
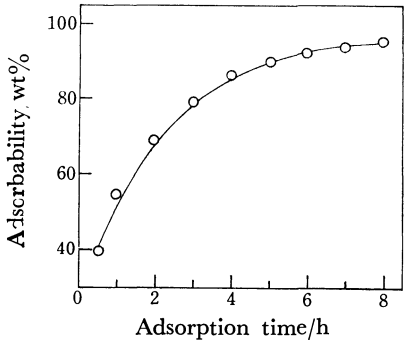

Fig. 4. Adsorption time dependence of chromate ion on cured DPP-PA resin. Conditions; amount of resin: 100 mg, pH: 3.2, concentration of CrO_4^{2-}: 1.0 mg/100 cm³, temp: 25 °C.

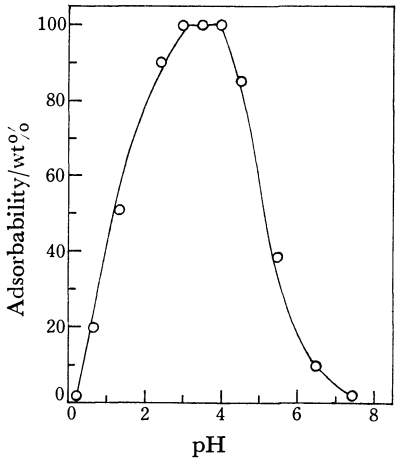

Fig. 5. Effect of pH on adsorption of chromate ion. Conditions; Amount of resin: 100 mg, Concentration of CrO_4^{2-}: 1.0 mg/100 cm³, Shaking time: 24 h, temp: 25 °C.

1 illustrates the relationship between the amount of curing agent, Fig. 2, the curing temperature and Fig. 3, the curing time and the degree of adsorption chromate ion. From these results, it has been found that the chromate ion is heavily adsorbed on the cured DPP–PA resin cured with an additional 20 wt% hexamethylenetetramine at 150 °C for up to 30 min.

The Rate of Adsorption. The rate of adsorption of the chromate ion on the cured DPP–PA resin has been examined, the results of which are shown in Fig. 4. It may be seen that the degree of adsorption of the chromate ion increases up to over 90 wt% in approximately 5 h. Subsequent adsorption proceeded slowly reaching 100 wt% after 16 h. The results of the adsorption of molybdate and tungstate ions were approximately the same.

Influence of pH. The effect of pH on the adsorption of the chromate ion has been examined by varying pH between 0 and 8.5, and the results are illustrated in Fig. 5. The residual Cr observed below pH 2.5 was Cr(III), Cr(VI) being absent. The residual Cr up to pH 4.5 was completely Cr(VI). It may be seen that the optimum pH range for the adsorption of the chromate ion 3.0—4.0. Similarly, the optimum pH range for the adsorption of molybdate and tungstate

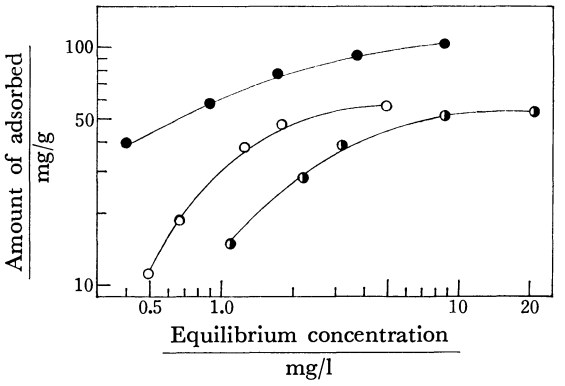

Fig. 6. Adsorption isotherm of Cr(VI), Mo(VI), and W(VI) on cured DPP–PA resin. Conditions; pH: 3.2, shaking time: 24 h, temp: 25 °C, ○: Cr(VI), ◑: Mo(VI), ●: W(VI).

Table 2. Desorption of chromium, molybdenum and tungsten from cured DPP-PA resin by aqueous HCl, H_2SO_4, and NaOH solution

Elute mol/l	Recovery of metal ion		
	Chromium wt%	Molybdenum wt%	Tungsten wt%
HCl			
0.05	46.4	0	0
0.1	60.0	10.6	2.1
0.5	63.0	21.2	10.2
1.0	80.0	26.5	25.0
4.0	81.0	42.5	40.0
H_2SO_4			
1.0	56.7	64.7	10.5
2.0	56.0	100	50.1
3.0	55.0		100
4.0	55.0		
NaOH			
0.1	100	100	100

ions was 3.0—4.0, consistent with the results for the chromate ion.

Degree of Adsorption. The degree of the adsorption of chromate ion on the cured DPP–PA resin was measured as follows; a series of K_2CrO_4 solutions containing 1.5—6.0 mg as Cr were added to the cured DPP–PA resin (100 mg). Each solution was adjusted to pH 3.2 and diluted with water to 100 cm³. Each adsorption was calculated and plotted against the equilibrium concentration of total Cr, the results of which are shown in Fig. 6. The degree of adsorption of each Cr unit to resin (1 g) was 20.5 mg. The degree of adsorption of molybdate and tungstate ions on the cured DPP–PA resin were measured in the same manner. The degree of adsorption of the Mo and W units to resin (1 g) were 40.5 and 80.0 mg, respectively.

Desorption. The desorption of chromate, molybdate and tungstate ions adsorbed on the cured DPP–PA resin were conducted using aqueous HCl, H_2SO_4 and NaOH solutions. The amounts of chromate, molybdate and tungstate ions desorbed with various concentration of acidic or basic solutions are

shown in Table 2. For the desorption of Cr it is more advantageous to use aqueous HCl rather than aqueous H_2SO_4 solution. Elution with 1.0 mol/l aqueous HCl solution, gave 80.0 wt% recovery of Cr. For the desorption of Mo and W, both ions were eluted with aqueous H_2SO_4 solution. Elution with 2.0 mol/l aqueous H_2SO_4 solution, gave 100 wt% recovery of Mo and 3.0 mol/l aqueous H_2SO_4 solution, gave 100 wt% recovery of W.

The residual weight of the cured DPP–PA resin after soaking in 50 vol% H_2SO_4 for two days was approximately 70 wt% as shown in Table 1. Consequently it has been concluded that the cured DPP–PA resin is very resistant to acid. The elution of Cr, Mo, and W by 0.1 mol/l aqueous NaOH solution, gave a recovery of 100 wt%, but as the cured DPP–PA resin was completely decomposed, elution with aqueous NaOH solution is not a suitable technique.

It has been observed that Cr eluted with HCl is recovered as Cr(III) and that Cr eluted with sodium hydroxide is Cr(VI) in 70 wt% of the total Cr content. Mo and W were recovered as Mo(VI) and W(VI) because of their lower oxidizing properties in comparison with Cr.

Mechanism of Adsorption. In order to elucidate the adsorption mechanism of the chromate ion on the cured DPP–PA resin, the IR and ESR spectra of the cured DPP–PA resin adsorbing chromate ion were measured. In the IR spectrum of the DPP–PA resin, the absorption bands assigned to the P–H and P=O bonds were observed at 2450 and 1250 cm^{-1}. In the IR spectrum of the cured DPP–PA resin adsorbing chromate ion, the absorption band of the P–H bond disappeared but the remaining absorption did not change. In the ESR spectrum, a signal with a g value of 1.97 and H_{msl} of 20, was observed together with a broad signal, the g value of which could not be determined. The two signals are thought to agree with the so-called β phase proposed by O'Reilly,[10] and thus it has been assumed that the former signal corresponds to Cr(V) while the latter corresponds to Cr(III). In the desorption of the chromate ion using aqueous sodium hydroxide solution, approximately 70 wt% in total Cr adsorbed on the cured DPP–PA resin was Cr(VI). This result does not agree with the ESR data which shows the presence of Cr(V) in the cured DPP–PA resin adsorbing chromate ion. The observed difference may be resolved assuming the β phase signal of Cr(V) is regarded as the signal associated with a three-chromium-atom center of mixed valency, Cr(VI)–Cr(III)–Cr(VI), as proposed by Spitz for the polymerization of olefins with a catalyst of chromium oxide.[11]

It has been reported[12] that the chromate ion reacts with phosphonic acid to produce the intermediate, $O_3CrO–P(OH)_2H$, and as the reaction proceeds furthermore, Cr(VI) is reduced to Cr(V) and finally to Cr(III). It is suggested that the P–H bond is broken in the rate-determining step of chromate ion reduction. It has been reported[13] that the P–H bond in the reaction of DPP with Cu(II) salts breaks as follows; $>P(O)H + H_2O \rightarrow >P(O)OH + 2H^+ + 2e$. Simultaneously the Cu(II) is reduced. It is suggested that the active center for the adsorption of the chromate ion on the cured DPP–PA resin is the P=O bond. In water solution the P=O bond reacts with a water molecule to form $>P(OH)_2H$,[1,13] and $>P(OH)_2H$ reacts with chromate ion as follows; $>P(OH)_2H + CrO_4^{2-} \rightarrow >P(H)O_2CrO_2 + 2OH^-$. At the same time the chromate ion is reduced by the P–H bond. It has been concluded that the chromate ion is adsorbed on the cured DPP–PA resin in the form of a mixed valency, Cr(VI)–Cr(III)–Cr(VI).

Degradation of Magnesium and Calcium Highpolyphosphate Coacervates[1)]

Takao UMEGAKI* and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received January 20, 1979)

The degradation of highpolyphosphates in the coacervates of magnesium and calcium is discussed on the basis of the results of viscosity measurement and paper chromatographic analysis of highpolyphosphates. The initial viscosity and transparency of some magnesium coacervates were maintained with little change at 30 °C for about 2 weeks, while most calcium coacervates changed within 10 days into wet cakes containing $Ca(H_2PO_4)_2 \cdot H_2O$ and $Ca_3(HP_2O_7)_2 \cdot 4H_2O$. The formation of pyrophosphates during the course of degradation of both coacervates is remarkable as compared with that on the hydrolysis of alkali highpolyphosphates in aqueous solutions.

In dilute aqueous solutions, highpolyphosphate chain-anion undergoes degradation to produce shorter chain polyphosphates, orthophosphates and ring phosphates. Studies have been carried out on the hydrolyses of alkali highpolyphosphates and their mechanisms.[2-4)] However, only a few reports have appeared on the degradation of non-alkali highpolyphosphates.

In the preceding paper[5)] the thermal change of magnesium highpolyphosphate coacervate(MPC) was discussed on the basis of the results of thermal analysis. For the analysis, the coacervate had to be heated and partially dehydrated at 100 °C in order to avoid swelling and foaming in the sample cell. Consequently, no detail was known about the degradation of MPC below 100°C.

The present paper deals with the viscosity changes of MPC and calcium highpolyphosphate coacervate (CPC) on degradation at temperatures form 25 to 90°C. The changes of the highpolyphosphate chain length were determined by paper chromatography.

Experimental

Materials. Coacervate samples were obtained by adding ethyl alcohol to mixtures of a sodium metaphosphate solution and a solution of magnesium or calcium chloride. The coacervates were also prepared by direct addition of $MgCl_2 \cdot 6H_2O$ or $CaCl_2 \cdot 2H_2O$ powder to a sodium metaphosphate solution. The coacervate was used immediately after coacervation caused by addition of ethyl alcohol or the respective chloride powder. Conditions for the preparation of coacervates were described in detail in a previous paper.[6)]

Paper Chromatography. Since MPC and CPC contain Mg^{2+} and Ca^{2+}, respectively, ETA (about 1% in a solution) was added to each solution of the coacervates, according to the analytical method proposed by Yamazoe *et al.*[7)] Each individual spot on the filter paper was washed with ammonia water. The phosphate solutions thus obtained were strongly acidified and boiled to give rise to hydrolysis. Phosphorus in the solutions was then analyzed by heteropoly blue colorimetry.

Total absorbance due to all the phosphates was obtained by summation of the individual absorbance values. The phosphorus content of each spot is expressed as a portion of total phosphorus present as follows:

$P(\%) = (\text{absorbance for each fraction/sum of absorbance}) \times 100$

Viscosity Measurement. The viscosities of the coacervates were measured with a rotational viscometer of cone-and-plate type.[6)]

X-Ray Analysis. X-Ray powder diffraction patterns of degradation products in coacervates were obtained with a Rigaku Denki Diffractometer Model D-3F.

Results and Discussion

Linearity of the flow curves for coacervates in the present work was obtained at shearing rates 10—600 s^{-1}. Consequently, all the coacervates used were assumed to be Newtonian.

Viscosity Change with Time at 30 °C. Figure 1 shows a typical viscosity change with time in one of the MPC samples turned into a coacervate by addition of ethyl alcohol. For the first two weeks viscosity lowering was not remarkable. However, short chain-phosphates such as ortho- and pyrophosphates were detected by paper chromatography. Thus, most highpolyphosphates of long chains probably remained without cleavage, degradation of MPC initially occurring only at terminal parts of the polyphosphates. In spite of the progress of degradation of highpolyphosphates, transparency of most samples was maintained, no precipitate being found in the coacervates at 30 °C for about two months.

Most CPC were less stable than MPC. The viscosity of CPC was lowered and a small amount of white powder began to be suspended in a transparent coacervate within a week. One or two days after the first appearance of the suspension, the coacervate completely turned into a wet cake of white powder, which might consist of calcium phosphates. A calcium pyrophosphate of $Ca_3(HP_2O_7)_2 \cdot 4H_2O$[8)] was identified one or two days after the cake formation, a mixture

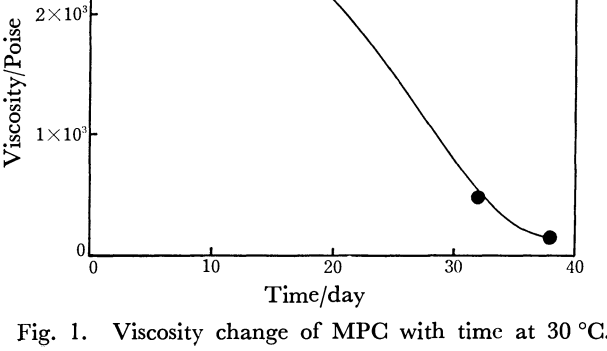

Fig. 1. Viscosity change of MPC with time at 30 °C.

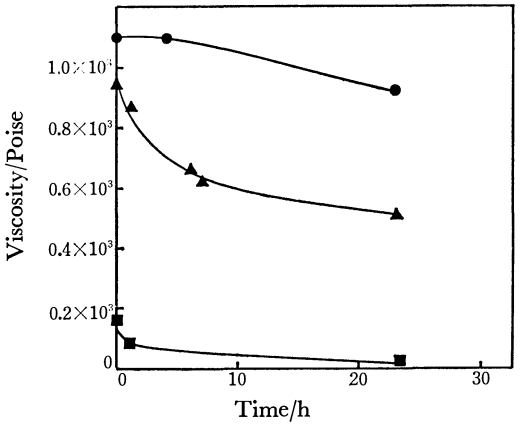

Fig. 2. Viscosity change of various MPC's with time at 50 °C. ●: Sample A, ▲: Sample B, ■: Sample C. (The initial viscosities of A, B, and C were 1.10×10^3, 0.95×10^3, and 0.16×10^3 Poise, respectively.)

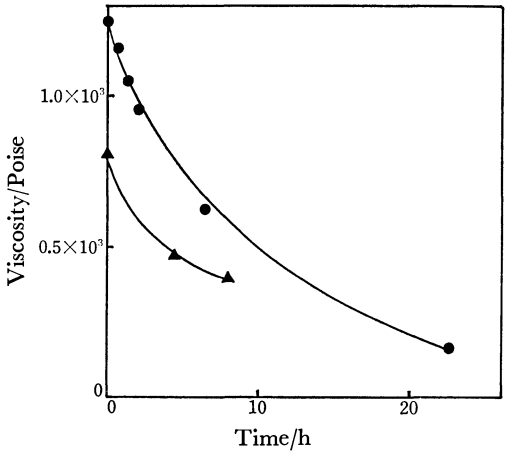

Fig. 3. Viscosity change of various CPC's with time at 50 °C. ●: Sample A, ▲: Sample B. (The initial viscosities of A and B were 1.24×10^3 and 0.80×10^3 Poise, respectively.)

of $Ca(H_2PO_4)_2\cdot H_2O$ and the pyrophosphate being obtained within 3 or 4 weeks after the beginning of degradation experiment.

The difference of stability between MPC and CPC may be interpreted in terms of solubilities of the salts of short chain-phosphates into the coacervates.

Viscosity Change of Coacervates with Various Initial Viscosities. The viscosity lowering of some MPC is slightly noticeable only at the first stage of experiments, while CPC became less viscous gradually and continually (Figs. 2 and 3). Concerning MPC, the degree of viscosity lowering decreases with increase in the initial viscosity. Highly viscous MPC is recognized to be considerably stable. From a comparison of viscosity changes in the coacervate samples with various initial viscosities, the mobility of phosphate ions in the coacervates is considered to be closely related to the rates of degradation.

Viscosity Changes at Various Temperatures. Viscosity changes with temperature of MPC and CPC are shown in Figs. 4 and 5, respectively. The viscosities of both coacervates lowered rapidly at 80—85 °C.

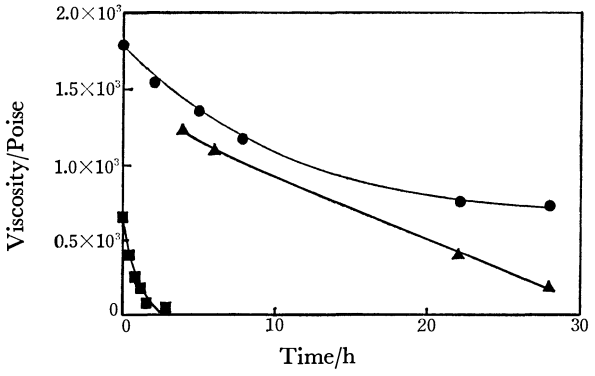

Fig. 4. Viscosity change of MPC with time at various temperatures. ●: 50 °C, ▲: 70 °C, ■: 85 °C.

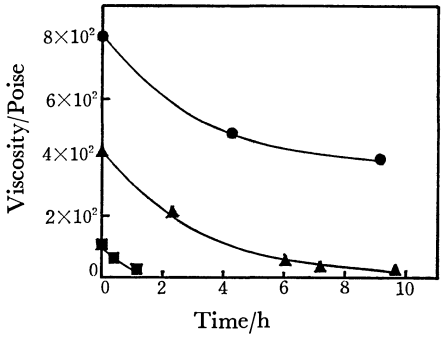

Fig. 5. Viscosity change of CPC with time at various temperatures. ●: 50 °C, ▲: 60 °C, ■: 80 °C.

The magnesium coacervates remained transparent while the calcium coacervates solidified within 10 h above 60 °C. In CPC cakes cooled to room temperature, $Ca(H_2PO_4)_2\cdot H_2O$ and $Ca_3(HP_2O_7)_2\cdot 4H_2O$ were detected by X-ray diffraction.

Short chain-phosphates formed are given in Table 1. On degradation of MPC, pyro- and tripolyphosphates appeared. On the other hand, only orthophosphates formed during the course of hydrolysis of $NaPO_3$.

As pointed out by van Wazer and his coworkers,[2] there are three alternative degradation paths of Graham's salts: Splitting of end PO_4 groups, random scission along the main chain of highpolyphosphates, and ring formation.

During the degradation of the coacervates, orthophsphates are probably formed by the cleavage of end phosphates, and pyro- and tripolyphosphates by the successive decomposition of highpolyphosphates to shorter chains. It seems difficult to give a quantitative kinetics for degradation on the basis of the results of paper chromatographic analysis since the homogeneity of coacervate samples is somewhat doubtful. However, the portion of pyrophosphates obtained on the degradation of MPC was larger than what might have been expected from the successive cleavage. The polymerization of orthophosphates into pyrophosphates is not likely to occur at low temperatures such as 30—50 °C.

Wieker[9] and Lowenstein[10] reported that pyrophosphates are formed by coupling between the terminal PO_4 of straight chain polyphosphates and orthophosphate ions in the presence of Mg ions during the

Table 1. Degradation of phosphate anions in magnesium coacervate

course of hydrolysis of hexakisguanidinium tetraphosphate and adenosintriphosphate, respectively. The above reactions occurred in alkaline solutions. However, the degraded coacervates probably contained a considerable amount of hydrogen ions since calcium acid phosphates were formed during the course of CPC degradation.

In addition to the three degradation processes proposed by van Wazer and his coworkers,[2] and the coupling in alkaline solutions, there may be some other decomposition paths of coacervates and pyrophosphate formation in degraded coacervates.

Conclusion

From the results of viscosity meausrement and paper chromatography of MPC and CPC, the following conclusions were obtained:

1) Most samples of MPC are more stable than those of CPC. No precipitate in magnesium coacervates was observed at 30 °C for about two months.

2) Most samples of CPC turn into wet cakes of such calcium phosphates as $Ca(H_2PO_4)_2 \cdot H_2O$ and $Ca_3(HP_2O_7)_2 \cdot 4H_2O$ at 30 °C in about 10 days.

3) Pyrophosphate may be formed in MPC and CPC probably through a certain path differing from that of degradation of alkali highpolyphosphates in aqueous solutions and also from that of the coupling reaction in alkaline solutions.

Transpiration Study of the Reaction of Water Vapor with Barium Oxide

Tadashi SASAMOTO,* Kentarō MIZUSHIMA, and Toshiyuki SATA
Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 23, 1979)

Barium oxide has been found to react with water vapor at temperatures from 1443 to 1593 K to form gaseous $Ba(OH)_2$ according to the reaction; $BaO(s)+H_2O(g)\rightarrow Ba(OH)_2(g)$. The standard free energy of formation is given by the equation, $\Delta G_r^\circ = 49400 - 16.6\ T$ (cal/mol) in the present temperature range. From the thermodynamic cycle the bond energy between barium and two hydroxyl groups has been found to be 196.8 kcal/mol.

The volatility of the alkaline earth oxides is greatly increased by the presence of water vapor due to the formation of volatile hydroxide vapors which result from the following reactions;

$$MO(s) + H_2O(g) \rightarrow M(OH)_2(g) \quad (1)$$

$$MO(s) + 1/2H_2O(g) \rightarrow M(OH)(g) + 1/4O_2 \quad (2)$$

where M is a Group IIa element. This has been verified for BeO,[1-3] MgO,[4,5] and BaO.[6] Stafford and Berkowitz[6] studied the $BaO-H_2O$ system mass-spectrometrically and found that dihydroxide vapor $Ba(OH)_2$, predominanted at temperatures between 1485 and 1785 K under a water pressure above 4×10^{-5} atm. The bond energy for $Ba(OH)_2$ was given by 206.3 kcal/mol. Mass-spectrometry is, however, often accompanied by errors due to the uncertainty of the relative cross section for ionization and the relative efficiency of the secondary-electron multiplier. Consequently it is necessary to confirm the value by other methods.

In the present study, the reaction of water vapor with solid barium oxide has been investigated by the transpiration method as a series of studies on the effects of water vapor upon the vaporization of alkaline earth oxides. The vapor pressures of gaseous $Ba(OH)_2$ formed according to Reaction 1 and the related thermodynamic properties have been evaluated.

Experimental

Transpiration Apparatus. Figure 1 shows a schematic drawing of the reaction zone in the apparatus used in this study. Approximately 2 g of sample was loaded into a Pt/20%Rh boat lined with magnesia. The vaporized species were collected in a condenser made of Pt/20%Rh alloy. The condenser had a capillary (0.7 mm i.d.×6 mm long) at one end. All other structual components except for those described above were made of alumina. Barium oxide reacts with alumina to form three barium aluminates, *i.e.*, $BaO\cdot 6Al_2O_3$, $BaO\cdot Al_2O_3$ and $3BaO\cdot Al_2O_3$, but the partial pressure of BaO(g) over these compounds is very small.[7,8] Therefore, it has been assumed that the formation of the barium aluminates has no effect on the equilibrium relation of the gas phase containing the barium bearing gaseous species. Temperatures were measured with a Pt/13%Rh thermocouple and regulated within ±1 °C.

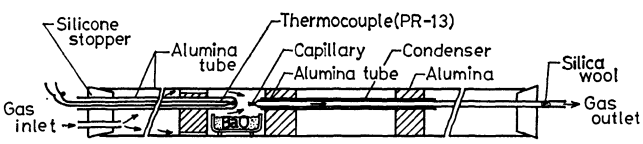

Fig. 1. Cross section of reaction zone in transpiration apparatus.

A wet gas mixture, Ar/H_2O, was obtained by passing argon gas three times through a water reservoir, the temperature of which was accurately controlled. The partial pressure of water vapor was determined from the weight increase of P_2O_5 placed in a stream of the wet gas.

Procedure. The argon carrier gas used was passed through the water reservoir described above and saturated with water vapor after passage through a KOH-column to remove carbon dioxide contained as an impurity, and then into the charge room at a given temperature. The water vapor reacted with BaO to form Ba-bearing hydroxide vapors. The carrier gas was saturated with vapors formed in the charge room at an appropriate flow rate and the vapors formed were transported by the carrier gas to the condenser. The condensate was removed into concentrated nitric acid solution and the barium in the solution was analyzed by chelatometry using EDTA and cresolphthalene complexon. The estimated analytical error is less than ±0.6% by weight of Ba.

The partial pressure of the volatile barium hydroxide compound has been calculated from the amount of collected barium, assuming that each molecule of the volatile species contains one atom of barium and that the vapor approximated to an ideal gas. Therefore, it follows that partial pressure at equilibrium is given by

$$p(Ba(OH)_{2x}) = n_v P/(n_c+n_v) \quad (3)$$

where n_c is the number of mole for the carrier gas, n_v for the sample vapor, and P the total pressure.

Sample. Guaranteed reagent-grade BaO with a 99.9% purity (supplied by Rare Metallic Co., Ltd.) was used. In order to stop dispersion of the fine particles in the carrier gas, the BaO was sintered at 1300 °C prior to use. The compacted sample was kept in a desiccator filled with pure argon to avoid reaction with water and carbon dioxide.

Results and Discussion

Effect of Flow Rate on Vapor Pressure. To determine the conditions for equilibrium a series of measurements was made at 1593 K with varying flow rates. Figure 2 illustrates the apparent vapor pressure of the assumed molecule, $Ba(OH)_{2x}$, calculated from Eq. 3 as a function of the flow rate. As can be seen from Fig. 2, the vapor pressures obtained are approximately constant in the range 1.3 up to 2.5 cm^3/s.

The decrease in vapor pressure, *i.e.*, $<1.2\ cm^3/s$, is thought due to escaping vapor from the space between the condenser and the support (alumina tube).

Water Vapor Dependence. A plot of the logarithm of the equilibrium pressure of the volatile complex as a function of the logarithm of the partial pressure

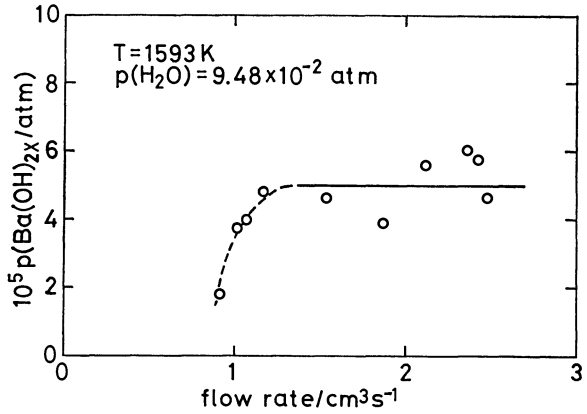

Fig. 2. Vapor pressure *vs.* the flow rate of carrier gas at $T=1593$ K and $p(H_2O)=0.0948$ atm.

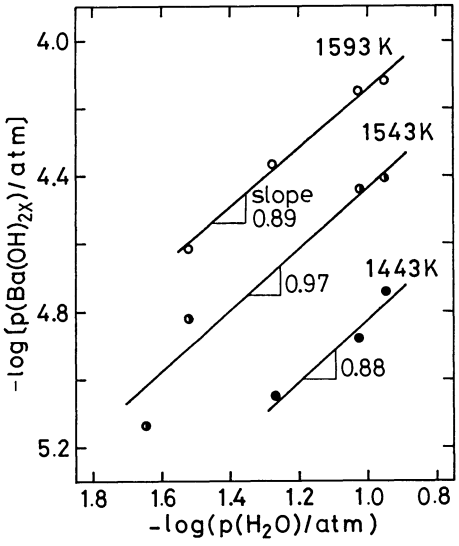

Fig. 3. Variation of log(vapor pressure of barium bearing species) *vs.* log(partial pressure of water).

of water at constant temperature and partial pressure of oxygen will indicate whether Reaction 1 or 2 occurs (this includes the correct value of x in $Ba(OH)_{2x}$) as outlined below.

Combining Reaction 1 with 2 yields the following equation for the BaO–H_2O system,

$$BaO(s) + xH_2O(g) \rightarrow Ba(OH)_{2x}(g) + \frac{(1-x)}{2}O_2(g) \quad (4)$$

The equilibrium constant k_p for the above reaction may be written as

$$k_p = \frac{p(Ba(OH)_{2x}) \cdot p(O_2)^{(1-x)/2}}{a(BaO) \cdot p(H_2O)^x} \quad (5)$$

Assuming $a(BaO)=1$ and taking logarithms of both sides;

$$\log p(Ba(OH)_{2x}) = x \log p(H_2O) - \frac{(1-x)}{2}\log p(O_2) + \log k_p \quad (6)$$

From Eq. 6 the value of x can be determined, *i.e.*, the contribution of Reactions 1 and 2 to Reaction 4.

No correction need be made for the partial pressure of BaO(g) since this is equal to only 3.54×10^{-7} atm

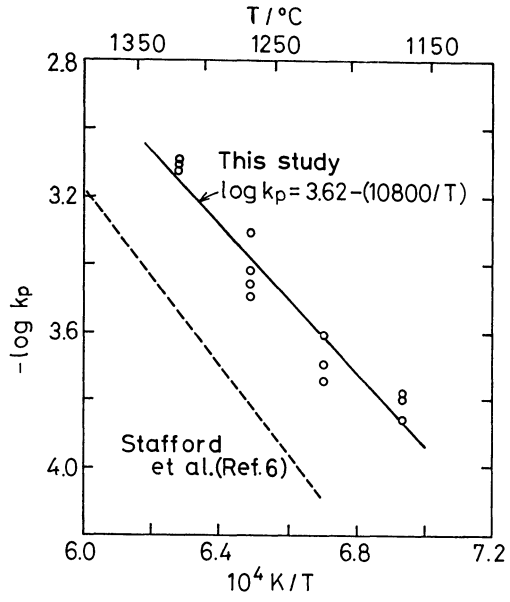

Fig. 4. Plot of equilibrium constant for the reaction $BaO(s)+H_2O(g)=Ba(OH)_2(g)$ *versus* reciprocal temperature.

at 1593 K, the highest temperature used in these measurements.

A series of measurements were made at 1443 to 1593 K with a varied vapor pressure of water at atmospheric pressure passing over the barium oxide, and the results of which are given in Table 1 are shown graphically in Fig. 3. The values of x obtained from the slopes of a $\log p(Ba(OH)_{2x})$ *versus* $\log p(H_2O)$ plot were 0.88, 0.97, and 0.89 at 1443, 1543, and 1593 K, respectively. The average value was 0.91 which was very close to unity. Considering the mass-spectrometric results of Stafford and Berkowitz,[6] the reaction form of the alkaline earth oxides with water vapor[1–6] and flame-experiment data,[9,10] the value of x has been determined as unity. Therefore the predominant reaction of water vapor with barium oxide under these conditions ($p(H_2O)=0.022$—0.112 atm) is:

$$BaO(s) + H_2O(g) \rightarrow Ba(OH)_2(g) \quad (7)$$

The selection of oxygen as the carrier gas would suppress the formation of gaseous Ba(OH) and lead to a value of x move close to unity. No examination in an oxidizing atmosphere was conducted, however, because normal barium oxide oxidizes at relatively low temperature to the per-oxide BaO_2.

The decomposition temperature of $Ba(OH)_2(s)$ is 408 °C, and hence no solid $Ba(OH)_2$ exists at the present temperature.

Vapor Pressure of $Ba(OH)_2(g)$ and Related Thermodynamic Values. The vapor pressures of gaseous $Ba(OH)_2$ and equilibrium constant k_p have been calculated from the amount of collected barium and the results are given in Table 1 and illustrated graphically in Fig. 4. The linear relationship obtained from a least squares treatment of the data corresponds to the expression,

$$\log k_p = -(10800\pm860)/T + 3.62\pm0.56 \quad (8)$$

and hence, the standard Gibbs energy for Reaction

a) Estimated a manner similar to that of Stafford and Berkowitz.[6]

7 is given by,

$$\Delta G_r^\circ = (49400\pm3900) - (16.6\pm2.6)T \quad (9)$$

This gives,

$$\Delta H_r^\circ(1500\ K) = 49.4\pm3.9\ kcal/mol \quad (10)$$

$$\Delta S_r^\circ(1500\ K) = 16.6\pm2.6\ cal/mol\ K \quad (11)$$

Using the ΔG_r° obtained and the JANAF data,[11] the changes in Gibbs energy, enthalpy and entropy for the following formation reaction,

$$Ba(g) + H_2(g) + O_2 = Ba(OH)_2(g) \quad (12)$$

are as follows;

$$\Delta G_f^\circ(Ba(OH)_2, (g)) = \Delta G_r^\circ + \Delta G_f^\circ(BaO, (s)) + \Delta G_f^\circ(H_2O, (g)) = 242400 \pm 4500 - (54.8\pm3.4)T \quad (13)$$

and

$$\Delta H_f^\circ(Ba(OH)_2, (g), 1500\ K) = 242.4\pm4.5\ kcal/mol \quad (14)$$

$$\Delta S^\circ(Ba(OH)_2, (g), 1500\ K) = 114.5\pm3.4\ cal/mol \quad (15)$$

The decomposition energy of $Ba(OH)_2(g)$ into two hydroxyl radicals and Ba vapor, $D_0^\circ(Ba\text{–}(OH)_2)$, has been estimated using the following thermochemical cycle;

$$\begin{array}{ccc} Ba(OH)_2(g) & \xrightarrow{D^\circ} & Ba(g) + 2(OH)(g) \\ \uparrow \Delta H_r^\circ & & \uparrow \Delta H_s^\circ \quad \uparrow \Delta H_f^\circ \\ BaO(s) + H_2O(g) & \xleftarrow{\Delta H_f^\circ} & Ba(s) + \frac{1}{2}O_2 + H_2O(g) \end{array} \quad (16)$$

whereby,

$$D_0^\circ(Ba\text{–}(OH)_2) = -\Delta H_{r,0}^\circ(Ba(OH)_2) - \Delta H_{f,0}^\circ(BaO) + \Delta H_{s,0}^\circ(Ba) + 2\Delta H_{f,0}^\circ(OH) \quad (17)$$

where $\Delta H_{r,0}^\circ(Ba(OH)_2)$ represents the heat of reaction for the Reaction 7, $\Delta H_{f,0}^\circ(BaO)$ the heat of formation for BaO(s), $\Delta H_{s,0}^\circ$ (Ba) the heat of sublimation for Ba(s) and $\Delta H_{f,0}^\circ(OH)$ the heat of formation for OH(g) from $H_2O(g)$ and O_2. The values required were 52.52 (last column in Table 1), −130.696,[12] 42.971,[13] and 37.84[11] kcal/mol at 0 K, respectively. Substitution of these values into Eq. 17 gives the value 196.8 kcal/mol as the value of $D_0^\circ(Ba\text{–}(OH)_2)$. This value differs from that of Stafford and Berkowitz[6] by 4.6%.

(Received January 25, 1979)

An equilibrium study of a part of the Fe–V–S system at sections with atomic Fe:V ratios 1:1, 3:2, and 71:29 was carried out. A gravimetric method using a quartz spring balance was employed in the range of $\log(P_{S_2}/\text{atm}) = -4$ to -0.8 at temperatures between 520 and 814 °C. Phase relations in the sulfur-rich portion of the Fe–V–S system were examined on the basis of the P_{S_2}-T-X relation and X-ray analyses of the quenched specimens. The phase diagram of the Fe–V–S system was tentatively constructed at about 570 °C. The compositional dependence of the lattice parameters of the $(Fe,V)_3S_4$ solid solution was studied from the crystallographic viewpoint.

The results of an equilibrium study of a part of the Fe–V–S system at sections with atomic Fe : V ratios 1 : 19, 13 : 37, and 7 : 13 were presented in an earlier publication.[1] It has been reported that the Fe–V–S system has extensive solid solution phases, such as $(Fe,V)_5S_8$, $(Fe,V)_2S_3$, and $(Fe,V)_3S_4$, which have a lattice intermediate between the NiAs-type and the $Cd(OH)_2$ lattice. However, the solid solution fields of these phases have not yet been determined completely. The detailed phase relations in the Fe-rich portion of the composition triangle of FeS–VS–S are still obscure, in spite of the extensive studies of the binary systems FeS[2] and VS.[3]

The present study is a continuation of this work using a further series of samples in the Fe–V–S system. The author reports in this paper the results of the equilibrium study of a part of the Fe–V–S system at sections with atomic Fe : V ratios 1 : 1, 3 : 2, and 71 : 29. The main thermochemical study was carried out with a gravimetric method, which used a quartz spring balance at high temperatures, above 500°C. The P_{S_2} (equilibrium sulfur pressure)-T (temperature)-X (composition) relations and the compositional dependence of lattice constants of several phases were investigated.

Experimental

The sulfide samples with atomic Fe:V ratios 1:1, 3:2, and 71:29 were synthesized by heating the mechanical mixtures of reagent grade $VOSO_4 \cdot 3H_2O$ and $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ in an H_2S atmosphere at 1050 °C for 4 h and were then used as starting materials. The equilibrium study of these samples was carried out by thermogravimetry at temperatures between 520 and 814 °C. The partial pressure of sulfur was controlled within the range of the $\log(P_{S_2}/\text{atm})$, from -0.8 to -4, in an N_2–sulfur vapor system. The general experimental procedures, the apparatus, chemical analyses, and phase identification of quenched specimens are the same as those described in the previous paper.[1]

A supplemental method employed in this study was the rigid silica tube, quench-type, annealing experiment. In experiments of this type the elements or previously synthesized sulfides were used as source materials. The bulk composition of the charge was adjusted correctly to the desired proportion by weighing on an analytical balance. All weighings were made to a precision of ±0.05 mg. The empty tube was weighed first, then with metal or sulfides inserted, and finally with sulfur added to them. Tubes thus prepared were heated in horizontal furnaces for various periods of time and at fixed temperatures, controlled to within ±3 °C. At the termination of a run the charge was quenched into cold water.

Results and Discussion

Composition versus P_{S_2} *Diagram in a Part of the Fe–V–S System.* The results of equilibrium studies of the Fe–V–S system at sections with atomic Fe:V ratios 1 : 1, 3 : 2, and 71 : 29 are shown graphically in Figs. 1—2 and 4. The variation of equilibrium sulfur pressure P_{S_2} with the composition of sulfides (X=S/(Fe+V)) are given as the isothermal curves, which were drawn by a smooth fitting of data points. The phases as revealed by X-ray diffraction of the quenched specimens are also shown in the figures. Some representative results of quench-type experiments are given in Table 1. In the following text of this paper, solid solution, liquid, and vapor are abbreviated as s.s., L, and v for convenience.

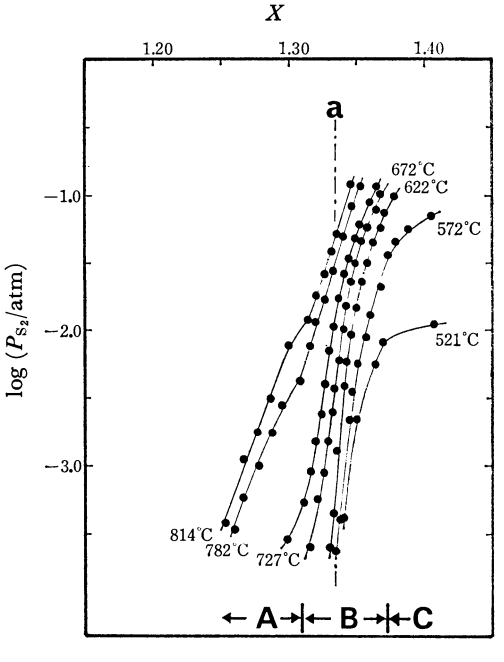

Fig. 1. P_{S_2}-composition (X=S/(Fe+V)) isotherms of $Fe_{0.50}V_{0.50}S_X$. Phase identifications of quenched specimens by X-ray powder diffraction method are shown in lower part of figure as follows A: $(Fe,V)_{1-\delta}S$ s.s.+$(Fe,V)_3S_4$ s.s. B: $(Fe_{0.50}V_{0.50})_3S_4$ s.s. C: $(Fe,V)_3S_4$ s.s.+FeS_2. The stoichiometric Fe+V: S=3:4 composition is designated as the symbol a.

a) Sealed tube method. b) Sulfur pressure control method.

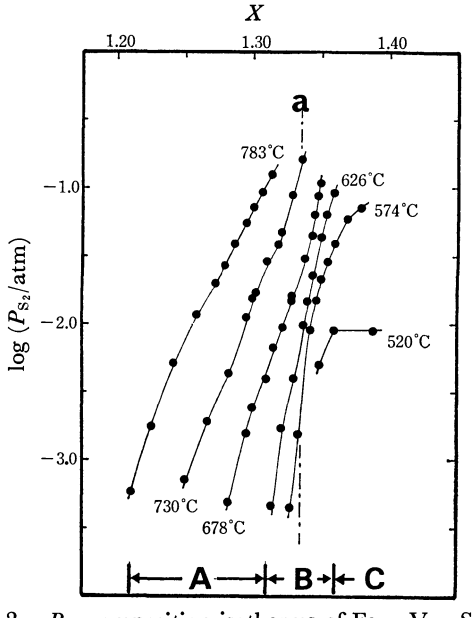

Fig. 2. P_{S_2}-composition isotherms of $Fe_{0.60}V_{0.40}S_X$. A: $(Fe,V)_{1-\delta}S$ s.s.+$(Fe,V)_3S_4$ s.s. B: $(Fe_{0.60}V_{0.40})_3S_4$ s.s. C: $(Fe,V)_3S_4$ s.s.+FeS_2. a: Stoichiometric Fe+V: S=3:4 composition.

Figure 1 shows isotherms with the composition $Fe_{0.50}V_{0.50}S_x$, where X ranges between 1.25 and 1.41 within the experimental temperature region. In this compositional range, several kinds of quenched specimens were identified by X-ray powder diffraction patterns. The following phases were found: hexagonal $(Fe,V)_{1-\delta}S$ s.s., monoclinic V_3S_4-type $(Fe,V)_3S_4$ s.s., and cubic FeS_2 (pyrite). In the range of composition between $X=1.25$ and $X=1.31$, a two-phase mixture of $(Fe,V)_{1-\delta}S$ s.s. and $(Fe,V)_3S_4$ s.s. was obtained below 814 °C. One phase of $(Fe_{0.50}V_{0.50})_3S_4$ s.s. was observed in the range $1.31 \leqq X \leqq 1.37$. Beyond $X=1.37$, FeS_2 appeared together with $(Fe,V)_3S_4$ s.s. at temperatures below 622 °C.

As shown in Fig.1, the steepest part of the isothermal curves is observed at the composition of about $X=1.33$, accompanied by the rapid change of sulfur pressure.

This feature of the isotherms in the one-phase region clearly indicates the existence of a stoichiometric (Fe+V):S=3:4 phase at temperatures below 727 °C. It is noted that isothermal curves for 814, 782, and 727 °C change their slopes slightly at about $X=1.31$. This composition corresponds to the metal-rich phase boundary of $(Fe_{0.50}V_{0.50})_3S_4$ s.s., which was determined from X-ray measurements of quenched specimens. In a two-phase field ($1.25<X<1.31$), however, the isotherms are not horizontal, as is often observed in the case of a two-phase equilibrium of binary systems, but represent rather a continuous variation of sulfur pressure with composition. The sulfur-rich limit of the $(Fe_{0.50}V_{0.50})_3S_4$ phase extends to the composition of $X=1.37$, where the isotherm becomes horizontal at 521°C due to the formation of FeS_2. However, the curvature change of the isotherm for 572 °C is observed at $X=1.38$ rather than at $X=1.37$. This suggests that the homogeneity range of $(Fe_{0.50}V_{0.50})_3S_4$ phase tends to be broadened slightly to the sulfur-rich side with increasing temperature.

A few remarks should be made here regarding the powder X-ray diffraction patterns of the FeS_2, which coexist with $(Fe,V)_3S_4$ s.s. phase. All the unit cell dimensions of FeS_2 in equilibrium with $(Fe,V)_3S_4$ s.s. are the same as those of pure FeS_2, within the limits of error. It may be concluded that FeS_2 does not take measurable amounts of vanadium or sulfur into solid solution and is a stoichiometric compound.

Figure 2 shows isotherms with the composition $Fe_{0.60}$-

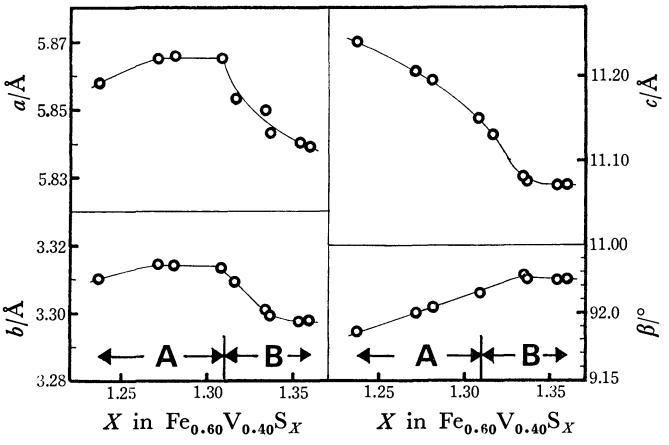

Fig. 3. Relationship between lattice constants of the coexisting phase ($(Fe,V)_3S_4$ s.s.) and the bulk composition. Region, A, is a two-phase field and region, B, a one-phase field.

$V_{0.40}S_X$, where X ranges between 1.21 and 1.39. As listed in Table 1, the following phase relations are found: a two-phase mixture of $(Fe,V)_{1-\delta}S$ s.s. and $(Fe,V)_3S_4$ s.s., $(Fe_{0.60}V_{0.40})_3S_4$ s.s. phase, and a two-phase mixture of FeS_2 and $(Fe,V)_3S_4$ s.s. in the compositional range of $X<1.31$, $1.31\leqq X\leqq 1.36$, and $1.36<X$, respectively.

Although the metal-rich phase boundary of $(Fe_{0.60}V_{0.40})_3S_4$ is determined to be about $X=1.31$ by X-ray powder diffraction of quenched specimens, no characteristic change of the curvature is observed at $X=1.31$ in the isotherms for 783, 730, and 678 °C. These isotherms exhibit rather continuous and gradual changes of sulfur pressure with composition. Within the one-phase region, a rapid increase of pressure is observed near the stoichiometric composition ($X=1.33$) at temperatures below 678 °C. This indicates the existence of the stoichiometric $(Fe_{0.60}V_{0.40})_3S_4$ phase. The isotherm for 520 °C is clearly horizontal at the composition of about $X=1.36$, due to the formation of FeS_2 in equilibrium with $(Fe,V)_3S_4$ solid solution. However, the isotherm for 574 °C does not show such an abrupt change of the slope as is observed at 520 °C.

In order to clarify the behavior of the isotherms on the metal-richer side beyond $X=1.31$, lattice parameters of several specimens quenched from 730 °C were examined by X-ray diffraction (Cu $K\alpha$). Figure 3 shows the relationships between the lattice constant of the coexisting phase ($(Fe,V)_3S_4$ s.s.) and the bulk composition within a two-phase field ($X<1.31$). The lattice constant c and β-angle of $(Fe,V)_3S_4$ s.s. in equilibrium with $(Fe,V)_{1-\delta}S$ s.s. change continuously with compositions, the lattice constants a and b remaining nearly the same in the range $1.27<X<1.31$. In general, shifts of lattice constant correspond to the compositional variation of the phase. Therefore, it may be concluded that solid solution limits of $(Fe,V)_3S_4$ phase vary smoothly with the equilibrium sulfur pressure, which is represented as the isothermal curve for 730 °C in Fig.2.

The high-temperature X-ray diffraction studies were made on a two-phase mixture of $(Fe,V)_3S_4$ s.s. and $(Fe,V)_{1-\delta}S$ s.s. with bulk composition of $X=1.28$

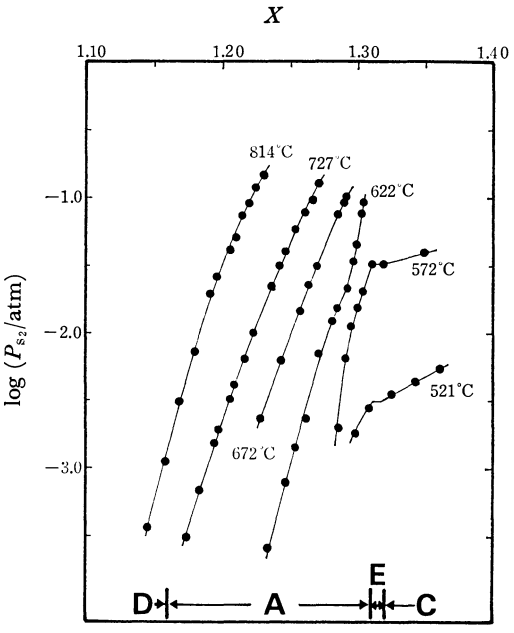

Fig. 4. P_{S_2}-composition isotherms of $Fe_{0.71}V_{0.29}S_X$. A: $(Fe,V)_{1-\delta}S$ s.s.+$(Fe,V)_3S_4$ s.s. C: $(Fe,V)_3S_4$ s.s.+FeS_2. D: $(Fe_{0.71}V_{0.29})_{1-\delta}S$ s.s. E: $(Fe,V)_{1-\delta}S$+$(Fe,V)_3S_4$ s.s.+FeS_2.

in order to observe the real phase relations directly. It was confirmed that (1) a high-temperature phase with trigonal structure is formed at temperatures above 850 °C due to the reaction of $(Fe,V)_{1-\delta}S$ s.s. with $(Fe,V)_3S_4$ s.s. and (2) the phase is unquenchable and readily inverts to the original, two different phases on quenching below 850 °C. From these results, the behavior of the isotherms for 783 and 730 °C may be interpreted as reflecting the sulfur activity change of solids at the intermediate state of phase formation or separation.

Figure 4 shows isotherms with the composition $Fe_{0.71}V_{0.29}S_X$, richer in Fe than that in Fig. 2. The region covered experimentally lies in the compositional range of $1.15<X<1.37$. From X-ray studies of the quenched specimens, the following phase relations were confirmed: $(Fe_{0.71}V_{0.29})_{1-\delta}S$ phase, a two-phase mixture of $(Fe,V)_{1-\delta}S$ s.s. and $(Fe,V)_3S_4$ s.s., and a two-phase mixture of $(Fe,V)_3S_4$ s.s. and FeS_2, in the compositional ranges of $X\leqq 1.16$, $1.16<X<1.315$, and $1.32\leqq X$, respectively.

With regard to the isotherm feature, it is noted that the isotherm for 814°C does not show any characteristic change of the curvature at the sulfur-rich limits of $(Fe_{0.71}V_{0.29})_{1-\delta}S$ phase ($X=1.16$) and exhibits continuous variations of sulfur pressure with composition in the range of $1.15<X<1.23$. This seemed to be indicative of the existence of a high-temperature phase. In this connection, X-ray studies of specimens with the bulk composition of $X=1.20$ were carried out at high temperatures. It was found that a two-phase mixture of $(Fe,V)_{1-\delta}S$ s.s. and $(Fe,V)_3S_4$ s.s. transforms to the high-temperature hexagonal $(Fe_{0.71}V_{0.29})_{0.83}S$ phase perfectly at temperatures above 800 °C. Therefore, it may be suggested that the homogeneity range of the high-temperature phase extends to $X=1.23$ under the present experimental conditions and, when quench-

ing, the specimens whose composition is richer than $X=1.16$ decompose to $(Fe,V)_{1-\delta}S$ and $(Fe,V)_3S_4$ s.s. phases.

The slope of isotherms for 572 and 521 °C changes abruptly at the composition of $X=1.31$ and a relatively small change in the pressure causes a large variation of the composition. The behavior of these isotherms may be interpreted in the same way as in the case of isotherms of $Fe_{0.60}V_{0.40}S_X$ for 520 °C. That is to say, FeS_2 begins to be formed at the composition above $X=1.31$ and the isotherms become horizontal.

However, the X-ray powder diffraction pattern of the specimen with the composition of $X=1.317$ seemed to show only the presence of one phase, $(Fe,V)_3S_4$ (Table 1); this result is inconsistent with the observation in Fig. 3. This is considered to originate from the difficulty that the small amount of $(Fe,V)_{1-\delta}S$ and FeS_2 in equilibrium with $(Fe, V)_3S_4$ can hardly be detected by X-ray powder analysis. On the basis of *in situ* observations described above, it can therefore be presumed that the three-phase field containing $(Fe, V)_{1-\delta}S$, $(Fe, V)_3S_4$, and FeS_2 occurs in the range $1.31<X<1.32$.

Tentative Phase Diagram of the Fe–V–S System at 570 °C. The isothermal tentative phase diagram in a part of the Fe–V–S system at about 570 °C was constructed mainly on the basis of the results of thermogravimetry. The phase relations and their compositional limits are summarized in Fig. 5.

Phase relations in parts of the Fe–S system at elevated temperatures have been clarified by earlier workers. Kullerud and Yoder[2] found that FeS_2 (pyrite), which has a cubic structure (Pa3), shows very little departure from the stoichiometric composition and melts incongruently at 743 °C. Arnold[4] studied equilibrium relations between $Fe_{1-\delta}S$ (pyrrhotite) and FeS_2 (pyrite) from 325 to 743 °C and determined the $Fe_{1-\delta}S$ solvus curve which represents the sulfur-rich limit of $Fe_{1-\delta}S$ coexisting with FeS_2. It is inferred from these studies that only two phases, $Fe_{1-\delta}S$ and FeS_2, are stable at about 570 °C. The sulfur-rich limit of $Fe_{1-\delta}S$ reaches about 46.2 atom%Fe at 570 °C, as can be estimated from Arnold's data.

The V–S system has recently been studied by many investigators. However, some inconsistencies exist in the reports, with respect to the phase relations and the homogeneity range of the phase. Using X-ray powder diffraction patterns of quenched specimens, de Vries and Jellinek[3] studied the V–S system, and reported that orthorhombic VS (range $VS—VS_{1.06}$), hexagonal $V_{1-\delta}S$ (range $VS_{1.06}—VS_{1.18}$), monoclinic V_3S_4 (range $VS_{1.20}—VS_{1.52}$), monoclinic V_5S_8 ($VS_{1.56}$), and trigonal V_3S_5 exist in the range $VS—VS_{1.67}$ at room temperature. Also, they found that the orthorhombic MnP-type VS transforms into hexagonal NiAs-type at about 600 °C for VS and at 350 °C for $VS_{1.05}$. Nakahira *et al.*[5] investigated the phase relations of the V–S system at 727 °C through *in situ* observations by means of a quartz spring balance and suggested the existence of sesquisulfide V_2S_3 with the homogeneity range of $VS_{1.45}—VS_{1.54}$. Recently, Wakihara *et al.*[6] examined the equilibrium phase relation between V_3S_4 and V_5S_8 in detail at temperatures from 650 to 800 °C and found that V_2S_3 appears to form below about 750 °C due to the phase separation of high-temperature V_3S_4, and that the homogeneity range of V_2S_3 extends from $VS_{1.446}$ to $VS_{1.520}$ at 650 °C. However, the existence of a V_2S_3 phase has not been confirmed at all from crystallographic viewpoint, because the X-ray diffraction pattern of the quenched V_2S_3 phase was very similar to that of the V_3S_4 phase. From the study of the chemical transport in the V–S system, Saeki *et al.*[7] found that the homogeneity range of V_5S_8 phase extends from $VS_{1.57}$ to about $VS_{1.64}$. The author showed in the previous paper[1] that the two-phase field of $(Fe,V)_2S_3$–$(Fe,V)_5S_8$ exists in the range from $X=1.55$ to $X=1.56$ at 622 °C, on the basis of experimental results of a part of the Fe–V–S system at sections with atomic Fe:V ratio 1 : 19.

A survey of the literature on the V–S system indicates that further detailed comprehensive studies are desirable to draw accurate phase diagrams at several temperatures. In the present study, the following phase relations of the V–S system are assumed for convenience: hexagonal $V_{1-\delta}S$ (range $VS—VS_{1.18}$), monoclinic V_3S_4 (range $VS_{1.20}—VS_{1.45}$), monoclinic V_2S_3 (range $VS_{1.46}—VS_{1.55}$), and monoclinic V_5S_8 (range $VS_{1.56}—VS_{1.64}$) exist at 570 °C. The trigonal V_3S_5 phase is omitted in this paper due to lack of data on its phase relation, homogeneity range, and equilibrium sulfur pressure and the possibility that it belongs to a high-pressure phase, as suggested by Nakano-Onoda *et al.*[8]

The sulfur-rich and poor limits of $(Fe,V)_3S_4$ phase are determined by a smooth fitting of the data points which are obtained in this study. The sulfur-rich boundary recedes progressively toward sulfur-poor compositions with increasing Fe content; the upper sulfur solubility limits are 58.0 and 57.8 atom % S in sections with atomic Fe : V ratio 1 : 1 and 3 : 2, respectively. On the contrary, the sulfur-poor limit of $(Fe,V)_3S_4$ phase shows a constant value of 56.7 atom % S in spite of a variation in Fe : V ratio like that described above. This boundary is drawn in Fig. 5 as a straight line in parallel with that joining VS–FeS. The Fe-rich limit of $(Fe,V)_3S_4$ s.s. phase reaches to about $0.30=V/(Fe+V)$ ratio.

Solubility of Fe in the V_5S_8 phase was determined by the supplemental, quench-type, rigid tube experiment (Table 1). The Fe-rich limit of $(Fe,V)_5S_8$ phase was confirmed to reach about 0.20, $Fe/(Fe+V)$ ratio, at 600 °C. This value is in good agreement with the Fe-rich limit of the $(Fe,V)_5S_8$ phase, which was reported by Oka *et al.*[9] As shown in Fig. 5, the phase boundary of $(Fe,V)_3S_4$, $(Fe,V)_2S_3$, and $(Fe, V)_5S_8$ on the side richer in V than $V/Fe=1$ is determined by a smooth fitting of data points. Two-phase regions of $(Fe,V)_3S_4$–$(Fe,V)_2S_3$ and $(Fe,V)_2S_3$–$(Fe,V)_5S_8$ are extended in parallel with the line joining FeS–VS from the VS–S side to the Fe-rich phase boundaries.

With respect to the lower part of the FeS–VS–S diagram, it is assumed that $Fe_{1-\delta}S$ and $V_{1-\delta}S$ phases form a complete $(Fe,V)_{1-\delta}S$ solid solution at 570 °C. With homogeneous ranges of compounds, as previ-

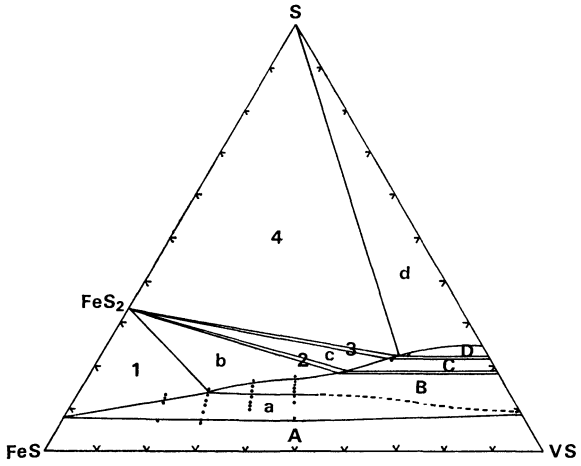

Fig. 5. Tentative phase diagram of the sulfur-rich portion of the Fe–V–S system at about 570 °C. Phase relations are represented as follows. Phase A: Monosulfide s.s. $(Fe,V)_{1-\delta}S$. B: $(Fe,V)_3S_4$ s.s. C: $(Fe,V)_2S_3$ s.s. D: $(Fe,V)_5S_8$ s.s. Two-phase regions are a: $(Fe,V)_3S_4$ s.s.+$(Fe,V)_{1-\delta}S$ s.s. b: $(Fe,V)_3S_4$ s.s.+FeS_2. c: $(Fe,V)_2S_3$ s.s.+FeS_2. d: $(Fe,V)_5S_8$ s.s.+L. Numbers in figure mean the univariant assemblages as follows. 1: FeS_2+$Fe_{1-\delta}S$+$(Fe,V)_3S_4$ s.s.+v. 2: FeS_2+$(Fe,V)_3S_4$ s.s.+$(Fe,V)_2S_3$ s.s.+v. 3: FeS_2+$(Fe,V)_2S_3$ s.s.+$(Fe,V)_5S_8$ s.s.+v. 4: FeS_2+$(Fe,V)_5S_8$ s.s.+L+v.

ously determined by Toulmin and Barton[10] and Arnold[4] for $Fe_{1-\delta}S$, and de Vries and Jellinek[3] for $V_{1-\delta}S$, it was possible to draw a monosulfide solid solution field of $(Fe,V)_{1-\delta}S$. This boundary is drawn qualitatively by a full line. The sulfur-rich limit of the monosulfide s.s. field reaches a maximum of 54.1 atom %S in the V–S side. It recedes progressively toward S-poor compositions with increasing Fe content till it reaches the middle part of the field. However, the upper sulfur solubility limits of monosulfide s.s. field are largely interpretative because of the lack of experimental data for compositions of $(Fe,V)_{1-\delta}S$ coexisting with $(Fe,V)_3S_4$.

As shown in Fig. 5, there are four univariant assemblages: $Fe_{1-\delta}S$–FeS_2–$(Fe,V)_3S_4$ s.s.-v, FeS_2–$(Fe,V)_3S_4$ s.s.–$(Fe,V)_2S_3$ s.s.–v, $(Fe,V)_2S_3$ s.s.–$(Fe,V)_5S_8$ s.s.–FeS_2-v, and FeS_2–$(Fe,V)_5S_8$ s.s.–L-v.

Relation of Lattice Parameters of $(Fe,V)_3S_4$ s.s. Phase with Composition. The $(Fe,V)_3S_4$ s.s. phase has the monoclinic V_3S_4-type structure (nonreduced space group I2/m referred to the fundamental NiAs-type cell), in which metal vacancies are ordered within alternate metal layers.[11] In the course of continuing the equilibrium study of the Fe–V–S system, several kinds of quenched specimens in the $(Fe,V)_3S_4$ s.s. field were examined by the X-ray powder diffraction technique in order to clarify the relation of lattice constant and composition. The lattice constants were calculated by the least-squares method from the data of powder diffractometer measurements using Cu $K\alpha$ radiation. Values of at least 20 reflections in the 2θ range of 10° to 70° were used in this computation. The compositional dependence of the unit cell dimensions are shown in Fig. 6—8.

It is found that the axial dimensions of the a-, b-,

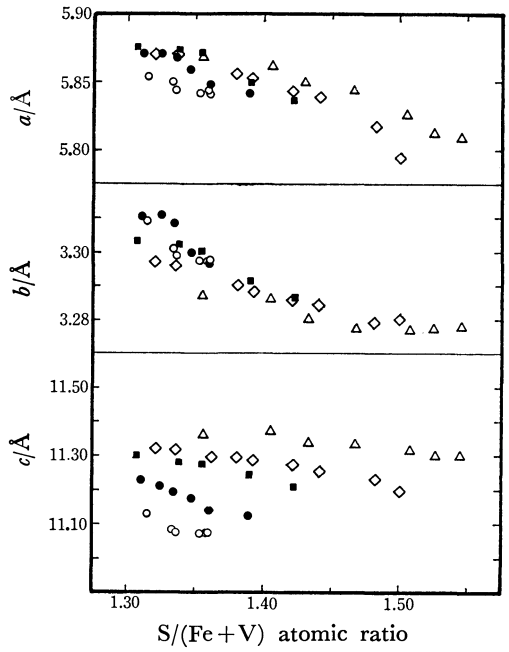

Fig. 6. Lattice constants of the unit cell of $(Fe,V)_3S_4$ s.s. phase as function of composition. △: Fe:V=1:19, ◇: Fe:V=13:37, ■: Fe:V=7:13, ●: Fe:V=1:1, ○: Fe:V=3:2.

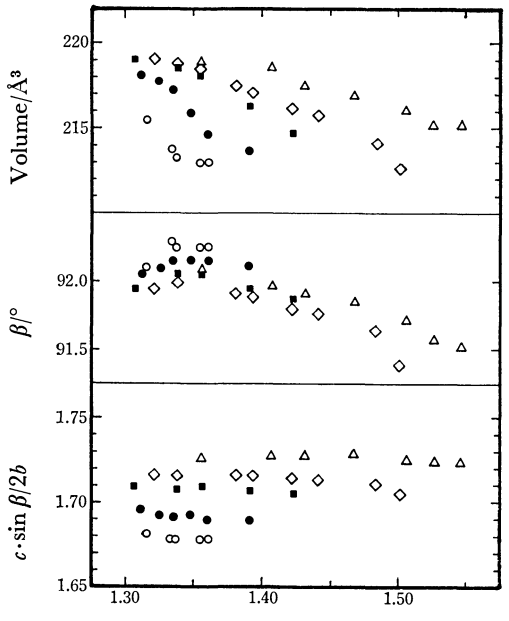

Fig. 7. Volume, β-angle and $c\cdot\sin\beta/2b$ of the unit cell of $(Fe,V)_3S_4$ s.s. phase as function of composition.

and c-axes and thus the cell volume decrease with increasing S content under the present experimental conditions. Also, the axial dimensions of the c-axis and the unit cell volume of $(Fe,V)_3S_4$ s.s. phase decrease with increasing Fe/V ratio, when the S/(Fe+V) ratio is held constant. This is in good agreement with that of $(Fe_xV_{1-x})V_2S_4$, which has been reported by Oka *et al.*[9] The c-dimensions of $(Fe,V)_3S_4$ with Fe:V=3 : 2 atomic ratio are about 2.6% smaller than that of V_3S_4.

As shown in Fig. 7, however, the behavior of the β-angle of the unit cell is quite different from those

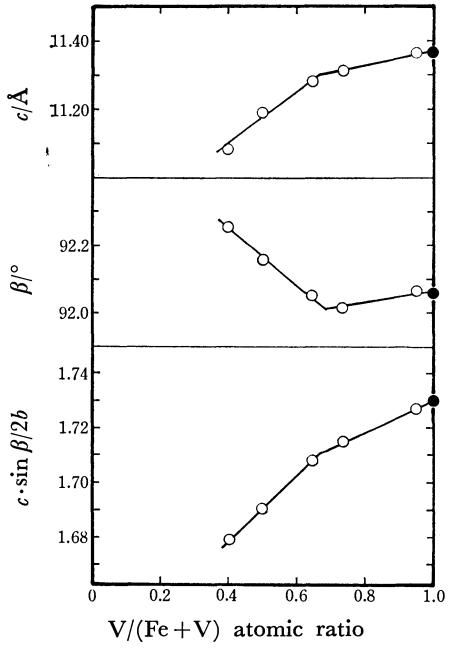

Fig. 8. Relation of c-dimension, β-angle and $c\cdot\sin\beta/2b$ of $(Fe,V)_3S_4$ compound with V/(Fe+V) atomic ratios. ●: De Vries and F. Jellinek (1974). ○: Present work.

of the a-, c-dimensions and the unit cell volume. Maximum values are observed at about $X=1.34$—1.35 in β-angle-composition relations of compounds with a constant Fe:V ratio. Also, the β-angle varies with the degree of the substitution of Fe for V in V_3S_4. It is apparent from Figs.7 and 8 that the β-angle decreases with increasing Fe content in the range of V/(Fe+V), from 1 to about 0.70, and increases with increasing Fe content in the range of V/(Fe+V), from 0.7 to 0.4.

In order to examine the directional character of the structure for several $(Fe,V)_3S_4$ s.s. phases, the $c\cdot\sin\beta/2b$ ratio in the monoclinic V_3S_4-type structure is calculated instead of the axial ratio of c/a in NiAs-type structure. As is evident in Fig. 7, the values of $c\cdot\sin\beta/2b$ of compounds with the constant Fe/V ratio are nearly equal over the whole range of composition. On the other hand, when the S content is held constant, the ratio value decreases with increasing Fe content. This result indicates that the interlayer spacing is reduced relative to the intralayer spacing by the substitution of Fe for V in V_3S_4.

Figure 8 shows the relations of c-dimension, β-angle, and $c\cdot\sin\beta/2b$ with V/(Fe+V) atomic ratio at the composition of about $X=1.33$. Data points do not fall on the same straight line and a change of the slope is observed at about V/(Fe+V)=0.67, whose composition corresponds to FeV_2S_4. From this results, it seems that the $(Fe,V)_3S_4$ s.s. phase can be divided into two types: one is the V_3S_4–FeV_2S_4 series, and the other is the FeV_2S_4–Fe_2VS_4 series. From the neutron diffraction studies of FeV_2S_4 compound,[12] it was found that all Fe atoms are confined to the partially filled metal layers and all V atoms to the filled metal layers. However, whether the $(Fe,V)_3S_4$ compound richer in Fe than FeV_2S_4 is an ordered phase or not as for the distribution of Fe and V atoms over all the metal sites is still an open question. Further detailed studies on the crystal structure and physical properties of $(Fe,V)_3S_4$ s.s. phase are necessary for a better understanding of the phase relations of the Fe–V–S system.

The author wishes to express his deep gratitude to professor Mitsuoki Nakahira of Okayama College of Science for his encouragement and helpful discussion throughout this study. Thanks are also due to Dr. H. Nakazawa for his guidance of the high-temperature X-ray measurements.

The Thermal Decompositions of Dialkyl Peroxides

Kazuya UETAKE,* Kenji UEDA,** and Noriyuki SAKIKAWA

Department of Industrial Chemistry, College of Science and Engineering, Nihon University, Chiyoda-ku, Tokyo 101

(Received September 30, 1978)

With the purpose of obtaining information needed for hazard prevention, pure liquid dialkyl peroxides (di-*t*-butyl peroxide (**1**), bis(1-methyl-1-phenylethyl) peroxide (**2**), *t*-butyl 1-methyl-1-phenylethyl peroxide (**3**), 2,5-bis(*t*-butyldioxy)-2,5-dimethylhexane (**4**)) were subjected to thermal-decomposition experiments, in which thermal analyses were conducted by the use of a thermogravimetry (TG)-differential scanning calorimetry (DSC) apparatus equipped with a pinholed pan with a minute pinhole. From the DSC curves recorded, we obtained the decomposition temperature of Samples **2**, **3**, and **4**, as a constant value for each sample, and the maximum exothermic peaks at the optimum pinhole diameters (0.07—0.2 mm). The heats of decomposition obtained could be considered appropriate, as they roughly agreed with the estimated value, on the other hand, **1** shows no exothermic peak under these condition. Plotting by the Coats-Redfern method based on the TG-curve data (**2**, **3**, and **4**) gave reaction orders of more than unity, activation energies of 33—37 $kcal_{th}$/mol, and frequency factors of 10^{16}—10^{18} s^{-1}. It is conceivable that these results could be derived by virtue of the TG–DSC curves that were suitable in obtaining thermochemical parameters. In other words, the analysis method introduced in this paper was found to be an efficient one for liquid peroxides that are difficult to analyze by a conventional TG–DSC method.

Organic peroxides are used as polymerization initiators, curing agents, and crosslinking agents in polymer industries,[1] but they are so unstable that they readily decompose or explode when affected by heat or impact.[2] From the viewpoint of hazard prevention, it is important to have knowledge about the thermal instability of organic peroxides,[3] and one of the means to achieve this is the measurement of the activation energy[4,5] as well as the heat of decomposition.[6] However, almost all reported examples have been measurements of activation energies and frequency factors through a determination of the thermal decomposition rates either in a gas phase or in a low-concentration solution diluted in a solvent.[4,5] Furthermore, there have been hardly studies of measuring heats of decomposition.[6]

Recently, thermogravimetry (TG), differential thermal analysis (DTA), and differential scanning calorimetry (DSC) have come to be commonly used in measuring the thermal decomposition of organic peroxides.[7] Uetake *et al.* determined the activation energy and heat of decomposition of benzoyl peroxide through thermal decomposition by means of a TG–DSC apparatus.[8] Although a TG–DSC for solid materials like this is generally satisfactory, an analysis of liquid materials is extremely difficult because of the influense of the vaporization of the sample.[9,10] The difficulties in performing an acurate measurememt come from the following facts: a TG curve is a result of the overlapping of the weight change pertaining to the reaction and the weight loss caused by the vaporization of the sample, while a DSC curve is the outcome of the overlapping of the exotherm, along with its apparent decrease caused by the sample loss, and the latent heat of vaporization. As a matter of fact, most organic peroxides are in a liquid state around their decomposition temperatures; hence, examinations of either the procedure or the apparatus used for measurement are necessary in order to obtain an appropriate TG curve or DSC curve by the use of a TG–DSC apparatus. A sealed cell reportedly gives an apparently lower heat of decomposition[11] and, furthermore, cannot provide a TG curve, so that it is not suitable for our present purpose, a comprehensive evaluation. The use of a pinholed pan can, though, be proposed as a solution to this problem.[12]

This study of such organic peroxides deals with experiments using an apparatus with a pinholed pan, and intends to establish the procedure for obtaining an appropriate TG–DSC curve and derive the basic data to provide useful knowledge for hazard prevention. From an analysis of the pyrolysis experiments, an evaluation of the values of the heat of decomposition obtained is also attempted.

Experimental

Materials. Selected dialkyl peroxides are: di-*t*-butyl peroxide (**1**), bis(1-methyl-1-phenylethyl) peroxide (**2**), *t*-butyl 1-methyl-1-phenylethyl peroxide (**3**), and 2,5-bis(*t*-butyldioxy)-2,5-dimethylhexane (**4**). The commercial product (Nippon Oil and Fats Co., Ltd.) for each was used after purification. Peroxide **2** was recrystallized from ethanol.[13] Peroxide **3** was recrystallized twice at −70 °C, and the product was distilled *in vacuo* at room temperature.[14] Both **1**[15] and **4**[16] were distilled *in vacuo* at room temperature. All the samples were at least 99.0% pure.

Measurement. An aluminum sealed-type cell, with an outer diameter of 4.6 mm, 2 mm deep, and 0.1 mm thick, was utilized as a sample cell for measurement. After placing a sample in it, it was covered with an aluminum cover pinholed beforehand and was sealed by hermetical pressing by the use of a sample sealer. Hereafter, this type of sample cell will be called "a pinholed pan." After sealing, the dimensions of the pinholed pan came to be 4.6 mm in outer diameter, 2.8 mm thick, and 46.5 mm^2 in capacity. The weighing of the sample taken in was quickly carried out just after the sealing. The pinhole was bored by a needle at the center of the cover, and its diameter was measured by a microscopic scale.

The behavior on the heating of the sample in a pinholed pan was followed by a standard-type TG–DSC apparatus made by Rigaku Denki. The conditions of measurement

** Present address: Yokohama City Fire Bureau, Hodogaya-ku, Yokohama 240.

were: sample weight, 1.2—2.0 mg; heating rate, 2.5 °C/min; air atmosphere. For comparison, experiments with an open cell with no cover and those with a sealed cell with no pinhole in the cover were also conducted.

The relationships between the pinhole diameter of the pinholed pan and the TG curve as well as the DSC curve were examined, and the activation energy, the frequency factor, and the reaction order were derived from the appropriate TG curve by the use of the Coats-Redfern method.[17] The decomposition temperature and the heat of decomposition were also derived from the DSC curve.

The pyrolysis gas-chromatograph apparatus employed has been described previously.[8] The procedures used for the pyrolysis of the sample and the analysis of the pyrolysis products are essentially the same as those reported in a previous paper.[18] About 1 milligram of **4** was used for pyrolysis.[19] Samples were then pyrolyzed rapidly at 330 °C. The analytical conditions were as follows; column, Porapak Q (100—120 mesh), 3 m, 70 °C (in the case of acetone, 150 °C); detector, FID, 220 °C; N_2-flow rate, 20 ml/min; injection temperature, 150 °C.

Results and Discussion

Before proceeding to a detailed evaluation of the thermal decomposition of dialkyl peroxides by the use of the TG–DSC apparatus with a pinholed pan, let us mention that a study was made of the effects of the sample weight and the heating rate, which could conceivably have influenced the results. In the sample-weight (1—4 mg)-dependence determinations, all the runs were made at a heating rate of 2.5 °C/min, while in the heating-rate (1.25—20 °C/min)-dependence determinations, the sample weight in each case was 1.0—2.0 mg.

Consequently, it was found in the present study that the exothermic peak areas decreased with an increase in either the heating rate or the sample weight. However, there were no detectable differences in the peak areas obtained under the conditions of a sample weight of 1.0—2.0 mg, and a heating rate of 2.5 °C/min. The standard procedure described above can, therefore, be employed and is, as a matter of fact, more desirable.

Pinhole-diameter Dependence of the Thermal Properties. Figure 1 shows the relationship between the TG–DSC curve and the pinhole diameter of the pinholed pan for **2**, **3**, and **4**. The TG curves for all three samples shift to the high-temperature side, and their slopes become gentle, with a decrease in the pinhloe diameters. In the case of **2**, no change was observed in the initial decomposition temperature for the pinhole diameter range of 0.05—0.08 mm, while with an open cell the initial decomposition temperature gave rise to a small shift to the low-temperature side. Similar tendencies were observed for **3** and **4**, while, with an open cell, the plateaus of the curves were scarcely observed at all because of the drastic vaporization loss.

As for the DSC curves, all three samples showed a somewhat different pattern in relation to the decrease in the pinhole diameter. In the case of **2** with a pinhole diameter of less than 0.15 mm, we observed an endotherm trough behind the exotherm peak. As an explanation for this, we can postulate that, with a

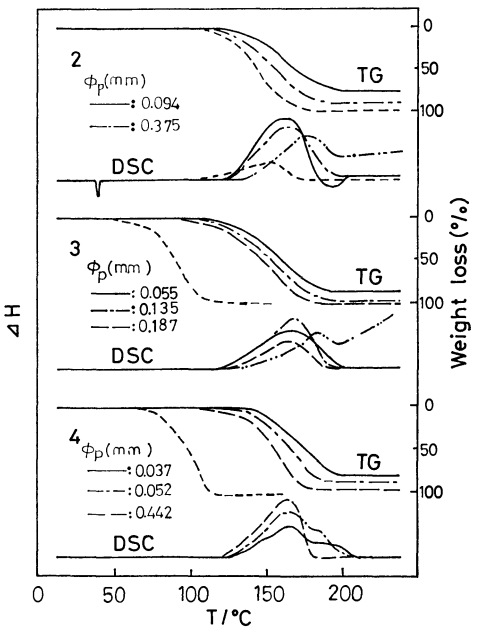

Fig. 1. Variations of TG and DSC curves for each of **2**, **3**, and **4** with various pinhole diameter (ϕ_p). ----: Open cell, ——; — — —; ——: pinholed pan —··—: closed cell.

decrease in the pinhole diameters, the high-boiling decomposition products come to remain in the cell for a longer period of time, giving rise to the appearance of an endotherm trough caused by their vaporization, accompanied by a tendency for the trough to deepen gradually. The run with a closed cell gives a reduced area of the exotherm peak. In the case with an open cell, the starting of the decomposition is obscure and the exotherm peak is small, making the analysis very difficult.

Peroxide **3** behaved very much like **2**, but it did not display a decomposition exotherm peak for the open cell. Peroxide **4** showed a similar tendency in the range down to the pinhole diameter of about 0.1 mm, but at a more reduced diameter (as low as 0.05 mm or below) a shoulder peak appeared behind the main exotherm peak; furthermore, at a diameter of 0.037 mm or below, another shoulder peak appeared before the main peak. These small peaks seem to be the outcome of the clear detection of such minute thermal changes that were not detectable with an open cell, but came to be apparent with a pinholed pan with a minute pinhole. Peroxide **1** gave neither a TG curve nor a DSC curve that could afford analysis, even with a pinholed pan with a minute pinhole (0.037 mm or below), because of its too rapid vaporization.

Figure 2, showing the DSC curve for **2**, presents the relationships of the starting of the exotherm peaks, the peak temperatures, and the end temperatures *versus* the pinhole diameters. These decomposition-related temperatures exhibit little change and are nearly constant with a decrease in the pinhole diameters. Peroxides **3** and **4** give nearly content values in a similar manner, except that the end temperature for **4** shifts almost linearly to the high-temperature side. This is understandably related to the phenomena pertaining

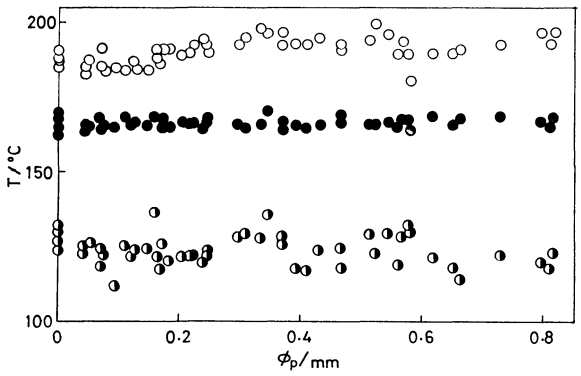

Fig. 2. The relationships of starting of exotherm peaks (◑), peak temperatures (●), and end temperatures (○) *vs.* pinhole diameters as related with the DSC curves for **2**.

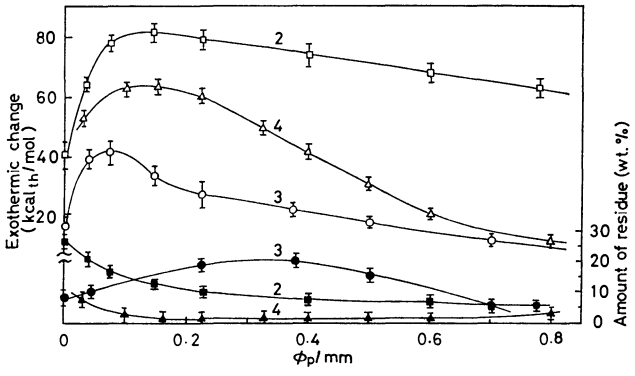

Fig. 3. Plots of exothermic change (□, ○, △) and amount of residues after decomposition (■, ●, ▲) *vs.* change in pinhole diameters for each of **2**, **3**, and **4**.

to the complicated decomposition reaction of **4** (see Fig. 1). The results of the decomposition-temperature measurements for these three samples are summarized in Table 1. The end temperature of **4** is shown for the run with a pinhole diameter of 0.1 mm (the value in the parentheses is for 0.6 mm).

Figure 3 shows the relationships of the heats of decomposition and the amounts of the residue after decomposition *versus* the change in the pinhole diameters. In the case of **2**, the heat of decomposition increases linearly with a decrease in the pinhole diameter and reaches the peak of 80.0 $kcal_{th}$/mol*** at the diameter of 0.2—0.1 mm. With a further reduction of pinhole diameter, the calorific value sharply decreases, giving the minimum value of 40.0 $kcal_{th}$/mol for the case with a closed cell. The amount of residue after the reaction increases slightly with a decrease in the pinhole diameter, while the rate of increase is enhanced by decreasing the diameter to 0.15 mm or below.

In contrast with **2**, **3**, and **4** exhibit somewhat different tendencies in both the heat of decomposition and the amount of residue after the reaction, but are similar to **2** in their maximum values of heat of decomposition: 41.5 $kcal_{th}$/mol at the pinhole diameter of 0.08 mm for **3** and 62.5 $kcal_{th}$/mol at the pinhole diameter of 0.13 mm for **4**.

*** Throughout this paper, cal_{th}=4.184 J.

Table 1. Values of the decomposition temperatures for these three samples

Compound	Starting of exothermic peak (°C)	Peak temperature (°C)	End temperature (°C)
2	123±3.8	165±3.5	186±4.0
3	126±4.0	167±3.0	196±5.0
4	123±4.0	163±3.2	200±4.0 (174±5.4)

From the above findings, it can be postulated that the increase in the apparent heat of decomposition with an early decrease in the pinhole diameter is caused by some suppression of the sample vaporization of the spreading of heat,[12] and that the decrease in the apparent heat of decomposition with a further decrease in the pinhole diameter, nearing the closed state, is the outcome of the suppression of the decomposition itself effected by the enhanced partial pressure of the produced gas.[20,21] In addition, the increased amount of tarry residue after the reaction at the smaller pinhole diameter suggests the occurrence of endothermic reactions associated with the conversion of products into high-boilers and the deposition of carbon.

Thermochemical Parameters. The results and discussion of the above experiments suggest that the TG curve best fitted for obtaining thermochemical parameters is the one obtained from a measurement using a pinholed pan with a pinhole diameter suitable for minimizing the overall effect of the sample vaporization and the partial pressure of the produced gas. From such a TG curve, the reaction order (n), activation energy (E_a), and frequency factor (A) were obtained by the Coats-Redfern method:

$$\log\left[\frac{1-(1-x)^{1-n}}{T^2(1-n)}\right] = \log\frac{AR}{\phi E_a}\left[1-\frac{2RT}{E_a}\right] - \frac{E_a}{2.3RT} \quad (1)$$

where x is the fraction of the sample decomposed at a certain time, t, and where ϕ is the heating rate. T is the absolute temperature, and R is the gas constant. This equation holds for an n-order reaction when n is not unity, and the left-hand side of the equation should be replaced by $\log[-\log(1-x)/2.3T^2]$ for a first-order reaction. Since the first term on the right-hand side of the equation can be considered nearly constant, the calculating of the left-hand side for an assumed n, followed by a plotting of this result against $1/T$, may give a straight line whose slope will give E_a and whose intercept will make possible the rough estimation of the A factor.

The results of analysis are listed in Table 2. The calculated values of the activation entropies (ΔS^*)[22] are also listed in this table. There are found in the literature some more data: for **2** in the solvent cumene,[23] A factor $10^{14.6}$ s^{-1} and E_a 34.8 $kcal_{th}$/mol; and for **3** in the solvent dodecane,[23] A factor $10^{14.4}$ s^{-1} and E_a 33.5 $kcal_{th}$/mol. The data for the two compounds under no-solvent conditions are not available. For **4**, neither data for a solution nor those for no-solvent conditions have been found in the literature. As for the reported data on various dialkyl peroxides other

a) Pyrolysis temperature, 230 °C. b) Pyrolysis temperature 280 °C.

than these three peroxides, the A factors are in the range of $10^{14.0}$—$10^{16.8}\ s^{-1}$, and E_a, in the range of 31—39 $kcal_{th}$/mol.[24-28] According to Benson,[29] the unimolecular fission of a large polyatomic molecule generally gives a large A factor ($10^{16\pm1.5}\ s^{-1}$) when the mother molecule splits into two polyatomic fragments. He suggests also that the A factor will become very large when reaction order becomes large, and when the rate of decomposition decreases with a rise in the pressure in a reaction, under pressure, with positive value of the activation volume and the ΔS^*.[30,31] Huyser and Van Scoy[32] have reported that ΔS^* becomes large when the apparent rate of decomposition decreases with a reaction in a solvent.[33] It has also been reported that a thermal decomposition accompanied by an increase in the number of moles would give positive values of the activation volume and the ΔS^*.[30]

The large A factors obtained in the above experiments on the thermal decomposition without a solvent seem to be understandable when one considers, along with above arguments, the following fators: the orders of reaction $n>1$; the reactions accompanied with an increase in the number of moles; the effect of the partial pressure change in the homolysis products in the pinholed pans with a minute pinhole, and the influence of the solvent behavior of the decomposition products.

Listed in Table 3 are the values for three samples estimated by means of Eqs. 2—4; we assume an ideal thermal decomposition, based on the heats of decomposition in pinholed pans at the optimum pinhole diameters and on the data of the pyrolysis (Table 4).[18]

$$\mathbf{2} \rightarrow 1.8CH_4 + 1.8C_6H_5COCH_3 + 0.2C_6H_5C(CH_3)_2OH \quad (2)$$

$$\mathbf{3} \rightarrow C_2H_6 + (CH_3)_2CO + C_6H_5COCH_3 \quad (3)$$

$$\mathbf{4} \rightarrow 0.3CH_4 + 0.8C_2H_4 + C_2H_6 + 4(CH_3)_2CO \quad (4)$$

If available, observed values were used as the heats of formation; if they were not available, the values obtained by the method of Benson and others,[34] which applies the group-additivity rule to organic peroxides, were used. These observed values were in approximate agreement with the estimated ones, although the former values were somewhat lower. The difference in ΔH_d may be due to the decomposition temperatures[35] and other factors. In order to make this clear, however, further work is necessary.

In conclusion, it can be proposed that the use of the pinholed pans are efficient for the thermal analysis of liquid organic peroxides by means of TG–DSC.

The authors wish to thank Dr. Masahiko Kotani for his helpful discussion and Mr. Reiji Fukasawa, Mr. Hikaru Sakurai, Mr. Yoshiaki Kurimura, and Mr. Touru Asakawa for the collection of the peroxide data used in this work.

(Received September 30, 1978)

Synopsis. The ENDOR spectrum of the 2,3-diphenyl-5,6-dihydro-1,4-dithiin cation radical, which was prepared with $AlCl_3$ in dichloromethane solution, has been observed. The spin density distribution of the new radical was also discussed and compared with the MO calculation.

ESR detections of the intermediate cation radical (g=2.0070+0.0005) formed by thallium(III) nitrate oxidation of 2,3-diphenyl-5,6-dihydro-1,4-dithiin have been previously reported.[1] Several ESR studies of 1,4-dithiin cation radicals have been published,[2] but no detailed data on the spin density distribution of the dihydro-1,4-dithiin cation radical have been given. In the present work, ENDOR observations are carried out for the intermediate cation radical produced by one electron oxidation of 2,3-diphenyl-5,6-dihydro-1,4-dithiin, and the spin density distribution of the new radical is investigated.

Experimental

The synthesis of materials has been described elsewhere.[1] Cation radicals of 2,3-diphenyl-5,6-dihydro-1,4-dithiin were prepared using thallium(III) nitrate as the oxidant. It was found, however, that the identical cation radical generated by $AlCl_3$ oxidation in CH_2Cl_2 showed a rather enhanced stability as compared with the case of thallium(III) oxidation, and no important change in the detailed hyperfine structures could be detected in the ESR spectrum. ENDOR observations were applied to this solution using a JEOL-type EX-EDX-1 spectrometer under the operating conditions similar to those described previously.[3]

Results and Discussion

Figure 1 shows the ENDOR spectrum of 2,3-diphenyl-5,6-dihydro-1,4-dithiin cation radical prepared with $AlCl_3$ oxidation in CH_2Cl_2. The four ENDOR signals (14.31, 14.76, 14.90, and 15.11 MHz) seen in the vicinity of the free proton frequency can be ascribed to the splitting due to the phenyl groups, with reference to the MO calculation of the spin densities summarized in Table 1. The ENDOR signals (17.20 and 22.73 MHz) detected at higher NMR frequency were safely assigned to either equatorial and axial protons in bridged methylene, as discussed later.

McLachlan's MO calculations (λ=1.0) were carried out using the following parameters: $\alpha(S)=\alpha(C)+1.0\beta$, $\alpha(CH_2)=\alpha(C)+2.0\beta$, $\beta(S\text{–}C)=0.6\beta(C\text{–}C)$, $\beta(S\text{–}CH_2)=0.4\beta(C\text{–}C)$, $\beta(C\text{–}\phi)=0.75\beta(C\text{–}C)$, and $\beta(CH_2\text{–}CH_2)=0$, where $\alpha(S)$ and $\alpha(CH_2)$ are the Coulomb integrals of sulfur atoms and of methylene carbon atoms, $\beta(S\text{–}C)$, $\beta(S\text{–}CH_2)$, and $\beta(C\text{–}\phi)$ are the resonance integrals defined for sulfur-ethylene carbons, sulfur-methylene carbons, and to ethylene bridging phenyl carbons, respectively. The present ENDOR measurement resolved four different hyperfine splittings, which could be assigned to the phenyl protons. An appropriate

d) The axial and equatorial protons (see Text).

space filling model suggests that a steric repulsion may work between sterically approaching ortho protons (12- and 14-positions) in phenyl groups. This causes different hyperfine splittings at the positions 8 and 12, and 14 and 18. Taking account of a perturbation on the spin densities affected by the steric interaction, a slightly electro positive value was assumed for the Coulomb integrals at the ortho positions, that is, α(C-12)$=\alpha$(C-14)$=\alpha-0.1\beta$, in the same manner as has been applied to the *o*-terphenyl anion radical.[4] The MO spin densities on the phenyl groups thus calculated gave good agreement with the experimental spin densities estimated from the Colpa-Bolton's equation,[5] as shown in Table 1. It is noteworthy that the MO spin densities on the sulfur atom (0.2195) are close to those of dithiin sulfur atoms determined from the extra splitting of S^{33} (0.289).[2] This suggests that the dihydrodithiin cation radicals can be regarded to be one of the π-radicals in nature.

Both axial and equatorial proton splittings (a^{ax}, a^{eq}) are calculated in terms of the $\cos^2\theta$ rule:

$$a^{ax} = B\rho_S \cos^2\theta,$$
$$a^{eq} = B\rho_S \cos^2(60-\theta),$$

where B is the hyperconjugation parameter between the sulfur and the methylene group, ρ_S is the spin density on the sulfur atoms, and θ is the usual dihedral angle between sulsur p-orbital and sp^3-CH orbital. With the observed values for a^{ax} and a^{eq} thus determined, the dihedral angle can be obtained to be $\theta\simeq 7°$. The B-value estimated here ($\rho_S=0.2195$) is 29.4 G, which shows a good agreement with the value previously estimated for the related sulfur containing a π-radical ($B=36.8$ G).[6]

A Theoretical Interpretation of the Half-wave Reduction Potentials of Chloronitrobenzenes

Shinichi YAMABE,* Tsutomu MINATO,** and Toshio ARAI

Department of Chemistry, Nara University of Education, Takabatake-cho, Nara 630

***Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606*

(Received November 16, 1978)

Synopsis. The half-wave reduction potential of chloronitrobenzenes has been studied with *ab initio* MO calculations. The relation between the energy of the lowest unoccupied MO and the reduction potential is given.

If the addition of the first electron to an aromatic hydrocarbon is the potential-determining step, there should be a relationship between the energy of the lowest unoccupied molecular orbital (LUMO) and the reduction potential.[1] We have carried out MO calculation in order to obtain possible relation between the half-wave reduction potentials ($E_{1/2}$'s) for a series of chloronitrobenzenes and the number and position of chlorine atoms attached to the benzene ring. The polarographic data are taken from the works of Fujinaga *et al.*,[2] and Kitagawa and Nakashima.[3] The MO calculation was made on the STO-3G minimal basis by use of the GAUSSIAN 70 program.[4] The coordinate and the geometrical parameters are shown in Fig. 1. For the sake of simplicity, all the bond angles in the X-Y plane are assumed to be 120° (sp^2 hybridization). The sole freedom of the geometrical change is the rotation (angle=θ°) of the nitro group around the C_1–N axis. According to X-ray analysis, pentachloronitrobenzene has θ=62°.[5] In the present study, the MO calculation is restricted to four molecules, Nos. 1, 2, 3, and 7 which are sufficient to explain the trend of $E_{1/2}$ values (Table 1).

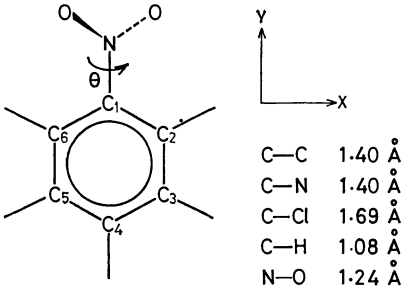

Fig. 1. The geometry taken for the MO calculation. All the bond angles are assumed to be 120°.

The values of $E_{1/2}$ are given for a variety of chloronitrobenzenes. We see a general tendency for the increase of chlorine substituents to give smaller negative values (easier reduction) except for *o*-dichloro-substituted nitrobenzenes (Nos. 7, 12, and 14). This is understandable in terms of the MO scheme, since the inclusion of hetero atoms lowers the LUMO of hydrocarbons.[1d] The greater the number of chlorine atoms attached to the benzene ring is, the more easily its anion radical is yielded through the acceptance of an electron into the LUMO. Of the three monochloronitrobenzenes

b) Evaluated from cyclic voltammogram of No. 15.

1, 2, and 3, the order of ease of one-electron reduction is *m*->*p*->*o*-chloronitrobenzene. In general, molecules with a greater amount of *meta*-Cl and a smaller amount of *ortho*-Cl are easily reduced. No. 9 (*m*-dichloro-substituted) is found to be most easily reduced among the series of dichloronitrobenzenes. The unfavorable role of the *ortho*-Cl against the easier reduction is observed typically in No. 7 with two Cl's. In spite of the inclusion of two hetero atoms, this molecule has a greater negative $E_{1/2}$ value (more difficult for reduction) than the parent nitrobenzene ($E_{1/2}$=−1.09). Such a trend holds also for the polychloronitrobenzenes.

The result given in Table 1 is interpreted theoretically in the MO scheme. First, the optimum θ of Nos. 1, 2, 3, and 7 is examined through a comparison of total energies. While No. 2 (*m*-Cl) and No. 3 (*p*-Cl) have a planar structure of θ=0° with the most widely spread π conjugation, No. 1 (*o*-Cl) and No. 7 (*o*-dichloro-substituted) have a nonplanar equilibrium structure with θ=54° and θ=71°, respectively. The *ortho*-Cl thus has a remarkable effect of steric hindrance on the nitro group. The question arises as to how such a nonplanar structure is related to the above mentioned result of $E_{1/2}$ of *ortho*-substituted nitrobenzenes. As θ becomes greater, the levels of LUMO 1 and 7 ascend sharply. These LUMO's are the π* orbital for θ=0°. The effect of the *ortho*-Cl on the value of $E_{1/2}$ is explained as follows. The *ortho*-Cl causes twisting of the nitro

group by steric hindrance. The subsequent nonplanar structure of the *o*-chloro-substituted nitrobenzenes raises the level of their LUMO's through the decrease of the extent of the π bonding between the benzene ring and the nitro group, resulting in the more difficult reduction, *i.e.*, a greater negative value of $E_{1/2}$. These molecules provide an interesting example of the "ortho effect" in their physical property *i.e.*, $E_{1/2}$.

Then, why does the *meta*-Cl make the reduction of nitrobenzene easier? In order to elucidate this effect, the mode of the π-MO interaction between the fragmental nitrobenzene and the chlorine atom is examined as to the planar monochloronitrobenzene. Of several π MO's of nitrobenzene, three unoccupied MO's, LUMO, (LU+1)MO, and (LU+2)MO are the most significant orbitals which contribute to the ascent or the descent of the LUMO of the monochloronitrobenzene. As for the chlorine atom, its $3p_z$ AO is the sole contributor to the LUMO of the monochloronitrobenzene. Figure 2a shows the nodal property of the π MO's of nitrobenzene and Fig. 2b the mode of the π-MO interaction between two fragmental sites. If only the LUMO of nitrobenzene interacts with the $3p_z$ AO, two kinds of orbitals, $\psi_{occ}^{o,m,p}$ and $\psi_{uno}^{o,m,p}$, are obtained. ψ_{occ} and ψ_{uno} indicate the occupied and unoccupied orbitals of the monochloronitrobenzene, respectively. The *o*, *m*, and *p* attached to the right shoulder denote the position, *ortho*, *meta*, and *para*, respectively, of the substituent. The (LUMO-$3p_z$) interaction causes the energy splitting between ψ_{occ} and ψ_{uno}, the degree of which depends entirely on the numerical value of the AO coefficients of the LUMO of nitrobenzene (Fig. 2a). Thus, the extent of energy splitting is *m*-Cl<*o*-Cl<*p*-Cl and the energy of the unoccupied level $\psi_{uno}^{m}<\psi_{uno}^{o}<\psi_{uno}^{p}$ (ψ_{uno}^{p} is highest). The secondary effect coming from the (LU+1)MO and (LU+2)MO of nitrobenzene should also be taken into account.[6] The energy levels of ψ_{occ} and ψ_{uno} produced primarily by the (LUMO-$3p_z$) interaction are lowered (Fig. 2b) according to the extent of the secondary MO interaction of (LU+1)MO and (LU+2)MO. As a result of such MO interactions, the energy level of the LUMO of nitrobenzene and monochloronitrobenzenes would have the order, *m*-Cl <*o*-Cl<*p*-Cl<nitrobenzene with no steric hindrance.

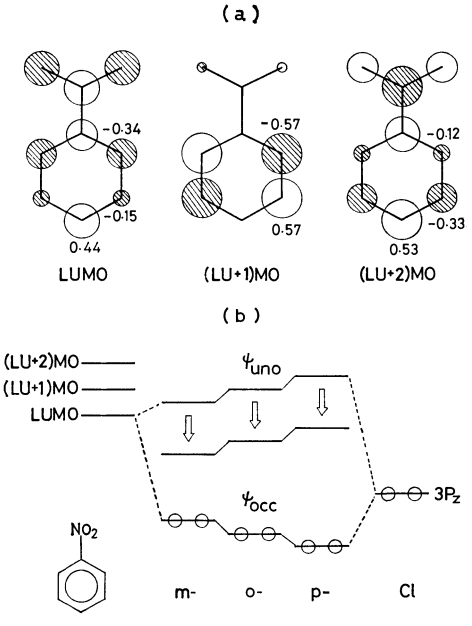

Fig. 2. (a); The AO coefficients of three π-type unoccupied MO's of nitrobenzene. (b); The mode of the orbital interaction between three unoccupied MO's of nitrobenzene and the $3p_z$ AO of Cl.

Thus, the correlation between the value of $E_{1/2}$, *i.e.*, the ε_{LUMO}, and the position of the substituent Cl is interpreted in terms of two independent factors; (a) the degree of the orbital interaction between the LUMO of nitrobenzene and the $3p_z$ AO of Cl, which depends on the numerical value of AO coefficients of the former MO, and (b) the steric hindrance caused by the *ortho*-Cl, resulting in the nonplanar structure of the *o*-chloro-substituted nitrobenzenes. In fact, the order of the experimental $E_{1/2}$ values is satisfactorily in line with that of the calculated ε_{LUMO} values.

All LUMO's of the four molecules adopted for the MO calculation are π^* (or almost π-type) orbitals. It is conceivable that, even when these molecules are reduced in one-electron step and their LUMO's accepted one electron, no dechlorination takes place. The first one-electron wave of polarography is reported to represent the reversible reduction of these compounds and the first wave corresponds to the formation of the relatively stable anion radical.

Permission to use the FACOM M-190 computer at the Data Processing Center, Kyoto University, is gratefully acknowledged. The work was carried out with Grant-in-Aid 139012 from the Ministry of Education.

Nonequilibrium Thermodynamics of Ionic Diffusion Coefficients in Binary Electrolyte Solutions

Eiichi KUMAMOTO* and Hideo KIMIZUKA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received December 18, 1978)

Synopsis. Ionic diffusion coefficients were treated on the basis of nonequilibrium thermodynamics. They were calculated for alkali metal chloride solutions and compared with the experimental data of self-diffusion coefficients.

Miller,[1] and Paterson *et al.*[2] treated transport phenomena in terms of nonequilibrium thermodynamics and calculated the phenomenological coefficients $l_{\alpha\beta}$ from the conductance λ, salt diffusion coefficient D_s, and transference number t_α in solutions of alkali and alkaline earth chlorides. However, no mention was given of the ionic diffusion coefficient which is an important transport coefficient describing the motion of an ion in an electrolyte solution.

In this paper, the ionic diffusion coefficient has been expressed as a function of $l_{\alpha\beta}$ and related to the other transport coefficients. The ionic diffusion coefficient D_α calculated from the $l_{\alpha\beta}$ coefficients has been compared with the self-diffusion coefficient D_α^* as well as $(D_\alpha)_{\text{N.E.}}$ calculated from the ion conductance by means of the Nernst-Einstein equation. The diffusion coefficient of a salt D_s calculated from the ionic self-diffusion coefficients by means of the Nernst equation was compared with the observed one.

Results and Discussion

The independent flow J_α for the binary electrolyte system is given by

$$J_\alpha = -l_{\alpha\alpha}\nabla\bar{\mu}_\alpha - l_{\alpha\beta}\nabla\bar{\mu}_\beta, \tag{1}$$

where the subscripts α and β refer to either cation or anion, and $\nabla\bar{\mu}_\alpha$ denotes the electrochemical potential gradient for ion α. In the absence of the electric current, we find by eliminating $\nabla\bar{\mu}_\beta$

$$-J_\alpha/\nabla\bar{\mu}_\alpha = z_\beta(l_{\alpha\alpha}l_{\beta\beta} - l_{\alpha\beta}^2)/(z_\alpha l_{\alpha\beta} + z_\beta l_{\beta\beta}), \tag{2}$$

where z is the charge number of ion. The $l_{\alpha\beta}$ is related to the element of mobility matrix $u_{\alpha\beta}$ as follows[3]

$$l_{\alpha\beta} = u_{\alpha\beta}|z_\beta/z_\alpha z_\beta|c_\beta/F, \tag{3}$$

where c_β and F are the concentration of ion β and Faraday constant, respectively. Substituting Eq. 3 into the right hand side of Eq. 2, we have

$$-J_\alpha/\nabla\bar{\mu}_\alpha = c_\alpha/f_\alpha, \tag{4}$$

where f_α denotes the friction coefficient of ion α:

$$f_\alpha = F(z_\alpha|z_\beta|u_{\alpha\beta} + z_\beta|z_\alpha|u_{\beta\beta})/z_\beta(u_{\alpha\alpha}u_{\beta\beta} - u_{\alpha\beta}^2). \tag{5}$$

Defining an ionic diffusion coefficient D_α by the Einstein equation

$$D_\alpha = \frac{RT}{f_\alpha} = RT\frac{z_\beta(l_{\alpha\alpha}l_{\beta\beta} - l_{\alpha\beta}^2)}{c_\alpha(z_\alpha l_{\alpha\beta} + z_\beta l_{\beta\beta})}, \tag{6}$$

and substituting Eq. 6 into Eq. 2, we obtain the Nernst-Planck equation

$$J_\alpha = -\frac{D_\alpha c_\alpha}{RT}\nabla\bar{\mu}_\alpha. \tag{7}$$

Thus we see that the Nernst-Planck equation holds only in the limited case of no electric current in the binary electrolyte system, and that the ionic diffusion coefficient is given by Eq. 6 as a function of $l_{\alpha\beta}$. Since the equivalent conductance λ_α is given by[3]

$$\lambda_\alpha = |z_\alpha|F^2(z_\alpha l_{\alpha\alpha} + z_\beta l_{\beta\alpha})/z_\alpha c_\alpha, \tag{8}$$

we obtain by dividing Eq. 6 by Eq. 8

$$\frac{|z_\alpha|F^2 D_\alpha}{RT\lambda_\alpha} = 1 - \lambda_{\alpha\beta}\left(\frac{1}{\lambda_\alpha} + \frac{1}{\lambda_\beta}\right) \equiv F(\lambda_{\alpha\beta}), \tag{9}$$

where

$$\lambda_{\alpha\beta} = z_\alpha z_\beta F^2 l_{\alpha\beta}/|z_\beta|c_\beta. \tag{10}$$

On the other hand, the diffusion coefficient of the salt D_s is expressed in terms of $l_{\alpha\beta}$ as

$$D_s^0 \equiv \frac{D_s}{1 + \dfrac{\mathrm{d}\ln\gamma_s}{\mathrm{d}\ln m_s}} = -\frac{z_\alpha z_\beta(\nu_\alpha + \nu_\beta)(l_{\alpha\alpha}l_{\beta\beta} - l_{\alpha\beta}^2)\nu_\alpha RT}{\nu_\alpha\nu_\beta(z_\alpha^2 l_{\alpha\alpha} + 2z_\alpha z_\beta l_{\alpha\beta} + z_\beta^2 l_{\beta\beta})c_\alpha}, \tag{11}$$

where γ_s and m_s are the activity coefficient and molality of the salt, respectively.[1] Comparing Eq. 11 with Eqs. 8 and 9 and rearranging, we get

$$\nu_\alpha|z_\alpha|F^2 D_s^0/(\nu_\alpha + \nu_\beta)RT\lambda t_\alpha t_\beta = F(\lambda_{\alpha\beta}), \tag{12}$$

where λ is the equivalent conductance of the salt. Equations 9 and 12 are reduced to the Nernst-Einstein equation

$$(D_\alpha)_{\text{N.E.}} = RT\lambda_\alpha/|z_\alpha|F^2, \tag{13}$$

and the Nernst-Hartley equation

$$(D_s)_{\text{N.H.}} = \frac{(\nu_\alpha + \nu_\beta)RT\lambda t_\alpha t_\beta}{\nu_\alpha|z_\alpha|F^2}\left(1 + \frac{\mathrm{d}\ln\gamma_s}{\mathrm{d}\ln m_s}\right), \tag{14}$$

respectively, provided $l_{\alpha\beta}=0$. Substituting Eq. 13 into Eq. 9, we get

$$D_\alpha/(D_\alpha)_{\text{N.E.}} = 1 - \lambda_{\alpha\beta}/\lambda t_\alpha t_\beta = F(\lambda_{\alpha\beta}), \tag{15}$$

which relates D_α to $(D_\alpha)_{\text{N.E.}}$. Eliminating $F(\lambda_{\alpha\beta})$ from Eqs. 9 and 12, we have

$$D_s^0/(\nu_\alpha + \nu_\beta)t_\beta = D_\alpha/\nu_\alpha, \tag{16}$$

which serves to estimate D_α from D_s^0 and t_β. Since $F(\lambda_{\alpha\beta})$ is a characteristic parameter for a given system, we have from Eq. 9

$$|z_\alpha|D_\alpha/|z_\beta|D_\beta = \lambda_\alpha/\lambda_\beta = t_\alpha/t_\beta. \tag{17}$$

Further, Eq. 16 leads to the Nernst equation

$$(\nu_\alpha + \nu_\beta)/D_s^0 = \nu_\alpha/D_\alpha + \nu_\beta/D_\beta. \tag{18}$$

It should be noted that Eqs. 16—18 also hold on the basis of nonequilibrium thermodynamics, although these equations can also be derived from the Nernst-Planck equation.

In Tables 1 and 2 are listed the ionic diffusion coefficients calculated by means of Eq. 6 from $l_{\alpha\beta}$ evaluated by Miller,[1] and Paterson *et al.*,[2] the results being compared with $(D_\alpha)_{\text{N.E.}}$ and D_α^* compiled by Anderson and Paterson.[4] D_α is closer to D_α^* than $(D_\alpha)_{\text{N.E.}}$, indicating that the isotope-isotope interaction is much smaller than the cation-anion interaction. It should be also noted that D_α is greater than $(D_\alpha)_{\text{N.E.}}$. According to Eq. 15, this can be accounted for by negative $\lambda_{\alpha\beta}$ or positive $l_{\alpha\beta}$. The positive values of the interionic interaction, $l_{\alpha\beta}$, have been verified with many electrolytes.[1,2] The increase in the values of $D_\alpha/(D_\alpha)_{\text{N.E.}}$ with increase in concentration (Tables 1 and 2) indicates the increase in the cation-anion interaction. This is also reflected in the decrease in λ with increasing concentration. The difference between D_α and D_α^* shows no conspicuous concentration dependence except for Li^+ and Na^+. The D_α values are larger than the D_α^* values for these ions, the order of magnitude being reversed for the other ions. The magnitudes of cationic and anionic diffusion coefficients are in the order $D_{Li}<D_{Na}<D_K<D_{Cs}$ and $D_{Cl}(LiCl)<D_{Cl}(NaCl)<D_{Cl}(KCl)<D_{Cl}(CsCl)>D_{Cl}(RbCl)$, respectively, the same as those in the case of the self-diffusion coefficients.

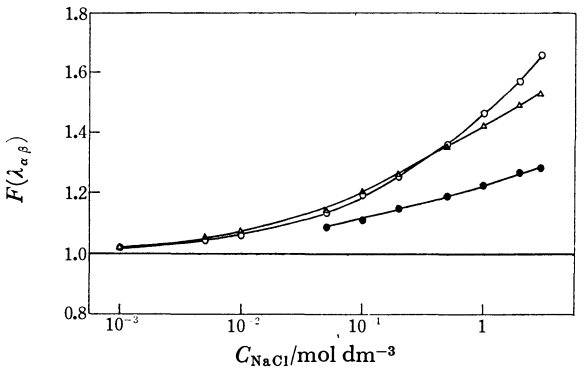

Fig. 1. $F(\lambda_{\alpha\beta})$ calculated from various origins. ○: From D_{Na}^*, ●: from D_{Cl}^*, △: from D_α. $F(\lambda_{\alpha\beta})=1$ corresponds to the calculated value from $(D_\alpha)_{\text{N.E.}}$. D_{Na}^* or D_{Cl}^* in the range 10^{-3}—10^{-1} mol/dm^3 were obtained from Mills' review.[5]

$F(\lambda_{\alpha\beta})$ in Eqs. 9 and 12 is a characteristic parameter for a given system and can be evaluated from $l_{\alpha\beta}$. Equation 9 also indicates that the values of the left hand side evaluated for both cation and anion should be the same. Since the ionic diffusion coefficient can not be measured directly, the self-diffusion coefficients were used for approximate evaluation of the value of the left hand side and the results compared with $F(\lambda_{\alpha\beta})$. An example is shown for aqueous sodium chloride solution in Fig. 1. $F(\lambda_{\alpha\beta})$ is closer to the values estimated from the self-diffusion coefficient than those predicted from the Nernst-Einstein equation or the Nernst-Hartley equation, $F(\lambda_{\alpha\beta})=1$.

Since the values of D_α are closer to those of D_α^* than $(D_\alpha)_{\text{N.E.}}$, the calculation of D_s from D_α^* by using Eq. 18 was also carried out. The difference between $(D_s)_{\text{calcd}}$ and $(D_s)_{\text{obsd}}$ is almost independent of concentration, the deviation being less than 15% for NaCl, KCl, and CsCl except for LiCl. $(D_s)_{\text{calcd}}$ is much closer to $(D_s)_{\text{obsd}}$ than $(D_s)_{\text{N.H.}}$.[6]

Scalar Coupling and Spin-rotation Interactions in the ^{13}C Nuclear Magnetic Relaxation of Methyl-d_3 Bromide

Masaru YANAGISAWA, and Osamu YAMAMOTO*

National Chemical Laboratory for Industry, 1-1-5, Honmachi, Shibuya-ku, Tokyo 151

(Received January 20, 1979)

Synopsis. ^{13}C NMR relaxation times have been obtained for methyl-d_3 bromide at room temperature, from which the spin-spin coupling constant between ^{13}C and ^{79}Br has been extracted and found to be 41.6±2.0 Hz. The contribution of the spin-rotation interaction to the ^{13}C relaxation is large in this molecule. This fact may be attributed to the presence of a methyl rotor, but cannot be satisfactorily interpreted in the framework of the present theories.

The dominant relaxation mechanism of the ^{13}C nucleus in bromomethanes has been found to be scalar coupling interaction owing to the fact that the resonance frequency of ^{13}C is close to that of bromine and that bromine has its relaxation mechanism by quadrupole interaction. We have shown that the relaxation curves for bromomethanes show non-exponential decay due to the presence of two bromine isotopes with a ratio of about 1:1.[1] By analyzing the relaxation curves we have been able to obtain the spin-spin coupling constants between ^{13}C and Br for three deuterated species, CD_2Br_2, $CDBr_3$, and CBr_4. For these species, other mechanisms contribute negligibly to ^{13}C relaxation. In methyl bromide, however, the spin-rotation mechanism may contribute to a large extent, even when the deuterated species are employed, because of the smaller size of the molecule and the presence of a methyl top. In the present paper, the spin-spin coupling constant between ^{13}C and ^{79}Br (J_{79}) for methyl-d_3 bromide has been obtained from ^{13}C relaxation time measurements, considering the contribution of the spin-rotation mechanism.

Experimental

Methyl-d_3 bromide was purchased from MSD, Canada, Ltd., and used without further purification. A high vacuum apparatus was empolyed for sampling. After several freeze-pump-thaw cycles, the sample was sealed into 8 mm dia. tube specially designed for the T_1 measurement. The sample remains in the liquid state in the sealed tube at room temperature. ^{13}C relaxation time measurements was conducted at 25.2 and 15.1 MHz with and without deuterium decoupling respectively, using a Varian XL-100-15 and a NEVA NV-14 spectrometers. Deuterium relaxation times was measured at 15.4 MHz by the XL-100-15. Other experimental details are the same as described in a previous paper.[1]

Results and Discussion

The relaxation curves obtained for ^{13}C in methyl-d_3 bromide at 15 and 25 MHz at room temperature show non-exponential decay, as predicted. The ^{13}C relaxation curve for CD_3Br is given by:[1]

$$\{I(\infty)-I(t)\}/I(\infty) = \exp(-t/T_1^s) + \exp(-t/T_1^l) \quad (1)$$

with $1/T_1^s = 1/T_1^\circ + 1/T_1^{79}$ and $1/T_1^l = 1/T_1^\circ + 1/T_1^{81}$ where T_1^{79} and T_1^{81} are the scalar relaxation (SC) times of ^{13}C bonded to a ^{79}Br and a ^{81}Br respectively, and T_1° is the relaxation time from other sources. The sum of the two exponentials in Eq. 1 may be separated into each exponetial by a nonlinear least squares fit to give T_1^s and T_1^l, the result of which is shown in Table 1.

TABLE 1. RERAXATION TIMES(S) IN CD_3Br OBSERVED AT 29.8 °C

Resonance freq.	T_1^s	T_1^l	T_1 of D
15 MHz	5.85±0.33	34.0±0.4	7.97±0.18
25 MHz	6.64±0.38	36.9±0.9	

The scalar coupling constant between ^{13}C and ^{k}Br (k=79 or 81), A_k ($=2\pi J_k$), may be obtained by solving the following set of equations.

$$1/T_1^k = (2/3)A_k^2 S(S+1)\tau_k/(1+\Delta\omega_k^2\tau_k^2) \quad (2)$$

where τ_k is the relaxation time of ^{k}Br, $\Delta\omega_k = \omega_C - \omega_{kBr}$, the resonance frequency difference, and S is the spin of bromine (3/2). T_1° includes the contributions from the dipole-dipole (DD) interaction between ^{13}C and D (T_{1D}^{CD}), from that between ^{13}C and Br (T_{1D}^{CBr}), from the spin rotation (SR) interaction (T_1^{SR}), and from intermolecular DD interactions (T_1^{inter}). Of these contributions T_{1D}^{CD} may be estimated by measuring the D relaxation time to obtain the correlation time of D using the known value of the deuterium quadrupole coupling constant in this molecule (166 kHz[2]). The contributions of T_{1D}^{CBr} ($\approx 5\times10^3$ s) and T_1^{inter} are so small that they can be neglected in the following calculation. Only the SR mechanism contributes to T_1°, and, in fact, it is a large part of $1/T_1^l$, the long component of the observed decay curve. Thus, an estimation of the SR contribution is essential for obtaining an accurate value of A_k.

T_1^{SR} and τ_k are all independent of variations in the magnetic field. Thus, the four equations such as 2 obtained from the T_1 measurements at two resonance frequencies, 15 and 25 MHz, may overdetermine the variables involved, since the independent variables are only three (A_{79}, τ_{79}, and T_{1C}^{SR}; A_{81} and τ_{81} are related to A_{79} and τ_{79} respectively). The measurements at the two fields have been carried out at 29.8 °C, and J_{79} has been determined so as to obtain agreement in τ_{79} and T_1° between the results at 15 and 25 MHz. The value of J_{79} thus obtained is 41.6 Hz, as shown in Table 2.

The values of J_{79} for methyl bromide and other bromomethanes[1] are plotted against the number of bromine atoms in Fig. 1, in which a similar plot for

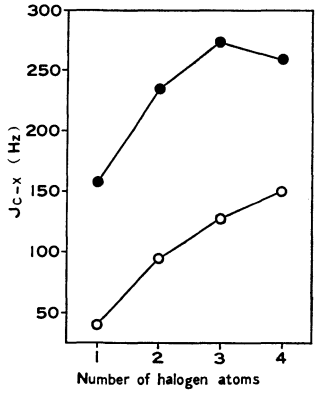

Fig. 1. Coupling Constants between ^{13}C and halogens in bromo- and fluoromethanes. ● Br, and ○ F.

fluoromethanes[3] is included for comparison. A parallelism between the two plots may be seen, *i.e.*, a monotonic increase of J_{CX} with increasing number of halogen atoms is observed. The smaller value for CF_4 than that for CHF_3 has been explained in terms of the double-bond-no-bond resonance effect.[4] In bromomethanes, such an effect seems to contribute little due to the less ionic character of Br.

McClung has developed the extended diffusion theory for molecular reorientation, in which rotational diffusion occurs through larger angle in liquid.[5] Assuming the J- or M-diffusion models, the angular momentum correlation time of the molecular reorientation, τ_θ^{eff}, which in turn, for methyl-d_3 bromide, is obtained independently from the D or Br relaxation time. Thus, the τ_J calculated from the D relaxation time should agree with that obtained from the Br relaxation time at the same temperature. As seen from Table 2, the two values well agree with each other in the J-diffusion model, but do not so in the M-diffusion model. This is consistent with the fact that the J-diffusion model also applies to CD_3CN,[6] which has nearly the same moment of inertia and approximately the same molecular geometry as CD_3Br.

The SR relaxation time in CD_3Br is *ca.* 40 s at room temperature. This value appears to be rather short, but may be compared with the values reported for CH_3CN (*ca.* 33 s at 30 °C[7]) and CH_3I (*ca.* 23.5 s at 25 °C[8]), molecules of similar size and structure, which may be roughly converted to the values for deuterated species by multiplying 1.39,[7] and then 46 and 33 s respectively. According to McClung,[5] the SR relaxation time may be calculated for τ_J and the known values of the SR coupling constants. The latter can be estimated from the relation which connects them to the average shielding value and the chemical shift anisotropy, $\Delta\sigma$.[9] Using the chemical shift data and $\Delta\sigma = -10$ ppm,[10] and taking the coupling constant of methane (−15.94 kHz[11]) as a reference, the SR coupling constant for CD_3Br is found to be $C_\perp = -0.96$ and $C_{//} = -9.86$ kHz.

The T_{1C}^{SR} calculated in this way is, however, too long to explain the experimental data, *i.e.*, 271 s at 29.8 °C, or 8 times the experimental value. This discrepancy between the experimental and estimated values is large, and a similar trend has been observed in other similar compounds. For CH_3I, the value estimated in a similar manner is 25 times the experimental value.[8] Goldammer *et al.*[7] assumed the SR coupling constants for methyl carbon which are much larger than that estimated by the chemical shift data in order to fit the experimental values of T_{1C}^{SR}. The calculations in these previous works are more or less based on the rotational diffusion theory of Hubbard[12] and Huntress,[13] which differs from that of McClung and is somewhat classical. However, the large discrepancy between the observed and the estimated values does not appear to stem from the calssical nature of the theory involved. All of the results including that of the present work suggest that the discrepancy arises from the presence of a methyl rotor, *i.e.*, the presence of a "fast internal rotation," as indicated by Gillen *et al.*[8] McClung's theory, which permits diffusive steps of arbitrary sizes, has been well adopted for reigid molecules such as benzene.[9] For the molecules with a methyl rotor, however, it appears to be still incomplete for the full description of the molecular reorientation. A more improved theory including the fast internal rotation is clearly needed.

Substitution Reactions of (Acetonitrile)chlorobis(triphenylphosphine)rhodium(I) in Benzene

Yoshimi OHTANI, Akihiko YAMAGISHI, and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 11, 1978)

Synopsis. The kinetics of the substitution reactions of $RhCl(NCCH_3)(PPh_3)_2$ in benzene was studied at 20 °C by the stopped-flow method under anaerobic conditions. The following mechanism was proposed:

$$RhCl(C_2H_4)(PPh_3)_2 \xrightarrow{H_2} RhClH_2(C_2H_4)(PPh_3)_2 \xrightarrow{C_2H_4}$$

$$RhClH_2(PPh_3)_2 \xrightarrow{CH_3CN} RhClH_2(NCCH_3)(PPh_3)_2.$$

In a previous paper we reported a kinetic study of a series of substitution reactions of Wilkinson's complex, showing that the substitution reaction, $RhCl(C_2H_4)(PPh_3)_2+H_2+PPh_3 \rightleftharpoons RhClH_2(PPh_3)_3+C_2H_4$, proceeds faster than the dissociation of C_2H_4 from $RhCl(C_2H_4)(PPh_3)_2$ as well as that of H_2 from $RhClH_2(PPh_3)_3$.[1] The results suggest an associative mechanism involving dihydrido-ethylene complex $RhClH_2(C_2H_4)(PPh_3)_2$ as a reaction intermediate, though it cannot be detected spectrophotometrically. In the present study, the substitution reaction of (acetonitrile)chlorobis(triphenylphosphine)rhodium(I) was investigated in comparison with that of chlorotris(triphenylphosphine)rhodium(I). The reaction was carried out in benzene at 20 °C.

Equilibria. The equilibrium constants $K=[RhClH_2(NCCH_3)L_2]/[RhCl(NCCH_3)L_2][H_2]$ and $K'=[RhCl(C_2H_4)L_2][CH_3CN]/[RhCl(NCCH_3)L_2][C_2H_4]$ were estimated from the measurements at $[CH_3CN]=$ 1.0, 1.9, and 3.8 mol dm^{-3} to be 2.5×10^4 mol^{-1} dm^3 and 3.4×10^2, respectively. The equilibrium constant for the substitution $K''=[RhClH_2(NCCH_3)L_2][C_2H_4]/[RhCl(C_2H_4)L_2][H_2][CH_3CN]\equiv K/K'$ was evaluated to be 74 mol^{-1} dm^3. The values of these equilibrium measurements indicate that hydrogen forms the final product $RhClH_2(NCCH_3)L_2$, but C_2H_4 cannot form the final product $RhCl(C_2H_4)(NCCH_3)L_2$. In the case of C_2H_4, substitution of CH_3CN in $RhCl(NCCH_3)L_2$ occurred to form a square planar complex $RhCl(C_2H_4)L_2$. The results may explain the low catalytic activity of Wilkinson's complex in acetonitrile solutions. The acetonitrile molecule competes with the olefin in the coordination to the central rhodium atom, as suggested by Schrock and Osborn.[3]

Kinetics. *Addition Reactions*: The addition of molecular hydrogen to $RhCl(NCCH_3)L_2$ and the substitution of the acetonitrile in $RhCl(NCCH_3)L_2$ complex by ethylene was found to proceed through both associative and dissociative paths based on the kinetic measurements:

$$\begin{array}{ccc} RhCl(NCCH_3)L_2 + S & \xrightarrow{\text{Associative path}} & RhCl(S)(NCCH_3)L_2 \\ \downarrow\uparrow & & \downarrow\uparrow \\ RhClL_2 + CH_3CN & + S \xrightarrow{\text{Dissociative path}} & RhCl(S)L_2 + CH_3CN, \end{array}$$

where S denotes hydrogen or ethylene. Though no accurate values could be obtained, the rate constant of the associative addition of hydrogen to $RhCl(NCCH_3)L_2$, k, was estimated to be *ca.* 1.4×10^2 mol^{-1} dm^3 s^{-1} from the addition rate of hydrogen obtained by extrapolating $[CH_3CN]$ to infinity. The value lies between that for $RhClL_3$ (4.8 mol^{-1} dm^3 s^{-1} at 25 °C) and that for $RhClL_2$ ($>7\times10^4$ mol^{-1} dm^3 s^{-1} at 25 °C).[4] The rate constant of the dissociation of hydrogen from $RhClH_2(NCCH_3)L_2$ is calculated to be 5.6×10^{-3} s^{-1} from k and K. The rate constant of the dissociation of C_2H_4 from $RhCl(C_2H_4)L_2$ was reported to be 0.4 s^{-1}.[1] The results indicate that the dissociation rates of H_2 from $RhClH_2(NCCH_3)L_2$ and C_2H_4 from $RhCl(C_2H_4)L_2$ are much lower than the rate of the substitution, $RhCl(C_2H_4)L_2+H_2+CH_3CN \rightleftharpoons RhClH_2(NCCH_3)L_2+C_2H_4$ (*vide infra*).

Substitution Reactions: Upon mixing a solution of $RhClH_2(NCCH_3)L_2$ with a solution containing C_2H_4, or a solution of $RhCl(C_2H_4)L_2$ with a solution containing H_2 and CH_3CN, the spectrum of the solution rapidly turned to that of an equilibrium mixture of $RhClH_2(NCCH_3)L_2$ and $RhCl(C_2H_4)L_2$. Since no hydrogenation of the coordinated C_2H_4 was observed during the course of measurement,[5] the observed process should be expressed by

$$RhCl(C_2H_4)L_2 + H_2 + CH_3CN \rightleftharpoons RhClH_2(NCCH_3)L_2 + C_2H_4.$$

Figure 1 gives the dependence of k_{obsd} for the above reaction on $[CH_3CN]$. The observed rate constant is larger than the dissociation rate constant of C_2H_4 from $RhCl(C_2H_4)L_2$ and that of H_2 from $RhClH_2(NCCH_3)L_2$, suggesting the existence of an associative intermediate. Increase in k_{obsd} with decreasing $[CH_3CN]$ suggests that, in the substitution reaction, the dihydrido complex $RhClH_2(NCCH_3)L_2$ is activated by the dissociation of CH_3CN molecule, as in the case of the dissociation of a PPh_3 molecule from Rh-

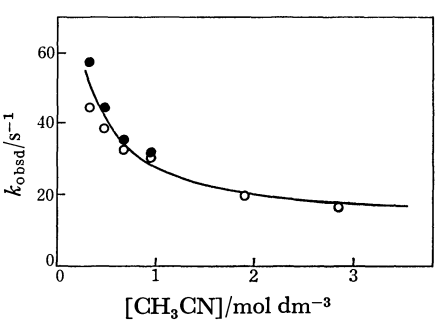

Fig. 1. The dependence of k_{obsd} on $[CH_3CN]$ for the reactions, $RhCl(C_2H_4)L_2+H_2+CH_3CN$ (○) and $RhClH_2(NCCH_3)L_2+C_2H_4$ (●). $[Rh]=1.0\times10^{-4}$, $[H_2]=1.4\times10^{-3}$, and $[C_2H_4]=7.5\times10^{-2}$ mol dm^{-3}. At 500 nm and 20 °C.

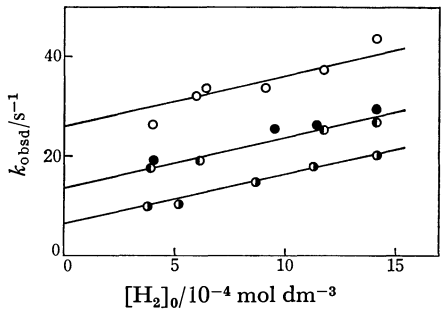

Fig. 2. The dependence of k_{obsd} on $[H_2]$, $[C_2H_4]$, and $[CH_3CN]$ for the reaction $RhCl(C_2H_4)L_2+H_2+CH_3CN$. The plot of k_{obsd} *vs.* $[H_2]$. $[Rh]=1.0\times10^{-4}$ mol dm^{-3}. $[C_2H_4]=7.5\times10^{-2}$ (○,◑,◑) or 3.8×10^{-2} (●) mol dm^{-3}. $[CH_3CN]=0.5$ (○,●), 1.0 (◐), or 1.9 (◑) mol dm^{-3}. At 500 nm and 20 °C.

ClH_2L_3.[1] Figure 2 shows the dependence of k_{obsd} on $[H_2]$, $[C_2H_4]$, and $[CH_3CN]$ for the reaction of $RhCl(C_2H_4)L_2$ with H_2 and CH_3CN. From Fig. 2 the k_{obsd} is expressed as

$$k_{obsd} = k[H_2] + k'\frac{[C_2H_4]}{[CH_3CN]}. \quad (1)$$

The following mechanism is proposed for the substitution reaction:

$$RhCl(C_2H_4)L_2 + H_2 + CH_3CN \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} RhClH_2(C_2H_4)L_2$$
$$+ CH_3CN \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} RhClH_2L_2 + C_2H_4 + CH_3CN \overset{K_3}{\rightleftharpoons}$$
$$RhClH_2(NCCH_3)L_2 + C_2H_4.$$

The steady-state approximation to $RhClH_2(C_2H_4)L_2$ and $RhClH_2L_2$ leads to

$$k_{obsd} = \frac{k_1k_2}{k_{-1}+k_2}[H_2] + \frac{k_{-1}k_{-2}}{(k_{-1}+k_2)K_3}\cdot\frac{[C_2H_4]}{[CH_3CN]}. \quad (2)$$

From Fig. 2, the values of $k_1k_2/(k_{-1}+k_2)$ and $k_{-1}k_{-2}/(k_{-1}+k_2)K_3$ are determined to be 9.6×10^3 mol^{-1} dm^3 s^{-1} and 1.7×10^2 s^{-1}, respectively. The value of $k_1k_2/(k_{-1}+k_2)$ agrees with that obtained previously (7.8×10^3 mol^{-1} dm^3 s^{-1}).[1]

The uni-molecular activation step $RhCl(C_2H_4)L_2\rightarrow Rh^*Cl(C_2H_4)L_2$ as observed in the case of $RhClL_3$,[1] was not observed in the present study. This would be interpreted as suppression of the reaction by acetonitrile. The proposed mechanism also suggests that the effect of acetonitrile on the catalytic activity of Wilkinson's complex is due to the formation of a catalytically inactive species $RhClH_2(NCCH_3)L_2$, the fraction of which is determined by the value of K''.

Experimental

A solution of $RhCl(NCCH_3)(PPh_3)_2$ was prepared by dissolving $RhCl(C_2H_4)(PPh_3)_2$ in oxygen-free benzene containing acetonitrile.[6] The coordinated ethylene was easily replaced by acetonitrile, leaving a pure $RhCl(NCCH_3)(PPh_3)_2$ in the solution.

$RhCl(C_2H_4)(PPh_3)_2$ was prepared from $RhCl(PPh_3)_3$ and ethylene. Benzene and acetonitrile were distilled. Commercial hydrogen and ethylene were used without further purification. Concentration and purity were determined by gas chromatography with a molecular sieve 5A.

All the measurements were carried out at 20±0.2 °C in oxygen-free benzene. The equilibrium of the reaction was measured with a Hitachi EPS-3T spectrophotometer. The kinetic measurements were made using a Union Giken RA-1300 stopped-flow apparatus under anaerobic conditions.

Adduct Formation of the Mixed Copper(II) 2-Thenoyltrifluoroacetonate-3-isopropyltropolonate Chelate with Tributyl Phosphate in Solvent-extraction Systems Containing These Ligands

Tatsuya SEKINE* and Teruyuki TOSAKA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received November 30, 1978)

Synopsis. From the extraction data of copper(II) in a perchlorate solution into carbon tetrachloride containing 2-thenoyltrifluoroacetone (Htta), 3-isopropyltropolone (Hipt), and tributyl phosphate (tbp), the formation of an adduct mixed chelate, Cu(tta)(ipt)(tbp), together with the $Cu(tta)_2$, $Cu(tta)_2(tbp)$, Cu(tta)(ipt), and $Cu(ipt)_2$ species, was concluded, and the formation constant of this adduct mixed chelate was calculated.

Synergism in metal chelate-extraction systems by neutral ligands is, in most cases, attributed to the adduct formation of the extracted chelate with the ligand.[1,2] It is often that the formation constants of adduct chelates of a certain metal ion with a certain given neutral ligand are very different when the chelating extractant is different.[3]

In a previous paper, this difference in the stabilities of adduct metal chelates was demonstrated by the enhancement of copper(II) extraction with 2-thenoyltrifluoroacetone (TTA) and 3-isopropyltropolone (IPT) by adding tributyl phosphate (TBP);[4] the extraction with TTA was very much enhanced by TBP, but that with IPT was not. From these results, it was concluded that the $Cu(tta)_2$ chelate formed a stable adduct, $Cu(tta)_2(tbp)$, while the $Cu(ipt)_2$ chelate formed no TBP adduct. The formation constant of the TTA-TBP adduct chelate was calculated from the enhancement of the TTA extraction, determined as a function of the concentration of TBP.

In another previous paper, the extraction of copper(II) in solvent-extraction systems containing both TTA and IPT was studied, and from the data, the extraction of the mixed chelate, Cu(tta)(ipt), together with the $Cu(tta)_2$ and $Cu(ipt)_2$ chelates, was concluded. The extraction constant of the mixed chelate was calculated from the data obtained at various molar ratios of TTA and IPT.[5]

In the present study, we have measured the distribution ratio of copper(II) in solvent-extraction systems containing TTA, IPT, and TBP; we have concluded that the mixed chelate, Cu(tta)(ipt), formed an adduct with TBP, Cu(tta)(ipt)(tbp).

Experimental

Reagents. All of the reagents were of an analytical grade. The extractants were supplied by the Dojindo Co., Kumamoto (TTA), by the Takasago Perfumery Co., Kanagawa (IPT), and by the Kanto Kagaku Co., Tokyo (TBP).

All of the experiments were made in a manner similar to that previously reported[4,5] except that the amount of copper(II) in the present study was measured by an atomic-absorption method. The temperature was 25±0.3 °C. The hydrogen-ion concentration was in stoichiometric units, as in previous studies.

Statistical

In this paper all the species in the organic phase will be denoted by the subscript "org". As has been described above, no formation of $Cu(ipt)_2(tbp)$ species was found previously. Thus, if higher adducts containing more than one TBP are negligible, the distribution ratio of copper(II) in the presence of TTA, IPT, and TBP may be written as:

$$\begin{aligned} D &= ([Cu(tta)_2]_{org} + [Cu(tta)_2(tbp)]_{org} + [Cu(tta)(ipt)]_{org} \\ &\quad + [Cu(tta)(ipt)(tbp)]_{org} + [Cu(ipt)_2]_{org})[Cu^{2+}]^{-1} \\ &= \{Kex_{2,0}[Htta]_{org}^2(1+\beta_{1(org)}^{tta}[tbp]_{org}) \\ &\quad + Kex_{1,1}[Htta]_{org}[Hipt]_{org}(1+\beta_{1(org)}^{mix}[tbp]_{org}) \\ &\quad + Kex_{0,2}[Hipt]_{org}^2\}[H^+]^{-2} \end{aligned} \quad (1)$$

where:

$$Kex_{2,0} = [Cu(tta)_2]_{org}[H^+]^2[Cu^{2+}]^{-1}[Htta]_{org}^{-2} \quad (2)$$

$$Kex_{1,1} = [Cu(tta)(ipt)]_{org}[H^+]^2[Cu^{2+}]^{-1}[Htta]_{org}^{-1}[Hipt]_{org}^{-1} \quad (3)$$

$$Kex_{0,2} = [Cu(ipt)_2]_{org}[H^+]^2[Cu^{2+}]^{-1}[Hipt]_{org}^{-2} \quad (4)$$

$$\beta_{1(org)}^{tta} = [Cu(tta)_2(tbp)]_{org}[Cu(tta)_2]_{org}^{-1}[tbp]_{org}^{-1} \quad (5)$$

$$\beta_{1(org)}^{mix} = [Cu(tta)(ipt)(tbp)]_{org}[Cu(tta)(ipt)]_{org}^{-1} \times [tbp]_{org}^{-1} \quad (6)$$

Results and Discussion

The organic solvent employed was carbon tetrachloride, and the aqueous phase contained 0.116 mol dm^{-3} of perchloric acid. The equilibrium constants defined by Eqs. 2 to 5 have already been reported in previous papers. They are given in Table 1, and they were employed for the analysis of the experimental data in the present study.

Several runs were made at various sets of concentrations of TTA, IPT, and TBP. It was found from the

results that the distribution ratio could be well explained by assuming the formation of only one adduct mixed chelate other than the four species already found. The formation constant of the adduct mixed chelate was calculated by introducing the extraction data and the values of the four constants into Eq. 1. Table 2 shows the data and the values of $\beta_{1(org)}^{mix}$ thus obtained from each set of data. In this table, the only data employed were those obtained under conditions where more than 25% of the copper(II) species in the organic phase was in the form of the adduct mixed chelate. The average value was log $\beta_{1(org)}^{mix}$ = 1.63, where the standard deviation was 0.08.

Figure 1 shows the percentage distribution of copper(II) species in the organic phase, as calculated by using the constants in Table 1. As may be seen from Fig. 1, the mixed species is always important in the high concentration range of TBP. For example, at $R=2$ and $[tbp]_{org}=0.1$ mol dm^{-3} more than 50% of the copper(II) in the organic phase is in the form of the adduct mixed chelate, Cu(tta)(ipt)(tbp).

The stability of adduct metal chelates in organic

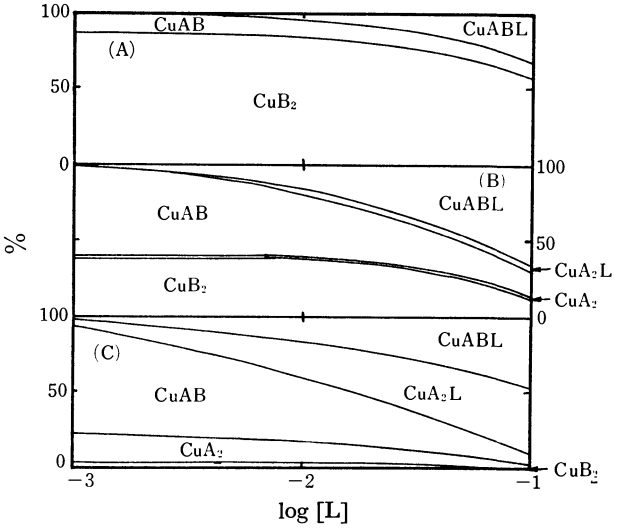

Fig. 1. The calculated percentage distribution of Cu(II) species in the organic phase as a function of the concentration ratio of the chelating extractants ($R=[HA]_{org}/[HB]_{org}$) and of L where HA is Htta, HB is Hipt, and L is tbp.
(A): $R=0.2$, (B): $R=2$, (C): $R=20$.

solvents is affected by several complicated factors, and no clear and systematic interpretation which allows a prediction of the stability of a certain given adduct metal chelate is available. Thus, we can not make any statistical estimation of the stability of the Cu(tta)(ipt)(tbp) adduct, even though we know the formation constants of the $Cu(tta)_2(tbp)$ and $Cu(ipt)_2(tbp)$ (the constant for the latter is zero). The present experimental results indicate that this adduct mixed chelate fairly stable, although it is less stable than the $Cu(tta)_2$(tbp).

No quantitative study of such adduct mixed chelate seems ever to have been made in other solvent extraction systems, but we presume that similar species would be formed in several of them containing various different sets of a metal ion, a chelating ligand, and an adduct-forming ligand.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (7), 2153—2154 (1979)

Kinetics on the Formation and Decomposition of $2Al_2O_3 \cdot B_2O_3$ from Mixed Powders Prepared by the Alkoxy-method

Osamu YAMAGUCHI,* Minoru TADA, Kiyoshi TAKEOKA, and Kiyoshi SHIMIZU*

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received January 11, 1979)

Synopsis. The formation of the alkoxy-derived $2Al_2O_3.B_2O_3$ was observed in the temperature range 820—930 °C. Crystallization isotherms were best described by the contracting cube equation, the activation energy being determined as 368 kJ/mol. The kinetics on the decomposition of $2Al_2O_3.B_2O_3$ was also studied.

Aluminum boron oxide is known to exist in three forms, $9Al_2O_3 \cdot 2B_2O_3$ (orthorhombic), $2Al_2O_3 \cdot B_2O_3$ (orthorhombic), and $Al_2O_3 \cdot B_2O_3$ (hexagonal).[1-7] The former two can be prepared by the solid-liquid reaction from oxide mixtures, such as the system $\alpha \cdot Al_2O_3$–B_2O_3,[2] $\gamma \cdot Al_2O_3$–B_2O_3,[5] and $Al(OH)_3$–H_3BO_3.[3] The last one $Al_2O_3 \cdot B_2O_3$ has been recognized as a mineral, jeremejective. In a previous paper[8] dealing with the formation of $9Al_2O_3 \cdot 2B_2O_3$ from the mixed powders prepared by the simultaneous hydrolysis of aluminum and boron alkoxides, it was shown that the reaction process is similar to that of mullite($3Al_2O_3 \cdot 2SiO_2$) formed by heating a clay mineral, kaolinite($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$). Several investigators[2,5,6] reported that $2Al_2O_3 \cdot B_2O_3$ melts incongruently at 1030—1050 °C to $9Al_2O_3 \cdot 2B_2O_3$ and liquid. No kinetic study, however, has been carried out. The present study is concerned with the kinetics of the formation and decomposition of the alkoxy-derived $2Al_2O_3 \cdot B_2O_3$.

Experimental

Boron triethoxide of guaranteed purity was used. Aluminum tris(isopentyl oxide) was synthesized by heating aluminum metal in an excess isopentyl alcohol with a small amount of mercury(II) chloride as a catalyst at 130 °C for 7 h.[9] Aluminum metal of purity 99.9% was used. A mixture of these alkoxides in the mole ratio $Al^{3+}/B^{3+}=2:1$ was prepared, and then poured into aqueous ammonia solution at 30 °C. The resulting mixed powders were washed with hot water and dried at 60 °C under reduced pressure. The average particle size of the mixed powders is *ca.* 550 Å. The X-ray diffraction(Cu $K\alpha$) pattern(Fig. 2(a)) is similar to that of the mixture whose Al^{3+}/B^{3+} mole ratio is 9:2. In view of the previous study,[8] the mixed powders are considered to be B^{3+}-substituted boemite(AlO(OH)) gel.

Results and Discussion

The TG of the mixed powders was carried out in the air from room temperature to 1000 °C(Fig. 1). The weight loss of 20.1% up to 710 °C is attributed to the loss of ammonia, absorbed water, hydrated water constitution water, and organic residue from the parent alcohol. DTA was also studied. Exothermic and endothermic reactions were observed at 820—930 °C and 1030—1250 °C, respectively. From the results of X-ray diffraction, the reactions were found to be

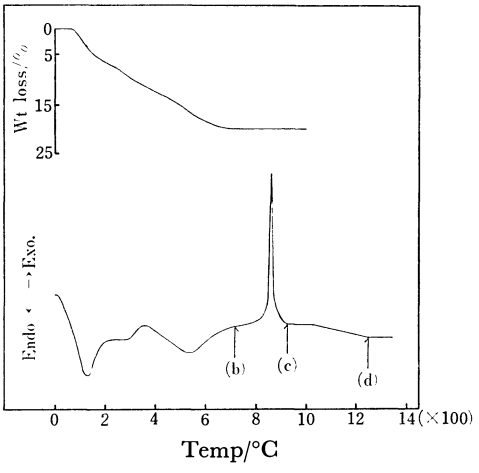

Fig. 1. TG and DTA curves of mixed powders as a raw material. Sample weight: 20 mg, heating rate: 10 °C/min.

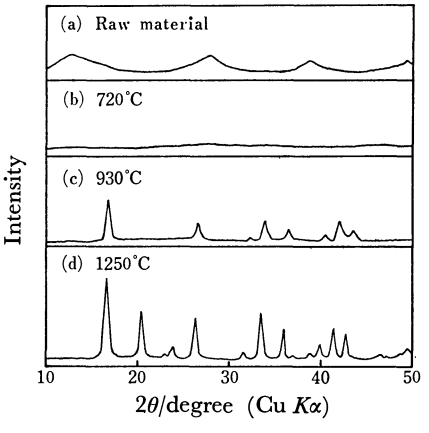

Fig. 2. X-Ray diffraction patterns of specimens with increasing temperature.
Heating rate: 10 °C/min.
(a) B^{3+}-substituted AlO(OH) gel, (b) amorphous material, (c) $2Al_2O_3 \cdot B_2O_3$, (d) $9Al_2O_3 \cdot 2B_2O_3$.

the crystallization of $2Al_2O_3 \cdot B_2O_3$ from an amorphous phase and the decomposition of $2Al_2O_3 \cdot B_2O_3$ into $9Al_2O_3 \cdot 2B_2O_3$ and liquid, respectively.

Figure 2 shows the variation of X-ray diffraction patterns of specimens with increasing temperature. The specimen heated at 720 °C after the completion of weight loss was amorphous, no significant changes being observed at 800 °C. The peaks corresponding to $2Al_2O_3 \cdot B_2O_3$ appeared at 820 °C for 25 min, the intensity increasing with increasing temperature and time. No other peaks were identified except for the $2Al_2O_3 \cdot B_2O_3$ spectrum up to 1000 °C. The peaks of $9Al_2O_3 \cdot 2B_2O_3$, as the decomposition product of

$2Al_2O_3 \cdot B_2O_3$, began to appear at 1030 °C. The specimen heated at 1250 °C showed the X-ray diffraction pattern of only $9Al_2O_3 \cdot 2B_2O_3$.

Figure 3 shows the fraction of the $2Al_2O_3 \cdot B_2O_3$ crystallization at 820, 840, and 870 °C. The mixed powders were pre-heated at 720 °C for 15 min. The average particle size of the specimen was 0.12 μm. The fraction of crystallization of each specimen was determined from the height of d=5.29 Å(2θ=16.7°) which is the strongest line of the $2Al_2O_3 \cdot B_2O_3$ spectrum. A well-crystallized specimen was obtained by heating the mixed powders at 950 °C for 30 min. Calcium fluoride was used as a standard material. Induction periods were observed, attempts being made to fit the results to kinetic laws by considering the induction periods. As shown in Fig. 4, crystallization isotherms are best described by the contracting cube equation $1-(1-\alpha)^{1/3}=k(t-t_0)$,[10] where α is the fraction of crystallization, t time and t_0 induction period. This indicates that the rate of crystallization is controlled by the rate of advance of the reaction interface. The rate constants were determined from the slopes of straight lines. The value of the activation energy calculated from the Arrhenius plot was 368 kJ/mol.

Figure 5 shows the fraction of decomposition of $2Al_2O_3 \cdot B_2O_3$ into $9Al_2O_3 \cdot 2B_2O_3$ and liquid as a function of time at different temperatures. The specimen heated at 950 °C for 30 min was used as a starting material. The fraction of decomposition of each specimen was determined by comparing the height of the d= 4.35 Å (2θ=20.4°) line with that of the same line of

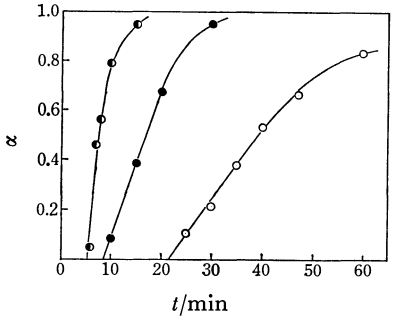

Fig. 3. Formation of $2Al_2O_3 \cdot B_2O_3$ as a function of time at different temperatures. ○: 820 °C, ●: 840 °C, ◐: 870 °C.

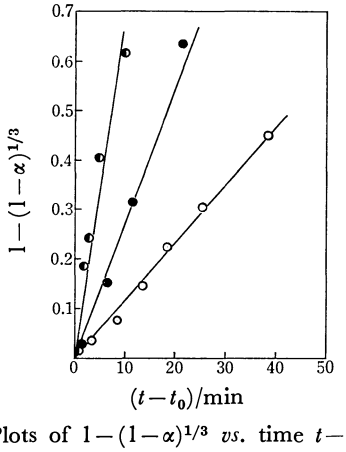

Fig. 4. Plots of $1-(1-\alpha)^{1/3}$ *vs.* time $t-t_0$ of the data shown in Fig. 3. ○: 820 °C, ●: 840 °C, ◐: 870 °C.

a fully decomposed specimen, $9Al_2O_3 \cdot 2B_2O_3$. The data can be interpreted in terms of the second-order equation, as a special case of the treatment by Avrami[11] and Czanderna *et al.*[12] Figure 6 shows the plots of $f/1-f$ against t, where f is the fraction decomposed in time t. The activation energy was 301 kJ/mol, representing that employed for establishing active growth centers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (7), 2155—2156 (1979)

Determination of Alkyl Thioureas, Isothiocyanates and Amines with Iodine Monochloride

Krishna K. VERMA

Department of Chemistry, University of Jabalpur, Jabalpur 482001, India

(Received August 26, 1978)

Iodine monochloride oxidizes thioureas to respective urea and sulfate in hydrogencarbonate medium. The iodine formed in the reaction is titrated with iodine trichloride to an Andrews end-point. This method has been applied to determine isothiocyanates and amines by their conversion to thioureas.

Most of the available procedures for determining thioureas by its oxidation to urea and sulfate require long standing periods in the range 5—60 min.[1-4]

A rapid and precise titrimetric method is described which requires a reaction period of about 30 s. Thioureas are reacted with iodine monochloride in hydrogencarbonate medium and the iodine formed is titrated with iodine trichloride to an Andrews end-point. This method does not require any blank determination and is unaffected by the presence of a number of concomitant substances.

This method of determining thioureas has been applied to analyze alkyl isothiocyanates involving conversion to substituted thiourea by reaction with 1-butylamine followed by oxidation with iodine monochloride. The present method has the advantage that basic or acidic impurities do not affect the results and that acid anhydrides and aldehydes, which interfere in acidimetric determination of isothiocyanates[5] by consuming amine *via* acylation and Schiff base formation respectively, can be tolerated. If the present method is coupled with acidimetry, the analysis of mixtures of isothiocyanates with isocyanates is possible since substituted ureas, formed by isocyanates, do not react with iodine monochloride.

The remarkable inertness of isothiocyanates towards several oxidizing agents, including iodine monochloride,[6] has added one more application. Primary and secondary amines react with an excess of 1-butylisothiocyanate and the substituted thiourea formed is again determined. Tertiary amines do not interfere.

Experimental

Reagents. Iodine monochloride[7] and iodine trichloride[8] solution, 0.1 mol dm^{-3} and 0.02 mol dm^{-3} respectively, were prepared in dilute hydrochloric acid and standardized iodometrically.[7]

Solutions of 1-butylamine, *ca.* 0.1 mol dm^{-3} and 1-butylisothiocyanate, *ca.* 0.1 mol dm^{-3} in dimethylformamide were used.

Test Compounds. All thioureas and amines were commercially available samples. Alkyl isothiocyanates were prepared and purified by the author.[9]

As a check independent methods were used to determine the purity of thioureas (Table 1). Solutions of amines and isothiocyanates, were prepared in dimethylformamide and the former were standardized by acidimetry[10] and the latter by the method of Vinson.[11]

Procedures. *Procedure for Thioureas*: Weigh or take an aqueous aliquot of sample containing 0.01—0.1 mmol of thiourea and dissolve or mix with 30 cm^3 of water, 2 g of sodium hydrogencarbonate and 10 cm^3 of carbon tetrachloride in a 250-cm^3 iodine flask. Introduce with swirling, 5—15 cm^3 of 0.1 mol dm^{-3} iodine monochloride, the excess being indicated by the appearance of iodine in organic layer. After swirling for 30 s, add cautiously 40 cm^3 of 6 mol dm^{-3} hydrochloric acid. When the evolution of carbon dioxide ceases, stopper the flask and shake vigorously. Titrate the liberated iodine by running in 0.02 mol dm^{-3} iodine trichloride until the solution becomes pale brown. Stopper the flask and shake well. Continue the addition of iodine trichloride in small portions, shaking vigorously after each addition, until the organic layer loses the last trace of violet color of iodine and becomes essentially colorless.

For a convenient and sharp end-point detection, invert the well-shaken-stoppered-flask and note the change from violet to colorless through the column of carbon tetrachloride at the neck of the flask.

Procedure for Isothiocyanates: Take a sample solution (5—10 cm^3) in dimethylformamide containing 0.01—0.1 mmol of isothiocyanate in a 250-cm^3 iodine flask and treat with 5 cm^3

TABLE 1. DETERMINATION OF THIOUREAS WITH IODINE MONOCHLORIDE

Thiourea, substituent	Purity, %				
	Present method	No. of detns.	Std. devn.	Comparison method	
—	99.9	8	0.08	99.8	Hypoiodite[4]
Methyl	99.7	10	0.10	99.9	Hexacyanoferrate (III)[12]
Allyl	99.5	6	0.10	99.2	Ce(IV) titration[13]
N,N'-Dimethyl	98.8	7	0.13	98.5	Bromine chloride[14]
Ethyl	98.5	6	0.09	98.7	Iodine[1]
N,N'-Diethyl	99.1	8	0.15	99.0	Iodine trichloride[15]
2-Propyl	99.0	6	0.12	99.3	Bromine[1]
1-Butyl	98.7	8	0.16	98.6	Bromine chloride[14]
2-Methyl-1-propyl	98.1	10	0.11	98.4	Ce(IV) titration[13]

of 0.1 mol dm^{-3} 1-butylamine. Swirl the solution and let stand for 10 min. Thereafter, add 30 cm^3 of water and determine the thiourea as before.

Procedure for Primary and Secondary Amines. Treat 5—10 cm^3 of sample solution in dimethylformamide containing 0.01—0.1 mmol of amine, with 5 cm^3 of 0.1 mol dm^{-3} 1-butylisothiocyanate in a 250-cm^3 iodine flask and age for 10 min. Dilute the contents with 30 cm^3 of water and determine the thiourea formed.

Results and Discussion

The iodine monochloride reacts with thiourea and its alkyl derivatives as follows:

$$RNHCSNHR + 8ICl + 5H_2O \longrightarrow RNHCONHR + 4I_2 + H_2SO_4 + 8HCl.$$

The reaction is slow in acid medium (20—30 min) but almost instantaneous and quantitative in the presence of hydrogencarbonate (Table 1). The concentration of hydrogencarbonate is not critical but it should be enough to neutralize the acid added with the reagent solution and that produced in the reaction. Iodine reacts with iodine trichloride as follows:

$$I_2 + ICl_3 \longrightarrow 3ICl.$$

The analysis of thiourea is utilized as a basis for the determination of isothiocyanate or amine if one of them is made to react with an excess of the other (Table 2):

Table 2. Determination of isothiocyanates and amines

Substance	Range determined (mg)	No. of detns.	Average % recovery	Standard deviation
Isothiocyanate				
Ethyl	0.89— 8.65	8	100.2	0.3
Propyl	1.08—10.10	6	99.8	0.2
1-Butyl	1.30—11.00	8	99.9	0.1
2-Propyl	1.45—10.28	7	98.9	0.3
2-Methyl-1-propyl	1.25— 9.65	9	99.3	0.2

Ethyl	0.45— 4.20	6	100.1	0.1
2-Propyl	0.62— 5.46	8	99.6	0.2
1-Butyl	0.87— 6.29	10	99.8	0.1
Diethyl	0.83— 6.07	6	99.7	0.3
Piperidine	0.89— 8.46	8	99.6	0.3

$$RNCS + RNH_2 \longrightarrow RNHCSNHR.$$

Mixtures of tertiary amines with primary or secondary amines can be analyzed if the total amine is known by acidimetry.[10] Then, tertiary amine can be obtained by subtracting the amine found by iodine monochloride method. Mixtures of isothiocyanates with isocyanates can be analyzed if a total of them is determined by the method of Vinson,[11] the isothiocyanate being known by the present method.

Iodine monochloride does not react with the following substances under the conditions of determination: citric acid, oxalic acid, glucose, glycine, alanine, arabinose, serine, diphenyldisulfide, carbon disulfide, formaldehyde, and benzaldehyde. Unsaturated compounds like allyl alcohol, cinnamic, and fumaric acids, that form addition compound with iodine monochloride, also do not interfere since the final titration involves determination of the liberated iodine.

Iodide, sulfide, sulfocyanide and thiosulfate interfere severely. Arylthioureas only reacted incompletely, therefore, the present method is not recommended for them.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (7), 2157—2158 (1979)

The Reaction of 2,4,6-Heptanetrione with *o*-Phenylenediamine†

Akiko FURUHASHI,* Koji AOKI, and Morihito SUGIMOTO**

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

***Department of Pollution Control, Nippon Electronics Engineering College, Nishikamata, Ota-ku, Tokyo 144*

(Received October 14, 1978)

Synopsis. 2,4,6-Heptanetrione forms 2-acetyl-4-methyl-1,5-benzodiazepine with *o*-phenylenediamine in alkaline ethanol. In acidic ethanol, it would be expected that the 2-acetyl-4-methyl-1,5-benzodiazepinium cation would be formed. Contrary to expectations, however, the cation seems to be unstable. 2,4-Dimethyl-1,5-benzodiazepinium salt was obtained instead.

2,4,6-Heptanetrione(diacetylacetone: daa) forms metal complexes through its oxygen atoms[1-2] and forms Schiff bases with ethylenediamine[3] in analogy with 2,4-pentanedione(acetylacetone), whereas it does not form dithio- or trithiodiacetylacetonato metal complexes.[4] The reaction of daa with *o*-phenylenediamine(opd) was studied.

By adding a potassium hydroxide ethanol solution to a mixture of daa and opd in ethanol, red crystals of 2-acetyl-4-methyl-1,5-benzodiazepine were obtained. On the other hand, in an ethanol solution containing hydrochloric acid, its azepinium cation seems to be destroyed and to become 2,4-dimethyl-1,5-benzodiazepinium.

Experimental

Instruments. The infrared spectra were obtained by the KBr disk or Nujol mull procedure, using a IRA-1-type infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. The electronic spectra were obtained with a Shimadzu Double-beam Spectrophotometer UV-200 in 64% w/w aqueous methanol, with the ionic strength of 0.3. The NMR spectra of the $CDCl_3$ solution were obtained with a Hitachi Perkin-Elmer Model-R-20 NMR Spectrometer. Tetramethylsilane(TMS) was used as the standard. The mass spectra were obtained with a Hitachi Model-RMU-6M-GC Mass Spectrometer.

The Syntheses of the Compounds. Diacetylacetone[1] was synthesized from dehydroacetic acid by the method of Bethell and Maitland.[5] 2-Acetyl-4-methyl-1,5-benzodiazepine was synthesized from daa and opd according to the method of Thile and Steimmig[6] as follows. Daa (0.71 g, 5×10^{-3} mol) in 20 ml of an ethanol solution was added to opd(0.54 g, 5×10^{-3} mol) in 2 ml of hot ethanol containing 1 ml of acetic acid, and then potassium hydroxide in ethanol was added to the mixture. The red crystals thus formed were filtered off and recrystallized from ethanol. (Found: C, 72.88; H, 6.60; N, 13.04%. Calcd for $C_{13}H_{14}N_2O$: C, 72.90; H, 6.54; N, 13.80%). Molecular weight, 214 (from the mass spectra). The compound forms orange crystals with cadmium chloride in ethanol.

On the other hand, when gaseous hydrochloric acid was added to the mixture (daa+opd+CH_3COOH) mentioned above, the solution turned violet. By adding petroleum ether, violet-colored crystals were obtained. The results of the elemental analyses agree with those of 2,4-dimethylbenzodiazepinium chloride.[7] (Found: C, 53.56; H, 6.98; N, 11.21%. Calcd for $C_{11}H_{13}N_2\cdot2H_2O$: C, 53.99; H, 7.00; N, 11.45%).

Results and Discussion

The proton NMR spectra of the red compound are shown in Table 1. The spectra fit the structure shown in Fig. 1, 2-acetyl-4-methyl-1,5-benzodiazepine.

TABLE 1. NMR SPECTRAL DATA

δ/ppm	Integrated for	Assignment
11.75	1H	hydrogen bond
6.75	4H	phenyl
4.90	1H	methine
3.39	2H	methylene
1.98	3H	methyl
1.81	3H	methyl

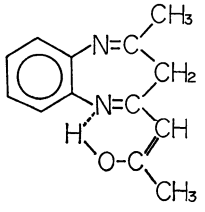

Fig. 1. 2-Acetyl-4-methyl-1,5-benzodiazepine.

The IR spectra also support the above assignment. The free C=O band which is usually expected about 1700 cm^{-1} was not observed, while three bands were observed in the 1515—1660 cm^{-1} region. These bands are likely to consist of (C=N), (C=C), and hydrogenbonded (C–O), or a mixture of them.[8]

On the other hand, the spectra of the violet compound obtained from the acidic solution are completely identical with those of the 2,4-dimethylbenzodiazepinium chloride, which does not show a peak at 1660 cm^{-1}.

The electronic spectra of the red azepine solution do not show any peak in the 350—600 nm range, whereas the addition of hydrogen chloride produced the band at 510 nm. This wavelength agrees well with that reported for the diazepinium cation.[9] (Fig. 2). The peak increased with the acid concentration, with an isosbestic point at 410 nm. It is, therefore, likely that the 2-acetyl-4-methyl-1,5-benzodiazepinium cations present in the solution. The 2,4-dimethyl-1,5-benzodiazepinium salt, however, was obtained

† A part of this work was presented at the 36th National Meeting of the Chemical Society of Japan, Osaka April 1977.

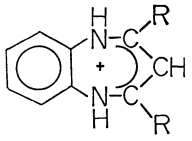

Fig. 2. Diazepinium cation.

by condensation or by adding petroleum ether. The acetyl group must interact with H^+ and be severed in an acidic solution, although the acetyl group was not determined to do so. The acetyl group seems to be relatively easily hydrolyzed because of the stabilization of the seven-membered azepinium ring, which has a resonance system.

We are pleased to acknowledge the considerable assistance of Professor Kan Kimura of Aoyama Gakuin University. The authors also wish to thank Professor Oyo Mitsunobu of Aoyama Gakuin University for his helpful advice.

The Condensation Products of Naphthanthrone

Shoji FUJISAWA,* Junji AOKI, Minoru TAKEKAWA, and Satoshi IWASHIMA†

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

†*Department of Chemistry, Faculty of Science and Technology, Meisei University, Hino, Tokyo 191*

(Received October 28, 1978)

Synopsis Three hydrocarbons, with absorption maximum at 510 nm, 533 nm, and 567 nm respectively, have been synthesized by the condensation of naphthanthrone in a mixed flux of zinc chloride and sodium chloride with copper powder. The structures of the hydrocarbons have been determined by comparison with the products obtained by the alkali fusion and reduction of naphthanthrone and 2-bromonaphthanthrone.

On heating naphthanthrone (6*H*-benzo[*cd*]pyren-6-one) (**1**) with copper powder in a mixed flux of zinc chloride and sodium chloride, three hydrocarbons with eleven benzene rings (**2**, **3**, **4**) have been obtained. These hydrocarbons, with overcrowed hydrogen atoms, are not only stereochemically interesting, but are also very important in the field of organic semiconductors because of their high photoconductivity.[1]

Clar *et al.* reported[2] that the fusion of **1** with zinc dust gave two hydrocarbons which had absorption maximum at 510 nm and 533 nm in benzene, respectively. The former was confirmed by X-ray analysis[3] to be diphenanthro[5,4,3-*abcd*:5′,4′,3′-*jklm*]perylene (DPP) (**2**) and the latter was tentatively assigned as dibenzoviolanthrene B (**3**) by Clar *et al.* A further hydrocarbon, with an absorption maximum at 567 nm, has been found in this laboratory and an attempt to structurally analyze this new hydrocarbon and the hydrocarbon with an absorption maximum at 533 nm has been conducted.

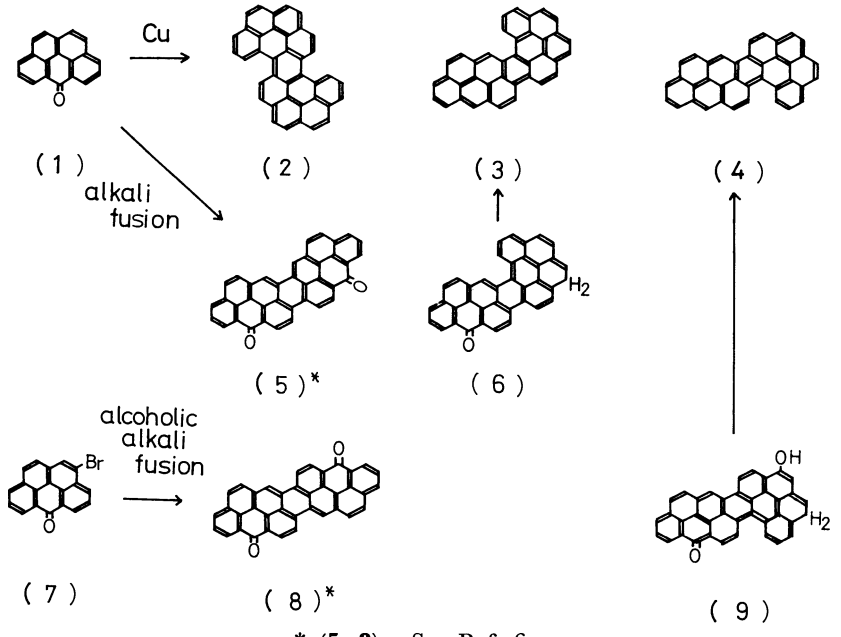
The convenient analytical methods of NMR and IR are of little use in the case of large condensed aromatic hydrocarbons because of the existence of many similar C–H bonds. Indeed the spectra are usually very complicated and consequently cannot be used as a basis for structural analysis.

X-Ray analysis is a further tool, but considerable difficulty has been met in the growing of single crystals of sufficient size. Furthermore X-ray analysis may not be easy even with good crystals.

In this paper the structures of these two hydrocarbons, deduced from the separate synthesis of each will be presented.

On the basis of the reaction used for the synthesis of violanthrones from benzanthrone,[4] the alkali fusion of **1** is expected to give dibenzoviolanthrones (**5**, **6**). Dibenzoviolanthrone B (**6**) was reduced to the corresponding hydrocarbon, dibenzoviolanthrene B (**3**), with zinc powder, melting at 378—379 °C and with an absorption maximum at 567 nm in benzene. Thus it has been concluded that dibenzoviolanthrene B (**3**) has an absorption maximum at 567 nm and not at 533 nm as suggested by Clar *et al.*[2]

On the basis of the reaction of 3-bromobenzanthrone,[4,5] the dibenzoisoviolanthrones (**8**, **9**) were prepared from 2-bromonaphthanthrone (**7**). Dibenzoisoviolanthrone B (**9**) was reduced to the corresponding hydrocarbon, dibenzoisoviolanthrene B (**4**), with zinc powder giving a hydrocarbon with an absorption max-



* (**5**, **8**). See Ref. 6.

Scheme.

imum at 533 nm in benzene. The absorption spectrum of this hydrocarbon was identical with that of one of the hydrocarbons obtained, and so it has been concluded that the hydrocarbon, with an absorption maximum at 533 nm, obtained both by authors and Clar *et al.* is dibenzoisoviolanthrene B (**4**), and not dibenzoviolanthrene B (**3**) as suggested by Clar *et al.*

Experimental

All melting points are uncorrected.

*Condensation of **1** with Copper Powder.* A mixture of **1** (2.0 g), copper powder (3.4 g), zinc chloride (17.0 g and sodium cholride (3.4 g) was kept at 270—280 °C for 1 h. The crude product was refluxed with benzene (100 ml) for 2 h and the insoluble residue, consisting mainly of copper powder, was removed by hot filtration. The filtrate on evaporation to dryness gave a dark brown solid (1.9 g). A benzene solution of this product was passed through a column of alumina and eluted with benzene. The absorbed layer was developed into three bands. The pale yellow band was separated and concentrated, giving red brown needles. Yield 0.5 g, mp 336—337 °C, $\lambda_{max}^{benzene}$ 510 nm. The intense yellow band was the recovered naphthanthrone. The pink band, overlapping with a small amount of the brown band, was eluted with benzene, and concentrated to give a pale brown solid (mp 379—380 °C). A benzene solution of this product had an absorption maximum at 533 nm and also a small shoulder at 567 nm. The melting point and absorption spectrum were very similar to that reported by Clar *et al.* The product was dissolved in a large amount of ethanol and the solution was put into a column of alumina. The absorbed layer was developed into two bands; the lower layer, a pale brown band, was separated, concentrated and gave pale brown needles. Yield 0.25 g; mp 362 °C; $\lambda_{max}^{benzene}$ 533 nm. The upper layer, an intense pink band, gave violet needles. Yield 0.17 g; mp 378—379 °C; $\lambda_{max}^{benzene}$ 567 nm.

*Synthesis of **6**.* To a mixture of potassium hydroxide (10.0 g) and phenol (1.0 g) heated at 260—270 °C, naphthanthrone (1.5 g) was added. The reaction mixture was maintained at the same temperature for 1 h, and then cooled and treated with water (500 ml). The insoluble residue was collected, suspended in water (300 ml) containing sodium hydroxide (10.0 g) and heated to 60 °C. In order to remove the dibenzoviolanthrone A (**5**), ethanol (100 ml) and sodium dithionite (10.0 g) were added. Compound **5** dissolved in the sodium dithionite forming a reddish purple solution, but **6** did not, thus enabling **6** to be separated from **5**. Subsequent hot filtration separated the insoluble material (0.8 g). This product was refluxed with glacial acetic acid (100 ml) for 2 h and the insoluble material was collected by hot filtration. Yield 0.7 g. This compound corresponds to **6**.

*Reduction of **6**.* A fine powder of **6** (0.7 g) was heated with zinc dust in a mixed flux of zinc chloride (5.0 g) at 270—280 °C for 1 h. In order to remove the excess zinc dust, concentrated hydrochloric acid (25 ml) was added to the solid suspended in water (100 ml), and the insoluble material was collected. Yield 0.6 g. The crude product was refluxed with trichlorobenzene (100 ml) for 2 h and the filtrate was evaporated to dryness, giving a dark violet solid (0.5 g). A toluene solution of this substance was passed through a column of alumina, and the eluent was evaporated to give deep violet needles. Yield 0.4 g; mp 378—379 °C; $\lambda_{max}^{benzene}$ 567 nm. Found: C, 95.65; H, 4.18%. Calcd for $C_{38}H_{18}$; C, 96.17; H, 3.83%.

*Synthesis of Dibenzoisoviolanthrone B (**9**).* A mixture of potassium hydroxide (10.0 g), phenol (2.0 g) and isopropyl alcohol (7.0 g) was heated at 170—180 °C. 2-Bromonaphthanthrone (**7**) (1.0 g) was added and the mixture was stirred for 4 h at the same temperature. The reaction mixture turned green immediately, then dark olive green, and finally blue green. The mixture was poured into water (100 ml) and oxidized by air. The precipitate was collected and suspended in water (200 ml) containing sodium hydroxide (10.0 g), ethanol (100 ml) and sodium dithionite (10.0 g), and maintained at 55—60 °C for 15 min. Compound **9** was collected by the same procedure used for the separation of **6** from **5** using sodium dithionite. After hot filtration, the insoluble material was collected. Yield 0.6 g. The product was boiled in glacial acetic acid (50 ml), cooled and the insoluble material was filtered. Yield 0.55 g. This product is assumed to be **9**.

*Reduction of **9**.* A fine powder of **9** (0.5 g) was treated with zinc dust (0.5 g) in a mixed flux of zinc chloride and sodium chloride at 270—280 °C for 1 h. The precipitate was filtered and dried. In order to remove the zinc dust, the precipitate was refluxed with toluene (100 ml) for 2 h and, after hot filtration, the filtrate was evaporated to dryness, giving a dark brown solid (0.4 g). Further purification was conducted by column chromatography of alumina with toluene.

The eluent was evaporated to dryness and gave pale brown needles. Yield 0.1 g; mp 362 °C; $\lambda_{max}^{benzene}$ 533 nm. Found: C, 95.85; H, 4.18%. Calcd for $C_{38}H_{18}$. C, 96.17; H, 3.83%.

(Received November 24, 1978)

Synopsis. The structure of the second main product, 4-acetoxy-1,7,8-trimethyltricyclo[5.4.0.0^{4,8}]undec-9-ene, in the rearrangement reaction of dihydromayurone with boron trifluoride in acetic acid–acetic anhydride at 50 °C, and reaction mechanism is presented and discussed.

In a preceding communication,[1] the formation of four kinds of corresponding acetates in the rearrangement reaction of dihydromayurone with boron trifluoride in acetic acid–acetic anhydride, has been described and related to the reaction temperature. The reaction at 50 °C afforded 7-acetoxy-2,2,3-trimethyltricyclo[5.2.2.0^{1,6}]undec-3-ene (**1**) in 45% yield. Chromatographic analysis of the reaction mixture over silica gel using benzene as the eluant gave compound **1**[1] as a fast eluent in 45% yield, and an oily product (**2**) as slow eluent in 30% yield. The IR spectrum bands at 3060 and 1690 cm^{-1} disappeared indicating the presence of a cyclopropyl and carbonyl group, and the band at 1738 cm^{-1} indicated the presence of an ester group. The PMR spectrum contained signals at δ 1.95, 5.21, and 5.81 ppm, indicating the presence of one acetyl group and two vinyl protones. And the mass spectrum showed a molecular ion peak at *m/e* 248 (M^+), and fragment of this at *m/e* 206 (M—42). Thus, the structture of **2** has been assumed to be a isomeric acetate in which the cyclopropane ring was cleaved.

Hydrolysis of **2** with ethanolic potassium hydroxide gave the alcohol (**3**), the IR spectrum of which exibited a strong band at 3355 cm^{-1}, indicating the presence of a hydroxyl group. The PMR spectrum of one vinyl proton shows a doublet of doublets of doublets (J= 10.8, 2.5, and 2.5 Hz) at 5.18, and the other vinyl proton shows a doublet of doublets of doublets (J= 10.8, 5.0, and 3.5 Hz) at 5.78 ppm. Analysis was conducted by the decoupling technique. The C^{13}-NMR spectrum exibited the presence of C–O (δ 80.6 ppm (s)), and –CH=CH– (δ 127.8 (d) and 130.0 ppm (d)) linkages (Fig. 1).

Thus, the structure of **3** has been assigned to be a tertiary alcohol including the partial structure (**a**)

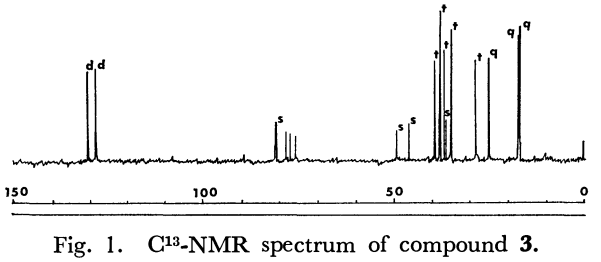

Fig. 1. C^{13}-NMR spectrum of compound **3**.

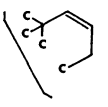
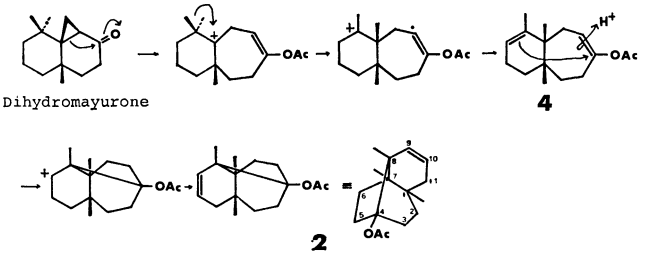


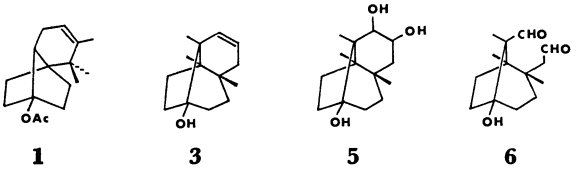
a

and tricyclic compound. This partial structure was unambiguously substantiated by the following chemical evidences. Oxidation of **3** with osmium tetraoxide in ether afforded a diol (**5**) and subsequent oxidation of **5** with lead tetraacetate gave a dialdehyde (**6**). The PMR spectrum showed signals at δ 9.73 (t, 1, J=3.0 Hz) and 9.75 ppm (s, 1), indicating the presence of two formyl groups.

An attempt was made to obtain the acetate (**2**) from the acetate (**4**)[1] under the above reaction conditions and the results indicate that **4** may be the precursor of **2**. The structure of **2** has been assumed to be 4-acetoxy-1,7,8-trimethyltricyclo[5.4.0.0^{4,8}] undec-9-ene on the basis of the above spectral data, the chemical evidence, and the reaction mechanism (Scheme 1).



Scheme 1.



1 **3** **5** **6**

Experimental

The melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. The PMR spectra were recorded at 60 MHz and 100 MHz on a JEOL PMX-60 and a JEOL PS-100 spectrometer respectively, using Me_4Si as an internal standard. The C^{13}-NMR spectra were recorded on a JEOL FX-100 spectrometer, using Me_4Si as an internal standard. The IR spectra were determined on a Shimadzu IR-400 spectrometer. The elemental analyses were performed on a Hitachi 026 CHN analyzer.

Isomerization of Dihydromayurone. A mixture of dihydromayurone (2.06 g, 10 mmol), acetic acid (10 ml), acetic anhydride (10 ml), and boron trifluoride etherate (2 ml, 4.5 mmol) was heated at 50 °C for 2 h. The dark brown reaction mixture was poured into ice-water (20 ml) and extracted with ether. The extract was washed with aqueous $NaHCO_3$ solution, water, dried (Na_2SO_4), and evaporated to give an oily residue (2.87 g). The products were separated by column chromatography using silica gel. Elution with benzene gave **1** (1.11 g) and **2** (0.8 g) as colorless liquids, respectively. **2**: MS *m/e* 248 (M^+) and 206 (M−42); IR (neat) ν 1738 cm^{-1}; PMR ($CDCl_3$) δ 0.81 (s, 6, $2CH_3$), 1.01 (s, 3, CH_3), 1.95 (s, 3, CH_3), 5.21 (ddd, 1, J=10.8, 2.5, and 2.5 Hz), and 5.81 (ddd, 1, J=10.8, 5.0, and 3.5 Hz).

Hydrolysis of 2. Compound **2** (1.24 g, 5 mmol) was hydrolyzed in alcohol (15 ml) with potassium hydroxide (560 mg, 10 mmol) at room temperature for 2 h. After the usual work-up a crude product (992 mg) was obtained. Recrystallization from hexane gave pure **3** (876 mg). **3**: Mp 145—148 °C; MS *m/e* 205 (M^+); IR (KBr) ν 3355 cm^{-1}; PMR ($CDCl_3$) δ 0.80 (s, 6, $2CH_3$), 1.02 (s, 3, CH_3), 5.18 (ddd, 1, J=10.8, 2.5, and 2.5 Hz), and 5.78 (ddd, 1, J=10.8, 5.0, and 3.5 Hz); C^{13}-NMR ($CDCl_3$) δ 17.0 (q), 17.2 (q), 24.9(q) 28.4(t), 34.6 (t), 35.7 (s), 36.3 (t), 37.4 (t), 39.3 (t), 45.9 (s), 49.0 (s), 80.6 (s), 127.8 (d), and 130.0 ppm (d). Found: C, 81.59; H, 10.66%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

Oxidation of 3 with Osmium Tetraoxide. To a stirred solution of **3** (782.8 mg, 3.8 mmol) in pyridine (2 ml) and ether (35 ml) was added dropwise a solution of osmium tetraoxide (1.0 g, 4.0 mmol) in ether (35 ml) under nitrogen at room temperature in 10 min. The mixture was subsequently stirred for 2 days. After the usual work-up a crude product (856 mg) was obtained. Recrystallization from ethyl acetate gave pure **5** (781 mg). **5**: Mp 210—212 °C; IR (KBr) ν 3350 cm^{-1}; PMR (DMSO-d_6) δ 0.72 (s, 3, CH_3), 0.97 (s, 3, CH_3), 1.05 (s, 3, CH_3), 3.57 (m, 1), and 4.61 (d, 1, J=6.0 Hz). Found: C, 70.42; H, 9.83%. Calcd for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07%.

Oxidation of 5 with Lead Tetraacetate. To a stirred solution of **5** (141.2 mg, 0.6 mmol) in acetic acid (5 ml), kept at 15 °C, was added lead tetraacetate (285 mg, 0.65 mmol) in portions over 20 min. The mixture was stirred for 5 h at room temperature. The usual work-up gave a crude product (140 mg), which was chromatographed on a sillica-gel column. Elution with ethyl acetate and benzene (10:1) gave **6** (126 mg). Recrystallization from benzene gave pure **6** (105 mg) as colorless crystals. **6**: Mp 186—189 °C; IR (KBr) ν 3500, 2700, and 1703 cm^{-1}; PMR ($CDCl_3$) δ 1.02 (s, 3, CH_3), 1.10 (s, 3, CH_3), 1.15 (s, 3, CH_3), 9.73 (t, 1, -CHO, J=3.0 Hz), and 9.75 (s, 1, -CHO). Found: C, 71.08; H, 9.01%. Calcd for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31%.

Isomerization of 4. A mixture of **4** (248 mg, 1 mmol), acetic acid (1.5 ml), acetic anhydride (1.5 ml), and boron trifluoride etherate (0.2 ml, 0.45 mmol) was heated at 50 °C for 2 h. The usual work-up as reported above gave **2** (178.6 mg).

A Hydroxyl Proton Magnetic Resonance Study of 2-Cyclohexen-1-ols, 1-Tetralols, 4-Chromanols, and 4-Thiochromanols in Dimethyl Sulfoxide

Kaoru HANAYA,* Hideaki KUDŌ, Kazuo GOHKE,** and Shin IMAIZUMI**

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata 990

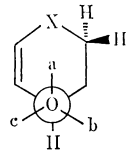
***Department of Applied Science, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980*

(Received January 12, 1979)

Synopsis. The proton magnetic spectra in dimethyl sulfoxide of 2-cyclohexen-1-ols, 1-tetralols, 4-chromanols, and 4-thiochromanols have been determined. In all cases, the pseudoaxial OH proton resonates at a higher field than the pseudoequatorial one. The spin-spin coupling between the hydroxyl and carbinyl protons is found to be greater for the pseudoequatorial epimer.

Dimethyl sulfoxide (DMSO) is known to be an excellent solvent for the facile observation of H–C–O–H splitting.[1] Recently two studies of the OH proton chemical shifts and coupling constants for a series of epimeric saturated cyclic alcohols have been reported.[2,3] The axial and equatorial hydroxyl groups in a saturated cyclanols can be clearly distinguished from the equatorial hydroxyl resonance at a lower field and a larger coupling constant.

However, no systematic study of the PMR spectra of α,β-unsaturated cyclanols in DMSO has yet appeared in the literature. In order to examine whether or not a relationship similar to those found in the case of the saturated cyclanols exists between the chemical shifts, coupling constants, and conformations of α,β-unsaturated cyclanols, we investigated the ^1H NMR spectra in DMSO of epimeric 2-cyclohexen-1-ols, 1-tetralols, 4-chromanols, and 4-thiochromanols in the low-concentration region, in which the chemical shift has been established as invariant. The results are summarized in Table 1. Table 1 shows the clear correlation that, in each epimeric set, the pseudoaxial OH proton resonates at a significantly higher field than its pseudoequatorial counterpart, as has previously been noted for the saturated cyclanols.[2,3] The chemical shift difference between the epimeric alcohols may be related to the solute-solvent hydrogen bonding. Hydrogen bonding is known to influence profoundly the chemical shift of a participating proton.[3] The coupling constant data in Table 1 also lend themselves to ready correlation with the conformation. In each set of epimers, the pseudoequatorial OH coupling constant is greater than that of its pseudoaxial epimers. The difference between the hydroxyl-carbinyl proton coupling constants for epimeric α,β-unsaturated cyclanols may be understood from a consideration of the conformational equilibria resulting from rotation about



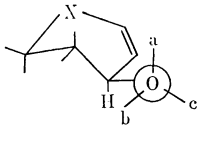


Table 1. Hydroxyl proton chemical shifts and coupling constants of epimeric α,β-unsaturated cyclanols in DMSO

13 $X=SO_2$, $R_1=CH_3$

the C–O bond.[2-4] The contribution of the **a**-type conformation, in which the OH bond is directed towards the center of the cyclohexene, dihydropyran, or dihydrothiopyran ring, may be smaller in the OH pseudoaxial epimer because of the 1,3-diaxial interaction.[5] Assuming that the H–C–O–H coupling constants vary with the dihedral angle in a manner similar to that for the H–C–C–H system, Rader *et al.*,[2] Sehgal *et al.*,[3] and Fraser *et al.*[6] were led to the conclusion that an equatorial alcohol should have a larger coupling constant than its axial epimer because of the greater contribution of the anti conformer, **a**, in the former.

From the present study, it is significant that, in view of the characteristic chemical shift differences and coupling constants, the NMR technique in DMSO can be used to distinguish not only the epimers of saturated cyclanols, but also those of α,β-unsaturated cyclanols. These observations appear to provide direct experimental evidence for the configuration and conformations of these epimers.

Experimental

Materials. All the compounds employed in this work have been previously reported: **1**,[7] **2**,[8] **3**,[9] **4**,[9] **5**,[10] **6**,[11] **7**,[12] **8**,[13] **9**,[14] and **10**—**13**.[15] The conformations of 2-cyclohexen-1-ols,[7] 1-tetralols,[5,16,17] 4-chromanols,[5,12,13,15,16] and 4-thiochromanols[15] were examined by means of their ^{1}H NMR, ^{13}C NMR, and IR spectra.

NMR Spectra. All the ^{1}H NMR spectra were taken with either a Hitachi H-60 or R-24B spectrometer at a probe temperature of 30 °C, unless otherwise noted. Tetramethylsilane was used as the internal standard; the concentrations were *ca.* 2×10^{-2} in the mole fraction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (7), 2165—2166 (1979)

Asymmetric Reactions. IV. Asymmetric, Catalytic Activity of Poly(2-quinuclidinylmethyl acrylate)

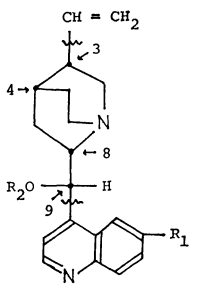
Tetsushi YAMASHITA,* Hiroshi YASUEDA, and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

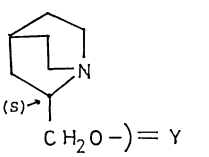
(Received January 12, 1979)

Synopsis. The asymmetric addition of methanol to phenylmethylketene has been conducted in the presence of poly(2-quinuclidinylmethyl acrylate) and 2-quinuclidinylmethyl propionate derived from (*S*)-2-quinuclidinylmethanol. The asymmetric functions of the above catalysts were similar to those of poly(*O*-acryloylquinine) and *O*-propionylquinine, which contain a quinoline ring and a vinyl group as additional groups to the quinuclidine ring.

Several workers[1-3] have recently studied asymmetric, catalytic reactions using chiral polymers derived from cinchona alkaloids. Cinchona alkaloids (**A**) consist of four asymmetric carbons (C_3, C_4, C_8, and C_9) and three main functional groups (a quinuclidinyl, a vinyl and a quinolyl group). In this paper, poly(2-quinuclidinylmethyl acrylate) (**HB**) and 2-quinuclidinylmethyl propionate (**LB**) were used to clarify the role of the quinuclidinyl group as an active site in cinchona alkaloid catalysts.



(A)



HB; $-(CH_2-CH)_n-CO-Y$
MB; $CH_2=CH-CO-Y$
LB; CH_3CH_2-CO-Y

(B)

High- or low-molecular-weight catalysts (**HB** or **LB**) have been prepared by the acylation of (*S*)-2-quinuclidinylmethanol, which was obtained by reduction of (*S*)-2-(ethoxycarbonyl)quinuclidine with lithium aluminum hydride; (*S*)-2-(ethoxycarbonyl)quinuclidine was obtained by optical resolution[4] of the racemic mixture[5,6] derived from 4-methylpyridine.

(*S*)-2-Quinuclidinylmethanol was allowed to react with propionic anhydride or acryloyl chloride giving 2-quinuclidinylmethyl propionate (**LB**) or 2-quinuclidinylmethyl acrylate (**MB**) respectively. A soluble polymer (**HB**) was obtained by the polymerization of **MB** using a catalytic amount of azobisisobutyronitrile as initiator. The catalytic activities of **LB** and **HB** have been examined for the asymmetric synthesis of methyl 2-phenylpropionate. The addition of methanol to phenylmethylketene has been conducted according to an earlier report.[1]

$$\mathrm{Ph-\underset{\displaystyle CH_3}{\underset{|}{C}}=C=O + CH_3OH \xrightarrow{\text{Catalyst}} Ph-\underset{\displaystyle CH_3}{\underset{|}{CH}}-COOCH_3}$$

Figure 1 shows plots of the optical purities (O.P.) of the addition products against reaction temperatures (T °C) for **HB** and **LB**. The results[1a] obtained previously with poly(*O*-acryloylquinine) (**HA**) and *O*-propionylquinine (**LA**) are also shown in Fig. 1 [Quinine catalysts (**A**): C_8, *S*-configuration; $R_1=OCH_3$; $R_2=$ acyl group].

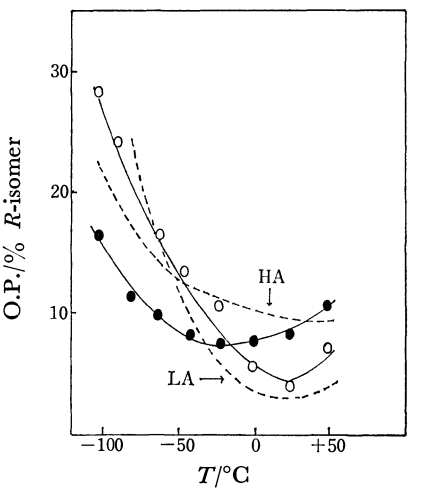


Fig. 1. Plots of optical purities[a] (O. P.) against reaction temperatures (T °C) in case of **HB** (●) and **LB** (○) (catalyst[b]: 0.025 mmol, phenylmethylketene: 2.500 mmol, methanol: 2.600 mmol, solvent: 25 ml of dry toluene).
a) The optical purity was calculated from the specific rotation of the product and that of optically pure methyl 2-phenylpropionate[1a] (*S*-form, $[\alpha]_D^{22}$ +109° in toluene). b) The molar equivalent amount of the polymeric catalyst was calculated on the basis of that of the monomer used in the polymerization.

All of the catalysts described above gave the addition products showing preference to the *R*-isomer in the range from −100 °C to +50 °C. Figure 1 also indicates that **HB** yielded a higher predominance of addition products with *R*-configuration than did **LB** above 0 °C. This sort of polymer effect was similar to that observed with quinine catalysts (**HA** and **LA**) above −50 °C.

Figure 1 suggests that the asymmetric functions of 2-quinuclidinylmethanol catalysts do not greatly differ from those of the quinine catalysts.

These results suggest that the configuration at C_8 of the quinuclidinyl group in cinchona alkaloid catalysts is very important in determining the configuration of products.

Experimental

A JASCO IRA-1 (IR) apparatus, a JEOL-60 MC (NMR)

apparatus, a Hitachi M52 (MS) apparatus, a Rex-automatic polarimeter (optical rotation, 10 cm cell) and a Knauer vapor pressure osmometer (molecular weight) were used.

*(S)-2-Quinuclidinylmethyl Acrylate (**MB**).* Powdered sodium hydroxide (2.25 mmol) was suspended in a solution of (*S*)-2-quinuclidinylmethanol[6] (1.50 mmol) in dry dichloromethane (15 ml) in argon at −10 °C. To the mixture was added a solution of acryloyl chloride (1.80 mmol) in dry dichloromethane (5 ml). The reaction mixture was stirred for 20 h at the same temperature and the precipitate filtered. The filtrate was dried and evaporated to dryness and the residue subjected to column chromatography on alumina (2×10 cm, 200 mesh, neutral). Elution with chloroform gave **MB** as an oily material which was distilled to give a colorless oil. Yield, 60%. Bp 100 °C at 1 mmHg. $[\alpha]_D^{24}$ −60° (*c* 1.23, benzene); IR (neat): 1727, 1632, 995 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.64—6.46 ppm; MS *m/e* 195 (M^+).

*Poly(2-quinuclidinylmethyl acrylate) (**HB**).* A solution of 2-quinuclidinylmethyl acrylate (80 mg) and azobisisobutyronitrile (3 mg) in dry benzene (0.4 ml) was polymerized at 80 °C for 40 h in a sealed tube filled with argon. The product was poured into ether, and the precipitate filtered and washed with ether. Yield, 60%. $[\alpha]_D^{16}$ −47° (*c* 1.3, benzene); mol wt 5850 (benzene).

*(S)-2-Quinuclidinylmethyl Propionate (**LB**).* **LB** was obtained in 75% yield as a colorless oil by the reaction of (*S*)-2-quinuclidinylmethanol with propionic anhydride in the presence of triethylamine. Bp 105 °C at 3 mmHg. $[\alpha]_D^{20}$ −50.8° (*c* 0.96, benzene); IR (neat): 1740, 1188, 1058 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.37, 1.13 ppm; MS *m/e* 197 (M^+).

Synthesis of (*S,S*)-2-Amino-3-phenylbutyric Acid

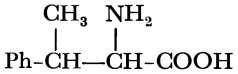
Gen-ichi TSUCHIHASHI,* Shuichi MITAMURA, and Katsuyuki OGURA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received January 20, 1979)

Synopsis. (*S,S*)-2-Amino-3-phenylbutyric acid was synthesized starting from diethyl (*R*)-(1-phenylethyl)malonate which was obtained by desulfurization of the adduct in the stereoselective Michael reaction of (*R*)-styryl *p*-tolyl sulfoxide with diethyl malonate. This synthetic amino acid was identical with the 2-amino-3-phenylbutyric acid obtained by degradation of bottromycin and thus the absolute configuration of the naturally occurring amino acid was proved to be (*S,S*).

In 1957, (—)-2-amino-3-phenylbutyric acid [(—)-**1**] was reported to be a component of bottromycin which was isolated from a culture of *Streptomyces bottropensis*.[1]

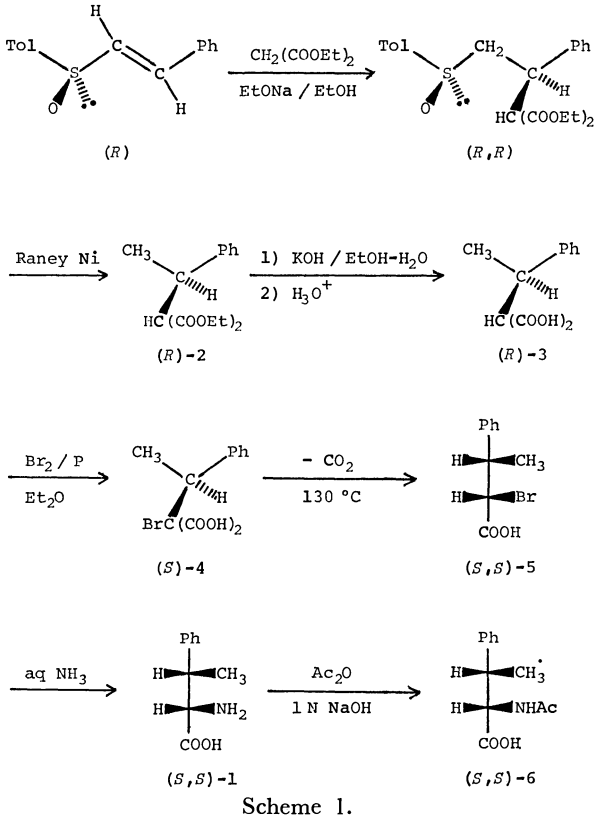


1

Since this amino acid contains two chiral centers, four isomers [(2*R*,3*R*), (2*R*,3*S*), (2*S*,3*R*), and (2*S*,3*S*)] are possible. As to the absolute configuration at the 2-position, (*S*) was suggested, based on the positive Cotton effect in the ORD of its *N*-ethylthiothiocarbonyl derivative, the resistance against a D-amino acid oxidase,[2] and the application of the Clough, Lutz, and Jirgensons rule to the optical rotatory powers of the amino acid and its derivatives.[3] Later, the diastereomeric relationship between the 2- and 3-positions was determined to be erythro by the chemical transformation[3] and the NMR study.[4]

We previously synthesized diethyl (*R*)-(1-phenylethyl)malonate [(*R*)-**2**] by desulfurization of diethyl (*R,R*)-[1-phenyl-2-(*p*-tolylsulfinyl)ethyl]malonate, which was obtained by the stereoselective Michael reaction of (*R*)-styryl *p*-tolyl sulfoxide with diethyl malonate.[5,6] Now, we have synthesized (*S,S*)-**1** starting from this (*R*)-**2** according to the Fischer's method[7-9] as shown in Scheme 1 and have found that the naturally occurring **1** is identical with this (*S,S*)-**1**.

(*R*)-(1-Phenylethyl)malonic acid [(*R*)-**3**], which was obtained by hydrolysis of (*R*)-**2** in 88% yield, was subjected to bromination with bromine–red phosphorus to give (*S*)-bromo(1-phenylethyl)malonic acid [(*S*)-**4**]. Thermal decarboxylation of (*S*)-**4** afforded a crystalline product which was recrystallized from benzene to give pure (*S,S*)-2-bromo-3-phenylbutyric acid [(*S,S*)-**5**; 40% overall yield from (*R*)-**3**]:[9] mp 167—168 °C; $[\alpha]_D^{30}$ −31.4° (*c* 0.327, benzene). Treatment of (*S,S*)-**5** with aqueous ammonia gave a mixture of (*S,S*)-2-amino-3-phenylbutyric acid [(*S,S*)-**1**] and ammonium bromide. This mixture was subjected to the reaction with acetic anhydride–1 M aqueous sodium hydroxide[1b] to afford (*S,S*)-2-acetylamino-3-phenylbutyric acid [(*S,S*)-**6**; 95% yield from (*S,S*)-**5**]: mp 188—190 °C (from 20% ethanol); $[\alpha]_D^{29}$ +34.8° (*c* 0.810, 96% ethanol). These values agree well with those reported



Scheme 1.

for the *N*-acetyl derivative of the naturally occurring **1** [mp 177—185 °C (from 20% ethanol) and $[\alpha]_D^{25}$ +35.0° (*c* 2%, 96% ethanol)].[1b]

The starting material of the present synthesis, (*R*)-**2**, was already connected to (—)-3-phenylbutyric acid,[5] whose absolute configuration was determined as (*R*) by the comparison with the authentic specimen synthesized from (*S*)-hydratropic acid.[10] Based on these relations, the present synthesis clearly established that the absolute configuration of the 2-amino-3-phenylbutyric acid from bottromycin is (*S,S*).

Experimental

All melting points were measured by a Yanagimoto micro melting point apparatus and uncorrected. Infrared spectra were taken on a Hitachi EPI-G3 spectrophotometer. NMR spectra were recorded on Varian T-60 and Varian HA-100 spectrometers. Optical rotations were measured on a Yanagimoto polarimeter OR 50.

Hydrolysis of (R)-*2*. To a solution of 472 mg (1.79 mmol) of (*R*)-**2** having $[\alpha]_D^{26}$ −21.0° (*c* 2.365, $CHCl_3$)[11] in 6 ml of ethanol, were added 3 ml of water and 550 mg of potassium hydroxide and the reaction mixture was stirred at 100 °C for 3 h. After cooling, 20 ml of water was added and the mixture was washed with dichloromethane (10 ml). The aqueous layer was acidified by adding concd hydrochloric

acid and extracted with diethyl ether (20 ml×4). The extract was washed with water (10 ml) and dried (Na_2SO_4). After evaporation *in vacuo*, the crystalline residue was recrystallized from benzene to afford 328 mg (88% yield) of (*R*)-**3** as colorless crystals: mp 94—96 °C; $[\alpha]_D^{21}$ −30.1° (*c* 0.866, methanol); IR (KBr): 3500—2800, 1740, 1695, 1220, 1200, 1155, 760, and 700 cm^{-1}; NMR ($CDCl_3$): δ=1.34 (3H, d, J=6 Hz), 3.2—3.8 (2H, m), 7.27 (5H, s), and 12.70 (2H, s). The NMR spectrum was identical with that of the racemic compound.[5,7]

Transformation of (R)-***3*** *into* (S,S)-***5*** via (S)-***4***. To a solution of 237 mg (1.14 mmol) of (*R*)-**3** in 5 ml of diethyl ether, were added a solution of 184 mg of bromine in 0.8 ml of dichloromethane and 1 mg of red phosphorus and the mixture was stirred for 45 min at room temperature. After reduction of remaining bromine by adding aqueous sodium thiosulfate, the mixture was extracted with diethyl ether (15 ml×4). The extract was dried ($MgSO_4$) and evaporated *in vacuo* to give crude (*S*)-**4** as an oil: NMR ($CDCl_3$): δ= 1.62 (3H, d, J=7 Hz), 3.77 (1H, q, J=7 Hz), 7.32 (5H, m), and 10.50 (2H, broad s). This oil was heated at 130 °C for 15 min under reduced pressure (*ca.* 20 Torr). The resulting crystalline product was recrystallized from benzene to give 105 mg (40% yield[9]) from (*R*)-**3**) of (*S,S*)-**5** as colorless crystals: mp 167—168 °C; $[\alpha]_D^{30}$ −31.4° (*c* 0.327, benzene); NMR (acetone-d_6): δ=1.43 (3H, d, J=7 Hz), 3.41 (1H, dq, J=10 and 7 Hz), 4.57 (1H, d, J=10 Hz), and 7.2—7.5 (5H, m). The NMR spectrum was identical with that of the racemic specimen.[7]

Synthesis of (S,S)-***6***. A mixture of 105 mg (0.43 mmol) of (*S,S*)-**5** and 4 ml of 28% aqueous ammonia was heated in a sealed tube at 90 °C for 2.5 h and then concentrated *in vacuo* to yield a mixture of (*S,S*)-**1** and ammonium bromide. After addition of 2.5 ml of 1 M aqueous sodium hydroxide to the above mixture, 0.15 ml of acetic anhydride and 1.3 ml of 1 M aqueous sodium hydroxide were simultaneously added over 5 min and the mixture was stirred for 1 h under ice-cooling. After simultaneous addition of 0.15 ml of acetic anhydride and 3 ml of 1 M aqueous sodium hydroxide, the resulting mixture was further stirred for 30 min under ice-cooling, acidified to pH 1 with concd hydrochloric acid, and extracted with ethyl acetate (15 ml×4). The extract was dried ($MgSO_4$) and evaporated *in vacuo* to afford 91 mg (95% yield) of (*S,S*)-**6** as colorless crystals: mp 188—190 °C (from 20% ethanol), $[\alpha]_D^{29}$ +34.8° (*c* 0.810, 96% ethanol) [lit,[1b] mp 177—185 °C (from 20% ethanol), $[\alpha]_D^{25}$ +35.0° (*c* 2%, 96% ethanol)]; IR (KBr): 3330, 1710, 1610, 1550, 1265, 765, 705, and 695 cm^{-1}; NMR (DMSO-d_6): δ=1.19 (3H, d, J=7 Hz), 1.68 (3H, s), 2.9—3.3 (1H, m), 4.42 (1H, t, J=8 Hz, 7.19 (5H, s), and 7.85 (1H, diffused d, J=8 Hz, NH). The NMR spectrum was identical with that of the racemic compound.[1c]

8) The identification of the synthetic **1** obtained by Fischer and Schmitz[7] with the naturally occurring **1** was unequivocally established.[1,3]

9) Fischer and Schmitz reported that the decarboxylation of racemic **4** resulted in the formation of a single compound (75% yield) which melted at 188—190 °C.[7] This compound was determined to have erythro, *i.e.* (*S,S*/*R,R*), configuration.[3] We traced Fischer's experiment and obtained the following results. When racemic **4** was heated at 130 °C under reduced pressure (*ca.* 20 Torr), carbon dioxide gas evolved, giving a crystalline material which was recrystallized from benzene to afford (*S,S*/*R,R*)-**5** (53% yield): mp 187—189 °C. Its NMR spectrum was in complete agreement with that of (*S,S*)-**5**. The mother liquor was concentrated *in vacuo* to give an oily residue (44% yield), which was shown by an NMR analysis to consist of (*S,S*/*R,R*)-**5** and (*S,R*/*R,S*)-**5** in a ratio of 1:2 [NMR of (*S,R*/*R,S*)-**5** (acetone-d_6): δ=1.53 (3H, d, J=7 Hz), 3.41 (1H, dq, J=10 and 7 Hz), 4.61 (1H, d, J=10 Hz), and 7.2—7.5 (5H, m)]. Thus, the ratio of (*S,S*/*R,R*)-**5**: (*S,R*/*R,S*)-**5** in the crude product can be calculated to be *ca.* 7:3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (7), 2169—2170 (1979)

A Facile Synthesis of 4,5-Dialkoxy-*o*-benzoquinones by the Oxidation of Catechol with Iodates in Alcohol

Yuji ITOH, Takuya KAKUTA, Masao HIRANO, and Takashi MORIMOTO*

Department of Industrial Chemistry, Faculty of Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received January 27, 1979)

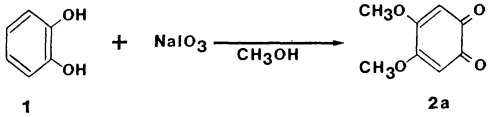
Synopsis. 4,5-Dimethoxy-*o*-benzoquinone has been prepared by the oxidation of catechol with sodium iodate in methanol. In higher alcohols, the same oxidation occurs in the presence of a crown ether to give the corresponding 4,5-dialkoxy-*o*-benzoquinones. In the latter cases using 18-crown-6, the potassium salt is more effective than the sodium salt.

o-Benzoquinone derivatives are conventionally prepared by the oxidation of the corresponding catechols. Wanzlick and Jahnke have reported the preparation of 4,5-dimethoxy- and 4,5-diethoxy-*o*-benzoquinones by the oxidation of catechol with lead(IV) oxide in methanol and ethanol, respectively, in the presence of alkoxide.[1]

In this note, a novel and simple method for the synthesis of 4,5-dialkoxy-*o*-benzoquinones from catechol will be reported using potassium and sodium iodates as oxidizing agents in alcohols from methyl to pentyl alcohol as solvents in the presence or absence of a crown ether. The products, except for dimethoxy and diethoxy derivatives, are unknown. 4-Substituted catechols have been oxidized with iodates to the corresponding quinones,[2,3] but to date there has been no report on the oxidation of unsubstituted catechol with the oxidants.

Results and Discussion

A mixture of catechol and two equivalents of sodium iodate in absolute methanol at 60 °C gradually darkened and became black after 20 h. Isolation by column chromatography gave 4,5-dimethoxy-*o*-benzoquinone (**2a**) in 58.3% yield. The structure of the quinone was elucidated from the spectral data and elemental analysis. The NMR spectrum of **2a** showed a singlet at τ=4.2 (2H; olefinic protons at C-3 and C-6) and a singlet at τ=6.1 (6H; methyl protons). The UV spectrum showed peaks at 413 nm (ε=560) and 287 nm (ε=12500). These data are consistent with those reported by Wanzlick and Jahnke.[1]



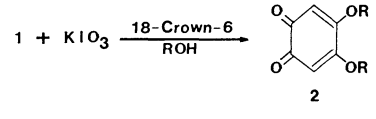
1 2a

The use of potassium iodate as the oxidant decreased the yield of the quinone to 36.9%.

The oxidation of catechol with sodium or potassium iodate in ethanol gave 4,5-diethoxy-*o*-benzoquinone (**2b**) in very low yield (less than 2% in both cases). No reaction occurred in propyl and higher alcohols.

The observation that the yield of the quinone decreases with the length of the alcohol chain is ascribed to the decrease in the solubility of the iodates in alcohols. Crown ethers have been well-known to enhance the solubility of inorganic salts in organic solvents,[4,5] and consequently the effect of 18-crown-6 has been examined using potassium iodate as the oxidant. The addition of 18-crown-6 (2.33 mmol) to the mixture of catechol (10 mmol) and potassium iodate (20 mmol) in absolute methanol (100 ml) increased the yield of **2a** to 49.2%. The effect was more dramatic in ethanol. Under similar conditions, the addition of 1.25 and 2.73 mmol of the crown ether gave **2b** in 20.7 and 44.4% yields, respectively.

The same method was employed for the preparation of several 4,5-dialkoxy-*o*-benzoquinones in higher alcohols.



2

a, R=CH_3 (49.2%)
b, R=C_2H_5 (44.4%)
c, R=n-C_3H_7 (35.3%)
d, R=n-C_4H_9 (31.1%)
e, R=i-C_4H_9 (30.7%)
f, R=n-C_5H_{11} (26.4%)
g, R=i-C_5H_{11} (43.3%)

In primary alcohols, catechol reacted with iodate to give the corresponding dialkoxy-quinones. All of the quinones exhibited a singlet at τ=4.2 in the NMR spectra and two peaks in the 413—416 and 289—291 nm region of the UV spectra.

In the alcohols which branched at the α-position of the hydroxyl group, *e.g.*, isopropyl and *t*-butyl alcohols, however, the reaction did not give the corresponding dialkoxy-*o*-benzoquinone derivative but a red amorphous solid. A similar product was obtained from the reaction in acetonitrile. In both cases, the IR spectrum of the product showed two absorption bands in the region of 1600—1700 cm^{-1}, possibly due to carbonyl groups. The solid however could not be purified because of the low solubility in organic solvents and a broad melting range.

There are few reports of the oxidation of substituted catechols by iodates to quinone derivatives in water and in water–alcohol mixtures during a short reaction period.[2,3] In such experiments here the products were complex substances which could not be separated.

Experimental

Melting points were determined with a Yamato Capillary Melting Point apparatus and are uncorrected. Proton magnetic resonance spectra were obtained on a JEOL Model JNM-C-HL spectrometer in deuterated chloroform. Electronic spectra were recorded on a Hitachi 124 spectrophotometer in ethanol. The alcohols were purified by distillation after drying over molecular sieves 4A. All other materials

were commercially available.

*Preparation of 4,5-Dimethoxy-o-benzoquinone (**2a**).* Sodium iodate (4.0 g, 20 mmol) was suspended in a solution of catechol (1.1 g, 10 mmol) in dry methanol (100 ml) and the mixture vigorously stirred for 20 h at 60 °C. After filtration, the filtrate was condensed on a rotary evaporator under reduced pressure to a volume of *ca.* 30 ml and cooled to −15 °C. The precipitate formed was filtered and washed with diethyl ether (50 ml). The precipitate was separated by column chromatography using silica gel (*ca.* 11 g) and chloroform. Evaporation of the solvent from the first orange elute gave orange needles (0.98 g, 58.3%), which were recrystallized from methanol: mp 230—233 °C (lit, 225—227 °C).[1] Found: C, 57.85; H, 4.74%. Calcd for $C_8H_8O_4$: C, 57.15; H, 4.80%.

*Preparation of 4,5-Diethoxy-o-benzoquinone (**2b**).* Potassium iodate (4.3 g, 20 mmol) was suspended in a solution of catechol (1.1 g, 10 mmol) and 18-crown-6 (0.72 g, 2.73 mmol) in absolute ethanol (100 ml) and the mixture vigorously stirred for 20 h at 65 °C. After filtration, the alcohol was evaporated under reduced pressure and the residue extracted twice with benzene (100 ml). The combined extracts were filtered and concentrated. The residual red-brown substance was further extracted with diethyl ether (150 ml). The residue was separated by column chromatography using silica gel and chloroform. Evaporation of the solvent from the first orange elute gave orange needles (0.87 g, 44.4%), which were recrystallized from ethanol: mp 172—174.5 °C (lit, 175 °C).[1] NMR ($CDCl_3$) τ=8.5 (6H, t), 5.9 (4H, q) and 4.25 (2H, s); UV_{max} (C_2H_5OH) 289 (ε=13700) and 416 nm (ε=535). Found: C, 61.60; H, 5.75%. Calcd for $C_{10}H_{12}O_4$: C, 61.22; H, 6.17%.

Preparation of the 4,5-Dialkoxy-o-benzoquinones. The method described for the preparation of diethoxy derivative (**2b**) was employed except that the reaction was conducted in the corresponding alcohol at 90—95 °C. The physical properties are as follows;

*4,5-Dipropoxy-o-benzoquinone (**2c**).* Mp 153—154.5 °C from CCl_4. NMR ($CDCl_3$) τ=8.95 (6H, t), 8.1 (4H, m), 6.0 (4H, t), and 4.25 (2H, s); UV_{max}(C_2H_5OH) 290 (ε=14000) and 415 nm (ε=532). Found: C, 65.20; H, 7.25%. Calcd for $C_{12}H_{16}O_4$: C, 64.29; H, 7.19%.

*4,5-Dibutoxy-o-benzoquinone (**2d**).* Mp 140.5—142 °C from CCl_4. NMR ($CDCl_3$) τ=9.0 (6H, t), 8.1 (8H, m), 6.0 (4H, t), and 4.3 (2H, s); UV_{max}(C_2H_5OH) 291 (ε=12800) and 414 nm (ε=487). Found: C, 67.18; H, 8.20%. Calcd for $C_{14}H_{20}O_4$: C, 66.65; H, 7.99%.

*4,5-Diisobutoxy-o-benzoquinone (**2e**).* Mp 157.5—159 °C from CCl_4. NMR ($CDCl_3$) τ=8.95 (12H, d), 7.95 (2H, m), 6.25 (4H, t), and 4.3 (2H, s); UV_{max}(C_2H_5OH) 290 (ε=13800) and 414 nm (ε=512). Found: C, 66.29; H, 7.89%. Calcd for $C_{14}H_{20}O_4$: C, 66.65; H, 7.99%.

*4,5-Bis(pentyloxy)-o-benzoquinone (**2f**).* Mp 130—131 °C from CCl_4–petroleum ether. NMR ($CDCl_3$) τ=9.0 (6H, t), 8.4 (12H, m), 6.0 (4H, t), and 4.3 (2H, s); UV_{max}(C_2H_5OH) 291 (ε=13400) and 413 nm (ε=496). Found: C, 68.36; H, 8.99%. Calcd for $C_{16}H_{24}O_4$: C, 68.55; H, 8.63%.

*4,5-Bis(isopentyloxy)-o-benzoquinone (**2g**).* Mp 119—120 °C from CCl_4–petroleum ether. NMR ($CDCl_3$) τ=9.0 (12H, d), 8.25 (6H, m), 5.95 (4H, t), and 4.3 (2H, s); UV_{max} (C_2H_5OH) 290 (ε=13800) and 414 nm (ε=512). Found: C, 68.61; H, 8.72%. Calcd for $C_{16}H_{24}O_4$: C, 68.55; H, 8.63%.

The authors wish to thank Mrs. Junko Takizawa and Mrs. Michiko Asuke of Tokyo University of Agriculture and Technology for the NMR measurements and elemental analysis.

Kinetics of the Aminolysis of α-Chloropropionic Acid. Reactivity of Aliphatic Amines[1)]

Yoshiro OGATA* and Yuya YAMAUCHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 31, 1979)

Synopsis. The kinetics for the reaction of α-chloropropionic acid with some amines (methylamine, dimethylamine, trimethylamine, ethylamine, and diethylamine) and ammonia have been studied in an aqueous solution. The reactivity of amines is discussed on the basis of the Swain-Scott and Taft equations.

The steric as well as polar effect was found to be important in the reaction of ammonia, alanine, and α,α′-iminodipropionic acid with α-chloropropionic acid.[2)] Hall Jr.[3)] reported that the data for the reaction of 30 amines with 15 substrates including chloroacetic acid are correlated by the Swain-Scott equation. We have studied the rate of the reaction of some amines with α-chloropropionic acid (CPA), forming *N*-alkylated alanine.

Discussion is given on the reactivity of amines on the basis of the Swain-Scott[4)] and Taft equations.[5)]

Results and Discussion

$$CH_3CHClCO_2H + R^1R^2R^3N \xrightarrow[-Cl^-]{\text{in } H_2O} CH_3\underset{\displaystyle N^+R^1R^2R^3}{\underset{|}{C}}HCO_2H + CH_3\underset{OH}{\underset{|}{C}}HCO_2H \quad (1)$$

	2a	**2b**	**2c**	**2d**	**2e**	**2f**

R^2	H	H	Me	Me	H	Et
R^3	H	H	H	Me	H	H

Aminolysis was conducted at 60 °C in an aqueous solution and the chloride ion produced was measured in order to follow the rate of reaction. The pseudo-first-order rate constants (k_{obsd}) were measured at various concentrations of amines. The plot of the pseudo-first-order rate constants against the initial concentrations of amines gives a straight line with an intercept. The rate equation fits the equation,

$$\frac{d}{dt}[Cl^-] = (k_1 + k_2[\text{Amine}]_{ex})[\text{CPA}]. \quad (2)$$

Where $[\text{Amine}]_{ex}$ is the excess concentration of amine to that of α-chloropropionic acid, *i.e.*, effective amine concentration. Rate constants, k_1 and k_2, evaluated from the intercept of the plot and the slope, are given in Table 1.

Independent experiments for pure hydrolysis of CPA were carried out. The first- and second-order rate constants thus obtained for the hydrolysis of CPA are $0.35\times10^{-5}\,s^{-1}$ (S_N1) and $0.76\times10^{-5}\,s^{-1}\,M^{-1}$ (S_N2), respectively (60 °C).

Thus, in the case of methylamine (**2b**), dimethylamine (**2c**), trimethylamine (**2d**), and ethylamine (**2e**), the hydrolysis is negligible, the rate equation being of second-order: $v=k_2[\text{Amine}]_{ex}[\text{CPA}]$.

In order to examine the effect of substituent on amines, Taft equations[5)] with $\log k_{2rel}=\rho_s E_s+\delta E_s$ and $\log k_{2rel}=\rho^*\sigma^*$ were applied, where k_{2rel} is the relative rate constant. The former equation including a steric term, δE_s, gave poor correlation (ρ_s ranging −2.50—59.5 and δ ranging −58.1—2.76), and we could not determine values of ρ_s and δ, whereas the latter equation including only a polar term gave ρ^* value of −1.8 from the plot of $\log k_{2rel}$ against $\Sigma\sigma^*$ (summation of Taft polar substituent constants), except **2d** and **2f** (Fig. 1). In other words, electron-releasing groups promote the reaction. This is expected from the nucleophilic nature of amines, but the steric effect becomes important for the reaction of **2d** and **2f**.

The Swain-Scott equation[4)] is given by

$$\log(k/k_0) = sn \quad (3)$$

where s is the sensitivity to nucleophiles and n is the nucleophilic parameter. The plot of $\log k_2$ against n gave a straight line except for **2d** and **2f**. The s value of 1.05 was obtained for the reaction of CPA

a) *n*-Values are the average of the caluculated values from Ref. 3.

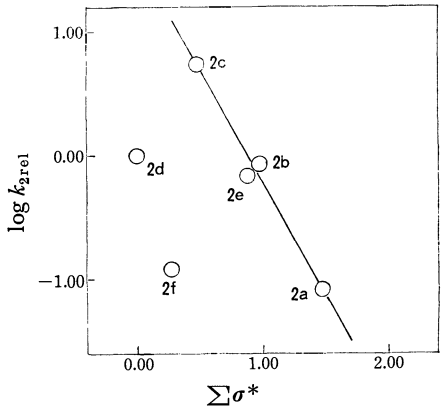

Fig. 1. Plot of k_{2rel} against $\sum\sigma^*$ for the reaction of α-chloropropionic acid with some amines in an aqueous solution at 60 °C.

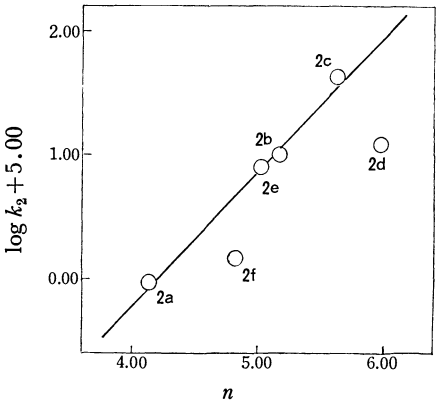

Fig. 2. Swain-Scott plot for the reaction of α-chloropropionic acid with some amines in an aqueous solution at 60 °C.

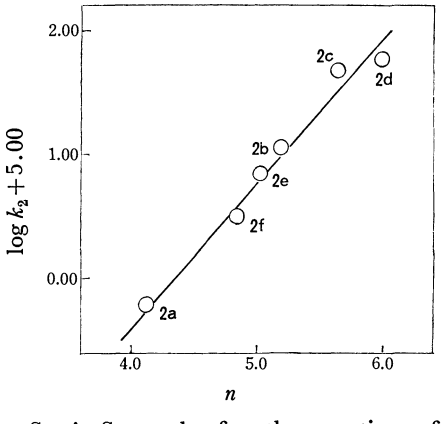

Fig. 3. Swain-Scott plot for the reaction of chloroacetic acid with some amines in an aqueous solution at 25 °C.

with some amines. Deviation from the straight line is larger with CPA (Fig. 2) than with chloroacetic acid (Fig. 3, $s=1.2$), especially with **2d** and **2f**. Since **2d** is tertiary and **2f** is secondary, the deviation may be due to the steric hindrance in the transition state. In aminolysis of phenethyl nitrite,[7] successive substitution of hydrogen by the methyl group in NH_3 leading to Me_3N always increases the relative rate, whereas in the reactions with CPA bearing α-methyl group, there is more interaction between substituent of amines than in those with chloroacetic acid or phenethyl nitrite, so that steric requirement decreases not only the reactivity of trimethylamine but also that of diethylamine.

Experimental

Materials. α-Chloropropionic acid bp 92—93 °C/15 Torr (lit,[8] 82.5—83.5 °C/12 Torr), aqueous 40% methylamine, 50% dimethylamine, 50% trimethylamine, 70% ethylamine, and 28% ammonia, and diethylamine of guaranteed reagent grade were used.

Kinetics. A solution of α-chloropropionic acid (1 M, 5 ml) was added to an aqueous solution of amines (1.2—3.5 M, 45 ml) in a glass-stoppered flask, which had attained thermal equilibrium at 60±0.1 °C in a thermostat. Aliquots (5 ml) were pipetted out at regular intervals and cold dil. HNO_3 was added to stop the reaction. The chloride ion concentration was determined by the Volhard method.[9] The pseudo-first-order rate was measured up to 30—60% conversion.

Products. NMR spectra were recorded on a Hitachi R-24B spectrometer. Under the kinetics conditions, the main product was *N*-alkylated alanine. On the basis of NMR spectra, the reaction products of α-chloropropionic acid with ammonia were found to be a mixture of alanine and lactic acid, and the products from diethylamine a mixture of *N,N*-diethyl alanine and lactic acid. They were produced by competitive aminolysis and hydrolysis, respectively. On the other hand, no lactic acid was detected in the case of the other amines.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (7), 2173—2174 (1979)

Syntheses of 3,5-Dimethylspiro[5.5]undeca-2,4-diene-1,8-dione and 7,11-Dimethylspiro[5.5]undeca-7,10-diene-2,9-dione

Kalyan Kumar BHATTACHARYA and Parimal Krishna SEN*

Department of Chemistry, Presidency College, Calcutta 700073, India

(Received July 8, 1978)

Synopsis. Syntheses of 1-diazo-5-(2-hydroxy-4,6-dimethylphenyl)-2-pentanone and 1-diazo-5-(4-hydroxy-2,6-dimethylphenyl)-2-pentanone and their acid catalysed spiroannulation to 3,5-dimethylspiro[5.5]undeca-2,4-diene-1,8-dione and 7,11-dimethylspiro[5.5]undeca-7,10-diene-2,9-dione respectively *via* Ar_1-6 participation are described. Succinylation of 3,5-dimethylanisole is also discussed.

Aryl participation of phenolic diazo ketones toward the formation of spirodienone have recently been developed. Mander and Beams[1] reported a spectral indication of the formation of spirodienone *via* Ar_1-6 participation route in connection with their study on intramolecular alkylation of phenolic diazo ketones. Here we report the syntheses of two intermediate phenolic diazo ketones, 1-diazo-5-(2-hydroxy-4,6-dimethylphenyl)-2-pentanone (**8**) and 1-diazo-5-(4-hydroxy-2,6-dimethylphenyl)-2-pentanone (**18**) and their conversion into the spirodienones, 3,5-dimethylspiro[5.5]undeca-2,4-diene-1,8-dione (**1**) and 7,11-dimethylspiro[5.5]undeca-7,10-diene-2,9-dione (**2**), respectively. The spirodienones were isolated and characterized by spectral analyses.

Succinylation of 3,5-dimethylanisole at −5 °C in 1,1,2,2-tetrachloroethane–nitrobenzene mixture afforded the ortho-isomer, 3-(2-methoxy-4,6-dimethylbenzoyl) propanoic acid (**3**), mp 101 °C, in an excellent yield. The NMR spectrum of the keto acid **3** showed two sets of distinct singlets at δ 2.08, 2.25 (aromatic methyls) and at δ 6.61, 6.71 (aromatic protons). Clemmensen reduction of **3** and subsequent demethylation gave the hydroxy acid **5**, mp 130 °C. The same compound was synthesised by Brown and McCall[2] from a different route, mp 130—132 °C. The hydroxy acid was converted into the hydroxy diazo ketone **8** *via* acetylation, diazo ketone formation and deacetylation. Consistency in spectral data due to non-equivalent aromatic protons and methyls has also been observed in each step reaction product in the synthesis of **7** starting from the succinylated product **3** (*vide* Experimental). Aryl participation of the phenolic diazo ketone **8** was carried out in thoroughly dried nitromethane in presence of boron trifluoride etherate catalyst in an atmosphere of dry nitrogen at room temperature. Two products **1** and **9** were isolated by column chromatography from the crude reaction mixture. The formation of **9** during spiroannulation can be explained simply by SN_2 attack of ambident nitromethane on protonated[3] diazo ketone **8**.

