials are given in Table 1.

Effect of the Polyester Concentration. The dependence of the packing character upon the polyester concentration was studied. Furthermore, the effect of coexisting diallyl isophthalate (DAIP) was studied, since this increases the degree of cross-linkage and the

a) Each run was tested in a 50cm × 3 mm i. d. stainless steel column at 150 °C, and each sample load was 0.5—1 μl. b) V': corrected retention volume. c) C_1: formic acid, C_2: acetic acid, C_3: propionic acid, C_4 : butyric acid. d) $\frac{\text{Peak-height from the valley between two overlaping peaks}}{\text{Height of } C_2 \text{ peak}}$. e) Tailing peak.

solvent stability of the polymerized polyester, *i.e.*, the modifier film, but decreases its acid value. With a decrease in the acid value of the modifier film, the peak tailing became remarkable and the separation of the peaks assigned to C_1- and C_2-acids became difficult. The peak-width was almost independent of the polyester concentration on the base polymer in the region of below about 25%, but becamc slightly broader with an increase in the concentration above this limit.

In connection with the above facts, the character of DAIP films of 44.5 and 66.8% (by weight) of the base polymer gave a sharp peak with a long tailing for C_1 acid, but sharp pekas for C_2–C_3 acids; the latter is shown in Fig. 2. In this case, there was no unfavourable effect, *i.e.*, broadening, caused by higher concentrations of DAIP.

These results are summarized in Table 2.

This difference between the concentration effects of DAIP and the polyesters may be attributed to that between their dispersive states on the base polymer. As for the polyester film before polymerization, films on beads stick to each other, and some beads become bare when they are prepared in a rotary evaporator; thus, the heterogeneous dispersion state is realized. This model is partly supported by the fact that the unfavourable concentration effect was not observed if the film was prepared in a beaker without any mechanical stirring. Also such phenomena were not observed with DAIP.

The degree of cross-linkage of the polyester on base beads was estimated by the following method. The PMP was put into a Soxhlet extractor and treated with benzene, and then the weight of extract was measured. The bare beads (Diaion HP 30) were similarly treated, but their weight loss was negligible. Hence, only partial TVF and TBPB were extracted from the coated beads. Since TBPB is easily extracted completely, one can estimate the amount of TVF extracted if the initial content of TBPB is known. The experimental results showed that only 6% of the TVF present was extracted. This means that the TVF film is highly cross-linked and stable.

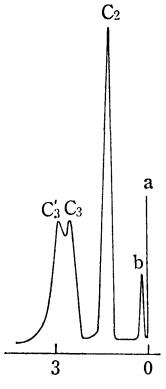

Fig. 2. Profile of propionic acid and acrylic acid on Diaion HP 30 modified by DAIP 44.5% (see Table 2, Expt. No. 7). Packed in a 50 cm × 3 mm i. d. stainless steel column. He flow-rate, 16 ml/min; column temperature, 140 °C; isothermal; sample load, 0.1 μl; recorder span, 2 mV. Peaks: C_3, propionic; C_3', acrylic acid; a and others; see Fig. 1.

Separation of Propionic Acid and Acrylic Acid. As can seen from Fig. 2, the peaks ascribed to propionic (C_3) and acrylic (C_3') acid were separated. This chromatogram was obtained with a short column 50 cm in length, much better separation can be expected with a column of the usual length. This separation may be attributed to the effect of polar groups in the DAIP molecule.

Conclusion

It has been established that α,β-unsaturated polyesters are good modifiers of prorous polymer beads, and that the higher the acid value, the better a modifier for the separation of FFA. In the present work, the best results were obtained with 25% TVF on the base beads. However, this value may depend upon the surface area of the base beads. The Diaion HP 30 used in the present work has a BET area of 200 m^2/g. The optimum concentration increases with the increase in the surface area.

The conventional modifiers presently used are apt to evaporate or be extracted in gas chromatography and liquid chromatography respectively. These unfavourable effects can be avoided by the use of the present techniques.

In the present work, we were mainly interested in the separation of FFA with an acidic modifier, not in the separation of amines. The latter may, however, be successfully done by basically modified packing, which can be obtained by an extension of the present techniques.

The author wishes to thank Professor Tetsuo Takaishi for his discussion.

Metal Halide Catalyst for Reduction of Nitric Oxide with Ammonia

Akio NISHIJIMA,* Yoshimichi KIYOZUMI, Akifumi UENO, Minoru KURITA, Hiroyuki HAGIWARA, Toshio SATO, and Naoyuki TODO

National Chemical Laboratory for Industry, 2-19-19, Mita, Meguro-ku, Tokyo 153

(Received May 10, 1979)

Counter anions of active components on catalysts were found to affect catalytic activities for NO reduction with NH_3. Halide ions promoted activity in copper and iron catalysts, but lowered it in chromium and manganese catalysts. The most favorable electronic state of a cation on catalysts was investigated by changing counter anions and/or carriers.

In the catalytic reduction of nitrogen oxides with ammonia the reduction rate is markedly accelerated by the presence of oxygen, no undesirable by-product being found by the reaction between reducing agents and components in flue gas. The method seems to be most advantageous for the reduction of nitrogen oxides (NO_x) emissions from stationary combustion equipments.[1-3] Metal oxide supported catalysts such as Fe_2O_3, V_2O_5, CuO, and MoO_3 on Al_2O_3 or TiO_2 are being employed. However, they are used at reaction temperatures above 300 °C in order to obtain effective reduction of NO_x. From an economical viewpoint, catalysts active at lower temperatures are desirable, since temperatures of flue gases emitted from a coke oven or sintering furnace are lower than 200 °C.

We have explored new catalysts having higher activity at low temperature and found that the activity of metal sulfate catalysts in the lower temperature region is higher than that of metal oxide catalysts.[4] This indicates that the anion of these metal compounds affects the catalytic activity for NO reduction. We have examined the effect of the counter anions and found that the halide catalysts are effective for producing activity at lower temperatures.[5]

In order to find the most favorable electronic state of cations of the catalysts, a study on metal halides has been made by changing anion species of the catalysts and carries.

Experimental

Catalyst. Metal halide and metal sulfate catalysts were prepared by impregnating preformed γ-Al_2O_3 (diam. 1.5 mm) with aqueous solutions of halides and sulfates, respectively. After being impregnated at 40 °C for 5 h, the catalysts were dried at 120 °C for 3 h, and then calcined at 200 °C for 3 h. In the case of metal oxide catalysts, the catalysts were prepared by calcining at 500 °C for 3 h, after being impregnated with metal nitrates, the cation contents being kept constant (8 wt % and 4.7 wt %) in order to examine the effect of counter anions. The copper catalysts used were $CuBr_2$–Al_2O_3, $CuSO_4$–Al_2O_3, $CuCl_2$–Al_2O_3, and CuO–Al_2O_3. In order to examine carrier effects on the catalytic activities, 15 wt % of $CuBr_2$ supported on SiO_2, active carbon and Al_2O_3 were used.

Activity Measurement. Figure 1 shows a flow diagram of the apparatus. The reactor is a stainless steel tube, length 200 mm, diam. 15 mm, set in a tubular furnace, length 250 mm. After introducing 10 ml of the catalyst into the reactor, activity measurements were carried out under space velocity of 15000 h^{-1}. As a standard feed stream, a gas mixture consisting of NO 300 ppm, NH_3 300 ppm, O_2 5 vol %, and N_2 balance gas was used. Analyses of NO, NO_2, and NH_3 were made by means of chemiluminescence type NO_x and NH_3 analyzer.

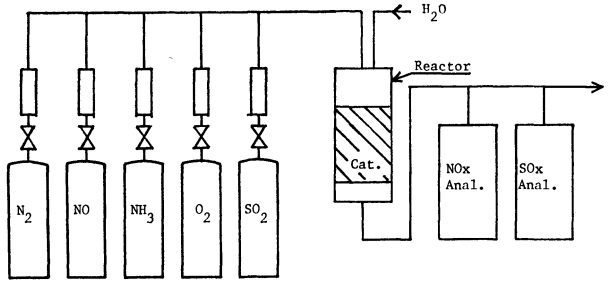

Fig. 1. Flow diagram of apparatus used.
□ : Rotor meter, ⋈ : variable valve.
Each cylinder contained 1 vol % of NO, NH_3, or SO_2.

Property of Catalyst. The amounts of NH_3 and NO adsorption on the catalysts were measured using a thermogravimeter (Shimadzu Co. DT 20) in N_2 feed stream (1 l/h) containing 5 vol % O_2. An X-ray photoelectron spectrometer (XPS) (Dupont Co. 650B) was used to measure the electronic states of the cations and anions in active components. Mg $K\alpha$ radiation was used to obtain XPS spectra. All binding energy values were refered to C 1s of contaminant carbon (285.0 eV).

Results

Copper Salt Catalyst. Effect of Anion on Catalytic Activity: In the reaction of NO removal, the activities of the catalysts increased with cation content, reaching a maximum at a certain cation content. Thus, for the measurement of relative activities the catalysts with lower cation content whose activity does not reach maximum were used. In the case of CuO–Al_2O_3, $CuSO_4$–Al_2O_3, and $CuCl_2$–Al_2O_3, Cu content was 8 wt%. In the case of $CuBr_2$–Al_2O_3 with 8 wt% of Cu, however, the activity attained saturation. The cupric ion content of 4.7 wt% was selected for a comparison of the anion effect of Br^- with that of Cl^- on the catalytic activities of $CuBr_2$ and $CuCl_2$ catalysts. The effect of anions on the catalytic activity is shown in Fig. 2. The activity order of the catalysts in lower temperature region was: $CuBr_2 > CuCl_2 > CuSO_4 > CuO$.

Effect of Carrier on Catalytic Activity: The effect of carriers on catalytic activity was investigated using γ-Al_2O_3, SiO_2, and active carbon (AC). The results are shown in Fig. 3. The activities decreased in the order: AC > γ-Al_2O_3 > SiO_2.

Amount of Adsorption of NO and NH_3: It was found

Space velocity: 15000 h^{-1}.

CuO–Al_2O_3 catalyst. The order of the amount of NH_3 adsorption is $CuSO_4$–Al_2O_3>$CuBr_2$–Al_2O_3>CuO–Al_2O_3, and that of NO adsorption on these three catalysts CuO–Al_2O_3>$CuBr_2$–Al_2O_3>$CuSO_4$–Al_2O_3.

Electronic State of Cation and Adsorbed NH_3 and NO: The effect of anions and carriers on electronic states of the cation in the catalysts obtained by using X-ray photoelectron spectrometer is given in Table 2. The electronic state of copper ions was found to depend on the kind of both anion and carrier. The electronic states of copper ions become electropositive in the order: $CuSO_4$>$CuBr_2$>CuO. On the other hand, when carriers were changed the electronic states of copper ions become Al_2O_3>AC>SiO_2. Binding energies of N 1s for adsorbed NH_3 and NO on the copper catalysts are given in Table 3. The binding energies of adsorbed NH_3 and NO agree with those of NH_4^+ and NO_3^-, respectively.

Iron Salt Catalyst. Similar experiments were carried out on iron salt catalysts. Figure 4 shows the result obtained for ferric salt supported catalysts. The effect of anions on activity was found to be in the same order as cupric salt catalysts: $FeBr_3$>$FeCl_3$>$Fe_2(SO_4)_3$ >Fe_2O_3.

Other Metal Salt Catalyst. Effects of anions on catalytic activity were also investigated for transition metal compounds. Some metal halide catalysts such as $CeCl_2$ or $MnCl_2$ were found to show high activity at lower temperatures (Fig. 5). No activity was observed on $CrBr_3$, $ZnBr_2$, and $NiBr_2$ supported catalysts at lower temperatures. In the case of chromium salt catalysts, the activity order of the catalysts is: Cr_2O_3>$Cr_2(SO_4)_3$ >$CrBr_3$.

Discussion

In the cases of Cu, Fe, and Ce, it was shown that the activity of metal halide supported catalysts is higher than that of oxide and sulfate supported catalysts. This indicates that among the anions we investigated, halide anions are the most effective for producing active states. However, catalytic activity and the activity order (Cu, Ce>Fe>Mn>Ti) obtained on metal halide suppored catalysts were found to differ from those of metal oxide suppored catalysts (Mn>Cr> Cu>Fe). In contrast, in the case of chromium metal, the activity of the halide supported catalyst was lower than that of oxide or sulfate supported catalyst. It seems that both cation and anion species of active components affect activity for NO reduction and that the selection of appropriate combination of a cation and an anion is essential for producing a highly active state.

Both copper oxide and halide supported catalysts show high activity at lower temperatures. Thus copper compound supported catalysts were studied in detail.

NO was predominantly reduced by NH_3 to N_2, no N_2O being detected. This is the most characteristic difference from the case in which CO or H_2 is used as a reduction agent. According to Otto and Shelef, in the reduction by CO or H_2, the participation of two molecules of NO is needed for the selective production of N_2; when NH_3 is used as a reduction agent, N–N bond is easily produced in the reaction of NO and NH_3.[6] In fact, Shelef found by using nitrogen isotope, that $^{15}N^{14}N$ is mainly produced by the reaction of ^{14}NO and $^{15}NH_3$.[7] This indicates that adsorption of both NH_3 and NO in the neighboring sites on the catalyst is necessary for reaction.

According to the results obtained by XPS, NH_3 and NO seem to undergo adsorption on the catalysts in the form NH_4^+ and NO_3^-, respectively.[8] It seems that the amount of NH_3 adsorbed on the catalysts decreases when the electronic state of the cation changes from an electropositive state to an electronegative one, and that the amount of NO adsorbed decreaes when the electronic state of the cation changes from an electronegative state to an electropositive one. Actually, the order of the amounts of NH_3 and NO adsorbed on the catalyst (Table 1) agreed with those of the electropositivity and the electronegativity of the cation (Table 2-A).

From the results we realize that the most favorable electronic state of the cation should be selected by changing counter anions in order to obtain proper amounts of both adsorbates of NH_3 and NO. In fact, the catalytic activity decreased when the electronic state of the cation changed to the electronegative ($CuSO_4$) or to the electropositive one (CuO) as compared with $CuBr_2$–Al_2O_3 catalyst (Fig. 2 and Table 2-A).

In these supported catalysts, Al_2O_3 or AC is usually employed as a carrier. The carriers are also considered to affect the electronic state of the cation of active components. When we change the carriers, the electronic state of the cation changes considerably (Table 2-B). The relation between the catalytic activity (Fig. 3) and the electronic states of the cation (Table 2-B) was the same as that obtained by changing counter anions. The result seems to support the above conclusion that the most favorable electronic state of the cation can be obtained by a proper combination of the cation

with a counter anion and a carrier for high activity.

From a practical viewpoint, catalysts are required to be resistant against water vapor or SO_2 in a reaction gas, since they are usually contained in a flue gas emitted from stationary combustion equipments. The metal halide catalysts which show high activity at lower temperatures were not poisoned by water vapor, but their catalytic activity was found to decrease gradually when SO_2 was contained in the reaction gas. This is due to the change of the active component from $CuBr_2$ to $CuSO_4$. The electronic state of copper ions in deactivated $CuBr_2$–Al_2O_3 catalysts was found to be the same as that of $CuSO_4$–Al_2O_3 catalyst.

Isothiocyanates. I.[1] Addition of Urea to Aroyl Isothiocyanates and Conversion of the Monoadducts into Monothiobiuret, 4-Thioxo-1,3,5-triazin-2-ones and 1,2,4-Thiadiazol-3-ones

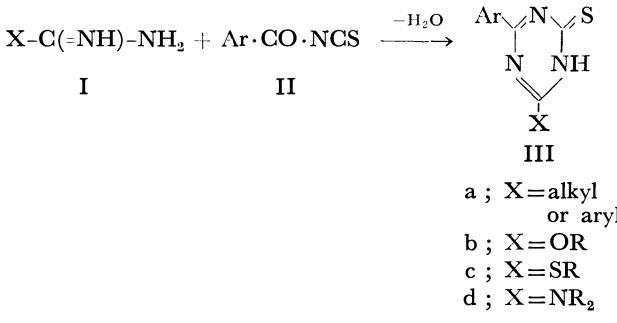
Mohamed Nabih BASYOUNI* and Abdel-Momen EL-KHAMRY

Chemistry Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt

(Received March 17, 1979)

The hitherto unknown 1-aroyl-2-thiobiurets were synthesized by addition of urea to aroyl isothiocyanates. Treatment of 1-benzoyl-2-thiobiuret with concentrated hydrochloric acid effected hydrolysis to monothiobiuret. On the other hand, treatment of 1-aroyl-2-thiobiurets with alkali gave 6-aryl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-ones.† Oxidation of the 1-aroyl-2-thiobiurets with hydrogen peroxide in the presence of hydrochloric acid gave 5-aroylamino-2,3-dihydro-1,2,4-thiadiazol-3-ones.

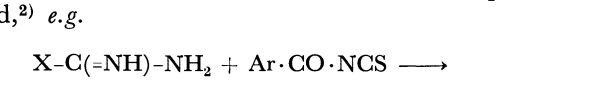
Amidines, isoureas, isothioureas and guanidines Ia—d have been added to aroyl isothiocyanates II to give 1,3,5-triazinethione derivatives IIIa—d.[2] Combination of weakly basic amidino compounds with weakly



I II III

a ; X=alkyl or aryl
b ; X=OR
c ; X=SR
d ; X=NR_2

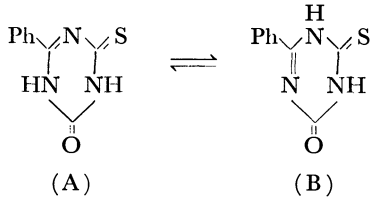
electrophilic isothiocyanates gave III in good yields. In other cases formation of aroylamidines predominated,[2] *e.g.*



Such an aroylation reaction during the course of addition of alkylamines[3] and hydrazines[4] to benzoyl isothiocyanate has been reported.

In the present investigation urea, a weaker nucleophile, was choosen for the study of its reaction with some aroyl isothiocyanates of varying electrophilicity, *i.e.* of different carbonyl activity, in order to obtain more precise information on the mode of addition of nucleophiles to the C=S and/or to C=O of the aroyl isothiocyanates. Reactions, *e.g.* actions of acids and alkalies and oxidation with hydrogen peroxide, on the monoadducts from the reaction under investigation were also carried out.

† Although the 2-phenyl derivative exists as tautomers (A) and (B),[2] it was erroneously named 6-oxo-2-phenyl-4-thioxo-1,4,5,6-tetrahydro-1,3,5-triazine. The present naming of this compound and its aryl analogs indicates that they can exist in two tautometric forms.



(A) (B)

Results and Discussion

Urea was added to the aroyl isothiocyanates IIa—f in dry acetone to give good yields (*cf.* Table 2) of the hitherto unknown 1-aroyl-2-thiobiurets IVa—f. Although equimolar amounts of the reactants were used, a small amount (see Experimental) of a diadduct V was obtained in the case of the addition of urea to benzoyl isothiocyanate IIa. However, when the addition was repeated using two moles of the benzoyl isothiocyanate the amount of the diadduct did not increase, the predominant product being the monoadduct IVa. The monoadducts IVa—f obtained from such a reaction could be obtained from urea by the reaction with the aroyl isothiocyanates prepared *in situ* from the corresponding aroyl chloride and ammonium thiocyanate in dry acetone (*cf.* Experimental).

f ; Ar=styryl

The structure of the monoadducts IVa—f was confirmed by their analytical data, infrared and electronic spectra. Thus, the strong absorption bands in the region 3360—3100 cm^{-1} can be correlated with ν_{NH} of primary and secondary amides (bonded NH);[5] those in the regions 1700—1680 cm^{-1} and 1740—1715 cm^{-1} can be attributed to the presence of acyclic thioimide groupings, namely ArCONHCS and CSNHCO.[5] The absence of a band at 2570 cm^{-1} suggests that the 1-aroyl-2-thiobiurets IVa—f exist in the thione form (thiolactam). The electronic spectra of IVa—c support their structural similarity. The infrared and electronic spectral data are given in Table 1. 1-Benzoyl-2-thiobiuret IVa was desulfurized[6] with aqueous chloroacetic acid to give benzoylbiuret[7] as an analytically pure sample.

Formation of the 1-aroyl-2-thiobiurets IVa—f in good yields by the addition of urea to the aroyl isothiocyanates IIa—f indicates that urea exclusively attacks the C=S function of the aroyl isothiocyanates. The

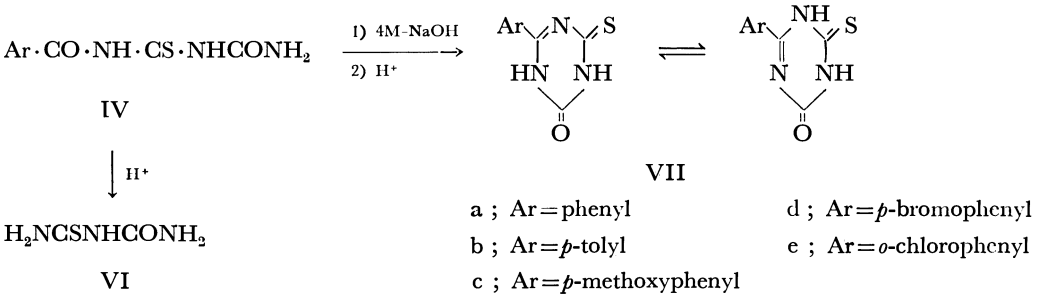
a) From ethanol. b) From acetic acid.

fact that no aroylureas were formed supports the view that no competing aroylation reaction, *i.e.* the direct nucleophilic substitution at the carbonyl function of the aroyl isothiocyanates IIa—f, of varying carbonyl activity, took place. This supports the previous conclusion[3,4] that only strong nucleophilic reagents such as alkylamines and hydrazines are capable of attacking the C=O function of the aroyl isothiocyanates to give the aroylated nucleophiles. The results show that the magnitude of the electrophilicity of the aroyl isothiocyanate makes a small contribution, if any, in determining the mode of addition of nucleophiles to the C=O and/or to the C=S of the dielectrophilic reagent, *i.e.* the aroyl isothiocyanate.

Treatment of an ethanolic solution of 1-benzoyl-2-thiobiuret IVa with concentrated hydrochloric acid (see Experimental) gave monothiobiuret VI, which is particularly useful as an intermediate in the production of thermoplastic and water-repellent resins and which may serve as a rubber accelerator, a plasticizer and an insecticide. The present route for the synthesis of VI from readily accessible starting materials is, therefore, superior to and more convenient than the reported procedures.[8–10]

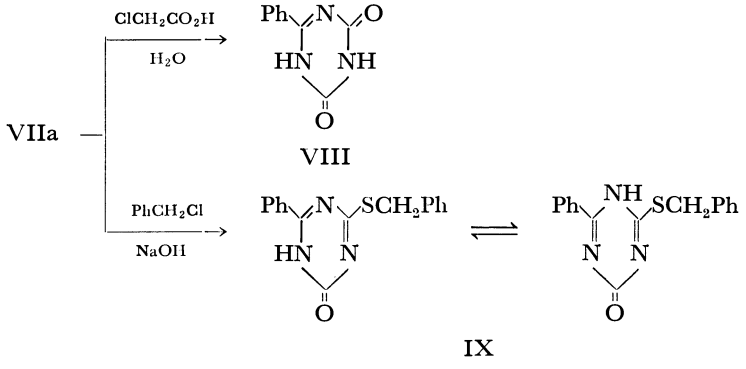
On the other hand, treatment of an ethanolic solution of each of IVa—e with aqueous 4 M sodium hydroxide afforded, after acidification, 6-aryl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-ones VIIa—e in a good yield.

The structure of the 4-thioxo-1,3,5-triazin-2-one derivatives VIIa—e was confirmed by analytical data, infrared and electronic spectra. Their infrared spectra (*cf.* Table 1) exhibit bands in the regions 3210—3050 cm^{-1} (ν_{NH}) and 1740—1675 cm^{-1} ($\nu_{C=O}$) and their electronic spectra reflect their structural similarity (*cf.* Table 1).



a ; Ar=phenyl
b ; Ar=*p*-tolyl
c ; Ar=*p*-methoxyphenyl
d ; Ar=*p*-bromophenyl
e ; Ar=*o*-chlorophenyl

Although 6-phenyl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-one VIIa, mp 264—266 °C, has been prepared[2] by a different route which involves acidic hydrolysis of III (Ar=phenyl; X=OC_2H_5) and is reported to have mp 246—248 °C, the structure of the compound in our hands was established from the following chemical evidence: 1) it was desulfurized[6] with aqueous chloroacetic acid to give 6-phenyl-1,2,3,4-tetrahydro-1,3,5-triazin-2,4-dione VIII, which was analytically pure and its mp was in good agreement with that reported previously[7] for the same compound prepared by a different route, and 2) benzylation with benzyl chloride in the presence of sodium hydroxide gave 4-benzylthio-6-phenyl-1,2(or 1,4)-dihydro-1,3,5-triazin-2-one IX which was identical (mp, mixed mp and infrared spectroscopy) with an authentic specimen prepared by a different route.[2]



Oxidation of IVa, c, and e with hydrogen peroxide in the presence of hydrochloric acid gave 5-aroylamino-2,3-dihydro-1,2,4-thiadiazol-3-ones (or 5-aroylimino-tetrahydro-1,2,4-thiadiazol-3-ones) Xa—c whose structures were confirmed by analytical data, infrared and electronic spectroscopy. Thus, the infrared spectra of the products Xa—c show bands in the ranges 3215—3100 cm^{-1} (ν_{NH}) and 1732—1675 cm^{-1} ($\nu_{C=O}$) and their electronic spectra reflect their structural similarity. The presence of the thiadiazole ring was inferred from their behavior towards the action of sodium plumbite as compared with their precursors, namely 1-aroyl-2-thiobiurets IVa, c, and e. The latter open-chain adducts deposited black lead sulfide at room temperature, but the thiadiazole derivatives Xa—c deposited lead sulfide after being boiled for a few minutes.

5-Aroylamino-2,3-dihydro-1,2,4-thiadiazol-3-ones Xa—c can exist in the tautomeric forms indicated.

Experimental

All melting points are uncorrected. Infrared and electronic spectra were measured on a Unicam SP 1200 spectrophotometer (KBr discs) and Beckmann DK-2A Ratio Recording spectrophotometer (in dioxane), respectively.

