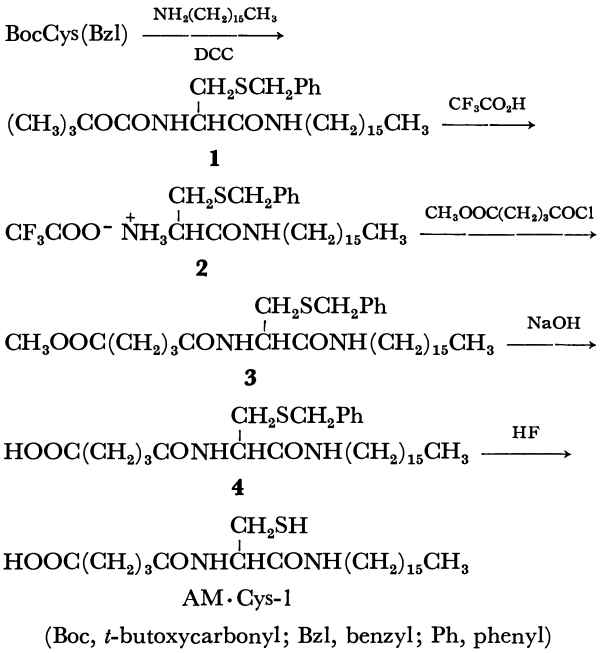
N-Hexadecanoyl-L-cysteine: mp 83—85 °C, nitroprusside positive, Ellman positive, $[\alpha]_D^{21}$ −26.0° (*c* 1.00, C_2H_5OH); R_f (silica gel IB of J. T. Baker, methanol), 0.80; R_f (silica gel IB of J. T. Baker, butanol–water–acetic acid at 4: 2: 1 by volume), 0.87. IR (KBr disc): 3320 (NH str.); 2920 and 2860 (CH str.); 1750 and 1650 cm^{-1} (C=O str.). NMR ($CDCl_3$, TMS): δ 0.86 (3H, t, $C\underline{H}_3(CH_2)_{13}CH_2$–), 1.25 (26H, broad, $CH_3(C\underline{H}_2)_{13}CH_2$–), 2.28 (2H, t, $CH_3(CH_2)_{13}C\underline{H}_2CO$–), 2.96 (2H, dd, –NHCH($C\underline{H}_2SH$)$CO_2H$), 4.80 (1H, t, –NHC$\underline{H}$-($CH_2SH$)$CO_2H$), 6.25 (1H, d, –N$\underline{H}$–), and 8.18 (1H, s, $-CO_2\underline{H}$). Found: C, 63.55; H, 10.16; N, 3.80%. Calcd for $C_{19}H_{37}NO_3S$: C, 63.47; H, 10.37; N, 3.90%.

The synthetic procedures for *N*-hexadecyl-N^{α}-glutaryl-L-cysteinamide (AM·Cys-1) is outlined in Scheme 1.



(Boc, *t*-butoxycarbonyl; Bzl, benzyl; Ph, phenyl)

Scheme 1. Synthetic procedures for AM·Cys-1.

N-*Hexadecyl*-N^{α}-t-*butoxycarbonyl*-S-*benzyl*-L-*cysteinamide* (*1*). *t*-Butoxycarbonyl-*S*-benzyl-L-cysteine (8.0 g, 23 mmol) and dicyclohexylcarbodiimide (4.7 g, 23 mmol) were dissolved in dichloromethane–acetonitrile (1: 1 by volume, 40 ml), and the solution was cooled down to 0 °C. Then, 1-aminohexadecane (5.5 g, 23 mmol) was added to the solution and the mixture was stirred for 3 h at 0 °C. Precipitated white solid was recovered by filtration and recrystallized from hexane–ethyl acetate (1: 1 by volume); yield 8.7 g (72%), mp 88—90 °C. IR (KBr disc): 3300 (NH str.); 2910 and 2850 (CH str.); 1695 and 1640 cm^{-1} (C=O str.). NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{15}$–), 1.27 (28H, s, $CH_3(C\underline{H}_2)_{14}$-$CH_2NH(CO)$–), 1.45 (9H, s, $(C\underline{H}_3)_3CO$–), 2.82 (2H, d, $-C\underline{H}_2SCH_2Ph$), 3.23 (2H, broad t, $CH_3(CH_2)_{14}C\underline{H}_2NH$-(CO)–), 3.75 (2H, s, $-CH_2SC\underline{H}_2Ph$), 4.57 (1H, broad t, –NHC$\underline{H}$(CH_2SCH_2Ph)CO–), and 7.31 (5H, s, phenyl H's).

N-*Hexadecyl*-N^{α}-*methylglutaryl*-S-*benzyl*-L-*cysteinamide* (*3*). Trifluoroacetic acid (5.7 g) was added to a dichloromethane solution (16 ml) of **1** (534 mg, 1.0 mmol), and the mixture was stirred for 1 h at room temperature. Evaporation of the excess trifluoroacetic acid *in vacuo* below 40 °C gave pale yellow crystals (**2**), mp 72 °C. Elimination of the *t*-butoxycarbonyl group was confirmed by the NMR spectrum. The crystals were used for the following reaction without further purification. Amine component **2** (210 mg, 0.38 mmol) and triethylamine (115 mg, 1.14 mmol) were dissolved in dichloromethane (5 ml) and cooled down to 5 °C. Methyl 4-chloroformylbutanoate (81 mg) dissolved in dichloromethane (2 ml) was added to the solution in 15 min at this temperature. The mixture was stirred for 1 h at 0 °C, for 1 h at room temperature, and refluxed for 10 min; and then washed with water (5 ml), 5% aqueous sodium hydrogencarbonate (5 ml ×2), water (5 ml×2), and 5% aqueous citric acid (5 ml×2) in this sequence. After being dried over anhydrous sodium sulfate, the mixture was evaporated *in vacuo* at 50 °C to give a white solid which was then purified by gel-filtration chromatography (Sephadex LH-20, 1: 1 chloroform–methanol as an eluant); yield 180 mg (50%), mp 86—88 °C. IR (KBr disc): 3275 (NH str.); 2900 and 2830 (CH str.); 1740 and 1640 cm^{-1} (C=O str.). NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{15}$–), 1.27 (30H, s, $CH_3(C\underline{H}_2)_{14}CH_2NH$– and $CH_3O_2CCH_2C\underline{H}_2CH_2CO$–), 1.75—2.55 (4H, m, CH_3O_2-$CC\underline{H}_2CH_2C\underline{H}_2CO$–), 2.71 (2H, d, –CHC$\underline{H}_2SCH_2$Ph), 3.24 (2H, broad t, $-NHC\underline{H}_2(CH_2)_{14}CH_3$), 3.66 (3H, s, $C\underline{H}_3O_2C$–), 3.74 (2H, s, $-SC\underline{H}_2Ph$), 4.57 (1H, t, –NHC$\underline{H}$(CH_2SCH_2Ph)-CO–), and 7.29 (5H, s, phenyl H's). Found: C, 67.96; H, 9.63; N, 4.87%. Calcd for $C_{32}H_{54}O_4N_2S$: C, 68.29; H, 9.67; N, 4.97%.

N-*Hexadecyl*-N^{α}-*glutaryl*-S-*benzyl*-L-*cysteinamide* (*4*). To a mixture of **3** (700 mg), dioxane (20 ml), and methanol (35 ml) was added 4% aqueous sodium hydroxide (9 ml). After being stirred for 6 h at room temperature, the mixture was evaporated *in vacuo* to remove methanol and then water (30 ml) was added to the residue. The solution was acidified to pH 5 by adding 10% aqueous citric acid. White precipitates were recovered by filtration and washed with water (5 ml× 10); yield 677 mg (99%), mp 101—102 °C. IR (KBr disc): 3250 (NH str.); 2900 and 2840 (CH str.); 1700, 1630, and 1525 cm^{-1} (C=O str.). NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{15}$–), 1.26 (30H, s, $CH_3(C\underline{H}_2)_{14}CH_2$– and $HO_2CCH_2C\underline{H}_2CH_2CO$–), 1.73—2.57 (4H, m, $HO_2CC\underline{H}_2CH_2$-$C\underline{H}_2CO$–), 2.71 (2H, d, –CH($C\underline{H}_2SCH_2Ph$)–), 3.24 (2H, broad t, $-NHC\underline{H}_2(CH_2)_{14}CH_3$), 3.74 (2H, s, $-SC\underline{H}_2Ph$), 4.57 (1H, t, –NHC$\underline{H}$(CH_2SCH_2Ph)CO–), and 7.29 (5H, s, phenyl H's). Found: C, 67.23; H, 9.48; N, 5.06%. Calcd for $C_{31}H_{52}O_4N_2S$: C, 67.84; H, 9.55; N, 5.10%.

N-*Hexadecyl*-N^{α}-*glutaryl*-L-*cysteinamide* (*AM·Cys-1*). L-Methionine (180 mg) and **4** (600 mg) were placed in a reaction vessel into which hydrogen fluoride (20 ml) was introduced. The mixture was stirred for 1 h at 0 °C, for 30 min at room temperature, and then evaporated *in vacuo* to remove hydrogen fluoride completely. Dichloromethane (30 ml) was added to the residue and white precipitates were recovered by filtration; this treatment was repeated four times. The white solid was dissolved in ethanol–chloroform (1: 1 by volume, 5 ml) and purified by repeated gel-filtration chromatography (Sephadex LH-20, 1: 1 ethanol–chloroform as an eluant); yield 135 mg (27%), mp 98—101 °C, nitroprusside positive. IR (KBr disc): 3250 (NH str.); 2910 and 2830 (CH str.); 1710, 1635, and 1535 cm^{-1} (C=O str.). NMR ($CDCl_3$, TMS): δ 0.88 (3H, broad t, $C\underline{H}_3(CH_2)_{15}$–), 1.27 (30H, s, $CH_3(C\underline{H}_2)_{14}CH_2$– and $HO_2CCH_2C\underline{H}_2CH_2CO$–), 1.75—2.55 (4H, m, $HO_2CC\underline{H}_2$-$CH_2C\underline{H}_2CO$–), 2.82 (2H, dd, –CH($C\underline{H}_2SH$)–), 3.20 (2H, broad t, $CH_3(CH_2)_{14}C\underline{H}_2NH$–), and 4.60 (1H, broad t, –NH-C$\underline{H}$(CH_2SH)–). Found: C, 63.63; H, 9.89; N, 5.93%. Calcd for $C_{24}H_{46}N_2O_4S$: C, 62.84; H, 10.10; N, 6.11%.

Kinetic Measurements. The concentration of free thiol for AM·Cys-1 and -2 was determined by using the Ellman's reagent (DTNB)[8] before kinetic runs. The reaction between a thiol compound and DTNB in 10% (v/v) aqueous ethanol

at pH 8.0 (μ 0.10 with KCl) and room temperature was followed at 412 nm to completion and the amount of free thiol was evaluated by using cysteine hydrochloride and/or 2-mercaptoethanol as a reference. The concentration of free thiol for AM·Cys-1 and -2 decreases upon oxidation to the corresponding disulfides at alkaline pH's, and the oxidation rate for the mercapto group of AM·Cys-2 was roughly estimated at several pH's by the Ellman's method. For example, the acyl transfer from an ester substrate to AM·Cys-2 was completed within 1 min at pH 11.82 while only a 5% amount of AM·Cys-2 was oxidized in 5 min. Under every conditions used in this work, the reaction between surfactant and ester species was fast enough to neglect oxidation of the mercapto group of the surfactants.

Rates of *p*-nitrophenol liberation from *p*-nitrophenyl esters were measured at 317 nm (pH<6) and 400 nm (pH>6) with a Hitachi 124 spectrophotometer. Each run was initiated by adding a dry dioxane solution (30 μl) of a substrate ester to a mixture of a reaction medium (3.0 ml) and a dry ethanol solution (30 μl) of a catalyst which was pre-equilibrated at 30.0±0.1 °C in a thermostatted cell set in the spectrophotometer. The reaction medium was prepared as follows: 10.0 ml of 1.0 M aqueous potassium chloride, 10.0 ml of an appropriate aqueous buffer, and 10.0 ml of dry ethanol were placed in a 100-ml volumetric flask; and subsequently the flask was filled with deionized and distilled water. Aqueous buffer solutions adopted in the present study were as follows: 1/10 M potassium dihydrogenphosphate–1/20 M sodium borate for pH 6—9, 1/20 M sodium borate–1/20 M sodium carbonate for pH 10—11, and 1/10 M sodium hydroxide–1/10 M sodium hydrogenphosphate for pH 11—12.

Determination of pK_a *Values.* The pK_a value for a mercapto group involved in AM·Cys-1 and -2 depends on their concentrations. The extent of dissociation of the mercapto group was evaluated by Eq. 1.

$$\alpha = \Delta\text{Abs(pH x)}/\Delta\text{Abs(pH 13.26)} \quad (1)$$

where ΔAbs(pH x) refers to the difference between absorbances at 235 (maximum) and 265 nm (minimum) in 10.8% (v/v) aqueous ethanol at pH x. ΔAbs for the completely ionized mercapto group of AM·Cys-1 was evaluated at pH 13.26. The modified Henderson-Hasselbalch equation as represented by Eq. 2 was adopted to evaluate pK_a values.

$$\text{pH} = pK_a + n\log\{\alpha/(1-\alpha)\} \quad (2)$$

In order to determine the true pK_a value in a micellar phase, the pK_a value was plotted against the concentration of AM·Cys-1 as shown in Fig. 4.

CMC Measurements. The critical micelle concentrations for AM·Cys-1 and -2 were determined at 30.0±0.1 °C, pH 9.30, and μ 0.10 (KCl) in 15.6%(v/v) and 11.5%(v/v) aqueous ethanol, respectively. Rhodamine 6G was used as a dye probe at 1.0×10^{-5} M. The difference spectra between 520 (maximum) and 543 nm (minimum) were taken and the difference in absorption was plotted against the concentration of a surfactant in reference to the method used for the determination of CMC values for *N*-acyl-DL-cysteines.[7]

Results and Discussion

The catalytic efficiency of the surfactants in the deacylation of *p*-nitrophenyl carboxylates has been investigated by the kinetic method in 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C and μ 0.10 (KCl). Apparent pseudo-first-order rate constants (k_{obsd}) were obtained by measuring the amount of liberated *p*-nitrophenol. The first-order kinetics was found to hold at least up to 80% conversion of the substrate for [C]≫[S]; C and S stand for catalyst and substrate species, respectively. Figure 1 shows the rate-concentration profile for the deacylation of *p*-nitrophenyl dodecanoate (PNPL) catalyzed by AM·Cys-1 and -2 at pH 9.3; k_1 refers to $k_{obsd}-k_{hyd}$. The apparent first-order rate constant (k_1) increases as the surfactant concentration is raised up to a certain concentration range which may be referred to the critical micelle concentration. The kinetic CMC values agree reasonably well with the corresponding values determined by the dye method as seen in Table 1. Beyond these concentration ranges, the k_1 values were nearly leveled off for both surfactant systems. The straight line portions below

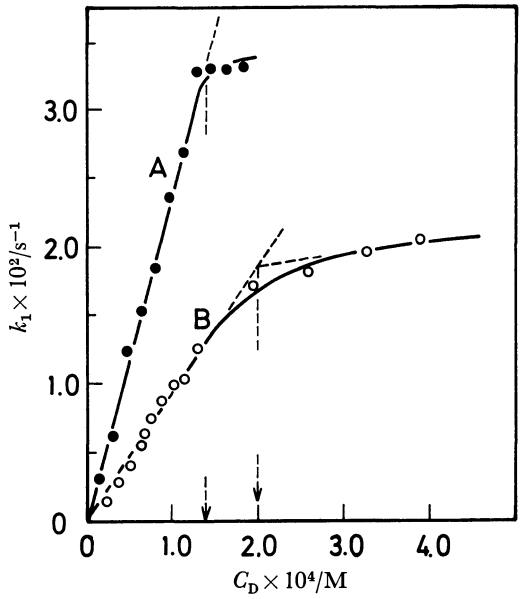


Fig. 1. Plots of first-order rate constant *vs.* surfactant concentration (C_D) for the deacylation of *p*-nitrophenyl dodecanoate in 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C, pH 9.3, and μ 0.10 (KCl): $k_1=k_{obsd}-k_{hyd}$; initial concentration of PNPL, 0.984×10^{-5} M; A, AM·Cys-1; B, AM·Cys-2. The rate was not measured for the AM·Cys-1 system beyond this concentration range due to its limited solubility.

Table 1. Critical micelle concentrations for AM·Cys-1 and -2

Surfactant	CMC×10⁴/M	
	Dye method	Kinetic method
AM·Cys-1	3.76[a)]	1.33[b)]
AM·Cys-2	1.40[c)]	2.00[d)]

a) In 15.6%(v/v) aqueous ethanol at 30.0±0.1 °C, pH 9.30, and μ 0.10 (KCl). b) In 15.6%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C, pH 9.28, and μ 0.10 (KCl); initial concentration of PNPL, 0.984×10^{-5} M. c) In 11.5%(v/v) aqueous ethanol at 30.0±0.1 °C, pH 9.30, and μ 0.10 (KCl). d) In 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C, pH 9.30, and μ 0.10 (KCl); initial concentration of PNPL, 0.984×10^{-5} M. All the concentrations throughout this paper are given in M; 1 M=1 mol dm^{-3}.

Table 2. Kinetic parameters for the catalyzed deacylation of *p*-nitrophenyl dodecanoate and acetate[a)]

Catalyst RSH	[RSH]×10⁵ / M	pK_a^{app}	pH	k_2/M⁻¹ s⁻¹ PNPL	k_2/M⁻¹ s⁻¹ PNPA
AM·Cys-1	9.82(<CMC)	10.5[c)]; 10.5[d)]	9.28	4180	0

	9830			0.012	—
OH^-[f)]				1.11	24.4

a) In 10.8% (v/v) ethanol–1.0% (v/v) dioxane–water at 30.0±0.1 °C and μ 0.10 (KCl). Initial concentrations: PNPL, 0.984×10⁻⁵ M; PNPA, 0.989×10⁻⁵ M. The relative rate (k_{obsd}/k_{hyd}) in the presence of AM·Cys(Bzl)-1 (39.9×10⁻⁵ M > CMC) is 0.48 at pH 11.13. b) In 10.8% (v/v) aqueous dioxane at 40.0±0.1 °C and μ 0.10 (KCl). c) Determined by the kinetic method (Eq. 3) as a dissociation constant for a mercapto group. d) Determined by the photometric titration as a dissociation constant for a mercapto group. e) Cited from literature: J. W. Ogilvie, J. T. Tildon, and B. S. Strauch, *Biochemistry*, **3**, 754 (1964). f) Alkaline hydrolysis.

CMC are referred to the apparent second-order kinetics with rate constant k_{2b} as catalyzed by the monomeric surfactants in the bulk phase, whereas those above CMC are due to the apparent second-order kinetics with rate constant k_{2m} as catalyzed by the micellar surfactants. The leveling-off behavior suggests that the micelle formation results in the loss of thiol-reactivity for the present surfactants.

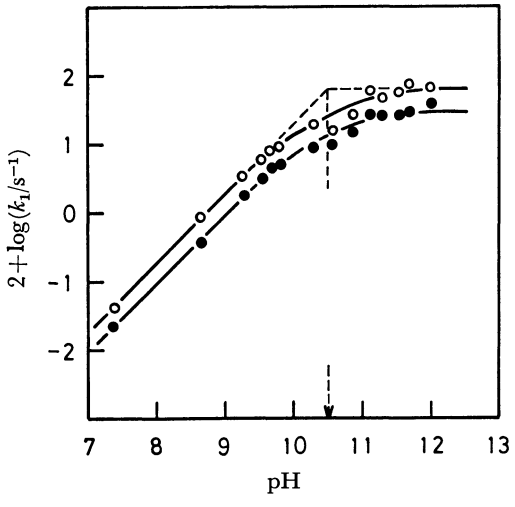

Fig. 2. pH-rate profiles for the deacylation of *p*-nitrophenyl dodecanoate as catalyzed by AM·Cys-1 above (○) and below (●) its CMC in 10.8% (v/v) ethanol–1.0% (v/v) dioxane–water at 30.0±0.1 °C and μ 0.10 (KCl). Initial concentrations: AM·Cys-1, 8.20×10⁻⁵ M (<CMC) and 1.63×10⁻⁴ M (>CMC); PNPL, 0.984×10⁻⁵ M.

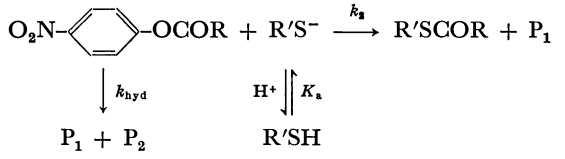
The pH-rate profiles for the decomposition of *p*-nitrophenyl dodecanoate (PNPL) as catalyzed by AM·Cys-1 below and above its CMC are shown in Fig. 2. A plot of log k_1 against pH exhibited a straight line of slope 1.0 below pH 10.5, and log k_1 is leveled off beyond this pH. The behavior indicates that the active group of the surfactant for the degradation of PNPL is the thiolate anion. The apparent pK_a value evaluated from Fig. 2 agrees satisfactorily with that determined by the photometric titration as seen in Table 2. The pH-rate profile for the surfactant-catalyzed degradation of PNPL above its CMC is almost identical with that observed below CMC. The result again indicates that the reactivity of AM·Cys-1 above its CMC is primarily due to the monomeric species. The similar behavior was observed for AM·Cys-2.

Reactivity of the Mercapto Group Below CMC's. The initial rapid release of *p*-nitrophenol from PNPL was followed by the slow process at pH 9.28 for [S]>[C]. The absorbance increase due to *p*-nitrophenol at 400 nm in the slow rate region is almost identical with that observed in the absence of the surfactants. The result indicates that the deacylation of the thiol ester yielded by the reaction between PNPL and surfactants can not proceed to any detectable extent under present conditions. Thus, the net reaction pathway below CMC is given by Scheme 2, where P_1 and P_2 stand for phenol and carboxylic moieties, respectively; k_2 refers to the true second-order rate constant for the acylation step and k_{hyd} to the rate constant for the alkaline hydrolysis of PNPL.



Scheme 2.

The true second-order rate constant for the below-CMC region was determined by the aid of Eq. 3, where k_2' is the apparent second-order rate constant at a given pH; $k_2'=k_1/[R'SH]_T$. A plot of $1/k_2'$ against $[H^+]$ is shown in Fig. 3 for the PNPL–AM·Cys-1 system.

$$\frac{1}{k_2'} = \frac{1}{k_2} + \frac{[H^+]}{k_2 K_a^{app}} \quad (3)$$

The k_2 values thus obtained are summarized in Table 2. The reactivity of the thiolate anion of the surfactants

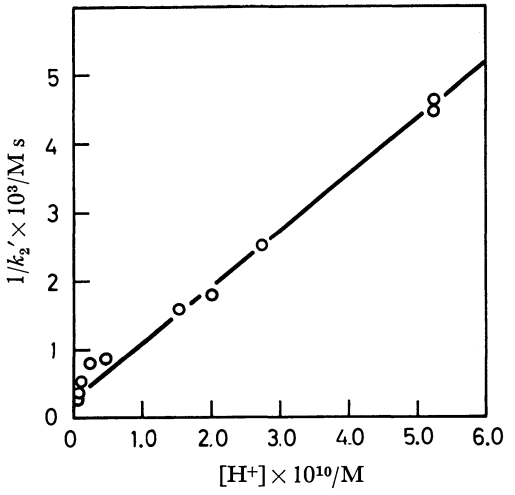


Fig. 3. A plot of $1/k_2'$ *vs.* $[H^+]$ for the deacylation of *p*-nitrophenyl dodecanoate as catalyzed by AM·Cys-1 in 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C and μ 0.10 (KCl). Initial concentrations: AM·Cys-1, 8.20×10^{-5} M; PNPL, 0.984×10^{-5} M.

on a carboxylic ester which bears a long alkyl chain (PNPL) in the aqueous phase is remarkably larger than that of the hydroxide ion as seen in Table 2, but not so on PNPA. The result also indicates that the catalytic activity of AM·Cys-1 in the decomposition of *p*-nitrophenyl dodecanoate is greater than that of AM·Cys-2 by 3.3 fold. A carboxylate anion as the surfactant-head would destabilize the anionic tetrahedral intermediate formed from the thiolate anion and the substrate in a manner as observed for the paracyclophane catalysis.[9] Therefore, the distance between the carboxyl group and the mercapto group in the surfactant molecules must control the reactivity toward ester substrates. The difference in reactivity between AM·Cys-1 and -2 would be attributed to the greater hydrophobic interaction of the former with PNPL.

N-Hexadecyl-N^{α}-glutaryl-*S*-benzyl-L-cysteinamide [AM·Cys(Bzl)-1], in which the mercapto group is protected with a benzyl group, did not show any meaningful effect on the hydrolysis of PNPL below its CMC. On the other hand, AM·Cys(Bzl)-1 retarded the alkaline hydrolysis above its CMC. The result indicates that the anionic micelle may incorporate PNPL into its hydrophobic core and the ester bond of PNPL is masked from the hydroxide attack. Anionic micelles of sodium dodecanoate were found to behave similarly for the hydrolysis of several *p*-nitrophenyl esters as reported recently by Menger *et al.*[10] Thiol catalysts bearing a long alkyl chain such as AM·Cys-1, -2, and 1-dodecanethiol (C_{12}-SH) show catalytic activity in the decomposition of PNPL, but smaller thiols such as glutathione (GSH) and 2-mercaptoethanol give out little catalytic activity (Table 2). These smaller thiols, however, catalyzed the decomposition of *p*-nitrophenyl acetate (PNPA) by using them in a large amount. AM·Cys-1, -2, and C_{12}-SH were not used in higher concentrations for the reaction with PNPA because of their limited solubility. As we clarified previously,[11] the reactivity of monomeric esters decreases with increasing the alkyl chain length due to their self-coiling behavior so as to mask the ester bond from the hydroxide attack. Thus, the hydrophobic interaction between the catalyst and the substrate may cause not only the access of both reactants (proximity effect) but also the decoiling of the alkyl chain of PNPL.

Both AM·Cys-1 and -2 showed a marked catalytic activity in the deacylation of PNPL at pH 9.30 below

Table 3. Relative catalytic activity of AM·Cys-1 and -2 for the deacylation of *p*-nitrophenyl carboxylates[a]

Substrate R[b]	pH 9.30			pH 12.00		
	$k_{hyd} \times 10^5$/s^{-1}	k_{rel}[c] AM·Cys-1	k_{rel}[c] AM·Cys-2	$k_{hyd} \times 10^4$/s^{-1}	k_{rel}[c] AM·Cys-1	k_{rel}[c] AM·Cys-2
CH_3–	72.2	1	1			
$CH_3(CH_2)_4$–	32.0	9.8	4.4	587	3.0	1.9
$CH_3(CH_2)_8$–	5.23	575	199	65.7	43.8	19.9
$CH_3(CH_2)_{10}$–	1.82	1509	441	8.08	267	138

a) In 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C and μ 0.10 (KCl). Initial concentrations: substrate, $0.984—1.00 \times 10^{-5}$ M; AM·Cys-1 and -2, 7.90×10^{-5} M. b) R for *p*-$NO_2C_6H_4OC(O)$R. c) $k_{rel} = k_{obsd}/k_{hyd}$: k_{obsd}, apparent first-order rate constant; k_{hyd}, hydrolysis rate constant in the absence of a catalyst.

their CMC's. These surfactants catalyzed not only the deacylation of *p*-nitrophenyl carboxylates bearing a long alkyl chain but also that of *p*-nitrophenyl esters of cyclohexane derivatives and *N*-benzyloxycarbonylglutarate as shown in Table 3. The present thiol catalysts exercise a significant activity toward hydrophobic substrates in their deacylation and the profound efficiency is observed selectively in the decomposition of esters bearing a longer alkyl chain.

Table 4. Effects of metal ions in the surfactant-catalyzed deacylation of *p*-nitrophenyl dodecanoate[a)]

Metal ion/M	$V_0 \times 10^8$/M s^{-1} [b)]	
	AM·Cys-1	AM·Cys-2
None	10.9	8.27

1.01×10^{-4}	10.9	8.27

a) In 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C, pH 9.27, and μ 0.10 (KCl). Initial concentrations: AM·Cys-1, 3.33×10^{-4} M; AM·Cys-2, 3.92×10^{-4} M; PNPL, 0.984×10^{-5} M. All the metal ions were used as nitrates. b) V_0 stands for the initial velocity of reaction.

Effects of Metal Ions on the Catalysis. It is expected that an appropriate metal ion would show somewhat a unique effect on the reactivity of surfactants which involve effective donor groups. The metal ions used here (Cu^{2+}, Zn^{2+}, and Mg^{2+}) did not give out any effect on the alkaline hydrolysis of PNPL, while the surfactant-catalyzed deacylation of the ester was markedly retarded by Cu^{2+} and Zn^{2+} as shown in Table 4. Such a behavior of the synthetic surfactants bears a resemblance to those of thiol proteases. Thiol proteases such as papain are extremely sensitive to the presence of heavy metal ions, and metal ions of groups IB and IIB such as Cu^{2+}, Zn^{2+}, and Hg^{2+} cause reversible inhibition of the enzyme catalysis. The inhibition seems to occur through formation of the thiolate complexes. Since the thiolate anion is one of the soft bases, the hard acid (Mg^{2+}) does not form the corresponding complex and consequently show no effect on the surfactant-catalyzed reaction.

Evaluation of True pK_a *Values for the Mercapto Group in Micellar Phase.* In order to clarify the reason why the catalytic activity of the surfactants markedly decreases above CMC for the deacylation of *p*-nitrophenyl esters, we evaluated true pK_a values for the mercapto group in micellar phase from the pK_a-concentration profiles. The pK_a- and *n*-values determined by Eq. 2 were plotted against the concentration of the surfactants as shown in Fig. 4. The pK_a-value of each surfactant increases as the concentration increases

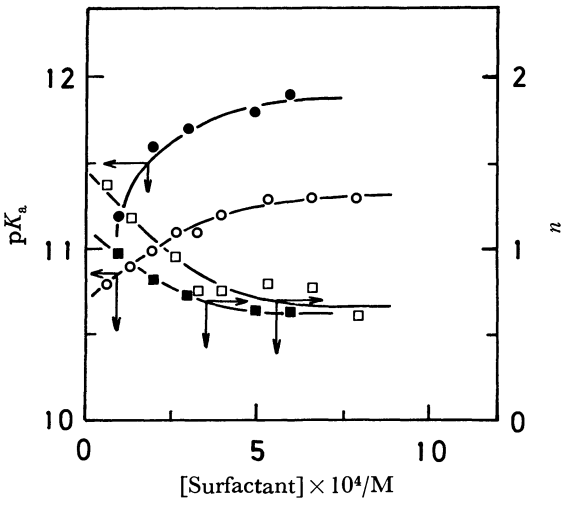

Fig. 4. Plots of pK_a- and *n*-values against concentration of the anionic surfactants. pK_a- and *n*-values were evaluated by the modified Henderson-Hasselbalch equation. For AM·Cys-1: ○, pK_a; □, *n*. For AM·Cys-2: ●, pK_a; ■, *n*.

to a certain extent which is considered to be the true pK_a in micellar phase: AM·Cys-1, 11.3; AM·Cys-2, 11.9. These values are larger than those for the corresponding monomeric surfactants. On the other hand, the *n*-value of each surfactant decreases as the surfactant concentration increases and levels off beyond a certain range: AM·Cys-1, 0.58; AM·Cys-2, 0.56. pK_a-Values are generally affected by electrostatic and hydrophobic fields. The result suggests that the electrostatic field effect overcomes the hydrophobic effect for the present surfactant systems since the evaluated pK_a-value for AM·Cys-2 is larger than that for AM·Cys-1 by 0.6 pK_a unit. The α-values for AM·Cys-1 and -2 are 3.57×10^{-4} and 2.30×10^{-5}, respectively, at pH 9.30. As a whole, the diminished reactivity observed for the micellar systems of AM·Cys-1 and -2 is primarily attributed to the decrease in pK_a of the mercapto group. The modified Henderson-Hasselbalch equation was applied to a micellar system of hexadecyl(imidazolylmethyl)-dimethylammonium chloride and a low *n*-value (0.8) was obtained.[12)]

Effects of CTAB Micelle on the Catalysis. The rate constant (k_{obsd}) for the deacylation of PNPL was measured in several micellar systems. Sodium dodecyl sulfate and α-hydro-ω-dodecyloxytricosa(oxyethylene) did not appreciably alter the rate relative to that for the alkaline hydrolysis, while a greater rate was observed in the presence of CTAB. Figure 5 shows the rate-concentration profiles for the decomposition of PNPA and *p*-nitrophenyl hexanoate (PNPH) as catalyzed by mixed CTAB–AM·Cys-1 micelle. A pronounced catalytic effect was observed with the mixed micelle and the profile is typical for the micellar catalysis. The reaction pathway for the decomposition of *p*-nitrophenyl esters as catalyzed by the mixed micelle is given by Scheme 3, where S stands for an ester substrate (PNPA or PNPH), CM for the mixed micelle formed with CTAB and a thiol surfactant, CM·S for a complex formed with the mixed micelle and a substrate, and P

Table 5. Kinetic parameters for the deacylation of *p*-nitrophenyl dodecanoate and acetate catalyzed by mixed micelles[a)]

Catalyst	[Catalyst]/[CTAB]	PNPH			PNPA		
		$k_m \times 10^2$ / s^{-1}	K_b / M^{-1}	k_m/k_{hyd}	$k_m \times 10^2$ / s^{-1}	K_b / M^{-1}	k_m/k_{hyd}
AM·Cys-1	1/20	4.41	885	3080	4.75	33.3	3320
AM·Cys-2	1/16	1.95	599	1360	0.874	71.4	611
	1/20	1.59	633	1110	0.526	117	368
C_{12}-SH	1/20	0.168	667	117	0.557	15.5	390

a) In 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C, pH 7.60, and μ 0.10 (KCl). Apparent first-order rate constants for the hydrolyses of PNPH and PNPA in the absence of the mixed micelles are 1.43×10^{-5} s^{-1} at pH 7.60.

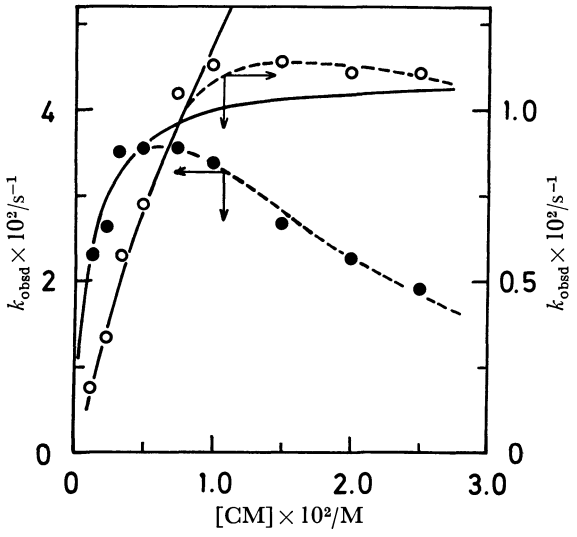

Fig. 5. Rate-concentration profiles for the deacylation of *p*-nitrophenyl hexanoate (●) and acetate (○) as catalyzed by CTAB–AM·Cys-1 mixed micelle in 10.8 %(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0± 0.1 °C, pH 7.63, and μ 0.10 (KCl). Initial concentrations: PNPA, 0.989×10^{-5} M; PNPH, 0.983×10^{-5} M. [CM]=[CTAB]+[AM·Cys-1]; [AM·Cys-1]/[CTAB] =1/20. Solid lines are the theoretical curves calculated by Eq. 5. The maximum rate constants for the hydrolysis of PNPA and PNPH in the CTAB micelle (0.125—2.50×10^{-2} M) are 3.75×10^{-5} and 2.73×10^{-5} s^{-1}, respectively, under the same kinetic conditions.

and P′ for reaction products; k_{hyd} and k_m refer to rate constants for product formation in the bulk phase and in the mixed micelle, respectively; K_b represents a binding constant for formation of the micelle-substrate complex.

$$\mathrm{CM} + \mathrm{S} \overset{K_b}{\rightleftharpoons} \mathrm{CM{\cdot}S} \overset{k_m}{\longrightarrow} \mathrm{P}$$
$$\Big\downarrow k_{hyd}$$
$$\mathrm{P'}$$

Scheme 3.

Under the present experimental conditions the reaction in the micellar phase resulted in the formation of the acylated micelle and any further reaction was not detected. For [CTAB]>CMC and [CTAB]>[Thiol surfactant]≫[Substrate], the pseudo-first-order rate constant (k_{obsd}) is given by Eq. 4[13] on the basis of Scheme 3.

$$k_{obsd} = \frac{k_{hyd} + k_m K_b[\mathrm{CM}]}{1 + K_b[\mathrm{CM}]} \quad (4)$$

Rearrangement gives Eq. 5.

$$\frac{1}{k_{obsd} - k_{hyd}} = \frac{1}{k_m - k_{hyd}} + \frac{1}{(k_m - k_{hyd})K_b[\mathrm{CM}]} \quad (5)$$

where [CM] refers to the sum of the initial concentrations of CTAB and a thiol surfactant. A plot of $1/(k_{obsd}-k_{hyd})$ *vs.* 1/[CM] allows to evaluate k_m and K_b. The kinetic parameters thus evaluated are summarized in Table 5 for the reactions catalyzed by mixed micelles; CTAB–AM·Cys-1, CTAB–AM·Cys-2, and CTAB–C_{12}-SH.

The binding constant (K_b) for the mixed micelles with PNPA changes depending upon the nature of the thiol surfactants, whereas K_b is constant with PNPH regardless of the surfactants. This seems to suggest that PNPH is incorporated into the hydrophobic core of the mixed micelles while PNPA into the hydrophilic Stern layer. The value of k_m stands for the acyl transfer from the substrates to the mercapto group of the thiol surfactants, and the hydrolysis rate (k_{CM}^{OH}) for the esters with the concentrated hydroxide ion in the Stern layer of the mixed micelles** is negligibly small relative to the acyl transfer rate for a neutral pH region. The most effective micellar catalyst was constructed with AM·Cys-1 and CTAB and the k_m value for the deacylation of PNPH is 3080 times as large as the corresponding k_{hyd} value as shown in Table 5. Some plausible explanations for the difference in reactivity among the mercapto groups of AM·Cys-1, -2, and C_{12}-SH placed in micellar CTAB are as follows.

(1) If the pK_a value for the mercapto group of AM·Cys-1 in micellar CTAB decreases more than those for AM·Cys-2 and C_{12}-SH in micellar CTAB, the difference in catalytic activity is attributed to variation in concentration of the active thiolate anion. This may not be the case since the mercapto group of AM·Cys-1 must be located in a more hydrophobic region than those of AM·Cys-2 and C_{12}-SH. In other words, the mercapto groups of AM·Cys-2 and C_{12}-SH are most likely

** The k_{CM}^{OH} values were evaluated from the hydrolysis of *p*-nitrophenyl carboxylates as catalyzed by micellar CTAB under the same conditions.

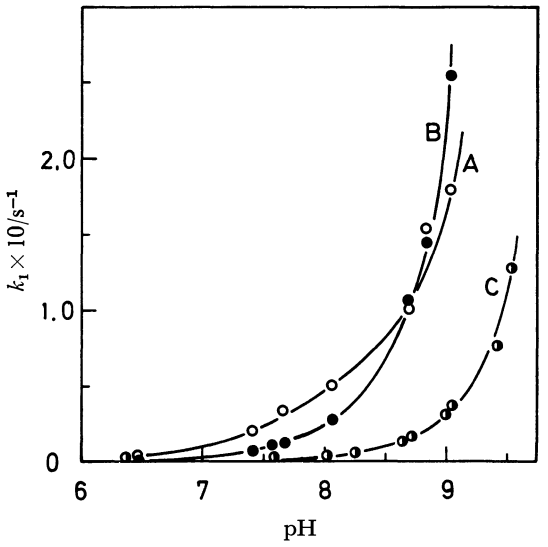

Fig. 6. pH-Rate profiles for the deacylation of PNPH as catalyzed by CTAB–AM·Cys-1 (A), CTAB–AM·Cys-2 (B), and CTAB–C_{12}-SH (C) mixed micelles in 10.8%(v/v) ethanol–1.0%(v/v) dioxane–water at 30.0±0.1 °C and μ 0.10 (KCl): $k_1=k_{obsd}-k_{CTAB}$; k_{CTAB}, apparent first-order rate constant for the hydrolysis of PNPH as catalyzed by hexadecyltrimethylammonium bromide. Initial concentrations: PNPH, 0.983×10^{-5} M; [CM]=[CTAB]+[Thiol surfactant], 0.50×10^{-2} M; [Thiol surfactant]/[CTAB]=1/20.

placed in the cationic Stern layer and, therefore, the pK_a values for these mercapto groups are expected to decrease more than that for the mercapto group of AM·Cys-1 in micellar CTAB. Figure 6 shows the pH-rate profiles for the deacylation of PNPH as catalyzed by the mixed micelles. These profiles indicate that the pK_a value for each thiol surfactant in the mixed micelle decreases by 1—2 pK_a unit relative to that for each surfactant monomer, and the greater reactivity of the thiol surfactants in mixed micelles is partly due to the pK_a effect. The pK_a value for AM·Cys-1 is almost comparable to that for AM·Cys-2 and *smaller than that for C_{12}-SH.*

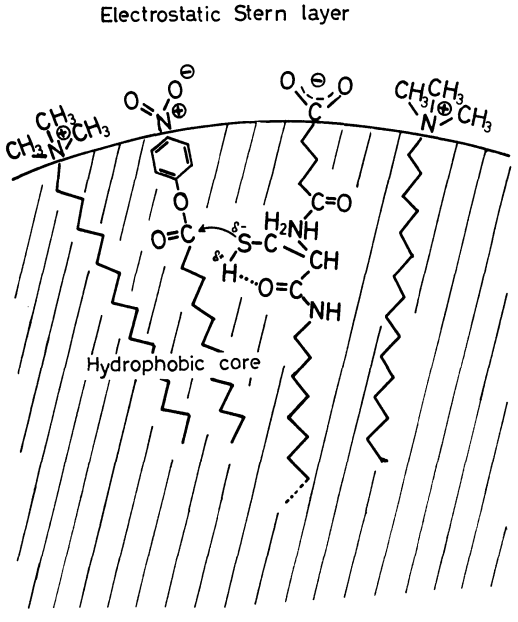

Fig. 7. Schematic representation of a plausible reaction mechanism for the deacylation of PNPH by CTAB–AM·Cys-1.

(2) The orientation of the ester bond of PNPH would be so arranged that an attack of the mercapto group on it is facilitated in the hydrophobic core.

(3) The intramolecular hydrogen bonding between the thiol and peptide-carbonyl groups as shown in Fig. 7 for the AM·Cys-1–CTAB system would enhance the nucleophilicity of the mercapto group in the effective hydrophobic core. Such development of a negative charge on the sulfur atom of the mercapto group in the hydrophobic core would be facilitated by the electrostatic field effect provided by the cationic micelle head in the transition state of acylation. Meanwhile, the mercapto groups of AM·Cys-2 and C_{12}-SH in the mixed micelle would not form an effective hydrogen bond since these may be placed in the more hydrophilic region. The reaction mechanism is analogous to that for papain catalysis proposed by Lowe[14] in which the nucleophilicity of a catalytic mercapto group is enhanced by its hydrogen bonding with an imidazolyl group.

Conclusion. The reactivity of mercapto groups drastically changes upon variation of their micro-environment. An electrostatic field provided by the Stern layer of an anionic micelle tends to increase pK_a of a mercapto group placed in such a micelle, so that the mercapto group is masked to reduce its reactivity in a neutral pH region against an ester substrate. However, pK_a of a mercapto group decreases when it is placed in a cationic micelle due to the effective electrostatic field effect provided by cationic heads. Furthermore, the nucleophilicity of the mercapto group placed in a hydrophobic core is enhanced by the intramolecular hydrogen bonding (Fig. 7) as well as by the electrostatic field effect transmitted into the hydrophobic core. These effects were demonstrated here with the mixed micelle composed of CTAB and AM·Cys-1 for the deacylation of ester substrates. The present results suggest that there are two kinds of mercapto groups; masked and super-reactive ones depending on their micro-environment and should be noted in connection with enzyme catalysis. In order to make a mercapto group more active in the hydrophobic region of micelles, it is required to introduce the second functional group at the juxtaposition of the mercapto group so that its nucleophilicity is much enhanced.

^{11}B-NMR Study of the Complex Formation of Borate with Catechol and L-Dopa

Kazuo YOSHINO,* Masahiro KOTAKA, Makoto OKAMOTO, and Hidetake KAKIHANA

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 30, 1979)

In the solution of catechol and borax at pH 11, the equilibria between catechol and the monomeric borate anion to form the 1:1 and 2:1 (catechol: boron) anionic complexes have been demonstrated by the existence of ^{11}B-NMR signals for the two complexes and the monomeric borate anion. In the solution of L-dopa and borax at pH 11, however, the signal for the 2:1 anionic complex was not observed, though it was observed below pH 7. By the ^{11}B-NMR spectra at pH 6.5, the complex formation constants, log K_1 and log K_2, have been estimated as 3.9 and 4.4 for catechol, and as 4.3 and 5.0 for L-dopa, respectively.

The neutron-capture therapy requires a boron-10-containing compound which concentrates selectively in cancer tissue and does not in normal tissue in order to collect boron-10 selectively in the malignant tumor.[1-3] L-Dopa is one of the precursors of melanine, which is produced in a great quantity in malignant melanoma. Planning to carry the boron-10 into melanoma using L-dopa as a carrier, the compound "dopaborate," which has one boron atom per molecule, has been synthesized. The present authors have investigated the structure and reactivety of this compound in an aqueous solution by means of the UV spectroscopic method.[4] It was thus recognized that the solution of "dopaborate" was just the same as that of a mixture of 1:1 L-dopa and boric acid at about pH 8.5, and in an aqueous solution the catechol site of L-dopa coordinates to the monomeric borate anion.

In the equilibrium system of catechol and the monomeric borate anion, the equlibria may be represented by the following equations (Equilibria 1—3). The equilibrium constants for these equilibria can be represented by Eq. 6—8. Since catechol itself is an acid, the acidic strength of which is comparable to that of boric acid, its dissociation reactions must also be taken into consideration (Equilibria 4 and 5).

$$B(OH)_3 + H_2O \overset{K_a}{\rightleftharpoons} B(OH)_4^- + H^+ \quad (1)$$
(BH) (B$^-$)

$$B(OH)_4^- + \text{(C) } \mathbf{1} \overset{K_1}{\rightleftharpoons} \text{(BC}^-\text{) } \mathbf{2} + 2H_2O \quad (2)$$

$$B(OH)_4^- + 2\,\text{(C) } \mathbf{1} \overset{K_2}{\rightleftharpoons} \text{(BC}_2^-\text{) } \mathbf{3} + 4H_2O \quad (3)$$

$$\text{(C) } \mathbf{1} \rightleftharpoons \text{(C}^-\text{)} + H^+ \quad (4)$$

$$\text{(C}^-\text{)} \rightleftharpoons \text{(C}^{2-}\text{)} + H^+ \quad (5)$$

$$K_a = [B^-][H^+]/[BH] \quad (6)$$

$$K_1 = [BC^-]/[B^-][C] \quad (7)$$

$$K_2 = [BC_2^-]/[B^-][C]^2 \quad (8)$$

Two methods have been developed to identify the equilibrium system of catechol and the monomeric borate anion. One is the potentiometric method,[5-8] and the other is the UV spectroscopic method.[9] In the case of potentiometry, the evidence concerning the complex formation is largely indirect. In the case of the UV method, though, since the absorption spectrum of the catechol–borate complex, (**2** or **3**), is different from that of catechol (**1**), the method offers direct evidence concerning the complex formation; however, since the absorption spectrum of the 1:1 catechol–borate complex (**2**) seems to be the same as that of the 2:1 catechol–borate complex (**3**), this method does not give directly the concentrations of the two complexes.

In many equilibrium systems of diol and the monomeric borate anion, ^{11}B-NMR spectroscopy demonstrated that the 2:1 complex has a chemical shift different from that of the 1:1 complex, and the ^{11}B-NMR spectra give the concentrations of the each boron species directly, which makes it possible to calculate the equilibrium constants.[10,11] Therefore, we have used ^{11}B-NMR spectroscopy in order to elucidate the nature of the equilibria of the catechol–borate and L-dopa–borate systems.

Experimental

Preparation of Solutions for ^{11}B-NMR Studies. Twice-distilled deionized water was used throughout the experiments. Dissolving the weighed amount of borax into water, a weighed amount of L-dopa (or catechol) was slowly added to the solution. Thereby the pH of the solution was kept higher than 8 by adding sodium hydroxide. After the L-dopa (or catechol) had been completely dissolved, the pH of the solution was adjusted to the required value with sodium hydroxide or hydrochloric acid, and the solution was diluted with water to 50 ml. These preparations were carried out in an N_2 atmosphere, because both L-dopa and catechol are oxidized by atmospheric oxygen, especially in an alkaline solution. The 2—4 ml aliquots were put into 8 mmϕ NMR quartz probes and sealed in an N_2 atmosphere to avoid oxidation; these probes were then placed into 10 mmϕ quartz probes which had D_2O as a lock.

^{11}B-NMR Measurements. The FT-NMR spectrometer used was JEOL FX-100. The operation were performed at

Table 1. ^{11}B-NMR spectroscopic data

The total concentration of boron is 0.5 mol dm^{-3}, except in the cases marked with *, which are 0.25 mol dm^{-3}. σ_n, the downfield chemical shift (in ppm) from sodium tetrafluoroborate; the width at half-height ($W_{0.5}$) is shown in brackets in Hz in cases where the values were obtained. A_n, the relative area of the signal at σ_n as % of the total area of the signals. In cases where the signals overlapped, the relative areas of the signals were obtained by computer simulation.[16]

31.96 MHz. The probe temperature was about 27 °C. The number of pulses (the repetition time is 1.0 s) was 100 except in the case of the 0.25 mol dm^{-3} boron concentration in which 400 pulses were needed. The solution of sodium tetrafluoroborate was used as an external reference.

Results and Discussion

The experimental conditions and the obtained data are summarized in Table 1.

A borax solution has only one ^{11}B-NMR signal in all the pH region, but the chemical shift of this signal changes from 20.6 ppm (pH 6.5) to 3.1 ppm (pH 12) with the increase in pH; these values are assigned to boric acid and the monomeric borate anion respectively.[10,12] The appearance of only one signal in the pH region in which both monomeric species exist indicates that Equilibrium 1 is rapidly interconverting.[10] Therefore, if any other boron species does not exist in this pH region, the chemical shift of the signal may be ascribed to the relative concentration of boric acid and the borate anion, and the line-width (the width at the half height) of the signal would be intermediate between those of the monomeric species. Figure 1 shows the ^{11}B-NMR spectra of the solution of borax at pH 7, 9, and 11. The boron concentration of each solution was 0.5 mol dm^{-3}. The signal at pH 11 is assigned to the almost monomeric borate anion. Since the signal at pH 7 has a shoulder peak, and since the line-width of the signal at pH 9 is broader than that of the signal at pH 7 and 11, there may be polyborates.[13,14]

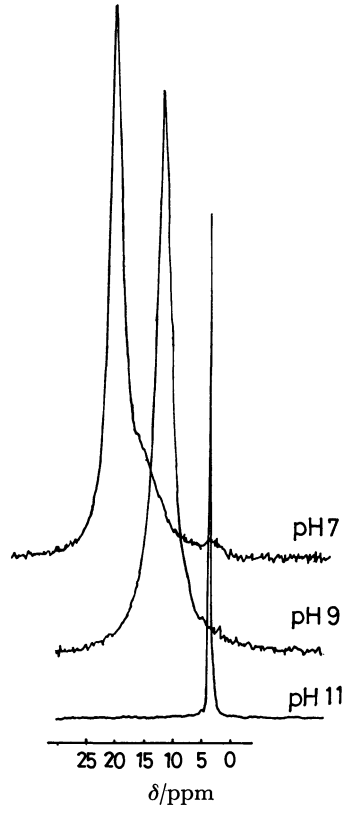

Fig. 1. ^{11}B-NMR spectra of borax solutions at pH 7, 9, and 11. The boron concentration of the solutions is 0.5 M (1 M=1 mol dm^{-3}). The reference signal of sodium tetrafluoroborate at δ 0.0 is not shown.

^{11}B-NMR Spectroscopic Examination at pH *11.*

The spectra of catechol–borax solutions (pH 11) at several molar ratios are illustrated in Fig. 2. The signal at 3.4 ppm corresponds exactly to that of the monomeric borate anion. The change in the signal intensity with the increase in the catechol concentration (the boron concentration is kept at 0.5 mol dm^{-3}) demonstrates that the low-field signals at 9.0 and 14.5 ppm can be assigned to the 1:1 (**1**) and 2:1 (**2**) complexes respectively. The line-width of the 1:1 catechol–borate complex has nearly the same value (27 Hz) in the spectra of three different molar ratios of catechol–boron.

Figure 3 shows the spectra of L-dopa–borax solutions (pH 11) at several molar ratios. The signal at 9.0 ppm,

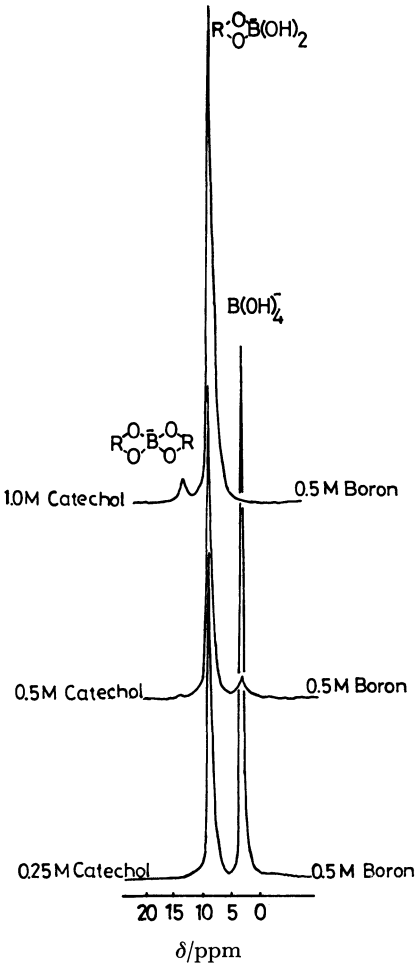

Fig. 2. ^{11}B-NMR spectra of catechol–borax solutions at 2: 1, 1: 1, and 0.5: 1 molar ratios of catechol and boron. In the solutions, the initial concentration of boron is 0.5 M (1 M=1 mol dm^{-3}) and pH is 11. The reference signal of sodium tetrafluoroborate at δ 0.0 is not shown.

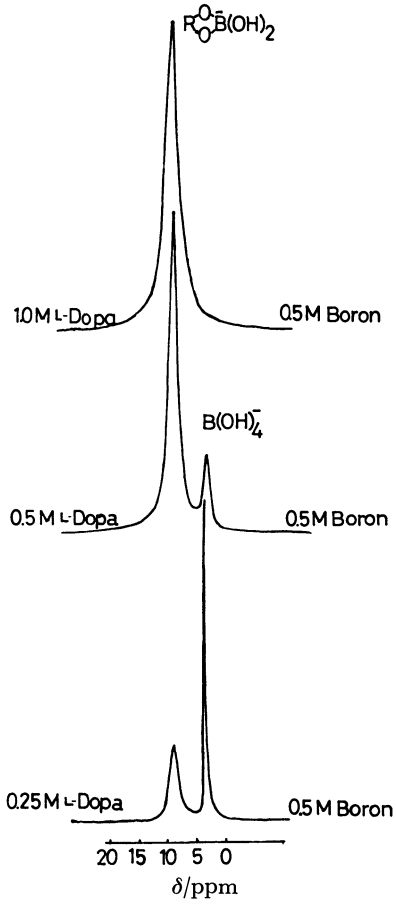

Fig. 3. ^{11}B-NMR spectra of L-dopa–borax solutions at 2: 1, 1: 1, and 0.5: 1 molar ratios of L-dopa and boron. In the solutions, the initial concentration of boron is kept 0.5 M (1 M=1 mol dm^{-3}) and pH is 11. The reference signal of sodium tetrafluoroborate at δ 0.0 is not shown.

which seems to be that of the 1: 1 L-dopa–borate complex, is not so sharp as that of catechol–borate complex, and the broadening of this signal with the increase in the molar ratio of L-dopa–boron is remarkable (the boron concentration is kept at 0.5 mol dm^{-3}). The signal of the 2: 1 L-dopa–borate complex could not be observed separately, not even in the L-dopa–borax solution with a L-dopa–boron ratio of 2: 1.

^{11}B-NMR Spectroscopic Examination for the 1: 1 L-Dopa–Boron Solution at Various pH *Values.* Figures 4 and 5 show the obtained spectra of the 1: 1 L-dopa–boron solutions at pH 12—pH 6.5. The boron concentration is kept at 0.5 mol dm^{-3}, except in the case with pH 6.5, in which the concentration is 0.25 mol dm^{-3}. In the case of pH 12—pH 9, the signal of the monomeric borate anion became smaller and at last disappeared at pH 10 with a decrease in the pH. There may be two reasons for this. One of these is that, in the dissociation equilibria in the catechol part of L-dopa, the amount of un-ionized dihydroxy species, which may coordinate with the monomeric borate anion, increases with the decrease in pH and the formation of the 1: 1 L-dopa–borate complex proceeds; as a result, the monomeric borate anion decreases by the corresponding amount. The other possible reason may be explained as follows. With a decrease in the pH, some monomeric borate anions become boric acid or polyborate anions, as was mentioned above, and the signals of these species overlap with that of the 1: 1 complex. The latter explanation is proved by the change in the line-width for the signal at 9.1 ppm. It becomes larger with a decrease in the pH. The constant chemical shift (9.1 ppm) in this pH region, however, makes it clear that most of the boron species is the 1: 1 L-dopa–borate complex. Figure 5 shows that, at pH 7, two signals (at 19.8 and 14.5 ppm) appear in addition to the signal of the 1: 1 complex. These signals are more clearly observed at pH 6.5. The signals at 19.8 (pH 7) and 20.4 (pH 6.5) ppm are ascribed to the free boron species, as is shown in Fig. 1, and that at 14.5 ppm, to the 2: 1 L-dopa–borate complex. The latter assignment is made by comparing this signal with that of the 2: 1 catechol–borate complex at 14.5 ppm, which was observed in Fig. 2. These assignments are also confirmed by a comparison of these spectra with the spectrum of the 1: 1 catechol–boron solution at pH 6.5, which is shown

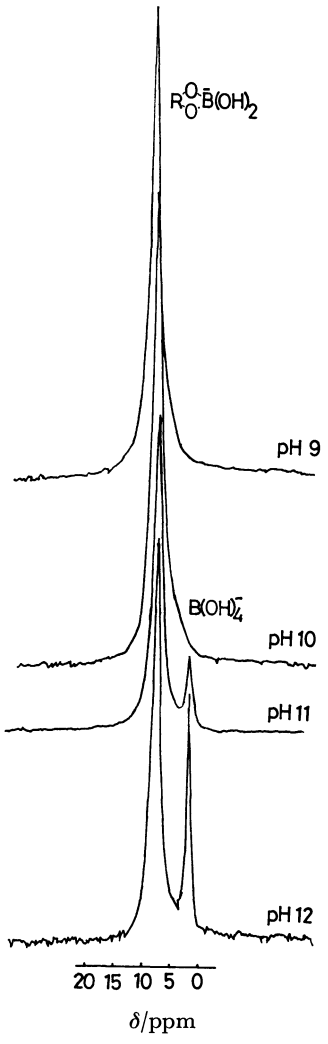

Fig. 4. ^{11}B-NMR spectra of L-dopa–borax solutions at pH 12—pH 9. In the solutions, the ratio of L-dopa and boron is kept 1: 1, and the initial concentration of boron is kept 0.5 M (1 M=1 mol dm^{-3}). The reference signal of sodium tetrafluoroborate at δ 0.0 is not shown.

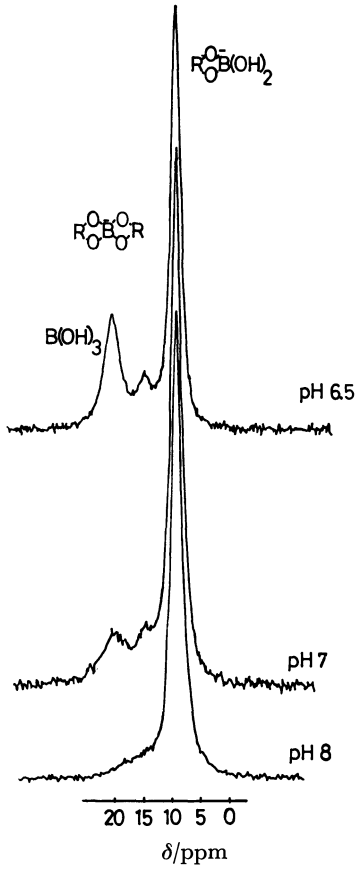

Fig. 5. ^{11}B-NMR spectra of L-dopa–borax solutions at pH 8—pH 6.5. In the solutions, the ratio of L-dopa and boron is kept 1: 1, and the initial concentration of boron is 0.5 M (1 M=1 mol dm^{-3}) except in the case at pH 6.5 in which 0.25 M. The reference signal of sodium tetrafluoroborate at δ 0.0 is not shown.

in Fig. 6 (the boron concentration is 0.25 mol dm^{-3}). The appearance of the 2: 1 L-dopa–borate complex might be explained as follows. As has been mentioned in the introduction, the complex formations may occur between the monomeric borate anion and the un-ionized catechol part of L-dopa. Therefore, under the present experimental conditions, in spite of the same initial concentrations of L-dopa and boron, the concentration of the monomeric borate anion is far less than that of the un-ionized catechol type of L-dopa. Therefore, the equilibrium not only for 1: 1 but also for 2: 1 L-dopa–borate complex formation is shifted to the right.

The Estimation of the Equilibrium Constants for the 1: 1 and 2: 1 Complex Formations. In the case of the catechol–borate complex formation, the equilibria which seem to take place in this experiment have already been summarized in Equilibria 1—5. In the case of L-dopa–borate complex formation, however, the equilibria are much more complicated, because L-dopa has an amino group, the acidic strength of which seems

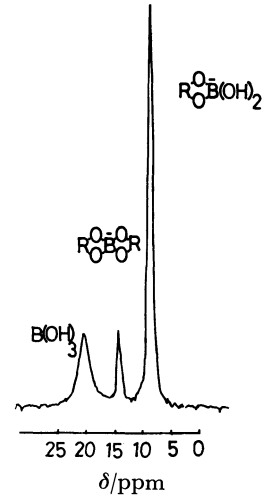

Fig. 6. ^{11}B-NMR spectrum of catechol–borax solution at pH 6.5. The ratio of catechol and boron is 1: 1, and the initial concentration of boron is 0.25 M (1 M =1 mol dm^{-3}). The reference signal of sodium tetrafluoroborate at δ 0.0 is not shown.

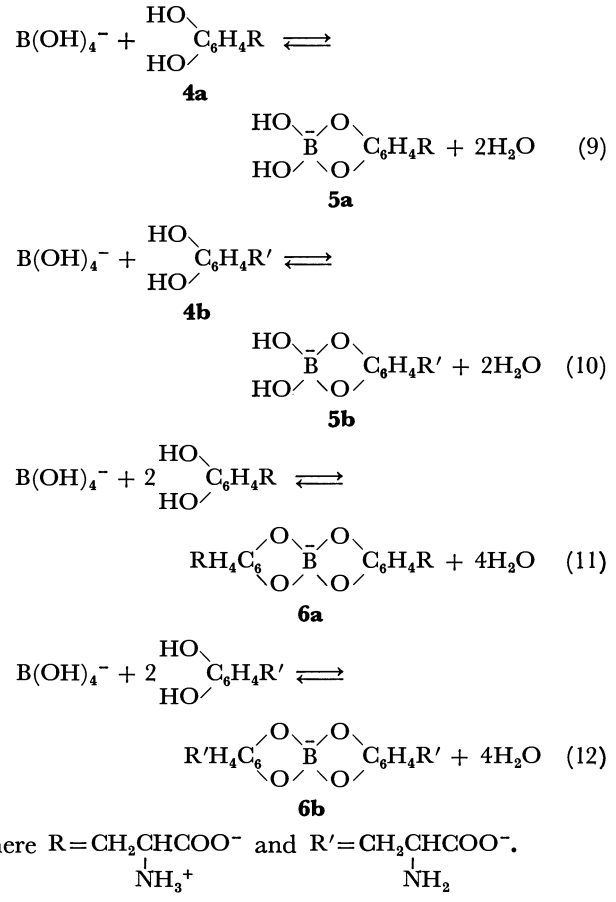
to be comparable to that of catechol or boric acid. Therefore, L-dopa has many dissociation equilibria

which must be taken into consideration; the equilibria for L-dopa–borate complex formation may be represented as follows in the experimental pH region:



where R=CH_2CHCOO^- (NH_3^+) and R′=CH_2CHCOO^- (NH_2).

In order to estimate the equilibrium constants by using the ^{11}B-NMR spectra, the concentrations of the monomeric borate anion ($B(OH)_4^-$) and un-ionized dihydroxy catechol (**1**) or un-ionized dihydroxy L-dopa (**4a**) and (**4b**) should be obtained. At pH 11, the free boron species is regarded as almost entirely the monomeric borate anion, and its concentration is calculated directly from the signal area of the ^{11}B-NMR spectra. However, the concentration of (**1**) cannot be obtained without using the dissociation constants of Equilibria 4 and 5, and the concentrations of (**4a**) and (**4b**) are hard to obtain, because the dissociation constants of L-dopa, which are needed to calculate the concentrations of (**4a**) and (**4b**), have not yet been determined. On the other hand, at pH 6.5, since free catechol and free L-dopa are regarded as (**1**) and (**4a**) respectively, these concentrations can be obtained from the ^{11}B-NMR spectra and the ionization constant of boric acid (K_a).

Calculation of Equilibrium Constants. *Catechol*: The three signal areas of the ^{11}B-NMR spectrum at pH 6.5 correspond to $[BC^-]$, $[BC_2^-]$, and $[B]+[B^-]$ respectively. The combination of these concentrations with the following equations gives the concentrations of all the species:

$$[B]_0 = [BH] + [B^-] + [BC^-] + [BC_2^-]$$
$$[C]_0 = [C] + [BC^-] + 2[BC_2^-]$$
$$K_a = [B^-][H^+]/[BH]$$

where $[B]_0$ is the initial concentration of boron and $[C]_0$ is the initial concentration of catechol. 9.00 was used for log K_a.[15]

L-*Dopa*: The method is the same as that used in the case of catechol, but in this case [C], $[BC^-]$, and $[BC_2^-]$ correspond to the concentrations of (**4a**), (**5a**), and (**6a**) respectively, and $[C]_0$ is the initial concentration of L-dopa.

Table 2. Comparison of equilibrium constants (K_1 and K_2) calculated from this ^{11}B-NMR study for catechol and L-dopa with the values obtained from other methods

Diol	Method	Temp	log K_1	log K_2	Remarks
Catechol	pH-Change[8]	25 °C	3.97	4.26	
	UV[9]		4.3	—	pH 7.8
	^{11}B-NMR	27 °C	3.9	4.4	pH 6.5
L-Dopa	pH-Change		—	—	
	UV[9]		4.2	—	pH 7.8
	^{11}B-NMR	27 °C	4.3	5.0	pH 6.5

The values thus obtained, log K_1 and log K_2, are shown in Table 2, along with the values of the other methods. The values obtained for catechol are consistent with the values obtained by potentiometry. Among the results obtained, it is found for the first time that the 2:1 L-dopa–borate complex is formed between L-dopa and the monomeric borate anion.

The authors wish to thank Professor Atsuo Nishioka and Dr. Isao Ando of the Tokyo Institute of Technology for their helpful discussion, and also JEOL for measuring the ^{11}B-NMR spectra.

p-Styrenesulfinic Acid and Its Polymer as Reactants

Hiroyoshi KAMOGAWA,* Hideaki INOUE, Hiromoto FUKUYAMA, and Masato NANASAWA

Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu, Yamanashi 400

(Received March 15, 1979)

The free-radical aqueous polymerizations of *p*-styrenesulfinates (Na, K, NH_4, $NHEt_3$-salts) provided water-soluble polymers with high molecular weights at low conversions. The polymers contained 62—84% of the sulfinate unit and indicated half-oxidation potentials ranging from 340 to 415 mV. The nucleophilic reactions of the sodium polysulfinate [poly(sulfinic acid)] prepared from cross-linked polystyrene are highly dependent upon the swelling nature of the solvent. The reactions consisting of (A) simple displacements with activated halomethyl groups, (B) reductive additions to quinonoid compounds such as TCNQ and alizarin, and (C) displacements of the activated aromatic nitro groups, *e.g.*, of 2,4,7-trinitrofluorenone have been investigated and the results compared with those of *p*-toluene and *p*-styrenesulfinates. The effect of the solvent on the reaction rate is in the order: DMSO>DMF> HMPA.

Arenesulfinic acids and their salts are of chemical interest since they are mild reductants and take the role of nucleophiles in many reactions.

From the standpoint of obtaining a novel and usefuel polymer reagent, *p*-styrenesulfinic acid and its salts have been synthesized and it has been shown that polymers of high-molecular weights are formed.[1)]

This paper summarizes the results of the investigations conducted on the redox properties of the pendant polymers synthesized from *p*-styrenesulfinates by free-radical polymerizations as well as the nucleophilic reactions of the *p*-styrenesulfinate (sulfinic acid) polymers prepared from polystyrene by means of polymer reactions, together with those of *p*-toluenesulfinate and *p*-styrenesulfinates (sulfinic acids).

The following nucleophilic reactions were examined:

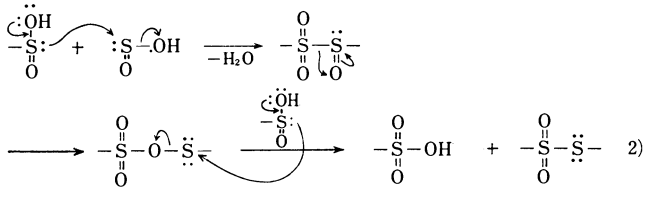
a) Aqueous solution with 10% monomer and 0.1% KPS. 70 °C×24 h. b) In water at 30 °C. c) By oxidative titration with bromine–water. d) Half-oxidation potential against a saturated calomel electrode at 20 °C.

Results and Discussion

The free-radical polymerizations of four *p*-styrenesulfinates as listed in Table 1 proceeded smoothly to afford water-soluble polymers of high molecular weights. The conversions were however rather low and the sulfinate contents in the polymers were reduced by possible side reactions:



The low conversion data listed in Table 1 appear to be caused by the reductive actions of the sulfinates which lead to the disappearances of growing radicals as well as the physical loss of polymers into precipitants.

The values of $[\eta]$ are, nevertheless, high, a characteristic of the aqueous polymerizations of ionic vinyl monomers.

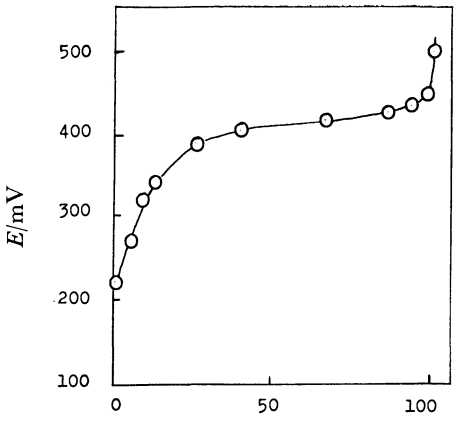


Fig. 1. Typical oxidative titration curve for sulfinate polymers. Sodium poly *p*-styrenesulfinate in aqueous solution (4×10^{-3} mol dm^{-3}) was titrated with aqueous bromine (0.0435 mol dm^{-3}) at 20 °C. *E*, oxidation potential against sat. calomel electrode.

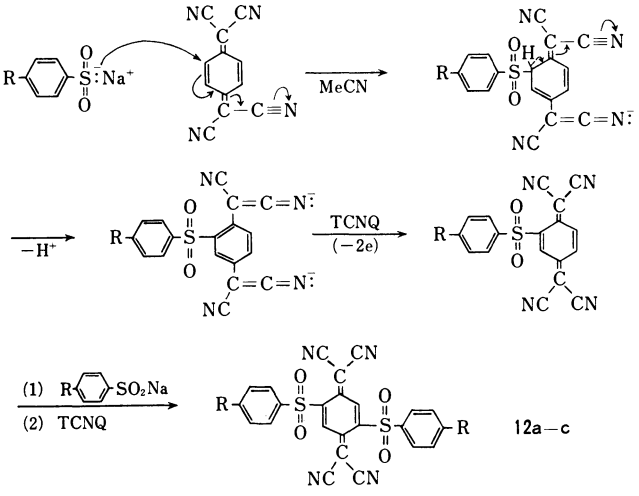
The half-oxidation potential (E_0) for each sulfinate ranges from 340 to 410 mV and is comparable with that (375 mV) for hydroquinone under the same titration conditions, indicating that these polymers are weak reductants. Figure 1 illustrates a typical oxidative titration curve for a sulfinate polymer.

The nucleophilic reactions of the sulfinate polymers and their low-molecular weight homologs investigated have been classified into three categories.

Simple Displacements (Reactions 1, 2, 3, and 7). Reactions 1, 2, and 3 are quite simple nucleophilic reactions, in which the sulfinate anions attack the activated halomethyl groups with the elimination of sodium halides. Satisfactory yields are attained for **1a** and **1b** at room temperature in dipolar aprotic solvents such as DMSO, DMF, and HMPA. In polymer **1c**, on the other hand, which was prepared from a porous crosslinked polystyrene, the swelling ability of the solvent plays a decisive role in determining the extent of reaction. Thus, in Reaction 1 conducted for 72 h at room temperature with a large excess of **2**, the **3c**-contents were 92.7, 79.7, and 31.7% in DMSO, DMF, and HMPA, respectively (on the basis of the initial **1c** unit). DMSO, the most favorable swelling solvent for polymer **1c**, provided the best results throughout the reactions. Reaction 7 with chloranil (**15**) appears to be somewhat complicated due to possible inactivation of the sulfinates and **15** as a result of oxidation to the sulfonates and reduction to tetrachlorohydroquinone, respectively. The extent of side reaction, however, appears to be small and does not appreciably affect the yield of **16c**.

Reductive Additions to Quinonoids (Reactions 4, 5, and 6). The nucleophilic addition reaction of sulfinic acid to *p*-benzoquinone[3] was applied to polysulfinic acid (**8**) in ethanol–water (1:1) to afford a 91 mol% addition of the hydroquinone unit (Reaction 4). Similarly, the reaction of oxidized alizarin with sulfinate[4] was applied to the polymer **1c** and gave satisfactory extents of Reaction 6.

The reactions of **1a** *and* **1b** *with TCNQ* (**11**) *in* acetonitrile giving the disubstituted products **12a** and **12b** which were analytically pure (Reaction 5) appears to proceed as follows:



The reaction of polymer **1c** with TCNQ also appears to take place in a similar manner.

Displacement of Aromatic Nitro Groups (Reactions 8, 9, and 10). The displacement reactions of aromatic nitro groups with arenesulfinate[5] were applied to **1a**—**c**. Thus, *o*-nitrobenzonitrile (**17**) possessing an activated nitro group reacted with polymer **1c** in DMSO at room temperature (Reaction 8). In the reactions of **1a** and **1b** with TNF (**19**) (Reaction 9), only single monosubstituted products (**20a** and **20b**) were isolated, indicating that the most activated 7-nitro group of **19** was predominantly replaced. The effect of the solvent on the extent of reaction for polymer **1c** (70 °C, 12 h) was also in the order: DMSO >DMF >HMPA. As anticipated, the reaction of **1c** with tetranitrofluorenone (**21**) was easier than that with TNF, but a product of unidentified structure was obtained.

The results indicate that the nucleophilic reactions of **1a**—**c** are generally very easy and provide satisfactory yields of products, sometimes with apparent selectivity.

The polymerization behavior of the styrenesulfonyl derivatives synthesized here has also been examined. The results so far obtained, however, indicate the predominance of polymer reactions.

Experimental

The IR, ^{1}H-NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively, all under standard measurement conditions. Elemental analyses were conducted using a Perkin-Elmer 250 instrument.

p-Styrenesulfinates. *p*-Styrenesulfinic acid, synthesized as in a previous paper,[1] was neutralized in aqueous or *t*-butyl alcoholic solutions with equimolar sodium hydroxide, potassium hydroxide, ammonia, and triethylamine and the resulting solutions freeze-dried to isolate the respective salts.

Polymerization of p-Styrenesulfinates. A solution of the monomer (0.5 g) and potassium persulfate (KPS, 0.005 g) in water (5 ml) was placed in a glass ampoule, which was evacuated twice by a standard freeze-thaw method, sealed, and maintained at 70 °C for 24 h. The viscous solutions were precipitated into appropriate precipitants (Table 1) to afford the polymers.

Preparation of Sodium Polystyrenesulfinate (1c) from Crosslinked Polystyrene. To a suspension of crosslinked polystyrene beads (1.2 g; 10 mmol; Aldrich Macroporous) in chloroform (50 ml) was added dropwise chlorosulfuric acid (8 ml; 100 mmol) and the mixture refluxed overnight. The brown reaction mixture was filtered and washed with chloroform, acetonitrile, and finally with cold water to leave white beads. The weight increase and IR data [disappearance of the absorption peaks at 680 and 740 cm^{-1} attributable to the monosubstituted styrene and appearance of a strong 820 cm^{-1} peak (*p*-disubstitution)] indicated that reaction was practically quantitative.

Poly(*p*-styrenesulfonyl chloride) thus prepared (2.0 g, 10 mmol) was converted to sodium poly(*p*-styrenesulfinate) (**1c**) by stirring in a solution of sodium sulfite (13 g, 100 ml) in water (50 ml) at 50—60 °C for 24 h. The **1c**-polymer was filtered and washed with water thoroughly to leave light brown beads (2.0 g). Iodometry on the sample stirred in excess aqueous bromine at room temperature overnight provided 90.9% of the sulfinate unit on the basis of available reaction sites.

Oxidative Titration. Oxidative titrations of the soluble sulfinate polymers were conducted in aqueous solutions with bromine (0.05 mol dm^{-3}) potentiometrically (electrodes: Pt–sat. calomel at 20 °C). Figure 1 illustrates a typical titration curve.

Reaction 1. As a typical example, 4-(vinylbenzylsulfonyl)styrene (**3b**) was prepared as follows: a solution of sodium *p*-styrenesulfinate (1.0 g, 5 mmol; **1b**) and vinylbenzyl chloride (1.0 g, 7 mmol; **2**, Seibi Chem. Co., *m*/*p*=60/40) in DMF (30 ml) was stirred at room temperature overnight. The reaction mixture was poured into water and the resulting precipitates were filtered and recrystallized from benzene–hexane to afford colorless crystals (mp 162—165 °C) in 26% yield. Found: C, 71.15; H, 5.59%. Calcd for $C_{17}H_{16}O_2S$: C, 70.82; H, 5.67%. IR (KBr): 3100—3000 (aryl), 3000—2920 (alkyl), 1310, 1150 (SO_2), 990, 910 (vinyl) cm^{-1}. NMR ($CDCl_3$) δ 4.4 (s, 2H, CH_2), 5.0—6.2 (m, 4H, 2×(-CH=C$\underline{H}_2$)), 6.7 (m, 2H, 2×(-C$\underline{H}$=CH_2)), 7.1—7.8 (m, 8H, ArH) ppm. Mass (*m*/*e*): 284 (M^+, 1.5), 117 (100).

4-(Vinylbenzylsulfonyl)toluene (**3a**) was synthesized in the same manner to afford colorless crystals (mp 147—148 °C) in 46% yield. Found: C. 70.44; H, 6.02%. Calcd for $C_{16}H_{16}O_2S$: C, 70.56; H, 5.89%. IR (KBr): 3100—3000 (aryl), 2920—2980 (alkyl), 1310, 1150 (SO_2), 990, 910 (vinyl) cm^{-1}. NMR ($CDCl_3$) δ 2.5 (s, 3H, CH_3), 4.4 (s, 2H, CH_2), 5.3 (d, 1H, C$\underline{H}_2$=CH–), 5.8 (d, 1H, C$\underline{H}_2$=CH–), 6.7 (q, 1H, CH_2=C$\underline{H}$–), 7.1—7.8 (m, 8H, ArH) ppm. Mass (*m*/*e*): 273 (M^+, 2.4), 117 (100).

In the case of polystyrenesulfinate (**1c**; 0.1 g), 72 h-reactions at room temperature with a large excess of **2** (1 ml) provided 92.7, 79.7, and 31.7% of **3c**-content in DMSO, DMF, and HMPA (each 10 ml), respectively. These were determined by the remaining $-SO_2Na$ in IR (960 cm^{-1}) on the basis of the initial **1c** unit. IR (KBr) indicated vinyl (1620, 990, 910 cm^{-1}) and SO_2 (1310 cm^{-1}) absorptions.

Reaction 2. **1a** (1.5 g, 7 mmol) was reacted for 15 h with vinyl chloroacetate (**4**, 1.0 g, 8 mmol) in HMPA solution (20 ml) at room temperature. Subsequent purification of the product by extraction with ether–water, washing of the colorless organic layer with aqueous sodium hydrogencarbonate, drying over anhydrous sodium sulfate, removal of the ether, extraction of the residue with petroleum ether, and vacuum drying afforded a colorless viscous oil in 65% yield. Found:

C, 54.83; H, 5.21%. Calcd for $C_{11}H_{12}SO_4$: C, 55.00; H, 5.00%. IR ($CHCl_3$): 1760 (ester); 1640, 940 (vinyl); 1320 (SO_2), 1120 (SO_2) cm^{-1}. NMR ($CDCl_3$) δ 2.5 (s, 3H, CH_3), 4.3 (s, 2H, CH_2), 5.0 (t, 2H, $C\underline{H}_2$=CH–), 7.1—8.6 (m, 5H, CH_2=C<u>H</u>–+ArH) ppm. Mass (*m/e*): 240 (M^+).

In the case of polymer **1c** (0.1 g) using a large excess of **4** (1.0 g) in DMSO (10 ml) at room temperature, the extent of reaction (IR) was 86 mol % over 72 h. IR (KBr) indicated 1760 (ester), 1310 (SO_2), 1120 (SO_2), 990, 950 (vinyl) cm^{-1}.

Reaction 3. 4-(Phenacylsulfonyl)toluene (**8a**; mp 109—110 °C) was synthesized in quantitative yield by allowing a solution of **1a** (1.5 g, 7 mmol) and phenacyl bromide (1.0 g, 5 mmol; **6**) in DMSO (30 ml) to stand for 20 h at room temperature. Subsequent precipitation into water and recrystallization from benzene–petroleum ether gave the product as colorless crystals. Found: C, 65.35; H, 5.26%. Calcd for $C_{15}H_{14}SO_3$: C, 65.69; H, 5.11%. IR (KBr): 3050 (aromatic) 3000—2850 (alkyl), 1660 (C=O), 1580 (aromatic), 1305, 1140 (SO_2) cm^{-1}. NMR ($CDCl_3$) δ 2.5 (s, 3H, CH_3), 4.8 (s, 2H, CH_2), 7.2—8.2 (m, 9H, ArH) ppm. Mass (*m/e*): 274 (M^+).

In the case of polymer **1c** (0.2 g), a large excess of **6** (1.0 g) in DMSO (10 ml) at room temperature gave a quantitative yield in 72 h as determined by IR (960 cm^{-1}). IR (KBr) also indicated 1660 (C=O), 1600 (aromatic), and 1310 (SO_2) cm^{-1} absorptions.

Reaction 4. Crosslinked poly(*p*-styrenesulfinic acid) (0.2 g, **8c**) was stirred in a solution of *p*-benzoquinone (**9**, 1 g) in ethanol–water (30 ml, 1: 1 v/v) for 48 h at room temperature. The brown reaction mixture was filtered and extracted with acetone to afford a brown powder, in which the hydroquinone unit existed in 91 mol %, as determined by both remaining $-SO_2Na$ and weight increase. IR (KBr) indicated absorptions at 1450 (hydroquinone), 1300 (SO_2), and 1200 (hydroquinone) cm^{-1}.

Reaction 5. 7,7,8,8-Tetracyanoquinodimethane (TCNQ, **11**; 1 g, 5 mmol) and **1a** (1 g, 5 mmol) in acetonitrile (50 ml) were refluxed for 8 h. The dark green solution containing a precipitate was poured into aqueous hydrochloric acid and the resulting precipitate extracted with chloroform. The red extract was filtered and evaporated *in vacuo* at 50 °C to give a green powder (**12a**) in 15% yield. Found: C, 61.37; H, 3.63: N, 10.82%. Calcd for $C_{26}H_{16}N_4S_2O_4$: C, 60.82; H, 3.12; N, 10.92%. IR (KBr): 2200 (CN), 1590 (aromatic), 1340, 1140 (SO_2) cm^{-1}. NMR (DMSO-d_6+$CDCl_3$) δ 2.5 (s, 6H, 2 CH_3), 7.2—8.3 (m, 10H, ArH+quinonoid) ppm. Mass (*m/e*): 512 (M^+).

The same procedure was applied for **1b** also to afford the disubstituted product **12b**. Polymer **1c** (0.1 g) and TCNQ (**11**, 0.5 g) in acetonitrile (25 ml) were refluxed for 24 h. The dark green product was extracted with hot acetonitrile. The extent of reaction, as determined by the remaining $-SO_2Na$ in IR and N-analysis, was 48%. IR (KBr) indicated absorptions at 2150 (CN), 1600 (aromatic), 1330 (SO_2) cm^{-1}.

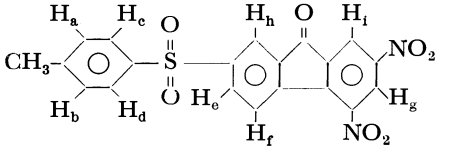
Reaction 6. To a solution of alizarin (**13**, 1 g) in DMSO (25 ml) was added a solution of sodium periodate (0.8 g) in water (5 ml). The mixture was stirred for a short time, then the polymer **1c** (0.2 g) was added. Stirring was continued at 70 °C overnight. The red reaction mixture was filtered and the polymer extracted with acetone to leave an orange powder. Weight increase and the remaining $-SO_2Na$ in IR indicated that the polymer contained 95 mol % of the **14c** unit. IR (KBr) indicated absorptions at 1660, 1630 (quinone), 1430 (phenol), 1340 (SO_2) cm^{-1}.

Reaction 7. A mixture of **1a** (1 g, 5 mmol), chloranil (**15**, 1.2 g, 5 mmol), and DMF (20 ml) was stirred at 50 °C for 15 h. The resulting brown solution containing a white precipitate was poured into water to give a gray powder. Recrystallization form benzene–petroleum ether containing bromine gave a yellow powder (**16a**, mp 140—142 °C) in 52% yield. Found: C, 42.89; H, 1.98%. Calcd for $C_{13}H_7SO_4Cl_3$: C, 42.68; H, 1.92%. IR (KBr): 1690 (quinone), 1580 (aromatic), 1370, 1160 (SO_2), 1100, 900 cm^{-1}. NMR ($CDCl_3$) δ 2.5 (s, 3H, CH_3), 7.0—8.3 (m, 4H, ArH) ppm. Mass (*m/e*): 290 (M^+—74).

Polymer **1c** (0.1 g) was stirred in a solution containing an excess of **15** (0.5 g) in DMSO (20 ml) for 24 h at room temperature. This was followed by filtration and subsequent extraction with acetone which gave a light orange powder. Weight increase and IR indicated that the extent of the reaction was 91% based on the available reaction sites of **1c**. IR (KBr) indicated characteristic absorptions at 1680 (quinone), 1580 (aromatic), 1370, 1180 (SO_2), 1120, 900 cm^{-1}.

Reaction 8. The polymer **1c** (0.1 g) was stirred in a solution of *o*-nitrobenzonitrile (**17**, 1 g) in DMSO (10 ml) for 72 h at room temperature. The reaction mixture was filtered and the polymer extracted with acetone to afford a light brown powder. IR and N-analysis indicated the presence of 43 mol % of the **18c** unit. IR (KBr) indicated 2200 cm^{-1} (CN) absorption.

Reaction 9. A solution of 2,4,7-trinitrofluorenone (**19**; 1 g, 32 mmol) and **1a** (0.57 g, 32 mmol) in DMSO (25 ml) was stirred at room temperature for 12 h. The brown solution was poured into iced hydrochloric acid to afford a white precipitate, which was recrystallized from acetonitrile–water. A yellow powder (**20a**) of mp 220—222 °C was isolated in 52% yield. Found: C, 56.49; H, 2.86; N, 6.78%. Calcd for $C_{20}H_{12}N_2SO_7$: C, 56.60; H, 2.83; N, 6.60%. IR (KBr): 3060 (aromatic), 2960—2840 (CH_3), 1720 (C=O), 1510 (NO_2), 1340, 1150 (SO_2) cm^{-1}. NMR (DMSO-d_6) δ 2.5 (s, 3H, CH_3), 7.5 (d, 2H, H_a, H_b), 8.0 (d, 3H, H_c, H_d, H_f), 8.4 (s, 1H, H_e), 8.7 (s, 2H, H_h, H_i), 8.9 (s, 1H, H_g) ppm. Mass (*m/e*): 424 (M^+, 11), 149 (100).



The same reaction procedure was applied to **1b** to afford a yellow powder (**20b**, mp 200—204 °C) in 44% yield. Found: C, 57.70; H, 2.79; N, 6.75%. Calcd for $C_{21}H_{12}N_2SO_7$: C, 57.80; H, 2.75; N, 6.42%. IR (KBr): 1720 (C=O), 1580 (aromatic), 1520 (NO_2), 1320, 1140 (SO_2), 990, 910 (vinyl) cm^{-1}. NMR (DMSO-d_6) δ 5.5 (d, 1H, $C\underline{H}_2$=CH–) 6.1 (d, 1H, $C\underline{H}_2$=CH–), 6.8 (q, 1H, CH_2=C<u>H</u>–), 7.8 (d, 2H, H_a, H_b), 8.2 (d, 3H, H_c, H_d, H_f), 8.4 (s, 1H, H_e), 8.7 (s, 2H, H_h, H_i), 9.0 (s, 1H, H_g) ppm. Mass (*m/e*): 436 (M^+, 30), 104 (100).

Polymer **1c** (0.1 g) was stirred in a solution of **19** (1 g) in DMSO (25 ml) at 70 °C for 12 h. The yellow-brown reaction mixture was filtered and the polymer extracted first with acetone, then with acetone–water (1: 1), and finally with acetone. A light yellow powder containing 77% of the **20c** unit, as determined by the remaining $-SO_2Na$ and N-analysis, was obtained. Reactions for 72 h at room temperature in DMSO, DMF, and HMPA provided 77.0, 57.8, and 35.0% extents of reaction, respectively. IR (KBr) indicated characteristic absorptions at 1730 (C=O), 1600 (aromatic), 1530 (NO_2), 1340 (SO_2) cm^{-1}.

Reaction 10. Polymer **1c** (0.2 g) was stirred in a solution of 2,4,5,7-tetranitrofluorenone (**21**, 1 g) in DMSO (25 ml) for 72 h at room temperature. The green reaction mixture was filtered and the polymer extracted first with acetone, then

with acetone–water (1: 1), and finally with acetone. A brown powder with the extent of reaction of 83 mol %, as determined by $-SO_2Na$ in IR, was obtained. IR indicated that the reaction proceeded *via* the formation of the SO_2 linkage (1350 cm^{-1}), but the number of replaced nitro groups in **21** was not established.

Characteristic absorptions in IR (KBr) were located at 1740 (C=O), 1600 (aromatic), 1540 (NO_2), 1350 (SO_2) cm^{-1}.

Photochemical Reaction at 3-*O*-Functional Group of Methyl 4,6-*O*-Cyclohexylidene-2-deoxy-2-methoxycarbonylamino-α-D-glucopyranoside Derivatives

Teruo KISHI, Tsutomu TSUCHIYA,* and Sumio UMEZAWA
Institute of Bio-organic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

(Received March 19, 1979)

3-*O*-Acetyl, 3-*O*-thiocarbonyl, and 3-*O*-sulfonyl derivatives of the titled compound have been irradiated in aqueous HMPT. Conversion of the 3-*O*-acetyl derivative to the corresponding 3-deoxy compound was most effective. 3-*O*-Dimethylthiocarbamoyl-, 3-*O*-(methylthio)thiocarbonyl- and 3-*O*-(1-imidazolyl)thiocarbonyl derivatives were found to give the 3-deoxy compound accompanied by 3-hydroxy compound, whereas the 3-*O*-phenyl(thiocarbonyl) derivative did not give the 3-deoxy compound. 3-*O*-Methylsulfonyl and 3-*O*-tolylsulfonyl derivatives gave the 3-hydroxy compound. Under low-energy irradiation, the (1-imidazolyl)thiocarbonyl derivative gave the 3-deoxy compound in moderate yield.

Deoxygenation of the hydroxyl group at C-3 of sugars and its application to aminoglycoside antibiotics[1] are of current interest, due to the marked activities of 3′-deoxy derivatives such as 3′-deoxykanamycin A,[2] 3′,4′-dideoxykanamycin B,[3] and 3′-deoxybutirosins[4] against resistant bacteria. In α-D-glucopyranosides, however, deoxygenation at C-3 is difficult[5] since the S_N2 process at this position is hindered in the majority of cases. Barton *et al.*[6] recently solved this problem by treating *O*-thiocarbonyl derivatives with tributylstannane and have synthesized the corresponding deoxy compounds in good yields. Pete *et al.*[7] succeeded in deoxygenation of the position by acetylating the 3-hydroxyl group followed by irradiation of the solution of the *O*-acetyl derivative in aqueous hexamethylphosphoric triamide (HMPT). Horton *et al.*[8] prepared the 2- and 3-deoxy sugars by irradiation of the methanol solution of 2- and 3-*O*-dimethylthiocarbamoyl derivatives. The present studies have been undertaken to investigate the photochemical treatment of several 3-*O*-thiocarbonyl and 3-*O*-sulfonyl sugars.

The starting materials, the 3-*O*-thiocarbonyl derivatives of methyl 4,6-*O*-cyclohexylidene-2-deoxy-2-methoxycarbonylamino-α-D-glucopyranoside[10] (**1**), namely, 3-*O*-dimethylthiocarbamoyl (**4**), 3-*O*-[(methylthio)thiocarbonyl] (**5**), 3-*O*-[(1-imidazolyl)thiocarbonyl] (**6**), and 3-*O*-phenyl(thiocarbonyl) (**7**) derivatives were prepared. In addition, the 3-*O*-acetyl derivative (**3**) was prepared.

In order to select the solvent for the photochemical reaction, compound **6**, a model compound, was dissolved in several solvents and each solution irradiated (with 2537 Å lamp) for 1.5 h in the manner described in the experimental. Photochemical reactions conducted in tetrahydrofuran, dioxane, methanol, ethanol, 2-propanol, 1-butanol, acetone, acetonitrile, dimethyl sulfoxide (all including the reactions in neat solvents and aqueous solvents=5: 95), *t*-butyl alcohol, benzene or sulforane gave the starting material (**6**) together with the formation of a slight amount of the 3-hydroxy compound (**1**). The low yield of the 3-deoxy compound (**2**) was found in the reactions in 2-propanol, 1-butanol,

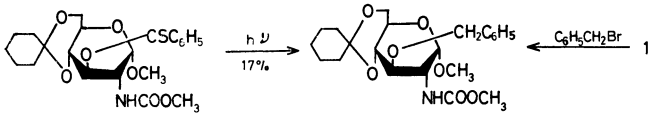
a) The figure 100 indicates that no product other than the starting material (st. m.) was produced. b) A large amount of unidentified product was formed, but the formation of **11** was not observed.

sulforane, and dimethyl sulfoxide (all including the reactions in neat solvents and in aqueous solvents= 5: 95). In the reaction in *N,N*-dimethylformamide and aqueous *N,N*-dimethylformamide (5: 95), **6** was converted to the dimethylthiocarbamoyl derivative (**4**). The reaction mechanism is thought to that **6** reacts with dimethylamine produced from *N,N*-dimethylformamide during the irradiation. **1** and **2** were however formed in trace amounts. The solution of **6** however in aqueous HMPT (5: 95) when irradiated produced the 3-deoxy compound (**2**) in 54% yield.

On the basis of these results **3**—**7** were treated photochemically (2537 Å lamp) in aqueous HMPT, the results of which are summarized in Table 1. The acetyl derivative (**3**) gave the best result, the deoxy compound (**2**) being formed exclusively. In the case of **4**, **2** was formed in good yield, but the reaction required a longer period and the product was contaminated by the 3-hydroxy compound (**1**). In the cases of **5** and **6**, **2** and **1** were formed but in the case of **7** the expected **2** was not formed, the 3-hydroxy compound (**1**) and an unidentifiable product being formed. Interestingly the 3-*O*-benzyl product (**11**) was found to be formed in this reaction. This product was proved by synthesis from **1** and α-bromotoluene.



7 11

Under low-energy irradiation (3000 Å lamp), only the (1-imidazolyl)thiocarbonyl compound (**6**) was converted to the 3-deoxy compound (**2**) in moderate yield, but other compounds except **7** were all stable after 14 h irradiation (Table 1). This demonstrates that low-energy irradiation, only the (1-imidazolyl)-thiocarbonyl group can be removed to give the deoxy compound in the presence of acetyl, dimethylthiocarbamoyl), (methylthio)thiocabonyl, methylsulfonyl, and *p*-tolylsulfonyl groups.

The deoxygenation at C-3 of α-D-glucopyranosides by treatment of the 3-*O*-dimethylsulfamoyl derivatives with sodium metal in liquid ammonia has been reported.[10] The mechanism of photochemical reaction and the reaction with sodium metal are both considered to be radical reactions and consequently the photochemical treatment of the 3-sulfonic esters (**8**—**10**) of **1** in aqueous HMPT (5: 95) were examined. On photochemical treatment of the 3-*O*-dimethylsulfamoyl derivative[10] (**8**), however, no deoxy compound was formed and the starting material was recovered (Table 1). In the cases of the 3-*O*-methylsulfonyl (**9**) and 3-*O*-(*p*-tolylsulfonyl) derivative (**10**), the 3-hydroxy compound (**1**) was formed in good yield. The ready removal of the 3-*O*-tosyl group of **10** offers a facile method for detosylation. Zen *et al.*[11] reported the photochemical detosylation of sugar tosylates in methanol containing sodium methoxide.

Experimental

PMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer. Thin-layer chromatography (TLC) was performed on Wakogel B-5 using a sulfuric acid spray for detection. Silica gel (Wakogel C-200) was used for separation of the products by column chromatography.

General Procedure for Photochemical Reaction. Nitrogen was bubbled through an aqueous HMPT (5: 95, ≈10 ml) solution of the starting material (**3**—**10**, 0.04—0.05 mmol) in a quartz tube (PQV-5 or -7, 13×180 mm) for 10 min. The solution was stoppered, set in a photo-reactor (Rayonet ® RPR 208 Preparative Photochemical Reactor with MGR-100 Merry-Go-Round) and irradiated with a RUL-2537 Å or RUL-3000 Å lamp (in the latter case, a Pyrex RPV-8 tube was used instead of a quartz tube). All apparatus used was manufactured by The Southern New England Ultraviolet Company, England. The speed of reaction was influenced by both the concentration and the volume of the solution in the tube of the starting material.

*Photochemical Reaction of **3** (2537 Å Lamp).* A solution of **3** (55 mg) in aqueous HMPT (30 ml) was divided between three quartz tubes and, after nitrogen was bubbled through the solution, the solution was irradiated at room temperature with a 2537 Å lamp for 1.5 h. The TLC plate was prepared as follows: a small portion of the solution was poured into aqueous ether and, after shaking the mixture vigorously, the separated ethereal solution was spotted with a glass capillary on the plate and developed with benzene–ethyl acetate=5: 1. The solution showed a single spot at R_f 0.38 (**2**) (*cf.* **3**, R_f 0.2). The solution was poured into water (150 ml) and the mixture extracted with ether (150+50 ml). The ethereal solution was washed with water, dried (sodium sulfate), and concentrated. The residue was chromatographed with benzene–ethyl acetate (5: 1) to give a HMPT-free syrup of **2**, which crystallized on standing, 41 mg (88%). Recrystallization from hexane gave granular crystals; mp 118—119 °C, $[\alpha]_D^{25}$ +77° (*c* 1, chloroform); PMR ($CDCl_3$): δ 1.3—2.2 (12H), 3.40 (3H s, CH_3O), 3.72 (3H s, CH_3OCO), 4.60 (1H d, J=3.5 Hz, H-1).

Found: C, 57.28; H, 7.82; N, 4.28%. Calcd for $C_{15}H_{25}NO_6$: C, 57.13; H, 7.99; N, 4.44%.

Decyclohexylidenation of **2** as previously described[10] gave methyl 2,3-dideoxy-2-methoxycarbonylamino-α-D-glucopyranoside.[10]

*Photochemical Reaction of **6** (2537 Å Lamp).* An aqueous HMPT solution (40 ml) of **6** (73 mg) in four quartz tubes was irradiated for 1.5 h. The standard work-up as described above gave a mixture of products. The mixture showed, on TLC with cyclohexane–ethyl acetate (5: 1), spots of R_f 0.23 (major, **2**), 0.11 (trace, **4**), and ≈0.05 (minor) (*cf.* **6**, R_f 0.05). Separation by column-chromatography with cyclohexane–ethyl acetate (5: 1) as eluent gave **2** (28 mg, 54%) and **4** (3.2 mg, 5%). Further elution with ethyl acetate gave **1** (9.1 mg, 17%).

*Photochemical Reaction of **6** (3000 Å Lamp).* An aqueous HMPT solution (40 ml) of **6** (41 mg) in four Pyrex tubes was irradiated with a 3000 Å lamp for 4 h. The standard work-up gave **2** (14.7 mg, 51%), **4** (2.9 mg, 8%), and **1** (7.9 mg, 26%).

*Photochemical Reaction of **7** (2537 Å Lamp).* A solution of **7** (183 mg) in aqueous HMPT (90 ml) was irradiated for 3 h. The solution was poured into water (500 ml) and the mixture extracted with ethyl acetate (150 ml×2, 50 ml×3). The combined solutions were washed with water, dried (sodium sulfate) and concentrated. The residue was chromatographed on a column of silica gel with cyclohexane–ethyl acetate (5: 1). **7** (12 mg, 7%, R_f 0.46 with benzene–ethyl acetate=5: 1), a mixture of **7** and **11** (6.8 mg), and **11** (29 mg, 17%, R_f 0.33) were eluted in this order. A change of eluent to ethyl acetate gave **1** (43 mg, 32%) and to methanol gave an unidentified product (≈130 mg).

Compound **11** was purified by column chromatography with benzene–ethyl acetate (15: 1) to give colorless powder, $[\alpha]_D^{25}$ +98° (*c* 1, chloroform); IR (KBr): 1735 cm^{-1}; PMR ($CDCl_3$): δ 1.3—2.5 (10H, cyclohexylidene), 3.37 (3H s, C_1OCH_3), 3.71 (3H s, CO_2CH_3); 2H AB q centered at 4.87 (J=12 Hz, $C_6H_5C\underline{H}_2O$), 4.74 (1H d, J=4 Hz, H-1), 4.83 (1H d, J=10 Hz, NH; disappeared on deuteration), 7.40 (5H s, C_6H_5).

Found: C, 62.86; H, 7.29; N, 3.15%. Calcd for $C_{22}H_{31}NO_7$: C, 62.69; H, 7.41; N, 3.32%.

Photochemical Reaction of ***10*** *(2537 Å Lamp).* An aqueous HMPT solution (20 ml) of **10** (41.5 mg) was irradiated for 4 h in the manner described. The solution was poured into water (100 ml) and the mixture extracted with ethyl acetate (100+50 ml). The organic solution was washed with water, dried, and concentrated. The residue was chromatographed with benzene–ethyl acetate (2: 1) to give **1**, 25.7 mg (91%), $[\alpha]_D^{25}$ +78° (*c* 1, chloroform).

*Methyl 3-O-Acetyl-4,6-O-cyclohexylidene-2-deoxy-2-methoxycarbonylamino-α-D-glucopyranoside (**3**).* Prepared from **1** with acetic anhydride in pyridine gave a yield of 76%, $[\alpha]_D^{25}$ +81° (*c* 1, chloroform); UV (ethanol): λ_{max} 203 nm (ε 270); PMR ($CDCl_3$): δ 2.10 (3H, s, Ac), 3.41 (3H s, CH_3O), 3.72 (3H s, CH_3OCO), 4.72 (1H d, J=3.5 Hz, H-1), 5.10 (1H t, J=10 Hz, H-3).

Found: C, 54.72; H, 7.10; N, 3.78%. Calcd for $C_{17}H_{27}NO_8$: C, 54.68; H, 7.29; N, 3.75%.

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-3-O-(dimethylthiocarbamoyl)-2-methoxycarbonylamino-α-D-glucopyranoside (**4**).* To an ice-cold solution of **1** (106 mg) in tetrahydrofuran–HMPT (1: 1, 2 ml), 50% oily sodium hydride (net wt 15 mg) was added and the mixture stirred for 10 min under an atmosphere of nitrogen. Dimethylthiocarbamoyl chloride[12] (59 mg) was added and the mixture stirred for 1 h at room temperature. The reaction mixture was poured into water and the mixture extracted with ethyl acetate. The organic solution was washed with water, dried (sodium sulfate), and concentrated to give a residue. The residue was chromatographed with chloroform–ethyl acetate (10: 1) to give a pale-yellow syrup. The solution of the syrup in hexane was concentrated *in vacuo* to give a solid, 83.3 mg (62%), $[\alpha]_D^{25}$ +32° (*c* 1, chloroform); UV (ethanol): λ_{max} 285 nm (log ε 3.00), 248 (4.18), 203 (3.95); PMR ($CDCl_3$); δ 3.14 (3H s, CH_3N), 3.41 and 3.42 (each 3H s, CH_3N and CH_3O), 3.65 (3H s, CH_3OCO), 4.79 (1H d, J=3.5 Hz, H-1), 5.99 (1H t, J=10 Hz, H-3).

Found: C, 51.65; H, 7.06; N, 6.73; S, 7.69%. Calcd for $C_{18}H_{30}N_2O_7S$: C, 51.66; H, 7.23; N, 6.69; S, 7.66%.

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-2-methoxycarbonylamino-3-O-[(methylthio)thiocarbonyl]-α-D-glucopyranoside (**5**).* To a solution of **1** (365 mg) in tetrahydrofuran (4.0 ml), 50% oily sodium hydride (net wt 55 mg) and imidazole (2 mg) were added and the mixture stirred for 30 min at room temperature. Carbon disulfide (0.50 ml) was added and the reaction mixture stirred for 1 h, then methyl iodide (0.12 ml) was added and stirring continued for further 30 min. After the addition of acetic acid (1.0 ml), the mixture was poured into a mixture of ice–water and chloroform and stirred vigorously. The chloroform solution was successively washed with a 5% potassium hydrogensulfate solution, sodium hydrogencarbonate solution, and water, dried (sodium sulfate) and concentrated. The residue was chromatographed with chloroform–ethyl acetate (5: 1) to give a pale-yellow syrup, which was dissolved in hexane and concentrated to give a solid, 373 mg (80%), $[\alpha]_D^{25}$ +48° (*c* 1, chloroform): UV (ethanol): λ_{max} 281 nm (log ε 4.00), 227 (3.78), 203 (3.85): PMR ($CDCl_3$): δ 2.60 (3H s, CH_3S), 4.77 (1H d, J=3.5 Hz, H-1), 6.15 (1H t, J=9 Hz, H-3).

Found: C, 48.69; H, 6.27; N, 3.23; S, 15.49%. Calcd for $C_{17}H_{27}NO_7S_2$: C, 48.44; H, 6.46; N, 3.32; S, 15.21%.

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-3-O-[(1-imidazolyl)thiocarbonyl]-2-methoxycarbonylamino-α-D-glucopyranoside (**6**).* To a solution of **1** (457 mg, 1.38 mmol) in tetrahydrofuran (5 ml), *N,N'*-thiocarbonyldiimidazole[13] (490 mg, 2.75 mmol) was added and the mixture refluxed for 4.5 h under an atmosphere of nitrogen. After the addition of chloroform (30 ml), the organic solution was washed successively with 5% potassium hydrogensulfate solution, sodium hydrogencarbonate solution, and water, dried (sodium sulfate) and concentrated to give a solid. Recrystallization from benzene–hexane gave needles, 499 mg (82%); mp 172—173 °C, $[\alpha]_D^{25}$ +62° (*c* 1, chloroform); UV (ethanol): λ_{max} 276 nm (log ε 4.08), 219 (3.70), 201 (3.70); PMR ($CDCl_3$): δ 3.46 (3H s, CH_3O), 3.61 (3H s, CH_3OCO), 4.78 (1H d, J=4 Hz, H-1), 5.10 (1H d, J=10 Hz, NH; disappeared on deuteration), 6.00 (1H t, J=10Hz, H-3); 7.09, 7.69, and 8.41 (each 1H s, imidazolyl).

Found: C, 51.95; H, 6.22; N, 9.48; S, 7.37%. Calcd for $C_{19}H_{27}N_3O_7S$: C, 51.69; H, 6.17; N, 9.52; S, 7.26%.

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-2-methoxycarbonylamino-3-O-phenyl(thiocarbonyl)-α-D-glucopyranoside (**7**).* A mixture of carboxymethyl dithiobenzoate[14] (157 mg) and 50% oily sodium hydride (net wt 36 mg) in tetrahydrofuran (20 ml) was stirred at room temperature for 5 min. Imidazole (101 mg) was added and the mixture refluxed for 5 min. Compound **1** (245 mg) dissolved in tetrahydrofuran (3 ml) was added and the mixture refluxed for a further 5 min. The reaction mixture was poured into a mixture of ice–water and chloroform and vigorously stirred. The separated organic layer was treated similarly as described for **5** to give a syrup. Chromatography with chloroform–ethyl acetate (10: 1) gave a pale-yellow solid of **7**, 200 mg (60%). Recrystallization from hexane gave yellow needles; mp 129—131 °C, $[\alpha]_D^{25}$ +48° (*c* 1, chloroform): UV (ethanol): λ_{max} 292 nm (log ε 4.00), 253 (3.90), 217 (3.90), 202 (4.04); PMR ($CDCl_3$): δ 3.48 (3H s), 3.57 (3H s), 4.80 (1H d, J=4 Hz, H-1), 5.15 (1H d, J=8 Hz, NH), 6.35 (1H t, J=9 Hz, H-3), 7.4—8.3 (5H).

Found: C, 58.32; H, 6.35; N, 2.86; S, 6.82%. Calcd for $C_{22}H_{29}NO_7S$: C, 58.52; H, 6.47; N, 3.10; S, 7.10%.

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-3-O-dimethylsulfamoyl-2-methoxycarbonylamino-α-D-glucopyranoside[10] (**8**).* Mp 136—137 °C (recrystallized from hexane), $[\alpha]_D^{25}$ +51° (*c* 1, chloroform).

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-3-O-methylsulfonyl-2-methoxycarbonylamino-α-D-glucopyranoside (**9**).* Prepared in the usual manner from **1** with methanesulfonyl chloride and pyridine; mp 147.5—148.5 °C (hexane), $[\alpha]_D^{25}$ +70° (*c* 1, chloroform); UV (ethanol): λ_{max} 223 nm (ε 160), 200 (200); PMR ($CDCl_3$): δ 3.10 (3H s, Ms), 3.42 (3H s), 3.74 (3H s), 4.66 (1H t, H-3), 4.78 (1H d, H-1).

Found: C, 47.07; H, 6.50; N, 3.43; S, 7.68%. Calcd for $C_{16}H_{27}NO_9S$: C, 46.93; H, 6.65; N, 3.42; S, 7.83%.

*Methyl 4,6-O-Cyclohexylidene-2-deoxy-2-methoxycarbonylamino-3-O-tosyl-α-D-glucopyranoside (**10**).* Prepared in the standard manner from **1** with tosyl chloride and pyridine to give a solid, $[\alpha]_D^{25}$ +44° (*c* 1, chloroform); UV (ethanol): λ_{max} 223 nm (log ε 4.00), 199 (3.88); PMR ($CDCl_3$): δ 2.44 (3H s, CH_3 of Ts), 3.41 (3H s), 3.69 (3H s), 4.72 (1H d, H-1), 4.75 (1H t, H-3).

Found: C, 54.70; H, 6.53; N, 2.67; S, 6.70%. Calcd for $C_{22}H_{31}NO_9S$: C, 54.42; H, 6.44; N, 2.89; S, 6.60%.

*Methyl 3-O-Benzyl-4,6-O-cyclohexylidene-2-deoxy-2-methoxycarbonylamino-α-D-glucopyranoside (**11**).* To a solution of **1** (121 mg) in tetrahydrofuran (3 ml), 50% oily sodium hydride (net wt 17 mg) and imidazole (1 mg) were added and the mixture stirred for 15 min in an ice bath. α-Bromotoluene

(0.065 ml) was added and the mixture stirred at room temperature for 47 h. After the addition of methanol (0.2 ml), the mixture was poured into water containing sodium chloride and the mixture extracted with ethyl acetate. Concentration of the extracts gave a residue which was chromatographed on a column of silica gel with benzene–ethyl acetate (10: 1) to give **11** (59 mg, 38%), which was identical with the product obtained by photochemical reaction of **7** in all respects. Changing the eluent to ethyl acetate gave recovered **1** (48 mg, 40%).

The authors are grateful to Prof. H. Umezawa, Director of the Institute of Microbial Chemistry, for his support and encouragement.

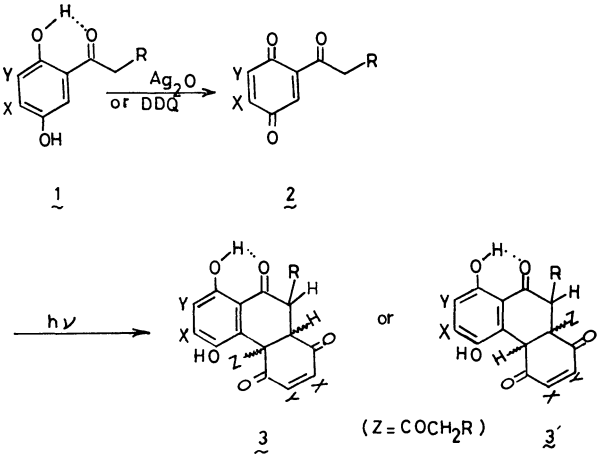
(Received March 28, 1979)

2-Acyl-1,4-benzoquinones and 2-acyl-1,4-naphthoquinones underwent a novel type of regiospecific and stereospecific cyclodimerization by photolysis. The reaction was general, being not affected by any variation in the substituents and solvents. The structure of the dimers was elucidated as 4aα-acyl-10β-alkyl-5,8-dihydroxy-4aα,10aα-dihydro-1,4,9(10*H*)-phenanthrenetriones and dibenzo[*b*,*h*]homologues (**8**). The structure of **8** suggests that the dimerization proceeds through *cis*-ring fusion, disposing two substituents of the dimer (an acyl and an alkyl group) to a *trans* configuration.

Many types of photochemical reactions have been reported for quinones and related compounds.[1] In the absence of other sustrates, 1,4-quinones undergo dimerization to give oxetanes and cyclobutanes. We wish to report here that acyl-1,4-quinones (**2**) suffer a novel and general type of dimerization upon irradiation.[2] For example, when a degassed solution of 2-butanoyl-1,4-benzoquinone (**2c**) in carbon tetrachloride was irradiated with a high-pressure mercury arc lamp in a Pyrex tube, a yellow solid product soon crystallized out, the yield of the product being up to 80% in 15 h. Elemental analysis and mass spectrometric data showed it to be a dimer of **2c**. When benzene was used as the solvent, none of the dimer crystallized out of the reaction solution, but the solution was deeply darkened because of the partial decomposition of the dimer formed. As is shown in Table 1, the reaction proceeded in the same fashion on acylquinones with a wide variety of substituents, and only a single compound was obtained in each case. The solutions of **2** gave no signs of affording such dimers after standing for a fairly long time without light at room temperature.

The isolation and purification of the dimers could not be performed under the same conditions since the dimers decomposed thermally or with a trace amount of water, sometimes even with moisture. Consequently, the yields of the purified dimers were of less constancy. This makes it hard to compare the each yields with others obtained under different conditions. However, there is a discernible tendency for the reaction to be considerably slower for acetylquinones **2** (R=H) than for the other acylquinones **2** (R≠H) (Table 1).

The Skeletal Structure of the Dimers. The structures of the dimers were determined by means of their ^{1}H NMR spectral data, which are listed in Table 2. They



1 2 3 3′

are all consistent either with **3** or **3′** (the usual double-resonance technique was used to determine the identity of protons causing ^{1}H-^{1}H couplings). The spectrum of a dimer of **2g** in $CDCl_3$ is exemplified, illustrated with the atoms denoted in Table 2.

Four methyl signals were observed. Two of them had coupling constants of 7.5 Hz; the triplet at 0.99 and the doublet at 1.29 were assigned to Me_A and Me_B, respectively. Although the triplet suggests the existence of the $COCH_2Me_A$ group, the spectrum lacked a quartet normally expected for a methylene group. Instead, a lot of weak signals were observed at 2.1—2.6. This suggests that the $COCH_2Me_A$ group might be bound to an asymmetric carbon atom. The third methyl signal, arising at 1.99 as a doublet (J=1.5 Hz), may be ascribed to Me_C. The signal was split by coupling with H_C, which showed its signal at 6.77 as a quartet (J=1.5 Hz). The fourth methyl group, Me_D, and the aromatic

a) a, benzene–cyclohexane (1 : 4, v/v); b, benzene; c, carbon tetrachloride.

proton, H_D, showed their signals as singlets at 2.30 and 6.84, respectively. The double quartet at 2.81 may be due to H_B, which was coupled with Me_B (J=7.5 Hz) and H_A (J=3.5 Hz). The doublet at 3.84 (J=3.5 Hz) was assigned to H_A, which was coupled with H_B. A chelated and a non-chelated hydroxyl proton resonated at 12.28 and 6.10, respectively.

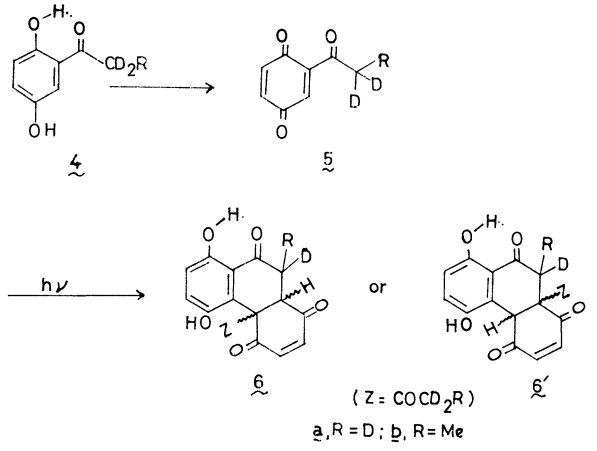
The other dimers showed similar spectra, but with partial variations dependent on their substituents.

i) The variation for R=H (the dimers of **2a** and **2f**). A set of signals of the ABX type was observed at about 3.0 (H_B and $H_{B'}$) and at about 4.1 (H_A). A singlet due to an acetyl group was observed at about 2.2.

ii) The variation for X=Y=H (the dimers of **2a**—**e**). Two AB quartets due to H_C and $H_{C'}$, and to H_D and $H_{D'}$, were observed at about 6.7 and about 7.1, respectively.

iii) The variation for X+Y=-(CH=CH)$_2$- (the dimers of **2l**—**m**). Two sets of four aromatic protons gave complex signals at 7.5—8.5.

The above assignments were substantiated by the spectra of the dimers (**6a**—**b** or **6'a**—**b**) of the partially deuterated monomers (**5a**—**b**), which were prepared from **4a**—**b**. The signals due to H_B and $H_{B'}$ (dABq at 3.08) and $COCH_3$ (s at 2.23) of **3a** disappeared, and the signal of H_A became a singlet upon deuteration. The doublets due to Me_B (1.45) and H_A (4.08) and the triplet due to Me_A (0.96) of **3b** all became singlets in **6b**.



However, all the types of spectra illustrated above may be explained by the alternative structure, **3'**, *i.e.*, an orientational isomer of **3**, though **3** is more feasible for the following reason. The value of the ^1H-^1H coupling constant, which had been ascribed above to the H_A–C–C–H_B coupling of **3g**, was 3.5 Hz. The corresponding values of the other dimers were also in the range of 3.0—4.0 Hz. They are a little too large for the H–C–C–C–H couplings, which should be in **3'**. The ^{13}C NMR data of the dimer of **2h** was also either compatible with **3h** or **3'h**, shown with **3h** in Fig. 1. As was stated in a previous communication,[2] **3'** was excluded on the basis of chemical evidence by converting

a dimer to a phenanthrenequinone derivative. Finally, **3** was confirmed by X-ray analysis.

The Stereochemistry of the Dimers. The structures of the dimers, including their stereochemistry, were unequinvocally resolved by X-ray structure analysis. It was carried out for the monoacetyl derivative of

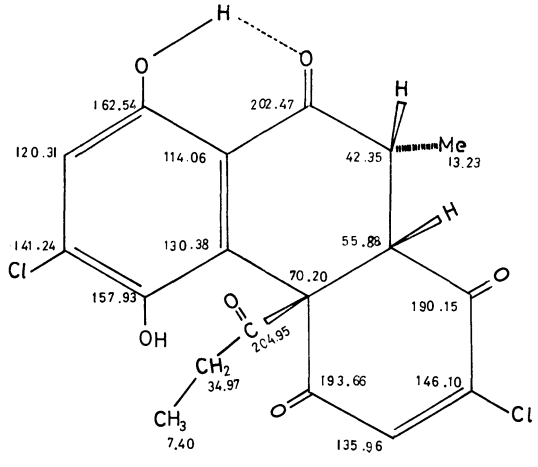

Fig. 1. Carbon chemical shifts of **3h** in $CDCl_3$(δ/ppm).

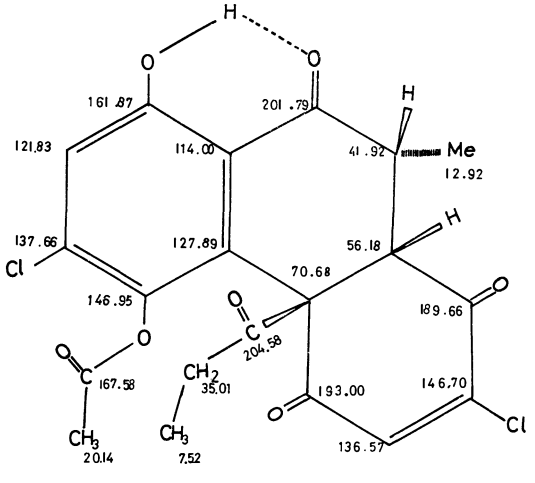

Fig. 2. Carbon chemical shifts of **7** in $CDCl_3$ (δ/ppm).

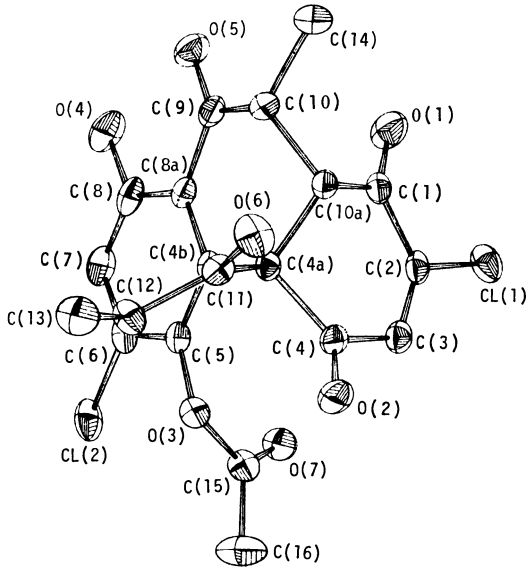

Fig. 3. Perspective view of **7**.

the dimer of **2h** because the dimer itself gave no satisfactory single crystals. The monoacetyl derivative was prepared by treating the dimer with Ac_2O–*p*-TsOH; it showed a ^1H NMR spectrum quite similar to that of the parent dimer (Table 2). Its ^{13}C NMR spectrum was also similar to that of the dimer (Fig. 2).

Figure 3 presents a stereoscopic view of one molecule. Here, the acetyl derivative has the structure and complete stereochemistry shown in **7**. Accordingly, those

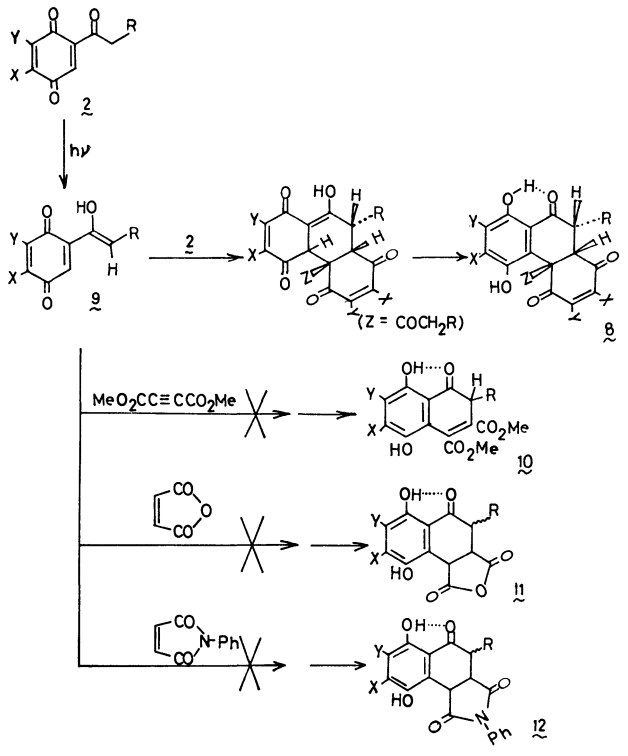
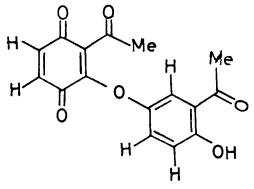
of the dimers should be shown as **8**, confirming **3** as the sketletal structure. The *cis* disposition of the hydrogen atom at C_{10a} and the acyl group at C_{4a} indicates that the condensation proceeds through a *cis* addition. The disposition of the hydrogen atoms at C_{10} and C_{10a} was also clarified as *cis*.

Mechanistic Consideration. The following mechanism may be the most plausible. In many cases, the Diels-Alder reaction resulted in the preferential formation of a certain one of the possible orientational and stereochemical isomers. Photochemically formed enols have been known to undergo the Diels-Alder reaction with dienophiles.[3] If the above mechanism indeed holds, the condensation of the enol, **9**, with the other kinds of dienophiles should proceed. However, the expected products, **10**, **11**, or **12**, were not obtained and the dimer **8** was still the only isolable product when the



reaction was carried out in the presence of twice as many moles of maleic anhydride, *N*-phenylmaleimide, or dimethyl acetylenedicarboxylate.

In contrast to the above dimerization, the other type of dimer, **13**, was obtained by the irradiation of degassed solutions of **2a**—**c** in the presence of Rose Bengal.[4] The mechanisms of the above two dimerizations are now under investigation.



13

Experimental

2-Acylhydroquinones (1). **1a**—**j** were prepared from hydroquinones and carboxylic acids by known methods.[5-7] **1k**—**m** were photochemically prepared from 1,4-naphthoquinone and aldehydes by a known method.[8] All the new compounds gave satisfactory results in elemental analyses and

a) Ref. 12. b) Satisfactory results were not obtained because of the hygroscopic character of the sample. c) Ref. 9.
d) Slightly splitting.

the expected values of *m/e* for the molecular peaks in the mass spectroscopy. The melting points of **1a**—**m** were: **a**, 200—202 °C, lit, 201—203 °C,[6] 204 °C;[7] **b**, 97—99 °C, lit, 96 °C;[7] **c**, 91 °C;[7] **d**, 61—62.5 °C; **e**, 82—83 °C; **f**, 149—150 °C, lit, 141 °C;[7] **g**, 110—116 °C; **h**, 127—129 °C; **i**, 144—156 °C; **j**, 121—123 °C; **k**, 215—216 °C, lit, 210—211 °C,[9] 206 °C,[10] and 216—217 °C;[11] **l**, 187—189 °C;[8] **m**, 151—153 °C.

2-(Acetyl-d_3)hydroquinone (4a) and 2-(Propanoyl-2-d_2)hydroquinone (4b). A solution of **3a** or **3b** (1 g) in dioxane (30 ml) and a solution of NaOH (1 equiv) in D_2O (3 ml) were successively syringed into a flask equipped with a rubber-serum cap and purged with nitrogen. The solution immediately turned reddish yellow. After stirring for 0.5 h, deuteriochloric acid (1.5 equiv) was added (the color of the solution thereupon turned back yellow). The solution was concentrated to yellow crystals, which were subsequently recrystallized from aqueous acetone to give **4a** or **4b**, respectively; mp: **4a**, 200—202 °C; **4b**, 96—98 °C. They showed no ^1H NMR signals due to methyl or methylene protons adjacent to a carbonyl group and the expected values of *m/e* for the molecular peaks in the mass spectroscopy.

2-Acyl-1,4-benzoquinones (2). These substances were prepared by one of the following methods. The yields were usually high, but showed less constancy. Their physical data are tabulated in Table 3.

Method A: This was originally described by Kloetzel *et al.*[12] A solution of **1** (1 g) in benzene (20 ml; for **1a**—**c**, **f**, and **g**) or diethyl ether (100 ml; for **1k**—**m**) was stirred with silver oxide (3 g) and magnesium sulfate (1.5 g) for 0.5 h. The powder was then filtered off and washed with diethyl ether under a slightly reduced pressure to prevent moisture from being condensed on the filtrate. The residue obtained by the concentration of the filtrate was submitted to sublimation under a vacuum to give **2a**—**j**. **2k**—**m** were purified by recrystallization from ligroin.

The partially deuterated monomers (**5a**—**b**) were prepared from **4a**—**b**. **5a**—**b** were not subjected to elemental analysis, but they gave satisfactory results in the mass and ^1H NMR spectroscopies.

Method B: When **1h** and **1i** were oxidized by Method A, many unsublimable solids remained. The use of DDQ was successful for oxidation. A solution of the calculated amount of DDQ in acetonitrile (20 ml) was added to a stirred solution of **1h** or **1i** (1 g) in acetonitrile (20 ml). Immediately the solution became deeply colored, and a colorless powder soon began to precipitate. After *ca.* 15 min the solution turned yellow and precipitation had ended. After filtration, the filtrate was concentrated to a residue, which was submitted to sublimation under a vacuum to give **2h**—**i**.

Method C: **2d** and **2e** were very hygroscopic. When Method A was apllied, a dirty colored syrup was left by the concentration of the filtered reaction solution. A method to avoid to contact with moisture was devised as follows. A solution of **1d** or **1e** (1 g) in acetonitrile (20 ml) was charged into a two-necked flask equipped with a rubber-serum cap. The flask was connected to a vacuum line, and the solution was then degassed by the thaw-freeze-pump method. Through the serum cap a solution of the calculated amount of DDQ in acetonitrile (10 ml) was syringed in. The change in the color of the reaction was the same as in method B. After *ca.* 15 min, the solvent was evaporated by bulb-to-bulb distillation through the vacuum line. The residual powder, composed of dichlorodicyanohydroquinone and **2**, was submitted to sublimation under a vacuum to isolate **2a**—**e**.

Preparation of the Dimers (3). Solutions of **2** were sealed in Pyrex glass tubes after having been degassed by the thaw-freeze-pump method and irradiated externally by means of a 300W high-pressure Hg-arc lamp for the appropriate times. The homogeneous reaction solutions, or the filtrates when solid products had been crystallized out, were concentrated to semi-solid residues, which were then submitted to sublimation under a vacuum to recover the **2**. The residues on sublimation were repeatedly rinsed with benzene to remove any tarry materials.[13] The remaining dirty yellow crystals, combined with the crystals which had been filtered off from the reaction solutions, were dissolved chloroform by slight warming. The solvent was evaporated in a desiccator by connecting it through a calcium chloride tube to a water pump. The solid residues were repeatedly rinsed with benzene. This process was repeated several times to give the pure dimers (**3**), *i. e.* **8**, which decomposed on silica-gel chromatography.

Table 4. Elemental analyses of the dimers **3**[a]

	Mp/°C[b]	Found (%) (Calcd (%)) C	H	X	Formula ($C_lH_mO_nX_x$): *l-m-n-x*
a	154—156	63.96 (64.00	4.25 4.03)	—	16-12-6
c	c	67.52 (67.40	5.61 5.66)	—	20-20-6
d	137—142	68.79 (68.73	6.41 6.29)	—	22-24-6
e	c	69.91 (69.88	6.99 6.84)	—	24-28-6
f	159—161	65.61 (65.85	4.80 4.91)	—	18-16-6
h	c	54.13 (54.41	3.46 3.53	18.09 17.88)	18-14-6-2
l	c	73.09 (72.89	4.40 4.71)	—	26-20-6
m	c	73.94 (73.67	5.44 5.30)	—	28-24-6

a) For **3b**,[c] **g**,[c] and **j**,[c] satisfactory results were not obtained because of the contamination by a trace amount of tarry materials, which could not be eliminated by repeated purification. b) Measured in a vacuum-sealed capillary. c) Melting gradually because of thermal decomposition.

The results of the elemental analyses are shown in Table 4. All the dimers gave the expected values of the molecular peaks in the mass spectrometry. Some of the dimers showed their melting points sharply in vacuum sealed capillaries, but the others melted gradually because of thermal decomposition. All the dimers showed similar IR and UV spectral data. Those of **3c** are representative; IR (KBr): ν 3500 (broad), 2980, 2950 (shoulder), 2880, 1720, 1695, 1680, 1645, 1610 (shoulder), 1595 cm^{-1}; UV (EtOH): λ_{max} (ε) 388 (5930), 300 (3650), 275 (3900), 222 (31200) nm.

The partially deuterated dimers (**6**) were similarly prepared from **5**. Elemental analyses were not performed for **6**, but satisfactory results were obtained in the mass spectrometry.

The Monoacetyl Derivative of 3h (7). A homogeneous solution obtained by the occasional swirling of a suspension of **3h** (0.5 g) in acetic anhydride (20 ml) containing one crop of *p*-toluenesulfonic acid was left standing at room temperature for 2 days. The solvent was then evaporated by bulb-to-bulb distillation through a vacuum line. Upon standing *in vacuo* overnight, the strupy residue became a semi-solid, which was subsequently dissolved in chloroform after rinsing with benzene.[14] The solution was concentrated to a solid, which was

again rinsed with benzene. By repeating this process, faint yellow crystals of **7** were obtained; 150 mg. These crystals gradually melted at 180—190 °C. Found: C, 54.30; H, 3.48; Cl, 16.01%. Calcd for $C_{20}H_{16}O_7Cl_2$: C, 54.66; H, 3.64; Cl, 16.17%. ^{1}H NMR ($CDCl_3$): δ 1.06 (3H, t, J=7 Hz, Me_A), 1.49 (3H, d, J=7 Hz, Me_B), 2.23 (3H, s, OAc), 2.68 (1H, dq, J=7 and 3.5 Hz, H_B), 4.21 (1H, d, J=3.5 Hz, H_A), 7.16 (1H, s, H_C), 7.32 (1H, s, H_D), 12.88 (1H, s, chelated OH) ($COCH_2$–Me_A: unclear). MS: *m/e* 440 and 438 (M^+).

X-Ray Structure Analysis. The molecular structure of **7** was determined by X-ray structure analysis. The crystal data were: monoclinic, $P2_1/c$, a=9.052 (2), b=13.512 (2), c=16.750 (3) Å, β=99.39 (2)°, V=2021.1 (7) Å^3. Z=4, D_m=1.449, D_c=1.445 g·cm^{-3}. A single crystal of approximately 0.26×0.25×0.18 mm was used for the intensity measurement. The cell constants were determined by the least-squares treatment of the angular settings of 20 reflections measured on a Rigaku computer-controlled four-circle diffractometer with Ni-filtered Mo $K\alpha$ radiation. The intensities were measured by the θ-2θ scan technique, with a scan speed of 2° min^{-1} in θ. The intensities of 3248 independent reflections were collected within $\sin\theta/\lambda \leq 0.65$. The structure of **7** was solved by the heavy-atom method and refined by the blok-diagonal least-squares method. The difference Fourier synthesis computed after the anisotropic refinement of the non-hydrogen atoms revealed the positions of all the hydrogen atoms except the methyl and hydroxyl hydrogen atoms. The final refinement, including the contribution of these hydrogen atoms with isotropic temperature factors, reduced the R-value to 0.074 without F_{obsd}=0. The final atomic coordinates are given in Table 5, while the bond lengths and angles are shown in Figs. 4 and 5 respectively.

We wish to thank Dr. Yoshitaka Itatani, Faculty of Pharmaceutical Sciences, Kanazawa University, for the NMR measurements and for his valuable discussions. One of the authors (Y. M.) is also especially grateful to The Institute for Protein Research, Osaka University, for supporting his stay for X-ray analysis.

Structure of a New Ionone Derivative, Nigakialcohol from *Picrasma ailanthoides* PLANCHON[1)]

Yayoi SUGIMOTO, Takaaki SAKITA, Toru IKEDA, Yoshihiko MORIYAMA, Tatsushi MURAE, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 31, 1979)

A new ionone derivative, nigakialcohol, was isolated from the leaves of *Picrasma ailanthoides* PLANCHON (Simaroubaceae), the structure being found to be (4*R*,5*S*)-4-[(*R*)-3-hydroxybutyl]-5-hydroxymethyl-3,3-dimethyl-1-cyclohexanone. Nigakilactones E, F, and H and vomifoliol were also isolated from the leaves.

Bitter principles isolated from Simaroubaceae have been extensively investigated.[2-4)] Some of them show antileukemic activity.[5)] *Picrasma ailanthoides* PLANCHON (Japanese name: Nigaki) is one of two species belonging to Simaroubaceae grown in Japan. A number of bitter principles were isolated from the bark and stem of the plant and their structures elucidated.[3,4)] In connection with these studies, we examined constituents of the leaves of the plant and isolated vomifoliol[6)] (blumenol A[7)]) and a new ionone derivative (**1**, named nigakialcohol) as non-bitter principles, as well as three bitter principles, nigakilactones E,[3a)] F,[3a)] and H.[3b)] In this paper we wish to report on the determination of the structure of nigakialcohol (**1**).

Dried leaves of the plant were extracted with hot water. The aqueous extract was concentrated and extracted with benzene. The benzene extract was subjected to separation by chromatography to afford a new compound (**1**; yield 0.003%, $[\alpha]_D^{24}$ 0°), which is not bitter. The IR and ^{1}H NMR spectra suggested the presence of two tertiary methyls (δ 0.80 and 1.08, each 3H, s), a secondary methyl (δ 1.23, 3H, d), two hydroxyls (δ 2.26, 2H, s-like; disappeared on addition of D_2O; ν_{OH} 3400 cm^{-1}), three protons (δ 3.30—4.10, 3H, m) attached to carbon atoms bearing hydroxyls, a saturated carbonyl group ($\nu_{C=O}$ 1700 cm^{-1}), and α- and α'-methylene protons (δ 2.00—2.60, 4H, m) adjacent to the carbonyl group. The molecular formula, $C_{13}H_{24}O_3$, was inferred from elemental analysis and high resolution mass spectrum which gave no molecular ion peak but a fragment ion peak at *m/e* 210.1620 ($C_{13}H_{22}O_2$) due to dehydration.

The presence of a primary alcohol and a secondary alcohol was suggested for **1** from the spectral data. This is supported by the following evidence. Acetylation of nigakialcohol (**1**) with acetic anhydride and pyridine afforded nigakialcohol diacetate (**2**) and monoacetate I (**3**). The NMR spectrum of the diacetate (**2**) showed that one acetoxyl is attached to a methylene carbon and another to a methine carbon, while the spectrum of the monoacetate I (**3**) revealed the presence of a secondary alcohol and an acetoxyl group on methylene carbon. On the other hand, another monoacetate, nigakialcohol monoacetate II (**4**) could be obtained by partial hydrolysis of diacetate (**2**) with alumina. The NMR spectrum of **4** showed the presence of a primary alcohol and an acetoxyl group on methine carbon (*cf.* Experimental).

In the NMR measurement of **1** using Eu(dpm)$_3$ as a shift reagent, one of three protons (due to –C<u>H</u>OH and –C<u>H</u>$_2$OH) giving a multiplet at δ 3.30—4.10, appeared at δ 13.85—14.65, the doublet corresponding to the secondary methyl being observed at δ 4.78 (d, J= 6 Hz). On irradiation at δ 14.28 (due to –C<u>H</u>OH), the doublet changed into a singlet. This shows the presence of the partial structure CH_3–C<u>H</u>–OH for nigakialcohol (**1**).

The molecular formula, $C_{13}H_{24}O_3$, of nigakialcohol and a comparison of the IR and NMR spectra of nigakialcohol with those of vomifoliol[6,7)] suggest the presence of an ionone skeleton for nigakialcohol. The above observation could lead to a structure **1a** for nigakialcohol.

1a

The presence of the ionone skeleton for **1** was shown as follows. Nigakialcohol (**1**) was subjected to Huang-Minlon reduction to afford deoxonigakialcohol (**5**) as an oil, $[\alpha]_D^{30}$ −28°. (±)-Deoxonigakialcohol was synthesized from (±)-γ-ionone (**6**) in four steps. (±)-γ-Ionone (**6**)[8,9)] was epoxidized with *m*-chloroperbenzoic acid in chloroform to afford a mixture of epoxy ketones (**7**) quantitatively.[10)] The mixture of epoxy ketones (**7**) gave one spot on TLC and a single peak on GLC examination. However, NMR measurement revealed that the product consists of two isomeric epoxy ketones in a ratio of 2:1 (*cf.* Experimental). The coupling constant values of the olefinic protons in the side chain for two isomers are identical, indicating that they are

configurational isomers between the side chain and the oxirane ring.

A mixture of **7** was treated with boron trifluoride etherate in toluene at 0 °C. An unsaturated keto aldehyde (**8**) obtained in 70% yield was found to be a mixture of two isomers in a ratio of 3:2 (by NMR measurement) which, without further separation, was subjected to reduction with sodium borohydride.

The reduction product was purified by column chromatography to give two diols **9** (R_f 0.36) and **9'** (R_f 0.30) in a ratio of 3:1. The IR and MS spectra of **9** and **9'** were almost the same. On GLC examination, each diol was found to be a mixture of two isomeric diols. NMR measurement also revealed that each diol consists of two isomers (*cf.* Experimental). In the NMR measurement using Eu(fod)$_3$-d_{27} as a shift reagent for **9** and **9'**, a doublet appearing at δ 1.26, changed into a pair of doublets at δ 2.25 (d, J=6 Hz) and δ 2.30 (d, J=6 Hz), and at δ 2.20 (d, J=6 Hz) and δ 2.25 (d, J=6 Hz), respectively.

Finally, the unsaturated diols **9** and **9'** were catalytically hydrogenated to afford saturated diols **10** and **10'**, respectively. **10** and **10'** gave almost the same IR spectra, minute differences being observed in the MS and NMR spectra. Each diol was found to be a mixture of two isomeric diols by NMR, GLC, and HPLC examinations. Their retention times on GLC and HPLC together with those of deoxonigakialcohol (**5**) are given in Table 1. Diol **10** was subjected to separation by preparative HPLC to give diols **10a** and **10b**. The synthetic diol **10a** was identical with deoxonigakialcohol (**5**) with respect to IR, MS, NMR, R_f on TLC, and R_t on GLC and HPLC (Table 1).

Table 1. R_f and R_t values on TLC, GLC, and HPLC for **5**, **10**, **10'**, **10a**, **10b**

	5	**10**	**10'**	**10a**	**10b**

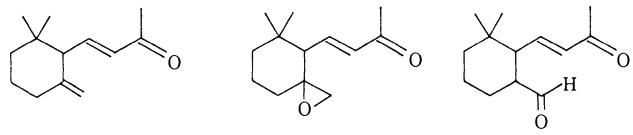
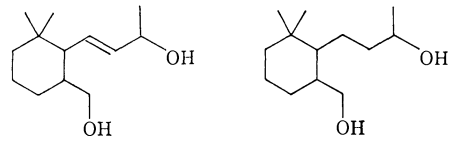
a) Developed with ether. b) Column: 10% FFAP Uniport B, 1.5 m, temperature 200 °C, a flow rate of N_2: 60 ml/min. c) Column: μ-Porasil 1/8 (inch) × 1 (foot), solvent system: 2.5% methanol–dichloromethane, flow rate: 0.5 ml/min, pressure: *ca.* 450 psi, detection: an RI detector.

The absolute configurations of chiral centers at C-5 and C-3' for nigakialcohol (**1**) were determined by an MTPA ester method; this method was recently developed by Yamaguchi and Yasuhara in order to determine the absolute configurations of secondary alcohols[11] and primary alcohols with the chiral center at the 2-position.[12]

Acetylation of deoxonigakialcohol (**5**) yielded a diacetate (**11**), which was partially hydrolyzed over alumina to afford deoxonigakialcohol monoacetate I and II (**12** and **13**). Nigakialcohol monoacetate I and II (**3** and **4**) and deoxonigakialcohol monoacetate II

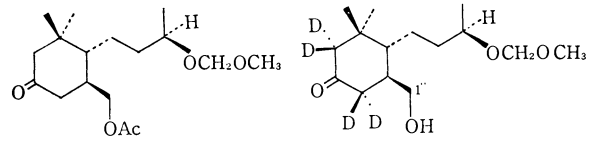


6 **7** **8**



9 **10**

(**13**) were converted into the corresponding (*R*)-(+)-α-methoxy-α-trifluoromethylphenylacetic acid [(*R*)-(+)-MTPA; Mosher's reagent] esters (**A**) and (*S*)-(−)-MTPA esters (**B**), respectively, by Mosher's method.[13] The LIS (lanthanoid induced shift) values of the three pairs of diastereomeric esters are given in Table 2. The ΔLIS_{OMe} values[11,12] (−0.46 and −0.60) for MTPA esters of nigakialcohol monoacetate II (**4**) and deoxonigakialcohol monoacetate II (**13**) show a negative sign, indicating that the chiral center at C-5 of **4** is in *S*-configuration.[12] On the other hand, the positive sign of ΔLIS_{OMe} value (+2.06) was observed for MTPA esters of nigakialcohol monoacetate I (**3**). This indicates that the chiral center at C-3' is in *R*-configuration.[11] This is in line with the absolute configuration determination by Horeau's method.[14]



14 **15**-d_4

Table 2. Lanthanoide induced shift (LIS) values of the methoxyl group in the acid moiety for (*R*)-(+)- and (*S*)-(−)-MTPA esters[a]

Monoacetate	LIS_{OMe} value for (*R*)-(+)-MTPA ester, **A**	LIS_{OMe} value for (*S*)-(−)-MTPA ester, **B**	ΔLIS_{OMe} value ($LIS_A - LIS_B$)	Absolute configuration
3	4.89	2.83	+2.06	*R*(C-3')
4	1.09	1.55	−0.46	*S*(C-5)
13	3.33	3.93	−0.60	*S*(C-5)

a) Determined at the molar ratio of Eu(fod)$_3$-d_{27}/each ester (1:1) for a *ca.* 1.3 mmol/ml solution of each ester in CCl_4.

The absolute configuration of the asymmetric center at C-4 could be determined by the measurement of coupling constant between $C_{(4)}$–H and $C_{(5)}$–H in a tetradeuterio derivative (**15**-d_4) derived from nigakialcohol (**1**). Nigakialcohol monoacetate I (**3**) was treated with dimethoxymethane[15] and phosphorus pentaoxide to afford nigakialcohol monoacetate I methoxymethyl ether (**14**). Deuteriation of **14** proceeded

with concomitant hydrolysis of the acetoxyl group at C-1″ to give **15**-d_4. In the NMR measurement of **15**-d_4 using Eu(fod)$_3$-d_{27} as a shift reagent, a broad signal due to a proton on C-5 and a broad signal due to methylene protons (-C$\underline{H}_2$OH) appeared at δ 2.20—2.50 and δ 4.25—4.66, respectively. On irradiation at δ 4.46, the broad signal due to the proton on C-5 collapsed into a doublet, coupled with a proton on C-4 with a coupling constant, J=11.5 Hz. Since the large coupling constant suggests a *trans*-relationship between $C_{(5)}$–H and $C_{(4)}$–H, the asymmetric carbon atom at C-4 position could be concluded to be in *R*-configuration.

The structure including the absolute configuration of nigakialcohol should be represented by (4*R*,5*S*)-4-[(*R*)-3-hydroxybutyl]-5-hydroxymethyl-3,3-dimethyl-1-cyclohexanone.