Uneyama *et al.*[4] succinylated 3,5-dimethylanisole under almost identical conditions, but they reported the formation of the para-isomer, 4-(4-methoxy-2,6-dimethylbenzoyl) propanoic acid (**20**), mp 102—102.5 °C, and further converted it into **14**. Their claim for the above para products is untenable on the ground of non-equivalent aromatic protons and methyls shown in their NMR spectra. Moreover, we have synthesised the para-isomer **14** independently from authentic 3-(4-methoxy-2,6-dimethylphenyl) propanoic acid[5] (**12**) by the Arndt-Eistert reaction. The product gave a singlet (δ 2.28) for two aromatic methyls and a singlet (δ 6.46) for two aromatic protons in the NMR spectrum suggesting the para structure. The mp and NMR data reported by Uneyama *et al.* for the same compound **14** are different. Following exactly their method we also succinylated 3,5-dimethylanisole and obtained the same ortho acid **3** (undepressed mixed mp and identical NMR spectra). We presume that Uneyama *et al.* also obtained the ortho-isomer **3** by succinylation of 3,5-dimethylanisole but reported it as the para-isomer **20**.

Cyanoethylation of 3,5-dimethylanisole gave a mixture of propionitriles where the para-isomer **10** predominated. The hydroxy propanoic acid **11** was prepared from the crude propionitrile by refluxing with hydrobromic acid–acetic acid mixture and subsequent separation from the δ-lactone produced from the ortho-isomer. Methylation, homologation by the Arndt-Eistert method, demethylation, acetylation, diazo ketone formation, deacetylation and finally acid-catalysed Ar_1-6 participation starting from **11** afforded **2** and **19** (*vide* Experimental).

Experimental

Light petrol and petroleum refer to the fraction of bp 40—60 °C and 60—80 °C, respectively. NMR spectra were recorded with a Varian EM 390 instrument.

3-(2-Methoxy-4,6-dimethylbenzoyl)propanoic Acid (3). Friedel-Crafts reaction of 3,5-dimethylanisole (2.7 g) with succinic anhydride (2.1 g) and anhydrous aluminium chloride (5.6 g) in dry 1,1,2,2-tetrachloroethane (23 ml) and nitrobenzene (6 ml) at −5 °C for 3 days yielded **3** (3.9 g, 84%) as

colorless cubes, mp 101 °C (ethanol–water); IR(KBr) 1710—1695 cm^{-1}; NMR [$(CD_3)_2SO$] δ 2.08 (s, 3H), 2.25 (s, 3H), 2.48 (t, 2H), 2.93 (t, 2H), 3.72 (s, 3H), 6.61 (s, 1H), 6.71 (s, 1H). Found: C, 65.91; H, 6.90%. Calcd for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78%.

4-(2-Methoxy-4,6-dimethylphenyl)butanoic Acid (4). Clemmensen reduction of **3** (2.3 g) gave **4** (2 g, 90%) as colorless crystals, mp 99 °C (petroleum–benzene): IR(KBr) 1705 cm^{-1}; NMR($CDCl_3$) δ 1.74—1.96 (m, 2H), 2.26 (s, 3H), 2.28 (s, 3H), 2.40—2.76 (m, 4H), 3.76 (s, 3H), 6.54 (s, 1H), 6.61 (s, 1H). Found: C, 70.13; H, 7.94%. Calcd for $C_{13}H_{18}O_3$: C, 70.27; H, 8.11%.

4-(2-Hydroxy-4,6-dimethylphenyl)butanoic Acid (5). Demethylation of **4** (2.2 g) with pyridine hydrochloride (7 g) at 210 °C under dry nitrogen gave **5** (1.9 g, 90%) as colorless crystals, mp 130 °C (benzene) (lit,[2]) mp 130—132 °C): IR-(KBr) 3250, 1705 cm^{-1}; NMR ($CDCl_3$) δ 1.75—1.96 (m, 2H), 2.20 (s, 3H), 2.22 (s, 3H), 2.32—2.78 (m, 4H), 6.46 (s, 1H), 6.52 (s, 1H). Found: C, 69.37; H, 7.48%. Calcd for $C_{12}H_{16}O_3$: C, 69.23; H, 7.69%.

4-(2-Acetoxy-4,6-dimethylphenyl)butanoic Acid (6). Acetylation of the phenolic acid **5** with acetic anhydride in aqueous sodium hydroxide at −5 °C gave **6** (65%) as colorless crystals, mp 93 °C (petroleum–benzene): IR(KBr) 1750, 1705 cm^{-1}; NMR (CCl_4) δ 1.56—1.88 (m, 2H), 2.20 (s, 3H), 2.26 (s, 6H), 2.32—2.68 (m, 4H), 6.60 (s, 1H) 6.80 (s, 1H), 11.26 (s, 1H). Found: C, 66.97; H, 7.31%. Calcd for $C_{14}H_{18}O_4$: C, 67.20; H, 7.22%.

1-Diazo-5-(2-acetoxy-4,6-dimethylphenyl)-2-pentanone (7). Acid chloride was prepared from **6** by the oxalyl chloride method. It was transformed into **7** (80%) by diazomethane as a light yellow oil: IR(neat) 2110, 1750, 1630 cm^{-1}; NMR ($CDCl_3$) δ 1.64—1.92 (m, 2H), 2.20 (s, 3H), 2.28 (s, 6H), 2.32—2.70 (m, 4H), 5.24 (s, 1H), 6.60 (s, 1H), 6.80 (s, 1H).

1-Diazo-5-(2-hydroxy-4,6-dimethylphenyl)-2-pentanone (8). Deacetylation of **7** by Na_2CO_3–$NaHCO_3$ solution gave **8** (75%) as a pale yellow oil: IR (neat) 3300, 2110, 1620 cm^{-1}; NMR ($CDCl_3$) δ 1.70—1.98 (m, 2H), 2.26 (s, 6H), 2.34—2.70 (m, 4H), 5.30 (s, 1H), 6.56 (s, 2H).

3,5-Dimethylspiro[5.5]undeca-2,4-diene-1,8-dione (1). A mixture of **8** (500 mg) and BF_3–etherate (5 drops) in thoroughly dried nitromethane (40 ml) was stirred for 15 min at 20 °C to afford a red oil after the usual work-up. It was purified by column chromatography. Petroleum eluted **7** (85 mg) as semi-solid mass: UV (MeOH) 232 (log ε 4.31), 280 (log ε 3.52), 312 nm (log ε 4.28); IR ($CHCl_3$) 1710, 1660, 1620, 1575 cm^{-1}; NMR ($CDCl_3$) δ 1.70—2.04 (m, 2H), 2.22 (s, 6H), 2.62—2.96 (m, 4H), 4.40 (s, 2H), 6.78 (s, 2H). Benzene eluted **9** (130 mg) as colorless crystals, mp 95 °C (light petrol–ether): IR(KBr) 3350—3250, 1715, 1600 cm^{-1}; NMR ($CDCl_3$) δ 1.64—1.96 (m, 2H), 2.16 (s, 3H), 2.18 (s, 3H), 2.36—2.62 (m, 4H), 2.98 (t, 1H, J 5 Hz), 4.20 (d, 2H, J 5 Hz), 5.36 (s, 1H), 6.42 (s, 1H), 6.50 (s, 1H). Found: C, 70.41; H, 8.02%. Calcd for $C_{13}H_{18}O_3$: C, 70.27; H, 8.11%.

3-(4-Hydroxy-2,6-dimethylphenyl)propanoic Acid (11). Cyanoethylation of dimethylanisole with acrylonitrile in 1,1,2,2-tetrachloroethane by use of anhydrous $AlCl_3$ and dry HCl gas gave **10** (62%), contaminated with a trace of ortho-isomer. Reaction of crude propionitrile **10** with HOAc–HBr mixture gave **11** (68%) as colorless needles, mp 125 °C (benzene) (lit,[5] mp 126—127 °C): IR (Nujol) 3450, 1705 cm^{-1}; NMR ($CDCl_3$) δ 2.30 (s, 6H), 2.50 (t, 2H), 3.0 (t, 2H), 6.50 (s, 2H) 8.50 (s, 2H). Found: C, 67.75; H, 6.86%. Calcd for $C_{11}H_{14}O_3$: C, 68.04; H, 7.22%.

3-(4-Methoxy-2,6-dimethylphenyl)propanoic Acid (12). Methylation of **11** with $(CH_3)_2SO_4$ gave **12** (82%) as colorless needles, mp 95 °C (petroleum): NMR ($CDCl_3$) δ 2.30 (s, 6H), 2.50 (t, 2H), 3.0 (t, 2H), 3.80 (s, 3H), 6.50 (s, 2H), 11.50 (s, 1H). Found: C, 68.94; H, 7.46%. Calcd for $C_{12}H_{16}O_3$: C, 69.23; H, 7.69%.

4-(4-Methoxy-2,6-dimethylphenyl)butanoic Acid (14). Diazo ketone **13** was prepared from **12** and the crude product was treated with Ag_2O in methanol. After saponification of the intermediate ester, methoxy acid **14** (75%) was obtained as colorless crystals, mp 108 °C (petroleum–benzene): NMR (CCl_4) δ 1.62—1.90 (m, 2H), 2.28 (s, 6H), 2.37—2.68 (m, 4H), 3.68 (s, 3H), 6.46 (s, 2H), 11.54 (s, 1H). Found: C, 70.39; H, 7.99%. Calcd for $C_{13}H_{18}O_3$: C, 70.27; H, 8.11%.

4-(4-Hydroxy-2,6-dimethylphenyl)butanoic Acid (15). Demethylation of **14** gave **15** (90%) as colorless crystals, mp 125 °C (benzene): IR ($CHCl_3$) 3250, 1705 cm^{-1}; NMR ($CDCl_3$) δ 1.60—1.92 (m, 2H), 2.32 (s, 6H), 2.38—2.70 (m, 4H), 6.50 (s, 2H). Found: C, 69.10; H, 7.51%. Calcd for $C_{12}H_{16}O_3$: C, 69.23; H, 7.69%.

4-(4-Acetoxy-2,6-dimethylphenyl)butanoic Acid (16). Acetylation of **15** gave **16** (60%) as colorless crystals, mp 96 °C (petroleum–benzene): IR ($CHCl_3$) 1750, 1715 cm^{-1}; NMR ($CDCl_3$) δ 1.62—1.90 (m, 2H), 2.25 (s, 3H), 2.32 (s, 6H), 2.38—2.72 (m, 4H), 6.72 (s, 2H), 11.30 (s, 1H). Found: C, 66.91; H, 7.08%. Calcd for $C_{14}H_{18}O_4$: C, 67.20; H, 7.20%.

1-Diazo-5-(4-acetoxy-2,6-dimethylphenyl)-2-pentanone (17). Diazo ketone **17** (91%) was prepared from **16** following the usual procedure as a pale yellow oil: IR ($CHCl_3$) 2100, 1750, 1635 cm^{-1}; NMR ($CDCl_3$) δ 1.62—1.90 (m, 2H), 2.26 (s, 3H), 2.32 (s, 6H), 2.40—2.82 (m, 4H), 5.20 (s, 1H), 6.75 (s, 1H).

1-Diazo-5-(4-hydroxy-2,6-dimethylphenyl)-2-pentanone (18). Deacetylation of **17** afforded **18** (90%) as a light yellow oil: IR ($CHCl_3$) 3300, 2100, 1630 cm^{-1}; NMR ($CDCl_3$) δ 1.62—1.92 (m, 2H), 2.32 (s, 6H) 2.40—2.78 (m, 4H), 5.20 (s, 1H), 6.48 (s, 2H).

7,11-Dimethylspiro[5.5]undeca-7,10-diene-2,9-dione (2). Ar_1-6 participation of **18** (500 mg) with BF_3–etherate gave a red oil. Dienone **2** (90 mg) was obtained from benzene elute as colorless needles, mp 128 °C (light petrol–ether): UV (MeOH) 246 nm (logε 4.40); IR ($CHCl_3$) 1710, 1660, 1625 cm^{-1}; NMR ($CDCl_3$) δ 1.67—1.87 (m, 4H), 2.06 (s, 6H), 2.23—2.48 (m, 4H), 6.05 (s, 2H); MS (50 eV) 204 (M^+), 176 (M−CO), 161 (M−CH_2CO), 134 [M−(C_2H_4, CH_2CO)], 91 [M−(C_2H_4, CH_2CO, CO, CH_3)] (100%). Found: C, 76.29; H, 7.96%. Calcd for $C_{13}H_{16}O_2$: C, 76.47; H, 7.84%. The hydroxy ketone **19** (120 mg) was obtained from benzene–ethyl acetate elute as colorless crystals, mp 100 °C (ether–light petrol): IR ($CHCl_3$) 3340—3250, 1715, 1600 cm^{-1}; NMR ($CDCl_3$) δ 1.64—1.90 (m, 2H), 2.30 (s, 6H), 2.36—2.64 (m, 4H), 4.20 (d, 2H), 5.0 (t, 1H), 6.50 (s, 2H). Found: C, 70.06; H, 8.10%. Calcd for $C_{13}H_{18}O_3$: C, 70.27; H, 8.11%.

Empirical Formula for Mass Transfer across the Boundary between Convections in a Two-layer System

Katsuyoshi KAMAKURA

Department of Industrial Chemistry, Toyama Technical College, Hongo-cho, Toyama 930-11

(Received April 7, 1978)

When a two-layer system which consists of water (upper layer) and an aqueous solution (lower layer) is heated from one side and cooled from the opposite side, a convection starts in each layer and a sharp horizontal boundary is formed by the two flows in opposite directions. The empirical formula for the transfer of a solute across the boundary was obtained by measuring the change in the concentration of a solute in the upper layer. The flux, W_A, of a solute, A, was expressed by

$$W_A = a_3(\Delta\rho_1 - \Delta\rho_0)D^{0.5}(\Delta c_I/\Delta\rho_2).$$

Here, a_3 is the mass-transfer coefficient; $\Delta\rho_1$, the density difference between the liquid on the heated wall and that on the cooled wall; $\Delta\rho_0$, the value of $\Delta\rho_1$ at which the convections start; D, the diffusion coefficient of a solute; and Δc_I and $\Delta\rho_2$, the concentration difference and the density difference, respectively, between the solution of the upper layer and that of the lower layer.

When a two-layer system which consists of water (A) and an aqueous solution (B) is heated from one side and cooled from the opposite side, the liquid adjacent to the hot vertical surface moves upward, while that adjacent to the cool vertical surface moves downward. A convection starts in each layer, and a sharp horizontal boundary is formed by the two flows in opposite directions, as is shown in Fig. 1. Two papers[1,2] have been published on this phenomenon, but no attempts have been made to estimate the rate of transfer of a solute across the boundary. This paper will describe the empirical formula of mass transfer in our model.

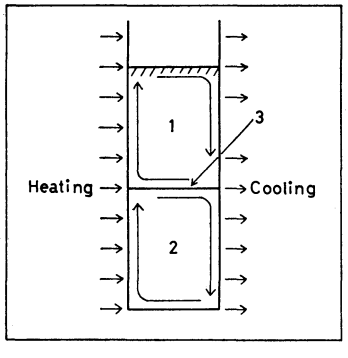

Fig. 1. Schematic illustration of the convections in two-layer system.
1: Upper layer (water), 2: lower layer (aqueous solution), 3: boundary.

Experimental

Materials. All the chemicals were reagent grade and were used without further purification. The sodium chloride was dried at 280 °C for 1 h, the copper sulfate and sucrose were used without drying, and the other salts were dried at 105—110 °C for 5 h.

Apparatus and Method. Figure 2 shows the apparatus used for measuring convections in the two-layer system; it is made of 200×50×3 mm glass plates joined by the use of epoxide resin as adhesive. Two glass rods, 3 mm in diameter and 50 mm in length, were fixed on both sides at a distance of 7 cm above the bottom in order to make the flows of the convections stable.

Water (63 cm³) was gradually poured over an aqueous solution (63 cm³) previously placed in the vessel at the flow speed of 2 cm³/min by the use of a micropump; the two-layer system was thus made. The temperature of the circulating water used for heating or cooling the wall was kept constant within ±0.05 °C.

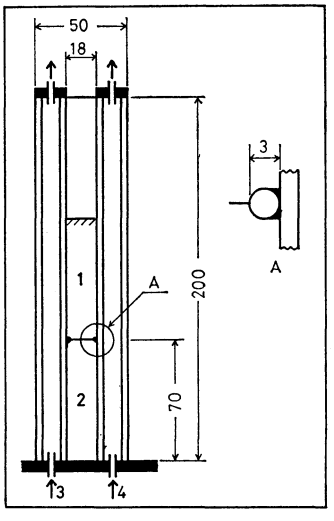

Fig. 2. Apparatus for measuring convections in two-layer system.
1: Upper layer, 2: lower layer, 3: hot water, 4: cold water.

The concentration of electrolytes was determined by the electric-conductance method. The conductance was measured with a conductometer (Toa Electronics CM-6A) equipped with electrodes formed of platinized platinum wires which were sealed at one end of a glass tube 6 mm in diameter. The electrodes were placed in the middle of the upper layer.

The concentration of sucrose was determined by colorimetry as reported by Dubois *et al.*[3] The samples (50 mm³) for the determination of the solute concentration were taken out from the solution in the middle of an upper layer.

Results and Discussion

Phenomenon of Mass Transfer. In a previous paper[2] it was shown that the concentration in each layer is uniform. Therefore, the rate of mass transfer across the boundary can be calculated from the incre-

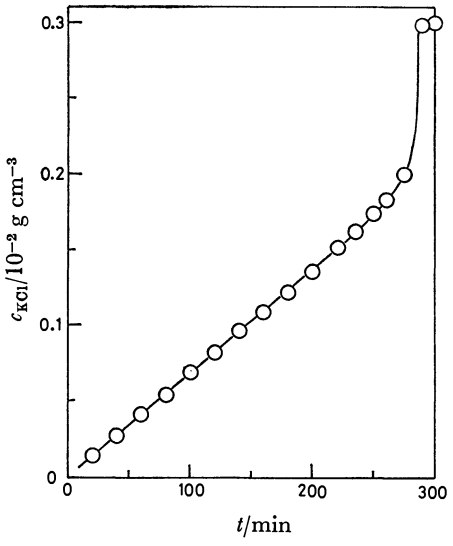

Fig. 3. Variation of the concn c_{KCl} in the upper layer with time t.
Concn of the lower layer at the start of the convections: 0.6 g/(100 cm^3), temps of heating and cooling water: 36 and 26 °C.

ment in the concentration of a solute in the upper la er. Figure 3 shows the variation in the concentration of a solute in the upper layer with the lapse of time. Within ten minutes from the beginning of the convections, each convection becomes a steady current; then the concentration in the upper layer increases linearly with the time. When the time has elapsed, the concentration difference between the two layers becomes small and the boundary unstable. Then, the boundary is destroyed and the two-layer system changes into a one-layer system. The flux (g cm^{-2} min^{-1}), W_A, of a solute, A, across the boundary was calculated by means of

$$W_A = \frac{V}{100S}\frac{\Delta c_A}{\Delta t}. \quad (1)$$

Here, c_A, S, t, and V are the concentration {g/(100 cm^3)} of a solute, A, in the upper layer, the area (cm^2) of the boundary, the time (min), and the volume (cm^3) of the upper layer, respectively.

Figure 4 shows the relation between W_{KCl} and the concentration in the lower layer at the start of the convections. It can be seen that W_{KCl} is independent of the concentration difference.

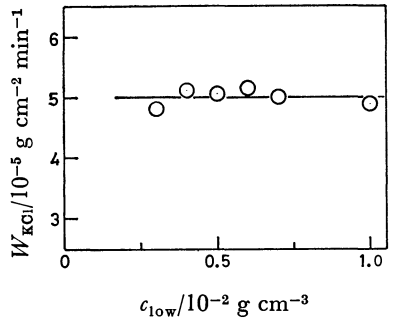

Fig. 4. Relation between W_{KCl} and concn c_{low} of KCl in the lower layer at the start of the convections.
Temps of heating and cooling water: 30 and 20 °C.

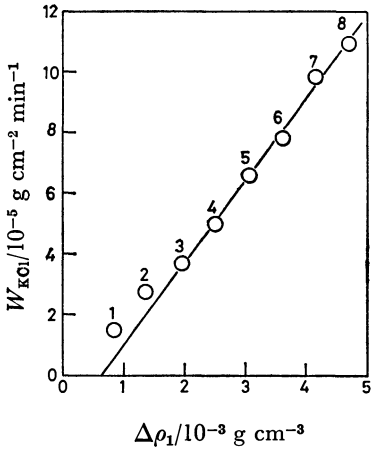

Fig. 5. Dependence of the flux W_{KCl} on the density difference $\Delta\rho_1$ between the liquids on the heated and the cooled wall.
Concns in the lower layer at the start of convections: 0.2—1.0 g/(100 cm^3).
Temps of heating and cooling water—1: 29 and 26 °C, 2: 30 and 25 °C, 3: 31 and 24 °C, 4: 32 and 23 °C, 5: 33 and 22 °C, 6: 34 and 21 °C, 7: 35 and 20 °C, 8: 36 and 19 °C.

Effect of Density Difference Caused by the Temperature. Figure 5 shows the dependence of W_{KCl} on the density difference, $\Delta\rho_1$, between the liquid on the heated wall and that on the cooled wall. This plot shows a straight line except for small values of the density difference. The value of $\Delta\rho_0 = 0.63 \times 10^{-3}$ g cm^{-3} was obtained by extrapolation of the linear portion of the plot to $W_{KCl} \to 0$. The convections in our two-layer system can be considered to occur above this value of $\Delta\rho_0$. Therefore, the following equation can be obtained:

$$W_A = a_1(\Delta\rho_1 - \Delta\rho_0). \quad (2)$$

Here, a_1 is the mass-transfer coefficient.

Effect of the Kind of Solute. The values of W_A may depend on the kind of solute through a variety of factors: (1) the diffusion coefficient of the solute; (2) the density difference between the liquid in the upper layer and that in the lower layer; and (3) the viscosity of the fluid. However, the rate of mass transfer may be expected to be practically unaffected by the viscosity, because this experiment was performed in dilute solutions. Therefore, the results were discussed from the viewpoints of the diffusion coefficient, D (cm^2 s^{-1}), and the density difference, $\Delta\rho_2$ (g cm^{-3}). The rate of mass transfer may be proportional to the x-th power of D with $0 \leqq x \leqq 1$, because the solute is transported across the boundary by eddy or by molecular diffusion.[4] The concentration difference, Δc_I {g/(100 cm^3)}, should be a driving force for this mass transfer. However, it has already been described that W_A is independent of Δc_I. Δc_I is proportional to $\Delta\rho_2$, so that the $\Delta c_I/\Delta\rho_2$ ratio should be constant for a given solute. Therefore, it is likely that W_A is proportional to $\Delta c_I/\Delta\rho_2$, and that, thus:

$$W_A = a_2 D^x \frac{\Delta c_I}{\Delta\rho_2}. \quad (3)$$

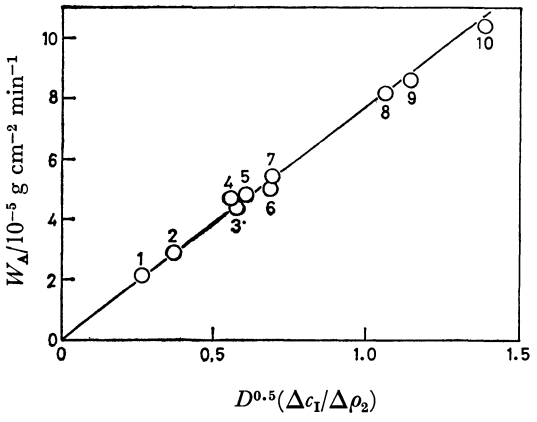

Fig. 6. Relation between W_A and $D^{0.5}(\Delta c_I/\Delta\rho_2)$.
Temps of heating and cooling water: 30 and 20 °C.
Solutes—1: $CuSO_4$, 2: Na_2SO_4, 3: CsCl, 4: NaCl, 5: sucrose, 6: KCl, 7: KNO_3, 8: NH_4NO_3, 9: HCl, 10: NH_4Cl.

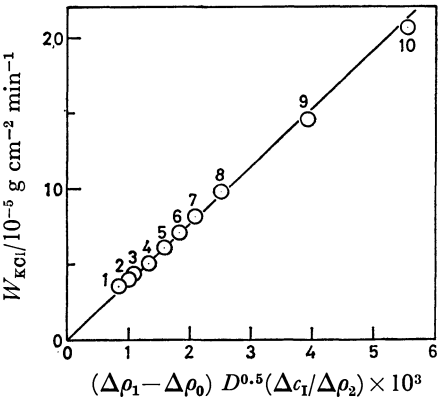

Fig. 7. Relation between W_{KCl} and $(\Delta\rho_1-\Delta\rho_0)D^{0.5}\cdot(\Delta c_I/\Delta\rho_2)$.
Concn in the lower layer at the start of convections: 0.25—1.00 g/(100 cm^3).
Temps of heating and cooling water—1: 24 and 14 °C, 2: 16 and 26 °C, 3: 27 and 17 °C, 4: 30 and 20 °C, 5: 23 and 33 °C, 6: 26 and 36 °C, 7: 29 and 39 °C, 8: 20 and 35 °C, 9: 20 and 40 °C, 10: 20 and 45 °C.

Here, a_2 is the mass-transfer coefficient. The value of $\Delta c_I/\Delta\rho_2$ was calculated approximately from

$$\frac{\Delta c_I}{\Delta\rho_2}=\left(\frac{\Delta\rho_2}{\Delta c_I}\right)^{-1}\approx((d_4^t)_s-(d_4^t)_w)^{-1}, \tag{4}$$

where $(d_4^t)_s$ is the specific gravity of the solution of 1 wt %, $(d_4^t)_w$ that of water, and t the mean temperature in the upper layer. For a number of solutes we measured W_A and made a plot of log $\{W_A/(\Delta c_I/\Delta\rho_2)\}$ *vs.* log D, from the slope of which we obtained $x=0.5$. Thus, W_A was found to be proportional to $D^{0.5}(\Delta c_I/\Delta\rho_2)$, as be shown in Fig. 6.

Empirical Formula for Mass-transfer Rate. Combining Eq. 2 with Eq. 3 yields the following final expression for W_A:

$$W_A=a_3(\Delta\rho_1-\Delta\rho_0)D^{0.5}\frac{\Delta c_I}{\Delta\rho_2}. \tag{5}$$

Here, a_3 is the mass-transfer coefficient. Figure 7 shows the plot of W_{KCl} *vs.* $(\Delta\rho_1-\Delta\rho_0)D^{0.5}(\Delta c_I/\Delta\rho_2)$ at different pairs of temperatures. This plot is linear except for the points obtained at low temperatures.

Vibrational Spectra and Rotational Isomerism of Isopropyl Methyl Selenide and Diisopropyl Selenide

Keiichi OHNO,* Akitoshi MITSUI, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received November 8, 1978)

The infrared and Raman spectra of isopropyl methyl selenide and diisopropyl selenide were measured for the liquid and solid states. The fundamental vibrations were assigned and the rotational isomerism was studied on the basis of the spectral observations and the normal coordinate treatment. For isopropyl methyl selenide, the C_1 and C_s forms coexisted in the liquid state and the enthalpy difference between them was obtained as $\Delta H(C_1-C_s)=-0.52\pm0.05$ kcal mol^{-1}. For diisopropyl selenide, it was presumed that only the C_2 form persisted in the solid state while the C_2, C_s, and C_1 forms coexisted in the liquid state, the C_2 form being the most stable.

The vibrational spectra of unbranched dialkyl ethers and sulfides have been studied extensively in relation to the rotational isomerism.[1] Recently, we have reported the existence of the rotational isomers about the C–Se axis[2] and the correlations of the C–Se stretching wave numbers to the molecular conformations.[3] Among the most simple molecules with the C–Y (Y= O, S, and Se) internal rotation axis, the T form is more stable than the G form for ethyl methyl ether,[4] but the reverse is true for ethyl methyl sulfide[5] and selenide.[2,6] Therefore, we have taken an interest in studying these molecules, in which the hydrogen of the methylene group is replaced by a methyl group, in order to obtain information on the stability of the molecular conformations. The studies for isopropyl methyl ether[7] and sulfide[8] have already been reported. In this paper, we will deal in detail with the molecular vibrations and rotational isomerism of isopropyl methyl selenide and diisopropyl selenide by treating their normal coordinates.

Experimental

The samples were prepared by the treatment of alkylhalides with selenium[9] and were purified by fractional distillation. The purities of the samples were checked by means of NMR and gas chromatography.

The Raman spectra in the region below 4000 cm^{-1} were recorded on a JEOL spectrophotometer (Model JRS 400D) with a Coherent Radiation CR-2 argon-ion laser. The Raman spectra were measured for the liquid state at various temperatures and for the solid state at liquid nitrogen temperature. For the determination of the enthalpy difference between isomers, the integrated intensities of the Raman lines were measured in the liquid state; each experiment was repeated several times after attaining a constant temperature. The infrared spectra in the 300—4000 cm^{-1} region were recorded on a Perkin-Elmer spectrophotometer (Model 621). The solid state was obtained by depositing vapor of the sample onto a CsI window cooled with liquid nitrogen and annealing it repeatedly.

Results and Discussion

Normal Coordinate Treatment. For isopropyl methyl selenide, the existence of the rotational isomers has already been reported[2] and the molecular forms have been determined from the calculation of the skeletal vibrations.[3] Thus, the normal vibrations were calculated in order to obtain a reasonable set of the force constants for the branched dialkyl selenide and information on the molecular forms and the vibrational assignment of diisopropyl selenide. The Urey-Bradley force field was used in the calculation. The structural parameters used were the same as those reported previously.[3] The force constants were initially transferred from those of isopropyltrichlorosilane[10] and dimethyl selenide[11] and some of them were adjusted by the least-squares method to reproduce better the observed wave numbers of isopropyl methyl selenide. The force constants obtained were then transferred to those of diisopropyl selenide. The accuracy of the calculation was good enough for analyzing the observed spectra. The observed and calculated wave numbers are given in Tables 1 and 2, together with the assignment based on the predominant potential energy distributions. The force constants used are listed in Table 3.

Vibrational Assignment. Figures 1—4 show the infrared and Raman spectra of isopropyl methyl selenide and diisopropyl selenide in the region below 1500 cm^{-1}. The observed wave numbers above 800 cm^{-1} resemble very closely those of the corresponding sulfides. In the region below 800 cm^{-1}, only the C–Se stretching, skeletal deformation, and torsional vibrations are expected. Therefore, the fundamental vibrations are easily assigned by comparing the spectra with those of the sulfides and the relative intensities between the infrared bands and the Raman lines. Table 4 lists the isopropyl group vibrations of the selenides, together with those of the corresponding ethers[7] and sulfides.[8] It is noteworthy that the wave numbers of the isopropyl group vibrations of isopropyl methyl selenide are nearly

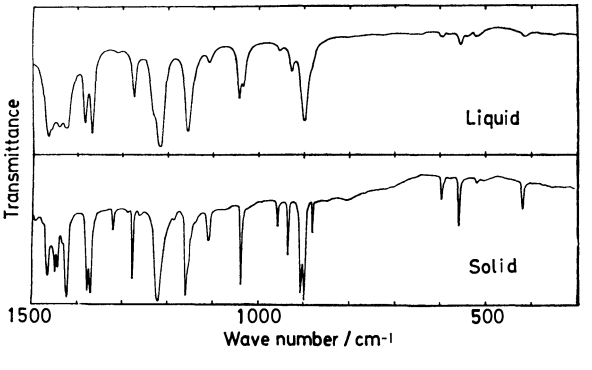

Fig. 1. Infrared spectra of isopropyl methyl selenide in the liquid and solid states in the 300—1500 cm^{-1} region.

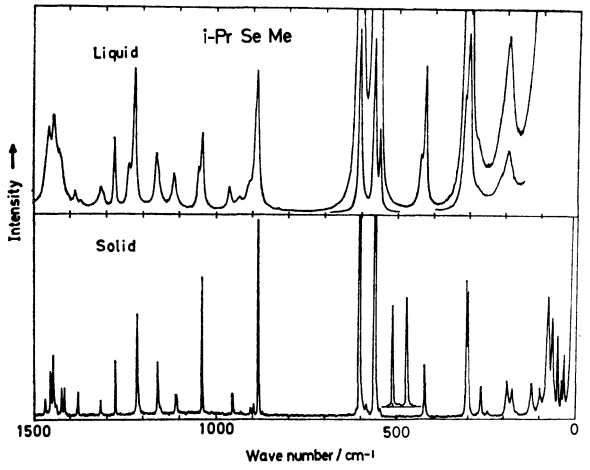

Fig. 2. Raman spectra of isopropyl methyl selenide in the liquid and solid states in the region below 1500 cm^{-1}.

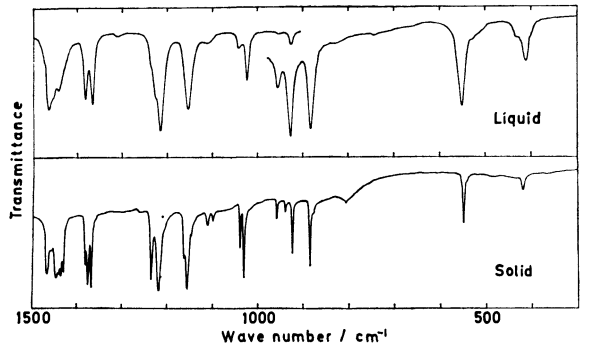

Fig. 3. Infrared spectra of diisopropyl selenide in the liquid and solid states in the 300—1500 cm^{-1} region.

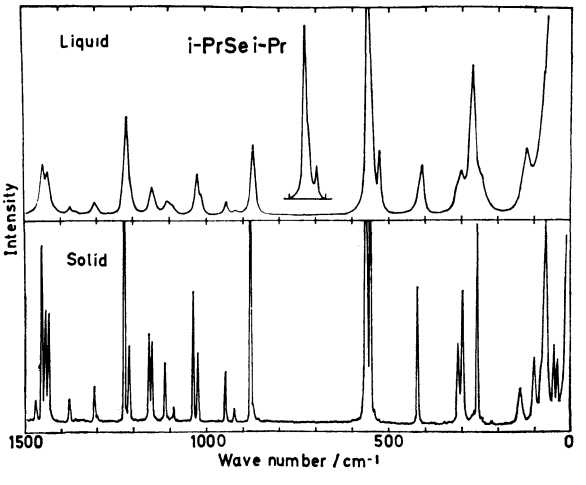

Fig. 4. Raman spectra of diisopropyl selenide in the liquid and solid states in the region below 1500 cm^{-1}.

the same as those of diisopropyl selenide and those of the sulfides.

Rotational Isomers. Isopropyl methyl selenide has one C–Se axis and has two possible rotational isomers, with the C_1 or C_s symmetry (the C_1 and C_s forms). Useful information on the rotational isomers has been obtained from the C–Se stretching vibrations. For isopropyl methyl selenide, the very intense Raman lines at 557 and 597 cm^{-1} in the solid state were assigned to the C–Se stretching vibrations of one isomer. The Raman line at 539 cm^{-1} in the liquid state was assigned to the C–Se stretching vibration of the other isomer. It has been reported[2] from the calculation of the skeletal vibrations that the Raman lines at 557 and 597 cm^{-1} can be assigned to the CH–Se and CH_3–Se stretching vibrations, respectively, of the C_1 form and the Raman lines at 539 and 597 cm^{-1} to those of the C_s form. This conclusion is also confirmed from the present normal coordinate treatment.

Diisopropyl selenide has two C–Se axes and has four possible isomers with the C_{2v}, C_2, C_s, or C_1 symmetry (the C_{2v}, C_2, C_s, and C_1 forms). All the fundamental vibrations for these molecular forms are infrared and Raman active, except for the vibrations of the A_2 species of the C_{2v} symmetry which are infrared inactive. For diisopropyl selenide, information of the rotational isomers is obtained only from the C–Se stretching and skeletal deformation vibrations. The comparison of the observed wave numbers with the calculated ones indicates that the Raman lines at 555 and 529 cm^{-1} are to be assigned to the CH–Se stretching vibration of the C_2 and C_s forms and the C_1 and C_{2v} forms, respectively. In the solid state, the former line persists but the latter disappears. However, the molecular form persisting in the solid state cannot be determined from the calculation, because the C_2 and C_s forms have nearly the same calculated wave numbers, as in the case of diisopropyl sulfide.[12] For diisopropyl selenide, the magnitude of the H···H nonbonded repulsion between the methyl groups is in the order: the C_{2v} form>the C_1 form$\gtrsim$the C_s form>the C_2 form. On the assumption that the stability of the molecular forms is mainly due to the nonbonded repulsion, it is expected that only the C_2 form persists in the solid state and that the C_2, C_s, and C_1 forms coexist in the liquid state. However, the existence of the C_{2v} form is unlikely, because the GG′ form, with the large H···H nonbonded repulsion between the methyl groups, has not been reported to exist for diethyl ether,[1] diethyl sulfide,[1] or diethyl selenide.[6]

Enthalpy Difference between Isomers. The enthalpy difference can be determined from the intensity ratios of the Raman lines belonging to different isomers. The relative intensities of the Raman lines assigned to the CH–Se stretching vibration were measured in the liquid

state at different temperatures. For isopropyl methyl selenide, Fig. 5 gives the intensity ratio of the Raman line at 555 cm^{-1} (the C_1 form) to that at 539 cm^{-1} (the C_s form). From the slope of the straight line of $\ln(I_{555}/I_{539})_c$ *vs.* $1/T$, the enthalpy difference $\Delta H(C_1-C_s)$ was obtained as -0.52 ± 0.05 kcal mol^{-1}.

For diisopropyl selenide, the relative intensity of the Raman line at 555 cm^{-1} belonging to the C_2 and/or C_s forms increases with decreasing temperature, as compared with that of the Raman line at 529 cm^{-1} belonging to the C_1 form. Therefore, for these compounds the molecular form with more C_1 conformations of the isopropyl parts is more stable than the others.

Stability of Molecular Conformation. For isopropyl methyl selenide, the C_1 form is found to be more stable than the C_s form by 0.52 ± 0.05 kcal mol^{-1} in the liquid

liquid state[6]).

The above results indicate that for isopropyl methyl sulfide and selenide the C_1 form with fewer methyl-methyl *gauche*-dispositions is more stable than the C_s form with more methyl-methyl *gauche*-dispositions, although for ethyl methyl sulfide and selenide the conformation with the methyl-methyl *gauche*-disposition (the G form) is more stable than the other (the T form). This inconsistency suggests the following. The H···H nonbonded repulsion between the methyl groups may affect the stability of the molecular forms and so the dihedral angles for the *gauche* $CH_3CH_2YCH_3$-type molecules (Y=O, S, and Se) and the C_1 form of the $(CH_3)_2CHYCH_3$-type molecules would be slightly larger than the 60° of the original *gauche* position. The C_s form of the $(CH_3)_2CHYCH_3$-type molecules (Y=O, S, and Se) inevitably has the dihedral angle of 60°. Therefore, the C_1 form may be more stable than the C_s form because of the H···H nonbonded repulsion. For ethyl methyl ether and isopropyl methyl ether with the shorter C–O bond length, the stability of the molecular forms can be interpreted in terms of the larger H···H nonbonded repulsion between the methyl groups.

Recently, Oyanagi and Kuchitsu[13] have reported from an electron diffraction study that the G form of ethyl methyl ether has the dihedral angle of 84±6°, far away from the original *gauche* position, and that the G form of ethyl methyl sulfide has an angle of 66±9°. For the *gauche* $CH_3CH_2YCH_3$-type molecules (Y=O, S, and Se), the nearest H···H nonbonded distances between the methyl groups were calculated by using the structural parameters determined by the electron diffraction study, where the values of ethyl methyl selenide were assumed to be the same as those of ethyl methyl sulfide, except for the C–Se bond of 1.943 Å and the CSeC valence angle of 96° 11′. The dihedral angle ϕ used in the calculation was taken as 60°, the original *gauche* position, and the values determined by the electron diffraction study. The H···H distance calculated is 1.74 Å (ϕ=60°) and 2.09 Å (ϕ=85°) for ethyl methyl ether, 1.95 Å (ϕ=60°) and 2.03 Å (ϕ=66°) for ethyl methyl sulfide, and 2.09 Å (ϕ=60°) and 2.17 Å (ϕ=66°) for ethyl methyl selenide. Therefore, the H···H nonbonded repulsion may rapidly decrease with increasing values of the dihedral angle under a potential such as the Lennard-Jones type. On the other hand, trithia[5]heterohelicene has been shown to have a spiral configuration because of the steric repulsion between the terminal atoms by the X-ray study.[14] The nearest H···H nonbonded distance of the terminal rings has been reported to be 2.15 Å. It should be noted that the nearest H···H nonbonded distance is in the range of about 2.03 to 2.15 Å for ethyl methyl ether with the dihedral angle of 85°, ethyl methyl sulfide with the dihedral angle of 66°, and trithia[5]heterohelicene.

The authors wish to express their thanks to Dr. Hiroatsu Matsuura for his valuable discussion.

Interaction of Excited Lithium Atom with Molecular Hydrogen. I. Preliminary Potential Energy Surfaces in an OVC MCSCF Approximation

Kimiko MIZUTANI,* Yoshihiro KURIBARA, Kazuko HAYASHI, and Shiro MATSUMOTO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received November 16, 1978)

Potential energy surfaces were computed for the Li–H_2 system of C_{2v} symmetry, which dissociates to a normal hydrogen molecule and a lithium atom either in its ground state or in the ^2P excited state, in order to get an idea of the quenching process of the atom by the molecule. The potential surfaces crossed in a line and two shallow minima appeared on the $^2B_2$ surface. Natural orbital analysis and electron density maps gave information on the charge transfer character of the interaction of the excited atom with the molecule.

Quenching of excited atoms by diatomics is of interest as a prototype of elementary processes involving crossovers between adiabatic potential energy surfaces, *e. g.*, the processes involving the conversion of electronic excitation energies to those of chemical bonds. The present work was undertaken with the view that detailed understanding of the representative case would be an essential step in the clarification of these attractive molecular phenomena.

Bauer and his coworkers[1] published detailed calculations of the quenching process. They described a scheme which could be adjusted to yield results in substantial agreement with experiments in certain important aspects; the gross features of the scheme appeared reasonable from general theoretical points of view. The method they used to construct potential curves, though, involved many arbitrary and *ad hoc* assumptions.

Krauss[2] seems to be the first who undertook to calculate directly the potential curves for the simplest system of the class —Li–H_2. His results contained many important conclusions about the features of the system, which are in agreement with those of the present more comprehensive calculations. A few published[3] and unpublished[4] calculations have been performed for the system since then. Unfortunately, although they used elaborate extended bases and configurational interactions, they were restricted to special geometries of the system. The general description of the processes which occur in the electronic environment when the components come to interact seems, as far as we know, to be undocumented to date.

MCSCF calculations using OVC approximation[5] seem to be one of the reliable means to compute at least qualitatively the electronic structures of simpler systems, when the nuclear geometry is varied. As is well known, however, MCSCF calculations often suffer convergence difficulties, especially when the geometry changes greatly. A number of procedures[6] have been reported to overcome these difficulties. Some earlier calculations in this work were done by a method of direct minimization of the energy functional,[6a] which showed excellent stabilities toward iterations. The convergence of the method was rather slow, however, and most of the later calculations were performed using the coupling operator method proposed by Hirao and Nakatsuji[7] and Carbo,[8] into which quadratic convergency was incorporated.

The present paper reports the preliminary potential energy surfaces of the lowest $^2A_1$ and $^2B_2$ states of the Li–H_2 system in the C_{2v} symmetry. These states seem to be appropriate in describing the quenching process of Li(^2P) by H_2. Some features of the electronic structure of the system at several representative points on the surfaces are given also. The surfaces cross in a line; somewhere around this crossing, non-adiabatic transitions will occur as the result of perturbations. Two shallow minima appear on the $^2B_2$ surface, which may lead to exciplex formation.

Preliminary calculations showed that the potential energy surfaces of two linearly arranged Li–H_2 systems, which correlated to the isolated Li(^2S)+H_2 and to the isolated Li(^2P)+H_2, did cross as in the case of C_{2v} geometry. The lowest point of the crosssection, however, had a much higher (*ca.* 50 kcal/mol) energy than the point for the isolated Li(^2P)+H_2 system. A process *via* such arrangements seems to be inefficient in the quenching of Li(^2P) compared with the process presented above (activation energy≈4 kcal/mol). The results for linear geometry and for the general C_s geometries will be reported later, together with more detailed calculations near the crossing region using extended basis sets.

Method of Calculation

Geometry was restricted to the C_{2v} symmetry shown in Fig. 1. The bases were minimal STO-3G functions, as suggested by Pople *et al.*[9] and full CI was

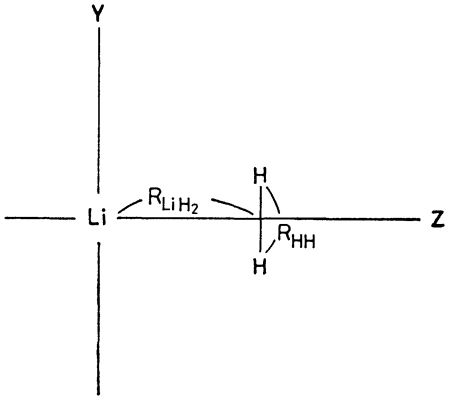

Fig. 1. Geometry of the system.

taken into account.

We take the OVC approximation[5] and express the electronic wavefunction Ψ as a linear combination of configurational wavefunctions differing only in the way the valence electrons occupy the molecular orbitals (MO):

$$\Psi = \sum_i A_i \Psi_{p_i r_i q_i}.$$

Of the five electrons of the system, two are assumed to occupy the core orbital and the remaining three are taken as valence electrons. In Ψ_{prq}, these electrons occupy p, r, and q valence orbitals with α, β, and α spin, respectively. When either p or q coincides with r, there is only one way of constructing a doublet configuration state function (CSF). If this is not the case, there arise two independent doublet CSF's of the same electronic configuration, and their forms are assumed to be

$$\Psi^{(1)}_{prq} = (D_{prq}+D_{rpq})/\sqrt{2}$$
$$\Psi^{(2)}_{prq} = (D_{prq}-D_{rpq}+2D_{pqr})/\sqrt{6},$$

where D_{prq} is the Slater determinant $(5!)^{-1/2}\,|\phi_1(1)\phi_{\bar{1}}(2)\phi_p(3)\phi_{\bar{r}}(4)\phi_q(5)|$. The energy expression for the OVC wave function is written:

$$E=\sum_{m,n}(h_{mn}+H^{core}_{mn})D^{core}_{mn}+\sum_{m,n}^{val.}\sum_{p,q}(C^{pq}h_{mn}+H^{pq}_{mn})b^p_m b^q_n,$$

where b^p_m are the expansion coefficients of the p-th orbital, h_{mn} are the matrix elements of the bare-nucleus Hamiltonian, and D^{core}_{mn} are the elements of the core density matrix $\sum_r^{core} b^r_m b^r_n$. H^{core}_{mn} and H^{pq}_{mn} are defined as

$$H^{core}_{mn} = h_{mn} + \sum_{k,l}\{D^{core}_{kl}+\sum_{p,q}^{val.} C^{pq}b^p_k b^q_l\}(2J_{mnkl}-K_{mnkl}),$$
$$H^{pq}_{mn} = C^{pq}\{h_{mn}+\sum_{k,l}D^{core}_{kl}(2J_{mnkl}-K_{mnkl})\} + \sum_{k,l}\sum_{r,s}^{val.} R^{pq}_{rs}b^r_k b^s_l J_{mnkl},$$

where J_{mnkl} and K_{mnkl} are the coulombic and the exchange repulsion integrals. C^{pq} and R^{pq}_{rs} are the coefficients of averaged occupancies of valence orbitals and have similar meanings to the terms $P^{(s)AO}_{1AB}$ and $P^{(s)AO}_{2ABCD}$ of Ref. 6a. In this special case, they are written as

$$R^{pq}_{rs} = 2\{\sum_{t(\neq r,s)} A_{tpr}A_{tqs}+\sum_{t(\neq p,q)} A_{prt}A_{qst}+\sum_t A_{ptr}A_{qts}\},$$
$$C^{pq} = \sum_t^{val.} R^{tt}_{pq}/2,$$

where A_{prq} are the expansion coefficients in $\Psi = \sum_{p,r,q} A_{prq}D_{prq}$. According to the formulation of Carbo,[8] every molecular orbital wavefunction ϕ^p is an eigenfunction of a coupling operator $\mathbf{R}$.

$$\mathbf{R}|\phi^p\rangle = |\phi^p\rangle\varepsilon^p \qquad (1)$$

When approximate orbital functions given by the last iteration are used as a temporary basis, the matrix elements of $\mathbf{R}$ are given as follows. For diagonal elements:

$$R_{rr} = \sum_i b^r_i F^r_i + \beta_r, \quad R_{vv} = \sum_{i,j} b^v_i H^{occ}_{ij} b^v_j + \beta_v$$

and for non-diagonal elements:

$$R_{rs} = \lambda_{rs}\sum_i (b^r_i F^s_i - b^s_i F^r_i), \quad R_{vr} = \sum_i b^v_i F^r_i,$$

$$R_{vv'} = \sum_{i,j} b^v_i H^{occ}_{ij} b^{v'}_j,$$

where $F^r_i = \sum_{s,j} H^{rs}_{ij} b^s_j$ (r,s: valence), $F^r_i = \sum_j H^{core}_{ij} b^r_j$ (r: core), and $\mathbf{H}^{occ} = 1/2\sum_{p,q}^{occ}(\mathbf{H}^{pq}+\mathbf{H}^{qp})$. Superfixes r and s refer to occupied orbitals and v and v' refer to vacant orbitals. The value β_p is the level shift given to the MO p. The absolute values of the nondiagonal matrix element λ_{rs} were usually taken to be unity. At later stage of iteration using Eq. 1 alone, the convergence was often slow, and quadratic convergency was incorporated into the computing program along with the Newton-Raphson procedure, as done by Hunt, Goddard, and Dunning.[10] The resultant formulation appears to be similar to that given by Hinze.[6b]

Results and Discussion

Potential Energy Surface. The computed energies of the ground state ($^2A_1$) and the first excited state ($^2B_2$) are shown in the contour maps of Figs. 2 and 3, respectively, as functions of two distances R_{HH} and R_{LiH_2}. The first state dissociates to a normal lithium

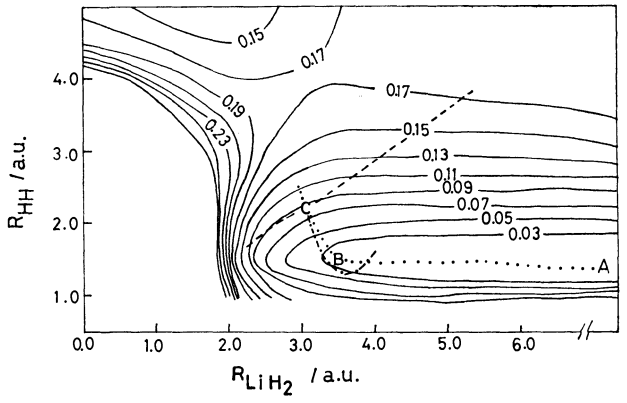

Fig. 2. Potential energy surface for $^2A_1$ ground state. R_{LiH_2} is the distance in bohrs from the Li nucleous to the midpoint of the line connecting the two hydrogens. R_{HH} is the distance between the hydrogens. The figures beside contours are energies in hartrees minus −8.47.

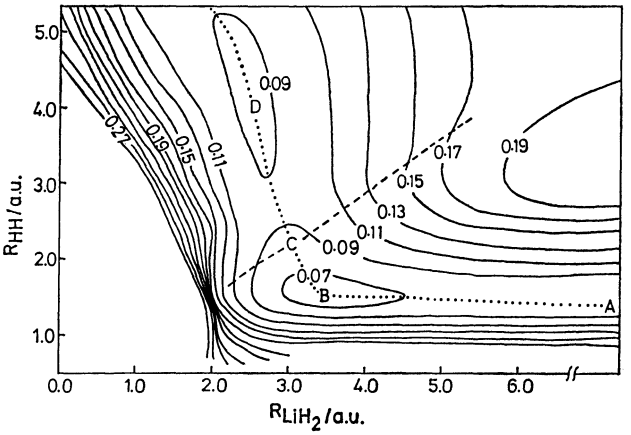

Fig. 3. Potential energy surface for the lowest $^2B_2$ state. The figures beside contours are energies in hartrees minus −8.47.

atom and a hydrogen molecule, while the latter is seen to dissociate to an excited lithium (^2P) atom and a hydrogen molecule in the ground state. The energy surface of the $^2B_2$ state is seen to have two minima, one at $R_{LiH_2}\approx3.5$ a.u., $R_{HH}\approx1.5$ a.u., and the other at $R_{LiH_2}\approx2.5$ a.u., $R_{HH}\approx4.0$ (a.u.). The calculated depth of the former was 9.5 kcal/mol, with respect to the isolated system of Li(^2P) and H_2 ($^1\Sigma_g$). The bottom of the latter was calculated to lie 6.2 kcal/mol above the isolated system, and to be separated by some potential barrier (see below). These minima might correspond to exciplexes, if any exist, between an excited Li atom and a hydrogen molecule. The general appearance of the $^2A_1$ surfaces is similar to that of the $^2B_2$ surface, but no minima appear in the lower-right valley, and the surface in Fig. 2 is more steeply ascending toward the upper-left region than is the $^2B_2$ surface in Fig. 3. The two potential surfaces intersect in a curve, which is shown by broken lines in Figs. 2 and 3.

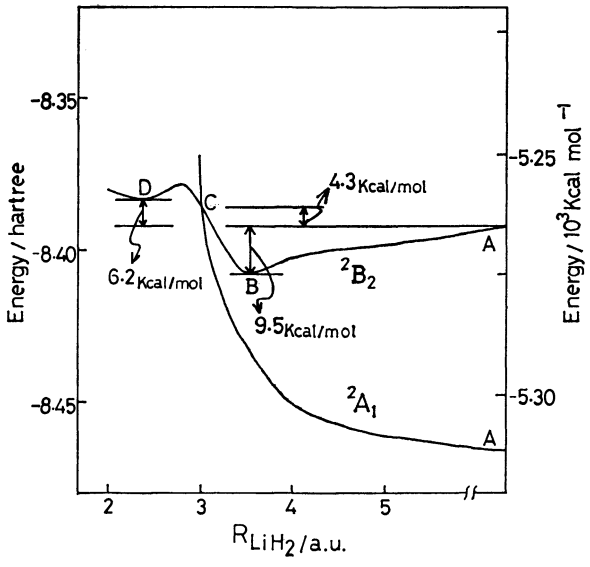

Fig. 4. Energies along minimum energy path.

On these potential surfaces, we might picture the quenching process of excited lithium atoms by hydrogen molecules through geometries close to C_{2v}. Starting from point A in Fig. 3, the path of energetically most favorable approach, *i.e.* the path of quasi-static approach, is shown by the dotted lines in Figs. 2 and 3, and the change of energy along the path is shown schematically in Fig. 4.** The crossing point of $^2A_1$ and $^2B_2$ curves in Fig. 4 is the point of lowest energy on the broken line of Fig. 3. The geometry was found to be $R_{HH}\approx3.0$ a.u. and $R_{LiH_2}\approx2.2$ (a.u.). Activation energy was 4.3 kcal/mol. Transitions at nearby geometries between the surfaces may become possible by contributions of vibrations of appropriate symmetry or by proper

** In actuality, the path would wander somewhat, as is shown partly by the chain line in Fig. 2, thus resulting in a vibrationally excited H_2 molecule. Some coupling of vibrational motion to the translational motion should also exist in the ascending path on the $^2B_2$ surface. To get actual reaction paths is, however, not in the scope of this paper.

deformations from C_{2v} symmetry. Thus the way in which the elcctronic energy is converted to the vibrational and translational energies of the hydrogen molecule may easily be visualized.

Some Remarks on the Wave Function. Tables 1 and 2 show the computed $^2B_2$ wave functions as expressed by natural orbital expansions at four typical geometries on the dotted line in Fig. 3. Tables 3 and 4 show, for comparison, the corresponding $^2A_1$ wave functions at these geometries. As is seen in Table 1, the predominant CSF in the expansion of the $^2B_2$ wave function is always $\Psi_{2a_1 2a_1 1b_1}$. Table 2 shows that the orbitals ϕ_{2a_1} and ϕ_{1b_1} are always bonding in the sense that they pile up electron densities between the Li atom and the H_2 molecule. They are seen, however, to cause electrons to migrate in opposite directions. The occupation of ϕ_{1b_1} means more and more electron migrations from the Li $2p_y$ atomic orbital to the $1\sigma_u$ hydrogen molecular orbital, as we go down the series of geometries from A to D. The occupation of ϕ_{2a_1} means, on the contrary, electron migrations from the fully occupied $1\sigma_g$ hydrogen MO to the nearly sp hybridized Li 2s and $2p_z$ atomic orbitals, though the extent of charge migration is less remarkable than in the case of ϕ_{1b_1}.

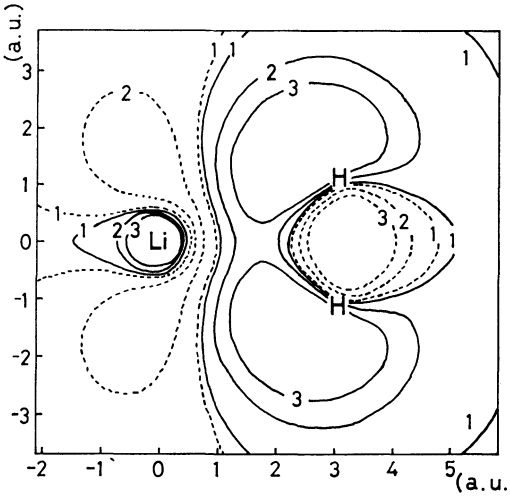

Fig. 5. Contour plots of total electron density of $^2B_2$ state at the geometry C in Fig. 3 minus the density of hypothetical $^2B_2$ state lacking in the interaction between Li and H_2. Full lines correspond to positive and broken lines to negative values of difference. The numbers 1, 2, 3 beside the contours indicate electron density change of 2.0×10^{-4}, 2.0×10^{-3}, 4.0×10^{-3} electrons/a.u.^{3}, respectively.

The predominant configuration in the $^2A_1$ state is $\Psi_{2a_1 2a_1 3a_1}$ for the geometries A, B, and C, but is $\Psi_{2a_1 1b_1 1b_1}$ for the geometry D. In the three former cases, double occupation of ϕ_{2a_1} effects a similar charge migration to that in the $^2B_2$ state and the occupation of ϕ_{3a_1} is seen to affect the charge migration only slightly. The net effect is that the electron transfer in the $^2A_1$ complex is in the opposite direction (from hydrogen toward lithium) to that in the $^2B_2$ complex. This may be important in the stabilization of the $^2B_2$ complex relative to the $^2A_1$ state. The situation at the C geometry is made more visual in Fig. 5, where the electron densities of the $^2B_2$ state minus the electron densities of a hypothetical system, in which the interactions between Li and H_2 have been artificially removed, are

plotted as contour lines: full-lines indicate an increase and dotted lines indicate a decrease in electron densities upon interaction. As noted above, the predominant configurations of the $^2A_1$ state at the D geometry has changed to $\Psi_{2a_1 1b_1 1b_1}$. In this case, the occupation of ϕ_{1b_1} also causes electrons to migrate from H_2 to Li, though the region of charge redistribution is different from that in the ϕ_{2a_1}. Fuller account of the analysis of the situation will be given in a succeeding paper.

The potential surfaces and electronic wave functions given here are preliminary in that the basis functions used are limited. It is hoped, however, that the results are at least qualitatively correct[4] and will be a useful starting point for more quantitative investigations. Work is going on to extend the bases to reach wave functions which could be used in a quantitative description of the non-adiabatic transitions in the interaction of excited atoms with molecules.

The authors wish to thank Dr. S. Iwata of the Institute of Physical and Chemical Research for his helpful discussions. They also express their gratitude to the Aoyama Gakuin Computing Center, where all computations were carried out on an IBM 370-138. Thanks are due to Miss J. Okamura, Miss J. Oga, Miss K. Yahata, and Mr. H. Miyoshi for their help in these computations.

Deuterium Tracer Study on Isomerization of Cyclopropane over Thorium Sulfate

Yuzo IMIZU, Hideshi HATTORI,* Kozo TANABE, and Toshihiko KONDO**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
***Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara 229*

(Received December 4, 1978)

Mechanistic study on the isomerization of cyclopropane into propene was made over $Th(SO_4)_2$ catalyst. With a fresh catalyst, an induction period was observed, disappearing in successive runs. Coisomerization of cyclopropane d_0/d_6 reveals that the reaction involves an intermolecular H(or D) transfer. Nearly random location of the H(or D) atom in the mono-exchanged propene-d_1, and -d_5 indicates that the isomerization proceeds *via* nonclassical carbonium ion in which seven hydrogen atoms are equivalent.

The isomerization of cyclopropane to propene is catalyzed by acidic oxides[1] and crystalline zeolites.[2] Deuterium tracer studies have been made over silica–alumina[3,4] and sodium Y zeolite.[5] On the basis of deuterium distributions in the reactant and product together with the kinetic data over silica–alumina, Hightower and Hall presented the non-classical carbonium ion of cyclopropane as an intermediate in which seven hydrogen atoms are equivalent.[3,4] Bartley *et al.* proposed a different type of nonclassical carbonium ion intermediate in which the hydrogen atom added is not equivalent to the original six hydrogen atoms.[5] They suggested that an intramolecular hydrogen transfer occurs after the ring of the nonclassical carbonium ion is opened, since the reaction partly involves an intramolecular hydrogen transfer.

However, the above discussions are based primarily on the deuterium contents of the reactant and product. The location of deuterium and hydrogen atoms in propene would provide important information as to whether the hydrogen atom added in the intermediate is equivalent to the original hydrogen atoms.

The present study was undertaken to elucidate the intermediate of the isomerization of cyclopropane over an acidic catalyst, thorium sulfate, by deuterium tracer studies. The locations of hydrogen and deuterium atoms in propene were determined by microwave spectroscopy.[6]

Experimental

Catalyst and Reactants. Thorium sulfate was obtained by heating its hydrated form (Wako Pure Chemical Ind., Ltd.) at 500 °C for 3 h in air. Prior to reaction, the catalyst was pretreated with O_2 at 500 °C followed by evacuation at 500 °C for more than 3 h. The BET surface area was 5 m^2/g.

Cyclopropane of 99.8% purity was supplied by Tokyo Kasei Ind., Ltd. Perdeuteriocyclopropane was prepared by repeated exchange reactions of cyclopropane with D_2 over aluminum oxide (Nishio AE 11) at 100 °C.[7] The isotopic purity was higher than 98.0%. The reactants were purified by passage through 4A molecular sieves at −94 °C.

Apparatus and Procedure. A 47 Torr of cyclopropane was allowed to react over 0.1—1 g of catalyst at 80—200 °C in *ca.* 400 ml of a recirculation reactor. The products were separated by gas chromatographic column of VZ-7 (5 m), collected in a liquid N_2 trap, and subjected to mass and microwave spectroscopic analyses in order to determine the deuterium content and the location of deuterium atoms in the product, respectively.

Results and Discussion

Cyclopropane underwent isomerization at 80 °C to yield only propene over a freshly pretreated catalyst with an induction time of 20 min. In the subsequent experiment carried out after brief evacuation at the reaction temperature, isomerization occurred without the induction time, a decrease in rate to some extent being observed (Fig. 1). The isomerization rate was of zero order in cyclopropane. The induction time was prolonged with lowering of reaction temperature. This indicates that the active sites are formed by the interaction of the substrate with a freshly pretreated surface. As observed for the other solid acid catalysts,[3,4] it is suggested that the active sites on $Th(SO_4)_2$ are polymeric residues which supply the protons to act as the Brönsted acid sites.

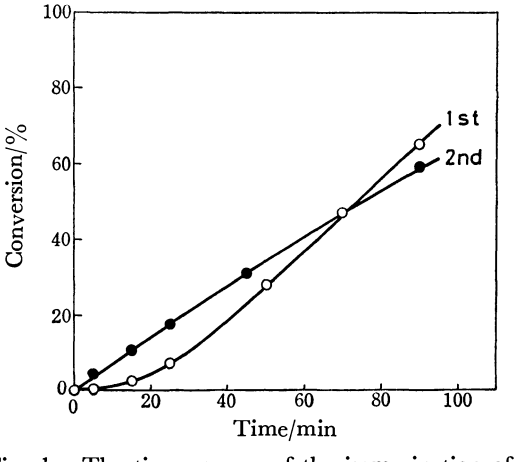

Fig. 1. The time courses of the isomerization of cyclopropane over $Th(SO_4)_2$ at 80 °C in the initial run (○) and in the successive run (●).

Coisomerization experiments were carried out at 100 °C and 200 °C with a mixture containing equal amounts of nondeuterio and perdeuteriocyclopropanes. Isotopic distributions at the two reaction temperatures were similar, those at 100 °C being given in Table 1. The product consisted primarily of non-exchanged isotopic species, d_0 and d_6, and mono-exchanged isotopic species, d_1 and d_5. The numbers of hydrogen atoms

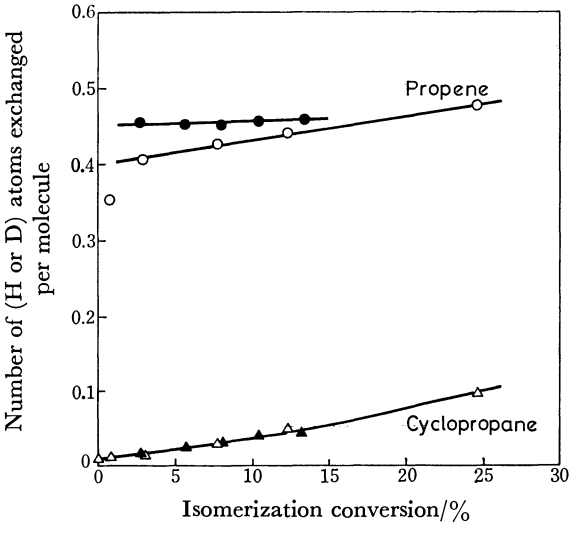

Fig. 2. Exchange concentration curves for coisomerization of cyclopropane-d_0 and -d_6 over $Th(SO_4)_2$. Open symbol: 100 °C, solid symbol: 200 °C.

exchanged per molecule at 100 °C and 200 °C are plotted against conversion in Fig. 2. Hydrogen atoms were exchanged into the unisomerized cyclopropane as well as the product. The superposition of the exchanged concentration curves for cyclopropane at the different reaction temperatures indicates that the activation energy for the exchange process is close to that for isomerization. A similar slope of the curves for cyclopropane and propene indicates that there is little further intermolecular scrambling of hydrogen atom among the propene molecules produced; this is consistent with the limitation of hydrogen exchange mainly to the mono-exchanged isotopic species. The zero conversion intercept of nearly 0.5 for propene demonstrates that one hydrogen atom per molecule is transferred intermolecularly during the course of isomerization.

If the reaction proceeds *via* classical carbonium ions in which no intramolecular hydrogen exchange occurs, the hydrogen atom added would be always left in the product molecule and the original hydrogen atom would be lost on the surface. The intercept for the exchange concentration curve for the product in the coisomerization experiment is expected to be 1/2. On the other hand, if the proton attacks the cyclopropane molecule to form a protonated nonclassical carbonium ion in which seven hydrogen atoms are equivalent, the hydrogen atom added has the same probability of being lost as the original hydrogen atoms when the reaction is completed. As a result, the intercept of the exchange concentration curve will be 6/14. The observed values of 0.45 and 0.40 at 200 °C and 100 °C, respectively, are close to 6/14. The ratio of light molecule (d_0—d_2) to heavy molecule (d_4—d_6) is plotted against conversion in Fig. 3. The zero conversion intercept divided by the initial ratio of light molecule to heavy molecule of reactant gives a kinetic isotope effect. The isotope effect was small or slightly inverse.

The locations of the deuterium atom in propene-d_1

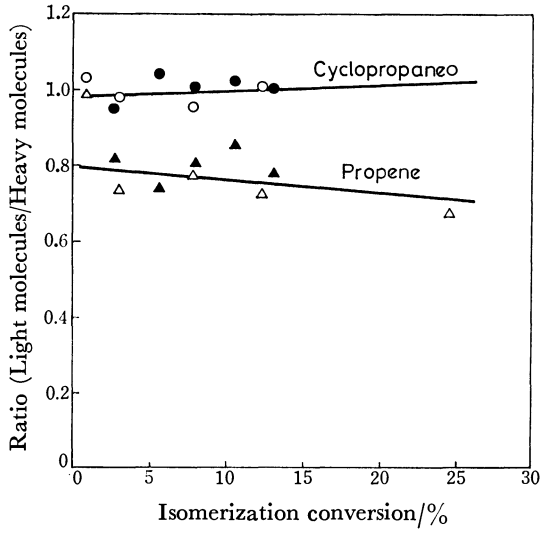

Fig. 3. The ratios of "light molecules" to "heavy molecules" with the conversion in the coisomerization of cyclopropane-d_0 and -d_6 over $Th(SO_4)_2$. Open symbol: 100 °C, solid symbol: 200 °C.

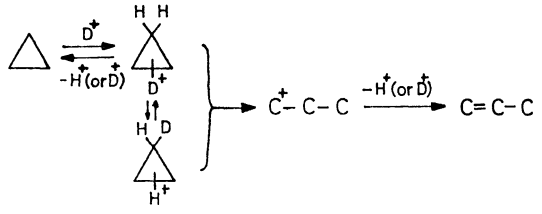
and of the hydrogen atom in propene-d_5 produced in the coisomerization are given in Table 2. The deterium or hydrogen atom was distributed throughout almost all positions instead of being localized at a certain carbon atom. This strongly suggests that the reaction proceeds *via* the nonclassical carbonium ion in which seven hydrogen atoms are equivalent.

If the reaction proceeded *via* classical carbonium ion, the distribution of hydrogen and deuterium atoms might be as follows. 1) A fast intramolecular H transfer occurs after the ring is opened. 2) An intermolecular hydrogen exchange occurs among the propene molecules produced. However, case 1) can be eliminated since the hydrogen transfer should involve the conversion of a stable secondary propyl cation into an unstable primary propyl cation, while in case 2), an extensive hydrogen scrambling among the products should proceed, which was not observed.

Thus, the reaction mechanism is suggested to be as follows: the nonclassical carbonium ion (protonated cyclopropane) is formed by the interaction of cyclopropane with a proton supplied by the surface residue followed by the opening of the ring to yield propene *via* primary propyl cation. The same intermediate, which discharges a proton to the surface and returns to the gas phase without the ring being opened, accounts for the incorporation of hydrogen or deuterium atoms into unisomerized cyclopropane.

This mechanism has been proposed for the reaction over silica–alumina[3,4] without determination of the location of hydrogen or deuterium atom in the product. By analysis of the position of deuterium and hydrogen



atoms in the product by microwave spectroscopy, the proposed mechanism became more plausible.

Neither kinetic isotope effect nor slightly reverse isotope effect appeared for the formation of propene. The cleavage of C–H bond should be fast. The slow step involves either the protonation to cyclopropane or the C–C bond cleavage of the protonated cyclopropane. Since, in both cases, the exchange concentration curves for cyclopropane at different temperatures are on the same line, the energy barriers to cyclopropane and to primary propyl cation from the nonclassical carbonium ion are similar.

Singlet Excitation Energy Migration in the Glassy Organics Blended with Polymer

Yumiko SANO, Yasuhiko SHIROTA, and Hiroshi MIKAWA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

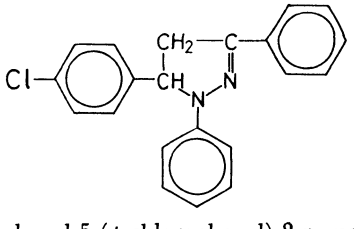
(Received December 6, 1978)

Studies have been made of the singlet excitation energy migration of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline in a glassy state blended with an ethylene–vinyl acetate copolymer by the fluorescence quenching method. The results are discussed in terms of the simple random energy migration model, showing that the efficiency of the singlet excitation energy migration does not differ between the glassy state and the polymer blend system.

Many organic photoconductors have been reported to function as photosensitive material for use in electrophotography. Among others, poly(*N*-vinylcarbazole) (PVCz) films sensitized with dyes such as benzopyrylium dyes[1–3] and the charge-transfer complex of PVCz with 2,4,7-trinitro-9-fluorenone (TNF)[4] are in commercial use. For the application of organic photoconductors to electrophotography, they are usually used as a blend system with an appropriate polymer which acts as a binder. Poly(*N*-vinylcarbazole) is also mixed with an appropriate polymer in order to improve the mechanical properties of the film. In the layered photoconductive system recently developed, organic photoconductors are dispersed in polymer materials.[5,6] Other blend systems of organic photoconductors with polymers have also been reported.[7]

From both scientific and practical aspects, it is of interest to investigate the transport phenomena in the photoconductor-polymer blend system. Studies have been carried out in detail on the carrier transport in the PVCz–TNF system.[8] The migration of the excitation energy in polymer blend systems has not been much investigated,[9–11] but it is an important precursory process for the photocarrier generation.

1,3,5-Triaryl-2-pyrazolines form a glassy state near room temperature, which is kept for quite a long period of time.[12,13] They have an intense fluorescent characteristic[14] and a photoconductive property.[15] We have made comparative studies of the singlet excitation energy migration of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline in the glassy and single crystalline states.[16] This compound is miscible with ethylene–vinyl acetate copolymer giving a transparent material over a wide blend ratio from the excess of pyrazoline to the excess of polymer. Thus the system may be appropriate for investigating the singlet excitation energy migration in the photoconductor-polymer blend system.



1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline

Experimental

Materials. 1,3-Diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline (glass transition point 16.5 °C) was prepared and purified by the zone refining technique. Dimethyl terephthalate was purified by repeated recrystallization from ethanol and then by sublimation.

Evaflex 210, a random copolymer of ethylene (*ca.* 72 wt %) and vinyl acetate (*ca.* 28 wt %) which softens at 80 °C (Mitsui Polychemicals Co., Ltd.) was reprecipitated four times from benzene with methanol. The polymer has low viscosity and is transparent after cycles of melting and cooling, the glass transition temperature being below −50 °C.

*Preparation of the Blend of 1,3-Diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline and the Polymer.* 1,3-Diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline doped with dimethyl terephthalate was prepared in a high vacuum. The doped material was diluted further with pure 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline and blended with the polymer in a pyrex glass tube (diameter 1.5 mm) by melting them together under a nitrogen atmosphere, degassed and sealed in a high vacuum (3×10^{-6} mmHg). The samples thus prepared were immediately cooled down to a liquid nitrogen temperature (77 K). This is a convenient method for keeping the samples transparent at room temperature.

Measurement. The degassed samples were subjected to measurement without being taken out from the pyrex glass tube in order to avoid exposure of the samples to oxygen. The fluorescence intensity was measured with a Hitachi fluorescence spectrophotometer MPF-3 by using a special sample holder which can hold the sample tube in a fixed position at constant temperature (10 °C).

Results and Discussion

The absorption and fluorescence spectra of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline in the glassy state are shown in Figs. 1(a) and (b), respectively. Even when the pure 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline glass is mixed with an equal amount of ethylene–vinyl acetate copolymer, the shape of the fluorescence spectrum remains unchanged (curve c). When pure 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline is mixed with a small amount of dimethyl terephthalate, the fluorescence of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline is partially quenched. Figure 1(d) shows the reduced fluorescence of pure 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline when $\approx10^{-3}$ mol/mol of dimethyl terephthalate is doped. The copolymer does not work as a trapping center of the pyrazoline excitation energy.

In the present study, the quenching of the fluorescence of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline in the polymer matrix was investigated by doping dimethyl terephthalate as a quencher. When the polymer

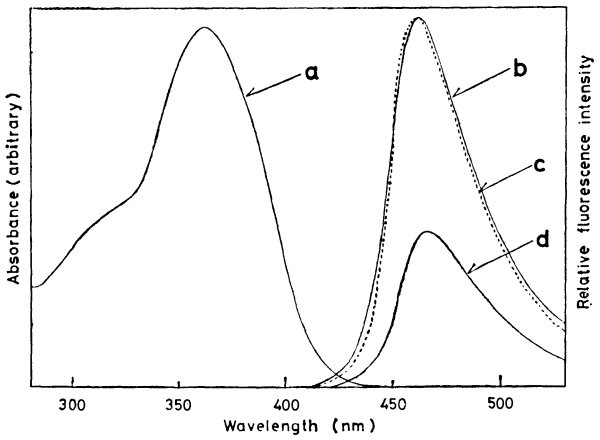


Fig. 1. Absorption and fluorescence spectra of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline in the glassy state. (a) Absorption spectrum; (b) fluorescence spectrum; (c) fluorescence spectrum when mixed with an equal amount of ethylene–vinyl acetate copolymer, the spectrum being normalized at the fluorescence peak of curve (b); (d) fluorescence quenching by 10^{-3} mol/mol dimethylterephthalate.

content is less than 20%, *viz.*, the content of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline exceeds 80%, no perfectly homogeneous transparent samples can be prepared, apparently due to the phase separation in the micro scale. Examination was therefore made with polymer content of more than 20%.

For such a homogeneous system, the Stern-Volmer type equation is expected to hold for the fluorescence quenching:

$$\frac{F_0(p)}{F(p)} = 1 + K_{sv}(p)\frac{(1-p)N_g}{N_h} \qquad (1)$$

where $F_0(p)$ and $F(p)$ are the fluorescence intensity of the pyrazoline in the absence and presence, respectively, of the quencher, in a system containing the polymer of the fraction p of the total. $K_{sv}(p)$ is the quenching constant, and N_h and N_g are the number of host and guest molecules, respectively. Since p stands for the volume fraction of the polymer, the quencher concentration is $N_g/[(N_h+N_g)/(1-p)] \fallingdotseq (1-p)N_g/N_h$. Figure 2 shows the Stern-Volmer plot for a system containing 80% polymer. As expected, the plot shows approximate linearity.

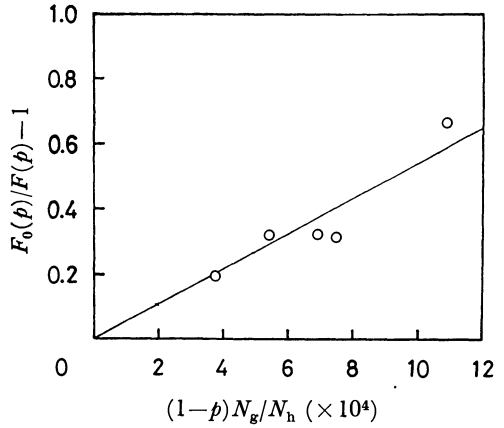

Fig. 2. Fluorescence quenching of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline in the ethylene–vinyl acetate copolymer matrix with dimethylterephthalate as a quencher. The polymer content is 80% by weight, which is almost equal to the volume %, if the specific volume of the polymer is assumed to be approximately equal to that of the pyrazoline. Based on this approximation, p represents the volume fraction of the polymer, $p=0.8$.

Equation 1 can be derived also in terms of a simple model of random energy migration. In the present system, energy migration from pyrazoline molecules to the polymer is energetically impossible. Thus the excitation energy migration should take place only from pyrazoline to pyrazoline. The probability of some site being the guest molecule should be $N_g/(N_h+N_g)/(1-p)$. Since the probability of an excited state at some site to migrate to the next site during the course of energy dissipation is $k_m(p)/(k_f(p)+k_i(p)+k_m(p))$, the probability $P_m(p)$ of the excited state reaching the guest molecule is

$$P_m(p) = \sum_{n=1}^{\infty}\left(\frac{k_m(p)}{k_f(p)+k_i(p)+k_m(p)}\right)^{n-1}\left(1-\frac{N_g}{N_h+N_g}\right)^{n-1}_{1-p} \times \frac{k_t(p)}{k_f(p)+k_i(p)+k_m(p)+k_t(p)}\frac{N_g}{N_h+N_g}_{1-p}$$

where $k_f(p)$, $k_i(p)$, and $k_m(p)$ are the rate parameters for radiative decay, non-radiative decay and migration, respectively, of the excitation energy in the pyrazoline-polymer blend system. $k_t(p)$ is the rate parameter for energy trapping by the guest molecule. In the case $k_t(p) \gg k_m(p)$, the above equation is written as

$$P_m(p) = \sum_{n=1}^{\infty}\left(\frac{k_m(p)}{k_f(p)+k_i(p)+k_m(p)}\right)^{n-1}\left(\frac{N_h+pN_g}{N_h+N_g}\right)^{n-1} \times \frac{(1-p)N_g}{N_h+N_g}.$$

The probability $P_f(p)$ with which the excited state releases the energy as fluorescence would be $P_f(p)=(1-P_m(p))k_f(p)/(k_f(p)+k_i(p))$. Since $F_0(p)/F(p)$ is the ratio of the fluorescence intensities for $N_g=0$ and $N_g=N_g$, which should be proportional to the probability $P_f(p)$, we can get Eq. 2 which is the same as Eq. 1 with $K_{sv}(p)=k_m(p)/(k_f(p)+k_i(p))$.

$$\frac{F_0(p)}{F(p)} = 1 + \frac{k_m(p)}{k_f(p)+k_i(p)}\frac{(1-p)N_g}{N_h} \qquad (2)$$

Since $1/(k_f(p)+k_i(p))$ is lifetime (τ_0) of the excited state of the pyrazoline in the absence of the quencher molecule, $k_m(p)/(k_f(p)+k_i(p))=n(p)$ is the number of hops of the singlet excitation energy over the pyrazoline molecules within its lifetime. The experimental results shown in Fig. 2 give the value $n(0.8)=538\pm32$. This does not differ within experimental errors from the value obtained for the pure glassy state of the pyrazoline $n(0)=523\pm9$.[16] This indicates that the number of hops $n(p)$ of the singlet excitation energy within its lifetime does not differ between the pure glassy state and the polymer blend system ($p=0.8$). In order to

confirm this for a wider range of the polymer content, it is necessary to carry out a series of similar fluorescence quenching experiments over various polymer contents; however, the following simple method was employed instead.

$F_0(p)/F(p)$ is plotted against the varying $(1-p)$ for Eq. 2 by keeping N_g/N_h constant and varying only the amount of the polymer (p). The amount of quencher molecule in the system is thus continuously varied by a factor $(1-p)$. Consequently, if $n(p)$ is independent of the polymer content as actually found to be the case for $p=0.8$, the plot of $F_0(p)/F(p)$ *vs.* varying $(1-p)$ (more strictly *vs.* $(1-p)N_g/N_h$ with constant N_g/N_h) for Eq. 2 would give a straight line; if $n(p)$ varies with polymer content the plot would not be linear.

1,3-Diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline containing 2.70×10^{-3} mol/mol of dimethyl terephthalate was prepared first and the doped pyrazoline was mixed with various amounts of the ethylene–vinyl acetate copolymer. The intensity of the fluorescence of the samples, $F(p)$, and that of each corresponding mixture of the undoped pyrazoline with the polymer, $F_0(p)$, were measured, the values of $F_0(p)/F(p)-1$ being plotted against $(1-p)$. As shown in Fig. 3, the results (open circles) lie on a straight line over the polymer content range from 90% $(1-p=0.1)$ to pure pyrazoline $(1-p=1.0)$. The black circle represents the value for the pure pyrazoline glass. The linearity indicates that $n(p)=k_m(p)/(k_f(p)+k_i(p))$ remains unchanged irrespective of the difference in polymer content. The results indicate that $k_m(p)$ is independent of polymer content, since the lifetime of the excited state, $\tau_0=1/(k_f(p)+k_i(p))$, is practically independent of polymer content.

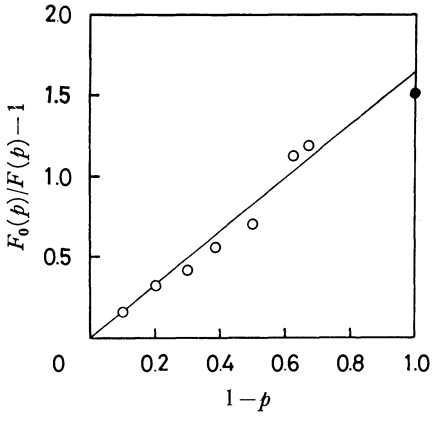

Fig. 3. Plot of $F_0(p)/F(p)-1$ as a function of $1-p$. $F_0(p)$ and $F(p)$ are the fluorescence intensities of the undoped and the doped materials, respectively, when the ethylene–vinyl acetate copolymer is blended with the fraction of p.

The efficiency of the singlet energy migration of 1,3-diphenyl-5-(*p*-chlorophenyl)-2-pyrazoline was found to be invariable between the pure glassy state and the polymer blend system over a wide range of polymer content when suitable polymers inert to excited molecules are chosen.

Determination of Heats of Adsorption of Triphenylchloromethane from Its Hexane Solution onto Dehydrated Silica-Alumina Surface

Hitofumi TANIGUCHI,* Tatsuo MASUDA, Kazuo TSUTSUMI, and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received December 15, 1978)

Heats of adsorption of gaseous triphenylchloromethane (TPC) onto silica–alumina surface were determined from the heat evolved with the immersion of silica–alumina into TPC–hexane solution. The heat of dissolution and the heat of sublimation of TPC and the heat of immersion of the sample into hexane were considered for their determination. It became clear that TPC molecules interacted with silica–alumina surface in two manners. The one was observed in smaller adsorbed amount (below 45 μmol/g), and the other in adsorbed amount from 45 to 100 μmol/g. The former could be attributed to the interaction between TPC and Lewis or oxidizing sites and the latter to the attractive interaction between the adsorbed molecules. The adsorbed amount in the first stage (4.7×10^{12} molecules/cm^2) agreed closely with the number of Lewis acid sites (5.0×10^{12} sites/cm^2) measured by Leftin and Hall.

Although the existence of two types of acid sites (Lewis and Brönsted type) on dehydrated silica–alumina surface has been known by IR spectroscopy,[1,2] the method of their quantitative determination has not yet been established. A great number of techniques has been reported for specific adsorption on each kind of acid sites. Okuda and Tachibana[3] observed that the cation radical $[NH_2C_6H_4NH_2\cdot]^+$ derived from adsorbed *p*-phenylenediamine $[NH_2C_6H_4NH_2]$ on silica–alumina surface appears under the existence of electron-acceptor sites. Leftin and Hall[4] reported that the amount of Lewis acid sites can be determined from the amount of triphenylmethylium ions formed when the acid center abstracts a hydride ion from triphenylmethane (TPM). The method was modified by Shiba and coworkers[5] who used triphenylchloromethane (TPC) instead of TPM. The adsorption equilibrium is much more readily attained for the former than for the latter. Besides above-mentioned methods, polycyclic condensed aromatics such as perylene and anthracene were used as the reagents for the specific adsorption on Lewis acid sites. The determinations of Lewis acidity in these methods were carried out by gravimetry, spectroscopy or electron-spin-resonance. Calorimetric studies for this purpose have hardly been done. If the reagents above-mentioned had sufficiently high vapor pressure at room temperature, the gas-adsorption-calorimetry[6–9] could be applied. In this study, the heat of adsorption was measured from TPC–hexane solution.

Experimental

Silica–alumina cracking catalyst (Al_2O_3: 13 wt %) was supplied by Catalysts and Chemicals Ind. Co., Ltd. Each sample was evacuated at 600 °C under 10^{-5} Torr for 5 h before measurement. Triphenylchloromethane and hexane were special grade reagents supplied by Wako Pure Chemical Industries, Ltd.

Calorimetric studies were carried out by a twin-conduction type calorimeter (Tokyo Riko Co., Ltd.).

Specific surface area of the sample was measured to be 575 m^2/g by the BET nitrogen method. Chemisorbed amount of TPC was determined spectroscopically after the extraction with dry hexane for 2 h.

Results and Discussion

The measurements of heats of adsorption of solute onto solid surface from the solution were extensively reported.[10–12] In these papers, heats of adsorption were determined by considering the heat of immersion of solid into solvent or the heat of dissolution of solute into solvent.

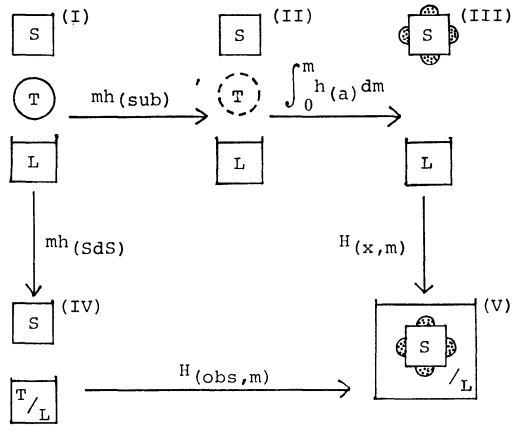

Fig. 1. Diagrammatic representation of the relation between the calorimetrically measured heat and the heat of adsorption of TPC.
S: Silica–alumina, T: TPC(triphenylchloromethane), L: hexane, T/L: TPC–hexane solution.
○: Solid, ○: gas.

Figure 1 shows the diagrammatic representation of the relation between the calorimetrically measured heat and the heat of adsorption of gaseous TPC, where $h_{(a)}$ is the enthalpy change with the adsorption of TPC(gas) onto silica–alumina surface (differential heat of adsorption), $H_{(obs,m)}$ the enthalpy change with the immersion of the sample into TPC–hexane solution, $h_{(SdS)}$ the molar enthalpy change with the dissolution of TPC-(solid) into hexane, $h_{(sub)}$ the molar enthalpy change with the sublimation of TPC(solid) and $H_{(x,m)}$ the enthalpy change with the change of state from (III) to (V). The additivity of these enthalpy changes is to be hold

for this cycle, therefore, if $h_{(sub)}$, h_{SdS}, and $H_{(x,m)}$ are obtained, $h_{(a)}$ can be derived from $H_{(obs,m)}$.

The $h_{(SdS)}$ was measured with a twin-conduction type calorimeter, and was positive value (endothermic) as shown in Fig. 3. The $h_{(sub)}$ was calculated from the temperature dependence of the vapor pressure of TPC by using Clausius-Clapeyron's equation. At the step (III) the sample is preadsorbed with gaseous TPC, hence $H_{(x,m)}$ must be obtained by the measurement of the heat evolved with the immersion of the sample partially preadsorbed with gaseous TPC into hexane. The vapor pressure of TPC is, however, extremely low and the stability of TPC molecules depends on the temperature very sensitively. Therefore, the partial preadsorption with TPC in gas phase was very difficult. The step from (III) to (V) consists of both the change of the adsorbed state of TPC and the immersion of the sample with the preadsorbed TPC into hexane. In this study, $H_{(x,m)}$ was calculated by using the following equation under the assumption that the former might be energetically negligible,

$$H_{(x,m)} = H_I \times (1-\theta(m)), \quad (1)$$

where H_I is the heat of immersion of bare silica–alumina into hexane and $\theta(m)$ the surface coverage of TPC. The relationship among these heat values is expressed as

$$mh_{(SdS)} + H_{(obs,m)} = mh_{(sub)} + \int_0^m h_{(a)}dm + H_{(x,m)} \quad (2)$$

which leads to

$$\int_0^m h_{(a)}dm = m[h_{(SdS)} - h_{(sub)}] + [H_{(obs,m)} - H_{(x,m)}]. \quad (3)$$

The term, $\int_0^m h_{(a)}dm$, will be refered to the cumulative heat of adsorption. The differential heat of adsorption, q, of gaseous TPC onto silica–alumina surface can be expressed by

$$q = -h_{(a)} = h_{(sub)} - h_{(SdS)} + \frac{\partial}{\partial m}[H_{(x,m)} - H_{(obs,m)}]. \quad (4)$$

If the variation of m is sufficiently small, in other words, if each difference of concentrations of solutions in the experiment is sufficiently small, q can be determined by graphical differentiation of the plot of $\int_0^m h_{(a)}dm$ against m.

When the pretreated silica–alumina was immersed into TPC–hexane solution, the heat was evolved as shown in Fig. 2. Two steps are observed in the heat curve, which suggests the existence of two kinds of surface reaction with TPC. On the other hand, the curve showing the relation between the chemisorbed amount and the concentration of solution has three steps, and first two correspond to the steps of heat curve. After the initial stage, the adsorbed amount gradually increased. The nature of Lewis acid sites has been characterized by the adsorption of TPC or TPM and their number has been determined after the extraction of physically adsorbed species by use of dry benzene.[4] While in this study the extraction was carried out with hexane because it dissolved TPC much more than benzene did and the heat of immersion of silica–alumina into it was lower, which were important factors in

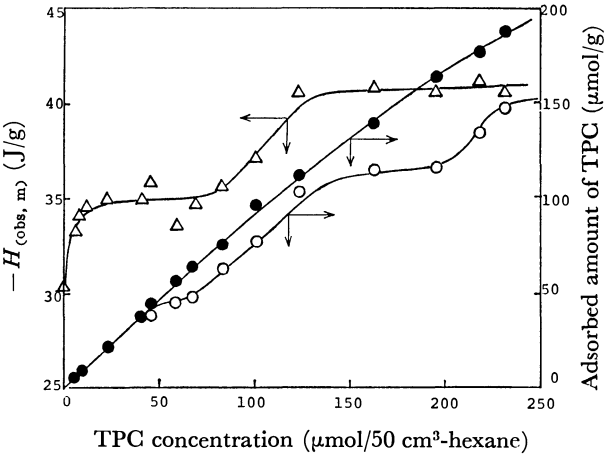

Fig. 2. The calorimetrically measured heats (△), the total adsorbed amount (●) and the chemisorbed amount of TPC (○) *vs.* the concentration of TPC–hexane solution. (The chemisorbed amount was equal to the total adsorbed amount below 45 μmol/g of adsorbed amount.)

calorimetric measurements. The extraction with benzene showed here that the chemisorbed amount was 43 μmol/g even at the solution concentration of 150 μmol/50 cm³ hexane. This value was in good agreement with that at the end point of the first stage in case of hexane extraction. However, the amount obtained after hexane extraction will be called "chemisorbed" one hereafter. In order to obtain the heat of adsorption of TPC, other enthalpy changes were measured or calculated as follows.

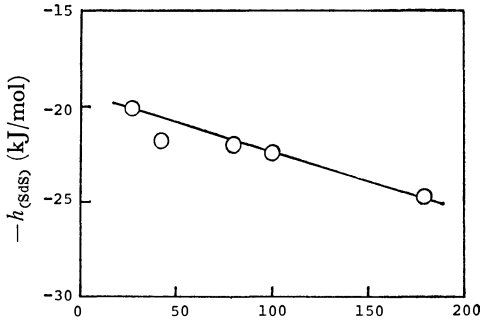

Fig. 3. Molar enthalpy change with the dissolution of TPC (solid) into hexane.

Figure 3 shows the integral heat of dissolution of TPC into hexane ($h_{(SdS)}$). A slite change was observed against the concentration of solutions, which seemed to be due to heat of dilution. The value corresponding to the amount adsorbed was applied for Eq. 3. The heat of sublimation of TPC ($h_{(sub)}$) was determined as mentioned above to be 34.6 kJ/mol. The heat of immersion of bare silica–alumina into hexane (H_I) was measured to be −30.3 J/g. $H_{(x,m)}$ was determined by use of Eq. 1 under the assumption that the surface coverage of TPC increased linearly with the adsorbed amount below 45 μmol/g and that it did not, however, change any

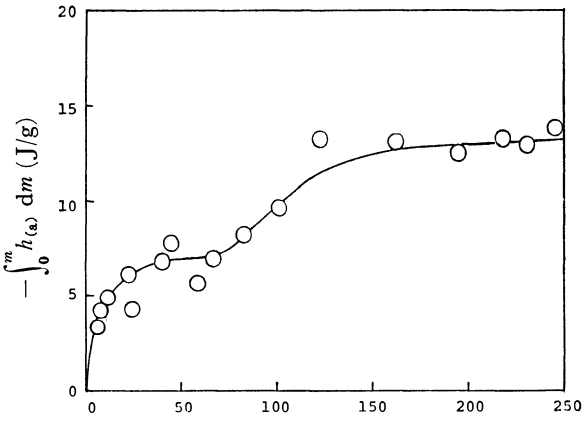

Fig. 4. Cumulative heat of adsorption of TPC *vs.* concentration of TPC–hexane solution.

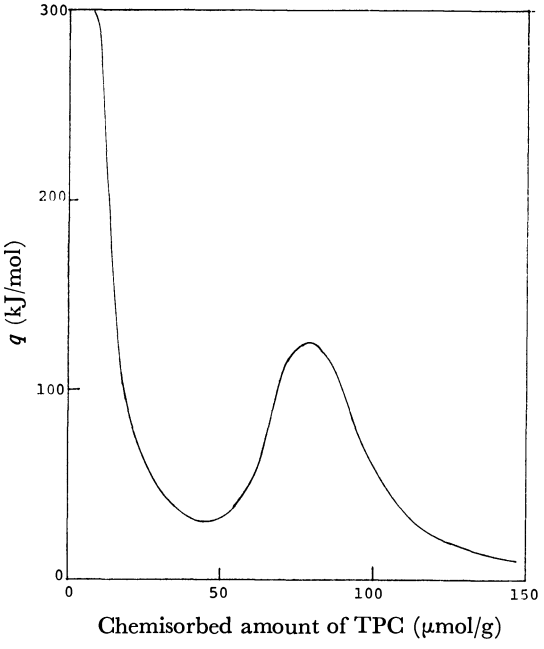

Fig. 5. Differential heat of adsorption of gaseous TPC onto silica–alumina surface.

more above 45 μmol/g. The reason for this assumption will be mentioned in the later section. The cross-sectional area of TPC molecule was taken as 1.54 nm².[13] The cumulative heat of adsorption against the solution concentration and the differential heat of adsorption are shown in Figs. 4 and 5, respectively. The determination of the differential heat of chemisorption was based on the assumption that the heat of physical adsorption was equal to the heat of sublimation of TPC, 34.6 kJ/mol. As shown in Figs. 4 and 5, two types of adsorption occured: the one was observed in the first stage where the chemisorbed amount of TPC was lower than 45 μmol/g, and the other was in the second stage where the chemisorbed amount was between 45 and 100 μmol/g. The visible reflection spectrum of the sample of the former type consisted of only 400—420 nm absorption band which was the same as that obtained with concentrated sulfuric acid–triphenylmethanol system (Fig. 6). Considered together with the results of Leftin and Hall, these species could be assigned to carbonium ions derived from TPC by its interaction with silica–alumina surface. The formation of triphenylmethyl radical by the interaction with oxidizing sites may be possible as reported by Arai and coworkers.[14] In the second stage, the new absorption bands (540, 640 nm) appeared besides that of carbonium ion. Since the adsorbed amount in this stage was nearly equal to that in the first one, this might be attributed to the interaction between carbonium ion or triphenylmethyl radical which had been formed on the surface and TPC molecules, and to the lateral interaction among adsorbed molecules. A maximum in the second stage of the plot of the heat of adsorption must be satisfactorily explained on the basis of these interactions. The chemisorbed species of this stage were removed by benzene extraction, but their chemical identification is not yet made.

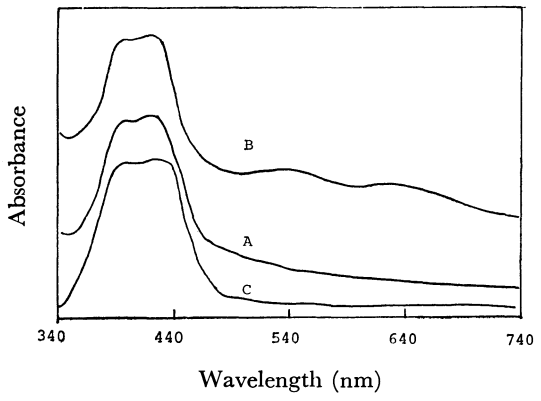

Fig. 6. Visible reflection spectrum of TPC adsorbed on silica–alumina surface.
A: Chemisorbed amount of TPC was less than 45 μmol/g, B: chemisorbed amount was more than 45 μmol/g, C: triphenylcarbinol in concd H_2SO_4.

Consequently, it was clarified by calorimetric measurement that the adsorption of TPC onto silica–alumina surface from its hexane solution consisted of at least two steps. At the intial stage, TPC molecules were chemisorbed on Lewis acid sites or oxidizing sites. The initial differential heat of adsorption was about 300 kJ/mol and the decrease hereafter was considerably steep. The adsorbed amount in this stage was about 45 μmol/g (4.7×10^{12} molecules/cm²), which agrees closely with the number of Lewis acid sites, 5.0×10^{12}/cm², measured by Leftin and Hall. After the initial stage, a rise in the heat of adsorption to give a maximum was observed, which must be ascribed to the attractive interactions between adsorbed molecules.

This work was partly supported by a Grant-in-Aid for Science Research from the Ministry of Education.

(Received December 18, 1978)

The He I spectra of 12-crown-4, 15-crown-5, 18-crown-6, dicyclohexyl-18-crown-6, and dibenzo-18-crown-6 have been measured. The features of the spectra are similar except for the case of dibenzo-18-crown-6, where two lower IP bands correlated with the highest occupied π-orbitals of benzene are observed together with the bands due to the polyether ring. By the aid of the CNDO/2 calculation, the lower IP bands of the spectra have been assigned to the MO's mainly due to the equatorial or axial type non-bonding orbitals of the oxygen atoms of the polyether rings.

There has been considerable interest in macrocyclic "crown" ethers since Pedersen reported their syntheses in 1967.[1,2] They are capable of binding with a wide variety of salts to form complexes and can thereby solubilize many inorganic reagents in nonaqueous solvents, in which the reagents exhibit enhanced anion activity.[3,4] Thus, crown ethers have been found to be very useful reagents in organic chemistry. In life sciences, they are also used as models for carrier molecules in the study of cation transport through membranes.[5]

In order to study the electronic structure of crown ethers, we have measured the He I spectra of 12-crown-4 (I), 15-crown-5 (II), 18-crown-6 (III), dicyclohexyl-18-crown-6 (IV), and dibenzo-18-crown-6 (V) (Fig. 1), and tried to assign the observed bands with the aid of molecular orbital calculations.

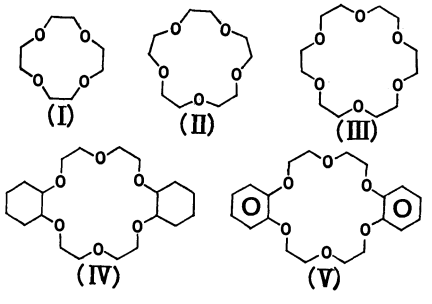

Fig. 1. Crown ethers.
(I) 12-Crown-4, (II) 15-crown-5, (III) 18-crown-6, (IV) dicyclohexyl-18-crown-6, (V) dibenzo-18-crown-6.

Experimental

Commercial crown ethers were purified by vacuum sublimation. He I spectra were recorded on a Perkin-Elmer PS-18 photoelectron spectrometer using the Ar and Xe doublets as internal standards. The resolution was less than 30 meV. The spectra of I and II were measured at room temperature, and those of the larger crown ethers at 70 °C (III), 150 °C (IV), and 190 °C (V).

Results and Discussion

Figure 2 shows the He I spectrum of 12-crown-4. Four broad peaks appear around 9.3, 9.9, 11.4, and 12.5 eV. In the higher IP region the spectrum is diffuse, as is frequently the case in large molecules.

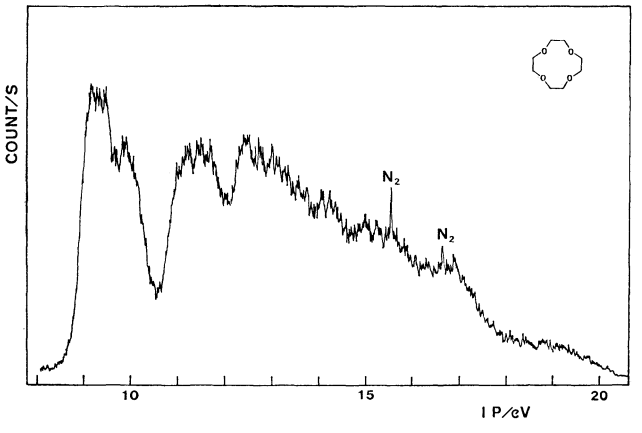

Fig. 2. He I spectrum of 12-crown-4.

The molecular structure of 12-crown-4 has not been determined experimentally. Pullman *et al.*[5] calculated the energies of two types of conformations, maxidentate (crown) and alternate forms (Fig. 3), using an *ab initio* LCAO MO method. According to them, the most stable conformer is a deformed alternate one; the value of its torsion angle τ about the C_2C_3 bond is 70°, while the symmetric alternate conformer (Fig. 3) has τ= 48.65°. We calculated the molecular orbitals of these alternate conformers by the CNDO/2 method. The energies of the upper occupied levels and the shapes of the corresponding wave functions are illustrated schematically in Fig. 4. The symmetric alternate conformer

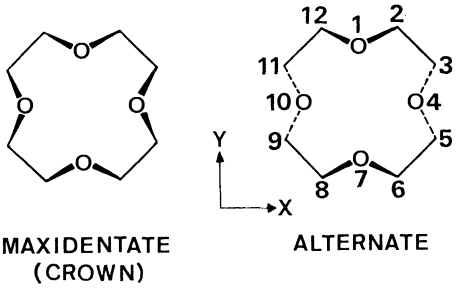

Fig. 3. Conformations of 12-crown-4. All the carbon atoms lie on the same plane.

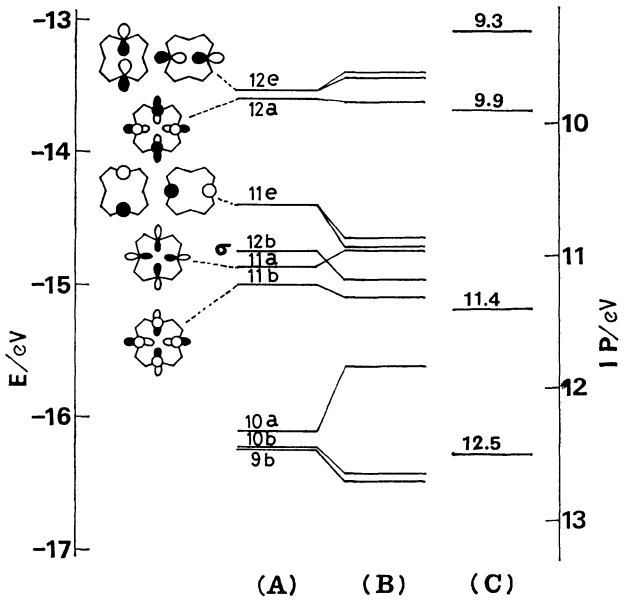

Fig. 4. The energies of the upper occupied levels and the shapes of the corresponding wave functions of 12-crown-4.

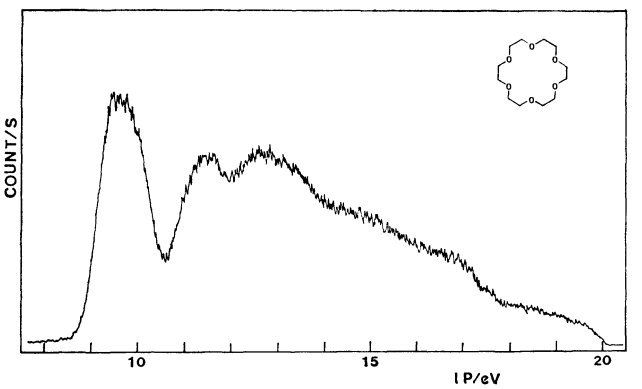

Fig. 6. He I spectrum of 18-crown-6.

belongs to the symmetry group S_4, having degenerate e orbitals, whereas the degeneracy is lifted in the stable one. The CNDO/2 calculation shows that the highest occupied e orbitals of the symmetric conformer (12e in Fig. 4) are mainly due to the non-bonding combination of the equatorial type lone pair orbitals (N_{eq}) of two oxygen atoms and the second highest (12a) to the bonding combination of four N_{eq} orbitals together with the anti-bonding combination of four axial type lone pair orbitals (N_{ax}). For the deformed form, the splitting of the 12e orbital is calculated to be only 0.04 eV (Fig. 4). Therefore, they may not be resolved in the observed photoelectron spectrum. Since the integrated intensity of the first (9.3 eV) band of 12-crown-4 is about twice as large as that of the second (9.9 eV) one, the first and second bands can be assigned to the 12e and 12a orbitals, respectively. Both these orbitals are due to lone pair type orbitals of oxygen atoms, having a similar localized nature. Thus the intensity ratio of the two bands due to the 12e and 12a orbitals can be expected to be 2 to 1, the ratio of their degeneracies.** Further, the assignment of the second band to the 12a orbital can be supported from a comparison of the spectrum of 12-crown-4 with spectra of the other crown ethers (see below). The intensity of the 11.4 eV band, as compared to those of the first and second bands, suggests that it corresponds to the removal of electrons from two or three occupied orbitals. Judging from the results of the calculation shown in Fig. 4, electrons from the 11e orbital, the anti-bonding combination of two N_{ax} orbitals, may contribute to this band.

Figures 5 and 6 show the He I spectra of 15-crown-5 and 18-crown-6, respectively. The appearance of the spectra is similar to that of 12-crown-4 (Fig. 2), except for the portion of the spectra between 8.5 and 10.5 eV. In the former spectra the 9.3 and 9.9 eV bands of 12-crown-4 appear to be mixed into one band located at intermediate positions: 9.58 eV for 15-crown-5 and 9.7 eV for 18-crown-6. This can be interpreted by assuming that orbitals having shapes similar to those of the 12e and 12a of 12-crown-4 are responsible for the first band in its higher homologs. Since 12e type orbitals due to anti-bonding combinations of N_{eq}'s become more stable and 12a type orbitals due to bonding combination of N_{eq}'s become less stable with increasing ring size of polyethers, the bands due to these two orbitals may not be resolved for 15-crown-5 and 18-crown-6. As for the second bands in Figs. 5 and 6, the peak positions (11.4 eV for 15-crown-5, 11.5 eV for 18-crown-6) are nearly the same as that in 12-crown-4. This is considered to be consistent with the previous assignment that the 11.4 eV band in 12-crown-4 is related to the 11e orbital, since the energy of the 11e type orbitals may not shift much with increasing ring size owing to the small interaction among N_{ax} orbitals.

** A similar intensity relation has been found in the photoelectron spectrum of biphenyl, in which the lowest three ionization bands are associated with the highest occupied π-orbitals of the benzene rings (J. P. Maier and D. W. Turner, *Faraday Discuss. Chem. Soc.*, **54**, 149 (1972)). The intensity ratio of approximately 1:2:1 has been observed for these three bands, of which the second one is due to almost doubly degenerate orbitals.

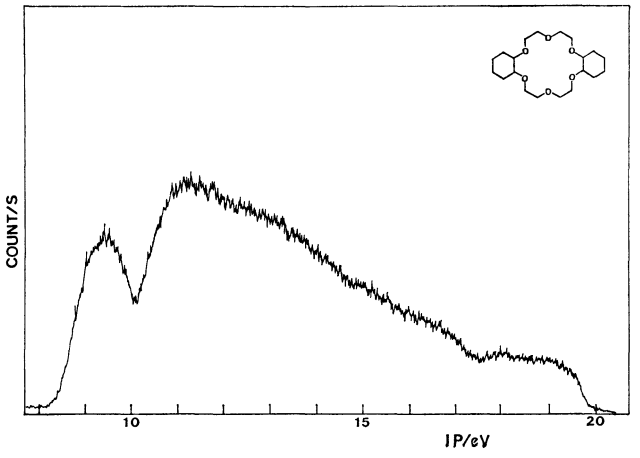

Fig. 7. He I spectrum of dicyclohexyl-18-crown-6.

Figure 7 shows the He I spectrum of dicyclohexyl-18-crown-6. With the introduction of two cyclohexane rings, the peak position of its first band (9.45 eV) is lowered by 0.25 eV as compared with that of 18-crown-6. Furthermore, in the 10—13 eV region the feature of the spectrum is different from those of the spectra of unsubstituted crown ethers. This may be due to the effect of the σ-orbitals of cyclohexane, the adiabatic IP of which is around 10.0 eV.[6]

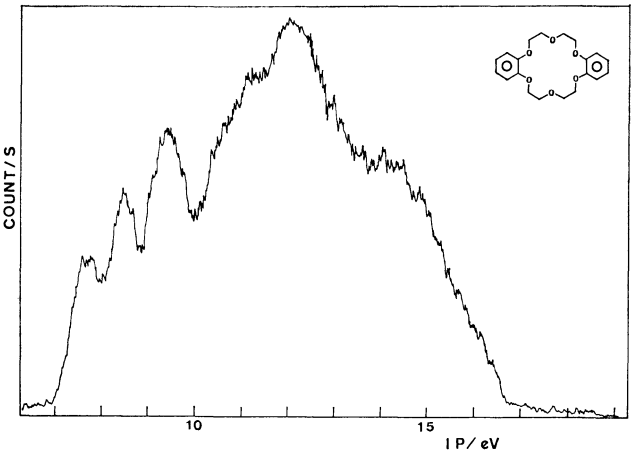

Fig. 8. He I spectrum of dibenzo-18-crown-6.

The He I spectrum of dibenzo-18-crown-6 is shown in Fig. 8. The third band located at 9.45 eV can be correlated to the first band of 18-crown-6. The first and second bands (vertical IP 7.70 eV, 8.50 eV) may be related to electrons from the highest occupied doubly degenerate π-orbitals (e_{1g}) of benzene rings. This assignment is supported by the fact that the *o*-dimethoxybenzene gives the first and second bands at vertical IP 8.20 and 8.91 eV,[7] which are associated with the e_{1g} orbitals of the benzene ring. Since there is interaction in this molecule, among the e_{1g} orbitals of the benzene ring (IP 9.24 eV for benzene) and the non-bonding orbitals of the oxygen atoms (IP 10.96 eV for methanol), the former orbitals are considered to split and give two bands in the lower IP region of the spectrum.*** The vertical IP's relating to these bands are further lowered by 0.4—0.5 eV for dibenzo-18-crown-6, where the π-conjugated system is larger than that of *o*-dimethoxybenzene.

As for the IP region higher than 10 eV the appearance of the spectrum in dibenzo-18-crown-6 is quite different from that of 18-crown-6 owing to the introduction of two benzene rings. However, the shoulder at 11.2 eV may be correlated to the second band of 18-crown-6.

The authors wish to thank Prof. A. Pullman, Institut de Biologie Physico-Chimique, C. N. R. S., for sending them the data on the atomic cordinates of the most stable conformer for 12-crown-4.

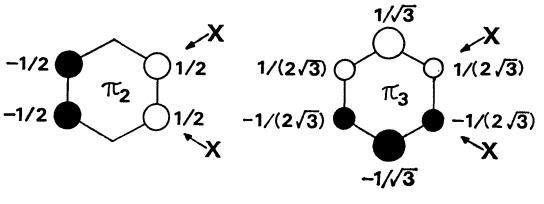
*** We can correlate the 8.20 and 8.91 eV bands of *o*-dimethoxybenzene with the π_2 and π_3 orbitals of the benzene ring, respectively, because, in *o*-dimethoxybenzene, the π_2 orbital of the ring having its maximun electron density at both points of substitution is more affected than the π_3 orbital.



Stability of Multi-center Bonds in Inorganic Cluster Compounds

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 19, 1978)

An ideal multi-center bond is a bond in which three or more atomic orbitals of the same kind, each from a different atom, interact equally with each other. Since such a multi-center bond can be regarded as a cyclic conjugated system, the graph theory of aromaticity can be applied to it. It was then found that multi-center bonds are aromatically stabilized to a great extent. Most inorganic cluster compounds are polyhedral in shape. This might be rationalized by the fact that polyhedrons are favorable to a formation of a multi-center bond or the like at the core.

Boranes and metal carbonyl clusters were once regarded as obscure chemical rule-breakers because of their unfamiliar bonding patterns. During the last decade a great deal of effort has been devoted to an understanding of chemical bonds in such non-classical cluster compounds.[1] The present-day situation can adequately be expressed by the following sentence: Gather any large group of inorganic chemists and they will start talking about metal clusters.[2] Pauling also pointed out that the bonding principle of metal carbonyl clusters is one of the most important problems yet to be solved.[3] In line with this, several skeletal electron-counting rules have been proposed as a theoretical basis for rationalizing the bonding pattern of cluster compounds.[4–8] However, these rules rarely provide explicitly for a measure of stabilization of the molecular clusters. In this paper, I would like to stress that a multi-center bond formation might often play a significant role in stabilizing non-classical molecular clusters.

Theoretical

Consider a multi-center bonding system in which three or more atomic orbitals of the same kind, each belonging to a different atom, interact equally with each other. The simplest multi-center bond is a central three-center BBB bond, in which each of the three boron atoms interacts equally with the other two.[9] When ten atomic orbitals interact in this manner to form a ten-center bond, its bonding pattern can be expressed as in Fig. 1. This is identical with a complete graph of degree ten, K_{10}, where the vertices indicate the atomic orbitals concerned. In general, a complete graph of degree n, K_n, is a graph in which each of the n vertices is connected to all the other vertices.[10] A conjugated system of the type K_n gives only one bonding molecular orbital,[8] the energy of which is equal to $(n-1)\beta$. All the other molecular orbitals are antibonding, and the energies are equal to $-\beta$. Therefore, any ideal multi-center bond has two bonding electrons with the bonding energy of $2(n-1)\beta$.

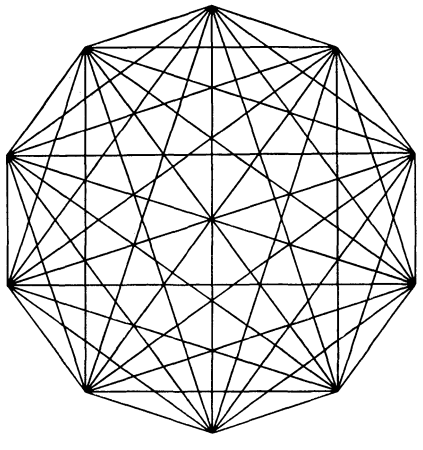


Fig. 1. A complete graph of degree ten, K_{10}.

Table 1. Resonance energies of K_n-type bonding systems

n	SC	RE/β	$\%RE$
3	3	0.536	15.5
4	3	1.331	28.5
5	15	2.286	39.6
6	15	3.351	50.4
7	105	4.499	60.0
8	105	5.711	68.9
9	945	6.975	77.3
10	945	8.281	85.2
11	10395	9.624	92.8
12	10395	10.998	100.0

In order to estimate stabilities of such multi-center bonding systems, it is instructive to examine the resonance energies calculated by means of the graph theory of aromaticity.[11] Resonance energies calculated for a series of K_n-type conjugated systems[12] are listed in Table 1. This type of resonance energy has been interpreted as an extra stabilization energy due to aromaticity.[11]

Results and Discussion

First of all, it is noteworthy that the resonance energy of any K_n-type bonding system is positive, indicating its aromaticity. The resonance energy (RE) is proportional to the logarithm of the Kekulé structure count (SC), *i.e.*, the number of Kekulé structures allowed for K_n. An analogous feature of resonance energies has already been reported for benzenoid hydrocarbons[13] and polyhedral boranes.[14] However, the situation is somewhat different from that for these compounds. As shown in Fig. 2, a correlation line for K_n with $n=2m-1$ obviously deviates downward from that for K_n with $n=2m$. Here, m is an arbitrary integer. For K_{2m}-type bonding systems

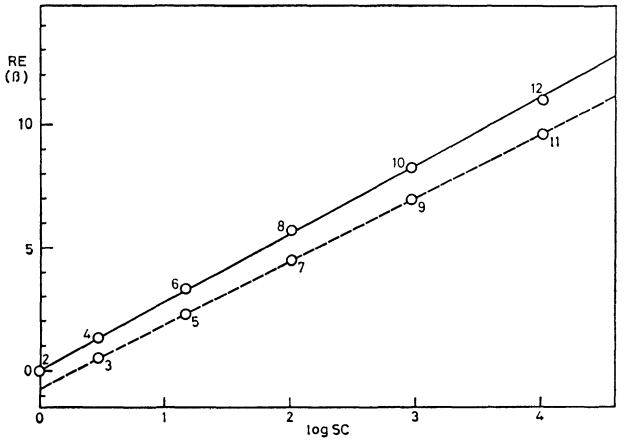

Fig. 2. *SC* Dependence of resonance energy for a series of K_n-type bonding systems.

$$RE = 2.768 \log SC, \quad (1)$$

and for K_{2m-1}-type bonding systems

$$RE = 2.573 \log SC - 0.710. \quad (2)$$

These relations hold well at least up to $m=6$.

One of the characteristics of such a multi-center bonding system is that its resonance energy is unusually large as compared with the energy of its olefinic reference structure, *i.e.*, the reference energy,[11] In order to see this aspect, a new quantity is defined as 100 times the resonance energy, divided by the reference energy, and it will be called the percent resonance energy (%*RE*). The %*RE* can be regarded as a practical index suitable for estimating aromatic stabilization of a conjugated system. The two largest %*RE*'s so far known among familiar compounds are 15.5 for a cyclopropenyl cation and 3.5 for benzene.[11] Note that a conjugated system of a cyclopropenyl cation is another example of a three-center bonding system.

In contrast to them, even for the next smallest multi-center bond, K_4, the %*RE* amounts to 28.5. The %*RE* increases as the degree of a complete graph increases. Such large %*RE* values cannot be imagined for any other kind of conjugated system. This means that a larger multi-center bonding system fixes itself more tightly, as long as the resonance integrals between the atomic orbitals remain almost unchanged.

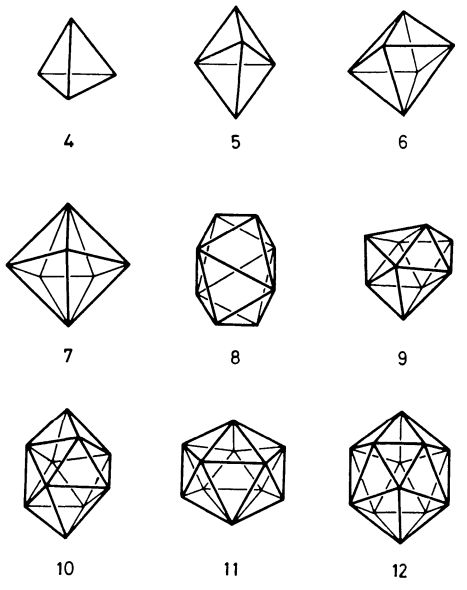
From the above energy consideration, we can fully expect the formation of bonding systems analogous to multi-center bonds in some way or other. When atoms M, each with an s-type atomic orbital, are employed for simplicity, molecular clusters with a general formula of M_n^{n-2} can be constructed so as to form K_n-type conjugated systems. The simplest example is a triangular H_3^+ ion.[15] When the size of such a cluster increases, an increased excess $(n-2)$ charge must be overcome either by some intramolecular balance or by the environment. In this sence, the realistic clusters of this type must be relatively small. The next promising species is of the type M_4^{2+}, where M is either an alkali or a coinage metal atom.

On the other hand, King and Rouvray presented a new bonding model of polyhedral systems, such as boranes $B_nH_n^{2-}$ and carboranes $B_{n-2}C_2H_n$.[8] According to it, the skeletal boron (or carbon) atom can be regarded as sp hybridized. The remaining two p orbitals, which are tangentially oriented with respect to the pseudo-polyhedron surface, are used for surface bonding. One sp hybrid orbital is used to bond the terminal hydrogen. The other sp hybrid orbital points radially in toward the center of the cluster. Such inward pointing sp hybrid orbitals emanating from all vertex atoms interact at the core of the polyhedral cluster. King and Rouvray assumed that the bonding pattern of these sp hybrid orbitals can roughly be represented by a complete graph.[8] In other words, all the inward pointing sp hybrid orbitals form a single multi-center bonding orbital with two electrons.

In a previous paper,[14] I calculated resonance energies of polyhedral boranes on the basis of the Kettle-Tomlinson bonding model,[16] in which borane molecular orbitals are depicted as a linear combination of localized three-center BBB bonding orbitals. The resonance energy obtained for every borane correlated well with the energy separation between the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO). We must, however, say that these resonance energies reflect primarily the stability of the surface bonding of the cluster because both LUMO and HOMO belong mostly to the surface bonding[1] and because the Kettle-Tomlinson model cannot fully express the multi-center bonding at the core of the cluster.[16] The weight of a core bonding system is obviously underestimated in this model.

On the contrary, the most distinct aspect of the King-Rouvray model is that a K_n-type core bonding system is factored out from an entire molecular cluster.[8] In accord with this, it has been shown that the core bonding can be factored out with some precautions to obtain an approximate picture of the valence structure.[17] Therefore, this model can be considered as a complement to the Kettle-Tomlinson model. The core bonding system is totally symmetric, and hence constitutes the lowest molecular orbital in a molecular cluster. It is often much lower in energy than the second lowest orbital.[18] Consequently, it naturally follows that, even if an actual core bonding system deviates more or less from a complete graph,[19] it should still contribute much to the stability of an entire cluster compound because an ideal multi-center core bonding orbital has both the largest bonding energy in the cluster and quite a large %*RE* value. This view is consistent, at least, with synthetic accessibility to many polyhedral boranes and metal carbonyl clusters and their stability. In these compounds, the overall charge which a cluster bears is generally small because most of the excess $(n-2)$ charge due to the K_n-type core bonding is cancelled by the polyhedral surface bonding.[8]

Conversely, we might safely say that an inorganic compound often tends to become polyhedral in shape so as to form a K_n-like core bonding system. This gives the major reason why shapes of most inorganic cage compounds are polyhedrons or polyhedral fragments. A multi-center bond formation thus appears to be one of the most workable ways to stability. Figure 3 shows typical shapes of polyhedral compounds (*e.g.*, closo-



iFg. 3. Shapes of typical polyhedral compounds.

boranes) which contain such multi-center core bonding systems. The number given below each polyhedron indicates the degree of a complete graph related to the core bonding,[19] and this is equal to the number of vertices of the polyhedron.

The present approach thus provides a convenient rationale for the existence and stability of polyhedral non-classical compounds, although it is simple and based on approximate bonding models. It goes without saying that the surface bonding may modify the degree of stability of an entire conjugated system to some extent. Considering that a surface bonding system is often a network of three-center bonds,[16] I feel confident that the concept of a multi-center bond is in some way essential to the stability consideration of not only homopolyatomic clusters formed by the s-like atomic orbitals but also general inorganic cage compounds including mixed clusters.[1]

The author expresses his gratitude to Professor R. B. King of the University of Georgia for critical but encouraging comments. The use of the facilities of the Hokkaido University Computing Center is acknowledged.

19) When the size of a molecular cluster increases, the geometry of the core bonding system will necessarily deviate from that of a complete graph. The β values in it will then be diversified, the absolute values being decreased to a varying extent. Such modification of the core bonding system will somewhat diminish both the resonance energy and the $\%RE$. This might be partially responsible for the fact that there are few polyhedral compounds which have more than eleven vertex atoms.[1]

Raman Spectra of Alkali Metal Oxalates in Aqueous Solution. Evidence for Ion-pair Formation

Kan KANAMORI,* Masamitsu MIHARA, and Kiyoyasu KAWAI

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received December 23, 1978)

Laser Raman spectra of aqueous solutions of lithium, potassium, and caesium oxalates have been obtained; their band contours were examined by curve analysis. The intensities of several bands show distinct concentration and cation dependences. This behavior is connected with the ion-pair formation of oxalate ions with alkali metal cations. The assignments of C=O stretching vibrations are also discussed.

Laser Raman spectroscopy has been widely used to explore the properties of ion-pairs formed in aqueous solutions of electrolytes. For the Raman spectra of aqueous solutions of metal sulfates or nitrates, many authors[1] have reported some additional bands which can give direct information on the ion-pairing. However, vibrational spectroscopic evidence for ion-pairing of carboxylate ions with metal cations is rarely found in earlier works, although thermodynamic evidence is presented by several authors.[2]

The oxalate ion has the simplest structure among the dicarboxylate ions. This anion is expected to have a comparatively large association constant owing to the formation of a chelate-like structure with metal cations in aqueous solutions.

The Raman spectra of aqueous oxalate solutions were studied by several authors in order to assign the symmetry of the free oxalate ion. Murata and one of us (K.K)[3] assumed that the oxalate ion had a planar D_{2h} symmetry because of the inconsistency between the IR and Raman frequencies for the potassium salt. The same symmetry was also assumed by Ito and Bernstein[4] for the ion, while a staggered form of D_{2d} symmetry was proposed by Begun and Fletcher[5] and Bardet and Fleury[6] on the basis of the aqueous IR and Raman spectra. Schmelz, Miyazawa, Mizushima, Lane, and Quagliano[7] assumed the ion to have a D_2 symmetry by comparing the infrared data of the solid salt with the Raman data of an aqueous solution reported by Edsall.[8]

In the present work Raman spectra of aqueous alkali metal oxalate solutions are interpreted in terms of coexistence of the free and the ion-paired oxalate ions. The assignment for the Raman bands of the free oxalate ion is also reexamined.

Experimental

The $Li_2C_2O_4$ and $K_2C_2O_4 \cdot H_2O$ used were reagent grade chemicals. $Cs_2C_2O_4$ was prepared by the reaction of Cs_2CO_3 with $H_2C_2O_4$; the crude product was purified by recrystallization. Aqueous solutions were prepared by dissolving a determined amount of these oxalates in distilled water. The solution were filtered through sintered glass filters prior to measurements of Raman spectra.

The Raman spectra were recorded on a JASCO Laser-Raman spectrometer (model R-800) using an Ar^+ ion (514.5 nm) laser as a excitation source at room temperature (20±1 °C). The frequencies of observed bands are accurate within ±2 cm^{-1}.

The band decomposition was carried out using the FACOM 230 computer at Toyama University Computer Center, with a Voight function[9] taken as the spectral distribution of a single band.

Results and Discussion

Polarized Raman spectra observed for a saturated solution of potassium oxalate are shown in Fig. 1. The isotropic spectrum in Fig. 1 is the same in general spectral features as that given previously by Begun and Fletcher,[5] except that two very weak polarized bands at 1750 and 1360 cm^{-1} were recognized in the present study. However, it was found that some of the observed bands have obvious asymmetries and some features show distinct dependence on stoichiometric concentration.

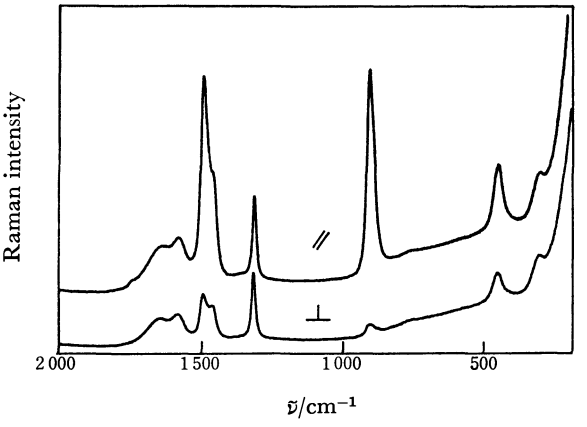

Fig. 1. Polarized Raman spectra of a satulated aqueous solution of potassium oxalate.

In previous works,[3-7] the band at *ca.* 900 cm^{-1} was assigned to the C–C stretching vibration as a single band. As shown by the solid line in Fig. 2, however, the isotropic and anisotropic band shapes observed for a saturated solution of potassium oxalate suggest that these bands consist of more than two components. We analyzed both the isotropic and anisotropic spectra, assuming that the components resolved in the isotropic spectrum are at the same frequencies as the corresponding ones in the anisotropic spectrum. As shown by broken lines in Fig. 2, both spectra can be resolved into three bands at 906, 891, and 872 cm^{-1}, of which the two high frequency bands are apparently polarized,

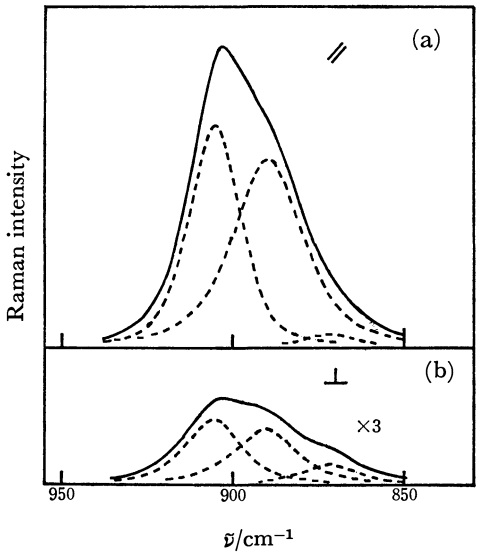

Fig. 2. The observed Raman contour (——) and the computer-analyzed components (----) in C–C stretching region of a saturated aqueous potassium oxalate. (a) Isotropic spectrum; (b) anisotropic spectrum.

while the low frequency weak one is depolarized. This depolarized band is irrelevant to the discussion on the C–C stretching vibration and may be assigned to a combination band of the two IR frequencies[5] (525+351=876 cm^{-1}), because regardless of the symmetry of the oxalate ion the C–C stretching vibration belongs to a totally symmetric species and no band was observed near 872 cm^{-1} in the infrared spectra of either aqueous solution or solid state.[5] The Raman contours observed in this region for solutions of different concentrations of $K_2C_2O_4$ or for the $K_2C_2O_4$–KCl–H_2O solution were satisfactorily decomposed into the three bands, but the relative intensities of the two polarized bands showed a marked stoichiometric concentration dependence. Integrated intensity ratios of the 891 cm^{-1} band to the 906 cm^{-1} one for these systems are shown in Table 1. One notices from Table 1 that the ratio (I_{891}/I_{906}) increases with increasing stoichiometric concentration of potassium oxalate or by the addition of potassium chloride. From this behavior, the band at 891 cm^{-1} can be reasonably assigned to the C–C stretching vibration

TABLE 1. INTENSITY RATIOS OF THE 891 TO 906 cm^{-1} BANDS[a]

System	I_{891}/I_{906}
0.1 M $K_2C_2O_4$	0.44
0.5 M $K_2C_2O_4$	0.51
0.7 M $K_2C_2O_4$	0.54
1.0 M $K_2C_2O_4$	0.58
1.5 M $K_2C_2O_4$	0.63
1.8 M $K_2C_2O_4$	0.69
0.5 M $K_2C_2O_4$+2.5 M KCl	0.73
0.5 M $Li_2C_2O_4$	0.88
0.5 M $Cs_2C_2O_4$	0.48

a) The *ca.* 900 cm^{-1} contour has been assumed to consist of three bands whose widths are invariant for the different systems.

of ion-paired oxalate and the band at 906 cm^{-1} to that of the free oxalate ion.

The Bjerrum theory[10] on ion association suggests that, in the systems which contain a common ion, the smaller the radius of the counter ion is, the larger the association constant which can be expected. In order to examine the effect of metal cations on the ion-pair formation, the Raman spectrum of an aqueous solution of lithium or caesium oxalate was also observed. The Raman contours of the C–C stretching region of these systems were also resolved into three bands. The frequency shifts of these bands with the variation of cations were about ± 3 cm^{-1}, and within the error estimated from both the measurements and the curve analysis. However, some cation dependence was found in the relative intensities of the two polarized bands. At the same stoichiometric concentration (0.5 M) the value of the I_{891}/I_{906} ratio, which is a measure of the degree of ion-pair formation, decreases in the order of lithium>potassium>caesium oxalate (see Table 1). This order also supports the above assignment of the C–C stretching region.

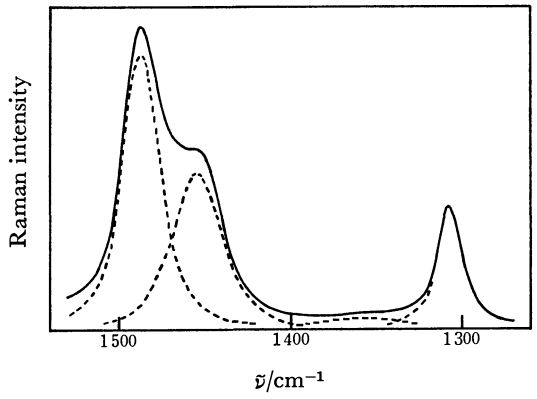

Fig. 3. The observed Raman contour (——) and the computer-analyzed components (----) from 1270 to 1530 cm^{-1} of a saturated aqueous potassium oxalate.

The spectrum in the C=O stretching region for a saturated solution of potassium oxalate is shown in Fig. 3 (solid line). The resolution of the band contour into components is also shown in Fig. 3 (broken line). The resulting bands are situated at 1308, 1360, 1456, and 1488 cm^{-1}. The very weak and broad band at 1360 cm^{-1} is polarized and may be assigned to a combination band such as the C–C stretching and the CO_2^- bending modes (906+450=1356 cm^{-1}). The two bands at 1456 and 1488 cm^{-1} are clearly polarized, as is seen in Fig. 1. As shown in Table 2, there is some confusion in the assignments of the bands in this region, particularly of the band at 1456 cm^{-1}, depending on the symmetry of the free oxalate ion in the previous studies.[3–7] The Raman contours from 1400 to 1550 cm^{-1} in various systems are shown in Fig. 4. The relative intensity of the 1456 cm^{-1} band distinctly depends on both the stoichiometric concentration of oxalate and the variation of cations, just as that of the 891 cm^{-1} band does.

Figure 5 shows integrated intensity ratios of the 1308, 1456, and 1488 cm^{-1} bands to the 906 or 891 cm^{-1}

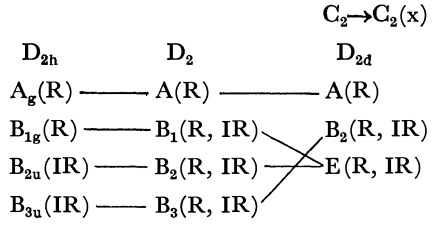
band *vs.* the stoichiometric concentration of potassium oxalate. Unfortunately, the integrated intensity of the band at 1575 cm^{-1} could not be obtained with enough accuracy for a quantitative discussion, because of its weakness and the overlapping with water bands. The independencies of the stoichiometric concentration are found for the intensity ratios of the 1308 and 1488 cm^{-1} bands to the 906 cm^{-1} band in Fig. 5. The same is true for the ratio of the 1456 cm^{-1} band to the 891 cm^{-1} band. The bands at 906, 1308, and 1488 cm^{-1} thus belong to the vibrations of the free oxalate, while the bands at 891 and 1456 cm^{-1} belong to those of the ion-paired oxalate.

Earlier studies on the vibrational spectrum of the oxalate ion were based mainly on the number of Raman active C=O stretching modes in the determination of the symmetry of the ion. The free oxalate ion in an aqueous solution should have one of three conformations: D_{2h} (planar), D_{2d} (two CO_2^- planes are at right angles), and D_2 (two CO_2^- planes are rotated with respect to each other by an angle which is not 90°). Symmetry correlations and vibrational activities related to the C=O stretchings are as follows.



An oxalate ion in solid $K_2C_2O_4 \cdot H_2O$ has a planar symmetry[11] and so the Raman and IR activities are mutually exclusive. Recently, Eriksson and Nielsen[12] found the Raman active antisymmetric and symmetric C=O stretching vibrations (A_g and B_{1g} modes) for polycrystalline and single crystal $K_2C_2O_4 \cdot H_2O$ at *ca.* 1600 and 1444 cm^{-1}, respectively. Two IR active stretching vibrations were observed for the salt at 1600 and 1310 cm^{-1} by Schmelz *et al.*[7] and at 1610 and 1312 cm^{-1} by Begun and Fletcher.[5] These vibrations were also examined in detail by Fukushima[13] in terms of the lattice vibrations of hydrated potassium oxalates. Schmelz *et al.*[7] have assigned the former to the antisymmetric vibration and the latter to the symmetric one. These assignments have been regarded as reasonable by the comparison of the frequencies with the Raman data,[12] though the opposite assignments had been given by Begun and Fletcher.[5] Cadene and Fournel[14] observed bands at *ca.* 1600 and *ca.* 1300 cm^{-1} in both the IR and Raman spectra of single crystal $(NH_4)_2C_2O_4 \cdot H_2O$, where the dihedral angle between two CO_2^- planes is 26.6°.[15] They have assigned the two bands to

the antisymmetric and symmetric (not totally) C=O stretching vibrations, respectively, though their assignments were made on the basis of the D_{2d} symmetry for the oxalate ion. By comparing the two antisymmetric C=O stretching vibrational frequencies obtained in the previous studies,[5,7,12,14] little difference was found between the two vibrational frequencies for the ion whose symmetry is D_{2h} or D_2. There may be an accidental degeneracy in some cases. If the ion has a D_{2d} symmetry, the two antisymmetric C=O stretching frequencies are degenerate. For the structure of the free oxalate ion in aqueous solution, Begun and Flecher[5] pointed out that the ion has D_{2d} symmetry, because they found the existence of three coincidences between the IR and the Raman bands in the C=O stretching region of the spectra for aqueous solutions of alkali metal oxalates. Because of the appearance of the *ca.* 1300 cm^{-1} Raman band, which is reasonably assigned to the symmetric C=O stretching vibration, we conclude that the free ion does not have a planar structure. The assignment of the proper symmetry (D_2 or D_{2d}) of free oxalate, however, is difficult, because of the possibility of the accidental degeneracy in the two antisymmetric C=O stretching vibrations or the serious overlapping of several bands at *ca.* 1600 cm^{-1}. The tentative assignments of C=O stretchings are shown in Table 2.

The reason why only a Raman band which belongs to the C=O stretching vibrations has been detectable for the ion-paired oxalate may be discovered on the assumption that the oxalate ion has a planar and quasi-centrosymmetric structure. If the symmetry of the ion-paired oxalate is closer to D_{2h}, the intensity of the Raman band due to the symmetric vibration at *ca.* 1310 cm^{-1} will be less intense. This assumption may be supported by the low frequency shifts of the C–C stretching and the totally symmetric C=O stretching vibrations for ion-paired oxalate, compared with those for free oxalate in aqueous solutions; these vibrations were observed at 881 and 1444 cm^{-1} for polycrystalline $K_2C_2O_4 \cdot H_2O$.[12] Some planarity of ion-paired oxalate will be brought preferably by the formation of a chelate-like structure; because the interaction between oxalate and alkali metal ions will be mainly ionic, the oxalate ion is also expected to be kept in a quasi-centrosymmetric structure. Even if the interaction between cation and anion were covalent to some degree and thus the oxalate ion lost its quasi-centrosymmetric structure, the Raman band due to the (not totally) symmetric C=O stretching vibration would not be detectable in the range 1300—1400 cm^{-1}; this result is suggested by the fact that no Raman band was detected in the range 1300—1400 cm^{-1} for oxalato aluminium[16] or beryllium complex.[17] The Raman active antisymmetric C=O stretching vibrations for ion-paired oxalate will be expected at *ca.* 1600 cm^{-1}. Serious overlapping of the bands with the free oxalate or water bands will then occur. No useful information on band overlapping has yet been provided by Raman spectral measurements in D_2O, but the broad Raman band at 1575 cm^{-1} may reflect such a situation.

The authors are indebted to Professor Yoichi Shimura of Osaka University and Dr. Isao Kanesaka of our university for their valuable discussions.

The Transport of Metal Ions against Their Concentration Gradients through a 1,2-Dichloroethane Membrane

Masaaki SUGIURA* and Toshio SHINBO

National Chemical Laboratory for Industry, Nishiyawata, Hiratsuka 254

(Received January 6, 1979)

The uphill transport of metal ions such as copper, zinc, cobalt, and iron(II) ions through a bulk 1,2-dichloroethane membrane in the presence of various chelating agents has been studied. The membrane separated two aqueous phases, one containing the metal ion and potassium or lithium sulfate, and the other containing the metal ion and lithium nitrate or chloride. The chelating agents used were derivatives of 1,10-phenanthroline and acetylacetone. The accumulation of the metal ions in the aqueous phase containing the potassium or lithium sulfate was observed for only the following chelating agents: copper: 4,7-diphenyl-2,9-dimethyl- and 4,7-diphenyl-1,10-phenanthroline; zinc: 4,7-diphenyl-, 3,8-diphenyl-, 2,9-dimethyl-, and 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline; cobalt: 3,8-diphenyl- and 4,7-diphenyl-1,10-phenanthroline; and iron(II): 3,8-diphenyl-1,10-phenanthroline. In the system containing lithium sulfate in the aqueous phase, the rate of transport of the metal ions was slightly higher than that in the system containing potassium sulfate. The reduction of the nitrate ion in the aqueous phase brought about a lowering of the rate of transport of the metal ions. The transport of the metal ions was, however, unaffected by the electrostatic effect. The metal ion complexed by the chelating agent may be transferred in the 1,2-dichloroethane phase, thus forming an ion-pair with the nitrate or chloride ion.

In a previous paper,[1] the present authors studied the uphill transport of the picrate anion through a bulk 1,2-dichloroethane membrane. The picrate anion was transported against its concentration gradient by coupling to a diffusion of potassium ions *via* various potassium ionophores.

Using a membrane system similar to that used for the picrate transport and various chelating agents, we have now made an attempt to make metal ions move against their concentration gradient. This report will concern the uphill transport of some metal ions, such as copper, zinc, cobalt, and iron(II) ions.

Experimental

Apparatus. The apparatus used for measuring the transport of the metal ions was the same as that used in the previous paper.[1] In the transport cell (cylindrical glass vessel:[2] 7 cm i.d.,; height, 7 cm), the dichloroethane phase (100 ml), containing a 10^{-3} M chelating agent, separated two aqueous phases (50 ml each), one (Phase I) containing 5×10^{-4} M metal sulfate and 0.05 M potassium or lithium sulfate, and the other (Phase II) containing 5×10^{-4} M metal sulfate and 0.1 M lithium nitrate or chloride.

Materials. As lipophilic chelating agents, derivatives of 1,10-phenanthroline and acetylacetone were used: the 5-methyl-, 5-nitro-, 5-chloro-, 2,9-dimethyl-, 4,7-dimethyl-, and 3,8-diphenyl-1,10-phenanthroline, dibenzoylmethane, benzoyltrifluoroacetone, and benzoylacetone were commercial products from the Tokyo Kasei Kogyo Co., Ltd., while the 4,7-diphenyl- and 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline and 2-thenoyltrifluoroacetone were from the Dojindo Lab. The metallic salts, copper, zinc, cobalt, and iron(II) sulfate and the other chemicals were reagent-grade and were not subsequently purified.

Procedure. The technique used for measuring the rate of transport of the metal ions and the membrane potential was the same as that described in the previous paper.[1] The measurements were carried out at 25 °C. The dichloroethane used as the liquid membrane was pre-equilibrated with a 5×10^{-4} M metal sulfate solution containing a potassium or lithium sulfate and lithium nitrate or chloride, whose concentrations were equal to those in the two aqueous phases, I and II. After this treatment, the membrane system was constructed in the transport cell as has been described above. The determination of the metal-ion concentration in Phases I and II at regular time intervals was carried out by a colorimetric method, after a small volume of the aqueous solutions had been pipetted off (copper; 0.5 ml, zinc; 0.2 ml, cobalt; 0.5 ml, iron(II); 0.5 ml); the concentration of copper was determined by the neocuproine method,[3] the zinc, by the zincon method,[4] the cobalt, by the 2-nitroso-1-naphthol method,[5] and the iron(II), by the 1,10-phenanthroline method.[6]

Results

Uphill Transport of Various Metal Ions. The rates of transport of the metal ions across the dichloroethane membrane in the presence of various chelating agents were measured. The uphill transport was, however, observed for only the following chelating agents: copper: 4,7-diphenyl-2,9-dimethyl-, and 4,7-diphenyl-1,10-phenanthroline; zinc: 4,7-diphenyl-, 3,8-diphenyl-, 2,9-dimethyl-, and 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline; cobalt: 3,8-diphenyl- and 4,7-diphenyl-1,10-phenanthroline; iron(II): 3,8-diphenyl-1,10-phenanthroline. The curves of the concentrations of the metal ions in both aqueous phases and the membrane potential against the time for these chelating agents are shown in Figs. 1 to 3. The solid and dotted lines in each figure (a) represent the concentration curves in Phases I and II respectively. The polarity of the membrane potential was positive in Phase II with respect to Phase I. In these systems, Phase I contained 0.05 M potassium sulfate, and Phase II, 0.1 M lithium nitrate.

In the present experiment, 10^{-3} M was chosen as the concentration of the chelating agents in the dichloroethane phase. It was the most effective concentration for the transport of the metal ions. As an example of the effect of concentration of the chelating agents on the transport of the metal ions, the curves of the copper concentrations in both aqueous phases and the membrane potential against the time for various concentrations of 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline are shown in Fig. 4.

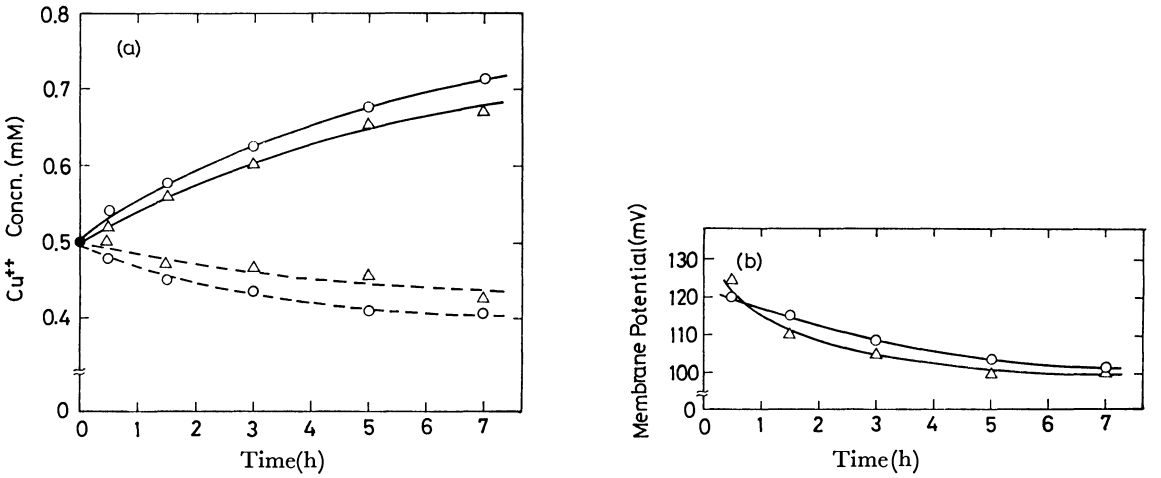

Fig. 1. (a) Copper concentrations in both aqueous phases against time curves. The solid and dotted lines represent the copper concentrations in Phases I and II respectively.
(b) Membrane potential against time curves for the copper.
Chelating agent;
○: 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline, △: 4,7-diphenyl-1,10-phenanthroline.
Phases I and II contained 0.05 M K_2SO_4 and 0.1 M $LiNO_3$ respectively.

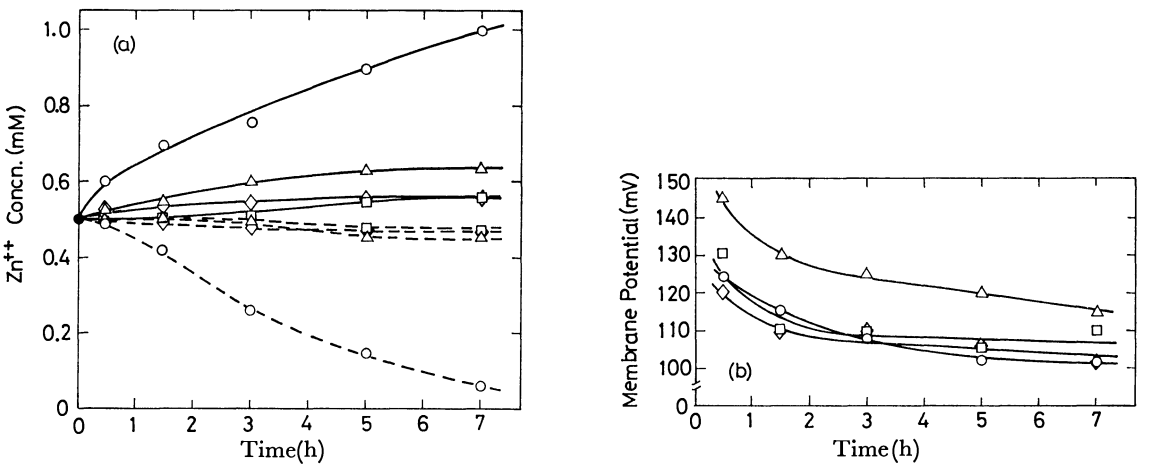

Fig. 2. (a) Zinc concentrations in both aqueous phases against time curves.
The curves have the same meanings as in Fig. 1.
(b) Membrane potential against time curves for the zinc.
Chelating agent;
○: 4,7-diphenyl-1,10-phenanthroline, △: 3,8-diphenyl-1,10-phenanthroline, ◇: 2,9-dimethyl-1,10-phenanthroline, □: 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline.
Phases I and II contained 0.05 M K_2SO_4 and 0.1 M $LiNO_3$ respectively.

In the case of the other phenanthroline and acetylacetone derivatives used, no transfer of the metal ions across the membrane was observed, though a membrane potential ranging from 100 to 200 mV was developed.

Effect of Potassium Ion and Lithium Counter-ions. When the lithium sulfate was added to Phase I in place of the potassium sulfate, the rate of transport of the metal ions increased slightly. The decrease in the concentration of the nitrate ion in Phase II brought about a lowering of the rate of transport of the metal ions. In the system containing the chloride in Phase II in place of the nitrate, a considerable high rate of transport of the metal ions was also observed. These results are illustrated in Fig. 5, which shows the data for the copper-4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline system.

In the system containing the potassium and lithium sulfates in Phases I and II respectively, a membrane potential of approximately 60 mV was developed by the addition of a potassium ionophore such as dicyclohexyl-18-crown-6. No transfer of the metal ions across the membrane was, however, observed in this system.

Effect of Membrane Potential. In order to examine the role of the membrane potential, the potential difference between Phases I and II was clamped at 0 mV by means of a short-circuit method.[7] The results obtained are shown in Fig. 6. The data for the transport of the metal ions obtained with the voltage clamp

agreed almost entirely with those obtained without the voltage clamp.

Discussion

In the previous paper,[1] the highest rate of picrate transport was observed in the system containing potassium sulfate and lithium nitrate in Phases I and II respectively. The membrane potential in this system was higher than that in the other systems used. Using the membrane system and various chelating agents, the present authors first attempted to make the metal ions move against their concentration gradient. As may be seen in Figs. 1 to 3, however, the uphill transport of the metal ions occurred for only some phenanthroline derivatives. In addition, the rate of transport of the metal ions differed from one another in the combination of chelating agent and metal ion.

The phenanthroline derivatives which can move the metal ions form complexes with the metal ions. However, they do not necessarily have a high stability constant for the formation of the complexes. Although some of the phenanthroline derivatives used form a stable complex with the metal ion,[8] they cannot move the metal ion. On the other hand, the metal ions which can be moved by the phenanthroline derivatives have almost constant ionic radii:[9] copper, 0.72 Å; zinc, 0.74 Å; cobalt, 0.72 Å; iron(II), 0.74 Å. The nickel and iron(III) ions whose ionic radii were 0.69 and 0.64 Å respectively could not be moved in the system used in the present experiment. It is assumed that the chelating agents can move the metal ions only when they form complexes with a specific structure which facilitates the transfer of the metal ions at the aqueous phase-

membrane interfaces; the formation of a more stable metal-complex brings about a lowering of the rate of dissociation of the metal-complex.[10]

The phenanthroline derivatives which can move the metal ions are composed of lipophilic groups with a high solubility in the organic solvent. The partition coefficients of their metal-complexes between the aqueous and membrane phases must, therefore, be higher than that of the other phenanthroline derivatives. This high solubility in the membrane phase may also facilitate the transfer of the metal ions.

The acetylacetone derivatives could not move the metal ions. These compounds form fairly stable complexes with potassium and lithium ions as well as with the metal ions;[11,12] in this respect, they differ from the phenanthroline derivatives. The transfer of the metal ions in the membrane may be prevented by the formation of complexes with the potassium and lithium ions.

In the system containing lithium sulfate in Phase I, the rate of transport of the metal ions was slightly higher than that in the system containing potassium sulfate. In the case of the potassium sulfate, the transfer of the metal ions from Phase II to Phase I may be somewhat depressed by the diffusion of lithium ions from Phase II to Phase I, whereas in the case of the lithium sulfate the diffusion of the lithium ions does not occur.

The reduction of the nitrate ion in Phase II brought about a lowering of the rate of transport of the metal ions. In addition, in the potassium sulfate–lithium sulfate system containing a potassium ionophore, the transfer of the metal ions was not observed. The data for the transport of the metal ions with the voltage clamp agreed almost entirely with those for the ions without the voltage clamp. These facts show that the transfer of the metal ions occurs only in combination with the diffusion of nitrate ions (or chloride ions), which can penetrate the membrane.

In the previous paper,[1] the picrate anion in Phase I was dissolved in the dichloroethane phase, forming an ion-pair with a complexed cation consisting of an ionophore and the potassium ion, and then liberated into phase II by the dissociation of the ion-pair. The

metal ions may also be transported by the same mechanism; the metal ion, complexed by the chelating agent in Phase II, was dissolved in the dichloroethane phase, thus forming an ion-pair with a nitrate ion (or a chloride ion), and then liberated into Phase I by the dissociations of the ion-pair and the complex.

A Study on Electronic Excited States of Iridium(III) Complexes Containing Bipyridine and Phenanthroline Ligands. Solvent Effect on Triplet-Triplet Absorption Spectra

Yukako OHASHI*,† and Takayoshi KOBAYASHI

The Institute of Physical and Chemical Research, Hirosawa, Wako 351

(Received January 26, 1979)

In order to study the solvent effect on the lowest excited state of *cis*-$[IrCl_2L_2]Cl$ (L=2,2′-bipyridine, 1,10-phenanthroline, and 4,7-dimethyl-1,10-phenanthroline), the triplet-triplet absorption spectra (15000 cm^{-1}—27000 cm^{-1}) were measured by the use of *N,N*-dimethylformamide–water mixed solvents. For the triplet-triplet spectra of the three iridium complexes, remarkable spectral changes were observed with the change of the solvent polarity. An SCF calculation of the triplet-triplet transitions was carried out for free bipyridine and free phenanthroline. By comparing the calculated results and the observed spectra, the solvent effect can be interpreted in terms of a model invoking $d\pi^*$-$\pi\pi^*$ interaction, as proposed by Crosby. The lowest triplet state of $[IrCl_2(phen)_2]Cl$ is predominantly a $d\pi^*$ state in 95% v/v DMF–water, but in water, by the reversal of the state ordering, the lowest state becomes a $\pi\pi^*$ state. Furthermore, a quite similar solvent effect which was observed on the lowest triplet state of $[IrCl_2(bpy)_2]Cl$ is discussed; this state is not expected to have a $d\pi^*$-$\pi\pi^*$ interaction.

It has been pointed out that, in contrast to the ruthenium(II) complexes,[1–4] the character of the lowest excited state of *cis*-$[IrCl_2(phen)_2]Cl$ (phen: phenanthroline) is very sensitive to the solvent. The emission spectra and lifetimes at 77 K show a distinct solvent effect as the solvent polarity changes. This effect has been interpreted in terms of a change in the character of the lowest excited state.[1–3] Since the lowest $d\pi^*$ state (metal-to-ligand charge transfer excited state) and the lowest $\pi\pi^*$ state (locally excited state of a ligand) lie very close to each other, the solvent polarity affects their energy separation, which changes the electronic character of the lowest excited state. Recently, the contribution of the lowest d-d (locally excited state of a metal) level to the lowest excited state was also shown to be important by photochemical measurements[4] and the temperature dependence of the emission spectra.[5]

Since the excited-state absorption spectrum is assumed to change sharply, as the character of the lowest excited state changes, we measured the triplet-triplet absorption spectra of three *cis*-biscoordinated complexes($[IrCl_2(phen)_2]Cl$, $[IrCl_2(4,7\text{-Mephen})_2]Cl$, and $[IrCl_2(bpy)_2]Cl$) (bpy: bipyridine) and one triscoordinated complex ($[Ir(bpy)_3](NO_3)_3$) at room temperature, by using the mixed solvents of *N,N*-dimethylformamide (DMF) and water. Large solvent effects on the triplet-triplet absorption spectra were observed for the three biscoordinated complexes, but almost no solvent effect was seen for the triscoordinated complex. Using these results, we discuss the electronic structure of these biscoordinated complexes.

Experimental

Materials. *cis*-Dichlorobis(1,10-phenanthroline)iridium(III) chloride trihydrate, $[IrCl_2(phen)_2]Cl\cdot 3H_2O$, was prepared by following the procedure of Broomhead and Grumly.[6] *cis*-Dichlorobis(4,7-dimethyl-1,10-phenanthroline)iridium(III) chloride pentahydrate, $[IrCl_2(4,7\text{-Mephen})_2]Cl\cdot 5H_2O$, wa prepared by the same procedure. *cis*-Dichlorobis(2,2′-bipyridine)iridium(III) chloride dihydrate, $[IrCl_2(bpy)_2]Cl\cdot 2H_2O$, was synthetized by the method of Watts and Crosby.[7] Tris(bipyridine)iridium(III) nitrate, $[Ir(bpy)_3](NO_3)_3$, was prepared by the method of Flynn and Demas.[8] The purity of the complexes was checked by measuring the phosphorescence spectra, decay times, and the excitation spectra. Dimethylformamide was of spectrophotometric grade and water was distilled four times.

Apparatus. The triplet-triplet absorption spectra were obtained at room temperature using a nitrogen laser as an exciting light source and a pulsed xenon flash as a monitoring light source.[9] In order to discuss the relative absorbance of the triplet-triplet spectrum, we made a correction for the concentration of the excited molecules. Since in iridium(III) complexes no fluorescence was observed and the phosphorescence quantum yield does not depend on the exciting wavelength, we can assume that the quantum yield of triplet formation is very close to unity. Then, the absorbance at 337 nm of the ground-state absorption of each sample is proportional to the concentration of the excited triplet molecules. The ethanol–methanol solution (4: 1, v/v) of $[IrCl_2(phen)_2]Cl$ was used as a standard sample. The absorbance of the standard solution was measured in the same laser conditions as that for each sample solution. With the use of the relative concentration of the excited molecules estimated by the 337 nm absorbance, we obtained the corrected triplet-triplet absorption spectra corresponding to the same concentration of the excited molecules.

Results and Discussion

Figure 1 shows the triplet-triplet absorption spectra of $[IrCl_2(bpy)_2]Cl$ in water, 45% v/v DMF–water and 95% v/v DMF–water, and the triplet-triplet spectrum of $[Ir(bpy)_3](NO_3)_3$ in ethanol–methanol (4: 1, v/v).

In our present experiment, the measurements were carried out at concentrations of $\approx 10^{-3}$ mol dm^{-3}. An absorbance of less than 0.01 could not be measured.

In the case of $[IrCl_2(bpy)_2]Cl$, the absorbance in the spectral region below 21000 cm^{-1} decreases and the absorbance above 23000 cm^{-1} increases, as the solvent becomes more polar. However, for $[Ir(bpy)_3](NO_3)_3$, no solvent effect on the absorption spectra was observed for water, 95% v/v DMF–water, and ethanol–methanol (4: 1, v/v). Figures 2 and 3 show the triplet-triplet

absorption spectra of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(4,7\text{-Mephen})_2]Cl$ in DMF–water mixed solvents. In both complexes, the absorbance decreases remarkably as the solvent polarity increases. Furthermore, the same shift of the spectra was observed as for the bis(bipyridine) complex.

Assignment of Excited States. The absorption spectrum of $[Ir(bpy)_3](NO_3)_3$ has no low-energy $^1d\pi^*$ band and resembles that of free bipyridine molecules.[8] Since the singlet-triplet energy separation of a $\pi\pi^*$ state is generally much larger than that of a $d\pi^*$ state, the emitting level of the tris(bipyridine) complex(E_0= 22350 cm^{-1}) was assigned to a $^3\pi\pi^*$ state. The phosphorescence lifetime we observed is 49 μs at 77 K in degassed methanol. This value is ten times as long as the typical lifetimes of $d\pi^*$ phosphorescence.[10]

From the absorption spectrum measurements,[1] the lowest singlet state of $[IrCl_2(bpy)_2]Cl$ at 21900 cm^{-1} and $[IrCl_2(phen)_2]Cl$ at 21700 cm^{-1} was assigned to a $^1d\pi^*$ state. The singlet-triplet energy separation is generally small for a $d\pi^*$ state, hence the $^3d\pi^*$ level lies just below the $^1d\pi^*$ level. On the other hand, both of the free ligands also have a $^3\pi\pi^*$ emission in this region: E_0=23500 cm^{-1} for free bipyridine and 22200 cm^{-1} for free phenanthroline, at 77 K in ethanol–methanol (4: 1, v/v). Thus, the energy separation between the lowest $^3d\pi^*$ state and the lowest $^3\pi\pi^*$ state is expected to be small. The stabilization energy by solvent polarization is different depending upon the types of the electronic structures, that is, the ground state, $d\pi^*$ states, and $\pi\pi^*$ states. These differences of polarization energy are assumed to be of the same order as the energy separation between the lowest $^3d\pi^*$ and $^3\pi\pi^*$ states. Therefore, the character of the observed lowest triplet state of biscoordinated complexes is sensitive to the environment, as is seen from Figs. 1 and 2. The emitting state of $[IrCl_2(bpy)_2]Cl$ is 21400 cm^{-1} and that of $[IrCl_2(phen)_2]Cl$ is 21000 cm^{-1}, in ethanol–methanol (4: 1, v/v). Since the $^3\pi\pi^*$ energy of free bipyridine is 1300 cm^{-1} higher than that of free phenanthroline, the interaction in $[IrCl_2(bpy)_2]Cl$ between $^3d\pi^*$ and $^3\pi\pi^*$ states is thought to be small, in contrast to the case of $[IrCl_2(phen)_2]Cl$.[2] However, the lowest $^3\pi\pi^*$ state of $[Ir(bpy)_3](NO_3)_3$ appears at 22350 cm^{-1}, 1200 cm^{-1} lower than that of free bipyridine. The red shift of the $\pi\pi^*$ peak upon complex formation is thus large for a bipyridine complex but very small for a phenanthroline complex. Therefore, the energy separation between the lowest $^3\pi\pi^*$ and $^3d\pi^*$ of $[IrCl_2(bpy)_2]Cl$ is very similar to that of $[IrCl_2(phen)_2]Cl$.

For the bis(phenanthroline) complex, the emission lifetime at room temperature decreases from 270 ns[4] to 13 ns(our data), when the solvent is changed from 95% v/v DMF–water to water. This rapid decrease of the lifetime is also observed for bis(bipyridine) complex. From this similarity we can conclude that the character of the lowest triplet state of $[IrCl_2(bpy)_2]Cl$ is analogous to $[IrCl_2(phen)_2]Cl$.

Recently, from the large temperature dependence of the emission spectra in glycerol, the lowest triplet state of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ was assigned to an excited state localized on the metal(dd).[5]

However, in ethanol–methanol (4: 1, v/v), we observed no shift between the emission spectra at 77 K and 300 K for $[IrCl_2(phen)_2]Cl$. Furthermore, in water and 95% v/v DMF–water, the emission of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ at room temperature also does not show any shift from the low-temperature emission.[4] Therefore, in the solvents used in our experiments, the contribution of a dd level to the lowest triplet state can be neglected.

Solvent Effect of Triplet-Triplet Absorption Spectra. For the three biscoordinated complexes, the ground-state absorption peaks show a blue shift of 400—1000 cm^{-1}, when the solvent is changed from 95% v/v DMF–water to water. The observed stabilization of the singlet energy levels in polar solvents were almost equal for the same type of transition. On the other hand, the observed strong triplet-triplet transitions are primarily assigned to the transitions between electronic states of the same type($d\pi^*$-$d\pi^*$ or $\pi\pi^*$-$\pi\pi^*$). For the triplet-triplet transition the solvent effect on both states is almost counterbalanced. Therefore, the observed solvent effects on the triplet-triplet absorption spectra shown in Figs. 1, 2, and 3 can not be explained only by the above-mentioned solvent shifts of the energy levels.

The lowest triplet state in a tris(bipyridine) complex is $^3\pi\pi^*$; hence the observed triplet-triplet absorption spectrum is assigned to a $\pi\pi^*$-$\pi\pi^*$ transition. In a bis(bipyridine) complex, since the $^3d\pi^*$-$^3\pi\pi^*$ energy separation is of the same order as the solvent shift of the energy levels, a reversal of the states can occur by changing the solvent polarity. If the lowest triplet state(T_1) is denoted as $T_1 = A_{CT}\Psi(d\pi^*) + A_{LE}\Psi(\pi\pi^*)$, where A_{CT} and A_{LE} are coefficients of the wave function, the observed triplet-triplet absorption spectrum changes from T_1-higher $d\pi^*$ transitions to T_1-higher $\pi\pi^*$ transitions, as the coefficient A_{LE} increases.

We carried out an SCF-CI calculation on the triplet-triplet transitions for free bipyridine and free phenanthroline molecules. Figure 4 shows the calculated transition energies. The observed triplet-triplet absorption spectrum of free phenanthroline and the $^3\pi\pi^*$-$^3\pi\pi^*$ absorption spectrum of $[Ir(bpy)_3](NO_3)_3$ in ethanol–methanol (4: 1, v/v) are shown in Fig. 4. SCF-CI calculations generally gives an over-estimate of the transition energy, so the observed spectrum of tris-(bipyridine) complex can be assigned to one strong and three weak $^3\pi\pi^*$-$^3\pi\pi^*$ transitions, and the observed one of free phenanthroline to several weak $^3\pi\pi^*$-$^3\pi\pi^*$ transitions. With respect to the $^3d\pi^*$-$^3d\pi^*$ transitions, the energies can be estimated from the differences in orbital energies. Using the orbital energies of our calculation, for a bipyridine complex, two bands at 16200 cm^{-1} and 29500 cm^{-1} are expected; for a phenanthroline complex, two bands at 20200 cm^{-1} and 30200 cm^{-1} are expected. Thus from our SCF-CI calculations, we conclude that the triplet-triplet transitions both to the higher $^3d\pi^*$ states and to higher $^3\pi\pi^*$ states from the lowest triplet state are expected in the wave number range of our experiment.

It was pointed out that in the bis(bipyridine) complex the lowest $^3\pi\pi^*$ state lies a little higher than the lowest $^3d\pi^*$ state in ethanol–methanol (4: 1, v/v).[1] 95% DMF–water has a similar polarity to that of ethanol–methanol, so spectrum 1 in Fig. 1 is assigned to $^3d\pi^*$-$^3d\pi^*$ transition. On the other hand, spectrum 3 in Fig. 1 shows the vibrational structure, which resembles closely that of a tris(bipyridine) complex. Therefore, in water the $\pi\pi^*$ component of the lowest triplet state is predominant. The spectrum in 45% v/v DMF–water is interpreted as a superposition of almost equal contributions from the T_1-$^3\pi\pi^*$ and T_1-$^3d\pi^*$ transitions.

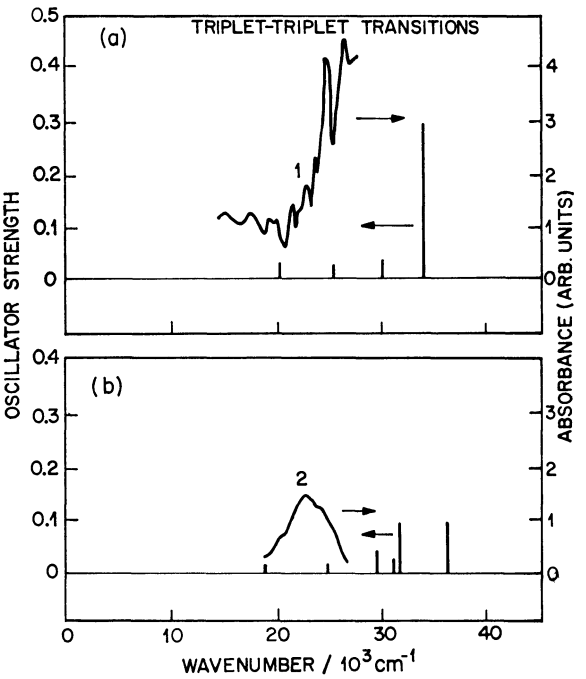

Fig. 4. Calculated triplet-triplet transition energies and their oscillator strength. (a) Free bipyridine, (b) free phenanthroline. Curves are the observed triplet-triplet absorption spectra of $[Ir(bpy)_3](NO_3)_3$ in 95% v/v DMF–water (curve 1) and free phenanthroline in ethanol–methanol(4: 1, v/v)(curve 2).

In the bis(phenanthroline) complex, the most distinct characteristics of the solvent effect on the triplet-triplet absorption spectrum is the large change in the absorption intensity. In 95% v/v DMF–water, the lowest triplet state is assigned to mainly $^3d\pi^*$, as in the bis(bipyridine) complex.[1] As the solvent becomes polar, the absorption intensity decreases rapidly and the peak maxima shift to slightly higher energy. This intensity decrease can be interpreted as a change in the character of T_1. In a bipyridine complex, the solvent affects only the absorption frequency, so the observed T_1-$^3\pi\pi^*$ transitions and T_1-$^3d\pi^*$ transitions have almost equal intensity. However, as is shown in Fig. 4, $^3\pi\pi^*$-$^3\pi\pi^*$ transitions of phenanthroline are weaker than the strong band of bipyridine. Therefore, an increase in the $\pi\pi^*$ component of T_1 results in a decrease of the intensity of the triplet-triplet absorption. Spectrum 3 in Fig. 2 can be assigned mainly to $^3\pi\pi^*$-$^3\pi\pi^*$ transitions. An analogous solvent effect was observed for bis(4,7-dimethyl-1,10-phenanthroline) complex (Fig. 3).

In conclusion, the excited states of the iridium(III) complexes with such ligands as bipyridine, phenanthroline, and their derivatives are very sensitive to the

environment. Changing the mixing ratio of DMF and water can cause changes in the character of the lowest triplet state as well as a reversal in the order of the state. Such solvent effects may become an important factor in the reactivity of these complexes in various solvents.

The authors are grateful to Professor Saburo Nagakura of the Institute for Solid State Physics for his kind support and valuable suggestions.

Photo-oxidation Effect of Poly(*N*-vinylcarbazole) Film on Photoconductivity and Electronic Spectra[1)]

Akira ITAYA,* Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received January 26, 1979)

The photo-oxidation effect on poly(*N*-vinylcarbazole) (PVCz) and amorphous 1,3-di(*N*-carbazolyl)propane films was studied by means of ultraviolet absorption, infrared absorption, and fluorescence spectra. The photoconductivity of the photo-oxidized PVCz films was also measured as a function of photoirradiation time. A photo-oxidation product which formed near the surface of films had a carbonyl substituent group, acted as a singlet exciton trap in competition with the excimer-forming sites, and formed an exciplex with an excited carbazolyl chromophore. The very slight amount of the photo-oxidation product enhanced the photoconductivity of PVCz films by a factor of *ca.* 15, suggesting that the product acted as an electron-accepting impurity in the photo-carrier-generation mechanism in the lowest π-π^* absorption region of PVCz films.

There have been many investigations concerning the photo-carrier-generation mechanism in the lowest π-π^* absorption region of poly(*N*-vinylcarbazole) (PVCz) film.[2-7)] The following mechanism is considered to be most appropriate at the present stage:[6,7)]

$$D^* + A \longrightarrow (D^*\cdots A) \longrightarrow {}^1(D^+\cdots A^-)$$

encounter complex; nonrelaxed exciplex state

$$^1(D^+\cdots A^-) \xrightarrow{F} D^+ + A^-$$

$$^1(D^+\cdots A^-) \longrightarrow (D^+\text{—}A^-)^*$$

$(D^+\cdots A^-)$: geminate ion pair; $(D^+\text{—}A^-)^*$: exciplex state

Scheme 1.

The singlet excited state(D*) (singlet exciton) of PVCz migrates effectively through the carbazole(Cz) chromophores and encounters some electron-accepting impurity (A) during its lifetime to form an encounter complex ($D^*\cdots A$). The complex goes through a rapid electron transfer and changes to a nonrelaxed exciplex state $^1(D^+\cdots A^-)$. The nonrelaxed exciplex state has some excess kinetic energy and undergoes a thermalization of the excess energy to give an electron-hole ion pair ($D^+\cdots A^-$) at a separation r_0. The electron-hole pair will either recombine geminately to give a relaxed fluorescence exciplex state $(D^+\text{—}A^-)^*$, or dissociate into free carriers (D^+, A^-) when it is assisted by an external electric field *F*. Taking account of the ionization potential (6.1 eV) and the electron affinity (1.5 eV) of PVCz in film, the electron affinity of the compound acting as an electron acceptor should be higher than 0.6—0.8 eV. Some unknown impurities contaminated in course of synthesis of the monomer and/or polymer, dissolved oxygen, or a photo-oxidation product of the polymer can be considered as the electron-accepting impurities in a PVCz film. Judging from the migration efficiency of the singlet exciton,[8-10)] a concentration of the electron-accepting impurity of about 10^{-3} mol/mol monomer unit seems to be necessary to interpret the high yield of photo-carrier-generation (*ca.* 0.1). Contamination by such a concentration of the impurity is improbable in course of the synthesis. In the case of triplet oxygen in the ground state, of which the electron affinity is *ca.* 0.42 eV,[11)] considerable thermal activation should be necessary to give the electron-hole ion pair. Therefore, it is impossible to explain the high yield of the photo-carrier-generation in PVCz films by considering only the unknown contaminating impurity and the oxygen. Then, a photo-oxidation product of PVCz should be considered as an electron-accepting impurity which might be effective for the photo-carrier-generation. Therefore, detailed information on the photo-oxidation of a PVCz film is very important in understanding the origin of the high photoconductive properties of the polymer. It has been briefly reported that photo-oxidation products were obtained by irradiation of PVCz suspended in sulfuric acid–ethanol solution in a stream of air[12)] and of a PVCz film in air.[6)] However, no detailed study has been reported on the photo-degradation of a PVCz film.

In the present research, we have investigated the photo-oxidation of an amorphous PVCz film and an amorphous 1,3-di(*N*-carbazolyl)propane (DCzP(a)) film,[13)] which is a dimeric model compound of PVCz, by measuring the change in the absorption and fluorescence spectra caused by photoirradiation and have compared the difference in behavior of the photo-oxidation between these two films. We have also investigated how the photo-oxidation affects the photoconductivity of a PVCz film.

Experimental

The PVCz was prepared by free-radical polymerization (initiator; AIBN) and was reprecipitated from benzene solution with methanol. Thin PVCz films used for measuring the absorption and fluorescence spectra were cast on quartz plates from benzene solution and dried *in vacuo*. Films of PVCz 10 μm thick for electrical measurements were cast on nesa-coated conductive quartz plates from benzene solution. A semitransparent gold main electrode was evaporated on the film to prepare a sandwich-type cell. The DCzP(a) films were prepared by the methods described previously.[13)]

The absorption and fluorescence spectra were measured with the apparatus described in a previous paper.[14)] The electrical measurements (photoconductivity and magnetic field effect on the photoconductivity) were carried out under a vacuum of 10^{-2} Torr at 20 °C by a DC method. Films were irradiated in air at atmospheric pressure though a water filter (21 cm) with the full spectrum of a 500 W high pressure mercury lamp. The radiation density ($\lambda < 350$ nm) was about 1×10^{17} photons/cm^2 s.

Results and Discussion

Electronic Spectra. Figure 1 shows the change in the absorption spectra of PVCz films caused by photo-irradiation. With irradiation time, the absorption intensity of Cz chromophores decreased and new absorption (300—340 nm and 350—420 nm) appeared and increased. Three isosbestic points were observed at 348, 341, and 303 nm. These new bands are attributed to a photo-oxidation product, because no change in the absorption was observed for a PVCz film irradiated under a vacuum of 10^{-1} Torr. The further irradiation caused a deviation from these isosbestic points and also a decrease of the absorption intensities of the photo-oxidation product, as is shown in Fig. 2. Similar phenomena (decrease in the absorption intensity of Cz chromophores and appearance of new absorption bands) were also observed for DCzP(a) film, although five isosbestic points were observed. The dependence of the absorption intensity (370 nm) due to the photo-oxidation product on irradiation time is shown in Fig. 2. Assuming that there is no remarkable difference in the molar extinction coefficient of the photo-oxidation product between PVCz and DCzP(a), Fig. 2 shows that the formation rate of the photo-oxidation product observed for a PVCz film is larger than that for a DCzP(a) film by a factor of *ca.* 4. This may be attributed to the presence in the polymer film of sites which are susceptible to photo-oxidation. Judging from the fact that the concentration of the sandwich-like excimer-forming sites in a PVCz film is higher than that in a DCzP(a) film, the sandwich-like excimer-forming sites seem to be susceptible in such a way. This would be supported by the fact that the decrease of the sandwich-like excimer fluorescence (*ca.* 23900 cm^{-1}) caused by photo-oxidation is larger than that of the second excimer fluorescence (*ca.* 26500 cm^{-1}), as is clearly shown in Fig. 4.

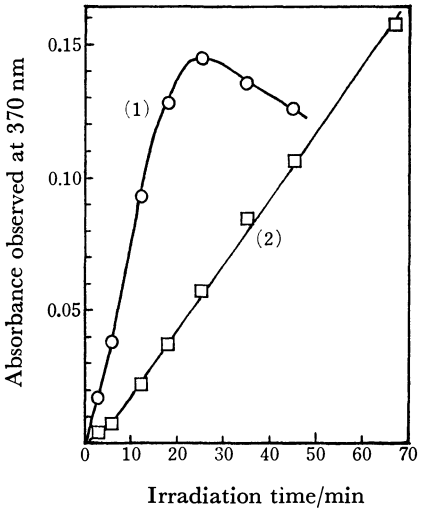

Fig. 2. Dependence of the absorption intensity at 370 nm on photoirradiation time for (1) PVCz and (2) DCzP(a) films.

Infrared spectra of photo-oxidized PVCz films are shown in Fig. 3. The increasing absorption observed at around 1700 cm^{-1} is attributable to carbonyl groups. A similar phenomenon was also observed for a DCzP(a) film. These results show that the photo-oxidation products formed in both PVCz and DCzP(a) films have carbonyl groups, which are electron-accepting substituents. The formation of the carbonyl group in a PVCz film by photo-oxidation is similar to the phenomenon observed for a photo-oxidized polystyrene (PSt) film.[15]

It has been reported that a PSt film becomes brittle by photo-oxidation, although extraction of the photo-oxidized PSt film with chloroform leaves a very small

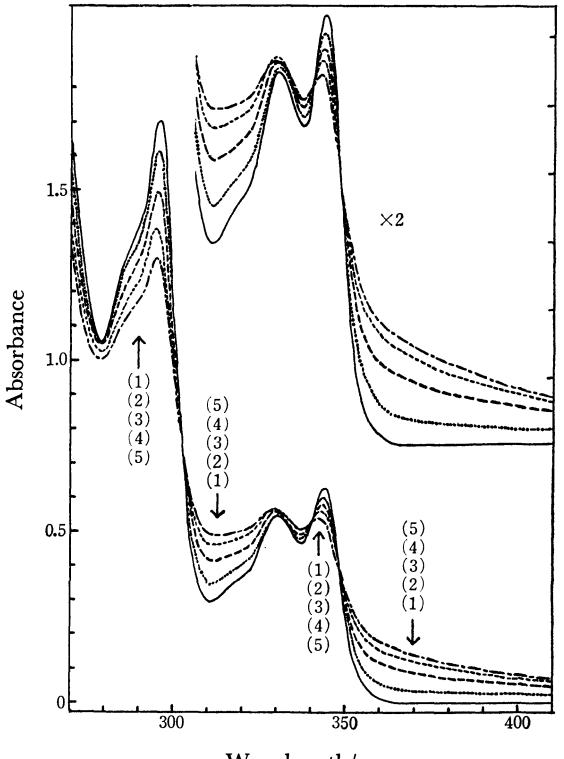

Fig. 1. Change in the absorption spectra of a PVCz film caused by photoirradiation. Irradiation time; (1) 0, (2) 6, (3) 12, (4) 18, and (5) 25 min.

amount of residue.[15] On the other hand, the heavily photo-oxidized PVCz film becomes insoluble in most solvents, such as benzene and 1,2-dichloroethane. This fact suggests that the disruption of the Cz chromophore and a crosslinking reaction seems to take place at the same time in a PVCz film.

The change in the fluorescence spectra of PVCz films caused by photoirradiation in air is shown in Fig. 4. Little change was observed in the fluorescence spectra of PVCz films by photoirradiation under a vacuum of 10^{-1} Torr. Remarkable changes in the fluorescence spectra were observed for very weakly photo-oxidized PVCz films, compared with the case of absorption spectra. With irradiation time, the excimer fluorescence of PVCz films decreased and a new fluorescence band in the longer-wavelength region ($\nu<20000$ cm^{-1}) appeared. Further irradiation caused a decrease of the excimer and the new fluorescence intensities. A quite similar phenomenon was observed for DCzP(a) films, as is shown in Fig. 5. The broad and structureless emission band with a peak (or shoulder) at 19000—20000 cm^{-1} of the weakly photo-oxidized PVCz and DCzP(a) films may be assigned to the exciplex fluorescence, which is formed between an excited Cz chromophore and the photo-oxidation product with the carbonyl substituent group. This assignment is supported by the following observation. The fluorescence observed at 515 nm for the weakly photo-oxidized PVCz film was partly quenched by applying an electric field and the decrease in the fluorescence showed a quadratic dependence on the field strength, as is shown in Fig. 6. It has been reported by Yokoyama *et al.* that a similar phenomenon is observed for the exciplex fluorescence of PVCz films doped with dimethyl terephthalate (DMTP).[6,16]

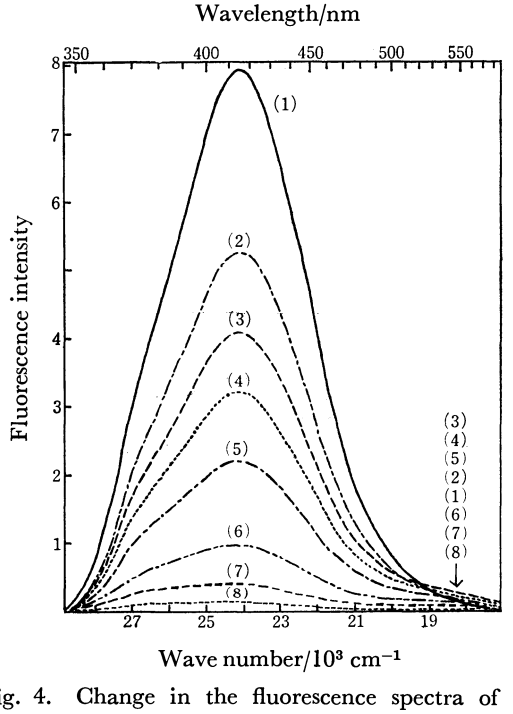

Fig. 4. Change in the fluorescence spectra of PVCz films caused by photoirradiation. Irradiation time; (1) 0, (2) 0.5, (3) 1, (4) 1.5, (5) 2.5, (6) 4.5, (7) 9, and (8) 15 min.

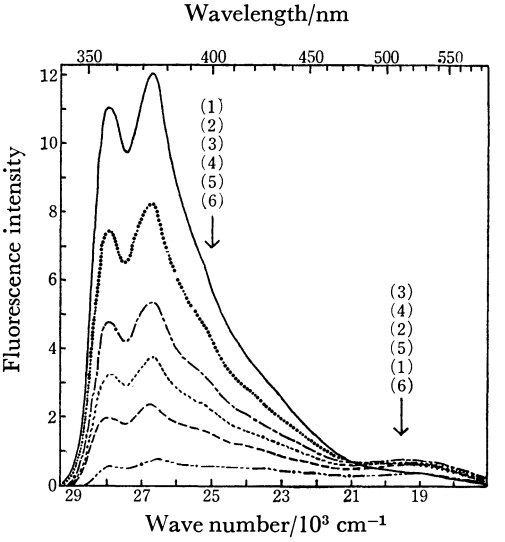

Fig. 5. Change in the fluorescence spectra of DCzP(a) films caused by photoirradiation. Irradiation time; (1) 0, (2) 0.17, (3) 0.5, (4) 1, (5) 1.5, and (6) 10 min.

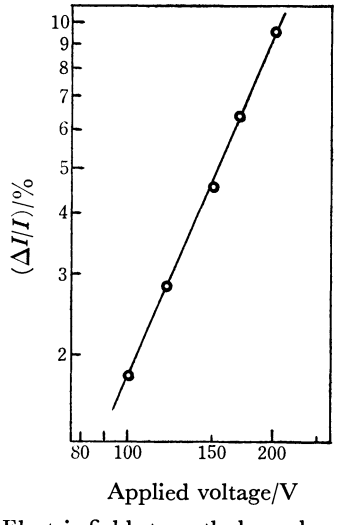

Fig. 6. Electric field-strength dependence of the fluorescence decrease observed at 510 nm for the weakly photo-oxidized PVCz film (≈0.5 μm thick). Irradiation time; 25 s. Excitation wavelength; 335 nm.

In order to represent the decrease of fluorescence, a quenching factor, Q, which has frequently been used in investigations of energy migration in polymer films,[8-10,17] is defined for convenience by the following equation:

$$Q_t = (I_0 - I_t)/I_t$$

where I_0 and I_t are fluorescence peak intensities before and after photo-irradiation, respectively. The dependence of the quenching factor of photo-oxidized PVCz and DCzP(a) films on the irradiation time is shown in Fig. 7. The value of Q obtained for thin films was larger than that obtained for thick films. This result suggests that the process of the photo-oxidation proceeds near the surface of films. Therefore, the photo-oxidation product is not formed in the bulk of film uniformly.

However, an approximately linear relationship existed between the quenching factor, Q, and the irradiation time, t, in an early stage of photoirradiation. This phenomenon seems to suggest that the photo-oxidation product acts as an exciton trap in competition with the excimer-forming sites. The value of Q obtained for DCzP(a) films was larger than that obtained for PVCz films. Considering that the concentration of the photo-oxidation product formed in PVCz films is higher than that formed in DCzP(a) films, as mentioned above, this fact suggests that the number of Cz chromophores covered by a singlet excition during its lifetime in a DCzP(a) film is larger than that in a PVCz film. This fact is consistent with the result obtained by investigation of the excitation energy migration, in which the fluorescence quenching by a guest molecule such as DMTP in PVCz and DCzP(a) films was investigated.[18]

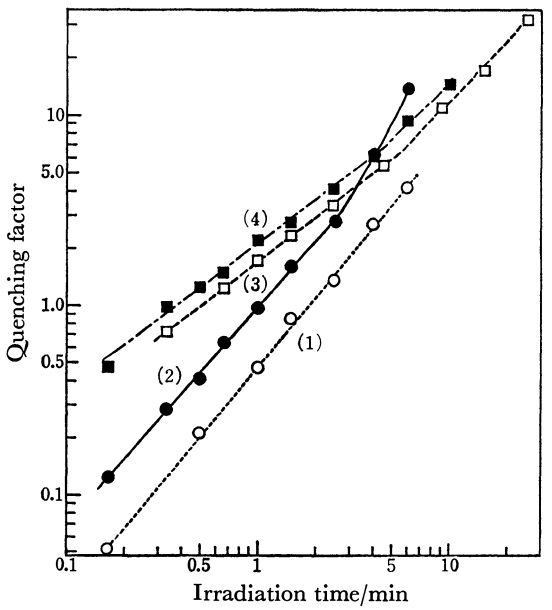

Fig. 7. Quenching factor *vs.* irradiation time. (1) PVCz film (≈0.7 μm thick), (2) PVCz film (≈0.2 μm thick), (3) DCzP(a) film (≈0.3 μm thick), and (4) DCzP(a) film (≈0.2 μm thick). Excitation wavelength; 330 nm.

The host fluorescence was depressed to half its original intensity ($Q=1$) at a guest concentration equal to the concentration of excimer-forming sites, in the case of PVCz films.[8–10] The concentration of excimer-forming sites in the PVCz film used in the present investigation was *ca.* 3×10^{-3} mol/mol basic unit.[10] Therefore, the concentration of the photo-oxidation product in a thin PVCz film (≈0.2 μm), where the product might be formed comparatively uniformly, became *ca.* 3×10^{-3} mol/mol basic unit by the irradiation for one minute, as is shown in Fig. 7. Considering the number of absorbed photons, the yield of the formation of the photo-oxidation product was estimated to be *ca.* 10^{-4}.

Photoconductivity. Dependence of the photocurrent of the photo-oxidized PVCz films on irradiation time is shown in Fig. 8. The photocurrent observed in the π-π^* absorption region increased steeply, by a factor of about 15, with photo-oxidation. It decreased when the film was exposed to radiation until a change in the absorption spectra by photo-oxidation could be observed. Voltage, spectral, light-intensity, and temperature dependence of the photocurrent of the photo-oxidized PVCz film were almost the same as those of the unirradiated PVCz film.[19]

It has been reported that an external magnetic field increased the photocurrent in a PVCz film and that this magnetic filed effect was enhanced by doping with a weak acceptor such as DMTP.[7] Figure 9 shows the dependence of the positive magnetic field effect of the photo-oxidized PVCz films on irradiation time. The effect was enhanced by a factor of about 3 by weak photo-oxidation.

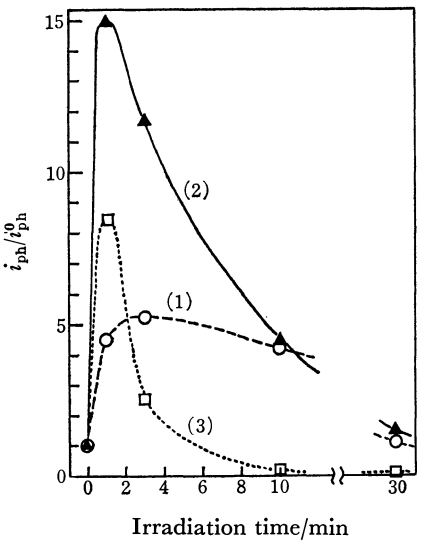

Fig. 8. Irradiation time dependence of the relative photocurrent(i^+_{ph}) of a photo-oxidized PVCz film under 35000 V/cm.
(1) 400, (2) 360, and (3) 330 nm.

(1) 400, (2) 360, and (3) 330 nm.

It is clear from the above-mentioned results that the yield of photo-carrier-generation of the weakly photo-oxidized PVCz films is much higher than the yield of the unirradiated PVCz films. That is, even if the concentration of the photo-oxidation product is too low to be detected by the absorption spectra, the product acts effectively as an electron-accepting impurity(A) in the Scheme 1 to enhance effectively the yield of photo-carrier-generation of a PVCz film. A high yield of photo-carrier-generation is obtained by a xerographic method,[5,20] where the surface of samples is exposed to a corona-charge under an ambient condition, and by measuring the photoconductivity of polymer films dried for a prolonged time under an ambient condition at a high temperature.[21] Such yields might be attributable to the mechanism of photo-carrier-generation described in Scheme 1, in which the electron-accepting impurity(A) seems to be a photo-oxidation product formed near the surface of PVCz films.

The present work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education.

(Received January 30, 1979)

X-Ray diffraction analysis was used to establish the molecular structures of some adducts of benzoyl isothiocyanate with hydrazones: benzaldehyde 4-benzoyl-2-phenylthiosemicarbazone (**1**), 2-benzoylimino-3,5-diphenyl-2,3-dihydro-1,3,4-thiadiazole (**2**), and 5-benzoylimino-2,2-dimethyl-4-phenyl-1,3,4-thiadiazolidine (**3**). In adducts **2** and **3**, a strong intramolecular interaction between sulfur and carbonyl oxygen atoms has been found. The S···O distance is 2.56 Å for **2** and 2.76 Å for **3**, and the oxygen atom lies approximately in the plane defined by the sulfur atom and the two carbon atoms bonded to the sulfur atom. The absence of a characteristic absorption due to a carbonyl group in the IR spectra of **2** and **3** reflects the intramolecular interaction. The crystal of **1** is triclinic, space group $P\bar{1}$, with $a=12.041$, $b=8.414$, $c=11.298$ Å, $\alpha=116.13$, $\beta=103.39$, $\gamma=103.27°$; that of **2** is monoclinic, space group $P2_1/c$, with $a=20.842$, $b=3.977$, $c=21.120$ Å, $\beta=103.55°$; and that of **3** is monoclinic, space group $P2_1$, with $a=12.559$, $b=6.910$, $c=10.283$ Å, $\beta=115.46°$. The structure has been refined by the block-diagonal least-squares method to $R=0.089$ with 2508 reflections for **1**, to $R=0.088$ with 1872 reflections for **2**, and to $R=0.098$ with 1031 reflections for **3**.

Previously Yamamoto *et al.* reported the reaction of benzoyl isothiocyanate with hydrazones and discussed the reaction mechanism; the reaction of benzoyl isothiocyanate with the derivatives of hydrazone yielded seven-membered ring compounds whose structures were assigned on the basis of their spectroscopic results.[1] In view of the novelty of their structures we have reexamined the molecular structures of the products by the X-ray diffraction method. We now report investigations leading to a revised structure **3**, together with establishment of the structures **1** and **2**.

Experimental

The space group and preliminary unit cell constants for each crystal were determined by oscillation and Weissenberg photographs. The accurate cell constants for each crystal were determined by the least-squares method using at least 39 reflections measured on a four-circle diffractometer. The density of each crystal was obtained by the flotation method.

Crystal Data. (a) Product (**1**), $C_{21}H_{17}N_3OS$: $M=359.4$, triclinic, $P\bar{1}$, $a=12.041$, $b=8.414$, $c=11.298$ Å, $\alpha=116.13$, $\beta=103.39$, $\gamma=103.27°$, $V=924.9$ Å^3, $Z=2$, $D_m=1.30$ g·cm^{-3}, $D_x=1.29$ g·cm^{-3}. (b) Product (**2**), $C_{21}H_{15}N_3OS$: $M=357.4$, monoclinic, $P2_1/c$, $a=20.842$, $b=3.977$, $c=21.120$ Å, $\beta=103.55°$, $V=1701.9$ Å^3, $Z=4$, $D_m=1.40$ g·cm^{-3}, $D_x=1.39$ g·cm^{-3}. (c) Product (**3**), $C_{17}H_{17}N_3OS$: $M=311.4$, monoclinic, $P2_1$, $a=12.559$, $b=6.910$, $c=10.283$ Å, $\beta=115.46°$, $V=805.7$ Å^3, $Z=2$, $D_m=1.28$ g·cm^{-3}, $D_x=1.28$ g·cm^{-3}.

Intensity Measurements of 1 and 3. The intensities were measured on a Rigaku tape-controlled four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The approximate crystal size used for these intensity measurements was $0.1\times0.1\times0.4$ mm for **1** and $0.3\times0.06\times0.1$ mm for **3**. The θ-2θ scan technique was employed with a scan speed of 4°/min for 2θ. The backgrounds were counted for 6 s at both sides of the scan range. The intensities of 2677 independent reflections were measured in the range $0<\sin\theta/\lambda<0.56$ for **1**, and those of 1031 independent reflections in the range $0<\sin\theta/\lambda<0.53$ for **3**.

Intensity Measurement of 2. The intensities of reflections with $\sin\theta/\lambda$ less than 0.53 were measured from a crystal with dimensions of $0.5\times0.1\times0.05$ mm with Ni-filtered Cu $K\alpha$ radiation. The stationary-crystal stationary-counter technique was applied using a Toshiba four-circle diffractometer. A background for each reflection was taken from a curve which was determined by a plot of the backgrounds measured at several values of 2θ against their 2θ values. A total of 2132 reflections were measured, of which 1872 were recorded as non-zero intensity.

The intensities were corrected for the Lorentz and polarization factors, but were not corrected for absorption.

Structure Determination of 1. The structure was solved by an application of the direct method.[2] An E map based on the phases of 207 reflections revealed the positions of all non-hydrogen atoms. The structure was refined by the block-diagonal least-squares method,[3] initially with isotropic temperature factors and subsequently with anisotropic ones. The atomic species were assigned by inspection of temperature factors as well as interatomic distances and angles. All hydrogen atoms were revealed on a difference Fourier synthesis. Final refinement, by including these hydrogen atoms with isotropic temperature factors, reduced the R value to 0.089 for 2508 non-zero reflections. In the final refinement, the following weighting scheme was adopted: $w=0.0$ for $F_o=0$, $w=1.0$ for $0\leqq F_o<10$, and $w=[1.0+0.15(F_o-10)]^{-1}$ for $10<F_o$. The final atomic coordinates are given in Table 1.

Structure Determination of 2. The structure was solved by the heavy atom method, and refined by the block-diagonal least-squares method in the same way as for **1**. Including the hydrogen atoms revealed on a difference Fourier synthesis,

Table 1. Final atomic coordinates of **1** with estimated standard deviations in parentheses

final refinement was carried out using the following weighting scheme: $w=0.0$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 24$, and $w=[1.0+0.67(F_o-24)]^{-1}$ for $24<F_o$. The final R value was 0.088 for 1872 non-zero reflections. The final atomic coordinates are given in Table 2.

Structure Determination of 3. The structure was solved by the direct method[2] followed by successive Fourier synthesis, and refined in the same way as for **1**. The final refinement, including the contribution of the hydrogen atoms and anomalous scattering of sulfur atom, reduced R to 0.098 for 1031 reflections ($R=0.088$ for non-zero reflections). The weighting scheme adopted in the final refinement was: $w=0.2$, for $F_o=0$, $w=1.0$ for $0<F_o\leqq 24$, and $w=[1.0+0.43(F_o-24)]^{-1}$ for $24<F_o$. The final atomic coordinates are given in Table 3.

The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[4] The temperature factors and the list of observed and calculated structure factors for each compound are kept as Document No. 7924 at the Chemical Society of Japan.

Results and Discussion

The present X-ray analysis has determined the molecular structures of the adducts unambiguously, showing the benzoyl isothiocyanate adducts with benzaldehyde phenylhydrazone to be benzaldehyde 4-benzoyl-2-phenylthiosemicarbazone (**1**) and 2-benzoyl-imino-3,5-diphenyl-2,3-dihydro-1,3,4-thiadiazole (**2**), and that with acetone phenylhydrazone to be 5-benzoyl-imino-2,2-dimethyl-4-phenyl-1,3,4-thiadiazolidine (**3**). Thus the structural formula (16a) which was given in Ref. 1 should be revised to **3**. The molecular structures and the numbering scheme used in the present paper are shown in Fig. 1, and the crystal structure of **3** in Fig. 2. Selected bond lengths and angles are given in Table 4, and the equations of the least-squares planes, deviations of atoms from each plane, and selected torsion angles in Table 5. The molecules of **2** are stacked along the b axis, with interplanar distances of about 3.6 Å. Except for the intermolecular hydrogen bond in the crystal of **3**, there is neither an intermolecular hydrogen bond nor any abnormally short intermolecular contact in the crystals of **1** and **2**.

Molecular Structure of ***1***. The S(1)–C(5) length of 1.646 Å is reasonable, compared with the thione bond lengths observed in various compounds, although these lengths differ from compound to compound.[6] The distribution of the bond lengths among the C(2), N(3), N(4), C(5), and C(7) atoms and the fact that these

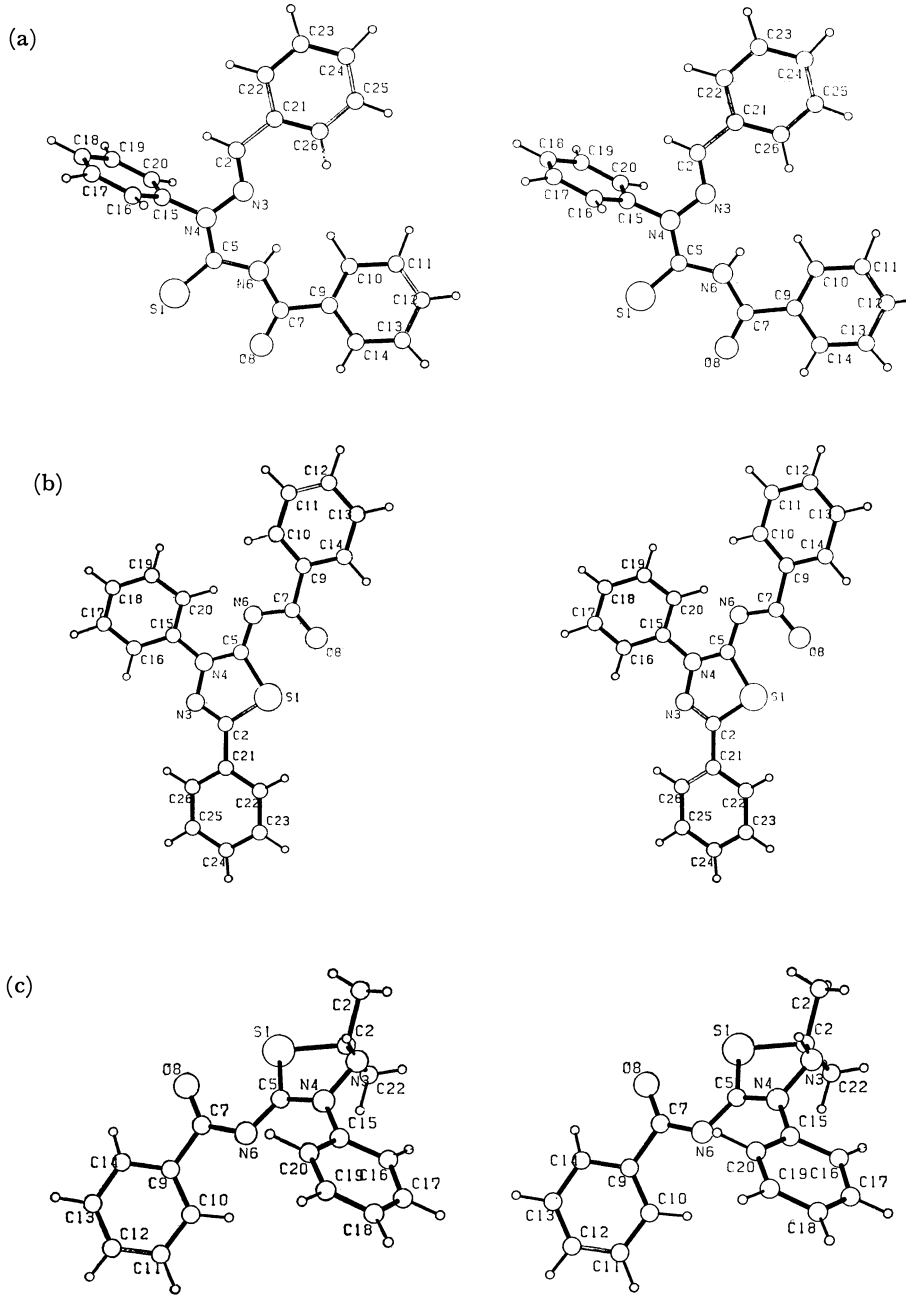

Fig. 1. Molecular structures and numbering schemes of (a) adduct **1**, (b) adduct **2**, and (c) adduct **3**.

atoms are nearly coplanar suggest appreciable delocalization of π electrons.

*Molecular Structures of **2** and **3** and S···O Interaction.* The benzoylimino group, the thiadiazoline ring, and the phenyl group of C(21)–C(26) in **2** are substantially coplanar. The geometry and the bond lengths of these groups indicate that a conjugated system exists among these groups. The five-membered ring of **3** has an envelope conformation with the C(2) atom deviating significantly from the plane through the S(1), N(3), N(4), and C(5) atoms; its conjugated system is disrupted by the C(2) and N(3) atoms, as expected from structural formula **3**.

The noteworthy feature of the molecular structures of **2** and **3** is the intramolecular S···O interaction; the distance between these atoms is 2.56 Å for **2** and 2.76 Å for **3**, which is significantly shorter than the sum of the van der Waals radii of the atoms. The oxygen atom of **3**, as well as that of **2**, lies approximately in the plane defined by S(1), C(2), and C(5) atoms. In the case of **3**, twists occur around the C(5)–N(6) double bond by 10° and the N(6)–C(7) bond by 21° such that the oxygen atom lies in the plane. Otherwise the deviation of the oxygen atom from the plane amounts to 0.7 Å, since the C(5)–N(6) bond deviates from the plane. The length of the intermolecular hydrogen bond between

TABLE 5. LEAST-SQUARES PLANES, DEVIATIONS OF ATOMS FROM EACH PLANE, (d/Å) AND SELECTED TORSION ANGLES (φ/°)

(a) Adduct **1**

(I) Plane through the atoms of S(1), N(4), C(5), and N(6) $0.534X-0.829Y-0.164Z=2.148$

S(1)	−0.004	N(4)	−0.004
C(5)	0.011	N(6)	−0.004
N(3)[a]	−0.023	C(7)[a]	0.004
O(8)[a]	0.231	C(15)[a]	−0.090

(II) Plane through the atoms of N(6), C(7), O(8), and C(9) $0.490X-0.791Y-0.366Z=1.679$

N(6)	0.002	C(7)	−0.006
O(8)	0.002	C(9)	0.002
S(1)[a]	−0.543	C(5)[a]	−0.190

The atoms of each benzene ring are coplanar, with r.m.s. of deviations being about 0.01 Å. The dihedral angle between the plane (I) and the benzene ring of C(15)–C(20) is 89.2°and that between the plane (II) and the benzene ring of C(9)–C(14) is 26.3.°

(III) Torsion angles

C(21)–C(2)–N(3)–N(4)	−179.4
N(3)–N(4)–C(5)–N(6)	− 0.4
N(4)–C(5)–N(6)–C(7)	180.0
C(5)–N(6)–C(7)–O(8)	− 11.5
N(6)–C(7)–C(9)–C(10)	− 26.8

(b) Adduct **2**

(I) Plane through all non-hydrogen atoms except the atoms of C(15)–C(20) $0.056X+0.893Y-0.446Z=-1.590$

S(1)	−0.028	C(2)	0.026
N(3)	0.002	N(4)	−0.047
C(5)	−0.072	N(6)	−0.087
C(7)	−0.063	O(8)	−0.087
C(9)	0.007	C(10)	0.045
C(11)	0.075	C(12)	0.050
C(13)	0.028	C(14)	−0.001
C(21)	0.051	C(22)	0.026
C(23)	−0.001	C(24)	0.008
C(25)	0.043	C(26)	0.053

The atoms of each of two six-membered and five-membered rings are coplanar, with the r.m.s. deviation being less than 0.01 Å. The dihedral angle between the above plane and the plane defined by the atoms of C(15)–C(20) is 31.3.°

(c) Adduct **3**

(I) Plane through the atoms of S(1), N(3), N(4), and C(5) $0.687X+0.702Y-0.188Z=1.415$

S(1)	0.01	N(3)	−0.01
N(4)	0.02	C(5)	−0.01
C(2)[a]	0.58	C(21)[a]	−0.06
C(22)[a]	2.09	N(6)[a]	−0.04
C(15)[a]	0.04		

The r.m.s. of the deviations of the atoms of benzene ring is about 0.01 Å.

(II) Torsion angles

C(5)–S(1)–C(2)–N(3)	−30.3
S(1)–C(2)–N(3)–N(4)	36.7
C(2)–N(3)–N(4)–C(5)	−27.9
N(3)–N(4)–C(5)–S(1)	3.0
S(1)–C(5)–N(6)–C(7)	−10.1
C(5)–N(6)–C(7)–O(8)	−21.1
N(6)–C(7)–C(9)–C(10)	−23.0
N(3)–N(4)–C(15)–C(16)	−50.5

a) Not included in the least-squares calculations.

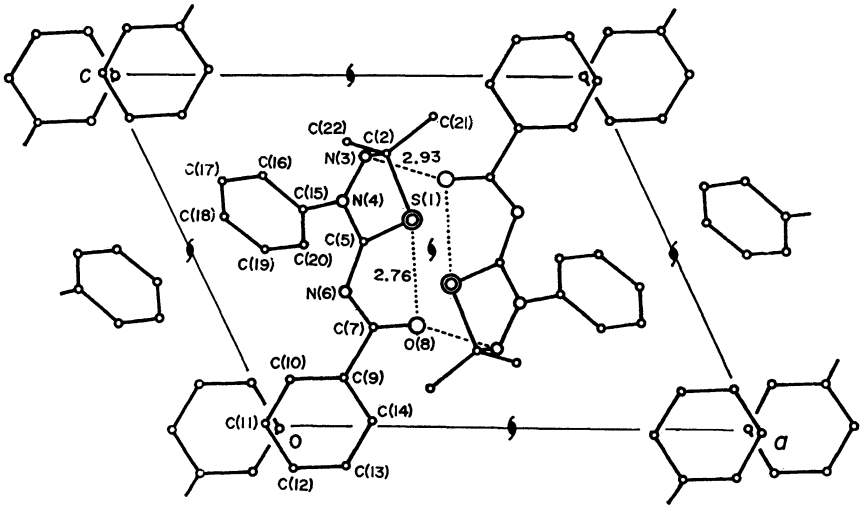

Fig. 2. Crystal structure of **3** viewed along the b axis. Broken lines indicate intermolecular hydrogen bond, and dotted lines S···O interaction (see text). Hydrogen atoms are omitted from the figure for the sake of clarity.

the N(3) and O(8) atoms is lengthened by the twists. A similar geometrical feature, where the oxygen atom lies in the plane defined by the sulfur atom and two adjacent atoms bonded to the sulfur atom, has been reported in other compounds.[7–11] The absence of a characteristic absorption due to C=O stretching in the IR spectra of **2** and **3** should be associated with the S···O interaction.[12]

We wish to thank Dr. Tomitake Tsukihara for his fruitful discussions. We are also grateful to Mr. Hiroshi Kuroda, Mr. Susumu Fujii, Mr. Keisuke Ohgitani, and Mr. Eiichi Waki for valuable assistance in X-ray work.

(Received February 8, 1979)

Two copper complexes containing L-histidine and L-asparagine crystallize from aqueous solution at pH 7.0. Both crystals are monoclinic, space group $P2_1$. L-Asparaginato-L-histidinatocopper(II): $a=10.913(3)$, $b=12.911(4)$, $c=10.206(3)$ Å, $\beta=113.83(2)°$, $Z=4$. L-Asparaginato-L-histidinatoaquacopper(II) trihydrate: $a=12.654(4)$, $b=11.623(4)$, $c=5.931(2)$ Å, $\beta=100.47(3)°$, $Z=2$. In both structures, four coordinating atoms in an approximately planar arrangement around copper are the α-amino and imidazole δ-nitrogen atoms of L-histidine and α-amino nitrogen and α-carboxyl oxygen of L-asparagine. The fifth coordination site is occupied by the α-carboxyl oxygen of L-histidine. Difference between the two complex crystals is found at the sixth coordination site; a water molecule is coordinated in the hydrated crystal to complete a distorted octahedral environment, while in the anhydrous crystal this site is unoccupied so that the geometry of the complex is square-pyramidal.

Studies of copper ion in normal human serum suggested that the complexes of copper and amino acids may play a part in the transport of Cu(II) between blood and tissues. Under physiological conditions, some copper complexes with mixed amino acid ligands are identified, in which histidine is primarily involved. When the second amino acid is asparagine, glutamine, or threonine, the stability of the complexes seems to be high by some cooperativity.[1,2] It is interesting to explore the coordination of these ternary complexes consisting of copper, histidine and the other amino acids at the physiological pH.

We have succeeded in preparing the single crystals of L-asparaginato-L-histidinatocopper(II) and its hydrate. The present paper deals with the structures of these two mixed ligand complexes determined by X-ray method.

Experimental

Copper hydroxide was obtained by the usual method from copper sulphate, 35% ammonia and sodium hydroxide. 1 mmol of L-asparagine (0.1311 g) and 1 mmol of L-histidine (0.1552 g), both of which were of reagent grade and purchased from Nihon Rigaku Corporation, were dissolved in 10 ml of ion-exchanged water. To this solution, 1 mmol of copper hydroxide (0.097 g) was added and the mixture was stirred for a few minutes, until intense blue colour developed. This solution was filtered to remove some copper oxide deposited in the bottom. The pH of the solution was about 7.0.

Anhydrous Crystal. Intense blue crystals with various polyhedral shapes were obtained from the filtrate by the vapor diffusion method using methanol, ethanol, or acetone. Elementary analysis. Calcd: C, 34.43; H, 4.33; N, 20.08% for $C_{10}H_{15}N_5O_5Cu$. Found: C, 34.23; H, 4.25; N, 20.04%.

Hydrated Crystal. *N,N*-Dimethylformamide was poured into the above-mentioned filtrate. Light blue single crystals were grown by standing it overnight at room temperature. The crystals were boat-shaped, the crystallographic c axis being parallel to the length of the boat. Elementary analysis. Calcd: C, 28.53; H, 5.51; N, 16.64% for $C_{10}H_{23}N_5O_9Cu$. Found: C, 28.37; H, 5.52; N, 16.58%.

Crystal Data

Anhydrous Crystal. Monoclinic, $a=10.913(3)$, $b=12.911(4)$, $c=10.206(3)$ Å, $\beta=113.83(2)°$, $D_m=1.76$ (by flotation), $D_x=1.76$ g·cm^{-3}, $Z=4$.

Hydrated Crystal. Monoclinic, $a=12.654(4)$, $b=11.623(4)$, $c=5.931(2)$ Å, $\beta=100.47(3)°$, $D_m=1.64$ (by flotation), $D_x=1.63$ g·cm^{-3}, $Z=2$.

Systematic absences for both crystals; $0k0$ for odd k. Space group $P2_1$; alternative space group $P2_1/m$ was excluded, since these crystals contain L-amino acids.

Accurate unit cell dimensions were obtained from a least-squares fit to the 2θ values measured by a diffractometer. Intensity data were collected on the Rigaku automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation at room temperature. A θ-2θ scan technique was employed, and reflexions for $2\theta \leqq 55°$ were recorded. A total of 2933 and 2067 non-zero reflexions out of 3154 and 2190 recorded ones were obtained for the anhydrous and hydrated crystals, respectively. Intensities were corrected for the Lorentz and polarization effects but not for absorption and secondary extinction.

Structure Determination

Anhydrous Crystal. Since Z is 4 in the space group $P2_1$, there are two molecules in an asymmetric unit. From two high peaks on the Harker section and two cross-vector peaks in general positions of the sharpened Patterson map, the coordinates of two copper atoms were deduced, the y coordinate of one copper atom being taken as 0.25. Ten light atoms around copper were located from the Fourier map phased with two copper atoms. The remaining non-hydrogen atoms were found on the next Fourier map. The structural parameters were refined by the block-diagonal least-squares method. The final R factor was 0.061 for all the reflexions and 0.049 for the non-zero reflexions.

Hydrated Crystal. The x and z coordinates of

copper were obtained from the Harker section and y was taken arbitrarily as 0.25. The Fourier map phased with the copper atom has shown a pseudo-mirror symmetry at $y=0.25$. Therefore, the positions of the nearest four atoms coordinating to the central copper atom were chosen appropriately. The other non-hydrogen atoms were obtained by successive Fourier syntheses. After the block-diagonal least-squares refinement, the final R factor was 0.093 for all the reflexions and 0.066 for the non-zero reflexions.

Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[3] The final atomic parameters are listed in Tables 1 and 2.[4]

Description of the Structure and Discussion

Crystal Structure. Figures 1 and 2 show the structures of the anhydrous and hydrated crystals, respectively, where hydrogen bonds are indicated by broken lines. Hydrogen bond lengths are listed in Table 3. In the hydrated crystal, the molecules are connected mainly through water molecules to form a three-dimensional hydrogen bond network. In the anhydrous crystal, many of the hydrogen bond lengths exceed 3 Å, suggesting that a three-dimensional

Table 1. The final fractional coordinates ($\times 10^4$) and thermal parameters ($\times 10^5$) for L-asparaginato-L-histidinatocopper(II)

Anisotropic thermal parameters are in the form: $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+hk\beta_{12}+hl\beta_{13}+kl\beta_{23})]$.
Estimated standard deviations are in parentheses.

hydrogen bond network is not so well constructed, probably owing to the absence of water of crystallization.

Molecular Structure. The anhydrous crystal contains two crystallographically independent complexes; they are abbreviated hereafter complexes A and B, respectively. Similarly, the complex in the hydrated crystal is called as aqua complex. Figure 3 shows the stereoviews of the structures of these complexes. The bond lengths and angles are given in Fig. 4 and Table 4, respectively. Fairly good agreement among the values for corresponding bonds is observed, except for the

values relating to the metal chelation.

For three kinds of complexes in common, L-asparagine molecule coordinates to copper through the α-amino nitrogen and α-carboxyl oxygen, and L-histidine through the α-amino nitrogen, imidazole δ-nitrogen, and α-carboxyl oxygen. These atoms except the last one occupy the corners of the planar coordination square. The coordination distances, especially for Cu–N(2) and Cu–N(11), vary significantly among three kinds of complexes (the maximum difference is 0.058 Å). But

Estimated standard deviations in the last digits are in parentheses.

there are no correlation between the distances and any other geometrical features. The α-carboxyl oxygen atom in L-histidine deviates from the normal axial position, the angle N(1)–Cu–O(1) being 74.2, 74.3, and 74.3° for A, B, and aqua complexes, respectively. Such deviations may be due to the constraint of the histidine molecule. Axial bond length in complex B, 2.285 Å, is the shortest among the copper complexes containing amino acids or peptides.[5] The coordination geometry of these three complexes is the same as that of L-histidinato-L-threoninatoaquacopper(II) hydrate reported by Freeman *et al.*[6] Since the N(1)–Cu–O(1) angle in this complex is 68.3°, overlapping between d_{z^2} of copper and

lone-pair orbital of oxygen is less, so that the Cu–O (axial) length (2.58 Å) is longer than the values in the present three complexes.

In the hydrated crystal, the copper coordination is octahedral; water molecule occupies the sixth coordination site at a distance of 2.642 Å. It is noted that this also occurs in rather oblique direction, O(water)–Cu–O(11) being 87.7°, perhaps owing to the trans effect. The atoms forming the coordination square are not precisely coplanar. Their deviations may be described as a very flattened tetrahedron. The dihedral angle between the two planes, N(1)–Cu–N(2) and N(11)–Cu–O(11), is 8.5(3)°. Such deformation from the square planar coordination is attributed to the geometrical constraint owing to the chelation of L-histidine as a tridentate ligand, since bishistaminocopper(II) perchlorate[7] has exactly and bis(L-asparaginato)copper(II)[8] has almost square-planar coordination.

In the anhydrous crystal, the copper atom is five-coordinated, forming a square pyramid. The copper atoms in A and B complexes are out of the best plane for the equatorial coordinating atoms toward the top of the pyramid (0.023 and 0.099 Å, respectively). This is because of the disproportion of the charge, and is the general trend for the square-pyramidal environment of copper complexes. The sixth sites are blocked by carbonyl oxygen O(12B) and amino nitrogen N(12B) for complex A and imidazole nitrogen N(3A) for complex B. The distances from these atoms to copper are 3.846(7), 3.631(9), and 3.295(7) Å, respectively.

The imidazole rings in these complexes are planar within the experimental errors. The ring planes make dihedral angles of 19.9(3), 11.5(3), and 13.1(3)° with the copper square planes for A, B, and aqua complexes, respectively.

Side chains of asparagine in anhydrous complexes have a compact form puckered onto the coordination square, as shown in Fig. 3, while that in aqua complex has an extended one. As for the conformation around C(12)–C(13), C(14) is gauche to C(11) and N(11) in the former, and C(14) is trans to C(11) in the latter. The conformation of the former may be stabilized by the intramolecular hydrogen bond O(13)···N(11) in both of A and B complexes.

For mixed ligand copper(II) complexes involving an acidic amino acid and a basic amino acid, the electrostatic ligand-ligand interaction between their charged side chains has been proposed on the basis of the synthetic and CD spectral studies.[9,10] Also, successful optical resolution of DL-histidine *via* formation of the ternary complex with L-asparagine has been inferred to be due to the intramolecular hydrogen bonding between the polar side chains[11] in solution. Although such ligand-ligand interactions have not been realized in the structures of the present three complexes, they may occur under favourable conditions by the conformational change around C(12)–C(13) and C(13)–C(14) of asparagine, and the present study has revealed that the conformation around these bonds is flexible for the change of crystalline environment.

The authors are grateful to Dr. Akio Takenaka of Tokyo Institute of Technology for his assistance in drawing the diagrams by the computer graphics. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, to which the author's thanks are due.

Solvent Effects on Raman Intensity and the Determination of Transition Hyperpolarizability Tensor Element

Tsunetake FUJIYAMA,* Haruo HATAKEYAMA, and Shi-aki HYODO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received February 14, 1979)

Raman intensities of methyl iodide were observed in carbon tetrachloride solution at various concentrations. The observed lines were ν_1, ν_2, ν_3, ν_5, and ν_6. From the observed data, the transition polarizabilities were determined for the ν_1, ν_2, and ν_3 fundamentals of methyl iodide and the transition hyperpolarizabilities were obtained for the ν_3 fundamental of methyl iodide in the form of tensor elements.

In preceding reports,[1,2] the solvent effects on the absolute infrared intensities and on the absolute Raman scattering cross-sections have been discussed quantitatively from the view-point of dipole-dipole interaction. It has been shown that the interaction of the dipole-dipole type is quite a reasonable model for explaining the spectroscopic information observed in various binary solutions. It has also been shown in these reports that the polarizability derivatives can be determined by observing the solvent effects on the infrared-absorption intensities and that the hyperpolarizability derivatives can be determined by observing the solvent effects on the Raman scattering cross-sections. In the report,[2] however, we could not obtain the hyperpolarizability derivatives in the form of a tensor element, but in the form of a linear combination of the products of polarizability and hyperpolarizability derivatives.

The present report will concern itself with the observation of the Raman intensities of methyl iodide in carbon tetrachloride solutions. Our interest lies in the possibility of determining the magnitude of polarizability and hyperpolarizability derivatives in the form of tensor elements through the observation of solvent effects on Raman intensities.

Experimental

The spectrometer used for the present work was designed and constructed by the authors. The instrument is composed of a He–Ne gas laser source (NEC, GLF-105, 15 mW), a JSG-125 grating monochromator (JEOL), a HTV R-374 photomultiplier (S-20 response), a lock-in amplifier (LI-573, NF), and a recorder. The linearity of the whole system with respect to an intensity axis was ascertained to be better than 1 percent of the full scale, as long as the output voltage was less than 10 V.

Attention was paid to the output power of the laser source. The stability of the laser output during the individual spectral measurements was observed by monitoring the light energy which penetrated through the 100 percent reflectance mirror of the laser cavity. When the power of the laser source drifted more than 1 percent during the measurements, the data observed were completly discarded.

The light scattered at 90° within a solid angle of 8×10^{-3} steradians was observed. The electric polarization of the incident light was rotated by the use of a half-wave plate (1419PA polarization rotator, Spex). The polarization characteristics of the monochromator and the frequency dependence of the photomultiplier sensitivity were calibrated by the use of a standard halogen lamp.

All the chemicals were commercial products of spectroscopic grade. Carbon tetrachloride and methyl iodide were doubly distilled following the directions given in the literature.[3]

The Raman intensities were observed for the ν_1, ν_2, ν_3, ν_5, and ν_6 bands of methyl iodide relative to the intensity of the ν_1 band of carbon tetrachloride for various concentrations.

Results and Discussion

Concentration Dependence of Relative Intensity. Consider the observation of the relative intensities of two Raman lines arising from two components of a binary solution. The quantities related to two Raman lines will be distinguished by the suffixes a and b. The observed intensity area I is proportional to the molar concentration c_m, the scattering cross section per molecules Ω, the instrumental factors $S\beta$, and the factor for the internal field effect:[4]

$$I_a = C\cdot c_{ma}\Omega_a\frac{1}{n_s}\left(\frac{n_a^2+2}{(n_a/n_s)^2+2}\right)^4 S_a\beta_a \quad (1)$$

$$I_b = C\cdot c_{mb}\Omega_b\frac{1}{n_s}\left(\frac{n_b^2+2}{(n_b/n_s)^2+2}\right)^4 S_b\beta_b \quad (2)$$

where C is a constant, S the relative sensitivity of the photomultiplier, β the transmittance of the monochromator for the light whose electric vector is polarized perpendicularly to the slit, and where n_a, n_b, and n_s are, respectively, the refractive indices of the a component, the b component, and the mixture of the a and b components. It can immediately be concluded from these equations that:

$$\frac{\Omega_a}{\Omega_b} = \frac{I_a}{I_b}\cdot\frac{c_{mb}}{c_{ma}}\left(\frac{n_b^2+2}{n_a^2+2}\,\frac{(n_a/n_s)^2+2}{(n_b/n_s)^2+2}\right)^4\cdot\frac{S_b\beta_b}{S_a\beta_a} \quad (3)$$

Thus we can obtain the ratio, Ω_a/Ω_b, of the scattering cross sections from the observed intensity ratio, I_a/I_b, because c_m, S, and β are known from the experimental conditions and because the refractive indices can be measured by the use of a refractometer.