Preparation of Aroyl Isothiocyanates IIa—f. These were prepared by known procedures.

a) *Benzoyl Isothiocyanate* IIa, bp 105—110 °C/5 mmHg. Bp 95—100 °C/2—3 mmHg by Kurzer and Hanks;[11] bp 143 °C/20 mmHg by Smith and Kan.[12]

b) p-*Toluoyl Isothiocyanate* IIb, bp 110—113 °C/1 mmHg; bp 92 °C/0.4 mmHg.[12]

c) p-*Anisoyl Isothiocyanate* IIc, bp 160—166 °C/4 mmHg; bp 148—152 °C/1 mmHg.[11]

d) p-*Bromobenzoyl Isothiocyanate* IId, mp 54—55 °C (from chloroform); mp 55 °C.[13]

e) o-*Chlorobenzoyl Isothiocyanate* IIe, bp 130—135 °C/5 mmHg; bp 119 °C/2 mmHg.[14]

f) *Cinnamoyl Isothiocyanate* IIf, bp 125—130 °C/4 mmHg; bp 119 °C/2 mmHg.[12]

Addition of Urea to Aroyl Isothiocyanates II. General Procedure Method A. To a solution of aroyl isothiocyanate (0.05 mol) in dry acetone (100 ml) was added urea (0.05 mol) portionwise with stirring. The reaction mixture was then refluxed for 2—3 h until all of the urea had dissolved. Evaporation of the acetone solution followed by trituration of the residue with hot water gave a crystalline solid. Recrystallization from an appropriate solvent gave 1-aroyl-2-thiobiurets IV. The results are given in Table 2.

a) From 1-butanol. b) From acetic acid.

The mother liquor obtained after separation of IVa deposited colorless crystals of the diadduct V, mp 175—178 °C (from aqueous methanol), in 3% yield. Found: C, 52.8; H, 4.0; N, 14.6; S, 16.6%. Calcd for $C_{17}H_{14}N_4O_3S_2$: C, 52.8; H, 3.6; N, 14.5; S, 16.6%.

Method B. Urea (0.05 mol) was added to an acetone solution of the aroyl isothiocyanate II [prepared *in situ*[15] from the corresponding aroyl chloride (0.05 mol) and ammonium thiocyanate (0.08 mol) in acetone (100 ml) by refluxing for 15 min followed by filtration of inorganic solid] and the reaction mixture refluxed for 2—3 h. The reaction mixture was worked up as described in *Method A*. The yields of the monoadducts 1-aroyl-2-thiobiurets IV obtained by this method are included in Table 2.

Desulfurization of 1-Benzoyl-2-thiobiuret IVa with Aqueous Chloroacetic Acid. A solution of chloroacetic acid (4 g) in water (10 ml) was mixed with 1-benzoyl-2-thiobiuret IVa (2 g) and heated on an oil bath at 150—160 °C for 30 min. After being cooled to room temperature, the product was filtered off and recrystallized from methyl cellosolve to give benzoylbiuret almost quantitatively, mp 220—221 °C (lit,[7] mp 220 °C). Found: C, 52.4; H, 4.7; N, 20.1%. Calcd for $C_9H_9N_3O_3$: C, 52.1; H, 4.3; N, 20.3%.

Action of Concentrated Hydrochloric Acid on 1-Benzoyl-2-thiobiuret IVa. Isolation of Monothiobiuret VI. Ethanol (*ca.* 10 ml) was added to a suspension of 1-benzoyl-2-thiobiuret IVa (2 g) in concentrated hydrochloric acid. The reaction mixture was then refluxed until most of the benzoic acid (mp and mixed mp 121 °C) had sublimed into the condenser. The solution was evaporated *in vacuo* and the residue was neutralized with sodium hydrogencarbonate and then recrystallized from water to give monothiobiuret VI in 65% yield, mp 185—186 °C (lit,[10] mp 187—189 °C). It gave the biuret reaction and showed its infrared spectrum bands for ν_{NH} at 3540, 3440, 3380—3300, 3280—3140 cm^{-1} and for $\nu_{C=O}$ at 1730, 1700, 1660 and 1640 cm^{-1}. Its electronic spectrum showed λ_{max} 256 nm (ε 15490). Found: N, 30.25; S, 22.9%. Calcd for $C_2H_5N_3OS \cdot H_2O$: N, 30.65; S, 23.35%.

Action of Aqueous Sodium Hydroxide on 1-Aroyl-2-thiobiurets IVa—e. Synthesis of 6-Aryl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-ones VIIa—e. 1-Aroyl-2-thiobiuret (0.01 mol) was dissolved in aqueous 4 M sodium hydroxide (60 ml) and ethanol (30 ml) and the reaction mixture was left to stand at room temperature overnight. Acidification with 1M aqueous sulfuric acid (pH 6) gave a precipitate (quantitative yield) which was recrystallized from an appropriate solvent to give 6-aryl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-one VII as yellow to orange crystals. The results are given in Table 3.

Desulfurization of 6-Phenyl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-one VIIa to 6-Phenyl-1,2,3,4-tetrahydro-1,3,5-triazin-2,4-dione VIII. Compound VIIa (2 g) was desulfurized with a solution of chloroacetic acid (4 g) in water (10 ml) to give 6-phenyl-1,2,3,4-tetrahydro-1,3,5-triazin-2,4-dione (quantitative yield). It was recrystallized from water, mp 286—288 °C; mp 286—287 °C.[7] Goerdeler and Neuffer[16] reported mp 283—285 °C for the same compound recrystallized from ethanol. Found: C, 57.4; H, 4.1; N, 22.1%. Calcd for $C_9H_7N_3O_2$: C, 57.1; H, 3.7; N, 22.2%.

Preparation of 4-Benzylthio-6-phenyl-1,2(or 1,4)-dihydro-1,3,5-triazin-2-one IX. Benzyl chloride (0.011 mol) was added while being warmed to a stirred solution of 6-phenyl-4-thioxo-1,2,3,4(or 2,3,4,5)-tetrahydro-1,3,5-triazin-2-one VIIa (0.01 mol) in aqueous 0.5 M sodium hydroxide (30 ml) and ethanol (70 ml) over a period of 10 min. After the addition had been completed, stirring was continued for 1 h. The reaction mixture was then diluted with water and the precipitate was filtered off and recrystallized from ethyl acetate to give the *title compound* in 80% yield, mp 229 °C (lit,[2] mp 229 °C). Found: C, 65.0 H, 4.6; N, 14.0; S, 10.6%. Calcd for $C_{16}H_{13}N_3OS$: C, 65.1; H, 4.4; N, 14.2; S, 10.9%.

Oxidation of 1-Aroyl-2-thiobiuret IV to 5-Aroylamino-2,3-dihydro-1,2,4-thiadiazol-3-ones X with Hydrogen Peroxide. Hydrogen peroxide (10%, 15 ml) was added to a boiling solution of each of IVa, c, or e (0.01 mol) in ethanol (20 ml) containing concentrated hydrochloric acid (1 ml) over a period of 5 min. After being cooled to room temperature, the precipitated solid was filtered off and recrystallized from a suitable solvent to give the thiadiazoles Xa, b, or c. The results are given in Table 4.

Action of Sodium Plumbite on 1-Aroyl-2-thiobiurets IV and 5-Aroylamino-2,3-dihydro-1,2,4-thiadiazol-3-ones X. When

sodium plumbite was added to IV, a black precipitate (lead sulfide) was formed immediately. On the other hand, no precipitate was formed at room temperature on addition of sodium plumbite to X; the black lead sulfide separated after being warmed, its amount increasing by boiling for 3—5 min.

Cell Design for Simultaneous Measurement of Photoacoustic and Fluorescence Spectra

Kenji KATO† and Yoshinori SUGITANI*

Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

(Received April 3, 1979)

Synopsis. A simple and convenient sample cell has been designed for the simultaneous detection of photoacoustic and fluorescent signals. Spectral measurement of natural zircon, using the designed cell, is presented.

There has been a growing interest in photoacoustic spectroscopy as a method for the characterization of solid materials, in addition to the conventional methods including fluorescence spectroscopy. Since photoacoustic spectroscopy depends on the radiationless process of de-excitation, it is complementary to fluorescence spectroscopy which deals with the radiative process of de-excitation. A combination of the two methods, and particularly the simultaneous measurement of photoacoustic and excitation spectra will be of great use in the study of the de-excitation process.

In this note, a cell design for the simultaneous detection of photoacoustic and fluorescent signals is presented together with a spectral measurement on natural zircon $ZrSiO_4$.

Cell Design

Figure 1 shows the sample cell which is designed for the simultaneous detection of photoacoustic and fluorescent signals of powdered specimens. The cell is composed of a cell body and a sample base. On the sample base, the powder specimen is spread with the aid of water, acetone, or alcohol. In the measurement, the cell body and the sample base are tightly coupled using a packing material such as PARAFILM (American Can Co., USA). The air space in the cell is approximately 0.4 cm^3 in the coupled state. The electlet-microphone attached onto the cell body is connected to the sample position *via* a channel (2 mmϕ × 40 mmL). The amount of sample necessary for the measurement is approximately 0.05 g.

Figure 2 shows the photoacoustic signal intensity of carbon black at the output terminal of the microphone with respect to the chopping frequency. The spectrometer was set at 500 nm as a filter with a slit width of 3.0 mm. The photoacoustic signal intensity is inversely proportional to the chopping frequency in the range 7 to 320 Hz.

The photoacoustic signal is considered to be generated in the boundary layer of gas (air) surrounding the sample. The thickness of the layer is given as

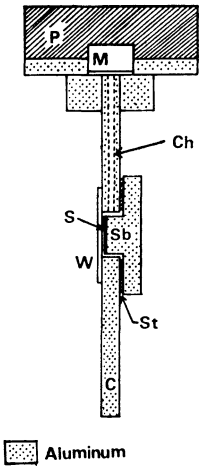

Fig. 1. Sample cell for simultaneous measurement of photoacoustic and fluorescent spectra. S: Sample, W: quartz window, St: sticky packing, Sb: sample base, Ch: channel, M: microphone, P: acoustic protector.

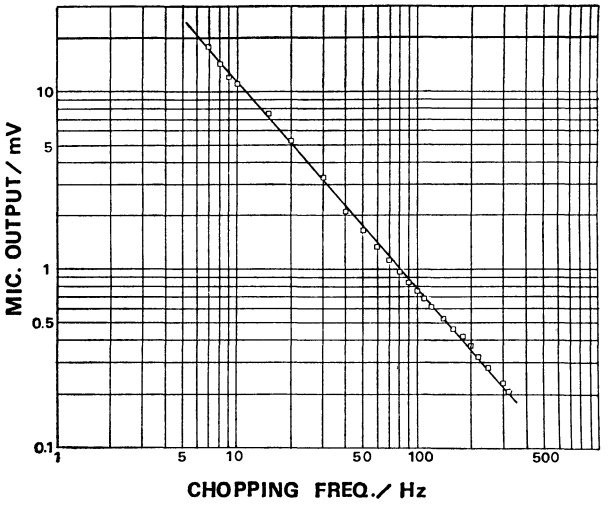

Fig. 2. Photoacoustic signal of carbon black at the output terminal of the microphone *vs.* chopping frequency.

$2\pi(2\alpha/\omega)^{1/2}$,[1] where ω is the chopping frequency and α, the thermal diffusivity of the gas. It is approximately 1 mm, at a chopping frequency of 100 Hz for example. This suggests that there is a limitation to the smallest air space in the coupled cell as well as to the lowest chopping frequency for effective detection of the photoacoustic signal. Beyond the limitation, losses

† Present address: National Chemical Laboratory for Industry, 1-1 Yatabe-cho Higashi, Tsukuba-gun, Ibaraki 305.

occur in thermal generation, resulting in a reduction of the signal intensity.[2,3] The optimum chopping frequency was found to be approximately 100 Hz.

J. F. McClelland *et al.* have discussed the influence of scattered light in the photoacoustic cell.[4] They have suggested that the scattered light was absorbed by the microphone diaphragm and a resultant spurious signal was detected. In the sample cell designed here, the microphone is isolated from the sample, so that the obtained spectra are completely free from the scattered light, as seen in the Fig. 3.

Other properties of the designed cell are; i) the system of the cell body and the sample base are of a simple type, so that spare parts, especially of the sample base, can be readily provided, ii) the quartz sample base allows the observation of transmitted light, iii) since the sample base is inserted in the cell body, the air volume in the cell is very small contributing to the enhancement of signal intensity.

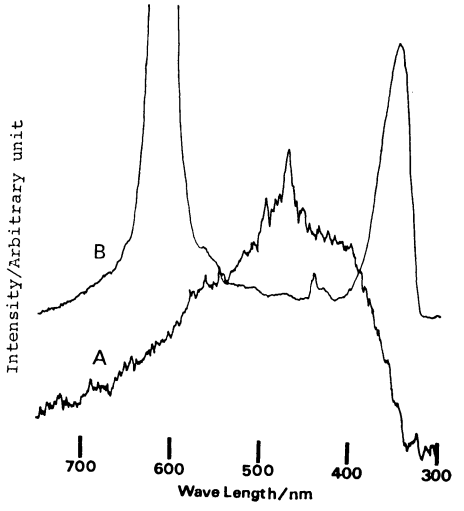

Fig. 3. Photoacoustic (A) and fluorescent excitation (B) spectra of natural zircon $ZrSiO_4$.

Simultaneous Measurement

Figure 3 shows the photoacoustic and excitation spectra simultaneously measured at room temperature for zircon $ZrSiO_4$ at a chopping frequency of 80 Hz. The scanning rate was 25 nm/min, and the slit of the spectrometer for incident light was 0.5 mm which corresponds to a resolution of 3 nm, and that for the emitted light was 1 mm. The time constant was 3 s for both of the lock-in amplifiers. Corrections for the light source intensity were not made, and the excitation spectra was monitored at 520 nm fluorescence output. The contrast between the photoacoustic and the excitation spectra is clearly seen and no additional signal due to the diaphragm was observed.

The authors wish to thank Prof. Kozo Nagashima of the University of Tsukuba, Institute of Chemistry, for his kind support during the course of this work.

The Effect of Configuration Interaction on the π-Bond Orders, and the Molecular Geometry of Coronene in Its Ground State

Mitsunobu NAKAYAMA,* Kenji MORIHASHI, Masato IGARASHI, and Keizo SUZUKI

(Received October 30, 1978)

Synopsis. Semiempirical MC-LCAO-MO calculations have been made on the ground-state coronene. The inclusion of the off-diagonal terms in the MC bond-order formula is, in this case, essential to improve the bond orders and the bond lengths over the usual single configuration calculation.

The geometrical structures of unsaturated hydrocarbons have long been yielded by computing the C–C bond distances through the linear relationship[1] between the bond length, r_{kl}, and the π-bond order, P_{kl}:

$$r_{kl} = r_0 - cP_{kl}. \quad (1)$$

The adequacy of the use of this relationship has been theoretically demonstrated by Julg[2] using a semiempirical SCF-MO formalism.

In a previous paper proposing a semiempirical MC-LCAO-MO method,[3] we introduced the multi-configuration (MC) π-bond order for a bond between two carbon atoms, k and l:

$$P_{kl} = \sum_m A_m^2 P_{kl}^{(m)} + 2\sum_{m<n}\sum' A_m A_n P_{kl}^{(m,n)}, \quad (2)$$

where A_m is the coefficient of the configuration function (CF), m, and $P_{kl}^{(m)}$ are the bond orders obtained from the mth CF, and $P_{kl}^{(m,n)}$ are those between the CF's m and n; henceforth, the first and second terms will be called the diagonal and off-diagonal terms respectively. Note that $P_{kl}^{(m,n)}$ are non-vanishing only when the CF's m and n differ in a pair of MO's for the same counterpart of an electron.

Julg[2] has proposed an MC bond-order formula which omits the off-diagonal terms from Eq. 2. McCoy and Ross[4] included all the terms in their singly-excited configuration interaction calculations for excited states of benzene, naphthalene, azulene, and anthracene. To our knowledge, however, no examination has been made concerning the effect of the off-diagonal terms.

In the present study we have made MC-LCAO-MO calculations on the ground-state coronene using the full form of Eq. 2 (Case I) and the formula without the off-diagonal terms (Case II). The computed P_{kl} values are used to calculate the bond length, r_{kl}, by means of Eq. 1, with r_0=1.523 Å and c=0.193. As in previous papers,[5] Approximation (1), $\beta_{kl}=\beta_0\exp[-(r_{kl}-b)/a]$, and Approximation (2), $\beta_{kl}=-KS_{kl}$(11.290 eV), are used with β_0=−2.38 eV, a=0.3938 Å, b=1.397 Å, and K=0.86291. The CI treatment includes 24 singly-excited configurations, 68 doubly-excited configurations, and 16 triply-excited configurations, together with the ground configuration. (Note that the MO's are of the Hückel type and not of the SCF type). These configurations were chosen successively from the energetically lowest configuration in each type belonging to the *gerade* representation of the D_{6h} point group. The explicit formulas of these functions are listed in Ref. 6.

This CI calculation yielded energy depressions of −0.529—−0.550 eV, depending on the approximations for β_{kl} and which case was used, I or II. Table 1 shows the bond lengths and π-bond orders calculated with and without the CI for the ground state of coronene. Bonds a, b, c, and d are illustrated in Fig. 1. It may be seen from the table that in Case II the bond orders obtained from the CI calculation are little different from those obtained without CI, with the largest difference being about 0.005 at bond d, while in Case I the differences between the bond orders computed with and without CI are quite large, being 0.017—0.043. In

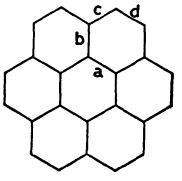

Fig. 1. Carbon skeleton of coronene.

TABLE 1. BOND LENGTHS (Å) AND π-BOND ORDERS OF THE GROUND-STATE CORONENE[a]

Bond	Approximation (1)			Approximation (2)			Exptl.
	No CI	Case I	Case II	No CI	Case I	Case II	
a	1.425	1.430	1.425	1.424	1.428	1.424	1.432
	(0.5097)	(0.4802)	(0.5092)	(0.5155)	(0.4922)	(0.5148)	
b	1.414	1.406	1.415	1.416	1.410	1.417	1.407
	(0.5655)	(0.6086)	(0.5609)	(0.5529)	(0.5867)	(0.5491)	
c	1.423	1.428	1.423	1.421	1.425	1.421	1.430
	(0.5175)	(0.4920)	(0.5182)	(0.5265)	(0.5066)	(0.5268)	
d	1.375	1.370	1.376	1.377	1.373	1.378	1.354
	(0.7689)	(0.7908)	(0.7635)	(0.7590)	(0.7762)	(0.7537)	

a) The "no CI" refers to the calculation with the ground configuration alone. The values in parentheses are the π-bond orders. The experimental values are averaged from the X-ray[7] and electron-diffraction[8] data.

Case I, the a and c bonds are lengthened, while the b and d bonds are contracted, because of CI. Thus, the CI effect on the bond orders in the ground state of coronene is significant only when the full Eq. 2 is employed, indicating that the off-diagonal terms are not necessarily negligible. The bond lengths predicted from the CI mixing in Case I are in good agreement with the experimental values except for the case of bond d. The bond lengths obtained without CI agree closely with the results obtained by Golebiewski[9] from the perturbed Hückel method.

Further, we have made several CI calculations including larger numbers of doubly-excited configurations (10—26 more functions), but without triply-excited configurations. The results were, however, not very different from those presented here; the differences in bond orders were, for all the bonds, less than 0.005 in Case I and less than 0.001 in Case II.

One of the present authors (Nakayama) is grateful to Dr. Tai-ichi Shibuya of Shinshu University for his helpful discussions. Thanks are also due to the referee for making valuable suggestions. The calculations were carried out on the TOSBAC-5600 Computer at the University of Tsukuba. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Singlet-excitation-energy Migration in an Amorphous-state Film of 1,3-Di(9-carbazolyl)propane

Akira ITAYA,* Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received May 1, 1979)

Synopsis. The singlet-excitation-energy migration in an amorphous film of 1,3-di(9-carbazolyl)propane(DCzP(a)) was studied by means of a fluorescene-quenching experiment. The results were compared with those of amorphous poly-(9-vinylcarbazole)(PVCz) and poly[2-(9-carbazolyl)ethyl vinyl ether](PCzEVE) films. The numbers of carbazolyl chromophores covered by a singlet exciton during the lifetime were in the following order: DCzP(a)>PCzEVE>PVCz.

1,3-Di(9-carbazolyl)propane (DCzP) is known as a dimeric model compound of poly(9-vinylcarbazole) (PVCz), which has received considerable interest in recent years in connection with the highly photoconductive vinyl polymers. DCzP forms an amorphous state by the fast evaporation of the solvent.[1] It is important to investigate singlet exciton migration in a DCzP(a) film and to compare it with that in a PVCz film, because the efficiency of the singlet exciton migration in a vinyl polymer is known as one of the factors determining whether or not the polymer has a large photoconductivity.

A few investigations have been carried out to ascertain how the efficiency of the singlet exciton migration changes when going from a crystalline to an amorphous state.[2] However, a comparison of the optical properties of an amorphous film of a model compound with the optical properties of an amorphous film of a corresponding vinyl polymer has not hitherto been performed.

In a previous paper,[1] the absorption and fluorescence spectra of a DCzP(a) film were investigated and compared with those of polycrystalline DCzP(DCzP(c)) and amorphous PVCz films. In the present work, the migration of the singlet excitation energy in a DCzP(a) film has been investigated in comparison with that of an amorphous PVCz film.

Experimental

The model compound (DCzP) and polymers (PVCz and poly[2-(9-carbazolyl)ethyl vinyl ether](PCzEVE)) were the same as those used before.[1,3] The dimethyl terephthalate (DMTP)and perylene were recrystallized twice from benzene and *p*-bis(trichloromethyl)benzene (TCB) from hexane. Subsequently, they were sublimed *in vacuo*. The DCzP(a) and polymer films were cast onto quartz or Pyrex-glass plates from a benzene solution. The fluorescence spectra were observed by front-surface excitation with the apparatus described in a previous paper.[4]

Results and Discussion

In a previous paper[1] we reported that the fluorescence spectrum of a DCzP(a) film seems to be composed of three components, monomer-like, second excimer ($\tilde{\nu}_{max}$: *ca.* 26700 cm^{-1}), and sandwich-like excimer ($\tilde{\nu}_{max}$: 23900 cm^{-1}) fluorescences, while a DCzP(c) film seems to show the monomer-like and second excimer fluorescences.

The presence of the second excimer and monomer fluorescences was supported also by the investigation of the temperature dependence of the fluorescence spectrum of a DCzP(a) film. As is shown in Fig. 1, the intensity of the second excimer fluorescence of a PVCz film increased with a decrease in the temperature, showing that the second excimer site is a shallow trap and acts more effectively as a trap at low temperatures. This is consistent with the results obtained by the investigation of the excitation-energy-migration.[4] The temperature dependence of the fluorescence spectrum of a DCzP(a) film was similar to that of a PVCz film, as is shown in Fig. 2. In the case of a DCzP(a) film, the structure band in the shorter-wavelength region, which appears with an increase in the temperature, is the monomer fluorescence, which increases with a decrease in the concentration of the trap sites.

By the doping of perylene, TCB, and DMTP, the host fluorescence decreased. The fluorescence spectra of DCzP(a) films doped with various concentrations of DMTP are shown in Fig. 3. The fluorescence in the longer-wavelength region ($\tilde{\nu}_{max}$: 21620 cm^{-1}) is attributable to the exciplex formed between DMTP and an excited Cz chromophore. The dipole-dipole resonance cannot be responsible for the energy transfer to TCB and DMTP, because these guest molecules have no absorption in the wavelength region where the fluores-

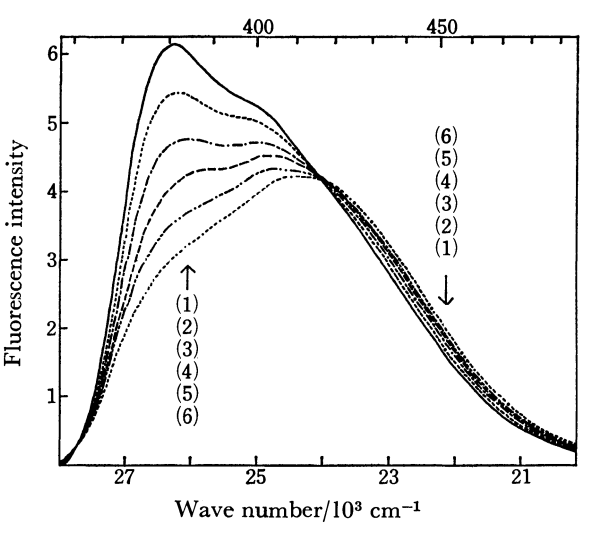

Fig. 1. Temperature dependence of the fluorescence spectra of a PVCz film. Excitation wavelength; 330 nm. (1) 121 K, (2) 140 K, (3) 163 K, (4) 187 K, (5) 210 K, and (6) 234 K.

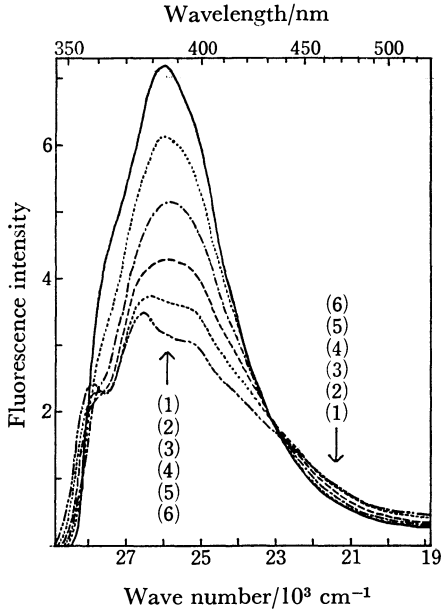

Fig. 2. Temperature dependence of the fluorescence spectra of a DCzP(a) film. Excitation wavelength; 330 nm. (1) 129 K, (2) 144 K, (3) 163 K, (4) 192 K, (5) 213 K, and (6) 236 K.

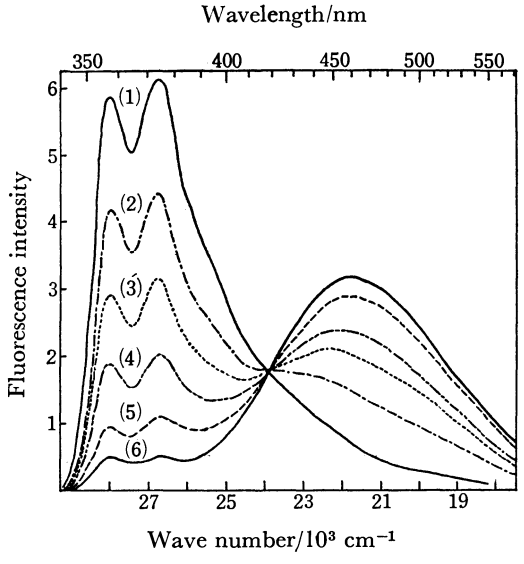

Fig. 3. Fluorescence spectra of DCzP(a) films doped with DMTP at room temperature. Excitation wavelength; 335 nm. DMTP concentration; (1) 0, (2) 3.54×10^{-4}, (3) 8.85×10^{-4}, (4) 1.80×10^{-3}, (5) 3.02×10^{-3}, and (6) 8.85×10^{-3} (mol/mol basic unit).

cense of the host film is observed. Therefore, the random-hopping model of monomer-exciton migration, in which both the intrinsic trap site and the guest molecule act competitively as exciton traps, is applicable. Then, the quenching factor of the host fluorescence, Q_H, is expressed by the following equation:[4,5]

$$Q_H = (\eta_{H0}-\eta_H)/\eta_H = nc/(1+nc_T) = n'c, \qquad (1)$$

where η_{H0} and η_H are the quantum efficiencies of the host fluorescence in the absence and in the presence of the guest molecule in a concentration of c (mol/mol basic unit); n and n' are the numbers of Cz chromophores covered by an exciton during the lifetime in the absence and in the presence of the intrinsic trap sites (second and sandwich-like excimer sites) in a concentration of c_T (mol/mol basic unit). The quenching factor of monomer fluorescence, Q_M, is expressed by

$$Q_M = nc_T. \qquad (2)$$

The bilogarithmic plots of Q_H and c gave a straight line with a slope of 1.0. The values of n' were obtained from the lines according to Eq. 1; they are listed in Table 1. The value of n' is dependent on the guest molecule. In the case of perylene, an energy migration with a subsequent long-range energy transfer seems to be observed.[6] This is why the value of n' for perylene is larger than those for the others.