Experimental

General Procedure. IR spectra were taken on a Hitachi 260-30 or a JASCO JIR-10 spectrometer. ^{1}H NMR spectra were measured on a Hitachi R-20B (60 MHz) or a JNM PS-100 (100 MHz) spectrometer (JEOL). Chemical shifts are expressed in δ (ppm) downfield from TMS as an internal standard and coupling constants in Hz. CD and ORD curves were measured on a JASCO Model J-20 spectrometer. Measurements of optical rotation $[\alpha]_D$ were carried out using a JASCO DIP-SL polarimeter. Mass spectra (MS) were obtained on a Hitachi RMU-6-Tokugata mass spectrometer and high resolution mass spectra on a Hitachi RMH-2 mass spectrometer. Gas chromatography (GLC) was carried out using Shimadzu 4A-PF equipped with a hydrogen flame ionization detector (column A: SP-1000, 2 m, N_2 60 ml/min; column B: 10% FFAP Uniport B, 1.5 m, N_2 60 ml/min). Liquid Chromatograph Model ALC/GPC 202/401 (Waters Assoc.) was used for high performance liquid chromatography (HPLC); column: μ-Porasil 1/8 (inch)×1 (foot). Thin layer chromatography (TLC) was carried out on Kieselgel GF_{254} and Kieselgel G (E. Merck) of 0.25 mm thickness for analytical and 0.5 mm thickness for preparative. Wakogel C-200 (Wako) and Activated Alumina mesh 200—300 (Showakagaku) were used for column chromatography.

*Isolation of Nigakialcohol (**1**).* Dried leaves (12 kg) of *Picrasma ailanthoides* PLANCHON were pulverized and extracted with hot water (90 °C, 70 L) for 4 h. Extraction under the same conditions was repeated twice. The combined extracts (*ca.* 200 L) were concentrated under reduced pressure to *ca.* 40 L and extracted continuously with benzene for 4 days. The benzene extracts (36.5 g), dissolved in benzene, were passed through a column of neutral alumina (2 kg, pretreated with dilute hydrochloric acid, washed with water until the washings became neutral, and then activated) and eluted with the following solvents (each fraction: 1 L). Fractions 1—4, benzene; frs 5—20, benzene–ether 1:1; frs 21—31, ether; frs 32—40, ether–ethyl acetate 1:1; frs 41—92, ethyl acetate. Fractions 60—90 (4.7 g) were subjected to separation by column chromatography on silica gel (300 g). Elution (each fraction: 40 ml) was carried out with benzene (100 ml), benzene–acetone, 4:1 (500 ml), 3:1 (800 ml), 2:1 (1.2 L), and then with 1:1 (1 L). Nigakialcohol (**1**; 306 mg) was obtained from fractions 46—76. Fractions 77—95 (129 mg) were combined and purified by rechromatography on silica gel (20 g) to afford additional nigakialcohol (**1**; 67 mg). Nigakialcohol (**1**): IR (neat) 3400 and 1700 cm^{-1}; $[\alpha]_D^{24}$ 0° (*c* 0.21, $CHCl_3$); CD (*c* 0.083, EtOH, at 24 °C) $[\theta]_{340}$ −50, $[\theta]_{323}$ 0, $[\theta]_{294}$ +310, $[\theta]_{278}$ 0, $[\theta]_{255}$ −460; ORD (*c* 0.083, EtOH, at 24 °C) $[\Phi]_{360}$ −27°, $[\Phi]_{345}$ 0°, $[\Phi]_{314}$ +180°, $[\Phi]_{298}$ 0°, $[\Phi]_{277}$ −410°, $[\Phi]_{260}$ 0°; NMR (60 MHz) δ ($CDCl_3$) 0.80, 1.08 (each 3H, s, *t*-CH_3), 1.23 (3H, d, J=6 Hz, *s*-CH_3), 2.00—2.60 (4H, m, -CH_2-CO-CH_2-), 2.26 (2H, s-like, 2×-OH; disappeared on addition of D_2O), and 3.30—4.10 (3H, m, -C$\underline{H}_2$OH and -$\underline{C}$HOH); High resolution MS, Found: *m/e* 210.1628. Calcd for $C_{13}H_{22}O_2$ $(M-H_2O)^+$: *m/e* 210.1620. Found: *m/e* 213.1456. Calcd for $C_{13}H_{21}O_3$ $(M-CH_3)^+$: *m/e* 213.1491; Found: C, 65.99; H, 10.67%. Calcd for $C_{13}H_{24}O_3 \cdot 1/2\ H_2O$: C, 65.79; H, 10.62%. NMR measurement using Eu(dpm)$_3$ as a shift reagent was effected for a 9% (w/v) solution of **1** in $CDCl_3$ in a molar ratio [**1**/Eu(dpm)$_3$] of 1:0.69.

Isolation of Vomifoliol and Nigakilactones E, F, and H. The benzene extracts (45 g), obtained from the dried leaves (15 kg) by the same procedure as described above, were dissolved in benzene and chromatographed on a column of neutral alumina (3 kg) using the following solvents (each fraction: 1 L) as eluents: benzene (frs 1—7), benzene–ether (1:1, frs 8—65), ether (frs 66—165), ether–ethyl acetate (3:1, frs 166—187), ether–ethyl acetate (2:1, frs 188—220), ether–ethyl acetate (1:1, frs 221—254), and ethyl acetate (frs 255—265).

Fractions 66—75 were combined and the solvent was distilled off. The residue (2.3 g) was further chromatographed on silica gel [dry column, 250 g, eluent: benzene–ether (from 1:1 to 1:3), each fraction 50 ml]. Fractions 27—34 were combined and crystallized from benzene to afford vomifoliol (1.2 g).[6,7]

Fractions 101—116 gave a residue (1 g) which was chromatographed on silica gel [dry column, 150 g, eluent: ethyl acetate–ether (1:4), each fraction 50 ml]. Fractions 31—33 were combined and crystallized from benzene and then from benzene–light petroleum to give nigakilactone E.[3a]

Fractions 144—170 were combined and the solvents were removed. The residue (1.5 g) was further chromatographed on silica gel [dry column, 200 g, eluent: benzene–acetone (3:1), each fraction 50 ml]. Fractions 7—9 gave a residue which was crystallized successively from benzene and aqueous methanol to yield nigakilactone F (153 mg).[3a]

Fractions 182—195 were combined (1.8 g) and chromatographed on silica gel [dry column, 200 g, eluent: benzene–acetone (from 3:1 to 1:1), each fraction 100 ml]. Fractions 7 and 8 were combined and crystallized from benzene and then from methanol to give nigakilactone H (17 mg).[3b]

*Acetylation of Nigakialcohol (**1**).* Nigakialcohol (**1**; 41.0 mg) was treated with acetic anhydride (3 ml) and pyridine (5 drops) at room temperature for 25 min. After addition of methanol, the reaction mixture was treated as usual to give a residue, which was dissolved in benzene and passed through a dry column of silica gel (5 g). On elution (each fraction: 1 ml) with ether, fractions 8—12 gave nigakialcohol diacetate (**2**; 24.4 mg, yield 43%) and fractions 15—26 afforded nigakialcohol monoacetate I (**3**; 26.7 mg, yield 55%). Nigakialcohol diacetate (**2**): IR (neat) 1740 and 1715 cm^{-1}; $[\alpha]_D^{27}$ +30° (*c* 0.098, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.81, 1.09 (each 3H, *t*-CH_3), 1.24 (3H, d, J=6 Hz, *s*-CH_3), 2.03, 2.07 (each 3H, s, CH_3COO-), 2.10—2.50 (4H, m, -CH_2-CO-CH_2-) 3.80—4.40 (2H, m, -C$\underline{H}_2$OAc), and 4.50—5.10 (1H, m, -$\underline{C}$HOAc); MS *m/e* 252 $(M-60)^+$; Found: C, 65.36; H, 8.93%. Calcd for $C_{17}H_{28}O_5$: C, 65.36; H, 9.03%. Nigakialcohol monoacetate I (**3**): IR (neat) 3450, 1740, and 1715 cm^{-1}; $[\alpha]_D^{26}$ +3° (*c* 0.094, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.82, 1.10 (each 3H, s, *t*-CH_3), 2.07 (3H, s, CH_3COO-), 1.22 (3H, d, J=6 Hz, *s*-CH_3), 1.67 (1H, s-like, -OH; disappeared on addition of D_2O), 2.05—2.70 (4H, m, -CH_2-CO-CH_2-), 3.45—4.05 (1H, m, -$\underline{C}$HOH), and 3.95—4.30 (2H, m,

$-C\underline{H}_2OAc$); MS *m/e* 210 $(M-60)^+$; High resolution MS, Found: *m/e* 210.1558. Calcd for $C_{13}H_{22}O_2$ $(M-CH_3COOH)^+$: *m/e* 210.1620.

Partial Hydrolysis of Nigakialcohol Diacetate (2) into Nigakialcohol Monoacetate II (4). A solution of nigakialcohol diacetate (**2**; 57.3 mg) in benzene was adsorbed on the neutral alumina (6 g, prepared by the same pretreatment as before) for 6 days at room temperature. Elution with ether afforded nigakialcohol monoacetate II (**4**; 22.4 mg, yield 46%), IR (neat) 3450, 1735, and 1715 cm^{-1}; $[\alpha]_D^{26}$ +21° (*c* 0.14, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.80, 1.08 (each 3H, s, *t*-CH_3), 1.25 (3H, d, J=6 Hz, *s*-CH_3), 2.01 (1H, s-like, –OH; disappeared on addition of D_2O), 2.05 (3H, s, CH_3COO–), 2.05—2.60 (4H, m, $-CH_2-CO-CH_2-$), 3.40—3.90 (2H, m, $-C\underline{H}_2OH$), and 4.60—5.20 (1H, m, $-\underline{C}\underline{H}OAc$); MS *m/e* 252 $(M-18)^+$; High resolution MS, Found: *m/e* 252.1727. Calcd for $C_{15}H_{24}O_3$ $(M-H_2O)^+$: *m/e* 252.1725, Found: *m/e* 210.1652. Calcd for $C_{13}H_{22}O_2$ $(M-CH_3COOH)^+$: *m/e* 210.1620.

Huang-Minlon Reduction of Nigakialchol (1). A mixture of nigakialcohol (**1**; 153.7 mg), diethylene glycol (16 ml), hydrazine hydrate (2.4 ml), and potassium hydroxide (1.6 g) was heated under reflux at 140 °C for 1 h under a nitrogen atmosphere, distillation being continued until the temperature of the vapor reached 218 °C. The reaction mixture was refluxed at 218 °C for 5 h, followed by extraction with chloroform and the usual treatment. The reaction product was dissolved in benzene and subjected to purification by chromatography on silica gel (5 g). Elution with ether afforded deoxonigakialcohol (**5**; 98.3 mg, yield 69%), IR (**5**; 3 mg/0.12 ml $CHCl_3$) 3380 cm^{-1}, (**5**; 12.5 mg/5.0 ml $CHCl_3$) 1450, 1388, 1088, 1061, and 945 cm^{-1}, $[\alpha]_D^{30}$ −28° (*c* 0.125, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.83, 0.94 (each 3H, s, *t*-CH_3), 1.19 (3H, d, J=6 Hz, *s*-CH_3), 2.27 (2H, s-like, 2× –OH; disappeared on addition of D_2O), and 3.35—4.05 (3H, m, $-C\underline{H}_2OH$ and $-\underline{C}\underline{H}OH$); High resolution MS, Found: *m/e* 196.1745. Calcd for $C_{13}H_{24}O$ $(M-H_2O)^+$: *m/e* 196.1827; GLC and HPLC (Table 1).

Acetylation of Deoxonigakialcohol (5). Deoxonigakialcohol (**5**; 110.3 mg) was treated with acetic anhydride (8 ml) and pyridine (10 drops) at room temperature for 6 h. After decomposition of excess acetic anhydride by addition of methanol and the usual work-up, the reaction product was dissolved in benzene and passed through a column of silica gel (5 g). On elution with benzene–ether (2: 1), deoxonigakialcohol diacetate (**11**; 122.0 mg, yield 79%) was obtained, IR (neat) 1742 cm^{-1}; $[\alpha]_D^{20}$ −17° (*c* 1.06, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.82, 0.93 (each 3H, s, *t*-CH_3), 1.21 (3H, d, J=6 Hz, *s*-CH_3), 2.02, 2.05 (each 3H, s, CH_3COO–), 3.60—4.40 (2H, m, $-C\underline{H}_2OAc$), and 4.60—5.10 (1H, m, $-\underline{C}\underline{H}$–OAc); MS *m/e* 238 $(M-60)^+$.

Partial Hydrolysis of Deoxonigakialcohol Diacetate (11). A solution of deoxonigakialcohol diacetate (**11**; 119.2 mg) in benzene was adsorbed on the neutral alumina (7 g, prepared by the same treatment as before) for 6 days. After benzene (20 ml) had been passed through the column, elution with benzene–ether (4: 1, each fraction: 10 ml) was followed. From fractions 1—5, the starting material (**11**; 26.0 mg) was recovered in 23% yield. Fractions 6—11 gave deoxonigakialcohol monoacetate II (**13**; 43.1 mg, yield 43%), IR (neat) 3430 and 1739 cm^{-1}; $[\alpha]_D^{30}$ −7° (*c* 0.40, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.81, 0.92 (each 3H, s, *t*-CH_3), 1.23 (3H, d, J=6 Hz, *s*-CH_3), 1.75 (1H, s-like, –OH; disappeared on addition of D_2O), 2.03 (3H, s, CH_3COO–), 3.30—3.90 (2H, m, $-C\underline{H}_2OH$), and 4.85 (1H, m, $-\underline{C}\underline{H}OAc$); MS *m/e* 196 $(M-60)^+$. Fractions 13—17 afforded deoxonigakialcohol monoacetate I (**12**; 10.4 mg, yield 10%), IR (neat) 3420 and 1739 cm^{-1}; $[\alpha]_D^{30}$ −36° (*c* 0.104, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$); 0.83, 0.94 (each 3H, s, *t*-CH_3), 1.20 (3H, d, J=6 Hz, *s*-CH_3), 1.65 (1H, s-like, –OH; disappeared on addition of D_2O), and 3.55—4.40 (3H, m, $-C\underline{H}_2OAc$ and $-\underline{C}\underline{H}OH$); MS *m/e* 196 $(M-60)^+$.

Epoxidation of (±)-γ-Ionone (6). (±)-γ-Ionone (**6**) was prepared from geraniol *via* Ψ-ionone[8] by the reported procedure.[9] The crude γ-ionone containing α- and β-ionones was chromatographed on a column of silica gel impregnated with 20% silver nitrate. Elution with 15% ether in hexane gave (±)-γ-ionone (**6**), the purity of which was examined by GLC (column: A, temperature 220 °C), IR (neat) 1676, 990, and 896 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.89, 0.93 (each 3H, s, *t*-CH_3), 2.27 (3H, s, CH_3CO–), 2.59 (1H, s, $-\underline{C}\underline{H}$–CH=CH–), 4.57, 4.81 (each 1H, s, $-C=CH_2$), 6.10 (1H, d, J=16 Hz, $-CH=C\underline{H}-CO-$), and 6.97 (1H, dd, J=10 and 16 Hz, $-\underline{C}\underline{H}-C\underline{H}=CH$); MS *m/e* 192 (M^+) and 43 (base peak).

(±)-γ-Ionone (**6**; 987.1 mg) in chloroform (100 ml) was treated with *m*-chloroperbenzoic acid (975.7 mg) at room temperature for 2 days with agitation. After addition of chloroform (100 ml), the reaction was stopped by addition of 10% sodium sulfite solution and the reaction product was extracted with chloroform. The usual treatment gave a mixture of isomeric epoxy ketones (**7**) in a quantitative yield, which showed a single peak on GLC (R_t 4.3 min, column: A, temperature 220 °C) and a single spot on TLC (R_f 0.38, developed with hexane–ether, 1: 1); IR (neat) 3030, 1662, 1250, and 900 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.92, 1.05 (each 3H×2/3, s, *t*-CH_3), 0.95, 1.01 (each 3H×1/3, s, *t*-CH_3), 2.24 (3H, s, CH_3CO–), 6.08 (1H×2/3, d, J=16 Hz, $-CH=C\underline{H}-CO-$), 6.05 (1H×1/3, d, J=16 Hz, $-CH=C\underline{H}-CO-$), 6.68 (1H×2/3, dd, J=10 and 16 Hz, $-\underline{C}\underline{H}-C\underline{H}=CH-$), 6.66 (1H×1/3, dd, J=10 and 16 Hz, $-\underline{C}\underline{H}-C\underline{H}=CH-$); MS *m/e* 208 (M^+) and 43 (base peak); Found: C, 74.68; H, 9.48%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

Keto Aldehyde (8). A few drops of boron trifluoride etherate solution were added with stirring to an ice-cooled solution of the epoxy ketone (**7**; 280.5 mg) in toluene (2.5 ml). After 15 min, 5% sodium hydroxide solution was added. The reaction product was then extracted with toluene and the extract was treated as usual to give a residue. The residue was subjected to purification by chromatography on a column of silica gel (6 g). Elution with ether afforded a mixture of isomeric keto aldehydes (**8**; 200.5 mg, yield 71.4%). The product showed one spot on TLC (R_f 0.44, developed with hexane–ether, 2: 3) and one peak on GLC (R_t 6.1 min, column: A, temperature 220 °C); IR (neat) 2830, 1715, and 1662 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.94 (6H×3/5, s, *t*-CH_3), 0.87, 1.10 (each 3H×2/5, *t*-CH_3), 2.24 (3H, s, CH_3CO–), 2.45—2.80 (2H, m, $-\underline{C}\underline{H}$–), 6.05 (1H×3/5, d, J=16 Hz, $-CH=C\underline{H}-CO-$), 6.12 (1H×2/5, d, J=16 Hz, $-CH=C\underline{H}-CO-$), 6.66 (1H×3/5, dd, J=8 and 16 Hz, $-\underline{C}\underline{H}-C\underline{H}=CH-$), 6.70 (1H×2/5, dd, J=8 and 16 Hz, $-\underline{C}\underline{H}-C\underline{H}=CH-$), 9.45 (1H×3/5, d, J=3.5 Hz, –CHO), and 9.56 (1H×2/5, s-like, –CHO); MS *m/e* 208 (M^+) and 43 (base peak); High resolution MS, Found: *m/e* 208.1464. Calcd for $C_{13}H_{20}O_2$: *m/e* 208.1463.

Reduction of Keto Aldehyde (8) into Unsaturated Diol (9). A solution of the keto aldehyde (**8**; 40.8 mg) in methanol (1.5 ml) was cooled with an ice bath and sodium borohydride (7.7 mg) was added to the solution. After 30 min, the reaction was stopped by addition of aqueous acetic acid, methanol was removed and extraction with ether was followed. The ether extract was treated as usual and the reaction product was chromatographed on a column of silica gel (10 g) eluting with ether to afford isomeric diols **9** (7.3 mg) and **9′** (2.4 mg). **9**: TLC R_f 0.36 (developed with ether); GLC R_t 24.4 and 25.8

min with peak area in a ratio of 3:2 (column: A, temperature 200 °C), R_t 18.3 and 19.0 min with peak area in a ratio of 3:2 (column: B, temperature 210 °C); IR (neat) 3330 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.85 (6H×3/5, s, *t*-CH_3), 0.80, 1.02 (each 3H×2/5, s, *t*-CH_3), 1.26 (3H, d, J=6 Hz, *s*-CH_3), 2.41 (2H, s-like, -OH), 3.15—3.65 (2H, m, -C$\underline{H}_2$OH), 4.05—4.50 (1H, m, -C$\underline{H}$OH), and 5.40—5.70 (2H, m, -CH=CH-); MS *m/e* 194 $(M-18)^+$ and 82 (base peak). **9′**: TLC R_f 0.30 (developed with ether); GLC R_t 26.1 and 27.1 min with peak area in a ratio of 5:3 (column: A, temperature 200 °C), R_t 18.4 and 18.8 min with peak area in a ratio of 5:3 (column: B, temperature 210 °C); IR (neat) 3330 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.82 (6H×5/8, s, *t*-CH_3), 0.77, 1.02 (each 3H×3/8, s, *t*-CH_3), 1.26 (3H, d, J=6 Hz, *s*-CH_3), 2.82 (2H, s-like, -OH), 3.20—3.75 (2H, m, -C$\underline{H}_2$OH), 4.00—4.40 (1H, m, -C$\underline{H}$OH), and 5.18—5.78 (2H, m, -CH=CH-); MS *m/e* 194 $(M-18)^+$ and 82 (base peak). The NMR measurement using Eu(fod)$_3$-d_{27} as a shift reagent was carried out for a 10% (9%) solution of **9** (**9′**) in $CDCl_3$ in a molar ratio [**9** (**9′**)/Eu(fod)$_3$-d_{27}] of 1:0.25 (0.17).

*Hydrogenation of Unsaturated Diols (**9** and **9′**).* Unsaturated diol (**9**; 59.8 mg) in ethanol (4 ml) was hydrogenated in the presence of 5% palladium charcoal (4.9 mg) at room temperature overnight. The reaction product was purified by chromatography on a column of silica gel (7 g). Elution with ether gave a mixture of saturated diols (**10a** and **10b**; 20.1 mg, yield 33.3%), R_f value on TLC, R_t value on GLC, and R_t values on HPLC are listed in Table 1; IR (neat) 3320 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.82, 0.90, 0.93, 1.00 (each s, total 6H, *t*-CH_3), 1.19 (3H, d, J=6 Hz, *s*-CH_3), 2.01 (2H, m, 2× -OH), and 3.55 (3H, m, -C$\underline{H}$OH and -C$\underline{H}_2$OH); MS *m/e* 196 $(M-18)^+$ and 69 (base peak).

Unsaturated diol (**9′**; 24.0 mg) in ethanol (4 ml) was hydrogenated in the presence of 5% palladium charcoal (4.9 mg) under the same conditions as above to afford a mixture of saturated diols (**10′a** and **10′b**; 9.8 mg, yield 40.5%), R_f value on TLC, R_t values on GLC, and R_t values on HPLC are shown in Table 1; IR (neat) 3320 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.82, 0.90, 0.93, 1.00 (each s, total 6H, *t*-CH_3), 1.19 (3H, d, J=6 Hz, *s*-CH_3), 2.06 (2H, s-like, 2× -OH), 3.40—4.20 (3H, m, -C$\underline{H}$OH and -C$\underline{H}_2$OH); MS *m/e* 196 $(M-18)^+$ and 69 (base peak).

*Separation of Diols (**10a** and **10b**) by HPLC.* A mixture of the diols (**10a** and **10b**; 12.6 mg) was subjected to separation by preparative HPLC under the same conditions as given in Table 1 to give diols **10a** (2.5 mg) and **10b** (3.0 mg). **10a**: R_f value on TLC, R_t value on GLC, and R_t value on HPLC given in Table 1; IR (**10a**; 2.5 mg/0.12 ml $CHCl_3$) 3380 cm^{-1}, (**10a**; 2.5 mg/1.5 ml $CHCl_3$) 1450, 1388, 1088, 1061, and 945 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.90, 1.00 (each 3H, s, *t*-CH_3), 1.21 (3H, d, J=6 Hz, *s*-CH_3), 1.80 (2H, s-like, 2× -OH), and 3.35—4.05 (3H, m, -C$\underline{H}$OH and -C$\underline{H}_2$OH); High resolution MS, Found: *m/e* 196.1830. Calcd for $C_{13}H_{24}O$ $(M-H_2O)^+$: *m/e* 196.1827. **10b**: R_f and R_t values given in Table 1; IR (**10b**; 3 mg/0.12 ml $CHCl_3$) 3380 cm^{-1}, (**10b**; 3.0 mg/1.5 ml $CHCl_3$) 1450, 1388, 1076, 1061, and 937 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.83, 0.94 (each 3H, s, *t*-CH_3), 1.19 (3H, d, J=6 Hz, *s*-CH_3), 1.74 (2H, s-like, 2× -OH), 3.35—4.05 (3H, m, -C$\underline{H}$OH and -C$\underline{H}_2$OH); High resolution MS, Found: *m/e* 181.1590. Calcd for $C_{12}H_{21}O$ $(M-H_2O-CH_3)^+$: *m/e* 181.1592.

*(R)-(+)-MTPA Ester of Nigakialcohol Monoacetate I (**3**).* Pyridine (0.3 ml) and (+)-MTPACl (25 μl) were added to a solution of nigakialcohol monoacetate I (**3**; 17.8 mg) in carbon tetrachloride (0.3 ml). The mixture was stirred for 2 h at room temperature and then *N,N*-dimethyl-1,3-propanediamine (50 μl) was added. After the usual treatment, the reaction product was dissolved in benzene and subjected to purification by chromatography on a column of silica gel (2 g). Elution with ether gave (*R*)-(+)-MTPA ester of **3** (24.0 mg, yield 74%), IR (neat) 1742 and 1720 cm^{-1}; NMR (60 MHz) δ (CCl_4) 0.77, 1.02 (each 3H, s, *t*-CH_3), 1.30 (3H, d, J=6 Hz, *s*-CH_3), 2.01 (3H, s, CH_3COO-), 3.49 (3H, -OCH_3), 3.90—4.15 (2H, m, -C$\underline{H}_2$OAc), 4.70—5.20 (1H, m, -C$\underline{H}$-OMTPA), and 7.20—7.70 (5H, m, arom H's); MS *m/e* 253 and 189 (base peak).

*(S)-(-)-MTPA Ester of Nigakialcohol Monoacetate I (**3**).* The same treatment of nigakialcohol monoacetate I (**3**; 23.1 mg) with (-)-MTPACl (25 μl) gave (*S*)-(-)-MTPA ester of **3** (29.2 mg, yield 70%); IR (neat) 1740 and 1720 cm^{-1}; NMR (60 MHz) δ (CCl_4) 0.65, 0.88 (each 3H, s, *t*-CH_3), 1.37 (3H, d, J=6 Hz, *s*-CH_3), 2.01 (3H, s, CH_3COO-), 3.55 (3H, -OCH_3), 3.85—4.05 (2H, m, -C$\underline{H}_2$OAc), 4.80—5.20 (1H, m, -C$\underline{H}$-OMTPA), and 7.20—7.65 (5H, m, arom H's); MS *m/e* 253 and 189 (base peak).

*(R)-(+)- and (S)-(-)-MTPA Esters of Nigakialcohol Monoacetate II (**4**).* (*R*)-(+)-MTPA ester (17.0 mg, yield 67%) and (*S*)-(-)-MTPA ester (24.3 mg, yield 89%) were prepared by the same procedure from nigakialcohol monoacetate II (**4**; 14.1 mg and 15.0 mg), respectively. (*R*)-(+)-MTPA ester: IR (neat) 1740 and 1720 cm^{-1}; NMR (60 MHz) δ (CCl_4) 0.78, 1.03 (each 3H, s, *t*-CH_3), 1.18 (3H, d, J=6 Hz, *s*-CH_3), 1.97 (3H, s, CH_3COO-), 3.50 (3H, -OCH_3), 3.90—4.40 (2H, m, -C$\underline{H}_2$OAc), 4.45—4.95 (1H, m, -C$\underline{H}$-OMTPA), and 7.20—7.60 (5H, m, arom H's); MS *m/e* 253 and 189 (base peak). (*S*)-(-)-MTPA ester: IR (neat) 1742 and 1720 cm^{-1}; NMR (60 MHz) δ (CCl_4) 0.78, 1.03 (each 3H, s, *t*-CH_3), 1.17 (3H, d, J=6 Hz, *s*-CH_3), 1.98 (3H, s, CH_3COO-), 3.52 (3H, -OCH_3), 4.20—4.40 (2H, m, -C$\underline{H}_2$OAc), 4.45—5.00 (1H, m, -C$\underline{H}$-OMTPA), and 7.20—7.70 (5H, m, arom H's); MS *m/e* 253 and 189 (base peak).

*(R)-(+)- and (S)-(-)-MTPA Esters of Deoxonigakialcohol Monoacetate II (**13**).* (*R*)-(+)-MTPA ester (16.7 mg, yield 65%) and (*S*)-(-)-MTPA ester (30.7 mg, yield 87%) were prepared from deoxonigakialcohol monoacetate II (**13**; 13.8 mg and 19.1 mg). (*R*)-(+)-MTPA ester: IR (neat) 1740 cm^{-1}; NMR (60 MHz) δ (CCl_4) 0.82, 0.92 (each 3H, s, *t*-CH_3), 1.17 (3H, d, J=6 Hz, *s*-CH_3), 1.96 (3H, s, CH_3COO-), 3.52 (3H, -OCH_3), 3.70—4.95 (3H, m, -C$\underline{H}_2$OAc and -C$\underline{H}$-OMTPA), 7.20—7.70 (5H, m, arom H's); MS *m/e* 280 and 189 (base peak). (*S*)-(-)-MTPA ester: IR (neat) 1740 cm^{-1}; NMR (60 MHz) δ (CCl_4) 0.82, 0.92 (each 3H, s, *t*-CH_3), 1.16 (3H, d, J=6 Hz, *s*-CH_3), 1.97 (3H, s, CH_3COO-), 3.53 (3H, -OCH_3), 3.90—4.50 (2H, m, -C$\underline{H}_2$OAc), 4.50—5.00 (1H, m, -C$\underline{H}$-OMTPA), and 7.20—7.65 (5H, m, arom H's); MS *m/e* 280 and 189 (base peak).

*Determination of the Configuration at C-3′ in Nigakialcohol Monoacetate I (**3**) by Horeau's Method.* Racemic α-phenylbutyric anhydride (60.3 mg, 0.194 mmol) and nigakialcohol monoacetate I (**3**; 20.0 mg; 0.074 mmol) were dissolved in pyridine (0.3 ml). After the solution had been allowed to stand at room temperature overnight, water (0.5 ml) was added and the mixture was left to stand for 1.5 h at room temperature. Benzene was added, followed by extraction with saturated sodium hydrogencarbonate solution. The benzene layer was washed with dilute hydrochloric acid and then with brine, and dried over sodium sulfate. Concentration *in vacuo* afforded 28.5 mg (0.069 mmol, yield 93%) of an α-phenylbutyrate of **3**. An NMR spectrum of this ester indicated that **3** was totally esterified. The sodium hydrogencarbonate extract was acidified with 3M hydrochloric acid and the acidified solution was extracted with chloroform. The chloroform extract was

washed with brine and treated as usual to yield 47.1 mg (0.287 mmol, yield 91%) of α-phenylbutyric acid, which showed $[\alpha]_D^{28}$ +2.1° (*c* 0.471, $CHCl_3$, optical yield 12%), suggesting that the asymmetric center (C-3′) of the secondary alcohol possesses *R*-configuration.

*Preparation of Tetradeuterionigakialcohol Methoxymethyl Ether (**15**-d_4).* Phosphorus pentaoxide (*ca.* 500 mg) was added to a solution of nigakialcohol monoacetate I (**3**; 26.7 mg) in chloroform (3 ml, freshly distilled from phosphorus pentaoxide) and dimethoxymethane (1.5 ml), and the mixture was stirred for 30 min at room temperature. The reaction mixture was washed with cold saturated sodium carbonate solution and then with brine, dried over sodium sulfate, and evaporated to afford a residue. The residue was dissolved in hexane and purified by column chromatography over silica gel (4 g). On elution (each fraction: 1 ml) with hexane–ether (2: 3), fractions 7—21 gave nigakialcohol monoacetate I methoxymethyl ether (**14**; 20.5 mg, yield 66%); IR (neat) 1740 and 1715 cm^{-1}; $[\alpha]_D^{26}$ +5° (*c* 0.140, $CHCl_3$); NMR (60 MHz) δ ($CDCl_3$) 0.82, 1.10 (each 3H, s, *t*-CH_3), 1.19 (3H, d, J=6 Hz, *s*-CH_3), 2.10—2.50 (4H, m, $-CH_2-CO-\underline{C}H_2-$), 2.18 (3H, s, CH_3COO-), 3.40—3.80 (1H, m, $-\underline{C}H-O-CH_2-$), 3.48 (3H, s, $-OCH_3$), 4.00—4.20 (2H, m, $-\underline{C}H_2OAc$), and 4.46, 4.60 (2H, ABq, J=7.5 Hz, $-O-CH_2-O-$); MS *m/e* 299 $(M-15)^+$.

The methoxymethyl ether (**14**; 30.0 mg) was deuteriated by treatment with sodium methoxide [prepared from sodium (*ca.* 60 mg) and deuterium oxide (1.2 ml)] in methanol-*d* (9 ml). The reaction mixture was heated under reflux for 4 days under nitrogen atmosphere. Neutralization with dilute hydrochloric [*D*] acid, extraction with dichloromethane, and the usual work-up gave a residual oil. The same deuteriation procedure was repeated twice to afford a deuteriated nigakialcohol methoxymethyl ether (**15**-d_4; 23.1 mg); IR (neat) 3440 and 1700 cm^{-1}; NMR (60 MHz) δ ($CDCl_3$) 0.79, 1.08 (each 3H, s, *t*-CH_3), 1.20 (3H, d, J=6 Hz, *s*-CH_3), 2.17 (1H, s-like, -OH), 3.40—4.00 (3H, m, $-C\underline{H}_2OH$ and $-\underline{C}H-O-CH_2-$), 3.38 (3H, s, $-OCH_3$), and 4.58, 4.68 (2H, ABq, J= 7.5 Hz, $-O-CH_2-O-$); δ (CCl_4) 0.78, 1.08 (each 3H, s), 1.26 (3H, d, J=6 Hz), 2.60 (1H, s-like; disappeared on addition of D_2O), 3.30—3.90 (1H, m), 3.31 (3H, s), and 4.47, 4.61 (2H, ABq, J=7.5 Hz); NMR (100 MHz) [**15**-d_4/Eu(fod)$_3$-d_{27} =1: 0.07; for 7% (w/v) solution of **15**-d_4 in $CDCl_3$] δ 1.03, 1.24 (each 3H, s, *t*-CH_3), 1.31 (3H, d, J=6 Hz, *s*-CH_3), 2.20 —2.50 (1H, m, $-\underline{C}H-CH_2O\cdots Eu$), 3.58 (3H, s, $-OCH_3$), 3.75—4.10 (1H, m, $-\underline{C}H-O-CH_2-$), 4.25—4.66 (2H, m, $-C\underline{H}_2O\cdots Eu$), and 4.87, 4.94 (2H, ABq, J=7.5 Hz, $-O-CH_2-O-$).

(Received April 13, 1979)

Nine of the title compounds were synthesized, and their solvolysis rates were determined in 80% (v/v) aq acetone at 45 °C. The effects of the *pi*-donor substituents for each substituent position are shown to be excellently described in terms of inductive(*I*) and *pi*-electronic(*Pi*) effects by means of the LSFE equation ($\log k/k_0=\rho_i\sigma_i+\rho_\pi^+\sigma_\pi^+$), just as with those in the 1-naphthyl systems. When those data are joined with all our substituent effects data for the phenyl, 4-biphenylyl, 2-fluorenyl, and 1-naphthyl systems under identical conditions, it is clear that the overall correspondence between the ρ_i values and Dewar's simple-field-effect function ($1/r$) is satisfactory. On the other hand, the ρ_π^+ values appear to give slightly different responses (separate correlations for the 1- and 2-naphthyl systems) to the SCF-π charge difference values; this may be ascribed to the steric effects on the *Pi* effect in only the 1-naphthyl-solvolysis sets. Furthermore, the position constancy of the *I* effect ($\rho_{i,6\text{-X-}2}/\rho_{i,7\text{-X-}2}=0.85$) has been observed in the present solvolysis and the available data for dissociation of 2-naphthalenecarboxylic acids involving relatively weak *Pi* effects; the figure is in good agreement with the ratio of $\rho_{i,para}/\rho_{i,meta}=0.85$. Analogous results were also achieved by the same treatment to 2-benzo[*b*]thienyl reactivities. All the results are discussed with respect to the validity of the LSFE equation.

It has been the well-accepted concept that substituent effects on reactivities can be described in a good approximation as an additive function of two basic components, polar (inductive, *I*) and resonance (*pi*-electronic, *Pi*) effects, each of which is given as a $\rho\sigma$ product.[2-4] Provided that there exists a universal set of inductive and *pi*-electronic substituent constants, the constants should be applicable in principle to any kinds of extended *pi*-system for various reactions. The term of universal substituent constants refers to the unchanged (inherent) electron-donating or -withdrawing capabilities of their own substituents, independent of any different reactivity classes.[2]

We have long focused on such separation and separability problems and have continued our studies of substituent effects on reactivities in certain *pi*-electronic systems. LArSR Eq. 1, originally based upon the phenyl system,[8-10] has been applied to 3′-, 4′-substituted 4-biphenylyl,[5] 7-substituted 2-fluorenyl,[1] and 3-, 4-substituted 1-naphthyl systems:[7]

$$\log k/k_0=\rho(\sigma^0+r^+\Delta\bar{\sigma}_R^+ + r^-\Delta\bar{\sigma}_R^-) \quad (1)$$

LArSR Eq. 1, however, stands on the reference scale of σ^0 for unexalted phenyl reactivities as a standard, which is separable further into two basic terms, *I* and *Pi* effects. The σ^0 scale also implies the effect of the substituent position, such as the meta or para position. Therefore, LSFE Eq. 2[6,10-12] is expected to be appropriate to an understanding of the general scheme of the substituent effect in extended *pi*-systems.

$$\log k/k_0=\rho_i\sigma_i+\rho_\pi^+\sigma_\pi^+ + \rho_\pi^-\sigma_\pi^- \quad (2)$$

The σ_i values are the inductive substituent constants, while the σ_π^+ or σ_π^- values the *pi*-electronic substituent constants for *pi*-donor($-R$) or *pi*-acceptor($+R$) substituents respectively, which, we believe, may be regarded as universal constants independent of any different reactivity classes; the numerical values are defined by $\sigma_i=0.74\sigma'$, $\sigma_\pi^+=0.415\Delta\bar{\sigma}_R^+$, and $\sigma_\pi^-=0.73\ \Delta\bar{\sigma}_R^-$. These scales hold a simple association with σ_p^0 by means of:

$$\sigma_p^0=\sigma_i+\sigma_\pi^+ + \sigma_\pi^-.[15] \quad (3)$$

The substituent-effect parameters obtained by means of the LArSR treatment can, then, be interconverted into those obtained by means of the LSFE treatment:[1]

$$\rho_i=\rho,\ \rho_\pi^+=\rho(1+r^+/0.415),\ \rho_\pi^-=\rho(1+r^-/0.73).$$

It must be noted that the different susceptibilities to *Pi* effects for donor and acceptor substituents, even in a given reaction, are essentially expressed as in LSFE Eq. 2. The duality of such ρ_π's is a significant implication of LArSR Eq. 1 and the inevitable conclusion to be induced from it.

On the other hand, DSP Eq. 4 by Taft has been widely applied to many chemical reactivities and physical properties:[2,4,13]

$$\log k/k_0=\rho_I\sigma_I+\bar{\rho}_R\bar{\sigma}_R \quad (4)$$

We can point out there remain three important differences between our LSFE Eq. 2 and Taft's DSP Eq. 4: that is, (1) the existence of universal *pi*-electronic substituent constants,[6,14] (2) the dual susceptibilities to the *Pi* effects,[6,14,16] and (3) the scaling of the inductive substituent constants.[17] A principal objective of our current studies has been to obtain evidence for the existence of a universal set of *pi*-electronic substituent constants.

A naphthyl system is suitable for studies of substituent effects because of its various substituent positions.[2a] We have already reported the correlations for the solvolysis of the 5-, 6-, and 7-substituted 1-naphthyl systems and for the pK_a of the corresponding 1-naphthalenecarboxylic acids with respect to *pi*-donor substituents, *i.e.*, by means of Eq. 5:[18]

$$\log k/k_0=\rho_i\sigma_i+\rho_\pi^+\sigma_\pi^+ \quad (5)$$

Here, we have worked with the alternative 2-naphthyl system and have examined the substituent effects at the B-ring positions, namely, the solvolysis of 6- and 7-substituted 1-(2-naphthyl)ethyl chlorides.

Surprisingly few substituent effect data have been published on 2-naphthyl reactivities;[24] available are

only data sets as four reactions, in which at least both 6- and 7-substituent effects were studied systematically: (I) the present solvolysis in 80% aq acetone, (II) the detritiation of 2-tritionaphthalenes in CF_3COOH at 70 °C,[19] (III) the dissociation of 2-naphthalenecarboxylic acids in 50% aq EtOH at 25 °C,[2a,20] and (IV) the alkaline hydrolysis of methyl 2-naphthalenecarboxylates in 70% aq dioxane at 25 °C.[21] These 2-naphthyl reactivities belong to the σ^+-type (I and II) as well as the σ-type category (III and IV) and are appropriate for a study of the accurate reaction dependencies of the *I* and *Pi* effects. Further, LSFE Eq. 5 will also be tested for some electrophilic reactivities of the relevant heteroaromatics, such as 2-benzofuryl and 2-benzo[*b*]-thienyl systems.[22,23a]

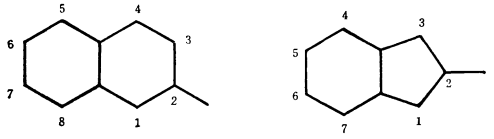

Chart 1.

Accordingly, the present results and discussion bear on the validity and utility of LSFE Eq. 2 in extended *pi*-systems and on the transmission efficiency of the *I* and *Pi* effects.

Experimental[25]

Materials. Commercial 2-acetylnaphthalene was purified through the recrystallization of its picrate (mp 82—83 °C), followed by the fractional distillation of the regenerated ketone using aq NH_3.

6-Substituted 2-Acetylnaphthalenes: 6-Methoxy-,[26] 6-methylthio-,[27] 6-methyl-,[28] and 6-bromo-2-acetylnaphthalenes[29] were prepared by following the literature methods of the Friedel-Crafts acetylation in nitrobenzene and were purified by fractional redistillation or by column chromatography over alumina (eluting with hexane–benzene) or by fractional recrystallization. The 6-bromo-2-acetylnaphthalene was converted to 6-cyano-2-acetylnaphthalene (mp 142—144 °C) by the ordinary method, using CuCN in DMF.[24c,30] The physical constants agreed well with the reported values, as is shown in Table 1.

7-Substituted 2-Acetylnaphthalenes: These compounds were prepared essentially by a combination of such well-known synthetic routes[31] of reactions as the following.

7-Methyl-2-acetylnaphthalene. 3-(*p*-Methylbenzoyl)propanoic acid was prepared by the Friedel-Crafts reaction of succinic anhydride with toluene and $AlCl_3$.[32] The acidification of the aq sodium salt solution gave colorless ppt (mp 129—131 °C; lit, 126—128 °C,[33] 124—126 °C),[34] which was then reduced by a Wolff-Kishner reaction with KOH, 80% aq NH_2NH_2 in diethylene glycol[35] to 4-(*p*-methylphenyl)-butanoic acid (recrystd from hexane, mp 57—58 °C; lit, 59—61 °C,[33] 60—61 °C)[31] and then esterified with 99% EtOH. Ethyl 4-(*p*-methylphenyl)butanoate was distilled at bp 97.5—98 °C/2 mmHg as a GLC pure sample. The ester (80 g) was treated with ethyl formate (64 g) and NaOEt in abs ether[36] to give ethyl 2-formyl-4-(*p*-methylphenyl)butanoate, along with about a half of the starting butanoate ester (43 g). The product was, then, cyclized to ethyl 3,4-dihydro-7-methyl-2-naphthoate, using phosphoric acid and concd H_2SO_4, according to the procedure described by Holmes and Trevoy.[36] The subsequent distillation of the desired ester gave a GLC

Table 1. Physical properties and analytical data of 2-acetylnaphthalenes, 1-(2-naphthyl)ethanols, and 1-(2-naphthyl)ethyl chlorides

a) 6-MeS-2, mp 100—102 °C. b) 6-Me-2, bp 115—116 °C/1.2 mmHg. Both 6-MeO-2 and 6-Br-2 derivatives were used immediately after the preparation of the chlorides, without distillation.

pure, colorless liquid (27.6 g); bp 142—144 °C/4 mmHg; NMR (CCl_4) δ=1.33 (3H, t, J=7.1 Hz, $CH_2C\underline{H}_3$), 2.29 (3H, s, $C\underline{H}_3$), 2.4—2.9 (4H, m, $C\underline{H}_2C\underline{H}_2$), 4.20 (2H, q, J=7.1 Hz, $C\underline{H}_2CH_3$), 6.94 (3H, s, Ar), and 7.36 (1H, olefinic); Found: C, 77.78; H, 7.30%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

The ethyl dihydronaphthoate (27 g) was dehydrogenated with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ, 32 g) in xylene (250 ml) under refluxing for 24 h. After a usual work-up, a major fraction of the distillation (bp 133—140 °C/2 mmHg) was collected (solidified on standing) and recrystallized from hexane to give pure ethyl 7-methyl-2-naphthalenecarboxylate (15 g); mp 64.5—65 °C; NMR (CCl_4) δ=1.42 (3H, t, J=7.1 Hz, $CH_2C\underline{H}_3$), 2.50 (3H, s, $C\underline{H}_3$), 4.37 (2H, q, J=7.1 Hz, $C\underline{H}_2CH_3$), and 7.2—8.4 (6H, m, Ar); Found: C, 78.38; H, 6.65%. Calcd for $C_{14}H_{14}O_2$; C, 78.48; H, 6.59%.

7-Methyl-2-naphthalenecarboxylic acid, obtained from the alkaline hydrolysis, was recrystallized from aq EtOH; mp 208—209 °C (lit, 207—209 °C).[31] 7-Methyl-2-acetylnaphthalene was similarly synthesized (*via* 7-methyl-2-naphthoyl chloride, as has been described elsewhere)[7,8a,18] and purified by recrystallization from hexane; mp 85.0—85.5 °C; NMR (CCl_4) δ=2.5_5 (3H, s, $C\underline{H}_3$), 2.6_4 (3H, s, $COC\underline{H}_3$), and 7.4—8.4 (6H, m, Ar).

7-Methoxy-2-acetylnaphthalene. 3-(*p*-Methoxybenzoyl)-propanoic acid (mp 148—150 °C; lit, 148—149 °C),[37,38] 4-(*p*-methoxyphenyl)butanoic acid,[38] and ethyl 4-(*p*-methoxyphenyl)butanoate (bp 133.5—134 °C/3 mmHg) were prepared successively by methods similar to those used for the above 7-methyl derivatives. The cyclization of ethyl 4-(*p*-methoxyphenyl)butanoate (74 g) *via* ethyl 2-formyl-4-(*p*-methoxyphenyl)butanoate gave ethyl 3,4-dihydro-7-methoxy-2-naphthalenecarboxylate (17.5 g); bp 169—175 °C/5—6 mmHg; NMR (CCl_4) δ=1.33 (3H, t, J=7.1 Hz, $CH_2C\underline{H}_3$), 2.4—2.9 (4H, m, $C\underline{H}_2C\underline{H}_2$), 3.74 (3H, s, $OC\underline{H}_3$), 4.19 (2H, q, J=7.1 Hz, $C\underline{H}_2CH_3$), 6.6—7.0 (3H, m, Ar), and 7.36 (1H, s, olefinic); Found: C, 72.50; H, 6.70%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%.

The dehydrogenation of the dihydronaphthalene (28.5 g) with DDQ gave ethyl 7-methoxy-2-naphthalenecarboxylate (21.5 g); bp 188—195 °C/5 mmHg (lit, mp 36—36.5 °C);[39] NMR (CCl_4) δ=1.42 (3H, t, J=7.1 Hz, $CH_2C\underline{H}_3$), 3.88 (3H, s, $OC\underline{H}_3$), 4.37 (2H, q, J=7.1 Hz, $C\underline{H}_2CH_3$), and 7.1—8.4 (6H, m, Ar).

After alkaline hydrolysis, 7-methoxy-2-naphthalenecarboxylic acid was obtained; recrystd from aq EtOH, mp 200.5—201 °C (lit, 194—195 °C,[40] 195.5—196 °C).[39] The naphthalenecarboxylic acid was converted to 7-methoxy-2-acetylnaphthalene, being distilled at 183—189 °C/5 mmHg, and was then recrystallized from hexane–benzene as colorless needles; mp 95.5—96.0 °C; NMR (CCl_4) δ=2.61 (3H, s, $COC\underline{H}_3$), 3.90 (3H, s, $OC\underline{H}_3$), and 7.1—8.2 (6H, m, Ar).

7-Bromo-2-acetylnaphthalene. 3-(*p*-Bromobenzoyl)propanoic acid (mp 148.5—150.5 °C; lit, 148—149 °C),[41] 4-(*p*-bromophenyl)butanoic acid (mp 68.5—69.5 °C; lit, 71—72 °C),[41] and ethyl 4-(*p*-bromophenyl)butanoate (bp 115—117 °C/2 mmHg) were similarly prepared as the corresponding Me and MeO derivatives. The ester condensation and successive cyclization of the ester (89 g) gave ethyl 3,4-dihydro-7-bromo-2-naphthalenecarboxylate, which was distilled at bp 140—153 °C/1 mmHg (35 g) and then recrystallized from hexane to afford the above named substance (mp 67—67.5 °C) as colorless crystals (30 g); NMR (CCl_4) δ=1.33 (3H, t, J=7.1 Hz, $CH_2C\underline{H}_3$), 2.4—2.9 (4H, m, $C\underline{H}_2C\underline{H}_2$), 4.21 (2H, q, J=7.1 Hz, $C\underline{H}_2CH_3$), and 6.9—7.3 (4H, m, Ar and olefinic); Found: C, 55.51; H, 4.42; Br, 28.53%. Calcd for $C_{13}H_{13}O_2Br$: C, 55.54; H, 4.66; Br, 28.42%.

The dihydronaphthalene was dehydrogenated with DDQ to give ethyl 7-bromo-2-naphthalenecarboxylate as colorless needles (recrystd from ligroin; mp 92.5—94 °C); NMR (CCl_4) δ=1.4_6 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 4.4_6 (2H, q, J=7 Hz, $C\underline{H}_2CH_3$), and 7.7—8.6 (6H, m, Ar); NMR ($CDCl_3$) δ=1.44 (3H, t, J=7.1 Hz, $CH_2C\underline{H}_3$), 4.45 (2H, q, J=7.1 Hz, $C\underline{H}_2CH_3$), and 7.6—8.5 (6H, m, Ar);[42a] C^{13}-NMR ($CDCl_3$) δ=14.40 ($CH_2\underline{C}H_3$), 61.38 ($\underline{C}H_2CH_3$), 120.80 (C_7), 125.93 (C_3), 128.27 (C_4),†,[42b] 129.00 (C_2), 129.59 (C_5),† 130.22 (C_1) 131.39 (C_8), 131.69 (C_6),† 133.84 and 134.03 (C_9 and C_{10}), and 166.60 ($\underline{C}OOEt$);[42b] Found: C, 55.93; H, 3.73; Br, 28.25%. Calcd for $C_{13}H_{11}O_2Br$: C, 55.94; H, 3.97; Br, 28.63%.

The alkaline hydrolysis of the ester afforded 7-bromo-2-naphthalenecarboxylic acid (mp 241—243 °C; lit, 238—240 °C),[40] which was similarly converted to 7-bromo-2-acetylnaphthalene, having been purified by distillation and then recrystallization from hexane; mp 94.5—95.5 °C; NMR (CCl_4) δ=2.6_5 (3H, s, $COC\underline{H}_3$) and 7.7—8.4 (6H, m, Ar).

1-(6- and 7-Substituted 2-naphthyl)ethanols and Their Chlorides. The alcohols and chlorides were prepared successively from the corresponding ketones with the standard method:[7,8a,18] (i) the reduction of the ketone with $LiAlH_4$ or $NaBH_4$ to give 1-(2-naphthyl)ethanol followed by (ii) the chlorination of the alcohol with dry HCl or $SOCl_2$ to provide 1-(2-naphthyl)ethyl chloride. The NMR data of 1-(7-substituted 2-naphthyl)-ethanols were as follows. 7-Me deriv; NMR (CCl_4) δ=1.47 (3H, d, J=6.3 Hz, $CHOHC\underline{H}_3$), 1.93 (1H, s, $O\underline{H}$), 2.48 (3H, s, $C\underline{H}_3$), 4.89 (1H, q, J=6.3 Hz, $C\underline{H}OHCH_3$), and 7.1—7.7

Table 2. Solvolysis data for 6- and 7-substituted 1-(2-naphthyl)ethyl chlorides in 80% aq acetone

a) Extrapolated from other temperatures by means of the Arrhenius equation. b) Previous value; 5.03 (5.18).[8a] c) Calculated from the LFER of (log k/k_0)$_{45\,°C}$ = 0.9436 (log k/k_0)$_{25\,°C}$ − 0.036 (r=0.9996, s=±0.057, n=5). d) For the 7-X-2 series, k_1=5.17×10^{-5} s^{-1} for the parent H-2 was used for the calculations of the relative rates because of the different batchs and different workers.

(6H, m, Ar). 7-MeO deriv; NMR (CCl_4) δ=1.48 (3H, d, J=6.4 Hz, CHOHC$\underline{H}_3$), 1.79 (1H, s, O$\underline{H}$), 3.85 (3H, s, OC$\underline{H}_3$), 4.89 (1H, q, J=6.4 Hz, C$\underline{H}$OHCH$_3$), and 7.0—7.7 (6H, m, Ar). 7-Br deriv; NMR (CCl_4) δ=1.49 (3H, d, J=6.4 Hz, CHOHC$\underline{H}_3$), 1.69 (1H, s, O$\underline{H}$), 4.94 (1H, q, J=6.4 Hz, C$\underline{H}$OHCH$_3$), and 7.4—7.9 (6H, m, Ar).

The physical properties and the microanalysis data of the ketones, alcohols, and chlorides are listed in Table 1.

Solvent and Kinetics: The 80% (v/v) aq acetone solvent was prepared by mixing 1 volume of deionized, distilled, and degassed water with 4 volumes of purified acetone at 25 °C, as has been described before.[7,8a,18] Different batches of the aq acetone solvent, which gave slightly different rate constants (Table 2), were employed without calibration for each series of measurements. The solvolysis reaction was followed by the usual titration method (chloride of *ca.* 0.02 M^{-1}, titer of *ca.* 0.02 M^{-1} aq NaOH, indicator of Bromocresol Purple). The bath temperature was controlled to $\pm$0.02 °C. At very low temperatures (−15 °C), the accuracy was estimated to be within 0.1 °C. The kinetic procedures were essentially the same as those reported before.[8a,45a]

All runs followed first-order kinetics, covering over 70—80% of the reaction, except for the 6-CN-2 derivative (50% reaction). The first-order rate constants were calculated by means of the least squares method using the mean infinity reading obtained after over 10 half-lives (corr coeff> 0.9999).[45b] The data points in a run were usually 12 points (2 for infinity reading), but in a few instances 7 points were used, covering up to *ca.* 70% of the reaction. The rate constants from duplicated runs were reproducible within $\pm$2% or better. Very reactive chloride, such as the 6-MeO-2 derivative, was used for the kinetic measurements immediately after the evaporation of the solvent and without purification.

The rate constants, $k_1(s^{-1})$, obtained at various temperatures are given in Table 2.

Results and Discussion

The logarithmic relative rates of 6- and 7-substituted 1-(2-naphthyl)ethyl chlorides with respect to the parent unsubstituted 2-naphthyl derivative in 80% aq acetone at 45 °C and 25 °C are summarized in Table 3, along with some activation parameters. The reaction conditions are our standard ones in our studies of a series of solvolysis reactions. The log k/k_0 values in Table 3 can, then, be directly compared with the other corresponding solvolysis sets in the phenyl,[8a] 4-biphenylyl,[5] 2-fluorenyl,[1] and 1-naphthyl systems.[7,18]

Table 3. log k/k_0 values for the solvolysis of substituted 1-(2-naphthyl)ethyl chlorides in 80% aq acetone

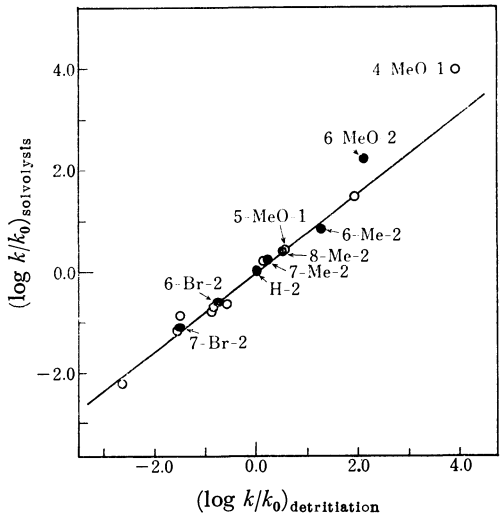

Fig. 1. A rate plot between the present solvolysis (45 °C) and the detritiation (70 °C) in the 2-naphthyl (closed circle) and in the 1-naphthyl (open circle) systems.

In the present 2-naphthyl series, the log k/k_0 varies widely not only with the substituent change, but also with the position change, just as in the 1-naphthyl series. Figure 1 shows a plot of the logarithmic relative rates for the present solvolysis, I (at 45 °C), against those for II (at 70 °C).[19a] Although common substituents are so limited, all the points except for the 6-MeO-2 derivative in the 2-naphthyl system (closed circle) fall on or near the line for the 1-naphthyl system (open circle).[18] The detritiation data for the 6-Cl-2 and 7-Cl-2 derivatives were employed in this figure instead of those for the Br derivatives.

The MeO group may be modified in CH_3COOH by hydrogen-bonding interaction, which appears to reduce mainly its ability to make a *pi*-electron donation.[18,46] The modification seems to be consistent with the fact that deviations are serious only in a strongly conjugative position, in which the *pi*-electronic contribution is important, but not appreciable in weakly conjugative (5-MeO-1) and essentially nonconjugative positions. The single correlation line for 1- and 2-naphthyl derivatives, except for such a single MeO group, reflects a similar blend of the *I*/*Pi* effects in the two naphthyl series between I and II.

On the contrary, Fig. 2 illustrates a plot of I (at 45 °C) against III (at 25 °C).[2a,20] Note that the plot does not show an overall linearity in the 2-naphthyl system from the MeO to the CN substituents (closed circle); the same is true in the 1-naphthyl system (open circle). This is similar to the plot of the σ^+ reactivity data against the σ values in the phenyl system: that is, (i) all the substituents at the conjugate position (7-MeO-2, 7-Br-2, 7-Me-2), the *pi*-acceptor ($+R$) substituents at the conjugate position (6-CN-2), and the unsubstituted one make a straight line, and (ii) the *pi*-donor ($-R$) substituents at the conjugate position (6-MeO-2, 6-Me-2, 6-Br-2) substantially deviate upward from the correlation line, the deviations depending upon the

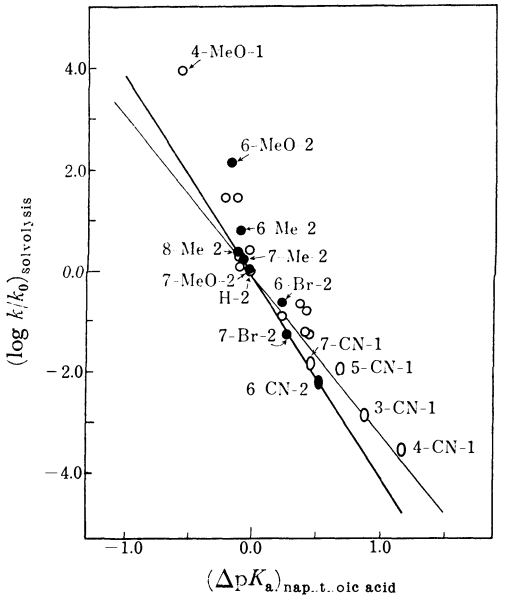

Fig. 2. A plot of the log k/k_0 in the present solvolysis (45 °C) *vs.* ΔpK_a in the corresponding naphthoic acids; closed circle for 2-naphthyl and open circle for 1-naphthyl systems.

order of the *pi*-donor ability: MeO>Me≥Br. Analogous phenomena have been observed in the 2-fluorenyl[1] and 4-biphenylyl systems.[5] As far as electrophilic reactivities are concerned, it can be generally deduced from extended *pi*-electron systems that the blend of the *I-Pi* effects of the donor substituents at the conjugate positions varies with the reactions of different electron demands, whereas the blend for acceptor substituents, even at conjugate positions, does not. All these facts are in line with the general features of the substituent effects observed in the Hammett-type treatment of general benzene reactivities.

The next feature of this figure is the separate slopes for the 2-naphthyl (a solid line) and 1-naphthyl (a fine line) systems; each line is drawn through the substituents for which no additional resonance exaltation effect can be expected. The slope for the 2-naphthyl system is 25% larger than that for the 1-naphthyl system. Any one of the three reactions (I, II, and III) has a higher sensitivity to the substituent changes in the 2-naphthyl than in the 1-naphthyl system. This probably arises from the different steric effects with the peri-hydrogen on the reaction center. Special care should be taken in the discussion of the apparent substituent constants in the 2-naphthyl system compared with the 1-naphthyl system, for example, the use of the ρ in the phenyl system. Since the ρ value for the solvolysis of 1-(3,4-X-1-naphthyl)ethyl chlorides (by LArSR or LSFE for 4-X-1) was found to be −5.1,[7] compatible with the ρ of −5.0 for the phenyl system,[8a] the separate lines in Fig. 2 imply the possibility that the treatment of the substituent effects for the dissociation of both 1- and 2-naphthalenecarboxylic acids with a single, common ρ[20] is not appropriate.

At the intermediate in the present solvolysis, where a positive charge is developed, the 6-X-2 naphthyl system can be stabilized by an extended quinoid structure throughout the A and B rings. The higher stability of 2,6-naphthoquinone than, for example, 1,7-naphthoquinone or 1,5-naphthoquinone[47] may tell us qualitatively of the larger contribution of such a 2,6-naphthoquinonoid structure. Our attempt to correlate the 6-X-2 reactivities with simple σ^+ parameters[48] appears to have been practically successful. It provides $\rho^+=-3.05$, with a correlation coefficient of 0.9990 ($s=\pm0.080$, $n=6$), suggesting quite a large *pi*-electronic exaltation effect in this series. The LArSR approach gives a more precise description (Fig. 3) by the use of:

$$\log k/k_0 = -3.275(\sigma_p^0+0.872\Delta\bar{\sigma}_R^+) - 0.053$$

with a corr coeff of 0.9997 and a standard deviation of ±0.044 ($n=6$).[49] On the basis of the ρ and r^+ values thus obtained, the LSFE ρ_i and ρ_π^+ values are estimated to be as listed in Table 4; the ρ_π^+/ρ_i ratio is *ca.* 3.1.

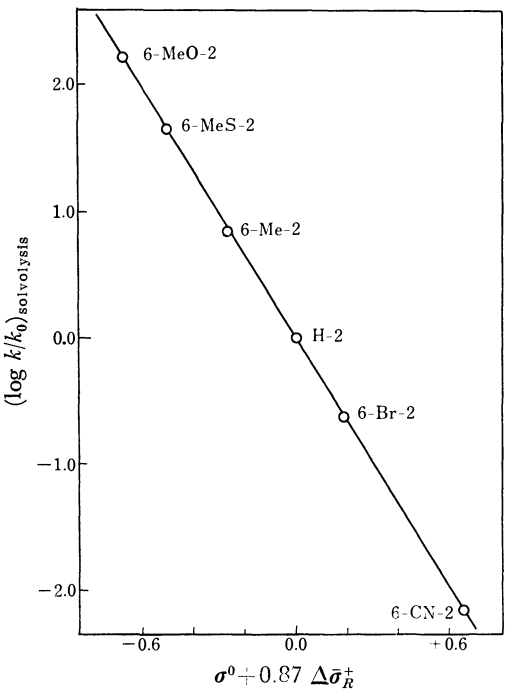

Fig. 3. The LArSR plot for the solvolysis of 6-substituted 1-(2-naphthyl)ethyl chlorides at 45 °C.

In the 7-X-2 naphthyl reactivities, there is no single σ-type parameter to describe the substituent effects. We arrived at the view that the effects for 7-X-2 of I may correlate well with the quantity of $(\sigma_p^0+\sigma_m)/2$ rather than with that of σ_p^0 or σ_m.[50] This indicates that the ρ_π^+/ρ_i ratio is close to 0.7 (rather than to 1.0 or 0.4).

For the present aim to ascertain the general features of the position dependency of the *I* and *Pi* components of substituents in extended *pi*-systems, it should be appropriate to use the LSFE approach, using their universal substituent constants. It would seem that a large number of data including both $-R$ and $+R$ substituents would give the most reliable statistical parameters of ρ_i, ρ_π^+, and ρ_π^- in LSFE Eq. 2 when three independent variables are used (σ_i, σ_π^+, and σ_π^-).[6,16,54] In the present cases, we have treated only *pi*-donor substituents and then utilized the simplified LSFE Eq. 5 for each substituent position in the naphthalene ring.

Table 4. Correlational parameters for the solvolysis of 1-(2-naphthyl)ethyl chlorides at 45 °C[a]

$\log k/k_0 = \rho_i\sigma_i + \rho_\pi^+\sigma_\pi^+ + (\rho_\pi^-\sigma_\pi^-)$

The regression parameters derived are given in Table 4. The substituent constants employed here are the same as those in previous reports.[18] The reliability of such statistically derived ρ_i and ρ_π^+ parameters depends greatly upon the variation in the electronic natures of the substituents as well as on those numbers.[2a,51,52] The present series involve four common, typical substituents—MeO, Me, Br, H. Such a variety should provide meaningful results for the present purpose.

In the case of the 6-X-2 naphthyl series, the parameters from LSFE Eq. 5 (without the CN group) agreed quite well with those from the LArSR treatment, including the CN group. The identity of the correlation parameters with and without the CN, associated with high correlation coefficients, suggests that the ρ_π^- value must be rather close to the ρ_i value. In a previous paper,[1] it has been demonstrated that the reactivities in the 6-X-2 naphthyl derivatives can generally be expressed by the LArSR approach, involving both *pi*-donor and *pi*-acceptor substituents (CN or NO_2). This means that $\rho_\pi^- \simeq \rho_i$ holds generally, as a good approximation, in spite of varying contributions by *Pi* effects of *pi*-donor groups.

To minimize the probability of an accidental correlation due to experimental error, *etc.*, we used here the correlation values of ρ_i and ρ_π^+, including the CN group, for wider coverage. The $-\rho_i$ value for 7-X-2 naphthyl has been shown to be larger than that for the 6-X-2 series. The $\rho_{i,6\text{-x-}2}/\rho_{i,7\text{-x-}2}$ ratio is calculated to be 0.85 by the use of −3.3/−3.9; this value is in good agreement with the $\rho_{i,para}/\rho_{i,meta}$ value of 0.85, but it seems to be slightly larger than the relevant values of $\rho_{i,6\text{-x-}1}/\rho_{i,7\text{-x-}1}$ or $\rho_{i,6\text{-x-}1}/\rho_{i,5\text{-x-}1}$ of *ca.* 0.75 in the 1-naphthyl series (see also Table 5).[18] It is apparent that the *I* effect of substituents from the 7-position is more effectively transmitted than that from the 6-position in the 2-naphthyl system. This can reasonably be related to the shorter distance or less intervening sp^2-carbons in the 7-X-2 system than in the 6-X-2 system. On the other hand, the resulting $-\rho_\pi^+$ for the 6-X-2 is larger by a factor of 3 than that for the 7-X-2 system; this is in qualitative accord with the prediction from MO calculations.[2a,3,19b,20,23]

In Table 5 are collected the full sets of ρ_i and ρ_π^+ values derived from our solvolysis rates. Figure 4 gives the overall correspondence of the empirical ρ_i sets to Dewar's $1/r$ function, which has been shown to be appropriate for 1-naphthyl reactivities.[18] The figure seems to justify again the soundness of the simple function, covering a wide enough range, from the phenyl to the 2-fluorenyl system. Although the deviation of the 7-X-2 naphthyl appears to be slightly large, no other complicated functions, such as $(\cos\theta)/r^2$ (Table 5), can provide any appreciable improvement in the correlation. Therefore, it is apparent that the angle factors are unimportant. Herein, the *r* refers to Dewar's simplest distance between the naphthyl carbons to which substituents and reaction site are attached,[3a] and θ is the angle between the above distance vector and a C–X dipole vector. It is characteristic that, instead of the 4-biphenylyl sets which had previously

a) Calcd with $\rho_i = \rho$, $\rho_\pi^+ = \rho(1 + r^+/0.415)$.[1] b) Calcd with $\rho_{i,meta} = 1.17\rho_{i,para}$.[15] c) The temperature factor of 0.957 was used from 25 °C to 45 °C.[5] d) See Text. e) Ref. 23b. f) Present study.

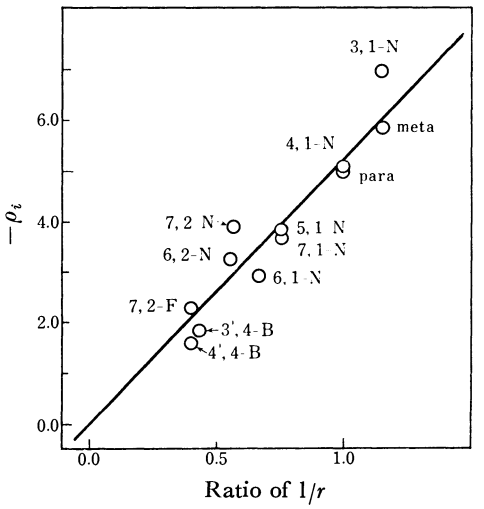

Fig. 4. A plot of the ρ_i values *vs.* a ratio of Dewar's $1/r$; N(Naphthyl), F(Fluorenyl), and B(Biphenylyl).

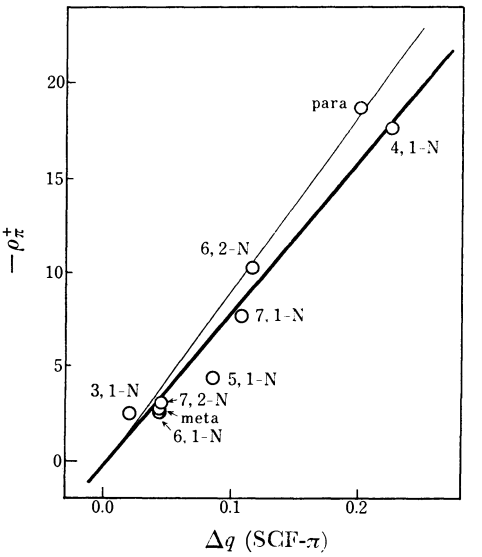

Fig. 5. A plot of the ρ_π^+ values *vs.* Δq of Forsyth's charge difference values by PPP SCF-π method.[23b]

been applied to Dewar's FM equation,[3a] the planar 2-fluorenyl set fits the line much more closely (Fig. 4). This observation is not inconsistent with our earlier conclusion of the $1/R^2$ dependence of the *I* effect in the 4-biphenylyl relative to the phenyl system.[5] Even bearing the crudeness of the approximation in mind, the inductive effect in various extended *pi*-systems for the present solvolysis series may be explicable in terms of Dewar's $1/r$ parameter (to a practical approximation) if the *peri*-hydrogen steric effect does not exert any observable effects on the ρ_i values. This conclusion will be further evaluated on the basis of available solvolysis data for heteroaromatics (see below).

In the solvolysis of 6-substituted bicyclo[4.4.0]dec-2-yl tosylates, which constitute a good model of the 6-X-2 naphthyl sigma skeleton, Tanida *et al.* suggested the importance of the field effect based upon the rate ratio of $k_{ax}/k_{eq}=0.7$—0.9.[55]

Previously, we noted a good relationship between the ρ_π^+ values and Forsyth's theoretical Δq_{ij} values (the regional charge difference at a substituent position).[53] Resently, Forsyth, Spear, and Olah have reported extensive sets of Δq; the change in charge density for the process of Ar→ArCH$_2^+$ was calculated by the use of a PPP SCF-π method.[23b,58] Figure 5 illustrates the correspondence between the empirical ρ_π^+ and the charge difference (Δq), giving two lines covering the 1- and 2-naphthyl and phenyl sets. The higher-slope line involves 4-X-1 phenyl and 6-X-2 naphthyl groups, while the lower line involves 4-X-1 naphthyl and 7-X-1 naphthyl groups; the four ρ_π^+ values of these groups are more reliable than the other groups in Fig. 5 because of their wider coverage of the reactivity change. The MO calculations do not involve any accounts of the steric effects. The separate response (Fig. 5) is explicable; that is, the 1-naphthyl ρ_π^+ sets, appreciably 4-X-1 and 7-X-1, are influenced more efficiently by steric effects caused by *peri*-hydrogen and give lower ρ_π^+ values than would be expected with other steric-free sets.

As a conclusion, the good coincidence between the empirical and theoretical coefficients with respect to the *I* and *Pi* effects, covering a wide range of *pi*-systems, provides evidence justifying the validity of the description of the substituent effects in terms of the *I* and *Pi* effects by means of the LSFE equation.

The LSFE approach has been further tested for other reactions[59] or other extended *pi*-systems: the III, IV, and the (V) solvolysis of 1-(2-benzofuryl)ethyl *p*-nitrobenzoates,[22] the (VI) solvolysis of 1-(2-benzo[*b*]-thienyl)ethyl *p*-nitrobenzoates,[23] the (VII) acetolysis of 2-(1-azulenyl)ethyl tosylates,[56a] and the (VIII) dissociation of 1-azulenecarboxylic acids.[56b] The correlation results are summarized in Table 6, in which almost all the series provide very satisfactory correlations ($R>0.995$).[61] Since common substituents are involved in most cases, the correlation parameters (ρ_i, ρ_π^+) can be estimated with a similar reliability without paying attention to improper substituent constants in certain groups.

In the case of the III and IV reactions, the $\rho_{i,7\text{-x-}2}$ is apparently larger than the $\rho_{i,6\text{-x-}2}$ and the $\rho_{i,6\text{-x-}2}/\rho_{i,7\text{-x-}2}$ ratio is calculated to be 0.85 for III and 0.87 for IV. The features are in line with that for the I solvolysis. The identical ρ_i ratio of 0.85, in spite of the obviously different amount of the *Pi* effect, means that the *I* effect in the 2-napthyl system also remains the position constant. At present, the meaning of the difference between the factor of the present 0.85 in the 2-naphthyl and the previous 0.75 in the 1-naphthyl[18] is not clear. The other sets of solvolysis data, such as for the 5-X-2 and 8-X-2 naphthyl systems, will clarify the significance of such a figure for the entire B-ring positions.

With this purpose in mind, the 2-benzofuryl and 2-benzothienyl reactivities have been chosen. These heteroaromatic systems are similar to the 2-naphthyl system; an oxygen or sulfur atom substituted for the CH=CH group. The empirical $-\rho_i$ values for 5- and 6-substituent positions in the two heteroaromatics are nearly equal: 4.1 ± 0.1 for V and 4.1 ± 0.2 for VI.

Table 6. Correlational parameters for reactivities in 2-naphthyl and relevant systems

	Reaction type[a]	Condition	Subst position	Method[b]	ρ_i	ρ_π^+	R	Subst and note

a) See text. b) A: Analysis with LSFE Eq. 2, B: with LSFE Eq. 5, C: calculation by means of the parameters of LArSR Eq. 1. c) $\rho_\pi^-=(0.96)$. d) Without OH; $\rho_\pi^-=(0.56)$. e) $r^+=0.17$[1] was used for the interconversion. f) Without NH_2; too limited data set. g) Too limited data sets for the 5-X-3 and 6-X-3 benzofuryl systems;[57] further, the data for the pK_a of 5,6-X-benzofurancarboxylic acids are not sufficient.[60] h) The log k/k_0 value for MeO (=0.53) was corrected and used; $(\log k/k_0)_{\text{benzofuryl}}=0.9842(\log k/k_0)_{\text{benzothienyl}}+0.013$. i) $\rho_\pi^-=-3.3$. j) $\rho_\pi^-=1.9$.

On the other hand, the $-\rho_i$ values for the 4- and 7-positions in the benzothienyl system are also nearly the same as the value of 4.9 ± 0.2 for VI. The ratio of the values is calculated to be 0.84 (by 4.1/4.9), identical with the position constant in the 2-naphthyl system. The ρ_i values thus obtained by the use of LSFE Eq. 5 may again be concluded to furnish the simple $1/r$ dependency well. Previously, Wells and Adcock argued for the requirement of some angle function, $(\cos\theta)/R^2$, in particular for the dissociation of the 8-X-2 naphthalenecarboxylic acids.[20] The orientational effect, if operative, may be expected to be relatively more important in the 4-X-2 benzothienyl system than in the 8-X-2 naphthyl system because of the larger angle of θ.[23a] However, no orientational factor can be detected in the present results. Further, the azulyl system gives a constant ratio of $\rho_{i,6\text{-x-}1}/\rho_{i,3\text{-x-}1}$ (0.84 for VII and VIII), independent of the different *Pi* effects. Since the reactivities are concerned with nonconjugate positions in the azulyl ring, more data at the conjugate positions would be of much interest.

From the values of ρ_π^+ relative to ρ_i in the series of the 2-benzothienyl system in Table 6, the 6-X-2 system ($\rho_\pi^+/\rho_i=2.8$) can be regarded as a system involving a strong *Pi* exaltation effect. Though the 7-X-2 benzothienyl system (0.7) also shows less exaltation than σ_p^0, as in the case of the 7-X-2 naphthyl, the 4-X-2 (1.4) and 5-X-2 (1.2) systems belong to the intermediate class, with a moderate *Pi* exaltation. These observations indicate the requirement of different resonance parameters of σ_R^+, σ_R^0, and σ_R(BA) for the respective sets to achieve the best fit to Taft's DSP Eq. 4. Generally speaking, however, there is no definite rule for the choice of the most appropriate parameters, especially for any intermediate class of reactivity ($\rho_\pi^+/\rho_i=2$—2.5). Since a different choice of $\bar{\sigma}_R$ causes different $\bar{\rho}_R$ values, the comparison of $\bar{\rho}_I$ and $\bar{\rho}_R$ between different sets of reactivity classes may be difficult. The present ρ_π^+ values, obtained for VI, satisfy not only the sequence, but also the magnitude of Δq, Forsyth's charge difference.[23a]

As has been mentioned before by us[18] and by others,[4] Dewar's FM[3] and many other modified methods for extended *pi*-systems[19,20,23] have, *a priori*, assumed transmission coefficients, especially for *Pi* effects, obtained by means of MO calculations and have then defined the substituent constants to fit the corresponding original phenyl set of reactivities. Although this kind of approach is successful with a very limited reactivity class, the approach can never handle variations in *Pi* effects depending on the types of reactions without any changes in substituent constants and/or model calculations.

In summary, it may be concluded that the electrophilic reactivity sets at B-ring positions in the 2-naphthyl and relevant extended systems can be adequately described by means of the LSFE equation. The resulting empirical ρ_i and ρ_π^+ parameters are reasonably correlated with certain physical properties characteristic of the system and are not inconsistent with our earlier conclusions with regard to the 1-naphthyl and other reactivities. The present discussion has been concerned

with the *pi*-donor substituents in electrophilic reactivities, but the treatment seems likewise promising for *pi*-acceptor substituents in nucleophilic reactivities.[50] We believe the present results provide further evidence for the significance of the LSFE equation as well as for the applicability of the universal substituent constants, independent of the reactivity classes.

25) All the mp's are uncorrected, as are the bp's. Elemental analysis was performed at the Material Analytical Center in ISIR, Osaka Univ. The IR absorption spectra were routinely recorded, to check the characteristic functional groups of the compounds prepared, on a JASCO model IR-G grating infrared spectrophotometer under neat or nujol conditions. Further, for most compounds, their purity was routinely checked with GLC or TLC (on silica gel). Analytical GLC was carried out on a Varian Aerograph, Model 2860-30, equipped with an integrator, using a column packed mainly with apieson grease L or silicone DC550 on Celite 545 (a TCD or FID mode detector was employed).

The proton NMR spectra were obtained using a Hitachi R-20 or R-24 spectrometer (60 MHz, CW) or JEOL JNM-FX100 (100 MHz, FT), with TMS as the internal standard. The carbon-13 NMR spectra were also obtained with the latter spectrometer at 25 MHz (FT). The chemical shifts are given in ppm downfield from TMS (δ value).

A programable Seiko 500 calculator was used to get k_1 and various correlational parameters by means of the least-squares method. For triple regression analysis, a Hewlett Packard 9821A calculator was employed.

The Transformation of 11-Deoxojervine into 18-Functional *C*-Nor-*D*-homosteroids[1,2]

Hiroshi SUGINOME,* Norio SATO, and Tadashi MASAMUNE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 23, 1979)

Deoxojervine, a *C*-nor-*D*-homosteroidal alkaloid, has been transformed into 17β-acetyl-12α-etiojervan-3β-ol acetate in 3 steps. Treatment with base gave the 17α-epimer. Reduction of the 17β-isomer with $NaBH_4$ afforded 17β-ethyl-12α-etiojervane-3β,20β-diol 3-acetate as a single product whereas reduction of the 17α-isomer afforded 17β-ethyl-12α-etiojervane-3β,20β-diol 3-acetate and the 20α isomer in an approximate 1 : 1 ratio. Irradiation of 17β-ethyl-12α-etiojervane-3β,20β-diol 3-acetate in cyclohexane in the presence of lead tetraacetate and iodine afforded a C-18 functional *C*-nor-*D*-homosteroid as a 18,20-epoxide which was oxidized to the corresponding γ-lactone with chromium trioxide. A mixture of the 17α-ethyl-12α-etiojervane-3β,20α-diol 3-acetate and its 20β isomer in contrast gave no 18-functional compounds upon irradiation under similar conditions.

Selective functionalization of inactive angular methyl groups by processes, which involve intramolecular free radical reactions[3] have been proven to be successful in steroids. There exists, however, no studies on the functionalization of inactive methyl groups by intramolecular radical processes in the field of *C*-nor-*D*-homosteroids. In this and subsequent papers the functionalization of the 13β-methyl group in the *C*-nor-*D*-homosteroid, derived from jerveratrum alkaloids by this process will be reported. These C-18 functional *C*-nor-*D*-homosteroids may be of value in further transformations of this important group of steroids.

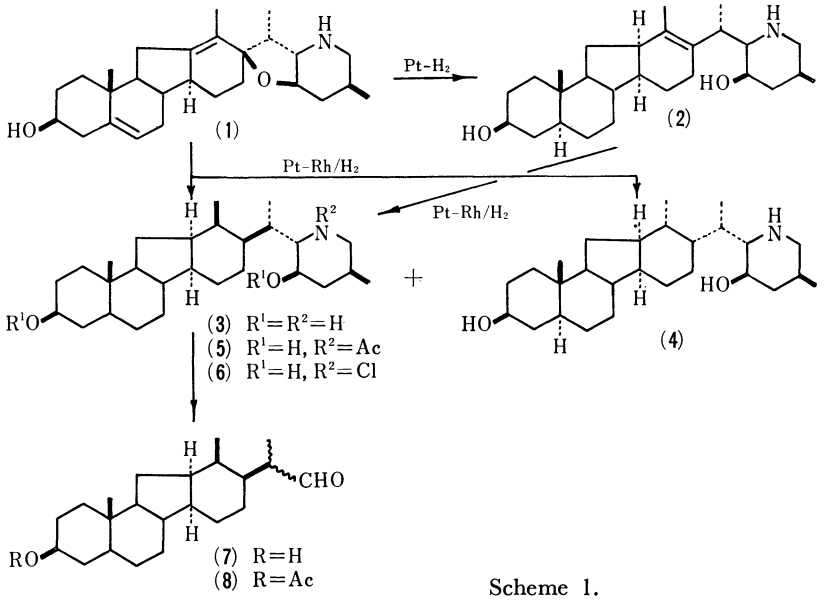
Results

Catalytic hydrogenation of tetrasubstituted double bonds in (22*S*,25*S*)-5α-veratr-13(17)-enine-3β,23β-diol (**2**), prepared by the platinum-catalyzed hydrogenation[4] of 11-deoxojervine (**1**),[5] was affected using a rhodium–platinum catalyst.[6] The perhydro derivative (**3**), mp 219—221 °C, was obtained in a 35% yield. The NMR spectrum of **3** exhibited a 3-H singlet at τ 9.20 due to the 19-H, and three 3-H doublets centered at τ 9.23 (J=*ca.* 6 Hz, a signal of the doublet coincided with 19-H), 9.11 (J=6.3 Hz) and 8.99 (J=6.3 Hz) due to the three secondary methyl groups. At lower field, after D_2O exchange, a broad 2-H multiplet at τ 6.47, attributable to the 3α-H and the 23-αH, a 1-H doublet at τ 7.52 (J=9.6) and a 1-H double doublet at τ 7.08 (J=12 and 4) presented themselves. Irradiation at τ 6.47 caused the doublet at τ 7.52 to collapse to a singlet and thus the doublet has been assigned to the 22β-H. The double doublet is then assignable to one of the 27-methylene protons. The stereochemistry was assumed to be (22*S*,25*S*)-5α-veratranine-3β,23β-diol (**3**) on the basis of the *cis* addition of hydrogen atoms to an isolated olefinic center from the less-hindered side of steroid molecules and confirmed by its transformation into 17β-acetyl-12α-etiojervan-3β-ol[7] (**10**) identical with a specimen derived from a *C*-nor-*D*-homosapogenin by Johns and Laos.[8] The configurations at C-12, C-13, and C-17 in the 3β-ol **10** were established by further transformations as described later in this paper.

It was subsequently found that the diol **3** could be directly obtained by the catalytic hydrogenation of 11-deoxojervine in the presence of a rhodium–platinum catalyst or a large amount of Adams' platinum catalyst in acetic acid. From the hydrogenation product using the rhodium–platinum catalyst, perhydro compound (**4**), mp 178—180 °C, isomeric with the diol **3** was isolated in a 4% yield. The NMR spectra of **4** and compound **3** were very similar exhibiting a 3-H singlet at τ 9.25 due to the 19-H, and 4 singlets due to the overlap of three doublets centered at τ 9.13 (J=6), 9.08 (J=6), and 9.00 (J=6) assignable to three secondary methyl groups. A broad 2-H multiplet at τ 6.47 attributable to an overlap of the 3α-H and the 23-αH, a 1-H doublet at τ 7.73 (J=9.9 Hz, 22-βH), and a 1-H double doublet after D_2O exchange at τ 7.03 (J=12 and 4, one of 27-CH_2) were also present further downfield in the spectrum. No evidence is available on the configurations at the C-13 and the C-17 centers, but the structure has been tentatively assigned as (22*S*,25*S*)-5α,13α,17α-veratranine-3β,23β-diol (**4**) resulting from *cis* addition of hydrogen atoms from a more-hindered side.

The heterocyclic ring of diol **3** was removed by the procedure devised by Frank and Johnson.[9,10] Treatment of the diol **3** in dry THF with *N*-chlorosuccinimide for 1 h in an atmosphere of nitrogen afforded a *N*-chloro derivative (**6**). This was treated *in situ* with sodium methoxide in methanol for *ca.* 24 h at 0—10 °C to afford an aldehyde (**7**), mp 109—110 °C, in a 95% yield. The NMR spectral data was in agreement with the structure assigned. The mass spectrum exhibited a base peak at *m/e* 274 resulting from a loss of the C-17-substituent from the molecular ion involving a McLafferty rearrangement of a γ-hydrogen.

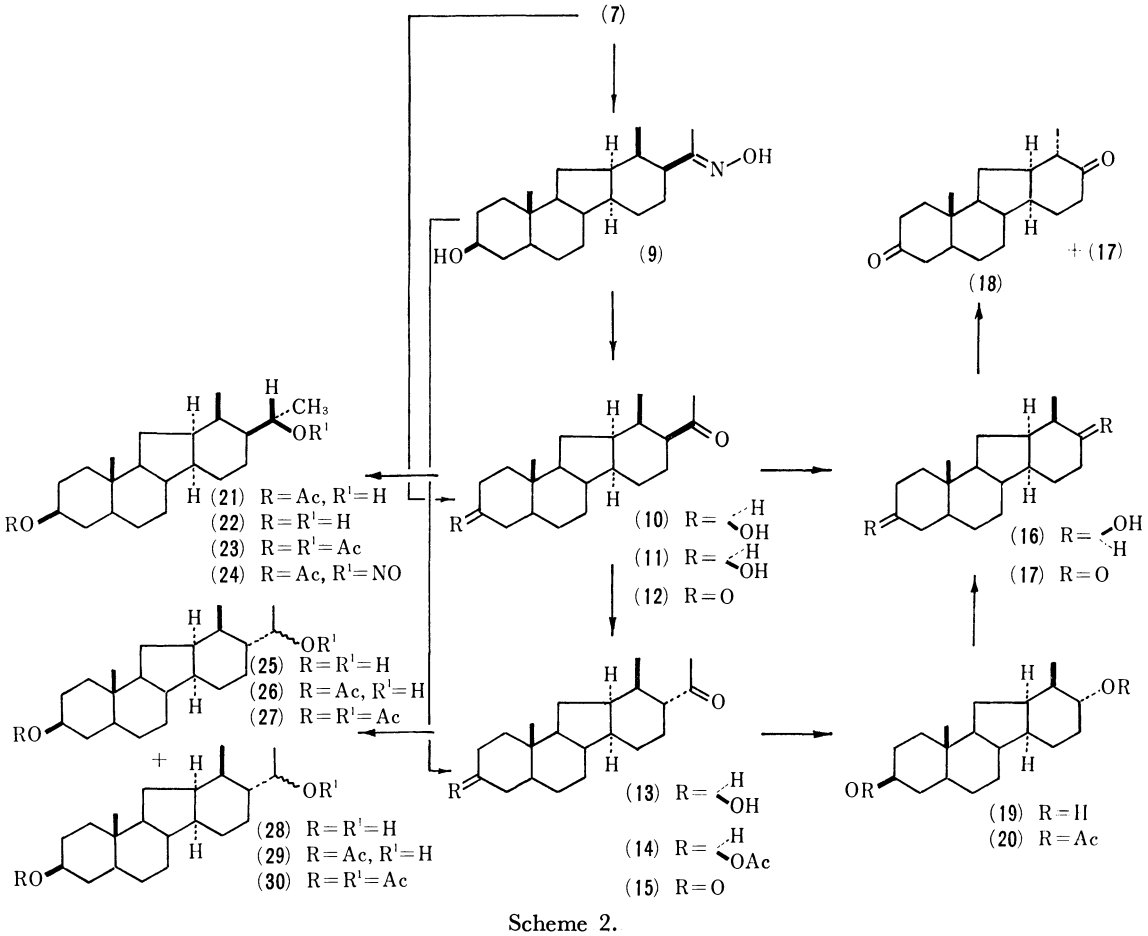
Treatment of the aldehyde **7** in THF with butyl nitrite in the presence of sodium methoxide afforded a ketone (**10**), mp 150—152 °C, in a 90% yield. Upon acetylation and oxidation with Jones reagent the 3-acetate (**11**), mp 116—118 °C, and a 3-one (**12**); mp 158—160 °C, were formed. The ketone **10** and acetate **11** were identical with the specimens[8] kindly provided by Dr. Johns. The corresponding oxime (**9**), mp 106—109 °C, which is characteristically obtained as the product in this reaction,[9] was isolated in only one experiment. Hydrolysis of the oxime with aq ethanolic HCl under reflux, however, gave an isomeric ketone which was identical with the ketone (**13**) obtained by treatment of the ketone **10** with base. It is assumed



Scheme 1.

to be epimeric with the ketone **10** at the C-17.

The configurations at C-12 and C-13 in methyl ketone **10** have been established by Johns and Laos by transformation into 12α-etiojervane-3,17-dione (**17**) by Baeyer-villiger oxidation, followed by hydrolysis and oxidation with Jones' reagent. Repetition of these experiments afforded a diol (**16**)[11] and a dione (**17**) which were identical with the specimens prepared by Johns and Laos from a *C*-nor-*D*-homosapogenin, by direct comparison. As described by Johns and Laos,[8] treatment of the dione **17** with methanolic 5% KOH for 1 h under reflux resulted in partial epimerization at C-13 and afforded an equilibrium mixture of 12α-etiojervane-3,20-dione **17** and 12α,13α-dione (**18**). Recrystallization of this mixture from aq acetone afforded a pure dione **18**, mp 136—140 °C, identical with a specimen obtained from *C*-nor-*D*-homosapogenin by Johns and Laos.[8] The configurations at the C-17



Scheme 2.

centers of methyl ketone **10** and consequently the diol **3**, and the aldehyde **7**, were confirmed as β on the basis of the following epimerization experiments.

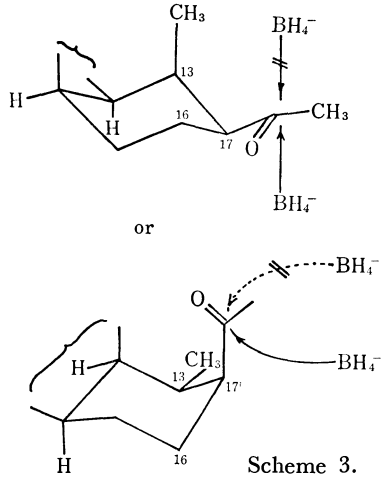
Treatment of the methyl ketone **10** with methanolic potassium hydroxide (2.5%) for 12 h at room temperature gave an isomeric ketone **13**, mp 140.0—141.5 °C, the acetate (**14**), mp 88.0—90.0 °C, of which was isomeric with methyl ketone acetate (**11**).

On Baeyer-Villiger oxidation, the isomeric ketone **13** afforded a new diol (**19**), mp 179.0—179.5 °C, which gave an acetate (**20**), mp 96—98 °C. The diol **19** was shown to be epimeric at C-17 with the diol **16** in that Jones' oxidation of the diol **19** afforded the dione **17** identical with the dione obtained by oxidation of the diol **16**. The D-ring of the ketones **10** and **13** is assumed to adopt one of four possible conformations, two *quasi* chair and two *quasi* boat forms. Regardless of these conformations, the 13β-methyl and the 17-acetyl substituents in the more stable ketone **13** will occupy more stable equatorial positions.

It follows that the 13β-methyl and the 17-acetyl substituents in the D-ring of the less stable ketone **10** and hence in the aldehyde **7** and the diol **3**, should be either in β-equatorial and β-axial or in β-axial and β-equatorial orientations. Thus, the isomerization of methyl ketone **10** into methyl ketone **13** demonstrates that the two substituents at C-13 and C-17 in the D-ring of compounds **3**, **7**, and **10** are oriented in the *cis* direction. The structures of the isomeric diols **16** and **19** have thus been assigned as 12α-etiojervane-3β,17β-diol and 12α-etiojervane-3β,17α-diol respectively.

Reduction of methyl ketone **11** with $NaBH_4$ in a mixture of ethanol and ethyl acetate gave a single product (**21**), mp 126—129 °C, in greater than 95% yield. Under these conditions both the 3β-ol (**22**) and the 20ξ-epimer of **21** were not formed. Hydrolysis and acetylation of the 20ξ-ol afforded 3β,20ξ-diol, mp 252—254 °C, and the diacetate (**23**), mp 84.5—87.0 °C.

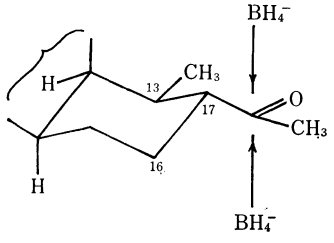
Reduction of isomeric 17α-acetyl-12α-etiojervan-3β-ol acetate with $NaBH_4$ under similar conditions afforded a mixture of 20ξ-ols (**26**)[4] and (**29**) which was hydrolyzed to a mixture of 3β,20ξ-diols. Separation by preparative TLC afforded 3β,20ξ-diol (**25**), mp 140.0—140.5 °C, and isomeric 3β,20ξ-diol (**28**), 187—189 °C, in 38 and 41% yields respectively.



Scheme 3.

No unambiguous spectral evidence with regard to the configurations of the hydroxyl group in the C-17 side chain of the etiojervanes (**21**, **26**, and **29**) was available. The stereochemistry can however be reasonably explained by considering the steric course of the reduction with complex metal hydrides. Examination of models of 17β-acetyletiojervane **11** indicates that regardless of the *quasi*-chair or *quasi*-boat conformation of the D-ring, the preferred conformation of the 17β-acetyl group would be such that the C=O bond eclipses the C-16–C-17 bond when the 13-methyl is axial and the 17β-acetyl is equatorial. Alternatively, with the 13-methyl equatorial and the 17β-acetyl group axial, the preferred conformation is for the carbonyl to lie orthogonal to the C-16–C-17 bond. In the former case, hydride ion attack would occur predominantly from the α-face due to the presence of the 13β-methyl group (steric approach control)[12] giving predominantly the β-ol **21** (Scheme 3). In the latter case, the hydride ion would attack predominantly from the front, and aided by the presence of the 13β-methyl and the predominant product would be the β-ol **21** (Scheme 3). In such cases, formation of the α-ol is unlikely.

The situation is analogous to the reduction of 20-oxopregnanes with complex metal hydrides where the predominant product is the 20β-isomer.[13]



Scheme 4.

Examination of the model of 17α-etiojervane in which the 13β-methyl and the 17α-acetyl both occupy equatorial positions, shows that the preferred conformation of the 17α-acetyl group is when the C=O bond eclipses the C-13–C-18 bond in order to minimize the interaction between the skeletal part and the C-17 acetyl methyl. Thus, the hydride ion can approach the C=O bond equally from both the α- and β-sides affording a 1: 1 mixture of the observed α- and β-ols **26** and **29** (Scheme 4).

20β-ol **21** in pyridine readily afforded a crystalline nitrite (**24**), mp 102—106 °C, by treatment with nitrosyl chloride–pyridine.

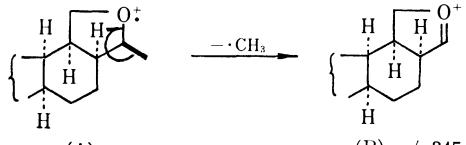
Irradiation of the nitrite in benzene for 230 min under an atmosphere of nitrogen afforded a mixture of products. The product, hydrolyzed with methanolic 5% potassium hydroxide at room temperature and subjected to recrystallization and preparative TLC afforded 3β,20β-diol **22** (23%) and 17β-acetyl-3β-ol **10** (15%).

Examination of the NMR spectra of the other fractions from the preparative TLC failed to identify the 18-functionalized derivative. The failure in obtaining the 13β-methyl functionalized product contrasts with the results for the normal steroids.[14]

Functionalization of the 13β-methyl in the 20β-ol **21**

was, however, achievable by the hypoiodide reaction (Scheme 5). Thus, 20β-ol **21** in cyclohexane containing iodine and lead tetraacetate was irradiated for 0.5 h with a 450 W high pressure Hg arc. Preparative TLC of the product afforded a crystalline 18,20-epoxide (**32**), mp 76—79 °C, resulting from intramolecular hydrogen abstraction, (16% yield) together with an amorphous substance (**31**). The NMR spectrum of the former exhibited two 3-H singlets at τ 9.22 and 7.98 which have been assigned 10β-methyl and OAc and a 3-H doublet (J=6.3 Hz) at τ 8.75 which has been assigned to the methyl attached to a carbon having an ether oxygen. The spectrum disclosed the absence of a signal attributable to the 13β-methyl and the presence of a multiplet due to the AB part of the ABX system from τ 5.88 to 6.91 ascribable to the 18-methylene protons. The mass spectrum was in full accordance with the epoxide structure (**32**). Thus, the prominent fragment ions (B) at *m/e* 345 (65%) and 285 (73%, $M^+-CH_3CO_2H-CH_3$) result from the expulsion of a methyl group from the molecular ion (A) and the molecular ion peak at *m/e* 360 (2%) and base peak at *m/e* 300 arise from the loss of acetic acid from the molecular ion. The amorphous substance **31** exhibited aromatic and cyclopropane protons in the NMR spectrum and contained iodine. No satisfactory structure has been evaluated for this compound.

Oxidation of (20*S*)-18,20-epoxy-17β-ethyl-12α-etiojervane-3β,20β-diol 3-acetate (**32**) with chromium trioxide afforded the corresponding γ-lactone (**33**), mp 89—90 °C, characterized by IR and NMR spectra [10β-methyl at τ 9.15 and 20ξ-methyl at τ 8.60 (J=6.0



(A) (B) *m/e* 345 and 285

a) Measured by 100 MHz instrument.

Hz)], in 19% yield.

A mixture of the isomeric 20ξ-ols (**26**) and (**29**) was subjected to the hypoiodite reaction but no 18-functional compound resulting from intramolecular hydrogen abstraction was obtained.

The foregoing results demonstrate that the functionalization of the 13β-methyl group in *C*-nor-*D*-homosteroids may be achieved by intramolecular hydrogen abstraction of the 20β-oxyl radical attached to the C-17β alkyl but not by 20α and 20β-oxyl radicals attached to the C-17 α-alkyl group.

Experimental

All melting points were determined with a hot-plate (Yanagimoto micro melting point) apparatus and are uncorrected. Unless stated otherwise, IR spectra were determined in Nujol with a JASCO DS-402G or JASCO model IR-E spectrophotometer. Unless stated otherwise, NMR spectra were determined with a JEOL 3H-60 high resolution spectrometer in deuteriochloroform solution using TMS as an internal reference. The course of reaction and column chromatography were followed by thin layer chromatography with Wakogel B-5. Mass spectra were determined with a RMU-6E spectrometer with the exception of the MS of compound **21** which was determined with a Hitachi JMS-D 300 spectrometer.

Catalytic Hydrogenation of (22S,25S)-5α-Veratr-13(17)-enine-3β,23β-diol (2). The diol **2** (1 g) in acetic acid (30 ml) containing a rhodium–platinum oxide catalyst (2 g) was hydrogenated with stirring. The theoretical amount of hydrogen was absorbed in 22 h. After the removal of the catalyst, the filtrate was made alkaline by the addition of aq 10% sodium carbonate solution. To the solution was added chloroform and the chloroform complex obtained was recrystallized from acetone to yield (22*S*,25*S*)-5α-veratratranine-3β,23β-diol (**3**), identical with the diol obtained by catalytic hydrogenation of 11-deoxojervine.

Catalytic Hydrogenation of 11-Deoxojervine (1). (a) Rhodium–Platinum Catalyst: 11-Deoxojervine (8 g) in glacial acetic acid (130 ml) containing rhodium–platinum oxide[6] (2.69 g) was hydrogenated with stirring. The absorption of hydrogen practically ceased after 69 h. The catalyst was removed by filtration and washed with hot methanol. The filtrate and methanol washings were combined and the solution concentrated. To this solution methanol was added followed by methanolic potassium hydroxide and finally a small volume of water to afford crude crystals of diol **3**. The total weight of crystals obtained (5 crops) was recrystallized to afford the pure diol (2.88 g). Specimens for analysis were obtained by recrystallization from methanol, mp 219—221 °C. IR: 3274 and 3338 (OH and NH), 1038, and 968 cm^{-1} NMR, see text. Found: C, 77.78; H, 11.25; N, 3.42%. Calcd for $C_{27}H_{47}O_2N$, C, 77.64; H, 11.34; N, 3.35%; MS (80 eV), *m/e* (rel. intensity) 417 (0.2, M^+), 402 (0.3, M^+-CH_3), 399 (0.4, M^+-H_2O), 384 (0.8, $M^+-CH_3-H_2O$), and 114 (100, ). The residue from the filtrate was dissolved in acetone and to this solution a small volume of methanol was added to afford the crystals on standing. Recrystallization from aq methanol gave (22*S*,25*S*)-5α,13α,17α-veratranine-3β,23β-diol (**4**) (0.36 g). Specimens for analysis were obtained by recrystallization from acetone. Mp 178—180 °C: IR: 3112—3432 (OH and NH), 1040, and 883 cm^{-1}; NMR, see text. Found: C, 78.11; H, 11.27; N, 3.33%. Calcd for $C_{27}H_{47}O_2N$, C, 77.64; H, 11.34; N, 3.35%; MS (80 eV), *m/e* (rel. intensity), 417 (0.3, M^+), 402 (0.4, M^+-CH_3), 399 (0.5, M^+-H_2O), 384 (1.1, $M^+-CH_3-H_2O$), and 114 (). The yields of diol **3** from of hydrogenation conducted under different ratios of substrate and catalyst and under different concentrations, are tabulated below.

Weight ratio between deoxojervine and the catalyst	Concentration of deoxojervine (g/100 ml)	Yield of diol **3** (%)
1:0.3	5.0	39
1:0.33	6.2	36
1:0.66	5.0	42
1:1	3.3	46
1:1.4	2.5	46

(b) Platinum Catalyst: 11-Deoxojervine (2.0 g) in glacial acetic acid (20 ml) containing Adams platinum oxide (0.68 g) was hydrogenated for 60 h under atmospheric pressure with stirring. The solution was worked up as described in procedure (a). The diol **3** obtained, was recrystallized from methanol (0.613 g).

Preparation of N-Acetyl-(22S,25S)-5α-veratranine-3β,23β-diol (5). The diol **3** was acetylated with acetic anhydride and pyridine at 60—70 °C for 3 h. After the usual work-up, an amorphous 3-*O*,23-*O*,*N*-triacetyl derivative of diol **3** [NMR τ 9.20 (3-H, s, 19-H), 7.84 and 7.95 (3-H and 6-H, s, N–Ac, and OAc)] was obtained. This triacetyl derivative was hydrolyzed with methanolic 2.5% potassium hydroxide at room temperature overnight. The usual work-up afforded the *N*-acetyl derivative **5** which was recrystallized from aq acetone. Mp 227—229 °C: IR: 3153 and 3429 (OH), 1602 cm^{-1} (NAc), 1025, and 986 cm^{-1}. Found: C, 75.76; H, 10.69; N, 2.84%. for $C_{29}H_{49}O_3N$; C, 75.77; H, 10.74; N, 3.05%.

N-Chloro-(22S,25S)-5α-veratranine-3β,23β-diol (6). The diol **3** (50 mg) and *N*-chlorosuccinimide (22 mg) in dry THF (8 ml) were stirred for 1 h under dry nitrogen atmosphere. After the addition of water, the resultant precipitate was collected by filtration. The crude *N*-chloro derivative was dissolved in chloroform, the solution filtered and the residue recrystallized from acetone to yield the pure *N*-chloro derivative, mp over 290 °C, in an almost quantitative yield. IR: 3399 cm^{-1} (OH), 1036, and 1019 cm^{-1}. Found: N, 2.97%. Calcd for $C_{27}H_{46}O_2NCl$, N, 3.10%.

Degradation of Diol 3 to 20-Formyl-17β-ethyletiojervan-3β-ol (7). The diol **3** (1.4 g) and *N*-chlorosuccinimide (0.63 g) in dry THF (250 ml) were stirred for 1 h under an atmosphere of nitrogen. The reaction mixture was cooled to −20—−40 °C and to this solution a mixture of sodium (4.0 g) in dry methanol (70 ml) was added within a period of 0.5 h. The mixture was allowed to stand at −2—−10 °C for 15 h and then at 0 °C for 9 h. This procedure was conducted under an atmosphere of nitrogen. The solution was concentrated (<35 °C) and water (300 ml) added to the solution. The mixture was neutralized with 6 M-hydrochloric acid (50 ml) at *ca.* −7—−4 °C and then stirred for 2.5 h at room temperature. The reaction mixture was extracted three times with chloroform and the combined chloroform solution were washed with water, dried and evaporated to afford crude aldehyde **7**. The products from other two identical procedures were combined (3.1 g, 95%). The crude aldehyde **7** was recrystallized from aq ethanol. Mp 109—111 °C: IR: 3363

(broad, OH), 1708 and 2703 (CHO), and 1024 cm^{-1}. Found: C, 79.22; H, 10.72%. Calcd for $C_{22}H_{36}O_2$: C, 79.46; H, 10.92%; MS, (80 eV), *m/e* (rel. intensity), 332 (2.0, M^+), 317 (0.7, M^+-CH_3), 314 (1.6, M^+-H_2O), 274 (100, M^+-H-C-17-substituent), 259 (20.5, M^+-H-C-17-substituent$-CH_3$), 257 (19.6, M^+-C-17-substituent$-H_2O$), 149 (44.2), 148 (49.5), and 107 (35.3). The acetyl derivative **8** was prepared by the usual method. Mp 114—116 °C (methanol): IR: 1720 and 1735 cm^{-1} (CHO), 1242, and 1028 cm^{-1}. Found: C, 76.48; H, 9.98%. Calcd for $C_{24}H_{38}O_3$: C, 76.96; H, 10.23%; MS (80 eV), *m/e* (rel. intensity) 374 (1.1, M^+), 316 (100, M^+-C-17-substituent$-H$), 257 (30.9, M^+-C-17-substituent$-CH_3CO_2H$), 256 (42.4, M^+-C-17-substituent$-H-CH_3CO_2H$), 149 (57.4), 148 (62.3), 107 (56.0), and 93 (56.0).

*Preparation of 17β-Acetyl-12α-etiojervan-3β-ol (**10**) and the 3-Acetate.* To a solution of the aldehyde **7** (1.3 g) and butyl nitrite (5 ml) in THF (10 ml) was added sodium (460 mg) in dry methanol (10 ml) under an atmosphere of nitrogen at −20 °C over 20 min. The mixture was set aside 25 h at 2—3 °C and neutralized by the addition of hydrochloric acid (3 ml) at 0——4 °C. The solution was concentrated (<35 °C) and extracted with chloroform. The chloroform solution was washed with water, dried and evaporated and the viscous residue subjected to silica gel column chromatography (Mallincrodt, 100 mesh). The column was successively eluted with hexane, benzene, chloroform, and diethyl ether. The chloroform and diethyl ether fractions afforded a ketone **10**, mp 145—150 °C (1.14 g, 90%). Specimens for analysis were obtained by recrystallization from aq ethanol; mp 150—152 °C (lit,[8] 154—156 °C); IR: 1699 (acetyl), 3523 (OH), 1193, and 1063 cm^{-1}. The acetyl derivative **11** was obtained in the usual manner and recrystallized from aq methanol. Mp 116—118 °C (lit,[8] 131—133 °C); IR: 1692 (Ac), and 1720 cm^{-1} (OAc), 1241, and 1030 cm^{-1}. Methyl ketone **10** and its acetate **11** were identical with specimens prepared by Johns and Laos[8] by direct comparison.

*Preparation of 17β-Acetyl-12α-etiojervan-3β-ol Oxime (**9**) and the Acid-catalyzed Hydrolysis to 17α-Acetyl-12α-etiojervan-3β-ol (**13**).*

The oxime **9** was obtained only from this precedure. To a solution of the aldehyde **7** (50 mg) and butyl nitrite (0.5 ml) in methanol (1.5 ml) was added sodium metal (62 mg) in dry methanol (1.5 ml) over 3 min in an atmosphere of dry nitrogen at −20 °C. The mixture was set aside for 27.5 h at 0 °C. The pH of the mixture was adjusted to 4 by the addition of hydrochloric acid (*ca.* 6 drops) at −20 °C. After removal of the solvent, the residue was extracted with chloroform. After the usual work-up, the residue (42 mg) was purified by preparative TLC to afford a crude oxime (36 mg). The oxime was recrystallized from acetone to yield the pure oxime, mp 106—109 °C. IR: no carbonyl band, 3336 cm^{-1} (OH), 1040, and 879 cm^{-1}. The oxime (*ca.* 20 mg) in ethanol (10 ml) containing hydrochloric acid (1 ml) was refluxed for 2 h for 40 min. The reaction mixture was concentrated and extracted with diethyl ether and water. The organic layer was worked up to afford a residue (17 mg). After recrystallization from aq methanol it was shown to be identical with 17α-ethyl-12α-etiojervan-3β,20ξ-ol (**13**), obtained by the isomerization of 17β-ketone **10**.

*Oxidation of 17β-Acetyl-12α-etiojervan-3β-ol (**10**) with Chromium Trioxide.* To the 3β-ol **10** (105 mg) in acetone (5 ml), cooled in an ice-water bath, was added Jones' reagent (7 drops) and the mixture stirred for 1 h. After the usual work-up, the residue (120 mg) was recrystallized from acetone to afford the 3,20-dione **12** in 95% yield. Specimens for analysis were obtained by recrystallization from acetone. Mp 158—160 °C. Found: C, 79.58; H, 10.07%. Calcd for $C_{21}H_{32}O_2$: C, 79.90; H, 10.19%: MS (80 eV), *m/e* (rel. intensity); 316 (65, M^+), 301 (19, M^+-CH_3), 232 (42), 231 (44), 203 (30), 163(55), 107(58), 95(86), 85(100), 55(87), and 43(91).

*Preparation of 12α-Etiojervane-3β,17β-diol (**16**) by the Baeyer-Villiger Oxidation of 17β-Acetyl-12α-etiojervan-3β-ol.* A solution of the 20-one **10** (178 mg) and perbenzoic acid (90% purity, 105 mg) in chloroform (0.75 ml) were allowed to stand for 7 days at room temperature. The excess of perbenzoic acid was decomposed by the addition of 10% aq sodium hydrogen sulfite and the reaction mixture extracted with chloroform and water. The organic layer was washed with 10% aq sodium carbonate and water successively and dried. After evaporation of the solvent the residue (150 mg) was dissolved in methanolic 5% potassium hydroxide solution (10 ml) and allowed to stand for 3 h at room temperature. The usual work-up of the solution afforded a residue which was subjected to preparative TLC with a 1:1 mixture of chloroform and diethyl ether. The starting material (20 mg) and 13β-etiojervane-3β,17β-diol **16** (49 mg) were obtained. Recrystallization from acetone–cyclohexane, gave **16** which melted at 167—169 °C (lit,[8] mp 169—170 °C). The diol was proved to be identical with a specimen prepared by Johns and Laos[8] by direct comparison. IR: 3339 (OH), 1036, and 1069 cm^{-1}.

*Oxidation of 12α-Etiojervane-3β,17β-diol (**16**) with Chromium Trioxide.* To the diol **16** (50 mg) in acetone (10 ml) cooled by ice–water, was added Jones' reagent (3 drops). The reaction mixture was stirred for 1 h. After the excess chromium trioxide was decomposed by the addition of 10% aq sodium hydrogen sulfite, the solvent was evaporated and the reaction mixture worked up in the usual manner. The dione **17** was recrystallized from acetone (42 mg). Specimens for direct comparison were obtained by recrystallization from diethyl ether. Mp 169—170 °C (lit,[8] 169—170 °C). This specimen was identical with dione **17** prepared by Johns and Laos by a direct comparison. IR 1700 and 1713 cm^{-1} (carbonyl).

*Isomerization of 12α-Etiojervane-3,17-dione (**17**) with Base.*

The dione (20 mg) in methanolic 5% potassium hydroxide solution (10 ml) was refluxed for 1 h under an atmosphere of nitrogen. The solution was concentrated and the residue extracted with diethyl ether and water. After the usual work-up, the residue was recrystallized from aq acetone to yield crystals (18 mg); mp 115—125 °C which were largely an isomer **18**, epimeric at the C-13 and contaminated with a small amount of the starting ketone as evidenced by a weak singlet at τ 9.09 due to 19-H of **17** in the NMR spectrum. The mixture was recrystallized twice to afford pure 12α,13α-etiojervane-3,17-dione (1 mg), mp 136—140 °C (lit,[8] mp 143—145 °C). This compound was identical with the specimen prepared by Johns and Laos[8] by a direct comparison.

*Base-catalyzed Epimerization of 17β-Acetyl-12α-etiojervan-3β-ol (**10**).* The 3β-ol **10** (100 mg) in methanolic 2.5% potassium hydroxide (10 ml) was allowed to stand for 12 h under an atmosphere of nitrogen. The solution was neutralized by the addition of dilute hydrochloric acid and extracted with chloroform. The organic layer was washed with water, dried and evaporated. The residue was recrystallized from a diethyl ether–hexane mixture to yield 17α-acetyl-12α-etiojervan-3β-ol (**13**) (78 mg). Specimens (57 mg) for analysis were obtained by recrystallization from aq methanol. Mp 140.0—141.5 °C: IR: 3450 (OH), 1695 (acetyl), 1166, 1069, and 1045 cm^{-1}. Found: C, 78.54; H, 10.49%. Calcd for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76%. The acetate (**14**) was prepared in usual way and was recrystallized from aq methanol. Mp 88—90 °C: IR: 1723 and 1701 cm^{-1}, (carbonyl and OAc), 1240, and 1030 cm^{-1}. Found: C, 76.67; H, 9.97%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%.

Oxidation of 17α-Acetyl-12α-etiojervan-3β-ol with Chromium Trioxide. To 17α-acetyl-12α-etiojervan-3β-ol (70 mg) in acetone (4 ml) cooled by ice-water, was added Jones' reagent and the solution stirred for 1 h. After the excess reagent was decomposed by the addition of 10% aq sodium hydrogen sulfite, the solution was worked up. The product (73 ml) was recrystallized from aq methanol to afford 17α-acetyl-12β-etiojervan-3-one, mp 87—88 °C, (48 mg). IR: 1700 cm^{-1} (broad, carbonyl). Found: C, 79.59; H, 10.12%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

*Preparation of 12α-Etiojervane-3β,17α-diol (**19**) by Baeyer-Villiger Oxidation of 17α-Acetyl-12α-etiojervan-3β-ol.* The reaction was conducted as described for the oxidation of the 17β-isomer **10**. The 20-one **13** (178 mg) afforded a crude product (200 mg) which was hydrolyzed in a manner similar to that for the 17β-isomer. The crude product was subjected to preparative TLC with a 5: 1 mixture of chloroform and acetone to afford the starting material (41 mg) and etiojervane-3β,17α-diol (83 mg). Specimens of the latter for analysis were obtained by recrystallization from aq methanol. Mp 179.0—179.5 °C; IR: 3240—3372 (OH) and 1034 cm^{-1}. Found: C, 78.05; H, 10.93%. Calcd for $C_{29}H_{32}O_2$: C, 78.03; H, 11.03%. Diacetate **20**, mp 96—98 °C, was prepared by the usual method. IR ($CHCl_3$), 1722 (broad, OAc), 1250, 1028, and 978 cm^{-1}. Found: C, 73.30, H, 9.82%; Calcd for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64%.

*Reduction of 17β-Acetyl-12α-etiojervan-3β-ol Acetate (**11**) with $NaBH_4$.* 17β-Acetyl-12α-etiojervan-3β-ol acetate (300 mg) and $NaBH_4$ (160 mg) in absolute ethanol (26 ml) containing ethyl acetate (0.75 ml) were stirred for 2.5 h. After the excess reagent was decomposed by the addition of acetic acid, the solvent was removed to afford a residue which was extracted with chloroform. After the usual work-up, the product (310 mg) was examined by TLC which indicated the formation of virtually a single product. The product was recrystallized from a diethyl ether–hexane mixture to yield pure 17β-ethyl-12α-ethiojervane-3β,20ξ-diol 3-acetate (**21**), in greater than 95% yield. Specimens for analysis were obtained by recrystallization from aq methanol. Mp 126—129 °C: IR: ($CHCl_3$), 1719 (OAc), 3519 and 3401 (OH), 1457, 1393, 1269, and 1027 cm^{-1}. Found: C, 75.62; H, 10.45%. Calcd for $C_{23}H_{38}O_3$: C, 76.19; H, 10.57%. MS (70 eV) *m/e* (relative intensity), 344 (56.3, M^+-H_2O), 329 ($M^+-H_2O-CH_3$), 315 (18.4), 302 (22.5, M^+—AcOH), 274 (47.5), 269 (26.6), 257 (88.3, M^+—C-17-side chain—AcOH), 147 (56.1), 107 (100), 95 (82.2), 93 (91.9), 81 (78.0), and 43 (74.3).

*Hydrolysis of 17β-Ethyl-12α-etiojervane-3β,20ξ-diol 3-Acetate (**21**).* The 3-acetate (60 mg) in methanolic 2.5% potassium hydroxide (15 ml) was allowed to stand for 3 h at room temperature under an atmosphere of nitrogen. The solution was concentrated and extracted with chloroform. The usual work-up afforded a residue which was recrystallized to afford 3β,20ξ-diol **22** (53 mg). Specimens for analysis were obtained by further recrystallization from aq methanol. Mp 252—254 °C; IR: 3247 (OH), 1064, 1048, 1027, and 1010 cm^{-1}. Found: C, 78.06; H, 11.13%. Calcd for $C_{21}H_{36}O_2$: C, 78.69; H, 11.32 %; MS (80 eV), *m/e* (relative intensity), 302 (59, M^+-H_2O), 287 (18), 273 (21), 257 (77, M^+-H_2O—C-17 substituent), 147 (65), 107 (99), 95 (100), 81 (91), 67 (79), and 55 (86).

*Acetylation of 17β-Ethyl-12α-etiojervane-3β,20ξ-diol 3-Acetate (**21**).* The 3-acetate (43 mg) and acetic anhydride (0.5 ml) in pyridine (0.5 ml) were allowed to stand for 3 h at room temperature. The usual work-up afforded the diacetate **23** (35 mg). Recrystallization from aq methanol gave the pure product, mp 84.5—87.0 °C. IR: 1718 cm^{-1} (OAc), 1239, 1051, and 1024 cm^{-1}. Found: C, 74.36; H, 9.70%. Calcd for $C_{25}H_{40}O_4$: C, 74.21; H, 9.97%.

*Reduction of 17α-Acetyl-12α-etiojervan-3β-ol Acetate(**14**) with $NaBH_4$.* 17α-Acetyl-12α-etiojervan-3β-ol acetate (**14**) (300 mg) and $NaBH_4$ (160 mg) in absolute ethanol (26 ml) containing ethyl acetate (0.75 ml) were stirred for 3 h at room temperature. The addition of acetic acid to the reaction mixture and extraction with chloroform afforded a product (332 mg). A portion of the product (178 mg) was treated with methanolic 5% potassium hydroxide solution and allowed to stand for 1 h. The usual work-up afforded products which were subjected to preparative TLC with a 5: 1 mixture of chloroform and acetone to afford two fractions. The more mobile fraction (63 mg) was recrystallized from aq methanol to afford 3β,20ξ-diol **25** (55 mg), mp 140.0—140.5 °C. IR: 3170—3310 (OH), 1038, 1009, and 895 cm^{-1}. Found: C, 78.50; H, 11.31%. Calcd for $C_{21}H_{36}O_2$: C, 78.69; H, 11.32%. The less mobile fraction (70 mg) was recrystallized from aq methanol to afford 3β,20ξ-diol **28** (59 mg), mp 187—189 °C. IR: 3336 (OH), 1063, 1038, and 895 cm^{-1}. Found: C, 78.87; H, 11.42%. Calcd for $C_{21}H_{36}O_2$: C, 78.69; H, 11.32%. The diacetates **27** and **30** of the diols **25** and **28** were prepared by standard methods. The diacetate **27** from diol **25**, mp 131—132 °C (aq methanol). IR: ($CHCl_3$), 1739, 1241, 1042, and 1030 cm^{-1}. Found: C, 74.63; H, 9.84%. Calcd for $C_{25}H_{40}O_4$: C, 74.21; H, 9.97%. The diacetate **30** from diol **28** was amorphous. IR: ($CHCl_3$), 1725 (OAc), 1255, and 1028 cm^{-1}.

*17β-Ethyl-12α-etiojervane-3β,20ξ-diol 3-Acetate 20-Nitrite (**24**).* 20ξ-Ol **21** (290 mg) in pyridine (2 ml) was nitrosated with nitrosyl chloride in pyridine at −20 to −30 °C by the standard method. The crude nitrite **24** was recrystallized from methanol. Mp 102—106 °C: IR: 1734 (OAc), 1631, 794, 774, (ONO), 1242, and 1031 cm^{-1}.

*Photolysis of Nitrite **24**.* The nitrite (200 mg) in dry benzene (10 ml) in a Pyrex vessel was irradiated with a 100 W high pressure Hg arc for 3 h and 50 min under an atmosphere of nitrogen. After evaporation of the solvent, the residue was examined by TLC which indicated at least 6 spots. The product was dissolved in chloroform and the solution washed with water, dried and evaporated. The residue was hydrolyzed with methanolic 5% potassium hydroxide solution (5 ml) at room temperature and under an atmosphere of nitrogen for 3 h. The usual work-up afforded a residue which was dissolved in acetone to yield crystals (38 mg) of 17β-ethyl-12α-etiojervane-3β,20ξ-diol (**22**). The residue from the filtrate was subjected to preparative TLC with chloroform. The plates were developed three times and the major three fractions, A (13 mg), B (48 mg), and C (60 mg) were obtained. The NMR spectra of fraction A showed the absence of a C-18 functionalized product. The amorphous fraction B was recrystallized from acetone to afford 17α-acetyl-12α-etiojervan-3β-ol (**13**) (25 mg). Fraction C exhibited three spots on TLC examination and this was subjected again to preparative TLC with a 40: 1 mixture of diethyl ether–methanol to afford two major fractions C-1 (35 mg) and C-2 (18 mg). The more mobile fraction C-1 was a mixture and fraction C-2 showed a single spot on the TLC. The NMR spectra of both fractions, however, showed the absence of a C-18 functionalized product.

The Hypoiodite Reaction of 17β-Ethyl-12α-etiojervane-3β,20ξ-diol 3-Acetate. Freshly prepared lead tetraacetate (600 mg) and sodium carbonate (200 mg) in cyclohexane (18 ml) were refluxed for 1 h and the solution brought to room temperature. To this solution, were added 17β-ethyl-12α-etiojervane-3β,20ξ-diol 3-acetate (180 mg) and iodine (160 mg) and the solution irradiated under reflux for 0.5 h with a 450 W high pressure Hg arc. The insoluble material was removed by filtration and washed with hot cyclohexane. The filtrate and washings were combined and the solution washed with 10% aq sodium

hydrogen sulfite and water successively. The organic layer was dried and evaporated to afford a brownish residue (0.2 g) which was dissolved in methanolic 2.5% potassium hydroxide solution (10 ml). The solution was allowed to stand for 3 h under an atmosphere of nitrogen, concentrated under reduced pressure and extracted with chloroform and water. The usual work-up of the organic layer gave a residue which showed two major and a very minor spot on TLC. The residue was subjected to preparative TLC with chloroform. The TLC plates were developed three times to afford three fractions. The most mobile amorphous fraction (79 mg) could not however crystallize but gave a positive Beilstein test and the chloroform solution developed an yellow color by the addition of tetranitromethane. UV λ_{max} (ethanol) 262 nm; NMR τ 2.99 (2H, q, possibly ortho aromatic protons), 8.92 (s, 19-H), 7.97 (s, OAc), 7.68 (s, possibly the methyl group attached to the aromatic ring), 8.01 (s), 9.38 (1H, d, J=1.7 Hz, the proton possibly attached to the cyclopropane ring). IR ($CHCl_3$) no carbonyl or hydroxyl groups. The second mobile fraction (4 mg) was an unidentified gum. The least mobile amorphous fraction (48 mg) was a deacetylated product of a 18,20-epoxide **32**. This fraction was acetylated with acetic anhydride (2 ml) and pyridine (2 ml). After the usual work-up, the product was recrystallized from aq methanol to yield a 18,20-epoxide (**32**) (29 mg), amorphous. IR: 1732 (OAc), 1024, and 1237 cm^{-1}. Found: C, 76.50; H, 9.92%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%; MS (80 eV), *m/e* (rel. intensity) 360 (2.4 M^+), 345 (65.0, M^+-CH_3), 316 (16.7), 300 (100, $M^+-CH_3CO_2H$), 285 (73.4, $M^+-CH_3CO_2H-CH_3$), 149 (92.2), 148 (92.2), and 141 (98.4).

*Oxidation of 18,20-Epoxide (**32**) with Chromium Trioxide.* To the 18,20-epoxide (25 mg) in glacial acetic acid, was added dropwise chromium trioxide (50 mg) in aq acetic acid (90%) (2 ml) a period over 0.5 h while the solution refluxed. The reaction mixture was further refluxed for 0.5 h and the solvent removed under reduced pressure. The residue was extracted with chloroform and water and the organic layer washed with water and dried (Na_2SO_4). The residue (23 mg) from the solution was dissolved in methanolic hydrochloric acid (10 ml) to hydrolyze the 3β-acetoxyl group and allowed to stand overningt. After removal of the solvent, the residue was dissolved in chloroform. The chloroform solution was worked up in the usual way to afford the crude lactone (20 mg). The lactone was subjected to preparative TLC with a 1: 20 mixture of benzene and chloroform to afford 6 fractions. The third mobile fraction (4 mg) was the major product. The product in pyridine was subjected to acetylation in the usual way. The usual work-up of the reaction mixture afforded a crystalline lactone **33** (5 mg) which was recrystallized from diethyl ether. Mp 89—90 °C; IR: 1752 (γ-lactone), 1726 (OAc), 1238, and 1029 cm^{-1}. Found: C, 73.64; H, 9.21%. Calcd for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64%.

The authors are grateful to Dr. W. F. Johns of C. D. Searle and Co., for the generous gift of several etiojervane samples for direct comparisons. Thanks are also due to Mr. S. Shimokawa of the Faculty of Engineering for the NMR measurements.

Aminosugars. XXXI. Preparation of Benzyl 2-Acylamino-4-azido-2,4-dideoxy-ribo- and -lyxopyranosides by Inversion of Hydroxyl Group on C-3[1)]

Hironobu HASHIMOTO,* Koichi ARAKI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received May 7, 1979)

Benzyl 2-acylamino-4-azido-2,4-dideoxypentopyranosides having α-D-*ribo*, β-L-*ribo*, α-D-*lyxo*, and β-L-*lyxo* configurations were derived from the corresponding α-D-*xylo*, β-L-*xylo*, α-D-*arabino*, and β-L-*arabino* isomers, respectively, by inversion of hydroxyl group on C-3. Displacement reaction of sulfonyloxy group with sodium acetate or benzoate in aqueous 2-methoxyethanol or anhydrous *N,N*-dimethylformamide, or oxidation-reduction method *via* ulose derivative was used properly according to the stereochemistry of the starting materials.

In the course of study on the relationship between the configuration and biological activity using diastereomers of an antifungal antibiotic, prumycin: 4-(D-alanyl)-amino-2-amino-2,4-dideoxy-L-arabinose, as model compounds, the *arabino* and *xylo* analogues could be synthesized *via* 2,3-anhydro-4-azido-4-deoxypentopyranosides.[1-3)] In order to complete the synthesis of the remaining diastereomers which have *ribo* and *lyxo* configurations, the inversion of hydroxyl group on C-3 was studied in this paper.

Being used often for the inversion of hydroxyl group, displacement reactions of its sulfonate on the pyranose ring are known to be restrained by the axial substituent on α- or β-carbon with respect to the sulfonyloxy group. Four isomers, namely, α-D-*arabino* (**9**), β-L-*arabino* (**10**), α-D-*xylo* (**11**), and β-L-*xylo* (**12**) diastereomers of benzyl 4-azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-*O*-methylsulfonylpentopyranoside, were prepared from the corresponding ammonolysis products (**1**—**4**) of benzyl 2,3-anhydro-4-azido-4-deoxy-pentopyranosides[1-4)] *via* their *N*-benzyloxycarbonyl derivatives (**5**—**8**). In order to predict the reactivity, the predominant conformers of these 3-*O*-methylsulfonyl derivatives together with the corresponding 3-*O*-acetyl ones (**13**—**16**) were examined by NMR data (Table 1). The conformational equilibria were estimated by the method of averaging of spin coupling[5)] using the values of $J_{4,5a}$ or $J_{4,5e}$† and $J_{2,3}$. Although the standard values for $J_{a,a}$ and $J_{e,e}$ should be determined in each case because of dependency of spin coupling on the substituent groups of the concerned system,[7)] the following values reported for the similar aldopyranoside systems were used: 11.1 and 1.5 Hz for $J_{4a,5a}$ and $J_{4e,5e}$,[8)] and 11.0 and 3.6 Hz for $J_{2a,3a}$ and $J_{2e,3e}$, respectively.[9)] In the cases of α-*arabino* and β-*xylo* isomers whose hydrogens on C-1 and C-2 have *trans* relationship, the ratios of two chair

† The methylene protons on C-5, *i.e.*, H_{5a} and H_{5e} were assigned due to Lemieux's empirical rules[6)] that an axial proton resonates at higher field than an equatrial one.

conformers were also calculated from the observed values of $J_{1,2}$ using 7.9[10] and 2.0[9] Hz as standards for $J_{1a,2a}$ and $J_{1e,2e}$, respectively. The results and predominant conformers were shown in Table 2. The ratios obtained from coupling constants between different ring protons gave good agreement with one another indicating that the standard coupling constants used here for the estimation of conformer ratios seem to be also applicable to the here examined system. The conformational equilibria of benzyl 4-azido-2-benzyloxycarbonylamino-

Table 1. NMR data of benzyl 4-azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-*O*-methylsulfonylpentopyranosides (**9**—**12**) and the corresponding 3-*O*-acetyl derivatives (**13**—**16**) at 100 MHz in $CDCl_3$

a) A, 2-methoxyethanol: water=19: 1; B, 2-methoxyethanol: water=4: 1; C, DMF. b) Not fully dissolved.

2,4-dideoxy-3-*O*-methylsulfonylpentopyranosides (**9**—**12**) accord with those of the corresponding 3-*O*-acetyl derivatives (**13**—**16**), and also with those of methyl tri-*O*-acetylpentopyranosides.[11] Among these predominant conformers only that of the β-L-*xylo* isomer (**12**) has no axial substituent on α- and β-carbons as shown in Table 2 (axial substituent with thick line) and seems to be most reactive for displacement reactions. Therefore, some displacement reactions of **12** were examined at first and the results were summarized in Table 3.

The S_N2 type displacements of methylsulfonyloxy group with hydroxyl and acyloxy groups in compound **12** were accomplished in the presence of sodium acetate in 2-methoxyethanol–water and by sodium acetate or benzoate in *N*,*N*-dimethylformamide (DMF), respectively. Under the first conditions, which are used generally for the similar conversion in acylamino sugar derivatives having *trans* vicinal amino alcohol structure in the aid of anchimeric assistance,[12] the desired compound, benzyl 4-azido-2-benzyloxycarbonylamino-2,4-dideoxy-β-L-ribopyranoside (**17**) was obtained as a major product together with benzyl 2-amino-4-azido-2-*N*: 3-*O*-carbonyl-2,4-dideoxy-β-L-ribopyranoside (**18**). Although configuration on C-3 in compound **17** was ascertained by the change of $J_{1,2}$ from the large value (7.5 Hz) in **12** to the small value (2.4 Hz)[3] in predominant $^4C_1$ conformation,[11] the structure was furthermore confirmed unambiguously by the NMR data of its 3-acetate (**19**) (Table 4). On the other hand, absence of benzyloxycarbonyl group ascertained by the NMR and

IR spectra of **18** and presence of a typical absorption at 1760 cm^{-1} in the IR spectra assigned to carbonate supported its structure. Moreover the NMR data, especially the large value (7.6 Hz) for $J_{2,3}$, indicated that **18** exists in a boat conformation ($B_{4,1}$).

As shown in Table 3 the higher base concentration, the lower water content of the solvent, and the higher reaction temperature accelerated the formation of both **17** and **18** (Runs 1—10). The last factor, however, favored the formation of **18**, so the ratio of **17** and **18** was changed from 3: 1 at 95—100 °C to nearly 1—2: 1 at 115—120 °C. Although the formation of **18** could not be completely suppressed, among the reaction conditions tested the most suitable combination for preparation of **17** seems to be as follows: concentration of sodium acetate, 0.8—1.5 M; water content of solvent (2-methoxyethanol), 5—20%; reaction temperature, 95—100 °C. All these reactions were carried out in sealed tubes to maintain the constant water content, but for preparative purpose more convinient open air system was examined. It was found that the compound **12** was heated under gentle reflux (in oil bath at 110—115 °C) with sodium acetate (1.5 M) in 20% water containing 2-methoxyethanol to give **17** in unexpectedly good yield (80%) as reported earlier.[3] Considering the azeotropic point (99.5 °C/750 mmHg) of this binary solvent system, these conditions seem to be very similar to the best combination of reaction conditions described above. The difference between closed and open system, however, remains unclear. Furthermore, displacement reaction with sodium acetate or benzoate in DMF gave the corresponding 3-acetate (**19**) or 3-benzoate (**20**) of **17** in good yields (Runs 11—14), while in the former case the aziridine derivative (**21**) in *ca.* 25% yield, and in the latter only at higher temperature the corresponding 3-benzoate (**22**) of **8** were also formed (Run 14). The structure of **19** and **20**, especially the configuration on C-3, was confirmed by the characteristic small coupling constants of all ring protons as shown in Table 4 indicating also that they exist in $^4C_1$ conformation predominantly. The aziridine derivative (**21**) showed no N–H absorption in IR and NMR spectra, and the latter showed typical two protons attached to the aziridine ring at higher magnetic field (δ 2.87 and 3.18) than other pyranoside ring protons. The structure of **22** was also elucidated by NMR spectra in comparison with that of **12** and **16**. The compound **22** may be formed *via* **21** or by the neighboring group participation of urethane carbonyl. The former case may be more reasonable considering relatively weak polarization of benzyloxycarbonyl group. The structure of **22** was also confirmed by its identification with the alternatively prepared 3-benzoate of **8**.

Thus, in the case of β-L-*xylo* isomer (**12**) the inversion reactions in the presence of sodium acetate in 80% 2-methoxyethanol and with sodium benzoate in DMF gave good results and then the same reactions of the other three diastereomers of **12** were also examined (Table 5). As expected these isomers resisted the displacement of methylsulfonyloxyl group with both hydroxyl and benzoyloxyl ones. So at the lower temperature (95—100 °C) both reactions did scarcely proceed, and higher temperature (over 120 °C) and higher base concentration promoted decomposition of the starting material and also DMF. In the first reaction the product characterized was only the 2-*N*: 3-*O*-carbonate derivative in each case. The β-L-*arabino* isomer (**10**) gave the β-L-*lyxo* carbonate (**23**) in 22% yield, while the α-D-*arabino* and α-D-*xylo* isomers (**9** and **11**) gave the corresponding α-D-*lyxo* and α-D-*ribo* carbonate (**24** and **25**) in very low yield. The structure of these carbonate derivatives was easily ascertained by IR absorption of the cyclic carbamate (1755—1760 cm^{-1}) and by NMR signal of the proton attached to the nitrogen, which show a typical broad singlet. The NMR data of **23** and **25** confirmed their structures indicating also the predominance of $^{4,1}B$ conformation. The compound **24** was, however, characterized only by the IR absorption of cyclic carbamate. Moreover, the inversion reaction with benzoate gave no desired product, and those obtained (**26** and **27** from **10**, and **28** from **9**) seem to be derived *via* the corresponding aziridine intermediate as supposed for the formation of **22** from **12**.

As shown in the substitution reaction of **12**, benzyloxycarbonyl group can participate or assist the displacement reaction of the neighboring carbon atom, but such ability is not so strong as those of acetyl, benzoyl and formyl groups.[13] Then, the similar displacement reaction of *N*-acetyl, *N*-benzoyl, and *N*-formyl derivatives was investigated. Because β-L-*ribo* and α-D-*ribo* isomers could be prepared by the above mentioned displacement reactions or by oxidation-reduction method as described below, respectively, only *arabino* isomers were examined in detail. The *N*-acetyl (**29**), *N*-benzoyl (**30**), and *N*-formyl (**31**) derivatives of **2** were prepared in the usual manner by treatment with acetic anhydride, benzoyl chloride, or *p*-nitrophenyl formate, respectively. These compounds were converted into the corresponding

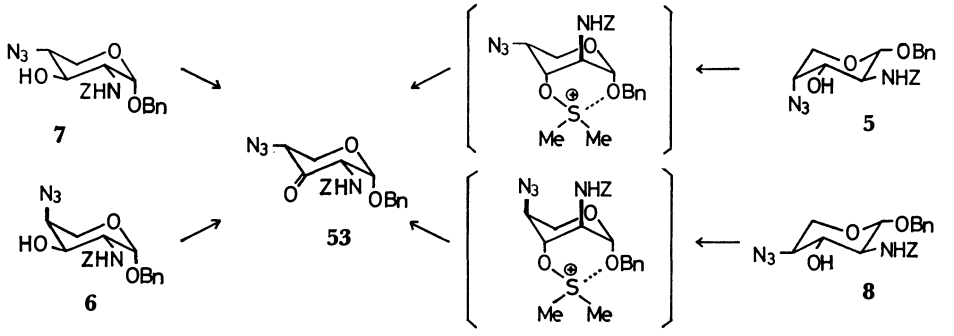
3-*O*-methylsulfonyl derivatives (**32**, **33**, and **34**) in high yields. The displacement reactions of **32**, **33**, and **34** using sodium acetate in 20% water-containing 2-methoxyethanol at 115 °C gave benzyl 2-acylamino-4-azido-2,4-dideoxy-β-L-lyxopyranosides; *N*-acetyl derivative (**35**) in quantitative yield, while, *N*-benzoyl one (**36**) in 60%, and *N*-formyl one (**37**) in 70—80% yield, respectively. The structure of these three compounds were ascertained by the NMR spectra of themselves and their 3-acetates (**38**, **39**, and **40**) as shown in Table 6. The coupling constants of ring protons supported the *β-lyxo* configuration and indicated the existence of nearly equal $^4C_1$ and $^1C_4$ conformers, which was deduced from the values of $J_{3,4}$ and $J_{4,5}$. In the case of *N*-benzoyl derivative an unidentified by-product was also obtained in 12% yield, which is deduced to be 2,3-oxazoline derivative having β-L-*lyxo* configuration by spectral data given in the Experimental. As *N*-acetyl and *N*-formyl derivative gave satisfactory results in the case of α-D-*arabino* isomer, only *N*-acetyl (**41**) and *N*-formyl (**42**) derivative of **1** were prepared. Although **41** could be converted into the corresponding 3-*O*-methylsulfonyl derivative (**43**) in high yield, the same conversion of **42** gave **44** in slightly lower yield (60%). Then, similar displacement reaction of *N*-acetyl derivative (**43**) in the presence of sodium acetate as described above gave the α-D-*lyxo* isomer (**45**) in quantitative yield, but the corresponding *N*-formyl derivative (**44**) did inversion product (**46**) in 54% yield. The slightly poor results of *N*-formyl derivative both in the 3-*O*-methylsulfonylation and the inversion reaction may be due to the fact that formyl group is not perfectly stable under these reaction conditions. Furthermore, *N*-acetyl derivative (**47**) of the α-D-*xylo* isomer (**3**) was converted into the corresponding α-D-*ribo* isomer (**49**) *via* the 3-methanesulfonate (**48**) in the same manner. The structures of these inversion reaction products (**45**, **46**, and **49**) were also elucidated by NMR data, especially by coupling constants of ring protons of the corresponding 3-acetates (**50**, **51**, and **52**, respectively).

On the other hand, the inversion of hydroxyl group *via* ulose derivative is also used widely for the synthetic purpose.[14] Then, all isomers (**1**—**4**) were subjected to oxidation with dimethyl sulfoxide–trifluoroacetic anhydride (DMSO–TFAA), which was applied recently to preparation of ulose by us.[15] To our surprise, all isomers gave only one ulose, benzyl 4-azido-2-benzyloxycarbonylamino-2,4-dideoxy-α-D-*erythro*-pentopyranosid-3-ulose (**53**), preferrentially in 80—85% yields. The IR spectrum of **53** shows a new absorption 1740 cm^{-1} due to carbonyl group and the signal of H-2 proton appears as a quartet indicating the proton has no vicinal one other than H-1 and NH. The structure of **53** was further ascertanied by conversion into the α-D-*ribo* derivative by reduction as described below. Thus, except the α-D-*xylo* isomer (**7**) the configuration of at least one substituent on C-2 and C-4 was inverted in the oxidation reaction. As the inversion of the axially oriented group adjacent to carbonyl group was observed often in DMSO oxidation,[16] the case of β-L-*arabino* isomer (**6**) could be explained in the same category. On the other hand, in the cases of α-D-*arabino* (**5**) and β-L-*xylo* (**8**) isomers the change of conformation from $^1C_4$ to $^4C_1$ at the intermediate stage of the reaction should occur, because the inverted groups have equatorial orientations originally. Such conformational change may be caused by the electrostatic attraction between the intermediate sulfonium ion and the lone pair of oxygen at C-1 as shown in Scheme 1.

Then, the reduction of **53** with sodium borohydride



Scheme 1.

in methanol gave stereoselectively the corresponding α-D-*ribo* isomer (**54**) in high yield. The structure of **54** was confirmed by NMR data of its 3-acetate (**55**), which show typical coupling constants of ring protons for α-ribopyranosides.

In conclusion, the four isomers of benzyl 4-azido-2-acylamino-2,4-dideoxypentopyranosides having *ribo* and *lyxo* configurations were prepared from the corresponding *xylo* and *arabino* isomers, and the following facts must be useful. Inversion of hydroxyl group by nucleophilic substitution of its sulfonate with sodium carboxylate can be applied only to β-*xylo* isomer which have no axial substituent in its predominant conformer. On the other hand, inversion using the corresponding 2-acetylamino derivative in the aid of anchimeric assistance can be applied surely to all *xylo* and *arabino* isomers. Furthermore, DMSO oxidation of all four *xylo* and *arabino* isomers followed by sodium borohydride reduction gave α-*ribo* isomer selectively in good yields, respectively.

Experimental

General Methods. Melting points were determined with a Mel-Temp melting point apparatus and not corrected. Optical rotations were measured in chloroform at *c* 1.0, unless otherwise stated, using a 0.5-dm tube with Carl Zeiss LEP-Al or JASCO DIP-4 polarimeter. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. NMR spectra were recorded with a JEOL JNM PS-100 spectometer in chloroform-*d* containing tetramethylsilane as the internal reference. Chemical shifts and coupling constants are recorded in δ and Hz units, and IR frequencies in cm^{-1}. Evaporations were conducted under diminished pressure. The products were recrystallized from ethanol unless otherwise stated.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxypentopyranosides (**5**, **6**, **7**, and **8**).* To a solution of benzyl 2-amino-4-azido-2,4-dideoxy-pentopyranoside (10 mmol) and sodium hydrogencarbonate (20 mmol) in 1:1 dioxane–water (50 ml) was added benzyloxycarbonyl chloride (13 mmol) dropwise with vigorous stirring at room temperature and stirring was continued overnight. The crystals separated during the reaction was filtered and recrystallized from ethanol to give pure *N*-benzyloxycarbonyl derivative in *ca.* 80% yield. The filtrate was evaporated to give a crystalline residue, which was extracted with chloroform. The extract was washed with water, dried, and evaporated to give a further crop of the product. The combined yield of the product was almost quantitative. In the cases of α-D- and β-L-*arabino* isomers the ammonolysis mixture which contain 2- and 3-amino derivatives in the ratio of 3:2[4] was directly subject to this reaction because of difficulty of separation of each component on a column in large scale, and the 2-benzyloxycarbonylamino derivative was obtained in *ca.* 40% yield by fractional crystallization from ethanol.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-α-D-arabinopyranoside (**5**)*: Mp 188—190 °C; $[\alpha]_D$ +24.2° (*c* 1.9 $CHCl_3$), +31.5° (*c* 0.7 MeOH): The reported value of −110° for the enantiomer of **5**[17] seems to be incorrect; IR (KBr): 3420 and 3320 (OH and NH), 2100 (N_3), 1690 and 1540 (urethane). Found: C, 60.12; H, 5.59; N, 14.02%. Calcd for $C_{20}H_{22}N_4O_5$: C, 60.29; H, 5.57; N, 14.06%. Acetylation of **5** with acetic anhydride in pyridine gave its 3-acetate (**13**) in quantitative yield. Mp 183—184 °C; $[\alpha]_D$ +18.8°; IR (KBr): 3300 (NH), 2100 (N_3), 1738 (ester), 1685 and 1540 (urethane), 730 and 698 (phenyl). Found: C, 59.66; H, 5.57; N, 12.83%. Calcd for $C_{22}H_{24}N_4O_6$: C, 59.99; H, 5.49; N, 12.72%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-β-L-arabinopyranoside (**6**)*: Mp 159—160 °C; $[\alpha]_D$ +143°; IR (KBr): 3315 (OH and NH), 2120 (N_3), 1690 and 1530 (urethane). Found: C, 60.45; H, 5.61; N, 13.99%. Calcd for $C_{20}H_{22}N_4O_5$: C, 60.29; H, 5.57; N, 14.06%. Acetylation of **6** in a usual manner gave its 3-acetate (**14**) in good yield. Mp 129—130 °C; $[\alpha]_D$ +134.0°; IR (KBr): 3340 (NH), 2120 (N_3), 1735 (ester), 1685 and 1515 (urethane), 735 and 703 (phenyl). Found: C, 60.09; H, 5.43; N, 12.63%. Calcd for $C_{22}H_{24}N_4O_6$: C,59.99; H, 5.49; N, 12.72%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideozy-α-D-xylopyranoside (**7**)*: Mp 114—115 °C; $[\alpha]_D$ +123.9°; IR (KBr): 3325 (OH and NH), 2100 (N_3), 1690 and 1530 (urethane), 733 and 695 (phenyl). Found: C, 60.00; H, 5.52; N, 13.87%. Calcd for $C_{20}H_{22}N_4O_5$: C, 60.29; H, 5.57; N, 14.06%. Acetylation of **7** in a usual manner gave its 3-acetate (**15**) in good yield. Mp 106—107 °C; $[\alpha]_D$ +157.3°; IR (KBr): 3400 (NH), 2098 (N_3), 1745 (ester), 1718 and 1502 (urethane), 735 and 690 (phenyl). Found: C, 59.90; H, 5.51; N, 12.24%. Calcd for $C_{22}H_{24}N_4O_6$: C, 59.99; H, 5.49; N, 12.72%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-β-L-xylopyranoside (**8**)* was already reported.[3] Acetylation of **8** in a usual manner gave its 3-acetate (**16**) in good yield. Mp 134—137 °C; $[\alpha]_D$ +13.6°; IR (KBr): 3305 (NH), 2110 (N_3), 1750 (ester), 1698 and 1540 (urethane), 738 and 695 (phenyl). Found: C, 60.10; H, 5.49; N, 12.76%. Calcd for $C_{22}H_{24}N_4O_6$: C, 59.99; H, 5.49; N, 12.72%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-O-methylsulfonylpentopyranosides (**9**, **10**, **11**, and **12**).* To a solution of the compound **5**, **6**, **7**, or **8** (2 mmol) in pyridine (5 ml) was added methylsulfonyl chloride (3 mmol) dropwise with stirring at 0 °C. Stirring was continued overnight at room temperature. The solution was poured into ice–water with

stirring. After 3 h, a crystalline precipitate separated was collected by filtration and recrystallized from ethanol to give the corresponding 3-*O*-methylsulfonyl derivative in 90—95% yield.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-O-methylsulfonyl-α-D-arabinopyranoside (**9**)*: Mp 160—162 °C; $[\alpha]_D$ +3.5°; IR (KBr): 3320 (NH), 2100 (N_3), 1690 and 1535 (urethane), 1335 (SO_2), 733 and 695 (phenyl). Found: C, 53.33; H, 5.20; N, 11.41; S, 6.68%. Calcd for $C_{21}H_{24}N_4O_7S$: C, 52.94; H, 5.08; N, 11.76; S, 6.72%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-O-methylsulfonyl-β-L-arabinopyranoside (**10**)*: Mp 139—140 °C; $[\alpha]_D$ +137.0°; IR (KBr): 3360 (NH), 2130 (N_3), 1690 and 1535 (urethane), 1365 (SO_2), 740 and 700 (phenyl). Found: C, 52.50; H, 5.07; N, 11.82; S, 6.96%. Calcd for $C_{21}H_{24}N_4O_7S$: C, 52.94; H, 5.08; N, 11.76; S, 6.72%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-O-methylsulfonyl-α-D-xylopyranoside (**11**)*: Syrup; $[\alpha]_D$ +124.5°; IR (NaCl): 3375 (NH), 2110 (N_3), 1695 and 1523 (urethane), 1345 and 1175 (SO_2), 740 and 700 (phenyl). Found: C, 53.25; H, 5.31; N, 11.32%. Calcd for $C_{21}H_{24}N_4O_7S$: C, 52.94; H, 5.08; N, 11.76%.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-3-O-methylsulfonyl-β-L-xylopyranoside (**12**)* was reported already.[3]

General Methods for Inversion Reaction with Sodium Acetate or Benzoate. All inversion reactions were carried out in sealed tubes or tightly stoppered test tubes at a temperature between 95 and 140 °C using 2-methoxyethanol–water or DMF as solvent.