In the previous report,[2] the expression for Raman intensity has been given for the case where the existence of the non-zero averaged molecular field introduces non-linear effects to the molecular polarizability. For the binary mixture of methyl iodide and carbon tetrachloride, the ratio of the scattering cross section of the ν_i band of methyl iodide, $\Omega(CH_3I;\nu_i)$, can be expressed by the equation:

$$\frac{\Omega(CH_3I;\nu_i)}{\Omega(CCl_4;\nu_1)} = \left(\frac{\lambda_1^4}{\lambda_i^4}\right)\frac{B+A\langle F_{0z}\rangle_{av}}{\varrho_1(\alpha_1^\circ)^2_{CCl_4}} \quad (4)$$

where λ_1 is the wavelength of the ν_1 line of carbon

tetrachloride, λ_i the wavelength of the ν_i line of methyl iodide, and ${}^{q_i}(\alpha_1^\circ)_{CCl_4}$ the transition polarizability of carbon tetrachloride related to the normal coordinate, Q_1.

$\langle F_{0z}\rangle_{av}$ of Eq. 4 is an averaged molecular field which is produced at the position of a methyl iodide molecule by the surrounding molecules. There are many types of intermolecular interactions which produce electric fields at the position of a given molecule in liquids or solutions. The simplest and most important of these is the interaction of a dipole-dipole type. Taking into account this type of interaction, $\langle F_{0z}\rangle_{av}$ for a binary solution has been calculated to be[5]

$$\langle F_{0z}\rangle_{av} = \frac{4\pi^2}{27}N_A{}^2\mu_0\left[\left(\frac{\mu_0{}^2}{kT}+3\bar{\alpha}\right)\frac{\rho c_m}{W_m}+\left(\frac{\mu_{0s}^2}{kT}+3\bar{\alpha}_s\right)\frac{8}{K}c_{ms}\right] + \frac{2\pi^4}{25\times 243}N_A{}^4\frac{\mu_0{}^3}{(kT)^3}\left[\mu_0{}^4\left(\frac{\rho}{W_m}\right)^3 c_m+\mu_{0s}^4\left(\frac{8}{K}\right)^3 c_{ms}\right]$$

with

$$K=\left[\left(\frac{W_m}{\rho}\right)^{1/3}+\left(\frac{W_{ms}}{\rho_s}\right)^{1/3}\right]^3 \qquad (5)$$

where μ_0 is a permanent dipole moment; $\bar{\alpha}$, the averaged polarizability defined by $3\bar{\alpha}=(\alpha_{xx}+\alpha_{yy}+\alpha_{zz})$; c_m, the molar concentration; ρ, the density; W_m, the molecular weight; T, the absolute temperature; k, the Boltzmann constant; and N_A, Avogadro number. The symbols suffixed by "s" correspond to the solvent molecule. As the $\langle F_{0z}\rangle_{av}$ is concentration dependent, we can determine the A and B values by plotting the observed $\mathcal{R}(CH_3I;\nu_i)/\mathcal{R}(CCl_4;\nu_1)$ values against the calculated $\langle F_{0z}\rangle_{av}$ values. In Table 1, the A and B values thus obtained are summarized. The value of 1.99×10^{-50} cm^6 observed by Kato *et al.*[6] was used for the ${}^{q_i}(\alpha_1^\circ)^2$ of carbon tetrachloride. As for the ν_1 and ν_2 lines of methyl iodide, accurate A values could not be obtained because their intensities were not strong enough for our instrument.

Table 1. The observed A and B values for methyl iodide in carbon tetrachloride solution

Calculation of Transition Polarizabilities. The parameters A and B of Eq. 4 can be expressed in terms of transition polarizability and transition hyperpolarizability.[2] In the case of a molecule belonging to a C_{3v} symmetry, A and B are expressed as:

1) an a_1-type vibration

1-a) for a parallel component,

$$A_{//}=\frac{1}{15\gamma(\lambda_i)}[(16\gamma(\lambda_i)+2){}^{q_i}(\alpha_1^\circ)_{xx}{}^{q_i}(\beta_1^\circ)_{xxz} +(6\gamma(\lambda_i)+2){}^{q_i}(\alpha_1^\circ)_{zz}{}^{q_i}(\beta_1^\circ)_{zzz} +(4\gamma(\lambda_i)-2){}^{q_i}(\alpha_1^\circ)_{xx}{}^{q_i}(\beta_1^\circ)_{zzz} +(4\gamma(\lambda_i)-2){}^{q_i}(\alpha_1^\circ)_{zz}{}^{q_i}(\beta_1^\circ)_{xxz}] \qquad (6a)$$

$$B_{//}=\frac{1}{15\gamma(\lambda_1)}[(8\gamma(\lambda_1)+1){}^{q_i}(\alpha_1^\circ)_{xx}^2 +(3\gamma(\lambda_1)+1){}^{q_i}(\alpha_1^\circ)_{zz}^2 +(4\gamma(\lambda_1)-2){}^{q_i}(\alpha_1^\circ)_{xx}{}^{q_i}(\alpha_1^\circ)_{zz}] \qquad (6b)$$

1-b) for a perpendicular component,

$$A_\perp=\frac{2(15\gamma(\lambda_1)+15)}{15\gamma(\lambda_1)}({}^{q_i}(\alpha_1^\circ)_{xx}-{}^{q_i}(\alpha_1^\circ)_{zz}) \times({}^{q_i}(\beta_1^\circ)_{xxz}-{}^{q_i}(\beta_1^\circ)_{zzz}) \qquad (7a)$$

$$B_\perp=\frac{1+\gamma(\lambda_1)}{15\gamma(\lambda_1)}({}^{q_i}(\alpha_1^\circ)_{xx}-{}^{q_i}(\alpha_1^\circ)_{zz})^2 \qquad (7b)$$

2) for an e-type vibration, and for a parallel component

$$A_{//}=\frac{4\gamma(\lambda_1)+3}{15\gamma(\lambda_1)}\cdot 4({}^{q_i}(\alpha_1^\circ)_{xy}{}^{q_i}(\beta_1^\circ)_{xyz}+{}^{q_i}(\alpha_1^\circ)_{yz}{}^{q_i}(\beta_1^\circ)_{yzz}) \qquad (8a)$$

$$B_{//}=\frac{4\gamma(\lambda_1)+3}{15\gamma(\lambda_1)}\cdot 2({}^{q_i}(\alpha_1^\circ)_{xy}^2+{}^{q_i}(\alpha_1^\circ)_{yz}^2) \qquad (8b)$$

where the molecular fixed Cartesian coordinates, x, y, and z, are defined so that the z-axis coincides with the molecular axis. For e-type lines, $A_\perp$ and $B_\perp$, which correspond to the perpendicular components, are: $A_\perp=(3/4)A_{//}$ and $B_\perp=(3/4)B_{//}$. In the above equations, $\gamma(\lambda_i)=\beta_\perp(\lambda_i)/\beta_{//}(\lambda_i)$, represents the ratio of the transmittances of the monochromator for the light whose electric vector is being polarized perpendicular to the slit, $\beta_\perp(\lambda_i)$, and that parallel to the slit, $\beta_{//}(\lambda_i)$, at the wavelength λ_i. In the case of an a_1-type vibration of a molecule belonging to a C_{3v} symmetry, the transition polarizability tensor can be completely determined if we know the elements ${}^{q}(\alpha_1^\circ)_{zz}$ and ${}^{q}(\alpha_1^\circ)_{xx}$, because the relations between the tensor elements are:

$${}^{q_i}(\alpha_1^\circ)_{xx}={}^{q_i}(\alpha_1^\circ)_{yy}\neq 0,\quad {}^{q_i}(\alpha_1^\circ)_{zz}\neq 0,$$
$${}^{q_i}(\alpha_1^\circ)_{xy}={}^{q_i}(\alpha_1^\circ)_{xz}={}^{q_i}(\alpha_1^\circ)_{yz}=0.$$

For an e-type vibration, it is necessary to know the elements ${}^{q}(\alpha_1^\circ)_{xy}$ and ${}^{q}(\alpha_1^\circ)_{yz}$, because the relations which hold in this case are:[7]

$${}^{q_i}(\alpha_1^\circ)_{xx}={}^{q_i}(\alpha_1^\circ)_{yy}={}^{q_i}(\alpha_1^\circ)_{zz}={}^{q_i'}(\alpha_1^\circ)_{zz}=0,$$
$${}^{q_i'}(\alpha_1^\circ)_{xy}={}^{q_i'}(\alpha_1^\circ)_{yz}={}^{q_i}(\alpha_1^\circ)_{xz}=0,$$
$${}^{q_i}(\alpha_1^\circ)_{xy}=-{}^{q_i'}(\alpha_1^\circ)_{yy}={}^{q_i'}(\alpha_1^\circ)_{xx},$$
$${}^{q_i}(\alpha_1^\circ)_{yz}=-{}^{q_i}(\alpha_1^\circ)_{xz}.$$

where Q_i and Q_i' refer to the doubly degenerated normal coordinate pair. Similar relations hold between transition hyperpolarizabilities, as has been shown in the previous report.[7]

Using the A and B values obtained for the a_1-type vibrations, we can obtain the transition polarizabilities and hyperpolarizabilities, ${}^{q}(\alpha_1^\circ)_{xx}$, ${}^{q}(\alpha_1^\circ)_{zz}$, ${}^{q}(\beta_1^\circ)_{xxz}$, and ${}^{q}(\beta_1^\circ)_{zzz}$. First, we can determine ${}^{q}(\alpha_1^\circ)_{xx}$ and ${}^{q}(\alpha_1^\circ)_{zz}$ by solving the simultaneous equation which is composed from Eqs. 6b and 7b. Then, the ${}^{q}(\beta_1^\circ)_{xxz}$ and ${}^{q}(\beta_1^\circ)_{zzz}$ values can be determined by putting the ${}^{q}(\alpha_1^\circ)_{xx}$ and ${}^{q}(\alpha_1^\circ)_{zz}$ values into Eqs. 6a and 7a and by solving the resultant simultaneous equation composed from Eqs. 6a and 7a. The polarizability derivative, $\partial\alpha^\circ/\partial Q$, is related to the transition polarizability, ${}^{q}(\alpha_1^\circ)$, as

$${}^{q}(\alpha_1^\circ)_{ij}=\left(\frac{\partial\alpha_{ij}^\circ}{\partial Q}\right)\langle I|Q|F\rangle$$

TABLE 2. PLAUSIBLE SETS OF POLARIZABILITY DERIVATIVES FOR a_1-TYPE LINES OF METHYL IODIDE (10^{-5} g$^{-1/2}$ cm^2)

#	$\partial\alpha_{xx}/\partial Q_1$	$\partial\alpha_{zz}/\partial Q_1$	$\partial\alpha_{xx}/\partial Q_2$	$\partial\alpha_{zz}/\partial Q_2$	$\partial\alpha_{xx}/\partial Q_3$	$\partial\alpha_{zz}/\partial Q_3$

where $\langle I|Q|F\rangle$ is a transition matrix element corresponding to the transition between the vibrational levels I and F.

As the Eqs. 6b and 7b are quadratic with respect to the polarizability derivatives, there are four possible sets of polarizability derivative values for each normal mode, Q_1, Q_2, and Q_3. Therefore, there can be obtained $4^3=64$ possible combinations of polarizability derivatives, which are summarized in Table 2. The sixty-four sets of polarizability derivatives can be classified into two groups whose polarizability derivatives have exactly the same absolute values with an opposite sign. As we have no way to distinguish these two groups at present, we assume that all the polarizability derivatives related with the normal mode Q_1 are positive.[8] Therefore, we consider only thirty-two sets of polarizability derivatives hereafter.

Determination of Transition Polarizability. In order to select the most reliable set of polarizability derivatives out of the thirty-two, we introduce the so-called bond polarizability theory which was proposed first by Wolkenstein[9] and Eliashevich[10] and was modified later by Long.[11] The basic idea of this theory is the assignment of a characteristic bond polarizability to each bond in the molecule. This bond polarizability is then defined completely in terms of a polarizability ellipsoid having the major axis coincident with the bond direction. Instead of an irreducible tensor expression which is used in Long's theory, we focus our attention on a reducible tensor, simply because it is more convenient for determining the elements of a transition polarizability tensor. The polarizability derivative, $\partial\alpha/\partial Q$, is expressed as a linear combination of the bond polarizability parameters:[12]

$$\frac{\partial\alpha}{\partial Q} = (J(\gamma_1')K^*L_x)\gamma_1' + (J(\delta_1')K^*L_x)\delta_1' + (J(\varepsilon_1)K^*L_x)\frac{\varepsilon_1}{r_{CI}} + (J(\gamma_2')K^*L_x)\gamma_2' + (J(\delta_2')K^*L_x)\delta_2' + (J(\varepsilon_2)K^*L_x)\frac{\varepsilon_2}{r_{CH}} \quad (9)$$

where $(\gamma_1', \delta_1', \varepsilon_1/r_{CI})$ and $(\gamma_2', \delta_2', \varepsilon_2/r_{CH})$ are the bond polarizability parameters related with the C–I and C–H bonds, respectively. The matrices J and K are determined only from the molecular geometry. The matrix L_x is the transformation matrix between the Cartesian displacement coordinates fixed in the molecule and the normal coordinates, and therefore can be calculated from the molecular force field. In the case of the a_1-type vibrations of methyl iodide, the transformation matrix (JKL_x) is 6×6, because the number of the bond

polarizability parameters is six, while the six elements of the bond polarizability derivative contribute to the scattering cross-section of the a_1-type vibrations. Therefore, we can in principle calculate the bond polarizability parameters by the use of the polarizability derivative values of Table 2. The transformation matrix (JKL_x), which was calculated by the use of the force constants reported by Crawford *et al.*,[8] relates the polarizability derivatives and the bond polarizability parameters:

$$\begin{bmatrix} \partial\alpha^\circ_{xx}/\partial Q_1 \\ \partial\alpha^\circ_{zz}/\partial Q_1 \\ \partial\alpha^\circ_{xx}/\partial Q_2 \\ \partial\alpha^\circ_{zz}/\partial Q_2 \\ \partial\alpha^\circ_{xx}/\partial Q_3 \\ \partial\alpha^\circ_{zz}/\partial Q_3 \end{bmatrix} = \begin{bmatrix} 0 & a & 0 & d & i & m \\ a & a & 0 & e & j & n \\ 0 & b & 0 & f & k & p \\ b & b & 0 & g & k & q \\ 0 & c & 0 & h & l & r \\ c & c & 0 & i & l & s \end{bmatrix} \begin{bmatrix} \gamma_1' \\ \delta_1' \\ \varepsilon_1/r_{CI} \\ \gamma_2' \\ \delta_2' \\ \varepsilon_2/r_{CH} \end{bmatrix} \quad (10)$$

Eq. 10 shows that the parameter ν_1 does not contribute to any polarizability derivatives and, therefore, the inverse matrix $(JKL_x)^{-1}$ does not exist. However, we can reduce the transformation matrix of Eq. 10 into:

$$\begin{bmatrix} \partial\alpha^\circ_{xx}/\partial Q_1 - \partial\alpha^\circ_{zz}/\partial Q_1 \\ \partial\alpha^\circ_{xx}/\partial Q_2 - \partial\alpha^\circ_{zz}/\partial Q_2 \\ \partial\alpha^\circ_{xx}/\partial Q_3 - \partial\alpha^\circ_{zz}/\partial Q_3 \end{bmatrix} = \begin{bmatrix} -a & d-l & m-n \\ -b & f-g & p-q \\ -c & h-i & r-s \end{bmatrix} \begin{bmatrix} \gamma_1' \\ \delta_2' \\ \varepsilon_2/r_{CH} \end{bmatrix} \quad (11)$$

Thus we can calculate the bond polarizability parameters, γ_1', γ_2', and ε_2/r_{CH}, by solving Eq. 11. By putting back the calculated bond polarizability parameters into Eq. 10 and by solving the linear equations composed from the first and the third columns of Eq. 10, we can obtain the remaining bond polarizability parameters, δ_1' and δ_2'. In other words, we can calculate the thirty-two sets of bond polarizability parameters, γ_1', γ_2', δ_1', δ_2', and ε_2/r_{CH}, which correspond to the thirty-two sets of polarizability derivatives. Finally, we calculate the polarizability derivatives, $\partial\alpha^\circ{}_{xx}/\partial Q_3$ and $\partial\alpha^\circ{}_{zz}/\partial Q_3$, using the fifth and sixth columns of Eq. 10: the results are summarized in Table 3. By comparing the calculated values of $\partial\alpha^\circ{}_{xx}/\partial Q_3$ and $\partial\alpha^\circ{}_{zz}/\partial Q_3$ with the observed values of Table 2, we can select the eight possible sets of molecular polarizability derivatives (#11, 12, 15, 16, 27, 28, 31, and 32) out of the thirty-two sets of Table 2.

The next step is to select more reliable sets of polarizability derivatives out of the eight sets. This can be done by calculating the remaining undetermined bond polarizability parameter, ε_1/r_{CH}, from the observed intensities related with the e-species Raman lines. For the e-type vibrations, the transformation matrix (JKL_x), which was calculated by the use of the force constants of Crawford,[8] relates the polarizability derivatives and the bond polarizability parameters:

$$\begin{bmatrix} \partial\alpha^\circ_{xy}/\partial Q_1 \\ \partial\alpha^\circ_{yz}/\partial Q_1 \end{bmatrix} = \begin{bmatrix} 0 & a & b \\ c & d & e \end{bmatrix} \begin{bmatrix} \varepsilon_1/r_{CI} \\ \gamma_2' \\ \varepsilon_2/r_{CH} \end{bmatrix} \quad (12)$$

By putting the eight possible sets of polarizability parameters previously calculated, γ_2' and ε_2/r_{CH}, into Eq. 12 and by putting Eq. 12 into Eq. 8b, we can derive the quadratic equation with respect to the remaining bond polarizability parameter, ε_1/r_{CI}. Thus the remaining bond polarizability parameter, ε_1/r_{CI}, can be calculated for both ν_5 and ν_6 lines corresponding to the eight possible sets of bond polarizability parameters. The results are summarized in Table 4. As the bond polarizability parameters should be real, the sets #11, 12, 15, 28, 31, and 32, can be discarded, because the calculated ε_1/r_{CI} values are imaginary. The remaining sets #16 and 27 are considered to be reasonable, because the ε_1/r_{CI} values which have been obtained are similar in magnitude for ν_5 and ν_6: 2.54×10^{-16} cm^2 (ν_5) and 2.24×10^{-16} cm^2 (ν_6) for #16, and -2.54×10^{-16} cm^2 (ν_5) and -2.24×10^{-16} cm^2 (ν_6) for #27. There is no way to distinguish these two sets of polarizability derivatives within the bond polarizability hypothesis. Fortunately, however, we can choose sets #16 as the most reliable set of molecular polarizability derivatives, because of the following reason.

In the preceding discussion, the transition polarizability related with the Q_3 normal mode, $^{0_1}(\alpha_1^\circ)_{zz}$, was obtained to be 2.94×10^{-25} cm^3 (for #16) or -2.94×10^{-25} cm^3 (for #27). According to our previous work

TABLE 3. POLARIZABILITY DERIVATIVES FOR Q_3 OF METHYLIODIDE CALCULATED FROM BOND POLARIZABILITY PARAMETERS (10^{-5}g$^{-1/2}$ cm^2)

#	$\partial\alpha_{xx}/\partial Q_3$	$\partial\alpha_{zz}/\partial Q_3$	#	$\partial\alpha_{xx}/\partial Q_3$	$\partial\alpha_{zz}/\partial Q_3$

TABLE 4. e_2/r_{CH} VALUES CALCULATED FOR ν_5 AND ν_6 LINES (10^{-16} cm^2)

#	11	12	15	16
ν_5	$3.61\pm1.96i$	$7.93\pm10.2i$	$8.12\pm13.0i$	$\begin{cases} 2.54 \\ -7.98 \end{cases}$
ν_6	$\begin{cases} -0.67 \\ -2.70 \end{cases}$	$3.35\pm9.39i$	$3.93\pm1.26i$	$\begin{cases} 2.24 \\ -0.05 \end{cases}$
#	27	28	31	32
ν_5	$\begin{cases} -2.54 \\ 7.98 \end{cases}$	$8.12\pm13.0i$	$7.93\pm10.2i$	$3.61\pm1.96i$
ν_6	$\begin{cases} -2.24 \\ 0.05 \end{cases}$	$3.93\pm1.26i$	$3.35\pm9.39i$	$\begin{cases} -0.67 \\ -2.70 \end{cases}$

on the solvent effect on the infrared absorption intensity for the ν_3 band of methyl iodide,[1] the $^{Q_1}(\alpha_1^\circ)_{zz}$ has been obtained to be -1.1×10^{-25} cm^3. We should not attach too much importance to the absolute values of these results, because the frequency region of the infrared measurement belongs to the resonant region, while that of the Raman measurement belongs to the off-resonant region. However, the minus sign attached to the $^{Q_1}(\alpha_1^\circ)_{zz}$ value is of much importance, because the signs attached to the $^{Q_1}(\alpha_1^\circ)_{zz}$ values of the Raman and infrared results should be the same. Thus we can say that set #16 is more reliable than set #27.

Determintaion of Transition Hyperpolarizability. Using the finally determined set of polarizability derivatives, that is,

$$^{Q_1}(\alpha_1^\circ)_{xx} = 1.05\times10^{-25} \quad (\text{cm}^3)$$
$$^{Q_1}(\alpha_1^\circ)_{zz} = 2.28\times10^{-25} \quad (\text{cm}^3)$$
$$^{Q_1}(\alpha_1^\circ)_{xx} = -2.10\times10^{-26} \quad (\text{cm}^3)$$
$$^{Q_1}(\alpha_1^\circ)_{zz} = -6.76\times10^{-26} \quad (\text{cm}^3)$$
$$^{Q_1}(\alpha_1^\circ)_{xx} = -3.14\times10^{-26} \quad (\text{cm}^3)$$
$$^{Q_1}(\alpha_1^\circ)_{zz} = -2.94\times10^{-25} \quad (\text{cm}^3)$$

and using Eqs. 6a and 7a, we can calculate the transition hyperpolarizability elements for Q_3:

$$^{Q_1}(\beta_1^\circ)_{xxz} = 7.07\times10^{-31} \quad (\text{cm}^3\ \text{dyn}^{-1}\ \text{esu})$$
$$^{Q_1}(\beta_1^\circ)_{zzz} = 8.88\times10^{-31} \quad (\text{cm}^3\ \text{dyn}^{-1}\ \text{esu})$$

which are certainly of the correct order of magnitude. The magnitude of the transition hyperpolarizability has been considered to be of the order of 10^{-31}—10^{-32} (cm^3 dyn^{-1} esu), although no direct measurement of transition hyperpolarizability has actually been reported yet.

Concluding Discussion. From the discussion of the previous paragraphs, a few important conclusions can be drawn.

1) It was shown that the hyperpolarizability, which is a higher order term of the polarizability, does change the Raman intensities through the existence of the averaged molecular field, $\langle \boldsymbol{F}_{0z} \rangle_{av}$, in solution. If the averaged molecular field is properly estimated, the transition polarizability and transition hyperpolarizability can be determined simultaneously in the form of tensor elements by observing the solvent effect on Raman intensity.

2) For determining the sign of the transition polarizability, the bond polarizability theory has been shown to be quite helpful. At the same time, the information about the sign of the transition polarizability which is observed in the solvent effect on infrared intensity is very important and convincing.

3) Incidentally, this seems to be the first work in which the transition hyperpolarizability is obtained in the form of a tensor element. The examination of the reliability of the resultant transition hyperpolarizability, however, will be left for future studies in which the transition hyperpolarizability will be directly observed by, for example, the intensity measurement of a hyper-Raman line.

(Received March 2, 1979)

Nitrogen screening constants are calculated by the sum-over-states method using INDO/S parameters and by the finite perturbation procedure employing INDO parameters. The solvaton model is employed to describe changes in nuclear screening as a function of the dielectric constant of the medium. The calculated variations of nitrogen screening are in reasonable agreement with the available experimental data. The effects on screening of hydrogen bonding are included in the sum-over-states calculations by means of dimer models.

In order to obtain a close comparison between theoretical and experimental estimates of nuclear screening some allowance should be made for medium effects. Contributions from the bulk magnetisation and the diamagnetic anisotropy of the solvent to the total screening can be effectively removed by a suitable choice of solvent and the use of an internal standard. Account should also be taken of van der Waals interactions between solute and solvent, which usually deshield the nucleus of interest,[1,2] polar effects due to the charge distribution in neighbouring solvent molecules and specific solute solvent interactions such as hydrogen bonding and complex formation.

The influence of van der Waals interactions are likely to be most pronounced in the case of relatively nonpolar systems. For polar molecules it seems reasonable to suppose that effects due to solvent-charge distribution and specific solute-solvent interactions will dominate.

The polar effects of solvents on nuclear screening may be accounted for by means of the solvaton model.[3] This has been successfully employed in the calculation of solvent effects on ^{13}C chemical shifts in a number of molecules.[4,5]

In the present study these investigations are extended to nitrogen chemical shifts. Since these are more sensitive to medium effects than ^{13}C chemical shifts,[6] it is anticipated that they may provide a closer insight into the effects of solute-solvent interactions on chemical shifts.

As discussed elsewhere[7] Pople's model[8,9] appears to provide the most acceptable basis for satisfactory discussions of nuclear screening. Calculations using semi-empirical MO parameter sets are often inadequate due to the difficulties involved in accurately determining the contributions to the paramagnetic component of the screening tensor from the excited states. Two approaches to this problem are currently available. The sum-over-states method incorporating parameter sets which provide a realistic description of the excited states. In addition, there is the finite perturbation procedure which does not explicitly involve the estimation of excited state eigenfunctions.

Both of these approaches are employed in the present work. The sum-over-states calculations use INDO/S parameters which have been demonstrated to provide a satisfactory account of nitrogen chemical shifts[10] and the finite perturbation method employs INDO parameters within a revised formulation.[11] In the latter case, the values of the bonding parameters β_H° and β_C°, for the hydrogen and carbon atoms respectively, are taken to be -13 eV and -15 eV. The correction factor K for π-π interactions takes the value of 0.85. Calculations incorporating these values provide a reasonable account of some ^{13}C chemical shifts.[11]

Results and Discussion

The results of the calculations of the total charge density on the nitrogen atom, q, the averaged value of its screening tensor, σ, and the relative chemical shift, δ, as a function of the dielectric constant of the medium, ε, for both the sum-over-states (SOS) and finite perturbation (FPT) calculations are presented in Table 1.

The decrease in screening of the nitrogen nucleus in nitromethane as ε increases is almost entirely due to changes in the paramagnetic contribution to the screening tensor. As ε increases from 1 to 80 the diamagnetic term reduces by 1.83 ppm in the sum-over-states calculations and 0.95 ppm in the finite perturbation results. This follows a reduction in the nitrogen charge density. In general, it is found that the calculated changes in the diamagnetic term, as a function of ε, are very small when compared with those in the paramagnetic contribution. Consequently only changes in the total nuclear screening are reported in Table 1.

The data reported in Table 1 imply that changes in q, as a function of ε, do not always follow in the same direction as variations in σ. This is most probably due to the fact that differences in σ are controlled by changes in the paramagnetic contribution which, in general, are not expected to depend linearly on charge density differences.[7]

Both sets of calculations qualitatively follow the trend of changes in nitrogen screening with ε for nitromethane reported experimentally.[6] More quantitative data would reveal whether the large change in σ, predicted by the sum-over-states calculations, or the smaller change indicated by the finite perturbation results is the more accurate.

The finite perturbation results reported in Table 1 do not contain the contribution to the diamagnetic term arising from the 1s electrons. Thus the values of σ reported are smaller than those obtained from the sum-over-states calculations. However, this should not influence the calculated changes in σ as a function of ε.

The sum-over-states results indicate a value of about -141 ppm for the nitrogen screening of neat nitromethane which is in reasonable agreement with the estimated

a) The chemical shifts are reported with respect to the isolated molecule, $\varepsilon=1$, shifts to higher frequency being positive.

value of −130 ppm.[6]

In the case of ammonia both sets of calculations predict an increase in nitrogen screening as ε increases. This appears to be in contradiction to the available experimental data which show a nitrogen screening decrease by up to 21 ppm when gaseous ammonia is dissolved in various solvents.[6] However, the nitrogen screening of the ammonium ion can be 40 to 50 ppm less then in ammonia[6] and since the available experimental solution data on ammonia involves media conductive to protonation and/or hydrogen-bonding the comparison with the theoretical results in Table 1 may not be a valid one.

The small increase in the nitrogen screening of pyridine as ε increases, from the sum-over-states calculations, follows the trend of the available experimental data for non-hydrogen bonding media.[6,12] In hydrogen-bonding solvents large increases in the nitrogen screening are reported which are dominated by changes in the paramagnetic term.[12] To investigate this we have calculated the nitrogen screening constant for the hydrogen-bonded pyridine–water dimer in a minimum

energy conformation obtained from an INDO geometry optimization procedure.

The results given in Table 2 reveal an increase in nitrogen screening of 15.79 ppm due to hydrogen-bond formation. This compares with a measured increase of about 25 ppm.[12] The increase arises from a reduction in the paramagnetic contribution to the screening as a result of increases of energy denominators weighted by transition elements in various transitions.[10] The major transition changes result from the effective removal of the nitrogen lone pair due to hydrogen-bond formation.

The finite perturbation results (Table 1) show a much larger increase in the nitrogen screening of pyridine, with an increase in ε, without specifically incorporating the formation of a hydrogen bond.

A similar situation arises in the case of acetonitrile. The observed increase in the nitrogen screening in methanol appears to be accounted for by the finite perturbation calculations on the solvaton model, whereas the sum-over-states method requires the acetonitrile-methanol dimer as a model (Table 2) to reproduce the experimental trend. The structure used in this calculation again corresponds to a minimum energy conformation as obtained from INDO calculations.

The available experimental data on the nitrogen resonance of methyl isocyanide[13] indicate that it is far less sensitive to changes in solvent than is its counterpart for acetonitrile. The calculations reported here support this conclusion. However, the opposing trends predicted by the two sets of calculations are probably indicative of medium effects which are not specifically incorporated in the solvaton model.

The sum-over-states calculations for the nitrate ion indicate that the nitrogen atom in the free ion suffers a large decrease in screening as ε increases. However, in the presence of water a hydrogen-bonded structure has been reported.[14] Calculations on this structure (Table 2) reveal an increase of nitrogen screening. The increase in nitrogen screening, as a function of ε, is predicted by the finite perturbation calculation without invoking hydrogen-bonding.

Since nitrate ion is usually used in aqueous media the opposing screening trends due to the solvaton and hydrogen-bonding interactions renders its nitrogen resonance position very susceptible to changes in concentration and pH. Taken together these effects make nitrate ion unsatisfactory as a reference standard for nitrogen NMR.[6]

The trend obtained (Table 1) by the sum-over-states calculations for the nitrogen screening of the ammonium ion, as a function of ε, is in reasonable agreement with the available experimental data.[6] The opposing trend suggested by the finite perturbation calculations implies that interactions other than those described by the solvaton model are operative.

For use as a nitrogen NMR reference material the position of a nitrogen signal should be relatively insensitive to solvent changes in order to compare results between different laboratories. The calculations reported here indicate that the ammonium ion is not to be recommended as a nitrogen standard.[6]

At present it is not clear why the sum-over-states calculations for pyridine, acetonitrile and nitrate ion require both solvaton and hydrogen bonding effects to reproduce experimental trends, whereas only solvaton interactions are necessary in the finite perturbation approach. However, in general, the effects of the medium on nitrogen chemical shifts appear to be reasonably well accounted for by the calculations reported here involving both the solvaton model and specified hydrogen-bonding interactions. To examine these data more searchingly further experimental results of changes in nitrogen screening as a function of ε are required.

Experimental

The sum-over-states calculations were performed on the CDC 7600 systems of the Universities of London and Manchester using a modified version of QCPE 174. Standard geometries[15] were used in the calculations. The finite perturbation calculations were performed on the HITAC M180 system of the Tokyo Institute of Technology.

Film Dichroism. III. Linearly-polarized Absorption Spectra of Highly Symmetric Triphenylmethane Dyes in the Stretched Poly(vinyl alcohol) Films

Yukio MATSUOKA and Kiwamu YAMAOKA*

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received March 9, 1979)

The linear dichroic absorption spectra of Pararosaniline (PR), Crystal Violet (CV), and Ethyl Violet (EV) were measured in the UV and visible regions by the stretched film technique. Poly(vinyl alcohol) was used as the film matrix. A method, which is expressed in the forms of reduced dichroism and dichroic ratio, was proposed for the analysis of the linear dichroism of disk-like molecules. The dyes PR, CV, and EV were shown to behave like disks regarding their orientation in the polymer matrix. The isotropic absorption spectra of PR, CV, and EV were resolved into the in-plane and out-of-plane polarized components by the reduction procedure. In each isotropic spectrum the out-of-plane component was found to overlap with the intense in-plane component in the UV and visible wavelength regions.

Crystal Violet (CV) has attracted considerable attention in the last decade because it is a typical non-intercalative dye which binds to biopolymers.[1,2] Measurements of the optical rotatory dispersion[1] and linear flow dichroism[2,3] of CV bound to deoxyribonucleic acid (DNA) were carried out to elucidate the binding mode of the dye. In order to obtain useful information on the optical properties of the DNA–CV complexes, however, it is of utmost importance to know the polarization direction of the electronic absorption bands of CV itself in detail, as pointed out in a previous paper.[4] In the assignment of the polarization direction for the disk-like molecules which belong to a D_{nh} or C_{nv} ($n \geqq 3$) point symmetry, a transition polarized perpendicularly to the molecular plane (*i.e.*, out-of-plane transition) should not be ignored. Since CV is most likely to belong to the D_{3h} or C_{3v} point symmetry, the out-of-plane transition must be taken into account in the analysis of its dichroic data.

Recently, Yogev *et al.*[5] reported the expressions for the linear dichroism of disk-like molecules in some special cases and thereby resolved the isotropic absorption spectra of penta- and hexahelicenes into the in-plane and out-of-plane polarized absorption components. For the triphenylmethane dyes such as CV and Malachite Green, both the measurements of dichroic absorption spectra and the interpretations of the dichroic ratio have been carried out.[6,7] Tanizaki[6] first determined the relative directions of the transition moments of CV for the visible absorption bands. Nordén[7] measured the dichroic ratios of some triphenylmethane dyes in the visible region and explained them qualitatively. Both of these workers have suggested the possibility of the presence of an out-of-plane polarized absorption component in the isotropic spectrum of CV, but they have failed to show the location and band shape of the component.

The main objects of this paper are, first, to determine the in-plane and out-of-plane polarized absorption components (the reduced spectra) of CV from its dichroic absorption spectra by the *reduction procedure*;[8] second, to apply the same procedure to the dichroic spectra of Pararosaniline (PR) and Ethyl Violet (EV), which belong to the same point symmetry as CV (*i.e.*, D_{3h}[7,9] or C_{3v}[2,10]); and finally, to compare their reduced spectra. The three dyes are all derivatives of triphenylmethane differing only in the amino substitution and, therefore, are expected to have closely related spectral properties. The evaluation of the reduced spectra of those disk-like triphenylmethane dyes must differ from the previous case for the acridine dyes of C_{2v} point symmetry,[4] because PR, CV, and EV all lack the longest dimension in the molecular shape but possess several symmetrically distributed axes of equivalence. A new formalism of the linear dichroism of these disk-like molecules is necessary for the interpretation of the dichroic results.

The resultant reduced spectra of each dye show both the in-plane and out-of-plane polarized absorption components in the visible and UV regions. The presence of the out-of-plane component in the visible region indicates that the effective symmetry of PR, CV, and EV is not D_{3h} but rather C_{3v} or D_3 in the poly(vinyl alcohol) (PVA) film.

Experimental

Materials. Dyes used were all in the monocationic form, the anion being chloride. CV was purified as described before,[11] and PR and EV were purified by the method of preparative thin-layer chromatography. The powdered PVA sample with a nominal degree of polymerization of 1750 was obtained from Tokyo Kasei Co., Ltd. The concentration of each dye was *ca.* 20 μM (1 μM = 1×10^{-6} mol dm^{-3}) in the 9.1 w/w % aqueous PVA solution prior to casting. Both sample and reference films were prepared as described before.[4]

Apparatus. The linear dichroic absorption spectra ($A_{\parallel}$- and $A_{\perp}$-spectra) of PR, CV, and EV were measured on a Hitachi EPS-3T double beam recording spectrophotometer equipped with a mechanical stretcher designed and constructed in this laboratory.[12] The sample and reference films were stretched simultaneously in the cell compartment of the instrument at about 80 °C. The stretch ratio (S) was defined as described elsewhere.[4,6]

Evaluation of Reduced Spectra. All PR, CV, and EV belong to a D_{3h} or C_{3v} point symmetry and possess no uniquely defined axis of orientation (the longest axis). However, they have several axes equally distributed in the molecular plane, according to the definitions of the axes for the disk-like molecule given in Ref. 8 (see Fig. 3). The experimental fact is that each dye in the stretched PVA film can be oriented; the

orientation should be ascribed to the redistribution of the "circular"plane from its random distribution before stretching. Therefore, the orienting property of all those dyes may be represented by the behavior of a disk molecule. When the in-plane or the out-of-plane polarized transitions are assumed in the isotropic spectrum of the disk-like molecule, the reduction procedure for the molecule will be employed to evaluate the reduced spectra, namely, the (A_y+A_z)-spectrum for the in-plane polarized absorption component of the isotropic spectrum and the A_x-spectrum for the out-of-plane polarized component.

If the disk-like molecules are oriented unidirectionally in the PVA film, the formulas necessary for the procedure are as follows:[8]

$$A_\perp - \frac{1}{d}A_\parallel = \frac{d-1}{d}A_x \quad (1)$$

$$A_\parallel - d_x A_\perp = \frac{d-1}{d}(A_y+A_z) \quad (2)$$

where d_x and d ($d=d_y=d_z$ for the disk-like molecule) are the *reduction factors*[8] which should be determined by the procedure. The *orientation factors*[8] K_x and K ($K=K_y=K_z$) are given by

$$K_x = \frac{d_x}{2+d_x} \quad \text{and} \quad K = \frac{d}{2+d} \quad (3)$$

Results and Discussion

Isotropic, Dichroic, and R_d-Spectra.[4] Figures 1a—1c show two kinds of isotropic spectra, *i.e.*, $\bar{k}\times A_0(S=1)$ (open circles) and $A=(A_\parallel+2A_\perp)/3$ (solid curve), for PR, CV, and EV in the PVA film at an S value of 3.7. A good agreement between these two isotropic spectra in each case suggests that the dye molecules are oriented unidirectionally in the stretched film. The observed isotropic spectrum of each dye in the film was similar to the spectrum in the corresponding aqueous PVA solution, except that the film spectrum was slightly shifted toward the long-wavelength side. There appear three peaks (designated as **A**, **C**, and **D**), shoulder(s) in the 340—400 nm region, and a shoulder (designated as **B**) in each film spectrum. These apparent wavelength positions are given for PR, CV, and EV in Table 1.

PR: Figure 2a shows the dichroic, $\Delta A/A$, and R_d-spectra of PR in the UV and visible regions. The $A_\parallel$-spectrum is always more intense than the $A_\perp$-spectrum over the entire wavelength. The R_d-spectrum decreases slightly on the long-wavelength side of the visible peak, but changes irregularly in the UV region. The R_d-spectrum becomes highest near the shoulder band at *ca.* 510 nm and the UV peak at 294 nm.

CV: Figure 2b shows the dichroic, $\Delta A/A$, and R_d-spectra of CV in the UV and visible regions. The

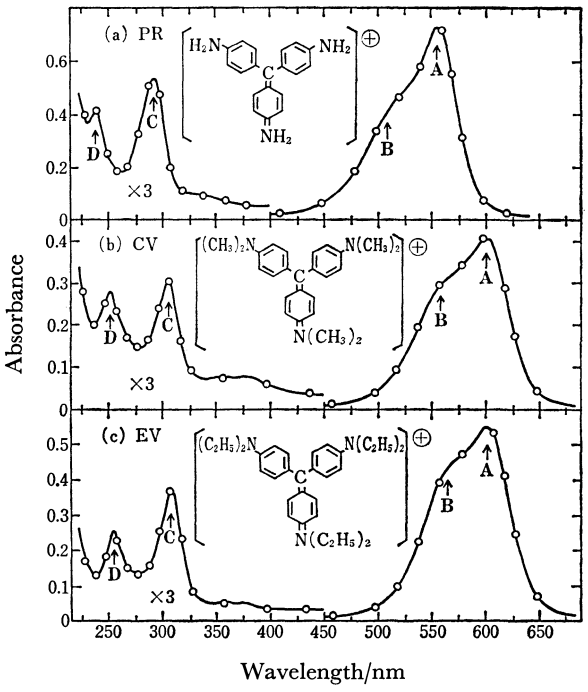

Fig. 1. Isotropic spectra of PR, CV, and EV in the stretched PVA film at $S=3.7$. The solid line (——) is the isotropic spectrum calculated from $A_\parallel$ and $A_\perp$ by the use of the relation, $A=(A_\parallel+2A_\perp)/3$. Circles (-o-o-) are the normalized isotropic absorbance calculated from $\bar{k}\times A_0(S=1)$. For the definition of these quantities, see Ref. 4. The values of $\bar{k}$ were 0.65 for PR and 0.61 for CV and EV. Letters **A** to **D** indicate the apparent peak or shoulder positions in each isotropic spectrum.

$A_\parallel$-spectrum is more intense than the $A_\perp$-spectrum except in the 280 nm region. There are two peaks in the 340—400 nm region, which were obscure in the dichroic spectra of PR. In spite of the simple profile of the isotropic absorption spectrum in the visible and UV regions, the R_d-spectrum is not flat but changes irregularly. The R_d-spectrum gives the highest value near the shoulder band at *ca.* 556 nm and the lowest value near 280 nm. A gradual decrease of the R_d-spectrum is noted near the principal peak in the visible region (570—670 nm). Those apparent dichroic features in the visible region are in excellent agreement with previous reports.[6,7]

EV: Figure 2c shows the dichroic, $\Delta A/A$, and R_d-spectra of EV. The $A_\parallel$-spectrum is always more intense than the $A_\perp$-spectrum in the UV and visible regions. The R_d-spectrum of EV behaves very much

Table 1. The apparent band positions (**A**—**D**) in the isotropic spectra and the transition moment angles (θ_A–θ_C) at the corresponding band positions of PR, CV, and EV

Dyes	Apparent positions[a] (nm)				Angles (deg)		
	A	**B**	**C**	**D**	θ_A	θ_B	θ_C
PR	557(549)	510(500)	294	241	48±1	48±1	49±1
CV	600(594)	560(550)	308(304)	252(251)	48±1	46±1	49±1
EV	603(601)	565(555)	310(308)	256(254)	49±1	47±1	47±1

a) The values in the parentheses are the corresponding positions in the aqueous PVA solution.

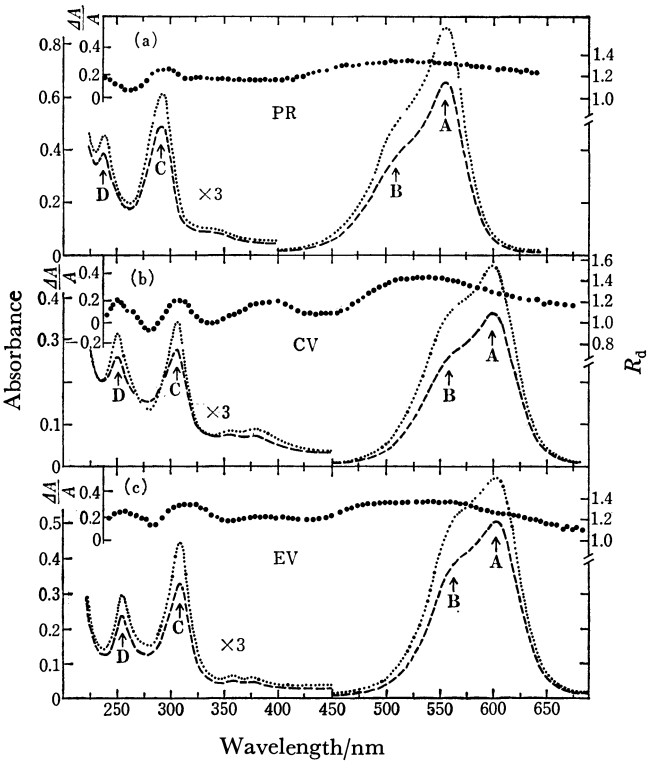

Fig. 2. Dichroic spectra and R_d-spectra of PR, CV, and EV in the stretched PVA film at $S=3.7$. The R_d-value can be converted into the reduced dichroism, $\Delta A/A$, which is referred to the left ordinate of each figure, by the use of Eq. 6 in Ref. 4. Symbols are: the parallel $A_{\parallel}$ (·····) and perpendicular $A_{\perp}$ (------) polarized spectra, and $\Delta A/A$ or R_d-spectrum (••••••). Letters **A** to **D** are the same as in Fig. 1.

like that of CV, although the R_d-values of EV at the UV peaks (**C** and **D**) are larger than those of CV at the corresponding positions.

Determination of Transition Moment Angles. In a previous paper we have dealt with the acridine dyes of C_{2v} point symmetry, each of which has a unique axis of orientation in the molecular plane (*i.e.*, the orientation axis). In that treatment the transition moment angles relative to the orientation axis were determined by the method of Tanizaki.[6] However, in the case of the disk-like molecule, such an orientation axis can not be assigned uniquely in the molecular plane because of its possible distribution in any direction. Nevertheless, if we presume an orientation axis (OA) in the molecular plane of the disk-like molecule, we can estimate the direction of a transition moment μ as the angle θ relative to the OA (Fig. 3a) by the method of Tanizaki. However, since this value of θ results from the averaging over μ around the out-of-plane axis (x-axis), it is only an apparent angle.

In the radially symmetrical molecules such as PR, CV, and EV, all in-plane polarized transitions will show a constant dichroic ratio at a given value of S.[5] Moreover, in the absence of the out-of-plane polarized transitions, the values of θ for the in-plane transitions of the disk-like molecule will become 45°.[5-7] In order to determine the values of θ, the dependence of R_d on S

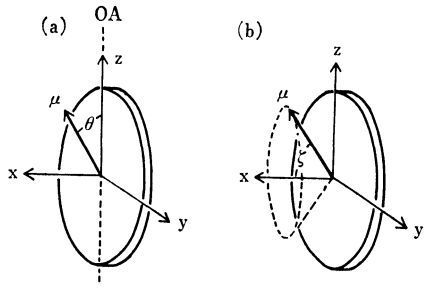

Fig. 3. Schematic illustration of the perfect orientation of a disk-like molecule in the stretched PVA film. The molecule has a transition dipole moment μ taking an arbitrary direction. The molecular coordinates are the y- and z-axes (in-plane) and the x-axis (out-of-plane), where the z-axis is tentatively taken along the stretching direction. (a) The direction of μ is measured by an angle θ relative to an orientation axis (OA) in the molecular plane. (b) The direction of μ is measured by an angle ζ with respect to the out-of-plane x-axis.

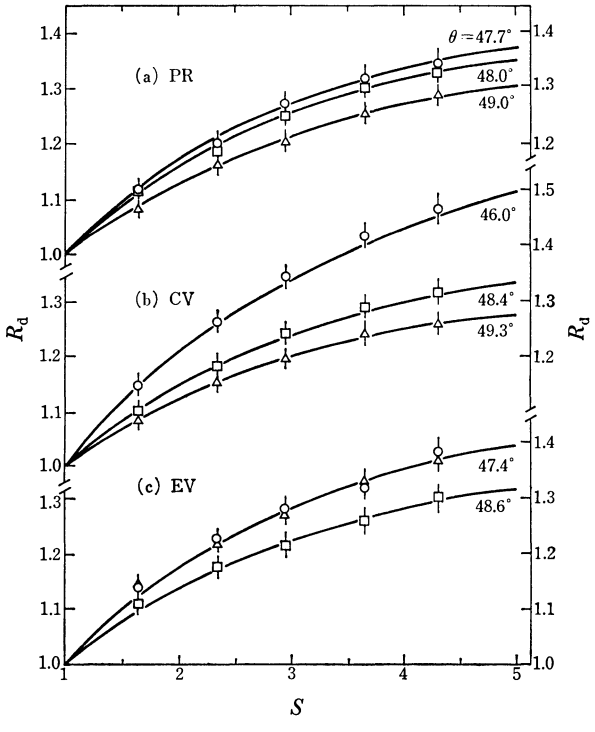

Fig. 4. Dependence of R_d on S for PR, CV, and EV. Symbols (□, ○, and △) denote the R_d-values at the wavelength positions of **A**, **B**, and **C** at five different S-values. Each solid curve is a theoretical one which fits best to those observed points. The value of the angle θ specifying each curve was determined by the method of Tanizaki.

was examined at the positions of **A**, **B**, and **C** for PR, CV, and EV. The results are shown in Fig. 4, where the values of θ were determined by the method of Tanizaki.[4,6] The observed values of R_d appear to fall on the respective theoretical curves indicated by the angle θ within experimental errors. As shown in Fig. 4, Tanizaki's method is applicable for the molecules which give rise to a small dichroic ratio. All values of θ for

PR, CV, and EV are given in Table 1. It should be noted that each θ is determined relative to an arbitrary and unspecified axis in the molecular plane and, hence, that the angle θ is only apparent. It is now clear that the values of θ are not equal to, but always larger than, 45° at the positions of **A**, **B**, and **C**, and that they differ from each other. These results are indeed strong and direct evidence that the apparent bands **A**, **B**, and **C** each contain not only the in-plane but also the out-of-plane transitions. The presence of the out-of-plane polarized transition(s) in those wavelength positions will be shown below.

The in-plane polarized transitions of the disk-like molecule can not be divided uniquely into the so-called y- and z-axis polarized components[4] because of the flatness of the R_d-spectrum. However, the isotropic spectrum should be divided into the in-plane and the out-of-plane polarized absorption components, as carried out by Yogev *et al.*[5] In order to determine these absorption components, it is necessary to differentiate the out-of-plane polarized transition from the in-plane polarized one in the same overlapping wavelength region in the isotropic spectrum. For this purpose, Yogev *et al.* have attempted to determine the direction of the out-of-plane transition moment by two angles of α and β relative to two particular axes in the molecular plane.[5] However, this determination of the direction is not well suited for the disk-like molecule of high symmetry, because the out-of-plane transition moment vector is generally distributed equally and evenly around the x-axis when the molecules are oriented unidirectionally. In order to find the in-plane and out-of-plane polarized transitions more convincingly, a new analysis of the linear dichroism for a disk-like molecule will be presented in the next section.

Analysis of Linear Dichroism for Disk-like Molecules. As a representative disk-like molecule, CV is chosen for illustration of procedures. Since CV does not possess a defined axis of orientation lying in the molecular plane, it will orient itself in the stretched PVA film preferentially with its plane parallel to the stretching direction. The definition of the molecular axes x, y, and z is shown in Fig. 3b, where a transition moment $\boldsymbol{\mu}$ of the molecule is directed along an arbitrary direction. The direction of the moment is measured with the angle ζ relative to the x-axis. According to this scheme, the reduced dichroism and the dichroic ratio ($\Delta A/A$ and R_d) for an assembly of like molecules are represented by Eqs. 4 and 5, respectively, by analogy with the case for the rod-like molecules:[13]

$$\frac{\Delta A}{A} = \frac{3(A_{\parallel}-A_{\perp})}{A_{\parallel}+2A_{\perp}} = \frac{3}{2}(3\cos^2\zeta-1)\varPhi \tag{4}$$

and

$$R_d = \frac{A_{\parallel}}{A_{\perp}} = \frac{2+2(3\cos^2\zeta-1)\varPhi}{2-(3\cos^2\zeta-1)\varPhi} \tag{5}$$

where $\varPhi$ is the orientation function[14] and takes any value between 0 and -0.5 depending on the orientability of a particular kind of dye embedded in the PVA film. The detailed discussion will be given later.[13] A very closely related orientation function has already been derived for the disk-shaped molecule in the study of electric dichroism.[15] The function $\varPhi$ may be connected to the degree of orientation, f ($0 \leqq f \leqq 1$), of the assembly of dye molecules in such a way that $f=-2\varPhi$. The value of f then represents a hypothetical fraction of the disk-like molecules having their planes in the direction of stretch at a given S. It should be noted that, at the limiting stretch ratio ($S\to\infty$), $\varPhi$ takes a value of -0.5 if the orientation is such that the y- or z-axis is parallel to the stretching direction, but it takes a value of 1 if the orientation is such that the x-axis is parallel to the stretching direction. (The latter is the case of a cylindrical molecule for which the x-axis is the longest.) Thus the general behavior of $\varPhi$ for the disk-like molecule differs from that for the rod-like molecule.[13]

On the basis of Eqs. 4 and 5, the analysis of the linear dichroism for the disk-like molecule will be shown below in order to differentiate the out-of-plane polarized transition from the in-plane polarized one. When dichroic absorption spectra are measured for a disk-like molecule, they should show that a transition moment with $\zeta=0°$ will preferentially absorb the light polarized perpendicularly to the direction of stretch. (In this case a negative linear dichroism should be observed.) If all molecules are oriented with their molecular plane perfectly parallel to the stretching direction (*i.e.*, $\varPhi=-0.5$ or $f=1$), the reduced dichroism, $\Delta A/A$, and the dichroic ratio, R_d, for the transition moment with $\zeta=0°$ would have the limiting values of -1.5 and 0 in Eqs. 4 and 5, respectively. If the molecules are partially oriented, the reduced dichroism and the dichroic ratio for the same transition moment would be a function of $\varPhi$ or f only and may be obtained from Eqs. 4 and 5 by substituting $\zeta=0°$:

$$\frac{\Delta A}{A} = 3\varPhi = -\frac{3}{2}f \tag{6}$$

$$R_d = \frac{1+2\varPhi}{1-\varPhi} = \frac{2(1-f)}{2+f} \tag{7}$$

Since $\varPhi$ varies between 0 and -0.5 (f varies between 0 and 1), $-1.5 \leqq \Delta A/A \leqq 0$ and $0 \leqq R_d \leqq 1$. On the other hand, the reduced dichroism and the dichroic ratio due to a transition moment polarized in the molecular plane may be given by substituting $\zeta=90°$ into Eqs. 4 and 5:

$$\frac{\Delta A}{A} = -\frac{3}{2}\varPhi = \frac{3}{4}f \tag{8}$$

$$R_d = \frac{2-2\varPhi}{2+\varPhi} = \frac{4+2f}{4-f} \tag{9}$$

In this special case, $0 \leqq \Delta A/A \leqq 3/4$ and $1 \leqq R_d \leqq 2$. Equations 7 and 9 are now reduced to the same expressions which have been derived by Yogev *et al.* (Eqs. 2 and 9 in Ref. 5). Thus, Eqs. 4 and 5 are more general and appropriate to the analysis of the dichroic spectra containing both the in-plane and out-of-plane polarized transitions.

The dependence of $\Delta A/A$ or R_d on wavelength makes it possible to distinguish between the in-plane and the out-of-plane transitions of the disk-like molecule. If only the in-plane or the out-of-plane polarized transitions are present in the observed wavelength region, the wavelength dependence of $\Delta A/A$ or R_d becomes flat throughout the region concerned at a given value of S. The

absolute values of $\Delta A/A$ or R_d depend only on the degree of orientation, as indicated by Eqs. 6 and 7 for the out-of-plane transition or by Eqs. 8 and 9 for the in-plane transition. If both the in-plane and the out-of-plane transitions are overlapped, the wavelength dependence is not constant any longer in a particular wavelength region, the former being located in the region with the large $\Delta A/A$ or R_d-value and the latter being located in the region with the small $\Delta A/A$ or R_d-value. This is because the values of $\Delta A/A$ and R_d of the out-of-plane transition should be smaller than those of the in-plane transition at a given value of S (for the details, see the next section).

Reduced Spectra of PR, CV, and EV. The following analysis is based on the assumption that the dyes PR, CV, and EV in the PVA film can be treated as disk-like molecules oriented with their molecular planes parallel to the stretching direction (see Fig. 3b). Since the structure of those dyes belong to a D_{3h} or C_{3v} point symmetry, the assumption is probably quite appropriate. Their absorption spectra then consist of the transitions which are allowed in the plane (yz-plane) perpendicular to the three-fold symmetry axis and possibly along the three-fold symmetry axis (x-axis), *i.e.*, the out-of-plane polarized transitions. The in-plane polarized transitions may lie along either the y- or z-axis. From the changes in each $\Delta A/A$ or R_d-curve of PR, CV, and EV (Figs. 2a—2c), the absorption band near the **B** position appears to be mainly composed of the in-plane transition because of the largest $\Delta A/A$ or R_d-value, whereas the absorption band near the **A** position appears to be composed of the intense in-plane and weak out-of-plane transitions because of the smaller $\Delta A/A$ or R_d-value.

On the basis of the apparent spectral features, the reduction procedure was applied to the dichroic absorption spectra of PR, CV, and EV measured at $S=3.7$. The reduction factors d_x and d in Eqs. 1 and 2 were sought out by means of the trial-and-error reduction search.[8] The best values are given in Table 2, together with the values of the orientation factors K_x and K calculated from Eq. 3. The resultant reduced spectra of those dyes are shown in Figs. 5a—5c. As expected from the R_d data in Figs. 2a—2c, an out-of-plane polarized transition is clearly unmasked in the visible band at *ca.* 577 nm for PR, 608 nm for CV, and 613 nm for EV in each A_x-spectrum (solid curve). The in-plane polarized transitions, probably y- and z-axis polarized, are dominant in the visible region, as indicated by the (A_y+A_z)-spectrum (dotted curve).

The isotropic spectrum of each dye in the visible region may contain three different electronic transitions: two lie in the molecular plane (the A_y- or A_z-component near the **B** position and the A_z- or A_y-component near the **A** position) and one lies out of the molecular plane (the A_x-component near the **A** position). The present analysis for CV is in good agreement with the qualitative interpretation proposed by Tanizaki[6] and Nordén.[2,7] Hidden in the isotropic spectrum in the visible region, the out-of-plane polarized transition is responsible for the decrease in the R_d-values near the principal band at **A** position (Figs. 2a—2c). The weak isotropic band in the 340—420 nm region mostly consists of the in-plane transitions, while the bands in the 220—340 nm region contain both the out-of-plane and intense in-plane transitions (see Fig. 5). Thus, the isotropic spectra of the highly symmetric triphenylmethane dyes such as PR, CV, and EV could now be resolved into their in-plane and out-of-plane components by the reduction procedure. The presence of the out-of-plane component may give a key for elucidating the configuration of triphenylmethane dyes[16] and, consequently, the metachromatic changes caused by interaction with various polyelectrolytes and biopolymers.[11,17,18]

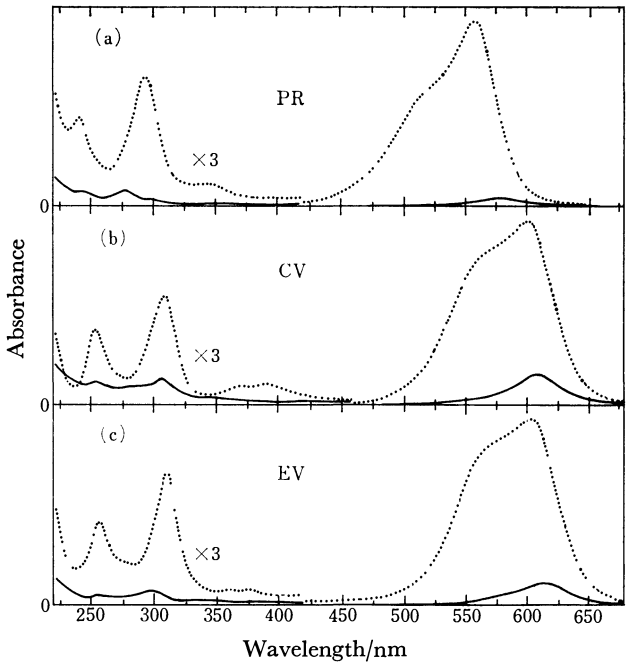

Fig. 5. The reduced (A_y+A_z)- and A_x-spectra of PR, CV, and EV. The in-plane (yz-plane) and the out-of-plane (x-axis) polarized absorbances (arbitrary units) are shown by the dotted and the solid curves, respectively.

Table 2. The average values of the reduction factors (d_x and d) and the orientation factors (K_x and K) of PR, CV, and EV at $S=3.7$

Dyes	d_x	$d=d_y=d_z$	K_x	$K=K_y=K_z$
PR	0.48	1.35	0.194	0.403
CV	0.30	1.54	0.130	0.435
EV	0.38	1.45	0.160	0.420

If triphenylmethane has a triangular and planar configuration with three benzene rings toward the corners (D_{3h} point symmetry), the resolved out-of-plane component may have to be attributed to n-π^* transitions. However, the presence of numbers of n-π^* transitions is unrealistic in the visible and near UV regions. The structure of the triphenylmethane skelton is probably distorted in such a way that the central carbon-phenyl ring bonds either form a pyramidal structure (C_{3v} point symmetry), remain co-planar with three phenyl rings being tilted (D_3 point symmetry), or a pyramidal structure with the tilted rings (C_3 point symmetry). In order to discuss the configuration of

the triphenylmethane dyes more in detail, a complete assignment of each absorption band may be necessary by taking into account both the in-plane and out-of-plane polarized transitions. Nevertheless, the optical properties now available for biologically important triphenylmethane dyes will facilitate the structural studies of the complexes between biopolymers and these dyes.[1,2,18–20]

Conclusions

Since the R_d-values of triphenylmethane dyes PR, CV, and EV were not large as compared with those of acridine dyes,[4] the values of the transition moment angles θ at the absorption band centers of each dye could be evaluated by the method of Tanizaki.[6] However, these values give rise to only the apparent angles for disk-like triphenylmethane dyes. The orientation of those highly symmetric dyes originates from a mechanism which differs from that of acridine dyes. To evaluate the reduced spectra of the disk-like molecule, a new analysis of the linear dichroism was presented (Eqs. 4 and 5). In this analysis the transition moment angle is measured relative to the x-axis, which is perpendicular to the molecular plane. This method differs from the one proposed by Yogev *et al.*[5] The major findings in this work are as follows: (1) In the isotropic spectra of PR, CV, and EV, both the out-of-plane and in-plane polarized electronic transitions are present and overlap each other in the UV and visible regions. In particular, the intense visible band is a composite of one out-of-plane and two in-plane transitions. (2) The behavior of the orientation function Φ for the disk-like molecule can be related to the degree of orientation f by $f=-2\Phi$, which differs from the relation $f=\Phi$ for the rod-like molecule.

The authors wish to thank Mrs. Mayumi Masujima for the purification of PR.

Thermodynamic Study of the Self-association of 6-Methylpurine in Water–1,4-Dioxane Solvent

Satoshi MORIMOTO

Research Institute for Polymers and Textiles, 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 300-21

(Received May 29, 1978)

Determination of the thermodynamic quantities of the self-association of 6-methylpurine in water(1)–1,4-dioxane(2) ($x_2=0$—0.36) mixed solvent has been made from heat of dilution measurements in various organic contents, at 25 °C. It was confirmed experimentally that the dissociation process of associating purine bases in solution is very fast by dilution. It was characteristic of this solvent system that the standard enthalpy and entropy changes, $\Delta H°$ and $\Delta S°$, of the association exhibited an abrupt behavior. These values decrease remarkably with 1,4-dioxane content up to a water-rich solvent composition below $x_2=0.012$. After that, they approach their relatively high values for the pure organic component, at first with a steep slope, later more gradually. This behavior is related to the structural changes of the solvent in an extremely sensitive way. In the case of water(1)–methanol(2) ($x_2<0.19$) mixed solvent system which has been investigated for comparison with the above system, minimum values of the same kind were found in the vicinity of $x_2=0.12$, at 25 °C.

There have been a number of studies of the self-association of purine bases in aqueous solution. So far, however, there appears to be little work[1–4] with emphasis on the solvent effects in various aqueous media. To obtain the relationships between the thermodynamic quantities of the association and the solvent characters or effects, the quantities of 6-methylpurine in water–1,4-dioxane solvent system were evaluated from directly measured integral heats of dilution and were investigated in relation to solvent composition. As the result, a characteristic behavior was found as a function of dioxane content in this system and is discussed in terms of the solvent characters.

Experimental

Materials. 6-Methylpurine from Sigma Chemical Co. (product No. M6502) was vacuum dried over P_2O_5 for about 48 h before use. The infrared spectrum of this sample agreed with the reported one.[5] The other purine derivatives, purine (No. P6880) and purine-riboside (No. P7005), were from the same source and they were subjected to the same drying and identification. Solvent water was obtained by distilling ion-exchange water from an alkaline potassium permanganate solution. 1,4-Dioxane and methanol were spectro-grade reagents of Wako Junyaku Co. Trace amounts of water remaining in them were removed by fractional distillation before use.

Heat of Dilution. The heat of dilution was measured at 25 °C by using a 8721-l solution calorimeter of the precision calorimetry system (LKB produkter AB). At the temperature, the enthalpy of solution of tris(hydroxymethyl)-aminomethane (NBS, 724a sample) in 0.100 M HCl was found to be -29.7704 ± 0.0264 kJ/mol; this agrees well with the reported values.[6] By this calibration, it was confirmed that this calorimeter was operating normally. In measuring the heat of dilution of each purine derivative solution, about 1 cm³ of sample solution was diluted in about 100 cm³ solvent with stirring at 500 r.p.m. Integral heats of dilution ΔH_∞ to zero concentration were obtained by normalizing the heats of dilution $\Delta h/n_i$ to finite dilution, where Δh is the actually observed heat and n_i is the number of moles in the initial solution. Assuming that the value $\Delta h/n_i$ at low concentrations would decrease linearly, it is regarded that the corrected heat of dilution to zero concentration added to the $\Delta h/n_i$ value is equal to the ΔH_∞ value. The calorimetric result in a typical system is shown in Table 1. Here, in the highest dilution process No. 7, the heat of dilution from $m_f=0.000367$ to zero concentration was obtained by extrapolating the two $\Delta h/n_i$ values at $m_i=0.03977$ and 0.000367 to zero concentration; all the ΔH_∞ values in this series were calculated on the basis of this corrected value, where m is molarity (mol/kg solvent) and suffixes i and f are for the initial and final situations. The heats of solution were measured at 25 °C by means of the same calorimeter and the values at infinite dilution were determined according to the same procedure.

Results

It should be noted, at first, that the dissociation process of associating purine bases in solution is very fast by dilution. It is therefore suitable to measure the dissociation enthalpy by using this calorimeter with a

constant environment temperature. An example of the measured thermistor resistance of the dilution process for the 1,4-dioxane aqueous solution of 6-methylpurine against time is shown in Fig. 1 as curve A; the fast dissociation rate can be recognized from this curve.

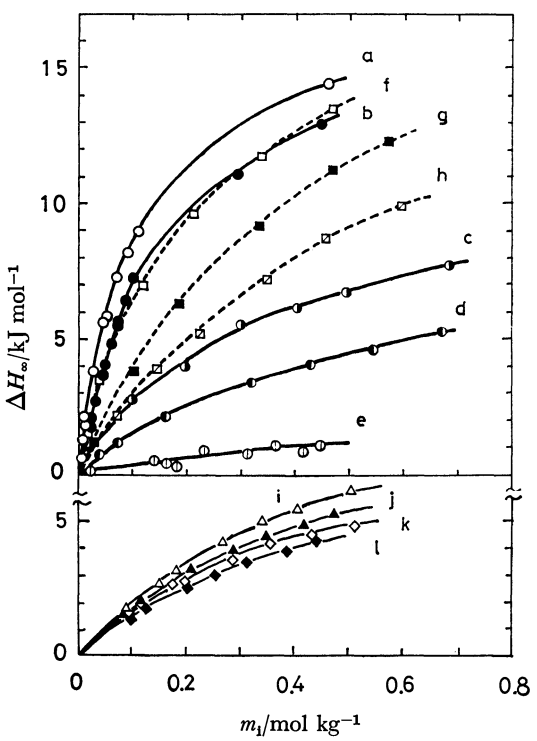

Fig. 2. Concentration dependence of the integral heats of dilution, at 25 °C.
Molarity of organic component (mol/kg water) in aqueous solvent: for 6-methylpurine solute systems; 1,4-dioxane aqueous, (a) 0, (b) 0.6400, (c) 2.761, (d) 6.166, (e) 19.58; methanol aqueous, (f) 1.423, (g) 5.359, (h) 10.67; for purine solute systems; 1,4-dioxane aqueous, (i) 0, (j) 0.6400; for purine–riboside solute systems; 1,4-dioxane aqueous, (k) 0, (l) 0.6400.

In the same figure, another example is shown: this is the dilution curve (B) of 2-pyridinol in 1,4-dioxane solvent, which can be ascribed to the association forming of the hydrogen-bonded dimers.[7] This may be compared with the above 6-methylpurine solution system. Curve B appears to reflect two thermal effects, which consist of exothermic dilution and endothermic dissociation enthalpies, and to have a time lag. The dissociation process of associating purine bases in organic aqueous solution by dilution was shown to be monotonous and very fast in this study.

In Fig. 2, the ΔH_∞ data in this work are all plotted against initial solute molarity m_i of solution. All the values are endothermic and gradually decrease with the ratio of organic component in mixed solvent, and all the curves intersect at the point zero. Curves k and l of solute purine-riboside have lower ΔH_∞ values, as compared with curves i and j of solute purine. This is probably an effect of steric hindrance from the association due to the large ribosil groups, as has been suggested by Marenchic and Sturtevant.[3]

Ts'o and Chan[8] have shown that 6-methylpurine is uncharged and that the equilibrium between various associated species in water can be characterized by a single equilibrium constant. Furthermore, the association of this monomeric solute has been supposed to proceed to an indefinite degree.[8,9] For an ideal self-association process, the ΔH_∞ values per mol of solute monomer would follow Eq. 1, as Stoesser and Gill have shown.[9] The data in Fig. 2 were all fitted

$$\Delta H_\infty = -\Delta H^\circ + (-\Delta H^\circ/K)^{1/2}(\Delta H_\infty/m_1)^{1/2} \qquad (1)$$

in Fig. 3 according to this equation, where K is the equilibrium constant, and ΔH° the standard enthalpy change of association. As shown by the straight lines

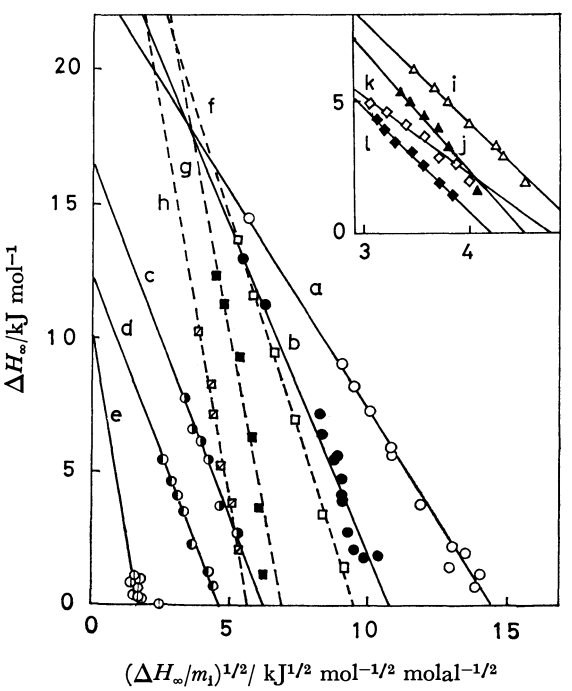

Fig. 3. Integral heat of dilution ΔH_∞ plotted against $(\Delta H_\infty/m_1)^{1/2}$, according to Eq. 1. All symbols are referred to Fig. 1.

in Fig. 3, the ΔH_∞ values determined for all systems in this study satisfy the equation under the assumption of the ideal process. Values of K and ΔH° were obtained from Eq. 1, and values of standard free energy change ΔG° and of entropy change ΔS° of association which were derived from these are shown in Tables 2 and 3 with the values for a few reported systems. These values in 6-methylpurine–water system in Table 2 agree well with the reported values determined by flow calorimetry[3,9] and the results in purine and purine–riboside–water systems in Table 3 agree approximately with reported values[10–13] determined by other methods, although the concentration ranges were slightly different.

Discussion

All the integral heats of dilution were in good agreement with ideal solution behavior, as is evident from Fig. 3. However, this result contains two problems, at least. One of them is the concentration range. It is better to measure the heat of dilution at very low concentrations[9] where more ideal solution behavior always occurs and dimerization becomes predominant. However, this could not be done here because it was difficult to obtain the heat of dilution at very low concentrations in this mixed solvent system. The other problem is the heat effect, which is the heat of dilution of solute species in each solvent. However ,as shown earlier,[14,15] the heat effect in this study can be taken to be insignificant compared with the experimental ΔH_∞ values. From Eq. 9 in Ref. 16, this effect is sufficiently less than 1% of each ΔH_∞ value even if the enthalpy parameter χ_H, for example, equals 2, which is quite large for a solute-solvent system which does not have particular interactions. This discussion will be done, therefore, on the basis of the thermodynamic quantities in Tables 2 and 3; we wish to focus attention on their solvent composition dependence.

Thermodynamic quantities evaluated in this study are shown in Fig. 4, including the values reported in references, as a function of solvent composition. The higher organic component systems were impossible to measure due to their solubilities. Our result, which covers a more extensive organic composition range in aqueous solvent, therefore helps to clarify the solvent effects of the association. In Fig. 4, thermodynamic values of the association in the same solvent system vary with the kinds of purine derivatives. The absolute values of 6-methylpurine are smaller than those of the other purine derivatives in the figure, *e.g.* 6-dimethylaminopurine, and they

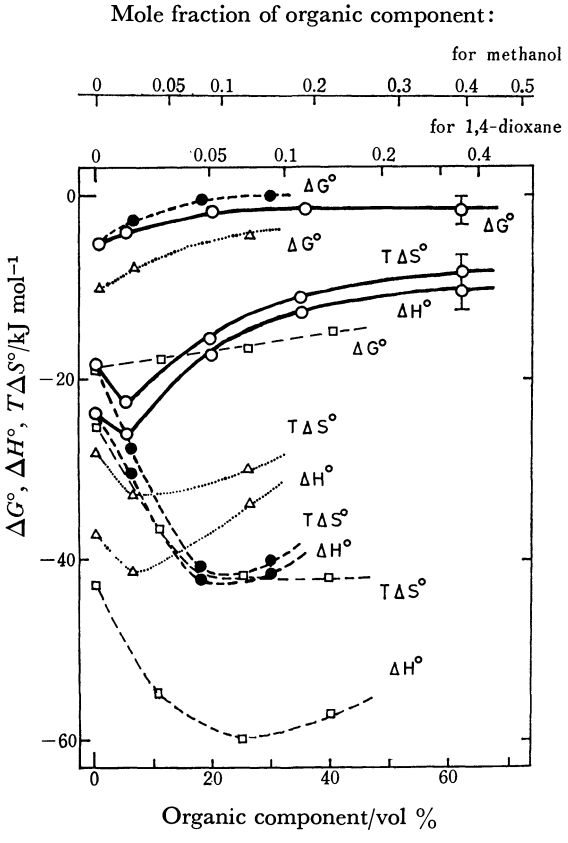

Fig. 4. Evaluated thermodynamic quantities of association plotted against organic component in aqueous solvent: (-○-) 6-methylpurine in 1,4-dioxane–, (-●-) 6-methylpurine in methanol–, (-□-) actinomycin-deoxyguanosine in methanol–[2], and (-△-) 6-dimethylaminopurine in acetonitrile–water[3] systems.

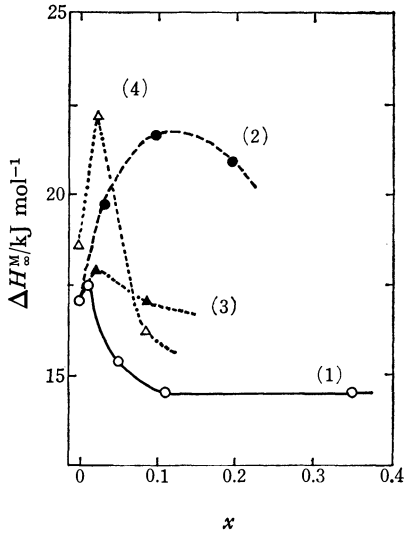

Fig. 5. Heats of solution ΔH_∞^M in purine derivatives–aqueous solvent systems, at 25 °C, plotted against mole fraction x of organic component in aqueous solvent: (1) 6-methylpurine–1,4-dioxane–, (2)–methanol–, (3)–acetonitrile– and (4) 6-dimethylaminopurine–acetonitrile–aqueous solvent systems.

are larger than those of purine in Table 3. These decreased and increased associations, as described by Marenchic and Sturtevant,[3] can be attributed mainly to the decreased and increased polarizabilities of the π-electron system[16] of these purine derivatives. Some part of the increasing and decreasing associations with variety of solvent system is presumed to be attributed to hydrophobic interactions,[17] which supposedly promote the stacking reactions of purine bases in aqueous solutions. Quantitative details of these phenomena must be left for a future study, which will compare the theoretical aspects[18–20] and the needed experimental quantities.

Recently, Leifer *et al.*[4] have studied aqueous purine solutions in the absence and presence of NaCl by vapor-pressure osmometry and high-resolution proton-magnetic-resonance spectroscopy. They have found that there is a sharp decrease in purine stacking at temperatures above 42 °C in the presence of NaCl; this salt-induced destacking of purine is consistent with the salt-induced breaking of the structure of solvent bulk water at the higher temperatures. This phenomenon is suggestive of biological systems and it must be emphasized that the solvent structure plays an important role in the association behavior. From our result, such a characteristic behavior is disclosed in the water–1,4-dioxane system. The values of $\Delta H°$ and $\Delta S°$ decrease remarkably with 1,4-dioxane content in the aqueous solvent until a water-rich binary solvent composition is reached. After the decrease, the values increase steeply, then approach gradually to their relatively high values, *i.e.*, low negative values, for pure dioxane. This tendency resembles the tendency of heat effects which occur from the solute-solvent interactions due to adding a third component to aqueous binary solvents,[21–24] although the decreasing and increasing tendencies of this study are of course opposite to the latter.

The heats of solution, *i.e.*, heats of mixing ΔH_∞^M at infinite dilution, of 6-methylpurine and 6-dimethylaminopurine in water or in some water-organic component solvents have thus been measured at the same temperature to determine the solvation effects on the $\Delta H°$ behavior. The results are shown in Fig. 5 as a function of mole fraction x of organic component in aqueous solvent. One can recognize the abrupt behavior similar to that of $\Delta H°$. Values of ΔH_∞^M do not agree, of course, with those of $\Delta H°$ even if their absolute values are compared. Fig. 6 shows a comparison of $\Delta H°$ with $-\Delta H_\infty^M$ in 6-methylpurine–1,4-dioxane aqueous solvent system. The heats of solution ΔH_∞^M would be more subjected to effects of solvation than the $\Delta H°$ because of the surface dimensions of the solute molecule. In the case of ΔH_∞^M, the solvation would be done all over the molecular surface including the hydrophilic part of solute, which is outside of the hydrophobic part which participates in the self-association. The difference between $\Delta H°$ and $-\Delta H_\infty^M$, consequently, indicates the contribution to the interaction energy of the hydrophilic part of solute. Some problems, for example, with the cavity term, the entropy term, and the relaxation term of association in the theoretical treatments[18,20] can be eliminated by this comparison between the two values, $\Delta H°$ and ΔH_∞^M. In Fig. 6, the difference between two curves appears to change the contribution from exother-

mic in water or water-rich binary solvent to endothermic in the higher organic contents. Therefore, the dependence of ΔH° on solvent composition is more remarkable than that of ΔH^M_∞. For the dissociation process of a third component, the maxima of enthalpy and entropy changes in water-rich binary solvents occur in the position of maximum structuredness of the solvent and, at this position, the interactions with solvent or the solvations of solvent molecules are minimized as a result of the solvent structure. The data of heat of mixing show that addition of 1,4-dioxane[25] or methanol[26] to pure water causes at first an increase in the solvent structuredness. The ΔH° and $T\Delta S^\circ$ curves in 1,4-dioxane, or methanol aqueous solution systems in Fig. 4, may be closely related to such variation of solvent structures.

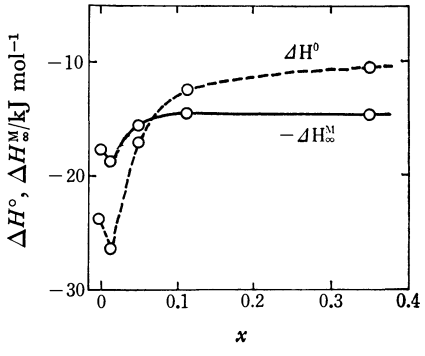

Fig. 6. Comparison of ΔH° with $-\Delta H^M_\infty$ in 6-methylpurine–1,4-dioxane aqueous solvent system, at 25 °C.

The heats of vaporization of purine derivatives have been reported to be about 80—130 kJ/mol.[27] That of 6-methylpurine has not yet been made clear, but the association heat of 6-methylpurine in gas phase will probably exhibit a similarly large negative value. From the trends shown in Figs. 5 and 6, it is assumed in this 6-methylpurine aqueous solution that the contributions of solvation or de-solvation due to hydrophobic interactions are strongly connected with the ΔH° values. The ΔH° behavior with organic component seems to be more influenced by the behavior of the other contributions, which reflect the variation of solvent structure. It could be considered that the characteristic behavior of ΔH° and ΔS° with the organic content generally come from the nature or the structure of the bulk solvent itself. The effects of solvent atmosphere, and especially the effects of the variation of solvent structures on the association, would considerably affect both ΔH° and ΔS° behaviors.

From Tables 2 and 3, a characteristic feature is recognized for purine and three purine derivatives: 6-methylpurine, 6-dimethylaminopurine, and purine-riboside, in water and 0.64 mol kg^{-1} 1,4-dioxane–water systems. Although the hydrophobic strength of the purine rings is considered to be different for each purine derivative, the thermodynamic values of association ΔH° and ΔS° in both solvent systems were almost identical, irrespective of the sort of purine derivatives. In all four systems, the entropy changes in aqueous solution of 0.64 mol kg^{-1} of 1,4-dioxane showed a decrease of about 12 to 17 J/deg mol, and the enthalpy changes showed a decrease of about 2.5 kJ/mol, in comparison with the ones of the system in pure water. These significant differences may be ascribed to the solvation changes of purine rings, and to the variation of bulk solvent structures around the dissolved purine derivative solutes. As a result, a characteristic abrupt change in thermodynamic quantities was found to be expressible as a function of 1,4-dioxane content in this solution system.

The author wishes to thank Mr. Yoshio Tani of Professor Masao Nakamura's Laboratory of Tokai University for his experimental help.

On the Critical Phenomena in the Decomposition of Hydroperoxides and in the Autoxidation of Cumene with Bis(acetylacetonato)manganese(II)

Shun-ichi FUKUZUMI and Yoshio ONO*

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 22, 1978)

The decomposition of 1-methyl-1-phenylethyl hydroperoxide and *t*-butyl hydroperoxide with $Mn(II)(acac)_2$ and the autoxidation of cumene with $Mn(II)(acac)_2$, $Mn(III)(acac)_3$, and $MnCO_3$ have been studied at 323 K. In the decomposition of the hydroperoxides with $Mn(II)(acac)_2$, the peroxyl radicals are observed only when the initial ratio of hydroperoxide to catalyst amount exceeds a certain value. The critical phenomenon is observed in the oxidation of cumene with $Mn(II)(acac)_2$ and also with $MnCO_3$. A scheme for the cause of the critical phenomena has been proposed.

It has been reported that, in the liquid phase oxidation of hydrocarbons with metal oxides, there is a critical amount of catalyst above which the reaction does not proceed.[1–10] A similar critical phnomenon was observed in the autoxidation with homogeneous catalysts.[11,12] Decrease of the oxidation rate at a high catalyst amount indicates that the solid acts as an inhibitor rather than as a catalyst. However, causes for the same substance having dual functions, *i.e.* it accelerates the oxidation rate at lower catalyst amount and inhibits the reaction at higher catalyst amount, and for the change from catalysis to inhibition occurring abruptly, have not been clarified.

As regards catalysis, it is accepted that the decomposition of the hydroperoxide on solid surface produces free radicals, which in turn, propagate the chain reactions in liquid phase.[1–10]

Interaction of hydroperoxide with surfaces also seems to cause the critical phenomena. Thus, a critical catalyst amount has been reported to depend on the initial concentration of the hydroperoxide.[1,3,7] Mukherjee and Graydon[1] found that there is a critical hydroperoxide to catalyst ratio, below which no reaction takes place in the oxidation of tetraline with Mn_2O_3. They assumed that there are two distinct sites on the catalyst, one preferentially adsorbing the hydroperoxide and the other taking part in the production of free radicals. When the amount of hydroperoxide is small, no reaction takes place, since all of it is consumed to saturate the inactive sites which do not contribute to radical formation.

The inhibiting action of the surface might depend also on the oxidation state of the metal cations. Manganese-catalyzed autoxidation was observed to start when Mn(II) was converted into Mn(III).[13] Inhibition of autoxidations by transition metals in low oxidation states such as Co(II) or Mn(II) was reported.[11,14–16] In cyclohexene oxidation with manganous heptanoate, Chalk and Smith[17] observed long induction periods, which do not terminate until sufficient hydroperoxide is formed to convert nearly all the manganous manganese into manganic state. The reaction of metal cations with peroxyl radicals has been postulated as one of the termination reactions also in the autoxidation with metal oxides.[7,10]

In the present work, we have found a critical phenomenon in the decomposition of hydroperoxides with bis(acetylacetonato)manganese(II), $Mn(II)(acac)_2$, and also in the oxidation of cumene with $Mn(II)(acac)_2$. No such phenomenon is observed in the oxidation with tris(acetylacetonato)manganese(III), $Mn(III)(acac)_3$, indicating the importance of the oxidation state of the cations for critical phenomena. The critical phenomenon in the oxidation and that in the hydroperoxide decomposition are closely related. A scheme for the cause of the critical phenomena is proposed. The critical phenomenon in the oxidation of cumene with $MnCO_3$ is also mentioned.

Experimental

Materials. Commercial cumene (reagent grade) was distilled and percolated through an activated alumina column three times prior to use in order to remove any trace of hydroperoxide. *t*-Butyl hydroperoxide and 1-methyl-1-phenylethylhydroperoxide(Nakarai Chem. Ltd.), were purified by vacuum distillation. Commercial $Mn(II)(acac)_2$, $Mn(III)(acac)_3$, and $MnCO_3$ were used.

Apparatus and Procedure. The apparatus has been described in detail.[18–20] Carbon tetrachloride was used as a solvent, since it is an inert solvent in autoxidation or hydroperoxide decomposition.[16–19] For example, the decay rate of 1-methyl-1-phenylethylperoxyl radical in CCl_4 was the same as that in cumene.[21] Measurements of the peroxyl radical concentration during the course of decomposition of hydroperoxide were performed as follows. The solvent (CCl_4 70 cm^3) and the catalyst ($Mn(II)(acac)_2$) were stirred in a flask and the part of the solution with the colloidal catalyst was circulated with use of a roller pump through the ESR cavity. The reaction was started by the addition of hydroperoxide (20—123 μl). ESR intensity of the peroxyl radicals was monitored with time by use of a JEOL-X-band spectrometer (JEOL-PE-1X) with 100 kHz magnetic modulation. The radical concentration was determined using 1,1-diphenyl-2-picrylhydrazyl in benzene as a reference.

The rates of oxygen absorption during the course of autoxidation of cumene with $Mn(II)(acac)_2$, $Mn(III)(acac)_3$, and $MnCO_3$ were measured with a gas burette or a gasometer. The radical concentration during the course of oxidation was determined in the same manner as above.

Results

Critical Phenomena in the Decomposition of Hydroperoxides by $Mn(II)(acac)_2$. The ESR spectrum of the

1-methyl-1-phenylethyl-peroxyl radical($RO_2\cdot$, $g=2.015\pm0.0002$) or the *t*-butylperoxyl ($BO_2\cdot$, $g=2.0144\pm0.0002$) was observed, when an amount of 1-methyl-1-phenylethyl hydroperoxide (ROOH) or *t*-butyl hydroperoxide (BOOH) exceeding a certain value was added to 70 cm^3 of CCl_4 solution containing 0.2 g of Mn(II)-$(acac)_2$, indicating the decomposition of hydroperoxide. The radical concentration increased markedly with reaction time, reaching a maximum, then decreasing. Typical examples are shown in Fig. 1.

The maximum concentration of the peroxyl radicals, $[RO_2\cdot]_{max}$, are plotted against the initial concentration of the hydroperoxides in Fig. 2. For concentrations of the hydroperoxides lower than 4.0×10^{-3} M, no peroxyl radicals were observed. By a slight increase of hydroperoxide concentration above 4.0×10^{-3} M, the peroxyl radicals were observed, the maximum radical concentration increasing linearly with an increase in initial hydroperoxide concentration. It is evident that critical phenomenon exists in the decomposition of hydroperoxides. The critical concentration of the hydroperoxides is the same (4.0×10^{-3} M) for ROOH and BOOH, the critical ratio of hydroperoxide to Mn(II)$(acac)_2$ amount being 1.4×10^{-3} mol/g-Mn(II)$(acac)_2$.

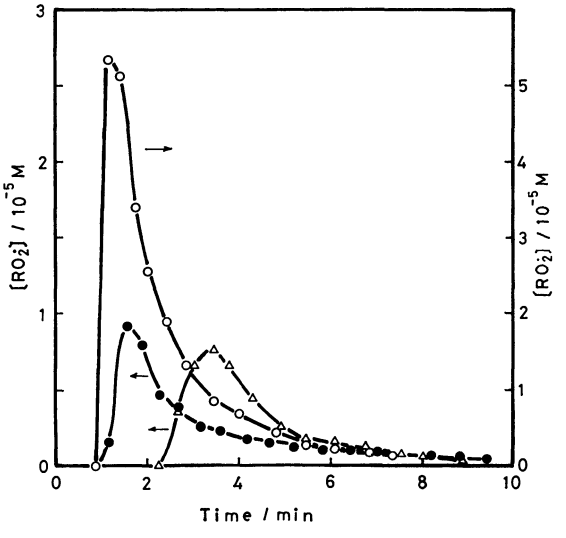

Fig. 1. Concentration of peroxyl radicals during the decomposition of *t*-butyl hydroperoxide and cumene hydroperoxide with Mn(II)(ffcac)$_2$ at 323 K plotted against reaction time; Mn(II)$(acac)_2$ 2.86 g l^{-1}, △ [BOOH] 4.47×10^{-3} M, ● [BOOH] 7.83×10^{-3} M, ○ [ROOH] 8.18×10^{-3} M.

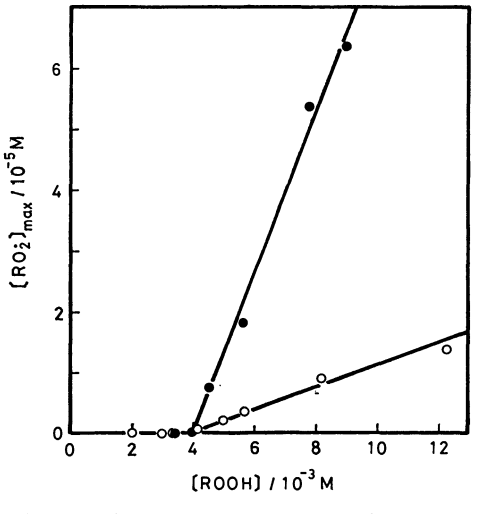

Fig. 2. Maximum concentration of peroxyl radicals during the decomposition of *t*-butyl hydroperoxide and cumene hydroperoxide with Mn(II)$(acac)_2$ at 323 K plotted against initial hydroperoxide concentration; Mn(II)$(acac)_2$ 2.86 g l^{-1}, solvent CCl_4, ● BOOH, ○ ROOH.

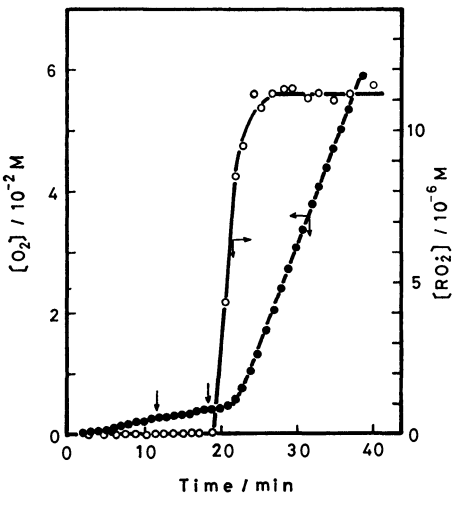

Fig. 3. Cumulative amount of oxygen absorbed and the concentration of cumylperoxyl radical during the autoxidation of cumene with Mn(II)$(acac)_2$ at 323 K plotted against reaction time; Mn(II)$(acac)_2$ 1.54 g l^{-1}, cumene 65 cm^3; Initial ROOH concentration is zero, 10 l of ROOH was added at 12 min (↓) and another 10 l of ROOH was added at 19 min (↓).

Critical Phenomena in the Autoxidation of Cumene with Mn(II)$(acac)_2$. In order to see whether the critical phenomenon is also observed in autoxidation with Mn-

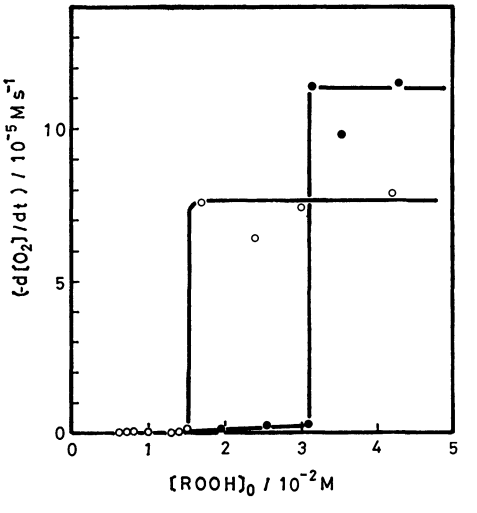

Fig. 4. Rate of oxygen absorption during the autoxidation of cumene with Mn(II)$(acac)_2$ at 323 K plotted against initial hydroperoxide concentration; Mn(II)-$(acac)_2$; ○ 10.34 g l^{-1}, ● 20.7 g l^{-1}.

(II)$(acac)_2$, the autoxidation of cumene with Mn(II)-$(acac)_2$ was studied at 323 K. As shown in Fig. 3, no peroxyl radicals were observed when no hydroperoxide was added, though a slow oxygen uptake was observed. Addition of 10 μl of ROOH caused no change in the situation. However, when another 10 μl of ROOH was added, peroxyl radicals were observed, the radical concentration and rate of oxygen absorption increasing markedly with time to reach a steady concentration and a steady rate, respectively.

Figure 4 shows the steady rate of oxygen absorption as a function of the initial hydroperoxide concentration. The rate of oxygen absorption is almost zero when the initial hydroperoxide concentrations are lower than 1.6×10^{-2} M and 3.1×10^{-2} M for 10.3 and 20.7 g l^{-1} of [Mn(II)$(acac)_2$], respectively. A slight increase in hydroperoxide concentration in excess of these values causes an abrupt increase in the oxidation rate, which does not change significantly by further increase in the hydroperoxide concentration (Fig. 4). The critical ratio of hydroperoxide to catalyst amount is 1.5×10^{-3} mol/g-Mn(II)$(acac)_2$.

It should be noted that the critical hydroperoxide concentration is doubled by doubling the amount of the catalyst, indicating that the parameter determining critical phenomenon is not hydroperoxide concentration but the ratio of the concentration to the catalyst amount, in agreement with the results of Mukherjee and Graydon,[1] and Neuberg *et al.*[3] This was confirmed also by examining the effect of catalyst amount on the rate of oxidation and on the concentration of peroxyl radical at a constant hydroperoxide concentration (1.56×10^{-2} M). The maximum rate of oxygen absorption and the maximum concentration of the peroxyl radical are plotted against the catalyst amount in Fig. 5. The rate of oxygen absorption increases with increases in the catalyst amount, reaching a constant value, and decreasing drastically above 12.1 g l^{-1} of Mn(II)-$(acac)_2$. The critical ratio of hydroperoxide to catalyst amount is 1.3×10^{-3} mol/g-Mn(II)$(acac)_2$, which is very close to that given in Fig. 4.

It should be noted that the critical ratio of hydroperoxide to catalyst ($1.3—1.5\times10^{-3}$ mol/g) in cumene autoxidation with Mn(II)$(acac)_2$ is the same as that in the decomposition of hydroperoxides with the same catalyst (1.4×10^{-3} mol/g).

As shown in Fig. 5, the rate of oxygen absorption and radical concentration behave in exactly the same manner, *viz.*, the rate of oxygen absorption is proportional to the concentration of peroxyl radical. This indicates that oxygen is absorbed mainly by the elementary reactions, $R\cdot+O_2\rightarrow RO_2\cdot$, and $RO_2\cdot+RH\rightarrow ROOH+R\cdot$.

Autoxidation of Cumene with Mn(III)$(acac)_3$. In order to find the effect of the oxidation state of manganese cation, the oxidation of cumene was studied with Mn(III)$(acac)_3$. The concentration of the peroxyl radical and the rate of oxygen absorption were measured simultaneously at 323 K. In the oxidation with Mn-(III)$(acac)_3$, the reaction proceeds even when the initial hydroperoxide concentration is much lower than the critical concentration in the oxidation with Mn(II)-$(acac)_2$. Figure 6 shows typical examples of the change in the rate of oxygen absorption and the peroxyl radical concentration with reaction time. When 4 μl of ROOH was added to 70 cm^3 of CCl_4 solution containing 0.60 g of Mn(III)$(acac)_3$, the peroxyl radical and the absorption of oxygen were observed after standing for 30 min. The hydroperoxide formed after prolonged standing might cause the reaction to proceed. When 150 μl of ROOH was added, the reaction proceeded immediately. In the case of Mn(II)$(acac)_2$, the reaction does not proceed when the initial ratio of hydroperoxide to catalyst amount is less than 1.5×10^{-3} mol/g-Mn(II)-

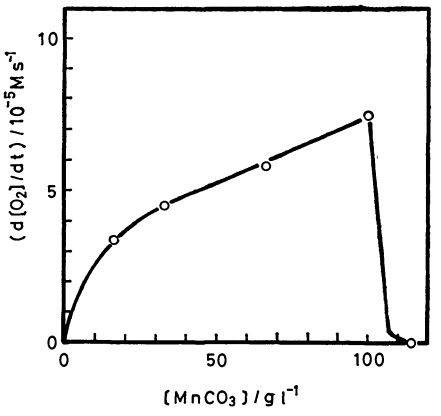

Fig. 8. Rate of oxygen absorption during the autoxidation of cumene by $MnCO_3$ at 323 K plotted against the ratio of catalyst weight to liquid volume; RH 7.18 M, ROOH 2.33×10^{-3} M.

(acac)$_2$; *e.g.*, ROOH 120 μl for Mn(II)(acac)$_2$ 0.60 g

The radical concentration and the rate of oxygen absorption increase with reaction time, reaching a maximum, then decreasing (Fig. 6). This might be due to the deactivation of catalyst. The effects of catalyst amount on the maximum rate of oxygen absorption and the maximum concentration of $RO_2\cdot$ are shown in Fig. 7. The rate of oxygen absorption and the radical concentration increase with increase in catalyst amount and reach a constant value, independent of the initial hydroperoxide concentration. As is the case of Mn(II)-(acac)$_2$, the rate of oxygen absorption and the radical concentration behave in the same manner, showing that the rate of oxygen absorption is proportional to the radical concentration in the case of Mn(III)(acac)$_3$ as well.

ESR Spectra during Autoxidation of Cumene with Mn(II)-(acac)$_2$ and Mn(III)(acac)$_3$. The ESR spectrum during the course of autoxidation of cumene with Mn-(II)(acac)$_2$ was measured. When the concentration of the hydroperoxide is below the critical concentration, the broad signal due to Mn(II) is observed. When a sufficient amount of hydroperoxide is introduced to start the oxidation, the intensity due to Mn(II) decreases with time and becomes constant, a sharp signal due to peroxyl radical being observed. The essentially same ESR spectrum was observed during cumene oxidation with Mn(III)(acac)$_3$, indicating that the state of manganese ion is the same irrespective of the valency of the starting complexes, once oxidation is started.

Critical Phenomenon in the Autoxidation of Cumene by $MnCO_3$. The autoxidation of cumene by $MnCO_3$ was studied for 2.33×10^{-3} M of initial hydroperoxide concentration at 323 K. As shown in Fig. 8, the rate of oxygen absorption increases with an increase in the catalyst amount, the rate declining drastically at high catalyst amount. The critical ratio of hydroperoxide to catalyst amount is 2.1×10^{-5} mol/g-$MnCO_3$, much less than the value in the case of oxidation with Mn(II)-(acac)$_2$.

Discussion

Resutts. The results in this study can be summarized as follows.

1. In the decomposition of ROOH and BOOH with Mn(II)(acac)$_2$ there is a critical ratio of hydroperoxide to catalyst amount (1.4×10^{-3} mol/g-Mn(II)(acac)$_2$) below which no peroxyl radicals are observed during the course of reaction.
2. In the autoxidation of cumene with Mn(II)-(acac)$_2$, there is a critical ratio of hydroperoxide to catalyst amount below which the oxidation does not proceed, the ratio being the same as that found in the hydroperoxide decomposition.
3. In the autoxidation of cumene with Mn(III)-(acac)$_3$, no critical phenomenon is observed.
4. The ESR signals due to manganese ion during the course of autoxidation of cumene with Mn(II)-(acac)$_2$ are the same as those with Mn(III)(acac)$_3$.
5. In the autoxidation of cumene by $MnCO_3$, there is also a critical ratio of hydroperoxide to catalyst amount (2.1×10^{-5} mol/g-$MnCO_3$), the critical value being much smaller than that in the case of Mn(II)(acac)$_2$.

Reaction Mechanism. Agreement of critical ratios in the hydroperoxide decompositions and in cumene oxidation (observations 1 and 2) indicates that the critical phenomenon in the autoxidation is substantially identical to the critical phenomenon in the hydroperoxide decomposition. Inhibition of oxidation below a critical hydroperoxide concentration might be caused by the fact that the hydroperoxide decomposition gives no peroxyl radicals available for chain propagation.

From the results given in 3, we see that the Mn(II) and not Mn(III) species play an essential role in the appearance of the critical phenomena. 4 suggests that there is a redox interconversion between Mn(II) and Mn(III) during the course of reaction. The mechanism for the autoxidation of cumene with Mn(II)(acac)$_2$ and

$Mn(III)(acac)_3$ can be written as follows:

Initiation

$$ROOH + Mn(II) \xrightarrow{fast} RO\cdot + Mn(III) + OH^- \quad (1)$$

$$ROOH + Mn(III) \longrightarrow RO_2\cdot + Mn(II) + H \quad (2)$$

Propagation

$$RO_2\cdot + RH \longrightarrow ROOH + R\cdot \quad (3)$$

$$R\cdot + O_2 \xrightarrow{fast} RO_2\cdot \quad (4)$$

$$RO_2\cdot + RO_2 \longrightarrow 2RO\cdot + O_2 \quad (5)$$

$$RO\cdot + ROOH \xrightarrow{fast} ROH + RO_2\cdot \quad (6)$$

Termination

$$RO_2\cdot + Mn(II) \longrightarrow (RO_2\cdot \cdots Mn(II)) \longrightarrow \text{inactive product} \quad (7)$$

$$RO_2\cdot,\ RO\cdot \longrightarrow \text{decay} \quad (8)$$

The reaction mechanism is the same as that proposed for the cumene oxidation with PbO_2,[16] except for elementary Reactions 1, 2, and 7. The initiation Reactions 1 and 2 are accepted for homogeneous systems.[22,23] Reaction 7 is included to account for the inhibiting action of the catalyst. The radical scavenging action of the lower oxidation state of metal cation has been postulated by several authors,[7,11,14,16,17,24] and the rate constants for reactions of peroxyl radicals and the metal cations have been estimated.[15,25,26]

Origin of Critical Phenomena. In order to confirm the origin of the critical phenomena in oxidation and hydroperoxide decomposition, we should consider relative rates of elementary reactions. Reaction 1 is much faster than Reaction 2 in the manganese system.[23] Reaction 7 is much faster than Reaction 3, hydrogen abstraction from RH by RO_2. Thus, the rate constant for the reaction of cumylperoxyl radical with manganous cation is $4.3\times10^4\ M^{-1}\ s^{-1}$ at 308 K,[15] while the rate constant for the reaction of the same radical and cumene is estimated to be $7.6\ M^{-1}\ s^{-1}$ at the same temperature.[17] Thus, in the presence of sufficient amount of Mn(II), the peroxyl radicals formed by Reactions 1 and 6 are scavanged by Mn(II), the autoxidation being inhibited. Above the critical ratio of hydroperoxide to Mn(II) amount, most of Mn(II) species are converted into Mn(III) by Reaction 1 and the remaining ROOH molecules are converted into peroxyl radicals by Reaction 2 and the oxidation can proceed through Reactions 4 and 5. Under these conditions, Reaction 7 is negligible because of low concentration of Mn(II). For the same reason, no critical phenomena would be observed if Mn(III) is used as a catalyst from the beginning.

Reactions 1 and 7 are only known in the case of transition metal cations which have variable oxidation states, such as Co(II)/Co(III) and Mn(II)/Mn(III). The fact that critical phenomena in the autoxidation of hydrocarbons have been observed only with such transition metal ions[1–10] also supports the view that the cause of critical phenomena can be attributed to Reactions 1 and 7.

Elimination of the elementary Reactions 3 and 4 from the above oxidation mechanism should give the mechanism for the hydroperoxide decomposition.[19,27] Since the mechanisms of initiation and chain scavenging remain identical to those in the autoxidation, the origin of the critical phenomena both in the hydroperoxide decomposition and the autoxidation should be common. This explains why both critical phenomena occur at the same ratio of the hydroperoxide to catalyst amount.

The critical molar ratio of hydroperoxide to Mn(II), expected from Reactions 1 and 7, is unity. But the experimental critical ratio of hydroperoxide to $Mn(II)(acac)_2$ amount is 1.5×10^{-3} mol/g-$Mn(II)(acac)_2$, that is, the critical molar ratio is 0.38, smaller than unity, probably because of the fact that $Mn(II)(acac)_2$ is partly heterogeneous during the course of reaction.

The critical phenomenon in the autoxidation of cumene by $MnCO_3$ can be explained similarly. Since $MnCO_3$ is a heterogeneous catalyst, and only Mn(II) on the surface is available for the initiation, the effective Mn(II) species in $MnCO_3$ are much less than those in $Mn(II)(acac)_2$, resulting in a much smaller critical ratio of hydroperoxide to catalyst amount.

We are very grateful to Professor T. Keii for helpful discussions.

Solubility Isotherm of Reciprocal Salt-Pairs Containing Bis(ethylenediamine)oxalatocobalt(III) (1*R*,3*S*,4*S*,7*R*)-3-Bromocamphor-9-sulfonate

Akira FUYUHIRO,* Kazuaki YAMANARI, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 30, 1979)

Four-component solubility isotherm of reciprocal salt-pairs consisting of (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)–(Cl$^-$, *d*-$C_{10}H_{14}OBrSO_3^-$)–H_2O has been determined experimentally at 25 °C. It was found that a pseudoracemate, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3)_2\cdot 2H_2O$, is present as the only double salt, optical resolution of the bis(ethylenediamine)oxalatocobalt(III) ion in this system at 25 °C being impossible as in the case of the ternary system, Λ-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)–Δ-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)–H_2O, at 25 °C.

The (1*R*,3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate(1—) anion, *d*-$C_{10}H_{14}OBrSO_3^-$ (abbreviated to *d*-bcs$^-$) is known as one of the most effective resolving agents for metal complexes. It was concluded from a study on the solubility isotherm of a ternary system, Λ-[Co(ox)(en)$_2$](*d*-bcs)–Δ-[Co(ox)(en)$_2$](*d*-bcs)–H_2O, that the resolving agent is unsuitable to the optical resolution of bis(ethylenediamine)oxalatocobalt(III) complex, [Co(ox)(en)$_2$]$^+$, at 25 °C because of the formation of a pseudoracemate, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$]-(*d*-bcs)$_2\cdot 2H_2O$.[1] Recently, we have found that the optical resolution is possible at temperatures lower than 19 °C, in spite of the existence of the pseudoracemate in the ternary system.[2] Nevertheless, it is interesting to see in which way the pseudoracemate behaves to prevent the optical resolution in a four-component system, since no four component system containing a pseudoracemate has been studied in view of solubility phase diagrams and their application to a practical optical resolution.

This paper deals with the determination of the solubility isotherm of the reciprocal salt-pairs, (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)–(Cl$^-$, *d*-bcs$^-$)–H_2O, at 25 °C. Discussion is given on the possibility of the optical resolution of the bis(ethylenediamine)-oxalatocobalt(III) ion as compared with two other successful cases of optical resolution of the complex.[3]

Experimental

Materials. [*Co*(*ox*)(*en*)$_2$]*Cl*·H_2O: The Λ- and Δ-complex chloride monohydrates were the same as reported.[3]

[*Co*(*ox*)(*en*)$_2$](d-*bcs*)·nH_2O: The Λ-diastereomeric salt monohydrate, Δ-diastereomeric salt 1.5-hydrate, and the pseudoracemate dihydrate, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$]-(*d*-bcs)$_2\cdot 2H_2O$, were the same as reported.[2]

Measurements. Solubility in water at 25 °C was determined in molality.[3] Optical densities were measured at 497 nm, and CD at 523 and 310 nm. The concentrations of {Λ-[Co(ox)(en)$_2$]$^+$+Δ-[Co(ox)(en)$_2$]$^+$} were determined from the observed optical densities, referring to the established molar absorption coefficients of the component ions; ε(497 nm) =120 for Λ- and Δ-[Co(ox)(en)$_2$]$^+$, and ε(497 nm)=0 for *d*-bcs$^-$. The concentrations of {Λ-[Co(ox)(en)$_2$]$^+$—Δ-[Co(ox)(en)$_2$]$^+$} were determined from the observed CD values in 523 nm, referring to the following data; $\Delta\varepsilon$(523 nm)= +2.71, −2.71, and 0 for Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$, and *d*-bcs$^-$, respectively. The concentrations of Λ- and Δ-[Co(ox)(en)$_2$]$^+$ were separately calculated from the concentrations of {Λ-[Co(ox)(en)$_2$]$^+$+Δ-[Co(ox)(en)$_2$]$^+$} and {Λ-[Co(ox)(en)$_2$]$^+$—Δ-[Co(ox)(en)$_2$]$^+$}. The concentrations of *d*-bcs$^-$ were determined from the observed CD values in 310 nm; $\Delta\varepsilon$(310 nm)=+3.23 for *d*-bcs$^-$ and $\Delta\varepsilon$(310 nm) =0 for Λ- and Δ-[Co(ox)(en)$_2$]$^+$.

The solid phases were identified from elemental analyses, absorption and CD spectra. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

The solubility data are given in Table 1, and Figs. 1 and 2. Solubility is expressed in molalities of component ions and are attributed to the molalities of

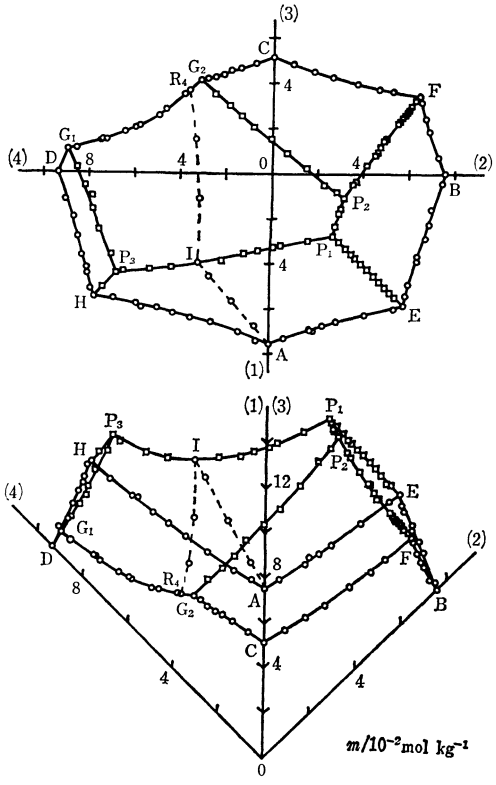

Fig. 1. The plane projection (upper) and the side elevation of the solubility isotherm of the system, (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)–(Cl$^-$, *d*-bcs$^-$)–H_2O, at 25 °C. Solubility is presented in molality *m* of anhydrous salt: (1) Λ-[Co(ox)(en)$_2$]Cl, (2) Δ-[Co(ox)(en)$_2$]-Cl, (3) Δ-[Co(ox)(en)$_2$](*d*-bcs), and (4) Λ-[Co(ox)-(en)$_2$](*d*-bcs); □, solubility of four-components; ○, solubility of two- or three-components.

Table 1. Equilibrium of (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, d-bcs$^-$)-H_2O system at 25 °C

In liquid phases, solubility is presented in molalities m of the component ions. Abbreviations are as follows: Λ-[Co(ox)(en)$_2$]$^+$=Λ^+, Δ-[Co(ox)(en)$_2$]$^+$=Δ^+, Λ-[Co(ox)(en)$_2$]Cl·H_2O=ΛCl, Δ-[Co(ox)(en)$_2$]Cl·H_2O=ΔCl, Δ-[Co(ox)(en)$_2$](d-bcs)·$4H_2O$=Δ(d-bcs), Λ-[Co(ox)(en)$_2$](d-bcs)·H_2O=Λ(d-bcs), and Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$=$\Lambda\Delta$(d-bcs)$_2$.

a) Positions of points shown in Figs. 1 and 2. G_1↔P_3, for example, does not contain points G_1 and P_3. Reported data for A, B, E, A↔E, and B↔E[3] and for C, C↔G_2, R_4, R_4↔G_1, G_1, and D[2] not shown. b) Number of components. c) Values in parentheses are estimated errors and calculated from twice the standard deviations of experimental measurements repeated 4—7 times. At a point in A↔I, I, and R_4↔I, the molality of d-bcs$^-$ ideally becomes twice those of Δ^+.

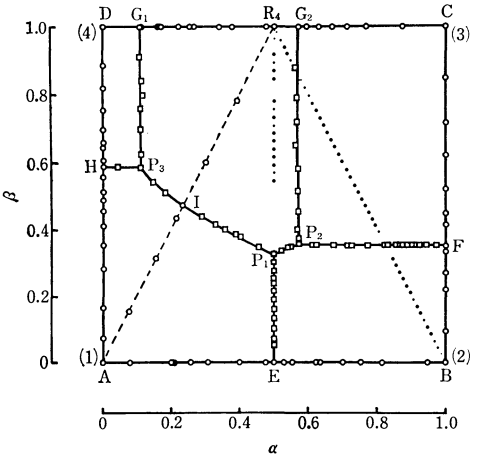

Fig. 2. The clinographic projection of the solubility isotherm of the system, (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)-(en)$_2$]$^+$–(Cl$^-$, d-bcs$^-$)–H_2O, at 25 °C: α, mole fraction of Δ-[Co(ox)(en)$_2$]$^+$ to all the cations; β, mole fraction of d-bcs$^-$ to all the anions; (1) Λ-[Co(ox)(en)$_2$]Cl, (2) Δ-[Co(ox)(en)$_2$]Cl, (3) Δ-[Co(ox)(en)$_2$](d-bcs), and (4) Λ-[Co(ox)(en)$_2$](d-bcs); □, solubility of four-components; ○, solubility of two- or three-components.

three salts.[3] Thus the solubility isotherm can be drawn in a space according to the definition of solubility diagrams of reciprocal salt-pairs; Figure 1 represents the plane projection and the side elevation, and Fig. 2 the clinographic projection.[3]

The isotherm shows that the pseudoracemic compound, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$, is present as the only double salt, no solid solution existing in this system. In the areas of AEP_1IP_3H, $EBFP_2P_1$, CG_2P_2F, $G_2R_4G_1P_3IP_1P_2$, and DHP_3G_1 in Figs. 1 and 2, which contain their boundaries, the saturated solutions are in equilibrium with the solids Λ-[Co(ox)(en)$_2$]Cl·H_2O, Δ-[Co(ox)-(en)$_2$]Cl·H_2O, Δ-[Co(ox)(en)$_2$](d-bcs)·$4H_2O$, Λ-[Co-(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$, and Λ-[Co-(ox)(en)$_2$](d-bcs)·H_2O, respectively. Points A, B, C, R_4, and D denote the solubility of binary systems, and the faces AEB, BFC, $CG_2R_4G_1D$, DHA, and AIR_4 that of ternary systems. The lines of EP_1, FP_2, G_2P_2, G_1P_3, and HP_3 in Fig. 2 are almost parallel to the abscissa or ordinate. This shows that the mole ratio of Λ-[Co(ox)(en)$_2$]$^+$ to Δ-[Co(ox)(en)$_2$]$^+$ or Cl$^-$ to d-bcs$^-$ is constant on these lines.[3]

On the "racemic line" ER_4 (Fig. 2) where the amounts of Λ- and Δ-[Co(ox)(en)$_2$]$^+$ ions are equal, the saturated solution is in equilibrium with the pseudoracemate, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$ (on P_1R_4), or the racemic mixture, [Co-(ox)(en)$_2$]Cl·H_2O (on EP_1). Thus, the system at 25 °C can not be applied successfully to practical optical resolution. One mole of *rac*-[Co(ox)(en)$_2$]Cl is dissolved in an excess of water and x mol of Ag(d-bcs) is added ($0<x<1$). The resulting precipitate AgCl is filtered off and the filtrate then concentrated at 25 °C. If we ignore the dissolved AgCl, this operation gives just the same conditions as the isotherm, (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)–(Cl$^-$, d-bcs$^-$)–H_2O, at 25 °C. In the case of $0<x<0.32$, the situation corresponds to the region of $E \leftrightarrow P_1$, giving the first precipitation of the racemic mixture, [Co(ox)(en)$_2$]Cl·H_2O, on concentrating at 25 °C. In the case of $x=0.32$ which corresponds to point P_1, the racemic mixture, [Co(ox)(en)$_2$]Cl·H_2O, and the pseudoracemate, Λ-[Co(ox)(en)$_2$]·Δ-[Co(ox)(en)$_2$](d-bcs)$_2$·$2H_2O$, will precipitate simultaneously. In the case of $0.32<x<1$ which is related to the region of $P_1 \leftrightarrow R_4$, the pseudoracemate deposits at first. The final liquid phase composition in this operation corresponds to point P_1 regardless of the value of x. Thus, optical resolution is impossible in this isotherm because of the formation of the racemic mixture or the pseudoracemic compound. No tie-line intersects the "racemic line".

There are three invariant points, P_1, P_2, and P_3, in the four-component system at 25 °C. When the unsaturated solution composition is in the region of AR_4D except for its boundary in Fig. 2, the concentration of this solution would bring the solution composition to point P_3. Thus, point P_3 represents the final liquid phase composition for the region AR_4D. Both points P_1 and P_2 also represent the final liquid phase compositions for the regions ABR_4 and BCR_4, respectively. Point P_2 is a kind of "pseudo invariant point,"[2] since the composition of P_2 exists not in the region BCR_4 but in ABR_4.

(Received March 9, 1978)

The thermochemical reactions of $[Ru(NH_3)_5N_2]X_2$ (X=Cl, Br, I) were investigated in the solid state. The ammonia ligand was liberated at a lower temperature (165—213 °C) than the nitrogen ligand (243—270 °C). The isothermal measurement reveals that the first step of the degradation of the complex can be expressed as: $[Ru(NH_3)_5N_2]X_2(s) \rightarrow [RuX(NH_3)_4N_2]X(s) + NH_3(g)$ (X=Cl, Br, or I). The rate of the reaction is first-order to $[Ru(NH_3)_5N_2]X_2$, and the first-order rate constant increased in the order of: chloride<bromide<iodide. The activation energies and the activation entropies (E/kJ mol^{-1} and ΔS^*/J K^{-1} mol^{-1} respectively) for the reaction were as follows: chloride (181 ± 1, 62 ± 1), bromide (99 ± 1, -95 ± 2), and iodide (89 ± 1, -102 ± 3). The values of ΔS^* suggest that the salt with Cl^- degrades through an S_N1-like mechanism, while those with Br^- and I^- degrade through an S_N2-type mechanism. The thermochemistry of $[Ru(NH_3)_5N_2]X_2$ has been discussed on the basis of the strong π-backbonding ability of the nitrogen ligand and the electronegativity of the outer-sphere ions.

After the isolation of Ru(II)–N_2 compounds by Allen and Senoff,[1] a number of nitrogen compounds of the transition metals (Co, Ir, Os, *etc.*)[2-4] have been synthesized. These nitrogen compounds have been energetically studied because they are known to play an important part in the fixation of the N_2 molecule. The X-ray analysis of the Ru(II)–N_2 compound has revealed that the Ru–N–N group is linear.[5] The Ru–N_2 bond is known to be stable because of the π-backbonding between the Ru d_π-orbital and the p_π-orbital of the N_2 ligand.[6] In an aqueous solution, however, the N_2 molecule is easily replaced by a water molecule. Therefore, it is worthwhile to investigate the nature of the Ru–N_2 bond. Some properties of $Ru(NH_3)_5N_2^{2+}$ in an aqueous solution have been reported,[7] but these seem to have been no report in the solid-state reaction.

In this work, the thermochemical behavior of the Ru(II)–ammine compounds containing molecular nitrogen has been studied in the solid state in order to obtain information about the lability of the Ru–N_2 and Ru–NH_3 bonds. The kinetics of the deammonation-anation reaction have also been studied. Furthermore, the application of the solid-state thermal reaction in convenient syntheses of dinitrogen compounds with various substituents has been researched.

Experimental

Materials. The $[Ru(NH_3)_5N_2]Cl_2$ complex was prepared according to the method described in the literature,[1] with caution taken, to avoid contamination with the binuclear species.[8] The bromide and the iodide were prepared by exchanging the chloride ion with the corresponding ions in an aqueous solution of sodium bromide and sodium iodide. The *cis*-$[Ru(NH_3)_4(OH_2)(N_2)]Br_2$ complex was prepared by the reaction of *cis*-$[RuBr_2(NH_3)_4]Br$ with sodium azide and methanesulfonic acid.[9] The purity of the compounds was confirmed by elemental analysis and by UV-spectral measurements.

Derivatographic and Isothermal Measurements. The derivatograms (TG and DTA) were obtained by using a Shimadzu DTG-20-type micro-differential thermobalance. The experiments were made in a constant nitrogen stream (50 ml/min) at a constant heating rate (5 °C/min), using about 10 mg of the sample in each run. The isothermal kinetic measurements were carried out as has been described in a previous report.[10] The UV and IR spectra of the initial compound and the reaction product were measured with a Shimadzu UV-200-type Spectrophotometer and a JASCO Model DS-403G Grating Infrared Spectrophotometer respectively.

Results and Discussion

Derivatographic Studies. The TG and DTA curves of $[Ru(NH_3)_5N_2]X_2$ (X=Cl, Br, and I) are given in Fig.

Calcd	(4.48, 31.34)	(3.36, 23.54)	(2.66, 18.63)
Electronic spectrum (λ_{max}/nm, ε/cm^{-1} mol^{-1} dm^{-3})	(225, 6.5×10^3)	(218, 5.8×10^3)	(232, 1.16×10^4)

1, while their data are summarized in Table 1. All the TG curves show three steps in the mass-loss stage. The initial mass-loss temperatures are 213, 195, and 165 °C for chloride, bromide, and iodide respectively. The DTA curves show endothermic peaks at the two initial mass-loss stages: P_1, Sh./252, 280 °C (chloride), P_1, P_2/243, 286 °C (bromide), and P_1, P_2/211, 240 °C (iodide). The curves show also two exothermic peaks in the succeeding, third mass-loss stage: P_2, P_3/362, 394 °C (chloride), P_3, P_4/379, 390 °C (bromide), and P_3, P_4/308, 318 °C (iodide). The magnitude of the mass-loss in the first stage corresponds to the liberation of four or five molecules of NH_3, and that in the second stage, to the liberation of N_2.

In order to obtain more detailed information on the first mass-loss stage, the isothermal pyrolysis was carried out. The compound was heated for 20—60 min at a constant temperature just below the initiation point of the mass-loss; the temperatures chosen were 201, 183, and 155 °C for chloride, bromide, and iodide respectively.

The analytical data of the isothermal-reaction products (Table 2) clearly indicate that the product has the $[RuX(N_2)(NH_3)_4]X$ formula; that is, the product is a substituent of one molar ammonia of the initial compound by one molar of the halide ion. Thus, the main reaction through the first endothermic peak can be expressed by Eq. 1:

$$[Ru(NH_3)_5N_2]X_2(s) \xrightarrow{\Delta T} [RuX(N_2)(NH_3)_4]X(s) + NH_3(g) \quad (X=Cl, Br, I) \quad (1)$$
$$[A]$$

The IR spectral data are shown in Table 3. The

absorption bands of the [A] product in the regions of 2152—2129 cm^{-1} and 510—474 cm^{-1} have been assigned to the stretching frequencies of ν(N–N) and ν(Ru–N_2) respectively. The N–N stretching shifted to a frequency higher by *ca.* 20 cm^{-1} on the deammonation. The Ru–N_2 stretching, on the contrary, shifted to a frequency lower by about 5—10 cm^{-1} on the reaction, whereas the Ru–NH_3 stretching shifted to a frequency higher by 5—15 cm^{-1} except for the chloride. Only in the chloride of [A] was a new absorption band, which can be assignable to ν(Ru–Cl),[11] observed in the lower region of 304 cm^{-1}. The ν(Ru–X) stretching frequency (X=Br, I) could not observed, but it can be expected to appear in a much lower region. The shifts may be caused by the deammonation and anation of the halide ion.

From the isothermal study described above, the first mass-loss stage have been ascribed to the quantitative liberation of ammonia as seen in amminehalogenoruthenium(III) complexes.[10,12] The second mass-loss stage seems due to the liberation of molecular nitrogen. The succeeding mass-loss stage, which shows exothermic peaks, might correspond to the continuous degradation reactions, such as the sublimation of ammonium halide and the evolution of free halogen.

As is pictured in Fig. 1, however, the non-isothermal (heating rate of 5 °C/min) derivatograms do not reveal the mass-loss stage of the liberation corresponding to the release of one molar ammonia. The TG curve of $[Ru(NH_3)_5N_2]Cl_2$ was obtained with a heating rate of 2 °C/min; it is shown again in Fig. 1. In this case, the initial mass-loss stage cleary corresponds to the liberation of one molar ammonia.

In order to confirm the stereochemical configuration of the [A] product, *cis*-type tetraamminebromodinitrogenruthenium(II) bromide [B] was prepared by employing a thermal-substitution reaction in the solid state:

$$cis\text{-}[Ru(NH_3)_4(OH_2)(N_2)]Br_2(s) \xrightarrow{\Delta T} cis\text{-}[RuBrN_2(NH_3)_4]Br(s) + H_2O(g)$$
[B]

The UV (218 nm) and IR spectra of [A(X=Br)] both agreed with those of [B]; this fact indicates that the thermal-reaction product [A] has a *cis*-configuration (Tables 2 and 3).

In conclusion, it is interesting to note that the Ru(II)–N_2 bond is more stable than the Ru(II)–NH_3 bond in this reaction.

Isothermal Kinetic Study. The kinetic measurements for the deammonation-anation reaction (1) (Fig. 2) show that Reaction (1) can be regarded as first-order with respect to the reactant. The first-order rate constants obtained and the activation parameters evaluated from the Arrhenius plot (Fig. 3) are given in Table 4. The rate constant of the bromide is about eleven times greater than that of the chloride. The rate constant of the iodide is about five times greater than that of the bromide. Consequently, the rate constant increases in this order: chloride<bromide<iodide; this relation is in accord with that among the Ru(III)–ammine compounds.[12] A more detailed discussion of this relation will be presented in the following section.

Reaction Mechanism. If the deammonation-anation reaction proceeds *via* an S_N1-like mechanism, the rate-

determinant step can be expected to be the Ru–NH_3 bond-rupture. Then, the rate constants may be practically independent of the nucleophilicity of the outer-sphere ions. On the contrary, if it proceeds through an S_N2-type mechanism, the rate constants might depend strongly on the outer-sphere ions. As may be seen in Table 4, the rate constants obtained largely depend on the outer-sphere ions; this suggests, then, that the deammonation-anation reactions proceed according to an S_N2-type mechanism.

The chloride, however, shows the smallest value of the rate constant among these three nitrogen compounds, while also revealing the largest value of the activation energy, E (181 kJ mol^{-1}), and the most positive value of the activation entropy, ΔS^* (62 J K^{-1} mol^{-1}). These results imply that the rate-determinant step is the Ru–NH_3 bond-breaking. In this case, a large activation energy is needed for bond-breaking; the increased activation entropy as a transitions-state complex can, therefore, be expected to be a five-coordinated intermediate. Therefore, the reaction of the pentaamminedinitrogenruthenium(II) chloride belongs to an S_N1-like mechanism.

On the other hand, the bromide and iodide reveal small values of E (99, 89 kJ mol^{-1}) and negative values of ΔS^* (−95, −102 J K^{-1} mol^{-1}). It is reasonable to consider that the mechanisms of the bromide and iodide of pentaamminedinitrogenruthenium(II) belong to an S_N2 category, because the values of E and ΔS^* obtained in the deammonation of $[Ru(NH_3)_5N_2]X_2$ [I] and $[Ru(NH_3)_6]X_3$ [II] (X=Br and I) are comparable with each other, and as the latter compounds are known to proceed through an S_N2 mechanism. The finding that the two types of complexes, [I] and [II], reveal comparable activation parameters might be explained by the π-backbonding of the N_2 ligand; that is, the effective charge on Ru(II) increases because the N_2 ligand is bound to the ruthenium, with the $3\sigma_g$-orbital as a σ-donor and with the $1\pi_g$*-orbital as a π-acceptor.[13]

Influence of Outer-sphere Ion. The rate constants of these compounds have revealed larger differences (*ca.* 8 (iodide) and 9 (bromide) times larger) in the $Ru(NH_3)_5N_2^{2+}$ compound than in the $Ru(NH_3)_6^{3+}$ compound. If the reactions proceed *via* an S_N2 mechanism, the increase in the nucleophilicity of the outer-sphere ion can be expected to give rate constants in the order of: I<Br<Cl. The rate constants, however, increased in the reverse order of: Cl<Br<I. This contradiction might be explained as follows. In the solid-state reaction, halogen's larger electronegativity in the outer-sphere might result in an increase in the net charge of the complex ion. In fact, ν(Ru–NH_3) and ν(Ru–N_2) in $[Ru(NH_3)_5N_2]X_2$ become higher with halogen's larger electronegativity (Table 3): I<Br<Cl. The smallest value of the rate constant in the chloride might be one of the supports for an S_N1-like mechanism. The difference in the rate constant between Ru(II) and Ru(III) complexes mentioned above might be contributed to by the difference in the number of halogen ions in the outer-sphere.

In conclusion, the thermochemical behavior of the pentaamminedinitrogenruthenium(II) compounds has been characterized by a stable Ru(II)–N_2 bond including a strong π-backbonding and by the electronegativity of the outer-sphere ions. Moreover, it might be due to the "*cis*-effect" of the N_2 ligand that the reaction product has a *cis*-form configuration, though this point needs a more detailed investigation. An isothermal reaction can be used for a convenient synthesis of the dinitrogenruthenium(II) compound with various substituents.

Equilibria of Imidazole Derivatives with (Protoporphyrin IX dimethyl ester)iron(III) Chloride

Tetsuhiko YOSHIMURA* and Tomio OZAKI

The Environmental Science Institute of Hyogo Prefecture, Yukihira-cho Suma-ku, Kobe 654

(Received September 1, 1978)

The equilibria of sterically hindered and unhindered imidazoles (B) with (protoporphyrin IX dimethyl ester)-iron(III) chloride (Fe(PPDME)Cl) have been spectrophotometrically investigated in chloroform and 1,2-dichloroethane. The addition reaction of hindered imidazole with Fe(PPDME)Cl proceeds in two steps to give $Fe(PPDME)B_2Cl$, with a formation constant, K_1, greater than K_2. The mono-adduct of hindered imidazoles exhibits an absorption band at around 590 nm, which shifts to longer wavelengths as the formation constant K_1 decreases in this order; 2,4-dimethyl-$>$2-methyl-$>$2-ethyl-$>$2-phenyl-$>$1,2-dimethylimidazole. The addition reaction of an unhindered imidazole with Fe(PPDME)Cl proceeds in an apparent one step to give $Fe(PPDME)B_2Cl$, with an overall formation constant of β_2. The log β_2 linearly increases with the basicity, $pK_a(BH^+)$, of unhindered imidazoles. The log β_2 for the system with NH-containing imidazoles is greater than that for the system with *N*-substituted imidazoles by about 3.1 log units, on the average, based on the stabilization of the positive charge on iron(III) through NH···Cl hydrogen bonding. The solvent effect on the formation constants is also discussed.

Imidazole is known to coordinate axially to heme iron in such hemoproteins as hemoglobin, myoglobin, cytochromes, peroxidases, and catalases.[1] The proximal and the distal histidine imidazoles play an important role in the heme-heme interaction and the Bohr effect in hemoglobin.[2] The state and the nature of the heme iron–imidazole bonds in the other hemoproteins are also closely related to the function of hemoproteins; thus, many investigations have been directed toward elucidating the thermodynamic properties of porphyrin iron model complexes with the imidazole derivatives.[3–21,23,25,26] La Mar and his coworkers have systematically investigated the kinetics and the thermodynamics of axial ligation in iron(III) complexes with synthetic porphyrins on the basis of proton NMR results.[21–26] Walker *et al.* followed the reaction of iron(III) para-substituted tetraphenylporphyrins with various imidazole derivatives by measuring the visible absorption spectrum in such noncoordinating solvents as chloroform, dichloromethane, and benzene; the effects of the solvent and the base on the equilibrium constant were also discussed.[14] The reaction of porphyrin iron(III) with imidazole in such coordinating solvents as dimethyl sulfoxide[18,19] and aqueous ethanol has also been studied.[5,6,12] The formation of a hemin complex with a mixed ligand of cyanide and imidazole in dimethyl sulfoxide has recently been studied by means of proton NMR.[20] Generally, the thermodynamics in coordinating solvents as compared with that in noncoordinating solvents is complicated by the solvation or the coordination of the solvent which remains unidentified.[19]

The imidazole derivatives are classified into two groups for steric reasons. They are sterically hindered imidazoles (2-methyl-, 1,2-dimethylimidazole, *etc.*), with significant steric interaction between the porphyrin core and the substituent adjacent to the bonding nitrogen, and unhindered imidazoles (imidazole, 4-methyl-, 1-methylimidazole, *etc.*). The majority of studies of porphyrin iron complexes with the imidazole derivatives as axial ligand(s) have been of unhindered imidazoles; there have been only a few of hindered imidazoles. The porphyrin iron complexes with unhindered imidazoles have been isolated as bis-adducts,[27–29] whereas those with hindered imidazoles have been isolated as mono-adducts.[30,31]

The reaction of porphyrin iron(III) chloride (FePCl) with nitrogenous bases (B) in solution is considered to proceed in two steps:

$$FePCl + B \overset{K_1}{\rightleftharpoons} FePBCl \quad (1)$$

$$K_1 = [FePBCl]/[FePCl][B] \quad (2)$$

$$FePBCl + B \overset{K_2}{\rightleftharpoons} FePB_2Cl \quad (3)$$

$$K_2 = [FePB_2Cl]/[FePBCl][B] \quad (4)$$

The overall reaction is:

$$FePCl + 2B \overset{\beta_2}{\rightleftharpoons} FePB_2Cl \quad (5)$$

$$\beta_2 = [FePB_2Cl]/[FePCl][B]^2 \quad (6)$$

$$(\beta_2 = K_1K_2)$$

Whether the chloride in the mono-adduct FePBCl is in the inner (six-coordinated) or outer coordination sphere (five-coordinated, ion-pair) is unknown, but in the former case the chloride ligand is considered to coordinate weakly to iron(III) because no change in the spin state ever occurs upon the addition of the first axial base.[11]

When unhindered imidazole is added to a porphyrin iron(III) chloride solution, the change in the visible absorption spectrum apparently exhibits the bis-adduct formation in general, though the isosbestic points indicating the mono-adduct formation are rarely found in the lower concentration of the imidazole.[14] Thus, the stepwise formation constant, K_2, is found to be much greater than K_1, so that only the overall formation constant, β_2, can be estimated from the finding regarding the spectral change. In the NMR spectrum of the porphyrin iron(III)–unhindered imidazole system, only the signals arising from the porphyrin iron(III) and the bis-adduct are detectable in solution.[21]

Upon the addition of hindered imidazole to a porphyrin iron(III) chloride solution, the NMR spectra exhibit only the bis-adduct formation for synthetic porphyrins,[25] whereas the visible absorption spectra exhibit the mono-adduct formation intermediately.[14]

It is known that the thermodynamics of metallopor-

phyrin complexes is highly sensitive to the porphyrin basicity[32] and that the basicity of the protoporphyrin IX, which occurs naturally, is different from that of such synthetic porphyrins as tetraphenyl- and octaethylporphyrin.[33] For understanding the nature of the iron–imidazole bond in the hemoproteins it is, therefore, considered useful to investigate the thermodynamics of the protoporphyrin iron complex with imidazole. In this paper we wish to report on our spectroscopic studies of the equilibria of sterically hindered and unhindered imidazoles with (protoporphyrin IX dimethyl ester) iron(III) chloride in chloroform and 1,2-dichloroethane, and to discuss the effect of the solvent and the base on the formation constant and the visible absorption spectra. Furthermore, the steric interaction of the porphyrin core with the base will be discussed.

The abbreviations used are as follows: (protoporphyrin IX dimethyl ester)iron(III) chloride, Fe(PPDME)-Cl. Unhindered imidazoles: imidazole, Im; 4-methylimidazole, 4MeIm; 4-phenylimidazole, 4PhIm; histamine, Him; 1-methylimidazole, NMeIm; 1-ethylimidazole, NEtIm; 1-acetylimidazole, NAcIm; 5-chloro-1-methylimidazole, 5ClNMeIm. Hindered imidazoles: 2-methylimidazole, 2MeIm; 2-ethylimidazole, 2EtIm; 2-phenylimidazole, 2PhIm; 2,4-dimethylimidazole, 2,4DMeIm; 1,2-dimethylimidazole, 1,2DMeIm.

Experimental

The Fe(PPDME)Cl was prepared as described before.[34] The Im, 4PhIm, NAcIm, 2MeIm, 2PhIm, and Him were recrystallized three times from chloroform–petroleum ether or acetone–petroleum ether and dried *in vacuo*. The 4MeIm, 2EtIm, and 2,4DMeIm were purified three times by vacuum sublimation and dried *in vacuo*. The NMeIm, NEtIm, 5ClNMeIm, and 1,2DMeIm were distilled four times at reduced pressure under N_2. Chloroform and 1,2-dichloroethane of an analytical grade were purified by the usual method. The ethanol was of a spectro-grade. The other reagents were of an analytical grade and were used without further purification.

The visible absorption spectrum was recorded on a Shimadzu MPS-5000 spectrophotometer at 25.0±0.2 °C. The plot of the absorbance at several wavelengths against the concentration of Fe(PPDME)Cl in chloroform was found to be linear in the concentrations below 0.3 mM; thus, the concentration of Fe(PPDME)Cl in measurements of the formation constants was maintained at 0.15 mM unless otherwise stated. The measurements of the spectral change upon the addition of bases to the Fe(PPDME)Cl solution were repeated several times in order to confirm the reproducibility.

Results

Absorption Spectra and Equilibria of the Fe(PPDME)Cl–Unhindered Imidazole System. The addition of imidazole to Fe(PPDME)Cl in chloroform resulted in the spectral changes shown in Fig. 1, which illustrates six concentrations of imidazole out of the 18 measured. The absorption maxima for the (protoporphyrin IX dimethyl ester)iron(III) complex with imidazole were 356.2 (26.1×10^3), 414.3 (124×10^3), 480.1 sh(7.65×10^3), 538.5 (10.8×10^3), and 563.4 sh(8.75×10^3), nm where sh is an absorption as a shoulder and where the

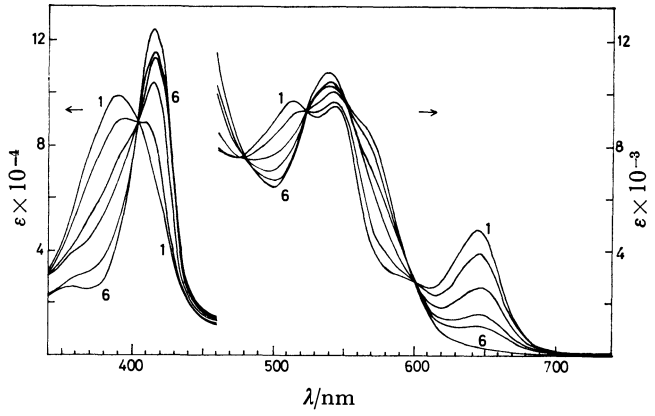

Fig. 1. Spectral changes observed upon addition of imidazole (0—12 mM) to an 0.15 mM solution of Fe(PPDME)Cl in chloroform (illustrated for 6 concentrations out of 18 ones measured). Imidazole concentrations: 1, 0 mM; 2, 0.3 mM; 3, 0.6 mM; 4, 0.9 mM; 5, 1.2 mM; 6, 12 mM.

values in parentheses are the molar extinction coefficients. The wavelengths of the absorption maxima in the case of the addition of the other seven unhindered imidazoles agreed with those of imidazole within ±2 nm. As is shown in Fig. 1, the isosbestic points were observed at 402, 480, 524, and 596 nm. For the molar ratios lower than [Im]/[Fe(PPDME)Cl]=2, the isosbestic point at 480 nm shifted slightly to the shorter wavelength side and the absorbance of the band at 540 nm was slightly lowered relative to that for Fe(PPDME)Cl; this behavior was found also in the case of the addition of the other seven unhindered imidazoles and was, indeed, even more distinct in the system with a smaller formation constant.

The spectral changes in Fig. 1, where the spectra of free Fe(PPDME)Cl changed to low-spin spectra,[35] indicate that the reaction of imidazole with Fe(PPDME)Cl proceeds in an apparent one step, based on the overall process of Eq. 5. Plots of A_0-A at 645 nm against log [B] are shown in Fig. 2, where A is the observed absorbance at a given wavelength, A_0 is the absorbance of Fe(PPDME)Cl in the absence of a base, and [B] is the

concentration of the base. A_0-A for all the unhindered imidazoles varies with log [B] with a similar tendency, showing that the reaction of the unhindered imidazole with Fe(PPDME)Cl proceeds in an apparent one step. Then, the overall formation constant (β_2) is given by

$$\beta_2 = \frac{[FePB_2Cl]}{([FePCl]_T-[FePB_2Cl])([B]_T-2[FePB_2Cl])^2} \quad (7)$$

where $[FePCl]_T$ and $[B]_T$ are the total concentrations of Fe(PPDME)Cl and a base respectively. Since $[FePB_2Cl]=(A-A_0)/(\varepsilon_2-\varepsilon_0)$[36] where ε_0 is the molar extinction coefficient of Fe(PPDME)Cl in the absence of a base and where ε_2 is that of $Fe(PPDME)B_2Cl$ in the presence of a large excess of a base, Eq. 7 becomes:

$$\beta_2 = \frac{(A-A_0)/(\varepsilon_2-\varepsilon_0)}{\{[FePCl]_T-(A-A_0)/(\varepsilon_2-\varepsilon_0)\}\{[B]_T-2(A-A_0)/(\varepsilon_2-\varepsilon_0)\}^2} \quad (8)$$

By the method of Momenteau,[8] $1/(A_0-A)$ was plotted against $1/[B]_T^2$ at the wavelengths at 500, 540, 560 (or 570), and 645 nm. From the data in the linear part of the plots, β_2 was calculated by means of Eq. 8, and then the mean values and the standard deviations were evaluated (Table 1). From the data in the nonlinear part of the plot at 500 nm in the lower base concentrations, in which the isosbestic point at 480 nm shifts as described above, the formation constant, K_1, could be estimated. From Eq. 2 and the relation $[FePBCl]=(A-A_0)/(\varepsilon_1-\varepsilon_0)$,[36] K_1 is given by

$$K_1 = \frac{(A-A_0)/(\varepsilon_1-\varepsilon_0)}{\{[FePCl]_T-(A-A_0)/(\varepsilon_1-\varepsilon_0)\}\{[B]_T-(A-A_0)/(\varepsilon_1-\varepsilon_0)\}} \quad (9)$$

where ε_1 is the molar extinction coefficient of Fe(PPDME)BCl. Assuming that the spectra of mono- and bis-adducts are similar at 500 nm, the value of ε_2 in the calculation of β_2 was used as that of ε_1 in Eq. 9.[14] Thus, the values of K_1 in Table 1 are only approximate, but they are, nevertheless, of the correct order of magnitude.

Absorption Spectra and Equilibria of the Fe(PPDME)Cl–Hindered Imidazole System. The addition of hindered imidazoles to Fe(PPDME)Cl in chloroform resulted in the spectral changes summarized in Figs. 3 (base: 2-methylimidazole) and 4 (base: 2-ethylimidazole). The absorption maxima of the product obtained were 360.0

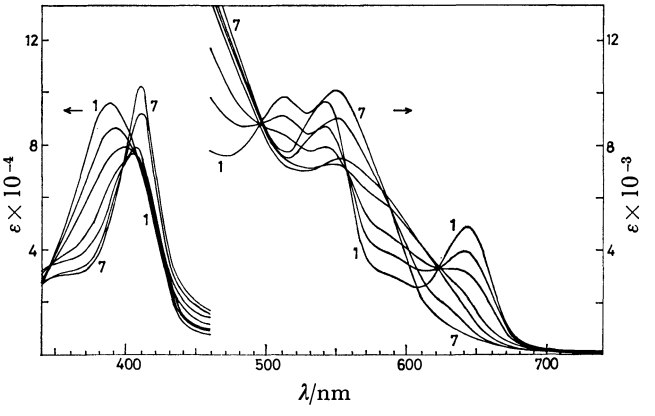

Fig. 3. Spectral changes observed upon addition of 2-methylimidazole (0—1.2 M) to an 0.15 mM solution of Fe(PPDME)Cl in chloroform (illustrated for 7 concentrations out of 18 ones measured). 2-Methylimidazole concentrations: 1, 0 mM; 2, 9 mM; 3, 15 mM; 4, 30 mM; 5, 90 mM; 6, 0.3 M; 7, 1.2 M.

sh, 410.6, 451.0 sh, and 550.0 nm for 2-methylimidazole, and 410.8, 450.0 sh, and 544 nm for 2-ethylimidazole. In the case of the addition of 2,4-dimethylimidazole, the spectral changes were similar to those in Fig. 3. In the case of the addition of 1,2-dimethyl- and 2-phenylimidazole, however, even when the base was added up to the solubility limit, the spectrum was not further changed from that similar to the intermediate spectrum in Fig. 3 and in Fig. 4 respectively. The isosbestic points for 2-methylimidazole (Fig. 3) were observed at 496, 558, and 625 nm for the lower molar ratios of [2MeIm]/[Fe(PPDME)Cl] and at 586 nm for the higher ratios, while those for 2-ethylimidazole (Fig. 4) were observed at 494, 563, and 628 nm for the lower molar ratios of [2EtIm]/[Fe(PPDME)Cl] and at 582 and 643 nm for the higher ratios. No distinct isosbestic points were present in the range of the Soret band, as is shown in Fig. 3. These spectral changes appear to be markedly different from those for unhindered imidazoles. The two sets of isosbestic points indicate that the equilibria involve mono- and bis-adducts.

This spectral behavior shows that the addition of hindered imidazoles to Fe(PPDME)Cl occurs in two steps. Since the equilibrium involve mono- and bis-adducts, the following relation can be derived:

$$[\mathrm{FePCl}]_T = [\mathrm{FePCl}] + [\mathrm{FePBCl}] + [\mathrm{FePB_2Cl}] \quad (10)$$

$$[\mathrm{B}]_T = [\mathrm{B}] + [\mathrm{FePBCl}] + 2[\mathrm{FePB_2Cl}] \quad (11)$$

$$A = \varepsilon_0[\mathrm{FePCl}] + \varepsilon_1[\mathrm{FePBCl}] + \varepsilon_2[\mathrm{FePB_2Cl}] \quad (12)$$

where the absorbances are for a 1-cm light path. In the second step of the reaction, $[\mathrm{FePCl}]_T$ can be approximately equal to $[\mathrm{FePBCl}]+[\mathrm{FePB_2Cl}]$, A, to $\varepsilon_1[\mathrm{FePBCl}]+\varepsilon_2[\mathrm{FePB_2Cl}]$, and $[\mathrm{B}]_T$, to $[\mathrm{B}]$, because a base was present in a large excess relative to $[\mathrm{FePCl}]_T$. Thus, K_2 is given by

$$K_2 = \frac{[\mathrm{FePB_2Cl}]}{([\mathrm{FePCl}]_T - [\mathrm{FePB_2Cl}])[\mathrm{B}]_T} \quad (13)$$

Then,

$$A = \varepsilon_1([\mathrm{FePCl}]_T - [\mathrm{FePB_2Cl}]) + \varepsilon_2[\mathrm{FePB_2Cl}],$$

and letting

$$A_1 = \varepsilon_1[\mathrm{FePCl}]_T, \quad (14)$$

we obtain:

$$[\mathrm{FePB_2Cl}] = (A - A_1)/(\varepsilon_2 - \varepsilon_1) \quad (15)$$

From Eqs. 13 and 15, the following equation is derived:

$$\frac{[\mathrm{FePCl}]_T}{A - A_1} = \frac{1}{K_2(\varepsilon_2 - \varepsilon_1)}\frac{1}{[\mathrm{B}]_T} + \frac{1}{\varepsilon_2 - \varepsilon_1} \quad (16)$$

Such a value of A_1 that a plot of $[\mathrm{FePCl}]_T/(A-A_1)$ against $1/[\mathrm{B}]_T$ gives a straight line at a given wavelength was convergently computed by the use of the least-squares method. From this straight line (its slope and intersection with the ordinate), the A_1 value, and Eq. 14, the values of ε_1, ε_2, and K_2 were obtained. Such a calculation was made on three or four wavelengths; the mean of the K_2 values thus obtained given in Table 2. The ε_1 value evaluated from the above calculation agreed reasonably well with that estimated directly from the results of spectral changes at some wavelengths (*e.g.*, at 586 nm in Fig. 3).

Further, by the use of the ε_1 value thus obtained, K_1 in the first step of the reaction was calculated by means of Eq. 9; then, the mean values and the standard deviations were evaluated (Table 3). In the case of 1,2-dimethyl- and 2-phenylimidazole, K_1 was calculated by the use of the ε_1 value estimated from the spectral changes.

Dissociation of Fe(PPDME)B_2Cl and Equilibria in a Chloroform–Ethanol Mixed Solvent. When the

a) See Footnote a of Table 1. b) β_2, in units of M^{-2}; K_1 and K_2, in units of M^{-1}.

reaction of (tetraphenylporphyrinato)iron(III) chloride (Fe(TPP)Cl) with 1-methylimidazole in chloroform was examined under a low concentration of Fe(TPP)Cl (7.6×10^{-7} M), the following equilibrium was observed in the system[14]

$$Fe(TPP)Cl + 2NMeIm \rightleftarrows Fe(TPP)(NMeIm)_2^+ + Cl^- \quad (17)$$

In this study, a similar examination was made in [Fe(PPDME)Cl] $= 7.5 \times 10^{-6}$ M. As is shown in Table 1, the value of β_2 was essentially independent of [Fe(PPDME)Cl], though the value and the deviation increased only slightly with lowering of [Fe(PPDME)Cl]. Thus, for Fe(PPDME)Cl in chloroform the influence of the equilibrium of Eq. 17 is considered to be negligible in concentrations higher than [Fe(PPDME)Cl] $= 7.5 \times 10^{-6}$ M.

The effects of the polar and hydrogen-bonding solvent on the formation constant were investigated in chloroform containing 1, 5, and 10 vol % ethanol for the three bases of imidazole, 1-methyl-, and 2-methylimidazole. For the addition of imidazole and 1-methylimidazole, the overall spectral changes in the mixed solvents were similar to those for imidazole in chloroform (in Fig. 1), whereas for the addition of 2-methylimidazole they were similar not to those for 2-methylimidazole in chloroform (in Fig. 3), but to those for 2-ethylimidazole in chloroform (in Fig. 4). As is shown in Table 4, β_2 decreased for imidazole, but increased for 1-methylimidazole, with an increase in the ethanol content. For 2-methylimidazole, as the ethanol content increased, K_1 markedly increased, whereas K_2 slightly decreased.

a) See Footnote b of Table 3.

The spectra of Fe(PPDME)Cl in these mixed solvent was unchanged at the content of ethanol lower than 20 vol %, whereas above that point spectral changes which seemed to originate from ethoxo coordination were observed.

Discussion

Absorption Spectra of the Fe(PPDME)Cl–Imidazoles System. Upon the addition of unhindered imidazole to a Fe(PPDME)Cl solution, the spectra changed from those of free Fe(PPDME)Cl (high-spin) to those of the bis-adduct, Fe(PPDME)B_2Cl (low-spin). These overall spectral changes are very similar to those for the (deuteroporphyrin IX dimethyl ester)iron(III)–imidazole system.[8] The fact that the low-spin bis-adducts formed have essentially identical spectra for the eight unhindered imidazoles indicates that the stereochemistry of the bis-adducts is not appreciably dependent on the nature of these axial bases.

Upon the addition of hindered imidazole to a Fe(PPDME)Cl solution, the spectra of mono-adduct Fe(PPDME)BCl was intermediately obtained in the course of spectral changes from Fe(PPDME)Cl to Fe(PPDME)B_2Cl, as is shown in Figs. 3 and 4.[37] The spectra of a bis-adduct with hindered imidazoles are similar to those with unhindered imidazoles, but the wavelengths of the absorption maxima at around 545 and 570 nm for the former were found to change with the degree of steric hindrance. It has been pointed out by Smith and Williams that these absorption bands in the low-spin spectra of the porphyrin iron(III) complex are sensitive to the nature of the axial ligands.[35] The wavelengths of the Soret and the characteristic bands (around 590 nm) in the mono-adduct spectra are given in Table 5. The wavelength of this Soret band is intermediate between that for Fe(PPDME)Cl and Fe(PPDME)B_2Cl. The band at around 590 nm is considered to be a charge-transfer band characteristic of high-spin five-coordinated porphyrin iron(III) complexes.[35,38] These mono-adducts may be either five-coordinated ion-pairs, in which chloride is in the outer coordination sphere, or

six-coordinated complexes in which the interaction of chloride with iron(III) is considerably weak. The wavelength of this characteristic band is comparable to those of the following complexes: (deuteroporphyrin IX dimethyl ester)iron(III) with fluoride,[38] ethoxo(protoporphyrin IX dimethyl ester)iron(III),[39] and μ-oxo-bis-(protoporphyrin IX dimethyl ester iron(III))[40] (Table 5). In these complexes, it is known that the interaction of iron with the axial ligand is relatively strong and that the iron atom is displaced from porphyrin plane toward the axial ligand[38]; thus, it seems that the second axial ligand can not readily coordinate to iron(III).

Effect of the Base on Formation Constant. In the case of hindered imidazoles, no correlation between the basicity of these bases and the formation constants is found, as is shown in Table 3. On the contrary, in the case of unhindered imidazoles such a correlation is clearly found, as is shown in Fig. 5; that for NH imidazoles (Im, 4MeIm, 4PhIm) is different from that for NR imidazoles (NMeIm, NEtIm, 5ClNMeIm), though the plots for histamine and 1-acetylimidazole in Fig. 5 deviate from straight lines.

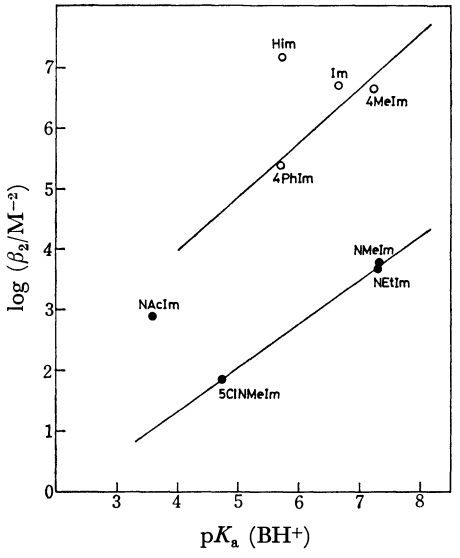

Fig. 5. Relationships between log β_2 and the basicity of unhindered imidazoles: ○, β_2 for NH imidazoles; ●, β_2 for NR imidazoles.

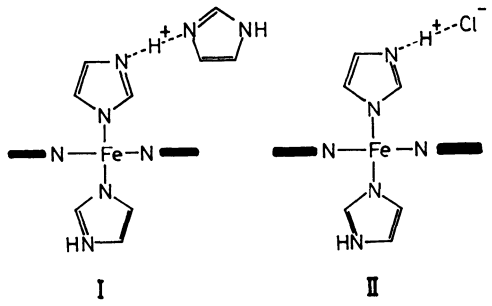
For the (protoporphyrin IX dimethyl ester)iron(III) and the (tetraphenylporphyrinato)iron(III) complexes, the log β_2 values for NH imidazole are larger than that for NR imidazole by about 3.1 and 3.3 log units on the average respectively. The larger value of β_2 for NH imidazole is considered to be based on the stabilization by the delocalization of the positive charge on iron(III) through Interaction I[14] or II.[25,26] In the case of the Interaction I, the delocalization of the positive charge on iron(III) leads to an increase in β_2, whereas the association between coordinated and free NH imidazole may lead to a decrease in β_2. Thus, it seems unlikely that the Interaction I contributes to the increase of about 3 log unit in β_2. The interaction of chloride with the NH group of imidazole has been suggested in a study of the crystal structure of bis(imidazole)tetraphenylporphyrinatoiron(III) chloride.[27] Furthermore, the appreciable



interaction of halide with the NH group of coordinated NH imidazoles has been confirmed by EPR and NMR measurements of the deuteroporphyrin IX dimethyl ester[9] and teraphenylporphyrin iron(III) complexes with NH imidazoles in solution.[26] Accordingly, the stabilization of the complex with NH imidazoles may be mainly due to Interaction II. Thus, it seems unreasonable that the complexes with NH imidazoles are represented by the formula of the ion-pair, Fe(PPDME)-$B_2^+Cl^-$.

The log β_2 for histamine is larger than that which would be predicted from the straight line of NH imidazole in Fig. 5, which is probably based on the additional stabilization of the complex by intramolecular hydrogen bonding between the amino group and the carbonyl group at the porphyrin periphery.[31] The log β_2 for 1-acetylimidazole is also larger than that which would be predicted from the straight line of NR imidazole in Fig. 5. In 1-acetylimidazole, which is known to be a good acetylating reagent, the nitrogen atom at the 1-position of the imidazole ring is susceptible to nucleophilic attack because the acetyl group with an electron-withdrawing ability attracts the electron on the nitrogen atom.[41] In this case, the chloride of the nucleophilic reagent in Fe(PPDME)Cl can interact with the nitrogen atom. Thus, through such interaction the positive charge on iron(III) is delocalized and stabilized; consequently, the formation constant may increase relatively.

In these cases, the two axial imidazoles of the bis-adduct are nonequivalent, because only one chloride is present in a bis-adduct molecule.[25] For both NH and NR imidazoles, the ratios of log K_1/log β_2 are in the narrow range of 0.3—0.4. Thus, it is not possible to specify whether the stabilization of the complex based on the interaction with chloride is accompanied by the axial coordination of NH imidazole in the first step, in the second step, or in the intermediate state.

The coordination of 4-substituted imidazoles to iron-(III) may be equivalent to that of 5-substituted ones caused by rapid tautomerism, for no lowering of the formation constants based on the steric effect was observed.

The basicity of the protoporphyrin IX dimethyl ester is higher than that of tetraphenylporphyrin and lower than that of octaethylporphyrin;[33] therefore the decreasing order of the formation constant for these porphyrin iron(III) complexes can be expected to be: TPP> PPDME>OEP.[21,22,32,42] Such a trend, however, is not clearly found in Table 2. The formation constants for (protoporphyrin IX dimethyl ester)iron(III) complexes should be compared with those for substituted deutero-

porphyrin iron(III) complexes, for which few data have been reported.

Solvent Effect on Formation Constants. The solvent effect on formation constants may be described in terms of the polarity and the hydrogen-bonding ability of the solvents. When the forms of mono- and bis-adducts are the ion-pairs of $Fe(PPDME)B^+Cl^-$ and $Fe(PPDME)B_2^+Cl^-$ respectively, these formation constants can be expected to increase with the polarity of the solvents.[10,11,15] The hydrogen bonding between base and solvent complicates the situation. As for the thermodynamics of the (tetraphenylporphyrinato)iron(III) complex with imidazole in various solvents (acetone, ethyl acetate, DMF, $CHCl_3$, and CH_2Cl_2), it has been reported by Ciaccio *et al.* that the hydrogen-bonding solvents combine with free imidazole to decrease the formation constants,[15] while Walker *et al.* have reported that chloroform, with a weak hydrogen-bonding ability, reduces the self-association of NH imidazole and thus allows the formation constants to be larger than in other solvents.[14]

NR imidazoles are not capable of self-association, but the nitrogen at the 3-position of free NR imidazole can hydrogen-bond to the hydrogen-bonding active group such as NH, OH, and CH in solvent molecules. Such a hydrogen bonding can decrease the formation constants, as has been pointed out by Ciaccio *et al.*[15] Since chloroform is stronger in hydrogen-bonding ability[43] and lower in polarity than 1,2-dichloroethane, β_2 ($CHCl_3$) $<\beta_2$ ($C_2H_4Cl_2$) for 1-methylimidazole in Table 1 seems to be reasonable.

On the contrary, for imidazole, 2-methyl-, and 1-acetylimidazole the formation constants in chloroform are larger than in 1,2-dichloroethane (Tables 1 and 2). The explanation for NH imidazole that the self-association is reduced with the hydrogen-bonding ability of solvents and that, thus, the formation constants are: in $CHCl_3$ $<$in $C_2H_4Cl_2$ is inapplicable to that for the 1-acetylimidazole of the NR imidazole.[44] A feature common to the complexes with these three imidazole bases is that the chloride strongly interacts with the coordinated base; thus, the complex is markedly stabilized, as described above. This interaction between the chloride and the coordinated base may be weakened with the solvent polarity because of a concomitant slight dissociation of the chloride ion; consequently, the formation constants of the complexes may decrease with the solvent polarity. To the solvent effect on the complex formation with these imidazole bases, the contribution of the polarity is considered to surpass that of the hydrogen-bonding ability.

Ethanol is the polar and the hydrogen-bonding solvent. The polarity of a chloroform–ethanol mixed solvent can increase with the ethanol content. The fact that β_2 for imidazole decreases with the ethanol content suggests that the interaction between the chloride and the imidazole NH group is weakened with the polarity of the solvent, thus lowering the stability of the complex (Table 4). Since the complex with 1-methylimidazole is an ion-pair in contrast to that with imidazole, the β_2 increases with the polarity of the solvent. Thus, for the system of imidazole and 1-methylimidazole, the effect of the addition of ethanol to the chloroform solution may be explained on the basis of the increase in polarity. The fact that K_1 for 2-methylimidazole markedly increases with the ethanol content, whereas K_2 slightly decreases, indicates that the stability of the mono-adduct is remarkably enhanced with the ethanol content; the reason for this remains to be clarified.

In the (protoporphyrin IX dimethyl ester)iron(III) complexes, the solvent effect is further complicated by the possibility of the hydrogen bonding of the solvent molecule with the ester carbonyl group at the porphyrin periphery relative to the cases of the tetraphenylporphyrin and octaethylporphyrin iron(III) complexes.

Steric Effect on Formation Constants. As is shown in Table 3, the formation constants of the complexes with hindered imidazoles are found to decrease with the degree of steric hindrance provided by the 2-substituent. The formation constant, K_1, for 1,2-dimethylimidazole is the smallest in the systems studied here, for the 1-methyl group hinders the bending of the 2-methyl group to avoid the steric interaction with the porphyrin plane.[25] The plot of log K_1 against the wavelength of the absorption maximum at around 590 nm characteristic of the mono-adduct is found to be linear, as is shown in Fig. 6. In the mono-adduct which exhibits this band on the longer-wavelength side, the displacements of the iron atom from the porphyrin plane are considered to be larger.

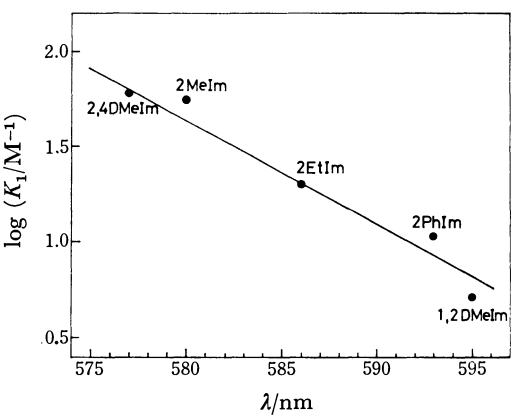


Fig. 6. Relationships between log K_1 and the wavelength of absorption maxima for the mono-adduct with hindered imidazole.

In the porphyrin iron(III) complex, in which a change in the spin state from high- to low-spin occurs upon the addition of the second axial base, the formation constant, K_1, can be smaller than K_2. Accordingly, the relation of $K_1>K_2$ for the complexes with hindered imidazoles is probably based on the steric reason. On the contrary, for the tetraphenylporphyrin iron(III) complex with 2-methylimidazole it is reported to be $K_1 <\beta_2/K_1$ ($=K_2$).[14] It seems that the bis-adduct of (protoporphyrin IX dimethyl ester)iron(III) with hindered imidazoles is not readily isolated because $K_1<K_2$.

Differential Determination of Tellurium(IV) and Tellurium(VI) by Atomic Absorption Spectrophotometry after Hydride Generation. Combined Use of Titanium(III) Chloride as a Prereductant and Sodium Borohydride Solution

Kazuo JIN,* Mitsuhiko TAGA,* Hitoshi YOSHIDA, and Seiichiro HIKIME

Department of Chemistry, Faculty of Science, Hokkaido University, Nishi-8-chome, Kita 10-jo, Kita-ku, Sapporo, 060

(Received September 2, 1978)

Sensitive determination of tellurium was investigated by atomic absorption spectrophotometry after hydride generation and differential determination of tellurium(IV) and tellurium(VI) in acidic solution was carried out. When sodium borohydride solution is used without any prereductant, only the signal from tellurium(IV) is obtained. On the other hand, when titanium(III) chloride solution is added before the addition of borohydride solution, total signal from tellurium(IV) and tellurium(VI) can be obtained; 30—60 s of prereduction is required. The effectiveness of the titanium(III) chloride–borohydride reduction system is shown in the interference study. The interference of selenium(IV) is eliminated up to 200 fold *vs.* 0.25 μg of tellurium(IV) in 20 cm^3 of 3 mol dm^{-3} hydrochloric acid by the use of 2 cm^3 of 5% w/v titanium(III) chloride solution as a prereductant. Tellurium in steel and sulfur (commercial reagent) can be determined satisfactorily without isolation of tellurium from matrix by this method. Detection limit of the method is 8 ng. The coefficient of variation of the method is 2.4% in the ten determinations of 0.25 μg of tellurium.

Determination of a trace amount of tellurium has become of interest in recent years. Tellurium is harmful to the strength of steel[1,2] and high temperature alloys[3] even in a low concentration; in geochemical aspects it is useful as an indicator element.[4–6] Bismuthiol-II is one of the most sensitive reagents in the spectrophotometric determination of tellurium(IV),[7–9] but complete separation of tellurium from interfering ions, *e.g.*, selenium, copper, vanadium, and palladium is required. Although flame atomic absorption spectrophotometry is especially convenient method for the determination of tellurium containing selenium,[10–12] the sensitivity is not yet sufficient for the determination of tellurium in concentration below ppm, and tellurium should be concentrated by solvent extraction[2,10] or coprecipitation with arsenic.[9,10] Hydride generation-atomic absorption spectrophotometry has also been applied to determine tellurium because of its high sensitivity.[13–15] In the method titanium(III) chloride together with magnesium[13] or sodium borohydride[14,15] has been used as a reductant to generate tellurium hydride. There have been no reports, however, on the differential determination of tellurium(IV) and tellurium(VI) in the same solution by atomic absorption spectrophotometry. In order to find suitable experimental conditions for determining tellurium by hydride generation-atomic absorption spectrophotometry, experiments have been carried out.

It was found that sodium borohydride reduces tellurium(IV) to tellurium hydride and is not effective for the reduction of tellurium(VI), and that titanium(III) chloride reduces tellurium(VI) to tellurium(0) *via* tellurium(IV). By utilizing the differences in ability of reduction for tellurium spieces, differential determination of tellurium(IV) and tellurium(VI) in the solution was satisfactorily carried out. When sodium borohydride solution was added alone to the mixed solution of tellurium(IV) and tellurium(VI), only the signal from tellurium(IV) was obtained and not from tellurium(VI). On the other hand, when titanium(III) chloride solution was added to the solution as a prereductant prior to the addition of borohydride solution, total signal from tetravalent and hexavalent tellurium was obtained. Both the concentration of titanium(III) chloride and the prereduction time affected the sensitivity of this method.

This procedure was applied to the determination of trace amounts of tellurium in steel and sulfur.

Experimental

Apparatus. A Hitach Model 170-50 type atomic absorption spectrophotometer with deuterium background corrector and a tellurium hollow-cathode lamp (Hamamatsu TV) were used. A modified Hitachi arsenic determination unit was used for the generation of tellurium hydride; a reaction vessel (vol 115 cm^3) was connected to a dispenser (REBURET, Nippon Garasu Ryoki Co., Ltd.) with a silicone tube (ϕ=1.5 mm) attached firmely to a teflon cap as shown in Fig. 1. A prescribed volume of borohydride solution was introduced

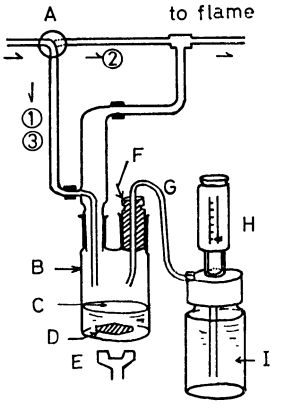

Fig. 1. Reaction vessel and piping diagram used for the evolution of tellurium hydride.
A: Electric valve, ①~③ flow paths of nitrogen; B: reaction vessel; C: sample solution; D: spin bar E: magnetic stirrer; F: Teflon cap; G: silicone tube; H: dispenser; I: sodium borohydride solution.

Table 1. Conditions for nitrogen-hydrogen flame

Wavelength		214.3 nm
Lamp current		4 mA
Slit width	inlet	0.4 mm
	outlet	0.5 mm
Nitrogen flow rate		8 dm^3 min^{-1}
Hydrogen flow rate		7 dm^3 min^{-1}
Aux. nitrogen flow rate		2.5 dm^3 min^{-1}
Height of beam above burner tip		20 mm

instantly from the dispenser into the reaction vessel through the silicone tube. Generated tellurium hydride was carried into a nitrogen-hydrogen flame (one slot burner with 10 cm) and atomic absorption signals were recorded with a Hitachi 056 type recorder. Conditions for the nitrogen-hydrogen flame are given in Table 1.

Reagents. Standard tellurium(IV) solution (1000 ppm Te(IV)–3 mol dm^{-3} hydrochloric acid): 2.000 g of metallic tellurium (99.999%) was dissolved in 8 cm^3 of nitric acid and 10 cm^3 of hydrochloric acid, and the solution was dried up on a water bath. Ten cm^3 of hydrochloric acid was added and the solution was dried up, the procedure being repeated three times. After addition of 500 cm^3 of hydrochloric acid, the solution was diluted exactly to 2000 cm^3 with water. The solution was used by sequential dilution. Standard tellurium(VI) solution: 1.072 g of sodium tellurate ($Na_2TeO_4 \cdot 2H_2O$) was dissolved in hydrochloric acid and diluted exactly to 500 cm^3 with water (1000 ppm Te(VI)–3 mol dm^{-3} hydrochloric acid). The solution was also used by sequential dilution. Titanium chloride(III) solution (5% w/v): 12.5 g of titanium(III) chloride was dissolved in 125 cm^3 of 6 mol dm^{-3} hydrochloric acid, and diluted to 250 cm^3. Sodium borohydride solution (5% w/v, 1% sodium hydroxide): Five grams of sodium borohydride was dissolved in 100 cm^3 of 1% w/v sodium hydroxide. Other reagents were of analytical reagent grade. Deionized water was twice distilled.

Procedure. Transfer a prescribed volume of sample solution containing less than 0.8 μg of tellurium into a reaction vessel, add 5 cm^3 of hydrochloric acid, and dilute the solution to 20 cm^3 with water. Put spin bar into the vessel and set up it on hydride generation unit. Pass nitrogen gas in the vessel for 20 s. Turn electric valve to pass nitrogen through bypass to burner, and start magnetic stirrer. Pour 5 cm^3 of 5% w/v borohydride solution into the vessel from a dispenser when stirring becomes stationary, and lead the generated tellurium hydride to burner with hydrogen generated at the same time and record the signal of tellurium on the recorder. Pass nitrogen through the vessel for cleaning when the signal returns to baseline. Then, exchange the reaction vessel for another one. Determination of one sample can be done within about 1 min.

Results and Discussion

For hydride generation-atomic absorption method, the geometry of reaction vessel, atomizer unit, flow rate of auxiliary nitrogen (or argon), volume and concentration of borohydride solution, volume of sample solution and its acidity play important roles in determining the detection limit and sensitivity. These factors were studied independently in order to elucidate individual effects.

Effect of the Concentration of Sodium Borohydride Solution. Effects of sodium borohydride solution in the concentration range 3—8% w/v and of the solution volume on the sensitivity were examined in 3 mol dm^{-3} hydrochloric acid. The use of low concentration of borohydride resulted in low sensitivity of the method and the solution of high concentration was less stable than that of low concentration. Increase of the volume of borohydride solution up to 8 cm^3 increased sensitivity of the method. On the other hand, the accuracy of the method decreased apparently when more than 5 cm^3 of borohydride was used. Because of these limitations, 5 cm^3 of 5% w/v sodium borohydride was used throughout this study in view of sensitivity and accuracy of the method.

Flow Rate of the Auxiliary Nitrogen. The flow rate of auxiliary nitrogen, which was made to flow through the reaction vessel, was chosen to be 0—5 dm^3 min^{-1}. With increase of the flow rate of nitrogen, the peak height of tellurium decreased gradually. Therefore, nitrogen was made to flow through a bypass after the removal of oxygen from the system. No significant difference in sensitivity appeared between nitrogen-hydrogen flame and argon-hydrogen flame.

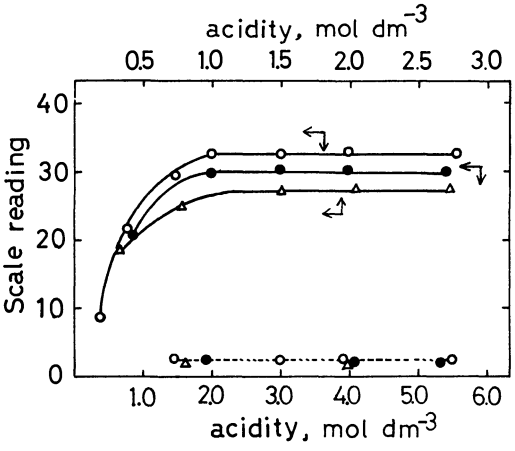

Fig. 2. Effect of acids on the sensitivity.

-○- HCl, -●- HNO_3, -△- H_2SO_4.
Broken line indicates blank values for acids.

Effect of Acid. The sensitivity of this method was examined with use of a borohydride solution in hydrochloric acid, nitric acid, or sulfuric acid. The results are shown in Fig. 2. The absorption peaks of tellurium are slightly less in the cases of nitric acid and sulfuric acid media than in the case of hydrochloric acid medium, but in each case constant signals were obtained in the acid concentration range 2—5.5 mol dm^{-3}.

When the reaction vessel was replaced by a small one (vol 50 cm^3), the difference in peak height decreased, almost the same signal being obtained in hydrochloric acid and nitric acid media.

Volume of Solution in the Reaction Vessel. The efficiency of the reduction of tellurium(IV) to tellurium hydride decreased almost linearly with increase of the volume of solution in the reaction vessel from 10 to 50 cm^3; *e.g.*, the peak height of 0.25 μg of tellurium in 50 cm^3 was about one fourth of that in 10 cm^3. Therefore the volume of sample solution was chosen to be 20 cm^3 in order to attain best detection limit and precision of the method.

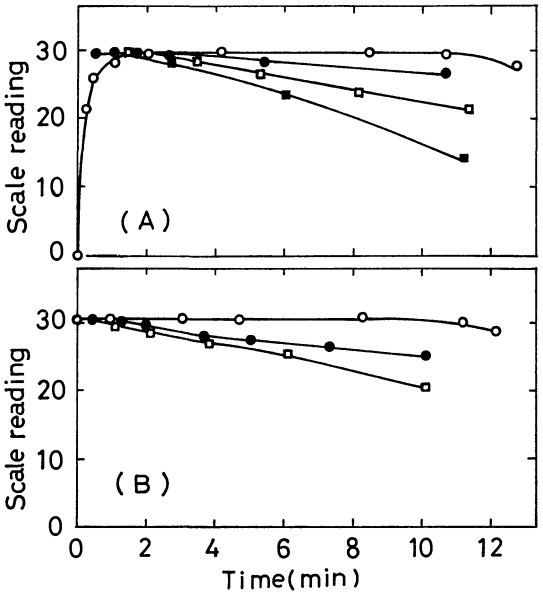

Fig. 3. Effect of the amount of titanium(III) chloride as a function of prereduction time.

Addition of Titanium(III) Chloride as a Prereductant of Tellurium(VI). Tellurium(VI) could not be reduced to tellurium hydride with borohydride alone (Fig. 3). Reduction of tellurium(VI) was carried out satisfactorily by the use of titanium(III) chloride together with borohydride. However, the peak height changes apparently with the concentration of titanium chloride(III) and prereduction time. In order to attain constant reduction of tellurium(VI) to tellurium(IV), the concentration of titanium(III) chloride and prereduction time, time from addition of the reagent to the injection of borohydride solution, were examined. The results are shown in Fig. 3. More than 120 s of prereduction time is required to obtain constant peak height when 1 cm^3 of 5% w/v titanium(III) chloride is used. When 2 cm^3 of 5% w/v titanium(III) chloride is used together with borohydride, almost constant peak height is obtained within 20—120 s of prereduction time. The peak height of tellurium is reduced considerably with increase in the volume of titanium(III) chloride and the prereduction time. This suggests that tellurium(VI) is reduced gradually to tellurium(0) *via* tellurium(IV) by titanium(III) chloride and precipitates in the reaction vessel. The same phenomenon is observed for tellurium(IV) as shown in Fig. 3. Within 90 s of prereduction time, addition of 2 cm^3 of 5% w/v titanium(III) chloride to the acidic tellurium(IV) solution before addition of borohydride solution does not reduce the peak height and gives satisfactory result.

Differential Determination of Tellurium(IV) and Tellurium(VI). Figure 3 suggested the possibility of differential determination of tellurium(IV) and tellurium(VI). Tellurium(IV) was determined by reduction with borohydride alone, and total amount of tellurium was determined by the reduction of tellurium using 2 cm^3 of 5% w/v titanium(III) chloride for one min, followed by addition of 5% w/v sodium borohydride. The results are shown in Fig. 4, in which total amount of tellurium is kept 0.4 μg and the mixing degree of tellurium(IV) and tellurium(VI) is varied. Tellurium(IV) can be determined regardless of tellurium(VI) by borohydride alone as a reductant.

a) The following ions does not influence in excess amount (2500 μg): Na, K, Mg, Ca, Sr, Ba, Zn(II), Cr(III), Al(III), Fe(III), Mo(VI), Mn(II), V(V), SO_4^{2-}, NO_3^-, $C_2O_4^{2-}$, Br^-, SiO_3^{2-}, CH_3COO^-, ClO_4^-; Te(IV) 0.25 μg/3 mol dm^{-3}–HCl, 20 cm^3; 5% w/v $NaBH_4$, 5 cm^3. b) 20% KI, 1 cm^3, prereduction: 5 min. c) 5% w/v $TiCl_3$, 2 cm^3. d) 5% $TiCl_3$, 1 cm^3+0.5 g Mg, 6 mol dm^{-3} HCl. e) No influence.

ions on the determination of tellurium(IV) is given in Table 2. When borohydride alone is used as a reductant, relatively large interference arises in the order: arsenic(III)>silver(I)>mercury(II)>bismuth(III)>selenium(IV), antimony(III)>arsenic(V), copper(II), and nickel(II). Various reductants were used together with borohydride in order to eliminate the interference. Tin(II) chloride cannot be used because of uncorrectable background absorption. Potassium iodide is useful for eliminating the interference of some coexisting ions, especially selenium(IV); coexisting 200 fold of selenium(IV) *vs.* tellurium(IV) does not interfere when 2 cm^3 of 20% w/v potassium iodide is used as a prereductant (5 min of prereduction time). Titanium(III) chloride is also useful for eliminating the interference of selenium(IV) (Table 2).

Titanium(III) chloride–magnesium system[13] was also reexamined as regards the generation of tellurium hydride, and the results were compared with that of titanium(III) chloride–borohydride reduction system. Granular magnesium, wrapped in a wafer sheet, was added to sample solution containing titanium(III) chloride (6 mol dm^{-3} hydrochloric acid). The effect of diverse ions on the determination of tellurium is almost the same in these two reduction systems. However, reduction of tellurium by borohydride is superior to titanium(III) chloride–magnesium system in sensitivity, reproducibility, and handling.

In each reduction system, anions listed in Table 2 do not interfere in 10000 fold excess of tellurium in the determination.

Detection Limit and Precision of the Method. Calibration curves for tellurium(IV) determination by borohydride reduction and for tellurium(VI) by titanium(III) chloride–borohydride reduction are both linear up to 0.8 μg of tellurium. The coefficients of variation in the determinations of 0.25 μg tellurium(IV) and the same amount of tellurium(VI) were 2.4% and 2.9%, respectively. Detection limit of the method is 8 ng (S/N=2).

Determination of Tellurium in Steel. Prior to application of the method, the effect of iron(III) matrix on the determination of tellurium was examined (Fig. 5). Iron(III) does not interfere up to 40 mg *vs.* 0.25 μg of tellurium(IV) by sodium borohydride, or 0.25 μg tellurium(VI) by titanium(III) chloride–sodium borohydride reduction system. No separation or preconcentration technique is required for the determination of ppm level of tellurium in iron matrix, if there is no other interfering ion. The standard steel was dissolved by the following procedure; 0.1 g steel was weighed precisely in a 50 cm^3 beaker. After addition of 3 cm^3 of hydrochloric acid and 1 cm^3 of nitric acid, the mixture was heated on a water bath, and the steel was dissolved. The solution was diluted to 50 cm^3 with water in a measuring flask after cooling. A prescribed volume of this solution was transferred to the reaction vessel and determination was carried out by means of the titanium(III) chloride–borohydride reduction(Table 3). The procedure could be completed within 30 min. Almost the same results were obtained in the standard addition and calibration curve techniques.

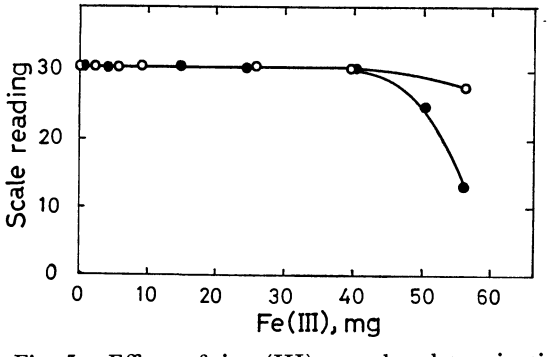

Fig. 5. Effect of iron(III) on the determination of tellurium.
-○- Te(IV) 0.25 μg/3 mol dm^{-3} HCl, 5% w/v $NaBH_4$, 5 cm^3. -●- Te(VI) 0.25 μg/3 mol dm^{-3} HCl, 5% w/v $TiCl_3$, 2 cm^3 (prereduction time, 40 s) 5% w/v $NaBH_4$, 5 cm^3.

Determination of Tellurium in Sulfur. The proposed technique was also applied to the determination of tellurium in commercial reagent sulfur. The results are given in Table 4. The modified procedure of Arikawa[12] was used: Sulfur powder (*ca.* 0.1 g) was weighed in a teflon beaker; 5 cm^3 of 3 mol dm^{-3} sodium hydroxide solution was added, and the mixture was heated on a hot plate (*ca.* 150 °C) in order to dissolve the powder. After cooling, 20 cm^3 of water was added, followed by 4 cm^3 of 30% w/v hydrogen peroxide solution to oxidize sulfur to hexavalent (tellurium is also oxidized to hexavalent). Excess hydrogen peroxide was then decomposed by careful heating. Finally, 10 cm^3 of hydrochloric acid was added, and the solution was diluted to 100 cm^3 with

water. An adequate volume of the solution was transferred to the vessel and the tellurium was determined by titanium(III) chloride–borohydride reduction system (2 cm^3 of 5% w/v titanium(III) chloride for 1 min of prereduction time). Though the titanium(III) chloride–borohydride reduction system cannot be applied to sulfuric acid medium, the presence of 2 mmol sulfuric acid in 3 mol dm^{-3} hydrochloric acid caused no interference. The standard addition technique and calibration technique gave almost the same results.

Curve Fitting Methods Applied to the Elucidation of Asymmetric Gas-Liquid Chromatographic Peaks

Koji TAKEUCHI and Tomihito KAMBARA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 8, 1978)

It was shown that the shape of gas-liquid chromatographic peak is expressed by the Gaussian distribution multiplied by a higher order algebraic equation of time. Application of the curve fitting methods, *i.e.*, the Newton's divided-difference formula and the orthogonal polynomials method, could well clear up the experimentally observed gas-liquid chromatograms of trailing and leading types, respectively. The asymmetric shapes of gas-liquid chromatographic peaks are attributed to the slowness of vaporization or dissolution in the partition process.

Although one observes in general the trailing type peaks in gas-solid adsorption chromatography, in gas-liquid partition chromatography the peaks of trailing and leading shapes[1–3] are observed at higher and lower column temperatures, respectively.

As to the asymmetric shapes of gas chromatographic peaks, there has been given only a qualitative explanation that the partition isotherm of a solute component between the mobile and stationary phases is nonlinear, as described in the several monographs.[4–6] A mathematical model for nonlinear partition based on the numerical solution by means of computer was proposed.[7] The theory by Schmauch[8] explains only the leading type peak, and on the contrary the papers by the Littlewood school[9,10] and others[11,12] deal with only the trailing peak expressed as the convolution of exponential decay constant. The derivative method for gas chromatograph developed by Saitoh *et al.*[2,13–17] is not only very useful in trace analysis but also gives important knowledges about the asymmetric shapes.

It is pointed out that the rate of vaporization is slow at lower temperature and on the other hand the rate of dissolution into stationary phase becomes too small at higher temperature, hence the partition equilibrium does hold no more. In this case a new theory dealing with the kinetically irreversible partition process between both phases is required.

As reported in our previous paper[18] the asymmetric gas-liquid chromatographic peaks are expressed by the series consisting of the Gaussian distribution G and its derivatives. In this paper the familiar curve fitting methods are applied to the mathematical analysis of the experimentally observed gas-liquid chromatograms of leading and trailing shapes.

Theoretical

The system of differential equations given by Kambara and Ohzeki[19] is as follows:

$$F\frac{\partial C}{\partial t} = -F\frac{\partial}{\partial x}\left(-\frac{D^*}{P}\frac{\partial C}{\partial x}+uC\right) + \alpha(K^{-1}C_s - C) \quad (1)$$

$$F_s\frac{\partial C_s}{\partial t} = -\alpha(K^{-1}C_s - C) \quad (2)$$

Equations 1 and 2 represent the concentration changes of the injected solute with time in the mobile and stationary phases, respectively. The meanings of symbols are summarized in Table 1. When the column temperature is lower than the optimum temperature, the rate of vaporization $\alpha K^{-1} C_s$ may be much smaller than that of dissolution αC. On the contrary, αC may be much smaller compared with $\alpha K^{-1} C_s$ at higher temperature. It is thus considered that the partition equilibrium would not hold at the column temperature much higher or lower than the optimum one.

The approximate solution of Eqs. 1 and 2 has been already presented as[19]

$$C(l, t) = \frac{p_o C_0 t_0}{p_l\sqrt{2\pi}\sigma}\exp\left\{-\frac{(t-t_R)^2}{2\sigma^2}\right\}. \quad (3)$$

On the basis of this expression the dependences of HETP on the flow rate of carrier gas,[20] on the column temperature[21] and on the column length[22] are elegantly clarified. For the convenience of the following treatment, one writes

$$\frac{p_o C_0 t_0}{p_l} = A, \quad (4)$$

$$t - t_R = \xi, \quad (5)$$

$$G(\xi) = \frac{1}{\sqrt{2\pi}\sigma}\exp\left(-\frac{\xi^2}{2\sigma^2}\right). \quad (6)$$

Therefore, Eq. 3 can be written as the product of peak area A and the normal or Gaussian distribution $G(\xi)$:

$$C(l, \xi) = AG(\xi) \quad (7)$$

At the appropriate temperature, both the rates of dissolution and vaporization being great, the term in the left-hand side of Eq. 2 is negligibly small compared with the two terms in the right-hand side. Then, one has

$$C_s(l, \xi) = KC = KAG(\xi). \quad (8)$$

Namely, the equilibrium holds at every position in the column. At higher or lower temperature, the concentrations in both phases are no more equilibrated. In this case one should treat the problem kinetically. As derived in our previous paper[18] the outlet concentration is shown by

$$C(l, \xi) = A(G \pm zG^{(1)} + z^2G^{(2)} \pm z^3G^{(3)} + z^4G^{(4)} \pm z^5G^{(5)} + \cdots), \quad (9)$$

where plus sign holds for trailing peak and minus sign for leading peak, respectively.

Furthermore, Eq. 9 can be rewritten in the alternative form. Derivatives of Gaussian distribution $G^{(n)}$ are calculated as

$$G^{(1)} = -\frac{\xi}{\sigma^2}G(\xi) \quad (10)$$

TABLE 1. LIST OF SYMBOLS

Symbol	Meaning	Units
A	peak area	mol s cm^{-3}
a_i	coefficient in Eq. 12	s^{-i}
b	z/σ	dimensionless
C	solute concentration in mobile phase	mol cm^{-3}
$C(l, \xi)$	outlet concentration in mobile phase, dependent on ξ	mol cm^{-3}
C_s	solute concentration in stationary phase	mol cm^{-3}
$C_s(l, \xi)$	outlet concentration in stationary phase, dependent on ξ	mol cm^{-3}
C_0	initial solute concentration injected	mol cm^{-3}
D^*	diffusion constant at unit pressure	cm^2 s^{-1} atm
F	volume fraction occupied by mobile phase	dimensionless
F_s	volume fraction occupied by stationary phase	dimensionless
$G(\xi)$	Gaussian distribution described by Eq. 6	s^{-1}
$G^{(n)}$	n-th derivative of $G(\xi)$	s$^{-(n+1)}$
h	peak height	mol cm^{-3}
K	partition coefficient (C_s/C at equilibrium)	dimensionless
l	column length	cm
p	pressure of carrier gas dependent on x	atm
p_1	pressure of carrier gas at column inlet	atm
p_0	pressure of carrier gas at column outlet	atm
R	skew ratio	dimensionless
t	time elapsed after solute fed	s
t_R	retention time of solute component	s
t_0	duration of concentration pulse injected	s
u	linear gas velocity dependent on x	cm s^{-1}
x	distance from inlet along the column	cm
y	a function expressed by $C(l, \xi)/AG(\xi)$	dimensionless
z	F_sK/α	s
α	rate constant of dissolution of solute	s^{-1}
σ^2	peak variance	s^2
ξ	time measured from retention time defined by Eq. 5	s

$$G^{(2)} = \frac{1}{\sigma^2}\left(\frac{\xi}{\sigma^2} - 1\right)G(\xi). \tag{11}$$

Insertion of these derivatives into Eq. 9 gives the following Eq. 12 in which the elution profile $C(l, \xi)$ is a product of $AG(\xi)$ and a high-order algebraic equation of ξ.

$$C(l, \xi) = AG(\xi)(a_0 + a_1\xi + a_2\xi^2 + a_3\xi^3 + a_4\xi^4 + a_5\xi^5 + \cdots) \tag{12}$$

The coefficient a_i (i=0, 1, 2, $\cdots$) is given by

$$\begin{aligned} a_0 &= 1 - b^2 + 3b^4 - \cdots \\ a_1 &= \pm\sigma^{-1}(b - 3b^3 + 15b^5 - \cdots) \\ a_2 &= \sigma^{-2}(b^2 - 6b^4 + 45b^6 - \cdots) \\ a_3 &= \pm\sigma^{-3}(b^3 - 10b^5 + 105b^7 - \cdots) \\ a_4 &= \sigma^{-4}(b^4 - 15b^6 + 210b^8 - \cdots) \\ a_5 &= \pm\sigma^{-5}(b^5 - 21b^7 + 378b^9 - \cdots) \end{aligned} \tag{13}$$

where

$$b = \frac{z}{\sigma} \tag{14}$$

Thus, a theoretical expression for the asymmetric elution profiles in partition chromatography is shown by Eq. 9 or 12, which is reduced to Eq. 3 when z tends to zero.

According to Eq. 12, $C(l, \xi)$ divided by $AG(\xi)$ is defined as

$$y = \frac{C(l, \xi)}{AG(\xi)} = a_0 + a_1\xi + a_2\xi^2 + a_3\xi^3 + a_4\xi^4 + a_5\xi^5 + \cdots \tag{15}$$

Experimental

Reagents and Apparatus. Helium was used as the carrier gas. Benzene and diethyl ether (Wako Pure Chemicals Co.) were used as solute and diluent, respectively. A Hitachi gas chromatograph, Model 063, with a flame ionization detector was employed. The output current of FID was amplified and then recorded with a Hitachi 056 recorder. The packing of 25% dinonyl phthalate on 60/80 mesh Shimalite supplied by Shimadzu Seisakusho Ltd. was packed into a stainless steel column of 4 mm i.d. and 1 m in length. A soap-film flowmeter was used for the measurement of flow rate.

The column temperature was varied in the range of 45.7—93.0 °C and maintained within ±0.1 °C of the set temperature. The temperatures of injection port and detector were fixed at 105 °C. Carrier gas flow rate was adjusted to 30.0±0.3 ml min^{-1}.

The solute amount smaller than 0.8 μl was confirmed to have no effect on the number of theoretical plates for benzene. Therefore, a 5-μl portion of benzene diluted 10-fold with diethyl ether was injected. The gas chromatograms are reproduced in Fig. 1.

Estimation of t_R and σ. The apparent retention time as measured at the peak maximum depends slightly on the solute amount fed when the column temperature deviates from the optimum one. The chromatograms with varying amounts of

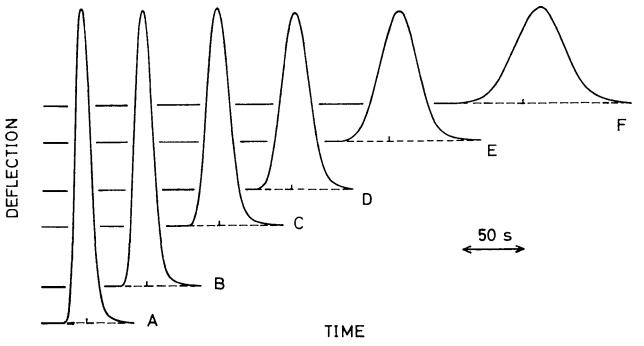

Fig. 1. Gas chromatograms of benzene at various temperatures. Sample size injected was 0.5 μl and detected by FID. Each peak was corrected for the temperature dependence of detector sensitivity to have the same peak area. Column temperature: A 93.0, B 83.3, C 74.1, D 64.8, E 55.0, F 45.7 °C. The mark on the base line indicates the corrected retention time. The other data are shown in Table 5.

benzene smaller than 0.5 μl were accurately superimposed on the one with 0.5 μl so as to give the true retention time. Retention time was determined by extrapolating the solute amount to zero, *i.e.*, at the point on which the line connecting the maxima of the peaks intersects the base line, as Fig. 2 shows.

The standard deviation σ, namely, the square root of the peak variance needs to be estimated. It was presumed that the quantity 2σ is given by the peak width at the peak height of $e^{-1/2} \cdot h$, where h is the maximum peak height. Peak area A was calculated by the so-called trapezoidal rule with the known $C(l, \xi)$ values at equi-spaced points. Skew ratio R is defined as the ratio of the slopes of tangents at the inflection points on both sides of the peak,[24] and calculated for each chromatogram as a measure of asymmetry.

Curve Fitting Methods. The mathematical expression for the experimentally observed y-function shown by Eq. 15 was determined by means of the familiar curve fitting methods. One is the Newton's divided-difference formula[25] and the other is the orthogonal polynomials.[25,26] The former is one of the interpolation formula which is advantageous in treating with a curve of the complicated form such as the results observed at higher temperatures (curves d and d′ in Fig. 2). The latter is the most general method of curvilinear regression by the method of least squares and suitable for the simple and monotone function as seen in the case obtained at lower temperatures (curves c and c′ in Fig. 2). Another advantage of the orthogonal polynomials is that one can easily decide what order of polynomials should be statistically significant when the analysis of variance table is constructed. The algebraic equations determined are plotted and this operation is repeated until the satisfactory fitting is confirmed.

Results and Discussion

The theoretical elution profiles were calculated with the derivative series including the fifth order derivative shown by Eq. 9, as reported before. When the value z was smaller than 0.45σ, Eq. 9 was found to fit well. A symmetric Gaussian peak is obtained when $z=0$ and the distortion of peak becomes more remarkable with increasing value of z. Skew ratio R was evaluated as 1.06 (leading), 0.94 (trailing) with $z=0.40\sigma$; 1.68 (leading), 0.60 (trailing) with $z=0.45\sigma$. With z-value greater than 0.45σ, Eq. 9 represents an inadequate curve, the concentration $C(l, \xi)$ showing negative values at the feet of the peak.

Thus Eq. 9 was confirmed to express well the asymmetric curves of both leading and trailing types. Furthermore, another verification of Eq. 9 with experimental chromatograms was attempted. Chromatograms with varying solute amounts of 0.1—0.5 μl were carefully superimposed on a chart. Figure 2 shows the typical leading and trailing chromatograms of benzene and the mathematical analysis of y-function.

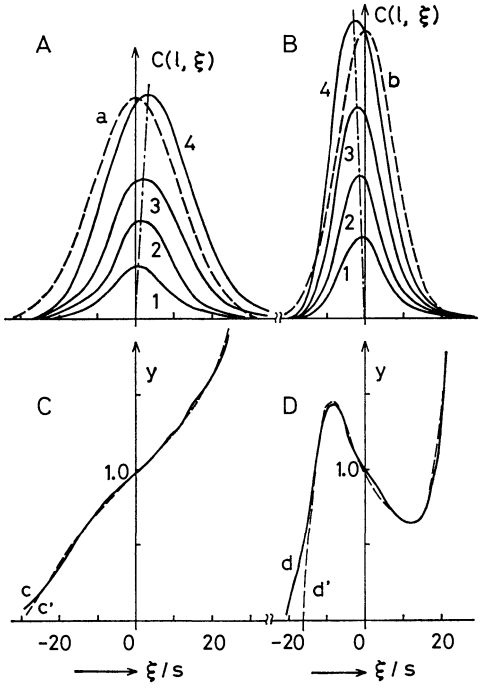

Fig. 2. Comparison of the experimentally recorded leading (curves A, 64.8 °C) and trailing (curves B, 83.3 °C) gas chromatograms of benzene (solid line) with the Gaussian peaks of the same σ-values (dashed line, curves a and b). The amount of benzene injected: 1 0.1, 2 0.2, 3 0.3, 4 0.5 μl. Curves C and D show the y-functions given by Eq. 15. Curves c and d (solid line): experimental value; curves c′ and d′ (dashed line): calculated value.

With increasing solute amount injected, the apparent rentention time of the peak maximum becomes longer in the case of leading peak, and on the contrary, it becomes shorter in the case of trailing peak (A and B in Fig. 2). The values of t_R, σ, and A were evaluated and the curves $AG(\xi)$ (dashed line, a and b in Fig. 2), which might be considered as a well-equilibrated elution profile of Gaussian type, were plotted for reference. The ratio of $C(l, \xi)$ to $AG(\xi)$ defined as y in Eq. 15 was then evaluated from experimental data (solid line, curves c and d in Fig. 2). The theoretical equations for these experimentally obtained y-functions were determined by the curve fitting methods (dashed line, curves c′ and d′). In the case of data at 83.3 °C, the Newton's divided-difference formula was applied as shown in Table 2. Several characteristic points including maximum, mini-

$\sum P_iy$		27.0442	106.0365	124.5588	87.2792	695.9422	173.0

a) Data of 64.8 °C, sample number $n=27$, sample space $h=2$. b) Values of orthogonal polynomials (P_i), its sum of squares (a_{ii}) and coefficient (λ_i) are quoted from Ref. 26. $\beta_i=\frac{\lambda_i\sum P_iy}{a_{ii}}$, $P_0(d)=1$, $P_1(d)=d$, $P_2(d)=d^2-\frac{1}{12}(n^2-1)$, $P_3(d)=d^3-\frac{1}{20}(3n^2-7)d$, $P_4(d)=d^4-(3n^2-13)d^2+\frac{3}{560}(n^2-1)(n^2-9)$, $P_5(d)=d^5-\frac{5}{18}(n^2-7)d^3+\frac{1}{1008}(15n^2-230n^2+407)d$ where $d=\frac{\xi-\bar{\xi}}{h}$. The regression equation is given by $y=\beta_0P_0(d)+\beta_1P_1(d)+\beta_2P_2(d)+\beta_3P_3(d)+\cdots$ Thus, in this case, the following regression equation is obtained.
$y=0.9900+0.02458\xi-1.481\cdot10^{-4}\xi^2+1.786\cdot10^{-5}\xi^3+4.495\cdot10^{-7}\xi^4$.

mum and inflection points are picked up and the difference between the adjacent y values is divided by the difference in ξ. Upon repeating this calculation, the interpolation equation is obtained as shown in Table 2.

In the case of data at 64.8 °C, the method of orthogonal polynomials was applied and the result is given in Table 3. In the calculation table the values of orthogonal polynomials P_i are cited, and the values of y, y,^{2} and P_iy are evaluated from the experimental data. Then the product of the coefficient λ_i and $\sum P_iy$ is divided by a_{ii} to give β_i which is the coefficient of the orthogonal polynomial of i-th order. The orthogonal polynomials can be added to an arbitrary higher order until the satisfactory fitting is obtained. The analysis of variance table given in Table 4 shows that for the data of 64.8 °C the fifth order polynomial is not significant since the sum of squares contributed by the fifth order term is smaller than the residual. Therefore, the use of polynomials until fourth order is sufficient in this case.

An excellent agreement between the experimental

values and the calculated y-function was seen in Fig. 2. This treatment shows that curves c and d were fourth and fifth order algebraic equations of ξ, respectively. The deviations in the feet of a peak where the absolute value of ξ is large, may be caused by the measuring error.

Thus, the actual chromatograms of leading and trailing types were found to be reasonably expressed by Eq. 12. Consequently, the present theoretical treatment can well clear up the asymmetric peak shapes. The results successfully obtained by the curve fitting methods for chromatograms at various temperatures were tabulated in Table 5.

The retention time as well as the standard deviation decreases with increasing temperature. Although the skew ratio R also decreases with increasing temperature, it lies at about 0.87 at the optimum temperature of 73.7 °C, deviating a little from unity. As for the coefficients in Eq. 12, the first term a_0 shows its maximum value near the optimum temperature, since the degree of symmetry is mainly governed by a_0.

Development of the Kinetic Theory. Proposal of the present theory is quite similar to the development of the polarographic theory. In 1935 Heyrovsky and Ilkovic postulated the dynamic equilibrium of oxidant and reductant concentrations at the surface of dropping mercury electrode depending on the potential. Thus they succeeded in elucidating the reversible wave, as described in several monographs.[27–29] Later in 1950's several kinetic theories were proposed dealing with the irreversible reduction in which the concentrations of oxidant and reductant are not equilibrated at the electrode surface.

Thanks are due to Dr. Kunio Ohzeki for his kind discussions.

Measurement of Ambient Nitrogen Oxides over an Extended Period of Time by Means of a Solid Absorber Technique

Takashi YASUOKA* and Shunmei MITSUZAWA

Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka 259-12

(Received October 27, 1978)

A new technique using a solid substance for the absorption of nitrogen oxides in the atmosphere was developed in order to obtain an average concentration of nitrogen oxides over a period of several weeks. Nitrogen oxides is absorbed by an absorbent (alkaline earth metal peroxide), and the nitrate produced in the absorber is extracted into water to determine the amount of nitrate by the ion-selective electrode method. The concentration of atmospheric nitrogen oxides is calculated from the amount of nitrate in the extract. A quantitative relation was found between the amount of nitrogen oxides collected on the absorber and that of nitrate in the extract. Hydrogen peroxide produced by the reaction of the absorber and water did not interfere with the measurement of nitrate by the ion-selective electrode technique. Practicability of this technique was demonstrated in comparison with the automatic recording analyzer (NO_x meter) with the Saltzman reagent.

Liquid absorber techniques using absorption bottles and impingers are the most popular and convenient for analysis of gaseous pollutants in the atmosphere.[1,2] These methods are suitable for obtaining hourly or short term concentrations of air pollutants. However, they require a tedious averaging process for weekly or monthly averages. A filter paper impregnated with some reagents can also be used for sampling gaseous pollutants, such as fluorides, sulfur dioxide and nitrogen dioxide, but no report seems to have apeared on the measurement of nitrogen oxides by this method. Cuddeback *et al.*[3] reported on the use of copper shot for the collection of nitrogen dioxide, but the sampling time of this method is 24 h or less. Measurement of average concentration over a long duration of time is often necessary for practical purposes such as the biological evaluation of air pollution and studies of the corrosion of metals.

In this investigation, we attempted to develop a technique to obtain an average concentration of nitrogen oxides over a period of several weeks, using a solid substance for the absorption of nitrogen oxides in the atmosphere. Peroxides of alkaline earth metals were chosen as absorbents since (1) they absorb nitrogen dioxide and (2) they oxidize the nitrogen oxide to dioxide in the presence of humidity and the resulting nitrogen dioxide is absorbed. The nitrate produced in the absorber is extracted into water for determination of the amount of nitrate by the ion-selective electrode method. The concentration of nitrogen oxides in the air can be calculated from the concentration of nitrate.

Experiments were carried out to study the possible interference by hydrogen peroxide in the determination of nitrate, to determine the capacity of the peroxide agents in the absorption of nitrogen oxides, and to examine relevant parameters. Among the peroxides of alkaline earth metals, barium peroxide was found to be the most suitable, and was rested over a period of two weeks. The practicability of this technique was demonstrated in comparison with the automatic recording analyzer (NO_x meter) with the Saltzman reagent.

Experimental

Apparatus and Reagents. Ion-selective electrode for nitrate: Type 93-07 (Orion Co.) electrode was used and the electrode potential was measured with a pH-mV meter (Type M-5, Hitachi-Horiba Co.) against a reference electrode, type 90-02 (Orion Co.), which has a double-junction reference electrode filled with the Orion filling solution (Cat. No. 90-00-02) in the inner chamber. The response of the (pH-mV) meter was recorded on a QPD-54 recorder (Hitachi Co.).

Absorbents for nitrogen oxides: Magnesium peroxide (Kyowa-Kagaku Co.) and commercial calcium peroxide, strontium peroxide and barium peroxide of the first grade were used. They were formed into tablets of $3\phi \times 5$ mm.

Autoanalyzer of nitrogen oxides: Type GP-5B, Denki-Kagaku-Keiki Co. using the Saltzman reagent.

Calibration Curve. The calibration curve of nitrate concentration was made with potassium nitrate (1—100 ppm). Calibration curves were prepared for each absorbent (MgO_2, CaO_2, or SrO_2) by dissolving 5 g of each in water and then adding a fixed amount of nitrate to the solution followed by dilution to 50 ml with water. A series of standard solutions thus prepared were passed through a filter paper to remove the peroxide and oxide from the solution, and the nitrate and a small amount of hydroxide of alkaline earth metals produced in the absorbent during the sampling were filtered off. 2 ml of 2M-$(NH_4)_2SO_4$ and 1 ml of 1M-H_3BO_3 were then added to the filtrate in order to adjust the ionic strength and to keep the stability of the nitrate in the measurement by an ion-selective electrode.[4] For the standard solution with barium peroxide, a procedure to remove the barium ions was necessary before the addition of $(NH_4)_2SO_4$ and H_3BO_3. For this purpose, excess 2M-$(NH_4)_2SO_4$ (2 ml) was added to the solution and the resulting $BaSO_4$ was filtered off. The volume of the solution was then made to 50 ml by adding water, with the addition of 1M-H_3BO_3 for the measurement of nitrate.

Capability Tests of Absorbents. The 1 ppm nitrogen dioxide gas was prepared by the nitrogen dioxide permeation tube technique with clean air, and the 1 ppm nitrogen oxide was prepared by the dilution of 50 ppm nitrogen oxide from the tank with clean air. Concentrations of these gases were measured with an automatic recording spectrometer using the Saltzman reagent. The amount of absorption of nitrogen oxide and nitrogen dioxide was determined by the difference in concentrations of these gases in the air flow before and after exposure to the absorbents, and the amount was compared with that of nitrate measured by the ion-selective electrode technique.

Results and Discussion

Calibration Curve. The calibration curves of nitrate for each absorbent are shown in Fig. 1. The

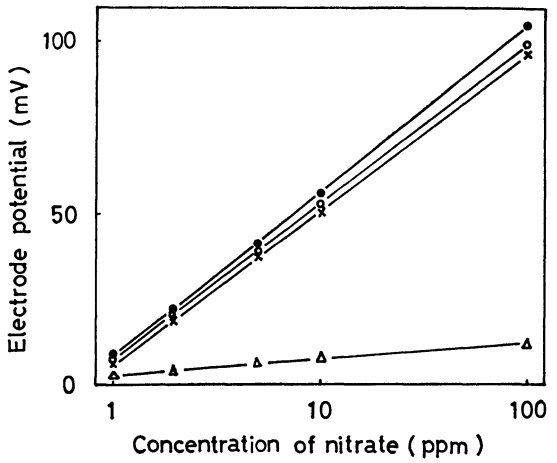

Fig. 1. Calibration curve of nitrate with each absorbent.
●: BaO_2, ○: CaO_2, ×: MgO_2, △: SrO_2.

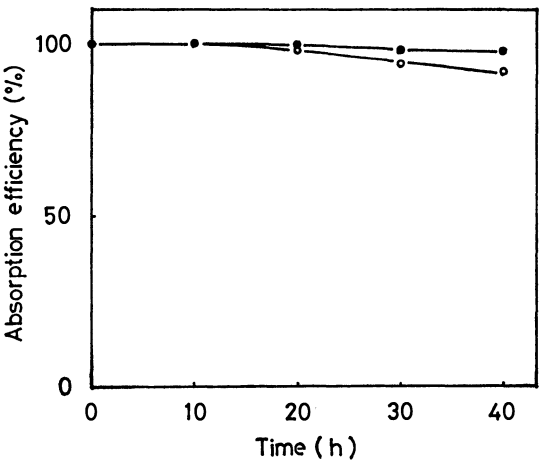

Fig. 2. Change in absorption efficiency of barium peroxide with time.
Weight of absorbent: 5 g, temperature: 25 °C, relative humidity: 50%, flow rate of gas: 300 ml/min.
Concentration of nitrogen oxide and dioxide: 1 ppm each.
●: NO_2, ○: NO.

sensitivity of nitrate measurement varies with peroxide, the order of sensitivity being $BaO_2 > CaO_2 > MgO_2 > SrO_2$. BaO_2, CaO_2, MgO_2 can be used, but BaO_2 was chosen for practical use because of its longer life as compared to that of the other peroxides.

Effect of Hydrogen Peroxide on the Nitrate Measurement by Ion-selective Electrode. Hydrogen peroxide is produced by dissolving the alkaline earth metal peroxides in water in a reaction as follows.

$$MO_2 + 2H_2O = M(OH)_2 + H_2O_2$$

where M denotes the atom of alkaline earth metal. The possible interference of hydrogen peroxide on the nitrate solutions of 10 and 100 ppm was examined by the addition of 30% hydrogen peroxide. The electrode potential generated by nitrate ions was not affected by hydrogen peroxide in the range 0.001—0.1%. This indicates that the influence of hydrogen peroxide is negligible in a solution containing 10—20 ppm of hydrogen peroxide. Kuroda endorsed this by an experiment in which he used a hydrogen peroxide solution containing phosphoric acid in the sampling of nitrogen oxides in the analysis of gaseous industrial effluents.[5] He reported that the presence of hydrogen chloride and sulfur dioxide does not interfere with analysis of nitrogen oxides. No examination of the interferences was carried out.

Absorption of Nitrogen Oxides by Barium Peroxide. The time variation of the absorption efficiency of nitrogen oxides to barium peroxide is shown in Fig. 2. Nitrogen oxide and dioxide each of concentration 1 ppm and 5 g of barium peroxide were used. The absorption efficiency of nitrogen dioxide did not change throughout 40 h, but that of nitrogen oxide decreased slightly with time, being higher than 90% after 40 h. The decrease of absorption might be attributed to a decrease in the power of the peroxide to oxidize the nitrogen oxide to dioxide.

It has been shown that 50 g of barium peroxide can remove more than 90% of nitrogen oxide from the air one month under sampling conditions of flow rate 300 ml/min and relative humidity<40%.[6] The absorption capacity of barium peroxide was demonstrated by the removal of nitrogen oxides from the air at the air inlet of an automatic NO_x meter; 50 g of barium peroxide showed complete removal of nitrogen oxides of background levels for two weeks. If an alkaline layer is placed before the peroxide layer, the former absorbs only nitrogen dioxide and the latter only nitrogen oxide. This could be utilized in a simultaneous measurement of nitrogen oxide and dioxide.

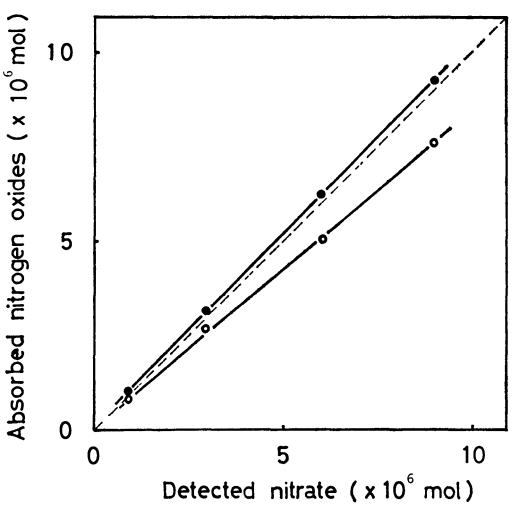

Fig. 3. Comparison of the amounts of absorbed nitrogen oxides and detected nitrate.
●: NO_2, ○: NO.
(Dotted line shows an ideal equivalent line.)

Relations between the amount of nitrogen oxides measured by NO_x meter and that of nitrate measured by the ion-selective electrode are shown in Fig. 3, where the amount of nitrate is 20% higher than that of nitrogen dioxide. The difference might be caused by the lower estimation of nitrogen oxide by the NO_x meter resulting

from the low oxidation efficiency of the $KMnO_4$–H_2SO_4 solution. If the low efficiency (80%) is corrected, the ratios of the amount of absorbed nitrogen oxides to the amount of nitrate measured by use of the peroxide become almost 1 both for nitrogen oxide and dioxide (Fig. 3). The amount of nitrogen oxides was controlled by changing the absorption time, keeping the concentration of nitrogen oxides constant.

Table 1. Comparison of data obtained by the solid sampling technique and by NO_x according to the conventional method

Date	From '78 Jan. 1st till '78 Jan. 14th		From '78 Jan. 15th till '78 Jan. 28th	
Analytical method	Solid absorbent method	Auto-analyzer	Solid absorbent method	Auto-analyzer
Concentration of NO_x in the atmosphere	0.061	0.048	0.052	0.045

Comparison of the Present Method with an Automatic NO_x *Meter.* Tests of our technique were made by setting up the barium peroxide samplers and an automatic recording analyzer for nitrogen oxides by absorption spectrometry with the Saltzman reagent for field measurements. These apparatus were operated together for two weeks, and data obtained from them were compared. Average concentrations of nitrogen oxide and dioxide during two weeks were calculated from the hourly values by the NO_x meter. The peroxide absorbent was pulverized in a mortar; 5.0 g out of the 50 g absorber was treated by the same procedure as that for the preparation of the calibration curve. The average concentrations during this period, in the first half and the latter half of January in 1978, were 0.061 and 0.052 ppm by the present method, and 0.048 and 0.045 ppm by the NO_x meter. If corrections owing to the low conversion efficiency of nitrogen oxide to dioxide were made on the latter, the data by NO_x meter would be 0.054 and 0.051. Real comparison would not be made in this way, but the concentrations obtained by the present technique are close to those by the NO_x meter. Advantages of the solid absorber technique are: (1) the size of sampling device is small, convenient for transport, (2) preparation and handling of the sampling tube is simple, (3) adjustment of the flow rate is simpler than that in the bubbling system, the shape and grain size of the peroxide being unchanged throughout the sampling period.

Conclusion

In a long run measurement, the average concentration of the nitrogen oxides can be obtained by a simple technique using a solid absorber of barium peroxide. The measurement was made by means of nitrate determination in the peroxide absorber by the use of an ion-selective electrode technique. Since the sensitivity of the ion-selective electrode, which requires 50 ml of an aliquot, is 1 ppm for the solution to be measured, the practical sensitivity of this technique for nitrogen oxides determination is 10^{-6} mol. No special cases or adjustments were required in two weeks sampling. The values of concentration of nitrogen oxides in the atmosphere were very close to those found by the NO_x meter. Advantages of this solid absorber technique are simplicity in operation and stability of air flow rate in sampling.

The Halomercury(II)-assisted Aquation of the Bromopentacyanocobaltate(III) Anions

Masayasu IIDA* and Hideo YAMATERA**

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
***Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464*

(Received November 8, 1978)

The aquation of the bromopentacyanocobaltate(III) ion was carried out in the presence of several kinds of hard acids or halomercury(II) complexes. The hard acids(H^+, Na^+, and Mg^{2+}) had small effects, while the addition of mercury(II) halides significantly accelerated the aquation. The effect of mercury(II) halides was attributed to the monohalomercury(II) cations, which were formed in a small amount by the dissociation of the dihalomercury(II) complexes. The effect of the dihalomercury(II) complexes was also studied in the presence of an excess of sodium halide. The rate constant for halomercury(II)-assisted aquation was expressed by:

$$k_{obsd} = k_0 + k_1[HgX^+] + k_2[HgX_2], \quad X^- = Cl^-, Br^-.$$

The values of k_1 and k_2 obtained ($k_1 = 1.6 \times 10^4$ mol^{-1} dm^3 s^{-1}, $k_2 = 1.0$ mol^{-1} dm^3 s^{-1}, for $X^- = Cl^-$; $k_1 = 2.0 \times 10^4$ mol^{-1} dm^3 s^{-1}, $k_2 = 1.6 \times 10^{-1}$ mol^{-1} dm^3 s^{-1}, for $X^- = Br^-$) were compared with the stability constants for the mercury(II) complexes formed by the combination with Br^-.

The metal ion-assisted aquation of halo-cobalt(III) and chromium(III) complexes has been extensively studied, and attempts have been made to correlate the rate constants with the stability constants for the respective halo complexes of the metal ions and with the electrostatic force between the reactants.[1] However, the mechanism of the reaction and the nature of the intermediate are not yet well characterized, and only cationic complexes have hitherto been studied, with a few exceptions.[2] Therefore, studies of the reaction of different types are necessary in order to generalize the reaction mechanism.

In this study, the anionic complex, $[CoBr(CN)_5]^{3-}$, was allowed to aquate in the presence of such metal ions as Na^+, Mg^{2+}, and Hg^{2+} or of the halomercury(II) complexes ($HgCl^+$, $HgBr^+$, $HgCl_2$, and $HgBr_2$). The results will be discussed in the light of those obtained for the halopentaamminecobalt(III) complexes.

Experimental

Materials. *Potassium Bromopentacyanocobaltate(III)*: The complex was prepared by Adamson's method.[3] The visible absorption spectrum of the product agreed with the published data.[3,4] Found: C, 15.39; N, 18.82%. Calcd for $K_3[CoBr(CN)_5]$: C, 15.55; N, 18.13%.

Magnesium Perchlorate Solution: Hydrous magnesium perchlorate, a guaranteed reagent of Wako Pure Chemical Industries, Ltd., was dissolved in a perchloric acid solution ($[HClO_4] = 0.05$ mol dm^{-3}) and was used as the stock solution. The magnesium concentration of this solution was determined by direct titration with EDTA (= ethylenediaminetetraacetic acid), using EBT (= Eriochrome Black T) as the indicator.

Mercury(II) Perchlorate Solution: Mercury(II) oxide was dissolved in a 5-mol dm^{-3} perchloric acid solution, and the mercury(II) perchlorate was crystallized out by cooling. The hygroscopic crystals were dissolved in a perchloric acid solution ($[HClO_4] = 0.05$ mol dm^{-3}) and thereafter used as the stock solution. The mercury(II) concentration was determined by back titration with EDTA in the presence of excess $Mg(edta)^{2-}$ ($EDTA = H_4edta$), using EBT as the indicator.

Mercury(II) Halides: Guaranteed reagents of E. Merck AG were used.

Solutions of Halomercury(II) Complexes: Proper amounts of mercury(II) halide and sodium halide were dissolved in a perchloric acid ($[HClO_4] = 0.05$ mol dm^{-3}) solution. The sodium halides used were guaranteed reagents of Wako Pure Chemical Industries, Ltd., and were dried at 110 °C before use.

Kinetic Runs. The rate of the absorbance change was measured at 35 °C for the solutions containing the complex (4.5×10^{-4} mol dm^{-3}) and the other salts. The change in absorbance was observed at 290 nm for all the solutions except for those containing tribromo- and tetrabromomercurate(II) ions, which were measured at 360 nm because of the strong absorption in the ultraviolet region.

A Hitachi 200-10 spectrophotometer was used for the slow reactions (with half-lives greater than 1 min) and a UNION RA-1300 stopped-flow spectrophotometer for the fast reactions (with half-lives less than 10 s).

The rates were determined by plotting $\ln(D_t - D_\infty)$ against the time, t, D_t, and D_∞ being the absorbances at the time t and at an infinite time respectively. The slope of this plot gives the pseudo-first-order rate constant, k_{obsd}.

Results and Discussion

Catalysis by Hard Acids. We first studied the effects of hard acids, such as protons, sodium ions, and magnesium ions, on the aquation rate of the bromopentacyanocobaltate(III) anion. The results given in Table 1 show that protons and sodium ions (ionic strength) have little effect, whereas magnesium ions slightly retard the aquation. This effect can be explain-

Table 1. Effect of hard acids on the rate of the aquation of $[CoBr(CN)_5]^{3-}$

Run	Medium (concentrations/mol dm^{-3})	$k_{obsd} \times 10^4$/s^{-1}
1	$HClO_4$ (0.084)	1.05
2	NH_4ClO_4(0.05)–NH_3(0.05) buffer pH *ca.* 9	1.12
3	NaOH (0.10)	1.09
4	$NaClO_4$ (0.14)	1.03
5	$NaClO_4$ (0.34)	1.02
6	$NaClO_4$ (0.54)	1.03
7	$NaClO_4$ (0.74)	1.02
8	$NaClO_4$ (0.97)	1.00
9	$Mg(ClO_4)_2$ (0.14)	0.85

a) $CoBr(CN)_5^{3-}\cdot Mg^{2+}$ b) $CoCl(NH_3)_5^{2+}\cdot SO_4^{2-}$

Fig. 1. Structures of ion-pairs.

ed on the basis of the postulate that the spontaneous aquation of the complex proceeds by means of the "D mechanism"[5] and that the formation of ion-pairs between the complex anion and magnesium cations suppresses the dissociation of the bromide ion (Fig. 1a). It is interesting to compare this slight retardation with the appreciable acceleration of the aquation of the pentaamminechlorocobalt(III) cation caused by ion-pairing with sulfate ions.[6] The latter reaction is also known to proceed dissociatively. When a multivalent anion associates with the complex cation, it will preferentially occupy a site opposite to the chloride ligand as a result of electrostatic repulsion, and will effectively push the chloride ion out of the complex (Fig. 1b). In the present reaction systems, however, all the ligands attached to the cobalt(III) are anionic, and so little preference is shown by the magnesium ion as to the site of association with the complex anion. Thus, the effect of magnesium ions on the complex anion spreads over all the ligands, resulting in only a slight retardation of the dissociation of the bromide ligand.

Interactions with Mercury(II) Ions. Bromopentacyanocobaltate(III) anions form a pale yellow precipitate with mercury(II) cations. This reaction appears to include a mercury(II)-assisted aquation, but the follow-up of the aquation was prevented by the formation of a precipitate even if the stopped-flow technique was used. An elemental analysis of this precipitate gave a composition suggesting a mixture of $Hg[Co(OH_2)(CN)_5]$ and $Hg_3[CoBr(CN)_5]_2$.

In order to gain further information, the infrared spectrum of the precipitate was compared with that of the reactant, $K_3[CoBr(CN)_5]$. The bromo complex has a strong absorption maximum at 2140 cm^{-1} assigned to the terminal C≡N stretching, while the precipitate exhibits two absorption maxima, at 2200 cm^{-1} (strong) and 2140 cm^{-1} (medium), assigned respectively to the bridging and to the terminal C≡N stretching. In the lower-frequency region, the bromo complex exhibits Co–C stretching bands at 550 and 570 cm^{-1} (shoulder) and a precipitate at 625 cm^{-1}. This shift can be attributed to the conversion of the terminal C≡N into the bridging C≡N.[7]

These infrared results show that mercury(II) ions reacted with both cyano and bromo ligands to form cyano-bridged and partially aquated polymers. This kind of bridging polymerization of the cyano complexes by heavy metals is well known in the formation of $KFe^{III}Fe^{II}(CN)_6$, $KFe^{II}Cr^{III}(CN)_6$, *etc.*[8]

Interactions with Chloromercury(II) Complexes. On the addition of mercury(II) chloride to a dilute perchloric acid solution containing bromopentacyanocobaltate(III) ions ($[HClO_4]=0.05$ mol dm^{-3}), a rapid change in the spectrum of the complex occurred, with isosbestic points at 340 nm and 400 nm. This spectral change can reasonably be associated with the aquation of bromopentacyanocobaltate(III) ions, forming aquapentacyanocobaltate(III) ions and no other cobalt complexes. The absorbance change at 290 nm was observed by means of the stopped-flow technique and was found to follow a pseudo-first-order law in the presence of a large excess of mercury(II) chloride(more than ten times the concentration of the cobalt(III) complex). At low concentrations of mercury(II) chloride near that of the cobalt(III) complex, the $\ln(D_t-D_\infty)$ *vs.* t plots showed deviations from linear relationships. Therefore, under such conditions, the linear portions of the plots were used to obtain the rate constants. The observed pseudo-first-order rate constants, k_{obsd}, depend on the $HgCl_2$ concentration (Table 2).

Table 2. Effect of mercury(II) chloride on the rate of the aquation of $[CoBr(CN)_5]^{3-}$ $[CoBr(CN)_5^{3-}]=4.5\times10^{-4}$ mol dm^{-3}, $[HClO_4]=0.05$ mol dm^{-3}, ionic strength $=1.0$ mol dm^{-3} ($NaClO_4$).