In the case of polymer film, where no monomer fluorescence was observed, $Q_M \gg 1$, as has previously been reported.[4,5] Therefore, $Q_H = c/c_T$. Then, $c_T = 1/n'$. Although Q_M could not be obtained for a DCzP(a) film, the value of c_T for the film seems to be smaller than $1/n'$. The values of c_T are also listed in Table 1.

Table 1. Energy transefr by the exciton-diffusion process

No.	Host	Guest	n'	$c_T\times10^3$ (mol/mol basic unit)
1	PVCz	Perylene	1200	0.83
2	PCzEVE	Perylene	3700	0.27
3	DCzP(a)	Perylene	5900	<0.17
4	PVCz	TCB	690	1.4
5	PCzEVE	TCB	2000	0.50
6	DCzP(a)	TCB	3600	<0.28
7	PVCz	DMTP	420	2.4
8	PCzEVE	DMTP	2900	0.34
9	DCzP(a)	DMTP	1300	<0.77

Concerning amorphous films, the value of c_T increases in the following order, irrespective of the guest molecule, except for PCzEVE film doped with DMTP: DCzP(a)< PCzEVE<PVCz. That is, the concentration of the trap sites for a DCzP(a) film is smaller than that for a PVCz film and that for a PCzEVE film, where it is difficult for Cz chromophores to form the intrinsic trap sites because of the large distance between neighboring Cz chromophores. This suggests that the excimer sites in a polymer film are formed with greater ease than the excimer sites in an amorphous film of the model compound, even if Cz chromophores are widely spaced on the skeletal chain.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (12), 3739—3740 (1979)

Syntheses and Electrical Properties of α,α,α',α'-Tetracyanodiphenoquinodimethane Complexes

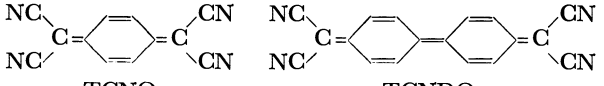
Minoru MORINAGA, Takashi NOGAMI,* and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 2, 1979)

Synopsis. Two charge-transfer complexes of α,α,α',α'-tetracyanodiphenoquinodimethane (TCNDQ), *i.e.*, *N*-methylphenazinium (NMP)–TCNDQ and *N*-methylquinolinium (NMQ)–TCNDQ, were synthesized. The electrical resistivities with pressed pellet samples were 7.1×10^{8} Ω cm for NMP^{+}-$TCNDQ^{-}$ and 6.9×10^{7} Ω cm for $NMQ^{+}TCNDQ^{-}$; they are thus much less conductive than the corresponding TCNQ complexes.

Great attention has been paid to the high electrical conductivities of tetracyanoquinodimethane (TCNQ) complexes.[1] The highly conductive properties of TCNQ complexes were analysed by means of the Hubbard model.[2] It was suggested that a large transfer integral (t) and a small Coulomb repulsion energy (U_{eff}) are needed for high conductivity. The large t is realized by the large overlap of the π-electron cloud between adjacent TCNQ anion radicals, and the small U_{eff} by the distant location of cyano groups in TCNQ and also by the polarization stabilization caused by the donor cation.

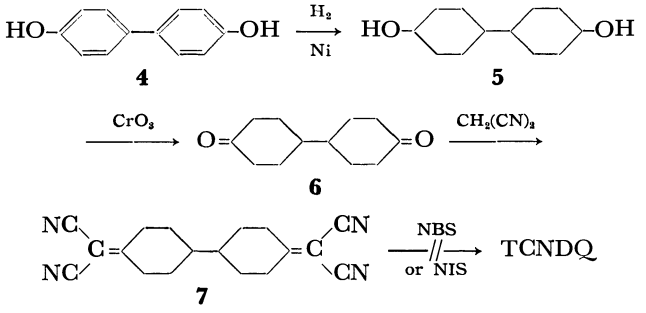


TCNQ TCNDQ

The separation of cyano groups in tetracyanodiphenoquinodimethane (TCNDQ) is greater than in TCNQ, thereby possibly resulting in a smaller U_{eff} than in TCNQ. Thus, the TCNDQ complexes are expected to be good candidates for highly conductive organic materials. However, no electrical property is known for TCNDQ.[3] We have synthesized two complexes, *N*-methylphenazinium (NMP)–TCNDQ and *N*-methylquinolium (NMQ)–TCNDQ, and measured their electrical resistivities, electronic absorption spectra, and ESR spectra.

Results and Discussion

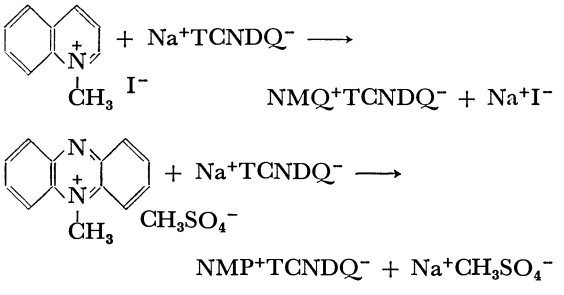
Synthesis of $Na^{+}TCNDQ^{-}$. $Na^{+}TCNDQ^{-}$ has usually been synthesized through several step-reactions starting from 4,4'-bis(bromomethyl)biphenyl (**1**).[3] However, the yield of **1** was low (4%),[4] thus limiting the total yield of $Na^{+}TCNDQ^{-}$. On the other hand, the yield of 4,4'-bis(chloromethyl)biphenyl (**2**)[5] was much higher (60%).[4] We succeeded in obtaining 4,4'-bis(cyanomethyl)biphenyl (**3**) (the second step material for the synthesis of $Na^{+}TCNDQ^{-}$) from **2** (50% yield). Thus, **2** should be used as a starting material for the synthesis of $Na^{+}TCNDQ^{-}$. We also tried another route for the synthesis of TCNDQ:



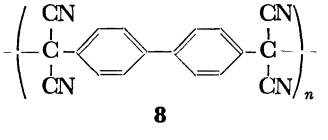
4 **5** **6** **7**

However, the attempted dehydrogenation of 4,4'-bis(dicyanomethylene)-1,1'-bicyclohexane (**7**) by *N*-bromosuccinimide (NBS) or *N*-iodosuccinimide (NIS) was unsuccessful, recovering only **7**.

Syntheses of $NMP^{+}TCNDQ^{-}$ and $NMQ^{+}TCNDQ^{-}$ Complexes. We have succeeded in obtaining $NMP^{+}TCNDQ^{-}$ and $NMQ^{+}TCNDQ^{-}$ by the following ion-exchange reactions:



We also tried other ion-exchange reactions of several systems, *i.e.*, the tetrabutylammonium iodide–$Na^{+}TCNDQ^{-}$, quinolinium iodide–$Na^{+}TCNDQ^{-}$, and *N,N,N',N'*-tetramethylbenzidinebromide–$Na^{+}TCNDQ^{-}$ systems. However, all these systems gave polymer **8**:



8

The attempt to obtain the complex salt $Na^{+}TCNDQ^{-}$-TCNQ by mixing the methanol solutions of $Na^{+}TCNDQ^{-}$ and TCNQ also gave polymer **8**.

Table 1. Electrical resistivities of the pressed pellet samples of TCNDQ and TCNQ complexes

	TCNDQ[a]	TCNQ[a]
Na	3.3×10^{3} [b]	3.0×10^{4} [d]
NMP	7.1×10^{8}	5.0×10^{-1} [c]
NMQ	6.9×10^{7}	1.0×10^{7} [d]

a) Ω cm. b) Ref. 3. c) Ref. 10. d) Ref. 11.

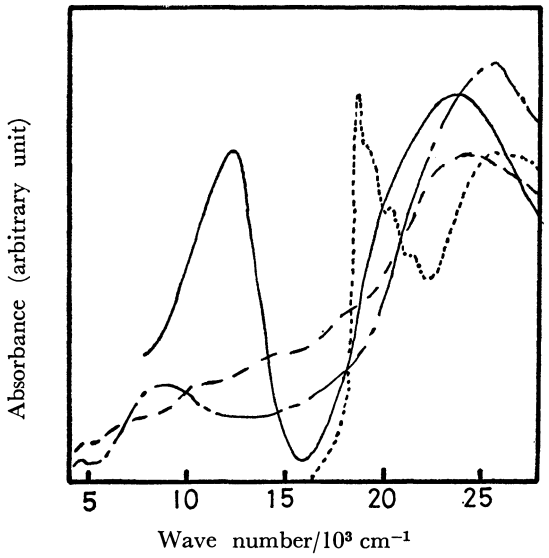


Fig. 1. Electronic absorption spectra of TCNDQ complexes. ·····Na⁺TCNDQ⁻ (in acetonitrile solution); ——Na⁺TCNDQ⁻ (KBr); —·—NMP⁺TCNDQ⁻ (KBr); – – – –NMQ⁺TCNDQ⁻ (KBr).

Properties of NMP⁺TCNDQ⁻ and NMQ⁺TCNDQ⁻ Complexes. Table 1 shows the electrical resistivities of the pressed pellet samples of Na⁺TCNDQ⁻, NMP⁺TCNDQ⁻, and NMQ⁺TCNDQ⁻, together with those of the TCNQ complexes for the sake of comparison. Na⁺TCNDQ⁻ is one order of magnitude more conductive than Na⁺TCNQ⁻. However, NMP⁺TCNDQ⁻ and NMQ⁺TCNDQ⁻ are much less conductive than the corresponding TCNQ complexes. Although we have no crystallographic data of TCNDQ complexes, one possibility is that the six-membered rings in TCNDQ may not be co-planar, thus leading to the poor conductivity.

The electronic absorption spectra of Na⁺TCNDQ⁻, NMP⁺TCNDQ⁻, and NMQ⁺TCNDQ⁻, as measured by the KBr disk method, are shown in Fig. 1. The spectrum of Na⁺TCNDQ⁻ in an acetonitrile solution is also shown in this figure. The solid-state spectrum of Na⁺TCNDQ⁻ shows a broad absorption band peaking at 23.5×10^3 cm^{-1} possibly ascribable to the local excitation band of TCNDQ⁻. The 12000 cm^{-1} band may be a charge-transfer band between adjacent TCNDQ anion radicals in the crystal. Thus, the interaction between TCNDQ anion radicals in Na⁺TCNDQ⁻ is expected to be large, suggesting the stacking structure of the anion site. NMP⁺TCNDQ⁻ and NMQ⁺TCNDQ⁻ also have two absorption bands in the IR and VIS regions, although in the latter spectrum the peak position of the lower energy band is not clear.

The ESR spectra of the powdered Na⁺TCNDQ⁻, NMP⁺TCNDQ⁻ and NMQ⁺TCNDQ⁻ showed strong single-line signals, with *g*-values of 2.003.

Experimental

Measurements. The electrical resistivity of the compaction sample was measured by means of a Takeda-Riken 8651 electrometer. The details of the measurements have been described before.[6] The electronic absorption spectra were measured by means of a Shimadzu MPS 50 L apparatus. The ESR spectra were measured by means of a Japan Electric Optics Laboratory Co., Ltd., JES-ME 2X apparatus.

Materials. *4,4′-Bis(cyanomethyl)biphenyl (3)*: The title compound was synthesized by the same procedure as that used in the synthesis of 1,4-bis(cyanomethyl)-2,5-diisopropylbenzene.[7]

4,4′-Bis(dicyanomethylene)-1,1′-bicyclohexane (7): The starting material, 1,1′-bicyclohexane-4,4′-dione was synthesized according to the literature.[8] 1,1′-Bicyclohexane-4,4′-dione (6 g), malononitrile (11.5 g), ammonium acetate (0.8 g), and acetic acid (2.4 ml) were added to benzene (80 ml) in a reaction vessel, and then the mixture was refluxed using a water separator until no water came out. The precipitate was collected, washed several times with water, and finally washed with ethyl acetate. The white powder product was dried under a vacuum to obtain 4,4′-bis(dicyanomethylene)-1,1′-bicyclohexane (**7**) (6 g, 67%); mp 229—231 °C; Found: C, 74.55; H, 6.17; N, 19.29%. Calcd for $C_{18}H_{18}N_4$: C, 74.49; H, 6.20; N, 19.31%. IR (KBr) 2200 (C≡N), 1580 cm^{-1} (C=C).

NMP⁺TCNDQ⁻ and NMQ⁺TCNDQ⁻. Na⁺TCNDQ⁻ (100 mg)[3] was dissolved in methanol (100 ml), and the solution was filtered. To the filtrate we then added a methanol solution of *N*-methylphenazinium methylsulfate or *N*-methylquinolinium iodide (50% excess molar ratio) from the dropping funnel under a nitrogen atmosphere and at the room temperature. The solution was then stirred for an additional 2 h under a nitrogen atmosphere. The precipitate (powder) was collected and washed with diethyl ether. NMP⁺TCNDQ⁻: Found:[9] C, 76.32; H, 3.85; N, 17.15%. Calcd for $C_{31}H_{19}N_6$: C, 78.32; H, 4.00; N, 17.68%. NMQ⁺TCNDQ⁻: Found:[9] C, 78.04; H, 4.22; N, 16.51%. Calcd for $C_{28}H_{18}N_5$: C, 79.25; H, 4.25; N, 16.13%.

(Received July 2, 1979)

Synopsis. In a TEA CO_2 laser-induced reaction of 1,1-dichloroethane, the relative quantities of the products, C_2H_2 and $ClHC{=}CH_2$, were found to vary with the laser wavelength, indicating that the C_2H_2 molecules are produced by two processes, directly and indirectly from $Cl_2HC{-}CH_3$ within the duration of a single laser pulse.

There have been a number of investigations demonstrating that infrared laser-induced reactions differ from thermal reactions. However, their reaction processes and mechanisms have not been elucidated. In a previous paper, we reported on TEA CO_2 laser-induced photoreactions of chloroethylene and chlorinated ethanes.[1] The experimental results for chlorinated ethanes have shown that rather larger amounts of acetylene than their thermal reaction products were obtained in addition to the major product of ethylene or chloroethylene. The acetylene may be produced by the following two processes, the direct process and the indirect 2-step process:

(a) The C_2H_2 molecules are directly produced from the ethane derivative by the irradiation of a single laser pulse.

(b) In the first process of the reaction, C_2H_4 or its chlorine derivative is produced; a subsequent infrared laser reaction of those molecules gives rise to the production of the C_2H_2 molecule.

In the previous study, no quantitative discussions of these reaction processes were made. Since the $Cl_2HC{-}CH_3$ molecule has infrared absorptions at the wavelengths of four regions of the CO_2 laser, *i.e.*, at P and R branches of both the 9.4 μm and 10.4 μm bands, their wavelengths are 9.6 μm, 9.3 μm, 10.6 μm, and 10.2 μm respectively. The irradiation of one of these lasers gives rise to the production of C_2H_3Cl and C_2H_2 in various concentrations. The TEA CO_2 laser-induced reaction of chlorine derivatives of hydrocarbons gives rise to the elimination of HCl from those molecules, and C_2H_3Cl molecules may be produced in the first stage of the present experiment. As the reaction product, C_2H_3Cl, has no absorption at the wavelength of 9.3 μm, the C_2H_2 molecule must be produced by the direct process in the 9.3 μm laser-induced reaction.

Recently we have made an analysis of the infrared laser-induced multiphoton dissociation of C_2F_3Cl by the phenomenological model calculation based on the Rice-Ramsberger-Kassel-Marcus statistical theory for unimolecular dissociation.[2] We thus confirmed that the observed results were in good agreement with the calculation. Together with the theoretical analysis of the infrared multiphoton dissociation of the SF_6 molecule by Grant *et al.*,[3] our analysis of the reaction of C_2F_3Cl can help to understand the reaction mechanism of the infrared photochemistry of $Cl_2HC{-}CH_3$.

For a detailed analysis of the reaction mechanism, we have observed the relative yields of the reaction products of C_2H_3Cl and C_2H_2 by the irradiation of various CO_2 laser lines; the analysis of the results enable us to understand the process of the production of C_2H_2.

The TEA CO_2 laser used in the present experiment was described in a previous paper.[1] The power output was about 1 J, with a pulse duration of 100 ns, its repetition rate being almost 1 Hz. For a selective oscillation of the appropriate line among the P and R branches of the 9.4 μm or 10.4 μm band, SF_6 or C_2H_3Cl gas of various pressures was introduced into a small cell in the laser cavity. A reaction cell was 50 mm in length and 20 mm in diameter. The sample gas in the reaction cell was irradiated by the laser pulse focused with a germanium lens of $f=5$ cm. The peak power of the laser at the focus was 1 GW/cm^2 when the laser of 1 J was used. The pressure of the sample gas was 10 Torr.

The relative amounts of the products obtained by the infrared photoreaction induced by the various branches of the CO_2 laser with the same power output of 500 mJ are listed in Table 1. The experimental results for the P branch of 10.4 μm band is not shown here, because the absorption at the wavelength of this region is weak for this molecule, and hence the yield of the reaction is relatively small.

The total amounts of the products, C_2H_3Cl and C_2H_2, depend upon the laser line used in the reaction, the yield being greatest for the 9.6 μm laser and least for the 9.3 μm laser; the ratio of the yields is 48: 100: 22 for the 10.2 μm, 9.6 μm, and 9.3 μm lasers respectively.

The ratio of the C_2H_3Cl to the C_2H_2 were determined to be 55: 45, 72: 28, and 80: 20 respectively in the products of 10.2 μm, 9.6 μm, and 9.3 μm laser reactions. As was described above, the productions of the C_2H_2

Table 1. Relative quantities of molecules produced by the infrared photoreactions of $Cl_2HC{-}CH_3$ induced by various branches of the CO_2 laser

Laser wavelength	10.2 μm	9.6 μm	9.3 μm
Relative quantities of products	48	100	22
% of products			
C_2H_3Cl	55	72	80
C_2H_2	45	28	20
% of C_2H_2 produced by			
(1) direct process	20	20	20
(2) 2-step process	25	8	0

molecules in the present experiment can be brought about by the two processes, the direct and indirect ones. It is appropriate to define the present classification of the reaction more rigidly. The infrared laser action gives rise to the cleavage of the C–Cl bond, producing the $ClHC–CH_3$ radical in an quasicontinuum state when the vibrational quantum number, v, is larger than 3. The interaction between Cl and the $ClHC–CH_3$ radicals eliminates the H atom from the latter, resulting in the production of the $ClHC{=}CH_2$ molecule in various vibrational states. The $ClHC{=}CH_2$ molecules in the quasicontinuum state can absorb infrared lasers of any frequency. Though the $ClHC{=}CH_2$ molecules in the ground state have no absorption at the 9.3 μm line of the CO_2 laser, the molecule in the quasicontinuum state absorb its infrared laser. Hence, if the laser field is still present for a sufficiently long time after the formation of the $ClHC{=}CH_2$ molecule in the quasicontinuum state, these molecules can readily absorb additional photons and the subsequent reaction may occur, producing the C_2H_2 molecule. The reaction process presented here is the direct production of the C_2H_2.

On the other hand, the indirect process is defined as the 2-step reaction in which the C_2H_3Cl molecules in the vibrational ground state or the discrete vibrational level (generally its vibrational quantum number $v<3$) are produced at the first stage of the reaction, and the successive absorption of the laser by C_2H_3Cl molecules gives rise to the reaction of these molecules. However, in the 9.3 μm laser-induced reaction of $Cl_2HC–CH_3$, the indirect process is prohibited, because the C_2H_3Cl molecule in the ground state or in the discrete levels (lower vibrational state) cannot absorb the 9.3 μm laser radiation. It is suggested, therefore, that all of the C_2H_2 molecules, 20% of the products, were produced directly from $Cl_2HC–CH_3$ when the 9.3 μm laser was used.

For the laser reaction of the 10.2 μm or 9.6 μm line, the rates of the C_2H_2 in the total amount of the products were 45% and 28% respectively. If we assume that the direct process in the 10.2 μm or 9.6 μm laser-induced reaction produces the same rate of the C_2H_2 as in the reaction of the 9.3 μm laser, the differences in the proportions of C_2H_2 between the reactions induced by the former lasers and the latter, (45—20)% and (28—20)%, are the proportions of the indirectly produced C_2H_2 by the 10.2 μm and 9.6 μm lasers respectively. The ratio of the amounts of C_2H_2 produced by the 2-step process with the 10.2 μm laser and that of the 9.6 μm laser is 0.25/0.08=3.1, while the ratio of the amounts of C_2H_2 produced from C_2H_3Cl by the 10.2 μm laser and the one produced by the 9.6 μm laser irradiation was 2.8. These values are almost equal, supporting our assumption presented here.

The relative concentrations of the C_2H_3Cl and C_2H_2 products were unaffected even when the repetition rates of the laser pulse were varied from 1 Hz to 0.1 Hz. In the latest repetition of the laser, the time interval of the two pulses is 10 s; therefore, the molecules, which have been dissociated by the first pulse at around the focus of the lens, may diffuse from this region before the second pulse is irradiated. This indicates that the 2-step reaction, $Cl_2HC–CH_3 \rightarrow ClHC{=}CH_2 \rightarrow C_2H_2$, may occur within a very short duration of 100 ns of the single laser pulse.

The conclusion derived above is supported by the theoretical analysis of the multiphoton dissociation, which has recently been applied to the 9.4 μm laser-induced chemical reaction of C_2F_3Cl. Our model calculation of the infrared photochemistry of C_2F_3Cl showed that if the rectangular pulse of 500 mJ with a 100 ns duration was employed, the following results were obtained:

1) Almost 80% of the molecules dissociate within 50 ns.

2) The decomposed molecules or radicals have excess energy in the range of $v=8$—16, the maximum distribution being in $v=12$. The average energy distribution in these molecules or radicals depends on the power output of the exciting laser.

These results have been obtained from the model calculation of the reaction yield for the 9.4 μm laser-induced photodissociation of C_2F_3Cl. It should be mentioned that the qualitative aspect of the infrared multiphoton reaction of any molecule can be deduced from the consideration presented here. The experimental results of the TEA CO_2 laser-induced reaction of $Cl_2HC–CH_3$ suggest that its reaction process is similar to that of C_2F_3Cl.

It may be concluded that the C_2H_2 molecules, 20% of the total products of the CO_2 laser-induced photochemistry of $Cl_2HC–CH_3$, are directly produced from the parent molecule, another part of the C_2H_2 being produced by the 2-step process within the time duration of the single laser pulse.

This research was supported partly by a Grant-in-Aid from the Ministry of Education, Science, and Culture.

(Received July 3, 1979)

Synopsis. ESR or ENDOR spectra were observed for the 2,6-di-*t*-butyl-4-methyl-, 4-ethyl-, 4-isopropyl-, and 4-cyclohexylphenoxyl radicals. From the analyses of the temperature dependence in β-proton splittings, the energy barriers to internal rotation of the alkyl group were estimated.

For a number of aromatic radicals, the restricted rotation of an alkyl group has been extensively studied by using ESR spectroscopy[1] and the rotational barrier of an alkyl group has been estimated based on the statistical procedure of observed β-proton splitting and its temperature dependence, in terms of the $\cos^2\theta$ rule.[2]

In previous papers,[3] the hindered rotation of the alkyl groups in the 4,4′-dialkybiphenyl anions was studied in detail. One interesting view is the fact that the secondary alkyl groups are likely to undergo a restricted rotation in a double-well potential function. In this work, the hindered internal rotation of the alkyl groups in the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals was studied in order to affirm the validity of applying the ESR approach to the study on the restricted rotation of an alkyl group. The results obtained have been compared with those for the 4,4′-dialkylbiphenyl anions previously studied.[3]

Experimental

General. The melting points and boiling point are uncorrected. The ESR and ENDOR spectra were recorded by JEOL-ME-3X and JEOL-EDX-1 spectrometers respectively. The operating conditions were similar to those described elsewhere.[4]

Materials. The 2,6-di-*t*-butyl-4-methylphenol is commercially available. The other 2,6-di-*t*-butyl-4-alkylphenols were prepared by the method previously described.[5] 2,6-Di-*t*-butyl-4-ethylphenol: bp 105—110 °C/5 Torr (lit,[5] 135—138 °C/10 Torr), 2,6-di-*t*-butyl-4-isopropylphenol: mp 38.0—38.5 °C (lit,[6] 38—42 °C), 2,6-di-*t*-butyl-4-cyclohexylphenol: mp 97.0—98.2 °C (lit,[5] 98—99 °C).

Each phenoxyl radical was prepared *in vacuo* by the oxidation of the phenol with lead dioxide in toluene.

Computations. The numerical computations were carried out on the HITAC 8700 system in the Hiroshima University Computing Center.

Results and Discussion

The ESR spectra of the 2,6-di-*t*-butyl-4-methylphenoxyl (Radical-I),[7] 2,6-di-*t*-butyl-4-ethylphenoxyl (Radical-II),[7] 2,6-di-*t*-butyl-4-isopropylphenoxyl (Radical-III),[8] and 2,6-di-*t*-butyl-4-cyclohexylphenoxyl (Radical-IV)[9] radicals were observed. The ENDOR spectra of III and IV were measured in the temperature range from −100 °C to −60 °C.

The proton hyperfine coupling constants of these radicals, measured under the identical conditions, are summarized in Table 1. The alkyl β-proton splitting (A_4^β) of each radical was precisely measured as a function of the temperature. The β-proton splittings for II, III, and IV show a large temperature dependence (see Fig. 1). In addition, the experimental results indicate that both $A_2^{t\text{-Bu}}$ and A_3^H remain almost unchanged upon the variation of the temperature and that no important deviations of these coupling constants can be detected for these radicals.