Inversion Reaction with Sodium Acetate in 2-Methoxyethanol–Water: The starting 3-metanesulfonate (50 mg, 0.1 mmol) and sodium acetate (50—380 mg, 0.55—4 mmol) were dissolved or suspended in 2-methoxyethanol–water (19: 1 or 4: 1, 3 ml) and heated. Undissolved material went into the solution during the reaction. Then, the reaction solution was evaporated directly to give a residue, which was extracted with acetone. The extract was concentrated to a small volume, and subjected to preparative TLC on silica gel.

Inversion Reaction with Sodium Acetate or Benzoate in DMF: A suspension of the 3-methanesulfonate (50 ml, 0.1 mmol) and sodium acetate (41 mg, 0.5 mmol) or benzoate (85 mg, 0.5 mmol) in DMF (3 ml) was heated. Sodium benzoate did not dissolved completely even at higher temperature, and formation of resin-like material was observed by long time heating at higher than 130 °C. Work-up was done in the same manner as described above.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-β-L-ribopyranoside (**17**) and Benzyl 2-Amino-4-azido-2-N: 3-O-carbonyl-2,4-dideoxy-β-L-ribopyranoside (**18**).* A mixture of **12** (95 mg, 0.2 mmol) and sodium acetate (656 mg, 80 mmol) in 80% 2-methoxyethanol (6 ml) was heated at 95—100 °C for 40 h. A mixture of products obtained as described above was separated on a silica gel TLC using 19: 1 benzene–methanol as a solvent to give **17** (51 mg) and **18** (14 mg), in 60 and 20% yields, respectively.

17: Syrup. The optical rotation, IR, and NMR spectra were identical with those reported previously.[3]

18: Syrup; $[\alpha]_D$ +71.0°; IR (NaCl): 3300 (NH), 2090 (N_3), 1760 (cyclic urethane), 735 and 695 (phenyl). Found: C, 53.44; H, 5.04; N, 18.93%. Calcd for $C_{13}H_{14}N_4O_4$: C, 53.79; H, 4.86; N, 19.30%.

*Benzyl 3-O-Acetyl-4-azido-2-benzyloxycarbonylamino-2,4-dideoxy-β-L-ribopyranoside (**19**) and Benzyl 4-Azido-N-benzyloxycarbonyl-2,3-epimino-2,3,4-trideoxy-β-L-ribopyranoside (**21**).* A mixture of **12** (50 mg, 0.1 mmol) and sodium acetate (54 mg, 0.65 mmol) in DMF (3 ml) was heated at 115—120 °C for 13 h. The similar work-up mentioned above gave **19** (27 mg) and **21** (10 mg) in 58 and 25% yields, respectively.

19: Syrup; $[\alpha]_D$ +76.6°; IR (NaCl): 3410 (NH), 2100 (N_3), 1745 (ester), 1720 and 1500 (urethane), 740 and 700 (phenyl). Found: C, 59.95; H, 5.48; N, 12.85%. Calcd for $C_{22}H_{24}N_4O_6$: C, 59.99; H, 5.49; N, 12.72%.

21: Syrup; The structure was ascertained only by NMR data (Table 4).

*Benzyl 4-Azido-3-O-benzoyl-2-benzyloxycarbonylamino-2,4-dideoxy-β-L-ribopyranoside (**20**) and -β-L-xylopyranoside (**22**).* A suspension of **12** (50 mg, 0.10 mmol) and sodium benzoate (85 mg, 0.5 mmol) in DMF (3 ml) was heated at 115—120 °C for 13 h. The similar work-up mentioned above gave **20** (39 mg, 68%) and **22** (10 mg, 17%). At lower reaction temperature (95—100 °C) only **16** was obtained in 69% yield.

20: Mp 88—90 °C; $[\alpha]_D$ +28.2°; IR (KBr): 3410 (NH), 2100 (N_3), 1720 (ester), *ca.* 1700 and 1500 (urethane), *ca.* 740 and 705 (phenyl). Found: C, 64.47; H, 5.26; N, 11.26%. Calcd for $C_{27}H_{26}N_4O_6$: C, 64.53; H, 5.22; N, 11.15%.

22: Mp 122.0—123.5 °C; $[\alpha]_D$ +25.5°; IR (KBr): 3330 (NH), 2110 (N_3), 1720 (ester), 1700, and 1520 (urethane), 710 and 698 (phenyl).

*Benzyl 2-Amino-4-azido-2-N: 3-O-carbonyl-2,4-dideoxy-β-L-lyxopyranoside (**23**).* A solution of **10** (128 mg, 0.26 mmol) and sodium acetate (170 mg) in 80% aqueous 2-methoxyethanol was heated at 110—115 °C and evaporated to dryness. The residue was shaken with chloroform and water. The chloroform layer was evaporated to give a dark brown syrup. The syrup was separated on preparative TLC with 8: 1 benzene–acetone to give **23** (18 mg, 23%). Mp 102—104 °C; $[\alpha]_D$ +126.0°; IR (KBr): 3300 (NH), 2090 (N_3), 1760 (cyclic urethane), 735 and 695 (phenyl). Found: C, 52.19; H, 4.88; N, 18.85%. Calcd for $C_{13}H_{14}N_4O_4 \cdot 1/2H_2O$: C, 52.17; H, 5.02; N, 18.71%.

*Benzyl 2-Amino-4-azido-2-N: 3-O-carbonyl-2,4-dideoxy-α-D-ribopyranoside (**25**).* Similarly, **25** was obtained from **11** in 17% yield. Mp 118—120 °C; $[\alpha]_D$ +130.0°; IR (KBr): 3260 (NH), 2100 (N_3), 1755 (cyclic urethane), 735 and 695 (phenyl). Found: C, 53.34; H, 4.88; N, 18.96%. Calcd for $C_{13}H_{14}N_4O_4$: C, 53.79; H, 4.86; N, 19.30%.

*Reaction of **10** with Sodium Benzoate.* A mixture of **10** (393 mg, 0.77 mmol) and sodium benzoate (540 mg) in DMF (20 ml) was heated at 140 °C for 17 h to give many products on TLC. Sodium benzoate did not dissolved completely during the reaction. The solution turned black was evaporated. The residue was shaken with chloroform and water. The chloroform layer was evaporated to give a black syrup. The syrup was separated on preparartive TLC with 8: 1 benzene–acetone to give benzyl 4-azido-2-benzyloxycarbonylamino-3-*O*-benzoyl-2,4-dideoxy-β-L-arabinopyranoside (**26**) and benzyl 4-azido-3-benzyloxycarbonylamino-2-*O*-benzoyl-3,4-dideoxy-β-L-xylopyranoside (**27**) in 3.8 and 3.0% yields, respectively. Besides **26** and **27**, benzyl 4-azido-3-*O*-benzoyl-2,4-dideoxy-2-(3,3-dimethylureido)-β-L-arabinopyranoside could be also obtained in 7.8% yield, but its structure was deduced only by the following spectral data. IR (NaCl): 3450 and 3470 (NH), 2120 (N_3), 1725 (ester), and 1660 and 1525 (amide), 710 (phenyl); NMR: 5.07 (H_1: d, $J_{1,2}$=3.0), 5.60 (H_3: dd, $J_{2,3}$=10.5, $J_{3,4}$=3.6), 5.12 (H_4: broad s), 4.06 (H_5: dd, $J_{4,5'}$=1.5, $J_{5,5'}$=12.8), 3.80 ($H_{5'}$: dd, $J_{4,5'}$=1.5), 2.74 (6H, *N*–CH_3: s).

26: Mp 85—87 °C; $[\alpha]_D$ +114.0°; IR (KBr): 3320 (NH), 2100 (N_3), 1715 (ester), 1685 and 1515 (urethane), 735, 705, and 695 (phenyl). Found: C, 64.83; H, 5.21; N, 11.30%. Calcd for $C_{27}H_{26}N_4O_6$: C, 64.53; H, 5.22; N, 11.15%.

27: Mp 142—144 °C; $[\alpha]_D$ +3.9°; IR (KBr): 3320 (NH), 2125 (N_3), 1715 (ester), 1695 and 1540 (urethane), 730, 700, and 690 (phenyl). Found: C, 64.60; H, 5.15; N, 10.96%.

Calcd for $C_{27}H_{26}N_4O_6$: C, 64.53; H, 5.22; N, 11.15%.

Reaction of **9** *with Sodium Benzoate.* A mixture of **9** (231 mg, 0.45 mmol) and sodium benzoate (278 mg) in DMF (10 ml) was heated at 110—115 °C for 5 days. The mixture of products obtained by the same work-up as described in the reaction of **10** was separated on preparative TLC with 7: 1 benzene–methanol to give benzyl 4-azido-3-*O*-benzoyl-2-benzyloxycarbonylamino-2,4-dideoxy-α-D-arabinopyranoside (**28**, 27 mg) in 13% yield. Mp 77—79 °C; $[\alpha]_D$ +29.9°; IR (KBr): 3325 (NH), 2105 (N_3), 1720 (ester), 1695 and 1530 (urethane), 735, 715 and 695 (phenyl). Found: C, 64.18; H, 5.36; N, 10.80%. Calcd for $C_{27}H_{26}N_4O_6$: C, 64.53; H, 5.22; N, 11.15%.

General Method for N-*Acetylation.* To a solution of 2-amino derivative (**2**, **1**, or **3**, 10 mmol) in ethanol (30 ml) was added acetic anhydride (15 mmol) dropwise with stirring at room temperature. After 30 min, water was added to a suspension of crystallized product, and this suspension was evaporated directly to give a crystalline residue, which was recrystallized from ethanol to give the corresponding *N*-acetyl derivative in 85—90%.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-β-*L*-arabinopyranoside (**29**)*: As in the preparation of **6** the ammonolysis mixture of benzyl 4-azido-2,3-anhydro-β-L-ribopyranoside was used, and **29** was obtained in *ca.* 40% yield by fractional crystallization from ethanol. Mp 178—180 °C; $[\alpha]_D$ +217.9° (MeOH); IR (KBr): 3455 and 3395 (OH and NH), 2130 (N_3), 1655 and 1550 (amide), 735 and 695 (phenyl). Found: C, 54.95; H, 5.83; N, 18.35%. Calcd for $C_{14}H_{18}N_4O_4$: C, 54.89; H, 5.92; N, 18.29%.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-α-*D*-arabinopyranoside (**41**)*: Mp 208—210 °C; $[\alpha]_D$ +47.2° (MeOH); IR (KBr): 3280 (OH and NH), 2110 (N_3), 1650 and 1550 (amide), 730 and 692 (phenyl). Found: C, 54.95; H, 5.84; N, 18.25%. Calcd for $C_{14}H_{18}N_4O_4$: C, 54.89; H, 5.92; N, 18.29%.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-α-*D*-xylopyranoside (**47**)*: Mp 160—161 °C; $[\alpha]_D$ +210.9° (MeOH); IR (KBr): 3500 and 3280 (OH and NH), 2105 (N_3), 1630 and 1525 (amide), 735 and 695 (phenyl). Found: C, 55.15; H, 5.95; N, 18.52%. Calcd for $C_{14}H_{18}N_4O_4$: C, 54.89; H, 5.92; N, 18.29%.

*Benzyl 4-Azido-2-benzoylamino-2,4-dideoxy-β-*L*-arabinopyranoside (**30**).* To a solution of **2** (2.0 g, 6.7 mmol) in 1: 1 dioxane–water (40 ml) was added potassium hydroxide (0.38 g, 6.7 mmol) and benzoyl chloride (1.54 g, 11 mmol) with stirring in an ice–water bath. After 3 h the solution was poured into ice-water. The crystalls separated were collected by filtration, washed with 1 M sodium hydroxide and recrystallized from ethanol to give **30** in a quantitative yield. Mp 167—170 °C; $[\alpha]_D$ +140.0° ($CHCl_3$); IR (KBr): 3275 (OH and NH), 2105 (N_3), 1630 and 1523 (amide), 732 and 692 (phenyl). Found: C, 62.24; H, 5.17; N, 14.91%. Calcd for $C_{19}H_{20}N_4O_4$: C, 61.94; H, 5.47; N, 15.21%.

*Benzyl 4-Azido-2,4-dideoxy-2-formylamino-β-*L*-arabinopyranoside (**31**) and -α-*D*-arabinopyranoside (**42**).* To a solution of 2-amino derivative (**2** or **1**, 1 mmol) in tetrahydrofuran (10 ml) was added a solution of *p*-nitrophenyl formate (2 mmol) in tetrahydrofuran (5 ml) dropwise with stirring at 0 °C. After standing overnight at room temperature, the solution was evaporated to give a crystalline residue, which was purified on a column of silica gel with 15: 1 benzene–ethanol to give the corresponding 2-formylamino derivative in good yield.

31: Mp 166—167 °C; $[\alpha]_D$ +205.0° (MeOH); IR (KBr): 3295 (OH and NH), 2140 (N_3), 1655 and 1545 (amide), 740 and 700 (phenyl). Found: C, 53.13; H, 5.54; N, 19.00%. Calcd for $C_{13}H_{16}N_4O_4$: C, 53.42; H, 5.52; N, 19.17%.

42: Mp 194—195 °C; $[\alpha]_D$ +44.7° (MeOH); IR (KBr): 3290 (OH and NH), 2110 (N_3), 1645 and 1530 (amide), 730 and 705 (phenyl). Found: C, 53.67; H, 5.53; N, 19.31%. Calcd for $C_{13}H_{16}N_4O_4$: C, 53.42; H, 5.52; N, 19.17%.

*Benzyl 2-Acetylamino-(or 2-Formylamino)-4-azido-2,4-dideoxy-3-O-methylsulfonylpentopyranosides (**32**, **34**, **43**, **44**, and **48**).* To a solution of the compound to be methylsulfonylated (**29**, **31**, **41**, **42** or **47**) (2 mmol) in pyridine (15 ml) was added methanesulfonyl chloride (3 mmol) dropwise with stirring at 0 °C. After stirring overnight at room temperature, water was added to the solution, and the solution was evaporated directly to give black syrupy residue. The residue was fractionated on a silica-gel column using 5: 1 benzene–acetone as eluant to give the corresponding 3-*O*-methylsulfonyl derivative in 80%—quantitative yield.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-3-O-methylsulfonyl-β-*L*-arabinopyranoside (**32**)*: Mp 137—138 °C; $[\alpha]_D$ +213.8° (*c* 1.0, MeOH); IR (KBr): 3305 (NH), 2120 (N_3), 1645 and 1530 (amide), 1365 and 1180 (SO_2), 735 and 698 (phenyl). Found: C, 46.58; H, 5.20; N, 14.95; S, 8.52%. Calcd for $C_{15}H_{20}N_4O_6S$: C, 46.87; H, 5.25; N, 14.58; S, 8.33%.

*Benzyl 4-Azido-2,4-dideoxy-2-formylamino-3-O-methylsulfonyl-β-*L*-arabinopyranoside (**34**)*: Syrup; IR (KBr): 3375 (NH), 2110 (N_3), 1665 (amide), 1345 (SO_2), 700 (phenyl). Beside spectral data (NMR data in Table 6), other characterization could not be done because of its unstability.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-3-O-methylsulfonyl-α-*D*-arabinopyranoside (**43**)*: Mp 148—150 °C; $[\alpha]_D$ +19.2° (*c* 1.0, MeOH); IR (KBr): 3250 (NH), 2100 (N_3), 1645 and 1545 (amide), 1360 and 1178 (SO_2), 750 and 695 (phenyl). Found: C, 47.13; H, 5.24; N, 14.87; S, 8.53%. Calcd for $C_{15}H_{20}N_4O_6S$: C, 46.87; H, 5.25; N, 14.58; S, 8.33%.

*Benzyl 4-Azido-2,4-dideoxy-2-formylamino-3-O-methylsulfonyl-α-*D*-arabinopyranoside (**44**)*: Mp 162—163 °C; $[\alpha]_D$ +15.4° (MeOH); IR (KBr): 3300 (NH), 2120 (N_3), 1662 and 1535 (amide), 1338 and 1175 (SO_2), 725 and 700 (phenyl). Found: C, 45.25; H, 4.92; N, 15.10; S, 8.53%. Calcd for $C_{14}H_{18}N_4O_6S$: C, 45.40; H, 4.90; N, 15.13; S, 8.45%.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-3-O-methylsulfonyl-α-*D*-xylopyranoside (**48**)*: Mp 115—117 °C; $[\alpha]_D$ +141.5° (*c* 1.0, MeOH); IR (KBr): 3275 (NH), 2100 (N_3), 1650 and 1510 (amide), 1345 (SO_2), 722 and 690 (phenyl). Found: C, 46.71; H, 5.15; N, 14.30; S, 8.17%. Calcd for $C_{15}H_{20}N_4O_6S$: C, 46.87; H, 5.25; N, 14.58; S, 8.33%.

*Benzyl 4-Azido-2-benzoylamino-2,4-dideoxy-3-O-methylsulfonyl-β-*L*-arabinopyranoside (**33**).* Compound **30** was methylsulfonylated as described in the preparation of **9**—**12** to give **33** in 95% yield. Mp 163—164 °C; $[\alpha]_D$ +150.7°; IR (KBr): 3320 (NH), 2140 (N_3), 1635 and 1530 (amide), 1362 and 1188 (SO_2), 730 and 695 (phenyl). Found: C, 54.03; H, 4.97; N, 12.37; S, 7.00%. Calcd for $C_{20}H_{22}N_4O_6S$: C, 53.81; H, 4.97; N, 12.55; S, 7.17%.

*Inversion Reaction of 2-Acylamino Derivatives (**32**, **33**, **34**, **43**, **44**, and **48**).* A solution of 2-acylamino derivative (1 mmol) and sodium acetate (5 mmol) in 80% 2-methoxyethanol was heated in a sealed tube overnight at 110—115 °C. The solution was evaporated and the residue was purified on a colomn of silica gel to give a product in various yields.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-β-*L*-lyxopyranoside (**35**)*: The inversion reaction of **32** as described above gave **35** in 89% yield. Mp 117—119 °C; $[\alpha]_D$ +116.8° (MeOH); IR (KBr): 3330 (OH and NH), 2110 (N_3), 1650 and 1520 (amide), 740 and 704 (phenyl). Found: C, 55.19; H, 5.95; N, 18.35%. Calcd for $C_{14}H_{18}N_4O_4$: C, 54.89; H, 5.92; N, 18.29%. A usual acetylation of **35** gave the corresponding 3-*O*-acetyl derivative (**38**): Only NMR spectra was taken (Table 6).

*Benzyl 4-Azido-2-benzoylamino-2,4-dideoxy-β-L-lyxopyranoside (**36**).* Similarly, **33** gave **36** in 60% yield. IR (KBr): 3420 (OH and NH), 2090 (N_3), 1630 (amide), 705 (phenyl). Further characterization was done as its 3-*O*-acetyl derivative (**39**): Syrup; $[\alpha]_D$ +62.4°; IR (NaCl): 3440 and 3360 (NH), 2105 (N_3), 1745 (ester), 1660 and 1510 (amide), 710 and 695 (phenyl). Found: C, 61.31; H, 5.48; N, 13.30%. Calcd for $C_{21}H_{22}N_4O_5$: C, 61.45; H, 5.40; N, 13.65%. The by-product obtained in a low yield and supposed to be an oxazoline derivative has the following spectral data. IR (NaCl): 2095 (N_3), 1720, 1640 and 695; NMR: 5.09 (H_1: d, $J_{1,2}$=4.0), 4.50 (H_2: dd, $J_{2,3}$=9.3), 4.70 (H_3: dd, $J_{3,4}$=6.8), 4.28 (H_4: ddd), 3.94 (H_{5a}: dd, $J_{4,5a}$=5.7, $J_{5a,5b}$=11.0), 3.43 (H_{5b}: t, $J_{4,5b}$=10.1), 4.83 and 4.65 (ABq. CH_2 in Bn), 7.26 (broad s, 5H), 7.48 (m, 2H) and 8.02 (m, 2H).

*Benzyl 4-Azido-2,4-dideoxy-2-formylamino-β-L-lyxopyranoside (**37**)*: Similarly, **34** gave **37** in 65% yield. Syrup, $[\alpha]_D$ +72.3° (MeOH); IR (NaCl), 3320 (OH and NH), 2100 (N_3), 1660 (amide), 735 and 695 (phenyl). Found: C, 53.21; H, 5.66; N, 18.81%. Calcd for $C_{13}H_{16}N_4O_4$: C, 53.42; H, 5.52; N, 19.17%. A usual acetylation of **37** gave the corresponding 3-*O*-acetyl derivative (**40**): Mp 99—101 °C; $[\alpha]_D$ +134.3°; IR (KBr): 3415 and 3180 (NH), 2105 (N_3), 1730 (ester), 1645 (amide), 695 (phenyl). Found: C, 53.68; H, 5.44; N, 16.65%. Calcd for $C_{15}H_{18}N_4O_5$: C, 53.88; H, 5.43; N, 16.76%.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-α-D-lyxopyranoside (**45**)*: Similarly, **43** gave **45** in quantitative yield. $[\alpha]_D$ +133.0° (MeOH); IR (KBr): 3325 (OH and NH), 2110 (N_3), 1645 and 1530 (amide), 728 and 700 (phenyl). Found: C, 53.72; H, 6.02; N, 17.74%. Calcd for $C_{14}H_{18}N_4O_4 \cdot 1/2H_2O$: C, 53.50; H, 6.05; N, 17.83%. NMR data of its 3-acetate (**50**): 4.74 (H_1: d, $J_{1,2}$=1.5), 4.65 (H_2: dq, $J_{2,3}$=4.5, $J_{NH,CH}$=9.0) 5.24 (H_3: dd, $J_{3,4}$=9.0)

*Benzyl 4-Azido-2,4-dideoxy-2-formylamino-α-D-lyxopyranoside (**46**)*: Similarly, **44** gave **46** in low yield. Mp 97—98 °C, $[\alpha]_D$ +72.9° (MeOH); IR (KBr): 3455, 3350 (NH and OH), 2080 (N_3), 1648 and 1505 (amide), 740 and 695 (phenyl). Found: C, 53.30; H, 5.83; N, 17.45%. Calcd for $C_{14}H_{18}N_4O_4 \cdot 1/2H_2O$: C, 53.33; H, 6.03; N, 17.78%.

*Benzyl 2-Acetylamino-4-azido-2,4-dideoxy-α-D-ribopyranoside (**49**)*: Similarly, **48** gave **49** in 83% yield. Mp 94—96 °C; $[\alpha]_D$ +72.9° (MeOH); IR (KBr): 3455 and 3350 (OH and NH), 2080 (N_3), 1648 and 1505 (amide), 740 and 695 (phenyl). Found: C, 53.30; H, 5.83; N, 17.45%. Calcd for $C_{14}H_{18}N_4O_4 \cdot 1/2H_2O$: C, 53.33; H, 6.03; N, 17.78%. NMR data of its 3-acetate (**52**): 4.70 (H_1: d, $J_{1,2}$=3.8), 4.39 (H_2: dt, $J_{2,3}$=3.8, $J_{NH,CH}$=9.5), 5.43 (H_3: t, $J_{3,4}$)=3.8).

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-α-D-erythro-pentopyranosid-3-ulose (**53**).* Dimethyl sulfoxide (2.65 g,34 mmol) and dichloromethane (5 ml) were put into Erlenmeyer flask with vigorous stirring at −76 °C. To this solution was added trifluoroacetic anhydride (3.56 g, 18 mmol) with vigorous stirring for 5 min at −76 °C and was added a solution of **6** (2.92 g, 6.75 mmol) in dichloromethane (20 ml). After 1 h, to this solution was added triethylamine (3 ml) dropwise. After 10 min, the solution was mixed with chloroform–water, and the chloroform layer was evaporated to give a crystalline, which was recrystallized from ethanol to give **44** in 81.7% yield (2.37 g): Mp 123—125 °C; $[\alpha]_D$ +173.8° ($CHCl_3$); IR (KBr): 3350 (OH and NH), 2100 (N_3), 1740 (ketone), 1720 and 1530 (urethane), 695 (phenyl). Found: C, 60.35; H, 5.13; N, 14.09%. Calcd for $C_{20}H_{20}N_4O_5$: C, 60.60; H, 5.09; N, 14.14%.

The stereoisomers of **6** (**5**, **7**, and **8**) were also oxidized in the same manner as described above to give the same ulose derivative (**53**) in 80—85% yields.

*Benzyl 4-Azido-2-benzyloxycarbonylamino-2,4-dideoxy-α-D-ribopyranoside (**54**).* To a solution of **53** (250 mg, 0.58 mmol) in methanol was added sodium borohydride (40 mg, 1.06 mmol) with stirring at room temperature. After 30 min, the solution was neutralized with 1 M hydrochloric acid. After evaporation of the solution the resulting residue was dissolved in chloroform. The chloroform solution was washed with water, dried with anhydrous sodium sulfate and evaporated to give a syrup. The syrup was first crystallized by evaporation of ethanol solution after decolorization with activated charcoal. Yield, 94.4%: $[\alpha]_D$ +97.2° ($CHCl_3$); IR (KBr): 3450 and 3340 (OH and NH), 2075 (N_3), 1680 and 1495 (urethane), 740 and 695 (phenyl). Found: C, 60.25; H, 5.57; N, 13.93%. Calcd for $C_{20}H_{22}N_4O_5$: C, 60.29; H, 5.57; N, 14.16%. Its 3-acetate (**55**); Syrup, $[\alpha]_D$ +70.8° ($CHCl_3$); NMR: 4.78 (H_1: d, $J_{1,2}$=3.3), 4.14 (H_2: dt, $J_{2,3}$=3.0, $J_{NH,CH}$=9.6), 5.75 (H_3: t, $J_{3,4}$=3.0) 3.94 (H_{5a}: dd, $J_{4,5a}$=3.6, $J_{5a,5b}$=12.3), 3.64 (H_{5b}: dd, $J_{4,5b}$=6.8).

The Hydrocracking of Solvent Refined Coals over Molten Salt Catalysts[1)]

Yohji NAKATSUJI,* Yasuhiko IKKAKU, Masakatsu NOMURA, and Shōichi KIKKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received December 14, 1978)

The hydrocracking of Yūbari SRC and Tempoku SRC over $ZnCl_2$/CuCl or $ZnCl_2$ molten salt was examined at 350 or 400 °C for 3 h in a batch autoclave system. The reactivity of SRC under the hydrocracking conditions with the molten salts was estimated mainly by comparison with the results obtained in the study using a variety of polynuclear aromatic hydrocarbons. The presence of hetero atoms (especially, the hydroxyl group) in SRC may be supposed to play an important role in this hydrocracking using molten salts. In addition, the average structures of SRC, according to the CAMSC method, are offered, and the usefulness is examined from the point of view of the reactivity of SRC in the presence of molten salts.

Although the structure of coal has not been appreciably clarified in detail, some structural analyses suggest that coal is a natural polymer consisting mainly of condensed rings. Consequently, in order to obtain liquid fuels from coal, it is necessary to decompose the condensed rings in addition to effecting the scission of the bonds between structural units. From this standpoint, the hydrocracking of model substances of coal (that is, a heavy anthracene oil[2)] and polynuclear aromatic hydrocarbons[3)]) over molten salts was investigated. On the basis of detailed product analyses, $ZnCl_2$/CuCl molten salt was found to be a superior hydrocracking catalyst for coal-related substances. In this paper, we will apply this catalyst system to the hydrocracking of solvent refined coals (SRC), which are considered to be representative of some of structural units of coal, and will clarify the catalytic action for SRC in comparison with that of $ZnCl_2$.

Experimental

The NMR spectra were recorded on a JEOL JNM-PS-100 spectrometer, using tetramethylsilane as the internal standard. $CDCl_3$ was used as the solvent for all the substances. The GLC analyses were performed on a Shimadzu GC-3AH apparatus for gaseous products and on a GC-4BPTF apparatus for liquid and solid products. The GC-MS spectra were taken with a Hitachi RMU-6MG spectrometer at 20 eV connected with a Hitachi M 5201 apparatus using a 3 m×3 mm column of 5% Silicone OV-1 on Uniport KS. The average molecular weights were determined with a Hitachi-Perkin Elmer 115 vapour-pressure osmometer in chloroform, with bibenzyl as the calibration standard. The zinc chloride and copper(I) chloride were obtained from Nakarai Chemicals, Ltd.

Preparation of SRC. The experiments were carried out in a 500 ml SUS 32 autoclave; 50 g of Yūbari coal (−200 mesh) and 100 ml of tetralin were placed in it, and hydrogen was added up to a pressure of 80 kg/cm². The rate of the temperature rise was controlled to about 3 °C/min up to 400 °C, after which the temperature was held for 3 h. The autoclave was shaken in a horizontal direction (70 strokes/min). No attempts were made to maintain the hydrogen pressure at a constant level during the reaction. After the system had been cooled to room temperature, the gases were collected in a gas holder and analyzed by GLC (60—80 mesh silica-gel column, 3 m×3 mm, TCD, 120 °C, N_2 carrier). The product was filtered, and the residue was extracted with benzene by means of a Soxhlet extractor. The above procedure was repeated 3 times. The benzene and tetralin were then removed from the combined mixture of filtrates and extracted solutions. The yield of Yūbari SRC was 90 g. In the case of the Tempoku coal, the reaction time was 30 min and the autoclave experiment was repeated 4 times. The yield of Tempoku SRC was 70 g. All the properties of coals and their SRC are shown in Table 1.

Hydrocracking of SRC. A stainless-steel vessel containing 8 g of SRC and the catalyst was placed in a SUS 32 autoclave with a capacity of 200 ml. The air in the autoclave was replaced by hydrogen, and then the system was filled with hydrogen to 100 kg/cm²; thereafter, the autoclave was heated up to the desired temperature. The time taken to reach the stage was from 60—70 min. The reaction system shaken in a horizontal direction (68 strokes/min) was maintained at the reaction temperature for 3 h. No attempts were made to maintain the hydrogen pressure at a constant level during the reaction. After the system had been cooled to room temperature, the gases were collected in a gas holder and analyzed by GC. The liquid and solid products were extracted with pentane by means of a Soxhlet extractor, and the residues were subjected to benzene extraction. Moreover, the pentane extracts were separated into two fractions (PSL and PSH) by means of vacuum distillation (−190 °C/3 mmHg). The lighter fraction (PSL) was analyzed by GC (4.5 m×3 mm packed with 20% SE-30 on Uniport B 60—80 mesh, programmed from 30—270 °C, 5 °C/min, TCD, H_2 carrier).

Table 1. Properties of coal and SRC

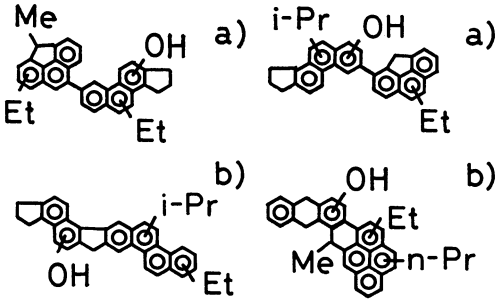
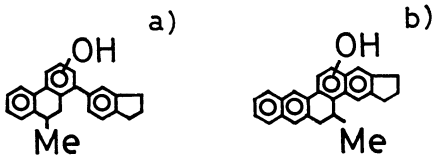
Results and Discussion

Average Structure of SRC. The SRC consists of large numbers of compounds possessing different molecular weights; moreover, the constituents cannot be determined. However, as these compounds may be supposed to consist of similar types of compounds, the concept of the average structure has been employed for a variety of structural analyses. In this investigation, the average structure of the SRC was estimated according to the CAMSC method proposed by Oka *et al.*[4] This CAMSC method attempts to represent the average structure as a combination of aromatic and aliphatic groups, in accordance with the input data represented as integral numbers based on the experimental data from the elemental, NMR, and molecular-weight analyses. The oxygen atoms were considered as a phenolic OH, as an ether, or as a carbonyl group; on the other hand, the sulfur and nitrogen atoms were not considered. The determination of the average structures has been carried out by means of a computer program prepared according to the flow chart and the classification method of Oka *et al.* The results for Yūbari SRC and Tempoku SRC are shown in Figs. 1 and 2 respectively. It may be supposed to be unreasonable to represent the average structure by a single structure. It is preferable to divide the average structures obtained by the CAMSC method broadly into two types, that is, the type containing a direct bond between two aromatic rings (a) and the type containing a large ring structure (b).



Experimental result: H_α=9.4, H_o=10.5, H_{al}=19.9, H_{ar}=12.2, C_{ar}=28.0, C_{al}=9.4, (OH=0.82).
Input data for CAMSC: H_α=9, H_o=11, H_{al}=20, H_{ar}=12, C_{ar}=28, C_{al}=9, (OH=1).

Fig. 1. Average structure of Yūbari SRC by CAMSC.



Experimental result: H_α=6.9, H_o=5.0, H_{al}=11.9, H_{ar}=9.6, C_{ar}=19.0, C_{al}=5.7, (OH=0.79).
Input data for CAMSC: a) H_α=7, H_o=5, H_{al}=12, H_{ar}=10, C_{ar}=18, C_{al}=6, (OH=1). b) C_{ar}=20.

Fig. 2. Average structure of Tempoku SRC by CAMSC.

Hydrocracking of SRC. The SRC, which underwent a thermal scission of the bonds between structural units and stabilization by hydrogen transfer from tetralin, is the primary hydrocracked product of coal and may be regarded as representative some of the structural units of coal. The difference in the structural parameters calculated using Brown-Ladner's method[5] and the average molecular weight between Yūbari SRC and Tempoku SRC suggest that the original structure of coal considerably influences the structure of SRC. On the other hand, as the SRC is molten at this reaction temperature and becomes a homogeneous liquid, the catalytic action of the molten salts on the SRC may be expected to be similar to that on polynuclear aromatic hydrocarbons (PAH). With these facts in view, the SRC was selected as a kind of model substance of coal.

The results of the hydrocracking of the SRC are shown in Table 2. The products were classified into Gas, PSL, PSH, and BS. The GC charts of the hydrocracked products (PSL) of Yūbari SRC are shown in Figs. 3 and 4. The products listed in Figs. 3 and 4 were identified by means of GC-MS and by reference to the GC charts of the hydrocracked products of PAH.[3] The structural parameters, the average molecular weight, and the nitrogen content of the hydrocracked products of Yūbari SRC are shown in Table 3. The catalytic action of molten salts will now be discussed on the basis of the product distribution shown in Table 2 and the properties shown in Table 3.

Table 2. Hydrocracking of Yūbari SRC[a]

	Run No.								
	1	2	3	4	5	6	7	8	9[b]
Catalyst	$ZnCl_2$	$ZnCl_2$/CuCl	—	$ZnCl_2$	$ZnCl_2$/CuCl	$ZnCl_2$	$ZnCl_2$/CuCl	$ZnCl_2$/CuCl	$ZnCl_2$/CuCl
(mol: mol)		(60:40)			(60:40)		(90:10)	(60:40)	(60:40)
Catalyst/Feed (wt/wt)	0.1	0.1	—	0.1	0.1	1	1	1	1
Reaction temp (°C)	350	350	400	400	400	400	400	400	400
Gas	2	3	9	13	14	25	29	36	40

PSH	25	34	19	39	41	28	22	13	8
BS	48	42	61	17	14	1	1	1	1

Reaction conditions: initial hydrogen pressure, 100 kg/cm²; reaction time, 3h; a) Yūbari SRC consists of 22% of PS, 61% of BS, and 17% of BIS. b) Tempoku SRC.

Table 4. Influence of OH substituent on the product distribution

Feed		Naphthalene		2-Naphthol	
Catalyst (mol: mol)		$ZnCl_2$	$ZnCl_2$/CuCl (60:40)	$ZnCl_2$	$ZnCl_2$/CuCl (60:40)
Products (wt %)	C_1–C_4 gases	3.4	45.7	26.3	56.0
	C_5–C_7 alkanes	—	3.7	1.1	2.9
	cycloalkanes	0.1	1.5	3.2	3.1
	monocyclic aromatics	2.0	46.4	18.7	33.7
	indans and tetralins	16.0	1.7	31.2	3.0
	naphthalene	77.9	0.5	9.3	0.7
	higher boiling products	0.7	—	10.3	0.6

Reaction conditions: initial hydrogen pressure, 100 kg/cm²; reaction time, 3h; reaction temperature, 400 °C. Catalyst/Feed=1(mol/mol).

At 350 °C (Runs 1 and 2), a difference in these two catalysts was observed in the yields of PSH and BS.

In the hydrocracking of PAH, it was clarified that the product distribution is dependent upon the original structure and that the methyl groups in the feed remarkably affect the compositions of monocyclic aromatics and of gases.[10] Based on the results obtained in the hydrocracking of SRC under conditions similar to those in the hydrocracking of PAH,[3] the structure of SRC will be discussed.

Table 5. Influence of ring size on the product distribution

Substance used for hydrocracking	Cycloalkanes/monocyclic aromatics[a]
Bicyclic compounds[b]	0.03—0.04
Tricyclic compounds[c]	0.14—0.42
Chrysene	0.70
Tempoku SRC[d]	0.82
Yūbari SRC[e]	1.11

a) wt/wt. b) Naphthalene, 1-methylnaphthalene, 2-methylnaphthalene, 2,6-dimethylnaphthalene. c) Anthracene, 2-methylanthracene, 9-methylanthracene, 9-propylanthracene, 9,10-dihydroanthracene, 9,10-dihydro-9-methylanthracene, 9,10-dihydro-9,10-dimethylanthracene, phenanthrene, 9-methylphenanthrene, 9,10-dihydro-9-methylphenanthrene, fluorene. d) Run 9. e) Run 8.

Monocyclic aromatics are relatively stable under these reaction conditions. On the other hand, cycloalkanes are mainly formed *via* highly hydrogenated compounds (for example, *unsym*-octahydrophenanthrene in the hydrocracking of phenanthrene[3]), and so the yield of cycloalkanes can be expected to increase as the size of the original ring structure increases. The ratio of the amounts of cycloalkanes to those of monocyclic aromatics in the hydrocracked products shown in Table 5 is considered to be a measure of the size of the ring structure. If the SRC consists of alkyl-substituted PAH, they are supposed to have larger a ring structure than chrysene, on the average. This finding suggests that the type containing a large ring structure (b) is more important than that containing a direct bond between two aromatic rings (a) in the average structures as determined by the CAMSC method. Table 5 also indicates that the average ring size of Yūbari SRC is larger than that of Tempoku SRC. The values shown in Table 5 are supposed to reflect the difference in the average structures, shown in Figs. 1 and 2, between these two SRC.

Table 6. Composition of monocyclic aromatics (mol %)

	Yūbari SRC[a]	Tempoku SRC[b]

In the hydrocracking of alkyl-substituted PAH,[10] the behavior of the alkyl group attached to the condensed ring has been found to be different. The methyl group was not completely dealkylated in the initial stage, but remained in the products as monocyclic aromatics; the extent of dealkylation had been found to be dependent upon the type of starting materials. Table 6 suggests that Yūbari SRC possesses many more alkyl groups as substituents than does Tempoku SRC. On the other hand, Table 7 indicates that the extent of dealkylation is similar to that in the case of Tempoku SRC. These results seem to support the idea that the average structures shown in Figs. 1 and 2 reflect quite well the characteristics of the real structures of these two SRC.

Vapor-phase Hydrolysis of Chlorobenzene Catalyzed by Copper(II) Ion-exchanged Zirconium Phosphate

Yusuke IZUMI*,† and Yukio MIZUTANI

Research and Development Division, Tokuyama Soda Co., Ltd., Mikage-cho 1-1, Tokuyama 745

(Received January 18, 1979)

Copper(II) ion-exchanged zirconium phosphate (ZP–Cu(II)) effectively catalyzed the vapor-phase hydrolysis of chlorobenzene to phenol at 450 °C under atmospheric pressure. Per-pass conversion of chlorobenzene was between 12 and 18% with selectivity for phenol from 90 to 95 mol %. The catalytic activity was influenced by the content of copper, the ratio of phosphate to zirconium, and the pH at which copper(II) ions were introduced into zirconium phosphate. ZP–Cu(II) catalyst was amorphous and it turned inactive by thermal treatment at above 800 °C, resulting in a crystalline substance. The active site of ZP–Cu(II) for this hydrolysis reaction appears to be the phosphate groups of ZP bearing copper(II) ion. The reaction seems to proceed *via* a Rideal mechanism in which an adsorbed chlorobenzene molecule reacts with water in the vapor phase at the catalyst surface. The desorption of hydrogen chloride was rate controlling.

Ion-exchange properties of zirconium phosphate (ZP) as well as its crystallography have been the subject of a great deal of research in the field of inorganic and nuclear chemistry. On the other hand, little interest have been shown in the catalysis of ZP since Austerweil first tried to employ ZP as a catalyst for the Pechmann condensation of malic acid with phenol into cumarins in 1959.[1–6] Recently, acidic characteristics of ZP have been investigated in detail in connection with its catalysis in dehydration of 2-propanol and isomerization of 1-butene.[7,8]

Since amorphous ZP has a large surface area (100—350 m^2/g) and it is also considerably durable against thermal and chemical treatments, ZP would be expected to show unique catalytic performance in several organic reactions when combined with various transition metal ions or metals through ion exchange or subsequent reduction. The authors have previously reported that the acidic amorphous ZP loaded with a small amount of finely dispersed palladium metal is an efficient bifunctional catalyst for the direct synthesis of isobutyl methyl ketone by the liquid-phase reductive aldol condensation of acetone.[9–11] As another attempt of applying ZP to catalyst, we have examined the vapor-phase hydrolysis of chlorobenzene to phenol over the ZP incorporating copper(II) ions through ion exchange (ZP–Cu(II)).

The Raschig process, an existing commercial technology of phenol synthesis, involves oxychlorination of benzene to yield chlorobenzene and subsequent vapor-phase hydrolysis of the chlorobenzene to phenol:

$$C_6H_6 + 1/2O_2 + HCl \longrightarrow C_6H_5Cl + H_2O,$$
$$\Delta H = -43 \text{ kcal/mol at } 500 \text{ K} \quad (1)$$

$$C_6H_5Cl + H_2O \longrightarrow C_6H_5OH + HCl,$$
$$\Delta H = -0.64 \text{ kcal/mol}, \; K_p = 0.877 \text{ at } 700 \text{ K}. \quad (2)$$

Although silica has been found effective for the second step reaction (Eq. 2),[12–14] calcium hydroxyapatite, often promoted by copper(II) ion, is commercially employed at present.[15] But this "calcium phosphate" catalyst (CP) still has drawbacks such as poor thermal durability and loss of copper at high temperatures (375—450 °C). It is, therefore, interesting to examine the applicability of thermally stable ZP catalyst to this hydrolysis reaction.

The present study concerns itself with a general examination of ZP-Cu(II) catalyst in the hydrolysis of chlorobenzene, its nature, and possible reaction mechanism.

Experimental

Catalyst Preparation. ZP–Cu(II) catalyst was directly prepared by reacting phosphate ion with zirconium salt in the presence of copper(II) ion at a pH around 4.0, because ZP was fully ion-exchangeable even in a state of hydrous gel. This method was preferable to obtain such ZP as contained homogeneously distributed metal cations in it. The standard ZP–Cu(II) catalyst was prepared as follows: 0.6 g of copper(II) chloride ($CuCl_2 \cdot 2H_2O$) was added to an aqueous solution of zirconium dichloride oxide ($ZrOCl_2 \cdot 8H_2O$ 24 g/H_2O 100 ml). Separatly, 8.0 g of sodium hydroxide was added to an aqueous phosphoric acid (85 vol% H_3PO_4 14.8 g/H_2O 100 ml). The former solution was added to the latter under vigorous stirring at room temperature. The ratio of phosphate to zirconium (P/Zr) was 2: 1. The mixture was then allowed to stand for 44 h. A light blue gel was precipitated, leaving a colorless liquid, pH of which was 4.08. The hydrous gel was filtered, washed with water, dried at 110 °C, and finally calcined at 400 °C for 3 h to yield 20 g of ZP–Cu(II) catalyst. The copper content was 1.1% by weight.

Calcium hydroxyapatite was prepared by a known procedure.[16] Copper doping of the calcium hydroxyapatite was carried out after Reichle.[15]

Chlorobenzene Hydrolysis. The reaction was carried out using a fixed-bed flow apparatus under atmospheric pressure. A Pyrex tube reactor (20 mmϕ × 400 mm) was placed in a fluidized alumina bath. The catalyst (18—28 mesh) was placed in the middle of the reactor, and the remainder was filled with catalytically inactive porcelain chips. Reaction temperature was measured with a thermocouple inserted in a Pyrex thermowell (7.5 mmϕ) extending longitudinary through the center of the reactor. Both water and chlorobenzene were continuously metered into the reactor by means of microfeeders. The products were withdrawn as oil and aqueous condensates in a receiver held in an ice bath. When the reaction was carried out with a nitrogen flow to dilute the reactants, a trap containing water was connected with the receiver in order to completely recover the produced hydrogen chloride.

† Present address: Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464.

Analytical Methods. The aqueous condensate was separated from the reaction products and extracted with benzene to recover the dissolving phenol. The extract was joined to the oil condensate and the mixture was analyzed by means of gas chromatography using a 3 m Silicone DC-550 column at 80 °C with a flow rate of carrier gas (H_2) 40 ml/min. The hydrogen chloride dissolving in the aqueous condensate was determined by means of alkalimetry. Thus the total per-pass conversion of chlorobenzene (x) was calculated from the amount of hydrogen chloride. The selectivity for phenol was calculated as $100\,m(1-x)/x$ (%), where m denotes the molar ratio of phenol to chlorobenzene in the reaction products that was determined by the above described analysis by gas chromatography.

Copper in catalyst was determined by means of iodometry. A powdered ZP–Cu(II) sample was previously treated with 1 M nitric acid at 80 °C to remove copper(II) ions.

The thermal analysis of catalyst was carried out by use of a differential thermal analyzer. A 20 mg sample was heated in an aerobic atmosphere at the rate of 10 °C/min using α-alumina as a reference.

Results and Discussion

Catalytic Activity. Figure 1 shows the results of the vapor-phase hydrolysis of chlorobenzene over ZP (P/Zr=2.0), standard ZP–Cu(II), CP and CP–Cu(II) (Cu 2.0 wt%). ZP–Cu(II) was very active compared with other catalysts. The rapid decrease in activity with the time on-stream observed for CP and CP–Cu(II) and the slow one for ZP–Cu(II) were both due to the formation of carbonaceous matter on the catalyst surface. The by-product was benzene. Each of the used catalysts nearly recovered its initial activity after it was regenerated with air to burn off the coke at 450 °C for 2 h. CP was considerably active without the aid of copper. But ZP itself was almost inactive,

and copper was essential to the catalysis of ZP for this hydrolysis reaction. These facts suggest that the catalytic performance of ZP is quite different from that of CP. Furthermore, the effect of copper seems to be specific to this reaction because other metal ions incorporated into ZP such as Ag(I), Ni(II), Fe(III), and Co(II) were all inactive except Ca(II) which was slightly effective (conversion=4.0%). The influence of copper content of ZP–Cu(II) (P/Zr=2.0) upon the activity is shown in Fig. 2 in more detail. The chlorobenzene conversion rapidly increased with the copper content until around 2.0% by weight (0.6 meq/g catalyst). On the other hand, the selectivity for phenol gradually decreased with the copper contents as a result of increasing catalytic decomposition of chlorobenzene to benzene. The optimum range of the copper content was between

1 and 2 wt % at which the maximum space-time yield of phenol was obtained.

Figure 3 shows the effect of the P/Zr molar ratio in ZP–Cu(II) catalyst. The ratio considerably affected the selectivity for phenol, though the conversion of chlorobenzene was almost unaffected except for a P/Zr ratio 3.0. The optimum P/Zr ratio was 2.0.

Characterization of ZP–Cu(II). The catalyst efficiency remarkably changed with the pH at which ZP–Cu(II) hydrous gel was precipitated (Fig. 4). The most active catalyst was obtained at a pH about 4.0 that was most preferable to introducing copper(II) ion into ZP hydrous gel through ion exchange. At a pH below 4.0 ion exchange became incomplete, while at a pH above 5.3 ineffective copper(II) hydroxide was deposited in ZP hydrous gel. Since not only fresh catalyst but also used one contained no chloride ion, ZP–Cu(II) catalyst appears to hold copper not as liberated copper(II) chloride but as copper(II) ion that is bound to its phosphate groups. In fact, it was experimentally found that both copper(II) chloride and copper(II) phosphate themselves were inactive for this reaction. The ion-exchange capacity of ZP (P/Zr=2.0) was measured 0.7 meq/g for copper(II) ion at a pH 4.0. This corresponded to 2.2 wt % as the copper content. Considering that the activity rapidly increased until around this value of copper content (Fig. 2), the active site of ZP–Cu(II) catalyst seems to be represented by the phosphate groups in ZP bearing a copper(II) ion.

Figure 5 illustrates the thermal change of the standard ZP–Cu(II) catalyst in an aerobic atmosphere, together with a thermogram of ZP (P/Zr=2.0). Although the catalyst was an amorphous solid, it was transformed into an unknown crystalline substance when heated at above around 800 °C, turning completely inactive. The ZP containing no copper was found to change into zirconium pyrophosphate (ZrP_2O_7) at above around 1000 °C.

Activity Maintenance. A continuous catalyst testing was performed by using ZP–Cu(II) (P/Zr=2.0, copper content=2.2 wt %). Although the catalyst was regenerated with air at 430 °C for 33 min every 3.5 h, the conversion of chlorobenzene gradually decreased with the time on-stream. This change in activity is mainly due to the loss of copper in catalyst because the surface area of catalyst was almost unchanged except for its rapid decrease observed during the initial 14 h (Table 1). The selectivity for phenol gradually increased due to the decrease in the copper content of catalyst with reaction time. The copper removed from the catalyst was detected as copper(II) chloride on the reactor wall. Probably, the copper(II) ion bonding to the phosphate groups in ZP reacted with hydrogen chloride to change into copper(II) chloride and vaporized out of the catalyst. Since the vapor pressure of copper(II) chloride is as much as 28 mmHg†† at 450 °C, the copper(II) chloride thus liberated on the catalyst surface seems to be liable to vaporize.

Table 1. Changes of surface area and copper content of ZP–Cu(II) with time on-stream of reaction

Time on-stream h	BET surface area m^2/g	Copper content wt %
0	169	2.16
14.3	118	1.06
47.5	114	0.39

In order to maintain the activity for longer duration, another catalyst testing with continual supply of copper was undertaken at 450 °C using a stainless steel reactor (28 mmϕ×400 mm). Preheated gaseous reactants had passed at 400 °C through a reactor zone packed with copper metal chips (15 mm in depth) before they reached the catalyst bed (40 mm in depth). The catalyst was regenerated with air at 450 °C for 33 min every 3.5 h, and at the same time the surface of the copper metal chips above the catalyst bed were also

†† (1 mmHg≈133.3 Pa).

oxidized. Copper(II) oxide thus formed catalyzed the decomposition of chlorobenzene and a small amount of hydrogen chloride was produced. The hydrogen chloride, in turn, reacted with the surface copper(II) oxide to form copper(II) chloride. The catalyst could be, therefore, continually supplied with the vapor of copper(II) chloride from the zone of copper metal chips. By means of such continual supply of copper, the ZP–Cu(II) catalyst maintained both the conversion and the selectivity at their stationary levels for 600 on-stream hours, except for a slight decrease in the conversion observed during the initial 140 h.

Reaction Mechanism. The kinetic data of the hydrolysis of chlorobenzene were obtained using small particles (18—24 mesh) of the standard ZP–Cu(II) catalyst. The linear velocity of the flow of gaseous reactants was kept above 22 cm/s at the reaction temperature. Under these conditions, the reaction rate was released from the influence of both external and internal mass-transport processes. The total pressure of the reactants was varied by the dilution with nitrogen. Figure 6 shows the changes in the initial reaction rate with the water to chlorobenzene molar ratio and with the total pressure of the reactants. The initial rate at each reaction temperature remained nearly unchanged under varied partial pressures of the reactants and different total pressures. At a reaction temperature as high as 400 to 450 °C, it is unlikely that the adsorption constant for chlorobenzene or for water is large enough to cancel the effect of the total pressure of the reactants on the initial rate. It is, therefore, probable that the desorption of one of the products was rate-controlling. Figure 7 gives the change in the initial rate when one of the products was added to the reactants beforehand. The rate again remained approximately constant with all the amount of hydrogen chloride added. On the other hand, the phenol in the feed clearly lowered the rate. Considering that the equilibrium constant for the over-all reaction

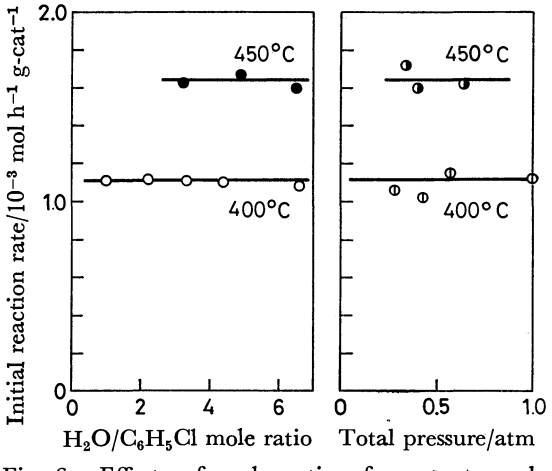

Fig. 6. Effects of mole ratio of reactants and total pressure on initial reaction rate. Data were obtained between initial 1.0 and 2.0 on-stream hours.
○: fresh catalyst, total pressure 1.0 atm; ●: regenerated catalyst, total pressure 0.7 atm; ⦶: fesh catalyst, H_2O/C_6H_5Cl 2.2; ◐: regenerated catalyst, H_2O/C_6H_5Cl 3.2.

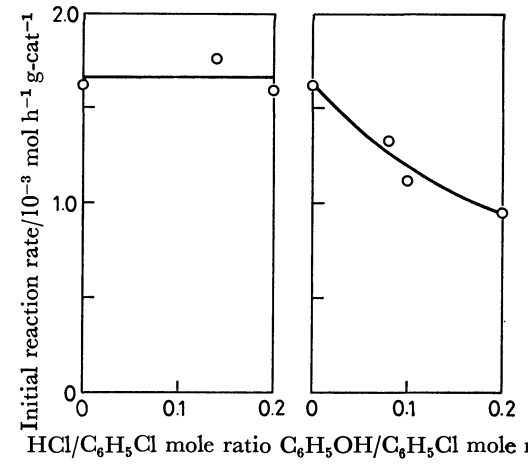

Fig. 7. Effects of hydrogen chloride and phenol on initial reaction rate at 450 °C. Data were obtained between initial 1.0 and 2.0 on-stream hours. Catalyst: regenerated, total pressure: 0.65 atm.

is less than unity at 400 to 450 °C, the above kinetic data are well interpreted by assuming that the desorption of hydrogen chloride is rate-controlling. The apparent activation energy was 8.6 kcal/mol at a reaction temperature between 400 and 450 °C.

Furthermore, in order to presume the reaction mechanism, it was examined at what stage in the reaction path phenol was formed. Water and chlorobenzene were alternately adsorbed on the catalyst surface and each desorbed product was analyzed (Fig. 8). It was found that phenol was formed only when water was supplied to the catalyst on which chlorobenzene had already been adsorbed, but on the other hand no phenol was detected in the reactor effluent when chlorobenzene was fed to the catalyst on which only water had been adsorbed. This experiment suggests that the reaction proceeded *via* a Rideal mechanism in which adsorbed chlorobenzene reacts with water in the vapor phase.

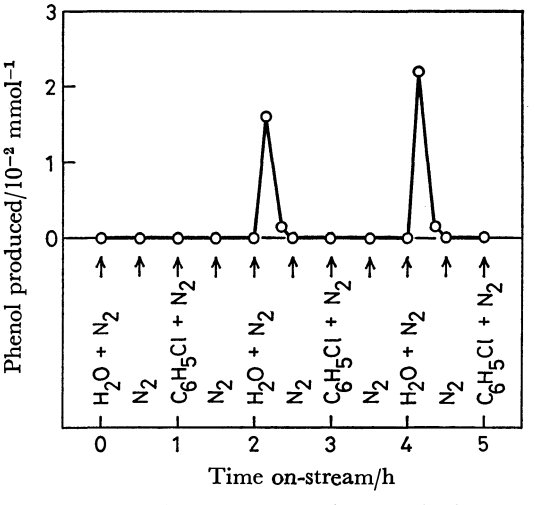

Fig. 8. Phenol formation by alternate feed of water and chlorobenzene at 305 °C.
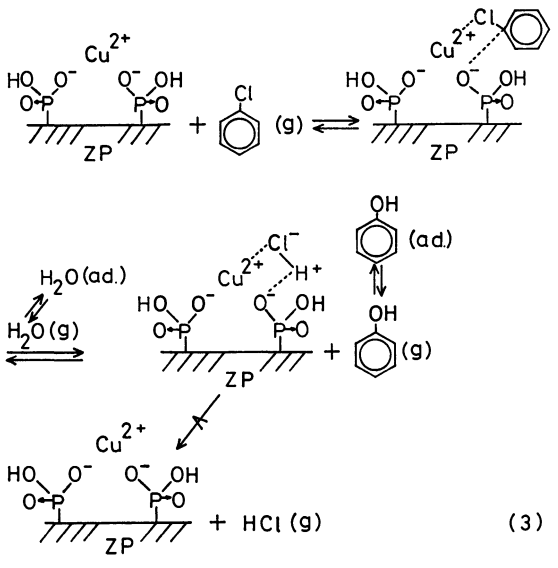
Catalyst: standard fresh ZP–Cu(II) 2.0 g, H_2O flow rate: 0.0992 mol/h, C_6H_5Cl flow rate: 0.0306 mol/h.

Considering the structure of the active site in ZP–Cu(II) discussed above, the vapor-phase hydrolysis of chlorobenzene over ZP–Cu(II) catalyst appears to proceed as follows:



(3)

A chlorobenzene molecule is first adsorbed on the active site and activated by copper(II) ion and phosphate group. The activated molecule is then hydrolyzed with the water in the vapor phase at the catalyst surface, and finally converted into phenol, leaving adsorbed hydrogen chloride behind. The rate-determining step is the desorption of hydrogen chloride.

Reichle[15] has previously investigated the vapor-phase hydrolysis of chlorobenzene over calcium hydroxyapatite promoted by copper(II) ion and proposed a mechanism of nucleophilic displacement of chlorobenzene by the hydroxide ion of the apatite. The copper(II) ion held in the apatite crystal would activate the formation of a Meisenheimer type complex from chlorobenzene and hydroxide ion. Thus the calcium apatite catalyst works as a nucleophile by itself:

$$2C_6H_5Cl + Ca_{10}(OH)_2(PO_4)_6 \longrightarrow 2C_6H_5OH + Ca_{10}Cl_2(PO_4)_6 \quad (4)$$

$$2H_2O + Ca_{10}Cl_2(PO_4)_6 \longrightarrow 2HCl + Ca_{10}(OH)_2(PO_4)_6 \quad (5)$$

On the other hand, ZP–Cu(II) in the present study catalyzes the reaction presumably in this way that both copper(II) ion and the phosphate group concertedly activate or polarize a chlorobenzene molecule and facilitate a nucleophilic attack of water on the chlorobenzene molecule.

The authors wish to thank Mr. Noboru Idemoto of Tokuyama Soda Co., Ltd. for a great deal of experimental help.

Theoretical Studies of Some Nonbenzenoid Hydrocarbons. V. Benzazulenes and Benzofluoranthenes

Archana Das Gupta, Subrata Chatterjee, and Nanda K. Das Gupta*,**,†

***Department of Chemistry, University of Alberta, Edmonton, Alta, Canada*

(Received March 11, 1978)

The molecules benzazulenes and benzofluoranthenes have been studied by the semi-empirical method for π-molecular systems, similar to that of Pariser-Parr and Pople. Ground state properties and $\pi^* \leftarrow \pi$ spectra have been predicted and compared with experiment. Agreement between the theoretical values and observed ones is good; that between the experimental value of half-wave reduction potential and values calculated by SCF(d) method is very good.

Dewar and coworkers[1] and Lo and Whitehead[2] predicted the ground state properties of many conjugated systems using the self-consistent field molecular orbital (SCF MO) theory with core resonance integral values determined either by a hypothetical thermocycle[1a,2] or utilising a relation[1a] between overlap integral and resonance integral. By means of their methods not only the ground state properties of some nonbenzenoid hydrocarbons can be predicted but also the $\pi^* \leftarrow \pi$ spectral transitions can be obtained with reasonable accuracy.[3] In most cases this spectra thus predicted are better than those predicted by the 'β-variable' SCF method with core resonance integral proposed by Yamaguchi *et al.*[4a] and modified by Das Gupta and Birss.[4b]

In this paper we would like to report the results of our calculations on some benzazulenes and benzofluoranthenes using the semi-empirical SCF MO method with resonance integral proposed by Chung and Dewar,[1a] Lo and Whitehead,[2] and Dewar and Harget.[1c] The results are compared with those obtained by the 'β-variable' SCF method, the methods being designated as SCF(a), SCF(b), SCF(c), and SCF(d). The molecules (Fig. 1) have also been studied theoretically by others[5] using different sets of parameters. We have studied how the properties of azulene and fluoranthene change with the fusion of benzene nucleus to them.

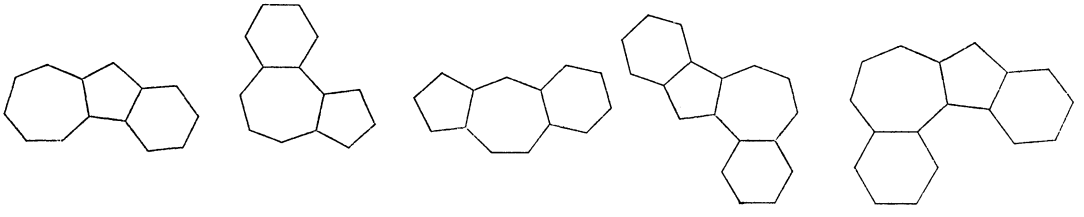
Method and Parameters

The method used here is the Pariser and Parr[6] and Pople[7] method within the zero-differential approximation.[8] The choice of parameters and mode of evaluation of certain integrals were reported.[3] For molecule **6** experimental structure[9] is available and core resonance integral and the two-center two electron repulsion integrals were evaluated by means of the structure. For other molecules whose experimental structure is not known we have used a planar and regular geometry with each bond length equal to 1.40 Å as far as possible for the evaluation of integrals.

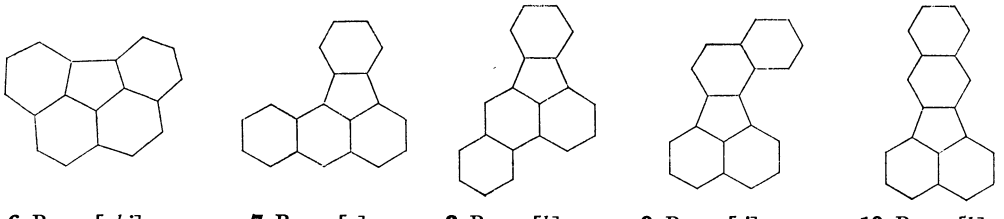
Results and Discussion

Bond Length. For monobenzazulenes the bond lengths calculated by the SCF(d) method is in good agreement with those of Dewar *et al.*[5f]

In the monobenzazulenes and dibenz[*a*,*e*]azulene the predicted bond lengths in the benzene ring have aromatic character, the bond length varying from 1.384



1 Benz[*a*]azulene **2** Benz[*e*]-azulene **3** Benz[*f*]-azulene **4** Dibenz[*a*,*e*]-azulene **5** Dibenz[*a*,*h*]azulene



6 Benzo[*ghi*]-fluoranthene **7** Benzo[*a*]-fluoranthene **8** Benzo[*b*]-fluoranthene **9** Benzo[*j*]-fluoranthene **10** Benzo[*k*]-fluoranthene

Fig. 1.

† On leave of absence from Chemistry Department, Visva-Bharati University, Santiniketan, West Bengal, India.

to 1.413 Å. In dibenz[*a*,*h*]azulene, however, the bond lengths of one of the benzene ring maintain the aromatic character whereas the bonds of the other benzene nucleus have marked deviation from aromatic character. In the first case they vary from 1.38 to 1.425 Å and in the second case from 1.36 to 1.45 Å. Thus the two benzene nuclei of the two dibenzazulenes are quite different; in one (Molecule **4**) both the six-membered rings have aromatic nature whereas in the other (Molecule **5**) only the benzene ring attached to the seven-membered ring maintains the character. This is also exhibited in the prediction of resonance energy. Molecule **4** has a higher value of resonance energy.

The peripheral bonds in azulene[3b] lie between 1.394 and 1.408 Å and are predicted to have aromatic character, but the fusion of benzene nucleus to azulene destroys the aromatic nature of the peripheral bonds in the five and seven-membered rings of the benzazulenes, except molecule **5** where the bond lengths predicted by the SCF(a), SCF(b), and SCF(d) methods have aromatic nature. The SCF(c) method gives the results which disagree. In all the molecules the common bond between the five and seven-membered rings has single bond character similar to that of azulene, the value lying between 1.45 and 1.47 Å calculated by these methods compared to 1.46 to 1.47 Å of azulene.[3b]

In the molecules **7**—**10** the fusion of a benzene ring in a fluoranthene moiety alters the predicted bond lengths of the six-membered ring to a considerable extent where the fusion takes place, the other bond lengths remaining almost the same as those of fluoranthene.[3e]

Resonance Stabilization

The heats of atomization (ΔH_a) and π-bond energy ($E_{\pi b}$) for the molecules calculated by the SCF(a), SCF(b), and SCF(c) methods are given in Table 1. The resonance energy (E_R) calculated by the methods of Lo and Whitehead[2], Dewar *et al.*[1] and Hess and Schaad[10] is given in Table 2, together with the resonance energy per C–C bond (E_R/C–C) since it is more useful for predicting the stability or aromaticity of a molecule. In benzazulenes the fusion of a benzene nucleus in azulene increases the E_R/C–C over that of azulene, whereas in benzofluoranthenes E_R/C–C is almost the same as that of fluoranthene. This suggests that all the benzazulenes should be more stable than azulene. It is also clear from the values of resonance energy and E_R/C–C bond that molecule **4**

†† Molecule **1** Refs. 11, 12; **2** Refs. 12, 5a; **3** Refs. 11, 12, 13; **4** Ref. 5b; **5—9** Ref. 11; **10** Refs. 11, 22, 23.
††† Calculated using the relation in Ref. 20. a) Ref. 5b, b) Ref. 5a; c) Ref. 5c; d) Ref. 21; e) Ref. 22.

should be more stable than molecule **5**. All the methods agree that the monobenzazulenes should be equally stable as shown by Dewar and Gleicher.[5f]

Molecules **7**, **8** and **9** or **10** can be treated as either anthracene and benzene, phenanthrene and benzene, and two naphthalene molecules joined by single bonds respectively. The resonance energy for these molecules corresponds almost to the sum of the resonance energies of anthracene and benzene, phenanthrene and benzene, and two naphthalene molecules. The best result is obtained by the method of Dewar and Harget.[1c]

$\pi^*\leftarrow\pi$ Spectra, Ionization Energy and Electron Affinity. The $\pi^*\leftarrow\pi$ spectra calculated by the SCF methods (except the SCF(c)[3] method which is not as good as the other SCF methods in predicting the spectral transitions) with and without configuration interaction (CI) along with the experimental spectra[11-13] are given in Table 3. For the sake of comparison, the results of other workers[5] are given. In the CI procedure the final vectors and integrals obtained by the SCF(d) method were used, all the single excitations being included. For benzazulenes our results are in good agreement with the experimental value, in particular, the results predicted by the CI method which is better than those predicted by Koutecky *et al.*[5b] The same conclusion can be drawn for the benzofluoranthenes (**7**—**10**). However, for molecule **6** the agreement between our results and experimental values is not so good; the results predicted by the CI method are better than the results predicted by other workers.[5b]

Although SCF(a) and SCF(b) methods were parameterized to predict the ground state properties, the spectral transitions predicted by them are in better agreement with the experimental values than the SCF(d) method which was parameterized to predict the $\pi^*\leftarrow\pi$ spectra. The same has been observed.[3]

According to Koopmans' theorem[14] ionization potential (*IP*) is equal to the highest occupied orbital energy. But *IP* predicted in this way is 1 or 2 eV higher than the true ionization potential. Hence a correction should be introduced. The ionization potential can be given by the relation

$$IP = -(\varepsilon_i + c)\ \text{eV}$$

where ε_i is the highest occupied orbital energy and 'c' is the correction term. Bloor[15a] used a value of 1.33 for the correction term 'c' and we have used it in predicting the *IP* by the SCF(a) or SCF(b) method. For the SCF(d) method the value of the correction term is 1.06 as suggested by Kunii and Kuroda.[16] It has been found that a value of 1.88[15b] for 'c' gives very good prediction of *IP* in SCF(c) method. The calculated values of ionization potential are given in Table 4. According to Bloor[15a] the half-wave reduction potential, measured in 95% aqueous dioxane, can be fitted by a relation. If the SCF(d) method is used, the half-wave reduction potential for molecules **7**—**10** are well reproduced by the relation

$$\varepsilon_{1/2} = -(\varepsilon_j + 4.60)\ \text{eV}$$

where ε_j is the lowest unoccupied orbital energy. The predicted values of half-wave reduction potential, $\varepsilon_{1/2}$, using the SCF(d) method along with the experimental values of $\varepsilon_{1/2}$ where available and calculated values of π-dipole moment are also given in Table 4. The experimental value $(1+0.2D)$[19] has been reported only for molecule **10**. For comparison we have included the values of Dewar *et al.*[5f] for monobenzazulenes.

The authors wish to thank Professor F. W. Birss for his comments, helpful discussions and financial support. Computational facilities were provided by the Computing Services, University of Alberta.

Conductometric Study of Ion-Ion and Ion-Solvent Interactions. I. Conductances of Silver Acetate in 0—50% (w/w) Methanol–Water Mixtures at 35 °C

J. Ananthaswamy, B. Sethuram, and T. Navaneeth Rao*
Department of Chemistry, Osmania University, Hyderabad 500007, India

(Received June 24, 1978)

Conductances of the solutions of silver acetate in 0 to 50% (w/w) methanol–water mixtures were measured at 35 °C. The association constants and molar conductances at infinite dilution were calculated using the Shedlovsky extrapolation technique and the Fuoss-Hsia equation with Fernandez-Prini coefficients. The log K_A *vs.* $1/D$ plot passes through the origin in accordance with the Denison-Ramsey theory of ion-pair formation. The results were interpreted in terms of the equilibrium between the solvent separated ion-pairs (SSIP) and contact ion-pairs (CIP).

Ion-association increases from lithium to cesium in solutions of alkali metal halides, and from cesium to lithium in solutions of alkali metal acetates, hydroxides and fluorides.[1] Ion-pair formation in solutions of alkali metal halides and halides of small metal ions has been extensively investigated[2] conductometrically both in aqueous and aquo-organic solvents. However, such studies on acetates[3] of small metal ions are very few. The electrical conductances of silver acetate were thus measured in order to understand the reverse trend of ion-association in acetates *etc.*, as compared to that in halides. The conductance data was analysed using the Fuoss-Hsia equation[4] with Fernandez-Prini coefficients[5] to evaluate the association parameters. The results were interpreted in terms of the equilibrium between the solvent separated ion-pairs (SSIP) and contact ion-pairs (CIP). The applicability of various theories of ion-pair formation such as those of Bjerrum,[6] Fuoss,[7] Denison-Ramsey[8] (DR), and Ebeling-Kraeft-Yokoyama and Yamatera[9,10] (EKYY) has been discussed.

Experimental

Silver acetate (Fluka: purum) was used after repeated recrystallizations from ethanol and drying. Methanol (BDH, electrolytic grade) was used without further purification. The specific conductance was found to be within $2-5\times10^{-8}$ S cm^{-1}. Water with a specific conductance less than 5×10^{-7} S cm^{-1} was used. Due correction was made for the solvent conductance in the conductance values of all the salt solutions. All solutions were prepared freshly just before use and protected from light by covering with a thick dark cloth. The experimental arrangement was the same as reported earlier.[11] The overall accuracy of the measured molar conductances was better than ±0.05%.

Results and Discussion

The molar conductances of the solutions of silver acetate in water and 10, 20, 30, 40, and 50% (w/w) methanol–water mixtures at 35 °C are given in Table 1. The dielectric constants and viscosities of methanol–water mixtures were taken from literature.[12a,b]

The conductance data were first analysed using the Shedlovsky extrapolation technique,[13]

$$1/\Lambda S(Z) = 1/\Lambda_0 + (K_A/\Lambda_0^2)(c\Lambda y_\pm^2 S(Z)), \quad (1)$$

where Λ and Λ_0 are the molar conductances at concentrations c mol dm^{-3} and zero (infinite dilution), respectively.

$$S(Z) = 1 + Z + Z^2/2 + Z^3/8 + \cdots, \quad (2)$$

$$Z = s(\Lambda c)^{1/2}/\Lambda_0^{3/2}, \quad (3)$$

s is the limiting law slope and K_A is the association constant. The activity coefficient ($y_\pm$) was calculated using the Debye-Hückel limiting law.[14]

$$\log y_\pm = -A(\propto c)^{1/2}, \quad (4)$$

where

$$A = 1.8246\times10^6/(DT)^{3/2}. \quad (5)$$

The degree of dissociation ($\propto$) is related to $S(Z)$ by

$$\propto = \Lambda S(Z)/\Lambda_0. \quad (6)$$

The association parameters obtained by this method are given in Table 2.

The conductance data was then analysed using the Fuoss-Hsia equation[4] with Fernandez-Prini coefficients[5] as in the following.

$$\Lambda = \Lambda_0 - s(\propto c)^{1/2} + E\propto c\ln(\propto c) + J_1(\propto c) - J_2(\propto c)^{3/2} - K_A\Lambda y_\pm^2\propto c \quad (7)$$

where the various symbols have their usual meanings. The activity coefficients ($y_\pm$) were calculated by the equation,

$$-\log y_\pm = A(\propto c)^{1/2}/\{1+Ba(\propto c)^{1/2}\}. \quad (8)$$

Equation 7 was solved as originally described by Justice[15] and subsequently clarified by Pethybridge and Spiers,[16] and Kubota and Yokoi.[17] The procedure envisages the replacement of the distance of closest approach of ions (a) by the Bjerrum critical distance (q). The standard deviation (σ) values were calculated from the relation:

$$\sigma = \{\sum(\Lambda_{exp}-\Lambda_{cal})^2/(N-3)\}^{1/2}. \quad (9)$$

All the calculations were done on TDC-12 computer and the results are given in Table 3.

We see from Table 2 that Λ_0 values obtained by the Shedlovsky method are higher than those obtained by use of the Fuoss-Hsia equation by 0.1—1.4%. The deviations in K_A values are 7.7—16.4% (50% methanol). Thus, the Λ_0 values obtained by the Shedlovsky method deviate to a lesser extent than the corresponding K_A values. Therefore, the Shedlovsky method may be used as a rapid first hand tool for evaluating Λ_0 values, even though the K_A values obtained by this method are not so reliable.

The functional dependence of log K_A on $1/D$ was used to test the applicability of the various theories

of ion-pair formation. A linear plot passing through the origin is expected according to the Denison-Ramsey (DR) theory whereas Bjerrum and EKYY theories predict curves which are concave downwards. The Fuoss theory predicts a straight line with a finite intercept. The least square regression line required by the experimental points has a correlation coefficient of 0.997 with slope and intercept values of 120.4 and −0.0453 respectively (Fig. 1). When we neglect the small intercept (−0.0453), the plot of $\log K_A$ *vs.* $1/D$ becomes a straight line passing through the origin. The following simple expression of DR theory closely

Table 2. Λ_0 and K_A values calculated according to the Shedlovsky method and their deviations from the corresponding values obtained by use of the Fuoss-Hsia equation

Solvent	Λ_0 / S cm^2 mol^{-1}	Deviation in Λ_0/%	K_A / dm^3 mol^{-1}	Deviation in K_A/%
50% MeOH	80.888	1.36	132.0	16.4
40% MeOH	81.453	0.963	93.36	14.8
30% MeOH	86.438	0.704	68.71	13.6

10% MeOH	105.84	0.377	37.93	11.8
Water	125.81	0.111	31.89	7.70

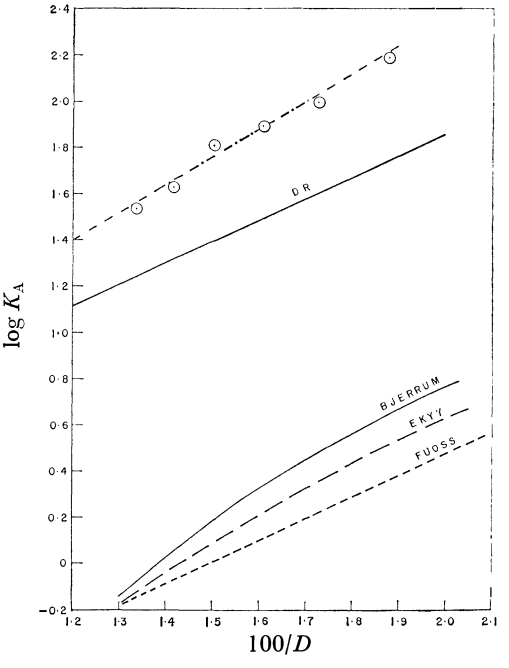

Fig. 1. $\log K_A$ *vs.* $100/D$.

reproduces the association constant data for silver acetate in 0—50% (w/w) methanol–water mixtures at 35 °C.

$$\log K_A = 120.4/D \tag{10}$$

or

$$K_A = \exp(277/D). \tag{11}$$

By comparing Eq. 10 with DR theory expression, we have

$$\log K_A = |Z_+Z_-|e^2/aDkT. \tag{12}$$

The distance of the closest approach of ions was found to be 2.02 Å. The ion-size parameters (a_K) required by various theories to give the experimental K_A values were also calculated. While the Fuoss, Bjerrum and EKYY theories require the a values to lie in the range 0.6—0.8 Å, the DR theory requires thom to be 2.01± 0.03 Å. Since the ionic radii of Ag^+ itself is 1.26 Å, an a value of 0.8 Å for silver acetate is incompatible. The DR theory is in better agreement with experimental results.

The ion-size parameter of the silver acetate was calculated[18] to be 2.53 Å from the known crystallographic data. The theoretical association constant

Table 3. Association parameters of silver acetate obtained by use of the Fuoss-Hsia equation

Solvent	q/Å	Λ_0 / S cm^2 mol^{-1}	K_A / dm^3 mol^{-1}	σ	$\Lambda_0\eta$
50% Methanol	5.095	82.006	157.9	0.121	0.9267
40% Methanol	4.697	82.245	109.6	0.072	0.9376
30% Methanol	4.358	87.051	79.49	0.097	0.9750
20% Methanol	4.075	96.240	65.40	0.382	0.9672
10% Methanol	3.835	106.24	43.01	0.054	0.9200
Water	3.613	125.95	34.55	0.091	0.9131

values for silver acetate according to Bjerrum, Fuoss, Denison-Ramsey (K_{DR}) and EKYY theories were calculated for various dielectric constants using the crystallographic ion-size parameter value, *i.e.* 2.53 Å. The plots of the logarithms of these theoretical association constants against $1/D$ are also shown in Fig. 1. It is evident that all the theories predict lower association constants than those obtained experimentally. However, K_{DR} values are comparatively nearer to the experimental values. The experimental results are in better agreement with the DR theory than the other theories. The same was concluded above from the nature of log K *vs.* $1/D$ plots. The experimental values are higher than the theoretical values, *i.e.* K_{DR}. This could be explained[19] by assuming the existence of two types of ion-pairs *i.e.* solvent separated ion-pairs (SSIP) and contact ion-pairs (CIP) in equilibrium. This involves a two step process:

$$M^+(S)_m + A^-(S)_n \underset{}{\overset{K_1}{\rightleftharpoons}} \underset{\text{(SSIP)}}{M^+SA^-(S)_{m+n-1}}$$

$$\Big\| K_2$$

$$\underset{\text{(CIP)}}{M^+A^-(S)_{m+n-1}} + S,$$

where S denotes a solvent molecule and m and n are the solvation numbers of ions. The overall association constant K_t for this process could be related to K_1 and K_2 by

$$K_t = K_1(1+K_2/[S]). \quad (13)$$

The values of K_2 were calculated by substituting the association constant values calculated using the DR theory with an a value of 2.53 Å for K_1 and experimentally obtained K_A values for K_t in Eq. 13. The results are given in Table 4. In Eq. 13, S was taken as the concentration of water in methanol–water mixtures since the medium activity coefficient data[20] shows that both Ag^+ and CH_3COO^- are preferentially hydrated in methanol–water mixtures.

The association constants of silver acetate increased from 34.55 in water (D=75.03) to 157.9 dm^3 mol^{-1} in 50% methanol (D=53.21). The values are unusually high as compared to those of alkali metal halides in these solvent systems. In a recent study[16] the K_A values of alkali metal fluorides in water at 25 °C were found to be 0.07 (CsF), 0.16 (RbF), 0.14 (KF), 0.47 (NaF) and 1.78 (LiF). In aqueous solutions[21] potassium, rubidium and cesium hydroxides are completely dissociated whereas lithium hydroxide (K_A= 0.81 dm^3 mol^{-1}) shows clear evidence of association.

Table 4. Equilibrium constants for the conversion of SSIP into CIP

Solvent	$K_1=K_{DR}$ / dm^3 mol^{-1}	$K_2=[S](K_t/K_1-1)$ / dm^3 mol^{-1}
50% Methanol	56.12	50.38
40% Methanol	40.97	55.87
30% Methanol	31.36	59.69
20% Methanol	25.06	71.54
10% Methanol	20.74	53.69
Water	17.40	54.76

An unusually high association constant of 200 dm^3 mol^{-1} was reported[22] for silver hydroxide. Similarly silver nitrate was found to be more associated than alkali metal nitrates in both methanol and ethanol.[23] This shows that ion-pair formation is higher in silver salts than in the corresponding alkali metal salts.

Thermochemistry of Copper(II) β-Diketonates. II.† Bis(benzoylacetonato)copper(II)

Manuel A. V. Ribeiro da Silva* and Ana Maria M. V. Reis

Chemistry Department, Faculty of Sciences, University of Oporto, P-4000 Porto, Portugal

(Received July 22, 1978)

The standard enthalpy of formation of crystalline bis(benzoylacetonato)copper(II) has been determined at 298.15 K by solution calorimetry: $\Delta H_f^\circ[Cu(bzac)_2]$ (c) $= -143.6 \pm 2.2$ kcal mol^{-1}. Enthalpy changes at 298.15 K for the following hypothetical gaseous reactions have been subsequently derived:

$$Cu(g) + 2bzac\cdot(g) = [Cu(bzac)_2](g) \qquad \Delta H = -165.9 \pm 14.3 \text{ kcal mol}^{-1}$$

$$Cu^{2+}(g) + 2bzac^-(g) = [Cu(bzac)_2](g) \qquad \Delta H = -747.3 \pm 14.4 \text{ kcal mol}^{-1}$$

The corresponding homolytic($\overline{E}$) and heterolytic($\overline{E}'$) copper(II)-oxygen mean bond energy parameters were calculated as

$$\overline{E}_{Cu-O} = 41 \pm 3 \text{ kcal mol}^{-1} \quad \text{and} \quad \overline{E}'_{Cu-O} = 187 \pm 3 \text{ kcal mol}^{-1}$$

respectively.

In a previous paper,[1] the standard enthalpy of formation of bis(tropolonato)copper(II) and the Cu(II)–O homolytic and heterolytic bond energies were presented. As it was pointed out in the discussion, the lack of knowledge of similar parameters for the Cu(II)–O bonds of other compounds, made it very difficult to discuss the calculated values of the Cu(II)–O bonds.

To close the gap we examine here the corresponding benzoylacetonate†† complex in order to compare the ligand structural effects in the copper–oxygen bond. The crystal structure of bis(benzoylacetonato)copper-(II) has been determined[2] and shows that the crystals are formed from separate components and that in each molecule the four oxygen atoms lie in the same plane as the copper atoms.

Experimental

The Solution Calorimeter. The LKB 8700 Reaction and Solution Precision Calorimeter was used for all solution reactions. The operation and calculation methods have been described before.[1]

Thermochemical functions are expressed in terms of the thermochemical calorie (defined as 4.184 J exactly) and refer to the isothermal process at 298.15 K and the true mass, calculated using the atomic weights of 1966 based on the isotope ^{12}C. A check on the accuracy of the calorimeter was carried out by determining the enthalpy of solution of *N,N′,N″*-tris(hydroxymethyl)methanetriamine, (tham) in excess 0.1 M hydrochloric acid. The result, -7110.2 ± 0.7 cal mol^{-1} is in excellent agreement with previous results[3] (-7115.4 ± 0.6 cal mol^{-1}).

The uncertainty range is twice the standard deviation of the mean (five determinations were made for each compound).

Materials. Benzoylacetone (Hbzac): 'AnalaR' Koch-Light benzoylacetone was recrystallized from ethanol-water and dried over silica gel; mp = 55 °C (lit, 56 °C[4]).

Found: C, 73.87; H, 6.26%. Calcd for $C_{10}H_{10}O_2$: C, 74.06; H, 6.22%.

Bis(benzoylacetonato)copper(II): $[Cu(bzac)_2]$ was prepared by a modification of the method of Hammond *et al*:[5] a solution of 'AnalaR' copper(II) sulfate (2.5 g) in water (100 cm^3) was buffered with sodium acetate (7.5 g) and then mixed with a solution of benzoylacetone (5 g) in ethanol (80 cm^3). The precipitated complex was washed on the filter with water and cold ether, filtered off, dried in the air, recrystallised from chloroform and stored in a desiccator over silica gel; mp = 189—190 °C.

Found: C, 62.00; H, 4.68; Cu, 16.41%. Calcd for $C_{20}H_{18}O_4Cu$: C, 62.25; H, 4.70; Cu, 16.46%.

Copper(II) Sulfate Pentahydrate: 'AnalaR' grade copper(II) sulfate pentahydrate was powdered and dried in a desiccator over silica gel for 48 h. Its composition was determined by means of a electrogravimetric copper analyses and found to be $CuSO_4 \cdot 5.00\, H_2O$. Periodical analyses showed no change in composition.

Sulfuric Acid: A molar solution of 'AnalaR' grade sulfuric acid was made up, by using a BDH concentrated volumetric solution; the concentration was checked by acid-base titration against $Na_2B_4O_7 \cdot 10H_2O$ and found to be (series of six titrations) 1.0000 ± 0.0004 M which corresponds[4] to the composition $H_2SO_4 \cdot 53.539(1)\ H_2O$.

1,4-Dioxane: 'AnalaR' dioxane was purified according to Refs. 6 and 7.

Constant Boiling Hydrochloric Acid, was prepared from 'AnalaR' HCl by dilution with distilled water. The concentration of the HCl solution was determined by titration against $Na_2B_4O_7 \cdot 10H_2O$. A series of six different determinations gave the result of 4.2172 ± 0.0004 M *i.e.* $HCl \cdot 11.911\ H_2O$.[4]

Analyses: All carbon and hydrogen analyses were carried out in the Microanalytical Service of the University of Surrey; copper in the complex was analysed by atomic absorption spectroscopy.

Method for Solution Calorimetry: Preliminary tests of solubility showed that although some species would dissolve very slowly in dilute acid solutions, satisfactory results were obtained using a solution of dioxane (75%) and 4.2 M HCl (25%) as calorimetric solvent, and dissolving stoichiometric quantities of the reactants and products in this mixed solvent.

Calculation: The standard enthalpy of formation of the bis(benzoylacetonato)copper(II) complex can be determined from reaction between the benzoylacetone and the copper(II) sulfate pentahydrate to give a solution of the copper(II) complex and sulfuric acid:

$$2Hbzac(c) + CuSO_4 \cdot 5H_2O(c) \xrightarrow{\Delta H_R} [Cu(bzac)_2](c) + H_2SO_4 \cdot 5H_2O(aq). \qquad (1)$$

The difference between the enthalpies of solution of the products and reactants in the same stoichiometric ratio gives the required enthalpy of formation, provided equilibrium is

† Part I is Ref. 1.

†† Benzoylacetone(Hbzac) = 1-phenyl-1,3-butanedione.

reached from either side within the period of the experiment.

To the calorimetric solvent (100.0 cm^3) ampoules with the appropriate amounts of water, benzoylacetone and $CuSO_4 \cdot 5H_2O$ were added consecutively and ΔH_1, ΔH_2, and ΔH_3 were measured. To a second portion of the same solvent (100.0 cm^3) were added consecutively ampoules of $H_2SO_4 \cdot 53.54\ H_2O$ and bis(benzoylacetonato)copper(II) and ΔH_4 and ΔH_5 were measured. The general procedure together with the general thermochemical cycle, is given in the Scheme. The quantities of reactants in a series of experiments were determined by the amount of bis(benzoylacetonato)copper(II) in a particular ampoule (about 2.5×10^{-4} mol); exact control of stoicheiometry was maintained throughout each series. When this procedure is used the value calculated for ΔH_R refers to the reaction indicated in the first line of the Scheme, provided that solutions (A_3) and (B_2) are identical and that the value of ΔH_6 is zero. As a check of the validity of this, ampoules of solutions (B_2) were broken into solution (A_3) in the calorimeter; no detectable heat exchange occurred.

Results and Discussion

The experimental data are presented in Table 1, leading to the value $\Delta H_R = +10.13 \pm 0.31$ kcal mol^{-1}.

The following values were taken from the literature:

$\Delta H_f^\circ[CuSO_4 . 5H_2O(c)] = -544.85$ kcal mol^{-1},[8]

$\Delta H_f^\circ[Hbzac(c)] = -81.2 \pm 1.1$ kcal mol^{-1},[9]

$\Delta H_f^\circ[H_2SO_4 \cdot 53.54H_2O(aq)] = -3869.5509$ kcal mol^{-1},[10]

$\Delta H_f^\circ[H_2O(l)] = -68.315$ kcal mol^{-1},[10]

and, according to the first line of the Scheme, the standard enthalpy of formation of crystalline bis(benzoylacetonato)copper(II) at 25 °C was calculated to be $\Delta H_f^\circ[Cu(bzac)_2](c) = -143.6 \pm 2.2$ kcal mol^{-1}.

Although the enthalpy of sublimation of the bis(benzoylacetonato)copper(II) has not yet been experimentally and accurately measured, the consideration of the existing data on similar compounds (other metal β-diketonates[11,12]) makes possible a reasonable estimate[1]; however, the uncertainty must be large, but if we take the upper value of ±10 kcal mol^{-1}, this only produces an uncertainty of *ca.* 2.5 kcal in the bond energy. Accordingly, if we assume $\Delta H_{sub}^\circ[Cu(bzac)_2](c) = 32.0 \pm 10.0$ kcal mol^{-1}, the standard enthalpy of formation of the gaseous complex is $\Delta H_f^\circ[Cu(bzac)_2](g) = -111.6 \pm 10.2$ kcal mol^{-1}.

As discussed previously,[11,12] the metal–oxygen bond strength can be equated to be the energy needed to break the molecule into the metal and ligand radicals, all referred to the gaseous state (Eq. 2), in order to remove the condensed state effects.

$$[Cu(bzac)_2](g) \xrightarrow{\Delta H_f(r)} Cu(g) + 2bzac\cdot(g) \qquad (2)$$

Since the oxygens in β-diketonates are known to be equivalent,[13] which is again supported by the crystal structure of this particular complex[2], the mean copper(II)–oxygen homolytic bond energy $\overline{E}$(Cu–O), is $\Delta H_f^\circ(r)/4$.

The value of the standard enthalpy of formation of the benzoylacetone radical itself can be calculated from the knowledge of the dissociation energy of the enolic hydrogen of benzoylacetone, that is the enthalpy of reaction of process(3)

$$Hbzac(g) \longrightarrow H\cdot(g) + bzac\cdot(g) \qquad (3)$$

According to previous work[1,11,14,15] we take 100±5 kcal mol^{-1} for the enolic hydrogen dissociation energy of gaseous Hbzac. Hence, from ΔH_{sub}°(Hbzac) =

Table 2. (all values in kcal mol^{-1})

Complex	ΔH_f°(c)	ΔH_r(r)	$\overline{E}$(Cu–O)	$\Delta H_f'$(i)	$\overline{E}'$(Cu–O)
$[Cu(trop)_2]$[24]	−99.13±0.42	−146.9±14.1	37±3	−728.0±11.4	182±3
$[Cu(bzac)_2]$	−143.6 ±2.2	−165.9±14.3	41±3	−747.3±14.4	187±3

20.02±0.10[16] kcal mol^{-1} one calculates ΔH_f°(Hbzac, g) = −61.2±1.1 kcal mol^{-1} and from the above values and ΔH_f°(H·,g) = 52.095 kcal mol^{-1},[10] the standard enthalpy of formation of the gaseous benzoylacetone radical, is derived as ΔH_f°(bzac·,g) = −13.3±5.1 kcal mol^{-1}.

As ΔH_f°(Cu,g) = 80.86 kcal mol^{-1},[8] the calculated value for the hypothetical gaseous reaction 2 is ΔH_r(r) = 165.9±14.3 kcal mol^{-1} and hence, the mean copper(II)–oxygen homolytic bond energy, $\overline{E}$(Cu–O) = 41±3 kcal mol^{-1} was calculated.

The bond energy in terms of the ions in defined by Eq. 4.

$$Cu^{2+}(g) + 2bzac^-(g) \xrightarrow{\Delta H_f(i)} [Cu(bzac)_2](g) \qquad (4)$$

Estimating the electron affinity of the β-diketonates[1] to be approximately equal to that of the oxygen atom for one electron (E_L = 1.465 eV = 33.8 kcal mol^{-1}),[17] the enthalpy of formation of the gaseous anion benzoylacetone is calculated as ΔH_f(bzac$^-$)(g) = −47.1± 5.1 kcal mol^{-1}, and using the literature value ΔH_f° (Cu^{2+})(g) = 729.93 kcal mol^{-1},[8] one calculates the value of ΔH_f(i) = 747.3±14.4 kcal mol^{-1} and hence the so called heterolytic copper(II)–oxygen mean bond energy, $\overline{E}'_{Cu-O} = \Delta H_f(i)/4$, is calculated as $\overline{E}'_{Cu-O}$ = 187±3 kcal mol^{-1}.

The stability of a co-ordination compound is commonly interpreted as referring to the process

$$M^{n+} + nL^- \longrightarrow [ML_n]$$

occurring in solution, which is a Lewis acid-base reaction and therefore the stability of the compound should increase as the strength of the Lewis base increases. One would expect therefore that the stability should be in the order of increasing dissociation constant pK of the ketone, *i.e.*, in the case of copper(II) β-diketonates, tropolone(7.0)[18] and benzoylacetone (8.94).[19] There is little data from stability constant studies which related directly to this system: copper(II) tropolonate has an overall stability constant of 15.4, at 30 °C in 50% dioxane–water[20–22] and copper(II) benzoylacetonate has an overall stability constant of 17.02 at 25 °C in 75% dioxane–water,[23] from which the free energies can be derived: $\Delta G[Cu(trop)_2]$ = −21.4 kcal mol^{-1} and $\Delta G[Cu(bzac)_2]$ = −23.2 kcal mol^{-1}.

This is quite a significant difference in free energy but the lack of values for the entalpy of formation of the complexes in solution prevents other conclusions.

However, the large value for the enthalpy of formation of copper(II) benzoylacetonate from its ions in the vapour state (−747 kcal mol^{-1}) shows the large importance of solvation effects in solution processes, and so, it is apparent from this, that stability constants can give very little direct information of metal–ligand bond energies.

Table 2 summarizes the relevant parameters for the copper(II) complexes of benzoylacetone and tropolone.[24]

Whether the Cu–O bond energy is expressed in terms of dissociation into radicals or ions, the uncertainty arising from the use of the estimated auxiliary data is sufficiently large to obscure any clear difference effect of ligand parameters, but it is noteworthy that a change in the dissociation constant of the ligand by almost 2 pK units causes a change in the heterolytic bond energy of less that 5 kcal (3%). Unfortunatly, the uncertainties ascribed to the bond energy parameters (±3 kcal mol^{-1}) are big enough to prevent one to conclude that the Cu–O bond energy is definitely larger in the benzoylacetonate complex than in the tropolonate one. Nevertheless, it seems reasonable to think that these results are in agreement with the Nakamoto's[25] statement that the value of the metal–oxygen bond energy in substituted β-diketonates increases with the introduction of a phenyl group in

the β-diketones and disagrees with Collman's[26] opposite statement.

Thanks are due to the Instituto Nacional de Investigação Científica, Lisboa, Portugal, for partial financial support of the research project.

Oxidation of Benzaldehydes by Peroxomonophosphoric Acid. A Kinetic and Mechanistic Study in Acid and Alkaline Media

G. P. PANIGRAHI* and Radhasyam PANDA

Department of Chemistry, Berhampur University, Berhampur 760007, Orissa, India

(Received October 7, 1978)

The oxidation of benzaldehydes by peroxomonophosphoric acid has been found to proceed by

(i) $-d[\text{peroxomonophosphoric acid}]/dt \propto [\text{benzaldehyde}][\text{peroxomonophosphoric acid}][H^+]^x$

where x=a fraction at $[H^+]<0.5$ M and $x=0$ at $[H^+]>0.5$ M and

(ii) $-d[\text{peroxomonophosphate}]/dt \propto [\text{benzaldehyde}][\text{peroxomonophosphate}][OH^-]^y$

where y=a fraction at $[OH^-]<0.1$ M and $y=0$ at $[OH^-]>0.1$ M.

In the alkaline oxidation Hammett relationship is obeyed excellently, unlike the oxidation in the acid medium. The oxidation mechanisms are discussed in terms of a nucleophilic attack of the peroxomonophosphoric acid species on the carbonyl carbon centre. Thermodynamic parameters have been evaluated to substantiate the mechanisms.

Peroxomonophosphoric acid (PMPA) is known to function through a polar mechanism in spite of the fact that these compounds are sources of free radicals due to homolysis of O–O bonds not only in homogeneous media but also in some heterogeneous reactions.[1-3] Operation of a polar mechanism in oxidations by peroxo compounds was first recognised by Swern.[4] Kinetics of oxidation of halide ions[5] by peroxomonophosphoric acid, peroxomonosulfuric acid and peracetic acid, and of iodide ion[6] by peroxomonophosphoric acid involve both H^+-dependent and H^+-independent terms.

A survey of literature, however, reveals that studies relating to PMPA oxidation of organic substrates are quite few. Hence it was thought worthwhile to investigate the possibility of the use of PMPA as an oxidant for organic substrates. More interesting is the use of PMPA in alkaline medium which is probably for the first time we have attempted to undertake. This report deals with the kinetics of oxidation of aromatic aldehydes by PMPA in acid and alkaline media.

Experimental

All the chemicals used were of Analar grade. Benzaldehydes used were freshly distilled or recrystallized samples. PMPA was prepared by the acid hydrolysis[5-7] of $K_4P_2O_8$. The acidity of the medium was adjusted with $HClO_4$ or H_2SO_4 as the case may be and the ionic strength of the medium was maintained by adding requisite amounts of $NaClO_4$ or $NaHSO_4$. In the case of experiments in alkaline medium, the acid after hydrolysis of peroxodiphosphate was first neutralised by adding a calculated amount of alkali and then a known excess of alkali was added so as to obtain the required hydroxide concentration. Reactions were followed by measuring the rate of disappearance of PMPA, the estimation of which was done in an acetic acid–acetate buffer of pH 4—5 by the usual iodometric procedure. In separate experiments, the oxidation rates followed by the disappearance of PMPA were found to check within 2—6% with the rates followed by measuring the formation of benzoic acid spectrophotometrically. The self decomposition of the oxidant was routinely checked and found to be either nil or negligibly small under our experimental conditions. The aerial oxidation of benzaldehyde was found to be negligible because the rates of oxidation in an atmosphere of nitrogen, in representative runs, agreed with in 3—5% to those in the presence of air.[8,9]

Results and Discussion

Reactions in Acid Medium. Stoichiometry: Experiments conducted with excess of PMPA, in the presence of air or under a nitrogen atmosphere, showed that the stoichiometry of aldehyde to PMPA is 1: 1 and the product is the corresponding benzoic acid.

Benzaldehyde has been oxidised by PMPA in aqueous medium in the presence of $HClO_4$ and H_2SO_4 at 35 °C at constant ionic strength. The reaction is found to be first order with respect to the disappearance of PMPA and to the substrate (Table 1).

Dependence on $[H^+]$: The variation of $[H^+]$ ($HClO_4$ or H_2SO_4) is accompanied by a variation of rate in the same direction suggesting the reaction to be acid-catalysed. However, this catalysis is observed upto $H^+=0.5$ M beyond which the rate tends to become independent of the acid concentration.

Effect of Added Substances: A change in the ionic strength of the medium or the addition of acrylamide or Cu^{2+} does not affect the oxidation rate. The decrease in the rate in the presence of HPO_4^{2-} may be due to the removal of H^+ from the reaction medium (Table 1).

Effect of Substituents: The second order rate constants (k_2') for the oxidation of benzaldehydes are summarised in Table 2. It is interesting to note that the substituent effect on the reaction rate is insignificant in acid medium; the electron-withdrawing *p*-nitro substituent and the electron-releasing *p*-methyl substituent only marginally influence the rate whereas the other substituents are without any effect. Such observations on anomalous substituent effect have been reported earlier.[10,10a] It might have arisen because of the operation of a preliminary hydration equilibrium,[10a]

$$XC_6H_4CHO + H_2O \overset{K_p}{\rightleftharpoons} XC_6H_4CH(OH)_2,$$

competing with the oxidation steps; an electron withdrawing *p*-nitro substituent would favour the formation of the hydrate, but would retard the oxidation process because of a fall in the effective concentration of benzaldehyde available for oxidation (benzaldehyde is prefered to the hydrate in the oxidation steps because otherwise the substituent effects would have been in the same direction; *e.g.*, an electron-withdrawing substituent

Table 1.[a] Oxidation of benzaldehydes by PMPA in acid medium

would have enhanced the rate and an electron-releasing substituent would have retarded it).

Solvent Effect: The oxidation rate is found to decrease marginally with increase in acetic acid content in the solvent mixture (Table 1). The marginal decrease in the rate with decrease in dielectric constant of the medium is to be expected for a reaction involving a neutral molecule and an ion[11] to which the present reactions probably conform.

Rate Law: The various equilibria involving PMPA in the solution are

$$H_3PO_5 \overset{K_1}{\rightleftharpoons} H_2PO_5^- + H^+, \quad (1)$$

$$H_2PO_5^- \overset{K_2}{\rightleftharpoons} HPO_5^{2-} + H^+, \quad (2)$$

$$HPO_5^{2-} \overset{K_3}{\rightleftharpoons} PO_5^{3-} + H^+. \quad (3)$$

K_1, K_2, and K_3 values are 8.0×10^{-2}, 4.2×10^{-6}, and 1.6×10^{-13} respectively at 25 °C.[7] Since in the [H$^+$] range used, PMPA exists[7] as H_3PO_5 and $H_2PO_5^-$, the oxidation steps may be written as

$$XC_6H_4CHO + H_2O \overset{K_p}{\rightleftharpoons} XC_6H_4CH(OH)_2, \quad (A)$$

$$H_2PO_5^- + H^+ \overset{K}{\rightleftharpoons} H_3PO_5, \quad (4)$$

$$H_2PO_5^- + XC_6H_4CHO \xrightarrow{k_1} XC_6H_4COOH + H_2PO_4^-, \quad (5)$$

and

$$H_3PO_5 + XC_6H_4CHO \xrightarrow{k_2} XC_6H_4COOH + H_3PO_4. \quad (6)$$

The reaction sequence leads to the rate law

$$-\frac{d[PMPA]}{dt} = [PMPA][XC_6H_4CHO]\left\{\frac{k_1+k_2K[H^+]}{1+K[H^+]}\right\} \times(1+K_p[H_2O]), \quad (7)$$

where

$$k_2' = \left\{\frac{k_1+k_2K[H^+]}{1+K[H^+]}\right\}(1+K_p[H_2O]). \quad (8)$$

Since $1/K_1=K$, and $K_p[H_2O]\ll1$,[15] Eq. 8 becomes

$$k_2' = \frac{K_1k_1+k_2[H^+]}{K_1+[H^+]}. \quad (9)$$

This rate law (Eq. 9) is in agreement with the experimental findings. The values of k_1 and k_2 have been calculated by the method of least squares from Eq. 9. The values of k_2 for benzaldehyde and *p*-nitrobenzaldehyde are 2.80×10^{-2} and 3.29×10^{-2} dm^3 mol^{-1} s^{-1} respectively. For both the compounds, the values of k_1 are small and negative and thus can be approximated to zero. Therefore the Eq. 9 reduces to

$$k_2' = \frac{k_2[H^+]}{K_1+[H^+]}. \quad (10)$$

The rate constants (k_2' calcd) as obtained from Eq. 10 at different [H$^+$] are recorded in Table 1. It appears that in the lower [H$^+$], k_2' calcd values for benzaldehyde are significantly higher than the experimental ones (k_2') and this can probably be ascribed to the contribution of the k_1 term at lower [H$^+$] to the observed k_2' as defined by Eq. 9. It is now evident that the species H_3PO_5 is important in the reaction. It is also natural

Table 3.[a] Oxidation of benzaldehydes by PMP in alkaline medium

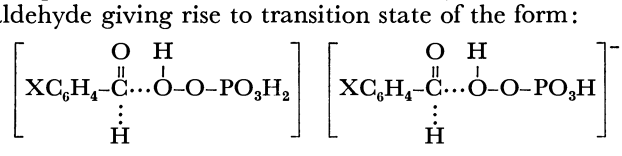
to expect a very insignificant value of k_1, since in the range of [H$^+$] used, PMPA would mainly exist as H_3PO_5.[7]

Peroxo compounds are known to act as nucleophiles since the peroxo group can attach itself to a reactive site (*i.e.*, a p-orbital of carbon). Thus the peroxomonophosphoric acid can attack the carbonyl carbon of the aldehyde giving rise to transition state of the form:



(I) (II)

This is consistent with the idea of Edwards[12] that in the reactions of peroxo compounds with inorganic and organic substrates, a fair degree of covalent bonding developes between the redox pair. The activation parameters calculated (Table 4) are also in agreement with the mechanism.

Table 4.[a] Oxidation of benzaldehydes by PMP: thermodynamic parameters

Substrate	$\Delta H^{\neq}$[b] / kJ mol^{-1}	$\Delta S^{\neq}$[b] / J mol^{-1} K^{-1}	$\Delta H^{\neq}$[c] / kJ mol^{-1}	$\Delta S^{\neq}$[c] / J mol^{-1} K^{-1}

p-Methyl-	33.4	−160.5	35.8	−156.1
p-Methoxy-	32.3	−163.7	—	—

a) Calculated at 298 K. b) H_2SO_4, 0.5 M; aqueous medium, I=1.5 M. c) OH^-, 0.2 M, aqueous medium, I=0.5 M.

Reactions in the Alkaline Medium: The oxidation of benzaldehydes by peroxomonophosphate (PMP) in alkaline medium follows a first order dependence each on oxidant and substrate as shown by the constancy of the pseudo first order rate constants (k_1'') upto a high percentage of the reaction in any single run and the constancy of $k_1''/[S]$ ($=k_2''$) values respectively. The dependence of rate on [OH$^-$] is peculiar; the rate increases with an increase in the [OH$^-$] at lower [OH$^-$] and tends to reach a limiting value at higher [OH$^-$] (Table 3).

Substituent Effect: Substituent effect in alkaline medium is another important observation made which is kinetically different from that in acid medium. The substituents manifest their influence implying electronic effects are prominent for the oxidation in alkaline medium. The rate variation is essentially in agreement with the Hammett's substituent constants, σ (Table 2); a plot of log k_2'' *vs.* σ is linear (r=0.992) with a positive slope (ρ=1.27), which is indicative of a developing negative charge in the side chain of the benzaldehyde molecule.[13] The magnitude of the ρ value is close to that observed for the ionization of benzoic acids (ρ=1.0).

Effect of Temperature: Identical enthalpy and entropy of activation observed for benzaldehyde and the *p*-methyl derivative (Table 4) suggest that oxidation of both the compounds are isoentropic; however, *p*-nitro derivative requires higher energy of activation and much higher entropy of activation compared to the other two derivatives, inspite of the higher reactivity of the *p*-nitro derivative. This is probably due to the reason that a greater concentration of *p*-nitrobenzaldehyde will be available in the hydrate form compared to that for benzaldehyde or *p*-methylbenzaldehyde.

Rate Law and Mechanism: At pH>11, peroxomonophosphate exists[7] as HPO_5^{2-} and PO_5^{3-}.

$$HPO_5^{2-} + OH^- \overset{K_4}{\rightleftharpoons} PO_5^{3-} + H_2O \qquad (11)$$

In alkaline medium benzaldehydes also exist[15,16] in the hydrated form because of the following equilibria:

$$XC_6H_4CHO + OH^- \overset{K_5}{\rightleftharpoons} XC_6H_4CH(OH)O^-, \qquad (12)$$

$$XC_6H_4CH(OH)O^- + H_2O \overset{K_6}{\rightleftharpoons} XC_6H_4CH(OH)_2 + OH^-. \qquad (13)$$

Even though the equilibrium (13) has been considered to be unimportant by earlier workers;[16] Sayer,[14] and Bell and Sorensen[15] attach significance to this equilibrium and have evaluated the formation constant for $XC_6H_4CH(OH)_2$. An examination of the formation constants though reveals the predominance of $XC_6H_4CH(OH)O^-$, $XC_6H_4CH(OH)_2$ is considered to be the reactive species in this oxidation process. This arises mainly from the following reasons (i) that the OH^--dependence would have been more than unity had the reacting species been the hydrate mono anion because of the participation of OH^- in steps (Eqs. 11 and 12), (ii) that there would have been a marked ionic strength effect if the reaction involved two ions. The marginal effect of ionic strength on rate points the reaction to involve at least one neutral molecule[17] and

(iii) that the attack of the PMP species on the more electrophilic $XC_6H_4CH(OH)_2$ will be favoured.

So the reaction would involve a nucleophilic attack of the peroxo di- and tri-anions on the carbonyl carbon of the aldehyde hydrate molecule giving rise to the transition states III and IV respectively. The thermodynamic parameters calculated are in the range expected for a bimolecular substitution reaction.

$$HPO_5^{2-} + XC_6H_4CH(OH)_2 \xrightarrow{k_3} \left[O_3P\text{–}O\text{–}O\cdots C(H,XC_6H_4)\cdots OH(H) \right]^{2-}$$

(III)

$$\longrightarrow XC_6H_4COO^- + H_2PO_4^- + H_2O \qquad (14)$$

$$PO_5^{3-} + XC_6H_4CH(OH)_2 \xrightarrow{k_4} \left[O_3P\text{–}O\text{–}O\cdots C(XC_6H_4)\cdots OH(H) \right]^{3-}$$

(IV)

$$\longrightarrow XC_6H_4COO^- + HPO_4^{2-} + H_2O \qquad (15)$$

On the basis of the proposed mechanism the rate law can be derived as:

$$-\frac{d[PMP]}{dt} = \left\{\frac{k_3K_hK_5K_6 + k_4K_5K_6[OH^-]}{K_h + [OH^-]}\right\} \times [PMP][XC_6H_4CHO], \qquad (16)$$

where

$$k_2'' = \frac{k_3K_hK_5K_6 + k_4K_5K_6[OH^-]}{K_h + [OH^-]} \qquad (17)$$

and

$$\frac{K_4}{[H_2O]} = \frac{1}{K_h}.$$ ($K_h = K_w/K_3$, where K_w is the ionic product of water and K_3 is the dissociation constant of HPO_5^{2-})

Rearrangement of Eq. 17 would give

$$k_2''(K_h + [OH^-]) = k_3K_hK_5K_6 + k_4K_5K_6[OH^-]. \qquad (18)$$

On plotting $k_2''(K_h + [OH^-])$ against $[OH^-]$, linearity ($r = 0.99$) is observed for both benzaldehyde and *p*-nitrobenzaldehyde.

From the intercept and slope of the plot, and employing the reported K_5 and K_6 values,[15] the values of k_3 and k_4 for *p*-nitrobenzaldehyde are calculated to be 0.34 $dm^3\,mol^{-1}\,s^{-1}$ and 6.76 $dm^3\,mol^{-1}\,s^{-1}$ respectively. The higher k_4 value is quite in agreement with the higher nucleophilic reactivity of PO_5^{3-} in alkaline medium. With these k_3 and k_4 values, the rate constants k_2'' (calcd) from Eq. 17 are collected in Table 3. In the case of benzaldehyde, since the least squares plot results in a very small and negative intercept, the value of k_3 is approximated to zero. The value of $k_4K_5K_6$, as given by the slope is 1.07×10^{-1}. The value of k_4 for benzaldehyde could not be calculated because of the non-availability of the K_5 and K_6 values.

The authors are thankful to Prof. P. S. Radhakrishna Murti, Dr. S. N. Mahapatro and Dr. R. K. Panda of this Department for helpful discussions and encouragement. Dr. Y. K. Gupta, Department of Chemistry, University of Rajasthan is gratefully acknowledged for the gift of the sample of peroxodiphosphate. One of the authors (R. S. P.) is grateful to C. S. I. R. (New Delhi) for the award of a Junior Research Fellowship.

Preparation and Characterization of Complexes of Dichlorobis-(cyclopentadienyl)zirconium(IV) with Bidentate, Terdentate, and Quadridentate Schiff Bases

Gopal GUPTA, Ram SHARAN, and Ramesh N. KAPOOR*
Department of Chemistry, University of Delhi, Delhi-110007, India
(Received May 12, 1978)

Bis(cyclopentadienyl)zirconium(IV) Schiff base derivatives have been synthesized by treating dichlorobis-(cyclopentadienyl)zirconium(IV) (Cp_2ZrCl_2) with bidentate Schiff bases (SBH) *viz.*, *N*-salicylidenaniline, *N*-salicylidene-*o*-toluidine, *N*-salicylidene-*m*-toluidine, *N*-salicylidene-*p*-toluidine, and *N*-(2-hydroxyl-1-naphthyl-iden)aniline, terdentate Schiff bases ($SB'H_2$) *viz.*, *N*-(3-oxo-1-methylbutyliden)-*o*-aminophenol and *N*-(3-oxo-1-phenylbutyliden)-*o*-aminophenol; quadridentate Schiff base ($SB''H_2$) *N,N'*-disalicylidene-*o*-phenylenediamine, in THF, in the presence of triethylamine at room temperature. The resulting derivatives of the type $Cp_2Zr(SB)Cl$, $Cp_2Zr(SB)_2$, $Cp_2Zr(SB')$, $Cp_2Zr(SB'')$, and $(Cp_2ZrCl)SB''$ [where $[SB]^-$, $[SB']^{2-}$, and $[SB'']^{2-}$ represent the anion of corresponding Schiff bases SBH, $SB'H_2$, and $SB''H_2$] have been characterised by their elemental analysis and by IR, electronic spectra, electrical conductance and molecular weight determinations.

A number of transition metal complexes of Schiff bases have been synthesized and characterized during recent years.[1,2] In view of the interesting synthetic and structural aspects of these complexes, interest in the study of Schiff base complexes continues to increase. However, few Schiff base complexes of organometallic derivatives such as dichlorobis(cyclopentadieyl)zirconium(IV) and dichlorobis(cyclopentadieyl)titanium(IV) have been studied.[3,4] Recently, a series of complexes of dichlorobis(cyclopentadienyl)-titanium(IV) with Schiff bases has been reported.[5] Now these studies have been extended to the complexes of dichlorobis(cyclopentadienyl)zirconium(IV) with bidentate, terdentate and quadridentate Schiff bases. Such a study appears to be useful in view of the fact that organometallic compounds of titanium[6] and zirconium[7] are found to be capable of activating molecular nitrogen. In one instance, alkoxy derivatives of zirconium(IV) have been investigated as potential agent in the nitrogen fixation processes.[8]

Experimental

Dichlorobis(cyclopentadienyl)zirconium(IV) was prepared by CpNa method.[9,10] Schiff bases were synthesised by the usual methods[11-13] and recrystallized from absolute ethanol.

THF (Baker AR) was dried by storage on sodium wire overnight and then refluxed until it gave a blue colouration with benzophenone. It was finally dried by distilling over $LiAlH_4$. Hexane was dried by distilling over sodium wire. Triethylamine was purified by the given method.[14] All the reactions were carried out in anhydrous conditions.

Zirconium was estimated gravimetrically as ZrO_2, chlorine as AgCl, and nitrogen was estimated by Kjeldahl's method. Analytical data of these complexes are given in Tables 1—3. The IR spectra were recorded on Perkin-Elmer IR-621 and IR-137 instruments in KBr phase in the ranges of 4000—200 cm^{-1} and 4000—700 cm^{-1}. The electronic spectra of the complexes were run on Perkin-Elmer 4000A in the range of 400—750 $cm.^{-1}$ Molecular weight of the complexes were determined by Gallen-Kamp Ebulliometer, W. G. Pye & Co. Electrical conductance measurements were carried out in nitrobenzene on a Beckmann conductivity Bridge Model RC-18A.

Reactions of Dichlorobis(cyclopentadienyl)zirconium(IV) (1 mol) with N-*Salicylidene*-p-*toluidine (1 mol).* Schiff base (0.64 g) was added to a solution of dichlorobis(cyclopentadienyl)-ziroconium(IV) (0.89 g) in dry THF (80 g). To this triethylamine (0.50 g) was added, the mixture was stirred for 24 h. Precipitated $Et_3N \cdot HCl$ was removed by filtration and the complex was crystallised by a hexane/THF mixture (yield 85%).

Reaction of Dichlorobis(cyclopentadienyl)zirconium(IV) (1 mol) with N-*Salicylidene*-p-*toludidine (2 mol).* To dichlorobis(cyclopentadienyl)zirconium(IV) (0.72 g) and Schiff base (1.05 g) dissolved in THF (80 g) was added triethylamine (0.51 g) and the mixture was stirred for 18 h. $Et_3N \cdot HCl$ which precipitated was removed by filtration. After distilling the solvent under reduced pressure, the product was recrystallised from a hexane/THF mixture (yield=82%).

Reaction of Dichlorobis(cyclopentadienyl)zirconium(IV) (1 mol) with N-*(3-Oxo-1-methylbutylidene)*-o-*aminophenol (1 mol).* A mixture of dichlorobis(cyclopentadienyl)zirconium(IV) (1.20 g) and Schiff base (0.72 g) was dissolved in THF (80 g) and triethylamine (0.84 g) was added. The mixture was stirred for 24 h. Precipitated $Et_3N \cdot HCl$ was removed by filtration and complex was crystallised from a hexane/THF mixture (yield 80%).

Reaction of Dichlorobis(cyclopentadienyl)zirconium(IV) (2 mol) with N,N'-*Disalicylidene*-o-*phenylenediamine (1 mol).* Schiff base (0.68 g) was added to a solution of Cp_2ZrCl_2 (1.27 g) in dry THF(75 g). To this triethylamine (0.88 g) was added, and the mixture was stirred for 30 h. $Et_3N \cdot HCl$ which precipitated out was removed and solvent was removed under reduced pressure. The complex was crystallized from a hexane/THF mixture (yield 83%).

Results and Discussion

Dichlorobis(cyclopentadienyl)zirconium(IV) reacts with bidentate Schiff bases (1:1 and 1:2 molar ratios) in anhydrous THF, in the presence of triethylamine.

$$Cp_2ZrCl_2 + SBH + Et_3N \xrightarrow[\text{room temp}]{\text{THF}} Cp_2Zr(SB)Cl + Et_3N \cdot HCl,$$

$$Cp_2ZrCl_2 + 2SBH + 2Et_3N \xrightarrow[\text{room temp}]{\text{THF}} Cp_2Zr(SB)_2 + 2Et_3N \cdot HCl,$$

where SB^- represents the anion of corresponding bidentate Schiff bases SBH.

Table 1. Reactions of Cp_2ZrCl_2 with bidentate Schiff bases

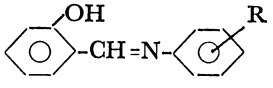
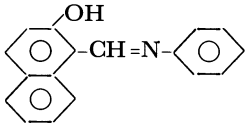
SBH = *N*-salicylidenaniline, SB'H = *N*-salicylidene-*o*-toludine, S'BH = *N*-salicylidene-*m*-toludine, S'B'H = *N*-salicylidene-*p*-toluidine and S''B''H = *N*-(2-hydroxy-1-naphthyliden)aniline.



[R = H, *o*-Me, *m*-Me, and *p*-Me]

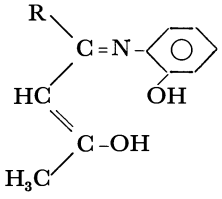


These Schiff base complexes are yellow to dark brown in colour and are soluble in benzene, tetrahydrofuran, chloroform and acetone. Analytical data and physical measurements are given in Table 1.

Reactions of Cp_2ZrCl_2 with terdentate Schiff bases (1:1 molar ratio) in THF, in the presence of triethylamine yielded complexes of the type $Cp_2Zr(SB')$.

$$Cp_2ZrCl_2 + SB'H_2 + 2Et_3N \xrightarrow[\text{room temp}]{\text{THF}} Cp_2Zr(SB') + 2Et_3N\cdot HCl$$

$[SB']^{2-}$ represents the anion of terdentate Schiff base $SB'H_2$



[R = Me, Ph]

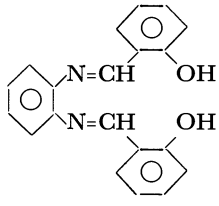
These complexes are yellowish green and orange in colour and are soluble in organic solvents. Analytical data and physical properties are given in Table 2.

Quadridentate Schiff base reacts with Cp_2ZrCl_2 (1:1 and 1:2 molar ratios) in anhydrous THF, in the presence of triethylamine giving soluble products.

$$Cp_2ZrCl_2 + SB''H_2 + 2Et_3N \xrightarrow[\text{room temp}]{\text{THF}} Cp_2Zr(SB'') + 2Et_3N\cdot HCl$$

$$2Cp_2ZrCl_2 + SB''H_2 + 2Et_3N \xrightarrow[\text{room temp}]{\text{THF}} (Cp_2ZrCl)_2SB'' + 2Et_2N\cdot HCl$$

$[SB'']^{2-}$ represents the anion of quadridentate Schiff base $SB''H_2$



These complexes are brown or dark brown in colour and are soluble in organic solvents. The analytical data of these complexes is given in Table 3.

All the above reactions are quite facile and the resulting compounds could be isolated in almost quantitative yields. The complexes are involatile, very senstive to oxygen but relatively stable in an inert atmosphere and decomposes on heating between 95—325 °C. All complexes are monomeric except binuclear complex(E) with a dimeric structure (Tables 1—3). Electrical conductance measured in nitrobenzene showed them to be essentially nonelectrolytes.

On the basis of elemental analysis, IR and electronic spectra, molecular weight determination and electrical conductance, following structures are tentatively assigned for the complexes of the type (A) $Cp_2Zr(SB)Cl$; (B) $Cp_2Zr(SB)_2$; (C) $Cp_2Zr(SB')$; (D) $Cp_2Zr(SB'')$ and (E) $(Cp_2ZrCl)_2SB$.

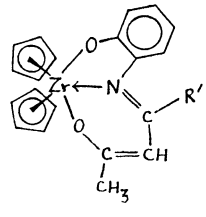
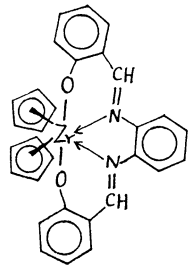
Complexes with terdentate Schiff bases:



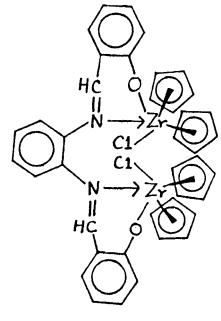
(C)

[R' = CH_3 and C_6H_5]

Complexes with quadridentate Schiff base:



(D)



(E)

Similar structures have been reported for oximate complexes of dichlorobis(cyclopentadienyl)ziroconium.[15] In all complexes having structures (A), (C), and (E), the coordination number of zirconium appears to be five. This coordination number is well known for zirconium complexes.[15,16] For complexes with structures (A) and (E), the appearance of band at $\approx$350 cm^{-1} due to ν(Zr–Cl) confirms the presence of coordinated chlorine. In complexes having structures (B) and (D)

zirconium attains the well known coordination number six.[15,17] In the structure (B) the Schiff base acts as a bidentate ligand while in the case of (D) the denticity of the ligand is four *i.e.* it behaves as quadridentate ligand. Both these complexes are examples of twenty-electron system which has been reported for several other titanium[18,19] and zirconium[15] complexes. A twenty-electron system is also well documented for nickelocene.[20]

In all the complexes the cyclopentadienyl rings are *cis*, as their IR frequencies in the complexes coincide with those of dichlorobis(cyclopentadienyl)zirconium-(IV), supporting "angular" sandwich structure as reported by Giddings *et al.*[21]

Infrared Spectra. The important IR frequencies are given in Table 4. Absorption bands occurring at $\approx 3000\ cm^{-1}$ ν(C–H), $\approx 1435\ cm^{-1}$ ν(C–C), $\approx 1020\ cm^{-1}$ $\delta^{i.p.}$(–CH), and at $\approx 810\ cm^{-1}$ $\delta^{o.p.}$(–CH) indicated the presence of the cyclopentadienyl groups. All these bands are similar to these of dichlorobis-(cyclopentadienyl)zirconium(IV).[22]

In the spectra of Schiff bases, a strong band is observed in the 1617—1613 cm^{-1} region, which can be assigned to the absorption basd of the azomethine group (>C=N–). In these complexes, this band is slightly shifted to the lower side as given in Table 4. Similar observations have also been made by a number of workers.[23,24] But in case of complexes with Schiff base, *N*-(2-hydroxy-1-naphtyliden)aniline, there is no appreciable shift in ν(C=N) band compared to Schiff base as reported by Bailar.[25]

The strong band in the region of 1300—1282 cm^{-1} in the Schiff bases is attributed to the phenolic ν(C–O) in view of previous assignments. This ν(C–O) band shifts by $\approx 30\ cm^{-1}$ towards higher frequency upon complexation, suggesting bonding between zirconium and oxygen as observed by Poddar *et al.*[26]

The disappearance of the weak and broad bands in the region 3300—3100 cm^{-1} (–OH) in the complexes suggests that the (–OH) group of the Schiff base has taken part in the bond formation, and confirms the complex formation. Bands in the region 570—530 cm^{-1} and 520—420 cm^{-1} are attributed to ν(Zr–N) and ν(Zr–O), respectively as reported.[27,28]

Electronic Spectra. The electronic spectra of all the Schiff base complexes of dichlorobis(cyclopentadienyl)zirconium(IV) complexes were recorded in chloroform and acetone. All complexes show a single band in the region 25250—24280 cm^{-1} which can be assigned to the charge transfer band,[29] and is in accordance with their $(n-1)d^0ns^0$ electronic configuration.

Two of the authors (G.G.) and (R.S.) thank the Council of Scientific and Industrial Research, New Delhi, for the award of junior Research Fellowship.

Reactions of 2-Ethoxycarbonyl-1,3-indandione with Aromatic Amines, Diazonium Salts, and Phenols

El-Sayed Afsah* and Tawfik Zimaity

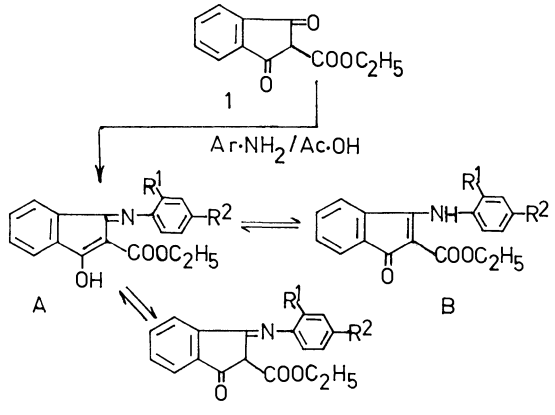
Department of Chemistry, Faculty of Science, Mansoura University, Mansoura, A. R. Egypt

(Received March 6, 1978)

2-Ethoxycarbonyl-1,3-indandione (**1**) was treated with primary aromatic amines in acetic acid to afford 3-hydroxy-1-(arylimino) derivatives (**2**). Treatment of **1** with excess *p*-toluidine gave 3-tolylimino-4′-methyl-indancarboxanilide (**3**). With *o*- or *p*-phenylenediamine it yielded 3,3′-dihydroxy-1′-(*o*- or *p*-phenylenedinitrilo)di-2-indenecarboxylate. The tetraazacycloeicosene derivative was obtained by the action of *p*-phenylenediamine on **1** in a 1:1 molar ratio. In boiling toluene **1** gave the corresponding 2-carboxanilides (**8**) which cyclized to the diazepinone or to the quinolone. The coupling of **1** and **8** with diazonium salts was also investigated. The condensation of **1** with phenols afford **14**, which were hydrolysed to 3-aryl-1-indenones.

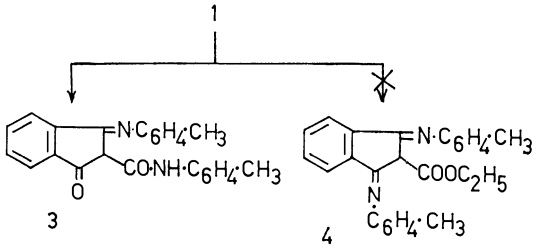
Many reactions of 1,3-indandione and its derivatives with various reagents have been reported.[1-5] However, little work has been done on the reactions of 2-ethoxycarbonyl-1,3-indandione.[6-7] The compound is considered to be an easily available starting material for the synthesis of some new 1,3-indandione derivatives.

We have found that 2-ethoxycarbonyl-1,3-indandione (**1**)[8] reacts with aromatic amines to give various products depending upon the reaction conditions. In hot acetic acid **1** reacts with primary aromatic amines to give ethyl 3-hydroxy-1-(arylimino)-2-indenecarboxylate (enolic form A; **2a**—**d**). Structure of **2** was elucidated on the basis of elemental analysis and IR spectra, which showed bands attributable to (C=N) 1630, enolised *β*-keto ester 1670, 3080 and (C=O) 1705 cm^{-1}. Furthermore, the lack of IR bands characteristic of the (NH) stretching mode ruled out the alternative structure B. Thus, it can be concluded that the structure of **2** is best represented by the enolic form A.

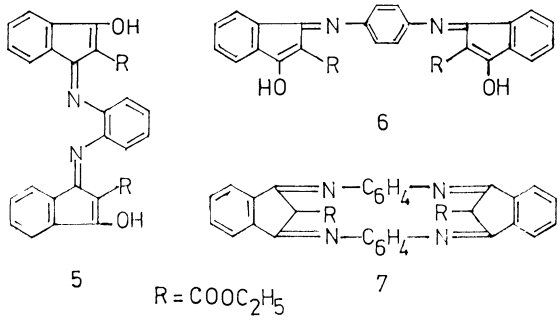


2 a: $R^1=R^2=H$
b: $R^1=H$, $R^2=OCH_3$
c: $R^1=H$, $R^2=CH_3$
d: $R^1=NH_2$, $R^2=H$

Treatment of **1** with excess *p*-toluidine in hot acetic acid gave 1-oxo-3-(*p*-tolylimino)-4′-methyl-2-indancarboxanilide (**3**). The IR spectrum of **3** indicated bands characteristic of the secondary amide group at 3400 (–NH) and 1630, 1540 cm^{-1} (–NHCO–). In particular, the presence of a –NHCO– grouping is confirmed by the NMR spectrum (*δ* 8.1, 1H, s). Attempts to prepare ethyl 1,3-bis(tolylimino)-2-indancarboxylate (**4**) failed.



Condensation of **1** with aromatic diamines was also investigated. The reaction of **1** with *o*-phenylenediamine in a 2:1 molar ratio in hot acetic acid yielded a mixture of two compounds, which were separated by their different solubilities in ethanol. The insoluble compound was found to be diethyl 3,3′-dihydroxy-1,1′-(*o*-phenylenedinitrilo)di-2-indenecarboxylate (**5**), while the ethanol soluble one was identified to be **2d** by elemental analysis, mixed mp and IR spectrum. Under essentially the same conditions, condensation of **1** with *p*-phenylenediamine afforded diethyl 3,3′-dihydroxy-1,1′-(*p*-phenylenedinitrilo)di-2-indenecarboxylate (**6**). The assigned structure for the two compounds, **5** and **6**, is inferred from their elemental analyses and the IR spectra. In the mass spectra of both compounds, the basic peak was *m/e* 362 corresponding to the splitting of the two ethoxycarbonyl groups.



Treatment of **1** with *p*-phenylenediamine in 1:1 molar ratio in acetic acid at 80 °C for 1 h, gave diethyl 7,10:19,22-diethano-5,24:12,17-dimethanodibenzo-[*c*,*m*][1,6,11,16]tetraazacycloeicosene-25,28-dicarboxylate (**7**). The results of the elemental analysis and the mass spectrum were in line with the molecular formula $C_{36}H_{28}N_4O_4$. The structure **7** was assigned

on the basis of its IR spectrum which shows bands at 1725 (ester group), 1200 (C–O stretching), and 1665 cm^{-1} (C=N), its mass spectrum showing a peak at mass *m/e* 490 ($M^+-2(OC_2H_5)$).

On the other hand, treatment of **1** with primary aromatic amines in boiling toluene afforded the corresponding 1,3-dioxo-2-indancarboxanilides (**8a—i**). The products **8** were characterized by analysis and spectral data. They all showed characteristic absorptions at 1680—1700 (C=O) and 1625, 1560 cm^{-1} (–NHCO–). The NMR spectra also exhibited one proton singlet at δ 8.1 due to (–NHCO–). Further, the identity is established by converting **8b** into **3**, by treatment with *p*-toluidine in acetic acid. The action of *o*-, or *p*-phenylenediamine on **1** in boiling toluene gave in each case a single product (**8f** and **g**), respectively. The mass spectra of both compounds, *m/e* 280 (M^+) and 173 ($M^+-NHC_6H_4NH_2$), confirm their structures. Upon treatment with boiling acetic acid, **8f** or **2d** afforded 10,10a,11,12-tetrahydrobenz-[*b*]indeno[1,2-*e*][1,4]diazepine-10,11-dione (**9**). The formation of the diazepine derivative **9** is in line with the work of Ried and Draisbach[9] on the condensation of ethyl 2-oxocyclohexanecarboxylate with *o*-phenylenediamine.

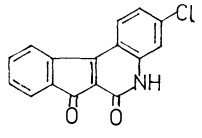
(9)



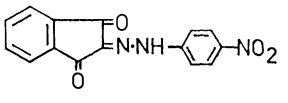
(10)

The synthesis of quinolones by the condensation between *β*-keto esters and primary aromatic amines was described in earlier reports.[10,11] The nature of the product depends on the conditions. Compounds **2** and **8** are considered to be suitable starting materials for the synthesis of new quinolones fused to the indanone and/or indenone nuclues. Thus, **8d** was cyclized according to the Knorr quinolone synthesis[10] by hot sulfuric acid to give 3-chloro-5*H*-indeno[2,1-*c*]quinoline-6,7-dione (**10**).

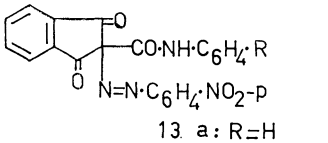
The structure of the quinolone derivative (**10**) was confirmed by elemental analysis and IR spectrum. An attempt to cyclize **2a** under conditions similar to those for Conrad-Limpach synthesis[11] gave only a black, intractable tar.

Treatment of **1** with diazotised *p*-nitroaniline or bis-(diazotised) benzidine, in basic medium, gave the expected result of a Japp-Klingemann reaction.[12] The ethoxycarbonyl group was cleaved with the formation of 1,2,3-indantrione 2-*p*-nitrophenylhydrazone (**11**), and 4,4′-bis(1,3-dioxo-2-indanylidenehydrazono) biphenyl (**12**) respectively. The melting point of **11** and **12** showed no depression on being mixed with an authentic sample.[13]

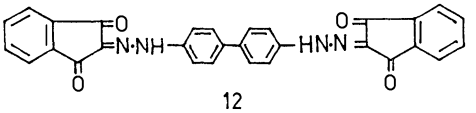
On the other hand, coupling of **8a—b** with diazotised



11



13 a: R=H
b: R=CH_3-p



12

p-nitroaniline in methanol afforded 2-(*p*-nitrophenylazo)-1,3-dioxo-2-indancarboxanilide (**13a**) and 2-(*p*-nitrophenylazo)-1,3-dioxo-4′-methyl-2-indancarboxanilide (**13b**), respectively. Structure of **13** was confirmed by elemental analysis and IR spectra. The coupling of *β*-keto anilides has been reported.[14] The formation of the azo derivatives (**13**) is in line with the work of Linstead and Wang[15] on the coupling of 2-oxocyclohexan-1-carboxanilide with benzenediazonium chloride.

The observation that *β*-keto esters react with phenols to form coumarin derivatives (Pechmann reaction),[16] prompted us to investigate the behaviour of **1** under similar reactions in order to obtain 3-arylindenones. Compound **1** was treated with resorcinol[17] and *p*-cresol in ethanolic-hydrogen chloride to give 3-hydroxy-, and 2-methyl-benz[*b*]indeno[1,2-*d*]pyran-6,7-diones (**14a—b**), respectively. Alkaline hydrolysis of **14**, followed by treatment with boiling hydrochloric acid afforded 3-(2-hydroxyphenyl)-1-indenones (**15**). The structure of indenones **15** has been confirmed by analytical data and IR spectroscopy.

a: R=OH-m
b: R=CH_3-p

Experimental

All melting points were determined in a capillary and are uncorrected. IR spectra were determined on KBr discs with a Unicam SP 2000 Infrared spectrophotometer. The NMR spectra in $CDCl_3$ solution were obtained on a Varian 60 MHz spectrometer with TMS as an internal standard. The mass spectra were obtained on MS 902 at 70 eV using a direct insertion probe at 250—300 °C.

Ethyl 3-Hydroxy-1-(arylimino)-2-indenecarboxylate (2). *General Procedure*: A mixture of **1** (1.1 g, 0.005 mol) and appropriate primary aromatic amine (2 g) in 10 ml acetic acid was heated at 60 °C for 5 min. After cooling and dilution with water the solid was filtered and crystallized from ethanol.

Ethyl 3-Hydroxy-1-(phenylimino)-2-indenecarboxylate (2a): Orange crystals, yield, 0.8 g (54.8%), mp 152 °C. IR: 3080, 1705, 1670, 1630, and 1040 cm^{-1}. Found: C, 73.81; H, 5.36; N, 4.31%. Calcd for $C_{18}H_{15}NO_3$: C, 73.70; H, 5.15; N, 4.77%.

Ethyl 3-Hydroxy-1-(p-methoxyphenylimino)-2-indenecarboxylate (2b): Brown crystals, yield, 1 g (62.5%), mp 162 °C (dec).

IR: 3085, 1700, 1665, 1630, and 1045 cm^{-1}. Found: C, 70.34; H, 5.11; N, 4.10%. Calcd for $C_{19}H_{17}NO_4$: C, 70.57; H, 5.30; N, 4.32%.

*Ethyl 3-Hydroxy-1-(*p*-tolylimino)-2-indenecarboxylate (**2c**)*: Orange crystals, yield, 0.9 g (58.8%), mp 174 °C. IR: 3080, 1700, 1660, 1625, and 1050 cm^{-1}. Found: C, 74.48; H, 5.61; N, 4.33%. Calcd for $C_{19}H_{17}NO_3$: C, 74.24; H, 5.57; N, 4.55%.

*Ethyl 3-Hydroxy-1-(*o*-aminophenylimino)-2-indenecarboxylate (**2d**)*: Dark brown crystals, yield, 0.5 g (32.4%), mp>300 °C. IR: 3280, 3100, 1690, 1650, and 1625 cm^{-1}. Found: C, 69.82; H, 5.13; N, 8.88%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.11; H, 5.20; N, 9.08%.

*1-Oxo-3-(*p*-tolylimino)-4'-methyl-2-indancarboxanilide (**3**)*: From 1.1 g (0.005 mol) of **1** and 3 g of *p*-toluidine dissolved in (10 ml) acetic acid, **3** was obtained by the same procedure as that for **2**. Recrystallization from methanol gave 0.8 g (43%) of **3** as a brown crystalline powder; mp 205 °C (dec). IR: 3400, 2920, 1670, 1630, 1540, 1525, and 1250 cm^{-1}; NMR ($CDCl_3$): δ; 2.6 (1H s, –CO–CH–CO–); 2.41 (6H s, $C_6H_4CH_3$); 7.33 (8H s, $C_6H_4CH_3$); 7.62 (4H d, *o*-substituted C_6H_4) and 8.1 ppm (1H s, –NH–CO–). Found: C, 78.31; H, 5.50; N, 7.31%. Calcd for $C_{24}H_{20}N_2O_2$: C, 78.23; H, 5.47; N, 7.60%.

*Diethyl 3,3'-Dihydroxy-1,1'-(*o*-phenylenedinitrilo)di-2-indenecarboxylate (**5**)*: A mixture of 1.1 g (0.005 mol) of **1** and 0.3 g (0.0025 mol) of *o*-phenylenediamine in 10 ml acetic acid was heated with stirring for 15 min. The reaction mixture gave a dark brown solid (0.8 g) on dilution with water, which on treatment with boiling ethanol gave **5** as an insoluble red solid (0.5 g). Recrystallization from acetic acid afforded **5** as red crystals; mp>300 °C. IR: 3100, 1700, 1650, and 1635 cm^{-1}. MS, *m/e* 362 (base, M^+-2 $COOC_2H_5$), 274, 104, and 76. Found: C, 71.00; H, 4.95; N, 5.37%. Calcd for $C_{30}H_{24}N_2O_6$: C, 70.85; H, 4.75; N, 5.51%.

Concentration of the ethanolic filterate after separation of **5** gave 0.14 g of **2d** as dark brown crystals, the IR spectrum of which was identical with that of the authentic sample of **2d** obtained above.

*Diethyl 3,3'-Dihydroxy-1,1'-(*p*-phenylenedinitrilo)di-2-indenecarboxylate (**6**)*: From 1.1 g (0.005 mol) of **1** and 0.3 g (0.0025 mol) of *p*-phenylenediamine dissolved in 10 ml acetic acid, **6** was obtained according to the same procedure as that for **5**. Recrystallization from benzene–ethanol gave 0.7 g (27.5%) of **6** as dark brown powder; mp>300 °C. IR: 3105, 1690, 1655, and 1640 cm^{-1}. MS, *m/e* 362 (base, M^+-2 $COOC_2H_5$), 274, 104, and 76. Found; C, 70.91; H, 4.66; N, 5.40%. Calcd for $C_{30}H_{24}N_2O_6$: C, 70.85; H, 4.75; N, 5.51%.

Diethyl 7,10:19,22-Dietheno-5,24:12,17-dimethanodibenzo [c,m]-*[1,6,11,16]tetraazacycloeicosene-25,28-dicarboxylate (**7**)*: A mixture of 1.1 g (0.005 mol) of **1** and 0.6 g (0.006 mol) of *p*-phenylenediamine in 20 ml acetic acid was heated at 80 °C for 1 h with stirring. The reaction mixture was diluted with water, and filtered to give dark green material (0. 6g). Crystallization from ethanol–benzene (1:1) afforded **7** as a dark green powder (0.4 g); mp 255 °C, IR: 1725, 1665, and 1200 cm^{-1}; MS, *m/e* 490 ($M^+-2(OC_2H_5)$), 366, 169, and 76. Found: C, 74.60; H, 4.90; N, 9.42%. Calcd for $C_{36}H_{28}N_4O_4$: C, 74.46; H, 4.86; N, 9.65%.

*1,3-Dioxo-2-indancarboxanilides (**8a—i**)*: A mixture of 1.1 g (0.005 mol) of **1** and 0.0055 mol of the appropriate primary aromatic amine in 50 ml toluene was refluxed for 30 min. The solid obtained after concentration and cooling was filtered. Recrystallization from benzene gave **8a—i** as yellow crystalline solids. The results are summarized in Table 1.

*Formation of **3** from **8b***: A mixture of 0.28 g (0.001 mol) of **8b** and 0.11 g (0.001 mol) of *p*-toluidine in 10 ml acetic acid was heated at 70 °C for 10 min. The solid obtained on dilution with water was filtered and crystallized from benzene to give 0.08 g of **3**. The IR spectrum of the product was identical with that of the authentic sample of **3**.

10,10a,11,12-Tetrahydrobenz [b] *indeno* [1,2-e] [1,4] *diazepine-10,11-dione (**9**)*: 0.5 g of **8f** or **2d** was refluxed in 30 ml acetic acid. The dark red solid obtained on cooling was filtered and recrystallized from acetic acid to give 0.22 g of **9** as a red crystalline solid; mp>300 °C. IR: 3210, 1705, 1650, 1630, and 1575 cm^{-1}. Found: C, 73.34; H, 4.10; N, 10.31%. Calcd for $C_{16}H_{10}N_2O_2$: C, 73.27; H, 3.84; N, 10.68%.

*3-Chloro-5H-indeno[2,1-c]quinoline-6,7-dione (**10**)*: 0.5 g of **8d** was heated with 20 ml of H_2SO_4 (85%) in an oil bath at 110 °C for 1 h. After cooling, the reaction mixture was diluted with 80 ml cold water, and the brown solid obtained was filtered. Crystallization from benzene–ethanol gave 0.16 g of **10**; mp>300 °C. IR: 2900, 1725, 1670, 1620, 1590, and 1450 cm^{-1}. Found: C, 67.91; H, 3.01; N, 4.66%. Calcd for $C_{16}H_8NO_2Cl$: C, 68.22; H, 2.86; N, 4.97%.