$[HgCl_2]$/ mol dm^{-3}	$[HgCl^+]$/ mol dm^{-3}	$[HgCl_3^-]$/ mol dm^{-3}	k_{obsd}/s^{-1}
1.00×10^{-1}	2.35×10^{-4}	8.45×10^{-5}	3.00
4.98×10^{-2}	1.51×10^{-4}	3.29×10^{-5}	2.15
2.99×10^{-2}	1.12×10^{-4}	1.60×10^{-5}	1.96
9.94×10^{-3}	6.12×10^{-5}	3.26×10^{-6}	0.956
4.96×10^{-3}	4.27×10^{-5}	1.17×10^{-6}	0.668
2.47×10^{-3}	3.00×10^{-5}	4.16×10^{-7}	0.410

Table 3. Dependence of the rate on the ionic strength for the mercury(II) chloride-assisted aquation of $[CoBr(CN)_5]^{3-}$ $[CoBr(CN)_5^{3-}]=4.5\times10^{-4}$ mol dm^{-3}, $[HClO_4]=0.05$ mol dm^{-3}, $[HgCl_2]=0.01$ mol dm^{-3}, at 35 °C.

$[NaClO_4]$/ mol dm^{-3}	Ionic strength /mol dm^{-3}	k_{obsd}/s^{-1}
0	0.05	1.89
0.20	0.25	1.48
0.40	0.45	1.15
1.00	1.05	0.96

The rate constant also depends on the ionic strength, as is shown in Table 3. This suggests that the reactions occur between the ions of opposite signs and, therefore that $HgCl^+$, produced through the dissociation of $HgCl_2$, may participate in the reaction rather than the $HgCl_2$ molecule. While the formation of chloromercury(II) complexes has been studied by many workers, the stability constants obtained by Sillén *et al.*[9] at 25 °C and at an ionic strength of 0.5 are adopted here:

$$Hg^{2+} + Cl^- \rightleftharpoons HgCl^+ \qquad \log K_1 = 6.74,$$

$$HgCl^+ + Cl^- \rightleftharpoons HgCl_2 \qquad \log K_2 = 6.48,$$

$$HgCl_2 + Cl^- \rightleftarrows HgCl_3^- \qquad \log K_3 = 0.85,$$
$$HgCl_3^- + Cl^- \rightleftarrows HgCl_4^{2-} \qquad \log K_4 = 1.00.$$

The correction of these values to the present condition of $I=1.0$ and 35 °C was made as follows.

According to the results of Scaife and Tyrrell[10] and of Vasil'kevich and Shilov[11] for halomercury(II) complexes, the logarithm of the formation constant decreased by 0.1 unit with the rise in temperature from 25 °C to about 35 °C. Therefore, the values at 35 °C were estimated to be Sillén's values minus 0.1. The resulting values were then corrected to the ionic strength of 1.0 by using the Davies equation:

$$\log y_i = -0.521 z_i^2 \left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I \right),$$

where y_i is the activity coefficient of the i ion; z_i, its charge number, and I, the ionic strength. The corrected values are $\log K_1' = 6.77$, $\log K_2' = 6.45$, $\log K_3' = 0.75$, and $\log K_4' = 0.83$. Using these values, one can calculate the concentrations of the halomercury(II) complexes existing in the mercury(II) chloride solutions. Among them, Hg^{2+} and $HgCl_4^{2-}$ are present only in trace amounts and can be neglected.

Table 2 shows the calculated concentrations of each chloromercury(II) complex and the observed rate constants. Whereas the values of k_{obsd} show an apparent dependence on $[HgCl_2]$ to the 0.6 power, their dependence on $[HgCl^+]$ is approximately linear.

In view of the fact that reaction rates of the first order with respect to the metal-ion concentrations have been observed in many metal-ion-assisted aquations,[12] the present results can be taken as suggesting that the catalyst in the present reaction system is actually $HgCl^+$.

In order to substantiate this view, the aquation was examined in solutions containing mercury(II) chloride and an excess of sodium chloride. The concentrations of the respective chloromercury(II) complexes were calculated for each run by the use of four equilibrium constants, K_1', K_2', K_3', and K_4'. In order to see how k_{obsd} depends on the concentration of each chloromercury(II) complex, $\log(k_{obsd}-k_0)$ is plotted against $\log[HgCl_n^{2-n}]$ ($n=1$—4) in Fig. 2. The observed value of 1.0×10^{-4} s^{-1} was used for the spontaneous aquation rate constant, k_0. Figure 2 shows that the $\log(k_{obsd}-k_0)$ values have no simple correlations with the $\log[HgCl_n^{2-n}]$ values in any case except for $n=2$. This can be taken as evidence that only $HgCl_2$ molecules effectively assisted the aquation in these runs. Therefore, the results were analyzed by using this equation:

$$k'_{obsd} = k_0 + k_2[HgCl_2]$$

(in solutions containing mercury(II) chloride and an excess of sodium chloride)

which gave $k_2=(1.0\pm0.1)$ mol^{-1} dm^3 s^{-1}. This value of k_2 shows that the contribution of $HgCl_2$ to the reaction can be neglected when mercury(II) chloride reagent is added. Therefore, from Table 2 the second-order rate constant, k_1, of the $HgCl^+$-assisted reaction was found to be $(1.6\pm0.2)\times10^4$ mol^{-1} dm^3 s^{-1}. Thus, the pseudo-first-order rate constant for the chloromercury(II)-assisted aquation can be expressed by this equation:

$$k_{obsd} = k_0 + k_1[HgCl^+] + k_2[HgCl_2].$$

An additional term, $k[Hg^{2+}]$, may be included when $[Hg^{2+}]$ is present in an appreciable concentration; however, this term could not be well characterized because of the strong interaction of the mercury(II) ions with the cyano ligands.

Interactions with Bromomercury(II) Complexes. The addition of mercury(II) bromide also accelerated the aquation of $[CoBr(CN)_5]^{3-}$, but to a smaller degree than in the case of mercury(II) chloride. This is reasonable if $HgBr^+$, by analogy with $HgCl^+$, acts as a virtual reacting species, since the dissociation constant of $HgBr_2$ is much smaller than that of $HgCl_2$. The $\ln(D_t-D_\infty)$ *vs.* t plot was not linear, not even at $HgBr_2$ concentrations as high as 1.0×10^{-2} mol dm^{-3}, nearly the highest one experimentally attainable. (The solubility is 2.2×10^{-2} mol dm^{-3} at 35 °C). Therefore, the rate constant was not obtained directly, but from the analysis of the results according to the following reaction scheme:

$$CoBr(CN)_5^{3-} + HgBr^+ \xrightarrow[\text{slow}]{k_{1(Br)}} Co(CN)_5^{2-} + HgBr_2 \qquad (1)$$
$$\xrightarrow[\text{fast}]{} Co(OH_2)(CN)_5^{2-} + HgBr_2$$

$$HgBr^+ + Br^- \overset{K_{2(Br)}}{\rightleftarrows} HgBr_2 \qquad (2)$$

$$HgBr_2 + Br^- \overset{K_{3(Br)}}{\rightleftarrows} HgBr_3^- \qquad (3)$$

where $\log K_{2(Br)}=8.28$ and $\log K_{3(Br)}=2.41$ ($I=0.5$), as has been reported by Sillén.[13]

The reaction rate can be expressed by

$$-\frac{d[CoBr]}{dt} = k_{1(Br)}[CoBr][HgBr^+], \qquad (4)$$

where $CoBr(CN)_5^{3-}$ is abbreviated as CoBr.

The expressions for Equilibria 2 and 3 are

$$K_{2(Br)} = \frac{c_{HgBr_2}}{[HgBr^+][Br^-]}, \qquad (5)$$

$$K_{3(Br)} = \frac{[HgBr_3^-]}{c_{HgBr_2}\cdot[Br^-]}, \qquad (6)$$

where c_{HgBr_2} represents the analytical concentration of $HgBr_2$ and is practically equal to its actual concentration

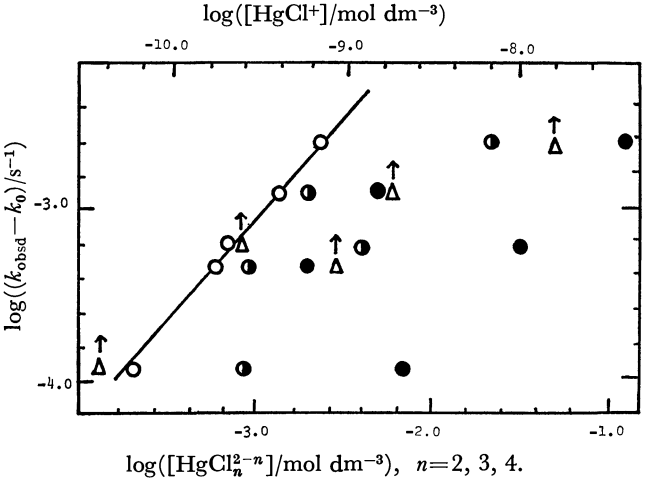

Fig. 2. Effect of chloromercury(II) complexes on the aquation rate of $[CoBr(CN)_5]^{3-}$.
$HgCl_4^{2-}$: ●, $HgCl_3^-$: ◑, $HgCl_2$: ○, $HgCl^+$: △.

at any stage of the reaction. At time 0, the following expression should hold in order for the system to be electrically neutral:

$$[HgBr^+]_0 = [Br^-]_0 + [HgBr_3^-]_0.$$

At time t this becomes

$$[HgBr^+] = [Br^-] - [CoBr]_0 + [CoBr] + [HgBr_3^-]. \quad (7)$$

Equations 6 and 7 are combined to give

$$[Br^-] = \frac{[HgBr^+]+[CoBr]_0-[CoBr]}{1+K_{3(Br)}c_{HgBr_4}}.$$

By substituting this expression for $[Br^-]$ in Eq. 5, one obtains

$$K_{2(Br)}[HgBr^+]^2 + K_{2(Br)}([CoBr]_0-[CoBr])[HgBr^+] - (K_{3(Br)}c_{HgBr_4}+1)c_{HgBr_4} = 0. \quad (8)$$

The elimination of $[HgBr^+]$ from Eqs. 4 and 8 gives a differential equation with respect to [CoBr]. From this equation, a reasonable $k_{1(Br)}$ value can be determined so as to fit the experimental results. The $K_{2(Br)}$ and $K_{3(Br)}$ values given for $I=0.5$, 25 °C were corrected to the present conditions in the same way as has been described above for the case of chloro complexes; then, with the corrected $K'_{2(Br)}$ and $K'_{3(Br)}$ values and an arbitrarily chosen $k_{1(Br)}$ values, the concentration of $[CoBr(CN)_5]^{3-}$ denoted by [CoBr] was calculated as a function of the time for each system. The best fit to the experimental values was obtained when $k_{1(Br)}$ was assumed to be 2.5×10^4 mol^{-1} dm^3 s^{-1} (Fig. 3). The calculations were carried out on a FACOM 270-20 computer for the two systems, with $[CoBr]_0=4.5\times10^{-4}$ mol dm^{-3} and $c_{HgBr_4}=7.63\times10^{-3}$ and 3.81×10^{-3} mol dm^{-3}.

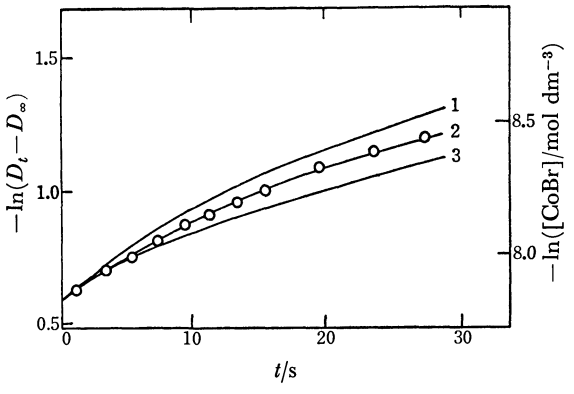

Fig. 3. Comparison of the experimental results(○) and the computational ones(—, scaled on the right-hand oridinate). $c_{HgBr_4}=7.63\times10^{-3}$ mol dm^{-3}. $[CoBr(CN)_5^{3-}]_0=4.5\times10^{-4}$ mol dm^{-3}, at 35 °C. $k_{1(Br)}$ was assumed to 3.0×10^4 mol^{-1} dm^3 s^{-1} (curve 1), 2.5×10^4 mol^{-1} dm^3 s^{-1}(curve 2), and 2.0×10^4 mol^{-1} dm^3 s^{-1} (curve 3).

Another indirect way of obtaining the second-order rate constant, $k_{1(Br)}$, is to carry out the aquation in the presence of an excess of $HgBr^+$ and Hg^{2+}. Under such conditions, the decrease in the concentration of $HgBr^+$, accompanies by the progress of the reaction can be neglected, and the $\ln(D_t-D_\infty)$ *vs.* t plots give straight lines. Since this disproportionation reaction:[13]

Table 4. Rapid aquation of $[CoBr(CN)_5]^{3-}$ in the presence of $HgBr^+$ (with Hg^{2+} and Br^- added in equal analytical concentrations)

[Hg(II)]/mol dm^{-3}	k_{obsd}/s^{-1}
9.83×10^{-3}	92.5
4.91×10^{-3}	41.9
1.96×10^{-3}	22.5

$2\,HgBr^+ \overset{K}{\rightleftarrows} HgBr_2+Hg^{2+}$ (log $K=-0.83$ at $I=0.5$) occurs, the rate constant for the $HgBr^+$-assisted aquation cannot be estimated independently of the effect of Hg^{2+}. As has been described above, Hg^{2+} interferes with the measurement of aquation by forming a precipitate. However, if $HgBr^+$ is present in excess of Hg^{2+}, the stopped-flow technique enables us to observe the aquation before the precipitation begins. Table 4 shows the results. In order to obtain the first-order rate constant, $k_{1(Br)}$, a certain magnitude of the relative effect of Hg^{2+} on the aquation has to be assumed. If Hg^{2+} has no effect, $k_{1(Br)}$ will be 1.8×10^4 mol^{-1} dm^3 s^{-1}, and if Hg^{2+} has an effect as large as that of $HgBr^+$, $k_{1(Br)}$ will be 1.3×10^4 mol^{-1} dm^3 s^{-1}. These values are somewhat smaller than that obtained from the other experiment described above (2.5×10^4 mol^{-1} dm^3 s^{-1}), but are comparable to that for $HgCl^+$. Therefore, the rate constant due to $HgBr^+$ can be $k_{1(Br)}=(2.0\pm0.5)\times10^4$ mol^{-1}dm^3 s^{-1}.

Table 5. Effect of bromomercury(II) complexes on the rate of aquation of $[CoBr(CN)_5]^{3-}$

$[HgBr_4^{2-}]$/ mol dm^{-3}	$[HgBr_3^-]$/ mol dm^{-3}	$[HgBr_2]$/ mol dm^{-3}	$(k_{obsd}-k_0)$/ s^{-1}
7.54×10^{-3}	1.09×10^{-2}	1.29×10^{-3}	2.28×10^{-4}
5.70×10^{-3}	3.95×10^{-2}	1.81×10^{-3}	2.66×10^{-4}
2.11×10^{-2}	2.58×10^{-2}	2.24×10^{-3}	3.50×10^{-4}

The effect of $HgBr_2$ was also examined in a manner similar to that described for the case of $HgCl_2$. Table 5 gives the results, from which the second-order rate constant, $k_{2(Br)}=(1.6\pm0.2)\times10^{-1}$ mol^{-1} dm^3 s^{-1}, was obtained.

The pseudo-first-order rate constant for the bromomercury(II)-assisted aquation can, then, be expressed by

$$k_{obsd}^{(Br)} = k_0 + k_{1(Br)}[HgBr^+] + k_{2(Br)}[HgBr_2].$$

Comparisons of $k_{1(Br)}$ and $k_{2(Br)}$ with k_1 and k_2 show that the effect of $HgBr^+$ is comparable to that of $HgCl^+$ and that $HgCl_2$ is a somewhat better catalyst than $HgBr_2$.

Table 6 summarizes the results obtained for the present systems as well as for the $CoBr(NH_3)_5^{2+}$–Hg^{2+} system.[14] The last column shows the stability constants for the mercury(II) complexes formed by the combination with Br^-. The constant for HgClBr has not been directly obtained, so we estimated it in the following manner.

These equilibria

$$Hg^{2+} + Br^- \rightleftarrows HgBr^+ \qquad \log K'_{1(Br)} = 9.08 \quad (9)$$

$$HgBr^+ + Br^- \rightleftarrows HgBr_2 \qquad \log K'_{2(Br)} = 8.22 \quad (10)$$

TABLE 6. HALOMERCURY(II)-ASSISTED AQUATION OF BROMOCOBALT(III) COMPLEXES

Ionic strength=1.0 mol dm^{-3} ($NaClO_4$), at 35 °C.

Complex		$\log k_i/k_0$	$\log K_i'$
$[CoBr(NH_3)_5]^{2+}$	Hg^{2+}	6.51[a]	9.08
$[CoBr(CN)_5]^{3-}$	$HgCl^+$	8.18	9.1[b]
	$HgBr^+$	8.3[b]	8.22
	$HgCl_2$	4.00	—
	$HgBr_2$	3.30	2.31

a) Unpublished result. Brønsted and Livingston obtained $\log k_i/k_0=6.28$ at the ionic strength of 0.03 and at 25 °C.[14] b) These values may contain larger errors than the others.

$$Hg^{2+} + Cl^- \rightleftharpoons HgCl^+ \qquad \log K_1' = 6.77 \qquad (11)$$

$$HgCl^+ + Cl^- \rightleftharpoons HgCl_2 \qquad \log K_2' = 6.44 \qquad (12)$$

$$\frac{1}{2}HgCl_2 + \frac{1}{2}HgBr_2 \rightleftharpoons HgClBr \qquad \log K' = 0.6[15] \qquad (13)$$

were considered.

From Eqs. 9 and 11,

$$\frac{[HgBr^+][Cl^-]}{[HgCl^+][Br^-]} = \frac{K_{1(Br)}'}{K_1'}. \qquad (14)$$

From Eqs. 10, 12, and 13,

$$\frac{[HgClBr]}{[HgCl^+][Br^-]}\frac{[HgClBr]}{[HgBr^+][Cl^-]}K_{2(Br)}'^{-1}K_2'^{-1} = (K')^2. \qquad (15)$$

Eliminating the $[HgBr^+][Cl^-]$ term in Eqs. 14 and 15, one obtains

$$\frac{[HgClBr]}{[HgCl^+][Br^-]} = K'K_2'^{1/2}K_{2(Br)}'^{1/2}K_{1(Br)}'^{1/2}K_1'^{-1/2} = 10^{9.1}.$$

The results listed in Table 6 show a roughly linear relation between the ratios of the second-order rate constant for each assisted aquation to the first-order rate constant for the spontaneous aquation (k_i/k_0) and the related stability constants (K_i').

The ratios of the rate constants for $CoBr(CN)_5^{3-}$ are significantly larger than that for $CoBr(NH_3)_5^{2+}$ in spite of the similar magnitudes of the stability constants. This difference may be attributed partially to the opposite sign of the electrostatic long-range interactions between the reactants and partially to the dissimilar short-range interactions; the latter is to be expected, since the two complexes differ greatly in their dipolar properties.

Two molecular species, $HgCl_2$ and $HgBr_2$, also showed appreciable effects on the rate of aquation of $[CoBr(CN)_5]^{3-}$. Although these effects are much smaller than those of $HgCl^+$ and $HgBr^+$, the present results show rare cases in which the effects of $HgCl_2$ and $HgBr_2$ on the aquations of metal complexes were experimentally detected. In these cases, the values of k_i/k_0 were greater than would be expected from the related equilibrium constants, K_i'. This also suggests that there exists a kind of short-range interaction between $[CoBr(CN)_5]^{3-}$ and dihalomercury(II) complexes.

We are grateful to Professor Shinichi Kawaguchi of Osaka City University for the use of the stopped-flow apparatus.

Thermodynamics of 1:1 Adduct-formation of Bis(trifluoroacetylacetonato)copper(II) with Lewis Bases

Yoshihiro SASAKI,* Matsujiro SAKURADA, Masakazu MATSUI, and Tsunenobu SHIGEMATSU

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received November 27, 1978)

Formation constants and thermodynamic parameters for the 1:1 adduct-formation reactions of bis(trifluoroacetylacetonato)copper(II), $Cu(tfac)_2$, with alkylamines, α-picoline, 2,6-lutidine, and THF have been determined spectrophotometrically. The $\Delta H°-\Delta S°$ plots for primary and secondary alkylamines gave a linear relationship for the thermodynamic parameters of the $Cu(tfac)_2$–heterocyclic base systems. The plots for the 2,6-lutidine, THF and tertiary alkylamine systems have been found consistent with a correlation between $\Delta H°$ and $\Delta S°$ values for bis(acetylacetonato)copper(II)–heterocyclic base systems. It has been subsequently deduced that the 1:1 adducts of $Cu(tfac)_2$ with Lewis bases possess a square-pyramidal structure on the basis of the ESR data for the $^{63}Cu(tfac)_2$–Lewis base systems.

The 1:1 adduct-formation constants of copper(II) complexes of β-diketonates with pyridine and its derivatives have been reported.[1] The systematic studies reveal that (i) substitution of one or both terminal methyl groups in acetylacetone by the trifluoromethyl group increases the formation constant, (ii) the greater the basicity of the donor atom, the greater the stability of the adduct formed, and (iii) the stability of the adducts of α-picoline and 2,6-lutidine are lower than that of the pyridine adduct. The explanation for (i) has been ascribed to the decrease in electron density around the central copper ion by the electron-withdrawing trifluoromethyl group and in (iii) to the steric hindrance of the methyl group in α-positions.

Graddon *et al.* measured the thermodynamic parameters for the 1:1 adduct-formation reactions of copper(II) complexes of fluorinated β-diketonates with heterocyclic bases and noted that the high stability of the bis(trifluoroacetylacetonato)copper(II) ($Cu(tfac)_2$) adduct with pyridine was largely due to an entropy factor.[2,3] Drago *et al.* found that the enthalpy change of 1:1 adduct-formation reactions of bis(hexafluoroacetylacetonato)-copper(II) with several Lewis bases did not obey the double-scale enthalpy equation proposed and brought this into close connection with the formation of different isomers in solution.[4] The 1:1 adduct of bis(3-trifluoromethyl-*d*-camphorato)copper(II) with α-picoline has been shown by the authors to be more stable than the pyridine adduct.[5] These results suggest that the factors affecting 1:1 adduct-formation equilibria of bis(β-diketonato)copper(II) with Lewis bases need further investigation. In this paper the 1:1 adduct-formation constants and thermodynamic parameters for the 1:1 adduct-formation reactions of $Cu(tfac)_2$ with alkylamines, THF, α-picoline and 2,6-lutidine will be reported together with an ESR investigation of the 1:1 adducts of $^{63}Cu(tfac)_2$ in an attempt to elucidate the geometries in solution. The adduct-formation constants have been determined spectrophotometrically.

Experimental

Materials and Measurements. $Cu(tfac)_2$ was prepared by the addition of an ethanol solution of trifluoroacetylacetone to an aqueous solution of copper acetate. The solution upon recrystallization from toluene gave dark blue crystals (Found: C, 32.67; H, 2.36; F, 31.14%). In the ESR spectra of $Cu(tfac)_2$, $^{63}Cu(tfac)_2$ was prepared from isotopically pure ^{63}CuO (99.8%). The bases were obtained commercially and distilled at reduced pressure. Dodecylamine and tertiary alkylamines were used without further purification. Reagent grade benzene was used without further purification as the solvent. Optical absorption measurements were made on a Hitachi 323 automatic recording spectrophotometer equipped with a water cooled cell holder. The temperature of the samples was maintained constant within ±0.1 °C. The absorbances were measured at 540 nm for THF and at 700 nm for the other bases. ESR measurements were made with a JEOL-ME-3X X-band ESR spectrometer at 77 K. The spectra were calibrated with Mn^{2+} in MgO and DPPH.

Calculation of 1:1 Adduct-formation Constant. The 1:1 adduct-formation constants in the primary alkylamine systems were determined graphically from the following equation:[6]

$$1/K_1 = \frac{A-A_0}{\varepsilon_2-\varepsilon_1} - a_0 - b_0 + a_0 b_0 \frac{\varepsilon_2-\varepsilon_1}{A-A_0} \quad (1)$$

where ε_1 and ε_2 are the molar extinction coefficients of $Cu(tfac)_2$ and the adducts formed, and a_0 and b_0 are the initial concentration of $Cu(tfac)_2$ and that of the primary alkylamine added, respectively, and $A_0=\varepsilon_1 a_0$, for the 1 cm cells were used in this study. The formation constants in secondary alkylamine systems are given by:

$$K_1 = \frac{A-A_0}{A_\infty-A} \times \frac{1}{b_0-a_0(A-A_0)/(A_\infty-A_0)} \quad (2)$$

where $A_\infty=\varepsilon_2 a_0$. K_1 and ε_2 cannot be experimentally evaluated at the same time. Thus the K_1 value giving the smallest standard deviation was found using various A_∞ values.[7] In the case that a_0 and b_0 are much greater than the concentration of adduct formed, Eq. 1 transforms into Eq. 3:

$$\frac{a_0}{A-A_0} = \left(a_0+\frac{1}{K_1}\right) \times \frac{1}{(\varepsilon_2-\varepsilon_1)} \times \frac{1}{b_0} + \frac{1}{\varepsilon_2-\varepsilon_1}. \quad (3)$$

Under the experimental conditions that $b_0-c \fallingdotseq b_0$, where c is the concentration of adduct formed, Eq. 1 transforms into a modified Benesi equation:[6]

$$\frac{a_0}{A-A_0} = \frac{1}{K_1(\varepsilon_2-\varepsilon_1)} \times \frac{1}{b_0} + \frac{1}{\varepsilon_2-\varepsilon_1}. \quad (4)$$

K_1 and ε_2 of α-picoline and 2,6-lutidine were determined from the plots of $a_0/(A-A_0)$ *vs.* $1/b_0$ according to Eq. 3, and those of the tertiary alkylamines and THF according to Eq. 4.

Results and Discussion

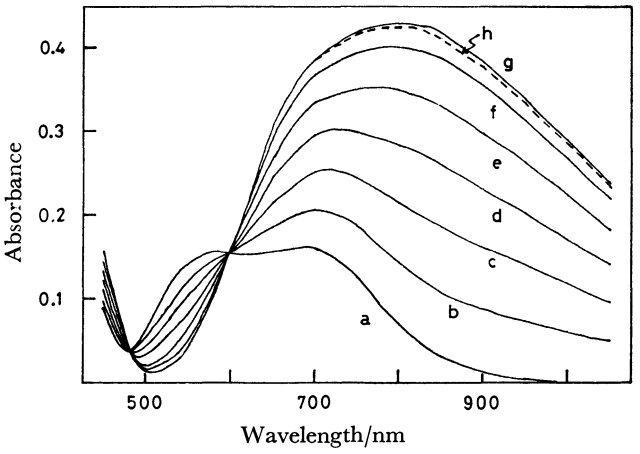

Fig. 1. Spectral change of $Cu(tfac)_2$ in benzene by the addition of octylamine at 20 °C. $a_0=5.43_4\times10^{-3}$ M, b_0/a_0; a: 0.0, b: 0.2, c: 0.4, d: 0.6, e: 0.8, f: 1.0, g: 3.0, h: 5.0 (1 M=1 mol dm^{-3}).

eters. The spectral change of $Cu(tfac)_2$ by the addition of octylamine at 20 °C is shown in Fig. 1 as an example. In the concentration-ratio range of 0—5.0 of the amine to $Cu(tfac)_2$ (b_0/a_0), three isosbestic points were observed at 426, 479, and 598 nm. The absorbance in the near-infrared region decreases at high concentration-ratio. The change in absorbance at 700 nm is large when $b_0/a_0<1$, but extremely small when $b_0/a_0>2$. Thus it has been concluded that only the 1 : 1 adduct is formed when the concentration-ratio is less than 1. Figure 2 shows a set of curves of $1/K_1$ *vs.* $\varepsilon_2-\varepsilon_1$ for the $Cu(tfac)_2$–octylamine system at 20 °C. Each curve was calculated from the observed $A-A_0$ value at one of the base concentrations according to Eq. 1. The coordinates for the intersection on the curves give the common solution for K_1 and ε_2. The set of curves calculated from Eq. 1 for the secondary alkylamine systems give only a dull intersecting point in a range of concentration-ratio (b_0/a_0) exhibiting isosbestic points. Thus the formation constants for the systems have been estimated according to the method described above.

Table 1 shows the 1 : 1 adduct-formation constants and the thermodynamic parameters calculated from the

a) From Ref. 3. log K_1 at 20 °C was calculated from the thermodynamic parameters.

van't Hoff plots of ln K_1, together with the K_1 values and the thermodynamic data of the pyridine and γ-picoline systems reported by Graddon and Ong.[3] The effect of self-association of primary alkylamine has not been taken into account because of the low concentration of the amines.[8] The 1 : 1 adducts of primary alkylamines are more stable than that of pyridine. The formation constants of the alkylamines increase in the order: primary alkylamine>secondary alkylamine≫tertiary alkylamine. The number of carbon atoms in the alkyl chains do not significantly affect the value of the formation constant. The formation constants of the bulky heterocyclic bases and THF, which is a weak base, are remarkably small, as previously reported. The enthalpy term for 2,6-lutidine which exhibits steric hindrance is smaller than that of pyridine. The magnitude of the enthalpy change for the pyridine and α-picoline systems is approximately equal. The thermodynamic data for the heterocyclic base systems show that the remarkably small formation constants of the α-picoline and 2,6-lutidine systems may be ascribed to the decrease in the entropy term. The enthalpy term of the primary alkylamines is smaller than that of the heterocyclic bases due to the strong basicity and the enthalpy change of the secondary alkylamines is larger than that of the primary alkylamines due to steric effects.

ESR Measurements. The ESR spectral change of isotopically enriched $^{63}Cu(tfac)_2$ in frozen toluene was measured by the addition of Lewis bases. Figure 3 illustrates the spectral change in the $g_{//}$ region by the addition of octylamine, which shows that only the 1 : 1 adduct is formed when $b_0/a_0<1$. The ESR data of the 1 : 1 adducts are given in Table 2. Trigonal-bipyramidal complexes of copper have a d_{z^2} ground state which gives rise to $g_\perp\simeq2.2$ and to $g_\perp<g_{//}$.[9,10] In the adducts studied here $g_{//}\simeq2.3$ and $g_\perp\simeq2.04$, which are typical values for square-pyramidal complexes with a $d_{x^2-y^2}$ ground state. Thus it has been assumed that the adducts possess a square-pyramidal structure. There are two

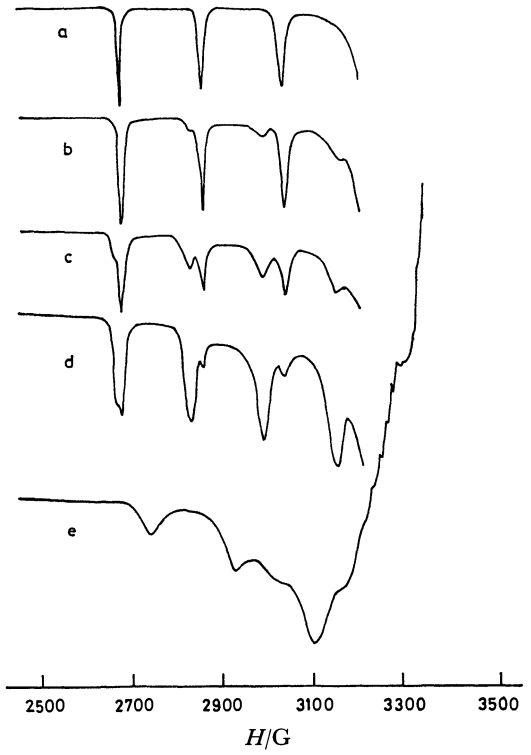

Fig. 3. ESR spectral change of $^{63}Cu(tfac)_2$ in toluene by the addition of octylamine at 77 K. $a_0=2.31_7\times10^{-3}$ M, b_0/a_0; a: 0.0, b: 0.3, c: 0.6, d: 0.9, e: 9.0 (1 M=1 mol dm^{-3}).

isomers for the limiting square-pyramidal structure. One involves apical coordination of a Lewis base molecule and the other involves basal coordination. ^{14}N ligand hyperfine structure was found in the frozen solution ESR spectrum of the 1:1 adduct of $Cu(hfac)_2$ with pyridine and it has been proposed that the adduct has a basal structure.[4,11] In the spectra of the adducts studied such ligand hyperfine splitting was not observed. This, however, does not necessarily indicate that the structure of the adducts is of an apical type.

Correlation between Thermodynamic Parameters. Figure 4 shows the relationship between $\Delta H°$ and $\Delta S°$ values. The $\Delta H°-\Delta S°$ plots of the primary and secondary alkylamines fit a linear relationship for the thermodynamic parameters of $Cu(tfac)_2$–heterocyclic base systems. The plots for THF and the bulky heterocyclic bases except α-picoline are consistent with a correlation between the thermodynamic parameters of bis(acetylacetonato)-

copper(II) ($Cu(acac)_2$)–heterocyclic base systems. One of the conditions for the existence of a set of reactions having such a linear relationship is that they should share a common interaction mechanism.[12] The fact that $\Delta H°$ of 2,6-lutidine is smaller than that of pyridine may also mean that the interaction mechanism in the 2,6-lutidine and pyridine systems is different. The ESR data show that the 1:1 adducts in this study exist in two square-pyramidal structures. The adduct of $Cu(acac)_2$ with quinoline is of an apical type.[13] Therefore, Fig. 4 suggests that the 1:1 adducts of $Cu(tfac)_2$ with THF and the bulky heterocyclic bases except α-picoline possess an apical structure and that those of pyridine and the primary and secondary alkylamines have a basal structure. It is known that in 1:1 adducts of bis(β-diketonato)copper(II) with Lewis bases, which have a square-pyramidal structure, the axial bond length is longer than the equatorial bond length.[13-15] Thus the axial ligation of a Lewis base molecule to $Cu(tfac)_2$ results in the formation of new, relatively longer Cu–N or Cu–O bonds normal to the almost undisturbed CuO_4 plane. The steric hindrance of the bulky heterocyclic bases may be weakened by this interaction mechanism. The structure of the adduct of α-picoline cannot, however, be presumed on the basis of the data in this study. It is reported that the 1:1 adduct of bis(α-nitroacetophenonato)copper(II) with α-picoline has a basal structure in which the methyl group in the α-position sticks out toward the sixth coordination position.[16]

There is a linear relationship between the log K_1 values of pyridine, γ-picoline and butylamine and the log K_H values in the aqueous solutions, while the plots for the secondary alkylamines lie below the line due to steric effects. This linear relationship is explainable by the fact that the strength of the bond between a ligand and a metal ions is determined to a first approximation by the same factors as those which determine the strength of protonation of the ligand. Butylamine is a σ-donor and γ-picoline has a considerably stronger σ-donor property. Thus it is suggested that in the adduct-formation of $Cu(tfac)_2$ with the heterocyclic bases, the σ-bond may play a more important role than the π-bond.

A Possible Method for Obtaining Precise Isotope Ratio of the Element Having Only Two Isotopes

Hitoshi KANNO
Department of Chemistry, Meisei University, Hino, Tokyo 191
(Received November 27, 1978)

As an extension of the atomic/molecular vaporization model, a new method is presented for correcting the isotopic fractionation effects in the multiple filament thermal ionization source (MFTIS). It is applicable to the isotope ratio measurements of the element having only two observable isotopes.

It is well known that the isotope ratio observed in a thermal ionization mass spectrometry is "fractionated"[1-7] due to the isotope effects in the vaporization process of the sample. As the correction methods for elements having more than three isotopes, normalization and double spike techniques[8-12] are usually adopted to obtain "precise" isotope ratio capable to interlaboratory comparison and geochemical uses. However, when the element in question has only two stable isotopes, it is almost impossible to estimate the extent of isotopic fractionation in an observed isotope ratio.

In this paper I propose a new method which may be used to overcome the limitation inherent to the element having only two isotopes for obtaining precise isotope ratio.

Theoretical

In a multiple filament thermal ionization source (MFTIS), sample evaporates in both atomic and molecular species

$$MX_{(s)} \longrightarrow M_{(g)} + X_{(g)}$$
$$MX_{(s)} \longrightarrow MX_{(g)}$$

and ionization occurs at or near the ionizing filament,

$$M \longrightarrow M^+$$
$$MX \longrightarrow M^+ + X^{(0,-)}$$
$$\searrow\ MX^+.$$

If molecular ions are stable enough to be observed as mass spectra and if metal counterpart (X in this case) consists of more than two isotopic species, we will observe (at least) following four peaks in the mass spectra of molecular ions

$$M_lX_l^+,\ M_lX_h^+,\ M_hX_l^+,\ \text{and}\ M_hX_h^+$$

where h and l denote heavy and light isotopes of the element M and its counterpart X. It is to be noted that the overlapping of mass peaks may sometimes occur due to the particular combination of mass numbers of M and X. In addition to these mass peaks, we can also get isotope ratio of the element M as usual from mass peaks of M^+ ions. Combination of isotope ratios of molecular ions and atomic ions may resolve the fractionation problem. This is shown in the following way. As in the previous analysis,[5] we assume that the molar quantity of MX (vapor B) is always k_m times as much as $M^{(0,+)}$ (vapor A) and k_x times as much as $X^{(0,+,-)}$(vapor C). Thus we get

$$\begin{aligned} d[B] &= k_m d[A] \\ d[B] &= k_x d[C] \end{aligned} \qquad (1)$$

where [Y] is the molar quantity of the vapor Y. It is easily seen from Eq. 1 that k_m is equal to k_x in the ideal case. For the simplicity of the discussion, we further assume that (1) the residual sample on the filament undergoes complete and continuous mixing and there is no isotopic fractionation between the compounds (chemical species) on the filament and (2) the residence time of the vapor in the ion source is short so that there are no isotopic exchanges in the successively evaporating chemical species. Here we assume that the element M and its counterpart X consist each of only two isotopes (isotopic species). The isotopic fractionation factors are defined as follows;

$$\begin{aligned} &\alpha = (M_h/M_l)^{1/2},\quad \beta = (M_h\bar{X}/M_l\bar{X})^{1/2}, \\ &\gamma_1 = (\bar{M}X_h/\bar{M}X_l)^{1/2},\quad \gamma_2 = (X_h/X_l)^{1/2} \end{aligned} \qquad (2)$$

where $\bar{M}$ and $\bar{X}$ are the average mass of the element M and its counterpart X, respectively. The isotope ratios R_a and R_b of the element M in the vapor A and vapor B evaporating from the filament are given by

$$R_a = \alpha R \text{ and } R_b = \beta R \qquad (3)$$

where R is the isotope ratio of the element M in the sample remaining on the filament.

The differential equation describing the change in the isotope ratio R in the course of evaporation is

$$\frac{1}{k_m+1}\left(\frac{\alpha R}{1+\alpha R}+\frac{\beta k_m R}{1+\beta R}\right)dQ = \frac{R\,dQ}{1+R} + \frac{Q\,dR}{(1+R)^2} \qquad (4)$$

where Q is the amount of sample on filament. The integration of Eq. 4 gives

$$\ln\left(\frac{Q}{Q_0}\right) = a_m \ln\left(\frac{R}{R_0}\right) + \ln\left(\frac{R+1}{R_0+1}\right) + b_m \ln\left(\frac{c_m+d_mR}{c_m+d_mR_0}\right) \qquad (5)$$

where Q_0: amount of sample originally on filament,
R_0: true isotope ratio of the sample at Q_0,

$$a_m = (k_m+1)/c_m,\quad b_m = (\alpha-\beta)^2k_m/(c_md_m),$$
$$c_m = (\alpha-1) + (\beta-1)k_m,$$
$$d_m = (\alpha-1)\beta + \alpha(\beta-1)k_m.$$

When we measure the metal ions M^+ for obtaining isotope ratio of the element M, the observed isotope ratio (R_{ob}) will be the mean isotope ratio of the vapor A and vapor B as expressed by

$$R_{ob} = \frac{(\alpha+\beta k_m I_m)R + \alpha\beta(k_mI_m+1)R^2}{(k_mI_m+1)+(\beta+\alpha k_mI_m)R} \qquad (6)$$

where $I_m = I_a/I_b$ and I_a and I_b are the ionization efficiencies (production rate of metal ion M^+) of the vapor A and vapor B, respectively.

Next we consider the change of isotope ratio of X during the course of evaporation of the sample MX. The isotope ratios r_b and r_c of X in the vapor B and vapor C (MX and X) are given by

$$r_b = \gamma_1 R_x \text{ and } r_c = \gamma_2 R_x \tag{7}$$

where R_x is the isotope ratio of X in the sample remaining on the filament. The equation corresponding to Eq. 4 is

$$\frac{1}{k_x+1}\left(\frac{\gamma_1 R_x}{1+\gamma_1 R_x}+\frac{\gamma_2 k_x R_x}{1+\gamma_2 R_x}\right)dQ_x = \frac{R_x dQ_x}{1+R_x} + \frac{Q_x dR_x}{(1+R_x)^2} \tag{8}$$

where Q_x is the amount of the sample (X-containing chemical species) remaining on the filament, and Eq. 8 is integrated to give

$$\ln\left(\frac{Q_x}{Q_0}\right) = a_x \ln\left(\frac{R_x}{R_x^\circ}\right) + \ln\left(\frac{R_x+1}{R_x^\circ+1}\right) + b_x \ln\left(\frac{c_x+d_x R_x}{c_x+d_x R_x^\circ}\right) \tag{9}$$

where R_x°: the initial isotope ratio of X on the sample filament,

$a_x = (k_x+1)/c_x$, $b_x = (\gamma_1-\gamma_2)^2 k_x/(c_x d_x)$,

$c_x = (\gamma_1-1) + (\gamma_2-1)k_x$,

$d_x = (\gamma_1-1)\gamma_2 + \gamma_1(\gamma_2-1)k_x$.

Thus the observed isotope ratio of X in the vapor of molecular ions MX^+ will be

$$r_{ob} = \frac{[M_l X_h^+]+[M_h X_h^+]}{[M_l X_l^+]+[M_h X_h^+]} = \gamma_1 R_x. \tag{10}$$

Here [Z] represents the peak height of mass spectrum at the mass number Z. If we use the sample MX as a working material in which the initial isotope ratio of X is precisely known, we can monitor the amount of the sample remaining on the filament Q_x (or Q) from the measured r_{ob} value, initial isotope ratio R_x° and the k_x value using Eqs. 7 and 9. Evaluation of k_m and k_x may be achieved by either calibration curve or thermodynamic studies on vapor composition in a thermal ion source. Recently Heald has attempted the computer calculation of equilibrium compositions of vapor species in a thermal ionization mass spectrometer.[13] Once we get Q_x ($Q_x \simeq Q$) value, it is easy to get the "precise" isotope ratio R_0 of the element M by use of Eqs. 5 and 6, evaluated k_m value and observed R_{ob} value.

Discussion

The crucial point of this method is whether the sample MX can form stable molecular ions to be observed as mass spectra. There have been only a few studies on the stability and intensity of molecular ions in a thermal ionization ion source as atomic ions have exclusively been the only target for observations in most isotope ratio measurements.[14-16] However, there is much evidence for the existence of molecular ions as well as atomic metal ions in a thermal ionization ion source.[14-18] Together with the high-temperature vaporization data of inorganic salts by Knudsen-cell effusion method,[19,20] recent extensive studies by NBS group[7] support the above contention. It is very common to observe not only atomic ions M^+ but also oxide ions such as MO^+ in the isotope ratio measurements of rare earth elements when nitrates or perchlorates are used as a chemical form of the sample.[14,15] In the experimental work by Gensho and Honda,[18] they used M_2BO_3 (M=Li, Na, K, and Rb) as a working material for obtaining precise isotopic abundance ratio of boron ($^{11}B/^{10}B$). When the metal M consists of more than two isotopes such as Li, K, and Rb, we can obtain more than three $M_2BO_2^+$ ion peaks. This makes it possible to evaluate the discrimination factor which would otherwise be unobtainable from only two peaks ($M_2{}^{10}BO_2^+$ and $M_2{}^{11}BO_2^+$). The merits of using M_2BO_3 (M=Li, K, and Rb) instead of Na_2BO_3 as a sample in measuring isotope ratio of boron are summarized by Gensho and Honda as follows: (a) three or more mass peaks are observable from the combination of isotopes of boron and alkali metal (Li, K, and Rb), (b) the discrimination factor (including fractionation effect) may be obtained using a synthetic mixture of isotopes of alkali metal, and (c) the relative peak heights can be adjusted by using a synthetic isotope mixture so as to minimize the reading error (the error arising from using different ranges for recordings of two peaks having a large difference in intensities).

It is important to know how high precision we have to evaluate Q_x (Q) for getting "precise" isotope ratio R_0 of M. The main sources for errors possibly caused in evaluating Q_x come from the evaluation of k_x and the measurement of R_x. From Eqs. 4 and 8, we obtain

$$\frac{\Delta Q}{Q} = \frac{(k_m+1)(\alpha R+1)(\beta R+1)}{(R+1)(c+dR)}\frac{\Delta R}{R},$$

$$\frac{\Delta R_x}{R_x} = \frac{(R_x+1)(c_x+d_x R_x)}{(k_x+1)(\gamma_1 R_x+1)(\gamma_2 R_x+1)}\frac{\Delta Q_x}{Q_x}.$$

Combination of these two equations with Eqs. 5 and 9 gives the magnitude of error permissible to the observed R_x or to the evaluation of Q as a function of Q (or Q_x). Table 1 shows an example of calculations for ΔR_x and ΔQ under the conditions: $k_m=k_x=1$, $Q=Q_x$, and $\Delta R/R=0.05\%$.

Remarkable points of the calculations are that relative

Table 1. The relative error permissible to the evaluation of Q or R_x as a function of Q

Q/Q_0	R ($^{39}K/^{41}K$)	$\Delta Q/Q$ (%)	R_x ($^{35}Cl/^{37}Cl$)	$\Delta R_x/R_x$ (%)

0.40	13.612	2.64	3.0669	0.05_4
0.30	13.537	2.64	3.0489	0.05_4
0.20	13.434	2.64	3.0238	0.05_4
0.10	13.258	2.64	2.9813	0.05_4
0.05	13.085	2.64	2.9394	0.05_4

R_0 ($^{39}K/^{41}K$)=13.850, R_x° ($^{35}Cl/^{37}Cl$)=3.1248, α=1.02532, β=1.01334, γ_1=1.01339, γ_2=1.02816, $Q=Q_x$, $k_m=k_x$=1.0, $I_m=I_x$=1.0, $\Delta R/R$=0.05%.

error permissible to the evaluation of Q is rather constant and large as expected and that the precision required to the measurement of R_x is comparable to the precision of the isotope ratio of M which we intend to obtain. The accuracy of the evaluation of Q_x (Q) can be improved by the least-squares curve fitting of several sets of Q and R_x data so that a lower accuracy for each R_x may be tolerable to get the required accuracy of Q. Probably the calibration curve which may be constructed by use of the synthetic isotope mixtures of both metal M and its counterpart X suffices this object because most accurate Q value is obtainable from the comparison of the calibration curve and observed R_x of the sample.

When molecules or molecular ions are the only entity of vaporizing species from sample filament, calculations become much simpler and easier. Equation 5 is reduced to

$$(\beta-1)\ln\left(\frac{Q}{Q_0}\right)=\ln\left(\frac{R}{R_0}\right)+(\beta-1)\ln\left(\frac{R+1}{R_0+1}\right)$$

and the observed isotope ratio of metal ions will be $R_{ob}=\beta R$. Equation 9 is also simplified to be

$$(\gamma_1-1)\ln\left(\frac{Q_x}{Q_0}\right)=\ln\left(\frac{R_x}{R_x^\circ}\right)+(\gamma_1-1)\ln\left(\frac{R_x+1}{R_x^\circ+1}\right)$$

and the observed isotope ratio of X in molecular ions MX^+ is $\gamma_1 R_x$. If we can observe X^{+or-} ions as mass peaks, the isotope ratio of X^{+or-} ions should be $\gamma_1 R_x$. The observation of X^{+or-} ions may be advantageous from the practical stand point as will be discussed later in more details.

In recent high precision mass spectroscopic studies, the synthetic mixture of isotopes from highly enriched isotopes plays an important role in getting high accuracy.[6] The use of a synthetic isotope mixture makes it feasible to apply the present method to various isotope ratio measurements. In fact, it is almost straightforward to make a rough estimation of Q value from the precisely known R_x° value and observed isotope ratio R_x of X. Furthermore, the isotope mixture of an appropriate composition can greatly improve the accuracy of isotope ratio of molecular ions, *e.g.*, if we use the sample of La_2O_3 in which the isotope ratio of $^{18}O/^{16}O$ is about 1122, we will have the comparable intensities for $^{139}La^{16}O^+$ ($m=155$) and $^{138}La^{18}O^+$ ($m=156$) peaks so that recording error will be minimized.

An alternative method for estimating Q is the measurements of isotope ratio of X by observing mass spectra of X ions. It is to be noticed that isotope ratios of chlorine and bromine can be obtained by measuring negative ions of these elements ionized in a thermal ionization ion source.[21,22] Chloride and bromide are the most common chemical form of the sample in a MFTIS. The advantage of measuring chloride or bromide ions is the possible applicability of the present method to most metal elements by adopting chloride or bromide as a chemical form of the sample. The simultaneous determinations of isotope ratios of M^+ and X^- in the same sample are attainable by simply changing polarity of the accerating voltage and magnetic current of a mass spectrometer. Instead of Eq. 10, the equation relating R_x and observed isotope ratio r_x in the vapor X^{-or+} is given by

$$r_x=\frac{(\gamma_1+\gamma_2 k_x I_x)R_x+\gamma_1\gamma_2(k_x I_x+1)R_x^2}{(k_x I_x+1)+(\gamma_2+\gamma_1 k_x I_x)R_x}$$

where $I_x=I_{xb}/I_{xc}$, and I_{xb} and I_{xc} are the ionization efficiencies of the vapor B and vapor C, respectively.

It is expected that the fractionation factor of $M\overline{X}$ (or $\overline{M}X$) varies according to the change in the average mass of $\overline{X}$ (or $\overline{M}$) as the sample evaporation proceeds. However, the change is usually so small that fractionation factors can be regarded constant in most cases without causing any detectable errors (Table 2).

Table 2. Fractionation factors of KCl as a function of average mass of potassium or chlorine

$R(^{39}K/^{41}K)$	$\overline{M}(K)$	$\gamma_1=(\overline{M}^{37}Cl/\overline{M}^{35}Cl)^{1/2}$
13.850	39.098_3	1.01339_2
13.700	39.099_6	1.01339_1
13.300	39.103_4	1.01339_1
12.900	39.107_4	1.01339_0
12.000	39.129_8	1.01338_5
$R_x(^{35}Cl/^{37}Cl)$	$\overline{X}(Cl)$	$\beta=(^{41}K\overline{X}/^{39}K\overline{X})^{1/2}$
3.1248	35.453_0	1.01333_9
3.0000	35.468_1	1.01333_6
2.8000	35.494_4	1.01333_2
2.5000	35.539_4	1.01332_4

As implicitly implied in the previous paper[5] and extensively studied by Moore *et al.*,[7] the change of k must be admitted during the vaporization process. In fact, not only k but also I varies in the actual experimental situation. In addition to the fractionation pattern, most anomalous phenomena associated with MFTIS may be explained by admitting the change in either k or I (or both) during analysis.[5,7] From the practical stand point, the entire fractionation curve can be constructed experimentally on a point-by-point basis with a standard sample in which initial isotope ratios of both M and X are precisely known. With experimental data of k and I (or the combination factor $L=k\,I$), incorporation of the changes of k and I will be made case by case by using Eqs. 4 and 8 as a starting point. Some examples of such attempts have been presented by Moore *et al.*[7]

Spectrophotometric Determination of Cobalt(II) with Eriochrome Black T after Extraction as Methyltrioctylammonium Tetrathiocyanatocobaltate(II)

Yuh'ichi ROKUGAWA, Masao SUGAWARA, and Tomihito KAMBARA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received December 20, 1978)

A sensitive extraction-spectrophotometric method for determination of cobalt(II) with Eriochrome Black T is described, which involves the preliminary separation of cobalt from aqueous solution by the benzene extraction of methyltrioctylammonium tetrathiocyanatocobaltate(II). The quantitative formation of ion pair between cobalt–Eriochrome Black T complex anion and the quaternary ammonium cation is attained by shaking the resulting extract with aqueous Eriochrome Black T solution of pH 5.5—8.2. Beer's law holds for 0.57—4.0 μg cobalt in 5 ml of the extract with the molar absorption coefficient of $\varepsilon_{587}=6.62\times10^4$ cm^{-1} mol^{-1} l (Sandell sensitivity 8.90×10^{-4} μg cm^{-2}). The composition of the extracted ion pair is estimated to be cobalt: Eriochrome Black T: methlytrioctylammonium ion = 1 : 2 : 3.

The use of 1-(1-hydroxy-2-naphthylazo)-6-nitro-2-naphthol-4-sulfonic acid, sodium salt (Eriochrome Black T, abbreviated to EBT) for extraction-spectrophotometric determination of metal ions has been described by several authors.[1–5] Fukamachi *et al.*[3] and Pyatnitskii *et al.*[5] reported that the color intensity of magnesium(II) complex in the organic phase is higher than that in the aqueous solution.

In the present paper a sensitive method for extraction-spectrophotometric determination of cobalt(II) with EBT is described, in which cobalt(II) is first separated into benzene as the methyltrioctylammonium tetrathiocyanatocobaltate(II) and the resulting extract, without stripping, is subjected to the procedure for color development.

Experimental

Reagents. Commercial Eriochrome Black T(Dojindo Laboratories Ltd.) was used without further purification. The solution (0.1 mM nominal, 1 M = 1 mol dm^{-3}) was daily prepared by dissolving the reagent in water and the concentration was corrected. The purity of EBT was evaluated as described in a previous paper[6] and found to be 52.6%.

A 5% benzene solution of methyltrioctylammonium chloride (Capriquat, Dojindo Laboratories Ltd., abbreviated as Q^+Cl^-) was converted into its thiocyanate form according to the method of Wilson and McFarland.[7] The stock solution was diluted with benzene as required.

A 0.01 M standard solution of cobalt(II) was prepared from its nitrate and standardized by means of the conventional chelatometric titration.

A mixture of 5 (v/v)% hydrogen peroxide and 10 μM manganese(II) buffered at pH 8.0 was freshly prepared before use by mixing the appropriate amounts of 30 (w/w)% hydrogen peroxide and 0.01 M manganese(II) chloride solutions and satd sodium tetraborate–0.1 M hydrochloric acid buffer solution.

Saturated sodium tetraborate–0.1 M hydrochloric acid or 0.1 M sodium hydroxide buffer and 0.2 M acetic acid–0.2 M sodium acetate buffer solutions were used. Deionized water was used. Other reagents used were all of analytical grade.

Apparatus. A Hitachi two-wavelength and double beam spectrophotometer 356 and a Shimadzu spectrophotometer, Model QV-50, 10-mm cells were used for absorptiometric measurements. A Yamato shaker, Model SA-31, was used for extraction. A Hitachi-Horiba glass electrode pH meter, Model F-5, was used for pH measurements.

Procedure. In a 100-ml separating funnel are taken 10 ml of the solution containing less than 4.0 μg of cobalt(II), 7 ml of a mixture of 1.5 M potassium thiocyanate, 1 M sodium citrate solutions and 0.15 M tris(hydroxymethyl)aminomethane–sulfuric acid buffer solution (pH 8.0). The mixture is shaken for 15 min with 5 ml of 0.5% benzene solution of methyltrioctylammonium thiocyanate(Q^+SCN^-). The organic phase is washed with 5 ml of a mixture of 0.5 M potassium thiocyanate, 0.7 M sodium citrate and 0.9 M sodium thiosulfate. After addition of 5 ml of 52.6 μM EBT solution and 10 ml of satd sodium tetraborate–0.1 M hydrochloric acid buffer solution (pH 7.5), the two phases are shaken for 5 min. The organic phase is washed twice with water and then shaken for 50 min with 15 ml of 5% hydrogen peroxide–10 μM manganese(II) solution of pH 8.0. The organic phase is transferred into a beaker containing anhydrous sodium sulfate and the absorbance of the extract is measured at 587 nm against a reagent blank.

Results and Discussion

Decomposition of the Excess EBT. The use of manganase(II)-catalyzed discoloration reaction for the decomposition of the excess *o,o'*-dihydroxy azo reagents was investigated in order to improve the sensitivity and selectivity of spectrophotometric determination of copper(II).[6,8,9] To apply this reaction to decompose the excess EBT in the benzene phase, effects of pH and shaking time were investigated. The decomposition of EBT proceeds efficiently (Fig. 1), when the extract is shaken for longer than 40 min with the aqueous solution of pH higher than 7.5 (5% in hydrogen peroxide and 10 μM in manganese(II)). Washing of the extract with water before this procedure is necessary for the complete decomposition of EBT.

Separation of Cobalt(II). A large number of metal ions such as copper(II), nickel(II), iron(III), and chromium(III) cause serious interference with the determination of cobalt(II) by forming colored, benzene-extractable complexes with EBT. In order to remove the interference a prior separation of cobalt(II) by means of the modified Vogel reaction was found to be useful. The procedure given here is based on the suggestion given by Wilson and McFarland,[7] except that the

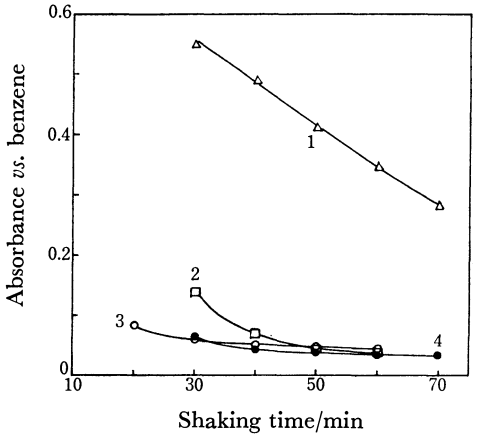

Fig. 1. Effects of pH and shaking time on the decomposition of 52.6 μM EBT in benzene with the aqueous solution of 5% hydrogen peroxide and 12 μM manganese(II).
$[QSCN]_0$=0.01 M, 587 nm, benzene as reference. pH (1): 7.0, (2): 7.5, (3): 8.0, (4): 9.0.

concentration of methyltrioctylammonium thiocyanate in benzene is lower than that recommended. The thiocyanate system is useful for the spectrophotometric determination of 1.2—59 μg of cobalt per milliliter. However, the extraction of smaller amounts of cobalt has not been reported. In order to determine the extractability of cobalt(II) at a few hundred ppb levels, the aqueous phase was repeatedly extracted with the benzene solution of methyltrioctylammonium thiocyanate and the extract was subjected to absorbance measurement. It was found that 2.3 μg of cobalt(II) is almost completely extracted by a single extraction with the 0.5% quaternary ammonium salt solution in benzene.

Absorption Spectra. Based on the observation that the methyltrioctylammonium cobaltothiocyanate in the benzene extract reacts with EBT forming an ion-pair of cobalt–EBT complex anion and the quaternary ammonium cation, the procedure for color development was determined as above. Absorption spectra of cobalt(II)–EBT complex in the aqueous solution and the ternary complex in the extract after the decomposition of excess EBT are shown in Fig. 2. A bathochromic shift of the absorption maxima, accompanied by the enhancement of the absorption intensity, is observed when the cobalt(II)–EBT complex anion is extracted as an ion-pair with the quaternary ammonium cation. The red-purple coloration of the ternary complex, the absorption maxima being 544 and 587 nm, is stable for at least 20 min.

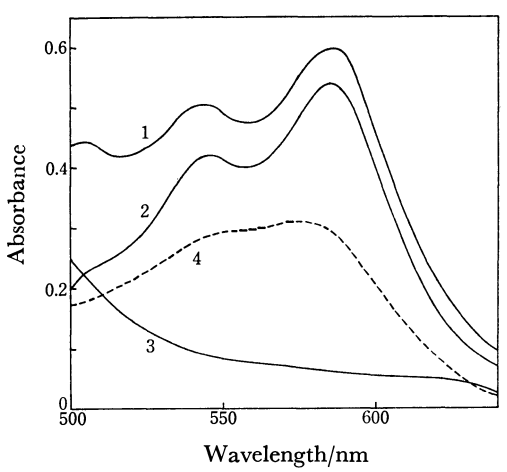

Fig. 2. Absorption spectra of cobalt–EBT complex in aqueous solution and the ternary complex in organic phase after decomposition of excess EBT.
1: Ternary complex *vs.* benzene; 2: ternary complex *vs.* reagent blank; 3: reagent blank *vs.* benzene; $[Co(II)]_0$=7.79 μM, $[EBT]_0$=52.6 μM, pH 8.0; 4: cobalt–EBT complex in aqueous solution *vs.* reagent blank; $[Co(II)]_w$=7.79 μM, $[EBT]_w$=40 μM, pH 10.5.

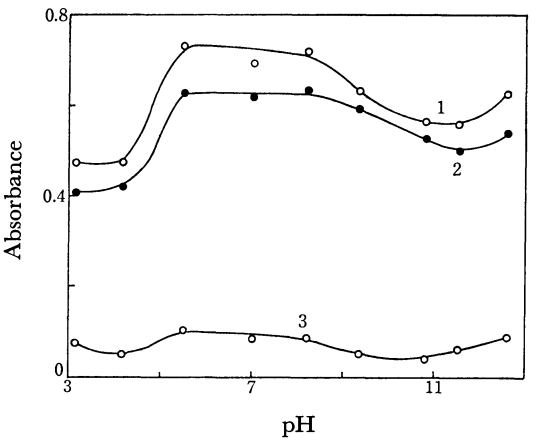

Fig. 3. Effect of pH on the absorbance of cobalt–EBT–Q ternary complex at 587 nm after decomposition of excess EBT. 1: Ternary complex *vs.* benzene; 2: ternary complex *vs.* reagent blank; 3: reagent blank *vs.* benzene; $[Co(II)]_0$=9.73 μM, $[EBT]_w$=17.53 μM, $[QSCN]_0$=0.01 M. Volume ratio of aqueous-to-organic phase is 3: 1.

Effects of pH *and EBT Concentration.* A constant and stable absorbance of cobalt–EBT–Capriquat ternary complex is obtained by shaking the extract with the EBT solution of pH 5.5—8.2 as shown in Fig. 3. For full development of color, addition of EBT in a small excess of the stoichiometrically necessary amount is sufficient.

Effect of Methyltrioctylammonium Thiocyanate Concentration. As described above, 0.5% methyltrioctylammonium thiocyanate in benzene is sufficient for the quantitative extraction of microgram amounts of cobalt(II) as the thiocyanate complex. It was found that the red-purple coloration of the ion-pair of cobalt–EBT complex anion and the quaternary ammonium cation is fully developed by shaking the extract for longer than 3 min with EBT solution. The ion-pair, once formed, is not stripped even by shaking with water and the mixture of hydrogen peroxide and manganese(II).

Calibration Curve and Sensitivity. The calibration curve conforms to Beer's law in the concentration range 0.57—4.0 μg cobalt in 5 ml of the extract, with the molar absorption coefficient of 6.62×10^4 cm^{-1} mol^{-1} l at 587 nm, which is higher than 4.04×10^4 cm^{-1} mol^{-1} l at 573 nm in the aqueous solution. The average of absorbance

Cobalt(II) taken: 2.29 μg.

obtained by three determinations was 0.386 and the range was 0.009 for 1.72 μg of cobalt(II) in the extract.

Effect of Foreign Ions. The results of tolerance test according to the above procedure are given in Table 1. The cations were added as nitrates, chlorides or sulfates and anions as sodium, potassium, or ammonium salts. Iron(III), copper(II), and nickel(II) form thiocyanate complexes which are extracted into benzene as the quaternary ammonium salts, interfering with the subsequent photometric analysis. The interference by these ions is removed by washing with the scrub solution mentioned above. Zinc(II) is extracted as the thiocyanate complex and reacts with EBT, forming a deep red complex. However, the complex is unstable and decomposed by shaking with the hydrogen peroxide–manganese(II) mixture.

Composition of the Extracted Species. Extraction of cobalt(II)–thiocyanate complex anion with amines and quaternary ammonium compounds has been investigated by many authors.[7,10–15] The blue color of the nonaqueous cobaltothiocyanate solution is attributable to $[Co(SCN)_4]^{2-}$ ion.[10,11,14,15] We might conclude that the faintly blue extract obtained with methyltrioctylammonium thiocyanate is due to the ion-pair of tetrathiocyanatocobaltate(II) anion with the methyltrioctylammonium cation. By using the familiar mole-ratio method, the molar ratio of EBT to cobalt(II) was found to be 2: 1 (Fig. 4). The molar ratio of methyltrioctylammonium cation to cobalt(II)–EBT chelate anion was determined by the method of equilibrium shift (Fig. 5). The distribution ratio D of cobalt(II) was evaluated from the molar absorption coefficient and the absorbance at 587 nm. The slope of the plot evaluated by the method of least squares is 2.87, indicating that the ternary complex has the composition of Co: EBT: Q=1: 2: 3. According to Kodama,[16] cobalt(II) ion forms a 1 to 1 complex with EBT in a weakly alkaline aqueous solution. If we assume that cobalt(II) ion forms the chelate anion

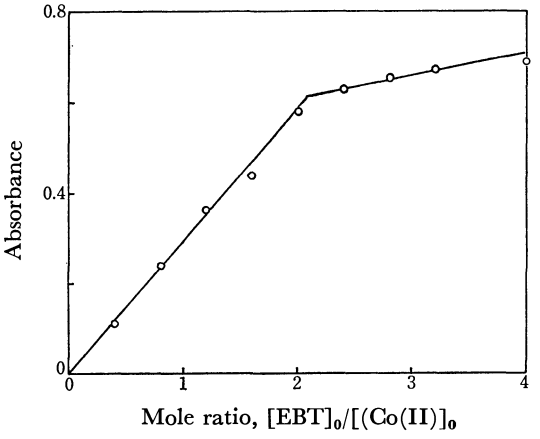

Fig. 4. Mole-ratio method applied to cobalt–EBT system in the extract. $[Co(II)]_w=9.73$ μM, $[KSCN]_w=0.6$ mM, $[QSCN]_0=0.01$ M, pH 8.9, 587 nm *vs.* benzene. The excess EBT was decomposed as above.

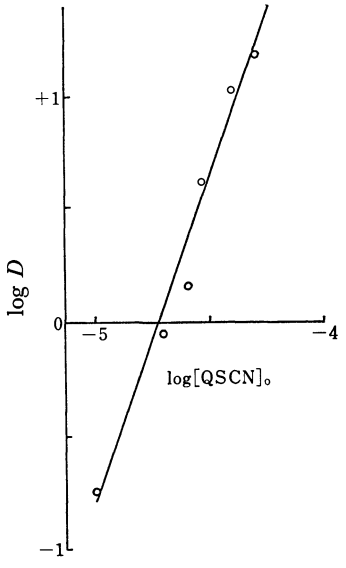

Fig. 5. The logarithm of distribution ratio D plotted *vs.* log $[QSCN]_0$ at pH 9.0 in the presence of 9.73 μM cobalt(II), 19.5 μM EBT and 0.5 mM KSCN.

with EBT which is extracted as the ion-pair with methyltrioctylammonium cation, the composition can be expressed by $[Co^{2+}(HEBT^{2-})(EBT^{3-})(Q^+)_3]_0$. The composition is comparable with $[Mg^{2+}(HEBT^{2-})(EBT^{3-})(Z^+)_3]_0$, that of magnesium complex reported by Pyatnitskii *et al.*,[5] where Z^+ indicates trioctylammonium ion. However, the possibility of +3 oxidation state of cobalt in the extract can not be excluded.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 347025).

The Electrochemical Oxidation of Aminopurines and Their Hydroxy Derivatives at the Glassy Carbon Electrode

Toshio YAO* and Soichiro MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591

(Received January 20, 1979)

The electrochemical oxidation of aminopurines and their hydroxy derivatives, which gave a single voltammetric peak at the glassy carbon electrode, was investigated by means of linear-sweep voltammetry, cyclic voltammetry, coulometry, and macroscale controlled-potential electrolysis. In general, the ease of oxidation of these compounds increased in proportion to the number of hydroxyl or amino groups on the molecule. The coulometric *n*-values for monosubstituted purines were 5.86—6.08, for disubstituted purines they were 3.90—4.20, and for trisubstituted purines they were 2.07—2.33. The electrochemical oxidation of the different aminopurines appeared to follow initially the same path as the enzymatic oxidation; *i.e.*, the primary attack for the electrochemical oxidation occurred first at the C-8 position, and then the C-2 position. Thus, aminopurines were oxidized in two sequential two-electron processes to give first 8-hydroxy and then 2,8-dihydroxy(or 6,8-dihydroxy) intermediates. Then, this latter intermediate was further oxidized in a two-electron process to produce a diimine intermediate, which was unstable and which then broke down to the ultimate products, such as parabanic acid, oxaluric acid, urea, ammonia, allantoin, and guanidine.

Aminopurines, especially the two bases of adenine and guanine, are important components of nucleic acids and play an important role in many metabolic processes. Several works[1–3] have suggested a possible parallelism between the modes of electrochemical process and the biological transformation, *e.g.*, the enzymatic oxidation. The enzymatic and biological oxidation of adenine and guanine have been examined; they are covered in part in the reviews by Lister[4] and Robins.[5] The oxidation of adenine by the enzyme xanthine oxidase gives 6-amino-8-hydroxypurine as an intermediate in the formation of 6-amino-2,8-dihydroxypurine.[6] Also, guanine is slowly oxidized to uric acid in the presence of very large excesses of xanthine oxidase;[7] this process may be brought about by traces of guanine present in the xanthine oxidase.

Most of the aminopurines were not reduced easily at the dropping mercury electrode(DME) in aqueous solutions. However, some aminopurines can be voltammetrically oxidized at the pyrolytic graphite electrode[2,8,9] and the glassy carbon electrode (GCE).[10–12]

In this paper, the electrochemical oxidation of the aminopurines and their hydroxy derivatives was investigated by means of linear-sweep voltammetry, cyclic voltammetry, controlled-potential coulometry, and the polarography of the oxidation products. On the basis of the data reported here, different and plausible oxidation products were proposed; the mechanisms for the electrochemical oxidation were also proposed. In order to compare the mechanisms and products of oxidation of aminopurines with those of previously known biological oxidations, these studies were carried out in some detail.

Experimental

Chemicals. The 6-aminopurine (adenine), 2-aminopurine, and 2-amino-6-hydroxypurine (guanine) were obtained from the Wako Pure Chemical Co. The 6-amino-2-hydroxypurine (isoguanine) and 2,6-diaminopurine were obtained from the Sigma Chemical Co. The 6-amino-8-hydroxypurine, 6-amino-2,8-dihydroxypurine, 2-amino-8-hydroxypurine, 2-amino-6,8-dihydroxypurine, and 2,6-diamino-8-hydroxypurine were all synthesized according to methods previously described.[13] All the products were recrystallized three times from distilled water before drying *in vacuo* at 60 °C, and their purities were checked by both elemental analysis and linear-sweep voltammetry.

Apparatus. The polarograms and anodic voltammograms were recorded using a Yanagimoto P-8 type Polarograph. The cyclic voltammograms were obtained with a versatile solid-state instrument constructed in this laboratory, with triangular voltage sweeps supplied by a NF Circuit Design Block Co. Model FG-104T function generator. The current-voltage curves were recorded on an IWATSU Model DS-5016 dual-beam oscilloscope equipped with a camera or on a Hewlett Packard Model 7045A X-Y recorder.

A three-electrode cell was used for all the experiments. A saturated calomel electrode (SCE) was used as a reference electrode, while a platinum wire was used as a counter electrode.

The DME used had the following characteristics: mercury flow rate, $m=2.32$ mg/s and drop time, $t=3.32$ s at an open circuit with a mercury head of 70 cm in 1 M H_3PO_4.

The working electrode used for anodic voltammetry, GCE, was constructed as has been described before.[10] The GCE was polished for about 30 s with 1500-grade emery paper and then a paste of CeO_2 on asphalt pitch until the surface of the electrode was brought to a mirror finish. Also, in order to obtain reproducible results, the standard pretreatment procedure described previously was applied before recording each voltammogram.[10]

Controlled-potential electrolysis was done at the potentials on the crest of the anodic peaks, with a NICHIA Model NP-1 potentiostat. A glassy carbon beaker (40 ml in volume; Tokai Electrode Co.) was used as the working electrode. The colorimetric determinations of oxidation products were done using a Shimadzu Model Spectronic 20.

Colorimetric Methods for the Determination of Oxidation Products. The urea was determined by a modification of Rosenthal's method.[14,15] The ammonia was determined by the Nessler method, following King and Faulconer.[16] The allantoin was determined by a modification of the Young and Conway procedure.[17] The guanidine was determined by the procedure described by Staron and Allard.[18]

Polarographic Methods for the Determination of Parabanic and

Oxaluric Acids. The parabanic acid was determined on the completion of the electrolysis by transferring about 10 ml of the electrolyzed solution (1 M H_2SO_4) into a polarographic cell, deaerating it, running a polarogram between 0 and −1.1 V *vs.* SCE, and then comparing the height of the wave at −0.53 V *vs.* SCE with a calibration curve prepared from authentic parabanic acid. The oxaluric acid was determined on the completion of the electrolysis in the same way, using the height of the wave at −0.87 V *vs.* SCE.

Results and Discussion

Anodic Voltammetry. Each of the aminopurines and their derivatives studied gave a voltammetric oxidation peak at a stationary GCE over a wide pH range. The half-peak potentials ($E_{p/2}$) of their oxidation peaks shifted linearly towards negative potentials with the increase in the pH, as is summarized in Table 1. Also, the peak current function, $i_p/ACV^{1/2}$, decreased gradually with the increase in the pH, but in the electrolytes with pH values below 2.8 the peak current functions for all the aminopurines studied remained almost constant in spite of the variations in the pH values. In 1 M H_2SO_4, good linear relationships were observed between the peak current and the concentration, and the peak current functions were almost independent of the scan rate. These facts imply that, in 1 M H_2SO_4, these voltammetric oxidations are diffusion-controlled processes. Accordingly, the peak current functions for all the compounds studied were determined in 1 M H_2SO_4; these results are shown in Table 1.

It was proved in the previous report[12)] that uric acid (2,6,8-trihydroxypurine) gives a well-defined oxidation peak when in acidic solutions, but the peak tends to be ill-defined because of the adsorption of a depolarizer on the electrode surface when in neutral or alkaline solutions, and that the oxidation peak obtained in acid solutions, such as 1M H_3PO_4 and H_2SO_4, is attributable to a two-electron, diffusion-controlled process. The value of the peak current function for uric acid was 47.1 $\mu A(cm^2 \cdot mM)^{-1}(mV/s)^{-1/2}$ in 1 M H_2SO_4. This value was compared with the values for all the compounds studied by assuming that their diffusion-constant values are equal to that of uric acid. The results indicated that the values of the peak current function for the oxidation peaks of monosubstituted purines were *ca.* 130—145 $\mu A(cm^2 \cdot mM)^{-1}(mV/s)^{-1/2}$, corresponding to a six-electron process. Similarly, it is feasible that disubstituted purines are oxidized in a four-electron process, and that trisubstituted purines are oxidized in a two-electron process.

Coulometry. The coulometric measurements at the controlled potentials were performed in order to determine the number of electrons involved in the overall electron-transfer reactions. In 1 M H_2SO_4, the time taken to oxidize completely all of the depolarizer was from one to two hours. However, in the Britton-Robinson buffers with pH values above 4, exhaustive electrolysis required a much longer time and the electrolytic current remained at a low value throughout the electrolysis; this is indicative of a very slow intermediate step in the oxidation, the deposition of an insoluble reaction product, film formation on the electrode surface, or a combination of these phenomena.

Consequently, the coulometric *n*-values were determined in 1 M H_2SO_4. The results are presented in Table 2; the *n*-values for monosubstituted purines were 5.86—6.08, for disubstituted purines they were 3.90—4.20, and for trisubstituted purines they were 2.07—2.33. These results were consistent with the *n*-values determined from the peak current functions of the voltammetric peaks.

a) in V *vs.* SCE.

Cyclic Voltammetry. Cyclic voltammograms at fast scan rates were recorded in 1 M H_2SO_4 for each of the four 6-aminopurines. The results are shown in Fig. 1. When scanning was done from 0.0 V at a clean electrode toward a positive potential, only a single anodic peak was observed for 6-aminopurine (Curve A). The principal point of interest in this voltammogram is that two new, small anodic peaks (Peaks I and II) were observed on the second sweep toward the positive potential at a fast scan rate of more than 0.25 V/s. Peak I appeared at almost the same peak potential as the original anodic peak of 6-amino-8- or 6-amino-2-hydroxypurine. Also, the peak potential of Peak II was the same as that of the anodic peak of 6-amino-2,8-dihydroxypurine. Each of 6-amino-8- and 6-amino-2-hydroxypurine gave a new anodic peak on the second sweep toward the positive potential; the peak potential of this new peak was consistent with that of the original peak of 6-amino-2,8-dihydroxypurine.

However, since the peak potentials of these new peaks were dependent on the pH of the electrolyte solutions, cyclic voltammograms were recorded in electrolyte solutions of various pH values. The results are shown in Table 3. At various pH values, Peak I and Peak II of 6-aminopurine coincided in potential with the original peak of 6-amino-8-hydroxypurine and 6-amino-2,8-dihy-

a) Exhaustive electrolysis of 1 mM aminopurines in 1M H_2SO_4.

droxypurine respectively. Also, the new anodic peaks of 6-amino-8- and 6-amino-2-hydroxypurine were observed at almost the same potentials at various pH values, and their peak potentials were in very close agreement with that of the original peak of 6-amino-2,8-dihydroxypurine.

Similarly, 2-aminopurine gave two new, small anodic peaks on the second sweep toward the positive potential. At various pH values, the peak potentials for these two peaks were the same as those of the anodic peaks for the oxidation of 2-amino-8-hydroxypurine and 2-amino-6,8-dihydroxypurine, as is shown in Table 3. Also, 2,6-diaminopurine gave a new anodic peak corresponding to an oxidation peak of 2,6-diamino-8-hydroxypurine on the second sweep toward the positive potential.

Controlled-potential Electrolysis. After the exhaustive electrolysis of 1 mM aminopurines, linear-sweep voltammetry at the GCE showed no anodic peak, but polarography at the DME showed two reduction waves. These waves were probably due to the reduction of the ultimate products produced by the oxidation; their half-wave potentials shifted toward negative potentials with the increase in the pH values of the electrolyte solutions. The polarographic behavior of the products in the electrolyzed solutions was compared with those of parabanic and oxaluric acids. In the case of 6-aminopurine,

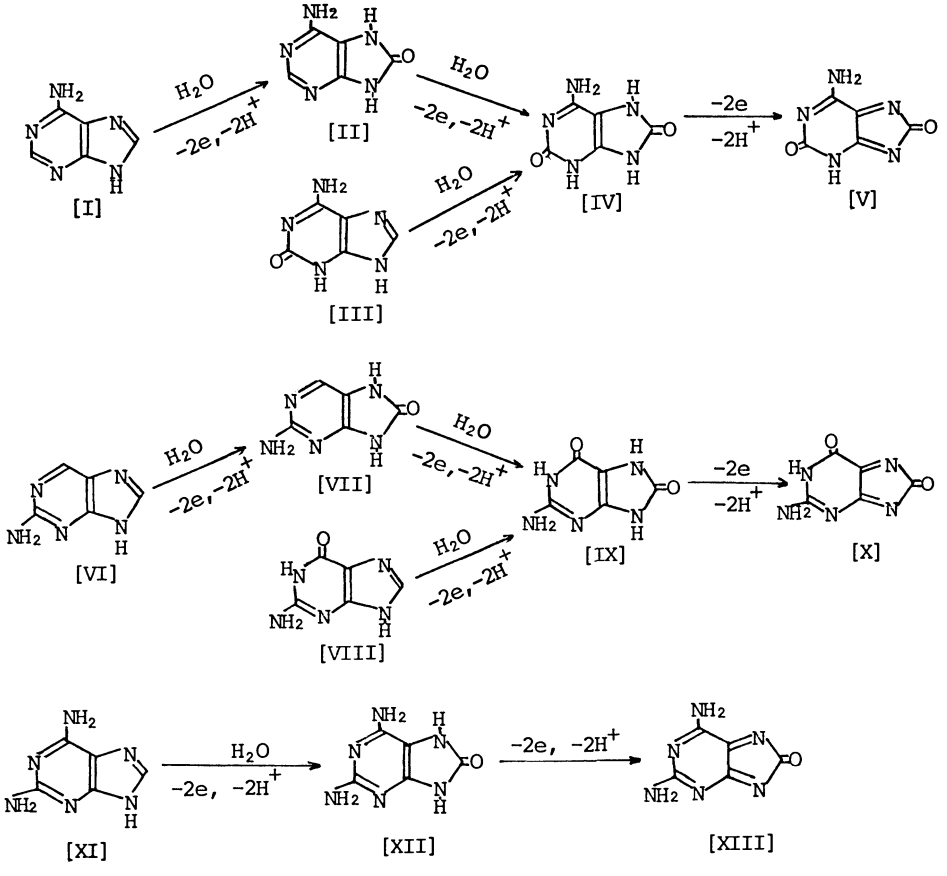

Fig. 2. Proposed primary electrochemical pathways for electrooxidation of different aminopurines.

the experimental results are summarized in Table 4. The $E_{1/2}$ values of the first and second waves agreed very closely with those of parabanic and oxaluric acids respectively.

The ultimate electroinactive products (urea, ammonia, allantoin, and guanidine) were determined by the colorimetric methods given in the Experimental section. The results are shown in Table 5.

Mechanisms. The characteristic ultraviolet absorption spectra of the aminopurines (λ_{max}=260—270 nm) are attributable mainly to the –C(4)=C(5)–C(6)=N(1)– chromophoric group.[19,20] The disappearance of these peaks after exhaustive electrolysis indicates that the –C(4)=C(5)– bond is ultimately oxidized and cleaved. In addition, an analysis of the product solutions after exhaustive electrolysis suggested the presence of parabanic acid, oxaluric acid, urea, ammonia, allantoin, and guanidine. The cyclic voltammetric data also suggested the presence of various intermediates which were more easily oxidized than their parent compounds. The presumed mechanisms of the primary oxidations of the different aminopurines studied at the GCE are summarized in Fig. 2.

The coulometric *n*-value for the oxidation of 6-aminopurine was *ca.* 5.86. Also, cyclic voltammetric experiments revealed the presence of both 6-amino-8-hydroxypurine(II) and 6-amino-2,8-dihydroxypurine(IV) as the electrochemical intermediates, both of which were more easily oxidized than 6-aminopurine(I). The coulometric *n*-values for the oxidation of Compounds II and IV were *ca.* 3.90 and 2.28 respectively. These facts supported the idea that the electrochemical oxidation of 6-aminopurine proceeds initially by two sequential two-electron steps to give first Compound II and then Compound IV. The latter compound was similar to uric acid except for the presence of an amino group in place of an hydroxyl group at the 6-position; then it was probably oxidized in a further two-electron step to produce a diimine intermediate(V) of the same type as that proposed for the electrochemical oxidation of uric acid.[1] The continuous oxidation to the diimine intermediate, as soon as the initial two-electron oxidation had occurred, was caused by the fact that the ease of oxidation generally increased with the number of hydroxyl groups on the molecule (see Table 1). Compounds II and IV were easily oxidized electrochemically than was 6-aminopurine itself and, consequently, were unstable with respect to the oxidation at the potential at which 6-aminopurine was oxidized. Also, an intermediate for the two-electron oxidation of 6-aminopurine was 6-amino-8-hydroxypurine, and no evidence for the presence of 6-amino-2-hydroxypurine(III) was given by cyclic voltammetry. In addition, both Compounds II and III were oxidized in a two-electron step to produce the same intermediate, Compound IV. Thus, under electrochemical conditions oxidation occurred first at the C-8 position and then at the C-2 position.

Similarly, 2-aminopurine(VI) was electrochemically oxidized to 2-amino-6,8-dihydroxypurine(IX) *via* 2-amino-8-hydroxypurine(VII). Also, 2,6-diaminopurine(XI) was oxidized in a two-electron step to produce 2,6-diamino-8-hydroxypurine(XII), as was shown by cyclic voltammetric experiments. Compounds IV, IX, and XII were oxidized in a two-electron step to produce the corresponding unstable diimine intermediates (V, X, and XIII), which were then hydrolyzed in water to the ultimate compounds, such as parabanic acid, oxaluric acid, urea, ammonia, allantoin, and guanidine.

Conclusions

The different aminopurines studied were electrochemically oxidized by a mechanism very similar to that observed for other naturally occurring purines, such as uric acid and xanthine. The evidence put forward supported the view that the locus of the initial electron removal was the same for enzymatic and electrochemical processes, *i. e.*, in both the enzymatic and electrochemical oxidations the attack was first at the C-8 position and then at the C-2 position. Unlike most enzyme reactions, where the 2-amino group of guanine is removed, this group remained intact under electrochemical oxidations, and further electrochemical reaction occurred at the –C(4)=C(5)– bond.

The Isolation of ^{227}Ac from ^{231}Pa and the Gamma-ray Spectra of ^{231}Pa, ^{227}Th, and ^{223}Fr

Toshiaki MITSUGASHIRA,* Hajimu YAMANA, and Shin SUZUKI

The Research Institute for Iron, Steel, and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received January 20, 1979)

A method for the isolation of ^{227}Ac and its daughter nuclides from ^{231}Pa was established. The γ-ray spectra of ^{231}Pa, ^{227}Th, and ^{223}Fr were investigated, and the γ-ray tables of these nuclides were presented. A decay scheme of ^{223}Fr was corrected so as to explain these γ-ray data.

Several handicaps for the radiochemical study of the natural actinium series are known. Some of them are as follows:

1. It is difficult to keep enough ^{231}Pa or ^{227}Ac.
2. No confidential method for the separation of ^{231}Pa and ^{227}Ac has been established.
3. The exact information about the complex γ-rays of the nuclides of the actinium series is not enough for the γ-ray spectrometries of these nuclides.

From the standpoint of radiochemical common sense, ^{231}Pa is a precursor of ^{227}Ac. However, it is widely believed that the radiochemical purity of ^{227}Ac isolated from ^{231}Pa is not enough, because the complete removal of the colloidal or polymeric species of ^{231}Pa is very difficult. ^{227}Ac is almost non-γ-radioactive. The decay chain is complicated. Also ^{231}Pa, ^{227}Th, and ^{223}Fr have many γ-rays of approximately equal energies. Therefore, it is difficult to certify the radiochemical purity by γ-ray spectrometry in spite of the recent development of solid-state detectors. On the other hand, ^{227}Ac is produced as the daughter of ^{227}Ra, which is produced by means of the ^{226}Ra(n, γ) ^{227}Ra reaction. This method is recommended today. However, we do not think that the production of ^{227}Ac from ^{226}Ra is a popular technique or a conventional method, considering that the geochemical abundance of ^{231}Pa is of the same order as that of ^{226}Ra. Therefore, we tried to isolate ^{227}Ac from ^{231}Pa. Recently, we presented a method for the mutual separation of ^{227}Ac, ^{227}Th, ^{223}Ra, and ^{223}Fr.[1] The combination of these two methods will be an answer to the second difficulty with the radiochemistry of the actinium series mentioned above.

Then we determined the γ-ray spectra of ^{231}Pa, ^{227}Th, ^{223}Ra, and ^{223}Fr by means of a high-resolution Ge(Li) detector or an intrinsic germanium detector with a higher resolution. Moreover, we will present the data on the γ-rays of these nuclides for the sake of the γ-ray spectrometric determination of these nuclides.

Experimental

Radioisotopes. ^{231}Pa was supplied by The Radiochemical-Centre (Amersham, England). A 10-mg portion of the ^{231}Pa was purified by the method reported by Suzuki and Inoue.[2] The purified ^{231}Pa was left to stand for seven years to grow enough ^{227}Ac and then used for the experiment.

Reagents. All the chemicals used were of an analytical grade. HBEHP (bis(2-ethylhexyl) phosphate) was purified by the method reported previously.[3]

Apparatus. The apparatuses used were as follows. Separatory funnel shaker: IWAKI KM type(200—400 min^{-1}); coaxial Ge(Li) detector: ORTEC model 8101—1820 (effective volume, *ca.* 60 cm^3); planar intrinsic germanium detector: ORTEC model 16300-1000 (Be window 25 μm thick; effective volume, *ca.* 1.4 cm^3); silicon surface-barrier α-ray detector: ORTEC model BE-16-160-100 (active area, 160 mm^2; depletion depth, 100 μm); multichannel pulse-height analyzer: TOSHIBA USC-1 model 10 4096 ch. (controlled by a minicomputer TOSBAC-40A); linear amplifier: ORTEC model 472 spectroscopy amplifier (the shaping time constant was fixed to 2 μs throughout the spectrum accumulation).

The dead-time ratio was monitored by USC-1 and was found to be less than 10%.

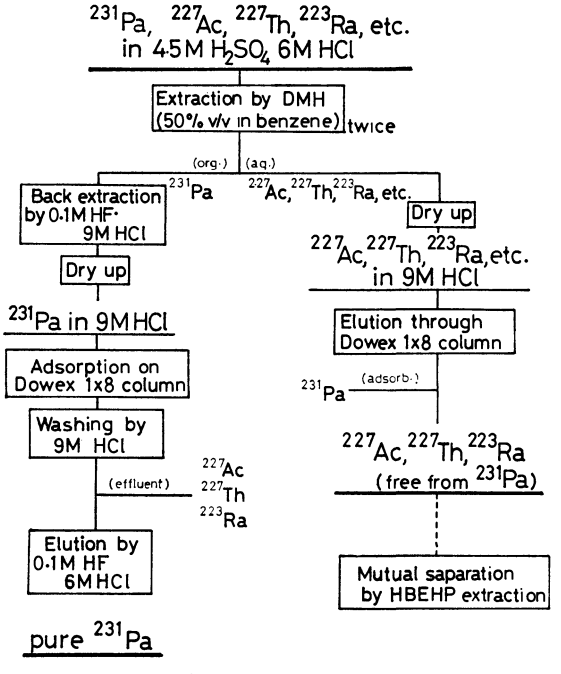

Fig. 1. The separation method for ^{231}Pa and ^{227}Ac.
In this figure 1 M=1 mol/dm^3.

Procedures. *Separation of ^{231}Pa and Its Daughter Nuclides*: A flow chart for the chemical separation of ^{231}Pa and ^{227}Ac is shown in Fig. 1. The meaning and the performance of the separation method will be described in the next section. From the isolated ^{227}Ac fraction, ^{227}Ac, ^{227}Th, and ^{223}Ra were purified by the method reported in Ref. 1. ^{223}Fr was milked from the purified ^{227}Ac by the method reported in Ref. 1.

Alpha-ray Spectrometry: In order to examine the radiochemical purity of the purified ^{231}Pa and ^{227}Ac, the α-ray spectra were compared. Thin sources for good resolution in the α-ray spectrum were prepared by the evaporation of aliquots of solutions of these nuclides onto glass plates. The apparent resolution of an α-ray peak was less than 20 keV in FWHM.

Gamma-ray Spectrometry: The γ-ray spectra of ^{231}Pa, ^{223}Fr,

and ^{223}Ra were determined by means of the Ge(Li) detector. The γ-ray spectrum of ^{227}Th was determined by the intrinsic germanium detector, because the spectrum is too complex to resolve each γ-ray by the Ge(Li) detector. For the calibration of energy and the efficiency of the acquisition system, the standard sources of ^{241}Am, ^{109}Cd, ^{144}Ce, ^{133}Ba, ^{22}Na, ^{106}Ru, ^{137}Cs, ^{54}Mn, and ^{60}Co were used. In addition, KX-rays of Ac, Ra, Rn, Po, Bi, and Pb were applied to the inner calibration. The highest resolution observed for the Ge(Li) detector was 1.2 keV in FWHM for 300 keV γ-ray of ^{231}Pa. The resolution of the intrinsic germanium detector was 300 eV at 20 keV, 400 eV at 50 keV, 500 eV at 100 keV, and 800 eV at 300 keV.

Plate sources of ^{231}Pa, ^{227}Th, and ^{223}Ra were prepared by the evaporation of aliquots of the purified stock solutions onto stainless steel plates. Liquid sources of ^{223}Fr were prepared by pipetting aliquots of the purified solution into polyethylene test tubes. The calibration factor for the self-absorption by the liquid sources was calculated by comparing the relative intensities determined with respect to the two kinds of sources of ^{227}Th, which has many γ-rays identical with ^{223}Fr.

All the spectra were analyzed by means of a nonlinear least-mean-squares fitting method to evaluate the peak position and the peak area. The least-mean-squares fitting method is based upon peak response functions rather than analytical functions in order to account for the histogram nature of the γ-ray spectrum accumulated by a multichannel pulse-height analyzer. Moreover, the peak response functions were determined from the γ-ray peak shapes of the γ-rays of the standard sources.

The relative intensities of the γ-rays of ^{227}Th, ^{223}Fr, and ^{223}Ra were determined by the decay analysis of the calculated peak areas. The abundances of the γ-rays of ^{223}Fr were calculated by normalizing the relative intensities to the α-disintegration rate of ^{227}Ac, which was in radioequilibrium with ^{223}Fr.

Results and Discussion

Radiochemical Purity of the Purified ^{231}Pa and ^{227}Ac. From the point of view of the decontamination of ^{227}Ac for ^{231}Pa, the anion-exchange chromatographic separation method reported by Suzuki and Inoue[2] is the best method if we can suppress the irreversible formation of colloidal or polymeric species of Pa(V), which is not adsorbed by the anion-exchange resin column. Therefore, we applied this method to the final stage of the separation of ^{227}Ac and ^{231}Pa, as is shown in Fig. 1. However, it was often observed that a small fraction of ^{231}Pa was eluted out with a loading solution when more than 1 mg of ^{231}Pa was introduced into the separation column. The fast, irreversible polymerization of Pa(V) in a hydrochloric acid solution has been reported.[4] Therefore, this eluted fraction of ^{231}Pa can be considered to be the polymeric species.

To get enough ^{227}Ac from ^{231}Pa, we must chemically process a weighable amount of ^{231}Pa. Quantitative information has not yet been obtained about the chemical behavior of polymeric Pa(V) in an aqueous solution. However, it is known that the polymerization of Pa(V) in an aqueous solution is negligible unless the solution is left to stand too long after the preparation and unless the concentration of Pa(V) is more than 10^{-7} mol/dm^3.[4-6] These facts show that, in order to suppress the formation of polymeric Pa(V) in a hydrochloric acid solution, the concentration of Pa(V) should be lower than 10^{-7} mol/dm^3.

On the basis of these considerations, we applied a preliminary separation based on the DMH(2,6-dimethyl-4-heptanol)-extraction of ^{231}Pa from a mixed acid solution of a sulfuric acid and a hydrochloric acid in order to lower the concentration of ^{231}Pa in the ^{227}Ac fraction. Pa(V) forms stable anionic complexes in a concentrated sulfuric acid solution and does not show the tendency to polymerize. Moreover, the extraction of macro amount of Pa(V) from the mixed acid gives very reproducible results. The extraction ratio of Pa(V) exceeds 99.95% by the use of DMH-extraction process shown in Fig. 1, while Ac is not extracted. The isolated ^{227}Ac fraction was processed by the HBEHP-extraction method to get the purified ^{227}Ac, ^{227}Th, ^{223}Ra, and ^{223}Fr.[1]

An α-ray spectrum of the purified ^{231}Pa is compared with a spectrum of ^{231}Pa before the separation in Fig. 2.

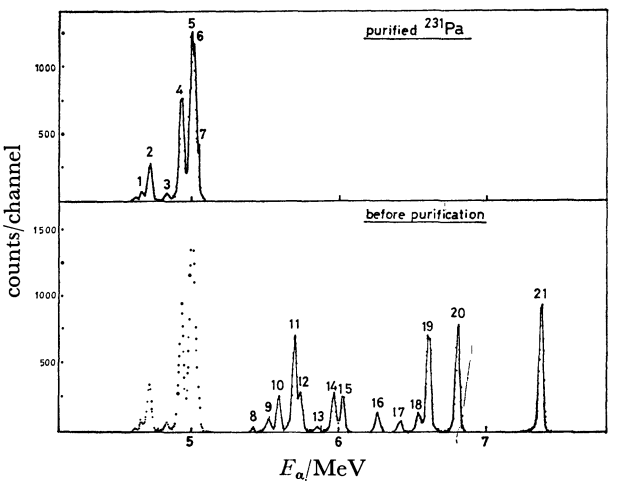

Fig. 2. Alpha-ray spectra of ^{231}Pa.
1, 4.671 MeV ^{231}Pa; 2, 4.727 MeV ^{231}Pa; 3, 4.844 MeV ^{231}Pa; 4, 4.943 MeV ^{231}Pa; 5, 5.007 MeV ^{231}Pa; 6, 5.023 MeV ^{231}Pa; 7, 5.052 MeV ^{231}Pa; 8, 5.432 MeV ^{227}Th; 9, 5.538 MeV ^{227}Th; 10, 5.605 MeV ^{223}Ra; 11, 5.71 MeV (complex) ^{227}Th and ^{223}Ra; 12, 5.755 MeV ^{227}Th; 13, 5.864 MeV ^{227}Th; 14, 5.976 MeV ^{227}Th; 15, 6.037 MeV ^{227}Th; 16, 6.278 MeV ^{211}Bi; 17, 6.423 MeV ^{219}Rn; 18, 6.551 MeV ^{219}Rn; 19, 6.622 MeV ^{211}Bi; 20, 6.817 MeV ^{219}Rn; 21, 7.384 MeV ^{215}Po.

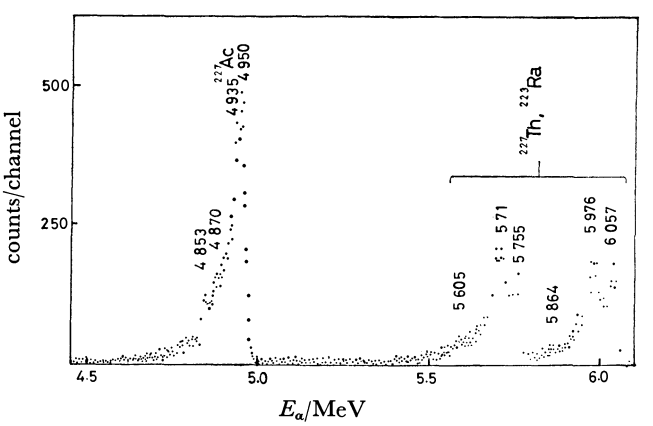

Fig. 3. Alpha-ray spectrum of the purified ^{227}Ac.

An α-ray spectrum of ^{227}Ac is also shown in Fig. 3. In Fig. 3, no α-rays of ^{231}Pa are observed, while α-rays of ^{227}Th and ^{223}Ra are observed. These daughter nuclides grow fast during the sample preparation and the spectrum acquisition. The branching ratio of the α-decay of ^{227}Ac is only 1.38%.[7] Therefore by comparing these three α-ray spectra, it can be concluded that the purified ^{227}Ac is completely free from the contamination of ^{231}Pa. On the other hand, no α-rays of ^{227}Th, ^{223}Ra, and their daughter nuclides appeared in the purified ^{231}Pa sample. This is evidence that the purified ^{231}Pa is free from any contamination of the daughter nuclides.

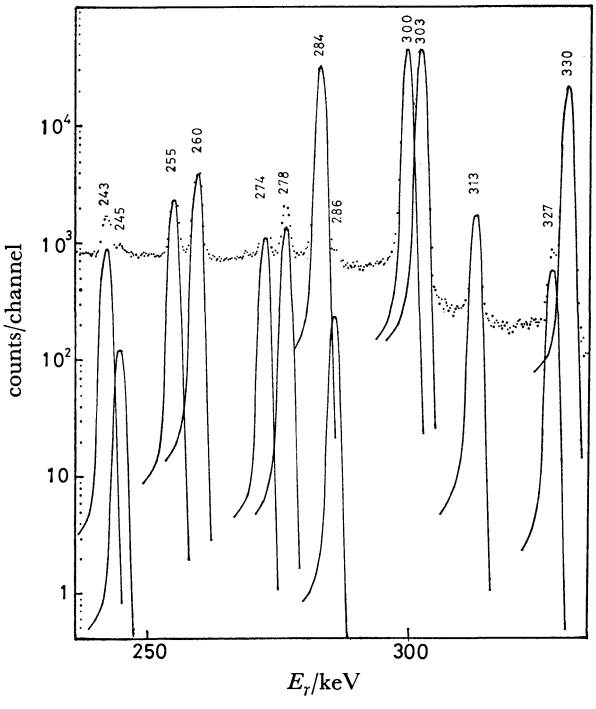

Fig. 5. Gamma-ray spectrum of ^{231}Pa, from 240 keV to 335 keV.

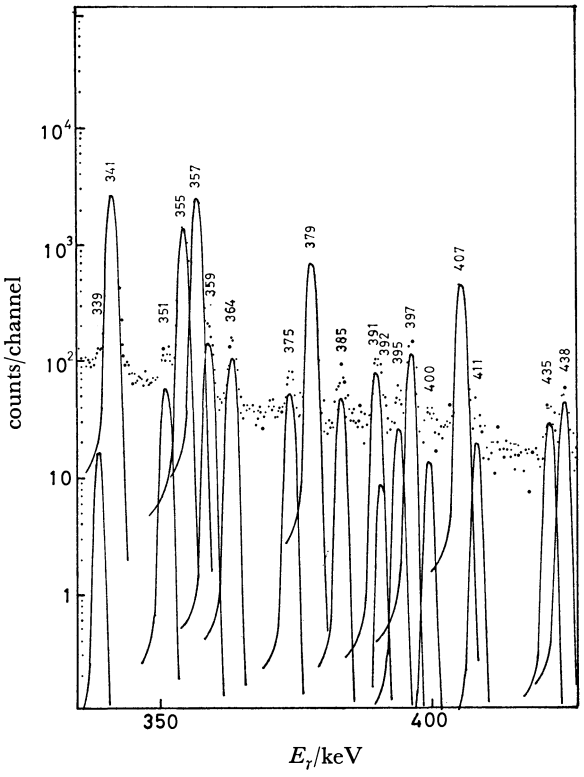

Fig. 6. Gamma-ray spectrum of ^{231}Pa, from 335 keV to 440 keV.

Gamma-ray Spectrum of ^{231}Pa. The γ-ray spectra of ^{231}Pa are shown in Figs. 4—6. In these figures, the peak components are shown as the peak shapes to illustrate the analysis of the γ-ray spectrum described in the Experimental section. The relative intensities of some γ-rays are shown in Table 1.

It is worthwhile to point out the following facts from Table 1:

1. Our data show the best correlation with the data of de Pinho *et al.*[8] The correlation is almost complete for the γ-rays whose intensities relative to that of 303

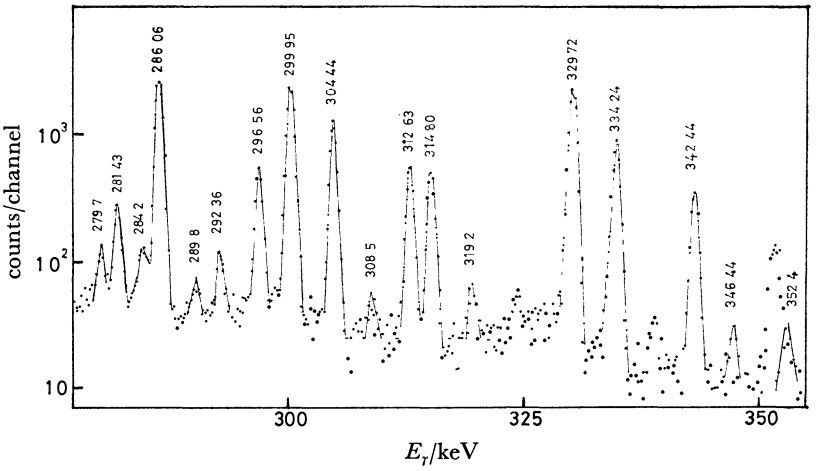

Fig. 10. Gamma-ray spectrum of ^{227}Th, from 278 keV to 355 keV.

keV γ-ray are greater than 0.01.

2. The data of Lange and Hagee[9] are quite erroneous, though they were employed in the γ-ray catalogue of Wakat.[10]

3. The data of Zaddach[11] are the latest. His data about abundances are identical with the data of Leang and since Zaddach did not describe his experimental technique, we considered the data of Leang. As will be described below, Leang's data are not very accurate and the intensities of the 255 keV, 284 keV, 300 keV,

The γ-rays which are important for the γ-ray spectrometry of the actinium series are tabulated in this table.
a) Intensities relative to the doublet of 300 keV and 303 keV. b) Observed.

and 313 keV γ-rays are obviously overcounted. These deviations, except that of the γ-ray of 255 keV, can be explained as resulting from the contamination of ^{233}Pa, which was spiked as a tracer in his experiment. Indeed, this contamination was mentioned by Leang in his raw γ-ray spectrum.[12]

As has been described above, we can conclude that our data and de Pinho's data about the relative intensity have a higher reliability than the other data. The abundances of the γ-rays of ^{231}Pa were determined by Leang; the abundance of 303 keV γ-ray is 2.3%.[12] As will be described below, the abundance of the γ-rays of ^{231}Pa are much smaller than those of ^{227}Th. Also, the measurement of the intensities of the main γ-rays of ^{231}Pa, *i.e.*, 284 keV, 300 keV, 303 keV, 341 keV, and 357 keV, is almost impossible if ^{227}Ac, ^{227}Th, or ^{223}Ra is in the sample of ^{231}Pa. Especially, it should be remenbered that 300 keV γ-rays of ^{231}Pa and ^{227}Th appear as a singlet peak even when a high-resolution Ge(Li) detector is used. Therefore, it is necessary to separate completely ^{227}Ac and its daughter nuclides from ^{231}Pa for the γ-ray spectrometric determination of ^{231}Pa. It is also necessary to certify the correlation between the relative intensities of the observed γ-rays and our data.

Gamma-ray Spectrum of ^{227}Th. The γ-ray spectra of ^{227}Th, as obtained by the intrinsic germanium detector, are shown in Figs. 7—10. Even in an initially pure ^{227}Th sample, ^{223}Ra and its daughter nuclides grow rather fast. Therefore, as has been described in the Experimental section, the decay in the γ-rays was examined until the transient equilibrium was attained between ^{227}Th, ^{223}Ra, and their daughter nuclides. Some examples of the decay curves are shown in Fig. 11. As is shown in Fig. 11, γ-rays of ^{227}Th can be easily determined to be monotonously decaying γ-rays. In Table 2, the relative intensities are shown along with the literature values.[13,14]

The data of Hesselink *et al.*[14] are the latest and were obtained by α,γ coincidence employing a Ge(Li) detector with a resolution of 2.3 keV at 120 keV and a silicon surface-barrier detector with a resolution of 30 keV. It is clear from Figs. 2 and 7—10 that the Ge(Li) detector and the silicon surface-barrier detector do not have efficient enough resolutions for the γ-ray spectroscopy of ^{227}Th. On the other hand, the works of Briancon *et al.*[13] consist of γ,γ coincidence and conversion electron spectroscopy. They also employed two Ge(Li) detectors with resolutions of 0.9 keV and 2.5 keV for 100 keV γ-ray. The resolutions of the Ge(Li) detectors employed by Briancon *et al.* were not good enough to resolve the complex structure of the γ-ray spectrum of ^{227}Th at the energy regions of 40 keV to 50 keV, 80 keV to 100 keV, 200 keV to 213 keV, 234 keV to 236 keV, 250 keV to 257 keV, 269 keV to 273 keV, 279 keV to 305 keV, 312 keV to 315 keV, and 350 keV to 353 keV. In spite of these difficulties, the two works agree well about existence of the main γ-rays. However, about the intensities of almost all the γ-rays and the existence of some weak γ-rays, the agreement between the two works is far from satisfactory. For the γ-ray spectrometry of ^{227}Th, the

a) Intensities relative to the doublet of 234.82 keV and 236.01 keV. b) Numbers in parentheses are estimated standard deviations in units of the last significant digit.

relative intensities of the γ-rays of 50 keV, 236 keV, 286 keV, and 300 keV are very important parameters as measures of the radiochemical purity of the sample, because the contamination by ^{231}Pa or ^{227}Ac influences the relative intensities of these γ-rays. These γ-rays are observed as multiplet γ-ray peaks, and the multiplicity depends on the resolution of the detector employed. Therefore, it is necessary to get data about the intensities of these γ-rays based upon more accurate basis than the two works in the literature in order to improve the accuracy of the γ-ray spectrometry of ^{227}Th.

On the other hand, the excellency of our measurement depends on the highest resolution of the detector employed. As is shown in Figs. 7—10, we obtained well-resolved γ-ray spectra, and so we can now consider the reason for the disagreement between the literature data.

Obviously, there is no doubt about the existence of

Only the γ-rays, which are important for γ-ray spectrometry of the actinium series, are tabulated.

the three γ-rays of 20.32 keV, 30.00 keV, and 31.78 keV reported by Briancon *et al.*[13] However, we could not find any γ-rays except the KX escape peaks of 50.17 keV γ-ray at 39.22 keV and 40.32 keV. It was found the intensity ratio of these two peaks in identical to that of the K_α and K_β rays of Ge. Thus, the intensity of the γ-ray of 40.1 keV reported in Ref. 13 seems to be doubtful. Similarly, we did not observe the 224.7 keV and 246.4 keV γ-rays except the KX escape peaks of the 236.01 keV and 256.24 keV γ-rays respectively, while these two γ-rays were reported in Ref. 14. For the sake of further consideration, a γ-ray table of ^{223}Ra and its daughter nuclides is shown in Table 3. In the γ-ray spectrum of ^{223}Ra, KX-rays of the daughter elements are also observed. In ^{227}Th, we observed rapidly growing KX-rays and γ-rays of 69.8 keV, 72.9 keV, 75.3 keV, 89.9 keV, 95.0 keV, 269.5 keV, 271.2 keV, 324.2 keV, 338.3 keV, and 351.1 keV. Many γ-rays with energies approximately equal to these KX-rays and γ-rays were reported in Refs. 13 and 14. For the γ-ray spectrometry of ^{227}Th, these γ-rays are not important because the many other intense γ-rays can be utilized. However for ^{223}Ra, 269 keV, 324 keV, and 338 keV γ-rays are important for the γ-ray spectrometry. According to Refs. 13 and 14, it seems necessary to correct the contribution by the interfering γ-rays in order to evaluate the intensities of these γ-rays accurately when the sample is contaminated with ^{227}Ac or ^{227}Th. However as is shown about the 269.46 keV γ-ray in Fig. 11, the correction is negligibly small.

According to Refs. 13 and 14, the abundances of the 50 keV, 236 keV, 256 keV, 286 keV, 300 keV, 304 keV, and 330 keV γ-rays of ^{227}Th are large enough to apply these γ-rays to the γ-ray spectrometry of ^{227}Th. We measured the abundance of the overlapped γ-rays of 234.82 keV and 236.01 keV and got a value of $(12.1\pm 0.6)\%$.[16] However, it should be mentioned that all these seven γ-rays are observed as complex overlapping peaks even when the spectrum is determined by a detector with the highest resolution. Therefore, it is very important to take into account the complex nature of the γ-ray spectrum of ^{227}Th in order to apply the γ-ray spectrometric technique to the determination of ^{227}Th. Today, ^{227}Th is often used as a radiochemical tracer for ^{231}Pa or ^{227}Ac in geochemical application. It should be mentioned that measurement by a few γ-rays, such as 50 keV, 236 keV, or 256 keV, can not be correct because of the complex nature of the decay chain and the γ-ray spectrum of ^{227}Th. The relative intensities of the observed γ-rays should be carefully examined to account for the radiochemical purity of the sample.

Gamma-ray Spectrum and Decay Scheme of ^{223}Fr. A γ-ray spectrum of ^{223}Fr is shown in Fig. 12. We observed 16 γ-rays which decayed with a half-life of ^{223}Fr in the energy region from 50 keV to 876 keV. Our observation is an additional proof of the characteristics of the γ-ray spectrum of ^{223}Fr, *i.e.*, the existence of two grounps of γ-rays, one in an energy region below 369 keV and the other in a region higher than 700 keV.[17,18] In Table 4, the relative intensities, abundances, and characteristics of the γ-rays are shown.

Among the works done previously, the work of Maria *et al.*[18] is the most comprehensive. However, we found some disagreements between the results. We found the relative intensity of the 50 keV γ-ray and the 235 keV γ-ray to be 13.9 whereas their value is only 10.[18] Another difference is in the point that they assigned the very weak γ-rays to ^{223}Fr. They used a large amount of ^{227}Ac precursor (740 MBq). Their experimental conditions are more suitable for the detection of weak γ-rays than our experimental conditions. Even so, an ambiguity remains with regard to the γ-rays of 256 keV and 286 keV, which were reported in Ref. 18. As has already been shown in Table 2, it is well known that the three γ-rays of 236 keV, 256 keV, and 286 keV are emitted from the same excited state of ^{223}Ra. Therefore, their result is erroneous in the point that they missed the 236 keV γ-ray, which is the most intense γ-ray among the three γ-rays. We did not observe any γ-rays between 240 keV and 289 keV which decayed with the half-life of ^{223}Fr. A possible explanation for these disagreements

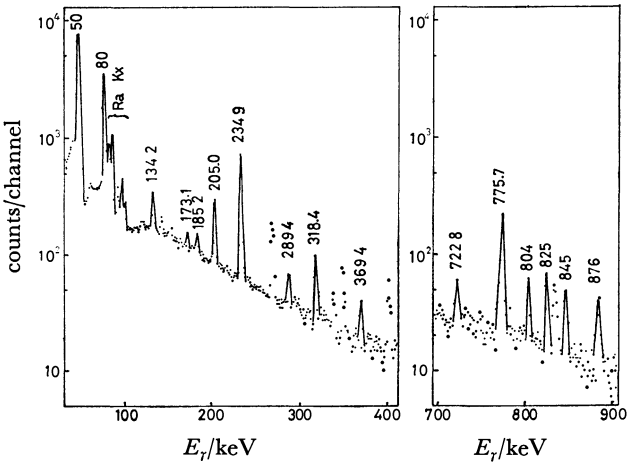

Fig. 12. Gamma-ray spectrum of ^{223}Fr.

a) Numbers in parentheses are estimated standard deviations in units of the last significant digit.

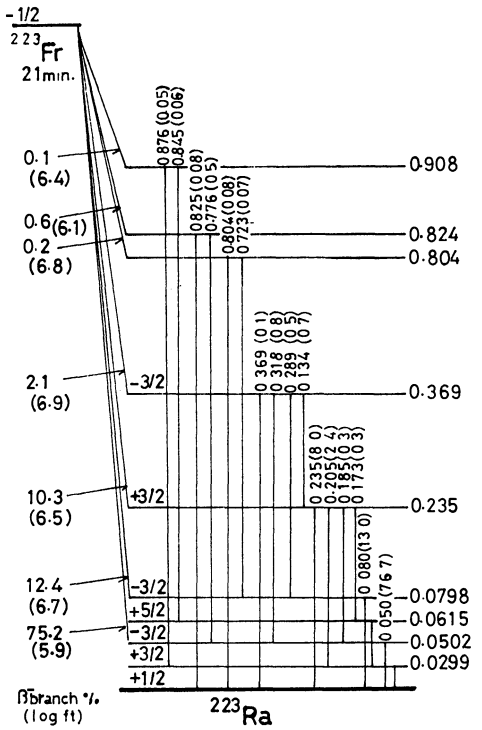

Fig. 13. Decay scheme of ^{223}Fr. Energies are given in MeV unit. Probabilities of γ-transitions per 100 β^- disintegrations are given in parentheses.

is as follows. As has been described before, the four γ-rays of 236 keV, 256 keV, 286 keV, and 50 keV are the main γ-rays of ^{227}Th. Moreover, the intensity of the overlapped γ-rays at 50 keV relative to the overlapped γ-rays at 236 keV is 0.65 for ^{227}Th. Therefore, it is reasonable to assume a trace contamination of ^{227}Th or ^{227}Ac in ^{223}Fr as an explanation of the low value of the relative intensity and of the exitence of the 256 keV and 286 keV γ-rays in the γ-ray spectrum of ^{223}Fr.

By investigations of the α-decay of ^{227}Th, we can utilize much information about the level structure of ^{223}Ra.[19] On this basis, we can conclude that all the γ-rays can be explained by the seven β^--transitions to the 50 keV (−3/2), 79.8 keV (+3/2), 235 keV (+3/2), 368 keV (+1/2), 804 keV, 824 keV, and 908 keV levels of ^{223}Ra. The decay scheme thus constructed is shown in Fig. 13. In this figure, the 29.9 keV (+3/2) and 61.5 keV (+5/2) levels are assumed to be the rotational excited states.[18,19] The classfications of the six γ-transitions from the 908 keV, 824 keV, and 804 keV levels are not known. However, the contribution of the conversion process to these γ-transitions can be neglected because of the high transition energies. For the other ten γ-transitions, the conversion coefficients were calculated by the use of the table of Hager and Seltzer.[20] Maria *et al.* also proposed a decay scheme.[18] Our modification involves the branching ratio of the most intense β^--transition to the 50 keV level.

As a conventional rapid method for the determination of non-γ-radioactive ^{227}Ac, γ-ray spectrometry of ^{223}Fr which is in radioequilibrium with ^{227}Ac is considered to be promising. Practically the methods can be classified into two types. One type is based on the measurement of the purified ^{223}Fr. The other type is based on the measurement of ^{223}Fr which is in the partial radioequilibrium with ^{227}Ac, when the other daughter nuclides has been removed from the sample. And then, the γ-ray spectrum of almost pure ^{223}Fr will be determined. In order to apply the former method, ^{223}Fr should be isolated from ^{227}Ac by a method which has a definite mean retention time for ^{223}Fr. Also, the mean retention time should be less than 1 min in the cow phase of ^{227}Ac to get more than 95% of ^{223}Fr. Therefore, the latter method seems to be more reliable. Of course, it is necessary to correct the contribution by ^{227}Th when the intensity of the sample is not large enough. However, the correction can be done with a high precision by referring to the relative intensities of the γ-rays of ^{227}Th tabulated in Table 2. Moreover, whether or not there is a necessity to correct can be easily desided when an abnormally low value of the relative intensity of the 50 keV γ-ray is measured.

The authors would like to thank Professor Kiyoteru Otozai, the Osaka University, for his helpful discussion of the γ-ray spectrometry and the decay scheme of ^{223}Fr.

Studies of the Metal Complexes of Cyclohexane Derivatives. VI.[1] The Thermal Transformation of Nickel(II) Complexes of 1,2-Cyclohexanediamine Isomers

Reiko SAITO* and Yoshinori KIDANI†

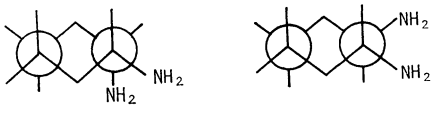
Aichi Junior College of Nursing, Kamishidanmi, Moriyama-ku, Nagoya 463

†*Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabedori, Mizuho-ku, Nagoya 467*

(Received January 25, 1979)

The thermal transformations of the following three types of nickel(II) complexes were investigated by means of TG-DSC analyses: $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$, $[Ni(c\text{-chxn})_3]X_2\cdot nH_2O$, and $[Ni(t\text{-chxn})_3]X_2\cdot nH_2O$ ($X=Cl^-$, Br^-, and NO_3^-), where *c*- and *t*-chxn denote *cis*- and *trans*-1,2-cyclohexanediamine respectively. The distorted octahedral $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ complexes ($X=Cl^-$ and Br^-) are thermally deaquated to form yellow complexes, which then turn into parental diaquabis-complexes in the air at room temperature. $[Ni(t\text{-chxn})_2(H_2O)_2](NO_3)_2$ undergoes a thermal deaquation-anation reaction. The octahedral tris(*c*-chxn) complex is converted into a square planar bis(*c*-chxn) one by the evolution of one molecule of the ligand upon heating, whereas tris(*t*-chxn) complex became a distorted octahedral bis(*t*-chxn) one with anion coordination. In this paper, the stereochemical thermal changes of the complexes in the solid state will be discussed with regard to the steric configuration of the ligands.

The present authors reported earlier the preparations of the copper(II) and the nickel(II) complexes of *cis*- and *trans*-1,2-cyclohexanediamine (abbreviated as *c*-chxn and *t*-chxn), and showed that the structures of the bis-complexes were greatly affected by the steric configurations of these diamines.[2] The ligand, *t*-chxn, whose amino groups bonded to the cyclohexane ring in the diequatorial conformation(b), as is shown below, can be expected to have a coordination ability closely related to that of ethylenediamine.[3-5] It affords violet paramagnetic bis-complexes such as $[Ni(t\text{-chxn})_2(H_2O)_2]Cl_2$. On the other hand, since the *c*-chxn has two amino groups in the axial and the equatorial positions (a), it preferentially forms yellow diamagnetic bis-complexes such as $[Ni(c\text{-chxn})_2]Cl_2$. The distances between N atoms of the diamine isomers are nearly equal, therefore, the structural differences among the complexes seem to be due to the degree of the steric hindrance of the cyclohexane ring. In this paper, the results of thermal reactions of the nickel(II) complexes in the solid state will be described and the steric influence of these ligands on coordination will be shown.



(a) *c*-chxn (b) *t*-chxn

Experimental

Measurements. Thermogravimetric(TG) and differential scanning calorimetric(DSC) curves were obtained with a Rigaku Denki 8185 DI apparatus at a 1.25 °C min^{-1} heating rate and with a 50 cm^3 min^{-1} flow rate of nitrogen gas. The reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer. The infrared spectra were recorded with a JASCO IRA-2 spectrophotometer by means of the HCB mull and the KBr disc method.

Preparations. The ligands, *c*-chxn and racemic *t*-chxn, were obtained in the manner reported previously.[6] $[Ni(t\text{-chxn})_2(H_2O)_2]Br_2$, $[Ni(c\text{-xhn})_3]Cl_2\cdot 1.5H_2O$, $[Ni(c\text{-chxn}_3)]Br_2\cdot H_2O$, and $[Ni(c\text{-chxn})_3](NO_3)_2\cdot 0.5H_2O$ were prepared by means of the previously described procedures.[2] $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ ($X=Cl^-$ and NO_3^-), $[Ni(t\text{-chxn})_3]Cl_2\cdot 2H_2O$, and $[Ni(t\text{-chxn})_3]Br_2\cdot 3H_2O$ were synthesized with reference to the methods described in the literature.[7,8] The chemical formulae were confirmed by elemental analyses.

Results and Discussion

The TG-DSC curves of the following three types of complexes, $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$, $[Ni(c\text{-chxn})_3]X_2\cdot nH_2O$, and $[Ni(t\text{-chxn})_3]X_2\cdot nH_2O$ ($X=Cl^-$, Br^- and NO_3^-), are shown in Figs. 1, 2, and 3 respectively, while the results are summarized in Table 1. It was confirmed that the colors of $[Ni(c\text{-chxn})_2]X_2$ complexes did not change in the temperature range from *ca.* 25 °C to 250 °C. Therefore, the square planar structures of these complexes are regarded as very stable. The *c*-chxn molecules in this structure make it unfavorable for water molecules or anions to approach the nickel(II) ion along

the z axes because of the steric hindrance caused by the cyclohexane rings, which are located obliquely above the chelate ring.

The diaquabis(*t*-chxn) complexes of three kinds of X anions liberated two molecules of coordinated water in the following order of increasing deaquation temperature; $X = NO_3^- < Br^- < Cl^-$, giving similar DSC curves. A few qualitative observations of this thermal behavior have been reported by Tsuchida.[7] The temperature at which thermal deaquation occurs seems to be dependent upon the degree of interaction between a water molecule and an anion, and also upon the degree of axial perturbation of the anions. The present authors have presumed on the basis of the infrared spectra, that, in the structures of these complexes, not anions, but water molecules are coordinated in the apical positions.[2] The coordination of water molecules is also suggested by the large endothermic peak of the DSC curves.

The complexes of this type are found to undergo thermal transformation in two ways with a variety of anions, like diaquabis(*N*,*N*-diethylethylenediamine)nickel(II) complexes.[9,10] In the cases of the chloride and the bromide, yellow complexes were obtained after deaquation, but they turned blue violet again when they were kept in the air at room temperature. The resultant blue violet complexes are assumed to be the initial diaquabis-complexes because the former exhibit infrared and electronic spectra almost identical with those of the latter. This indicates the reversible transformation from a square planar structure to a distorted octahedron by the coordination of water molecules in the apical positions in the solid state. On the other hand, the color of $[Ni(t\text{-chxn})_2(H_2O)_2](NO_3)_2$ did not change on deaquation. Figure 4 shows the infrared spectra of the nitrate complex and the sample obtained by heating. The broad ν_{NO} of the initial diaquabis-complex splits into two peaks, at 1310 and 1432 cm^{-1}, after deaquation. They can reasonably be assigned to the ν_{NO} stretching

Table 1. DSC peak temperature (t_m/°C), weight-losses ($-\Delta W$/%), and color changes in thermal analyses

a) The deaquation change occurred so gradually that the DSC peak temperature could not be measured exactly. b) The weight-losses in the deaquation step could not be measured independently, so the ΔW values in the Liberation of ligand column contain ΔW in the deaquation step.

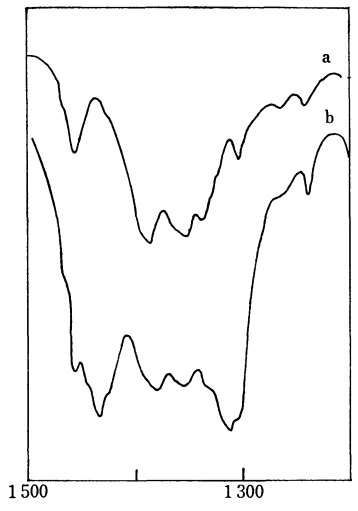

Fig. 4. Infrared spectra of $[Ni(t\text{-chxn})_2(H_2O)_2](NO_3)_2$: (a) before heating, (b) after heating.

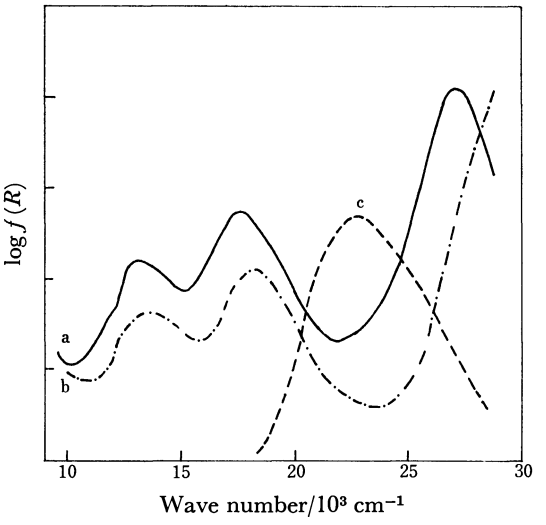

Fig. 5. Reflectance spectra of the samples, after heating, (a) $[Ni(t\text{-chxn})_3]Br_2 \cdot 3H_2O$ at 260 °C, (b) $[Ni(t\text{-chxn})_2(H_2O)_2](NO_3)_2$ at 100 °C, and (c) $[Ni(c\text{-chxn})_3]Cl_2 \cdot 1.5H_2O$ at 220 °C.

of the unidentate nitrate anion.[11] In the reflectance spectrum of the corresponding anhydrous complex, three characteristic maxima, at 12300 (sh), 13500, and 17200 cm^{-1}, were observed (Fig. 5), they are ascribable to the trans tetragonal structure, although the band near 28000 cm^{-1} could not be observed due to the charge-transfer band of a nitrate anion. Therefore, in the case of nitrate, deaquation-anation seems to take place simultaneously. This thermal reaction is parallel to that found by Inoue[12] and Curtis[11] for $[Ni(en)_2(H_2O)_2](NO_3)_2$.

The tris-complexes of *c*-chxn changed to yellow complexes, liberating some water of crystallization and one molecule of ligand on heating, although no distinct plateau on the TG curves for the deaquation process were observed. The spectral patterns of the yellow complexes are in good agreement with those of the corresponding diamagnetic $[Ni(c\text{-chxn})_2]X_2$.[2] Nishimoto reported the thermal transformation from the octahedral structure of tris(*meso*-2,3-butanediamine)nickel(II) halide to a square planar structure.[13] It was revealed that the cyclohexane ring of *c*-chxn had steric effects on the configuration of the nickel(II) complexes similar to those of the ethylenediamine derivative with substituents on the C atoms.

The tris-complexes of *t*-chxn with halide ions gave blue violet bis-complexes, releasing one molecule of a ligand, upon heating. The visible reflectance spectra of the resultant bis-complexes show ν_{max} at 12100 (sh), 13500, 17500, and 27400 cm^{-1} ($X=Cl^-$), and at 11800 (sh), 13200, 17500, and 27500 cm^{-1} ($X=Br^-$), respectively (Fig. 5). The resemblance of these spectra to those of dihalogenobis(*N,N'*-dimethylethylenediamine)nickel(II)[14] suggests that the bis-complexes have a tetragonally distorted octahedral structure, with halide ions coordinated in the apical positions. The *t*-chxn is assumed to prefer the above structure because of the ample spaces in the z axes. The corresponding nitrate released a ligand at higher temperatures and gave a brown material as a result of the successive decomposition. It is of interest to note that the temperatures of the eliminating ligand for each type of tris-complex, *c*-chxn and *t*-chxn, increase in the following order; $X=Cl^-<Br^-<NO_3^-$, the reverse of that in the case of the deaquation of diaquabiscomplexes.

(Received February 8, 1979)

The conditions of formation of the A and B forms of $Fe(H_2PO_4)_3$ by the reaction of Fe_2O_3 and H_3PO_4 have been established, and the thermal changes and structural changes in humid atmospheres investigated. 1) The A and B forms of $Fe(H_2PO_4)_3$ were readily formed by secondary heat treatment at 150 °C and 125 °C, respectively. 2) The forms of $Fe(H_2PO_4)_3$ were largely dependent on the heating rate in the primary heat treatment, *i.e.*, at a mean heating rate less than 7 °C/min the A form predominated, whereas above 60 °C/min the B form predominated. A heating rate between 7 and 60 °C/min gave a mixture of the A and B forms. 3) A close relationship between the water content of the primary product and yields of the A and B forms of $Fe(H_2PO_4)_3$ was found, *i.e.*, only the B form was obtained when the water content of the primary product was less than 7%, while the A form was readily formed when the water content was greater than 11%. 4) Heating the primary product under various degrees of humidity enabled the formation of $Fe(H_2PO_4)_3$ to be investigated. The effect of heating atmosphere was small except under vacuum. 5) The structural changes of the A and B forms of $Fe(H_2PO_4)_3$ under several humid atmospheres are summarized as follows:

$$Fe(H_2PO_4)_3\ \text{B form} \underset{P_2O_5}{\overset{\text{air}}{\rightleftarrows}} FeH_6(PO_4)_3 \overset{\text{wet air}}{\underset{P_2O_5}{\rightleftarrows}} \text{amorphous}$$

$$\text{iron phosphate} \xrightarrow{\text{air}} FeH_3(PO_4)_2\cdot 2.5H_2O$$

$$Fe(H_2PO_4)_3\ \text{B form} \quad \text{air} \uparrow\downarrow P_2O_5$$

$$Fe(H_2PO_4)_3\ \text{A form} \xrightarrow{\text{air}} FeH_6(PO_4)_3 \overset{\text{wet air}}{\underset{SiO_2}{\rightleftarrows}} \text{amorphous}$$

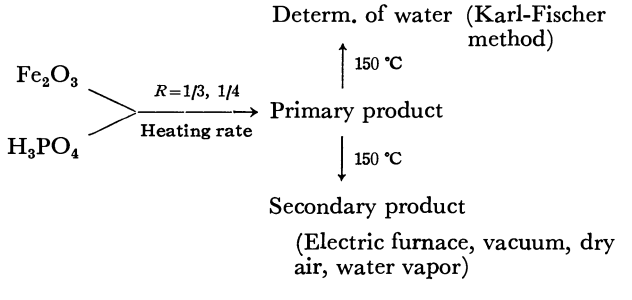
$$\text{iron phosphate} \xrightarrow{\text{air}} FeH_3(PO_4)_2\cdot 2.5H_2O$$

Iron phosphates have been studied for several years and already in 1878 several iron phosphates had been synthesized by Erlenmeyer.[1] Since then the structural chemistry of several natural iron phosphates, such as strengite $FePO_4\cdot 2H_2O$,[2] vivianite $Fe_3(PO_4)_2\cdot 8H_2O$,[3] ludlamite $Fe_3(PO_4)_2\cdot 4H_2O$[4] and the like,[5–7] have been conducted by many researchers. Carter,[8] Jameson[9] and Kobayashi[10] have studied the phase diagram of the Fe_2O_3–P_2O_5–H_2O system at 25 °C and several iron phosphates synthesized. d'Yvoire[11] has studied in detail the similarity of structure between iron phosphate and aluminum phosphate.

Recently, fundamental studies of iron phosphate as an inorganic ion exchanger have been published,[10,12–14] but a systematic study of the preparation of iron phosphates remains absent. Consequently it is difficult to obtain iron phosphates with fine reproducibility. In the present study, the authors investigated the preparative methods for the A and B forms of iron hydrogen orthophosphate $Fe(H_2PO_4)_3$, and established the preparative conditions in the reaction of Fe_2O_3 and H_3PO_4. The thermal changes of the A and B forms of $Fe(H_2PO_4)_3$ as well as the structural changes under several different humid atmospheres were also investigated.

Experimental

Preparation of Iron Phosphate. Ferric oxide Fe_2O_3 (E. Merck) and 85% orthophosphoric acid were mixed in a gold or porcelain crucible in molar ratios Fe_2O_3/P_2O_5 (R) of 1/3 and 1/4. The mixture was heated at various heating rates by a weak flame with vigorous agitation to obtain a grey, highly viscous product. (This is designated as the primary heat treatment, giving the primary products.) A small amount (0.5—0.6 g) of the primary product was accurately weighed, and the water content determined by the Karl-Fischer method at 150 °C. Another portion was heated at 150 °C for 5 h in a thermostated electric furnace, under vacuum (0.01 mmHg), in dry air (50 ml/min, vapor pressure 0—1 mmHg), and in water vapor (500 g H_2O/h, vapor pressure 760 mmHg). (This is designated as the secondary heat treatment, giving the secondary products.) The experimental method may be shown schematically as follows:



The temperature of the primary heat treatment is affected by the amount of starting material, the molar ratio R and the heating rate; the temperature being generally approximately 70—170 °C.

The iron phosphates prepared at 150 °C were relatively hard, but absorbed moisture on standing in air. Thus, X-ray

analysis, differential thermal analysis (DTA), and thermogravimetry (TG) of iron phosphates were conducted immediately after preparation.

Apparatus and Methods. The X-ray analysis was conducted with a Rigaku Denki Geigerflex X-ray diffractometer, using Ni filtered Cu $K\alpha$ radiation. A Kyoto Denshi Karl-Fischer Titrator was used for the determination of water. A Rigaku Denki Differential Thermogravimetric Analyzer, 8076E1, was used for the DTA and TG. The X-ray analysis, differential thermal analysis, and thermogravimetry of iron phosphates were conducted by the methods described in a previous paper.[15]

The yields of the A and B forms of $Fe(H_2PO_4)_3$, $FeHP_2O_7$, $Fe_4(P_2O_7)_3$ and $FeH_6(PO_4)_3$ were determined from the integrated intensities of the characteristic X-ray diffraction peaks; *i.e.*, type A of $Fe(H_2PO_4)_3$ by the peak at $d=3.634$ Å; type B of $Fe(H_2PO_4)_3$, by that at 7.724 Å; $FeHP_2O_7$, by that at 3.860 Å; $Fe_4(P_2O_7)_3$, by that at 5.336 Å; and $FeH_6(PO_4)_3$, by that at 8.776 Å.

Results and Discussion

Relationship between Yields of Iron(III) Phosphates and Heating Temperature. Figure 1 shows the relationship between the heating temperature and the yields of iron phosphates in the reaction of Fe_2O_3 and H_3PO_4 at a molar ratio P_2O_5/Fe_2O_3 ($1/R$) of 3. As seen, the crystalline iron phosphates formed at temperature below 250 °C were four, namely, the A and B forms of $Fe(H_2PO_4)_3$, $FeHP_2O_7$, and $Fe_4(P_2O_7)_3$. At temperatures below 200 °C, iron hydrogen orthophosphate predominated, whereas above 225 °C pyrophosphate predominated. The A form of $Fe(H_2PO_4)_3$ was formed at temperatures below 200 °C, and especially at 150 °C. The B form was formed at temperatures below 175 °C, particularly readily at 125 °C. At temperatures above 225 °C $FeHP_2O_7$ and $Fe_4(P_2O_7)_3$ were obtained in a mixture, but in the temperature range 200—250 °C, the presence of large quantity of amorphous iron phosphate was proved by X-ray diffraction. The poor yields of $FeHP_2O_7$ and $Fe_4(P_2O_7)_3$ may be explained in terms of the mixing rate (R) of phosphoric acid and Fe_2O_3. $R=1/3$ corresponds to the meta-composition, and the quantity of phosphoric acid is too large to form iron pyrophosphate. No distinct difference could be established between the temperature of formation of $FeHP_2O_7$ and that of $Fe_4(P_2O_7)_3$, while considerable difference was observed between the temperature of formation of the A form of $Fe(H_2PO_4)_3$ and that of the B form. This establishes that the B form is prefered at low temperatures. At 150 °C, however, both forms were obtained in a mixture, and the reproducibility of yield was poor. It was also discovered that the yields were affected not only by the heating temperature but also by the conditions of the primary heat treatment. Maintaining the molar ratios and the temperatures of the primary and secondary heat treatments did not always give the same form of $Fe(H_2PO_4)_3$. Thus, the primary heat treatment, heating rate, the state of the primary product, the water content and heating atmosphere in the secondary heat treatment were further investigated. With molar ratios $1/R$ of 4 and 3, almost the same results were obtained. At a secondary heat treatment temperature below 110 °C, the product did not solidify and crystalline iron phosphate could not be obtained.

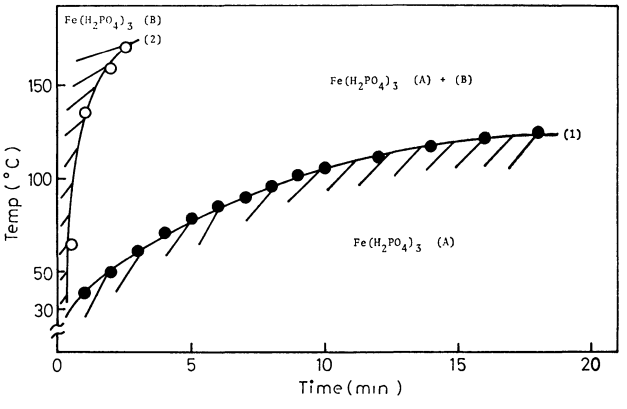

Fig. 2. Relationship between the formation of $Fe(H_2PO_4)_3$ (A), (B) and heating rate in the primary heat treatment. Molar ratio (P_2O_5/Fe_2O_3);3, heating rate; (1): 7 °C/min, (2): 60 °C/min, secondary heat treatment; 150 °C, 5 h.

Relationship between the Formation of the A and B Forms of $Fe(H_2PO_4)_3$ and the Heating Rate. Figure 2 illustrates the change in formation of the A and B forms of $Fe(H_2PO_4)_3$ with changes in the heating rate in the primary heat treatment. As shown by curve (1) in Fig. 2, slow heating at a mean heating rate less than 7 °C/min results in the exclusive formation of the A form. As can be seen from curve (2), rapid heating at a rate in excess of 60 °C/min produces exclusively the B form. Heating at a rate between 7 and 60 °C/min (the region surrounded by curves (1) and (2) in Fig. 2) results in a mixture. The A form, however, predominates at a lower heating rate (10—20 °C/min), whereas the B form predominates at a higher heating rate (40—60 °C/min). The above results were highly reproducible, there being only a few exceptions in 80 experiments. These results are only applicable for highly viscous primary products. Further heating of the viscous primary product and subsequent solidification in the course of the primary heat treatment, however, gave a different relationship, the results of which are shown in Fig. 3. At a primary heat treatment of heating rate below 2.5 °C/min (curve (1) in

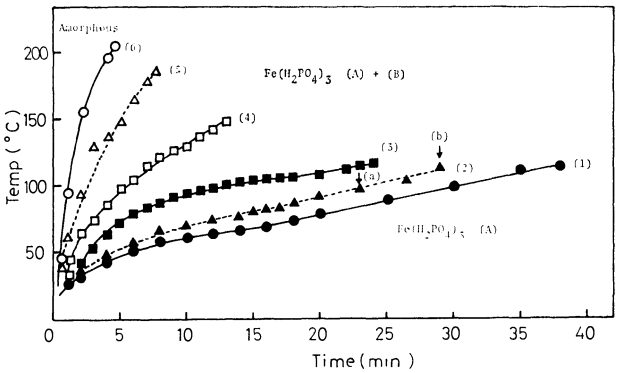

Fig. 3. Relationship between the formation of $Fe(H_2PO_4)_3$ (A), (B) and heating rate in the primary heat treatment. Fig. 4. Relationship between water content of the primary product and the yields of the A and B types of $Fe(H_2PO_4)_3$.
-●-: $Fe(H_2PO_4)_3$ A type, -○-: $Fe(H_2PO)_3$ B type, Molar ratio (P_2O_5/Fe_2O_3): 3, secondary heat treatment: 150 °C, 5 h.

Fig. 3), only the A form of $Fe(H_2PO_4)_3$ was obtained. At a primary heat treatment of heating rate above 40 °C/min (curve (6)), no crystalline iron phosphate was formed. At a primary heat treatment of heating rate of 3—40 °C/min (curves (2)—(5)), a mixture of the A and B forms was produced. Thus, only the B form of $Fe(H_2PO_4)_3$ could not be obtained from the solidified primary products. Two samples of the primary product obtained at a mean heating rate of about 3.7 °C/min (curve (2)), one of which was a highly viscous nature corresponding to point (a) and other the solidified state corresponding to point (b), were submitted for secondary heat treatment at 150 °C for 5 h. The iron phosphate formed from the former was the A form of $Fe(H_2PO_4)_3$, while that from the latter was a mixture of both A and B forms. The amounts of water liberated on heating the primary products corresponding to points (a) and (b) at 150 °C were 13.5% and 9.4%, respectively, indicating that since the primary product of the solidified state which was subjected to primary heat treatment at a higher temperature than that of the highly viscous state, the water content of the latter, corresponding to point (a), may be more than that of the former, corresponding to point (b). Based on this, it may be seen that the formation of both forms is strongly dependent on the state of the primary products, *i.e.*, at the same heating rate, the formation regions of the A and B forms for the highly viscous primary products differ from those for the solidified primary products. Furthermore, as can be seen from Figs. 2 and 3, the formation region of the mixture of both forms in the solidified primary product is greater than that in the highly viscous primary product.

Relationship between Water Content of the Primary Product and Yields of Iron(III) Hydrogen Orthophosphate. As described above, the formation of the A and B forms of $Fe(H_2PO_4)_3$ strongly depend on the heating temperature, heating rate and the state of the primary product. Thus, the relationship between the water content of the primary product and yields of the A and B forms of $Fe(H_2PO_4)_3$ was investigated, the results of which are shown in Fig. 4. From a primary product containing approximately 7% or less of water, only the B form of $Fe(H_2PO_4)_3$ was obtained, while from a primary product containing 11% or more of water, only the A form was obtained. From primary products having between 7.5 and 10.5% water content, a mixture of both A and B forms was obtained. The results of DTA and TG of the primary products suggest that the water liberated on heating the primary product at 150 °C may be water loosely bound on the solid surface, and not the structural water (P–OH) of iron phosphate. It is evident, therefore, that the water content (loosely bound water) of the primary product strongly affects the formation of the A and B forms of $Fe(H_2PO_4)_3$. It was also estab-

Product, A: $Fe(H_2PO_4)_3$ A form, B: $Fe(H_2PO_4)_3$ B form.

lished that the water content was inversely proportional to the heating rate of the primary heat treatment, *i.e.*, the water content decreased with increase in the heating rate.

In conclusion the A form of $Fe(H_2PO_4)_3$ is formed more readily at a low rate of heating, namely in the region in which the water content of the primary product was high. The B form is prefered at a higher heating rate, *i.e.*, at lower water content of the primary product.

Formation of Iron(III) Phosphates in Several Heating Atmospheres. The primary products prepared by the above-mentioned methods at various heating rates, *i.e.*, primary products containing various water contents were heated at 150 °C for 5 h in various water vapor pressures and the formation of iron phosphate investigated. The results are summarized in Table 1. As can be seen from Table 1, the formation of iron hydrogen orthophosphate is only slightly dependent on the heating atmosphere, but strongly affected by the heating rate of the primary heat treatment and consequently, by the water content of the primary product. This strongly supports the relationship reported above between the water content of the primary product and yields of the A and B forms of $Fe(H_2PO_4)_3$, *i.e.*, at a low heating rate the A form predominates, while at a high heating rate, the B form predominates. In vacuum, the formation of the B form of $Fe(H_2PO_4)_3$ was not observed, amorphous iron phosphate being obtained at low water content.

DTA and TG of the A and B Forms of $Fe(H_2PO_4)_3$.

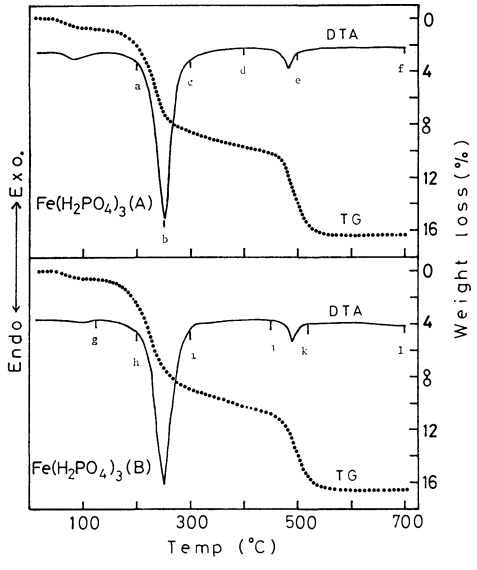

Fig. 5. DTA and TG of $Fe(H_2PO_4)_3$ (A), (B). Sample; 20—22 mg, heating rate; 10 °C/min.

Figure 5 illustrates the results of DTA and TG for the A and B forms of $Fe(H_2PO_4)_3$. For the A form, endothermic peaks were observed at approximately 75—80, 250, and 475 °C. The products corresponding to each point, a (200 °C), b (250 °C), c (300 °C), d (400 °C), e (500 °C), and f (700 °C) on the DTA curve were investigated by powder X-ray diffraction. At point a, only the starting material, the A form of $Fe(H_2PO_4)_3$ was observed. Thus, the small endothermic peak at approximately 75—80 °C, which is accompanied by a slight weight loss (0.9—1.2%), may be attributed to the removal of water adhering to the solid surface, namely adhesive water. Furthermore, from the X-ray diffraction patterns of the products corresponding to points b and c, it was shown that the A form of $Fe(H_2PO_4)_3$ is transformed into amorphous iron phosphate through the strong endothermic reaction with a weight loss caused by dehydration at about 250 °C. At point d, the amorphous iron phosphate was partially transformed into the B and C forms of $Fe(PO_3)_3$. Furthermore, the endothermic reaction at approximately 475 °C (point e), the amorphous iron phosphate was completely transformed into the C form of $Fe(PO_3)_3$, which did not change at 700 °C (point f). The results of the DTA and TG of the B form of $Fe(H_2PO_4)_3$ were almost identical with those of the A form. For the B form of $Fe(H_2PO_4)_3$, a small endothermic peak, accompanied by a 0.5—0.8% weight loss, was observed at approximately 75—80 °C. This weak endothermic reaction may be considered as the removal of adhesive moisture, since the X-ray diffraction patterns of the products at points g (120 °C) and h (200 °C), the B form of $Fe(H_2PO_4)_3$ did not change due to this endothermic reaction. Furthermore, a large endothermic peak with an accompanying weight loss was observed at 250 °C. In this endothermic reaction, the B form of $Fe(H_2PO_4)_3$ was dehydrated and transformed into amorphous iron phosphate, as shown by the X-ray diffraction patterns of the product corresponding to point i (300 °C). At point j (450 °C), the amorphous iron phosphate was partially transformed into a mixture of the A, B, and C forms of $Fe(PO_3)_3$. At approximately 500 °C, and endothermic peak with a weight loss due to dehydration of structural water (P–OH) was observed. It was shown by the X-ray diffraction pattern of the product corresponding to point k (520 °C) that in this endothermic reaction, the amorphous iron phosphate was completely transformed into a mixture of the A, B, and C forms of $Fe(PO_3)_3$. In the temperature range from 520 to 700 °C, no changes were observed on the DTA curve, but the X-ray diffraction pattern of the product corresponding to point l (700

°C) showed that both the A and B forms of $Fe(PO_3)_3$ had already transformed into the C form of $Fe(PO_3)_3$.

The thermal changes of $Fe(H_2PO_4)_3$ at temperatures corresponding to points a—l on the DTA curves of the A and B forms of $Fe(H_2PO_4)_3$ were also investigated, the results of which are summarized in Tables 2 and 3. In all experiments, the samples were heated for 5 h. The results of the thermal changes of the A and B forms of $Fe(H_2PO_4)_3$ in an electric furnace largely support the results of the DTA study described above. The results of the thermal changes of both A and B forms in an atmosphere of water vapor differ considerably from those in other heating atmospheres, *i.e.*, in an atmosphere of water vapor below 300 °C, the A form of $Fe(H_2PO_4)_3$ gives $FeHP_2O_7$ and is transformed into $Fe(PO_3)_3$ at 400 °C. At a temperature above 700 °C, $Fe(PO_3)_3$, liberating white P_2O_5 fumes, decomposes to form $FePO_4$. The formation of $FePO_4$ may be interpreted in terms of evaporation of the P_2O_5 component caused by the flow of water vapor at high temperature. Under vacuum, both A and B forms of $Fe(H_2PO_4)_3$ begin to transform into amorphous iron phosphate at 200 °C. This transformation temperature is approximately 50—100 °C lower than in the electric furnace. Under vacuum, furthermore, the formation of $Fe(PO_3)_3$ was observed at 300 °C. Thus, it may be concluded that the thermal changes shift to lower temperatures under vacuum.

From the above experimental results, the thermal changes in air of the A and B forms of $Fe(H_2PO_4)_3$ may be given by:

$$Fe(H_2PO_4)_3 \text{ A form} \xrightarrow{250\,^\circ C} \text{amorphous iron phosphate}$$

$$\xrightarrow{400\,^\circ C} Fe(PO_3)_3 \text{ B + C form} \xrightarrow{500\,^\circ C} Fe(PO_3)_3 \text{ C form}$$

$$Fe(H_2PO_4)_3 \text{ B form} \xrightarrow{250\,^\circ C} \text{amorphous iron phosphate}$$

$$\xrightarrow{450\,^\circ C} Fe(PO_3)_3 \text{ A+B+C form} \xrightarrow{700\,^\circ C} Fe(PO_3)_3 \text{ C form}$$

Changes of the A and B Forms of $Fe(H_2PO_4)_3$ in Various Humid Atmospheres. The structural changes of the A and B forms of $Fe(H_2PO_4)_3$ after standing in various humid atmospheres are shown in Figs. 6a—6c. As may be seen from Fig. 6a, the B form of $Fe(H_2PO_4)_3$ was completely transformed into $FeH_6(PO_4)_3$, on standing in air for 4 days. The X-ray diffraction pattern of the product was in fair agreement with that of $FeH_6(PO_4)_3$ already reported by Kobayashi.[10] The compound $FeH_6(PO_4)_3$ obtained under the above conditions, on standing in a desiccator with P_2O_5, was transformed into the B form of $Fe(H_2PO_4)_3$ starting from the third day. The amount of $FeH_6(PO_4)_3$ gradually decreases with time, virtually disappearing on the seventh day. Thus, the B form of $Fe(H_2PO_4)_3$, on standing in air, absorbs moisture to form $FeH_6(PO_4)_3$, but the latter is dehydrated in a desiccator with P_2O_5, reverting to the former again. As may be seen from Fig. 6b, on standing in wet air (water vapor 20—25 mmHg) for 2 h, the B form is completely transformed into amorphous iron phosphate. This amorphous iron phosphate is transformed into $FeH_6(PO_4)_3$ on standing in a desiccator with P_2O_5 for 24 h. On standing in a desiccator with P_2O_5 for more than 7 days, $FeH_6(PO_4)_3$ is further dehydrated to give the B form of $Fe(H_2PO_4)_3$. This suggests that the changes of the B form of $Fe(H_2PO_4)_3$ into $FeH_6(PO_4)_3$ and amorphous iron phosphate caused by moisture absorption may be reversible. The A form of

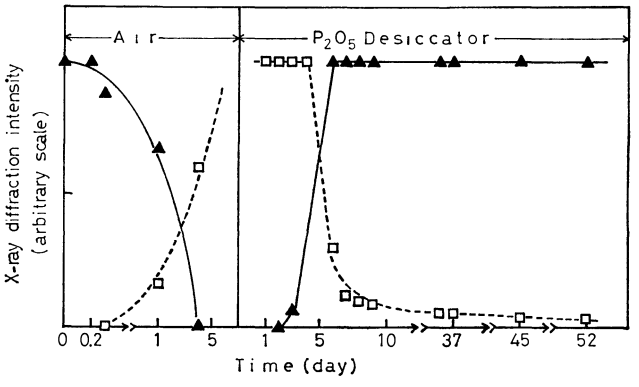

Fig. 6a. Structural change of iron phosphate in various humid atmospheres.
—▲—: $Fe(H_2PO_4)_3$(B), ···□···: $FeH_6(PO_4)_3$.

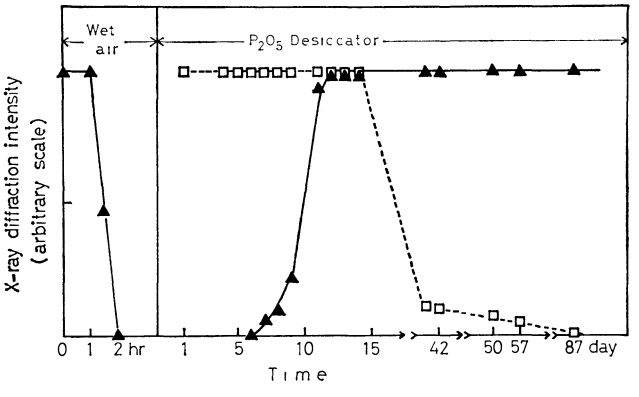

Fig. 6b. Structural change of iron phosphate in various humid atmospheres.
—▲—: $Fe(H_2PO_4)_3$(B), ···□···: $FeH_6(PO_4)_3$.

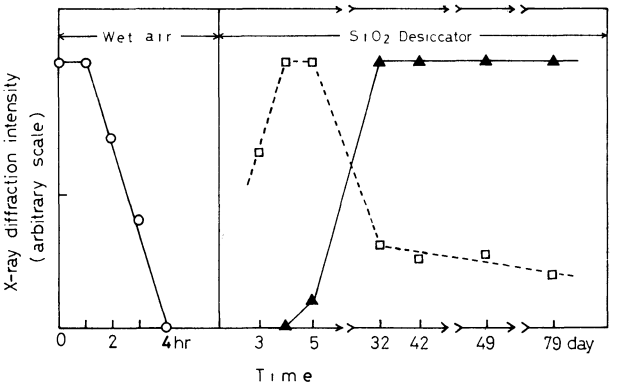

Fig. 6c. Structural change of iron phosphate in various humid atmospheres.
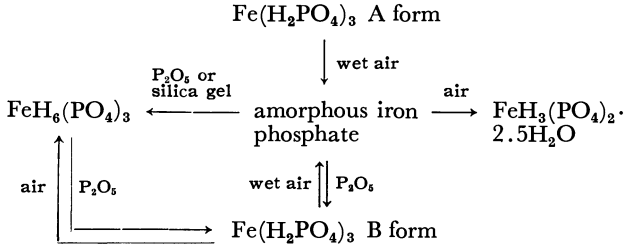
—○—: $Fe(H_2PO_4)_3$ (A), --▲--: $Fe(H_2PO_4)_3$ (B), —□—: $FeH_6(PO_4)_3$.

$Fe(H_2PO_4)_3$, as seen from Fig. 6c, is rapidly transformed into amorphous phosphate on standing in wet air, a result similar to that for the B form. Amorphous iron phosphate, on standing in a desiccator with silica gel, is transformed into $FeH_6(PO_4)_3$, which, beginning on the fifth day, is gradually transformed into the B form of $Fe(H_2PO_4)_3$ over a long time. $FeH_6(PO_4)_3$, on standing in a desiccator with P_2O_5, is transformed into the B form of $Fe(H_2PO_4)_3$, beginning on the third day and almost completely within two weeks. It is of interest that the A form of $Fe(H_2PO_4)_3$ is transformed into amorphous iron phosphate or $FeH_6(PO_4)_3$ with moisture absorption, and by dehydration of $FeH_6(PO_4)_3$ in a desiccator with P_2O_5 or silica gel, the B form and not the A form of $Fe(H_2PO_4)_3$ is directly obtained. From these facts, it is suggested that changes in the structures of the A and B forms of $Fe(H_2PO_4)_3$ caused by moisture absorption are completely different from each other.

From the results shown in Fig. 6, it is suggested that $FeH_6(PO_4)_3$ may contain more water than the A and B forms of $Fe(H_2PO_4)_3$. Based on the reversible change between $FeH_6(PO_4)_3$ and $Fe(H_2PO_4)_3$ structures caused by moisture absorption, it may be more reasonable to regard $FeH_6(PO_4)_3$ as another form of $Fe(H_2PO_4)_3$ since the A and B forms of $Fe(H_2PO_4)_3$ are isomorphous with the A and B forms of $Al(H_2PO_4)_3$, respectively. The existence of the C and D forms of $Al(H_2PO_4)_3$ other than the A and B forms has been reported,[11] while the C and D forms of $Fe(H_2PO_4)_3$, isomorphous with those of $Al(H_2PO_4)_3$, are unknown. Consequently, $FeH_6(PO_4)_3$ may be tentatively assigned the E form of $Fe(H_2PO_4)_3$. The experimental results are summarized schematically as follows:



Amorphous iron phosphate obtained from the A and B forms of $Fe(H_2PO_4)_3$ and $FeH_6(PO_4)_3$ by moisture absorption gave crystalline $FeH_3(PO_4)_2 \cdot 2.5H_2O$ on standing in air over 20 days. This product may be formed by the hydrolysis of amorphous iron phosphate.

Solvation of Anions in Solvent Mixtures as Deduced from the Rates of the Finkelstein Reaction

Yasuhiko KONDO,* Akira NISHIKATA, Akiteru YOSHIOKA, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received July 19, 1978)

The Finkelstein reaction has been studied in five dipolar aprotic–dipolar aprotic solvent mixtures and one protic–dipolar aprotic solvent mixture. The theoretical equations for the rate constant as a function of solvent composition derived previously have been reformulated in terms of the solvent exchange model on the solvation site, taking into account the two main features of solvation: the number of the solvation sites on the solvent molecule and the equilibrium constant for the solvent exchange process. The results obtained previously, together with present results, are comprehensively discussed and the solvent mixtures are classified into four groups from the viewpoint of solute-solvent interaction in the region near the ion, using derived theoretical equations.

Thermodynamics of transfer of a single ion from one solvent to another as expressed in terms of a solvent activity coefficient has been accepted as an important criteria, when discussing solvent effects on reaction rates and mechanisms in solution.[1,2] In the course of the development of the concept, most attention seems to have been paid to the hydrogen bonding interaction, and polarizability effects, between solute and solvent. Even though this is quite useful in discussing the gross features of a solute in pure solvents, more sophisticated versions on the solute-solvent interactions in the vicinity of an ionic solute are required, when analyzing chemical phenomena in mixed solvents.[3,4]

In previous papers[5,6] we have dealt with the analysis of reaction rates of the Finkelstein reaction in acetonitrile–protic solvent mixtures from the viewpoint of the specific solvation of the anion in the solvent mixtures. In the present work we set up a generalized model for describing the cluster distribution of anion solvates in solvent mixtures, and derive the theoretical equations for the reaction rate in solvent mixtures on the basis of the model. By the mathematical analysis of reaction rates in solvent mixtures, solvent mixtures are classified into four groups from the viewpoint of ion-solvent interactions in the region near the ion.

Experimental

Materials: *N,N*-Dimethylacetamide, Wako's guaranteed reagent, was distilled from barium oxide and from calcium hydride under reduced pressure. Ethyl methyl ketone, Wako's extra pure reagent, was distilled twice after storage over anhydrous sodium sulfate. γ-Butyrolactone, Wako's extra pure reagent, was distilled twice under reduced pressure after storage over calcium hydride. Sulfolane, Wako's reagent, was distilled three times under reduced pressure after storage over sodium hydroxide. Propylene carbonate, Wako's extra pure reagent, was stored over freshly activated molecular sieves and distilled twice under reduced pressure. Other materials were treated as described elsewhere.[5]

Kinetic measurements and calculations were carried out as described elsewhere.[5]

Density measurements were performed with a glass dilatometer consisting of a bulb and two graded stems (*ca.* 40 ml capacity).

Densities and rate constants are summarized in Tables 1 and 2.

Results and Discussion

without any clear pattern, except for methanol solvent, in which the enthalpy term is the predominant factor responsible for the much reduced rate.

As summarized in Table 4, logarithmic relative rates are well correlated with the single ion solvent activity coefficient of bromide ion, for both protic and dipolar aprotic solvents.[7–9] The transition state anion-neutral molecule assumption[1,7] was used to obtain the bromide ion activity coefficient.[1]

The sensitivity of a bulky transition state to a change in solvent is believed to be less than that of a compact reactant anion in solvent mixtures as well as in pure solvents.[1] The principal feature of the log k_{mix} *vs.* composition profile (Figs. 1, 2, and 3) should be ascribed to the change in the solvation of a reactant anion, even though there must be differences in the solvent activity coefficient of the transition state.

Reaction Rates in Binary Mixed Solvents. Thermodynamic Treatments: In the previous papers of this series[5,6] it was shown that the chemical equilibria and the reaction rates in binary mixed solvents could be reproduced by treating the solvation change of the respective solute in terms of *m* successive solvent exchange processes.

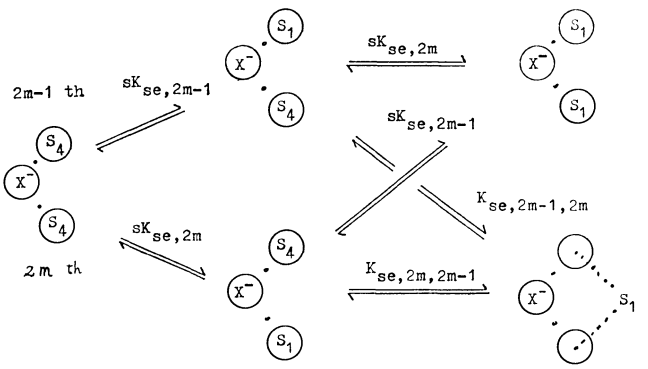
For formal simplicity of the derived equations it is necessary to assume that the true solvation number of a solute,[5] or the number of a solvation site Z° is an even integral value and that these sites are grouped into



Scheme 1. Solvent exchange scheme on $2m-1$ th and $2m$ th solvation sites.

adjacent pairs of sites which are independent of each other in the respective pair, as well as of the members of other pairs.

As was suggested previously[6] and will be suggested also later, in some cases it is feasible that a solvent molecule can interact with a solute by simultaneously occupying a pair of solvation sites, if the solvent molecule contains multiple functional solvating groups. In the following treatment we will deal with the cluster distribution in solvent mixtures in which a component solvent, 4, has only one functional group, whereas a solvent, 1, has s equivalent functional groups.

Consider the frequencies of occupation of a given pair of sites which are referred to as $2m-1$ th and $2m$ th solvation site on the basis of the above solvent exchange scheme, where $K_{se,2m-1}$ and $K_{se,2m}$ refer to the equilibrium constants for the solvent exchange process on the $2m-1$ th and the $2m$ th solvation site, and $K_{se,2m-1,2m}$ refers to that of the bidentate solvent exchange process.

The number of ways of occupation of the solvation site is given as follows:

S_4 on both $2m-1$ th and $2m$ th site; x_4^2

S_4 on $2m-1$ th and S_1 on $2m$ th site; $sK_{se,2m}x_1x_4$

S_1 on $2m-1$ th and S_4 on $2m$ th site; $sK_{se,2m-1}x_1x_4$

different S_1 molecules on both $2m-1$ th and $2m$ th site; $s^2K_{se,2m-1}K_{se,2m}x_1^2$

same S_1 molecule on both $2m-1$ th and $2m$ th site; $sK_{se,2m-1}K_{se,2m-1,2m}x_1=sK_{se,2m}K_{se,2m,2m-1}x_1$

When the average monodentate and bidentate solvation equilibrium constants, $K_{ms,2m}$ and $K_{bs,2m}$ are defined by the equations,

$$K_{ms,2m} = (K_{se,2m-1}K_{se,2m})^{1/2}$$

$$K_{bs,2m} = (K_{se,2m-1,2m}K_{se,2m,2m-1})^{1/2}$$

the distribution of cluster as defined by the way of occupation of Z° solvation sites on a solute, M, is given by the equation,

$$\prod_{m=1}^{Z^\circ/2}\{(x_4+sK_{se,2m-1}x_1)(x_4+sK_{se,2m}x_1)+sK_{ms,2m}K_{bs,2m}x_1\}. \quad (1)$$

The activity coefficient of a solute, M, in the solvent mixture, $\beta_{M,mix}$, is given by the equation derived in the previous paper,[5]

$$\lim_{x_M\to 0}\beta_{M,mix} = f_M^\circ/[1+K_0\prod_{m=1}^{Z^\circ/2}\{(x_4+sK_{se,2m-1}x_1)(x_4+sK_{se,2m}x_1) + sK_{ms,2m}K_{bs,2m}x_1\}](V_{mix}/RT) \quad (2)$$

where f_M° is the fugacity of equibrated vapor of a pure solute, M,[5] and V_{mix} is the mean molar volume of the mixed solvent; K_0 is the equilibrium constant for the reaction,

$$M + Z^\circ S_4 = M\cdot(S_4)_{Z^\circ}.$$

As was mentioned above and discussed elsewhere,[1,5] the rate of the Finkelstein reaction seems to be predominantly controlled by the solvation of a nucleophile. Thus, by the same procedure as described in the previous paper,[5] the rate constants in solvent mixtures, k_{mix}, and the ratio of the rate constants in solvent 4 and 1, (k_4/k_1), are given by the equations,

$$\ln k_{mix} = \ln k_1 + \ln \prod_{m=1}^{Z^\circ/2} (s^2K_{se,2m-1}K_{se,2m} + sK_{ms,2m}K_{bs,2m}) - \ln \prod_{m=1}^{Z^\circ/2} \{(x_4 + sK_{se,2m-1}x_1)(x_4 + sK_{se,2m}x_1) + sK_{ms,2m}K_{bs,2m}x_1\} + \ln (V_{mix}/V_1) \quad (3)$$

$$(k_4/k_1) = \prod_{m=1}^{Z^\circ/2} (s^2K_{se,2m-1}K_{se,2m} + sK_{ms,2m}K_{bs,2m}) \times (V_4/V_1) \quad (4)$$

where V_4 and V_1 stand for the molar volumes of solvents 4 and 1.

Comparisons with the Experimental Results. Case I. Alcohol and Acetonitrile Mixtures (Fig. 1): Both alcohol and acetonitrile contain only one functional group each. Thus, by setting s equal to unity, and $K_{bs,2m}$ equal to zero, Eqs. 3 and 4 reduce to Eqs. 5 and 6, which are the same formulae as derived previously.[5]

$$\ln k_{mix} = \ln k_1 + \ln \prod_{m=1}^{Z^\circ} K_{se,m} - \ln \prod_{m=1}^{Z^\circ} (x_4 + K_{se,m}x_1) + \ln (V_{mix}/V_1) \quad (5)$$

$$(k_4/k_1) = \prod_{m=1}^{Z^\circ} K_{se,m}(V_4/V_1) \quad (6)$$

Equation 6 gives the boundary conditions for $\prod_{m=1}^{Z^\circ} K_{se,m}$. Under these conditions, the theoretical values of the rate constants were obtained as a function of the solvent compositions on the basis of Eq. 5 for a definite set of Z° and $K_{se,2m}$'s. The calculations were repeated by a trial and error-method, systematically changing the equilibrium constants for the respective solvation number and afterwards for the different values of Z°.

In applying Eqs. 5 and 6 to the experimental data, only those equilibrium constants which are larger than unity are detectable from the solvent exchange studies,[5] since the term $x_4 + K_{se,m}x_1$ reduces to unity when $K_{se,m}$ becomes unity.[5]

One noticeable trend observed in the solvent mixtures is a large attenuation effect in $K_{se,m}$ as described previously.[5] Similar effects were observed in Ag^+ solvation exchange studies in *N,N*-dimethylthioformamide–propylene carbonate, $-H_2O$, and –acetonitrile mixtures.[10] Similar but rather smaller attenuation effects were also observed in NMR chemical shift studies in solvent mixtures.[11] Throughout these studies, the solvent exchange processes with up to four steps are sufficient to reproduce the data.[5,10,11]

In alcoholic and dipolar aprotic solvents, only proton and first row elements can interact with the anion. These have respective Slater orbital exponents which crucially effect the interaction distances between ion and solvents. The variation in the interaction distances, which would alternatively be stated as a change in the degree of covalency in the interaction,[10] is the predominant feature with regard to the inequivalence of the respective solvation sites.

Case II. Acetonitrile–Ethyl Methyl Ketone, and N,N-*Dimethylacetamide Mixtures (Fig. 2)*: These component solvents contain only one solvation site each as in case I. In contrast, experimental results were reproduced by taking the same equilibrium constant throughout the solvent exchange processes concerned and by taking the number of solvation site as equal to a normal coordination number, *i.e.*, six,[12] as expressed in Eqs. 7 and 8.

$$\ln k_{mix} = \ln k_1 + \ln (K_{se,1})^6 - \ln (x_4 + K_{se,1}x_1)^6 + \ln (V_{mix}/V_1), \quad (7)$$

$$(k_4/k_1) = (K_{se,1})^6(V_4/V_1). \quad (8)$$

Similar patterns of solution phenomena *vs.* composition profile were observed previously,[10,13] where the pattern was designated as binomial distribution of cluster.

In the solvent mixtures of this class, all the component solvents retain first row elements as a binding site with the anion. Their Slater orbital exponents resemble each other in magnitude, thus leading to a similar interaction distance with the anion. This can be considered as a major factor in indiscriminating the essentially inequivalent solvation sites.

Case III. Glycol–Acetonitrile Mixtures: In glycol two hydroxyl groups are available for interaction with the anion, so that s is equal to 2. When a pair of sites are considered as approximately equivalent to one another, and only one pair of sites contribute predominantly to the total solvation exchange, that is to say the contributions from the remaining sites are minor and masked by the much larger terms from the first pair of sites, then Eqs. 3 and 4 reduce to Eqs. 9 and 10, since for the other pair of sites, the term, $\{(x_4 + 2K_{ms,2m}x_1)^2 + 2K_{ms,2m}K_{bs,2m}x_1\}$, should be equal to unity irrespective of the value, x_1.

$$\ln k_{mix} = \ln k_1 + \ln \{2K_{ms,2}(2K_{ms,2} + K_{bs,2})\} - \ln \{(x_4 + 2K_{ms,2}x_1)^2 + 2K_{ms,2}K_{bs,2}x_1\} + \ln (V_{mix}/V_1). \quad (9)$$

$$(k_4/k_1) = 2K_{ms,2}(2K_{ms,2} + K_{bs,2})(V_4/V_1). \quad (10)$$

Equations 9 and 10 are equivalent to those derived previously on a less sophisticated basis.[6] Rates *vs.* composition profile in five glycol–acetonitrile mixtures were satisfactorily reproduced by these equations.[6]

Case IV. Propylene Carbonate–, Sulfolane–, and γ-Butyrolactone–Ethyl Methyl Ketone Mixtures (Fig. 3): Propylene carbonate, sulfolane and γ-butyrolactone each have multiple solvation sites. When the same conditions as mentioned in case III also hold for the solvent mixtures of this class, Eqs. 9 and 10 would apply to the present cases. As a matter of fact, experimental results were satisfactorily reproduced by the simplest formulae *i.e.*, Eqs. 11 and 12 as obtained by setting $sk_{ms,2m}=1$ for $m \geqq 1$ in Eqs. 9 and 10.

$$\ln k_{mix} = \ln k_1 + \ln (1+K_{bs,2}) - \ln (1+K_{bs,2}x_1) + \ln (V_{mix}/V_1), \quad (11)$$

$$(k_4/k_1) = (1+K_{bs,2})(V_4/V_1). \quad (12)$$

They are formally equivalent to the formulae as derived from Eqs. 5 and 6 under the conditions, $K_{se,m}=1$ for $m \geqq 2$. Thus, on purely mathematical grounds, the present systems are indistinguishable from the systems stet case I. Other mechanistic criteria are necessary in order to establish the solvation pattern. On the basis of the results of model CNDO/2 calculations,[14] the present systems would preferably be classified as a special case of a concurrent monodentate-bidentate solvation system, *i.e.*, the special case of case III.

In acetonitrile and propylene carbonate, rate constants and activation parameters are quite similar in value (Table 3), and do not indicate any marked mechanistic difference for Finkelstein reactions in the two solvents; the activity coefficient for bromide ion (Table 4) is also nearly the same in these solvents.

However, logarithmic rate *vs.* composition profiles are quite different for systems containing acetonitrile or propylene carbonate (*e.g.* for the acetonitrile–ethyl methyl ketone and propylene carbonate–ethyl methyl ketone systems). The use of solvent mixtures and the mathematical analysis of the results have thus provided information on solute-solvent interactions in the vicinity of the bromide ion that cannot be obtained from studies of data in the two pure single solvents.

We wish to thank Dr. M. H. Abraham, University of Surrey, England for his discussions and for his comments on the original version of the manuscript.

Crystal and Molecular Structure of Mitomycin C, an Anticancer Antibiotic

Keizo OGAWA,* Akiko NOMURA, Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Yamada-kami, Suita, Osaka 565

(Received August 28, 1978)

The crystal structure of mitomycin C was determined by means of X-ray diffraction. Mitomycin C was crystallized in the orthorhombic space group $P2_12_12_1$, with $a=12.887$, $b=13.851$, $c=9.718$ Å, and $Z=4$, and its structure solved by the trial and error method using the rigid-body approximation. The absolute configuration was determined by referring to that of *N*-(*p*-bromobenzoyl)mitomycin C. The carbamoyloxymethyl side chain participates in hydrogen bonds as in the case of other mitomycins in the crystalline state.

Mitomycins extracted from Streptomyces species, known to be antibiotics having anticancer activity, have the chemical structures shown in Fig. 1. Mitomycins were found to crosslink to double-stranded DNA by covalent bonds and to inhibit a duplication of DNA.[1] Szybalski and Iyer proposed that atoms C1 and C10 of mitomycin bind covalently to atoms O6 of guanine bases of the DNA duplex after enzymic reduction.[2] An intercalative model of mitomycin with DNA in the form of a semiquinone radical followed by the covalent bond formation was proposed by Tomatz *et al.*,[3] who stated that mitomycin might interact specifically with double-stranded polynucleotides, since no complex formation of the antibiotic with monomeric nucleotides or guanylyl(3′,5′)cytidine was observed. A recent CD study showed that mitomycin might interact with the fragment having the GpC(deoxyguanosine-phosphate-deoxycytidine) base sequence in DNA.[4]

7-hydroxyl-porfiromycin	CH_3	CH_3	OH

Fig. 1. Structures of mitomycins and porfiromycins.

This paper deals with the three-dimensional structure analysis of mitomycin C, and a structural comparison with *N*-brosylmitomycin A,[5] 7-demethoxy-7-(*p*-bromoanilino)mitomycin B[6] and *N*-(*p*-bromobenzoyl)mitomycin C.[7]

Experimental

Mitomycin C crystallized in the form of dark violet plates from a 50% aqueous ethanol solution. Oscillation and Weissenberg photographs showed the crystal to be orthorhombic with the space group $P2_12_12_1$. The crystallographic data are given in Table 1. The density measurement made by a floatation method using a benzene–carbon tetrachloride mixture revealed that an asymmetric unit contains one mitomycin C and two water molecules.

Table 1. Crystal data

Formula	$C_{15}H_{18}N_4O_5\cdot 2H_2O$
Formula weight	370.37
Crystal system	Orthorhombic
Space group	$P2_12_12_1$
a	12.887(2) Å
b	13.851(2) Å
c	9.718(1) Å
V	1734.6(3) Å^3
Z	4
D_m	1.423(4) Mg/m^3
D_x	1.418 Mg/m^3

Three-dimensional intensity data were collected on a computer-controlled four-circle diffractometer using Ni-filtered Cu $K\alpha$ radiation. Employing ω-2θ scan technique with a scan speed of 4°/min(2θ) and 10 s. background measurement at each end of the scan, 1145 independent structure factor magnitudes greater than three times their standard deviations were obtained within $\sin\theta/\lambda=0.547$ Å^{-1}.

Structure Determination and Refinement

Orientation of the molecule in the crystal was determined by the rigid group convolution and search method (RICS).† The coordinates of 17 atoms involving ring portion in 7-demethoxy-7-(*p*-bromoanilino)mitomycin B solved by Yahashi and Matsubara[6] were utilized as a model. The convolution calculated from the model having the benzoquinone ring vertical to the b-axis showed good agreement with the three-dimensional Patterson peaks around the origin. However, the translation search procedure failed to find the correct position in the crystal by employing the resultant model. This might be due to the peculiar molecular packing. Thus the R-map method was tried using a program written by one of the authors (K. O.). The minimum *R*-value (0.51) was obtained by translating the model having the C5A–C6 vector parallel to the c-axis. Using the coordinates of 17 atoms obtained by the above method, an electron density map was constructed to find all nonhydrogen atoms.

† The rigid group convolution and search programs were written by Dr. I. Tanaka.

The structure was refined by the full-matrix least-squares method with isotropic temperature factors, and then by the block-diagonal least-squares method with anisotropic temperature factors for all nonhydrogen atoms. At this stage, difference Fourier synthesis was carried out, the result being unsatisfactory for full detection of hydrogen atoms. At the final refinement, following weighting scheme was employed; $w=0.0$ for $F_o=0.0$, $w=1.0$ for $F_o \leqq 45.0$, and $w=1.0/(1.0+0.235(F_o-45.0))$ for $F_o \leqq 45.0$. The final R-value is 0.080 for all reflections. The final atomic parameters are given in Table 2 with their estimated standard devia-

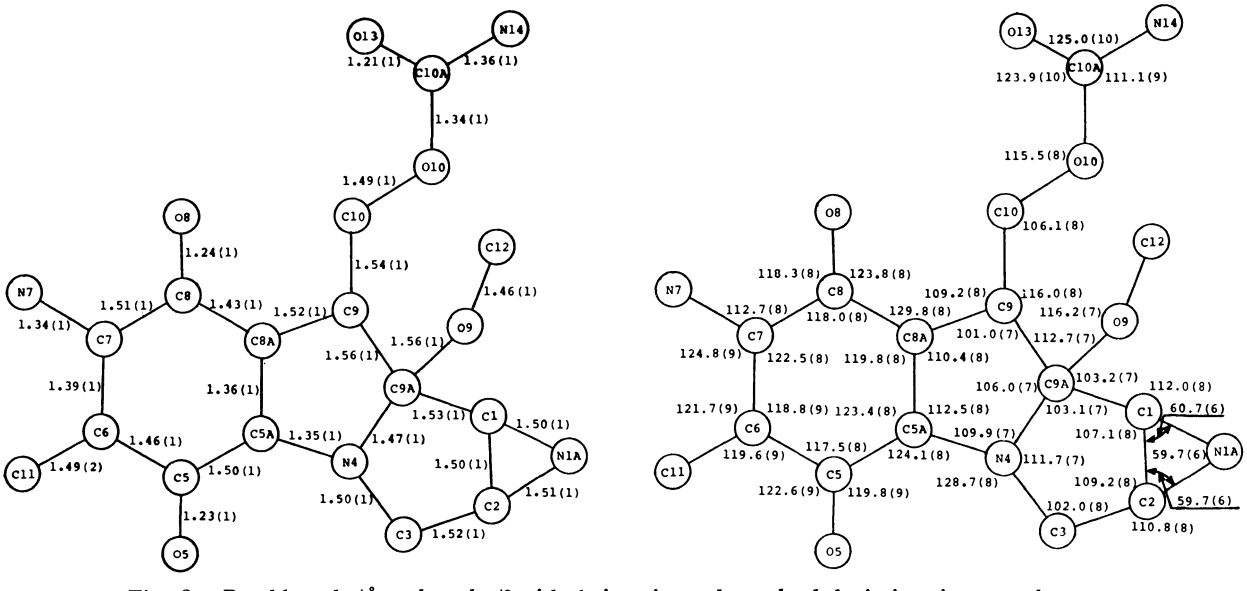

Fig. 2. Bond lengths/Å and angles/° with their estimated standard deviations in parentheses.

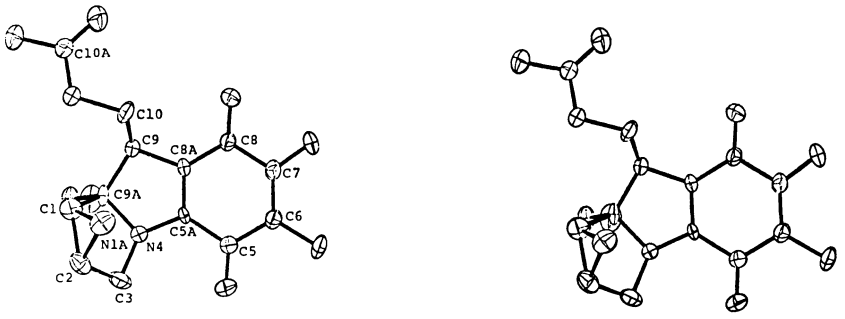

Fig. 3. Stereoscopic view of mitomycin C molecule.

tions. The observed and calculated structure factors are given in Table 3.†† The absolute configuration of mitomycin C was determined by referring to that of *N*-(*p*-bromobenzoyl)mitomycin C.[7]

The computations were performed on a NEAC 2200-700 computer at the Computing Center of this University, using Universal Crystallographic Computing System-Osaka.[8]

Results and Discussion

The bond lengths and angles are given in Fig. 2. A stereoscopic view of the mitomycin C molecule is shown in Fig. 3. The molecular geometry is essentially similar to that of the bromo derivative of mitomycin A,[5] exclusive of the conformation of the carbamoyloxymethyl side chain. The torsion angles of the side chain in four kinds of mitomycins are shown in Table 4. The variance among these torsion angles may be due to the difference in packing force acting on each molecule in the crystal, suggesting that the group is flexible in solution. The fact that the carbamoyl group of the side chain participates in intermolecular hydrogen bond formations, and the configuration of C9(R) is invariant in all cases,[5-7] seems to give valuable information on the interaction mechanism of mitomycin with DNA.

The strain of the indolequinone ring in mitomycins is dependent on the side chain configurations at positions C9 and C9A, *viz.*, the trans-arrangement of carbamoyloxymethyl and methoxy groups in mitomycins A and C

Table 4. Torsion angles in carbamoyloxymethyl side chain

	θ (C8A–C9–C10–O10)	ϕ (C9–C10–O10–C10A)	ψ (C10–O10–C10A–O13)
Br-A	179.5°	166.2°	1.8°
Br-B	298.5	160.1	344.8
Br-C	180.5	280.7	353.9
C	182.4	244.0	2.3

a) Angles are measured in the clockwise sence, faking the cis position as 0°. The notations θ, ϕ, and ψ are shown in Fig. 5. Br-A; *N*-brosylmitomycin A[5] Br-B; 7-demethoxy-7-(*p*-bromoanilino)mitomycin B[6] Br-C; *N*-(*p*-bromobenzoyl)mitomycin C[7] C; mitomycin C.

†† Table 3 is kept as a Document at the Office of The Chemical Society of Japan(Document No. 7925).

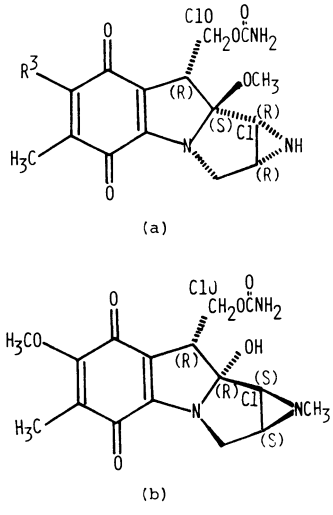

Fig. 4. Absolute configurations.
(a) Mitomycins A and C, (b) mitomycin B.

may release the intramolecular short contacts between these groups. The least-squares plane through the indolequinone ring including atoms C11 and N7 is represented by $-0.035x-0.994y-0.106z+5.225=0.0$. The mean deviation of the atoms from this plane is 0.024 Å, smaller than in mitomycin B (0.079 Å)[6] and close to that in mitomycin A(0.026 Å).[5] The configurations at C9A, C1, and C2 are, respectively, (S), (R), and (R) in mitomycins A[5] and C,[7] differing from those in mitomycin B[6] as shown in Fig. 4. Consequently, significant differences can be seen between the molecular structures of mitomycin B and mitomycins A or C,

C	D	98.4	100.0	97.4	97.9

The notations A, B, C, and D are shown in Fig. 5.

Table 6. Hydrogen bond distances and short contacts

Hydrogen bonds		Short contacts	
O13–OW1	2.76 Å	C5A–N14[a]	3.40 Å
N14–OW2	3.07	C5–N14[a]	3.30
OW1–OW2	2.86	O5–C10A[d]	3.44
O8–N1A[a]	2.96	O5–O9[d]	3.40
O9–N7[b]	2.92	C7–OW2[d]	3.41
N1A–N14[a]	3.03	N7–OW2[d]	3.23
OW1–OW2[e]	2.70	O13–C5[e]	3.46

Symmetry codes;

a) $\frac{1}{2}-x, 1-y, \frac{1}{2}-z$ b) $x, y, -1+z$

c) $-\frac{1}{2}-x, 1-y, \frac{1}{2}+z$ d) $\frac{1}{2}+x, \frac{3}{2}-y, 1-z$

e) $-\frac{1}{2}+x, \frac{1}{2}-y, 1-z$

especially in the dihedral angles between the least-squares planes given in Table 5. For example, in mitomycins A and C, the dihedral angles between planes B and C and between B and D become larger than those in mitomycin B, probably to avoid the short contact between C1 and C10.

The crystal structure is shown in Fig. 6. The molecules at the positions (x, y, z), $(x, y, 1+z)$, and $(1/2-x, -y, 1/2+z)$ are linked by seven intermolecular hydrogen bonds to form a double layered structure (Table 6 and Fig. 6). These layers are held together mainly by van der Waals forces. The indolequinone ring and carbamoyl group with atom O10 are almost vertical to the b-axis, the interplanar spacing being about one-eight of the b-axis dimesion.

A discussion on the interaction between mitomycin and the double-stranded DNA was given in a previous paper.[9] The intercalative model for the interaction of mitomycin with DNA could be built by using the space-filling model and the Kendrew-Watson skeletal model. As the atomic coordinates of base-pair and sugar-phosphate backbone of DNA, the structural data of B-DNA[10] and the crystalline complex of ethidium bromide (2,7-diamino-9-phenyl-10-ethylphenanthridinium bromide) and iodoCpG(5-iodocytidylyl(3′,5′)-guanosine)[11] were referred to.

Although a favorable intercalation model of mitomycin with the GpC fragment of the double-stranded DNA was obtained by examining the stacking and hydrogen bonding, further evidence is necessary before the validity of the intercalative model is discussed.

We thank Dr. Kazuo Yamaguchi for supplying atomic coordinates of *N*-(*p*-bromobenzoyl)mitomycin C.

Relative Spin-trapping Ability of *N*-Benzylidene-*t*-butylamine Oxide, *N*-Benzylideneaniline Oxide, and 2,3,5,6-Tetramethylnitrosobenzene towards Phenyl and Phenylcyclohexadienyl Radicals

Mariko KAMIMORI,* Hirochika SAKURAGI, Katsuhiko SAWATARI,† Tadashi SUEHIRO,††

(Received September 27, 1978)

N-Benzylidene-*t*-butylamine oxide (PBN), *N*-benzylideneaniline oxide (DPN), and 2,3,5,6-tetramethylnitrosobenzene (ND) trap phenyl radicals in a relative rate of 1: 0.72: 2.6, whereas they trap phenylcyclohexadienyl radicals in a relative rate of 1: 2.3: 130. The origin of such different spin-trapping abilities of these spin traps towards phenylcyclohexadienyl radicals is discussed.

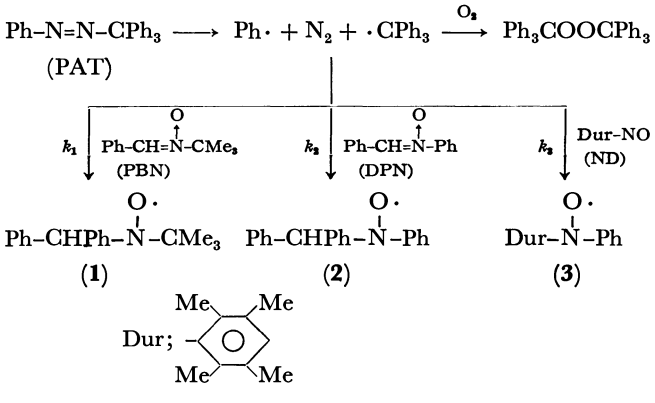
The spin-trapping technique has been widely employed for the characterization of transient reactive free radicals, and various kinds of spin traps have been reported.[1] However, the spin-trapping abilities of various spin traps towards a given free radical have remained obscure.

It is well known that the thermal decomposition of phenylazotriphenylmethane (PAT) in benzene produces triphenylmethyl and phenyl radicals. The latter radicals add to benzene to give phenylcyclohexadienyl radicals, which subsequently either recombine or disproportionate with triphenylmethyl radicals, thus leading to 1,4-dihydro-4-triphenylmethylbiphenyl or triphenylmethane and biphenyl.[2] We have reinvestigated this reaction in the presence of such spin traps as *N*-benzylidene-*t*-butylamine oxide (*N*-*t*-butyl-α-phenylnitrone, PBN), *N*-benzylideneaniline oxide (α,*N*-diphenylnitrone, DPN), and 2,3,5,6-tetramethylnitrosobenzene (nitrosodurene, ND), and have found that while all these spin traps gave their spin adducts with phenyl radicals, only ND afforded the spin adduct with phenylcyclohexadienyl radicals also.[3] Obviously, these facts indicate that spin traps have different reactivities towards phenyl and phenylcyclohexadienyl radicals. In order to confirm this, we have undertaken to determine the relative spin-trapping ability of the spin traps towards phenyl and phenylcyclohexadienyl radicals by competitive methods; our results are described in this paper.

Results

Relative Reactivity of PBN, DPN, and ND towards Phenyl Radicals. PAT was allowed to decompose at a low conversion rate in carbon tetrachloride in the presence of PBN, DPN, and ND under an argon atmosphere at 80 °C. The subsequent examination of the reaction solution by ESR showed signals attributable to phenyl spin adducts of the respective spin traps,[4] along with those attributable to triphenylmethyl radicals. The signals attributable to the triphenylmethyl radicals disappeared on the exposure of the reaction solution to oxygen, but the signals of the nitroxides remained. With authentic specimens of the nitroxides, their stability against oxygen, prolonged heating, and the spin traps was confirmed. Since the nitroxides were produced only in minor amounts (*ca.* 10^{-7} mol l^{-1}), their scavenging by phenyl radicals under the present reaction conditions is very inconsiderable. These results enabled us to determine the relative reactivity of the spin traps towards phenyl radicals by the competitive method.

When PAT was decomposed in the presence of a mixture of PBN (1.5×10^{-2} mol l^{-1}) and DPN (5.0×10^{-3} mol l^{-1}) in carbon tetrachloride at 80 °C, the ESR signals due to the phenyl spin adducts of PBN and DPN (**1** and **2**) were observed (Scheme 1) (Fig. 1). The ratio



Scheme 1.

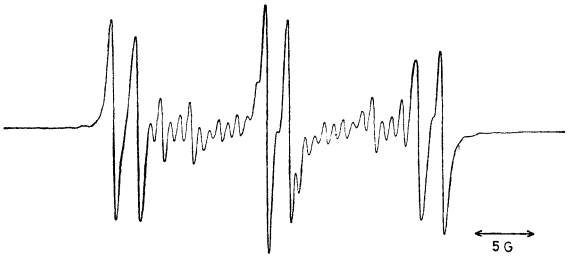


Fig. 1. The ESR spectrum of **1** and **2** obtained from the decomposition of PAT in carbon tetrachloride at 80 °C in the presence of PBN (5.0×10^{-3} M) and DPN (1.5×10^{-2} M). For **1**, a_N=14.1, $a_{\beta\text{-H}}$=2.1 G; for **2**, a_N=10.1, $a_{\beta\text{-H}}$=3.4, $a_{o,p\text{-H}}$=2.5, $a_{m\text{-H}}$=0.9 G.

of the concentrations of the two spin adducts ([**2**]/[**1**]) was obtained as 0.24 by means of the double integration of the ESR signals. Combining this value with the concentrations of PBN and DPN, the ratio of the rate constants of the addition of phenyl radicals to PBN (k_1) and DPN (k_2) was obtained as $k_2/k_1=0.72$ at 80 °C by the use of this equation: $[\mathbf{2}]/[\mathbf{1}]=k_2[\mathrm{DPN}]/k_1[\mathrm{PBN}]$. Triplicated runs afforded the same value within the limits of experimental error. At the concentrations of DPN$=5.0\times10^{-2}$ mol l^{-1} and PBN$=1.5\times10^{-2}$ mol l^{-1}, k_2/k_1 is 0.68 and is almost unchanged as to the relative concentrations of the spin traps.

The decomposition of dibenzoyl peroxide (BPO) in the presence of DPN (5.0×10^{-3} mol l^{-1}) and PBN (1.5×10^{-2} mol l^{-1}) in carbon tetrachloride gave their phenyl spin adducts in a ratio of [**2**]/[**1**]$=0.23$, which led to the value of k_2/k_1 ($=0.69$), similar to that obtained from PAT. Apparently, the relative reactivity towards phenyl radicals (k_2/k_1) is independent of the sources of phenyl radicals. Thus, the possibility that the nitroxides are scavenged by triphenylmethyl radicals concurrently formed in the decomposition of PAT can be disregarded. Accordingly, it is concluded that PBN traps phenyl radicals 1.4 times faster than does DPN.

Likewise, the decomposition of PAT in the presence of ND (4.9×10^{-3} mol l^{-1}) and PBN (5.2×10^{-3} mol l^{-1}) in carbon tetrachloride at 80 °C gave the phenyl spin adducts of ND (**3**) and PBN (**1**) in a ratio of [**3**]/[**1**]$=$ 2.5 (Fig. 2). This value leads to this ratio of the rate constants: $k_3/k_1=2.6$, in which k_3 is the rate constant for the addition of phenyl radicals to ND. The same value was obtained in the decomposition of BPO in the presence of ND (4.5×10^{-3} mol l^{-1}) and PBN (5.5×10^{-3} mol l^{-1}). Therefore, the rate constant for the addition of phenyl radicals to ND (k_3) is approximately 3 times larger than that to PBN (k_1) at 80 °C.

All the above reactions were carried out in carbon tetrachloride, from which phenyl radicals are known to abstract a chlorine atom to yield trichloromethyl radicals. However, none of the spectrum caused by the trichloromethyl spin adduct was hitherto observed. This finding suggests either that phenyl radicals add to the spin traps more rapidly than they abstract a chlorine atom from carbon tetrachloride or that trichloromethyl radicals are not efficiently captured by the spin traps. Therefore, it can safely be said that this side reaction, even if it occurs concurrently, does not affect the rate ratios, k_2/k_1 and k_3/k_1.

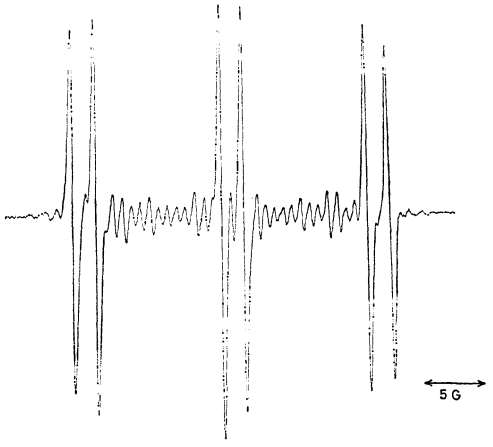

Fig. 2. The ESR spectrum of **1** and **3** obtained from the decomposition of PAT in carbon tetrachloride at 80 °C in the presence of PBN (5.2×10^{-3} M) and ND (4.9×10^{-3} M). For **1**, $a_N=14.4$, $a_{\beta\text{-H}}=2.1$ G; for **3**, $a_N=9.5$, $a_{o,p\text{-H}}=2.7$, $a_{m\text{-H}}=0.9$ G.

Relative Reactivity of PBN, DPN, and ND towards Phenylcyclohexadienyl Radicals. In an attempt to determine the relative reactivities of the spin traps towards phenylcyclohexadienyl radicals, 1,4-dihydro-4-triphenylmethylbiphenyl (DTB) was used as the source of this radical. The thermal decomposition of 2-chloro-1,4-dihydro-4-triphenylmethylbiphenyl in benzene was previously shown to generate triphenylmethyl and 1-chloro-6-phenyl-2,4-cyclohexadienyl radicals, which subsequently disproportionate into 2-chlorobiphenyl and triphenylmethane.[5]

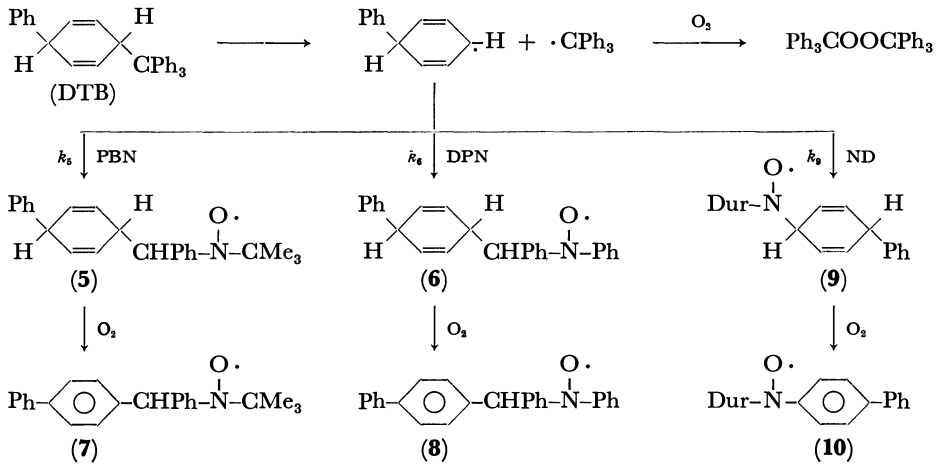
The decomposition of DTB in benzene at 80 °C in the presence of PBN, DPN, and ND under an argon atmosphere produced their phenylcyclohexadienyl spin adducts (**5**, **6**, and **9**) and biphenylyl spin adducts (**7**, **8**, and **10**) along with triphenylmethyl radicals (Scheme 2). On the exposure of the reaction mixture to atmospheric oxygen, the triphenylmethyl radicals were eliminated and the phenylcyclohexadienyl spin adducts were converted to the biphenylyl spin adducts, the concentration of which was subsequently determined quantitatively. The stability of the biphenylyl spin adducts to oxygen, prolonged heating, and spin traps was previously confirmed.[2,6]

The thermal decomposition of DTB in benzene in the presence of a mixture of PBN (3.0×10^{-2} mol l^{-1}) and DPN (3.0×10^{-2} mol l^{-1}) under an argon atmosphere at 80 °C produced triphenylmethyl radicals and nitroxides (**5**, **6**, **7**, and **8**). When oxygen was passed into the reaction mixture, two nitroxides (**5** and **6**) were completely oxidized to **7** and **8** respectively. The ratio of their concentrations ([**8**]/[**7**]) was determined to be 2.3, which gives the realtive reactivity of DPN (k_6) and PBN (k_5) towards phenylcyclohexadienyl radicals as $k_6/k_5=2.3$ in benzene at 80 °C.

Likewise, the decomposition of DTB in benzene in the presence of PBN (9.8×10^{-2} mol l^{-1}) and ND (4.9×10^{-3} mol l^{-1}) at 80 °C, followed by treatment with oxygen, gave their biphenylyl spin adducts (**7** and **10** respectively). The ratio of their concentrations, [**7**]/[**10**], was determined to be 0.15, from which the relative reactivity of PBN (k_5) and ND (k_9) towards phenylcyclohexadienyl radicals was obtained as $k_5/k_9=7.7\times10^{-3}$ at 80 °C. Therefore, ND traps phenylcyclohexadienyl radicals 130 times faster than does PBN.

Discussion

The present results indicate that the nitrones (PBN and DPN) and ND trap phenyl radicals with similar rate constants. Janzen and Evans reported that phenyl radicals add to PBN in methanol at a rate constant of 1.2×10^7 mol l^{-1} at 80 °C.[7] The activation energy for the above reaction probably does not exceed that for the addition of benzoyloxyl radicals to benzene, which



Scheme 2.

has been found to be 6 kcal mol^{-1}.[8] If it is assumed that the rate constant for the spin trapping in carbon tetrachloride is the same as in methanol, and that the activation energy is equal to 6 kcal mol^{-1}, the rate constant for the addition of phenyl radicals to PBN (k_1) in carbon tetrachloride at 80 °C can be estimated as 1.0×10^8 mol l^{-1} s^{-1}. The combination of this value with the observed rate ratios (k_2/k_1 and k_3/k_1) gives k_2 and k_3 as 7.2×10^7 and 2.6×10^8 mol l^{-1} s^{-1} respectively at 80 °C. The above large rate constants for the spin-trapping processes, as much as 10^8 mol l^{-1} s^{-1}, may be responsible for the lower selectivity between the spin traps in these reactions.

On the other hand, ND is now found to trap phenylcyclohexadienyl radicals nearly 130 times faster than the nitrones. A triphenylmethyl radical does not add at all to PBN,[9] DPN,[6] and ND,[10] probably because its addition to the spin traps is highly endothermic. The absolute rate constants for the addition of phenylcyclohexadienyl radicals to the spin traps cannot be estimated. However, as phenylcyclohexadienyl radicals are stabilized, though to a lesser extent, like triphenylmethyl radicals through the delocalization of the unpaired electron, it is suspected that phenylcyclohexadienyl radicals do not react with the spin traps so rapidly as do phenyl radicals.

Recently, Schmid and Ingold reported that 5-hexenyl radicals react with PBN at a rate constant of 1.3×10^5 mol l^{-1} s^{-1} at 40 °C in benzene and more rapidly with ND (3.9×10^7 mol l^{-1} s^{-1} at 40 °C).[11] It is worthwhile noting that ND tends to trap phenylcyclohexadienyl radicals and 5-hexenyl radicals more rapidly than the nitrones, whereas ND and the nitrones capture phenyl radicals with similar rate constants. The above fact may be interpreted in terms of the fact that phenylcyclohexadienyl radicals and 5-hexenyl radicals would suffer more steric hindrance on approaching to the nitrones to give the spin adducts than would phenyl radicals, whereas none of these radicals would suffer any serious steric hindrance in the reaction with ND.

Experimental

Materials. Nitrosodurene (ND),[12] *N*-*t*-butyl-α-phenylnitrone (PBN),[13] α,*N*-diphenylnitrone (DPN),[14] phenylazotriphenylmethane (PAT),[15] and 1,4-dihydro-4-triphenylmethylbiphenyl (DTB)[2] were prepared according to the methods in the literature.

Examination of the Stability of the Nitroxides, 1, 2, and 3. Benzhydrylphenylnitroxide (**2**) was prepared by the oxidation of benzhydrylphenylhydroxylamine[16] with silver oxide in carbon tetrachloride. A mixture of the precipitates was removed by filtration, and the filtrate was used in situ for examining the stability of **2**.

2,3,5,6-Tetramethyldiphenylnitroxide (**3**) was prepared by the complete decomposition of PAT in carbon tetrachloride at 80 °C in the presence of ND; oxygen was passed through the solution to eliminate triphenylmethyl radicals.

Benzhydryl-*t*-butylnitroxide (**1**) was prepared according to the method in the literature.[17]

Each nitroxide solution in carbon tetrachloride was heated for 30 min at 80 °C, was treated with oxygen by passing it in for 3 min, or was mixed with the corresponding spin traps. The intensity of the ESR signals of each nitroxide did not vary under the above conditions.

Decomposition of PAT, DTB, and BPO in the Presence of the Spin Traps. A solution (0.3—0.4 ml) of PAT (2.0×10^{-3} mol l^{-1}) and the spin traps (PBN, 5.0×10^{-3}—5.0×10^{-2} mol l^{-1}; DPN, 1.5×10^{-2} mol l^{-1}; ND, 4.9×10^{-3} mol l^{-1}) in carbon tetrachloride was heated at 80 °C for 3 min under an atmosphere of argon, and then oxygen was passed through the solution in order to remove the triphenylmethyl radicals. The reaction mixture was subsequently purged with argon, and the ESR spectra were recorded.

DTB (8.0×10^{-3} mol l^{-1}) was similarly decomposed in benzene in the presence of the spin traps (PBN, 3.0—9.8×10^{-2} mol l^{-1}; DPN, 3.0×10^{-2} mol l^{-1}; ND, 4.9×10^{-2} mol l^{-1}) at 80 °C for 30 min. The reaction mixture was then treated similarly.

The decomposition of BPO (2.0×10^{-3} mol l^{-1}) was carried out in carbon tetrachloride in the presence of the spin traps (PBN, 5.0×10^{-3} mol l^{-1}; DPN, 1.5×10^{-2} mol l^{-1}; ND, 4.5×10^{-3} mol l^{-1}) at 80 °C for 3 min. Thereafter, the ESR spectra were measured immediately.

The ESR spectra were recorded on a JEOL JES-ME-1X spectrometer. The peak heights were converted to area units by the use of a double integrator. The ratio of the concentrations of the two spin adducts was determined by double integration.[18] The peak-overlap effects of two nitroxides were taken into account by a computer simulation of the summed spectra.

The authors are grateful to Professors Kunio Nakano and Hiroshi Tadano of Rikkyo University for their suggestions regarding the construction of the double integrator.

A Comparative Study of Nickel and Cobalt Catalysts in the Hydrogenation of Substituted Acetophenones. Dependence of Hydrogenation Rate and Adsorption Strength on Substituents and Solvents

Masatsugu KAJITANI,* Naoki SUZUKI, Tsutomu ABE, Yoshimitsu KANEKO, Kazuhiko KASUYA, Kazunori TAKAHASHI, and Akira SUGIMORI

(Received October 4, 1978)

The difference in the nature of nickel and cobalt catalysts has been investigated by a comparative study of the competitive hydrogenation of substituted acetophenones. The electronic and steric effects of substituents and the effects of solvents on the adsorption strength of acetophenones are greater for the reactions over R-Ni than for those over R-Co. On R-Co catalyst acetophenones substituted with electron attracting groups (3-methoxyl, 3-hydroxyl, and 4-fluoro groups with $\sigma^0>0$) are adsorbed more strongly than those with electron donating groups (2-, 3-, and 4-alkyl and 4-methoxyl groups with $\sigma^0<0$). Over R-Ni catalyst the adsorption of acetophenone is greater than that of any substituted acetophenones. The rates of hydrogenation over R-Ni are more susceptible to the effects of substituent and solvent than those over R-Co. Over both R-Ni and R-Co the rates of hydrogenation of unsubstituted acetophenones are greater than those of substituted acetophenones with either electron donating or electron attracting groups.

Heterogeneously catalyzed reactions involve the adsorption of substrates on the catalyst surface and the reaction on the catalyst surface. Solvents can affect both processes in different ways.

In recent years, it has become possible to examine the adsorption step by a method of competitive reaction. The following systems have been studied by the competitive reaction: cyclohexanone–its 4-alkyl derivatives,[1] cyclohexanone–its alkyl-substituted derivatives,[2] acetone–alkyl methyl ketones,[3] acetophenone–its substituted derivatives,[4] benzene–polymethylbenzenes,[5,6] cyclohexene–cyclooctene,[7,8] 1-hexene–olefinic substrates,[9,10] 2-phenyl-3-methyl-2-butene–its substituted derivatives,[11] cyclohexene–cycloalkenes,[12] 1-phenyl-2-propane–4-nitrotoluene,[13] and nitrobenzene–its substituted derivatives.[14]

Reports appeared on the effects of substituents and ring size on the strength of adsorption in the hydrogenation of cycloalkenes[7] and *p*-substituted nitrobenzenes[14] over various nickel catalysts. Bekkum and his coworkers reported that in the hydrogenation over palladium catalyst the adsorption of acetophenones in an alkaline ethanol solution is influenced to a lesser extent by electronic and steric substituent effects than the rate of hydrogenation and that the hydrogenation is accelerated by electron attracting groups and retarded by electron donating groups.[4]

In this work, the effectiveness of nickel and cobalt catalysts in the individual and competitive hydrogenation of substituted acetophenones in various solvents are compared. In order to confirm that the observed differences are attributable to the difference in metallic properties of nickel and cobalt, the effects of substituents (electronic and steric) on the rate of hydrogenation and on the strength of adsorption were examined mainly over Raney nickel (R-Ni) and Raney cobalt (R-Co) catalysts. The solvent effects were also investigated.

Experimental

Materials and Solvents. Commercial reagent grade R-Ni alloy (Ni;48 %), R-Co alloy (Co; 48—50%), zinc dust, nickel(II) chloride hexahydrate, cobalt(II) chloride hexahydrate (Guaranteed Reagent grade; GR), sodium tetrahydroborate (Wako Pure Chemical Industries) were used without further purification.

Acetophenone (GR), 4-methyl-(Extra Pure grade; EP), and 4-carboxyacetophenone (GR) (Wako Pure Chemical Industries Co.) and 4-amino-(GR), 2-methyl-(GR), 3-methyl-(GR), 4-chloro-(EP), and 4-methoxyacetophenone (EP) (Tokyo Kasei Kogyo Co.) were purified by fractional distillation or recrystallization.

4-Ethyl-, 4-isopropyl-, and 4-*t*-butylacetophenone[15] and 4-fluoroacetophenone[16] were synthesized from the corresponding alkylbenzenes and fluorobenzene by Friedel-Crafts reactions. After distillation, 4-methyl-, 4-ethyl-, and 4-*t*-butylacetophenone were purified as the corresponding oximes by fractional crystallization in aqueous methanol. The purified oximes were hydrolyzed in an aqueous solution of 25% hydrochloric acid, the ketones being again purified by fractional distillation.

Commercial reagent grade isopropyl alcohol (*i*-PrOH), methyl alcohol (MeOH), ethyl alcohol (EtOH), propyl alcohol (*n*-PrOH), *t*-butyl alcohol (*t*-BuOH), cyclohexane, benzene, and toluene were purified by the methods given in literature.[17] Each alcohol was dehydrated by refluxing with calcium hydride and then distilled.

Both the ketones and the solvents thus purified were gas-chromatographically pure.

Catalysts. R-Ni and R-Co were prepared by the modified method of Adkins and Billica[18] described in the preceding paper.[19] Urushibara nickel B (U-Ni-B) and Urushibara cobalt B (U-Co-B) catalysts were prepared by the simplified methods.[20] Nickel boride (Ni_2B) and cobalt boride (Co_2B) catalysts were prepared as reported by Paul *et al.*, by reducing nickel(II) chloride or cobalt(II) chloride with sodium tetrahydroborate in aqueous solutions.[21]

The catalysts were washed thoroughly with water until the washings were neutral to phenolphthalein. When a solvent immiscible with water was used, the catalysts were further washed with *i*-PrOH to remove water and finally with the solvent.

Urushibara catalysts, metal boride catalysts, and R-Co catalysts each containing 1 g of Ni or Co, and R-Ni containing

0.5 g of Ni were used for hydrogenation.

Hydrogenation. For individual hydrogenation, the substrate (5.2×10^{-3} mol) was hydrogenated with various nickel and cobalt catalysts in 10 cm^3 of solvent at 30 °C and under atmospheric pressure of hydrogen in a glass reaction vessel shaken at 350—400 strokes per minute.

For competitive hydrogenation, an equimolar mixture of two substrates (5.2×10^{-3} mol of acetophenone and of substituted acetophenone) was used. Hydrogenation was pseudo zero order with respect to the substrate and first order with respect to catalyst. The rate of hydrogenation is expressed in terms of the initial rate of hydrogen uptake per g catalyst (mol min^{-1} g^{-1}).

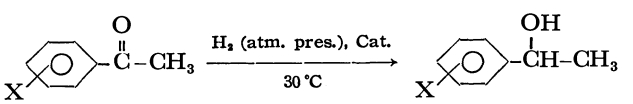
Analysis. The products were identified by comparison of their NMR spectra recorded on a Hitachi R-24 (60 MHz), IR spectra recorded on a Hitachi 215, melting point, boiling point, and retention time in gas chromatography with those of authentic samples prepared by the sodium tetrahydroborate reduction.[22]

In the course of competitive hydrogenation, samples of 0.1—0.2 cm^3 were withdrawn at appropriate intervals of hydrogen uptake (0—30%) for gas-chromatographic analysis.

Gas-chromatographic analyses of the reaction mixtures were performed with Shimadzu GC6A (detector, FID; carrier gas, N_2) and Shimadzu GC5A (detector, TCD; carrier gas, He) equipped with a column of 5% Silicone OV-17 on Uniport B (80/100 mesh) and of 10% PEG 20M on Celite 545 (60/80 mesh) (Gasukuro Kogyo Co.). The column temperatures employed in the case of OV-17 were 125—150 °C for acetophenone–alkylacetophenones, 170 °C for acetophenone–3-hydroxyacetophenone and acetophenone–4-fluoroacetophenone, and 200 °C for acetophenone–4-methoxyacetophenone.

Results and Discussion

Behavior of Substituted Acetophenones for the Catalytic Hydrogenation with Nickel and Cobalt. Alkyl-, methoxyl-, hydroxyl-, and fluoro-substituted acetophenones were hydrogenated to the corresponding 1-arylethanols in alcohol or hydrocarbon solutions over Ni and Co.



X=–H, –CH_3, –CH_2CH_3, –$CH(CH_3)_2$, –$C(CH_3)_3$, –OCH_3, –OH, –F

Neither hydrogenolysis of the carbonyl group nor hydrogenation of the aromatic ring was observed at the initial stage of reaction of these substrates.

4-Chloro-, 4-carboxy-, and 4-aminoacetophenone were not studied in detail because of their abnormal behavior during the course of hydrogenation. When 4-chloroacetophenone was subjected to catalytic hydrogenation, the reaction stopped after a slight hydrogen uptake, and the reaction mixture turned green, indicating nickel ion formation. Hydrogenation of 4-aminoacetophenone over nickel catalysts was accompanied by hydrogenolysis.

Kinetics. Kinetic measurements were performed under conditions at which the reaction rates are independent of mass transfer. The rate of hydrogenation was found to be first order with respect to catalysts.

The dependence of the initial reaction rate of hydrogenation of acetophenone on its concentration over R-Ni and R-Co in *i*-PrOH solutions is shown in Fig. 1. The

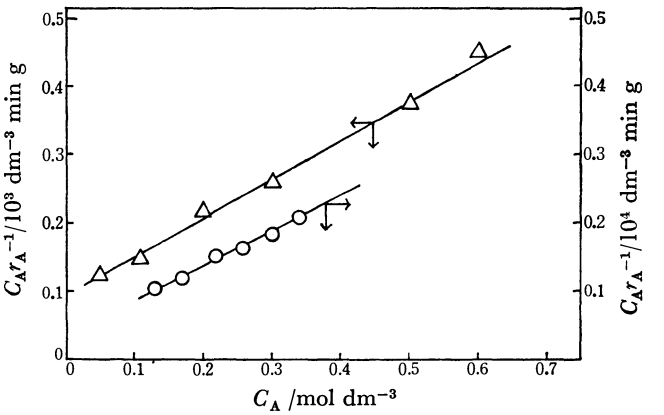


Fig. 1. Langmuir plot for hydrogenation of acetophenone in *i*-PrOH solution over R-Ni and R-Co catalysts.
△: R-Ni, ○: R-Co.

linear correlation of the reciprocals of the hydrogenation rate (r_A) *vs.* the concentration of the substrate (C_A) satisfies the Langmuir isotherm

$$r_A = -\frac{dC_A}{dt} = k_A\theta_A = \frac{k_A K_A C_A}{1+K_A C_A}$$

where k_A is the reaction rate constant of A, θ_A the fractional surface coverage of A, and K_A the adsorption equilibrium constant of A. In the region of [acetophenone]>0.2 mol dm^{-3}, the rate of hydrogen uptake is zero order with respect to the concentration of acetophenone, thus, $r_A=k_A$. The hydrogenation was carried out by using a solution of [ketone]≥0.52 mol dm^{-3} in which the reaction rates are independent of the concentration of substrate.

In the competitive hydrogenation of substrates A and B, assuming that the rate of hydrogenation of A (or B) is proportional to the amount of adsorbed A (or B) and that the adsorption of A (or B) follows the Langmuir isotherm, the following equation is obtained:[1,4]

$$K_{B,A} = S_{B,A}/r_{B,A}$$

where $K_{B,A}$ is the relative adsorption coefficient of B to A and used as a measure for the strength of adsorption, $r_{B,A}$ the ratio of the rates in the individual reaction and $S_{B,A}$ the ratio of the product concentration formed in the competitive hydrogenation between A and B. $S_{B,A}$ was determined in the range where the relative rate is independent of time. Thus, $S_{B,A}$ is unaffected by C_A and C_B.

Substituents Effects on the Hydrogenation of Acetophenones over R-Ni and R-Co. The results of hydrogenation (individual and competitive) of acetophenones over R-Ni and R-Co in *i*-PrOH solutions are shown in Table 1. The rate of hydrogenation and the strength of adsorption of acetophenones over R-Ni and R-Co are affected by the nature (electronic and steric effects) of the substituents. In view of substituent effects, the differences in the characteristics of nickel and cobalt catalysts can be summarized as follows:

(1) Electronic Effects of Substituents. The electronic effects of substituents on the strengths of adsorption and the rates of reaction over R-Ni and R-Co in *i*-PrOH solution are shown in terms of Hammett's relationship

Table 1. Substituent effects on the hydrogenation of acetophenone and substituted acetophenone over R-Ni and R-Co catalysts (solv.: *i*-PrOH 10 cm³)

Substituent (X=)	R-Ni $K_{X,H}(S_{X,H}/r_{X,H})$	R-Co $K_{X,H}(S_{X,H}/r_{X,H})$
H	1	1
2-Me	0.21(0.16/0.76)	0.27(0.18/0.66)
3-Me	0.50(0.44/0.88)	0.95(0.80/0.84)
4-Me	0.37(0.29/0.78)	0.93(0.71/0.76)
4-Et	0.36(0.24/0.67)	0.54(0.39/0.72)
4-*i*-Pr	0.42(0.21/0.50)	0.58(0.36/0.62)
4-*t*-Bu	0.37(0.11/0.30)	0.59(0.33/0.56)
4-OMe	0 (≈0/0.54)	0 (≈0/0.56)
3-OMe	0.99(0.83/0.84)	1.52(1.32/0.87)
3-OH	0 (≈0/0.49)	4.07(2.36/0.58)
4-F	0.48(0.29/0.60)	1.35(0.97/0.72)

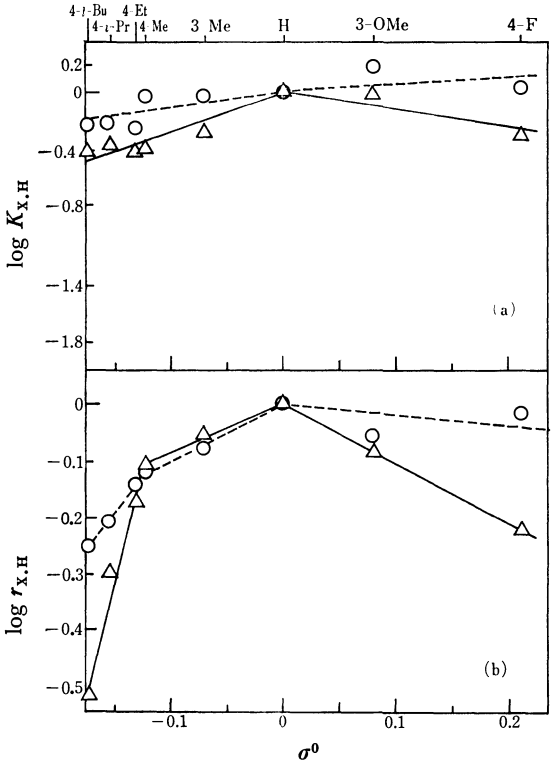

Fig. 2. log $K_{X,H}$ and log $r_{X,H}$ plotted against σ^0 values for the competitive hydrogenation of substituted acetophenones in *i*-PrOH solution over R-Ni and R-Co catalysts.

using σ^0[11,23] in Figs. 2a and 2b, respectively.

Strength of Adsorption: Over R-Co the strength of adsorption is greater for the acetophenones with electron attracting groups and smaller for those with electron donating groups than for unsubstituted acetophenone. The ρ value of Hammett plot in the region $\sigma^0<0$ is somewhat higher than that in the region $\sigma^0>0$.

Over R-Ni the adsorption of acetophenone is the strongest. On the two sides of $\sigma^0>0$ and $\sigma^0<0$, the Hammett plot forms approximately straight lines with different slopes. The adsorption over R-Co is affected by substituents to a lesser extent as compared with that over R-Ni.

In the competitive hydrogenation of acetophenone and 3-methoxyacetophenone or 4-fluoroacetophenone, the $K_{X,H}$ values are always larger over R-Co than over R-Ni. The values for 3-methoxyacetophenone over R-Co are much greater than unity (Table 2b). 3-Methoxyacetophenone is more strongly adsorbed on R-Co than acetophenone.

Rate of Hydrogenation: Over both R-Ni and R-Co, the rate of hydrogenation of unsubstituted acetophenone is greater than that of substituted acetophenones with either electron donating or electron attracting groups (Fig. 2b). The Hammett plot for the reaction rates shows greater deviation from the linear relationship than that for the adsorption coefficients. The hydrogenation over R-Ni was affected to a greater extent by substituents than that over R-Co.

Table 2. Solvent effects on competitive hydrogenation over R-Ni and R-Co catalysts (solv.: 10 cm³)

(a) Hydrogenation of acetophenone and 3-hydroxyacetophenone.

Solvent	$K_{3\text{-OH},H}(S_{3\text{-OH},H}/r_{3\text{-OH},H})$ R-Ni	R-Co

Concerning the rates of hydrogenation over nickel catalysts, similar effects of substituents have been recently reported in the reaction of substituted acetophenones by Nitta *et al.*[24] In the hydrogenation of substituted acetophenones over carbon-supported palladium catalyst, Bekkum *et al.* obtained $\rho=0.7$.[4]

The $S_{X,H}$ values of 3-hydroxyacetophenone and 4-methoxyacetophenone are exceptionally low (Table 1). The deactivating effects of substituents are particularly noticeable with 3-hydroxyacetophenone (over R-Ni in Table 2a) and 4-methoxyacetophenone (over R-Ni and R-Co) which is not hydrogenated at all before acetophenone is completely consumed in alcoholic solutions.

(2) Steric Effects of Substituents. Strength of Adsorption: Both over R-Ni and R-Co, the effects of increase in size of alkyl groups at the 4-position of acetophenone on the strength of adsorption are not significant. However, the alkyl group (methyl-) at the 2-positions brings about a decrease in the strength of adsorption.

Rate of Hydrogenation: The rate of hydrogenation (Table 1) of 4-alkylacetophenones over R-Ni and R-Co in *i*-PrOH solution decreases in the order: H>4-Me>4-Et>4-*i*-Pr>4-*t*-Bu. This indicates that the bulkiness of the substituents at the 4-position plays an important role in the reaction rates, which depend on steric effects rather than electronic effects.

The reaction over R-Ni is more sensitive to the steric substituent effects than that over R-Co, with respect to both the hydrogenation rate and the adsorption strength.

(3) Solvent Effects. The hydrogenation of acetophenones is strongly affected by the solvent used, particularly on the adsorption strength of acetophenones over Ni catalysts.

From the results (Tables 2b and 2c), the differences between R-Ni and R-Co became apparent by varying the solvents. In general, in the hydrogenation of acetophenones both the rate of hydrogenation and the strength of adsorption over R-Ni are susceptible to solvents to a greater extent than over R-Co.

The adsorption of 4-alkylacetophenones over R-Ni in MeOH and EtOH solvents is very weak, as compared with that of acetophenone (Table 2b). The selectivity of adsorption in MeOH and EtOH solutions is higher for 4-*t*-Bu ($K_{X,H}=0.06$—0.07) than for 4-Me ($K_{X,H}=0.16$—0.17). On the other hand, the adsorption strengths of 4-methylacetophenone and 4-*t*-butylacetophenone over R-Co are hardly affected by solvent, as can be seen from the values of EtOH and *i*-PrOH solvents.

The solvent effects on the rate of hydrogenation and strength of adsorption can be correlated with the relative dielectric constant ε_r (Figs. 3a and 3b). In the case of R-Ni, both $r_{X,H}$ and $K_{X,H}$ values decrease with increase in the dielectric constant ε_r. In the case of R-Co, both $r_{X,H}$ and $K_{X,H}$ values are affected to a lesser extent by ε_r.

Effects of the Method of Catalyst Preparation. In order to know whether the above differences between Ni and Co catalysts are essential or not, the effects of the method of catalyst preparation were studied.

The results of competitive hydrogenation of acetophenone and 4-methylacetophenone over the catalysts obtained by three methods are given in Table 3. The $K_{X,H}$ values of R-Ni, U-Ni-B, and Ni_2B catalysts agree

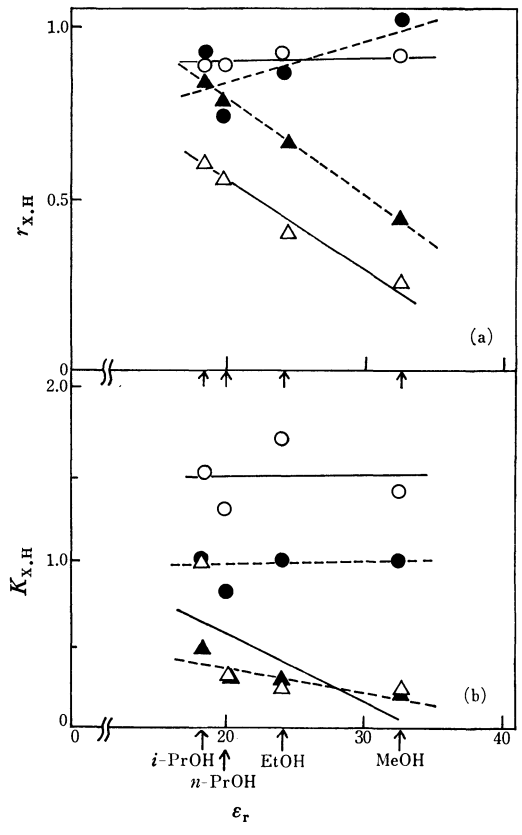

Fig. 3. Relationship between $K_{X,H}$ and $r_{X,H}$ and relative dielectric constants (ε_r) in the hydrogenation of 3-methoxyacetophenone and 4-fluoroacetophenone over R-Ni and R-Co catalysts.

Catalyst	Solvent	
	MeOH	*i*-PrOH
Ni_2B	0.09	0.86
Co_2B	0.86	0.91
R-Ni	0.10	0.83
R-Co	1.27	1.32

within the range 0.16—0.17, as is the case for the three cobalt catalysts.

A comparison between Ni_2B and Co_2B with respect to the $S_{X,H}$ values in the competitive hydrogenation of acetophenone and 3-methoxyacetophenone shows nearly the same tendency as shown by Raney catalysts (Table 4).

Dependence of $S_{X,H}$ values on the conditions of catalyst preparation was examined in the competitive hydrogenation between acetophenone and 3-methoxyacetophenone. Concerning the effect of aging time in *i*-PrOH solution on the $S_{X,H}$ values, R-Ni is somewhat more susceptible to aging as compared with R-Co (Fig. 3b).[25] The digestion time of Raney alloy by 20% NaOH solution has no influence on the $S_{X,H}$ values, despite the presumed gradual decrease in Al content with digestion time. The effect of Al components on $S_{X,H}$ values seems negligible.