As has been explained in detail in previous works,[3] the β-proton splitting at any temperature was calculated by using following equations:[10]

$$A_4^\beta = B\rho_4^\pi\langle\cos^2\theta\rangle \qquad \theta = \alpha + \theta_0 \tag{1}$$

Table 1. Proton hyperfine coupling constants of the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals (G)

Alkyl		$A_2^{t\text{-Bu}}$	A_3^H	A_4^γ	A_4^β
Methyl[a]	ESR	—	1.63	—	11.22
Ethyl	ESR	0.06	1.60	—	8.21
Isopropyl	ENDOR	0.07	1.66	0.38	4.05
Cyclohexyl	ENDOR	0.08	1.60	0.60,0.47	4.09

The observed temperature is −60 °C. a) At −45 °C.

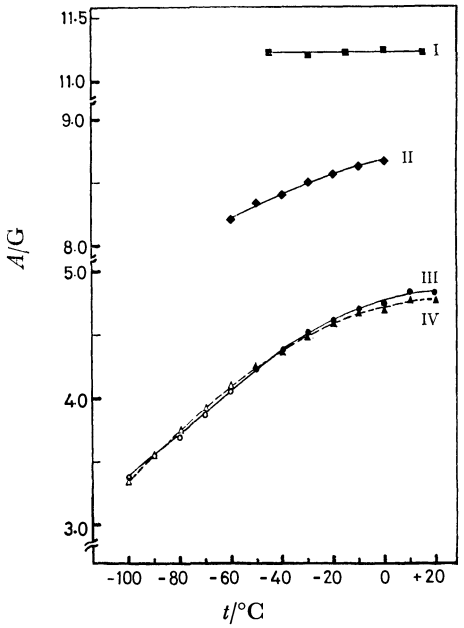

Fig. 1. Temperature dependence of the β-proton splittings observed with the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals. I: Methyl, II: ethyl, III: isopropyl, IV: cyclohexyl.

■,◆,●,▲; ESR data, ○,△; ENDOR data.

$$\langle\cos^2\theta\rangle = \frac{\sum_{i=0}^{\infty}\langle\psi_i(\alpha)|\cos^2(\alpha+\theta_0)|\psi_i(\alpha)\rangle e^{-E_i/kT}}{\sum_{i=0}^{\infty}e^{-E_i/kT}} \quad (2)$$

$$-(\hbar^2/2I)(d^2\psi_i/d\alpha^2) + [V(\alpha) - E_i]\psi_i = 0 \quad (3)$$

where ρ_4^π is the spin density at the *p*-position and where θ is the so-called dihedral angle. The value of $B\rho_4^\pi$ was estimated to be 2×11.20 G from the methyl proton splitting of I. A free rotation is assumed for the methyl group, because the methyl proton splitting shows no detectable change throughout the entire temperature range. The moment of inertia, I, of the molecular fragment, Ar-R, can be calculated to be 5.0, 8.8, and 17 ($\times10^{-39}$) g cm^2 for II, III, and IV respectively.

With reference to the rotational functions of the alkyl groups for the 4,4′-dialkylbiphenyl anions,[3] where the steric factor affecting the rotating alkyl groups would be identical with those considered for the alkylphenoxyl radicals, the potential barrier, $V(\alpha)$, of each alkylphenoxyl has been assumed as follows. For the ethyl group, the potential function, $V(\alpha)$, is approximately the two-fold potential (Eq. 4), and for the isopropyl and cyclohexyl groups, with a double-well potential, wherein one of the minima lies higher in energy (Eq. 5):

$$V(\alpha) = (V_0/2)((1 - \cos 2\alpha) \quad (4)$$

$$V(\alpha) = V_0\sum_{i=0}^{3}a_i\cos 2i\alpha \quad (5)$$

$$a_0 = (1/18)(9V_m/V_0+4) \qquad a_1 = -4/9$$

$$a_2 = -2/9 \qquad a_3 = (1/18)(8 - 9V_m/V_0)$$

In Eq. 4, V_0 is the energy difference between the lowest potential state (a) and the highest one (b), as displayed in Fig. 2. In Eq. 5, V_0 and V_m are the energy differences between the lowest potential at state (c) and the highest one at state (d), and between the lowest one at state (c) and the medium one at state (e), respectively, as is illustrated in Fig. 2. At the most stable conformation, each of the equilibrium dihedral angles, θ_0, is equal to $\pi/3$, $\pi/2$, and $\pi/2$ for II, III, and IV respectively (see Fig. 2). The Hamiltonian matrix $\langle i|\mathcal{H}|j\rangle$ was diagonalized by expanding the wave function into a Fourier series.

We have calculated the temperature dependence of the $\langle\cos^2\theta\rangle$ as a function of the potential barriers, V_0 and V_m, for these radicals. The best agreement

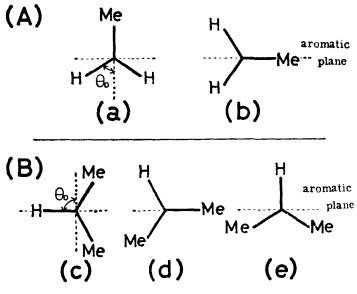

Fig. 2. Conformations of the alkyl groups in the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals.
A: Ethyl, B: isopropyl, and cyclohexyl.

Table 2. The values of rotational barriers for the 2,6-di-*t*-butyl-4-alkylphenoxyl and 4,4′-dialkylbiphenyl anion radicals (kcal/mol)

	Alkyl	$\langle\cos^2\theta\rangle$	V_0	V_m
Phenoxyl	ethyl	0.37 (at −60 °C)	1.1	—
	isopropyl	0.18 (at −60 °C)	1.6	0.7
	cyclohexyl	0.18 (at −60 °C)	1.6	0.7
Biphenyl anion	ethyl	0.36 (at −90 °C)	1.0	—
	isopropyl	0.21 (at −85 °C)	1.2	0.5
	cyclohexyl	0.20 (at −85 °C)	1.2	0.6
Non-bonded interaction energy[3]	ethyl	—	1.3	—
	isopropyl	—	1.4	0.7

between the calculated and experimental temperature dependences of $\langle\cos^2\theta\rangle$ is obtained with the choice of $V_0=1.1$, $V_0=1.6$, $V_m=0.7$, $V_0=1.6$, and $V_m=0.7$ kcal/mol as the parameters for II, III, and IV respectively. Thus, each potential barrier obtained for the phenoxyl radicals coincides with the one for the 4,4′-dialkylbiphenyl anions, furthermore, these values agree with those obtained from the calculation of the non-bonded interaction between the rotating alkyl group and the aromatic protons[3] (see Table 2).

From the above results, we concluded that the ethyl group attached to the benzene ring may undergo a restricted rotation in the two-fold potential, which has a barrier height of 1.0—1.2 kcal/mol, and that the rotation of isopropyl and cyclohexyl groups restricted in a double-well potential, which has, as potential barrier heights, $V_0=1.2$—1.6 and $V_m=0.6$—0.7 kcal/mol. These results, furthermore, suggest that the rotational barrier of the alkyl group is mainly due to the steric repulsion between the rotating alkyl group and the neighbouring aromatic ring protons in the case of both anion and neutral free radicals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (12), 3745—3746 (1979)

Reduction of Transition-metal Salts by *N*-Propyl-1,4-dihydronicotinamide

Tadashi OKAMOTO,* Atsuyoshi OHNO, and Shinzaburo OKA

Institute for Chemical Research, Kyoto University, Uji 611

(Received May 18, 1979)

Synopsis. It was found that *N*-propyl-1,4-dihydronicotinamide reduces bis(benzonitrile)dichloropalladium, palladium(II) acetate, and chlorides of rhodium(III), platinum(IV), and ruthenium(III) smoothly in organic solvents affording a facile method for the preparation of low valent catalysts *in situ*.

Many reagents are known to reduce high valent transition-metal salts to metals or metal complexes of lower oxidation state, typical ones being metal hydrides, alkylmetals, ethanolic potassium hydroxide, metals, and hydrazine.[1] They are used for the preparation of low valent transition-metal catalyst. Mild reducing agents not attacking other organic molecules in the system are desirable in the preparation of a catalyst *in situ*. Zinc powder is a mild reductant but its heterogeneity often gives irreproducible results. We would like to report that a well-known 1,4-dihydropyridine derivative, mild and soluble in organic solvents, behaves as an effective organic reductant of some transition-metal salts.

Palladium(II) acetate and bis(benzonitrile)dichloropalladium were reduced to palladium metal by *N*-propyl-1,4-dihydronicotinamide (PNAH), but not phosphine complexes of palladium(II) such as dichlorobis(triphenylphosphine)palladium(II) or dichloro-1,2-bis(diphenylphosphino)ethanepalladium(II). This might suggest that the dissociation of a ligand(s) is essential for the reaction. Platinum(IV) chloride and ruthenium(III) chloride were reduced to platinum(II) and ruthenium(II), respectively. No reduction was observed for copper(I) chloride, nickel(II) acetate, or iron(II) nitrate.[2] For iron(II) chloride and cobalt(II) nitrate, change takes place in the spectrum in methanol in contrast to the case in water.[3] Attempt to identify the product was unsuccessful. A complex (or salt) of $PtCl_4(PNA^+)_2$ was isolated (65% yield) by the reduction of platinum(IV) chloride hydrate.

In the presence of triphenylphosphine, which stabilizes the low oxidation state of transition metals, reduction by PNAH gives low valent complexes such as chlorotris(triphenylphosphine)rhodium(I) (87%) and tetrakis(triphenylphosphine)palladium(0) (63%).

$$RhCl_3 \cdot 3H_2O + PNAH \xrightarrow[PC_{18}H_{15}]{\text{Lutidine}} RhCl(PC_{18}H_{15})_3 + PNA^+$$

This procedure affords a facile method for the preparation of catalytically active low valent transition-metal complexes *in situ* because the reagent is insensitive to air and moisture, not attacking organic compounds except activated carbonyl compounds and cationic compounds.[4] Since the standard reduction potential for PNAH is -0.387 V,[5] reduction of metal ions or complexes with higher electrode potentials than the value could be achieved by this reagent. The resulting low valent complexes or metals were stable under the reaction conditions. PNAH did not attack chlorotris(triphenylphosphine)rhodium(I) even under reflux in ethanol.

Experimental

Changes of the spectra in the reactions were monitored with a Union Giken SM 401 spectrophotometer in organic solvents such as benzene, acetonitrile, ethanol, and methanol, which were purified by the usual manner. Products were identified by elemental analyses, NMR and IR.

Reduction of Bis(benzonitrile)dichloropalladium(II) or Palladium(II) Acetate. PNAH was added to a solution of the palladium species in order to precipitate black palladium powder quantitatively.

Preparation of Tetrakis(triphenylphosphine)palladium(0). Palladium(II) acetate, 0.89 mmol, triphenylphosphine, 4.96 mmol, and PNAH, 1.80 mmol were placed in a flask and deaerated. Benzene (30 cm^3) and 2,6-lutidine (0.1 cm^3) were injected into the flask and the solution was stirred overnight. The resulting precipitate was filtered off, the filtrate being concentrated and then treated with ethanol. Brown precipitate was washed with ether to give tetrakis(triphenylphosphine)palladium(0), 648 mg (0.56 mmol, 63%), which showed a spectrum identical with that of the authentic sample (Found: C, 73.61; H, 5.28%).

Preparation of Chlorotris(triphenylphosphine)rhodium(I). A solution of rhodium(III) chloride hydrate, 0.38 mmol, triphenylphosphine, 1.53 mmol, PNAH, 0.42 mmol, and 2,6-lutidine, 0.38 mmol in ether was stirred under nitrogen at room temperature for 2.5 h. The precipitate was collected and washed with 5 cm^3 of ethanol, and with three portions of 5 cm^3 of ether. After being dried under nitrogen, 305 mg (0.33 mmol, 87%) of the complex was obtained, which showed a spectrum identical with that of the authentic sample (Found: C, 69.42; H, 4.79%).

Reduction of Platinum(IV) Chloride. Platinum(IV) chloride hydrate (0.12 mmol) was dissolved in 5 cm^3 of methanol, and a solution of PNAH (0.60 mmol) in 3.5 cm^3 of methanol was added to the solution. After being stirred for 3 h under nitrogen, the white precipitate was collected and washed with methanol to give 52 mg of $PtCl_4(PNA)_2$ (0.08 mmol, 65%). Found: C, 31.85; H, 3.94; N, 8.12%. Calcd for $C_{18}H_{26}N_4Cl_4O_2Pt$: C, 32.29; H, 3.92; N, 8.04%. IR(KBr) 3390 (amide), 3195 (amide), 3060 (=C–H), 2940 (C–H), 1688 (C=O), and 1618 (C=C) cm^{-1}.

Reduction of Other Salts. Experimental conditions were the same as in the case of $PtCl_4$. Ruthenium(II) chloride hydrate was reduced to blue Ru(II) which turned yellow ($Ru^{II}(NH_3)_4$) in the presence of aqueous ammonia. No further attempt was made to isolate the product. Pink solution of cobalt(II) nitrate turned orange on addition of PNAH solution. The solution obtained was air sensitive but gave

† Presented at the 35th National Meeting of the Chemical Society of Japan, Sapporo, August 1976.

no characteristic color of $Co^{I}(bipy)_3$ by the addition of 2,2′-bipyridine.[6]

The Effect of Halo Ligand on the Rate of Hydrogenation of Coordinated Olefin in Dihydrido-olefin Complexes $RhXH_2(ol)(PPh_3)_2$ (X=Cl, Br, I)

Yoshimi OHTANI,* Akihiko YAMAGISHI, and Masatoshi FUJIMOTO*

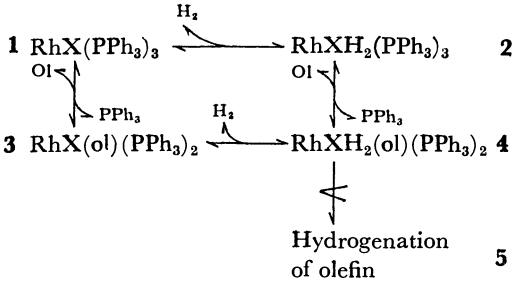
(Received November 18, 1978)

Synopsis. The formation constant of $RhXH_2(ol)(PPh_3)_2$ (ol=acrylonitrile or styrene, X=Cl, Br, or I) and the rate of hydrogenation of coordinated olefin in $RhXH_2(ol)(PPh_3)_2$ were determined. The effects of halo ligand on the equilibrium and rate constants showed a different trend for the two olefin complexes.

Knowledge of the effect of halo ligand on the catalytic activity of Wilkinson's complex is necessary for understanding electronic factors of individual steps in the catalytic hydrogenation reaction (Scheme 1).



Scheme 1.

The effects of halo ligand and other tertiary phosphine ligand analogs were studied,[1-3] but in most investigations only the overall rate of catalytic reactions were reported. Since both the complex formation constants and hydrogenation rate of coordinated olefin may vary with change of ligand, discussions based only on the observed rate constants of the overall reaction sometimes leave ambiguities. Thus, it is necessary to know the effects of ligands on the complex formation and on the rate of the hydrogenation of coordinated olefin, separately. In particular, information concerning a catalytically active intermediate (**4**) is required to elucidate the nature of Wilkinson's complex as a catalyst.

Recently, we detected a catalytically active intermediate, $RhClH_2(ol)(PPh_3)_2$ (ol=acrylonitrile or styrene), in benzene under anaerobic conditions.[4,5] Detection of the intermediate made it possible to determine accurately the equilibrium and/or rate constants of the individual steps in Scheme 1. We have studied a bromo and an iodo complex in a manner similar to that for the chloro complex to elucidate the effects of halo ligand on each step composing the catalytic reaction.

The results are summarized in Table 1. The effects of halo ligand on equilibrium and rate constants differ largely for acrylonitrile and styrene. The values of K_{34} (and also K_{24}), stability constants of dihydrido-olefin complex, increase in the order Cl<Br<I for acrylonitrile, and decrease in the order Cl>Br>I for styrene. The difference might be attributed to that in the coordinating properties of the two olefins. The coordination of acrylonitrile, which has an electron-withdrawing cyano group, would decrease the electron density of rhodium atom. On the other hand, the coordination of styrene, which has an electron-releasing phenyl group, would increase the electron density of rhodium. In the case of acrylonitrile, the iodo complex with the least electronegative ligand gives the largest stability of $RhXH_2(ac)(PPh_3)_2$. In the case of styrene, the chloro complex with the most electronegative ligand gives the largest stability of $RhXH_2(st)(PPh_3)_2$. The most stable dihydrido-olefin complex would be formed by the halo ligand, which offsets the change in electron density of central rhodium atom induced by the coordination of olefin.

As regards the effect of halo ligand on k_{45}, it is concluded that the complex which has a larger value of K_{34} gives the smaller value of k_{45}, a less stable dihydrido-olefin complex having a larger rate constant for the hydrogenation of coordinated olefin. The rate of the migratory insertion of olefin into Rh–H bond would be slowed down as the Rh–H bond becomes strong.

The effects of coordinated halo ligand on the stability constants of dihydrido-olefin complex may also be interpreted by the Dewar-Chatt-Duncanson model.[6] Figure 1 shows tentative schematic diagrams of energy levels. The energy level of rhodium atom is taken to be consistent with the present experimental results. In the case of acrylonitrile complex, back-donation from rhodium atom to acrylonitrile would be predominant for the coordination of acrylonitrile, as the π^* energy level of acrylonitrile lies near the highest occupied

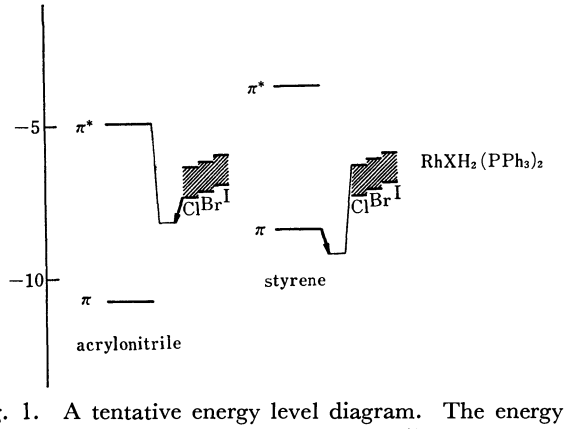


Fig. 1. A tentative energy level diagram. The energy levels of of rhodium are taken arbitarily so as to be consistent with the experimental results.

ac=acrylonitrile and st=styrene. K_{ij} and k_{ij} denote the equilibrium and rate constants of the reactions from species i to species j, respectively, shown in Scheme 1. a) Calculated from $K_{24}=K_{13}K_{34}/K_{12}$.

energy level of rhodium. Since the electron density of central rhodium atom increases in the order chloro< bromo<iodo complex, the highest occupied energy level of rhodium atom would be the highest for iodo complex. The distance between π^* energy level of acrylonitrile and the highest occupied energy level of rhodium would be the shortest for the iodo complex, $RhXH_2(ac)(PPh_3)_2$ thus being the most stable for iodo complex. In contrast, donation from styrene to rhodium would be predominant for the coordination of styrene. $RhXH_2(st)(PPh_3)_2$ is the most stable when X=Cl.

In the case of acrylonitrile, the value of k_{45} was found to be 100 times as small as that of k_{43} for all three halo complexes. It should be noted that both k_{43} and k_{45} decrease in the same order Cl>Br>I. k_{43} corresponds to the dissociation rate of hydrogen from the $RhXH_2(ac)(PPh_3)_2$ complex, while k_{45} corresponds to the migratory insertion rate of coordinated olefin into Rh–H bond in the same complex. It is suggested that both reactions proceed through a similar activated state, where Rh–H bond becomes weak.

Experimental

All measurements were carried out at 20±1 °C in oxygen-free benzene. Solutions of $RhCl(ol)(PPh_3)_2$ and $RhBr(ol)(PPh_3)_2$ were prepared as described.[4] A solution of $RhI(ol)(PPh_3)_2$ was prepared by dissolving $RhI(PPh_3)_3$ in benzene containing acrylonitrile or styrene. A small amount of free PPh_3 dissociated from $RhI(PPh_3)_3$ was neglected for the stopped-flow measurements. For the measurements of hydrogen gas uptake, the total concentration of PPh_3 was taken as the sum of the concentration of added PPh_3 and $RhI(PPh_3)_3$. The procedure of measurements is described in previous papers.[4,5]

Synthesis of a Few Derivatives of Cycloiridated 2-(2-Thienyl)pyridine

Matsuo NONOYAMA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received March 27, 1979)

Synopsis. A few derivatives of cycloiridated 2-(2-thienyl)pyridine were prepared and characterized by infrared and ^{1}H NMR spectra.

Numerous cyclometallation reactions of benzene derivatives with transition metal compounds have been reported,[1,2] but only a few cases are known of cyclopalladation and cycloplatination of thiophene derivatives.[3,4] Since various chemical properties of thiophene are similar to those of benzene, cyclometallation reactions found for benzene derivatives might occur also for thiophene derivatives. We have studied reactions of 2-(2-thienyl)pyridine with some platinum-metal halides and found the first example of cycloiridation of the thiophene ring. The results are reported in this paper.

2-(2-Thienyl)pyridine (abbreviated as H(2-thpy)) reacted with hydrated iridium(III) chloride in boiling 2-methoxyethanol to give an orange complex, $[\{IrCl(2\text{-thpy})_2\}_2]$. The complex reacted easily with unidentate ligand (L) to give the adducts, $[IrClL(2\text{-thpy})_2]$ (L=pyridine (py), tributylphosphine (PBu_3), and dimethyl sulfoxide (dmso)). The new complexes are air-stable; spectral data are given in Table 1 and Fig. 1.

The infrared spectrum of free H(2-thpy) shows bands at 844, 856, and 894 cm^{-1} characteristic of 2-substituted thiophene in the region of C–H out-of-plane deformation vibrations.[5] These bands are replaced by a single band at 884 cm^{-1} in the spectrum of $[\{IrCl(2\text{-thpy})_2\}_2]$, indicating that the thiophene ring is 2,3-disubstituted.[3] The 60 MHz ^{1}H NMR spectrum of free H(2-thpy) is complicated. Only one signal of 6-H(py)[6] is distinctly separated from the main signals, lying at δ=8.61 ppm (as a doublet of triplets, J=5.0; 1.3 Hz). The ^{1}H NMR spectrum of $[\{IrCl(2\text{-thpy})_2\}_2]$ is shown in Fig. 1 and Table 1 together with assignments. A sharp doublet with a relative intensity 1 H at 5.94 ppm becomes a singlet upon irradiation of a sharp doublet with an intensity 1 H at 7.17 ppm (J=4.9 Hz) and *vice versa*. The two doublets are assigned to thiophene ring protons. Each of the signals assigned to 5-H(py) and 6-H(py) has an intensity 1 H and the relative intensity of the multiplet assigned to 3-H(py) and 4-H(py) amounts to 2 H. The results, together with the infrared spectra and the evidence for cyclopalladated cycloplatinated 2-thpy complexes[3] suggest that 3-H(th) of H(2-thpy) is lost and that the two 2-thpy ligands of $[\{IrCl(2\text{-thpy})_2\}_2]$ are equivalent. Significant shielding seems to be operative for 4-H(th). This can be explained in terms of Structure I,[7] where 4-H(th) is nearly above the pyridine ring of the other 2-thpy ligand, thus being

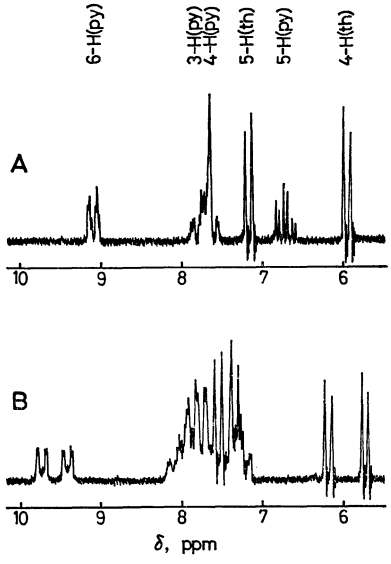

Fig. 1. 60 MHz ^{1}H NMR spectra of $[IrCl(2\text{-thpy})_2]_2$ in CD_2Cl_2 (A) and $[IrCl(dmso)(2\text{-thpy})_2]$ in DMSO-d_6 (B).

shielded by the aromatic ring current. Structure I is in line with low ν(Ir–Cl) frequency, since the chloride ligand is coordinated *trans* to a σ-carbon donor with strong *trans*-influence.

TABLE 2. YIELDS, MELTING POINTS AND ANALYTICAL RESULTS

Complex	Yield %	Mp °C	Found (Calcd), % C	H	N
$[IrCl(2\text{-thpy})_2]_2$	31	310 (dec)[a]	39.33(39.45)	2.23(2.21)	4.80(5.11)
$[IrCl(py)(2\text{-thpy})_2]$	73	300 (dec)	44.07(44.05)	2.52(2.73)	6.60(6.70)
$[IrCl(dmso)(2\text{-thpy})_2]$	75	240 (dec)	38.34(38.36)	2.91(2.90)	4.20(4.27)
$[IrCl(PBu_3)(2\text{-thpy})_2]$	77	122—124	48.60(48.02)	5.30(5.24)	3.73(3.73)
$[IrBr(PBu_3)(2\text{-thpy})_2]$	64	203—205	45.65(45.33)	4.88(4.95)	3.20(3.52)
$[IrI(PBu_3)(2\text{-thpy})_2]$	83	230 (dec)	43.01(42.80)	4.62(4.67)	3.03(3.33)

Structure II is proposed for the complexes [IrClL(2-thpy)$_2$] on the basis of the following spectral data. In the ^{1}H NMR spectra of the complexes, the signal due to 4-H(th) splits into two doublets with a relative intensity 1 H (Fig. 1), that due to 6-H(py) also splitting into two apparent doublets with an intensity 1 H. The remaining protons give a complicated pattern with an intensity 8 H. Thus the two 2-thpy ligands are not equivalent in [IrClL(2-thpy)$_2$]. In the case of L=PBu$_3$, an additional small splitting (J(P–H)=1.5 Hz) is observed for one of the two doublets of 4-H(th) and the doublet, which shifts hardly upon exchange of halide donors, is assigned to 4-H of the thiophene ring coordinated *trans* to PBu$_3$. However, the other downfield doublet shifts to higher field in the order Cl<Br<I, and is assigned to 4-H of the thiophene ring coordinated *trans* to halide donors.

The separation of two doublets of 6-H(py) depends upon L. In the case of L=py, one of the two doublets is significantly shielded. This might be caused by anisotropic shielding by a pyridine (L) donor, since its least sterically hindered coordination brings the pyridine (L) ring nearly perpendicular to one of the chelated 2-thpy ligands. One 6-H(py) lies, therefore, nearly above the pyridine (L) ring. The other 6-H(py) is directed toward a Cl donor and the chemical shifts are almost independent of L.

The chemical shifts of 6-H(py) of [IrX(PBu$_3$)(2-thpy)$_2$](X=Cl, Br, I) are of interest. The positions of higher field doublets are nearly constant irrespective of the nature of halide donors, while the lower field doublets shift to a lower field in the order Cl<Br<I with increasing van der Waals radius of halide ions. The same trend was reported for square-planar palladium(II) complexes of pyridine derivatives,[8] the origin being interpreted as the result of spatial crowding between 6-H(py) and a halide ligand. The low ν(Ir–Cl) frequencies are in line with Structure II. The band at 1109 cm^{-1} of [IrCl(dmso)(2-thpy)$_2$] is assigned to ν(S=O), suggesting *S*-coordination of dmso.