*Coupling of **1** with* p*-Nitrobenzenediazonium Chloride and Bis-(diazotised) Benzidine*: Diazotised *p*-nitroaniline (0.005 mol), or bis(diazotised) benzidine (0.0025 mol), was added with stirring to a cold solution of **1** (0.005 mol) in 50 ml 2.5% aq NaOH. Sodium acetate (2 g) was added, and the reaction mixture was left to stand under cooling overnight. The brown solid obtained was crystallized from acetic acid to give **11** and **12**, respectively, in a 75% yield. Compounds **11** and **12** were identical with the corresponding authentic samples prepared from 1,3-indandione by the method of Das and Ghosh.[13]

*Coupling of **8a—b** with Diazotised* p*-Nitroaniline*: Diazotised *p*-nitroaniline (0.003 mol) was added with stirring to a cold solution of **8a** or **8b** (0.003 mol) in 60 ml methanol, followed by addition of lg of sodium acetate in 5 ml water. The

solid obtained was crystallized from methanol to give **13a—b**, respectively.

*2-(p-Nitrophenylazo)-1,3-dioxo-2-indancarboxanilide (**13a**)*: Orange crystals, yield, 0.19 g (15.3%), mp 132 °C. IR: 3060, 1700, 1650, 1580, 1340, and 890 cm^{-1}. Found: C, 63.61; H, 3.17; N, 13.68%. Calcd for $C_{22}H_{14}N_4O_5$: C, 63.76; H, 3.40; N, 13.52%.

*2-(p-Nitrophenylazo)-1,3-dioxo-4′-methyl-2-indancarboxanilide (**13b**)*: Yellow crystals, yield, 0.16 g (12.5%), mp 158 °C. IR: 3065, 1700, 1640, 1585, 1345, and 890 cm^{-1}. Found: C, 64.22; H, 3.68; N, 12.88%. Calcd for $C_{23}H_{16}N_4O_5$: C, 64.48; H, 3.76; N, 13.07%.

*Condensation of **1** with Phenols*: Cold saturated ethanolic hydrogen chloride (10 ml) was added with stirring to a mixture of 2 g of **1** and resorcinol or *p*-cresol (6 g) in 30 ml ethanol. After 24 h the yellow crystalline product was filtered, washed with ethanol and acetone to give **14a—b** respectively.

3-Hydroxybenz[b]*indeno*[*1,2*-d]*pyran-6,7-dione (**14a**)*: Yellow crystals, yield, 1 g (37.8%). Its mp and IR spectrum were identical with those of an authentic sample.[17]

2-Methylbenz[b]*indeno*[*1,2*-d]*pyran-6,7-dione (**14b**)*: Recrystallized form ethanol, pale yellow crystals, yield, 0.5 g (19%), mp 265 °C. IR: 1740, 1720, 1590, and 1470 cm^{-1}. Found: C, 77.67; H, 4.00%. Calcd for $C_{17}H_{10}O_3$: C, 77.85; H, 3.84%.

*3-(2-Hydroxyphenyl)indenones (**15**)*: A solution of aq NaOH (5%, 20 ml) was added to boiling solution of **14a** or **14b** (0.002 mol) in ethanol (40 ml). The reaction mixture was refluxed for 1 h, acidified with dil hydrochloric acid and the resulting precipitates were filtered and dried to give **15a**, 0.15 g (32%). Recrystallization from methanol afforded greenish-yellow crystals; mp 177 °C. IR: 3410, 1740, 1630, 1375, 1270, and 1180 cm^{-1}. Found: C, 75.46; H, 4.06%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

*3-(2-Hydroxy-*m*-tolyl)indenone (**15b**)*: Orange crystals from methanol, yield, 0.2 g (42%), mp 147 °C. IR: 3400, 1735, 1620, 1370, 1270, and 1185 cm^{-1}. Found: C, 81.16; H, 5.22%. Calcd for $C_{16}H_{12}O_2$: C, 81.33; H, 5.12%.

We wish to express our sincere gratitude to Dr. A. M. Dawidar for the NMR and mass measurements.

Synthesis and Absorption Spectra of Some 6-Hydroxythiazolo[3,2-*a*]-benzimidazoles and Their Quaternary Derivatives

R. P. Soni and J. P. Saxena*

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received January 30, 1979)

A series of substituted 6-Hydroxythiazolo[3,2-*a*]benzimidazoles has been synthesized. Their quaternary derivatives showed characteristic absorption maxima at longer wavelengths in visible region. The spectral study of parent compounds in the visible region shows a red shift at higher pH which is attributed to the dipolar nature of these compounds.

The chemotherapeutic importance of imidazole derivatives is well recognized.[1–3] The effectiveness of condensed heterocycles containing thiazole and imidazole rings as antiprotozoal agents,[4] anticonvulsants,[5] antidepressants,[6] antihelminthic agents,[7–10] antidiabetic,[11] and as inhibitors of dihydrofolate[12] led us to synthesize a new series of thiazolobenzimidazoles in a manner analogous to Schmid and Czerney's[13] synthesis of 8-hydroxypyrido[1,2-*a*]benzimidazole. Rudner[14] synthesized some of the 6-hydroxy-substituted thiazolo[3,2-*a*]benzimidazoles by the condensation of substituted 2-aminothiazoles with *p*-benzoquinone in acetic acid. We followed the same procedure and obtained more new compounds of the above series. A study of their finer structure through spectral analysis was made. The thiazolobenzimidazoles so obtained were quaternized with ethyl bromide giving the corresponding 9-ethyl-6-hydroxythiazolo[3,2-*a*]benzimidazolium bromides. These quaternary compounds gave intense yellow color with dilute aqueous alkali due to the formation of phenol betaines.[15–16] The colored betaines could be extracted in the chloroform layer giving a deep violet color. The color was discharged on acidification which is the reversal of the mode of formation of these betaines.

Experimental

All the reagents were thoroughly dried and purified before use. All melting points were determined on Kofler instrument and were uncorrected. IR spectra were recorded on a Perkin-Elmer 577 spectrophotometer in KBr. UV absorption spectra were scanned in Beckman spectrophotometer, Model DU-2.

2-Aminothiazoles: These compounds were prepared by known method.[17]

*6-Hydroxythiazolo[3,2-*a*]benzimidazoles (I).* A solution of *p*-benzoquinone (0.01 mol) in glacial acetic acid (10 ml) was added in small portions to the substituted 2-aminothiazole (0.01 mol) in acetic acid (10 ml) with shaking. The mixture was left aside for 30 min. After addition of 20 ml of 50% aq HCl, the solution was diluted with water, and extracted with ether to remove any unreacted quinone and hydroquinone. The resulting solution was made alkaline with aq sodium carbonate when the desired compound precipitated. After treatment with charcoal in ethanol, the compound was recrystallized from ethanol. The yields, mp; *etc.* are given in Table 1.

*9-Ethyl-6-hydroxythiazolo[3,2-*a*]benzimidazolium Bromides (II).* A mixture of I (0.01 mol) and ethyl bromide (0.01 mol) in a minimum quantity of acetone was boiled under reflux for 1 h. The solvent was evaporated to dryness under reduced pressure and the residue was crystallized from ethanol–ether. The yields, mp *etc.* are given in Table 2.

Discussion

All these compounds are deep colored powdery substances, insoluble in water but are readily soluble in ethanol. They do not melt upto 330 °C. The structure of these compounds has been determined on the basis of IR spectra and elemental analysis. The IR spectra of these compounds showed bands at 3210, 1200 (phenolic OH), 1610(C=N), 1310(C–N), and 1440 cm^{-1} (aromatic

ring breathing).

A study of the absorption spectra of various substituted 6-hydroxythiazolo[3,2-*a*]benzimidazoles in ethanol at different pH shows a bathochromic shifting of the absorption maxima in both acidic and alkaline media. The observed bathochromic shift might be explained by the canonical quinonoid structure shown in Scheme 1. Same phenomenon is observed when these compounds are quaternized with ethyl bromide which results into further red shifting of absorption maxima in visible region.

For the sake of comparison of the absorption spectra of these title compounds (I), 8-hydroxypyrido[1,2-*a*]-benzimidazole was synthesized by the method described by Schmid and Czerney.[13] A study of its absorption spectra in ethanol under various conditions (Table 3) also shows a red shifting of absorption band in the longer wavelengths in alkaline medium whereas in acid medium the spectra remain practically unaltered.

Table 3. Absorption spectra of 8-hydroxy-pyrido[1,2-*a*]benzimidazole

S. No.	Compound	λ_{max}/nm (log ε)			
1	Parent base in ethanol	—	360 (3.78)	300 (3.76)	248 (4.5)
2	Parent base in alkaline ethanol	405 (3.87)	—	268—270 (4.49)	242 (4.36)
3	Parent base in acidic ethanol	—	358 (3.94)	292 (3.71)	238 (4.17)

It has been observed by Edger *et al.*[18] that the 5- or 6-chlorobenzimidazoles do not show any shifting of absorption maxima in ethanolic solution of different pH. It indicates that the presence of 6-hydroxyl group in these title compounds which being more acidic causes the molecule to attain greater dipolar character at different pH thereby facilitating absorption in the longer wavelengths.

Thanks are due to Professor R. C. Kapoor for providing necessary laboratory facilities and to the U. G. C., New Delhi for awarding a research scholarship to one of them (R. P. S). We are also thankful to the Director, C. D. R. I. Lucknow for the IR spectra and elemental analysis.

Formation of Benzyl Radicals by Pulse Radiolysis of Benzyltriphenylphosphonium Chloride in Aqueous Solutions

Hideo Horii,* Shinichi Fujita, Toshiaki Mori, and Setsuo Taniguchi

Department of Chemistry, Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received February 19, 1979)

Synopsis. The reaction of benzyltriphenylphosphonium ion ($PhCH_2P^+Ph_3$) with e^-_{aq} has been studied. The benzyl radical and triphenylphospine are formed by the reaction: $PhCH_2P^+Ph_3+e^-_{aq}\rightarrow PhCH_2\cdot+Ph_3P$, with the rate constant $(2.7\pm0.3)\times10^{10}$ M^{-1} s^{-1}. The benzyl radical decays in a bimolecular reaction with $2k=(2.7\pm0.4)\times10^9$ M^{-1} s^{-1}.

Tetraphenylphosphonium ions (Ph_4P^+) are reduced with hydrated electrons to form $Ph_4P\cdot$ radicals which decay by disproportionation.[1]

On the other hand, optically active tertiary phosphines have been prepared without racemization by electrochemical reduction of quaternary phosphonium salts having the benzyl group.[2,3] This indicates that the electron is transferred directly to the benzyl group and not to the phosphorus atom, causing fission to form a tertiary phosphine and benzyl radical, since nucleophilic attack on phosphorus leads to inversion of configuration.[4] The present investigation deals with the direct confirmation of this scheme by the pulse radiolysis method.

Experimental

The experimental details and dosimetry were reported.[5] A 500 W Xe lamp was used to follow the decay of the hydrated electron and observe other transient and permanent absorptions. All solutions were prepared from triply distilled water. The solutions were buffered with 1 mM phosphate. Deaeration of solutions was performed by argon bubbling for about 2 h. The reagents were of analytical grade and used without further purification. A fresh solution was used for each pulse. Ph_3P aqueous solution used for the absorption spectra was prepared by mixing 5×10^{-5} M Ph_3P EtOH solution with H_2O.

Results and Discussion

Pulse radiolysis of deaerated neutral aqueous solutions of benzyltriphenylphosphonium chloride yielded a transient species and products. Figure 1 shows the spectra observed immediately and 5 ms after the cessation of pulse in a buffered solution at pH 7 of 2×10^{-5} M benzyltriphenylphosphonium chloride containing 0.2 M *t*-butyl alcohol as an OH radical scavenger. The absorption at 5 ms after cessation of the pulse seems to be permanent from oscilloscopic tracing. On saturating the solution with dinitrogen oxide which converts e^-_{aq} into OH radicals, the transient absorption almost disappeared. Thus, transient and permanent absorptions are caused by the reaction of the phosphonium ion with e^-_{aq}.

Figure 2 shows the spectrum of the intermediate

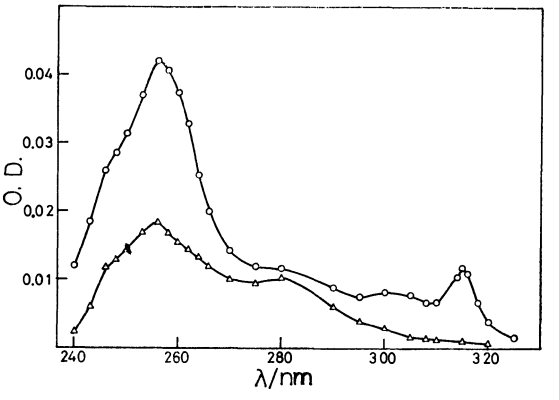

Fig. 1. Absorption spectra observed after pulse irradiation in a deaerated aqueous solution of 2×10^{-5} M benzyltriphenylphosphonium chloride, 0.2 M *t*-butyl alcohol at pH 7. Dose, 430 rad: (○) end of the pulse; (△) 5 ms after the pulse.

obtained by subtraction of the absorption taken 5 ms after cessation of the pulse from that taken immediately on cessation (Fig. 1). The spectrum has three maxima at 258, 305, and 315 nm with the estimated extinction coefficients 13300, 3400, and 5900 M^{-1} cm^{-1}, respectively, taking $G(e^-_{aq})=2.7$. The spectrum is very similar to that of the benzyl radical[6] in aqueous solutions, which has three maxima at 258, 307, and 317.5 nm with extinction coefficients 14000, 3300, and 5500 M^{-1} cm^{-1}, respectively.

Figure 3 shows the absorption spectrum at 5 ms after the pulse corrected for the depletion of the solute ($PhCH_2P^+Ph_3Cl^-$), and that of aqueous Ph_3P solution

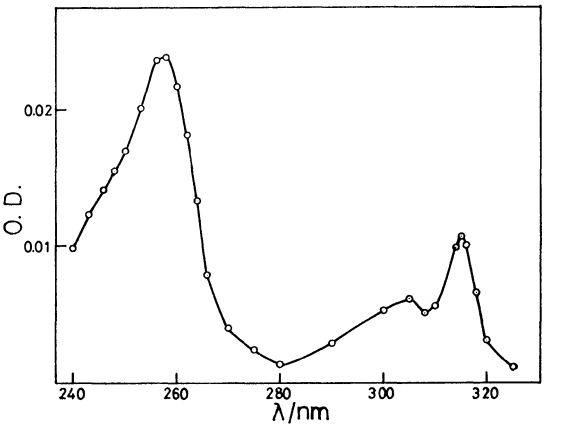

Fig. 2. Transient spectrum corrected for the permanent absorption obtained from Fig. 1.

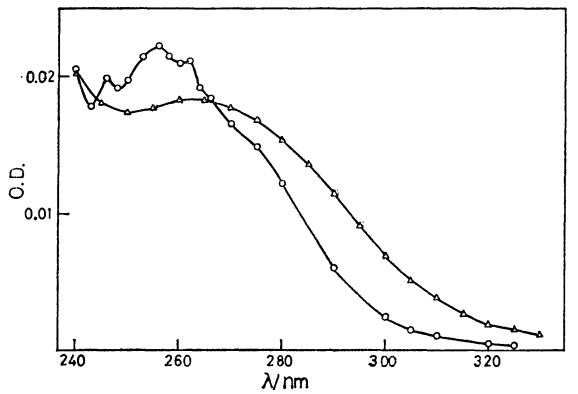

Fig. 3. Absorption spectra of the stable products corrected for depletion of the substrate obtained from Fig. 1 (○) and that of ethanolic aqueous solution of Ph_3P corresponding to the e^-_{aq} concentration in Fig. 1 (△).

corresponding to the concentration of the e^-_{aq} produced under the conditions of Fig. 1. The absorption spectrum of Ph_3P in Fig. 3 was obtained from that of 9×10^{-6} M Ph_3P aqueous solution containing 20 vol% EtOH, which has an absorption maximum at 260—265 nm with $\varepsilon=10300\ M^{-1}\ cm^{-1}$. The permanent absorption spectrum formed by pulse radiolysis probably comes from PPh_3, since the two spectra are considerably similar. The small difference in the absorption spectra below 260 nm may be due to bibenzyl[7] produced by the recombination of benzyl radicals and the one beyond 270 nm may arise from undissolved triphenylphosphine in water.

The transient absorption at 315 nm (Fig. 2) disappears in a bimolecular reaction with $2k=(2.7\pm0.4)\times10^9\ M^{-1}\ s^{-1}$. The absorption at 258 nm, which is corrected for the permanent one, decays by a second-order kinetics with the same rate constant as that at 315 nm within an experimental error. This indicates that the permanent absorption takes place immediately on cessation of the pulse. The rate constant agrees with the previous values $(3.1\pm0.3)\times10^9$,[6] $2.4\times10^9\ M^{-1}\ s^{-1}$.[8]

The results suggest that the $PhCH_2P^+Ph_3$ ion is reduced with e^-_{aq} to dissociate into the benzyl radical and triphenylphosphine. The following reaction scheme may be suggested:

$$H_2O \rightsquigarrow e^-_{aq},\ H,\ OH,\ etc. \quad (1)$$

$$OH + t\text{-BuOH} \longrightarrow t\text{-BuOH radical} + H_2O \quad (2)$$

$$PhCH_2P^+Ph_3 + e^-_{aq} \longrightarrow PhCH_2\cdot + Ph_3P \quad (3)$$

$$PhCH_2\cdot + PhCH_2\cdot \longrightarrow \text{Products} \quad (4)$$

$$e^-_{aq} + N_2O \longrightarrow OH + OH^- + N_2 \quad (5)$$

The rate constant for the reaction of the $PhCH_2P^+Ph_3$ ion with e^-_{aq} is $(2.7\pm0.3)\times10^{10}\ M^{-1}\ s^{-1}$, which was determined from the decay of e^-_{aq}. The rate constant is diffusion controlled, similar to that[1] of Ph_4P^+ with e^-_{aq}.

The phosphoranyl radical $PhCH_2\dot{P}Ph_3$ might not be sufficiently stable to be observed in the microsecond pulse radiolysis. It seems reasonable to assume that e^-_{aq} attacks the $PhCH_2$ group, and causing release of the benzyl radical before the electron is delocalized to form the phosphoranyl radical.

The reaction mechanism might be similar to that of the electroreduction of quaternary ammonium compound.[9,10]

Phase Transition of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$, Anion Radical Salts. Thermodynamical Stability of the Solid Solutions

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 28, 1979)

Synopsis. The phase transition and the thermodynamic properties of solid solutions were studied with anion radical salts of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$. The stability condition of the solid solutions was examined in both the low- and high-temperature phases.

Much attention has been paid to solid anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) because of their prominent electronic properties.[1-12] In particular, the anion radical salt of methyltriphenylphosphonium, $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, undergoes a solid-state phase transition at 315.7 K.[1-8] The methyltriphenylarsonium salt, $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, although it exhibits electronic properties very similar to those of the phosphonium salt, shows no such phase transition up to the decomposition temperature at 1 atm pressure.[1-3,6-11] Moreover, one can prepare the salts containing the mixed cations represented by $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$.[1,2,6-11] The phase transitions of these mixed anion radical salts have been studied, as a function of the composition parameter, by observing anomalies in the temperature dependence of the static magnetic susceptibilities and the electrical conductivities and also by means of thermal analyses.[2,6-8] The experimental relation between the transition temperature and the composition parameter (x) at 1 atm pressure is illustrated in Curve (a) of Fig. 1. In order to understand the thermodynamic behavior of the phase transitions against the composition parameter, we proposed in a previous paper a thermodynamical theory of binary regular solid solution model for those TCNQ mixed crystals.[11] In the present paper, we shall examine the condition of the thermodynamical stability of the solid solutions and investigate the mechanism of the phase transitions.

According to the previous paper,[11] a thermodynamical theory of binary regular solid solution model is applicable to $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$. This model assumes an ideal mixing of the two components of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, $(x=0.00)$, and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, $(x=1.00)$, because the crystal structure and the chemical properties of the phosphonium salt are very similar to those of the arsonium salt. The model further assumes that the phase transition of a solid solution does not change the manner of ideal mixing of the two components. In this respect, it is important to note that the phase transition of our system is not the usual order-disorder type with respect to the mixing of the two components. Moreover, we could well assign the low- and high-temperature phases of the solid solutions at 1 atm pressure as $\alpha\gamma$ and $\beta\gamma$ phases, respectively.[9-11] Their Gibbs free energies per mol were expressed by

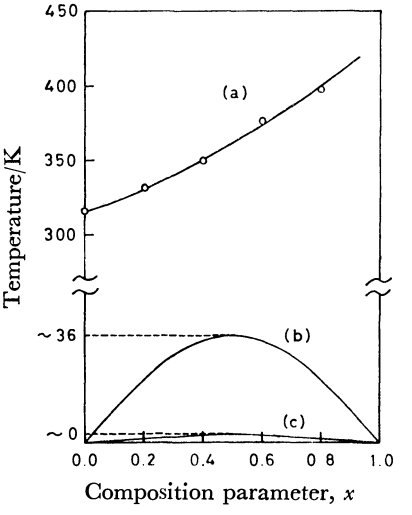

Fig. 1. Curve (a) shows the experimental relation between the temperature of the $\alpha\gamma \rightarrow \beta\gamma$ phase transition and the composition parameter (x) of the solid solutions of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$, anion radical salts at 1 atm pressure. Curves (b) and (c) show boundaries between the solid solution and the segregated region for the $\beta\gamma$ and $\alpha\gamma$ phases of the solid solutions, respectively. See text.

$$G^{i\gamma}(T,p,x) = (1-x)G_1^{i}(T,p) + xG_2^{\gamma}(T,p) + H_m^{i\gamma}(1-x)\cdot x + RT\{(1-x)\ln(1-x) + x\ln x\}, \quad (i=\alpha,\beta), \tag{1}$$

where T and p represent temperature and pressure, respectively, and where $(1-x)$ and x are the mole fractions of the component $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, respectively. $G_1^{\alpha}(T,p)$ and $G_1^{\beta}(T,p)$ are the Gibbs free energies per mol for the low-temperature (α) and high-temperature (β) phases of pure phosphonium salt, respectively, while $G_2^{\gamma}(T,p)$ is that of the (γ) phase of pure arsonium salt at 1 atm pressure. $H_m^{i\gamma}$ is the heat of mixing per mol for each phase, and is assumed to be independent of temperature. The phase transitions of the solid solutions at 1 atm pressure can then be assigned to the $\alpha\gamma \rightarrow \beta\gamma$ process. By analyzing the experimental relation between the transition temperature of the $\alpha\gamma \rightarrow \beta\gamma$ phase transition and the composition parameter (Curve (a) of Fig. 1), we obtained the difference of the heat of mixing between the $\alpha\gamma$ and $\beta\gamma$ phases as $H_m^{\beta\gamma} - H_m^{\alpha\gamma} = 0.594 \pm 0.021$ kJ/mol.[11]

For either of the low-temperature ($\alpha\gamma$) or high-temperature ($\beta\gamma$) phase of our solid solutions, if the value of $H_m^{i\gamma}$, (i=α or β), is positive, the solid solutions are unstable below certain critical temperature and the segregation into the phosphonium salt and the arsonium salt should take place. It is well known that the theoretical relation between the mole fraction of the two components and the critical temperature at which the breaking of solid solution occurs can be determined by solving the equation

$$H_m^{i\gamma}(1-2x) + RT\ln\frac{x}{1-x} = 0. \quad (2)$$

In the region above critical temperature the solid solutions are thermodynamically stable with ideal mixing of the two components, while the solid solutions do not exist below critical temperature. In the temperature region above $T_m^{i\gamma}=H_m^{i\gamma}/2R$, the solid solutions can be obtained with all compositions ranging from $x=0.00$ to $x=1.00$.

In the case of $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, ($0\leq x\leq 1$), anion radical salts, although we have no information about the individual value of $H_m^{\alpha\gamma}$ or $H_m^{\beta\gamma}$, we can safely assume that the value of $H_m^{\alpha\gamma}$ may be very nearly equal to zero kJ/mol for the low-temperature ($\alpha\gamma$) phase, because the crystal and molecular structures of the α phase of the phosphonium salt are almost identical with those of the γ phase of the arsonium salt.[12] Moreover, there acts no specific interaction between the methyltriphenylphosphonium and methyltriphenylarsonium cations in the $\alpha\gamma$ phase and the chemical properties of the phosphonium salt are very similar to those of the arsonium salt. The assumption of $H_m^{\alpha\gamma}\approx 0$ kJ/mol is also strongly supported by the reason to be mentioned in the following. Then, we have $H_m^{\beta\gamma}\approx 0.594$ kJ/mol for the high-temperature ($\beta\gamma$) phase of the solid solutions. This positive $H_m^{\beta\gamma}$ value is reasonable, because the molecular and crystal structures of the β phase of the phosphonium salt are closely related to those of the γ phase of the arsonium salt but a difference was found in the conformation of the methyltriphenylphosphonium cation with respect to the intramolecular rotation of the phenyl groups.[12]

First, we neglect the effect of the $\alpha\gamma\rightarrow\beta\gamma$ phase transition, and only consider the $\beta\gamma$ phase of the solid solutions. By the use of $H_m^{\beta\gamma}\approx 0.594$ kJ/mol, together with Eq. 2, the boundary between the solid solutions and the segregated region is obtained as shown in Curve (b) of Fig. 1. In the region above Curve (b) the solid solutions composed of ideally mixed β form of the phosphonium salt and the γ form of the arsonium salt are stable, while they have to be segregated into two components below Curve (b). $T_m^{\beta\gamma}$ at $x=0.50$ is calculated to be about 36 K.

In view of these results, we can understand the importance of the $\beta\gamma\rightarrow\alpha\gamma$ phase transitions (Curve (a) of Fig. 1) of the solid solutions. If there were no such phase change, the $\beta\gamma$ phase would become unstable in going to low temperatures and the crystals of the solid solutions would break. Actually, however, the solid solutions change into the $\alpha\gamma$ phase at Curve (a) of Fig. 1, which lies in the temperature region much higher than does Curve (b) of Fig. 1. As for the $\alpha\gamma$ phase, since $H_m^{\alpha\gamma}\approx 0$ kJ/mol and thus $T_m^{\alpha\gamma}\approx 0$ K, the boundary between the solid solutions and the segregated region is schematically given by Curve (c) of Fig. 1, that is, the solid solutions composed of the α form of the phosphonium salt and the γ form of the arsonium salt will be stable down to 0 K in all compositions. This prediction may be supported by the experimental results by Kosaki *et al.*[8] For example, the fact that the observed heat capacity *versus* temperature curve of the $\alpha\gamma$ phase of the solid solution with the composition $x=0.449$ is smooth down to about 10 K means that the solid solution does not break and that the $\alpha\gamma$ phase is stable at least down to 10 K. This experimental result also implies very small value (less than 0.17 kJ/mol) for $H_m^{\alpha\gamma}$ in the $\alpha\gamma$ phase.

Our investigation clearly shows that, because of the $\beta\gamma\rightarrow\alpha\gamma$ phase transition, the solid solutions of $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, ($0\leq x\leq 1$), anion radical salts are stable both in the temperature range from 0 K up to decomposition temperatures and in the whole composition range from $x=0.00$ to $x=1.00$. So far, this conclusion agrees well with the experimental observations.[1-8] Another important conclusion is concerned with the mechanism of the phase transition of the solid solutions. The existence of the $\beta\gamma\rightarrow\alpha\gamma$ phase change is necessary to avoid breaking of the $\beta\gamma$ phase at low temperatures.

Decomposition of Ozone on Natural Sand

Shin SUZUKI,* Yoshio HORI, and Osamu KOGA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho 1-33, Chiba 260

(Received December 11, 1978)

Synopsis. Ozone decomposition on natural sand has been studied with a flow system. Ozone decomposed significantly on natural sand and in particular on iron sand. Silica, alumina, and iron oxides, the major components of the sand, were also capable of decomposing ozone.

Ozone is one of the major photochemical pollutants and its behavior in the environment has been reported. Ozone is reactive, which suggests that ozone may be decomposed on terrestrial substances on the ground or in airborne dusts. There have been several reports describing the heterogeneous decomposition of ozone on solids. Harteck and Dondes reported the decomposition of ozone on glass wool,[1] and Mahieux studied the decomposition of ozone on glass, aluminium, copper, silica gel, and active charcoal.[2] These investigations were qualitative and conducted at relatively high concentration (several %). No report has been published concerning the decomposition of ozone at low levels of concentration *e.g.*, several ppm.

The present paper describes the decomposition of ozone on natural sea sand in order to clarify the decomposition of ozone on terrestrial substances. Natural sea sand was used since it is easy to handle and has a relatively uniform composition.

Experimental

Materials. *Natural Sea Sand*: The sample was supplied from the seashore of Futsu Cape, Tokyo Bay, Japan. The sample was sieved between 80 and 120 mesh, and dried at 150 °C for three hours in an electric furnace.

Iron Sand and Remainder-sand: Natural sea sand was subdivided into iron sand and remainder-sand by means of a magnet and dried identically.

Silica, Fe_2O_3, Fe_3O_4, and Al_2O_3: Commercial reagents were employed; silica(α-quartz), α-Fe_2O_3(hematite), Fe_3O_4 (magnetite), and α-Al_2O_3(corundum). They were dried identically.

Instruments. Reactions were conducted in a flow system. An ozone generator (Tokyo Kogyo Co.) supplied a given concentration of ozone (0—5 ppm). The air containing ozone was blown into the reaction cell, filled with the appropriate sample powder. Sample powders were supported on glass frit and Teflon filters. The concentration of ozone was measured by a UV absorption type ozone monitor (Dasibi Co.) at the inlet and the outlet of the reactor. The flow rate of the ozonized air was regulated at 2 l/min by the suction pump of the ozone monitor.

Results and Discussion

Ozone Decomposition on Natural Sea Sand. No ozone was decomposed in blank tests in the absence of sample materials in the reactor. Ozone decomposition was seen to take place on the natural sand sample charged in the reactor. Figure 1 shows the variation

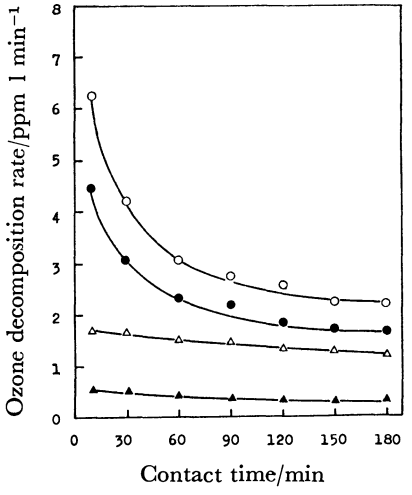

Fig. 1. Decomposition rate of ozone on natural sand (5 ml) *versus* contact time.
Concentration of ozone at inlet; -○-: 5 ppm, -●-: 3.5 ppm, -△-: 1.0 ppm, -▲-: 0.25 ppm.

in the rate of decomposition of ozone with contact time on the natural sand (5 ml). The decomposition rate was determined as follows:

$$\text{Decomposition rate} = ([O_3]_i - [O_3]_o) \times f$$

$[O_3]_i$: Inlet ozone concentration (ppm)
$[O_3]_o$: Outlet ozone concentration (ppm)
f: Flow rate of air (l/min)

The rate of decomposition decreased gradually with increase in concentration, whereas the rate remained almost constant at low ozone concentration.

The decomposition rate of ozone at constant concentration (3.5 ppm) increased in proportion to the volume

of the sand.

Individual Activity of the Components of Natural Sand in Ozone Decomposition. The decomposition was studied on several components of sand; iron sand, remainder-sand and some reagents. The reagents are those which were found by chemical analysis to be the major components of the sand; *i.e.* silica, iron oxides, and alumina. The major component of iron sand is known to be Fe_3O_4, so that α-Fe_2O_3 and magnetite were investigated.

Natural sand was analyzed by chelatometry and atomic absorption spectrometry, the results of which are given in Table 1. The sand used in the experiments contained more iron oxides than the original non-sieved sand probably because the iron sand grain size is mainly distributed in the 80—120 mesh range. In measurements of ozone decomposition the amounts of samples used were: remainder-sand (5 ml), iron sand (5 ml), silica (5 ml), Fe_2O_3 (5 ml), alumina (1 g), and Fe_3O_4 (1 g). Figure 2 shows the rates of ozone decomposition on iron sand, remainder-sand and natural sand. The rate on iron sand was higher than that on natural sand suggesting that iron sand more effectively decomposes ozone than remainder-sand.

The decomposition rates on alumina, Fe_2O_3 and Fe_3O_4 were lower, whereas that on silica remained almost constant as shown in Fig. 3. The decomposition on Fe_3O_4, a major component of iron sand, behaved very similarly to that on iron sand as shown in Figs. 2 and 3.

The authors wish to express their sincere thanks to Dr. Ryozo Nakagawa for the analysis of natural sand. Thanks are also due to Mr. Hiroo Takagi and Miss Hiromi Miyamoto for their collaboration in the experimental works. The present work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Polarographic Reduction and UV Spectral Properties of Pentaamminecarboxylatoruthenium(III) Complexes

Akira OHYOSHI* and Kenichiro YOSHIKUNI
Department of Industrial Chemistry, Kumamoto University, Kumamoto 860
(Received January 22, 1979)

Synopsis. Pentaamminecarboxylatoruthenium(III) complexes are reversibly reduced to the corresponding Ru(II) complexes by means of a one-electron transfer at the dropping mercury electrode in aqueous solutions. The absorption maxima, which ranged from 34.6×10^3 cm^{-1} (trichloroacetato complex) to 33.6×10^3 cm^{-1} (glycinato complex) were assigned to the charge-transfer from ligand to metal; they were linearly related to the reversible half-wave potential.

Recent polarographic reduction studies of ruthenium(III) carboxylato complexes[1-3] have revealed that the complexes are reversibly reduced at the dropping mercury electrode through the process of one-electron-transfer. For the series of ammineruthenium(II, III) complexes,[4-9] formal reduction potentials (E_f) were measured and a linear relationship was found to exist between the E_f and the charge-transfer energy from metal to ligand.[8] Hence, it seemed of interest to check whether or not a similar relationship exists between the $E_{1/2}$ and the CT-energy from ligand to metal for ruthenium(III) complexes. In the present paper, a similar relationship was confirmed between them for the series of Ru(III) complexes.

Experimental

Reagents and Materials. All the chemicals used were of a reagent grade. Twice-distilled water was used in all the experiments. The ionic strength and the acidity of the electrolyte solution were adjusted with *p*-toluenesulfonic acid and its sodium salt. Pentaammineformatoruthenium(III) and other carboxylato complexes were prepared by the method described in the literature[10] starting from pentaamminechlororuthenium(III) chloride, the corresponding buffer solution, and zinc amalgam. The complexes thus prepared were analyzed by the usual elemental analysis, and their chemical purities were confirmed.

Apparatus and Procedures. A Shimadzu RP-50 polarograph was employed with a circuit for an extendable and adjustable applied potential. An H-cell with a saturated calomel electrode (SCE) was used. The capillary used had an *m*-value of 1.82 mg s^{-1} and a drop time of 5.0 s in distilled water at a mercury height of 61.5 cm with an open circuit. All the measurements were carried out in a thermostat of (25.0±0.1) °C. Gelatin was used as the maximum suppressor. Polarographic measurements were made after the removal of oxygen by bubbling nitrogen gas through the electrolyte solution. The half-wave potentials were determined from the extended polarograms by means of the plotting. The potential values were corrected for the *iR* drop by using the minimum value of the cell resistance. A Shimadzu UV-200 spectrophotometer was used to measure the electronic spectra of the ruthenium complexes.

Results and Discussion

Electrode Process in the Polarographic Reduction of a Complex. Each complex exhibits a single well-defined reduction wave at a potential near zero volt *vs.* SCE. The limiting current, i_l, was proportional to the concentration of the complex ion. Plots of i_l *vs.* the square root of the mercury head, h, were linear. Thus, the electrode process posseses a high degree of diffusion control. The plots of $E_{d.e.}$ *vs.* log $[i/(i_d-i)]$ are almost linear for all the complexes (Fig. 1). The numbers of electrons involved in the reduction was determined to be almost one from the slope of this plot. Thus, each low-spin $(t_{2g})^5$ ruthenium(III) complex was found to undergo a ready one-electron reduction, which might be regarded as completing the metal t_{2g} subshell. In each case, the reciprocal slope of the logarithmic plot is (60±2) mV, indicating that the electrode reaction is a reversible step, with a one-electron transfer. The half-wave potentials measured in solutions of pH 5.0—7.5 and at an ionic strength of 0.1 mol dm^{-3} are almost constant; they are given in Table 1. However, the half-wave potentials shifted slightly in a positive direction with a lowering of the pH of the solution, as is exemplified in Fig. 1. This fact may be attributable to the increase in the reversibility of the electrode reaction resulting from the stabilization of the reduced Ru(II) species.

The redox potential of the Ru(III)/Ru(II) couple for the complexes of the $[Ru(O_2CR)(NH_3)_5]$ type shifts in a negative direction in this ligand order: $O_2CCCl_3<O_2CCHCl_2\approx O_2CCH_2F<O_2CCH_2Cl\approx O_2CCH_2Br\approx O_2CCH_2I<O_2CH<O_2CCH_2NH_2<$

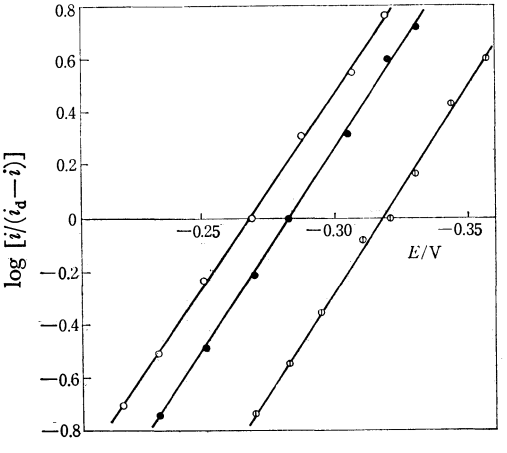

Fig. 1. Plots of log $[i/(i_d-i)]$ *vs.* $E_{d.e.}$.
$[Ru(O_2CH)(NH_3)_5]^{2+}$, ○: 0.008 mol dm^{-3} *p*-toluene sulfonic acid, 0.092 mol dm^{-3} sodium *p*-toluenesulfonate, ●: 0.1 mol dm^{-3} sodium *p*-toluenesulfonate.
$[Ru(O_2CCH_2OH)(NH_3)_5]^{2+}$ ⊕: 0.1 mol dm^{-3} sodium *p*-toluenesulfonate.

$O_2CCH_2OH < O_2CCH_3 \approx O_2CC_2H_5 \approx O_2CCH(CH_3)_2$. This order agrees with that for the increasing pK_a values of the ligand acids, except for the glycinato complex.

When the complex ion reacts with the electrode as a depolarizer, the reduction is regarded as comprising the acceptance of an electron into the lowest unoccupied orbital of the complex. For the reduction process, the rate and mechanism of the overall process will be dictated by the localization and energy of the lowest orbital.[12] The Ru(III) complex with an electronic configuration of $(t_{2g})^5$ tends to take the $(t_{2g})^6$ configuration because of the high electron affinity of the unoccupied orbital, partly filled with one electron. Thus, the values of the redox potentials measured in this experiment are correlated with the energy level of the lowest unoccupied orbital of Ru(III) in the coordination sphere of pentaamminecarboxylato complexes.

Electronic Spectra of Ru(III) Complexes. The electronic spectra of all the complexes measured in a solution of 0.1 mol dm^{-3} *p*-toluenesulfonate at 25 °C exhibit an intense band in the energy region from 34.6×10^3 cm^{-1} to 33.6×10^3 cm^{-1}, as is shown in Table 1. These bands are assigned to the charge-transfer transition from ligand $p\pi$ to Ru(III) $d\pi$ orbitals on the basis of their intensity and spectral energies, and on the basis of a comparison of these data with those of the other related complexes.[13] The $p\pi$-$d\pi$ charge-transfer energy in $[Ru^{III}O_2CR(NH_3)_5]$ complexes regularly decreases upon R-substituents of RCO_2 ligands in this order: $O_2CCCl_3 > O_2CCHCl_2 > O_2CCH_2F > O_2CCH_2Cl > O_2CCH_2Br \approx O_2CCH_2I > O_2CH \approx O_2CCH_2OH > O_2CCH_3 \approx O_2CC_2H_5 > O_2CCH(CH_3)_2 > O_2CCH_2NH_2$. This order agrees with that of the increasing pK_a values of the ligand acids except for the case of iso-butyric acid and glycine (Table 1).

It is of interest to examine whether or not there exists a direct relationship between the electrochemical stabilization of Ru(III) towards cathodic reductions, as expressed in terms of $E_{1/2}$ values, and the LMCT

Table 1. Half-wave potentials and optical parameters of pentaammineruthenium(III) complexes and dissociation constants of ligand acids

a) Supporting electrolyte solution: 0.1 mol dm^{-3} sodium *p*-toluenesulfonate. b) mol^{-1} dm^3 cm^{-1}. c) From Ref. 11.

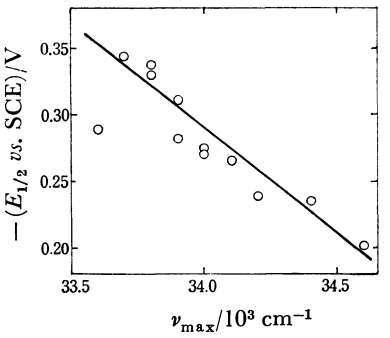

Fig. 2. Plot of half-wave potential $E_{1/2}$ of the $Ru(O_2CR)(NH_3)_5^{2+/+}$ couples *vs.* the wave number of the ligand-to-metal charge-transfer maxima for the $Ru(O_2CR)(NH_3)_5^{2+}$ complexes.

spectral energies. The plots of $E_{1/2}$ *vs.* ν_{max} (LMCT) are approximately linear for various pentaammine-carboxylatoruthenium(III) complexes, as is shown in Fig. 2. A linear relationship between the formal redox potential and the absorption maximum of the metal to ligand charge-transfer (MLCT) has been found to exist for various benzonitrile and pyridine complexes of Ru(II).[8] The charge-transfer energy is related only to the energy difference between $p\pi$ and $d\pi$ orbitals. On the contrary, the reversible half-wave potential is directly related to the energy level of a singly occupied $d\pi$ orbital. Therefore, this $d\pi$ orbital energy level may be a determinant factor for both the redox potential and the charge-transfer energy for pentaammine-carboxylatoruthenium(III) complexes.

Metal-substitution of 12-Heteropolymolybdate with Iron Atoms

Kenji NOMIYA, Motoki SUGAYA, and Makoto MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180

(Received April 6, 1979)

Synopsis. Triheteropolymolybdates of $[XFeMo_{11}O_{40}H_2]$- and $[XFeMo_{11}O_{40}H_3]$-type have been synthesised by the metal-substitution reaction of 12-heteropolymolybdate of $[XMo_{12}O_{40}]$-type (X is Si or P) and their properties have been investigated.

Although triheteropolymolybdate, a mixed-metal polyoxoanion, was expected to be a new catalyst of reversible oxidation in homogeneous system,[1] the compound, generally prepared in only a narrow pH range, is more easily hydrolyzed than the corresponding saturated heteropolymolybdate. We have examined the metal substitution of 12-heteropolymolybdate possessing well-known Keggin structure with Fe(II) and Fe(III) ions. We report on the isolation of the reaction products, the anions of $[XFeMo_{11}O_{40}H_2]$- and $[XFeMo_{11}O_{40}H_3]$-type as tetrabutylammonium salts, where X is Si or P. So far as Fe-ion substituted products derived from heteropolyanions of $[XMo_{12}O_{40}]$-type are concerned, no precedent has been reported except for $[SiFeMo_{11}O_{40}H_2]^{5-}$.[2]

The reaction of $[SiMo_{12}O_{40}]^{4-}$ with $FeCl_3$ in aqueous solution containing potassium acetate and glacial acetic acid gave mainly $[SiFeMo_{11}O_{40}H_2]^{4-}$, where Fe is tervalent and all Mo are sexivalent cations. The complex was isolated as a stable tetrabutylammonium salt. The reaction of $[SiMo_{12}O_{40}]^{4-}$ with $FeCl_2$ under similar conditions gave $[SiFeMo_{11}O_{40}H_3]^{5-}$, where Fe is also tervalent, only one Mo being quinquevalent and the others sexivalent cations. During the course of substitution, bivalent Fe ion turns into a tervalent cation by the intrinsic strong oxidation property of the parent anion. Such a compound has also been isolated as a tetrabutylammonium salt and purified by recrystallization from acetonitrile. By the reaction of $[PMo_{12}O_{40}]^{3-}$ with Fe(II) or Fe(III) ion, the corresponding one iron substituted derivatives were obtained. In these reactions no further substitution of Mo ion was observed.

The K^+, Na^+, and NH_4^+ salts of heteropolymolybdate containing an iron atom, once formed in aqueous solutions of limited pH range, are sparingly recrystallized from an aqueous solution because of their extremely low solubility and hydrolytic instability. However, by using tetrabutylammonium cation as precipitants, such unstable anions were converted into stable compounds for recrystallization from a nonaqueous solvent such as acetonitrile. The treatment makes the determination of anionic charge, elemental analysis, spectroscopic characterization easy, giving good yield of compounds. Furthermore, in a nonaqueous solvent, these compounds obtained as a tetrabutylammonium salt do not decompose even in the presence of an organic base such as pyridine and triphenylphosphine.

The heteropolyanions obtained are formulated as follows;

$[SiFe^{III}Mo^{VI}_{11}O_{40}H_2]^{5-}$ (yellow, **1**),
$[SiFe^{III}Mo^{V}Mo^{VI}_{10}O_{40}H_3]^{5-}$ (yellow-green, **2**),
$[PFe^{III}Mo^{VI}_{11}O_{40}H_2]^{4-}$ (pale yellow, **3**),
$[PFe^{III}Mo^{V}Mo^{VI}_{10}O_{40}H_3]^{4-}$ (dark green, **4**),

their analytical data being given in Table 1.

Yellow compounds **1** and **3** are written as $[XFeMo_{11}O_{40}H_2]$ (X=Si, P), where "H_2" is included in the formula not only to make the total oxidation number consistent; X (+4 or +5 corresponding to Si or P), Fe (+3), Mo (+6), O (−2) and two H (+1), but is arised from the hydrogen part of coordinating water molecule. Existence of a coordinating water molecule was determined by IR study. The complexes were recrystallized several times from dry acetonitrile in order to remove solvated water molecules entirely. In this case, the characteristic bands of coordinating water at *ca.* 3400 and 1630 cm^{-1} were observed, but not in the case of parent anion $[XMo_{12}O_{40}]$-type. Thus if Fe ion is considered as a central ion, the compounds obtained are considered to be a hexa-coordination complex of Fe coordinated by quinquedentate ligand "$XMo_{11}O_{39}$" and unidentate ligand H_2O.

The green compounds **2** and **4** with the formula $[XFeMo_{11}O_{40}H_3]$-type also possess the water molecule coordinated to tervalent Fe ion and one hydroxyl group coordinated to one quinquevalent Mo ion in quinquedentate ligand "$XMo_{11}O_{39}$." The presence of the coordinating hydroxyl group is strongly suggested from the reduction of parent anion $[SiMo_{12}O_{40}]^{4-}$ by alcohols leading to the formation of the blue anion of $[SiMo_{12}O_{40}H_n]$-type, where n=2—4 and Mo ions of the corresponding numbers are quinquevalent.[3]

IR and electronic spectral data of heteropoly anion obtained together with parent molybdosilicate and molybdophosphate, are given in Tables 2 and 3,

respectively. Typical electronic spectra are dominated by two or three bands in the 240—500 nm region, which are based on the charge transfer transition of intra-ligand, *viz.* intra-"$XMo_{11}O_{39}$" moiety. The absorption due to the low spin Fe(III) complex under such ligand fields is extremely weak, the whole spectral aspect resembling that of the parent anion. However, the intensity at near 300 nm strongly reflects the effect of metal substitution and/or the degree of reduction of molybdenum atom. The characteristic spectra of compounds **2** and **4** containing a reduced molybdenum ion have weak intensity bands in a longer wave-length region than 700 nm. The data (Table 2) reveal that the metal substitution and/or heteroatom substitution directly influence the IR bands due to the M–O–M, X–O and M–O stretching modes.[4] All such bands are shifted to the low frequency region on replacement of one Mo ion in $[XMo_{12}O_{40}]$ with one Fe ion.

Experimental

IR spectra (KBr and Nujol) were recorded with a JASCO IR-G spectrophotometer and electronic spectra with a Hitachi 124-Model spectrophotometer. In the measurements of the tetraalkylammonium salts of heteropolyanions, both the KBr pellet method and the Nujol mull method gave the same results. $[SiMo_{12}O_{40}]^{4-}$ was prepared according to the method of North and Haney.[5] Its tetrabutylammonium salt was obtained by adding excess tetrabutylammonium halide. Commercial $[PMo_{12}O_{40}]^{3-}$ (Wako Pure Chemicals Co., Ltd.) was used. Its tetrabutylammonium salt was prepared by a similar work-up. The contents of Fe in the heteropolymolybdates was determined by the analytical method in the presence of Mo.[6]

Preparation. $K[(C_4H_9)_4N]_4[SiFeMo_{11}O_{40}H_2]\cdot CH_3CN$, ***1***: A solution of 1 g (0.478 mmol) $H_4[SiMo_{12}O_{40}]\cdot15H_2O$ dissolved in 3 ml water was gently heated to 60 °C. To this were added in succession a 1 ml solution mixture of 15 g (0.15 mol) CH_3COOK and 25 ml water containing 1 ml glacial acetic acid, and a 2 ml solution of 1.2 g (7.39 mmol) $FeCl_3$ dissolved in 20 ml water. The mixture was refrigerated overnight. The white precipitate produced was filtered off. The filtrate was evaporated under 50 °C until some crystal appeared, and then refrigerated overnight. The resulting yellow needle compound of $K_5[SiFeMo_{11}O_{40}H_2]$ was dissolved in a small amount of warm water, and then an aqueous solution containing excess tetrabutylammonium bromide was added. The product was washed several times with water, dried *in vacuo*, and recrystallized from dry acetonitrile (yield 35%, pale yellow).

$K[(C_4H_9)_4N]_4[SiFeMo_{11}O_{40}H_3]$, ***2***: 0.94 g (7.39 mmol) of $FeCl_2$ was dissolved in 20 ml water containing 0.5 ml concd HCl. Except for use of this solution instead of the $FeCl_3$ aqueous solution in the preparation of **1**, the product was obtained by a similar work-up (yield 38%, yellow-green).

$[(C_4H_9)_4N]_4[PFeMo_{11}O_{40}H_2]\cdot12H_2O$, ***3***: A solution of 1 g $H_3[PMo_{12}O_{40}]$ in 3 ml water was gently heated to 65 °C. A 1 ml solution of 15 g (0.15 mol) CH_3COOK in 25 ml water containing 1 ml glacial acetic acid was added and stirred thoroughly. A 2 ml solution of 1.2 g (7.39 mmol) $FeCl_3$ in 20 ml water was then added and refrigerated overnight. The precipitate was dissolved in water. To this yellow clear solution was added a small amount of solution containing excess tetrabutylammonium bromide. The product was thoroughly washed with water and dried *in vacuo* (yield 95%, pale yellow).

$[(C_4H_9)_4N]_4[PFeMo_{11}O_{40}H_3]\cdot9H_2O$, ***4***: 0.94 g (7.39 mmol) of $FeCl_2$ was dissolved in 20 ml water containing 0.5 ml concd HCl. Except for use of the solution mixture instead of the $FeCl_3$ aqueous solution in the preparation of **3**, the product was obtained by a similar work-up (yield 62%, dark green).

Synopsis. Mono-*O*-trityl derivatives of methyl α- and β-L-rhamnopyranoside have been prepared and the structures established by PMR analysis.

Hockett and Hudson[2)] described the tritylation of methyl α-L-fucopyranoside which contains only secondary hydroxyl groups.

Recently, the preparation of methyl 2-*O*- and 3-*O*-trityl-α-D-fucopyranoside has been reported.[3)] This paper represents on extention of that work and reports the tritylation of methyl α- and β-L-rhamnopyranoside.

Results and Discussion

The reaction of **1** with 2.5 molar equivalents of trityl chloride in pyridine afforded three mono-*O*-trityl ethers: the 3-*O*- (**3a**), 4-*O*- (**4a**) and 2-*O*-trityl derivative (**5a**) in 57, 2.8 and 1.4% yields, respectively, which were converted to the corresponding di-*O*-acetates **3b**, **4b**, and **5b**. The PMR spectra were analyzed with a favorable 1C conformation[4)] confirming the structure. The PMR data for the compounds described are summarized in Tables 1 and 2. Detritylation of **3b**, **4b**, and **5b** with HBr in glacial acetic acid at low temperature gave the corresponding di-*O*-acetates: **6**, **7**, and **8**. Methylation of **3a** and **4a**, followed by detritylation and acetylation gave the *O*-acetyl-di-*O*-methyl derivatives **9b** and **10b**, the structures of which were established by PMR analysis. Gas chromatography-mass (GC-MS) spectra of the intermediary di-*O*-methyl derivatives (**9a** and **10a**) were similar to the

methyl 2,4- and 2,3-di-*O*-methyl-α-D-fucopyranosides,[3] respectively, supporting the proposed structures. The analogous triethylation of **2** gave a 2:1 mixture of two mono-*O*-trityl ethers: 3-*O*- (**11a**) and 4-*O*- (**12a**), in a combined yield of 52%. The structures were established by PMR analysis of the corresponding di-*O*-acetates (**11b** and **12b**) and *O*-acetyl-di-*O*-methyl derivatives (**13b** and **14b**) of **2**. The equatorial OH-3 having a vicinal cis hydroxyl group (OH-2) was most reactive towards tritylation as shown in the selective acetylation of the pyranosides.[4]

Experimental

General Methods. The solution were evaporated under reduced pressure below 40 °C. Optical rotations were measured with a Japan Spectroscopic DIP-SL polarimeter. PMR spectra were recorded on a NEVA NV-14 (60 MHz) or Varian EM-360 (60 MHz) spectrometer, deuteriochloroform being used as the solvent and tetramethylsilane as an internal standard. The multiplicities of the signals have been designated s for a singlet, d for a doublet, dd for a doublet of doublets, qd for a quartet of doublets and m for a multiplet. GC-MS was conducted using the Varian MAT 111 GC/MS system. An electron energy of 80 eV was applied. A glass column (5′×1/8″) packed with 5% NPGS/Chromosorb W was used for the GC. TLC and preparative column chromatography were performed with Wakogel B-10 and C-300 (Wako Junyaku Co., Ltd.), respectively.

Tritylation of Methyl α- (1) and β-L-Rhamnopyranoside (2). Rhamnosides **1** and **2** were prepared from commercial L-rhamnose monohydrate. A mixture of **1** or **2** and trityl chloride in a molar ratio of 1:2.5 dissolved in dry pyridine (×5) was allowed to stand for five days at room temperature. A small amount of water was added to the solution. After concentration, the residue was dissolved in (×5) toluene. Triphenylmethanol was filtered from the toluene solution and the triphenylmethanol-free concentrate subjected to recycling column chromatography five-times on silica gel (50 g) with 5% acetone/benzene. Evaporation of the solvent fractions having R_f values of 0.45, 0.42, and 0.39 on TLC in 15% acetone/benzene gave 973 mg (57.2%) of **3a**, 62 mg (3.7%) of **4a** and 29 mg (1.6%) of **5a**, respectively, as an amorphous solid. $[\alpha]_D^{20}$ in chloroform: **3a**, −50.6° (*c* 2.7); **4a**, −88.4° (*c* 1.0); **5a**, +45.0° (*c* 1.1). Found: **3a**, C, 74.26; H, 6.82%; **4a**, C, 74.37; H, 6.79%; **5a**, C, 73.86; H, 6.73%. Calcd for $C_{26}H_{28}O_5$: C, 74.26; H, 6.71%.

The triphenylmethanol-free concentrate from **2** (1780 mg) was chromatographed on silica gel (50 g) with 5% acetone/benzene three-times. Concentration of the fractions having R_f values of 0.56 and 0.37 on TLC with 12.5% acetone/benzene two developments gave 1522 mg (36.5%) of **11a** and 633 mg (16.7%) of **12a** as an amorphous solid, respectively. $[\alpha]_D^{20}$ in chloroform: **11a**, +55.2° (*c* 0.9); **12a**, +13.2° (*c* 0.7). Found: **11a**, C, 74.26; H, 6.71%; **12a**, C, 73.94; H, 6.80%. Calcd for $C_{26}H_{28}O_5$: C, 74.26; H, 6.71%. Compound **12a** was recrystallized as a monobenzene complex from benzene: $[\alpha]_D^{20}$ +14.7° (*c* 1.2, chloroform), mp 67—68 °C. Found as a benzene complex: C, 77.65; H, 7.07%. Calcd for $C_{32}H_{34}O_5$: C, 77.52; H, 6.87%.

Acetylation of Methyl O-Tritylrhamnopyranoside. Each sample was acetylated under standard conditions for 2 days. After chromatographic purification, the acetates were recrystallized (except **4b** and **5b**) from 80% aqueous acetone in yields of 70—80%. Mp: **3b**, 127—130 °C; **11b**, 188—190 °C; **12b**, 186—188 °C. $[\alpha]_D^{20}$ in chloroform: **3b**, −7.9° (*c* 3.3); **4b**, −86.7° (*c* 0.7); **5b**, +31.6° (*c* 0.5); **11b**, +53.6° (*c* 1.1); **12b**, −42.3° (*c* 1.35). Found: **3b**, C, 71.12; H, 6.61%; **4b**, C, 71.16; H, 6.44%; **5b**, C, 71.11; H, 6.51%; **11b**, C. 71.16; H, 6.46%; **12b**, C, 71.15; H, 6.46%. Calcd for $C_{30}H_{32}O_7$: C, 71.41; H, 6.40%.

Detritylation of Tritylacetyl Derivatives of Methyl Rhamnopyranosides. The detritylation procedure for **3b**, **4b**, and **5b** was almost identical to that for the tritylacetylsucroses.[6] The corresponding di-*O*-acetates were purified on a silica-gel column eluted with 5% acetone/benzene. The yields of detritylation products were 80—85%. Recrystallization (except 7) from 80% aqueous acetone gave the products as needles. Mp: **6**, 116 °C; **8**, 119—120 °C. $[\alpha]_D^{20}$ in chloroform: **6**, −106.5° (*c* 1.7); **8**, −97.4° (*c* 1.0). Found: **6**, C, 75.24; H, 7.12%; **8**, C, 74.91; H, 7.17%. Calcd for $C_{28}H_{32}O_5$: C, 74 97; H, 7.19%.

Methylation of Methyl O-Tritylrhamnopyranosides. Methylation was conducted according to the Purdie method.[7] The products were purified on a silica-gel column eluted with 1% acetone/benzene, after the column was washed with benzene. The yields were approximately 70%. Recrystallization from 80% aqueous acetone gave the products as needles Mp: **3c**, 101—104 °C; **4c**, 138—139 °C; **11c**, 158—159 °C; **12c** 174—178 °C. $[\alpha]_D^{20}$ in chloroform: **3c**, −30.0° (*c* 6.7); **4c**, −96.5° (*c* 0.7); **11c**, +67.3° (*c* 2.7); **12c**, +18.5° (*c* 1.5). Found: **3c**, C, 75.24; H, 7.12%; **4c**, C, 74.81; H, 7.17%; **11c**, C, 74.72; H, 7.17%; **12c**, C, 74.81; H, 7.19%. Calcd for $C_{28}H_{32}O_5$: C, 74.97; H, 7.19%.

Detritylation of Methyl O-Trityl-di-O-methylrhamnopyranoside and Acetylation of the Corresponding Methyl Ethers. Detritylation was conducted by heating the sample with 80% aqueous acetic acid at 90 °C for 1 h. The corresponding methyl ethers were purified on a silica-gel column eluted with 20% acetone/benzene. After acetylation of the methyl ethers, the corresponding acetates were purified on a silica-gel column, the acetates being eluted with 3% acetone/benzene after the column was washed with benzene. The yields of detritylation and acetylation products were greater than 90%. Mp: **13a**, 73.5 °C; **14a**, 63—64 °C; **14b**, 83—84 °C. $[\alpha]_D^{20}$: **9a**, −63.2° (*c* 1.2, methanol); −53.3° (*c* 1.2, chloroform); lit,[8] $[\alpha]_D^{22}$ −68.0° (*c* 4.1, methanol); **9b**, −46.5° (*c* 0.8, chloroform); lit,[8] −51.1° (*c* 0.8, chloroform); **10a**, −22.8° (*c* 1.0, methanol); −18.2° (*c* 1.0, chloroform); lit,[9] $[\alpha]_D$ −14° (*c* 1.94, methanol); **10b**, −32.5° (*c* 1.4, chloroform); **13a**, +88.2° (*c* 1.4, chloroform); **13b**, +89.9° (*c* 1.4, chloroform); **14a**, +68.3° (*c* 3.2, chloroform); **14b**, +89.2° (*c* 2.3, chloroform). Found: **10b**, C, 53.40; H, 7.60%, **13b**, C, 53.17; H, 7.92%, **14b**, C, 53.72; H, 7.49%. Calcd for $C_{11}H_{20}O_6$: C, 53.21; H, 8.12%.

A Synthetic Method for *N*-Benzyloxycarbonyl Hydroxy Amino Acid *t*-Butyl Esters

Hideki KINOSHITA,* Hajime ISHIKAWA, and Hiroshi KOTAKE

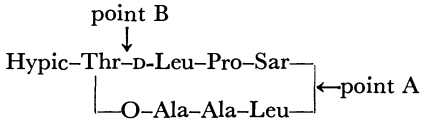
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received September 13, 1978)

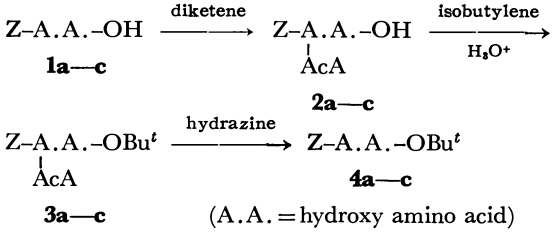
Synopsis. A preparative method for the *N*-benzyloxycarbonyl hydroxy amino acid *t*-butyl esters using the acetoacetyl group as a protecting group for the hydroxyl group of hydroxy amino acids is described. The acetoacetyl group is readily introduced into the hydroxyl group with diketene and effectively deprotected from the O-protected compounds using hydrazine.

Recently, a new method for the synthesis of a peptide lactone as exemplified in the preparation of *N*-(3-hydroxypicolinyl) threonyl-D-leucyl-propylsarcosyl-leucyl-alanyl-alanine threonine lactone, *via* peptide cyclization between sarcosine and leucine (Fig. point A) has been reported.[1] The peptide lactone has also been synthesized by an alternative route, in which peptide cyclization was achieved by peptide bond formation between threonine and D-leucine (Fig. point B).[2] In the latter case it was necessary to prepare *N*-benzyloxycarbonyl threonine *t*-butyl ester (**4a**) as a starting material.

N-benzyloxycarbonyl amino acids are readily esterified by treating the acid with isobutylene in the



presence of an acid catalyst. In the case of *N*-benzyloxycarbonyl hydroxy amino acids, however, this method is accompanied by simultaneous *O*-alkylation. A novel preparation of *t*-butyl ester of the hydroxy amino acids **4a**—**c** *via* protection of the hydroxyl group of **1a**—**c** effectively overcomes this problem. For the O-protection the acetoacetyl (AcA) group proved very effective for this purpose, the synthetic route of which is shown in Scheme 1. A practical example will be given to illustrate the route for the case of threonine derivatives. The reaction of Z–Thr–OH (**1a**) with diketene was conducted in dichloromethane in the presence of an equimolar amount of triethylamine at room temperature to give Z–Thr(AcA)–OH (**2a**) in 96% yield. Esterification of **2a** with isobutylene in the presence of a catalytic amount of concd sulfuric acid gave the *t*-butyl ester **3a** in 65% yield.



Scheme 1.

Similarly, but without isolation of **2b**—**c**, compounds **1b**—**c** were converted into the corresponding esters **3b**—**c**. Attempts to protect the hydroxyl group of **1a**—**c** by acetylation gave unsatisfactory results.

Removal of the protecting group from compound **3a** was achieved by treatment with a twicemolar amount of hydrazine in ethanol for 30 min, the yield of deprotected product **4a** being 94%. Similarly, the deacylated products **4b**—**c** were prepared from compounds **3b**—**c**, the results of which are listed in Table 1.

Table 1. Preparation of *N*-benzyloxycarbonyl hydroxy amino acid *t*-butyl esters **4a**—**c** from *N*-benzyloxycarbonyl hydroxy amino acids **1a**—**c**

Starting material	Yield/%	
	3a—**c**	**4a**—**c**
Z–Thr–OH (**1a**)	65[a]	94
Z–Ser–OH (**1b**)	65[b]	96
Z–Hyp–OH (**1c**)	80[b]	quant.

a) Yield based on **2a**. b) Yields based on the corresponding **1b**—**c**.

Experimental

All melting points are uncorrected. The NMR spectra were recorded on a JEOL/MH-60. The chemical shifts are reported on the δ scale relative to TMS as an internal standard. The IR spectra were measured with a JASCO IRA-1 diffraction grating infrared spectrometer. The optical rotation values were measured with a JASCO DIP-SL polarimeter.

Z-Thr(AcA)-OH (2a). To a suspension of Z–Thr–OH (**1a**) (506 mg, 2 mmol) in dichloromethane (10 ml) was added triethylamine (202 mg, 2 mmol). To the resulting clear solution, diketene (168 mg, 2 mmol) was added. After stirring at room temperature for several hours, the reaction mixture was evaporated to dryness under reduced pressure. The residual oil was dissolved in ethyl acetate and the organic layer washed with 1M HCl (2.2 ml) and water, and dried over Na_2SO_4. After evaporation of the solvent, the desired product was obtained as an oil (96% yield; 646 mg): IR (neat) 3300, 2990, 1710, 1530, 1060 cm^{-1}; NMR ($CDCl_3$) δ 1.30 (d, 3H, J=7 Hz), 2.14 (s, 3H), 3.36 (s, 2H), 4.30—4.65 (dd, 1H, J=9 Hz), 5.07 (s, 2H), 5.27—5.90 (m, 2H), 7.24 (s, 5H), 8.75 (bs, 1H). DCHA salt of **2a**: mp 140—141 °C; $[\alpha]_D^{25}$ +3.0° (0.67, absEtOH); Found: C, 64.80; H, 8.26; N, 5.26%. Calcd for $C_{28}H_{42}N_2O_7$: C, 64.84; H, 8.16; N, 5.40%.

Z-Thr(AcA)-OBu^t (3a). Compound **2a** (337 mg, 1 mmol) was dissolved in dichloromethane (10 ml) and the solution saturated with isobutylene in the presence of concd sulfuric acid (0.05 ml). The reaction mixture was allowed to stand at room temperature for 65 h, evaporated *in vacuo* and the residue dissolved in ethyl acetate. The organic layer was washed with 10% $NaHCO_3$ and water, dried over Na_2SO_4

and filtered. Then it was evaporated to dryness *in vacuo* to give the crude product. The crude oil was subjected to preparative TLC using benzene–ethanol (10: 1 v/v) as solvent to give the desired product **3a** as an oil in 65% yield (254 mg): IR (neat) 3320, 2960, 1720, 1510, 1150, 1060 cm^{-1}; NMR (CCl_4) δ 1.25 (d, 3H, J=7 Hz), 1.37 (s, 9H), 2.09 (s, 3H), 3.22 (s, 2H), 4.10—4.42 (bd, 1H, J=9 Hz), 5.00 (s, 2H), 5.17—5.75 (m, 2H), 7.20 (s, 2H).

*Z–Ser(AcA)–OBu^t (**3b**)*: Oil, IR (neat) 3320, 2960, 1715, 1420, 1050 cm^{-1}; NMR (CCl_4) δ 1.39 (s, 9H), 2.08 (s, 3H), 3.25 (s, 2H), 4.32 (m, 3H), 4.97 (s, 2H), 5.62—5.95 (m, 1H), 7.19 (s, 5H).

*Z–Hyp(AcA)–OBu^t (**3c**)*: Oil, IR (neat) 2960, 1740, 1700, 1050 cm^{-1}; NMR (CCl_4) δ 1.39 (d, 9H, J=8 Hz), 2.12 (s, 2H), 2.30 (m, 2H), 3.29 (s, 2H), 3.65 (m, 2H), 4.18 (t, 1H, J=7 Hz), 5.01 (s, 2H), 5.22 (bs, 1H), 7.20 (s, 5H).

*Z–Thr–OBu^t (**4a**)*. To a solution of **3a** (100 mg, 0.25 mmol) in ethanol (2 ml), was added a solution of hydrazine hydrate (25 mg, 0.50 mmol) in ethanol. The reaction mixture was stirred at room temperature for 30 min, and evaporated to dryness under reduced pressure. The residue was dissolved in ethyl acetate and filtered. After evaporation of the solvent, the residue was subjected to preparative TLC using benzene–ethanol (10: 1 v/v) as solvent to give the desired product **4a** (74 mg, 94%), which was recrystallized from benzene–hexane: mp 66—67 °C; $[\alpha]_D^{26}$ −20.6° (1.07, absEtOH); IR (KBr) 3400, 3180, 1738, 1705, 1220, 1090, 1065 cm^{-1}; NMR (CCl_4) δ 1.15 (d, 3H, J=7 Hz), 1.43 (s, 9H), 2.70 (d, 1H, J=4 Hz), 3.29—4.23 (m, 2H), 5.03 (s, 2H), 5.64 (bd, 1H, J=9 Hz), 7.26 (s, 5H); Found: C, 61.90; H, 7.32; N, 4.68%. Calcd for $C_{16}H_{23}NO_5$: C, 62.12; H, 7.49; N, 4.53%.

*Z–Ser–OBu^t (**4b**)*: Mp 93—95 °C; $[\alpha]_D^{26}$ −16.5° (1.03, absEtOH); IR (KBr) 3400, 3260, 1710, 1704, 1235, 1045 cm^{-1}; NMR (CCl_4) δ 1.46 (s, 9H), 2.60 (s, 1H), 3.83 (d, 2H, J=4 Hz), 4.20 (m, 1H), 5.03 (s, 2H), 5.70 (d, 1H, J=8 Hz), 7.86 (s, 5H); Found: C, 61.32; H, 7.04; N, 4.58%. Calcd for $C_{15}H_{21}NO_5$: C, 61.00; H, 7.17; N, 4.74%.

*Z–Hyp–OBu^t (**4c**)*: Mp 62—63 °C; $[\alpha]_D^{27}$ −68.6° (1.09, absEtOH); IR (KBr) 3440, 1730, 1665, 1370, 1040 cm^{-1}; NMR (CCl_4) δ 1.31 (d, 9H, J=7 Hz), 2.20 (m, 2H), 3.39 (m, 2H), 3.73—4.38 (m, 3H), 4.89 (s, 2H), 7.02 (s, 5H); Found: C, 63.66; H, 6.96; N, 4.31%. Calcd for $C_{17}H_{23}NO_5$: C, 63.53; H, 7.21; N, 4.36%.

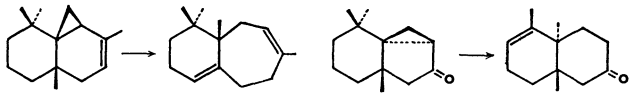
(Received November 13, 1978)

Synopsis. 4,6,10,10-Tetramethyltricyclo[4.4.0.0^{1,3}]-undec-4-ene-5-carboxylic acid has been converted to a tricyclic γ-butyrolactone by perchloric acid catalyzed isomerization. Acetalization of the ketocarboxylic acid afforded an acetal derivative of γ-butyrolactone.

The acid-catalyzed rearrangement of cyclopropylcarbonyl or cyclopropylcarbinyl systems have been extensively investigated. Most of these reactions have known to undergo acid-catalyzed cleavage of the cyclopropane ring and migration of the angular methyl group and/or one of a *gem*-dimethyl groups. For example, under acid conditions, *cis*-thujopsene (**1**) is converted by ring enlargement and angular methyl group migration into a diene (**2**).[1] The acid-catalyzed isomerization of 6,10,10-trimethyl-4-oxotricyclo-[4.4.0.0^{1,3}]decane (**3**) caused ring enlargement and *gem*-dimethyl group migration giving the product **4**.[2]

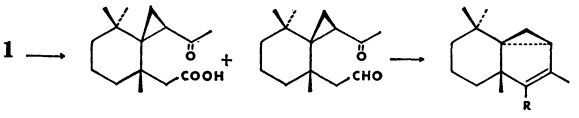


1 **2** **3** **4**

Marshall and Ellison[3] reported that cyclopropylmethanols were subjected to solvolysis in aqueous acid to give γ-butyrolactones fused with cycloheptene and cyclohexene rings. Interest in these reactions prompted the authors to investigate the acid-catalyzed isomerization of 4,6,10,10-tetramethyltricyclo[4.4.0.0^{1,3}]undec-4-ene-5-carboxylic acid (**8**) and its related compound (**5**). It was found that compounds **5** and **8** were converted into the γ-butylolactones (**9** and **11**) *via* cleavage of the cyclopropane ring, and that migration of the angular methyl or *gem*-dimethyl group of **5** and **8** did not occur.

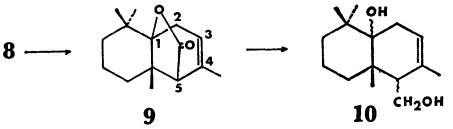
The starting materials (**5** and **8**) were synthesized from *cis*-thujopsene (**1**) as follows. Ozonolysis of *cis*-thujopsene (**1**) in acetic acid gave **6** (47.5%) and **5** (26.6%). The IR and NMR spectra of **6** were identical with those of the sensitized photo-oxidation products of *cis*-thujopsene (**1**).[4] Compound **5** was identical with the spectra of the ozonolysis products of *cis*-thujopsene (**1**) obtained in methanol and ethyl acetate by Norin.[5] One of the ozonolysis products (**6**) was converted into a carboxylic acid (**8**) *via* the aldehyde (**7**)[4,6] as reported by Ohloff *et al.*[6]

The reaction of tricyclic carboxylic acid (**8**) with 70% perchloric acid in benzene gave a γ-butyrolactone (**9**) in 65.5% yield. The structure of **9** was deduced from the spectral data together with the following evidence. The IR absorption of **9** at 1760 cm^{-1} shows the presence of γ-butyrolactone. The presence of a methyl group



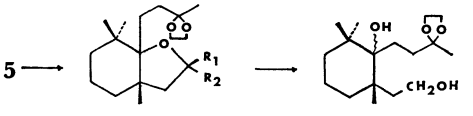
5 **6** **7**: R=CHO **8**: R=COOH

on the olefinic carbon, a C_5–H proton, and a vinyl proton are indicated by the NMR signals at δ 1.80, 2.35, and 5.45 ppm, respectively. Reduction of **9** with lithium aluminium hydride in ether gave an alcohol (**10**). The IR absorptions of **10** at 3260 and 3100 cm^{-1} show the presence of a hydroxyl group. The presence of a methyl group on the olefinic carbon, a vinyl proton, and a hydroxymethyl group are indicated by the NMR signals at δ 1.75, 5.41, and 2.78 ppm (d, J=3.0 Hz), respectively.



9 **10**

The other ozonolysis product (**5**) was refluxed for 10 h with ethylene glycol and *p*-toluenesulfonic acid in benzene and the reaction mixture chromatographed to give compound **11**. The structure of **11** was deduced from the spectral data as well as the following evidence. The IR absorption of **11** at 1755 cm^{-1} shows the presence of an γ-butyrolactone ring. Reduction of **11** with lithium aluminium hydride in ether at room temperature gave the lactol (**12**). The lithium aluminium hydride reduction of **11** in ether at boiling point however for 2 h gave the diol (**13**).



11: R_1=R_2=O **12**: R_1=H, R_2=OH **13**

Experimental

The melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. The NMR spectra were recorded on a JEOL PMX-60 spectrometer at 60 MHz, using Me_4Si as an internal standard. The IR spectra were determined on a Shimadzu IR-400 spectrometer. Elemental analyses were performed by a Hitachi 026 CHN analyzer. The analytical GLC was performed on a Shimadzu GC-4B apparatus with a 3 m stainless steel column packed with 3% SE-30, at 10 °C/min 150—250 °C.

Ozonolysis of cis-*Thujopsene (1).* A stream of ozone at 20—35 °C was passed through a stirred solution of **1** (20.4 g, 0.1 mol) in acetic acid (200 ml), until all the starting material had disappeared. The reaction mixture was subsequently treated with zinc dust (30 g) for 1 h at 60—70 °C to reduce the ozonide, filtered, and concentrated. The residue was dissolved in ether (500 ml) and the ether solution washed with 5% aqueous NaOH (50 ml×3), water, dried (Na_2SO_4), and evaporated to give an oily residue (16.2 g). The product was purified by column chromatography using silica gel. Elution with benzene gave **6** (11.2 g) as a colorless liquid. **6**; NMR ($CDCl_3$) δ 0.72 (s, 3, CH_3), 1.13 (s, 3, CH_3), 1.30 (s, 3, CH_3), 2.37 (s, 3, CH_3), 3.00 (dd, 1, J=10.0 and 3.5 Hz), and 9.68 (t, 1, J=3.0 Hz). The combined water layer was acidified with 10% HCl, and extracted with ether. The ether solution was washed with water, dried (Na_2SO_4), and evaporated to give a solid residue (7.9 g). A pure sample of **5** was obtained by recrystallization from hexane. **5**; mp 165—168 °C (lit,[6] mp 166—168 °C).

Cyclization of 6. To a stirred solution of **6** (10.5 g, 40 mmol) in ethanol (200 ml), maintained at 15 °C was added powdered KOH (50 mg, 10 mmol). The solution was stirred for 2 h at room temperature, and then the solvent evaporated under reduced pressure and the residue diluted with water and extracted with ether. The ether solution was washed with water, dried (Na_2SO_4), and evaporated to give an oily residue (9.8 g). The product was separated by column chromatography using silica gel. Elution with benzene gave colorless crystals (**7**) (5.2 g). A pure sample of **7** was obtained by recrystallization from hexane. **7**; mp 73.5—75 °C (lit,[6] mp 73—74 °C).

Oxidation of 7. Compound **7** (2.16 g, 10 mmol) was oxidized in acetone (25 ml) with Jones reagent (8 mole ratio, 2.8 ml) at room temperature for 1 h. The mixture was evaporated and ice-cooled water poured into the resulting residue, which was then extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated to give crude crystals (1.98 g). Recrystallization from hexane gave pure **8**. **8**; mp 148—149 °C (lit,[6] mp 147—149 °C).

Lactonization of 8. A mixture of **8** (1.16 g, 5 mmol) and perchloric acid (70%, 0.5 ml) in benzene was refluxed for 5 min. The reaction mixture was washed with water, dried (Na_2SO_4), and evaporated to give an oily residue (1.1 g). The product was separated by column chromatography using silica gel. Elution with benzene gave colorless crystals **9** (0.81 g). A pure sample of **9** was obtained by recrystallization from hexane. **9**; mp 122—125 °C; IR (KBr) ν 1760 cm^{-1} (γ-butyrolactone); NMR ($CDCl_3$) δ 1.03 (s, 6, $2CH_3$), 1.10 (s, 3, CH_3), 1.80 (d, 3, CH_3, J=3.0 Hz), 2.35 (s, 1, C_5–H), 2.48 (m, 2, C_2–H), and 5.45 (m, 1). Found: C, 76.97; H, 9.35%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

Reduction of 9. A mixture of **9** (117 mg, 0.5 mmol) and $LiAlH_4$ (46 mg, 1.2 mmol) in ether was refluxed for 3 h. To the stirred reaction mixture was added water (2 ml), and extracted with ether. The ether solution was washed with water, dried (Na_2SO_4) and evaporated to give a solid residue (116.5 mg). A pure sample of **10** was obtained by recrystallization from hexane. **10**; mp 140—141 °C; IR (KBr) ν 3250 and 3100 cm^{-1}; NMR ($CDCl_3$) δ 0.95 (s, 3, CH_3), 1.13 (s, 6, $2CH_3$), 1.75 (broad s, 3, CH_3), 2.78 (d, 2, $-CH_2OH$, J= 3.0 Hz), and 5.41 (m, 1).

Lactonization of 5. A benzene solution of **5** (2.52 g, 10 mmol), ethylene glycol (740 mg, 12 mmol), and *p*-TsOH (19 mg, 0.1 mmol) was refluxed for 10 h. The reaction mixture was washed with water, dried (Na_2SO_4), and evaporated to give an oily residue (3.17 g). The product was separated by column chromatography using silica gel. Elution with benzene gave colorless crystals (**11**) (1.58 g). A pure sample of **11** was obtained by recrystallization from hexane. **11**; mp 65—67 °C; IR (KBr) ν 1755 cm^{-1} (γ-butyrolactone); NMR ($CDCl_3$) δ 1.10 (s, 6, $2CH_3$), 1.25 (s, 3, CH_3), 1.32 (s, 3, CH_3), and 3.95 (s, 4, $-CH_2CH_2-$). Found: C, 69.02; H, 9.56%. Calcd for $C_{17}H_{28}O_4$: C, 68.89; H, 9.52%.

Reduction of 11 at Room Temperature. To a stirred solution of **11** (296 mg, 1 mmol) in ether (3 ml), maintained at 10 °C, $LiAlH_4$ (45.6 mg, 1.2 mmol) was added and the solution stirred for 2 h at room temperature. Water (1 ml) was added to the stirred solution, and the aqueous solution extracted with ether. The ether solution was washed with water, dried (Na_2SO_4), and evaporated to give an oily residue (294.2 mg). **12**; IR (neat) ν 3400 cm^{-1} (–OH); NMR ($CDCl_3$) δ 0.98 (s, 6, $2CH_3$), 1.10 (s, 3, CH_3), 1.33 (s, 3, CH_3), 3.97 (s, 4, $-CH_2CH_2-$), and 5.33 (m, 1).

Reduction of 11 at Boiling Point. A mixture of **11** (296 mg, 1 mmol) and $LiAlH_4$ (91 mg, 2.4 mmol) in ether (3 ml) was refluxed for 2 h. Water (2 ml) was added to the stirred solution and the aqueous solution extracted with ether. The ether solution was washed with water, dried (Na_2SO_4) and evaporated to give an oily residue (116.5 mg). **13**; IR (neat) ν 3395 cm^{-1} (–OH); NMR ($CDCl_3$) δ 0.95 (s, 3, CH_3), 1.07 (s, 6, $2CH_3$), 1.32 (s, 3, CH_3), 2.90 (broad s, 2, –OH), 3.68 (t, 2, $-CH_2OH$, J=6.0 Hz), and 3.97 (s, 4, $-CH_2CH_2-$).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (10), 3115—3116 (1979)

Notiz über die Säurekatalysierte Umwandlung von 7a-Methyl-5,6,7,7a-tetrahydroindan-1,5-dion in 1-Methylbrexan-4,9-dion

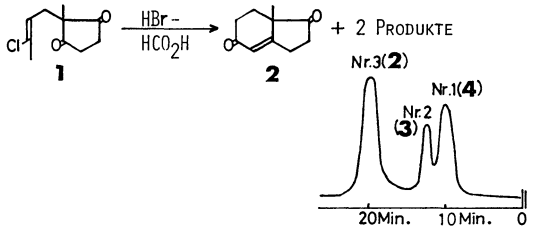
Makoto KOBAYASHI, Takashi MINAMI, und Takeshi MATSUMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Eingegangen November 20, 1978)

Synopsis. Beim Erhitzen in HCO_2H mit Mineralsäure wurde 7a-Methyl-5, 6, 7, 7a-tetrahydroindan-1, 5-dion sauer katalysiert in 1-Methylbrexan-4,9-dion umgewandelt. Ein Zwischenprodukt, 7a-Methylhexahydro-2-inden-1,5-dion konnte gaschromatographisch abgetrennt werden.

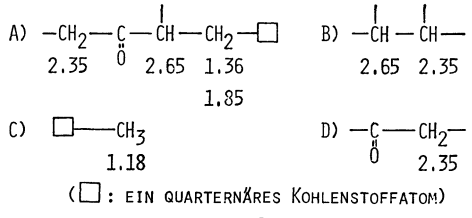
Wir haben schon berichtet, dass α-(3-Chlor-2-butenyl)ketone wie **1** unter Rückfluss in HCO_2H in Anwesenheit von Mineralsäure 2-Cyclohexenon-Derivate liefern.[1] Unter diesen Bedingungen der modifizierten Wichterle-Reaktion wurde aus **1** 7a-Methyl-5,6,7,7a-tetrahydroindan-1,5-dion (**2**) in mässiger Ausbeute erhalten, wobei 1-Methylbrexan-4,9-dion (**4**) (1-Methyltricyclo[4.3.0.0^{3,7}]nonan-4,9-dion) als Nebenprodukt entstand, dessen Konstitution ohne Diskussion bereits erwähnt wurde.[1b] Aus der weiteren Untersuchung zeigte sich, dass **4** nicht direkt aus **1**, sondern aus **2** durch die sauer katalysierte Umwandlung entsteht. Hier beschreiben wir eingehend die spektroskopisch aufgeklärte Konsitution von **4** sowie einem Zwischenprodukt, das gaschromatographisch in geringer Ausbeute isoliert wurde.



GASCHROMATOGRAMM: QF-1, 180 °C

Abb.-1

Im analytischen Gaschromatogramm des durch die Behandlung von **1** mit HBr–HCO_2H erhaltenen Rohproduktes erschienen 3 Peaks (Abb. 1). Die GC-MS-Messung zeigte, dass alle diese Substanzen das selbe Molekulargewicht (M^+ 164) besitzen. Es wurde durch Vergleich mit der authentischen Probe festgestellt, dass der dritte Peak mit der längsten Retentionszeit dem erwünscheten Produkt **2** entspricht. Durch Säulenchromatographie an SiO_2 wurde das Rohprodukt vorsichtig abgetrennt und die dem Peak Nr. 1 entsprechende Substanz **4** wurde in 10%-iger Ausbeute rein isoliert. Die Analyse zeigte eine Molekularformel $C_{10}H_{12}O_2$. Im IR-Spektrum erscheint eine charakteristische Band für gesättigtes 5-gliedriges Keton (1740 cm^{-1}). Ausserdem war kein besonderes Band für C=C-Doppelbindung, Hydroxy-, Ester-, sowie Ethergruppen zu beobachten. Dies zeigt, dass zwei Sauerstoffatome an zwei Cyclopentanringen vorliegen. Im NMR-Spektrum waren erkennbar: ein Singulett für eine anguläre Methylgruppe bei 1.18 ppm, ein Dublett (1H) mit J=15 Hz bei 1.36 ppm, ein doppeltes Dublett (1H) mit J=6 und 15 Hz bei 1.85 ppm, ein breites Singulett (5H) bei 2.35 ppm und ein Multiplett (2H) bei 2.65 ppm. Durch Einstrahlen bei 2.65 ppm geht das doppeltes Dublett bei 1.85 ppm in ein Dublett mit J=15 Hz über. Diese Daten weisen auf das Vorliegen der Teilkonstitutionen A, B, C, und D hin (Abb. 2).



(□: EIN QUARTERNÄRES KOHLENSTOFFATOM)

Abb.-2

Wie schon erwähnt, enthält diese Substanz 10 Kohlenstoffatome. Da in den Teilkonstitutionen A—D insgesamt 11 Kohlenstoffatome vorliegen, so müssen die Zeichen □ in A und C das gleiche Kohlenstoffatom darstellen. Daraus folgt, dass die Verbindung **4** ein tricyclisches Molekül mit zwei Cyclopentanringen ist. Aufgrund dieser spektroskopischen Befunde und der mechanistischen Überlegung sowie Annahme, dass **4** ein Folgeprodukt von **2** sein sollte, folgt für diese

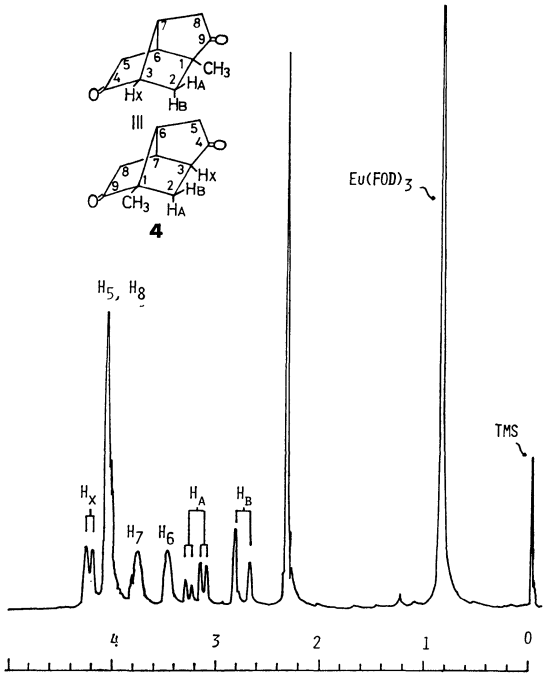


Abb.-3 Ein mit Eu(Fod)$_3$[15 mol %] verschobenes NMR-Spektrum von **4**.

Substanz die Konstitution eines 1-Methylbrexan-4,9-dions (**4**).[2] Die nicht beobachtete Kopplungskonstante J_{BX} wird dadurch erklärt, dass das H_B-Atom am C-2 zum H_x-Atom am C-3 in einem Winkel ≈90° steht. Das Molekülmodell zeigte, dass die beide Winkel $\angle H_{8\alpha}C_8H_{8\beta}$ und $\angle H_{5\alpha}C_5H_{5\beta}$ durch die Carbonylgruppen halbiert werden. Im Einklang damit bleiben diese Methylenprotonen im mit Eu(Fod)$_3$(Tris(heptafluorbutanoylpivaloylmethan)europium) verschobene NMR-Spektrum auch fast äquivalent (Abb. 3). In der demethylierten analogen Verbindung von **4** sollten die Protonen H_A und H_B bzw. H_6 und H_7 äquivalent sein.[3] Bei **4** ist die Symmetrie durch die Methylgruppe am C-1 erniedrigt. Wegen deren C–CH_3 Bindungsanisotropie sind die H_B und H_6-Protonen zu höherem Feld verschoben als H_A- und H_7-Protonen.

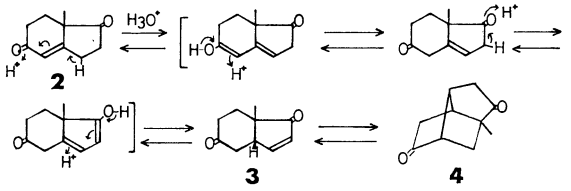

Abb.-4

Ein denkbarer Bildungsmechanismus von **4** ist in Abb.-4 wiedergegeben.[4] **1** wurde zuerst mit HBr–HCO_2H zum **2** cyclisiert, das unter der Umwandlung der Doppelbindung zum **3** isomerisiert. **3** liess sich durch sauer katalysierte intramolekulare Michael-Reaktion weiter in **4** umwandeln. Das oben angenommene Reaktionsbild konnte in der Tat bestätigt werden. Die Behandlung von **2** in HCO_2H mit HBr ergab auch **4** in einer Ausbeute von 6% neben polymeren Produkten. Das Gaschromatogramm war identisch mit dem in Abb. 1 gezeigten. Es wurde dann versucht, die dem Peak Nr. 2 entsprechende Substanz **3** abzutrennen. Diese konnte mit Hilfe der präparativen Gaschromatographie isoliert werden. Das NMR-Spektrum dieser Verbindung zeigt ein Singulett für eine anguläre Methylgruppe bei 1.24 ppm, ein Singulett (1H) mit Feinstruktur bei 2.99 ppm und zwei doppelte Dubletts bei 6.25 ppm (1H, J=1.5, 6 Hz) bzw. 7.52 (1H, J=2, 6 Hz). Durch Einstrahlen bei 7.52 ppm geht das Signal bei 6.25 ppm in ein Dublett mit J=1.5 Hz über. Demgemäss wurden die zwei doppelten Dubletts dem AB-Teil eines ABX-Systems zugeordnet. Entsprechend erscheint im IR-Spektrum die Absorption der α,β-ungesättigten Carbonylgruppe bei 1710 cm^{-1}. Der Substanz könnte somit die Konstitution von *cis*-7a-Methylhexahydro-2-inden-1,5-dion (**3**) zugewiesen werden, die auch durch den Basis-Peak des MS-Spektrums bei *m/e* 55 (O^+≡C–CH=CH_2) bekräftigt wird.

New Synthesis of Alkyl Polysulfides by Treatment of Thiols, Disulfides and Thionitrites with Anhydrous Copper(II) Chloride

Yong Hae KIM, Kōichi SHINHAMA, and Shigeru OAE*

Department of Chemistry, University of Tsukuba, Niiharigun, Ibaraki 300-31

(Received January 16, 1979)

Synopsis. Reaction of several divalent organic sulfur compounds with copper(II) chloride in acetonitrile gave the corresponding disulfides or other polysulfides in good yields under mild conditions.

In the course of our studies on the synthetic applications of thionitrites, the initial intermediates in the oxidation of either thiols or disulfides, we found that *t*-alkyl thionitrites were readily converted to the trisulfides upon treatment with anhydrous copper(II) chloride. Various other divalent organic sulfur compounds such as *t*-BuSH and di-*t*-butyl disulfide have now been found to react similarly with anhydrous copper(II) chloride under mild conditions to give either the corresponding disulfides or other polysulfides in good yields, as shown in Table 1. This paper deals with these reactions.

A few dialkyl trisulfides or tetrasulfides have been prepared either by the reaction of the corresponding disulfides[1] or thiols[2] with sulfur, by treatment of alkanesulfenyl chlorides with hydrogen sulfide,[3] or by the reaction of sulfur monochloride with alkanethiols.[4] Our new method which involves only mixing anhydrous copper(II) chloride with divalent organic sulfur compounds is simple and especially useful to prepare di-*t*-alkyl trisulfides or di-*t*-alkyl tetrasulfides. This method is also quite useful to prepare various disulfides from corresponding thiols upon slight modifications.

Di-*t*-butyl disulfide was added to a stirred mixture of acetonitrile and anhydrous copper(II) chloride at room temperature. After 5 h under nitrogen, the starting material disappeared completely and di-*t*-butyl trisulfide and di-*t*-butyl tetrasulfide were obtained (Run 1). The trisulfide and the tetrasulfide were separated by distillation, and then identified by elemental analysis. The main product was the tetrasulfide (63%).

Meanwhile, treatment of anhydrous copper(II) chloride with *t*-BuSH or *t*-BuSNO in acetonitrile was found to afford di-*t*-butyl trisulfide as the main product (Runs 2 and 5).

When di-*t*-butyl disulfide was treated with anhydrous iron(III) chloride in ether, the corresponding tri- and tetrasulfides were also obtained, though the reaction was slow and a small amount of the starting material always remained even after a prolonged reaction time (Run 8).

Treatment of *s*-BuSH with anhydrous copper(II) chloride at room temperature afforded di-*s*-butyl disulfide in a good yield without forming any di-*s*-butyl trisulfide or di-*s*-butyl tetrasulfide (Run 11). However, the same treatment of *s*-BuSH or di-*s*-butyl disulfide at a high reaction temperature (under reflux) gave di-*s*-butyl trisulfide in 66—79% yields (Runs 12 and 13).

Primary and aromatic divalent sulfur compounds did not give the corresponding trisulfides and tetrasulfides even after a prolonged reaction time, but gave the corresponding disulfides selectively only in several

minutes (Runs 15, 16, 17, 18, and 20). It is interesting to note that the treatment of *t*-BuSH with anhydrous copper(I) chloride in the presence of air at the room temperature also gave selectively di-*t*-butyl disulfide, no formation of the trisulfide or the tetrasulfide being confirmed (Run 9). Oxidation of thiols with CuCl was found to require atomospheric oxygen, while oxidation with $CuCl_2$ proceeded under nitrogen. Thus, the reaction is quite useful to prepare symmetrical polysulfides.

These experimental observations seem to suggest that the C–S bond in *t*-alkyl compounds is readily cleaved to form the relatively stable *t*-alkyl cation upon treatment with copper(II) ion.

Thus the following mechanism may be conceivable for the reaction with di-*t*-alkyl disulfide. Other *t*-alkyl sulfur compounds would behave similarly. Copper(II) chloride would be reduced to Cu^0 or copper(I) chloride.

$$\underset{\mathbf{1}}{R\text{–}S\text{–}S\text{–}R} + Cu^{II} \longrightarrow \underset{\mathbf{2}}{R\text{–}S\text{–}S\text{–}R} \longrightarrow R^+ + \underset{\mathbf{3}}{Cu^{II}\text{–}SSR}$$
$$\qquad\qquad\qquad\qquad\quad \downarrow Cu^{II}$$

$$\mathbf{3} + \mathbf{1} \longrightarrow R\text{–}S\text{–}S\text{–}S\text{–}R + \underset{\mathbf{5}}{RS\text{–}Cu^{II}}$$
$$\qquad\qquad\quad \mathbf{4}$$

$$\mathbf{5} + \mathbf{1} \longrightarrow R^+ + \mathbf{4} + [Cu^0] \xrightarrow{Cu^{II}} [Cu^I]$$
$$\qquad\qquad\qquad\qquad\quad \mathbf{6} \qquad\quad \mathbf{7}$$

$$\mathbf{5} + \mathbf{4} \longrightarrow R^+ + R\text{–}S\text{–}S\text{–}S\text{–}S\text{–}R + \mathbf{6} \xrightarrow{Cu^{II}} \mathbf{7}$$

The gas evolved during the reaction of di-*t*-butyl disulfide with anhydrous copper(II) chloride was analyzed through mass spectroscopy which gave a strong peak of 56 (C_4H_8). Thus *t*-butyl cation was found to be converted to the olefin. Meanwhile, the lack of C–S bond cleavage in primary and aromatic sulfur compounds and the low reactivities of the secondary sulfur compounds are also in keeping with the relative stabilities of the respective carbonium ions.

Experimental

All the melting points and boiling points were uncorrected. Elemental analysis of sulfur was carried out by Sagami Chemical Research Center and the analyses of other elements were carried out by the analytical labolatory in our university. Analytical determinations by GLC were performed on a Hitachi 163 gas chromatograph fitted with the following column (3 mm o.d. ×3 m): 10% SE-30 on Chromosorb W. ^{1}H-NMR spectra were taken at 60 MHz on a Hitachi R-24 A apparatus. IR spectra were recorded with a Hitachi 215 spectrometer. Mass spectra were recorded with a Hitachi RMU-6M spectrometer. Thionitrites were prepared from corresponding thiols by the method reported by us.[5] The followings are typical runs.

Reaction of Di-t-butyl Disulfide and Anhydrous Copper(II) Chloride. Di-*t*-butyl disulfide 3.56 g (20 mmol) was added to a stirred mixture of anhydrous copper(II) chloride 5.38 g (40 mmol) in 50 ml of anhydrous acetonitrile. The mixture was stirred at room temperature for 5 h. A saturated NaCl aq solution was added to the dark brown mixture and extracted with ether. The ethereal extract was dried ($MgSO_4$), concentrated, and distilled, giving pure trisulfide and tetrasulfide. The amounts of the products were estimated by GLC: Di-*t*-butyl trisulfide 0.69 g (25%), di-*t*-butyl tetrasulfide 1.52 g (63%). Di-*t*-butyl trisulfide; mp 14—15 °C (lit,[6] 16.63 °C). Di-*t*-butyl tetrasulfide; bp (bath temperature), 80—90 °C/2 mmHg (lit,[6] 70 °C/2 mmHg).

t-Butyl thionitrite and *t*-BuSH were found to react similarly, and the results are shown in Table 1 while the physico-chemical properties are listed in Tables 2 and 3.

Reaction of Di-s-butyl Disulfide with Anhydrous Copper(II) Chloride. Di-*s*-butyl disulfide 1.16 g (6.5 mmol) and anhydrous copper(II) chloride 2.62 g (19.5 mmol) was refluxed in anhydrous acetonitrile for 6 h under nitrogen. The saturated NaCl aq solution was added into the mixture which was extracted with ether. The amount of di-*s*-butyl trisulfide was calibrated by GLC: 0.694 g (79%). The ethereal extract was dried ($MgSO_4$), concentrated and distilled giving 0.623 g of trisulfide: bp (bath temperature) 100—110 °C/2 mmHg (lit,[3] bp 79—80 °C/0.4 mmHg).

Primary and secondary thiols were found to react similarly and the results, physical properties and analytical data on the resulted products are listed in Tables 1, 2, and 3 respectively.

Enantioselective Alkylation Using Optically Active Phase Transfer Catalyst

Kazuhiko SAIGO,* Hiroshi KODA, and Hiroyuki NOHIRA

Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-ohkubo, Urawa, Saitama 338

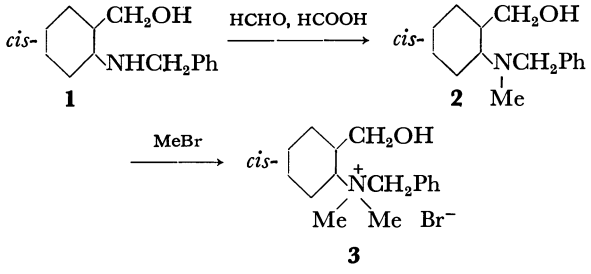
(Received February 1, 1979)

Synopsis. Synthesis of optically active benzyl[*cis*-2-(hydroxymethyl)cyclohexyl]dimethylammonium bromide (**3**) and its application to asymmetric synthesis were studied. It was found that **3** was as effective as (−)-*N*-benzyl-*N*-methylephedrinium bromide in the enantioselective alkylation of active methylene compounds when it was employed as a chiral phase transfer catalyst.

As part of ongoing program of study on the use of optically active benzyl[*cis*-2-(hydroxymethyl)cyclohexyl]amine (**1**), prepared by the lithium aluminium hydride reduction[1] of optically active *cis*-2-benzamidocyclohexanecarboxylic acid,[2] application of **1** to the asymmetric synthesis and induction was initiated. Among many papers about asymmetric synthesis and induction, there is only one report concerning enantioselective alkylation of active methylene compounds using a chiral phase transfer catalyst.[3] This prompted us to prepare a new chiral catalyst from **1** and to employ it in the enantioselective alkylation.

Both enantiomers, (+)- and (−)-**1**, were prepared in 30—40% overall yields and in high optical purities from commercially available *cis*-1,2-cyclohexanedicarboxylic anhydride *via* six steps as reported.[1,2]

Treatment of **1** with aq formaldehyde and formic acid under gentle refluxing gave *N*-methylated product, namely, benzyl[*cis*-2-(hydroxymethyl)cyclohexyl]methylamine (**2**) in a good yield. By the quaternization of **2** with methyl bromide, benzyl[*cis*-2-(hydroxymethyl)-cyclohexyl]dimethylammonium bromide (**3**) was obtained in a moderate yield.

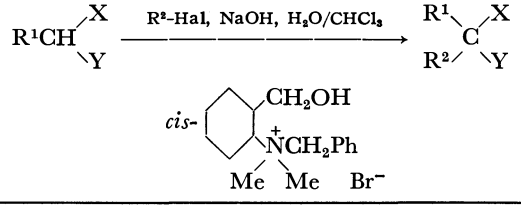


These reaction conditions are completely free from epimerization and/or racemization. Therefore, (+)- and (−)-**3** are considered to be optically pure when optically pure **1** is used as a starting material.

In the next stage, the enantioselective alkylation of active methylene compounds (**4**) was carried out using (+)- or (−)-**3** as an asymmetric phase transfer catalyst.

The solvent effect on the alkylation of ethyl 2-oxocyclohexanecarboxylate (**4a**) with allyl bromide was studied in ether, benzene, dichloromethane, and chloroform, and chloroform was found to be a suitable solvent. Both chemical yield and optical purity of ethyl 1-allyl-2-oxocyclohexanecarboxylate (**5a**) were fairly improved when the alkylation was carried out in

TABLE 1. ENANTIOSELECTIVE ALKYLATION OF ACTIVE METHYLENE COMPOUNDS



Run	Active Methylene Compound	Halide	**3**/**4** Ratio mol%	Solvent	Temp	Product	Yield/%	$[\alpha]_D$/°
1	**4a**	CH_2=$CHCH_2Br$	3	Et_2O	r.t.	**5a**	0	—

3	**4a**	CH_2=$CHCH_2Br$	3	CH_2Cl_2	r.t.	**5a**	54	−0.9
4	**4a**	CH_2=$CHCH_2Br$	3	$CHCl_3$	r.t.	**5a**	60	−3.3
5	**4a**	CH_2=$CHCH_2Br$	3	$CHCl_3$	0 °C	**5a**	74	−7.0
6	**4a**	CH_2=$CHCH_2Br$	5	$CHCl_3$	0 °C	**5a**	84	−7.4
7[a]	**4a**	CH_2=$CHCH_2Br$	5	$CHCl_3$	0 °C	**5a**	79	+7.7
8[a]	**4a**	CH_5CH_2Br	5	$CHCl_3$	0 °C	**5a′**	71	+4.7
9[a]	**4b**	CH_2=$CHCH_2Br$	5	$CHCl_3$	0 °C	**5b**	68	+18.2
10[b]	**4c**	CH_3I	5	$CHCl_3$	0 °C	**5c**	65	+1.7
11[b]	**4d**	CH_2=$CHCH_2Br$	5	$CHCl_3$	0 °C	**5d**	86	+0.4

a) (+)-Ammonium bromide, (+)-**3**, was used, and in the other runs (−)-**3** was employed. b) 5% Aq NaOH (40 ml) was used. Runs (5—11) were carried out twice, and comparing their specific rotations lower ones are listed.

chloroform at 0 °C. No reaction proceeded when allyl chloride was employed as an alkylating agent.

Under optimum conditions, the enantioselective alkylation of ethyl 2-oxocyclohexanecarboxylate (**4a**), 2-acetylcyclohexanone (**4b**), ethyl 2-oxocyclopentanecarboxylate (**4c**), and ethyl 2-cyano-2-phenylacetate (**4d**) was carried out giving ethyl 1-allyl-2-oxocyclohexanecarboxylate (**5a**), ethyl 1-benzyl-2-oxocyclohexanecarboxylate (**5a'**), 2-acetyl-2-allylcyclohexanone (**5b**), ethyl 1-methyl-2-oxocyclopentanecarboxylate (**5c**),[4] and ethyl 2-cyano-2-phenyl-4-pentenoate (**5d**).[5] The results are summarized in Table 1.

Fiaud reported that specific rotations of **4a** and **4b** were −8.2° and −23.5°, respectively, when (−)-*N*-benzyl-*N*-methylephedrinium bromide (**6**) was used as a catalyst.[3] Thus, **3** is considered to be as effective as **6** in the enantioselective alkylation of active methylene compounds. In contrast to that only one enantiomer, namely, (−)-**6** is usually available because it is derived from a natural product, both enantiomers of **3** are conveniently prepared, and alkylated products having the desired configuration are easily given choosing the suitable enantiomer. In this respect, **3** is considered to be advantageous as a chiral phase transfer catalyst.

Experimental

The melting points were determined on a Laboratory Devices Mel-Temp apparatus and are uncorrected. The boiling points are also uncorrected. The NMR spectra were recorded on a Varian A-60 spectrometer at 60 MHz using Me_4Si as an internal standard. The IR and MS spectra were determined on a JASCO IR-2A spectrometer and on a JEOL-01SG instrument, respectively. The values of specific rotation were obtained on JASCO DIP-181 digital polarimeter. Optically active **1** was prepared as reported.[1,2] (+)-Form: mp 68—69 °C, $[\alpha]_D^{32}$ +40.4° (*c* 1.00, dry Et_2O). (−)-Form: mp 68—69 °C, $[\alpha]_D^{24}$ −40.6° (*c* 1.00, dry Et_2O).

Benzyl[cis-*2-(hydroxymethyl)cyclohexyl*]*methylamine* (**2**). To (+)-**1** (5.48 g, 25 mmol) was added under cooling with an ice bath 35% aq formaldehyde (2.15 g, 25 mmol) followed by dropwise addition of formic acid (4.14 g, 90 mmol). Then, the mixture was allowed to stand at room temperature for 15 min, and was gently refluxed for 8 h. To the ice cooled reaction mixture was added concd HCl (13 ml), and the solution was concentrated under reduced pressure to give viscous brown residue. The residue was treated with 4 M NaOH (50 ml) and was extracted with three 30 ml portions of ether. The ethereal extract was dried ($MgSO_4$), concentrated, and distilled giving 4.59 g (79%) of (+)-**2**: bp 141—142 °C/0.2 Torr; $[\alpha]_D^{30}$ +22.8° (*c* 1.14, $CHCl_3$); IR (neat) 3300 (OH), 1030 (OH), 740 (Ph), and 695 cm^{-1} (Ph); NMR (CCl_4) δ=1.1—2.1 (8H, m), 2.10 (3H, s), 2.2—2.7 (2H, m), 3.3—4.3 (4H, m), 4.87 (1H, *quasi* s) and 7.22 (5H, s); MS *m/e* 233 (M^+); Found: N, 6.31%. Calcd for $C_{15}H_{23}NO$: N, 6.00%.

In a similar manner, (−)-**2** was obtained in 75% yield: bp 130—132 °C/0.08 Torr; $[\alpha]_D^{24}$ −22.4° (*c* 0.98, $CHCl_3$); MS *m/e* 233 (M^+).

Benzyl[cis-*2-(hydroxymetyl)cyclohexyl*]*dimethylammonium Bromide* (**3**). To a solution of (+)-**2** (4.00 g, 17 mmol) in methanol (30 ml) was bubbled methyl bromide gas for about 8 h at 0 °C. After removal of the solvent, the residual crystals were recrystallized from 2-propanol giving 3.87 g (69%) of (−)-**3**: mp 176—177 °C; $[\alpha]_D^{29}$ −34.6° (*c* 1.00, $CHCl_3$); IR (KBr) 3450 (OH), 1040 (OH), 730 (Ph) and 700 cm^{-1} (Ph); NMR ($CDCl_3$) δ=1.1—2.5 (8H, m), 2.6—3.0 (1H, bs), 3.17 (3H, s), 3.67 (3H, s), 3.7—4.2 (3H, m), 4.7—5.2 (3H, m) and 7.2—7.7 (5H, m); Found: N, 4.29%. Calcd for $C_{16}H_{26}BrNO$: N, 4.27%.

Similarly, (+)-**3** was prepared from (−)-**2** in 54% yield: mp 175—176 °C; $[\alpha]_D^{21}$ +34.6° (*c* 1.04, $CHCl_3$); Found: N, 4.21%. Calcd for $C_{16}H_{26}BrNO$: N, 4.27%.

General Procedure for the Alkylation of Active Methylene Compounds (**4**). To an ice cooled solution of active methylene compound (**4**) (20 mmol), alkylating agent (22 mmol), and (+)- or (−)-**3** (328 mg, 1.0 mmol) in chloroform (20 ml) was added 10% NaOH (20 ml), and the mixture was stirred overnight at 0 °C. After separation of the chloroform layer, the aqueous layer was extracted with three 40 ml portions of chloroform. The chloroform solution combined was concentrated under reduced pressure. Ether (about 100 ml) was added to the concentrated oily product, and residue was separated by decantation. The ethereal solution was dried (Na_2SO_4), evaporated, and distilled giving **5**.

5a: Yield 3.53 g (84%); bp 84—85 °C/2 Torr; $[\alpha]_D^{25}$ −7.4° (*c* 1.51, $CHCl_3$); IR (neat) 1740 (shoulder, C=O), 1705 (C=O) and 1200 cm^{-1} (C–O–C); NMR (CCl_4) δ=1.23 (3H, t, *J*=7 Hz), 1.4—2.2 (6H, m), 2.2—2.7 (4H, m), 4.15 (2H, q, *J*=7 Hz), 4.7—5.0 (1H, m), 5.0—5.2 (1H, m), and 5.4—6.1 (1H, m).

5a': Yield 3.69 g (71%); bp 140—141 °C/3 Torr; $[\alpha]_D^{25}$ +4.7° (*c* 1.15, $CHCl_3$); IR (neat) 1730 (C=O), 1710 (C=O), 1190 (C–O–C), 740 (Ph) and 700 cm^{-1} (Ph); NMR (CCl_4) δ=1.12 (3H, t, *J*=7 Hz), 1.4—2.2 (6H, m), 2.2—2.6 (2H, m), 2.77 (1H, d, *J*=13.5 Hz), 3.19 (1H, d, *J*=13.5 Hz), 4.01 (2H, q, *J*=7 Hz) and 7.10 (5H, s).

5b: Yield 2.44 g (68%); bp 119—120 °C/11 Torr; $[\alpha]_D^{28}$ +18.2° (*c* 1.48, $CHCl_3$); IR (neat) 1710 (C=O) and 1695 cm^{-1} (C=O); NMR (CCl_4) δ=1.3—2.2 (6H, m), 1.99 (3H, s), 2.2—2.6 (4H, m), 4.8—5.0 (1H, m), 5.1 (1H, *quasi* s) and 5.2—5.8 (1H, m).

5c: yield 2.21 g (65%); bp 101—102 °C/14 Torr; $[\alpha]_D^{22}$ +1.7° (*c* 10.33, $CHCl_3$); IR (neat) 1745 (C=O) and 1725 cm^{-1} (C=O); NMR (CCl_4) δ=1.22 (3H, s), 1.25 (3H, t, *J*=7 Hz), 1.6—2.6 (6H, m) and 4.08 (2H, q, *J*=7 Hz).

5d: yield 3.95 g (86%); bp 111—112 °C/1 Torr; $[\alpha]_D^{20}$ +0.4° (*c* 10.0, $CHCl_3$); IR (neat) 2250 (C≡N) and 1740 cm^{-1} (C=O); NMR (CCl_4) δ=1.17 (3H, t, *J*=7 Hz), 2.5—3.3 (2H, m), 4.15 (2H, q, *J*=7 Hz), 5.0—6.1 (3H, m) and 7.2—7.7 (5H, m).

Methylation of Purine 2′-Deoxynucleosides with Trimethyl Phosphate

Toshizumi TANABE,* Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 2, 1979)

Synopsis. Trimethyl phosphate was found to methylate deoxyadenosine (N-1) and deoxyguanosine (N-1, N-7, and O-6) in a homogeneous aqueous phase at 37 and 60 °C, giving the corresponding methyl derivatives.

The alkylation of nucleic acids, especially deoxyribonucleic acid (DNA) *in vivo*, is considered to be closely related to carcinogenesis or mutagenesis, and various alkylating agents have been employed for alkylation studies of nucleic acids and their components.[1-8]

Methylation reactions of nucleic acid-bases,[9] pyrimidine 2′-deoxynucleosides,[10] and ribonucleosides[11] were carried out successfully in a homogeneous aqueous phase using trimethyl phosphate (TMP) as a methylating agent.

In this paper, we wish to describe the reactions of deoxyadenosine (**1**) and deoxyguanosine (**4**) with TMP in an aqueous phase.

The reactions were carried out at 37 and 60 °C by stirring a mixture of 2′-deoxynucleoside and TMP in water at an appropriate pH (7—10 for **1** and 10—11 for **4**). The products were conveniently identified by comparison of their R_f values and UV spectra with those of the authentic samples, their yields being determined by means of UV spectra. The results are summarized in Table 1.

TABLE 1. METHYLATION OF PURINE 2′-DEOXYNUCLEOSIDES (dNu) WITH TRIMETHYL PHOSPHATE (TMP)[a]

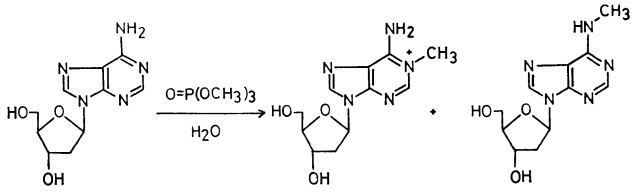
a) Reaction size: deoxyadenosine (0.25 mmol)+TMP (3.8 or 15.0 mmol)+H_2O (2.5 ml); deoxyguanosine (0.05 mmol)+TMP (0.7 or 3.0 mmol)+H_2O (0.5 ml). b) dA and dG refer to deoxyadenosine and deoxyguanosine, respectively.

Compound **1** and adenosine are generally alkylated with methyl iodide[1] or diazomethane[6] at the N-1 position. Singer *et al.* reported the formation of 1-ethyl- and 7-ethyladenosine in the reaction of adenosine with diethyl sulfate.[3]

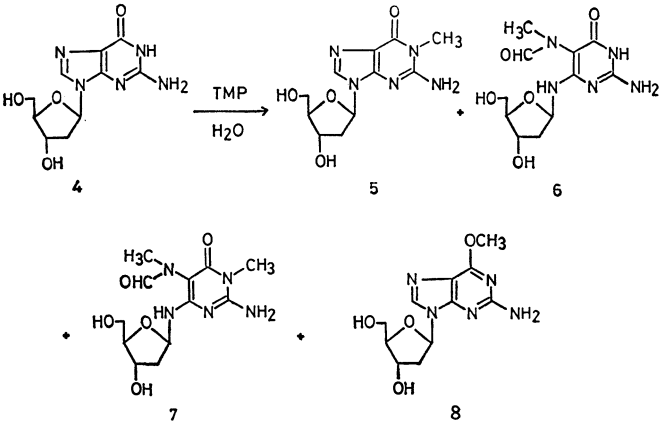
TMP also alkylates **1** at the N-1 position to give 1-methyldeoxyadenosine (**2**) and N^6-methyldeoxyadenosine (**3**) which arose from **2** by the Dimroth rearrangement under alkaline conditions. Two minor products obtained in the reaction at 60 °C, pH 10, were considered to be 5′ (or 3′)-*O*-methylated products found also in methylation of pyrimidine 2′-deoxynucleosides under similar conditions.[10]



1 2 3

In deoxyguanosine (**4**), the N-1 and N-7 positions are subjected to alkylation in preference to the other positions by alkylating agents.[1,2,4,7,8]

In the present method with TMP, **4** was methylated at the N-1, N-7, and O-6 positions giving 1-methyl- (**5**), imidazole ring opened 7-methyl- (**6**), imidazole ring opened 1,7-dimethyl- (**7**), and O^6-methyldeoxyguanosines (**8**). Identification of **5**, **6**, and **7** was based on comparison of their R_f values and UV spectra with those of the authentic samples, **8** being tentatively assigned through its UV spectra and characterestic fluorescence under UV light.



4 5 6 7 8

Thus, methylation of the N-1 position of **4** was found to be accelerated by the increase of pH of the reaction medium, the reactivities of the N-1 position of **1** and the N-7 position of **4** being independent of pH.

Occurrence of O^6-methylation of **4** may be worth remarking, since O^6-alkylation of guanine moiety in DNA seems to be related closely to the mutagenecity and the carcinogenecity through atypical base-pairing.[12]

Experimental

Melting points are uncorrected. UV spectra were recorded on a Hitachi 3T spectrometer, and NMR spectra on a Hitachi Perkin-Elmer R-20 spectrometer with a dilute solution in deuterioxide and sodium 3-(trimethylsilyl)propionate-d_4 as an internal standard. Thin-layer chromatography was performed on silica gel [GF_{254}(type 60), Merck] or cellulose (13254, Eastman) using the following solvents; A: chloroform–methanol, 5: 1, B: 2-propanol–water, 7: 3. Column chromatography was carried out using silica gel (Merck, Art. 7734, 70—230 mesh).

Commercial deoxyadenosine (**1**) and deoxyguanosine (**4**) were used without further purification. Trimethyl phosphate (TMP) was distilled prior to use.

Methylation of Deoxyadenosine (1). A mixture of **1** (125 mg, 0.5 mmol) and TMP (7.5 or 30 mmol) in water (5 ml) was stirred at 37 or 60 °C at an appropriate pH maintained throughout the reaction by occasional addition of 2 M sodium hydroxide. At an appropriate reaction time, 4 μl of the reaction mixture was spotted on silica gel TLC plate, which was developed immediately using solvent A. Two UV-absorbing products (**2** and **3**) were observed (R_f; **1**: 0.29, **2**: 0.01, **3**: 0.41). In the reaction at 60 °C, pH 10, additional two spots (Unknown A and B) appeared (R_f; A: 0.54, B: 0.60). Each product was identified by a comparison of its R_f and UV spectrum with those of the authentic sample and the yield was calculated from its UV spectrum in a similar way to that reported.[9] The results are summarized in Table 1.

The authentic sample of 1-methyldeoxyadenosine was prepared according to the procedure of Jones and Robins.[1]

N^6-Methyldeoxyadenosine was isolated as follows.

A mixture of **1** (1.0 g, 4.0 mmol) and TMP (8.4 g, 60.0 mmol) in water (10 ml, pH 10, NaOH) was stirred at 60 °C for 48 h. After the reaction mixture had been neutralized by concentrated hydrochloric acid, the solvent was removed by evaporation. The residue was purified by silica gel column chromatography (2.5×50 cm). Elution with chloroform afforded unchanged TMP, **3** being obtained by subsequent elution with chloroform–methanol (7: 1) (349 mg, 33%); mp 200—201 °C (lit,[1] 206—208 °C); UV λ_{max} (H_2O) nm: pH 1, 262.0, pH 7, 265.0, pH 13, 265.0 (lit,[1] pH 1, 261.0, pH 7, 265.0, pH 11, 265.0).

Methylation of Deoxyguanosine (4). The reaction of **4** (0.05 mmol) with TMP (0.7 or 3.0 mmol) in water (0.5 ml) at 37 °C, pH 10 or 11 afforded four UV-absorbing products (**5**, **6**, **7**, and **8**) on cellulose TLC which was developed using solvent B (R_f; **4**: 0.46, **5**: 0.67, **6**: 0.59, **7**: 0.73, **8**: 0.83). At an appropriate reaction time, the yield of each product was calculated in a similar way to that mentioned above. The UV spectrum of each product was as follows; **5**: λ_{max} (H_2O) nm: pH 1, 257.0, 280.0 (shoulder), pH 7, 255.5, 271.0 (shoulder), pH 13, 255.5, 272.0 (shoulder) (lit,[2] pH 1, 257.0, pH 11, 254.0); **6**: λ_{max} (H_2O) nm: pH 1, 272.0, pH 7, 273.0, pH 13, 266.0 (lit,[13] pH 1, 270.5, pH 11, 265.0); **7**: λ_{max} (H_2O) nm: pH 1, 272.0, pH 7, 273.0, pH 13, 273.0 (lit,[4] pH 1, 272.0, pH 13, 273.0); **8**: λ_{max} (H_2O) nm: pH 1, 241.0, 286.0, pH 7, 249.0, 279.0 (lit,[7] pH 1, 244.0, 286.0 pH 7, 248.0, 277.0, pH 13, 247.0, 278.0). The R_f and UV spectrum of each product agreed with those of the authentic sample or reported values. Products and their distribution are summarized in Table 1.

The authentic sample of **5** was prepared from the reaction of **4** with trimethylsulfonium hydroxide,[14] and that of **6** was given by the alkaline treatment of 7-methyldeoxyguanosine prepared according to the procedure of Jones and Robins.[1]

Compound **7** was prepared as follows. A mixture of **5** (57 mg, 0.2 mmol) and TMP (0.84 g, 6.0 mmol) in water (2 ml, pH 10, NaOH) was stirred at 60 °C for 30 h. The TLC of the reaction mixture showed only one UV-absorbing spot whose aqueous extract had λ_{max} at 273.0 nm. After the reaction mixture had been neutralized with concentrated hydrochloric acid, unchanged TMP was removed by extraction with chloroform. Evaporation of the water layer gave the residue which was washed with acetone several times. The acetone solution was concentrated and poured into a large excess of ether, giving white hydroscopic precipitate of **7** (31 mg, 49%); NMR (DMSO-d_6) δ=2.65 and 2.71 (0.8 H+2.2 H, two s, N(CHO)CH_3), 3.05 (3H, s, N–CH_3), 5.05—5.60 (1H, complex m, 1′-CH), and 7.55 and 7.62 (0.25H +0.75H, two s, N(CHO)CH_3); UV λ_{max} (H_2O) nm: pH 1, 272.0, pH 7, 273.0, pH 13, 273.0.

Reactive Troponoids and *o*-Aminophenol. IV. The Synthesis of 8-Arylazocyclohepta[*b*][1,4]benzoxazine by the Reaction of Arylazotropolone with *o*-Aminophenol[1)]

Taichi SOMEYA

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received February 17, 1979)

Synopsis. 8-Phenylazocyclohepta[*b*][1,4]benzoxazine was obtained by the dehydration of 5a-hydroxy-8-phenylhydrazonocyclohepta[*b*][1,4]benzoxazine, which had itself been obtained by the reaction of 5-phenylazotropolone with *o*-aminophenol.

In previous papers, we have reported the formation of cyclohepta[*b*][1,4]benzoxazine (**1a**) and its derivatives by the reactions with *o*-aminophenol of troponoids which have one or two leaving groups.[2-4)] Many years ago, Nozoe and his coworkers found that 5-nitrosotropolone (**2a**) and 5-arylazotropolone (**2b**) reacted with *o*-phenylenediamine to give quinoxalotropone derivatives,[5)] while 5-nitrosotropolone gave the condensation products (**3a**) by a reaction with *o*-aminophenol; the latter reaction has not, however, been examined in detail.[6)]

In this paper, the present author wishes to describe the results of the reactions of 5-phenylazo- and 5-(*p*-tolylazo)tropolone with *o*-aminophenol.

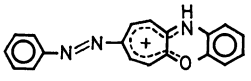
Results and Discussion

The heating of 5-phenylazotropolone (**2b**) with *o*-aminophenol (**4**) in ethanol under reflux resulted in the repid, quantitative precipitation of sparingly soluble crystals (**3b**). From elemental analysis ($C_{19}H_{15}N_3O_2$), the mass-spectral determination of mol wt (*m/e* 317 (M^+)), and other spectral data, **3b** seems to be 5a-hydroxy-8-phenylhydrazonocyclohepta[*b*][1,4]benzoxazine. Similarly, 5a-hydroxy-8-(*p*-tolylhydrazono)cyclohepta[*b*][1,4]benzoxazine (**3c**) was obtained from 5-(*p*-tolylazo)tropolone (**2c**) and **4**. It is because of the contribution of the arylazo or nitroso group that **3b,c** and **3a** do not undergo dehydration to form **1b,c** and **1d** respectively under these reaction conditions.

When **3b** and **3c** were left in acetic acid in the presence of sulfuric acid, they underwent dehydration to form 8-phenylazo- (**1b**) and 8-(*p*-tolylazo)cyclohepta[*b*][1,4]benzoxazine (**1c**) respectively. These structures were determined by mass and elemental analyses and by means of the spectral data. When **1b,c** were allowed to stand in ethanol, upon the addition of 1 M NaOH or 1 M HCl at room temp. for 3 h, **1b,c** reverted to **3b,c**, which were then decomposed into **2b,c** and **4** when heated with an excess of alkali for 2 h.

The dehydration of **3a** failed to produce 8-nitrosocyclohepta[*b*][1,4]benzoxazine (**1d**) under the same reaction conditions as were used in the case of **3b,c** to **1b, c**.

The NMR data of **1b** measured in trifluoroacetic acid and chloroform-*d* show a sflift of the seven-membered ring protons by 0.86—1.07 ppm and that of the benzene ring protons by only 0.10—0.22 ppm towards a lower magnetic field. This indicates that the positive charge of the cation (**5**) derived from **1b** is delocalized over both the seven-membered ring and the heterocyclic part, as in the case of cyclohepta[*b*][1,4]-benzoxazine (**1a**).[2)]



5

Experimental

If not otherwise stated, the instruments and methods were as previously described.[2)]

5a-Hydroxy-8-phenylhydrazonocyclohepta[b][*1,4*]*benzoxazine(3b)*: A mixture of 5-phenylazotropolone (**2b**) (2.0 g, 8.7 mmol), *o*-aminophenol (**4**) (2.0 g, 18.3 mmol), and ethanol (16 ml) was refluxed for 3 h. After cooling, the resulting red crystals (3.2 g) were filtered and recrystallized from ethanol to give 2.7 g (96%) of **3b**; red needles; mp 198 °C; λ_{max}^{MeOH} nm (log ε): 205 (4.73), 234 (4.36), 278 (4.06), and 440 (4.32); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 277 (4.05), 410 (4.00)^{sh}, and 472 (4.20); IR (KBr): 3300 (NH) and 3200 cm^{-1} (OH); NMR (60 MHz in DMSO-d_6): δ 9.72 (br. s, 1H, OH), 9.09 (s, 1H, NH), and 6.2—8.0 ppm (m, 13H). Found: C, 71.88; H, 4.86; N, 13.50%; M^+, 317. Calcd for $C_{19}H_{15}N_3O_2$: C, 71.91; H, 4.76; N, 13.24%; M, 317.

*5a-Hydroxy-8-(*p*-tolylhydrazono)cyclohepta*[b][*1,4*]*benzoxazine (3c)*. A mixture of 5-(*p*-tolylazo)tropolone (**2c**) (2.0 g, 8.2 mmol), **4** (1.8 g, 16.4 mmol), and ethanol (4.5 ml) was refluxed for 9 h. After cooling, the resulting crystals were filtrated. Recrystallization from ethyl acetate gave 2.3 g (87 %) of **3c** as orange red needles; mp 231 °C; λ_{max}^{MeOH} nm (log ε): 205 (4.72), 250 (4.35), 300 (4.04), and 442 (4.33); $\lambda_{max}^{MeOH+NaOH}$

nm (log ε): 293 (4.05), 405 (4.09), and 480 (4.26); IR (KBr): 3400 (NH) and 3250 cm^{-1} (OH); NMR (60 MHz in DMSO-d_6): δ 9.40 (s, 1H, NH), 6.9—8.2 (m, 12H), and 2.40 ppm (s, 3H, CH_3). Found: C, 72.20; H, 5.13; N, 12.33%; M^+, 331. Calcd for $C_{20}H_{17}N_3O_2$: C, 72.49; H, 5.17; N, 12.33%; M, 331.

5a-Hydroxy-8-(hydroxyimino)cyclohepta[b][*1,4*]*benzoxazine (**3a**).* A mixture of 5-nitrosotropolone (**2a**) (400 mg, 2.6 mmol), **4** (290 mg, 2.66 mmol), and MeOH (40 ml) was stirred at room temp. The suspension became clear once, and then yellow crystals were precipitated. After filtration, recrystallization from ethyl acetate gave 540 mg (86%) of **3a**; pale yellow needles; mp 198 °C.

8-Phenylazocyclohepta[b][*1,4*]*benzoxazine (**1b**).* A mixture of **3b** (800 mg, 2.5 mmol), acetic acid (15 ml), and concd sulfuric acid (1.4 ml) was allowed to stand at room temp for 1 day. The solution was then neutralized with aq $NaHCO_3$ and extracted with ether. The extract was concentrated, and the residue was chromatographed on a silica-gel column. From the benzene fraction, 600 mg (80%) of **1b** was obtained as brown, triangular structures; mp 210 °C (from benzene); λ_{max}^{MeOH} nm (log ε): 205 (4.45), 231 (4.32), 263 (4.44), 322 (4.30), 450 (4.43)^{sh}, 471 (4.48), 500 (4.40)^{sh}, and 570 (3.76)^{sh}; $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 205 (4.38), 235 (4.37), 265 (4.38), 274 (4.41), 333 (4.26), and 535 (4.39); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 258 (4.32), 321 (4.14), 448 (4.52), 505 (4.28)^{sh}, and 570 (4.16)^{sh}; NMR (100 MHz in $CDCl_3$): δ 7.76 (2H, m, $C_{2',6'}$–H), 7.43 (3H, m, $C_{3',4',5'}$–H), 7.14 (1H, dd, J=13.0, 2.0 Hz, C_9–H), 6.89 (1H, dd, J=10.5, 2.0 Hz, C_7–H), 6.86 (3H, m, $C_{1,2,3}$–H), 6.51 (1H, m, C_4–H), 6.29 (1H, d, J=13.0 Hz, C_{10}–H), and 5.72 ppm (1H, d, J=10.5 Hz, C_6–H); NMR (100 MHz in $CDCl_3$+CF_3COOD): δ 8.06 (C_9–H, $\Delta\delta$=0.92 ppm), 7.90 ($C_{2',6'}$–H, $\Delta\delta$=0.14 ppm), 7.88 (C_7–H, $\Delta\delta$=0.99 ppm), 7.53 ($C_{3',4',5'}$–H, $\Delta\delta$=0.10 ppm), 7.15 (C_{10}–H, $\Delta\delta$=0.86 ppm), 6.96 ($C_{1,2,3}$–H, $\Delta\delta$=0.10 ppm), 6.79 (C_6–H, $\Delta\delta$=1.07 ppm), and 6.73 ppm (C_4–H, $\Delta\delta$=0.22 ppm). Found: C, 76.23; H, 4.19; N 13.77%; M^+, 299. Calcd for $C_{19}H_{13}N_3O$: C, 76.24; H, 4.38; N, 14.04%; M, 299.

8-(p-Tolylazo)cyclohepta[b][*1,4*]*benzoxazine (**1c**).* A mixture of **3c** (400 mg, 1.2 mmol), acetic acid (10 ml), and concd sulfuric acid (0.5 ml) was heated at 75—80 °C for 2 h After standing over night, water (50 ml) was added to the solution, and it was neutralized with $NaHCO_3$ and extracted with benzene. The extract was chromatographed on a silica-gel column. From the benzene–ethyl acetate (20: 1) fraction, 250 mg (64%) of **1c** was obtained as brown needles; mp 219 °C (from benzene); λ_{max}^{MeOH} nm (log ε): 206 (4.39), 230 (4.25), 264 (4.41), 328 (4.28), 455 (4.45)^{sh}, 474 (4.49), 500 (4.41)^{sh}, and 560 (4.37)^{sh}; $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 206 (4.31), 233 (4.28), 265 (4.36), 275 (4.39), 341 (4.17), and 540 (4.37); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 268 (4.35), 333 (4.21), 475 (4.50), 510 (4.37)^{sh}, and 570 (4.02)^{sh}; NMR (60 MHz in $CDCl_3$): δ 7.70 (2H, m, $C_{2',6'}$–H), 7.30 (2H, m, $C_{3',5'}$–H), 7.10 (1H, m, C_9–H) 6.87 (1H, m, C_7–H), 6.80 (3H, m, $C_{1,2,3}$–H), 6.45 (1H, m, C_4–H), 6.27 (1H, d, J=13 Hz C_{10}–H), 5.70 (1H, d, J=10 Hz C_6–H), and 2.38 ppm (3H, s, CH_3). Found: C, 76.67; H, 4.63; N, 13.06%; M^+, 313. Calcd for $C_{20}H_{15}N_3O$: C, 76.66; H, 4.83; N, 13.41%, M, 313

*Conversion of **1b,c** into **3b,c**.* A solution of **1b,c** (5 mg) in ethanol (1 ml) and three drops of 1 M HCl or 1 M NaOH was allowed to stand at room temp for 3 h. The neutralized solution was found to be **3b,c** by means of the TLC and UV absorptions

A solution of **1b,c** or **3b,c** (5 mg) in ethanol (1 ml) and 1 M NaOH (1 ml) was refluxed or 2 h. The neutralized solution was found to be a mixture of **2b,c** and **4** by means of the TLC and UV absorptions.

The author wishes to express his deep gratitude to Professor Emeritus Tetsuo Nozoe and Professor Kahei Takase (Tohoku University) for their encouragement and advice, and also to Dr. Haruki Tsuruta (Takasago Perfumery Co., Ltd.) for his valuable discussion.

Mesomorphic 4-Alkylphenyl 4-Benzoyloxybenzoate Bearing a Terminal Vinyl Group

Hiroyoshi KAMOGAWA,* Masayuki SEKIGAWA, Tomohiro NAKANO, Shin IZAWA, and Masato NANASAWA

Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu, Yamanashi 400

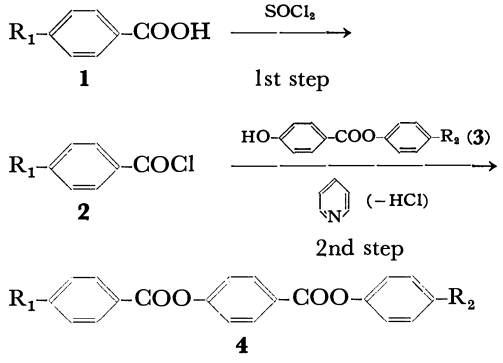
(Received March 31, 1979)

Synopsis. 4-Alkylphenyl 4-(4-vinyl-, methacryloyloxy-, and methacrylamido-benzoyloxy)benzoates have been synthesized by the reactions of 4-alkylphenyl 4-hydroxybenzoates with the corresponding substituted benzoyl chloride in pyridine. The mesomorphic ranges of these novel monomers are highly dependent upon the type of substituent at both ends of the molecules.

Phenyl 4-benzoyloxybenzoates such as 4-hexylphenyl 2-chloro-4-(4-hexylbenzoyloxy)benzoate have been reported[1] to possess low mesomorphic ranges as well as to be more stable against hydrolysis as compared with the Schiff bases commonly used for liquid crystal applications.

In the course of synthetic studies of mesomorphic organic compounds bearing terminal vinyl groups and their polymers,[2,3] several novel 4-alkylphenyl 4-benzoyloxybenzoates bearing terminal vinyl groups have been synthesized.

The synthetic route adopted was as follows.



The 4-vinyl-, methacryloyloxy-, and methacrylamido-benzoic acids (**1**) synthesized were converted to the respective acyl chlorides (**2**), which were subsequently reacted with 4-alkylphenyl 4-hydroxybenzoate (**3**) in

TABLE 1. MESOMORPHIC RANGE FOR SUBSTITUTED PHENYL 4-BENZOYLOXYBENZOATES

a) For purified products. b) C: crystal; S: smectic; N: nematic; I: isotropic.

anhydrous pyridine to afford the desired product **4**. The yields however were not high. The success of this synthetic route depends on the 2nd step. The nature of R_1 appears to markedly affect the yield and the extent of side reactions, *e.g.*, the use of acryloyloxyl or acrylamido groups as R_1 resulted in little reaction or polymerization. Substitution of *N,N*-dimethylaniline for pyridine as the HCl-acceptor did not give satisfactory results.

The novel vinyl monomers thus synthesized are listed in Table 1, where it may be seen that the effect of R_1 and R_2 on the mesomorphic range is large. It is anticipated that branching in the alkyl group R_2 brings about a narrower mesomorphic range. Normal alkyl groups were however not introduced due to the lack of raw materials. The use of vinyl (**4-1**—**4-5**), methacryloyloxyl (**4-6** and **4-7**), and methacrylamido (**4-8** and **4-9**) as R_1 markedly affected the mesomorphic range. The vinyl group appears to afford the lowest CN or SN transition temperature and the widest nematic range, which appear to be comparable with those with freely rotatable alkyl groups.[1)]

The compounds not only indicate mesomorphic ranges as they are, but also they might afford polymers with mesomorphic ranges due to pendant portions by suitable polymerization methods.

Experimental

Mesomorphic ranges were determined by means of a Yamato MP-21 melting point apparatus. 4-Alkylphenyl 4-hydroxybenzoates (**3**) were synthesized according to the reported method.[1)]

*4-s-Butylphenyl 4-(4-Vinylbenzoyloxy)benzoate (**4-1**).* To a solution of 4-*s*-butylphenyl 4-hydroxybenzoate (**3**, 1.3 g, 4.7 mmol) and 4-*t*-butylcatechol (50 mg) in anhydrous pyridine (25 ml), 4-vinylbenzoyl chloride (**2**, 0.8 g, 5.0 mmol) prepared by the room temperature reaction of 4-vinylbenzoic acid (**1**) and thionyl chloride was added with ice-cooling. The solution was allowed to stand at room temperature for 18 h with the exclusion of moisture. The reaction mixture was then poured into iced water and the precipitated crude product was recrystallized three times from ethanol to afford colorless crystals (0.7 g, 36% yield). Found: C, 77.49; H, 6.05%. Calcd for $C_{26}H_{24}O_4$: C, 77.98; H, 6.04%. IR (KBr) 1720 (C=O), 995, 900 (vinyl) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ 0.8 (t, 3H, CH_3), 1.2 (d, 3H, CH_3), 1.6 (t, 2H, CH_2), 2.6 (q, 1H, CH), 5.4 (d, 1H, $C\underline{H}_2$=CH–), 5.8 (d, 1H, $C\underline{H}_2$=CH–), 6.7 (q, 1H, CH_2=C$\underline{H}$–), 7.3 (q, 8H, ArH), 8.2 (t, 4H, ArH) ppm. Mass (*m/e*) 400 (M^+, 6), 131 (100).

The monomers **4-2**—**4-5** were synthesized in the same manner, their analytical data being also satisfactory.

*4-(1-Methylbutyl)phenyl 4-[4-(Methacryloyloxy)benzoyloxy]benzoate (**4-7**).* The same procedure as that for monomer **4-1** was applied for **3** (R_2=1-methylbutyl; 1.3 g, 5.0 mmol) prepared from 4-(methacryloyloxy)benzoic acid (**1**), which was itself synthesized by the reaction of sodium 4-hydroxybenzoate with methacryloyl chloride in aqueous solution, to afford colorless crystals (0.2 g, 9% yield). Found: C, 73.74; H, 5.49%. Calcd for $C_{29}H_{28}O_6$: C, 73.69; H, 5.99%. IR (KBr) 1740 (C=O), 950, 885 (CH_2=CCH_3) cm^{-1}. NMR ($CDCl_3$+DMSO-d_6) δ 0.8 (t, 3H, CH_3), 1.3 (d, 3H, CH_3), 1.6 (m, 4H, CH_2CH_2), 2.1 (s, 3H, CH_2=C$C\underline{H}_3$), 2.5 (m, 1H, CH), 5.8 (s, 1H, CH_2=), 6.4 (s, 1H, CH_2=), 7.4 (m, 8H, ArH), 8.3 (d, 4H, ArH) ppm. Mass (*m/e*) 472 (M^+, 2), 190 (100).

Monomer **4-6** was synthesized in the same manner with satisfactory analytical data.

*4-t-Pentylphenyl 4-[4-(Methacrylamido)benzoyloxy]benzoate (**4-9**).* Compound **3** (R_2=*t*-pentyl; 1.3 g, 4.7 mmol) and 4-(methacrylamido)benzoyl chloride (**2**, 1.1 g, 5.0 mmol), prepared by the reaction of sodium 4-aminobenzoate with methacryloyl chloride in aqueous solution, when subjected to the same reaction procedure as described above, gave colorless crystals (0.4 g, 20% yield). Found: C, 73.80; H, 6.50; N, 3.16%. Calcd for $C_{29}H_{29}NO_5$: C, 73.87; H, 6.20; N, 2.97%. IR (KBr) 1740 (ester), 1680 (amide), 960, 860 (CH_2=CCH_3) cm^{-1}. NMR ($CDCl_3$) δ 0.7 (t, 3H, CH_3), 1.3 (s, 6H, 2 CH_3), 1.6 (t, 2H, CH_2), 2.1 (s, 3H, CH_2=C$C\underline{H}_3$), 5.5 (s, 1H, CH_2=), 5.8 (s, 1H, CH_2=), 7.0—8.3 (m, 13H, ArH+CONH) ppm. Mass (*m/e*) 471 (M^+, 3), 190 (100).

Monomer **4-8**, synthesized in the same manner, also provided satisfactory analytical data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (10), 3127—3128 (1979)

A New Triterpene Glucoside from *Terminalia arjuna*. Arjunglucoside III

Takahiko TSUYUKI, Yuriko HAMADA, Tadashi HONDA, Takeyoshi TAKAHASHI,* and Kazuhiro MATSUSHITA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
***Application Center, Scientific Instrument Project, JEOL Ltd., Nakagami, Akishima, Tokyo 196*

(Received April 24, 1979)

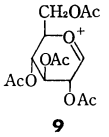
Synopsis. The structure of a new triterpene glucoside, arjunglucoside III, isolated from *Terminalia arjuna* was found to be β-D-glucopyranosyl 2α,3β,19α-trihydroxy-11-oxoolean-12-en-28-oate.

The isolation and structure determination of sitosterol, ellagic acid, D-(+)-mannitol, (+)-leucocyanidin, (+)-leucodelphinidin, oleanolic acid, arjunic acid (**1**), arjunolic acid (**2**), and arjunetin (**3**) from *Terminalia arjuna* have been reported.[1,2] In a previous paper,[3] a report was given on three new constituents, arjungenin (**4**) and arjunglucosides I (**5**) and II (**6**) from the bark of plant. We describe the structure determination of a minor glucoside, arjunglucoside III (**7**), isolated from the same plant.

Arjunglucoside III (**7**) was obtained from the methanol extract of the bark of *Terminalia arjuna* in *ca.* 0.01% yield based on the bark. Crystallization from methanol gave a crystal, mp 241.5—243.5 °C, $[\alpha]_D^{19}$ +4.8°; UV λ_{max} 255.5 nm (ε 9600). The ^{13}C NMR spectra of arjunglucoside III (**7**) together with those of arjunetin (**3**) and arjunglucoside II (**6**) are given in Table 1. The results led to the proposal[4,5] that the structure of arjunglucoside III (**7**) can be formulated as glucopyranosyl 2,3,19-trihydroxy-11-oxoolean-12-en-28-oate.

The ^{13}C NMR spectrum of methyl 3β-acetoxy-11-oxoolean-12-en-29-oate shows its C-9 signal at δ 61.9, C-11 signal at δ 200.2, and C-12 signal at δ 128.9, while that of the corresponding 11-deoxo derivative, methyl 3β-acetoxyolean-12-en-29-oate shows its C-9 signal at δ 47.7, C-11 signal at δ 23.6, and C-12 signal at δ 123.0.[5] The ^{13}C NMR and UV spectra strongly suggest the 11-oxoolean-12-ene structure for arjunglucoside III (**7**); this was confirmed by the following evidence.

	R^1	R^2	R^3	R^4
1	H	H	H	OH
2	H	OH	H	H
4	H	OH	H	OH



9

	R^1	R^2	R^3	R^4	R^5
3	H	H	H	OH	H_2
5	H	OH	H	OH	H_2
6	H	OH	H	H	H_2
7	H	H	H	OH	O
8	Ac	H	H	OH	O
10	Ac	H		=O	O
11	Ac	H	H	OH	H_2

Arjunglucoside III (**7**) was treated with acetic anhydride in pyridine to afford an acetate (**8**), mp 272—275 °C, UV λ_{max} 250 nm (ε 11500). The mass spectrum showed a molecular ion peak at *m/e* 916 and a base peak at *m/e* 331. The molecular ion peak together with elemental analysis led to the molecular formula, $C_{48}H_{68}O_{17}$, the base peak due to a fragment ion (**9**)[6] suggesting the presence of a glucosyl moiety in the molecule. The ^1H NMR spectrum showed the presence of seven tertiary methyls, two acetoxyls, an α-proton (at C-9) adjacent to the carbonyl group, an allylic proton (at C-18β), and a proton attached to a carbon atom (C-19) bearing a hydroxyl group (the presence of which was supported by the IR spectrum at 3540 cm^{-1}), besides a tetra-*O*-acetyl-D-glucopyranosyl moiety (*cf.* Experimental). The acetate (**8**), on oxidation with the Collins reagent,[7] gave an oxidation product (**10**), mp 215—218 °C, which was found to be identical with the 11,19-dioxoolean-12-ene derivative obtained by the same oxidation reaction of known arjunetin hexaacetate

^{13}C FT NMR spectra were measured with a JEOL FX-100 spectrometer at 25.05 MHz using pyridine-d_5 solutions (*ca.* 100 mg/cm^3) in 10 mm o.d. egg-shape cells. FT conditions: spectral width, 5 kHz; pulse flipping angle, 60°; pulse repetition time, 1.0 s; number of data points, 4 K; number of transients, 5 K—40 K. Chemical shifts are expressed by δ (ppm downfield from internal TMS).

(**11**), tetra-*O*-acetyl-β-D-glucopyranosyl 2α,3β-diacetoxy-19α-hydroxyolean-12-en-28-oate.[1,3] Arjunglucoside III should be β-D-glucopyranosyl 2α,3β,19ξ-trihydroxy-11-oxoolean-12-en-28-oate.

Since the tetra-*O*-acetyl-D-glucopyranosyl group preferentially exists as C1 form, the ^{1}H NMR spectrum of the hexaacetate (**8**) ($J_{1',2'}$=8 Hz) provides support for the presence of a β-glucosyl linkage in the molecule.[8] The α-orientation of the hydroxyl group at C-19 was suggested from the ^{1}H NMR spectrum of the acetate (**8**), which showed a broad signal ($W_{1/2}$ 6 Hz) at δ 3.20 due to a proton on C-18 (β-axial) and a triplet-like signal ($W_{1/2}$ 6 Hz) at δ 3.47 (β-equatorial) due to a proton on C-19. The values are in good accord with those of 18β- and 19β-protons of arjunetin hexaacetate (**11**) and arjungenin methyl ester triacetate,[3,9] suggesting the α(axial)-orientation of the hydroxyl group of arjunglucoside III (**7**).

In conclusion, the structure of arjunglucoside III (**7**) is β-D-glucopyranosyl 2α,3β,19α-trihydroxy-11-oxo-olean-12-en-28-oate.