-△-: R-Ni, -○-: R-Co.

Difference between Ni and Co Catalysts. The above results suggest that the characteristic difference between R-Ni and R-Co can be essentially attributed to the difference between Ni and Co metals. Ni is more susceptible to the effects of substituent groups and solvents as compared with Co. The difference between the two catalysts is in line with our observation that the selectivity over Co catalysts in the selective hydrogenation of 2-naphthol is influenced to a lesser extent by the solvents, as compared with Ni catalysts.[19] In their study of infrared spectra, Blyholder and Shihabi reported that acetone undergoes chemisorption on silica-supported Ni and Co at 25 °C, the amount on Ni being less than that on Co, and that a metal–oxygen bond rather than a metal–carbon bond is responsible for the bonding between acetone and the metal surfaces.[26] In the hydrogenation of acetophenones over various Ni catalysts, Nitta *et al.* reported that the rate of hydrogenation is proportional to the surface d-electron density of catalysts, whereas the strength of adsorption of the reactants on the catalyst is inversely proportional to the surface d-electron density of catalysts.[24]

The reaction over Co catalyst is not very susceptible to the effects of substituents and the strength of adsorption, as compared with that over Ni catalyst. This suggests that the carbonyl group of acetophenone is adsorbed more strongly over Co than over Ni. The characteristic difference between Ni and Co catalysts can be attributed to the difference of the surface d-electron density between the two metals; the surface d-electron density of Co is smaller than that of Ni. The results support observations concerning the relationship between the strength of adsorption and the surface d-electron density.[24] However, the effects of substituents on the strength of adsorption and the rate of hydrogenation are still not completely explained on the basis of only this relationship. The difference between Ni and Co catalysts should be further discussed from the standpoint of their difference in physical properties as related to the mechanisms of hydrogenation.

We wish to thank Professor Shigeo Nishimura, the Tokyo University of Agriculture and Technology, for his valuable discussion.

Effect of Hydration on the Thermal Stability of Protein as Measured by Differential Scanning Calorimetry. Lysozyme-D_2O System

Yukihisa FUJITA* and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663

(Received October 9, 1978)

The thermal denaturation of the deuterated lysozyme has been investigated by differential scanning calorimetry in the range of deuterium oxide (D_2O) content from 0.03 to 1.6 g of D_2O per g of protein. At D_2O contents above 0.55 g/g, the temperature, T_d, and enthalpy change, ΔH_d, of denaturation were almost independent of the degree of hydration. At lower D_2O contents, however, both T_d and ΔH_d showed marked dependence on the degree of hydration. The values of T_d increased with a decrease in the D_2O content. Whereas the values of ΔH_d decreased with a decrease in the D_2O content in the same region. The degree of hydration dependency of ΔH_d exhibited a break at approximately 170 mol/mol, which indicates that at least two types of hydration contributes to the thermal stability of the protein. The conformational enthalpy change of the protein and the enthalpy change of the hydration layer have also been estimated from the degree of hydration dependency of ΔH_d. The results have been compared with those of the lysozyme–H_2O system.

There has been a great deal of experimental evidence which has established that the interaction of water with proteins has an important role in determining the structure and biological function of the protein. This role, however, is poorly understood. The physical properties of water in the protein solution have been extensively investigated by several techniques, such as dielectric relaxation measurement,[1] NMR spectroscopy,[2] and calorimetry.[3] The studies have revealed that the properties of the interacting water are evidently different from those of pure water *e.g.*, lower mobility and reduced freezing point. It has been also observed that the hydration values in globular proteins do not differ greatly, being approximately 0.3 g of water per g of protein.[4]

In a previous paper,[5] the effect of hydration on the thermal stability of lysozyme was investigated by differential scanning calorimetry (DSC). It was observed that the essential hydration for stabilizing the spatial structure of lysozyme in water was completed at about 0.75 g/g. Below this water content, both the temperature and enthalpy change of denaturation showed a marked dependence on the degree of hydration. It was further suggested that at least two types of hydration contributed to the thermal stability of the protein, the threshold water content being approximately 0.33 g/g.

The present work was undertaken to investigate the effect of hydration of deuterium oxide (D_2O) on the thermal stability of deuterated lysozyme by DSC and to compare the results with those of the lysozyme–H_2O system.

Experimental

Materials. The hen egg-white lysozyme used in the present study was a recrystallized ($\times 6$) sample from Seikagaku Kogyo Co. The deuterium oxide (D_2O, purity 99.8%) was purchased from Aldrich Chemical Co.

Methods. Prior to calorimetric measurement, the lysozyme sample was deuterated as follows: the lysozyme was dissolved in D_2O(approximately 3% concentration), shaken for 50 h at 313 K, and lyophilized. After reaction, the extent of hydrogen-deuterium exchange was estimated by IR absorption according to the methods described by Blout *et al.*[6] and Nakanishi *et al.*[7] The amount of undeuterated peptide group was taken as proportional to the ratio of the absorbance of the amide II (at 1540 cm^{-1}) to that of the amide I (at 1650 cm^{-1}). In the absorbance measurement, the baseline for the amide I band was drawn parallel to the 100% transmittance at 1800 cm^{-1}, and the baseline of the amide II band taken as the absorption of the completely deuterated lysozyme. Complete deuteration was achieved by heating a solution of the exchanging protein at 353 K. From the IR measurements, approximately 83% of the total hydrogen atoms of the peptide exchanged, this amount corresponding to 106 peptide groups per molecule. It is a valid assumption that the hydrogen atoms of the protein side chain more rapidly exchange compared with those of the peptide group. In the lysozyme molecule there are in all 260 exchangeable hydrogen atoms.[8] The degree of deuteration which accounted for the number of deuterium atoms in the side chain was 92%, therefore, the molecular weight of the deuterated lysozyme has been taken as 14500.

The D_2O content of the sample was adjusted by conditioning in constant humidity apparatus at the appropriate relative humidity for 7 days. Higher D_2O contents were adjusted either by directly adding D_2O or by placing the sample in the saturated vapor at 293 K for an appropriate period. The relative humidity was maintained by a saturated aqueous solution in contact with an excess of solute at 293 K.[9]

The thermal denaturation of lysozyme was measured with a Rigaku Denki standard-type differential scanning calorimeter. For calorimetric measurements, the heating rate was 2.5 K/min.

The exact dry weight and D_2O content of sample were determined gravimetrically by drying the punctured sample pan at 378 K *in vacuo* for 24 h.

Results and Discussion

The thermal denaturation of deuterated lysozyme has been measured in the D_2O content range from 0.03 to 1.6 g/g. The temperature, T_d, and the enthalpy change, ΔH_d, of denaturation have been estimated from the temperature of the peak and the peak-area of the thermogram obtained, and plotted as a function of the D_2O content as shown in Figs. 1 and 2, respectively.

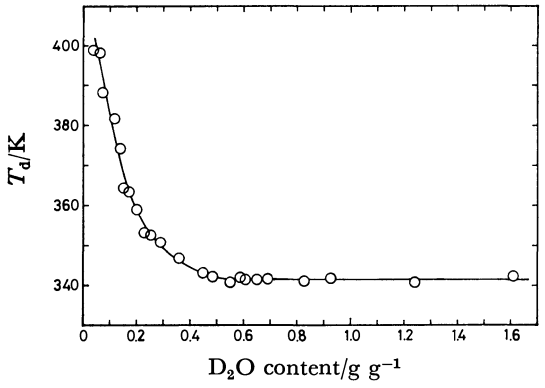

Fig. 1. The temperature of denaturation, T_d, of deuterated lysozyme as a function of the D_2O content.

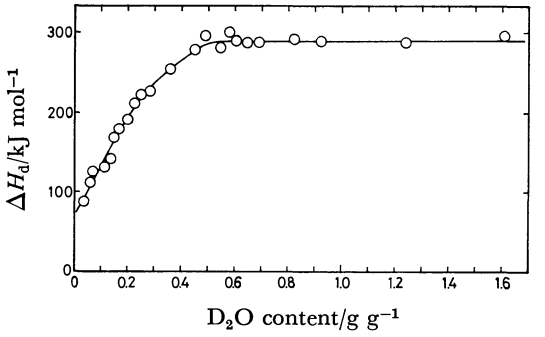

Fig. 2. The enthalpy change of denaturation, ΔH_d, deuterated lysozyme as a function of the D_2O content.

The data shows a marked dependency on the D_2O content, and the behavior has a resemblance to that for the lysozyme–H_2O system.

Both T_d and ΔH_d were slightly dependent on the D_2O content above 0.55 g/g which was a lower value than that reported for the lysozyme–H_2O system. The mean values in this region were 341.4 K and 298 kJ/mol, values which are almost identical not only with those for the lysozyme–H_2O system above 0.75 g/g, but also with those for lysozyme in aqueous solution.[10,11] The thermal denaturation of several proteins has been investigated in both H_2O and D_2O solutions and differences in the thermal stability of proteins in H_2O and D_2O solutions have been reported.[12,13] Nakanishi *et al.*[14] have, however, reported from UV measurements that the temperature of denaturation of lysozyme in D_2O solution was identical with that in H_2O solution. From NMR spectroscopic studies, McDonald *et al.*[15] also observed that the extent of denaturation of lysozyme in D_2O exhibited the same temperature dependency as that in H_2O. It appears reasonable to assume that a similar conformational change which takes place in solution occurs in the solid state containing a lot of water and that the conformational change of lysozyme by thermal denaturation makes little difference in H_2O and D_2O. In addition, the indication is that the hydration, an essential process for stabilizing the spatial structure of lysozyme in water, is completed at about 0.55 g/g for the lysozyme–D_2O system, which is a smaller value than that reported for the lysozyme–H_2O system, namely 0.75 g/g.

Below a D_2O content of 0.55 g/g, the T_d increased gradually with decrease in the D_2O content. The increase became much more marked at D_2O contents lower than 0.2 g/g. The ΔH_d, on the other hand, decreased with decrease in the D_2O content in the same region. In order to analyze the experimental data in this region of D_2O content it has been assumed that the observed enthalpy change of denaturation, ΔH_d, may be expressed as follows:

$$\Delta H_d = \Delta H_{conf} + n_{hyd}\Delta H_{hyd}$$

where ΔH_{conf} is the enthalpy change due to conformational changes in the protein, n_{hyd} is the degree of hydration, expressed by the number of mol of water adsorbed per mol of protein, and ΔH_{hyd} is the enthalpy change of the hydration layer, expressed on the basis of one mol of water per mol of protein. A plot of ΔH_d against n_{hyd} is shown in Fig. 3 together with that for the lysozyme–H_2O system. As may be seen, the relationship may be represented by two segments of a straight line, with the break occurring at 170 mol/mol which is a lower value than that for the lysozyme–H_2O system, namely 260 mol/mol. This indicates that at least two types of hydration exist and contribute to the thermal stability of the protein.

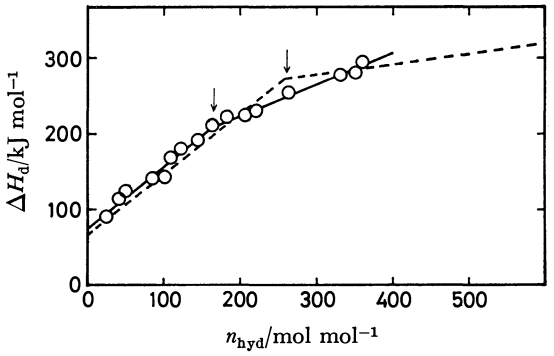

Fig. 3. The plots of the enthalpy change of denaturation, ΔH_d, of lysozyme against the degree of hydration, n_{hyd}, for lysozyme–D_2O system(solid line) and lysozyme–H_2O system (broken line).

Calorimetric studies of frozen protein solutions have revealed that water in protein solutions may be classified into four different states.[16,17] The four states are described as (1) non-freezable water, (2) freezable water with both heat and temperature of fusion different from the values for bulk water, (3) freezable water with the heat of fusion of bulk water, but a temperature of fusion lower than that of bulk water, and (4) bulk water. From recent NMR studies of aqueous protein solutions, Grosch and Noack[18] have suggested that at least three types of water which may be distinguished: (a) "rotationally bound" water, the rotational motion of which is considerably hindered by strong interactions with the protein, (b) "translationally hindered" water, the translational diffusion of which is hindered by interaction with the protein surface, and (c) "free bulk" water, the motion of which is not appreciably altered by interaction with the protein.

It has been assumed here that the hydration may be classified into two types as follows: (1) primary hydration *i.e.*, below n_{hyd} of 170 mol/mol for the lysozyme–D_2O system and 260 mol/mol for the lysozyme–H_2O system, and (2) secondary hydration *i.e.*, the range of n_{hyd} from 170 to 400 mol/mol for the lysozyme–D_2O system and from 260 to 600 mol/mol for the lysozyme–H_2O system. The values of ΔH_{hyd} and ΔH_{conf} have been estimated from the slopes and the intercepts, respectively, and are summarized in Table 1.

Table 1. The enthalpy change due to conformational changes of the protein, ΔH_{conf}, and the enthalpy change of hydration layer, ΔH_{hyd}, in primary and secondary hydration

Hydration	Water content	n_{hyd}	ΔH_{conf}	ΔH_{hyd}
	g g^{-1}	mol mol^{-1}	kJ mol^{-1}	kJ mol^{-1}
Lysozyme–D_2O system				
primary	0.23	170	72	0.83
secondary	0.55	400	140	0.43
Lysozyme–H_2O system				
primary	0.33	260	66	0.80
secondary	0.75	600	240	0.14

Primary hydration was completed at about 170 mol/mol for the lysozyme–D_2O system and 260 mol/mol for the lysozyme–H_2O system. The values of ΔH_{hyd} in the primary hydration region for both systems were considerably larger compared with those in the secondary hydration region. This indicating that the water molecules in this region contribute significantly to the stability of the protein compared with those in the secondary hydration region. The values of 170 mol/mol and 260 mol/mol correspond approximately to 1.0 and 1.5 molecules of water per hydrogen-bonding site, polar amino acid residue and peptide group, on the lysozyme molecule, respectively.[8] In this region, the water molecules are assumed to be tightly bound to the hydrogen-bonding sites, probably corresponding to the "rotationally bound" water molecules or state (1) in the calorimetric studies. It appears probable that the water molecules are selectively arranged in the vicinity of the polar regions of the protein by hydrogen bonds and form part of a first hydration monolayer.

The values of ΔH_{hyd} were almost identical for D_2O and H_2O in the primary hydration region. It is suggested that the primary hydration for D_2O contributes to the thermal stability of lysozyme in a similar manner to that for H_2O: the strength of interaction between the protein and D_2O are the almost identical to that between the protein and H_2O. The amount of primary hydration for the lysozyme–D_2O system, however, was considerably smaller than that for the lysozyme–H_2O system.

Secondary hydration was completed at about 400 mol/mol for the lysozyme–D_2O system and 600 mol/mol for the lysozyme–H_2O system. These values are comparable to approximately 3 and 5 molecules of water per amino acid residue on the lysozyme molecule, respectively. In the secondary hydration region, it is probable that the water molecules interact with the surface of the protein by repulsive hydrophobic interactions with the nonpolar parts of the protein and by hydrogen bonds on the some polar groups of the protein, correspond to the "translationally hindered" water molecules or states (2) and (3) in the calorimetric studies. It has also been assumed that the water molecules form parts of second and higher hydration layers which ambivalently interact not only with the water molecules in the primary hydration region, but with the normal bulk water.

The differences in ΔH_{hyd} between the lysozyme–D_2O system and the lysozyme–H_2O system in the secondary hydration region were considerable by a factor of approximately 3. It is suggested that the contribution of secondary hydration to the thermal stability of lysozyme is larger for D_2O than for H_2O. In this region, the D_2O molecules may interact more strongly with the protein compared with the H_2O molecules. The amount of secondary hydration for the lysozyme–D_2O system was smaller than that for the lysozyme–H_2O system. The differences in degree of hydration between D_2O and H_2O are too large to explain purely in terms of molecular size. Nemethy and Scheraga[19] compared the structures of H_2O and D_2O and noted that the hydrogen bond was stronger in D_2O than in H_2O and, therefore, more structural order existed in D_2O than in H_2O. One of the reasons for the lower degree of hydration and the higher value of ΔH_{hyd} in the secondary hydration region for the lysozyme–D_2O system may arise from the stronger intermolecular interaction for D_2O. It appears probable that the increase in strength of the hydrophobic interaction of the protein results from the increasing strength of interaction between the D_2O molecules. Secondary hydration may be affected markedly by the strength of the intermolecular interactions.

In primary hydration, the value of ΔH_{conf} for the lysozyme–D_2O system was slightly larger than that for the lysozyme–H_2O system. The ΔH_{conf} in this region may be associated with the intramolecular interactions, probably hydrogen bonds, in the protein molecule. Presumably, the small difference in ΔH_{conf} reflects the increase in strength of the intramolecular hydrogen bond of the protein by deuteration. A more accurate measurement, however, is necessary in order to discuss the structure of the protein in detail from the value of ΔH_{conf}. The variation of ΔH_{conf} in primary and secondary hydration regions suggests that the exhaustive removal of the water molecules associated with the protein brings about changes in the structure of the protein, as reported by Hanafusa.[20]

The higher contribution of hydration to the stabilization of the protein in the secondary hydration region may compensate for the lower degree of hydration in the lysozyme–D_2O system compared with the lysozyme–H_2O system. The thermal stabilities of lysozyme in H_2O and in D_2O are, therefore, almost identical.

Stereochemistry in the Hydrosilylation of Substituted Cyclohexanones Catalyzed by Chlorotris(triphenylphosphine)rhodium and the Silica-linked Rhodium(I) Complex

Jun-ichi ISHIYAMA,* Yasuhisa SENDA, Isamu SHINODA, and Shin IMAIZUMI
Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai 980
(Received November 13, 1978)

The homogeneous and heterogeneous hydrosilylation of simple substituted cyclohexanones catalyzed by chlorotris(triphenylphosphine)rhodium, $RhCl(PPh_3)_3$, and the silica-linked rhodium(I) complex, $(\equiv Si\text{–}O\text{–}\overset{|}{\underset{|}{Si}}CH_2CH_2PPh_2)_3RhCl$, was examined. The stereoselectivity exhibited by the homogeneous catalyst was found to be nearly the same as that exhibited by the heterogeneous catalyst. The silica-linked rhodium catalyst could be re-used several times without any significant loss of the catalytic activity.

Although the homogeneous hydrosilylation of terpene ketones catalyzed by $RhCl(PPh_3)_3$ has been reported in detail by Ojima *et al.*,[1,2] that of simple cyclohexanones with alkyl substituents has not yet been studied. In order to shed further light on the reaction mechanism, we have now undertaken an investigation of the hydrosilylation of some simple substituted cyclohexanones by Et_3SiH, Ph_2SiH_2, and $PhSiH_3$ with the homogeneous rhodium(I) and the heterogeneous silica-linked rhodium(I) complexes. We have examined how the stereoselectivity is dependent on substrates, reagents, and catalysts. The stereoselectivity in the hydrosilylation effected by the recovered heterogeneous catalyst was also checked.

Results and Discussion

The results of the hydrosilylation of alkyl-substituted cyclohexanones with three kinds of hydrosilanes catalyzed by $RhCl(PPh_3)_3$ are presented in Table 1. In the reaction of 4-methyl- (**2**), 4-*t*-butyl- (**3**), 3-methyl- (**4**), and 3-*t*-butylcyclohexanone (**5**), the bulkiness of the silanes was not an important factor in controlling the stereoselectivity. However, the effects of the bulkiness of the silanes on the stereochemical course of the reduction became significant in the hydrosilylation of 2-methyl- (**6**) and 2-*t*-butylcyclohexanone (**7**). The relative amount of the more stable alcohol increased with an increase in the bulkiness of the hydrosilanes used. This trend was also realized in 3,3,5-trimethylcyclohexanone (**8**), which bears an axial methyl substituent at the 3-position. Thus, the results of **6**—**8** are in good agreement with those of menthone (**9**) and camphor (**10**).[1]

The relative rates of the hydrosilylation for alkyl-substituted cyclohexanones catalyzed by $RhCl(PPh_3)_3$ were estimated by a comparison of conversion in competitive reactions employing a binary mixture of cyclic carbonyl compounds. The results are listed in Table 2. With each hydrosilane, the relative rates of unhindered cyclohexanones, such as **1**—**5**, were not very different from each other, while those of hindered cyclohexanones, such as **6**—**8**, were found to be smaller than those of unhindered ones. These differences in relative rates seem to be due to the steric interaction between substituents at the 2- or 3-position and hydrosilanes in the transition state. It has previously been reported that the relative rate of $PhSiH_3$ or Ph_2SiH_2 increases remarkably compared to that of Et_3SiH in the cases of terpene ketones and other acyclic carbonyl

compounds.[5,6] In this study, for example, the conversion of **8** employing $PhSiH_3$ or Ph_2SiH_2 was over 90% in 15 min, but that employing Et_3SiH was 60% in 3 h. Our results also showed that the relative rate of trihydro or dihydro-silane increased compared to that of monohydro-silane in the reaction of alkyl-substituted cyclohexanones.

The hydrosilylation using (≡Si–O–SiCH$_2$CH$_2$PPh$_2$)$_3$RhCl showed stereoselectivities similar to those using $RhCl(PPh_3)_3$. These results are summarized in Table 3. The stereoselectivity exhibited by the re-used catalyst was not significantly different from that of the original one.

The effect of repeated use on the catalytic activity of this heterogeneous catalyst was examined employing cyclohexanone (**1**) as a standard substrate (Table 4). The conversion of **1** was 70% at room temperature using the original heterogeneous catalyst, but it went up to 83% at 50 °C. As can be seen in Table 4 (Entry Nos. 1—5), the activity gradually deteriorated upon repeated use, apparently because of the repeated contact with the air. Practically speaking, however, the results of Entry Nos. 1—4 (conversion 70—44%) suggest that the silica-linked catalyst could be re-used several times. Although a closer examination is still needed of the effect of the temperature in repeated use, it should be noted that, judging from the above results, this heterogeneous rhodium complex catalyst has the advantage that the separation of the products from the catalyst is easier than in homogeneous metal complexes and that the re-use is possible.

Table 4. Change by repeated use in silica-linked catalyst[a]

Substrate	Entry[b] No.	Reaction time/h	Conversion /%
 (**1**)	1	3	70(83)[c]
	2	3	69
	3	3	54
	4	3	44
	5	3	13

a) Et_3SiH was employed as the hydrosilane. b) The entry number also represents the time of repeated use. c) At 50 °C.

In order to examine the regioselectivity, the competitive hydrosilylation of a binary mixture of heptanal, 2-heptanone, and 4-heptanone with Et_3SiH was performed employing the two rhodium(I) complex catalysts. The results are shown in Table 5. The rate difference between the reaction with (≡Si–O–SiCH$_2$CH$_2$PPh$_2$)$_3$RhCl was notably greater than between those with $RhCl(PPh_3)_3$. The relative rates for 2- and 4-heptanone were 0.11 and 0.074 on respectively $RhCl(PPh_3)_3$, while the values changed to 0.02 and 0.008 with (≡Si–O–SiCH$_2$CH$_2$PPh$_2$)$_3$RhCl. These results show that the reactivity toward the internal carbonyl group in the heterogeneous catalyst is very low compared to that in the homogeneous one. The observed difference in regioselectivity between the reactions catalyzed by the two catalysts suggests that the silica support acts as a steric bulk.

Ojima *et al.* reported that the stereoselectivity in the hydrosilylation is governed only by the size of the silyl

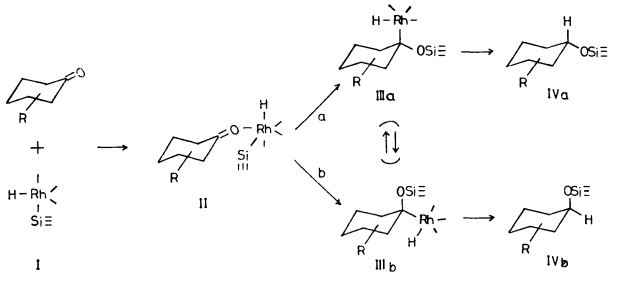
Table 5. Regioselectivities in hydrosilylation by triethylsilane–rhodium(I) complex combination

			$RhCl(PPh_3)_3$	1[a]	0.11	0.074
(≡Si–O–SiCH$_2$CH$_2$PPh$_2$)$_3$RhCl	1[a]	0.02	0.008

a) For each catalyst, the relative rates of hydrosilylation are normalized to 1.00 for heptanal.

moiety. Consequently, it has been mentioned that the bulkier the substituents on silicon, the more pronounced may be the formation of the α-silyloxyalkylrhodium complex IIIa, which is a precursor of the more stable alcohol.[1,6] Although a similar change in the stereoselectivity depending on hydrosilanes was also observed in the reaction of hindered cyclohexanones (**6**—**8**), no change was found in the reaction of unhindered cyclohexanones (**2**—**5**), which gave equatorial alcohols predominantly. *A priori*, the stereoselectivity in the hydrosilylation of alkyl-substituted cyclohexanones is governed kinetically by the insertion step from II to III. Our results clearly show that, in the reaction of unhindered cyclohexanones (**2**—**5**), the axial attack of Rh predominates at the insertion step. Klein and others[7-9] have proposed a stereochemical control based on orbital-symmetry arguments. On the basis of the orbital-distortion theory, Klein[9,10] has reported that, in the absence of steric factors, an electrophilic reagent attacks the cyclohexanone from the equatorial side and a nucleophile attacks from the axial side. As is envisioned in the scheme, the transfer of Rh is supposed to be a nucleophilic reaction; hence, the predominant formation of equatorial alcohol can be accounted for in terms of Klein's criterion. On the other hand, the axial attack of Rh on hindered cyclohexanones (**6**—**8**) is restricted by the substituents at the 2- or 3-position. Consequently, the equatorial attack of Rh predominates in the reaction of hindered cyclohexanones (**6**—**8**), supporting results presented by previous workers.[1,6]

The influence of the bulkiness of silanes was thus significant only in the reaction of hindered cyclohexanones, such as **6**—**10**. These changes in the product distribution may be attributed to the equilibrium between IIIa and IIIb originating in the large interaction between the axial silyloxyl group and the substituents in the IIIb complex.[1] Therefore, the bulky silyloxyl group may occupy the less-hindered position when the silyloxyl group becomes larger than the rhodium moiety, which is kept constant in the III complex.



Experimental

A typical procedure will be described for the hydrosilylation of 4-methylcyclohexanone (**2**): To a mixture of 2 mmol of **2** and hydrosilanes, 5.2×10^{-3} mmol of $RhCl(PPh_3)_3$ or 0.1 g of $(\equiv Si-O-\overset{|}{Si}CH_2CH_2PPh_2)_3RhCl$ was added. The amount of $RhCl(PPh_3)_3$ was equalized in Rh content to that of $(\equiv Si-O-\overset{|}{Si}CH_2CH_2PPh_2)_3RhCl$, which had been found to contain 0.54 wt % of Rh. The mixture was stirred for 15 min ($PhSiH_3$), for 30 min (Ph_2SiH_2), and for 3 h (Et_3SiH) at room temperature under a nitrogen atmosphere. The silyl ether thus obtained was hydrolyzed by a MeOH–KOH–H_2O soln. to afford cyclohexanol quantitatively. The worked-up mixture was analyted by GLC.

Silica-linked Rhodium (I) Complex.[3,4] $(\equiv Si-O-\overset{|}{Si}CH_2CH_2PPh_2)_3RhCl$ was prepared from chlorotris[diphenyl[2-(triethoxysilyl)ethyl]phosphine]rhodium, $[(EtO)_3SiCH_2CH_2PPh_2]_3RhCl$, and silica gel (pore radius, 150 Å; surface area, 270 m^2/g; surface OH concentration, *ca.* 4 mmol/g) by refluxing with anhydrous benzene. The heterogeneous catalyst used was washed several times with pentane and dried under reduced pressure. This catalyst was then re-used.

Competitive Hydrosilylation. In a flask containing 5.2×10^{-3} mmol of $RhCl(PPh_3)_3$, 0.05 mmol each of two carbonyl compounds and 0.1 mmol of a hydrosilane were stirred at room temperature under a N_2 atmosphere. The composition of the mixture was checked in order to stop the reaction when half of the hydrosilane had been consumed. Water and crushed ice were added, and the resultant silyloxy compounds were hydrolyzed with a sufficient quantity of the MeOH–KOH–H_2O solution. The aqueous layer was extracted with ether, which had been washed with brine and dried over Na_2SO_4. The soln. was concentrated by removing a part of the ether, and the residual solution was subjected to GLC.

Solvolysis in Carboxamides. VI.[1] Kinetic, Product, and Deuterium Tracer Studies on the *N,N*-Dimethylacetamide Solvolysis of *threo*-2-(*p*-Methoxyphenyl)-1-methylpropyl Brosylate. Nature of the k_Δ Pathway

Seiki SAITO,* Kenji DOIHARA, Toshio MORIWAKE, and Kunio OKAMOTO**

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

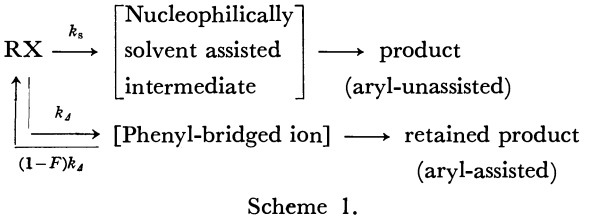
(Received November 13, 1978)

Solvolysis of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl brosylate (**1**) and its deuterium derivative (**1**-2-*d*) has been carried out in *N,N*-dimethylacetamide (DMA) as solvent at 50.0 and 75.0 °C. Product examination revealed that in the presence of water (0.17 mol/dm^3) the main product is *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl acetate (73% at 50 °C), but in the absence of water (*Z*)-2-(*p*-methoxyphenyl)-2-butene (**5**) (*ca.* 70% at 50 °C). Both of these products are derived from a *threo*-imidatonium ion [*threo*-R-Amide]$^+$ which is produced by DMA capture of the tight ion-pair [R$^+$OBs$^-$] (**2**) from the front-side. A part (*ca.* 14% yield) of the (*Z*)-olefin **5** is directly led from the tight ion-pair **2**. The formation of the olefin **5** can not be explained by intervention of the phenyl-bridged ion. Although the rate of the brosylate **1** exhibits the k_Δ portion deviating upwards from the Hammett plot for **a** series of *threo*-2-aryl-1-methylpropyl brosylates, the Schleyer's k_Δ-k_s treatment for the rate-(retained)product correlation was unsatisfactory. The classical simple S_N1 mechanism can preferably elucidate the product distribution, including the isotope distribution, without intervention of the phenyl-bridged ion intermediate.

Neighboring β-aryl participation in solvolytic reaction has received considerable attention in recent years.[2] The parent phenyl derivative among a series of substituted 1-methyl-2-phenylpropyl system exhibited remarkable stereospecificity in acetolysis[3] but its rate was unexpectedly slow.[4] This apparent discrepancy has been a starting point of the controversy[2,5] with regard to the role of β-aryl groups and the existence of a phenyl-bridged intermediate in solvolytic reactions.

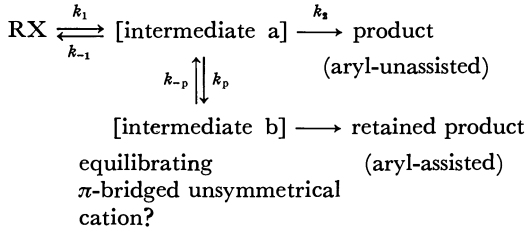
Schleyer and his collaborators[6] have recently suggested a dual-mechanism in that the solvolysis of β-arylalkyl systems proceeds through aryl-assisted (k_Δ) and/or aryl-unassisted (k_s) pathways; they have divided the observed rate constant (k_t) into discrete Fk_Δ and k_s components, and the Fk_Δ was estimated from the upward deviation from the normal line in Hammett correlation. They have also postulated that the k_Δ pathway prodeeds *via* a phenyl-bridged ion giving a retained product (Scheme 1[6h]).



Scheme 1.

Although this dissection has been followed in 2-aryl-1-methylpropyl system by Brown and Kim,[7a] these investigators have proposed another mechanism which postulates prior formation of a tight ion-pair followed by subsequent k_p and k_2 pathways,[7a,b] which are respectively designated as aryl-assisted and aryl-unassisted pathways (Scheme 2[7a]). In addition, there still remains an original controversy as regards intervention of the phenyl-bridged ion in the k_Δ pathway.[7b]

In connection with our previous studies,[1,8-11] which disclosed several characteristics of carboxamide solvolysis, it was tempting to speculate that carboxamide solvolysis serves as a probe to scrutinize the reaction scheme (dual[6h] or single[7a]) and to examine the nature of so-called k_Δ pathway, especially as regards the intervention of the phenyl-bridged ion.

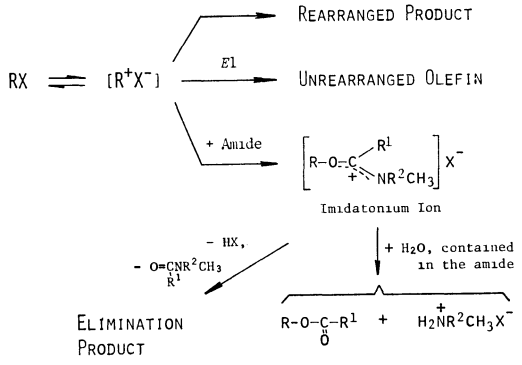


Scheme 2.

In the previous trial[1] of dissection of the observed rate (k_t) of *N,N*-dimethylacetamide (hereafter DMA) solvolysis into k_s and k_Δ components, it has been disclosed that the solvolysis of *threo*-1-methyl-2-phenylpropyl brosylate proceeds by complete (100%) k_s pathway, but the methoxy derivative, *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl brosylate (**1**), predominantly reacts by the k_Δ route. As a model reaction to scrutinize k_Δ process the DMA solvolysis of the methoxyl derivative **1** was selected.

Results and Discussion

Product Distribution in the Presence of Water. In a series of our previous investigation for typical secondary cycloalkyl systems (4-*t*-butylcyclohexyl,[8] 7β-methylbicyclo[3.3.1]non-3β-yl,[9] and *exo*-2-norbornyl[11] systems), it has been revealed that the carboxamide solvolysis proceeds through an intermediate, characterized as a tight ion-pair [R$^+$X$^-$] (classical), and subsequently the intermediate undergoes a variety of processes such as *E*1 deprotonation, solvent capture (formation of an imidatonium ion), and rearrangements (Scheme 3).



Scheme 3.

The unstable imidatonium ion, which otherwise decomposes to give elimination products, can be readily trapped by water to yield the carboxylic ester (Scheme 3); the efficient trapping with sufficient amounts of water has been successfully utilized in the previous works[1,9,11] to estimate the amount of the imidatonium ion and also to investigate the stereochemistry of its formation from the tight ion-pair.

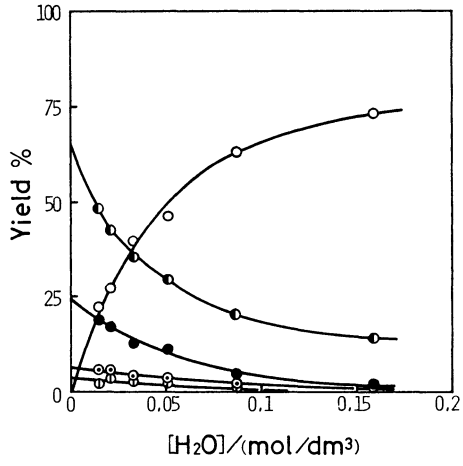


Fig. 1. Effect of water content of DMA on the formations of (*Z*) olefin **5** (◐), (*E*)-olefin **6** (●), 2-(*p*-$MeOC_6H_4$)-1-butene **7** (⊙), 3-(*p*-$MeOC_6H_4$)-1-butene **8** (⊕), and *threo*-acetate **9** (○), at 50 °C.

Table 1. Effect of added water on product distribution for the DMA solvolysis of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl brosylate **1**[a]

T / °C	$[H_2O]$ / mol/dm³	Yield/%

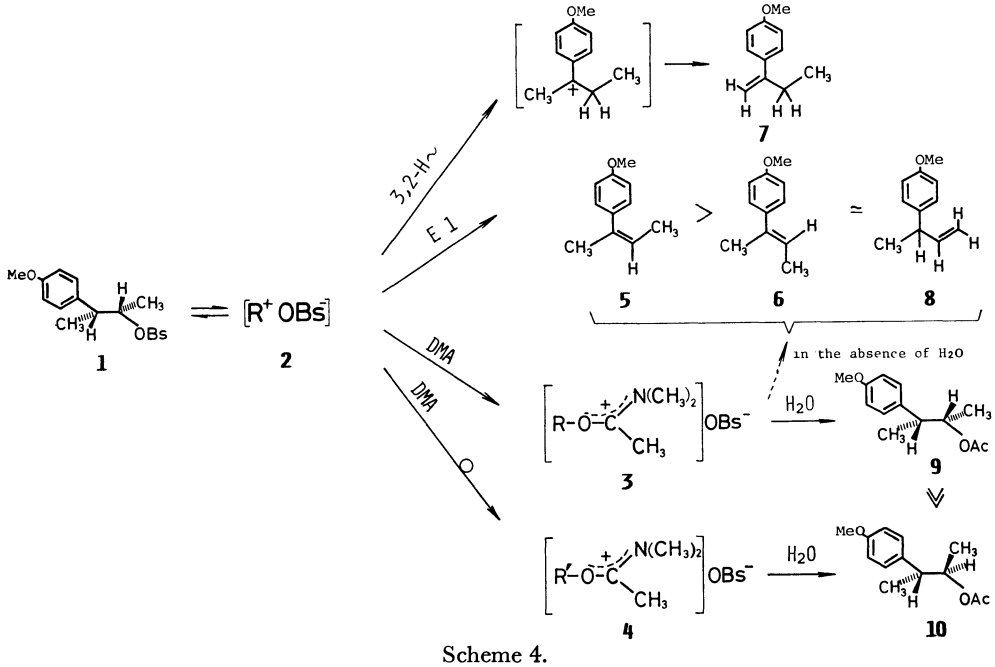
	0.159	14.4	2.2	1.0	0.6	73.1	3.1	5.3	0.3
75	0.170	17.1	5.2	5.1	2.3	60.1	2.6	7.3	0.3

a) [**1**]=0.075 mol/dm³; [C_5H_5N]=0.077 mol/dm³.



Scheme 4.

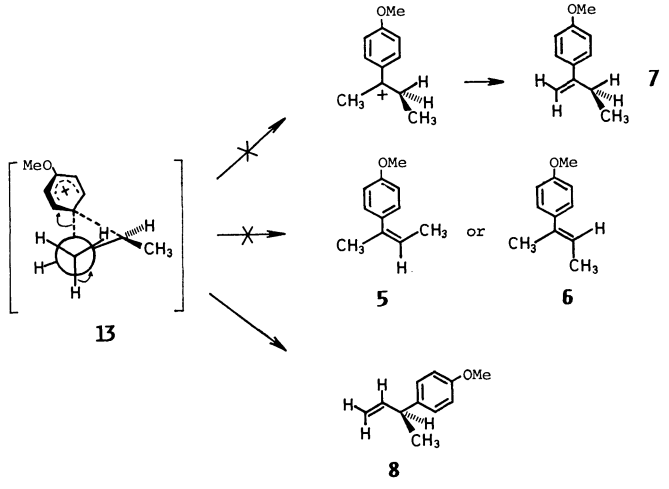
Thus the product distribution was determined in the presence of water, sufficient (0.16—0.17 mol/dm^3) to trap the imidatonium ion at 50.0 and 75.0 °C. The results are summarized in Table 1 and illustrated in Fig. 1 and Scheme 4.

The retained acetate, *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl acetate (**9**), was a major product (60% at 75 °C; 73% at 50 °C), indicating that the most of the tight ion-pair (**2**) is captured by DMA from the retentive site to give a *threo*-imidatonium ion [*threo*-R-Amide]$^+$ (**3**). The rest of the tight ion-pair **2** undergoes 2,1-hydride shift and elimination. It is clear from attenuation of increase in the *threo*-acetate yield (Fig. 1) that 0.16—0.17 mol/dm^3 of water is almost sufficient to convert all imidatonium ion to the acetate.

As another retained product *threo*-3-(*p*-methoxyphenyl)-2-butanol (**11**) was obtained, though in a small amount (7% yield at 75 °C), indicating that the hydrolysis of the *threo*-brosylate **1** also proceeds with predominant retention of configuration (*cf.* the *erythro*-alcohol (**12**) in Table 1).

As regards these retentive pathways, it has been reported that in the acetolysis of various *threo*-2-aryl-1-methylpropyl brosylates the amount of retained product, *i.e.*, the *threo*-acetates, agrees well with the predicted value which was calculated by 100 (Fk_Δ/k_t) provided that the k_Δ pathway leads solely to the retained acetate.[7a] Furthermore, as shown in a recent tabulation of the rate-(retained)product correlations for β-arylalkyl systems,[12] satisfactory rate-(retained)product correlation has been observed for acetolysis of many other primary and secondary β-arylalkyl substances.

Therefore, the predominant formation of the retained product might predict a satisfactory rate-(retained)-product correlation in DMA solvolysis. However, the observed amounts of the retentive products (7%+60%, at 75 °C, Table 1) does not agree with the one (83%) calculated by 100(Fk_Δ/k_t) from the Fk_Δ and k_t in the previous work.[1] This discrepancy implies existence of a mechanism different from the acetolysis and also a need to consider about a reaction pathway which affords the retained product without intervention of a phenyl-bridged ion.



Scheme 5.

Besides the retained substitution products, **9** and **11**, (*Z*)-2-(*p*-methoxyphenyl)-2-butene (**5**), albeit in low yield (17% at 75 °C; 14% at 50 °C), was obtained. This olefin must be derived by *anti*-elimination from the tight ion-pair **2**, competing with DMA capture. Direct formation of the olefin **5** by the *E*2 reaction is less probable in view of the low basicity of DMA. When this olefin is derived from the tight ion-pair **2**, the ion-pair can not have a phenyl-bridged structure, because it has been suggested that the formation of the conjugated olefin such as **5** may be forbidden from the bridged ion **13**, because of the rigid and unfavorable dihedral angle (120°) between the C(1) and C(2) hydrogen and the departing aryl ring (Scheme 5).[13]

Another minor product, (*E*)-2-(*p*-methoxyphenyl)-2-butene (**6**), can not be derived from the bridged ion **13** either for the same reason (Scheme 5).

A terminal olefin, 2-(*p*-methoxyphenyl)-1-butene (**7**), which must be derived *via* 1-(*p*-methoxyphenyl)-1-methylpropyl cation, a 2,1-hydride shift product, can not obviously be led from the bridged ion **13** (Scheme 5).

The sole olefin, which can be derived from the phenyl-bridged ion **13**, is 3-(*p*-methoxyphenyl)-1-butene (**8**) (Scheme 5). This is actually found in the products, but is in very minor amount (less than 2%).

From these results it is concluded that the tight ion-pair can not be a phenyl-bridged ion, although it affords the retained imidatonium ion **3** and also the

Table 2. Isotopic scrambling of the products for the DMA solvolysis of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl-2-*d* brosylate **1**-2-*d*[a]

Product		Yield/% (Composition/%)[b] 50 °C	75 °C

a) [**1**-2-*d*]=0.075 mol/dm^3; [C_5H_5N]=0.077 mol/dm^3; [H_2O]=0.17 mol/dm^3. b) The accuracy for NMR measurement of isotopic content was $\leq$1%; reproducibility=$\pm$3%. c) Precise determination of an isotopic distribution was not made: the label would be scrambled more extensively than in the case at 75 °C, in view of the trend found in the other products **5**, **6**, **7**, and **8** at 50 and 75 °C.

retained alcohol **11**. Possible and the simplest reaction pathways for the formation of these olefins can be depicted as illustrated in Scheme 4 along with those for the imidatonium ion formation and its water trapping pathway.

Product Distribution in the Absence of Water. From variation in the yield at 50 °C (Fig. 1), caused by change in water concentration in DMA, it is indicated that in completely dried DMA the olefins are sole products and among them (*Z*)-2-(*p*-methoxyphenyl)-2-butene (**5**) is a major product (65% yield) along with minor amounts of olefins **6**, **7**, and **8**. Thus it is clear that the imidatonium ion **3**, which gave the retained acetate **9** in the presence of water, can afford mainly the 2-butenes (Saytzeff products) as the final product in the absence of water.

As mentioned above, in the presence of water (0.16 mol/dm^3) the small amounts (3.8% in composite yield) of olefins **6**, **7**, and **8** were produced besides the olefin **5**. However, in the absence of water a fair amounts (*ca.* 30% in composite yield) of these olefins have been obtained. Consequently, most of these olefins (30%—3.8%=26.2% in composite yield) must have come from the imidatonium ion **3** (Fig. 1).

The (*Z*)-olefin **5** was produced in 14% yield from the tight ion-pair **2** in the presence of water (Table 1), but in the absence of water it should be led also from the imidatonium ion **3** in about 51% (*ca.* 65%—14%) yield.

Among these olefins only **8** (*ca.* 3% yield) can be derived from the phenyl-bridged ion. Therefore in the course of the olefin formation from the *threo*-imidatonium ion **3** a possibility of intervention of the phenyl-bridged ion is mostly ruled out.

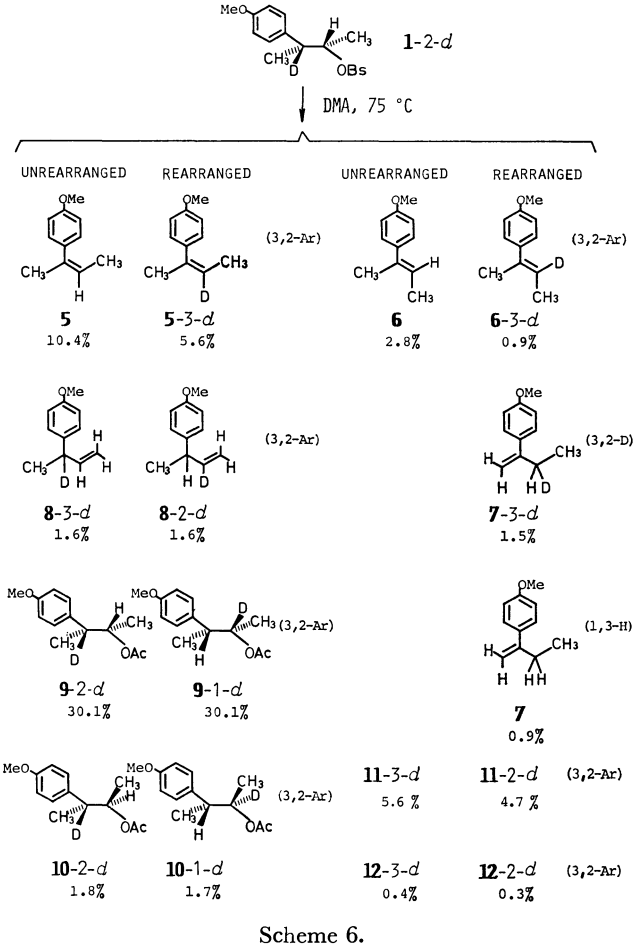
Deuterium Distribution in the Products. In order to examine the reaction pathways thoroughly, the deuterium scrambling in the products **5**—**12**, which were isolated from the wet DMA solvolysis mixture of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl-2-*d* brosylate (**1**-2-*d*), was examined by the use of previously reported ^{1}H NMR spectroscopic method.[1] The results are summarized in Table 2 and illustrated in Scheme 6.

The rearrangement in the product amounts to 50% (complete scrambling) for the acetates **9** and **10** (64% in composite yield), but for the elimination products (**5**, **6**, and **7**, except for **8**) and the hydrolysis products (**11** and **12**) it does not reach complete scrambling. The incomplete scrambling in the elimination and the hydrolysis clearly indicates that the tight ion-pair **2** does not have such symmetrical structure as a phenyl-bridged ion structure.

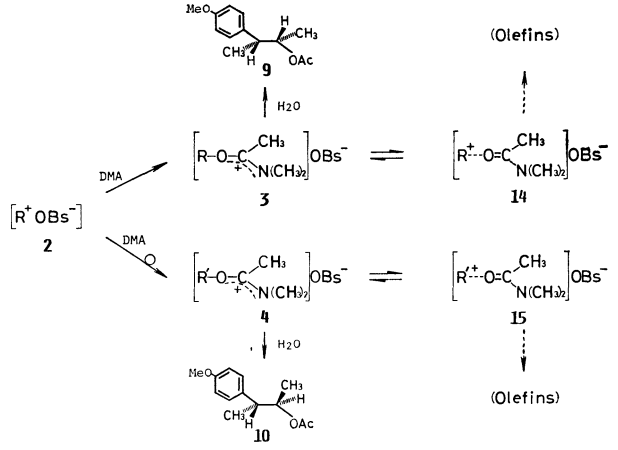
When the scrambling in the tight ion-pair **2** is so incomplete, the scrambling in the imidatonium ion **3** should also be incomplete, because the imidatonium ion is a primary product from the ion-pair **2** as illustrated in Scheme 4. This indicates in turn that the scrambling in the acetate **9** would not be complete. However, it is not the case.

Thus, the complete scrambling in the acetate **9** implies that it must occur in the process of the hydrolysis of the imidatonium ion **3**. Since the hydrolysis does not proceed on the carbenium ion center of the imidatonium ion **3** but on the carbonyl carbon, it seems difficult to find a reasonable explanation for the scrambling in the imidatonium-ion hydrolysis. However, as one of possible explanations, it might be helpful to consider about a hidden scrambling process during the hydrolysis as illustrated in Scheme 7.

Since in the absence of water the imidatonium ion **3** can give rise to the olefins, these olefins should be produced *via* a new ionized intermediate **14** (Scheme 7). This ionization process might be hidden in the presence of water, because the rate of hydrolysis might overwhelmingly exceed the elimination rate in spite of rapid equilibration between the imidatonium ion **3** and the



Scheme 6.



Scheme 7.

new ionized intermediate **14**. Conceivably, the hidden ionization would bring about the complete scrambling in the acetate **9**. As mentioned above, most of the olefins formed from the imidatonium ion **3** (in the absence of water) can not be derived from a phenyl-bridged ion. This indicates, consequently, that the intermediate **14** does not have the phenyl-bridged ion structure either.

Furthermore, it is notable that the inverted *erythro* acetate **10**, albeit in very low yield (3% at 50 °C and 2% at 75 °C), also undergoes complete scrabling of deuterium at C(2) and C(3) at 50 °C. The inverted acetate **10** can not be led from the *threo*-phenyl-bridged ion. Therefore, when we follow the reaction schemes shown in Scheme 1, it must be derived *via* k_s route[6h] starting from the *threo*-brosylate **1**. If it is derived *via* k_s route, complete scrambling in the *erythro* acetate **10** is possible only when the scrambling in the unchanged *threo*-brosylate **1**-2-*d* is complete at an early stage of the solvolysis. However, when unchanged brosylate was reclaimed at a half-life, only 30% of deuterium was found at C(2). Consequently, the formation of the *erythro*-acetate **10** *via* k_s route would be ruled out. The rear-side attack of DMA on the tight ion-pair **2** could explain the formation of completely scrambled *erythro*-acetate **10**, if we assume a rapid equilibration between **4** and **15** (Scheme 7). The cross-over between *threo* and *erythro* open carbenium ions in the tight ion-pair **2** or the intermediates **14** and **15** is conceivable, but it is not clear since in the reclaimed brosylate **1** scarecely was contained the *erythro* brosylate.

In conclusion, so far as the DMA solvolysis of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl brosylate is concerned, the intervention of the bridged ion is mostly improbable and the discrete k_Δ-k_s dual mechanism does not give a satisfactory explanation for the rate-(retained)product correlation but the usual S_N1 mechanism, *i.e.*, the prior formation of a tight ion-pair intermediate followed by various subsequent routes such as 2,1-aryl shift, 2,1-hydride shift, *anti*-elimination, and DMA capture, can account for the product and deuterium distributions. For elucidation of the excessive rate enhancement by methoxyphenyl or by the aryl participation, an examination of the linear free-energy relationship, especially reactivity-selectivity correlation, may served as a new probe and this is the subject of the succeeding paper.

Experimental

Melting points determined on a Yamato Model MP-1 apparatus were uncorrected. NMR spectra were recorded on either a Hitachi R-24, JEOL JNM-MH 100, or JEOL JNM-FX 100 instrument, and spectral data were obtained in $CDCl_3$ solution. Both analytical and preparative GLC's were conducted on a Hitachi K-53 gas chromatograph attached with a thermal conductivity detector by the use of helium as carrier gas. The following column was used: 3 m×3 mm 10% PEG 6000 on 60—80 mesh Chromosorb W (NAW).

Materials. DMA was purified in the identical manner as described in the previous paper.[9] $NaBD_4$ (97.0 D-atom %) was supplied from CEA. Ether, THF, diglyme, and pentane, used as reaction medium or solvent for recrystallization, were distilled from sodium–benzophenone ketyl before use. Reagent grade chemicals were used without further purification unless otherwise noted.

threo-*3-(*p*-Methoxyphenyl)-2-butanol-3*-d *and Its Brosylate* **1***-2*-d. Deuterium at C(3) position was introduced by deuterioboration of (*E*)-2-(*p*-methoxyphenyl)-2-butene prepared in the same manner as reported.[1] Deuterioboration–oxidation was carried out according to the published method.[14] Diborane-d_6 was generated externally from $NaBD_4$ and boron trifluoride etherate in diglyme and introduced into THF solution of the olefin. The deuterated alcohol was obtained in 83% yield after the purification by column chromatography (Al_2O_3). The brosylate **1**-2-*d* was synthesized from this alcohol in the usual manner[15] in 87% yield. **1**-2-*d*: mp 100—101 °C (lit,[16] 97.5—98.5 °C for the unlabeled sample); NMR (100 MHz) δ=1.19 (3H, s, C(4)H_3). 1.30 (3H, d, C(1)H_3), 3.79 (3H, s, OCH_3), 4.70 (1H, quartet, C(2)H), 6.88 (4H, d of d, Ar–H), and 7.55 ppm (4H, s, Ar–H). ^1H and ^{13}C NMR spectra showed the absence of deuterium scrambling during the synthesis and an isotopic purity of 97%.

Product Analysis. The method employed was identical with that used in the preceding work.[1] Unlike the parent phenyl derivative, the acetates **9** and **10**, obtained from the DMA solvolysis of **1** or **1**-2-*d*, could not be separated on GLC. Therefore, the ratio (**9**: **10**) was determined by means of GLC with the corresponding alcohols which was derived from the esters by hydrogenolysis with $LiAlH_4$ in ether: the ester mixture was isolated from the product mixture by column chromatography (SiO_2).

Partial Solvolysis and Isolation of Unchanged Brosylate. The brosylate recovered from half-life solvolysis of **1**-2-*d* in DMA solvent was isolated from the reaction mixture by repeated recrystallization from ether–pentane at −78 °C. Colorless crystalline brosylate was obtained almost quantitatively based on theoretical amount. The sample was dried by keeping under high vacuum over P_2O_5 at room temperature overnight. ^1H NMR spectrum (100 MHz) of the sample exhibited no sign of contamination with the solvolysis products and also of an existence of *erythro*-isomer.

Deuterium Distribution Analysis. The deuterium distribution was determined by means of ^1H NMR spectroscopy (100 MHz) in the Fourier transform mode. The operating parameters employed in NMR works were identical with those reported in the preceding paper.[1] Analytical procedures and sample preparations were performed in the same manner as described in the paper,[1] except for the sample of the acetate **9** or **10**.

The mixture of the acetates **9** and **10** was isolated by column chromatography (SiO_2) and was hydrogenolyzed ($LiAlH_4$ in ether) into the corresponding mixture of alcohols from which each isomer was separated by preparative GLC. Each isomeric alcohol was transformed again into the corresponding acetate **9** or **10** in the usual manner (acetic anhydride–pyridine) in order to avoid an overlapping of NMR signals due to *O*-methyl and C(1)–H protons.

Kinetic Measurements. All kinetic runs were carried out in the same way as described in the previous papers.[1,11]

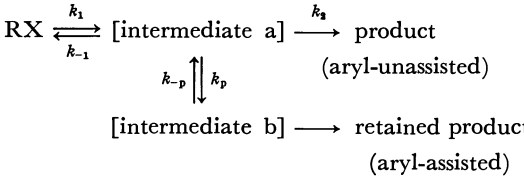
(Received December 1, 1978)

Solvolysis of a series of *threo*-2-aryl-1-methylpropyl brosylates (*p*-MeO, *p*-Me, H, *p*-Cl, *m*-Cl, *m*-CF_3, and *p*-NO_2; **1a**—**g**) has been carried out in four carboxamides, *N*-methylformamide (NMF), *N*-methylacetamide (NMA), *N*,*N*-dimethylformamide (DMF), and *N*,*N*-dimethylacetamide (DMA), as solvent. Fractions of k_s and Fk_Δ pathway were determined on the basis of the upward drift from the Hammett plot of the rate constant (k_t); the extra acceleration by *p*-MeO and *p*-Me substituents was assigned to the Fk_Δ fraction. The Fk_Δ/k_t values were not in agreement with the amount of retained products (*threo*-acetate and *threo*-alcohol) obtained in NMA and DMA solvolysis of **1a**—**c**, although they should be in line with each other on the basis of the bridged-ion theory. The C(2)-deuterated phenyl derivative (**1c**-2-*d*) was solvolyzed in NMF, NMA, and DMF to give retained carboxylates (acetate or formate). However, the isotope scrambling at C(2) and C(1) of the carboxylates is incomplete, indicating that a symmetrical ion, such as a phenyl-bridged ion, can not be the intermediate of the carboxamide solvolysis. A good correlation of log k_t for substrates (**1a**—**g**) with log (% *threo*-acetate/% *erythro*-acetate) or with log (% *threo*-acetate/% olefinic products) was found for solvent systems such as NMA, DMA, and acetic acid, indicating that the reactions of all substituted substrates can be explained by intervention of a common intermediate [R^+X^-], a classical tight ion-pair from which the final products are derived. Such reactivity-selectivity relationship also holds between log k_t's of **1c** in a series of carboxamide and logarithms of *threo-erythro* ratio in acetate or formate. Through-space interaction between a face of aryl ring and carbenium ion center in the transition state is considered as a possible cause for the anomalous acceleration by the activating aryl groups.

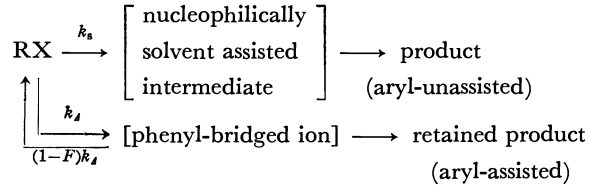
Although a phenyl-bridged ion has been postulated as an intermediate in acetolysis of diastereomeric 2-aryl-1-methylpropyl tosylates accounting for remarkably high stereospecificity of the substitution,[2] the rate enhancement expected in such participation phenomena is not significant in this system.[3] This apparent discrepancy between rate and product stereochemistry has long been a subject of dispute.[4-16]

Brown and Kim[7a] carried out acetolysis of a series of ring substituted *threo*-1-methyl-2-phenylpropyl brosylates and found that this system displays excellent rate-(retained)product correlation. They pointed out that the nature of the k_s pathway in the acetolysis can be recongnized as S_N1 mechanism, and proposed the following mechanism (Scheme 1)[7a] in which the reaction proceeds *via* a tight ion-pair followed by k_p and k_2 processes, denoting aryl-assisted and aryl-unassisted pathways, respectively.



Scheme 1.

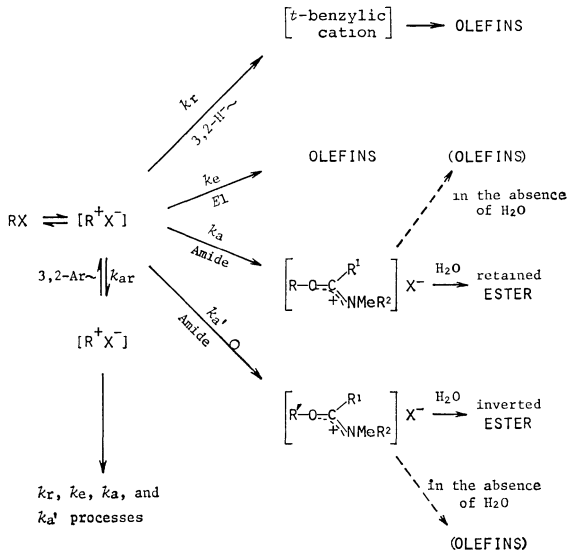
Schleyer and his collaborators[6] suggested that solvolysis of all primary and most of secondary β-arylalkyl systems proceeds through discrete aryl-assisted (k_Δ) and/or aryl-unassisted, *i.e.*, nucleophilically solvent-assisted (k_s), pathways (dual mechanism, Scheme 2).[6h] They considered the rate enhancement due to activated phenyl groups to result from the incursion of the k_Δ process with a phenyl-bridged ion, and the substrate containing a deactivated phenyl group to be a good model for the anchimerically unassisted route (k_s). They showed that the values of Fk_Δ/k_t determined independently from the rate data and product stereochemistry (rate-product correlation) are in agreement with each other for several β-arylalkyl solvolyses.[4]



Scheme 2.

In our effort to scrutinize the nature of carboxamide solvolysis of secondary substrates,[1,17-20] it was found that solvolysis of *threo*-1-methyl-2-phenylpropyl brosylate (**1c**)[20] and that of its *p*-methoxyphenyl derivative (**1a**)[1] in *N*,*N*-dimethylacetamide (DMA) are represented respectively by 100% k_s and 83% k_Δ (17% k_s) solvolysis in the k_Δ-k_s dissection method.[6] However, on the basis of the lack of rate-product correlation, and from an examination of deuterium distribution in the reaction products or unchanged starting brosylates and the nature of the olefinic products, it was disclosed that the solvolysis of these 1-methyl-2-phenylpropyl systems proceeds without intervention of a phenyl-bridged ion but a classical tight ion-pair intermediate, subsequent processes such as *E*1 reaction, phenyl- or hydride-shift, and solvent capture occurring competitively (Scheme 3).[1,20]

In order to obtain further information on such mechanism, we extended the investigation to a series of ring substituted *threo*-1-methyl-2-phenylpropyl brosylates (**1a**—**g**) and other carboxamide solvents such as



Scheme 3.

N-methylformamide (NMF), *N*-methylacetamide (NMA), and *N*,*N*-dimethylformamide (DMF).

The present paper describes the results of the examinations of the Hammett correlation for the solvolysis of **1a**—**g** in NMF, NMA, and DMF as solvent, the product distribution in NMA and DMA solvolyses, deuterium distribution in the products for NMF, NMA, and DMF solvolyses of C(2)-deuterated parent phenyl derivative (**1c**-2-*d*), and the reactivity-selectivity relationships. The mechanistic implications of the results, especially in the light of classical solvolysis mechanism, are also discussed.

Results and Discussion

Unsatisfactory Rate-product Correlation. First-order rate constant (k_t) for the respective carboxamide solvolyses (NMF, NMA, and DMF) of the substrates **1a**—**g** have been determined titrimetrically.[19,20] The results are summarized in Table 1. The Hammett plot for each carboxamide solvolysis, including DMA solvolysis,[1,20] is given in Fig. 1.

A satisfactory linear correlation holds solely for the substrates containing deactivating and, partly, activating phenyl groups with ρ-values, −0.69, −0.64, −0.57,

and −0.72, respectively, for NMF, NMA, DMF, and DMA solvent. Such linear portions of the Hammett plot give the k_s values for **1a**—**c** by the least-squares treatment, from which the predicted amounts of retained product arising from the so-called k_Δ route was calculated by $100Fk_\Delta/k_t$, where $Fk_\Delta=k_t-k_s$. The results are given in Table 2.

The rate-(retained)product correlation is used as a probe for the dual mechanism concept and the phenyl-bridged ion intervention.[6] However, there are cases in which the agreement between the predicted and observed values is less satisfactory.[4,7] Acetolysis of a series of *threo*-2-aryl-1-methylpropyl brosylates has provided a representative example in which the agreement between the predicted and observed values is excellent.[7a]

Table 3. Comparison of the predicted and observed amounts of retained product arising from the carboxamide solvolysis of *threo*-2-aryl-1-methylpropyl brosylates at 75 °C

Substrate	Amide	Retained product yield/%	
		Predicted	Obsd
1a (OCH_3)	DMA[c]	83	67
	NMA[d]	95	91
1b (CH_3)	DMA[d]	0	16
	NMA[d]	50	43
1c (H)	DMA[e]	0	4
	NMA[d]	27	13

a) See Table 2. b) Amounts of sum of *threo*-acetate and *threo*-alcohol. c) Ref. 1. d) See Table 5. e) Ref. 20.

When the correlation was examined on the NMA and DMA solvolysis (Table 3), the results were far less satisfactory, a gap between predicted and observed values clearly existing. This suggests that a dual mechanism (Scheme 2) can not be applied to the carboxamide solvolysis; the mechanism shown in Scheme 3, postulated for the DMA solvolysis of **1a**[1] or **1c**,[20] is applicable to the NMA solvolysis and the other carboxamide solvolysis in NMF and DMF.

Incomplete Scrambling of Deuterium in the Products of Carboxamide Solvolysis of ***1c****-2*-d. In order to test whether Scheme 3, which does not need the intervention of the phenyl-bridged ion, can serve as a generalized reaction scheme in carboxamide solvolysis, the deuterium distribution in the products of the NMF, NMA, and DMF solvolysis of **1c**-2-*d* was examined by means of ^{1}H NMR spectroscopic method.[20] The results are summarized in Table 4.

Although the amounts of the retained products, *i.e.*, the sum of *threo*-ester and *threo*-alcohol, increase in the order NMF>NMA>DMF>DMA[20] in accord with the order of increase in the amount of Fk_Δ component (Table 2), the deuterium label is situated more at position C(2) than C(1) in the retained *threo*-1-methyl-2-phenylpropyl acetate or formate. This indicates that a symmetrical intermediate such as a phenyl-bridged ion is ruled out as a precursor of the retained products.

Linear Reactivity-Selectivity Relationship in Carboxamide Solvolysis. The product distribution, rearrangement, and steric course in carboxamide solvolysis can not be explained by means of the k_Δ-k_s rate treatment.[1,20] The linear reactivity-selectivity relationship[21] in the solvolysis of a series of substrates in a series of solvents has been utilized to prove the existence of a common intermediate which produces more than two products.[22] The relationship was examined for a series of the 1-methyl-2-phenylpropyl system (**1a**—**g**) independent of the k_Δ-k_s analysis.[6]

When the log k_t values are plotted against the

logarithms of the ratio (% yield of the retained acetate: % yield of the inverted acetate) or (% yield of the retained acetate: % yield of the olefinic products) for the DMA or NMA solvolysis of a series of *threo*-2-aryl-1-methylpropyl brosylates, a good reactivity-selectivity relationship was found. The results are shown in Figs. 2.1, 2.2 with use of the data in Table 5.

The linear relationships observed between log k_t and log (% *threo*-ROAc/% olefin) suggest that such processes as k_a, k_r, and k_e, (Scheme 3) result from a single intermediate [R^+X^-]. The proposed classical *E*1-S_N1 competition mechanism is substantiated from the carboxamide solvolysis.

An examination of these treatments was also carried out for the log k_t's of the acetolysis of a series of *threo*-2-aryl-1-methylpropyl brosylates using the data of Brown and Kim.[7a] As in the case of the DMA or NMA, solvolysis, excellent linear relationships were observed (Fig. 3), indicating that even for the acetolysis, in which the rate-(retained)product correlation satisfactorily holds the reaction proceeds through a single intermediate, the open ion-pair (Scheme 1).

When the log k_t values of the brosylate **1c** in a series of amide solvents are plotted against the logarithm of the ratio (% yield of the retained ester: % yield of the inverted ester), an excellent linear relationship is observed (Fig. 4, correlation coefficient=0.990). Pertinent data for the test are given in Table 6.

On the basis of this linear relationship, it is deduced that both the retained and inverted esters stem from a

single solvolytic species, a tight ion-pair intermediate, as shown in Scheme 3. The *threo*-type imidatonium ion (retained), which leads to *threo*-ester by hydrolysis, is formed by the front-side attack of the carboxamide on the tight ion-pair. A front-side solvent capture may

NMF [d]	38.5	19.9%	1.18

a) See Table 1. b) Acetate for DMA or NMA and formate for DMF or NMF. c) Ref. 20. d) The solvolysis was conducted under the same conditions as those described in Ref. 20. e) See Table 5.

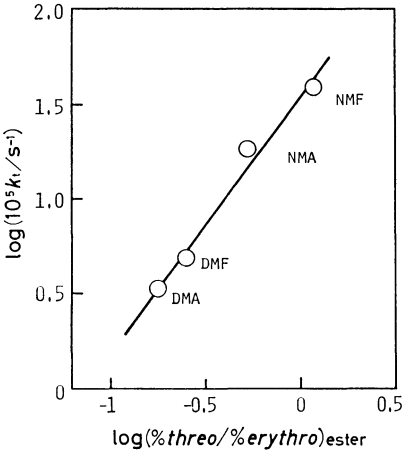

Fig. 4. Linear reactivity-selectivity relationship between log k_t and log (% *threo*-ester/% *erythro*-ester) for the carboxamide solvolysis of **1c** at 75 °C; correlation coefficient=0.990.

have an advantage over a rear-side solvent capture when the rate of 2,1-phenyl migration becomes fast enough to shield the rear-side effectively. Thus, as the selectivity increases on going from DMA solvolysis to NMF solvolysis (Table 6), the extent of deuterium scrambling in the ester products becomes greater (Table 4). This might explain why the DMF solvolysis produces retained ester in a larger amount with more scrambling of the deuterium label than the DMA solvolysis (Table 4). The dual mechanism (Scheme 2) gives no explanation.

Possible Origin of the Rate Enhancement. From a kinetic point of view, there is another mechanistic feature for the solvent effect on the carboxamide solvolyses. When the log k_t values for the NMF, NMA, and DMF solvolysis, or the acetolysis[7a] of a series *threo*-2-aryl-1-methylpropyl brosylates **1a**—**g** are plotted against those for the DMA solvolysis,[20] satisfactory linear free-energy relationships are observed (Fig. 5): correlation coefficients are 0.988, 0.997, 0.995, and 0.971, respectively.

If the observed titrimetric rate constant (k_t) is represented by the sum of two independent processes, k_s and Fk_Δ, no such linear correlation would hold. Consequently, the deviation of the points for the

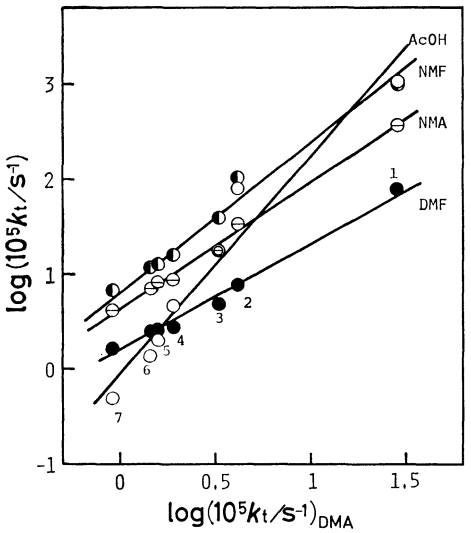

Fig. 5. Linear free-energy relationships between log k_t (DMA) and log k_t (DMF (●), NMA (⊖), NMF (◐), or AcOH (○)) for **1a**—**g** (1=**1a**, 2=**1b**, 3=**1c**, 4=**1d**, 5=**1e**, 6=**1f**, and 7=**1g**) at 75 °C; slope and correlation coefficient are 1.11 and 0.995 (DMF), 1.29 and 0.997 (NMA), 1.47 and 0.988 (NMF), and 2.27 and 0.971 (AcOH); for the rate constants in DMA and AcOH, see Refs. 20 and 7a, respectively.

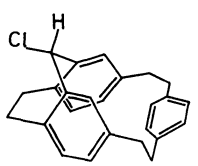
substrates containing activating phenyl groups in the Hammett plot (Fig. 1) should be attributed to cause other than the intrusion of the Fk_Δ component and of the phenyl-bridged ion.

According to Tabushi *et al.*,[23] the remarkable rate enhancement is observed in the solvolysis of pseudo-axial system of [2.2.2]paracyclophane derivative (**2**) in which the developing carbenium ion center can advantageously interact with the face of benzene ring through space; solvolysis rate of the pseudo-axial substrate was accelerated by a factor of $10^{14.7}$ as compared with corresponding pseudo-equatorial substrate. The same type of interaction, therefore, might be operative between the β-aryl group and the carbenium ion center. The proposal is, however, qualitative. Confirmation of the cause of the deviation in the Hammett plot (Fig. 1) would be achieved by a precise estimation of the intrinsic magnitude of such a transannular interaction between the individual β-aryl group and a p-orbital of the cationic carbon in the transition state.



2

In conclusion, the mechanism which formulates the initial ionization as formation of tight ion-pair (open or classical), followed by a variety of competing processes (k_r, k_e, k_a, k_a', and k_{ar} pathways, Scheme 3), can explain the results of carboxamide solvolysis. This is essentially the same as that proposed by Brown *et al.*[5b] No intervention of a phenyl-bridged ion is necessary for the carboxamide solvolysis.

Experimental

The four carboxamides were purified in the same way as described.[18] The substrates **1a**—**g** and **1c**-2-*d* were the products from the same lot employed in the previous work; product analysis and deuterium distribution analysis were performed in the same manner as reported.[20] Kinetic measurements were carried out following the method described previously.[19]

Effect of Complexation by Crown Ethers on Anisochrony of Diastereotopic Groups in NMR Spectra

Nobuharu ANDO, Yukio YAMAMOTO, Jun'ichi ODA, and Yuzo INOUYE*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received November 20, 1978)

Anisochrony of geminal methyls in alkylamines bearing a chiral center in the molecule is affected by complexation with crown ethers, which amplify the chemical shift non-equivalence in NMR. The resolved signal of *gem*-methyls in valine methyl ester were unequivocally assigned to *pro-R* and *pro-S* methyl groups respectively.

In principle, different NMR chemical shifts are to be expected for diastereotopic groups, since they experience different molecular environments. However, these groups, particularly in acyclic compounds, are often accidentally isochronous because of the practically close similarity of individual surroundings. This situation can often be circumvented by such techniques as to ensure improvement of resolving ability or a change in magnetic environments, probably resulting in manifestation of the latent anisochrony. For example, the application of a higher magnetic field,[1] a change in the solvent medium, and use of NMR shift reagents[2] have generally been employed for this purpose.

Crown ethers have recently been introduced to organic chemistry and proved to be versatile from the viewpoint of both synthetic and mechanistic utilities.[3] Complexation with primary ammonium salt is one of the most important properties of crown ethers.

We now describe the notable effect of crown ethers on anisochrony of diastereotopic groups in amino compounds owing to complexation. Crown ethers were found to realize the potential anisochrony and amplify the chemical shift non-equivalence of paired ligands in alkylamines.

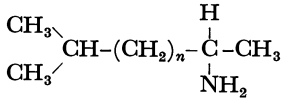
In alkylamines **1** and **2**, the signals for *gem*-methyls were unresolved in the form of free amine, but non-equivalence was observed in the hydrochloride; the chemical shift difference, 0.01 ppm for **1** and 0.02 ppm for **2**. Complexation by 18-crown-6 enhanced the difference up to 0.06 ppm, which probably arised from decrease in conformational mobility and/or the shielding effect of the crown ether. In complexes with dibenzo-18-crown-6, the $\Delta\delta$ value varied in a characteristic way depending on the length of the methylene chain, which may be ascribed to the benzene ring-currents. The chemical shift differences between *gem*-methyls were no longer observed for **3** at any state.

Amino acid esters were also of our great concern from the viewpoint of anisochrony of diastereotopic groups. In contrast to alkylamines, methyl doublets of valine methyl ester (**4**) were unresolved in the hydrochloride, whereas those of the free amine were resolved with $\Delta\delta$ of 0.07 ppm. Here again, a significant difference was caused by complexation with 18-crown-6; 0.14 ppm. The chemical shift difference was furthermore magnified in the case of dibenzo-18-crown-6, 0.22 ppm.

Non-equivalence was not observed in the spectra of leucine methyl ester in any form except for the dibenzo-18-crown-6 complex, for which a significant but rather small $\Delta\delta$ of 0.04 ppm was observed. In ^{13}C-NMR measurements, chemical shift differences of leucine methyl ester were enhanced in the order of the hydrochloride, the free amine, and the complex with 18-crown-6; 0.5, 1.2, and 1.4 ppm, respectively, which was also the case in ^{1}H-NMR of **4**.

In order to assign the resolved signals of *gem*-methyls in **4** ^{1}H-NMR spectra were investigated in every form of isoleucine (**5**) and alloisoleucine (**6**) methyl esters, whose configurations were unambiguously established. For the hydrochloride, the spectral feature of **5** and **6** very much resembled each other, and both of them can not be distinguished by ^{1}H-NMR. Liberation from the hydrochloric salt caused a slight variation in spectra and the complexes with the crown ether showed quite a remarkable difference over the methyl region between the two isomeric amino acid esters. The chemical shift differences of the methyl groups of **5** and **6**, corresponding to R^2 and R^1 respectively, were enhanced as one

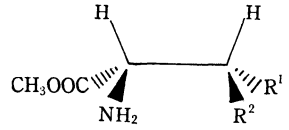
Table 1. Chemical shifts,[a,b] δ of methyl doublets in alkylamine



Compound	n	Free amine	Hydrochloride	18-Crown-6 complex[c]	Dibenzo-18-crown-6 complex[c]
1[d]	0	0.89(0.00)	$\begin{matrix}0.98\\0.97\end{matrix}$(0.01)	$\begin{matrix}1.01\\0.95\end{matrix}$(0.06)	$\begin{matrix}0.63\\0.59\end{matrix}$(0.04)
2	1	0.88(0.00)	$\begin{matrix}0.92\\0.90\end{matrix}$(0.02)	$\begin{matrix}0.97\\0.91\end{matrix}$(0.06)	$\begin{matrix}0.70\\0.56\end{matrix}$(0.14)
3	2	0.89(0.00)	0.88(0.00)	0.89(0.00)	0.80(0.00)

a) The coupling constant has a value of about 6—7 Hz.
b) The value in parentheses represents the chemical shift difference ($\Delta\delta$, ppm).
c) The ratio of substrate/crown ether in $CDCl_3$ is 1.0 ± 0.1 (except for **3**; 4.0).
d) For "hydrochloride in $CDCl_3$," the chemical shift difference was 0.01 ppm.

Table 2. Chemical shifts,[a,b] δ, of methyl doublets in amino acid ester



Compound	R^1	R^2	Free amine	Hydrochloride	18-Crown-6 complex[c]	Dibenzo-18-crown-6 complex[c]
4	CH_3	CH_3	0.97 0.90(0.07)	1.04(0.00)	1.11 0.97(0.14)	0.77 0.55(0.22)
5	C_2H_5	CH_3	0.94 0.82(0.12)	1.00 0.98(0.02)	0.95 1.09(0.14)	0.56 0.78(0.22)
6[d]	CH_3	C_2H_5				
7	OCH_3	CH_3	1.23 1.12(0.11)	1.32 1.26(0.06)	1.29 1.33(0.04)	—
8	CH_3	OCH_3				—
Leucine methyl ester			0.94(0.00)	0.96(0.00)	0.98(0.00)	0.63 0.59(0.04)
			[23.0 21.8(1.2)	24.1 23.6(0.5)	22.8 21.4(1.4)][e]	

a) The coupling constant has a value of about 6—7 Hz (except for leucine methyl ester, about 5—6 Hz).
b) The value in parentheses represents the chemical shift difference ($\Delta\delta$, ppm).
c) The ratio of substrate/crown ether in $CDCl_3$ is 1.0 ± 0.1.
d) For simplification's sake, the configuration is depicted here for L-alloisoleucine methyl ester, although the actual experiment was carried out on the enantiomer.
e) ^{13}C chemical shifts (δ_C, ppm from TMS).

traversed from the hydrochloride (0.02 ppm), the free amine (0.12 ppm), the 18-crown-6 complex (0.14 ppm) to the dibenzo-18-crown-6 complex (0.22 ppm), which was also in keeping with the the order found for **4**.

Since the chemical shift difference of *gem*-methyls in **4** corresponds correctly to that between methyl doublets in **5** and **6** at any state, it can be safely concluded that the substitution of ethyl for methyl groups did not make any noticeable change in the magnetic environment or the conformation.

In the spectra of free amino acid esters, the methyl doublet of **6** was located in the magnetic field higher than that of **5**. The situation was reversed in the spectra of the complexes with crown ethers. Consequently, in the presence of chirality as depicted in Table 2, R^2-methyl group was shielded more than R^1-methyl in the complexes with crown ethers. It then follows that, in the case of **4**, the methyl doublets in the higher field in the free amines and in the crown ether complexes can be safely ascribed to the *pro-S* methyl (R^1) and the *pro-R* methyl (R^2), respectively.

In order to simplify ^1H-NMR spectra in the methyl region and to ascertain the above conclusion, *O*-methylthreonine (**7**) and *O*-methylallothreonine (**8**) methyl esters were subjected to the same ^1H-NMR tests. In this case, the trend of augmentation in the chemical shift differences between R^1 and R^2 was different from that found for valine series; the 18-crown-6 complex (0.04 ppm), the hydrochloride (0.06 ppm), and the free amine (0.11 ppm). However, the same situation as in the valine series prevailed for the relative positions of signals; the methyl doublet of **8** appears at a field higher than that of **7** for the free amino esters and the reverse for 18-crown-6 complexes.

The causes of the amplified anisochrony observed for diastereotopic groups in crown ether complexes are still obscure. Since dibenzo-18-crown-6 has a well-defined shielding effect, the relative spatial position can

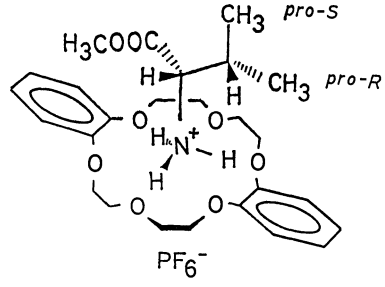


Fig. 1. The relative spatial disposition of *pro-S* and *pro-R* methyls in the valine methyl ester–dibenzo-18-crown-6 complex.

be safely allotted to the methyl groups. That is, *pro-R* methyl of valine methyl ester appearing in a higher magnetic field is disposed closer to the phenyl nuclei than the *pro-S* counterpart, as depicted in Fig. 1, which is consistent with the coupling constant of C_α–H; 4 Hz.

Enhancement of anisochrony of diastereotopic groups by complexation with crown ethers may possibly be applicable for the establishment of stereochemistry, especially of the *erythro-threo* isomerism, and may substitute partially for shift reagents in resolution of complicated spectra.

Experimental

Melting points were measured on hot plate and uncorrected. NMR chemical shifts were given as δ (ppm from TMS) in deuterochloroform (except for hydrochlorides, from DSS, in deuterium oxide) and were determined at 23 °C on a Varian EM-360 (60.00 MHz, with an error of 0.02 ppm) and/or a JEOL JNM-FX 100 (99.55 MHz for ^1H-NMR, 25.00 MHz for ^{13}C-NMR; 5 mm tube; FT conditions: acquisition time 4.1 s for ^1H-NMR, 0.68 s for ^{13}C-NMR; pulse width 38 μs (90°) for ^1H-NMR, 12 μs (90°) for ^{13}C-NMR; spectral width 1000 Hz for ^1H-NMR, 5000 Hz for ^{13}C-NMR; pulse repetition time 6.0 s for ^1H-NMR, 2.5 s for ^{13}C-NMR; number of data points 8192; number of transients 4 or 8 for ^1H-NMR,

20000 for ^{13}C-NMR; and with an error of 0.003 ppm for ^{1}H-NMR, 0.05 ppm for ^{13}C-NMR).

Material. Valine, isoleucine, alloisoleucine, and leucine methyl ester were supplied from commercial source. Esterification of amino acid was carried out according to Fischer's method. *O*-Methylallothreonine methyl ester (**8**) was prepared by the method of West[4] from crotonic acid. All the compounds were purified in the state of hydrochloride by recrystallization from ethanol–ether and the relevant data were listed in Table 3. The amines were liberated with 2 M aq sodium hydroxide just before use. All products gave satisfactory microanalyses (C=±0.80%, H=±0.27%, N=±0.33%).

Typical Procedure for Preparations of Alkylamines. 2-Amino-4-methylpentane (2): 4-Methyl-2-pentanone (20 g, 0.20 mol), sodium acetate (19.7 g, 0.24 mol) and hydroxylamine (16.7 g, 0.24 mol) were dissolved in ethanol (200 ml). After heating under reflux for 5 h, the mixture was filtered and the filtrate was evaporated and the residue was extracted with chloroform. The chloroform layer was washed with sat. aq sodium carbonate and dried over sodium sulfate. Distillation gave the oxime (bp 85—87 °C/19 Torr, 19.6 g, 85%). The oxime (19.0 g) dissolved in dry ether (50 ml) was added dropwise into lithium aluminum hydride (9.7 g) in dry ether (150 ml) and the mixture was heated under reflux for 13 h. The mixture was treated by dropwise addition of water (9.7 ml), 15% sodium hydroxide (9.7 ml), and water (29 ml) successively. The mixture was filtered and dried over sodium sulfate. The filtrate was distilled to give (**2**) (bp 112—114 °C, 6.8 g, 37%).

O-Methylthreonine Methyl Ester (7).[5] Methyl *erythro*-2-bromo-3-methoxybutyrate[4] (1.25 g, 6 mmol, bp 84—85 °C) prepared from methyl crotonate, sodium azide (0.79 g, 20 mmol), and (2,2,1)-cryptand (50 mg) were dissolved in acetonitrile (10 ml). After heating for 42 h under reflux, the mixture was filtered and the filtrate was evaporated. The residue was hydrogenated over 5% Pd–C (100 mg) in methanol (10 ml). The mixture was filtered, evaporated and then purified by passing through IR 120 B resin (2×50 cm column; About 500 ml of distilled water was passed through the column followed by effluence with 3% aqueous ammonia). The product was esterified by Fischer's method to give an amorphous solid (220 mg, 20%).

Table 3. Physical constants of amino compounds

Compound	Bp(°C)	Mp of hydrochloride (°C)
1	83—84	213
2	112—114	143
3	135—136	117—118.5
4	—	112—113
5	—	95—96.5
6	—	126
7	—	—[a]
8	—	164—165(dec)
Leucine methyl ester	—	154—154.5

a) Amorphous solid.

Method of Complexation with Crown Ether.[6] The mixture of crown ether (0.063 mmol) in deuterochloroform (0.35 ml), hydrochloride of amino compound (0.373 mmol) in deuterium oxide (0.40 ml), and lithium hexafluorophosphate (0.373 mmol) was shaken in ice bath for 5 min. After standing for about 30 min, the deuterochloroform layer was separated for spectral measurement at 60 and/or 100 MHz.

The Transformations of Terpene Ketones by Oxygen. II. The Base-catalyzed Autoxidation of Pulegone and Fukinone and Their Dihydro Compounds

Akio HORINAKA, Eiyu YO, Otoji MORI, and Keizo NAYA*

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662

(Received November 21, 1978)

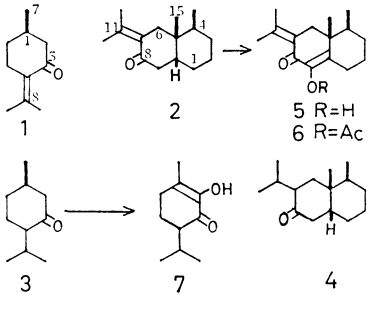
Upon autoxidation in alkaline media, pulegone and fukinone (**2**) gave pairs of hydroxy ketones respectively as the major products; also, hydroxyeremophilone was isolated as its acetate from **2**. On the other hand, their dihydro compounds afforded hydroxy ketones, diosphenols, and acids.

It is well known that enolizable ketones are oxidized rapidly in strongly basic media. This type of autoxidation has been widely applied to the transformations of the naturally occurring terpene ketones and has produced interesting types of substances related to the biosynthesis.[1] It has been pointed out that oxygen attacks at the site of enolization—for example, 3-keto 5β- and the 5α-steroids[2] gave the oxygenation products at the C-4 and C-2 positions respectively.

Since pulegone (**1**) and fukinone (**2**),[3] together with their dihydro derivatives, (**3** and **4**), could be regarded as the logical precursors of the further oxygenated congeners, the autoxidation has been attempted in order to clarify the nature of the products thoroughly.

The autoxidation of **2** and **3** (a mixture of menthone and neomenthone) would be expected to furnish hydroxyeremophilone (**5**)[4] and buccocamphor (**7**),[5] which are found in the oil of *Eremophila mitcelli* and in the essential oils of various *Barosma* or *Mentha* species respectively. In fact, **5** was isolated, but in a poor yield, as the acetate (**6**) from the oxidation mixture. We wish now to report the base-catalyzed autoxidation of the titled compounds and the structural assignments of the products.

The oxidation was carried out under the following three conditions: a) potassium *t*-butoxide/*t*-butyl alcohol; b) potassium *t*-butoxide/*N*,*N*-dimethylformamide, and c) sodium *t*-butoxide/*t*-butyl alcohol, *N*,*N*-dimethylformamide, and tetrahydrofuran in the presence of triethyl phosphite as a reducing reagent.[6] Under the above conditions, **1** and **2** gave pairs of diastereomeric hydroxy ketones, (**8a** and **8b**) and (**9a** and **9b**) respectively. The dihydro analogues, **3** and **4**, gave also pairs of hydroxy ketones, (**10a** and **10b**) and (**11b** and **12**), besides diosphenols (**14** and (**16** and **17**)), and acids (**18** and **19**), respectively. The oxidation products are shown in Table 1, along with their yields based on the consumed starting materials. The acidic products were isolated as the methyl esters.



Hydroxy ketones, **8a**, **8b**, **9a**, and **9b**, were prepared independently from pulegone α- and β-epoxide,[7] and fukinone α- and β-epoxide,[8] respectively by treatment with *p*-toluenesulfonic acid in benzene.[9] They were also found as the minor products among the photosensitized oxygenation products of **1**[10] and **2**.[11] The absolute configuration of **9b** was established by X-ray analysis.[12] The saturated hydroxy ketones, **10a**, **10b**, and **11b**, were obtained by the hydrogenation of the respective hydroxy ketones, **8a**, **8b**, and **9b**. The spectral data of **10a** and **10b** were in good agreement with those given in the literature.[13] It is obvious that a hydroxy ketone, **12**, is the rearranged product from **11b** by the stereospecific acyloin rearrangement[14] in an alkaline medium, though **11b** seems to resist the rearrangement in the aprotic solvent, as in the b) condition. The **12** structure was ascertained by its conversion to the ketone (**13**), which was identical with the authentic sample prepared from **4**.[3] On the other hand, the isomeric hydroxy ketone (**11a**) appears to undergo further oxidation without the subsequent rearrangement.

The diosphenol, **14**, was positive to a ferric chloride test (black color), exhibiting an UV maximum at 275 nm and a broad IR band at 1670 cm^{-1} characteristic

TABLE 1. YIELDS OF OXIDATION PRODUCTS DEPENDING ON THE REACTION CONDITIONS

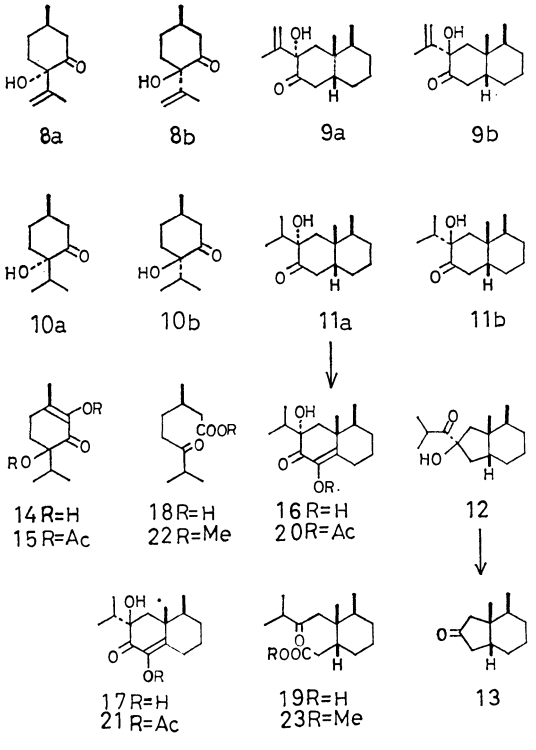
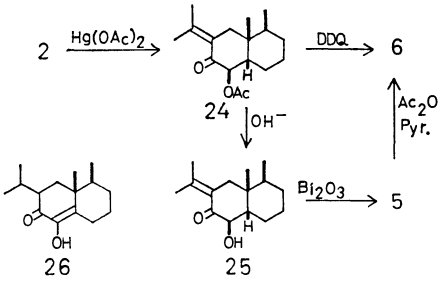
a) Identification could not be done because of the small amount.

of diosphenol. Upon acetylation with acetic anhydride–pyridine, **14** readily afforded its acetate (**15**), whose configuration at C-4 remains to be determined. From **4** we obtained an inseparable mixture of the epimeric diosphenols, **16** and **17**, while the acetate was separated into **20** and **21** by preparative TLC. However, the amount of **21** was too minute for further purification. Upon autoxidation, **11a** gave a diosphenol, **16**, whose acetate was identical with the **20** obtained by the autoxidation of **4**. Accordingly, the configurational assignments to **20** and **21** were established.

The acidic products, **18** and **19**, were isolated as methyl esters (**22** and **23**), after esterification with diazomethane; their structures were confirmed by their preparations from **3** and **4** respectively by the following reaction sequences of Baeyer-Villiger oxidation, alkaline hydrolysis, methylation, and oxidation with chromium trioxide.[15,16] The acidic products are derived from the starting ketone *via* α-hydroperoxy ketones, involving the cleavage of the bond adjacent to the carbonyl group.[17]



Hydroxyeremophilone (**5**) was subjected to considerable decomposition when left standing in the air, and it was carefully isolated as the acetate (**6**) by chromatography on deactivated silica gel. **6** was synthesized from **2** as follows. 9-Acetoxyfukinone (**24**) was obtained by the treatment of **2** with mercury(II) acetate in acetic acid.[18] The PMR spectrum of **24** showed the signal at δ 5.38 (d, J=12 Hz) attributable to the hydrogen attached to the carbon bearing an acetoxyl group. From an examination of the dihedral angle between 9-H and 10β-H, the coupling constant (12 Hz) can be accounted for by the relative orientation of the α-axial 9-H and β-equatorial 9-acetoxyl groups in a steroidal conformation. The treatment of **24** with DDQ in the presence of hydrogen chloride[19] furnished **6** in a poor yield (10%, based on the consumed **24**). Next, the mild alkaline hydrolysis of **24** and the subsequent oxidation of the product (**25**) with bismuth oxide in acetic acid, as shown previously in the oxidation of 2-hydroxypulegone,[19] gave **5**, which was then immediately acetylated with acetic anhydride–pyridine to yield **6**. These two acetates, prepared independently, showed the same R_f value, 0.75 (silica gel; benzene–ethyl acetate, 10: 1), IR, and PMR spectra. Their characteristic IR bands, UV absorption maxima, and specific rotation agree with those given in the literature.[4] There was no sign of the existence of the monoterpene analogue of **5** in the autoxidation products of **1**. The base-catalyzed autoxidation of the terpene ketones under investigation resulted in poor yields of the products, suggesting that the products tend to collapse readily into undesired compounds under the reaction conditions. In spite of the many visualized spots on TLC, attempts to separate the esters derived from the acidic products in the autoxidation of the conjugated ketones, **1** and **2**, were unsuccessful.



The product oxidized only at the 9-methylene position, namely, buccocamphor, **7**, and its sesquiterpene analogue (**26**) could not be detected in the reaction mixture of the saturated ketones, **3** and **4**. On the other hand, only **11a** among the hydroxy ketones was found to afford a diosphenol, **16**, in a low yield by autoxidation under the b) reaction conditions, but **11a** could not be found in the autoxidation mixture of **4**. No conclusive proof, therefore, could be obtained as to whether diosphenols, **14**, **16**, and **17**, can be produced *via* hydroxy ketones, **10a,b** and **11a,b** or *via* **7** and **26**. The intermediates presumably suffered rapid oxidation to give the diosphenols.

Finally, it should be noted that the relative ratio of the epimeric 4- or 7-hydroxy ketones is markedly affected by the reaction conditions (Table 1). This may reflect the dependence of the preferential conformation of the enolate anions on the reaction conditions.

Experimental

The IR, UV, and mass spectra were taken with Hitachi EPI-G_3, Shimadzu Spectronic 505, and Hitachi RMU-6 spectrophotometers respectively. The PMR spectra were recorded with a Hitachi R-20B (60 MHz) spectrometer, and the chemical shifts are reported in δ-values, with TMS as the internal reference. The optical rotations were measured with a Perkin-Elmer 141 polarimeter. Analytical and preparative GLC were performed with a Shimadzu GC-1C apparatus on a stainless steel column (ϕ=3 mm). The TLC were run on

silica gel (Merck Kieselgel G). All the melting and boiling points are uncorrected.

General Procedure of Autoxidation. *a) Oxidation Catalyzed by Potassium* t-*Butoxide in* t-*Butyl Alcohol*: A ketone (600—800 mg) was dissolved in a solution of 0.5 M potassium *t*-butoxide in *t*-butyl alcohol (20—30 ml). The mixture was stirred vigorously under the bubbling of oxygen at room temperature for 20—40 min, until 1 mol of oxygen has been consumed, and was then diluted with water, acidified with 10% aqueous sulfuric acid, and extracted with ether. The extract was shaken with a saturated sodium hydrogencarbonate solution. The extract was washed with water and dried over sodium sulfate. The removal of the solvent gave an oil, which was subsequently chromatographed on silica gel. Elution with light petroleum–ether (50: 1) or benzene afforded non-acidic products. The sodium hydrogencarbonate solution was acidified with 10% aqueous sulfuric acid and extracted with ether. The extract was treated with diazomethane–etherate. The removal of the solvent gave an oil which was chromatographed on silica gel. Elution with light petroleum–ether (50: 1) gave a methyl ester of the acidic product.

b) Oxidation Catalyzed by Potassium t-*Butoxide in* N,N-*Dimethylformamide*: To a solution of potassium *t*-butoxide (*ca.* 9 mmol) in *N,N*-dimethylformamide (15 ml) we added a ketone (600—800 mg). The solution was stirred vigorously under an oxygen atmosphere at −20——10 °C for 4—40 min, until 1 mol of oxygen had been consumed, and was then worked-up in essentially the same manner as Procedure *a*).

c) Oxidation Catalyzed by Sodium t-*Butoxide in* t-*Butyl Alcohol*, N,N-*Dimethylformamide, and Tetrahydrofuran in the Presence of Triethyl Phosphite*: Sodium hydride (300 mg, 50%) was dissolved in *t*-butyl alcohol (2 ml) and *N,N*-dimethylformamide (3 ml). To this solution we added triethyl phosphite (1 ml) in *N,N*-dimethylformamide (3 ml) and then a ketone (0.8—1.0 g) in tetrahydrofuran (7 ml). Oxygen was passed for 1 h into the cooled mixture at −30——20 °C. After the addition of a solution of sodium hydroxide (0.5 g) in methanol–water (2: 1, 15 ml) the reaction mixture was stirred at room temperature for 20 min and then acidified with acetic acid. After the removal of the solvent *in vacuo* and dilution with water, the mixture was extracted with ether. Subsequently, the extract was worked up in a manner similar to that described above.

*Autoxidation Products of Pulegone (**1**) and Dihydropulegone (**3**).* **8a** and **8b** were found to be identical with authentic samples[9] by a comparison of the IR and GLC (EGA, 2.6 m; column temperature, 140 °C; H_2-flow rate, 60 ml/min; retention time, **8a**: 9.8 min, **8b**: 13.6 min).

The saturated hydroxy ketones (**10a** and **10b**) were found to be identical with the hydrogenation products of **8a** and **8b** respectively by a comparison of the IR and GLC (EGA, 2.6 m; column temperature, 140 °C; retention time, **10a**: 7.5 min, **10b**: 9.4 min); also, their spectral data were in agreement with those given in the literature.[13]

*Diosphenol (**14**)*: A colorless oil; UV: λ_{max}^{MeOH} 275 nm (ε, 4300); IR(film): 3420, 1705, 1670, 1635 cm^{-1}; PMR(CCl_4): 1.82 (t, J=1.0 Hz, 7-Me), 0.94 and 0.69 (each d, J=6.0 Hz, 9- or 10-Me). **14** (28 mg) was acetylated with acetic anhydride–pyridine in the usual manner to give **15** (15 mg).

*Acetate (**15**)*: A colorless oil; UV: λ_{max}^{MeOH} 242 nm (ε, 8100); IR (film): 3450, 1750, 1670, 1640, 1200 cm^{-1}; PMR(CCl_4): 3.24 (br s, OH), 2.15 (s, OAc), 1.78 (s, 7-Me), 0.94 and 0.68 (each d, J=6.0 Hz, 9- or 10-Me).

*Keto Ester (**22**)*: A colorless oil; bp 125—129 °C (bath temperature)/16.5 mmHg†; $[\alpha]_D^{22}$ +9.7° (*c*, 0.51, MeOH); MS: *m/e* 200, M^+, *m/e* 125, base peak; IR(film): 1730, 1710, 1250, 1200, 1160 cm^{-1}; PMR(CCl_4): 3.59 (s, OMe), 1.03 (d, J=7.0 Hz, 9- and 10-Me), 0.89 (d, J=5.0 Hz, 7-Me). **22** was found to be identical with the authentic sample prepared from **3** by a comparison of the IR and GLC (PEG 20M, 2.6 m; column temperature, 146 °C; H_2-flow rate, 58 ml/min; retention time, 24 min) (see below).

*Autoxidation Products of Fukinone (**2**) and Dihydrofukinone (**4**).*

*Hydroxy Ketone (**9a**)*: Mp 47—53 °C, colorless needles (from pentane); MS: *m/e* 236 M^+, *m/e* 109 base peak; IR(CCl_4): 3480, 3060, 1710, 1635, 902 cm^{-1}; PMR(CCl_4): 4.82 (slightly split s) and 4.65 (s) (12-C=CH_2), 3.27 (s, OH), 1.78 (s, 13-Me), 1.03 (s, 15-Me), 0.87 (d, J=6.0 Hz, 14-Me). **9a** was contaminated by a slight amount of **9b**, but **9a** showed the same physical properties as the authentic sample prepared from fukinone α-epoxide in a comparison of the TLC, IR, and PMR. The preparation of **9a** will be described later.

*Hydroxy Ketone (**9b**)*: Mp 73.5—74.0 °C, colorless prisms (from pentane); $[\alpha]_D^{23}$ −80° (*c*, 0.99, $CHCl_3$); MS: *m/e* 236 M^+, *m/e* 109 base peak; IR(CCl_4): 3460, 3060, 1705, 1635, 900 cm^{-1}; PMR(CCl_4): 4.85 (slightly split s) and 4.58 (s) (12-C=CH_2), 3.55 (s, OH), 1.84 (d, J=1.0 Hz, 13-Me), 0.89 (s, 15-Me), 0.87 (d, J=6.0 Hz, 14-Me).

Found: C, 76.10; H, 10.10%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%. **9b** was found to be identical with the authentic sample prepared from fukinone β-epoxide by a comparison of the IR, PMR, and TLC and by a mixed-melting-point determination.

*Hydroxy Ketone (**11b**)*: Mp 40.0—41.0 °C, colorless prisms (from pentane); $[\alpha]_D^{23}$ −69° (*c*, 1.0, $CHCl_3$); MS: *m/e* 238 M^+, *m/e* 109 base peak; IR(CCl_4): 3450, 1705 cm^{-1}; PMR (CCl_4): 3.47 (s, OH), 0.99 and 0.64 (each d, J=6.5 Hz, 12- or 13-Me), 0.92 (d, J=6.5 Hz, 14-Me), 0.87 (s, 15-Me).

Found: C, 75.42; H, 10.89%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%. **11b** was found to be identical with the hydrogenation product of **9b** by a comparison of the TLC, IR, and PMR and by a mixed-melting-point determination. The preparation of **9b** and **11b** will be described later.

*Hydroxy Ketone (**12**)*: A colorless oil; $[\alpha]_D^{23}$ +33.7° (*c*, 1.03, $CHCl_3$); MS: *m/e* 238 M^+, *m/e* 109 base peak; IR(CCl_4): 3450, 1693 cm^{-1}; PMR(CCl_4): 3.43 (s, OH), 1.08 (d, J=6.0 Hz, $CHMe_2$), 1.00 (s, 15-Me), 0.81 (d, J=6.0 Hz, 14-Me).

Found: C, 75.41; H, 10.94%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%. **12** was found to be identical with the rearranged product of **11b** by a comparison of the IR, PMR, and GLC (SF 96, 35 cm; column temperature, 100 °C; H_2-flow rate, 115 ml/min; retention time, 9.5 min). The rearrangement of **11b** will be described later.

*A Mixture of Diosphenols (**16** and **17**)*: A colorless oil; bp 116—135 °C (bath temperature)/0.04 mmHg; UV: λ_{max}^{MeOH} 282 nm (ε, 10000); IR(film): 3430, 1660, 1630 cm^{-1}. This mixture (104 mg) was acetylated with acetic anhydride–pyridine in the usual manner. The mixture was then separated into (**20**) and (**21**) by repeated column chromatography on silica gel, with benzene as an eluent, and by subsequent preparative TLC (benzene–ethyl acetate, 10: 1).

*Acetate (**20**)*: R_f: 0.68, benzene–ethyl acetate, 10: 1; mp 99.5—100.0 °C, colorless prisms (from light petroleum); $[\alpha]_D^{22}$ −80° (*c*, 0.52, $CHCl_3$); IR(KBr): 3450, 1760, 1685, 1635, 1210 cm^{-1}; PMR(CCl_4): 3.11 (br s, OH), 2.18 (s, OAc), 1.27 (s, 15-Me), 0.96 and 0.68 (each d, J=6.0 Hz, 12- or 13-Me), 0.91 (d, J=5.5 Hz, 14-Me).

Found: C, 69.39; H, 8.89%. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

*Acetate (**21**)*: R_f, 0.73; a colorless oil; $[\alpha]_D^{25}$ +20° (*c*, 0.26, MeOH); UV: λ_{max}^{MeOH} 249 nm (ε, 8200); IR(film): 3450, 1750, 1675, 1635, 1200 cm^{-1}.

*Keto Ester (**23**)*: Bp 120—122 °C (bath temperature)/0.02

† mmHg=133.322 Pa

mmHg; a colorless oil; $[\alpha]_D^{22}$ +41° (*c*, 0.85, MeOH); MS: *m/e* 237 M^+-31, *m/e* 109 base peak; IR(film): 1735, 1710 cm^{-1}; PMR(CCl_4): 3.56 (s, OMe), 1.01 (s, 15-Me), 0.98 (d, J=6.5 Hz, $CHMe_2$), 0.86 (d, J=7.0 Hz, 14-Me).

Found: C, 71.40; H, 10.56%. Calcd for $C_{16}H_{28}O_3$: C, 71.60; H, 10.52%. **23** was found to be identical with an authentic sample prepared from **4** by a comparison of the IR and GLC (PEG 20M, 2.6 m; column temperature, 195 °C; retention time, 14.9 min). The preparation of **23** will be described later.

*Preparation of the Autoxidation Products. Preparation of Hydroxy Ketones (**9a**, **9b**, **11a**, and **11b**).* A solution of fukinone α-epoxide (1.015 g) and *p*-toluenesulfonic acid (250 mg) in dry benzene (270 ml) was stirred at 40 °C for 7 h. Working-up in the usual manner gave a brown oil, which was subsequently chromatographed on silica gel (30 g, Grade II). Elution with light petroleum–ether (50: 1) gave (**9a**) in a 49% yield as the major product. **9b** was obtained in a similar manner from fukinone β-epoxide.

The catalytic hydrogenation of **9a** and **9b** with 10% palladium charcoal gave the saturated hydroxy ketones (**11a** and **11b**) respectively, in quantitative yields.

*Hydroxy Ketone (**9a**)*: Mp 61.5—62.0 °C; colorless needles (from pentane); $[\alpha]_D^{28}$ +91° (*c*, 1.02, $CHCl_3$).

Found: C, 76.26; H, 10.27%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

*Hydroxy Ketone (**9b**)*: Mp 73.5—74.0 °C; colorless prisms (from pentane); $[\alpha]_D^{23}$ −80° (*c*, 0.99, $CHCl_3$). The further details of **9a** and **9b** will be reported in the succeeding paper on the acid-catalyzed reaction of fukinone epoxides.

*Hydroxy Ketone (**11a**)*: Mp 47—48 °C; colorless prisms (from pentane); $[\alpha]_D^{28}$ +112° (*c*, 1.02, $CHCl_3$); MS: *m/e* 238 M^+, *m/e* 109 base peak; IR(CCl_4): 3480, 1703 cm^{-1}; PMR(CCl_4): 2.89 (s, OH), 0.93 (s, 15-Me), 0.81 (d, J=6.0 Hz, 14-Me), 0.91 and 0.70 (each d, J=6.0 Hz, 12- or 13-Me).

Found: C, 75.31; H, 10.95%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%. For the data of **11b**, see the above description.

*Rearrangement of Hydroxy Ketone (**11b**) with Potassium* t-*Butoxide in* t-*Butyl Alcohol.* The hydroxy ketone (**11b**) (22.8 mg) was dissolved in 0.5 M potassium *t*-butoxide–*t*-butyl alcohol and then left at room temperature for 5 min. The reaction mixture was diluted with water, acidified with 10% aqueous sulfuric acid, and extracted with ether. The extract was washed with water and dried over anhydrous sodium sulfate. The subsequent removal of the solvent gave an oil which was chromatographed on silica gel (0.5 g). Elution with light petroleum–ether (100: 1) gave a hydroxy ketone (**12**) (19 mg in an 83% yield).

*Reaction of Hydroxy Ketone (**12**) with Periodic Acid.* The hydroxy ketone (**12**) (60 mg) in ethanol (6 ml) was added to a solution of potassium periodate (150 mg) in 1 M aqueous sulfuric acid (7 ml), and the resulting solution was kept at 45 °C for 9.5 h. The reaction mixture was then diluted with water and extracted with ether. The extract was washed with a saturated sodium hydrogencarbonate solution and then water. The dried extract was evaporated to give an oil, which was subsequently chromatographed on silica gel (1 g). Elution with light petroleum–ether (200: 1) gave a ketone (**13**) (17 mg), which was identical with the authentic sample[3] by a comparison of the IR and GLC (SPE, 2.6 m; column temperature, 150 °C; H_2-flow rate, 32 ml/min; retention time, 17.7 min).

*Autoxidation of Hydroxy Ketone (**11a**).* The hydroxy ketone (**11a**) (280 mg) was stirred into a solution of potassium *t*-butoxide (*ca.* 30 mmol) in *N,N*-dimethylformamide (15 ml). After vigorous stirring in the air for 20 min, the mixture was worked-up in the usual manner gave a yellow oil which was subsequently chromatographed on silica gel (2.5 g). Elution with light petroleum–ether (30: 1) afforded diosphenol (**16**) (20 mg); mp 134.0—135.0 °C, colorless prisms (from light petroleum), $[\alpha]_D^{23}$ +150° (*c*, 1.05, $CHCl_3$); MS: *m/e* 252 M^+, *m/e* 41 base peak; UV: λ_{max}^{MeOH} 282 nm (ε, 11400); IR(KBr): 3480, 3400, 1660, 1630, 1000, 990 cm^{-1}; PMR(CCl_4): 1.21 (s, 15-Me), 0.98 and 0.90 (each d, J=6.0 Hz, 12- or 13-Me), 0.71 (d, J=7.0 Hz, 14-Me). The acetylation of (**16**) in the usual manner gave an acetate (**20**) which was found to be identical with the authentic acetate prepared from dihydrofukinone (**4**) mentioned above by a comparison of the IR and PMR spectra and by a mixed-melting-point determination.

*Preparation of Keto Ester (**22**) from Dihydropulegone (**3**).* A solution of dihydropulegone (**3**) (232 mg) in chloroform (1 ml) was added, at 0 °C, to a solution of perbenzoic acid (3 mmol equivalent) in chloroform (12.5 ml) in the presence of a catalytic amount of concentrated sulfuric acid. The mixture was then allowed to stand in a refrigerator for 3 days. The reaction mixture was subsequently concentrated, diluted with water, and extracted with ether. The extract was washed successively with a saturated aqueous sodium hydrogencarbonate solution, a saturated aqueous ferrous sulfate solution, and water. The dried extract was evaporated to give an oil which was chromatographed on silica gel (4 g). Elution with benzene gave a lactone as an oil (156 mg, 61%); IR(film): 1710, 1280, 1225 cm^{-1}; PMR(CCl_4): 4.00 (m, CH–O–), 2.45 (d, J=10 Hz, CO–CH_2–), 0.98 (d, J=6.0 Hz, 7-Me), 0.93 (d, J=6.0 Hz, $CHMe_2$).

A solution of the lactone (103 mg) and potassium hydroxide (1 pellet) in methanol (5 ml) was refluxed for 5 h, and then methyl iodide (1.5 ml) was added. After refluxing for a further 3 h, the resulting mixture was concentrated, acidified with 10% aqueous sulfuric acid, and extracted with ether. The dried extract was evaporated to give an oil which was chromatographed on silica gel (2 g) by elution with benzene to furnish a hydroxy ester (76 mg, 62%); IR(film): 3400, 1720 cm^{-1}. The hydroxy ester (36 mg) in pyridine (0.5 ml) was stirred, drop by drop, into a slurry mixture of chromium trioxide (100 mg) in pyridine (1 ml) under cooling, after which the mixture was kept overnight at room temperature under stirring. Subsequent working-up in the usual manner gave a keto ester (**22**) (17 mg, 48%).

*Preparation of Keto Ester (**23**) from Dihydrofukinone (**4**).* A hydroxy ester (**23**)[15] was prepared from dihydrofukinone (**4**) by essentially the same method described above; the subsequent Jones' oxidation gave a keto ester (**23**) in a 58% yield.

*Isolation of Hydroxyeremophilone Acetate (**6**).* Fukinone (**2**) (1.239 g, 5.62 mmol) was dissolved in 0.5 M potassium *t*-butoxide–*t*-butyl alcohol (40 ml), and the mixture was stirred vigorously in the air at room temperature for 3.5 h. Working-up in the usual manner gave a brown oil (1.226 g), which was then chromatographed on deactivated silica gel (Grade II, 24 g). Elution with light petroleum–ether (50: 1) gave a mixture of hydroxyeremophilone (**5**) and (**2**) (327 mg). Subsequent elution with light petroleum–ether (20: 1) afforded a mixture of two epimeric hydroxy ketones (**9a** and **9b**) (77 mg). The mixture of **5** and **2** was immediately treated with acetic anhydride–pyridine. Working-up in the usual manner gave a yellow oil, which was chromatographed on silica gel (Grade II, 5 g). Elution with light petroleum–ether (50: 1) gave **2** (220 mg) and then hydroxyeremophilone acetate (**6**) (35 mg; 5.6% yield based on the **2** consumed), which was recrystallized from light petroleum; mp 53.5—54.0 °C; colorless prisms; $[\alpha]_D^{25}$ +143° (*c*, 1.02, $CHCl_3$); MS: *m/e* 276 M^+, *m/e* 43 base peak; UV: λ_{max}^{MeOH} 285 nm (ε, 7100), 255 nm (ε,

9300); IR(CCl_4): 1760, 1665, 1635, 1203 cm^{-1}; PMR(CCl_4): 2.17 (s, OAc), 2.06 and 1.84 (each s, 12- or 13-Me), 1.01 (s, 15-Me), 0.99 (d, J=6.0 Hz, 14-Me).

Found: C, 73.69; H, 8.41%. Calcd for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75%.

*Preparation of 9β-Acetoxyfukinone (**24**).* A mixture of fukinone (**2**) (3.446 g, 15.6 mmol) and mercuric acetate (8.45 g, 26.5 mmol) in glacial acetic acid (30 ml) was refluxed for 3.5 h. The resulting dark mixture was decanted to remove the mercury into water and then extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. The removal of the solvent gave a dark viscous oil (3.515 g), which was subsequently chromatographed on silica gel (80 g). Elution with light petroleum–ether (50: 1) afforded the recovered fukinone (**2**) (0.93 g) and 9β-acetoxyfukinone (**24**) (1.357 g, 31%), which was distilled at 130—140 °C (bath temperature)/0.02 mmHg and then crystallized from light petroleum as colorless leaflets; mp 67—68 °C, $[\alpha]_D^{23}$ +160° (c, 1.23, $CHCl_3$); MS: m/e 278 M^+, m/e 28 base peak; UV: λ_{max}^{MeOH} 253 nm (ε, 5800); IR(CCl_4): 1755, 1740, 1707, 1640, 1233 cm^{-1}; PMR(CCl_4): 5.38 (d, J=12 Hz, 9-CH), 2.10 (s, OAc), 1.80 (t, J=1.5 Hz, 12- and 13-Me), 1.00 (s, 15-Me), 0.84 (d, J=6.5 Hz, 14-Me).

Found: C, 73.59; H, 9.38%. Calcd for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41%. Before crystallization it showed a PMR signal at 5.26 (d, J=5.0 Hz) besides that at 5.38, indicating the existence of a small amount of the 9α-acetoxyl isomer.

*Preparation of Hydroxyeremophilone Acetate (**6**).* a) Into a solution of 9β-acetoxyfukinone (**24**) (303 mg, 1.08 mmol) and DDQ (270 mg, 1.19 mmol) in dry dioxane (20 ml) we bubbled anhydrous hydrogen chloride with stirring for 1 min; the stirring was then continued at room temperature for 4 h. After subsequent filtration and evaporation of the solvent, the residue was taken up in ether, washed with a 1% aqueous sodium hydroxide solution, and water. The evaporation of the solvent gave a viscous light brown oil (211 mg), which was chromatographed on silica gel (Grade II, 6 g). Elution with light petroleum–ether (30: 1) gave the recovered **24** (196 mg) and then hydroxyeremophilone acetate (**6**) (20 mg, 10% based on the **24** consumed).

b) An aqueous potassium hydroxide solution (*ca.* 1.8%) was added, over a period of 2 weeks under a nitrogen atmosphere, to a solution of **24** (281 mg, 1.01 mmol) in methanol (10 ml), in the presence of 1 drop of 1% phenolphtalein in ethanol, at such a rate that the solution was kept faintly alkaline. The reaction mixture was then diluted with water and extracted with ether. The extract was worked-up in the usual manner to give a pale yellow oil (165 mg), which was subsequently chromatographed on silica gel (Grade II, 7 g). Elution with benzene gave 9β-hydroxyfukinone (**25**) (144 mg, 61%); a colorless oil; $[\alpha]_D^{23}$ +122° (c, 0.68, $CHCl_3$); UV: λ_{max}^{MeOH} 252 nm (ε, 4500); IR(CCl_4): 3460, 1760 (sh), 1708 (sh), 1692, 1640 cm^{-1}; PMR(CCl_4): 4.17 (d, J=11 Hz, 9α-H), 3.50 (s, OH), 1.87 (d, J=1.5 Hz) and 1.81 (d, J=1.0 Hz) (12- and 13-Me), 0.95 (s, 15-Me), 0.83 (d, J=6.0 Hz, 14-Me).

A mixture of **25** (109 mg, 0.46 mmol) and bismuth oxide (111 mg, 0.24 mmol) in glacial acetic acid (2 ml) was stirred at 120 °C for 10 min. The solution was decanted to remove the bismuth metal into water (20 ml) and then extracted with ether. The subsequent working-up as usual gave a brown oil, which was subjected to preparative TLC to afford **5** (64 mg, 59%). Its acetate (**6**) was obtained in the usual manner.

The authors wish to thank the staff of the Research Laboratory, Toyo Jozo, Co., Ltd., for the microanalysis and MS measurements, and the Institute of Food Chemistry for the measurement of the MS spectra.

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received December 14, 1978)

The alkylations of benzene with optically active 3-chloro-1-butanol, 3-chlorobutanoic acid and their esters in the presence of aluminium chloride gave the corresponding 3-phenyl substituted derivatives in good optical yield. All these reactions were found to proceed with inversion of configuration at the attacking carbon atom. The products were not racemized under the conditions used, while the starting materials were racemized to a considerable extent during the reaction. Taking into account of the optical purity of the starting material recovered before the completion of reaction, net stereospecificity of each reaction was calculated to be about 90% except for the case of 3-chloro-1-butanol and its acetic ester. The high degree of stereospecificity of the reaction can be interpreted by the mechanism involving cyclic intermediate formed from the alkylating reagent and aluminium chloride.

Compared to extensive studies on the Friedel-Crafts alkylation of aromatic hydrocarbons with alkyl halide or alcohol, the stereochemistry of these reactions received relatively little attentions.[2] Generally, Friedel-Crafts type alkylation has long been pointed out to proceed with almost complete recemization when an optically active alkylating reagent was used.[3] Some examples of the stereospecific reaction were recently reported, *e.g.* the alkylation of benzene with (+)-γ-valerolactone and (+)-2-methyltetrahydrofuran in the presence of aluminium chloride proceeded with 47% and 35% net inversion of configuration at the attacking carbon, respectively.[4,5] We also observed complete inversion in the reaction of benzene with (+)-propylene oxide[6] and (+)-1,2-epoxybutane[7] by Lewis acid catalysts. The stereospecificity in these reactions has been explained on the basis of the cyclic nature of the alkylating reagents or the enforced proximity of ion pairs produced by the ring opening reaction. Furthermore, (−)-2-chloro-1-phenylpropane reacted with benzene in the presence of aluminium chloride or iron(III) chloride to give (−)-1,2-diphenylpropane with 70—95% retention of configuration.[8] This result was interpreted by the participation of the neighboring phenyl group to the reaction center.

In connection with these observations, it is interesting to investigate the stereochemistry of Friedel-Crafts reaction with acyclic alkylating reagents such as 3-chloro-1-butanol, 3-chlorobutanoic acid and their esters. Little is known about Friedel-Crafts reactions with halogenated alcohol, halogenated carboxylic acid and their ester.[9] In a communication we demonstrated that the alkylation of benzene with optically active 3-chloro-1-butanol (Ia) and 3-chlorobutanoic acid (Ib) by aluminium chloride catalyst proceeded with inversion of configuration to give 3-phenyl-1-butanol (IIa) and 3-phenylbutanoic acid (IIb), respectively.[10] In the present paper, we have extended our previous work on Ia and Ib to their esters, ethyl 3-chlorobutanoate (Ic), 3-chlorobutyl benzoate (Id), and 3-chlorobutyl acetate (Ie) with a view to obtaining more information on the stereochemistry of the Friedel-Crafts alkylation. Furthermore, the net stereospecificity of reaction was determined by taking into account of the remaining optical activity of the starting materials recovered.

Results and Discussion

At first, the reaction was run in usual manner in order to know a general tendency on the stereochemistry of the reaction. The alkylating reagent was gradually added to a stirred mixture of aromatic hydrocarbon and Lewis acid at such a rate that the temperature of the reaction mixture does not rise higher (see the method A in Experimental). Optically active Ia, Ib, Ic, Id, and Ie reacted with benzene in the presence of 1.2 equivalents of aluminium chloride at −5—50 °C to give the corresponding 3-phenyl substituted derivatives, 3-phenyl-1-butanol (IIa), 3-phenylbutanoic acid (IIb), ethyl 3-phenylbutanoate (IIc), 3-phenylbutyl benzoate (IId), and 3-phenylbutyl acetate (IIe), respectively, in optically active form. The results are described in Table 1.

In these reactions, by-products such as haloalkylated and haloacylated compounds and rearrengement products were not obtained under the conditions used. However, the esters (Ic, Id, and Ie), when treated under higher temperature (over 40 °C), gave considerable amounts of the hydrolyzed products (IIb from Ic, and IIa from Id or Ie) along with the normal products. Furthermore, diphenylbutane was also obtained in the case of Id and Ie. These by-products seem to arise from the primary products. This was confirmed by the experimental result that IIc and IId (or IIe) reacted with aluminium chloride in benzene to yield IIb and IIa, respectively.

The absolute configurations of the dextrorotatory chlorides (Ia, Ib, and Ic) and the levorotatory products (IIa, IIb, and IIc) have been established to be *S*[11] and *R*,[12-14] respectively, whereas those of Id, Ie, IId, and IIe are not known yet. The configurations of (+)-Id and (+)-Ie were correlated with that of (+)-Ia (see Experimental) and assigned to be *S*. In the same way, (−)-IId and (−)-IIe were correlated to *R*-(−)-IIa. Consequently, it is apparent that all these reactions proceeded with inversion of configuration at the attacking carbon atom. The optical yield of each reaction was calculated by the use of maximum rotations in Table 2.

Ib, IIb: Y=COOH Ie, IIe: Y=CH_2OCOCH_3
Ic, IIc: Y=$COOC_2H_5$

These reactions were so sensitive both to the moisture and to the activity of aluminium chloride used that it was diffcult to control the extent of the stereospecificity with sufficient reproducibility. The observed stereospecificity was found to be 20—30% for the reaction with alcohol (Ia) and its ester (Id and Ie), and 40—50% for that with chloroalkanoic acid (Ib) and its ethyl ester (Ic). The stereospecificity decreased slightly with an increase in reaction temperature. When these reactions were carried out in the presence of aluminium chloride equimolar to the alkylating reagent, the alkylation of benzene did not take place and the starting material was recovered without racemization.

In order to estimate the net stereospecificity of these reactions, one must know whether the starting chloride or the product is racemized in the course of reaction.

TABLE 3. TREATMENT OF THE ALKYLATED PRODUCT WITH ALUMINIUM CHLORIDE IN BENZENE[a]

Alkylated products	Temp °C	Time h	Specific rotation[b]/° Before reaction	Specific rotation[b]/° After reaction

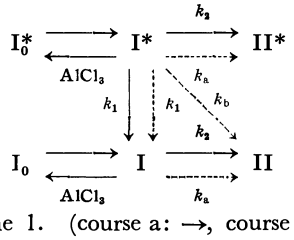
a) Molar ratio; $CH_3CH(Cl)\ CH_2Y$: $AlCl_3$: C_6H_6 = 1: 1.2: 30—40. CS_2 was added in the reaction below 5 °C. b) Rotation was measured in $CHCl_3$ (c 5.0), unless otherwise noted. c) See Table 1, footnote c. d) See the text. e) See the description in the text (Eq. 3). f) Measured in benzene (c 5.0). g) Measured in toluene (c 10). h) Neat liquid. i) By the ^1H NMR method using tris[trifluoroacetyl-(+)-camphorato]europium (III) as shift reagent.

At first, to examine the possibility of racemization of the product during the reaction, optically active IIa, IIb, IIc, IId, and IIe were treated with aluminium chloride in benzene under the same conditions as those of the alkylation. The specific rotation of these compounds remained almost unchanged before and after the treatment (Table 3). Thus, it turns out that the lesser stereospecificity in alkylation is not attributed to the successive racemization of the product. Next, we examined the possibility of simultaneous racemization of the starting chloride by observing the optical activity of that recovered before the completion of reaction; the reaction was quenched at about 30—70% conversion of the starting material after all reactants were mixed rapidely at lower temperature (see the method B in Experimental). The results are tabulated in Table 4. The starting chloride was racemized to a considerable extent as the reaction proceeds, and the optical yield of product decreased with the progress of reaction. Thus, these alkylation were found to be accompanied with simultaneous racemization of the starting material.

We have attempted to evaluate the extent of stereospecificity in the alkylation. The net stereospecificity of each reaction can be estimated from the extent of alkylation and the remaining optical activity of the starting material both observed at the same reaction time, by considering a kinetic model as shown in Scheme 1. I_0, I, and II indicate the starting material, the complex with aluminium chloride, and the alkylated product, respectively, and the asterisk indicates optically pure species. For convenience in the analysis we



Scheme 1. (course a: →, course b: ⇢)

assumed this reaction model in terms of optically pure and racemic species, although use of the enantiomers would be correct. The concentration of the complex (I* or I) would be equal to that of the starting material (I_0* or I_0) since the reaction from I_0* (or I_0) to I* (or I) is considered to be very rapid. In the conversion of I* into II* and II, two reaction courses are considered as shown in Scheme 1. The course a involves the reaction of I* to II* and the consecutive reaction of I* to II through I. The course b involves the direct conversion of I* into II in addition to the course a. Assuming that the racemization and disappearance of the starting material are pseudo-first-order in I* (or I), the reaction rates, k_1 and k_2, can be deduced from the fraction of the remaining optical activity in the starting material and that of the remaining starting material observed at the same time.[15] Thus, the optical yield of the product in the course a should be represented by Eq. 1.[16]

$$\left(\frac{[II^*]}{[II]+[II^*]}\right)_{\text{course a}} = \frac{k_2}{k_1+k_2}\,\frac{(1-e^{-(k_1+k_2)t})}{(1-e^{-k_1t})} \qquad (1)$$

In the course b, k_a and k_b represent the psendo-first-order rate constants for the formation of II* from I* (or of II from I) and that for the direct conversion of I* into II, respectively. Here,

$$k_a + k_b = k_2.$$

Thus, the optical yield of the product in the course b can be represented by Eq. 2, and corresponds to the observed optical yield.

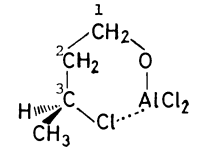
$$\left(\frac{[II^*]}{[II]+[II^*]}\right)_{\text{course b}} = \frac{k_a}{k_1+k_2}\,\frac{(1-e^{-(k_1+k_2)t})}{(1-e^{-k_1t})} \qquad (2)$$

Consequently, the net stereospecificity $(k_a/(k_a+k_b))$ should be given by Eq. 3.[17]

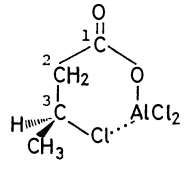
$$\left(\frac{[II^*]}{[II]+[II^*]}\right)_{\text{course b}} \Big/ \left(\frac{[II^*]}{[II]+[II^*]}\right)_{\text{course a}} = \frac{k_1+k_2}{k_2}\,\frac{(1-e^{-k_1t})}{(1-e^{-(k_1+k_2)t})} \times (\text{observed optical yield \%}) \qquad (3)$$

For example, in the alkylation with (−)-Ib at 10 °C (90 min), (+)-IIb was obtained in 24% yield and in 80% optical yield, and the optical activity of the starting material was depressed to 84% of the initial value. The k_1 and k_2 values were calculated to be $1.94\times10^{-3}\,min^{-1}$ and $3.05\times10^{-3}\,min^{-1}$ based on ln[fraction of remaining optical activity (0.84)] and ln[fraction of remaining chloride (0.76)], respectively. Therefore, the "true stereochemical consequence (net stereospecificity)" of this reaction was calculated to be 87%. Furthermore, the k_1/k_2 value (0.64) suggests that the rate of the alkylation is appreciably faster than that of the racemization of the starting material. The calculated values of the net stereospecificity and k_1/k_2 are given in the 11th and 12th column of Table 4, respectively.

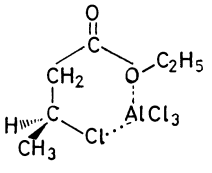
Such high stereospecificities have not been reported in the Friedel-Crafts alkylation with acyclic alkylating reagent. In this case, the polar group (OH, COOH, and COOR) being a part of the alkylating reagent would be responsible for the high stereospecificity of the reaction. The predominance of inversion in the alkylation is reasonably interpreted by considering the formation of cyclic intermediates as follows.



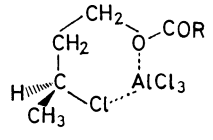
(Ia′)



(Ib′)



(Ic′)



(Id′: R=C_6H_5)
(Ie′: R=CH_3)

In the initial stage of the reaction with Ia and Ib, we observed the evolution of appreciable amounts of hydrogen chloride. This suggests that Ia (or Ib) reacted with aluminium chloride to form the salt evolving hydrogen chloride. The aluminium atom in the salt would coordinate with the chlorine atom at C_3 to form six-membered quasi-ring structure (Ia′ and Ib′), and the C_3–Cl bond would be polarized appreciably. Then, benzene would attack the C_3 atom from the back-side of the leaving chlorine atom. Even if the abstraction of the chlorine atom took place initially to give the carbonium ion (C_3^+), the interaction between the cation and the leaving chloride anion would prevent the rotation about the C_2–C_3 bond. Thus, the stereospecificity of the reaction may be interpreted in terms of the stability of the ring structure and the tightness of this ion pair. The increased tightness of the ion pair would increase the stability of the quasi-ring structure and thus the stereospecificity of the reaction. The higher stereospecificity of the reaction with Ib compared to Ia may be attributed to the enforced tightness of the ion pair by the electron withdrawing effect of the carbonyl group.

In the case of esters, Ic, Id, and Ie, the ether oxygen of ester group coordinates with aluminium chloride to form similar quasi-ring structures (Ic′, Id′, and Ie′). The high stereospecificity in the alkylation may also be interpreted in terms of the tightness of the ion pair as mentioned above. However, the large difference in the stereospecificity between the reaction with Id and Ie remained unexplainable.

The k_1/k_2 value for the reaction with Ia or Ib was found to be 0.6—1.3 while that for the reaction with esters was over 2. The lower value of k_1/k_2 in the former case may be attributed to lesser amounts of aluminium chloride remaining in the reaction mixture, because most of aluminium chloride were consumed for the salt-formation with Ia (or Ib).

Experimental

The optical rotations were taken on a JASCO DIP-SL polarimeter with use of 0.05 and 0.1 dm tubes at 25—30 °C. The NMR spectra were recorded on a JEOL JNM PS-100 spectrometer. Chemical shifts are given in ppm downfield from internal TMS. The IR spectra were determined on a JASCO DS-301 spectrometer. GLPC analyses were carried out on a 3 m column of 10% Carbowax 20 M on Diasolid L for IIa, IIb, and IIc, and on a 2 m column of 10% High Vacuum Silicon grease on Diasolid L for IId and IIe, with a Shimadzu GC-3A instrument.

Commercial grade aluminium chloride was purified by sublimation under nitrogen gas stream. Benzene was washed with concentrated sulfuric acid and water, and distilled after drying on sodium ribbon. Other solvents were dried by the most efficient ways reported in the literature[18] and distilled before use.

(+)-3-Chlorobutanoic Acid (Ib). Racemic Ib was prepared by addition of hydrogen chloride to crotonic acid[19] and resolved by the use of quinine[20] or (+)-ephedrine. When quinine was used as a resolving agent, (+)-Ib was obtained in about 50% optical purity, $[\alpha]_D$ +25.0° (*c* 10, $C_6H_5CH_3$), lit,[19] $[\alpha]_D$ +46.6° (*c* 10, $C_6H_5CH_3$). When (+)-ephedrine was used, (+)-Ib was obtained in lower optical purity, $[\alpha]_D$ +7.82° (neat). In both cases, (−)-Ib was recovered from the mother liquors.

(+)-3-Chloro-1-butanol (Ia). (+)-Ib ($[\alpha]_D$ +22.5°) was reduced with lithium aluminium hydride according to the procedure of Searles[22] to give (+)-Ia, bp 68 °C/20 mmHg, $[\alpha]_D$ +23.5° (neat), optical purity 48.3%.

(+)-Ethyl 3-Chlorobutanoate (Ic). (+)-Ib was esterificated with anhydrous ethanol in the presence of boron trifluoride to give (+)-Ic, bp 62—63 °C/20 mmHg, $[\alpha]_D$ +4.80° (neat). Optically pure (+)-Ic was prepared from thionyl chloride and (+)-ethyl 3-hydroxybutanoate obtained by the yeast reduction of ethyl acetoacetate as follows:[21] ethyl acetoacetate (100 g, 0.77 mol) was treated with baking yeast (1 kg) and sugar (1 kg) in water (10 liter) at 35 °C. After 24 h, (+)-ethyl 3-hydroxybutanoate was isolated by the repeated extraction with ether, bp 75—77 °C/15 mmHg, $[\alpha]_D$ +28.3° (*c* 5.0, $CHCl_3$), yield 56%. The hydroxybutanoate was converted with thionyl chloride in pyridine to (+)-Ic, yield 67%, $[\alpha]_D$ +18.8° (*c* 5.0, $CHCl_3$).

(−)-3-Chlorobutyl Benzoate (Id) was prepared by the esterification of (−)-Ia ($[\alpha]_D$ −46.6° (*c* 5.0, $CHCl_3$) with benzoyl chloride in pyridine at 100 °C, bp 101—102 °C/0.7 mmHg, $[\alpha]_D$ −41.2° (*c* 5.0, $CHCl_3$), yield 81%.

(−)-3-Chlorobutyl Acetate (Ie) was prepared from (−)-Ia ($[\alpha]_D$ −46.6°) and acetyl chloride in pyridine, bp 76—77 °C/17 mmHg, $[\alpha]_D$ −38.4° (*c* 5.0, $CHCl_3$), yield 60%.

Reaction Procedures and Product Identification. Method A: To a stirred mixture of dry benzene (20 ml) and aluminium chloride (9.8 mmol) was added a solution of the starting chloride (Ia, Ib, Ic, Id, or Ie) (8.3 mmol) in benzene (20 ml) at a rate sufficient to maintain the temperature shown in Table 1. The reaction mixture was stirred at that temperature until the starting chloride was almost consumed, and then was poured onto a mixture of crashed ice and 20 ml of concentrated hydrochloric acid. In the case of the reaction with Ia, Id, and Ie, the resulting mixture was treated as follows. The benzene layer was separated and the aqueous layer was extracted three times with 30 ml portions of ether. The combined organic layers were washed with water and dried over anhydrous sodium sulfate. After the removal of solvent, the residue was distilled *in vacuo* to give the corresponding 3-phenyl derivatives (IIa, IId or IIe). The results were summarized in Table 1.

In the case of the reaction with Ib and Ic, the reaction mixture was treated as follows. The benzene layer was separated and extracted five times with 30 ml portions of 5% sodium hydrogencarbonate solution and dried over anhydrous sodium sulfate. After the removal of benzene, the residue was distilled *in vacuo* to give IIc. The hydrogencarbonate solution was acidified with 6 M hydrochloric acid and extracted five times with 30 ml portions of ether and dried over anhydrous sodium sulfate. After the removal of the ether, the residue was distilled *in vacuo* to give IIb.

Method B: In order to estimate the net stereospecificity of the reaction, the experiment was carried out as follows.

To a cooled (−10 °C) suspension of aluminium chloride (5.6 mmol) in dry benzene (6 ml) was added, all at once, a solution of the chloride (4.7 mmol) in benzene (6 ml), and the reaction mixture was stirred at the prescribed temperature for the prescribed period (see Table 4). The resulting mixture was worked up as mentioned above. The unreacted starting material and the product were separated by fractionated distillation *in vacuo*. The results were summarized in Table 4.

(+)-3-Phenyl-1-butanol (IIa): IR(neat); 3340 (νOH), 1600 (skeletal vibration of phenyl ring), 1050 (νC–OH), 760, and 700 cm^{-1} (δCH, monosubstituted phenyl). NMR ($CDCl_3$, 7%); δ 1.26 (d, J=7.0 Hz, 3H, $-CH_3$), 1.70 (s, 1H, –OH), 1.72—1.96 (m, 2H, $-CH_2-$), 2.68—3.07 (m, 1H, –CH=), 3.54 (t, J=6.9 Hz, 2H, $-CH_2O-$), and 7.09—7.39 ppm (m, 5H, phenyl). The GLPC retention time was identical with that of the authentic sample.

(+)-3-Phenylbutanoic Acid (IIb): Bp 106 °C/2.0 mmHg, $[\alpha]_D$ +15.8° (neat), IR(neat); 3000 (νOH, dimeric carboxylic acid), 1710 (νC=O), 1605 (skeletal vibration of phenyl ring), 1300 (νC–O), 760, and 700 cm^{-1} (δCH, monosubstituted phenyl). NMR($CDCl_3$, 7%); δ 1.30 (d, J=7.2 Hz, 3H, $-CH_3$), 2.46—2.63 (m, 2H, $-CH_2-$), 3.03—3.42 (m, 1H, –CH=), 7.21 (s, 5H, phenyl), and 10.30 ppm (s, 1H, –COOH).

(−)-Ethyl 3-Phenylbutanoate (IIc): Bp 118—119 °C/17 mmHg, $[\alpha]_D$ −3.04° (neat). IR (neat); 1740 (νC=O), 1604 (skeletal vibration of phenyl ring), 1170 (νC–O–C), 760, and 700 cm^{-1} (δCH, monosubstituted phenyl). NMR ($CDCl_3$, 7%); δ 0.89 (t, J=7.5 Hz, 3H, $-CH_2C\underline{H}_3$), 1.18 (d, J=6.9 Hz, =CHC$\underline{H}_3$), 2.10—2.77 (m, 2H, $-OC\underline{H}_2CH=$), 3.11—3.48 (m, 1H –CH=), 3.91 (q, J=7.5 Hz, 2H, $-C\underline{H}_2CH_3$), and 7.04—7.38 ppm (m, 5H, phenyl).

(+)-3-Phenylbutyl Benzoate (IId): Bp 140—141 °C/0.5 mmHg, $[\alpha]_D$ +18.8° (*c* 5.0, $CHCl_3$). IR (neat); 1724 (νC=O), 1604 (skeletal vibration of phenyl ring), 1280 (νC–O–C), 758, and 710 cm^{-1} (δ CH, monosubstituted phenyl). NMR ($CDCl_3$, 5%); δ 1.36 (d, J=7.3 Hz, 3H, $-CH_3$), 1.96—2.20 (m, 2H, $-CH_2-$) 2.76—3.15 (m, 1H, –CH=), 4.00—4.42 (m, 2H $-CH_2O-$), 7.24 (s, 5H, =CH–$C_6\underline{H}_5$), 7.14—8.20 ppm (m, 5H, $-OC-C_6H_5$).

(+)-3-Phenyl Butyl Acetate (IIe): Bp 130 °C/14 mmHg, $[\alpha]_D$+15.8° (*c* 5.0, $CHCl_3$). IR (neat); 1745 (νC=O), 1604 (sketetal vibration of phenyl ring), 1245 (νC–O–C), 765, and 700 cm^{-1} (δCH, monosubstituted phenyl). NMR ($CDCl_3$, 7%); δ 1.26 (d, J=7.2 Hz, 3H, $-CH_3$), 1.73—2.05 (m, 2H, =CHC$\underline{H}_2-$), 1.96 (s, 3H, $-COCH_3$), 2.64—3.00 (m, 1H, =CH–), 3.96 (t, J=6.9 Hz, 2H, $-OCH_2O-$), and 7.18—7.37 (m, 5H, phenyl).

The GLPC retention time of the recovered chloride (Ia, Ib, Ic, Id, and Ie) was identical with that of the corresponding starting material, respectively.

Reaction of Optically Active IIa, IIb, IIc, IId, and IIe with Aluminium Chloride. To a stirred mixture of benzene (20 ml) containing aluminium chloride (5.6 mmol) was added a solution of optically active IIa IIb, IIc, IId, or IIe (4.7 mmol) in benzene (5 ml) at the prescribed temperature for 2—3 h. The reaction mixture was worked up as mentioned above. The data of specific rotation of II before and after the reaction were presented in Table 3.

15) Strictly speaking, rate constant should be estimated for homogeneous reaction. As pointed out by Brauman *et al.*,[4] however, it will be possible to estimate the rate constant with appreciable accuracy by assuming that the complex formation is relatively fast compared to the other steps, and that only dissolved complex takes part in the reaction. In our case,

aluminium chloride was gradually dissolved as the reaction proceeds although the reaction was heterogeneous in the initial stage.

16) For the analysis of complex reaction, see, for example, A. A. Frost and R. G. Pearson, "Kinetic and Mechanism," 2nd ed, John Wiley and Sons, Inc., New York (1953), p. 166.

17) The net stereospecificity in the alkylation of benzene with (+)-γ-valerolactone was calculated using the value of k_1/k_2 obtained in the initial stage of reaction and that of the observed inversion % obtained after the completion of reaction.[4] The stereospecificity calculated in such a manner corresponds to that at $t=\infty$ in our Eq. 3.

Preparation of Chlorophyll-a and Chlorophyll-b by Column Chromatography with Sephasorb HP Ultrafine

Masahiko YOSHIURA, Keiji IRIYAMA,* Masaru SHIRAKI, and Akira OKADA

Research Institute for Polymers and Textiles, Sawatari 4-1, Kanagawa-ku, Yokohama 221

(Received December 21, 1978)

A method for the preparation of chlorophyll-a (Chl-a) and chlorophyll-b (Chl-b) by column chromatography with Sephasorb HP Ultrafine has been developed. The partially purified chlorophyll preparation containing Chl-a, Chl-b and nonsorbed carotenes was applied to a Sephasorb HP Ultrafine column and good separation of Chl-a and Chl-b achieved with a solvent program of (I), a diethyl ether/hexane mixture (1 : 9, volume ratio) followed by 0.2 and 0.5 vol % isopropyl alcohol in (I). 13.1 mg of Chl-a and 7.6 mg of Chl-b were obtained from 24.7 mg of the partially purified chlorophyll using the above method.

One of the methods for separation and isolation of chlorophyll in quantities of 0.01—1 g is column chromatography with powdered sugar. Recently, a method has been developed for the partial purification of chlorophyll-a (Chl-a) and chlorophyll-b (Chl-b) extracted from spinach leaves using dioxane[1] and subsequent washing with 80 vol % aqueous methanol[2] prior to chromatographic separation and isolation. Chl-a and Chl-b in the partially purified chlorophyll preparation were subsequently separated and isolated by passage through a powdered sugar column.[3] Special care is, however, required to prepare a powdered sugar column of good quality with good reproducibility, as powdered sugar has a strong tendency to adsorb moisture from the air and the presence of any trace water affects the separation of the pigments. Angapindu *et al.*[4] reported that cellulose was superior to powdered sugar as an adsorbent since passage through the cellulose columns was faster and the carrying capacity greater. Strain and Sato[5] found that the pigment bands were better defined on sugar rather than on cellulose columns. Shimizu[6] reported that the separation between Chl-a and Chl-b zones could not be performed by column chromatography with Sephadex LH-20 eluted with chloroform, although the mobility of Chl-a was greater than that of Chl-b. Sephadex LH-20 is a hydroxypropyl derivative of cross-linked dextran. Sephasorb HP Ultrafine is similar in structure to Sephadex LH-20, but has a higher matrix density making it suitable for the adsorption of a wide range of compounds soluble in organic solvents. The authors have found that the pigment bands are better defined on Sephasorb HP Ultrafine columns than on powdered sugar or cellulose.

Experimental

Materials. All solvents were of reagent grade further purified, by the methods described.[7] Sephasorb HP Ultrafine was purchased from Seikagaku Kogyo Co.

Preparation of Partially Purified Chl-a and Chl-b. The partially purified chlorophyll preparation was obtained according to the method of Iriyama *et al.*[1,2] All procedures for the preparation were conducted at 5 °C in total darkness or under dim green light. Spinach leaves (100 g fresh weight) were homogenized for 3 min in a Waring blender with chilled acetone (500 ml). The dark green extract obtained was filtered through a paper towel to remove the coarse material and the filtrate centrifuged at 10000×g for 5 min to remove the insoluble materials. The deep-green supernatant solution was employed in the partial purification of chlorophyll by the dioxane method.[1] The chlorophyll preparation, twice precipitated from acetone–dioxane solution by the drop-wise addition of water, was dissolved in methanol (500 ml) containing petroleum ether (125 ml, bp 20—40 °C) and then distilled water (250 ml) was added to the solution. The upper petroleum ether layer was washed with 80 vol % aqueous methanol several times to eliminate the remaining photosynthetic yellow pigments from the solution.[2] The solution was evaporated and dried in a vacuum desiccator to give dark-green microcrystals. Thin-layer chromatographic analysis according to the method of Shiraki *et al.*[8] revealed that the dark-green microcrystals (Ppt III) thus obtained contained Chl-a, Chl-b and nonsorbed carotenes. Ppt III was dissolved in a minimum volume of mixed solvent (diethyl ether: petroleum ether=1 : 9, volume ratio) and the solution (developing solution I) applied to the Sephasorb HP Ultrafine column.

Identification and Determination of Chl-a and Chl-b. The pigments were characterized by comparison of the visible absorption spectra with the literature values. The molar extinction coefficients of Comar and Zscheile[9] were used to determine the purity of the Chl-a and Chl-b preparations as standard values. In addition, the purity and chemical stability of Chl-a and Chl-b were examined by chromatography, since it has been recognized by Strain and Svec[10] that spectroscopic observations need to be supplemented by chromatographic tests to demonstrate that the chlorophyll molecules had not been altered. The purity and chemical stability of the pigments were examined by thin-layer chromatography[8] since the technique was simple and rapid. Where necessary, the thin-layer chromatographic observations were supplemented by high-performance liquid chromatographic tests according to the methods described.[11,12] High-performance liquid chromatography[11,12] is relatively complicated, but has the advantage of greater sensitivity. Qualitatively it was possible to detect the pigments in the order of 10^{-8} g and 10^{-10} g using thin-layer chromatography[8] and high-performance liquid chromatography,[11,12] respectively.

Preparation of a Sephasorb HP Ultrafine Column. A wet column was employed using a Pharmacia R25 chromatographic tube (2.5×45 cm) connected, through the UV monitor (JASCO UVIDEC-100), to a fraction collector. The bed volume (cm^3/g dry Sephasorb HP Ultrafine) in petroleum ether was 1.3. 97 g of Sephasorb HP Ultrafine suspended in petroleum ether. The suspension was poured into the chromatographic tube, providing a 26 cm column. The column thus prepared had a capacity of approximately 30 mg of Chl-a+Chl-b without being overloaded. The column was washed with petroleum ether (1000 ml) before use to eliminate the soluble materials from the Sephasorb HP Ultrafine.

Sephasorb HP Ultrafine Column Chromatography. Percolation of the pigment solution and the developing solvents were accelerated by the application of pressure from a rotary pump (SJ-1210, Mitsumi; flow speed: approximately 21.4 ml h^{-1} cm^{-2}) connected to the top of the chromatographic tube by way of a Teflon tube. Chromatograms were monitored by a monochromatic light of 380 nm and each of the pigment fractions collected by a fraction collector.

Results

All experiments were conducted at 20 °C in total darkness or under a dim green light unless otherwise stated.

The developing solution I containing Chl-a, Chl-b and nonsorbed carotenes was added to the top of the Sephasorb HP Ultrafine column and the column washed with the developing solvent system I (diethyl ether: hexane=1: 9, volume ratio) to adsorb the pigments at the top of the column and to elute the nonsorbed carotenes from the column. Subsequently the column was washed with 0.2 vol % isopropyl alcohol in the solvent system I to elute Chl-a from the column. After most of the Chl-a had been eluted, the column was washed with 0.5 vol % isopropyl alcohol in the solvent system I to accelerate the elution of Chl-b. The elution pattern is presented in Fig. 1, where the void volume of the column used here was about 59 ml. The chromatogram shows complete separation between Chl-a, Chl-b and nonsorbed carotenes. The Chl-a and Chl-b preparation thus obtained were evaporated and dried in a vacuum desiccator.

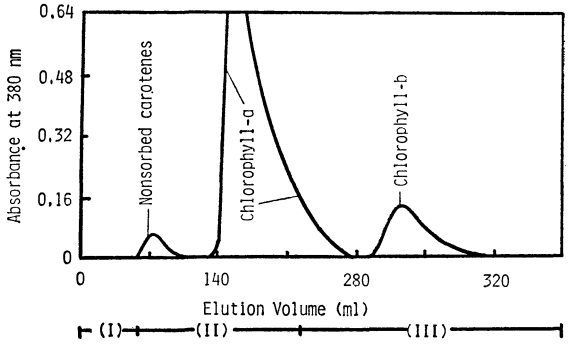

Fig. 1. Chromatogram for Ppt III.[a] Solvent systems for I, II, and III are a diethyl ether/hexane mixture (1: 9, volume ratio), 0.2 vol % isopropyl alcohol in I, and 0.5 vol % isopropyl alcohol in I.
a) For the explanation, see the text.

Thin-layer chromatographic examination of the Chl-a and Chl-b preparations on commercial silica gel sheets showed single spots, respectively. The purity of the Chl-a and Chl-b preparations were further examined by high-performance liquid chromatography[11,12] which supplemented the thin-layer chromatographic observations. The absorption spectra of the Chl-a and Chl-b preparations dissolved in diethyl ether did not show any significant differences in comparison with the literature within experimental error. The ratio of absorbance of the Soret peak at 427.0±1.0 nm to the red peak at 660.0±0.5 nm was 1.30±0.1 for the Chl-a preparation and the ratio of absorbance of the Soret peak at 452.8± 0.3 nm to the red peak at 642.3±0.3 nm was 2.83±0.1 for the Chl-b preparation. The purity of the Chl-a and Chl-b preparations obtained here was greater than 99% on a dry weight basis. 13.1 mg of Chl-a and 7.6 mg of Chl-b were obtained from 24.7 mg of Ppt III using the method developed here. 3.4 mg of nonsorbed carotenes were also isolated. Recovery of the chlorophylls in the column chromatography with Sephasorb HP Ultrafine was about 97%.

The chlorophyll preparations, when isolated in the solid state and stored in evacuated and sealed ampules in total darkness at −20 °C, could be preserved for at least three months without change or alteration. In a few cases, however, the chlorophyll molecules were degraded. For example, Chl-a was converted to chlorophyll-a′ (Chl-a′) and pheophytin-a. Chl-a and Chl-a′ are spectroscopically very similar as well as interconvertible[13] and subsequently spectroscopic observations provide no indication that Chl-a molecules had not altered. It should be noted that the purity of the chlorophyll preparations should be checked by thin-layer or high-performance liquid chromatography before use.

Table 1. Spectral properties of chlorophyll-a and chlorophyll-b with values reported by some authors[a]

	Red peak (nm)	Blue peak (nm)	Absorbance ratio (blue peak/red peak)	Authors
Chlorophyll-a	660.0	429.0	1.32	Comar and Zscheile[b]
	662.0	430.0	1.31	Smith and Benitez[c]

Discussion

The spectral properties of Chl-a and Chl-b in diethyl ether with values reported by some authors are listed in Table 1. The extinction coefficients for Chl-a and Chl-b were not established due to the volatility of diethyl ether at room temperature (20 °C±5). In addition, as diethyl ether has a strong tendency to adsorb moisture from the air and the migration of trace water into chlorophyll solutions in diethyl ether influences the peak positions of Chl-a and Chl-b, the peak positions were shifted to the blue or red regions depending on the water content in solution. Nevertheless, the absorption spectra of the Chl-a and Chl-b preparations dissolved in diethyl ether did not show any significant differences in comparison with the literature values within experimental error as is shown in Table 1. The molar extinction coefficients of Comar and Zscheile,[9] which have been widely used, were used to determine the purity of the Chl-a and Chl-b preparations in this study. The values for the purity of the Chl-a and Chl-b preparations were greater than 99%. Subsequently, the presence of colorless substances as possible contaminants was examined. According to the method of Strain and Svec[10] the preparations were subjected to the test. The purity of the chlorophyll preparations, however, was not higher. In addition, it was found that the Chl-a and Chl-b molecules were degraded during the course of the chlorophyll purification. Thus, the procedure for the elimination of colorless substances from the chlorophyll preparations was not suitable in this case.

There have been no reports on the column chromatographic separation and isolation of chlorophylls with Sephasorb HP Ultrafine and Sephadex LH-20. Sephasorb HP Ultrafine was stable in the solvent systems used in this study as developing solvents. The bed volume obtained on swelling 1 g of dry Sephasorb HP Ultrafine in the solvent systems were relatively small (approximately 1.3 cm^3/g dry gel). No detectable and undesirable substances extracted from Sephasorb HP Ultrafine with the developing solvents used were found. The preparation of Sephasorb HP Ultrafine columns was relatively simple and the column could be used repeatedly for the separation of chlorophylls. In addition, good separation between Chl-a, Chl-b, and nonsorbed carotenes was achieved and Sephasorb HP Ultrafine did not react with chlorophyll molecules to form degradation products of the pigment molecules. For these reasons, Sephasorb HP Ultrafine may be one of the best adsorbents for separating chlorophylls.

The method developed here is suitable for the preparation of Chl-a and Chl-b from Ppt III, which was prepared from spinach leaves according to the method of Iriyama *et al.*[1,2]

Acetoxymethylation of Coumarins by Manganese(III) Acetate

Kazu KUROSAWA* and Hironobu HARADA

Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860

(Received December 27, 1978)

The reactions of 4-methoxy-, 7-methoxy-, 6,7-dimethoxy-, and 7,8-dimethoxycoumarins with manganese(III) acetate in boiling acetic acid containing acetic anhydride gave 3-(acetoxymethyl)coumarins as the major product. The reactions of coumarin, and 6-methoxy- and 8-methoxycoumarins with manganese(III) acetate yielded a mixture of 3-(diacetoxymethyl)- and nuclear acetoxymethylated coumarins. The reaction of 7-methoxycoumarin with lead(IV) acetate gave 7-methoxy-3-methylcoumarin.

In a previous publication[1] we have reported the oxidation of 2-hydroxybenzophenones with manganese(III) acetate, that gave 9-xanthenones and acetoxymethylated 9-xanthenones. The reactions of aromatic hydrocarbons,[2,3] aromatic ethers,[4] and benzofuran,[5] with manganese(III) acetate have been reported to give acetoxymethylated products. The reaction mechanisms were discussed by Heiba *et al.*[2] However, these papers were primarily concerned with the product analyses and the reaction mechanisms, and the synthetic utility was not investigated in detail. In this paper we will describe the reaction of methoxy-substituted coumarins with manganese(III) acetate, that gave 3-(acetoxymethyl)-, 3-(diacetoxymethyl)-, and di(acetoxymethyl)-coumarins. We have also carried out the reaction of 7-methoxycoumarin with lead(IV) acetate, which yielded mainly 7-methoxy-3-methylcoumarin.

The coumarins studied were coumarin (**1a**), 4-methoxycoumarin (**1b**), 6-methoxycoumarin (**1c**), 7-methoxycoumarin (**1d**), 8-methoxycoumarin (**1e**), 6,7-dimethoxycoumarin (**1f**), and 7,8-dimethoxycoumarin (**1g**). The reactions were carried out in boiling acetic acid containing acetic anhydride, and in boiling acetic anhydride, using 6—12 equivalents of manganese(III) acetate dihydrate for 1 equivalent of the substrate. The reactions were continued until the color of manganese(III) acetate disappeared.

The reaction of **1d** in acetic acid containing acetic anhydride in the substrate/oxidant ratio of 1 : 6 gave an acetate (**2d**) (entry 4). The NMR spectrum indicated the presence of an acetoxymethyl group {δ 2.24 (3H, singlet) and δ 5.03 (2H, doublet, J=1.0 Hz)}. The acetoxymethyl group can be located at 3-position, since the methylene protons at δ 5.03 couple with a lower field proton which appeared at δ 7.69 (1H, broad singlet) as was confirmed by a decoupling experiment. An ABX pattern of three aromatic protons was found in the spectrum {δ 6.75—6.90 (2H, multiplet) and 7.48 (1H, m)}. The yield of **2d** increased with increase of the molar ratio of manganese(III) acetate and the maximum yield was attained for the substrate/oxidant ratio of 1 : 10 (entry 6). When the reaction was conducted for this molar ratio, another product (**4d**) was isolated from the reaction mixture, the structure of which was elucidated as before by the NMR spectrum. It showed the presence of two acetoxyl group at δ 2.15 and a doublet proton at δ 7.66 (J=1.0 Hz), indicating that a diacetoxymethyl group is present in the molecule. The presence of an ABX pattern of three aromatic protons and a lower field proton (δ 7.80, broad s) suggested that the diacetoxymethyl group can be located at 3-position (Fig. 1). When the reaction of **1d** with manganese(III) acetate was conducted in acetic anhydride, a complex mixture of products was obtained. In acetic acid, on the other hand, the reaction did not take place. **1b**, **1f**, and **1g** gave the corresponding 3-(acetoxymethyl)coumarin, **2b**, **2f**, and **2g** in the reaction, respectively (entries 2, 13, and 14). In the case of **1g**, 3,6-di(acetoxymethyl)-7,8-dimethoxycoumarin (**5g**) was obtained in a low yield.

In contrast to the coumarins described above, the reactions of **1a**, **1c**, and **1e** with manganese(III) acetate showed a very different product distribution. In the case of **1a**, 3-(diacetoxymethyl)coumarin (**4a**) was the major product and a small amount of impure 3-(acetoxymethyl)coumarin (**2a**) was isolated (entry 1). **1c** gave 3-(diacetoxymethyl)-6-methoxycoumarin (**4c**) and a mixture of 5- and 7-(acetoxymethyl)coumarins (**3c** and **3c'**). The reaction of **1e** with manganese(III) acetate gave three products: **3e**, **4e**, and **6e** (entry 12). The structure of **3e** was elucidated by the NMR analysis: the chemical shifts of an AB system due to the protons at 6- and 5-positions (δ_A=7.00 and δ_B=7.21, J_{AB}=9.0 Hz) are characteristic of the 7,8-disubstituted

14	**1g**	$Mn(OAc)_3$	1:10	AcOH, Ac_2O	90	**2g**(55)	**5g**(3)		

a) The reactions were carried out at reflux temperature.
b) Yields are based on the amount of coumarin consumed.
c) The values were estimated from the NMR spectrum.

coumarin (**1g**), in which the corresponding protons appeared at δ 6.91 and 7.23.

The results described above showed that coumarins bearing a methoxyl group at 4- or 7-position react with the carboxymethyl radical,[2] which is formed from the decomposition of manganese(III) acetate, predominantly at the 3-position, where the electron density is much greater than in the other positions owing to the resonance effect of the methoxyl groups. In coumarins bearing no methoxyl group in either position, the competitive reactions occur at the 3-position and at *ortho*-positions to the methoxyl group on the aromatic nucleus. Diacetoxymethylation takes place in the case when a substrate has no sufficient activating group at 4- or 7-position (entries 1, 3, and 12) or when the oxidant is used in large excess (entry 7). On the contrary, the reaction of **1d** with lead(IV) acetate gave 7-methoxy-3-methylcoumarin (**7d**), when treated with 5 equivalents of lead(IV) acetate in boiling benzene. The methylation of aromatic compounds by lead(IV) acetate has precedence.[1,6] The reaction of **1d** with lead(IV) acetate in acetic acid yielded **2d** and **7d** and in acetic anhydride **2d**, **4d**, and **7d**, but they have no synthetic values.

It is thus concluded that the reaction of coumarins bearing a methoxyl group at 4- or 7-position with manganese(III) acetate can give the corresponding 3-(acetoxymethyl)coumarin in moderately good yields.

Experimental

All ^1H chemical shifts (δ) were recorded for the deuteriochloroform solution with a Hitachi R 24 NMR spectrometer with TMS as an internal standard. The IR spectra were recorded for the chloroform solution with a JASCO IRA-1 grating spectrometer. The mass spectrum was recorded with a JEOL JMS-01 SG-2 mass spectrometer. Melting points were determined on a Yanagimoto hot-stage and are uncorrected. The compounds were recrystallized from ethanol, unless otherwise stated, and the yields are summarized in Table 1.

Coumarins. Coumarin (**1a**) was commercially available. 4-Methoxycoumarin (**1b**) was obtained from commercial 4-hydroxycoumarin by methylation.[7] 6-Methoxycoumarin (**1c**) was obtained from coumarin (**1a**) by potassium peroxodisulfate oxidation followed by methylation.[8] 7-Methoxycoumarin (**1d**) was prepared by the Pechmann reaction[9] of resorcinol and malic acid, followed by methylation. 8-Methoxycoumarin (**1e**) was obtained by the reaction of *o*-vaniline and acetic anhydride.[10] 6,7-Dimethoxycoumarin (**1f**) and 7,8-dimethoxycoumarin (**1g**) were prepared by the Pechmann reaction of the corresponding phenols and malic acid.

*Oxidations of Coumarins (**1a—g**) with Manganese(III) Acetate.* A typical oxidation of coumarin was as follows. A mixture of a coumarin (2 mmol), manganese(III) acetate dihydrate[3] (12—24 mmol), and a solvent (50 ml) (if acetic acid was used as the solvent, acetic anhydride (24—48 mmol) was added) was heated under reflux for the time shown in Table 1. After the removal of the solvent *in vacuo*, the resulting mixture was extracted with chloroform. The chloroform solution was evaporated and chromatogrammed on TLC using chloroform as the developing solvent.

1a yielded 3-(acetoxymethyl)coumarin (**2a**). Mp: 106.5—107.5 °C; IR 1740 cm^{-1}; NMR 2.15 (3H, s, OAc), 5.07 (2H, d, J=1.0 Hz, $-CH_2-$), 7.1—7.7 (4H, m, aromatic), and 7.74 (1H, t, J=1.0 Hz, $H_{(4)}$); 3-(diacetoxymethyl)coumarin (**4a**): Mp 139—140 °C; IR 1750 and 1780 cm^{-1}; NMR 2.18 (6H, s, 2×OAc), 7.1—7.7 (4H, m, aromatic), 7.75 (1H, d, J=1.0 Hz, >CH–), and 7.92 (1H, broad s, $H_{(4)}$); MS *m/e* 276 (M^+), 233, 216, 191, 176, 175, 174, 173, 149, and 146 (Found: C, 60.99; H, 4.41%. Calcd for $C_{14}H_{12}O_6$: C, 60.87; H, 4.38%).

1b gave 3-(acetoxymethyl)-4-methoxycoumarin (**2b**). Mp: 114—115 °C; IR: 1740 cm^{-1}; NMR: 2.10 (3H, s, OAc), 4.16 (3H, s, OCH_3), 5.18 (2H, s, $-CH_2-$), 7.15—7.90 (4H, m, aromatic) (Found: C, 63.00; H, 4.92%. Calcd for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%).

1c yielded a mixture of 5-(acetoxymethyl)- and 7-(acetoxymethyl)-6-methoxycoumarins (**3c** and **3c'**). Mp: 119—123 °C.

(Found: C, 63.22; H, 4.90%. Calcd for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%); 3-(diacetoxymethyl)-6-methoxycoumarin (**4c**). Mp: 175—177 °C; IR: 1745 and 1778 cm^{-1}; NMR: 2.15 (6H, s, 2×OAc), 3.85 (3H, s, OCH_3), 6.9—7.4 (3H, m, aromatic), 7.70 (1H, d, J=1.0 Hz, >CH–), and 7.83 (1H, broad s, $H_{(4)}$) (Found: C, 58.62; H, 4.62%. Calcd for $C_{15}H_{14}O_7$: C, 58.82; H, 4.61%).

1d gave 3-(acetoxymethyl)-7-methoxycoumarin (**2d**). Mp: 118—119 °C; IR: 1725 and 1755 cm^{-1}; NMR: 2.24 (3H, s, OAc), 3.86 (3H, s, OCH_3), 5.03 (2H, d, J=1.0 Hz, $-CH_2-$), 6.75—6.90 (2H, m, $H_{(6)}$ and $H_{(8)}$), 7.48 (1H, m, $H_{(5)}$), and 7.69 (1H, broad s, $H_{(4)}$) (Found: C, 62.72; H, 4.93%. Calcd for $C_{13}H_{12}O_5$: C, 62.90: H, 4.87%); 3-(diacetoxymethyl)-7-methoxycoumarin (**4d**). Mp: 147—149 °C; IR: 1745 and 1775 cm^{-1}; NMR: 2.15 (6H, s, 2×OAc), 3.89 (3H, s, OCH_3), 6.79—6.95 (2H, m, $H_{(6)}$ and $H_{(8)}$), 7.40 (1H, d, J=9.5 Hz, $H_{(5)}$), 7.66 (1H, d, J=1.0 Hz, >CH–), and 7.80 (1H, broad s, $H_{(4)}$) (Found: C, 58.72; H, 4.69%. Calcd for $C_{15}H_{14}O_7$: C, 58.82; H, 4.61%).

1e yielded 7-(acetoxymethyl)-8-methoxycoumarin (**3e**). Mp: 121—122 °C; IR: 1750 cm^{-1}; NMR: 2.05 (3H, s, OAc), 3.92 (3H, s, OCH_3), 5.21 (2H, s, $-CH_2-$), 6.48 (1H, d, J=10.0 Hz, $H_{(3)}$), 7.00 (1H, d, J=9.0 Hz, $H_{(6)}$), 7.21 (1H, d, J=9.0 Hz, $H_{(5)}$), and 7.90 (1H, d, J=10.0 Hz, $H_{(4)}$) (Found: C, 62.73; H, 5.18%. Calcd for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%); 3-(diacetoxymethyl)-8-methoxycoumarin (**4e**). Mp: 130—131 °C (CCl_4); IR: 1752 and 1775 cm^{-1}; NMR: 2.15 (6H, s, 2×OAc), 3.96 (3H, s, OCH_3), 6.8—7.4 (3H, m, aromatic), 7.70 (1H, d, J=1.0 Hz, >CH–), 7.85 (1H, broad s, $H_{(4)}$) (Found: C, 58.90; H, 4.72%. Calcd for $C_{15}H_{14}O_7$: C, 58.82; H, 4.61%); 3-formyl-8-methoxycoumarin (**6e**). Mp: 166—168 °C; IR: 1724 and 1750 cm^{-1}; NMR: 3.97 (3H, s, OCH_3), 7.24 (3H, s, aromatic), 8.36 (1H, s, $H_{(4)}$), and 10.17 (1H, s, CHO) (Found: C, 64.70; H, 3.89%. Calcd for $C_{11}H_8O_4$: C, 64.70; H, 3.95%).

1f gave 3-(acetoxymethyl)-6,7-dimethoxycoumarin (**2f**). Mp: 140—141 °C; IR: 1730 and 1740 cm^{-1}; NMR: 2.14 (3H, s, OAc), 3.91 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 5.06 (2H, d, J=1.0 Hz, $-CH_2-$), 6.85 (1H, s, $H_{(5)}$ or $H_{(8)}$), 6.91 (1H, s, $H_{(5)}$ or $H_{(8)}$), and 7.70 (1H, broad s, $H_{(4)}$). Found: C, 60.30; H, 5.15%. Calcd for $C_{14}H_{14}O_6$: C, 60.43; H, 5.07%.

1g yielded 3-(acetoxymethyl)-7,8-dimethoxycoumarin (**2g**). Mp: 140 °C; IR: 1750 cm^{-1}; NMR: 2.14 (3H, s, OAc), 3.95 (6H, s, 2×OCH_3), 5.00 (2H, d, J=1.0 Hz, $-CH_2-$), 6.92 (1H, d, J=9.0 Hz, $H_{(6)}$), 7.22 (1H, d, J=9.0 Hz, $H_{(5)}$), and 7.69 (1H, t, J=1.0 Hz, $H_{(4)}$) (Found: C, 60.32; H, 5.02%. Calcd for $C_{14}H_{14}O_6$: C, 60.43; H, 5.07%); 3,6-di(acetoxymethyl)-7,8-dimethoxycoumarin (**5g**). Mp: 159—160 °C; IR: 1750 cm^{-1}; NMR: 2.09 (3H, s, OAc), 2.14 (3H, s, OAc), 3.96 (6H, s, 2×OCH_3), 5.00 (2H, d, J=1.0 Hz, $-CH_2-$), 5.23 (2H, s, $-CH_2-$), 6.91 (1H, s, $H_{(5)}$), and 7.87 (1H, t, J=1.0 Hz, $H_{(4)}$) (Found: C, 58.59; H, 5.25%. Calcd for $C_{17}H_{18}O_8$: C, 58.28; H, 5.18%).

Oxidation of ***1d*** *with Lead(IV) Acetate.* A mixture of **1d** (2 mmol), lead(IV) acetate[11] (10 mmol), and a solvent (50 ml) was heated under reflux for the time shown in Table 1. After the removal of the solvent *in vacuo*, the resulting mixture was extracted with chloroform. The chloroform solution was evaporated and then chromatogrammed on TLC, giving **2d**. Mp: 118—119 °C. **4d**. Mp: 147—149 °C. 7-Methoxy-3-methylcoumarin (**7d**). Mp: 144 °C (lit,[12] mp 144 °C); IR: 1725 cm^{-1}; NMR: 2.17 (3H, d, J=1.5 Hz, CH_3), 3.85 (3H, s, OCH_3), 6.65—6.90 (2H, m, $H_{(6)}$ and $H_{(8)}$), 7.39 (1H, m, $H_{(5)}$), and 7.44 (1H, q, J=1.5 Hz, $H_{(4)}$).

A Simple Synthesis of α-Ylidene γ-Lactones from γ-Trimethylsiloxy Nitriles

Isamu MATSUDA,* Shizuaki MURATA, and Yusuke IZUMI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 5, 1979)

α-Cyano carbanions which are generated from γ-trimethylsiloxy nitriles have been found to react with aldehydes to give α-(1-hydroxyalkyl)-γ-trimethylsiloxy nitriles (**6**). α-Ylidene γ-lactones (**5**) are derived from **6** in two steps; hydrolytic lactonization to α-(1-hydroxyalkyl) γ-lactones and dehydration. The stereochemistry of the lactones **5** with one exception have been found to be of the *E* form on the basis of the NMR spectra.

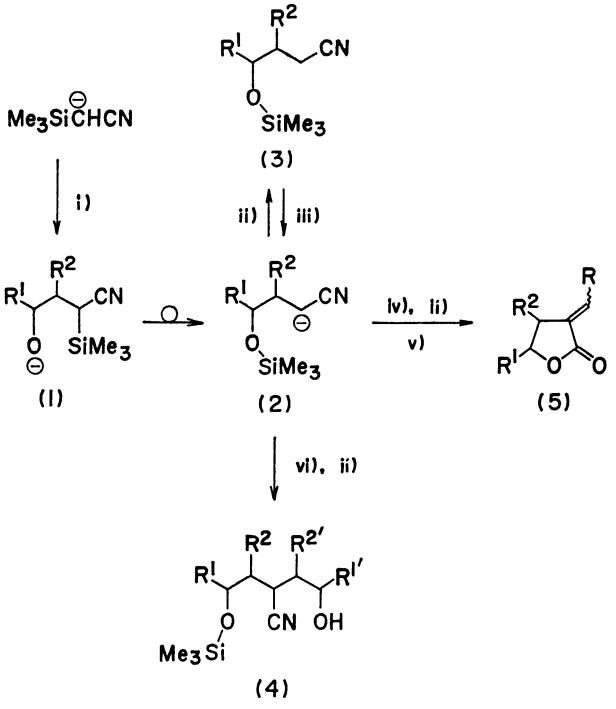
α-Methylene-γ-butyrolactones have recently been the subject of extensive research since several sesquiterpenes possess cytotoxic and/or antitumor properties, largely attributed to this system.[1,2] A variety of methods have been developed for the synthesis of this moiety,[3,4] most of the procedures involving the introduction of the α-methylene group into a preformed lactone *via* the enolate anion.[5,6]

In a previous paper,[7] it was shown that the trimethylsilylacetonitrile (TMSAN) anion reacts readily and selectively with epoxides to produce γ-trimethylsiloxy nitriles **3** which are a possible synthetic equivalent of γ-lactones. This paper will report a method for the facile introduction of the α-methylene or alkylidene equivalent group into γ-lactones by the reaction of α-cyano carbanions **2** with aldehydes as a demonstration of the synthetic versatility of γ-trimethylsiloxy nitriles **3**.

Results and Discussion

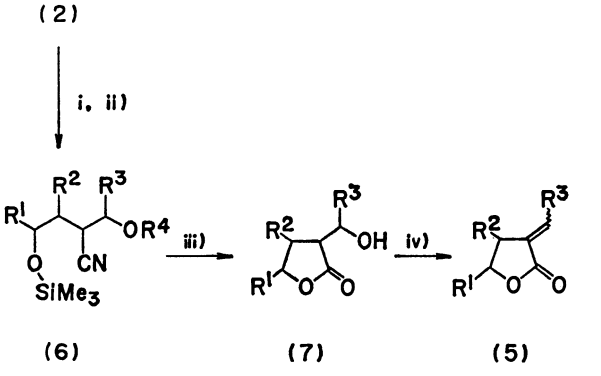
The dianion character of TMSAN has been suggested in the stepwise ring opening of two equivalents of epoxide.[7] This unusual character is brought about by the intermediate **2** which is generated as a result of the migration of the trimethylsilyl group from the carbon atom to the oxy anion in **1** as shown in Scheme 1. The intermediate **2** has been confirmed by the stepwise addition of different types of epoxide. Substitution of aldehydes in place of epoxides in the reaction of the anion **2** would be expected to give the α-(1-hydroxyalkyl)-γ-trimethylsiloxy nitriles as products which lead to α-alkylidene γ-lactones by additional two steps.

An equivalent of benzaldehyde was added to a solution of **2b** (R^1=Me, R^2=H) formed from the TMSAN anion and propylene oxide in 1,2-dimethoxyethane (DME) and quenched with water, which produced an unexpected product, α-benzylidene γ-lactone **5b** (7%) in addition to other products. Lactone **5c** (6%) was obtained by a similar reaction of benzaldehyde with **2c** [R^1, R^2=$-(CH_2)_4-$]. Lactones **5b** and **5c** were given after purification of the reaction mixture by column chromatography on silica gel. Despite the low yield of **5** under optimum conditions, the result is noteworthy since this one pot reaction provides a general synthetic method for **5**. The reactivity of the anion **2** to aldehydes may decrease since it takes several hours to complete the formation of **2**. Therefore, alternative anions **2** from γ-trimethylsiloxy nitriles **3** have been used in order to enhance the selectivity of nucleophilic attack on the aldehydes. An efficient preparative method for γ-trimethylsiloxy nitriles **3** has been exploited on a large scale.[8] The outline of the procedure is summarized in Scheme 2.



Scheme 1. i) $R^1CH(O)CHR^2$, ii) aq NH_4Cl, iii) LDA, iv) RCHO, v) Silica gel, vi) $R^1CH(O)CHR^2$.

α-Cyano carbanions **2** are generated smoothly by the interaction of nitriles **3** with an equivalent of butyl-



Scheme 2. i) R^3CHO, ii) aq NH_4Cl or Me_3SiCl, iii) 1.5 M. HCl, iv) $MeSO_2Cl$/pyridine, reflux.

TABLE 1. YIELDS OF PRODUCTS AND STEREOISOMERS OF **5**

h	$-(CH_2)_4-$		H	H	77	85	47	—

lithium or lithium diisopropylamide (LDA) in tetrahydrofuran (THF) at −78 °C and react with aldehydes at ambient temperature. After quenching the reaction mixture with either aqueous ammonium chloride (a, b, c, f, g, and h) or chlorotrimethylsilane (d and e), α-(1-hydroxyalkyl)- or (1-trimethylsiloxyalkyl)-γ-trimethylsiloxy nitriles **6** are given. Compounds **6** hydrolyzed with 1.3 M hydrochloric acid in aqueous methanol spontaneously give α-(1-hydroxyalkyl)-γ-lactones **7**. The elimination of water from **7** is achieved by the use of methanesulfonyl chloride in pyridine giving α-alkylidene γ-lactones **5**, the results of which are summarized in the Table.

The structure of **5**, **6**, and **7** have been elucidated on the basis of IR, NMR, and elemental analyses. The IR spectra of **6** is analogous to **4**. The splitting of the trimethylsilyl group in the NMR spectra of **6** reflects the discrimination of diastereomers caused by asymmetric carbon atoms.[7] For example, two separate signals of the trimethylsilyl group at 0.16 and 0.20 ppm are observed and the terminal methyl group is clearly distinguished at 1.28 and 1.40 ppm in the case of **6f**.

The NMR spectra of **7** are more complicated due to the increase in rigidity of the conformations with the formation of lactone rings. The ring methyl group of **7e** appears as a double doublet (J=6.45 and 2.1 Hz) including long range coupling at 1.18 ppm while a pair of doublet at 1.37 and 1.43 ppm (J=6.3 Hz) has been assigned to the terminal methyl of the 1-hydroxyethyl group.

From the NMR spectra and an inspection of the CPK models it was possible to establish the stereochemistry around the olefinic part of the obtained α-alkylidene γ-lactones **5**. The chemical shift of the olefinic proton (6.81 and 6.36 ppm for *E* and *Z* isomers, respectively) is the most remarkable diagnostic point to discriminate between the geometrical isomers of α-ethylidene-γ-butyrolactone **5d**.[9] The observed values of the olefinic proton, 6.77, 6.64, and 6.51 ppm in a series of α-ethylidene γ-lactones (**5d**, **5e**, and **5f**) enabled the *E* isomers to be differentiated. This was coupled with the knowledge that the vinyl proton located in the cis position to the carbonyl group shows significant down field shift (0.6—0.9 ppm) compared with the trans proton in the cases of α-methylene cycloalkanones[10] and α-methylene γ-lactones **5g** and **5h**.

With respect to the α-benzylidene γ-lactones **5a**, **5b**, and **5c**, the olefinic protons show peaks at 7.54, 7.3, and 6.53 ppm, respectively. Relatively sharp peaks at 7.45 and 7.30 ppm have been observed for the phenyl protons of **5a** and **5b**. The multiplet pattern of the phenyl protons divided in two groups with a 3:2 intensity ratio at 7.3 and 7.7 ppm for **5c**, reflecting the different susceptibility among the phenyl protons towards the magnetic anisotropy effect by the carbonyl group. Therefore, it has been concluded that lactones **5a**[11] and **5b** are the *E* isomers whereas **5c** is the *Z* isomer based on the above data. The other isomer is not detectable from the NMR spectra. The selective formation of the isomer **5a**—**5f** shows that the elimination step (**7** to **5**) is a thermodynamically controlled reaction *via* a carbocation intermediate under the above conditions. The formation of the *Z* isomer in **5c** is consistent according to a comparison of both isomers by the CPK models. The *Z* isomer of **5c** is sterically less hindered than the *E* isomer.

The ring juncture in the bicyclo system **5c**, **5f**, and **5g** has been designated trans based on the following. The starting material **3c** has been prepared by the ring opening of cyclohexene oxide with the acetonitrile anion, which arranges the trans relationship between the two substituents.[12] The coupling pattern of the junctional proton in close proximity to the oxygen atom in **5c**, **5f**, and **5g** shows a typical doublet of triplet composed of six peaks (see Experimental). The coupling constants of this pattern reflect the presence of two axial and an equatorial vicinal protons, which suggests a trans juncture in **5**.

The synthesis is attractive as one of the preparative methods of versatile α-ylidene γ-lactones since the preparation involves no specific reagent.

Experimental

The IR spectra were recorded on JASCO IR-403G and IR-S instruments. A JEOL C-60 HL instrument was used to record the ^1H NMR spectra using tetramethylsilane as the internal standard. Trimethylsilylacetonitrile[7] and γ-trimethylsiloxy nitriles[8] were prepared according to the literature. Formaldehyde was generated by the cracking of dried paraformaldehyde. Acetaldehyde was distilled prior to use. Purification of the products was conducted by column chromatography on silica gel using a mixed solvent as eluent (benzene: hexane: ethanol=1: 1: 1/20—1/40).

Synthesis of 5. *α-Benzylidene-γ-valerolactone (5b)*: To a DME (25 ml) solution of the TMSAN anion prepared from TMSAN (1.70 g, 15.0 mmol) and an equivalent of LDA was added a DME (3 ml) solution of propylene oxide (0.87 g, 14.9 mmol) at −78 °C. After stirring for 5 h at −30 °C—

−20 °C, the reaction mixture was cooled to −78 °C and a DME (5 ml) solution of benzaldehyde (1.59 g, 15.0 mmol) added at the same temperature. After the addition, the mixture was stirred for 1 h at −30 °C and for 14 h at ambient temperature and quenched with saturated aqueous NH_4Cl (25 ml). The organic layer was extracted with dichloromethane (20 ml×5). The combined extracts were washed with saturated brine and dried over anhydrous $MgSO_4$. The solvent was evaporated under reduced pressure. Column chromatography of the residue gave 1.20 g (47%) of **3b** and 0.614 g of a yellow oily product ($\nu_{C=O}$ 1750 cm^{-1}). The oily product gave the pure lactone **5b** (0.196 g, 7%) as a yellow oil after purification, which crystallized on standing, mp 54—54.5 °C. Found: C, 76.65; H, 6.73%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%. IR (KBr disk) 1741 ($\nu_{C=O}$) and 1652 cm^{-1} ($\nu_{C=C}$). ^1H NMR (CCl_4) δ 1.42 (d, J=6.3 Hz, 3H, C<u>H</u>$_3$), 2.63 (d of double d, J=17.3, 5.7, and 3.3 Hz, 1H, C<u>H</u>$_2$), 3.28 (d of double d, J=17.3, 7.8, and 3.1 Hz, 1H, C<u>H</u>$_2$), 4.59 (dd of quartet, J=7.8, 5.7, and 6.3 Hz, 1H, C<u>H</u>–O), and 7.30 ppm (m, 6H, Ph and C=C(H)Ph).

trans-9-Benzylidene-7-oxabicyclo[4.3.0]nonan-8-one (5c): Similarly, from a DME (25 ml) solution of the TMSAN anion (8.05 mmol), cyclohexene oxide (0.793 g, 8.08 mmol), and benzaldehyde (1.02 g, 9.59 mmol), pure **5c** (0.11 g, 6%) was obtained as colorless needles in addition to **3c** (0.989 g, 58%), mp 146—147.5 °C. Found: C, 78.93; H, 7.37%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.07%. IR (KBr disk) 1740 ($\nu_{C=O}$) and 1652 cm^{-1} ($\nu_{C=C}$). NMR ($CDCl_3$) δ 1.2—1.7 (m, 9H, cyclohexyl ring protons), 3.75 (d of t, J=3.9 and 10.7 Hz, 1H, C<u>H</u>–O), 6.35 (d, J=3.0 Hz, 1H, C=C(H)), 7.3 (m, 3H, Ph), and 7.7 ppm (m, 2H, Ph).

Synthesis of α-(1-Hydroxyalkyl)-γ-trimethylsiloxy Nitriles (6).

2-Cyano-1-phenyl-4-trimethylsiloxy-1-butanol (6a): To a THF solution of LDA (10.5 mmol) was added a THF (5 ml) solution of **3a** (1.57 g, 9.99 mmol) at −78 °C. The mixture was stirred for 1 h at the same temperature to complete the formation of the anion **2a**. A THF (5 ml) solution of benzaldehyde (0.536 g, 5.05 mmol) was added to the anion solution at −78 °C. The mixture was stirred for 30 min at −78 °C and for 15 h at ambient temperature and the reaction mixture quenched with saturated aq NH_4Cl (30 ml). The organic layer was decanted and the water layer extracted with dichloromethane (20 ml×5). The organic layer and the extracts were collected, washed with saturated brine, and dried over $MgSO_4$. The residue obtained after evaporation of the solvent under reduced pressure was chromatographed to give 1.65 g (63%) of a pale yellow oil, **6a**. Found: C, 63.72; H, 8.13; N, 5.41%. Calcd for $C_{14}H_{21}NO_2Si$: C, 63.84; H, 8.04; N, 5.32%. IR (CCl_4) 3620, 3440, (ν_{O-H}), 2270 ($\nu_{C\equiv N}$), and 1250 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.12 (s, 9H, Si–C<u>H</u>$_3$), 1.6—2.0 (broad m, 2H, C<u>H</u>$_2$CCN), 3.12 (q, J=6.0 Hz, 1H, C<u>H</u>–CN), 3.80 (t, J=6.0 Hz, 2H, C<u>H</u>$_2$–O–Si), 4.2 (broad, 1H, O<u>H</u>), 4.9 (broad, 1H, C<u>H</u>–Ph), and 7.50 ppm (s, 5H, Ph).

2-Cyano-1-phenyl-4-trimethylsiloxy-1-pentanol (6b): The analogous treatment of **3b** (0.957 g, 5.59 mmol) with butyllithium (5.1 mmol) and benzaldehyde (0.536 g, 5.05 mmol) in THF (25 ml) gave pure **6b** as a yellow oil (1.14 g, 82%). Found: C, 64.71; H, 8.57; N, 5.13%. Calcd for $C_{15}H_{23}NO_2Si$: C, 64.94; H, 8.34; N, 5.05%. IR (CCl_4) 3620, 3430 (ν_{O-H}), 2260 ($\nu_{C\equiv N}$), and 1249 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.10 (s, 9H, Si–C<u>H</u>$_3$), 1.12 (d, J=6.0 Hz, 3H, C<u>H</u>$_3$), 1.55 (m, 2H, C<u>H</u>$_2$), 2.78 (m, 1H, C<u>H</u>–CN), 3.9 (broad m, 2H, O–<u>H</u> and SiO–C<u>H</u>), 4.57 (broad, 1H, Ph–C<u>H</u>–O), and 7.23 ppm (s, 5H, Ph).

3-Hydroxy-3-phenyl-2-(trans-2-trimethylsiloxycyclohexyl)propionitrile (6c): The analogous treatment of **3c** (1.50 g, 7.09 mmol) with LDA (7.40 mmol) and benzaldehyde (0.781 g, 7.40 mmol) in THF (25 ml) gave **6c** as a yellow oil (1.88 g, 84%). Found: C, 68.13; H, 8.62; N, 4.48%. Calcd for $C_{18}H_{27}NO_2Si$: C, 68.09; H, 8.57; N, 4.41%. IR (CCl_4) 3640, 3430 (ν_{O-H}), 2265 ($\nu_{C\equiv N}$), and 1249 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.10 (s, 9H, Si–C<u>H</u>$_3$), 1.0—2.1 (broad m, 9H), 2.96 (broad s, 1H, O<u>H</u>), 3.26 (double d, J=9.2 and 2.9 Hz, 1H, C<u>H</u>–CN), 3.4 (broad m, 1H, C<u>H</u>–OSi), 4.68 (d, J=9.2 Hz, 1H, Ph–C<u>H</u>–O), and 7.34 ppm (m, 5H, Ph).

3-Cyano-1,4-bis(trimethylsiloxy)pentane (6d): LDA (10.4 mmol), **3a** (1.55 g, 10.1 mmol), and acetaldehyde (0.6 ml, 10.7 mmol) were mixed in a similar manner in THF (30 ml) and quenched with Me_3SiCl (1.56 g, 14.4 mmol). After evaporation of the solvent, the residue was diluted with Et_2O (30 ml) and the solution filtered. Pure **6d** (1.77 g, 65%) was obtained as a yellow liquid. Found: C, 52.43; H, 9.75; N, 5.40%. Calcd for $C_{12}H_{27}NO_2Si_2$: C, 52.69; H, 9.95; N, 5.12%. IR (CCl_4) 2280 ($\nu_{C\equiv N}$) and 1248 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.14, 0.16 (each s, 18H, Si–C<u>H</u>$_3$), 1.29 (d, J=6.3 Hz, 3H, C<u>H</u>$_3$), 1.74 (q, J=6.3 Hz, 2H, C<u>H</u>$_2$CCN), 2.2—2.9 (m, 1H, C<u>H</u>–CN), 3.74 (t, J=6.3 Hz, 2H, C<u>H</u>$_2$–O), and 3.93 ppm (q, J=6.3 Hz, 1H, C<u>H</u>–O).

3-Cyano-2,5-bis(trimethylsiloxy)hexane (6e): The analogous treatment of **3b** (1.38 g, 8.03 mmol) with acetaldehyde (0.5 ml, 8.9 mmol) and Me_3SiCl (1.31 g, 12.1 mmol) gave pure **6e** (1.59 g, 69%) as a pale yellow liquid. Found: C, 54.54; H, 10.02; N, 4.91%. Calcd for $C_{13}H_{29}NO_2Si_2$: C, 54.30; H, 10.17; N, 4.87%. IR (CCl_4) 2265 ($\nu_{C\equiv N}$) and 1249 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.12, 0.14 (each s, 18H, Si–C<u>H</u>$_3$), 1.18 (d, J=6.9 Hz, 3H, O–C–C<u>H</u>$_3$), 1.25 (d, J=7.2 Hz, 3H, O–C–C<u>H</u>$_3$), 1.65 (t, J=6.9 Hz, 2H, C<u>H</u>$_2$), 2.43 (m, 1H, C<u>H</u>–CN), and 3.89 ppm (m, 2H, 2×C<u>H</u>–O).

3-Hydroxy-2-(trans-2-trimethylsiloxycyclohexyl)butyronitrile (6f): The analogous treatment of **3c** (3.85 g, 18.2 mmol) with LDA (18.7 mmol) and acetaldehyde (1.1 ml, 19 mmol) in THF (60 ml) gave a colorless oil of pure **6f** (2.96 g, 64%). Found: C, 61.10; H, 9.80; N, 5.44%. Calcd for $C_{13}H_{25}NO_2Si$: C, 61.13; H, 9.87; N, 5.48%. IR (CCl_4) 3660, 3390 (ν_{O-H}), 2275 ($\nu_{C\equiv N}$), and 1250 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.16, 0.20 (each s, 9H, Si–C<u>H</u>$_3$), 1.28, 1.40 (each d, J=6.0 Hz, 3H, C<u>H</u>$_3$), 1.1—2.1 (m, 9H, ring protons), 2.4—2.9 (m, 1H, C<u>H</u>–CN), and 3.2—4.1 ppm (m, 3H, O–H and 2×C<u>H</u>–O).

2-Hydroxymethyl-4-(trimethylsiloxy)pentanenitrile (6g): Into a solution of **2b** formed from LDA (10.5 mmol) and **3b** (1.71 g, 9.99 mmol) was bubbled gaseous formaldehyde (0.61 g, 20.4 mmol) in a stream of nitrogen at −78 °C in THF (40 ml). After a work up of the mixture similar to that described above, pure **6g** (1.18 g, 59%) was obtained as a colorless oil. Found: C, 53.45; H, 9.74; N, 7.05%. Calcd for $C_9H_{19}NO_2Si$: C, 53.69; H, 9.51; N, 6.96%. IR (CCl_4) 3650, 3460 (ν_{O-H}), 2270 ($\nu_{C\equiv N}$), and 1246 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.13, 0.15 (each s, 9H, Si–C<u>H</u>$_3$), 1.20 (d, J=6.0 Hz, C<u>H</u>$_3$), 1.45—1.93 (m, 2H, C<u>H</u>$_2$–C–O), 2.7 (m, 1H, C<u>H</u>–CN), 3.72 (d, J=6.0 Hz, 2H, C<u>H</u>$_2$–O), 3.7 (broad, 1H, O–<u>H</u>), and 3.93 ppm (quint, J=6.0 Hz, C<u>H</u>–O).

3-Hydroxy-2-(trans-2-trimethylsiloxycyclohexyl)propionitrile (6h): The analogous treatment of **3c** (2.55 g, 12.0 mmol) with LDA (12.5 mmol) and formaldehyde (30 mmol) gave pure **6h** as a colorless oil (2.22 g, 77%). Found: C, 59.93; H, 9.88; N, 6.16%. Calcd for $C_{12}H_{23}NO_2Si$: C, 59.71; H, 9.60; N, 5.80%. IR (CCl_4) 3660, 3440 (ν_{O-H}), 2270 ($\nu_{C\equiv N}$), and 1249 cm^{-1} ($\delta_{s,Si-C_3}$). NMR (CCl_4) δ 0.15 (s, 9H, Si–C<u>H</u>$_3$), 1.1—2.0 (broad, 9H, ring protons), 2.93 (broad s, 1H, O–<u>H</u>), 3.0—3.6

(m, 2H, CH–CN and CH–O), and 3.6—3.85 ppm (m, 2H, CH_2–O).

Synthesis of α-(1-Hydroxyalkyl) γ-Lactones (7). *α-(α-Hydroxybenzyl)-γ-butyrolactone (7a)*: A solution of **6a** (1.27 g, 4.71 mmol) in concd HCl (3 ml) and MeOH (22 ml) was refluxed for 4 h. The mixture was poured into H_2O (100 ml), neutralized with aq $NaHCO_3$, and extracted with dichloromethane (20 ml×5). The extracts were combined, washed with water, and dried over $MgSO_4$. The crude product obtained after evaporation of the solvent was purified by chromatography to give pure **7a** (0.697 g, 77%) as colorless needles, mp 107—109 °C. Found: C, 68.81; H, 6.29%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%. IR (KBr disk) 3420 (ν_{O-H}) and 1744 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$) δ 1.75—2.7 (m, 2H, CH–CH_2), 2.75—3.1 (m, 2H, CH–C=O and O–H), 3.9—4.4 (m, 2H, CH_2–O), 4.81, 4.84 (each d, J=8.7 Hz), 5.38, 5.39 (each d, J=5.0 Hz, 1H for 4 peaks, CH–O), and 7.30 ppm (s, 5H, Ph).

α-(α-Hydroxybenzyl)-γ-valerolactone (7b): The treatment of **6b** (2.06 g, 7.43 mmol) with concd HCl (4 ml) in MeOH (25 ml) gave pure **7b** (1.17 g, 73%) as a yellow oil. Found: C, 69.80; H, 7.14%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%. IR (CCl_4) 3630, 3460 (ν_{O-H}), and 1765 cm^{-1} ($\nu_{C=O}$). NMR (CCl_4) δ 1.22 (d, J=6.4 Hz), 1.32 (d, J=5.5 Hz, 3H for two signals, CH_3), 1.5—2.5 (m, 2H, CH_2), 2.6—3.0 (m, 1H, CH–C=O), 4.0 (broad, 1H, O–H), 4.1—5.2 (m, 2H, 2×CH–O), and 7.20 ppm (m, 5H, Ph).

trans-*9-(α-Hydroxybenzyl)-7-oxabicyclo[4.3.0]nonan-8-one (7c)*: **6c** was treated (1.53 g, 4.83 mmol) with concd HCl (3 ml) in DME (30 ml) and pure **7c** (0.571 g, 48%) was obtained as pale yellow needles, mp 180—183 °C. Found: C, 73.42; H, 7.67%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%. IR (KBr disk) 3450 (ν_{O-H}) and 1755 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$) δ 1.0—2.3 (m, 9H, ring protons), 2.73 (double d, J=12.0 and 3.0 Hz, 1H, CH–C=O), 2.93 (broad, 1H, O–H), 3.64 (m, 1H, CH–O), 5.38 (broad d, J=3 Hz, 1H, Ph–CH–O), and 7.32 ppm (m, 5H, Ph).

α-(1-Hydroxyethyl)-γ-butyrolactone (7d): Treatment of **6d** (1.33 g, 4.87 mmol) with concd HCl (4 ml) in MeOH (30 ml) gave **7d** (0.397 g, 63%) as a pale yellow liquid. Found: C, 55.18; H, 7.96%. Calcd for $C_6H_{10}O_3$: C, 55.37; H, 7.75%. IR ($CHCl_3$) 3620, 3480 (ν_{O-H}), and 1764 cm^{-1} ($\nu_{C=O}$). NMR (CCl_4) δ 1.30 (d, J=6.2 Hz, 3H, CH_3), 1.8—2.6 (m, 3H, CH–C=O and CH_2–CH), and 3.3—4.5 ppm (m, 4H, O–H, CH–OH, and CH_2–O).

α-(1-Hydroxyethyl)-γ-valerolactone (7e): Treatment of **6e** 0.68 g, 2.36 mmol) with concd HCl (2 ml) in MeOH (15 ml) gave **7e** (0.237 g, 70%) as a yellow liquid. Found: C, 58.05; H, 8.55%. Calcd for $C_7H_{17}O_3$: C, 58.31; H, 8.39%. IR ($CHCl_3$) 3480 (ν_{O-H}) and 1755 cm^{-1} ($\nu_{C=O}$). NMR (CCl_4) δ 1.18 (double d, J=6.45 and 2.1 Hz, 3H, CH_3–CH), 1.37 (d, J=6.3 Hz), 1.43 (d, J=6.3 Hz, 3H for two signals, CH_3–C–O), 1.9—2.7 (m, 3H, CH_2 and CH–C=O), 3.7—4.0 (m, 2H, O–H and CH–O–C=O), and 4.3—4.8 ppm (m, 1H, CH–O).

trans-*9-(1-Hydroxyethyl)-7-oxabicyclo[4.3.0]nonan-8-one (7f)*: Treatment of **6f** (1.75 g, 6.84 mmol) with concd HCl (4 ml) in DME (25 ml) gave pure **7f** (0.865 g, 69%) as colorless needles, mp 99—105 °C. Found: C, 65.10; H, 8.98%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%. IR (KBr disk) 3430 (ν_{O-H}), 1764 and 1749 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$) δ 1.42 (d, J=6.2 Hz, 3H, CH_3), 1.2—2.5 (m, 10H), and 4.2 ppm (broad, 3H, O–H and 2×CH–O).

α-Hydroxymethyl-γ-valerolactone (7g): Treatment of **6g** (1.08 g, 15.36 mmol) with concd HCl (3 ml) in MeOH (25 ml) gave pure **7g** (0.445 g, 63%) as a colorless liquid. Found: C, 55.55; H, 7.99%. Calcd for $C_6H_{10}O_3$: C, 55.37; H, 7.75%. IR ($CHCl_3$) 3400 (ν_{O-H}) and 1759 cm^{-1} ($\nu_{C=O}$). NMR (CCl_4) δ 1.25—1.50 (m, 3H, CH_3), 1.9—2.9 (m, 2H, CH_2), and 3.5—4.9 ppm (m, 4H, O–H, CH–O, and CH_2–O).

trans-*9-Hydroxymethyl-7-oxabicyclo[4.3.0]nonan-8-one (7h)*: Treatment of **6h** (0.490 g, 2.03 mmol) with concd HCl (2 ml) in DME (15 ml) gave pure **7h** (0.293 g, 85%) as a colorless solid, mp 55—56 °C. Found: C, 63.54; H, 8.43%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. IR (KBr disk) 3415 (ν_{O-H}) and 1756 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$) δ 1.2—2.8 (m, 11H, ring protons, CH–C=O, and O–H), and 3.7—4.3 ppm (m, 3H, CH_2–O and CH–O).

Synthesis of α-Alkylidene γ-Lactones (5). *α-Benzylidene-γ-butyrolactone (5a)*: A mixture of **7a** (0.305 g, 1.48 mmol) and methanesulfonyl chloride (0.14 ml) in pyridine (5 ml) was refluxed for 3 h. The reaction mixture was poured into ice (50 g) and concd HCl (15 ml) and the organic materials extracted with dichloromethane (20 ml×5). The extracts were combined and washed with 1 M HCl, water, and 5% aq $NaHCO_3$. After drying over $MgSO_4$, the solvent was evaporated under reduced pressure. The residue was chromatographed to give **5a** (0.153 g, 87%) as colorless needles, mp 115—115.5 °C. Found: C, 75.75; H, 5.75%. Calcd for $C_{11}H_{10}O_2$: C, 75.84; H, 5.79%. IR (KBr disk) 1739 ($\nu_{C=O}$) and 1650 cm^{-1} ($\nu_{C=C}$). NMR ($CDCl_3$) δ 3.20 (doublet of t, J=2.7 and 7.1 Hz, 2H, CH_2–C–C=O), 4.45 (t, J=7.1 Hz, 2H, CH_2–O), 7.45 (s, 5H, Ph), and 7.54 ppm (t, J=2.7 Hz, 1H, C=C(H)).

α-Benzylidene-γ-valerolactone (5b): Similarly, from **7b** (0.305 g, 1.48 mmol), pure **5b** (0.174 g, 63%) was obtained as a yellow oil which solidified in storage.

trans-*9-Benzylidene-7-oxabicyclo[4.3.0]nonan-8-one (5c)*: Similarly, from **7c** (0.607 g, 2.46 mmol), pure **5c** (0.253 g, 45%) was obtained as colorless needles.

α-Ethylidene-γ-butyrolactone (5d): **7d** (0.397 g, 3.07 mmol) gave **5d** (0.228 g, 66%) as a pale yellow liquid by a similar treatment to that described above. Found: C, 64.01; H, 7.45%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%. IR (CCl_4) 1768 ($\nu_{C=O}$) and 1685 cm^{-1} ($\nu_{C=C}$). NMR (CCl_4) δ 1.91 (t of doublet, J=2.0 and 7.4 Hz, 3H, CH_3), 2.88 (m, 2H, CH_2–C=C), 4.41 (t, J=7.2 Hz, 2H, CH_2–O), and 6.77 ppm (t of quartet, J=3.0 and 7.4 Hz, 1H, vinyl proton).

α-Ethylidene-γ-valerolactone (5e): **7e** (0.237 g, 1.64 mmol) gave **5e** (0.170 g, 82%) as a yellow liquid by a similar treatment. Found: C, 66.35; H, 8.29%. Calcd for $C_7H_{10}O_2$: C, 66.65; H, 7.99%. IR (CCl_4) 1767 ($\nu_{C=O}$) and 1683 cm^{-1} ($\nu_{C=C}$). NMR (CCl_4) δ 1.41 (d, J=6.5 Hz, 3H, CH_3–CH), 1.83 (t of d, J=2.2 and 7.4 Hz, 3H, CH_3–C=C), 2.35 (t of double d, J=3.4, 6.1, and 17.0 Hz, 1H, CH_2–C=C), 3.03 (t of double d, J=3.4, 7.7, and 17.0 Hz, 1H, CH_2–C=C), 4.60 (double d of quartet, J=7.7, 6.1, and 6.5 Hz, 1H, CH–O), and 6.64 ppm (t of quart, J=3.4 and 7.4 Hz, 1H, vinyl proton).

trans-*9-Ethylidene-7-oxabicyclo[4.3.0]nonan-8-one (5f)*: **7f** (0.917 g, 4.96 mmol) gave **5f** (0.318 g, 39%) as a yellow oil by a similar treatment. Found: C, 72.21; H, 8.72%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%. IR (CCl_4) 1778 ($\nu_{C=O}$) and 1689 cm^{-1} ($\nu_{C=C}$). NMR (CCl_4) δ 1.3—2.6 (m, 9H, ring protons), 1.86 (double d, J=7.2 and 1.7 Hz, 3H, CH_3), 3.56 (doublet of t, J=3.7 Hz and 9.0 Hz, 1H, CH–O), and 6.51 ppm (d of quart, J=3.0 and 7.5 Hz, 1H, vinyl proton).

α-Methylene-γ-butyrolactone (5g): A benzene solution of **7g** (0.445 g, 3.42 mmol), methanesulfonyl chloride (0.35 ml), and 1,5-diazabicyclo[5.4.0]undec-5-ene (1 ml) was stirred for 1 h

at ambient temperature. The mixture was poured into water (20 ml) and extracted with dichloromethane (10 ml × 7). The extracts were combined, washed with 1 M HCl (20 ml) and water (20 ml), and dried over $MgSO_4$. After evaporation of the solvent under reduced pressure, the residue was chromatographed to give a pale yellow liquid **5g** (0.081 g, 21%). Found: C, 64.05; H, 7.44%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%. IR (CCl_4)[13] 1772 ($\nu_{C=O}$) and 1671 cm^{-1} ($\nu_{C=C}$). NMR (CCl_4)[13] δ 1.39 (d, J=6.1 Hz, 3H, C$\underline{H}_3$), 2.42 (t of double d, J=3.3, 6.6, and 16.7 Hz, 1H, C$\underline{H}_2$), 3.06 (t of double d, J=2.4, 7.2, and 16.7 Hz, 1H, C$\underline{H}_2$), 4.55 (quart of double d, J=6.1, 6.6, and 7.2 Hz, 1H, C$\underline{H}$–O), 5.50 (double d, J= 6.6 and 7.2 Hz, 1H, ), and 6.06 ppm (double d, J=6.6 and 7.2 Hz, 1H, ).

trans-*9-Methylene-7-oxabicyclo[4.3.0]nonan-8-one (5h)*: In a similar manner, **7h** (0.745 g, 4.38 mmol) gave colorless needles of **5h** (0.315 g, 47%), mp 39—41 °C. (lit,[14] 39—41 °C). Found: C, 71.09; H, 8.03%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%. IR (KBr disk)[5] 1758 ($\nu_{C=O}$) and 1673 cm^{-1} ($\nu_{C=C}$). NMR (CCl_4)[6] δ 1.1—2.6 (m, 9H, ring protons), 3.63 (double t, J=3.8 and 10.5 Hz, 1H, C$\underline{H}$–O), 5.32 (d, J=3.0 Hz, 1H, ), and 5.96 ppm (d, J=3.0 Hz, 1H, ).

The authors would like to thank the Ministry of Education, Japan, for a Grant-in-Aid 375469 and Shinetsu Chemical Company for the supply of chlorotrimethylsilane.

The Difference in Solvolytic Reactivity between Diastereomers in α-(*trans*-2-Arylcyclopropyl)arylmethyl 3,5-Dinitrobenzoates

Toshimasa TAKATA, Hajime MATSUSAKI, Katsuo OHKATA, and Terukiyo HANAFUSA*

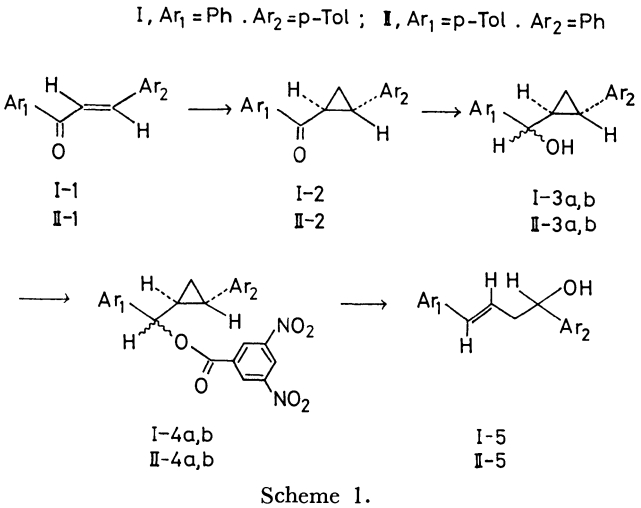
Chemistry Department, Faculty of Science, Hiroshima University, Higashi-senda-cho, Hiroshima 730

(Received January 6, 1979)

Each diastereoisomeric pair of α-(*trans*-2-*p*-tolylcyclopropyl)benzyl and α-(*trans*-2-phenylcyclopropyl)-*p*-tolylmethyl 3,5-dinitrobenzoates (**I-4a, b, II-4a, b**) has been synthesized. The relative solvolytic rates of **I-4b** to **I-4a** and of **II-4b** to **II-4a** in 80% aqueous acetone have been found to be 3.59 and 1.86 respectively at 25 °C. In the presence of 2,6-lutidine, the major products in the solvolysis were homoallylic alcohols.

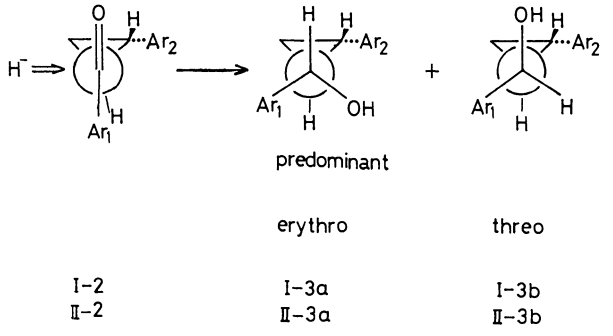
Although there have been many stereochemical studies in the rate comparisons of rigid cyclic compounds in the solvolysis of cyclopropylmethyl systems,[1-3] no investigations of the difference in reactivity between a diastereoisomeric pair of such systems in which a cyclopropyl group can freely rotate have been reported. One of the reasons for this may be the experimental difficulty in the separation of such diastereomers. It may be of importance, however, to study the conformational situation of a participating cyclopropyl group at the transition state when the free rotation of the group is permitted in the substrate molecule.[4] In connection with our previous researches,[5] we wish now to report such a reactivity difference between diastereoisomers of certain arylcyclopropylmethyl systems.

Each isomer of the titled esters (**I-4a, b** and **II-4a, b**) has been synthesized and successfully isolated by Scheme 1, shown below. The physical properties and spectral and analytical data are summarized in Table 1.



Scheme 1.

The parent alcohols (**I-3a, b** and **II-3a, b**) were mixtures of diastereoisomers, in which one of the diastereoisomers was preferentially produced in the hydride reduction of the ketones (**I-2, II-2**). The chemical shift of the carbinyl proton (a doublet) in the predominant alcohols (**I-3a** and **II-3a**) was slightly higher than that of the other (**I-3b** and **II-3b**). The hydride attack on the carbonyl group generally takes place from the less hindered side of the favorable conformer of the ketones, as is shown in Scheme 2. This reduction results in the preferential formation of



Scheme 2.

the erythro isomer (**I-3a, II-3a**) according to the above scheme. This interpretation accords with the previous result suggested for a similar system by Descotes *et al.*[6] and is consistent with Cram-Prelog rule.[7] If it is assumed that the two most bulky aromatic groups are situated in a *trans* relation in the stable, staggered conformation of the alcohol molecule, the carbinyl proton of *erythro*-isomer (**I-3a** and **II-3a**) may be more highly shielded by the effect of a cyclopropane ring.[8] Thus, the two diastereoisomers in a pair could be distinguished.

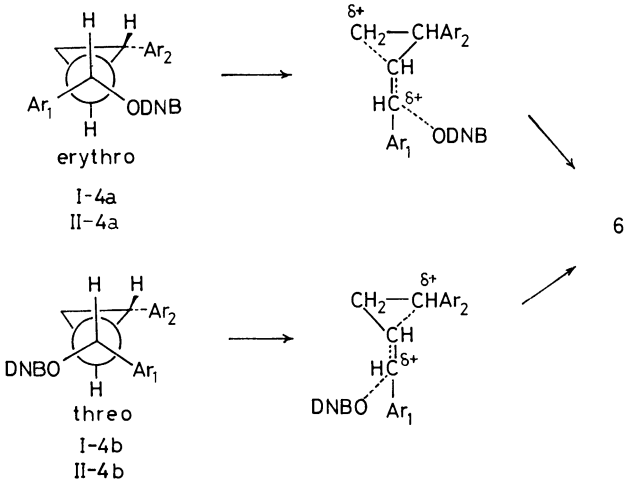
The diastereomerically mixed alcohols were converted into 3,5-dinitrobenzoates (**I-4a, b** and **II-4a, b**) by a usual procedure. Separation was made by the fractional recrystallization of the 3,5-dinitrobenzoates. As may be seen from Table 2, all these 3,5-dinitrobenzoates were solvolyzed smoothly in accordance with first-order kinetics. Thus, it was found that the *threo* isomer (**I-4b** or **II-4b**) was more reactive than the *erythro* isomer (**I-4a** or **II-4a**) in the solvolysis of both pairs in 80% aqueous acetone. The order of the difference in reactivity (3.59—1.86) is comparable with that for some rigid polycyclic systems.[3a,d]

When the reaction was interrupted during the course of solvolysis, each starting 3,5-dinitrobenzoate could be recovered in a good yield and neither the homoallylic nor the diastereomeric isomer of the reactant was detected for either series. Thus, it was experimentally confirmed that there was no interconversion between homoallylic and cyclopropylmethyl systems, or between the *erythro* and *threo* isomers, in the present solvolysis.

A product study was carried out in the presence of 2,6-lutidine under solvolytic conditions, since it was preliminarily found that the parent alcohols (**I-3a, b** and **II-3a, b**) and homoallylic alcohols (**I-5, II-5**) were stable under these conditions. The major solvolysis

products after 30 half-lives were homoallylic alcohols, as is shown in Table 3. These alcohols should be produced directly from the 3,5-dinitrobenzoates (**I-4a, b** and **II-4a, b**) under those reaction conditions, since rearranged homoallylic 3,5-dinitrobenzoates could not be solvolyzed under similar conditions.

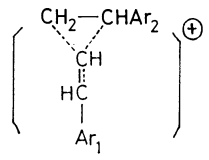
Starting from the diastereomerically different 3,5-dinitrobenzoates, the same *trans*-homoallylic alcohol was obtained as the sole product, so that it is reasonable to assume the intervention of the common carbocation in the reactions for both diastereomers. In contrast with this finding, a considerable rate difference has been found between *erythro* and *threo* isomers in kinetic studies of the two systems (I and II). Also, the rates are accelerated by the order of 10^4 in comparison with simple secondary arylmethyl systems. This may be attributed to participation by the α-substituted 2-arylcyclopropyl group. In order to attain a transition state which leads to a common carbocation in the present solvolysis, the C_1–C_2 bond of a cyclopropyl group is inevitably antiparallel to the leaving 3,5-dinitrobenzoate group in the *threo* isomers. Then, the aryl group on C_2 of a cyclopropyl group could accommodate the partial positive charge developed at the transition state. In the case of the *erythro* isomers, such



Scheme 3.

concomitant participation from the most stable conformer may result in the formation of a different transition state in which the C_1–C_3 bond is antiparallel to the leaving group. Both transition states are illustrated in Scheme 3. These situations might cause the above rate difference between diastereomeric isomers, although the solvolysis products were the same. Thus, an unsymmetrical participation of a cyclopropyl group has been kinetically demonstrated in systems in which the cyclopropyl group can freely rotate. Regarding with the common intermediate that is a close precursor to the *trans*-homoallylic alcohol, there has been no direct experimental evidence in this study. However, the structure may be illustrated as a homoallylic cation, **6**, which might presumably be stabilized by homoconjugation.

In view of the facts that the secondary benzylic system



6

is subject to almost no anchimeric assistance, and that the conformational requirement for the transition state in the solvolysis of compounds in which the free rotation of the α-substituted cyclopropyl group is permitted is not so strict as in a rigid polycyclic system, the present results seem to be rather interesting. A related investigation is now in progress.

Experimental

All the melting points are uncorrected. The IR spectra were obtained with a Hitachi 215 grating IR spectrophotometer. The NMR measurements were carried out on a Varian T-60 instrument, using tetramethylsilane as the internal reference. The physical properties of each compound are summarized in Tables 1 and 3.

Phenyl trans-*2*-p-*Tolylcyclopropyl Ketone (I-2) and* p-*Tolyl* trans-*2-Phenylcyclopropyl Ketone (II-2).* The cyclopropyl ketones (**I-2** and **II-2**) were prepared from benzylideneacetophenone derivatives[9] and trimethyloxosulfonium iodide by a previously reported method.[10]

*α-(*trans-*2*-p-*Tolylcyclopropyl)benzyl Alcohol (I-3a, b) and* α-*(*trans-*2-Phenylcyclopropyl)*-p-*tolylmethanol (II-3a, b).* To a stirred suspension of 2 g of $LiAlH_4$ in 200 ml of dry ether were added 13 g (55 mmol) of **I-2** dissolved in 100 ml of dry ether. The mixture was then stirred for 25 h before the excess hydride was carefully decomposed with a minimum amount of water. The mixture was filtered, and the precipitates were washed several times with ether. After the combined ether layer had then been dried, the removal of the solvent gave 10.5 g of **I-3a, b**, a colorless solid. It was found from the NMR spectrum that the solid consists of two diastereoisomers (**I-3a**: **I-3b**=3: 2). When the solid product was recrystallized from petroleum ether, a pure sample of **I-3a** (mp 52—53 °C) was obtained.

Found: C, 85.83; H, 7.59%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

Another pair of alcohols (**II-3a, b**) was prepared by a similar method in a 89% yield; the recrystallization of the crude product from petroleum ether gave rise to a pure sample of **II-3a** (mp 95—97 °C).

Found: C, 85.55; H, 7.73%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

*α-(*trans-*2*-p-*Tolylcyclopropyl)benzyl 3,5-Dinitrobenzoate (I-4a, b) and* α-*(*trans-*2-Phenylcyclopropyl)*-p-*tolylmethyl 3,5-Dinitrobenzoate (II-4a, b).* The 3,5-dinitrobenzoate (**I-4a, b**) was prepared by allowing 4.5 g (19 mmol) of **I-3a, b** to react with 5.2 g (22 mmol) of 3,5-dinitrobenzoyl chloride in 75 ml of dry pyridine at room temperature for 30 h. The product was extracted with ether, and the organic layer was successively washed with water, 1M-hydrochloric acid, 5% aqueous sodium hydrogencarbonate, and water. The ether layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure. In the same ratio as the parent alcohols (**I-3a** and **3b**), 3,5-dinitrobenzoate (**I-4a, b**; 6.5 g) was obtained. Recrystallization from benzene and petroleum ether

I-3 and **II-3** were obtained with a mixture of two diastereoisomers. The alcohol in which the doublet of the α- the **b**-series. d) Yield from a mixture of two diatereoisomers of alcohol.

to a pure 3,5-dinitrobenzoate (**I-4a**; 92% yield). The geometry of this 3,5-dinitrobenzoate (**I-4a**) should eventually correspond to that of the *erythro* isomer of its parent alcohol (**I-3a**).

3) The chemical shift of the carbinyl proton in **I-4b** is about 0.1 ppm lower than that in **I-4a**. An analogous relation is observed between parent alcohols (**I-3a** and **b**), as has been described before.

Treatment of I-3a, b and II-3a, b with Perchloric Acid. A solution of **I-3a, b** (1.0 g) and 0.2 ml of 70% perchloric acid dissolved in 50 ml of 80% aqueous acetone was stirred at 25 °C for 24 h. After a work-up, 950 mg of a colorless solid were obtained in a 95% yield. Recrystallization from petroleum ether gave rise to a pure sample, *trans*-1-phenyl-4-*p*-tolyl-3-buten-1-ol (**I-5**). Another homoallylic alcohol (II-5) was obtained by a similar method in a 92% yield and was recrystallized from petroleum ether. The spectral data of **I-5** and **II-5** are shown in Table 3.

Preparative Solvolysis of 3,5-Dinitrobenzoate (I-4a, b and II-4a, b). A solution of 388 mg (1 mmol) of **I-4a** and 0.5 ml (*ca.* 4.6 mmol) of 2,6-lutidine in 200 ml of 80% aqueous acetone was heated at 45 °C for 30 half-lives. After the solution had then been concentrated under reduced pressure, 100 ml of water was added and the resulting suspension was extracted with ether. The combined ether extracts were washed with water and dried over anhydrous K_2CO_3. The removal of the solvent under reduced pressure gave 171 mg (71%) of a yellow solid. The other esters (**I-4b** and **II-4a, b**) were solvolyzed in the presence of 2,6-lutidine by a similar method. Each product in solvolysis was identified on the basis of a comparison of its NMR spectra with those of an authentic sample. The product distributions were determined from the ratio of the NMR integral intensities of the α-hydrogen signal for cyclopropyl methanol and the vinylhydrogen signal for homoallyl alcohol. The major products were homoallylic alcohols (**I-5, II-5**), accompanied by a trace of the parent alcohols (**I-3, II-3**).

A mixture containing 110 mg (0.46 mmol) of **I-3a**, 0.3 ml of 2,6-lutidine and 98 mg (0.46 mmol) of 3,5-dinitrobenzoic acid in 100 ml of 80% aqueous acetone was heated at 45 °C for 8 h (*ca.* 5 half-lives). After a usual work-up, 95 mg of a colorless solid were obtained. A comparison of the NMR spectrum before and after heating showed that **I-3a** was stable under these reaction conditions. Also, **II-3b** was not changed into **II-5** under these conditions.

Kinetic Procedures. The acetone was purified by distillation from potassium permanganate, followed by drying (K_2CO_3) and distillation. The water used in the kinetic studies was demineralized and distilled. 80% aqueous acetone (v/v) was prepared at 25 °C by mixing 4 volumes (accurately pipetted) of purified acetone with 1 volume of purified water.

THE HOMOALLYLIC ALCOHOLS (**I-5** and **II-5**)

in $CDCl_3$				Found (Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%)
α	Allylic	Hydroxylic	Methyl	
4.75 (t, J=6 Hz,1H)	2.62 (t, J=6 Hz, 2H)	2.13 (s, 1H)	2.33 (s, 3H)	C, 85.96; H, 7.62%
4.77 (t, J=6 Hz, 1H)	2.63 (t, J=6 Hz, 2H)	1.97 (s, 1H)	2.33 (s, 3H)	C, 85.44; H, 7.65%

For each run, approximately 100 mg (*ca.* 0.25 mmol) of 3,5-dinitrobenzoate (**I-4a, b** or **II-4a, b**) was weighed into a 100 ml volumetric flask and dissolved in 80% aqueous acetone (*ca.* 2×10^{-3} M). Aliquots of the solution (*ca.* 6 ml) were transferred as quickly as possible into glass ampoules, which were in turn sealed and immersed simultaneously into a constant-temperature bath. After approximately 5 min, one ampoule was removed and immediately plunged into an ice–water bath. The rate at each temperature was measured by quenching 5.00 ml aliquots in 25 ml of dry acetone and then immediately titrating with a standard aqueous sodium hydroxide solution (8.357×10^{-3} M), using a Hitachi-Horiba automatic titrator with a glass electrode. The infinite titer was measured after *ca.* 10 half-lives, and 95—103% of 3,5-dinitrobenzoic acid was removed. The rate constants obtained by such procedures were consistent with that obtained by the indicator method using Bromothymol Blue.

A solution of 240 mg of **I-4b** in 200 ml of 80% aqueous acetone was kept in a flask at 35 °C for 1.5 h (*ca.* 1/2 half life). The solution was then poured into a mixture of ether (300 ml) and water (500 ml). The ether layer was washed with water and dried over anhydrous sodium sulfate. The solvent was removed at reduced pressure, the solid residue weighed 230 mg. A comparison of the NMR spectra before and after the reaction indicated that **I-4b** was not isomerized into **I-4a** under the solvolysis conditions. Also, **I-4a** was not converted into the isomeric 3,5-dinitrobenzoate (**I-4b**) under the reaction conditions.

Mechanism for Reaction of *p*-Nitrotoluene with Sodium Polysulfide to Form *p*-Aminobenzaldehyde

Yoshiro OGATA,* Atsushi KAWASAKI, Yasuhiko SAWAKI, and Yoshiaki NAKAGAWA[1)]

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

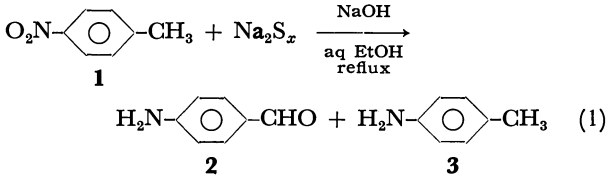
(Received January 13, 1979)

The conversion of *p*-nitrotoluene to *p*-aminobenzaldehyde was found to be most effectively done by a mixture of Na_2S_4 and *ca.* two equivalents of NaOH to *p*-nitrotoluene. After examination of probable intermediates, toluidine, *p*-nitrobenzaldehyde and *p*-nitrosotoluene were discarded as the intermediate. The reaction of carbanion $ArCO\bar{C}HAr$ with the sulfide and the effect of some nitrobenzenes as an electron accepter were examined. These results suggest a mechanism involving a simultaneous oxidation-reduction in a nitrotoluene molecule.

Sulfur frequently shows a unique ability by which the substrate is oxidized at one site but reduced at another site. A typical example is the conversion of *p*-nitrotoluene to *p*-aminobenzaldehyde. In aqueous ethanolic solution of sodium polysulfide, *p*-nitrotoluene is converted to *p*-aminobenzaldehyde. This reaction is known to be the best route for synthesis of *p*-aminobenzaldehyde. But the reaction mechanism is still obscure and unconvincible.[2,3)] We wish to clarify it by examining the effects of reaction conditions and substrate structure and by isolating intermediates, since the kinetic study was difficult.

Results and Discussion

Effect of Na_2S_x and NaOH. *p*-Nitrotoluene was allowed to react with polysulfide (Na_2S–Na_2S_5). It was found that Na_2S_4 was the best reagent (Table 1) and that elemental sulfur itself was not always essential for this reaction.



(1)

With 1.9 mol of NaOH for one mol of *p*-nitrotoluene, the highest yield of *p*-aminobenzaldehyde was obtained. If a less amount of NaOH was used, the yield of *p*-toluidine increased, but that of *p*-aminobenzaldehyde decreased remarkably. This may be due to the Eq. 2[4)] which consumes NaOH, decreasing the concentration of benzyl anion (Table 2).

TABLE 1. YIELD OF PRODUCTS IN A REACTION OF *p*-NITROTOLUENE (**1**) WITH Na_2S_x IN AQUEOUS ETHANOL BY REFLUXING FOR 3 h[a)]

Na_2S_x	Yield	
	2 (%)	**3** (%)
$x=1$	6.1	60.1
2	9.3	94.3
3	35.4	21.5
4	43.5	16.4
5	24.4	43.3

a) **1** (0.037 mol), NaOH (0.068 mol).

$$6NaOH + 1/2S_8 \longrightarrow 2Na_2S + Na_2S_2O_3 + 3H_2O \quad (2)$$

Time Conversion. Figure 1 shows the consumption of *p*-nitrotoluene and the yields of *p*-toluidine and *p*-aminobenzaldehyde. The formation of *p*-toluidine stopped after 30 min.