The ligand H(2-thpy) behaves in a similar way to that of the corresponding benzene derivatives such as 2-phenylpyridine and benzo[*h*]quinoline.[7] H(2-thpy) has also been cyclorhodated to give [{RhCl(2-thpy)$_2$}$_2$] like 2-phenylpyridine and benzo[*h*]quinoline.[9] Structures I and II proposed above correspond to those of the complexes of these benzene derivatives.

Experimental

Measurements. Measurements were carried out by the methods reported.[10]

Synthesis of the Complexes. Yields, melting points and analytical results are given in Table 2.

[{*IrCl(2-thpy)*$_2$}$_2$]: A mixture of 3 mmol of hydrated iridium(III) chloride with 9 mmol of H(2-thpy) in 50 cm^3 of 2-methoxyethanol was refluxed for 6 h to give a brown powder. The product was washed with ethanol, dried in air, and dissolved in dichloromethane. Addition of hexane to the filtered, concentrated dichloromethane solution gave an orange powder.

[*IrClL(2-thpy)*$_2$](*L=py or PBu*$_3$): To a solution of [{IrCl-(2-thpy$_2$}$_2$] in dichloromethane was added a stoichiometric amount of PBu$_3$ or 3-fold excess of pyridine. The mixture was stirred on a hot plate for 1 h. Hexane was added to the concentrated dichloromethane solution to precipitate a yellow orange product.

[*IrCl(dmso)(2-thpy)*$_2$]: One-fifth mmol of [{IrCl(2-thpy)$_2$}$_2$] was dissolved in 1 cm^3 of dimethyl sulfoxide on a steam bath. To the solution was added 20 cm^3 of ethanol to precipitate an orange yellow product.

[*IrX(PBu*$_3$)(*2-thpy)*$_2$](*X=Br or I*): To a solution of one-fourth mmol of [IrCl(PBu$_3$)(2-thpy)$_2$] in a mixture of 20 cm^3 of dichloromethane and 10 cm^3 of ethanol was added 1 mmol of lithium bromide or lithium iodide. The mixture was warmed on a hot plate for 3 h and concentrated to a small volume to give bromide or iodide complex.

The 2:1 Adduct of Chloro[*N*-(2-dimethylaminoethyl)salicylideneaminato]copper(II) with Chlorides of Copper(II), Manganese(II), and Nickel(II)

Tadashi Tokii, Makoto Kaneko, Kusuo Yamanaka, Yoneichiro Muto,* and Michinobu Kato†

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

†*Aichi Prefectural University, Mizuho-ku, Nagoya 467*

(Received April 4, 1979)

Synopsis. The adducts listed in the title have been prepared, and their trimeric nature confirmed on the basis of elemental analysis and IR and electronic spectra. The magnetic properties of the $MnCl_2$ and $NiCl_2$ adducts have been analyzed in terms of a linear trimer model.

Chloro[*N*-(2-dimethylaminoethyl)salicylideneaminato]-copper(II), Cu(sal·en·NMe_2)Cl, was originally synthesized and investigated by Sacconi *et al.*; a monomeric planar structure, I, was proposed for this complex based on the electronic reflectance spectrum.[1] The monomeric nature was confirmed by cryomagnetic and IR spectral studies.[2] Based on the monomeric structure and the knowledge that phenolato and chloro ligands form bridges between pairs of metal ions, it is expected that the complex can be used as a bidental complex-ligand[3] in the synthesis of polynuclear metal complexes. In the reaction of Cu(sal·en·NMe_2)Cl with metal salts MCl_2(M=Cu(II), Mn(II), and Ni(II)) 2:1 adducts of [Cu(sal·en·NMe_2)Cl]$_2$·MCl_2 were formed. A similar adduct of chloro[*N*-(2-methylaminoethyl)salicylideneaminato]copper(II), Cu(sal·en·NHMe)Cl, with copper-(II) chloride has also been prepared.

The spectral and magnetic studies will be reported in this paper.

Experimental

Synthesis. A typical synthetic method is as follows. A solution of one of the metal salts MCl_2 (10 mmol) in ethanol (50 ml) was added to a solution of one of the parent complexes, Cu(sal·en·NMe_2)Cl and Cu(sal·en·NHMe)Cl, and the mixture stirred on a hot plate for 1/2 h. The crystals thus precipitated were collected, washed repeatedly with ethanol and dried. Anal. **1.** [Cu(sal·en·NMe_2)Cl]$_2$·$CuCl_2$. Found: C, 36.84; H, 4.19; N, 7.86; Cu, 26.43%. Calcd for $C_{22}H_{30}N_4O_2Cl_4Cu_3$: C, 36.96; H, 4.23; N, 7.84; Cu, 26.66%. **2.** [Cu(sal·en·NHMe)Cl]$_2$·$CuCl_2$. Found: C, 34.75; H, 3.85; N, 8.17; Cu, 27.55%. Calcd for $C_{20}H_{26}N_4O_2Cl_4Cu_3$: C, 34.97; H, 3.82; N, 8.16; Cu, 27.75%. **3.** [Cu(sal·en·NMe_2)Cl]$_2$·$MnCl_2$. Found: C, 37.54; H, 4.37; N, 7.80; Cu, 17.95; Mn, 7.82%. Calcd for $C_{22}H_{30}N_4O_2Cl_4Cu_2Mn$: C, 37.41; H, 4.28; N, 7.93; Cu, 17.99; Mn, 7.78%. **4.** [Cu(sal·en·NMe_2)Cl]$_2$·$NiCl_2$. Found: C, 37.01; H, 4.20; N, 7.91; Cu, 17.78; Ni, 8.58%. Calcd for $C_{22}H_{30}N_4O_2Cl_4Cu_2Ni$: C, 37.21; H, 4.26; N, 7.89; Cu, 17.90; Ni, 8.27%.

Physical Measurements. The IR spectral measurements were made with a Hitachi EPI-G2 IR Spectrophotometer in the 400—4000 cm^{-1} region in Nujol. The reflectance spectra were recorded with a Hitachi Recording Spectrophotometer 323. The magnetic susceptibilities in the temperature range 80—300 K were determined by the Faraday method using $HgCo(SCN)_4$ as a calibrant.

Results and Discussion

The IR spectra of the adducts prepared in this study all show an intense band in the range 1550—1555 cm^{-1} (**1**, 1555; **2**, 1554; **3**, 1550; **4**, 1551 cm^{-1}), while the band in the spectra of the parent complexes, Cu(sal·en·NMe_2)Cl and Cu(sal·en·NHMe)Cl, appears at 1534 and 1531 cm^{-1} respectively. This band shift towards higher frequencies (15—20 cm^{-1}) indicates the presence of bridging phenolic oxygen atoms in the adducts.[2]

A remarkable feature in the reflectance spectra of the $CuCl_2$ adducts (**1** and **2**) is the appearence of a band in the 9000—10000 cm^{-1} region (Fig. 1) which is absent in the spectra of the parent complexes.[1,2] This feature indicates the presence of Cu(II) in pseudo-tetrahedral coordination.[2,4] The $MnCl_2$ adduct spectrum shows a broad band at *ca.* 15000 cm^{-1} with a shoulder at *ca.* 11000 cm^{-1} (Fig. 1). This band has been attributed to the d-d transition of Cu(II) since Mn(II) complexes have no d-d band below 15000 cm^{-1} regardless of stereochemistry (octahedral or tetrahedral) or spin-states (high- or low-spin). This type of spectra is indicative of five-coordination around Cu(II) and is to be compared with the spectra reported for some distorted square-pyramidal Cu(II) complexes.[2,5] The spectrum of the $NiCl_2$ adduct shows a broad band at *ca.* 15000 cm^{-1} with a shoulder at *ca.* 11000 cm^{-1} and a weak band at *ca.* 6500 cm^{-1} (Fig. 1). Assignment of the former band could not be unambiguously performed since the d-d bands of both Ni(II) and Cu(II) appear

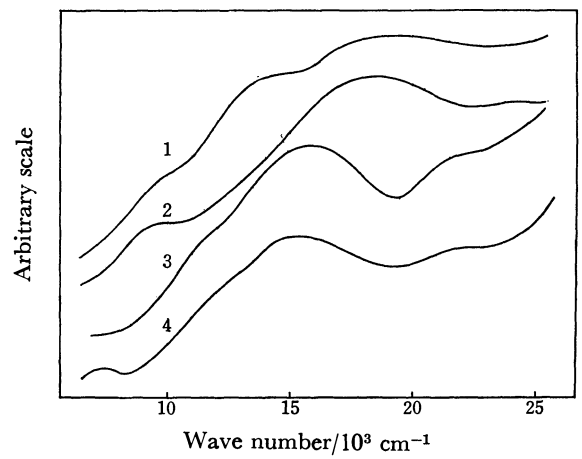

Fig. 1. Reflectance spectra of [Cu(sal·en·NMe_2)Cl]$_2$·$CuCl_2$ (1), [Cu(sal·en·NHMe)Cl]$_2$·$CuCl_2$ (2), [Cu(sal·en·NMe_2)Cl]$_2$·$MnCl_2$ (3) and [Cu(sal·en·NMe_2)Cl]$_2$·$NiCl_2$ (4).

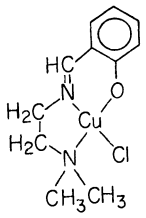
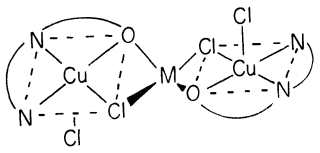


I



II

in this region. The latter band has been attributed to the transition in the Ni(II) in this adduct and may be assigned to the d-d band in the Ni(II) with a pseudo-tetrahedral geometry. The assignment has been based on the following observations: 1) in the region below 8000 cm^{-1}, no band was observed in the spectra of the other adducts (**1**—**3**) and 2) the position, shape and absorption intensity of the band closely resembles the bands observed at *ca.* 6700 cm^{-1} for pseudo-tetrahedral bis(*N*-alkylsalicylideneaminato)nickel(II) complexes.[6]

On the basis of the analytical and spectral data the adducts have been assigned a trinuclear structure represented schematically by II. Each of the terminal Cu(II) ions(five-coordination) is bridged to the central metal ion(pseudo-tetrahedral four-coordination) with one phenolic oxygen atom and one chloro donor.

The variable-temperature magnetic susceptibility data observed for the $CuCl_2$ adducts (**1** and **2**) followed the Curie-Weiss law ($\chi_M = C/T-\theta$) with $\theta = -7$ and $+6$ K respectively, indicating no appreciable magnetic interaction in the adducts. The pseudo-tetrahedral geometry of the central Cu(II) in the adducts would be expected to be the main structural factor for the magnetism.[7] The cryomagnetic data of the $MnCl_2$ adduct has been analyzed using the theoretical equation 1[3] based on a symmetric linear trimer of Cu–Mn ($S=5/2$)–Cu, assuming no magnetic interaction between the terminal Cu(II) ions. Similarly, the data for the $NiCl_2$ adduct may be expressed by Eq. 2[3] for a Cu–Ni($S=1$)–Cu trimer (Fig. 2);

$$\chi_M = \frac{N\beta^2g^2}{4k(T-\theta')}[35+84\exp(5J/kT)+35\exp(-2J/kT) + 10\exp(-7J/kT)]/[3+4\exp(5J/kT) + 3\exp(-2J/kT)+2\exp(-7J/kT)] + N\alpha \quad (1)$$

$$\chi_M = \frac{2N\beta^2g^2}{k(T-\theta')}[1+5\exp(2J/kT)+\exp(-2J/kT)]/ [3+5\exp(2J/kT)+3\exp(-2J/kT) + \exp(-4J/kT)] + N\alpha \quad (2)$$

where χ_M represents the molar susceptibility corrected for diamagnetism (-384×10^{-6} and -382×10^{-6} cgs emu respectively) using Pascal's constants, J represents the exchange integral between the central and terminal metal ions, g represents the average g value over the three metal ions, θ' represents the Weiss constant term for inter-cluster interaction, and $N\alpha$=T.I.P. per

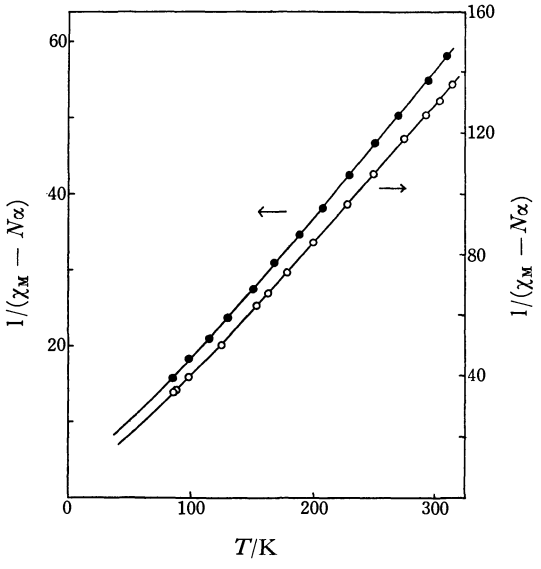


Fig. 2. Variation of reciprocal magnetic susceptibilities with temperature. (●) $[Cu(sal\cdot en\cdot NMe_2)Cl]_2\cdot MnCl_2$, (○) $[Cu(sal\cdot en\cdot NMe_2)Cl]_2\cdot NiCl_2$. The solid curves were calculated from Eqs. 1 and 2 respectively.

Cu_2Mn or Cu_2Ni. Using Eq. 1, the best fit of the experimental data observed for the $MnCl_2$ adduct gave the following values: $J=+19.4$ cm^{-1}, $g=1.997$ and $\theta'=-25.7$ K with $R=6.63\times10^{-3}$ ($R=[\sum(\chi_{exp}-\chi_{calcd})^2/\sum\chi_{exp}^2]^{1/2}$; discrepancy index), assuming $N\alpha=120\times10^{-6}$ cgs emu.[3] Similarly, the $NiCl_2$ adduct gave the following values: $J=+36.4$ cm^{-1}, $g=2.130$ and $\theta'=-17.8$ K with $R=4.81\times10^{-3}$, assuming $N\alpha=320\times10^{-6}$ cgs emu.[3] The positive J values indicating an intramolecular ferromagnetic interaction may also be related to the geometry of the central metal ion in the adducts. In the case of the $NiCl_2$ adduct, the close agreement between the observed and calculated temperature dependence with very low value of R indicates a negligible orbital contribution to the magnetic susceptibility. This factor may be primarily due to the pseudo-tetrahedral geometry of the central Ni(II) ion.[8]

Complexes of Zinc-group Metals with 8-Amino-2-methylquinoline

Akiko FURUHASHI* and Hiroshi YOKOTA

Department of Chemistry, College of Science and Engineering, Aoyama-Gakuin University, 6-16-1 Chitosedai, Setagaya-ku Tokyo 157

(Received May 12, 1979)

Synopsis. Some complexes of zinc-group metals with 8-amino-2-methylquinoline have been synthesized. They are seemed to have a monomeric tetrahedral form except for the mercury(I) complex containing a perchlorate ion as a counter anion.

8-Amino-2-methylquinoline (amq) is obtained by the reduction of 8-nitro-2-methylquinoline.[1-2] Although it is expected that the quinoline is able to coordinate to metal ions, in analogy with 8-aminoquinoline, which has essentially the same structure as the amq some differences might exist for the methyl group on the 2-position. The present authors, therefore, synthesized zinc-group metal complexes of amq and studied their properties by electronic, IR and/or far IR spectra, and molar conductances. The experimental results show the metal complexes to have a tetrahedral form, different from the zinc complex synthesized by Litzow and his coworkers.[3-7]

Experimental

Physical Measurements. The IR spectra in the NaCl region were measured with a JASCO IRA-1 type spectrophotometer as a nujol mull or a KBr disk. The far-IR spectra were obtained by means of a nujol mull using a JASCO DS 403G IR spectrophotometer. The reflectance spectra were obtained with a Shimadzu Double-beam UV-200 spectrophotometer. The electronic conductivities were measured using a Toa Conduct Model CM-1DB and a cell with a cell constant of 0.9845 cm^{-1}. The measurements were made at 25 °C by employing a 10^{-3} mol/dm^3 *N,N*-dimethylformamide solution.

Materials. Metal perchlorate and halide of a GR-grade reagent of the Wako Chemical Co., Ltd., were used as starting materials without any further purification. 8-Amino-2-methylquinoline of the Tokyo Kasei Co., Ltd., was used after recrystallization with ligroin.

Syntheses. The metal complexes were prepared the following manner. To an ethanol solution containing 0.0025 mol of metal salt, about 0.0065 mol of a ligand in ethanol was added, after which the mixture was allowed to stand for several hours. The precipitate thus formed was filtered off. After washing with ethanol, it was dried in a vacuum desiccator over anhydrous calcium chloride.

Results and Discussion

The color and elemental analyses of the metal complexes are given in Table 1, together with the yields based on the starting materials.

As is shown in Table 2, the molar conductances may be classified into two values. The values of the type of $M(amq)_2(ClO_4)_2$ and $Hg_2(amq)_2(ClO_4)_2$ lie in the 130—170 S cm^2 mol^{-1} range. The values are representative for 1:2 electrolytes in *N,N*-dimethylformamide.[8] On the other hand, the conductances of $M(amq)X_2$ are all under 30 S cm^2 mol^{-1} except $Zn(amq)I_2$. Consequently, these complexes seem to be essentially non-electrolyte, and they seem to be interact with solvent molecules. In the case of $Zn(amq)I_2$, it

$Hg(amq)Cl_2$	4.3
$Hg_2(amq)_2(ClO_4)_2$	168.8

amq: 8-amino-2-methylquinoline.

appears that the complex undergoes considerable solvolysis in the solution the following manner,

$$Zn(amq)I_2 \overset{DMF}{\rightleftharpoons} [Zn(amq)I(DMF)]^+ + I^- \quad (1)$$

$$[Zn(amq)I(DMF)]^+ \overset{DMF}{\rightleftharpoons} [Zn(amq)(2DMF)]^{2+} + I^- \quad (2)$$

The IR spectra of free amq show two peaks, at 3440 and 3320 cm^{-1}, of ν_{NH_2}, The peaks shift to the 3120—3280 cm^{-1} range in the metal complexes. A peak about 1340 cm^{-1} in the free ligand also shifts to the lower-wave-number side in 15—20 cm^{-1}. In these metal complexes, therefore, the quinoline seems to bond to the metal ion, with its two nitrogen atoms as a bidentate ligand.[9] The strong bands in the range 950—1140 and about 620 cm^{-1} in the complexes containing a perchlorate group are regarded as simple perchlorate ions.[6-7,10-11] In general, terminal M-X stretching bands of metal complexes with a metal-halogen bond appear in the regions of 200—400 cm^{-1} for MCl, 200—300 cm^{-1} for MBr, and 100—200 cm^{-1} for MI.[12] The wave number observed in the 150—600 cm^{-1} region can be assigned to that of the terminal M-X bands.

The reflectance spectral data in the visible region are shown in Table 3. The bands are all regarded as CT bands. The absorption peaks of the bands change in accordance with the bathochromic effect in the $M(amq)X_2$ type of complexes.[13]

From the experimental results presented above, it is presumed that the metal complexes obtained are in a tetrahedral configuration, since the four coordinated zinc-group metal ions are usually in the tetrahedral form.[14]

In the case of $Hg_2(amq)_2(ClO_4)_2$, the mercury is +1 of the oxidation state. It is qualitatively confirmed in the usual manner that Hg(I) forms a black color when reacted with an alkali solution. Therefore, the complex appears to be dimeric with the $(Hg–Hg)^{2+}$ ion, and the dimers appear to interact with each other in the solid state with mercury, but the structure has not been revealed.

The authors would like to thank Dr. Henry Freiser of the University of Arizona, who gave them a chance to do this work. The authors also wish to express their gratitude to Dr. Yukichi Yoshino of Tokyo University for his continuing encouragement. The authors thank Drs. Kan Kimura and Yoshimitsu Hirao of Aoyama-Gakuin University for their useful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (12), 3755—3756 (1979)

Reaction of Guaioxide with *N*-Bromosuccinimide and the Preparation of 4,6-Guaiadien-3-one and 1-Epi-4,6-guaiadien-3-one[1)]

Hiroshi HIROTA, Yoshihiko MORIYAMA, Hidekazu SHIRASAKI, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*

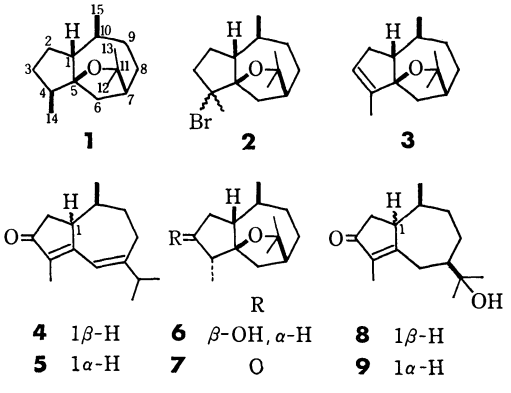
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received July 18, 1979)

Synopsis. Treatment of guaioxide with *N*-bromosuccinimide gave 4-bromoguaioxide, which was dehydrobrominated to yield 3-dehydroguaioxide. The olefin was then converted into 8-deoxytorilolone and 8-deoxy-1-epitorilolone by the known procedures. Dehydration of these deoxy derivatives in benzene in the presence of *p*-toluenesulfonic acid gave 4,6-guaiadien-3-one and 1-epi-4,6-guaiadien-3-one, respectively.

Guaioxide (**1**; $C_{15}H_{26}O$)[2)] was isolated from guaiac wood oil as a minor constituent, and also obtained by acid-catalyzed cyclization of guaiol.[2,3)] Because of the absence of hydrogen on the two carbons attached to an ether oxygen atom, the sesquiterpene ether (guaioxide) is particularly inert towards common chemical reagents. By the microbial oxidation technique, hydroxyl groups were successfully introduced to the molecule. This led to the elucidation of the structure of guaioxide (**1**).[4)] In this paper we wish to report on the introduction of a functional group into guaioxide by chemical method. The reaction of guaioxide (**1**) with *N*-bromosuccinimide (NBS) gave a monobromide (**2**) which in turn afforded an olefin (**3**). Conversion of **3** into two diastereomeric α,β: γ,δ-unsaturated ketones (**4** and **5**) is also described.

Friedelane reacts with NBS or bromine to give friedel-18-ene which may be formed *via* 18-bromofriedelane.[5)] When guaioxide (**1**) was treated with 1—1.2 mol equivalent of NBS in carbon tetrachloride under reflux, a monobromide (**2**) and an olefin (**3**) were obtained in isolation yields 3—10% and 5—15%, respectively.[6)] Bromide (**2**) was heated under reflux with potassium hydroxide in ethanol to give the same olefin (**3**) in 45—65% yield which was found to be identical with 3-dehydroguaioxide (**3**).[4)] This shows that the bromination of **1** took place on $C_{(4)}$ to give **2**. Bromination of **1** in carbon tetrachloride with a large excess of NBS or bromine resulted in the formation of a complex mixture of reaction products, separation of which was unsuccessful.



By the known procedures,[4)] olefin (**3**) was converted *via* 3β-hydroxyliguloxide (**6**)[4,7)] and 3-oxoliguloxide (**7**), into a hydroxy α,β-unsaturated ketone (**8**; 8-deoxytorilolone), which isomerized into a diastereomeric hydroxy α,β-unsaturated ketone (**9**; 8-deoxy-1-epitorilolone).[4)] These hydroxy unsaturated ketones (**8** and **9**) were dehydrated to give 4,6-guaiadien-3-one (**4**) and 1-epi-4,6-guaiadien-3-one (**5**), respectively, in a quantitative yield, by refluxing with *p*-toluenesulfonic acid in benzene. When **4** was heated under reflux with methanolic potassium hydroxide, no isomerization detectable by NMR measurement took place, while more than 90% of **5** isomerized into **4** by the same treatment.[8)] In the NMR spectra, the $C_{(10)}$-methyl signal of **5** appears at a fairly higher field (δ 0.73) as compared with the corresponding signal (δ 1.06) of **4**. This suggests that the $C_{(10)}$-methyl of **5** is shielded by π-electron cloud of the α,β: γ,δ-unsaturated ketone moiety. This is in line with the UV spectra of **4** and **5** which show that the molecular extinction coefficient (ε) at 293 nm of **5** is smaller by *ca.* 20% than that of **4**.

Experimental

IR and UV spectra were measured with a Hitachi EPI-G2 spectrometer and a Hitachi 340 spectrophotometer, respectively, ^{1}H-NMR spectra with a Varian EM-390 (90 MHz) or a Hitachi R-20B (60 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, single-focus mass spectra with a Hitachi RMU-6-Tokugata mass spectrometer, and double-focus mass spectra with a JEOL D-300, with direct inlet system operating at 70 eV. Measurements of optical rotation were carried out with a JASCO polarimeter DIP-SL. CD spectra were taken on a JASCO model J-20. For column chromatography Wakogel C-200 (Wako Pure Chemical Industries) was used. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness. Vapor-phase chromatographic (VPC) analyses were performed on a Shimadzu gas chromatograph model GC-6A.

Bromination of Guaioxide (1) with NBS. NBS (3.32 g; 18.7 mmol) was added to a solution of guaioxide (**1**; 4.00 g; 18.0 mmol) in carbon tetrachloride (20 ml), and the mixture was heated under reflux for 1.5 h by means of an infrared lamp. The reaction mixture was then cooled and filtered. The solvent was removed under reduced pressure to give a residue which was chromatographed on a column of silica gel. Elution with petroleum ether–benzene (4: 1) gave a *ca.* 1: 1 mixture (800 mg) of 4-bromoguaioxide (**2**) and unchanged guaioxide (**1**). Though **2** decomposed easily on contact with silica gel, a small amount of **2** was isolated from the mixture of **1** and **2** by rechromatography. 4-Bromoguaioxide (**2**): an oil, $[\alpha]_D^{22}$ +1.4° (*c* 3.25; EtOH); IR (film): 1140, 1060, 875, 800, and 740 cm^{-1}; NMR ($CDCl_3$); δ 0.85—0.95 (3H,

diffused d; $C_{(10)}$-CH_3), δ 1.32, 1.34 (each 3H, s; $C_{(11)}$-$(CH_3)_2$), and δ 1.88 (3H, s; $C_{(4)}$-CH_3); MS: *m/e* 302 and 300 (relative abundance, each 2%; M^+), *m/e* 287 and 285 [each 20%; $(M-CH_3)^+$], *m/e* 221 [25%; $(M-Br)^+$], and 205 [100%, $(C_{14}H_{21}O)^+$]. Found: *m/e* 302.1075. Calcd for $C_{15}H_{25}O^{81}Br$: M, 302.1069. Found: *m/e* 300.1108. Calcd for $C_{15}H_{25}O^{79}Br$: M, 300.1089. The bromide showed one spot on thin-layer chromatogram. The fact that the NMR spectrum shows no other methyl signals suggests that bromide (**2**) contains no epimer on $C_{(4)}$. However, the configuration at $C_{(4)}$ of **2** remained undetermined due to its easy decomposition as previously stated.