Experimental

The general procedure is the same as described in a previous paper[3] except UV measurement, which was carried out on a Hitachi 340 spectrometer. High resolution mass spectrum was taken on a JEOL JMS-D300 mass spectrometer.

Isolation of Arjunglucoside III (7). The bark (1.5 kg) of *Terminalia arjuna* was pulverized and extracted with methanol (8 l) for 10 days. The methanol extract afforded a residue (10.5 g), which was subjected to separation by column chromatography on silica gel (500 g). Elution was carried out with chloroform containing methanol of the following concentration: frs 1—13, 2%, each 200 ml; frs 14—17, 4%, each 250 ml; frs 18 and 19, 6%, each 500 ml; frs 20—24, 8%, each 200 ml; frs 25—30, 10%, each 200 ml; frs 31—35, 12%, each 160 ml; frs 36—43, 14%, each 200 ml; frs 44—51, 16%, each 200 ml; frs 52—60, 18%, each 160 ml. After arjunic acid (**1**), arjunolic acid (**2**), and arjungenin (**4**) had been eluted, arjunetin (**3**; 2.4 g) was eluted in frs 41—49 and a mixture (102 mg) of arjunetin (**3**) and arjunglucoside III (**7**) was eluted in fr 50. Fr 51 mainly consisted of arjunglucoside III (**7**; 96 mg) and frs 52—58 afforded arjunglucoside II (**6**; 1.4 g). The mixture containing arjunglucoside III (**7**) was subjected to separation by column chromatography under the same conditions as above to give additional arjunglucoside III (**7**; *ca.* 20 mg). Two crops of crude arjunglucoside III were combined and purified by crystallization from methanol to give 64 mg of arjunglucoside III (**7**), mp 241.5—243.5 °C (with decomposition); $[\alpha]_D^{19}$ +4.8° (*c* 0.83, C_2H_5OH); IR (Nujol) 3380, 1725, and 1630 cm^{-1}; UV (C_2H_5OH) λ_{max} 255.5 nm (ε 9600); ^{13}C NMR (Table 1); MS *m/e* 470, 455, 410, 395, and 69 (base peak) (no molecular ion peak was observed), characterized as its hexaacetate (**8**).

Acetylation of Arjunglucoside III (7). Arjunglucoside III (**7**; 45 mg) was treated with acetic anhydride (0.2 ml) and pyridine (0.2 ml) at room temperature overnight. After the usual treatment, crystallization from ethanol gave arjunglucoside III hexaacetate (**8**; 42 mg), mp 272—275 °C; $[\alpha]_D^{20}$ +12.6° (*c* 1.9, $CHCl_3$); IR (Nujol) 3540, 1765, 1755, 1730, 1660, and 1240 cm^{-1}; UV ($CHCl_3$) λ_{max} 250 nm (ε 11500); ^{1}H NMR (100 MHz) δ ($CDCl_3$) 0.92 (6H, s), 0.96, 1.25 (each 3H, s), 0.99 (9H, s), 1.99 (3H, s), 2.05 (9H, s), 2.08 (6H, s), 2.55 (1H, s), 3.20 (1H, br s), 3.47 (1H, t-like, $W_{1/2}$ 6 Hz), 3.82 (1H, m), 4.06 (1H, as A part of ABX-system, $J_{6',6'}$=12 and $J_{5',6'}$=2 Hz), 4.32 (1H, as B part of ABX-system, $J_{6',6'}$=12 and $J_{5',6'}$=4 Hz), 4.74 (1H, d, $J_{2\beta,3\alpha}$=10 Hz), 5.20 (4H, m), 5.62 (1H, d, $J_{1',2'}$=8 Hz), and 5.77 (1H, s); MS *m/e* 916 (M$^+$), 856, 796, 649, 483, 465, 335, 331 (base peak), 271, and 169; Found: C, 62.76; H, 7.62%. Calcd for $C_{48}H_{68}O_{17}$: C, 62.87; H, 7.47%.

Oxidation of Arjunglucoside III Hexaacetate (8). Chromium trioxide (160 mg) was added to a mixture of pyridine (0.4 ml) and dichloromethane (4 ml) with stirring for 15 min.[7] To the solution was added arjunglucoside III hexaacetate (**8**; 28 mg) in dichloromethane (0.3 ml) and the reaction mixture was stirred at room temperature for 1.5 h. The usual treatment and crystallization from ethanol gave tetra-*O*-acetyl-β-D-glucopyranosyl 2α,3β-diacetoxy-11,19-dioxoolean-12-en-28-oate (**10**; *ca.* 20 mg), as white needles, mp 215—218 °C; $[\alpha]_D^{23}$ +21° (*c* 0.85, $CHCl_3$); the IR, UV, ^{1}H NMR, and MS spectra were identical with those of the sample prepared from arjunetin hexaacetate (**11**).

Oxidation of Arjunetin Hexaacetate (11). Arjunetin hexaacetate[1,3] (**11**; 36 mg, mp 233.5—235.5 °C) was oxidized with the Collins reagent according to the same procedure as above. The reaction product was crystallized from ethanol to give tetra-*O*-acetyl-β-D-glucopyranosyl 2α,3β-diacetoxy-11,19-dioxoolean-12-en-28-oate (**10**; *ca.* 20 mg) as white needles, mp 215—218 °C; $[\alpha]_D^{23}$ +13° (*c* 0.93, $CHCl_3$); IR (Nujol) 1760, 1750, 1712, 1663, and 1230 cm^{-1}; UV ($CHCl_3$) λ_{max} 246 nm (ε 8300); ^{1}H NMR (100 MHz) δ ($CDCl_3$) 0.92 (9H, s), 1.17, 1.25 (each 3H, s), 1.22 (6H, s), 1.99 (3H, s), 2.02 (9H, s), 2.08 (6H, s), 2.53 (1H, s), 3.82 (1H, m), 4.06 (1H, as A part of ABX-system, $J_{6',6'}$=12 and $J_{5',6'}$=2 Hz), 4.30 (1H, as B part of ABX-system, $J_{6',6'}$=12 and $J_{5',6'}$=4 Hz), 4.72 (1H, d, $J_{2\beta,3\alpha}$=10 Hz), 5.23 (4H, m), 5.60 (1H, s), and 5.68 (1H, d, $J_{1',2'}$=8 Hz); MS *m/e* 914 (M$^+$), 854, 794, 647, and 522; Found: *m/e* 914.4162. Calcd for $C_{48}H_{66}O_{17}$: M 914.4298; Found: C, 62.40; H, 7.22%. Calcd for $C_{48}H_{66}O_{17}\cdot 1/2\ H_2O$: C, 62.39; H, 7.31%.

The authors wish to express their thanks to Dr. Kazuo Tori, Shionogi Research Laboratory, for his helpful discussion.

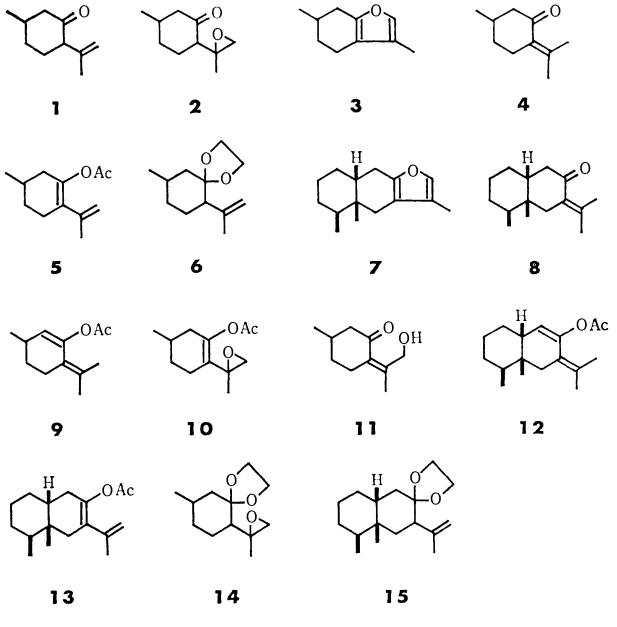
(Received April 27, 1979)

Synopsis. Pulegone was transformed into isopulegone enol acetate or isopulegone ethylene acetal, which was treated with *m*-chloroperbenzoic acid and then with acid to give menthofuran. Fukinone was converted into furanoeremophilane by the same procedure.

It has been reported that oxidation of isopulegone (**1**) with perbenzoic acid and subsequent treatment of a keto epoxide (**2**) with hot dilute acid give menthofuran (**3**) in 13% yield.[2)] The present paper deals with a convenient preparation of **3** from pulegone (**4**) *via* isopulegone enol acetate (**5**) or isopulegone ethylene acetal (**6**). Although the preparation is similar to that reported, the yield was much improved. Preparation of furanoeremophilane (**7**) from fukinone (**8**) by the same procedure is described.

Enol acetylation of pulegone (**4**) gave a mixture of **5** and pulegone enol acetate (**9**) quantitatively in a *ca.* 5:3 ratio. Enol acetate (**5**) with isopropenyl double bond was isolated in 59% yield, epoxidized with *m*-chloroperbenzoic acid in the presence of phosphate buffer solution (pH 7.2),[3)] and the reaction mixture was treated with *p*-toluenesulfonic acid to afford menthofuran (**3**)[4)] in 68% yield. The reaction of **5** to form **3**[1,5)] may proceed through an epoxide (**10**) and (or) a hydroxy ketone (**11**)[6)] as an intermediate. However, no information could be obtained about the intermediate due to its labile nature.

Similarly, fukinone (**8**)[7)] was enol acetylated to give two enol acetates **12** and **13** in 27% and 40% yields, respectively. The enol acetate (**13**) was treated successively with *m*-chloroperbenzoic acid and *p*-toluenesulfonic acid to afford furanoeremophilane (**7**)[8)] in 42% yield.



Acetalization of pulegone (**4**) proceeded quantitatively to give **6**. Epoxidation of **6** with *m*-chloroperbenzoic acid gave an epoxide (**14**) in 89% yield showing two peaks in a *ca.* 2:1 ratio on GLC examination. The major epoxide was separated by means of preparative TLC and converted into menthofuran (**3**) by acid treatment (2 M hydrochloric acid–pentane).[9)] When the reaction was carried out without separation of the intermediates **6** and **14**, **3** was obtained from **4** in 90% yield.

An ethylene acetal (**15**) with terminal double bond was formed as the sole product on acetalization of fukinone (**8**). Treatment of **15** with peroxy acid and then with acid gave furanoeremophilane (**7**) in 74% yield from **15**.

These two methods are useful for the synthesis of 3-methylfuran derivatives from α-isopropylidene ketones.

Experimental

UV spectra were measured on a Hitachi 124 spectrophotometer, and high resolution mass (MS) spectra on a JEOL JMS-D300 spectrometer. Other details are the same as described in a previous paper.[10)]

Enol Acetylation of Pulegone (4). A mixture of **4** (3.60 g), isopropenyl acetate (4.17 g), and *p*-toluenesulfonic acid (0.5 g) was stirred under nitrogen at room temperature for 15 h. The reaction mixture was passed through a column of silica gel (100 g). An excess of isopropenyl acetate was eluted with pentane. Elution with pentane–ether (50:1) afforded isopulegone enol acetate (**5**; 2.69 g; yield 59%), an oil (one spot on TLC), bp 74.5—77 °C/533 Pa; IR (neat) 1760, 1635, and 900 cm^{-1}; UV_{max} (EtOH) 223 nm (ε 5700); NMR (CS_2) δ 0.88 (3H, d, J=6 Hz), 1.74 (3H, d-like, J=1.5 Hz), 1.92 (3H, s), and 4.73 (2H, m); NMR (CCl_4) δ 1.03 (3H, d, J=6 Hz), 1.78 (3H, d-like, J=1.5 Hz), 1.98 (3H, s), and 4.77 (2H, m). Found: *m/e* 194.1308. Calcd for $C_{12}H_{18}O_2$: M, 194.1307. Successive elution with the same solvents gave pulegone enol acetate (**9**; 1.50 g; yield 33%), an oil (one spot on TLC); IR (neat) 1760 cm^{-1}; UV_{max} (EtOH) 241 nm (ε 3400); NMR (CCl_4) δ 1.00 (3H, d, J=6.5 Hz), 1.74 (3H, br. s), 1.82 (3H, br. s), 2.00 (3H, s), and 5.07 (1H, d, J=3 Hz). Found: *m/e* 194.1278. Calcd for $C_{12}H_{18}O_2$: M, 194.1307.

Menthofuran (3) from Isopulegone Enol Acetate (5). A buffer solution (pH 7.2; 20 ml; prepared from KH_2PO_4–NaOH–H_2O) and *m*-chloroperbenzoic acid (2.3 g) in ether (30 ml) were added to a solution of **5** (250 mg) in ether (10 ml) at 0 °C, and the mixture was stirred for 30 min. The organic layer was washed with a 10% aqueous sodium thiosulfate solution and treated with *p*-toluenesulfonic acid (30 mg) in ether at room temperature for 2 min. The ethereal solution was washed with a 5% sodium hydroxide solution and brine, dried ($MgSO_4$) and evaporated, giving a residue which was chromatographed (silica gel, 5 g; elution with pentane) to

afford menthofuran (**3**; 132 mg; yield 68%), an oil (one spot on TLC); IR (neat) 1635 and 1560 cm^{-1}; NMR (CS_2) δ 1.09 (3H, d, J=5.5 Hz), 1.85 (3H, d, J=2 Hz), and 6.84 (1H, m); NMR (CCl_4) δ 1.06 (3H, d, J=5.5 Hz), 1.86 (3H, d, J=2 Hz), and 6.88 (1H, m). Found: *m/e* 150.1032. Calcd for $C_{10}H_{14}O$: M, 150.1045.

Furanoeremophilane (7) from Fukinone (8). Fukinone (**8**; 351 mg) was treated with isopropenyl acetate (300 mg) in the presence of *p*-toluenesulfonic acid (50 mg) under nitrogen with stirring at room temperature for 15 h. The reaction mixture was passed through a column of silica gel (10 g). An excess of isopropenyl acetate was eluted with pentane. Elution with pentane–ether (25: 1) gave an enol acetate (**13**; 164 mg; yield 40%), an oil (one spot on TLC); IR (neat) 1760 and 895 cm^{-1}; NMR (CS_2) δ 0.88 (3H, d, J=6.5 Hz), 0.91 (3H, s), 1.73 (3H, d-like, J=1.5 Hz), 1.92 (3H, s), 4.68 (1H, m), and 4.77 (1H, m); MS *m/e* 262 (M^+). Successive elution with the same solvent mixture gave another enol acetate (**12**; 114 mg; yield 27%), an oil (one spot on TLC); IR (neat) 1760 cm^{-1}; NMR (CS_2) δ 0.70 (3H, d, J=6 Hz), 0.90 (3H, s), 1.74 (3H, br s), 1.81 (3H, br s), 2.00 (3H, s), and 4.80 (1H, d, J=3 Hz); MS *m/e* 262 (M^+).

The enol acetate (**13**; 85 mg) was dissolved in ether (10 ml), and treated with *m*-chloroperbenzoic acid (650 mg) in ether (50 ml) at 0 °C for 1 h with stirring in the presence of the phosphate buffer solution (10 ml; *vide supra*). The organic layer was treated as described above (including the treatment with *p*-toluenesulfonic acid, 10 mg) to give a residue which was chromatographed (silica gel, 5 g; elution with pentane) to give furanoeremophilane (**7**; 30 mg; yield 42%). The IR and NMR spectra were identical with those of an authentic **7**.[8]

Acetalization of Pulegone (4). Ethylene glycol (2.5 ml) and *p*-toluenesulfonic acid (100 mg) were added to a solution of **4** (2.24 g) in benzene (20 ml) and the mixture was refluxed under nitrogen for 7.5 h using a Dean-Stark water separator. The organic layer was washed with aqueous sodium hydrogencarbonate solution and brine, dried ($MgSO_4$), and evaporated, giving a residue. This was passed through a column of silica gel (30 g) [elution with hexane–ether (20: 1)] to give isopulegone ethylene acetal (**6**; 2.84 g; yield 98%), an oil showing one spot on TLC and one peak at R_t=8.7 min on GLC examination [column, SP-1000 (10%), 3(mm)×2(m); 160 °C; N_2 flow rate, 40 ml/min]; IR (neat) 1640 and 890 cm^{-1}; NMR (CCl_4) δ 0.90 (3H, d, J=6 Hz), 1.74 (3H, m), 3.78 (4H, br s), and 4.74 (2H, m). Found: *m/e* 196.1455. Calcd for $C_{12}H_{20}O_2$: M, 196.1464.

Menthofuran (3) from Isopulegone Ethylene Acetal (6). A solution of *m*-chloroperbenzoic acid (266 mg) in ether (20 ml) was added to **6** (304 mg) in ether (10 ml) at 0 °C, and the mixture was stirred for 15 h. The ethereal solution was washed with a 10% aqueous sodium thiosulfate solution, aqueous sodium hydroxide solution and brine, and dried ($MgSO_4$). The solvent was removed under reduced pressure (at below 20 °C) to give a residue which was chromatographed on a column of Florisil (5 g). Elution with pentane–ether (5: 1) gave an epoxide (**14**; 294 mg; yield 89%) as an oil. The epoxide (**14**) showed two spots on TLC and two peaks at R_t=10.1 min (a major epoxide) and R_t=10.8 min (a minor epoxide) in a ratio of *ca.* 2: 1 on GLC examination under the same conditions as described above. Epoxide (**14**) was further chromatographed [silica gel, 3 g; elution with pentane–ether (5: 1)] to afford the major epoxide, an oil (one spot on TLC); NMR (CCl_4) δ 0.89 (3H, d, J=6 Hz), 1.19 (3H, s), 2.46 and 2.67 (each 1H, J=6 Hz, CH_2 in an oxirane ring), and 3.86 (4H, m, O–CH_2–CH_2–O). Found; C, 68.05; H, 9.58%. Calcd for $C_{12}H_{20}O_3$: C, 67.89: H, 9.50%. The minor epoxide could not be obtained as a pure sample.

To this major epoxide (1024 mg) in pentane (15 ml) was added 2 M hydrochloric acid (15 ml), and the mixture was stirred at room temperature for 1.5 h. The pentane layer was separated and the aqueous layer was further extracted with pentane (total 50 ml). A combined pentane solution was washed with aqueous sodium hydrogencarbonate solution and brine, dried ($MgSO_4$), and evaporated (at below 28 °C), giving a residue which was chromatographed on a column of Florisil (5 g). Elution with pentane afforded menthofuran (**3**; 674 mg) in 93% yield, identical (IR, NMR, MS, and TLC) with the authentic sample (*vide supra*).

Acetalization of Fukinone (8). Fukinone (160 mg) in benzene (7 ml) was acetalized with ethylene glycol (1 ml) in the presence of *p*-toluenesulfonic acid (30 mg; in benzene, 5 ml) under reflux (12 h) using a Dean-Stark water separator. After the usual work-up, the residue was chromatographed [silica gel, 10 g; elution with hexane–ether (20: 1)] to give an ethylene acetal (**15**; 112 mg) in 58% yield, an oil (one spot on TLC); IR (neat) 1635 and 890 cm^{-1}; NMR (CCl_4) δ 0.88 (3H, d, J=5 Hz), 0.97 (3H, s), 1.78 (3H, m), 3.78 (4H, m), and 4.50 (2H, m); MS *m/e* 264 (M^+). Further elution with the same solvents gave fukinone.

Furanoeremophilane (7) from the Ethylene Acetal (15). A solution of **15** (44 mg) in ether (10 ml) was epoxidized with *m*-chloroperbenzoic acid (55 mg; in ether, 20 ml) at 0 °C (4.5 h). The ether solution was washed with a 10% aqueous sodium thiosulfate solution, a 5% sodium hydroxide solution, and brine, and then treated with 2M hydrochloric acid (10 ml) under nitrogen at room temperature for 20 min. The ether layer was separated and the aqueous layer was further extracted with ether (total 20 ml). The combined ether solution was treated as usual to give a residue which was chromatographed on a column of silica gel (2 g). Elution with pentane afforded furanoeremophilane (**7**; 27 mg; yield 74%), identical with the authentic specimen.[8]

Selective Spectrophotometric Determination of Zinc with Di-2-pyridylmethanone 2-Pyrimidylhydrazone

R. B. SINGH, H. KULSHRESHTHA, B. S. GARG, and R. P. SINGH*

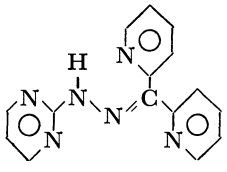
Department of Chemistry, University of Delhi, Delhi 110007, India

(Received December 4, 1978)

Synopsis. Synthesis of a new 2-pyrimidylhydrazone *i.e.* di-2-pyridylmethanone 2-pyrimidylhydrazone (DPMPH) and its application in the selective determination of micro-amounts of zinc is presented. DPMPH reacts with zinc to form a yellow complex in the pH range 7.9—11.1 with molar absorptivity 5.2×10^4 l mol^{-1} cm^{-1} at 430 nm. Beer's law is obeyed upto 1.56 ppm of zinc. Zinc has also been determined in several alloys.

In recent years many nitrogen containing heterocyclic hydrazones derived from 2-hydrazinopyridine[1-4] and 2-hydrazinoquinoline[5-8] have been prepared and tested as possible analytical reagents. Lions *et al.*[9,10] first reported the analytical properties of these compounds. However, hydrazones derived from 2-hydrazinopyrimidine have not been investigated in detail for analytical purpose.

In this note, synthesis of di-2-pyridylmethanone 2-pyrimidylhydrazone (DPMPH, I) and its application in the determination of micro-amounts of zinc is described.



DPMPH, I

This method is based upon a differential demasking technique proposed by Platte and Marcy.[11] According to this technique utilized here zinc was determined with DPMPH in the presence of interfering metals, such as iron and copper. The cyanide complexes of the metals present in the solution were formed and the zinc complex was preferentially destroyed by chloral hydrate. The zinc–DPMPH complex formed by the liberated zinc was measured spectrophotometrically, before interfering metals were liberated from its cyanide complex. It was reported[12-14] that the cyanide complexes of Cu(II) and Fe(III) are not stable enough to prevent interferences of copper and iron in the determination of zinc according to the above procedure and the reduction of Cu(II) and Fe(III) with ascorbic acid was proposed.[15] The Cu(I) and Fe(II) cyanide complexes are more stable against chloral hydrate.

Experimental

Apparatus. A Unicam SP600 spectrophotometer was used for measuring absorbance and a Beckman Expandomatic SS-2 pH meter was used for pH measurements.

Reagents. *Synthesis of Di-2-pyridylmethanone 2-Pyrimidylhydrazone*: 2-Chloropyrimidine was prepared by the method of Kogon *et al.*[16] and converted to 2-hydrazinopyrimidine by the method of Shirakawa *et al.*[17] An ethanolic solution of equimolar quantities of 2-hydrazinopyrimidine and di-2-pyridylmethanone (Fluka A. G.) was refluxed for 6 h. The residue obtained after the removal of ethanol, by using a rotatory evaporator, was crystallized from benzene to give pale yellow crystals (mp 160 °C). Purity was checked by TLC. Elemental analysis confirmed the synthesis (Calcd: C, 65.2; H, 4.3%. Found: C, 65.5; H, 4.9%).

DPMPH solutions were prepared in ethanol (95%) and stored in amber glass bottles. Such solutions are stable for several weeks.

Ascorbic Acid Solution (10% w/v): This solution was prepared on alternate days and stored in amber glass bottles.

Buffer Solution: Borax (4.5 g) and KCN (0.2 g) were dissolved in 20 ml of 4 M NaOH and the solution was diluted to 50 ml with distilled water. When 1 ml of buffer is mixed with 5 ml of working standard or blank, the resulting pH should fall between 8.5—9.5 usually. If it does not, the preparation must then be repeated by changing the amount of alkali added and the pH is checked again. Once the final conditions have been established for this solution, it is easy to prepare new buffer when it is needed.

Standard Zinc Solution: A standard solution of zinc was prepared by dissolving the analytical reagent grade zinc sulfate heptahydrate in doubly distilled water.

Chloral Hydrate Solution (1.5%): Chloral hydrate solution was prepared for differential demasking of zinc from cyanide complex.

All other solutions were prepared with analytical grade reagents in doubly distilled water.

Recommended Procedure. To an aliquot containing 2.6—13.0 μg of Zn(II), add 1 ml of ascorbic acid solution, followed by 2 ml of buffer solution. Then add 1 ml of ethanolic 10^{-2} M solution of DPMPH and dilute the contents to 10 ml. Measure the absorbance of the solution within 25 min after the addition of DPMPH at 430 nm against reagent blank prepared under the identical conditions.

Absorption Spectra, Effect of pH *and Reagent Concentration*: A pH study of the complexation of DPMPH with Zn(II) showed that the yellow complex (λ_{max}=430 nm) gives a constant absorbance in the pH range 7.9—11.1. Carrying out the proposed procedure it has been found that the pH adjustment in the desirable range was more effectively achieved when the buffer solution and the masking agent *i.e.* the cyanide, are added simultaneously. It was observed that a separate addition of cyanide and buffer, irrespective of their order of addition, did not give good results in pH adjustments. For complete complexation 6-fold excess of reagent is necessary. The absorbance of the reagent at the wavelength of maximum absorbance of its zinc complex *i.e.* at 430 nm, is negligible. This is advantageous because the excess of reagent is not critical.

Stability of the Complex. It was also observed that addition of chloral hydrate is not necessary after the addition of DPMPH, for the destruction of zinc–CN complex and for full colour development. The zinc–CN complex is completely

destroyed within 5 min and zinc–DPMPH is formed even in the absence of chloral hydrate. This must be related to the strength of the stability constants of zinc–CN and zinc–DPMPH complexes. This complex is stable upto 25 min. While by addition of chloral hydrate (1.5%) solution, zinc–DPMPH complex is formed as soon as it is added and remains stable for 5 min, then it diminishes. However, full colour development takes place in both the cases. Hence readings of the absorbance of the test solution should be taken within 5—25 min after the addition of DPMPH in the first case and within 5 min in the second case.

Effect of Diverse Ions: Synthetic solutions containing known amounts of zinc(II) and varying amounts of diverse ions were prepared and the recommended procedure was followed for the determination of zinc(II). An error of $\pm 2\%$ in the absorbance reading was considered tolerable. In the determination of 0.65 ppm of zinc, the ions tolerated (given in ppm in parentheses) are as follows:

Chloride, bromide, iodide, fluoride, citrate, tartrate, thiourea, acetate, sulfite, nitrite, nitrate (2000 ppm each); thiocyanate (1000 ppm); thiosulfate, oxalate (500 ppm each); phosphate (150 ppm); Ca(II), Sr(II), Ba(II), Mg(II), Pb(II), Mo(VI), W(VI) (1000 ppm each); Al(III), Sn(II), Be(II), Sb(III), (800 ppm each); Ru(III), Rh(III), Ir(III), Au(III), Os(VIII), Ti(IV), Mn(II), Ag(I) (500 ppm each); Pd(II), Ni(II), Co(II), Cd(II), Hg(II), V(V) (200 ppm each); Cu(II) and Fe(II) (100 ppm each). However, EDTA interferes seriously.

Calibration Curve: Beer's law is obeyed upto 1.56 ppm of Zn(II) in presence or absence of chloral hydrate. The optimum concentration range evaluated by Ringbom's method is 0.26—1.30 ppm. The Sandell's sensitivity is 0.0012 μg Zn cm^{-2} and the molar absorptivity is 5.2×10^4 l mol^{-1} cm^{-1} at 430 nm. The composition of the complex as determined by Job's method of continuous variations shows that metal to ligand ratio is 1 : 2.

Determination of Zinc in Alloys. Dissolve 1.0 g of brass or gun metal in 10 ml of concentrated nitric acid, evaporate to dryness, extract with 4 ml of concentrated sulfuric acid and dilute to 250 ml.

Table 1. Determination of zinc (in %) in alloys

Alloy	Zn reported	Zn found	n[a)]	R.s.d. (%)
Brass (BCS No. 5g)	30.0	29.8	6	1.40
Gun metal (BCS No. 6g)	1.5	1.43	6	2.96
6% Zn–Al alloy (BCS No. 300)	5.98	5.76	6	1.49

a) The average of n determinations is reported with the relative standard deviation.

Dissolve 1.0 g of the aluminium alloy in aqua regia, evaporate to small volume, add 10 ml of concentrated hydrochloric acid and dilute to 250 ml.

Suitable aliquot solution is taken and recommended general procedure is followed for the determination of zinc in alloys. The results of alloy analysis are summarized in Table 1.

Selective and sensitive method for the determination of zinc is proposed. Determination can be carried out in aqueous solutions and there is no need of extraction *etc.* Zinc can be determined in alloys, without its separation from other metals present in the alloys.

Authors are thankful to the Centre of Advanced Studies in Chemistry, University of Delhi (India) for the award of teacher-fellowship to one of them (RBS).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (10), 3133 (1979)

On Thallium(I) Chelates of 1,2-Cyclohexanediamine-*N,N,N',N'*-tetraacetic Acid and Diethylenetriaminepentaacetic Acid

Giorgio ANDEREGG* and Emilio BOTTARI
Laboratorium für Anorganische Chemie, ETHZ, 8092-Zürich, Switzerland

(Received February 8, 1979)

Synopsis. The stability constants of the complexes mentioned in the title obtained by us by potentiometric pH measurements are compared with those of Kodama *et al.* Because sodium ion forms quite a stable 1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetate (CyDTA) complex, the discrepancy of the values can be explained. Further new calculations confirm the formation of protonated chelate with CyDTA but in a very limited pH range.

Kodama *et al.* have determined the stability constants of thallium(I) complexes with diethylenetriaminepentaacetate (DTPA)[1] and 1,2-cyclohexanetetraacetate (CyDTA)[2] ions using polarographic measurements. Their values (K. and T.) are given together with those obtained by us[3] (A. and B.) with pH measurements in the Table 1. The difference between the results of the two works can be partly caused by the different ionic strengths used but the discrepancies with CyDTA as ligand is too large to be explained in this manner. The preference given by us to the potassium nitrate as inert salt is justified by the fact that potassium ion forms very weak complexes with amino polycarboxylate ligands and the ligand protonation constants in this medium at $I=0.1$ are known.[4,5] Kodama and Tominaga have preferred $NaClO_4$ solutions ($I=0.4$ resp. 0.3) in spite of the greater stability of the sodium complexes[4,7] and have calculated the dissociation constants of the acids using the pK values of Schwarzenbach and Ackermann,[6] correcting for the change in the ionic strength by means of the Davies equation. The calculation of the activity coefficients of high charged ions as those involved here can only give very approximative results. Further the pK value of $HCyDTA^{3-}$ of the above work was found to be too low.[5] The better agreement of the results in the case of DTPA indicates that the discrepancies for CyDTA cannot be due only to these reasons.

K. and T. followed from the constancy of $(E_{1/2})_{Tl^{Z}}$ in the pH range from 10 to 11.7 the formation of the protonated chelate $TlHZ^{2-}$. This constancy is due to the fact that beside the unprotonated complex TlZ^{3-} "uncomplexed" ligand is mainly present as sodium complex NaZ^{3-} in that pH range. Indeed from our pK values[4,5] and some new measurements—the pK of $HCyDTA^{3-}$ at $I=0.1$ ($NaNO_3$) and 20 °C is found to be 9.80—for that complex a stability constant of approximately $10^{2.7}$ is estimated. Therefore in 0.3 ($NaClO_4$) and pH=10 already more than 80% of the uncomplexed ligand is present as NaZ^{3-}. As described in our work[3] for the determination of the stability of the thallium(I) complexes alkalimetric titration have been used, in which solutions containing the diprotonated ligand H_2Z^- and thallium(I) nitrate have been titrated with 0.1 M KOH. In Fig. 1 of reference[3] the curve obtained with EDTA as ligand is given. Starting from 100 ml of a solution containing 10^{-4} mol H_2CyDTA and Tl^+ by addition of 0.1 M KOH the following data have been obtained: (ml/pH): 0.4/5.919: 0.6/6.259: 0.8/6.686: 0.9/6.986: 0.95/7.178: 1.0/7.409: 1.05/7.637: 1.1/7.823: 1.2/8.136: 1.3/8.399: 1.4/8.626: 1.5/8.858: 1.6/9.098: 1.65/9.218: 1.7/9.478: 1.8/9.605. The calculations were done considering the following equilibria:

$$H_2L^{2-} \overset{pK_3}{\rightleftharpoons} HL^{3-} \overset{pK_4}{\rightleftharpoons} L^{4-}$$

$$Tl^+ + H_2L^{2-} \rightleftharpoons TlHL^{2-} \rightleftharpoons TlL^{3-}$$

and inserting for pK_3 6.12 and pK_4 12.3.

New calculations show that in the solutions at lower pH, between 5 and 8, also $TlHL^{2-}$ is formed, being its maximal concentration always lower than 10% of the total amount of the metal ion. The values given in the table are calculated using differents titration curves. As found by K. and T. Tl^+ forms with CyDTA also an hydrogen complex $TlHL^{2-}$, with a limited pH range of existence (pK of $TlHL^{2-}$=7.32).

An Ultrasonic Absorption Study of the DMF–Water System

Fumio KAWAIZUMI,* Hiroyasu NOMURA, Makoto OHNO, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received September 12, 1978)

Using the pulse method, the ultrasonic absorption was measured for binary mixtures of water and *N*,*N*-dimethylformamide (DMF) at 5.5 and 57 MHz in the temperature range of 5—45 °C. At lower temperatures α/f^2 as a function of the concentration produces a plateau up to x (x is the mole percent of DMF in solution)= 1.5, a minimum point at $x=6$, and a maximum point at $x=25$. An increase in the temperature causes these characteristic features of α/f^2 to disappear. At 45 °C the values of α/f^2 increase monotonically. No relaxation process is observed in the frequency range of this work. The general features of the concentration dependence of α/f^2 resemble those of the urea–water system in a water-rich region and those of the dioxane–water system in a DMF-rich region. The mechanism of the plateau can be explained by the cooperative nature of the formation and breaking of water clusters. The maximum of α/f^2 is ascribed to the complex formation between DMF and water molecules, while the minimum of α/f^2 arises from the competition between the breaking-down of the water structure and the complex formation in solution. The maximum behavior in the ultrasonic absorption can be interpreted in terms of a kinetic model, $DMF+mH_2O \rightleftharpoons DMF\cdot(H_2O)_m$. m is determined to be 3, and the following values have been obtained for the model mentioned above: $\Delta V_m \simeq 1$ cm³/mol, $K_m=10\pm2$.

In a previous paper[1] the ultrasonic and volumetric behavior of aqueous solutions of amides (*N*-methylformamide, *N*,*N*-dimethylformamide and *N*,*N*-dimethylacetamide) was studied at 25 and 35 °C over the entire concentration range. The velocity maxima were observed for all three of the amide solutions, while the minima in the partial molar volume were observed for DMF and DMAA. A tentative interpretation has been proposed that the velocity maxima are ascribable to the complex formation between water and amide molecules, while the minima in the partial molar volume are to be ascribed to the competition between the volume increase due to the complex formation and the volume decrease due to the breaking-down of the water structure.

In order to obtain further information on the interaction between water and amide molecules, ultrasonic absorption measurements have been carried out on the DMF–water system. From among three types of amide–water systems investigated previously, the DMF–water system is chosen because this system is one of the most widely used systems of polar mixed solvents.

Experimental

The DMF used was of a spectral grade obtained from Nakarai Chemicals and was used without further purification. The distilled water was degassed prior to each measurement.

The ultrasonic pulse method was used for the measuremet of the absorption coefficients of solutions. The details of the apparatus and the experimental procedures have been reported previously.[2,3] The measurements of the absorption coefficient were done at 5.5 and 57 MHz in the temperature range of 5—45 °C. The data are reproducible within ±1% at 57 MHz and within 5% at 5.5 MHz. The temperature was controlled to ±0.1 °C.

Results

Temperature and Concentration Dependences of α/f^2. Figure 1 shows the concentration dependences of α/f^2 at various temperatures. At lower temperatures, the curves show a minimum point at x (x is the mole percent of DMF in solution)=5—8 and a maximum point at *ca.* $x=25$. With the rise in the temperature, the height of $(\alpha/f^2)_{max}$ and the depth of $(\alpha/f^2)_{min}$ decrease, and the width of the maximum peak shows a broadening with a slight shift of PSAC (the peak sound absorption concentration) towards higher concentrations of DMF. At temperatures higher than 35 °C, the minimum and the maximum points disappear and the values of α/f^2 increase monotonically. The appearance of the minimum point in the relation of α/f^2 *vs.* concentration in a small concentration of solute has not been observed in other aqueous solutions of nonelectrolytes except the work of Takenaka *et al.*[4] who found the appearance of the minimum in the α/f^2 *vs.* concentration curves for this system (20 and 25 °C, 15—45 MHz), but who mentioned nothing further about it.

Figure 2 is an expanded representation of Fig. 1 in the water-rich region. Two characteristic features should be noted regarding the temperature dependence of α/f^2 in this region. The first is, as has been described above, the appearance of the minimum point, while the second is the appearance of the plateau, in which α/f^2 is relatively insensitive to the quantity of DMF added. With a decrease in the temperature, this region increases from $x=0$ at 45 °C to $x=2$ at 5 °C. At 35 °C, the values of α/f^2 remain constant up to $x=7$, but this constant-value region does not correspond to the true plateau. From the comparison of the plateau region at different temperatures, it may be concluded that the constant-value region observed at 35 °C is the result of the opposite effects of the decrease of α/f^2 in the 2—6 mol% concentration range and the increase of α/f^2 in the concentration range of more than 6 mol%. The overlooking of the plateau in this system by Takenaka *et al.*[4] is due to the incompleteness of their measurements.

The general behavior of the DMF–water system in a small concentration of a solute shown in Fig. 2 resembles the results observed by Arakawa *et al.*[5] in the aqueous solutions of urea and guanidine hydrochloride. In urea solutions, the magnitudes of α/f^2 first decreased very slowly (it is more correct to say that the α/f^2 remains constant) with the concentration, and then, decreased rapidly in the range *ca.* 0.5 to

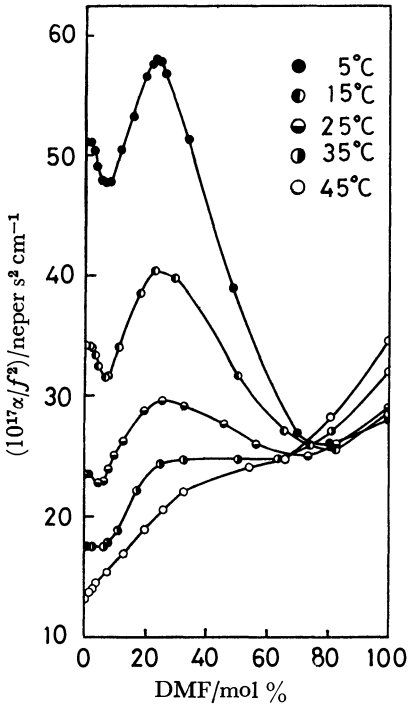

Fig. 1. Temperature and concentration dependence of α/f^2 in DMF–water system.

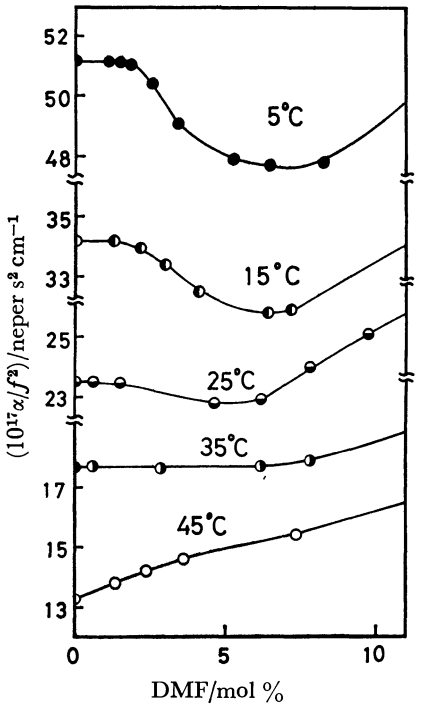

Fig. 2. Expanded representation of Fig. 1 in water-rich region.

3 M. The temperature rise causes these concentration dependences to disappear. The similarities between the urea–water system and the present one will be clearer if the results shown in Fig. 2 are represented in a molar scale (see Fig. 6(a) of Ref. 5).

As is shown in Fig. 1, in the DMF-rich region the values of α/f^2 measured at higher temperatures are larger than those measured at lower temperatures. These phenomena correspond well to those observed in the dioxane–water system.[5]

Frequency Dependence of α/f^2. The values of α/f^2 at 5.5 MHz are always larger than those at 57 MHz. However, the differences are so small (at most 4×10^{-17} neper s^2 cm^{-1} at 25 °C) that it is reasonable to conclude that the relaxation process does not exist in the present frequency range. Takenaka *et al.*[4] have also reported that the relaxation process is not observed in the frequency range of 15—45 MHz.

Discussion

Plateau and Minimum in the Water-rich Region. In spite of many theories of water structure and the ambiguities involved in them, it is widely recognized that the temperature-rise breaks down the hydrogen-bonding of water, resulting in increases in the fraction of unbonded or smaller-cluster molecules in water. The ultrasonic absorption coefficient of water, expressed as α/f^2 decreases monotonically with the temperature. The variation in the relation of α/f^2 *vs.* concentration in a small concentration of solute reflects the effects of the addition of DMF upon the water structure. The present experimental results indicate that the added DMF molecules have the same effects as the temperature-rise upon the ultrasonic absorption coefficient. Therefore, DMF molecules act as a structure breaker in water. Some experimental evidences have been found that DMF is a water-structure breaker.[7–9]

As has already been mentioned in the preceding section, the behavior of α/f^2 observed in the urea–water system and in the present one in their water-rich regions is very similar. Urea acts as a water-structure breaker. Both urea and DMF molecules have the $\rangle$N–C– group. These facts led us to adopt
O
the same interpretation of the concentration dependence of α/f^2 in the DMF–water system in a small concentration region of the solute as that proposed for the urea–water system.[5] Arakawa *et al.*[5] have argued that the characteristic feature in the α/f^2 *vs.* concentration curve found in the small concentration region is attributable to the cooperative nature of the formation and breaking of water clusters. When a very small amount of DMF is added to water, the influence of the DMF molecules upon the structure of water is isolated and the cooperative formation of clusters is not affected by the added DMF. When the amount of DMF is greater, however, the influence becomes appreciable and DMF affects the clusters cooperatively, disrupting them into unbonded monomers and/or small clusters.

Blandamer[6] has insisted that, if the liquid clathrate model is accepted, the plateau region is the zone of the enhanced water structure in the system of water–alcohols (alcohols are water-structure formers). His interpretation, however, can not be applied in the present system, for the DMF molecule is a water-structure breaker.[7–9]

The minimum sound absorption concentration

(hereafter abbreviated as MSAC) corresponds to the concentration at which the partial molar volume of DMF reaches a minimum point. MSAC becomes more remarkable with a decrease in the temperature. This phenomenon suggests that MSAC is intimately related to the structure of water. In the preceding paper,[1] the minimum in the partial molar volume of DMF in the aqueous solution is ascribed to the competition between the volume increase due to the complex formation and the volume decrease due to the breaking-down of the water structure. A similar conclusion can be drawn in the case of MSAC observed in the present work. In other words, MSAC arises from the competition between the decrease in α/f^2 due to the breaking-down of the water structure and the increase in α/f^2 due to the complex formation in DMF with water, which will be discussed below from another point of view.

PSAC and Excess Absorption due to the Complex Formation between DMF and Water. Two different approaches are possible to account for the abnormal ultrasonic absorption in the liquid mixture. One is the fluctuation theory proposed by Romanov *et al.*,[10] while the other is a kinetic model of complex formation between solute and solvent. The following factors indicate that the interpretation based on the complex formation is more suitable in the present system. First, Assarsson and Eirich[11] have shown the complex formation of such alkyl-substituted amides as *N,N*-dimethylacetamide with water from the data of viscosity and the phase diagram of these systems. Therefore, the complex formation in the DMF-water system is higly probable. Second, PSAC agrees fairly well with the concentration of the velocity maximum, *ca.* $x=20$. Third, the peak in the ultrasonic absorption observed in the present system is less steep than in the system consisting of water and alcohols, to which the fluctuation theory has been applied. Finally, the effects of the temperature rise on the PSAC and the width of the maximum peak in the ultrasonic absorption are small in comparison with those found in the aqueous solutions of alcohols.

Various kinetic models of complex formation have been put forward.[12] The model adopted by the present authors to interpret the ultrasonic absorption behavior observed in the DMF–water system is represented by this equation:

$$\mathrm{A} + m\mathrm{B} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} \mathrm{AB}_m \qquad \text{(I)}$$

The principal reason for adopting this model is the extreme unsymmetry in the relationships of α/f^2 with the concentration of DMF. In Model (I), it is assumed that the DMF molecule, represented by the symbol A, combines in a single step with m water molecules, represented by the symbol mB. Let the mole fraction, x, of the solute and the z of the complex be such that when the total number of solute and water molecules, including those in the complex, is unity, x is the total number of solute molecules and z is the number of complexes in the A+B⇌AB model. If the variables x and z are transformed to

$$x_m = \frac{x}{x+(1-x)/m} \quad \text{and} \quad z = \frac{z}{x+(1-x)/m},$$

PSAC is situated at $x_m=0.5$ or PSAC$=x=1/(1+m)$. Therefore, in this model, $m=(1-\mathrm{PSAC})/\mathrm{PSAC}$ is the optimum water-to-solute ratio. Using the usual analysis of the ultrasonic absorption data, the following physical properties concerning the excess absorption can be obtained;

$$\mu_{\max}^{\mathrm{excess}} = \frac{\pi}{4}\cdot\frac{dc^2}{V_m RT}(\Delta V_m)^2\frac{(1-\beta_m)}{K_m\beta_m} \qquad (1)$$

$$\Delta V_m = (\partial V/\partial z_m)_{p,T} \qquad (2)$$

$$\beta_m{}^2 = 1 - 4x_m(1-x_m)K_m{}^2/(1+K_m)^2 \qquad (3)$$

and;

$$K_m = z_m/(x_m-z_m)(1-x_m-z_m), \qquad (4)$$

where $\mu_{\max}^{\mathrm{excess}}$, V_m, and K_m refer to the excess absorption per wavelength at the maximum, the molar volume of the complex, and the equilibrium constant in Model (I) respectively. The theory enables a match to be made of the position of the experimental absorption peak by adjusting the value of m, of the height of the peak, by adjusting ΔV_m, and of the mean width of the peak by adjusting K_m. Here m is taken to be 3, as PSAC is found at *ca.* $x=25$ in Fig. 1. μ^{excess} is given by this relation; $\mu^{\mathrm{excess}}=(\alpha/f^2)^{\mathrm{excess}}\cdot fc$, where f is the frequency, and c, the velocity of the ultrasonics.

In the course of calculation, the values of the ultrasonic velocity, c, and the density, d, introduced on the right-hand side of Eq. 1 should not be the real values, but the ones at the "*hypothetical state*" of the solution without complex formation, because only the excess contribution originating from the complex formation is considered. The values of d and c at these "*hypothetical state*," d_{hyp}, and c_{hyp} respectively, were estimated on the basis of the ideal additivity of the volume of solution and the ideal additivity of the compressed volume in solution:

$$V_{\mathrm{hyp}} = x_1V_1 + x_2V_2 = \frac{M_1x_1+M_2x_2}{d_{\mathrm{hyp}}} \qquad (5)$$

$$V_1x_1\kappa_1 + V_2x_2\kappa_2 = V_{\mathrm{hyp}}\kappa_{\mathrm{hyp}} = \frac{M_1x_1+M_2x_2}{d_{\mathrm{hyp}}}\cdot\frac{1}{(c_{\mathrm{hyp}})^2d_{\mathrm{hyp}}} \qquad (6)$$

The final results of calculation are shown in Fig. 3, where PSAC is at $x_m=0.5$, as predicted by Eqs. 1 and 3. The improper choice of m does not lead to the results shown in Fig. 3. The small non-symmetry in the curve of Fig. 3 is not significant and the variation in the mean width of the peak with the temperature can be taken to be negligible if due consideration is paid to the experimental errors and the analysis of the data. The average values of $(x_m)_{1/2}$ are found to be 0.72 and 0.28. As $(x_m)_{1/2}$ is obtained by solving Eq. 3 at $\mu_{\max}^{\mathrm{excess}}/2$, the sum of the two values of $(x_m)_{1/2}$ is always 1. The most appropriate values of K_m compatible with these values of $(x_m)_{1/2}$ were numerically determined through the use of Eqs. 1 and 3: $K_m=10\pm2$. This value and the values of μ^{excess} at PSAC make possible the evaluation of ΔV_m. At this stage, the sign of ΔV_m remains undetermined. It is, however, the same as that of ΔH_m (see Eq. 7 below). The temperature dependence of the latter leads to the assignment of the negative sign to ΔH_m. The values of ΔV_m thus obtained are

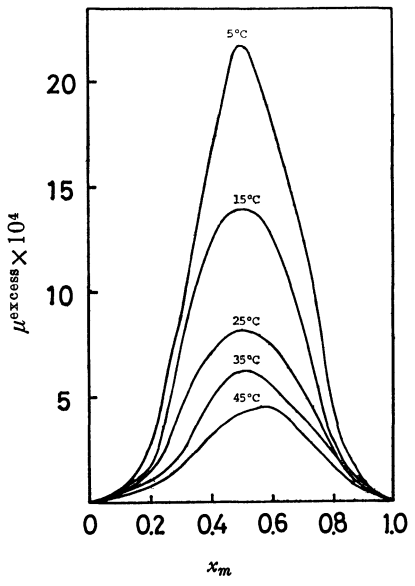

Fig. 3. Excess absorption plotted against x_m at various temperatures.

T/°C	5	15	25	35	45
ΔV_m/cm^3 mol^{-1}	1.12	0.93	0.74	0.67	0.61

These values have been determined on the assumption that the thermal contribution to the relaxation strength of the ultrasonic absorption is negligible compared with the isothermal one. In other words, the observed behavior in the ultrasonic absorption has been ascribed to the volume changes of complex formation between DMF and water. Denote these values of ΔV_m by ΔV_m^{ls}. If we consider that the thermal contribution is dominant in the ultrasonic absorption behavior, the contribution denoted by the enthalpy change, ΔH_m^{th}, can also be estimated. ΔH_m^{th} is obtained with recourse to this equation:

$$V\theta\Delta H_m^{th} = C_p\Delta V_m^{ls} \quad (7)$$

where θ is the volume expansibility of the solution. The basis of Eq. 7 is that the same value of μ_{max}^{excess} is produced either by ΔV_m^{ls} or ΔH_m^{th}. Therefore, the values of ΔH_m^{th} determined by Eq. 7 correspond to those at the maximum contribution. Using the values of $\Delta V_m \simeq 1$ cm^3/mol and θ and C_p data at $x=25$ found in the literature,[13] $\Delta H_m^{th} \simeq 5.06$ J/mol. This value gives the temperature dependence of K_m: 10.7 at 5 °C and 9.4 at 45 °C. The small variations in K_m with the temperature well correspond to the experimental fact that the mean width of the peak in Fig. 3 is almost independent of the temperature in the present system.

The values of ΔV_m^{ls} is small in comparison with the results found in the systems of acetone–, dimethylamine–, methyldiethylamine–, and *n*-amylamine–water.[14] The complex formation in the aqueous solution of DMF produces rather minor changes in the intermolecular distances between DMF and water molecules. The complex formed in the solution becomes looser with an increase in the temperature, as is seen in the variation of ΔV_m with the temperature. This fact confirms the views described in our preceding paper[1] that the structure of the complex in amide–water systems may not be similar to those in an ordinary clathrate-like 17 hydrate or $8X \cdot 136H_2O$.

A part of the cost of this work was defrayed by the support given to F. K. from Hattori Ho-ko-kai.

Effect of Diffusion Layers on Bi-ionic Potentials across Liquid Ion-exchange Membranes

Nobuo YOSHIDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received September 28, 1978)

In a bi-ionic system in which a liquid membrane is interposed between aqueous solutions containing different counterions, the solution composition is often not maintained uniform right up to the membrane–solution interface owing to the presence of diffusion layers adjacent to the interface. Taking the effect of the diffusion layers into account, an expression is derived for the bi-ionic potential across a membrane having completely dissociated ion-exchange sites and counterions. The expression contains as an empirical parameter the ratio between the thicknesses of the diffusion layers at the solution and membrane sides of the interface. The expression is found to agree with experimental data, with the parameter given a single value.

The electric potential difference, V, between two aqueous solutions (′) and (″) separated by a liquid ion-exchange membrane is usually given in the form of the following empirical equation:[1–3]

$$V = \frac{RT}{F} \ln \frac{a_i' + \sum_j K_{i,j}^{pot} a_j'}{a_i'' + \sum_j K_{i,j}^{pot} a_j''}, \quad (1)$$

where a_i and a_j are the activities of univalent counterions i and j, respectively, in solutions (′) and (″), and $K_{i,j}^{pot}$ is the potentiometric selectivity coefficient of ion j over ion i. In particular, when ion-exchange sites and counterions are completely dissociated in the membrane, Eq. 1 was also derived theoretically by Conti and Eisenman,[4] who showed that the selectivity coefficient is given by

$$K_{i,j}^{pot} = \frac{\bar{u}_j k_j}{\bar{u}_i k_i}, \quad (2)$$

where $\bar{u}_i$ and $\bar{u}_j$ are the mobilities of ions i and j, respectively, in the membrane, and k_i and k_j are the single-ion distribution coefficients between the membrane solvent and water. However, Eq. 1 is sometimes observed to be only approximate, since the selectivity coefficient changes with the solution concentration and composition. In a previous study,[5] electric potentials were measured for liquid membranes having dissociated sites and counterions, and the results were compared with those predicted by the Conti-Eisenman theory. The theory was found to be applicable only when the concentrations of aqueous solutions were sufficiently high in comparison with that of an ion exchanger in the membrane. Deviation from the theory occurring in other cases was attributed to the ionic composition at the membrane–solution interface differing from that in the bulk solution owing to the presence of diffusion layers adjacent to the interface. The effect of diffusion layers on the membrane potential has been discussed quantitatively for solid ion-exchange membranes,[6–8] but not for their liquid counterpart.

In the present paper, the Conti-Eisenman theory is extended so as to incorporate the effect of the diffusion layers, and an expression is derived for the membrane potential in a bi-ionic system. The validity of this expression is examined by a comparison with experimental results.[5]

Theoretical

The system considered is a bi-ionic cell in which a liquid membrane with an ion exchanger RY is interposed between two aqueous solutions (′) and (″) containing different counterions X and Y of equal valence z, respectively, but with a common co-ion M of valence z_M:

Solution (′)	Liquid membrane	Solution (″)
MX	RY	MY .

(3)

(The treatment given below can be readily extended to more general systems in which the solutions and membrane contain both counterions.) It is assumed that the ion-exchange sites (R) and counterions are completely dissociated in the membrane and that the aqueous and membrane phases are impermeable to R and M, respectively. In cell (3), a continuous exchange of the counterions occurs across the membrane–solution (′) interface. As a result, the concentrations of the counterions at the interface generally differ from those in the bulk phases, since two diffusion layers (through which the transport of the ions can take place by diffusion only) are present adjacent to the interface. The situation is schematically shown in Fig. 1, where C is the concentration of the counterions; a and b refer to the membrane–solution (′) and membrane–solution (″) interfaces, respectively; a superscript bar refers to the membrane phase; and δ and $\bar{\delta}$ are the thicknesses of the diffusion layers at the solution and membrane sides of interface a, respectively. Contamination of the bulk phases by the counterion exchange, however, is assumed to be negligible in the present treatment.

In order to obtain an expression for the total membrane potential in cell (3), the two phase-boundary potentials ($\bar{\phi}^a - \phi^a$) and ($\phi'' - \bar{\phi}^b$) and the two dif-

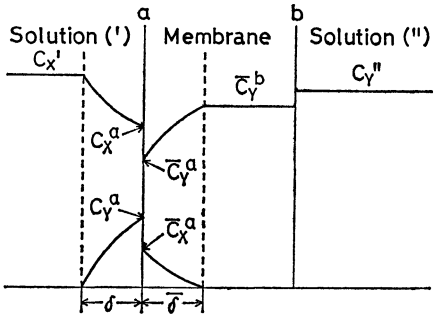

Fig. 1. Concentration profiles of counterions X and Y in the bi-ionic system (schematic).

fusion potentials within the diffusion layers ($\phi^a - \phi'$) and ($\bar{\phi}^b - \bar{\phi}^a$) should be evaluated, where ϕ is the electric potential. If thermodynamic equilibrium is assumed to be established at the membrane–solution interfaces, the electrochemical potentials of the counterions are continuous at the interfaces. Thus we have at interface a,

$$\mu_X^\circ + RT\ln y_X' C_X^a + zF\phi^a = \bar{\mu}_X^\circ + RT\ln \bar{y}_X \bar{C}_X^a + zF\bar{\phi}^a, \quad (4)$$

$$\mu_Y^\circ + RT\ln y_Y' C_Y^a + zF\phi^a = \bar{\mu}_Y^\circ + RT\ln \bar{y}_Y \bar{C}_Y^a + zF\bar{\phi}^a, \quad (5)$$

where μ° is the standard chemical potential and y the activity coefficient, for which the superscript a is not used since it is assumed to be constant throughout the diffusion layers. Rearrangement of Eq. 4 yields

$$\bar{\phi}^a - \phi^a = \frac{RT}{zF}\ln\frac{k_X y_X' C_X^a}{\bar{y}_X \bar{C}_X^a}, \quad (6)$$

where k is the single-ion distribution coefficient defined by

$$k = \exp\left(\frac{\mu^\circ - \bar{\mu}^\circ}{RT}\right). \quad (7)$$

Subtraction of Eq. 4 from Eq. 5 gives

$$\frac{C_Y^a \bar{C}_X^a}{C_X^a \bar{C}_Y^a} = K, \quad (8)$$

where K is the equilibrium selectivity coefficient given by

$$K = \frac{k_X y_X' \bar{y}_Y}{k_Y y_Y' \bar{y}_X}. \quad (9)$$

At interface b, we get an equation corresponding to Eq. 6:

$$\phi'' - \bar{\phi}^b = \frac{RT}{zF}\ln\frac{\bar{y}_Y \bar{C}_Y^b}{k_Y a_Y''}, \quad (10)$$

where a_Y'' is the activity of counterion Y in solution ('').

The diffusion potentials can be evaluated by considering the steady transport of the ions inside the diffusion layers. Expressing the ionic fluxes by the Nernst-Planck equations, we have, for the diffusion layer at the solution side of interface a,

$$J_X = -u_X C_X \frac{d}{dx}(RT\ln C_X + zF\phi) = \text{const}, \quad (11)$$

$$J_Y = -u_Y C_Y \frac{d}{dx}(RT\ln C_Y + zF\phi) = \text{const}, \quad (12)$$

$$J_M = -u_M C_M \frac{d}{dx}(RT\ln C_M + z_M F\phi) = 0, \quad (13)$$

where J is the ionic flux, u the mobility (assumed to be constant throughout the diffusion layer), and x the space coordinate perpendicular to the membrane–solution interfaces. Since no electric current flows through the present system,

$$J_X + J_Y = 0. \quad (14)$$

Substitution of Eqs. 11 and 12 into Eq. 14 yields

$$\frac{d\phi}{dx} = -\frac{RT}{zF}\frac{d\ln(u_X C_X + u_Y C_Y)}{dx}. \quad (15)$$

Integration of Eq. 15 across the diffusion layer leads to

$$\phi^a - \phi' = \frac{RT}{zF}\ln\frac{u_X C_X'}{u_X C_X^a + u_Y C_Y^a}. \quad (16)$$

Alternatively, the electric potential gradient $d\phi/dx$ can be expressed from Eq. 13 as

$$\frac{d\phi}{dx} = -\frac{RT}{z_M F}\frac{d\ln C_M}{dx}, \quad (17)$$

so that

$$\phi^a - \phi' = \frac{RT}{z_M F}\ln\frac{C_M'}{C_M^a}. \quad (18)$$

The diffusion layer at the membrane side of interface a can be treated by regarding the co-ions as the sites in the above calculation. Thus, we get an equation corresponding to Eq. 16:

$$\bar{\phi}^b - \bar{\phi}^a = \frac{RT}{zF}\ln\frac{\bar{u}_X \bar{C}_X^a + \bar{u}_Y \bar{C}_Y^a}{\bar{u}_Y \bar{C}_Y^b}. \quad (19)$$

Combining Eqs. 6, 10, 18, and 19 and using Eqs. 8 and 9, we have the total membrane potential V:

$$V = \phi'' - \phi' = \frac{RT}{F}\left\{\frac{1}{z}\ln\frac{y_Y'(K\bar{r}C_X^a + C_Y^a)}{a_Y''} + \frac{1}{z_M}\ln\frac{C_M'}{C_M^a}\right\}, \quad (20)$$

where

$$\bar{r} = \bar{u}_X/\bar{u}_Y. \quad (21)$$

With the use of the electroneutrality condition

$$zC_X + zC_Y + z_M C_M = 0, \quad (22)$$

Eq. 20 is written as

$$V = \frac{RT}{zF}\ln\left[\frac{y_Y' C_X'}{a_Y''}\left\{(K\bar{r}-1)\frac{C_X^a}{C_X'} + \frac{C_M^a}{C_M'}\right\}\left(\frac{C_M^a}{C_M'}\right)^{-z/z_M}\right]. \quad (23)$$

For the calculation of V the concentrations C_X^a and C_M^a at interface a are required. They can be determined in the following way. It follows from Eqs. 15 and 17 that within the diffusion layer at the solution side,

$$C_M^{-z/z_M}(u_X C_X + u_Y C_Y) = \text{const}. \quad (24)$$

Applying Eq. 24 to both ends of the diffusion layer and taking Eq. 22 into account, we get

$$C_X^a = \frac{z_M}{z}\frac{1 - r(C_M^a/C_M')^{z/z_M - 1}}{r-1}C_M^a \quad (25)$$

or

$$\frac{C_X^a}{C_X'} = \frac{r(C_M^a/C_M')^{z/z_M - 1} - 1}{r-1}\frac{C_M^a}{C_M'}, \quad (26)$$

where

$$r = u_X/u_Y. \quad (27)$$

Likewise, the following relation holds inside the diffusion layer at the membrane side:

$$\bar{C}_R^{-z/z_R}(\bar{u}_X \bar{C}_X + \bar{u}_Y \bar{C}_Y) = \text{const}, \quad (28)$$

so that

$$\bar{C}_X^a = \frac{z_R}{z}\frac{1 - (\bar{C}_R^a/\bar{C}_R^b)^{z/z_R - 1}}{\bar{r}-1}\bar{C}_R^a, \quad (29)$$

where the electroneutrality condition in the membrane

$$z\bar{C}_X + z\bar{C}_Y + z_R\bar{C}_R = 0 \quad (30)$$

has been used. Introducing Eqs. 25 and 29 into Eq. 8, taking Eqs. 22 and 30 into account, we obtain

$$\left(\frac{\bar{C}_R{}^a}{\bar{C}_R{}^b}\right)^{z/z_R-1}=\frac{(K\bar{r}-1)r(C_M{}^a/C_M{}')^{z/z_M-1}-K\bar{r}+r}{(K-1)r(C_M{}^a/C_M{}')^{z/z_M-1}-K+r}. \quad (31)$$

It is now necessary to derive another relationship between the unknown quantities $C_M{}^a$ and $\bar{C}_R{}^a$. Combination of Eqs. 11, 12, and 22 gives

$$\frac{J_X}{u_X}+\frac{J_Y}{u_Y}=\frac{z_M}{z}RT\frac{dC_M}{dx}+z_MFC_M\frac{d\phi}{dx}. \quad (32)$$

Using Eqs. 14 and 17 to eliminate J_Y and $d\phi/dx$ and integrating, we have

$$J_X=\left(1-\frac{z_M}{z}\right)RT\frac{u_X}{r-1}\frac{C_M{}^a-C_M{}'}{\delta}. \quad (33)$$

A similar expression is valid for the diffusion layer at the membrane side:

$$\bar{J}_X=\left(1-\frac{z_R}{z}\right)RT\frac{\bar{u}_X}{\bar{r}-1}\frac{\bar{C}_R{}^b-\bar{C}_R{}^a}{\bar{\delta}}. \quad (34)$$

In the steady state ($J_X=\bar{J}_X$), it follows from Eqs. 33 and 34 that

$$\frac{(C_M{}^a/C_M{}')-1}{1-(\bar{C}_R{}^a/\bar{C}_R{}^b)}=\frac{(1-z_R/z)\bar{u}_X(r-1)\delta\bar{C}_R{}^b}{(1-z_M/z)u_X(\bar{r}-1)\bar{\delta}C_M{}'}. \quad (35)$$

Thus, the membrane potential can be calculated from Eqs. 23, 26, 31, and 35, if the mobilities of the counterions and the quantities K and $\delta/\bar{\delta}$ are known. The effect of the diffusion layers appears through the parameter on the right-hand side of Eq. 35. Two limiting cases are noted. When the parameter is very small, it is seen from Eqs. 35, 31, and 26 that $C_M{}^a/C_M{}'$ and $C_X{}^a/C_X{}'$ approach unity, *viz.*, the effect of the diffusion layers becomes negligible. Under such circumstances Eq. 23 is reduced to the form of Eq. 1 with the selectivity coefficient $K_{Y,X}^{pot}$ given by $\bar{r}(k_X\bar{y}_Y/k_Y\bar{y}_X)$. The latter equation is identical with that of Conti and Eisenman[4] for the system in question, if the ratio of the activity coefficients in the membrane $\bar{y}_Y/\bar{y}_X$ is taken as equal to unity (see Eq. 2). On the other hand, when the above parameter is extremely large, it is found from Eqs. 35, 31, and 26 that $(C_M{}^a/C_M{}')^{1-z/z_M}\to r$ and $C_X{}^a/C_X{}'\to 0$. In other words, the concentration gradient of counterion X (in the diffusion layer at the solution side) reaches its maximum value, and there are no concentration gradients within the membrane. The situation corresponds to what is known as "film diffusion control" in solid membrane systems.[6] For this case the membrane potential is obtained from Eq. 23 as

$$V=\frac{RT}{zF}\ln\frac{ry_Y{}'C_X{}'}{a_Y{}''}. \quad (36)$$

In particular, when the mobilities of the counterions are the same in both solutions and membrane ($u_X=u_Y=u$ and $\bar{u}_X=\bar{u}_Y=\bar{u}$), Eq. 23 takes a simpler form. Since Eqs. 22 and 24 show that the concentration C_M of the co-ions is constant across the diffusion layer, Eq. 23 becomes

$$V=\frac{RT}{zF}\ln\frac{y_Y{}'C_X{}'\{(K-1)(C_X{}^a/C_X{}')+1\}}{a_Y{}''}. \quad (37)$$

Here $C_X{}^a/C_X{}'$ is evaluated as follows. From the constancy of C_M and Eqs. 22, 17, and 11, we get

$$C_Y{}^a=C_X{}'-C_X{}^a, \quad (38)$$

$$J_X=RTu(C_X{}'-C_X{}^a)/\delta. \quad (39)$$

Similarly, for the diffusion layer at the membrane side, we have

$$\bar{C}_Y{}^a=\bar{C}_Y{}^b-\bar{C}_X{}^a, \quad (40)$$

$$\bar{J}_X=RT\bar{u}\bar{C}_X{}^a/\bar{\delta}. \quad (41)$$

Equating Eq. 39 with Eq. 41, we get

$$\bar{C}_X{}^a=(u\bar{\delta}/\bar{u}\delta)(C_X{}'-C_X{}^a). \quad (42)$$

Introducing Eqs. 38, 40, and 42 into Eq. 8 and solving the result with respect to $C_X{}^a/C_X{}'$, we find that

$$\frac{C_X{}^a}{C_X{}'}=\left(\left\{K\left(1-\frac{\bar{u}\delta\bar{C}_Y{}^b}{u\bar{\delta}C_X{}'}\right)-2\right\}+\left[\left\{K\left(1-\frac{\bar{u}\delta\bar{C}_Y{}^b}{u\bar{\delta}C_X{}'}\right)-2\right\}^2+4(K-1)\right]^{1/2}\right)\Big/2(K-1). \quad (43)$$

In this case, the effect of the diffusion layers is given in terms of the parameter $\bar{u}\delta\bar{C}_Y{}^b/u\bar{\delta}C_X{}'$. It is negligible when $\bar{u}\delta\bar{C}_Y{}^b/u\bar{\delta}C_X{}'\to 0$, and largest when $\bar{u}\delta\bar{C}_Y{}^b/u\bar{\delta}C_X{}'\to\infty$.

Comparison with Experimental Results

Experimental data were reported for the bi-ionic potentials across liquid anion membranes [nitrobenzene solutions of a Crystal Violet (CV) salt] separating aqueous solutions containing $NaClO_4$, NaSCN, or NaI.[5] Values of k_X/k_Y were also determined by measuring the distribution coefficients of the counterions between nitrobenzene and water. The results are as follows: $k(ClO_4^-)/k(I^-)=84.7$, $k(ClO_4^-)/k(SCN^-)=27.0$, $k(SCN^-)/k(I^-)=3.13$. The assumptions made in the present treatment seem to be satisfactory for these membrane systems. The counterions have approximately the same mobility in both water and nitrobenzene, the ratio being less than 1.16 and 1.12 at infinite dilution in water[9] and nitrobenzene,[10] respectively. The experimental potentials are therefore compared with those expected from Eqs. 37 and 43. (The small difference between the counterion mobilities is disregarded here and hence Eq. 23 is not employed, in view of the approximate nature of the assumption involved in the theory that the counterion mobilities are constant throughout the diffusion layers.)

In the calculation of membrane potentials, the data on k_X/k_Y given above were used to obtain the selectivity coefficient K. The activity coefficient y in solutions was calculated from the Debye-Hückel equation with Kielland's ion-size parameters.[11] In the membrane the activity coefficient $\bar{y}$ was assumed to be the same for all the counterions. The mobility ratio $\bar{u}/u$ was evaluated from the mobilities of iodide ions estimated from the equivalent conductance data for NaI[12] in water and CV–I[13] in nitrobenzene by assuming that their transport numbers are independent of concentrations and equal to those at infinite dilution. The value of $\delta/\bar{\delta}$ can be determined by means of Eqs. 37 and 43 from one potential measurement with a system of known values of K and $\bar{u}/u$, and can be used to predict all other membrane potentials, as long as cell geometry and stirring conditions in the membrane

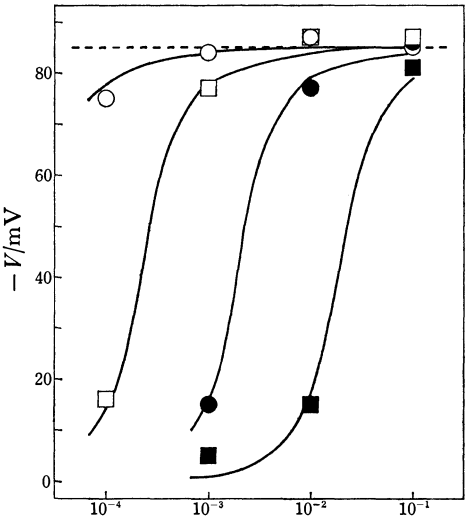

Fig. 2. Comparison of experimental potentials (points) with those calculated from Eqs. 37 and 43 (solid curves) for the bi-ionic system $NaClO_4$(′)/CV–SCN in nitrobenzene/NaSCN (″). The value of the empirical parameter $\delta/\bar{\delta}$ (see Fig. 1) is taken as 1.8. Exchanger (CV–SCN) concentrations: ○, 5×10^{-5} M; □, 5×10^{-4} M; ●, 5×10^{-3} M; ■, 5×10^{-2} M. The broken line indicates the value of the potential expected from the Conti-Eisenman theory, or from Eq. 37 when the effect of diffusion layers is neglected, *i.e.*, $C_X^a/C_X' = 1$.

and solutions remain unchanged. In the experimental work mentioned above, neither the membrane nor the solution phases were stirred. The value of $\delta/\bar{\delta}$ was taken here as 1.8.

Figure 2 shows membrane potentials in the bi-ionic system $NaClO_4$–NaSCN in which a membrane (nitrobenzene solution of CV–SCN) is interposed between aqueous solutions of the two counterions (ClO_4^- and SCN^-) at the same concentration and at the same activity.* The experimental potentials are indicated by points. When the effect of diffusion layers is absent, the membrane potential for this system is calculated from the Conti-Eisenman theory, or from Eq. 37 with $C_X^a/C_X' = 1$. It is independent of the concentrations of the aqueous solutions and of the ion exchanger in the membrane. The calculated value is 85 mV and is given by a broken line. The Conti-Eisenman theory is seen to be valid only when the solution concentration is more than *ca.* 20 times as high as the exchanger concentration. The solid curves, on the other hand, represent values of the potential predicted from Eqs. 37 and 43.[14] They reproduce the experimental values quantitatively.

In Figs. 3 and 4, membrane potentials observed with the systems $NaClO_4$–NaI and NaSCN–NaI are plotted as a function of iodide ion activity.[15] The curves represent the values calculated by Eqs. 37 and 43. Agreement between the calculated and experimental potentials is good. The effect of diffusion layers is absent only in systems of the type:

* In this paper 1 M = 1 mol dm^{-3}.

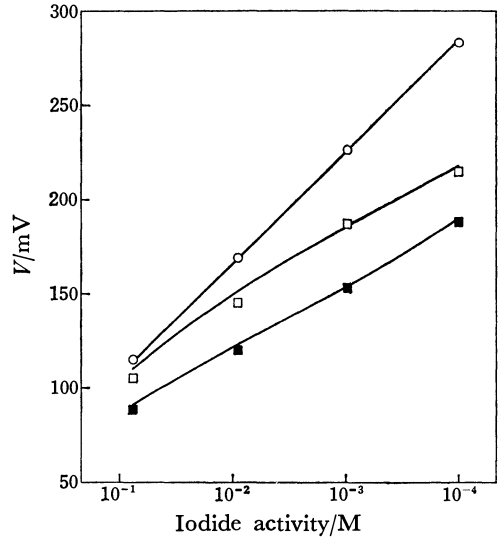

Fig. 3. Comparison of experimental potentials (points) with those calculated from Eqs. 37 and 43 with $\delta/\bar{\delta}=1.8$ (curves) for systems of the types: ○, 0.1 M $NaClO_4$ (′)/5×10^{-4} M CV–I in nitrobenzene/NaI (″); □, NaI (′)/5×10^{-4} M CV–ClO_4 in nitrobenzene/0.1 M $NaClO_4$ (″); ■, NaI (′)/10^{-2} M CV–ClO_4 in nitrobenzene/0.1 M $NaClO_4$ (″). The potentials are shown as positive.

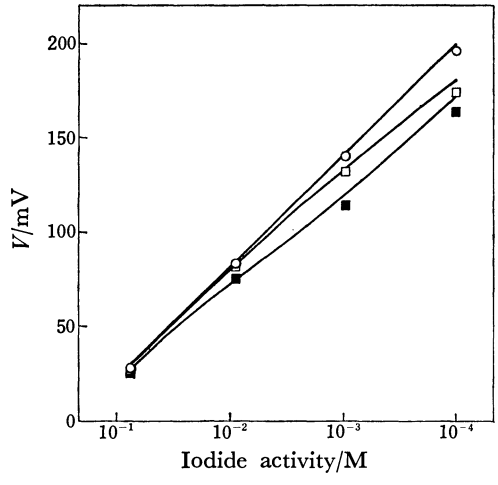

Fig. 4. Comparison of experimental potentials (points) with those calculated from Eqs. 37 and 43 with $\delta/\bar{\delta}=1.8$ (curves) for systems of the types: ○, 0.1 M NaSCN (′)/5×10^{-4} M CV–I in nitrobenzene/NaI (″); □, NaI (′)/5×10^{-4} M CV–SCN in nitrobenzene/0.1 M NaSCN (″); ■, NaI (′)/10^{-2} M CV–SCN in nitrobenzene/0.1 M NaSCN (″). The potentials are shown as positive.

0.1 M NaX (′)/5×10^{-4} M CV–I in nitrobenzene/NaI (″) where $X = ClO_4^-$ or SCN^-.

The results indicate that the concept of diffusion layers is useful in the theoretical interpretation of liquid membrane potentials.

A Vapor-Liquid Equilibrium Still Suitable for Small Amounts of Samples*

Sadao TAKAGI**

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 588

(Received November 16, 1978)

Details are described for the apparatus and procedures for the accurate measurement of vapor–liquid equilibria by use of small amounts of samples. The new recirculation still described is a modification of the Brown's still (*Aust. J. Sci. Res., A*, **5**, 530 (1952)) and its total amount of operating charge is *ca.* 53 cm³, of which each 7 cm³ is in the vapor- and liquid-sample traps and *ca.* 23 cm³ is in the boiler. A method of determining an optimum value of the heating current of the boiler is described. Partial condensation of the vapor and entrainment of the liquid phase into the vapor were eliminated. Some results obtained for the system hexane+chlorobenzene at 338.15 K agreed with the thermodynamically consistent values of Brown, showing the reliability of this still operating with the samples having relative volatilities up to 13. The construction of a thermostatted sample vessel without vapor space for a Pulfrich refractometer is also illustrated which is suitable for small quantity of volatile or hygroscopic solution.

Vapor pressures of binary solutions may be measured[1,2] by the static method, the boiling-point method, the gas-saturation method, the isopiestic method, the dew-point method, the method used with the so-called vapor phase osmometer or vapor pressure osmometer, and others. Of those the first two methods are most widely used. The boiling-point method is preferred when both components of a binary solution are volatile, because the sufficient amounts of representative samples of vapor and liquid phases can easily be obtained if the apparatus is properly handled, and hence the thermodynamic consistency among the values obtained for the temperature, pressure, and compositions of vapor and liquid phases can be checked by means of the Gibbs-Duhem relation. In this paper the author will describe a recirculation still which was constructed to obtain sufficient amounts of representative samples of both vapor and liquid phases with use of relatively small amounts of solution.

After a survey of literatures of existing stills, including some actual trials, the equilibrium still of Brown (the still No. 2)[3] was selected as a basis for modification. The Brown's still incorporates many refinements designed to ensure that the samples of condensate and liquid accurately reflect the equilibrium compositions at a well-defined temperature and pressure. Using his still, Brown obtained the thermodynamically consistent results for miscible systems having a relative volatility in the range 1.0 to 14.[3] The amount of operating charge of his still is, however, approximately 200 cm³.

Apparatus

Description of the Vapor–Liquid Equilibrium Still. The design of the new still is shown in Fig. 1. This still was made of borosilicate glass. Its total amounts of operating charge are approximately 53 cm³, of which 7 cm³ is in each trap and about 23 cm³ is in a boiler. On the inner surface of boiler B finely powdered borosilicate glass was sintered to promote even bubbling which ensures effective stirring of the content. The outer heater O is a nichrome ribbon heater wound on the outer wall. The internal heater P is a closely coiled platinum wire[4] whose diameter is *ca.* 0.1 mm. It was spot-welded with tungsten wires which had been sealed with a glass ground joint S. For being insulated thermally and increasing the heat capacity, the boiler was pasted thick with asbestos leaving each peep slit in front and behind, through which condition of the platinum coil and mode of bubbling were observed. The Cottrell pump C is *ca.* 39 cm long and its inside diameter is *ca.* 3.5 mm. The equilibrium chamber A has a thermometer well Q whose depth is *ca.* 9.0 cm and inside diameter is 10 mm. A spiral guide made of glass cane was welded on the outside wall of the thermometer well to ensure sufficient thermal contact of the liquid and vapor with the well. Three concentric tubes in the equilibrium chamber form two annular spaces, of which the outer space is *ca.* 6 to 7 mm wide and it serves as a vapor jacket to prevent fractional condensation of the vapor phase in the inner space. The inner annular space of *ca.* 5 mm width may contribute to eliminate entrainment of liquid phase into the vapor. The upper end of the middle tube was slightly bent toward the center to prevent entering of sprays. The narrowest width of this annular space is 3 mm. Special care was taken to eliminate spattering of sprays as follows. The middle and lower portions of the middle tube were gently tapered. The bottom of the innermost tube was slightly made narrower so as to drain for the liquid gently along the wall of the middle tube. The equilibrium chamber was completely enclosed in a vacuum jacket R whose wall was silvered except vertical peep slits. The inside diameter of condenser D is *ca.* 12 mm. A vertical condenser E (shown as B in Fig. 2) is a total condenser whose vacuum jacket has been silvered leaving peep slits. Inside diameters of the tubes designated U and L are *ca.* 4 mm and *ca.* 5 mm, respectively. The extended portion I, *ca.* 20 mm i.d., and the constriction J in a return path were inserted so as to reduce fluctuations of the liquid level. About 8.5 cm long U-shaped tube K was required to avoid flowing upstream. Inside diameters of this portion are 2 to 3 mm. The vertical extension of a capillary,

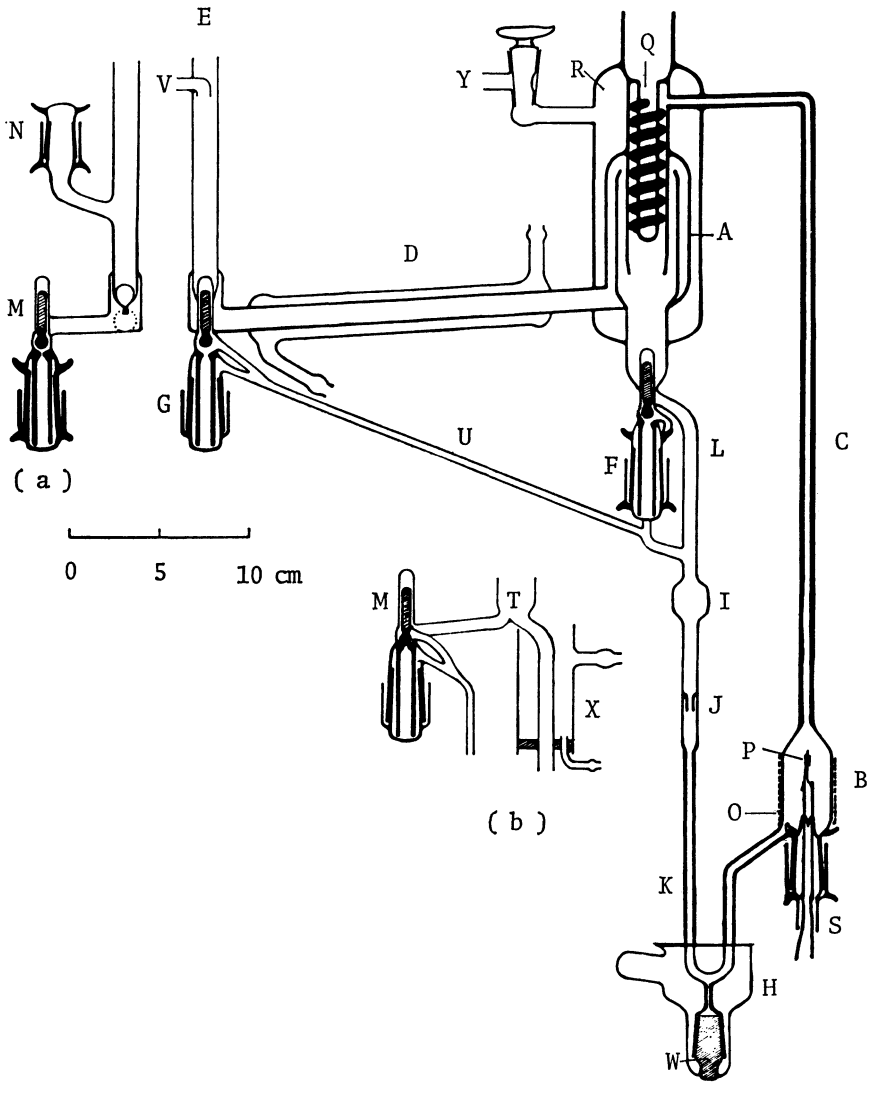

Fig. 1. Equilibrium still. (a) and (b) are side views of the sample traps G and F and their neighbors.
A: Equilibrium chamber, B: boiler, C: Cottrell pump, D: condenser, E: to a total condenser (shown in Fig. 2, B), F: liquid sample trap, G: vapor sample trap, H: cup for collecting the contents, I and J: devices for reducing fluctuations of the liquid level, K: U-shaped tube, L: path of a main flow of the liquid, M: magnetically operated ball valve, N: opening for filling, O: outer heater, P: internal heater, Q: thermometer well, R: vacuum jacket, S: tapered ground stopper, T: ridge for dividing liquid into two 2 : 1 portions, U: path of the returning condensate, V: vent for filling by distillation, W: ground stopper, X: cooler, Y: to a diffusion pump through a liquid nitrogen trap.

ca. 3.5 cm long and *ca.* 0.1 mm i.d., was connected with a ground tapered joint. A cup H with the core of ground joint W for collecting the contents of the still was copied from that originally introduced by Smit and Ruyter.[5] Both the vapor trap G and the liquid trap F are essentially similar to those introduced by Brown:[3] each trap has a small vapor hold-up, a small area of free surface of liquid, and a magnetically operated ball valve M. The both surfaces of the ball and the top of the trap were well ground. In the design of this still a spiral heat-exchanger B of the Brown's still was omitted for simplification of the design and reduction of the volume of dead space. However, a small cooler of *ca.* 6 cm long was mounted on L as shown in Fig. 1, (b) after the construction was completed. A vent V was provided for filling hygroscopic liquids by distillation through a mercury cut-off (shown in Fig. 2). All tapered joints of F, G, and N and the ground stoppers S and W were supported with springs and hooks and sealed with mercury in use.

Measurement of Pressure. The apparatus for the control and measurement of pressure was essentially the same as that used by Scatchard *et al.*[6] It is illustrated schematically in Fig. 2. The maintenance of constant pressure was ensured by connecting the still with a manostat through a liquid nitrogen trap D. The manostat F filled with dry nitrogen is a

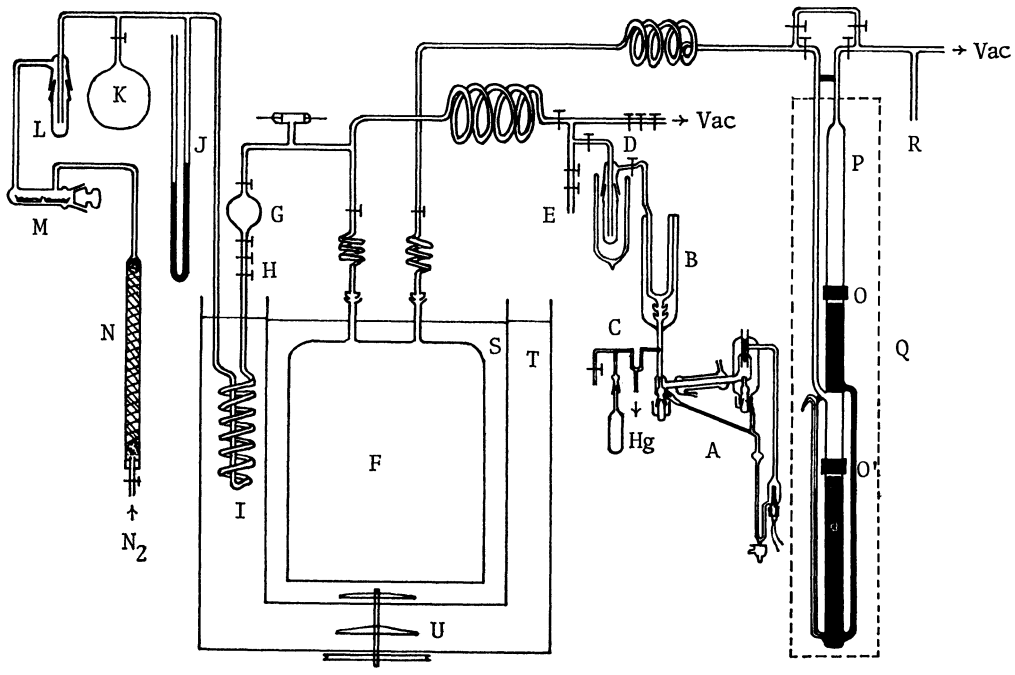

Fig. 2. Arrangement of pressure measuring apparatus.
A: Main part of the still, B: total condenser, C: distillation device for hygroscopic liquid, D: liquid nitrogen trap, E: openning for atmosphere or a dry nitrogen reservoir, F: manostat, G and H: bulb and stopcocks for fine adjustment of nitrogen pressure, Hg: to a mercury reservoir, I: heat-exchanger for nitrogen, J: rough manometer, K: dry nitrogen reservoir, L: liquid nitrogen trap for drying nitrogen gas, M: P_2O_5, N: silica-gel column, N_2: nitrogen from a cylinder, O and O': tubular brass screens, P: precision manometer, Q: thermostat, R: to a rotatable McLeod gauge, S and T: inner and outer baths of a double water thermostat, U: stirrer, Vac: to a high vacuum system.

painted 100-dm³ iron tank submerged in a double thermostat S and T made of tinplate whose temperature was regulated to within ±0.001 K. The pressure of dry nitrogen in the manostat F was measured with a precision manometer P immersed in a thermostat Q in which the thermostatted water in the outer thermostat T was circulated. The circulating water was ejected through three nozzles as jet streams into the thermostat Q and the water was gently stirred with a stirrer driven with a synchronous motor so as to prevent any temperature difference along the manometer P. A high quality plate glass for mirror was used for the front window of the thermostat. A good quality tubing with constant bore size, 20 mm i.d., and uniform thickness was used for making the precision manometer. Two brass collars O and O' painted black were fitted around the tubes and connected to an adjustment device. The readings of mercury menisci were made with a 1-m Shimazu cathetometer readable to 0.05 mm under illumination of a diffuse pale yellow, vertically parallel light from behind; an angular displacement of *ca.* 30° from the diametrical position. The pressure in the vacuum side of manometer was checked with a rotatable McLeod gauge. The temperature of the scale was read with a thermometer immersed in a mercury pool attached to the cathetometer.

Measurement of Temperature. Temperatures were measured with a specially constructed platinum resistance thermometer of the four-lead type,[7,8] a Yokogawa P-7 vernier potentiometer, and a calibrated 100-ohm standard resistance of four-lead type. A lead storage battery was lagged with foamed polystyrene boards. The thermometer was calibrated at the triple point of water[9] and compared with a Leeds and Northrup No. 8163 platinum resistance thermometer calibrated by the National Bureau of Standards, U.S.A. The values obtained of the coefficients of the Callendar equation:[7]

$$t/°\mathrm{C} = \frac{R_t - R_0}{\alpha R_0} + \delta\left(\frac{t/°\mathrm{C}}{100} - 1\right)\frac{t/°\mathrm{C}}{100} \qquad (1)$$

were

$$\frac{R_{100}}{R_0} = 1.39145, \quad \alpha = 0.0039145_1, \quad \text{and} \quad \delta = 1.49225, \qquad (2)$$

which indicated the platinum to be of the requisite purity. A clearance of *ca.* 0.7 mm wide between the outer wall of thermometer and the inside wall of thermometer well was filled with silicone oil. A space between the thermometer and a wide tube welded on the top of thermometer well was plugged with cotton wool.

Operation of the Still

After the solution was charged, the still was evacuated and kept to boil below the room temperature for a few minutes. Then, it was isolated from the vacuum line and connected to the manostat whose pressure had been adjusted to an approximately predicted value.

Heating was commenced adjusting the pressure to the value corresponding to the required temperature by using a calibrated mercury-in-glass thermometer at first and finally the platinum resistance thermometer. After the still was allowed to make steady boiling, the valves on the traps were closed, and the samples were withdrawn for analysis.[3)]

The measured height h_T between the menisci was converted to the pressure P given in the standard mm of mercury† by Eqs. 3 and 4.[10)] The corrections due to the capillary depressions of the mercury were found to be negligible.

$$\frac{h^{\circ}_{273.15}}{\text{mm}} = \frac{h_T}{\text{mm}} \times \frac{1+1.84\times10^{-5}\{(T_S/\text{K})-293.15\}}{1+1.818\times10^{-4}\{(T/\text{K})-273.15\}} \quad (3)$$

$$\frac{P}{\text{mmHg}^{\dagger}} = \frac{h^{\circ}_{273.15}}{\text{mm}} - 0.0974_8\left(\frac{h^{\circ}_{273.15}/\text{mm}}{100}\right) \quad (4)$$

Here T_S and T are the temperatures of the cathetometer scale and the manometer, respectively.

Performance Tests

Optimum Value of Heating Current. Electric currents were supplied to the outer and internal heaters under observation on each ammeter. A fine adjustment was made with each autotransformer whose input voltage was adjusted to ten volts. The heating current of the internal heater was fixed so as to ensure smooth bubbling of the liquid. The current through the outer heater was changed and the plots of equilibrium temperature *vs.* heating current were made. A range of the optimum heating currents was determined from a horizontal portion of the curve where the equilibrium temperature was independent of the value of current supplied. As the range of optimum values of heating current was dependent on the concentration of solution, boiling temperature, or systems to be measured, this test was carried out before the measurement. Portions of the Cottrell pump were wrapped with asbestos ropes, if necessary.

Entrainment of the Liquid Phase into the Vapor. A saturated ethanolic solution of fluorescein at a room temperature (296 K) was charged into the boiler and a lower portion of the return line by means of a syringe fitted with a bent needle. The liquid trap was filled with this solution and the vapor trap was filled with pure ethanol. After 5-h recirculation at atmospheric, 542-mmHg, and 330-mmHg pressures, no color could be detected in the vapor trap.

Comparison with the Reported Values of Hexane+Chlorobenzene at 338 K. *Materials*: Reagent grade hexane was passed through a column filled with silica gel six times to remove aromatics. The hexane obtained was rectified and the portion of distillates boiling at 341 to 342 K was collected. This material was shaken with chlorosulphonic acid to remove methylcyclopentane by means of the method described by Brown,[3,11)] and finally rectified over phosphorus pentaoxide through a 1-m column packed with Dixon packing. The boiling temperature of the purified material was 341.83 K. Gas-chromatography analysis showed that the impurities having shorter retention times than hexane were completely removed and methylcyclopentane was almost completely removed. Reagent grade chlorobenzene showed only very small peaks of a gas-chromatography curve in the shorter side of retention time apart from the main peak. It was rectified, shaken with 10% aqueous solution of sodium hydroxide, washed with water, dried over anhydrous calcium chloride and then phosphorus pentaoxide, and finally rectified over phosphorus pentaoxide through the column described above. The boiling temperature was 404.85 K.

† Throughout this paper 1 mmHg=133.3224 Pa.

(1 mmHg=133.3224 Pa)

x_1	y_1	P/mmHg	α
0.089	0.564	174.2_1	13.2
0.321	0.822	344.7_0	9.8
0.442	0.870	410.1_6	8.4

Procedures and Results: Since the refractive indices of both components agreed with those reported by Brown,[3)] the equilibrium compositions were determined by the refractive index *vs.* mole fraction curve which had been drawn from his data. The refractive indices of small quantities of samples were accurately measured on a Pulfrich refractometer by use of the thermostatted liquid vessel without gas phase designed by the author as shown in Fig. 3. The results of vapor–liquid equilibria obtained are given in Table 1. These values agreed well with the Brown's data[3)] within the experimental error. Since the Brown's data for this system satisfied the Gibbs-Duhem relation well,[3)] the vapor–liquid equilibrium still for small sample size, *ca.* 52 cm^3, here described is also reliable to operate

with the samples having relative volatilities up to $\alpha=13$.

The author wishes to thank Professor Emeritus Ryoichi Fujishiro of Osaka City University, and Professor Syûzô Seki of Osaka University for their continuing interest and encouragements. He is also thankful to Professor Syûzô Seki, Dr. Hiroshi Suga, and Dr. Minoru Sakiyama, Osaka University, for the loan of their precision platinum resistance thermometer, Leeds and Northrup No. 8163.

^{35}Cl-NQR of Some Chlorocarbons and Oxochlorocarbons with a Small Ring†

Koichi MANO, Takefumi MATSUKURA,** and Akira FUJINO*

Research Institute for Atomic Energy, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received December 25, 1978)

^{35}Cl-NQR of two chlorocarbons and six oxochlorocarbons, all having a small ring, were measured in the temperature range 77—300 K. The NQR line groups for the allylic and vinylic chlorine atoms appear separately in the five-membered ring compounds, whereas they are concentrated in a rather narrow region near 38 MHz in the four-membered ones. Perchlorocyclopropene possesses at least three crystal modifications at 77 K, the most stable one of which has only two lines in the temperature range examined. The line assignments, and the hyperconjugative effect in some of them, are discussed with reference to the CNDO/2 MO calculation data.

By means of ^{35}Cl-NQR we can discuss the hyperconjugative effects in the ground state of an organic molecule. Unexpected lowering of the observed frequencies in chlorofluoromethanes, chloromethyl ethers,[1,2] and benzyl chlorides[3] was explained by the interaction between the C–Cl σ bond and the p-orbital of the adjacent first-row substituents. Considering the fitness of chlorocarbons (no hydrogen bond in or between the molecule(s)) for the purpose, we examined the ^{35}Cl-NQR of some cyclic chloro- and oxochlorocarbons in which all the chlorine atoms on the ring carbons have a rigid conformation. We found that in some of them the hyperconjugative effect causes a significant frequency shift from the expected value.

Experimental

Except for commercial perchlorocyclopropene, all the specimens were prepared according to the methods described.[4-8] They were purified by monitoring their IR spectra and elemental analyses. Melting points are: perchloro-4-cyclopentene-1,3-dione (**1**), 68 °C; perchloro-2-cyclopentenone (**2**), 28 °C; perchloro-3-cyclopentenone (**3**), 89 °C, perchloro-3,4-dimethylenecyclobutane-1,2-dione (**4**), 167 °C; perchloro-2,3-dimethylenecyclobutanone (**5**), 68 °C; perchloro-2-cyclobutenone (**6**), −1 °C (by DSC); perchlorocyclobutene (**7**), 50 °C.

A Decca Radar NQR Spectrometer and a superregenerative spectrometer were used. Temperature dependence of the NQR signals was measured by Hashimoto's method.[9] Resonance frequency values obtained by extrapolating the observed variation to 0 K were taken for minimizing the thermal effect of the crystalline lattice on frequencies.

Results and Discussion

The resonance frequencies of six oxochlorocarbons (**1**—**6**) and two chlorocarbons (**7** and **8**) at several temperatures are given in Table 1. The stick diagram (Fig. 1) shows the values at 0 K together with those of the related compounds, perchlorocyclopentene (**9**) and perchloro-1,2-dimethylenecyclobutane (**10**).

Five-membered Ring Compounds. The resonance lines of all oxo compounds as well as the reference chlorocarbon **9** fall into two clearly separated frequency regions, one lower than 38.1 MHz, and the other above 39.1 MHz. The lower group corresponds to the vinylic (*v*-), and the higher to the allylic (*a*-) chlorine substituents. The numbers of observed lines for **1** and **3** were two and three, respectively, indicating that the former molecule has a C_2 and/or two C_s, and the latter a C_2 or C_s symmetry element(s) in their crystals.

The lowest line ν_6 in **2** is easily assigned to a *v*-Cl, β-positioned to the carbonyl group. The two-paired *a*-Cl's resonate in sufficiently separated regions, re-

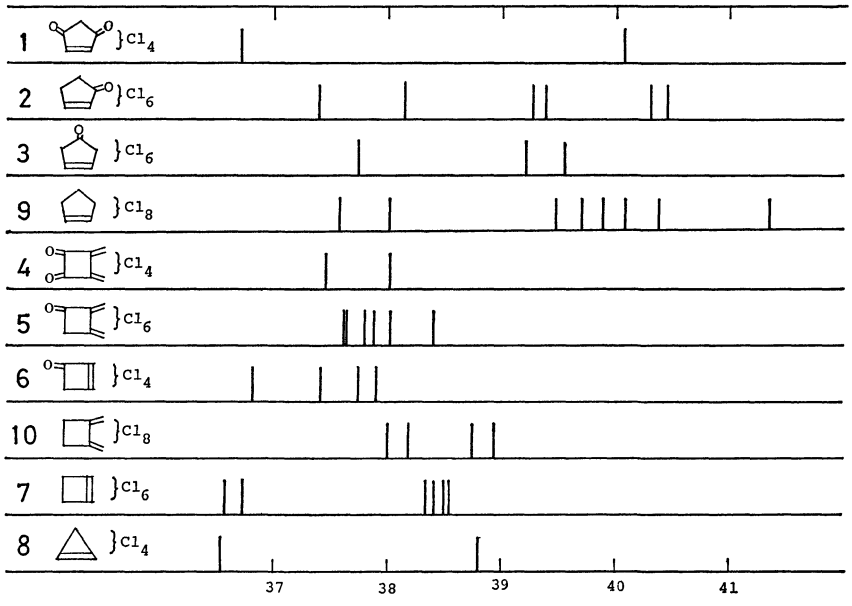

Fig. 1. Resonance lines obtained by extrapolating the thermal variation to 0 K.

spectively *ca.* 39.3 and 40.4 MHz. The highest two among them can be explained in terms of the hyperconjugative interaction between the C_5–Cl bond and the carbonyl group which unusually decreases the ionicity of the allylic chlorine (the term "allylic" is also applied to the chlorine atom α-positioned to the carbonyl group). The remaining pairing lines, ν_3 and ν_4, can be assigned to the *a*-Cl's at C_4.

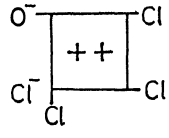
The *a*-Cl (ν_1) in **1** appears in a region similar to the highest one in **2**. In this case, we see no additive effect of hyperconjugation due to the second carbonyl group.

The frequency of *v*-Cl in **3** is situated roughly at an average of the highest two lines for **9**. The *a*-Cl's resonate in the same frequency region as do the *a*-Cl's at C_4 in **2**. Thus, the carbonyl seems to have no influence on all the resonance frequencies.

Four-membered Ring Compounds. In contrast to the above, all the NQR lines of oxochlorocarbons **4**—**6** were observed in a narrow range near 38 MHz. Dioxo compound **4** gave two lines which suggest a C_2 and/or a C_s symmetry in the crystal, its splitting (*ca.* 600 kHz) due to inner and outer *v*-Cl's being appreciably larger than the corresponding one in chlorocarbon **10**. The large splitting suggests a difference in contribution of each carbonyl group to the conjugation with chlorine atoms between the inner *v*-Cl and the outer one. Preliminary MO calculation data (CNDO/2)[11] indicate that the lower line corresponds to the inner substituent.

Mono oxo compound **5** has five lines at 77 K. However, temperature dependence observation of these lines revealed that **5** has essentially six lines in the range 77—310 K; three (ν_1, ν_2, and ν_3) of them having a steeper temperature gradient, *ca.* 4.2 kHz/K, and the rest having *ca.* 2.9 kHz/K. All the lines appear in the *v*-Cl region after 0 K extrapolation, suggesting that the hyperconjugation with C=C double bond would be dominant over that with the C=O group. Reflecting this situation, the calculation gave an appreciably large N_z (1.233, AO population of p_z) of the *a*-Cl. Such a polarization in the Cl at C_4 is due to the contribution of a stabilized allylic cation with full π-conjugation. It was difficult to assign the six lines because of their concentration in a narrow range within crystal field effects. However, the calculated line pattern for **5** with a twisted geometry of $C{=}Cl_2$ groups resembles the observed one.[11,12]

Compound **6**, having four NQR lines all in the *v*-Cl region (below 38.0 MHz), shows an almost simultaneous fade-out at around 210 K, which seems to be related to the phase transition at 220 K evidenced by DSC analysis. The extraordinary low values for the *a*-Cl's suggest the contribution, in the ground state, of some stabilized structure, perhaps an aromatized one as shown below, rather than a hyperconjugated. In a compound like **7**, where no similar contribution can be expected, six lines appear in two groups well separated.



Three-membered Ring Compound. Perchlorocyclopropene **8** is an interesting compound in view of NQR spectra. Lucken and Mazeline reported six lines at 77 K, falling into two frequency groups (four: 38.2—38.8; two: 36.4—36.8 MHz).[13] They assigned the higher line group to *a*-, and the lower to *v*-Cl's. Smith and West later gave a completely inversed assignment on the basis of the data for some chlorocyclopropene derivatives.[14] We found from both NQR and DSC studies that **8** possesses at least three crystal modifications at 77 K. The most stable form, obtained by annealing **8** at Dry Ice temperature for 72 h, has only two NQR lines with very strong intensities in the temperature range 77—233 K (mp). Thus, it should have a C_2 and/or two C_s symmetry in the crystal.

Prediction from MO calculation strongly supports West's assignment.[14] The inversion of the frequency region between *a*- and *v*-Cl is attributed to both an extraordinary increase in N_z of the *a*-Cl (1.261) and a decrease in that of *v*-Cl (1.181).[11] The former is caused by the hyperconjugation with the C=C bond which stabilizes its cyclopropenium cationic structure in the ground state of the molecule.

On the Phase Transitions in Ammonium Hexafluoroaluminate(III)

Keiichi MORIYA,* Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka Osaka 560

(Received January 5, 1979)

The heat capacities of $(NH_4)_3[AlF_6]$ were measured between 11 and 300 K with an adiabatic calorimeter. Two anomalies were found at (193.0±0.3) K and (220.79±0.05) K. The enthalpy and entropy of the phase transitions are (790±150) J mol^{-1} and (4.2±0.8) J K^{-1} mol^{-1} for the former, and (4030±150) J mol^{-1} and (18.5±0.7) J K^{-1} mol^{-1} for the latter, respectively. The total anomalous entropy, (22.7±1.5) J K^{-1} mol^{-1}, is in agreement with $R \ln 16 = 23.05$ J K^{-1} mol^{-1} predicted by a model involving orientational disorder of the hexafluoroaluminate(III) and the ammonium ions. Discontinuities in fluorine T_1 and $T_{1\rho}$ at 221 K by pulse NMR measurement also support this model. The potential barrier height of the hindered rotation of the NH_4^+ ion was estimated to be 7 kJ mol^{-1} from the heat capacity data. The intermediate phase undercooled and coexisted with the low temperature phase in a limited range of temperature. The upper phase transition is of the first order but the anomalous heat capacity follows the Landau theory of the phase transitions of the second kind. The high symmetry of the crystal structure of the present crystal at room temperatures in comparison with that of the alkali cryolites was discussed in terms of the hydrogen bonding, molecular disorder and packing consideration.

There is currently a considerable interest in the phase transitions of crystals containing $[AX_6]^{n-}$ ions, where A is a multivalent atom and X halogen. The phase transitions hitherto studied of this type of compound appear to be displacive if X is chlorine, *e.g.*, $K_2[SnCl_6]$,[1,2] $(NH_4)_2[SnCl_6]$,[3] $K_2[ReCl_6]$,[4] $K_2[OsCl_6]$,[4] and $(NH_3CH_3)_2[SnCl_6]$.[5] Spectroscopic studies have shown that low-frequency rotational vibrations of $[ACl_6]^{2-}$ ion play an important role in the phase transitions in these crystals.[2,3,5] The entropy of transition, in case where calorimetric data are available, is relatively small in agreement with the displacive mechanism of the transitions. For X= fluorine, we have shown that the phase transition is of order-disorder type in $(NH_4)_3[FeF_6]$ crystal.[6] The large entropy of transition ($\Delta S \simeq 24.8$ J K^{-1} mol^{-1}) was accounted for in terms of a model involving orientational disorder of both the ammonium and hexafluoroferrate (III) ions. It was pointed out that the same orientational disorder explains, albeit qualitatively, why ammonium hexafluoroferrate(III) crystal is cubic at room temperature while alkali hexafluoroferrates(III) are not.

In the present paper we will report a calorimetric and NMR study of phase transitions in ammonium hexafluoroaluminate (ammonium cryolite), $(NH_4)_3[AlF_6]$. It will be shown that this crystal is very similar to ammonium hexafluoroferrate(III) in regard to the ionic disorder but the low temperature behavior, having an additional phase transition, is more complicated than in the iron compound.

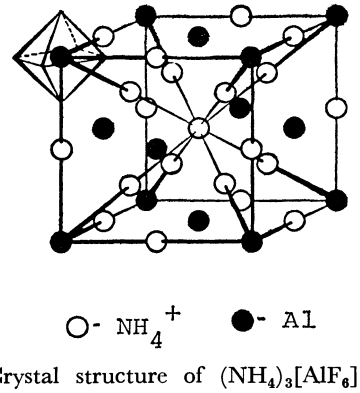

Fig. 1. Crystal structure of $(NH_4)_3[AlF_6]$.

$(NH_4)_3[AlF_6]$ at room temperature is isomorphous with cubic $(NH_4)_3[FeF_6]$. The structure[7] is illustrated in Fig. 1. The aluminum atoms occupy the corner (0,0,0) and face-center (1/2,1/2,0) of the cube. The fluorines are placed tentatively on the four-fold axis of the crystal to form a regular octahedron around the aluminum. There are two sites for the ammonium ions. One is on the edge of the cube (1/2,0,0) and the other (1/4,1/4,1/4). There are four of the former in the unit cell of the fcc Bravais lattice and eight of the latter.

The crystal is not cubic at 93 K. Steward and Rooksby[7] called it pseudo tetragonal. Schwarzmann[8] found that $(NH_4)_3[InF_6]$ belongs to the monoclinic system (C_{2h}^5-$P2_1/n$) and that $(NH_4)_3[AlF_6]$ undergoes a phase transition at 224 K which he described as displacive. Thus it has been known that there is a phase transition between the room temperature and 93 K. It will be shown below that there are in fact two phase transitions.

Comparison of the crystal structure of alkali and ammonium hexafluoroaluminates and analogous hexafluoroferrates(III) shows that there is similar behavior as the size of cation increases in these two families. In Table 1[9] which summarizes the crystal system and the molar volume of the cryolite family, it is shown that smaller alkali cations excluding lithium tend to form less symmetric crystals. The molar volume of the ammonium cryolite is intermediate between those of Rb and Cs compounds. The fcc symmetry of the ammonium cryolite is thus anomalously high in

TABLE 1. THE CRYSTAL SYSTEM AND MOLAR VOLUME OF CRYOLITE-TYPE COMPOUNDS $A(I)_3[AlF_6]$ AT ROOM TEMPERATURE

A(I)	Crystal system	Molar volume / cm^3 mol^{-1}
Li	orthorhombic	58.9
Na	monoclinic	72.0
K	tetragonal	90.4
Rb	tetragonal	102.0
Cs	tetragonal	117.4
NH_4	cubic	107.2

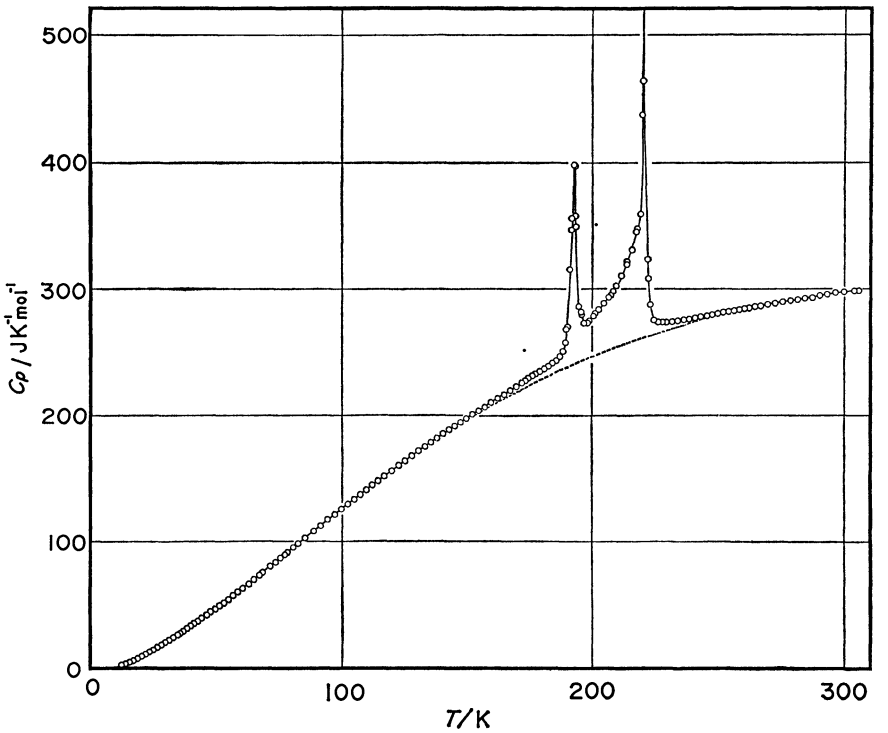

Fig. 2. Molar heat capacity of $(NH_4)_3[AlF_6]$.

this family. It will be shown below that the anomalous property of the ammonium compound is closely related to the orientational disorder and packing of the ions.

Experimental

Sample Preparation. Metallic aluminum of stated 99.99% purity was dissolved in extra-pure reagent of hydrofluoric acid (Wako Pure Chemical Industries, Ltd.). The aluminum fluoride solution thus prepared was added to the aqueous solution of the 1.5 times equivalent amount of extra-pure reagent of ammonium fluoride (Wako Pure Chemical Industries, Ltd.). The reaction was performed at 60 °C. The precipitated crystal, $(NH_4)_3[AlF_6]$, was repeatedly digested at 90 °C. The crystal obtained was separated by filtration, washed with methanol and dried *in vacuo* at 90 °C. Polyethylene or teflon laboratory ware was used exclusively throughout the sample preparation. The crystal was kept in an evacuated desiccator together with calcium oxide before heat capacity measurement. The elemental analysis was made by oxine gravimetric method for Al, by thorium nitrate titration for F and gravimetric method for N and H. The values given below in parentheses are calculated for the chemical formula $(NH_4)_3[AlF_6]$; Al: 13.80±0.04 (13.83%), F: 58.3±0.4 (58.5%), H: 6.17±0.20 (6.20%), N: 21.3±0.2 (21.54%).

Differential Thermal Analysis and X-Ray Powder Photograph. The thermal behavior was first examined by differential thermal analysis (DTA).[10] Only one exothermic peak was detected at 220 K on cooling at the rate of 3 K/min down to 100 K. On the other hand two peaks were observed in the heating run around 190 K and 220 K, respectively. This behavior was reproducible with the same crystal. X-Ray powder photographs taken at 125, 216 and 293 K gave different diffraction patterns. The pattern at 293 K was fully indexed with the fcc lattice. The intermediate and the lowest-temperature patterns were increasingly complicated and could not be indexed. However, by the DTA and the Debye-photograph data it became evident for the first time that ammonium hexafluoroaluminate is trimorphic below the room temperature. The hysteresis phenomenon in DTA was confirmed in the heat capacity measurement as will be discribed below.

Heat Capacity Measurement. The heat capacity was measured from 11 K to 300 K with an adiabatic calorimeter. The calorimeter consists of the sample cell and double adiabatic jackets surrounding it. They are suspended in a vacuum chamber. The temperature of the cell was measured with a platinum resistance thermometer calibrated in terms of the IPTS-68. Precision of the heat capacity measurement was ±0.05% in the temperature range above 50 K, and the estimated accuracy ±1% at 20 K and 0.1% above 50 K. Details of the construction of the calorimeter were published elsewhere.[11]

The calorimeter cell, a chromium plated thin-walled copper cylinder with the thermometer and heater, was loaded with 44.296 g (0.22706 mol) of the $(NH_4)_3[AlF_6]$ crystal, evacuated to approximately 1 Pa, filled with 10^5 Pa of He gas at 20 °C and then sealed off with low melting solder. The increment of the temperature in one measurement of the heat capacity was 1—3 K in the normal temperature region and less than 0.1 K in the transition region. The experimental heat capacity values are given in Table 2 and shown in Fig. 2. Two heat capacity peaks were found at (193.0±0.3) K and (220.79±0.05) K, respectively. These temperatures agree well with the DTA result. The high temperature anomaly has a premonitory effect already at 193 K where the peak height of the low temperature anomaly reaches maximum. The apparent heat capacity reached 23000 J K^{-1} mol^{-1} at the upper phase transition. The time required for thermal equilibration in the neighbourhood of both phase transitions increased to about an hour, compared with ten minutes normally required in normal region. Such a behavior is often observed in the first order transitions. Figure 3 shows the cooling curve obtained by slow removal

of heat from the specimen. The cooling rate 0.7 K/h at the normal region was effected by introduction of an appropriate back-up potential in the cell-jacket thermocouple circuit. The temperature arrest occurred at (220.79±0.05) K which was in good agreement with the temperature of the heat capacity peak. No temperature halt was observed, however, at the lower temperature where the low temperature transition was expected to occur. This is consistent with the DTA result that the low temperature anomaly is observed only in the heating run. The hysteresis was then studied by the heat capacity measurement. The crystal was first cooled down to 186.8 K, 6.2 K below the lower transition temperature. Subsequent measurement of the heat capacity gave the curve that joins smoothly to the heat capacity of the intermediate phase, as shown by the Series 2 curve in Fig. 4. The crystal was cooled then to 180.9 K and again the heat capacity was measured, giving the Series 3 curve. There occurred a small anomaly at 193.0 K in this series. Similar series of measurements after precooling to increasingly lower temperatures gave Series 4 (173.9 K)- and 5 (171.3 K)- curves in Fig. 4, respectively. In these measurements, the temperature drift was less than the observational limit, 0.1 mK h^{-1}. It is therefore concluded that the two phases (the intermediate and the low temperature phases) coexist side by side indefinitely in the temperature range between 193.0 K and the temperature of the precooling. The heat capacity values above 80.15 K plotted in Fig. 2 and given as the 3rd series in Table 2 pertain to the crystal cooled to 78 K and are believed to represent the crystal fully converted to the low temperature phase.

Thermodynamic Quantities. The tempered enthalpy, entropy and heat capacity of $(NH_4)_3[AlF_6]$ crystal are given in Table 3. These values refer to the stabilized crystal.

The Proton and Fluorine Nuclear Relaxation Times.† The

† More detailed NMR study was presented at the Symposium on Molecular Structures and Molecular Electronic States, Tokyo, 1976 (Title: "Nuclear magnetic relaxation and molecular motion of ^{1}H, ^{19}F, ^{27}Al in $(NH_4)_3[AlF_6]$" by Yoshihiro Furukawa, Hideko Kiriyama, Keiichi Moriya and Takasuke Matsuo).

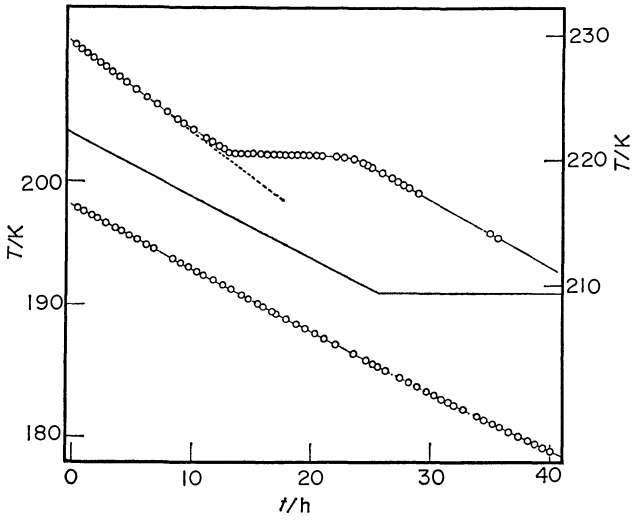

Fig. 3. Cooling curve of $(NH_4)_3[AlF_6]$.

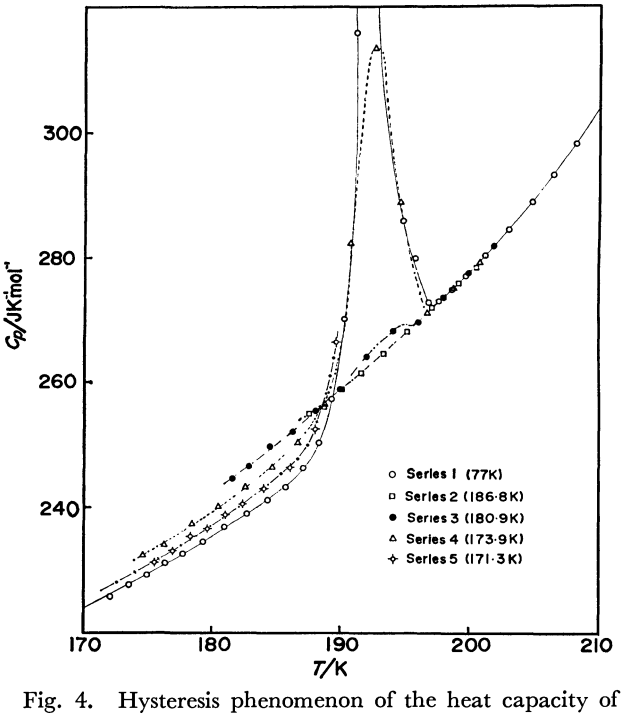

Fig. 4. Hysteresis phenomenon of the heat capacity of $(NH_4)_3[AlF_6]$ around the lower phase transition.

spin relaxation time T_1 was measured for the proton and fluorine nucleus by use of a pulse NMR spectrometer, Brucker Model BK-322S, in the temperature range between 15 and 350 K. The T_1 was measured at 60 and 20 MHz by the 180°-τ-90° method, and, at lower temperatures, by the 90°-τ-90° method. $T_{1\rho}$ in the rotating frame was also measured by the method of Look *et al.*[12] The powder sample was sealed in a thin-wall glass ampule of 5 mm diameter together with He gas. The sample temperature was measured with either a copper-constantan or copper cobalt-doped-gold thermocouples, depending on the temperature region. The temperature was stabilized at least 30 min in each of the measurements.

The T_1 and $T_{1\rho}$ for the proton are shown in Fig. 5. On cooling the crystal from the room temperature, T_1 decreased gradually and underwent a jump at 222 K to a lower value. The gradually decreasing portion of the curve was fitted to the Arrhenius equation and gave an activation enthalpy

of 14.6 kJ mol^{-1}. The T_1 at 20 MHz reached the maximum value at approximately 357 K, indicating onset of another relaxation mechanism operating at higher temperature. The same relaxation mechanism showed itself in $T_{1\rho}$ which reached the maximum value at 250 K and decreased with the increasing temperature. The activation enthalpy derived from the $T_{1\rho}$ is 22.5 kJ mol^{-1}. This is assigned tentatively to diffusional motion of the ammonium ion, as the AC conductivity[13] increased rapidly above the room temperature.

In the intermediate phase, a T_1 minimum of the proton of 5.4 ms occurred at (200±2) K for $\omega_0/2\pi=20$ MHz. The corresponding T_1 minimum for $\omega_0/2\pi=60$ MHz, as calculated by the BPP equation, will be 16.2 ms and may be identified with the experimental value of 16.2 ms at (213±2) K.

The T_1 value shows a hysteresis at the lower transition consistently with the calorimetric observations. The cooling run gave slightly larger T_1. Below 200 K, T_1 remained more or less constant down to 78 K with shallow minima in the T_1 *vs.* $1/T$ curve. In the temperature range from 111 to 197 K, slight deviation from the exponential law was observed in the magnetization *vs.* τ curve. This may be reasonable in view of the presence of the proton and fluorine nuclei in the crystal. It was not possible, however, to evaluate separately the two T_1 values characterizing the cross relaxations. The values plotted in Fig. 5 are those of the faster relaxation process.

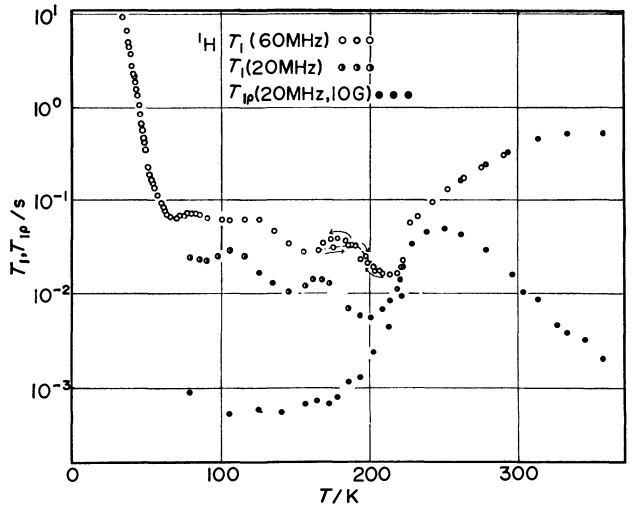

Fig. 5. Proton T_1 and $T_{1\rho}$ in $(NH_4)_3[AlF_6]$, plotted semi-logarithmically against temperature.

The temperature dependence of the fluorine T_1 (Fig. 6) is similar to that of the proton. In the high temperature phase, the T_1 at 20 MHz and 60 MHz are the same at least to 291 K. It increased with the increasing temperature,

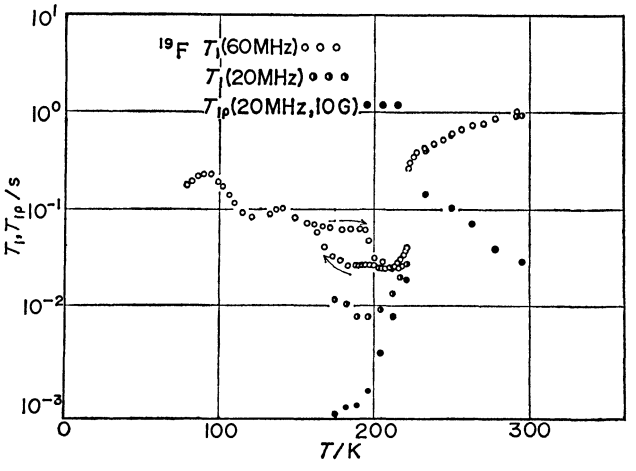

Fig. 6. Fluorine T_1 and $T_{1\rho}$ in $(NH_4)_3[AlF_6]$, plotted semi-logarithmically against temperature.

while the $T_{1\rho}$ measured at $H_1=10$ G decreased with the increasing temperature. There is a large jump of the fluorine T_1 at the upper transition temperature. The ratio of the T_1 of the high temperature phase to that of the intermediate phase at the transition temperature is four times as large for the fluorine resonance as for the proton. A T_1 minimum of 8.7 ms for 20 MHz occurred at (193±2) K. This value pertains to the intermediate phase because the data was taken in a cooling run. A hysteresis behavior was found again around the intermediate-to-the-low-temperature phase transition. The difference in the T_1 values obtained in the cooling and heating runs is larger for the fluorine resonance than for the proton.

Discussion

Heat Capacity of the High Temperature Phase. One does not expect that the heat capacity of a complex compound should be equal to the sum of the heat capacities of the components of the compound. However, approximate equality holds between the heat capacity of an alloy and that of the component metals and is known as the Neumann-Kopp law. We have examined the validity of the additivity of the heat capacity of the hexafluoroaluminates as shown in Fig. 7 where the difference (ΔC_p) between the experimental value and the Neumann-Kopp sum are plotted in ordinate. The heat capacity data were taken from Furukawa, Saba and Ford ($Li_3[AlF_6]$)[14], Clusius, Goldmann and Perlick (LiF)[15], and King ($Na_3[AlF_6]$, NaF, and AlF_3)[16]. ΔC_p is very small for these hexafluoroaluminates between 220 and 300 K considering that the total heat capacity amounts to 200 J K^{-1} mol^{-1} of $M_3[AlF_6]$, although the fractional difference increases with the decreasing temperature at lower temperature as Furukawa, Saba and Ford noted. Similar calculation was done for the high temperature phase of $(NH_4)_3[AlF_6]$ by using the present heat capacity data and those by Benjamins and Westrum (NH_4F)[17] and King (AlF_3)[16]. There is a large positive deviation from the Neumann-Kopp law as shown in Fig. 7. The internal vibrations of the $[AlF_6]^{3-}$ and NH_4^+ ions are practically independent of their environment as far as their contribution to the heat capacity is

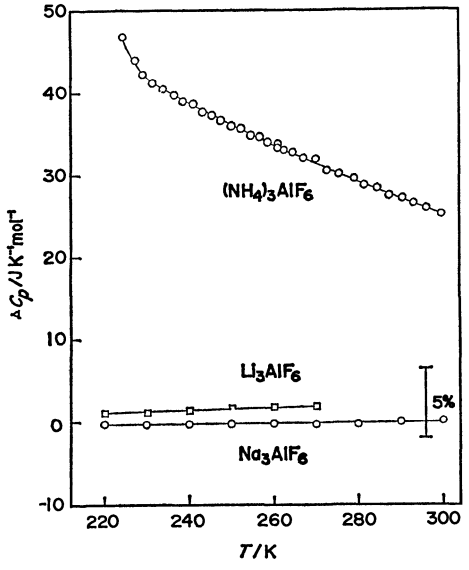

Fig. 7. Additivity of the heat capacity of hexafluoroaluminates.
$3C_p(3M(I)F)+C_p(AlF_3)=C_p(M(I)_3[AlF_6])$

concerned. One may, therefore, attribute the positive deviation from the Neumann-Kopp law to the difference in the external vibrations of the ammonium ions in NH_4F and $(NH_4)_3[AlF_6]$. There are two types of the external vibrations, translational and rotational. Translational vibrations of the cation are involved also in $Li_3[AlF_6]$ and $Na_3[AlF_6]$. But the Neumann-Kopp law holds to a good approximation for these substances. Therefore, the rotational motion of the ammonium ions is responsible to the non-additivity of the heat capacity. It is very reasonable to assume that the rotational motion of the ammonium ion is much more hindered in NH_4F than in $(NH_4)_3[AlF_6]$ in view of the strong NH···F hydrogen bonding in the former crystal[18]. The fluorine atoms in fluorocomplex ions such as $[SiF_6]^{2-}$, $[PF_6]^-$ and $[BF_4]^-$ are generally poor hydrogen-bond acceptors in comparison with the fluoride ion F^-, as is evident from the higher N–H stretching frequencies in these compounds.[19–21]

An estimate of the rotational heat capacity of NH_4^+ ion in $(NH_4)_3[AlF_6]$ crystal is obtained by addition of three times the rotational heat capacity of the ammonium ion in NH_4F to the heat capacity difference given in Fig. 7. The former is calculated by the harmonic approximation by using the three-fold degenerate frequency of 523 cm^{-1}.[18] The result of the calculation for the present crystal is plotted in Fig. 8 (data designated by (B)) for one mole of NH_4^+ ion.

A slightly different estimate of the rotational heat capacity is obtained by subtraction of the heat capacity of $Na_3[AlF_6]$ from that of $(NH_4)_3[AlF_6]$ and making a small correction for the internal vibration of the ammonium ion. This is equivalent to assuming that all the translational vibrations and the internal vibrations and rotational parts of the external vibrations of the $[AlF_6]^{3-}$ anion in $(NH_4)_3[AlF_6]$ crystal are the same as the corresponding vibrations in $Na_3[AlF_6]$ crystal, as far as their contributions to the heat capacity are concerned. The difference between the C_p and

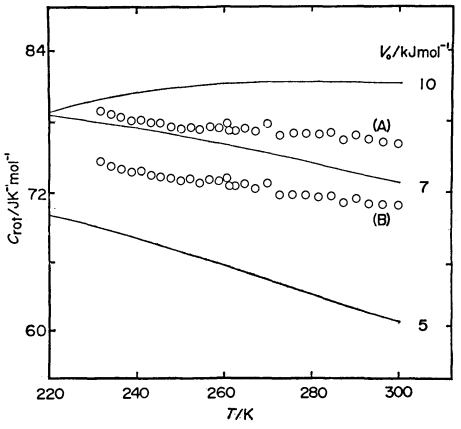

Fig. 8. NH_4^+ ion rotational heat capacity in $(NH_4)_3[AlF_6]$ by two methods
(A) $C_{rot}=C((NH_4)_3[AlF_6])-C(Na_3[AlF_6])-3C(NH_4^+$ internal).
(B) $C_{rot}=C((NH_4)_3[AlF_6])-C(AlF_3)-3C(NH_4F)+9C$(Harmonic, $\sigma=523$ cm^{-1}).

C_v is also assumed to cancel out by the subtraction. The estimated rotational heat capacity is plotted also in Fig. 8 as data (A). Accuracy of the assumptions made here is difficult to assess. But the good agreement of two independent estimates (difference 7%) indicates the essential correctness of the derived rotational heat capacity. The derived value is approximately equal to the heat capacity of three harmonic oscillators in the classical limit. However, it decreases with increasing temperature. This behavior is often observed in a high-temperature heat capacity of a hindered rotator. In Fig. 8, approximate calculations for the hindered rotational heat capacity are plotted for the hindering potential V_0 of 5, 7 and 10 kJ mol^{-1}. The calculation with $V_0=7$ kJ mol^{-1} reproduces fairly well the experimental heat capacity. Here, three dimensional rotation of the ion was approximated as the sum of one dimensional rotations[22] and the two ammonium ions at (1/2,0,0) and at (1/4, 1/4,1/4) were assumed to have the same heat capacity. In spite of these limitation one may conclude that the barrier hindering the rotation of the ammonium ion is much lower in $(NH_4)_3[AlF_6]$ than in NH_4F[23] for which the barrier height of 42 kJ mol^{-1} was reported. This may be another instance of a general observation that fluorocomplex ions are poor hydrogen-bond acceptors.

The activation enthalpy derived from the T_1 measurement, 14.6 kJ mol^{-1} differs from the calorimetric barrier height. Quantitative comparison of the two values will be justified when quantum mechanical calculation of three dimensional motion[24] of the ion is performed for the present compound.

Ionic Motion in the Intermediate and Low Temperature Phases. The T_1 minimum of the proton for $\omega_0/2\pi=20$ MHz indicates that the correlation time of the reorientational motion of the ammonium ion is 4.9 ns at (200±2) K. The activation enthalpy from the temperature dependence of T_1 near the minimum is ≈23 kJ mol^{-1} and the pre-exponential factor of the correlation time τ_0 4.8 fs. An approximately equal value is obtained from the T_1 value at 60 MHz. The minimum value of T_1, 5.4 ms, at 20 MHz is comparable with 3.1—4.3 ms calculated for a reasonable range of the proton–proton distance in ammonium ion by use of the BPP mechanism involving random reorientation of the ion.[25,26] The second moment of the proton resonance absorption is 5.4 G^2 in the intermediate phase[27] and supports the rapid reorientation model. In the calculation of the T_1 minimum all of the ammonium ions are assumed to have the same correlation time. The fair agreement of the experimental and calculated values appears to support this simplification. The relatively short T_1 found in the low temperature phase suggests the occurrence of some reorientational motion of the ammonium ions in this phase. However, detailed interpretation of the shallow T_1 minima is not possible at present because of lack of the structural information.

The T_1 minimum of 8.7 ms of the fluorine resonance occurs in the intermediate phase for $\omega_0/2\pi=20$ MHz. The activation enthalpy derived from the fluorine T_1 is 23 kJ mol^{-1} and equal to that derived from the proton T_1. This suggests that the same mechanism (reorientation of NH_4^+) is involved in the proton and fluorine relaxations, though reorientation of hexafluoroaluminate ion cannot be ruled out. In the cubic $(NH_4)_2[SiF_6]$, reorientation of $[SiF_6]^{2-}$ octahedron begins to take part in the fluorine relaxation above 360 K and the fluorine second moments retains its rigid lattice value up to 300 K.[28] On the other hand, fluorine T_1 minimum occurs in the temperature range 130—245 K for the low temperature phase of $Na[PF_6]$, $K[PF_6]$ and $Rb[PF_6]$.[29] These minima are caused by reorientation of the fluorine octahedron. In $NH_4[PF_6]$ both proton and fluorine T_1's show minima due to the reorientation of $[PF_6]^-$[30] at 125 K. The second moment of the fluorine resonance of $(NH_4)_3[AlF_6]$ is 3.1 G^2 in the intermediate phase.[23] It is evident that the $[AlF_6]^{3-}$ ion reorients rapidly and that the same motion can well contribute to the nuclear relaxation at some appropriate temperature. T_1 measurements of $(ND_4)_3[AlF_6]$ will be interesting in this respect. This will disentangle the probable complication arising from the motion of ammonium and hexafluoroaluminate ions and cross relaxation through the interaction of the proton and fluorine.

Increase of the proton T_1 in the temperature range 30—50 K gives an activation enthalpy of 2.5—3 kJ mol^{-1}. It is not clear if this really corresponds to a potential barrier hindering another reorientational motion of the ammonium ion. Effect of the tunnelling motion of the ammonium ion is excluded because the second moment of the proton resonance increases toward the rigid lattice value around 80 K[27] and the T_1 value becomes very high (≈100 s) at 15.8 K. Interestingly, the activation energy corresponds to 210—250 cm^{-1} of the wave number or the frequency of typical optical lattice vibration of translational or rotational origin. Physical implication of the coincidence of these two energy parameters is not clear at present.

Mechanism of the Phase Transitions. The enthalpy and entropy of the phase transitons were evaluated

220.79±0.05	4030±150	18.5±0.7

by integrating the excess heat capacity over the normal value. The normal heat capacity was determined by smooth interpolation of the low and the high temperature heat capacities into the anomalous region. The normal heat capacity employed here is given in Table 4. The entropies and enthalpies of both transitions are given in Table 5.

If one assumes that the orientation of the ions is uniquely fixed in the low temperature phase, the entropy of transition ΔS is related to the number W of different orientations allowed to the ions in the high temperature phase through the equation, $\Delta S = R \ln W$, provided that the vibrational entropy is adequately taken into account by the lattice heat capacity. The sum of the entropies of the two transitions (22.7± 1.5) J K^{-1} mol^{-1} corresponds to $W=15.3\pm3.0$. An approximately equal value was found for the entropy of transition in $(NH_4)_3[FeF_6]$.[6] One interpretation of $W=16$ is to ascribe it entirely to the disorder of the ammonium ion. $[AlF_6]^{3-}$ ion having the O_h symmetry occupies the site of O_h symmetry, the (0,0,0) position in the fcc Bravais lattice, and is assumed to have uniquely fixed orientation. There are two types of the ammonium ions, one in the (1/2,0,0) position and the other in the (1/4,1/4,1/4). One formula unit of $(NH_4)_3[AlF_6]$ contains one of the former ammonium and two of the latter. The experimental transition entropy may be interpreted formally by allowing four orientations to each of the former ammonium and two to the latter, or $W=4\times2\times2=16$. However, four equivalent orientations of the NH_4^+ ion in the (1/2, 0,0) position is inconceivable from the geometrical viewpoint. Moreover, absence of phase transitions in the cubic $(NH_4)_2[SiF_6]$ disfavors this model. In the cubic $(NH_4)_2[SiF_6]$, the ammonium ions are all equivalent and occupy the (1/4,1/4,1/4) positions. In this case the site symmetry is T_d so that the ammonium ions occupy the site without two-fold disorder. As will be discussed below, the ammonium ion in the (1/4,1/4,1/4) position appears to stabilize the cubic structure energetically. Another interpretation of $W=16$ proposed earlier[6] will be appropriate to the present crystal also. It involves orientational disorder of the $[AlF_6]^{3-}$ ion. Because of the O_h symmetry of the Al site, the orientational disorder has to be one-fold (ordered) or eight-fold. The latter corresponds to rigid rotation of the fluorine octahedron which shifts the fluorine atom from (x,0,0) to a general position. There are eight different orientations of this type.[6] Allowing two orientations to the (1/2,0,0) ammonium in conformity with the site (O_h) and ionic (T_d) symmetries one of which is related to the other by a 90° flipping, one obtains $8\times2=16$ states for one formula unit of $(NH_4)_3[AlF_6]$.

These two models of ionic disorder in the cubic phase predict the same entropy of transitions $\Delta S = R \ln 16 = 23.05$ J K^{-1} mol^{-1} which is in agreement with the experimental data. In addition to the symmetry argument, the NMR result favors the second model. It was pointed out that discontinuity in T_1 at the upper transition is much larger for the fluorine resonance than for the proton. One should not expect the large T_1 change in the fluorine resonance if the phase transition involved only the orientational disorder of the ammonium ions. Thus the NMR data supports the second model rather than the first.

Comparison with the Alkali Cryolites. As shown in Table 1, $(NH_4)_3[AlF_6]$ alone is cubic in the cryolite family at the room temperature. This high symmetry is a result of replacement of the spherical alkali ion by the tetrahedral ammonium ion. Three reasons may be advanced for explanation of this fact. The first is that the ammonium occupying the (1/4,1/4,1/4) position will stabilize the cubic structure. The twelve fluorine atoms surrounding the ammonium ion are grouped into four clusters of three. The four clusters, each belonging to different $[AlF_6]^{3-}$ ion, form a regular tetrahedron around the ammonium. The (1/2,0,0) ammonium and the equivalents occupy the corners of another tetrahedron which forms, together with the four aluminum atoms, the cube of the one-eighth volume of the fcc unit cell. Thus there are positive charges (NH_4^+ ions) at the four of the eight corners of the cube and negative charges (cluster of fluorine atoms) at the other four corners. The central ammonium ion will be situated stably in this tetrahedral field with its hydrogen atoms pointing toward the negative corners. Consequently, the cubic structure is stabilized by the presence of the (1/4,1/4,1/4) ammonium. This will also explain the fact that the cubic $(NH_4)_2[SiF_6]$ remains cubic at least down to 25 K:[31] the crystal has ammonium ions only in the (1/4,1/4,1/4) positions which favors the stability of the cubic lattice without orientational disorder. In alkali cryolites, the alkali ions in the (1/4,1/4,1/4) position do not offer any particular advantage for the cubic structure because the spherical alkali ions have no special reason to favor the tetrahedral environment. The structure of alkali cryolites will be dominated by the packing consideration and (at higher temperatures) by the entropy effect of the $[AlF_6]^{3-}$ disorder.

The second of the explanations for the stability of the cubic structure of the ammonium cryolite is that the orientational disorder of the (1/2,0,0) ammonium ion will decrease the free energy of the cubic phase relative to the non-cubic phase at sufficiently high temperature. Position of the (1/2,0,0) ammonium ion is not known at present. However, it will be reason-

able to suppose that orientational disorder (and decrease of the free energy) is possible only in the cubic phase, as the experimental transition entropy indicates. Such a stabilization of the cubic phase is not available to the alkali cryolites because alkali ions lack orientational degree of freedom. In passing it may be interesting to note here that $A[PF_6]$ crystals, where A is alkali or ammonium ion, are all cubic (except for Li salt) at room temperatures and undergo phase transitions at lower temperature.[1,29,30] It may be argued that orientational disorder of $[PF_6]^-$ ions stabilizes the cubic phase of these crystals.

Finally, the third of the factors contributing to the stability of the cubic ammonium cryolite is that the ionic radius of the ammonium ion may be favorable for the packing of the ions in the cubic lattice. Comparison of the unit cell dimensions of the ammonium, rubidium and caesium cryolites gives some support to this view. If we define the cubicity ratio $\gamma_c=c/(\sqrt{2}\,a)$ where a and c are unit cell lengths of the tetragonal crystal, we obtain $\gamma_c=1.0098$ for $Rb_3[AlF_6]$ and 0.9945 for $Cs_3[AlF_6]$ from the X-ray data of Holm.[32] Linear interpolation between the Rb and Cs gives $\gamma_c=1.0043$ for $(NH_4)_3[AlF_6]$ where the cubic cell dimension (0.893 nm) was taken from Steward and Rooksby.[7] The calculated cubicity ratio of the ammonium cryolite is not exactly equal but closer to the ideal cubic value 1 than the corresponding ratios of the rubidium and caesium cryolites are. Thus, it may be argued that as the size of cation increases the tetragonal cell changes from prolate to oblate and the ammonium happens to have the size that is favorable for the cubic packing. This will decrease the anisotropy of the environment of the ammonium ion and thus increase the tendency toward disordering of the ion discussed above.

We have presented triple reasons, the first energetic, second entropic and the third due to packing consideration, to explain the apparently contradictory fact that less symmetric ammonium ion forms more symmetric crystal in the cryolite family. Alkali cryolites undergo phase transition at higher temperatures.[32,33] It will be interesting to study the heat capacity of these substances to see if the orientational disorder of $[AlF_6]^{3-}$ ion proposed here will be substantiated by the experimental data for the entropy of transition.

Temperature Dependence of the Anomalous Entropy. In Fig. 9, the excess entropy $\Delta S(T)$ is plotted against the temperature. This quantity was calculated by integrating the excess heat capacity,

$$\Delta S(T) = \int^{T} \{\Delta C(T')/T'\} \cdot \mathrm{d}T'.$$

The anomalous entropy increases gradually in the intermediate phase and jumps discontinuously at the upper transition temperature to the high temperature value. Thus, the phase transition is of the first order in agreement with the T_1 discontinuity at the transition. The discontinuous part of the anomalous entropy is 13.2 J K^{-1} mol^{-1} in the total of 22.7±1.5 J K^{-1} mol^{-1}. This behavior is very similar to that observed in $(NH_4)_3[FeF_6]$[6] (discontinuity 18.5 J K^{-1} mol^{-1}, total 24.8±1.9 J K^{-1} mol^{-1}).

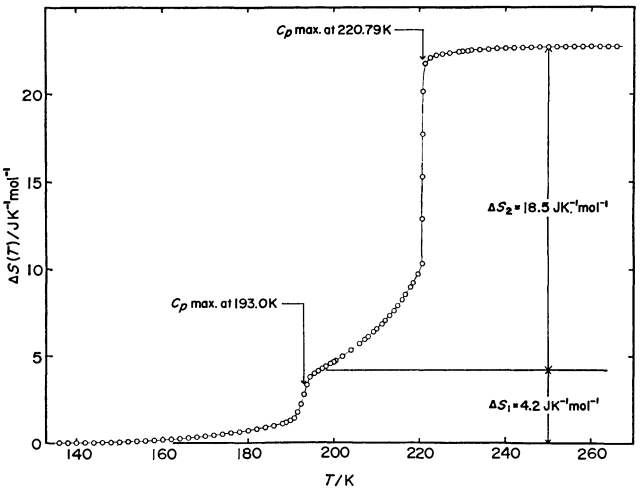

Fig. 9. Temperature dependence of the anomalous entropy $\Delta S(T)$.

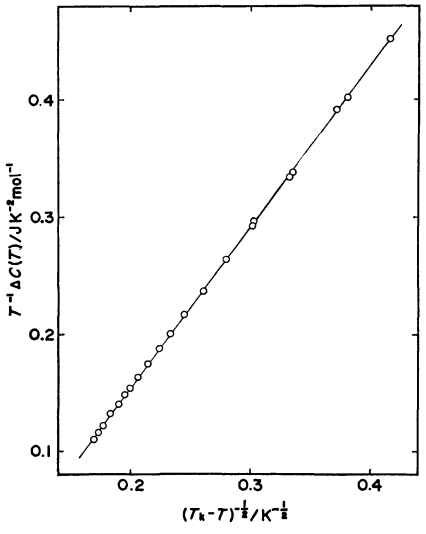

Fig. 10. $\Delta C(T)/T$ plotted against $(T-T_k)^{-1/2}$ with $T_k=224.9$ K.

The gradual increase of the entropy near the upper phase transition will be described by the Landau theory of the phase transition. The free energy of a crystal is expanded in powers of a certain order parameter.

$$G = (T-T_c)a\eta^2 + \frac{1}{2}b\eta^4 + \frac{1}{3}c\eta^6.$$

By differentiation of the free energy, one obtains the heat capacity. Figure 10 shows the plot of the anomalous encraty $(\Delta C_p/T)$ against $(T_k-T)^{-1/2}$ for $T_k=$ 224.9 K. The linearity of the plot between 190 K and 220 K is very satisfactory up to the onset of the first order transition. The parameter values derived from the best fit are as follows.

$a = 18.4\,\mathrm{J\,K^{-1}\,mol^{-1}}$, $b = -995\,\mathrm{J\,mol^{-1}}$, $c = 819\,\mathrm{J\,mol^{-1}}$.

In the lower temperature region between 180 K and 200 K of the intermediate phase where the extent of the disorder is small, the anomalous heat capacity will be expressed as

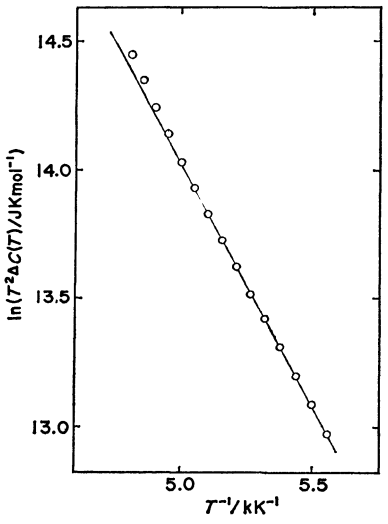

Fig. 11. $\ln(T^2\Delta C(T))$ plotted against inverse temperature.