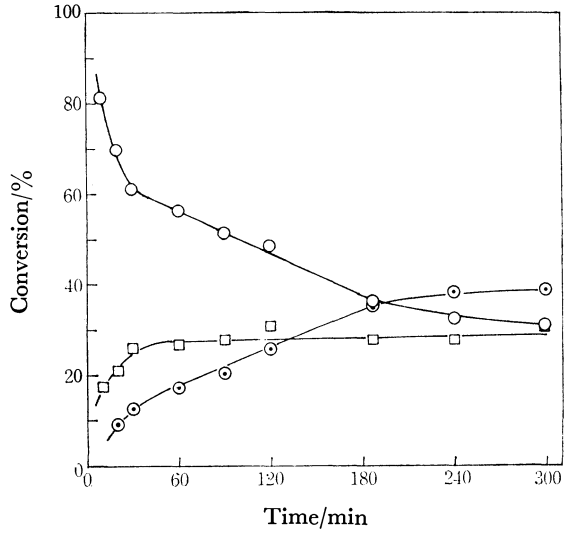

Fig. 1. Reaction of *p*-nitrotoluene with Na_2S_4 in 90% aqueous ethanol at 80 °C. The initial amount of reagents were: *p*-nitrotoluene 0.037 mol; Na_2S_4 3.30 g; NaOH 0.068 mol: (○) *p*-nitrotoluene, (□) *p*-toluidine, (⊙) *p*-aminobenzaldehyde. (*p*-Aminobenzaldehyde was estimated by subtracting the sum of the amount of *p*-nitrotoluene and *p*-toluidine from 0.037 mol.)

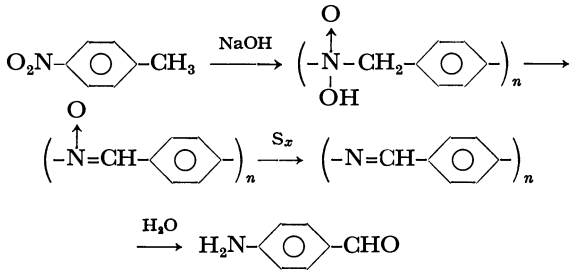
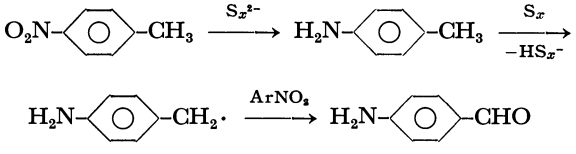
Discussion of Mechanisms. Information thus far obtained suggests several mechanisms which will be discussed below.

(I) Mechanism via *Anthranil Nitrone*: Shchukina *et al.*[3)]



Scheme 1.

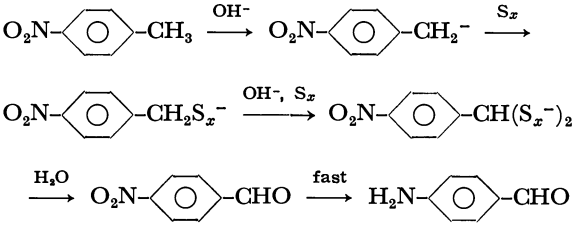
proposed a mechanism involving polynitrone formation (Scheme 1). This mechanism employs sulfur as a reducing agent. So that we replaced sulfur with triphenylphosphine which is known to be a strong reductant for nitrone,[5] but no *p*-aminobenzaldehyde was obtained. Hence this mechanism is of doubt.



Scheme 2.

(II) Mechanism via p-*Toluidine*: Polysulfenyl radicals are electrophilic,[6] and therefore an amino group would increase the rate of attacks of these radicals on the benzylic position, if the oxidation involved hydrogen abstraction by sulfenyl radicals. But the reaction of *p*-toluidine with Na_2S_x gave no *p*-aminobenzaldehyde even in the presence of a strong electron-accepter such as *m*-dinitrobenzene. Hence, this mechanism can also be eliminated.

(III) Mechanism via p-*Nitrobenzaldehyde*: Hodgson *et al.*[2] proposed a mechanism *via p*-nitrobenzaldehyde. Indeed, substitution of electron-attracting *p*-NO_2 group stabilizes benzyl anion and increases its concentration in a basic solution. The *p*-nitrobenzyl anion may attack



Scheme 3.

the S–S bonds as a nucleophile[7] or it may be converted to a radical by loss of one electron, and then links with polysulfenyl radical to form benzylpolysulfide, which is hydrolyzed to *p*-nitrobenzaldehyde (Scheme 3). The electron-attracting formyl group should accelerate the reduction of nitro group as apparent from our reported Hammett's ρ value of $+3.55$.[8] But our attempt for detection of *p*-nitrobenzaldehyde itself by UV spectrum and trapping *p*-nitrobenzaldehyde by phenylhydrazine were unsuccesful, but in view of its low concentration this mechanism *via p*-nitrobenzaldehyde cannot completely be excluded.

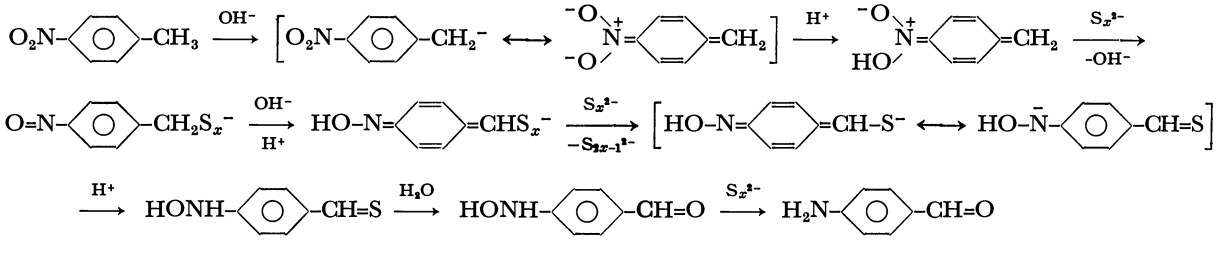
To test the possibility of oxidation of another carbanion with sulfur, *p*-chlorodeoxybenzoin, which loses proton easily with base, was reacted with polysufides but no *p*-chlorobenzil was obtained. Moreover, an attempted reaction of *p*-chlorodeoxybenzoin in the presence of nitrobenzene and Na_2S_x gave virtually no reaction. Hence, a nitro group is necessary for this type of reaction.

(IV) A Probable Mechanism: There are still left two mechanisms as probable candidates. One is the intramolecular direct migration of oxygen and hydrogens, and another is the concurrent oxidation and reduction in a molecule.

The reaction of 4-nitro-*m*-xylene with Na_2S_x gave 3-methyl-4-aminobenzaldehyde (7%) and 4-amino-*m*-xylene (*ca.* 8%), but no 5-methyl-2-aminobenzaldehyde. Therefore, the direct internal migration of oxygen to the nearest ortho position is disfavored. The very low yield of oxidation product (aldehyde) may be due to the electron-releasing methyl group, which lowers the concentration of benzyl anion.

In conclusion, a plausible mechanism which does not contradict with our observations described above may be as shown in Scheme 4.

This tentative mechanism involves conversion of *p*-nitrotoluene to the benzyl anion with hydroxide ion and protonation at the nitro group resulting in the formation of quinonoid isomer of *p*-nitrotoluene. This is a kind of olefin, which may undergo a Michael type addition of polysulfide ion[9] assisted by the electron-attracting *p*-NO_2 group with simultaneous or subsequent elimination of hydroxide ion, giving a hypothetical nitrosobenzyl polysulfide intermediate. Analogous base-catalyzed prototropy would give its quinonoid isomer, whose sulfur atom at the β-position to the benzylic carbon atom would be attacked by polysulfide ion, giving thiobenzaldehyde derivative. The thiolate ion attacks more easily on sulfur atom than on carbon atom, the reaction rate being fast.[10] Further, formation



Scheme 4.

of thiocarbonyl as an intermediate of Willgerodt reaction of acetophenone with ammonium polysulfide has been reported.[11] The *p*-hydroxyaminothiobenzaldehyde is easily hydrolyzed[11a] and reduced to *p*-aminobenzaldehyde[12] as apparent from the literature.

Another evidence for supporting this mechanism is that *o*-nitrotoluene can give *o*-aminobenzaldehyde,[13] but *m*-nitrotoluene cannot give *m*-aminobenzaldehyde albeit the simple discussion as an unpublished data.[14] Further, no effect of bubbling air (oxygen) on the conversion of *p*-nitrotoluene was observed, and also neither 4,4′-dinitrobibenzyl nor 4,4′-dinitrostilbene can be detected in the reaction products. Therfore, a mechanism *via* radical, $p\text{-}NO_2\text{–}C_6H_4\text{–}CH_2\cdot$, is less probable.

Experimental

Melting points were measured by a Yanagimoto micro melting point apparatus and were not corrected. IR and NMR spectra were recorded on a Perkin-Elmer 337 spectrophotometer and a Hitachi R-24B NMR spectrometer using Me_4Si as an internal standard. The GLC analysis was performed with a Yanagimoto 550-F gas chromatograph with a flame ionization detecter.

Materials. Sodium polysulfide were prepared by the method of Gabel *et al.*;[15] a yellow hygroscopic solid. Melting points and boiling points of principal reactants were: *p*-nitrotoluene, mp 53—54 °C; *p*-toluidine mp 44—45 °C; 4-nitro-*m*-xylene bp 125—127 °C/15 Torr.

Reaction of p-*Nitrotoluene (1) with* Na_2S_x.[16] A hot aqueous solution (90 ml) of $Na_2S\cdot 9H_2O$ (0.013 mol), S (0.047 g atom), and NaOH (0.067 mol) was poured into a 300 ml round-bottomed flask containing a hot ethanolic solution (30 ml) of **1** (0.036 mol). The mixture was heated under reflux for 3 h and then steam-distilled. The distillate was extracted with ether and the extract was analyzed by GLC. GLC analysis was conducted at 80—250 °C using two sorts of columns (1 m): PEG 20 M, 10% on Chromosorb WAW; Silicon OV 17, 5% on Simalite 201D. The residue was filtered while hot, and then chilled in an ice bath. The crystals of *p*-aminobenzaldehyde (**2**) were collected and washed with ice water. The product was identified by the NMR and IR in comparison with the authentic specimen. The yield of **2** was 52%.

Reaction of **1** *with* Na_2S *to* Na_2S_5. According to the procedure of the reaction of **1** with Na_2S_x, we used Na_2S–Na_2S_5 instead of $Na_2S\cdot 9H_2O$ and S.

Conversion of **1**. A mixture of **1** (0.037 mol), NaOH (0.068 mol), Na_2S_4 (3.3 g), ethanol (90 ml), and water (10 ml) was placed in a 200 ml two-necked flask and refluxed. One ml of sample was pippetted out at appropriate time intervals. Ethanol (5 ml) was added, and the solution was analyzed by GLC (PEG 20 M).

Reaction of p-*Toluidine (3) with* Na_2S_x. According to the procedure of the reaction of **1** with Na_2S_x, a mixture of **3** (0.035 mol), $Na_2S\cdot 9H_2O$ (0.015 mol), S (0.046 g atom), and NaOH (0.071 mol) was allowed to react. The recovery of **3** was 50%. Similarly, a mixture of same reactions as above and *m*-dinitrobenzene (0.036 mol) was allowed to react. The recovery of **3** was 63% and the yield of *p*-nitroaniline was 23%.

Attempted Trap of p-*Nitrobenzaldehyde.* A hot aqueous solution (12 ml) of NaOH (0.013 mol) and Na_2S_4 (0.70 g) was added to a hot ethanolic solution (6 ml) of **1** (7.3×10^{-3} mol) and phenylhydrazine (7.4×10^{-3} mol), refluxed for 1 h and cooled rapidly. The extract with ether was hydrolyzed with 4 N HCl (100 ml), and the ether extract was analyzed by GLC (PEG 20 M).

Reaction of 4-Nitro-m-*xylene (6) with* Na_2S_x. Similar work up for the reaction of **1** with Na_2S_x was applied to **6**; *i.e.*, a mixture of **6** (0.036 mol), $Na_2S\cdot 9H_2O$ (0.014 mol), S (0.055 g atom), and NaOH (0.068 mol) was allowed to react. The yield of 3-methyl-4-aminobenzaldehyde was 70%; mp 104—107 °C (lit,[17] 92 °C); NMR ($CDCl_3$): δ 2.18 (s, 3H, CH_3), 4.19 (s, 2H, NH_2) 6.65 (d, 1H, ArH, J=9 Hz), 7.55 (d, 1H, ArH, J=9 Hz), 7.57 (m, 1H, ArH), 9.70 (s, 1H, CHO).

Reaction of m-*Nitrotoluene (7) with* Na_2S_x. According to the procedure for **1** with Na_2S_x, a mixture of **7** (0.037 mol), $Na_2S\cdot 9H_2O$ (0.013 mol), S (0.050 g atom), and NaOH (0.069 mol) was allowed to react. The recovery of **7** was 30% and the yield of *m*-toluidine was 65%, but no trace of *m*-aminobenzaldehyde was detected with NMR.

Effect of Oxygen on p-*Nitrotoluene Conversion.* A mixture of **1**, NaOH (0.051 mol), Na_2S_4 (3.1 g), ethanol (90 ml), and water (10 ml) was placed in a 200 ml two-necked flask. After the flask had been thermostated at 50±0.5 °C, air was bubbled into the reaction mixture during the run. Two ml of the sample was pippetted out at appropriate time intervals. An ethanolic solution (1 ml) of biphenyl as an internal standard was added, and the solution was analyzed by GLC (PEG 20 M). The similar work up without bubbling of air was also carried out. The conversions (%) at various times were as follows, where figures in parenthesis indicate the conversion without air bubbling; 5 min: 12 (9), 10 min: 30 (24), 15 min: 41 (35), 20 min: 46 (46), 25 min: 47 (47), 30 min: 48 (52).

Catalytic Hydrolysis of Dinitrophenyl Sulfate by Poly(ethylenimine) Derivatives†

Toyoki KUNITAKE* and Tetsuo SAKAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received January 29, 1979)

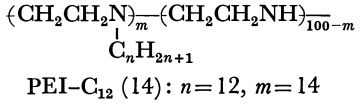
The catalytic hydrolysis of nitrophenyl sulfates by poly(ethylenimine)(PEI) derivatives was investigated at 30 °C in aqueous buffers. PEI derivatives which were made partly hydrophobic by incorporation of higher alkyl groups include alkylated PEI's, quaternized PEI's, and PEI's with imidazole and hydroxamate functions. Nitrophenyl sulfates could not be cleaved by these polymers. The catalytic hydrolysis of 2-hydroxy-5-nitrophenyl sulfate by an PEI with imidazolylmethyl and dodecyl substituents failed to proceed in spite of the contrary report by Kiefer *et al.* 2,4-Dinitrophenyl sulfate was cleaved fairly readily by PEI derivatives. Simple sulfate transfer was observed in the case of alkylated PEI, but the catalytic hydrolysis proceeded according to the Michaelis-Menten kinetics in the case of quaternized PEI. Partly quaternized PEI's showed highest catalytic efficiencies reported to date for the hydrolysis of dinitrophenyl sulfate.

Poly(ethylenimine) and its derivatives have been used widely as catalysts for hydrolysis[1–5] and decarboxylation.[6,7] Poly(ethylenimine)s with hydrophobic alkyl substituents are particularly interesting because their compact conformations in water provide excellent model enzyme systems.[8] Most of the hydrolytic study have been carried out by using phenyl ester substrates, and some functionalized poly(ethylenimine)s were shown to possess extremely high catalytic activities.

The hydrolysis of sulfate monoesters is usually not markedly accelerated by polymer catalysts. A unique exception is the hydrolysis of 2-hydroxy-5-nitrophenyl sulfate catalyzed by an imidazole-containing poly(ethylenimine). This catalytic hydrolysis was reported to be faster by a factor of more than 10^{12} fold than the imidazole-catalyzed hydrolysis and the catalytic efficiency exceeds that of arylsulfatase A (2-hydroxy-5-nitrophenyl sulfate is the specific substrate for this enzyme).[9]

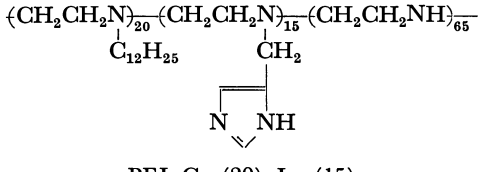
We have found that some cationic micelles which contain the hydroxamate nucleophile cleave a dinitrophenyl sulfate quite efficiently.[10] Therefore, the functionalized poly(ethylenimine) is also expected to be a good catalyst for the hydrolysis of sulfate esters. In this study, we report the catalytic hydrolysis of nitrophenyl sulfates by various poly(ethylenimine) derivatives. The hydrolysis of a phenyl ester by these polymer catalysts was also examined for comparison. The structures of the polymer catalysts and substrates and their abbreviations are given below:

polymer:

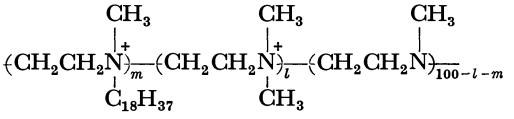


PEI-C_{12} (14): $n=12$, $m=14$

PEI-C_{16} (8) : $n=16$, $m=8$



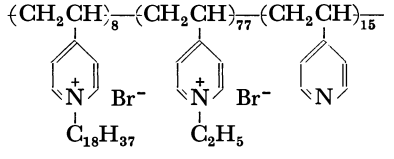
PEI-C_{12} (20)-Im (15)



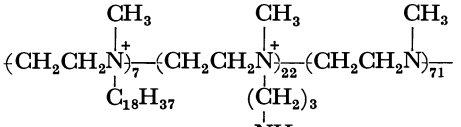
PEI$^+$-C_{18}(9) : $m=9$, $l=0$

PEI$^+$-C_{18}(16): $m=16$, $l=0$

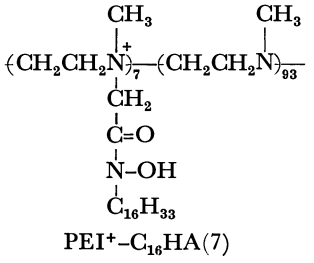
PEI$^+$-C_{18}(12)-C_1(68): $m=12$, $l=68$



PVP$^+$-C_{18}(8)-C_2(77)

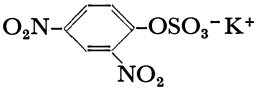


PEI$^+$-C_{18}(7)-NH_2(22)

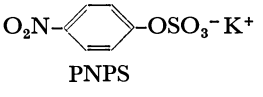


PEI$^+$-C_{16}HA(7)

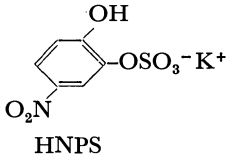
substrate:



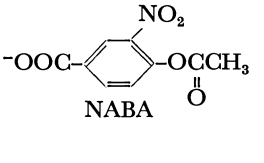
DNPS



PNPS



HNPS



NABA

Experimental

Preparation of Substrates. Potassium 2,4-dinitrophenyl sulfate (DNPS) was prepared according to the procedure of

† Contribution No. 511 from Department of Organic Synthesis.

Sunamoto *et al.*[10,11] Potassium *p*-nitrophenyl sulfate (PNPS) and potassium 2-hydroxy-5-nitrophenyl sulfate (HNPS) were prepared by following the procedures reported by Fendler and Fendler,[12] and Robinson, *et al.*,[13] respectively. The elemental analyses agreed with the calculated values. The preparation of 3-nitro-4-acetoxybenzoic acid (NABA) was reported previously.[14]

Partially Alkylated Poly(ethylenimine). An aqueous solution of commercial poly(ethylenimine) (Tokyo Kasei Co., *MW* 40000—50000, highly branched) was concentrated *in vacuo*, ethanol added to the residue and the solution was again concentrated. This procedure was repeated in order to completely replace water with ethanol. Finally, dry ethanol was added to obtain a 2—5 wt % solution, which was stored over molecular sieve 4A for the later use. The ethanolic solution was concentrated and 10—15 mol % of alkyl iodides (n-$C_{12}H_{25}I$ or n-$C_{16}H_{33}I$) were added. The mixture was heated at 60—70 °C for 24 h under nitrogen, concentrated and poured into excess ether. The yellowish powder was recovered, and washed several times with ether. The polymer was dissolved in water and purified by dialysis. The extent of alkylation was determined by the relative peak area of the main chain methylene proton (at *ca.* 2.7 ppm) and the alkyl proton (at *ca.* 1.3 ppm) in the NMR spectrum (D_2O solution).

Quaternized Poly(ethylenimine).[4] All the primary and secondary amino groups in poly(ethylenimine) were converted to the tertiary amino group by treating with formic acid and formalin. The product polymer was parly quaternized by octadecyl bromide in ethanol. The extent of quaternization was determined by NMR spectroscopy as mentioned above. Further quaternization was performed with methyl bromide in order to obtain PEI^+–C_{18}(16)–C_1(68).

Introduction of Functional Groups. The incorporation of the imidazole group into alkylated poly(ethylenimine) was carried out according to the procedure of Kiefer, *et al.*:[9] PEI–C_{12}(20)–Im(15). The methylated poly(ethylenimine) was allowed to react with *N*-(3-bromopropyl)phthalimide and then with dodecyl bromide and treated with hydrazine hydrate to give PEI^+–C_{18}(7)–NH_2(22).[15] The content of the aminopropyl group was determined from the relative peak area of the aromatic proton prior to the hydrazine treatment and by reaction with 2,4,6-trinitrobenzenesulfonic acid after the hydrazine treatment.[2] The hydroxamate function was introduced by reaction of a polymer with benzyl *N*-hexadecylchloroacetohydroxamate (see below). The hydroxamate content in the polymer was determined from the peak area of the aromatic proton. The benzyl group was removed by treatment with 30% hydrogen bromide in acetic acid. The complete removal was confirmed by NMR spectroscopy. The polymer was purified by reprecipitation after each stage.

Other Materials. The preparation of quaternized poly(vinylpyridine)s was described elsewhere.[16] Commercial hexadecyltrimethylammonium bromide (CTAB) was recrystallized two times from ethanol. For the preparation of benzyl *N*-hexadecylchloroacetohydroxamate, 25.2 g (0.11 mol) of benzyl benzohydroxamate in dry acetone was treated with 12.4 g (0.22 mol) of powdered KOH and 19.5 g (0.055 mol) of hexadecyl iodide. The oily alkylation product was hydrolyzed in a mixture of ethanol and concentrated hydrochloric acid to give *O*-benzyl-*N*-hexadecylhydroxylamine hydrochloride; colorless flakes after two recrystallizations from acetone, yield 16.0 g (75%), mp 77—79 °C. This compound (7.0 g, 0.018 mol) and 4.0 g (0.040 mol) of triethylamine were dissolved in 100 ml of dry ether and 2.1 g (0.018 mol) of chloroacetyl chloride was added dropwise. After the usual work-up, the product was recrystallized from acetone: mp< 30 °C, yield 4.3 g (56%). NMR and IR spectra were consistent with the expected structure.

Polymer Recovery. In connection with the elucidation of the hydrolysis mechanism, the polymer catalyst was recovered after reaction with the substrate under the standard conditions. A polymer catalyst (100 mg, 8—16 unit mM) was mixed with 100—500 mg (3.3—16 mM) of DNPS in 100 ml of 0.01 M borate buffer (pH 9.0) and allowed to stand at 30 °C overnight (1 M = 1 mol dm^{-3}). The mixture was dialyzed for 24 h using a cellophane tube and then concentrated by ultrafiltration (DIAFLO Ultramembrane UM-2, Amicon Co., Exclusion limit 1000). A saturated aqueous solution of KBr was added and the resulting solution was concentrated by ultrafiltration. The ultrafiltration was repeated after addition of water. The concentrate was dried *in vacuo* and its sulfur content was determined.

Kinetic Measurements. The sulfate esters were dissolved in a 3:7 mixture of water and acetonitrile and kept in an ice bath. The substrate solution and an aqueous solution of the polymers were added to buffer solutions (borate or Tris) in a quartz cell which had been maintained at 30 °C. Water was added so that the fraction of acetonitrile became 3 v/v %. The ionic strength was adjusted to 0.01 by KCl. The reaction was followed by using the absorbance increase at 360 nm of 2,4-dinitrophenolate anion ($\varepsilon = 12800\ M^{-1}\ cm^{-1}$) in the case of DNPS substrate. The λ_{max} at 401 nm was used for PNPS. Hitachi UV-visible spectrophotometers (type 124 or 200) equipped with jacketed cell compartments were used. The pH measurement was done by using TOA Electronics MH-10 glass electrodes and the pH change during the hydrolysis was within 0.03. Excess polymers were used relative to substrates and the reaction obeyed the pseudo first-order rate law for more than 80% completion. The overall rate constant of phenol release was corrected for that of the spontaneous release.

Results

Reaction of Sulfate Esters with PEI Derivatives. Nitrophenyl sulfates, PNPS and HNPS, did not react with poly(ethylenimine) derivatives under the reaction conditions employed. For example, a reaction mixture which contain 1.77×10^{-3} M of PEI–C_{12}(20)–Im(15) and 1.0×10^{-4} M of HNPS was allowed to stand for 20 h at 30 °C (pH 8.8, 0.01 M borate buffer and μ= 0.01). No change was detected in the visible spectrum during this period. Nitrocatechol was not detected in the product by thin layer chromatography using the solvent system similar to that of Ref. 9. Therefore, the pseudo first-order rate constant, $k_{1,obsd}$ should be much smaller than $1 \times 10^{-5}\ s^{-1}$ or $k_{2,obsd}$ (apparent second-order rate constant) $\ll 5 \times 10^{-3}\ M^{-1}\ s^{-1}$. This is contrary to the efficient hydrolysis reported by Kiefer *et al.*[9]

On the other hand, DNPS was smoothly cleaved by these polymers. Table 1 summarizes $k_{1,obsd}$ of phenol release from DNPS by various PEI derivatives. In the last column are given $k_{2,obsd}$ values which were derived simply by dividing $k_{1,obsd}$ by the polymer concentration. It is clear from Table 1 that the catalytic groups such as imidazole, hydroxamate or primary amine are not appreciably effective for the sulfate cleavage. However, all of the PEI derivatives are more effective than the conventional cationic micelle (CTAB) or polysoap(PVP^+–C_{18}(8)–C_2(77)). In the subsequent

experiments, two types of PEI derivatives, alkylated PEI(PEI–C_{16}(8)) and quaternized PEI(PEI^+–C_{18}(16)) were used for more detailed study.

Product Analysis. Excess amounts of DNPS substrate (3—10 fold excesses) were allowed to react with the above-mentioned two PEI derivatives. The time course of the formation of 2,4-dinitrophenol after correction for the spontaneous release is given in Fig. 1. In the case of alkylated PEI's (Fig. 1a and 1b), the reaction slows down at the release corresponding to *ca.* 0.3 equivalent (in monomer unit) of the polymer. In contrast, the reaction proceeds beyond the concentration of the quaternized polymers (Fig. 1c, 1d, and 1e). These results suggest the presence of different mechanisms of the phenol release for the two types of the polymers.

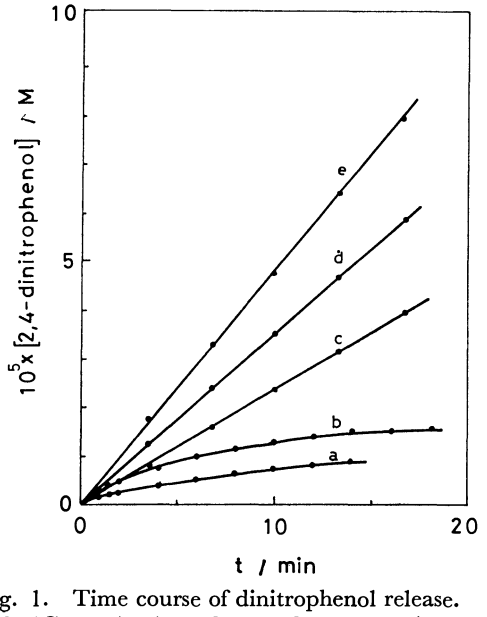

Fig. 1. Time course of dinitrophenol release.

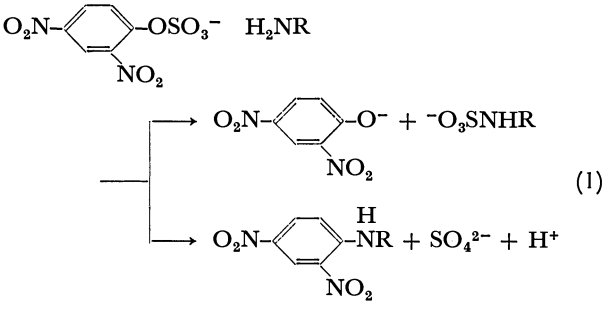
Polymer concentrations: a, [PEI–C_{16}(8)]$=3.95\times10^{-5}$ M; b, [PEI–C_{16}(8)]$=5.92\times10^{-5}$ M; c, [PEI^+–C_{18}(16)]$=2.05\times10^{-5}$ M; d, [PEI^+–C_{18}(16)]$=4.08\times10^{-5}$ M; e, [PEI^+–C_{18}(16)]$=6.16\times10^{-5}$ M.

TABLE 2. SULFUR CONTENT OF PEI CATALYSTS AFTER REACTION WITH DNPS SUBSTRATE

Polymer	Treated with DNPS	Sulfur content /%
PEI–C_{16}(8)	No	—
PEI–C_{16}(8)	Yes	7.06
PEI^+–C_{18}(16)	No	0.00
PEI^+–C_{18}(16)	Yes	0.35

Table 2 summarizes the sulfur content of the polymers before and after the reaction (see Experimental). Apparently, the sulfate group is fixed to the partially alkylated polymer, PEI–C_{16}(8) but not to the quaternized polymer, PEI^+–C_{18}(16). The small sulfur content of the latter polymer is close to the experimental error. The sulfur content of 7% corresponds to the presence of 16 mol % (per monomer unit) of the amidosulfate group according to scheme 1. This value is smaller than the amidosulfate content (30%) estimated from the dinitrophenol release (Eq. 1). Apparently, some of the amidosulfate group was hydrolyzed during the work up of the polymer, as reported by Benkovic and Benkovic in a related system.[17)]

The amino group in the partially alkylated PEI may react with phenyl sulfates *via* sulfate transfer (formation of amidosulfate) or nucleophilic aromatic substitution as shown in Eq. 1. This problem was discussed most recently by Fendler, *et al.*[18)] for the reaction of primary and secondary amines in the micellar system.



(1)

The occurrence of the nucleophilic aromatic substitution would decrease the sulfur content of the polymer.

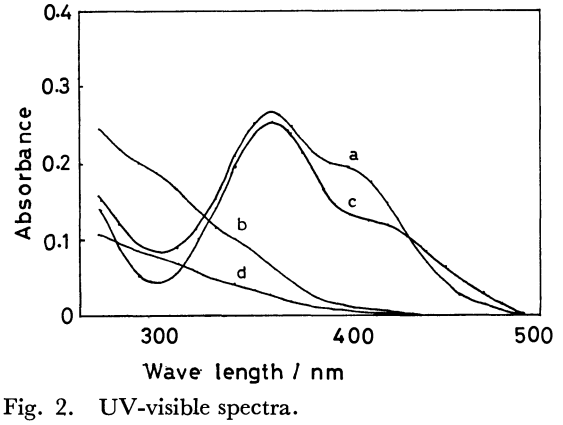


Fig. 2. UV-visible spectra.
a: 1 h after mixing of 1.9×10^{-5} M DNPS and 1.0×10^{-3} unit M PEI–C_{16}(8), pH 8.8, 30 °C. b: The same mixture adjusted to pH 1.6 by hydrochloric acid. c: 1.9×10^{-5} M *N*-methyl-2,4-dinitroaniline, pH 2.1. d: 1.9×10^{-5} M 2,4-dinitrophenol, pH 2.1.

Figure 2 shows a UV-visible spectrum of the reaction mixture after 1 h. (Fig. 2a). Also shown are spectra of the same solution after acidification to pH 1.6 by hydrochloric acid (Fig. 2b) and of *N*-methyl-2,4-dinitroaniline and 2,4-dinitrophenol at pH 2.1 (Fig. 2c and 2d, respectively). The spectrum of the acidified reaction mixture clearly indicates the absence of the dinitroaniline moiety. Therefore, it is concluded that the aromatic substitution path is negligible for alkylated PEI under the present reaction conditions.

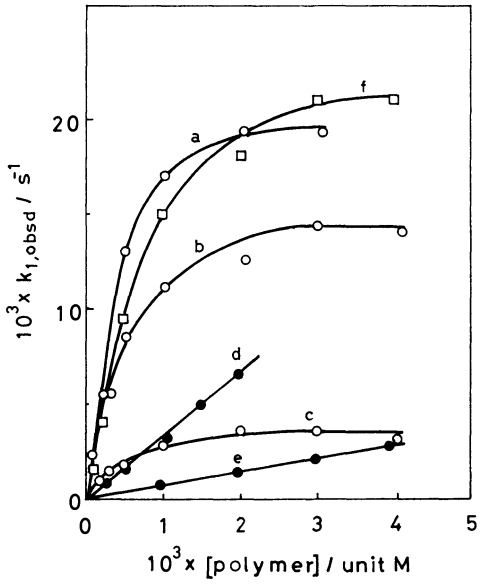

Fig. 3. Dependence of the rate of DNPS cleavage on the concentration of PEI derivatives.
30 °C, 3 v/v % EtOH–H_2O, μ=0.01(KCl), 0.01—0.02 M borate, [DNPS]=2.0×10^{-5} M.
Polymer: PEI$^+$–C_{18}(16)(-○-) a, pH 9.5; b, pH 7.7; c, pH 6.2; PEI–C_{16}(8) (-●-) d, pH 9.0; e, pH 10.1; PEI$^+$–C_{18}(9) (-□-) f, pH 8.5.

Rate Dependence on Polymer Concentration. Figure 3 shows the dependence of $k_{1,obsd}$ of dinitrophenol release on the polymer concentration. In the case of alkylated PEI, $k_{1,obsd}$ increases linearly with the polymer concentration in the range of (1—40)$\times10^{-4}$ M. The results with the quaternized PEI are contrasting in that saturation phenomena are observed. The ease of saturation depends on the pH of the medium.

The saturation kinetics were analyzed according to the Michaelis-Menten kinetics

$$C + S \underset{}{\overset{K_b}{\rightleftharpoons}} CS \xrightarrow{k_{cat}} C + P_1 + P_2 \qquad (2)$$

where C, S, P_1, and P_2 denote polymer, substrate, SO_4^{2-} and 2,4-dinitrophenol, respectively, and CS is the polymer-substrate complex.

Since excess polymer is present ($[C]_0 \gg [S]_0$), the following equations obtain.

$$v = k_{1,obsd}[S]_{total} = k_{cat}[CS] \qquad (3)$$
$$\text{and } [S]_{total} = [S] + [CS]$$

$$K_b \text{ (binding constant)} = \frac{[CS]}{[C][S]} \qquad (4)$$

$$k_{1,obsd} = \frac{k_{cat}\cdot K_b\cdot[C]_0}{K_b[C]_0+1} \qquad (5)$$

Therefore

$$\frac{1}{k_{1,obsd}} = \frac{1}{k_{cat}} + \frac{1}{k_{cat}\cdot K_b\cdot[C]_0} \qquad (6)$$

The data for the PEI$^+$ system in Fig. 3 were plotted using Eq. 6 and linear relations were obtained with satisfactory correlation coefficients. The K_b and k_{cat} thus derived are given in Table 3. As is clear from the data for PEI$^+$, the binding constant K_b decreases with increasing pH but the intra-complex rate constant k_{cat} increases with increasing pH.

Table 3 also contains $k_{2,obsd}$ for PEI–C_{16}(8) determined from the data of Fig. 3. $k_{2,obsd}$ decreases with increasing pH.

pH *Rate Profiles.* Figure 4 illustrates the pH dependence of $k_{1,obsd}$ in the presence of PEI derivatives and a quaternized poly(vinylpyridine). PEI–C_{16}(8) polymer gives a bell-shaped pH dependence with a maximum at *ca.* pH 8. The rate determination was difficult at pH below 7 because of precipitation. A similar pH-rate profile was obtained with an anionic ester substrate NABA (Fig. 5).

On the other hand, when quaternized PEI was used as catalyst, log $k_{1,obsd}$ initially increased linearly with increasing pH and became constant at pH above 8. The log $k_{1,obsd}$ value for NABA (Fig. 5) showed a linear correlation with pH in the pH range studied (pH 7—10). The rate of hydrolysis of NABA by PEI$^+$–C_{18}(16) is 10—100 times slower than that by PEI–C_{16}(8), but the relative effectiveness is reversed in the hydrolysis of DNPS. The reversal suggests that the rate enhancement mechanisms are different between the two systems.

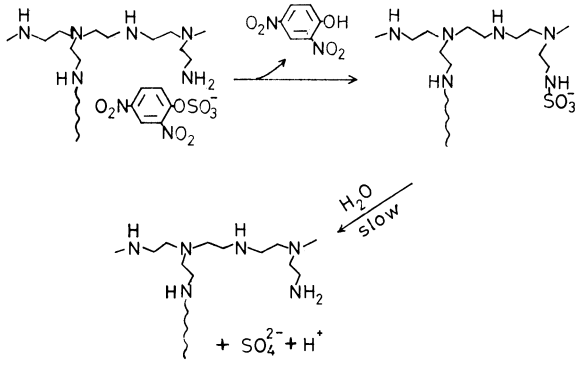
Discussion

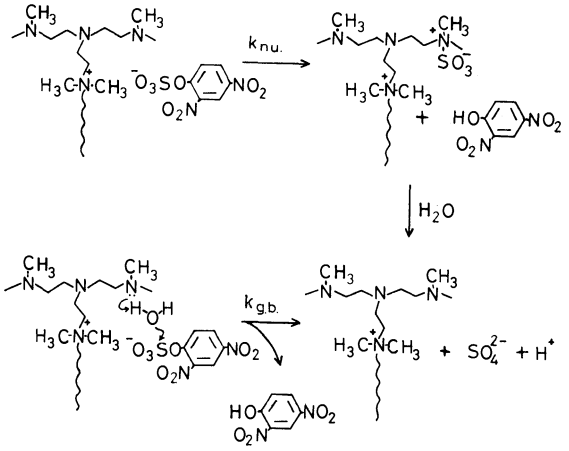
Reaction Scheme. The reaction scheme of alkylated PEI is obviously different from that of quaternized PEI. The most probable mechanisms for these PEI derivatives are shown in Scheme 1. In the case of alkylated PEI, the sulfate group is transfered from DNPS substrate to the nucleophilic amino group. The nucleophilic aromatic substitution was not detected (see above). The amidosulfate group is accumulated with the progress of the reaction, and, as shown in Fig. 1, the remaining amino group becomes less reactive. The zwitterionic adduct, if formed by the nucleophilic attack of tertiary amines toward nitrophenyl sulfates, should be hydrolytically unstable.[19] The accumulation of the amidosulfate group thus indicates the preferential sulfate transfer to the primary and/or secondary amines. This is contrary to the fact that tertiary amines are in general more nucleophilic toward nitrophenyl sulfates than primary and secondary amines.[17,18] The lack of sulfate transfer to the tertiary amino group in PEI may be attributed to severe steric hindrance. The nucleophilic reactivity of sterically-hindered tertiary amines (small molecules) toward sulfate esters is in fact very small.[17] The general-base catalysis by the tertiary amino group, which is sterically less demanding, could not be detected because it is probably less efficient than simple sulfate transfer to the primary and secondary amino groups.



Scheme 1.

The initial rate of sulfate transfer was first order with respect to substrate and polymer. There was found no evidence for substrate binding. However, the bell-shaped pH rate profile of Fig. 4 indicates the cooperative action of substrate attraction by the positively-charged polymer and of the effective neutral nucleophile. Therefore, the imcomplete reaction of the polymer-bound amino group is probably caused by neutralization of the positive charge of alkylated PEI by the negative charge of the amidosulfate group formed. The enhanced catalytic action of partly protonated poly(vinylpyridine) and poly(vinylimidazole) has been known for a long time.[20,21]

On the other hand, the partly quaternized PEI does not contain the primary and secondary amino groups and acts as true catalyst. This is readily seen from the turnover of the polymer catalyst (Fig. 1) and the absence of the intermediate accumulation (Table 2). The catalysis follows the Michaelis-Menten kinetics. The substrate binding is ascribed to both of the hydrophobic and electrostatic attractions between the polymer and substrate. The contribution of the electrostatic interaction is apparent in the fact that K_b decreases with increasing pH.



Scheme 2.

The intra-complex catalysis will involve the general-base and/or nucleophilic action of the tertiary amino group (Scheme 2). The turnover could result from the nucleophilic attack of the tertiary amino group which produces the unstable zwitterionic adduct. However, the tertiary amino group in PEI's does not appear to be sufficiently nucleophilic because of steric hindrance, as discussed above. Then, the general-base action may become the preferred pathway. The nucleophilic and general-base mechanisms are usually discriminated by the kinetic solvent isotope effect. However, this technique cannot be applied to the present system, since the side chain aggregation (hence the characteristics of the catalytic domain) would be quite different in H_2O and in D_2O. This effect renders the interpretation of the isotope effect very difficult.

A third possibility is the hydroxide-catalyzed cleavage of the bound substrate. However, this mechanism is not likely, as extensively quaternized PEI, PEI^+–$C_{18}(12)$–$C_1(68)$ is much less effective. The activity of the CTAB micelle and the quaternized poly(vinylpyridine) is also much smaller (Table 1). If the hydroxide-catalyzed hydrolysis is the major catalytic pathway, these systems should be at least equally effective, because of their high densities of the positive charge.

These results are contrasting with those of the NABA hydrolysis. The linear relation of Fig. 5 suggests that the phenyl ester is cleaved by the hydroxide ion which is concentrated in the domain of PEI^+–$C_{18}(16)$. The nucleophilic cleavage of NABA is reflected in a greater efficiency of PEI–$C_{16}(8)$ relative to that of PEI^+–$C_{18}(16)$, as also shown in Fig. 4.

Efficiency of Sulfate Cleavage. Table 4 summarizes the kinetic parameters reported for the cleavage of DNPS in the past. Sulfate esters seem to be less reactive with simple anionic nucleophiles. For instance, either A_1 or general-acid mechanism was suggested to occur for the cyclodextrin-catalyzed hydrolysis.[22] The hydroxamate ion in the cationic micelle is not particularly effective for the sulfate cleavage in spite of its enormous reactivity toward phenyl esters. However, sulfate transfer to the zwitterionic hydroxamate proceeds smoothly in the hydrophobic microenvironment.[10] It appears that basic groups act on sulfate esters particularly effectively (either as nucleophiles or as general bases) when they are fixed at positions close to the quaternary ammonium group in the hydrophobic microenvironment.

A comparison of the rate constants between the piperidine–CTAB system and PEI^+–$C_{18}(16)$ is interesting. Both of the catalytic systems contain the amino group, the dense positive charge and the hydrophobic domain. However, the PEI^+ system is 10^2—10^3 times more efficient in the sulfate transfer than the CTAB system. The difference is even greater when the fact that clean turnover is observed for PEI^+–$C_{18}(16)$ is taken into account. The quaternized PEI is the most effective catalyst and the apparent catalytic rate constant is more than 10^7 times greater than that of the spontaneous hydrolysis.

Finally it is noted that the nitrophenyl sulfates HNPS and PNPS were not cleaved by PEI derivatives under the same condition as used for DNPS hydrolysis: 30 °C, pH 8—10. Therefore $k_{2,obsd}$ should be less than 10^{-3} $M^{-1}\,s^{-1}$. These results are totally different from that reported by Kiefer *et al.*[9] These authors reported the apparent catalytic rate constant of 18 $M^{-1}\,s^{-1}$ which is more than 10^{12} larger than that of imidazole. The discrepancy between the two sets of experiment amount to the order of at least 10^4 in the rate constant. The composition of the imidazole-containing PEI prepared

Reinvestigation of the Mechanism of the Reaction of *N,N*-Dimethylaniline *N*-Oxide with Acetic Anhydride

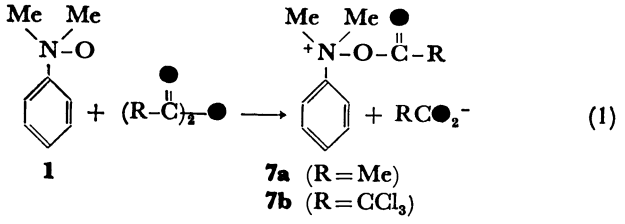
Shigeru OAE,* Nobuyoshi ASAI, and Ken FUJIMORI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

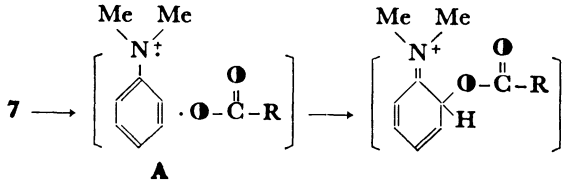
(Received February 2, 1979)

The mechanism of the reaction between *N,N*-dimethylaniline *N*-oxide **1** and acetic anhydride to give 2-acetoxy-*N,N*-dimethylaniline **2a** has been reinvestigated by means of our more refined ^{18}O-tracer experiments. Other products of the reaction are 4-acetoxy-*N,N*-dimethylaniline, *N,N*-dimethylaniline **4**, *N*-methylacetanilide, and bis(4-dimethylaminophenyl)methane. The reaction of **1** with ^{18}O-labeled acetic anhydride is considered to involve the initial formation of carbonyl-^{18}O-labeled *N*-acetoxy-*N,N*-dimethylanilinium ion **7a** and the subsequent intramolecular rearrangement of **7a** into **2a** in which the original ^{18}O-label in **7a** is unequally partitioned into two oxygen atoms of **2a** (phenolic oxygen: ethereal oxygen=*ca.* 4: 1). The reaction of **1** with trichloroacetic anhydride gave solely 2-trichloroacetoxy-*N,N*-dimethylaniline but not any **4** which should be formed *via* the free radical mechanism. These observations suggest the occurrence of the two concerted path *via* polarized six-(major) and four-(minor) membered cyclic transition states and rule out the free radical pair mechanism which was proposed ealier by us.[2]

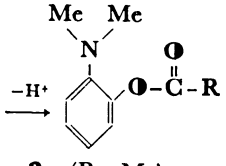
The reaction between *N,N*-dimethylaniline *N*-oxide **1** and acetic anhydride was first investigated in somewhat detail by Huisgen *et al.*[1] Soon after, we also investigated the mechanism by ^{18}O-tracer technique and proposed the radical pair mechanism (**A**) for the formation of 2-acetoxy-*N,N*-dimethylaniline **2a** based on the observation that both carbonyl and ethereal oxygen atom in **2a** was nearly completely equilibrated in the course of the rearrangement from **7a** to **2a**.[2]



1 **7a** (R=Me) **7b** (R=CCl_3) (1)



A

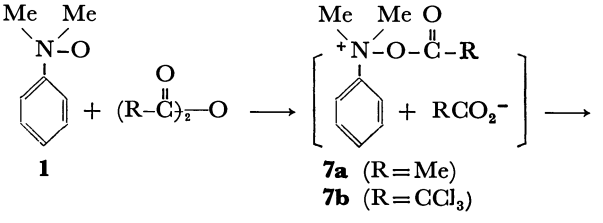


2a (R=Me) **2b** (R=CCl_3) (2)

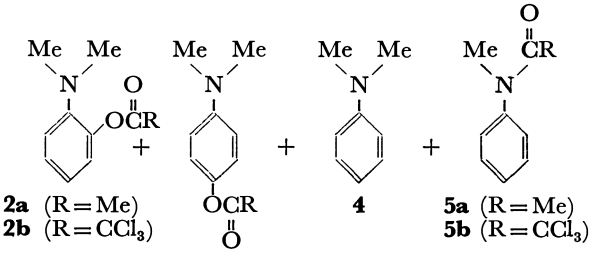
Later, Iwamura *et al.* observed a CIDNP signal only for *N,N*-dimethylaniline **4** but not for **2a** and *N*-acetyl-*N*-methylaniline **5a**, and the radical mechanism **A** has become quite dubious.[3] In our extensive investigations of the mechanisms of the rearrangement reactions of tertiary amine *N*-oxides with acylating agents by means of ^{18}O-tracer technique, we have seldom encountered the case in which the reaction proceeded solely *via* radical mechanistic path.[4] Thus, the reaction between **1** and acetic anhydride has been reinvestigated by aid of our more sophisticated ^{18}O-tracer technique.

Results and Discussion

The reaction between *N,N*-dimethylaniline *N*-oxide **1** and acetic anhydride was found to give products **2**—**4**, while the distribution of products clearly depends on the solvent as seen in Table 1.



1 **7a** (R=Me) **7b** (R=CCl_3)



2a (R=Me) **2b** (R=CCl_3) **3a** (R=Me) **4** **5a** (R=Me) **5b** (R=CCl_3)

a) Ref. 1.

In such an aprotic solvent as acetonitrile, demethylation by Polonovski reaction giving **5a** was predominant, however, the rearrangement to afford **2a** was the major course of the reaction in protic media. The first step of the reaction has been believed to be the acetylation of **1** to form *N*-acetoxy-*N*,*N*-dimethylanilinium ion **7** which is then partitioned to go through the different paths (Eq. 1). In acetonitrile, the acetate anion is considered to be a base strong enough to abstract proton from the *N*-methyl group of **7a** to promote the Polonovski reaction eventually to give **5a**; whereas in protic media, the basicity of acetate anion should be markedly reduced by the solvation, and hence the alternative rearrangement reaction becomes predominant.[1,2]

Upon the usual treatment of the *N*-oxide with ^{18}O-labeled acetic anhydride in protic media, **2a** was isolated from the mixture, purified and allowed to react with phenylhydrazine to give crystalline products, *i.e.* 2-hydroxy-*N*,*N*-dimethylaniline and 1-acetoxy-2-phenylhydrazine, which were carefully purified and then subjected to the routine ^{18}O-analysis (Table 2).[5] Meanwhile all the conceivable intermediates and/or transition states of this rearrangement may be illustrated from **A** to **K**.

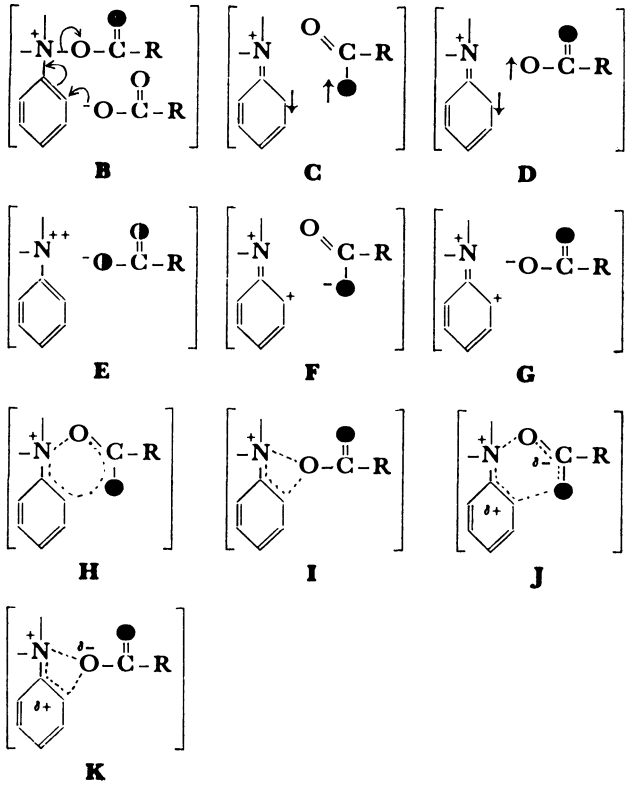

Table 2. ^{18}O-Tracer result of the reaction between **1** and $(MeC)_2{}^{18}O$

Compound	^{18}O-Content of the compd (excess atom %)[a]	
	in 50% MeCN–H_2O	in H_2O
1-Acetyl-2-phenylhydrazine[b]	0.854	0.854

1-Acetyl-2-phenylhydrazine	0.178	0.133

a) ± 0.005 atom %. b) Derived from the starting acetic anhydride.

When the calculated ^{18}O-distributions in **2a** resulted from all these possible mechanistic routes are compared with the observed values in Table 3, the mechanism involving the attack of external acetate anion *via* **B** is obviously ruled out, in keeping with our original argument suggested earlier.[2] Although the observed ^{18}O-data cannot be explained by the radical mechanism **A** (Eq. 2), the possibility of homolytic cleavage of N–O bond of **7a** cannot be rejected completely. Namely, if the radical pair would be a very short lived singlet radical pair such as either **C** or **D**, as suggested by Iwamura *et al.*,[3] the ^{18}O-label may not be completely scrambled in **2a**, since the two oxygens of the acetoxyl radical formed incipiently should be sterically unequal. The formation of **4** which has been confirmed as the radical reaction product by CIDNP study[3] must be produced *via* homolytic cleavage of **7a**. Indeed the reaction of **1** with acetic anhydride initiates the polymerization of styrene.[1,6] These observations seem to imply the involvement of these singlet radical pairs **C** and **D** at least partially.

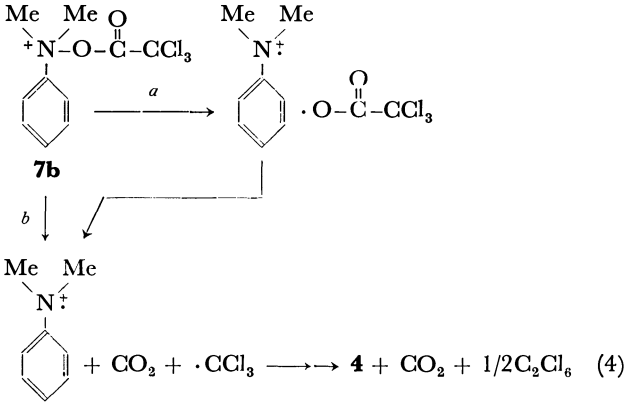
In order to examine the possible involvement of such a homolytic cleavage, trichloroacetic anhydride was allowed to react with **1**. If the intervention of radical pairs **C** or **D** or both would be responsible for the formation of **2**, the yield of radical reaction product, **4**, should markedly increase in the reaction of **1** with trichloroacetic anhydride (Eq. 4),[7] since the decarboxylation of trichloroacetoxyl radical is well known to be very fast.[8] However, since the reaction of **1** with trichloroacetic anhydride gave only **2b**, but neither any **4** nor hexachloroethane, all the free radical mechanisms **A**, **C**, and **D** cannot be responsible for the major path of the rearrangement.[9]

Thus the ionic mechanisms **E**—**K** still remain. Among these, however, the ion pair mechanisms seem to be highly unlikely, since the ionic cleavage of the N–O bond of **7a** leads to the formation of a highly

Table 3. Theoretical and experimental ^{18}O-distribution in **2a** obtained from **1** and ^{18}O-labeled acetic anhydride[a]

Oxygen	Experimental		Theoretical			
	in 50% MeCN–H_2O	in H_2O	**B**	**A**,**E**	**C**,**F**,**H**,**J**	**D**,**G**,**I**,**K**
Phenolic	79%	84%	100%	50%	100%	0%
Carbonyl	21	16	100	50	0	100

a) Original ^{18}O-content of carbonyl oxygen of **7a** is defined as 100%.



7b

$$+ CO_2 + \cdot CCl_3 \longrightarrow\!\!\rightarrow \mathbf{4} + CO_2 + 1/2C_2Cl_6 \quad (4)$$

energetic double cation species of **4**. Indeed, the ion pair mechanism **E** cannot be accepted since the ^{18}O-distribution in **2a** is uneven and the oxygen scrambling in **2a** decreases with the increase of solvating power of the medium. Only in the case if the ion pair is a very short lived intimate one as illustrated by **F** or **G**, the two oxygen atoms of the acetate anion might not be sterically equal and could give **2a** in which ^{18}O-label is not completely equilibrated. The mechanisms *via* **F** and **G** may also be eliminated in view of the highly unstable *N,N*-dimethylaniline double cation. Meanwhile product ratio **2a** *vs.* the radical product **4** from **7a** was found to increase with the increase of the polar nature of the solvent.[10] Whereas when acetic anhydride was changed to trichloroacetic anhydride, no free radical products were obtained despite the facile homolytic bond cleavage of **7a** by concerted two bond fission to give cation radical of **4**, CO_2, and trichloromethyl radical.[7] All these observations do not seem to be in accordance with the mechanism involving the sigmatropic shift such as **H** or **I**, however, can be best explained in terms of the concurrent heterolytic cleavage of N–O bond of **7a** and a new C–O bond forming *via* such transition states as illustrated by **J** (major path) and **K** (minor path) which are represented as a hybrid of canonical forms, **C**, **F**, and **H** for **J** and that of canonical forms, **D**, **G**, and **I** for **K**. The contribution of each of these canonical forms is considered to depend on the nature of solvent and R group of the acid anhydride used. Similar polarized cyclic transition state has been suggested for the rearrangement of *O*-benzoyl-*N*-(*p*-tolylsulfonyl)-*N*-arylhydroxylamine **8** to 2′-benzoyloxy-*p*-toluenesulfonanilide **9** as shown in Eq. 5.[11]

Experimental

N,N-Dimethylaniline *N*-oxide **1** was prepared by oxidation of *N,N*-dimethylaniline **4** with hydrogen peroxide in methanol according to the method of Huisgen, Bayerlein, and Hegkamp.[1]

Oxygen-18-labeled acetic anhydride was prepared by the method reported by Oae, Kitao, and Kitaoka;[12] bp 137.5—139 °C. By treatment with phenylhydrazine, a small amount of the acetic anhydride was converted to crystalline 1-phenyl-2-acetylhydrazine which was recrystallized from benzene; mp 129—129.5 °C, and subjected to the ^{18}O-analysis (0.854 excess atom %).

*Reaction between **1** and Acetic Anhydride in 50%(v/v) CH_3CN–H_2O.* Acetic anhydride (1.3 g, 13 mmol) was added dropwise into a solution of **1** (1.0 g, 7.3 mmol) in 14 ml of 50%(v/v) CH_3CN–H_2O with stirring at 0 °C under nitrogen atmosphere. The mixture was stirred for 2 h at 0 °C, then the reaction mixture was treated with an aqueous solution of sodium carbonate under cooling in an ice bath, then extracted with ether and dried. To the solution, 725 mg of 2,4-dichloronitrobenzene was added as the internal standard for the analysis by a GLPC equipped with 2 m stainless steel column packed with 5% PEG-20M on 80 mesh celite. The chromatogram was recorded on Shimadzu GC-6A GLPC instrument.

*Reaction between **1** and Acetic Anhydride in CH_3CN.* The reaction and product analysis were carried out in a same manner described for the reaction in 50%(v/v) CH_3CN–H_2O.

*Reaction between **1** and Trichloroacetic Anhydride.* *N,N*-Dimethylaniline *N*-oxide **1** (100 mg, 0.73 mmol) in 3 ml of dry CH_3CN was treated dropwise with trichloroacetic anhydride (430 mg, 1.4 mmol) at 0 °C under nitrogen atmosphere. The reaction mixture was treated with aqueous solution of sodium carbonate and extracted with ether and dried over sodium sulfate. Into this solution, tetralin (102 mg) was added as the internal standard for GLPC analysis through a stainless steel column packed with 5% SE-30 on 80 mesh celite. The gas chromatogram of the sample solution was recorded on Hitachi 163 GLPC instrument, and only one peak of 2-hydroxy-*N,N*-dimethylaniline was observed.

*Oxygen-18-tracer Experiment of the Reaction between **1** and Acetic Anhydride.* *In 50%(v/v) CH_3CN–H_2O*: The reaction between 1.0 g of **1** and 1.36 g of ^{18}O-labeled acetic anhydride was carried out in a similar manner which was applied for the product analysis. 2-Acetoxy-*N,N*-dimethylaniline **2a** was separated by preparative TLC (Kieselgel G_{254}) at 5 °C with 5% acetone–hexane as an eluent (isolated yield 0.567 g). The product **2a** was treated with 0.377 g of phenylhydrazine and the mixture was allowed to stand overnight at room temperature. A solid mass, separated, was collected and washed with benzene, gave 0.33 g of 1-phenyl-2-acetylhydrazine, which was recrystallized from benzene and subjected to the ^{18}O-analysis; mp 129—129.5 °C. The filtrate was washed with water to remove unreacted phenylhydrazine, dried and solvent was removed. Preparative TLC (Kieselgel GF_{254}) of the residue with 5% acetone–dichloromethane as an eluent gave 0.406 g of 2-hydroxy-*N,N*-dimethylaniline which was distilled under reduced pressure and subjected to the ^{18}O-analysis, mp 44—44.5 °C.

In H_2O: The reaction was carried out in a same manner described above.

Control Experiment on Dilution of ^{18}O-Label in Acetic Anhydride during the Reaction. A solution of 500 mg (4.9 mmol) of ^{18}O-labeled acetic anhydride and 400 mg (0.33 mmol) of **1** in 1 ml of 50%(v/v) CH_3CN–H_2O was stirred for 2 h at 0 °C

under nitrogen atmosphere. Into this solution 520 mg of *N*-methylaniline was added and the solution was stirred for addtional 1 h at room temperature. After the solvent was removed, the residue was washed with benzene to obtain 240 mg of *N*-methylacetanilide which was recrystallized from benzene; mp 102—102.5 °C. Since ^{18}O-content of the *N*-methylacetanilide (0.855 excess atom %) was found to be same to that of 1-acetyl-2-phenylhydrazine (0.854 excess atom %) which was derived from starting ^{18}O-labeled acetic anhydride (Table 2), there is no ^{18}O-dilution of acetic anhydride during the reaction with **1** in the presence of H_2O.

Determination of Oxygen-18 Content. ^{18}O-analysis was carried out by the method developed by Rittenberg-Ponticorbo.[5] Twenty mg of sample was pyrolyzed with 300 mg of purified $HgCl_2$ and $Hg(CN)_2$ respectively, in an evacuated, sealed silica tube at 550 °C for 12 h. Then the tube was broken in a vacuum line and CO_2 formed was purified by distillation and the mass peaks *m/e* 44 and 46 which correspond to $C^{16}O_2$ and $C^{16}O^{18}O$, respectively, were recorded on Hitachi RMU-6MG mass spectrometer. An error of ^{18}O-content was within ± 0.005 atom %. $HgCl_2$ was purified by sublimation under reduced pressure and $Hg(CN)_2$ was purified by recrystallization from absolute ethanol before use.

The Nucleophilic Reaction of Electron-deficient Pyridone Derivatives. I. The Ring Transformation of 1-Substituted 3,5-Dinitro-2-pyridones with Sodio β-Keto Esters

Eizo MATSUMURA, Masahiro ARIGA,* and Yasuo TOHDA
Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received February 9, 1979)

A novel ring transformation is found in a series of reactions of 1-substituted 3,5-dinitro-2-pyridones, electron-deficient substrates, with monosodium salts of β-keto esters. A variety of 1-substituted 3,5-dinitro-2-pyridones are treated with diethyl sodio-3-oxopentanedioate and ethyl sodioacetoacetate to give, in addition to *N*-substituted nitroacetamides (**3**), 2,6-bis(ethoxycarbonyl)-4-nitrophenol (**2**), and 2-ethoxycarbonyl-4-nitrophenol (**4**) respectively. The bicyclic intermediates, 2-azabicyclo[3.3.1]nona-3,7-dienes, can be isolated on the reaction of 3,5-dinitro-1-methyl-2-pyridone at room temperature. The phenol derivatives (**2** and **4**) may consist of the reagent and a C_4–C_5–C_6 moiety of the parent pyridone, while *N*-substituted nitroacetamides, **3**, may result from the other fragment, N–C_2–C_3, of the pyridone. A probable course of the reaction, involving the step-by-step nucleophilic attack of the ambident nucleophiles, sodio β-keto esters, at the ambident electrophilic centers of 2-pyridones to form bicyclic intermediate, is proposed.

In our earlier studies[1] of the nucleophilic substitution reactions of pyridine derivatives, we showed that the reaction of 1-methyl-2-(pyridiniomethyl)pyridinium salt or its homologues with potassium hydroxide solution at a low temperature gave 1-methyl-2-pyridone or its homologues respectively.

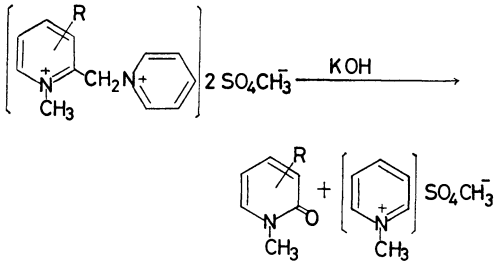

Fig. 1.

In these reactions, the bis(quaternary salts) were converted, without the heterolysis of the N–C_2 bond, to 1-methyl-2-pyridone or its homologues by the easy loss of the pyridiniomethyl group. This reaction has since offered a convenient route for the preparation of 1-methyl-2-pyridone homologues.

On the other hand, the ease of the heterolysis at the N–C_2 bond of the well-known Zincke reaction[2] of 2,4-dinitrophenylpyridinium chloride under similar basic conditions may be ascribed to the presence of a strongly electron-attractive 2,4-dinitrophenyl group on the nitrogen atom.

We have also shown[3] that the reaction of 3-bromo-4-nitropyridine *N*-oxide with one of the monosodium salts of β-keto esters (*i.e.*, ethyl sodioacetoacetate) gave the β-substituted product (*i.e.*, 3-[acetyl(ethoxycarbonyl)-methyl]-4-nitropyridine *N*-oxide), from which 2,3-disubstituted furo[3,2-*c*]pyridine *N*-oxide (*i.e.*, 3-ethoxycarbonyl-2-methylfuro[3,2-*c*]pyridine *N*-oxide) was obtained when it was warmed for a short time in an ethanol solution of sodium ethoxide.

This reaction is an example of a reaction which proceeds step-by-step between an ambident nucleophile and an ambident electrophile.

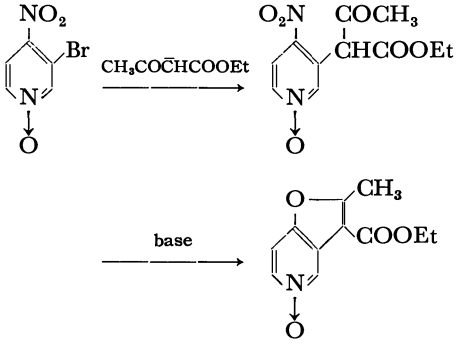

Fig. 2.

The above interesting results prompted us to expand the related reactions in this series to the nucleophilic reaction of 1,3,5-trisubstituted 2-pyridones with monosodium salts of β-keto esters and β-diketones.

Results and Discussion

The reaction of 3,5-dinitro-1-methyl-2-pyridone (**1a**) with 1.5 equimolar amounts of diethyl sodio-3-oxopentanedioate (Na·DOPD) at 50 °C in pyridine gave, after neutralization, 2,6-bis(ethoxycarbonyl)-4-nitrophenol (**2**) and *N*-methyl-α-nitroacetamide (**3a**). The same reaction of **1a** with 3 equimolar amounts of ethyl sodioacetoacetate (Na·EAA) at 70 °C gave 2-ethoxycarbonyl-4-nitrophenol (**4**) and **3a** in good yields. These

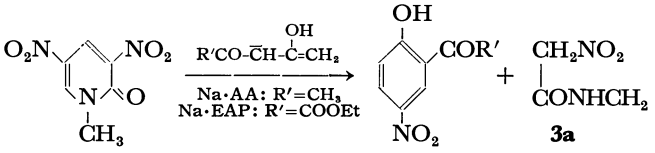
Table 1. Reaction of 3,5-dinitro-1-methyl-2-pyridone (**1a**) with sodium salts of β-keto esters and β-diketones

Substrate	Reagent	Reaction conditions: Solvent	Mole ratio	Temp °C	Time h	Product (Yield/%)	
1a	Na·DOPD	Pyridine	1.5	50	5	**2** (90.4)	**3a** (28.3)
1a	Na·EAA	Pyridine	3.0	70	5	**4** (61.0)	**3a** (16.9)
1a	Na·AA	DMF	3.0	70	5	**5** (53.0)	**3a** (11.5)
1a	Na·EAP	Pyridine	3.0	110	5	**6** (42.0)	**3a** (8.3)

products were identified by their IR, NMR, and results of elemental analysis, and by a mixed-melting-point determination with authentic samples.

The reaction of **1a** with monosodium salts of β-diketones were also carried out. The reaction of **1a** with sodioacetylacetone (Na·AA) gave 2-acetyl-4-nitrophenol (**5**) and **3a**, and a similar reaction of **1a**, at a higher temperature (110 °C), with ethyl sodioacetopyruvate (Na·EAP) gave 2-ethoxyoxalyl-4-nitrophenol (**6**) and **3a**.



1a **3a**

5: R'=CH_3
6: R'=COOEt

Fig. 4.

It may be considered to be characteristic of these reactions to form a phenol derivative from the active methylene compound used as the ambident nucleophile and the pyridone moiety containing C_4, C_5, and C_6. The formation of the residual moiety of the pyridone would lead to *N*-methyl-α-nitroacetamide (**3a**).

In order to prove the generality of these reactions, various kinds of 1-substituted 3,5-dinitro-2-pyridones, such as 1-(*m*-nitrobenzyl)- (**1b**), 1-(2-pyridylmethyl)- (**1c**), 1-unsubstituted- (**1d**), 1-(2,4-dinitrophenyl)- (**1e**), 1-(2-pyridyl)- (**1f**), 1-(4-methyl-2-pyridyl)- (**1g**), 1-(5-methyl-2-pyridyl)- (**1h**), 1-(6-methyl-2-pyridyl)- (**1i**), 1-hydroxy- (**1j**), 1-methoxy- (**1k**), and 1-(*p*-nitrobenzyloxy)- (**1l**), were prepared and then reacted with either Na·DOPD or Na·EAA.

The reaction of each 1-substituted 3,5-dinitro-2-pyridone with Na·DOPD gave 2,6-bis(ethoxycarbonyl)-4-nitrophenol (**2**) and the corresponding *N*-substituted nitroacetamide (**3**). With each 1-substituted 3,5-dinitro-2-pyridone and Na·EAA, on the other hand, 2-ethoxycarbonyl-4-nitrophenol (**4**) and the corresponding *N*-substituted nitroacetamide (**3**) were obtained.

The results of the above reactions and the spectral data (NMR and IR) of *N*-substituted nitroacetamides are shown in Tables 2 and 3 respectively.

In the case of the reaction of 3,5-dinitro-1-(2-pyridyl)-2-pyridone (**1f**) with Na·DOPD or Na·EAA, the same yellow compound, **7f**, was obtained, together with **3f** and either **2** or **4** respectively. The empirical formula,

7g: R''=8-CH_3
7h: R''=7-CH_3
7i: R''=6-CH_3

Fig. 5.

$C_7H_5N_3O_2$, of this yellow compound corresponded to the loss of one molecule of water from *N*-(2-pyridyl)-α-nitroacetamide (**3f**). The IR spectra of **7f** showed the presence of an *N*-oxide group (1205 cm^{-1}), a carbonyl group (1730 cm^{-1}), and a C=N double bond (1650 cm^{-1}), while the absorption bands due to the nitro group and the N–H bond which were confirmed in that of **3f** were absent. During the melting-point measurement, **3f** was converted to **7f** by heating it to 120 °C in a capillary. Compound **7f** was also prepared from ethyl nitroacetate and 2-aminopyridine by only heating. The catalytic reduction of **7f** on Raney Nickel in ethanol at 110 °C under 50 atm gave ethyl 2-pyridylcarbamate. From the above observations, 2-oxo-2*H*-pyrido[1,2-*b*]-[1,2,4]triazine 4-oxide was assigned to **7f**, though the C_3 proton was not observed in the NMR spectra of **7f** in trifluoroacetic acid or trifluoroacetic acid-d_1. With **1g**, **1h**, and **1i** all of which correspond to the homologues of **1f**, and Na·DOPD or Na·EAA, **7g**, **7h**, and **7i** were obtained respectively, but on the reaction of **1g**, **7g** was obtained exclusively without any isolation of *N*-(4-methyl-2-pyridyl)-α-nitroacetamide (**3g**). The ease of the cyclization of *N*-(2-pyridyl)-α-nitroacetamide to **7f** in an aqueous solution is likely to be due to the increasing acidic α-amino group which is bonded to the electron-attractive nitroacetyl and 2-pyridyl group, accordingly, the conversion of the resultant *N*-anion with a 1,6-dipole structure to the **7f** compound is favorably oriented for an intramolecular nucleophilic attack on the ω-nitronium ion with a loss of water. Under the same conditions, the fused-ring products (**7h** and **7i**) were also obtained from **3h** and **3i** respectively.

Further information was obtained under milder conditions. From the reaction of **1a** with Na·DOPD

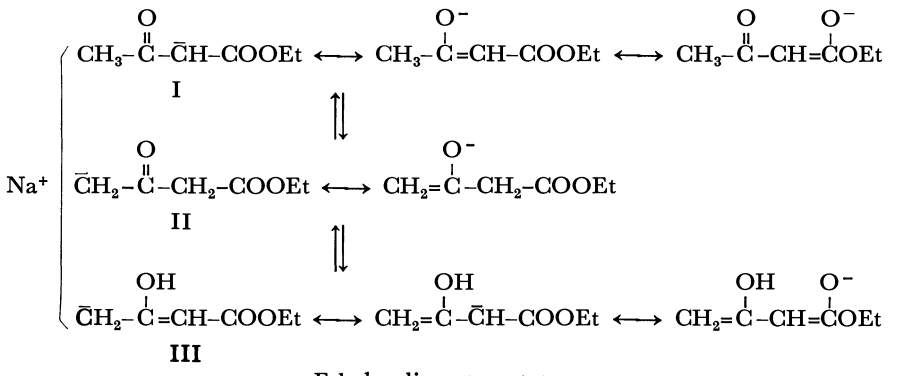
at room temperature, a colorless crystalline product (**8a**) (mp 155.0—156.0 °C) was obtained in addition to **2** and **3a**. The empirical formula of **8a**, $C_{12}H_{15}N_3O_8$, suggests that it is an adduct of **1a** and diethyl 3-oxopentanedioate. The IR spectra of **8a** showed the presence of a nitro group (1540, 1350 cm^{-1}) and a carbonyl group (1730 cm^{-1}). The NMR spectra of **8a** showed the following: aromatic proton signals of the parent pyridone and the singlet methyl and methylene signals of the reagent disapeared, and the four aliphatic proton signals coupled with each other were observed in the range between 3.9 and 5.4 ppm. Two singlets due to the enol 7-hydroxyl group at 12.64 ppm and due to the strongly hydrogen-bonded 3-hydroxyl group at 18.82 ppm were also observed. On the treatment with only ethanolic sodium ethoxide at 70 °C or with Na·DOPD in pyridine, **8a** was easily converted to **2** and **3a**. On the basis of the above physical and chemical data, 6,8-bis(ethoxycarbonyl)-3,7-dihydroxy-2-methyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene was assigned to **8a**. Similarly, with **1a** and Na·EAA 6-ethoxycarbonyl-3,7-dihydroxy-2-methyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene (**9a**) was obtained.

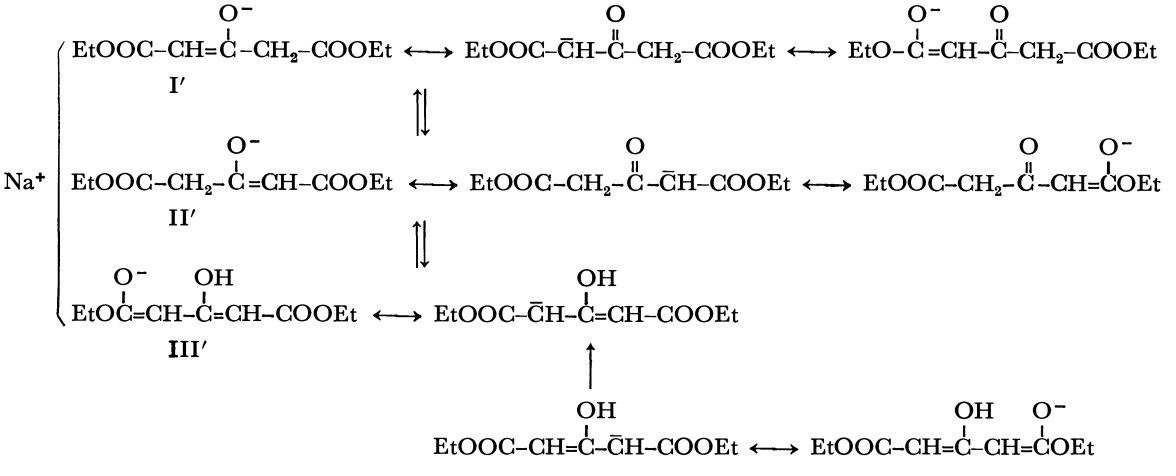
Meta-bridging bicyclic structures anoalogous to **8a** and **9a** have been described by Strauss *et al.*[4] and Momose *et al.*[5] in connection with the reaction of electron-deficient aromatics (*e.g.*, 1,3,5-trinitrobenzene or 3,5-dinitrobenzene derivatives) with active methylene compounds under basic conditions, but these addition compounds were sodium derivatives.

From the above results, the formation of the intermediate, **8a** or **9a**, may be ascribed to the reaction of an ambident electrophilic end at the 4 and 6-positions of 1,3,5-trisubstituted 2-pyridones with the ambident nucleophilic end of the enolate ion which is obtained from the sodio β-keto esters.

The treatment of ethyl acetoacetate and diethyl 3-oxopentanedioate with 1 mol of sodium ethoxide in ethanol easily gives ethyl sodioacetoacetate and diethyl 3-oxopentanedioate respectively. These ambident



Ethyl sodioacetoacetate



Diethyl sodio-3-oxopentanedioate

anions can be accounted for as shown above:

In the respective ambident tautomers, the enol types of III and III′ are softer uncleophiles than the enolate types of the others. For example, in the case of III with 3,5-dinitro-1-methyl-2-pyridone, the softer C_α-anion would be favorably attacked at the softer C_6-atom of the pyridone nucleus, and another soft C_γ-anion of the resultant adduct (**10**) at the soft C_4-atom, by the step-by-step nucleophilic and intramolecular nucleophilic mechanism leading to **8a** and **9a**.

The ring transformation of **8a** and **9a** which are obtained by the reaction at a low temperature, to **2** and **4** can be carried out by heating under basic conditions. It is proposed that the transformation of the inter-

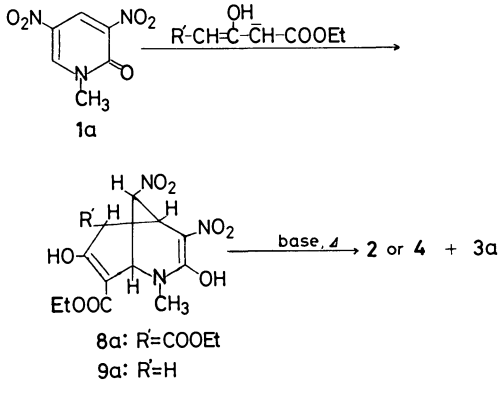


Fig. 6.

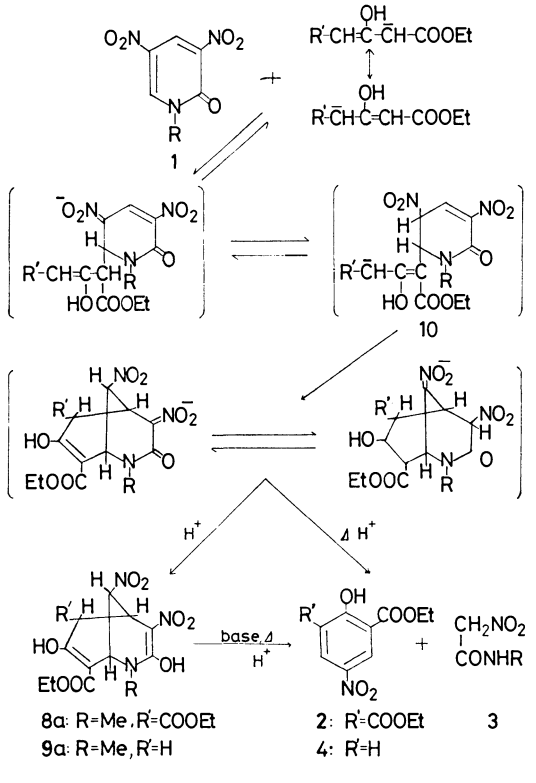

Scheme 1.

mediate **8a** or **9a** into **2** or **4** proceeds by means of the initial nucleophilic attack of the 9-carbanion on the C_5-atom, with the concomitant heterolysis of the C_4–C_5 bond, leaving the electron pair at the C_4-atom. The aromatization of the resultant homolytic moiety, which leads to **2** or **4** can occur with the heterolysis of the C_1–N bond, leaving the electron pair at the N-atom. The residual moiety of the 2-pyridone nucleus yields **3**. In the reaction at a higher temperature, the same products can be obtained without the isolation of the intermediates.

Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Hitachi EPI-S2 as Nujol mulls. The NMR spectra were recorded on a Hitachi R-20B or JEOL FX-100 (unless otherwise noted the former was used), with TMS as the internal standard.

*3,5-Dinitro-1-methyl-2-pyridone (**1a**).* To 30 ml of fuming nitric acid (*d* 1.52) we added 5.0 g of 1-methyl-2-pyridone,[6] then the mixture was heated at 80 °C for 5 h. After almost all the nitric acid has been evaporated under reduced pressure, the mixture was poured onto crushed ice, and the precipitates were recrystallized from water to give 4.7 g (51.4%) of 3,5-dinitro-1-methyl-2-pyridone (**1a**); mp 178.0—179.0 °C (lit, mp 178 °C).[7] IR: 1700 cm^{-1} (C=O), 1530, 1350 (NO_2). NMR (DMSO-d_6): δ 3.65 (3H, s), 8.93 (1H, d), 9.52 (1H, d).

*3,5-Dinitro-1-(m-nitrobenzyl)-2-pyridone (**1b**).* Five grams of 1-(*m*-nitrobenzyl)-2-pyridone[8] were worked-up according to the above method to give 3.1 g (30.0%) of 3,5-dinitro-1-(*m*-nitrobenzyl)-2-pyridone (**1b**); mp 139.0—141.0 °C (recrystallized from aqueous acetic acid). IR: 1690 cm^{-1} (C=O), 1530, 1340 (NO_2). NMR (DMSO-d_6): δ 5.43 (2H, s), 7.62 (1H, d), 7.80 (1H, dt), 8.03 (1H, dt), 8.31 (1H, t), 8.96 (1H, d), 9.84 (1H, d). Found: C, 44.91; H, 2.46; N, 17.71%. Calcd for $C_{12}H_8N_4O_7$: C, 45.01; H, 2.52; N, 17.50%.

*3,5-Dinitro-1-(2-pyridylmethyl)-2-pyridone (**1c**).* Similarly, the nitration of 2-amino-1-(2-pyridylmethyl)-pyridinium chloride, which had been prepared from 2-chloromethylpyridine and 2-aminopyridine by heating, gave 3,5-dinitro-1-(2-pyridylmethyl)-2-pyridone (**1c**) in a 32.0% yield; mp 155.0 °C with dec (water). IR: 1700 cm^{-1} (C=O), 1580, 1340 (NO_2). NMR (DMSO-d_6): δ 5.52 (2H, s), 7.1—7.9 (3H, m), 8.43 (1H, dd), 8.97 (1H, d), 9.49 (1H, d). Found: C, 47.66; H, 2.61; N, 20.16%. Calcd for $C_{11}H_8N_4O_5$: C, 47.85; H, 2.92; N, 20.28%.

*3,5-Dinitro-2-pyridone (**1d**).* This pyridone was obtained by the method of Takahashi *et al.*[9]

*3,5-Dinitro-1-(2,4-dinitrophenyl)-2-pyridone (**1e**).* A mixture of a sodium salt of 2-hydroxypyridine and a 1.1 equimolar amount of 2,4-dinitrochlorobenzene in DMSO was heated at 140 °C for 5 h. The subsequent evaporation of the solvent was followed by extraction with chloroform to give 1-(2,4-dinitrophenyl)-2-pyridone (mp 163.8—164.2 °C) in a 48.0% yield. To a solution of 5.0 g of 1-(2,4-dinitrophenyl)-2-pyridone in 50 ml of fuming sulfuric acid (30% SO_3) we added 9.7 g of potassium nitrate, portion-by-portion, the mixture was then heated at 130 °C for 5 h. The reaction mixture was poured onto crushed ice, the precipitates were recrystallized from aqueous acetic acid to give 3.3 g (49.0%) of 3,5-dinitro-1-(2,4-dinitrophenyl)-2-pyridone (**1e**); mp 165.3—165.5 °C. IR: 1720 cm^{-1} (C=O), 1530, 1350 (NO_2). NMR (DMSO-d_6): δ 7.92 (1H, d), 8.07 (1H, dd), 8.11 (1H, d), 9.18 (1H, d), 9.68 (1H, d). Found: C, 37.84; H, 1.36; N, 20.04%. Calcd for $C_{11}H_5N_5O_9$: C, 37.60; H, 1.44, N, 19.95%.

*3,5-Dinitro-1-(2-pyridyl)-2-pyridone (**1f**).* Three grams of 1-(2-pyridyl)-2-pyridone[10] were treated according to the above method to give 3.05 g (66.7%) of 3,5-dinitro-1-(2-pyridyl)-2-pyridone (**1f**); mp 179.5—180.5 °C (aqueous acetic acid). IR: 1710 cm^{-1} (C=O), 1540, 1350 (NO_2). NMR (DMSO-d_6): δ 7.4—8.1 (3H, m), 8.60 (1H, dd), 9.02 (1H, d), 9.42 (1H, d). Found: C, 45.81; H, 2.31; N, 21.37%. Calcd for $C_{10}H_6N_4O_5$: C, 45.76; H, 2.16; N, 21.67%.

*3,5-Dinitro-1-(4-methyl-2-pyridyl)-2-pyridone (**1g**).* Similarly, the nitration of 1-(4-methyl-2-pyridyl)-2-pyridone[10] gave 3,5-dinitro-1-(4-methyl-2-pyridyl)-2-pyridone (**1g**) in a 63.8% yield; mp 164.0—165.0 °C (aqueous acetic acid). IR: 1720 cm^{-1} (C=O), 1530, 1355 (NO_2). NMR (DMSO-d_6): δ 2.43 (3H, s), 7.41 (1H, dd), 7.30 (1H, d), 8.44 (1H, dd), 9.03 (1H, d), 9.39 (1H, d). Found: C, 48.08; H, 2.73; N, 20.29%. Calcd for $C_{11}H_8N_4O_5$: C, 47.83; H, 2.92; N, 20.29%.

*3,5-Dinitro-1-(5-methyl-2-pyridyl)-2-pyridone (**1h**).* The similar nitration of 1-(5-methyl-2-pyridyl)-2-pyridone[10] gave 3,5-dinitro-1-(5-methyl-2-pyridyl)-2-pyridone (**1h**) in a 53.9% yield; mp 174.0—175.0 °C (aqueous acetic acid). IR: 1720 cm^{-1} (C=O), 1535, 1330 (NO_2). NMR (DMSO-d_6): δ 2.40 (3H, s), 7.8 (2H, m), 8.5 (1H, m), 9.05 (1H, d), 9.40 (1H, d). Found: C, 47.64; H, 2.69; N, 20.01%. Calcd for $C_{11}H_8N_4O_5$: C, 47.83; H, 2.93; N, 20.29%.

*3,5-Dinitro-1-(6-methyl-2-pyridyl)-2-pyridone (**1i**).* Similarly, 3,5-dinitro-1-(6-methyl-2-pyridyl)-2-pyridone (**1i**) was obtained from 1-(6-methyl-2-pyridyl)-2-pyridone[10] in a 58.8% yield; mp 175.5—176.5 °C (aqueous acetic acid). IR: 1710 cm^{-1} (C=O), 1530, 1340 (NO_2). NMR (DMSO-d_6): δ 2.67 (3H, s), 7.4 (1H, m), 7.7 (1H, m), 8.3 (1H, m), 9.02 (1H, d), 9.48 (1H, d). Found: C, 47.96; H, 2.80; N, 20.38%. Calcd for $C_{11}H_8N_4O_5$: C, 47.83; H, 2.93; N, 20.29%.

*3,5-Dinitro-1-hydroxy-2-pyridone (**1j**).* The pyridone was obtained according to the method in the literature[11] in an 80.0% yield; mp 190.0—191.0 °C.

*3,5-Dinitro-1-methoxy-2-pyridone (**1k**).* A mixture of 7.0 g of 1-methoxy-2-pyridone[12] and 70 ml of fuming nitric acid (*d* 1.52) was heated at 80 °C for 10 h. The cold reaction mixture was then poured onto crushed ice, the precipitates were collected by filtration, the filtrate was concentrated, and diluted with water, and the second crop was obtained combined with the above precipitates, and crystallized from water to give 6.5 g (54.0%) of 3,5-dinitro-1-methoxy-2-pyridone (**1k**); mp 158.0—159.0 °C. IR: 1740 cm^{-1} (C=O), 1560, 1330 (NO_2). NMR (DMSO-d_6): δ 3.25 (3H, s), 8.95 (1H, d), 9.82 (1H, d). Found: C, 33.57; H, 2.50; N, 19.50%. Calcd for $C_6H_5N_3O_6$: C, 33.50; H, 2.34; N, 19.54%.

*3,5-Dinitro-1-(p-nitrobenzyloxy)-2-pyridone (**1l**).* 1-(*p*-Nitrobenzyloxy)-2-pyridone[12] was nitrated according to the preceding method to give 3,5-dinitro-1-(*p*-nitrobenzyloxy)-2-pyridone (**11**) in a 70.0% yield; mp 192.0—193.0 °C (water). IR: 1730 cm^{-1} (C=O), 1535, 1330 (NO_2). NMR (DMSO-d_6): δ 5.45 (2H, s), 7.85 (2H, d), 8.25 (2H, d), 9.02 (1H, d), 10.00 (1H, d). Found: C, 42.92; H, 2.28; N, 16.38%. Calcd for $C_{12}H_8N_4O_8$: C, 42.86; H, 2.40; N, 16.67%.

*General Procedure of the Reaction of Pyridones (**1**) with Sodium Salts.* To a solution of pyridone (**1**) in pyridine we added a solution of sodium salt in pyridine with cooling, then the mixture was heated at the required temperature for 5—10 h. The solvent was evaporated under reduced pressure, and the residue was neutralized to pH 3—4 with dil. Hydrochloric acid and then extracted with chloroform. After the extract has been dried over anhydrous sodium sulfate, the chloroform was distilled off, and the residual syrup was column-chromatographed on silica gel (Wakogel C-300). From the benzene elute, phenol derivatives (**2**, **4**, **5**, and **6**)

were obtained, and from the diethyl ether elute, *N*-substituted nitroacetamide (**3**).

*Reaction of 3,5-Dinitro-1-methyl-2-pyridone (**1a**) with Diethyl Sodio-3-oxopentanedioate.* To a solution of 1.0 g of 3,5-dintro-1-methyl-2-pyridone (**1a**) in 100 ml of pyridine we added diethyl sodio-3-oxopentanedioate, prepared from 0.17 g of sodium and 1.7 g of diethyl 3-oxopentanedioate in absolute ethanol, in pyridine with cooling. When the mixture was heated at 50 °C for 5 h and then worked-up according to the general procedure, 1.3 g of (90.4%) of 2,6-bis(ethoxycarbonyl)-4-nitrophenol (**2**)[13] was obtained from the benzene elute and 0.17 g (28.3%) of *N*-methyl-α-nitroacetamide (**3a**),[14] from the diethyl ether elute.

2,6-Bis(ethoxycarbonyl)-4-nitrophenol (**2**); colorless needles (petroleum benzine); mp 58.0—59.0 °C. IR: 3100 cm^{-1} (O–H), 1720 (C=O), 1540, 1340 (NO_2). NMR ($CDCl_3$): δ 1.42 (6H, t), 4.45 (4H, q), 8.81 (2H, s), 12.42 (1H, s). Found: C, 50.94; H, 4.64; N, 4.81%. Calcd for $C_{12}H_{15}NO_7$: C, 50.84; H, 4.63; N, 4.95%.

N-Methyl-α-nitroacetamide (**3a**); colorless needles (diisopropyl ether); mp 75.0—76.0 °C. IR: 3300 cm^{-1} (N–H), 1670 (C=O), 1570, 1340 (NO_2). NMR (acetone-d_6): δ 2.78 (3H, d), 5.16 (2H, s), 7.00 (1H, d). Found: C, 30.32; H, 5.09; N, 23.70%. Calcd for $C_3H_6N_2O_3$: C, 30.51; H, 5.08; N, 23.73%.

*2-Ethoxycarbonyl-4-nitrophenol (**4**).* The treatment of 1.0 g of 3,5-dinitro-1-methyl-2-pyridone (**1a**) with ethyl sodioacetoacetate, prepared from 0.3 g of sodium and 2.2 g of ethyl acetoacetate, at 70 °C for 5 h gave 0.65 g (60.8%) of 2-ethoxycarbonyl-4-nitrophenol (**4**)[15] and 0.05 g (16.9%) of **3a**.

2-Ethoxycarbonyl-4-nitrophenol (**4**); colorless plates (petroleum benzine); mp 97.5—98.0 °C. IR: 3420 cm^{-1} (O–H), 1680 (C=O), 1524, 1335 (NO_2). NMR ($CDCl_3$): δ 1.45 (3H, t), 4.45 (2H, q), 7.03 (1H, d), 8.03 (1H, dd), 8.67 (1H, d), 11.35 (1H, s). Found: C, 51.46; H, 4.24; N, 6.45%. Calcd for $C_9H_9NO_5$: C, 51.19; H, 4.30; N, 6.63%.

*2-Acetyl-4-nitrophenol (**5**).* Colorless needles (petroleum benzine); mp 101.0—102.0 °C (lit, mp 101—102 °C).[16] IR: 3365 cm^{-1} (O–H), 1650 (C=O), 1520, 1350 (NO_2). NMR ($CDCl_3$): δ 2.71 (3H, s), 7.05 (1H, d), 8.26 (1H, dd), 8.62 (1H, d), 12.76 (1H, s). Found: C, 52.98; H, 3.77; N, 7.45%. Calcd for $C_8H_7NO_4$: C, 53.05; H, 3.90; N, 7.73%.

*2-Ethoxyoxalyl-4-nitrophenol (**6**).* Colorless needles (petroleum benzine); mp 57.5—58.5 °C. IR: 3360 cm^{-1} (O–H), 1730 (C=O), 1690 (C=O), 1530, 1340 (NO_2). NMR ($CDCl_3$): δ 1.45 (3H, t), 4.51 (2H, q), 7.11 (1H, d), 8.38 (1H, dd), 8.76 (1H, d), 11.73 (1H, s). Found: C, 50.35; H, 3.66; N, 5.57%. Calcd for $C_{10}H_9NO_6$: C, 50.21; H, 3.77; N, 5.86%.

N-*(m-Nitrobenzyl)-α-nitrocaetamide (**3b**).* Colorless needles (benzene); mp 152.0—153.0 °C. NMR (acetone-d_6): δ 4.47 (2H, d), 5.38 (2H, s), 7.55—8.15 (4H, m), 9.10 (1H, br). Found: C, 45.02; H, 3.53; N, 17.33%. Calcd for $C_9H_9N_3O_5$: C, 45.19; H, 3.79; N, 17.57%.

N-*(2-Pyridylmethyl)-α-nitroacetamide (**3c**).* Colorless needles (diisopropyl ether); mp 83.0—84.0 °C. NMR (acetone-d_6): δ 4.55 (2H, d), 5.40 (2H, s), 7.0—7.9 (3H, m), 8.20 (1H, br), 8.44 (1H, d). Found: C, 49.55; H, 4.29; N, 21.62%. Calcd for $C_8H_9N_3O_3$: C, 49.25; H, 4.65; N, 21.53%.

N-*(2,4-Dinitrophenyl)-α-nitroacetamide (**3e**).* Pale yellow needles (benzene); mp 120.4—121.1 °C. NMR (DMSO-d_6): δ 5.62 (2H, s), 8.5 (2H, m), 8.9 (1H, m), 11.10 (1H, br). Found: C, 35.53; H, 2.08; N, 20.54%. Calcd for $C_8H_6N_4O_7$: C, 35.56; H, 2.24; N, 20.76%.

N-*(2-Pyridyl)-α-nitroacetamide (**3f**).* Colorless needles; dec 120 °C. NMR (acetone-d_6): δ 5.62 (2H, s), 7.1—8.2 (4H, m), 9.85 (1H, br). Found: C, 46.63; H, 3.67; N, 23.26%. Calcd for $C_7H_7N_3O_3$: C, 46.41; H, 3.87; N, 23.20%.

*2-Oxo-2H-pyrido[1,2-b][1,2,4]triazine 4-Oxide (**7f**).* After *N*-(2-pyridyl)-α-nitroacetamide (**3f**) had been obtained, the column was washed with acetone and ethanol to give 0.21—0.24 g (3.5—3.8%) of 2-oxo-2*H*-pyrido[1,2-*b*][1,2,4]-triazine 4-oxide (**7f**); yellow needles (water); dec 210 °C. NMR (CF_3COOD): δ 7.5—7.9 (2H, m), 8.52 (1H, dt), 9.65 (1H, dd). Found: C, 51.35; H, 2.97; N, 25.89%. Calcd for $C_7H_5N_3O_2$: C, 51.54; H, 3.09; N, 25.76%.

*8-Methyl-2-oxo-2H-pyrido[1,2-b][1,2,4]triazine 4-Oxide (**7g**).* Yellow needles (water); dec 210 °C. IR: 1730 cm^{-1} (C=O), 1635 (C=N), 1210 (N→O). NMR (CF_3COOD): δ 3.58 (3H, s), 7.70 (1H, d), 8.35 (1H, dd), 9.38 (1H, d). Found: C, 54.10; H, 3.73; N, 23.60%. Calcd for $C_8H_7N_3O_2$: C, 54.23; H, 3.98; N, 23.72%.

N-*(5-Methyl-2-pyridyl)-α-nitroacetamide (**3h**).* Colorless needles; dec 120 °C. NMR (acetone-d_6): δ 2.43 (3H, s), 5.52 (2H, s), 7.56 (1H, dd), 7.87 (1H, d), 8.11 (1H, s), 10.98 (1H, s). Found: C, 49.38; H, 4.71; N, 21.50%. Calcd for $C_8H_9N_3O_3$: C, 49.23; H, 4.65; N, 21.53%.

*7-Methyl-2-oxo-2H-pyrido[1,2-b][1,2,4]triazine 4-Oxide (**7h**).* Yellow needles (water); dec 248 °C. IR: 1735 cm^{-1} (C=O), 1645 (C=N), 1210 (N→O). NMR (CF_3COOD): δ 2.50 (3H, s), 7.70 (1H, d), 8.37 (1H, dd), 9.37 (1H, d). Found: C, 54.36; H, 3.82; N, 23.68%. Calcd for $C_8H_7N_3O_2$: C, 54.23; H, 3.98; N, 23.72%.

N-*(6-Methyl-2-pyridyl)-α-nitroacetamide (**3i**).* Colorless needles; dec 120 °C. NMR (acetone-d_6): δ 2.36 (3H, s), 5.62 (2H, s), 6.96 (1H, dd), 7.61 (1H, dd), 7.87 (1H, dd), 9.95 (1H, s). Found: C, 49.11; H, 4.55; N, 21.73%. Calcd for $C_8H_7N_3O_3$: C, 49.23; H, 4.65; N, 21.53%.

*6-Methyl-2-oxo-2H-pyrido[1,2-b][1,2,4]triazine 4-Oxide (**7i**).* Yellow needles (water); dec 182 °C. IR: 1730 cm^{-1} (C=O), 1640 (C=N), 1210 (N→O). NMR (CF_3COOD): δ 2.54 (3H, s), 6.5—6.9 (2H, m), 7.5—7.8 (1H, m). Found: C, 54.48; H, 3.81; N, 23.61%. Calcd for $C_8H_7N_3O_2$: 54.23; H, 3.98; N, 23.72%.

*2-Oxo-2H-pyrido[1,2-b][1,2,4]triazine 4-Oxide (**7f**) from N-(2-Pyridyl)-α-nitroacetamide (**3f**).* A mixture of 0.5 g of *N*-(2-pyridyl)-α-nitroacetamide (**3f**) in 10 ml of water was refluxed for 30 min. The mixture was then cooled and the precipitates were collected by filtration to give 0.44 g (98.0%) of 2-oxo-2*H*-pyrido[1,2-*b*][1,2,4]triazine 4-oxide (**7f**). Similarly, **7h** and **7i** were obtained quantitatively from **3h** and **3i** respectively.

*2-Oxo-2H-pyrido[1,2-b][1,2,4]tiazine 4-Oxide (**7f**) (Alternative Method).* A mixture of 2.0 g of 2-aminopyridine and 2.0 g of ethyl nitroacetate[17] was heated slowly then kept at 90 °C for 1 h. When to the reaction mixture we then added a small amount of ethanol, 2.1 g (85.5%) of 2-oxo-2*H*-pyrido[1,2-*b*][1,2,4]triazine 4-oxide (**7f**) were obtained.

*Catalytic Hydrogenation of 2-Oxo-2H-pyrido[1,2-b][1,2,4]-triazine 4-Oxide (**7f**).* A mixture of 0.5 g of 2-oxo-2*H*-pyrido[1,2-*b*][1,2,4]triazine 4-oxide (**7f**), 0.1 g of Raney Nickel, and 50 ml of ethanol in a 100 ml autoclave was heated at 100 °C under 100 atm of hydrogen gas for 5 h. After filtration, the ethanol was distilled off, and the residual syrup was column-chromatographed on silica gel; 0.3 g of ethyl 2-pyridylcarbamate[18] was obtained from the benzene elute, and 0.05 g of 2-aminopyridine, from the diethyl ether elute.

*Reaction of 3,5-Dinitro-1-methyl-2-pyridone (**1a**) with Diethyl Sodio-3-oxopentanedioate at a Low Temperature.* One gram of 3,5-dinitro-1-methyl-2-pyridone (**1a**) was worked-up according to the general procedure at room temperature with diethyl sodio-3-oxopentanedioate, and then before column-

chromatography, diethyl ether was added to the residual syrup. Crystalline precipitates were collected by filtration to give 1.3 g of **8a**, and the filtrate was column-chromatographed with benzene. From the benzene elute 0.13 g of **2**, and from the chloroform elute, and additional 0.3 g of **8a** were obtained.

6,8-Bis(ethoxycarbonyl)-3,7-dihydroxy-2-methyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene (**8a**); colorless plates; mp 155.0—156.0 °C (ethanol). IR: 1740 cm^{-1} (C=O), 1730 (C=O), 1560, 1335 (NO_2). NMR (JEOL FX-100)($CDCl_3$): δ 1.35 (3H, t), 1.42 (3H, t), 3.20 (3H, s), 3.95 (1H, d, J= 2 Hz, H-6), 4.29 (2H, q), 4.40 (2H, q), 4.42 (1H, ddd, J=2, 3, and 4 Hz, H-5), 5.15 (1H, dd, J=4 and 3 Hz, H-1), 5.42 (1H, dd, J=4 and 4 Hz, H-9), 12.64 (1H, s), 18.82 (1H, s). Found: C, 45.31; H, 4.71; N, 10.53%. Calcd for $C_{15}H_{19}N_3O_{10}$: C, 45.26; H, 4.77; N, 10.42%.

*Reaction of 3,5-Dinitro-1-methyl-2-pyridone (**1a**) with Ethyl Sodioacetoacetate at a Low Temperature.* Similarly, the reaction of 1.0 g of 3,5-dinitro-1-methyl-2-pyridone (**1a**) with 3 equimolar amounts of ethyl sodioacetoacetate gave 0.1 g of **4**, 0.05 g of **3a**, and 0.9 g of 8-ethoxycarbonyl-3,7-dihydroxy-2-methyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene (**9a**); colorless needles (ethanol); mp 190.0—191.0 °C. IR: 1730 cm^{-1} (C=O), 1550, 1340 (NO_2). NMR (JEOL FX-100) ($CDCl_3$): δ 1.41 (3H, t), 2.84 (1H, d, J=4 Hz, H-6), 2.99 (1H, d, J=2 Hz, H-6), 3.20 (3H, s), 4.30 (1H, ddt, J=3, 4, and 2 Hz, H-5), 4.37 (2H, q), 4.71 (1H, dd, J=3 and 2 Hz, H-1), 5.30 (1H, t, J=3 Hz, H-9), 12.59 (1H, s), 18.83 (1H, s). Found: C, 43.48; H, 4.31; N, 12.76%. Calcd for $C_{12}H_{15}N_3O_8$: C, 43.79; H, 4.56; N, 12.76%.

*Treatment of 6,8-Bis(ethoxycarbonyl)-3,7-dihydroxy-2-methyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene (**8a**) with Sodium Ethoxide.* A solution of 0.5 g of **8a** and 0.4 g of sodium ethoxide in 50 ml of ethanol was refluxed for 2 h. The solvent was then distilled off, and the residue was neutralized to pH 3.5 with dil. hydrochloric acid and extracted with chloroform. After the extract had then been dried over anhydrous sodium sulfate, the chloroform was evaporated to dryness and the residual syrup was column-chromatographed on silica gel. From the benzene elute 0.1 g of **2**, and from the diethyl ether elute, 0.06 g of **3a** were obtained.

*Treatment of 6,8-Bis(ethoxycarbonyl)-3,7-dihydroxy-2-methyl-4,9-dinitro-2-azabicyclo[3.3.1]nona-3,7-diene (**8a**) with Diethyl Sodio-3-oxopentanedioate.* A mixture of 0.5 g of **8a** and diethyl sodio-3-oxopentanedioate, prepared from 0.03 g of sodium and 0.3 g of diethyl 3-oxopentanedioate, in pyridine was heated at 70 °C for 2 h. The reaction mixture was then worked-up according to the usual procedure to give 0.20 g of **2** and 0.06 g of **3a**.

Electron-organic Chemistry. IV.[1] Structure—Anodic Potential Relationship and Electron-transfer-induced Reactions of [2.2]Para- and -Metaparacyclophanes

Takeo SATO,* Koichi TORIZUKA, Motomu SHIMIZU, Yukio KURIHARA, and Noriko YODA

Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received February 16, 1979)

The anodic peak potentials of [2.2]para- and -metaparacyclophanes were found to be highly dependent on the solvent. A cleavage reaction occured when [2.2]paracyclophane was electrolyzed anodically, using acids or alcohols as nucleophilic solvents, whereas lead tetraacetate oxidation in trifluoroacetic acid–dichloromethane gave nuclear substitution products. The cathodic reduction in hexamethylphosphoric triamide–lithium chloride–acetic acid gave 1,2-di-*p*-tolylethane and its Birch reduction products. On anodic oxidation, [2.2]metaparacyclophane gave a rearrangement reaction product, 4-hydroxy[2.2]metacyclophane. Possible reaction pathways for these reactions were formulated.

The dependence of the half-wave potentials on a molecular geometry and the reaction of the resulting radical ions have aroused considerable current interests.[1-5] Recent findings that cyclophane-radical ions undergo intramolecular reactions,[3-5] such as a transannular reaction, as well as rearrangement and fragmentation reactions led us to investigate the electron-transfer-induced reactions of basic cyclophanes [2.2]-paracyclophane (**1**) and [2.2]metaparacyclophane (**13**).

The anodic half-wave potential of **1**, +1.52 V *vs.* SCE in acetonitrile–tetrabutylammonium perchlorate[4] (+1.47 V in acetonitrile–lithium perchlorate[6]), is anomalously low and is more cathodic by *ca.* 0.5 V[4] than those of [*m*]paracyclophane or 1,2-bis(4-alkylphenyl)ethane. This fact indicates that one of the benzene rings serves as an internal π donor for stabilizing the aryl-cation radical formed. The enhanced π basicity of **1** towards tetracyanoethylene is explainable along the same lines.[7] The anodic peak potential, E_{pa}, for [2.2]metaparacyclophane (**13**) was determined by the cyclic voltammetry at 250 mV/s and was found to be +1.79 V in acetonitrile–tetrabutylammonium perchlorate.[4] It is more cathodic than those of the above model compounds by *ca.* 0.3 V.

The peak potential for these compounds, as determined by the cyclic voltammetry, showed a marked solvent dependence. The results are summarized in Table 1. At the scan rate of 250 mV/s, E_{pa} for **1** varied from +1.57 V in acetonitrile to +1.12 V in trifluoroacetic acid–dichloromethane (1 : 1). A slight cathodic shift was also observed in solutions containing acetic acid, but no peak was recorded in acetic acid–sodium acetate or in acetic acid–ammonium salts.

The controlled potential electrolysis of **1** was carried out in trifluoroacetic acid or trifluoroacetic acid–dichloromethane, using tetrabutylammonium fluoroborate (TBAF) at +1.5—1.7 V, but no product was obtained. When **1** was electrolyzed in acetic acid–TBAF[8] at +1.7—1.9 V, 1,2-bis[4-(acetoxymethyl)-phenyl]ethane (**2**) was obtained in a 24% yield. The structure was confirmed by the ^{1}H NMR and MS spectra and by elemental analyses.

Compound **2** was also formed in a 15% yield when **1** was electrolyzed anodically in acetic acid–sodium acetate.[9] When a similar reaction was carried out in propionic acid–TBAF bispropionate, **3** was obtained.

In order to compare the electrochemical results with these of a chemical method, **1** was treated with lead tetraacetate in acetic acid–dichloromethane.[10] This resulted in the formation of **2** and [2.2]paracyclophan-4-yl acetate (**7**)[11] in 21 and 13% yields respectively. When the oxidation was carried out in trifluoroacetic

Table 2. The reaction of [2.2]paracyclophane (**1**) with lead tetraacetate[a)]

Compd **1**, mmol	$Pb(OAc)_4$, mmol	Yield/%		
		1	**6**	**8**
3.0	1.5	50	15	trace
3.0	3.0	17	14	12
3.0	7.5	0	0	39

a) The reaction was carried out in trifluoroacetic acid–dichloromethane (1:2) at 0 °C for 12 h.

acid–dichloromethane at 0 °C, however, no cleavage products were obtained.[12)] Instead, 4-hydroxy[2.2]-paracyclophane (**6**)[11)] and *pseudo-para*-dihydroxy[2.2]-paracyclophanes (**8**)[13)] were formed. The results are shown in Table 2. The ready hydrolysis of trifluoro-acetate during handling was noticed.

The formation of **7** is assumed to involve the nucleophilic reaction of acetic acid towards the [2.2]paracyclophane cation radical, **9**, to give **10**, which then undergoes further electron transfer and deprotonation. Oxidation with lead tetraacetate appears to favor this route, especially when trifluoroacetic acid is used as the solvent, for it is known to stabilize aryl-cation radicals.[14)]

On the other hand, the electron abstraction of **1** on a platinum anode gives the cation radical, **11**, which, *via* the acetate radical, **12**, gives diacetate, **2**. The expected side-chain acetoxylation[10)] did not occur, possibly because of an excessive internal strain[15)] present in **1** which was relieved by going into **11**. It is highly probable that electron-transfer and acetoxylation to give (**12**) occur in a concerted manner.

Solvolytic anodic-cleavage reactions occurred in alcoholic solvents, though in low yields. 1,2-Bis[4-(methoxymethyl)phenyl]ethane (**4**) was obtained when **1** was electrolyzed anodically in methanol–TBAF at +1.39 V using a platinum electrode. A similar reaction in ethanol gave a diethoxy compound, **5**.

The anodic electrolysis of **13** in acetic acid–sodium acetate at the controlled potential of +1.80 V gave 4-hydroxy[2.2]metacyclophane (**17**) in a 20% yield, together with the recovered material. The rearranged structure, **17**, was confirmed by comparing the sample with an authentic material prepared from [2.2]meta-cyclophane by treatment with benzoyl peroxide and copper(II) chloride, followed by hydrolysis.[16)] Although [2.2]metacyclophane and derivatives have been shown[4)] to undergo easy transannular dehydrogenation reaction by means of the anodic reaction in acetonitrile, no such reaction was found to occur in acetic acid–sodium acetate. Conversely, no skeletal change occurred when **13** was electrolyzed in a solvent containing acetonitrile.

The possible reaction scheme for the formation of **17** involves the oxygenation of the cation radical, **14**, to give **15**, which is then rearranged to **16**. The deprotonation of **16**, followed by hydrolysis, gives **17**. The addition of water increased the yield of **17**, and it might be possible that water instead of the presumed acetoxylation is responsible for the introduction of the hydroxyl group. That **17** was the initial product of the reaction was shown by gas chromatography of the reaction mixture, which was carefully handled to avoid hydrolysis.

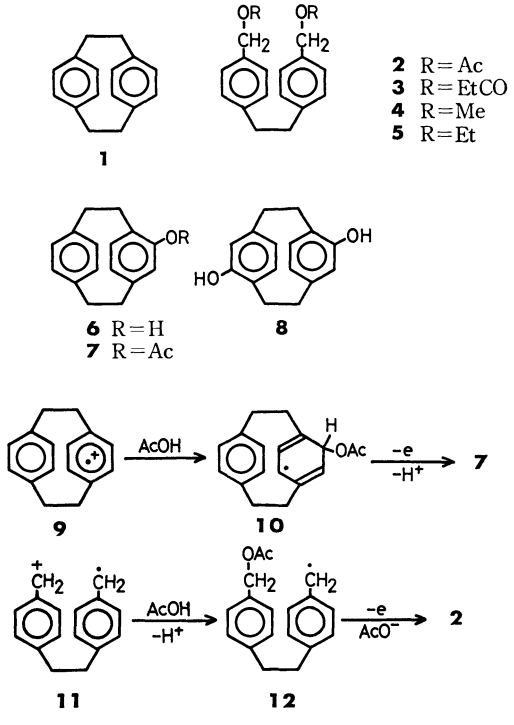
The cathodic reduction of **1** was then carried out under conditions which involved a solvated electron.[17)] To a solution of **1** in hexamethylphosphoric triamide containing lithium chloride, acetic acid was added as a proton source, after which the mixture was electrolyzed cathodically under constant current conditions using a current density of 12 mA/cm². As cathodes, titanium, lead, and platinum were used, while a platinum wire was used as the anode. We thus obtained three cleavage products, **18**—**20**, which were separated by column chromatography on alumina containing silver nitrate. Of the cathode materials, titanium gave the highest yield of cleavage products. When 7.4 F/mol of electricity was passed through, *ca.* 50% of the material was cleaved. The results are summarized in Table 3.

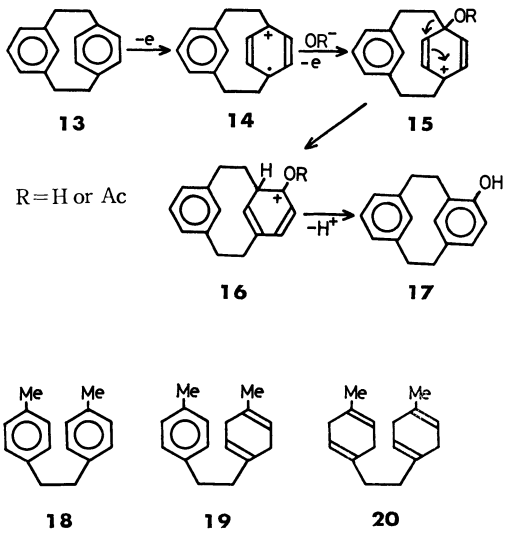
Table 3. The constant-current cathodic reduction of [2.2]paracyclophane (**1**)[a)]

Electrode	Yield/%		
	18	**19**	**20**
Ti	17	21	7.5
Pb	5	trace	trace
Pt	trace	—	—

a) The reaction was carried out in hexamethylphosphoric triamide–lithium chloride–acetic acid at the current density of 12 mA/cm².

A usual Birch reduction using liq ammonia–tetrahydrofuran–ethanol–sodium gave only *dl*-tetrahydro-(**1**),[18)] although a modification of the procedure reported by Marshall *et al.*[19)] gave **18**, but no further reduction products. The cathodic reduction of **18** carried out in the same way as above gave **19** and **20**.





Experimental

Cyclic Voltammetry. Cyclic voltammetry was performed at room temperature using the combination of a generator, Hokuto HB-107A, and a potentiostat, Hokuto HA-101. The H-type cell used consisted of an anode compartment (20 ml) and a cathode compartment separated by a glass frit. A platinum inlay electrode, Beckman No. 39273, was used as the anode, while platinum wire was inserted to serve as the counter electrode. The reference SCE electrode was connected to the side-arm with the aid of two junction bridges, each fitted with a ceramic plug. These were filled with saturated KCl solution and solution containing anolyte.

Controlled-potential and Controlled-current Electrolyses. A Hokuto potentiostat/galvanostat HA-101 (max. output 30 V, 0.1 A) or HA-105 (max. output 200 V, 1 A) was used as the dc source. Coulometry was performed by a Hokuto digital coulometer, HF-102.

A cylindrical cell is equipped with two side arms for connecting the SCE and a nitrogen bubbler. A ceramic thimble was used as the divider. A punched platinum electrode with an area of 40 cm^2 was used as the anode, while a platinum wire was used as the cathode for the anodic experiments. The electrodes used for solvated-electron reduction (Ti, Pb, and Pt) have an area of 8.5 cm^2.

The reference electrode was connected to the side arm through two junction bridges, each fitted with a ceramic plug and each containing a saturated KCl solution and the reaction medium.

1,2-Bis[4-(acetoxymethyl)phenyl]ethane (2). A mixture of **1** (200 mg, 0.91 mmol) in acetic acid (100 ml) containing TBAF (0.1 M) was electrolyzed at the controlled potential of +1.7—1.9 V. When 2F/mol of the electricity had been consumed, the electrolysis was stopped and the resultant reaction mixture was neutralized with aqueous sodium hydrogen carbonate. The ether extracts were evaporated and passed through a Florisil column, using benzene as the eluent. The products were further purified by liquid chromatography on a prepacked silica gel column (Lobar column from Merck). Compound **2** was obtained as colorless crystals (mp 77—78.5 °C (recrystallized from benzene–hexane)) in a 24% yield. The material recovery was 16%. The rest of the material was a colored, tarry matter. ^1H NMR ($CDCl_3$) δ 2.08s (6H), 2.90s (4H), 5.08s (4H), and 7.24s (8H).

Found: C, 73.29; H, 6.75%. Calcd for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%.

The electrolysis of **1** in acetic acid–sodium acetate also produced **2** in a 15% yield.

1,2-Bis[4-(propionyloxymethyl)phenyl]ethane (3). A mixture of **1** (208 mg, 1.0 mmol) in propionic acid (50 ml) and dichloromethane (150 ml) containing TBAF (0.1 M) was electrolyzed until 1.8 F/mol of electricity had been consumed. Subsequent chromatography on Florisil eluted with benzene–hexane gave **3** as a viscous oil in a 9% yield; this substance solidified on long standing; mp 29—30 °C. The starting material was recovered in a 70% yield. ^1H NMR ($CDCl_3$) δ 1.17t (6H), 2.23q (4H), 5.03s (4H), and 7.20s (8H); MS *m/e* 297 [M^+-57 (COC_2H_5)].

Found: C, 73.76; H, 7.26%. Calcd for $C_{22}H_{26}O_4$: C, 74.55; H, 7.39%.

1,2-Bis[4-(methoxymethyl)phenyl]ethane (4). A mixture of **1** (500 mg, 2.4 mmol) and TBAF (1.1 g, 33 mmol) in methanol (500 ml) was electrolyzed at the constant potential of +1.39 V. A usual work-up, followed by chromatography on silica gel, gave **4** as colorless needles; mp 69—72 °C (recrystallized from hexane); ^1H NMR ($CDCl_3$) δ 2.83s (4H), 3.38s (6H), 4.43s (4H), and 7.16s (8H).

Found: C, 79.98; H, 8.26%. Calcd for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

Cathodic Reduction of 1. The constant-current cathodic reduction of **1** was carried out in hexamethylphosphoric triamide containing lithium chloride (0.3 M), using acetic acid as a proton source, at the current density of 12 mA/cm^2. The results are summarized in Table 3.

The typical reaction was carried out as follows: a mixture of **1** (610 mg, 2.9 mmol), hexamethylphosphoric triamide (75 ml) containing lithium chloride (0.3 M), and acetic acid (2 g) was electrolyzed until 7.4 F/mol of electricity had been consumed, using a titanium cathode and a platinum anode. The voltage between the working and reference electrodes was −2.66——3.2 V. The ether extract was passed through a column packed with Wakogel C-200 containing 20% silver nitrate. The column was then eluted with hexane–benzene.

Compounds **18** (17%), **19** (21%), and **20** (7.5%) were successively eluated. Compound **18** was obtained as colorless needles; mp 80—81.5 °C; ^1H NMR ($CDCl_3$) δ 2.28s (6H), 2.82s (4H), and 7.06s (8H).

Compound **19** was obtained as colorless needles; mp 48—49.5 °C; ^1H NMR δ 1.67s (3H), 2.28s (3H), 2.10—2.40m (4H), 2.57m (4H), 5.40m (2H), and 7.04s (4H); MS *m/e* 212.

Found: C, 89.93; H, 9.39%. Calcd for $C_{16}H_{20}$: C, 90.50; H, 9.50%.

Compound **20** was obtained as colorless needles; mp 57—58 °C; ^1H NMR δ 1.67s (6H), 2.08s (4H), 2.56m (8H), and 5.40m (4H); MS *m/e* 214.

Found: C, 88.54; H, 10.06%. Calcd for $C_{16}H_{22}$: C, 89.65; H, 10.35%.

When **18** was subjected to similar reaction conditions, **19** (13%) and **20** (42%) were obtained.

Anodic Rearrangement of 13. A solution of **13** (52 mg, 0.25 mmol) in acetic acid (50 ml) containing sodium acetate (0.2 M) was electrolyzed at +1.80 V. After 2.8F/mol of electricity had been passed through the reaction mixture was handled as usual and was analyzed by column chromatography on silica gel. In addition to the recovered **13** (36%), 4-hydroxy[2.2]metacyclophane (**17**) (mp 161—164 °C) was obtained in a 20% yield. It was identical with the authentic material prepared according to the literature.[19]

The Reaction of 1 with Lead Tetraacetate. Compound **1** was treated with lead tetraacetate in acetic acid–dichloromethane or in trifluoroacetic acid–dichloromethane.

The reaction in trifluoroacetic acid–dichloromethane is summarized in Table 2. A typical run was carried out as

follows: to a solution of **1** (625 mg, 3.0 mmol) in dichloromethane (80 ml), a solution of lead tetraacetate (670 mg, 1.5 mmol) in TFA (10 ml) was added at 0 °C. After 9 h the reaction mixture was worked-up as usual. Column chromatography on Florisil eluted by benzene gave **1** (50%), **6** (15%) (mp 184—193 °C),[11] and a trace amount of **8**. Compound **8** was obtained in a 39% yield when an excess amount of lead tetraacetate was employed; mp 229—231 °C.[13]

Phosphinyl- and Phosphinothioylamino Acids and Peptides. V. Preparation of Dimethylphosphinothioylamino Acids and Solid Phase Peptide Synthesis

Masaaki UEKI,* Toshiyuki INAZU, and Shigeru IKEDA

Department of Chemistry, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162

(Received February 19, 1979)

The use of the dimethylphosphinothioyl(Mpt) group for protection of N^{α}-amino functions of amino acids has been studied as the most readily removable group in the phosphinothioyl series. The Mpt-amino acids have been prepared by the alkaline hydrolysis of Mpt-amino acid esters and Schotten-Baumann type reactions of free amino acids. The Mpt group has been removed using a solution of triphenylphosphine dihydrochloride in dichloromethane. L-Leu^5- and D-Ala^2, L-Leu^5-enkephalins have been synthesized by a solid phase method and synthetic L-Leu^5-enkephalin exibited identical activity with an authentic sample.

Recently it has been established that a series of phosphinothioyl groups serve to protect the N^{α}-amino functions of amino acids.[1,2] In a previous paper it was shown that the diphenylphosphinothioyl(Ppt) group was the most useful group since diphenylphosphinothioyl chloride(Ppt–Cl) is readily available from the Friedel-Crafts reaction of benzene and thiophosphoryl chloride and could be used for the preparation of Ppt-amino acids by the Schotten-Baumann type reaction.[3,4] The Ppt group was removed by hydrogen chloride reagents to reproduce the Ppt–Cl. The chloride was relatively inactive to the indole moiety of tryptophan and no other active intermediate was generated during the course of deprotection, and consequently the Ppt-amino acids were successfully utilized for the solid phase synthesis of oligopeptides containing tryptophan.[5] The conditions for removal of the Ppt-group however apper inappropriate for the synthesis of larger peptides on solid supports. In this paper the use of the dimethylphosphinothioyl(Mpt) group has been studied as the most readily removable group in the phosphinothioyl series.

Cleavage of the phosphinothioyl groups is greatly facilitated in the presence of methyl group as substituent on the phosphorus atom.[1] The dimethylphosphinothioyl group was selected in this study since this avoided the introduction of a new asymmetric center on the phosphorus atom. Dimethylphosphinothioyl chloride (**1**) was obtained by chlorinating tetramethyldiphosphine disulfide[6] with sulfuryl chloride.[7]

The Mpt-amino acids were prepared by two methods: the alkaline hydrolysis of Mpt-amino acid esters (Method A) and the direct phosphinothioylation of free amino acids (Method B).

(Method A)

$$(CH_3)_2P(=S)\text{-}Cl + H_2NCHRCO_2R' \xrightarrow{(C_2H_5)_3N} Mpt\text{-}NHCHRCO_2R'$$

1

$$\downarrow \text{1) } OH^- \text{ 2) } H^+$$

(Method B)

$$\mathbf{1} + H_2NCHRCO_2H \xrightarrow[\text{2) } H^+]{\text{1) } OH^-} Mpt\text{-}NHCHRCO_2H$$

The chloride **1** reacted rapidly with the amino acid esters to give the corresponding Mpt-amino acid esters, which were subsequently hydrolysed by aqueous sodium hydroxide to yield Mpt-amino acids. In the case of Mpt-glycine the product was partially extracted by organic solvents from the acidified aqueous reaction mixture saturated with sodium chloride. A small amount of the analytically pure sample of the dicyclohexylamine salt was obtained by laborious extraction, but regeneration of the free acid before use proved impossible. Homologous diethylphosphinothioyl(Ept)-glycine was prepared in a similar manner and substituted for Mpt-glycine in the following peptide synthesis. No difficulty was encounterd in the preparation and isolation of this compound and also in the deprotection of the Ept group as described later. The tyrosine ester reacted with **1** to give a mixture of N^{α}-Mpt and N^{α}-, *O*-bis-Mpt derivatives. Mpt-tyrosine was obtained by alkaline hydrolysis in a similar manner to that for the Ppt-derivatives.[4]

TABLE 1. PREPARATION OF Mpt-L-METHIONINE DCHA SALT

Temperature	Mpt–Cl(eq)	Base	Yield(%)
RT	1.0	1 M NaOH	0
0 °C	1.0	1 M NaOH	58
0 °C	1.0	2 M NaOH	48
0 °C	1.1	1 M NaOH	59
0 °C	1.1(ether solution)	1 M NaOH	68
0 °C	1.2	1 M NaOH	78

In the direct synthesis of Mpt-amino acids by the Schotten-Baumann type reaction several problems were encountered. **1** was rapidly hydrolysed in an alkaline solution, a reaction not found with Ppt–Cl. This problem was solved by conducting the reaction at low temperature with an excess of reagent. The addition of **1** in an ether solution improved the yield as shown in Table 1. The hydrolysis product of **1**, dimethylphosphinothioic acid was not extractable by organic solvents in acidified aqueous solution, and consequently the use of excess reagent did not complicate the purification. The Mpt-amino acids were stored in their dicyclohexylamine(DCHA) or cyclohexylamine(CHA) salts. The physical properties and elemental analysis data are summarized in Table 2.

Removal of the Mpt group was accomplished by hydrogen chloride in organic solvents, in a similar manner to that for the Ppt group, but much more

rapidly. A solution of triphenylphosphine dihydrochloride in dichloromethane[2,5] effectively increased the rate of removal of the Mpt by a factor of 60 compared to the *t*-butoxycarbonyl(Boc) group;[8] this reagent appears to be very convenient in solid phase synthesis. Deprotection of Mpt-L-phenylalanine resin was completed within 10 min by treatment with 0.5 M (1 M= 1 mol dm^{-3}) hydrogen chloride in dichloromethane containing 0.25 M triphenylphosphine and within 30 min with 0.25 M hydrogen chloride solution.[2]

To demonstrate the synthetic utility of Mpt-amino acids, the solid phase syntheses of L-Leu^5-enkephalin (L-Tyr–Gly–Gly–L-Phe–L-Leu) and the D-Ala^2 analog were attempted. Mpt-L-leucine was esterified with a chloromethyl resin by the caesium salt method.[9] Deprotection of the Mpt group was achieved by treatment with 0.2 M hydrogen chloride solution in dichloromethane containing 0.2 M triphenylphosphine for each 30 min (twice). Coupling of the Mpt- and Ept-amino acids were mediated with the oxidation-reduction condensation method[10] using a 3-fold excess of tris(*p*-methoxyphenyl)phosphine[11] and 2,2′-dithiodipyridine. This enabled tyrosine could be used without protection of the side chain hydroxyl group. Crude peptides were removed from the resin by treatment with hydrogen bromide in trifluoroacetic acid[12] in the presence of anisole. Separation by preparative thin layer

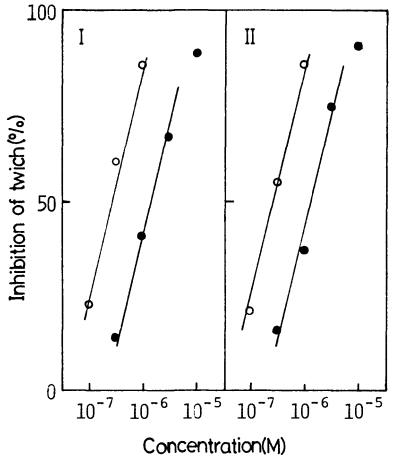

Fig. 1. Dose-response curve of synthetic L-Leu^5-enkephalin (I) and an authentic sample (II). (○: agonist alone, ●: agonist+naloxone 10^{-8} M).

chromatography on silica gel and purification by gel chromatography on Sephadex LH-20 gave the desired compounds in 52 and 40% yields, respectively. The activity of the synthetic L-Leu^5-enkephalin as an opioid agonist in logitudial muscle strips of guinea-pig ileum was identical with that of an authentic sample (Protein Research Foundation, Osaka) as shown in Fig. 1. The activity of D-Ala^2, L-Leu^5-enkephalin is now being studied and the results will be published in due course.

Experimental

Thin layer chromatography (TLC) was performed on silica gel plates (Merck $60F_{254}$) in the following solvent systems: chloroform–methanol–aqueous ammonia (60: 30: 5, R_f^1), 1-butanol–acetic acid–ethyl acetate–water (1: 1: 1: 1, R_f^2) and ethanol–water (7: 3, R_f^3). The peptides were detected on the TLC plates using ultraviolet light, iodine vapor and ninhydrin.

Dimethylphosphinothioyl chloride was prepared according to the literature.[6,7] Distillation of the product was achieved after decomposition of the contaminating dimethylphosphinyl chloride by shaking with water. The chloride **1** solidified on cooling and was stored for several months, without change, in a refrigerator.

N^{α}-Dimethylphosphinothioylamino acids were prepared by the alkaline hydrolysis of N^{α}-dimethylphosphinothioylamino acid esters obtained by the reaction of dimethylphosphinothioyl chloride with amino acid esters(Method A) and the reaction of an ethereal solution of dimethylphosphinothioyl chloride and α-amino acids (or α-amino acids bearing a protected side-chain functional group) in aqueous alkaline solution at controlled pH. The dimethylphosphinothioylamino acids thus prepared were isolated as the dicyclohexylamine(DCHA) or cyclohexylamine(CHA) salts.

Method A. To a suspension of the amino acid ester hydrochloride (5 mmol) in chloroform (10 ml) and triethylamine (10 mmol), Mpt–Cl (5 mmol) in chloroform (5 ml) was added at 0 °C. After stirring at room temperature for 6 h, the solution was washed with water, ice-cold 5% citric acid solution, water, 5% $NaHCO_3$ solution and saturated NaCl solution, dried and evaporated to dryness. The oily residue was dissolved in ethanol (5 ml) and to this solution was added 1 M NaOH solution (5 ml). The reaction mixture was stirred at room temperature for 4 h. After removal of ethanol *in vacuo*, the aqueous solution was extracted twice with ethyl acetate and the ethyl acetate extracts back extracted with 5% $NaHCO_3$ solution. The combined aqueous solutions were acidified at 0 °C to pH 4—5 with solid citric acid, saturated with NaCl and extracted 5 times with ethyl acetate. The ethyl acetate extracts were effectively washed with saturated NaCl solution and dried over anhydrous Na_2SO_4. After removal of the drying reagent, DCHA was added to effect separation of the corresponding salt. On certain occasions the addition of the same volume of ether was necessary to induce precipitation. The product was filtered off and washed with ethyl acetate or ether.

Method B. The amino acid (50 mmol) was dissolved in 1 M NaOH solution (50 ml), and Mpt–Cl (55 mmol) in ether (50 ml) added dropwise at 0 °C. The mixture was vigorously stirred to initiate immediate reaction. 1 M NaOH solution was added at a rate which maintained the pH of the solution at 9.5—10.0. Subsequently the reaction mixture was treated as described in Method A. The product was isolated as the DCHA or CHA salt and purified by recrystallization from ethanol, ethyl acetate or a methanol–ether mixture.

Dichloromethane Solution of Triphenylphosphine Dihydrochloride. Dry hydrogen chloride was passed through a dichloromethane solution of triphenylphosphine and saturated at room temperature. An aliquot of the solution was added to water and titrated with 1 M NaOH solution using phenolphthalein as the indicator to determine the concentration of HCl.

Solid Phase Synthesis of L-Leu^5-enkephalin. Mpt-L-leucine was esterified on resin support by treatment of the caesium salt with a chloromethyl resin prepared by chloromethylating the Bio-Beads S-X1 (Bio-Rad Laboratories) (Leu content; 0.63 mmol/g). The ester resin (1 g) was placed in the reaction vessel of the Beckman model 990 peptide synthesizer using the program described before.[4] Removal of the Mpt group was affected by 0.2 M HCl in dichloromethane solution containing 0.2 M triphenylphosphine (twice for 30 min). After neutralization with 10% triethylamine in dichloromethane, the couplings were mediated with the oxidation-reduction condensation method using tris(*p*-methoxyphenyl)phosphine and 2,2′-dithiodipyridine. Glycine was used as the Ept derivative. The Mpt-L-Leu^5-enkephalin-resin was finally deprotected, washed and dried *in vacuo*. A sample was hydrolysed in 12 M HCl–propionic acid at 130 °C for 2 h[13] to give the amino acid ratios: $Tyr_{0.99}$, $Gly_{1.89}$, $Phe_{1.06}$, $Leu_{0.99}$. The penta-peptide was removed from the resin by bubbling a stream of anhydrous hydrogen bromide through a suspension of the peptide resin in trifluoroacetic acid (10 ml) containing 50 equivalents of anisole for 90 min at room temperature. The filtrate and three trifluoroacetic acid (30 ml) washings were combined and evaporated *in vacuo*. The residue was separated and purified by silica gel preparative layer chromatography using the solvent system 1. The desired band (R_f=0.3—0.4) was eluted with methanol and evaporated *in vacuo* to give a white solid. The solid was dissolved in a small amount of methanol and applied to a Sephadex LH-20 (3×80 cm) column in order to remove the silica gel contaminents. The individual fractions collected (8 ml each) were examined by UV absorbancy at 280 nm. The eluates containing a single component (tube Nos. 27—33) were combined and evaporated to give white crystals; 167 mg (52% from Mpt-L-Leu-resin). An analytical sample was obtained by recrystallization from methanol, mp 158—160 °C (lit,[14] 157—167 °C, lit,[15] 206—208 °C); $[\alpha]_D^{25}$ +27.8° (*c* 0.9, MeOH) (lit,[15] +32.3° (*c* 0.9, MeOH), lit,[16] +20° (*c* 1, MeOH)); R_f^1 0.35 (lit,[17] 0.33), R_f^2 0.73 (lit,[16] 0.85), R_f^3 0.74 (lit,[17] 0.77). Amino acid ratios in hydrolysate by 6 M HCl at 110 °C for 24 h: $Tyr_{0.98}$, $Gly_{2.02}$, $Phe_{0.99}$, $Leu_{1.01}$. Found: C, 59.14; H, 6.95; N, 12.30%. Calcd for $C_{28}H_{38}N_5O_7 \cdot 1/2H_2O$: C, 59.46; H, 6.95; N, 12.38%.

D-Ala^2, L-Leu^5-enkephalin. This peptide was synthesized in a similar manner to above using Mpt-D-alanine at the third acylation step. The desired compound was obtained in 40% yield (from Mpt-L-Leu-resin) as white crystals. An analytical sample was obtained by recrystallization from methanol, mp 182—184 °C; $[\alpha]_D^{25}$ −25.0° (*c* 0.1, MeOH); R_f^1 0.49, R_f^2 0.83, R_f^3 0.71. Amino acid ratios in hydrolysate by 6 M HCl at 110 °C for 24 h: $Tyr_{0.99}$, $Ala_{0.99}$, $Gly_{0.97}$, $Phe_{1.02}$, $Leu_{1.00}$. Found: C, 58.75; H, 7.47; N, 10.94%. Calcd for $C_{29}H_{39}N_5O_7 \cdot 2MeOH$: C, 58.75; H, 7.48; N, 11.05%.

The authors wish to thank Prof. Tetsuo Oka (Tokai University) for the biological activity measurements.

Raman Spectrum of the Complex of Nitrobenzene with Aluminum Chloride

Kunio FUKUSHIMA

Department of Chemistry, Faculty of Science, Shizuoka University, 836 Oya, Shizuoka 422

(Received March 31, 1979)

Synopsis. Raman spectrum of the complex of nitrobenzene with aluminum chloride in a nitrobenzene solution was measured. The shift frequencies and the degree of depolarization of Raman bands of the nitrobenzene in the complex are different from those of nitrobenzene. The differences were discussed based on the prior assignment of Raman bands of nitrobenzene.

Aluminum complex of nitrobenzene is well-known as the acceptor in many charge transfer complexes. Although infrared spectra were reported recently,[1] laser Raman spectral data are not available. In the present study, a laser excited Raman spectrum of the complex of nitrobenzene with aluminum chloride was measured in order to get information of the structure of the complex primarily based on the degree of depolarization.

Experimental

Raman spectrum of the nitrobenzene saturated with anhydrous aluminum chloride at room temperature was measured using 0.1 ml Raman cell. The spectrum was recorded on a Japan Spectroscopic Co., Ltd. Model R-800T Raman Spectrophotometer, being excited with a Spectra Physics argon ion laser (model 165) using 514.5 nm line (300 mW). The Raman shift frequencies, the intensities, and the degree of depolarization are shown in Table 1.

Results and Discussion

The observed Raman bands are classified into two groups. One consists of the Raman bands of the complex, whose shift frequencies are almost the same as those of nitrobenzene and are overlapped by nitrobenzene bands, while the other consists of those marked with C in Table 1. The Raman bands of the latter group except for those having the shift frequencies, 1470 and 1182 cm^{-1}, are due to the nitro group. All the Raman bands of both groups have the values of degree of depolarization smaller than 0.75, showing that the complex has neither symmetry axes nor symmetry planes. Especially, the degree of depolarization ($\rho=0.67<0.75$) of the Raman band (shift frequency, 180 cm^{-1}), which corresponds to an out-of-plane bending vibration (b_1 symmetry species), suggests that the plane including the benzene ring and the nitro group no longer exists in the complex or the plane is no longer symmetry plane, even if it existed. Remarkable changes of the shift frequencies of the nitro group in the complex formation show the coordination of aluminum atom to oxygen atom. The shift frequency, 398 cm^{-1}, of the Raman band of aluminum chloride in the complex is different from those of corresponding bands (a_1 symmetry species; 350 cm^{-1} for acetonitrile solutions;[3] 371 cm^{-1} for the vapor state[4]), but is almost the same as that of monomeric aluminum chloride in argon matrix.[5] Therefore, the almost planar structure similar to that of aluminum chloride in argon matrix,[5] persists even in the complex.

Table 1. Observed shift frequencies (in cm^{-1}), intensities (I) and degree of deaolarization (ρ) of the Raman bands of the nitrobenzene saturated with aluminum chloride at room temperature

Synopsis. In the aqueous solutions of some sulfates, the contraction of water molecules in a hydration shell and the hydration number were estimated by using the data of the limiting equivalent conductance of the ion and the partial molal volume of electrolytes at an infinite dilution.

In a previous paper,[1] we estimated the partial molal volumes of the ion pairs of some sulfates in aqueous solutions by using the data obtained from the molar conductances obtained under high pressures and discussed the tendency of the metal ion to form an outer-sphere ion pair with the sulfate ion. The partial molal volumes of the electrolytes and the volume changes of the dissociation of the ion pairs in the aqueous solutions at an infinite dilution were always negative. This may be mainly ascribed to the contraction of water molecules in the hydration shell with ions so that the density of water in the neighborhood of an ion may be higher than that of the bulk water.

From the conductance data, the volume of the hydration shell of an ion or electrolyte and the hydration number can be found by applying the Stokes law and the Robinson and Stokes method[2] as follows:

$$r_s = \frac{0.820|z|}{\lambda^\circ \cdot \eta}, \tag{1}$$

where λ° is the limiting equivalent conductance of an ion with the Stokes radius of r_s and an absolute charge, $|z|$, and where η is the viscosity of pure water. r_s is corrected to the effective radius, r_e, by means of the Robinson-Stokes correction factor, f,

$$r_e = r_s \cdot f. \tag{2}$$

Then, the volume of the hydration shell in the neighborhood of the ion, V_H, can be represented by this equation

$$V_H = \frac{4}{3}\pi L(r_e^3 - r_c^3), \tag{3}$$

where L is Avogadro's number, and r_c, the crystallographic radius of the ion. The hydration number, h, is given by this equation

$$h = \frac{V_H}{V_E}, \tag{4}$$

where V_E is the molar volume of water in the hydration shell in the neighborhood of the ion. In most cases, V_E was assumed to be equal to the molar volume of the bulk water, V_B,[2,3] so the hydration number may be underestimated.

As has been mentioned above, the contraction of water molecules surrounding an ion may occur upon a change in the states of the water molecules from the bulk to the hydration during the dissolution and dissociation of electrolyte. It has been shown by Padova[4] that the average theoretical contraction due to the electrostriction per mole of water is $\Delta V = -2.1$ cm^3/mol. Millero *et al.*[5] have determined $\Delta V = V_E - V_B = -3.0$ cm^3/mol from the isothermal compressibility data of aqueous solutions of various salts. Recently, Millero *et al.*[6] have determined the amount of water lost in the ion-pairing process of an aqueous $CaSO_4$ solution by using the value of $V_E - V_B = -3.8$ cm^3/mol.

The partial molal volume of an electrolyte at an infinite dilution, $\bar{V}^\circ(M^{2+}) + \bar{V}^\circ(SO_4^{2-})$, may be represented by the sum of the two major components resulting from the simple model for hydration[7]

$$\bar{V}^\circ(M^{2+}) + \bar{V}^\circ(SO_4^{2-}) = \bar{V}^\circ(\text{int}) + \bar{V}^\circ(\text{elect}), \tag{5}$$

and

$$\bar{V}^\circ(\text{int}) = \frac{4}{3}\pi L[r_c(M^{2+})^3 + r_c(SO_4^{2-})^3], \tag{6}$$

where $\bar{V}^\circ$(int) is the intrinsic partial molal volume of the electrolyte, and $\bar{V}^\circ$(elect), the electrostriction partial molal volume. Then, the electrostriction partial molal volume of the electrolyte can be estimated by using the partial molal volume of the electrolyte at an infinite dilution and related to the hydration number of the electrolyte, n_H, by this equation

$$\bar{V}^\circ(\text{elect}) = n_H(V_E - V_B).^{4,7,8} \tag{7}$$

We assume that n_H in Eq. 7 is equal to the sum of $h(M^{2+})$ and $h(SO_4^{2-})$ in Eq. 4 as a first approximation, though the hydration numbers obtained by the various methods do not always coincide with each other. From Eqs. 4 and 7, we obtain this equation,

$$\frac{V_H(M^{2+}) + V_H(SO_4^{2-})}{V_E} = \frac{V_H(M^{2+}) + V_H(SO_4^{2-})}{V_B + (V_E - V_B)} = \frac{\bar{V}^\circ(\text{elect})}{V_E - V_B}. \tag{8}$$

$V_E - V_B$ for each electrolyte was estimated by means of Eq. 8 with the values of $V_H(M^{2+}) + V_H(SO_4^{2-})$ and $\bar{V}^\circ$(elect) in Tables 1 and 2, and with $V_B = 18.05$ cm^3/mol at 25 °C. These results are also shown in Table 2. The mean value of $V_E - V_B$ is found to be

TABLE 1. LIMITING EQUIVALENT CONDUCTANCE, STOKES, EFFECTIVE, AND CRYSTALLOGRAPHIC RADII, HYDRATION VOLUME, AND HYDRATION NUMBER AT 25 °C

Ion	λ°	r_s / nm	r_e / nm	r_c[9] / nm	V_H / cm^3 mol^{-1}	h

$CuSO_4$	−8.1	−60.3	18.3	−3.3
$ZnSO_4$	−8.0	−60.3	18.3	−3.3

−3.3 cm³/mol. This value is in good agreement with those estimated by Padova[4] and Millero *et al.*[5,6] V_E is about 14.8 cm³/mol, and the density of the water in the hydration shell in the neighborhood of the ions is estimated to be about 1.22 g/cm³, comparable to the densities of ice III and/or V under high pressures. The hydration number of the ion, h, is also shown in Table 1. These values are in reasonable agreement with those estimated by Padova[4] and suggest that, especially in a metal ion, the hydration shell may contain the water molecules not only in the first layer, but also in the second and the outer layers.

A Study of Catalysis by Metal Phosphates. V.[1] The Alkylation of Toluene with Methanol over Metal Phosphate Catalysts

Toshiaki SODESAWA,* Isao KIMURA, and Fumio NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260

(Received January 10, 1979)

Synopsis. The side chain alkylation of toluene with methanol over the catalyst of $Ca_3(PO_4)_2$ or K_3PO_4 supported on active carbon gave more ethylbenzene than that over MgO. It was found that there are correlations between the catalytic activities and acid-base properties.

In a previous paper a report was given on the alkylation of phenol with methanol over metal phosphate catalysts.[1] It is well-known that metal phosphates have acid properties. However, it was found that $Ca_3(PO_4)_2$ and K_3PO_4 have not only acidic but also basic sites.[2,3] In this paper, the correlation between the catalytic activity of metal phosphates and their acid-base properties are discussed. The activity sequence and catalytic behavior of metal phosphates are compared with those of other solid acid-base catalysts.

Experimental

The metal phosphates, MgO, and CaO catalysts were prepared according to the method reported.[1] Commercial chemicals of guaranteed grade were used: H-Zeolon, SiO_2–Al_2O_3, $Al_2(SO_4)_3$, Al_2O_3, Na_2WO_4. The catalysts of Na_3PO_4 and K_3PO_4 supported on active carbon (Tsurumicoal Kogyo Co.) were prepared by the impregnating method, the concentration being made about 15 wt %. All the catalysts were activated by calcination in a stream of nitrogen gas at 500 °C for 1 h prior to each test.

The acidity of catalysts was measured by Benesi's method,[4] using the following Hammett indicators: Neutral Red (pK_a = +6.8), Methyl Red (+4.8), Dimethyl Yellow (+3.3), 4-phenylazodiphenylamine (+1.5), dicinnamylideneacetone (−3.0), benzylideneacetophenone (−5.6), anthraquinone (−8.2). As a titration reagent *n*-buthylamine of 0.1 mol/l in benzene solution was added to a known amount of catalysts calcined at 500 °C for 4 h. Hammett indicators were then added and the resulting with coloration was compared visually. Titration with benzoic acid of 0.1 mol/l using Bromothymol Blue (pK_a=7.1), phenolphthalein (9.3), 2,4-dinitroaniline (15.0), and 4-chloro-2-nitroaniline (17.2) as indicators was carried out in order to measure the basicity of catalysts. The procedure was almost the same as in the acidity measurements.

The apparatus and procedure were almost the same as described previously. The reaction products were trapped with ice and analyzed by gas chromatography on a 3 m column of Benton 34(5%)+DNP(5%), hydrogen being passed through as a carrier gas.

Results and Discussion

In the case of alkylation of phenol with methanol over $Ca_3(PO_4)_2$ catalyst, the main products are *o*-cresol and 2,4-xylenol which are produced by the ortho-position alkylation of benzene ring. Results of alkylation of toluene with methanol over various catalysts are given in Table 1. We see that the alkylation of toluene does not occur readily as compared with that of phenol. The methylation of benzene ring over BPO_4 and $Zr_3(PO_4)_2$ gave selectively as much xylenes as that over SiO_2–Al_2O_3 and H-Zeolon catalysts. The BPO_4 catalyst showed the highest activity of all the metal phosphates and produced much *o*-xylene in all xylenes, while $Ca_3(PO_4)_2$ and K_3PO_4 gave only ethylbenzene by the alkylation of side chain. The results differ from those in the case of the base catalyst such as MgO which produced both ethylbenzene and styrene. The Na_3PO_4 catalyst supported on active carbon gave both xylenes and ethylbenzene. The active carbon gave only benzene and no alkylated products. This seems to be in line with other reported results.[5,6] The activity of K_3PO_4 catalyst for the side chain alkylation was not higher than that of MgO–TiO_2[7,8] and Zeolite catalysts exchanged K cation.[9] Improvement in the preparation

TABLE 1. ACTIVITIES OF CATALYSTS FOR ALKYLATION OF TOLUENE

Conditions: reaction temperature t=500 °C (except for SiO_2–Al_2O_3 and H-Zeolon catalysts, in which t was 400 °C), W/F=14.8 g h/mol, feed molar ratio of methanol/toluene/N_2=1/2/5.3.

Catalyst	Conversion of toluene (%)	Yield (%)					
		Ethylbenzene	Styrene	*o*-Xylene	*m*-Xylene	*p*-Xylene	Benzene
BPO_4	9.6	0	0	4.6	3.2	1.8	0
$Zr_3(PO_4)_4$	0.7	0	0	0.3	0.2	0.2	0

SiO_2–Al_2O_3	21.7	0	0	9.0	7.0	5.7	0
H-Zeolon	32.6	0	0	9.0	16.0	7.6	7.6
MgO	1.0	0.3	0.7	0	0	0	0

a) AC denotes activated carbon used as a carrier. Na_3PO_4 or K_3PO_4 was supported to make the concentration about 15 wt %.

Table 2. Acid-base properties of catalysts

Catalyst[a]	pK_a							
	−8.2	−5.6	−3.0	+3.3	+4.8	+6.8	+7.1	+9.3
BPO_4	−	+	0.160[b]	+	+	+	−	
$Zr_3(PO_4)_4$	−	+	0.063[b]	+	+	+	−	
$Ca_3(PO_4)_2$				−	+	+	+	0.001[c]
Na_3PO_4					−	+	+	0.006[c]
K_3PO_4						−	+	0.010[c]
SiO_2–Al_2O_3	+	+	0.471[b]	+	+	+	−	
H-Zeolon	+	+	0.513[b]	+	+	+	−	
MgO					−	+	+	0.007[c]
CaO					−	+	+	0.011[c]

a) Calcined at 500 °C. + and − denote positive and negative, respectively. b) Acidity (mmol/g) measured at $H_0 \leqq -3.0$. c) Basicity (mmol/g) measured at $H_0 \geqq 9.3$.

of these catalysts might afford higher activity. The alkylation of ethylbenzene with methanol over K_3PO_4 and Na_3PO_4 supported on active carbon gave a greater amount of cumene than over MgO or CaO. The alkylation over the metal phosphates is essentially different in the reaction route from that of solid base catalysts such as MgO.

The acidity and basicity of various catalyst surfaces were measured (Table 2). It is obvious that the BPO_4 and $Zr_3(PO_4)_4$ catalysts, being as active as SiO_2–Al_2O_3 and H-Zeolon for xylene production in toluene alkylation, have acid sites at $H_0 \leqq -3.0$, while the $Ca_3(PO_4)_2$ and K_3PO_4 being as effective as MgO for ethylbenzene formation have basic sites at $H_0 \geqq 9.3$. The catalytic activities in each case seem to be strongly related to acid or base amounts of each catalyst. However, the route of side chain alkylation over $Ca_3(PO_4)_2$ or K_3PO_4 seems to differ from that over MgO which gives both ethylbenzene and styrene.

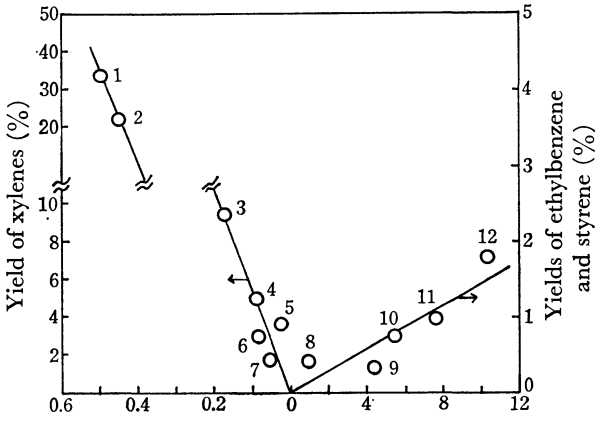

Fig. 1. Correlation between the catalytic activity and the acidity or basicity of various catalysts in the alkylation of toluene with methanol (acidity; $H_0 \leqq -3.0$, basicity; $H_0 \geqq 9.3$)
1: H-Zeolon, 2: SiO_2–Al_2O_3, 3: BPO_4, 4: $Al_2(SO_4)_3$, 5: Al_2O_3, 6: $CrPO_4$, 7: $Ti_3(PO_4)_4$, 8: $Ca_3(PO_4)_2$, 9: Na_2WO_4, 10: Na_3PO_4–AC, 11: MgO, 12: K_3PO_4–AC.

The correlations between the acid-base properties and the activities of various solid catalysts in the alkylation of toluene are shown in Fi . 1. There are correlations between the yields of xylenes and the acidity at $H_0 \leqq -3.0$ or the yields of ethylbenzene and styrene and the basicity at $H_0 \geqq 9.3$. The correlation between the acid-base property and the catalytic activity of $Ca_3(PO_4)_2$ calcined at various temperatures in the alkylation of phenol was reported.[1] It was found that the catalytic activities can be classified into three types of linear relationships, (a) highly dependent on acidity, (b) strongly dependent on basicity, (c) dependent on both acidity and basicity as indicated over $Ca_3(PO_4)_2$ catalyst. In the case of toluene (Fig. 1), it seems that the alkylation is highly related to acidity or basicity of catalysts. The alkylation of toluene over $Ca_3(PO_4)_2$ or K_3PO_4 supported on the active carbon is strongly related to base amounts of the catalyst.

Analysis of Glass Films Prepared from Alkoxides on Glass Substrates

Akira Iino and Atsushi Mizuike*

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 30, 1979)

Synopsis. Sodium in 50 nm thick ZrO_2–SiO_2 glass films has been determined by secondary ion mass spectrometry. A remarkable sodium contamination from the Pyrex glass substrate has been confirmed.

The coating of glass surfaces with glass films of different kinds, prepared *in situ* by hydrolyzing mixtures of alkoxides, offers a new technique to improve the chemical and optical properties of glass surfaces.[1] By this technique, thin homogeneous glass films of various kinds, not obtainable by conventional techniques, may be prepared easily near the transition temperature of the glass.[2] To improve the chemical resistance of Pyrex glass ware, the present authors coated the glass surfaces with ultrathin films of 22 ZrO_2–78 SiO_2 mol% glass prepared from silicon tetraethoxide and zirconium tetrapropoxide. Contamination of sodium from the substrate during the preparation may occur and deteriorate the film. No information on this phenomenon is available to date and consequently the sodium in the films has been determined by secondary ion mass spectrometry (SIMS), which is the most suitable technique at present for the quantitative analysis of ultrathin films.

The glass films were transparent, homogeneous, and 50 ± 5 nm thick. Under the scanning electron microscope (2000X and 10000X), the surfaces of the films were found to be smooth and without pinholes and cracks. The films were not damaged by abrasive action with the fingers. Figure 1 shows the SIMS spectra of 22 ZrO_2–78 SiO_2 mol% glass films and Pyrex and silica glass substrates. In the film on the Pyrex glass substrate, sodium was found, but boron, aluminum, and potassium were found to be absent. The SIMS spectrum of the film on the silica glass substrate was identical with that of 22 ZrO_2–78 SiO_2 mol% glass flakes. The secondary ions originate from the region 10 nm from the surface.[3] The films were ion-etched only about 15 and 10 nm before and during the SIMS measurements, respectively, and therefore, the pure spectra of the films were obtained without interference from the substrate by this technique.

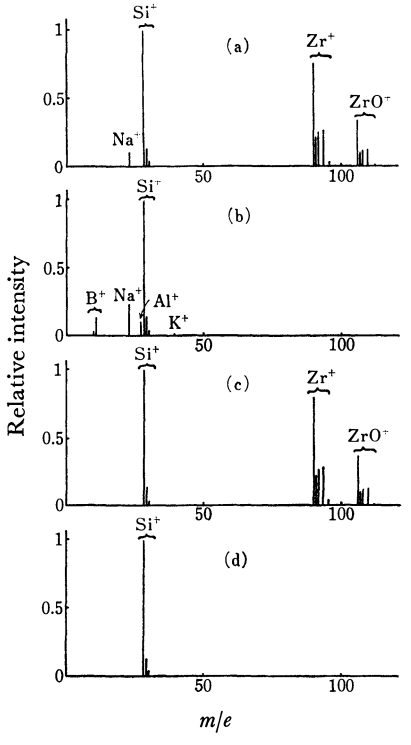

Fig. 1. SIMS spectra.
(a): ZrO_2–SiO_2 glass film on Pyrex glass, (b): Pyrex glass substrate, (c): ZrO_2–SiO_2 glass film on silica glass, (d): silica glass substrate.

Table 1. Sodium concentrations (Na_2O, mol %)

In glass flakes[a)]	In glass films[b)]	(Substrates)
0.0	1.4	(Pyrex)
0.0	0.0	(Silica)
0.29	0.31	(Silica)
2.5	2.5	(Silica)
5.2	5.5	(Silica)

a) Determined by flame photometry (maximum relative error ± 3%). b) Determined by SIMS (maximum relative error ± 10%).

In Table 1, the concentrations of sodium in the coating films have been compared with those in the corresponding glass flakes. Only the Pyrex glass substrate interacts with the glass film. The sodium concentrations in the films were constant between 20 and 35 nm from the surfaces. Additional heating at 450 °C for 5 h did not increase the sodium concentration. Therefore, the sodium contamination from the Pyrex substrate probably resulted from the presence of water in the film[2] between 200 and 400 °C during the preparation of the film.

Experimental

Preparation of Mixed Alkoxide Solutions. Into a 100 ml round-bottomed flask, silicon tetraethoxide (4 ml) (Nakarai Chemicals), zirconium tetrapropoxide (3 ml) (Ventron Corp.), sodium methoxide (0 to 0.6 ml) (Wako Pure Chemical Industries), and 1-butanol (13 ml) (dehydrated with Molecular Sieve 4A) were placed. A reflux condenser was attached to the flask, and the contents were well mixed with a magnetic stirrer for 3 h at 85 ± 5 °C in a stream of nitrogen (10 cm^3 min^{-1}, dried with calcium chloride). The mixture was cooled and stored in a glass stoppered bottle in a desiccator.

Coating. An 8×5 mm Pyrex or silica glass piece, 1 or 1.5 mm thick, was immersed in a 1 : 1 mixture of concentrated

nitric and sulfuric acids for 24 h, rinsed thoroughly with water, and dried over silica gel. The piece was immersed in a mixed alkoxide solution (100-ml beaker), and withdrawn vertically at a speed of 4 mm min^{-1} by a motor to form a film of uniform thickness. Hydrolysis was effected by placing the piece in a desiccator containing a saturated potassium sulfate solution (relative humidity 95%) at 50 °C for 60 min. The piece was heated at 150 °C for 60 min in an electric muffle furnace. Then the temperature was raised at a rate of 10 °C min^{-1}, kept at 550 °C for 30 min, and lowered to 350 °C at a rate of 1 to 2 °C min^{-1}. The piece was then cooled to room temperature.

Preparation and Analysis of Glass Flakes. A mixed alkoxide solution (1 ml) was placed in a 50 ml silica beaker, and allowed to stand for 24 h at ambient temperature (20—25 °C; relative humidity, 40—50%) to effect evaporation of the solvent and hydrolysis. The resulting flakes (*ca.* 3 mm × 3 mm × 50 μm) were heat-treated and annealed as described in the last paragraph, except that the heating time at 150 °C was increased to 2 h. The transparent glass flakes were used as standards in the SIMS determination of sodium in glass films on glass substrates. For standardization, the flakes were decomposed with hydrofluoric and hydrochloric acids, and sodium and zirconium were determined by flame photometry at 589.3 nm and inductively coupled plasma-optical emission spectrometry at 339.2 nm.

SIMS and Other Measurements. A Hitachi IMA-2 ion microanalyzer was operated under the following conditions: primary ions, argon; primary ion accelerating voltage, 5 kV; primary ion current, 0.1 μA; beam diameter, 250 μm; sample chamber pressure, 3×10^{-5} Pa; secondary ion accelerating voltage, 1.5 kV; electron-multiplier voltage; 2 kV. The electric charges accumulated on the glass surfaces were eliminated by the electron spray method. The SIMS spectra were recorded after ion etching 15 nm from the surface by rastering the primary beam (total number of scanning lines, 500; line frequency, 100 Hz) over a square area of 0.8 mm around the spot to be measured. For the determination of sodium in glass films, peak ratios of $^{23}Na^+$ to $^{28}Si^+$ were measured, and the sodium concentrations were obtained from a calibration curve. The curve (peak ratio *vs.* atom % Na) was prepared using glass flake standards [(22—21)ZrO_2–(78—74)SiO_2–(0—5)Na_2O mol % glasses] and was a straight line through the origin. The thickness of the glass films was measured with a Mizojiri Kogaku model II multiple beam interferometer (Hg 546.1 nm, magnification 40X), with a maximum error of ±3 nm.

The Stability of Bis(8-quinolinolato)copper(II)

Hideo AKAIWA* and Hiroshi KAWAMOTO

Department of Applied Chemistry, Faculty of Technology, Gunma University, Kiryu 376

(Received February 5, 1979)

Synopsis. The IR spectra of the titled and related compounds have been measured, and the stabilities of the chelates characterized by the relative strengths of the metal-nitrogen bonds. An explanation has been made by comparing the extraction behavior of Cu(II) and Fe(III) chelates.

The stability constants for several metal complexes of 8-quinolinol and related substances have been determined by Irving and Rossotti, and the contribution of the metal-nitrogen bonds to the stability of the copper-(II) complex of 8-quinolinol demonstrated although no experimental evidence was presented.[1)]

In the work described below, the stability of the metal chelate has been characterized through the effect of the methyl group of the 8-quinolinol skeleton on the metal-nitrogen bonds.

Experimental

Reagents and Apparatus. 8-Quinolinol was obtained from Wako Pure Chemicals. The methyl derivatives of 8-quinolinol were prepared as described by Phillips and Merritt,[2)] and the purity confirmed through melting point measurements, elemental analysis, IR, and NMR spectra.

The IR spectra were measured by a Nippon Bunko IR-F type spectrophotometer. Samples were in the form of Nujol mulls between polyethylene sheets.

Determination of Acid Exponents for the Reagents. The distribution ratios of 8-quinolinol and the methyl derivatives between chloroform and the aqueous phase of $\mu=0.2$ ($NaClO_4$) were measured at 20 °C as a function of pH, and the distribution data analysed according to Dyrssen.[3)]

Synthesis of Copper(II) Complexes. An ethanolic solution of 8-quinolinol and an aqueous solution of copper(II) acetate were mixed in a molar ratio of 2 to 1, and the mixture allowed to stand for two days. The resulting precipitate was filtered, washed with ethanol and dried over a steam bath. The anhydrous copper(II) complexes of the methyl-substituted 8-quinolinols were obtained according to the above procedure.

Extraction Curves. An aqueous solution ($\mu=1.0$: $NaClO_4$) of copper(II) or iron(III) was equilibrated with an equal volume of chloroform containing the reagent (5.0×10^{-3} mol dm^{-3}), the pH of the aqueous phase and the absorbance of the organic phase being measured after separation.

Results and Discussion

The values of the partition coefficients D_R, acid exponents pK_{OH} and pK_{NH} for 8-quinolinol and the methyl-derivatives are given in Table 1, the data of which are in good agreement with the literature values.[4)] The pK_{HO} values for the methyl derivatives are similar whereas the pK_{NH} values increase in the order; 8-quinolinol <5-methyl-8-quinolinol <4-methyl-8-quinolinol. The inductive and resonance effects due to the methyl-group are reflected in the above trend, and thus the stability of a metal complex can be predicted by choosing an appropriate derivative.

Table 1. Equilibrium constants for 8-quinolinol and its derivatives

Reagent	log D_R	pK_{OH}	pK_{NH}
8-Quinolinol	2.37±0.02	9.77±0.10	4.67±0.14
4-Methyl-8-quinolinol	2.65±0.05	10.28±0.19	5.23±0.17
5-Methyl-8-quinolinol	2.83±0.02	10.10±0.21	5.05±0.09

Table 2. Most important IR absorption bands for copper(II) complexes

Ligand	$\bar{\nu}$/cm^{-1} Cu–O	$\bar{\nu}$/cm^{-1} Cu–N
8-Quinolinol	325	290
4-Methyl-8-quinolinol	326	310
5-Methyl-8-quinolinol	321	300

The assignments of the $\bar{\nu}$(Cu–O) and $\bar{\nu}$(Cu–N) frequencies were conducted according to the work of Ohkaku and Nakamoto,[5)] and the results are summarized in Table 2. It should be noted that the bis(8-quinolinolato)copper(II) obtained by the above procedure was of the β-type, which is known to be a dimer having bridged oxygen atoms. As seen from Table 2, the effect of substitution is negligible on the $\bar{\nu}$(Cu–O) frequency indicating that the stability of bis(8-quinolinolato)copper(II) may depend on the strength of the metal-nitrogen bonds. The increasing order of the pK_{NH} values supports the increasing order of the $\bar{\nu}$(Cu–N), strongly suggesting that the stability for the copper(II) complex is mainly due to the metal-nitrogen bonds.

In order to examine the stability of the copper(II) complex in solution, solvent extraction studies were conducted and the extraction behavior of copper(II) compared with that of iron(III) which is a harder acid than copper(II). The extraction curves for iron(III) obtained by using 8-quinolinol and the methyl derivatives were almost identical, which were shown by a single curve having a $pH_{1/2}$ of 1.54±0.05. A notable effect of the substituent on the extraction of copper(II) was however, observed, and $pH_{1/2}$ values decreased in the following order; 8-quinolinol ($pH_{1/2}=2.0$)>5-methyl-8-quinolinol(1.90)>4-methyl-8-quinolinol(1.76).

The above differences in extraction behavior of the metals may be caused by a difference in the acid strength between the ions. The metal-oxygen bonds in tris(8-quinolinolato)iron(III) play an important role in stabilizing the complex. In contrast, the stability for the copper(II) complex depends mainly upon the metal-nitrogen bonds, as is shown by the present IR studies.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, No. 147033.

Phenanthro[4,5-*bcd*]furan Derivatives. V. The Cyclization of (Dibenzofuran-1-yl)acetic Acid Derivatives

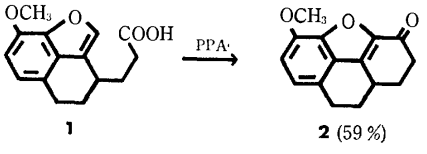
Takaaki HORAGUCHI* and Teishiro ABE†

Department of Chemistry, Faculty of Science, Niigata University, Ikarashi, Niigata 950-21
†*Department of General Education, Niigata University, Ikarashi, Niigata 950-21*

(Received October 16, 1978)

Synopsis. The cyclization of (6-methoxy-1,2,3,4-tetrahydrodibenzofuran-1-yl)acetic acid (**3b**) and (6-methoxy-1,2,3,4,4a,9b-hexahydrodibenzofuran-1-yl)acetic acid (**5**) to the corresponding phenanthro[4,5-*bcd*]furans have been examined. The cyclization of **3b** was difficult, while that of **5** was easy. The difficult cyclization of **3b** has been attributed to strains in the reaction intermediate.

Dendy *et al.*[1] attempted to cyclize the (1,2,3,4-tetrahydrodibenzofuran-1-yl)acetic acids (**3a** and **3b**) to the corresponding phenanthro[4,5-*bcd*]furans (**4a** and **4b**) for the purpose of synthesizing morphenol. All attempts to cyclize **3a** were, however, unsuccessful. **4b** was obtained from Friedel-Crafts reaction of the acid chloride of **3b** but the yield was very low. Dendy *et al.* attributed the failure to ring strain in the products (**4a** and **4b**). 3-(8-Methoxy-4,5-dihydro-3*H*-naphtho-[1,8-*bc*]furan-3-yl)propionic acid (**1**) was readily cyclized by polyphosphoric acid (PPA) to the corresponding phenanthro[4,5-*bcd*]furan (**2**) which has a similar ring skeleton to **4b** in good yield.[2] Therefore, it is improbable that there is great strain in the **4b** molecule. It has previously been reported that the difficult cyclization of **3b** to **4b** may be due to strain in the reaction intermediate (**10**) rather than that of the product (**4b**).[3] Hydrogenation of the carbon-carbon double bond in the furan ring of **3b** would facilitate ready cyclization since the acetic acid side chain would closely approach the benzene ring in molecular terms. Thus, the saturated dibenzofuran derivative (**5**) could be readily cyclized. Consequently the cyclization of **5** to phenanthro[4,5-*bcd*]furan (**6**) has been attempted.



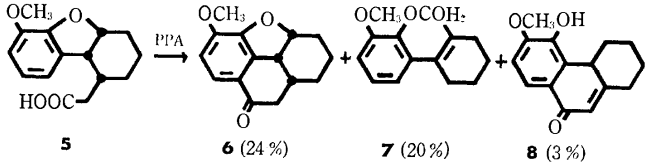


Fig. 1.

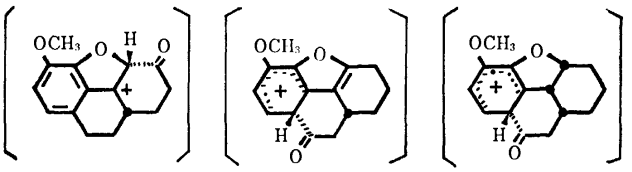

Fig. 2.

The ester (**13**) has been obtained by the Reformatsky reaction of the ketone (**12**). The formation of the ester (**14**) has been reported by Dendy *et al.*,[1] but the IR and NMR spectra of the product here were compatible with the structure of **13**. **13** was hydrogenated in the presence of palladium on charcoal and subsequently hydrolyzed to give **5**. It appears that the configuration of **5** is *cis-syn* as shown, since the furan ring is preferentially hydrogenated from the less hindered face after reduction of the exo-double bond. **5** was heated at 45 °C with PPA, and the desired phenanthro[4,5-*bcd*]-furan (**6**; 24%) was obtained together with a lactone (**7**; 20%) and a hydroxyl ketone (**8**; 3%). Cleavage of the furan ring before the formation of a carbonyl compound yields **7**. Cyclization and subsequent cleavage of the furan ring yields **8**. **5** was heated at 80 °C with PPA and the only product was **8** (40% yield). Under the same conditions (45 and 80 °C), **3b** did not give **4b**, the starting material being recovered. Thus, **5** was cyclized with greater facility than **3b**, as predicted.

These observations suggest that the conformation of the intermediate (**10**) is cup-shaped and possesses a large strain, whereas **11**, the intermediate in the cycliza-

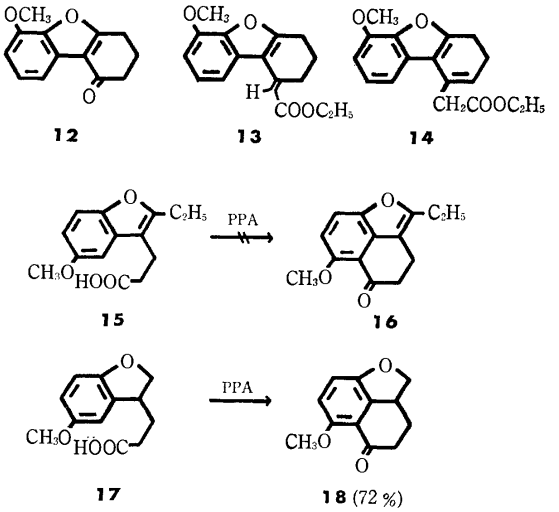

Fig. 3.

tion of **5** to **6**, possesses little strain owing to the saturated furan ring. The strain in the intermediate (**9**) is not large strain as the flexible propionic acid rest of **1** is attached very favorably for the cyclization reaction of **1** to **2**. Support for the above explanation is found in the facts that the cyclization of **15** to **16** is difficult but that of **17** to **18** is easy.[4]

Experimental

*The Cyclization of **5** with Polyphosphoric Acids.* A mixture of **5** (2.0 g) and 20% polyphosphoric acid (160 g) was heated with stirring at 45 °C for 7 h. The mixture was worked up in the usual manner. The resulting oil was chromatographed (benzene–ether 95: 5) on silica gel to give three products.

*Loctone (**7**).* 370 mg (20% yield). Colorless prisms from benzene–hexane; mp 81—82 °C. IR (KBr): ν_{max} 1765 (COO–Ar) cm^{-1}. NMR ($CDCl_3$): δ 1.66—1.81 (4H, m), 2.35 (4H, broad s), 2.89 (2H, s), 3.87 (3H, s), 6.82—7.33 (3H, m).

Found: C, 73.52; H, 6.67%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

*5-Hydroxy-6-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene-9-one (**8**).* 60 mg (3% yield). Colorless plates from acetone–benzene; mp 144—145 °C. IR (KBr): ν_{max} 1665 (C=O), 3200, 3440 (OH) cm^{-1}. NMR (CD_3COCD_3): δ 1.28—1.79 (4H, m), 1.83—2.17 (2H, m), 2.39 (1H, dd, J=3 and 12 Hz), 2.83 (1H, dd, J=5 and 12 Hz), 3.12—3.31 (1H, m), 3.92 (3H, s), 6.20 (1H, s), 7.09 (1H, d, J=8 Hz), 7.62 (1H, d, J=8 Hz), 7.73 (1H, s).

Found: C, 73.51; H, 6.48%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

*5-Methoxy-1,2,3,3a,8,9,9a,9b-octahydrophenanthro[4,5-bcd]furan-8-one (**6**).* 440 mg (24% yield). Colorless needles from benzene–hexane; mp 101—102 °C. IR (KBr): ν_{max} 1690 (C=O) cm^{-1}. NMR ($CDCl_3$): δ 1.02—1.30 (3H, m), 1.53—1.70 (2H, m), 1.95—2.18 (1H, m), 2.40—2.75 (1H, m), 2.50 (1H, dd, J=2 and 17 Hz), 2.79 (1H, dd, J=5 and 17 Hz), 3.81 (1H, t, J=7 Hz), 3.94 (3H, s), 5.10 (1H, q, J=8 Hz), 6.83 (1H, d, J=9 Hz), 7.41 (1H, d, J=9 Hz).

Found: C, 73.58; H, 6.77%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

*Ethyl (6-Methoxy-1,2,3,4-tetrahydrodibenzofuran-1-ylidene)-acetate (**13**).* **13** was prepared by Dendy's method.[1] Colorless needles from ethanol; mp 96—97 °C. (**14**, prepared by Dendy *et al.*;[1] mp 97 °C). IR (KBr): ν_{max} 1695 ($COOC_2H_5$). NMR ($CDCl_3$): δ 1.32 (3H, t, J=7 Hz), 1.90—2.15 (2H, m), 2.90 (2H, t, J=6 Hz), 3.21 (2H, dt, J=1 and 6 Hz), 3.98 (3H, s), 4.21 (2H, q, J=7 Hz), 6.30 (1H, t, J=1 Hz), 6.78 (1H, d, J=7 Hz), 7.18 (1H, t, J=7 Hz), 7.38 (1H, d, J=7 Hz).

*(6-Methoxy-1,2,3,4,4a,9b-hexahydrodibenzofuran-1-yl)acetic Acid (**5**).* Ester **13** (3 g) in ethanol (50 ml) was hydrogenated in the presence of 10% palladium on charcoal (3 g) for 15 h at 7 atm and 60 °C. The resulting ester was purified by chromatography (benzene–ether 95: 5) on silica gel and hydrolyzed to give 1.6 g (59%) of **5**. Colorless needles from benzene–hexane; mp 79—80 °C. IR (KBr): ν_{max} 1710 (COOH) cm^{-1}. NMR ($CDCl_3$): δ 1.10—2.10 (6H, m), 2.25—2.53 (1H, m), 2.43 (2H, broad s), 3.60 (1H, dd, J=3 and 8 Hz), 3.86 (3H, s), 4.86—5.03 (1H, m), 6.72—6.90 (3H, m).

Found: C, 68.58; H, 6.71%. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

The authors wish to express their thanks to Mr. Yoshiaki Takahashi for the elemental analyses and Mr. Takao Oono for the nuclear magnetic resonance analyses.

Sesquiterpenoids. LIV.[1] Absolute Configuration of Eudesma-4(14),7(11)-dien-8-one

Katsuya ENDO and Hiroshi HIKINO*

Pharmaceutical Institute, Tohoku University, Aoba-yama, Sendai 980

(Received December 26, 1978)

Synopsis. (+)-Eudesma-4(14),7(11)-dien-8-one (**1**) isolated from *Atractylodes* rhizomes has been degraded with basic alumina to the trisnor ketone (**3**). From the CD spectra of **1** and **3**, the absolute configuration of **1** has been established to be 5*S*, 10*R*, which has so far been allocated to the (−)-enantiomer.

During the course of our study on the physiologically active constituents of Oriental medicines, it was found that a methanol extract of *Atractylodes japonica* rhizomes showed a significant antiinflammatory activity. Fractionation of the extract monitored by a pharmacological assay afforded active fractions from which an oily substance was isolated. The mass spectrum of the substance ($[\alpha]_D$+92.6°) showed it to be a sesquiterpenoid having the composition of $C_{15}H_{22}O$. The spectral data, in particular a UV absorption maximum at 246 nm and IR bands at 1676 and 1620 cm^{-1} demonstrated the presence of a conjugated enone system in a six- or larger-membered ring. In the IR and ^1H NMR spectra, peaks compatible with one tertiary methyl (δ 0.73), two vinyl methyls (δ 1.78 and 1.90) and an exo-methylene (1640 and 882 cm^{-1}, δ 4.56 and 4.80) were observed. These structural characteristics indicated that this compound was (+)-eudesma-4(14),7(11)-dien-8-one (**1**) obtained recently from the same plant.[2] The conclusion was substantiated by direct comparison with an authentic specimen.

The substance (**1**) is very unstable when subjected to alumina chromatography. A ketonic compound (**3**) was isolated from the decomposition products in varying yields. The compound (**3**) exhibited in its mass spectrum the molecular ion peak at *m/e* 178 corresponding to the composition $C_{12}H_{18}O$. The presence of a saturated carbonyl (1710 cm^{-1}), a tertiary methyl (δ 0.70) and an exo-methylene (1643 and 886 cm^{-1}, δ 4.48 and 4.77) was observed. The structure of the ketone (**3**) was assigned to 1-methyl-7-methylenebicyclo[4.4.0]decan-3-one, the structure being confirmed by direct comparison with an authentic specimen.[3]

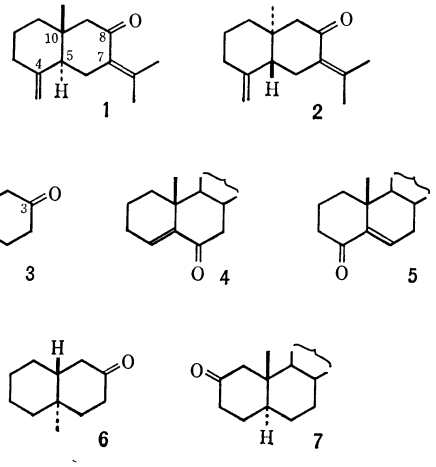
Eudesma-4(14),7(11)-dien-8-one was first isolated in the laevorotatory form ($[\alpha]_D$−55.6°) from *Asarum caulescens*, and was assigned to the stereochemistry **1** although no evidence for it was described.[4] The laevorotatory enantiomer ($[\alpha]_D$−87.4°) was also recently isolated from *Peteravenia schultzii* and assigned to the same stereochemistry (**1**),[5] where specific rotations at 589, 578, 546, and 436 nm were recorded, but no evidence for the assignment was given.

When (+)-eudesma-4(14),7(11)-dien-8-one was isolated from *Atractylodes japonica*, the enantiomeric stereostructure (**2**) was first allocated for it,[6] since its CD curve was found to be enantiomeric with that of the (−)-isomer from *Asarum caulescens* which had been reported to possess the stereostructure **1**. The proposed stereochemistry of the (+)-isomer from *A. japonica* was later altered to **1**, no evidence being reported.[2]

As a result, the same stereostructure **1** is now attributed to both of the (+)- and (−)-isomers with no evidence for the stereochemistry.

The substance (**1**) with the dextrorotatory activity isolated from *A. japonica* exhibited a negative Cotton effect for the n-π^* transition in the ORD and CD curves. The A/B ring fusion of the substance (**1**) was considered to be *trans* by the transformation of germacrone to the *trans*-fused selinane,[4,7] and is now substantiated by the transformation of the substance (**1**) into the trisnor ketone (**3**) having the *trans* ring fusion. The observed negative Cotton effect indicated that the chiral situation of the cisoid enone system is anticlockwise, identical with that of cholest-4-en-6-one (**4**)[8] and enantiomeric with that of cholest-5-en-4-one (**5**).[8] Furthermore, the ketone (**3**) showed a negative Cotton effect at 290 nm for the n-π^* transition in the CD curve. Inspection of the octant diagram demonstrated the absolute configuration of the ketone (**3**) to be 5*S*, 10*R*, identical with the decalone (**6**)[9] and enantiomeric with cholestan-2-one (**7**).[8] These observations led to the conclusion that the absolute configuration of the (+)-enantiomer corresponds to **1**, and consequently that of the (−)-enantiomer to **2**.

Although the reasons for the previous assignments for the absolute stereochemistry are unknown, the ORD curve of the (−)-isomer from *P. schultzii* measured in the range 589—436 nm might be considered as part of a negative Cotton curve but is in fact composed of a positive Cotton curve on a negative plane curve.



Experimental

The homogeneity of each compound was ascertained dy

silica gel thin layer chromatography (Merck Kieselgel GF_{254} with various solvent systems, the spots being visualized by heating with dil. sulfuric acid), and by gas-liquid chromatography with 10% Silicone SE-30 on Chromosorb-W (Φ 3 mm × 1 m glass column). In the ^1H NMR spectra, chemical shifts (δ) are expressed in ppm downfield from internal TMS. Abbreviations: s=singlet, br=broad.

Isolation of (+)-Eudesma-4(14),7(11)-dien-8-one from Atractylodes japonica *Rhizomes.* The crude drug (435 g), the dried rhizomes of *Atractylodes japonica*, was extracted 6 times with refluxing MeOH (1 liter) for 5 h (each extraction). The MeOH solutions were combined and concentrated to dryness to afford an extract (118 g). The MeOH extract (104 g) was diluted with water and extracted with light petroleum, yielding a petroleum soluble portion (27 g) and a water soluble portion (77 g). The former was applied to a column of silica gel (300 g) and eluted with benzene to give an antiinflammatory active fraction (2.7 g) which was again chromatographed over silica gel (100 g). An eluate (1.0 g) with AcOEt–hexane (1: 49) was purified by repeated silica gel chromatography to give (+)-eudesma-4(14),7(11)-dien-8-one (**1**) as a colorless oil: $[\alpha]_D^{20}$ +92.6° (*c* 0.034, MeOH); ORD (*c* 0.0113, MeOH) $[\alpha]_D^{20}$ +90.8° (589), +110° (546), +181° (436), +187° (414), +57.2° (356) (trough), +3420° (300) (peak), and +4240° (290 nm); CD (*c* 0.0004, MeOH) $[\theta]^{24}$ -3.56×10^3 (320 nm) (negative maximum); MS *m/e* 218 (M^+); UV_{max} (hexane) 246 nm (log ε 3.90); IR (liquid) 1676 (conj. C=O), 1640 (C=C), and 882 ($C=CH_2$); ^1H NMR (100 MHz, CCl_4) δ 0.73 (3H, s, CH_3), 1.78 (3H, s, CH_3), 1.90 (3H, s, CH_3), 4.56 and 4.80 ppm (1H each, br s, $C=CH_2$). These spectral data are in line with those reported.[2,4] The substance showed identical behavior on thin layer chromatography and gas-liquid chromatography with that of an authentic **1**.

*Alumina Treatment of (+)-Eudesma-4(14),7(11)-dien-8-one to (−)-*trans*-1-Methyl-7-methylenebicyclo[4.4.0]decan-3-one.* The compound **1** (1.0 g) was applied to a column of basic alumina (300 g). Elution with AcOEt–hexane (3: 97) (300 ml) afforded the unchanged **1** (0.4 g). Further elution with AcOEt–hexane (1: 1) (130 ml) afforded an oily product (449 mg), which was purified by repeated chromatography over silica gel to furnish (−)-*trans*-1-methyl-7-methylenebicyclo[4.4.0]decan-3-one (**3**) as a colorless oil: $[\alpha]_D^{20}$ −6.6° (*c* 0.0085, MeOH); CD (*c* 0.001, MeOH) $[\theta]^{24}$ -6.74×10^3 (290 nm) (negative maximum); MS *m/e* 178 (M^+); IR (CCl_4) 1710 (C=O), 1643 (C=C), and 886 cm^{-1} ($C=CH_2$); ^1H NMR (60 MHz, CCl_4) δ 0.70 (3H, s, CH_3), 4.48 and 4.77 ppm (1H each, br s, $C=CH_2$). The IR spectrum was superimposable with that of a synthetic (±)-**3**.

We are indebted to Drs. Yoichi Nishikawa and Ichiro Yasuda, Tokyo Metropolitan Research Laboratory of Public Health, and Dr. Ken'ichi Takeda, Shionogi Research Laboratory, for identification of the compounds.

A Convenient Method for the Preparation of 4-(3-Halogenatedphenyl)- and 4-(3,5-Dihalogenatedphenyl)-4-oxobutyric Acids

Teruomi JOJIMA, Hideo TAKESHIBA,* and Takao KINOTO

Agricultural Chemicals Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo 140

(Received January 12, 1979)

Synopsis. Various 4-(3-halogenatedphenyl)- and 4-(3,5-dihalogenatedphenyl)-4-oxobutyric acids were synthesized by the nuclear halogenation of the corresponding 4-aryl-4-oxobutyric acids in the presence of an excess of aluminum chloride. In most of these reactions, consecutive succinoylation and halogenation of the aromatic compounds were carried out in one pot operation.

When aromatic aldehydes and ketones are halogenated in the presence of a sufficient amount of aluminum chloride to complex completely the carbonyl groups, halogenation takes place in the benzene rings rather than in the side chains[1] (swamping catalyst method). Krausz *et al.*[2] prepared 4-(3-chloro-4-isopropylphenyl)-, 4-(3-chloro-4-*t*-butylphenyl)-, and 4-(3-chloro-4-cyclohexylphenyl)-4-oxobutyric acids from the corresponding 4-aryl-4-oxobutyric acids by this method. However, halogenation of other 4-aryl-4-oxobutyric acids and the usage of halogenating agents other than chlorine have not been reported.

In connection with the synthesis of fungicidal 6-aryl-3(2*H*)pyridazinones, it became necessary for us to prepare various 4-aryl-4-oxobutyric acids bearing halogens on their 3′- and(or) 5′-positions.[3] These acids are required as starting materials for the synthesis of the heterocycles mentioned above.[4]

It is reported that the Friedel-Crafts reaction of *o*-chlorotoluene with succinic anhydride gave rise to 4-(4-chloro-3-methylphenyl)-4-oxobutyric acid (**4**) owing to a *p*-directing effect of the chlorine atom.[5] In our experiment, this result was also confirmed and the reaction of 2,6-dichlorotoluene with succinic anhydride under the same conditions produced only 4-(2,4-dichloro-3-methylphenyl)-4-oxobutyric acid (**5**). Accordingly, the swamping catalyst method would be very helpful to obtain the 3′- and(or) 5′-halogenated products.

shown along with the reaction conditions in Table 1. Mostly the starting acids (**2**) were prepared *in situ* from the corresponding aromatic compounds and succinic anhydride under the usual Friedel-Crafts conditions.[6] The reaction courses were monitored by high-pressure liquid chromatography (HPLC) in every case. The monohalogenation proceeded smoothly for every halogenating agent used, and the acids halogenated at 3′-position were obtained in good yields.

Next, certain 4-aryl-4-oxobutyric acids were dihalogenated on the 3′- and 5′-positions using more than two molar equivalents of halogenating agents. The dichlorination of the *para*-methyl analog (**2a**) at low temperatures gave higher yield of the product (**6a**) than at elevated temperatures. The nuclear dibromination of **2a** as well as its consecutive chlorination and bromination gave the desired acids (**6a** and **6b**) in good yields. In the case of 4′-isopropyl analog (**2g**), a mixture of variously chlorinated products was obtained, and the desired product (**6c**) could not be isolated.

The dichlorination of 4-(4-methoxyphenyl)-4-oxobutyric acid (**2i**) gave 4-(3,5-dichloro-4-hydroxyphenyl)-4-oxobutyric acid (**6g**) in a good yield. The HPLC indicated that the dichlorination and demethylation took place almost simultaneously in this case. The reaction of 2,6-dichloroanisole with succinic anhydride under the usual Friedel-Crafts conditions produced only tarry materials which could not be purified.

The above experiments have shown that certain 4-aryl-4-oxobutyric acids with halogens on their 3′- and(or) 5′-positions can be conveniently obtained by one pot operation starting from benzene or substituted benzenes.

Experimental

All melting points are not corrected. IR and NMR spectra were recorded on a JASCO IRA-2 spectrophotometer and Varian A-60 nuclear magnetic resonance spectrometer, respectively. HPLC apparatus used was a Hitachi Model 635-T high-pressure liquid chromatograph. Column used was 5×50 cm glass, packed with Hitachi gel 3010. Elution system was MeOH–H_2O–AcOH (94: 5: 1), and wave length was 248 nm through the experiments of monohalogenation and 236 nm through dihalogenation.

Materials. The 4-aryl-4-oxobutyric acids, **2a**,[7] **2f**,[8] **2g**,[9] and **2i**[10] were prepared by the methods described in the literature. 4-(4-*n*-Butylphenyl)-4-oxobutyric acid (**2h**, mp 101 °C) was prepared by a similar method.

Preparation of 4-(3-Halogenatedphenyl)-4-oxobutyric Acids (3) and 4-(3,5-Dihalogenatedphenyl)-4-oxobutyric Acids (6). As a typical run, consecutive succinoylation and chlorination of **1a** are described here. To a mixture of aluminum chloride (32 g, 0.24 mol) and DCE (120 ml) was added portionwise powdered succinic anhydride (11 g, 0.11 mol) with stirring at room temperature. Stirring was continued for further 10 min. Then, toluene (9.2 g, 0.1 mol) was added dropwise in 30 min at 10 °C. After stirring for 1.5 h at 10—15 °C, the reaction mixture was warmed to 30 °C. Chlorine gas (8 ml, 0.17 mol), trapped in a Dry Ice acetone bath was introduced into the reaction mixture in 1 h at 30—40 °C. Stirring was continued thereafter, until the peak due to the monochloro derivative (**3a**) became a maximum on HPLC (relative peak height, *ca.* 95%). Then, the reaction mixture was poured into a mixture of ice (500 g) and concentrated HCl (60 ml), and the resulting oily solid was extracted with ethyl acetate (1 l). The organic solution was repeatedly washed with water, and dried over Na_2SO_4. The filtered ethyl acetate was evaporated *in vacuo*, and the crude product was recrystallized from benzene–hexane (1: 1, 200 ml) to give 16.3 g of 4-(3-chloro-4-methylphenyl)-4-oxobutyric acid (**3a**), as colorless leaflets; mp 150—156 °C. IR (Nujol): 2500—2800 (COOH) and 1700 cm^{-1} (broad, CO). NMR (DMSO-d_6): δ 2.40 (3H, s, CH_3), 2.58 (2H, t, J=6 Hz, $-CH_2-$), 3.25 (2H, t, J=6 Hz, $-CH_2-$), 7.48 (1H, d, J=8 Hz, H-5′), 7.85 (1H, dd, J=8 and 2 Hz, H-6′), and 7.92 (1H, broad s, H-2′). Found: C, 58.80; H, 4.88; Cl, 15.67%. Calcd for $C_{11}H_{11}ClO_3$: C, 58.29; H, 4.89; Cl, 15.64%.

The halogenation of other 4-aryl-4-oxobutyric acids were conducted basically as above. The conditions and results are summarized in Table 1.

Reaction of 2,6-Dichlorotoluene with Succinic Anhydride. To a mixture of aluminum chloride (40 g, 0.3 mol) and DCE (100 ml) was added portionwise powdered succinic anhydride (10 g, 0.1 mol) with stirring. The resulting deep red solution was refluxed for 1 h. The reaction mixture was treated as above to give a crude oily solid (32 g). Recrystallization of this from benzene–hexane (1: 2, 300 ml) gave 7.8 g (30%) of 4-(2,4-dichloro-3-methylphenyl)-4-oxobutyric acid (**5**) as colorless needles; mp 92—94 °C. IR (Nujol): 2500—2800 (COOH), 1700 cm^{-1} (CO); NMR (DMSO-d_6): δ 2.50 (3H, s, CH_3), 2.82 (2H, t, J=6 Hz, $-CH_2-$), 3.14 (2H, t, J=6 Hz, $-CH_2-$), 7.35 (2H, AB-d, aromatic), 9.45 (1H, broad s, OH). Found: C, 50.29; H, 3.77; Cl, 26.95%. Calcd for $C_{11}H_{10}Cl_2O_3$: C, 50.60; H, 3.86; Cl, 27.16%.

The authors are grateful to Dr. Kazuo Tomita and Dr. Takashi Matsui for valuable discussions. They are also thankful to Mr. Toshiaki Yanai, Mr. Tadashi Murakami, Mr. Sohji Sugai, and Mr. Junzo Tobitsuka for technical assistances.

Oxidation-Reduction Equilibrium between Cation Radicals. An Approach to Determine Ionization Potentials of Electron Donor Molecules

Yôichi IIDA* and Akihiko YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 15, 1979)

Synopsis. For several electron donor molecules, the adiabatic ionization potential and the oxidation-reduction potential in the formation of cation radical from its parent molecule were estimated by using the equilibrium constant of a preferred electron transfer reaction from neutral donor molecule to another cation radical molecule in solution.

Earlier, we presented a method for determining electron affinity values of electron acceptor molecules by using preferred electron transfer (*i.e.*, oxidation-reduction) reaction between anion radicals in solution.[1] In this method, we measured the equilibrium constant of such reaction spectrophotometrically, so that we could estimate the difference of the oxidation-reduction potential and the electron affinity between two acceptor molecules.

In a similar way, if we observe chemical equilibrium of preferred electron transfer reaction from neutral electron donor molecule to another cation radical molecule in solution, we can obtain some knowledge regarding the ionization potentials of donor molecules as well as the oxidation-reduction potentials in the formation of their cation radicals. In the present paper, we apply this approach to several donor molecules with low ionization potentials such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD), *N,N*-dimethyl-*p*-phenylenediamine (DMPD), *N,N,N',N'*-tetramethylbenzidine (TMB) and phenothiazine (PT).

In previous papers,[2] we examined the chemical equilibria of such preferred electron transfer reactions in various solvents. First, we shall derive oxidation-reduction potentials for those donor molecules. Hereafter, $E_1(M^{+\cdot}, M)$, $E_2(M^{+\cdot}, M)$, and $E_3(M^{+\cdot}, M)$, (M= TMPD, DMPD, TMB, or PT), are denoted as reversible one-electron reduction potentials of $M^{+\cdot}+e \rightleftarrows M$ in (1 : 3) ethanol–water solution, in aqueous solution and in acetonitrile solution, respectively.

The reaction between neutral phenothiazine and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine cation radical was examined in (1 : 3) ethanol–water solvent. The oxidation-reduction equilibrium is expressed by

$$PT + TMPD^{+\cdot} \rightleftharpoons PT^{+\cdot} + TMPD. \quad (1)$$

If we neglect the effect of counter anions and assume that the activity coefficients of the solutes are unity, the equilibrium constant of this reaction is simply given by

$$K = \frac{[PT^{+\cdot}][TMPD]}{[PT][TMPD^{+\cdot}]}. \quad (2)$$

The equilibrium constant, K, was determined spectrophotometrically to be 0.96×10^{-6} at 10 °C. Using Nernst equation, we obtain a relation of reduction potentials, $E_1(PT^{+\cdot}, PT)=E_1(TMPD^{+\cdot}, TMPD)+0.34$V.

In a similar way, we examined the following reactions and obtained the relations of reduction potentials. In the reaction between neutral phenothiazine and *N,N*-dimethyl-*p*-phenylenediamine cation radical in (1 : 3) ethanol–water solution, $PT+DMPD^{+\cdot} \rightleftharpoons PT^{+\cdot}+DMPD$, $K=[PT^{+\cdot}][DMPD]/[PT][DMPD^{+\cdot}]=(3\pm1)\times10^{-5}$ at 10 °C, and $E_1(PT^{+\cdot}, PT)=E_1(DMPD^{+\cdot}, DMPD)+0.26$ V. From the relation between $E_1(PT^{+\cdot}, PT)$ and $E_1(TMPD^{+\cdot}, TMPD)$, we can estimate the relation, $E_1(DMPD^{+\cdot}, DMPD)=E_1(TMPD^{+\cdot}, TMPD)+0.08$ V. The reaction of $DMPD+TMPD^{+\cdot} \rightleftharpoons DMPD^{+\cdot}+TMPD$ was examined in two different solvents. In aqueous solution, $K=[DMPD^{+\cdot}][TMPD]/[DMPD][TMPD^{+\cdot}]=(2.8\pm0.6)\times10^{-2}$ at 10 °C and $E_2(DMPD^{+\cdot}, DMPD)=E_2(TMPD^{+\cdot}, TMPD)+0.087$ V, while in acetonitrile solution $K=(3.8\pm1.5)\times10^{-2}$ at 10 °C and $E_3(DMPD^{+\cdot}, DMPD)=E_3(TMPD^{+\cdot}, TMPD)+0.078$ V. For the reaction of $DMPD+TMB^{+\cdot} \rightleftharpoons DMPD^{+\cdot}+TMB$ in acetonitrile solution, $K=[DMPD^{+\cdot}][TMB]/[DMPD][TMB^{+\cdot}]=(3\pm1)\times10^{3}$ at 10 °C and $E_3(TMB^{+\cdot}, TMB)=E_3(DMPD^{+\cdot}, DMPD)+0.20$ V. From the relation between $E_3(DMPD^{+\cdot}, DMPD)$ and $E_3(TMPD^{+\cdot}, TMPD)$, we can further obtain $E_3(TMB^{+\cdot}, TMB)=E_3(TMPD^{+\cdot}, TMPD)+0.28$V.

Although we obtained the reduction potentials of TMPD, DMPD, TMB and PT, the used solvents are different from each other. The reason for this is that we have to observe chemical equilibrium between cation radicals and that the stability of the cation radicals greatly depends on the solvents. Rigorously speaking, we cannot compare the values of the reduction potentials in different solvents, and only the comparison of the values in the common solvents is meaningful. However, as was shown above, the dependence of the $E_i(TMPD^{+\cdot}, TMPD)-E_i(DMPD^{+\cdot}, DMPD)$ value, (i=1, 2, or 3), on the solvents used appears to be within ±0.005 V.

Next, we consider the ionization potentials of TMPD, DMPD, TMB and PT on the basis of the above discussion. In a reversible one-electron addition to cation radical molecule, $D^{+\cdot}$, to form neutral molecule, D, in solution, $D^{+\cdot}+e \rightleftharpoons D$, the free energy change in the presence of mercury electrode is given by

$$\Delta G^{\circ}(D) = -I_p(D) + \Delta\Delta G^{\circ}_{solv}(D, D^{+\cdot}) + \chi_{Hg}, \quad (3)$$

where $I_p(D)$ is the ionization potential of the molecule, D, in gas phase, $\Delta\Delta G^{\circ}_{solv}(D, D^{+\cdot})$ is the difference in free energy of solvation between D and $D^{+\cdot}$, and χ_{Hg} is the electron work function of the mercury surface. Note that $I_p(D)$ corresponds to an adiabatic ionization potential, because the reaction involves thermodynamical equilibrium. In the case of oxidation-reduction equilibrium between D_1 and $D_2^{+\cdot}$ in solution, $D_1+D_2^{+\cdot} \rightleftharpoons D_1^{+\cdot}+D_2$, the observed equilibrium constant,

K, is related with ΔG°'s,

$$-RT\ln K = \Delta G^{\circ}(D_2) - \Delta G^{\circ}(D_1) = I_p(D_1) - I_p(D_2) + \Delta\Delta G^{\circ}_{solv}(D_2, D_2^{+\cdot}) - \Delta\Delta G^{\circ}_{solv}(D_1, D_1^{+\cdot}). \quad (4)$$

Therefore, if one assumes that the solvation energy, $\Delta\Delta G^{\circ}_{solv}(D_2, D_2^{+\cdot})$, is almost equal to $\Delta\Delta G^{\circ}_{solv}(D_1, D_1^{+\cdot})$, one can determine from Eq. 4 the difference of the ionization potentials between the D_1 and D_2 molecules. At the present time, although we have not enough knowledge regarding the solvation energy of neutral donor molecule and its cation radical, for neutral acceptor molecule, A, and its anion radical, $A^{-\cdot}$, the magnitude of $\Delta\Delta G^{\circ}_{solv}(A^{-\cdot}, A)$ is found to be hardly influenced by the species of the acceptor molecules, as long as the molecular sizes and the shapes are similar to one another.[1]

Assuming $\Delta\Delta G^{\circ}_{solv}(D_1, D_1^{+\cdot}) \approx \Delta\Delta G^{\circ}_{solv}(D_2, D_2^{+\cdot})$, we will discuss the ionization potentials of TMPD, DMPD, TMB and PT in the following. So far, the ionization potential of TMPD has been studied in most detail.[3,4] Therefore, if the value is one given for I_p(TMPD), the absolute values of I_p(DMPD), I_p(TMB), and I_p(PT) will be determined from Eq. 4 and the observed equilibrium constants. Photoionization of TMPD in gas phase was measured by Batley and Lyons and later by Nakato *et al.*[3,4] The energy for onset of photoionization curve was assumed to correspond to the adiabatic ionization energy, but the onset was rather gradual in the case of TMPD. Batley and Lyons estimated the upper limit of the adiabatic ionization potential as I_p(TMPD)$\leq$6.25 eV, while Nakato *et al.*, I_p(TMPD)$\leq$6.20 eV. In the present paper, referring to Nakato's value, we take I_p(TMPD)=6.20 eV as a standard. Then, by the use of the observed equilibrium constants of oxidation-reduction reactions, together with Eq. 4, the adiabatic ionization potentials of DMPD, TMB, and PT were estimated to be 6.28 eV, 6.48 eV, and 6.54 eV, respectively.

On the other hand, in Table 1, we compare the data with those measured by photoionization method. As has been mentioned, because of gradual onset of photoionization, it is rather difficult to determine exactly the adiabatic ionization energies by photoionization method, where only the upper limits of the ionization energies were estimated. In particular, the onset of ionization of phenothiazine is more gradual than the other diamine compounds. For each of the compounds, however, a fairly good agreement of the adiabatic ionization energies was obtained between the oxidation-reduction equilibrium method and the photoionization method. The order of the adiabatic ionization potentials was estimated as I_p(TMPD)$<I_p$(DMPD)$<I_p$(TMB)$<I_p$(PT) by our method, while in photoionization it appears that I_p(TMPD)$<I_p$(TMB)$\lesssim I_p$(DMPD)$<I_p$(PT). As for the magnitudes of I_p(DMPD) and I_p(TMB) in photoionization, the former value was measured by Nakato *et al.*,[4] while the latter, by Batley and Lyons.[3] Therefore, we consider that systematic determination of the I_p(DMPD) and I_p(TMB) values in photoionization is desirable to compare those values with ours.[6]

Table 1. Adiabatic and vertical ionization potentials (eV) of electron donor molecules

Compound	Adiabatic ionization potential	Vertical ionization potential	Reference
N,N,N',N'-Tetramethyl-*p*-phenylenediamine	$\leq$6.20	6.75	Ref. 4
	$\leq$6.25	6.47	Ref. 3

	6.28		This work
N,N,N',N'-Tetramethyl-benzidine	$\leq$6.40	6.55	Ref. 3
	6.48		This work
Phenothiazine	$<$7.0	7.38	Ref. 3
		7.26	Ref. 5
	6.54		This work

In Table 1, the data on vertical ionization energies are also given for purposes of comparison. Usually, vertical energies exceed adiabatic energies because of a change of shape of the molecule upon ionization. The difference between the adiabatic and vertical energies is considerable in DMPD and PT, where it amounts up to 0.7 eV. This implies a considerable structural change upon ionization in those molecules. For example, the molecular structure of neutral PT is of bent form, while its cation radical may become planar.[7,8]

So far, photoionization method in gas phase has been widely used to determine vertical ionization potentials of a number of organic molecules, but has some difficulties in obtaining adiabatic ionization potentials. Alternatively, the present approach of oxidation-reduction equilibrium is a useful method to determine adiabatic ionization potentials of such molecules. One of the difficulties of this method lies in the assumption of $\Delta\Delta G^{\circ}_{solv}(D_1, D_1^{+\cdot}) \approx \Delta\Delta G^{\circ}_{solv}(D_2, D_2^{+\cdot})$ in Eq. 4. The problem of the solvation energies of neutral molecule and its cation radical should be solved in order to obtain more exact adiabatic ionization potentials of a number of electron donor molecules.

6) In oxidation-reduction equilibrium method, we assume a constant value of $\Delta\Delta G^{\circ}_{solv}(D, D^{+\cdot})$, and the assumption will be justified as long as the sizes and shapes of molecules are similar. However, the size of TMB molecule is rather bigger than those of TMPD and DMPD molecules, and the $\Delta\Delta G^{\circ}_{solv}$(TMB, TMB$^{+\cdot}$) value may be different from the $\Delta\Delta G^{\circ}_{solv}$(TMPD, TMPD$^{+\cdot}$) or $\Delta\Delta G^{\circ}_{solv}$(DMPD, DMPD$^{+\cdot}$) value. This may be a reason why the I_p(TMB) value derived from our method is somewhat greater than the value obtained from photoionization method.

Synthesis and Absorption Spectra of 1,4-Diazaanthraquinone Derivatives

Hiroyuki NAKAZUMI,* Testuro AGAWA, and Teijiro KITAO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai 591

(Received February 20, 1979)

Synopsis. A new 5-amino-1,4-diazaanthraquinone and related compounds were prepared from 2,3-dichloro-1,4-naphthoquinone by two different methods. The transition energies and electron densities of 5-amino-1,4-diazaanthraquinone and 1-aminoanthraquinone were calculated by a variable β,γ-modification of the PPP method.

Anthraquinone dyes are of great value as synthetic coloring matter. We have attempted to prepare new azaanthraquinone derivatives for dyes. Although a few styryl derivatives of diazaanthraquinone dyes have been reported,[1] the preparation and absorption spectra of other diazaanthraquinone derivatives for dyes are little known.

In this paper, we wish to report the syntheses and absorption spectra of new 5-amino-1,4-diazaanthraquinone **4** and related compounds which were prepared from 2,3-dichloro-1,4-naphthoquinone by two different methods (Scheme 1). Compound **4** was prepared as follows: Method A. Reduction of 5-nitro-1,4-diazaanthraquinone **3** prepared by the nitration of 1,4-diazaanthraquinone (DAQ) **2**,[2] with sodium sulfide for 2 h gave **4** in 34% yield. Method B. Condensation of 2,3,5-triamino-1,4-naphthoquinone **6**[3] prepared from 2,3-dichloro-1,4-naphthoquinone **1** *via* several steps (**1**→**5**→**6**), with 40% aqueous glyoxal at 90 °C for 3 h gave **4** in 92% yield. Method B is favorable as regards yield. No diazaanthraquinone derivative (**2**, X=CH_3) could be obtained by the Friedel-Crafts reaction of pyrazinedicarboxylic anhydride with toluene. Compounds **3** and **4** were confirmed by the appearance of peaks at 255 and 225, respectively, in the mass spectra. Since the purification of compound **4** was difficult, it was converted into acetylamino (**7**) and benzoylamino derivatives (**8**). These compounds gave satisfactory results of microanalysis. Bromination of **4** gave a mono bromo derivative **9**. The dye properties of these compounds are under investigation.

The absorption spectra of new 1,4-diazaanthraquinones in EtOH are as follows: 5-NH_2-DAQ **4**: λ_{max} 500 nm (ε 5.7×10^3), 5-$NHCOCH_3$-DAQ **7**: λ_{max} 414 nm (ε 4.5×10^3), 5-$NHCOC_6H_5$-DAQ **8**: λ_{max} 424 nm (ε 5.5×10^3), 5-NH_2-6(or 8)-Br-DAQ **9**: λ_{max} 490 nm (ε 6.2×10^3). The absorption maxima of diazaanthraquinone derivatives **4** and **7** were found at longer wavelength (10—20 nm) than those of their carbon analogues, *e.g.*, 1-aminoanthraquinone **10**: λ_{max} 478 nm, 1-acetylaminoanthraquinone **11**: λ_{max} 400 nm. In the benzene solution, the absorption maxima of **4** and **10** lie at 476 and 465 nm, respectively. The solvent-induced wavelength shift for **4** is larger than that for **10**. Calculation of the first excited energy by the variable β,γ-modification of the PPP method for **10** and **4** predicts a small bathochromic shift for the latter compound (**10**: 2.95 eV (f=0.246), **4**: 2.93 eV (f=0.226)). As shown in Fig. 1 the migration of π-electron accompanying the first electron exitation for **4** is from the donor amino group and substituted ring to two carbonyl groups and the pyrazine ring, as well as for carbon analogue **10**. From the result, it is expected that the characterization of the absorption properties of diazaanthraquinone derivatives is similar to that of anthraquinones.

Experimental

Infrared spectra were recorded on a Hitachi ESI-S2 spectrophotometer using KBr pellets, UV spectra on a Hitachi EPS-3T spectrophotometer, and mass spectra on a Hitachi RMU-6E mass spectrometer operating at 80 eV. Elemental analyses were recorded on a Yanaco CHN recorder MT-2.

5-Nitro-1,4-diazaanthraquinone **3**. 1,4-Diazaanthraquinone[1] (3.8 g, 0.018 mol) was dissolved in concd H_2SO_4 (10 g), and a mixture of concd H_2SO_4 (15 g) and fuming HNO_3 (d=1.52, 2.1 g) was added dropwise to this solution at 75—80 °C. The mixture was stirred at 75—80 °C for 5 h. After cooling, the mixture was poured into cold water. The resulting solid was separated and washed with water. Recrystallization from benzene gave **3** (1.0 g); yield 22%, mp 275—278 °C, Found: C, 57.64; H, 2.19; N, 15.67%; ν_{CO} 1690 cm^{-1}, NMR (DMSO-d_6) δ=9.10 (2H, s) and 7.50—8.50 (3H, m), MS (80 eV), *m/e* (rel intensity), 255 (M, 100), 225 (85), and 209 (54).

5-Amino-1,4-diazaanthraquinone **4**. Method A. Compound **3** (1.0 g, 0.0039 mol) was added to an aqueous solution (100 ml) of sodium sulfide (1.14 g) and sulfur (0.15 g). The mixture was stirred under reflux for 2 h, and the resulting solid was separated. Recrystallization from water and/or pyridine gave **4** (0.3 g). Method B. To a suspension of 2,3,5-triamino-1,4-naphthoquinone (7.7 g, 0.038 mol) in water (230 ml) was added 40% aqueous glyoxal (7.7 g) at 90 °C. The mixture was stirred at 90 °C for 3 h. After cooling, the resulting solid was separated. Recrystallization from water and/or pyridine gave **4** (7.9 g). Microanalysis of compound **4** gave unsatisfactory results as follows. Found: C, 62.98; H, 3.05; N, 18.34%. Calcd for $C_{12}H_7N_3O_2$: C, 64.00; H, 3.11; N, 18.67%, ν_{CO} 1680 and 1650 cm^{-1}, MS (80 eV), *m/e* (rel intensity) 225 (M, 100), 197 (39), 169 (33), and 143 (18).

5-Acetylamino-1,4-diazaanthraquinone **7**. A solution of **4** (0.5 g) in acetic anhydride (25 ml) was stirred under reflux for 2 h. After cooling, the resulting solid was separated and washed with water. Recrystallization from xylene gave **7** in 67% yield: ν_{CO} 1700 and 1665 cm^{-1}, MS (80 eV), *m/e* (rel intensity), 267 (M, 17), 225 (100), 210 (19), and 197 (39). Found: C, 63.09; H, 3.30; N, 16.11%. Calcd for $C_{14}H_9N_3O_3$: C, 62.92; H, 3.37; N, 15.73%.

5-Benzoylamino-1,4-diazaanthraquinone **8**. Benzoyl chloride (2.6 g) was added dropwise to a solution of **4** (1.4 g) in nitrobenzene (45 ml) at 125 °C for 1.5 h. The mixture was then heated for 1.5 h at the same temperature. After cooling, the resulting solid was separated and washed with ligroin and methanol. Recrystallization from acetonitrile gave **8** (1.3 g) in 64% yield: ν_{CO} 1700 and 1665 cm^{-1}. Found: C, 69.21; H, 3.24; N, 12.93%. Calcd for $C_{19}H_{11}O_3N_3$: C, 69.30; H, 3.34; N, 12.77%.

5-Amino-6(or 8)-bromo-1,4-diazaanthraquinone **9**. Bromine (5.3 g) was added dropwise to a solution of **4** (3.0 g) in *o*-dichlorobenzene (100 ml) at 165—170 °C for 1 h. The mixture was stirred under reflux for 7 h. After cooling, the resulting solid was separated and washed with benzene, methanol, and water. Recrystallization from EtOH gave **9** in 45% yield: ν_{CO} 1700 and 1665 cm^{-1}. Found: C, 46.44; H, 2.08; N, 14.20%. Calcd for $C_{12}H_6N_3BrO_2$: C, 47.38; H, 1.97; N, 13.82%, MS (80 eV), *m/e* (rel intensity), 305 (100), 303 (99), 225 (90), 197 (44), and 169 (48).

Method of SCF-MO Calculation. The calculation was carried out by the Pariser-Parr-Pople method with variable β,γ-approximation. The resonance integrals, β_{rs}'s, were adjusted at each iteration of the SCF calculations by means of the following equations.[4]

$$\beta_{CC} = -1.84 - 0.51P_{CC}$$
$$\beta_{CN} = -2.02 - 0.53P_{CN}$$
$$\beta_{CO} = -2.20 - 0.56P_{CO}$$

where P_{rs} is a bond order between the r and s atoms. The two center repulsion integrals γ_{rs}'s were calculated by the Nishimoto-Mataga equation[5] using the following R_{rs}:

$$R_{CC} = 1.517 - 0.18P_{CC}$$
$$R_{CN} = 1.451 - 0.18P_{CN}$$
$$R_{CO} = 1.410 - 0.18P_{CO}$$

The ionization potentials, $I_{p(r)}$'s, and one-center repulsion integrals, γ_{rr}'s, for carbon, nitrogen, and oxygen atoms were chosen as:

I_p(C)	= 11.16 eV	γ_{rr} = 11.13 eV
I_p(N)	= 14.12 eV	= 12.34 eV
I_p(NH$_2$)	= 26.7 eV	= 17.44 eV
I_p(O)	= 17.7 eV	= 15.23 eV

The authors would like to thank Mr. Y. Kogo, Nippon Kayaku Co., Ltd., for assistance in the molecular orbital calculations.

Reactions of 2-Tosyloxy- and 2-Chlorotropones with Hydrazine, Methylhydrazine, and Phenylhydrazine

Kimiaki IMAFUKU,* Katsuya KAMACHI,† Yasunori MATSUDA,†† and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received February 22, 1979)

Synopsis. The reactions of 2-tosyloxytropones or 2-chlorotropones with hydrazine, methylhydrazine, and phenylhydrazine gave 2-hydrazinotropones, 2-(α-methylhydrazino)-tropones, and 2-(β-phenylhydrazino)tropones, respectively. All the reactions are normal substitution at C-2 position of the tropone ring. No ciné reaction was observed. The reactivity of hydrazines decreases in the order: $NH_2NH_2 > CH_3NHNH_2 \gg PhNHNH_2$.

In troponoids, ciné substitution very often occurs besides normal substitution, especially when the leaving group is a tosyloxy or halogen group, rather than a methoxyl group.[1] The reactions of tropolone methyl ethers with hydrazine afford 2-hydrazinotropones, which are useful as synthetic intermediates, by normal substitution at the C-2 atom. However, little is known about the reaction of 2-tosyloxytropones or 2-chlorotropones with hydrazine. We wish to report on the reactions of these reactive troponoids with hydrazine, methylhydrazine, and phenylhydrazine.

Scheme 1.

Results and Discussion

Reactions with Hydrazine. 2-Tosyloxytropone (**1a**) was refluxed with hydrazine hydrate in methanol for 30 min to afford 2-hydrazinotropone (**3a**)[2] in 48% yield. 4- (**1b**) and 6-methyl-2-tosyloxytropone (**1c**) also gave the corresponding 4- (**3b**)[3] and 6-methyl-2-hydrazinotropone (**3c**)[3] in 31 and 41% yields, respectively.

In a similar manner, the reactions of 2-chlorotropones (**2a**—**c**) with hydrazine hydrate gave 2-hydrazinotropones (**3a**—**c**) in 92, 89, and 91% yields, respectively, all the reactions being normal substitution at the 2-position of tropones.

Reactions with Methylhydrazine. The reactions of 2-tosyloxytropones (**1a**—**c**) with methylhydrazine under reflux in methanol gave 2-(α-methylhydrazino)tropones (**4a**—**c**) in 31, 38, and 34% yields, respectively. The NMR spectrum of **4a** shows peaks at δ 3.29 (s, 3H) for CH_3 and δ 4.29 (br, 2H) for NH_2, indicating the presence of an α-methylhydrazino group. The spectra of **4b** and **4c** also show the presence of the α-methylhydrazino group (Table 1). The position of the *C*-methyl substituent in **4b** and **4c** were confirmed by alkaline hydrolysis to 4-methyltropolone.[4]

Heating of 2-chlorotropone (**2a**—**c**) with methylhydrazine afforded the same products (**4a**—**c**) in 69, 72, and 64% yields, respectively. Thus, all the reactions with methylhydrazine are normal substitution reactions, giving no abnormal substitution products.

Reactions with Phenylhydrazine. Heating of 2-tosyloxytropone (**1a**) with phenylhydrazine in methanol under reflux for 30 min gave no product in isolable amount. Prolonged reaction (8 h) afforded 2-(β-phenylhydrazino)tropone[5,6] (**5a**) in only 18% yield. Similarly, both the reactions of 4- (**1b**) and 6-methyl-2-tosyloxytropone (**1c**) gave the corresponding 2-(β-phenylhydrazino)tropones (**5b** and **5c**) in 24 and 14% yields, respectively. Presence of the β-phenylhydrazino group was confirmed by the NMR spectra which show two peaks at δ 5.7—5.8 (br, 1H) for N**H**–Ph and δ 8.2—8.25 (br, 1H) for N**H**–tropone. Palladium-catalyzed hydrogenolysis of **5b** and **5c** yielded 4-[7] and 6-methyl-substituted 2-aminotropones,[3] respectively.

† Present address: Eiken Chemical Co., Ltd., Bunkyo-ku, Tokyo 113.

†† Present address: Yoshitomi Pharmaceutical Industries Ltd., Bunkyo-ku, Tokyo 113.

This indicates that the reactions of **1b** and **1c** with phenylhydrazine are normal substitutions.

Furthermore, the reactions of 2-chlorotropones (**2a**—**c**) with phenylhydrazine gave normally-substituted 2-(β-phenylhydrazino)tropones (**5a**—**c**) in 10, 16, and 16% yields, respectively.

Reactivity of Hydrazines. The reactivity of hydrazines based on the product yields decreases in the following order:

$$NH_2NH_2 \gtrsim CH_3NHNH_2 \gg PhNHNH_2$$

In methylhydrazine, the reactivity enhancement by the +I effect of the methyl group is overcome by its steric effect. Thus, its reactivity might be comparable to that of hydrazine.

On the other hand, the reactivity of phenylhydrazine is considerably decreased by both the −I and steric effects of the phenyl group. The reactivity order is in line with the order of basicity (pK_a) of hydrazines:

$$NH_2NH_2\ (8.07)^{8)} > CH_3NHNH_2\ (7.87)^{8)} \gg PhNHNH_2\ (5.27)^{9)}$$

Experimental

Measurements. Melting points were determined with a Yanagimoto micro-melting point apparatus and are uncorrected. IR spectra were taken on a JASCO IRA-1 spectrophotometer, and UV spectra on a Hitachi EPS-3T spectrophotometer. NMR spectra were recorded on a Hitachi R-24 spectrometer (60 MHz).

Materials. All the known compounds were prepared according to the methods described: **1a**, mp 155.5—156.5 °C (lit,[10] 159—159.5 °C); **1b**, mp 114—118 °C (lit,[11] 117—118 °C); **1c**, mp 165—167 °C (lit,[11] 168—169 °C); **2a**, mp 66—67 °C (lit,[12] 66—67 °C).

4- (2b) and 6-Methyl-2-chlorotropone (2c). 4- (**2b**) and 6-methyl-2-chlorotropone (**2c**) were prepared by the reaction of the corresponding tosylates (**1b** and **1c**) with concentrated hydrochloric acid in dioxane according to the most advantageous method reported.[13,14] **2b**, mp 49—50 °C (lit,[7] 49—51 °C); **2c**, mp 59—60 °C (lit,[7] 60—61 °C).

Reactions with Hydrazine. A mixture of **1** or **2** (1 mmol) and 80% hydrazine hydrate (3 mmol, 185 mg) in methanol (5 ml) was refluxed for 30 min on a water-bath. The reaction mixture was diluted with water and extracted with chloroform. The extract was chromatographed on a Wakogel B-10 plate (30×30 cm²) with ethyl acetate to afford the corresponding 2-hydrazinotropone (**3**) (from benzene–hexane). **3a**, mp 91—93 °C (lit,[2] 95—96 °C); **3b**, mp 120—123 °C (lit,[3] 124 °C); **3c**, mp 122—124 °C (lit,[3] 134—135 °C).

Reactions with Methylhydrazine. The active troponoid (**1** or **2**) (1 mmol) reacted with methylhydrazine (3 mmol, 138 mg) in methanol (5 ml) to give the corresponding 2-(α-methylhydrazino)tropone (**4**) (from benzene–cyclohexane). Characteristic data are given in Table 1.

Alkaline Hydrolysis of 4- (4b) and 6-Methyl-2-(α-methylhydrazino)tropone (4c). *a*) **4b** (15 mg) was heated on a water-bath for 2 h with 10% potassium hydroxide/ethanol–water (1: 1) (4 ml). The reaction mixture was neutralized with 2 M hydrochloric acid and extracted with chloroform. The extract was dried over sodium sulfate, giving pale yellow crystals (11 mg, 88%) by evaporation of chloroform. The crystals were recrystallized from petroleum ether to afford 4-methyltropolone. Mp 73—76 °C (lit,[4] 76—77 °C). *b*) Alkaline hydrolysis of **4c** (210 mg) also gave 4-methyltropolone. Yield 120 mg (69%).

Reactions with Phenylhydrazine. A mixture of **1** or **2** (1 mmol) and phenylhydrazine (3 mmol, 324 mg) in methanol (5 ml) was refluxed for 8 h and worked up to afford the corresponding 2-(β-phenylhydrazino)tropone (**5**) (from ethyl acetate) (Table 1). Compound (**5a**) has been reported (mp 175 °C[5] and 163 °C[6]).

Hydrogenolysis of 4- (5b) and 6-Methyl-2-(β-phenylhydrazino)-tropone (5c). *a*) **5b** (0.5 mmol, 113 mg) in acetic acid (100 ml) was stirred for an hour under hydrogen atomosphere in the presence of 5% palladium–charcoal (100 mg). After removal of the catalyst, the reaction mixture was diluted with water, neutralized with solid sodium carbonate, and extracted with chloroform. The chloroform solution was washed with water, dried over sodium sulfate, and chromatographed on a Wakogel B-10 plate (20×20 cm²) with chloroform to give 2-amino-4-methyltropone. Yield 27 mg (40%); mp 120—121 °C (lit,[7] 122—123 °C). *b*) In a similar manner, hydrogenolysis of **5c** (0.5 mmol, 113 mg) gave 2-amino-6-methyltropone. Yield 32 mg (47%); mp 110—112 °C (lit,[3] 111—112 °C).

We wish to thank Dr. Tetsuo Nozoe, Professor Emeritus of Tohoku University, for his helpful discussion and encouragement. We are also grateful for the supply of methylcyclopentadiene dimer from Hitachi Chemical Co., Ltd.

(Received August 7, 1978)

Synopsis. The calcination of synthetic hydrotalcites of different compositions gave aluminium magnesium double oxides with strong basic sites and a high catalytic activity towards the polymerization of β-propiolactone. The strong basic sites were determined and compared with the apparent polymerization rates, suggesting that the strong basic sites are active sites towards the reaction.

Many catalytic reactions precipitated by either aluminium oxide or magnesium oxide have appeared in the literature; however, only a few works have been found regarding aluminium magnesium double oxide catalyses: the polymerization of formaldehyde,[1] the methylation of 3,5-xylenol,[2] and the depolymerization of paraldehyde.[3] In the last work, the correlation between the reactivity and the acid strength of the catalysts was mentioned. These catalysts were prepared by the calcination of hydroxides, nitrates, or carbonates.

Fukuda *et al.*[4] calcined synthetic hydrotalcites[5] with various molar ratios of the two metals in order to prepare aluminium magnesium double oxides, and studied their catalytic activity towards the decomposition of 4-hydroxy-4-methyl-2-pentanone and the methylation of phenol with methanol. The polymerization of propylene oxide was also found to be catalyzed by the oxide.[6] In this paper, these double oxides will be shown to catalyze the polymerization of β-propiolactone, and the active sites for the reaction will be discussed.

Experimental

Reagents. The hydrotalcites were supplied by the Kyowa Chemical Co., Ltd. The β-propiolactone was obtained commercially, dried over anhydrous sodium sulfate, and distilled under 10 Torr. The toluene was dried over calcium hydride and distilled under nitrogen. The acetone, ethanol, and chloroform used were of a reagent grade.

Calcination of Hydrotalcite. About 0.5 g of air-dried hydrotalcite was placed in a 20 ml test tube, calcined in air at elevated temperatures up to 450 °C, and kept at this temperature for 1 h. Then, the calcined hydrotalcite was cooled to 300 °C in air and subsequently to room temperature over anhydrous calcium chloride. After the determination of the calcination loss of hydrotalcite, the air in the tube was replaced with nitrogen and the tube was sealed with a stop cock.

Polymerization Procedure. To the oxide in the tube, 3 ml of toluene, 3 ml of β-propiolactone, and a magnetic stirring bar were added and the tube was sealed off. The reaction was carried out under stirring at a constant temperature for the necessary period of time. Then the reaction mixture was poured into ethanol, and the resulting precipitate was filtered and dried *in vacuo*. The polymer was extracted from the polymer-oxide composite with hot acetone for 10 h, using a Soxhlet extraction apparatus. The viscosity of the extracted polymer was measured at 30 °C in chloroform (0.5 g/dl).

Results and Discussion

The calcination of synthetic hydrotalcite at 450 °C for 1 h caused an almost complete decomposition, evolving carbon dioxide and water; consequently, aluminium magnesium double oxide was formed. The results of the chemical analysis and the measurement of the surface area are summarized in Table 1. A colour change in the indicator adsorbed on the oxide surface was observed for methyl red ($pK_a=4.8$), but not for phenylazonaphthylamine ($pK_a=4.0$). Therefore, the most acidic sites had acid strengths of $4.8 \geqslant H_0 \geqslant 4.0$. In the same manner, the most base strength of the oxides was determined to be $18.0 \geqslant H_- \geqslant 17.2$.