Successive elution with the same solvents gave the starting compound (**1**; 3.1 g; 78%) and a dehydrobrominated material (**3**; 240 mg; 6.1%).

When the reaction of **1** with NBS was carried out under a nitrogen stream in order to remove the hydrogen bromide generated during the course of reaction, olefin (**3**) could be obtained in better yield (15—35%).

Dehydrobromination of 4-Bromoguaioxide (2). The bromide (**2**; 100 mg; 0.33 mmol) in an ethanolic potassium hydroxide (KOH 220 mg, EtOH 5 ml) was heated under reflux for 2.5 h and the reaction mixture was treated as usual to give a residue which was chromatographed on a column of silica gel. Elution with petroleum ether–benzene (2: 1) gave the olefin (**3**; 36 mg; 0.17 mmol; 50% yield), an oil, $[\alpha]_D^{22}$ +15.0° (*c* 1.45; EtOH); IR (film): 1660, 1640, 1130, 1040, 1010, 885, and 815 cm^{-1}; NMR ($CDCl_3$): δ 0.85—0.95 (3H, diffused d; $C_{(10)}$-CH_3), δ 1.23, 1.34 (each 3H, s; $C_{(11)}$-$(CH_3)_2$), δ 1.67 (3H, d, J=1.3 Hz; $C_{(4)}$-CH_3), and δ 5.39 (1H, q, J=1.3 Hz; $C_{(3)}$-H); MS: *m/e* 220 (21%; M^+), *m/e* 205 [100%; $(M-CH_3)^+$], *m/e* 202 [56%; $(M-H_2O)^+$], *m/e* 187 [26%; $(C_{14}H_{19})^+$], and *m/e* 159 [53%; $(C_{12}H_{15})^+$]. Found: *m/e* 220.1814. Calcd for $C_{15}H_{24}O$: M, 220.1827. This olefin was found to be identical with 3-dehydroguaioxide (**3**)[4] and also with the olefin obtained by the reaction of **1** with NBS.

Conversion of 3-Dehydroguaioxide (3) into 8-Deoxytorilolone (8) and 8-Deoxy-1-epitorilolone (9). According to the procedures described by Ishii *et al.*,[4] the olefin (**3**) was converted, *via* the alcohol (**6**)[4,7] and the ketone (**7**), into 8-deoxytorilolone (**8**), which was isomerized into a 1: 1 mixture of **8** and 8-deoxy-1-epitorilolone (**9**). The formation of each compound (**6**, **7**, **8**, and **9**) was confirmed by identity of their spectral data with those of authentic samples (**6**, **7**, **8**, and **9**).

Dehydration of 8-Deoxytorilolone (8). *p*-Toluenesulfonic acid (67 mg; 0.35 mmol) was added to a solution of α,β-unsaturated ketone (**8**; 56 mg; 0.23 mmol) in benzene (17 ml), and the solution was heated under reflux for 3.5 h. The reaction mixture was treated as usual to give a single product, 4,6-guaiadien-3-one (**4**; 52 mg; quantitative yield), an oil, IR (film): 1690, 1625, 1590, 1340, 1285, 1050, and 870 cm^{-1}; UV (EtOH): λ_{max} 293 nm (ε 20700); CD (c 6.43×10^{-4}, EtOH): $[\theta]_{365}$ ±0, $[\theta]_{295}$ +18300, and $[\theta]_{240}$ ±0; NMR ($CDCl_3$): δ 1.06 (3H, d, J=6 Hz; $C_{(10)}$-CH_3), δ 1.09 (6H, d, J=7 Hz; $C_{(11)}$-$(CH_3)_2$), δ 1.75 (3H, s; $C_{(4)}$-CH_3), and δ 6.35 (1H, br s; $C_{(6)}$-H); MS: *m/e* 218 (100%; M^+), *m/e* 203 [32%; $(M-CH_3)^+$], and *m/e* 175 [73%; $(M-C_3H_7)^+$]. Found: *m/e* 218.1662. Calcd for $C_{15}H_{22}O$: M, 218.1671.

Dehydration of 8-Deoxy-1-epitorilolone (9). By the same treatment as above, **9** was transformed quantitatively into 1-epi-4,6-guaiadien-3-one (**5**), an oil, IR (film): 1690, 1630, 1590, 1330, 1290, 1055, and 880 cm^{-1}; UV (EtOH): λ_{max} 293 nm (ε 16500); CD (c 9.70×10^{-5}, EtOH): $[\theta]_{380}$ ±0, $[\theta]_{335}$ −6080, $[\theta]_{317}$ ±0, $[\theta]_{297}$ +5050, and $[\theta]_{265}$ ±0; NMR ($CDCl_3$): δ 0.73 (3H, d, J=6.5 Hz; $C_{(10)}$-CH_3), δ 1.11 (6H, d, J=6.5 Hz; $C_{(11)}$-$(CH_3)_2$), δ 1.73 (3H, s; $C_{(4)}$-CH_3), and δ 6.34 (1H, br. s; $C_{(6)}$-H); MS: *m/e* 218 (100%; M^+), *m/e* 203 [18%; $(M-CH_3)^+$], and *m/e* 175 [50%; $(M-C_3H_7)^+$]. Found: *m/e* 218.1649. Calcd for $C_{15}H_{22}O$: M, 218.1617.

Alkaline Treatment of the α,β: γ,δ-Unsaturated Ketones (4 and 5). 4,6-Guaiadien-3-one (**4**; 13 mg) was treated with potassium hydroxide (100 mg) in methanol (5 ml) under reflux for 2 h under a nitrogen atmosphere. The reaction product (8 mg) was obtained after the usual treatment, and found by NMR measurement to consist of only the unchanged **4**. When 1-epi-4,6-guaiadien-3-one (**5**) was subjected to the same alkaline treatment, NMR measurement showed that more than 90% of **5** isomerized into **4**. Since the retention times for **4** and **5** were too close to each other, the accurate ratio of the products could not be determined by VPC measurement (column: Dexsil-300, SP-1000, and SE-30).

The authors wish to thank Dr. Hiroshi Ishii, Shionogi Research Laboratory, Osaka, for the spectral data of authentic compounds (**3**, **6**, **7**, and **8**).

6) Isolation yields of both **2** and **3** were poor, a large amount (55—80%) of **1** being recovered unchanged. This was due to a) reaction products (**2** and **3**) being unstable on silica gel, and b) R_f values on TLC of **1**, **2**, and **3** being very close to one another. When the first three reactions, namely, NBS bromination and dehydrobromination followed by hydroboration, were carried out without purification, 200 mg of 3β-hydroxyliguloxide (**6**) was obtained from 1.0 g of guaioxide (overall yield, 18.5%).

Catalytic Hydrogenolysis of 1,1-Dichloro-3-methyl-2-phenylcyclopropane

Koji ISOGAI* and Shigeru HIRABAYASHI**

Department of Applied Chemistry, Faculty of Engineering, Niigata University, Ikarashi, Niigata-shi, Niigata 950-21

(Received January 12, 1979)

Synopsis. The title compound was hydrogenolyzed over PdO or Raney nickel. The C_2–C_3 bond of the cyclopropane ring underwent cleavage exclusively over PdO. Cleavage of the C_1–C_2 and C_2–C_3 bonds occurred competitively over Raney nickel. A probable pathway is suggested.

The position of ring cleavage on the catalytic hydrogenolysis of cyclopropanes is determined by substituents.[1,2] However, little attention has been given to the role of negative substituents such as halogens in the regioselectivity of the ring cleavage. The hydrogenolysis of 1-bromo-1-fluoro-2-phenylcyclopropane over palladium oxide catalyst (PdO) has been investigated.[3] Cleavage of the C_2–C_3 bond of the cyclopropane ring occurred exclusively, two olefins being obtained as intermediates. In order to clarify the behavior of halogens in the regioselective hydrogenolysis of cyclopropane ring, we have studied the hydrogenolysis of 1,1-dichloro-3-methyl-2-phenylcyclopropane (**1**).

The results of catalytic hydrogenolysis of **1** are given in Table 1. When PdO was used as a catalyst, hydrogenolysis of **1** was reduced in the presence of potassium hydroxide, but proceeded smoothly in the absence of potassium hydroxide, giving butylbenzene (**5**) exclusively. On the other hand, with use of Raney nickel (R-Ni), only in the presence of potassium hydroxide, it gave a mixture of stereoisomeric 1-chloro-*r*-3-methyl-*t*-2-phenylcyclopropane (**2**) (*r*-1-chloro-*c*-3-methyl-*t*-2-phenylcyclopropane (**2t**) and *r*-1-chloro-*t*-3-methyl-*c*-2-phenylcyclopropane (**2c**)), *r*-2-methyl-*t*-1-phenylcyclopropane (**3**), isobutylbenzene (**4**) and **5**. In the presence of potassium hydroxide, the product composition for R-Ni catalyzed hydrogenolysis varied with the progress of reaction. The main products in the early stage of the hydrogenolysis were **2** and **4**. After **1** almost disappeared, **2** decreased gradually, **5** increasing in proportion to the decreased amount of **2**. **2** and **3** were hydrogenolyzed over R-Ni in a manner similar to that observed in the case of **1**. Hydrogenolysis of **2** gave **4** (15.2%) and **5** (64.2%); that of **3** gave predominantly **4** (83.0%) with a small amount of **5** (3.1%). PdO catalyzed hydrogenolysis of 1-bromo-1-fluoro-2-phenylcyclopropane (**6**) gave 2-fluoro-3-phenylpropene (**7**) and (*Z*)-2-fluoro-1-phenylpropene (**8**) as intermediates.[3] They were finally hydrogenolyzed to propylbenzene (**9**) and 2-fluoro-1-phenylpropane (**10**). The formation of these olefins can be explained by assuming that **6** adsorbed on the catalyst by C_2–C_3 bond undergoes cleavage accompanied by elimination of bromide ion. Hydrogenolysis of **1** over PdO seems to proceed in a similar manner to that above, a plausible pathway being shown in Scheme 1. Since palladium catalyst has greater affinity to carbon–carbon π-bond than to negative groups such as oxygen or nitrogen,[4,5] and the affinity to chlorine lone pairs is not very high,[6,7] the hydrogenolysis occurs selectively through the adsorption state (A) chemisorbed by the C_2–C_3 bond of the cyclopropane ring and phenylgroup followed by the formation of C_2,C_3-diadsorbed species (B). The elimination of chloride ion (or chlorine atom) from (B) is caused by the electron transfer from C_2–metal or C_3–metal bond to give (C) or (D). Since (D) forms π-benzyl complex with catalyst, elimination of the chlorine atom seems to prefer course (b). Absence of the expected olefins in the reaction mixture seems to be due to their rapid hydrogenation to the final product **5** under the experimental conditions.

The R-Ni catalyzed hydrogenolysis of **1** is complicated. Predominant formation of **2** and **4** at the

** Present address: Department of Dental Engineering, School of Dental Medicine, Tsurumi University, Tsurumi, Tsurumi-ku, Yokohama 230.

early stage of the hydrogenolysis of **1** is ascribed to the adsorption by the chlorine atom which has high affinity to nickel catalyst,[6,7] phenyl group and C_1–C_2 bond of **1**, followed by competitive hydrogenolysis of C_1–C_2 bond (path I) and C–Cl bond (path II) as shown in Scheme 2. The hydrogenolysis of C–Cl bond from the adsorbed species (F) seems to occur readily, giving **4**. The formation of **5** is mainly due to the hydrogenolysis of **2** *via* adsorbed species (H) since the stepwise hydrogenolysis of **2** *via* adsorbed species (G) gives predominantly **4**.

The adverse effect of potassium hydroxide in the PdO and R-Ni catalyzed hydrogenolysis of **1** might be explained in terms of the adsorption states of substrate. When PdO is used as a catalyst, the presence of potassium hydroxide prevents adsorption of the phenyl group and cyclopropane (adsorption state (A)) as in the case of carbon–carbon π-bond. The accelerating effect of potassium hydroxide in the case of R-Ni catalyzed hydrogenolysis is due to the inhibition of the production of Ni^{2+} ion, *viz.* poison of nickel catalyst, caused by removal of chloride ion as a salt.

Experimental

*1,1-Dichloro-*r*-3-methyl-*t*-2-phenylcyclopropane (1).* To a mixture of petroleum ether (200 ml), β-methylstyrene (29.5 g, 0.25 mol) and potassium *t*-butoxide prepared from 10 g of potassium metal was added dropwise 30 g (0.25 mol) of chloroform at −10 °C over a period of 3 h. **1**: bp 86.5—88 °C/3.5 mmHg, 19.5 g (39% yield) was obtained. R_t: 29.0 min, MS *m/e*: 200 (M^+). Found: C, 59.76; H, 4.90%. Calcd for $C_{10}H_{10}Cl_2$: C, 59.72; H, 5.01%.

Catalysts. Palladium oxide (Nippon Engelhard Co.) and Raney nickel alloy NDH (Kawaken Fine Chemical Co.) were used. The alloy was treated according to the W-5 method[8] and washed with water until the washings showed no coloration with phenolphthalein.

Catalytic Hydrogenolysis of 1. **1** (5 mmol) was hydrogenated for 24 h over R-Ni (1 g, as Ni) or PdO (0.2 g) in methanol (25 ml) at room temperature under atmospheric pressure in the presence or absence of potassium hydroxide (10 mmol). The composition of products was determined by VPC (TCP 2 m: 130 °C) at appropriate time intervals.

Identification of Products. **1** was hydrogenolyzed over R-Ni under similar conditions to those described above. Hydrogenation was stopped after 1 h, the reaction mixture was subjected to measurement of GC-MS. For measurement of NMR and elementary analysis, each component of the products was separated preparatively by VPC.

r-*1-Chloro-*c*-3-methyl-*t*-2-phenylcyclopropane (2t)*: R_t: 17.3 min, MS *m/e*: 166 (M^+), NMR (CCl_4): δ=1.86 (1H, dd, $\underline{H}_a$–C–Ph), 3.30 (1H, dd, $\underline{H}_x$–C–Cl, $J(H_a–H_x)$=3.8 Hz). Found: C, 72.27; H, 6.80%. Calcd for $C_{10}H_{11}Cl$; C, 72.09; H, 6.66%.

r-*1-Chloro-*t*-3-methyl-*c*-2-phenylcyclopropane (2c)*: R_t: 19.8 min, MS *m/e*: 166 (M^+), NMR (CCl_4): δ=2.04 (1H, dd, $\underline{H}_a$–C–Ph), 3.08 (1H, dd, $\underline{H}_x$–C–Cl, J ($H_a–H_x$)=7.8 Hz). Found: C, 72.18: H, 6.67%. Calcd for $C_{10}H_{11}Cl$: C, 72.09; H, 6.60%.

r-*2-Methyl-*t*-1-phenylcyclopropane (3)*: R_t: 4.2 min, MS *m/e*: 132 (M^+). Found: C, 90.16; H, 9.3%. Calcd for $C_{10}H_{12}$: C, 90.58; H, 9.15%.

Isobutylbenzene (4): R_t: 2.2 min, MS *m/e*: 134 (M^+), NMR (CCl_4): δ=0.91 (6H, d, $-CH(C\underline{H}_3)_2$), 1.84 (1H, m, $-C\underline{H}-(CH_3)_2$).

Butylbenzene (5): R_t: 3.0 min, MS *m/e*: 134 (M^+), NMR (CCl_4): δ=0.90 (3H, t, $-C\underline{H}_3$), 1.4 (4H, m, $-C\underline{H}_2-C\underline{H}_2-$).

Catalytic Hydrogenolysis of 2 and 3. **2** (**2t**/**2c**=44/56) and **3** were hydrogenolyzed in a similar manner to that for hydrogenolysis of **1**, respectively.

The authors are grateful to Japan Spectroscopic Co., Ltd. Tokyo, for the GC-MS measurements.

syn- and *anti*[3.3](1,4)Naphthalenophanes[1)]

Minoru YOSHINAGA, Tetsuo OTSUBO, Yoshiteru SAKATA, and Soichi MISUMI*

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received February 13, 1979)

Synopsis. The title compounds were prepared by pyrolysis of disulfones. The absorption spectra depend rather on the stacking mode between two naphthalene rings than ring-to-ring distance, whereas for the emission spectra the reverse is the case. A [4+4]photocycloaddition and a reverse reaction were observed between *anti*-form and its photoisomer.

In order to clarify the effects of ring-to-ring distance and stacking mode between two naphthalene rings on the naphthalene excimer emission,[2,3)] the title compounds were studied as more suitable models than *syn*- and *anti*[2.2](1,4)naphthalenophanes (**1** and **2**)[4)] because the [3.3]phane system with longer ring-to-ring distance must be less strained than the [2.2]phane system.

The two isomeric [3.3](1,4)naphthalenophanes (*syn* **3** and *anti* **4**)[5)] were prepared by our method in which pyrolytic desulfurization of disulfone was the key step of [3.3]phane formation.[6)] 1,4-Bis(bromomethyl)naphthalene **5**[7)] was converted to 1,4-bis(2-mercaptoethyl)-naphthalene **10** in the conventional way of five steps. A coupling of **5** with mercaptan **10** gave 2,17-dithia[4.4]-(1,4)naphthalenophane **11**. The NMR spectrum of **11** shows the *anti*-conformer to be predominant though both conformers are easily interconvertible. After **11** was oxidized with *m*-chloroperbenzoic acid, pyrolysis of the resulting disulfone **12** led to a mixture of the desired phanes **3** and **4** with a 2: 3 ratio. The separation into the two isomers was performed by fractional crystallization and column chromatography on silica gel.

The structures of **3** and **4** were determined by NMR data characteristic of *syn*- and *anti*-conformers, respectively. Thus, the ring current effect due to the opposite naphthalene ring brings about upfield shifts of all the aromatic protons for *syn*-form **3** and of only H_a proton for *anti*-form **4**. These upfield shifts are, as expected, a little less, compared to those of *syn*- and *anti*[2.2]analogs **1** and **2**.

Fig. 1 shows electronic absorption spectra of **1**—**4**. Evidently, the spectra depend rather on the stacking mode of two naphthalene rings than on the ring-to-ring distance. Thus, the spectral shapes of both conformers **3** and **4** are markedly different, whereas each spectrum is quite similar to that of the same conformer of [2.2]-analog. This phenomenon can be interpreted by only exciton interaction of the two chromophores although a contribution of charge-transfer interaction is not neglected.[3,8)]

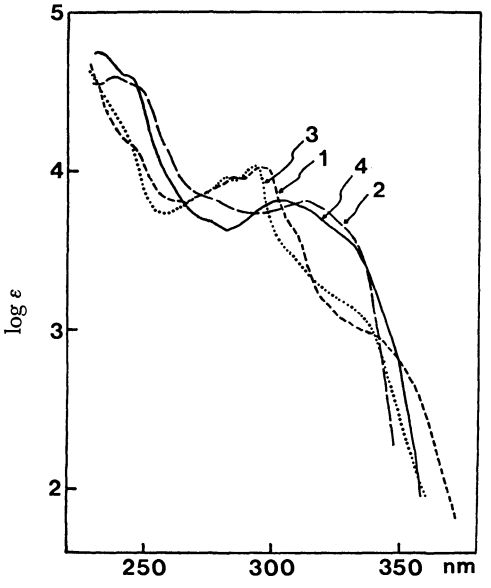

Fig. 1. Electronic spectra of **1**—**4** in tetrahydrofuran.

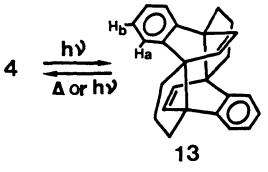

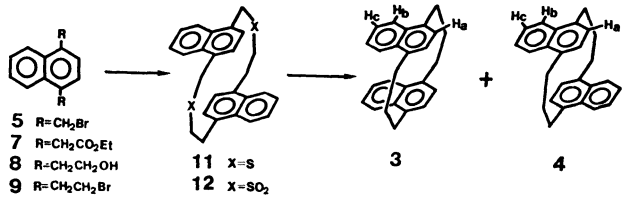

The emission spectra of **3** and **4** show a broad fluorescence band of excimer type (λ_{max} 430 nm for **3** and 420 nm for **4**) and a phosphorescence band with fine structure (λ_{max} 494, 530, 570 nm for **3** and 530, 570 nm for **4**). These data suggest that the naphthalene excimer (λ_{max} 400—410 nm) has not necessarily a closely fixed sandwich structure, that is, the ease of the excimer formation is not correlated to the extent of overlapping between two naphthalene rings. The naphthalene excimer is presumed to be in a parallel slided conformation with a distance comparable to the ring-to-ring distance in [3.3]phane system.

Although *anti*-form **2** with [2.2]system undergoes two types of intramolecular photocycloaddition, *i.e.*, a formally two-fold [4+2]cycloaddition to dibenzoequinene[9)] and a [4+4]cycloaddition,[10)] *anti*-form **4** with [3.3]system undergoes onyl [4+4]photocycloaddition to afford photoisomer **13** in quantitative yield. Cycloadduct **13** is stable at room temperature and undergoes a reverse aromatization above 130 °C to regenerate **4**.[5)] The retro-conversion of **13** to **4** also was accomplished on irradiation with light at 253.7 nm.

Experimental

Melting points are uncorrected. NMR ($CDCl_3$), MS, UV, and emission (degassed EPA) spectra were recorded with a JEOL FX-100 (100 MHz), a Hitachi RMU-7, a Hitachi EPS-3T, and a Hitachi MPF-2A (HIV R-446 photomultiplier) spectrometers, respectively.

1,4-Bis(2-hydroxyethyl)naphthalene ***8***. The reduction of diester **7** (7.6 g, 25 mmol), which was derived by cyanation of 1,4-bis(bromomethyl)naphthalene **5**,[7] followed by esterification, in dry THF (200 ml) with $LiAlH_4$ (4.8 g, 127 mmol) in dry THF (270 ml) and recrystallization of the resulting glycol from ethyl acetate gave 89% (4.8 g) yield of **8**, colorless plates, mp 119.5—120 °C. NMR δ=3.31 (2H, t, J=6.1 Hz, CH_2), 3.97 (2H, t, J=6.1 Hz, CH_2), 7.30 (2H, s, ArH), 7.50 (2H, m, ArH), and 8.11 (2H, m, ArH). Found: C, 77.97; H, 7.54%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

1,4-Bis(2-bromoethyl)naphthalene ***9***. Dibromide **9** was obtained by refluxing a mixture of glycol **8** (3.5 g, 16 mmol), 47% HBr (200 ml), and conc H_2SO_4 (90 ml) for 2 h. The mixture was worked up and chromatographed on silica gel with benzene. **9**: colorless plates from benzene–hexane, yield 2.6 g (47%), mp 131—131.5 °C. NMR δ=3.65 (8H, m, CH_2), 7.35 (2H, s, ArH), 7.65 (2H, m, ArH), and 8.10 (2H, m, ArH). Found: C, 49.32; H, 4.41; Br, 46.27%. Calcd for $C_{14}H_{14}Br_2$: C, 49.15; H, 4.13; Br, 46.72%.

1,4-Bis(2-mercaptoethyl)naphthalene ***10***. A mixture of **9** (4.5 g, 13 mmol), thiourea (2.6 g, 34 mmol), and ethanol (180 ml) was treated in the same way as the preparation of 1,4-bis(2-mercaptoethyl)benzene.[1] The resulting oil crystallized after chromatography on silica gel with benzene, yield 1.0 g (31%), mp 108.5—109.5 °C. The dithiol was essentially pure and used in the next step without further purification. NMR δ=1.44 (2H, t, J=7.8 Hz, SH), 3.06 (4H, m, CH_2), 3.40 (4H, m, CH_2), 7.25 (2H, s, ArH), 7.49 (2H, m, ArH), and 8.05 (2H, m, ArH).

2,17-Dithia[4.4](1,4)naphthalenophane ***11***. The coupling of dibromide **5** (700mg, 2.3 mmol) with dithiol **10** (600 mg, 2.4 mmol) in benzene (400 ml) was carried out according to the general procedure in the preceding paper.[1] **11**: colorless plates from benzene–hexane, yield 200 mg (22%), mp 256—257 °C. NMR δ=3.18 (8H, A_2B_2m, CH_2), 3.78 (4H, s, CH_2), 6.00 (2H, s, ArH), 6.37 (2H, s, ArH), 7.47 (4H, m, ArH), and 7.90 (4H, m, ArH). Found: C, 77.72; H, 6.05; S, 16.29 %; MS *m/e* 400 (M^+). Calcd for $C_{26}H_{24}S_2$: C, 77.95; H, 6.04; S, 16.01%; M 400.

2,17-Dithia[4.4](1,4)naphthalenophane 2,2,17,17-Tetraoxide ***12***. The preparation of disulfone **12** was carried out according to the general procedure (with *m*-chloroperbenzoic acid) in the preceding paper.[1] **12**: quantitative yield, mp 324 °C (dec). It was used for the next step without purification.

[3.3](1,4)Naphthalenophanes, syn ***3*** *and* anti ***4***. Pyrolysis of disulfone **12** (50 mg, 0.108 mmol) was carried out by the same method as previously reported (650 °C, 0.2 mmHg).[6] The collected product was purified by column chromatography on silica gel with benzene and then gel-permeation liquid chromatography to give a mixture of *syn*- and *anti*-isomers with a 2:3 ratio, yield 10 mg (28%). Recrystallization from hexane afforded pure *anti*-isomer **4**, colorless needles, mp 214—216 °C. NMR δ=2.32 (4H, m, CH_2), 2.72 (4H, m, CH_2), 3.43 (4H, m, CH_2), 5.99 (4H, s, H_a), 7.51 (4H, q, J=7.0, 2.0 Hz, Hc), and 8.06 (4H, q, J=7.0, 2.0 Hz, Hb). Found: C, 92.80; H, 7.21%, MS *m/e* 336 (M^+). Calcd for $C_{26}H_{24}$: C, 92.81; H, 7.19%; M 336.

Careful column chromatography of the mother liquid of above recrystallization on silica gel with CCl_4 afforded pure *syn*-isomer **3** after the elution of *anti*-isomer. Recrystallization from ethanol gave colorless plates, mp 229—229.5 °C. NMR δ=2.80 (8H, m, CH_2), 3.60 (4H, m, CH_2), 6.93 (4H, s, H_a), 6.98 (4H, q, J=7.6, 2.0 Hz, H_c), and 7.12 (4H, q, J=7.6, 2.0 Hz, H_b). Found: *m/e* 336.18601. Calcd for $C_{26}H_{24}$: M, 336.18779.