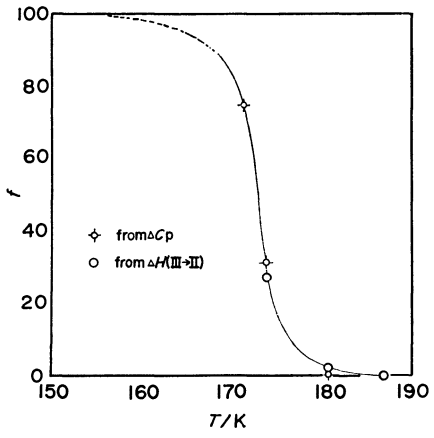

Fig. 12. Fraction of the low temperature phase *vs.* the lowest temperature to which the crystal was precooled before each measurement.

$$\Delta C(T) = R\left(\frac{\varepsilon}{RT}\right)^2 \exp[S^*/R]\cdot\exp[-\varepsilon/RT],$$

where R is the gas constant, S^* an entropic parameter (not equal to the total transition entropy and ε the molar energy required to excite the ion to the "misoriented" state in the ordered crystal. In Fig. 11, $\ln T^2\Delta C(T)$ is plotted against $1/T$. As expected the experimental heat capacity satisfies the linearity in this plot. The parameter values are $\varepsilon=15.6$ kJ mol^{-1} $S^*=51.8$ J K^{-1} mol^{-1}. In the same low temperature approximation, the anomalous entropy is given by the expression,

$$\Delta S(T) = R(\varepsilon/RT+1)\exp[S^*/R]\exp[-\varepsilon/RT].$$

By use of this equation, one can calculate the entropy which the crystal would acquire if the anomalous heat capacity of the intermediate phase continued down to zero Kelvin without being disrupted by the low temperature phase transition. $\Delta S(T=197.10\text{ K})$ calculated by this equation is equal to 2.86 J K^{-1} mol^{-1}, where the temperature 197.10 K corresponds to the minimum of the anomalous heat capacity just above the lower phase transition. The experimental value of the anomalous entropy (Fig. 9) determined by the integration of the anomalous heat capacity including that due to the lower phase transition is 3.2 J K^{-1} mol^{-1} at 197.10 K. Thus large fraction of the entropy of the lower phase transition is accounted for by the disrupted part of the upper phase transition.

It is tempting to assume that ammonium and hexafluoroaluminate ions contribute to the lower and the upper transitions separately, but the entropy of the lower transition is too small as compared with R ln 2 to support this view. At present we have no ready explanation to the fact that the phase transition in $(NH_4)_3[AlF_6]$ proceeds in two steps while the isomorphous $(NH_4)_3[FeF_6]$ has only one phase transition.

Undercooling of the Intermediate Phase. It was pointed out in the experimental section that the intermediate phase undercools and that the heat capacity of the intermediate phase was measured in its metastable temperature region. Undercooling of the present substance is very different in its character from that of typical first order transitions, *e.g.* crystallization of a simple liquid. Once the nucleation takes place in a typical undercooled liquid, the crystallization proceeds to completion consuming the liquid phase entirely, as the Gibbs phase rule dictates. In contrast, the present crystal exists in two different forms over a range of temperature. In Fig. 12, the fraction (f) of the low temperature phase is plotted against the temperature to which the crystal was cooled just before the heat capacity measurement. The measurement after precooling to 78 K gave the same heat capacity as after the precooling down to 13 K. This was taken to represent the completely transformed crystal. The fraction of the low temperature phase was calculated by two methods, one from the enthalpy of the low-temperature-to-intermediate phase transition and the other from the heat capacity difference at 184 K (see Fig. 4). The two methods gave a consistent result. A similar suspended phase change was reported in $K_4Fe(CN)_6\cdot 3H_2O$.[34] In this case, a monotropic transformation (in contrast to enantiotropic of the present crystal) from the metastable tetragonal phase to the stable low temperature phase stops in the midway depending on the temperature to which the tetragonal crystal is cooled. A simple interpretation of these anomalous metastabilities would be that slow atomic motion hinders the progress of the phase transition in these crystals. The fact that simple liquids never exhibit the anomalous metastability seems to support this interpretation because the molecular motion is certainly rapid there. However, the nuclear relaxation data presented above shows that the ionic motion is very rapid at the temperature where the under cooling of the intermediate phase occurs. Therefore the immobility of the ions cannot be the explanation of the anomalous metastability. It should be added that similar hysteresis phenomena have been reported in $Rb[PF_6]$ and $Cs[PF_6]$.[29,35] Most probably, interfacial and strain free energies caused by coexistance of the two phases will have to be taken into account for correct understanding of these phenomena.

We should like to express our best thanks to Professor Ryôichi Kiriyama, Professor Hideko Kiriyama and Dr. Masahiro Furukawa for the kind cooperation in the NMR measurement and for the fruitful discussion of the result. The X-ray powder photographs were taken with the help of Associate Professor Yôzô Chatani to whom we are grateful for his kindness. We are also indebted to Messers Masakazu Okumiya and Hiroshi Minari for the chemical analysis.

Film Dichroism. II. Linearly-polarized Absorption Spectra of Acridine Dyes in the Stretched Poly(vinyl alcohol) Films[1)]

Yukio MATSUOKA and Kiwamu YAMAOKA*

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received January 5, 1979)

The linear dichroic absorption spectra of the protonated and quaternized acridine dyes were measured in the UV and visible regions by the stretched film technique. The dyes examined were acridine, 10-methylacridine, Proflavine, Trypaflavine, Acridine Yellow, 10-Methylacridine Yellow, Acridine Orange, and 10-Methylacridine Orange, all of which belong to the C_{2v} point symmetry group. Poly(vinyl alcohol) was used as a film matrix. The absorption spectrum of each dye was resolved into the long-axis and short-axis polarized components. Two orthogonally-polarized electronic transitions (the ^1L_a and ^1L_b bands) of 3,6-disubstituted acridine dyes were reduced to overlap in the visible region of the spectra. The orientation factors K_y and K_z of each dye were evaluated at a constant degree of stretching and were related to the geometry of the dye molecule.

Studies of the interaction between acridine dyes and natural or synthetic polymers have been carried out by various optical methods.[2-8)] However, the optical properties of the dyes *per se* were treated qualitatively in those studies. To obtain useful and unambiguous information on the optical properties of those polymer-dye complexes, it is imperative to accumulate the detailed data on the polarization direction of the electronic bands of individual dyes.[9-11)]

One promising technique is the measurement of the linear dichroism of dyes oriented in a film by mechanical stretching. The importance of this method has been recognized in the assignment of the polarization directions of absorption bands.[12-18)] Tanizaki[12)] derived a theoretical expression which relates the dichroic ratio to the stretch ratio of a matrix film, and applied it to the absorption band of naphthols[13)] and acridine[14)] to determine the relative directions of their transition moments. Thulstrup *et al.*[15)] reported a method (the reduction procedure) for the quantitative evaluation of "reduced spectra" from the dichroic absorption spectra of planar molecules belonging to the C_{2v} or D_{2h} point symmetry group.

The first paper of this series has established the groundwork for the measurement and analysis of the dichroic spectra.[19)] The purposes of this paper are, therefore, (1) to determine the relative direction of the transition moment of eight acridine dyes,[20,21)] (2) to divide the isotropic spectrum of each dye into the long-axis and short-axis polarized components (the reduced spectra), (3) to evaluate the orientation factors K_y and K_z for each dye, and (4) to relate the molecular shape of the dye with the orientation factors. The major findings are as follows: (1) Isotropic spectra of acridine and 10-methylacridine contain a short-axis polarized (^1L_a) and two long-axis polarized transitions (^1B_b and ^1L_b). (2) The isotropic spectrum of each 3,6-disubstituted acridine dye consists of two orthogonally-polarized transitions (^1B_a and ^1B_b) in the UV region, a dominant long-axis polarized transition (^1L_b) and a weak short-axis polarized transition (^1L_a) in the visible region. (3) The values of K_y and K_z obtained for acridine and 10-methylacridine change remarkably upon substitution of the amino or dimethylamino groups at the 3,6-positions of the acridine nucleus. (4) Both Acridine Yellow and 10-Methylacridine Yellow behave like a rod-shaped molecule as regards their orientation property.

Experimental

Materials. Acridine dyes were all in the monocationic form, the anion being chloride (for details, see Ref. 20): Acridine (Acr) and 10-methylacridine (MeAcr), 3,6-diaminoacridine or Proflavine (PF) and 3,6-diamino-10-methylacridine or Trypaflavine (TF), 3,6-diamino-2,7-dimethylacridine or Acridine Yellow (AY) and 3,6-diamino-2,7-dimethyl-10-methylacridine or 10-Methylacridine Yellow (MeAY), 3,6-bis(dimethylamino)acridine or Acridine Orange (AO) and 3,6-bis(dimethylamino)-10-methylacridine or 10-Methylacridine Orange (MeAO). All these dyes were purified by recrystallization from ethanol and their purity was confirmed by the method of thin layer chromatography. The powdered poly(vinyl alcohol) (PVA) samples were obtained from Tokyo Kasei Co., Ltd., and Kuraray Co. (Kuraray Poval 117-H). Their nominal degrees of polymerization were 1750 and 1680, respectively.

Preparation of Sample Films. A stock aqueous PVA solution (*ca.* 9.1 wt %) was prepared as described elsewhere.[19)] To the stock PVA solution (5×10^{-2} dm^3), an aqueous dye solution (*ca.* 1×10^{-3} mol dm^{-3}) was added dropwise. The mixture was then stirred for 20—30 min to make a dye-PVA solution (the final dye concentration was about 1×10^{-5} mol dm^{-3}). (Each solution spectrum was measured at this stage to compare with the corresponding film spectrum.) To prepare a nonoriented sample film, the dye-PVA solution was spread onto a glass plate and kept for 7—10 days in an open room to ensure dryness. The glass plate was adjustable horizontally by screws and equipped with four removable sides (10×10 cm) which allowed the dried film to be detached easily from the glass surface. The reference film was prepared from an aqueous PVA solution which contained no dye under the same conditions.

Measurements and Analyses of Dichroic Spectra. Dichroic spectra were measured on a Hitachi EPS-3T double beam recording spectrophotometer equipped with a mechanical stretcher that could stretch both sample and reference films simultaneously inside the cell compartment.[19)] In each optical path, a schlieren-free grade Glan-Taylor calcite polarizer (Karl Lambrecht Corp., Chicago) was mounted in front of the stretcher. The stretch ratio, S, of the film was defined as the axial ratio, a/b, (a and b are the semi-major and -minor axes) of an ellipse deformed from a circle of radius r which was initially drawn on the film.[12,19)] Uniform stretching of the film was tested at each S by comparing an imaginary volume of $4\pi ab^2/3$ with the initial volume of $4\pi r^3/3$. These two volumes agreed within an experimental

uncertainty of 4%.

The absorbances of dye molecules in the film, with polarizers arranged parallel, $A_{\parallel}$ and perpendicular, $A_{\perp}$ to the direction of stretch, should satisfy the relation

$$k \times A_0 = \frac{A_{\parallel} + 2A_{\perp}}{3} \tag{1}$$

where k is the normalization factor, which depends on S, and A_0 is the absorbance of the nonstretched film. The dichroic ratio, R_d, or the reduced dichroism, $\Delta A/A$, of partially oriented rod-shaped molecules can be related to the transition moment angle, θ, which is defined as the angle between the direction of the transition moment and the orientation axis of a molecule, as[19,22]

$$R_d = \frac{A_{\parallel}}{A_{\perp}} = \frac{2+2(3\cos^2\theta-1)\Phi}{2-(3\cos^2\theta-1)\Phi}, \tag{2}$$

or

$$\frac{\Delta A}{A} = \frac{3(A_{\parallel}-A_{\perp})}{A_{\parallel}+2A_{\perp}} = \frac{3}{2}(3\cos^2\theta-1)\Phi, \tag{3}$$

where Φ is called the *orientation function* which represents the degree of orientation of an assembly of like molecules. An orientation function was derived for the rod-shaped molecule as[19]

$$\Phi(S) = \frac{3}{2}\frac{S^2-S^2(S^2-1)^{-1/2}\tan^{-1}(S^2-1)^{1/2}}{S^2-1} - \frac{1}{2}. \tag{4}$$

By using Eqs. 2 and 4 or Eqs. 3 and 4, the transition moment angle can be determined according to the method of Tanizaki.[12]

Since the acridine dyes studied in the present work belong to the C_{2v} point symmetry group, the reduction procedure[15] can be employed for evaluating the A_y-spectrum (the short-axis polarized component of isotropic spectrum) and the A_z-spectrum (the long-axis polarized component) from the observed dichroic spectra. In the spectral region between 220 and 550 nm, the out-of-plane polarized component may be ignored (*i.e.*, $A_x=0$); therefore, if the molecules in the film are oriented uniaxially, the formulas necessary for the procedure are as follows:[15]

$$A_{\perp} - d_{\perp}A_{\parallel} = \frac{K_z-K_y}{2K_z}A_y$$

and (5)

$$A_{\parallel} - d_{\parallel}A_{\perp} = \frac{K_z-K_y}{1-K_y}A_z,$$

where $d_{\perp}$ and $d_{\parallel}$ are the reduction factors. The constants K_y and K_z are termed the *orientation factors* and are given by[15]

$$K_y = \frac{d_{\parallel}}{d_{\parallel}+2} \quad \text{and} \quad K_z = \frac{1}{2d_{\perp}+1} \tag{6}$$

Results and Discussion

Isotropic, Dichroic, and R_d-Spectra. Figures 1 to 4 show the *dichroic spectra, i.e.*, the $A_{\parallel}$-spectrum (dotted curve) and the $A_{\perp}$-spectrum (dashed curve), of eight acridine dyes at a particular stretch ratio, together with the wavelength dependence of the dichroic ratio R_d (filled circles), which is termed the R_d-spectrum. An error bar on the dichroic ratio indicates the experimental uncertainty. The dichroic ratio can be converted into the reduced dichroism,[19] which should be referred to the left ordinate of each figure. Two

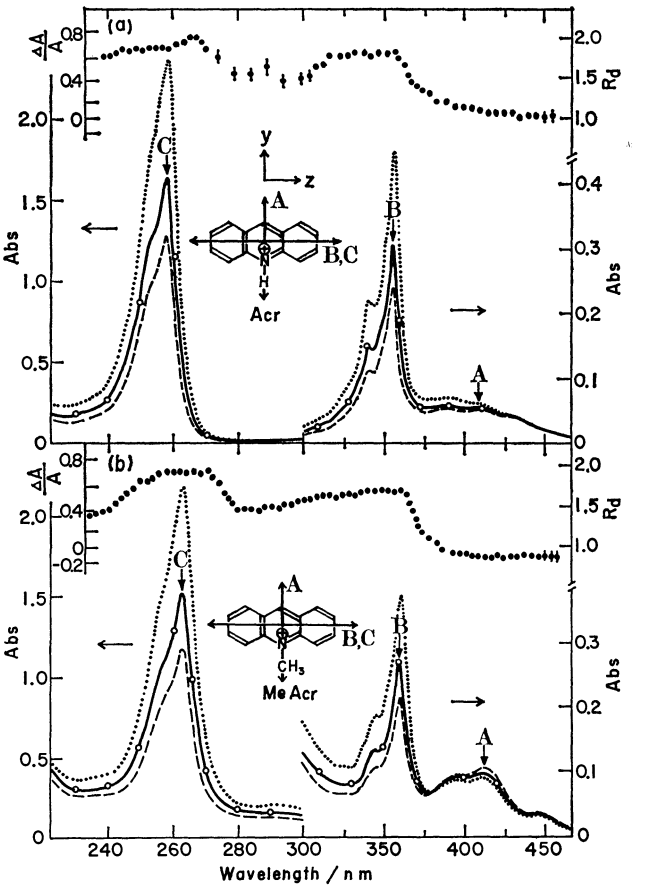

Fig. 1. Isotropic, dichroic, and R_d-spectra of Acr and MeAcr in the stretched PVA film. Symbols are: the isotropic spectrum (——), the parallel (·····) and perpendicular (----) polarized spectra, the R_d-spectrum (••••) and the normalized isotropic absorbance (○). Letters **A** to **F** indicate the apparent peak or shoulder positions in each isotropic spectrum and the polarization directions in the acridine nucleus. Acr at $S=4.3$ and $\bar{k}=0.62$. MeAcr at $S=4.3$ and $\bar{k}=0.65$. Factor $\bar{k}$ is an average of the values of k at about 30 wavelengths.

kinds of isotropic spectra are also shown in each figure: one, $k\times A_0$ (open circles), was obtained from the left hand side of Eq. 1 and the other, A (solid curve), was calculated from the right hand side of the same equation. An excellent agreement between these two isotropic spectra suggests that the dye molecules are indeed oriented uniaxially in the stretched film. The observed isotropic spectra of all the acridine dyes in the PVA film were similar to the spectra of the dyes in aqueous PVA solution. The apparent band positions of each dye are shown in Table 1.

The dye AO has drawn special attention because of its strong ability of dimerization in aqueous solution. The "monomer" spectrum, which was unmasked by the monomer-dimer analysis, gave a value of 1.5—1.6 for the ratio of the peak intensity (492 nm) to the shoulder intensity (≈470 nm).[23,24] The spectrum of AO in an aqueous PVA solution (2.5×10^{-5} mol dm^{-3} in 9.1 wt %) also gave nearly the same value, which indicates AO is probably in the monomeric form.

Table 1. The apparent band positions (**A**—**F**) in the isotropic spectra and the transition moment angles (θ_A—θ_F) at the corresponding band positions of eight acridine dyes

Dyes	Positions[a]/nm			Angles/deg		
	A	**B**	**C**	θ_A	θ_B	θ_C
Acr	408 (403)	356 (354)	258	54±1	41±1	40±1
MeAcr	412 (416)	360 (358)	263	58±1	40±1	38±1
	D	**E**	**F**	θ_D	θ_E	θ_F
PF	465 (452)	305	263 (261)	8±2	—	22±2
TF	470	305	265	8±2	—	24±2
AY	467 (453)	314	266 (265)	—	—	—
MeAY	471 (461)	317	270 (267)	8±2	—	23±2
AO	502 (496)	330	272 (271)	12±2	70±2	23±2
MeAO	506 (500)	335	274 (272)	10±2	—	27±2

a) The values in the parentheses are the corresponding positions in the aqueous PVA solution.

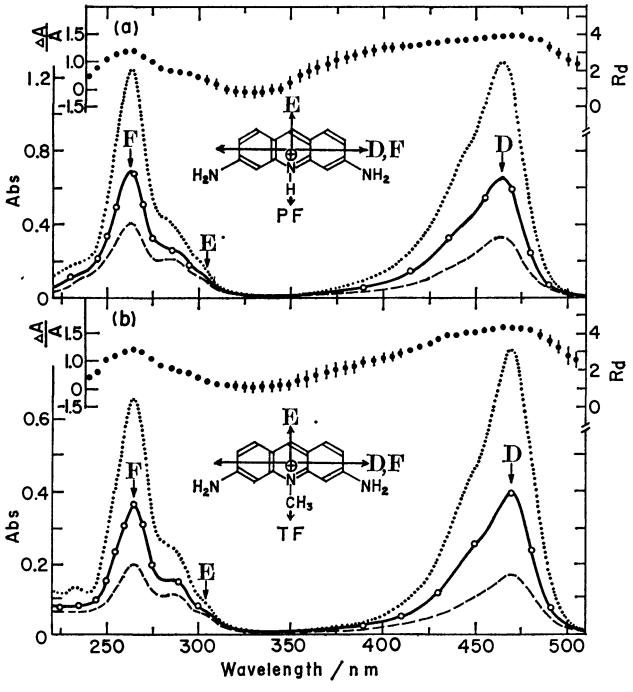

Fig. 2. Isotropic, dichroic, and R_d-spectra of PF and TF in the stretched PVA film. Symbols are the same as in Fig. 1. PF at $S=3.7$ and $\bar{k}=0.65$. TF at $S=3.7$ and $\bar{k}=0.65$.

In the isotropic spectrum of AO in the PVA film (Fig. 4a), the ratio was as high as 2.0. This value compares favorably with the values of 2.1 in chloroform ($1—10\times10^{-6}$ mol dm^{-3}) and 1.9 in ethanol (2×10^{-5} mol dm^{-3}). These data suggest that AO is also in the monomeric form in the PVA film. Results similar to the above were observed for such associative dyes as PF,[25,26] TF,[26] and MeAO. Therefore, the isotropic spectra in Figs. 1 to 4 were concluded to be essentially the monomer spectra of the respective dyes.

Acridines: Both the dichroic and R_d-spectra of Acr and MeAcr are shown in Fig. 1. In order to ascertain that Acr is fully protonated, an appropriate amount of HCl (0.1 mol dm^{-3}) was added to the aqueous dye–PVA solution prior to casting. The isotropic spectrum of Acr in the film resembles the solution spectrum of the acridinium ion. The $A_\parallel$-spectrum of Acr is always more intense than the $A_\perp$-spectrum, except for the long-wavelength region. The R_d-spectrum of Acr is nearly flat in 460—400 nm ($R_d=1.0$—1.1) and again in 360—320 nm ($R_d\approx1.7$), sharply changing at about 370 nm. Another plateau region is observed in 260—240 nm ($R_d\approx1.8$). These dichroic features are in excellent agreement with a previous report.[27] The isotropic spectrum of MeAcr shifts toward the red, as compared with the spectrum of Acr, because of the substitution of a methyl group on the ring nitrogen. The R_d-spectrum is constant over 460—390 nm ($R_d\approx0.9$), 360—330 nm ($R_d\approx1.8$), and 270—250 nm ($R_d\approx1.9$).

3,6-Diaminoacridines: Figure 2 shows the dichroic and R_d-spectra of PF and TF, which are 3,6-diamino derivatives of Acr and MeAcr, respectively. The isotropic spectra of PF and TF differ from those of Acr and MeAcr in that PF and TF show a deceptively simple absorption peak in the visible region and two conspicuous shoulders in 280—320 nm. In spite of the simple isotropic absorption in the visible region, the R_d-spectra of PF and TF are not flat: the largest values occur near 465 nm and 470 nm, respectively. They descend rather sharply on the long-wavelength side and slowly but irregularly on the short-wavelength side. These descending trends are well beyond the experimental uncertainty.

3,6-Diamino-2,7-dimethylacridines: Figure 3 shows the dichroic data of AY and MeAY, which are 3,6-diamino-2,7-dimethyl derivatives of Acr and MeAcr, respectively. In the isotropic spectrum of AY, there are at least three humps at *ca.* 445, 428, and 400 nm, and a shoulder at *ca.* 255 nm. The profile of the isotropic spectrum of MeAY resembles that of AY in the visible and UV regions. A new feature was discovered for MeAY in the 340—310 nm region, where the $A_\perp$-spectrum is more intense that the $A_\parallel$-spectrum (inset of Fig. 3). Such a reverse trend is always found for more heavily substituted dyes, such as AO and MeAO. The R_d-spectra of AY and MeAY give the highest value near the main peak in the visible region and show the lowest value in the 340—310 nm region.

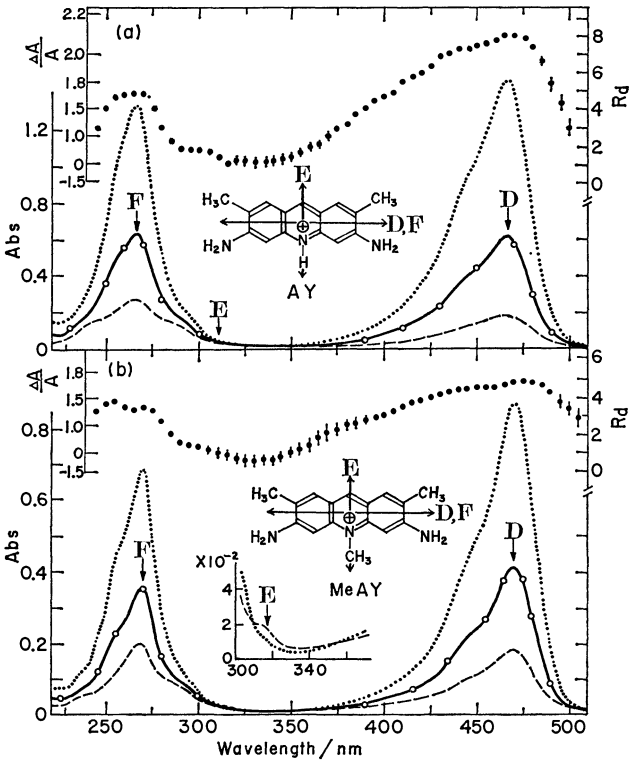

Fig. 3. Isotropic, dichroic, and R_d-spectra of AY and MeAY in the stretched PVA film. Symbols are the same as in Fig. 1. AY at $S=4.3$ and $\bar{k}=0.57$. MeAY at $S=4.3$ and $\bar{k}=0.62$.

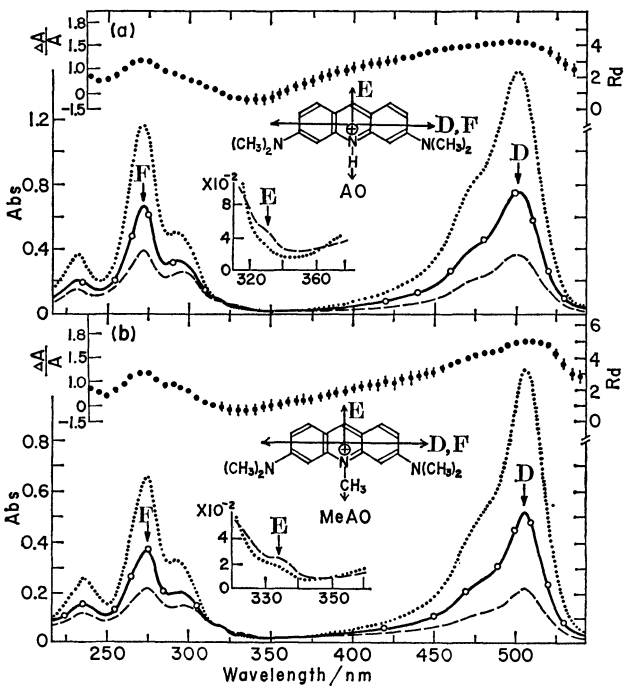

Fig. 4. Isotropic, dichroic, and R_d-spectra of AO and MeAO in the stretched PVA film. Symbols are the same as in Fig. 1. AO at $S=4.3$ and $\bar{k}=0.55$. MeAO at $S=4.3$ and $\bar{k}=0.60$.

Especially, the R_d-value becomes smaller than unity for MeAY, indicating that a weak absorption band exists in 340—310 nm. On the analogy of the R_d-spectrum of MeAY in 340—310 nm, all AY, TF, and PF should also have such a weak band in the same region.

3,6-Bis(dimethylamino)acridines: The dichroic and R_d-spectra of AO, which is the 3,6-bis(dimethylamino) derivative of Acr, are shown in Fig. 4a. The $A_\parallel$-spectrum is more intense than the $A_\perp$-spectrum in the entire spectral region, except for the 360—320 nm region, where the behavior of the $A_\parallel$- and $A_\perp$-spectra is reversed. Such a reverse trend has also been reported.[28,29] The R_d-spectrum of AO descends on the long-wavelength side of the 502 nm principal band, while it decreases irregularly on the short-wavelength side and becomes smallest at *ca.* 330 nm. Figure 4b shows the dichroic data of MeAO. The isotropic spectrum of MeAO is bathochromic relative to AO; the spectral features are almost the same. The reverse trend of the dichroic spectra was also observed in the 350—320 nm region. The changes in the R_d-spectrum on both sides of the 506 nm principal band become more pronounced than those of AO. The change of the R_d-spectrum of MeAO in the visible region can be explained reasonably well by introducing the short-axis polarized transition (the ^1L_a band) with a vibrational structure which is overlapped by the 506 nm band (the ^1L_b band). Similar interpretations can be put on the changes of the R_d-spectra of all 3,6-disubstituted dyes: AO, AY, MeAY, PF, and TF.

Determination of Transition Moment Angles. If a planar molecule has at least one C_2 symmetry axis in the molecular plane, the observed isotropic spectrum can be divided into two components (*i.e.*, the divided spectra)[13] which are polarized parallel and perpendicular to the symmetry axis, respectively. In order to obtain the divided spectra of each acridine dye, the transition moment angle must be evaluated correctly.[13,30] For this purpose, the dichroic spectra were analyzed, in the first place, by Tanizaki's method.[12] As examples, the dependences of R_d (and $\Delta A/A$) on S are shown for Acr and AY in Fig. 5. The transition moment angles, θ, relative to the orientation axis are given in Table 1, together with those of the remaining acridine dyes.

The sums of the transition moment angles of θ_A and θ_C, and θ_A and θ_B, for Acr are 94° and 95°, respectively. These values are in good agreement with the results obtained by Yoshino *et al.*,[27] and assure the equal precision of the experimental procedures of the present work. From the symmetry consideration, the transition moments of the **A** and **C** bands of Acr or MeAcr (each band can be regarded as a single transition from the flatness of the R_d-spectrum) should be orthogonal *i.e.*, $\theta_A+\theta_C=90°$. However, the values are 94° for Acr and 96° for MeAcr, always larger than 90°. The deviation from the orthogonality is more conspicuous for MeAcr than Acr; this implies that those transition moment angles contain some kind of systematic error which is associated with the molecular shape, *i.e.*, the shape of Acr or MeAcr can not be generally represented by a rod, but is more likely to be planar. The most unrealistic example is AY, for which the dependence of R_d (or $\Delta A/A$) on S at position **D** exceeds the theoretically permissible curve

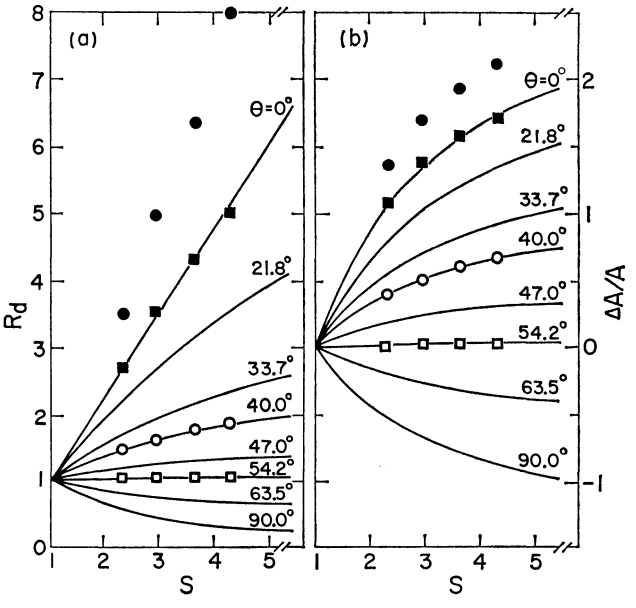

Fig. 5. Dependence of (a) the observed R_d and (b) $\Delta A/A$ on S for Acr and AY. Symbols (□ and ○) denote the values of Acr at wavelength positions **A** and **C**; and (■ and ●) denote the values of AY at **F** and **D**, respectively. Solid curves are theoretical and calculated with the angle θ specified for respective curves by the use of Eqs. 2, 3, and 4.

($\theta=0°$), as shown in Fig. 5. In fact, the R_d-values of AY are very large in the visible absorption peak, as compared with those of PF and AO. (The dichroic spectra of AY were measured several times to confirm the reproducibility of the R_d-values.)

The above findings suggest that the orientation function given by Eq. 4 does not represent the degree of orientation of AY and Acr correctly. Since this equation was derived from the distribution of unit vectors and contains the variable S only, no consideration has been given to the geometrical shape of a particular guest molecule. For instance, the large R_d-values of AY at two main peaks (467 and 266 nm), as compared with those of MeAY, can be accounted for by assuming that AY is better oriented than MeAY at a given S. Hence, the actual orientation mechanism of dyes in the stretched polymer film seems to be more complex than that described by the orientation function (Eq. 4). The stretch ratio S may need a more critical evaluation: the true stretch ratio for AY could possibly be greater than the macroscopic S. The discrepancy between the true and calculated angles of a transition moment may become pronounced, if any transition moment of the molecule is nearly parallel or perpendicular to the orientation axis, *i.e.*, if the angle θ approaches either 0° or 90°. Because of the reasons cited in this section, the reduction procedure,[15] which does not need to assume the degree of orientation of the guest molecules, was employed to determine the reduced spectra of each dye.

Reduced Spectra of Eight Acridine Dyes. Since each dye belongs to the C_{2v} point symmetry group, its transition moment should be in the molecular plane and along the long (z) or short (y) axis in the visible and UV regions. According to many film dichroism measurements, the molecules embedded in the PVA matrix are generally known to orient predominantly with their long axes aligned to the direction of stretch. This means that an absorption band whose transition moment is polarized along the long axis rather than the short axis should give a larger R_d-value. For example, in the dichroic spectra of Acr and MeAcr (Fig. 1), the change of each R_d-curve indicates the existence of at least one short-axis polarized (denoted as **A**) and two long-axis polarized (denoted as **B** and **C**) transitions. In contrast, the R_d-curves of the 3,6-disubstituted acridine dyes (Figs. 2 to 4) reveal the existence of at least one short-axis polarized (**E**) and two long-axis polarized (**D** and **F**) transitions. On the basis of these apparent spectral features, the reduced spectra of each dye were determined with a HITAC-8700 computer according to the reduction procedure.[15]

The resultant reduced spectra of Acr are shown in the upper half of Fig. 6a. As expected from Fig. 1, the A_z-spectrum (solid curve) gives rise to two strong long-axis polarized transitions at *ca.* 356 and 258 nm (the ^1L_b and ^1B_b bands), while the A_y-spectrum (dotted curve) manifests a short-axis polarized transition at *ca.* 408 nm (the ^1L_a band). These assignments are in excellent agreement with the results of fluorescence polarization[31] and film dichroism.[27] It is interesting to note that the A_y-spectrum is much better resolved with the reduction procedure than the D_y-spectrum,[27] which appears to contain some remaining contributions from the intense D_x-spectrum between 370 and 320 nm. The reduced spectra of MeAcr are shown in the lower half of Fig. 6a. Just as noted for Acr, the A_z-spectrum of MeAcr gives two long-axis polarized transitions at *ca.* 360 and 263 nm (the ^1L_b and ^1B_b bands), whereas the A_y-spectrum shows a short-axis polarized transition at *ca.* 412 nm (the ^1L_a band).[32] The higher-energy transition polarized along the short axis (the ^1B_a band) is rather obscured in the reduced spectra, but can possibly be at 260 nm for Acr and at 280 nm for MeAcr, as was shown for Acr previously,[27] or it may be hidden in the higher-energy region, as in anthracene.[33]

The reduced spectra of 3,6-disubstituted acridine dyes are shown in Figs. 6b to 6d. As already expected from the R_d-spectra in Figs. 2 to 4, there are generally two strong long-axis polarized transitions (the ^1L_b and ^1B_b bands) in the A_z-spectrum and a short-axis polarized transition (the ^1B_a band) in the A_y-spectrum.[34] In addition to these transitions, there is definitely a short-axis polarized, weak transition (probably the ^1L_a band)[34] in the visible region, the presence of which has long been a point of controversy.[35] It should be this transition, hidden in the isotropic spectrum, that is responsible for the decrease in the R_d-values on both sides of the principal peak in the visible region.

From comparison of the reduced spectra between Acr and PF or between MeAcr and TF, it is clear that the ^1L_a and ^1L_b bands of Acr or MeAcr are shifted, on the substitution of amino groups at 3,6-positions, toward the long wavelength in such a way that the ^1L_b band overtakes the ^1L_a band.[36] The ^1B_a transition is definitely unraveled in the UV regions of PF and

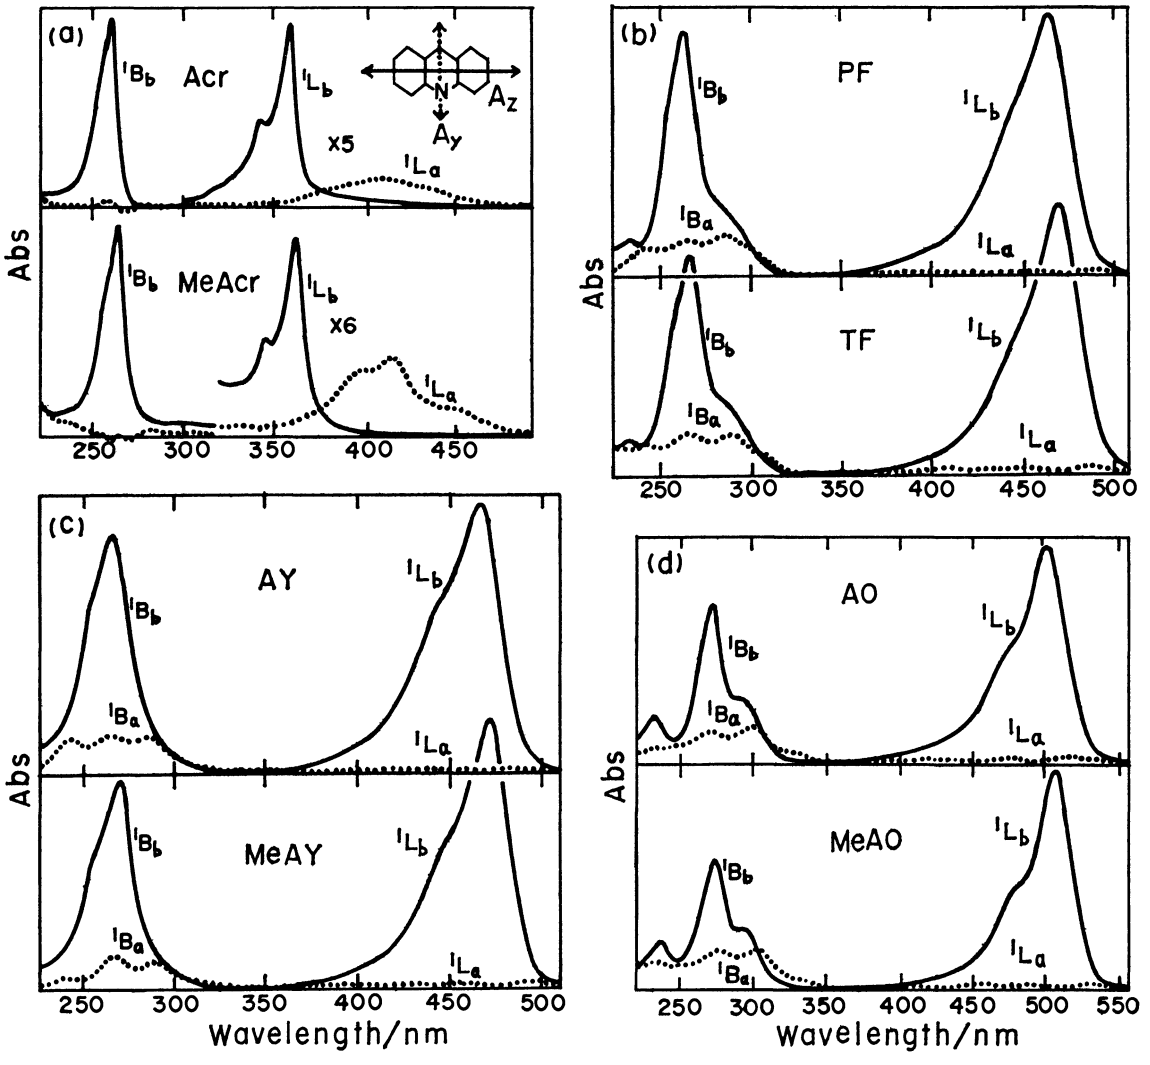

Fig. 6. The reduced spectra (the A_z-spectrum and the A_y-spectrum) of eight acridine dyes at $S=4.3$. The long-axis (z-axis) and short-axis (y-axis) polarized absorbances (arbitrary units) are shown by the solid and the dotted curves, respectively. (a) Acr and MeAcr (The absorbance between 320 and 480 nm is expanded as indicated.), (b) PF and TF, (c) AY and MeAY, and (d) AO and MeAO.

TF, in contrast to the reduced spectra of Acr and MeAcr. These features of the reduced spectra are also evident from Figs. 6c and 6d for AY and AO relative to Acr and for MeAY and MeAO relative to MeAcr.

The A_y-spectrum of AO shows the ^1L_a band in 550—400 nm (probably the 0-0 transition near 518 nm). This 0-0 transition of the ^1L_a band is mostly responsible for the decrease of the R_d-spectrum of AO (also PF, TF, AY, MeAY, and MeAO) on the long-wavelength side of the visible peak. In 350—310 nm, the A_y-spectra of AO and MeAO are more intense than the corresponding A_z-spectra. This trend is in excellent accord with the result that the R_d-spectra of AO and MeAO become smallest at *ca.* 330 nm. (This statement is also valid for PF, TF, AY, and MeAY.) Since the 330 nm band is expected to be an in-plane transition, it may be assigned to be the 0-0 transition of the ^1B_a band.

A comprehensive assignment of polarization was tentatively carried out for the reduced spectra of 3,6-disubstituted acridine dyes on the basis of the data of Acr and MeAcr. In order to obtain the complete and detailed assignment of all the transition moments of those dyes, each reduced spectrum should be resolved into individual component bands, the isotropic spectrum should then be reconstructed from those decomposed bands, and above all, the observed R_d-spectrum should be reproduced fully by simulation. The details will be reported shortly.

Relation between Molecular Shape and Orientation Factors. The orientation factors K_y and K_z were determined from the reduction factors $d_\parallel$ and $d_\perp$ with the aid of Eq. 6. The values of $d_\parallel$, $d_\perp$, K_y, and K_z obtained for each dye at $S=4.3$ are listed in Table 2. In order to find out the relation between the molecular shape and the orientation factors, the points (K_y,K_z) for all the dyes are plotted in Fig. 7. All these points lie either inside or on the periphery of the "orientation triangle".[18] The accuracy of each point is roughly indicated by its size.

The location of each point in the orientation triangle

Table 2. The average values of the reduction factors ($d_{\parallel}$ and $d_{\perp}$) and the orientation factors (K_y and K_z) at $S=4.3$ of eight acridine dyes

Dyes	$d_{\parallel}$	$d_{\perp}$	K_y	K_z
Acr	0.95	0.54	0.322	0.481
MeAcr	0.88	0.53	0.305	0.485
PF	0.52	0.21	0.206	0.704
TF	0.47	0.18	0.190	0.735
AY	0.23	0.12	0.099	0.806
MeAY	0.30	0.19	0.130	0.725
AO	0.47	0.24	0.190	0.676
MeAO	0.37	0.18	0.156	0.735

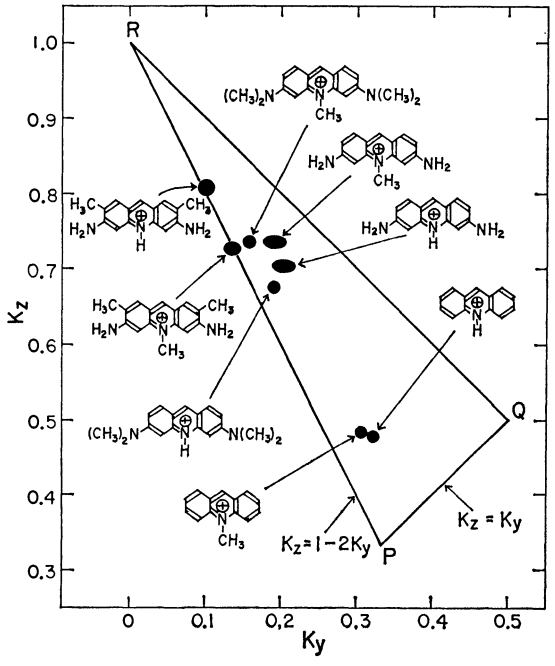

Fig. 7. The orientation factors K_y and K_z of eight acridine dyes at $S=4.3$ in the coordinates (K_y, K_z). The orientation triangle is denoted by PQR.

is clearly related to the molecular shape of dye. For example, the points for Acr and MeAcr are closest to the apex P (1/3,1/3), indicating that both Acr and MeAcr are the least orientable among those dyes studied here. This is probably due to their molecular shape, which lacks the 3,6-substituents and, as a result, is least prolate. The distance between the apex P and each point increases remarkably on the substitution of the amino or dimethylamino groups at the 3- and 6-positions of acridine nucleus (AO, PF, TF, MeAO, MeAY, and AY in this order). Since these dyes are oriented more favorably than Acr and MeAcr, the increase in the distance is attributable to the lengthening of the molecular shape. The factor K_z is larger for AY than for the quaternized, 10-methyl substituted MeAY, which implies that the quaternization of AY may alter the orientability along the z-axis. However, this tendency is reversed for pairs of PF and TF, and AO and MeAO, which possess the same substituents (either amino or dimethylamino) at 3- and 6-positions but a different one at 10-position (hydrogen or methyl). The reason for this reversal is not yet clear.

Since the points for AY and MeAY are nearly on the line PR ($K_z=1-2K_y$), these two dyes can be approximated as a rod-like molecule in their orientation property.[18] It may then be concluded that AY and MeAY are geometrically more symmetric than PF and TF with respect to the z-axis and, accordingly, the orientation axis nearly coinsides with the z-axis. The points for Acr, MeAcr, PF, TF, AO, and MeAO lie not on the line PR but inside the orientation triangle. This result indicates that the orientation axis of each of those six dyes does not coincide with the z-axis but should be somewhere between the y- and z-axes in the molecular plane. Thus the locations of the points in Fig. 7 are related to the molecular shape and, as a consequence, to the orientability of dyes. With the location of those points determined at a single S value, however, the degree of orientation of an assembly of like molecules can not be specified as yet. In this connection, a more comprehensive theory of the film dichroism must be developed under due consideration of the dependence of the degree of orientation on the geometrical shape of the guest molecules.

Conclusion

The film dichroism method has proved to be powerful for obtaining information on the polarization directions and the presence of weak bands for 3,6-disubstituted acridine dyes. From the dependence of R_d on S, the transition moment angle relative to the orientation axis could be determined, only when the R_d-values are near unity. By the reduction procedure, the reduced spectra and the orientation factors for acridine dyes of C_{2v} symmetry could be estimated at a given S without recourse to the orientation function of the guest molecules. The orientation factors of these dyes could be related to their molecular shapes.

The authors thank Mr. Takumi Matsuda for his skilled computer programming, which was used in calculating the reduced spectra.

The Determination of the Formation Constant of Triiodide Ion in Micellar Solution of Dodecyltrimethylammonium Chloride

Katumitu HAYAKAWA,* Mitsuo KANDA, and Iwao SATAKE

Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890

(Received January 27, 1979)

Spectrophotometric measurements were undertaken at 360 nm in order to estimate the formation constant of triiodide ion in micellar solution of dodecyltrimethylammonium chloride. The absorption spectra of the solutions suggested that both iodine molecule and triiodide ion are solubilized in a hydrophilic surface region of the surfactant micelle. The apparent formation constant of triiodide ion, K_a, was found to be much larger in micellar solution than in water. It was also shown that the value of K_a decreases regularly with increasing surfactant concentration. A tentative estimation based on a lamellar micelle model led to the intrinsic formation constant of triiodide ion of 650 mol^{-1} dm^3 or less at 30 °C, which is comparable with that in water. The thermodynamic consideration revealed that the formation reaction of triiodide ion from iodine and iodide ion in micellar solution is accompanied by an anomalous entropy decrease.

In a previous paper,[1] we have reported the spectrophotometric measurements of the effect of solvent composition on the formation constant, K_c, of triiodide ion in water–methanol and water–ethanol mixed solvents. We found that in both systems the value of K_c increases remarkably with increasing mole fraction of alcohol, *e.g.*, it varies rapidly with methanol concentration from 730 in water to 12200 mol^{-1} dm^3 in methanol at 25 °C. Similar increases in K_c were also found in 2-propanol[2] and acetonitrile.[2,3]

In connection with a remarkable effect of solvent properties on K_c, it is of great interest to study the formation constant of triiodide ion in a solution of surfactant, since this provides an aqueous as well as a hydrophobic environment by forming a micelle, which consists of a hydrocarbon core with polar groups at the surface. In particular, the cationic surfactant micelle may be anticipated to affect K_c significantly through a strong coulombic interaction with iodide and triiodide ions. However, such studies have not been performed so far. The estimation of K_c in micellar solution is also essential for the clear understanding of our recent studies on the rate of catalytic oxidation of formate ion by iodine in micellar solutions.[4]

The present paper is concerned with the spectrophotometric determination of the formation constant of triiodide ion in a micellar solution of dodecyltrimethylammonium chloride.

Experimental

Materials. Dodecyltrimethylammonium chloride (DTAC), purchased from Tokyo Kasei Kogyo Co., Ltd., was recrystallized twice from methanol. Other chemicals were of guaranteed grade. Sodium iodide was dried at 120 °C and used without further purification. Iodine was purified further by sublimation.

Measurements. The apparent formation constant of I_3^- in a mixed solution of I_2, NaI, and DTAC was determined spectrophotometrically at 360 nm. The absorption spectra were recorded on a Hitachi spectrophotometer model 200-20 equipped with a thermoregulated cell compartment. The change in absorbance at 360 nm was followed as a function of NaI concentration at constant concentrations of I_2 and DTAC.

The chloride ion activity in DTAC solution was measured potentiometrically by using a National chloride ion selective ceramic electrode IE-510103. The electromotive force was measured with an Orion digital pH/mV meter model 701A with an accuracy of ±0.1 mV. In the concentration range below the critical micelle concentration (CMC) of DTAC, the semilogarithmic plots of electromotive force *versus* chloride ion activity taken from Kieland's data[5] gave a linear relation with an ideal Nernst slope, suggesting that the electrode responds exclusively to chloride ions.

All measurements were conducted at 21, 30, and 40 °C.

Results and Discussion

The Absorption Spectra. In the presence of DTAC micelles, the absorption spectrum of the solution of I_2 and NaI is characterized by an absorption band at 360 nm. Figure 1 shows the typical change in

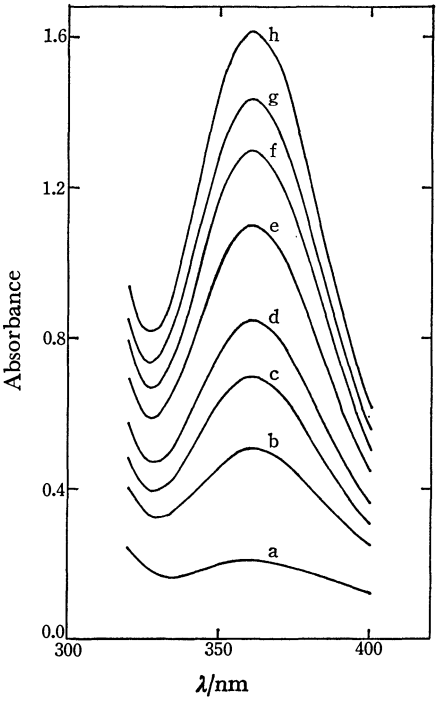

Fig. 1. The dependence of the absorbance spectrum of iodine in DTAC micellar solution on the concentration of sodium iodide at 30 °C; I_2 7.82×10^{-5} mol dm^{-3}, DTAC 0.13 mol dm^{-3}, NaI a: 0, b: 3.36, c: 6.71, d: 10.1, e: 16.8, f: 25.2, g: 33.6, h: 58.2×10^{-5} mol dm^{-3}.

absorption spectrum with NaI concentration, under the condition where concentrations of I_2 and DTAC are kept constant. Similar results were also obtained at the different DTAC concentrations studied. The important aspects of Fig. 1 are that the absorbance at 360 nm increases progressively with increasing NaI concentration, while the peak location is independent of NaI and DTAC concentrations. Unfortunately, only limited data are available in the concentration range of DTAC below CMC, since the occurrence of an appreciable amount of precipitate makes it difficult to obtain the reliable absorption spectra. However, the measurement of I_2 solution, though it was somewhat less accurate, showed that the absorption peak shifts successively from 460 to 360 nm with increasing DTAC concentration. At higher DTAC concentrations above CMC, the complex redissolved and the peak location remained at 360 nm. These observations suggest that an iodine molecule can interact strongly with a DTAC ion to give rise to a complex which is sparingly soluble in water but is easily solubilized in DTAC micelle.

The absorption spectrum of an iodine molecule is known to depend significantly on the polarity of the surrounding medium. Thus, an iodine molecule has the absorption band with a peak at 525 nm in a hydrophobic medium such as hexane,[6] but at 460 nm in water.[7] It is, therefore, reasonable to assume that the iodine molecules in micellar solution of DTAC are solubilized not in the hydrocarbon core but in a hydrophilic surface region of the DTAC micelle. The pronounced blue shift in peak location from 460 nm in water to 360 nm in micellar solution would provide additional evidence for the strong interaction between the iodine molecule and the ionic head group of DTAC.

As is shown in Fig. 1, the addition of sodium iodide results in a successive increase in absorbance but in no shift in peak location. This change can reasonably be ascribed to the formation of triiodide ion. Since, however, the peak location is red-shifted by 8 nm in micellar solution as compared with that in water,[7] triiodide ion is also considered to be solubilized in the surface region of the DTAC micelle.

The Formation Constant of Triiodide Ion. The foregoing considerations suggest that the formation reaction of triiodide ion in micellar solution will take place at the micellar surface, *i.e.*, between the iodine molecules solubilized in the surface region of DTAC micelle and the surrounding iodide ions in the close neighborhood of the micellar surface. Thus, if the inside and outside regions of micellar surface are denoted by suffix m and s respectively, the formation reaction of triiodide ion can be written as

$$I_{2,m} + I_s^- \rightleftharpoons I_{3,m}^-. \tag{1}$$

By taking into account the fact that the electrical potential at I_s^- is virtually identical with that at $I_{3,m}^-$, we can safely set the activity coefficient ratio of these ions equal to unity without introducing serious errors. Moreover, the activity coefficient of $I_{2,m}$ may probably be set equal to unity, since the total concentration of I_2 is sufficiently small as compared with that of DTAC under our experimental conditions. With this simplification, the intrinsic formation constant of triiodide ion may be written as

$$K_c = [I_3^-]_m/[I_2]_m[I^-]_s, \tag{2}$$

where the bracket represents an equilibrium concentration in moles per liter of the respective phase. Denoting the electrical potential at the micellar surface by ψ_0, the concentration of iodide ion near the micellar surface, $[I^-]_s$, can be described in terms of the apparent iodide ion concentration, $[I^-]_t$, as

$$[I^-]_s \exp(-e\psi_0/kT) = \gamma_-[I^-]_t, \tag{3}$$

where γ_- is the activity coefficient of the iodide ion. Since both iodine molecule and triiodide ion are solubilized in the same surface region of the DTAC micelle, their concentration ratio $[I_3^-]_m/[I_2]_m$ in Eq. 2 may be replaced by the ratio of the number of moles of solubilized triiodide ions per mole of iodine molecules. Therefore, if we denote an apparent concentration in moles of solubilized species per liter of solution by suffix t, we have

$$[I_3^-]_m/[I_2]_m = [I_3^-]_t/[I_2]_t. \tag{4}$$

Substitution of Eqs. 3 and 4 into Eq. 2 gives

$$K_c = K_a/\gamma_- \exp(e\psi_0/kT), \tag{5}$$

where K_a represents an apparent formation constant of triiodide ion defined by

$$K_a = [I_3^-]_t/[I_2]_t[I^-]_t. \tag{6}$$

It is worth noting here that in micellar solution the counterion concentration is a primary determinant of ψ_0 and γ_-. Accordingly, K_a can be regarded as constant at a given concentration of DTAC, because the iodide ion does not contribute appreciably to the total counterion concentration. Denoting $[I_3^-]_t$ by x, and the total concentrations of iodine and sodium iodide by a and b, we have

$$K_a = x/(a-x)(b-x). \tag{7}$$

Substituting $y=x/a$ and $z=b/a$, Eq. 7 may be rearranged to

$$y/(1-y) = K_a a(z-y). \tag{8}$$

Eq. 8 suggests that $y/(1-y)$ should be proportional to $(z-y)$. Since sodium iodide and DTAC do not show an appreciable absorption at 360 nm, the absorption coefficient of the solution, A, may be written as

$$A = \varepsilon_0(a-x) + \varepsilon_1 x = A_0 + (A_1-A_0)y \tag{9}$$

with

$$A_0 = \varepsilon_0 a, \qquad A_1 = \varepsilon_1 a, \tag{10}$$

where ε_0 refers to the molar absorption coefficient of iodine and ε_1 to that of triiodide ion, respectively. Equation 9 allows one to estimate the value of y as a function of b or z, with the knowledge of $\Delta A_\infty (= A_1-A_0)$ which corresponds to an increment in absorbance of a hypothetical solution in which iodine molecules are converted completely to triiodide ions. In order to estimate ΔA_∞, therefore, the increment in absorbance, $\Delta A (= A-A_0)$, was conveniently plotted against the reciprocal of sodium iodide concentration and was extrapolated to infinite iodide concentration. Using the value of y so determined, we can easily evaluate the apparent formation constant at a given

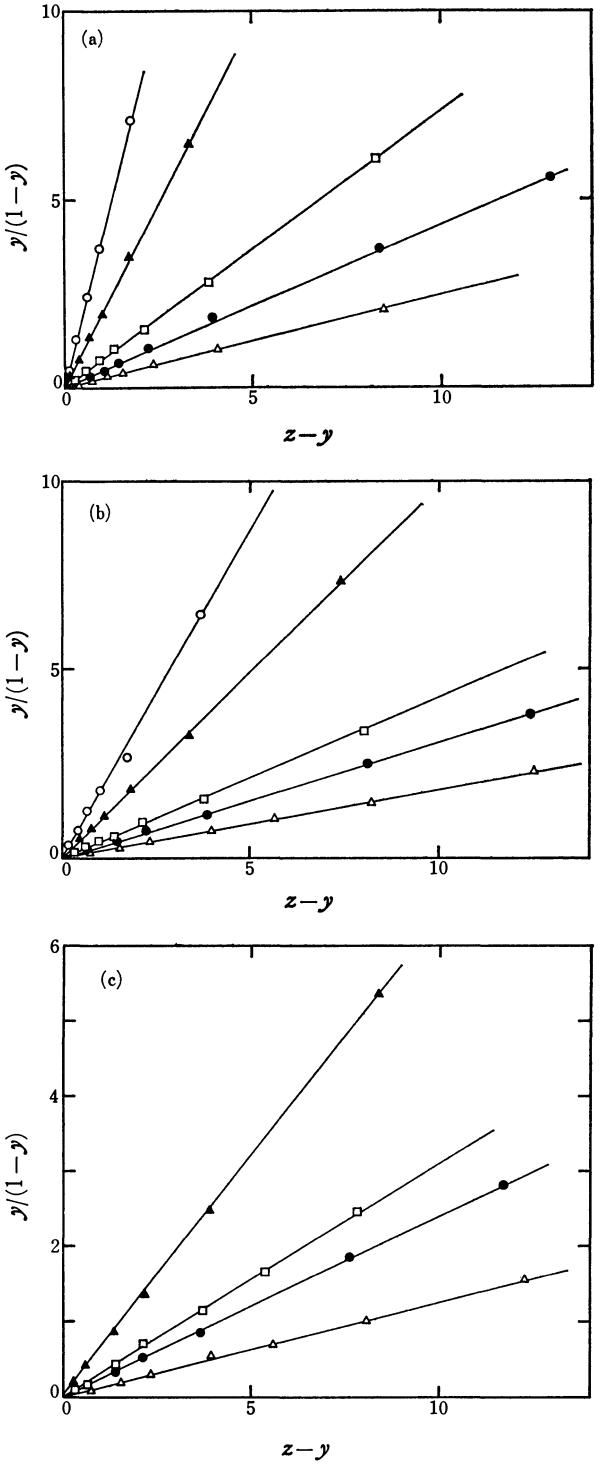

Fig. 2. The plot of $y/(1-y)$ *versus* $z-y$. (a): 21 °C, (b): 30 °C, (c): 40 °C; [DTAC] ○: 0.03, ▲: 0.04, □: 0.06, ●: 0.08, △: 0.13 mol dm^{-3}.

surfactant concentration from the slope of $y/(1-y)$ *versus* $(z-y)$ plots according to Eq. 8. Equation 5 then serves to estimate the intrinsic formation constant, K_c, provided that an appropriate expression is available for ψ_0.

Figure 2 shows $y/(1-y)$ *versus* $(z-y)$ plots at the given concentrations of iodine and surfactant. In all cases, the linearity of the plots is satisfactory over the whole concentration range of sodium iodide studied.

Table 1. The apparent formation constant of triiodide ion in DTAC micellar solution

[DTAC] / mol dm^{-3}	$10^{-4}K_a$/mol^{-1} dm^3 (21 °C)	(30 °C)	(40 °C)
0.03	10.4	4.35	—
0.04	4.97	2.47	1.8
0.06	2.05	1.16	0.80
0.08	1.20	0.82	0.60
0.13	0.67	0.48	0.32

Standard deviation: 2% at 21 and 30 °C, 7% at 40 °C.

The values of K_a calculated from Eq. 8 are summarized in Table 1. According to Eq. 5, K_a should decrease with increasing surfactant concentration, since both ψ_0 and γ_- are decreasing functions with respect to surfactant concentration. This is the case for the present results. The value of K_a shown in Table 1 tends to decrease regularly with increasing DTAC concentration, reflecting the significant contribution of electrostatic term in Eq. 5. It should also be noted that even in the highest concentration of DTAC studied the observed values of K_a are much larger than those in water.

Information regarding the intrinsic formation constant of triiodide ion can now be obtained by introducing an appropriate expression for the electrical work, $e\psi_0$, into Eq. 5. To this end, we applied an expression based on the lamellar micelle with uniformly charged surface. It is well known that the lamellar model can account for most of the interesting features of ionic surfactant solutions, *e.g.*, the effect of added salt on CMC, and a linear dependence of log CMC on the number of carbon atoms, m, for the homologous series of surfactants described as[8]

$$\log \mathrm{CMC} = A - Bm. \tag{11}$$

In his theoretical study of ionic surfactant solutions, Shinoda[8] has derived the following expression for the effective electrical work, E_{el}, needed to introduce a unit charge e into the surface of a lamellar micelle, by taking into consideration the counterion fixation effect of a highly charged micellar surface.

$$E_{el} = K_g kT \ln(2000\pi\sigma^2/\varepsilon_r N_A kTC_g) \tag{12}$$

where, σ is the surface charge density, ε_r the relative permittivity of the solution, and C_g the total counterion concentration in equivalents per liter; other symbols than K_g have their usual meanings. For a given homologous series of surfactants, K_g is an experimental constant which can be correlated to the constant B in Eq. 11 by

$$B = \omega/2.303(1+K_g)kT, \tag{13}$$

where ω refers to the cohesive energy change involved in transferring one methylene group from a hydrocarbon environment to an aqueous medium.[8] The value of ω was estimated by Shinoda[9] to be $1.08\,kT$. By introducing the critical micelle concentrations reported for dodecyltrimethyl- and hexadecyltrimethylammonium chlorides,[10] K_g for alkyltrimethylammonium chloride may be estimated from Eqs. 11 and 13 to be 0.62 at 30 °C. It is to be noted that K_g is nearly

Table 2. The formation constant of triiodide ion in some solvents

Medium	K_c/mol^{-1} dm^3			ΔH/kJ mol^{-1}
DTAC	910 (21 °C)	650 (30 °C)	430 (40 °C)	−30
H_2O	1010 (9.5 °C)	730 (25 °C)	550 (38 °C)	−15.4
MeOH	13600 (20 °C)	10900 (31 °C)	9590 (39 °C)	−14.3
EtOH	28700 (17 °C)	20700 (28 °C)	15100 (39 °C)	−21.4

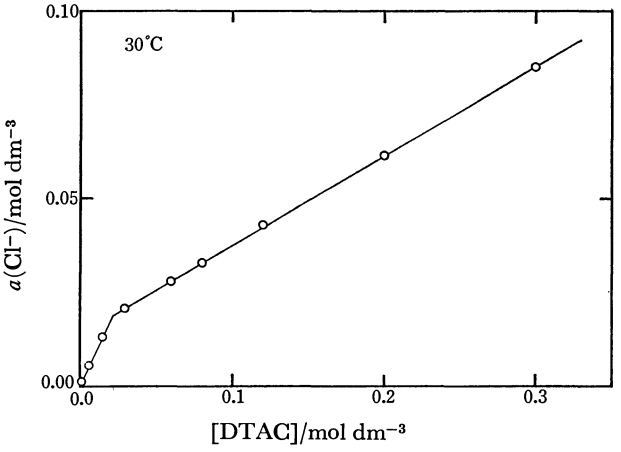

Fig. 3. The plot of chloride ion activity *versus* the total concentration of DTAC at 30 °C.

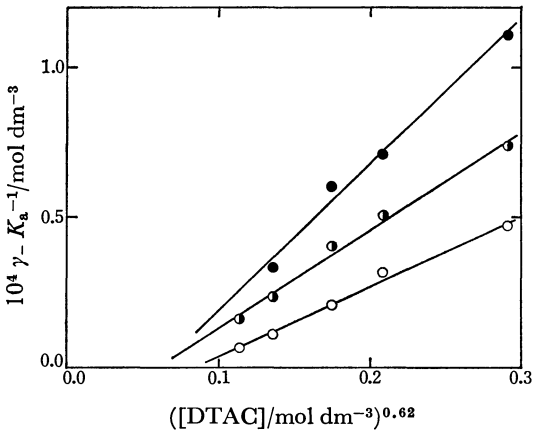

Fig. 4. The plot of γ_-/K_a *versus* $C_g^{0.62}$. ●: 40 °C, ◑: 30 °C, ○: 21 °C.

independent of temperature.[8]

Substituting E_{el} for $e\phi_0$ in Eq. 5, we have

$$\frac{\gamma_-}{K_a} = \frac{1}{K_c}\left(\frac{\varepsilon_r N_A kT}{2000\pi\sigma^2}\right)^{K_g}(C_g)^{K_g}. \qquad (14)$$

This equation implies that γ_-/K_a should be proportional to $(C_g)^{K_g}$ if surface charge density σ remains constant over the concentration range of DTAC studied. Though C_g in Eq. 14 can safely by replaced by the total concentration of DTAC, the use of this equation still requires a knowledge of the activity coefficient of an iodide ion in the presence of excess chloride ions, which is experimentally rather difficult to estimate. Therefore, on the assumption that the activity coefficient of iodide ion is equal to that of chloride ion, we made the potentiometric measurements of chloride ion activity in a solution of DTAC alone. Figure 3 shows the typical plot of chloride ion activity *versus* the total concentration of DTAC at 30 °C. Similar results were also obtained at different temperatures. In agreement with the results reported for counterion activities in solutions of various ionic surfactants,[11] the observed chloride ion activity first increases almost linearly with increasing DTAC concentration up to CMC, then it continues to increase linearly but less steeply with further increases in DTAC concentration. According to the earlier assumption, this chloride ion activity divided by total DTAC concentration gives γ_- in Eq. 14. In Fig. 4, γ_-/K_a is plotted against $C_g^{0.62}$. As would be expected, the plots are linear, but the straight lines do not converge to the origin. At the present time, no conclusive explanation can be offered as to whether the observed deviation in the intercept comes from the underlying lamellar model which assumes an infinitely extended plane surface with uniform charge density or from the assumption of equal activity coefficients for iodide and chloride ions. In fact, the micellar aggregation number of DTAC was determined from a light scattering experiment to be 57 in 0.05 mol dm^{-3} sodium chloride solution.[12] However, in view of the fact that the predicted linear relationship is found between γ_-/K_a and $C_g^{0.62}$, Eq. 14 can presumably be applied for a tentative estimation of the intrinsic formation constant of triiodide ion, K_c. On the basis of geometric considerations, Tanford[13] has calculated the surface area per polar head group of micelle forming surfactant molecules, S, for various micelle shapes as a function of micellar aggregation number. According to his calculation for globular micelles, the micellar aggregation number of 57 corresponds to the value of S of 78 A^2. Substituting e/S for σ and assuming that S is independent of temperature, the values of K_c were tentatively estimated from the slopes of straight lines given in Fig. 4. The results are summarized in Table 2 together with those in various solvents.[1] It should be emphasized that the value of K_c estimated above depends considerably on the selected value of S. For instance, it decreases up to 190 at 30 °C if we assume $S \approx 30$ A^2, which corresponds to the surface area per polar head group of a lamellar micelle.[13] With these reservations in mind, the intrinsic formation constant of triiodide ion in DTAC micellar solution is expected to be comparable with or slightly less than that in water, but small enough as compared with those in alcohols. This result supports well the assumption that the formation reaction of the triiodide ion in the micellar solution will take place at a hydrophilic surface region of the micelle. Thus the remarkable increase in the apparent formation constant of triiodide ion may be ascribed to an increase in surface concentration of iodide ions due to the strong coulombic interaction between iodide

ion and polyvalent micellar ion. Other factors seem to play at best a minor role.

Apart from a plausible estimation of K_e, we can easily evaluate the enthalpy change for Reaction 1 from the change in the slope of the straight line in Fig. 4 with temperature. As can be seen from Eq. 14, the enthalpy change so calculated is independent of the value of σ, so long as it remains constant over the temperature range studied.

It is worth noting that the enthalpy change in micellar solution shown in Table 2 is not only negative but about twice as large as that in water. Nevertheless, the values of K_e are nearly the same in both solvents. This implies that the formation reaction of triiodide ion in micellar solution is accompanied by an anomalous entropy decrease, contrary to the increases observed in water and alcohols.[1] The situation is somewhat complicated by the fact that in micellar solution both iodine molecule and triiodide ion are solubilized in the surface region of the micelle. It seems probable that the solubilized triiodide ions are restricted in their molecular motion through a strong coulombic interaction with highly charged micellar surface.

The authors wish to express their thanks to Associate Professor Norinobu Yonehara, Kagoshima University, for use of the Hitachi Spectrophotometer.

Disintegration of Sulfonated Poly(1,4-piperazinediylterephthaloyl) Microcapsules by 1-Dodecylpyridinium Chloride

Shiro SUZUKI, Takashi NAKAMURA, and Tamotsu KONDO*,†

Department of Domestic Science, Ferris Women's College, Naka-ku, Yokohama 231

† *Faculty of Pharmaceutical Sciences, Science University of Tokyo, Shinjuku-ku, Tokyo 162*

(Received February 19, 1979)

Partially sulfonated poly(1,4-piperazinediylterephthaloyl)(SPP) microcapsules were found to undergo disintegration by the action of dodecylpyridinium ions when the surfactant cation concentration exceeded a certain value which was dependent on pH of the medium. At their lower concentrations, dodecylpyridinium ions interacted with negatively charged SPP microcapsules to produce aggregation of the latter. A polyelectrolyte-type viscosity behavior was observed with the complex formed between SPP and dodecylpyridinium ions in the disintegration process of the microcapsules. Crosslinking of the terminal amino groups of SPP microcapsules prevented disintegration from taking place.

Since the earliest work was carried out on protein-anionic surfactant systems in the 1940's,[1] interactions in aqueous media between polyelectrolytes and oppositely charged surfactants have been under study for more than 30 years.[2–8] In almost all systems studied so far, the interaction causes precipitation of a complex which can be resolubilized by excess surfactant. In general, maximum precipitation seems to correspond to a single layer of surfactant adsorbed on the polymer, and the resolubilized form to a double layer of surfactant.

Meanwhile, it has become possible to prepare microcapsules composed of polyelectrolytes and to study their various physical properties.[9] Since such an electrically charged microcapsule can be regarded as a matrix of polyelectrolyte molecules assembled in a very thin spherical shell the interaction of the microcapsule with oppositely charged surfactants in aqueous media will be worth studying on the ground that understanding of this type of interaction should help us elucidate the mechanisms of the action of ionic surfactants on biological cells such as erythrocytes.[10]

The present paper deals with the interaction between partially sulfonated poly(1,4-piperazinediylterephthaloyl)(SPP) microcapsules and 1-dodecylpyridinium chloride(C_{12}PyCl) as a function of the cationic surfactant concentration at different degrees of sulfonation and pH of the medium, which leads to disintegration of the microcapsules at high concentrations of the surfactant. The effect of crosslinking with glutaraldehyde of the terminal amino groups of the polymers constituting the microcapsules on the interaction will also be discussed.

Experimental

Preparation of Microcapsules. SPP microcapsules were prepared by the method described in a previous paper.[11] The degree of sulfonation was varied by changing the molar ratio of 4,4′-diaminostilbene-2,2′-disulfonic acid to piperazine in the diamine mixture to be used as the water-soluble monomer in the preparation. When the ratio was fixed at 1:2, 1:3, and 1:5, the microcapsules obtained were named SPP-2, -3, and -5 microcapsules, respectively.

Microscopic Observation of Disintegration. To a dialyzed suspension of each of SPP-2, -3, and -5 microcapsules (*ca.* 5×10^7 capsules cm^{-3}) in test tubes was added an equal volume of various concentrations of aqueous C_{12}PyCl solution. The pH and ionic strength of the medium were adjusted by the addition of HCl or NaOH and NaCl, respectively.

The mixtures were then allowed to stand for 1 h with shaking in a thermostated water bath maintained at 35 °C. At the end of this period, a small portion of each of the mixtures was withdrawn by a capillary tube and placed on a slide glass to observe if SPP capsules were disintegrated or not.

Treatment of Microcapsules with Glutaraldehyde. The terminal amino groups of SPP microcapsules were crosslinked with glutaraldehyde in the same way as in the previous work.[11]

Adsorption of Dodecylpyridinium Ions to Microcapsules. Adsorption of C_{12}Py ions to noncrosslinked and crosslinked SPP microcapsules was measured by an equilibrium dialysis technique in the following manner.

Seventy cm^3 each of surfactant solution and microcapsule suspension were placed respectively in two compartments separated by a Cellophane membrane of an equilibrium dialysis cell made of methacrylate. The cell was immersed in a constant temperature bath kept at 35 °C. The content of each compartment was stirred with a two-blade glass stirrer. Equilibrium was attained within 4 h in all cases.

After equilibration, an aliquot of solution was withdrawn by a pipet from the compartment containing surfactant solution and its concentration was determined by the Few-Ottewill method.[12]

The amount of adsorption was calculated from the difference between the surfactant concentrations before and after adsorption.

Viscosity of Solubilized Complex. An Ostwald viscometer was used to measure the viscosity of solutions containing the solubilized complex formed between SPP and C_{12}Py ions. All measurements were made at 35 °C.

Sample solutions were prepared by diluting the solubilized complex solution with NaCl solutions of appropriate concentrations. The ratio of the specific viscosity to the dilution was defined as the viscosity number.

Results

Microscopic Observation. Disintegration of SPP microcapsules by C_{12}Py ions was dependent greatly on the surfactant cation concentration and slightly on the pH of the medium. The degree of sulfonation and the ionic strength of the medium had no effect on the disintegration phenomenon.

SPP microcapsules were disintegrated by the action of C_{12}Py ions when their concentration exceeded a certain value at all pH studied. Lower concentrations

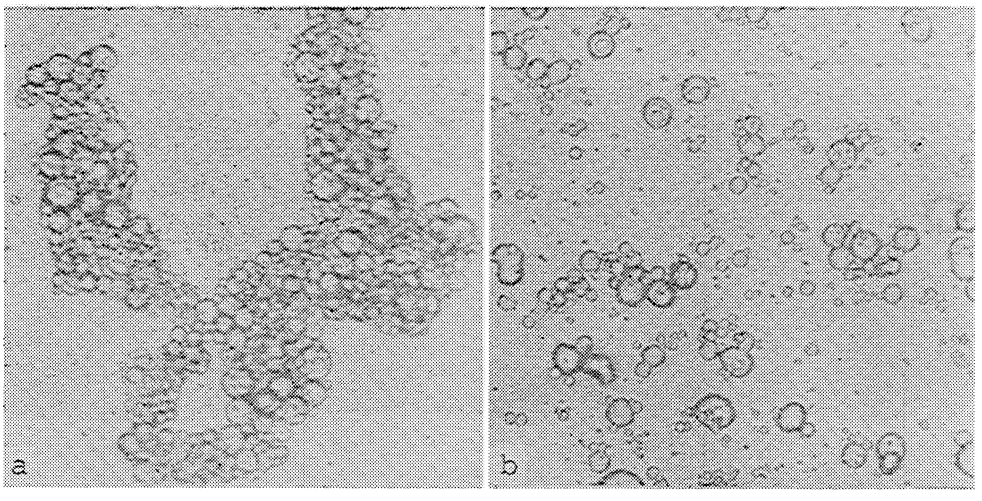

Fig. 1. Photomicrographs of SPP-5 microcapsules aggregated by 10^{-4} M $C_{12}PyCl$ (a) and partially redispersed by 10^{-2} M $C_{12}PyCl$ (b) at pH 7.0 and ionic strength 0.1.

of the surfactant cation caused aggregation of the microcapsules. Complete disintegration of the microcapsules was observed at surfactant concentrations higher than 7×10^{-2} M.** The minimum surfactant concentration needed for complete disintegration slightly decreased with increasing pH of the medium.

Table 1 gives the dependence of the phenomenon on the two variables at an ionic strength of 0.1.

Disintegration of glutaraldehyde-treated SPP microcapsules was never observed even when the highest concentration of $C_{12}PyCl$ was used. Instead, redispersion of the crosslinked microcapsules aggregated by low concentrations of $C_{12}PyCl$ took place in the presence of a large excess of the surfactant as shown in Fig. 1.

Surfactant Adsorption. Adsorption of $C_{12}Py$ ions on SPP microcapsules was affected by the surfactant cation concentration, the pH of the medium, the degree of sulfonation, and crosslinking of the terminal amino groups.

All adsorption isotherms exhibited a definite step in the surfactant concentration range of 10^{-2} to 10^{-3} M. The number of $C_{12}Py$ ions adsorbed on the microcapsules increased with increasing pH of the medium. This trend was more remarkable at low concentrations than at high concentrations of the surfactant cation. Increase in the degree of sulfonation gave rise to an increase in the amount adsorbed of $C_{12}Py$ ions.

Some of the adsorption isotherms for SPP-2 and SPP-5 microcapsules at an ionic strength of 0.1 are shown in Figs. 2 and 3, respectively, where the number of $C_{12}Py$ ions adsorbed on unit weight of the microcapsules is plotted against the initial surfactant concentration in logarithmic scale.

Crosslinking with glutaraldehyde of the terminal amino groups of SPP microcapsules caused a significant decrease in the number of adsorbed $C_{12}Py$ ions. Examples of the adsorption isotherms obtained at pH 7.0 and an ionic strength of 0.1 are given in Fig. 4 where isotherms for noncrosslinked SPP microcapsules are also shown for comparison.

Viscosity Behavior. The viscosity of solubilized complex formed between SPP molecule and $C_{12}Py$ ions exhibited a concentration dependence which is characteristic of polyelectrolytes.

The viscosity number of the solubilized complex

** 1 M=1 mol dm^{-3}.

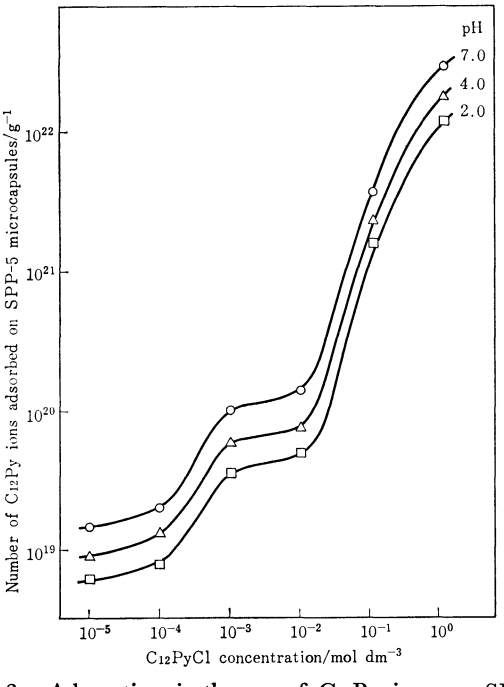

Fig. 3. Adsorption isotherms of $C_{12}Py$ ions on SPP-5 microcapsules at different pH and ionic strength 0.1 (35 °C).

at high ionic strength decreased linearly with increasing dilution while that at low ionic strength showed an uprising tendency at high dilutions. At intermediary ionic strength, the viscosity curve lay on a position between those at lower and higher ionic strengths. An example is illustrated in Fig. 5.

Discussion

It is quite obvious that aggregation of SPP microcapsules observed at low surfactant concentrations is

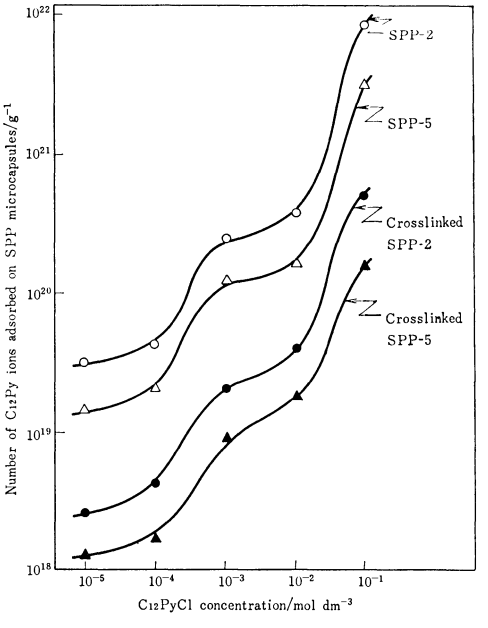

Fig. 4. Adsorption isotherms of $C_{12}Py$ ions on crosslinked and noncrosslinked SPP microcapsules at pH 7.0 and ionic strength 0.1 (35 °C).

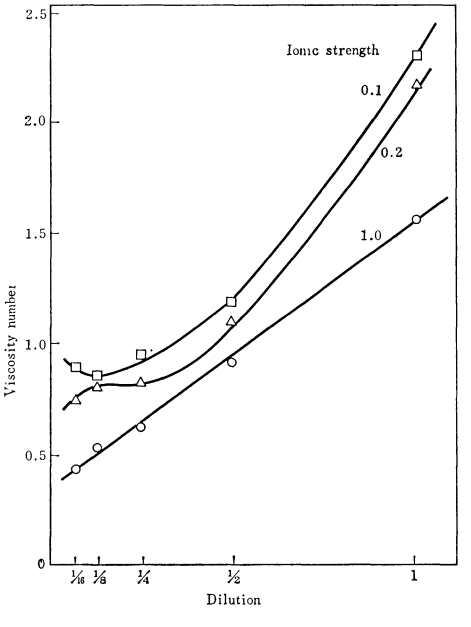

Fig. 5. Viscosity of solubilized $C_{12}Py$-SPP complex as a function of dilution at 35 °C.

caused by adsorption of $C_{12}Py$ cations with their hydrophobic tails directing outwards on sulfonato groups of the polymers constituting the microcapsules to form a hydrophobic complex. As the number of sulfonato groups on the polymers is slightly pH dependent, this head-to-head adsorption is also slightly pH dependent. This type of adsorption of the surfactant cations diminishes the electrostatic repulsion and at the same time augments the van der Waals attraction between the microcapsules, thus causing their aggregation.

When the $C_{12}Py$ ion concentration is increased beyond a value of 10^{-2} M adsorption of the surfactant cations rises steeply to form a step on the adsorption

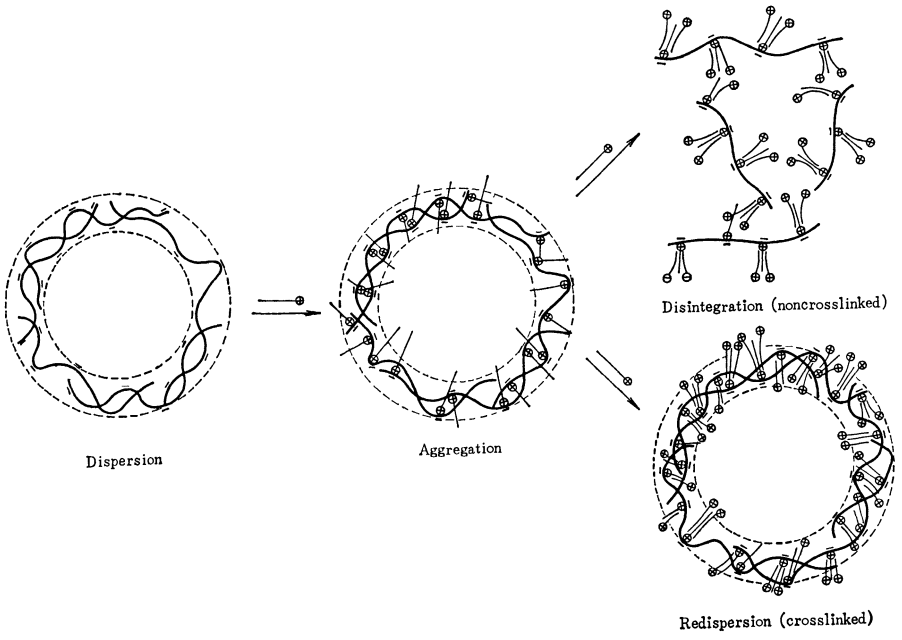

Fig. 6. Model for aggregation, disintegration, and redispersion of SPP microcapsules caused by $C_{12}Py$ ions.

isotherm (Figs. 2 and 3). The rise in adsorption is likely to correspond to the start of tail-to-tail adsorption onto the anionic sites modified by head-to-head adsorption and hydrophobic binding onto lipophilic sites on the polymer chains of $C_{12}Py$ ions. This view is supported by the fact that the number of the surfactant cations adsorbed at the concentration of 10^{-2} M on the capsules is comparable to that of anionic sites on the polymer chains.[11] Both types of adsorption generate positive charges on the polymer chains. The number of positive charges thus created will be larger, though not remarkably, at higher pH of the medium because the number of anionic sites along the polymer chains increases slightly with increasing pH as dissociation of sulfonato groups on the polymer proceeds while the number of lipophilic sites is independent of pH. It continues to increase with further rise in the surfactant cation concentration and the amount of adsorbed surfactant cations will then be enough to solubilize the polymer chains since the number of adsorbed surfactant cations reaches a value far larger than that of sulfonato groups on the polymer chains (Figs. 2 and 3).[11]

As the degree of sulfonation rises the number of sulfonato groups on the polymer chains also increases, and this in turn brings about an increase in the number of adsorbed $C_{12}Py$ ions as indicated from comparison of Fig. 2 with Fig. 3.

Increase in the number of positive charges on the constituent polymer chains of the microcapsules will cause dissociation of the chains, which leads to disintegration of the microcapsules, owing to the increased electrostatic repulsion between the chains. As is seen from Fig. 5, the viscosity of solubilized complex undergoes a marked increase with dilution when the ionic strength of the medium is low. This behavior of viscosity is characteristic of polyelectrolytes. Hence, each of the dissociated and solubilized polymer chains can be regarded as a polyelectrolyte.

Crosslinking of the constituent polymer chains prevents them from separating each other though they acquire some positive charges as a result of adsorption of $C_{12}Py$ ions on them. Consequently, disintegration of the microcapsules is never observed and instead redispersion occurs. Adsorption is rather limited in this case as the positively charged polymer chains are connected to each other by covalent bonds, and hence, an electric field exists around each capsule which is strong enough to repel the free surfactant cations approaching from the bulk of solution after adsorption proceeds to a certain degree (Fig. 4).

Figure 6 gives a proposed model for disintegration and redispersion of SPP microcapsules by the action of $C_{12}Py$ ions based on the experimental findings described in the previous section and the arguments made so far.

Polarized Absorption and Reflection Spectra of the Single Crystals of Benzidine–7,7,8,8-Tetracyano-*p*-quinodimethane Molecular Complexes

Kyuya YAKUSHI, Masaaki IGUCHI, and Haruo KURODA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received March 9, 1979)

Polarized absorption and reflection spectra were observed on the single crystals of the solvent-free and solvent-containing modifications of benzidine (BD)–7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) molecular complex, by using the microspectrophotometers of transmission and reflection types. The absorption spectra obtained by the dispersion analyses of the reflection spectra agreed fairly well with those directly observed by the transmission method. The spectra showed that the BD–TCNQ complex has non-ionic ground state in all modifications although the intermolecular interaction is considerably strong and is appreciably affected by the inclusion of solvent molecules. In all modifications, the second charge-transfer band was confirmed to be polarized in the direction almost perpendicular to the direction of the donor-acceptor stack, while the first charge transfer band is polarized in the direction of the donor-acceptor stack as it is usually found for a typical charge-transfer complex. This anomaly of the polarization direction of the second charge-transfer band was concluded to be due to a strong mixing between the charge-transfer excitation and the local excitation associated with TCNQ.

The charge-transfer complex which involves benzidine (BD) as electron donor and 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) as electron acceptor, exhibits anomalous behaviors in several respects. First, BD–TCNQ is not a radical salt, but a charge-transfer complex with essentially non-ionic ground state, although BD is an electron donor with considerably low ionization potential (7.0 eV) and TCNQ is an electron acceptor with very high electron affinity (2.8 eV).[1] Second, when BD–TCNQ complex is crystallized from solution, it forms either a crystal including solvent molecules in the crystal lattice or a crystal of the solvent-free form, depending on the solvent used, and the semiconductive properties of the solvated modifications are markedly different from those of the solvent-free modification.[2,6] The crystal structure analyses revealed that, in the solvated modifications, solvent molecules are included in the channel-like free space in the BD–TCNQ host-lattice, while BD and TCNQ molecules are closely packed without leaving any space to accommodate solvent molecules in the case of the solvent-free modification.[3–5] From these structural studies, the solvated modifications of BD–TCNQ complex were concluded to be a new type of the inclusion compound where the intermolecular hydrogen bonds and intermolecular charge-transfer interaction are responsible for the formation of the channeled structure of the host lattice. The third point of interest is that, according to our preliminary study on the absorption spectrum of BD–TCNQ crystal,[1] the polarization direction of the second charge-transfer band is perpendicular to the direction of the BD–TCNQ stack while the first charge transfer band is parallel to the stacking direction as it is usually expected for a typical charge-transfer band.

In view of those anomalous behaviors of BD–TCNQ system, it seemed of great interest to investigate the optical properties of the single crystals of the solvent-free and solvated modifications of BD–TCNQ complex.

As we have pointed out in our previous papers,[3–5] the obtainable modifications of BD–TCNQ complex can be classified into three types according to the difference as regards the structure of the BD–TCNQ sub-lattice: the one is the solvent free modification, the second is the modification which includes an aliphatic solvent molecule such as dichloromethane and the third is the one which includes benzene or its derivatives. Thus, in the present study, we have taken up one representative example for each of these three types: the solvent-free crystal (BD–TCNQ–[n]), the dichloromethane-containing crystal (BD–TCNQ–[CH_2Cl_2]), and the benzene-containing crystal (BD–TCNQ–[C_6H_6]). We will show the absorption and reflection spectra of these crystals measured by means of the microspectrophotometric technique. Discussion will be given on the interpretation of the observed spectra and on the charge-transfer interaction between BD and TCNQ molecules, using the results of the molecular orbital calculations on the models of isolated BD–TCNQ molecular pair.

Experimental

Materials. The crystals of the solvent-free modification of BD–TCNQ complex were obtained by crystallizing the complex from chloroform solution. The crystals of each solvated modification were prepared from the solution where appropriate amounts of BD and TCNQ were dissolved in the solvent which was to be included in the crystal. The details of the procedure of preparation and the characterization of each modification were described in our previous paper.[6]

Absorption Spectrum. The absorption spectrum was measured on very small single crystals by use of plane-polarized light, using the Olympus MSP-A-IV microspectrophotometer which we had modified for the purpose of the measurement of crystal spectrum. The details of this apparatus and the procedure of measurement have been described elsewhere.[7] All absorption spectra were observed at room temperature.

Reflection Spectrum and Its Analysis. We have newly constructed an apparatus for the measurement of the reflection spectrum of a very small single crystal. Figure 1 shows the block diagram of this apparatus. We used Sylvania 650 W halogen lamp as the light source for infrared and visible region. The light is monochromatized by means of JASCO-CT52 grating monochromator with the focal length of 50 cm and the *f*-number of 4.5. The monochromatic light is put into the microscope optical system, Olympus

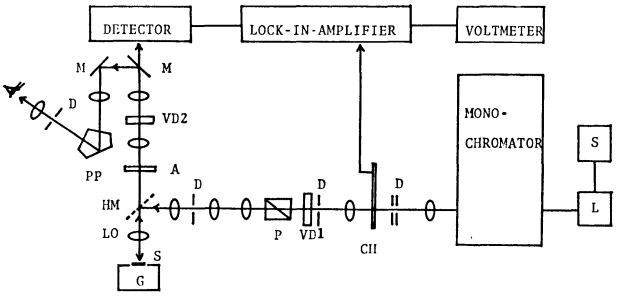

Fig. 1. The optical system of the Olympus MMSP-RK and the block diagram of the microspectrophotometer for reflection spectra. S: A.c. stabilizer, L: 650 W halogen lamp, D: diaphragm, CH: chopper, VD: variable diaphragm, P: polarizer, HM: half mirror, M: mirror, A: analyzer, PP: pentaprism, S: sample, G: goniometer head.

MMSP-RK, the structure of which is schematically illustrated in Fig. 1. In this optical system, the light which has passed through a variable diaphragm (VD1), is converted to a plane-polarized light by a Glan-Thompson prism (P), reflected by a half-mirror (HM), and focussed down onto the sample crystal through an objective lens (LO). The size of the light spot on the sample can be varied from 10 $\mu m\phi$ to 196 $\mu m\phi$ by changing the opening of the variable diaphragm (VD1) and the magnification of the objective lens. The reflected light passes again through the same objective lens, is focussed at the second variable diaphragm (VD2), and the intensity of the light passes through the above diaphragm is measured by the detector. Three detectors, having different spectral sensitivities, are installed and selectively used depending on the wavelength by changing the optical path by means of a mirror system: A photomultiplier tube HTV R435 is used for 400—700 nm region, another tube HTV R316 for 700—1100 nm region and a PbS photoconductive cell, cooled with Dry Ice–methanol mixture, for 1100—2500 nm region.

The output signal from the detector is amplified by a lock-in-amplifier, Brookdeal M9503, by being synchronized to the signals from the remote sensor which detects the rotation of the light chopper (CH), and the final output is read with a digital voltmeter.

The sample crystal is mounted on a goniometer head so that we can select out the crystal face on which the measurement of reflection spectrum is carried out, and can orient the observing crystal face exactly normal to the light axis. The goniometer head is transferable to X-ray diffraction camera to examine the crystallographic character of the observing crystal face. The goniometer head mentioned above is mounted on a rotatable sample stage which also has a mechanism to move in two horizontal directions.

Strictly speaking, the condition of normal incidence is not filled in our optical system, since the light is focussed down onto the sample through the objective lens. The reflectance we are observing, is the one averaged over the contributions of the *s*- and *p*-polarized components of the light beams with the incident directions within the cone of the focusing light. Naturally, the deviation from the normal incidence condition will be larger as the aperture angle of the objective lens is larger. The aperture angles of our lenses are 5.8°, 14.5°, and 23.6° for the magnifications of ×5, ×10, and ×20, respectively. We carried out numerical calculation by computer on the variation of reflectance with incident angle for *s*- and *p*- polarizations.[8] This calculation showed that, when the deviation from the normal incidence direction is less than 24°, the average of the reflectances of the *s*- and *p*-components remains at almost the same value, because the reflectance increases for the *s*-polarization while decreases for the *p*-polarization on increasing the deviation from the normal direction. In effect, the reflectance data which were obtained on the same sample by using the three lenses mentioned above, agreed with each other within the experimental error. Thus we concluded that the reflectance data which are obtainable with our microspectrophotometer can be regarded to be effectively the same as those obtained under the normal incidence condition.

To obtain absolute reflectance values, we have to compare the intensity of the light reflected from the sample with that reflected from a standard reflector of known reflectivity. The single crystals of silicon[9] and saphire[10,11] were used as the standard reflector, since the reflectances of their polished surfaces, in the near-infrared and visible region, are of the same order of magnitude with those of our samples and their surfaces are very stable so that their reflectance values do not vary with time.

On each modification of BD–TCNQ complex, we carried out the measurement on several different crystals. Although the obtained spectral shape were almost the same, the absolute reflectance values were different at most 10% ($\Delta R/R<0.1$) from crystal to crystal depending on the quality of the crystal surface. We considered that the spectrum showing the highest reflectance value at each reflectance maximum, are the best observed result.

There are several different method to obtain optical constants from a reflection spectrum. The Kramers-Kronig analysis is the most direct way if one can use reflectance data over a wide wavelength region. However, in the present study, the observation was limited only in the near-infrared and visible region, and, furthermore, our samples had strong absorption bands around the long and short wavelength limits of the observed range. These situations make it difficult to perform a direct Kramers-Kronig analysis. The method proposed by Roessler[12] and its modification[13] are also hard to be used in the present case. Therefore, we used the so-called dispersion analysis method, describing the complex dielectric function $\varepsilon(\omega)$ by the following equation based on the model of uncoupled Helmholtz-Kettler oscillators:[8]

$$\varepsilon(\omega) = \varepsilon_c + \sum_{j=1}^{N} \frac{S_j\omega_j^2}{(\omega_j^2-\omega^2)-i\gamma_j\omega_j\omega} \tag{1}$$

There is the following relation between the reflectance $R(\omega)$ and the complex dielectric function $\varepsilon(\omega)$.

$$R(\omega) = \frac{|\varepsilon(\omega)|+1-\sqrt{2}\{|\varepsilon(\omega)|+\mathrm{Re}[\varepsilon(\omega)]\}^{1/2}}{|\varepsilon(\omega)|+1+\sqrt{2}\{|\varepsilon(\omega)|+\mathrm{Re}[\varepsilon(\omega)]\}^{1/2}} \tag{2}$$

Treating the constants ε_c and (ω_j, γ_j, S_j), as adjustable parameters, we determined their values so as to give the best agreement between the observed and calculated reflectance. In this curve-fitting procedure, we defined an error function as $\sum_k[R_{obsd}(\omega_k)-R_{calcd}(\omega_k)]^2$, and looked for the set of the parameter values which minimize the above error function, by means of the Fletcher-Powell method,[14] using computer. By use of the known relations, $\mathrm{Re}[\varepsilon(\omega)]=n(\omega)^2-k(\omega)^2$ and $\mathrm{Im}[\varepsilon(\omega)]=2n(\omega)k(\omega)$, we calculated the optical constants, $n(\omega)$ and $k(\omega)$, from the obtained complex dielectric function. Then, the molar extinction coefficient $\mu(\omega)$ was calculated by Eq. 3

$$\mu(\omega) = \frac{2\omega k(\omega)}{c}\cdot\frac{1000d}{M}, \tag{3}$$

where c is the light velocity in vacuum, d is the density of

the crystal, and M is the molecular weight of the complex. In practice, we used one oscillator function for each transition in describing the complex dielectric function by Eq. 1. The oscillator strength of the j-th electronic transition was calculated by the following equation.

$$f(j) = \frac{m}{2\pi^2 e^2 n} \int_0^\infty \mathrm{Im}\varepsilon^{(j)}(\omega)\omega \mathrm{d}\omega \qquad (4)$$

where $\varepsilon^{(j)}(\omega) = S_j\omega_j^2/[(\omega_j^2-\omega^2)-i\gamma\omega_j\omega]$, n is the number density of electrons concerned with the j-th transition, m is the electron mass, and e is the electron charge.

Results and Discussion

Solvent-free Modification, BD–TCNQ–[n]. The crystal of BD–TCNQ–[n] is monoclinic with the space group C2/m. The lattice constants are $a=12.231$ Å, $b=12.679$ Å, $c=6.477$ Å, and $\beta=104.84°$. Two molecular units are contained in the unit cell. As shown in the projection of the structure onto the (010) planes (Fig. 2), BD and TCNQ molecules are alternately stacked along the c axis, orienting their molecular planes almost perpendicular to the axis, and their long molecular axes are in the [201] direction. The overlap of BD and TCNQ molecules in this crystal is of the type A shown as Fig. 3(a), having the average intermolecular separation of 3.24 Å, between BD and TCNQ. We measured the reflection spectrum as well as the transmission spectrum on the (010) face of this crystal.

The observed reflection spectra are shown in Fig. 4, and the absorption spectra directly observed by the transmission method are shown in Fig. 5 (solid lines). It should be noted in Fig. 5 that the absorption spectra obtained by the two entirely different experimental methods are in satisfactory agreement with each other. As we will show later, a similarly good agreement between the spectra obtained by the two methods could be found in all cases studied in the present study. This fact provides an evidence for the validity of the procedure which we have adopted for the measurement and analysis of reflectance data.

As shown in Fig. 5, the //c absorption spectrum exhibits a strong absorption band with a maximum at 7.4×10^3 cm^{-1} and a shoulder at about 9×10^3

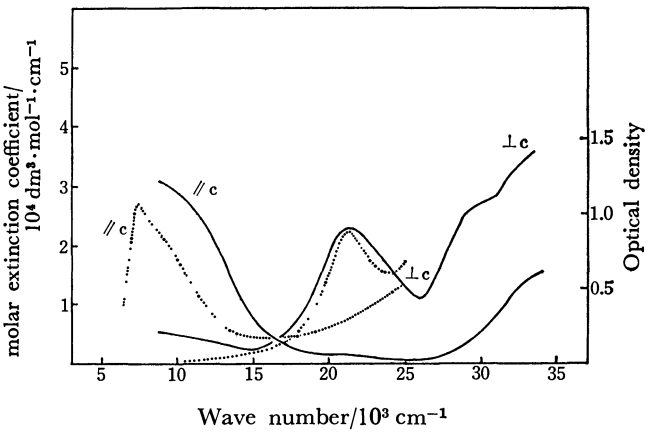

Fig. 5. Absorption spectra on the (010) plane of BD–TCNQ–[n]. The solid lines are the absorption spectra measured by the transmission method. The ordinate is optical density. The dotted lines are absorption spectra calculated by the reflection spectra. The ordinate is molar extinction coefficient.

cm^{-1}. This infrared absorption band is strongly polarized in the c axis direction (BD–TCNQ stacking direction). On the other hand, the ⊥c spectrum shows an absorption band at 21.2×10^3 cm^{-1}, completely polarized in the [201] direction. The ⊥c spectrum measured by the transmission method shows another two absorption bands in the ultraviolet region, the one being at 29×10^3 cm^{-1} and the other at above 33×10^3 cm^{-1}. Figure 6 shows the absorption spectra of BD and TCNQ molecules observed on their dichloromethane solutions, and the charge-transfer bands of the BD–TCNQ complex formed in the chloroform solution. The absorption spectrum of BD shows a broad absorption band in the region from 30×10^3 cm^{-1} to 40×10^3 cm^{-1} (the maximum is at 35×10^3 cm^{-1}). This band can be assigned mainly to the π-π^* transition ($^1B_{3u}\leftarrow{}^1A_g$) polarized along the long molecular axis of BD. According to the molecular orbital calculation, there must be a weak absorption band associated with the short-axis polarized π-π^* transition ($^1B_{2u}\leftarrow{}^1A_g$) in the same region. Seemingly, this weak band is hidden under the strong absorption band mentioned above. In the solution spectrum of TCNQ, the absorption band at 25.4×10^3 cm^{-1} is due to the lowest π-π^* transition ($^1B_{3u}\leftarrow{}^1A_g$), polarized in the long-axis direction. BD and TCNQ molecules form a stable charge-transfer (CT) complex in the chloroform solution. As shown in Fig. 6, this molecular complex exhibits the first CT band at 10.3×10^3 cm^{-1} and the second one at 20×10^3 cm^{-1}. It was found in our previous study that the energy separation between the first and second CT bands was always about 1.3 eV in the solution spectra of a series of the molecular complexes which involve BD as the donor, irrespective of the acceptor, and the separation of the two CT bands is approximately equal to the energy difference between the highest and second highest occupied orbitals of BD. These facts indicate that the second CT band of the solution spectrum of BD–TCNQ complex is associated with the charge transfer from the second highest occupied molecular orbital (second HOMO) of BD to the lowest unoccupied molecular orbital (LUMO) of TCNQ, while the first CT band is associated with that from the HOMO of BD to the LUMO of TCNQ.

Let us compare the crystal spectrum of BD–TCNQ–[n] with the solution spectra discussed above. The 7.4×10^3 cm^{-1} band of the //c spectrum undoubtedly corresponds to the first CT band of the solution spectrum of BD–TCNQ complex, although its shift, 3×10^3 cm^{-1}, to lower energy is a little larger than the shift usually found for a typical CT complex.

From the simple comparison of the crystal spectrum with the solution spectra of BD, TCNQ, and their complex, we could conclude that the 21.2×10^3 cm^{-1} band of the crystal spectrum corresponds to the second CT band of the solution spectrum of BD–TCNQ complex, and the 29×10^3 cm^{-1} band and the band above 33×10^3 cm^{-1} are the local-excitation bands associated with the transitions in TCNQ and BD, respectively. However, it should be noted that the 21.2×10^3 cm^{-1} band of the crystal spectrum is polarized perpendicular to the direction of the BD–TCNQ stack. This is unusual for a CT band. On the other hand, if the 21.2×10^3 cm^{-1} band is due to the $^1B_{3u}\leftarrow{}^1A_g$ transition of TCNQ, we must consider that it is shifted by 4×10^3 cm^{-1} to lower energy as compared with the solution spectrum.

A BD molecule overlaps with the adjacent TCNQ molecule, in the manner shown in Fig. 3(a). In this case, the overlap integral between the HOMO (b_1) of BD and the LUMO (b_1) of TCNQ is large, but the overlap integral between the second HOMO (a_1) of BD and the LUMO (b_1) of TCNQ must be zero. This means that the absorption band, which has been tentatively attributed to the charge transfer from the second HOMO of BD to the LUMO of TCNQ, cannot appear unless the above CT configurations is mixed with another excited configuration which gives a strong absorption band. The most probable mechanism would be the mixing of the local excitation associated with the lowest π-π^* transition ($^1B_{3u}\leftarrow{}^1A_g$) of TCNQ. In order to confirm this idea, we carried out a molecular orbital calculation on the isolated BD–TCNQ pair of the geometry found in the crystal. The method of calculation is the same as the one which was previously used by Ohta, Kuroda, and Kunii for the molecular complexes of polycyclic aromatic hydrocarbon

with tetracyanoethylene.[15] A π-orbital of a supermolecule, BD–TCNQ pair, is expressed by the linear combination of $2p_z$ AO's as follows.

$$\phi_i = \sum_{\mu=1}^{n_d+n_a} C_{i\mu}\phi_\mu \tag{5}$$

where ϕ_μ with $\mu=1$—n_d are the AO's associated with the donor and those with $\mu=n_d+1$—n_d+n_a are the AO's associated with the acceptor. In order to see the contributions of the donor and acceptor for the i-th molecular orbital, we define D_i and A_i as follows.

$$D_i = \sum_{\mu=1}^{n_d} C_{i\mu}^2 \qquad A_i = \sum_{\mu=n_a+1}^{n_d+n_a} C_{i\mu}^2 \tag{6}$$

The π-orbital scheme calculated for the BD–TCNQ pair and those for the constituent molecules are illustrated in Fig. 7, where the values (D_i, A_i) are given for each molecular orbital of BD–TCNQ pair. With the aid of D_i and A_i values and the symmetry consideration, we derived the correlation between the orbitals of BD–TCNQ pair and those of BD and TCNQ molecules as illustrated in Fig. 7 with dotted lines.

The excited states of BD–TCNQ pair were calculated by taking into account the configuration interaction of all singly-excited configurations. The results of this calculation are summarized in Table 1. The electronic transitions in a molecular pair DA can be classified into four categories: (a) the local excitation LE(D*) associated with a transition in the donor molecule D, (b) the local excitation LE(A*) associated with a transition in the acceptor molecule A, (c) the charge-transfer excitation CT(D→A), (d) the back charge-transfer excitation CT(A→D). The excitation of an electron from the i-th orbital to the j-th orbital of the molecular pair, Φ_{ij}, generally has a character that LE(D*), LE(A*), CT(D→A), and CT(A→D) are mixed with the weights proportional to D_iD_j, A_iA_j, D_iA_j and A_iD_j, respectively. When the CI (configuration interaction) wavefunction of the m-th excited state, Ψ_m, is expressed as,

$$\Psi_m = \sum_{ij} b_{ij,m}\Phi_{ij} \tag{7}$$

we define the following quantities.

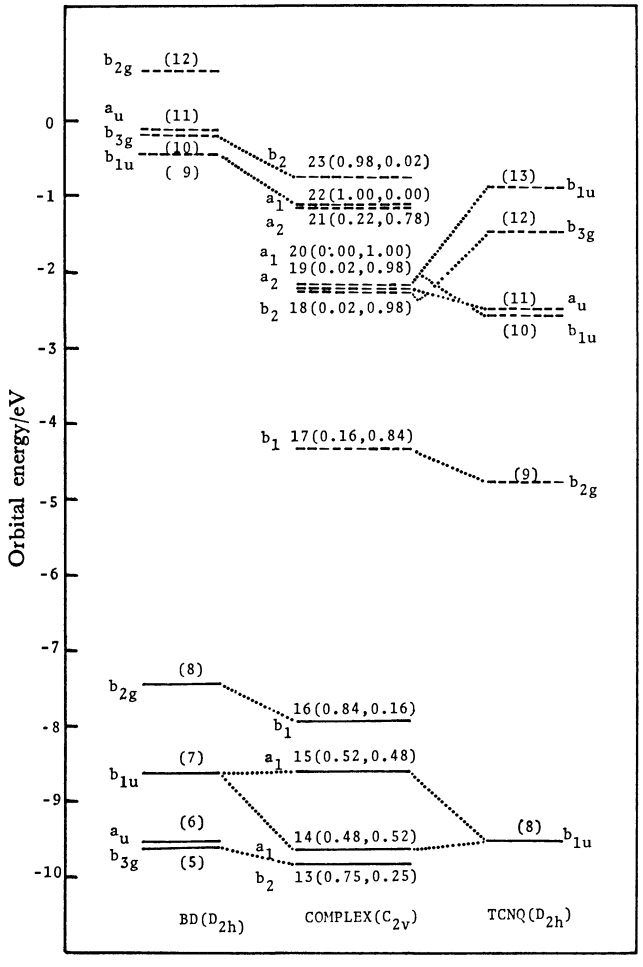

Fig. 7. Molecular orbitals of BD, TCNQ, and BD-TCNQ complex. The numerical values in the parenthesis correspond to the weight of the donor and acceptor character.

$$\begin{aligned}(DD)_m &= \sum_{ij} b^2_{ij,m}D_iD_j \\ (AA)_m &= \sum_{ij} b^2_{ij,m}A_iA_j \\ (DA)_m &= \sum_{ij} b^2_{ij,m}D_iA_j \\ (AD)_m &= \sum_{ij} b^2_{ij,m}A_iD_j\end{aligned} \tag{8}$$

The values of $(DD)_m$, $(AA)_m$, $(DA)_m$, and $(AD)_m$ give the weights of the characters of LE(D*), LE(A*), CT(D→A), and CT(A→D) in the m-th excited state, respectively. The above values of each transition are also given in Table 1. For example, in the case of the transition (1) which is predicted at 12.51×10^3 cm^{-1}, the $(DA)_m$ value is about 0.7, which indicates that this transition is mainly associated with a charge transfer from BD to TCNQ. In effect, the transition moment is predicted to be in the direction connecting the centers of BD and TCNQ molecules. The result for the transition (2) is most interesting. This transition is predicted to have its transition moment parallel to the long axes of BD and TCNQ molecules. In this case, $(DA)_m$ is 0.43 and $(AA)_m$ is 0.38. This means that the transition has a character that CT (D→A) and LE(A*) are mixed with almost equal weights. The same can be said for the third transition predicted at 24.52×10^3 cm^{-1}. When we calculate the transitions in TCNQ molecule using the same method, the lowest π-π^* transition ($^1B_{3u}\leftarrow{}^1A_g$) is predicted at 22.18×10^3 cm^{-1}, which is lower by about 3×10^3 cm^{-1} than the experimental value. From the comparison of the results of the calculation on BD–TCNQ pair and those on TCNQ molecule, we can conclude that the CT configuration associated with the charge transfer from the second HOMO of BD to the LUMO of TCNQ and the LE(A*) configuration associated with the lowest singlet π-π^* excitation of TCNQ, are strongly mixed with each other in BD–TCNQ pair to give the transitions (2) and (3).

Although the crystal of BD–TCNQ–[n] is not composed of isolated BD–TCNQ pairs, the results of the above calculation can be used to interprete the crystal spectrum, since the main features of the crystal spectrum of a CT complex is determined by the interaction between neighboring donor and acceptor molecules. The z and x axes in Table 1 correspond to the //c and ⊥c directions of the crystal of BD–TCNQ–[n], respectively. Consequently, the transition (1) which is predicted to be polarized in the z axis direction will appear in the //c spectrum, while the x axis polarized transitions, (2), (3), (5), and (9) are expected to appear in the ⊥c spectrum. Therefore, we can assign the 7.4×10^3 cm^{-1} band in the //c spectrum to the transition (1), and the 21.2×10^3 cm^{-1} and 29×10^3 cm^{-1} bands in the ⊥c spectrum to the transitions (2) and (3), respectively. The strong absorption band at above 33×10^3 cm^{-1} in the ⊥c spectrum is likely to correspond to the transition (9) which is mainly associated with the lowest π-π^* transition of BD. We were not able to observe any absorption maximum corresponding to the transition (5). Seemingly, it is hidden under the strong absorption bands corresponding to the transitions (3) and (9).

The low frequency dielectric constants of the microcrystalline powders of molecular complexes were studied by Ishii *et al.*[16] by use of the microwave cavity perturbation method. It was revealed that the observed dielectric constants are always larger than the values estimated under the assumption that the molecular polarization of a complex is equal to the simple sum of the molecular polarizations of the

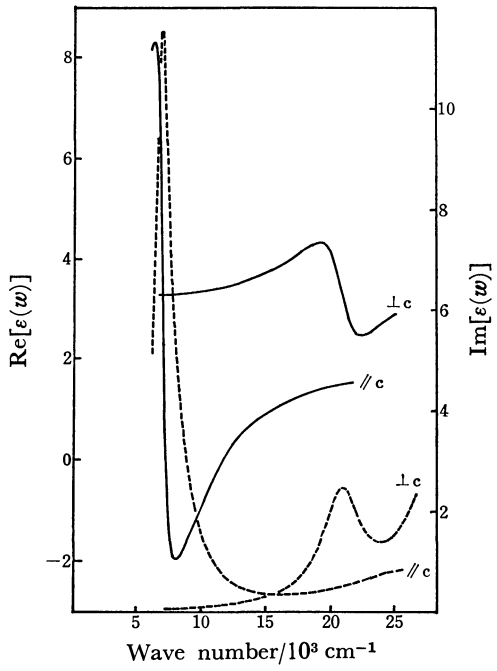

Fig. 8. The real (——) and the imaginary (----) parts of the dielectric function of BD–TCNQ–[n].

constituent molecules. The dielectric constant of the BD–TCNQ–[n] powder is 6—7 according to the above paper. If we estimate the molecular polarization of BD–TCNQ system as the simple sum of the molecular polarizations of BD and TCNQ, and assume the Clausius-Mossotti equation, the dielectric constant of BD–TCNQ–[n] is estimated to be about 4, which is smaller by 2—3 than the observed dielectric constant. This difference must be due to the enhancement of dielectric constant by the intermolecular interaction. It is most likely that the above enhancement arises mainly from the CT interaction between BD and TCNQ. To confirm this idea, we carried out the following analysis.

Fig. 8 shows the real and imaginary parts of the frequency-dependent dielectric functions obtained from the //c and ⊥c reflection spectra. The static dielectric constant $\varepsilon(0)$ can be estimated from the complex dielectric function $\varepsilon(\omega)$ by means of the Kramers-Kronig equation for an insulator.

$$\varepsilon(0) = 1 + \frac{2}{\pi}\int_0^\infty \frac{\mathrm{Im}\varepsilon(\omega)}{\omega}\mathrm{d}\omega \tag{9}$$

According to this relation, the contribution of the CT transitions to $\varepsilon(0)$ can be expressed as follows.

$$\Delta\varepsilon(\mathrm{CT}) = \frac{2}{\pi}\int_{\omega_1}^{\omega_2} \frac{\mathrm{Im}\varepsilon(\omega)}{\omega}\mathrm{d}\omega \tag{10}$$

where ω_1 and ω_2 are the low- and high-frequency limits of the region of CT band. Taking $\omega_1=4\times10^3$ cm^{-1} and $\omega_2=24\times10^3$ cm^{-1}, we performed the above integration using the complex dielectric functions obtained from the //c and ⊥c reflection spectra. The $\Delta\varepsilon$(CT) value thus calculated was 3.0 and 0.5 for the //c and ⊥c polarizations, respectively. The $\Delta\varepsilon$ (CT) value must be zero for the //b polarization since the CT transitions concerned here has no //b component. In order to compare with the dielectric behavior

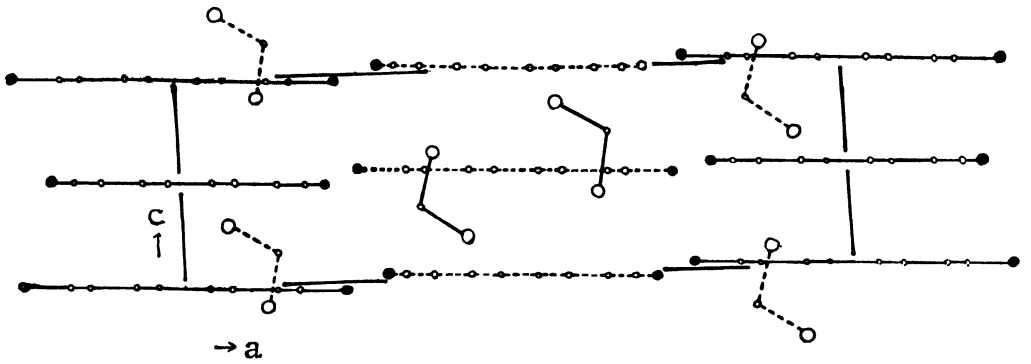

Fig. 9. The crystal structure of BD–TCNQ–[CH_2Cl_2] projected onto the (010) plane.

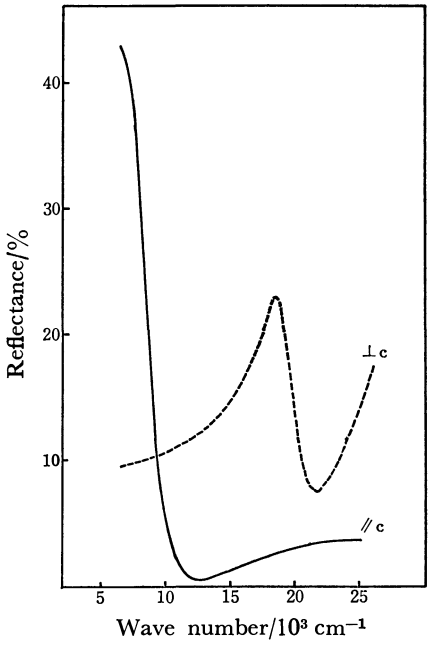

Fig. 10. Reflection spectra on the (010) plane of BD–TCNQ–[CH_2Cl_2].

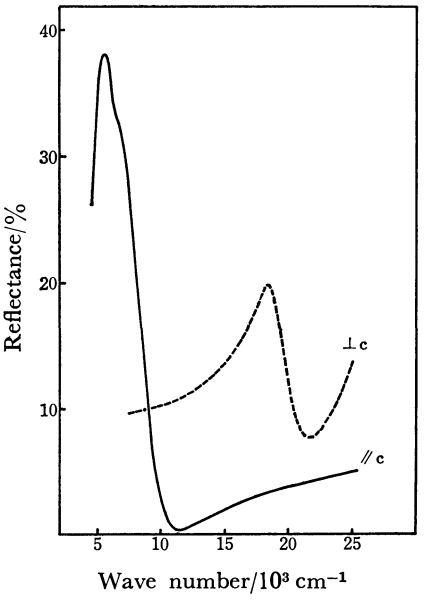

Fig. 11. Reflection spectra on the (100) plane of BD–TCNQ–[CH_2BrCH_2Br].

of the microcrystalline powder, we have to take the average of the $\Delta\varepsilon$(CT) values for the three polarizations. This average value is calculated to be 1.2. Although it is a little smaller than the enhancement of dielectric constant, estimated from the data by the microwave cavity perturbation method, the above result indicates that the enhancement of dielectric constant is indeed mainly due to the intermolecular charge-transfer interaction.

BD–TCNQ–[CH_2Cl_2] and BD–TCNQ–[CH_2BrCH_2Br]. The crystal of BD–TCNQ–[CH_2Cl_2] is monoclinic, with the space group I2/m. The lattice constants are $a=20.892$ Å, $b=9.950$ Å, $c=6.445$ Å, and $\beta=91.92°$.[3] Two molecular units are contained in the unit cell as shown in Fig. 9. The BD and TCNQ molecules are alternately stacked along the c axis to form a BD–TCNQ column, in which the molecular overlap of BD and TCNQ are almost the same as that in BD–TCNQ–[n] except that the average separation of the molecular planes, 3.22 Å, is a little smaller than that in the latter. The main difference between BD–TCNQ–[CH_2Cl_2] and BD–TCNQ–[n] is that, in the former crystal, there are channels surrounded by four BD–TCNQ columns, in which dichloromethane molecules are included, while BD–TCNQ columns are closely packed in the crystal of BD–TCNQ–[n]. The adjacent BD–TCNQ columns in BD–TCNQ–[CH_2Cl_2] are connected with each other by the intermolecular hydrogen bonds between C≡N group of TCNQ and NH_2 group of BD. These hydrogen bonds seem to contribute to the stabilization of the channeled structure of BD–TCNQ sublattice of the solvated modification.

The crystal of BD–TCNQ–[CH_2BrCH_2Br] is orthorhombic with the space group Immm. The lattice constants are $a=10.205$ Å, $b=20.785$ Å, and $c=6.525$ Å. The a and b axes in this crystal correspond to the b and a axes of BD–TCNQ–[CH_2Cl_2], respectively, and the structure of BD–TCNQ sub-lattice is almost the same as that of the latter crystal, except that the average separation between the molecular planes of BD and TCNQ is 3.26 Å.

The reflection spectrum measured on the (010) face of BD–TCNQ–[CH_2Cl_2] and that measured on the corresponding crystal face, (100), of BD–TCNQ–[CH_2BrCH_2Br] are shown in Fig. 10 and Fig. 11, respectively. From the analyses of these spectra, we obtained the absorption spectra shown in Figs. 12 and 13. In Fig. 12, we have also shown the absorption

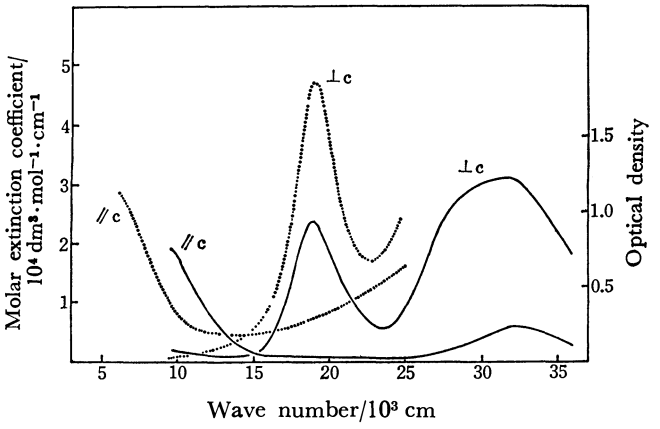

Fig. 12. Absorption spectra on the (010) plane of BD-TCNQ-[CH_2Cl_2]. The continuous lines are the absorption spectra measured by transmission method. The ordinate is optical density. The dotted lines are absorption spectra calculated by the reflection spectra. The ordinate is molar extinction coefficient.

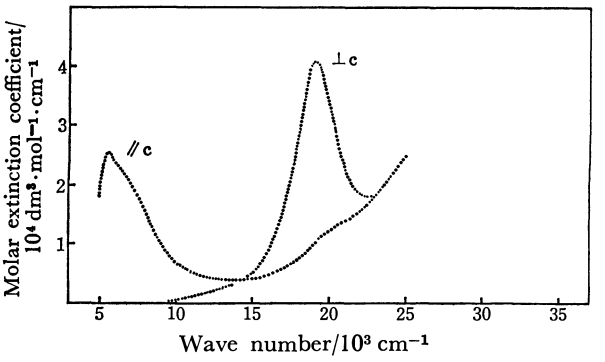

Fig. 13. Absorption spectra on the (100) plane of BD-TCNQ-[CH_2BrCH_2Br] calculated by the reflection spectra. The ordinate is molar extinction coefficient.

spectrum measured on the same crystal face directly by the transmission experiment.

The spectra of BD-TCNQ-[CH_2Cl_2] and BD-TCNQ-[CH_2BrCH_2Br] are very similar to each other as we can expect from the similarity of BD-TCNQ sub-lattice in these two crystal forms. In both cases, the //c spectrum exhibits a strong absorption band in the near-infrared region. The maximum of this band is located at 5.7×10^3 cm^{-1} in the case of BD-TCNQ-[CH_2BrCH_2Br]. Seemingly the absorption maximum is at almost the same wave number in the case of BD-TCNQ-[CH_2Cl_2]. This infrared band is the CT band corresponding to the 7.4×10^3 cm^{-1} band of BD-TCNQ-[n]. There are three absorption bands in the ⊥c spectrum: a relatively sharp one at 19.0×10^3 cm^{-1} and two broad ones at 27×10^3 and 32×10^3 cm^{-1}, respectively. These bands must correspond to the absorption bands observed at 21.2×10^3, 29×10^3, and above 33×10^3 cm^{-1}, respectively, in the ⊥c spectrum of BD-TCNQ-[n]. It should be noted that all absorption bands are shifted to lower wave number by about 2×10^3 cm^{-1} in the spectrum of BD-TCNQ-[CH_2Cl_2] as compared with the spectrum of BD-TCNQ-[n], and the intensity of 19.0×10^3 cm^{-1} band is markedly enhanced in the solvated modifications.

We carried out the molecular orbital calculation on the BD-TCNQ pair taking the separation of the molecular planes as 3.22 Å as in the crystal of BD-TCNQ-[CH_2Cl_2]. This calculation shows that the transitions which are responsible for the observed absorption bands, are shifted to lower wave number on decreasing the molecular separation from 3.24 Å to 3.22 Å. But the predicted shift is 50 and 300 cm^{-1} for the transitions (1) and (2), respectively, and 600 cm^{-1} for the transitions (3) and (8) of Table 1. These

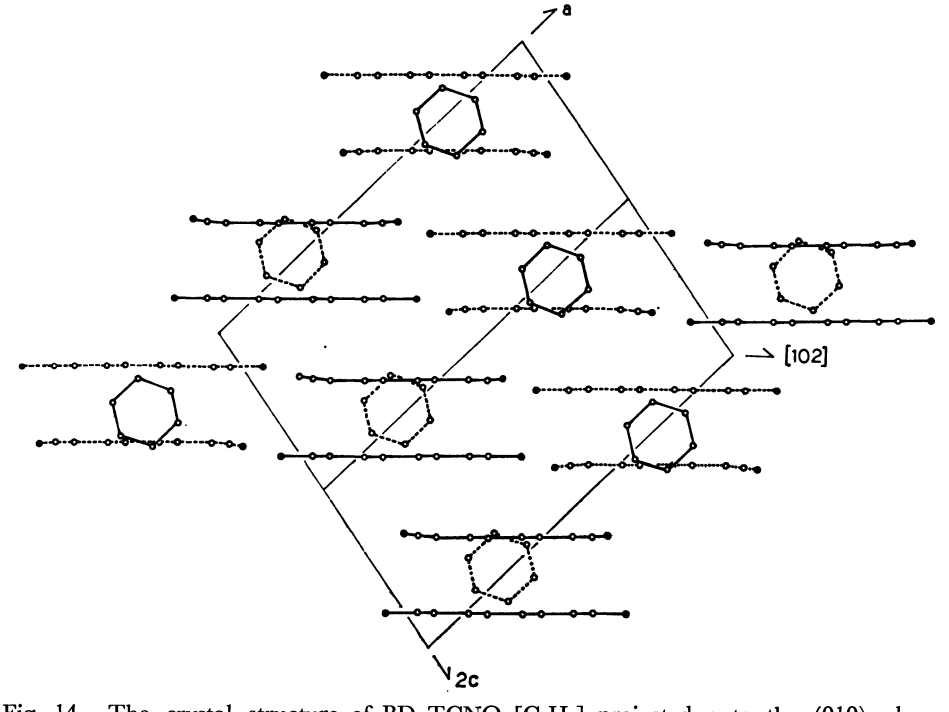

Fig. 14. The crystal structure of BD-TCNQ-[C_6H_6] projected onto the (010) plane.

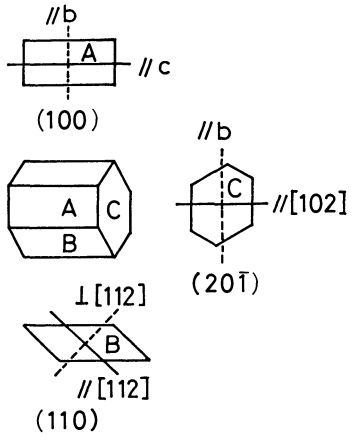

Fig. 15. Crystal morphology and principal axis directions for BD-TCNQ-[C_6H_6] single crystal.

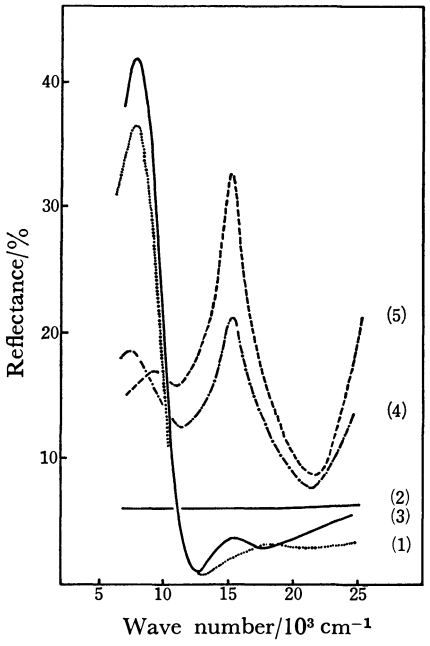

Fig. 16. Reflection spectra of BD-TCNQ-[C_6H_6]. The numbers correspond to the spectra polarized to (1) //c on the (100) (2) //b on the (100) (3) ⊥[112] on the (110) (4) //[112] on the (110) (5) //[102] on the (201).

are too small to explain the observed difference between the spectra of BD-TCNQ-[CH_2Cl_2] and BD-TCNQ-[n]. The oscillator strength of the transition (2) is predicted to increase only by about 15 percent on decreasing the molecular separation from 3.24 Å to 3.22 Å, while the observed oscillator strength of the 19.0×10^3 cm^{-1} band of BD-TCNQ-[CH_2Cl_2] is almost twice that of the 21.2×10^3 cm^{-1} band of BD-TCNQ-[n]. Thus, the observed differences between the spectra of BD-TCNQ-[CH_2Cl_2] and BD-TCNQ-[n] cannot be simply explained from the decrease of the intermolecular separation. Seemingly, it is necessary to take into account the effects of the intermolecular hydrogen bonds and the presence of solvent molecules in order to fully understand the observed differences.

BD-TCNQ-[C_6H_6]. The crystal of BD-TCNQ-[C_6H_6] is monoclinic with the space group $P2_1/m$, the lattice constants being $a=17.184$ Å, $b=9.852$ Å, $c=7.680$ Å, and $\beta=100.3°$.[5] The unit cell contains two molecular units. The structure of BD-TCNQ sub-lattice in this crystal is quite different from

a) The numbers of the spectrum correspond to those in Fig. 17. b) f_{obsd} is the oscillator strength obtained from each reflection spectrum. $f(a)$ is the projected value of the predicted oscillator strength of the transition (a) on each observed polarization-direction.

the cases discussed above. The BD-TCNQ sub-lattice is definitely composed of BD-TCNQ pairs (see Fig. 14). The molecular overlap within the BD-TCNQ pair is of the same type as those in BD-TCNQ-[n] and BD-TCNQ-[CH_2Cl_2], which are shown in Fig. 3(a), but with a very short intermolecular separation of 3.09 Å. On the other hand, the BD-TCNQ overlap between the adjacent pairs is of the type shown in Fig. 3(b) with an intermolecular separation of 3.27 Å. Here again, the hydrogen bonds between C≡N group of TCNQ and NH_2 group of BD stabilize the channeled structure of the BD-TCNQ sub-lattice.

The typical shape of the crystal of BD-TCNQ-[C_6H_6] is a hexagonal prism with the developed crystal faces (100), (110), and (201) as shown in Fig. 15. The reflection spectra were measured on all of the above three crystal faces. Fig. 16 shows the observed spectra. The spectra (1) and (2) were obtained on the (100) face for the light polarizations parallel to the c and b axes, respectively; the spectra (3) and (4) were obtained on the (110) face for the polarizations parallel and perpendicular to the [112] direction; the spectrum (5) is the one obtained on the (201) face for the polarization parallel to the [102] direction. The spectrum (1) shows two reflectance maxima at 7.6×10^3 and 15.5×10^3 cm^{-1}, while the spectrum (2) exhibits no indication of dispersion in the whole observed range. The spectra (3) and (4) also exhibit a reflectance maximum at about 7.6×10^3 cm^{-1}, but the spectrum (5) shows a small maximum at 9.0×10^3 cm^{-1} instead of 7.6×10^3 cm^{-1}. This fact indicates that there are two kinds of transitions in the infrared region. In the visible region, the spectra (1), (4), and (5) exhibit a reflectance maximum at 15.5×10^3 cm^{-1}, but the spectrum (3) shows a maximum at 19×10^3 cm^{-1}. We note

also in the spectra (4) and (5), the shape of the reflectance curve at the high energy side of the 15.5×10^3 cm^{-1} maximum suggests the presence of another dispersion.

The absorption spectra obtained by the analysis of the reflectance data are shown in Fig. 17, together with the absorption spectra directly observed by the transmission experiment on the (100) plane of the relatively thick crystal.

We carried out the molecular orbital calculations on the two models of BD–TCNQ pair corresponding to the two kinds of BD–TCNQ molecular overlap in BD–TCNQ–[C_6H_6]. The model (a) is the one corresponding to the arrangement of BD and TCNQ molecules within the BD–TCNQ pair and the model (b) is the one corresponding to that between adjacent pairs. The transitions which are predicted for the two models are listed in Table 2. Since the short molecular axis of TCNQ has been taken as the y axis direction in the above Table, the transition polarized in the y axis direction are expected to appear only in the //b spectrum, while other transitions are expected to have their transition moments within the (010) plane. Thus the comparison of the observed absorption band with the predicted transitions can be made as shown in Table 3. As indicated in this table, it is most likely that the absorption bands in the infrared region is associated with the transitions (1) and (1′), and those in the visible region are associated with the transitions (2), (2′), and (3′). Using the predicted oscillator strengths and the crystal structure data, we estimated the components of the oscillator strengths parallel to the polarization direction of each observed spectrum. The results are listed in Table 4 together with the observed values. Naturally it is difficult to expect a good quantitative agreement between the experimental and predicted values. But the general features of the absorption spectra can be understood from the results of the calculation. The results shown in Table 4 suggest that the absorption band at about 9×10^3 cm^{-1} observed in the spectra (4) and (5) of Fig. 17 is the one associated with the transition (1′), while the strong infrared band in the spectra (1) and (3), is due to the superimposition of the bands associated with the transitions (1) and (1′). This means that the absorption band corresponding to the transition (1) is located at about 7×10^3 cm^{-1}, and is energetically lower than the one corresponding to the transition (1′), although the transition (1′) is predicted to be energetically lower than the transition (1), according to the calculation on the models of isolated BD–TCNQ pair. For the visible region, we can conclude that the weak absorption band at 19×10^3 cm^{-1} in the spectrum (3) is due to the transition (2′), while, in the spectra (4) and (5), the strong peak at 15.5×10^3 cm^{-1} is associated with the transition (2) and its high-energy tail is associated with the transition (3′). There exists a discrepancy as regards the spectral shape in the visible region between the spectrum (1) and the absorption spectrum measured directly by the transmission method on the same crystal plane (100). In this case, the absorption spectrum derived from the reflectance data seems to be less reliable since the reflectance of the (100) face in the above region is very small for the //c polarization, so that there could be relatively large errors in the process of their analysis. We consider that the absorption spectrum directly observed on a thick crystal is more reliable in this case than the spectrum derived from the reflectance data. The former shows a weak and broad visible absorption band with an indication that it is actually composed of three transitions. Indeed this is consistent with the results of calculation shown in Table 4.

Summary and Conclusion. In the present study, we have observed the absorption and reflection spectra on the known crystallographic faces of the single crystals of BD–TCNQ–[n], BD–TCNQ–[CH_2Cl_2], BD–TCNQ–[CH_2BrCH_2Br], and BD–TCNQ–[C_6H_6]. Usually in the case of the direct measurement of absorption spectrum by the transmission experiment with a microspectrophotometer, there remains some ambiguity as regards the identification of the crystallographic nature of the observing crystal face since it is hard to identify it directly by X-ray diffraction. On the other hand, in the case of the measurement of reflection spectrum by the microspectrophotometric technique, we can use a relatively large crystal, so that we can directly determine the observing crystal face by means of the X-ray diffraction, and it is also possible to observe the reflection spectrum on several different crystal faces. Thus we can determine the direction of the transition moment of an absorption band without any ambiguity. By this method, we confirmed that the first absorption band at about $6—8\times10^3$ cm^{-1} is polarized in the direction of BD–TCNQ stack, but the second absorption band at about 17×10^3 cm^{-1} is polarized parallel to the direction of the long molecular axes of BD and TCNQ in the cases of BD–TCNQ–[n], BD–TCNQ–[CH_2Cl_2], and BD–TCNQ–[CH_2BrCH_2Br]. The situation is a little complicated in the case of BD–TCNQ–[C_6H_6]. The transmission experiment was possible only on the (100) face of the crystal of this modification, and the observed absorption spectra indicated that both the first and second band appear in the //c spectrum. However, by examining the reflection spectra obtained on three different crystal faces, we revealed that there exist two absorption bands of different polarizations in the infrared region, and three bands in the visible region. We carried out molecular-orbital calculations on the models of BD–TCNQ pair, and showed that the observed spectra can be satisfactorily interpreted by using the results of these calculations. It has been thus concluded that, in BD–TCNQ complexes, the infrared absorption band is associated with the charge transfer from the HOMO of BD to the LUMO of TCNQ, but the second CT excitation associated with the charge transfer from the second HOMO of BD to the LUMO of TCNQ is strongly mixed with the local excitation from the HOMO to the LUMO of TCNQ to give a visible absorption band and an absorption band at about 29×10^3 cm^{-1}. This can be understood as follows from the consideration of the orbital symmetries. BD and TCNQ molecules overlap on each other as shown in Fig. 3(a), having their molecular axes exactly on each

Table 5. Observed oscillator strengths of the charge-transfer bands of BD-TCNQ complexes

	CT1		CT2[a]		Intermolecular spacing	
	$\nu_{max}/10^3$ cm^{-1}	f	$\nu_{max}/10^3$ cm^{-1}	f	Å	
BD-TCNQ-[n]	7.4	0.8	21.3	0.7	3.24	
BD-TCNQ-[CH_2Cl_2]	<6.2	(0.8)	19.1	1.6	3.22	H-bond

BC-TCNQ-[C_6H_6] (a)	7.5	≈1.2	15.3	(<2.8)[b]	3.09	H-bond
(b)	≈10		19.5		3.29	

a) This is not a pure charge-transfer band. Refer the text for the nature of this band. b) The contribution of the transition (3′) is included in this value.

other. As shown in Fig. 7, the HOMO of TCNQ and the second HOMO of BD have the same orbital symmetry b_{1u}. Therefore, the electronic excitations from these orbitals to the LUMO (b_{2g}) of TCNQ belong to the same symmetry, and can strongly mix with each other. On the other hand, because of the above orbital symmetries, the overlap integral between the second HOMO of BD and the LUMO of TCNQ must be zero. Thus the moments of the optical transition where the above two excitations are mixed, will be entirely due to the contribution of the excitation from the HOMO to the LUMO of TCNQ. This is the reason why the visible absorption band, which was tentatively considered as the second CT band in our previous study, is polarized perpendicular to the direction of BD–TCNQ stack.

We noted that the CT bands are very strong in the crystal spectra of BD–TCNQ complex as compared with the crystals of typical CT complexes such as pyrene–TCNE. From the analysis of reflectance data, we can determine the absolute oscillator strength of each absorption band. The values thus determined are given in Table 5. It should be noted that the oscillator strength of the first CT band is as large as 0.8. Interestingly, this is about twice the oscillator strength predicted for a BD–TCNQ pair by the molecular orbital calculations. The experimentally determined oscillator strength is much larger for the second CT band. This is primarily due to the effect of the mixing of the local excitation associated with the strong $^1B_{3u} \leftarrow {}^1A_g$ transition of TCNQ.

Finally, we wish to point out that, when dichloromethane or dibromoethane is included in the BD–TCNQ lattice, the absorption bands are shifted to lower energy by about 2×10^3 cm^{-1}. Since the strucuture within the BD–TCNQ stack remains almost the same except a slight change of the intermolecular separation, the above shifts must be due to the effect of included solvent molecules and/or to that of the formation of intermolecular hydrogen bonds.

We wish to thank Dr. T. Ohta in our laboratory for helping us to use his computer program for the molecular orbital calculation of supermolecule system.

We are grateful to Olympus Optical Co., Ltd. for their generous offer of Olympus MMSP-RK used in this study.

(Received March 10, 1979)

The metathesis of 1,5-cyclooctadiene (COD) was investigated over supported rhenium oxide catalysts in terms of carrier effects, acid properties of the catalysts, product distributions, and the reversibility of the reaction. Only alumina plays an effective role as a support. The reaction of COD over rhenium oxide–alumina catalyst yields oligomers, C_{8n}, sesqui-oligomers, C_{8n+4}, and polymers. The important results are as follows: 1) The product distribution in terms of the carbon number of the products shows a decay curve with maxima around C_{12}, C_{16}, and C_{20}. 2) The reaction of oligomers gives COD and some products similar to those of COD. 3) The reactivity of 1,5,9-cyclododecatriene (CDT) was low compared with COD, 1,5,9,13-cyclohexadecatetraene (CHT), and 1,5,9,13,17-cycloeicosapentaene (CEP). 4) A reaction of a mixture of macrocyclic polyenes and polymers gave appreciable amounts of CDT, CHT, and CEP, whereas no COD was obtained. On the basis of the results, we conclude that the products, oligomers, sesqui-oligomers, and polymers, are formed independently from the active intermediary polymers which are formed from COD.

The metathesis of acyclic alkenes has been investigated extensively both in homogeneous and heterogeneous systems. It is known that the effective catalysts for this reaction include compounds or complexes of Mo, W, and Re.[1–3]

One of the characteristics in the metathesis reaction of cyclic alkenes is to form two kinds of homologues, cyclic oligomers and polyalkenes,[4,5] which are not obtained in the disproportionation of acyclic alkenes. Though some studies on the polyalkenenes have been reported[6] and put into practical applications in high polymer industries because of their high selectivity for ring-opening polymerization,[6] less attention has been paid to the formation of cyclic oligomers.

1,5-Cyclooctadiene (COD) was reportedly catalyzed by homogeneous metal complexes to yield not only cyclic oligomers and poly(octadiene) but "sesqui-oligomers."[5–8] In a previous paper,[8] we briefly reported a heterogeneous catalytic metathesis of COD on Re_2O_7–Al_2O_3, yielding oligomers and sesqui-oligomers, in which the distribution of C_{12}—C_{32} cyclopolyenes was different from that in homogeneous catalyst system.

It will also be quite interesting to investigate how the sesqui-oligomers (C_{8n+4}) are formed from COD (eight membered ring diene) and what kind of reaction path is dominant and will give the three types of products: poly(octadiene) (polymers), cyclic oligomers (oligomers), and sesqui-oligomers.

In this study, supported rhenium oxides were used in the metathesis of COD; their catalytic activities and selectivities are compared with surface properties. The reactivity of 1,5,9-cyclododecatriene (CDT, C_{12}), 1,5,9,13-cyclohexadecatetraene (CHT, C_{16}), and 1,5,9,13,17-cycloeicosapentaene (CEP, C_{20}), and the reversibility of the reaction are discussed and a probable reaction path is proposed.

Experimental

Materials. *Catalyst Preparation*: Supported molybdenum and rhenium oxide catalysts were prepared by impregnating various metal oxide supports with aqueous solutions of ammonium heptamolybdate (Wako Pure Chemical Ind., Ltd., GR) and ammonium perrhenate (Engelhard), respectively, followed by drying and calcining at desired temperatures in air for more than two hours. The supports tested here were SiO_2–Al_2O_3, Al_2O_3, MgO, TiO_2, ZnO, ZrO_2, SnO_2, La_2O_3, ThO_2, WO_3, and MgO–ZnO. SiO_2–Al_2O_3 was obtained from Nikki Chemical Co., and contained 15 wt% of Al_2O_3. Magnesium oxide was the GR grade of Kanto Chemical Co. Aluminas were "an activated alumina" from Nishio Industry Co., Ltd, N611 from Nikki Chemical Co., A022 and TK13R from Tokai Konetsu Kogyo, Neobead MSC from Mizusawa Chemical Co., Ltd., and Albes FE and FF from Showa Tansan Kaisha, Ltd. An alumina was prepared by neutral hydrolysis of aluminum triisopropoxide (Wako Pure Chemical Ind. Ltd.). Titanium dioxide, ZnO, ZrO_2, SnO_2, and La_2O_3 were prepared by hydrolysis of titanium tetrachloride (Wako, GR), zinc nitrate (Nakarai Chemicals, Ltd., GR), zirconium(IV) dichloride oxide (Wako, GR), tin(IV) chloride (Wako, GR), and lanthanum nitrate (Nakarai Chemicals, Ltd., extra pure) with aqueous ammonia, respectively, followed by washing, drying, and calcining in air at 500 °C for 3 h. Thorium oxide and WO_3 were obtained by thermal decomposition of thorium nitrate (Wako, GR) at 550 °C for 1 h and of ammonium dodecatungstate (Wako, GR) at 550 °C for 10 h, respectively. A mixed oxide MgO–ZnO (1:9 in molar ratio) was provided by hydrolysis of aqueous mixture of $Zn(NO_3)_2$ and $MgCl_2$ with 28% aqueous ammonia, followed by washing, drying, and calcining in air at 500 °C for 3 h.

6.5 wt% of Re_2O_7 was mounted on all carriers except Al_2O_3, on which the amount of Re_2O_7 was varied from 0.5 to 10 wt%. The amount of MoO_3 supported was 5.1 wt%.

Reactants and Solvents: COD (Shell) was distilled under atmospheric pressure without using any drying reagents.

CDT, CHT, and CEP were obtained by fractional distillation from the reaction mixture of COD. Polymers which contain the open-chain polymers and macrocyclics higher than C_{56} were also prepared from COD products by distillation.

Solvent purifications are as follows. Benzene and cyclohexane (Wako, GR) were distilled over metallic sodium. 1,2-Dichloroethane (Wako, GR) was distilled over phosphorus pentaoxide. Heptane and ethyl alcohol (Wako, GR) were dried over molecular sieves; carbon tetrachloride (Wako, Pure Grade) was dried over calcium chloride. Hexane, ethyl acetate (Wako, GR), and dioxane (Kanto, GR) were used without further purifications.

Procedure. The reactions were carried out at 0 to

80 °C with continuous stirring in a round bottom flask which contained 0.5 ml of COD with 5 ml of solvent and 0.2 g of catalyst. Small amounts of samples for analysis were taken out from the reaction mixture at appropriate time intervals.

The reaction products were analyzed by three sets of gas chromatographs: (A) equipped with a 3 m column of Silicone DC 200 at 200 °C for lower molecular weights macrocyclics (C_8—C_{20}) analysis. (B) equipped with a 1 m column of SE-30 with temperature programming for the analysis of an internal standard and C_8—C_{28} macrocyclics. (C) equipped with a 1 m column of Dexsil 300 GC (3%) with temperature programming for C_{16}—C_{56} macrocyclics analysis.

Products were identified by gas chromatography, IR, and mass spectra, in comparison with their authentic samples. Quantitative analyses were made by using an absolute calibration curve.

Measurement of Surface Acidity. Acidic properties of the catalysts were examined by the butylamine titration method using Hammett indicators.

Definition of Terms. The term "the conversion of COD" was defined as a percentage ratio of the converted COD to the initial amount of COD. The term "the amount of polymers" was defined as the difference between the amount of COD converted and the total amount of the products which can be analyzed by gas chromatography. "Catalytic activity" and "selectivity" were defined as the ratio of the total amount of macrocyclics to the initial amount of COD and the ratio of macrocyclics to the converted COD, respectively.

$$\text{Conversion} = \frac{\text{Converted COD}}{\text{Initial COD}} \times 100\%$$

$$\text{Amount of Polymers} = (\text{Converted COD}) - (\text{Total Product})$$

$$\text{Catalytic Activity} = \frac{\text{Total Macrocyclics}}{\text{Initial COD}}$$

$$\text{Selectivity} = \frac{\text{Macrocyclics Individual}}{\text{Converted COD}}$$

Results and Discussion

Effect of Carriers on Catalytic Activity. The reactions were carried out over single or impregnated oxides. Only Re_2O_7–Al_2O_3 showed an activity for the formation of macrocyclic polyenes and polymers; the following catalysts were completely inactive: MoO_3, WO_3, Re_2O_7, Al_2O_3, Re_2O_7–MgO, Re_2O_7–TiO_2, Re_2O_7–ZnO, Re_2O_7–ZrO_2, Re_2O_7–SnO_2, Re_2O_7–La_2O_3, Re_2O_7–ThO_2, Re_2O_7–MgO–ZnO, and Re_2O_7–SiO_2·Al_2O_3 or MoO_3–Al_2O_3. The high catalytic activity of Re_2O_7–Al_2O_3 implies that only alumina plays a special role in the formation of the active sites. Such a specific role of Al_2O_3 is also reported in the disproportionation of propylene over MoO_3–Al_2O_3[9] and Re_2O_7–Al_2O_3.[10] Various aluminas, which were supplied by different industries, were examined to investigate the role of Al_2O_3. Table 1 lists the names of these aluminas, their crystal forms, and their surface areas. The numbers correspond to that of Fig. 1. As Fig. 1 shows, catalytic activities are well correlated with the surface area of supports and do not depend on crystal forms (α, γ, *etc.*). Therefore, in the following studies, the alumina which had the largest surface area was used as the carrier of rhenium oxide.