Table 1. Characterization of aluminium magnesium double oxides

Oxide	**1**	**2**	**3**	**4**	**5**
Calcination loss (wt %)	42.5	42.1	41.2	42.9	42.3
Chemical analysis					
MgO (wt %)	47.3	56.7	62.5	72.7	79.4
Al_2O_3 (wt %)	48.0	37.7	30.2	19.7	11.4
MgO/Al_2O_3 (molar ratio)	2.49	3.80	5.23	9.33	17.6
Amount of acid[a] (mmol/g)	0.41	0.32	0.21	0.06	0
Amount of base[b] (mmol/g)	0.63	0.54	0.73	0.85	0.94
Surface area[c] (m^2/g)	216	133	137	187	209

a) This was measured by the titration of butylamine (0.1 mol dm^{-3}) in benzene, using methyl red ($pK_a=4.8$) as an indicator. b) The value was obtained by the titration of benzoic acid (0.1 mol dm^{-3}) in benzene, using 2,4-dinitroaniline ($pK_a=15.0$) as an indicator. c) The surface area was measured by the BET method.

In order to examine the effects of these strong basic sites on the polymerization, the basic sites which have the base strength of $H_- \geqslant 15.0$ were determined (Table 1). The amount of the base was shown to increase with an increase in the molar ratio of magnesium oxide to aluminium oxide, except for the oxides **1** and **2**. This might be due to the increase in the surface area. The amount of the acid ($H_0 \leqslant 4.8$) correlates reversely with the magnesium oxide content. By X-ray analysis, the oxides showed only magnesium oxide diffraction patterns and no hydrotalcite patterns. The aluminium oxide moiety was likely to make a non-crystalline structure.

The results of the polymerization of β-propiolactone

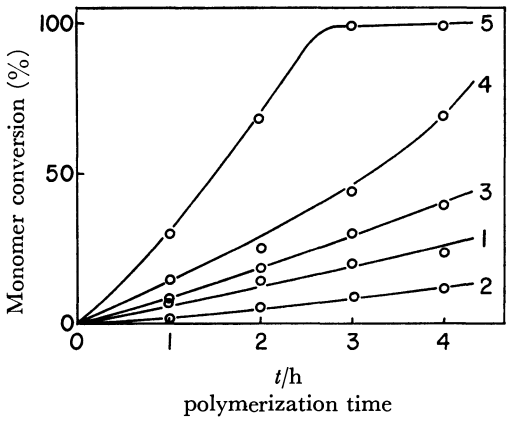

Fig. 1. Time-conversion curves for the polymerization of β-propiolactone catalyzed by the oxides listed in Table 1. β-propiolactone 3 ml, toluene 50 vol % solution, at 50 °C. Oxides **1** to **5** were prepared by the calcination of 0.5 g of corresponding hydrotalcites.

using the oxides in Table 1 as catalysts are summarized in Fig. 1. Since the reproducibility of the reaction was poor, *e.g.*, the variation coefficient of the monomer conversion (oxide **3**; 50 °C; 3 h) over 10 runs was 13%, the calcination and polymerization for hydrotalcites in a experiment were carried out at the same time. From the reaction products (reaction time 3 h; *cf.* Fig. 1), polymers were extracted with acetone. The polymers exhibited ester bands at 1730 and 1170 cm^{-1} in the ir spectra. The values of the weight per centage of the extracted polymer to the polymer-oxide compositions were 31, 36, 34, 25, and 8 for oxides **1** to **5** respectively. The values of the intrinsic viscosity were found to be 0.21, 0.11, 0.25, 0.36, and 0.26, showing that the polymers obtained did not have large molecular weights.[7]

A comparison of the amounts of the bases ($H_- \geqslant 15.0$) of the oxides in Table 1 with the overall initial polymerization rates in Fig. 1 implies that the reaction was initiated by a strong base. On the addition of a small amount of water, the oxides lost their polymerization activity. A carbon dioxide atmosphere also deactivated them. Such variations in the reaction conditions were found to diminish the amount of the strong base. Therefore, the active sites seem to correlate with the basic sites. However, the calcination of hydrotalcites at a reduced pressure (*ca.* 3 Torr) was also found to give oxides with a poor catalytic activity. This finding will be discussed elsewhere.

According to Malinowski's report,[8] magnesium oxide may have two kinds of basic sites on the surface: a strong basic site, O^{2-}, and a weak basic site, OH^-. The probable active site might be attributed to the strong basic surface oxygen. The role of aluminium oxide in the reaction is not yet clear; however, it contributed to the appearance of the strong basic sites ($H_- \geqslant 15.0$) on the double oxide. Magnesium oxide alone, prepared by the calcination of magnesium carbonate, did not exhibit such a strong basicity nor any polymerization activity.

The authors wish to thank Mr. Teruhiko Kumura for the generous gift of hydrotalcites and for the measurement of the surface area.

The Structure of the Cyclodextrin Complex. VIII. Crystal Structures of α-Cyclodextrin Complexes with 2-Pyrrolidone and *N,N*-Dimethylformamide

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221†

(Received October 2, 1978)

Crystal structures of α-cyclodextrin complexes with *N,N*-dimethylformamide and 2-pyrrolidone were determined by the X-ray method. The pentahydrated crystals of both complexes are orthorhombic, and the space group is $P2_12_12_1$ with $Z=4$. The cell dimensions are $a=13.750(1)$, $b=15.318(1)$, and $c=24.544(2)$ Å for the *N,N*-dimethylformamide complex, and $a=13.852(1)$, $b=15.373(1)$, and $c=24.353(2)$ Å for the 2-pyrrolidone complex. The structures were determined by assuming the same α-cyclodextrin packing in the crystal as that found in the isomorphous *p*-nitrophenol complex, and refined by the block-diagonal least-squares method to the final *R*-values of 0.054 for the *N,N*-dimethylformamide complex (5151 reflections) and 0.051 for the 2-pyrrolidone complex (5165 reflections). In both complexes, the guest molecules are included in the α-cyclodextrin cavity. The *N,N*-dimethylformamide molecule is in van der Waals contact with the host α-cyclodextrin molecule, while the 2-pyrrolidone molecule forms a weak N–H···O hydrogen bond with a glycosidic oxygen atom of α-cyclodextrin. The carbonyl oxygen atom of *N,N*-dimethylformamide and 2-pyrrolidone is hydrogen-bonded to water molecules of hydration located at the primary hydroxyl side of α-cyclodextrin. The tilt-angle of the glucose residue against the plane through six glycosidic oxygen atoms indicates clearly that the macro-cyclic conformation of α-cyclodextrin is affected by the packing as well as the size and shape of the guest molecule. The α-cyclodextrin molecules in the crystal are arranged parallel to the ac plane to form molecular layers. Three water molecules are located near the guest molecule, while the other two water molecules fill the intermolecular space.

Crystal structures of several α-cyclodextrin (α-CDx) complexes with benzene derivatives have already been determined by the X-ray method,[1–6] and it has been shown that the benzene ring can be included in the α-CDx cavity. On the other hand, the circular dichroism studies have shown that cyclodextrins form complexes with non-aromatic ring compounds, such as substituted cyclohexanones.[7] In this paper, we deal with the crystal structure of the α-CDx–2-pyrrolidone (1:1) complex to investigate the geometry of inclusion of a non-aromatic compound.

α-CDx dissolves in organic solvents such as DMSO and *N,N*-dimethylformamide (DMF). The X-ray study of α-CDx crystals obtained from a DMSO–methanol solution has shown that the α-CDx molecule includes DMSO and methanol molecules simultaneously.[8] The crystal structure of α-CDx crystallized from DMF–water solution was also determined to investigate the α-CDx–DMF interaction.

Experimental

Crystals of the α-CDx complex with 2-pyrrolidone (PRD) were obtained by cooling an aqueous solution containing α-CDx and PRD in 1:1 molar ratio. The α-CDx–DMF (1:1) complex was crystallized from a DMF–water (1:1) solution. Lattice parameters and reflection intensities were measured on a Rigaku automatic four-circle diffractometer with graphite-monochromatized Cu $K\alpha$ radiation. Intensity data were collected up to 150° in 2θ by using the θ-2θ scan technique. For the DMF complex, 5465 independent reflections were obtained, but 314 reflections with $|F_o|<3\sigma(F)$ were treated as unobserved. The same treatment was done for 245 reflections of the 5410 observed ones for the PRD complex. No corrections were made for absorption and extinction.

Crystal Data: α-CDx–MDF pentahydrate, $C_{36}H_{60}O_{30}\cdot C_3H_7ON\cdot 5H_2O$: *F.W.*=1136.0, orthorhombic, space group $P2_12_12_1$, $Z=4$, $a=13.750(1)$, $b=15.318(1)$, $c=24.544(2)$ Å, $V=5169.5(2)$ Å^3, $D_x=1.460$, $D_m=1.454$ g·cm^{-3}.

α-CDx–PRD pentahydrate, $C_{36}H_{60}O_{30}\cdot C_4H_7ON\cdot 5H_2O$: *F.W.*=1148.0, orthorhombic, space group $P2_12_12_1$, $Z=4$, $a=13.852(1)$, $b=15.373(1)$, $c=24.353(2)$ Å, $V=5186.2$ Å^3, $D_x=1.470$, $D_m=1.461$ g·cm^{-3}.

Determination and Refinement of the Structure

Crystals of the α-CDx complexes with DMF and PRD are isomorphous with the crystals of di-substituted benzene complexes.[1,2,5] A set of coordinates of α-CDx found in the *p*-nitrophenol complex[5] was used to determine initial phases for these complexes. The guest and water molecules were found on Fourier and difference-Fourier maps. Seventy hydrogen atoms in the DMF complex and sixtyfive ones in the PRD complex were found on the difference-Fourier maps. A primary hydroxyl group (O(6,G4)) and two water molecules (W4 and W5) were revealed to be statistically disordered in both complexes. Their occupancies were estimated from an electrondensity map, but they were not refined. The refinement of atomic parameters was carried out by the block-diagonal least-squares method, the quantity minimized being $\Sigma w(|F_o|-|F_c|)^2$, with $w=1.0$ for all the reflections used. Temperature factors of hydrogen atoms were not refined, but fixed as equal to the isotropic ones of heavier atoms to which the hydrogen atoms are bonded. The final *R*-values were 0.054 and 0.051 for the DMF and PRD complexes, respectively. The atomic parameters are listed in Tables 1 and 2.*

† New address: 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 300-01.

* The tables of observed and calculated structure factors of both complexes and those of bond distances, bond angles, and conformation angles are kept at the Office of the Chemical Society of Japan (Document No. 7927).

TABLE 1. FINAL ATOMIC PARAMETERS ($\times 10^4$) FOR THE NON-HYDROGEN ATOMS

The anisotropic temperature factors are of the form: $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{23}kl+B_{31}lh)]$. OC indicates the occupancy factor for the disordered atom.

Description and Discussion of the Structure

The atom numbering for α-CDx in both complexes (Figs. 1 and 2) is the same as that used in other complexes with the isomorphous structure.

Structure of α-CDx. Average bond distances and bond angles over six glucose residues in the α-CDx moiety are shown in Fig. 3. The corresponding distances and angles in the both complexes are in good agreement. No significant differences were observed when they were compared with those found in the α-CDx complexes with *p*-nitrophenol and *p*-hydroxybenzoic acid.[5] The primary hydroxyl group in the G4 residue is statistically disordered (Figs. 1 and 2), and shows *gauche-gauche* and *gauche-trans* conformations, while other primary hydroxyl groups are in the *gauche-*

gauche conformation. A similar disordered conformation of the primary hydroxyl group has been found in other α-CDx complexes[1,2,5] isomorphous to these complexes, although the shape and size of the guest molecule are quite different. The C(6,G4)–O(6B,G4) bond is oriented to the inside of the α-CDx ring, but shows no short contact with the included guest molecule. Therefore, the disorder of the G4 hydroxyl group may not be caused by the inclusion of the guest molecule, but by the packing requirement.

The geometry of the α-CDx ring is given in Tables 3—5. The O(4)···O(4) distances between adjacent glucose residues indicate that the deformation of the pyranose ring is slightly smaller than that found in the complexes with *p*-nitrophenol (4.016—4.493 Å) and *p*-hydroxybenzoic acid (4.053—4.509 Å).[5] The torsion-angle indices[9] (see Table 3) also show a similar tendency: they are 111.4—148.1° in the *p*-nitrophenol complex and 108.9—145.9° in the *p*-hydroxybenzoic acid complex. Between the O(4)···O(4) distances and

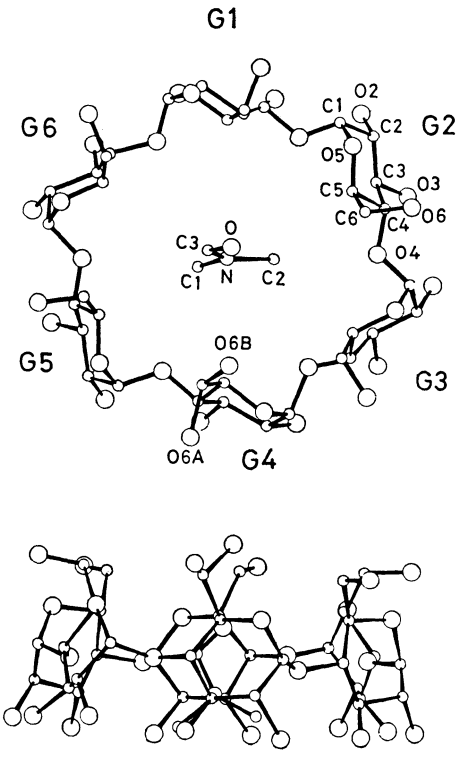

Fig. 1. Structure and numbering scheme of the α-cyclodextrin–*N*,*N*-dimethylformamide complex. O6A and O6B indicate the disordered hydroxyl oxygen atom.

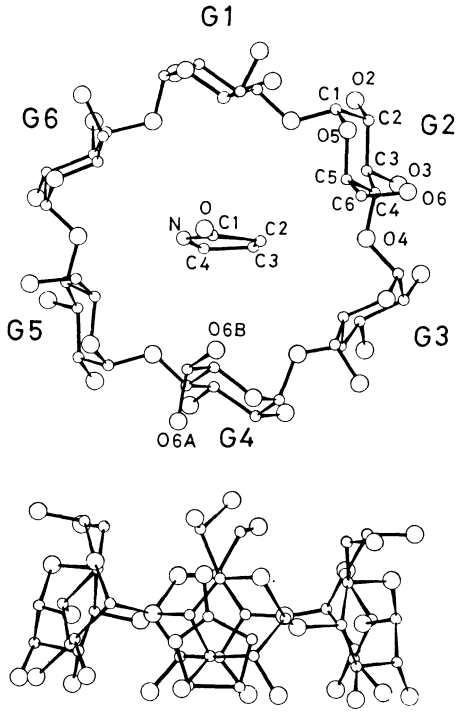

Fig. 2. Structure and numbering scheme of the α-cyclodextrin–2-pyrrolidone complex. O6A and O6B indicate the disordered hydroxyl oxygen atom.

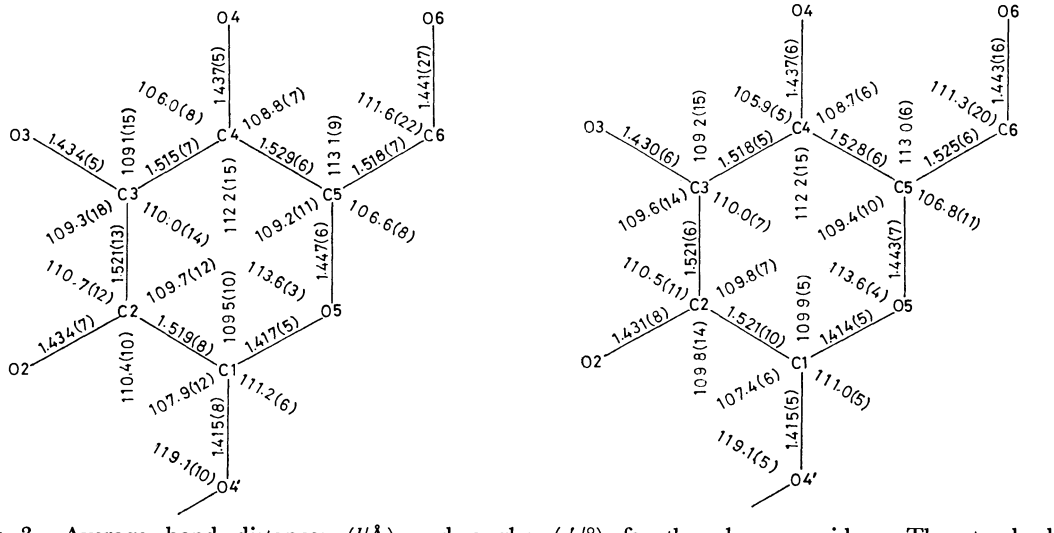

Fig. 3. Average bond distances (l/Å) and angles (ϕ/°) for the glucose residue. The standard deviations were estimated according to the equation $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$, Where x_i referes to the bond distances or angles in the i-th residue and $\bar{x}$ is the average value.

the torsion-angle index there existed a linear correlation, which was also found in other α-CDx complexes having the isomorphous structure.

The diagonal distances between glycosidic oxygen atoms (8.231—8.906 Å in the DMF complex and 8.294—8.735 Å in the PRD complex) show the distorsion of the α-CDx ring from a regular hexagonal symmetry. The longest diagonal is found along the molecular plane of the guest molecule. The deformation of the α-CDx ring in both complexes is less than that observed in the *p*-nitrophenol and *p*-hydroxybenzoic acid complexes because of the smaller size of the guest molecule. The macro-cyclic conformation of α-CDx ring has usually been described in terms of the conformation angle involving the glycosidic oxygen atoms. Owing to the ring structure of α-CDx, however, the conformation angle is found in a relatively restricted region, and does not seem to be sensitive to the conformational change. The deformation of the α-CDx ring apparently has a much greater effect on the tilt of the glucose residue against the α-CDx molecular plane. Since the planarity of the plane defined by six O(4) atoms is fairly good, in spite of the deformation of the α-CDx ring (Table 4), the tilt angle between the O(4) plane and the plane through O(4′), C(1), C(4), and O(4) for each glucose residue was calculated. These tilt-angles (Table 5) show that the G1 residue is almost perpendicular to the O(4) plane while the G5 residue is most tilted. The standard deviation for the average tilt-angle of the G6 residue is about twice as large as the standard deviation of other residues, indicating that the tilt of the G6 residue is most affected by the guest molecule.

Table 3. Selected geometrical data for α-cyclodextrin

I. Distances between glycosidic oxygen atom (l/Å)[a]	DMF complex	PRD complex
i) O(4)···O(4) distances between adjacent glucose residues		
O(4,G1)···O(4,G6)	4.347	4.300
O(4,G1)···O(4,G2)	4.201	4.201
O(4,G2)···O(4,G3)	4.110	4.131
O(4,G3)···O(4,G4)	4.439	4.399
O(4,G4)···O(4,G5)	4.212	4.205
O(4,G5)···O(4,G6)	4.190	4.199
ii) Diagonal O(4)···O(4) distances		
O(4,G1)···O(4,G4)	8.231	8.294
O(4,G2)···O(4,G5)	8.906	8.735
O(4,G3)···O(4,G6)	8.329	8.384

II. Torsion-angle index (ϕ/°)[b] Residue	DMF complex	PRD complex
G1	121.1	124.7
G2	131.6	132.3
G3	141.9	138.9
G4	112.6	115.6
G5	134.6	133.6
G6	144.7	135.0

a) Estimated standard deviations are in the range from 0.004 to 0.006 Å. b) The torsion-angle index is defined as follows: $|\phi(C(1)\text{-}C(2))| + |\phi(C(2)\text{-}C(3))| + |\phi(C(5)\text{-}O(5))| + |\phi(O(5)\text{-}C(1))| - |\phi(C(3)\text{-}C(4))| - |\phi(C(4)\text{-}C(5))|$, when the conformation angle of C(1)-C(2)-C(3)-C(4) is expressed as ϕ(C(2)-C(3)).

α-CDx - Guest Interaction. Figure 4 shows bond distances and angles in DMF and PRD, and intermolecular atomic contacts between α-CDx and these guests. The bond distances and angles in PRD are in good agreement with those found in (*S*)-5-iodomethyl-2-pyrrolidone and (*S*)-5-oxo-2-pyrrolidinecarboxamide.[10] On the other hand, a rather short C(3)–O distance (1.10 Å) and large C(3)–N–C(2) angle (133°) are found in DMF. This may be due to the large thermal motion of the DMF molecule. A similar effect has

been observed in the α-CDx complexes with a small guest molecule.[11-13] DMF and PRD show good planarity: the maximum deviation from the plane is 0.046 Å in PRD and 0.027 Å in DMF.

In the α-CDx cavity, the DMF and PRD molecules are located nearly parallel to the O(4,G2)···O(4,G5) diagonal line. In the DMF complex, two methyl groups are located at the O(2), O(3) side, while the C(3) atom is nearly on the O(4) plane. The shortest intermolecular distance between DMF and α-CDx is 3.76 Å, found between O(4,G6) and C(3,DF), indicating that the DMF molecule is in van der Waals contact with the host α-CDx molecule. In the PRD complex, the C(3)–C(4) bond is nearly on the plane composed of twelve secondary hydroxyl groups, and the carbonyl oxygen atom is located at a similar position to that of the oxygen atom found in the DMF complex. Some relatively short contacts are found in the PRD complex: O(4, G2)···C(2,P) of 3.32 Å and O(4,G5)···N(P) of 3.20 Å. The O(4)···N distance indicates the formation of a weak O(4)···H–N hydrogen bond between α-CDx and PRD, since the N–H bond is oriented to the O(4,G5) atom. Thus, the PRD complex shows that the non-aromatic ring compound can be included in the α-CDx cavity.

Molecular Packing and Hydrogen Bonds. Three types of crystal structures have already been found in α-CDx complexes. The "channel-type" structure is built up by a linear stack of α-CDx molecules to form endless channels.[3,4,6,11,14] In the "cage-type"

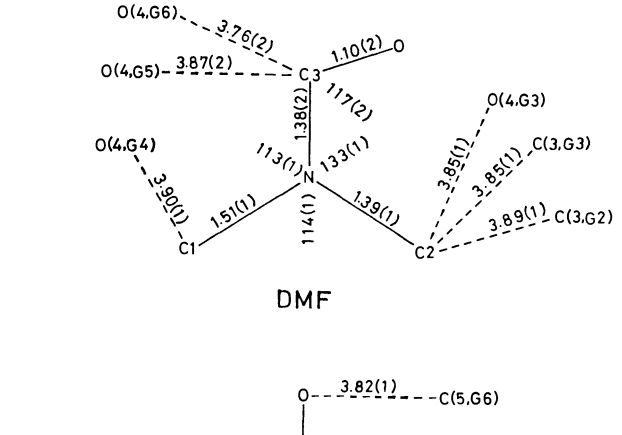

Fig. 4. Bond distances (l/Å) and angles (ϕ/°) in *N*,*N*-dimethylformamide and 2-pyrrolidone. Broken lines indicate contacts with the host α-cyclodextrin.

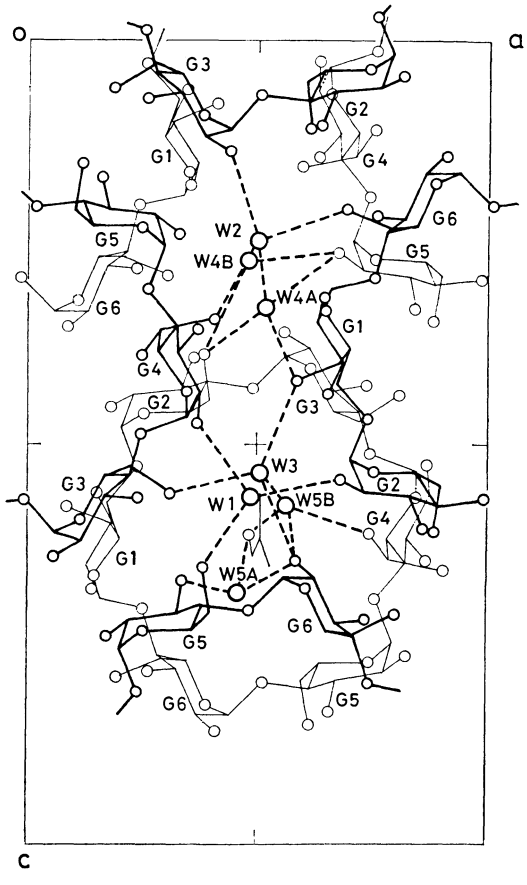

Fig. 5. A schematic drawing of the hydrogen-bond network involving water molecules in the α-cyclodextrin–*N*,*N*-dimethylformamide complex. Small circles indicate hydroxyl groups of α-cyclodextrin. Water molecules are shown by large circles.

structure, α-CDx molecules are arranged in a fish-bone-like fashion, producing an isolated cavity to accommodate a guest molecule.[12,13,15–17] The DMF and PRD complexes have the "layer" structure, in which α-CDx molecules are arranged to form molecular layers in the crystal (Fig. 5).[1,2,5,8]

Hydrogen-bond distances and angles are given in Table 6, and the hydrogen-bonding network involving water molecules is shown in Fig. 5. Several differences are found in the hydrogen-bonding contacts compared with other complexes having the "layer" structure. In the DMF and PRD complexes, five intramolecular O(2)···O(3) hydrogen bonds are observed, but unlike the complexes with *p*-nitrophenol and *p*-hydroxybenzoic acid,[5] the G5 residue forms no hydrogen bond with the G6. These residues seem to be linked by the O(2)···water···O(3) hydrogen bond. Significantly short intermolecular distances are found in the contacts of O(2,G6)···W5, 2.371 Å (O(W5B)) in the DMF complex and 2.340 Å (O(W5A)) in the PRD complex. These may be due to errors caused at the stage of the structure refinement, owing to the low population of the disordered water and the relatively large thermal motion of O(2,G6) (5.4 Å^2 in the DMF complex and 7.9 Å^2 in the PRD complex) compared with the other secondary hydroxyl oxygen atoms (2.1—3.8 Å^2). A similar short contact has been also found in the α-CDx–*p*-nitrophenol complex.[5]

In a layer composed of α-CDx molecules, hydrogen bonds are found between G2 and G6, and G3 and G5. No hydrogen bond was found between G1 and G4, although they face each other (Fig. 5). The adjacent layers are also linked by G1···G3 and G2···G4 hydrogen bonds. The DMF and PRD complexes have different hydrogen-bonding directions. The O(3,G2)–H···O(3,G4)–H···O(2,G5) linkage in the DMF complex is changed to the O(3,G2)···H–O(3,G4)···H–O(2,G5) linkage in the PRD complex.

In the α-CDx complexes with *p*-iodoaniline,[1] *p*-iodophenol,[2] *p*-nitrophenol, and *p*-hydroxybenzoic

acid,[5] the guest molecules are so bulky that a part of the guest molecule protrudes from the secondary hydroxyl side of the α-CDx cavity. The environment of the guest molecule is schematically shown in Fig. 6. In the DMF complex, the open end of the primary hydroxyl side of α-CDx is blocked by two water molecules. One (W3) is located near the position found in the *p*-iodoaniline or *p*-nitrophenol complex, but the other (W5) is not found in the complexes with the aromatic guest. W3 is linked to the adjacent three α-CDx molecules. The DMF molecule is so small that the vacant space is filled by W5, which is statistically disordered and occupies two sites. W1 blocks the secondary hydroxyl side of the α-CDx cavity, but it is replaced by the amino or hydroxyl group of the guest molecule in the complexes with *p*-iodoaniline and *p*-nitrophenol. W2, W4A, and W4B are found at the same position as those found in other α-CDx complexes with the "layer" structure. They are arranged in the space elongated along the two-fold screw axis perpendicular to the α-CDx molecular plane (Fig. 5).

So far, it has been considered that the "layer" structure is formed when the guest molecule is too bulky to be enclosed in the α-CDx cavity. But, the DMF and PRD complexes show that a complex with a small guest molecule can also form the "layer" structure. α-CDx crystallized from an ethanol–water solution may also have a layer structure, since the lattice dimensions are almost the same as those of the complexes with the "layer" structure; $a=13.39$, $b=15.49$, $c=24.06$ Å, and the space group $P2_12_12_1$.[18] The α-CDx crystal obtained from a methanol–water or 1-propanol–water solution gives the "cage-type" structure.[15,17] It is very interesting to speculate why the ethanol complex does not form the "cage-type" structure.

The author wishes to thank Dr. Hisashi Uedaira for supporting this study and for helpful discussions. The computaion was done on a HITAC M-160II computer at this institute. Programs used were written in the author's laboratory.

Rayleigh Ratio for Benzene and Its Temperature Dependence

Toshio KAMATA* and Hisae NAKAHARA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151†

(Received October 9, 1978)

The temperature dependence of the Rayleigh ratio for benzene was studied for the purpose of comparing various reported values obtained at different temperatures with each other. The following relationship was obtained for a wavelength of incident light of $\lambda_0=435.8$ nm:

$$R_{90}=(0.1377t+43.06)\times10^{-6}\ \mathrm{cm}^{-1}$$

where t is temperature (°C). Light-scattering photometers were calibrated with benzene purified by a preparative gas chromatograph by using a value of the Rayleigh ratio for benzene of $R_{90}=46.5\times10^{-6}$ cm^{-1} (25 °C, $\lambda_0=435.8$ nm). In order to verify the validity of the calibrations, molecular weight determinations were run on three standard substances: egg white lysozyme, raffinose, and sucrose. The temperature of benzene was directly measured by inserting the sensor of a thermistor thermometer into the benzene within the cell.

Various methods have been proposed for calibrating light scattering photometers. The validity of such calibrations is often examined by comparing the observed values of the Rayleigh ratio, R_{90}, for benzene with the literature data or by determining the molecular weights of proteins or low molecular-weight compounds whose molecular weights are known. However, the most probable value of R_{90} for benzene has been the subject of controversies for many years among investigators, because there were considerable discrepancies among the observed values. In 1962, Kratohvil *et al.*[1] in their critical survey on the calibration of light-scattering photometers criticized most of the published values of the Rayleigh ratio for benzene for being somewhat too high, and suggested a value of $R_{90}\leq 46.5\times10^{-6}$ cm^{-1} as the most probable one at 20 °C for a wavelength of incident light of 435.8 nm. Most later reports[2–6] published since the critical survey of Kratohvil *et al.* support the credibility of this so-called "low value," and now the controversies about the correct R_{90} value for benzene appear to have subsided.

However, since somewhat different temperatures were employed for measurements by different authors, a correct knowledge of the temperature dependence of Rayleigh ratios is essential for comparing literature values with each other. A temperature coefficient of the Rayleigh ratio for benzene determined precisely would also be convenient, in that it would help readily check the adequacy of any value of the Rayleigh ratio for benzene determined at any temperature.

The temperature dependence of the Rayleigh ratio for benzene has been reported by Schmidt,[7] Ehl *et al.*,[8] and Cohen and Eisenberg.[9] The temperature coefficient reported by Schmidt ($\lambda_0=435.8$ nm) and that of Ehl *et al.* ($\lambda_0=546.1$ nm) differ too widely from each other, even if the difference in the wavelength at which measurements were made is taken into account. Cohen and Eisenberg[9] studied the temperature dependence of the Rayleigh ratios for benzene and water at both 435.8 and 546.1 nm. Unfortunately, however, the lack of description for the numerical values of R_{90} at various temperatures or for the temperature coefficient of Rayleigh ratio in their paper makes it difficult to compare their results with those of Schmidt and of Ehl *et al.* Judging from the figures given by them, the temperature coefficient does not depend on the wavelength at which measurements were made.

Such considerable discrepancies among the values obtained by different authors for the temperature coefficient of the Rayleigh ratio for benzene might have partly been caused by the fact that there has always been some kind of uncertainty in measuring the temperature of the benzene on which the Rayleigh ratio measurements are being made. When a heating medium is recirculated to regulate temperature, a difference in temperature between the heating medium and the benzene within the cell develops and increases with increasing temperature. Schmidt[7] measured the temperature of the heating medium and took it as the temperature of benzene. Such a method does not measure the correct temperature of benzene.

In the present study, therefore, the temperature of benzene was directly measured by inserting the sensor of a thermistor thermometer into benzene within the cell as the determination of the Rayleigh ratio was being made.

Prior to determining the temperature dependence of the Rayleigh ratio for benzene, we tried to determine a reference value of the Rayleigh ratio by using standard substances with known molecular weights. Since the use of a single standard substance might lead to an accidental coincidence of the molecular weight found experimentally with that calculated from the molecular formula, three different standard substances, *i.e.*, sucrose, raffinose, and lysozyme, which have different molecular weights and specific refractive index increments, dn/dc, were used to avoid such an accidental coincidence.

The value of the Rayleigh ratio for benzene considered as the most probable since the critical survey by Kratohvil *et al.*,[1] $R_{90}=46.5\times10^{-6}$ cm^{-1} (25 °C, $\lambda_0=435.8$ nm), was adopted for calibrating the light-scattering photometer. Light-scattering measurement were then made on the three standard substances mentioned above and the molecular weights found by experiments and those calculated from the molecular formulas were compared.

Benzene used for calibrating the light-scattering photometer and for determining the temperature dependence of the Rayleigh ratio was a guaranteed reagent further purified by a preparative gas chromatograph.

The temperature dependence of the Rayleigh ratio

† New address: Yatabe, Ibaraki 300-21.

for benzene obtained in this manner was compared with the literature values. At the same time, the literature values of the Rayleigh ratio for benzene were compared with each other by taking into account the effect of temperature on this quantity.

Experimental

Materials. Benzene used was a special grade reagent supplied by Wako Jun'yaku Kogyo Co., purified by a preparative gas chromatograph and freshly distilled prior to light-scattering measurements.

Egg white lysozyme used was a seven-times recrystallized sample supplied by Seikagaku Kogyo Co. Its high purity was confirmed by elementary analysis, sedimentation patterns from the ultracentrifuge technique, chromatograms, and amino acid composition as well as N-end group assay.

Sucrose used was a GR reagent supplied by Kokusan Kagaku Co., twice recrystallized from the system water–ethanol.

As raffinose, a GR reagent from Tokyo Kasei Kogyo Co. was used.

Light Scattering. *Apparatus and Calibration*: Since it is difficult to measure scattered light from solutions of low molecular-weight compounds and to determine their depolarizations correctly using only one light-scattering photometer, two of them were employed to determine Rayleigh factors and depolarizations. For the Rayleigh factor determinations, use was made of a Shimadzu PG-21 light-scattering photometer equipped with a Hamamatsu TV Co's R-105 UH high sensitive photomultiplier tube (anode sensitivity: 1530 μA/μlm). Depolarizations were determined by using a Shimadzu DL-10 model with minor modifications.[10] All light-scattering measurements were made by using a mercury spectral line with the *in vacuo* wavelength of 435.8 nm. First the Rayleigh factor was measured with the PG-21 photometer, and then the light-scattering cell was transferred to the DL-10 apparatus for depolarization measurements, the isotropic part being calculated by using the Cabannes factor.[11]

The photometers were calibrated with respect to the Rayleigh ratio of benzene, for which the previously mentioned value of $R_{90}=46.5\times10^{-6}$ cm^{-1} (25 °C, $\lambda_0=435.8$ nm) was employed.

In order to examine the temperature dependence of the Rayleigh ratio of benzene, a cell jacket was used; through this, thermostated water was recirculated. The temperature of benzene was measured by dipping the tip of a thermistor sensor (glass tube, 3 mm o.d.) attached to a Takara thermistor thermometer STM-005-15 (divided to 0.05 °C) into the benzene within the cell. Readings were taken to the last 0.01 °C. The sensor was thoroughly washed with clean benzene and was so located as not to interfere with the scattered light. The liquid in the cell was gently agitated with a teflon-covered spin bar, 2 mm o.d. and 15 mm long, driven by a magnetic stirrer to prevent any temperature gradient development.

Optical Clarification: A lysozyme solution (in an acetate buffer) was centrifuged for 1 h at 10 °C at 360000 g max. by using a Spinco L_4 preparative ultracentrifuge, and then directly filtered into the light-scattering cell through a Corning ultrafine glass filter. The aqueous solutions of raffinose and sucrose were centrifuged for 1 h at 20 °C at 360000 g max. and then directly filtered into the light-scattering cell through a Millipore filter VS (pore size : 25±3 nm). Benzene, freshly distilled, was filtered through a Corning glass filter into the light-scattering cell for measurements.

Concentration of Solution: Since the concentration of solutions may change during the ultracentrifuge and filtering operations, the solutions in the cell were analyzed for their concentrations. The lysozyme concentration was calculated from the N content by the Kjeldahl method.

Refractive Index Increment: Refractive index increments were measured with a Shimadzu differential refractometer. The values of dn/dc at 20 °C for the wavelength of 435.8 nm for a lysozyme–acetate buffer solution (pH 3.6), an aqueous raffinose solution, and an aqueous sucrose solution were 0.1941, 0.1512, and 0.1484 cm^3/g, respectively.

Refractive Index: The refractive index of benzene at 20 °C for wavelength of 435.8 nm was calculated by substituting the reference value listed in the International Critical Tables into Cauchy's dispersion formula:

$$n = A + B/\lambda^2 + C/\lambda^4. \quad (1)$$

The refractive indices, n, at 435.8 nm of benzene for various temperatures were calculated from the following equation:

$$n = 1.52317 - 0.000665(t-20.00), \quad (2)$$

where t is temperature (°C). As the temperature coefficient of refractive index, that of Coumou[12] was adopted.

Results and Discussion

Effect of Purity on the Rayleigh Ratio of Benzene. In order to know the extent of purification required for benzene to be used as a standard substance, light-scattering measurements were run on special grade benzene further purified by gas chromatography. The results are shown in Table 1.

As seen from the table, the chromatographically purified benzene did not show much difference from the starting special grade reagent. On the contrary, there was a definite difference between the freshly distilled and undistilled samples. Consequently, it was concluded that a purification of the special grade benzene by distillation just before use would be sufficient, and no further purification by preparative gas chromatograph was required. If the special grade benzene is used without any distillation, it may get contaminated by organic substances or sometimes by polymeric as well as fluorescent materials that can not be removed by ultracentrifuging nor by filtration and could seriously affect light-scattering measurements.

Determination of Molecular Weights of Standard Substances. The molecular weights of egg white lysozyme, raffinose, and sucrose were determined with the same light-

Table 1. Rayleigh ratio for benzene purified by various methods

Original sample	Purification	$R_{90}\times10^6$(cm^{-1})
Special grade benzene	Purified by preparative gas chromatography and distilled before light scattering measurement	46.50
Special grade benzene	Distilled before light scattering measurement	46.52
Special grade benzene	——	48.09

scattering photometer that had been calibrated by using the Rayleigh ratio for benzene of $R_{90}=46.5\times10^{-6}$ cm^{-1} (25 °C, 435.8 nm). Egg white lysozyme is regarded as a suitable standard sample, because its molecular weight can be calculated from the knowledge of its higher-order structure determined by amino acid composition as well as by X-ray structural analysis, and because high-purity samples of it can readily be obtained. However, since the possibility of molecular association exists for egg white lysozyme in a certain pH region, it is necessary to find the pH range where no such association will take place before molecular weight measurements are undertaken. Figure 1 shows the molecular weights of lysozyme determined at various pH's. The data of the present work show a slight inconsistency with those of Sophianopoulos and Van Holde[13] obtained by the sedimentation equilibrium method, but in either case, substantially no association was found to occur within a pH range of 3 to 5. Therefore, light-scattering measurements were carried out in this pH region of 3 to 5. Figure 2 shows the light-scattering data for egg white lysozyme in an acetate buffer (pH 3.6). Figures 3 and 4 show the light-scattering plots for raffinose and sucrose, respectively.

The molecular weight was calculated from the following equation:

$$Kc/R_{90} = 1/(M_w P(90°)) + 2A_2c. \quad (3)$$

The isotropic excess light scattering in the 90° direction, R_{90}, was calculated from the Rayleigh factor

determined in unpolarized light, $(R_{90})_u$, using the Cabannes factor, $f_u(90°)$, as follows:

$$R_{90} = (R_{90})_u/f_u(90°), \quad (4)$$

$$f_u(90°) = (6+6\rho_u)/(6-7\rho_u), \quad (5)$$

where ρ_u is the degree of depolarization.

The value of $P(90°)$ was calculated from the dimensions of a lysozyme molecule determined by X-ray structural analysis. Actually, however, since this value (0.9994) was found to be very close to unity, the molecular weight of lysozyme was calculated by assuming $P(90°)=1$.

Likewise, since the raffinose and sucrose molecules are very small compared to the wavelength of incident light, calculation was made by assuming $P(90°)=1$.

The deviation, ΔM, from the true molecular weight, M, of the apparent molecular weight, M_{app}, obtained by approximating the light scattering due to fluctuation of fluid density by that due to fluctuation of the density of pure solvent, was also calculated by the use of the Bullough's approximation.[14] For further details, reference should be made to the literature.[10]

The results of the molecular weight determinations

Table 2. Results for standard substances

Substances	Solvent	dn/dc (cm³/g)	$(Kc/R_{90})_{c\to 0}$	M_{app}	ΔM	M	M(formula)	δ_{app} (%)	δ (%)
Sucrose	Water	0.1484	2.906×10^{-3}	344	3	341	342.3	+0.5	−0.4
Raffinose	Water	0.1512	1.982×10^{-3}	505	3	502	504.2	+0.2	−0.4
Lysozyme	Acetate buffer 0.15 M NaCl (pH 3.6)	0.1941	7.02×10^{-5}	14250	2	14248	14307	−0.4	−0.4

$\delta_{app}=(M_{app}/M(\text{formula})-1)\times100$, $\delta=(M/M(\text{formula})-1)\times100$.

are listed in Table 2. Since the effect of the deviations, ΔM, caused by density fluctuations on the observed values of molecular weight was small, as shown in Table 2, ΔM was neglected in comparing the apparent molecular weight, M_{app}, with that calculated from the molecular formula. Such a comparison resulted in a good agreement, within ±1% in either case. This suggests that the calibration of the light-scattering photometer, using the value of the Rayleigh ratio for benzene of $R_{90}=46.5\times10^{-6}$ cm^{-1} (25 °C, $\lambda_0=435.8$ nm), was reasonable. If the small deviations of molecular weights caused by density fluctuations were considered, the molecular weights observed for egg white lysozyme, raffinose, and sucrose became slightly lower than those calculated from the molecular formulas, the mean deviation being −0.4%. To attribute such discrepancies to the particular value of the Rayleigh ratio for benzene that was adopted for calibrating the light-scattering photometer, however, remains open to question. There is a great difference between the refractive index for benzene and that for the water used as a solvent in light-scattering measurements of three standard substances. It is thus difficult to exclude some uncertainty, however small, that may accompany the operation of converting the apparatus constant, ϕ_{90}, determined by the use of the Rayleigh ratio for benzene to the other, ϕ'_{90}, for water as the solvent. Therefore, our effort to estimate the Rayleigh ratio for benzene by means of standard substances was abandoned. Instead, we confined ourselves to reconfirming the likeliness of the value of $R_{90}=46.5\times10^{-6}$ cm^{-1} (25 °C, $\lambda_0=435.8$ nm), known to be the most probable so far.

Temperature Dependence of Rayleigh Ratio for Benzene. The temperature dependence of the Rayleigh ratio for benzene was studied by assuming the most probable value at 25 °C to be $R_{90}=46.5\times10^{-6}$ cm^{-1}. The results are summarized in Table 3. Also, the variation of the Rayleigh ratios for benzene with temperature is plotted in Fig. 5.

As seen from the plots in Fig. 5, a linear relationship exists between R_{90} and temperature, t, correlated by the following equation:

$$R_{90} = (0.1377t+43.06)\times10^{-6}\ \text{cm}^{-1}. \quad (6)$$

Ehl *et al.*[8] studied the temperature dependence of Rayleigh ratios at a wavelength of 546.1 nm, and reported that it could be expressed as follows by taking the value of R_{90} at 25 °C as a reference:

$$(R_{90})_t = (R_{90})_{25}[1+\alpha(t-25)], \quad (7)$$

where the temperature coefficient was found to be $\alpha=0.368\times10^{-2}$.

Equation 7 yields $\alpha=0.306\times10^{-2}$ from our data and $\alpha=0.220\times10^{-2}$ from those of Schmidt,[7] both at the same wavelength ($\lambda_0=435.8$ nm); there is very poor agreement between the two observations. One of the possible causes for this can be the difference

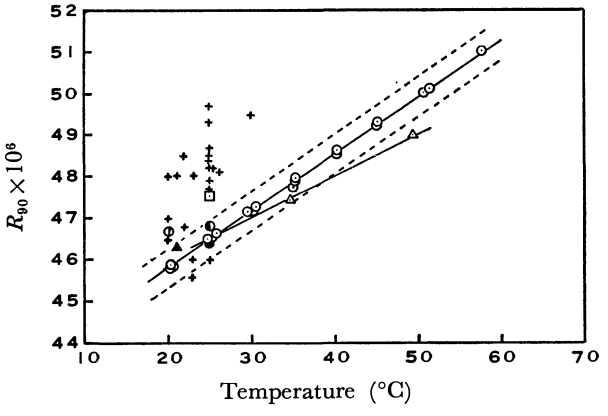

Fig. 5. Temperature dependence of Rayleigh ratio for benzene. ⊙: Present work, ●: Claesson and Ohman,[2] ▲: Huisman,[3] ◫: Bello and Guzman,[4] ◐: Deželić,[5] ⊡: Parfitt and Wood,[6] ◭: Schmidt,[7] +: Reference values listed on critical survey of Kratohvil *et al.*[1] Dashed lines show the experimental error range of ±1%.

in temperatures at which measurements were made. While the present authors inserted the sensor of a thermistor thermometer into the fluid and directly measured the temperature of benzene, Schmidt measured the temperature of the recirculated water and took it as that of the benzene. The temperature of the fluid within a light scattering cell usually shows some deviations from that of the recirculated water, and such deviations tend to become more significant at higher temperatures. The somewhat lower value of Schmidt as compared with ours could have been caused by such a deviation in temperature. Our value of α was a little lower than that of Ehl *et al.*, although both figures were obtained at different wavelengths. Cohen and Eisenberg[9] determined the temperature dependence of Rayleigh ratios at both 435.8 and 546.1 nm, but the lack of the numerical values of R_{90} at various temperatures in their paper inhibits calculation of α values by means of Eq. 7. However, the figures of the temperature dependence of the Rayleigh ratio given in their paper permits us to estimate a temperature coefficient which is closer to ours than to the value of Ehl *et al.*

A number of literature values of the Rayleigh ratio for benzene so far reported (corresponding to $\lambda_0=$ 435.8 nm) are compared in Fig. 5 by considering the temperature effect. As seen from this figure, all literature data[2-6] reported since the critical survey[1] of Kratohvil *et al.* agree within $\pm 2\%$ with the value taken as the most probable one. Particularly, the reported values of Deželič,[5] Huisman,[3] and Claesson and Ohman[2] showed an agreement within $\pm 1\%$. On the other hand, the literature values published before the critical survey mentioned above, except for some which showed agreements within $\pm 2\%$, generally deviated widely even if the temperature dependence was considered.

The author's acknowledgements are due to Dr. S. Nishi, who kindly purified the benzene by preparative gas chromatography, and to Dr. Y. Morita, who conducted the nitrogen analysis.

Structural Interconversions of Dichlorobis(triphenylphosphine)-nickel(II) in Various Solvents

Hajime KATÔ,* Kazuko YORITA, and Yoshifumi KATO

Department of Chemistry, Faculty of Science, Kobe University, Kobe 657

(Received November 15, 1978)

Structural interconversions, ligand exchange, the temperature- and concentration-dependent equilibrium of configurational isomers, and the solvolysis of $NiCl_2(Ph_3P)_2$ in various solvents have been studied. The MCD and absorption spectra were employed, together with the calculation based on ligand-field theory and the NMR spectra. Paramagnetic tetrahedral $NiCl_2(Ph_3P)_2$ and the solvated paramagnetic octahedral $NiCl_2(Ph_3P)_2(dmso)_2$ are in equilibrium in the coordinating solvent DMSO. The ratio of the former to the latter increases with the rise of concentration and temperature. Configurational isomers of $NiCl_2(Ph_3P)_2$, a paramagnetic tetrahedral one and a diamagnetic square-planar one, are found in a non-coordinating solvent $CHCl_3$. The former species decreases gradually and a yellow precipitate is formed. The same two species, and two other solvated paramagnetic tetrahedral and octahedral species, $NiCl_2(CH_3CN)_2$ and $NiCl_2(CH_3CN)_4$, are found to be in equilibrium in CH_3CN.

Dihalogenonickel(II) tertiary phosphine complexes have been used as a catalyst for a number of synthetic reactions. The solvent and the temperature are often important factors for the catalytic activity. A number of studies[1–5] have been reported on the dynamic interconversion between the paramagnetic tetrahedral form and the diamagnetic square-planar form of these complexes in non-coordinative solvents. By measuring the absorption spectra and the magnetic susceptibility of $NiCl_2(Ph_3P)_2$ in a solution of inert solvents (for example, $CHCl_3$ and benzene), it has been shown that there is a small amount of the trans-square-planar diamagnetic species in equilibrium with the tetrahedral paramagnetic species.[2,3] However, few investigations on the molecular conformation and the dynamic behavior in coordinative solvents are reported.

The molecular structure of $NiCl_2(Ph_3P)_2$ in crystal form is known[6] to be: Ni–Cl=2.27 Å, Ni–P=2.28 Å, ∠Cl–Ni–Cl=123°, ∠P–Ni–P=117°. Its polarized single-crystal electronic spectrum was assigned by taking the effective site-symmetry as C_{2v}.[7] When the molecule is dissolved in various solvents, it may take a tetrahedral, a square-planar, or an octahedral form, and will show a characteristic electronic spectrum depending on each configuration. In addition, the magnetic circular dichroism (MCD) spectrum has the sign as well as the magnitude characteristic of each electronic transition,[8,9] and can be a very powerful means for clarifying the complexity of the absorption spectra, providing further information with which to understand the molecular state.

The absorption and MCD spectra indicate simply the sum of spectra arising from each species in the equilibrium mixture. On the other hand, NMR spectra can be used in another way: if the frequency separation between resonance lines of species in equilibrium is smaller than the frequency of the interconversion or the ligand exchange, only a single line at the average frequency is observed. NMR spectra will thus provide the evidence for the degree of molecular lability and the rate of ligand exchange.

We have therefore studied the structural interconversions of $NiCl_2(Ph_3P)_2$ in various solvents, such as dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF), acetonitrile (CH_3CN), *etc.*, by the MCD and absorption spectra, the calculations based on ligand-field theory, and the NMR spectra.

Experimental

The following compounds used in this study were prepared and recrystallized according to previously reported procedures; $NiCl_2(Ph_3P)_2$,[1] $Ni(SCN)_2(Ph_3P)_2$,[1] $(Et_4N)_2NiCl_4$,[10] $[Ni(dmf)_6](ClO_4)_2$,[11] $[Ni(dmso)_6](ClO_4)_2$.[12] All solvents were obtained commercially (Guaranteed Reagent of Nakarai Chemical Co.). Acetonitrile was dried and purified by fractional distillation with anhydrous calcium chloride.

Absorption spectra in the range 10000 to 13000 cm^{-1} were measured by a JASCO J-40 spectrophotometer, to which an electro-magnet of field strength 8.9 kG is attached. The spectra in the other ranges were measured with the apparatus previously described.[13,14] NMR spectra were obtained by using a JEOL JNM-PS-100 instrument equipped with a variable-temperature probe. All of the spectra were measured just after preparing the solution, unless otherwise specified.

Results and Discussion

MCD and Absorption Spectra. The MCD spectra of the charge-transfer bands in tetrachloro nickel(II) ions have been studied,[15] but the MCD spectra of the d-d transitions have not yet been reported. The spectrum in solution shows a great change depending on the solvent. The MCD and the absorption spectra of a solution of $(Et_4N)_2NiCl_4$ in CH_3CN are shown in Fig. 1. The absorption spectrum is very similar to the spectrum of Ni(II) ion in tetrahedral sites in the crystal of Cs_2ZnCl_4,[16] and it does not show any significant change when the excess tetramethylammonium chloride (Et_4NCl) is added to the solution. Therefore we may consider that the spectrum arises from a tetrahedral $NiCl_4^{2-}$ ion. The absorption band in the range 13000—17000 cm^{-1} has been assigned as a transition $^3T_1(F)\rightarrow{}^3T_1(P)$.[17] The MCD spectrum in this absorption region shows a dispersion with positive sign in the lower energy region and negative sign in the higher energy region (let us call this "*positive dispersion*").

The MCD spectra of d-d transitions in some octahedral nickel(II) complexes have been studied extensively.[18,19] In octahedral nickel(II) complexes, there are three spin-allowed d-d transitions: $^3A_2\rightarrow{}^3T_2$, $^3T_1(F)$,

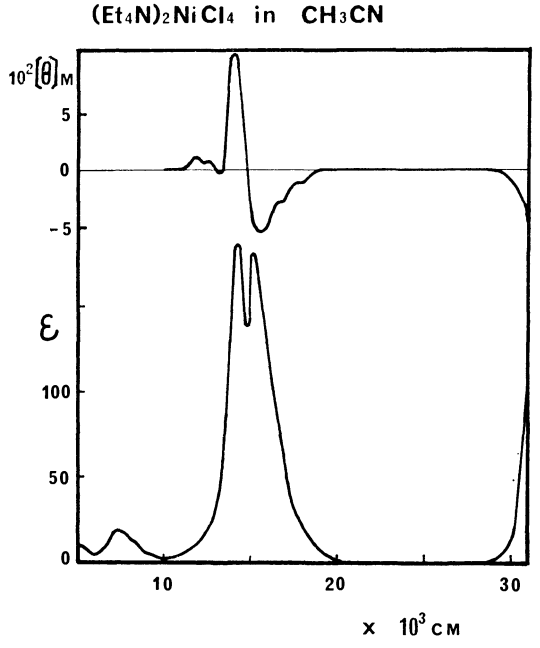

Fig. 1. MCD and absorption spectra of $(Et_4N)_2NiCl_4$ in CH_3CN at room tempepature. $[\theta]_M$ is the molar ellipticity per unit magnetic field. ε is molar extinction coefficient.

and $^3T_1(P)$, in the region from near-infrared to visible. The molar extinction coefficients of these d-d transitions are smaller than those in the tetrahedral complexes, because in the latter complexes there is no center of inversion symmetry and there is greater d-p mixing. The MCD and absorption spectra of a solution of $[Ni(dmf)_6](ClO_4)_2$ in DMF and a solution of $[Ni(dmso)_6](ClO_4)_2$ in DMSO are shown in Figs. 2 and 3 respectively. The MCD spectrum of the band in the 12000—16000 cm^{-1} region is mainly negative and shows a small positive value in the higher energy region (let us call this "*negative dispersion*"). The sign of the dispersion is opposite to that of the tetrahedral complex observed in the 13000—17000 cm^{-1} region. This characteristic difference is very useful in distinguishing whether the complex in solution is in octahedral or in tetrahedral symmetry.

The compounds NiX_2L_2 (L=tertiary phosphines, X=Cl, Br, I, and SCN) have been studied in a series of papers.[1-3] Some of them were found to be in equilibrium of the paramagentic tetrahedral form and the diamagnetic square-planar form in inert solvents. The thiocyanato-complex, $Ni(SCN)_2(Ph_3P)_2$, has been found to be diamagnetic and trans-square planar.[3] The MCD and absorption spectra are shown in Fig. 4. The absorption spectrum shows bands only at energy regions higher than 15000 cm^{-1} and the high-intensity absorption bands at about 24000 and 31000 cm^{-1} are generally referred to as charge-transfer bands. The magnitude of the MCD in comparison with that of the absorption, which may be indicated by the magnitude of $[\theta]_M/\varepsilon$, in the diamagnetic square planar nickel(II) complex is less than 10% of those found in the paramagnetic tetrahedral and the paramagnetic octahedral nickel(II) complexes. This characteristic difference can be useful in finding whether the complex in solution is paramagnetic or diamagnetic.

The MCD and absorption spectra of dichlorobis(triphenylphosphine)nickel(II), $NiCl_2(Ph_3P)_2$, were found to change greatly depending on the solvent, the concentration of the solution, and the temperature. The dependence on the concentration in DMSO is shown in Fig. 3. It shows a drastic change in a narrow range of the concentration. The spectrum of 0.25 M solution shows a strong absorption band in the range 14000—18000 cm^{-1}, and the MCD of the band shows a positive dispersion, which is characteristic of the paramagnetic tetrahedral species. However, as the concentration is reduced to 0.05 M, the intensity of the band in this range decreases and the intensities of the bands at about 7500, 12500, and 23000 cm^{-1} increase. This fact indicates that the paramagnetic tetrahedral species and the paramagnetic octahedral

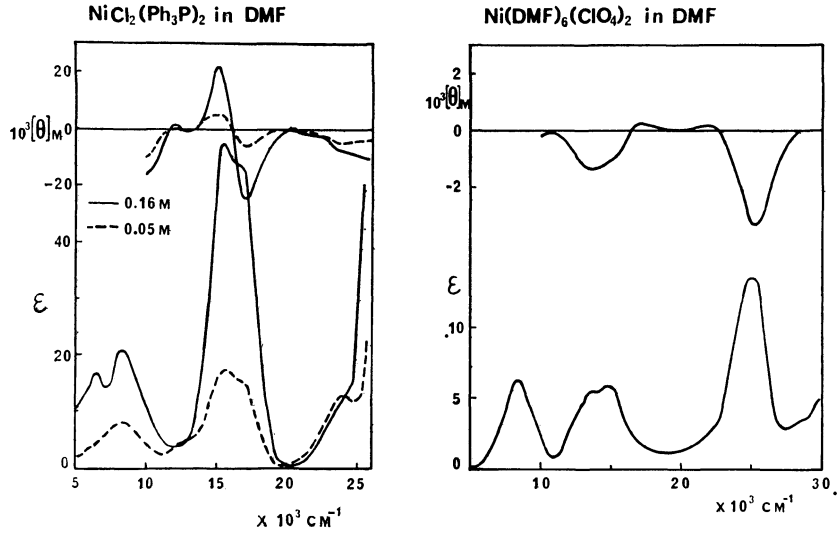

Fig. 2. MCD and absorption spectra of $Ni(dmf)_6(ClO_4)_2$ and the concentration dependence of the spectra of $NiCl_2(Ph_3P)_2$ in DMF at room temperature.

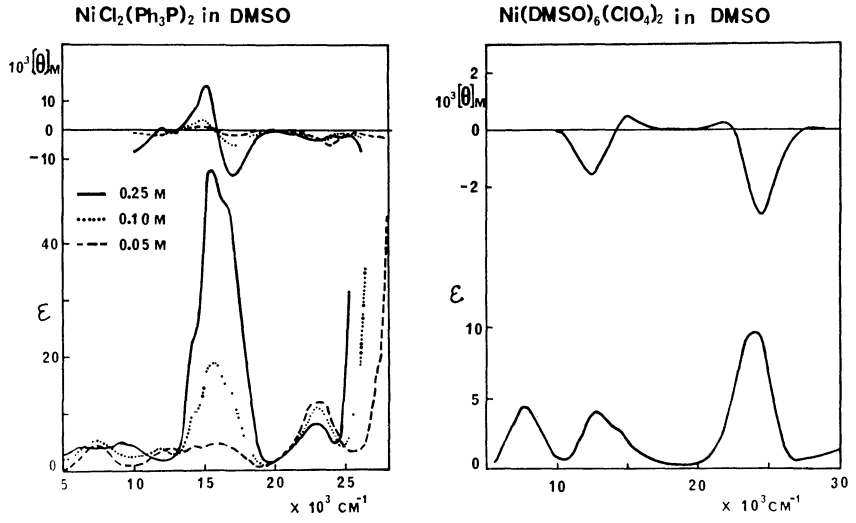

Fig. 3. MCD and absorption spectra of $Ni(dmso)_6(ClO_4)_2$ and the concentration dependence of the spectra of $NiCl_2(Ph_3P)_2$ in DMSO at room temperature.

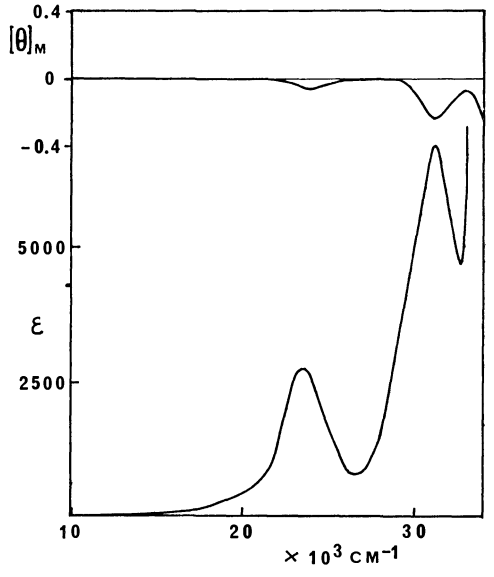

Fig. 4. MCD and absorption spectra of 0.02 M solution of $Ni(SCN)_2(Ph_3P)_2$ in benzene at room temperature.

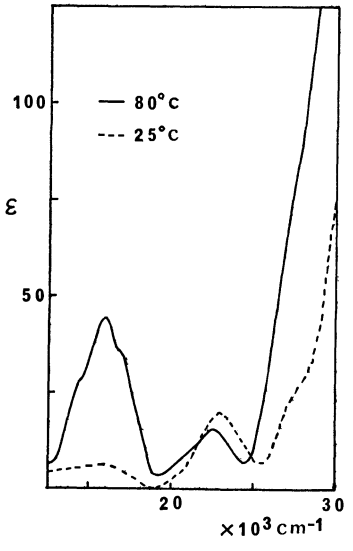

Fig. 5. Temperature dependence of the absorption spectrum of 0.05 M solution of $NiCl_2(Ph_3P)_2$ in DMSO.

species are in equilibrium in the solution and the ratio of the former to the latter decreases as the concentration decreases.

When the temperature of the 0.05 M solution is raised (see Fig. 5), the absorption spectrum becomes very similar to the one observed in the solution of higher concentration at room temperature. When this solution is cooled to room temperature again, the spectrum returns to the one measured before heating. This fact indicates that the octahedral complex in 0.05 M solution at room temperature is $NiCl_2(Ph_3P)_2(dmso)_2$, and as the temperature is raised it tends to become tetrahedral $NiCl_2(Ph_3P)_2$ by expelling the coordinated solvent molecules.

The spectrum is found to change slowly in the course of time (see Fig. 6), and the crystal of triphenylphosphine (Ph_3P) is found to grow in a couple of days after preparing the solution. The spectrum, which is measured after several days, is identified to that of a paramagnetic octahedral species, but it is not identical with the spectrum of $Ni(dmso)_6^{2+}$. It appears therefore that the coordinated Ph_3P tends to be removed gradually and thus the solvated compound $NiCl_2(dmso)_4$ is produced.

In 0.25 M solution, the intensities of absorption bands due to the terahedral species are much greater than those due to the octahedral species. However the molar concentrations of the tetrahedral species and the octahedral species would be almost the same, since the molar extinction coefficients of the bands due to the tetrahedral species are much greater than those due to the octahedral ones.

The spectral behavior observed in DMF solution is similar to that observed in DMSO solution. If we compare the spectrum of 0.05 M $NiCl_2(Ph_3P)_2$ solution in DMF with that in DMSO at room temperature

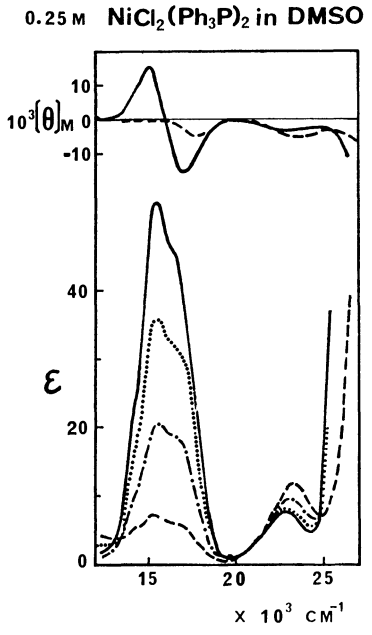

Fig. 6. Change of MCD and absorption spectra of 0.25 M $NiCl_2(Ph_3P)_2$ solution in DMSO at room temperature as a function of time. Measured immediately after preparing the solution (——), after 24 h (----), after 72 h (·—·—), after one week (— —). The sample was kept in dark place at 25 °C.

(Figs. 2 and 3), it is understood that the tetrahedral form of $NiCl_2(Ph_3P)_2$ is slightly more stable in DMF than in DMSO.

The spectrum of $NiCl_2(Ph_3P)_2$ in CH_3CN (Fig. 7) shows that the paramagnetic tetrahedral form of this complex is more stable in CH_3CN than in DMSO or in DMF. The absorption band in the range 14000—18000 cm^{-1} is assigned as a transition $^3T_1(F) \rightarrow {}^3T_1(P)$ of a tetrahedral species, because of the magnitude of the extinction coefficient and because of the MCD spectrum, whose sign and magnitude are very similar to those of $NiCl_4^{2-}$ ion (see Fig. 1). The extinction coefficient of this band in 0.01 M solution is as large as those observed in the more concentrated solutions in DMSO and in DMF (0.25 M in the former and 0.16 M in the latter. See Figs. 2 and 3). If the observed absorption bands were due to a fairly large amount of octahedral species, the apparent molar extinction coefficient should be much smaller. Therefore the complex will be mostly tetrahedral in 0.01 M solution in CH_3CN.

The extinction coefficient of the shoulder-like absorption band at about 24000 cm^{-1} in Fig. 7 is greater than that of the transition $^3A_2 \rightarrow {}^3T_1(P)$ of an octahedral species. The ratio $[\theta]_M/\varepsilon$ is smaller than that of the paramagnetic species, and it is close to the value of $[\theta]_M/\varepsilon$ observed in $Ni(SCN)_2(Ph_3P)_2$ solution in benzene (see Fig. 4), the complex in the solution is known to be diamagnetic square plane.[3] Since the molar extinction coefficient of the diamagnetic species is much greater than that of the paramagnetic species, even a small amount of diamagnetic species causes a strong absorption. Thus the band at about 24000 cm^{-1} may be identified as the absorption due to a small amount of diamagnetic square-plane species in CH_3CN solution.

Absorption bands in the energy region higher than about 27000 cm^{-1} will be mainly attributed to the charge transfer bands of the paramagnetic tetrahedral species, since the sign and magnitude of the MCD and the ratio $[\theta]_M/\varepsilon$ are in good agreement with those observed in charge transfer bands of tetrahalogenonickel(II) complexes.[15]

The spectra of $NiCl_2(Ph_3P)_2$ in non-coordinating solvents, such as chloroform, dichloromethane, and benzene, are different from those in coordinating solvents. The spectrum of 0.05 M solution in $CHCl_3$ is shown in Fig. 8. The absorption spectrum in the

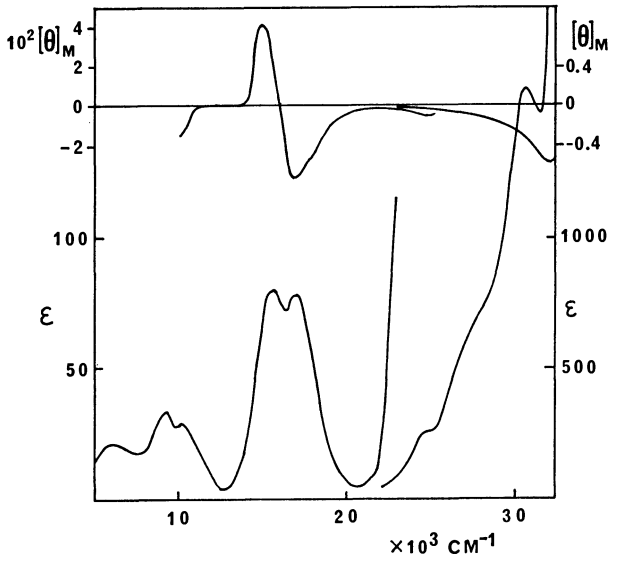

Fig. 7. MCD and absorption spectra of 0.01 M solution of $NiCl_2(Ph_3P)_2$ in CH_3CN at room temperature.

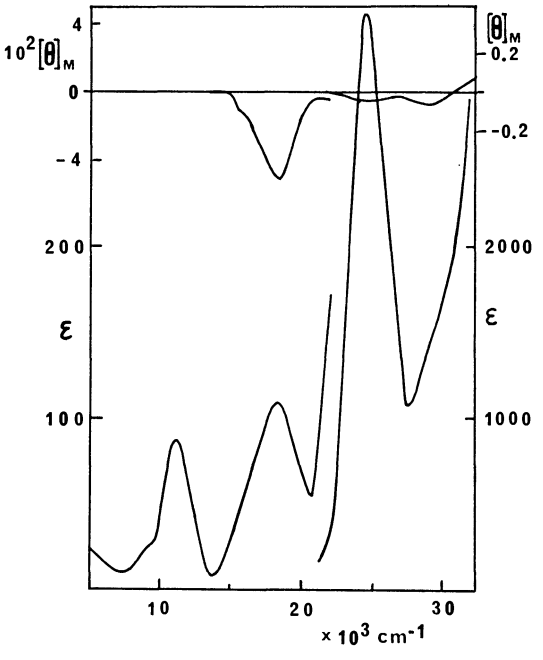

Fig. 8. MCD and absorption spectra of 0.05 M solution of $NiCl_2(Ph_3P)_2$ in $CHCl_3$ at room temperature.

range 5000—20000 cm^{-1} is similar to the crystal absorption spectra of $NiCl_2(Ph_3P)_2$, in which the nickel(II) ion is reported to be in "effective" C_{2v} point-group symmetry.[7] This presumably means that the molecule, which shows a similar absorption spectrum to that in crystal, retains the distorted tetrahedral configulation in non-coordinating solvents. It should be noted that the MCD spectrum of the band in the region of 15000—20000 cm^{-1} is simply negative and that it is different from those observed in coordinating solvents.

The absorption bands in the energy region higher than 22000 cm^{-1} will be of the diamagnetic square-plane species, since the ratios $[\theta]_M/\varepsilon$ of the bands are very close to the one observed in $Ni(SCN)_2(Ph_3P)_2$ solution in benzene. The high extinction coefficient and the small value of $[\theta]_M/\varepsilon$ for the absorption band at about 25000 cm^{-1} are characteristic of diamagnetic square-plane nickel(II) complexes. The intensity of the band is stronger in $CHCl_3$ than in CH_3CN. It appears therefore that the proportion of the diamagnetic species is greater in $CHCl_3$ than in CH_3CN.

Calculations Based on Ligand-field Theory. Energy levels of $NiCl_2(Ph_3P)_2$ and $NiCl_2(Ph_3P)_2(dmso)_2$ are calculated by the following approximation. The magnitude of ligand field parameters D_q of $NiCl_4^{2-}$, $Ni(Ph_3P)_4^{2+}$ in T_d symmetry and $Ni(dmso)_6^{2+}$ in O_h symmetry are estimated to be 350, 550, and 850 cm^{-1} respectively. The ligands, Cl, Ph_3P, and DMSO, are approximated by point charges and the magnitudes of the point charges $-Ze$ are evaluated by using the relation: $D_q=2Ze^2\langle r^4\rangle/27a^5$ in T_d symmetry and $D_q=Ze^2\langle r^4\rangle/6a^5$ in O_h symmetry, where $-Ze$ is the point charge and a is the distance between the nickel atom and the point charge. From the data of X-ray analysis,[17] we assumed the distances between the point charges and nickel atom to be Ni–Cl=2.27 Å and Ni–P=2.28 Å in tetrahedral form, and Ni–Cl=2.38 Å, Ni–P=2.39 Å, and Ni–O=2.10 Å in octahedral form. The values of $\langle r^2\rangle$ and $\langle r^4\rangle$ were calculated by using an analytical SCF function for nickel atoms obtained by Clementi:[20] $\langle r^4\rangle_{Ni(3d)}=3.997a_0^4$ and $\langle r^2\rangle_{Ni(3d)}=1.220a_0^2$, where a_0 is the Bohr radius. The point charges of $NiCl_2(Ph_3P)_2$ are put in the direction of the regular tetrahedron. This may not be an accurate structure since the crystal-structure determination shows that the Cl–Ni–Cl and P–Ni–P bond angles are 123° and 117°, respectively, which are greater than the tetrahedral 109°28′. The effect of lower symmetry C_{2v} is reflected in the magnitude of point charges and distances from the metal. The point charges of $NiCl_2(Ph_3P)_2(dmso)_2$ are put in the direction of regular octahedron so that the same ligands are in trans positions. All the possible configurations of d^8 electrons are considered, and the effect of the spin-orbit interaction is included completely. The spin-orbit coupling constant ζ is assumed to be that of free nickel(II) ion: $\zeta=649$ cm^{-1}. The results of energy level calculations are shown schematically in Figs. 9 and 10.

The energy levels of $NiCl_2(Ph_3P)_2(dmso)_2$ are similar to those of $Ni(dmso)_6^{2+}$. The MCD of the paramagnetic octahedral nickel(II) complexes has been found to arise from the MCD C-term,[18,19] which originates in the population difference among the levels of the ground state $^3A_2$ split by the Zeeman effect. Since the ground state of $NiCl_2(Ph_3P)_2(dmso)_2$ has the same spin de-

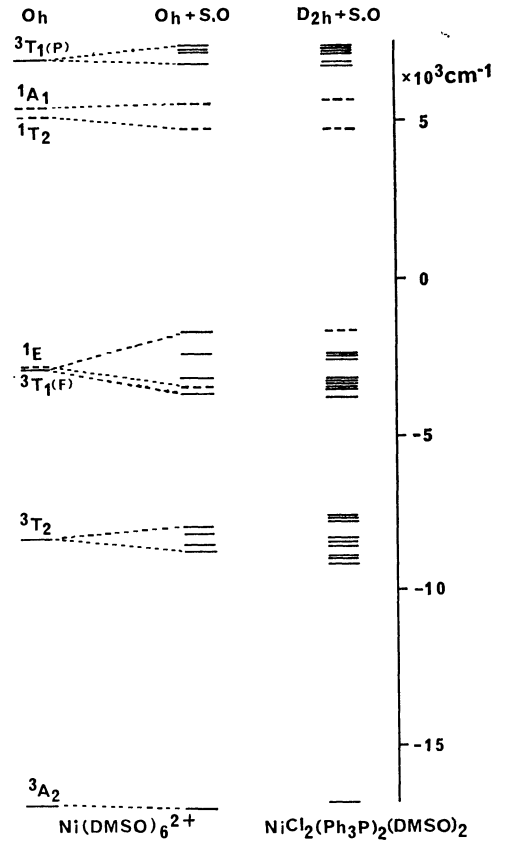

Fig. 9. Calculated energy levels of $Ni(dmso)_6^{2+}$ and $NiCl_2(Ph_3P)_2(dmso)_2$.

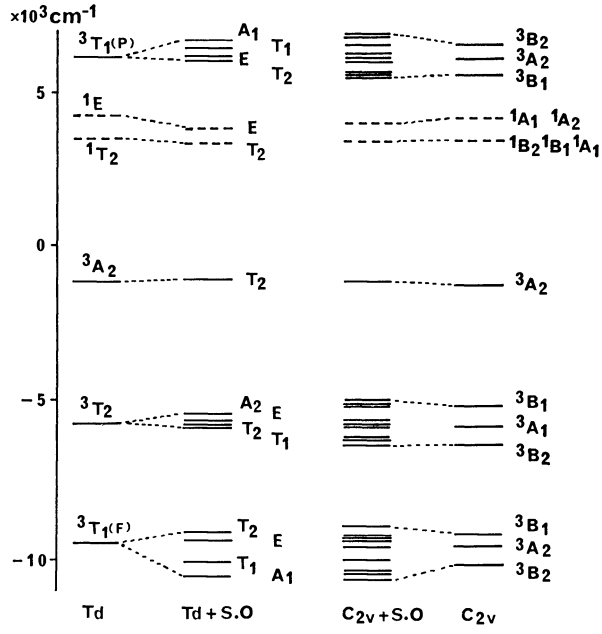

Fig. 10. Calculated energy levels of $NiCl_2(Ph_3P)_2$. The energy levels in rigorously tetrahedral field and in the lower symmetry field are denoted as T_d and C_{2v}, respectively. The inclusion of spin-orbit coupling is shown by adding +S.O.

generacy as that of $Ni(dmso)_6^{2+}$ and their MCD spectra are similar to each other, the MCD spectrum of $NiCl_2(Ph_3P)_2(dmso)_2$ may arise from the MCD C-term.

It has been shown that the major contribution to the MCD of charge-transfer bands of tetrahalogenonickel(II) complexes comes from the C-term, because of the variation of the MCD spectrum with temperature.[15] The analysis of the MCD spectra of the paramagnetic tetrahedral complex $NiCl_2(Ph_3P)_2$ was done for the following two cases. *Case A)* The energy levels are calculated by the above approximation. The calculated energy levels are shown in Fig. 10 as C_{2v}+S.O. *Case B)* The ligand field is assumed to be rigorously tetrahedral and the effect of spin-orbit coupling is included. The magnitude of ligand field parameter D_q is assumed to be 450 cm^{-1}, which is a simple numerical average of the D_q's of $NiCl_4^{2-}$ and $Ni(Ph_3P)_4^{2+}$. The calculated energy levels are shown in Fig. 10 as T_d+S.O.

By using the eigen-functions in *case B)*, we have calculated the levels of MCD parameters A and C for all the allowed transitions among the levels split by spin-orbit interaction in the $^3T_1(F)\rightarrow{}^3T_1(P)$ absorption band; the results are given in Table 1. In the calculation of the MCD parameter B the mixing of the charge transfer states will be significant, but it is hard to evaluate it correctly. Therefore we neglected B. The calculated value of A for the transition $A_1\rightarrow T_2$ is negative, and it leads to a positive dispersion of the MCD spectrum. We shall use the dipole strength D defined in Ref. 9. The calculated value of A/D for the transition $A_1\rightarrow T_2$ is in good agreement with the experimental value -8.4β, which is obtained by assuming that the MCD of 0.01 M solution of $NiCl_2(Ph_3P)_2$ in CH_3CN in the range 14000—18000 cm^{-1} is dominated by the A-term. The magnitudes of the A- and C-terms are dependent, furthermore, on the frequency (ν), the width at half-maximum height of the absorption line (Γ), and temperature (T).[8,9] If we assume $\Gamma h/2\pi\approx 4000$ cm^{-1} and $kT\approx 200$ cm^{-1}, where h is Planck's constant and k is the Boltzmann constant, the A-term for the transition $A_1\rightarrow T_2$ is almost the same order of magnitude as the C-term for the transitions $T_1\rightarrow T_1$, E, and T_2. The A-term is dominant for the transition $A_1\rightarrow T_2$ and the C-term is dominant for the transitions $T_1\rightarrow T_1$, E, and T_2. The C-terms of the latter compose a positive dispersion of the MCD spectrum. Therefore, a positive dispersion of the observed MCD spectrum can be interpreted as the overlap of line shapes due to the A-term of the transition $A_1\rightarrow T_2$ and the C-terms of the transitions $T_1\rightarrow T_1$, E, and T_2.

Table 1. Calculated values of MCD and absorption parameters[a] for the transitions from each level split from $^3T_1(F)$ to each level split from $^3T_1(P)$

Transition	Excitation energy (cm^{-1})	A[b]	C[b]	D[c]	A/D
$A_1\rightarrow T_2$	16400	−79.4	0	95.3	-8.3β
$T_1\rightarrow T_1$	16380	−6.3	3.0	7.2	-8.8β
$\rightarrow E$	16150	−0.5	1.1	2.5	-0.2β
$\rightarrow T_2$	16010	−0.7	−2.7	6.4	-1.1β
$E\rightarrow T_1$	15690	0.3	0.0	0.8	0.4β
$\rightarrow T_2$	15320	0.0	0.0	0.0	0.0
$T_2\rightarrow A_1$	15690	0.0	0.0	0.1	0.0
$\rightarrow T_1$	15460	0.0	0.0	0.0	0.0
$\rightarrow E$	15230	0.0	0.0	0.0	0.0
$\rightarrow T_2$	15090	0.0	0.0	0.0	0.0

a) All values of parameters A, C, and D include the Boltzmann distribution factor of the initial state at room temperature. b) In units of $10^4\beta p^2$, where β is the Bohr magneton and $p=\langle t_2\|er\|e\rangle$. c) In units of 10^3p^2.

In *case A)*, the effects of lower symmetry field and the spin-orbit coupling are comparable. Both the spin and the orbital degeneracies are removed. However, since the eigen-functions are not real, the MCD parameters A, B, and C are nonzero. We have estimated the B-term with the following approximation. As the states to be mixed into one of the states split from $^3T_1(F)$ by the external magnetic field, we have considered only the rest of the states split from $^3T_1(F)$. In the same way, we have considered only the rest of the split states as the states to be mixed into one of the states split from $^3T_1(P)$. By using the eigen-functions in *case A)*, we have calculated the values of MCD parameters A, B, and C. Contrary to our expectation, all of these parameters are found to be smaller than about 1% of the values obtained in *case B)*. Therefore, in this case we cannot explain the observed magnitude of $[\theta]_M$. The main cause of such small valuse seems to be the fact that we estimated the effect of the lower symmetry field and the spin-orbit coupling to be of the same order of magnitude. In fact, the effective field operating in $NiCl_2(Ph_3P)_2$ in solution might be very close to that of tetrahedral symmetry. More extensive study would be necessary with respect to this point.

Proton Nuclear Magnetic Resonance Studies. Proton NMR spectra of dihalogenobis(tertiary phosphine)-nickel(II) complexes have been investigated extensively.[21-26] The signals of the phenyl ring protons of the paramagnetic tetrahedral species are usually substantially displaced from the resonance positions of the diamagnetic species. The shift is upfield for the ortho and para protons and downfield for meta protons; it is interpreted as arising from a contact interaction with unpaired electrons which have been partially delocalized from a nickel atom to the π-orbital of the ligand.[21,22] The kinetics of ligand exchange in the tetrahedral complexes and the thermodynamics and kinetics of the diamagnetic planar↔paramagnetic tetrahedral interconversion have been studied,[23-26] but these studies were done only on the solutions in inert solvents. As we have shown in the studies of the MCD and absorption spectra, the complex $NiCl_2(Ph_3P)_2$ in coordinating solvents can be in equilibrium between a paramagnetic tetrahedral form and a paramagnetic octahedral form.

The proton NMR spectra of $NiCl_2(Ph_3P)_2$ in DMSO at various concentrations are shown in Fig. 11. As the concentration increases, the splitting of the ortho,

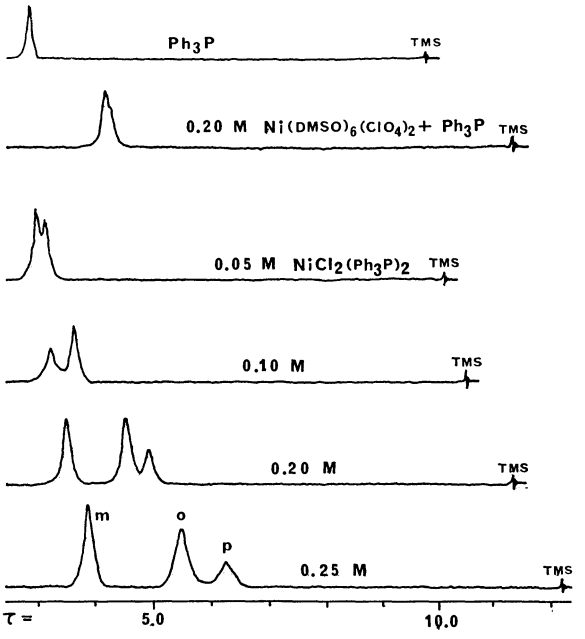

Fig. 11. Proton NMR spectra at several concentrations of the solution of $NiCl_2(Ph_3P)_2$ in DMSO at room temperature. Proton shifts are shown relative to the protons of tetramethylsilane (TMS) in CCl_4 ($\tau=10.0$) as an external standard. The signal of TMS as an internal standard shifts depending on the concentration of nickel(II) ions, and the position is shown as TMS in each spectrum. The spectrum of triphenylphosphine which is added to 0.20 M solution of $Ni(dmso)_6(ClO_4)_2$ in DMSO and the spectrum of triphenylphosphine dissolved in DMSO are shown for comparison.

meta and para protons increases and the signals of phenyl ring protons generally shift upfield. When some excess Ph_3P is added to the 0.2 M solution of $NiCl_2(Ph_3P)_2$, the splitting of the phenyl ring protons decreases and all the signals approach the resonance position of the Ph_3P which is added to the 0.2 M solution of $Ni(dmso)_6(ClO_4)_2$ in DMSO. The signal of the TMS added to a 0.2 M solution of $Ni(dmso)_6(ClO_4)_2$ in DMSO and that of Ph_3P added to the same solution both shifted by 1.5 ppm from the respective signals in the absence of the nickel complex. The signal of TMS in 0.2 M solution of $NiCl_2(Ph_3P)_2$ in DMSO also shifted by the same magnitude. Thus there are nearly the same amount of paramagnetic nickel(II) ions in both 0.2 M $NiCl_2(Ph_3P)_2$ in DMSO and 0.2 M $Ni(dmso)_6(ClO_4)_2$ in DMSO. With respect to the signal of non-coordinating Ph_3P, the ortho and para protons are shifted upfield and the meta protons are shifted downfield. The characteristic shifts are interpreted as arising from the contact shift originating in the paramagnetic tetrahedral form. The configurational equilibrium is significantly dependent on the concentration, and the increase of concentration is favorable for the tetrahedral form in DMSO. The rate of ligand exchange or structual interconversion is fast, since no new peaks and only averaged resonances are observed, showing that it is faster than 10^2 s^{-1}. The splitting of the phenyl ring protons decreases

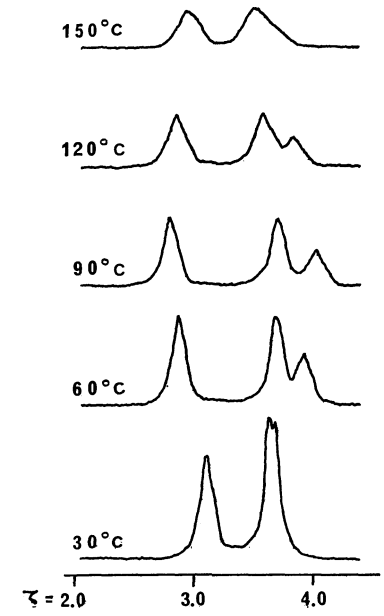

Fig. 12. Proton NMR spectra of 0.1 M solution of $NiCl_2(Ph_3P)_2$ in DMSO in the temperature range 30 to 150 °C.

gradually, within the time scale shown in Fig. 6, and the signals approach the position of the non-coordinating Ph_3P.

The proton NMR spectrum of 0.1 M solution of $NiCl_2(Ph_3P)_2$ in DMSO in the temperature range 30 to 150 °C is shown in Fig. 12. An increase of the contact shift, which reveals the increase of the paramagnetic tetrahedral complex, is observed as the temperature is raised up to 90 °C. As the temperature is raised further, the contact shift begins to decrease and the line broadening is observed. The temperature dependent behaviour may be interpreted as showing that the solvated octahedral molecule $NiCl_2(Ph_3P)_2$-$(dmso)_2$ tends to become tetrahedral $NiCl_2(Ph_3P)_2$ by expelling the coordinated solvent as the temperature is raised; then the rate of ligand exchange increases and the effect becomes predominant at temperatures higher than 100 °C. However, such a change of the proton NMR spectrum is not observed in the

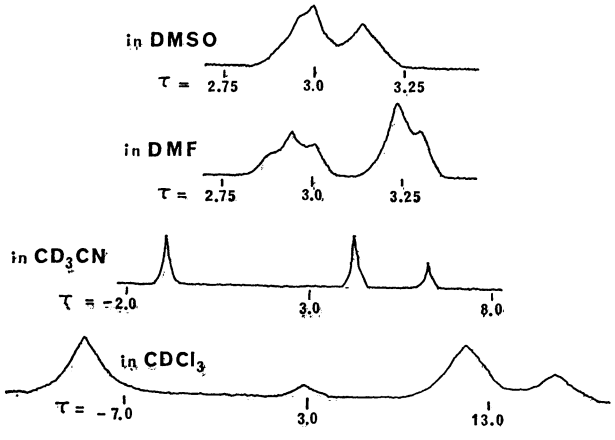

Fig. 13. Proton NMR spectra of $NiCl_2(Ph_3P)_2$ in various solvents at the same concentration; 0.05 M.

solutions in either CH_3CN or $CHCl_3$. The contact shift increases as the temperature is cooled down to -50 °C in both CH_3CN and $CHCl_3$.

The proton NMR spectra of $NiCl_2(Ph_3P)_2$ in various solvents at the same concentration, 0.05 M, are shown in Fig. 13. The ratio of the paramagnetic tetrahedral form of $NiCl_2(Ph_3P)_2$ increases in the solutions in the order DMSO<DMF<CH_3CN<$CHCl_3$. When excess Ph_3P is added to these solutions, all the signals are found to approach the position of the signal of non-coordinating Ph_3P. Therefore the rate of ligand exchange of Ph_3P is faster than 10^2 s^{-1} in all these solutions. It should therefore be noted that the weak signal at about $\tau=3$ in $CDCl_3$ solution is not a signal of the non-coordinating Ph_3P.

Conclusions

The MCD, absorption, and proton NMR spectra thus exhibit consistently the structural interconversions of $NiCl_2(Ph_3P)_2$ in various solvents. Generally, the paramagnetic tetrahedral form of this compound is more stable at high concentrations in both coordinating and non-coordinating solvents. In coordinating solvents, such as DMSO and DMF, the solvent-coordinated paramagnetic octahedral species $NiCl_2(Ph_3P)_2$(solvent molecule)$_2$ are found to increase as the concentration of $NiCl_2(Ph_3P)_2$ is decreased and also as time goes on after making the solution. Further, it is found that the coordinated Ph_3P tends to leave gradually and the solvated complex $NiCl_2$(solvent molecule)$_4$ is formed. However, these solvent molecules will not be so strongly coordinative in comparison with Ph_3P, since it is found that the ratio of the paramagnetic tetrahedral species $NiCl_2(Ph_3P)_2$ increases as the temperature of the solution containing the solvated species is raised.

In non-coordinating solvent $CHCl_3$, no solvated octahedral compound is observed. Configurational isomers of a paramagnetic tetrahedral and a diamagnetic square-planar $NiCl_2(Ph_3P)_2$ are observed. The molecule of the former isomer will retain the distorted tetrahedral configuration which it has in the crystal. The magnitude of the proton NMR signal at $\tau=3$ grows gradually and coincidently all the other signals, which are due to the paramagnetic tetrahedral species, are reduced in intensity without changing their positions. At the same time, the absorption spectra of the solution change to show the bands only in the energy region higher than 25000 cm^{-1}; these bands have a strong resemblance to those of $Ni(SCN)_2(Ph_3P)_2$ (Fig. 4) and may be identified as those of a diamagnetic square-planar species. The rate of interconversion between the paramagnetic tetrahedral form and the diamagnetic square-planar form is sufficiently slow on the NMR time scale, *i.e.* less than 10^2 s^{-1}. It seems to be almost one-way from the paramagnetic tetrahedral form to the diamagnetic square-planar form and irreversible. As the former form decreases gradually, a yellow precipitate is observed to grow. The ratio of the former form to the latter one is greater at high concentrations, and the yellow precipitate grows faster at low concentrations. When the filtrate of the yellow precipitate is dried, only Ph_3P remained. We identified this yellow precipitate to be $NiCl_2$ by measuring the magnetic susceptibility and the melting point. It appears therefore that the paramagnetic tetrahedral $NiCl_2(Ph_3P)_2$ decomposes gradually to $NiCl_2$ and $2Ph_3P$, and since the solvent does not coordinate, $NiCl_2$ precipitates as Ph_3P leaves.

The paramagnetic octahedral species, the paramagnetic tetrahedral species, and the diamagnetic square-planar species seem to coexist in the solution of $NiCl_2(Ph_3P)_2$ in CH_3CN. Some nickel(II)–acetonitrile complexes, $Ni(CH_3CN)_6(BF_4)_2$, $NiCl_2(CH_3CN)_4$, and $NiCl_2(CH_3CN)_2$, have been reported. A chloride ion is well known to be a stronger coordinating ligand than CH_3CN.[27] The MCD and absorption spectra show that the proportion of the diamagnetic species is smaller in the solution in CH_3CN than in $CHCl_3$. The proton NMR spectra show a greater contact shift in $CHCl_3$ than in CH_3CN. This will be due to the liability of ligand exchange between Ph_3P and CH_3CN. Most of the absorption in the range 14000 to 19000 cm^{-1} in Fig. 7 will be due to the tetrahedral $NiCl_2(Ph_3P)_2$, since the tetrahedral complex $NiCl_2(CH_3CN)_2$ will show an absorption band with the peak at about 13000 cm^{-1}. As the time goes on after dissolving $NiCl_2(Ph_3P)_2$ in CH_3CN, a pale yellow precipitate is observed to grow, but it is not so much as in the solution in $CHCl_3$ and the proton NMR signal at about $\tau=3$ is found to grow gradually. The absorption spectrum does not change drastically as in the case of $CHCl_3$ solution; it changes only slightly, suggesting the coexistence of a small amount of a tetrahedral $NiCl_2(CH_3CN)_2$ and an octahedral $NiCl_2(CH_3CN)_4$.

A Theoretical Consideration of the ^{13}C NMR Chemical Shift of Protonated Systems. I. The Acetone–Sulfuric Acid System

Isao ANDO, Masahiro KONDO, Atsuo NISHIOKA, and Shosuke WATANABE

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 14, 1978)

A quantum-chemical method has been developed using a point-charge model to calculate the ^{13}C chemical shift for protonation in an acidic solution. This method has been applied to the acetone–sulfuric acid system; the gross tendencies between the observed and calculated results agree.

The NMR parameter, the chemical shift, is closely associated with the electronic structure of a molecule. In solution, the electronic structure of the molecule is affected by the surrounding molecules; thus, the chemical shift is solvent-dependent. The nature of the solvent effects may be mainly classified into the following two categories:

(i) The molecule considered forms a loose bonding with a solvent, such as hydrogen bonding or protonation.

(ii) Without such a bonding, the molecule is affected by intermolecular interaction with the surrounding molecules.

For Case (ii), we have successfully interpreted the observation of the solvent effect of the ^{13}C chemical shift[1,2] and the long-range chemical shift by magnetic anisotropy[3] in some organic compounds, acetone, acetonitrile and other compounds, by the application of Klopman's solvaton model[4] to the MINDO/2[5] and CNDO/2 methods.[6] It is the purpose of this work to treat quantum-chemically the protonation in Case (i) and use it in interpreting the behavior of the ^{13}C chemical shift of the protonated acetone molecule which occurs in a strongly acidic solution such as a sulfuric acid solution.

A study of the effect of protonation on the ^{13}C chemical shift of acetone was first done by de Jue[7] using the average-excitation-energy approximation. However, this approximation is too gross to enable us to discuss exactly the nature of the ^{13}C chemical shifts of the molecule being considered. We will, therefore, discuss the behavior of the ^{13}C chemical shifts of the protonated acetone using our proposed model for protonation without the average-excitation-energy approximation.

Theoretical

As a model of protonation we assume that a positive point charge approaches and loosely bonds to the oxygen atom in the carbonyl group of acetone. In order to formulate this model generally, we consider a molecular system with M electrons and N nuclei, adding a point charge. On the basis of this model, the Hamiltonian, H, of the specified molecular system consists of the inherent term, H_{inh}, and the protonation term, H_{prot}, and is given as (in atomic units)

$$H = H_{\mathrm{inh}} + H_{\mathrm{prot}}, \tag{1}$$

$$H_{\mathrm{inh}} = \sum_{i=1}^{M}\left[\left(-\frac{1}{2}\nabla_i^2 - \sum_{n=1}^{N}\frac{Z_n}{r_n}\right) + \frac{1}{2}\sum_{j=1}^{M}\frac{1}{r_{ij}}\right] + \frac{1}{2}\sum_{m=1}^{N}\sum_{n=1}^{N}\frac{Z_m Z_n}{r_{mn}}, \tag{2}$$

$$H_{\mathrm{prot}} = -\sum_{i=1}^{M}\frac{Q_{\mathrm{a}}}{r_{\mathrm{a}i}} + \sum_{n=1}^{N}\frac{Q_{\mathrm{a}}Z_n}{r_{\mathrm{a}n}}, \tag{3}$$

where Q_{a} is the magnitude of the point charge, $r_{\mathrm{a}i}$ and $r_{\mathrm{a}n}$ are the point charge-electron and the point charge-nucleus distances respectively, and Z_n is the charge on the nucleus, n. In these calculations, two additional assumptions were made for Eq. 3; (1) if the electron and the point charge are associated with the same atomic center, the point charge-electron distance, $r_{\mathrm{a}i}$, is taken to be the van der Waals radius of the oxygen atom, and (ii) if the electron and the point charge are associated with different atomic centers, the point charge is assumed to be centered on the atomic center associated with Q_{a}, and then the point charge-electron distance, $r_{\mathrm{a}i}$, is evaluated as the distance between their atomic centers.

Using the Roothaan's matrix notation, the total energy, E_{T}, of the system is given as

$$E_{\mathrm{T}} = 2\sum_{i}^{\mathrm{occ}}\boldsymbol{C}_i^*\boldsymbol{H}\boldsymbol{C}_i + \sum_{i}^{\mathrm{occ}}\sum_{j}^{\mathrm{occ}}\boldsymbol{C}_i^*(2\boldsymbol{J}_j - \boldsymbol{K}_j)\boldsymbol{C}_i + \frac{1}{2}\sum_{m}^{N}\sum_{n}^{N}\frac{Z_m Z_n}{r_{mn}} + \left[2\sum_{i}^{\mathrm{occ}}\boldsymbol{C}_i^*\boldsymbol{D}\boldsymbol{C}_i + \sum_{n}^{N}\frac{Q_{\mathrm{a}}Z_n}{r_{\mathrm{a}n}}\right]. \tag{4}$$

The fourth term is due to the contribution of the protonation, where the elements of D are given as

$$D_{ij} = \int \phi_i^*(1)\left(-\frac{Q_{\mathrm{a}}}{r_{\mathrm{a}1}}\right)\phi_j(1)\mathrm{d}\tau(1) \tag{5}$$

D_{ij} are estimated according to similar procedures developed by Germer.[8]

The integral:

$$D_{\mathrm{ss}} = D_{\mathrm{A}} \tag{6}$$

is calculated for each atomic center, A, using the S orbitals of the atom. The $D_{\mu\nu}$ is approximated as

$$D_{\mu\nu} = \frac{1}{2}S_{\mu\nu}(D_{\mathrm{A}} + D_{\mathrm{B}}), \tag{7}$$

where $S_{\nu\mu}$ is the overlap integral, μ and ν being valence orbitals on the A and B atoms respectively. This approximation was incorporated into the MINDO/2 MO method.

As the effective van der Waals radius of the oxygen atom, 1.4 Å is used.[9]

According to Pople, the ^{13}C chemical shift, σ^{T}, is estimated by the sum of the diamagnetic and paramagnetic contributions. These contributions were calculated according to Pople's GIAO-MO theory[10] without the average-excitation-energy approximation.

The bond lengths and bond angles used are standard values proposed by Pople and Gordon.[11] All the calculation were carried out with the HITAC-8800

computer of the Computer Center of the University of Tokyo.

Experimental

High-resolution pulsed FT ^{13}C NMR spectra were obtained at 25.15 MHz using a JEOL PS-100 spectrometer equipped with a PFT-100 Fourier transform system, a JEC-6 spectrum computer, a ^{2}D field-frequency lock, and a noise-modulated proton-decoupling system. The observed free induction decay after a 90° pulse was sampled at 8192 data points. A deuteron signal of benzene-d_6 sealed in a capillary inserted into an 8 mm o.d. tube was employed for the lock signal, where ^{13}C-enriched tetramethylsilane(20%) dissolved in benzene-d_6 was used as the reference. The ^{13}C chemical shift was corrected for bulk magnetic susceptibility.[12] The bulk magnetic susceptibility for a solution, χ_{soln}, is given as

$$\chi_{soln} = \sum_{i}^{n} \phi_i \chi_i, \quad (8)$$

where χ_i and ϕ_i are the bulk magnetic susceptibility and the volume fraction of the i-th component molecule in solution respectively.

In a strongly acidic solution, the protonation of the acetone molecule may occur. The concentration of acetone is 2 mol % in various sulfuric acid–water concentration ratios. The sulfuric acid concentration varies from 0 to 25 mol % in the total solution.

Results and Discussion

In Fig.1 the ^{13}C chemical shifts of the carbonyl and methyl carbons are shown for 2 mol % acetone in various sulfuric acid–water concentration ratios. The carbonyl carbon chemical shift moves to a much lower field with an increase in the concentration of sulfuric acid. On the other hand, the methyl carbon chemical shift moves to an appreciably lower field upon protonation. These trends agree with de Jue's results,[7] although the concentrations of acetone are different in the two cases.

Let us analyze this behavior upon protonation on the basis of our calculations. The values of the excess charges on the carbon and oxygen atoms in acetone molecules are plotted against the magnitude of the charge, Q_a, associated with the oxygen atom in the carbonyl group in Fig. 2. The electron densities on the oxygen and carbon atoms in the carbonyl group increase with an increase in Q_a, while, on the other hand, that on the methyl carbon decreases. In this molecule, the electrons are drawn to the oxygen atom and the distribution of electrons is polarized by an inductive $-I^-$ type effect, $O^-{=}C^+{-}C^-$. However, its effect decreases by the association with the charge, Q_a. The electron densities on the carbonyl oxygen and carbon atoms increase, and that on the methyl carbon atom decreases, with an increase in Q_a. Then, the charge on the methyl carbon atom becomes positive.

The charges of this distribution of the electron density with an increase in the Q_a in this system cannot explain the observed results. For example, the increase in the electron density on carbonyl carbon with an increase in the Q_a cannot explain the observed low-field shift with an increase in the concentration of sulfuric acid. This suggests that the change in the excitation energy may play an important role in the observation of the chemical shift. Some typical examples of the calculated diamagnetic, ρ^d, paramagnetic, ρ^p, and total chemical shifts are shown against the value of Q_a in Table 1. The calculated chemical shifts are also plotted in Fig. 2. The major part of the Q_a dependence of the chemical shift arises from variations in σ^p. The chemical shifts of the carbonyl and methyl carbons shift to a lower field with an increase in the value of Q_a, and the change in the former is larger than that in the latter. These tendencies agree with the observed ones, but the change in the methyl carbon is too large.

The observed chemical shift of carbonyl carbon

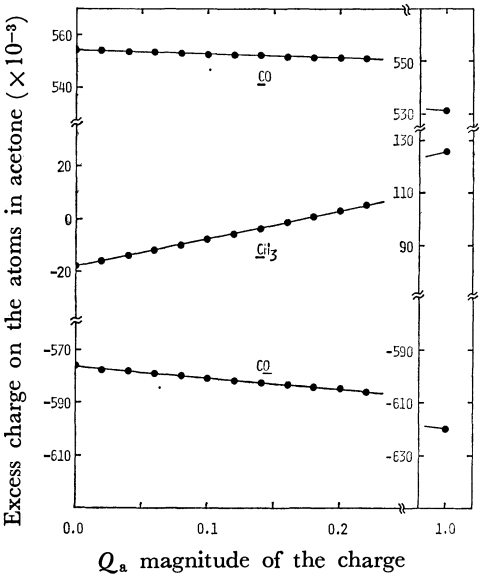

Fig. 2. Dependence of excess charge on carbon and oxygen atoms in acetone upon the magnitude of the charge Q.

Table 1. Dependence of the calculated chemical shifts of methyl and carbonyl carbons in acetone upon the magnitude of the charge, Q_a

Q_a		Calculated chemical shift (ppm)		
		Diamagnetic contribution σ^d	Paramagnetic contribution σ^p	Total contribution σ^T
0.0	CH_3	57.99	−211.55	−153.56
	CO	52.81	−352.58	−299.76
0.01	CH_3	57.99	−212.26	−154.27
	CO	52.81	−354.41	−301.59
0.02	CH_3	57.98	−212.98	−154.99
	CO	52.82	−356.25	−303.43
0.05	CH_3	57.96	−215.14	−157.19
	CO	52.82	−361.94	−309.12
0.10	CH_3	57.91	−218.86	−160.95
	CO	52.83	−371.90	−319.08
0.20	CH_3	57.83	−226.62	−168.79
	CO	52.84	−393.96	−341.11
0.50	CH_3	57.52	−253.95	−196.44
	CO	52.91	−479.29	−426.38
1.00	CH_3	56.30	−320.44	−263.64
	CO	53.04	−738.67	−685.63

moves to a lower field by about 30 ppm for the concentration variation of sulfuric acid from 0 to 25 mol %. This value corresponds to the one calculated when the value of Q_a is about 0.15. When the value of Q_a is 1.0, the calculated value shifts to considerably a lower field. According to these results, if the protonation is complete, dose such a low-field shift arise? This may be interesting problem.

Reviewing our results from the viewpoint of the exchange between free and protonated molecules, the finding that the value of Q_a is about 0.15, considerably smaller than 1, is not surprising. Although, in this work, we have chosen a simple system in applying our developed procedure to the protonation, we should apply a more complicated system to ascertain the applicability of our model.

Topological Ligand Design. I. Definition and Derivation of Simple Ligand Graph*

Susumu TAKAMOTO

Department of Chemistry, Faculty of Sciences, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received December 18, 1978)

A simple ligand graph and a pattern graph are defined topologically in order to design the patterns of the chelating ligands. This ligand graph, which comprises m donor atoms and n carbon chains capable of forming medium-sized chelate rings, is an irregular graph containing neither multiple lines nor self-loops. All the ligand graphs with $m \leqq 8$ can be systematically obtained from fifty pattern graphs. These are derived from fifteen basic pattern graphs, which are cubic general graphs containing some multiple lines and self-loops. A pattern code and a set of series indices are tabulated for each ligand graph with $m \leqq 8$. For the ligand graphs with $m \leqq 6$, all the geometric isomers of their octahedral chelates are also illustrated.

The chemistry of metal chelates has been remarkably developed and is widely applied. The properties and the reactions of the metal chelates are closely related to their structure. When one seeks the most suitable new chelating reagents for a certain purpose, it would be of great use to look over all the patterns of ligand structures. In their reviews on the ligand design, Goodwin[1] and Black and Hartshorn[2] were chiefly concerned with the systematic outline and classification of the chelate agents already prepared, but their topological diagrams were mathematically incomplete. Thus, purely geometrical investigations are not available for the sysematic derivation of ligand patterns or for the design of new ligands. The graph theory and computer studies have been successfully applied to the numeration and the documentation of the chemical isomers or the homologs for some special kinds of organic compounds.[3] In order to cover all the ligands, one has to treat all the organic compounds, since every compound containing some oxygen- or nitrogen-group elements has more or less ability to coordinate to a metal ion. This designing work is limited to those practical ligands which can form five- or six-membered chelate rings with a metal ion.

Theory and Results

A ligand can be considered as a set of some donor atoms joined by several carbon chains capable of forming medium-sized chelate rings. Then a simple ligand graph L(m, n) can be defined for each ligand, where m is the number of points which correspond to the donor atoms, and n is the number of lines which correspond to the carbon chains. The ligand graph must meet the following requirements: (1) The graph is connected. (2) It is planar. (3) The degree of each point is one, two, or three (The degree of a point is the number of lines incident with it). The first condition is self-evident. A planar graph can be drawn on a plane so that no two lines cross each other. According to the graph theory such a graph is identical to a spherical graph. To be spherical is needed for two carbon chains not to cross each other on a coordination sphere, because these chains are too short to detour. Three would be the maximum degree of a point in any kind of donor atom. Then, for instance, ethylenediamine, 1,3-propylenediamine, 2,3-butenediamine, N,N,N',N'-tetramethylethylenediamine, 1,2-phenylenediamine, and 1,2-cyclohexenediamine are represented by the same ligand graph L(2, 1), since these ligands contain two donor atoms and only one carbon chain which can form a chelate ring. The graph L(2, 1) is unique, but it should be noted that a graph L(m, n) is not generally determined only by a set of m and n.

A graph in the narrow sense of the word does not include multiple lines; that is, two points may be joined by only one line. Molecules such 1,4-diazacycloheptane, for example, can form metal chelates, so some double lines may be included in the ligand graph. But relatively few such ligands form stable chelates because of the steric hindrance and the bond strains. Moreover, this limited number of double lines can be easily derived by joining a pair of adjacent points of degree one or two in a simple ligand graph. Therefore, no multiple lines are included in this simple ligand graph. Also, no self-loop is needed in this graph, since it forms no chelate ring. Thus the simple ligand graph is a normal irregular graph.

Some new terms should be defined. When all the points of degree two in a ligand graph are neglected, the remainder is named a pattern graph P(p, q), and each line in the pattern graph is called a series. Although an isolated circle without a point may not be generally accepted as a graph, in this study it is by exception admitted as a pattern graph. The degree of every point in the pattern graph is one (end point) or three (branch point). A pattern graph may contain some triple and double lines and some self-loops. This value of p is always an even number because the degree of every point is odd.

When all side-chains are removed from a pattern graph, the remainder is called a basic pattern graph B(r,s). All basic pattern graphs but the isolated circle B(0,1) and an isolated line B(2,1) are cubic general graphs; that is, all their points have the same degree of three, and they also may have multiple lines and self-loops. Examples of each graph are shown in Fig. 1.

All the cubic general graphs for $m \leqq 8$ can be constructed from the two simplest cubic graphs B(2,3)

* A preliminary report of this work was presented at the 28th Symposium on Coordination Chemisrty, Matsuyama, October 1978.

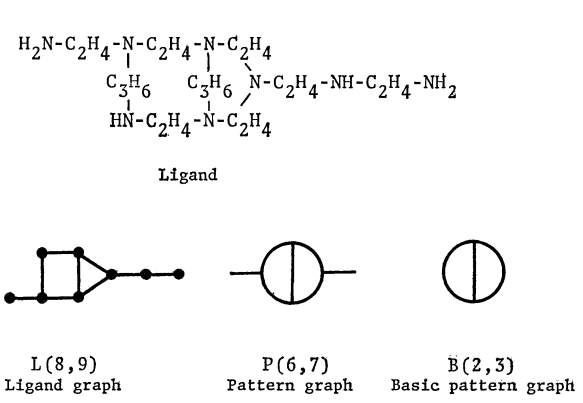

Fig. 1. Reduction of a ligand structure into the basic pattern graph.

by adding new branch lines one by one avoiding the duplication of patterns, up the maximum values of r:

$$r \leqq m - d - 2t - 2l - 3c \tag{1}$$

where d, t, l, and c are the numbers of double lines, triple lines, self-loops, and isolated circes. This restriction is needed to exclude all the multiple lines and self-loops from the ligand graphs which are derived from the pattern graphs. Naturally r is even number.

All the basic pattern graphs for $m \leqq 8$ are shown in Fig. 2. The values of t and c are only applicable in the case of (2-1) and (1-1) in Fig. 2 respectively. Then, for example, (4-2) and (4-4) are not the basic pattern graphs for $m \leqq 7$, because d of (4-2) is 2, and l of (4-4) is 1.

The sum of the degree of the points of a graph $G(x, y)$ is twice the number of lines, and the number of independent cycle i is equal to $y-x+1$. Then in any cubic graph $B(r, s)$ the following relationships are obtained:

$$s = 3r/2, \tag{2}$$

$$i = 1 + r/2. \tag{3}$$

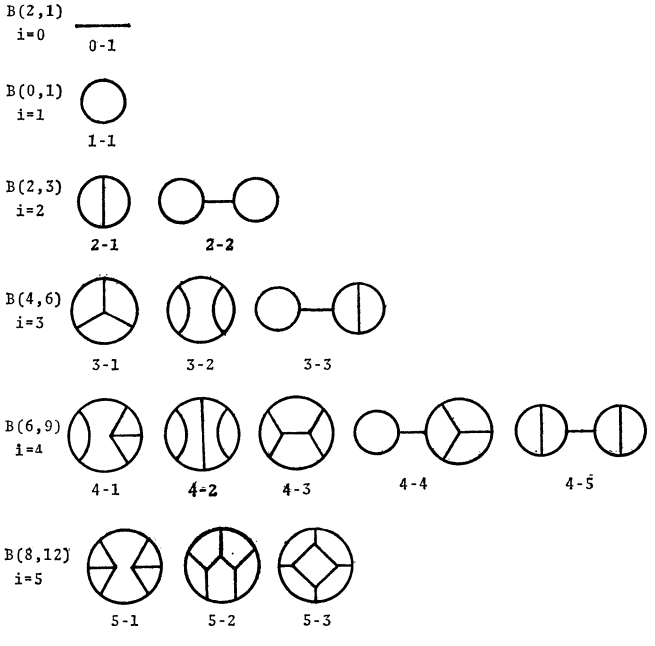

Fig. 2. Basic pattern graphs ($m \leqq 8$).

The pattern graphs are systematically derived from the basic pattern graphs by adding some side-chains one by one, while basic pattern graphs themselves belong to the set of pattern graphs. The maximum valuse of p is also restricted by the right hand side of Eq. 1, although p is not less than r of the original basic pattern graph. Fifty pattern graphs thus obtained for $m \leqq 8$ are illustrated in Fig. 3. As the numbers of points and lines are incresed by the same integer by adding a side-chain to a graph, $q-p$ is always equal to $s-r$ of its original basic pattern graph. However, the number of independent circles i is unchanged by any addition of side-chains.

Similarly, all the ligand graphs are derivable by allotting a definite number of points of degree two to each series of the pattern graph. Ligand graphs thus derived from the same pattern graph are topologically homeomorphic to one another. In this study a pattern graph is simply denoted by a pattern code classified by the basic pattern groups, and alphabetical labels ***a*** to ***h*** are assigned to each series of the pattern graphs, as shown in Fig. 3. Then all the simple ligand graphs can be characterized by a pattern code and a set of eight series indices, which express the number of the points of degree two allotted to each labeled series of the pattern graph. These allotted numbers are properly restricted so that the numerating repetition which is caused by the symmetry of the ligand graph may be avoided, and so that every cycle in ligand graphs may contain at least three points, which are needed to exclude any multiple lines and self-loops. In the case of Fig. 1, two points of degree two are allotted for series ***a*** and ***h*** of the pattern graph (24), because series ***a*** has the highest priority among the four equivalent series ***a***, ***b***, ***c***, and ***d*** in order to avoid the repetition. All the ligand graphs with $m \leqq 8$ and their pattern codes and series indices are listed in Table 1. The numbers of the simple ligand graphs thus designed and of their double-line derivatives are summarized in Table 2.

Each ligand may form some configurationally isomeric chelates with a metal ion in a certain coordination structure. As an example, all the geometric configurations in the octahedral coordination for every simple ligand graph with $m \leqq 6$ are illustrated in Table 3. They were confirmed by use of molecular models.

Discussion

In this study double lines are not included in the simple ligand graph, but double-line derivatives have been derived from the simple ligand graph. All of them, as well as the simple ligand graphs, can directly be derived from the pattern graphs if the restriction 1 is moderated as follows:

$$r \leqq p \leqq m - t - l - 2c. \tag{4}$$

Then the numbers of the pattern graphs and the basic pattern graphs are increased from 50 and 15 to 112 and 34 respectively. There is little merit in complicating the pattern graphs so much, since the number of such less important ligands is limited.

Mechanical derivations of compounds often have

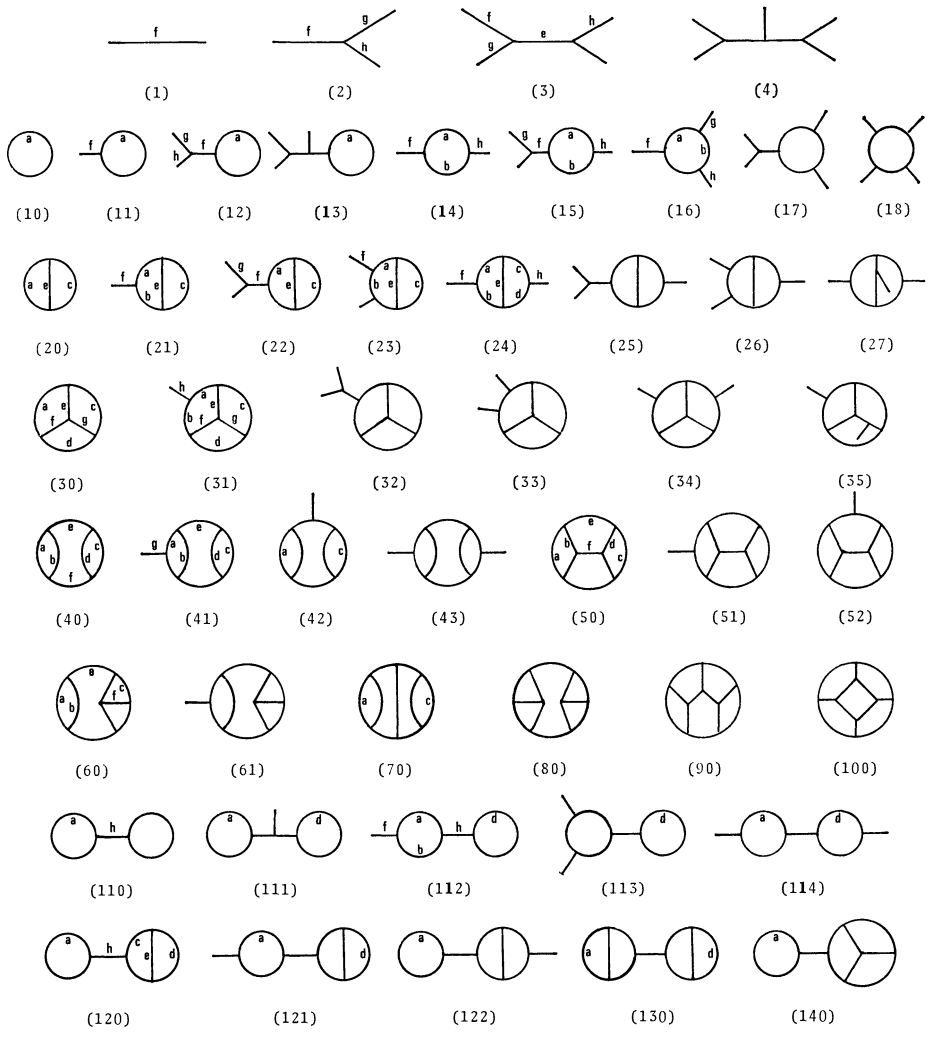

Fig. 3. Pattern graphs and labeling of series ($m \leqq 8$).

a tendency to introduce some useless ligands which may offer some difficulties for coordinating. The present manner of deriving the ligand graphs is sufficiently systematic that it produces no such worthless ligands.

Every ligand graph with $m=5$ can cover all the trigonalbipyramidally or square-pyramidally disposed positions. Every planar graph with $m=6$ can also cover all the octahedral points, but not all the points of a trigonal prism. The planar m-polygonal corners can be covered with only two ligand graphs of order m which have a linear or a circular shape.

Since any donor atoms of nitrogen or oxygen group elements may be held at any points of a ligand graph, ligands of mixed donor atoms may also be expressed by the same ligand graphs. Then, for example, most of the simple cryptands belong to No. 8-055, and edta or its analogs to No. 6-04 in Table 1. The lines in a simple ligand graph might represent not only a carbon chain but also boron-, silicon-, or any other chains.

Previously, the author[4] reported that 1,4,7-triazacyclononane (a type of No. 3-02) forms the most stable metal chelates in all the triamines, and that 1,2-di(1,4,7-triazacyclononan-1-yl)ethane, which is composed of two such triazacycloalkanes connected by a ethylene group (a type of No. 6-28) is also a good chelating agent.[5] Since cyclam (a type of No.4-03) is well known for the extreme stability of its chelates, a ligand of type No. 6-26, which is composed of two triazacycloalkanes and one tetraazacycloalkane, should form the most stable chelates.

Ligands of type No.4-06 or No.6-27 have a basketlike structure. All the lone-pair electrons of their donor atoms are directed to the center of the polyhedron, so no metal ion might enter inside or be coordinated. But if these ligands could be synthesized around a metal ion by some means, the metal atom should be confined completely within their network, and a hydrophobic spherical cation would be produced.

It may be seen from the above lists that only a few types of ligands have ever been prepared; many types with interesting structures still remain unknown. For example, most studies on sexidentate ligands were focused upon only five types of No.6-01 to No.6-05 among the twenty eight ligand graphs with $m \leqq 6$; therefore a number of new ligands with various patterns can be synthesized and investigated in the near future. Showing their possibilities is the most important aim and the successful fruit of this work.

A ligand containing some special branched carbon atoms, where the branches might form several chelate rings, cannot be represented by a simple ligand graph, for a line of a graph can branch only at the point representing a donor atom. In order to express such complicated ligands the definition of the ligand graph must further be extended. These studies will be reported in a later paper.

The author wishes to express his thanks to Prof. Takeshi Iizuka of Gunma University for valuable suggestions. The present work was partially sup-

ported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

(Received January 16, 1979)

A theoretical consideration on the nature of solute-water and solute-solute interactions in aqueous solutions has been performed. Thermodynamic functions for the creation of cavities accommodating solute molecules were calculated by the use of the scaled particle theory, and the "negative hydration" effect of univalent ions such as Rb^+, Cs^+, Cl^-, I^- *etc.*, which was proposed first by Samoilov, Krestov and others, was interpreted and discussed. The nature of solute-water and solute-solute interactions in aqueous solutions of inert gases and hydrocarbons was elucidated in comparison with the interactions in nonaqueous solutions of those solutes.

Since the presentation of Frank and Evans' work,[1] the anomalously large and negative entropy of solution of nonpolar gases and liquids in water as well as the enormous partial molal heat capacity of those has generally been interpreted as the evidence that the solute molecules cause an increase of "ordering" around themselves within water, that is, the formation of "icebergs." Then, the cause of hydrophobic interactions between nonpolar groups or radicals in aqueous systems was ascribed to the disappearance of "icebergs" at the overlapped co-sphere region about those having direct contacts with each other.[2,3] The problems of the formation of "icebergs" and of the nature of hydrophobic interactions have become an object of increasing amount of debates since then.[4,5]

On the other hand, concerning the nature of ionic hydrations, Samoilov, Krestov and others proposed a dynamic model of ionic hydration and introduced the concept of "negative hydration" for univalent ions such as Cl^-, I^-, Cs^+ *et al.* from the consideration of diffusional behaviors of those within water.[6] The Samoilov model is a kind of the dynamical representation of ion-water interactions at the nearest neighbor of ions, while the Frank-Wen model[7] is a kind of the statical representation of those around ions.[5]

The formation of "icebergs" and the presence of "negative hydration" effect for comparatively large univalent ions are both closely related to the liquid structure of water, and many discussions have been made though no decisive conclusions are obtained at present.

The purpose of the present work is to give an explanation of those effects on the basis of a more sound theoretical ground.

While a number of new statistical mechanical approaches to treat fluids and fluid mixtures have been given for these two decades, the scaled particle theory[8] proposed by Reiss, Frisch, Lebowitz *et al.* has turned out to be one of the most useful approaches.[9] For hard-sphere fluids the theory gives an identical equation of state with that derived from the Percus-Yevick equation, and at the same time it is intuitive like a usual model theory. It gives a simple and useful method to calculate thermodynamic functions for the creation of cavities in fluids.[10] Then, the authors have applied the theory to aqueous solutions of ions as well as to those of nonpolar molecules such as inert gases and hydrocarbons *etc.*

With respect to the nature of the "negative hydration" an explanation of the effect has been given from theoretical viewpoint in the present paper. Concerning the hydrophobic interactions in aqueous systems a great deal of efforts have been devoted to the elucidation of the interactions until now, though many ambiguities are present among the results of those studies.[3–5,11] In the present paper the experimental data from various sources have been examined by the use of the scaled particle theory, and some detailed discussions have been given in combination with those results including the results of computer experiments.[12]

Calculation of Thermodynamic Functions for the Creation of Cavities

The Scaled Particle Theory. The theory is based on the consideration of the properties of a new distribution function $G(r)$ for a fluid composed of spherical molecules, where "$\rho G(r)$ is defined as the local concentration of molecular centers adjacent to a spherical cavity of radius r from which all molecular centers are excluded."[8] ρ is the number density of the fluid. The key relation of the theory is expressed as

$$G(a) = g(a), \tag{1}$$

where $g(r)$ is the ordinary radial distribution function at a separation r and a is a hard-sphere diameter of molecules. Noting that Eq. 1 is an exact relation for a hard-sphere fluid, Reiss *et al.* derived an approximate analytical expression for $G(r)$, and gave an equation of state for a hard-sphere fluid, which has turned out to be identical with the equation as an analytical solution of the Percus-Yevick equation for the fluid.[8]

The dissolution process of a solute molecule into a solvent can be regarded as consisting of two steps: the first step is "the creation of a cavity in the solvent of a suitable size to accommodate the solute molecule" and the second step is "the introduction into the cavity of a solute molecule which interacts with the solvent," as Pierotti stated.[13] According to the scaled particle theory, the reversible work $W \equiv \overline{G}_c$ for the creation of cavities suitable for the accommodation of solute molecules of a diameter a_2 within a fluid composed of N molecules (diameter a_1) at temperature T and

pressure p becomes

$$\overline{G}_c(a_{12}) \equiv W(a_{12}) = K_0 + K_1 a_{12} + K_2 a_{12}^2 + K_3 a_{12}^3, \quad (2)$$

$$K_0 = NkT\left[-\ln(1-\xi)+\frac{9}{2}\left(\frac{\xi}{1-\xi}\right)^2\right]-\frac{\pi}{6}Na_1^3 p,$$

$$K_1 = -\frac{NkT}{a_1}\left[\frac{6\xi}{1-\xi}+18\left(\frac{\xi}{1-\xi}\right)^2\right]+\pi N a_1^2 p,$$

$$K_2 = \frac{NkT}{a_1^2}\left[\frac{12\xi}{1-\xi}+18\left(\frac{\xi}{1-\xi}\right)^2\right]-2\pi N a_1 p,$$

$$K_3 = \frac{NkT}{a_1^2}\frac{4}{3}\pi N p,$$

where k is the Boltzmann constant, $\xi=\pi a_1^3\rho/6$ the packing fraction in the fluid and $a_{12}=(a_1+a_2)/2$.[14]

The enthalpy $\overline{H}_c(a_{12})$ for the creation of the cavities of the diameter a_2 becomes

$$\overline{H}_c = \alpha NkT^2\{\xi/(1-\xi)\}[\{6/(1-\xi)\}\{2(a_{12}/a_1)^2-(a_{12}/a_1)\} + \{36\xi/(1-\xi)^2\}\{(a_{12}/a_1)^2-(a_{12}/a_1)+1/4\}+1], \quad (3)$$

where α is the thermal expansion coefficient.

From Eqs. 2 and 3 we obtain the entropy for the creation of the cavities as

$$\overline{S}_c = (\overline{H}_c-\overline{G}_c)/T. \quad (4)$$

Equations 3 and 4 show that the magnitudes of $\overline{H}_c$ and $\overline{S}_c$ are determined by the parameters a_1, ξ, and α for the fluid as well as by the size a_2 of the cavities, and also show that the attractive molecular interactions in the fluid exert upon $\overline{H}_c$ and $\overline{S}_c$ through α and ξ implicitly.

Calculation of $\overline{H}_c$ and $\overline{S}_c$ for the Creation of Cavities in Water. As the basis for the discussions about the behaviors of solute molecules in water we have calculated $\overline{H}_c$ and $\overline{S}_c$ according to Eqs. 2—4 using the observed values for α and ρ. In Fig. 1 the values of $\overline{S}_c$ for the creation of a cavity are plotted against the diameter of the cavity a for several temperatures from 0 to 70 °C. In the application of the scaled particle theory the determination of molecular parameters, especially diameters of molecules, is important.

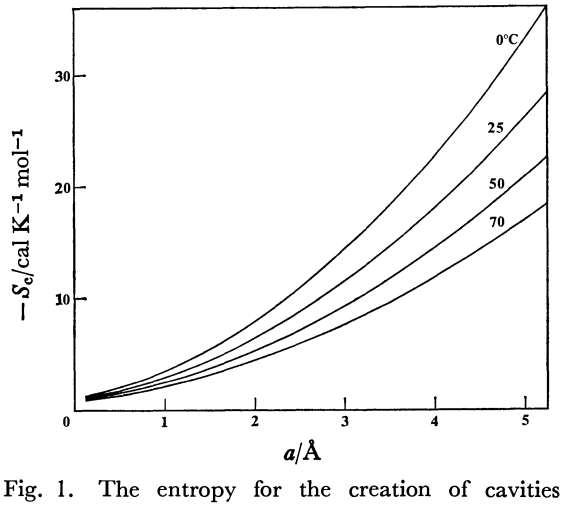

Fig. 1. The entropy for the creation of cavities in water. a: The diameter of the cavities.

The values given in Fig. 1 are those for $a_1=2.82$ Å, where a_1 is the effective hard-core diameter of water molecules.[15] We have calculated those values for another assignment of $a_1=2.75$ Å for comparison, which are given in the tables in later sections. Some deviations are seen, though the deviations have turned out to bring no important influence upon the conclusions in the present paper. The values of $\overline{H}_c$ are also shown in the tables in later sections.

The Nature of Ionic Hydrations: A Consideration from the Entropy of Hydration of Ions

A great deal of efforts have been devoted to make clear the nature of ionic hydrations. However, the results are greatly diversified, as clearly seen in a comprehensive review by Hinton and Amis (1971),[16] many problems being left unsolved for further studies.

Samoilov, Krestov and others proposed a kind of the dynamic model on ionic hydrations,[5,6,17] where the concept of the negative hydration was introduced. However, from the view-point of the statistical theory of fluids no clear explanation of the concept has been given until today. Then, we have attempted here to give an explanation in this section.

The entropy of hydration ΔS_h of ions for the transfer from hypothetical 1 atm in the gas phase to hypothetical 1 M in the aqueous phase is expressed as

$$\Delta S_h = \Delta S_{ideal} + \overline{S}_c + \delta S. \quad (5)$$

In Eq. 5 $\Delta S_{ideal}=R\ln(\overline{V}_2/V_g)$ is the contribution of ions to the entropy of transfer from the state V_g at 1 atm to the state $\overline{V}_2$, where V_g is the molar volume of an ideal gas at the temperature T and $\overline{V}_2$ the volume of the aqueous solution containing 1 mol of ions. $\overline{V}_2$ is 1 dm^3 in this case. $\delta S=\Delta S_h-(\Delta S_{ideal}+\overline{S}_c)$ is an excess entropy, which have been obtained by subtracting the calculated values of $(\Delta S_{ideal}+\overline{S}_c)$ from the experimental values of ΔS_h. δS is ascribed to the contribution caused by the direct ion-water interactions.

The values of ΔS_h, ΔS_{ideal}, $\overline{S}_c$, and δS are given in Table 1. Those determined for $a_{H_2O}=2.75$ Å are given together in the table for comparison, and a certain appreciable differences are seen between the values for $a_{H_2O}=2.82$ Å and those for $a_{H_2O}=2.75$ Å though it does not exert any influences upon the conclusions of the following discussions.

As clearly seen in the table the values of δS for alkali ions larger than K^+ and those for halide ions (Cl^-, Br^-, and I^-) are positive. This supports the idea that these ions exert a structure-breaking action upon the liquid structure of water[5,15] on the whole, which is the so-called "negative hydration" effect of these ions. For alkali ions smaller than K^+ as well as for bivalent and trivalent ions the values of δS become minus, which corresponds to the usual "positive hydration" effect.

In the case of K^+ the values of δS becomes small

Table 1. The entropy of hydration of ions at 25 °C (cal K^{-1} mol^{-1})

The ionic radii of polyvalent ions are those determined by taking the value of 6 for their solvation numbers. b) H. L. Friedman and C. V. Krishnan, "Water," ed by F. Franks, Plenum, New York (1973), Vol. 3, Chap. 1, Table V.

and minus, while Samoilov and others proposed that it behaves as a structure breaker (at 25 °C).[6] This contradiction can not be explained successfully at present. At any rate $|\delta S|$ for K^+ is clearly small. As seen in the table, the transition from the positive to negative hydration behavior for univalent ions occurs at about 1.4 Å of ionic radius, which is nearly identical with the effective hard-sphere radius for water molecules, while Samoilov and others proposed it to occur at about 1.1 Å.[6] The presence of negative hydration effect for univalent ions at room temperature is explained here by the application of the scaled particle theory to the calculation of the entropy for the creation of cavities, with the exception of the case of K^+ which is left to further investigations.

A Consideration on Hydrophobic Interactions in Aqueous Solutions

Solubilities of Nonpolar Gases. Determination of Molecular Parameters: The determination of molecular diameters for nonpolar gases has been performed according to the procedures proposed by Bienkowski and Chao by the application of the Percus-Yevick equation in combination with critical data for those.[18]

The diameter a is calculated from the following equation,

$$\frac{a}{\left(\frac{6}{\pi}\frac{\tilde{V}_c}{\tilde{N}}\right)^{1/3}} = 0.544046 - 0.010218T_r, \quad (6)$$

where $\tilde{V}_c$ is the critical molar volume and T_r the reduced temperature. This equation was derived by applying the Percus-Yevick (PY) equation. The formula derived from Carnahan-Starling (CS) equation also was used by Bienkowski and Chao. The values determined by the use of the PY equation as well as those by the CS equation are given together in Table 2. The differences between these two are clearly small. Then we have used the values of the second column (PY), because the CS equation is essentially a conventional one.

Table 2. Effective hard-sphere diameters (Å)

	a (PY)	a (CS)

A Consideration on Solute-Water Interactions in Comparison with Solute-CCl_4 Interactions: An investigation on the behaviors of nonpolar solute molecules (Table 3) in aqueous environments has been performed by the examination of solubility data from various sources.

The molar entropy and enthalpy of transfer of a solute species from an ideal gas phase at 1 atm to an aqueous solution at an equilibrium concentration x_2, $\overline{S}_2(x_2)-S_2^g$, and ΔH_s, are expressed as

$$\overline{S}_2(x_2)-S_2^g = \Delta S_{ideal} + S_c + \delta S, \quad (7)$$

and

$$\Delta H_s = \overline{H}_c + \delta H + (\alpha RT^2 - RT), \quad (8)^{9)}$$

respectively. ΔS_{ideal} is determined according to the similar procedure to the case of ionic solutions in the preceding section, where the magnitude of $\overline{V}_2(x_2)$, the molar volume of the solution containing 1 mole of solute species at an equilibrium concentration x_2, becomes a function of x_2 in this case, and its magnitude varies in different species being in contrast to the case of ionic hydration as in Table 1. The experimental

values of $\bar{S}_2(x_2)$, ΔH_s, and x_2 have been taken from various sources cited in the footnote of Table 3. The calculated values of the enthalpy and entropy of the creation of cavities, $\bar{H}_c$ and $\bar{S}_c$, are shown in the seventh and ninth columns of the table, respectively, and the excess enthalpy $\delta H=\Delta H_s-(\bar{H}_c+\alpha RT^2-RT)$ and the excess entropy $\delta S=(\bar{S}_2(x_2)-S_2{}^g)-(\Delta S_{ideal}+\bar{S}_c)$ are given in the eighth and tenth colums. In the table the values of $\Delta C_{p,c}$ which are determined from the temperature dependence of $\bar{H}_c$ are given in the eleventh column.

For the purpose of comparing the values of various thermodynamic functions given in Table 3 with those for a nonpolar solvent we have carried out a calculation for the CCl_4 solutions of the same species according to the quite identical procedures described above. The results are given in Table 4.

The features on the whole, which are seen in Tables 3 and 4, are summarized in Table 5 and the temperature dependence of the thermodynamic functions for the creation of cavities is shown in Table 6.

In CCl_4 solutions the negligibly small values of $\bar{S}_c$ suggest that no appreciable perturbation on the liquid structure occurs by the creation of cavities. The enthalpic terms are supposed to be dominant in the solute-solvent interactions in CCl_4 solutions of nonpolar gases. On the contrary the dominant features in aqueous solutions are large minus values of $\bar{S}_c$ and small positive values of $\bar{H}_c$. The greater part of large minus values of $(\bar{S}_2(x_2)-S_2{}^g)_{obsd}$ is attributed to $\bar{S}_c$, and further the small values of $\bar{H}_c$ in sharp contrast to those in CCl_4 solutions are the cause of large minus values of ΔH_s observed. As clearly seen in Table 3, the small values of $\bar{H}_c$ in aqueous solutions comes from

Table 3. The enthalpy (cal mol^{-1}) and entropy (cal K^{-1} mol^{-1}) of transfer of nonpolar solutes from an ideal gas phase at 1 atm to water (25 °C)

the small values of α for water, which is the direct evidence of the presence of some "bulky structure" decreasing with temperature. This is supposed to be closely related to the behavior of $(\partial U/\partial V)_T$ for water in comparison with that for carbon tetrachloride, which is calculated using the following thermodynamical formula

$$\left(\frac{\partial U}{\partial V}\right)_T = \frac{\alpha T}{\beta} - p, \tag{9}$$

where U is the internal energy. The magnitude of $(\partial U/\partial V)_T$ for water at 25 °C is 1500 atm which is smaller than a half of that for CCl_4.

The magnitudes of $\Delta C_{p,c}$ for water are about three times larger than those for CCl_4, and contribute to the greater part of the enormous partial molal heat capacity for aqueous solutions of nonpolar solutes. Then, it may be said that the cause of icebergs formation proposed first by Frank and Evans is attributed to the effect of the large minus $\bar{S}_c$ and the small positive $\overline{H}_c$ for the creation of cavities in water.

The Nature of Hydrophobic Interactions. The hydrophobic interaction is stated as the "tendency of nonpolar groups of proteins to adhere to one another in aqueous environments" according to Kauzmann,[2] and for the case of two methane molecules in water Ben-Naim made an assertion that the quantity $\delta A_M^{HI} = \Delta\mu_E^\circ - 2\Delta\mu_M^\circ$ serves as a useful measure for the hydrophobic interaction in aqueous media where $\Delta\mu_E^\circ$ and $\Delta\mu_M^\circ$ are the standard free energy of solution of ethane and methane, respectively.[11] Recently, Dashevsky and Sarkisov have carried out a Monte-Carlo calculation in order to examine the nature of the hydrophobic interactions of nonpolar molecules in water.[12]

A Measure for Hydrophobic Interactions: Ben-Naim stated that the magnitude of δA_M^{HI} became about −2.15 kcal mol^{-1} at 25 °C when observed values were used for $\Delta\mu_E^\circ$ and $\Delta\mu_M^\circ$. It is certainly stabilized to the amount of about 0.6 kcal mol^{-1} in comparison with that in alcoholic solutions, and then, he asserted that the quantity δA_M^{HI} might serve as a useful index for measuring hydrophobic interactions in water.[11] Further, the recent remarkable results of Monte-Carlo calculations by Dashevsky and Sarkisov have shown that the free energy of hydrophobic attractions between two methane molecules in 62 water molecules becomes about −2 kcal mol^{-1},[12] and this supports the idea of Ben-Naim that $\delta A_M^{HI} = \Delta\mu_E^\circ - 2\Delta\mu_M^\circ$ is useful as a relative measure for hydrophobic interactions between two methane molecules in aqueous environments. However, it is not exact to assert directly, as Ben-Naim stated, that "the excess attraction, in water, helps the two particles to approach each other in spite of the thermal energy,"[11] since in aqueous solutions of methane under ordinary conditions the dimerization of two methane molecules does not occur. The reason for that will be explained in the next section.

As a result of the present calculation, the free energy for hydrophobic interactions between two methane molecules in aqueous environments, ΔG^{HI}, is expressed as a sum of three terms, except the effect of the mixing entropy term which will be introduced later.

$$\Delta G^{HI} = \Delta\overline{G}_c^{HI} + \Delta(\delta H)^{HI} + \overline{U}_{CH_4-CH_4}, \tag{10}$$

where $\Delta\overline{G}_c^{HI}$ is the contribution from the cavity effect, $\Delta(\delta H)^{HI}$ that from solute-water interactions, and $U_{CH_4-CH_4}$ the direct solute-solute interactions. $\Delta\overline{G}_c^{HI} = \Delta\overline{H}_c^{HI} - T\Delta\bar{S}_c^{HI}$, where $\Delta\bar{S}_c^{HI}$ and $\Delta\overline{H}_c^{HI}$ are expressed as $\Delta\bar{S}_c^{HI} = \bar{S}_{c,C_2H_6} - 2\bar{S}_{c,CH_4}$ and $\Delta\overline{H}_c^{HI} = \overline{H}_{c,C_2H_6} - 2\overline{H}_{c,CH_4}$, respectively. The valuse of $\Delta\bar{S}_c^{HI}$ and $\Delta\overline{H}_c^{HI}$ are 11.1 cal K^{-1} mol^{-1} and −650 cal mol^{-1}, respectively. Then, $\Delta\overline{G}_c^{HI}$ becomes −3960 cal mol^{-1}. The magnitude of $\Delta(\delta H)^{HI} = \delta H_{C_2H_6} - 2\delta H_{CH_4}$ becomes 2220 cal mol^{-1} using the values given in Table 3. The values of $\overline{U}_{CH_4-CH_4}$ is about 300 cal mol^{-1} according to the calculation by Dashevsky and Sarkisov.[12] Thus, the magnitude of ΔG^{HI} at 25 °C becomes about −2 kcal mol^{-1}. This agrees to the estimation by Dashevsky and Sarkisov using the Monte-Carlo method as well as to that by Ben-Naim. It is noticeable that the largest minus contribution to ΔG^{HI} comes from $\Delta\overline{G}_c^{HI}$ and, further, essencially from $\Delta\bar{S}_c^{HI}$.

The Effect of the Change of Mixing Entropy by Hydrophobic Association: According to the result of the Monte-

Carlo calculation by Dashevsky and Sarkisov two methane molecules in 62 water molecules have a trend to associate and the free energy of the methane-methane pair in water becomes about -2 kcal mol^{-1}. Then, the association occurs actually in their simulation. However, in the aqueous solutions of methane being in equilibrium with methane gas at 1 atm no association of solute molecules occurs. The different behavior of methane molecules in these two cases is ascribed to the difference in the concentration of solute particles: in the former case the mole fraction of methane x is about 3×10^{-2} and in the latter x is of the order of 10^{-5}. In order to estimate the effect of concentration thermodynamically we must consider the mixing entropy.

The entropy of mixing for an ideal solution is expressed as

$$\Delta S_{\mathrm{mix}}(x) = -R\{x\ln x+(1-x)\ln(1-x)\}. \quad (11)$$

When all solute molecules are present as dimers, $\Delta S_{\mathrm{mix}}(x)$ varies to $\Delta S_{\mathrm{mix}}(x/2)$, and then the difference $\delta(\Delta S_{\mathrm{mix}})$ becomes

$$\begin{aligned}\delta(\Delta S_{\mathrm{mix}}) &= \Delta S_{\mathrm{mix}}(x/2) - \Delta S_{\mathrm{mix}}(x)\\ &= R\{(x/2)\ln(2x)+(1-x)\ln(1-x)\\ &\quad -(1-x/2)\ln(1-x/2)\}. \quad (12)\end{aligned}$$

In the case of $x\ll1$, $\delta(\Delta S_{\mathrm{mix}})$ becomes, to the order of x^2,

$$\delta(\Delta S_{\mathrm{mix}}) = R\left\{\frac{x}{2}(\ln(2x)-1)+\frac{3}{8}x^2\right\}. \quad (14)$$

For nonpolar molecules such as those tabulated in Table 3 the magnitudes of x are very small and of the order of 10^{-5}, and the change of the mixing entropy per mole of solute molecules by dimerization is safely expressed as $\delta(\Delta S_{\mathrm{mix}})/x=1.15\log x-0.15$ according to Eq.14. For methane x is 2.48×10^{-5} and the value becomes -10.9 cal K^{-1} mol^{-1}. That is, if a dimerization $2(CH_4)\rightarrow(CH_4)_2$ would occur in aqueous solutions of methane at equilibrium with methane gas (1 atm), the change of the mixing entropy per mole of solute species amounts to -10.9 cal K^{-1} mol^{-1}. This contributes to the free energy for the formation of methane-methane pairs in water to about $+3$ kcal mol^{-1} at 25 °C and its total amount becomes positive, and thus, the dimerization can not occur. In the case of Dashevsky and Sarkisov's simulation, x is about 3×10^{-2} and the magnitude becomes -3.8 cal K^{-1} mol^{-1}, and the contribution to free energy is about 1.1 kcal mol^{-1}. Thus, the total amount of free energy remains negative and the dimerization occurs.

As a result of the consideration described above, we can say conclusively as follows:

a) methane molecules (or methyl groups) certainly have a tendency to adhere to one another in aqueous environments, its magnitude being expressed by ΔG^{HI} (authors) or δA^{HI} (Ben-Naim),

b) the largest minus contribution to ΔG^{HI} comes from the cavity effect $\Delta\bar{S}_c^{\mathrm{HI}}$,

c) in the aqueous solutions of methane at ordinary conditions the association of solute molecules does not occur, because the decrease of the mixing entropy fully cancels out the entropy ascribed to the cavity effect,

d) in more concentrated solutions ($x\gtrsim0.01$), for example, in the aqueous solutions of proteins where the local concentration of hydrophobic groups becomes larger to the order of $x\simeq0.01$ or more, the decrease of the mixing entropy becomes smaller in magnitude than the entropy from the cavity effect, and then the tendency to adhere to one another appears actually. This may be also the case for the formation of micelles.

Calculations of the Rate Constants for the HX+NO ⇌ HNO+X Reactions (X=H, F, Cl, Br, and I)

Tetsuo HIGASHIHARA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received February 9, 1979)

The rate constants for these hydrogen-transfer reactions:

$$HX+NO \rightleftharpoons HNO+X \quad (X=H, F, Cl, Br, \text{and } I)$$

have been calculated by means of the transition-state theory combined with the BEBO method over the temperature range of 250—4000 K. The calculated rate constants were then compared with the experimental kinetic data.

There have been many attempts to estimate the rate constants theoretically for bimolecular reactions; these attempts have been, for example, collision theories, the transition-state theory combined with the BEBO or LEPS method, trajectory calculation, and so on. Although the bond energy-bond order (BEBO) method is an empirical one, this method has many advantages: calculations are easy, there are no parameters which need to be adjusted for each reaction, and the predicted activation energies are generally in good agreement with the experimental kinetic data.

In this study, in order to clarify the effect of the difference in X on the rate constants for these reactions:

$$HX + NO \rightleftharpoons HNO + X \quad (X=H, F, Cl, Br, \text{and } I),$$

the rate constants for these reactions were calculated by using the transition-state theory combined with the BEBO method. The rate constants for these reactions:

$$H_2 + NO \longrightarrow HNO + H \quad (1)$$

$$HCl + NO \longrightarrow HNO + Cl \quad (3)$$

$$HBr + NO \longrightarrow HNO + Br \quad (4)$$

$$HI + NO \longrightarrow HNO + I \quad (5)$$

have been determined by Ando and Asaba[1] for Reaction 1 in shock waves, by Higashihara *et al.*[2,3] for Reactions 3 and 4 in shock waves, and by Holmes[4] for Reaction 5 in a static system. The rate constant of Reaction −1:

$$H + HNO \longrightarrow H_2 + NO \quad (-1)$$

has also been determined by several groups[5] by using various experimental methods over a wide temperature range. Although many kinetic data have thus been accumulated, there have been no theoretical studies for these reactions. Therefore, it is also interesting to try to explain these kinetic data consistently with a theory.

Calculations

The following linear three-atom model was used for the calculations of the BEBO potential energy curve:

The detailed procedures of calculations were summarized by Johnston (Ref. 6b, p. 339). It should, however, be noted that the following two points were modified in this calculation. First, the new Pauling constant, 0.28, which was evaluated by Gillion,[7] was used instead of 0.26 in Eq. I:

$$r = r_s - 0.28 \ln m \text{ (or } n), \quad \text{(I)}$$

where the subscript s denotes the length of a single bond and where m (or n) is the bond order of H–N (or X–H). Second, the new f value, 0.45,[7] in the Sato anti-Morse function (Eq. II) was used instead of 0.25:

$$V_{tr} = f\{D_e(1+e^{-\beta(r-r_s)})^2 - 1\}, \quad \text{(II)}$$

where β is the Morse parameter. All the molecular parameters necessary for the calculations are sum-

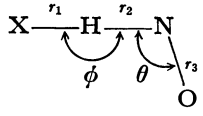
a) 10^{120} (g cm)^3.

marized in Table 1. The bond-order index (p or q) was calculated from this equation:

$$p(\text{or } q)=0.28 \ln (D_e/D_x)/(r_x-r_s), \quad \text{(III)}$$

where D_x and r_x are the bond strength and the length of the corresponding noble gas molecule respectively. The BEBO properties of the activated complexes calculated by using this model are summarized in Table 2. In the case of the HI–NO reaction, the maximum value of the potential energy did not exist. In this case, the distance of H–I in the activated complex was assumed to be the same as the He–Kr Lennard-Johnes internuclear distance, and from this distance the bond orders, m and n, were calculated.

The vibrational frequencies of the activated complexes were calculated according to the method of the ***GF*** matrix by using the following model:



As is shown in Table 2, the bond order of H–N (m) in the activated complex is nearly unity in all cases. This means that the bond angle of H–N–O and the bond length of N–O in the complex may be nearly the same as those of the HNO molecule. Then, $\theta=108.5°$ and $r_3=1.211$ Å, values which are the same as those of the HNO molecule, were assumed. The **G** matrix was constructed according to this model from Table, 7-4 of Ref. 8 (p. 135). The force constants used for each activated complex are listed in Table 3. The values of F_{33} and F_θ in this table are the same as those used by Brown and Pimentel[9] in the calculations of the vibrational frequencies of the HNO molecule.[10] The values of F_{11}, F_{22}, F_{12}, and F_ϕ were calculated by means of the three-atom BEBO method according to the procedures of Ref. 6b. The rest of the interaction force constants were assumed to be 0. The calculated vibrational frequencies are listed in Table 3 for each activated complex. In this table, the moments of inertia, I, of the activated complex and the activation energies, E_0 of the forward and backward reactions are also listed for each activated complex. Though the bending-force constant of H–N–O in the activated complex was assumed to be the same as that of the HNO molecule, this force constant might be appreciably affected by X. Therefore, the vibrational analysis was also carried out using a value one-half the normal F_θ value. The results of the calculations shown in the parentheses of Table 3 indicate that the change in the value of F_θ does not affect the vibrational frequencies very much.

Table 2. Properties of activated complexes calculated from the three-atom BEBO model

	n	m	r_1 / Å	r_2 / Å	V^{*} a) / kcal mol^{-1}
H-H-NO	0.028	0.972	1.741	1.071	56.89
F-H-NO	0.019	0.981	2.030	1.068	88.1

Br-H-NO	0.002	0.998	3.160	1.064	36.77
I-H-NO	0.0004	0.9996	3.8	1.063	20.16

a) V^* is the maximum value of the potential energy.

The rate constants were calculated according to this familiar expression from the transition-state theory:

$$k=(kT/h)(Q^*/Q_{\text{react.}}) \exp(-E_0/RT), \quad \text{(IV)}$$

where Q^* and $Q_{\text{react.}}$ are the partition functions of the activated complex and the reactants respectively and where E_0 is the theoretical activation energy.

Furthermore, the rate constants of Reactions 1, 2, 3, 4, and 5 were calculated by using the simple collision theory to check the reliability of the observed kinetic data. The molecular diameters of the reactants

and the calculated rate constants are listed in Table 4. The last column of this table shows the steric factor which was obtained from a comparison of the calculated rate constant with the experimental one at the middle temperature of each experiment. The steric factor of Reaction 2 was determined by comparison with the calculated value by using the transition-state theory combined with the BEBO method, since there are no rate data for this reaction. In general, the steric factors for abstraction reactions lie in the 0.01—0.1 range. As is shown in Table 4, the steric factors for these reactions (except for that for Reaction 5) lie in this range; this fact indicates that the observed rate constants are reasonable.

Discussion

As is shown in Table 2, in all the activated complexes the bond order of H–N (m) is very large compared with that of X–H (n). This trend is always observed in the cases of large endothermic or exthothermic reactions, it can be ascribed to the large contribution of the bonding term compared with that of the repulsive one. The bond order, n, gradually decreased as X changed from F to I because of the decrease in the triplet repulsion energy.

Figure 1 compares the calculated rate constants with the experimental ones for Reaction 3. The rate constants were calculated by using two different values of F_θ, since one can not precisely estimate the effect of the X–H bond in the activated complex on the value of F_θ. The solid and dash-dot lines in Fig. 1 show the rate constants calculated by using values of $F_\theta=0.52\times10^{-8}$ and $F_\theta=0.26\times10^{-8}$ N/Å respectively. Thus, the calculated rate constants were not sensitive to the values of F_θ. The circles in this figure are the rate constants determined by Higashihara *et al.*[2] and are compatible with the theoretical values.

Figure 2 compares the experimental rate constants (broken lines) with the theoretical ones (solid lines) for Reactions 1, 4, and 5. The experimental con-

ditions and techniques for the data cited in this figure are summarized in Table 5. Unfortunately, there are no rate data for Reaction 2: HF+NO→HNO+F. For Reactions 1 and 4, the agreement between the experiment and theory seems to be reasonable in the temperature ranges within which experiments were carried out. The calculated rate constant for Reaction 5 is greater by about two orders in magnitude than that observed. This is the only example of a large difference between the experimental and theoretical rate constants.

As is listed in Table 5, there are many data for Reaction −1 obtained over the wide temperature range from room temperature to 2177 K by using various experimental techniques. Therefore, this reaction is very suitable for use in testing the application of the BEBO method to the group of reactions considered here. Baulch *et al.*[12] recommended in their data book a value of $k=4.8\times10^{12}\ cm^3\ mol^{-1}\ s^{-1}$ at 2000 K based on the data of Halstead and Jenkin.[5e] At room temperature they suggested that a value of $k\geqq3\times10^{10}\ cm^3\ mol^{-1}\ s^{-1}$ determined by Clyne and Thrush[5a] was likely. Recently, Ando and Asaba[1] determined the rate constant for the $H_2+NO\rightarrow HNO+H$ reaction at 3000 and 3500 K by using a shock-tube method. By combining their value of the rate constant with the equilibrium constant, the rate constant of Reaction −1 can be calculated. The value thus obtained is about one order larger than that recommended by Baulch *et al.* More recently, Washida *et al.*[5g] determined the lower limit for this reaction at room temperature as $k\geqq9.63\times10^{11}\ cm^3\ mol^{-1}\ s^{-1}$ by a method combining a photoionization mass spectrometer with a dischargeflow system. This value is also larger (by more than one order) than that of Clyne and Thrush. Thus, recent studies suggest that this reaction is very fast. Figure 3 shows a comparison of the experimental rate constants (broken lines and circles) with the theoretical ones (solid and dash-dot lines). It may be found from Fig. 3 that the theoretical rate constants are consistent with the recent rate data.

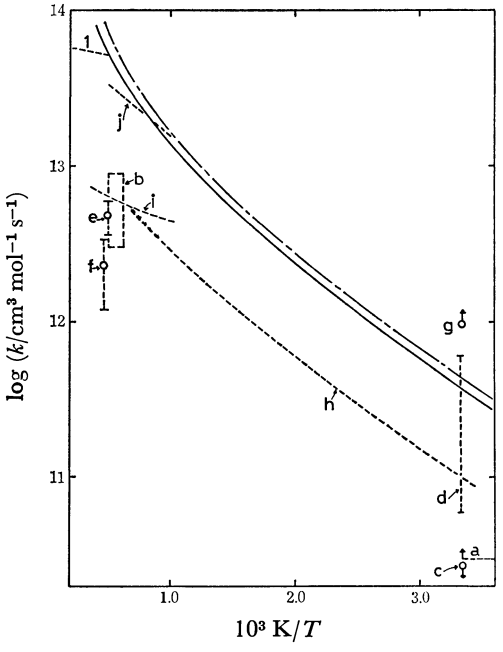

Fig. 3. Comparisons of the calculated rate constants (solid ($F_\theta=0.25\times10^{-8}$ N/Å) and dash-dot ($F_\theta=0.26\times10^{-8}$ N/Å) lines) with the experimental ones for the reaction $H+HNO\rightarrow H_2+NO$. The letters a—j and the number 1 represent the referencies indicated in Table 5.

There is a possibility of tunneling in the cases of hydrogen-transfer reactions at temperatures lower than 1000 K. Therefore, tunneling correction was considered for this reaction. If $u^*\leqq\pi$, where $u^*=h\nu_i/KT$, and $\pi V^*/h\nu_i>1$, where V^* is the maximum value of the potential energy, an approximate tunneling correction[6b] (this is generally known as a high-temperature approximation) is sufficient and the correction factor is given by

$$\Gamma^*_{\text{tt}}=0.5u^*/\sin(0.5u^*).$$

The value of Γ^*_{tt} for this reaction was calculated

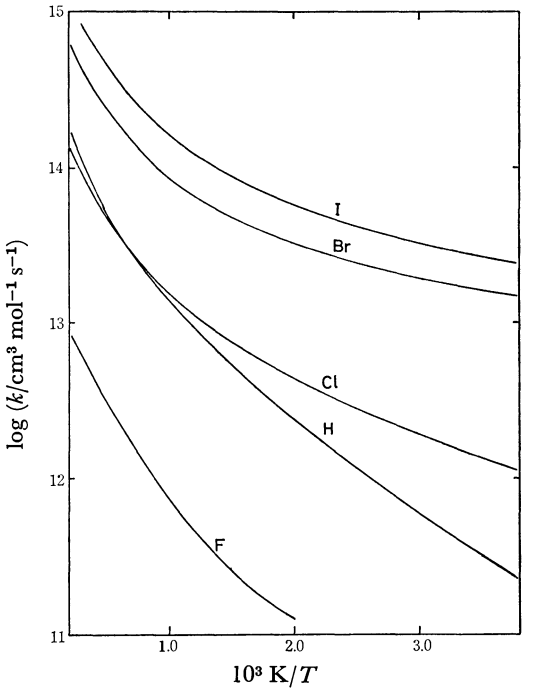

Fig. 4. Calculated rate constants for the reactions X+HNO→HX+NO.

to be 1.04 at 250 K. Thus, this effect was negligibly small and was not taken into account thereafter. Figure 4 shows the calculated rate constants for Reactions −1, −2, −3, −4, and −5. There are no rate data for any of these reactions except Reaction −1.

As is shown in Figs. 2 and 4, the rate constants for both the forward (Reactions 1, 2, 3, 4, and 5) and backward (Reactions −1, −2, −3, −4, and −5) reactions become larger as X changes from F to I. For the forward reactions, this trend may be attributed to two reasons. First, the activation energy becomes smaller as X changes from F to I. Second, as is shown in Table 3, the partition functions of the activated complexes, especially those of the rotation and X–H–N bending modes, become much larger as X changes from F to I, but those for the reactants do not change so much. On the other hand, for the backward reactions the activation energies do not differ very much. Therefore, the trend is mainly a result of the difference in the partition functions of the activated complexes, and is the reverse of that for the $X+H_2 \rightarrow HX+H$ reactions,[6a] in which the rate constant becomes smaller as X changes from F to I, mainly because of the difference in the activation energy.

Conclusion

1. The rate constants determined experimentally for the HX+NO⇄HNO+X reactions were in fair agreement with those predicted by the transition-state theory combined with the BEBO method. Thus, the rate constants for analogous reactions may reasonably be calculated by this method.

2. For the temperature dependence, some difference between the experiment and theory exist. Apparently, more experimental data over a wide temperature range are necessary for all the reactions.

The author wishes to thank Assistant Professor Ichiro Murakami and Dr. Ko Saito for their helpful discussions and guidance throughout this work. He also acknowledges the helpful discussions of Mr. Keijiro Taga and Miss Michiko Miura with respect to the vibrational analysis.

Electrical Properties and Constitution of Several Low-resistivity Iodine Complexes

Susumu Doi, Akiyoshi Fujita, Shigeo Ikeura, Tamotsu Inabe, and Yoshio Matsunaga*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 13, 1979)

The electrical resistivity and Seebeck coefficient of the iodine complexes with eight aromatic compounds were examined as functions of the composition and the temperature. The formation of complexes is indicated by maxima or shoulders in the resistivity-composition isotherms at the following compositions: (anthanthrene)$_2$I$_9$, (6,12-dioxoanthanthrene)I$_2$, (6,12-dioxoanthanthrene)I$_3$, (pyranthrene)I$_3$, (violanthrene)$_2$I$_7$, (phthalocyanine)I$_2$, (phthalocyanine)I$_5$, (phenoxazine)$_2$I$_3$, (pyridazine)$_5$I$_9$, and (*N*,*N*′-diphenyl-*p*-phenylenediamine)$_5$I$_{13}$. Furthermore, some sharp resistivity minima are considered as evidence of the complex formation: *e.g.*, (6,12)-dioxoanthanthrene)$_2$I$_3$ and (phthalocyanine)$_2$I$_3$. On the basis of these compositions, a nonintegral formal oxidation state for the organic molecules and the presence of iodine as triiodide or higher polyiodide ions are established for most of the complexes.

In an earlier report from this laboratory, it was demonstrated that the careful examination of the electrical properties as functions of the composition is a powerful tool for elucidating the constitution of semiconducting thiazine–iodine complexes.[1] For example, the resistivity-composition isotherm of the phenothiazine–iodine system shows a shoulder as high as 800 Ω cm at a composition of two molecules of the thiazine to five atoms of iodine and also a minimum as low as 20 Ω cm at a composition of one molecule to three atoms. Moreover, a decrease in the activation energy for semiconduction by a factor of a half and a change in the sign of the Seebeck coefficient from negative to positive can be observed at the former composition. The similarity in vibrational spectrum between the iodine complex and the complex cation radical bromide of the 2 : 1 type, together with the above-mentioned electrical features, led us to propose the formation of a complex cation radical pentaiodide, $(C_{12}H_9NS)_2^+I_5^-$. The complex deposited from solutions is of a mole ratio of 2:3 and deviates as much as a half mole of iodine from this composition. There is no doubt that this amount of extra iodine plays an important role in the occurrence of the unusually low electrical resistivity. In the present paper, we wish to summarize the results of analogous studies on the iodine complexes with the following eight aromatic compounds: anthanthrene (dibenzo[*def*, *mno*]chrysene), 6,12-dioxoanthanthrene, pyranthrene, violanthrene, 29*H*,31*H*-phthalocyanine, phenoxazine, pyridazine, and *N*,*N*′-diphenyl-*p*-phenylenediamine (see the structural formulas given in Fig. 1). The composition ranges examined here were limited mostly by the thermodynamic instability of the iodine-rich complexes. Nevertheless, we believe that our study could cover the low-resistivity complexes in which we were interested.

Before presenting the results, we wish to review briefly the electrical behavior of mixtures. If two coexisting phases are strictly stoichiometric and mechanically mixed without interaction, the logarithmic mixing rule may apply for the resistivity. The composition of a distinct complex may correspond to a minimum in the resistivity-composition isotherm if its resistivity is lower than those of the neighboring

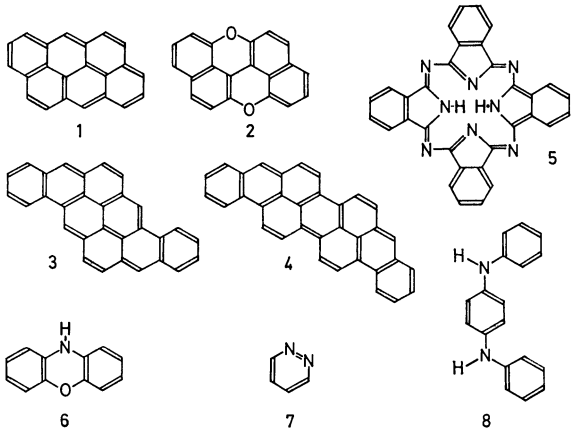

Fig. 1. Structural formulas of the organic component compounds; 1) anthanthrene, 2) 6,12-dixoanthanthrene, 3) pyranthrene, 4) violanthrene, 5) 29*H*,31*H*-phthalocyanine, 6) phenoxazine, 7) pyridazine, and 8) *N*,*N*′-diphenyl-*p*-phenylenediamine.

complexes, or a maximum if its resistivity is higher. On the other hand, the behavior may depend quite differently upon the composition, when the incorporation of a marked stoichiometric imbalance is conceivable for a given phase. As additional carriers are introduced by the imbalance, the stoichiometric composition of a low-resistivity complex may be indicated by a sharp maximum rather than a minimum in the isotherm. In such a case, the nearby minima may be considered to be indicative of the lower and upper limits of the deviation from stoichiometry. When the maximum is too low to be detected, the appearance of a rather broad minimum covering the stoichiometric composition may be expected. Therefore, the formation of complexes can be undoubtedly established by maxima appearing in the resistivity-composition isotherm but not necessarily by minima.

Experimental

Materials. The anthanthrene obtained commercially was reduced to the hydrocarbon by the zinc-dust fusion method.[2] Anthanthrene thus prepared was purified by repeated sublimation in a vacuum. 6,12-Dioxoanthanthrene was synthesized starting from 2,2′-binaphthol, as described

by Pummerer *et al.*[3] Pyranthrene was obtained by the reduction of commercial pyranthrone with zinc dust, pyridine, and acetic acid.[4] By vacuum sublimation through a thin layer of activated alumina the hydrocarbon became orange colored. The violanthrene, supplied some twenty years ago by Prof. Junji Aoki, now of Toho University, was purified by sublimation in a vacuum. Phthalocyanine, pyridazine, and *N,N'*-diphenyl-*p*-phenylenediamine employed in the present work were commercial products. The diamine was recrystallized from ethanol. Phenoxazine was prepared by the condensation of *o*-aminophenol in the presence of iodine.[5] All the iodine complexes, unless otherwise stated, were obtained by careful grinding of the weighed organic compound or complex of a known composition and iodine in an agate mortar in the presence of a small amount of benzene. The phthalocyanine complexes were made by boiling a benzene solution of iodine with powdered phthalocyanine. The iodine contents were determined by microanalysis.

Measurements. The electrical resistivities and Seebeck coefficients of polycrystalline compactions were recorded as functions of the temperature.[1]

Results and Discussion

Anthanthrene–Iodine. As early as 1939, Brass and Clar reported the isolation of the triiodide from a benzene solution;[6] however, no attention has been paid to the electrical properties. In Fig. 2, the electrical resistivity values at 20 °C are plotted against the number of iodine atoms per anthanthrene molecule, *n*. The shaded circles indicate that the samples were treated with a boiling benzene solution of iodine. They might therefore be more homogeneous than those indicated by open circles. There are a maximum of about 20 Ω cm at $n=4.5$ and minima of about 7 Ω cm near $n=4$ and 5 in the resistivity-composition isotherm. This behavior appears to be indicative of the nonstoichiometric nature of the complex. The formation of $(\text{anthanthrene})_2{}^+\text{I}_9{}^-$ may be deduced from the location of the maximum. The incorporation of an excess of either the hydrocarbon or iodine of as much as a half mole into this complex appreciably decreases the resistivity. It must be added that no anomalous features were noted at the composition reported by Brass and Clar, namely $n=3$. The temperature dependence of the resistivity, ρ, follows the typical semiconductor behavior: $\rho=\rho_0\exp(E/kT)$. The values of the activation energy for semiconduction, E, near room temperature are mostly in the range from 0.05 and 0.07 eV. No abrupt change could be detected even at the composition of the resistivity maximum.

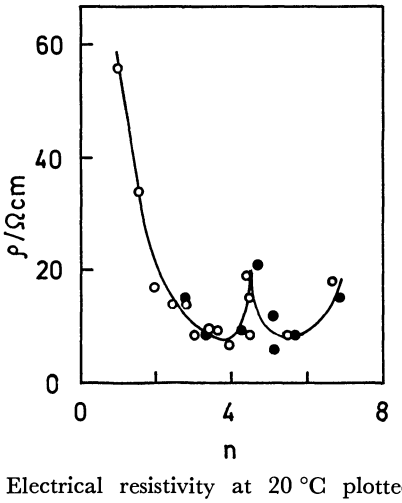

Fig. 2. Electrical resistivity at 20 °C plotted against the iodine content in the anthanthrene-iodine system. The shaded circles indicate that these samples were treated with a boiling benzene solution of iodine.

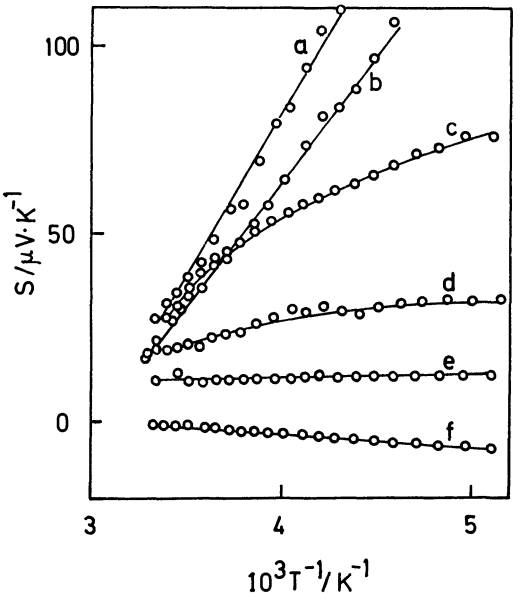

Fig. 3. Seebeck coefficient of the anthanthrene-iodine complexes; a) $n=1.51$, b) 3.70, c) 4.23, d) 4.41, e) 5.07, and f) 6.68.

The variation of the Seebeck coefficient, S, with the reciprocal temperature for six representative samples is illustrated in Fig. 3. Among them, samples b, c, and e are those indicated by shaded circles in Fig. 2. The variation depends markedly upon the composition. At $n=1.5$, a linear relationship with the reciprocal temperature is observed over the whole range (see Curve a). The positive slope may indicate that the contribution of holes to the conduction is larger than that of electrons. By the incorporation of additional iodine the slope in the low-temperature range becomes more gentle. As is shown by Curves c and d, such a tendency is especially large when the composition is close to the above-mentioned complex. The coefficient becomes essentially independent of the temperature near $n=5$ and then changes not only its sign but also the sign of the slope (see Curves e and f). These observations may imply that the ratio of the electron mobility to the hole mobility is nearly unity in the phase of $(\text{anthanthrene})_2\text{I}_9$. The Seebeck coefficient at −23 °C is plotted against n in Fig. 4. The values are rather scattered; nevertheless, it is evident that the coefficient decreases almost linearly with n and becomes zero near $n=6$. As is readily understood from Fig. 3, this slope and the composition where the coefficient changes its sign is not independent of the temperature.

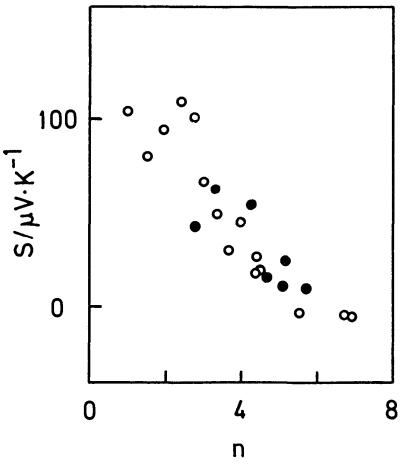

Fig. 4. Seebeck coefficient at −23 °C plotted against the iodine content in the anthanthrene–iodine system. As to the shaded circles, see the caption of Fig. 2.

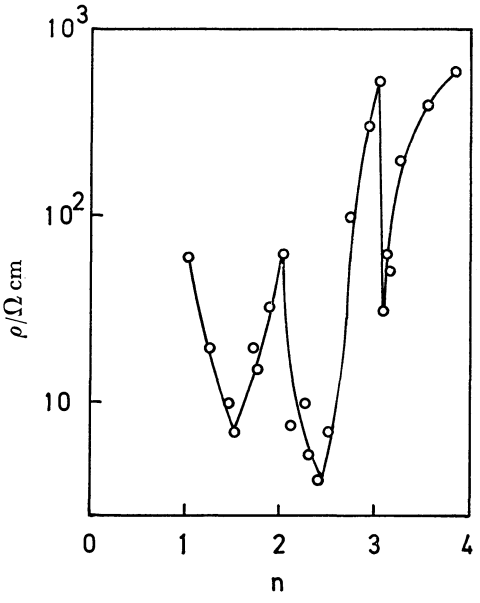
6,12-Dioxoanthanthrene–Iodine. This compound has the same framework as anthanthrene and has been reported to form a monoiodide by Brass and Clar.[6] The introduction of two oxygen atoms into the framework gives rise to significant localization of the electrons in the highest occupied level, as revealed by a decrease in the total span of the ESR spectrum.[7] In view of these facts, it seemed to be of interest to compare the formation of iodine complexes of these two component compounds.

As is shown in Fig. 5, the resistivity is far more sensitive to the composition than that in the anthanthrene–iodine system. Note that the scale on the ordinate is logarithmic. One maximum with a resistivity of about 60 Ω cm, is located at $n=2$ and the other one at $n=3$. The latter is about tenfold higher than the former. As the ionization potential is known to be close to that of anthanthrene,[7] the formation of cation radical salts is more likely than the formation of molecular adducts. Therefore, the products corresponding to these n values may be (6,12-dioxoanthanthrene)$_3^{2+}(I_3^-)_2$ and (6,12-dioxoanthanthrene)$^+I_3^-$. Thus, the compound differs considerably from anthanthrene in the behavior of iodine complex formation. It is not clear to what extent the former compound is nonstoichiometric. The sharp minima located at $n=1.5$ and 2.5 might be an indication of the formation of (6,12-dioxoanthanthrene)$_2^+I_3^-$ and (6,12-dioxoanthanthrene)$_2^+I_5^-$. The minimum appearing a little above $n=3$ may be due to the nonstoichiometry of the phase at $n=3$. The effect of an excess of the component on the resistivity is so pronounced that the ratio of the value at $n=3$ to that at the last minimum is more than ten. The activation energy for semiconduction in the range from $n=1$ to 3 is 0.08—0.12 eV. At higher iodine contents, a gradual increase is found, reaching almost 0.2 eV by $n=4$.



Fih. 5. Electrical resistivity at 20 °C plotted against the iodine content in the 6,12-dioxoanthanthrene–iodine system.

The Seebeck coefficient of this system is independent of the temperature up to $n=2$. The coefficient is as much as +220 μV K^{-1} at $n=1$ and is reduced by a factor of a half by $n=1.5$ and further by the same factor by $n=2$. Above this composition, a positive slope is noted in the plot of S against the reciprocal temperature. The slope becomes steeper as n increases; therefore, the room temperature value changes its sign near $n=3.5$ and is −40 μV K^{-1} at $n=4.9$, which is the highest iodine content examined. In this system, holes appear to be the major carriers in the whole composition range.

Pyranthrene–Iodine. This hydrocarbon is known to form black complexes with bromine and iodine.[8,9] The ESR absorption and the electrical resistivity of the iodine complex were reported for a composition of $n=4$.[9,10] The resistivity-composition isotherm at room temperature is presented in Fig. 6. The presence of a maximum of 35 Ω cm at $n=3$ and minima at $n=2.5$ and 3.5 is clearly noted; therefore, the formation of a simple cation radical triiodide, (pyranthrene)$^+I_3^-$, is feasible. We failed to obtain samples with $n>4$. The activation energy for semiconduction is about 0.06 eV throughout the examined composition range.

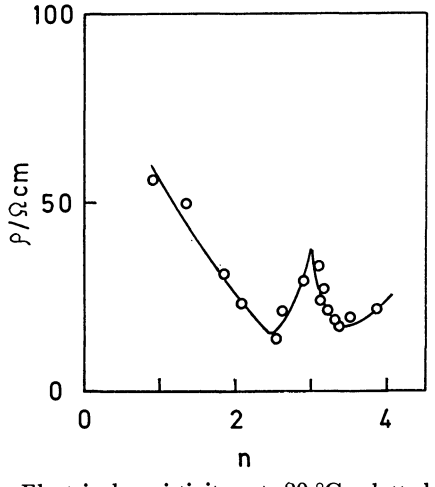


Fig. 6. Electrical resistivity at 20 °C plotted against the iodine content in the pyranthrene–iodine system.

The Seebeck coefficients at room temperature are scattered in a narrow range of +5 to +10 $\mu V\ K^{-1}$ and decrease linearly with the reciprocal temperature at all the compositions. Although the slope tends to be steeper and negative values are observed at low temperatures when n is small, the dependence on the composition is not large enough to find out the correlation between S and n at any temperature.

Violanthrene–Iodine. The formation of the bromine and iodine complexes was described in 1955.[11] The latter is very stable and is one of the halogen complexes most extensively studied in those days. The diamagnetic susceptibility of the violanthrene–iodine system was shown to vary linearly with the halogen content, but the value was found to be markedly less than the one estimated by the application of the additivity rule. The deviation reaches its maximum at $n=4$.[11] The ESR study made later revealed the presence of just enough unpaired electrons to account for the observed deviation.[9] The resistivity-composition isotherm published in 1956 has a broad minimum around $n=4$, the value at this composition being 40 Ω cm.[8] The complex was concluded to be nonstoichiometric on the basis of the equilibrium concentration of iodine in carbon tetrachloride, examined as a function of the composition of the solid complex.[12] No sharp peak was observed in the X-ray diffraction pattern of the samples with $n\simeq4$, suggesting that they are amorphous.[12]

Figure 7 presents the newly-determined resistivity-composition isotherm at room temperature. The shaded circles indicate that these samples were prepared by the treatment of the powdered hydrocarbon with a boiling benzene solution of iodine. This is the method in the previous work for the preparation of a complex.[8,11,12] Contrary to the diagram reported earlier, a maximum can be located at $n=3.5$ and minima around $n=3$ and 4. The observed feature is consistent with the reported nonstoichiometry; the idealized composition may be expressed by the formula (violanthrene)$_2^+I_7^-$. The upper limit of the homogeneity range of this complex is probably near $n=4$. The

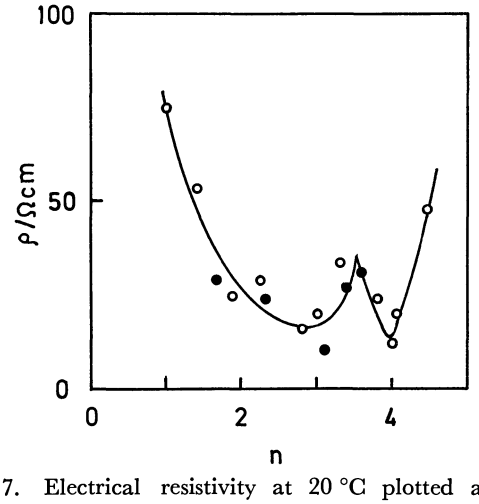

Fig. 7. Electrical resistivity at 20 °C plotted against the iodine content in the violanthrene–iodine system. The shaded circles indicate that these samples were prepared in a boiling benzene solution of iodine.

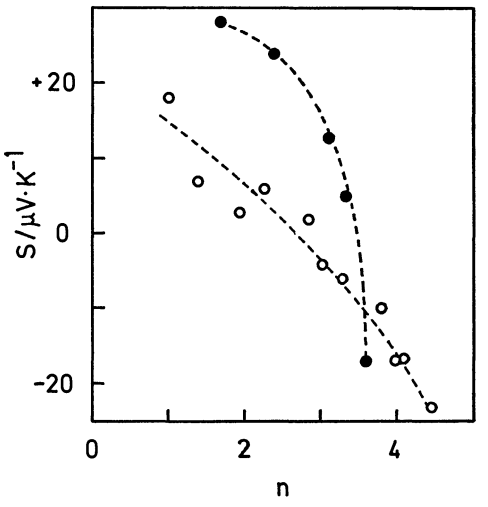

Fig. 8. Seebeck coefficient at 20 °C plotted against the iodine content in the violanthrene–iodine system. As to the shaded circles, see the caption of Fig. 7.

activation energies for semiconduction were scattered in a range from 0.08 to 0.12 eV and the correlation with the composition could not be established.

As is shown in Fig. 8, the room-temperature value of the Seebeck coefficient is positive at $n=1$ and decreases as the iodine content increases. In contrast to the electrical resistivity, the Seebeck coefficient of this system is significantly affected by the method of sample preparation. The open circles and shaded circles are clearly on different curves. The change of the sign occurs below $n=3$ for the samples indicated by open circles, while almost at $n=3.5$ for the samples indicated by shaded circles. When the coefficient is plotted against the reciprocal temperature, the slope in the high-temperature region is negative throughout the examined composition range and becomes more gentle as the iodine content increases. The value tends to saturate at low temperatures. This tendency is observed at higher temperatures when the complex contains more iodine.

Contrary to an earlier observation that the specific volume of the complex with $n<4$ is larger than the sum of the specific volumes of the constituents,[12] no deviation from the additivity could be detected with our polycrystalline compactions.

29H,31H-Phthalocyanine–Iodine. The resistivity of phthalocyanine has been shown by Aoyagi *et al.* to be considerably lowered by the addition of a small amount of iodine.[13] The dark solids obtained by the oxidation of a number of metal phthalocyanines by iodine have been reported to exhibit resistivities of the order of 0.1 to 1 Ω cm by Petersen *et al.*[14] The exact composition of their iodine complexes has been noted to depend on the preparation conditions.

The resistivity-composition isotherm of the phthalocyanine–iodine system presented in Fig. 9 shows a maximum at $n=2$, a shoulder at $n=5$, and minima, at $n=1.5$ and about 6. On the basis of these findings the presence of phases expressed by (phthalocyanine)$_3^{2+}(I_3^-)_2$ and (phthalocyanine)$^+I_5^-$ seems to be certain. The activation energy for semiconduction

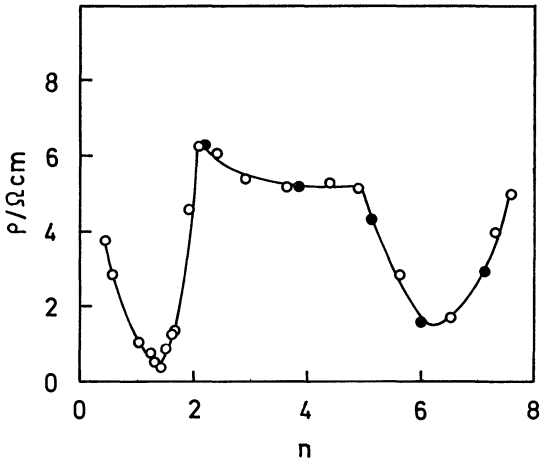

Fig. 9. Electrical resistivity at −23 °C plotted against the iodine content in the phthalocyanine-iodine system. The shaded circles indicate that these samples were made by the addition of iodine to those shown by open circles.

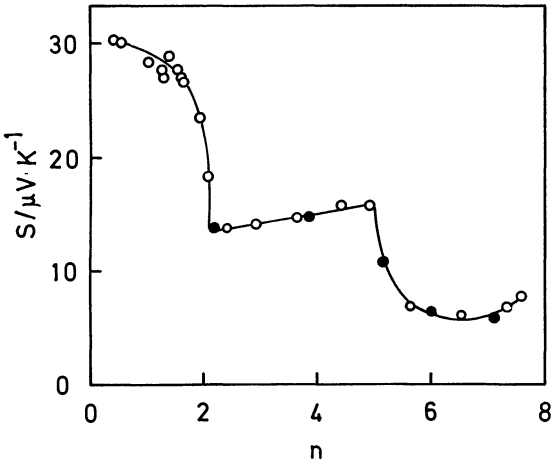

Fig. 10. Seebeck coefficient at −23 °C plotted against the iodine content in the phthalocyanine-iodine system. As to the shaded circles, see the caption of Fig. 9.

is as small as 0.015 eV up to $n=1.5$ and then sharply increases to 0.05 eV by $n=2$. Therefore, the compound, $(\text{phthalocyanine})_2{}^+I_3{}^-$, may be formed in this system. Between $n=2$ and 5 the activation energy stays around 0.04 eV and then around 0.03 eV.

The Seebeck coefficient is positive for all the samples prepared and over the temperature range examined. The slope is mostly negative when plotted against the reciprocal temperature. As is shown in Fig. 10, the values at −23 °C ($10^3/T=5$) are between +27 and +30 μV K^{-1} up to $n=1.5$ and then sharply decrease by a factor of a half by $n=2$. Between $n=2$ and 5 the values remain around +15 μV K^{-1}. Above $n=5$, the coefficient decreases again by a factor of a half. In the last iodine-content range, the Seebeck coefficient shows an increase at low temperatures.

Phenoxazine–Iodine. The organic constituent is structurally related to phenothiazine studied in our previous work[1] and is known to form an iodine complex, the composition of which is the same as that of the sulfur analog; that is, $n=3$.[15] Nevertheless,

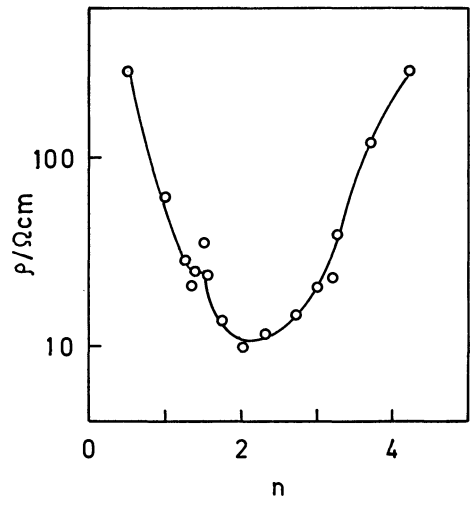

Fig. 11. Electrical resistivity at 20 °C plotted against the iodine content in the phenoxazine-iodine system.

the resistivity-composition isotherm presented in Fig. 11 is distinctly different from that of the phenothiazine-iodine system. A shoulder is located at $n=1.5$ instead of $n=2.5$. Furthermore, the minimum is found at $n=2$ instead of $n=3$. No anomalous feature is observed at $n=3$, which is the composition of the complex crystallized from a benzene solution. The overall appearance is less dramatic; that is, the resistivity at the shoulder is only about threefold larger than that at the minimum. On the other hand, the corresponding ratio in the sulfur analog–iodine system is as much as forty. The activation energy for semiconduction is about 0.13 eV throughout the examined composition range.

The Seebeck coefficient at 20 °C was reported to be slightly positive at $n=3$ and to decrease drastically by lowering the temperature. The coefficient in the composition range of $n=1$—1.5 is about −10 μV K^{-1} and independent of the temperature. When n is increased to 1.5, the room-temperature value is unchanged but the slope is slightly negative against the reciprocal temperature. Above $n=1.5$, the slope becomes increasingly negative. As the dependence on the composition near room temperature is rather small, the coefficient at 70 °C is plotted against n in Fig. 12. The sign changes from negative to positive near $n=1.5$.

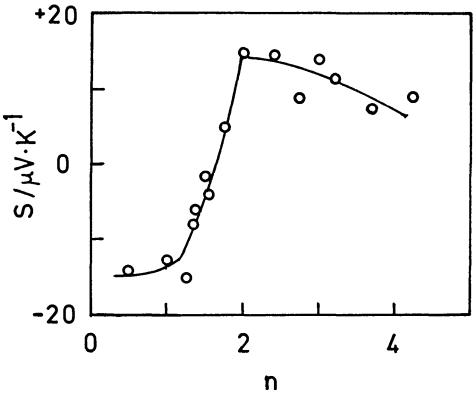

Fig. 12. Seebeck coefficient at 70 °C plotted against the iodine content in the phenoxazine-iodine system.

Of course, the behavior depends markedly upon the temperature selected. If one chooses a low temperature, say −70 °C, the sign is negative over the whole range of n; however, an abrupt change of magnitude may be found above $n=1.5$. The results described above clearly indicate the formation of a complex at $n=1.5$, while no support for the existence of a complex at $n=3$ could be obtained by the present method.

Although the vibrational spectrum could not be examined with the complex crystallized from a benzene solution because of the difficulty of pulverization,[15] samples prepared for this work are composed of fine powders and allow such measurements. As is known for this kind of materials, the spectrum in the rock-salt region is dominated by the electronic absorption. At $n=1.75$, the observed vibrational bands are broad and give a pattern very different from that of the parent organic compound. When a large amount of iodine is added to this sample, say $n>5$, a pattern consisting of sharp bands is recorded. By analogy with the case of the phenothiazine–iodine, the latter spectrum may be assigned to the monopositive ion of phenoxazine. The complex formed at $n=1.5$ is perhaps a complex cation radical salt which can be expressed by (phenoxazine)$_2^+I_3^-$.

Pyridazine–Iodine. Hoare and Pratt have reported that a pyridazine molecule combines with 2—2.8 atoms of iodine to form a black solid and that the resistivities measured using two-probe technique fall in the range of 1—50 Ω cm at room temperature.[16] This organic compound has the lowest molecular weight among the compounds known to form low-resistivity iodine complexes.

There are a peak at $n=1.8$ and minima at about $n=1.6$ and 2 in the resistivity-composition isotherm shown in Fig. 13. The activation energy for semiconduction shows also a discontinuous change at $n=1.8$; namely, the value up to this composition is about 0.035 eV and then suddenly drops to about 0.02 eV. These observations unambiguously establish the idealized composition of a complex in this system, (pyridazine)$_5I_9$. Though the present work provides no evidence for the nature of the iodine, it is likely that the iodine is in the form of a triiodide ion. If so, the above-mentioned product may be expressed by (pyridazine)$_5^{3+}(I_3^-)_3$. The resistivity observed near $n=2$, which may be the upper limit of the homogeneity range including the maximum or may be in an entirely different phase, is as low as 0.4 Ω cm. The Seebeck coefficient is essentially unchanged by the temperature and is scattered in a narrow range of +3 to +10 μV K^{-1}.

N,N′-*Diphenyl*-p-*phenylenediamine–Iodine.* This is one of the iodine complexes of oligoanilinic derivatives extensively studied by Honzl *et al.*[17] The crystal structure of this complex with $n=2.4$ has been analysed by Huml.[18] The diamine molecules are arranged one below the other in layers spaced 3.77 Å apart and the iodine atoms are arranged in chains almost perpendicular to the layers. On the basis of the distribution of distances of iodine atoms, the chains are considered to consist of triiodide ions. Hádek *et al.* have reported the electrical and magnetic properties of the complex with the above-mentioned composition.[19–21] According to their work, the activation energy for semiconduction observed with polycrystalline compactions is 0.07 eV in the temperature range of −50 to +50 °C and 0.21 eV below this range. The Seebeck coefficient is negative near room temperature and changes sign below −70 °C. In addition, the measurements on a complex with $n=2$ are available due to the of work of Sano *et al.*[22] They have concluded that the conductivity due to electrons is larger, but only slightly, than that due to holes; however, the work described below indicates that the behavior may not be so simple as they supposed.

As is illustrated in Fig. 14, the room-temperature resistivity gradually decreases by the increase of iodine content up to $n=2$ and then increases by a factor of ten between $n=2.4$ and 2.6. The value in the range of $n=1.8$ to 2.4 is 4—5 Ω cm. There is a shoulder at $n=2.6$. The activation energy for semiconduction near room temperature is about 0.07 eV over the range

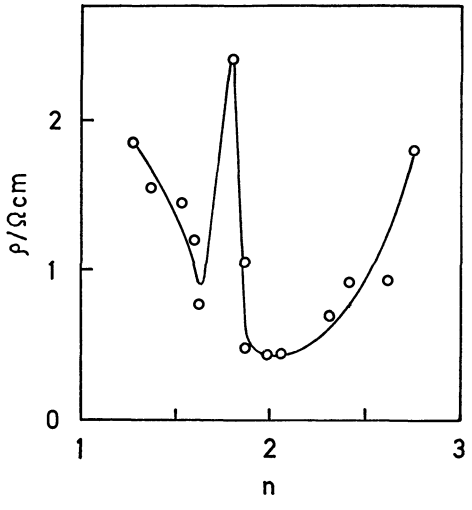

Fig. 13. Electrical resistivity at 20 °C plotted against the iodine content in the pyridazine–iodine system.

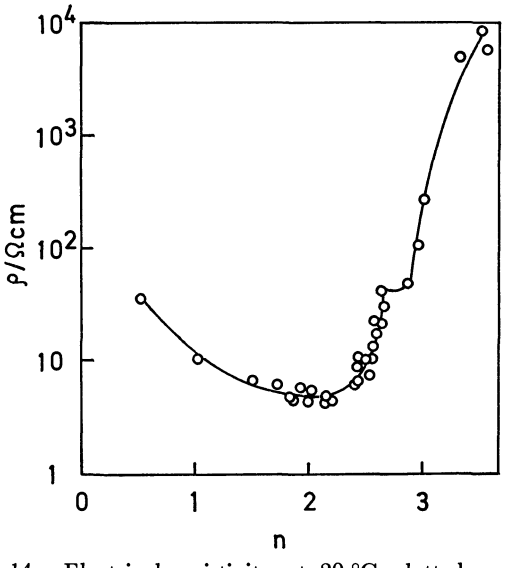

Fig. 14. Electrical resistivity at 20 °C plotted against the iodine content in the *N,N′*-diphenyl-*p*-phenylenediamine-iodine system.

of $n=0.5$—2.4, in accordance with the work by Hádek, and about 0.13 eV in the range of $n=2.5$—2.6. The change of the activation energy by lowering the temperature to about 0.22 eV in both the composition ranges was found around −20 °C, which is displaced by 30° above the temperature reported by Hádek.[19]

Although the Seebeck coefficient at room temperature is negative regardless of the wide variation in composition, the whole range can be divided into three sections according to the magnitude and the temperature dependence: namely, $n<2.4$, $n=2.4$—2.9, and $n>3$. In the first range, the value is −20—−30 $\mu V\ K^{-1}$ at room temperature and shows a minimum of about −60 $\mu V\ K^{-1}$ near −70 °C. The change of the sign occurs at a lower temperature, the value at −130 °C (the lowest temperature examined) being about +90 $\mu V\ K^{-1}$. Thus, the relative contribution of electrons and holes to the conductivity seems to vary with the temperature. The second range cannot be distinguished from the first by the room-temperature value alone but the minimum is more negative and the value is about −50 $\mu V\ K^{-1}$ even at −130 °C. The room-temperature value in the third range is significantly more negative, for example, about −200 $\mu V\ K^{-1}$ at $n=3.30$. The low-temperature value is negative but vanishingly small, passing through a minimum of about −350 $\mu V\ K^{-1}$ located around −20 °C. Thus, the compound appearing in the second composition range seems to be nonstoichiometric to some extent and its composition may be represented by $(N,N'$-diphenyl-p-phenylenediamine$)_5I_{13}$. Because of the relatively small change in resistivity around $n=2$, the resistivity-composition isotherm method fails to establish the ideal composition of the low-resistivity complex studied by Hádek *et al.* and also by Sano *et al.*

The present work was partly supported by the Grant-in-Aid for Scientific Research No.234028 from the Ministry of Education, Science, and Culture.

The Solvent Extraction of Uni- and Bivalent Metal Picrates by Dibenzo-24-crown-8

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received February 23, 1979)

The overall extraction equilibrium constants (K_{ex}) for the 1:1:1 and 1:1:2 complexes of dibenzo-24-crown-8 (DB24C8) with several uni- and bivalent metal picrates between benzene and water have been determined at 25 °C. The K_{ex} sequences of the uni- and bivalent metal ions with DB24C8 are $Tl^+ > Cs^+ > Ag^+ > Rb^+ > K^+ > Na^+ \gg Li^+$ and $Ba^{2+} \gg Pb^{2+} \gg Sr^{2+} > Ca^{2+}$, respectively. DB24C8 shows the highest selectivity for Ba^{2+} among all the alkali and alkaline earth metal ions, but no selectivity for the alkali metal ions. The extractability of DB24C8 for the alkali metal ions is not sensitive to the ratio of the ionic size to the cavity size of DB24C8. The plots of log K_{ex} values *vs.* reciprocal crystal ionic radii of the alkali and alkaline earth metals give straight lines, indicating that these straight lines are related to Born's formula of solvation free energy.

Dibenzo-24-crown-8 (DB24C8) forms stoichiometric complexes with alkali metal ions; the alkali metal ion in the complex is trapped in the cavity of the DB24C8 ring by ion-dipole forces.[1] Since DB24C8 is a flexible crown ether and has a large cavity size (>4.0 Å[2]) compared to the alkali metal ionic size, in its complex with the alkali metal ion it is partially wrapped around the alkali metal ion.[1a] Accordingly, when the complex reaction between DB24C8 and metal ions occurs, the metal ion may be expected to require almost complete desolvation, as found in the NMR studies of nonactin.[3] Dicyclohexyl-18-crown-6 (DC18C6) and dibenzo-18-crown-6 (DB18C6), which are rigid crown ethers, show pronounced cation selectivities,[1b,4] while DB24C8 does not.[1b,4a] Some solvent extraction studies of alkali metal ions with DC18C6 and DB18C6 have been reported and these data show that the extractability of the metal ion is very sensitive to the ratio of the ionic size to the cavity size of the crown ether.[5] However, there is only one paper about the solvent extraction study of DB24C8 up to date and in this paper the extraction equilibria have not been discussed in detail.[2] Therefore, the present study was undertaken to determine the extraction constant values of the DB24C8-uni- and bivalent metal picrates and to compare these extraction constant values with those of DB18C6, in order to clarify the role of DB24C8 in the extraction process. Since a large anion is easily extracted into nonpolar solvents, the picrate anion was used as the counter ion. Benzene was used as the solvent because of its nonpolarity.

Experimental

Materials. DB24C8 was obtained from Nisso Co., Ltd. It was dissolved in hexane, and filtered while hot. Then it was recrystallized from hexane and, before use, dried at 50 °C in a vacuum oven. Analytical-grade benzene, HNO_3, $LiOH \cdot H_2O$, NaOH, KOH, $Ca(NO_3)_2 \cdot 4H_2O$, $Sr(NO_3)_2$, $Ba(NO_3)_2$, $Pb(NO_3)_2$, and reagent-grade $TlNO_3$ were purchased from Wako-Pure Chemicals Ltd. $AgNO_3$ and picric acid were analytical grade from Koso Chemical Co., Ltd. Reagent-grade RbOH and CsOH were obtained from Mitsuwa Pure Chemicals Ltd. and Kanto Chemical Co., Inc., respectively. The purities of $TlNO_3$ and the bivalent metal nitrates were determined by means of EDTA titration, and the concentrations of $AgNO_3$, the picric acid, and the alkali metal hydroxide solutions were determined by means of KCl, basic, and acid ones, respectively. Benzene was washed twice with distilled water.

Apparatus and Procedures. The organic phase of DB24C8 (9.2×10^{-5}—2.1×10^{-2} M) and the aqueous phase of the univalent metal hydroxide or nitrate (9.9×10^{-4}—2.9×10^{-2} M), or the bivalent metal nitrate (2.0×10^{-3}—1.1×10^{-1} M) and the picric acid (8.8×10^{-4}—2.7×10^{-2} M) were placed in a stoppered glass tube (volume 30 ml), shaken in a thermostated water bath for about 30 min at 25±0.2 °C, and separated by centrifugation. The initial volume of each phase was 10 ml in all cases. A portion of the aqueous phase about 8 ml was transferred to a 10 ml beaker and the hydrogen ion concentration was determined by a Hitachi-Horiba F-5 pH meter. In the cases of the univalent metal hydroxide, the univalent metal nitrate, and the bivalent metal nitrate, the extractions were carried out at pH 10.0—12.1, 2.3—2.6, and 1.6—2.7, respectively. For the systems of Ag, Tl, and the bivalent metals, the metal in the organic phase was back-extracted into 8 ml of 1 M nitric acid aqueous solution. The Ba concentration of this aqueous phase was determined by flame photometry and the others by atomic absorption spectroscopy using a Seiko SAS-725 atomic absorption spectrophotometer. For the systems of the alkali metals, the picrate in the organic phase was back-extracted into 8 ml of 0.01 M NaOH aqueous solution and the picrate concentration was determined at 356 nm by a Shimadzu UV-200 spectrophotometer ($\varepsilon = 1.45 \times 10^4$ cm^{-1} M^{-1}). In blank experiments, for the alkali metals no detectable extraction was found in the absence of DB24C8, and for Ag and Tl a little detectable extraction was found in the absence of either DB24C8 or picric acid. It was impossible to extract any Mg and Hg into the organic phase.

The Distribution Coefficient of DB24C8. A 100 ml portion of a benzene solution containing DB24C8 and an equal volume of distilled water were placed in a 300 ml separatory funnel and shaken under the same conditions as given above. The concentration range of DB24C8 was from 5.0×10^{-3}—1.0×10^{-2} M. After centrifugation, DB24C8 in the aqueous phase was extracted into chloroform (90 ml). A 80 ml portion of the organic phase was transferred to a 200 ml beaker and left until evaporation was complete. The residue in the beaker was dissolved by chloroform (10 ml) and the DB24C8 concentration was determined spectrophotometricall at 277 nm ($\varepsilon = 5.25 \times 10^3$ cm^{-1} M^{-1}). The average value of the distribution coefficient determined in this way is 1.1×10^3.

Results

When equilibrium takes place between an aqueous solution of a metal ion, M^{m+}, and a picrate ion, A^-,

and a benzene solution of a crown ether, L, the equilibrium constants may be defined by the following equations:

$$K_{ex} = [MLA_m]_o[H^+]^m/[M^{m+}][L]_o[HA]_o^m \quad (1)$$

$$K_{D,L} = [L]_o/[L] \quad (2)$$

$$K_{ex}(HA) = [HA]_o/[H^+][A^-] \quad (3)$$

$$K_{ML} = [ML^{m+}]/[M^{m+}][L] \quad (4)$$

$$K_{ex'} = [MLA_m]_o/[ML^{m+}][A^-]^m \quad (5)$$

where the subscript "o" and the lack of a subscript designates the organic and the aqueous phase, respectively; square brackets indicate the molar concentrations. The distribution ratio of the metal may be represented by

$$D_M = [MLA_m]_o/([M^{m+}] + [ML^{m+}]) \quad (6)$$

In the case of $[M^{m+}] \gg [ML^{m+}]$, Eq. 6 may be transformed into

$$D_M = K_{ex}K_{ex}(HA)^m[L]_o[A^-]^m \quad (7)$$

For the univalent metal ion system the $\log(D_M/[A^-])$ *vs.* $\log[L]_o$ plot in Fig. 1 shows a straight line with a slope of 1 in every case, indicating that DB24C8 forms the 1:1 complex with the univalent metal ion. For the bivalent metal ion system the $\log(D_M/[A^-]^2)$ *vs.* $\log[L]_o$ plot in Fig. 2 and the $\log(D_M/[L]_o)$ *vs.* $\log[A^-]$ plot in Fig. 3 always show lines with slopes of 1 and 2, respectively, indicating that DB24C8 forms the 1:1:2 complex with the bivalent metal ion and the picrate ion. The values of $[L]_o$ and $[A^-]$ in Eq. 7 were calculated from Eqs. 8 and 9 respectively.

$$[L]_o = [L]_t - [MLA_m]_o \quad (8)$$

$$[A^-] = ([HA]_t - m[MLA_m]_o)/\{1 + (K_{HA} + K_{ex}(HA))[H^+]\} \quad (9)$$

where the subscript "t" denotes the total concentration. The value of $K_{ex}(HA)$ was spectrophotometrically determined to be 247 by using the association constant of picric acid ($K_{HA} = 1.9_5$[6]). The equilibrium constants obtained from these data are summarized in Table 1, together with those from the literature.

Discussion

The plots of log K_{ex} value *vs.* crystal ionic radius for the DB24C8 and the DB18C6 systems are given in Fig. 4. Table 1 shows that the log K_{ex} value sequences for the alkali metal and the alkaline earth metal ions with DB24C8 are $Cs^+ > Rb^+ > K^+ > Na^+ \gg Li^+$ and $Ba^{2+} \gg Sr^{2+} > Ca^{2+}$ respectively, indicating that in both cases the nearer the crystal radius of the metal ion approaches to the cavity radius of DB24C8 (>2.0 Å[2]), the more extractable the metal ion is, as can

Table 1. Equilibrium constants at 25 °C

Crown ether	$K_{D,L}$	Cation	log K_{ex}
DB24C8	1.1×10^3	Li^+	−1.72
		Na^+	−0.34
		K^+	0.40
		Rb^+	0.61
		Cs^+	0.76
		Ag^+	0.70
		Tl^+	1.67
		Ca^{2+}	−1.72
		Sr^{2+}	−0.80
		Ba^{2+}	2.07
		Pb^{2+}	1.53
DB18C6	8×10^2 [5c]	Na^+	−0.18[5c]
		K^+	2.26[5c]
		Rb^+	1.36[5c]
		Cs^+	0.68[5c]

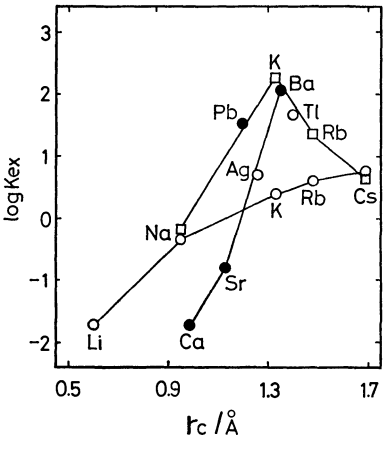

Fig. 4. Plots of log K_{ex} *vs.* crystal ionic radii, r_c, of uni- and bivalent metals for the DB24C8 and DB18C6 systems. ○: DB24C8-univalent metal, ●: DB24C8-bivalent metal, □: DB18C6-univalent metal.

be seen in Fig. 4. DB18C6, which is a rigid ligand,[1b] shows the highest selectivity for K^+ of all the alkali metal ions, and the extractability of DB18C6 for the alkali metal ions is very sensitive to the ratio of the crystal ionic radius to the cavity radius (1.3—1.6 Å[4a]). On the other hand, DB24C8, which is a flexible ligand,[1b] displays no peak selectivity for any alkali metal ion. The extractability of DB24C8 for the alkali metal ions is not sensitive to the ratio of the crystal ionic radius to the cavity radius (Fig. 4), and in the case of DB24C8 the difference in the log K_{ex} values of the neighboring alkali metal ions decreases gradually with an increase in the ionic size (Table 1). It may be noted from Fig. 4 that DB24C8 reveals the highest selectivity for Ba^{2+} among all the alkali and alkaline earth metal ions. It is very noticeable that the difference in the log K_{ex} values of Ba^{2+} and Sr^{2+} with DB24C8 (2.87) is markedly larger than those with 15-crown-5 (−0.50[9]) and 18-crown-6 (0.00[9]). This fact suggests that DB24C8 will be an useful reagent for separating a small amount of Ba from large amounts of Sr by a solvent extraction method.

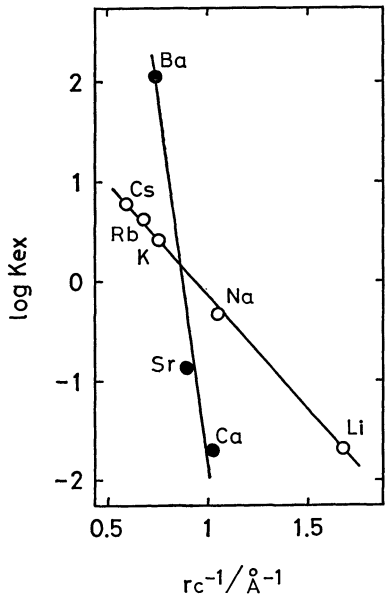

Fig. 5. Plots of log K_{ex} *vs.* reciprocal crystal ionic radii of alkali and alkaline earth metals for the DB24C8 system.

As can be seen from Fig. 4, the crystal radii of Ag^+ (1.26 Å[7]) and Tl^+ (1.40 Å[7]) are nearly equal to that of K^+ (1.33 Å[7]) and those of K^+ and Rb^+ (1.48 Å[7]) respectively. However, the log K_{ex} value of DB24C8 for Ag^+ is larger than that for K^+ and that for Tl^+ is much larger than those for K^+ and Rb^+. The log K_{ex} value of DB24C8 for Pb^{2+}, whose crystal radius (1.20 Å[8]) is nearly identical with that of Sr^{2+} (1.13 Å[7]), is much larger than that for Sr^{2+} (Fig. 4). The extractability of DB24C8 for Tl^+, whose ionic size is nearer to the cavity size of DB24C8 than is that of Ag^+, is much greater than that for Ag^+ (Fig. 4). The crystal radii of Ba^{2+} (1.35 Å[7]) and K^+ are nearly equal and the log K_{ex} value of DB24C8 for Ba^{2+} is much larger than that for K^+, while Ca^{2+} (0.99 Å[7]) and Na^+ (0.95 Å[7]) have nearly identical crystal radii and the log K_{ex} value of DB24C8 for Ca^{2+} is much smaller than that for Na^+ (Fig. 4).

The plot of log K_{ex} value *vs.* the reciprocal crystal ionic radius for the DB24C8 system is given in Fig. 5. The larger the crystal radii of the alkali and alkaline earth metal ions are, the more extractable these ions are. The plots of log K_{ex} values *vs.* the reciprocal crystal ionic radii of the alkali and alkaline earth metals give straight lines with slopes of −2.3 and −13.9 respectively, and the slope of the alkaline earth metal ions is about 6 times steeper than that of the alkali metal ions. Thus, it seems that these straight lines in Fig. 5 are related to Born's formula of solvation free energy.

The author thanks Mr. Hiroshi Gotō and Mr. Fujio Takahashi of this laboratory for their experimental assistance.

Measurement and Analysis of the ν_3 Band of CF_4

Tetsuo SUZUKI, Hiroshi OKADA, and Tsunetake FUJIYAMA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received March 2, 1979)

The ν_3 fundamental of carbon tetrafluoride has been measured with a tunable diode laser-source spectrometer. The following molecular constants were obtained: $\nu_0-2(B\zeta_3)_{eff}=1283.4067$ cm^{-1}, $B_{eff}^{PR}+B_0-2(B\zeta_3)_{eff}=7.210\times10^{-2}$ cm^{-1}, $B_{eff}^{PR}-B_0=-5.290\times10^{-4}$ cm^{-1}, and $\delta_3=6.153\times10^{-4}$ cm^{-1}. Using the r_g-structure obtained from the gas-electron diffraction study, the above molecular constants were reduced to be: $\nu_0=1283.7181$ cm^{-1}, $B_{eff}^{PR}=0.1915$ cm^{-1}, $B_0=0.1920$ cm^{-1}, and $(B\zeta_3)_{eff}=0.1557$ cm^{-1}. From the $(B\zeta_3)_{eff}$ value, the Coriolis coupling constant for the ν_3 was estimated to be $\zeta_3=0.811$.

Although carbon tetrafluoride is one of the most simple and basic molecules belonging to the point group T_d, very few studies of its rotation-vibration spectra have been reported. This has been largely due to the deficiency in the resolving power of the spectrometers. Edgell *et al.* have observed the ν_3 and ν_4 fundamentals with a rather low-resolution spectrometer and estimated the Coriolis coupling constants, ζ_3 and ζ_4, by analyzing the band contours.[1] The rotation-vibration spectra have been observed for the ν_4 fundamental by Maki *et al.* with a resolution of 0.06 cm^{-1}. From the *J*-structure analysis, the molecular constants, ν_0, $B(1-\zeta_4)$, and B_4-B_0, were determined.[2] The ν_4 fundamental of three isotope species, ^{12}C, ^{13}C, and ^{14}C, were observed with a resolution of 0.06 cm^{-1} by Jones *et al.*[3] The observed spectra were well resolved into *J*-structures, and the molecular constants for the three isotope species were determined.

In the case of the ν_3 fundamental, however, the spacing of the rotational structure is so narrow that the conventional spectrometer cannot resolve its fine structures. The present report will concern itself with the measurement of the rotation-vibration spectra for the ν_3 fundamental of carbon tetrafluoride by the use of a tunable diode laser-source spectrometer and with the analysis of the rotation-vibration spectra.

Experimental

The sample used in this study was a commercial product and was used without further purification. The survey spectrum of the ν_3 band of carbon tetrafluoride was recorded from 1270 to 1290 cm^{-1} using a Nicolet 7199 Fourier transform infrared spectrometer at a 0.06-cm^{-1} resolution. The observation was made at room temperature using a 10-cm gas cell. The sample pressure was about 0.5 Torr.

The high-resolution spectrum was recorded from 1281.28 to 1282.92 cm^{-1} by the use of a tunable diode laser-source spectrometer, (Laser Analytics model LS series). The observation was made at room temperature using a 15-cm gas cell. The pressure was 0.1—0.2 Torr. The resolution of the instrument was 10^{-4}—10^{-3} cm^{-1}; therefore, the line width of the observed spectrum was governed by the Doppler broadening. The line frequencies were calibrated by the use of the (100-000) and (11^10-01^10) transition frequencies of the N_2O vapor[4,5] and the interference fringes arising from a germanium etalon whose free spectral range was 0.04841 cm^{-1} at 1282 cm^{-1}. The precision of the frequency measurement was believed to be 0.002 cm^{-1}, while the accuracy of the frequency measurement was restricted by the ambiguity to be expected in the determination of the band origin of the standard lines. It was, however, believed to be better than 0.005 cm^{-1}.[4,5]

Observed Spectra

The spectra of the ν_3 band recorded by the Fourier transform spectrometer is shown in Fig. 1. There appear an R branch centered around 1285—1286 cm^{-1}, a strong Q branch at 1283 cm^{-1}, and a broad P branch. Overlapped with the P branch, there appear a relatively strong absorption maximum at 1281 cm^{-1} and a weak absorption maximum at 1279 cm^{-1}. Probably the two absorption maxima arise from hot bands. As is shown in Fig. 1, the P and R branches are resolved into fine structures. However, these fine structures cannot easily be identified as *J*-components because their intensities and spacings do not show any apparent regularities.

The intensities of the Q branch at 1283 cm^{-1} and the Q branch of the hot band at 1281 cm^{-1} were carefully measured at various sample pressures. The observed intensity ratio was 1 : 0.231. As the intensity ratio of the Q branch of the ν_3 fundamental and that of the $\nu_3+\nu_2-\nu_2$ hot band is 1 : 0.238, the relatively strong absorption maximum observed at 1281 cm^{-1} is identified as the Q branch of the $\nu_3+\nu_2-\nu_2$ hot band.

The high-resolution spectrum observed by the use of the diode laser-source spectrometer is shown in Fig. 2. In the region from 1281.80 to 1282.72 cm^{-1}, a series of *J*-components of the P branch can be seen clearly, and each *J*-component is further resolved into sub-structure components. The spectrum in the 1282.72—1282.92 cm^{-1} region is quite complex because it is overlapped with the strong Q branch. As the frequency decreases, the spacing of the sub-structure components becomes larger relative to the spacing of the *J*-components. Therefore, it becomes difficult to identify a *J*-component as a definite line group.

It seems that most of the sub-structure components are not completely resolved, because their line-widths are much broader than the Doppler width. The Doppler width is estimated to be about 0.002 cm^{-1} under these experimental conditions.

Analysis of the Observed Band

Rotational Energy Levels of the Ground and Excited Vibrational States. The present analysis is based on the theoretical work reported by Herranz.[6]

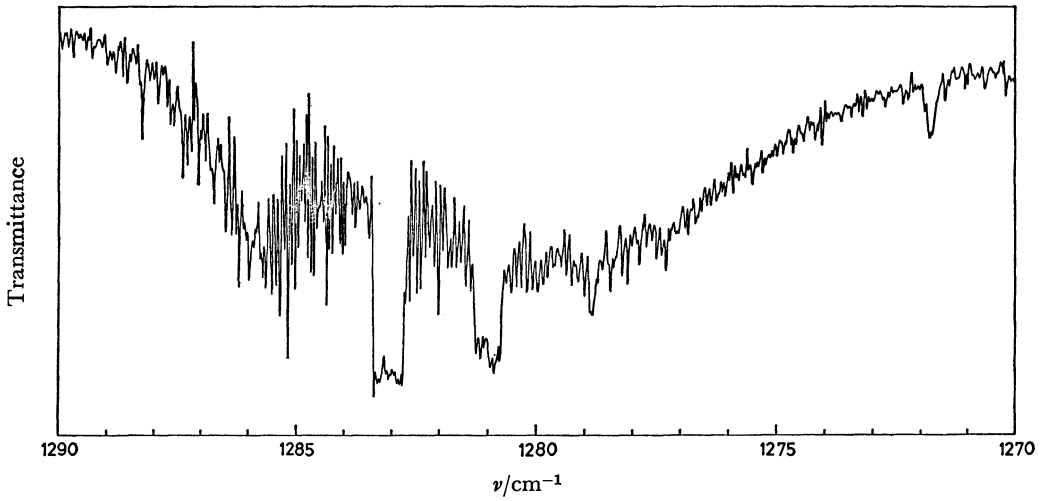

Fig. 1. The spectrum of the ν_3 band recorded by the Fourier transform spectrometer.

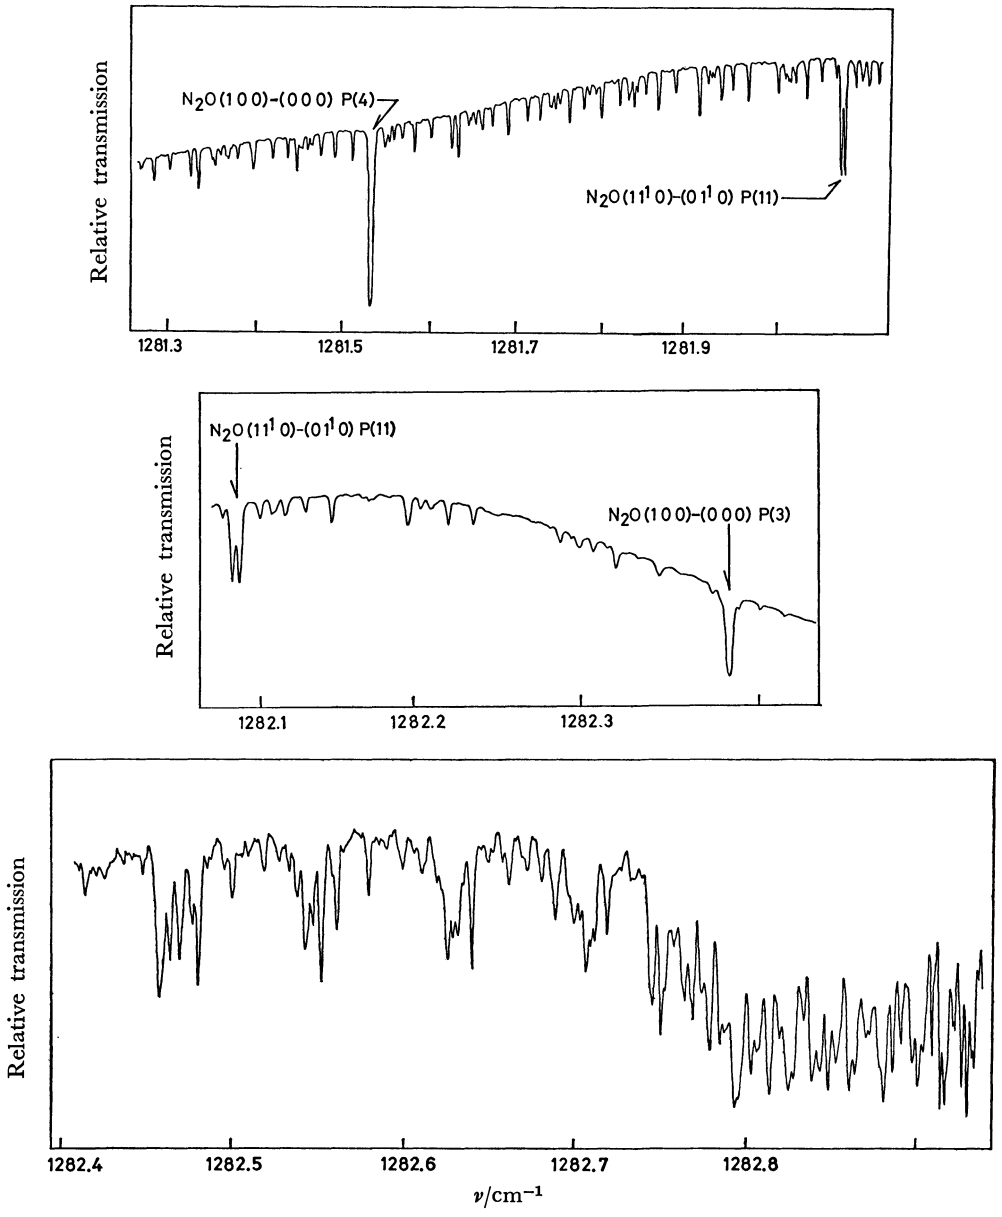

Fig. 2. The high resolution spectrum of the ν_3 band observed by the use of the tunable diode laser source spectrometer.

The term values for the rotational levels of the ground state of an XY_4-type spherical-top molecule can be written as:

$$F_0(J,\tau) = B_0J(J+1) - D_0^JJ^2(J+1)^2 - D^{J\tau}S_{J,\tau}, \quad (1)$$

where B_0 and $D_0{}^J$ are the rotational constant and the centrifugal distortion constant for the ground state respectively. The last term of Eq. 1 represents the splitting of the rotational levels into their sublevels as a consequence of centrifugal distortion. There are $2J+1$ sublevels for each J value including degeneracy; these sublevels are designated by an index, τ. $S_{J,\tau}$ is the eigenvalue of the angular momentum operator:

$$S = P_x^4 + P_y^4 + P_z^4 - (3/5)P^4 + (1/5)P^2, \quad (2)$$

where:

$$P^2 = P_x^2 + P_y^2 + P_z^2, \text{ and } P^4 = (P_x^2+P_y^2+P_z^2)^2.$$

When the wavefunctions of an axially symmetric rotor are chosen as a basis set, the nonvanishing matrix elements for S are:

$$(J,K|S|J,K) = (3/20)(J^2+J)(J^2+J-2-10K^2) + (1/4)K^2(7K^2+5) \quad (3a)$$

and:

$$(J,K|S|J,K\pm4) = (1/8)\{(J\mp K)(J\mp K-1)\times(J\mp K-2)(J\mp K-3)(J\pm K+1)\times(J\pm K+2)(J\pm K+3)(J\pm K+4)\}^{1/2} \quad (3b)$$

when the triply degenerate vibrational mode is excited, the interaction of rotation and vibration removes the degeneracy; therefore, each J level splits into three levels. They are designated by (+), (0), and (−). Each of these levels is further split into sublevels. These sublevels are designated by the same index, τ, as in the ground state. For each J value the number of sublevels is $2J+3$ for the (+), $2J+1$ for the (0), and $2J-1$ for the (−) levels.

The term values for the rotational levels of the excited vibrational state are given by:

$$F^{(+)}(J,\tau) = B_{eff}^{PR}J(J+1) + 2(B\zeta_3)_{eff}J - D_1^JJ^2(J+1)^2 + \frac{S_{J+1,\tau}}{2J^2+3J+1}\{\delta_3 - D^{J\tau}(2J^2-5J+3)\} \quad (4a)$$

$$F^{(0)}(J,\tau) = B_{eff}^{Q}J(J+1) - 2(B\zeta_3)_{eff} - D_1^JJ^2(J+1)^2 - \frac{S_{J,\tau}}{J^2+J}\{\delta_3 + D^{J\tau}(J^2+J-10)\} \quad (4b)$$

$$F^{(-)}(J,\tau) = B_{eff}^{PR}J(J+1) - 2(B\zeta_3)_{eff}(J+1) - D_1^JJ^2(J+1)^2 + \frac{S_{J-1,\tau}}{2J^2+J}\{\delta_3 - D^{J\tau}(2J^2+9J+10)\} \quad (4c)$$

where B_{eff}^{PR} is the effective rotational constant for the (+) and (−) levels, while B_{eff}^{Q} is that for the (0) level. The δ_3 parameter represents the splitting of the J level resulting from the instantaneous breakdown of symmetry which is produced by the vibrational mode. The explicit expression for δ_3 is given in Ref. 6. In order to further specify the characteristics of the sublevels, the τ index is replaced by a double index, nT. The symbol T specifies the type of degeneracy of the sublevel; that is, $T=A$, $T=E$, and $T=F$ refer to nondegenerate, doubly degenerate, and triply degenerate sublevels respectively. The symbol n differentiates the sublevels belonging to the same J and T; that is, $n=1$ refers to the sublevel of the largest $S_{J,\tau}$, $n=2$ refers to the sublevel of the second largest $S_{J,\tau}$, and so on.

The selection rules for electric dipole transitions are:

$$\Delta\tau = 0 \text{ and } \Delta J = -1 \text{ for } F^{(+)}\leftrightarrow F_0$$
$$\Delta J = 0 \text{ for } F^{(0)}\leftrightarrow F_0$$
$$\Delta J = 1 \text{ for } F^{(-)}\leftrightarrow F_0.$$

Taking account of these selection rules, the line frequencies of the fundamental band are expressed as: for the P branch:

$$\nu^P(J,\tau) = \nu_0 - 2(B\zeta_3)_{eff} - \{B_{eff}^{PR}+B_0-2(B\zeta_3)_{eff}\}J + \{(B_{eff}^{PR}-B_0)-(D_1^J-D_0^J)\}J^2 + 2(D_1^J+D_0^J)J^3 - (D_1^J-D_0^J)J^4 + \frac{S_{J,\tau}}{2J^2-J}\{\delta_3+(8J-10)D^{J\tau}\} \quad (5a)$$

for the Q branch:

$$\nu^Q(J,\tau) = \nu_0 - 2(B\zeta_3)_{eff} + (B_{eff}^{Q}-B_0)J(J+1) - (D_1^J-D_0^J)J^2(J+1)^2 - \frac{S_{J,\tau}}{J^2+J}(\delta_3-10D^{J\tau}) \quad (5b)$$

and for the R branch:

$$\nu^R(J,\tau) = \nu_0 - 2(B\zeta_3)_{eff} + \{B_{eff}^{PR}+B_0-2(B\zeta_3)_{eff}\}(J+1) + \{(B_{eff}^{PR}-B_0)-(D_1^J-D_0^J)\}(J+1)^2 - 2(D_1^J-D_0^J)(J+1)^3 - (D_1^J-D_0^J)(J+1)^4 + \frac{S_{J,\tau}}{2J^2+5J+3}\{\delta_3-(8J+18)D^{J\tau}\}. \quad (5c)$$

J takes the values 1, 2,⋯; 1, 2,⋯, and 0, 1, 2,⋯ for the P, Q, and R branches respectively.

The relative intensities of the lines are given by:

$$I_P(J,\tau) = g_T(2J-1)\nu^P(J,\tau)\exp\left\{-\frac{hcF_0(J,\tau)}{kT}\right\}\times\left[1-\exp\left\{-\frac{hc\nu^P(J,\tau)}{kT}\right\}\right]$$

$$I_Q(J,\tau) = g_T(2J+1)\nu^Q(J,\tau)\exp\left\{-\frac{hcF_0(J,\tau)}{kT}\right\}\times\left[1-\exp\left\{-\frac{hc\nu^Q(J,\tau)}{kT}\right\}\right]$$

$$I_R(J,\tau) = g_T(2J+3)\nu^R(J,\tau)\exp\left\{-\frac{hcF_0(J,\tau)}{kT}\right\}\times\left[1-\exp\left\{-\frac{hc\nu^R(J,\tau)}{kT}\right\}\right] \quad (6)$$

where g_T is the nuclear spin statistical weight factor; T, the temperature; h, the Planck constant; c, the light velocity, and k, the Boltzmann constant. As the spin value of a fluorine atom is 1/2, the g_T values are given by:

$$g_A = 5,\ g_E = 2, \text{ and } g_F = 3. \quad (7)$$

Assignment. First our attention was focused on the high-resolution spectrum from 1282.00 to 1282.72 cm^{-1}, because a clear series of J-components appears. These lines certainly belong to a P-branch-line series of $J>7$. The definite assignment of each line can

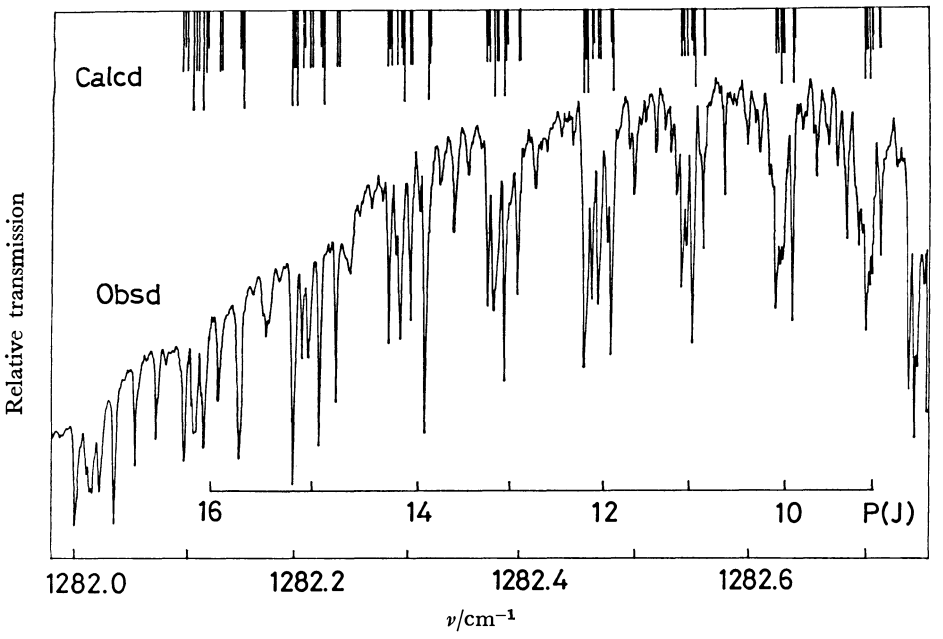

Fig. 3. The observed and calculated spectra in the frequency region of 1282.0—1282.7 cm^{-1}.

be made by calculating the theoretical relative intensities and the relative spacings of the sub-structure components. In Fig. 3, the spectrum calculated from Eqs. 5a, 6, and 7 is compared with the observed spectrum. It can be seen from the figure that some of the observed lines are not completely resolved into the sub-structure components. The Doppler width is sometimes larger than the spacing of the sub-structure components. It is not possible at present to resolve the spectrum of this band into the sub-structures completely by the use of an ordinary spectroscopic method. Therefore, we defined the hypothetical observed frequency for the unresolved lines as:

$$\nu_{max} = \frac{\sum \nu(J,\tau) I(J,\tau)}{\sum I(J,\tau)}. \qquad (8)$$

By doing so, the frequency at the intensity maximum of an unresolved line can be used as an observed frequency. The molecular constants, $\nu_0 - 2(B\zeta_3)_{eff}$, $B_{eff}^{PR} + B_0 - 2(B\zeta_3)_{eff}$, and δ_3 were tentatively determined from the P-branch lines of $9 \leq J \leq 16$ by the least-squares method. Smaller weights were given for the lines which were not fully resolved. Then, the final assignment of all the observed lines from 1281.3 to 1282.72 cm^{-1} was made by the use of the approximate frequencies of the transition lines calculated from these tentatively determined molecular constants and the theoretical relative intensities. The P-branch lines of $J \leq 8$ cannot be found, because they are buried in the strong Q branch.