Photoisomer ***13***. *anti*[3.3](1,4)Naphthalenophane **4** (1.6 mg) was dissolved in 5 ml of benzene in a Vycor tube. The solution was irradiated with a high pressure mercury lamp (400 W) for 2 h under a nitrogen atmosphere. Evaporation of the solvent gave colorless solid of photoisomer **13** in a quantitative yield. NMR δ=1.79 (4H, m, CH_2), 2.16 (4H, m, CH_2), 2.71 (4H, m, CH_2), 5.47 (4H, s, olefin), 7.16 (4H, q, J=6.1, 2.8 Hz, H_b), and 7.36 (4H, q, J=6.1, 2.8 Hz H_a). Found: *m/e* 336.18645. Calcd for $C_{26}H_{24}$: M 336.18779.

It melted at 130 °C, resolidified above the temperature, and remelted at the melting point of **4**. The regeneration of **4** was confirmed by heating **13** at 132 °C in DMSO for 20 min and also by irradiating **13** with a low pressure mercury lamp for 4 h under a nitrogen atmosphere.

Reaction of Nitrosodurene with Grignard Reagents

Masao Ōkubo* and Tomoko Takahashi

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received March 14, 1979)

Synopsis. Nitrosodurene was allowed to react with alkyl- and arylmagnesium halides and the reaction was followed by ESR. The spectrum of nitrosodurene anion radical was observed, the stability sequence of alkyl duryl nitroxides being discussed on the basis of the coupling constants of α-hydrogen atoms of alkyl groups.

Study on the reaction of nitrosobenzenes with Grignard reagents started early,[1,2] the formation of diphenyl nitroxide radical on the reaction with phenylmagnesium bromide (PhMgBr) being studied precisely by ESR, but no resolvable spectrum was obtained on the reaction with methyl- and ethylmagnesium bromide (MeMgBr and EtMgBr) even at lower temperatures.[3] On the other hand, the development of spin-trapping studies[4] shed light on nitrosodurene as an especially useful spin-trap because of its stability and also the simple ESR spectra of the corresponding nitroxide radicals.[5] We wish to report the results obtained on the Grignard reaction of nitrosodurene.

The reaction was carried out in tetrahydrofuran (THF). Since the solubility of nitrosodurene dimer in ordinary solvents is very low, the substrate had to be added as a suspension in THF. When the suspension was added to an equimolar solution of PhMgBr at 0 °C, almost all of the solid nitrosodurene remained undissolved. The reaction started when the mixture was warmed up to about 30 °C, the solid dissolving gradually giving reddish brown coloration. Dark brown crystalline needles (**1**) were obtained by quenching the reaction mixture with saturated aqueous NH_4Cl followed by extraction with diethyl ether and removal of the solvent: mp 96—98 °C after recrystallization from petroleum benzine. A dilute solution of **1** in THF gave an ESR spectrum consisting of a set of coupling constants agreeing with that of phenyl duryl nitroxide: a_N=9.93 G, $a_{o,p\text{-}H}$=2.76 G and $a_{m\text{-}H}$=0.90 G. However, the magnetic susceptibility measurement gave only a 51% free spin, and the IR spectrum showed a broad and strong ν_{OH} absorption band at 3240 cm^{-1}. Thus the crystalline product **1** was suggested to be a hydrogen-bonded dimeric nitroxide-hydroxylamine complex. This was confirmed by conversion of **1** into deep red "free" nitroxide (crude, mp 116—123 °C, 88% free spin) by oxidation with Ag_2O in anhydrous diethyl ether.[6]

The coupling constants obtained directly from the reaction mixture with *p*-fluoro- and *p*-methoxyphenylmagnesium bromides are given in Table 1. The spin coupling with the *p*-hydrogen atom of the duryl group is usually unresolvable. However, it was resolved in the case of *p*-methoxyphenyl duryl nitroxide. The radical concentration of this nitroxide increased much faster than that of the *p*-fluoro derivative, indicating that the electron-donating substituent facilitates the reaction.

In the reaction with alkyl Grignard reagents, easily analyzable ESR spectra were obtained at room temperature. The results are summarized in Table 2. Since the nitroxyl oxygen atom coordinates to the ^+MgBr species present in our reaction system, all the a_N values are smaller than those obtained in the cases of "free" nitroxides obtained photolytically.[5] The a_N value (9.93 G) of the molecular complex **1**, in which the nitroxyl oxygen atom coordinates to the hydrogen atom, is also smaller than that obtained previously (10.11 G[5]).

When an equimolar MeMgBr was allowed to react with nitrosodurene, the ESR-spectrum obtained at the initial stage of the reaction consisted of a broad triplet signal due to the nitrogen atom (a_N=12.69 G), the spectrum changing rapidly into a set of weak signals of methyl duryl nitroxide.[5] When six molar equivalents of MeMgBr were used, the signals disappeared much faster. Three molar equivalents proved to give the strongest signals of the nitroxide, which disappeared in *ca.* 1 h. The triplet signal observed at the initial stage of the reaction could be ascribed to the anion radical of nitrosodurene formed as the result of electron-transfer from the Grignard reagent.[7] A similar phenomenon was observed in the reaction with isopropylmagnesium bromide. A set of broad quintet was observed at the initial stage the spectrum changing rapidly into a set of doublets of triplet assignable to isopropyl duryl nitroxide. Since a quintet (1 : 2 : 3 : 2 : 1) signal is observable when a free spin is delocalized on two equivalent nitrogen atoms,[8] the quintet could be assigned to the dimeric anion radical illustrated below. The appreciably small a_N value (9.6 G) is compatible with the proposed structure **2**.

The correlation of the order of the value of $a_{\alpha\text{-}H}$

Table 1. Coupling constants of aryl duryl nitroxides formed on the reaction with ArMgBr

ArMgBr	a_N	a_F	$a_{o\text{-}H}$	$a_{m\text{-}H}$	$a_{p'\text{-}H}$
F-C$_6$H$_4$-MgBr	10.19	6.57	2.78	0.92	—
MeO-C$_6$H$_4$-MgBr	10.44	—	2.78	0.83	0.42

Table 2. Coupling constants of alkyl duryl nitroxides formed in the reaction with RMgX

RMgX	a_N	$a_{\alpha-H}$	Order of radical concn[a)]	a_N of "free" nitroxides[5)]
CH_3MgBr	13.60	12.08	3	13.70
$PhCH_2MgCl$	13.58	7.92	2	13.61
$(CH_3)_2CHMgBr$	13.58	6.69	1	13.72

a) One indicates the highest concentration observed.

with that of radical concentration (Table 2) is of interest. The largest $a_{\alpha-H}$ value for methyl duryl nitroxide is responsible for its instability due to decomposition probably involving hydrogen-abstraction. The medium $a_{\alpha-H}$ value for benzyl duryl nitroxide is unambiguously due to the spin-delocalization on the phenyl group giving fair stability to the nitroxide. The smallest $a_{\alpha-H}$ value for isopropyl duryl nitroxide seems to be due to the steric effect of the two α-methyl groups. Since the degree of spin-distribution on these methyl groups should be very low, the small $a_{\alpha-H}$ value can be understood by considering the direction of the orbital of free spin on the nitrogen atom to be not parallel with that of the C_α–H_α bond. The low value is in line with the great stability of the radical.

Nitrosodurene was found to be a useful spin-trap also in the reaction with Grignard reagents. The hindered nitrosobenzene made it possible to observe easily analyzable spectra of nitroxides as well as the initially formed anion radical. A similar steric hindrance effect was discussed in detail.[7)]

Experimental

Materials. Nitrosodurene was prepared by the method of Smith and Taylor[9)] through mercuriation of durene followed by nitrosation: mp 160 °C. For the Grignard reaction tetrahydrofuran was dried over sodium wire, distilled, and stored on sodium wire. For ESR measurements it was dried by sodium hydride, frozen, degassed repeatedly, and distilled in a solvent reservoir on a vacuum line containing Na–K alloy. *p*-Fluorobromobenzene was prepared from fluorobenzene[10)] (Daikin Industrial Co.). Commercial halogen compounds were used (reagent grade). Half molar stock solutions of Grignard reagents in THF were prepared and stored under, N_2.

Procedures for Measurements. The apparatus used for the measurements was constructed according to the method reported by Maruyama.[3)] Nitrosodurene (0.0136 g, 0.25 mmol) was weighed and introduced into a reaction vessel, 5 ml of THF being distilled into it from a solvent reservoir using vacuum line. Only a small portion of nitrosodurene went into the solution with weak green coloration. When the two reactants were mixed by breaking the seal, the color of the resultant mixture turned yellow or orange due to the formation of nitroxide radical accompanied by the dissolution of the solid nitrosodurene dimer. In order to obtain hyperfine structures, a small part of the reaction mixture transferred into the measurement cell was diluted by distilling the solvent from the reaction vessel.

The authors wish to thank Dr. Shuji Emori, Saga University, for the measurement of magnetic susceptibility.

The Preparation of *N*-Benzyl-α-ethoxycarbonylnitrone and Its Reactions with Some Olefins

Yoshinobu INOUYE,* Yuko WATANABE, Satoru TAKAHASHI, and Hiroshi KAKISAWA

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305

(Received June 11, 1979)

Synopsis. *N*-Benzyl-α-ethoxycarbonylnitrone (**1**) was prepared from ethyl glyoxylate and *N*-benzylhydroxylamine. The reactions of **1** with isobutylene, methyl acrylate, and methyl crotonate are described.

In the course of our synthetic studies of the hydroxy amino acid moiety *via* 1,3-dipolar cycloaddition,[1,2] *N*-benzyl-α-alkoxycarbonylnitrone (*e.g.*, **1**) was expected to be a suitable 1,3-dipole, especially for the preparation of the γ-hydroxy α-amino acid.

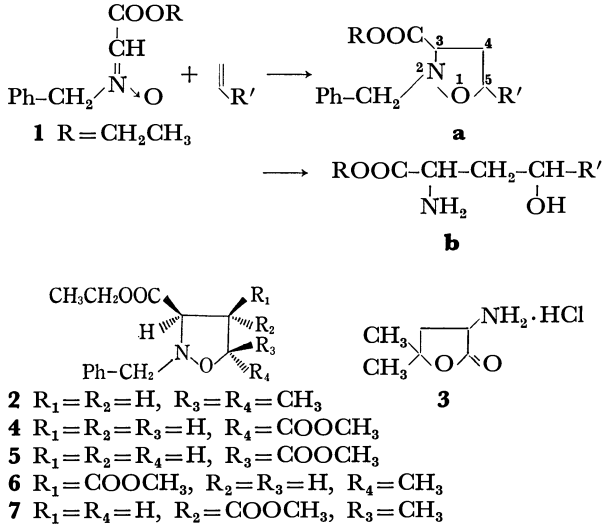
The removal of the benzyl group and the fission of the N–O bond in the adduct, **a**, would be attained simultaneously under such conditions of catalytic hydrogenolysis, and the stereochemistry of the product, **b**, would directly reflect the regio- and stereospecificities in the 1,3-dipolar cycloaddition of the nitrone.[3]

A hitherto unknown nitrone, **1**, was prepared by the condensation of ethyl glyoxylate and *N*-benzylhydroxylamine in the presence of calcium chloride.[4] **1** crystallized easily, but it was found to be a mixture of *Z*(**1a**) and *E*(**1b**) isomers (*Z*: *E*=1: 2), as is shown in its NMR spectrum. The two singlets at 5.69 and 4.96 are assignable to the methylene protons at the benzylic position in **1b** and **1a** respectively. The difference in chemical shift can be explained by the effect of the neighboring ester group. The ratio depends slightly on the reaction and/or recrystallization conditions.

When the nitrone **1**(*Z*: *E*=1: 2) and isobutylene in benzene were heated at 80 °C for 3 d, only a single adduct was isolated by distillation. The structure of the adduct was characterized as 2-benzyl-5,5-dimethyl-3-ethoxycarbonylisoxazolidine (**2**) from its spectroscopic properties and its conversion to the known[5] γ-hydroxyleucine lactone hydrochloride (**3**) by hydrogenolysis over $Pd(OH)_2$.[6]

The reaction of the nitrone **1** (*Z*: *E*=1: 2) with methyl acrylate proceeded at room temperature, and two adducts, **4** and **5** (**4**: **5**=4: 1), were isolated in 84% yield. Two pairs of doublets, at 4.68 and 3.78, in the NMR spectrum of **4**, and similar pairs at 4.65 and 3.61 in **5**, reveal the substitution pattern on the isoxazolidine ring in both **4** and **5** to be a 2,3,5-trisubstituted one. The stereochemistry of **4**, assumed to be *trans* from the pseudocontact shift with $Eu(fod)_3$ (see Experimental), was confirmed by subjecting **4** to catalytic hydrogenolysis over $Pd(OH)_2$, followed by hydrolysis with 6 M (1 M=1 mol dm^{-3}) hydrochloric acid. In the amino acid chromatogram[7] of the products, almost all (>94%) of the γ-hydroxyglutamic acids and their lactones were recognized as having the *threo*-configuration.

Among the various dipolarophiles reported, the cycloadducts from the crotonic ester have been shown to have a "reverse" regioselectivity.[8] This was observed also in the present case. The mixture of **1** (*Z*: *E*=1: 3.5) and methyl crotonate was allowed to stand at room temperature to give **6** and **7** (4.4: 1) in 83% yield. The arrangement of substituents and the stereochemistry of **6** and **7** were assumed from the analyses of the NMR spectra. Of the three protons on the isoxazolidine ring, H^5 is the most downfield in both **6** (δ at 4.40) and **7** (δ at 4.56) and is assignable to the partial structure –O–C**H**^{5}(CH_3)–CH– on the basis of the chemical shifts and multiplicities. The differences in the chemical shifts of H^3 (Δ 0.35) and H^4 (Δ 0.40) of **7** as compared with those of **6** are attributable to a deshielding effect of the neighboring ester group, which is *cis* to the protons in question in the case of **7**. The two ester groups, thus, can be arranged *cis* to each other in **6** and *trans* in **7**. The *trans* relationship between C_4 and C_5 was assumed from the reaction mechanism.[9]



Experimental

All the melting points are uncorrected. The IR spectra were recorded on a Hitachi 215 grating spectrophotometer, and the NMR spectra were obtained on a Hitachi H-60 and a JEOL MH-100 spectrophotometers, using TMS as an internal standard.

N-Benzyl-α-ethoxycarbonylnitrone (1). To an ice-cooled mixture of 5.3 g of *N*-benzylhydroxylamine and 1.5 g of calcium chloride in 40 ml of ether,[4] 4.5 g of ethyl glyoxylate was added dropwise, after which the whole was stirred at 0 °C for 1 h. The solids were removed by filtration through an anhydrous sodium sulfate layer, and the filtrate was evaporated to give crystalline **1** (7.8 g, 88%). Two recrystallizations from benzene afforded an analytical sample of **1**: mp 84.0—86.5 °C; ν(KBr): 1720, 1560, 1200 br, 1045, 965, 825, and 700 cm^{-1}; δ ($CDCl_3$): 7.4 (m, 5H), 7.17 (**1b**)

and 7.09 (**1a**) (s, 1H), 5.69 (**1b**) and 4.96 (**1a**) (s, 2H), 4.25 (**1b**) and 4.22 (**1a**) (q, 2H, J=7 Hz), and 1.30 (**1b**) and 1.27 (**1a**) (t, 3H, J=7 Hz). Found: C, 63.93; H, 6.31; N, 6.82%. Calcd for $C_{11}H_{13}NO_3$: C, 63.75; H, 6.32; N, 6.76%. The ratio of Z(**1a**) and E(**1b**) was calculated as 1:2 from the peak areas of the benzylic methylene signals. The ratio changed between 1:2 and 1:3.5 according to the difference in preparation and/or recrystallization, but attempts at the separation of each isomer were unsuccessful, and so the mixture of a known ratio was used in the subsequent reactions.

2-Benzyl-5,5-dimethyl-3-ethoxycarbonylisoxazolidine (2). A mixture of 535 mg of **1**(Z: E=1:2), 3.1 g of isobutylene, and 12 ml of benzene in a sealed tube was heated at 80 °C for 3 d. The subsequent evaporation of the solvent gave **2**(630 mg). An analytical sample was obtained by Kugelrohr distillation (bath temp: 144—145 °C/2 mmHg). ν($CHCl_3$): 1730, 1600, 1375, and 1365 cm^{-1}; δ ($CDCl_3$): 7.3 (m, 5H), 4.07 (s, 2H), 4.07 (q, 2H, J=7 Hz), 3.52 (dd, 1H, J=7.5 and 9.5 Hz, C part of ABC), 2.3 (m, 2H, AB part of ABC), 1.38 (s, 3H), 1.30 (s, 3H), and 1.21 (t, 3H, J=7 Hz). Found: C, 68.39; H, 7.97: N, 5.40%. Calcd for $C_{15}H_{21}NO_3$: C, 68.41; H 8.03; N, 5.31%.

γ-Hydroxyleucine Lactone Hydrochloride (3). A mixture of 188 mg of **2**, 90 mg of $Pd(OH)_2$,[6] and 40 ml of methanol was shaken under a hydrogen atmosphere (3 atm) for 3 d. After the removal of catalysts by filtration, the filtrate was concentrated to give an oily solid (118 mg); ν($CHCl_3$): 1760 cm^{-1}. A part of the oily solid was dissolved in ethanol, and 1.1 eq of hydrochloric acid was added. The whole was left in a desiccator *in vacuo* to give **3**: mp 206—207 °C (from ethanol); the IR spectrum (KBr disk: 3500—2400 br, 1765, 1575, and 1490 cm^{-1}) of **3** was coincident with that of the authentic γ-hydroxyleucine lactone hydrochloride (mp 208—209 °C).[5]

trans-2-Benzyl-3-ethoxycarbonyl-5-methoxycarbonylisoxazolidine (4) and cis-2-Benzyl-3-ethoxycarbonyl-5-methoxycarbonylisoxazolidine (5). A solution of 200 mg of the nitrone **1**(Z: E=1:2) and 175 mg of methyl acrylate in 3 ml of benzene was stirred at room temperature for 36 h. The subsequent evaporation of the solvent gave an oil (285 mg), which showed three spots on TLC (Merk silica gel 60, 0.25 mm; hexane–ethyl acetate =3:1). The oil was chromatographed on silica gel (30 g) with benzene–ethyl acetate (100:2) to give an unidentified compound (R_f=0.30, 6 mg), 158 mg of **4**(R_f=0.22), 55 mg of a mixture of **4** and **5**(2:1), and 27 mg of **5**(R_f=0.17). Analytical samples were prepared by a flash chromatography[10] (hexane–ethyl acetate=3:1), followed by Kugelrohr distillation.

4: Bath temp 131—134 °C/0.08 mmHg; ν (CCl_4): 1755 sh, 1735, and 1190 cm^{-1}; δ ($CDCl_3$, 100 MHz; Δ values show the pseudocontact shifts upon the addition of 0.8 eq of Eu(fod)$_3$): 7.3 (m, 5H), 4.68 (dd, 1H, J=6 and 8 Hz, Δ 0.18), 4.16 (AB center, 2H, J=13 Hz, Δ 0.52), 4.14 (q, 2H, J=7 Hz, Δ 0.02), 3.78 (dd, 1H, J=6 and 8 Hz, Δ 0.66), 3.76 (s, 3H, Δ 0.06), 2.92 (ddd, 1H, J=8, 6 and 14 Hz, Δ 0.38), 2.68 (ddd, 1H, J=6, 8, and 14 Hz, Δ 0.48), and 1.24 (t, 3H, J=7 Hz, Δ 0.00). Found: C, 61.29; H, 6.47; N, 4.92%. Calcd for $C_{15}H_{19}NO_5$: C, 61.42; H, 6.52; N, 4.77%.

5: Bath temp 140—145 °C/0.1 mmHg; ν (CCl_4): 1769 sh, 1730, and 1190 cm^{-1}; δ ($CDCl_3$, 100 MHz): 7.4 (m, 5H), 4.65 (dd, 1H, J=5.5 and 8.5 Hz), 4.15 (q, 2H, J=7 Hz), 4.15 (s, 2H), 3.77 (s, 3H), 3.61 (dd, 1H, J=6 and 8 Hz), 2.6—3.1 (m, 2H), and 1.24 (t, 3H, J=7 Hz). Found: C, 61.55; H, 6.50; N, 5.08%. Calcd for $C_{15}H_{19}NO_5$: C, 61.42; H, 6.52; N, 4.77%.

Amino Acid Analysis.[7] A solution of 364 mg of **4** in 50 ml of methanol was hydrogenolyzed over 100 mg of $Pd(OH)_2$ under a hydrogen atmosphere (3 atm) for 2 d. After the catalysts had then been removed, the filtrate was concentrated to give an oil. The oil was refluxed for 4 h with 20 ml of 6 M hydrochloric acid. After decolorizing with activated carbon, the solution was concentrated to give crystals (234 mg). The amino acid chromatogram of the crystals showed the presence[2] of *threo*-γ-hydroxyglutamic acid (0.270 mmol), *erythro*-γ-hydroxyglutamic acid (0.023 mmol), and *threo*-γ-hydroxyglutamic acid lactone (0.113 mmol).

2-Benzyl-r-3-ethoxycarbonyl-c-4-methoxycarbonyl-t-5-methylisoxazolidine (6) and 2-Benzyl-r-3-ethoxycarbonyl-t-4-methoxycarbonyl-c-5-methylisoxazolidine (7). A mixture of 205 mg of the nitrone **1** (Z: E=1:3.5), 198 mg of methyl crotonate, and 5 ml of benzene was stirred at room temperature for 3 d. The subsequent removal of the solvent gave an oil containing some crystals. VPC analysis (5% OV-1, 1.7 m, 180 °C) showed that two components of R_t=6 min and R_t=7 min were present in the product. They were separated by column chromatography on silica gel (33 g). Elution with benzene–ethyl acetate (98:2) afforded 47 mg of **7** (R_t=6 min) and 206 mg of **6** (R_t=7 min).

6: Mp 41.5—42.5 °C (from pentane); ν ($CHCl_3$): 1735 cm^{-1}; δ ($CDCl_2$, 100 MHz): 7.3 (m, 5H), 4.40 (dq, 1H, J=8 and 6 Hz), 4.14 (q, 2H, J=6 Hz), 4.10 (AB center, 2H, J=14 Hz), 3.78 (d, 1H, J=8 Hz), 3.66 (s, 3H), 3.12 (t, 1H, J=8 Hz), 1.36 (d, 3H, J=6 Hz), and 1.22 (t, 3H, J=6 Hz). Found: C, 62.43; H, 6.72; N, 4.50%. Calcd for $C_{16}H_{21}NO_5$: C, 62.52; H, 6.88; N, 4.55%.

7: Liquid, bath temp 105—109 °C/0.09 mmHg; ν($CHCl_3$): 1735 cm^{-1}; δ ($CDCl_3$, 100 MHz): 7.4 (m, 5H), 4.56 (quint, 1H, J=6 Hz), 4.18 (q, 2H, J=7 Hz), 4.14 (s, 2H), 4.13 (d, 1H, J=8 Hz), 3.79 (s, 3H), 3.52 (dd, 1H, J=6 and 8 Hz), 1.44 (d, 3H, J=6 Hz), and 1.24 (t, 3H, J=7 Hz). Found: C, 62.92; H, 6.94; N, 4.56%. Calcd for $C_{16}H_{21}NO_5$: C, 62.52; H, 6.88; N, 4.55%.

We are deeply indebted to Dr. Minoru Tamura, The University of Tsukuba, for his measurements of the amino acid chromatograms.

Synthesis of 2,5-Diphenylbicyclo[4.2.0]octa-2,4-diene. Exclusive Existence in the Bicyclic Form and a Correction of the Reported Structure of 2,5-Diphenyl-1,3,5-cyclooctatriene

Masaji ODA* and Yoshinori KANAO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received June 14, 1979)

Synopsis. 2,5-Diphenylbicyclo[4.2.0]octa-2,4-diene has been found to exist exclusively in the bicyclic form, giving rise to questioning the reported structure of 2,5-diphenyl-1,3,5-cyclooctatriene. The structure of 1,4-diphenyl-1,3,6-cyclooctatriene is proposed for the compound.

Courtot and Rumin reported that reduction of the dimesylate of *cis*-5,6-bis(hydroxymethyl)-1,4-diphenyl-1,3-cyclohexadiene (**1**) with lithium aluminum hydride gives 2,5-diphenyl-1,3,5-cyclooctatriene (**2**) along with 5,6-dimethyl-1,4-diphenyl-1,3-cyclohexadiene (**3**) and 1,4-diphenyl-5-methylbicyclo[4.1.0]hept-3-ene (**4**).[1]

In the course of studies on unsaturated eight-membered ring compounds, we prepared 2,5-diphenylbicyclo[4.2.0]octa-2,4-diene (**5**), a valence isomer of **2**, and found that compound **5** exclusively exists in the bicyclic form at room temperature to 100 °C. This gave rise to questioning the reported structure of **2**. A reasonable alternative structure for the compound of Courtot and Rumin seems to be 1,4-diphenyl-1,3,6-cyclooctatriene (**6**) for several reasons.

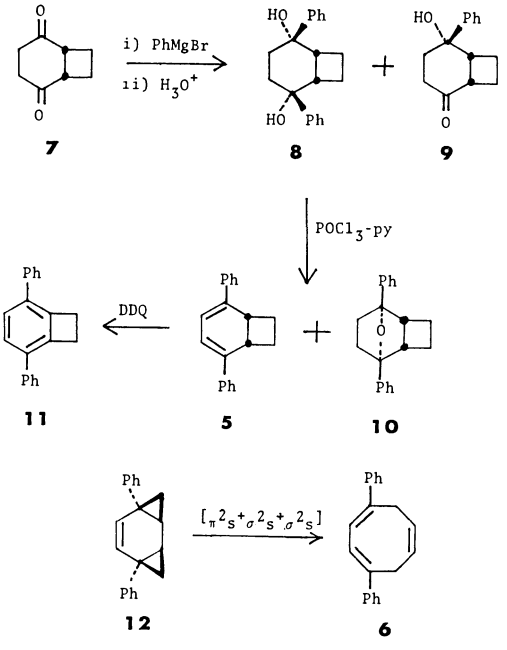
Scheme 1.



7 8 9 11 5 10 12 6

Scheme 2.

Reaction of bicyclo[4.2.0]octane-2,5-dione (**7**)[2] with phenylmagnesium bromide (five equivalents) gave 2,5-diphenylbicyclo[4.2.0]octane-*r*-2,*c*-5-diol (**8**) and 5-hydroxy-5-phenylbicyclo[4.2.0]octan-2-one (**9**). The stereochemistry of these compounds was assigned from a steric point of view. Dehydration of **8** with phosphoryl chloride in pyridine gave **5** and 1,6-diphenyl-9-oxatricyclo[4.2.1.$0^{2,5}$]nonane (**10**).