Table 1. List of Alumina Used

No.	Name	Crystal form	Surface area / $m^2\,g^{-1}$
1	Albes-FF	(fibrillar)	330
2	TK-13R	γ-	230
3	Albes-FE	(fibrillar)	110
4	N-611	γ-	200
5	Neobead M6C	γ-	210
6	A-022	α-	1

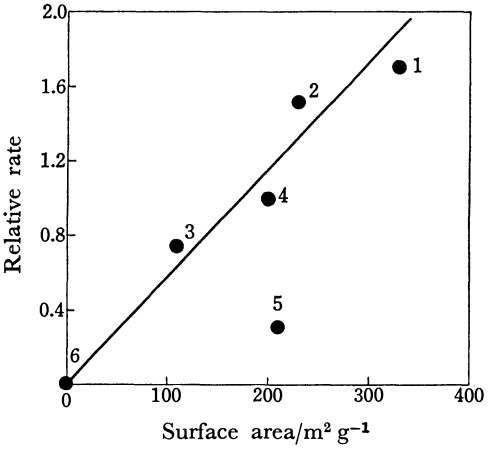

Fig. 1. Correlation between surface area and relative rate. Numbers correspond to those in Table 1.

The amount of Re_2O_7 supported was varied from 0.5 to 10 wt% to Al_2O_3. The catalytic activity increased up to 3 wt% and became constant above this range.

Optimum and reproducible activity was obtained by calcining the catalyst at 600 °C in air for more than 2 h.

Catalytic Activities and Acid-Base Properties of Catalysts. Since some relationships were suggested between the acidic properties of catalysts and the catalytic activities for the metathesis of alkenes,[11–15] the acidic strength and the acidity (number of acid sites) of the catalytically active Re_2O_7–Al_2O_3 and the inactive MoO_3–Al_2O_3 were compared. These catalysts have strong acid sites ($pK_a = -5.6$) which were not found on the component oxides themselves, *i.e.*, the strong acid sites were created by the combination of those oxides. Though both catalysts have fairly large amounts of acid sites, one of the catalysts, MoO_3–Al_2O_3, does not show any catalytic activity. However, the activity of Re_2O_7–Al_2O_3 was decreased with the increase of the amount of NaOH added and completely lost by the addition of 1.24 mmol/g NaOH. These results seem to indicate that the acidic property does not directly dominate the catalytic activity, but is one of the important factors which control the activity.

Effect of Solvent on Catalytic Activity. It is known that some particular solvents are favorable for a high conversion or a high selectivity in metathesis.[16,17] The solvents used in this study are listed in Table 2, together with the conversion of COD, the catalytic

Table 2. Effect of solvents[a)]

Solvent	Reaction time / min	Conversion / %	Activity / %	Selectivity / %

activity, and the selectivity. Besides benzene and cyclohexane, which are known as suitable solvents in homogeneous systems, carbon tetrachloride is also a good solvent for obtaining high conversion, activity, and selectivity. On the other hand, in ethyl alcohol, dioxane, and ethyl acetate, no product was obtained. Product distributions did not depend on the solvents used. Though the effective solvents seem to be good for polymers as well as oligomers, further studies should be done to clarify the role of solvents.

Product Distributions. As in the case of homogeneous systems, the metathesis of COD over Re_2O_7–Al_2O_3 yields oligomers, C_{8n}, sesqui-oligomers, C_{8n+4}, and polymers. Figure 2 shows the dependency of the product distribution in terms of the carbon number of macrocyclics. The spectrum seems to be a decay curve over C_{20} product, with an ambiguous maximum around the first three products: CDT, CHT, and

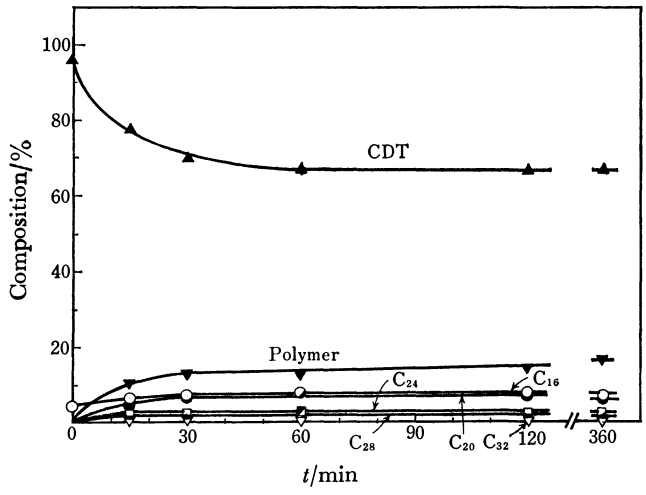

Fig. 3. Reaction of CDT ▲: CDT, ▼: polymer, ○: C_{16}, ●: C_{20}, □: C_{24}, ■: C_{28}, ▽: C_{32}.

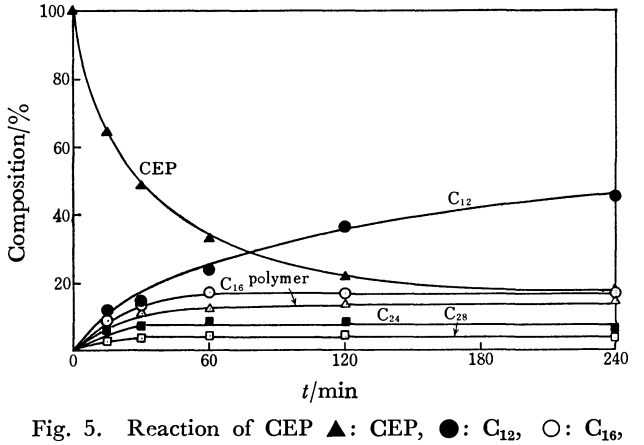

Fig. 5. Reaction of CEP ▲: CEP, ●: C_{12}, ○: C_{16}, △: polymer, ■: C_{24}, □: C_{28}.

CEP. The product distributions were essentially unchanged through the entire reaction period, until most of the COD was consumed. These results suggest that oligomers and sesqui-oligomers are formed by parallel paths but not by a consecutive reaction path.

The Reaction of Oligomers and Sesqui-oligomers. The results of the individual reactions of CDT, CHT,

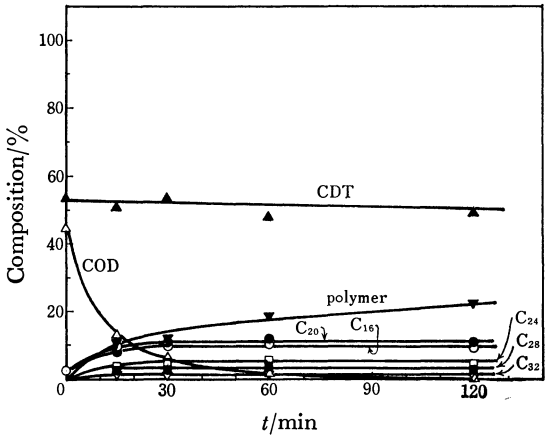

Fig. 6. Competition reaction of COD and CDT ▲: CDT, △: COD, ▽: polymer, ●: C_{20}, ○: C_{16}, □: C_{24}, ■: C_{28}, ▽: C_{32}.
Reaction mixture contains 0.4% of COD, 0.5% of CDT, and benzene as solvent.

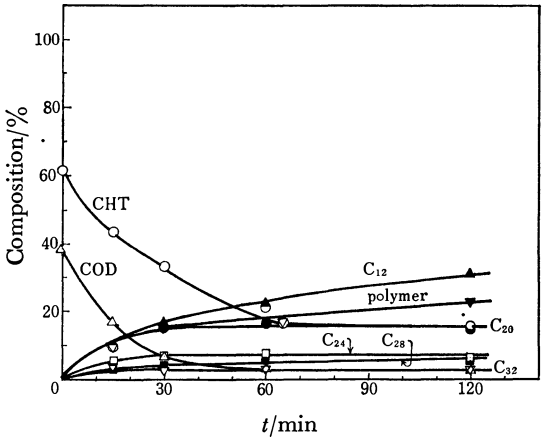

Fig. 7. Competition reaction of COD and CHT ○: CHT, △: COD, ▲: C_{12}, ▼: polymer, ●: C_{20}, □: C_{24}, ■: C_{28}, ▽: C_{32}.

and CEP are shown in Figs. 3, 4, and 5, respectively. Sesqui-oligomers react and give similar products to those of oligomers, except there is no production of COD. Such results are consistent with the results shown in Fig. 2, which indicate that the product distributions of both oligomers and sesqui-oligomers produced by the metathesis of COD are on the same line.

If we assume that those products were formed by a consecutive oligomerization reaction, it is expected that the product distribution may be different in reactions in which CDT, CHT, or CEP is used as a reactant, since they are supposed to be the intermediate reaction products in the consecutive reaction. Thus, the data which suggest similar product distributions (Figs. 3, 4, and 5) lead us to conclude that each product, CDT, CHT, or CEP, is formed independently and not by a consecutive step.

In the competitive reaction of CDT or CHT with COD, the product distributions hardly differed from those in the reaction of individual materials, as shown in Figs. 6 and 7. This reveals that the competitive reaction is the simple superposition of two independent

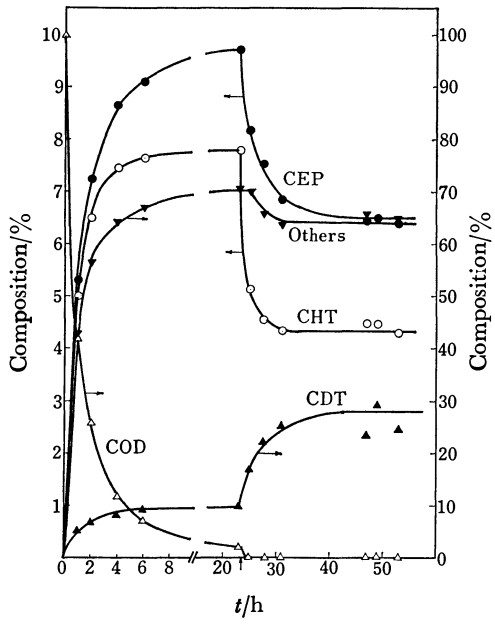

Fig. 8. Reaction of COD △: COD, ▲: CDT, ○: CHT, ●: CEP, ▼: polymer. An arrow on the time scale indicates the addition of a new catalyst.

reactions of COD and other cyclic polyenes.

The reactivity of macrocyclics can be estimated from the competitive reactions and the individual ones. COD is the most reactive and is followed by CHT and CEP. The low reactivity of CDT is indicated by the following observations. (1) the reaction seems to stop at about 30% conversion within 1 h, when CDT is used as the reactant, while CHT and CEP react over 70% within 1 h and keep converting to the products. (2) CDT is continuously formed as the product during the reaction, while the additional formation of other products such as C_{20}, C_{24}, and C_{28} was not observed after 1 h. (3) in a competitive reaction of COD and CDT, only COD was a reactive component.

Though CHT gives a small amount of COD (about 3%), CDT and CEP do not give any. No production of COD in the latter case may be due to the absence of a reverse reaction or to the rapid disappearance of the COD formed. Since the reactivity and the distribution of the products from CHT do not differ markedly from that of CEP or CDT, it will be reasonable to conclude that no reverse reaction takes place from CDT or CEP to COD. The formation of COD from oligomers, such as CHT, will be a simple deoligomerization. The difficulty in the formation of COD from sesqui-oligomers will be understood by considering that such a reaction must accompany the C_4 fragments.

Depolymerization and Equilibrium. A depolymerization of macrocyclic polyenes and polymers was examined to elucidate the reversibility of the reaction; a 1 wt% mixture containing 75.5 wt% of C_{24}—C_{52} macrocyclics and 24.5 wt% of polymers was used at 40 °C. The composition of the mixture after 4 h reaction was as follows: 13.5% of CDT, 8.5% of CHT, 12% of CEP, 35% of macrocyclics, and 31% of polymers. No COD was obtained. These results are coin-

cident with those which have been obtained in homogeneous catalyst systems. Scott *et al.* found the formation of C_{12}—C_{32} materials in the reaction of a diluted solution of the "extracted high molecular weight COD polymers" by using the system WCl_6–$EtAlCl_2$–EtOH.[7]

Figure 8 shows the result of the prolonged reaction of COD. When the amount of COD is sufficient (more than 5%), the ratios of the first three products, CDT, CHT, and CEP, are held almost constant at about 9.5:8:9.5, and the reaction seems to reach equilibrium. However, after the amount of COD decreased below 5%, an addition of a fresh catalyst leads a remarkable change in the ratio of the first three products. The amount of CDT increases abruptly and the amounts of CHT and CEP decrease rapidly, while the amount of the higher molecular weight products becomes a little smaller. After a long period, COD disappeared completely from the reaction mixture and the reaction seems to reach equilibrium again, where the composition of the products is CDT=25, CHT=4.5, CEP=6.5, and others=64.

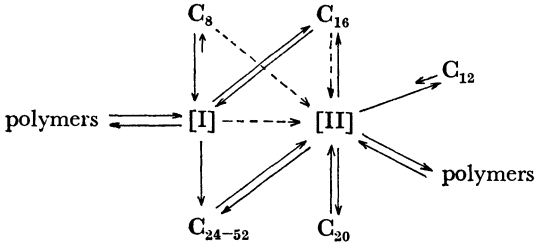
Reaction Route. Before presenting a probable reaction route, it will be convenient to summarize the important findings.

a) COD is formed by a degradation of the oligomers (dimer, trimer, tetramer, *etc.*) but not from the sesqui-oligomers.

b) Some oligomers and sesqui-oligomers are formed by the back reaction of the polymers which contain chained species of high molecular weight and large ring-size polyenes.

c) The consecutive reaction is unlikely.

The following reaction scheme interprets the observations.



I and II represent active intermediary polymers (AIP). An assumption of two intermediates is based on the observations that CDT and CEP did not give any COD. Arrows with different lengths between C_8 and I and between C_{12} and II mean that, for instance, the rate of formation of I from C_8 is faster than that of C_8 from I. The dotted arrows indicate that it is uncertain whether II is formed directly from C_8 and C_{16} or indirectly *via* II.

Formation of Polymers. The polymers will be formed either as the desorption products of one part of the "active intermediary polymers" (AIP) or as the product of the ring-opening polymerization of COD with the AIP. A sufficient amount of COD will give a large amount of polymers by the latter reaction. The polymers produced may readsorb on the sites to form the AIP and may give the oligomers. A large amount of polymers produced may inhibit the reaction by covering the active sites.[18]

Formation of Oligomers and Sesqui-oligomers. Oligomers will be formed by an intramolecular disproportionation of the AIP. COD does not participate in this reaction process. The oligomers produced can be reconverted to the AIP and give polymers or other oligomers with a new product distribution. The AIP from the oligomers can produce COD by an intramolecular reaction of the AIP, while the AIP from the sesqui-oligomers does not. Presumably, the latter AIP is different from the others.

The oligomers and the sesqui-oligomers will be formed by the intramolecular reaction process, *i.e.*, by the "pinch off" process proposed by Scott *et al.*[7] As already shown in Fig. 2, the distribution of the reaction products shows a decay curve, as the ring-size of the products increases. Especially, the distribution of the products which have larger ring-size than C_{20} is expressed very well by a single curve. This indicates that the product distribution will dominantly depend on the "pinch off" probability of the intramolecular reaction in the formation of the individual products, where the production of the smaller polyenes is much higher than that of the higher ones. The deviation of the product distribution of the three products, C_{12}, C_{16}, and C_{20}, from this plot will be brought about from the following reactions: CDT (C_{12}), which is the product of the intramolecular reaction of polyenes, reacts with COD (C_8) to form CEP (C_{20}) or dimerizes to give C_{24} species. The former reaction ($C_{12}+C_8$) will take place more easily than the latter ($C_{12}+C_{12}$), because COD is more reactive than CDT (C_{12}). Dimerization of COD to form CHT (C_{16}) should also be taken into consideration.

Formation of AIP. Though the AIP are supposed to be the macrocyclic polyenes[19] or open-chain polymers which are adsorbed on the catalyst at multiple points, it is not clear how the AIP forms from COD. One possible way is to assume a chain reaction, as Chauvin has proposed,[20] in which a carbene intermediate mechanism was proposed for the polymerization of cycloolefins. Considering the reaction time-course, the AIP is supposed to be formed at a very early stage of the reaction.

A Thermodynamic Study on the Hydrolysis of Beryllium Ion in Dioxane–Water Mixed Solvents

Shin-ichi ISHIGURO and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 18, 1979)

The hydrolytic reactions of beryllium(II) ions were calorimetrically studied at 25 °C in aqueous solution and dioxane–water mixtures, both containing 3.0 mol dm^{-3} (Li)ClO_4 as a constant ionic medium. On the basis of the formation constants previously determined,[10–12] the enthalpy and entropy changes for the reaction, $qBe^{2+}+pH_2O=Be_q(OH)_p^{(2q-p)+}+pH^+$, were estimated for the Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes in aqueous solution and 0.1 mole fraction dioxane–water mixture and for Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, and $Be_2(OH)_2^{2+}$ complexes in 0.2 mole fraction dioxane–water mixture. The enthalpy and entropy changes of formation of the $Be_q(OH)_p^{(2q-p)+}$ complex obtained in solutions of various mole fractions of dioxane were as follows: $2Be^{2+}+H_2O=Be_2OH^{3+}+H^+$; ΔH_{12} (mole fraction: 0.0)$=18.6\pm0.2$ kJ mol^{-1}, $T\Delta S_{12}$(mole fraction: 0.0)$=1.3\pm0.2$ kJ mol^{-1}, ΔH_{12} (0.1)$=15.2\pm0.2$ kJ mol^{-1}, $T\Delta S_{12}(0.1)=-3.4\pm0.2$ kJ mol^{-1}, $\Delta H_{12}(0.2)=8.4\pm0.4$ kJ mol^{-1}, $T\Delta S_{12}(0.2)=-12.4\pm0.4$ kJ mol^{-1}, $3Be^{2+}+3H_2O=Be_3(OH)_3^{3+}+3H^+$; $\Delta H_{33}(0.0)=61.7\pm0.2$ kJ mol^{-1}, $T\Delta S_{33}(0.0)=12.2\pm0.2$ kJ mol^{-1}, $\Delta H_{33}(0.1)=59.4\pm0.2$ kJ mol^{-1}, $T\Delta S_{33}(0.1)=10.0\pm0.2$ kJ mol^{-1}, $\Delta H_{33}(0.2)=59.0\pm0.4$ kJ mol^{-1}, $T\Delta S_{33}(0.2)=9.1\pm0.4$ kJ mol^{-1}, $2Be^{2+}+2H_2O=Be_2(OH)_2^{2+}+2H^+$; $\Delta H_{22}(0.2)=42.3\pm0.4$ kJ mol^{-1}, $T\Delta S_{22}(0.2)=1.3\pm0.4$ kJ mol^{-1}. The enthalpy and entropy changes of the reaction, $H_2O=H^++OH^-$, in the solutions of the same compositions were also determined as $\Delta H_w(0.0)=56.6\pm0.1$ kJ mol^{-1}, $T\Delta S_w(0.0)=-22.6\pm0.1$ kJ mol^{-1}, $\Delta H_w(0.1)=58.1\pm0.1$ kJ mol^{-1}, $T\Delta S_w(0.1)=-25.3\pm0.1$ kJ mol^{-1}, $\Delta H_w(0.2)=61.2\pm0.1$ kJ mol^{-1}, $T\Delta S_w(0.2)=-26.6\pm0.1$ kJ mol^{-1}. These results were discussed in connection with interactions between the hydroxo complexes and the solvent molecules and with those between solvent molecules in the mixed solvents.

It has been said that the thermodynamic parameters of transfer of electrolytes from aqueous to aqueous organic mixed solvents would be a measure of solute–solvent and solvent–solvent interactions.[1–4] The change in strength of carboxylic acids in mixed solvents may be a typical example, where the acidity usually decreases with increasing mole fraction of organic component.[5,6] On the other hand, the acidity of ammonium ion and its homologues increases with the concentration of an organic solvent and then sharply decreases after passing through a maximum.[7–9] In the preceding studies of hydrolytic reactions of metal ions in mixed solvents,[10–12] we pointed out that hydrated metal ions behave in different manner from these two types of acids, that is, the acid dissociation (*i.e.*, hydrolysis) constant of a hydrated metal ion is not practically influenced by the solvent composition of aqueous organic mixtures.

Since no data have been available for the enthalpy and entropy changes of hydrolytic reactions of metal ions in aqueous organic mixtures, we carried out calorimetric measurements of hydrolytic reactions of metal ions in order to investigate solute–solute and solute–solvent interactions in the reactions. Beryllium ion was first chosen as a target of the aim, because it has been investigated in detail in aqueous and aqueous organic mixtures containing various ionic media.[10–12] Since the complex formation proceeds rather slowly at a high pH range,[12] the experiments in this study were carried out in the range pH$\lesssim$4.

Experimental

Reagents and Analysis. *Beryllium Perchlorate*: Beryllium oxide of reagent grade was heated for several hours with an excess of perchloric acid. Residual beryllium oxide was filtered off with a glass filter and beryllium perchlorate thus prepared was recrystallized three times from water. The concentration of beryllium ions in the stock solution was determined gravimetrically.[13]

Lithium Perchlorate: Lithium perchlorate was prepared as described in Ref. 14. Crystals of lithium perchlorate were dried at about 200 °C in an electric oven.

Lithium Hydroxide: A lithium hydroxide solution was prepared by electrolysis of an aliquot of the lithium perchlorate stock solution under an atmosphere of nitrogen in a polyethylene bottle. The concentration of hydroxide ions thus prepared was determined by Gran's method[15] by titrating with a standard perchloric acid solution.

Perchloric Acid: Perchloric acid of super special grade was used without further purification.

Dioxane: Dioxane was purified by the method described in Ref. 10.

The concentrations of hydrogen ions contained in the stock solutions were coulometrically determined by Gran's method.[15]

Preparation of Test Solutions. Test solutions were contained 3.0 mol dm^{-3} perchlorate ions as a constant ionic medium. In each titration, two test solutions were prepared, both containing the same total concentration of beryllium ion at a given concentration of dioxane in the solutions. One (Solution S) contained hydrolyzed beryllium ions and the other (Solution T) contained unhydrolyzed beryllium ions and a known concentration of perchloric acid, and the former was titrated by the latter. The total concentration of beryllium ion was kept practically constant during the titration.

The Method of Measurements. The measurements were carried out in a thermostated room at 25.0±0.5 °C. All the cells used were Dewar vessels, which were immersed in a thermostated water bath. The temperature fluctuated by ±0.0007 °C at 25.00±0.05 °C. First, about 150 cm^3 of test solution S was placed in a titration vessel. The temperature change in the titration vessel was detected by use of a micro volt meter (Model AM-1001, Ohkura Electric Co., Ltd.) and a couple of thermisters which were introduced into the titration and reference vessels. Temperature in

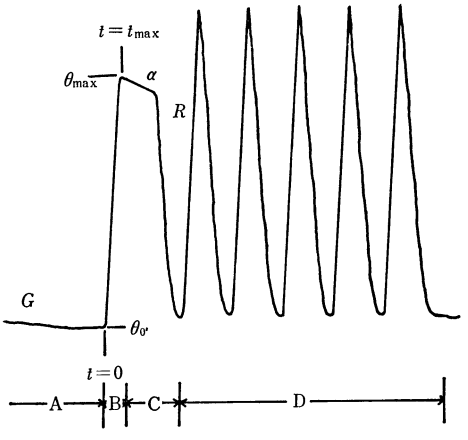

Fig. 3. Determination of heat evolved per addition of the titrant.

the reference vessel, to which the temperature change in the titration vessel was referred, was kept constant throughout the titration. At the thermal equilibrium, temperature in the titration vessel was usually slightly higher than that in the thermostated water bath because of joule heat by agitation. Therefore, in order to keep temperature of the titrant practically the same as that of the test solution, another cell was used as a heat exchanger through which the titrant T was introduced into the titration vessel. The heat exchanger was also agitated with a stirring bar to keep the same temperature in the heat exchanger with that in the titration vessel. The cell arrangement was depicted in Fig. 1. Heat evolved per addition of the titrant was about 6—20 J, which corresponded to the change of about 200—700 μV. The estimated uncertainty (σ) of the heat measurements was about $\pm 0.4\,\mu$V or ± 0.00005 °C. The on-line controlled enthalpy titration system was developed in order to make precise determinations of heat evolved and to spare time for measurements.

The On-line Controlled Enthalpy Titration System. The on-line controlled enthalpy titration system is schematically shown in Fig. 2. The temperature change in the titration vessel was monitored by a JEC-6 spectrum computer (JEOL Co., Ltd.) through a micro volt meter and a 10-bit AD converter. Throughout the measurements, time was controlled by means of a pulse generator.

The procedure of a heat measurement per addition of the titrant consisted of four steps, A through D, as is shown in Fig. 3.

A Region: Before addition of the titrant, the temperature difference between the titration and reference vessels was measured every 10 seconds and a set of continued 50 data was analyzed to give the temperature gradient G ($=\mathrm{d}\theta/\mathrm{d}t$) by assuming the temperature (θ) changing linearly with time, and, at the same time, the uncertainty δG was estimated. If G and δG obtained did not fall within specified ranges, one more temperature-difference was measured, and the same procedure was repeated using a new set of 50 data. When G and δG fell within given ranges, and thus the test solution was reached the thermal equilibrium with the thermostated bath, the temperature at the equilibrium θ_0 and its uncertainty $\delta\theta_0$ were recorded.

B Region: When the test solution was reached the thermal equilibrium with the thermostated bath, the titrant T was added from a piston buret to the test solution. The operation of adding the titrant usually took a few minutes. When the temperature in the titration vessel rose over a level of $10\delta\theta_0$, the temperature change was read every second. The procedure was continued until the temperature in the titration vessel started to decrease, and the time (t_{max}) when the temperature reached the maximum was determined (the maximum temperature: θ_{max}).

C Region: The temperature in the titration vessel decreased approximately linearly after passing through the maximum. The temperature change in the C region could be expressed by the following equation:

$$\theta(t) = (\theta_{max}-\theta_0)\{1-\alpha(t-t_{max})\} \quad (1)$$

where α denotes a constant. The values of θ_{max} and α were determined using a set of 100 data in this region which were measured every second. Then, a cooler was operated to cool the test solution to approximately the same temperature as θ_0.

D Region: When the cooling of the test solution was finished, the test solution was heated by using a standard heater which evolved a constant joule heat q. During the evolution of heat, the temperature change was read every second. The heating of the test solution was continued until a set of 100 data was recorded, then the cooler was again operated. The set of 100 data was analyzed by assuming that temperature rose with a constant rate, and the rate R ($=\mathrm{d}\theta/\mathrm{d}t$) was determined. The determination of R was repeated five times and the mean value was used to estimate the heat capacity C_p of the test solution $C_p=q/RV$, where V denotes the volume of the test solution. The un-

certainty in R was usually within $\pm 0.3\%$. Thus, the heat evolved in the course of one titration q was determined by the following equation:

$$q = k_1 C_p V f(\theta_{max} - \theta_0) + k_2 \quad (2)$$

where f stands for a correction of heat escaped from the titration vessel until temperature reached the maximum in the B region,

$$f = 1/(1 - \alpha t_{max}/2 + \alpha^2 t_{max}^2/3) \quad (3)$$

and k_1 and k_2 represent empirical constants (k_1 was nearly unity and k_2 was nearly zero) which had been determined by separate experiments using a standard heater.

All procedures were automatically operated under the controll by the JEC-6 electronic computer. A least-squares method was employed for the analysis of the sets of data obtained. One procedure of the measurement from A to D usually finished within 40 min. In one run of the whole titration, ten experimental points were usually measured with the total volume of the titrant of about 20 cm³.

Results

The Enthalpy Change for the Autoprotolysis Reaction of Solvents. The enthalpy change for the autoprotolysis reaction of the solvents were measured by titrating a standard lithium hydroxide solution with perchloric acid in mixed solvents containing 3.0 mol dm^{-3} perchlorate ions. The enthalpy change ΔH_w for the reaction, $H_2O = H^+ + OH^-$, is given by the equation:

$$Q = \sum q = \Delta H_w c_H v \quad (4)$$

where Q, q, c_H, and v stand for the total heat evolved, the heat evolved per addition of the titrant, the concentration of hydrogen ions in the titrant and the total volume of the titrant added, respectively. A plot of Q/c_H against v might give a straight line. The plots in various solvents are shown in Fig. 4, and ΔH_w was given as the slope of the straight line.

The Enthalpy Changes of Formation of the Hydroxo Complexes of Beryllium(II). In aqueous solution and 0.1 mole fraction dioxane–water mixture, the only Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes were formed in the pH range examined (pH$\lesssim$4). Therefore, the heat evolved was expressed as follows:

$$Q = \sum q = \Delta H_{12}\delta n_{12} + \Delta H_{33}\delta n_{33} \quad (5)$$

where δn_{pq} denotes the total change in the number of moles of the $Be_q(OH)_p^{(2q-p)+}$ complex when the titrant was added. The δn_{pq} was calculated on the basis of the formation constants previously determined.[10–12] Plots of $Q/\delta n_{33}$ against $\delta n_{12}/\delta n_{33}$ gave a straight line with the slope of ΔH_{12} and the intercept of ΔH_{33}. The plots are shown in Fig. 5.

In 0.2 mole fraction dioxane–water mixture, the $Be_2(OH)_2^{2+}$ complex was formed together with the Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes. Therefore, the heat evolved was expressed as follows:

$$Q = \Delta H_{12}\delta n_{12} + \Delta H_{33}\delta n_{33} + \Delta H_{22}\delta n_{22} \quad (6)$$

When we applied a least-squares method to Eq. 6 in order to evaluate the values ΔH_{12}, ΔH_{33}, and ΔH_{22}, reasonable values were not obtained. A possible reason may be that δn_{22} was approximately proportional to δn_{33} under the experimental conditions examined. Since the formation of the $Be_2(OH)_2^{2+}$ complex was small (about 20%) compared with that of the $Be_3(OH)_3^{3+}$ complex, we assumed at a first step of approch that the only Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes were present. Thus, the same plots as those demonstrated for the aqueous solution and 0.1 mole fraction dioxane–water mixture were possible and are shown in Fig. 6. A relatively good straight line was obtained to give approximate values of ΔH_{12} and ΔH_{33}. Using the value of ΔH_{12} thus obtained, the values of ΔH_{33} and ΔH_{22} were estimated by Eq. 7:

$$(Q - \Delta H_{12}\delta n_{12})/\delta n_{33} = \Delta H_{33} + \Delta H_{22}(\delta n_{22}/\delta n_{33}) \quad (7)$$

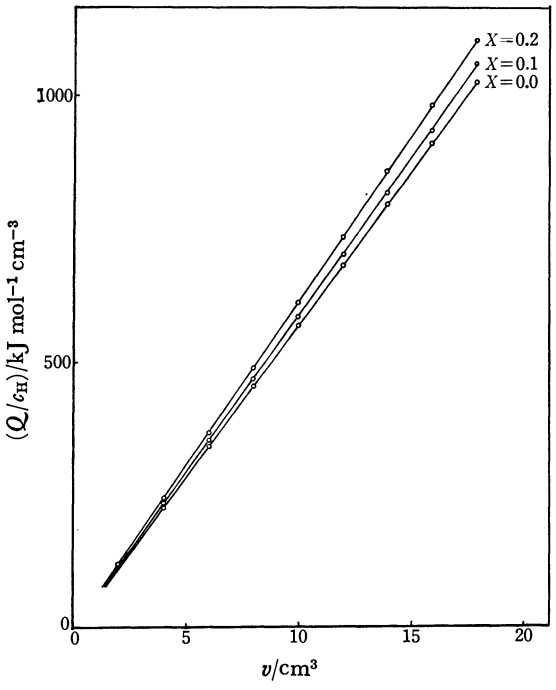

Fig. 4. Determination of the enthalpy change for the autoprotolysis reaction of water in dioxane–water mixture. X represents mole fraction of dioxane in the mixture.

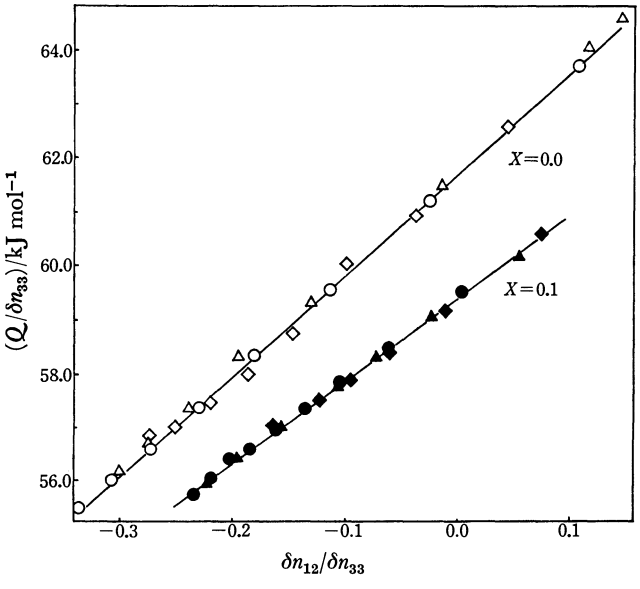

Fig. 5. Determinations of the enthalpy changes of formation of the Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes in aqueous solution and 0.1 mole fraction dioxane–water mixture. Total concentration of beryllium ions c_{Be} (mol dm^{-3}): ○ 0.1620, △ 0.0967, ◇ 0.0506 ▲ 0.0995, ◆ 0.0831, ● 0.0652. X represents mole fraction of dioxane in the mixture.

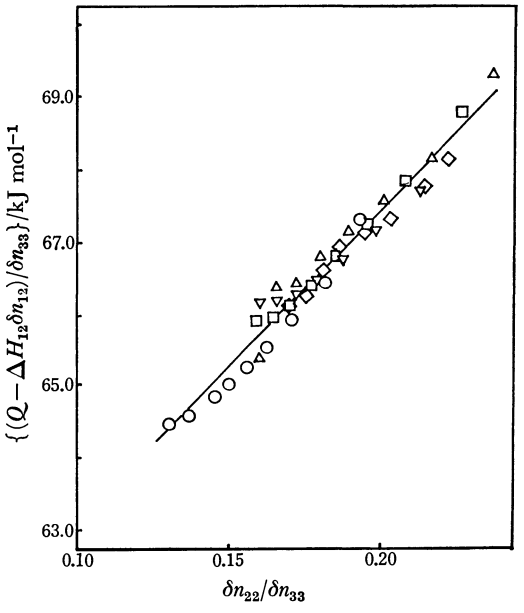

Fig. 7. Determination of the enthalpy changes of formation of the $Be_2(OH)_2{}^{2+}$ and $Be_3(OH)_3{}^{3+}$ complexes in 0.2 mole fraction dioxane–water mixture. Total concentration of beryllium ions c_{Be} (mol dm^{-3}): ○ 0.1183, △ 0.0855, □ 0.0847, ▽ 0.0646, ◇ 0.0390.

The plots of $(Q-\Delta H_{12}\delta n_{12})/\delta n_{33}$ against $\delta n_{22}/\delta n_{33}$ for a given total concentration of beryllium ions gave a straight line with the slope of ΔH_{22} and the intercept of ΔH_{33}. By changing ΔH_{12} around the value firstly obtained, the procedure was repeated until the plots for all given total concentrations of beryllium ions examined were converged on the same line. The plots are shown in Fig. 7. The value of ΔH_{33} finally obtained was 59.0 kJ mol^{-1}, which was in good agreement with the value of 59.2 kJ mol^{-1} firstly approximated. The thermodynamic parameters for the formation of the hydroxo complexes of beryllium ions and for the autoprotolysis reaction of the solvents thus obtained are summarized in Table 1. The results obtained in aqueous solution are in good agreement with those obtained previously.[16,17]

Discussion

Ion–solvent and solvent–solvent interactions in dioxane–water mixtures have so far been studied by using various methods and the following conclusions are generally accepted. 1) The hydrogen bonded structure of water is broken down by the addition of dioxane (it has also been reported that the structure of water may be enhanced by the addition of dioxane less than 0.05 mole fraction[18]). The fact is directly confirmed by means of NMR. The PMR signal of the water molecules shifts to the higher magnetic field on dilution with dioxane.[19] 2) The interaction between cations and solvent molecules is enhanced as the dioxane content of the solvent increases, while the reverse is the case for the interaction between anions and solvent molecules. The cation–solvent interaction is usually larger than the anion–solvent interaction. It has been shown that the enthalpy changes of transfer of most electrolytes from aqueous solution to dioxane–water mixture are negative (exothermic) and become more negative as the dioxane content of the mixtures increases.[20–22] The results are explained as follows: Solvent structure plays an important role in determining the thermodynamic parameters of transfer of electrolytes.[23,24] A dioxane–water mixture is less structured than an aqueous solution, and therefore, ions have a larger solvent-ordering effect (or an enhanced solvation structure of ions) in the dioxane–water mixture. 3) The inner-sphere structure of a complex ion is not practically influenced by the addition of dioxane. It has been found that metal ions are primarily solvated with water molecules in water-rich dioxane–water mixtures (*e.g.*, the dioxane content less than 0.5 mole fraction).[25,26]

On the basis of these facts, the solvent effects on the autoprotolysis of water and the formation of hydroxo complexes of beryllium ion are discussed in the following sections.

Autoprotolysis Reaction of the Solvents. The difference between the enthalpy changes for the autoprotolysis reaction of water, $H_2O=H^+ + OH^-$, in a dioxane–water mixture and an aqueous solution is represented as follows:

$$\Delta H_w^t = \Delta H_w(\text{mixed}) - \Delta H_w(\text{aqueous}) = \Delta h_H^t + \Delta h_{OH}^t - \Delta h_{H_2O}^t \quad (1)$$

where Δh_i^t stands for the partial molar enthalpy change of transfer of species i from aqueous solution to a dioxane–water mixture. As is seen from Table 1, the enthalpy changes in both aqueous solution and dioxane–water mixtures were positive. ΔH_w^t was also positive and became more positive with increasing concentration of dioxane. This result for ΔH_w^t is in contrast to those of dissociation reactions of weak acids (*e.g.*, acetic acid), in which ΔH_w^t is usually negative.[5] Since the sum of the partial molar enthalpy changes of transfer of H^+ and OH^- ions from water to a dioxane–water mixture is negative,[20] the positive ΔH_w^t obtained indicated that $\Delta h_{H_2O}^t$ must be more negative than the sum of Δh_H^t and Δh_{OH}^t. Since the hydrogen bonded structure of water is broken down by the addition of dioxane, the negative $\Delta h_{H_2O}^t$ may be caused by enhancement of the intramolecular interaction of a water molecule (*i.e.*, the strength of the O–H bond) in dioxane–water mixtures.

Formation of Hydroxo Complexes of Beryllium Ion. A hydrolytic reaction of beryllium ions may be expressed as follows:

$$q\mathrm{Be}^{2+} + p\mathrm{H_2O} = \mathrm{Be}_q(\mathrm{OH})_p^{(2q-p)+} + p\mathrm{H}^+ \quad (2)$$

Similar to Eq. 1, Eq. 3 can be represented as follows:

$$\Delta H^{\mathrm{t}}_{pq} = \Delta H_{pq}(\mathrm{mixed}) - \Delta H_{pq}(\mathrm{aqueous}) = \Delta h^{\mathrm{t}}_{pq} + p\Delta h^{\mathrm{t}}_{\mathrm{H}} - q\Delta h^{\mathrm{t}}_{\mathrm{Be}} - p\Delta h^{\mathrm{t}}_{\mathrm{H_2O}} \quad (3)$$

In order to estimate the extent of the direct beryllium–dioxane interaction, Raman spectra of aqua beryllium ions in dioxane–water mixtures were measured. Raman bands of aqua beryllium ions in aqueous solution were held at the same frequencies in dioxane–water mixtures examined, and therefore, beryllium ions may be preferentially solvated with water molecules in the mixtures. Although no direct evidence has been given for hydroxo complexes, beryllium ions within the hydroxo complexes may also be preferentially solvated with water molecules in water-rich dioxane–water mixtures, and the structure of the skeleton (*i.e.*, –Be–OH– bonds) of the hydroxo complexes may not be appreciably influenced by the solvent composition. Therefore, we assumed that $\Delta h^{\mathrm{t}}_{pq}$, as well as those of simple ions, reflected the change in the solvation structure of the $\mathrm{Be}_q(\mathrm{OH})_p^{(2q-p)+}$ complex when the hydroxo complex was transferred from water to a dioxane–water mixture. Solvation of the hydroxo complex may occur at the beryllium ions within the complex. Charges of beryllium ions within the $\mathrm{Be}_q(\mathrm{OH})_p^{(2q-p)+}$ complex may partially be compensated with those of hydroxide ions, and therefore, the charge per beryllium ion of the $\mathrm{Be}_q(\mathrm{OH})_p^{(2q-p)+}$ complex may be smaller than +2. Thus, the relation $\Delta h^{\mathrm{t}}_{pq} > q\Delta h^{\mathrm{t}}_{\mathrm{Be}}$ may generally be held.

As is seen from Table 1, the enthalpy changes of formation of the $\mathrm{Be_2OH^{3+}}$ complex in aqueous solution and dioxane–water mixtures were both positive, but $\Delta H^{\mathrm{t}}_{12}$ became negative with the increase in the concentration of dioxane. On the contrary, the enthalpy changes of the $\mathrm{Be_3(OH)_3^{3+}}$ complex was practically independent of the concentration of dioxane, and $\Delta H^{\mathrm{t}}_{33}$ was approximately zero. The different tendencies in $\Delta H^{\mathrm{t}}_{pq}$ between $\mathrm{Be_2OH^{3+}}$ and $\mathrm{Be_3(OH)_3^{3+}}$ complexes may be caused by the difference in $\Delta h^{\mathrm{t}}_{pq}$, or in other words, the different solvation structures of the complexes.

Table 1. The formation constants and the changes in enthalpy (ΔH_{pq}/kJ mol^{-1}) and entropy ($T\Delta S_{pq}$/kJ mol^{-1}) of the hydrolytic reaction of beryllium ion in dioxane–water mixtures

$$q\mathrm{Be}^{2+} + p\mathrm{H_2O} = \mathrm{Be}_q(\mathrm{OH})_p^{(2q-p)+} + p\mathrm{H}^+$$
$$\beta^*_{pq} = [\mathrm{Be}_q(\mathrm{OH})_p^{(2q-p)+}][\mathrm{H}^+]^p/[\mathrm{Be}^{2+}]^q$$

		Mole fraction of dioxane 0.0	0.1	0.2
$\mathrm{Be_2OH^{3+}}$	$-\log\beta^*_{12}$	3.04[11]	3.29[11]	3.64[10]
	ΔH_{12}	18.6	15.2	8.4
	$T\Delta S_{12}$	1.3	−3.4	−12.4
$\mathrm{Be_3(OH)_3^{3+}}$	$-\log\beta^*_{33}$	8.671[11]	8.65[11]	8.763[10]
	ΔH_{33}	61.7	59.4	59.0
	$T\Delta S_{33}$	12.2	10.0	9.1
$\mathrm{Be_2(OH)_2^{2+}}$	$-\log\beta^*_{22}$	—	—	7.11
	ΔH_{22}	—	—	42.3
	$T\Delta S_{22}$	—	—	1.3
$\mathrm{H_2O=H^+ + OH^-}$	pK_w	13.867[6]	14.610[6]	15.376[6]
	ΔH_w	56.6	58.1	61.2
	$T\Delta S_w$	−22.6	−25.3	−26.6

In order to compare $\Delta h^{\mathrm{t}}_{12}$ and $\Delta h^{\mathrm{t}}_{33}$ with $\Delta h^{\mathrm{t}}_{\mathrm{Be}}$, the values of $\Delta H^{\mathrm{t}}_{\mathrm{A}}$ and $\Delta H^{\mathrm{t}}_{\mathrm{B}}$ of the following reactions were calculated, where the contributions of hydrogen ions and water molecules to the reactions are same.

$$6\mathrm{Be}^{2+} + 3\mathrm{H_2O} = 3\mathrm{Be_2OH^{3+}} + 3\mathrm{H}^+; \quad \Delta H^{\mathrm{t}}_{\mathrm{A}} = 3\Delta H^{\mathrm{t}}_{12} \quad (4)$$

$$3\mathrm{Be_2OH^{3+}} + 3\mathrm{H_2O} = 2\mathrm{Be_3(OH)_3^{3+}} + 3\mathrm{H}^+; \quad \Delta H^{\mathrm{t}}_{\mathrm{B}} = 2\Delta H^{\mathrm{t}}_{33} - 3\Delta H^{\mathrm{t}}_{12}. \quad (5)$$

The values of $\Delta H^{\mathrm{t}}_{\mathrm{A}}$ and $\Delta H^{\mathrm{t}}_{\mathrm{B}}$ from water to 0.2 mole fraction dioxane–water mixture were −30.6 and 25.2 kJ mol^{-1}, respectively. Equations 6 and 7 can be derived by using partial molar enthalpy changes of transfer of the relevant species as follows:

$$\Delta H^{\mathrm{t}}_{\mathrm{A}} = 3(\Delta h^{\mathrm{t}}_{12} - 2\Delta h^{\mathrm{t}}_{\mathrm{Be}}) + 3(\Delta h^{\mathrm{t}}_{\mathrm{H}} - \Delta h^{\mathrm{t}}_{\mathrm{H_2O}}) \quad (6)$$

$$\Delta H^{\mathrm{t}}_{\mathrm{B}} = (2\Delta h^{\mathrm{t}}_{33} - 3\Delta h^{\mathrm{t}}_{12}) + 3(\Delta h^{\mathrm{t}}_{\mathrm{H}} - \Delta h^{\mathrm{t}}_{\mathrm{H_2O}}) \quad (7)$$

and

$$\Delta H^{\mathrm{t}}_{\mathrm{A}} < \Delta H^{\mathrm{t}}_{\mathrm{B}} \quad (8)$$

Therefore, the relation

$$2\Delta h^{\mathrm{t}}_{33} - 3\Delta h^{\mathrm{t}}_{12} > 3\Delta h^{\mathrm{t}}_{12} - 6\Delta h^{\mathrm{t}}_{\mathrm{Be}} \quad (9)$$

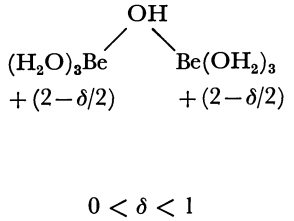
or

$$0 > 2\Delta h^{\mathrm{t}}_{33} \gg 3\Delta h^{\mathrm{t}}_{12} > 6\Delta h^{\mathrm{t}}_{\mathrm{Be}} \quad (10)$$

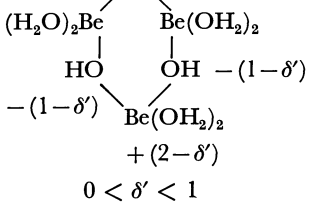
was readily obtained.

As has been pointed out by earlier workers,[18–26] the enthalpy change of transfer of an ion from water to dioxane–water is due to the change in secondary or more hydration spheres of the ion and the enthalpy change of transfer becomes large for ions having a large charge density. Therefore, the relationship given in Eq. 10 leads to the charge density per metal ion of aqua and hydroxo complexes of beryllium ions decreasing in the order of $\mathrm{Be^{2+}}$, $\mathrm{Be_2OH^{3+}}$, and $\mathrm{Be_3(OH)_3^{3+}}$. Although the formal charges calculated on the beryllium atoms within the aqua and hydroxo complexes are +2, +1.5, and +1 for $\mathrm{Be^{2+}}$, $\mathrm{Be_2OH^{3+}}$, and $\mathrm{Be_3(OH)_3^{3+}}$, respectively, the results given in Eq. 10 suggested that much more positive charges might locate at the beryllium atoms within the hydroxo complexes.

The charge distributions within the $\mathrm{Be_2OH^{3+}}$ and $\mathrm{Be_3(OH)_3^{3+}}$ complexes may be represented as follows:[27]



$0 < \delta < 1$



$0 < \delta' < 1$

In the models it was simply assumed that solvation of a hydroxo complex of beryllium ions occurred at the beryllium ion, and a hydroxide ion within the complex acted as a joint between beryllium atoms and as to decrease their charges.

The interaction between a beryllium ion and solvent molecules may be essentially electrostatic, so that the bond energy (or the enthalpy of solvation) may be approximately proportional to $z\mu/r^2$, where z, μ, and r stand for the formal charge of beryllium ion in the complex, the dipole moment of the water molecule and the distance between the beryllium ion and the water molecule, respectively. If we assumed that the enthalpy of solvation of a beryllium ion within a hydroxo complex is proportional to the charge of the beryllium ion, the relationship $\delta<\delta'$ may be derived from Eq. 9. Thus, the charge on the hydroxide ions within the Be_2OH^{3+} complex may be larger than that within the $Be_3(OH)_3{}^{3+}$ complex.

Raman spectroscopic measurements of aqua beryllium ions in aqueous solution showed a band at 527 cm^{-1} due to the total symmetric stretching vibration of $Be(OH_2)_4{}^{2+}$.[28] Corresponding frequencies(ν) of the Be–OH_2 stretching vibration within the Be_2OH^{3+} and $Be_3(OH)_3{}^{3+}$ complexes shifted to 497 and 408 cm^{-1}, respectively.[28] The shift of the band of the Be_2OH^{3+} complex is comparatively less than that of the $Be_3(OH)_3{}^{3+}$ complex. If we simply assumed that the interaction between a beryllium ion and water molecules within a complex is purely electrostatic, and thus, ν^2 is approximately proportional to the charge of the beryllium ion, the formal charge of the beryllium ions within the Be_2OH^{3+} and $Be_3(OH)_3{}^{3+}$ complexes were estimated to be $+1.78$ and $+1.20$, respectively, or $\delta=0.44$ and $\delta'=0.80$. The results coincided with that derived from a qualitative comparison between Δh_{12}^{t} and Δh_{33}^{t} described above.

Although these considerations were very approximate, the results obtained suggested that the charge distribution within the hydroxo complexes may be strongly related to the enthalpy of solvation, and thus the partial molar enthalpy change of transfer of the complexes from one solvent to another.

Molecular Structure of Trimethylphosphine-boron Trichloride by Gas Electron Diffraction

Kinya IIJIMA and Shuzo SHIBATA*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received March 22, 1979)

The molecular structure of trimethylphosphine-boron trichloride $(CH_3)_3P\cdot BCl_3$ has been determined from gas electron-diffraction data. The structure parameters and uncertainties are r_g(P–B) = 1.941(16) Å, r_g(B–Cl) = 1.851(7) Å, r_g(C–P) = 1.800(4) Å, r_g(C–H) = 1.099(5) Å, r_g(Cl···Cl) = 3.022(5) Å, and r_g(C···C) = 2.936 (10) Å. The potential barrier about the P–B axis is 3.8±0.7 kcal mol^{-1} in the gas phase. The data show that the molecular structure in the gas phase is nearly equal to that in the solid phase.

The molecular structures of several phosphorus-boron donor-acceptor complexes have been investigated in the gas and solid phases by microwave spectroscopy[1–5] and X-ray diffraction,[6] respectively. According to these studies the distances of the P–B dative bond in the complexes are very different from each other. The experimental data showed that the P–B distances in $F_3P\cdot BH_3$[1] and $H_3P\cdot BH_3$[2] are 1.836±0.006 Å and 1.937±0.005 Å, respectively, and the P–B distances of the other complexes are somewhat between these values. Therefore, the P–B dative bond appears to considerably change in length according to circumstances surrounding the bonded atoms. It has been noted that there appears to be no correlation between the distance of the P–B dative bond and the stability of the complex.[4] For example, the $F_3P\cdot BH_3$ complex is extensively dissociated in the gas phase at room temperature, while the $(CH_3)_3P\cdot BH_3$ complex, which has a greater P–B distance, 1.901±0.007 Å,[4] is more stable and can be heated to approximately 200 °C without appreciable decomposition.[7] Rudolph and Parry have proposed a theory to account for the unusual properties of the P–B bond,[8] but more structural data appears to be necessary in order to understand the nature of the P–B dative bond. It has been reported that the distance of the N–B dative bond in trimethylamine-boron trihalide is significantly larger in the gas phase than in the solid phase.[9–11] It is therefore of interest to compare the P–B distance of trimethylphosphine-boron trihalide in the gas phase with that in the solid phase.[6] Thus the present study was undertaken in order to determine the molecular structure of gaseous trimethylphosphine-boron trichloride $(CH_3)_3P\cdot BCl_3$.

Experimental

Trimethylphosphine was prepared by the dropwise addition of phosphorus trichloride into an ethereal solution of methyllithium, and the distilled trimethylphosphine solution added to an ethereal solution of boron trichloride. After removal of the ether, the trimethylphosphine-boron trichloride complex was recrystallized from acetone and water, and sublimed under vacuum. The purity of the complex was verified by IR analysis.[12] In the electron-diffraction experiment the sample was vaporized at approximately 190 °C by means of a high temperature nozzle, and photographs taken with an r^3-sector at camera distances of 144 and 294 mm. The accelerating voltage was 40 kV, and the exposure time for the long camera distance was 25 s using an electron-beam current of 0.7 μA. For the short camera distance the exposure time was 80 s using a beam current of 0.9 μA. The pressure in the diffraction chamber was approximately 1×10^{-5} Torr during the experiment. The electron wavelength was measured by means of diffraction patterns of thallium chloride powder.[13] Photographs were recorded on Kodak electron-image plates, and the optical densities of the three plates taken at each camera distance were measured at 0.4 mm intervals by means of a digital microphotometer. The electron-diffraction unit and digital microphotometer used in the present study have been described elsewhere.[14]

Analysis and Results

The scattering intensities were obtained in the ranges of s = 2.5—17.3 Å^{-1} and 5.0—34.2 Å^{-1} from the photographic plates at long and short camera distances, respectively. The intensities were divided by the theoretical backgrounds, and the leveled intensities of several plates for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer *et al.*[15] and Cromer and Mann,[16] respectively. The background curves were drawn by hand for the long distance data and fitted to a 7th degree polynomial for the short distance data. The molecular intensities for each camera distance were joined at s = 14.8 Å^{-1}, and the curve, shown in Fig. 2, used for the analysis. Figure 3 shows the radial distribution curve, which suggests that the molecular structure of $(CH_3)_3P\cdot BCl_3$ is staggered.

The molecular parameters were determined by a least-squares analysis of the molecular intensities. It was assumed that the $(CH_3)_3P\cdot BCl_3$ molecule has C_{3v} symmetry in the staggered form, and that the methyl group has local C_{3v} symmetry and is staggered with respect to the P–B bond. The mean amplitudes and the corrections for the shrinkage effects,[17] $r_a - r_\alpha$, were calculated on the basis of the force field for $(CH_3)_3P\cdot BCl_3$[12] and are given in Table 1. The

geometrical parameters and the mean amplitudes determined by the least-squares analysis are as follows: r(B–Cl), r(P–B), r(C–P), r(C–H), r(Cl···Cl), r(C···C), ∠PCH, l(B–Cl), l(C–P), l(C–H), l(Cl···Cl), l(*trans* C···Cl), l(*gauche* C···Cl), l(P···H). The mean amplitudes for the other atomic pairs were fixed to the calculated values shown in Table 1. The asymmetry parameter, κ, for the C–H bond was assumed to be 1.2×10^{-5} Å^3 by a diatomic approximation.[18] The asymmetry parameters for the other atomic pairs were neglected.

Table 1. Calculation of mean amplitudes and shrinkage effects for $(CH_3)_3P \cdot BCl_3$ (in 10^{-4} Å)

	l	$r_a - r_\alpha$		l	$r_a - r_\alpha$

The numbering of the atoms is shown in Fig. 1.

In the force field treatment by Drake *et al.*[12] the torsional vibrations around the C–P and P–B bonds were not taken into consideration. In the present study the force constant for the torsional vibration around the C–P bond was assumed to be 0.08 mdyne Å. This value was estimated from the potential barrier for trimethylphosphine, 2.6 kcal mol^{-1}.[19] Since the torsional vibration around the P–B bond contributes considerably to the mean amplitude of the *gauche* C···Cl pair, the force constant for this motion, Y(P–B), was adjusted to fit the calculated mean amplitude of the *gauche* C···Cl pair to the observed one from the analysis of electron-diffraction intensities.[11] Thus Y(P–B) was estimated to be 0.12± 0.02 mdyne Å, and the potential barrier of the torsional vibration around the P–B bond was evaluated as 3.8±0.7 kcal mol^{-1}.

The r_α parameters and mean amplitudes determined by the analysis are given in Tables 2 and 3 together

with their 99% confidence errors, respectively. The errors were estimated from random errors in the least-squares calculations and systematic errors originating from the measurements of camera distance and electron wavelength. The comparatively large errors of r(B–Cl), r(P–B), and l(B–Cl) are attributable to the large correlations between other parameters. The correlation matrix is listed in Table 4, and the best-fit theoretical intensity curve is shown in Fig. 2.[20] The calculations of mean amplitudes, shrinkage effects, and method of least-squares were conducted on a HITAC 8800/8700 computer in the Computer Center of the University of Tokyo.

Discussion

From a comparison of the molecular structure of the $(CH_3)_3P\cdot BCl_3$ complex to those of the component molecules of $(CH_3)_3P$[21] and BCl_3[22] (Table 2), it can be seen that complex formation increases the CPC angle by 11% and the B–Cl distance by 6%, and decreases the C–P distance by 3% and the ClBCl angle by 9%. Both the CPC and the ClBCl angles in the complex are almost tetrahedral. The above changes can be interpreted in terms of the valence-shell electron-pair repulsion theory.[23]

The structural change of the donor molecule by the formation of $(CH_3)_3P\cdot BCl_3$ is quite different from that by the formation of the trimethylamine complex, since in the former the CPC angle increases and the C–P distance decreases while in the latter the CNC angle decreases (2°) and the C–N distance increases (0.04 Å).[10] With respect to the acceptor molecule, however, the structural change is rather similar in both complexes (a decrease of 8% in the ClBCl angle and an increase of 6% in the B–Cl distance in the $(CH_3)_3N\cdot BCl_3$ complex[10]). There is another difference between both complexes. The molecular structure of $(CH_3)_3N\cdot BCl_3$ in the gas phase[10] differs from that in the solid phase.[24] For example, the N–B dative bond is much greater in the gas phase than in the solid phase. The molecular structure of gaseous $(CH_3)_3P\cdot BCl_3$ is however nearly equal to that in the solid phase.[6]

The rotational barrier of $H_3P\cdot BH_3$ about the P–B bond is 2.47±0.05 kcal mol^{-1} according to a MW spectroscopic study.[2] The fluorine-substituted compounds of $F_3P\cdot BH_3$ and $H_3P\cdot BF_3$ have slightly larger barriers, 3.24±0.15 and 3.39±0.40 kcal mol^{-1}, respectively.[1,3] The H···H distance in $H_3P\cdot BH_3$, the F···H distance in $F_3P\cdot BH_3$ and that in $H_3P\cdot BF_3$ are virtually identical, which suggests that the increment in the barrier for the fluorine-substituted compounds is probably due to the large steric repulsion of the fluorine atoms. On this bases, it might be expected that in $(CH_3)_3P\cdot BCl_3$ the methyl groups and chlorine atoms increase the barrier around the P–B bond through large steric effects. The barrier was however found to be 3.8±0.7 kcal mol^{-1}, which is equal to that reported for $F_3P\cdot BH_3$ and $H_3P\cdot BF_3$ within the limits of experimental error. This could be attributed to the considerably large C···Cl distances in $(CH_3)_3P\cdot BCl_3$.

Anodic Oxidation of 2-Aminofluorene at a Platinum Electrode in Acetonitrile Solutions

Kazuo YASUKOUCHI, Isao TANIGUCHI,* Hiroko YAMAGUCHI, Katsuji MIYAGUCHI, and Koji HORIE

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, 2-39-1, Kurokami, Kumamoto 860

(Received April 16, 1979)

Anodic oxidation of 2-aminofluorene in acetonitrile solutions at a Pt electrode was investigated by using electrochemical techniques and by preparative-scale electrolyses. The cyclic voltammogram of 2-aminofluorene exhibited two anodic waves, which had peak potentials at 0.45 V (I_a) and 1.15 V (II_a) *vs.* Ag/0.01 M $AgClO_4$. Wave II_a was due to oxidation of protonated 2-aminofluorene. In the voltammogram of repetitive sweeps, another redox couple (III_a/III_c) was observed at 0.13 V for III_a and 0.06 V for III_c, respectively. This indicates that at wave I_a, a species which is more easily oxidized than 2-aminofluorene was produced by follow-up chemical steps. By controlled-potential electrolysis at 0.5 V of a 2-aminofluorene solution containing pyridine as a proton acceptor, a dark green product, 3-(2-fluorenylimino)-2,3-dihydro-2-fluorenimine (**5**) (or 1-(2-fluorenylimino)-1,2-dihydro-1-fluorenimine (**5′**)), precipitated as the main product in more than 70% yield. The oxidation pathway of 2-aminofluorene (Eqs. 1—4) has been proposed on the bases of the following results: (i) The apparent *n*-value was 1.95, (ii) two protons/molecule of 2-aminofluorene were released in the follow-up chemical steps, and (iii) the peak potential for oxidation of 2′-amino-2,3′-difluorenylamine (**3**) (or 2-amino-1,2′-difluorenylamine (**3′**)) was in good agreement with that of wave III_a, and the anodic oxidation of **3** (or **3′**) gave the same product as that obtained by oxidation of 2-aminofluorene.

Anodic oxidation of aromatic amines has been extensively studied in both aqueous and nonaqueous solutions, and some general rules for reaction pathways have been obtained for mononuclear aromatic amines.[1—5] For polynuclear aromatic amines, however, little is known about the oxidation pathway. This is partially because in many cases the oxidation products film the electrode surface and no product could be isolated. Most investigations of these compounds have been limited to the measurement of the oxidation half-wave potentials which are correlated with the HMO energies of the highest occupied molecular orbitals.[6,7] Recently, however, electrochemical pathways of polynuclear aromatic amines have become increasingly important biologically. This is because, (i) since these compounds are typical carcinogens and their azo and/or hydrazo derivatives are important metabolic intermediates of the carcinogens,[8,9] information which elucidates the carcinogenic mechanism may be obtained, and (ii) an electrochemical technique for the synthesis of biologically important compounds can be developed. Furthermore, it would be worthwhile to study the oxidation of polynuclear aromatic amines to examine whether or not the general rules for the oxidation mechanism proposed for mononuclear aromatic amines can be applicable for polynuclear ones.

In the present study, anodic oxidation of 2-aminofluorene, whose reaction pathway has not yet been reported, was investigated.

Experimental

Reagents were analytical GR grade and used without further purification unless otherwise noted. Sodium perchlorate was recrystallized twice from ethanol, dried overnight under a reduced pressure (400 Pa), and stored over silica gel. Acetonitrile was purified by distillation with P_2O_5 and with K_2CO_3, and then twice by slow fractional distillation. The MeCN was used within two weeks after purification. The water concentration of the test solution was determined to be less than 0.2 wt% by the Karl-Fischer titration.

The cyclic voltammograms were measured at a Pt disk electrode (2.0×10^{-3} cm^2) using a Yanaco P8 polarograph. The electrode was polished with an oil stone before each measurement. Rotating disk electrode (RDE) voltammetry was carried out using a commercially available instrument constructed by Nikko Keisoku. The kinematic viscosity (ν) of the solution used was 0.00441 cm^2 s^{-1}. The diffusion coefficient (D) of 2-aminofluorene was estimated to be 1.55×10^{-5} cm^2 s^{-1} by the Levich equation.

Controlled-potential electrolysis was undertaken using a Nikko Keisoku NPGS 301 potentiostat. A two-compartment cell with a fine glass frit was used. The working (50 cm^2) and the counter electrodes were Pt plates. During electrolysis, cyclic voltammograms of the solution were measured to check the change of the composition of the solution. The working electrode for preparative-scale electrolysis was reactivated, when necessary, by burning, because the product which adhered on the electrode surface caused a steep decrease in current. In the time scale for voltammetric measurements, however, no serious adsorption of the product was observed.

An Ag/0.01 M $AgClO_4$ couple in MeCN was used as the reference electrode and potentials appearing in this paper are referred to this electrode. All electrochemical experiments were carried out at 25±0.5 °C under an atmosphere of nitrogen. Throughout this paper, 1 M=1 mol dm^{-3}.

After exhaustive electrolysis of 2-aminofluorene, the solution was concentrated and water was added to precipitate a dark green product. The precipitate was separated by centrifugation and filtered off. The crude product was washed more than six times with each 10 ml of water to remove trace amounts of 2-aminofluorene which remained unreacted, and then recrystallized from either aqueous methanol or aqueous *N*,*N*-dimethylformamide. Thus, for example, 19 mg of the product (I) was obtained by electrolysis of 27 mg of 2-aminofluorene (150 ml of 1 mM solution); the yield is more than 70%. The product I was then chromatographed on both silica gel (Wako B-10) and alumina (Wako B-10) with either benzene, acetone, or ethanol, and detected with iodine. In each case only a single spot was

observed. The analytical data on the product I are: mp> 300 °C; UV-Vis$_{max}$ (MeCN) 277 (log ε 4.3) and 660 nm (log ε 3.4); NMR (C_5D_5N) δ=3.76 (4H, s, CH_2) and 6.9—7.8 (13H, m, Ar–H); IR (KBr) 3370 (ν N–H) and 1610 cm^{-1} (ν C=N). Found: C, 87.2; H, 5.4; N, 7.4%; M$^+$, 358. Calcd for $C_{26}H_{18}N_2$: C, 87.1; H, 5.1; N, 7.8%; M, 358.4. The product I was easily soluble in *N*,*N*-dimethylformamide, fairly soluble in pyridine, soluble in MeCN, methanol, and ethanol, but almost insoluble in water.

Acetylation of I was performed by a method similar to that described by Bridger *et al.*[10] In the IR spectrum of the acetylated product, the absorption of N–H stretching at 3370 cm^{-1} disappeared, and those of C=O stretching and C–CH_3 bending appeared at 1720 and 1370 cm^{-1}, respectively (=NH→=N–C(=O)–CH_3). The number of NH groups was estimated to be one by the ratios of the number of methyl protons introduced by acetylation to those of methylene protons and aromatic protons of the fluorene ring in the NMR spectrum of the acetylated product.

2′-Amino-2,3′-difluorenylamine (**3**) was prepared according to the literature,[11] where it had not been determined whether the compound was **3** or 2-amino-1,2′-difluorenylamine (**3′**). No data for distinguishing between **3** and **3′** were obtained in the present study; we denote this compound as **3** just for convenience. Oxidation of **3** was carried out electrochemically by a method similar to that used for the oxidation of 2-aminofluorene, except for the applied potential.

The IR and UV spectra were obtained using a Hitachi 125-G (using KBr pellet technique) and a Hitachi 200-10 spectrophotometer, respectively. The NMR spectra were measured using a JEOL MH-100 spectrometer in either pyridine-d_5 or $CDCl_3$ containing TMS as an internal standard. The mass spectra were recorded using a JEOL JMS D-100 spectrometer.

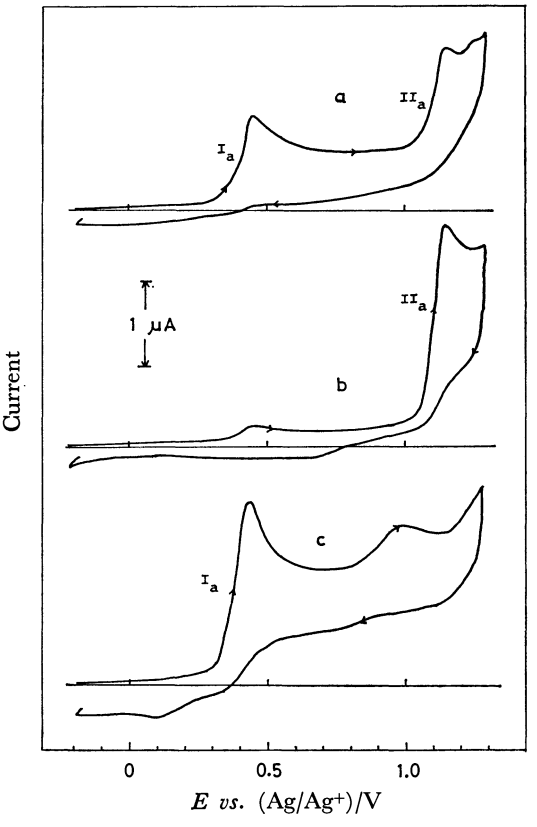

Fig. 1. Cyclic voltammograms of 1 mM 2-aminofluorene in 0.1 M $NaClO_4$–MeCN at the scan rate of 0.2 V s^{-1}. a; With no additive, b; with 1 mM $HClO_4$, and c; with 2 mM pyridine. The direction of the potential sweep is shown by arrows on the voltammograms.

Results and Discussion

The cyclic voltammogram of 2-aminofluorene showed two anodic waves having peak potentials, E_p, of 0.45 (I_a) and 1.15 (II_a) (Fig. 1a). Wave II_a was due to oxidation of protonated 2-aminofluorene. When the concentration of proton added was equal to that of 2-aminofluorene, only this wave was observed (Fig. 1b). Further increase in proton concentration did not cause appreciable change in the shape or height of the wave. On the other hand, the height of wave I_a increased with increasing amounts of pyridine added. Finally, in the solution containing twice as much pyridine as the concentration of 2-aminofluorene, the peak current of I_a became twice the value observed in the solution with no pyridine, whereas wave II_a disappeared and a wave due to oxidation of pyridine at E_p=0.95 V was observed (Fig. 1c). These cyclic voltammetric data show that 2-aminofluorene acted as a base in the follow-up chemical steps, but pyridine replaced 2-aminofluorene as a proton acceptor.

By controlled-potential electrolysis of 1 mM 2-aminofluorene solution with no pyridine, the *n*-value (electrons consumed/molecule of the starting amine) observed was 0.5—0.6, and a dark green precipitate and protonated 2-aminofluorene were produced. During electrolysis, the color of the solution turned green and then reddish purple. The latter color was due to protonated species of the dark green product, because an acetonitrile solution of the green product changed from green to reddish purple when perchloric acid was added to the solution. Thus, in order to reduce the complication caused by the protonation of both the starting amine and the product, preparative-scale electrolyses at 0.5 V of 1 mM 2-aminofluorene solution containing 2—5 mM pyridine were carried out. During electrolysis, the dark green product was generated as the main product in a yield of more than 70%, and the *n*-value of 1.95 was obtained by coulometry. The color of the solution became dark green and no further change to reddish purple was observed even at the end of the electrolysis. In the cyclic voltammograms of the solution during electrolysis, the peak current of I_a decreased and a new reduction wave (IV_c) due to reduction of protonated pyridine appeared (Fig. 2). The peak current of wave IV_c observed at the end of the electrolysis indicates that two protons per molecule of 2-aminofluorene were released in the follow-up chemical steps. No appreciable change in the results was observed by varying the concentration of pyridine (2—5 mM).

Oxidation Product. The structure of the dark green product is now considered in detail. In general, anodic oxidation of aromatic amine gives three types of compounds, namely, azo type (which is formed by N–N coupling of the intermediates), ortho-semidine type (by ortho C–N coupling), and benzidine type

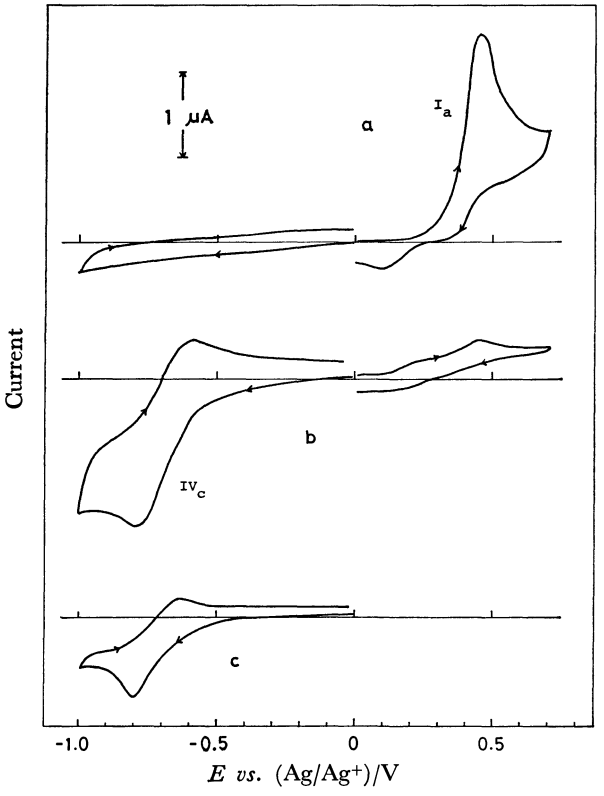

Fig. 2. Cyclic voltammograms of 1 mM 2-aminofluorene in 0.1 M $NaClO_4$–MeCN containing 3 mM pyridine (a and b), and of 1 mM protonated pyridine (c) in 0.1 M $NaClO_4$–MeCN. a; Before, and b; after exhaustive oxidation at 0.5 V. c; 1 mM pyridine solution containing 1 mM $HClO_4$. Scan rate: 0.2 V s^{-1}.

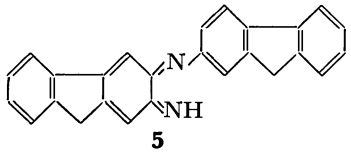
compounds (by C–C coupling). For product I, 2,2′-azofluorene must be rejected because no appreciable UV absorption for 2,2′-azofluorene or 2,2′-hydrazofluorene[12] was observed. A benzidine type compound may also be unlikely because of the structural hindrance of 2-aminofluorene. Thus, an ortho-semidine type is most probable, and 2′-amino-2,3′-difluorenylamine (**3**), which seems to be an intermediate in the present reaction, was synthesized according to the literature[11] (see experimental section).

By anodic oxidation of **3** at 0.3 V, the slightly orange-colored solution turned green and a product was obtained, which was identical with that obtained by oxidation of 2-aminofluorene, judging from their NMR, IR, and UV spectra. Thus, the following structure, **5**, is suggested for product I:



5

To further clarify the structure, the product was analyzed by several methods (see experimental section). The following analytical data support the structure **5**: (i) In the IR spectrum of I, N–H stretching absorptions for 2-aminofluorene at 3360 and 3450 cm^{-1} changed to a single band at 3370 cm^{-1} and a C=N

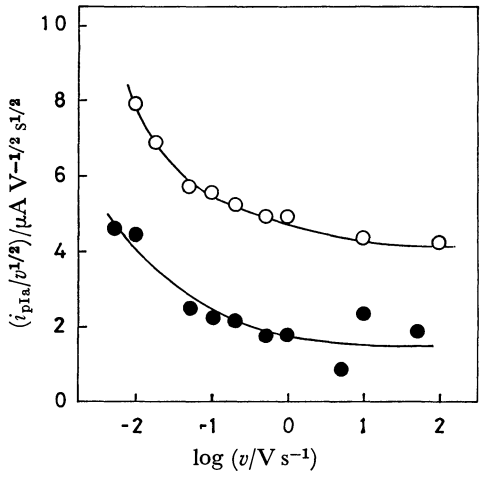


Fig. 3. The ratio of the peak current for wave I_a of 1 mM 2-aminofluorene solution to the square root of the scan rate, $i_{pIa}/v^{1/2}$, as a function of the scan rate in 0.1 M $NaClO_4$–MeCN. (○); With 2 mM pyridine, and (●); without.

stretching absorption at 1610 cm^{-1} was observed ($-NH_2 \rightarrow >C=NH$). (ii) Acetylation of I took place, and the number of N–H groups per molecule of I was estimated to be one from the NMR spectrum of the acetylated product. (iii) Results of elementary analysis and molecular weight (=358) are in good agreement with those calculated for **5**. (iv) The NMR spectrum showed that the number of aromatic protons and that of methylene protons are reasonably explained in terms of the structure of **5**, though no appreciable peak for N–H protons was observed.

Oxidation Pathway. To clarify the mechanism for the formation of **5**, further cyclic voltammetric investigations were carried out. The ratio of the peak current of wave I_a to the square root of the scan rate of the potential, $i_{pIa}/v^{1/2}$, decreased with an increase in the scan rate (Fig. 3). In repetitive cyclic voltammograms, a couple of waves (III_a/III_c) at potentials less anodic than that of wave I_a were observed (Fig. 4). These results indicate that for oxidation at wave I_a a primary one-electron transfer occurred to form a cation radical, and then a species which is more easily oxidized than the starting amine was produced by a chemical reaction and was further oxidized; this would be like a so-called ECE mechanism. Wave III_a in the cyclic voltammogram of 2-aminofluorene was in good agreement with the oxidation wave of **3** in both the peak potential and the wave shape (Fig. 4). The differences in shape and the peak potential observed between wave III_c and the corresponding re-reduction wave of **3** are probably because the oxidation product adsorbed on the electrode shifts the re-reduction wave of **3** to more negative potentials (Fig. 4c). During controlled-potential electrolysis of **3** at 0.3 V, two electrons per molecule of **3** were consumed, and the number of protons liberated was estimated to be two from the peak current for the reduction of protonated pyridine.

Thus, taking into account the results that (i) the over-all *n*-value for oxidation of 2-aminofluorene was two, and (ii) two protons with respect to the starting

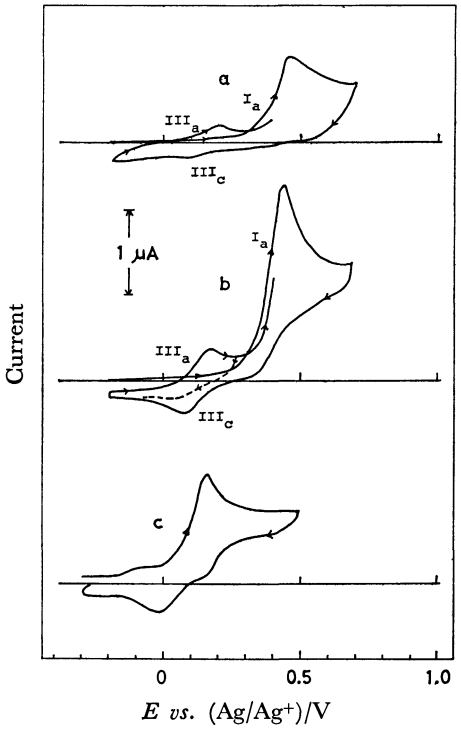

Fig. 4. Repetitive cyclic voltammograms of 1 mM 2-aminofluorene (a and b), and of 0.5 mM of **3** (c) in 0.1 M $NaClO_4$–MeCN containing a; 0 mM, b; 2 mM, and c; 5 mM pyridine. Scan rate: 0.2 V s^{-1}.

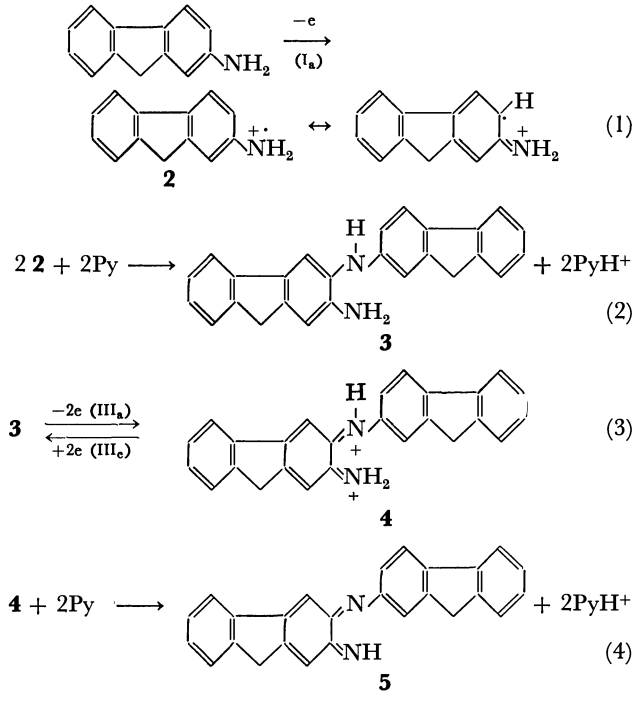
amine were released in the follow-up chemical steps to produce **5**, we propose that **5** is formed by the following reactions in a solution containing pyridine (Py):



where the formation of **5′**, an isomer of **5**, is also possible *via* similar reactions. In the present experiment, no data for distinguishing between **5** and **5′** have yet been obtained; to determine the correct structure of the product I, further experiments, for example ^{13}C NMR measurements, are required, and some investigations are now in progress.

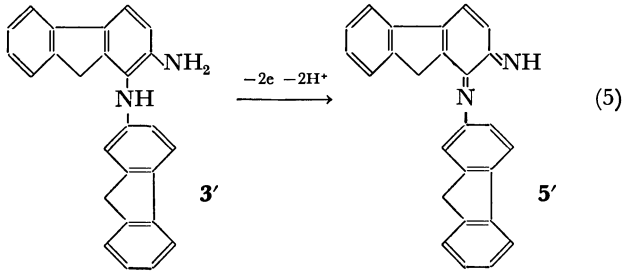
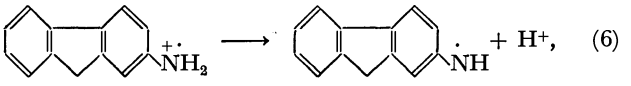
a) The area of the electrode was 0.0707 cm^2. b) The values adopted are the average of more than five independent experiments. c) The values of k were estimated using Eq. 7 of Ref. 14, where $D=1.55\times10^{-5}$ cm^2 s^{-1} and $\nu=0.00441$ cm^2 s^{-1}. d) The mean of the values obtained at $83.8<\omega<314.2$ rad s^{-1}.



Since the potentials for the waves III_a/III_c and I_a were not affected by the presence of pyridine, similar reactions to those described above (Eqs. 1—4) also occurred in the solution with no pyridine, except that the protonations of the starting amine and of the product **5** occurred in this solution. The proposed reactions for 2-aminofluorene are similar to those usually observed for mononuclear aromatic amines. However, the predominant formation of the ortho-semidine type dimer should be noted because several compounds involving polymers are usually formed for mononuclear amines. This probably results from the structures of 2-aminofluorene and its generated cation radical.

Preliminary Information for the Chemical Steps. Due to protonations of both 2-aminofluorene and the product, it appears difficult to measure kinetic data on the chemical steps. However, some preliminary information on the rate of chemical steps may be obtained. Since the peak current of the wave III_c increased when pyridine was added, the deprotonation in Eq. 2 was accelerated by pyridine, whereas the deprotonation in Eq. 4 was probably slow and the addition of pyridine did not affect the rate. Thus, in the solution with no pyridine, the step of deprotonation of the cation radical generated by the primary electron transfer,



(6)

becomes a rate-determining step for oxidation at wave I_a. To confirm this consideration, RDE voltammetry was applied for 2-aminofluorene solution with no pyridine. The value of $i_l/\omega^{1/2}$, where i_l is the limiting current at an RDE and ω is the rotation speed of the electrode, decreased to a limiting value ($I_{l\lim}$) with an increase in the rotation speed (Table 1). The limiting value, $I_{l\lim}$, corresponds to the initial one-electron oxidation. The values of n_{app} ($=i_l\omega^{-1/2}/I_{l\lim}$) for lower rotation speeds depend on the rotation speed but are independent of the concentration of 2-aminofluorene. This is explained in terms of a first-order reaction for the chemical step,[13,14] namely, deprotonation. The rate constant of the deprotonation in Eq. 6 was thus estimated to be about 0.2 s^{-1} using Eq. 7 of Ref. 14 (Table 1).

This work was supported in part by the Asahi Glass Foundation for the Contribution to Industrial Technology.

Emission Spectra of 1,4-Naphthoquinone and Its 2-Methyl Derivative in the Vapor Phase

Takao ITOH and Hiroaki BABA*

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received April 21, 1979)

The emission spectra of 1,4-naphthoquinone (NQ) and 2-methyl-1,4-naphthoquinone (MNQ) vapors have been investigated at various temperatures in the presence of added foreign gases ($\approx$100 Torr). The results indicate that in both NQ and MNQ the emission consists of $T_1(n, \pi^*) \rightarrow S_0$ phosphorescence and weak E-type delayed fluorescence, $S_1(n, \pi^*) \rightarrow S_0$, the latter lying at higher frequencies. This new interpretation of the vapor-phase emission spectra of the naphthoquinones, which is substantially different from the interpretations given by previous authors, is based on and consistent with the following observations: (1) When the temperature is raised, the ratio of the fluorescence intensity to the phosphorescence intensity increases; (2) the S_1—T_1 energy separations, 1365$\pm$60 and 1500$\pm$200 cm^{-1} for NQ and MNQ, respectively, determined from the temperature dependence of the emission intensities agree with the corresponding values obtained from spectral data; (3) the emission lifetimes obtained by monitoring the fluorescence and phosphorescence are identical.

1,4-Naphthoquinone (NQ) is one of the representative quinones and shows strong emission in the visible region in rigid glass solution at 77 K. This emission has been identified as the phosphorescence from the lowest triplet state of n, π^* type, on the basis of the prominent progression in the C–O stretching vibration, the short lifetime, and the band position.[1] A comparison of the phosphorescence and absorption spectra of NQ indicates that the energy difference between the lowest excited singlet and triplet states is very small.

It is known that NQ exhibits weak emission in the vapor phase, and studies have been made on both emission[2,3] and absorption spectra[4] of NQ vapor. The vapor-phase emission spectrum of NQ was obtained in the presence of added benzene by Singh and Singh[2] and by Longin[3] with the aid of discharge excitation, but their assignments of the emitting states are inconsistent with each other. The former authors interpreted the emission spectrum in terms of fluorescence from a $^1(n, \pi^*)$ state and phosphorescence from a $^3(n, \pi^*)$ state, with the origins at 21945 and 18782 cm^{-1}, respectively, while the latter regarded the spectrum as due to two kinds of fluorescence from different n, π^* states with the origins at 22163 and 21974 cm^{-1}.

The emission and absorption spectra of 2-methyl-1,4-naphthoquinone (MNQ) vapor also were reported by Baruah *et al.*[5] They interpreted the emission as consisting of fluorescence from a $^1(n, \pi^*)$ state and phosphorescence from a $^3(n, \pi^*)$ state, with origins at 22075 and 20262 cm^{-1}, respectively.

Since the phosphorescent carbonyl compounds having a small S_1-T_1 energy separation often show weak E-type delayed fluorescence at room temperature,[6] one must take this into account in the assignment of the emitting states of NQ or MNQ vapor.

The purpose of the present study is to clarify the emitting states of NQ and MNQ in the vapor phase. Particular attention has been directed to the change of emission spectra with temperature. It is shown that, at high total pressure ($\approx$100 Torr) in the presence of a foreign gas, the emission spectra of NQ and MNQ vapors consist of $T_1(n, \pi^*) \rightarrow S_0$ phosphorescence and weak E-type delayed fluorescence, $S_1(n, \pi^*) \rightarrow S_0$. The S_1-T_1 energy gaps obtained from the temperature dependence of emission spectra are in agreement with those obtained from the band positions. The results of the decay measurement also support the present assignment.

Experimental

Materials. 1,4-Naphthoquinone (NQ), obtained from Wako Pure Chemical Industries, was recrystallized several times from ethanol, passed through a silica-gel column with benzene or petroleum benzine as the solvent, and finally sublimed *in vacuo*. 2-Methyl-1,4-naphthoquinone (MNQ) from Tokyo Chemical Industries was recrystallized several times from ethanol and sublimed *in vacuo*. It was confirmed that the emission spectra of these purified materials in a rigid glass at 77 K agree well with those reported previously.[1,7] Carbon tetrachloride of spectroscopic quality from Merck and benzene of chromatographic quality from Nakarai Chemicals were used as foreign gases without further purification.

Apparatus and Procedure. Emission and excitation spectra were measured with a high-sensitivity spectrophotometer based on the photon-counting method; it is equipped with a xenon lamp and a double monochromator for excitation, and with an HTV R-585 photomultiplier.[8] Two reflecting concave mirrors were placed beside the sample cell so as to intensify the emission signal. Absorption spectra were obtained with a Hitachi EPS-3 or a Cary-15 spectrophotometer. Emission decays were measured with a spectrophosphorimeter which was specially designed for measuring lifetimes ranging from 10^{-2} to 10^{-5} s by means of the photon-counting method.[9] Quartz cells of 35-mm path length were used for measuring emission and excitation spectra as well as emission decays. Samples were degassed in a mercury-free vacuum system.

Emission spectra were corrected for the spectral sensitivity of the monochromator-photomultiplier system with a solution of quinine in 0.5 M sulfuric acid as a standard. Excitation spectra were corrected for the spectral intensity distribution of the exciting light by the use of an aqueous solution of rhodamine B as a quantum counter. Emission quantum yields were determined by comparing the corrected emission spectra of the sample vapors with that of quinine in 0.5 M sulfuric acid, which is known to have an emission quantum yield of 0.51.[10]

Results

Figure 1 shows the corrected emission spectra in

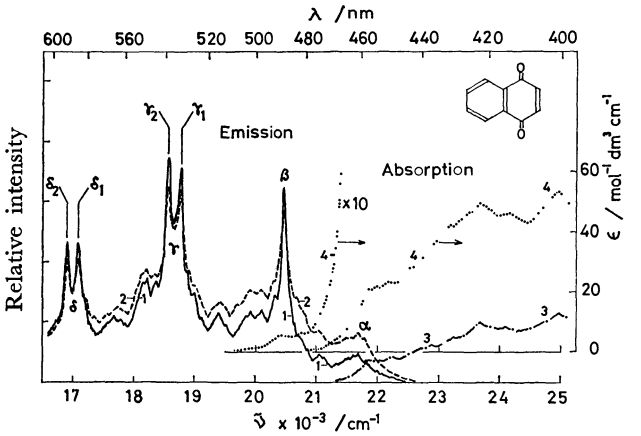

Fig. 1. Vapor-phase emission spectra (corrected) in the presence of benzene vapor (≈100 Torr) at different temperatures (1 and 2) and absorption spectra (3 and 4) of 1,4-naphthoquinone: (1) at 15 °C; (2) at 85 °C; (3) in the vapor phase; (4) in isopentane solution at room temperature. The intensity of spectrum 2 is arbitrarily chosen with no relation to that of spectrum 1. Emission spectra were obtained with a bandwidth of 1.0 nm.

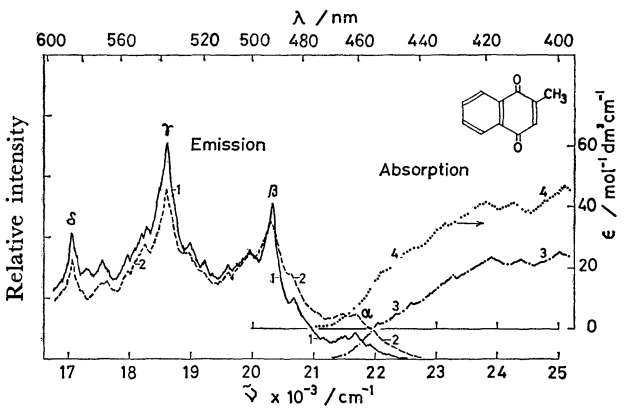

Fig. 2. Vapor-phase emission spectra (corrected) in the presence of benzene vapor (≈100 Torr) at different temperatures (1 and 2), vapor-phase excitation spectrum (3), and absorption spectrum in isopentane at room temperature (4) of 2-methyl-1,4-naphthoquinone: (1) at 25 °C; (2) at 80 °C. The intensity of spectrum 2 is arbitrarily chosen with no relation to that of spectrum 1. Emission spectra were obtained with a bandwidth of 2.0 nm.

the presence of benzene (≈100 Torr) at two temperatures and the absorption spectrum of NQ vapor, where the main emission bands are denoted by α, β, γ, and δ. Bands γ and δ split into doublets, *i.e.* γ_1 and γ_2, and δ_1 and δ_2, respectively. When the temperature is raised, the ratio of the intensity of band α to that of band β, γ, or δ increases. Band α has a sort of mirror-image relation to the vapor-phase absorption spectrum. Band β agrees in position with the very weak band which appears at about 20500 cm^{-1} in the absorption spectrum in isopentane solution (Fig. 1). This weak absorption band can be attributed to $S_0 \rightarrow T_1(n, \pi^*)$ transition on account of its small molar extinction coefficient ($\varepsilon \simeq 0.4$ mol^{-1} dm^3 cm^{-1}). The excitation spectra monitored at bands α, β, γ_1, and γ_2 agree well with the absorption spectrum. The absorption spectrum of NQ vapor ranging from 2.1 to 2.8×10^4 cm^{-1} can safely be assigned as the $S_0 \rightarrow S_1(n, \pi^*)$ transition on the basis of the molar extinction coefficients for the corresponding absorption in isopentane, although Singh and Singh[4] regarded it as consisting of transitions from the ground state to a $^1(n, \pi^*)$ state and a $^3(n, \pi^*)$ state with the origins at 23161 and 21944 cm^{-1}, respectively.

Figure 2 shows the corrected emission spectra of MNQ vapor in the presence of benzene (≈100 Torr) at two temperatures, the vapor-phase excitation spectrum, and the absorption spectrum in isopentane solution. As is seen in Fig. 2, the intensity distribution of the emission spectrum changes with temperature in much the same way as that of NQ vapor. Band α for MNQ vapor also has a sort of mirror-image relation to the vapor-phase excitation spectrum and to the absorption in isopentane solution in the $S_0 \rightarrow S_1(n, \pi^*)$ region. The absorption spectrum of MNQ vapor in the $S_0 \rightarrow S_1$ region could not be obtained. It is assumed that the vapor-phase excitation spectrum, which resembles the absorption spectrum in isopentane, can be used as a substitute for the vapor-phase absorption spectrum. The excitation spectrum of MNQ vapor in the $S_0 \rightarrow S_2(\pi, \pi^*)$ region ($2.8—3.6 \times 10^4$ cm^{-1}) was found to agree well with the corresponding vapor-phase absorption spectrum. The emission spectra of NQ and MNQ vapors obtained in the present study are somewhat different in structure from the previous results.[2,3,5]

In the present experiment, carbon tetrachloride as well as benzene was used as a foreign gas. These compounds have the same effect on NQ and MNQ vapors with respect to the temperature dependence of the emission spectra and to the relation between excitation and absorption spectra. Both benzene and carbon tetrachloride are considered to induce collisional deactivation of excited vibronic levels of NQ and MNQ vapor. Benzene, however, has an additional effect: When NQ (or MNQ) vapor is excited in the presence of benzene at wavelengths where benzene absorbs (<260 nm), intense emission is observed. The spectrum of this emission is identical with the emission spectrum of NQ (or MNQ), but the excitation spectrum for the emission agrees with the absorption spectrum of benzene vapor. On reference to the electronic energy levels of NQ (or MNQ) and benzene, one is led to the conclusion that actually the emission in question occurs through energy transfer from benzene to NQ (or MNQ). We thus utilized benzene not only as an inert foreign gas but also as an energy donor in order to obtain strong emission from NQ (or MNQ).

Figure 3 shows the emission spectra of NQ and MNQ in rigid glass solution at 77 K. Except for the absence of band α, these spectra resemble the corresponding vapor-phase emission spectra. With NQ in the rigid glass solution, however, the second and third bands, which belong to the prominent progression in the C–O stretching vibration, do not show such doublets as observed in the case of the vapor-phase emission spectrum (bands γ_1 and γ_2, and δ_1 and δ_2 in Fig. 1).

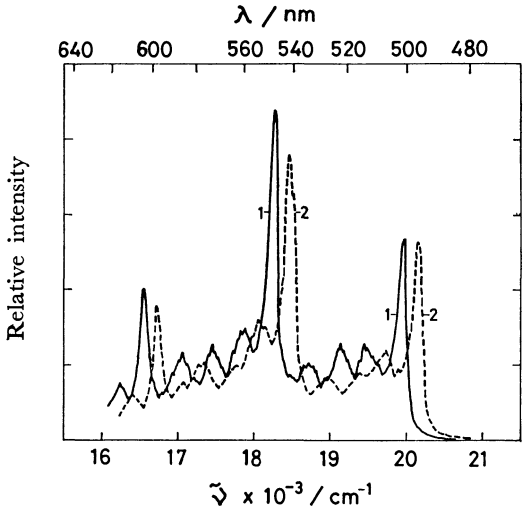

Fig. 3. Emission spectra (corrected) of 1,4-naphthoquinone (1) and 2-methyl-1,4-naphthoquinone (2) in an isopentane-methylcyclohexane (1:1) mixture at 77 K.

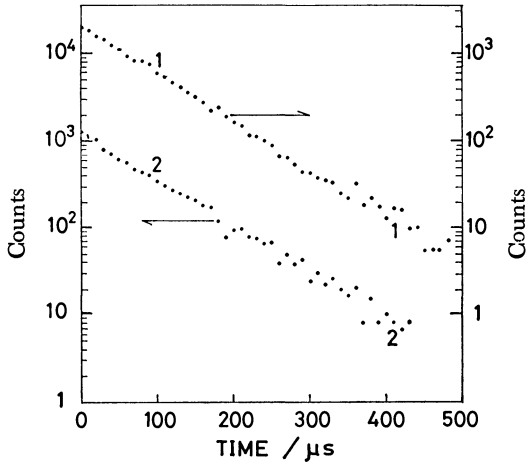

Fig. 4. Typical semilogarithmic plots of emission intensity vs. time for 1,4-naphthoquinone vapor in the presence of added CCl_4 ($\approx$100 Torr) at 80 °C: (1) monitored at band α; (2) at band β. Emission decays were obtained with a bandwidth of 20 nm for the detection monochromator.

Emission decays of NQ vapor in the presence of carbon tetrachloride ($\approx$100 Torr) are shown in Fig. 4. The lifetimes monitored at bands α, β, and γ_1 were found to be the same (84 μs) and independent of the excitation energy. The decay of the emission of MNQ vapor could not be measured because of its low quantum yield. The emission quantum yields were determined to be 1.5×10^{-2} for NQ and 9.5×10^{-4} for MNQ vapor at 80 °C in the presence of carbon tetrachloride.

Discussion

The vapor-phase emission spectra of NQ and MNQ obtained in the present study show characteristic temperature dependence; that is, the ratios of the intensity of band α to those of the other bands increase, when

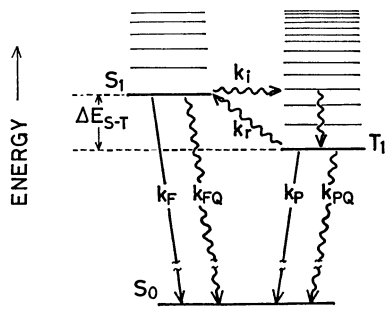

Fig. 5. Kinetic scheme and the rate constants for the radiative (→) and nonradiative (⇝) processes of naphthoquinone vapors in the presence of an added foreign gas.

the temperature is raised. We assign band α to the $S_1(n, \pi^*)\rightarrow S_0$ fluorescence and bands β, γ, and δ to the $T_1(n, \pi^*)\rightarrow S_0$ phosphorescence. This assignment is based on the mirror-image relation between vapor-phase emission and absorption spectra and on the similarity between the emission spectrum in the vapor and the phosphorescence spectrum in the rigid glass. For both NQ and MNQ vapors (Figs. 1 and 2), band β can be taken as the origin of the phosphorescence; and the peak on the higher-wavenumber side of band α is taken as the fluorescence origin, since it coincides in position with a peak that appears in the vapor-phase absorption or excitation spectrum. Thus, the origins of phosphorescence are located at 20460 and 20340 cm^{-1}, and those of fluorescence at 21830 and 21950 cm^{-1}, respectively, for NQ and MNQ vapors. The S_1-T_1 energy separations, ΔE_{S-T}, are thus found to be 1370 cm^{-1} for NQ and 1610 cm^{-1} for MNQ vapor. It then follows from Figs. 1 and 2 that the ratio of the fluorescence intensity to the phosphorescence intensity increases with temperature. In view of this observation, we assign the fluorescence of the naphthoquinone vapors to E-type delayed fluorescence.

The kinetic scheme for the electronic relaxation processes in the naphthoquinone vapors, including E-type delayed fluorescence, is illustrated in Fig. 5 together with various rate constants: k_F and k_P are the radiative rate constants, and k_{FQ} and k_{PQ} are the nonradiative rate constants, respectively, from S_1 and T_1 to the ground state, S_0; k_I represents the rate constant for the intersystem crossing; k_r is the rate constant for thermal activation to upper vibrational levels of T_1 followed by reverse intersystem crossing to S_1, and it can be written in the form[11]

$$k_r = k_r^0 \exp\left(\frac{-\Delta E_{S-T}}{kT}\right), \quad (1)$$

where k and T are the Boltzmann constant and absolute temperature, respectively, and k_r^0 represents a temperature-independent term.

According to the kinetic scheme, the ratio of the quantum yield of the delayed fluorescence, Φ_{DF}, to that of phosphorescence, Φ_P, is given by

$$\frac{\Phi_{DF}}{\Phi_P} = \frac{k_F k_r^0}{k_P(k_F+k_{FQ}+k_I)} \exp\left(\frac{-\Delta E_{S-T}}{kT}\right). \quad (2)$$

Therefore, ΔE_{S-T} can be derived from the variation

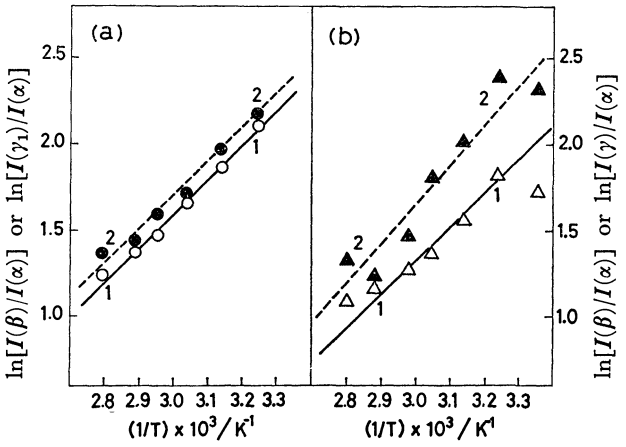

Fig. 6. Temperature dependence of ratios between band intensities for (a) 1,4-naphthoquinone and (b) 2-methyl-1,4-naphthoquinone vapors: (1) $\ln[I(\beta)/I(\alpha)]$ *vs.* $1/T$; (2) $\ln[I(\gamma_1)/I(\alpha)]$ or $\ln[I(\gamma)/I(\alpha)]$ *vs.* $1/T$. Essentially the same results were obtained by using benzene and carbon tetrachloride as foreign gases.

of Φ_{DF}/Φ_P with T. We use peak-intensity ratios instead of the quantum-yield ratios; the peak intensities of bands α, β, and γ will be denoted by $I(\alpha)$, $I(\beta)$, and $I(\gamma)$, respectively.

Figure 6 shows the plots of $\ln[I(\beta)/I(\alpha)]$ and $\ln[I(\gamma)/I(\alpha)]$ against $1/T$ for NQ and MNQ vapors. In the case of NQ, the peak intensity of band γ_1 is used instead of $I(\gamma)$. The plots give straight lines, and the values of ΔE_{S-T} calculated from the slopes are 1365 ± 60 and 1500 ± 200 cm^{-1} for NQ and MNQ vapors, respectively. These values agree well with the spectroscopically estimated gaps of 1370 cm^{-1} for NQ and 1610 cm^{-1} for MNQ, thus confirming the occurrence of E-type delayed fluorescence. Since the intensities of the emission bands other than band α change in the same way when the temperature is changed, the main emission bands located at wavenumbers lower than about 2.1×10^4 cm^{-1} can be regarded as due to a single electronic transition, $T_1\rightarrow S_0$, for both NQ and MNQ vapors.

The fact that the lifetimes of NQ vapor monitored at bands α and β are the same also supports our interpretation of the emission spectra, because according to the kinetic scheme in Fig. 5 the concentration of the S_1 molecule is to be proportional to that of the T_1 molecule. It is certain that the T_1 state is of an n, π^* type on account of its relatively short lifetime.

Our assignment for NQ vapor differs entirely from the ones presented by the previous authors. There are marked differences between the present and previous assignments also for MNQ vapor. The previous authors[5] assigned a relatively weak band of MNQ at 20262 cm^{-1} to the origin of phosphorescence and some of very strong bands at wavenumbers lower than 2.1×10^4 cm^{-1} to fluorescence. Moreover, none was pointed out as to the mechanism of the occurrence of fluorescence emission. Although our spectral measurement was performed with lower resolution, the temperature dependence of the emission spectra along with the results of the lifetime measurement indubitably indicates that the emission spectra of NQ and MNQ vapors at high total pressures consist of phosphorescence and E-type delayed fluorescence.

Competitive Redox Reactions at the ZnO Semiconductor Photoelectrode

Tooru INOUE,* Akira FUJISHIMA, and Kenichi HONDA
Department of Synthetic Chemistry, Faculty of Engineering,
The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113
(Received April 23, 1979)

The study of the photoanodic reaction at the ZnO electrode in an electrolyte solution containing redox agents was carried out by means of the rotating ring-disk electrode technique. The competition reactions between the photocorrosion of ZnO and the oxidation of reducing agents were discussed focusing on the potentials of the electroactive species at the semiconductor-solution interface. The ZnO photoelectrode was stabilized in the course of the oxidation of a strong reducing agent dissolved in a solution.

Photo-induced redox reaction at the semiconductor-liquid junction have been extensively investigated with photoelectrolytic synthesis or solar energy conversion in mind.[1-6] The most recent interest in the electrochemical photocells has been the suppression of the photocorrosion of the semiconductor electrode itself during the operation.[7] The stabilization of the photocorrosive semiconductor electrode has been much investigated from several experimental approaches[7-18] and also discussed from the point of view of thermodynamic points.[19,20] However, the charge-transfer kinetics of a photogenerated hole-electron pair is not well understood, so the investigation of photoelectrochemical competitive oxidations at the ZnO electrode by means of the rotating ring-disk electrode (RRDE) is the subject of this work.

The photoanodic reaction of the ZnO electrode in the supporting electrolyte solution is known to consist of the photocorrosion[21-23] of the electrode *per se* by photoholes (p^+):

$$ZnO + 2\,p^+ \longrightarrow Zn^{2+} + 1/2O_2 \qquad (1)$$

Though ZnO has a demerit as the photoelectrode in an electrochemical photocell because of its large bandgap (*ca.* 3.2 eV), the stabilization of ZnO under operation in a solution is necessary for it to be used as a semiconductor-solution photodiode. When we introduce a certain reducing agent into an electrolyte solution, the oxidation (2) of a reducing agent can occur in competition with Process 1:

$$\underset{\text{form}}{\text{reduced}} + n\,p^+ \longrightarrow \underset{\text{form}}{\text{oxidized}} \qquad (2)$$

By using the rotating ring-disk electrode with a semiconductor disk and a metal ring, one can instantaneously ascertain the competition efficiencies of Processes 1 and 2 under illumination by comparing the collection ring currents caused by the reduction of the oxidized products with the geometrical collection current.[10,17,22]

Experimental

The semiconductor electrode used in this experiment was sintered polycrystal ZnO which had been prepared by pressing the reagent-grade ZnO powder at 1.0 t/cm^2 and then heated at 1300 °C for 3 h in the air. The sintered polycrystal was shaped into a disk 6.0 mm in diameter and 1.0 mm in thickness. Indium–gallium alloy was painted onto one face of the polycrystal in order to insure an ohmic contact with the copper conducting wire. Then, the ZnO disk was mounted on a Teflon rod using epoxy resin, together with a Au ring 7.0 mm in inner diameter and 9.0 mm in outer diameter, thus producing a ring-disk electrode system. Sometimes a Au-ring electrode was also amalgamated. The polycrystal face of ZnO was polished with alumina powder, etched in 6 M (M=mol dm^{-3}) HCl for 10 s, and washed with water. The ring-disk electrode thus prepared was connected into an RRDE measurement system (Nikko Keisoku), which has been described elsewhere.[7,10,11,22,24] The light source was a 500 W high pressure mercury arc lamp, while the illuminating wavelengths was selected with a glass filter from 300 to 400 nm. The supporting electrolyte was 0.2 M Na_2SO_4, and all the redox agents used were reagent-grade.

Results

The curves of the ring current, I_R, *vs.* the ring potential, E_R, where the disk photocurrents are constant at the disk potential of 1.0 V *vs.* SCE, are shown in Fig. 1.

Photogenerated carriers (holes) produced by the illumination of the absorbable light, whose energy is greater than a bandgap (3.2 eV) of ZnO, are forced to the surface by the electric field in a space charge layer and then oxidize the electroactive species at the interface. The collection current at the ring electrode caused by the discharge of the oxidized product which flows from the disk electrode gives information about the photoassisted oxidation, the photocorrosion of ZnO, and the oxidation of reducing agents. Cathodic currents which appear at the Au ring electrode in the solution without reducing agents indicate the reduction of the oxygen produced by the photocorrosion process (1). In the presence of a reducing agent in an electrolyte solution, a two-step cathodic current appears at the Au ring electrode, where the first wave of the cathodic current depends on the reduction of an oxidized redox agent produced by Process 2, while the second wave depends on the reduction of the oxygen produced by Process 1. Therefore, we can calculate the competition ratios[6,24] between Processes 1 and 2 from the height of the reduction current at the Au ring electrode.

Figure 2 shows the relation curves of the competitive oxidation ratios of various reducing agents *versus* their concentrations. The competition ratio increases in general with an increase in the concentration of a redox agent, while its value is different for different kinds of reducing agents. When a redox agent is present in a high concentration (*ca.* 1.0 M) in the solution, it is nearly 100%, oxidized by photogenerated holes, while the ZnO photoelectrode is stabilized against

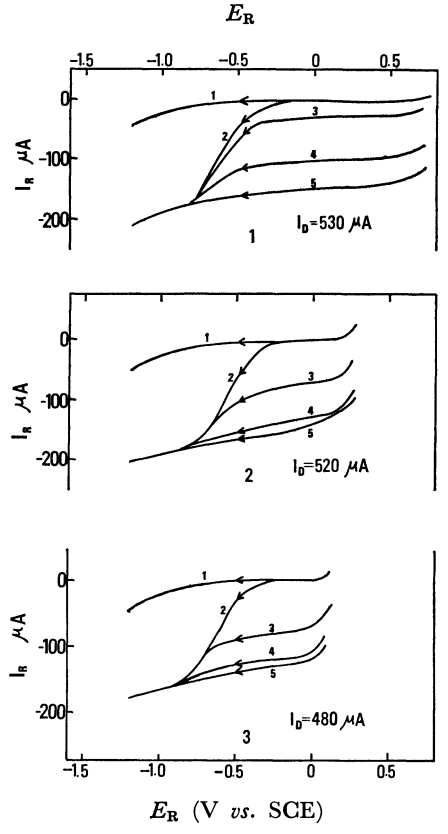

Fig. 1. Current-potential (I_R-E_R) curves at the Au ring electrode at the rotational speed of 1000 rpm with reducing agents in the electrolyte solution. Potential of the ZnO disk electrode was 1.0 V *vs.* SCE. (1) In addition of Br^-, (2) in addition of I^-, (3) in addition of $Fe(CN)_6^{4-}$: 1, in dark with and without reducing agents (red.); 2, in a supporting electrolyte solution; 3, in addition of 10^{-3} M red.; 4, in addition of 10^{-2} M red.; 5, in addition of 10^{-1} M red.; 2—5, under illumination.

the photocorrosion process (1).

Figure 3 shows the competitive oxidation ratios (stability ratios) of a variety of reducing agents (10^{-2} M) as a function of their redox potentials. The results indicate that the reducing agent with a more negative redox potential has a larger competition ratio and can better stabilize the photoelectrocorrosive ZnO electrode.[9]

Discussion

For charge transfer across the semiconductor-solution junction, the statistical equations have been established by several investigators.[26] The photocurrent at the illuminated n-type semiconductor electrode is determined by the overlap of the relative distributions of states in the valence band holes and of the reducing agents in the electrolyte solution; that is,

$$I_{ox} = k^\circ [\mathrm{Red}] \int_{-\infty}^{0} K^\circ(\mathrm{E}) D_+(\mathrm{E}) W_R(\mathrm{E}) \mathrm{d}E \qquad (3)$$

where I_{ox} is the anodic photocurrent, [Red] is the concentration of a reducing agent in a solution, $D_+(\mathrm{E})$ is the density of photogenerated holes in a semiconductor, and $W_R(\mathrm{E})$ is the distribution function of

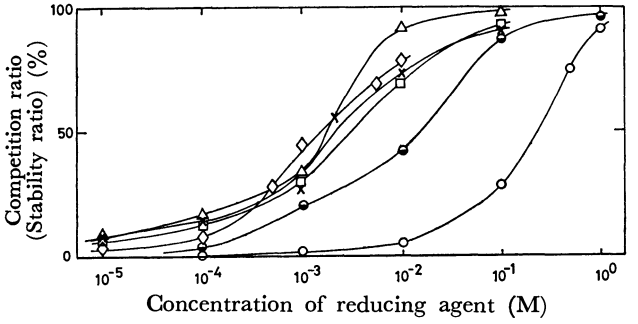

Fig. 2. Concentration dependences of competition ratios for various reducing agents.

a reducing agent. Figure 4 shows the schematic distributions between the states of the ZnO electrode and a redox agent ($Fe(CN)_6^{3-/4-}$) in the solution. The distribution functions (W_{ox}, W_{red}) of this redox couple are given by;

$$W_{red} = \exp[-\lambda(E-E^\circ_{F,el}+\lambda)^2/4kT]$$

$$W_{ox} = \exp[-(E-E^\circ_{F,el}-\lambda)^2/4kT\lambda]$$

where λ denotes a reorganization energy (*ca.* 0.75 eV[27,28]), $E^\circ_{F,el}$ denotes the Fermi level of the electrolytes, and E denotes the energy level. It can be expected from the mapping between $D_+(\mathrm{E})$ and $W_{red}(\mathrm{E})$ that it will be difficult for $Fe(CN)_6^{4-}$ to be oxidized by the photogenerated holes in the valence band, whereas $Fe(CN)_6^{3-}$ will be reduced by the electrons in the conduction band. However, $Fe(CN)_6^{4-}$ is actually oxidized well by the photogenerated holes at the ZnO photoelectrode, as is shown in Fig. 3.

Therefore, for the elucidation of the photo-hole

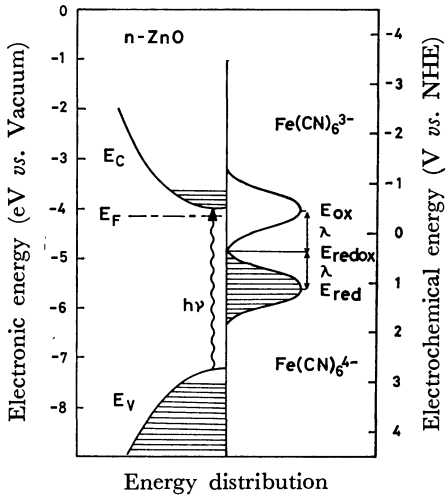

Fig. 4. Schematic illustration of the energy distributions between ZnO and a redox agent ($Fe(CN)_6^{3-/4-}$) in the solution.

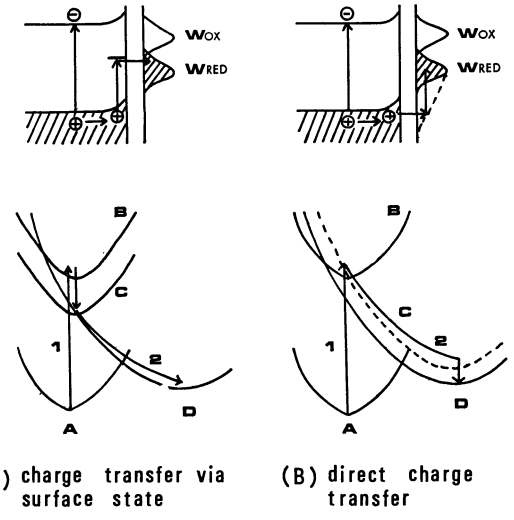

Fig. 5. Schematic explanation for charge transfer kinetics, upper illustration for hole transfer and lower one for reaction coodinations. transfer across the semiconductor-solution interface, the following two schemes are considered to be probable. One process is the charge transfer *via* surface states within a bandgap, when the overlap between distributions of surface states and of reducing species is necessary. For the explanation of this scheme, some investigators have reported that positively charged holes could transfer to reducing species *via* the surface states at the ZnO photoelectrode.[29,30] Another process is the direct transfer of a positively charged hole to the excited states of reducing species, when the distribution of reducing species becomes an unsymmetrical one. Figure 5 presents schematic representations of the above two processes. However, from this experiment it is hard to decide which process is more acceptable.

As for the stability of the photoelectrodes, the guidance has been presented from the point of view of thermodynamics[19,20] and on the basis of the experimental results,[10,31] focusing upon the redox reactivities of electroactive species at the semiconductor-solution interface. The stability of an n-type semiconductor photoelectrode in a supporting electrolyte solution is determined by the potentials of the competitive oxidations between the photocorrosion of a semiconductor and the oxidation of water, as schematically shown in Fig. 6. From this consideration, while TiO_2 is a stable photoelectrode because this oxidative decomposition potential is more positive than the oxidation potential of water, the ZnO photoelectrode becomes a stable photoanode in the course of the competitive oxidation of dissolved reducing agents whose redox potentials are more negative than the decomposing potential of ZnO.

(2) Stabilized case of an unstable photoelectrode in the course of photoelectrolytic oxidation of reducing agents.

Conclusion

Many semiconductor electrodes cause photocorrosion by means of an action of photogenerated carriers when they are illuminated in water. However, once a photocorrosive semiconductor electrode is stabilized, a new way of its use may be developed, for example, as photosensitive devices,[32] including the photoelectrode in the electrochemical photocell.

An Interpretation of the "Molecular Space" on the Basis of Quantum Chemical Calculations of Hydrated Ions

Shizuo FUJIWARA* and Bernd M. RODE**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 25, 1979)

Quantum chemical calculation has been made for the sizes of the hydration shells of the metal ions as well as for the binding energies of water molecules in the hydration shells. The results of the both calculations give the basis of the size of the molecular space.[1] Although the experimental value of the molecular space, $(20\pm 5\text{A})^3$, does not exactly agree with the calculated value, we assume that the quantum chemically obtained hydration sphere refers to the molecular space.

Several experimental results concerning aqueous solutions of salts have indicated that there exists a well defined minimal volume of solvent which is needed by each ion to maintain "regular" behavior in a thermodynamic as well as in a kinetic sense.[1,2] ESR investigations of aqueous solutions in gels allowed to determine this volume to be $(20\pm 5\text{A})^3$ for copper and some other simple organic molecules.[1] Hence this apparently essential volume was named "molecular space."[1] Within this context it is of particular interest that the concentration of salt in the sea water as well as the salt concentration in "biosolutions" as human blood serum is adjusted to an amount, which still corresponds to the maintenance of this "molecular space" for the ions.

Previous quantum chemical calculations on ions linked to linear water polymers have shown that the upper limit of ion solvent interaction corresponds to the size of the experimentally determined molecular space for a series of monovalent and divalent ions.[3] These calculations could give, however, only an estimation of upper limit of interaction range and, due to methodical simplification, not yet reflect well the situation of a fully solvated ion in solution.

Using the common *ab-initio* MO-SCF calculation method, the treatment of such large systems (an ion surrounded by several hydration layers) will lead to dimensions of the calculation, which cannot be managed so far. On the other hand, semiempirical methods are also not suitable for the correct description of such systems[4,5] and also lead to rather ambiguous results due to the neglect of most 2-electron integrals and introduction of numerous empirical parameters.

The recently developed MESQUAC (Mixed Electrostatic Quantum Chemical) MO-SCF method allows a treatment of quite large complex systems at a reasonable computational effort.[6,7] The results obtained for some hydrated ions[6] are in very satisfactory agreement with experimental values and with results obtained by *ab initio* calculations near HF-limit. It was to be expected, therefore, that this method should be the most useful way for calculating ions with several hydration layers and to obtain therby a theoretical explanation for the experimental facts concerning molecular space.

Experimental

MESQUAC Concept. The details of the method have been published already elsewhere,[6] so that at this point a very brief survey will be given. The principle of the method is a separation of the total system into an "essential" part (usually the ion +1 or several ligands) and a second part ("outer part"), including the other ligands or even some bulk solvent. The "essential part" is calculated within the framework of the all-electron *ab initio* MO-SCF method, the "outer part" introduced as electrostatic perturbation term to the Hamiltonian, constructed according to the molecular geometry of the ligands in this outer part. The electrostatic fractional charges used in building up this perturbation terms are those being obtained from previous *ab initio* calculations on smaller ion-ligand-systems, performing a MULLIKEN population analysis.[6]

The method could be shown recently to work also satisfactorily in the case of transition metal ions,[8] and even for these systems computing times are still quite short. For this reason, we have chosen the monovalent ions of Li(I), Na(I) and K(I), and the divalent ions of Mg(II), Ca(II), Mn(II) and Zn(II) for this work. Mn(II) and Zn(II) seemed to be a useful supplement to the main group metal ions, since they also possess a "symmetrical" electron configuration (d^5 and d^{10}, respectively), one being a typical open shell (high spin) system, the other one a closed shell system, but containing d electrons.

Performance of the Calculations. The Gaussian basis sets being used for ions and ligands have been given already in the references.[5,6,8] The geometries of the first hydration shells have been chosen according to experimental results of X-ray investigations of aqueous salt solutions[9,10] or to optimized MO-SCF geometries.[12,13] The geometries of the further solvation layers were constructed assuming hydrogen bonding of each water molecule to two water molecules in the next higher shell (0···0 distance 2.70 Å), in a 90° twisted configuration. For most of the ions both tetrahedral and octahedral coordinations have been considered. Some data obtained for Ti(III) aquacomplexes[8] are included for comparison of the results of this work with those of a tervalent ion.

The calculations were performed in part at the HITAC 8700/8800 computer of the University of Tokyo, in part at the CDC Cyber 174 computer of the Vienna TU computer center.

Results and Discussion

In Table 1, the binding energies per water molecule, calculated for the first, second and third hydration shells of the ions, are listed. For the discussion of

** On leave from Institut für Anorganische und Analytische Chemie Uuiversität Innsbruck, Innrain 52a, A-6020, Innsbruck, Austria.

Table 1. Calculated binding energies per water molecule of the first (E-I), second (E-II), and third (E-III) hydration shells, for tetrahedral (Td) and octahedral (Oh) coordinations, in kcal/mol

Ion	Coordination	E-I	E-II	E-III
Li(I)	Td	25.7	9.8	1.5
	Oh	22.1	9.4	1.6
Na(I)	Td	17.3	7.6	1.5
	Oh	15.4	7.6	1.5
K(I)	Td	14.7	7.2	1.5
	Oh	14.2	6.4	1.3
Mg(II)	Td	59.4	21.6	3.3
	Oh	50.5	20.9	3.2
Ca(II)	Td	47.1	19.9	3.0
	Oh	46.9	18.3	3.0
Mn(II)	Oh	73.8	22.1	5.4
Zn(II)	Oh	71.0	22.4	5.5
Ti(III)	Oh	100.0	34.5	8.8

Table 2. Calculated volumes for the hydrated ions including hydration layers, n being the number of hydration shells

Values are given in (hartree)^3.

Ion	V_1	V_2	V_3	V_4	V_5
Li(I)	457	2668	9209	24300	46870
Na(I)	681	3352	10730	27160	51271
K(I)	1051	4361	12860	31000	57160
Mg(II)	475	2668	9209	24300	46870
Ca(II)	754	3561	11182	27900	52540
Mn(II)	612	4151	10292	26340	50020
Zn(II)	537	2922	9775	25390	48550

these energy values, the hydrogen bond energy between the solvent molecules themselves (6.8 kcal/mol with the basis set used) represents a crucial limit, since stabilization and structural influence of the ion by full or partial formation of a hydration shell is not to be expected, if the energy gain by solvation does not exceed this value to some extent. The larger the difference between binding energy in the hydration layer and hydrogen bond level is, the more stable and rigid the hydration shell will be.

According to our results (Table 1), almost all ions show such a stabilization up to the second hydration shell, I(I) and Ti(III) ion being the lower and upper limit, showing possibly a somewhat different behavior (no influence on second shell for K(I), partial formation of a third shell for Ti(III)).

These results are in good agreement with some preliminary calculations one on the hydrated divalent ions Fe(II), Co(II), Ni(II), and Cu(II), which also let expect a quite strong influence on the second shell, and the other on the binding energies for the third shell below hydrogen bond level.[14]

Experimental X-ray investigations of aqueous salt solutions[9–11,15] also support our results, showing a significant structural influence of the ions up to a radius of about 5 Å around the ion, which corresponds to the distance including two hydration layers. X-Ray data have been evaluated, however, usually only for the first shell, for which the peaks are more strong and easier to analyze. The existence of the second shell (and sometimes even of a third shell) has been pointed out, however, by some of the authors.[11,15]

Discussing now the results of our calculations in connection with the concept of molecular space, another consideration will be useful and necessary, namely that of the volume occupied by an ion surrounded by 1,2,3, or more solvation layers. In Table 2, these volumes are given, as they result from the geometries being used in the MESQUAC MO calculations.

From the values for the necessary volume being assigned to an ion including 1, 2, or more solvation layers we can see that the volume corresponding to an ion with two layers —which are expected according to the calculations for most of the ions— is always smaller than 6800 hartree^3, corresponding to a sphere of 10 Å diameter. The volume needed after addition of a third shell will exceed, however, in all cases this value. It can be concluded, therefore, that the space being "structured" by the ions in aqueous solution corresponds to a sphere of about 10 Å in diameter.

Summarizing the results of the calculations presented here, we believe that they seem to give a reasonable theoretical foundation for the experimentally observed size of the molecular space. They are expected also to be a useful basis for further investigations of aqueous and nonaqueous electrolyte solutions by means of the calculation method being employed.

Photoelectron Spectra of Hydrogen-bonded Complexes

Chikatoshi UTSUNOMIYA, Tsunetoshi KOBAYASHI,† and Saburo NAGAKURA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

†*The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received April 26, 1979)

The photoelectron spectra of typical hydrogen-bonded complexes, CF_3COOH–$(C_2H_5)_2NCH_3$, CF_3COOH–$(n\text{-}C_3H_7)_3N$, CF_3CF_2COOH–$(C_2H_5)_2NCH_3$, and CF_3CF_2COOH–$(n\text{-}C_3H_7)_3N$ were observed in the gas phase. It was found that the nonbonding orbital of the proton acceptor is stabilized significantly by hydrogen-bond formation while the three higher occupied orbitals of the proton donor are destabilized. The large orbital energy changes due to hydrogen-bond formation strongly support the charge-transfer model for the hydrogen bond.

Photoelectron spectroscopy is expected to give effective informations concerning the electronic structure of hydrogen-bonded systems and also concerning the nature of hydrogen bond. This is because the photoelectron spectrum of the hydrogen-bonded complex gives the orbital energy shifts due to hydrogen-bond formation within the limitation of Koopmans' theorem.

In a previous paper,[1] we reported the photoelectron spectra of some electron donor-acceptor complexes in the gas phase, and found that this technique was quite effective for the study of the intermolecular interaction. In this paper, in order to clarify the nature of hydrogen bond, we have studied the He I photoelectron spectra of hydrogen-bonded complexes between carboxylic acids as proton donors and alkylamines as proton acceptors in the gas phase. In actuality, *N,N*-diethylmethylamine and tripropylamine are taken as proton acceptors, and trifluoroacetic acid and pentafluoropropionic acid as proton donors.

Experimental

N,N-Diethylmethylamine (DEMA) and tripropylamine (TPA) were purified by distillation. Commercially available trifluoroacetic acid (TFAA) and pentafluoropropionic acid (PFPA) were used without further purification. Purity of the amines and the carboxylic acids was checked by NMR spectroscopy. An aliphatic amine and a carboxylic acid were introduced through needle valves into a 5-liter gas reservoir and were mixed with each other. The nonexistence of chemical products except for hydrogen-bonded complexes in the mixtures was checked by NMR spectroscopy for the liquid phase. The mixed gas was introduced into the ionization chamber of a photoelectron spectrometer, the details of which were described in a previous paper.[2] The photoelectron spectra of the hydrogen-bonded complexes and their component molecules were measured at room temperature, the He I resonance line being used as the excitation source. At the initial stage of the measurement of the mixed gases, the bands of the free amines added in slight excess appear strongly in addition to those of the hydrogen-bonded complexes. The bands of the free amines, however, rapidly decreased in intensity, and the spectra turned out to be composed almost completely of the bands of the hydrogen-bonded complexes.

Results and Discussion

The photoelectron spectra of hydrogen-bonded systems such as TFAA–DEMA, PFPA–DEMA, TFAA–TPA, and PFPA–TPA are shown in Fig. 1, together with those of component molecules. The measurements were performed with very high sensitivity for the hydrogen-bonded complexes because of their low vapour pressure. This is the reason why the signal of only a trace of water appears in the spectra of the complexes. The vertical ionization potentials (I_v) of the hydrogen-bonded complexes and the component molecules are summarized in Table 1.

Thomas[3] has assigned the first band of TFAA to the nonbonding (n) orbital mainly localized on the oxygen atom of the carbonyl group, the second band to a π orbital, and the third band to a σ orbital which is denoted by n′ hereafter. The shapes of the higher occupied molecular orbitals of TFAA obtained by the CNDO/2 calculation are schematically shown in Fig.

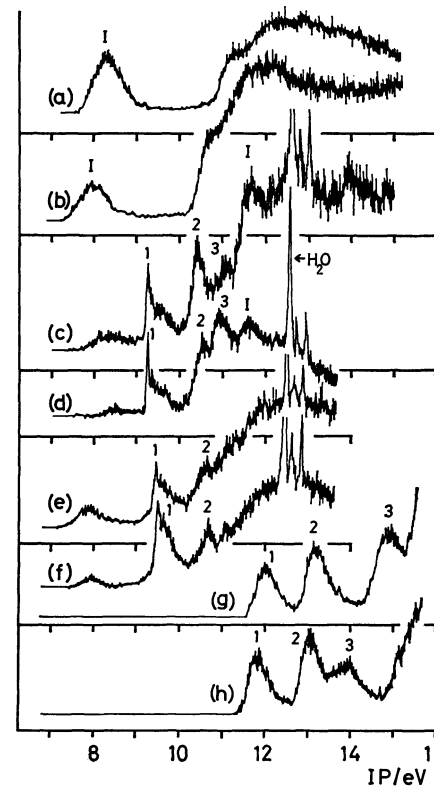

Fig. 1. Photoelectron spectra of hydrogen-bonded complexes and their component molecules: curve (a), DEMA; curve (b), TPA; curve (c), TFAA–DEMA complex; curve (d), PFPA–DEMA complex; curve (e), TFAA–TPA complex; curve (f), PFPA–TPA complex; curve (g), TFAA; curve (h), PFPA.

Table 1. Vertical ionization potentials, $I_v(J)$, of hydrogen-bonded complexes and their component molecules

Species	$I_v(J)$/eV			
J[a)]	1	2	3	I
TFAA	12.00	13.16	14.83	
PFPA	11.94	13.09	14.04	
DEMA				8.32
TPA				7.94
TFAA-DEMA	9.26	10.41	11.23	11.64
PFPA-DEMA	9.24	10.38	10.94	11.63
TFAA-TPA	9.53	10.71		
PFPA-TPA	9.49	10.67		

a) J shows the numbering of the photoelectron spectral band given in Fig. 1 from which the vertical ionization potential in this table was obtained.

Table 2. Photoelectron spectral band shifts, $\Delta I_v(J)$, due to hydrogen-bond formation

Species	$\Delta I_v(J)$/eV			
	Carboxylic acid			Amine
J[a)]	1(n)	2(π)	3(n′)	I(n)
TFAA-DEMA	−2.74	−2.75	−3.60	3.32
PFPA-DEMA	−2.70	−2.71	−3.10	3.31
TFAA-TPA	−2.47	−2.45		
PFPA-TPA	−2.45	−2.42		

a) See the footnote a) for Table 1.

2. The ordering of the first three bands of PFPA may safely be regarded to be the same as in the case of TFAA judging from the band shapes and positions. The first band of the alkylamine is assigned to the nonbonding orbital localized on the nitrogen atom.

Let us turn to amine–carboxylic acid systems. As is seen in Fig. 1 which shows the photoelectron spectra of the TFAA–DEMA, PFPA–DEMA, TFAA–TPA, and PFPA–TPA systems, each of the amine–carboxylic acid systems has several bands pertinent to the corresponding hydrogen-bonded complex, in addition to the band around 8 eV due to the corresponding free amine added in excess. The bands due to the complex are numbered as shown in Fig. 1. The energy separation between bands 1 and 2 of the hydrogen-bonded complex is nearly equal to that of the free carboxylic acid. This means that bands 1 and 2 of the hydrogen-bonded complex correspond to bands 1 and 2 of the carboxylic acid, respectively. The CNDO/2 calculations made for the TFAA–DEMA system taken as an example show that the energy separation is almost unaffected by hydrogen-bond formation (1.51 eV for the free acid; 1.49 eV for the weak complex with the N–H distance of 1.6 Å; 1.42 eV for the strong complex with the distance of 1.2 Å). This is consistent with the present assignment. According to this assignment, the shifts of bands 1 and 2 due to hydrogen-bond formation amount to 2.70—2.75 eV for the systems containing DEMA and to 2.42—2.47 eV for the systems containing TPA (see Table 2).

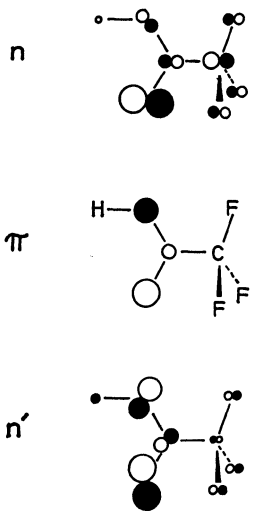

Fig. 2. Schematic representation of the higher occupied molecular orbitals of trifluoroacetic acid.

Another possible assignment of bands 1 and 2 of the hydrogen-bonded complexes is to assign one of them to the n orbital of the amine and the other band to the n orbital of the carboxylic acid. This assignment, however, may lead to unreasonable band shifts. Let us consider, as an example, the case in which bands 1 and 2 are assigned to the n orbitals of the amine and the carboxylic acid, respectively. The shift of the amine band due to complex formation with TFAA is 0.94 eV for DEMA and 1.59 eV for TPA. This apparently indicates that TPA is stronger as proton acceptor than DEMA. On the other hand, the shift of the carboxylic acid band due to complex formation with the amine is 1.59 eV for DEMA and 1.29 eV for TPA. This seems to show that TPA is weaker as proton acceptor than DEMA. From the above consideration, the assignment of either of bands 1 and 2 to the n orbital of the amine is unacceptable.

Judging from the orbital shape of the carboxylic acid shown in Fig. 2, the shift due to hydrogen-bond formation is larger for band 3 (n′ band) than for band 1 (n band). Therefore, it is expected that band 3 of PFPA at 14.04 eV appears below 11.34 eV for the PFPA–DEMA hydrogen-bonded system. Thus, the third and fourth bands of the system are assigned to the shifted bands of the third band of PFPA and of band I of DEMA, respectively. From an analogy with the PFPA–DEMA system, the third and fourth bands of the TFAA–DEMA system are tentatively correlated with band 3 of TFAA and band I of DEMA, respectively. In the TFAA–TPA and PFPA–TPA complexes, bands 3 and I are covered with a background band and their exact positions can not be decided.

The band shifts due to hydrogen-bond formation are summarized in Table 2. We can see that the n bands of the proton acceptors (amines) shift towards the higher-IP region by hydrogen-bond formation while the n bands, π bands, and n′ bands of the proton donors (carboxylic acids) shift towards the lower-IP region. These tendencies can well be explained by the contribution of the dative structure (–COO⁻···

H–$N^{+}\leftarrow$) as is expected from the charge-transfer mechanism[4] of hydrogen-bond formation. The large energy shifts of the bands of the component molecules due to hydrogen-bond formation indicate that the contribution of the dative structure to these hydrogen-bonded complexes is quite significant.

The n, π, and n′ bands of the proton donor and the n band of the proton acceptor shift a little more in the system containing TFAA as the proton donor than in the system containing PFPA. This suggests that TFAA is slightly stronger as the proton donor than PFPA. Concerning proton acceptors, the band shift due to hydrogen-bond formation is less in the system containing TPA. This is reverse to the order of the proton-accepting ability expected from their ionization potentials. This contradiction may be explained in terms of the steric hindrance effect.

Vibrational Distribution of $CS(X^1\Sigma^+)$ Fragments Formed in the UV Flash Photolysis of CS_2

Takayuki EBATA, Masahiro KAWASAKI†, Kin-ichi OBI, and Ikuzo TANAKA*

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received April 26, 1979)

The vibrational distribution of the CS(X) fragment has been studied by the UV flash photolysis and kinetic spectroscopic technique. The CS fragment was generated by the flash photolysis of CS_2 at $\approx$200 nm. The vibrational distribution is well represented by a sum of two modified Poisson distributions with different mean values. This distribution is explained by assuming the following two photodissociation processes of CS_2; one is a predissociation through a triplet state and the other is a direct photodissociation.

$$CS_2 + h\nu \begin{cases} \rightarrow CS_2(\tilde{A}^1B_2) \rightarrow CS_2(T) \rightarrow CS(X^1\Sigma^+, v'') + S(^3P), \\ \rightarrow CS(X^1\Sigma^+, v'') + S(^1D). \end{cases}$$

The photodissociation dynamics of triatomic molecules has been of theoretical interest and simple models for the vibrational distribution have been developed.[1] The vibrational distribution of CS fragments in the photodissociation of CS_2 is a good test for these models. Early works[2–4] reported that the vibrationally excited $CS(X^1\Sigma^+)$ radicals are formed in the flash photolysis of CS_2. Lee and Judge[5] pointed out that the vibrational population of $CS(A^1\Pi)$ produced in the vacuum-UV photolysis of CS_2 is approximately represented by a modified Poisson distribution. Bersohn and co-laborators[6] measured the translational energy distribution of photofragments, CS and S, by photodissociating a CS_2 molecular beam with a pulsed ArF excimer laser at 193 nm. They observed that the translational energy distribution can be represented by a sum of two distributions.

In this study, using the flash photolysis and kinetic spectroscopic technique, the vibrational distribution of $CS(X^1\Sigma^+)$ has been determined in the photolysis of CS_2 at quartz UV region.

Experimental

The set-up of quartz UV flash photolysis and kinetic spectroscopic system has been described previously.[7] In brief, the mixture of CS_2 (0.2 Torr) and Ar (5.0—200 Torr) was flash-photolyzed in a quartz cell which contained a multiple reflection mirror system. The 1000 J photolysis and 50 J spectroscopic flash lamps gave 8 and 5 μs light pulses, respectively. The absorption spectra of CS were photographed with a Nikon G-500 spectrograph on Kodak 2475 recording films in the wavelength range between 255 and 275 nm. We assumed that in this wavelength range the spectral sensitivity of the film was constant. The absorption intensity of each vibrational band at "no delay" was obtained by extrapolating the decay curve to $t=0$.

CS_2 (Wako Chemical) was degassed under vacuum and Ar (Takachiho Chemical Ind., 99.99%) was used without further purification. The mixture was left in a 20-l glass bulb for 4 h before photolysis. Under our experimental conditions, the absorption spectrum of CS ($A^1\Pi$, $v'=0 \leftarrow X^1\Sigma^+$, $v''=0$) could be observed even a few minutes after one flashing because of its stability. Therefore after each flashing, the mixture was pumped out.

Results and Discussion

Vibrational Distribution of the $CS(X^1\Sigma^+)$ Photofragment. Figure 1 shows relative excited population density which is determined by folding the lamp spectral irradiance into the absorption spectrum of the CS_2 molecule. The population density is centered at $\approx$200 nm. The FWHM is $\approx$1700 cm^{-1} which corresponds to less than two vibrational quanta of CS $(X^1\Sigma^+)$.

The absorption spectra of the $CS(X^1\Sigma^+)$ fragment formed in the photodissociation of CS_2 by quartz flash lamp were observed up to five vibrational quanta. The pressure effect of Ar buffer gas was not observed under our experimental conditions. In order to obtain the vibrational population of $CS(X^1\Sigma^+)$ at $t=0$, the optical density of each vibrational band is plotted against delay time as shown in Fig. 2, where $OD_t(0, 0)$ is normalized to unity. The plots show good linear relations between $\log[OD_t(v', v'')/OD_t(0, 0)]$ and delay time. Using the extrapolated values of the optical

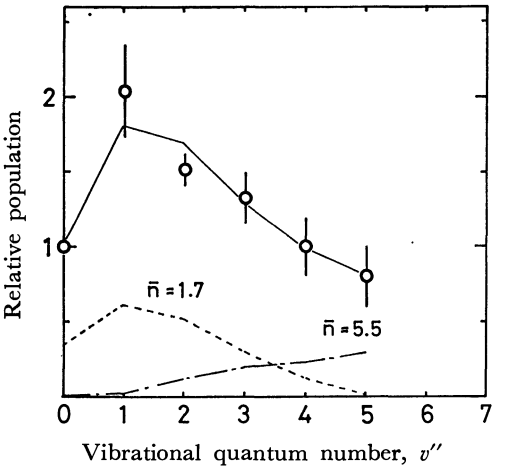

Fig. 3. The vibrational population of the $CS(X^1\Sigma^+)$ state formed in photodissociation. The solid line shows the best fit curve obtained by summing up the two distributions. See text.

density at $t=0$, the vibrational population $N_{v''}$ is obtained by,

$$\frac{N_{v''}}{N_0}=\frac{OD_0(v', v'')}{OD_0(0, 0)}\frac{q_{00}}{q_{v'v''}}\frac{R_e^2(\bar{r}_{00})}{R_e^2(\bar{r}_{v'v''})} \quad \text{(I)}$$

where $q_{v'v''}$ is the Franck-Condon factor of CS(A-X) and R_e is the electronic transition moment which is given by $R_e(\bar{r}_{v'v''})=c(1-0.39\bar{r}_{v'v''})$ with the r-centroid in Ångstrom units. In order to evaluate the ratio $N_{v''}/N_0$, we used the Franck-Condon factors which were calculated by Coxon *et al.*[8] with the RKR potential and obtained experimentally by Lee and Judge[5] with correction for the change of the electronic transition moment (Table 1). The averaged values of $N_{v''}/N_0$ against vibrational quantum numbers are plotted in Fig. 3. A population inversion between $v''=0$ and 1 levels is evident. The FWHM is approximately four vibrational quanta which is wider than that of the population density of the parent molecule of Fig. 1, indicating vibrational excitation of CS in photodissociation processes.

The vibrational excitation of the CS fragment is explained both in terms of the comparison of the CS internuclear distance of CS_2* with that of the electronically ground state of CS radical and in terms of the dynamical energy transfer during photodissociation.[9] If we assume that both the vibrational levels $i=0$ and 1, are *initially* populated and the energy transferred by dynamical interaction is the same for two vibrational states, the population in the vibrational level v'' is given by "modified Poisson distribution" in the impulsive half-collision model[1]

$$N_{v''}=(\bar{n})^{v''}\frac{(\bar{n})^2+(\alpha-2v'')\bar{n}+v''^2}{v''![(\bar{n})^2+(\alpha-2)\bar{n}+1]}\exp(-\bar{n}) \quad \text{(II)}$$

where α is the ratio of the population in the $i=0$ state to that in the $i=1$ state, and $\bar{n}$ is the averaged vibrational state.[5] Assuming two photodissociation processes, *i.e.*, two vibrational distributions, the result of the best fit to the observed populations using Eq. II is shown in Fig. 3. The best fit curve was obtained by summing up two distributions of the ($\bar{n}$, α) values of (1.7, ∞) and (5.5, 19.0) almost equally weighted. The former means that CS fragments are not *initially* vibrationally excited, while the latter indicates the *initial* vibrational excitation of the CS photofragments.

Photodissociation Processes. The vibrationally hot CS fragments may be directly produced by the photolysis of CS_2. Since the absorption of light is centered at ≈200 nm in this experiment, photolysis occurs with sufficient energy to leave an excess of ≈40 kcal/mol after production of electronically ground state fragments. In the photolysis of the CS_2 molecular beam

at 193 nm,[6] the translational energy distribution of the fragments consists of two distributions; one peaks sharply at ≈8 kcal/mol and the other extends broadly with its peak at ≈15 kcal/mol. From both these data and ours, it is expected that there are two photodissociation processes of CS_2 at ≈200 nm and that the CS fragment is vibrationally and/or rotationally excited.

The absorption spectrum of gaseous CS_2 around at 200 nm consists of a single progression of bands superimposed on the continuum. The variation of the contours of the bands may result from varying degrees of predissociation.[10] The maximum quantum yield of $\approx 10^{-3}$ has been reported for the fluorescence of CS_2 and it is concluded that the main fate of CS_2^* is photodissociation.[11]

The following two processes are energetically possible in the photolysis at ≈200 nm,

$$CS_2 \begin{cases} \rightarrow CS(X^1\Sigma^+) + S(^3P), & \Delta H_0^\circ = 102.9 \text{ kcal/mol} \quad (1) \\ \rightarrow CS(X^1\Sigma^+) + S(^1D). & 129.3 \quad (2) \end{cases}$$

Concerning the photodissociation process (1) which is spin-forbidden, it is postulated that CS_2 is decomposed through a triplet excited state[4]

$$CS_2 + h\nu \rightarrow CS_2(\tilde{A}^1B_2) \rightarrow CS_2(T) \rightarrow CS(X^1\Sigma^+) + S(^3P). \quad (1a)$$

The CS_2 absorption band near 200 nm has been assigned to the transition to the $\tilde{A}^1B_2$ state[10] which is nonlinear with a C–S bond distance of $r_e = 1.66$ Å. Once this singlet state crosses over to the repulsive triplet state, CS_2 will simultaneously decompose to the fragments. If this is the case, the CS fragment is vibrationally excited before photodissociation because the CS equilibrium bond distance of the excited $CS_2(\tilde{A}^1B_2)$ is longer than that of $CS(X^1\Sigma^+)$ by 0.13 Å. Furthermore, during dissociation the fragment is vibrationally excited by the actual repulsive force, *i.e.*, dynamical excitation. Because the $\tilde{A}^1B_2$ state has the S–C–S angle of 153°, the CS fragments are thought to be rotationally excited. The spectator model predicts that the rotational energy will be one fourth of the vibrational energy.[12]

Concerning the photodissociation process (2), Donovan *et al.*[13] reported the preliminary results which showed the yields of $S(^1D_2)$ in the photolysis of CS_2 at 200 nm. As the process (2) is thought to be the direct photodissociation, the singlet excited state must have very short lifetime in which the linear structure of the ground state of $CS_2(\tilde{X}^1\Sigma^+)$ is retained during the decomposition. Although no rotational excitation is possible in this case, $\bar{n}$ is smaller because available energy for the process (2) is smaller than that for (1) by 26.4 kcal/mol.[14] Because the CS bond distance (1.55 Å) of $CS_2(\tilde{X})$ is almost same as that of CS(X) (1.53 Å), the value of α in Eq. II is expected to be infinite, *i.e.* only $i=0$ is *initially* populated. From the above discussion it is concluded that the vibrational distribution with the lower vibrational quanta $(\bar{n}, \alpha) = (1.7, \infty)$ corresponds to the process (2), while that with $(\bar{n}, \alpha) = (5.5, 19.0)$ corresponds to the process (1) because of the *initial* excitation of the CS fragment.

Proton Magnetic Relaxation Study of Oxalic Acid Dihydrate

Takehiko CHIBA

Department of Chemistry, Nihon University, Sakurajosui, Setagaya-ku, Tokyo 156

(Received May 26, 1979)

Proton magnetic relaxation times T_1, $T_{1\rho}$, and T_{1D} were measured on a single crystal of α-form oxalic acid dihydrate in two modes: temperature dependence at one or two specific crystal orientations, and angular dependence at several temperatures. Results were compared with the calculation based on an isolated three proton system for the assumed modes of motions. The temperature dependence of T_1 and that of $T_{1\rho}$ and T_{1D} in the low temperature range are reasonably accounted for by the 180°-flip of the water molecule. The activation energy for the motion of 43.6 kJ mol^{-1} is obtained. $T_{1\rho}$ and T_{1D} above about 35 °C decreased as the temperature was raised. The comparison of the observed results in this temperature range with the calculated ones suggests that there is exchange motion among the three spins. An activation energy for this motion of 80.8 kJ mol^{-1} is obtained. This three spin exchange motion may be considered as a combination of a jump of carboxyl proton to a higher potential trough corresponding to the ionic configuration and the three-fold reorientation of the hydronium ion thus formed.