The observed spectral features of the Q branch were so complex that its analysis was abandoned.

Determination of the Molecular Constants. The molecular constants were determined from the P-branch lines of $9 \leq J \leq 24$ by the least-squares method. The lines which were not fully resolved were given smaller weights. As the number of the observed lines is not enough, the following assumptions were made in the present analysis: $D_1^J = D_0^J$ and the value of D_0^J was fixed at 2.5×10^{-7} cm^{-1}, which has been obtained from the analysis of the ν_4 fundamental.[3] In addition, as the value of $D^{J\tau}$ is theoretically estimated to be 4×10^{-8} cm^{-1} by using the rotational constant[7] and the harmonic force field,[8] the effect of this constant can be regarded as negligible on analyzing the absorption lines of $J \leq 24$. Therefore, we put $D^{J\tau} = 0$ in the least-squares fitting.[9]

The molecular constants which were obtained from the least-squares fitting are listed in Table 1. The observed and calculated frequencies are summarized in Table 2. The standard deviation of the fit is 0.0023 cm^{-1}. For the P(15) lines, the differences between the observed and calculated frequencies are about two times as large as those for the other lines; the reason for this is not yet clear.[10]

Table 1. The molecular constants obtained from ν_3 band of CF_4 (in cm^{-1})

$\nu_0 - 2(B\zeta_3)_{eff}$	1283.4067±0.0044
$B_{eff}^{PR} + B_0 - 2(B\zeta_3)_{eff}$	(7.210±0.054) $\times 10^{-2}$
$B_{eff}^{PR} - B_0$	− (5.290±0.160) $\times 10^{-4}$
δ_3	(6.153±0.110) $\times 10^{-4}$

The uncertainties are twice the standard deviations.

Discussion. The molecular constants, ν_0, $(B\zeta_3)_{eff}$, B_{eff}^{PR}, and B_0, cannot be determined independently from the analysis of the P branch of the ν_3 band alone. However, these constants can be independently determined if we use the r_g-structure obtained from the gas-electron-diffraction study. The rotational constant in the ground state can be calculated following the idea of Morino *et al.*[11]

The nuclear-distance parameter, r_α, is expressed as:

$$r_\alpha = r_g - \frac{\{\langle(\Delta x)^2\rangle + \langle(\Delta y)^2\rangle\}}{2r_e} - \delta_r \qquad (9)$$

where $\langle(\Delta x)^2\rangle$ and $\langle(\Delta y)^2\rangle$ are the mean-square

a) Δ = (calculated frequency) − (observed frequency). b) Not observed because of overlapping with N_2O lines.
c) Not observed because of overlapping with other lines.

amplitudes of the harmonic vibrations perpendicular to the internuclear axis, r_g is the internuclear distance which is directly observed by the gas-electron-diffraction method, and δ_r is the small correction for the centrifugal distortion. On the other hand, a moment of inertia in the ground state, I_{zero}, is expressed as:

$$I_{zero} = I_0\left(1-\sum_s \frac{g_s}{2B_0}\alpha^{harm.}\right) \quad (10)$$

where I_0 is effective moment of inertia obtained from spectroscopy, $\alpha^{harm.}$, the harmonic part of the vibration-rotation constant, and g_s, the degree of vibrational degeneracy. The relation between the nuclear-distance parameter, r_z, which is derived from I_{zero}, and the nuclear distance parameter, r_α, of Eq. 9 is:

$$\lim_{T\to 0} r_\alpha \equiv r^0 = r_z. \quad (11)$$

Therefore, r_α can be regarded as r_z if the normal frequencies are much larger than kT/hc. In the case of carbon tetrafluoride, therefore, we get:

$$r_z(\text{C-F}) = (1.3172\pm0.0004)\times10^{-8}\,\text{cm}, \quad \text{and}$$
$$B_0 = 0.1920\pm0.0001\,\text{cm}^{-1},$$

using $r_g(\text{C-F})=(1.3197+0.0004)\times10^{-8}$ cm, which was determined by Fink *et al.*,[7] and the harmonic force field of Ref. 8. The values of the molecular constants which were calculated from the B_0 value and the molecular constants of Table 1 are summarized in Table 3.

Table 3. The molecular constants (in cm^{-1}) determined by using the r_g-structure and the present results

ν_0	1283.7181±0.0044
B_{eff}^{PR}	0.1915±0.0001
B_0	0.1920±0.0001
$(B\zeta_3)_{eff}$	0.1557±0.0003

It is of some interest to estimate the Coriolis coupling constant from the observed $(B\zeta_3)_{eff}$ value. $(B\zeta_3)_{eff}$ is written as:[6]

$$(B\zeta_3)_{eff} = B_e\zeta_3 + (3/4)\beta_3 \quad (12)$$

where;

$$\beta_3 = (1/3)(B_{eff}^{Q}-B_{eff}^{PR}). \quad (13)$$

From these equations, ζ_3 is given by:

$$\zeta_3 = \frac{(B\zeta_3)_{eff}-(1/4)(B_{eff}^{Q}-B_{eff}^{PR})}{B_e}. \quad (14)$$

In order to determine the ζ_3 value, the as-yet-undetermined B_{eff}^{Q} and B_e values are necessary. If we assume that these relations hold:

$$|B_{eff}^{Q}-B_{eff}^{PR}| \lesssim |B_{eff}^{PR}-B_0|$$

and:

$$|B_0-B_e| \lesssim |B_{eff}^{PR}-B_0|,$$

then ζ_3 is approximately expressed as:

$$\zeta_3 \simeq (B\zeta_3)_{eff}/B_0. \quad (15)$$

The error expected in the ζ_3 value thus calculated is of the order of $(2|B_{eff}^{PR}-B_0|)/B_0$. Thus, we obtained $\zeta_3=0.811\pm0.006$. Edgell *et al.* determined the Coriolis conpling constant for the ν_3 band, $\zeta_3=0.84$, by an analysis of the P-R-branch separation of the ν_3 envelope.[1] The present result is significantly smaller than their result. The Coriolis coupling constant for the ν_4 band was obtained by Jones *et al.*[3] Their result, $\zeta_4=-0.366$, predicts that the ζ_3 value will be about 0.866, because of the Corilois sum rule, $\zeta_3+\zeta_4=0.5$. The present estimation is much smaller than their prediction. The reason for this disagreement is not yet clear and must be left for future study.

Incidentally, we wish to add a few lines on a future problem in high-resolution spectroscopy using a tunable diode laser-source spectrometer. In this study, detailed molecular constants could not be obtained, although the spectra have been recorded by the use of a tunable diode laser-source spectrometer whose instrumental resolution was 10^{-4}—10^{-3} cm^{-1}. The reason for this are thought to be:

1) The precision and accuracy of the frequency measurement is not satisfactory enough, although the instrumental resolution surprisingly high.

2) It is difficult to tune a diode laser in the required frequency region and over a wide frequency range.

3) Since an observed linewidth is governed by the Doppler broadening, an effective spectral resolution is not essentially improved very much.

The authors wish to express their thanks to Dr. Shigeo Kondou, of the National Chemical Laboratory for Industry, for obtaining the spectrum recorded by the Fourier transform spectrometer. The authors also would like to thank professor Eizi Hirota, of the Institute for Molecular Science, for giving them the opportunity to use the tunable diode laser-source spectrometer.

9) We tried to determine the molecular constants, including the centrifugal distortion constants, with the assumption that $D_0^J=D_1^J$. The following molecular constants were obtained by the least-squares method:

$$\nu_0-2(B\zeta_3)_{eff} = 1283.2978\pm0.0092\,\text{cm}^{-1}$$
$$B_{eff}^{PR}+B_0-2(B\zeta_3)_{eff} = (5.050\pm0.178)\times10^{-2}\,\text{cm}^{-1}$$
$$B_{eff}^{PR}-B_0 = -(1.876\pm0.110)\times10^{-4}\,\text{cm}^{-1}$$

$D_0^J = (6.93 \pm 0.56) \times 10^{-6}\ cm^{-1}$

$\delta_3 = (6.123 \pm 0.054) \times 10^{-4}\ cm^{-1}$

However, these results seem to be unreasonable. The transition frequency of the R-branch line which is calculated from these molecular constants takes a maximum value at $J=11$ and then decreases $J>11$ as the J value increases. This is not consistent with the observed band profile of the R branch (see Fig. 1).

10) Even if we give zero weight to the P(15) lines in the least-squares fitting, the resultant molecular constants are very close to those in Table 1.

Vibration Spectra and Rotational Isomerism of Chain Molecules. VIII.[1] 1-Chloro-, 1-Bromo-, and 1-Iodopentanes, and 1,4-Dichloro- and 1,4-Dibromobutanes

Hiroatsu MATSUURA,*,† Shuji IMAZEKI, Yoshiki OGAWA, Masaaki SAKAKIBARA,††
Issei HARADA, and Takehiko SHIMANOUCHI†††

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 26, 1979)

The Raman and infrared spectra of 1-chloro-, 1-bromo-, and 1-iodopentanes $CH_3(CH_2)_4X$ (X=Cl, Br, and I), and 1,4-dichloro- and 1,4-dibromobutanes $X(CH_2)_4X$ (X=Cl and Br) were measured for the gaseous, liquid, glassy, and crystalline states. The normal coordinates were calculated for these molecules by the use of a consistent set of force constants. The rotational isomerism was studied by analyzing the spectra with reference to the results of the calculation. The study clarified the isomers present not only in the crystalline state but also in other states of aggregation. In the crystal, 1-chloro-, 1-bromo-, and 1-iodopentanes take the *trans-trans-trans* form and 1,4-dichloro- and 1,4-dibromobutanes take the *gauche-trans-gauche'* form.

Many studies have been made of the rotational isomerism of 1-halogenopentanes[2–7] and 1,4-dihalogenobutanes[8–11] by means of Raman, infrared, and NMR measurements. As a result, the conformer in the crystalline state has been made clear for each of these molecules. However, the rotational isomers existing in other states such as liquid and glass have not yet been fully explored.

In the preceding paper of this series,[1] we reported the vibration spectra and the rotational isomerism of 1-halogenopropanes and 1-halogenobutanes, and obtained information on the conformational stabilities of these molecules. In the present work, we extended our studies to longer halogenoalkanes: 1-halogenopentanes $CH_3(CH_2)_4X$ (X=Cl, Br, and I) and 1,4-dihalogenobutanes $X(CH_2)_4X$ (X=Cl and Br). The rotational isomerism was studied by analyzing the Raman and infrared spectra with reference to the results of the normal coordinate calculation.

Experimental

All the samples used in this study were purchased from Tokyo Kasei Kogyo Co., Ltd. and were distilled prior to the spectroscopic measurements. The Raman and infrared spectra were measured for the gaseous (only for 1-chloropentane), liquid, glassy, and crystalline states by the method reported previously.[12,13] The glassy state for Raman measurements was obtained by immersing the liquid sample enclosed in an ampoule in liquid nitrogen for rapid cooling, and the glassy state for infrared measurements by depositing the gaseous sample onto a cooled plate of KBr or KRS-5. The glassy state of 1,4-dichloro- and 1,4-dibromobutanes for Raman measurements and that of 1,4-dibromobutane for infrared measurements could not be obtained because of rapid crystallization.

Normal Coordinate Treatment

The normal coordinate calculations were carried out with a computer program NCTB2[14] and a HITAC 8800/8700 computer system at the Computer Center of the University of Tokyo. The detailed procedure of the calculations on unbranched halogenoalkanes has been described in the previous paper.[1] The observed frequencies for the molecules treated in this study together with those of the shorter molecules (1-halogenopropanes, 1-halogenobutanes, and 1,3-dihalogenopropanes) were used in the refinement of the force constants.

In the analyses of the observed spectra, the calculation of the normal coordinates plays an important role, since the assignments of the bands to individual conformers rely largely on the calculated frequency values. Therefore, the accuracy of the calculated frequencies has to be high enough to allow the spectral analyses. The high accuracy is particularly required for large molecules, such as those studied in this work, which give many bands in the spectra.

The force constants used in this study have been obtained by the least-squares procedure from about 340 observed frequencies for chloroalkanes, 400 for bromoalkanes, and 400 for iodoalkanes,[15] with root-mean-square deviations of 5.6, 6.1, and 6.5 cm^{-1}, respectively, between the observed and calculated frequencies. These accuracies of the calculations, we believe, are high enough to analyze the spectra of 1-halogenopentanes and 1,4-dihalogenobutanes in this study.

Results

Figures 1—10 show the observed spectra of the 1-halogenopentane and 1,4-dihalogenobutane molecules in various states of aggregation in comparison with the calculated frequencies.[17]

1-Halogenopentane molecules have, as given in Table 1 of Part I of this series,[12] fourteen possible rotational isomers, TTT, TTG, TGT, GTT, TGG, GTG, GGT, TGG', GTG', GG'T, GGG, GGG', GG'G, and GG'G', where the first conformation symbol in each isomer designation is that for the CH_3CH_2–CH_2CH_2 axis and the last for the CH_2CH_2–CH_2X axis. Of these, the isomers with a sequence of the GG' conformation, *i.e.* TGG', GG'T, GGG', GG'G, and GG'G' are unlikely to exist because of the strong

a) Ref. 6. b) Spectral measurements were not made. c) Two crystal modifications have been obtained. For the TTG form, see Ref. 20.

steric hindrance. In fact, existence of the GG′ form of pentane[18] or of 1-halogenobutanes[1] has not been identified in any state of aggregation. 1,4-Dihalogenobutane molecules have ten possible rotational isomers, TTT, TTG, TGT, TGG, GTG, TGG′, GTG′, GGG, GGG′, and GG′G. Of these, the TGG′, GGG′, and GG′G forms are again unlikely to exist.

In the following subsections, the rotational isomerism of the individual molecules is described. For the spectral analyses, the bands due to the skeletal deformation, skeletal stretching, and CH_2 rocking vibrations were primarily used to identify the existing rotational isomers.

1-Chloropentane (See Figs. 1 and 2). The crystalline-state spectra are explained by the existence of the TTT form, since the Raman bands at 263, 347, 448, 714, 737, 759, 835, 892, (and 900), and 955 cm^{-1} are all assigned consistently to this form. The calculated frequencies are 256, 354, 462, 727, 729, 754, 833, 901, and 956 cm^{-1}, respectively.

In the liquid and glassy states, the spectra exhibit many bands to be assigned to various rotational isomers. It is evidently shown that the TTT and TTG forms exist in these states. The relative intensities of the Raman bands at 400, 455, 653, 788, 838, 908, and 923 cm^{-1}, together with those of the bands which have been assigned to the TTT form, increase in going from the liquid state at room temperature to the glassy state at liquid nitrogen temperature. All of these bands correspond to the calculated frequencies for the TTG form: 401, 456, 656, 791, 838, 916, and 929 cm^{-1}.

The liquid- and glassy-state spectra have further additional bands. Spectral observations indicate that these bands lose their intensities largely, when temperature is lowered, as compared with the bands which have been assigned to the TTT and TTG forms. According to the results of the normal coordinate treatment, the bands at 375 and 822 cm^{-1} are assigned to the GTG form (the calculated frequencies: 369 and 823 cm^{-1}), those at 387 and 878 cm^{-1} to the TGG form (384 and 886 cm^{-1}), those at 712, 764, and 855 cm^{-1} to the TGT form (714, 761, and 856 cm^{-1}), and that at 933 cm^{-1} to the GTG′ form (938 cm^{-1}).

Existence of the GTT form is uncertain, since all of the calculated frequencies of this form are almost coincident with those of the other forms mentioned above. For the GGG and GGT forms, no positive evidence of their existence was obtained. According to the calculation, the former form is expected to exhibit bands around 325 and 410 cm^{-1} and the latter at 475 cm^{-1}, but no recognizable bands are actually observed in these frequency regions. Therefore, the GGG and GGT forms do not seem to exist in the liquid or glassy state.

The gaseous-state Raman spectrum is essentially the same as the liquid-state Raman spectrum but relative intensities of several bands are different between them. This suggests that the gaseous and liquid molecules have the same kinds of rotational isomers with different distributions.

The temperature dependence of the liquid-state Raman spectra shows that the TTT and TTG forms have much higher stabilities than the other forms in this state. These two forms are also dominant conformers in the glassy state at liquid nitrogen temperature. These observations are consistent with the result obtained for 1-chlorobutane that the TT and TG forms are more stable than the other forms.[1]

1-Bromopentane (See Figs. 3 and 4). The spectra of the crystalline state is explained by the existence of the TTT form, since the Raman bands at 216, 334, 433, 638 (and 644), 731, 753, 828, 894 (and 899), and 944 cm^{-1} are assigned consistently only to this form. The calculated frequencies are 215, 341, 446, 642, 729, 751, 825, 899, and 943 cm^{-1}, respectively.

In the liquid and glassy states, the existence of the TTT and TTG forms is clear, similarly to the case of 1-chloropentane. In going from the liquid state to

For the TTT and GTG′ forms, the open and filled circles indicate Raman- and infrared-active vibrations, respectively.

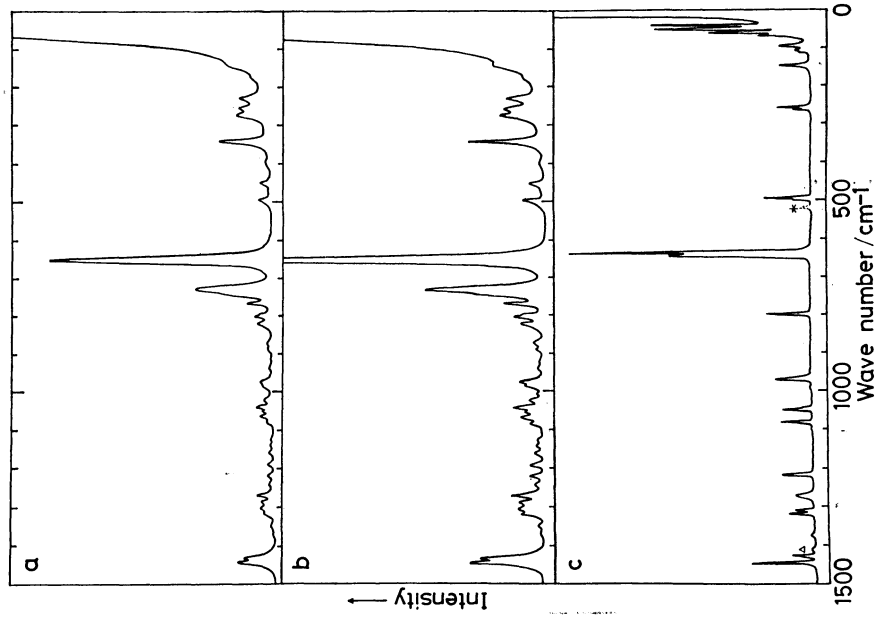

Fig. 7. Raman spectra of 1,4-dichlorobutane. a: Liquid (23 °C), b: liquid (−35 °C), c: crystal (liquid nitrogen temperature).

the glassy state, the relative intensities of the Raman bands at 398, 437, 562, 728, 780, 825, 906, and 918 cm^{-1} of the TTG form increase together with those of the TTT form. The calculated frequencies of the TTG form are 400, 438, 563, 731, 784, 827, 912, and 926 cm^{-1}, respectively.

In addition to the Raman bands of the TTT and TTG forms, the liquid- and glassy-state spectra exhibit many other bands. On the basis of the results of the normal coordinate treatment, the band at 323 cm^{-1} is assigned to the GTT form (the calculated frequency: 326 cm^{-1}), that at 487 cm^{-1} to the GTG form (485 cm^{-1}), those at 843 and 875 cm^{-1} to the TGG form (844 and 874 cm^{-1}), that at 847 cm^{-1} to the TGT form (847 and 850 cm^{-1}), and those at 930 and 957 cm^{-1} to the GTG′ form (936 and 955 cm^{-1}). It is likely that the GGG form is also present in the liquid state, since a very weak Raman band is observed as a shoulder at 866 cm^{-1}, which corresponds to the calculated frequency 867 cm^{-1} of this form.

Existence of the GGT form in the liquid and glassy states is uncertain, as all of the calculated frequencies of this form are almost coincident with those of the other forms mentioned above. Also, the GTT and GGG forms are not confirmed to exist in the glassy state, because their characteristic bands are too weak to identify them in this state.

The TTT and TTG forms are far more stable than the other forms in the liquid state as shown from the temperature dependence of the Raman intensities, and are also predominating isomers in the glassy state. These findings are similar to those for 1-chloropentane.

1-Iodopentane (See Figs. 5 and 6). The molecule takes the TTT form in the crystalline state, since the observed Raman bands at 205, 329, 432, 593, 715, 745, 813, and 898 cm^{-1} are assigned consistently to this form which gives calculated frequencies 191, 331, 438, 590, 721, 736, 811, and 898 cm^{-1}.

The existence of the TTT and TTG forms in the liquid and glassy states is clearly shown from the spectral observation that the bands whose intensities increase at lower temperature are assigned to these forms. The Raman bands of the TTG form are those at 395, 427, 506, 726, 768, 807, 902, and 917 cm^{-1} which are compared with the calculated frequencies 399, 426, 506, 731, 769, 808, 908, and 922 cm^{-1}, respectively.

In addition to the TTT and TTG forms, the existence of other forms in the liquid and glassy states is confirmed by the spectral observations incorporated with the normal coordinate treatment. Of the Raman bands which have not been assigned to the TTT or TTG form, the bands at 458 and 525 cm^{-1} are interpreted to be due to the TGG form (the calculated frequencies: 463 and 516 cm^{-1}), those at 602 and 837 cm^{-1} to the TGT form (598 and 837 cm^{-1}), those at 782 and 799 cm^{-1} to the GTG form (784 and 791 cm^{-1}), that at 817 cm^{-1} to the GTG′ form (814 cm^{-1}), and that at 875 cm^{-1} to the GTT form (883 cm^{-1}).

It is likely that the GGG form exists in the liquid state, since a very weak Raman band is observed at 385 cm^{-1} at room temperature, which is in agreement with the calculated frequency 387 cm^{-1} of this form. However, in the glassy-state spectrum, this band is too weak to confirm existence of this form. Therefore, it is not certain whether the GGG form is present in this state. Existence of the GGT form in the liquid and glassy states is also uncertain, since all of the calculated frequencies are almost coincident with those of the other forms.

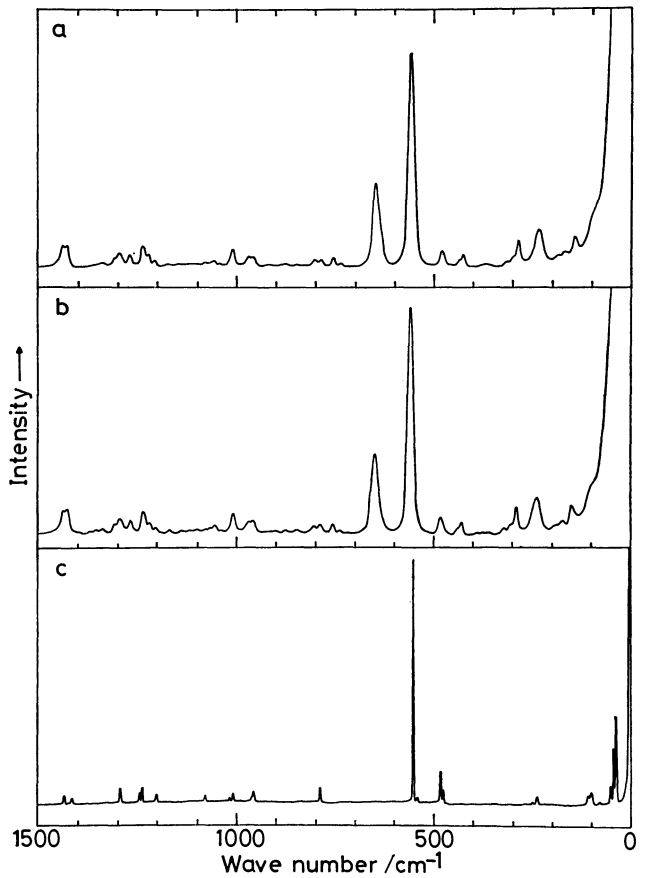

Fig. 9. Raman spectra of 1,4-dibromobutane. a: Liquid (23 °C), b: liquid (−20 °C), c: crystal (liquid nitrogen temperature).

The glassy-state spectra and the temperature dependence of the liquid-state spectra show that the conformational stabilities of the TTT and TTG forms are higher than those of the other forms.

The spectra of the liquid and glassy states exhibit in the C–I stretching region four Raman bands at 506, 525, 592, and 602 cm^{-1} and the corresponding infrared bands at 506, 522, 593, and 603 cm^{-1}. According to the normal coordinate calculation, the TTG, GTG, and GTG′ forms (having the *trans-gauche* conformation about the CC–C–CI axes) give the C–I stretching frequencies of about 505 cm^{-1}, the TGG and GGG forms (having the *gauche-gauche* conformation) about 515 cm^{-1}, the TTT and GTT forms (having the *trans-trans* conformation) about 590 cm^{-1}, and the TGT and GGT forms (having the *gauche-trans* conformation) about 600 cm^{-1}. The observed bands are reasonably assigned to these four groups of conformers. This spectral observation indicates that the C–I stretching frequency can be used to examine the conformation not only about the CC–CI axis but also about the adjacent CC–CCI axis.

1,4-Dichlorobutane (See Figs. 7 and 8). In the crystalline state, the Raman and infrared spectra are quite different from each other and the mutual exclusion in the Raman and infrared activities is clearly observed. Of the two conformers TTT and GTG′ having a center of symmetry, the observed C–Cl stretching frequencies of about 640 cm^{-1} are consistent only with the latter form. The observed frequencies of other bands are also explained by this form. Thus, the molecule in the crystal is found to take the centrosymmetrical GTG′ form.

The observed spectra in the liquid state are explained by the coexistence of the GTG′, TTT, TTG, GTG, GGG, and TGG forms. The bands which are characteristic of the individual conformers are: 175, 452, and 974 cm^{-1} of the TTG form (the calculated frequencies: 181, 456, and 988 cm^{-1}); 230 (Raman) and 414 cm^{-1} (infrared) of the TTT form (213 and 428 cm^{-1}); 393, 797, 909, and 935 cm^{-1} of the GGG form (400, 798, 923, and 933 cm^{-1}); 467 and 925 cm^{-1} of the TGG form (465 and 932 cm^{-1}); and 505 and 870 cm^{-1} of the GTG form (504 and 864 cm^{-1}). In the glassy-state infrared spectrum, most of the liquid-state bands persist but the bands assignable to the TGG form are not observed definitely. Accordingly, the conformers mentioned above for the liquid state but the TGG form are confirmed to be present in the glassy state as well. Existence of the TGT form is not certain in the liquid and glassy states, since all of their frequencies are almost coincident with those of the other forms.

The spectral change with temperature variation in the liquid state shows that the Raman bands at 494, 505, 803, 870, and 974 cm^{-1} are enhanced at lower temperature. This indicates that the GTG′ and GTG forms, to which these bands are assigned, are more stable than the other forms coexisting in the liquid state.

1,4-Dibromobutane (See Figs. 9 and 10). In the crystalline state, the Raman and infrared spectra show the mutual exclusion activities, similarly to the case of 1,4-dichlorobutane. The observed frequencies and the Raman and infrared activities of the individual vibrations agree with those for the GTG′ form, indicating the existence of this form in the crystalline state.

Analyses of the liquid-state Raman and infrared spectra show that all of the seven possible conformers, GTG′, TTT, TTG, GTG, GGG, TGG, and TGT, are present in this state. The following bands give evidences for the existence of these conformers: 148 (Raman), 325 (Raman), 354 (infrared), and 743 cm^{-1} (infrared) of the TTT form (the calculated frequencies: 142, 331, 366, and 735 cm^{-1}); 190, 368, 474, and 787 cm^{-1} of the GGG form (200, 371, 464, and 787 cm^{-1}); 303, 484, and 817 cm^{-1} of the GTG form (305, 481, and 819 cm^{-1}); 318, 443, and 873 cm^{-1} of the TGG form (321, 435, and 878 cm^{-1}); 387 cm^{-1} of the TGT form (399 cm^{-1}); and 428 and 289 cm^{-1} of the TTG form (432 and 289 cm^{-1}).

In the liquid-state Raman spectra, the intensities of the bands at 481, 787, and 959 cm^{-1} are enhanced at lower temperature as compared with those of other bands. The GTG′ form, giving these bands, is thus found to have higher stability than others in the liquid state.

Rotational Isomerism in Comparison with Previous Results. In Table 1, the rotational isomerism of the five molecules studied in this work is summarized. The result of 1-fluoropentane $CH_3(CH_2)_4F$ is also included in this table.

Many studies have been made of the rotational isomerism of 1-halogenopentanes[2–7] and 1,4-dihalogenobutanes.[8–11] Brown and Sheppard[2,9] studied the infrared spectra of many halogenoalkane molecules in the liquid and crystalline states. They concluded that the crystalline-state isomer of 1-bromopentane has a planar conformation of the carbon and bromine atoms. For 1,4-dichloro- and 1,4-dibromobutanes, they showed that these molecules take in the crystalline state the GTG′ conformation with a center of symmetry.

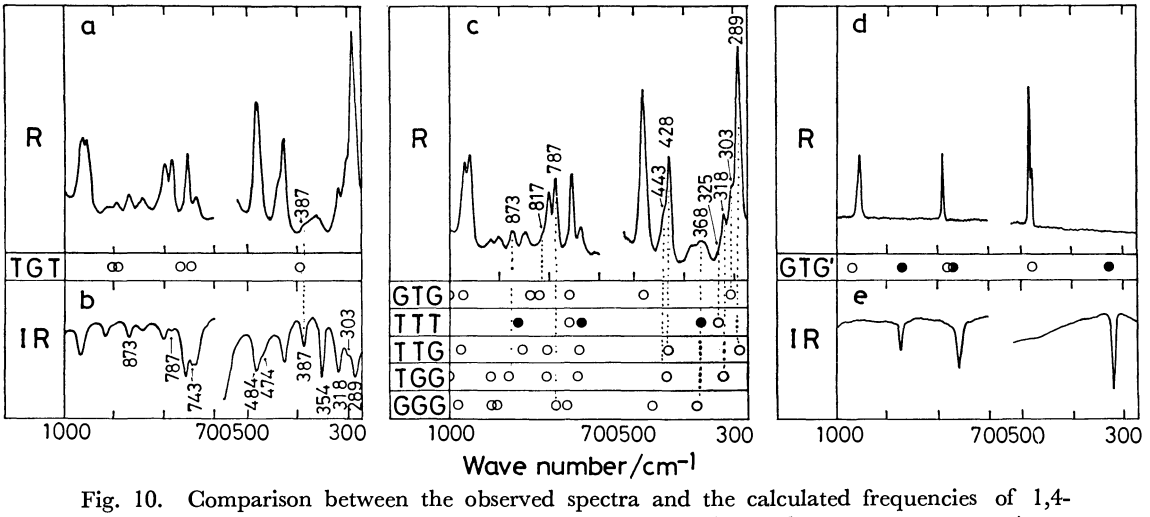

Fig. 10. Comparison between the observed spectra and the calculated frequencies of 1,4-dibromobutane. a: Liquid (Raman, 23 °C), b: liquid (infrared, room temperature), c: liquid (Raman, −20 °C), d: crystal (Raman, liquid nitrogen temperature), e: crystal (infrared). For the TTT and GTG′ forms, the open and filled circles indicate Raman- and infrared-active vibrations, respectively.

Snyder and Schachtschneider[5] measured the infrared spectra of $CH_3(CH_2)_nCl$ (n=1—5) in the crystalline and glassy states. For 1-chloropentane, they concluded on the basis of the normal coordinate analysis that the spectrum of the former state could be explained by the existence of the TTT form and that of the latter state by the coexistence of the TTT and TTG forms.

Crowder and coworkers, on the other hand, interpreted the infrared spectra of 1-iodopentane[7] and 1-fluoropentane[6] in the liquid, glassy, and crystalline states, taking account of only two among various isomers, the TTT and TTG forms. Their observed data for 1-fluoropentane were analyzed in the light of our normal coordinate calculation,[1,14] and it is now shown that the TGT and GTT forms, in addition to the TTT and TTG forms they mentioned, are confirmed to exist in the liquid state. Crowder and Ali[11] also measured the spectra of 1,4-diiodobutane.

The present results of the rotational isomerism in the crystalline state agree with the previous results mentioned above. This study further clarified the rotational isomers present in the liquid and glassy states as well on the basis of the careful spectral observations and the systematic normal coordinate calculation.

Discussion

In our previous study,[1] it was demonstrated that the skeletal deformation vibrations were important for studying the rotational isomerism of halogenoalkanes. In the present study on the longer molecules, the bands in the skeletal deformation region were efficiently used in analyzing the spectra and identifying the rotational isomers present in various states of aggregation. The bands due to the skeletal stretching and the CH_2 rocking vibrations were also found to be useful for studying the rotational isomers.

From the results in this and previous[1] studies on $CH_3(CH_2)_nX$ (n=2—4; X=Cl, Br, and I) and $X(CH_2)_4X$ (X=Cl and Br), it has become clear that the *gauche* conformation about the CC–CX axis is more stable than or as stable as the *trans* conformation in the liquid state. However, in the crystalline state, the accessible conformation about this axis is likely to depend on the subtle balance between the intramolecular forces favoring the *gauche* conformation rather than the *trans* and the intermolecular forces favoring the *trans* conformation. For $X(CH_2)_3X$ (X=Cl, Br, and I)[9,19] and $X(CH_2)_4X$ (X=Cl and Br), the non-planar GG and GTG′ forms exist in the crystalline state. On the other hand, for $CH_3(CH_2)_nX$ (n=2—4; X=Cl, Br, and I), the all-*trans* form exists in the crystalline state. A crystal consisting of the TTG form of $CH_3(CH_2)_4Br$ has also been obtained.[20] It is thus probable that the balance of the intra- and intermolecular forces mentioned above is responsible, at least in part, for the thermodynamic properties of these molecular crystals.

Through this series of studies on the vibration spectra and the rotational isomerism of chain molecules, a reliable and consistent set of force constants has been obtained, which has been satisfactorily utilized for predicting vibrational frequencies of various molecules. The present method of analyzing the spectra in conjunction with the use of the refined force field encourages us to make further studies on the rotational isomerism of large molecules.

The present series of studies has also provided us with various important information for making more advanced investigations in the field of structural chemistry. The conformational polymorphism of halogenoalkane molecules[20] has been in fact investigated in close relation to our fundamental studies in this series.

An MO Study of Organic Sulfur Compounds. Comparison with the Corresponding Oxygen Compounds

Toshio MATSUSHITA, Yoshihiro OSAMURA, Nobuaki MISAWA, Kichisuke NISHIMOTO,* and Yuuho TSUNO†

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

†*Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

(Received March 31, 1979)

The contribution of 3d orbitals of sulfur atom to the electronic structures of the sulfur compounds, H_2CS, CH_3SH, C_6H_5SH, and $C_6H_5SCH_3$ have been studied by means of *ab initio* MO method. The results have been compared with those of the corresponding oxygen compounds in order to clarify the peculiar properties of the sulfur compounds. The global molecular properties are scarcely affected by the 3d orbitals of sulfur atom since they are energetically highly located. However, the local characters such as charge distributions and LUMO are largely varied by the participation of 3d orbitals.

Sulfur forms not only organic sulfur compounds analogous to oxygen compounds but also various stable hypervalent compounds. It is well known that the nucleophilicity of the lone pair of sulfur atom is larger than that of oxygen. However, the basicity of sulfur atom is smaller than that of oxygen, reversely. In this manner, sulfur has some different chemical properties from those of oxygen. Thus it is of interest to investigate the electronic structures of sulfur compounds and consider the origin of peculiar properties theoretically.

We have investigated the effect of 3d orbitals of sulfur atom on the electronic structures of sulfur compounds. 3d orbitals of sulfur are thought to participate in the chemical bonding. The SCF calculation of α-thiocarbanion[1] and the GVB calculation of SF_6[2] showed that the effects of 3d orbitals on the stability and the reactivity are small. The contribution of vacant 3d orbitals to the global molecular properties may be small since they are energetically highly located.

However, in order to explain the NMR chemical shifts of substituted thiophenes in view of charge distribution, the contribution of 3d orbitals can not be neglected.[3] Furthermore, as Inagaki *et al.*[4] pointed out, vacant 3d orbital participation is important in determining the stereochemical courses of reactions where sulfur compounds undergo the attack of nucleophilic reagents.

In the present study, an *ab initio* MO calculation has been carried out for thioformaldehyde, methanthiol, thiophenol, thioanisole, phenol, and anisole in order to clarify the nature of electronic structures of organic sulfur compounds, especially the differences in the role of sulfur and oxygen atoms on the electronic structures of molecules. We have also calculated the rotational barriers of substituted benzenes and consider the steric effect. On the basis of the calculated results, the vacant 3d orbital participation to some molecular properties, such as reactivity, polarity, *etc.* is discussed.

Calculation

Ab initio MO calculation is carried out using a minimal STO-3G basis set with the POLYATOM version 2[5] and GAUSSIAN 70[6] program packages. For sulfur atom, the five 3d functions are added to the minimal basis set. The orbital exponent ζ of 3d functions is obtained by optimizing the total energy of H_2S. The optimized value is found to be 1.77. Boer and Lipscomb[7] reported $\zeta=1.71$, obtained by means of the basis set of Slater type AO's. The orbital exponent of 3d functions optimized for CH_3SH also gives $\zeta=1.77$. This value is used for all the other molecules in the present calculation.[8]

Figure 1 shows the geometric parameters of H_2S, H_2CS, CH_3OH, and CH_3SH used in the present MO calculation. These geometries are taken from experimental data.[9] We assume C_{3v} symmetry for a methyl group. C–S double bond length (1.61 Å) and C–S single one (1.82 Å) are about 0.4 Å longer than the corresponding C–O bond lengths.

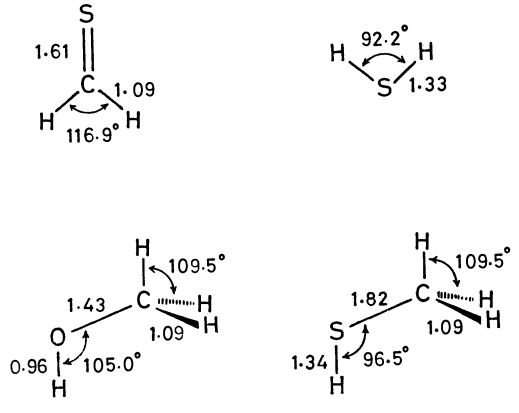

Fig. 1. Geometries of H_2S, H_2CS, CH_3OH, and CH_3SH used in this calculation. Units are shown in Å and degree.

The geometric parameters of C_6H_5OH, C_6H_5SH, $C_6H_5OCH_3$, and $C_6H_5SCH_3$ are given in Fig. 2(a). For phenyl and methyl groups, the geometries of benzene and methanol are used respectively, a staggered conformation being used for $C_6H_5OCH_3$ and $C_6H_5SCH_3$. The numbering of atoms of substituted benzenes is shown in Fig. 2(b).

Results and Discussion

Molecular Orbitals. In order to discuss the difference between the electronic structures of oxygen and

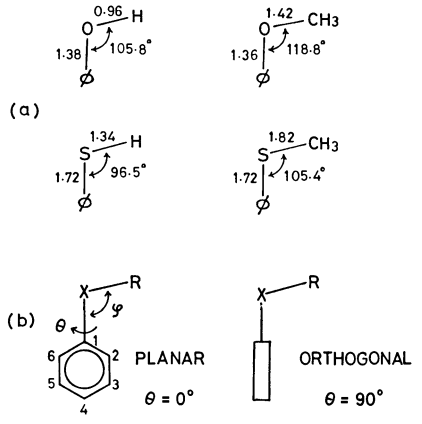

Fig. 2. (a) Geometries of benzene derivatives. Units are shown in Å and degree.
(b) The definition of angle θ and ϕ and the numbering of atoms.

sulfur compounds, we have used a composite molecular model in which the molecular orbitals of whole molecules are represented in terms of the molecular orbitals of the composite subsystems. Using this model, the effects of substituted groups and 3d orbitals on the parent molecules would be clarified in view of the orbital interaction.

The thiocarbonyl group undergoes nucleophilic attacks at the sulfur atom in contrast to the corresponding oxygen compounds.[10] Inagaki *et al.*[4] interpreted this in terms of the orbital interaction based on semi-empirical MO method. The vacant 3d orbitals of sulfur play a significant role in determining the stereochemical courses of the nucleophilic reactions of sulfur compounds. We have investigated the 3d participation by means of *ab initio* MO method.

The modes of orbital interaction between the π orbitals of benzene and π-type orbitals of OH, SH, and SCH_3 groups are shown in Figs. 3—5, the numbering of π orbitals of benzene being given in the left hand side of Fig. 3.

Since the energy of 2p-π of OH group lies lower than that of HOMO's (π_2 and π_3) of benzene, the main component of HOMO of phenol is the π_3 orbital

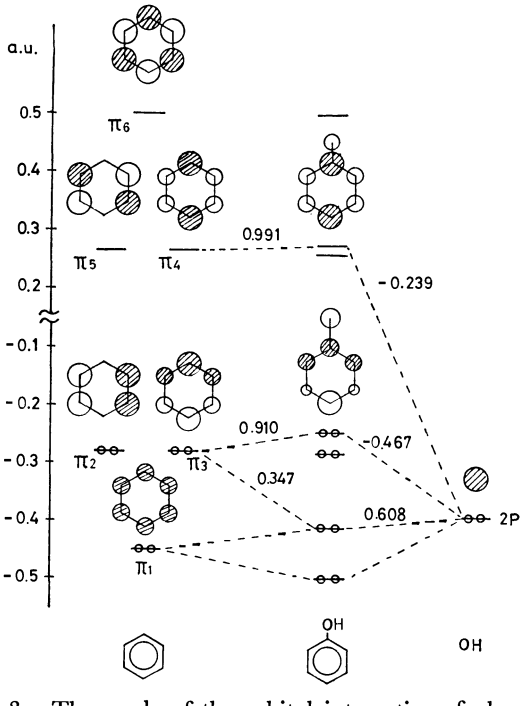

Fig. 3. The mode of the orbital interaction of phenol.

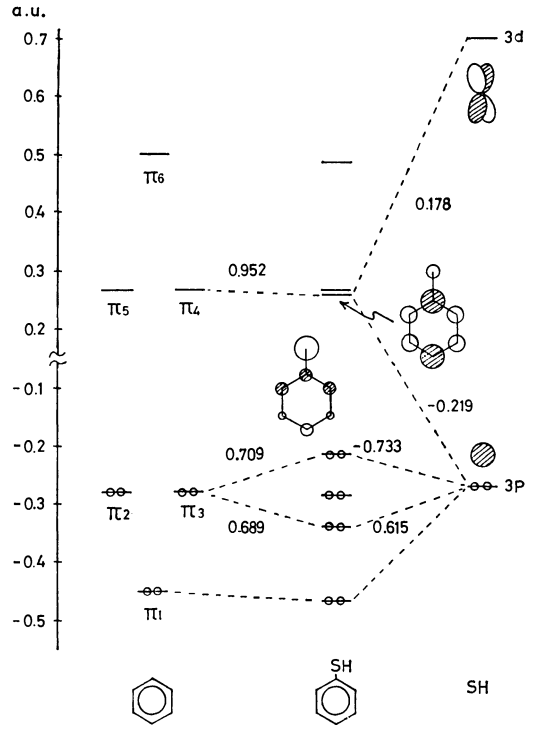

Fig. 4. The mode of the orbital interaction of thiophenol.

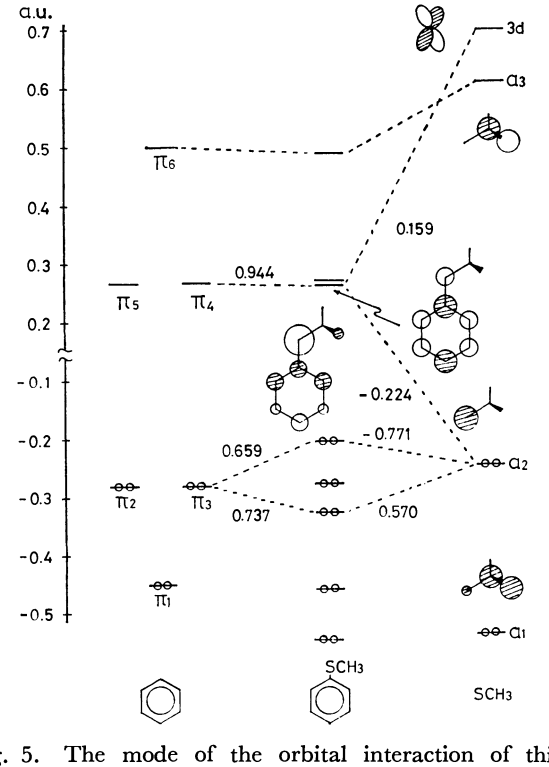

Fig. 5. The mode of the orbital interaction of thioanisole.

of benzene (Fig. 3). The interaction between the π-type orbital of a substituent and π_2 (or π_5) of benzene is symmetry forbidden. In C_6H_5SH (or $C_6H_5SCH_3$), 3p-π of SH group (or a_2 orbital of SCH_3 group) and π_3 orbital mix with each other in nearly equal weight, since the orbital energy of 3p-π of SH group (or a_2 orbital of SCH_3 group) is very close to the π_3 orbital of benzene (Fig. 4 or 5). Consequently the HOMO's of C_6H_5SH and $C_6H_5SCH_3$ have large amplitude at the sulfur atom in contrast to the cases of phenol and anisole. On the other hand, the contribution of the vacant 3d orbitals to *occupied* MO's is small and can be neglected.

The chemical reactivity of a given molecule can be explained qualitatively in terms of the frontier orbitals.[11]

HOMO plays the most important role for the electrophilic reaction. For thiophenol and thioanisole, 3p-π of the sulfur atom has the largest amplitude at HOMO. There are some experimental data showing that an electrophilic reagent attacks the sulfur atom first.[12]

Let us consider LUMO's of molecules, which are responsible for the nucleophilic reaction.

LUMO of C_6H_5SH (or $C_6H_5SCH_3$) has a π_4 character (Fig. 4 or 5) for the following reasons. π_4 is mixed by out of phase combination with 3p-π of the SH group (or a_2 orbital of the SCH_3 group), which gives rise to some increase in orbital energy. However, π_4 interacts strongly with the vacant 3d orbitals. As a result, the π_4 orbital energy is decreased. π_5 orbital also interacts with 3d orbital which is antisymmetric on the molecular axis, but this interaction is very small.

The orbital mixing of π_4 and 2p-π of OH group in phenol should be out of phase so that the orbital energy is increased, but π_5 orbital interacts hardly with oxygen 2p-π (Fig. 3). Thus, the main component of LUMO of phenol is π_5 orbital of benzene.

The LUMO's of benzene are scarcely influenced by the CH_3 group of OCH_3 and SCH_3, since the perturbation of their a_3 orbitals localized mainly in the CH_3 group is very small. It is concluded that the reversal of π_4 and π_5 in thiophenol and thioanisole is clearly due to the contribution of 3d orbitals.

Charge Distribution. Let us consider the effect of 3d orbitals on the charge distribution of the molecules.

Figure 6 shows the net charges of CH_3SH and H_2CS calculated without and with 3d orbitals. In the corresponding oxygen compounds, the electronegative oxygen atom pulls the bonding electrons, so that the neighboring atom has the positive net charge. It should be noted that when the heteroatom is sulfur, the neighboring carbon atom has negative charge (Fig. 6). This tendency is encountered also in other molecules (C_6H_5SH and $C_6H_5SCH_3$). In both cases, CH_3SH and H_2CS, the positive net charges on sulfur atoms are decreased by including the 3d orbitals. This effect is larger in the compound containing C–S double bond (H_2CS) than that with C–S single bond (CH_3SH).

The calculated total electron populations of substituted benzenes are summarized in Table 1. From a comparison of the charge distributions on the phenyl group, it is found that the polarization of the phenyl group in phenol or anisole is larger than that in the corresponding sulfur compounds. Thus, phenol and anisole should show stronger orth-, para-orientation than thiophenol and thioanisole.

The charge density has a linear relationship with NMR chemical shift.[13] The ^{13}C NMR chemical shifts for these molecules are also given in Table 1.[14] The NMR result shows that the polarization of the phenyl

group in phenol derivatives is very large and that in thiophenol derivatives is rather small. Thus the calculated electron populations are in good accord with experimental data.

It should be noted that the calculated charge densities of C-1 in C_6H_5SH and $C_6H_5SCH_3$ without 3d orbitals can not explain the ^{13}C NMR data. The calculation without 3d orbitals gives too large a negative charge on C-1, but chemical shifts shows that the charge of this carbon is less negative than that of other ones. On the other hand, the inclusion of 3d orbitals reduces the negative net charges on C-1 in C_6H_5SH (−0.018) and in $C_6H_5SCH_3$ (−0.023) which are smaller than those of all other positions. Therefore, these results show that the effect of 3d orbitals is important for the charge distribution of sulfur compounds.

It is interesting to analyze the electron distribution in a substituted benzene in terms of the intramolecular charge transfer between phenyl group (Ph) and the substituent {XR, (X=O, S and R=H, CH_3)}. This analysis clarifies the difference between oxygen and sulfur compounds for the π (or σ) type donor-acceptor interaction. Figure 7 shows the movements of π and σ electrons. The value of π electron movement gives a measure of the π donating ability of the substituent.

When the substituent has an oxygen atom, it acts as π-donor and σ-acceptor for the phenyl group {Fig. 7(a)}, whereas when the substituent has a sulfur atom, it acts as π-donor and σ-donor for the phenyl group {Fig. 7(c)}. In the cases of both phenol and anisole, the OH and OCH_3 groups always behave as a better π donor than the SH and SCH_3 groups, while the magnitude of charge transfer is almost the same.

The calculation of thioanisole without 3d orbitals shows larger π electron donating ability of the SCH_3 group than that of the OCH_3 group {Fig. 7(b)}. However, since the ^{13}C NMR chemical shift in para-position gives a measure of the π donating ability of the substituent, NMR data indicate that the OCH_3 group is a better π-donor than the SCH_3 group to the phenyl group. Thus the calculation of thioanisole without 3d orbitals is inconsistent with the ^{13}C NMR result. Whereas, the inclusion of 3d orbitals on sulfur atom reduces the magnitude of the charge transfer (0.05) Thus the effect of 3d orbitals seems to be important in view of the π electron donating ability of substituent to the phenyl group.

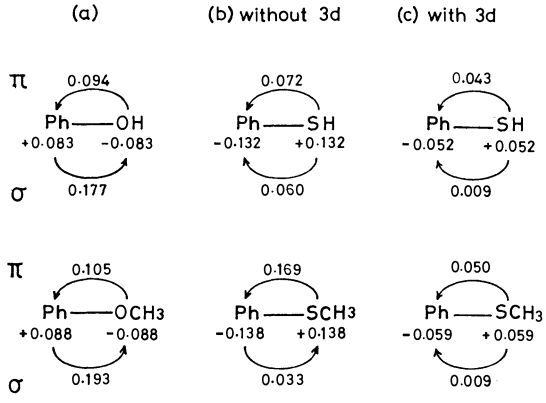

Fig. 7. The net charges and the charge movements of σ and π electrons due to the interaction between phenyl group and substituents.

Rotational Barrier. Let us consider not only the electronic effect but also the steric one. Both effects determine the most stable conformations of C_6H_5SH, $C_6H_5OCH_3$, and $C_6H_5SCH_3$ and the barriers of internal rotation. Our particular interest lies in the 3d orbital contribution of sulfur atom to the rotational barrier and conformation. As mentioned above, it is shown that the effect of 3d orbitals on the charge distribution is important. Let us see whether the participation of 3d orbitals to the rotational barrier is important or not.

Energy variation with the rotation of the SH group in C_6H_5SH is shown in Fig. 8. The bond angle $<$CSH, ϕ, {see Fig. 2(b)} is fixed at 96.5° for this molecule.[15] The planar structure is the most stable, and the calculated rotational barriers without and with 3d are 3.99 and 3.65 kcal·mol^{-1}, respectively. There are no significant changes in both the rotational barrier and the shape of the energy curve caused by including 3d orbitals. The experimental value of rotational barrier of C_6H_5SH is smaller than 0.8 kcal·mol^{-1}.[16] Since the present calculation uses the small basis set, the rotational barrier of C_6H_5SH may be overestimated. Rigorous calculation using a more extended basis set would give a lower rotational barrier.

The energy curve of $C_6H_5SCH_3$ calculated without 3d orbitals is shown in Fig. 9. The change of angle ϕ in $C_6H_5SCH_3$ is very important because of steric hindrance. Thus the rotational energy curve of this molecule is obtained by optimization with respect to angle ϕ. In this molecule, the planar conformations is probably most stable but the energy curve is very flat. (The energy difference between the planar and orthogonal conformations is to be 0.317 kcal·mol^{-1}.) Thus, it seems that the SCH_3 group of $C_6H_5SCH_3$

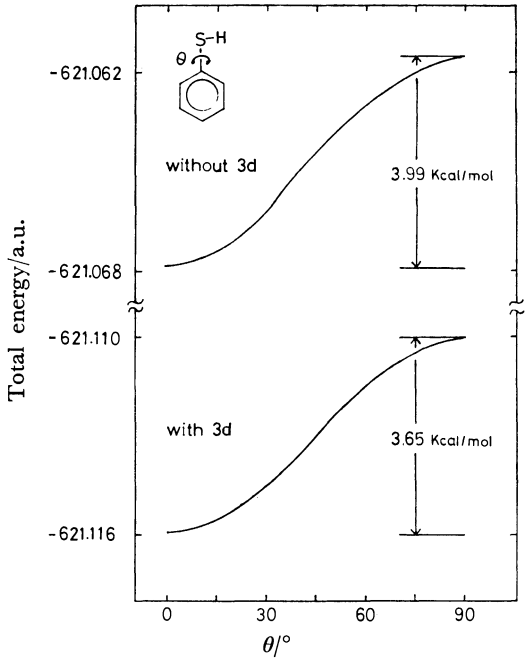

Fig. 8. The energy curve of C_6H_5SH as a function of rotation angle θ.

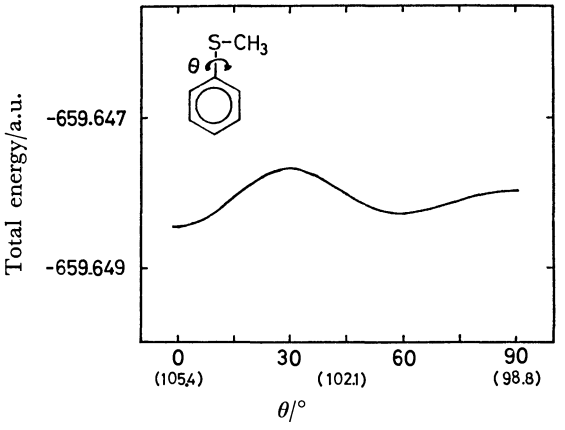

Fig. 9. The energy curve of $C_6H_5SCH_3$ as a function of rotation angle θ. The optimized angle ϕ at each angle θ (0°, 45°, and 90°) is also given in parentheses.

rotates almost freely.

It will be necessary to know the effect of 3d orbitals on the rotational barrier in $C_6H_5SCH_3$. So, we carried out MO calculation including 3d orbitals for planar and orthogonal conformations of this molecule. The geometry of $C_6H_5SCH_3$ optimized with respect to the angle ϕ by a basis set without 3d orbitals is used for the calculation with 3d orbitals. The energy difference is to be 0.237 kcal·mol^{-1}, which is almost the same as the result without 3d orbitals. Therefore, we might conclude that there is very small effect of 3d orbitals on the stable conformations and the rotational barriers in C_6H_5SH and $C_6H_5SCH_3$.

Let us compare oxygen (C_6H_5OH and $C_6H_5OCH_3$) and sulfur compounds (C_6H_5SH and $C_6H_5SCH_3$). The rotational barrier of C_6H_5SH is smaller than that of C_6H_5OH (5.2 kcal·mol^{-1}).[17] The energy curve of $C_6H_5OCH_3$ shown in Fig. 10 is somewhat complicated. The potential curve has two minima at $\theta=0°$ and $\theta=90°$, there are maximum at about $\theta=30°$—$40°$ and $\theta=140°$—$150°$. The stabilization at $\theta=90°$ is probably caused by releasing the steric hindrance between the phenyl and OCH_3 groups, and that at $\theta=0°$ is brought forth by the strong conjugation between these groups. Whereas, $C_6H_5SCH_3$ gives a very flat energy curve because of the cancellation between the conjugation and steric hindrance between the phenyl and SCH_3 groups.

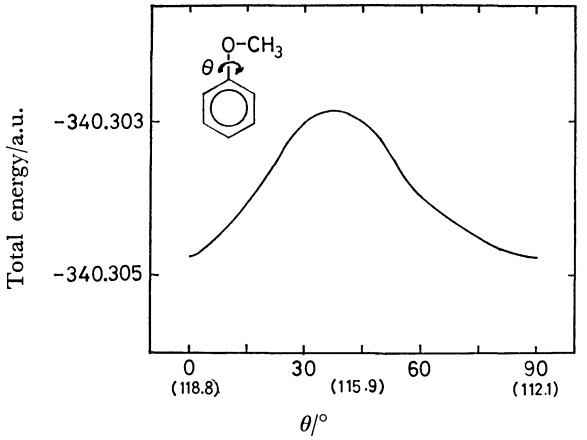

Fig. 10. The energy curve of $C_6H_5OCH_3$ as a function of rotation angle θ. The optimized angle ϕ at each angle θ (0°, 45°, and 90°) is also given in parentheses.

Conclusion

We have discussed the effect of 3d orbitals of sulfur on the electronic structures of molecules and the difference of the electronic structures between the oxygen and sulfur compounds. The calculated results suggest that the contribution of 3d orbitals to the charge distribution is important, but that to the stable conformation and rotational barrier is very small. Since the orbital energies of 3p AO of sulfur atom are almost the same as the 2p AO of carbon atom and the 3p orbitals of sulfur atom are rather diffuse, the molecular properties of sulfur compounds differ somewhat from the corresponding oxygen compounds. The shape and energy of LUMO are particularly sensitive to the participation of 3d orbitals.

The authors would like to express their gratitude to the staff of the Data Processing Center, Kyoto University, for use of the FACOM M190 computer. They thank Dr. Shinichi Yamabe, Nara University of Education, for use of the Gaussian 70 program. This study was partly supported by a Scientific Research Grant (No. 254165) from the Ministry of Education of Japan.

Kinetic Studies of the Proton-transfer of the Bivalent Anions of *ortho*-Hydroxy Azo Compounds in Dioxane–Water Media†

Noboru YOSHIDA and Masatoshi FUJIMOTO*

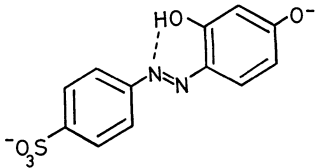
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 13, 1978)

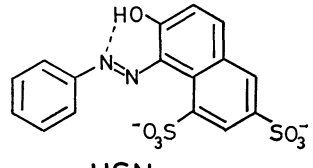
Kinetics of the proton-transfer reactions in dioxane–water media between hydroxide ion and the bivalent anions of 4-(2,4-dihydroxyphenylazo)benzenesulfonic acid (TPO) and 7-hydroxy-8-phenylazo-1,3-naphthalenedisulfonic acid (HPN) were studied by means of the temperature-jump method. For the change in the mole fraction of dioxane from 0 to 0.174, the acid-dissociation constant, $K_a^c(s)$, was found to decrease from 1.07×10^{-11} to 5.25×10^{-14} mol dm^{-3} for HPN and from 1.32×10^{-12} to 7.08×10^{-15} mol dm^{-3} for TPO.

One of the most pronounced and general features in the chemical effects caused by the change in the solvent composition in binary mixed solvents is the change in the degree of ionic dissociation of weak electrolytes. Dependence of the acid-dissociation constants on the solvent composition is explained in terms of both the dielectric constant of the medium and the solute-solvent interactions.[1]

In dioxane–water media the decrease in the acid-dissociation constants of the bivalent anions of *o*-hydroxy azo compounds such as HPN and TPO is mainly due to the decrease in the dielectric constant of the medium.



TPO



HSN

In the present study we have found that the recombination rate constant, k_f, for the proton-transfer reaction

$$HA^{2-} + OH^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} A^{3-} + H_2O$$

between hydroxide ion and HPN and TPO decreases with decrease in the dielectric constant of the medium, while the backward rate constant, k_r', is influenced only a little by the change in dielectric constant. Based on the kinetic and the equilibrium data in dioxane–water media, the authors aimed to elucidate the solvent effects on the proton-transfer reaction of HPN and TPO.

Experimental

Water was deionized and distilled. Dioxane was distilled over sodium and used without further purification.[2] HPN and TPO (Wako) were recrystallized from an ethanol–water solution.

Kinetic measurements were carried out at 25 °C; I=0.1 mol dm^{-3} (KNO_3) with a Union Giken co-axial cable temperature-jump apparatus Model RA-105 under compressed nitrogen gas at *ca.* 2 atm to avoid cavitation upon very fast temperature rise. A Hitachi EPS-3T recording spectrophotometer was used in the equilibrium measurements.

The measurements of pH in the mixed solvent were reported in the previous paper.[3] The apparent ionic product K_w^c=[H]·[OH] of the water in dioxane–water was obtained with a Hitachi-Horiba pH-meter F-7ss equipped with a glass electrode 1026A and Ag–AgCl reference electrode type 2010-05T. The values of pK_w^c are summarized in Table 1. The function log U_H is defined as log U_H=pC_H−pH*, where C_H denotes the analytical concentration of proton, and pH* pH-meter readings.

Results and Discussion

The final step of the acid-dissociation of HPN and TPO can be expressed by

$$HA^{2-} \underset{}{\overset{K_a^c}{\rightleftharpoons}} A^{3-} + H^+. \qquad (1)$$

The acid-dissociation constant, K_a^c, is expressed in terms of the absorbance and the equilibrium concentration of proton, $\bar{C}_H$,

$$C/\Delta A = 1/\Delta\varepsilon + \bar{C}_H/(\Delta\varepsilon\cdot K_a^c) \qquad (2)$$

where $\Delta A=A-A'$, $\Delta\varepsilon=\varepsilon_A-\varepsilon_{HA}$, and $A'=\varepsilon_{HA}C$, ε is the molar absorption coefficient, A the absorbance at the wavelength of the base form of HPN or TPO, and C the total concentration of the Brønsted acid. The plot of $C/\Delta A$ against $\bar{C}_H$ gives straight lines for each solvent composition, yielding $\Delta\varepsilon$ and $K_a^c(s)$ from the intercept and the slope, respectively. In Fig. 1 the acid-dissociation constants determined spectrophotometrically are plotted against the mole fraction of dioxane, x_{dlox}. Increase in the dioxane content in the medium, *viz.*, the decrease in the dielectric constant of the medium leads to a decrease in the dissociation constant of HA^{2-}. Such dependency of $K_a^c(s)$ on the solvent composition has also been observed in the case

† Presented in part at the 26th Annual Meeting on Coordination Chemistry, Sapporo, August 30, 1976, Abstract p. 252 and at the 27th Annual Meeting on Coordination Chemistry, Matsumoto, September 28, 1977, Abstract, p. 233.

of the univalent anion of 4-(*p*-nitrophenylazo)-resorcinol.[3]

The proton-transfer reaction between hydroxide ion and the bivalent Brønsted acids, HA^{2-}, is expressed by

$$HA^{2-} + OH^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} A^{3-} + H_2O \qquad (3)$$

with the equilibrium constant $K_b^c = k_f/k_r' = \bar{C}_A/(\bar{C}_{HA} \cdot \bar{C}_{OH})$, where $k_r' = k_r(H_2O)$. The relaxation time, τ, for Reaction 3 is related to the rate constants as follows.

$$\tau^{-1} = k_f(\bar{C}_{HA} + \bar{C}_{OH}) + k_r'. \qquad (4)$$

If the equilibrium concentration of hydroxide ion is much larger than that of the bivalent anion, Eq. 4 is approximated to $\tau^{-1} = k_f\bar{C}_{OH} + k_r'$ (Fig. 2). The rate constants and equilibrium constants at each solvent composition are summarized in Tables 2 and 3. In

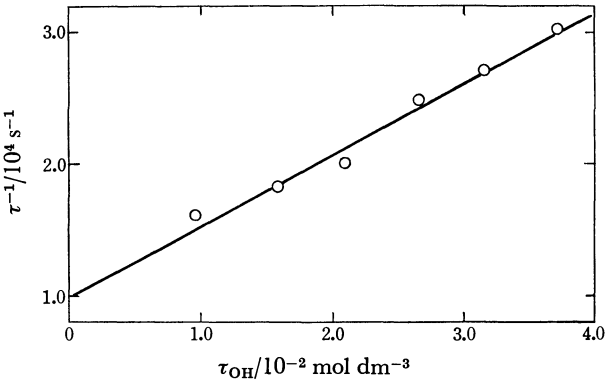

Fig. 2. Plot of the reciprocal relaxation time *vs.* the equilibrium hydroxide ion concentration at x_{dlox}= 0.083 (TPO), 25 °C, and I=0.1 mol dm^{-3} (KNO_3).

a) The values of pK_a^c in parentheses are obtained from the relationship, $pK_a^c = pC_H + \log[(D_B - D)/(D - D_A)]$, where D is the absorbance, subscripts A and B are for the acid and the base form of TPO, respectively. b) $K_a = a_{H^+} \cdot C_A/C_{HA}$, where a_{H^+} is the activity of the proton.

the case of HPN, the value of k_f slightly decreases with increase in the mole fraction of dioxane, x_{dlox}, and that of k_r increases from 1.5×10^2 mol^{-1} dm^3 s^{-1} at $x_{dlox}=0$ to 3.1×10^2 mol^{-1} dm^3 s^{-1} at $x_{dlox}=0.174$ with increase in x_{dlox}. The value of k_f for TPO also gradually decrease with increase in x_{dlox}. The value of k_r' for TPO changes quite a little.

The detailed mechanism of the proton-transfer reaction may be written as follows.[2,3]

$$HA^{2-} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} HA^{*2-}, \quad (5a)$$

$$HA^{*2-} + OH^- \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} HA^{*2-}\cdots(H_2O)_n\cdots OH^- \quad (5b)$$

$$HA^{*2-}\cdots(H_2O)_n\cdots OH^- \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} A^{3-} + H_2O, \quad (5c)$$

where HA^{2-} stands for the bivalent anion having an intramolecular hydrogen-bond and HA^{*2-} an intermediate species without an intramolecular hydrogen-bond. Assuming the steady state for HA^{*2-} and $HA^{*2-}\cdots(H_2O)_n\cdots OH^-$ and the relationships $k_{21}\gg k_{23}\bar{C}_{OH}$ and $k_{34}\gg k_{32}$, the observed rate constants in Eq. 3 are expressed as follows.

$$k_f = K_{12}k_{23} = (k_{12}/k_{21})k_{23} \quad (6)$$

and

$$k_r = k_{32}/K_{34} = k_{32}/(k_{34}/k_{43}). \quad (7)$$

As shown in Fig. 3 the value of k_f decreases with the decrease in the dielectric constant of the solution, while the value of $k_r'=k_r$ (H_2O) varies little with change in the solvent composition particularly in the case of HPN. The decrease in k_f would be mainly due to the dependence of k_{23} on the dielectric constant provided that the change in the value of K_{12} for the intramolecular process is small.[3] By neglecting the ionic-atmosphere term in Brønsted-Christiansen-Scatchard equation,[4] we obtain

$$\mathrm{d}\log(k_f/\mathrm{mol^{-1}\,dm^3\,s^{-1}})/\mathrm{d}\,D^{-1} = \mathrm{d}\log(k_{23}/\mathrm{mol^{-1}\,dm^3\,s^{-1}})/\mathrm{d}\,D^{-1} \quad (8)$$

and

$$\mathrm{d}\log(k_{23}/\mathrm{mol^{-1}\,dm^3\,s^{-1}})/\mathrm{d}\,D^{-1} = -(z_iz_je^2)/(kTr^*), \quad (9)$$

where z_i and z_j represent the charge of the reactants, D is the dielectric constant of the medium, k Boltzmann's constant, T absolute temperature, r^* the phenomenological reaction distance, and e elementary charge. From the slope in Fig. 3 the value of r^* for TPO is obtained to be 23 Å and that for HPN 26 Å from the plot in lower dioxane content and 66 Å from that in higher dioxane content, respectively. Actually, however, the phenomenological reaction distance r^* should be calculated by considering the ionic strength term, leading to a smaller value for r^*. From the value of r^* there would be intervening water molecules in the encounter complex, $HA^{*2-}\cdots(H_2O)_n\cdots OH^-$.

The kinetic $pK_a^c(k)$ was derived from the following relation.

$$K_a^c(k) = K_b^c(k)\cdot K_w^c(s). \quad (10)$$

In the case of the bivalent anion of a water-soluble Brønsted acid the difference between $pK_a^c(s)$ and $pK_a^c(k)$ (Fig. 1) is large, particularly in the higher dioxane content. On the other hand, in the case of the univalent anion of the sparingly water-soluble Brønsted acid such as 4-(*p*-nitrophenylazo)resorcinol (MAG) the difference is small.[3] Such difference in $pK_a^c(k)$ and $pK_a^c(s)$ would be ascribed to that in the microscopic environment around the solute such as TPO, HPN, and MAG.

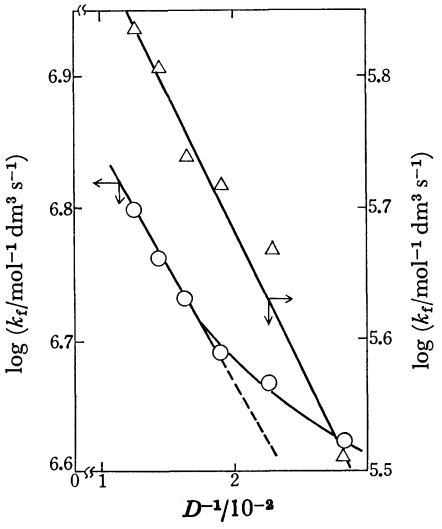

Fig. 3. Dependence of log k_f on the inverse dielectric constant of the medium. ○ The plot for HSN; △ the plot for TPO.

The linear relationship between log (k_f/mol^{-1} dm^3 s^{-1}) and pK_a^c for HPN is as follows (Fig. 4).

$$\log k_f = -1.1\times10^{-1}\,pK_a^c(k) + 8.0 \quad (11)$$

and

$$\log k_f = -7.5\times10^{-2}\,pK_a^c(s) + 7.6 \quad (12)$$

On the other hand, the relationship between pK_w^c and pK_a^c for HSN is expressed by

$$pK_a^c = -\log k_f + \log k_r' + pK_w^c. \quad (13)$$

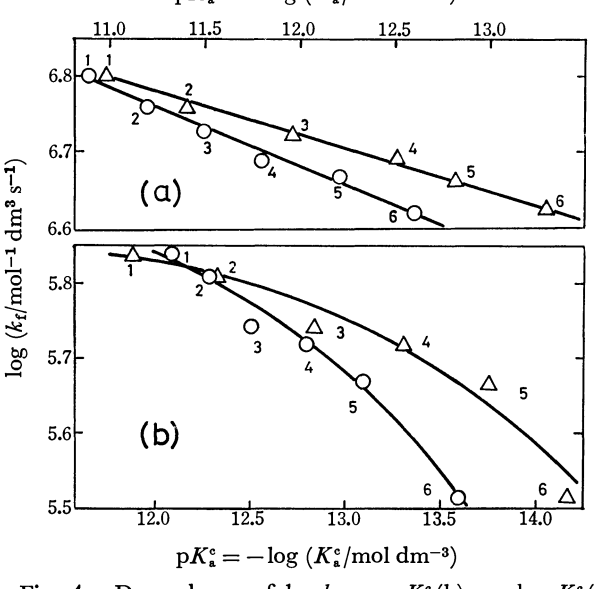

Fig. 4. Dependence of log k_f *vs.* $pK_a^c(k)$ and $pK_a^c(s)$ for HSN (a) and TPO (b): ○, log k_f *vs.* $pK_a^c(K)$. △, log k_f *vs.* $pK_a^c(s)$. x_{dlox}: (1) 0.000, (2) 0.023 (3) 0.050, (4) 0.083, (5) 0.128, and (6) 0.178.

From the plot of pK_w^c against pK_a^c for HPN, the following empirical equations are obtained.

$$pK_w^c = 0.95\, pK_a^c(k) + 3.38 \quad (14)$$

$$pK_w^c = 0.64\, pK_a^c(s) + 6.72 \quad (15)$$

Equations 11 and 13 gives the relationship $pK_w^c = 0.89\, pK_a^c(k) + 8.0 - \log k_r'$ which agrees with Eq. 14, since the value of $\log k_r'$ is evaluated to be 3.93 (Table 2). Equations 12 and 13 give the relationship $pK_w^c = 0.93\, pK_a^c(s) + 7.6 - \log k_r'$ which does not agree with Eq. 15. In the case of TPO, no linear relationships are observed (Fig. 4). The linear relationship between $\log k_f$ and pK_a^c observed for HPN is explained by the constancy of the values of k_r' with variation in solvent composition.

(Received November 25, 1978)

Reactions of 1-ethyl-2-phenylimidazole (Hepim) with lithium tetrachloropalladate(II) and palladium(II) acetate give dichlorobis(1-ethyl-2-phenylimidazole, 3-*N*)palladium(II) and a new cyclopalladated binuclear complex, di-μ-acetato-bis[2-(1′-ethyl-2′-imidazolyl)phenyl, 1-*C*, 3′-*N*]dipalladium(II), respectively. The latter complex is readily converted by a metathetical reaction with sodium chloride into a chloro-bridged analogue, [{PdCl(epim)}$_2$]. The chloro-bridged complex reacts with 4-picoline, tertiary phosphines, thallium(I) acetylacetonate, sodium diethyldithiocarbamate, and 2,2′-bipyridyl to give the corresponding mononuclear cyclopalladated complexes. All the complexes prepared in this study are characterized by means of IR, ^{1}H-NMR, and mass spectroscopies.

Cyclometallation reactions have recently received considerable attention in view of the formation of stable transition metal-carbon σ-bonds[1–3] and availabilities for the organic syntheses.[3] With respect to the cyclometallation reactions involving aryl-substituted five-membered heterocycles, several works have been reported concerning 1-phenylpyrazole,[4–6] 2,4-diphenyloxazole,[4] and 2-phenyl-3*H*-indole.[7]

It is interesting to investigate the susceptibility to the cyclometallation reactions of aryl-substituted heterocycles. In this paper, we report the cyclopalladation reaction of 1-ethyl-2-phenylimidazole (Hepim) resulting in the formation of an acetato-bridged binuclear complex, a metathetical reaction of the acetato complex into a chloro-bridged one, and the bridge-splitting reactions of the latter complex with 4-picoline (pic), tertiary phosphines, thallium(I) acetylacetonate [Tl(acac)], sodium diethyldithiocarbamate [Na(dedc)], and 2,2′-bipyridyl (bpy).

Experimental

Materials and General Procedures. All the experiments were carried out in an atmosphere of dry dinitrogen. Solvents were dried by usual methods and distilled. 1-Ethyl-2-phenylimidazole,[8] diphenyl-*p*-tolylphosphine,[9] Tl(acac),[10] and thallium(I) cyclopentadienide[11] were prepared according to the published procedures.

IR spectra were measured on a Hitachi model 285 and a Shimadzu IR 450 spectrophotometers. ^{1}H- and ^{13}C-NMR spectra were recorded on JEOL JNM-MH-100 and PFT-100 spectrometers, respectively, using tetramethylsilane as an internal standard. Conductivity measurement was carried out for 1.0×10^{-3} M acetonitrile solution at 25 °C on a Toa Electronics CM-6A conductance meter. Melting points were determined with a Yanaco micro melting point apparatus and are uncorrected. Mass spectra were obtained with a Nichiden-Varian TE-600 gas chromatograph-mass spectrometer.

*Preparation of [PdCl$_2$(Hepim)$_2$] **1**.* 1-Ethyl-2-phenylimidazole (6.56 mmol) in 30 ml of methanol was added to a solution of lithium tetrachloropalladate(II) (3.28 mmol) in 30 ml of methanol. A yellow precipitate formed immediately, which was filtered after standing for 20 h at room temperature and washed with methanol several times. Recrystallization from boiling toluene gave 0.75 g of **1** as yellow needles; yield 44%, mp 242—244 °C (dec).

*Preparation of [{Pd(O$_2$CCH$_3$)(epim)}$_2$] **2**.* To a solution of palladium(II) acetate (17.8 mmol) in 50 ml of acetic acid was added Hepim (21.1 mmol) in 30 ml of acetic acid at room temperature. After refluxing for 30 min, the resulting black mixture was diluted with water and extracted with eight 50 ml portions of dichloromethane. The combined brownish-yellow extracts were concentrated and chromatographed on silica gel. A yellow band eluted by dichloromethane/ethanol (4/1) was collected and the solvent was evaporated. Recrystallization from boiling benzene gave 2.5 g of **2** as yellow crystals; yield 42%, mp 180—219 °C(dec).

*Preparation of [{PdCl(epim)}$_2$] **3**.* Sodium chloride (7.4 mmol) in 60 ml of water was added to a solution of **2** (3.7 mmol) in 200 ml of acetone. A pale yellow precipitate formed immediately, which was filtered after stirring for 20 h at room temperature and washed with water and diethyl ether. Yield 2.0 g, 86%; mp 274—278 °C(dec).

*Reaction of **3** with pic.* 4-Picoline (5.11 mmol) was added to a suspension of **3** (0.64 mmol) in 10 ml of dichloromethane. A clear solution formed immediately, which was concentrated after stirring for 5 h at room temperature. Addition of pentane gave 0.35 g of [PdCl(epim)(pic)] **4** as off white crystals, yield 67%, mp 161—162 °C(dec).

*Reactions of **3** with Triphenylphosphine and Diphenyl-p-tolylphosphine.* These reactions were carried out in the same way as described for **4**, and off white crystals, [PdCl(epim)(PPh$_3$)] **5** and [PdCl(epim)(PPh$_2$–C$_6$H$_4$–CH$_3$-*p*)] **6** were produced: **5**, yield 86%, mp 232—235 °C(dec); **6**, yield 57%, mp 232—234 °C(dec).

*Reaction of **6** with Lithium Bromide.* An acetone suspension containing **6** (0.40 mmol) and lithium bromide monohydrate (2.00 mmol) was refluxed for 10 h. The mixture was filtered and the filter residue was washed with water and diethyl ether. Recrystallization from dichloromethane and pentane gave 0.16 g of [PdBr(epim)(PPh$_2$–C$_6$H$_4$–CH$_3$-*p*)] **7** as pale yellow crystals; yield 74%, mp 229—231 °C(dec).

*Reaction of **3** with Tl(acac).* Thallium(I) acetylacetonate (1.54 mmol) was added to a suspension of **3** (0.64 mmol) in 10 ml of dichloromethane, and the mixture was stirred for 20 h at room temperature. The mixture was filtered and subsequent evaporation of the solvent gave a pale yellow oil. The oil was purified by passing through a short silica gel columm with dichloromethane, and 0.3 g of [Pd(acac)(epim)] **8** was obtained as pale yellow crystals: yield 63%; mp 187—190 °C(dec); Found: M$^+$, 376. Calcd for C$_{16}$H$_{18}$N$_2$O$_2$Pd: M$^+$, 376.

*Reaction of **3** with Na(dedc).* An ethanol suspension containing Na(dedc) (1.92 mmol) and **3** (0.80 mmol) was stirred for 20 h at room temperature. The mixture was evaporated to dryness and the resulting solid was extracted

with dichloromethane. Addition of hexane to the extract afforded pale yellow crystals, [Pd(dedc)(epim)] **9**: yield 78%; mp 178—181 °C(dec); Found: M^+, 425. Calcd for $C_{16}H_{21}N_3S_2Pd$: M^+, 425.

Reaction of ***3*** *with bpy.* 2,2′-Bipyridyl (1.76 mmol) was added to a suspension of **3** (0.80 mmol) in 20 ml of methanol. A yellow clear solution immediately formed. After stirring for 4 h at room temperature, the solution was treated with sodium perchlorate monohydrate (1.60 mmol) to give 1.13 g of [Pd(epim)(bpy)]ClO_4 **10** as yellow crystals; yield 90%, mp 276—277 °C(dec).

Results and Discussion

Elemental analyses and ^{1}H-NMR spectra of all the new complexes prepared in this study are summarized in Table 1.

The reaction of Hepim with lithium tetrachloropalladate(II) in methanol at room temperature afforded dichlorobis(1-ethyl-2-phenylimidazole, 3-*N*)palladium-(II) **1** as yellow needles. In the ^{1}H-NMR spectrum of **1**, the phenyl protons of Hepim appeared as two multiplets at δ 7.4—7.7 (6H) and 7.75—8.0 (4H), similar to the signals of uncoordinated Hepim {two multiplets at δ 7.3—7.5 (3H) and 7.5—7.65 (2H)}. This indicates the presence of unsubstituted phenyl group. Judging from the results of elemental analysis and the ^{1}H-NMR spectrum, **1** contained two moles of Hepim as ligands coordinated only with a nitrogen donor site, but not a cyclopalladated moiety.

$$Li_2[PdCl_4] + 2Hepim \xrightarrow[r.t.]{methanol} [PdCl_2(Hepim)_2]\ \mathbf{1} + 2LiCl$$

1-Ethyl-2-phenylimidazole also reacted with palladium(II) acetate in refluxing acetic acid to produce a new complex **2**, whose IR spectrum exhibited two strong absorption bands due to bridging acetato ligand at 1570 and 1410 cm^{-1}.[13] On the basis of elemental analysis and the characterization of the derivatives from **2** as stated later, **2** was assigned to a binuclear cyclopalladated complex, di-μ-acetato-bis[2-(1′-ethyl-2′-imidazolyl)phenyl, 1-*C*, 3′-*N*]dipalladium(II). It is noteworthy that Hepim reacted with tetrachloropalladate(II) ion to give only the addition product **1** and with palladium(II) acetate to afford the cyclopalladated complex **2**, similar to the case of *N*-benzylideneaniline.[13] As for the ^{1}H-NMR spectrum of **2**, the methyl resonance of bridging acetato ligand showed a sharp singlet at δ 2.20 together with two weak resonances at δ 2.12 and 2.29. These resonances were

$$2[Pd(O_2CCH_3)_2] + 2Hepim \xrightarrow[reflux]{acetic\ acid} [\{Pd(O_2CCH_3)(epim)\}_2]\ \mathbf{2} + 2CH_3CO_2H$$

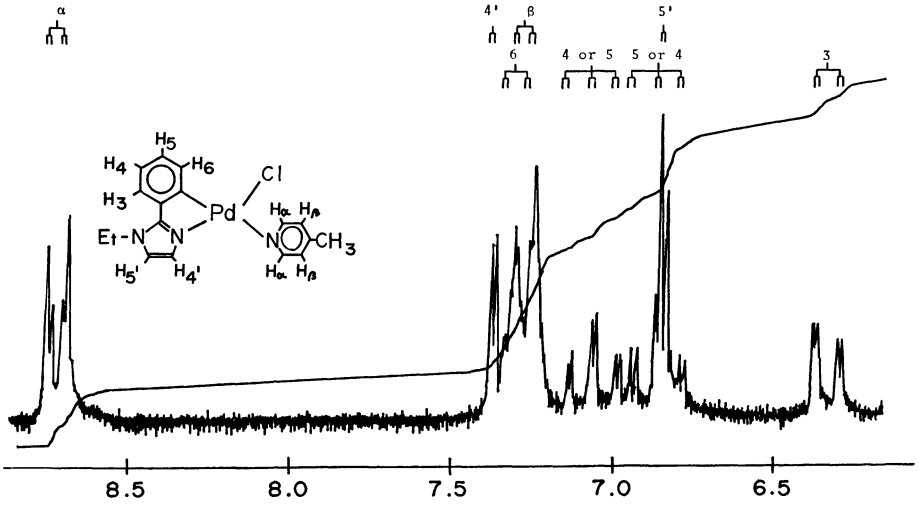

Fig. 2. ^{1}H-NMR spectrum of **4** in CD_2Cl_2 solution (δ-value from TMS).

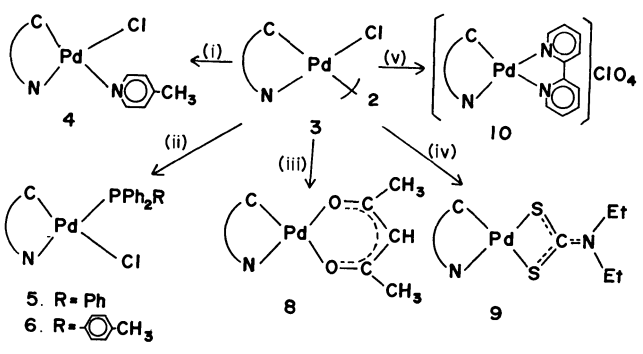
ascribed to two structural isomers as shown in Fig. 1;[14] the former was to two magnetically equivalent methyl protons in an *ab-hg* type and the latters were to non-equivalent methyl ones in an *ab-gh* type (the isomer ratio *ab-hg* : *ab-gh*=5 : 1, approximately).

Complex **2** was readily converted by metathetical reaction with sodium chloride in acetone into the chloro-bridged analogue, [{PdCl(epim)}$_2$] **3**. The

$$[\{Pd(O_2CCH_3)(epim)\}_2] + 2NaCl \xrightarrow[\text{r.t.}]{\text{acetone}} [\{PdCl(epim)\}_2]\ \mathbf{3} + 2CH_3CO_2Na$$

^{1}H-NMR spectrum of **3** could not be measured owing to its insolubility in usual organic solvents. However, **3** underwent typical bridge-splitting reactions with various reagents as shown in Scheme 1. Reactions of **3** with unidentate ligands, pic, triphenylphosphine, and diphenyl-*p*-tolylphosphine gave neutral mononuclear complexes **4**, **5**, and **6**, respectively.

The ^{1}H-NMR spectrum of **4** (Fig. 2) showed a typical ABCD system characteristic of the *o*-phenylene protons in the 2-(1′-ethyl-2′-imidazolyl)phenyl moiety, differing from the aromatic region of Hepim or **1**. The 6-H of *o*-phenylene group appeared at δ *ca.* 7.3, overlapping with two H_β protons of the picoline ligand (total intensity 3H). The 4- or 5-H was observed at δ 7.06 (1H) or 6.86 (1H) as a double triplet due to coupling with other ring protons. The 3-H appeared at δ 6.33 (1H) as a double doublet due to coupling with 4- and 5-H. The coupling constants were $^3J_{HH}$=7.5 Hz and $^4J_{HH}$=1.5 Hz. These results indicate unambiguously that **4** has the cyclopalladated structure of epim.



Scheme 1. Bridge-splitting reactions of **3**. Reagents; (i) pic, (ii) PPh_2Ph(for **5**) or PPh_2–C_6H_4–CH_3-*p*(for **6**), (iii) Tl(acac), (iv) Na(dedc), (v) bpy, $NaClO_4$.
$\binom{C}{N}$ = (epim,1-*C*,3′-*N*).

In the far-IR spectrum of **6**, a band at 304 cm^{-1} was assigned to ν(Pd–Cl) frequency in comparison with the corresponding bromo derivative **7**. On the other hand, **4** showed two bands at 316 and 266 cm^{-1} in the range of 350—250 cm^{-1}. The former was assigned to ν(Pd–Cl) frequency and the latter to the palladium-nitrogen stretching one.[15] As for the configuration of **4**, **5**, or **6**, there are two possible isomers as shown in Fig. 3. Crociani *et al.* reported that the ν(Pd–Cl) frequencies trans to an aromatic nitrogen atom and an aryl-carbon one fell in the range of 353—321 and 299—280 cm^{-1}, respectively.[15] Moreover, ^{1}H-decoupled ^{13}C-NMR spectrum of **5** in $CDCl_3$ exhibited a doublet at δ 151.9, which was due to coupling with ^{31}P nucleus ($^2J_{CP}$=27.6 Hz) and assignable to palladium-substituted *o*-phenylene carbon (1-C). This small coupling constant reveals that triphenylphosphine ligand is located at cis position to the 1-C.[16] On the basis of both far-IR and ^{13}C-NMR data, **5** and **6** were ascribed to configuration B. However, **4** could not be assigned whether it had the configuration A or B only from a far-IR spectrum datum.

In the ^{1}H-decoupled ^{13}C-NMR spectrum of **5**, the 2′-, 4′-, and 5′-C's of imidazole ring were observed

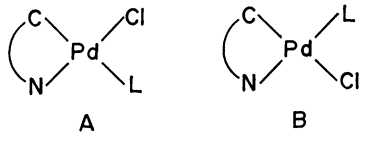


Fig. 3. Possible configurations of **4**, **5**, and **6**.
$\binom{C}{N}$ = (epim,1-*C*,3′-*N*).

at δ 127.2 (doublet, $^3J_{CP}$=4.9 Hz), 139.6 (doublet; $^3J_{CP}$=12.2 Hz, $^1J_{CH}$=146 Hz), and 132.2 (singlet),[17] respectively. A singlet at δ 137.7 was ascribed to imidazole-substituted *o*-phenylene carbon (2-C), and other four carbons (3-, 4-, 5-, and 6-C) upon the phenylene group appeared as four singlets at δ 119.2, 121.7, 123.9, or 126.5. These six kinds of the *o*-phenylene carbons also confirm that **5** contains the cyclopalladated epim structure.

Thallium(I) acetylacetonate and Na(dedc) reacted with **3** to produce neutral complexes **8** and **9**, respectively. The ^{1}H-NMR spectrum of **8** afforded two multiplets; one(1H) at δ 7.57—7.70, assignable to 6-H, the other (4H) at δ 6.99—7.26, which corresponded to 3-, 4-, and 5-H's and overlapped with 4'-H of the imidazole ring. The ^{1}H-NMR spectrum of **9** exhibited a complicated pattern due to the *o*-phenylene protons (4H) in the region of δ 6.95—7.36. The mass spectrometry gave peaks at *m/e* 376 (parent ion corresponding to ^{106}Pd) and 277 (loss of acac) for **8**, and at *m/e* 425 (parent ion corresponding to ^{106}Pd) and 277 (loss of dedc) for **9**. These results confirm the presence of the cyclopalladated structure of epim in both **8** and **9**.

As for the ^{1}H-NMR spectrum of **9**, two methyl protons of diethyldithiocarbamato ligand were unequivalent, indicating that a carbon-nitrogen double bond character is present in this ligand.[18] On the other hand, the methylene protons were observed as one quartet, which was considered to arise from an accidental magnetic degeneracy.

Complex **3** also reacted with bpy in the presence of sodium perchlorate to form a complex **10**. The IR spectrum of **10** showed a strong ν(Cl–O) band at 1080 cm^{-1}, characteristic of perchlorate anion. Molar conductivity (Λ_M=140 Ω^{-1} cm^2 mol^{-1}) in acetonitrile solution indicates that **10** is a uni-univalent electrolyte. The product from the reaction of **3** with thallium(I) cyclopentadienide was too unstable to be isolated in a pure state.

We wish to express our gratitude to Professor Keinosuke Hamada and Mr. Hirofumi Morishita of Nagasaki University for the far-IR measurements, and to Dr. Hideomi Koinuma, the University of Tokyo, for the ^{13}C-NMR measurements, and also to Mrs. Hisako Mazume and Miss Yumi Kojima of Nagasaki University for their technical assistances.

Kinetics of the Reduction Reaction of Tetranitromethane by Thiosulfate Ion in the Absence and Presence of Copper(II) Ion in Aqueous Mixtures of Methanol and Ethanol

Masaru KIMURA* and Makiko SHUKUTANI

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received December 4, 1978)

The kinetics of the reduction reaction of tetranitromethane by the thiosulfate ion in the absence and presence of the copper(II) ion have been investigated in aqueous solution and aqueous mixtures of methanol and ethanol. The mechanism of reaction has been thought to be the following:

$$C(NO_2)_4 + S_2O_3^{2-} \xrightarrow{k_1} C(NO_2)_3^- + NO_2 + S_2O_3^-$$

$$Cu(II) + S_2O_3^{2-} \xrightarrow{k_2} Cu(I) + S_2O_3^-$$

$$C(NO_2)_4 + Cu(I) \xrightarrow{k_3} C(NO_2)_3^- + NO_2 + Cu(II)$$

$$2S_2O_3^- \xrightarrow{\text{rapid}} S_4O_6^{2-}$$

The rate constants k_1 and k_2 have been determined under several conditions. The value of k_1 was hardly affected by ionic strength, permittivity, and acetate ion concentration in the reaction solution, whereas k_2 was markedly increased with decreasing ionic strength (μ), permittivity (D), and acetate ion concentration. For k_2, plots of $\log k_2$ *vs.* $\mu^{1/2}/(1+\mu^{1/2})$ and $\log k_2$ *vs.* $1/D$ gave linear relationships. Under the specified conditions the k_2-term in the reaction mechanism accounts for up to 90% of the reaction, the reaction being composed of a copper(II) catalyzed-chain reaction.

Tetranitromethane (TNM) is reduced by solvated electrons and other reducing radicals such as $H^{\cdot}$, $O_2^{\cdot-}$, $CO_2^{\cdot-}$, $\dot{C}H_2OH$, and so forth,[1–7] becoming the nitroform anion (NF^-) which has a strong absorption peak at 350 nm. Most studies on the TNM reduction reaction have been made by pulse radiolysis techniques, and thus the reducing substances have been restricted to the radical species. The reduction reaction of TNM by reducing agents such as thiosulfate has received little investigation.

Recently, Sellers and Simic[2] and Asmus *et al.*[7] reported that tetranitromethane is easily reduced to the nitroform anion by the copper(I) ion. It is known that the copper(II) ion undergoes facile reduction to the copper(I) ion by the thiosulfate ion in aqueous solution. Thus, it is assumed that tetranitromethane would be reduced by the copper(I) ion which is produced by the reaction between the copper(II) ion and thiosulfate ion. The present paper reports the TNM reduction reaction induced by the reaction between the copper(II) ion and the thiosulfate ion. The large molar absorptivity of the nitroform ion permits low concentrations of the reactants to be used, thus reducing or eliminating problems from the limited solubility of the tetranitromethane and complexing side reactions related to the thiosulfate reaction. The concentrations used were 1×10^{-5}—3×10^{-4} mol dm^{-3} in TNM, 5×10^{-4}—5×10^{-3} mol dm^{-3} in sodium thiosulfate, and 0—2×10^{-4} mol dm^{-3} in copper(II) sulfate.

Experimental

Chemicals. Sodium perchlorate used for adjusting the ionic strength was recrystallized twice from aqueous solution. Methanol and ethanol were distilled in a glass still. Deionized water was further distilled through permanganate solution in a glass still. All other chemicals used were of analytical reagent grade.

Procedure and Apparatus. Unless otherwise stated the reaction of tetranitromethane with thiosulfate ion in the presence of the copper(II) ion was initiated by the addition of thiosulfate solution into the mixture of tetranitromethane and copper(II) under the conditions given. The nitroform anion which is the reduction product of tetranitromethane has an extremely large absorptivity $\varepsilon=1.5\times10^4$ dm^3 mol^{-1} cm^{-1} at 350 nm,[8] and the other species in the reaction solution are transparent under the given concentrations. Consequently the absorbance of the nitroform anion (NF^-) formed was measured at appropriate time of reaction using a Hitachi Model 100-40 spectrophotometer. The cell housing was thermostatted at constant temperature, and in the dark except for the time measuring absorbance.

Results and Discussion

In the Absence of Copper(II). Tetranitromethane was slowly reduced by thiosulfate ion. The reduction rate may be described by Eq. 1.

$$-d[TNM]/dt = d[NF^-]/dt = k_1[TNM][S_2O_3^{2-}] \quad (1)$$

With excess thiosulfate, Eq. 2 is deduced:

$$\ln(A_\infty - A_t)/A_\infty = -k_{obsd}t \quad (2)$$

where $k_{obsd}=k_1[S_2O_3^{2-}]$; A_∞ and A_t indicate the absorbance of NF^- formed at infinity and time t, respectively. A plot of the left-hand side of Eq. 2 against time gave a linear relationship over three half-lives, and the value of A_∞ was proportional to the amount of tetranitromethane added initially. An example of the plots according to Eq. 2 is given in Fig. 1. All the rate constants k_1 obtained are tabulated in Tables 1 and 2, and given in Figs. 4 and 5 together with the rate constant k_2 in the presence of copper(II) (*vide infra*).

Reaction in the Presence of Copper(II). The reduction rate of tetranitromethane by thiosulfate ion was greatly accelerated by the addition of small amounts of copper(II) ion. The rate did not obey Eq. 2. The plots of A_t against reaction time showed a linear

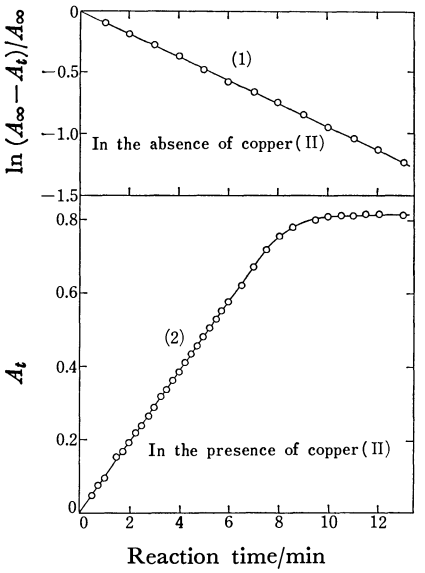

Fig. 1. Examples of the kinetic run in the absence and presence of copper(II) ion. 4.0×10^{-3} mol dm^{-3} in sodium thiosulfate and 5.4×10^{-5} mol dm^{-3} tetranitromethane for line 1; 1.0×10^{-3} mol dm^{-3} in sodium thiosulfate, 5.4×10^{-5} mol dm^{-3} tetranitromethane, and 5.0×10^{-5} mol dm^{-3} in copper(II) sulfate for curve 2; 25 °C; the other conditions as in Table 2.

relationship over half-life time of reaction, indicating the reaction to be of zero order with respect to the TNM concentration. An example of the kinetic behavior is illustrated in Fig. 1 together with the plot according to Eq. 2 in the absence of copper(II) ion. The initial rate of the reaction in the presence of copper(II) ion $V_i=\mathrm{d[NF^-]}/\mathrm{d}t$, was evaluated from the initial slope of the plot of A_t *vs.* t.

Dependence of the Reaction Rate on TNM Concentration. The dependence of the reaction rate on the tetranitromethane concentration was examined at zero, 5.0×10^{-5}, and 2.0×10^{-4} mol dm^{-3} in copper(II) sulfate and is illustrated in Fig. 2. With a concentration of [TNM]≥[Cu(II)], the slopes in the plots became equal to each other irrespective of the copper(II) ion concentrations, and the values of the intercept extrapolated to zero TNM increased with increasing copper(II) concentration.

Dependence of the Reaction Rate on Concentration of Copper(II) and Thiosulfate. Plots of V_i against copper(II) concentration showed linear relationships, and both the intercepts and slopes were found directly proportional to the thiosulfate concentration. Some examples of the plots are given in Fig. 3. The rate constant k_2 was evaluated from the slope of the plot of V_i *vs.* [Cu(II)].

Reaction Mechanism. All the results obtained are accounted for by Reactions 3—6, and the rate law (7).

$$C(NO_2)_4 + S_2O_3^{2-} \xrightarrow{k_1} C(NO_2)_3^- + NO_2 + S_2O_3^- \quad (3)$$

$$Cu(II) + S_2O_3^{2-} \xrightarrow{k_2} Cu(I) + S_2O_3^- \quad (4)$$

$$C(NO_2)_4 + Cu(I) \xrightarrow{k_3} C(NO_2)_3^- + Cu(II) + NO_2 \quad (5)$$

$$2S_2O_3^- \xrightarrow{\text{rapid}} S_4O_6^{2-} \quad (6)$$

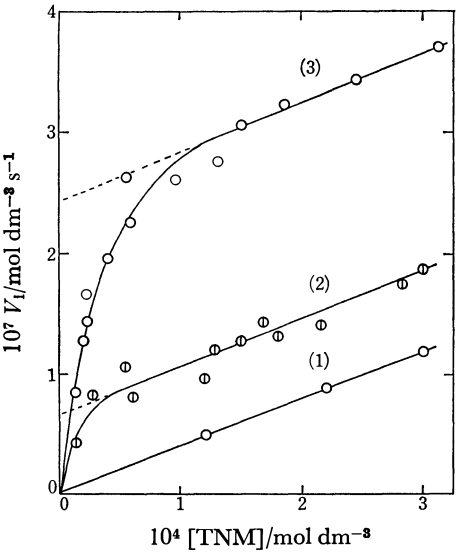

Fig. 2. Dependence of initial rate on the tetranitromethane concentration. Zero, 5.0×10^{-5}, and2.0×10^{-4} mol dm^{-3} in copper(II) sulfate for curves 1, 2, and 3, respectively; varied concentrations of tetranitromethane; 25 °C; the other conditions as in Table 2.

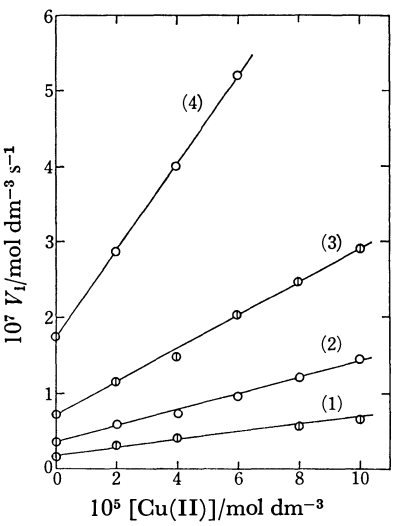

Fig. 3. Dependence of initial rate on concentrations of copper(II) and thiosulfate ions. 5.0×10^{-4}, 1.0×10^{-3}, 2.0×10^{-3}, and 5.0×10^{-3} mol dm^{-3} in sodium thiosulfate for lines 1, 2, 3, and 4, respectively; 20 °C; varied concentrations of copper(II) sulfate; the other conditions as in Table 2.

Under the conditions of $k_3[C(NO_2)_4][Cu(I)] \gg k_2[Cu(II)][S_2O_3^{2-}]$, the rate of formation of the nitroform anion is described by Eq. 7.

$$V_i = \mathrm{d[NF^-]}/\mathrm{d}t = k_1[TNM][S_2O_3^{2-}] + k_2[Cu(II)][S_2O_3^{2-}] \quad (7)$$

Under the condition of the k_2-term in Eq. 7 being much larger than the k_1-term, the rate shows zero-order with respect to the TNM concentration. Reactions 4 and 5 as alternative mechanisms could be also represented by Reactions 4′ and 5′.

$$Cu(II) + S_2O_3^{2-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Cu(II)\cdot S_2O_3^{2-} \quad (4')$$

$$C(NO_2)_4 + Cu(II)\cdot S_2O_3^{2-} \xrightarrow{k_3} C(NO_2)_3^- + Cu(II) + S_2O_3^- + NO_2 \quad (5')$$

Assuming the steady concentration for $Cu(II)\cdot S_2O_3^{2-}$ under the conditions of $k_3[TNM] \gg k_{-2}$, an equation identical to Eq. 7 is formed.

Ionic Strength Dependence on k_1 and k_2. Although the values of k_1 were independent of the ionic strength of the reacting solution, the values of k_2 decreased with increasing the ionic strength. Plots of the extended Debye-Hückel equation are given in Fig. 4. The value of the slope of log k_2 *vs.* $\mu^{1/2}/(1+\mu^{1/2})$ was -1.53 a value somewhat smaller than the absolute value predicted for the reaction between divalent ions.

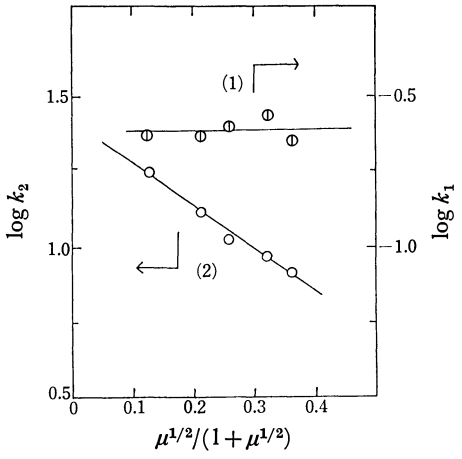

Fig. 4. Ionic strength effects on the rate constants. 0.01 mol dm^{-3} in perchloric acid ; 0.02 mol dm^{-3} in sodium acetate; 20 °C; varied ionic strengths ($NaClO_4$); the other condtions as in Table 1.

This may indicate that the copper(II) ion exists as acetato complexes so that the effective charges reveal smaller values than the divalent ion. Using the data, $K_1=1\times10^2$ dm^3 mol^{-1} and $\beta_2=1\times10^3$ dm^6 mol^{-2} for the formation constants of acetato- and diacetato-copper(II) complexes, respectively,[9] in a solution of 1×10^{-4} mol dm^{-3} copper(II) and 0.01 mol dm^{-3} acetate ion the copper(II) exists as 4.8×10^{-5} mol dm^{-3} Cu_{aq}^{2+} + 4.8×10^{-5} mol dm^{-3} $CuOAc^+$ + 4×10^{-6} mol dm^{-3} $Cu(OAc)_2$ in aqueous solution. Therefore, approximately 50% of copper(II) exists as $CuOAc^+$ species.

Permittivity Dependence of k_1 and k_2. The addition of methanol and ethanol to the reaction solution remarkably accelerated the rate of reaction between tetranitromethane and thiosulfate ion in the presence of the copper(II) ion. Plots of log k_1 *vs.* $1/D$ and log k_2 *vs.* $1/D$ are given in Fig. 5.

Assuming $Z_aZ_b=-4$ for the k_2 reaction, the distance of the closest approach of the reactants in the transition state has been calculated to be 3×10^{-8} cm. The dependence of k_1 on the permittivity was much smaller than for k_2. The dependence of k_1 may indicate that the tetranitromethane molecule is polarized in the transition state, and that side reactions may occur with increasing alcohol concentration.

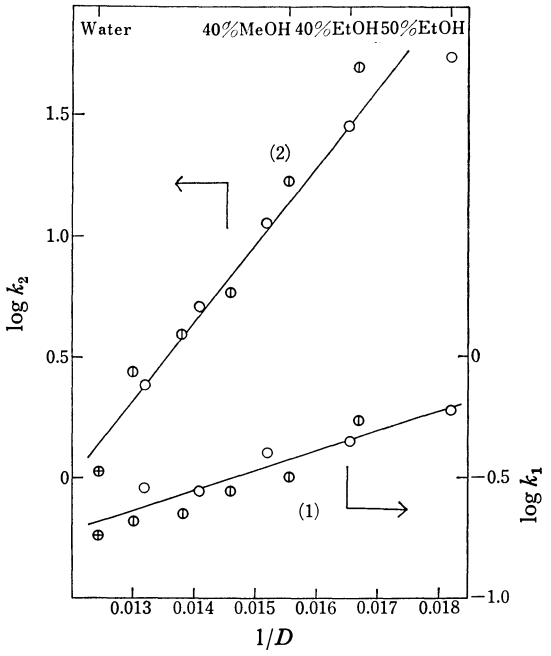

Fig. 5. Permittivity dependence on the rate constants. Plots ⊕, ⊕, and ○ indicate the data in aqueous solution, those in aqueous mixtures with methanol, and those in aqueous mixtures with ethanol, respectively. Varied concentrations 0, 5.0×10^{-6}, 1.0×10^{-5}, 2.0×10^{-5}, 3.0×10^{-5}, 4.0×10^{-5}, and 5.0×10^{-5} mol dm^{-3} in copper(II) sulfate for the aqueous mixtures with methanol and ethanol; 0, 2.0×10^{-5}, 5.0×10^{-5}, 1.0×10^{-4}, and 1.5×10^{-4} mol dm^{-3} in copper(II) sulfate for the aqueous solution; 20 °C; the other conditions as in Table 2. Values of permittivity were cited from a literature by Åkerlöf.[14]

Effect of Acetate Ion. The rate constant k_1 was not affected by the acetate ion concentration, whereas k_2 remarkably decreased with increasing acetate ion concentration. This strong retardation may be due to complex formation of the copper(II) ion with the acetate ion. Assuming that the aquated copper(II) ion is the main reacting species, k_2 should be described by Eq. 8.

$$k_2 = k_2^\circ/(1+K_1[OAc^-] + \beta_2[OAc^-]^2) \quad (8)$$

where k_2° indicates k_2 in the absence of acetate ion. Using values of $k_2^\circ=20$ dm^3 mol^{-1} s^{-1}, $K_1=1\times10^2$ dm^3 mol^{-1}, and $\beta_2=1\times10^3$ dm^6 mol^{-2}, k_2 has been calculated to be 20, 9.5, 5.9, 3.0, 1.9, and 1.0 dm^3 mol^{-1} s^{-1} for zero, 0.01, 0.02, 0.04, 0.06, and 0.10 mol dm^{-3} concentrations of OAc^-, respectively. The values calculated are in good agreement with those obtained experimentally. The rate constants k_1 and k_2 obtained are tabulated in Table 1.

Temperature Dependence. The values of k_1 and k_2 were determined in aqueous solution at an ionic strength of 0.2 mol dm^{-3} containing 0.1 mol dm^{-3} acetate ion at 15, 20, 25, 30, and 35 °C the results of which are listed in Table 2. The values of k_1 and k_2 are described by:

$$k_1 = 1.4\times10^9 \exp[-54000\,\text{J mol}^{-1}/RT]\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$$

and

respectively.

Mixing Order of Reactants. The addition of the copper(II) ion to the thiosulfate solution before the addition of tetranitromethane results in the formation of copper(I) in solution and the concentration of the copper(I) increases with standing of the copper(II)–thiosulfate mixture. The addition of tetranitromethane to the mixture after a certain time of standing resulted in the tetranitromethane reacting rapidly with all the copper(I) produced during the standing time resulting in the nitroform ion. After the rapid formation of nitroform ion, the nitroform ion concentration increased with time. An example of the behavior is given in Fig. 6.

The values extrapolated to zero time in Fig. 6 correspond to the concentrations of copper(I) formed during the standing time. The extrapolated values, plotted against the standing time of the copper(II)–thiosulfate mixture are given in Fig. 7 together with the results obtained under different conditions.

The slopes in Fig. 7 at zero to about ten min correspond to the rate of reaction between copper(II) and thiosulfate, and increases with decreasing acetate ion concentration. This trend is the same as seen in the values of k_2 in Table 1. From the initial slopes in Fig. 7 k_2 has been evaluated approximately as 4 to 6 dm^3 mol^{-1} s^{-1} and 1 dm^3 mol^{-1} s^{-1} in 0.01 and 0.1 mol dm^{-3} acetate ion, respectively. It is seen from Fig. 7 that the amount of nitroform formed is not related to the molecular oxygen dissolved in solution. Fouda *et al.*[10,11] reported that at temperatures up to 50 °C and

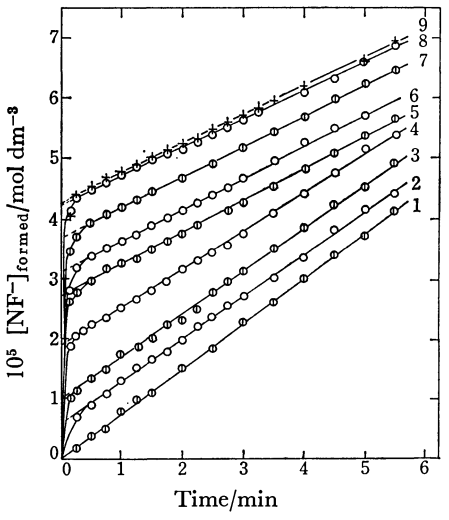

Fig. 6. An example for the kinetic behavior in the addition of tetranitromethane to the copper(II)–thiosulfate mixture after a certain time of standing. The standing time of the mixture is 0, 1, 2, 5, 10, 20, 30, 60, and 120 min for curves 1, 2, 3, 4, 5, 6, 7, 8, and 9, respectively. 1.0×10^{-4} mol dm^{-3} tetranitromethane; 1.0×10^{-4} mol dm^{-3} in copper(II) sulfate; 20 °C; the other conditions are the same as in Table 2.

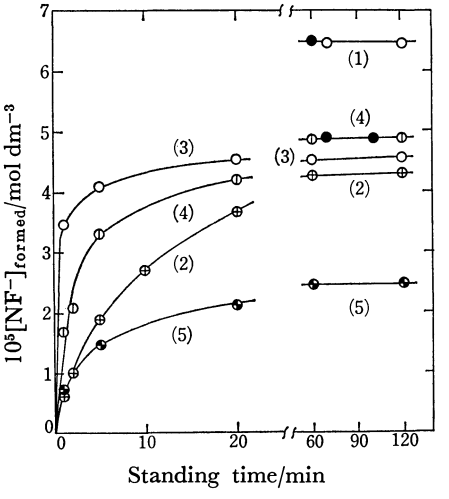

Fig. 7. The values extrapolated to time-zero in the plots of $[NF^-]_{formed}$ *vs.* t were plotted against time of standing. Conditions are 1.0×10^{-4} mol dm^{-3} tetranitromethane, ionic strength 0.2 mol dm^{-3}, 20 °C, and pH 4.7 with 0.2 mol dm^{-3} sodium acetate–0.1 mol dm^{-3} perchloric acid for curves 1 and 2, and with 0.02 mol dm^{-3} sodium acetate–0.01 mol dm^{-3} perchloric acid for curves 3, 4, and 5. Other conditions are 1.0×10^{-3} mol dm^{-3} thiosulfate and 2.0×10^{-4} mol dm^{-3} copper(II) for curve 1; 1.0×10^{-3} mol dm^{-3} thiosulfate and 1.0×10^{-4} mol dm^{-3} copper(II) for curves 2 and 3; 5.0×10^{-4} mol dm^{-3} thiosulfate and 1.0×10^{-4} mol dm^{-3} copper(II) for curve 4; 1.0×10^{-3} mol dm^{-3} thiosulfate and 5.0×10^{-5} mol dm^{-3} copper(II) for curve 5. Plots of ● indicate the data in the absence of oxygen, by bubbling nitrogen gas through the copper(II)–thiosulfate mixture during time of standing.

atmospheric pressure, the copper(I)–thiosulfate species resulting from the reduction of the copper(II) ion in aqueous solution by excess thiosulfate are stable with respect to reoxidation by molecular oxygen to copper(II). Ryabchikov and Sil'nichinko[12] reported that thiosulfate in excess over copper(II) (thiosulfate: copper(II)>3 : 1) results in the reaction:

$$2CuSO_4 + 6Na_2S_2O_3 \longrightarrow 2Na_3[Cu(S_2O_3)_2] + Na_2S_4O_6 + 2Na_2SO_4.$$

The $S_4O_6^{2-}$ ion forms no complexes with the copper(I) ion. Thiosulfate concentrations in the present investigation were 2.5 to 25 times in excess of the copper(II) concentration, and so the conditions are similar to those used by Fouda *et al.*[10,11] and Ryabchikov and Sil'nichinko.[12]

Byerley *et al.*[13] reported that complicated reactions occur in the reaction between the copper(II) ion and thiosulfate ion. It appears however that such complicated reactions do not occur under the present conditions which are designed for extremely low concentrations of copper(II) and thiosulfate ions.

Preparation and Properties of "β_1 and β_2"-Isomers of the Salicylato(triethylenetetramine)cobalt(III) Complex

Yoshihisa YAMAMOTO* and Eiko TOYOTA

Faculty of Pharmaceutical Science, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received January 12, 1979)

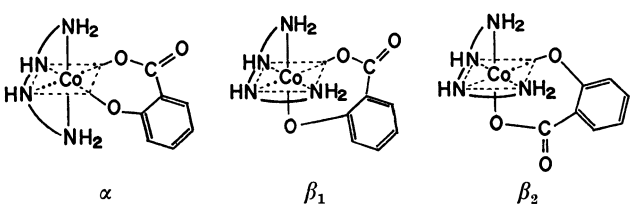
β-Salicylato(triethylenetetramine)cobalt(III) chloride monohydrate has been obtained from salicylic acid and β-dichloro(triethylenetetramine)cobalt(III) chloride at pH 10—11. The separation of "β_1 and β_2" isomers was attempted by using ion exchange. The IR spectra of the "β_1 and β_2" complexes showed four strong absorption peaks in the 990—1100 cm^{-1} region. This indicates that the complexes assume the β-form. The ^{1}H-NMR spectrum of ammine protons of coordinated triethylenetetramine of the β_1 complex showed six signals with an intensity ratio of 1:1:1:1:1:1, while that of the β_2 complex showed five signals with an intensity ratio of 1:1:1:1:2, in 1.8 mol dm^{-3} D_2SO_4. The order of the chemical shifts in ppm is $N(2)H<N(3)H<N(4)H_2<N(1)H_2$. Thus, the protons of the secondary N(3)H of coordinated triethylenetetramine absorb at lower fields than the terminal $N(1)H_2$ protons. The ^{13}C-NMR spectra of the "β_1 and β_2" complexes in heavy water showed six signals for trien-ligand carbons and seven signals for salicylato-ligand carbons. The spectra of these complexes have shown two different configurations of the "β_1 and β_2" complexes.

The preparation[1–3] and some properties[3–6] of salicylato- or cresotinato(tetraammine)cobalt(III) chloride monohydrate and aslicylato- or cresotinatobis(ethylenediamine)cobalt(III) chloride dihydrate with the formula of  (L: NH_3, L_2: en, R: H, CH_3) have already been reported. The present paper deals with the isolation of β_1 and β_2 isomers of salicylato(triethylenetetramine)cobalt(III) chloride monohydrate[7] and their properties.

As far as the present authors know, no report has appeared on the configuration of a cobalt(trien) complex which is chelated by two oxygen atoms as in the present example, although studies of the stereochemistry of the $[Co(trien)(amino\text{-}acidato)]^{2+}$ complex (trien=triethylenetetramine, amino-acidato=glycinato, sarcosinato···) have been reported by some authors.[8,9]

Results and Discussion

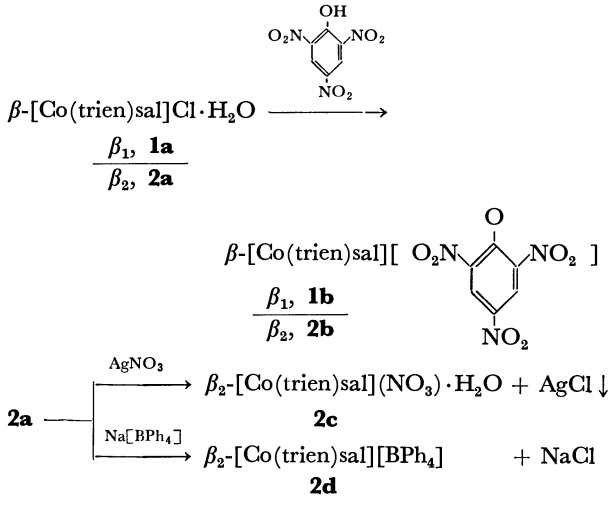
Complexes. Three isomeric forms are possible for the salicylato(triethylenetetramine)cobalt(III) complex, as is shown in Fig. 1. A mixture of β_1 and β_2-salicylato(triethylenetetramine)cobalt(III) chloride monohydrate was obtained from salicylic acid and β-dichloro(triethylenetetramine)cobalt(III) chloride at pH 10—11. The separation of the isomers was achieved by the use of ion-exchange resin. Attempts to obtain the α-form using α-dichloro(triethylenetetramine)cobalt(III) chloride invariably resulted in the isolation of a mixture of the β_1 and β_2-forms at pH 2—8. The α-form may, then, be thermodynamically unstable.[10] The α-glycinato(triethylenetetramine)-cobalt(III) chloride can not be prepared at pH 7—8,[10,11] but it can be prepared at pH 3[11] from glycine and α-dichloro(triethylenetetramine)cobalt(III) chloride.



α β_1 β_2

Fig. 1. The α, β_1, and β_2 configurations of $[Co(trien)sal]Cl\cdot H_2O$.

The β_1 and β_2-salicylato(triethylenetetramine)-cobalt(III) picrate complexes have been prepared



from picric acid and the corresponding chloride monohydrate. The β_1 and β_2 chloride monohydrate complexes (hereafter denoted as **1a** and **2a** respectively) are russet, while the corresponding picrates (denoted by **1b** and **2b** respectively) are orange. They are insoluble in most organic solvents, but the **1a** and **2a** complexes are soluble in water, methyl alcohol, and dimethyl sulfoxide. Salicylato(triethylenetetramine)cobalt(III) nitrate monohydrate (**2c**) has been prepared from silver nitrate and the corresponding chloride monohydrate (**2a**). It is russet and soluble in water. The corresponding tetraphenyl borate (**2d**) has been prepared from sodium tetraphenyl borate and the **2a** complex. It is pink and soluble in acetone and dimethyl sulfoxide. When the **1a** and **2a** complexes are treated with 60% nitric acid, very deep green solutions are formed. They should contain complexes[3–6] similar to $[CoL_4 5\text{-}NO_2sal]^{2+}$ (L: NH_3, L_2:

en). The **1a** and **2a** complexes are diamagnetic and should be a cobalt(III) complex of the low-spin type. The absorption spectra of the **1a**, **1b**, **2a**, **2b**, **2c**, and **2d** complexes are collected in Table 1.

IR Spectra. Buckingham *et al.*, who studied the IR spectra of α, β_1, and β_2-[Co(trien)gly]$^{2+}$,[9,10] reported that the IR spectra of (trien)cobalt(III) complexes showed at least two strong absorption bands for α-complexes and at least four strong absorption bands for β-complexes in the 990—1100 cm^{-1} region. They also reported that the IR spectra of α-complexes showed three absorption bands, while those of β-complexes showed more complicated and usually four strong (and, in some cases, five) absorption bands, in the 3000—3300 cm^{-1} region.[12] The IR spectra of the **1a** and **2a** complexes have four strong peaks in the 990—1100 cm^{-1} region (Table 1) and four peaks in the 3000—3300 cm^{-1} region; *i.e.*, the IR spectrum of the **1a** complex has peaks at 2950, 3075, 3150, 3220, and 3275(sh), and that of the **2a** complex has peaks at 2875, 2950, 3050, 3150(sh), 3200, and 3275(sh), which is the shift on deuteration[12] to 2250—2450 cm^{-1}. This indicates that the complexes assume the β-form. The IR spectral data of the **1a**, **1b**, **2a**, **2b**, **2c**, and **2d** complexes are collected in Table 1.

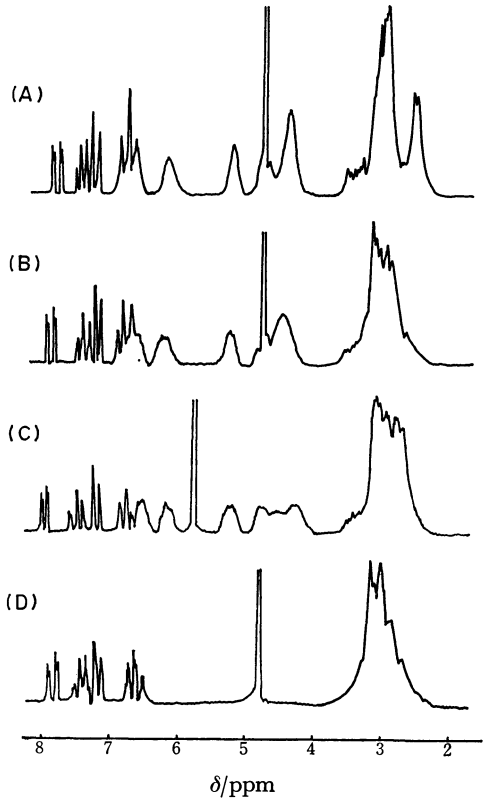


Fig. 2. The ^{1}H-NMR spectra of **1a** and **2a** complexes.

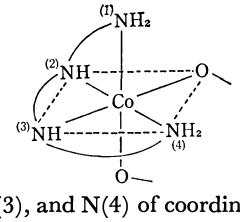
(B): β_1-[Co(trien)sal]Cl·H_2O in 0.1mol dm^{-3} D_2SO_4.
(C): β_1-[Co(trien)sal]Cl·H_2O in 1.8 mol dm^{-3} D_2SO_4.
(D): β_1-[Co(trien)sal]Cl·H_2O in heavy water containing NaOH. Standard: internal DSS.



N(1), N(2), N(3), and N(4) of coordinated trien ligand.

NMR Spectra. The ^{1}H-NMR spectra of the **1a** and **2a** complexes were measured in 0.1 mol dm^{-3} DCl, 0.1 mol dm^{-3} D_2SO_4, and 1.8 mol dm^{-3} D_2SO_4. In Fig. 2, the signals (2.3—3.8 ppm, 12H) at the highest field are assigned to the methylene protons of the coordinated trien. The signals of 4.0—6.7 ppm are assigned to the protons of the NH and NH_2 group. The multiplet (6.5—8.2 ppm) at the lowest field is assigned to the protons of the salicylato ligand. The signal of the methylene protons of the coordinated trien of the **1a** complex showed one peak, and that of **2a** showed two peaks in the 2.3—3.8 ppm region, as is shown in Fig. 2 and Table 1. The protons of both the NH and NH_2 groups of the coordinated trien of the **1a** and **2a** complexes showed five signals in the intensity ratio of 1 : 1 : 1 : 1 : 2 in 0.1 mol dm^{-3} D_2SO_4 or in 0.1 mol dm^{-3} DCl. They disappeared in heavy water containing NaOH. Buckingham *et al.* reported that the order of chemical shifts in ppm is $NHR_1R_2 < NH_2R < NH_3$.[11,13] Thus, in β_1 and β_2 also, the proton of the secondary NH of coordinated trien is considered to absorb at lower fields than the terminal NH_2 protons. Marzilli and Buckingham[10] also found that, in the spectra of the β_2-[Co(trien)sar]$^{2+}$ ion, the NH_2 protons in a position *trans* to the coordinated carboxyl oxygen of the sarcosinato ligand absorb at a higher field than those in a position *cis* to the coordinated carboxyl oxygen. If the same relation holds in our β_1 and β_2 complexes, the N(1)H_2 protons of coordinated trien is thought to absorb at a higher field than the N(4)H_2 protons, while the N(3)H proton probably absorbs at a higher field than the N(2)H proton, because N(1) and N(3) are at positions *trans* to the coordinated carboxyl oxygen or phenoxy oxygen.[6] Thus, the order of the ^{1}H chemical shifts in ppm should be: N(2)H<N(3)H<N(4)H_2<N(1)H_2. Now, in the [Co(NH_3)$_4$sal]$^+$ ion[6] it has been found that the NH_3 protons in a position *trans* to the coordinated carboxyl

oxygen of the salicylato ligand absorb at the highest field. As for the **1a** and **2a** complexes in a 0.1 mol dm^{-3} D_2SO_4 solution, the chemical shift (4.40 ppm) of the proton signal of the $N(1)H_2$ group of the **2a** complex is at a higher field than that (4.50 ppm) of the **1a** complex, as is shown in Fig. 2 and Table 1. Therefore, the $N(1)H_2$ group of the **2a** complex is considered to be at a position *trans* to the carboxyl oxygen of the salicylato ligand, which is more electronegative than the phenoxy oxygen.[6] Thus, the **2a** and **1a** complexes can be assigned to β_2 and β_1 respectively.

In the 1.8 mol dm^{-3} D_2SO_4 solution, the spectrum of the **1a** complex showed six peaks with an intensity ratio of 1 : 1 : 1 : 1 : 1 : 1, while that of the **2a** complex showed five peaks with an intensity ratio of 1 : 1 : 1 : 1 : 2. The signal at 4.50 ppm of the highest field, based on the $N(1)H_2$-group protons of the coordinated trien of the **1a** complex, split into two signals at 4.34 and 4.57 ppm. This seems to be a result of the formation of hydrogen bonding[14] between the carbonyl oxygen of the salicylato ligand and protons of sulfuric acid. The carbonyl oxygen of the coordinated salicylato of the **1a** complex is near to the $N(1)H_2$ protons in a position *trans* to the coordinated phenoxy oxygen of that complex. This is also in harmony with the assignment of the **1a** complex assuming it to have the β_1 form.

In the ^{13}C-NMR spectra of the **1a** and **2a** complexes in heavy water, there have been observed six signals for the trien ligand and seven signals for the salicylato ligand. The chemical shifts of the salicylato ligands of the **1a** and **2a** complexes agreed with each other, but those of the trien ligand were different, as is shown in Fig. 3 and Table 1. The chemical shifts of the salicylato ligand are assigned on the basis of the chemical shift of the salicylato(tetraammine)cobalt(III) chloride monohydrate.[6] Those of the trien ligand are difficult to assign to the individual carbon atom. They have shown the two different configurations of the β_1 and β_2 complexes. The NMR spectral data of the **1a**—**1b** and **2a**—**2c** complexes are collected in Table 1.

Experimental

Measurements. The NMR spectra were recorded with a FX-60 apparatus (JEOL) for ^{13}C-NMR and an R-40 apparatus (Hitachi) for ^1H-NMR. The IR spectra were recorded in potassium bromide disks with a IR-27G apparatus (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by the Gouy method using a magnetic balance (Shimadzu) at room temperature. The pH was measured with a Toa Electronics pH-meter HM-5B. The electric conductivity of an aqueous solution were determined by the use of a conductometer, CM-30 (Shimadzu), at room temperature.

Preparation of Complexes. β-Salicylato(trien)cobalt(III) Chloride Monohydrate: This complex was prepared from β-dichloro(trien)cobalt(III) chloride[15] (46 g, 148 mmol dm^{-3}) and salicylic acid (20.5 g, 148 mmol dm^{-3}) at pH 10—11 by Morgan's method[2] and was then recrystallized from water. Yield: 40.46 g (69.3%).

*Separation of β_1-Salicylato(trien)cobalt(III) Chloride Monohydrate (**1a**) and β_2-Salicylato(trien)cobalt(III) Chloride Monohydrate (**2a**)*: Five-tenths of a gram of β-[Co(trien)sal]$Cl\cdot H_2O$ was dissolved in 1.5 ml of water, and the solution was passed through a large column of cation-exchange resin (2.5×50 cm, Dowex 50W-X2). Two red bands separated on elution with a 0.3 mol dm^{-3} NaCl solution. The solution of the first band (**1a**) and that of the second band (**2a**) were concentrated in a rotary evaporator, and the NaCl was removed by filtration. The **1a** and **2a** complexes were both recrystallized from water. Yields: 0.022 g (4.4%) for **1a**; 0.42 g (84%) for **2a**; Found **1a**: C, 39.47; H, 6.07; N, 14.45; Cl, 8.76%. **1b**: C, 39.68; H, 6.14; N, 14.39; Cl, 9.00%. Calcd for $CoC_{13}H_{24}N_4O_4Cl$: (*MW* 394.75) C, 39.56; H, 6.13; N, 14.19; Cl, 8.98%.

*β_1-Salicylato(trien)cobalt(III) Picrate (**1b**) and β_2-Salicylato(trien)cobalt(III) Picrate (**2b**)*: An aqueous solution of the **1a** or **2a** complex (0.5 g, 1.27 mmol dm^{-3}) was added to a solution of picric acid (0.29 g, 1.27 mmol dm^{-3}), the mixture was stirred, and the separated orange complex was filtered and recrystallized from water. Yields: 0.36 g (50%) for **1b**; 0.42 g (58.2%) for **2b**; Found **1b**: C, 39.99; H, 4.63; N, 16.96%. **2b**: C, 40.24; H, 4.46; N, 17.06%. Calcd for $CoC_{19}H_{24}N_7O_{10}$: (*MW* 569.37) C, 40.08; H, 4.25; N, 17.22%.

*β_2-Salicylato(trien)cobalt(III) Nitrate Monohydrate (**2c**)*: An aqueous solution of silver nitrate (0.45 g, 2.65 mmol dm^{-3}) was added to an aqueous solution of **2a** (1.0 g, 2.53 mmol dm^{-3}), the mixture was stirred, and the precipitated silver chloride was filtered. The filtrate was concentrated and recrystallized from water as russet crystals. Yield: 0.65 g (60.9%); Found: C, 37.29; N, 5.67; N, 16.56%. Calcd for $CoC_{13}H_{23}N_5O_7$: (*MW* 421.30) C, 37.06; H, 5.74; N, 16.62%.

*β_2-Salicylato(trien)cobalt(III) Tetraphenylborate (**2d**)*: An aqueous solution of the **2a** complex (1.0 g, 2.53 mmol dm^{-3}) was added to a solution (0.95 g, 2.78 mmol dm^{-3}) of sodium tetraphenylborate, the mixture was stirred, and the precipitated pink complex was filtered off and washed with water, and ethanol and dried *in vacuo*. Yield: 1.45 g (86.7%); dec 216 °C, Found: C, 67.12; H, 6.60; N, 8.58%. Calcd for $CoC_{37}H_{42}N_4O_3B$: (*MW* 660.51) C, 67.28; H, 6.41; N, 8.48%.

The authors wish to express their gratitude to Professor Masayasu Mori of Osaka City University for his discussions.

X-Ray Diffraction Studies on the Structures of Diammine- and Aquasilver(I) Complexes in Aqueous Solution

Masunobu MAEDA,** Yoshiteru MAEGAWA, Toshio YAMAGUCHI, and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta, Midori-ku, Yokohama 227

(Received January 12, 1979)

X-Ray diffraction studies were carried out for aqueous diamminesilver(I) nitrate, silver(I) perchlorate and nitrate solutions. The radial distribution curve of the diamminesilver(I) nitrate solution showed that the length of the Ag–NH_3 bond is (2.22±0.02) Å. In the aqueous silver(I) perchlorate solution, a silver(I) ion is combined with two water molecules at a distance of (2.41±0.02) Å, the result being in good agreement with that obtained for the nitrate solution.

It is well known that silver(I) ion forms the stable diammine complex and the diamminesilver(I) ion is believed to have a linear structure. X-Ray structure analysis[1] showed that in crystals of diamminesilver dinitritoargentate, $[Ag(NH_3)_2]Ag(ONO)_2$, the diamminesilver(I) cation has a linear structure, the Ag–NH_3 bond length being 2.11 Å. However, no X-ray diffraction study of the diamminesilver(I) complex in aqueous solution has been carried out. Miles *et al.*[2] and Geddes and Bottger[3] measured infrared and Raman spectra of various diammine silver salts in crystals and solutions, suggesting a linear structure of the complex.

Most authors reported 2 for the hydration number of silver ion in aqueous solution with various methods.[4–7] On the other hand, an NMR method[8] gave a smaller value (0.7) and conductivity[9] and compressibility[10] measurements gave values of 3—4. The X-ray diffraction study on the aquasilver(I) ion has been carried out neither in the crystalline state nor in aqueous solution, because no crystal containing aquated silver(I) ion has been found and aqua silver(I) ion is readily reduced by X-ray irradiation.

In the present work, we aimed at determining the structures of the diammine- and aquasilver(I) complexes in aqueous nitrate and perchlorate solutions by the X-ray diffraction method with a special precaution for reduction of silver by X-rays.

Experimental

Preparation and Analysis of Sample Solutions. A diamminesilver(I) nitrate solution was prepared by dissolving the required amount of recrystallized silver(I) nitrate in a concentrated ammonia solution. The mole ratio of NH_3/Ag in the solution was adjusted to about 2.5 in which each silver(I) ion should be coordinated with two ammonia molecules according to the stability constant of the complex[11,12] The concentration of the silver(I) ion was determined both by gravimetry as AgCl and by electrogravimetry as Ag. The results obtained by the two independent methods were consistent with each other within 0.2%. The ammonia content of the sample solution was determined by the Kjeldahl method. The concentration of the nitrate ion was determined by the stoichiometry of the silver(I) nitrate.

A silver(I) perchlorate solution was prepared by adding silver(I) carbonate crystals to a boiling $HClO_4$ solution, the crystals having been precipitated by adding a sodium carbonate solution to a solution of silver(I) nitrate and then decanted repeatedly with water until no sodium ion was detected by the flame test.

A silver(I) nitrate solution was prepared by dissolving recrystallized silver(I) nitrate in distilled water.

The concentration of the anion in each solution was determined as previously mentioned.[13] The density of the solutions was measured with pycnometers. The compositions of the sample solutions are given in Table 1.

TABLE 1. COMPOSITIONS (g-atoms/dm³) AND THE STOICHIOMETRIC VOLUMES V PER Ag ATOM OF THE SAMPLE SOLUTIONS

X-Ray Scatterings. X-Ray measurements were carried out at (25±1) °C with a JEOL θ-θ diffractometer using a Philips Mo X-ray tube (λ=0.7107 Å) over the s range from 0.6 to 16 Å^{-1} ($s=4\pi\sin\theta/\lambda$), where 2θ is the scattering angle. The details of the diffractometer, measurements and data treatments are reported elsewhere.[13–15] Preliminary X-ray measurements revealed that precipitates of silver metal reduced by X-rays appeared on the surface of a solution within a few days. Therefore, prior to measurements, the change of scattered intensities was examined with the elapse of time at two fixed scattering angles of 12° and 60°. In the case of the diamminesilver(I) nitrate solution, the change of scattered intensities was found to be less than 1.5% within two days of X-ray irradiation. The silver(I) perchlorate and nitrate solutions showed a change of less than 2% within one day. Thus, an irradiated sample was replaced by a new one during the experiments every two days for the diamminesilver(I) nitrate solution and every day for the silver(I) perchlorate and nitrate solutions.

Intensities of X-rays scattered were corrected for background, absorption in the sample,[16] polarization[16] and incoherent scatterings,[13] and then scaled to electron units by the conventional methods.[13,17,18] The values of coherent, incoherent and anomalous scatterings of all atoms were quoted from the literature.[19] In the case of the silver(I)

** Present address: Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso, Showa-ku, Nagoya 466.

perchlorate and nitrate solutions the molecular form factor for H_2O[20] was used when we calculated the interaction among water molecules in the systems. Reduced intensities $i(s)$ obtained by subtraction of independent scatterings of each atom and water molecules from the scaled intensities were Fourier transformed into the radial distribution function $D(r)$ after smoothing correction.[21] The modification function used was $\{(f_{Ag}(0)+\Delta f'_{Ag})^2+(\Delta f''_{Ag})^2\}/\{(f_{Ag}(s)+\Delta f'_{Ag})^2+(\Delta f''_{Ag})^2\}\exp(-0.01s^2)$ where f_{Ag}, $\Delta f'_{Ag}$, and $\Delta f''_{Ag}$ are the scattering factor, the real and the imaginary parts of anomalous dispersion of Ag atom, respectively. Spurious ripples found in the hard-core region of the $D(r)$ curves were removed by the previous manner.[13] Experimental scaled intensities, reduced intensities multiplied by s, the $D(r)$ and $D(r)-4\pi r^2\rho_0$ curves for the solutions investigated are shown in Figs. 1—4. Theoretical reduced intensities $i(s)_{calcd}$ of given atom pairs were calculated by Eq. 1 and they were transformed into the theoretical radial distribution curves by Fourier inversion.

$$i(s)_{calcd} = \sum_{i}\sum_{j\neq i} n_{ij}\{(f_i+\Delta f_i')(f_j+\Delta f_j')+(\Delta f_i'')(\Delta f_j'')\} \times \frac{\sin(sr_{ij})}{sr_{ij}} \exp(-b_{ij}s^2) \quad (1)$$

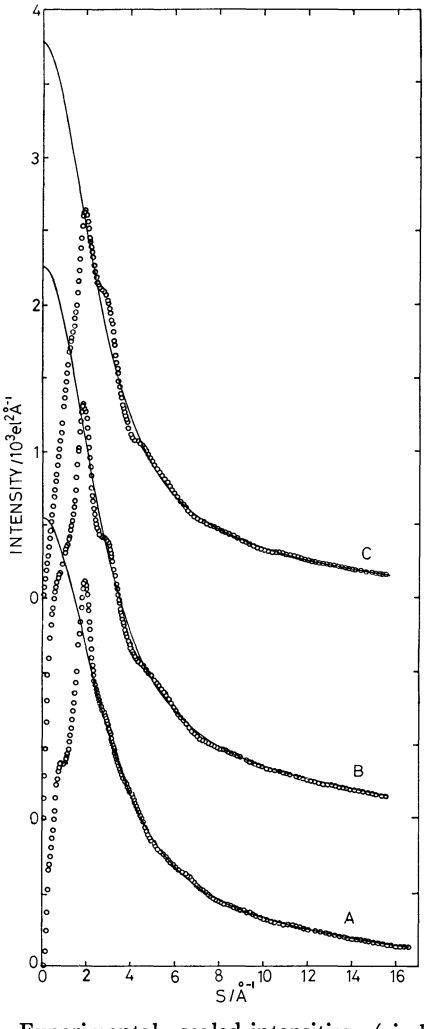

Fig. 1. Experimental scaled-intensities (circles) and calculated intensities (solid lines) of independent scatterings for solutions: A. $Ag(NH_3)_2NO_3$; B. $AgClO_4$; C. $AgNO_3$.

The values of the averaged distance r_{ij} between atoms i and j, the temperature factor $b_{ij}=1/2\langle\Delta r^2\rangle$ ($\langle\Delta r^2\rangle$ is the mean square amplitude of the molecular vibration) and the frequency factor n_{ij} were refined by the least squares method where the following function U was minimized.

$$U = \sum_{s_{min}}^{s_{max}} s^2(i(s)_{obsd}-i(s)_{calcd})^2 \quad (2)$$

Here s_{max} and s_{min} are the upper and lower limits of selected s regions. All calculations were performed with the aid of the M 180 computer by the KURVLR[22] and NLPLSQ[14] programs.

Results

Diamminesilver(I) Nitrate Solution. In the $D(r)$ and $D(r)-4\pi r^2\rho_0$ curves of solution A, three peaks appeared at 1.2, 2.2, and 3—5 Å. The first peak around 1.2 Å corresponds to the N–O bond within NO_3^- ion.[23,24] The O–H and N–H bonds within H_2O and NH_3 molecules also contribute in part to this peak. The second and rather distinct peak appeared at 2.2 Å, which can be ascribed to the distance between Ag and NH_3 molecules. The O–O interaction within the planar NO_3^- ion partly contributes to the peak ($1.26\text{ Å}\times\sqrt{3}=2.18$ Å). The structure of the diamminesilver(I) complex ion was determined by analyzing

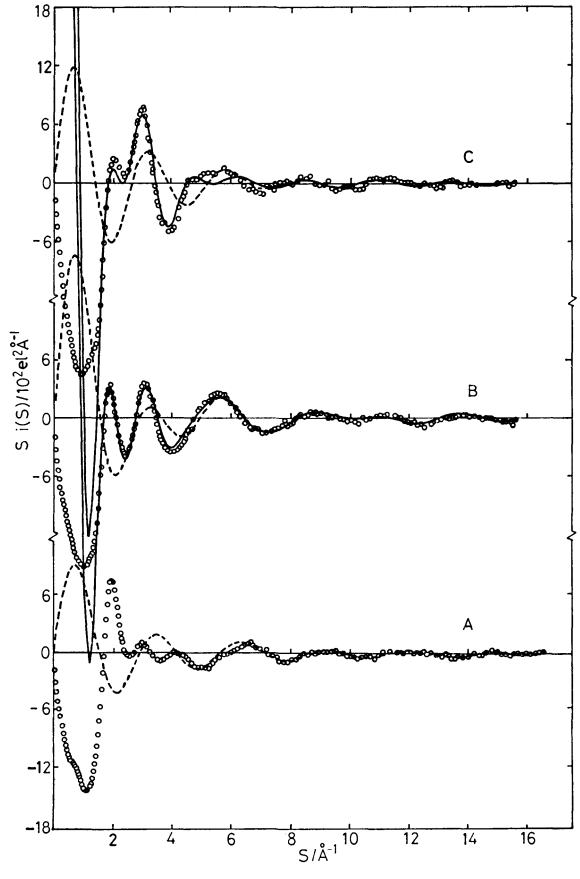

Fig. 2. Observed $s\cdot i(s)$ values (circles) for solutions A, B and C. Dashed and solid lines show the calculated $s\cdot i(s)$ values for the short- and (short+long)-range interactions, respectively, with parameter values listed in Table 3.

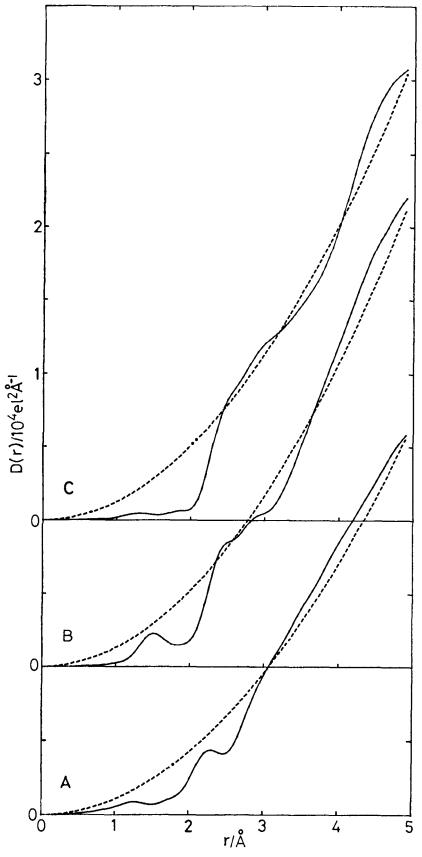

Fig. 3. Radial distribution functions $D(r)$ (solid lines) and $4\pi r^2\rho_0$ (dashed lines) for solutions A, B, and C.

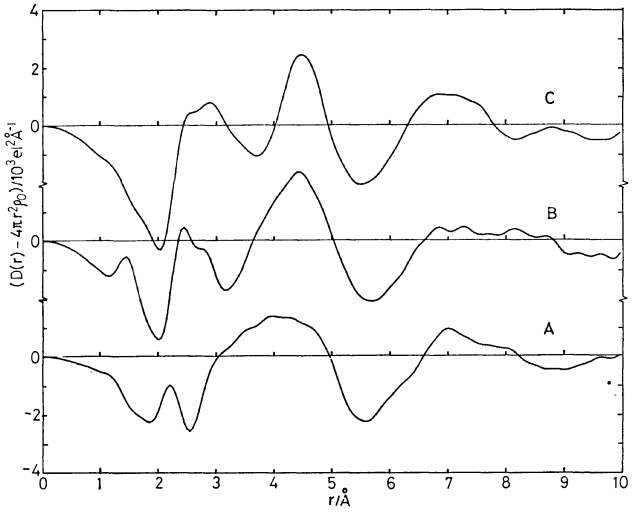

Fig. 4. The $D(r)-4\pi r^2\rho_0$ curves for solutions A, B, and C.

the second peak after subtraction of the peaks due to the N–O and O–O pairs within NO_3^- ion from the $D(r)$ curves. The average distances of the atom pairs used in the calculation were those given in the literature[24] and the temperature factors were calculated from spectroscopic data[25] by the Cyvin method,[26] the values being listed in Table 3.

The chain lines in Fig. 5 (a and b) show the residual

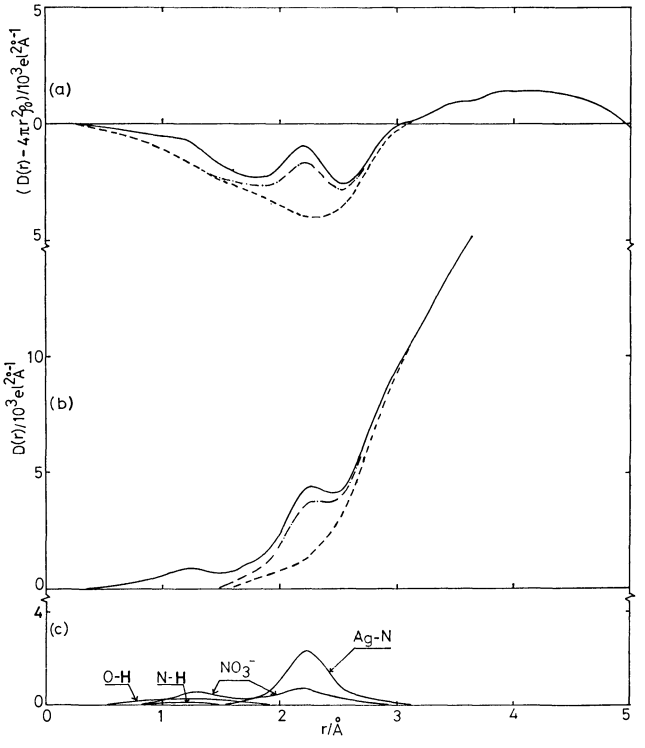

Fig. 5. (a) The $D(r)-4\pi r^2\rho_0$ curve for diamminesilver(I) nitrate solution. The chain line shows the residual curve after subtraction of the theoretical peaks from original curve (solid line), the peaks being those for the O–H and N–H bonds within H_2O and NH_3, respectively, and the N–O and O–O pairs within NO_3^- ion. The dashed line gives the difference between the original curve and the sum of the whole theoretical peaks shown in (c). (b) The corresponding $D(r)$ curve. (c) The theoretical peak shapes of each atom pair.

curves obtained by subtraction of the theoretical curves of the O–H bond within H_2O, the N–H bond within NH_3, the N–O, and O–O contacts within NO_3^- ion from the original curves (solid lines). The length of the Ag–NH_3 bond and the coordination number of the silver ion were determined from the residual curve by the trial-and-error method. The Ag–NH_3 bond length finally determined was (2.22±0.02) Å. The number of ammonia molecules coordinated to a silver(I) ion was estimated to be about 2 from the peak area. The temperature factor for the Ag–NH_3 bond was determined to be 0.002—0.003 Å^2, which was in good agreement with the value of 0.0018 Å^2 calculated by using spectroscopic data.[27] Further subtraction of the theoretical peak due to two Ag–NH_3 bonds from the residual curve gave a smooth background curve (dashed line), which shows no more appreciable intramolecular interaction left within 3 Å, except for a broad peak around 2.8 Å due to the bulk structure.[28]

The theoretical $s\cdot i(s)$ curve of the diamminesilver(I) nitrate solution was calculated on the basis of the proposed models for the complex, nitrate ion, ammonia, and water molecules. The theoretical values (dashed line in Fig. 2, curve A) of $s\cdot i(s)$ thus evaluated were compared with the experimental ones (circles). Over the range of 4 Å^{-1} $<s<$ 15 Å^{-1} satisfactory agreement

was found between them. Discrepancy in the calculated and experimental values at $s<4$ Å^{-1} is due to neglect of long-range interactions in the theoretical calculations.

Silver(I) Perchlorate and Nitrate Solutions. In Fig. 3, we see a peak around 1.5 Å in the $D(r)$ curve obtained for the perchlorate solution (curve B), which is due to the Cl–O bond within the perchlorate ion. A peak around 1.2 Å found in the nitrate system (curve C) is ascribed to the N–O bond within the nitrate ion. Peaks around 2.5, 2.8, and 4.3 Å are seen in the $D(r)$ and $D(r)-4\pi r^2\rho_0$ curves for both the solutions (see Figs. 3 and 4). The second peak around 2.5 Å can be attributed to the Ag–OH_2 bond within the hydrated silver(I) ion, which is expected from the sum of the radius of Ag^+ (1.26 Å[29]) and the size of a water molecule (1.40 Å[30]). The O–O contacts within the anions also contribute to the peak (1.5 Å$\times\sqrt{8/3}$=2.4 Å for tetrahedral ClO_4^- and 1.2 Å$\times\sqrt{3}$= 2.1 Å for planar NO_3^-). The peak around 2.8 Å is due to the hydrogen-bonded H_2O–H_2O interaction in the bulk water structure. Since the peaks at about 2.5 Å and 2.8 Å are overlapped, analysis of the structure of the aquasilver(I) ion from the peak shape at 2.5 Å was not possible without taking into account the contribution of the H_2O–H_2O interaction in the bulk. The wing of the peak due to long-range interactions which appeared at 4.3 Å may partly contribute to the peak at 2.5 Å. The 4.3 Å peak also influences the shape of the 2.8 Å peak. Therefore, in order to analyze the peak shape at 2.5 Å, interactions included in the peaks at 2.8 Å and 4.3 Å must be taken into consideration. The long-range interactions may be estimated on the basis of appropriate models of molecular interactions. The peak at 4.3 Å might include the interaction between silver ion and water molecules in the second hydration sphere.[31] Interactions between the central atoms of the perchlorate and nitrate ions and water molecules hydrated with the anions may also contribute to the broad peak. According to X-ray diffraction studies on concentrated HNO_3[23] and NH_4NO_3[24] aqueous solutions, the N(within NO_3^-)–O(within H_2O in the hydration sphere) interaction should appear at about 3.4 Å. For the perchlorate system, on the other hand, the corresponding Cl–O interaction is expected to appear around 3.6 Å, which is seen as a hump in curve B of Fig. 4. Such a hump has been observed in concentrated $Fe(ClO_4)_3$ aqueous solutions.[32]

Short-range intramolecular interactions mainly contribute to the high angle part of the $s\cdot i(s)$ function, whereas long-range intermolecular interactions largely contribute to the low angle part of the function and rapidly diminish with increasing s values. We have seen in the silver nitrate–ammonia system (Fig. 2, curve A) that the short-range interactions for the diamminesilver(I) nitrate solution are responsible for the $s\cdot i(s)$ values at $s>4$ Å^{-1}. Therefore, at a first step of approach in estimating the parameter values of the short-range interactions in the silver(I) perchlorate

and nitrate solutions, the least squares method was applied to the $s \cdot i(s)$ values of variable subsets covering various s ranges ($5\,\text{Å}^{-1} \leq s \leq 15\,\text{Å}^{-1}$). Then, long-range interactions were taken into consideration for explaining the data of almost whole angle range of the $s \cdot i(s)$ values.

Short-range Interactions: The structures of hydrated $Ag(OH_2)_n^+$ and the anion (ClO_4^- or NO_3^-) were taken into consideration in calculation of $s \cdot i(s)$ values over the range of $5\,\text{Å}^{-1} \leq s \leq 15\,\text{Å}^{-1}$ with variable s_{min}, the minimum value of the s range. In the calculation, the Ag–OH_2 distance, the temperature factor, and the number of the bond (n) were independently varied. For the tetrahedral ClO_4^- or planar NO_3^- ion, the only Cl–O or N–O distance was independently refined. The temperature factors of the perchlorate and nitrate ions were kept constant at the values calculated from spectroscopic data: 0.00076 Å^2 (Cl–O) and 0.0012 Å^2 (O–O) for ClO_4^-;[33] 0.00086 Å^2 (N–O) and 0.0010 Å^2 (O–O) for NO_3^-.[25]

Table 2 gives the parameter values thus obtained for the short-range intramolecular interactions of the siver(I) perchlorate solution with varying s ranges. As is seen from Table 2, the results were practically independent of selection of the s_{min} values. The values of the parameters determined in the range of $6\,\text{Å}^{-1} \leq s \leq 15\,\text{Å}^{-1}$ are taken as the best ones for both the perchlorate and the nitrate solutions. Calculated $s \cdot i(s)$ curves by using the parameter values thus obtained are shown by dashed lines in Fig. 2 (curves B and C).

Long-range Interactions: Interactions between silver(I) ion and water molecules in the second hydration sphere (abbreviated as Ag–$(H_2O)_{II}$) and the Cl–H_2O or N–H_2O interaction due to the hydration of perchlorate or nitrate ion were taken into account in calculation of $s \cdot i(s)$ values over much wider s ranges. The H_2O–H_2O interaction in the bulk phase was so approximated that "free" water molecules formed tetrahedral frameworks, the parameter values of the tetrahedral pentamer moiety of water, $(H_2O)_5$, being quoted from the work by Narten.[30]

When we took into account the long-range interactions in addition to the short-range intramolecular interactions previously discussed, satisfactory agreements were obtained between the experimental and theoretical $s \cdot i(s)$ values in both the perchlorate and nitrate systems over the whole range of s except $s < 1.5\,\text{Å}^{-1}$, where much longer-range intermolecular interactions and the scattering from the "holes" in an uniform medium[22] contribute to the $s \cdot i(s)$ values. The distance between silver(I) ion and water molecules in the second coordination sphere was estimated to be 4.3—4.4 Å. The Cl(within ClO_4^-)–H_2O and N(within NO_3^-)–H_2O distances were converged to 3.57 Å and 3.17 Å, respectively. The final results are summarized in Table 3, together with the values for the diamminesilver(I) nitrate solution given in the previous section. A small deviation of the theoretical $s \cdot i(s)$ curve from the experimental one was observed in the range of $5\,\text{Å}^{-1} < s < 6\,\text{Å}^{-1}$ in the silver(I) nitrate system. However, no further refinement was possible with any other models of the system. Figure

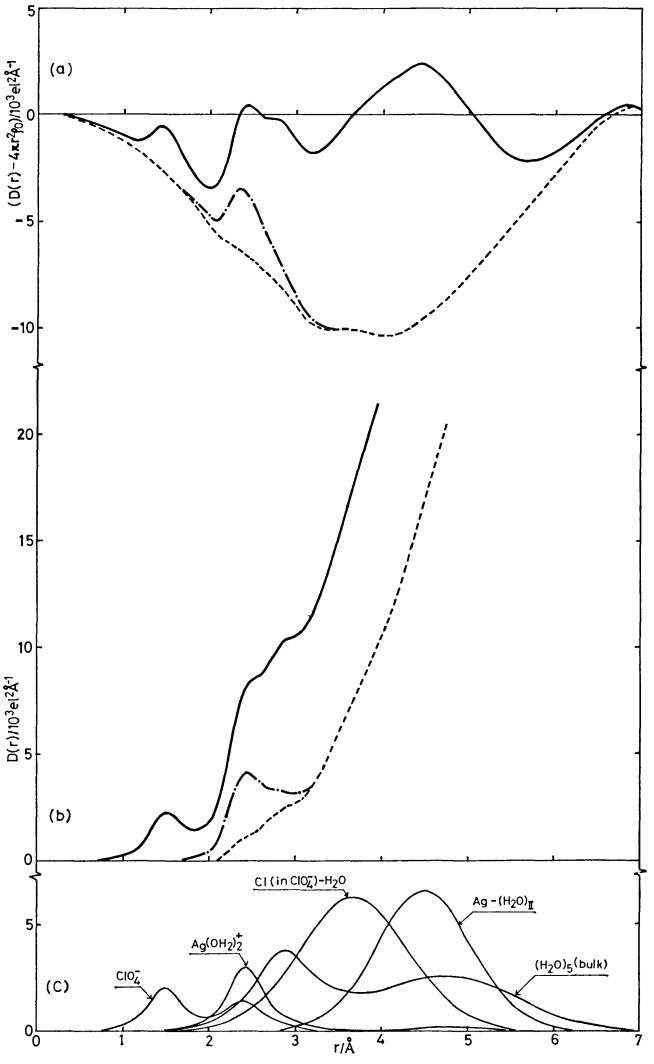

Fig. 6. (a) The $D(r) - 4\pi r^2 \rho_0$ curve for silver(I) perchlorate solution. The chain line shows the residual curve after subtraction of the theoretical peak shapes shown in (c) except for the peak due to the Ag–OH_2 bond from the original curve (solid line). The dashed line indicates the difference between the original curve and the sum of theoretical peak shapes shown in (c). (b) The corresponding $D(r)$ curve. (c) The theoretical peak shapes for each atom pair.

6(c) shows the radial distribution curve of each interaction in the silver perchlorate system estimated from the analysis of the $s \cdot i(s)$ curve described above. The peaks due to the Ag–OH_2 bond are clearly seen at 2.4 Å, shown by chain lines in Fig. 6 (a and b), when the theoretical peaks due to the intra- and intermolecular interactions except for the Ag–OH_2 bond were subtracted from the original curves shown by solid lines in Fig. 6 (a and b). Further subtraction of the peak due to the Ag–OH_2 bond from the residual curves gave smooth background curves, which indicated no other intra- and intermolecular interactions shorter than 6 Å.

Discussion

X-Ray diffraction data revealed that an Ag(I) ion

is coordinated with two ammonia molecules at a distance of 2.22 Å in aqueous solution and no water molecule combines with the diamminesilver(I) complex. The Ag–NH_3 bond in the $Ag(NH_3)_2^+$ complex in solution is longer than that in crystal.[1] In the present X-ray analysis we could not draw a definite conclusion that the complex has a linear structure because non-bonded NH_3–NH_3 distance was not determined. According to the preceeding work,[1] $Ag(NH_3)_2^+$ complex in $[Ag(NH_3)_2]Ag(NO_2)_2$ crystals has a linear structure. Therefore, we would like to say that the diamminesilver (I) ion has a linear structure in solution as well as in crystals. The aquasilver(I) ion may also have a linear structure. The values of the distance between a silver(I) ion and a water molecule r_{Ag-OH_2} and the coordination number of the silver(I) ion n_{Ag-OH_2} in the nitrate system are slighly different from those of the perchlorate system (Table 3). However, the difference is not significant.

It should be noted that the Ag–NH_3 distance is much smaller than the Ag–OH_2 distance observed in the present work, the fact suggesting the formation of strong coordination bonds between silver ion and ammonia molecules compared with that between silver ion and water molecules.

The present work has been partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Oxidation and Reduction of MoO_2–MoO_3 Studied by Infrared Emission Spectroscopy

Akifumi UENO* and Carroll O. BENNETT†

National Chemical Laboratory for Industry, 2-19-19, Mita, Meguro-ku, Tokyo 153

† *Department of Chemical Engineering, University of Connecticut, Storrs, Connecticut 06268*

(Received January 27, 1979)

A sample preparation technique was developed for the study of infrared emission spectroscopy. The emission spectrum of MoO_3 showed peaks at 987 and 925 cm^{-1} in the temperature range of 185 through 505 °C. Peak intensities were proportional to the sample weight. The background intensity in the emission spectrum was measured at 1050 cm^{-1} and it was also proportional to the sample weight. In order to apply emission spectroscopy to the study of reaction kinetics, the reduction of MoO_3 by H_2 and the oxidation of MoO_2 by O_2 were chosen as model reactions. These reactions were studied at 425 to 485 °C and the activation energy for the reduction of MoO_3 was 43 kcal/mol and that for the oxidation of MoO_2 was 38 kcal/mol. The activation energy for the formation of the terminal Mo=O bond was, however, 71.2 kcal/mol.

Oxides of molybdenum are important as oxidation catalysts. In connection with a recent study[1] of the partial oxdation of methanol on MoO_3–Fe_2O_3, attempts were made to investigate the state of the surface of the catalyst by infrared spectroscopy. As a first step it seemed logical to work with pure MoO_3, but we found that it was not possible to prepare a suitable disk of this material for study by the usual scattered transmission tehnique. Although the catalytic behavior of some noble metals such as platinum seem little affected by supports, such is not the case for most transition metals, and *a fortiori* for metal oxides. Thus we have searched for a means of studying unsupported MoO_3. Previous infrared work[2,3] on molybdenum oxides has been done on supported catalysts or by the Nujol method. Vanadium oxides have been studied in KBr disks.[4] These methods are obviously not suited to the observation of the catalyst during catalysis, our ultimate goal.

Although it seems attractive to use emission spectroscopy to observe catalysts at reaction temperatures, typically 200—500 °C, few papers have been published on this subject. Eischens and Pliskin[5] observed the spectrum of a thin layer of oleic acid on an aluminum rod at 200 °C. Low and Inoue[6] used an aluminum plate as the sample substrate. In an ideal arrangement only the sample would be heated, but radiation from the polished heated aluminum is small. Koga *et al.*[7] have used an infrared beam to heat their sample, so that the rest of the cell remained cooler, and interfering radiation was minimized. They observed the emission spectrum of formate ions on the surface of Al_2O_3. Dewing[8] deposited bismuth molybdate on a heated gold foil and observed the emission spectrum of the solid. Cavallini *et al.*[9] showed the utility of infrared emission spectroscopy as applied to the study of the oxidation of metal surfaces.

The experimental arrangement which we have used to obtain the infrared spectrum of CO_2 adsorbed on unsupported NiO[10] is readily adapted to the emission mode. If the temperature is higher than about 200 °C, the source can be turned off and emission spectra obtained. As pointed out by Dewing,[8] a thin layer (about 1 mg/cm^2) of solid must be used so that the black-body radiation of the solid does not overwhelm the emission peaks. For the study of MoO_3, we have evaporated on a stainless-steel mirror a suspension of finely divided ($\approx$5 μm particles) oxide. This sample gives a good emission spectrum of MoO_3 or, after reduction, MoO_2. However, its surface area is so small that there is not enough adsorbed CH_3OH, for example, on the solid to give a spectrum of adsorbed species. In future work it should be possible to use highly divided oxide (100—200 Å) prepared in a flame reactor[11] to permit the observation of adsorbed species. Such solids were not available to us at the time of the work reported here.

Infrared spectroscopy can be used to study the kinetics of changes of solids and species adsorbed on solids by the use of the transient method.[9,12,13] In the work reported here we have applied this method to the reduction and oxidation of the system MoO_3–MoO_2.

Experimental

Sample Preparation. MoO_3 was obtained by the decomposition of ammonium molybdate at 340 °C in air. It was ground to less than 200 mesh. These finely divided particles were suspended in water, and some of the finest part of the suspension was pipetted onto a well polished stainless steel mirror (1.0 cm^2) and then dried at 110 °C. The mean particle size of the sample was about 5 μm, measured by optical microscopy. After weighing, the mirror coated with catalyst was placed in the reaction cell and heated at 485 °C for 16 h with oxygen flow.

Reaction Cell and Optics of Spectrometer. The reaction cell used is the same as the one used in the previous work,[3] except that it was fitted with a BaF_2 window instead of an IRTRAN 6(CdTe) window; the BaF_2 window allows us to use higher temperatures than 300 °C. The window was glued into a stainless steel holder with Vacseal, although this adhesive was prone to leak after some exposure to temperatures above 400 °C. The cell was always used under positive pressure.

The optics of the infrared spectrometer is also the same as previously used,[10] except that the infrared radiation source was turned off to obtain the emission spectrum. The slits were not programmed in the present work and were set at 4.0 mm for all experiments.

In the present experiments, not only the emission from the sample but also that from the stainless steel mirror were recorded. Therefore, a correction was always made by the

subtraction of the emittance due to the mirror from that recorded due to the mirror with its sample. The emission spectrum of the mirror was not sensitive to its degree of polish for all those tested.

The intensities of the emission spectra were expressed in terms of μV on the lock-in amplifier (P.A.R. Model 128).

Chemicals. The gases used in the present experiments were obtained from Matheson. A cooling trap at −50 °C was used for H_2 and O_2 to remove water, and for Ar a Hydrox purifier was used to eliminate water and oxygen. These gases were introduced into the reaction cell with a flow rate of 3.0 ml/s, which corresponds to about 1 s of residence time in the reaction cell.

Procedure for Measurement of Reaction Rates. In order to obtain the reduction rate of MoO_3 by H_2 and the oxidation rate of MoO_2 by O_2, the wave numbers of the emission spectrum were fixed at 1050, 987, and 925 cm^{-1}, and the changes in the emission intensities were recorded separately for each experimental run. The emission spectrum of MoO_3 has peaks at 987 and 925 cm^{-1}, and they represent the termical Mo=O bond and the Mo–O–Mo net plane vibration.[3,9] For the experimental convenience, the increase in the background intensity at 1050 cm^{-1} is chosen to represent the change of bulk MoO_3 to MoO_2 and *vice versa*. The background intensity was sensitive to the oxidation states of molybdenum oxides at the higher wave numbers, and at the lower wave numbers around 825 cm^{-1} it became less sensitive (see Fig. 5). Therefore, the peak heights at 987 and 925 cm^{-1} were calculated by linear interpolation as follows every 1.0 min for the reduction of MoO_3 or every 5.0 s for the oxidation of MoO_2.

$$I_{987}(t) - \left(\frac{987-825}{1050-825}\right)I_{1050}(t) = P_{987}(t) \quad (1)$$

$$I_{925}(t) - \left(\frac{925-825}{1050-825}\right)I_{1050}(t) = P_{925}(t) \quad (2)$$

where $I_{987}(t)$ represents the intensity emitted from the sample at time t after the addition of H_2 (or O_2) at 987 cm^{-1}, and $I_{1050}(t)$, $I_{925}(t)$ also represent the emission at 1050 and 925 cm^{-1} respectively. From $P_{987}(t)$ and $P_{925}(t)$, the rates of reduction or oxidation could be obtained.

X-Ray Diffraction. The identification of MoO_2 and the Mo metal was obtained by X-ray powder diffraction by using Mo or Cu tubes with 40 kV and 20 mA. When the sample was studied by X-ray diffraction, it was exposed to air at room temperature. We confirmed that the sample was not oxidized by air at room temperature as follows: MoO_3 set in the reaction cell was reduced by the addition of H_2 at 485 °C, but the reduction stopped when H_2 was switched to Ar, as determined by the emission spectrum. Then the temperature was decreased to room temperature, keeping the sample in Ar, and its infrared transmission spectrum was observed. This spectrum did not change at all even when exposed to pure O_2 for several days at room

temperature.

Results

Emission Spectra. Figure 1 shows the emission spectra at 485 °C for various sample weights deposited on the mirror. The intensities, corrected for radiation from the mirror, are plotted in Fig. 2 as a function of sample weight. Up to 0.8 mg/cm² a linear relation is obtained; such curves facilitate the comparison of spectra obtained from different samples. Higher sample loadings may show some effect of the submergence on the individual bands by black body radiation for thick samples. This effect is often mentioned, for example by Dewing.[8]

The effect of temperature on the emission spectra is shown in Fig. 3, and the intensities of the various bands vary with temperature as shown in Fig. 4. The surprising linearity of these relations is not in disagreement with the fourth-power law of radiation, as illustrated by the following analysis.

A simple balance of radiant energy at the detector equates the energy received from the sample at T to that lost to the surroundings at ambient temperature T_0:

$$K_1(T^4 - T_d^4) = K_2(T_d^4 - T_0^4) \quad (3)$$

were T_d is the temperature of the detector. The signal depends on T_d, given by

$$T_d = \left(\frac{K_1T^4 + K_2T_0^4}{K_1 + K_2}\right)^{1/4} \quad (4)$$

K_1 and K_2 depend on view factors and emissivities in a complicated fashion, but to a first approximation

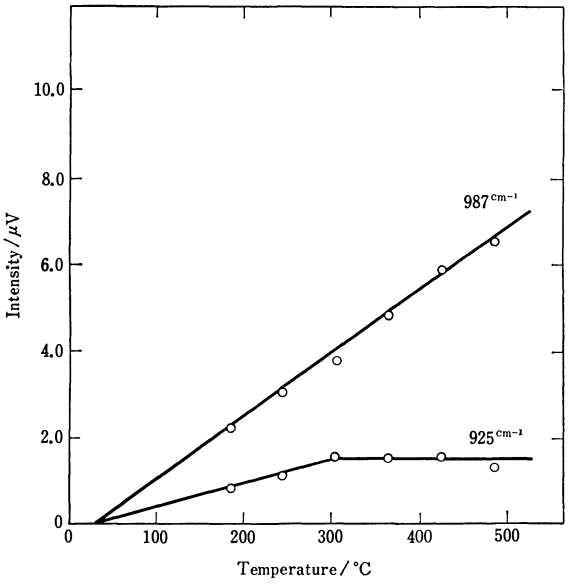

Fig. 4. Effect of temperature on emission intensity.

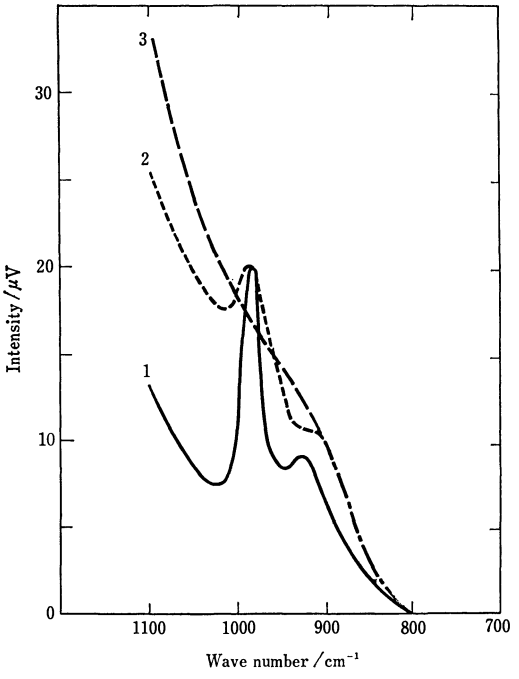

Fig. 5. Changes in emission spectrum of MoO_3 caused by addition of H_2 at 485 °C and 1 atm.
1: In O_2 (1 atm), 2: in H_2 for 2 min, 3: in H_2 for 10 min.

Reduction past MoO_2 toward Mo.

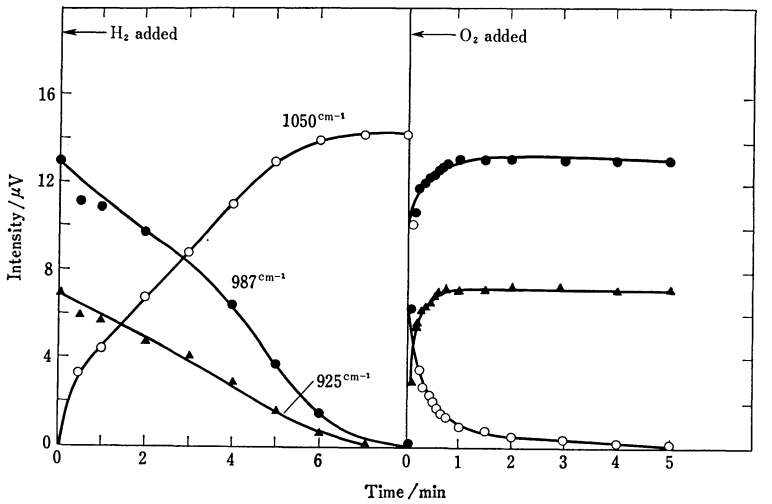

Fig. 7. Variation of emission intensities during reduction of MoO_3 to MoO_2 and during oxidation of MoO_2 to MoO_3, at 485 °C.

they are equal. We then have

$$T_d = \left(\frac{T^4 + T_0^4}{2}\right)^{1/4} \quad (5)$$

For T_0=300 K and T varying from 450 K to 750 K, the relation between T_d and T is almost linear. When T equals T_0, T also equals T_d, and there is no signal. No explanation is offered for the break in the curve for 925 cm^{-1} in Fig. 4.

Application to Kinetics. The MoO_3 sample was exposed to CO over the temperature range 25—485 °C but no adsorption bands nor reduction of the catalyst was observed. CO_2, CH_3OH, HCOOH, and HCHO also had no effect. However, exposure to hydrogen reduced the catalyst to MoO_2 and eventually partly to Mo. The emission spectra changed as shown in Fig. 5; the Mo=O (987 cm^{-1}) and Mo–O–Mo (925 cm^{-1}) bands are removed as the sample is reduced. Flow rates of all these gases were about 3 ml/s.

A quantitative study of the kinetics of reduction by hydrogen (≈1 atm) and oxidation by oxygen (≈1 atm) was made. The intensities at 987 cm^{-1} and 925 cm^{-1} were calculated from Eqs. 1 and 2, and the displacement of the background at 1050 cm^{-1} was measured, taking MoO_3 as zero. These intensities were measured as a function of time during reduction and oxidation at various temperatures. A typical result at 485 °C is shown in Figs. 6 and 7. At various times the sample was "frozen" by switching to argon and cooling as already described. The X-ray diffraction peaks obtained are shown in Fig. 8. We interpret the maximum in the background (1050 cm^{-1}) to be the point where the MoO_3 is exhausted and where Mo metal starts to appear, reducing the emissivity of the sample. We decided to limit our quantitative studies to the interconversion of MoO_3 and MoO_2 only, as shown in Fig. 7. The reduction is stopped when the intensity at 1050 cm^{-1} reaches its maximum.

The experiments described above were repeated at 425, 445, 465, 485, and 505 °C. From the initial slopes of curves such those of Fig. 7 the initial rate

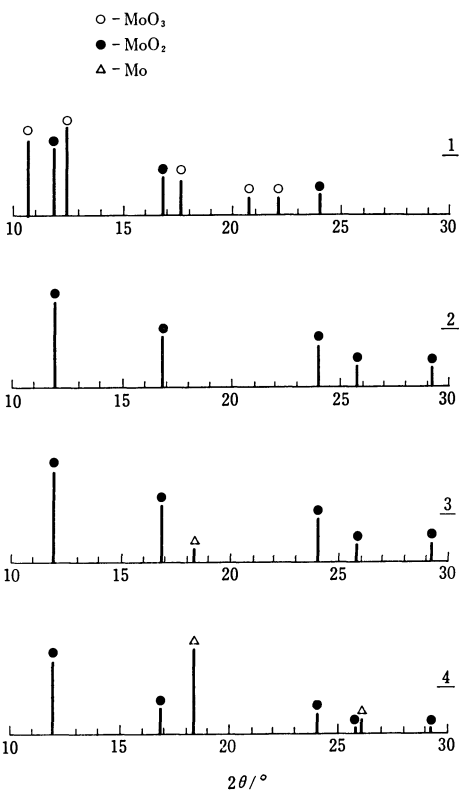

Fig. 8. X-Ray diffraction results during reduction of MoO_3 at 485 °C in H_2 for various times of exposure. 1: 3 min, 2: 6 min, 3: 8 min, 4: 20 min.

can be calculated in arbitrary units such as μV/s. These rates at various temperatures are used to construct the Arrhenius-type diagrams of Figs. 9 and 10. For the reduction of MoO_3 all three lines give an activation energy of 43 kcal/mol (179.7 kJ/mol). For the initial rate of oxidation of MoO_2, the activation energies are different for the three bands: 38.3 kcal/mol for 1050 cm^{-1}; 37.6 kcal/mol for 925 cm^{-1}; and 71.2 kcal/mol for 987 cm^{-1}. The rate of oxidation is so fast that these results are probably less precise than

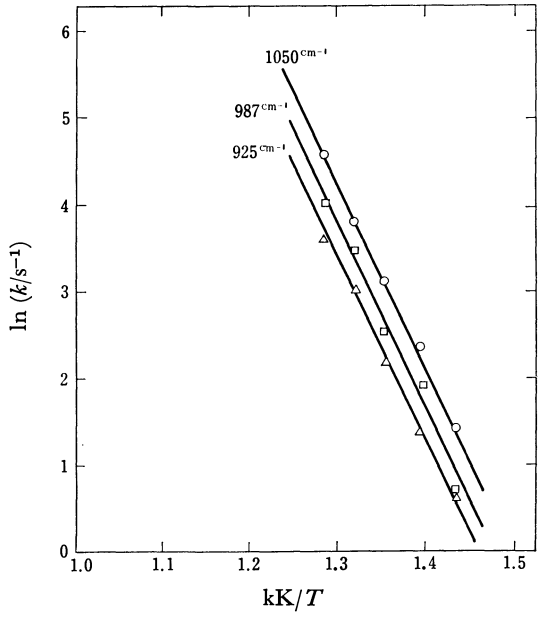

Fig. 9. Reduction rates of MoO_3.

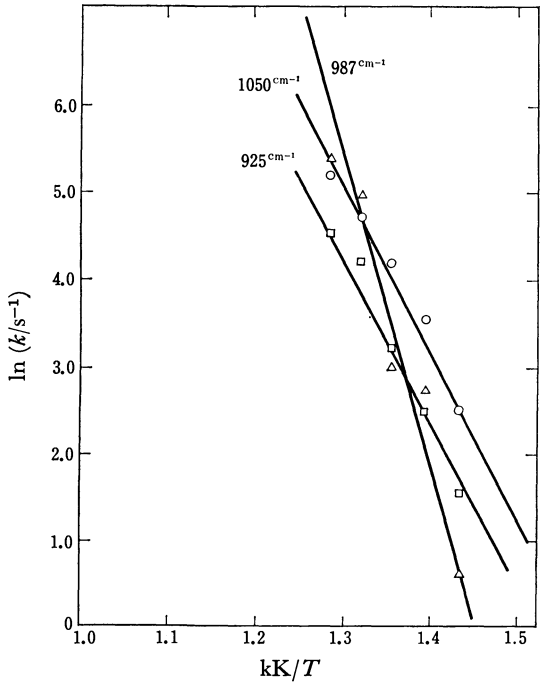

Fig. 10. Oxidation rates of MoO_3.

those for the reduction.

Earlier studies[14,15] of the reduction of MoO_3 by H_2 reported activation energies of 46—48 kcal/mol for the temperature range 365—445 °C, similar to our result of 43 kcal/mol. For the oxidation of MoO_2, Ramodorai *et al.*[15] report $E=40\pm2$ kcal/mol at about 465 °C, in qualitative agreement with our results based on the rate of change at 1050 cm^{-1} or 925 cm^{-1}. Possibly the formation of Mo=O starts only after most of the bulk is oxidized, so that our initial rates based on 987 cm^{-1} are too low. Recent studies[16–18] show that the system is quite complicated.

Summary

Emission spectroscopy can be used to study the structure and kinetics of reduction and oxidation of unsupported MoO_3–MoO_2, a system which has been difficult to study *in situ* by infrared techniques. In accord with Dewing,[8] we find that a sample loading of about 1 mg/cm^2 or less is suitable for the emission work. Infrared spectroscopy can now be used for kinetic measurements in catalysis.[2,3] For the MoO_3–MoO_2 system it furnishes a convenient method of measuring rates of reduction and oxidation.

(Received February 5, 1979)

The copper chelate of APDC was adsorbed on microcrystalline naphthalene to determine trace amounts of copper. The optimum pH range for the adsorption is 1.5—10.5. The chelate in dimethylformamide has an absorption maximum at 435 nm. Beer's law holds in the range 2.5—48 μg of copper in 10 ml of dimethylformamide. The molar absorptivity is 1.3×10^4 l·mol^{-1}·cm^{-1} and the sandell sensitivity 4.8×10^{-3} μg of copper per cm^2. Other factors such as amounts of reagent and naphthalene, shaking time, standing time and diverse ions were studied. The method can be applied to the determination of copper in Bovine Liver and human hair.

Ammonium pyrrolidinedithiocarbamate(APDC) is useful for solvent extraction and atomic absorption spectrophotometric determination of various metal ions. It was used for the extraction and spectrophotometric determination of copper by Looyenga and Boltz.[1]

We have developed a new method involving solid-liquid separation after liquid-liquid extraction, and have applied it to the determination of copper, bismuth and cobalt with APDC as a chelating agent by the naphthalene extraction method.[2] The method is based on the formation of metal chelate which is extractable quantitatively with molten naphthalene. The extract is separated from the aqueous solution and dissolved in a suitable organic solvent, the trace amounts of metal being determined spectrophotometrically.

Most metal chelates in aqueous solution can be easily adsorbed with microcrystalline naphthalene by vigorous shaking for 1 min at room temperature. The method was applied to the spectrophotometric determination of trace metals.[3,4] In the present study, APDC was used as a chelating agent for the determination of trace copper. Satisfactory adsorption of copper chelate on naphthalene is discussed in detail.

Experimental

Reagents. Standard copper solution, 5 ppm. Prepared by diluting 5 ml of standard copper solution (1000 ppm, Wako Pure Chemical Co.) to 1000 ml with water.

APDC solution, 0.2%. Prepared by dissolving 0.2 g of APDC in 100 ml of water.

Buffer Solutions. Prepared from 1 M acetic acid and 1 M ammonium acetate for pH 3—6, and from 1 M aqueous ammonia and 1 M ammonium acetate for pH 8—11.

Naphthalene solution, 20%. Prepared by dissolving 20 g of naphthalene in 100 ml of acetone.

Naphthalene, acetone, dimethylformamide, and all other reagents of analytical grade were used without further purification.

Apparatus. Absorption measurements were made with matching 10 mm glass cells on a Hitachi Model 200-20 spectrophotometer.

pH measurements were made with a Toa-Dempa HM-5A pH meter.

Naphthalene was dried with a Tabai Model K-2 drier (Tabai Mfg. Co., Ltd.).

Samples were ashed with an International Plasma Corp. low-temperature asher, IPC-1000 AN TM1640.

Procedure. Transfer 1—10 ml of 5 ppm standard copper solution to a 100-ml stoppered Erlenmeyer flask, and dilute with water to *ca.* 40 ml. Add 1.5 ml of 0.2% APDC solution and adjust pH to 5.0 with 2.0 ml of buffer solution. Mix the solution well, let stand for 10 min, add 2.0 ml of 20% naphthalene solution and shake vigorously for 1 min. Filter off on a filter paper (*e.g.*, No. 5C, Toyo Roshi Co.) placed flat on a filter plate in a funnel. Wash with water, and dry at 50—60 °C when necessary. Dissolve the crystals with dimethylformamide, dilute to 10 ml and measure the absorbance in a 10-mm cell at 435 nm against the reagent blank prepared similarly.

Results and Discussion

Absorption Spectra. Absorption spectra of the reagent blank and the copper chelate in naphthalene–dimethylformamide solution are shown in Fig. 1. The copper chelate has an absorption maximum at 435 nm where there is practically no absorption due to the reagent blank. Thus, 435 nm was chosen as

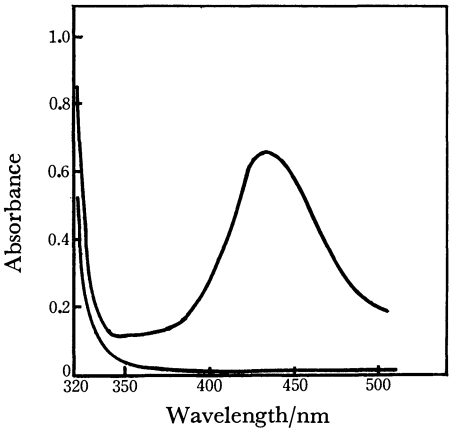

Fig. 1. Absorption spectra of APDC and copper complex in naphthalene–DMF solution.
Cu: 25 μg; 0.2% APDC: 1.5 ml; pH: 5.3; digestion time: 10 min; 20% naphthalene: 2.0 ml; shaking time: 1 min; reference: water; (1) reagent blank, (2) copper complex.

the most suitable wavelength.

Effect of pH. After the pH of sample solutions containing 25 μg of copper and 1.5 ml of 0.2% APDC solution had been controlled to desired values with different buffer solutions or hydrochloric acid, adsorption of the chelate was carried out. The result is shown in Fig. 2. The adsorption of the chelate starts from 2 mol dm^{-3} hydrochloric acid solution, reaches a maximum at pH 1.5, and thereafter remains constant over the range 1.5—10.5. Thus, the pH of the solution was adjusted to 5.3 for adsorption of the chelate.

Effect of Reagent Concentration. Various amounts of 0.2% APDC solution were added to the sample solution containing 25 μg of copper and 2.0 ml of the buffer solution(pH 5.3), the following procedure being the same as above. Figure 3 shows the variation in absorbance with the reagent concentration. The absorbance increases sharply with increase in the amount of reagent up to 0.1 ml of 0.2% APDC solution, becoming almost constant over the range 0.1—5.0 ml. Thus, 1.5 ml of 0.2% APDC solution was used for adsorption of the chelate.

Effect of Buffer Solution. The effect of buffer solution on the absorbance was examined. Addition of 0.5—5.0 ml of the acetate buffer solution caused practically no variation in absorbance. Thus, 2.0 ml of the buffer solution was added for adsorption of the chelate.

Effect of Digestion Time. A solution containing 25 μg of copper, 2.0 ml of the buffer solution(pH 5.3) and 1.5 ml of 0.2% APDC solution was digested at room temperature, the following procedure being the same as above. The absorbance increases with increase in digestion time up to 2 min, remaining almost constant for 2—30 min of digestion time. Thus, 10 min of digestion time was chosen for adsorption of the chelate.

Effect of Naphthalene Concentration. Adsorption of the chelate was carried out by changing the volume of 20% naphthalene–acetone solution added to the solution containing copper chelate. Figure 4 shows the effect of naphthalene concentration on the absorbance. The absorbance increases with increase in the amount of naphthalene up to 0.3 ml of 20% naphthalene solution, becoming almost constant for 0.3—5.0 ml. Thus, 2.0 ml of 20% naphthalene solution was used for adsorption of the chelate.

Effect of Shaking Time. Two ml of 20% naphthalene solution was added to the solution containing the copper chelate, and the mixed solution was shaken vigorously for 100 s. The chelate was completely collected on naphthalene by vigorous shaking for a few seconds. Shaking for 1 min was found to be satisfactory for complete adsorption.

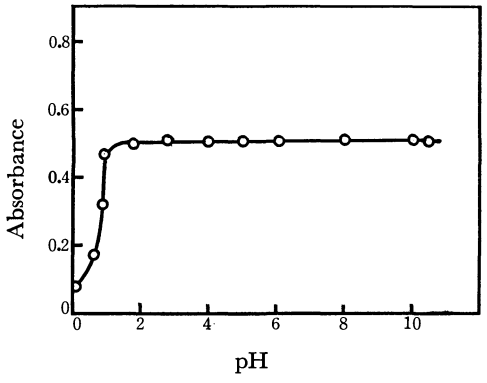

Fig. 2. Effect of pH.

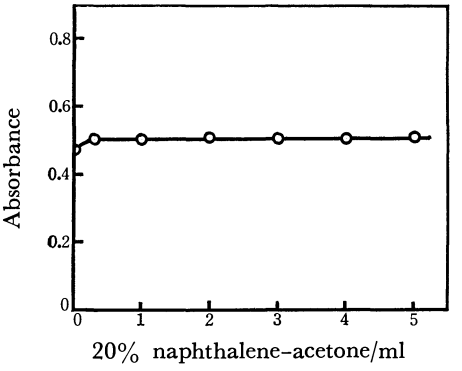

Fig. 4. Effect of naphthalene concentration.
Cu: 25 μg; wavelength: 435 nm; pH: 5.3; 0.2% APDC: 1.5 ml; digestion time: 10 min, reference: reagent blank.

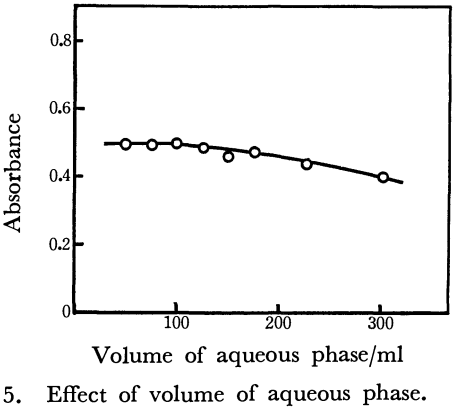

Fig. 5. Effect of volume of aqueous phase.
Cu: 25 μg; wavelength: 435 nm; pH: 5.3; 0.2% APDC: 5.0 ml; 20% naphthalene: 3.0 ml; shaking time: 5 min; reference: reagent blank.

Effect of Volume of Aqueous Phase. The volume of aqueous phase was varied between 50 and 300 ml while other factors were kept constant. Figure 5 shows the effect of volume of aqueous phase on the absorbance. The absorbance was almost constant up to about 100 ml, but decreasing gradually with increase in the volume of aqueous phase. For volumes exceeding 80 ml, the adsorption of the chelate on naphthalene was carried out by using a larger volume of the reagent solution, shaking for a long time and digesting at 40—50 °C. In this series of tests, 5.0 ml of the reagent solution was taken ; the mixed solutions were shaken for 10 min and digested for 20 min, 3.0 ml of 20% naphthalene solution being used.

Table 1. Effect of diverse alkali salts

Alkali metal salt	Amount added (mg)	Absorbance (435 nm)

Cu: 25.0 μg; pH: 5.3.

Effect of Standing Time. A mixture of copper chelate and naphthalene was dissolved in dimethylformamide, and the effect of standing time on the absorbance was studied. The color of the chelate in naphthalene–dimethylformamide solution remained unchanged even after 10 h.

Calibration Curve. The absorbances for varying concentration of copper were measured at 435 nm against the reagent blank under the optimum conditions described above. The absorbance shows a linear relationship to the concentration of copper in the range 2.5—48 μg in 10 ml of dimethylformamide. The molar absorptivity is 1.3×10^4 $l \cdot mol^{-1} \cdot cm^{-1}$, the sensitivity being 4.8×10^{-3} μg per cm^2 for an absorbance of 0.001. Ten replicate determinations of the sample solution containing 25 μg of copper give a mean absorbance of 0.500 with a relative standard deviation of 0.89%.

Choice of Solvent. Tests were made with various organic solvents in order to dissolve the mixture of the chelate and naphthalene. The chelate is soluble in organic solvents such as benzene, toluene, xylene, chlorobenzene, *o*-dichlorobenzene, dichloroethane, chloroform, nitrobenzene, acetone, acetonitrile, propylene carbonate, dimethylformamide at room tem-

Table 2. Effect of diverse metal ions

Metal ion	Added as	Ion added (μg)	Absorbance (435 nm)
—	—	—	0.500

Cd^{2+}	Chloride	100	0.500
Cr^{6+}	Dichlomate	10	0.494
Cr^{6+}	Dichlomate	50	0.499
Cr^{6+}	Dichlomate	100	0.495
Hg^{2+}	Chloride	10	0.507
Hg^{2+}	Chloride	50	0.499
Hg^{2+}	Chloride	100	0.504

perature. It undergoes decolorization in dioxane and MIBK.

Effect of Diverse Ions. Sample solutions containing 25 μg of copper and various amounts of diverse alkali metal salts or metal ions were prepared, the effect of diverse interfering salts and metal ions on copper determination being studied. The pH of solution was adjusted to 5.3. The results are given in Tables 1 and 2. The following species gave no interference: Na_2SO_4, NaCl, NH_4Cl, $Na_2C_2O_4$, $NaH_2PO_4 \cdot 2H_2O$, $Na_2HPO_4 \cdot 12H_2O$, Na_2CO_3, KNO_3, Na_2SO_3, CH_3COONa, KBr, sodium tartrate, sodium citrate, KCN, EDTA, Cd^{2+}, Pb^{2+}, Bi^{3+}, Mg^{2+}, Ca^{2+}, Zn^{2+}, Cr^{6+}, Hg^{2+}. Fe^{3+}, Ni^{2+}, and Co^{2+} gave interference.

From the results we see that the present method gives the same molar absorptivity, sensitivity, precision and selectivity as those by the chloroform method.[1] The pH range for the adsorption being wider.

Analysis of Copper in Biological Sample. The method was applied to the analysis of copper in Bovine Liver(N. B. S., SRM-1577) and human hair by using spectrophotometry and atomic absorption spectrophotometry. Low-temperature ashed samples were dissolved in concentrated nitric acid on a hot plate and evaporated to dryness. The residue was dissolved with 10 ml of redistilled water. An aliquot of this sample was taken for analysis. Iron(III) was masked with triethanolamine at pH 9.0. The results of Bovine Liver and human hair for copper by the two methods are satisfactory (Tables 3 and 4).

Table 3. Analysis of Bovine Liver for copper

Sample	Certified value (μg/g)	Spectrophotometric value (μg/g)	A.A.S (direct method) value (μg/g)
N.B.S SRM Bovine Liver 1577	193±10	190	191

Ylide–Metal Complexes. III. Preparation and Properties of Gold(I) Complexes of Alkylidenetriphenylphosphoranes and -arsoranes[1]

Yoshihisa YAMAMOTO* and Zenjiro KANDA

Faculty of Pharmaceutical Science, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received February 9, 1979)

Ylide-gold complexes of the type triphenylphosphine(triphenylphosphonium alkylide)gold(I) chloride, $[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}Au\text{-}PPh_3]Cl$, and bis(triphenylphosphonium alkylide)gold(I) chloride, $[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}Au\text{-}\overset{R}{\overset{|}{C}}HPPh_3]Cl$, have been obtained from alkylidene triphenylphosphoranes, $Ph_3P{=}CH\text{-}R$ (R: H, CH_3, $CH(CH_3)_2$), and (triphenylphosphine)gold(I) chloride, Ph_3PAuCl. Bis(triphenylarsonium methylide)gold(I) chloride, $[Ph_3AsCH_2\text{-}Au\text{-}CH_2AsPh_3]Cl$, has been synthesized from methylenetriphenylarsorane and Ph_3PAuCl. In these organogold complexes, the ylides are attached to the gold atom through the carbanionic donor atom. The ^{1}H-NMR spectra of $[Ph_3PCH_2\text{-}Au\text{-}PPh_3]Cl$ indicates an intermolecular exchange process in the temperature range $+25$——-50 °C.

The chemistry of ylide complexes of the transition metals has been actively investigated in recent years,[2] in particular, the complexes of methylenetrimethylphosphorane, $(CH_3)_3P{=}CH_2$.[3] The alkylidenetriphenylphosphoranes, $Ph_3P{=}CH\text{-}R$ have, however, been the subject of little research. Previous papers have been concerned with the preparation and physical properties of stable 2/1 complexes[4] of type $[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}M\text{-}\overset{R}{\overset{|}{C}}HPPh_3]Cl$ and stable 1/1 complexes[5] of type $[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}MCl]_n$ (M: Cu, Ag; R: H, CH_3, $CH(CH_3)_2$). 2/1 complexes[6] of $[Ph_3AsCH_2\text{-}Cu\text{-}CH_2AsPh_3]Cl$ and 1/1 complexes[6] of $[Ph_3AsCH_2\text{-}AgCl]_n$ have also been reported. The present paper deals with the preparation and ^{1}H- and ^{13}C-NMR measurements of triphenylphosphine(triphenylphosphonium alkylide)gold(I) chloride $[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}Au\text{-}PPh_3]Cl$, bis(triphenylphosphonium alkylide)gold(I) chloride $[Ph_3\overset{R}{\overset{|}{P}}\text{-}\overset{R}{\overset{|}{C}}H\text{-}Au\text{-}\overset{R}{\overset{|}{C}}HPPh_3]Cl$ and bis(triphenylarsonium methylide)gold(I) chloride $[Ph_3AsCH_2\text{-}Au\text{-}CH_2AsPh_3]Cl$.

Results and Discussion

Ylides. Alkylidenetriphenylphosphoranes, $Ph_3P{=}CH\text{-}R$ (**La**, R=H[7]; **Lb**, R=CH_3[8]; **Lc**, R=$CH(CH_3)_2$[4]), were prepared by the reaction of the corresponding phosphonium bromide with sodium amide in dry THF(tetrahydrofuran). Methylenetriphenylarsorane, **Ld** ($Ph_3As{=}CH_2$), was obtained from methyltriphenylarsonium bromide and sodium amide as reported in the literature.[6,9]

^{13}C-NMR data of the phosphonium ylides(**La**—**Lc**) are given in Table 1, the ^{13}C-NMR spectra of **Lb** and **Lc** being reported for the first time. The coupling constants ($^1J_{CP}$) of those are larger than that of the ylide **La**. This effect should be attributed to both electronic and structural effects.[10]

1/1 Ylide–Gold Complexes. Triphenylphosphine(triphenylphosphonium alkylide)gold(I) chlorides, $[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}Au\text{-}PPh_3]Cl$, have been obtained from ylide $Ph_3P{=}CH\text{-}R$, (triphenylphosphine)gold(I) chloride Ph_3PAuCl, and triphenylphosphine in a solvent at -45 °C (Eq. 1). Attempts to obtain these complexes at room temperature (r.t.) invariably resulted in the isolation of a mixture of 2/1 complexes of the type bis(triphenylphosphonium alkylide)gold(I) chloride and unreacted starting materials, Ph_3PAuCl and PPh_3 as shown in Eq. 2.

$$Ph_3P{=}CH\text{-}R + Ph_3PAuCl \xrightarrow[\text{THF, } PPh_3]{-45\,^\circ C} [Ph_3\overset{R}{\overset{|}{P}}CH\text{-}Au\text{-}PPh_3]Cl \quad (1)$$

R	H	CH_3	$CH(CH_3)_2$
	1a	**1b**	**1c**

$$\xrightarrow[\text{or r. t., } C_6H_6]{\text{r. t., THF}} 1/2[Ph_3\overset{R}{\overset{|}{P}}CH\text{-}Au\text{-}\overset{R}{\overset{|}{C}}HPPh_3]Cl + 1/2PPh_3 + 1/2Ph_3PAuCl \quad (2)$$

All complexes except **1c** are soluble and stable in dichloromethane. The isolation of **1a** requires an excess of triphenylphosphine as a supporting ligand, and the selection of a suitable reaction temperature and solvent is very important. For example, **1a** was not obtained at room temperature or in benzene (Eq. 2). This result differs as in the case of trimethylphosphine(trimethylphosphonium methylide)gold(I) chloride,[11] $[(CH_3)_3PCH_2\text{-}Au\text{-}P(CH_3)_3]Cl$, **2**, which could be isolated from benzene at room temperature. Also, for the preparation of **2** no excess of trimethylphosphine was necessary. This result may depend on the reduced coordination capacity of triphenylphosphine as compared with that of trimethylphosphine. Steric factors[12] seem not to be dominating for metals of coordination number 2.

The ^{1}H-NMR data of **1a** and **1b** are given in Table 1. The ^{1}H-spectrum of **1a** at -50 °C in CD_2Cl_2 showed a double-doublet signal of the methylene protons at 2.31 ppm. This signal broadened at -30 °C, and became a sharp doublet at -10 °C (Fig. 1). The process is reversible. This temperature dependence indicates an intermolecular exchange process in solution (Eq. 3). The chemical shift of the methylene group at -10 °C corresponds to the weighted average for

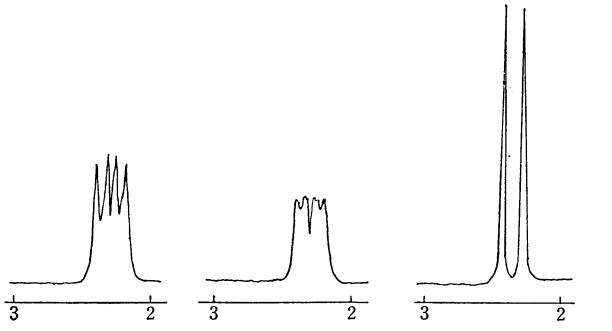

Fig. 1. ^1H-NMR spectra of complex **1a**, $[Ph_3PCH_2$–Au–$PPh_3]Cl$, at three different temperatures.

two species in Eq. 3. The small variation of chemical shifts with temperature suggest a small degree of dissociation:[13]

$$[Ph_3PCH_2\text{-Au-}PPh_3]Cl \rightleftarrows [Ph_3PCH_2\text{-Au}]Cl + PPh_3 \quad (3)$$

2/1 Ylide–Gold Complexes. Bis(triphenylphosphonium alkylide)gold(I) chlorides, $[Ph_3\overset{R}{\overset{|}{P}}CH\text{–Au–}\overset{R}{\overset{|}{C}}HPPh_3]Cl$, (R=H, **3a**; R=$CH_3$, **3b**; R=$CH(CH_3)_2$, **3c**), were prepared by the reaction of ylides Ph_3P=CH–R, with (triphenylphosphine)gold(I) chloride in dry THF at room temperature. **3a** is stable in dichloromethane at room temperature, whereas the corresponding complexes of copper and silver decompose in dichloromethane at room temperature and are stable only at −40 °C and −60 °C, respectively.

The ^1H- and ^{13}C-NMR data of **3a** and **3b** are summarized in Table 1. The data for **3c** is absent due to decomposition in the solvent.

Bis(triphenylarsonium methylide)gold(I) chloride, $[Ph_3AsCH_2\text{–Au–}CH_2AsPh_3]Cl$, **4a**, was obtained from methylene–triphenylarsorane Ph_3As=CH_2 and Ph_3AuCl in dry THF at room temperature.

The ^1H- and ^{13}C-NMR data of **4a** are shown in Table 1. The ^1H-NMR spectrum of **4a** showed a singlet for the methylene group at 1.99 ppm and a multiplet for the phenyl groups at 7.5 ppm in a ratio of 2 : 15.

Experimental

Measurements. The NMR spectra were measured with an FX-60 spectrometer (JEOL) for ^{13}C-NMR, a JNM-PMX-60 (JEOL) and a R-40 (Hitachi) for ^1H-NMR.

Starting Materials. Methylene-,[7] ethylidene-,[8] isobutylidene-[4] triphenylphosphonium ylides were prepared from the corresponding phosphonium bromides by the sodium amide method. Methylenetriphenylarsorane was prepared from methyltriphenylarsonium bromide and sodium amide.[6,9] (Triphenylphosphine)gold(I) chloride was synthesized by the method of Kowala and Swan.[14]

*Preparation of 1/1 Complexes. Triphenylphosphine(triphenylphosphonium methylide)gold(I) Chloride (**1a**):* (Triphenylphosphine)gold(I) chloride (0.24 g, 0.485 mmol dm^{-3}), methylenetriphenylphosphorane (0.115 g, 0.416 mmol dm^{-3}), and triphenylphosphine (0.14 g, 0.534 mmol dm^{-3}) were suspended in dry THF (15 ml) at −60 °C and stirred for approximately 1 h at −45 °C under nitrogen. The color of the ylide changed from yellow to colorless. The white complex precipitated was filtered at −70 °C, washed with

dry pentane and dried under vacuum. Yield 0.28 g (87.3%), mp 139—141 °C, Found: C, 57.40; H, 4.34%. Calcd for $C_{37}H_{32}AuClP_2$; (*MW* 771.03) C, 57.64; H, 4.18%.

*Triphenylphosphine(triphenylphosphonium ethylide)gold(I) Chloride (**1b**)*: (Triphenylphosphine)gold(I) chloride (0.71 g, 1.44 mmol dm^{-3}), ethylidenetriphenylphosphorane (0.42 g, 1.45 mmol dm^{-3}), and triphenylphosphine (0.52 g, 1.98 mmol dm^{-3}) were stirred in THF (25 ml) at −60 °C for 50 min under nitrogen. The color of the ylide changed from orange to colorless. The white precipitate was filtered at −70 °C, washed with dry pentane and dried under vacuum. Yield 0.90 g (79.6%), mp 94—96 °C. Found: C, 57.24; H, 4.43%. Calcd for $C_{38}H_{34}AuClP_2$: (*MW* 785.05) C, 58.14; H, 4.37%.

*Triphenylphosphine(triphenylphosphonium isobutylide)gold(I) Chloride (**1c**)*: (Triphenylphosphine)gold(I) chloride (0.55 g, 1.11 mmol dm^{-3}), isobutylidenetriphenylphosphorane (0.36 g, 1.13 mmol dm^{-3}), and triphenylphosphine (0.39 g, 1.49 mmol dm^{-3}) were stirred in THF (20 ml) at −60 °C for 50 min under nitrogen. The color of the ylide changed from red to colorless. The white complex precipitate was filtered at −70 °C, washed with dry pentane and dried. Yield 0.85 g (94.2%), mp 92—93 °C. Found: C, 58.32; H, 4.96%. Calcd for $C_{40}H_{38}AuClP_2$: (*MW* 813.11) C, 59.09; H, 4.71%. This complex was unstable.

*Preparation of 2/1 Complexes. Bis(triphenylphosphonium methylide)gold(I) Chloride (**3a**)*: (Triphenylphosphine)gold(I) chloride (0.41 g, 0.829 mmol dm^{-3}) was added to a dry THF (20 ml) solution of methylenetriphenylphosphorane (0.54 g, 1.95 mmol dm^{-3}) at −60 °C under nitrogen. The mixture was stirred for 2 h at room temperature and the white precipitate filtered off, washed with dry pentane and dried under vacuum. Yield 0.58 g (89.1%), dec 174 °C. Found: C, 57.66; H, 4.36%. Calcd for $C_{38}H_{34}AuClP_2$: (*MW* 785.05) C, 58.14; H, 4.37%.

*Bis(triphenylphosphonium ethylide)gold(I) Chloride (**3b**) and Bis(triphenylphosphonium isobutylide)gold(I) Chloride (**3c**)*: Complex **3b** was prepared from (triphenylphosphine)gold(I) chloride (0.34 g, 0.69 mmol dm^{-3}) and ethylidenetriphenylphosphorane (0.42 g, 1.45 mmol dm^{-3}) according to the procedure for **3a**. Complex **3c** was prepared from (triphenylphosphine)gold(I) chloride (0.43 g, 0.87 mmol dm^{-3}) and isobutylidenetriphenylphosphorane (0.60 g, 1.88 mmol dm^{-3}) according to the procedure for complex **3a**. Yield 0.48 g (85.6%) for **3b** and 0.67 g (88.6%) for **3c**. Dec 154 °C **3b**, 153 °C for **3c**. Found **3b**: C, 59.33; H, 4.90%. **3c**: C, 60.95; H, 5.83%. Calcd for **3b** $C_{40}H_{38}AuClP_2$: (*MW* 813.11) C, 59.09; H, 4.71%. **3c** $C_{44}H_{46}AuClP_2$: (*MW* 869.21) C, 60.80; H, 5.33%.

*Bis(triphenylarsonium methylide)gold(I) Chloride (**4a**)*: (Triphenylphosphine)gold(I) chloride (0.11 g, 0.222 mmol dm^{-3}) was added to a THF (15 ml) solution of methylenetriphenylarsorane (0.153 g, 0.478 mmol dm^{-3}) at −70 °C under nitrogen. The mixture was stirred for several minutes at −40 °C, and then for 1 h at room temperature. The precipitated white complex was filtered, washed with pentane and dried under vacuum. Yield 0.10 g (51.6%), dec 141 °C. Found: C, 51.80; H, 4.16%. Calcd for $C_{38}H_{34}AuClAs_2$: (*MW* 872.95) C, 52.28; H, 3.93%.

The authors wish to express their thanks to Professor Hubert Schmidbaur of the Technical University of Munich, Germany for his helpful discussions. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Extraction of the Chromium(III) Ion from Trichloroacetate Solutions to Inert Solvents Containing Trioctylphosphine Oxide

Hisanori IMURA,*,** Toshiyasu KIBA, and Takaharu HONJO

Department of Chemistry, Faculty of Science, Kanazawa University, 1-1 Marunouchi, Kanazawa 920

(Received February 16, 1979)

Chromium(III) has been extracted with 0.1 mol dm^{-3} trioctylphosphine oxide(TOPO) in various inert solvents from a 0.1 mol dm^{-3} trichloroacetate(TCA^-) buffer solution of pH 3.5 to 6.0. As diluents of TOPO, hexane and cyclohexane are most effective, while chloroform is quite ineffective. The extraction mechanism has been clarified by analyzing separately the distribution of water, trichloroacetic acid(HTCA), and the Cr(III) ion between the aqueous and organic phases. Water and HTCA are present in the cyclohexane phase as $H_2O\cdot$TOPO and HTCA·TOPO respectively. Chromium(III) is extracted with TOPO into cyclohexane as an ion-association complex like $Cr(H_2O)_6^{3+}(TCA^-)_3\cdot 3TOPO$, and the extraction constant is $10^{7.68}$. It is concluded that the hexahydrated Cr(III) ion is solvated by three molecules of TOPO, forming an ion pair with three trichloroacetate anions. The extractability of Cr(III) in the present system depends most effectively on the concentration of HTCA-free TOPO in the organic phase.

In a previous report,[1] the present authors found that many metal ions, such as Th(IV), Bi(III), Tm(III), Fe(III), Cr(III), Al(III), Hg(II), Co(II), Mn(II), Ba(II), Ca(II), and Cs(I), could be extracted from trichloroacetate(TCA^-) buffer solutions into polar solvents involving a donor oxygen atom, but not into inert solvents. Additionally, chromiun(III) could be quantitatively extracted with not only polar organic solvents such as isopentyl alcohol, but also with benzene containing trioctylphosphine oxide(TOPO). From the similarity of the visible absorption spectra and the paper electrophoretic behavior of the extracted metals to those of the corresponding metal ions in the aqueous solution, an extraction mechanism of metal ions involving the formation of ion pairs of hydrated metal ions with trichloroacetate anions and solvation by polar solvents has previously been proposed.[1] On the other hand, recently several authors have reported that trichloroacetic acid(HTCA) forms extractable mixed-ligand complexes[2,3] or ion-pair complexes with positively charged chelates.[4]

The extraction of Cr(III) from trichloroacetate buffer solutions with inert solvents containing TOPO is very interesting as a means of clarifying the extraction mechanism in the ion-association system. In the present system, water, trichloroacetate, and TOPO all participate in the extraction process of Cr(III); their effects have been analyzed separately.

Experimental

Reagents. The trichloroacetic acid was purchased from the Kishida Chemical Co. and was dissolved in re-distilled water. A series of buffer solutions (pH 0—10) was prepared by mixing a HTCA solution (10^{-3}—0.2 mol dm^{-3}) and a sodium hydroxide solution of the same concentration as the HTCA solution used. Hereafter, a series of buffer solutions, for instance, prepared by mixing 0.2 mol dm^{-3} HTCA and 0.2 mol dm^{-3} NaOH, will be noted as the 0.1 mol dm^{-3} trichloroacetate buffer solution.

The trioctylphosphine oxide was obtained from the Dojindo Co.

The chromium(III) solution was prepared by dissolving its high-purity metal in 2 mol dm^{-3} hydrochloric acid. The radioisotope, ^{51}Cr, used as a tracer was purchased from the New England Nuclear Co. (U.S.A.).

The organic solvents, such as cyclohexane, benzene, carbon tetrachloride, and chloroform, were purified by the usual methods. The other reagents were of a guaranteed reagent grade and were used without further purification.

Apparatus. The electronic absorption spectra were measured with a Hitachi Model 323 recording spectrophotometer.

The pH value of an aqueous phase was measured with Hitachi-Horiba pH meters, M-5 and M-7.

A Kobe Kogyo Co., Model STL-200(NaI(Tl) crystal), well-type scintillation counter was used for the γ-counting.

An Iwaki KM-Shaker was used for the agitation of an aqueous and an organic phase at 340 strokes per min.

The water content of an organic phase was determined by using a Karl Fisher-Titrator E 452 Metrom.

Extraction and Back-extraction Procedure. In a 50-cm^3 centrifuge tube with a ground-glass stopper, 10 cm^3 of an inert organic solvent containing from 10^{-3} to 10^{-1} mol dm^{-3} TOPO was placed, then 10 cm^3 of a trichloroacetate buffer solution, adjusted to the desired pH value, containing from 10^{-4} to 10^{-1} mol dm^{-3} of the Cr(III) ion, and its radioactive tracer were added. Then the contents were vigorously shaken by using a shaker for 1 to 20 min at room temperature (20—25 °C). After centrifugation, a 3-cm^3 portion was pipeted out from each phase, then the radioactivity was counted by the use of a scintillation counter, and the percentage of extraction($\%E$) of Cr(III) was calculated from the ratio of the counting rate of the two phases: $\%E=D/(1+D)\times 100$, where D is the distribution ratio of Cr(III). The pH value of the aqueous phase was measured after the extraction equilibrium had been established in all cases.

In the back-extraction procedure, 5 cm^3 of the organic phase, prepared by the extraction procedure described above, was shaken with 5 cm^3 of a trichloroacetate buffer solution adjusted to the desired pH value for from 1 to 20 min. The percentage of back-extraction($\%E_b$) was determined in the same manner as in the extraction procedure.

Determination of Trichloroacetic Acid. The method described in the literature[5] was somewhat modified for the determination of the trichloroacetate ion in the present investigation: the concentration of the trichloroacetate buffer solution used in this investigation was too high to be determined by Fujiwara's pyridine-alkali reaction; therefore, after

** Present address: Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980.

the extraction, 5 cm^3 of the aqueous phase was taken out and diluted with water to form about a 10^{-4} mol dm^{-3} trichloroacetate solution. Thus, a test solution was prepared. In a 20-cm^3 centrifuge tube, a 1-cm^3 portion of the test solution was placed together with 5 cm^3 of pyridine. Ten cm^3 of a 10 mol dm^{-3} sodium hydroxide solution was then added, and the content were vigorously shaken for 1 to 2 min. The tube was kept at 92±2 °C for just 3 min in a thermostat. After dipping the tube in water to cool it for 3 min, it was allowed to stand at room temperature for 30 to 60 min. Immediately after centrifugation, the absorbance of the pyridine layer was measured at 520 nm against the reagent blank.

Determination of Water Content of Organic Phase. In order to determine the water content of the cyclohexane phase after the extraction, an aliquot of the organic phase was submitted to Karl Fisher titration by the amperometric method. The potencies of the Karl Fisher reagent used were 1.9 to 2.6 mg H_2O/cm^3.

Results and Discussion

We tried to use various solvents as diluents of TOPO for the extraction of Cr(III) from a 0.1 mol dm^{-3} trichloroacetate buffer solution. The results are shown in Fig. 1, where the extraction decreases in this order: hexane, cyclohexane>toluene>benzene>nitrobenzene, carbon tetrachloride>chloroform. This order agrees with that observed in the extraction of europium nitrate with tributylphosphate in various diluents.[6] In the present extraction system, the effect of diluents may be ascribable to the differences in the interaction between TOPO and each diluent molecule, *e.g.*, dispersion forces, dipole-dipole interactions, or hydrogen bonds. In Fig. 1 the lowering of the distribution ratio of Cr(III) in the range of pH values higher than 5 is ascribed to the precipitation of the hydrated Cr(III) oxide in this pH range.

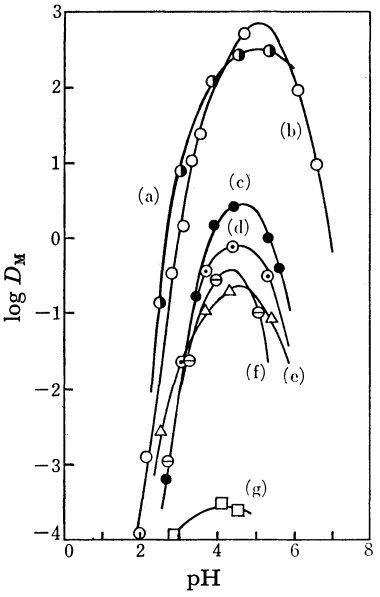

Fig. 1. Extraction of Cr(III) from 0.1 mol dm^{-3} TCA^- buffer solution into various organic solvents containing TOPO in 0.1 mol dm^{-3}. Hexane(a), cyclohexane(b), toluene(c), benzene(d), nitrobenzene(e), carbon tetrachloride(f), chloroform(g).

Chromium(III) could also be extracted from perchlorate solutions into cyclohexane containing 0.1 mol dm^{-3} TOPO, but the percentages of extraction from 0.1 mol dm^{-3} and 0.5 mol dm^{-3} perchlorate solutions at a pH value of 4.0 were only 22% and 85% respectively. In view of this fact, in place of perchlorate sodium chloride was used in order to keep the ionic strength of the aqueous phase constant (0.1). The concentrations of TOPO in cyclohexane and of trichloroacetate in the aqueous phase were kept as low as below 0.1 mol dm^{-3} in order to minimize the difference between the molar concentration and the thermodynamic activity.

Extraction of Water with TOPO. The extraction equilibrium of water by TOPO in cyclohexane can be given as follows:

$$H_2O + qTOPO_{(org)} \rightleftharpoons H_2O \cdot qTOPO_{(org)}, \quad (1)$$

where (org) designates the organic phase. Since the concentration of water in dilute solutions is considered constant, the extraction constant of water is written as

$$K_{H_2O} = \frac{[H_2O \cdot qTOPO]_{org}}{[TOPO]^q_{org}}. \quad (2)$$

Taking logarithms,

$$\log [H_2O \cdot qTOPO]_{org} = q\log [TOPO]_{org} + \log K_{H_2O}, \quad (3)$$

where $[TOPO]_{org}$ means the equilibrium concentration of the free TOPO. The amount of free TOPO remaining in the organic phase was calculated by deducting the amount of TOPO combined with water in the organic phase from that of the TOPO initially taken.

The plot of $\log[H_2O]_{org}$ *vs.* $\log[TOPO]_{org}$ gave a straight line with a slope of unity. From this slope, the species in cyclohexane was determined to be $H_2O \cdot TOPO$, which was just compatible with the $H_2O \cdot TOPO$ in carbon tetrachloride reported by Conocchioli *et al.*[7]

Extraction of Trichloroacetic Acid with TOPO. The extraction equilibrium may be written as

$$HTCA + iTOPO_{(org)} \rightleftharpoons HTCA \cdot iTOPO_{(org)}. \quad (4)$$

Therefore, the extraction constant of trichloroacetic acid is

$$K_{HTCA} = \frac{[HTCA \cdot iTOPO]_{org}}{[HTCA][TOPO]^i_{org}}. \quad (5)$$

In the above equation, water is put aside out of consideration. As will be described later, the water molecule present as $H_2O \cdot TOPO$ in the organic phase may be readily exchanged with trichloroacetic acid. Therefore, it can be assumed that the formation of the water complex of TOPO has no influence on the extraction of trichloroacetic acid. Then, the dissociation equilibrium of trichloroacetic acid in the aqueous phase is also given:

$$HTCA \rightleftharpoons TCA^- + H^+. \quad (6)$$

The acid dissociation constant of HTCA is

$$K_a = \frac{[TCA^-][H^+]}{[HTCA]}. \quad (7)$$

Equation 5 is rewritten by putting Eq. 7 in it,

$$K_{HTCA} = \frac{K_a[HTCA \cdot iTOPO]_{org}}{[TCA^-][H^+][TOPO]^i_{org}} = \frac{D_{HTCA}K_a}{[H^+][TOPO]^i_{org}}, \quad (8)$$

where D_{HTCA} is the distribution ratio of trichloroacetic acid. Taking logarithms of Eq. 8,

$$\log D_{HTCA} = i\log[TOPO]_{org} - pH - \log K_a + \log K_{HTCA}. \quad (9)$$

D_{HTCA} was determined at varying pH values of the aqueous phase for the equilibrium with various concentrations of TOPO as has been described above. Some of the results obtained are shown in Fig. 2, which indicates that the concentration of trichloroacetic acid in the organic phase decreases with the increase in the pH. This suggests that the concentration of TOPO free from trichloroacetic acid increases with the increase in the pH and that almost all of the TOPO becomes free from acid above pH 5.0.

On the other hand, the equilibrium concentration of water in the organic phase after the extraction of trichloroacetic acid is shown against the pH value of the aqueous phase in Fig. 3(a). Water is found to be released from cyclohexane with a lowering of the pH value until pH 2, and then the water concentration nearly reaches solubility in pure cyclohexane. Superposing this Fig. 3(a) on Fig. 2, it can be seen that TOPO tends to combine more strongly with trichloroacetic acid than with water, because the concentration of trichloroacetic acid in the organic phase shows a reverse trend to that of water.

Since TOPO molecules combined with water are readily available for the extraction of trichloroacetic acid, the complex formation of TOPO with water may be negligible in this acid-extraction equilibrium. Therefore, in Eq.9 the equilibrium concentration of TOPO was calculated by deducting the amount of

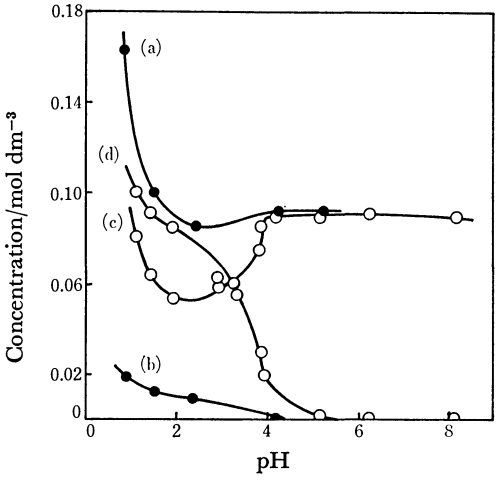

Fig. 2. Concentration of trichloroacetic acid in the organic and the aqueous phase after the extraction from 0.1 mol dm^{-3} TCA$^-$ buffer solution of various pH values. (a) and (c): HTCA in the aqueous phase, (b) and (d): HTCA in the organic phase, (a) and (b): the concentration of TOPO in cyclohexane is 0.01 mol dm^{-3}. (c) and (d): The concentration of TOPO in cyclohexane is 0.1 mol dm^{-3}.

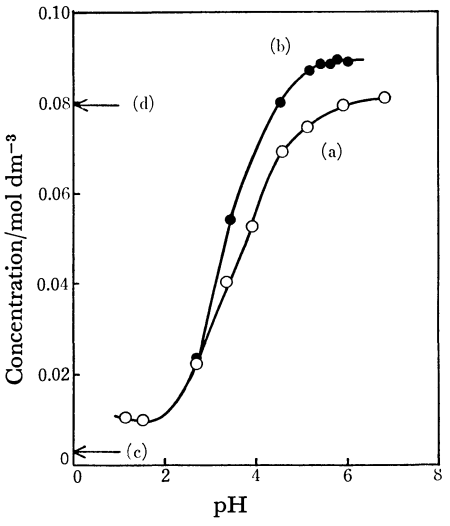

Fig. 3. Water content in the organic phase after the extraction at various pH values. (a): 0.1 mol dm^{-3} TOPO in cyclohexane—0.1 mol dm^{-3} TCA$^-$ buffer solution system, (b): in the presence of 1.9×10^{-3} mol dm^{-3} Cr(III), (c): water content in pure cyclohexane, (d): water content in cyclohexane containing TOPO in 0.1 mol dm^{-3}.

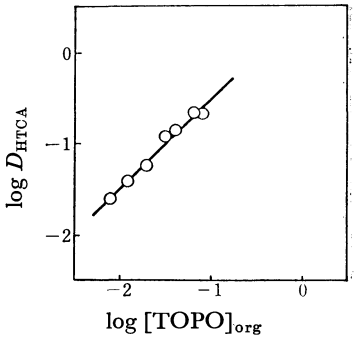

Fig. 4. Plot of log D_{HTCA} *vs.* log[TOPO]$_{org}$ at pH 4.0. Aqueous phase: 0.1 mol dm^{-3} TCA$^-$ buffer solution.

TOPO combined with trichloroacetic acid in the organic phase from that of TOPO initially taken, that is, [TOPO]$_{org}$ (acid extraction)=[TOPO](initial) $-i$[HTCA·iTOPO]. From Fig. 2, the concentration of TOPO combined with trichloroacetic acid was obtained directly from the concentration of trichloroacetic acid in the organic phase. The log-log plot of D_{HTCA} *vs.* the equilibrium concentration of TOPO obtained by calculating as $i=1$ is shown in Fig. 4, in which the log-log plot has a slope of unity. When the D_{HTCA} was plotted against the equilibrium concentration of TOPO obtained by assuming $i=2$ or $i=3$, no slope consistent with the assumed value of i was obtained. Consequently, the species of trichloroacetic acid extracted in cyclohexane was identified as HTCA·TOPO, and the extraction constant of trichloroacetic acid, $K_{HTCA}=10^{3.8}$ was obtained by putting known numerical values in Eq. 9. Compared with the extraction of other acids with TOPO,[8] the extraction constant of trichloroacetic acid is larger than those of such other acid as perchloric and thiocyanic acid. This may be attributed to the larger molar

volume of trichloroacetic acid.