The ^{1}H-NMR spectrum of **5** (CCl_4) exhibits signals at δ 2.3—2.8 (4H, m, H-7,8), 3.92 (2H, m, H-1,6), 6.38 (2H, s, H-3,4), and 7.0—7.5 (10H, m, aromatic protons), in line with the bicyclic structure. The spectrum did not change even after heating the solution at 100 °C for 4 h. Treatment of **5** with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone readily gave 2,5-diphenylbicyclo[4.2.0]-octa-1,3,5-triene (**11**).

The results indicate that between the bicyclic structure (**5**) and the ring-opened structure (**2**), the former is thermodynamically favorable. Thus, the reported structure of **2** is questionable. The reasonable structure of Courtot's compound is probably 1,4-diphenyl-1,3,6-cyclooctatriene (**6**) for the following reasons: (i) The methylene protons of **2** appear at δ 3.20 in the ^{1}H-NMR spectrum. The chemical shift is 0.77 ppm lower than that of 1,3,5-cyclooctatriene itself (δ 2.43),[3] being nearer to that of 1,3,6-cyclooctatriene (δ 2.70).[4] In structure **6**, the phenyl group would exert relatively large down-field anisotropy effect on the adjacent methylene protons, whereas, in structure **2**, no such large effect is expected. (ii) Similar reduction of the *trans* isomer of **1** was reported to give a *trans*-bis-σ-homobenzene derivative as the main product.[1] Therefore, it would be highly probable that Courtot's compound was obtained from the *cis*-bis-σ-homobenzene derivative (**12**) by $[\pi 2_s+\sigma 2_s+\sigma 2_s]$ cycloreversion. *cis*-Bis-σ-homobenzenes have been reported to undergo cycloreversion readily.[5]

The reason for compound **5** exclusively existing in the bicyclic form should be noted. 1,3,5-Cyclooctatriene itself is at equilibrium with bicyclo[4.2.0]octa-2,4-diene with free energy difference of only 1.1 kcal mol^{-1} (89.2: 10.8 at 60 °C).[6] The ratio is largely affected by introduction of substituents.[6,7] Since the cyclohexadiene moiety of **5** should be almost planar, the gain of conjugative energy by the introduction of the phenyl groups at C-2 and -5 might be sufficient to favor the bicyclic form. Such an effect by phenyl has also been observed in cycloheptatriene-norcaradiene equilibrium.[8]

Experimental

Melting points were determined with a Thomas-Hoover apparatus and are uncorrected. IR, UV, and ^{1}H-NMR spectra were recorded with a Hitachi 215, a Hitachi 323, and a JEOL PMX 60 spectrometer, respectively. Microanalyses were performed at the Microanalytical Laboratory in this department.

Reaction of Bicyclo[4.2.0]octane-2,5-dione (7) with Phenylmagnesium Bromide. An ethereal solution (20 ml) of **7** (1.38 g, 10 mmol) was added dropwise at room temperature over a period of 15 mın to an ethereal solution (*ca.* 100 ml) of phenylmagnesium bromide prepared from bromobenzene (7.85 g, 50 mmol) and magnesium (1.21 g, 50.4 mmol).[9] Dry tetrahydrofuran (150 ml) was added and the mixture was stirred under nitrogen for 16 h. 1 M Sulfuric acid (20 ml) and then water (200 ml) was added. The products were extracted ethyl acetate (2×50 ml). The extracts were washed with water, and brine, and dried over $MgSO_4$. After removal of the solvent the residue was chromatographed on silica gel. Elution with dichloromethane gave, in the order of elution, 2,5-diphenylbicyclo[4.2.0]octane-*r*-2,*c*-5-diol (**8**) (0.640 g, 20.5 %) and 5-hydroxy-5-phenylbicyclo[4.2.0]octan-2-one (**9**) (1.18 g, 54.6%). (**8**): colorless crystals from benzene–dichloromethane; mp 140—142 °C; IR (KBr) ν 3300, 1498, 1453, 1006, 753, 703 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.9—2.4 (8H, m), 3.03 (2H, m), 3.57 (2H, s, OH), 7.2—7.6 (10H, m). Found: C, 81.69; H, 7.78%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%. (**9**): colorless crystals from benzene–dichloromethane; mp 162—162.5 °C; IR (KBr) ν 3350, 1695, 967, 752, 698 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.9—2.7 (8H, m), 3.0—3.5 (2H, m), 7.2—7.5 (5H, m). Found: C, 77.71; H, 7.65%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

Dehydration of the Diol (8). A solution of the diol (**8**) (318 mg, 1.08 mmol) and phosphoryl chloride (1.67 g, 11 mmol) in pyridine (5 ml) was heated under nitrogen at 50 °C for 3.5 h. The cooled mixture was poured into cold 6 M hydrochloric acid (15 ml) and extracted with benzene (2× 20 ml). The extracts were washed with water and dried. The solvent was removed and the residue was chromatographed on silica gel. Elution with benzene–hexane gave, in the order of elution, 2,5-diphenyl-bicyclo[4.2.0]octa-2,4-diene (**5**) (120 mg, 43%) and 1,6-diphenyl-9-oxatricyclo[4.2.1.0^{2,5}]-nonane (**10**) (45.6 mg, 15%). (**5**): yellow needles from ethanol–dichloromethane; mp 131—133 °C; IR (KBr) ν 1590, 1546, 1495, 1450, 850, 765, 745, 684 cm^{-1}; UV (cyclohexane) λ 233 (log ε 4.06), 358 (4.36), 366 nm (sh. 4.34). Found: C, 92.84; H, 7.32%. Calcd for $C_{20}H_{18}$: C, 92.98; H, 7.02%, (**10**): colorless crystals from hexane; mp 83—84 °C; IR (KBr) ν 1600, 1010, 967, 754, 700 cm^{-1}; ^{1}H-NMR (CCl_4) δ 1.5—1.9 (4H, m), 1.97 (4H, s), 2.97 (2H, m), 7.0—7.5 (10H, m). Found: C, 86.81; H, 7.38%. Calcd for $C_{20}H_{20}O$: C, 86.92; H, 7.29%.

Dehydrogenation of the Diene (5). A mixture of the diene (**5**) (30.3 mg, 0.117 mmol) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (28.3 mg, 0.124 mmol) in benzene (2 ml) was stirred at room temperature for 40 h. Filtration gave 2,3-dichloro-5,6-dicyanohydroquinone (22.5 mg). The filtrate was chromatographed on silica gel, eluted with benzene, to give 2,5-diphenylbicyclo[4.2.0]octa-1,3,5-triene (**11**) (17.7 mg. 59%); colorless crystals from hexane–dichloromethane; mp 182—183 °C; IR (KBr) ν 3050, 1590, 1472, 1451, 1067, 1021, 777, 759, 752 cm^{-1}; UV (cyclohexane) λ 289.5 nm (log ε 4.47); ^{1}H-NMR ($CDCl_3$) δ 3.45 (4H, s), 7.2—7.8 (12H, m). Found: C, 93.43; H, 6.48%. Calcd for $C_{20}H_{16}$: C, 93.71; H, 6.29%.

The Reaction of 2,4,6-Triphenyl-1,3-thiazinylium Perchlorate with Active Methylenes

Isao SHIBUYA

National Chemical Laboratory for Industry (Tsukuba Research Center), Yatabe, Ibaraki 305

(Received June 18, 1979)

Synopsis. The reaction of 2,4,6-triphenyl-1,3-thiazinylium perchlorate (**4**) with several active methylenes was studied. Methyl cyanoacetate or benzoylacetonitrile reacted with **4** to give 3-cyano-2,4,6-triphenylpyridine, while malononitrile led to 1-mercapto-1,3-diphenyl-4,4-dicyanobutadiene and cyanoacetamide led to 2-hydroxy-3-cyano-4,6-diphenylpyridine. The reaction of diethyl malonate, nitromethane, or nitroethane with **4** gave 2-[bis(ethoxycarbonyl)methyl]-, 2-nitromethyl-, or 2-(1-nitroethyl)-2,4,6-triphenyl-2*H*-1,3-thiazine respectively. These results showed that the reaction manner of **4** to these active methylenes is significantly different from that of 2,4,6-triphenyl-1,3-oxazinylium salt.

Concerning the reaction of 2,4,6-triphenylpyrylium salt (**1**) and its S-analog, 2,4,6-triphenylthiopyrylium salt (**2**), with active methylenes, **1** and **2** usually lead to the same products, 1-substituted 2,4,6-triphenylbenzenes; however, with malononitrile and nitromethane **1** and **2** lead to different products.[1,2] This fact suggested that the reactivities of **1** and **2** are slightly different from each other. The reaction of 2,4,6-triphenyl-1,3-oxazinylium perchlorate (**3**) with active methylenes gives various pyridine derivatives *via* butadienes as intermediates;[3,4] however, the reactivity of the S-analog of **3**, 2,4,6-triphenyl-1,3-thiazinylium perchlorate (**4**) has not yet been investigated. In this study, the reaction of **4** with several active methylenes was examined, and the reactivity of **4** was compared with those of **1**, **2**, or **3**.

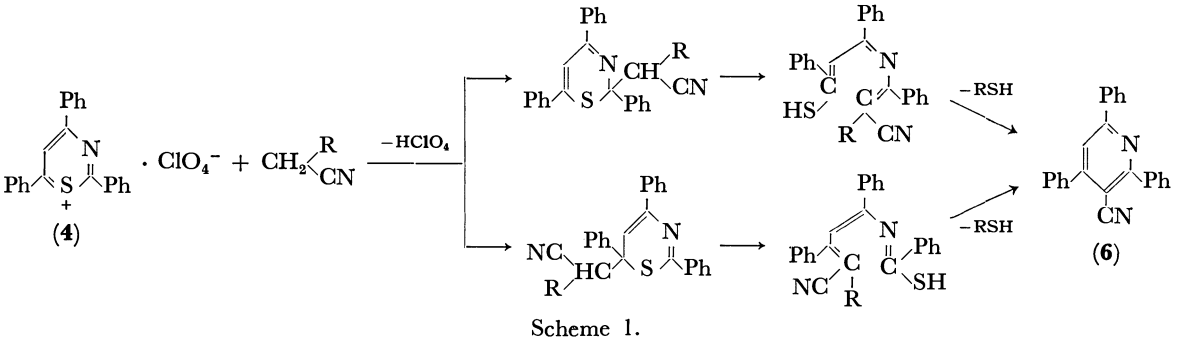
Results and Discussion

On treatment with methyl cyanoacetate, **1** or **2** leads to 2,4,6-triphenylbenzonitrile (**5**),[1,2] while **3** gives 2-benzoylamino-3-methoxycarbonyl-4,6-diphenylpyridine.[3] When **4** was refluxed with this reagent in MeOH–MeONa, 3-cyano-2,4,6-triphenylpyridine (**6**) was given in a good yield. **6** is the N-analog of **5**; consequently, the behavior of **4** in response to this reagent is different from that of **3**, but similar to that of **1** or **2**. Two courses may be supposed for this reaction, as is shown in Scheme 1 (R=$COOCH_3$).

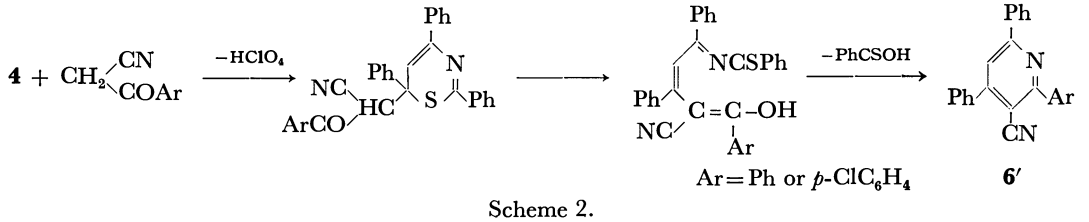
On treatment with benzoylacetonitrile, **1** and **2** also give **5**. On the other hand, it has been shown that **3** with this reagent undergoes the reaction of Scheme 2 and leads to **6′** (Ar=Ph).[4] The reaction of **4** with this reagent also gave **6**. This indicates at least three courses in Scheme 1 (R=Ph) and Scheme 2 (Ar=Ph). In order to check the course, **4** was treated with *p*-chlorobenzoylacetonitrile, and the resulting product was identified as **6**. The reaction course in Scheme 2 was, thus, obviated, and one of the two ways of Scheme 1 was suggested to be the reaction course. Therefore, **4** is different from **3** in its behavior in reaction to this reagent.

Cyanoacetamide leads to **5** on treatment with **1** or **2**. The reaction of **3** with this reagent gives 2-hydroxy-3-cyano-4,6-diphenylpyridine (**7**).[4] On the other hand, treatment with **4** resulted in **7**; for this reaction, the two courses may also be supposed. It is, however, difficult to study their reaction courses more closely because the reactions of these three reagents with **4** proceed very readily without the isolation of their intermediates.

Malononitrile behaves quite differently in response to **1**, **2**, or **3** to give different products.[1-3] The reaction of **4** with this reagent gave **8**, with a small amount of **6**. The reaction course for **6** was supposed to be as is shown

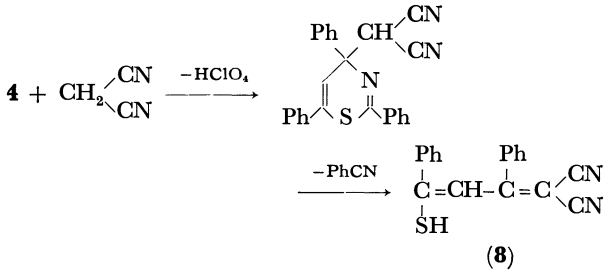


Scheme 1.



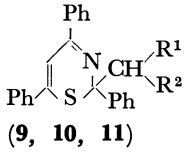
Scheme 2.

in Scheme 1 (R=CN), while **8** was identified as 1-mercapto-1,3-diphenyl-4,4-dicyanobutadiene, which is given on the treatment of 3,5-diphenyl-1,2-dithiolylium salt with this reagent;[5] it was found that this reaction mode was unique, as is shown in Scheme 3.



Scheme 3.

Diethyl malonate, nitromethane, and nitroethane reacted with **4** in dioxane-triethylamine to afford **9**, **10**, and **11** respectively. Their analytical data and the molecular weights by MS spectrometry showed that they were adducts of the 1,3-thiazinylium cation and the carbanion of active methylenes. Since their IR spectra had no absorption assigned to N–H and S–H stretching, it was suggested that these products were not chain compounds. The UV spectra were closely similar to each other (λ_{max}=244 nm, ε=25800—27600); consequently, they were thought to have the same skeletal structure. According to their CMR spectra, which was checked by means of the ^{1}H-off-resonance method, **9**, **10**, and **11** were confirmed to be 2-[bis(ethoxycarbonyl)methyl]-, 2-nitromethyl-, and 2-(1-nitroethyl)-2,4,6-triphenyl-2*H*-1,3-thiazine respectively.



(**9**, **10**, **11**)

9: R^1=$COOC_2H_5$, R^2=$COOC_2H_5$
10: R^1=H, R^2=NO_2
11: R^1=CH_3, R^2=NO_2

The reaction of **4** with other active methylenes, such as dibenzoylmethane, ethyl benzoylacetate, benzoylacetamide, and ethyl carbamoylacetate, gave no product.

Hence, it is proved that **4** is less active than **3** against several active methylenes, and that the reaction manners of **3** and **4** are significantly different from each other.

Experimental

3-Cyano-2,4,6-triphenylpyridine (6). Into a solution of 3 mmol of methyl cyanoacetate, benzoylacetonitrile, or *p*-chlorobenzoylacetonitrile in 4 ml of 1.0 mol dm^{-3} MeOH–MeONa, 0.86 g (2 mmol) of **4** was stirred at room temperature for 10 min, and then the mixture was refluxed for 1 h. The reaction mixture was poured into dilute hydrochloric acid. The resulting precipitate was collected by filtration and recrystallized from acetic acid to give 0.54 g (81%), 0.58 g (87%), or 0.39 g (59%) of **6** (mp=225.3 °C) respectively. The IR spectrum of **6** was completely superimposed on that of an authentic sample.[4]

2-Hydroxy-3-cyano-4,6-diphenylpyridine (7). Cyanoacetamide was treated with **4** by the procedure described above. The resulting precipitate was purified by reprecipitation from aqueous sodium hydroxide–hydrochloric acid to give 0.39 g (72%) of **7** (mp>300 °C). The IR spectrum of **7** agreed with that of an authentic sample.[3]

1-Mercapto-1,3-diphenyl-4,4-dicyanobutadiene (8). Into a solution of 0.20 g (3 mmol) of malononitrile in 4 ml of 1.0 mol dm^{-3} MeOH–MeONa, 0.86 g (2 mmol) of **4** was stirred at room temperature for 10 min, and then the mixture was refluxed for 1 h. The reaction mixture was allowed to stand overnight and then filtered to separate the resulting crystalline (0.12 g, 18%) of **6**. The filtrate was poured into dilute hydrochloric acid, and the resulting precipitate was recrystallized from acetonitrile to give 0.34 g (59%) of **8** (mp=225.5 °C).[5] Found: S, 11.09%. Calcd for $C_{18}H_{12}N_2S$: S, 11.12%.

2-[Bis(ethoxycarbonyl)methyl]-, 2-Nitromethyl-, or 2-(1-Nitroethyl)-2,4,6-triphenyl-2H-1,3-thiazine (9, 10, 11). Into a solution of 3 mmol of diethyl malonate, nitromethane, or nitroethane and 0.4 ml of triethylamine in 4 ml of dioxane, 0.86 g (2 mmol) of **4** was stirred at room temperature, after which the solution was allowed to stand for 5 d. The reaction mixture was poured into dilute hydrochloric acid, and the resulting precipitate was recrystallized from methanol (**9**) or acetic acid (**10**, **11**) to yield 0.71 g (73%), 0.48 g (62%), or 0.44 g (55%) respectively. Their data are shown as follows.

9: Mp, 118.0 °C; MS, 485 (M^+), 412 ([M−$COOC_2H_5$]$^+$). 326 ($C_{22}H_{16}NS^+$), 237 ($C_{15}H_{11}NS^+$), and 121 *m/e* ($C_6H_5CS^+$); IR (KBr), 1750, 1625, 1490, 1445, 1360, 1325, and 1300 cm^{-1}; UV (EtOH), λ_{max} 244 nm (25800); CMR ($CDCl_3$), 167.19 (-COOR), 142.27, 137.46, 137.34, 132.71—126.13 (arom.), 120.13 (=CH–), 69.04 (–$\overset{|}{C}$–), 64.00 (–$\overset{|}{C}$H–), 61.18 (–CH_2–), 14.05 (–CH_3), and 13.75 ppm (–CH_3). BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (12), 3769—3770 (1979)

Synthesis of *t*-2, *t*-3-Dicarboxy-*r*-1-cyclopentylacetic Acid

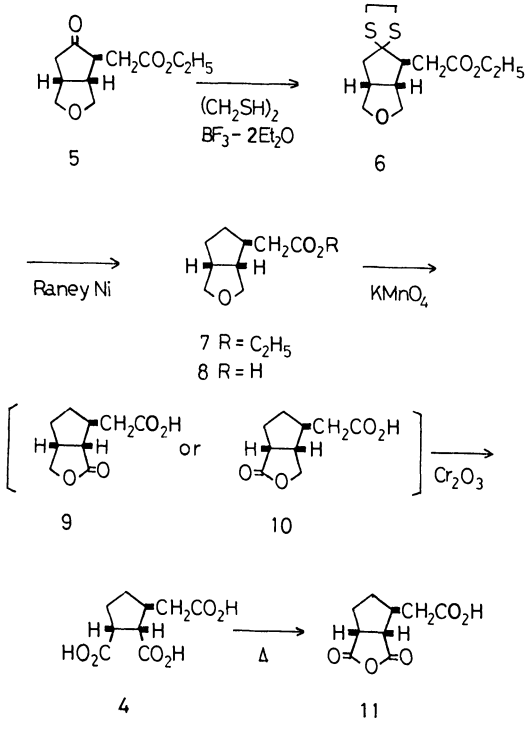
Heitaro OBARA,* Hiroshi KIMURA, Masanobu SUZUKI, and Shigenobu YAMADA

Department of Applied Chemisty, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received April 14, 1979)

Synopsis. One of the four stereoisomers of 2,3-dicarboxycyclopentylacetic acid, the *t*-2, *t*-3, *r*-1-isomer, has been synthesized from (1*RS*, 5*SR*, 6*SR*)-6-ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]octan-7-one in five steps.

The three stereoisomers of 2,3-dicarboxycyclopentylacetic acid, *c*-2, *c*-3, *r*-1-, *c*-2, *t*-3, *r*-1-, and *t*-2, *c*-3, *r*-1-isomers (**1**, **2**, and **3**), have been synthesized as the key compounds in the determination of the carbon skeleton of aucubin.[1,2] Attempts to synthesize the *t*-2, *t*-3, *r*-1-isomer (**4**) have however been unsuccessful. In this paper, the synthesis of **4** from (1*RS*,5*SR*,6*SR*)-6-ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]octan-7-one (**5**)[3,4] will be reported according to the following scheme.



Scheme 1.

(1*RS*,5*SR*,6*SR*)-6-Ethoxycarbonylmethyl-3-oxabicyclo-[3.3.0]octan-7-one (**5**) was converted into thioacetal **6** with 1,2-ethanedithiol in the presence of boron trifluoride etherate, and **6** was desulfurized with Raney Nickel in dilute ethanol to give ethyl (1*RS*, 5*SR*, 6*RS*)-3-oxabicyclo[3.3.0]octane-6-acetate (**7**). The ester (**7**) was hydrolyzed to the carboxylic acid **8** by heating with 2 M hydrochloric acid. Oxidation of **8** with potassium permanganate gave the lactone carboxylic acid **9** or **10**, which was further oxidized with chromium trioxide to give *t*-2, *t*-3-dicarboxy-*r*-1-cyclopentylacetic acid (**4**). The overall yield of **4** based on the ester (**5**) was 20%.

The structure of **4** was confirmed by elemental analysis and by conversion into the anhydride **11**.[5] Compound **4** showed a melting point depression in agreement with those of the other three stereoisomers, (**1**, **2**, and **3**). The synthesis of the four stereoisomers of 2,3-dicarboxycyclopentylacetic acid (**1**, **2**, **3**, and **4**) is now completed.

Experimental

All boiling and melting points are uncorrected. The IR spectra and mass spectra were recorded with a Hitachi 135 spectrophotometer and a Hitachi RMU-6M mass spectrometer, respectively. The PMR spectrum was recorded with a Hitachi R-22 spectrometer (90 MHz), using tetramethylsilane as an internal standard.

*(1*RS,*5*SR,*6*SR)-*6-Ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]-octan-7-one (5).* The keto ester was prepared as conducted in a previous report.[4] Bp 140—144 °C/4 mmHg, IR (neat) 1730 cm^{-1} (C=O). Found: C, 61.89; H, 7.44%; M^+, 212. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%; M, 212.

*Ethyl (1*RS,*5*SR,*6*RS)-*3-oxabicyclo[3.3.0]octane-6-acetate (7).* To a mixture of 1,2-ethanedithiol (5 ml) and boron trifluoride etherate (5 ml) was added **5** (3.0 g), and the reaction mixture stirred for 20 min. After removal of the excess reagents *in vacuo*, the resulting thioacetal (**6**) was refluxed in 70% ethanol (300 ml) for 14 h in the presence of Raney Nickel prepared from 90 g of alloy. The reaction mixture was filtered and the filtrate evaporated *in vacuo*. The remaining oil was extracted with ether and the solvent removed. After drying over anhydrous Na_2SO_4, the yield of **7** was 0.7 g (35%); bp 82—83 °C/3 mmHg, MS *m/e* 198 (M^+), IR (neat) 1730 cm^{-1} (C=O). PMR ($CDCl_3$) δ 1.22 (3H, t, J=7.6 Hz, $-CH_2\underline{CH_3}$), 1.70—2.90 (9H, m), 3.67 (4H, m, $-CH_2OCH_2-$), 4.18 (2H, q, J=7.6 Hz, $-\underline{CH_2}CH_3$).

t-*2*,t-*3-Dicarboxy*-r-*1-cyclopentylacetic Acid (4).* A mixture of **7** (0.4 g) and 2 M hydrochloric acid (10 ml) was refluxed for 3 h. The reaction mixture was evaporated *in vacuo* to yield (1*RS*,5*SR*,6*RS*)-3-oxabicyclo[3.3.0]octane-6-acetic acid (**8**). The compound **8** was used in the subsequent reaction without purification.

To a solution of **8** (0.32 g) in water (10 ml) was added dropwise and with stirring $KMnO_4$ (0.6 g) dissolved in water (20 ml) over a period of 9 h at room temperature. After decomposition of the excess $KMnO_4$ with ethanol, the reaction mixture was heated at 80 °C and filtered using a glass filter packed with Celite-545 (Johns-Manville Sales Corp). The filtrate was acidified with 6 M hydrochloric acid and extracted several times with hot ethyl acetate. The ethyl acetate solution was washed with water, dried over anhydrous Na_2SO_4, and freed from ethyl acetate to give the lactone carboxylic acid (**9** or **10**) (0.3 g, 84%) as a viscous oil. IR (neat) 1710 and 1755 cm^{-1} (C=O).

To a solution of the above oxidation product (0.3 g) in acetic acid (50 ml) was added a mixed solution of chromic anhydride (0.4 g), concd H_2SO_4 (0.7 ml), and water (1.4 ml) over a period of 1 h cooling by ice-cold water. The reaction mixture was allowed to stand for 5 days and the remaining

chromium trioxide decomposed with methanol (2 ml). After removal of the solvent *in vacuo*, the residue was extracted with ethyl acetate. The ethyl acetate solution was dried over anhydrous Na_2SO_4 and freed from ethyl acetate to give crude crystals (0.26 g). Recrystallization from ethyl acetate gave **4** (115 mg, 42% yield from **7**) as colorless prisms; mp 167—168 °C. IR (KBr) 3230, 1710, 1422, 1223, 1187, 923, and 780 cm^{-1}. Found: C, 49.70; H, 5.70%; M^+, 216. Calcd for $C_9H_{12}O_6$: C, 50.00; H, 5.56%; M, 216. The carboxylic acid **4** showed melting point depression with the other three stereoisomers (**1**, **2**, and **3**), respectively.

t-*3-(Carboxymethyl)*-r-*2*,c-*3-cyclopentanedicarboxylic Anhydride (11)*. Tricarboxylic acid **4** (16 mg) was heated in an oil bath at 175—195 °C under reduced pressure (3 mmHg) to yield the anhydride **11** (14 mg); mp 141—142 °C (benzene–petroleum ether). IR (KBr) 2940, 1852, 1784, 1682, 1438, 1417, 1343, 1280, 1226, 1103, 1072, 1032, 978, 928, and 812 cm^{-1}. Found: C, 54.28; H, 5.25%; M^+, 198. Calcd for $C_9H_{10}O_5$: C, 54.54; H, 5.05%; M, 198.

The authors wish to express their thanks to Mr. Takashi Saito for the microanalyses.