Because nuclear magnetic relaxation in a low field can be very effectively caused by a slow nuclear motion, measurement of $T_{1\rho}$ is an important means to study such motion. In the course of $T_{1\rho}$ and T_{1D} measurements on powdered samples of oxalic acid dihydrate, we found a decrease in these relaxation times with temperature which cannot be accounted for by the familiar 180°-flip of the water molecule of hydration. Our primary purpose in this paper is to elucidate the motion responsible for the above finding from the relaxation time study on single crystals.

We will describe first the calculation of relaxation times for assumed modes of motion, then experimental procedures, results of temperature and magnetic-field-direction dependence of relaxation times, and comparison of these results with the calculated values.

Calculation of the Relaxation Rates

The crystal of α-form oxalic acid dihydrate is monoclinic, and its structure is accurately known.[1] Hydrogen atoms in this crystal are incorporated in a hydrogen bond network, as shown in Fig. 1. For simplicity, calculations of relaxation rates are made for an isolated three spin system of H_1, H_2, and H_3. The atomic positions obtained from neutron diffraction studies are used.[2] For proton resonance, an isolated three spin system may be a reasonable approximation, because inter-proton distances within the three spin group are 2.05, 2.12, and 1.53 Å, while those between the adjacent groups are 3 Å or greater, except the $H_3\cdots H_3'$ value of 2.78 Å.

Calculation of Relaxation Rates due to 180°-Flip of Water Molecule. Relaxation Rate in the Laboratory Frame: Along the line of Look and Lowe's standard treatment,[3] the relaxation rate T_1^{-1} due to random modulation of the dipole interaction between the carboxyl proton and two protons of a water molecule executing 180°-flip motion with a probability w_I can easily be calculated as

$$T_1^{-1} = \frac{3}{4}\gamma^4\hbar^2\left\{\frac{\tau_I}{1+\omega_0^2\tau_I^2}[|\chi_{12}^{(1)}|^2+|\chi_{13}^{(1)}|^2 - 2\mathrm{Re}(\chi_{12}^{(1)*}\chi_{13}^{(1)})]+\frac{\tau_I}{1+4\omega_0^2\tau_I^2}\times[|\chi_{12}^{(2)}|^2+|\chi_{13}^{(2)}|^2-2\mathrm{Re}(\chi_{12}^{(2)*}\chi_{13}^{(2)})]\right\} \quad (1)$$

where $\tau_I=1/2w_I$ defines the correlation time of the motion. χ's are given by

$$\left.\begin{aligned}\chi_{\alpha\beta}^{(1)} &= r_{\alpha\beta}^{-3}\sin\theta_{\alpha\beta}\cos\theta_{\alpha\beta}\exp(-i\varphi_{\alpha\beta}),\\ \chi_{\alpha\beta}^{(2)} &= r_{\alpha\beta}^{-3}\sin^2\theta_{\alpha\beta}\exp(-2i\varphi_{\alpha\beta}),\end{aligned}\right\} \quad (2)$$

where $r_{\alpha\beta}$, $\theta_{\alpha\beta}$, and $\varphi_{\alpha\beta}$ are the polar coordinates of a vector joining site α to site β in the coordinate system with its polar axis along the static field H_0, site 1 for carboxyl proton, sites 2 and 3 for those of a water molecule. ω_0 is the Larmor angular frequency and other symbols have their usual meanings.

Relaxation Rate in the Rotating Frame: In a same manner $T_{1\rho}^{-1}$ can be calculated for the present case.[3] Since $T_{1\rho}\ll T_1$ in the present experiment, we retain only the dominant terms in the expression of $T_{1\rho}^{-1}$ involving ω_1 and neglect those terms involving ω_0 and $2\omega_0$, where $\omega_1=\gamma H_1$. $T_{1\rho}^{-1}$ is then given by

$$T_{1\rho}^{-1} = 3\gamma^4\hbar^2\frac{\tau_I}{1+4\omega_1^2\tau_I^2}d_0^2, \quad (3)$$

where

$$d_0 = \frac{1}{4}(\chi_{12}^{(0)}-\chi_{13}^{(0)}), \quad (4)$$

with

$$\chi_{\alpha\beta}^{(0)} = r_{\alpha\beta}^{-3}(1-3\cos^2\theta_{\alpha\beta}). \quad (5)$$

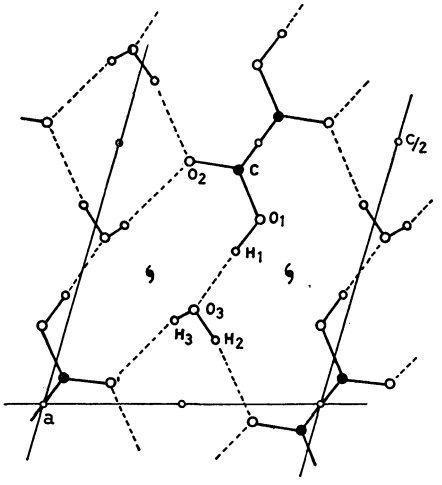

Fig. 1. Crystal structure of α-oxalic acid dihydrate: b axis projection.

When $\omega_1\tau_1 \ll 1$, we have

$$T_{1\rho}^{-1} = 3\gamma^4\hbar^2\tau_I d_0^2. \tag{6}$$

Relaxation Rate in the Dipole Field in the Rotating Frame: Because under the conditions of the present measurement of T_{1D}, τ_I is always much smaller than the Larmor period in the local field, we only consider the case of the short correlation time limit. We start from the general perturbation equation of relaxation rate[4] in which the dipole Hamiltonian in the rotating frame is divided into two parts: $\mathcal{H}_{d_0}$, the motion averaged part, and $\mathcal{H}_{d_1}$, the time-varying part (perturbation term).

$$T_{1D}^{-1} = -[2\hbar^2\mathrm{Tr}\{(\mathcal{H}_{d_0})^2\}]^{-1} \times \int_{-\infty}^{+\infty} d\tau \mathrm{Tr}\{\langle[\mathcal{H}_{d_1}^*(\tau), \mathcal{H}_{d_0}] \times [\mathcal{H}_{d_1}^*(0), \mathcal{H}_{d_0}]\rangle\}, \tag{7}$$

where

$$\mathcal{H}_{d_0} = a_0(D_{IJ}+D_{IK}) + b_0 D_{JK}, \tag{8}$$

$$\mathcal{H}_{d_1} = d(t)(D_{IJ}-D_{IK}), \tag{9}$$

$$\mathcal{H}_{d_1}^*(t) = \exp\left(-i\frac{\mathcal{H}_{d_0}}{\hbar}t\right)\mathcal{H}_{d_1}(t)\exp\left(i\frac{\mathcal{H}_{d_0}}{\hbar}t\right), \tag{10}$$

and

$$\left.\begin{aligned} a_0 &= \frac{1}{4}(\chi_{12}^{(0)}+\chi_{13}^{(0)}), \\ b_0 &= \frac{1}{2}\chi_{23}^{(0)}. \end{aligned}\right\} \tag{11}$$

D_{IJ} *etc.* are of the form,

$$D_{IJ} = \gamma^2\hbar^2(3I_Z J_Z - \boldsymbol{I}\cdot\boldsymbol{J}). \tag{12}$$

I is a spin at site 1, J and K are those flipping between sites 2 and 3, and

$d(t)=d_0$ if J spin is in site 2 at time t,
$=-d_0$ if J spin is in site 3 at time t.

In the short correlation time limit it is permissible to replace $\exp\left(i\frac{\mathcal{H}_{d_0}}{\hbar}t\right)$ in Eq. 10 by 1. We then have

$$T_{1D}^{-1} = -[2\hbar^2\mathrm{Tr}\{(\mathcal{H}_{d_0})\}^2]^{-1}\mathrm{Tr}\{[(D_{IJ}-D_{IK}), \mathcal{H}_{d_0}]^2\} \times \int_{-\infty}^{+\infty}\langle d(\tau)d(0)\rangle dt. \tag{13}$$

The integral gives $2\tau_I d_0^2$. Traces in Eq. 13 are evaluated straightforwardly, leading to the final expression

$$T_{1D}^{-1} = \frac{3}{2}\gamma^4\hbar^2\tau_I d_0^2, \tag{14}$$

which is 1/2 the $T_{1\rho}^{-1}$ of Eq. 6.

It is noted here that when $\mathcal{H}_{d_0}+\mathcal{H}_Z$ is used instead of $\mathcal{H}_{d_0}$ in Eq. 7, where $\mathcal{H}_Z = -\gamma\hbar H_1(I_x+J_x+K_x)$ is the effective Zeeman Hamiltonian in the rotating frame, a straightforward calculation similar to the above yields

$$T_{1\rho}^{-1} = \frac{3}{2}\gamma^4\hbar^2\tau_I d_0^2(H_L^2+2H_1^2)/(H_L^2+H_1^2), \tag{15}$$

where the local field in the rotating frame H_L is by definition

$$H_L^2 = [3/N\gamma^2\hbar^2 I(I+1)(2I+1)^N]\mathrm{Tr}\{(\mathcal{H}_{d_0})^2\},$$

and expressed in this case as

$$H_L^2 = \frac{1}{2}\gamma^2\hbar^2(2a_0^2+b_0^2). \tag{16}$$

Equations 6 and 14 are the two limiting cases of Eq. 15 for $H_L \ll H_1$ and $H_1 \to 0$, respectively.

Relaxation due to Slow Motional Processes. Relaxation Rate in the Rotating Frame due to Exchange between Carboxyl and Water Protons, or a Three-fold Reorientation: In the present work, in the temperature range where relaxation effects of slow motion appear, we consider the situation where exchange between H_1 and H_2 or H_3 occurs. This may be viewed as a slow three-fold reorientation in addition to the rapid flip motion of the water molecule. We will discuss the actual mode of motion later.

We assume that exchange occurs among the spin arrangements i, ii, and iii with a probability w_{II}.

	site 1	sites 2 and 3
i	I	J, K
ii	J	K, I
iii	K	I, J

Look and Lowe's treatment[3] is again followed and $T_{1\rho}^{-1}$ is expressed by

$$T_{1\rho}^{-1} = \frac{2}{3}\gamma^4\hbar^2(a_0-b_0)^2\frac{\tau_{II}}{1+(4\omega_1\tau_{II}/3)^2}, \tag{17}$$

or

$$T_{1\rho}^{-1} = \frac{3}{8}\gamma^4\hbar^2\frac{(a_0-b_0)^2}{\omega_1^2}\cdot\frac{1}{\tau_{II}} \tag{18}$$

in the limit of slow motion ($\omega_1\tau_{II} \gg 1$). Here we take the correlation time of the exchange motion as $\tau_{II} = 1/w_{II}$.

When $T_{1\rho}^{-1}$ of Eq. 18 is compared with T_{1D}^{-1} of Eq. 24 to be given in the next section, we have

$$T_{1\rho}^{-1}/T_{1D}^{-1} = \frac{3}{4}H_L^2/H_1^2. \tag{19}$$

According to Slichter and Ailion,[5] for the relaxation by slow motion

$$T_{1\rho}^{-1}/T_{1D}^{-1} = H_L^2/(H_1^2+H_L^2), \tag{20}$$

when H_1 is comparable to or less than H_L, and

$$T_{1\rho}^{-1}/T_{1D}^{-1} = \frac{3}{4}H_L^2\Big/\left(H_1^2+\frac{3}{4}H_L^2\right), \tag{21}$$

when H_1 is sufficiently greater than H_L so that cross-relaxation between the Zeeman and the secular part of the dipole energy in the rotating frame can be neglected. In the present experiment the largest H_L amounts to $\approx$3.7 G, while the H_1 used is 6.2 G. Rigorously, $T_{1\rho}^{-1}$ of Eq. 18 needs adjustment for H_L due to the relation given by Eq. 20 or 21. These correction factors, however, turn out to be small (estimated to be not more than 20% in the worst case) and are therefore neglected.

Relaxation Rate in the Dipole Field in the Rotating Frame due to Slow Exchange between the Carboxyl and Water Protons: T_{1D}^{-1} in the present case can be given by[5]

$$T_{1D}^{-1} = (1-p)\frac{1}{\tau_{II}}, \tag{22}$$

with

$$(1-p) = \sum_{q,s} A_q(A_q-A_s)/\sum_{q,s} A_q^2, \tag{23}$$

where A's are the lattice part of the dipole interaction (a_0 between sites 1 and 2 or 3, and b_0 between sites

2 and 3), q denotes a spin pair before the reorientational jump and s denotes that after the jump, and the summation is carried out over all possible processes and possible spin pairs. For each jump from one of the arrangements, i, ii, and iii, to another the numerator of Eq. 23 will be given by $(a_0—b_0)^2$ because in the process of i→ii, for instance, one of the three spin pairs (IJ) makes no contribution to it while for the others, (IK) has $a_0(a_0—b_0)$ and (JK) has $b_0(b_0—a_0)$. Each jump contribution to the denominator of Eq. 23 is simply $2a_0^2+b_0^2$; thus we have

$$T_{1D}^{-1} = \frac{(a_0-b_0)^2}{(2a_0^2+b_0^2)} \cdot \frac{1}{\tau_{II}}. \tag{24}$$

Relaxation Rate due to Diffusion. Diffusion of water molecules or carboxyl protons may be another motion which is likely to exist at high temperatures. Here we consider the following two cases of diffusional jump (the three-spin system is considered as before):

Case 1: all dipole interactions are destroyed.

Case 2: dipole interactions between carboxyl protons and water protons are destroyed but that within the water molecule is retained. As will be described later, these diffusion mechanisms do not give satisfactory angular dependence of relaxation rates; thus only the proportionality relations resulting from these mechanisms, which are necessary for later discussion, will be presented.

When an expression for relaxation rate by slow motion similar to Eq. 22 is applied, we have for Case 1,

$$T_{1D}^{-1} \propto \frac{2a_0^2+b_0^2}{2a_0^2+b_0^2} \cdot \frac{1}{\tau_d} = \frac{1}{\tau_d}, \tag{25}$$

independent of the field direction, because the entire dipole interaction is destroyed by a diffusional jump. τ_d denotes the correlation time for diffusion. From the relation of $T_{1\rho}^{-1}$ and T_{1D}^{-1} mentioned before we can expect to have an approximate relation:

$$T_{1\rho}^{-1} \propto \frac{2a_0^2+b_0^2}{\omega_1^2} \cdot \frac{1}{\tau_d}. \tag{26}$$

A similar argument for Case 2 leads to

$$T_{1D}^{-1} \propto \frac{2a_0^2}{2a_0^2+b_0^2} \cdot \frac{1}{\tau_d}, \tag{27}$$

and

$$T_{1\rho}^{-1} \propto \frac{a_0^2}{\omega_1^2} \cdot \frac{1}{\tau_d}. \tag{28}$$

Experimental

Single crystals of α-form oxalic acid dihydrate $(COOH)_2 \cdot 2H_2O$ are grown by slowly cooling a saturated aqueous solution. The crystal is mounted on a teflon holder which fits in the probe head. Alignment of the crystalline axes in the probe head is made visually. The alignment error is estimated to be less than 2°. Measurements are made at the Larmor frequency of 30 MHz. A single coil coupling arrangement is used. Recovery time of the receiving system is about 8 μs. T_1 is measured by 90° pulse comb-90° pulse sequence. For rotating frame experiments the spin locking state is prepared by turning on H_1 slowly (in a time of ≈1 ms), and at the same time the initially offset rf frequency is swept to the exact resonance.

Accuracy of the relaxation time measurement depends strongly on the appearance of free induction decay signals. In most unfavorable cases the error in the relaxation time probably amounts to 20%, but in most cases the estimated error is 10% or less.

Temperature control below room temperature is made by regulation of intermittent flushing of liquid nitrogen directly onto the thick-wall copper shield casing of the sample coil.[6]

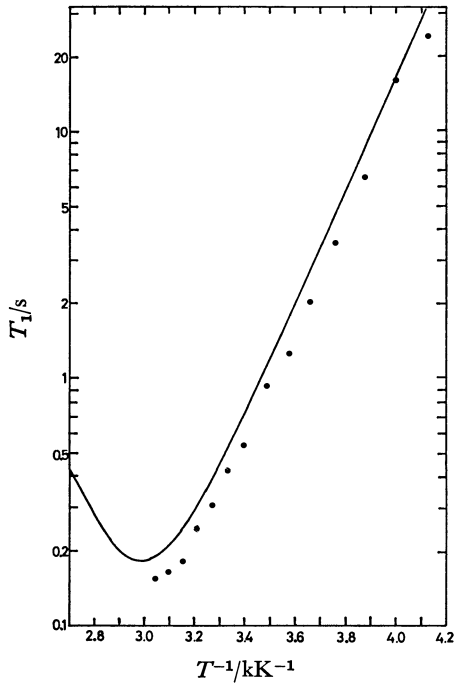

Fig. 2. Temperature dependence of T_1 at $\varphi_H=172°$, φ_H being defined in the text.

Results

T_1. Temperature dependence of T_1 as shown in Fig. 2 is measured at $\varphi_H=172°$, where φ_H denotes the angle of rotation of H_0 from the a axis toward the c axis in the ac plane. To avoid damage of the sample due to dehydration the measurement is not carried out to the point of T_1 minimum. However, from the appearance of Fig. 2, we estimate this to occur at about 61 °C. The theoretical T_1 curve of Eq. 1 with τ_I of Arrhenius form is fit to the observed one in the following two respects: (1) the slope of log T_1 against $1/T$, and (2) the temperature of the T_1 minimum. The following parameters are obtained:

$$\left.\begin{aligned} &\tau_I = 4.37 \times 10^{-16} \exp(\Delta E_I/RT), \\ &\Delta E_I = 43.6\ \mathrm{kJ\ mol^{-1}}. \end{aligned}\right\} \tag{29}$$

The calculated T_1 from Eq. 1, also shown in Fig. 2, is in satisfactory agreement with the observed value, considering that only isolated three-proton system is taken into account.

In Fig. 3, T_1^{-1} at 1.4 °C with H_0 in the ac plane, and that with H_0 in the b axis are compared with the theoretical curve with τ_I of Eq. 29. The agreement is generally satisfactory.

$T_{1\rho}$ and T_{1D}. The temperature dependence of $T_{1\rho}$ and T_{1D} is measured at $\varphi_H=47°$ and 172° where the free induction decay signal is not exceedingly short,

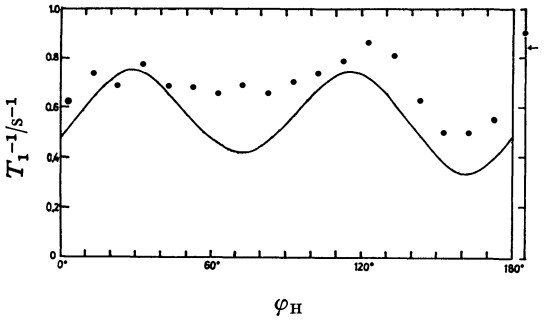

Fig. 3. Angular dependence of T^{-1} at 1.4 °C. The calculated curve from Eq. 1 is also shown. The value with H_0 along the b axis is shown at the far-right of the figure; an arrow indicates a calculated value.

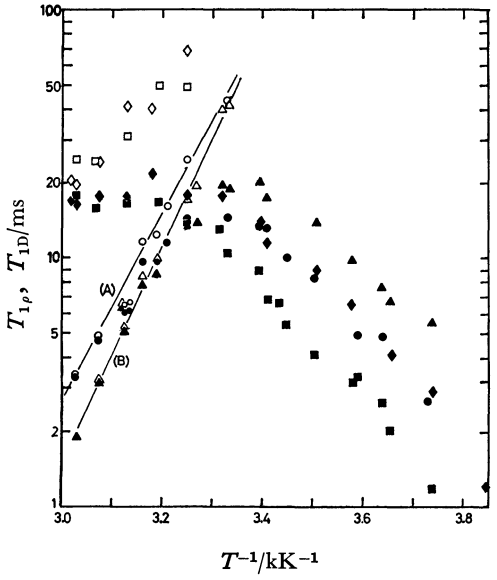

Fig. 4. Temperature dependence of $T_{1\rho}$ and T_{1D}. ■, ●: $T_{1\rho}$ and T_{1D}, respectively, measured at φ_H= 172°. ◆, ▲: those measured at φ_H=47°. The values corrected for relaxation rates due to 180°-flip are indicated by open marks, □, *etc.*

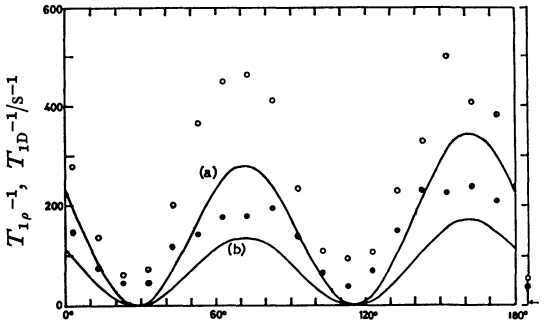

Fig. 5. Angular dependence of $T_{1\rho}^{-1}$(○) and T_{1D}^{-1} (●) at 0 °C. (a): $T_{1\rho}^{-1}$ from Eq. 6, (b): T_{1D}^{-1} from Eq. 14. Values at the b axis are presented at the far-right (calculated $T_{1\rho}^{-1}$ value indicated by an arrow).

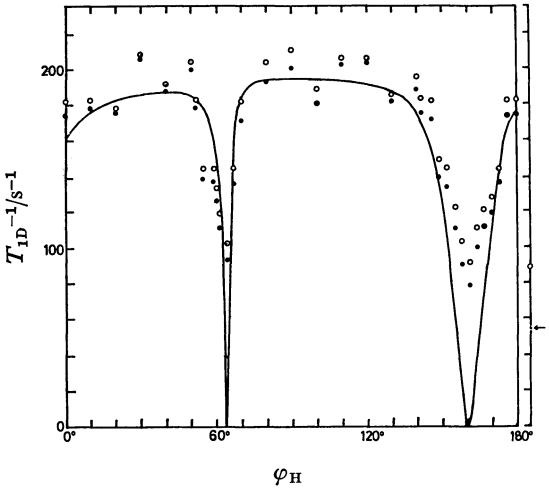

Fig. 6. Angular dependence of T_{1D}^{-1} at 47 °C (solid circles) with H_0 in the ac plane and along the b axis, the latter being shown at the far-right of the figure. Open circles are those corrected for contribution from 180°-flip motion. Calculated curve from Eq. 24 is also shown.

so that a relatively accurate measurement of relaxation time is possible. The results are shown in Fig. 4 as a semilog plot against $1/T$. Each curve shows a maximum, indicating the presence of at least two different modes of motion.

Positively Temperature Dependent Range. The slopes of the curves in this range are nearly the same as that of Fig. 2. This indicates that the relaxation times are governed by the fast 180°-flip of water molecule ($\tau_I\gamma H_1 \ll 1$ or $\tau_I\gamma H_L \ll 1$). The ΔE_I values derived from $T_{1\rho}$, ≈47 kJ mol^{-1} (φ_H=172°), and ≈41 kJ mol^{-1} (φ_H=47°) are in satisfactory agreement with ΔE_I of Eq. 29. Calculated $T_{1\rho}$ and T_{1D} from Eqs. 6 and 14 with τ_I from Eq. 28 are a factor of about 1.5 greater than the observed values of φ_H=172° and a factor of about 2.2 greater than those of φ_H=47°.

The angular dependences of $T_{1\rho}^{-1}$ and T_{1D}^{-1} measured at 0 °C are shown in Fig. 5. Calculated angular dependences due to fast 180°-flip from Eqs. 6 and 14 with Eq. 28 are also shown in the same figure. The agreement with the experimental values is generally satisfactory. Discrepancies may be partly ascribed to the assumption of the isolated three spin system.[7]

Negatively Temperature Dependent Range. At temperatures above the T_{1D} maximum, relaxation rates due to the high-temperature-mode motion are estimated by subtracting the contribution due to the 180°-flip motion of water molecule from the observed relaxation rates. The latter values are estimated by extrapolating relaxation rates from the low temperature values, by assuming the activation energy determined above. The corrected values are also shown in Fig. 4. An average value of activation energy for the high-temperature-mode motion of 80.8 kJ mol^{-1} is obtained from lines (A) and (B) fit to the temperature dependence of T_{1D} of Fig. 4. The same trend at high temperatures is apparent for both $T_{1\rho}$ and T_{1D} but the high temperature mode motion has less effect on $T_{1\rho}$. Therefore, $T_{1\rho}$ data are not used for deriving the activation energy.

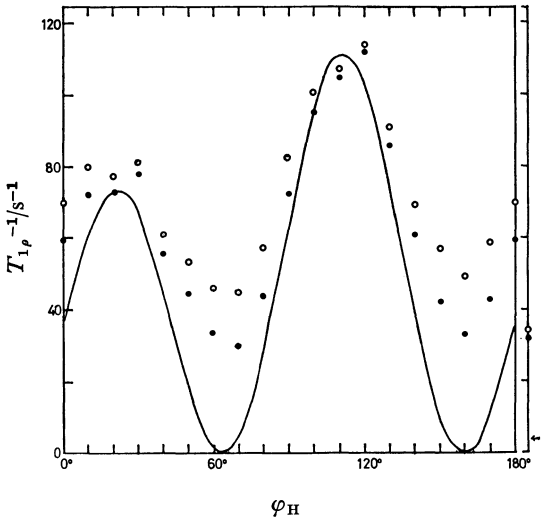

Fig. 7. Angular dependence of $T_{1\rho}^{-1}$ at 55.3 °C (solid circles) with H_0 in the ac plane and along the b axis. Open circles are values corrected for contribution from 180°-flip motion. Calculated curve from Eq. 18 is also shown.

To understand the mode of motion responsible for the high temperature relaxation, angular dependences of T_{1D} at 47 °C and $T_{1\rho}$ at 55.3 °C are measured. These relaxation rates are shown in Figs. 6 and 7. Also shown in these figure are the rates corrected for the small contribution due to the 180°-flip. The amounts of correction at these temperatures are assumed to be the fraction theoretically expected from the temperature variation in correlation time of the relaxation rates of Fig. 5 at 0 °C.

Theoretical curves of the angular dependence of relaxation rates due to carboxyl–water proton exchange motion from Eqs. 18 and 24 are also shown in Figs. 6 and 7. Numerical values of τ_{II} used in drawing these curves are to be described later. Except for the field direction in which the second moment of the three spin system becomes very small and where such an approximation is by no means a good one, the agreement of angular dependence between observed T_{1D}^{-1} and the one calculated for the three spin exchange motion appears excellent. The observed angular dependence of $T_{1\rho}^{-1}$ in Fig. 7 is also in satisfactory agreement with the curve for the exchange mechanism.

Before concluding that the exchange mechanism is the high temperature motional mode of this crystal, however, we need to examine whether a diffusion mechanism can also explain the observed results. The angular dependences of diffusion mechanisms expected from relations (25)—(28) are shown in Fig. 8. Diffusional motion of Case 2 can be definitely eliminated from the appearance of the curve. As for Case 1, though T_{1D}^{-1} from (25), which is angular independent, disagrees with the observed curve of Fig. 6, two dips on the curve which are located around the second moment minimum might be a consequence of inappropriate assumption of the isolated three spin system at these angles. Unfortunately, this cannot be decided by the angular dependence of $T_{1\rho}^{-1}$, because the curves of Fig. 7 and Fig. 8 (d) have similar appearance.

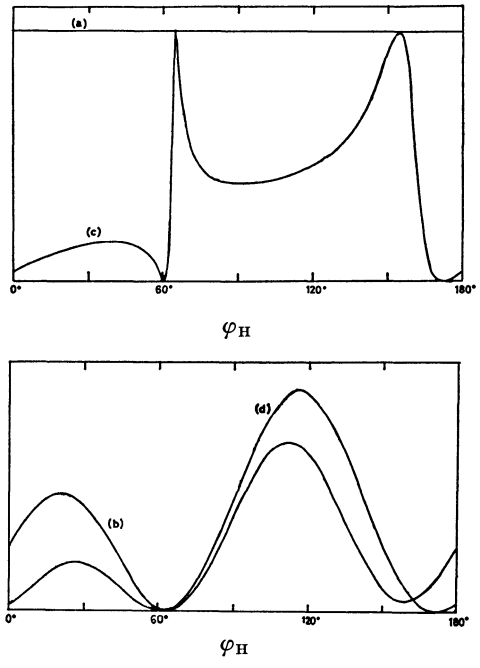

Fig. 8. Angular dependence of T_{1D}^{-1} and $T_{1\rho}^{-1}$, in the ac plane from assumed diffusional mechanisms. (a) and (b) represent T_{1D}^{-1} and $T_{1\rho}^{-1}$, respectively, for Case 1 ((25) and (27)). (c) and (d) represent T_{1D}^{-1} and $T_{1\rho}^{-1}$, respectively, for Case 2 ((26) and (28)). Each curve is drawn to arbitrary scale.

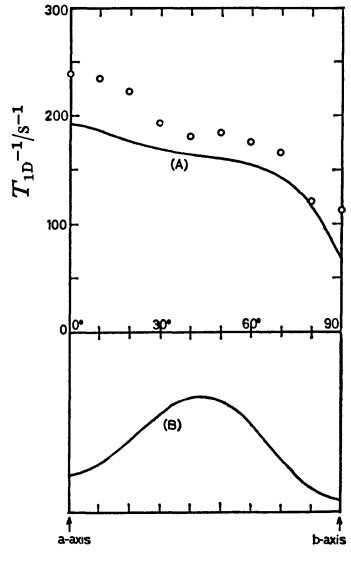

Fig. 9. T_{1D}^{-1} at 49 °C as H_0 is rotated from the a to b axis. (A): Calculated curve from Eq. 24. (B): calculated angular dependence of second moment (scale arbitrary); this curve is to show no extremely small values of H_L is present in these directions.

In order to draw a definite conclusion to this problem, the angular dependence of T_{1D} with H_0 in the ab plane is measured. In this case the three spin system has two different orientations with respect to H_0, and T_{1D}^{-1} is calculated as the mean value for these two orientations, as shown in Fig. 9. It is noted that the theoretical T_{1D}^{-1} due to three spin exchange motion decreases steadily as the field is rotated from

the a axis to the b axis. The observed values of T_{1D}^{-1}, also shown in Fig. 9, are in satisfactory agreement with the curve calculated for the exchange mechanism,[8] but they disagree with the diffusional motion of Case 1, where a constant value over the whole range is expected. A diffusion mechanism is therefore excluded.

From the maximum value of T_{1D}^{-1} at 47 °C of Fig. 6, $\tau_{II}=7.7$ ms is obtained using Eq. 24. With this τ_{II} and the activation energy obtained above, we have

$$\left.\begin{aligned}&\tau_{II} = 5.3 \times 10^{-16} \exp(\Delta E_{II}/RT),\\ &\Delta E_{II} = 80.8 \text{ kJ mol}^{-1}.\end{aligned}\right\} \quad (30)$$

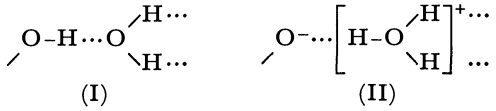
Similarly, from the maximum value of $T_{1\rho}^{-1}$ at 55.3 °C of Fig. 7, $\tau_{II}=2.8$ ms is obtained using Eq. 18; this is in fair agreement with 3.5 ms at that temperature from Eq. 30.

Discussion

T_1 and the low temperature part of $T_{1\rho}$ and T_{1D} are consistently explained by a 180°-flip motion of water molecule. The activation energy for this motion has been obtained from the temperature dependence of T_1 of the deuteron in the α-form $(COOD)_2 \cdot 2D_2O$ crystal to be 9.7 kcal mol^{-1} (=40.6 kJ mol^{-1}).[9] There is a small difference in ΔE_I of the previous report from the present result; this may be ascribed to experimental error rather than indicating an isotope effect.[10]

While relaxation rates in the rotating frame are most sensitive to slow motion at $H_1 \to 0$, for a rapid motion this is not the case. As seen in Eqs. 6 and 14, T_{1D} is twice the $T_{1\rho}$ in the case of rapid two-fold reorientation.[11] The relation may be utilized to detect slow motion in the presence of rapid reorientation, for $T_{1D}/T_{1\rho}$ may be a sensitive measure of additional slow motional processes.

The case dealt with in the present study revealed an interesting three spin exchange motion in a system in which H_3O^+ is not formed. It seems more reasonable to consider this motion as involving the following excited configuration rather than a simple three-fold reorientation. The system in the ground configuration (I) is first excited to the excited configuration (II),



(I) (II)

followed by a three-fold reorientation of H_3O^+ in that state, and then it returns to (I). Schematic illustration of the potential curve of the system is shown in Fig. 10. The observed ΔE_{II} may be interpreted as the sum of E_1+E_3 if $E_2 \lesssim E_3$, or interpreted as E_1+E_2 if $E_2>E_3$; in the latter case the jump of the carboxyl proton to the upper state and the three-fold reorientation take place in one step. The activation energy for the three-fold reorientation of H_3O^+ is reported to be 4.82 kcal mol^{-1} (=20.17 kJ mol^{-1}) in H_3O^+-ClO_4^-,[12] and that of 34 kJ mol^{-1} is obtained for $H_3O^+HSO_4^-$ from our T_1 measurement.[13] Though the interpretation of the energy relations given here is very approximate, with E_3 in the range of activation energy of H_3O^+ reorientation quoted above, a reasonable estimate of the upper limit of E_1 may be around 60 kJ mol^{-1}.

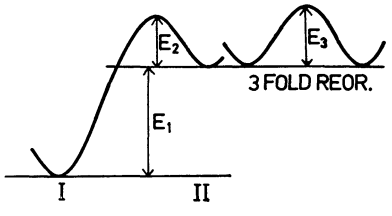


Fig. 10. Schematic illustration of the potential curves for water and carboxyl proton exchange motion.

The mechanism of motion proposed above involves jumps between unequal levels of the carboxyl proton. Usually in a case like this the motion is relatively ineffective for relaxation due to the short residence time in the less stable site.[14] In the present case, however, the carboxyl proton which moved to the high energy site can exchange position with the water protons by the three-fold reorientation and therefore the whole sequence can provide an efficient mechanism for relaxation.[15]

From the positive temperature dependence of the deuteron quadrupole coupling of carboxyl deuteron in deuterated oxalic acid dihydrate, a weakening of the hydrogen bond with temperature is suggested.[9] If this is the case it would result in an increase in the activation energy ΔE_{II} with temperature. However, if such an effect is taken into consideration, the resulting pre-exponential factor, τ_{II}^0, becomes unreasonably small. For instance, a linear temperature dependence of ΔE_{II} of only 4.2 kJ mol^{-1}/100 °C leads to ΔE_{II} at 350 K of 88 kJ mol^{-1} and τ_{II}^0 of 10^{-17}. Though there seems to be thus some incongruity between the previous deuteron resonance result and the present work, for which at the moment no explanation is available, we conclude that ΔE_{II} of Eq. 30 is substantially correct and that the positive temperature dependence in ΔE_{II}, if it exists, is not large.

The chemical shift of oxalic acid dihydrate at room temperature has been measured by high resolution NMR in solids.[16] Because the chemical shift spectrum is also sensitive to slow motional processes, it is hoped that such study will be extended to higher temperatures to see if supporting results can be obtained.

7) For the calculation of $T_{1\rho}^{-1}$, Eq. 6 is used throughout, and no correction (Eq. 15) due to nonvanishing H_L is made. In directions where $T_{1\rho}^{-1}$ becomes large, H_L is relatively

small, and the theoretical curve is not greatly influenced by this correction.

8) Some discrepancy of theoretical and observed T_{1D}^{-1} is seen in the vicinity of the a axis direction. This might be due to a small error in crystal orientation, because crystal setting in this case was more difficult than in the case of the b axis rotation. Therefore, theoretical curves for up to 10° misalignment in the a axis were also examined and found not to affect the above conclusion.

Theory of A.c. Polarization and A.c. Polarography and Voltammetry of Surface Redox Reaction

Tadaaki KAKUTANI* and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606

(Received May 30, 1979)

Theoretical equations are presented of the a.c. polarization and of the a.c. polarography and voltammetry for the surface redox reaction ($O_{ad}+ne\rightleftharpoons R_{ad}$) in which charge transfer reaction takes place exclusively between the adsorbed reactants O_{ad} and R_{ad}, and both reactants are adsorbed so strongly that the amount of O or R brought to or removed from the electrode surface can be neglected. The interaction between adsorbed molecules is assumed to be expressed by Frumkin's *a*-parameters. Also the effect of the double layer impedance is taken into account. Some simplified cases are discussed in detail.

Electrochemistry with electroactive reactants irreversibly or strongly adsorbed on or chemically bonded to electrode surface is an active field of current research (for reviews, see Refs. 1 and 2). In the majority of cases the electrochemical behavior of such electrodes has been studied by using linear sweep cyclic voltammetry and differential pulse polarography. Also the coulostatic technique[3] and the second harmonic a.c. voltammetric technique[4] were used for the study of electron transfer reactions between reactants irreversibly or strongly adsorbed on or chemically bonded to electrode surface. We have applied the a.c. polarographic technique to elucidate the electrode processes of ferredoxins irreversibly adsorbed on the surface of mercury electrode.[5a] The results indicated that the a.c. polarography is a powerful technique, in particular, for determining the electrochemical kinetic parameters.

Theory of the faradaic impedance or a.c. polarography of the electrode processes with specific adsorption has been given in a general form[6] which involves terms of mass transfer, adsorption and charge transfer. Although the general expressions are very involved, the expressions will become very simple[7] when the charge transfer reaction takes place exclusively between adsorbed molecules and the amount of electroactive species (O or R) brought to or removed from the electrode surface by mass transfer can be neglected in comparison with the amount which remains adsorbed. These conditions will be satisfied in the case of strongly or irreversibly adsorbed or chemically bonded species.

In this paper, we present theoretical expressions of the faradaic impedance and of the a.c. polarography and voltammetry of the electrode processes with reactants irreversibly adsorbed on or chemically bonded to electrode surface (hereafter we call this the "surface redox reaction") on the basis of the general expressions[6]. In the following derivation we shall make several assumptions: (a) the charge transfer reaction takes place exclusively between the adsorbed molecules, (b) both O and R are adsorbed so strongly (irreversibly) that the amount of O or R brought to or removed from the electrode surface can be neglected, and (c) the interaction between adsorbed molecules can be expressed by Frumkin's *a*-parameters. The effect of the double layer impedance is also considered.

Theory of Faradaic and Non-faradaic Currents

We consider an *n*-electron surface redox reaction,

$$O_{ad} + ne \rightleftharpoons R_{ad}. \tag{1}$$

Since the surface redox reaction proceeds exclusively between the adsorbed molecules (assumption (a)), the faradaic current density I_F is a function of the electrode potential, E, and the surface concentrations of the adsorbed species O and R, Γ_O and Γ_R; $I_F=g(E, \Gamma_O, \Gamma_R)$. For small variations of the potential, δE, superimposed on the "d.c." potential, E_{dc}, ($E=E_{dc}+\delta E$), the surface concentration will change around the mean ("d.c.") value, $\overline{\Gamma}_i$, with small variations, $\delta\Gamma_i$; $\Gamma_i=\overline{\Gamma}_i+\delta\Gamma_i$ (i=O and R) and the faradaic current will be given by[6]

$$I_F = I_{dc} + \delta I_F. \tag{2}$$

Thus we have for the first harmonic of faradaic current, $\delta_1 I_F$,

$$\delta_1 I_F = (\partial I/\partial E)\delta_1 E + (\partial I/\partial \Gamma_O)\delta_1\Gamma_O + (\partial I/\partial\Gamma_R)\delta_1\Gamma_R, \tag{3}$$

where $\delta_1 E$ and $\delta_1\Gamma_i$'s represent the first harmonic variations of E and Γ_i's respectively. From the assumption (b) we further have[6]

$$d(\delta_1\Gamma_i)/dt = j\omega\delta_1\Gamma_i = \pm(\delta_1 I_F/nF). \tag{4}$$

Here the upper and lower sings correspond to O and R, respectively, j is the operator $(-1)^{1/2}$, and ω the angular frequency of sinusoidal variations.

By combination of Eqs. 3 and 4 we obtain the *I-E* characteristic for sinusoidal variations of small amplitude,

$$\delta_1 I_F = \delta_1 I_F^{real} + j\delta_1 I_F^{imag} = (r-jy)^{-1}\delta_1 E, \tag{5a}$$

$$\delta_1 I_F^{real} = \frac{(r/y)^2}{1+(r/y)^2}\cdot\frac{1}{r}\delta_1 E, \tag{5b}$$

and

$$\delta_1 I_F^{imag} = \frac{1}{1+(r/y)^2}\cdot\frac{1}{y}\delta_1 E, \tag{5c}$$

where $\delta_1 I_F^{real}$ and $\delta_1 I_F^{imag}$ are the real and imaginary components of the faradaic a.c. current, respectively, and r and y are given by

$$r = 1/(\partial I/\partial E), \tag{6a}$$

and

$$y=y_O + y_R = (1/nF\omega)[-(\partial I/\partial\Gamma_O)/(\partial I/\partial E) + (\partial I/\partial\Gamma_R)/(\partial I/\partial E)]. \tag{6b}$$

In harmony with the assumption (b) (see Eq. 4) the general theory[6] would give the same expressions as above when

$$(\partial\phi_O/\partial\Gamma_R) = (\partial\phi_R/\partial\Gamma_O) = 0, \quad |\zeta_i| \ll 1,$$
$$\text{and } (\omega/2D_i)^{1/2}(\partial\Gamma_i/\partial C_i^\circ) \gg 1$$

(see Ref. 6 regarding the notations).

Because of adsorption of O and R, the double layer impedance, *i.e.*, the non-faradaic impedance may differ from that observed in the absence of O and R. In this case we can assume that the surface charge density on the electrode, q, is a function of E, Γ_O, and Γ_R only, so that for sinusoidal variations of the non-faradaic current-density we have for the first harmonic[6,8]

$$\delta_1 I_{NF} = (dq/dt)_{ac} = j\omega[(\partial q/\partial E)\delta_1 E + (\partial q/\partial\Gamma_O)\delta_1\Gamma_O + (\partial q/\partial\Gamma_R)\delta_1\Gamma_R]. \quad (7)$$

From Eqs. 4 and 7, we obtain for the non-faradaic ac current

$$\delta_1 I_{NF} = (1/nF)[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]\delta_1 I_F + j\omega(\partial q/\partial E)\delta_1 E. \quad (8)$$

Thus we have for the total (faradaic and non-faradaic) ac current

$$\delta_1 I_t = \delta_1 I_F + \delta_1 I_{NF} = \{1 + (1/nF)[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]\}\delta_1 I_F + j\omega(\partial q/\partial E)\delta_1 E, \quad (9)$$

and the observable real and imaginary components are

$$\delta_1 I_{obsd}^{real} = \{1 + (1/nF)[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]\}\delta_1 I_F^{real}, \quad (10a)$$

and

$$\delta_1 I_{obsd}^{imag} = \{1 + (1/nF)[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]\}\delta_1 I_F^{imag} + \omega(\partial q/\partial E)\delta_1 E, \quad (10b)$$

respectively. The second term on the right-hand side of Eq. 10b, $\omega(\partial q/\partial E)\delta_1 E$, (*i.e.*, so-called "wahre Käpazität" term[8]) can be estimated from double-layer capacity measurements employing very high frequencies. This term is generally a reverse-S-shaped or S-shaped variation of the capacity current and for practical purpose can approximately be eliminated by a conventional method of correction for ac base current as usually used in a.c. polarographic technique:

$$\delta_1 I_{corr}^{imag} = \delta_1 I_{obsd}^{imag} - \omega(\partial q/\partial E)\delta_1 E = \{1 + (1/nF)[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]\}\delta_1 I_F^{imag}. \quad (10c)$$

On the other hand it is very difficult to estimate the term $[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]$ experimentally. However, since the potential range in which the faradaic current appears does not exceed a few tenths of a volt, it can be assumed that this term is practically a constant within the range studied:

$$\delta_1 I_{obsd}^{real} = (m/n)\delta_1 I_F^{real}, \quad (11a)$$
$$\delta_1 I_{corr}^{imag} = (m/n)\delta_1 I_F^{imag}, \quad (11b)$$
$$(m/n) = \{1 + (1/nF)[(\partial q/\partial\Gamma_O) - (\partial q/\partial\Gamma_R)]\} \quad (11c)$$

We call the constant, m, defined by Eq. 11c the apparent number of electrons associated with the surface redox reaction (1).

Equations for Faradaic Impedance and A.c. Polarography and Voltammetry

Laitinen and Randles[9] first gave theoretical expressions of the faradaic impedance for the surface redox reaction. However, they did not take the interaction between the adsorbed molecules into account. We assume that the current-potential-concentration characteristic can be written as[7]

$$(I_F/nF) = \overleftarrow{V} - \overrightarrow{V}, \quad (12a)$$

$$\overleftarrow{V} = k_s'(1-f)\theta_t B_R^{-1} \exp[\beta(nF/RT)(E-E_0)] \times \exp[-a_{RR}(1-f)\theta_t - a_{RO} f\theta_t], \quad (12b)$$

$$\overrightarrow{V} = k_s' f\theta_t B_O^{-1} \exp[-\alpha(nF/RT)(E-E_0)] \times \exp[-a_{OO} f\theta_t - a_{OR}(1-f)\theta_t], \quad (12c)$$

where B_i is the constant representing the adsorption energy of i on the electrode surface at $E=E_0$, E_0 being the reference electrode potential (see below), a_{ij} the Frumkin's a-parameter of interaction between the adsorbed molecules i and j (a_{ij} is positive for an attraction and negative for a repulsion),[10] θ_t the total coverage defined by $\theta_t = \Gamma_t/\Gamma_m = \theta_O + \theta_R$ with $\theta_O = \Gamma_O/\Gamma_m$, $\theta_R = \Gamma_R/\Gamma_m$, and $\Gamma_t = \Gamma_O + \Gamma_R = \overline{\Gamma}_O + \overline{\Gamma}_R$, Γ_m the maximum value of the total surface concentration, $f = \theta_O/\theta_t$, $k_s' = k_s\Gamma_m$ and k_s (in s^{-1}) the rate constant of the charge transfer reaction at the standard potential of the surface redox reaction, E_0', which is defined by

$$E_0' = E_0 + [RT/(\alpha+\beta)nF][\ln(B_R/B_O) - (1/2)(a_{OO} - a_{RR} + a_{OR} - a_{RO})\theta_t]. \quad (13)$$

The equilibrium dc potential, E_{eq}, at $I_F=0$ is given by

$$E_{eq} = E_0' + [RT/(\alpha+\beta)nF][\ln(f/(1-f)) + (1/2)(1-2f)G\theta_t]_{eq} \quad (14)$$

where G is defined by Eq. 19. α and β are the transfer coefficients for cathodic and anodic charge transfer reaction, respectively. Similar expression of the current-potential-concentration characteristic has been used by Conway *et al.*[11,12] in the kinetic theory of the linear sweep voltammetry of the surface redox reaction, and by Laviron,[13] Brown and Anson,[14] and Murray *et al.*[15] in theoretical expressions of the reversible linear sweep voltammogram of the surface redox reaction. It can generally be shown that the peak potential of the d.c. reversible (*i.e.*, d.c. Nernstian) linear sweep voltammogram, E_p^{dc}, is equal to E_0' defined by Eq. 13. In the following we assume that the a_{ij}-parameters are independent of the electrode potential. In Eqs. 12b and 12c the terms $\exp[\beta(nF/RT)(E-E_0)]$ and $\exp[-\alpha(nF/RT)(E-E_0)]$ represent the dependence of both the activation free energy of charge transfer and the adsorption free energy of reactants on the electrode potential. The quadratic dependence of these energies on the electrode potential has been described. In the following, however, we assume in the first approximation that the coefficients α and β are independent of the electrode potential. The reference electrode potential, E_0, may be considered as corresponding to the standard potential of the redox couple

supposedly in the bulk of solution.

From Eqs. 6a, 6b, 12a, 12b, and 12c we obtain

$$r = (1/nF)[\beta(nF/RT)\overleftarrow{V}_{dc}+\alpha(nF/RT)\overrightarrow{V}_{dc}]^{-1} \quad (15)$$

and

$$y = (r/\omega)\{\overrightarrow{V}_{dc}[(1/\overline{\Gamma}_O)-(a_{OO}-a_{OR})(\theta_t/\Gamma_t)] + \overleftarrow{V}_{dc}[(1/\overline{\Gamma}_R)-(a_{RR}-a_{RO})(\theta_t/\Gamma_t)]\}. \quad (16)$$

Here $\overleftarrow{V}_{dc}=\overleftarrow{V}(E=E_{dc}, f=\bar{f})$ and $\overrightarrow{V}_{dc}=\overrightarrow{V}(E=E_{dc}, f=\bar{f})$ with $\bar{f}=\overline{\Gamma}_O/\Gamma_t$ and these are related to the dc faradaic current by

$$(I_F)_{dc}/nF = \overleftarrow{V}_{dc} - \overrightarrow{V}_{dc}. \quad (17a)$$

When the surface redox reaction is d.c. reversible (dc Nernstian), *i.e.*, $(4RTk_s/nF\nu)\gg 1$ in a.c. voltammetry with the potential sweep rate, ν, or $k_s\tau\gg 1$ in a.c. polarography with the drop time, τ, $\bar{f}$ or $\overline{\Gamma}_O$, and $\overline{\Gamma}_R$ can be estimated by

$$(\overleftarrow{V}_{dc}-\overrightarrow{V}_{dc})_{dc\ reversible} = 0 \quad (17b)$$

and given by

$$E_{dc} = E_0' + [RT/(\alpha+\beta)nF] \times [\ln(\bar{f}/(1-\bar{f}))+(1/2)(1-2\bar{f})G\theta_t], \quad (18)$$

with

$$G = a_{OO} + a_{RR} - a_{OR} - a_{RO}. \quad (19)$$

In this case r and y are given by

$$r = \frac{1}{(\alpha+\beta)}\cdot\frac{RT}{nF}\cdot\frac{1}{I_0}, \quad (20)$$

and

$$y = \frac{1}{(\alpha+\beta)nF(nF/RT)\omega\Gamma_t}\cdot\frac{1-G\theta_t(1-\bar{f})\bar{f}}{(1-\bar{f})\bar{f}}, \quad (21)$$

where I_0 is the exchange current density at $E=E_{dc}$ and given by

$$I_0 = nFk_s\Gamma_t\bar{f}^{\beta/(\alpha+\beta)}(1-\bar{f})^{\alpha/(\alpha+\beta)}B_O^{-\beta/(\alpha+\beta)}B_R^{-\alpha/(\alpha+\beta)} \times \exp\{-(\beta/(\alpha+\beta))[a_{OO}\bar{f}+a_{OR}(1-\bar{f})]\theta_t\} \times \exp\{-(\alpha/(\alpha+\beta))[a_{RR}(1-\bar{f})+a_{RO}\bar{f}]\theta_t\}. \quad (22)$$

The phase angle, ψ, is given by

$$\cot\psi = (r/y) = (\delta_1 I_F^{real}/\delta_1 I_F^{imag}) = (\delta_1 I_{obsd}^{real}/\delta_1 I_{corr}^{imag}) = \frac{\omega}{\phi_0}\cdot\frac{(1-\bar{f})\bar{f}}{1-G\theta_t(1-\bar{f})\bar{f}}, \quad (23)$$

with $\phi_0=I_0/nF\Gamma_t$.

These equations 18, 20, 21, and 23 are applicable without alteration to a.c. polarization of the surface redox reaction at the equilibrium (dc) potential.

Simplified Cases

In the following we shall consider several simplified cases, in which the surface redox reaction is assumed to be dc reversible.

A.c. Reversible Case. When the rate constant is so large that the condition $(r/y)\ll 1$ is satisfied, Eqs. 5a, 5b, and 5c are reduced to

$$(\delta_1 I_F)_{rev} = (\delta_1 I_F^{imag})_{rev} = \frac{1}{y}\delta_1 E = (\alpha+\beta)nF(nF/RT)\omega\Gamma_t\cdot\frac{\bar{f}(1-\bar{f})}{1-G\theta_t(1-\bar{f})\bar{f}}\delta_1 E, \quad (24)$$

and $\cot\psi=0$. That is, $\delta_1 I_F^{real}$ becomes vanishingly small and ψ approaches 90°. The a.c. wave has a maximum at $\bar{f}=1/2$ and is symmetrical with respect to the peak potential. The peak current, $(\delta_1 I_F^p)_{rev}$, peak potential, E_p^{rev}, and half-peak width, $\Delta E_{p/2}^{rev}$, are given by

$$(\delta_1 I_F^p)_{rev} = (\alpha+\beta)nF(nF/RT)\omega\Gamma_t(4-G\theta_t)^{-1}\delta_1 E, \quad (25)$$

$$E_p^{rev} = E_0', \quad (26)$$

and

$$\Delta E_{p/2}^{rev} = \frac{2RT}{(\alpha+\beta)nF}\left|\ln\frac{1+\gamma}{1-\gamma}-(1/2)G\theta_t\gamma\right| \quad (27)$$

with

$$\gamma = \sqrt{(4-G\theta_t)/(8-G\theta_t)}. \quad (28)$$

As seen from these equations, both $(\delta_1 I_F^p)_{rev}$ and $\Delta E_{p/2}^{rev}$ depend remarkably on the adsorption parameter $G\theta_t$ and also on the coefficient $(\alpha+\beta)$. It is noted that these equations are the same as those of the reversible linear sweep voltammogram[13] if the term $\omega\delta_1 E$ is replaced by the sweep rate ν. Namely, in this case the shape of the a.c. wave is the same as that of the reversible linear sweep voltammogram and E_p^{rev} coincides with E_p^{dc}.

Case of $a=a_{OO}=a_{RR}=a_{OR}=a_{RO}$. In this case r and y are reduced to

$$r = [(\alpha+\beta)nF(nF/RT)k_{sap}\Gamma_t\rho^{\beta/(\alpha+\beta)}(1+\rho)^{-1}]^{-1}, \quad (29)$$

and

$$y = [(\alpha+\beta)nF(nF/RT)\omega\Gamma_t\rho(1+\rho)^{-2}]^{-1}, \quad (30)$$

where

$$k_{sap} = k_s B_O^{-\beta/(\alpha+\beta)}B_R^{-\alpha/(\alpha+\beta)}\exp(-a\theta_t), \quad (31)$$

$$\rho = \exp[(\alpha+\beta)(nF/RT)(E_{dc}-E_0')], \quad (32)$$

with $E_0'=E_0+[RT/(\alpha+\beta)nF]\ln(B_R/B_O)$, because $a_{OO}-a_{RR}+a_{OR}-a_{RO}=0$ in this simplified case (see Eq. 13). Introducing Eqs. 29 and 30 into Eqs. 5b and 5c leads to equations of the two components of the a.c. wave, from which the two peak potentials, E_p^{real} and E_p^{imag}, are given as functions of the kinetic parameters, α, β and k_{sap}, which implicitly depends on the adsorption parameter a, as shown, for example, for the case of $\alpha+\beta=1$ in Fig. 1.

For the phase angle we obtain

$$\cot\psi = (\delta_1 I_F^{real}/\delta_1 I_F^{imag}) = (\omega/k_{sap})\rho^{\alpha/(\alpha+\beta)}(1+\rho)^{-1}. \quad (33)$$

Accordingly a plot of $\cot\psi$ against E_{dc} at any frequency has a maximum at the potential

$$[E_{dc}]_{\cot\varphi=max} = E_0' + [RT/(\alpha+\beta)nF]\ln(\alpha/\beta) \quad (34)$$

with a magnitude

$$[\cot\psi]_{max} = (\omega/k_{sap})[(\alpha/\beta)^{-\alpha/(\alpha+\beta)} + (\alpha/\beta)^{\beta/(\alpha+\beta)}]^{-1}. \quad (35)$$

The relations 33 to 35 are important because we do not need the knowledge on $[(\partial q/\partial\Gamma_O)-(\partial q/\partial\Gamma_R)]$.

When $\alpha+\beta=1$, we can determine the kinetic param-

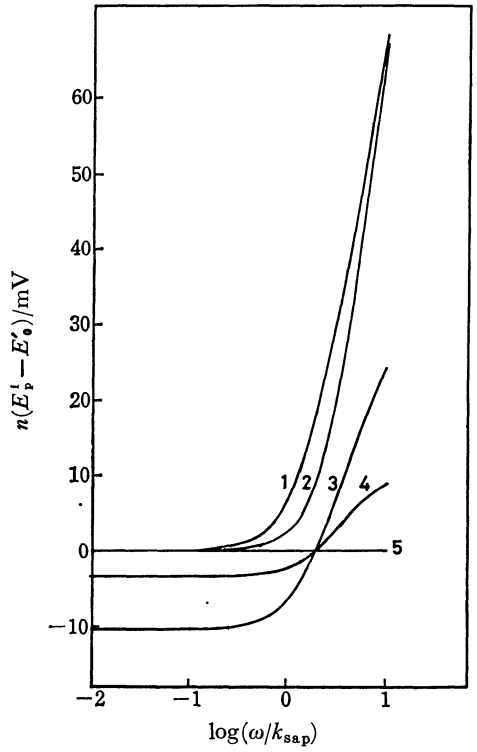

Fig. 1. Variations of E_p^{real} and E_p^{imag} as a function of $\log(\omega/k_{sap})$ for the case (2) with $\alpha+\beta=1$. E_p^{imag}: (1) $\alpha=0.2$, (2) $\alpha=0.4$, (5) $\alpha=0.5$ E_p^{real}: (3) $\alpha=0.2$, (4) $\alpha=0.4$, (5) $\alpha=0.5$.

eters, k_{sap} and α, from the relations 33 to 35. Then the adsorption parameter, a, can be determined from the slope of a plot of ln k_{sap} *versus* θ_t. Furthermore if $\alpha=\beta=0.5$, we have the following simplified relations for the half-peak widths of the two a.c. components, $\Delta E_{p/2}^{real}$ and $\Delta E_{p/2}^{imag}$, and the half-peak width of the cot ψ *versus* E_{dc} curve, $\Delta E_{p/2}(\cot\psi)$:

$$\Delta E_{p/2}^{i}(\text{i=real or imag}) = (2RT/nF)\,|\ln[(1+\eta^i)/(1-\eta^i)]|, \quad (36)$$

$$\Delta E_{p/2}(\cot\psi) = 5.27(RT/nF), \quad (37)$$

In Eq. 36 $\eta^{real}=\sqrt{1-4\xi_{real}}$ with ξ_{real} representing the solution of the equation,

$4[4+(\omega/k_{sap})^2]\xi_{real}^{3/2}=(\omega/k_{sap})^2\xi_{real}+1$, and

$\eta^{imag}=\sqrt{[4+(\omega/k_{sap})^2]/[8+(\omega/k_{sap})^2]}$.

When $\alpha+\beta=1$ and $a=0$, theoretical equations of the a.c. wave are reduced to

$$\delta_1 I_F^{real} = nF(nF/RT)\omega\Gamma_t\frac{\rho}{(1+\rho)^2}\cdot\frac{\omega/(\vec{k}+\overleftarrow{k})}{[(\omega/(\vec{k}+\overleftarrow{k}))^2+1]}\delta_1 E, \quad (38)$$

$$\delta_1 I_F^{imag} = nF(nF/RT)\omega\Gamma_t\frac{\rho}{(1+\rho)^2}\cdot\frac{1}{[(\omega/(\vec{k}+\overleftarrow{k}))^2+1]}\delta_1 E, \quad (39)$$

where $\vec{k}=k_s B_O^{-\beta/(\alpha+\beta)}B_R^{-\alpha/(\alpha+\beta)}\rho^{-\alpha}$ and $\overleftarrow{k}=k_s B_O^{-\beta/(\alpha+\beta)}B_R^{-\alpha/(\alpha+\beta)}\rho^{\beta}$. If $B_O=B_R=1$, Eqs. 38 and 39 are reduced to the equations which were previously

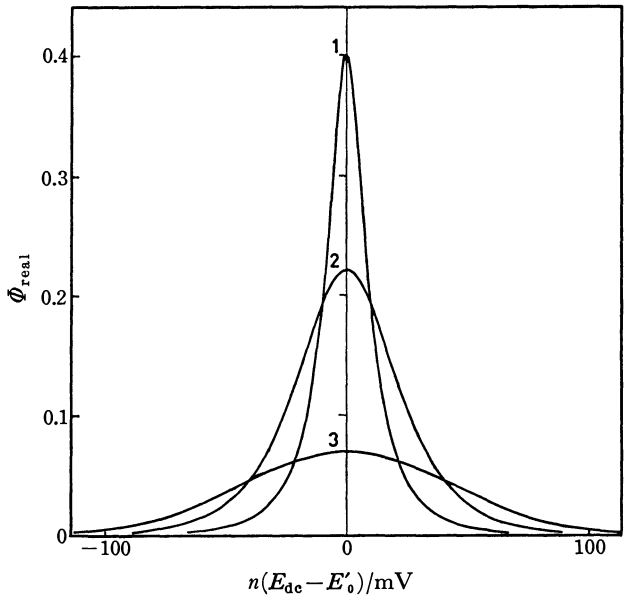

Fig. 2. Normalized real component of a.c. wave calculated by Eqs. 5b, 40, 41 and 44 with $\alpha=\beta=0.5$ and $(\omega/k_{sap})=1$. $G\theta_t$: (1) 3, (2) 1, (3) −1.

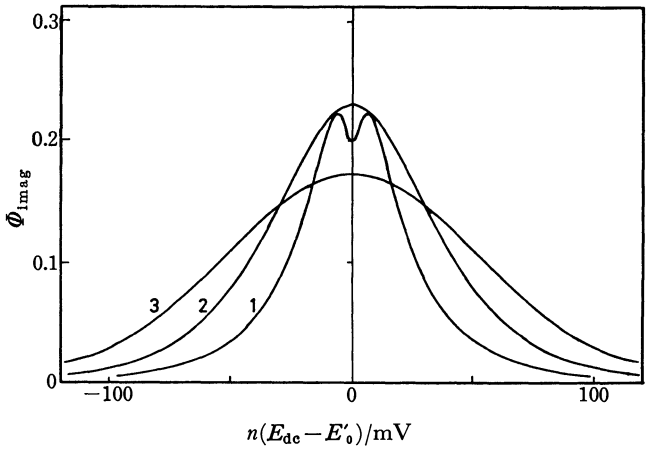

Fig. 3. Normalized imaginary component of a.c. wave calculated by Eqs. 5c, 40, 41 and 44 with $\alpha=\beta=0.5$ and $(\omega/k_{sap})=1$. $G\theta_t$: (1) 3, (2) 1, (3) −1.

derived for analysing the electrode processes of ferredoxins irreversibly adsorbed on the mercury electrode.[5a,5b] Quite recently theoretical equations, essentially the same as Eqs. 38 and 39, have been reported by Laviron.[16]

Case of $a_{ii}=a_{OO}=a_{RR}$, $a_{ij}=a_{OR}=a_{RO}$ *and* $\alpha=\beta$. In this case the terms r and y are reduced to

$$r = [2\alpha nF(nF/RT)k_{sap}\Gamma_t\bar{f}^{1/2}(1-\bar{f})^{1/2}]^{-1}, \quad (40)$$

$$y = \left[2\alpha nF(nF/RT)\omega\Gamma_t\frac{(1-\bar{f})\bar{f}}{1-G\theta_t(1-\bar{f})\bar{f}}\right]^{-1}. \quad (41)$$

where

$$k_{sap} = k_s(B_O B_R)^{-1/2}\exp[-(1/2)(a_{ii}+a_{ij})\theta_t] \quad (42)$$

and

$$G = 2(a_{ii}-a_{ij}). \quad (43)$$

The relation between E_{dc} and $\bar{f}$ is given by

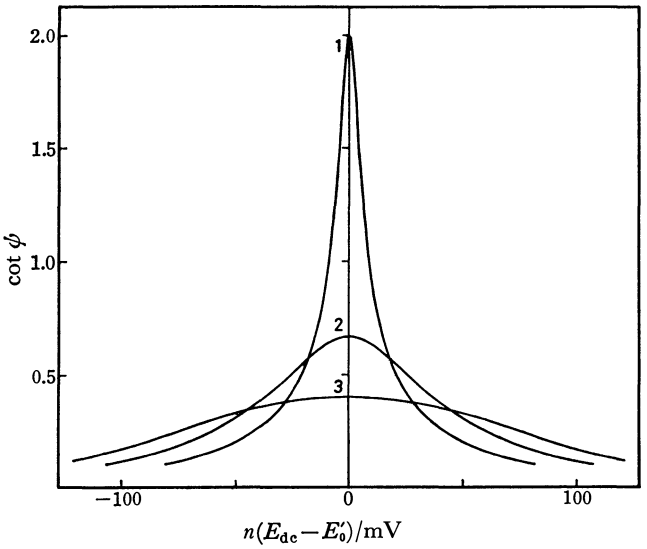

Fig. 4. D.c. dependece of phase angle calculated by Eqs. 45 and 44 with $\alpha=\beta=0.5$ and $(\omega/k_{sap})=1$. $G\theta_t$: (1) 3, (2) 1, (3) -1.

$$E_{dc} = E'_0 + (RT/2\alpha nF)[\ln(\bar{f}/(1-\bar{f})) + (1/2)(1-2\bar{f})G\theta_t] \tag{44}$$

with $E'_0=E_0+(RT/2\alpha nF)\ln(B_R/B_O)$, because $a_{OO}-a_{RR}+a_{OR}-a_{RO}=0$ in this simplified case. Thus the a.c. wave is expressed by Eqs. 5a, 5b, and 5c with Eqs. 40, 41, and 42 and is shown to be symmetrical with respect to the potential $E'_0=E_p^{dc}$. Also Eq. 42 predicts that ln k_{sap} depends lineally on θ_t. The normalized a.c. waves, $\Phi_{real}\equiv\delta_1 I_F^{real}/nF(nF/RT)\omega\Gamma_t\delta_1 E$ and $\Phi_{imag}\equiv\delta_1 I_F^{imag}/nF(nF/RT)\omega\Gamma_t\delta_1 E$, for different values of $G\theta_t$ at $\alpha=\beta=0.5$ and $(\omega/k_{sap})=1$ are illustrated in Figs. 2 and 3.

Furthermore we obtain

$$\cot\psi = \frac{\omega}{k_{sap}}\cdot\frac{(\bar{f})^{1/2}(1-\bar{f})^{1/2}}{1-G\theta_t(1-\bar{f})\bar{f}} \tag{45}$$

This equation predicts that the $\cot\psi$ *versus* E_{dc} curve has a maximum for $4>G\theta_t\geqslant -4$ or minimum for $G\theta_t<-4$ at E'_0 with a magnitude

$$[\cot\psi]_{E_{dc}=E'_0} = (\omega/k_{sap})[2/(4-G\theta_t)] \equiv \lambda. \tag{46}$$

Figure 4 shows the $\cot\psi$ *versus* E_{dc} curves for different values of $G\theta_t$ at $\alpha=\beta=0.5$ and $(\omega/k_{sap})=1$.

In this case we can determine the kinetic and adsorption parameters by the following two methods if α is known.

Method (a): When $\alpha=\beta=$A, $\Delta E_{p/2}^{i}$ is given by (for $G\theta_t\neq 0$)

$$\Delta E_{p/2}^{i} = (RT/AnF)\left|\ln\frac{1+\sqrt{1-4\xi_i}}{1-\sqrt{1-4\xi_i}} - (1/2)G\theta_t\sqrt{1-4\xi_i}\right|. \tag{47}$$

In this equation i=real or imag and ξ_{real} and ξ_{imag} respectively are the solutions of the following two equations; $(4-G\theta_t)^2(1+\lambda^2)\xi_{real}^{3/2}=(1-G\theta_t\xi_{real})^2+(\lambda/2)^2(4-G\theta_t)^2\xi_{real}$ and $(1-G\theta_t\xi_{imag})^2+(\lambda/2)^2(4-G\theta_t)^2\xi_{imag}=2(4-G\theta_t)(1+\lambda^2)(1-G\theta_t\xi_{imag})\xi_{imag}$, where λ is defined by Eq. 46. Dependences of $\Delta E_{p/2}^{i}$'s on $G\theta_t$ for different values of λ at $\alpha=\beta=0.5$ are shown in Figs. 5 and 6. Since λ can be estimated from

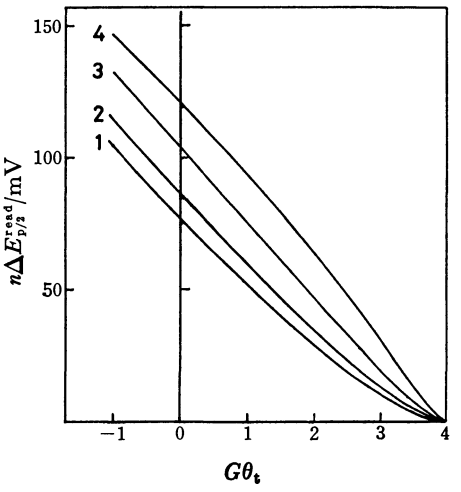

Fig. 5. Variations of $n\Delta E_{p/2}^{real}$ as a function of $G\theta_t$ calculated by Eqs. 36 and 47 with $\alpha=\beta=0.5$. λ: (1) 0.5, (2) 1, (3) 2, (4) 4.

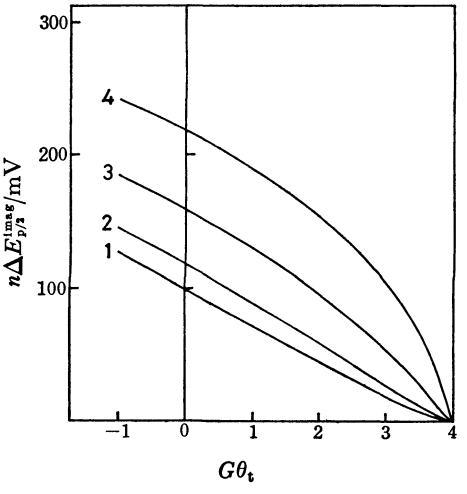

Fig. 6. Variations of $n\Delta E_{p/2}^{imag}$ as a function of $G\theta_t$ calculated by Eqs. 36 and 47 with $\alpha=\beta=0.5$. λ: (1) 0.5, (2) 1, (3) 2, (4) 4.

$(\delta_1 I_F^{real}/\delta_1 I_F^{imag})_{E_{dc}=E'_0}$ and $\Delta E_{p/2}^{i}$'s are functions of $G\theta_t$ and λ only, we can determine k_{sap} and $G\theta_t$ from λ and either $\Delta E_{p/2}^{real}$ or $\Delta E_{p/2}^{imag}$. As shown in Fig. 3, $\delta_1 I_F^{imag}$ has a maximum or minimum at $E_{dc}=E'_0$. When $\delta_1 I_F^{imag}$ has a minimum at $E_{dc}=E'_0$, $\Delta E_{p/2}^{imag}$ of Eq. 47 means a difference between the dc potentials at which the current value is one-half that observed at $E_{dc}=E'_0$.

Method (b): The half-peak width of the $\cot\psi$ *versus* E_{dc} curve, $\Delta E_{p/2}$ $(\cot\psi)$, depends on $G\theta_t$ ($G\theta_t\neq 0$ in this case) only and is given by

$$\Delta E_{p/2}(\cot\psi) = (RT/AnF) \times\left|\ln[(1+\sqrt{1-4\delta})/(1-\sqrt{1-4\delta})] - (1/2)G\theta_t\sqrt{1-4\delta}\right| \tag{48}$$

with

$$\delta = [1/2(G\theta_t)^2]\{[2G\theta_t+(4-G\theta_t)^2] - \sqrt{[2G\theta_t+(4-G\theta_t)^2]^2-4(G\theta_t)^2}\}.$$

Thus we can determine $G\theta_t$ from this relation and

finally k_{sap} from λ when $G\theta_t$ is given. As described above, the cot ψ *versus* E_{dc} curve has a minimum at E'_0 when $G\theta_t<-4$. In this case $\Delta E_{p/2}(\cot\psi)$ of Eq. 48 means a difference between the dc potentials at which the value of cot ψ is one-half that observed at $E_{dc}=E'_0$.

Finally since the sum of the parameters, $(a_{ii}+a_{ij})$, can be determined from the slope of a plot of ln k_{sap} against θ_t, the two parameters, a_{ii} and a_{ij}, can be determined when G is given.

Application of these simplified equations to the electrode processes of ferredoxins irreversibly adsorbed on the surface of the dropping mercury electrode[17] will be reported in a succeeding paper.

(Received March 13, 1978)

A molecular orbital (MO) approach to a radical-radical reacting system is proposed within the isolated molecule approximation. The interaction energy, ΔW, is defined as the sum of four components, Coulomb, exchange, charge transfer and polarization energies. The four terms are calculated in the recombination of two methyl radicals. The origin of the deformation of methyl radical ($D_{3h} \rightarrow C_{3v}$) and the rotational barrier (staggered→eclipsed) in the course of the recombination was found to be the exchange energy caused by the interaction of both doubly occupied MO's. The difference-density map shows the characteristic role of exchange and charge transfer interactions for charge redistribution.

The molecular orbital (MO) method has been found to be fairly satisfactory for describing a reasonable reaction path and the activation energy of ionic[1] and addition[2] reactions, but not those of radical-radical reactions. Multi-determinantal wave functions such as those obtained by the MCSCF[3] and natural orbital[4] methods have also been utilized. However, enormous computer time is required for molecules with size of chemical interest, and difficulty in convergence is sometimes encountered. In addition, the methods give no vivid orbital picture which appeals to organic chemists as regards the interpretation of reactivity. In view of the fact that the path of the radical-radical reaction does not yet seem to be understood theoretically,[5] a new means to analyze the mechanism with a clear orbital concept is desirable.

In 1968, two of us (K.F. and H.F.) proposed a method for the general reactivity index ("ΔW method") based on the isolated molecule approximation.[6] Various calculations of model reacting systems showed that the ΔW method is effective for interpreting the reactivity of closed-shell molecules.[7]

In view of the applicability of this method to the elucidation of the reaction mechanism and the necessity to investigate the radical-radical reaction theoretically, an extension of the method was carried out, the aim of the work being to simulate and analyze the reaction within the framework of the MO calculation. Since the ΔW method is based on the *static* model, dynamic processes in the reaction such as the relaxation of vibration energy are beyond the scope of the present approach.

Definition of Interaction Energy

The derivation of the interaction energy (ΔW) is based on the configuration interaction (CI) procedure in terms of the electronic structure of two independent radicals, essentially similar to the case of the reaction between two closed-shell molecules.[6] The wave function ($\Psi^{s,t}$) of the whole reacting system is represented by a linear combination of various configuration functions (Fig. 1).

$$\Psi^{s,t} = C_0\Psi_0^{s,t} + \sum_p C_p\Psi_p^{s,t} \qquad (1)$$

Each Slater determinant of $\Psi_0^{s,t}$ and $\Psi_p^{s,t}$ is composed of the MO's, a_l,[8] a_o, b_k, and b_o, which are the solutions of the doublet spin state of two *independent* radicals. Once they are included within one Slater determinant and the electron exchange between them is allowed, the non-orthogonality condition makes the evaluation of expected values difficult. The tedious derivation was carried out in this work. Configurations other than $\Psi_0^{s,t}$ in Eq. 1 are all possible one-electron transferred (from i→l to o→o′) and excited (from i→j to o′→l) ones which have the forms as the eigenstate of the spin augular momentum $\hat{S}^2$. The minimum total energy of $\langle\Psi^{s,t}|\mathbf{H}|\Psi^{s,t}\rangle/\langle\Psi^{s,t}|\Psi^{s,t}\rangle$ is determined by the secular equation according to the usual CI procedure. In order to get a succinct expression of the interaction energy (ΔW), the secular determinant is expanded perturbationally. We obtain ΔW in the following partitioned form.

$$\Delta W = E_Q + E_K - D - \Pi \qquad (2)$$

E_Q is the classical Coulombic energy and E_K the exchange energy caused by the overlap of the electron cloud between two radicals. These two are the first-order energies in the sense of the Rayleigh-Schrödinger perturbation. On the other hand, fourteen terms of the second-order perturbation form corresponding to the electron configurations (except $\Psi_0^{s,t}$) (Fig. 1) are divided into two groups, D and Π, according to the type of electron jumping. D is the stabilization energy due to the mixing of the one-electron transferred configurations and Π the stabilization energy by the one-electron excited configurations. ΔW is a general index of the reactivity for both singlet and triplet radical-radical interactions. This simplified form of interaction energy which can be grasped intuitively is based on the idea of *isolated molecule approximation.* The mode of molecular interaction is entirely dependent on the electronic structure of two monomers. In order to get a more explicit form of the four terms in Eq. 2, we rewrite them as the sum of various molecular integrals, taking into account the possible permutation of electrons within each Slater determinant. Thus, E_K, D, and Π are generally represented as a power series of the MO overlap (s_{ik}). As long as the interaction is weak enough to be dealt with by perturbation, the MO overlap of the high order caused by the multiple permutation is negligible. The validity of this

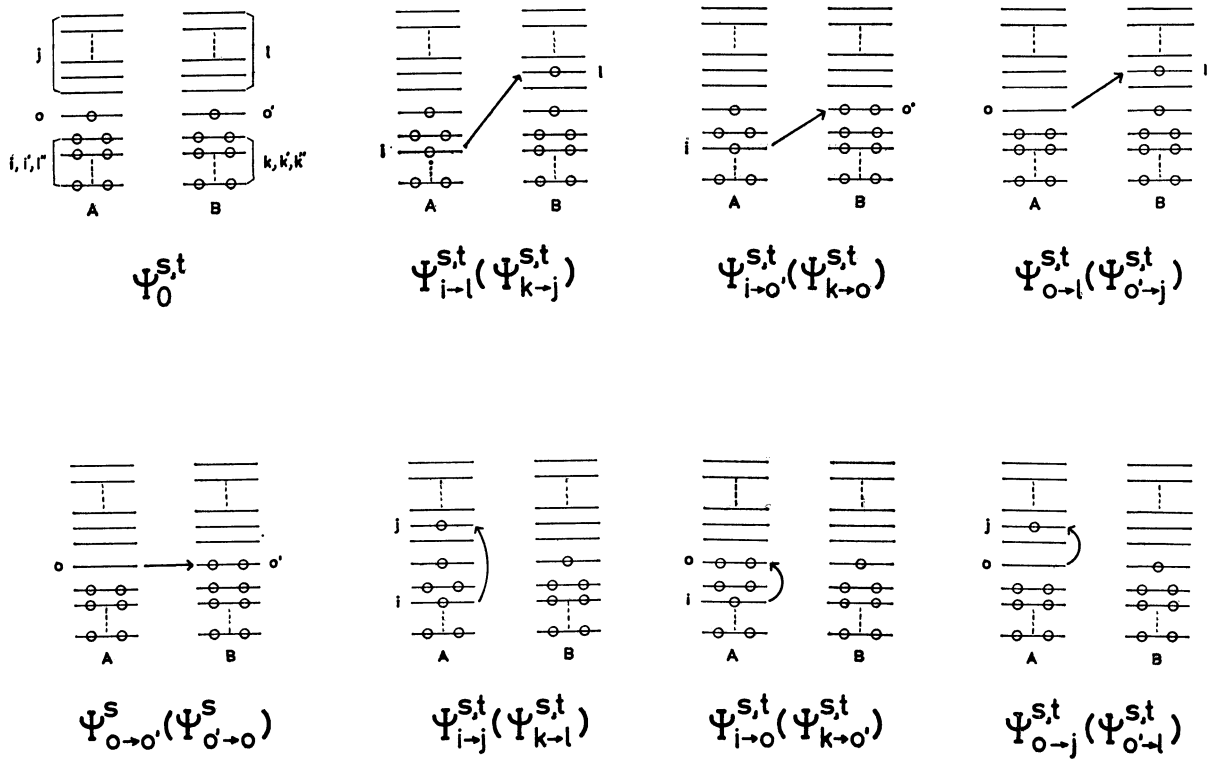

Fig. 1. Electronic configurations adopted for the present CI procedure. The "zero confiuration." $\Psi_0^{s,t}$, retains the original electronic structure at the infinite separation between two radical monomers, A and B.

truncation can be confirmed numerically by calculating some terms of MO overlap.

Coulomb Energy E_Q. This energy depends only on the occupation number of electrons in each MO regardless of the spin multiplicity of the system. The derivation is straightforward.

Exchange Energy E_K. In the present scheme, E_K can be partitioned into four pairs of occupied MO's.

$$E_K = E_K(i', k') + E_K(i', o') + E_K(o, k') + E_K(o, o') \quad (3)$$

Their schematic representation is shown in Fig. 2. $E_K(i',k')$ expresses the interaction between doubly occupied MO's, working repulsively. Both $E_K(i',o')$ and $E_K(o,k')$ are also repulsive energies (>0). Whether $E_K(o,o')$ is repulsive or attractive depends on the spin multiplicity of the system. When the spin coupling between the electrons of MO's, a_o and $b_{o'}$, gives the singlet state, $E_K(o,o')$ represents attraction, when it gives the triplet state, $E_K(o,o')$ represents repulsion.

Charge Transfer Energy D. D consists of eight different terms of the second-order perturbational form corresponding to charge-transferred configurations (Fig. 1). The difference in the normalization factors (*e.g.*, $\langle\Psi_{i\to l}^{s,t}|\Psi_{i\to l}^{s,t}\rangle$ and $\langle\Psi_0^{s,t}|\Psi_0^{s,t}\rangle$) for expected values are explicitly considered. For the sake of convenience, D is represented as the sum of eight components.

$$D = D(i\to l) + D(k\to j) + D(i\to o') + D(k\to o) + D(o\to l) + D(o'\to j) + D(o\to o') + D(o'\to o) \quad (4)$$

In line with the fact that $\Psi_{o\to o'}$ and $\Psi_{o'\to o}$ have only singlet spin state that can not mix with Ψ_0^t, the stabilization energies $D(o\to o')$ and $D(o'\to o)$ are zero for triplet. D is usually positive, acting as the stabilization energy in ΔW of Eq. 2. The denominator of each component of Eq. 4 becomes negative in some cases.[9]

Polarization Energy Π. In Eq. 2, the residual part of the second-order perturbational form, Π, consists of six different terms corresponding to local one-electron excited configurations (Fig. 1). Π can be represented by the sum of six components.

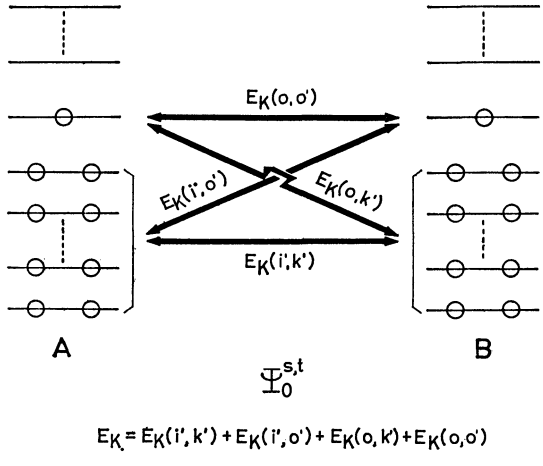

Fig. 2. The schematic representation of four types of exchange interaction. The reason why the doubly occupied MO's, i and k, have the prime in the figure is that exchange energy is caused by the electron permutation for which the prime is imposed on MO's.

$$\Pi = \Pi(\mathrm{i}\to\mathrm{j}) + \Pi(\mathrm{k}\to\mathrm{l}) + \Pi(\mathrm{i}\to\mathrm{o}) + \Pi(\mathrm{k}\to\mathrm{o}') + \Pi(\mathrm{o}\to\mathrm{j}) + \Pi(\mathrm{o}'\to\mathrm{l}) \quad (5)$$

Difference Density. The difference density map of the radical-radical reaction system visualizes the change of the electron density during the course of reaction. Here, the case of singlet interaction is dealt with. The spinless difference density $\Delta\rho(1|1)_{E_K}$ which includes the exchange interaction is derived by the use of Eq. (A.3),[10] and is partitioned into four components according to the decomposition of E_K in Eq. 3.

$$\Delta\rho(1|1)_{E_K} = \Delta\rho(1|1)_{E_K(\mathrm{i}',\mathrm{k}')} + \Delta\rho(1|1)_{E_K(\mathrm{i}',\mathrm{o}')} + \Delta\rho(1|1)_{E_K(\mathrm{o},\mathrm{k}')} + \Delta\rho(1|1)_{E_K(\mathrm{o},\mathrm{o}')} \quad (6)$$

The difference density including the exchange and charge-transfer interactions, $\Delta\rho(1|1)$, is also given as

$$\Delta\rho(1|1) = \mathrm{M}\int \Psi'^{s}(1,2,\cdots,\mathrm{M})\Psi'^{s}(1,2,\cdots,\mathrm{M})\mathrm{d}\xi_1\mathrm{d}\tau_2\cdots\mathrm{d}\tau_{\mathrm{M}} - \rho(1|1)_{\mathrm{A}} - \rho(1|1)_{\mathrm{B}} \quad (7)$$

where $\Psi'^{s}(1,2,\ldots,\mathrm{M})$ is the wavefunction of Eq. 1 without the six polarization-type configurations and M the total number of electrons of the system. $\Delta\rho(1|1)$ can be obtained numerically.[11]

Recombination of Methyl Radicals

As a test of the ΔW method, the recombination between two methyl radicals was examined. In the assumed model of the D_{3d} symmetry (*i.e.*, elongated staggered ethane), two variables (R and θ) are changed to simulate the reaction. R is the C···C distance and θ is the <HCC angle. The C–H bond length (1.079 Å)[12] of the monomer radical is kept constant throughout the calculation. The interaction energy is computed approximately in terms of the semi-empirical all-valence-electron UHF MO including overlap integrals. In a strict sense, the RHF MO which is the doublet spin eigenfunction should be employed as MO's, i, k, j, and so forth (Fig. 1). However, the MO gives unacceptable physical properties such as ionization potential and electron affinity. Since the orbital energy is crucial to evaluate the second-order terms (D and Π), we are obliged to use the UHF MO instead of the RHF MO. The former MO, although somewhat deviated from the spin eigenfunction, can reproduce the property well. The way of estimating semi-empirical parameters to evaluate MO integrals is the same as that used in a previous paper.[7a] Calculated results of the singlet ΔW along the approaching path of two radicals with plausible values of R and θ are given in Fig. 3a and Table 1 and those of the triplet ΔW in Fig. 3b and Table 2. R is restricted to the range 2.85 Å—2.40 Å, since the perturbational expansion of the CI matrix elements was used in this work. The two methyl radicals approach in an eclipsed manner (D_{3h}), the other models having D_{3d} symmetry.

First, the singlet ΔW is examined. E_Q is found to have a positive (repulsive) and small value throughout the adopted models (Table 1). Since the present neutral system consists of only carbon and hydrogen atoms, E_Q is obviously small, the positive value being caused by the C···C electrostatic repulsion, overcoming the C···H attraction.

The singlet E_K in Eq. 2 is also positive. Of its four components the largest (absolute value) at R=

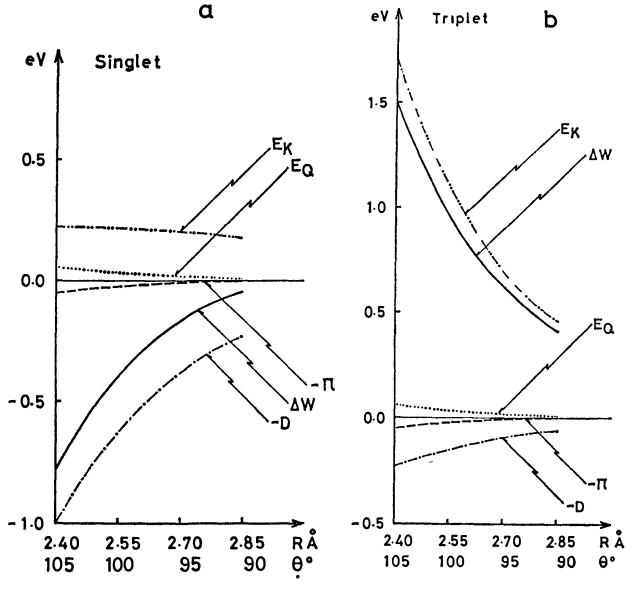

Fig. 3a. The change of the singlet interaction energies along the adopted staggered path with the deformation of the methyl-radical geometry. The deformation of methyl radical is found to smooth the increase of the global E_K as R becomes smaller, and consequently the stabilization of the system becomes large.

3b. The change of the triplet interaction energies along the adopted staggered path with the deformation of the methyl-radical geometry.

2.85 Å is E_K(i′,k′), while that at R=2.40 Å is E_K(o,o′). This shows that a_o-b_o' MO interaction grows discriminatively along the progress of the reaction. Such remarkable growth of a particular MO interaction plays a key role to determine the reaction path. Thus, the repulsive character of the exchange energy which is unfavorable to the enhancement of the reaction is considerably weakened by E_K(o,o′).

D is found to give the largest attractive energy throughout the adopted staggered models, the increase of the energy along the C···C approach being drastically large. It is noteworthy that D(i→l) [or D(k→j)] has a small value in spite of many (a_i,b_l) pairs. This is because both a_1 and b_1 do not have their spatial extension toward the intermolecular C···C region, the MO overlap between them thus being small. The strength of the MO overlap is a crucial criterion to determine the extent of the (a_i→b_l) charge transfer (CT) interaction. Since the "symmetry-forbidden" CT interaction (*e.g.*, from the a_1-symmetry MO of one radical to the e-symmetry MO of the other) has no contribution to D, the non-zero components of D(i→l) are actually limited to three. D(o→l) and D(o′→j) have also small values for the following reason. The singly occupied (SO) MO's, a_o and b_o', which are of $a_1(\sigma)$-symmetry, can overlap only one unoccupied a_1 MO with its spatial extension localized on three hydrogens. However, owing to the largest separation between the density of a_o (or b_o') and that of the one σ type a_1 MO, no effective CT interaction occurs. As for D(i→o′) [or D(k→o)] there is only one occupied $a_1(\sigma)$ MO with its substantial localization on the carbon 2s atomic orbital,[13] which is able to mix with the a_1 type MO, a_o or b_o'. Contrary to the case of D(i→l), the combination of a_1 and b_o' gives an appreciable MO overlap, s_{io}', resulting in the large value of D(i→o′) (Fig. 4a). The largest two equivalent CT terms, D(o→o′) and D(o′→o),

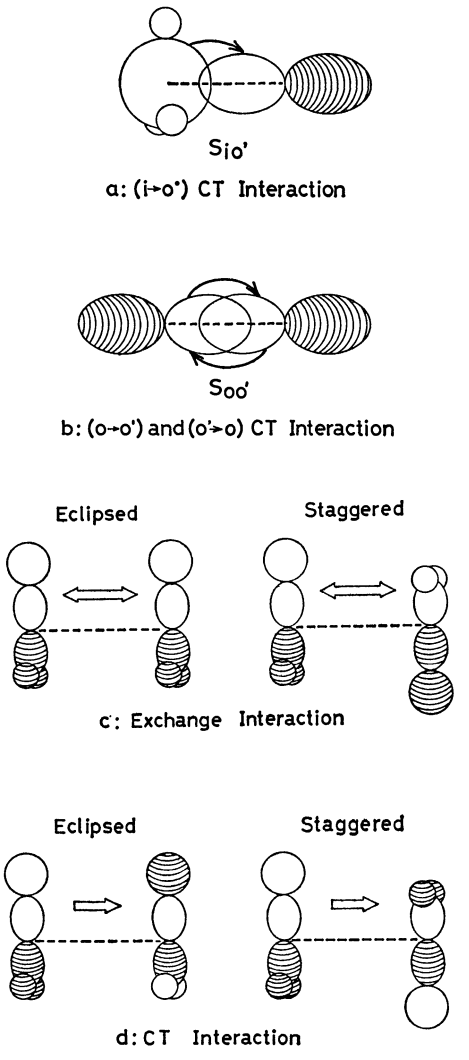

Fig. 4. Schematic representation of the mode of dominant MO interactions.

have their common origin from the huge MO overlap, s_{oo}', shown in Fig. 4b. In view of this, the MO overlap, s_{oo}', is a crucial factor to give the large stabilization energies, D(o→o′) and D(o′→o) as well as E_K(o,o′) in the case of singlet interaction. Thus, the important role of the particular MO interaction to control the reaction is demonstrated.

The polarization energy Π (Table 1) has the smallest absolute value among the four terms of ΔW regardless of the C···C distance R, reflecting the "neutral" character of the system without heteroatoms.

Summing up E_Q, E_K, D, and Π according to Eq. 2, we obtain the total singlet energy, ΔW (Table 1). Its value indicates that the electronic interaction energy gives considerable stabilization energy at the perturbational region between two radicals. Comparing the two ΔW's (θ=90° and 105°) at R=2.40 Å, we see a remarkable difference in E_K. Thus, the geometrical deformation of methyl radical (planar→pyramidal) in the course of the reaction brings about the decrease in the exchange repulsion resulting in the decrease of ΔW and ease in recombination. Terms other than E_K are not influenced so much by the θ variation. Of the four terms of E_K, E_K(i′,k′) of θ=90° differs a

great deal from that of $\theta=105°$ at $R=2.40$ Å. Thus, for the progress of the reaction it is very important to avoid the exchange repulsion of doubly occupied MO's by deformation. The enlargement of lobes of SOMO's (a_o and $b_{o'}$) which makes $E_K(o,o')$, $D(o\rightarrow o')$ and $D(o'\rightarrow o)$ more attractive terms is found to be a secondary factor for this acceleration. Even if the geometrical deformation is accompanied by the destabilization of the monomer total energy in its isolated state, it is covered entirely by the electronic stabilization energy.[14]

A comparison of the interaction energy between the D_{3d} staggered and the D_{3h} eclipsed models is made at $R=2.85$ Å. As expected, the staggered path gets more stabilization energy ($\Delta W=-0.0364$ eV) than the eclipsed path ($\Delta W=-0.0203$ eV). What is the origin of this rotational barrier in the course of the reaction? Comparing all the components of ΔW, we find that the sole component, E (i',k'), gives the energy difference. This is because the σ type MO overlap such as $s_{oo'}$ is insensitive to the rotation of the π type electronic cloud around the C···C σ axis. Only the π-π' type exchange interaction which is included in E_K(i',k') depends on the rotation angle. The mode of the MO overlap, the origin of E_K(i',k'),[15] for the two approaching models is shown in Fig. 4c. It is evident that the eclipsed approach gets the larger MO overlap than the staggered one. On the other hand, CT interaction does not give a large energy difference between the two approaches (Fig. 4d). The negligible difference in CT interaction arises from the nodal property of the π type unoccupied MO. Sovers and his coworkers made an extensive study on the internal rotation barrier of ethane by use of the bond-orbital wavefunction and concluded that the main source of the barrier is the overlap repulsion between localized C–H bond orbitals with the closed shell.[16] Although ethane itself is not dealt with in this work, the present result seems to help to elucidate the origin of the rotational barrier.

The sharp increase of ΔW is due mostly to E_K (Fig. 3b). This indicates that the triplet interaction makes the recombination (D_{3d}) path unfavorable. The triplet E_K (Table 2) differs considerably from the singlet E_K (Table 1). The greater destabilization due to the triplet E_K is ascribed to the change of the sign attached to $E_K(o,o')$. The minor difference of E_K(i',k'), E_K(i',o') and E_K(o,k') between singlet and triplet is due to that of the normalization factor of Ψ_0. Contrary to the case of singlet, the triplet a_o-$b_{o'}$ MO interaction contributes to the exchange energy as repulsive. The triplet D is much smaller than the singlet D, which is mostly due to the absence of both $\Psi^{s}_{o\rightarrow o'}$ and $\Psi^{s}_{o'\rightarrow o}$ configurations in Eq. 1. However, the triplet Π is almost the same as the singlet Π. The global term, ΔW, of triplet is positively large. This reflects the fact that two electrons with parallel spins can not occupy the same space (along the C···C axis) according to the Pauli exclusion principle.

The density distribution is analyzed in terms of the various difference densities given by Eqs. 6 and 7. Of the four terms of Eq. 6, $\Delta\rho(1|1)_{E_K(i',k')}$ of the singlet radical-radical interaction is shown in Fig. 5a. This is regarded as the electron rearrangement through the mutual overlap between both doubly occupied MO's, i' and k'. We see a large amount of decreased density in the C···C region. This quantity corresponding to the positive E_K(i',k') usually appears when the exchange interaction is taken up in the system of closed-shell molecules. Instead, the electron density, shifting from the central C···C region, is piled up around respective carbon and hydrogen atoms. In the case of $\Delta\rho(1|1)_{E_K(i',o')}$ (Fig. 5b), E_K(i',o') is the repulsive energy (Table 1). The repulsive character is reflected in the large area of the negative density along the C···C line (Fig. 5b). However, the center of the negative part is located almost at the left end of the C···C region. The shift of the region of the intermolecular decreased density is due to the fact that the differential MO overlap, i'(1)o'(1), which is the main origin of the $\Delta\rho(1|1)_{E_K(i',o')}$ has a maximum in the region. The trend always appears in the overlap between the s type and p type orbitals.[17] The counterpart of the decreased density is accumulated at each carbon site, which is similar to the case of $\Delta\rho(1|1)_{E_K(i',k')}$. As regards $\Delta\rho(1|1)_{E_K(o,o')}$ (Fig. 5c), since $E_K(o,o')$ is a considerable stabilization energy, $\Delta\rho(1|1)_{E_K(o,o')}$ is expected to give the large bonding density at the central C···C region, competing with the decrease by $\Delta\rho(1|1)_{E_K(i,'k')}$, $\Delta\rho(1|1)_{E_K(i',o')}$ and $\Delta\rho(1|1)_{E_K(o,k')}$. An egg-shaped increased density is observed in the middle of the C···C line. This also demonstrates the important role of the a_o-$b_{o'}$ MO interaction on bond formation. The decreased quantity opposing the drastic bonding density is found just around each carbon atom. Thus, the change in density distribution is interpreted as follows. The MO overlap, $s_{oo'}$, absorbs the electron density from the MO's a_o and $b_{o'}$.

Of the four components of $\Delta\rho(1|1)_{E_K}$ the origin of the geometrical deformation. ($D_{3h}\rightarrow C_{3v}$) of methyl radical is brought about by $\Delta\rho(1|1)_{E_K(i',k')}$ (Fig. 5-a).[18] The other three difference densities exhibit a nearly equivalent electron redistribution around both hydrogen and carbon atoms or represent only the motion of translation of the C–H bond. However, $\Delta\rho(1|1)_{E(i',k')}$ has a positive contour line just around the front side of the pyramidal methyl carbon which pulls the carbon atom so as to decrease the C···C distance,[19] whereas the hydrogen atom does not move toward any direction. The discussion based on the "force" criterion[20] is in line with the result of interaction energy. E_K(i',k') affects mostly nuclear deformation of the methyl radical among the four energy terms of E_K.

The change of the electron distribution due to the exchange and CT interactions in Eq. 7 is shown in Fig. 5d. No polarization interaction is taken into account in the present analysis, since the reacting system is neutral and the interaction is not so important. A huge accumulation of the intermolecular bonding density in the central C···C region is noteworthy. As compared with that of $E_K(o,o')$, the global bonding density in the C···C region is much more increased. This indicates the significant role of the $a_o\rightarrow b_{o'}$ and

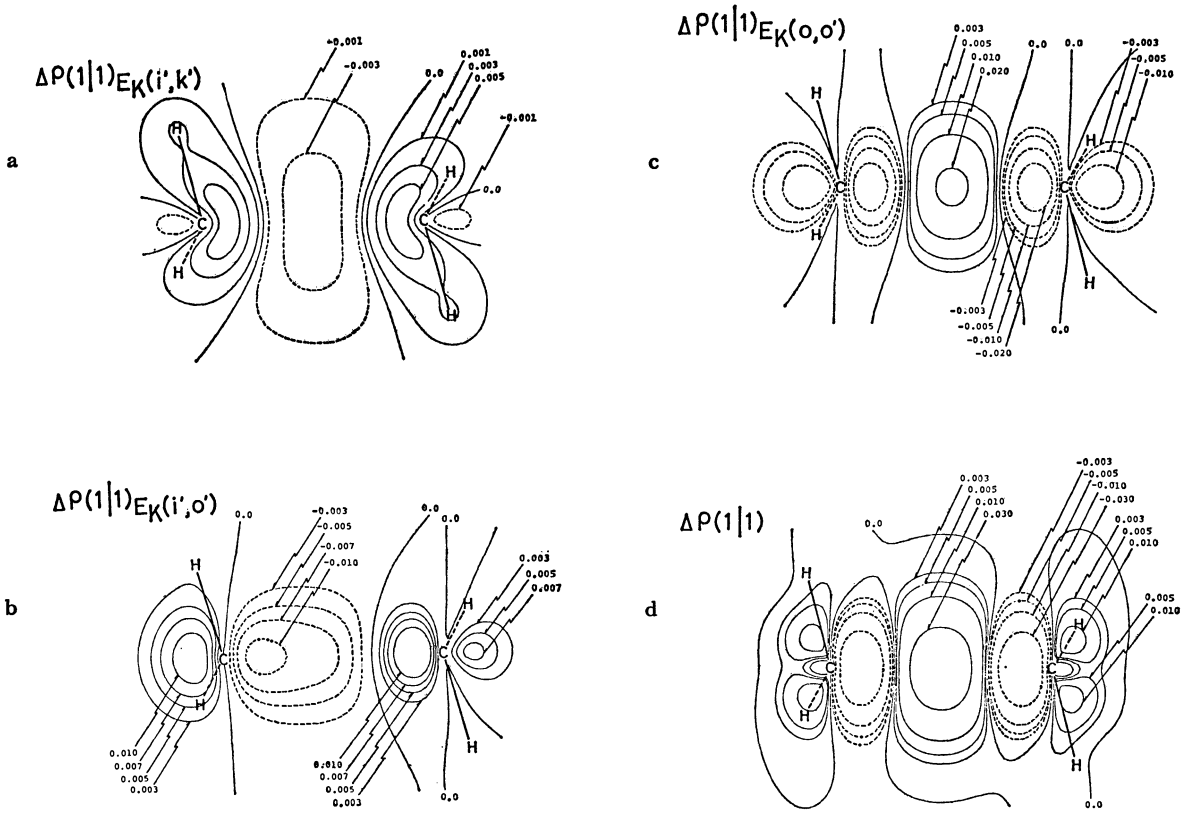

Fig. 5a. The difference density map of $\Delta\rho(1|1)_{E_K(i',k')}$ for the singlet interaction. The value attached to each contour line is in $e/Å^3$.

5b. The difference density map of $\Delta\rho(1|1)_{E_K(i',o')}$ for the singlet interaction. The map of $\Delta\rho(1|1)_{E_K(o,k')}$ is obtained through the 180° rotation of this figure around the center of C···C line in the cut plane.

its reverse $b_o' \rightarrow a_o$ CT interactions to pile up the density. The decreased density which sandwiches the central increased density arises, to a great extent, from the exchange interaction, $\Delta\rho(1|1)_{E_K(o,o')}$.

Conclusion

In the present work, a means to investigate the mode of interaction between two radicals has been proposed. The interaction energy, ΔW, has been partitioned into four terms, E_Q, E_K, D, and Π.

As a result of analysis of its four components for the $CH_3 \cdots CH_3$ reaction, the ease of the recombination in this neutral system is attributed to the SOMO–SOMO interaction. If the deformation ($D_{3h} \rightarrow C_{3v}$) is added to each methyl radical, the singlet W gains a greater stabilization. The deformation enlarges the a_o-b_o' MO interaction and reduces the exchange repulsion between both doubly occupied MO's. The latter effect in particular is remarkable. The rotational barrier between staggered and eclipsed approaches was examined and found to be almost due to the exchange interaction of both doubly occupied MO's.

A density map of the same system has been constructed, in order to examine the role of the four components of E_K. Accumulation of the bonding density in the $\Delta\rho(1|1)_{E_K(o,o')}$ is remarkable, contributing to the new C–C bond formation.

Since the present study is made within the scope of perturbation procedure with the use of semi-empirical MO, each term calculated so far should be regarded as qualitative. The ΔW method employed simplifies the reaction as a static model, the energy obtained thus having hardly anything to do with measurable property. In spite of these handicaps, the present method seems to give an idea of how to interpret and understand the radical-radical reaction in terms of the partitioned energies. Applicability of the orbital picture to this reaction could be successfully demonstrated. We may take up two important types of interaction contributing to the progress of recombination, $E_K(i',k')$ which has a role to deform the monomer radical, and the a_o-b_o' MO overlap [$E_K(o,o')$, $D(o \rightarrow o')$, and $D(o' \rightarrow o)$] which operates to make the new C···C bond.

Permission to use the FACOM 230-75 computer at the Data Processing Center of Kyoto University is gratefully acknowledged. The MO calculations were carried out with Grant-in-Aid No. 139012 from the Ministry of Education.

(Received December 26, 1978)

The temperature dependences of reorientational and vibrational relaxation times of benzene and benzene-d_6 in the solid and liquid phases were measured by means of Raman line shape analysis. The temperature dependence of the reorientational relaxation times was in very good agreement with that published previously. The vibrational relaxation times of benzene changed drastically at the solid to liquid phase transition point both in C_6H_6 and C_6D_6. We consider that this effect is due to the non-radiative energy transfer and the pure dephasing process by molecular collisions in the liquid state.

Some time ago, the ultrasonic technique was the only method available to measure the vibrational relaxation times of molecules in the liquid state.[1] However, more recently some other methods have been used to study the molecular orientational and vibrational relaxation processes in the liquid phase. In particular, it is known that one may analyse separately the effects of reorientational and vibrational motions from the profiles of the isotropic and anisotropic Raman scattering. Also, spectroscopic techniques using high powered pulsed laser have been applied to the investigation of vibrational relaxation in liquids.[2-5]

Recently, Griffiths, Clerc, and Rentzepis applied the Raman and picosecond pulsed spectroscopic methods to study the intermolecular vibrational energy transfer between C_6H_6 and C_6D_6.[6]

Several mechanisms may contribute to the shape of the vibrational correlation function, but the two most common interpretations are energy relaxation to lower vibrational levels (the lowest of which is the ground vibrational state) through a collisional non-radiative mechanism, and phase relaxation, which also involves a collision induced process. Both mechanisms are subject to molecular collisions in the liquid phase.

An intuitive argument suggests that the molecules in the solid phase freeze out orientational motions and collisions, which are effective for the exchange of the energy. Therefore the vibrational relaxation time in the solid state is expected to be much longer than in the liquid state. A discontinuity in the vibrational relaxation times is expected at the solid-liquid phase change.

In this work, we report the experimental results of the temperature dependence of the reorientational and vibrational relaxation times of C_6H_6 and C_6D_6 in solid and liquid phases and discuss the process of the vibrational energy transfer of C_6H_6 and C_6D_6 in the liquid phase.

Experimental Details and Data Analysis

The apparatus used consisted of an argon ion laser (800 mW at 488 nm) produced by the Coherent Radiation Co., Ltd., and a Laser Raman Spectrometer of JRS-U1 type JEOL, Ltd., Japan.

In order to obtain the reorientational and vibrational relaxation times, the Raman line shapes of the $\nu_2(a_{1g})$ and $\nu_1(a_{1g})$ fundamental modes of ring and C–H or C–D stretching were analyzed. The Raman spectrum was observed at 90° with respect to the linearly polarized incident light. With $I_{\parallel}(\omega)$ and $I_{\perp}(\omega)$ respecting the strong and weak components of the scattered light, one can write:

$$I_{\parallel}(\omega) = I_{\mathrm{isot}}(\omega) + 4/3\, I_{\mathrm{anis}}(\omega) \quad (1)$$

$$I_{\perp}(\omega) = I_{\mathrm{anis}}(\omega) \quad (2)$$

$$\rho_s = I_{\perp}(\omega)/I_{\parallel}(\omega) \quad (3)$$

where ρ_s is the depolarization ratio. $I_{\mathrm{isot}}(\omega)$ represents the intrinsic vibrational line shape, and $I_{\mathrm{anis}}(\omega)$ is a convolution of the vibrational line shape and the orientational spectrum.

The Raman lines of C_6H_6 and C_6D_6 were measured using a constant mechanical slit width, 30 μm. The Raman bands obtained are broadened by the slit and the spectrum measured is a convolution of the true Lorentzian spectrum and the slit function, $S(\omega)$. As the spectral slit function is well approximated by a Gaussian function,[7] one can write

$$I(\nu) = N\int_{-\infty}^{\infty} \frac{1}{\beta_L^2 + (\nu-\nu')^2} \exp\left\{-\left(\frac{\nu'}{\beta_g}\right)^2\right\} d\nu' \quad (4)$$

where β_L is the true half-width and $\beta_g = S/2\sqrt{\ln 2}$,[8] where S is the spectral slit width; $S = 0.741\ \mathrm{cm^{-1}}$ at 30 μm. By curve fitting of Eq. 4 to the measured spectrum, we determined the true half-width β_L of each measured Raman line. $\omega_{\mathrm{isot}}(1/2)$ and $\omega_{\mathrm{anis}}(1/2)$, hereafter, refer to the true half-width, β_L, of the isotropic and anisotropic Raman line, respectively. From $I_{\parallel}(\omega)$ of the $\nu_2(a_{1g})$ band of C_6D_6 in the liquid phase, the $\omega_{\mathrm{isot}}(1/2)$ obtained was $0.73\ \mathrm{cm^{-1}}$, corresponding to a vibrational relaxation time of 7.42×10^{-12} s. This value is in excellent agreement with that obtained by Griffiths *et al.* from direct measurements using picosecond spectroscopy and the Raman line width.

Temperatures were in the range from −50 to 60 °C. A variable temperature Raman cell of the Harney-Miller type was used.

Results

The temperature dependence of $\omega_{\mathrm{isot}}(1/2)$ and $\omega_{\mathrm{anis}}(1/2)$ of ν_1 and ν_2 bands of C_6H_6 are shown in Fig. 1 and those of ν_1 and ν_2 bands of C_6D_6 are shown in Fig. 2, together with the values obtained by Griffiths *et al.*[9] In Figs. 1 and 2, in the solid phase, $\omega_{\mathrm{anis}}(1/2)$ apparently equals $\omega_{\mathrm{isot}}(1/2)$ for C_6H_6 and C_6D_6 at each Raman line but, as pointed out by many workers,[10,11] we can not directly reduce the above relation in the crystalline state from this experimental

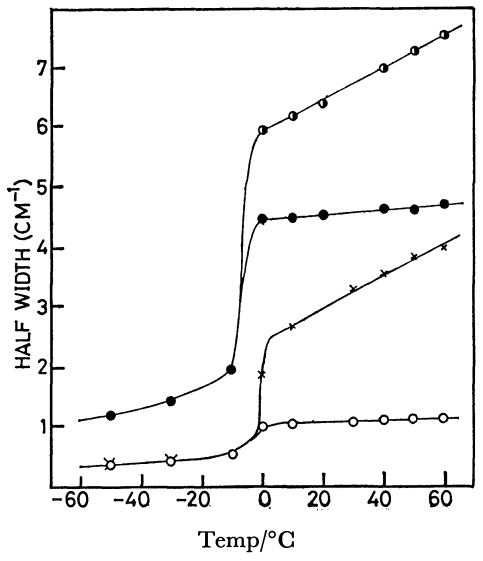

Fig. 1. Temperature dependences of half-width of ν_1 and ν_2 bands of C_6H_6. ●; $\omega_{isot}(1/2)$ of ν_1 band, ◑; $\omega_{anis}(1/2)$ of ν_1 band, ○; $\omega_{isot}(1/2)$ of ν_2 band, ×; $\omega_{anis}(1/2)$ of ν_2 band.

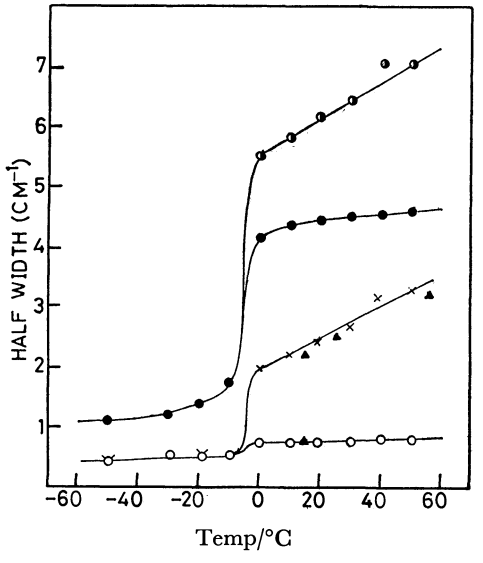

Fig. 2. Temperature dependences of half-width of ν_1 and ν_2 bands of C_6D_6. ▲; $\omega_{anis}(1/2)$ of ν_2 band (Griffiths *et al.*) and the other symbols are the same as those in Fig. 1.

data. However, as the Raman intensities of the isotropic light were very much stronger than those of the anisotropic light, the values of $\omega_{isot}(1/2)$ in the solid state may be considered significant.

As is seen in Figs. 1 and 2, the values of $\omega_{isot}(1/2)$ are dependent on the vibrational modes and increase slightly with increasing temperature in the solid and liquid phases.

From these results, we can obtain the vibrational and reorientational relaxation times from the following equations:

$$\tau_v = (2\pi c\omega_{isot}(1/2))^{-1} \quad (5)$$

$$\tau_{or} = (2\pi c\omega_{or}(1/2))^{-1} \quad (6)$$

where $\omega_{or}(1/2)=\omega_{anis}(1/2)-\omega_{isot}(1/2)$.

Discussion

Reorientational Relaxation Times of C_6H_6 and C_6D_6. The relationship between ln τ_{or} and $10^3/T$ is shown in Fig. 3. As is seen in Fig. 3, the reorientational relaxation times of C_6H_6 and C_6D_6 obtained from the ν_2 bands are in good agreement with those obtained from their ν_1 bands. The isotope effect, $\tau_{or}(C_6D_6)/\tau_{or}(C_6H_6)=1.102$, is in good agreement with the value calculated for the small step Brownian diffusion (1.10).

The relationship between ln τ_{or} and T can be expressed by

$$\ln \tau_{or} = A + \Delta U/RT \quad (7)$$

The values of ΔU are 2.83 and 2.76$_4$ kcal/mol for C_6H_6 and C_6D_6, respectively. These values are in very good agreement with those published previously.[9]

Vibrational Relaxation Times of ν_1 and ν_2 Modes. As is seen in Figs. 1 and 2, the half-widths of ν_2 fundamentals in C_6H_6 and C_6D_6 are 1.09 and 0.72 cm^{-1} at 30 °C and slightly depend on the temperature.

Griffiths *et al.* explained this difference as follows.[6] During collisions, the vibrational energy from one molecule is more readily transferred to a lower neighboring energy level in a second molecule if the vibrational energy levels are close together. In C_6H_6, there are two vibrational levels, ν_7 at 985 (b_{2g}) and ν_{19} at 970 (e_{2u}) cm^{-1}. During collisions, the near resonance energy condition would favor the non-radiative transition. On the contrary, the closest level in C_6D_6 is the $\nu_{17}(e_{2g})$ fundamental at 867 cm^{-1}. The energy difference between the $\nu_2(a_{1g})$ and the $\nu_{17}(e_{2g})$ fundamental modes is $\Delta E=78$ cm^{-1} in C_6D_6. This value is much larger than the energy differences $\Delta E=6$ cm^{-1} between the $\nu_2(a_{1g})$ and the $\nu_7(b_{2g})$, and $\Delta E=21$ cm^{-1} between the $\nu_2(a_{1g})$ and the $\nu_{19}(e_{2u})$. Therefore, in C_6D_6 a non-radiative transition such as is observed in C_6H_6 should not contribute significantly to a change in life time of the ν_2 state of C_6D_6. Although there is one more level, $\nu_6(b_{1u})$, at 963 cm^{-1} near the ν_2 fundamental, this excitation energy level is higher

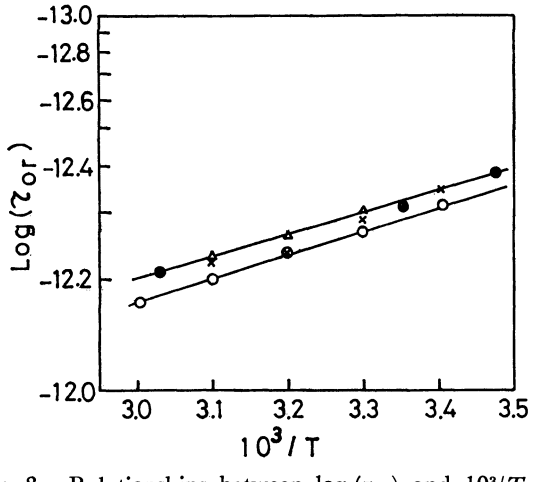

Fig. 3. Relationships between log (τ_{or}) and $10^3/T$. ○; C_6H_6, obtained from ν_2 band, ●; C_6D_6, obtained from ν_2 band, △; C_6D_6, Griffiths *et al.*, ×; C_6D_6, obtained from ν_1 band.

than ν_2 at 945 cm^{-1}; so this level may not contribute significantly to the relaxation mechanism of the ν_2 mode of C_6D_6.

At the transition point, the values of $\omega_{isot}(1/2)$ for C_6D_6 changed from 0.52 in solid state to 0.72 cm^{-1} in liquid state. This broadening can only be interpreted by considering some other mechanisms besides those proposed by Griffiths *et al.*

Similarly, as is seen in Figs. 1 and 2, the half-widths of the ν_1 fundamental mode are broader than those of the ν_2 mode in liquid phase. The differences in $\omega_{isot}(1/2)$ of ν_1 solid and liquid phases are about 2.8 cm^{-1}, which is about 6 and 10 times those of the ν_2 band of C_6H_6 and C_6D_6, respectively.

As mentioned above, there is one more dominant mechanism which contributes to the vibrational relaxation, that is, the phase relaxation or so-called "pure dephasing process,"

Fischer and Laubereau[12] have presented the following expression for the vibrational dephasing relaxation time:

$$\tau_{ph} = \frac{2}{9}\frac{M^2\omega^2L^2}{\mu\gamma^4k_BT}\tau_c \tag{8}$$

where M is the reduced mass of the oscillator with frequency ω, and L measures the range of interactions between colliding molecules. The μ and γ are parameters defined by them.[12]

As a first approximation, the energy dissipation and pure dephasing which are caused by the molecular collisions in liquid phase are considered to be an independent process. The vibrational relaxation time of this mechanism, τ_v', can be written as follows:

$$1/\tau_v' = 1/\tau_{ph} + 1/\tau_e \tag{9}$$

in a practical case, $(1/\tau_v')$ can be estimated from the difference of $\omega_{isot}(1/2)$ between the solid and the liquid phase. In ultrasonic studies of liquid C_6H_6 and C_6D_6, the relaxation process was found to have the frequency of about 2 GHz.[13,14] This relaxation has been considered to be due to the vibrational process. The total relaxation strength of the ultrasonic relaxation was found to be in very good agreement with those calculated from the Einstein equation, assuming the relaxation to be that of vibrational specific heats. From these ultrasonic data and a liquid model, τ_e in Eq. 8 can be estimated as about 0.79×10^{-13} s.[1]

Recently, Tanabe and Jonas have reported that the line broadening effects of Raman lines can be interpreted by the pure dephasing model as caused by the molecular collisions in the liquid phase, using Eq. 8.[15,16] The values obtained are summarized in Table 1. The vibrational relaxation mechanism of ν_2 band in the liquid C_6H_6 involves the non-radiative transition mentioned above. So, as is seen in Table 1, the difference of the $\omega_{isot}(1/2)$ of ν_2 band between in C_6H_6 and C_6D_6, about 0.3 cm^{-1}, can be considered to be due to the non-radiative transition mechanism proposed by Griffiths *et al.* In the case of ν_1 band, the value of δ_v' of C_6H_6 is comparable to that of C_6D_6.

As indicated in Table 1, the values of δ_v' obtained in this experiment are quite different from those of δ_{ph} estimated from Eq. 8. In the dephasing mechanism explained by Eq. 8, a binary collision is assumed and only the repulsive part of the intermolecular potential is considered. Intrinsically, the above dephasing mechanism should be applied to the diatomic molecule. In a polyatomic molecule such as benzene, the interactions between intramolecular modes should be involved. Recently, the vibrational dephasing of polyatomic molecules was treated by the intermolecular vibrational energy exchange model.[17] In the exchange model, the dephasing arises from random modulation of the vibrational frequency caused by intramolecular anharmonic coupling to low frequency modes which are undergoing intermolecular energy exchange with the bath. Therefore, the δ_v' obtained in this experiment could not be explained by the dephasing mechanism expressed by Eq. 8.

Table 1. Estimated vibrational widths (cm^{-1})

Mode	Assignment	C_6H_6		C_6D_6	
		δ_v'	δ_{ph}	δ_v'	δ_{ph}
$\nu_1(a_{1g})$	C-H or C-D stretching	2.8	6.3_5[a]	2.8	3.5_5[a]
$\nu_2(a_{1g})$	C-C stretching	0.5	0.4_0[a]	0.2	0.4_5[a]

a) The dephasing widths calculated by Tanabe and Jonas.[15]

$\delta_v' = (2\pi c\tau_v')^{-1}$ and $\delta_{ph} = (2\pi c\tau_{ph})^{-1}$.

In the C–H or C–D stretching vibration region, there are a few Raman forbidden bands; for example, the 2264 and 2294 cm^{-1} bands which lie close to ν_1 band of C_6D_6. At this stage, it is impossible to rule out the energy transfer mechanism due to the non-radiative transition as in the case of ν_2 band of C_6H_6.

As indicated above, the vibrational relaxation mechanism of benzene is very complicated. Further theoretical and experimental investigations are needed and continuing.

The authors are grateful to Prof. D. Nakamura of Nagoya University for many stimulating discussions. This work was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Resistmetric Study of the Potential-sensitive Surface Layer Formed on VO_2 Electrode in a Neutral Solution

Toyohisa NAKAMURA* and Shiro HARUYAMA**

Technical High School, Faculty of Engineering, Tokyo Institute of Technology, 3-3-6, Shibaura, Minato-ku, Tokyo 108

***Faculty of Engineering, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152*

(Received December 27, 1978)

The formation of a potential-dependent surface layer on VO_2 electrode has been investigated from the change in conductance of a thin VO_2 film electrode by galvanostatic polarization. The VO_2 electrode dissolved as vanadate with 100% current efficiency by anodic polarization. At potentials negative to the immersion potential, the VO_2 electrode functioned as an insoluble electrode with the formation of the potential-dependent surface layers of the vanadium oxides by lower valence. The change in composition of the surface layers was traced by resistmetry and coulometry, and illustrated against the amount of electric charge passed, taking V_7O_{13}, V_6O_{11}, V_5O_9, V_4O_7, V_3O_5, and V_2O_3 as the possible oxides. The composition at vanadium oxides of outer-most layer was plotted against the electrode potential. The plot shows a multi-step figure as in the equilibrium partial pressures of oxygen on vanadium oxides at high temperatures, suggesting a model in which the composition of the outer-most layer of the oxide responds to the electrode potential applied.

Resistmetry, a method based on the resistance measurement of a thin film electrode, was first applied to the studies of anodic oxide film on metals by Haruyama and Tsuru[1-4] as an *in-situ* method of measuring the thickness and the electric properties of anodic oxide film.

The potentiostatic transient current on VO_2 electrodes in the cathodic potentials between -0.30 and -1.00 V (SCE) decreases in proportion to the inverse of time asymptotically, the stationary cathodic being below 10^{-5} A/cm^2.[5] In this potential region, the VO_2 electrode functions as an insoluble electrode. A similar behavior has often been observed on transition metals in passive potentials, anodic current flowing in this case.

Iron in passive potentials carries a thin duplex oxide film which consists of an outer γ-Fe_2O_3 and an inner Fe_3O_4 layer.[4-6] It was found by resistmetric studies on passive iron that the structure of the cation-vacant outer-most layer responds to the applied potential.[4] We have applied resistmetry to the thin VO_2 electrode in order to establish the structure of the surface layer formed at the potentials negative to the immersion potential, where the VO_2 electrode works as an insoluble electrode.

Method

When no dissolution process takes place, cathodic polarization of VO_2 electrode yields a thin oxide layer with lower valence on the surface. The conductance of a VO_2 film electrode changes during the course of cathodic reduction. The total conductance of the film electrode is assumed to be the sum of the conductance of the VO_2 substrate and that of the surface layers thus formed. The conductance of each layer is given by

$$K_j = 1/R_j = wt_j/\rho_j l, \tag{1}$$

where t_j and ρ_j are the thickness and the resistivity of j-th layer, respectively, w and l are the width and length of the electrode, respectively. Thus, when a vanadium oxide VO_n is reduced giving VO_{n-x} according to the electrochemical reaction

$$VO_n + 2xH^+ + 2xe^- = VO_{n-x} + xH_2O, \tag{2}$$

the change in conductance Δk_1 during the reduction is given by

$$\Delta k_1 = \frac{W}{2xFl}\left[\frac{M_{n-x}}{\sigma_{n-x}\rho_{n-x}} - \frac{M_n}{\sigma_n\rho_n}\right]Q_1, \tag{3}$$

where M is the molecular weight, ρ the electric resistivity, σ the density, Q the amount of charge passed (C/cm^2), x the number of electron concerned, and suffixes n and $n-x$ represent VO_n and VO_{n-x}, respectively. When the VO_{n-x} formed is reduced to $VO_{n-(x+y)}$,

$$VO_{n-x} + 2yH^+ + 2ye^- = VO_{n-(x+y)} + yH_2O, \tag{4}$$

the change in conductance Δk_2 dealing with Eq. 4 is given by

$$\Delta k_2 = \frac{w}{2yFl}\left[\frac{M_{n-(x+y)}}{\sigma_{n-(x+y)}\rho_{n-(x+y)}} - \frac{M_{n-x}}{\sigma_{n-x}\rho_{n-x}}\right]Q_2, \tag{5}$$

Therefore, the change in conductance Δk ($=\Delta k_1+\Delta k_2$) caused by the reactions of Eqs. 2 and 4 is given by

$$\frac{Q_1}{x}\left[\frac{1}{\rho_{n-x}} - \frac{1}{\rho_n}\right] + \frac{Q_2}{y}\left[\frac{1}{\rho_{n-(x+y)}} - \frac{1}{\rho_{n-x}}\right] = \frac{2Fl\sigma\Delta k}{Mw}, \tag{6}$$

$$Q_1 + Q_2 = Q, \tag{7}$$

where Q represents the total amount of charge passed.

Since the resistivities of vanadium oxides differ a great deal from each other in comparison with the differences in the molecular weight or the density of oxides, the latter differences can be neglected. Thus, we have

$$M \fallingdotseq M_{n-x} \fallingdotseq M_{n-(x+y)} \tag{8}$$

$$\sigma \fallingdotseq \sigma_{n-x} \fallingdotseq \sigma_{n-(x+y)} \tag{9}$$

According to Eqs. 6 and 7, it is possible to separate Q into Q_1 and Q_2 by using the Δk *vs.* Q diagrams and the data of resistivity of oxides. The change in the composition of surface layer of the VO_2 electrode during the course of galvanostatic polarization can be estimated from the k *vs.* time curve and chronopotentiogram. A similar treatment is also possible for the anodic oxidation of the surface layer in a reduced

state.

Experimental

Specimen. The VO_2 film electrode was prepared by the dry oxidation of a vanadium foil. A pure vanadium foil (99.98%) of 0.125 mm thick was oxidized at first in a stream air (1.2 m^3/h) at 873 K for 4 h. The X-ray diffraction pattern of the oxidized surface layer of vanadium shown in Fig. 1-A indicates that the oxidation product consists of V_2O_5, V_6O_{13}, and VO_2. The oxidized vanadium was then reduced in a stream of SO_2 gas (1.2 m^3/h) at 773 K for 2 h. The oxide layer changed to a single phase of VO_2 (Fig. 1-B).[7-8] Since the oxidation process proceeds *via* the vacancy diffusion mechanism, a number of voids should be concentrated at the metal-oxide boundary. The oxide layer can be easily removed from the metallic substrate. In order to prepare the VO_2 film electrode, the oxidized vanadium sample was covered first with an epoxy resin, and then with an acryl resin plate. After the elapse of 12 h for the solidification of the epoxy resin, the VO_2 layer was taken off with the acryl plate from the vanadium substrate. The dimension of the VO_2 electrode thus prepared was 0.015×0.02 m and 10^{-5} m thick. Both ends of the specimen were connected to lead wires by an electric conductive cement and then covered with epoxy resin. The electrode surface was a sort of cleavage surface of black color and moderate brightness.

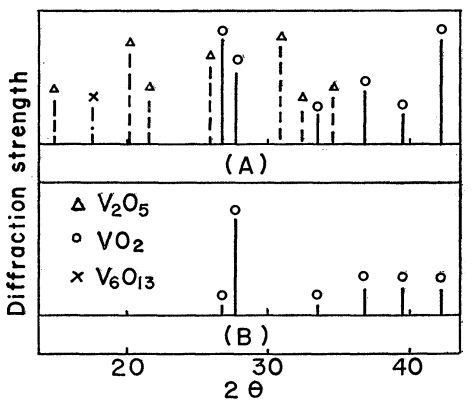

Fig. 1. X-Ray diffraction patterns of vanadium oxides. Preparation of specimen; (A) oxidation of vanadium in air at 873 K for 4 h; (B) reduction of specimen (A) in SO_2 at 773 K for 2 h.

Solution. A mixture of 0.2 mol/l boric acid and 0.05 mol/l sodium borate solution (pH 8.39) was used as an electrolyte solution. Reagent grade chemicals and twice-distilled water were used to prepare the solution. The solution was kept in a storage vessel and deaerated for more than 20 h by bubbling nitrogen gas purified through an active copper bed at 473 K. The solution was transferred from the vessel to the cell or removed from the cell under a nitrogen atmosphere.

Electrical Circuit. The electrical circuit of the resistance measurement is shown in Fig. 2. The change in conductance of the film electrode was traced by recording the unbalanced output voltage of the bridge through a pre-amplifier and a rectifier. The a-c signal between both ends of the film electrode was maintained below 0.005 V in order to minimize an undesirable change in film composition and the by-pass current through the solution. Polarization experiments were carried out with an electronic galvanostat and a counter

electrode made of a platinum plate. The potential of the film electrode was measured against a saturated calomel electrode *via* a Luggin capillary and a salt bridge. A two-pen recorder was used to record the change in both the potential and the conductance of the film electrode.

Procedure. All the experiments were carried out after anodic treatment at a constant current density of 10^{-5} A/cm^2. After the electrolyte solution had been replaced, the specimen was polarized cathodically at 10^{-5} A/cm^2. The VO_2 electrode did not dissolve except at the final stage of the anodic polarization. The amount of vanadium ion dissolved was analyzed by a colorimetric analysis using the 4-(2-pyridylazo) resorcinol method.[9] The experiments were carried out under a nitrogen atmosphere at 298 K. In order to confirm semiconductive property, the experiment was carried out also under illumination with a 500 W lamp. Illumination effected neither the potential nor the conductance of the film electrode.

Results

Chronopotentiogram of VO_2 Electrode. The VO_2 electrode did not dissolve, functioning as an insoluble electrode at the potentials negative to 0.05 V (SCE) in a solution of pH 8.39.[5] The potentiostatic transient current decreased in proportion to the inverse of time.[5] This indicates the formation of an oxide layer with low valence on the VO_2 electrode, since a similar transient phenomenon is often observed in a film-forming reaction.[6] The VO_2 film electrode was cathodically reduced at first until the potential reached a certain value and then anodically oxidized at a constant current density of 10^{-5} A/cm^2. The chronopotentiograms of the galvanostatic polarization of the VO_2 electrode are shown in Fig. 3. The cathodic polarization of VO_2 electrode was terminated at various potentials, followed by anodic polarization. In the initial periods of cathodic polarization, the potential decreased steeply toward the negative direction to reach E_1, then showing an asymptotic behavior. The chronopotentiogram of the succeeding anodic polarization exhibits two potential arrests E_2 and E_3. Potential E_3 corresponds to a stationary state of the anodic polarization where the anodic dissolution of VO_2 occurred. The amount of electric charge relating to the arrest E_2 increases with the extension of the periods of cathodic polarization.

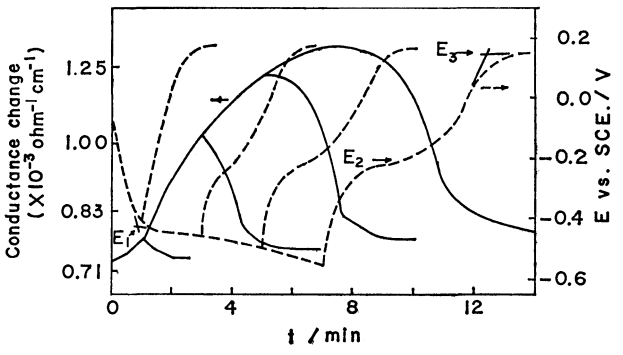

Fig. 3. Change in potential and conductance of VO_2 film during cathodic and anodic polarization at 10^{-5} A/cm².
Solid lines —— conductance change; dashed lines – – potential change.

Anodic Dissolution of VO_2. The VO_2 electrode dissolved at the final stage of anodic polarization. In order to determine the dissolution scheme, the solution after the anodic polarization was examined by colorimetry. The amount of vanadium dissolved and that of the electric charge passed are summarized in Table 1, together with the calculated value of the number of electron in the anodic dissolution of VO_2 electrode. The sample solution for the spectrophotometric analysis was prepared by the anodic dissolution of the VO_2 electrode at a constant current density of 5.0×10^{-5} A/cm² for 21 min. The expected concentration of vanadate(V) was 4.1×10^{-5} mol/l. The absorbance curve of the solution, shown in Fig. 4, is in good agreement with the data of vanadate HVO_4^{2-} reported by Newman *et al.*[10] The anodic dissolution of VO_2 (Fig. 4 and Table 1) proceeds with one electron,

$$VO_2 + 2H_2O = HVO_4^{2-} + 3H^+ + e^-. \quad (10)$$

Change in Conductance on VO_2 Film Electrode During Galvanostatic Polarization. The change in conductance of the VO_2 film electrode during polarization is plotted against the amount of charge passed in Fig. 3, together with corresponding change in potential. In the initial periods of polarization where a steep change in potential is observed, the conductance changes slowly with time. After the potential reaches the arrest E_1, the conductance increases steeply, then exhibiting an asymptotic behavior. The conductance *vs.* time curves of the subsequent anodic polarization are nearly symmetrical to those of the cathodic branch. The conductance of the electrode reverts nearly to the original value at the end of anodic polarization and the electric charge needs to reach the original conductance value increased with extension of the periods of cathodic polarization.

Discussion

Since the VO_2 electrode did not dissolve during the course of polarization at the potentials negative to 0.05 V, the change in conductance (Fig. 3 and Fig. 5-A) is attributed to the formation and the reduction of the oxide layers with different electric resistivity.

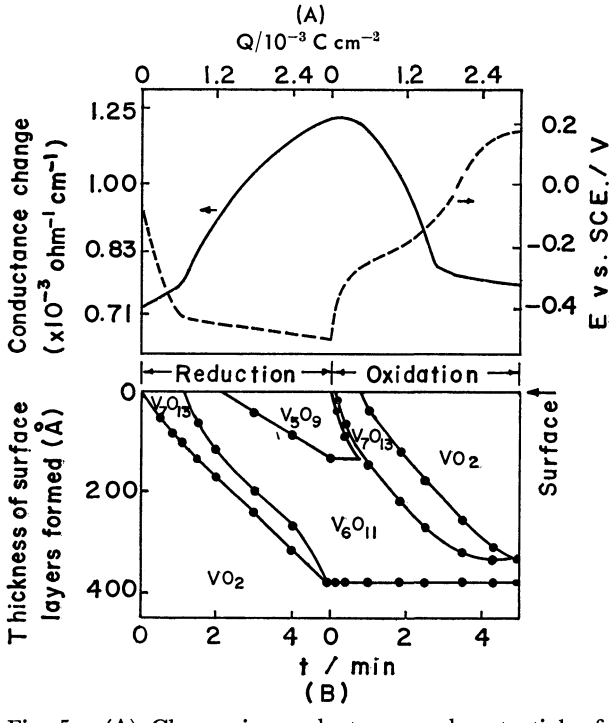

Fig. 5. (A) Change in conductance and potential of VO_2 film during cathodic and anodic polarization curves at 10^{-5} A/cm².
(B) Change in composition of surface layers during cathodic reduction and anodic oxidation of VO_2 film.

TABLE 2. ELECTRIC RESISTIVITY OF VANADIUM OXIDES[11]

Oxide form	Resistivity/Ω cm
VO_2	250
V_7O_{13}	50
V_6O_{11}	4.4
V_5O_9	142
V_4O_7	13.3
V_3O_5	1000
V_2O_3	0.04

In order to estimate the constitution of the surface layers formed by the cathodic polarization, Eqs. 6 and 7 were solved for Q_1 and Q_2, by using the change in conductance and the electric resistivities of vanadium oxides.

The values of resistivity of vanadium oxides show an appreciable scattering. The data given in Table 2[11] were chosen in the following calculation. The thickness of each layer was calculated from Q_1 and Q_2, by means of Eqs. 2 and 4, and the densities of oxides. The species and thicknesses of oxide layers were estimated on the following assumptions.

(1) The VO_2 electrode is reduced in the decreasing order of oxidation state with formation of a multilayer film on surface

$$VO_2 \underset{Q'_1}{\overset{Q_1}{\rightleftharpoons}} V_7O_{13} \underset{Q'_2}{\overset{Q_2}{\rightleftharpoons}} V_6O_{11} \underset{Q'_3}{\overset{Q_3}{\rightleftharpoons}} V_5O_9 \underset{Q'_5}{\overset{Q_4}{\rightleftharpoons}} V_4O_7$$

$$\underset{Q'_5}{\overset{Q_5}{\rightleftharpoons}} V_3O_5 \underset{Q'_6}{\overset{Q_6}{\rightleftharpoons}} V_2O_3$$

where Q'_n is the amount of charge concerned with respective reaction.

(2) The thickness of each layer increases or decreases monotonically with time, the total thickness of the surface layers being nearly proportional to the duration of cathodic reduction.

(3) The calculation based on Eqs. 6 and 7 can be applied to the thicknesses of V_7O_{13} and V_6O_{11} in the initial stage of reduction, where only two layers are formed. When the third layer participates in the growth with the progress of reduction, a supplementary procedure is used in the calculation. The growth of the V_7O_{13} layer (Fig. 5-A) follows the following equation in the initial stage of cathodic reduction

$$d = 2.47 \times t^{0.85} \qquad (11)$$

where d represents the thickness of the V_7O_{13} layer (Å) and t the time (s). It was assumed that the thickness of the V_7O_{13} layer increases according to Eq. 11 even after the V_5O_9 layer has appeared. The thickness of the V_6O_{11} and V_5O_9 layers was calculated by means of Eqs. 6 and 7 and that of V_5O_9 layer was estimated by Eq. 11.

The results of calculation are illustrated against time in Fig. 5-B. The unit time (1 min) corresponds to 6×10^{-4} C/cm^2, since the polarization experiment was carried out at a constant current density of 10^{-5} A/cm^2. The surface of the VO_2 electrode is seen to be reduced first to V_7O_{13}, and then to V_6O_{11}, which is further reduced to V_5O_9. During the course of reduction process, the VO_2 substrate is consecutively reduced to the low-valence oxides, the total thickness of the oxide layer increasing in proportion to the amount of electric charge passed. The V_7O_{13} layer vanishes after 5 min of cathodic polarization (3×10^{-3} C/cm^2), the final structure of surface layer consisting of V_5O_9 and V_6O_{11}.

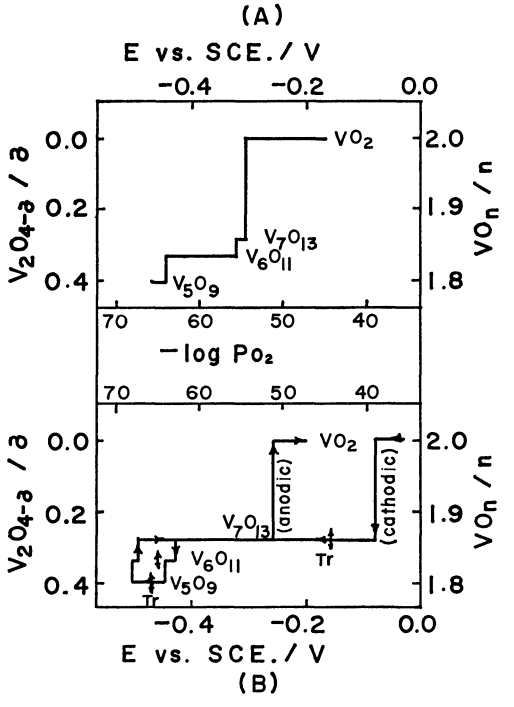

Fig. 6. (A) Relation between vanadium oxides and their eqilibrium pressures of oxygen (from Okinaka's data).
(B) Potential dependency of surface oxides on VO_2 (present work). Tr: Transition potential.

In the subsequent anodic oxidation, V_5O_9 is oxidized to VO_2 *via* V_6O_{11} and V_7O_{13}. Using Fig. 5-B, the oxidation state of the outer-most layer of the VO_2 electrode is plotted against the potential in Fig. 6-B. Since the ohmic drop inside the oxide electrode was estimated to be of the order of 10^{-4} V at the current density chosen, the potential difference should appear mainly at the oxide/electrolyte interface.

The transition from VO_2 to V_7O_{13} occurs at -0.08 V (SCE) in the cathodic process, and at -0.26 V in the anodic process. A similar hysteresis of the transition potential between the cathodic and anodic branch is observed on the transition between V_7O_{13} and V_6O_{11} on that between V_6O_{11} and V_5O_9. Further experiments are necessary to explain, the hysteresis in the transition potential, since it is a sort of underpotential phnomenon.

Thermodynamic properties of vanadium oxides were reported[12-14] mainly from the measurement of the equilibrium partial pressure of oxygen p_{O_2} at high temperature. The composition *vs.* log p_{O_2} diagram of vanadium oxides at 298 K (Fig. 6-A) was estimated by the extrapolation of the data at high temperature to those at 298 K according to the Van't Hoff equation. The log p_{O_2} scale at 298 K was also converted into the potential scale, by considering the Nernst equation

Table 3. Thermodynamic data of vanadium oxides

	Data extrapolated from high temperature measurement (Okinaka *et al.*[13])			Data calculated from transition potential (present work)		
	ΔG°_{298} / kJ mol^{-1}	$-\log p_{O_2}$	E(SCE) pH 8.39	ΔG°_{298} / kJ mol^{-1}	$-\log p_{O_2}$	E(SCE) pH 8.39
VO_2	−658			−658		
		54.6	−0.312		45.1	−0.170
V_7O_{13}	−4447			−4474		
$VO_{13/7}$	−653			−639		
		55.7	−0.328		64.5	−0.465
V_6O_{11}	−3789			−3809		
$VO_{11/6}$	−631			−635		
		64.1	−0.452		67.9	−0.505
V_5O_9	−3127			−3142		
$VO_{9/5}$	−626			−628		

on the reversible potential of oxygen, thus

$$O_2 + 2H_2O + 4e^- = 4OH^- \quad (12)$$

$$E^{rev}_{O_2} = 1.229 + 0.015 \log p_{O_2} - 0.060\ pH \quad (13)$$

Figure 6-A and B are so arranged that the scale of $\log p_{O_2}$ and that of potential correspond to each other according to Eq. 13.

Transition potentials and the $(-\log p_{O_2\ 298K})$ at the equilibrium between two oxides are summarized in Table 3, together with the free energy of the formation $\Delta G_{f'298K}$ of the vanadium oxides. The free energy of formation was calculated from $(-\log p_{O_2\ 298K})$ and the transition potentials, assuming that $\Delta G_{f'298K}$ of VO_2 is −314.3 kcal/mol. There is an appreciable disagreement between the values of $\Delta G^\circ_{f'298K}$ calculated from the data of equilibrium partial pressure of oxygen at high temperatures and those from the transition potentials. The former values might be less reliable since they are based on an extended extrapolation from the data at temperatures over 1273 K by using the Van't Hoff equation. On the other hand, uncertainity also exists in the latter method especially on the hysteresis of the transition potentials.

The potential dependency of the surface layer on the VO_2 electrode estimated from the resistmetry (Fig. 5-B) exhibits a quite reasonable behavior as compared with that obtained from the equilibrium partial pressures of oxygen at high temperatures. The results strongly support the model in which the composition of the outer-most layer oxide electrodes changes responding to the applied potential.

The authors wish to thank Prof. Masao Taniguchi, Dr. Tooru Tsuru, and Dr. Masataka Wakihara for their discussions.

Hydrogen–Deuterium Equilibration Reaction over Platinum Supported on Polyamide-6

Yasunobu INOUE,* Seiji HACHO, Eizo MIYAZAKI, and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 27, 1979)

Catalysis by platinum supported on polyamide-6 was examined for the H_2–D_2 equilibration reaction at 0 °C in the pressure range of 5—20 Torr (1 Torr=133.3 Pa). Three kinds of polyamides with different molecular weights were prepared as support; the concentration of platinum varied from 0.5 to 2.7 wt%. With preadsorption of hydrogen at 0 °C, the rate of the reaction was found to increase up to 10 times as high as the original level. The rate k_m (HD molecule s^{-1}Pt $atom^{-1}$) showed a maximum, depending on surface area of the polyamides used, in the range 0.8—1.0 wt% of Pt content and its dependence on total pressure is represented by $k_m=K_1P/(1+K_2\sqrt{P})^2$ irrespective of Pt content. No significant isotope effect was observed at 0 °C. It was found that a linear relationship exists between the enhancement of k_m and the amount of hydrogen preadsorbed, indicating an important role of the preadsorbed hydrogen in activation of the catalysts. In contrast to k_m, the turn-over frequency k_t (HD molecule s^{-1} $site^{-1}$) was nearly independent of Pt concentration. The exchange reaction is explained in terms of the Bonhoeffer-Farkas mechanism. XPS spectra provided the evidence for the presence of Pt(II) complexes on the surface. The structure of active sites is discussed.

Catalysis by metals dispersed on organic polymers has been the subject of particular interest, because the catalytically active sites are different in electronic and geometric factors from metals on inorganic supports. The pioneering work on this subject has been done by Izumi,[1] who employed silk fibroins as supports for palladium and studied the hydrogenation of various organic compounds. Harrison and Rase[2] studied the hydrogenation of benzene on platinum supported on polyamides. They reported the capacity of the catalysts to produce cyclohexene, which is scarcely formed at all on silica-supported platinum. They used polymers with different periodic structures, and pointed out the importance of the geometric arrangement of Pt metal atoms correlating to the position of the amide group in the polymer chains. Dini *et al.*[3] examined the number of chlorine atoms remaining in the catalysts and showed the presence of bivalent platinum ions which are available as sites for the formation of cyclohexene.

The structures and distributions of active sites on polyamides are of interest. So we will examine systematically the effect of platinum metal dispersion upon catalytic activity, since the number of the active sites is likely to depend on that of NHCO and/or NH_2 groups exposed to the surface to which Pt is considered to be bonded. Further information is obtained from the change in catalytic activity which occurs when the polyamides which differ as much in molecular weight as possible are used.

In our preliminary study[4] on the hydrogenation of acetylene and butadiene over the Pt–polyamide catalysts, it was found that the major products of the reactions were the saturated hydrocarbons instead of the corresponding monoolefins, indicating that the reactions are quite different in selectivity from those on metal powder and silica-supported catalysts reported earlier.[5] Preadsorbed hydrogen promoted the reactions and there were optimum conditions to give the stable and high catalytic activity, which is apparently associated with the pretreatment by hydrogen. These results led to the consideration that an interaction of hydrogen with Pt on the polymer is characteristic, but no extensive study has been done so far. Thus, the present study was undertaken to examine the equilibration reaction between H_2 and D_2 on Pt–polyamide catalysts and to determine the effect of Pt dispersion on catalytic activity. In order to get information on the states of Pt supported on polyamides, X-ray photoelectron Spectroscopy (XPS) was employed in this study.

Experimental

Catalyst Preparations. Polyamide-6 (PA) was obtained by the polymerization of ε-caprolactam (Wako Pure Chemical Co.) initiated with 1.0 wt% of 6-aminohexanoic acid at 250 °C in a stream of nitrogen. Unreacted monomer, oligomers, and cyclic oligomers were eliminated from the products with hot water. The polyamide-6 was dissolved into formic acid of extra pure grade, and then the PA powder was obtained by transferring the solution to ion-exchanged water and drying *in vacuo* at room temperature. Three kinds of polyamide-6 with different molecular weights of 6.8×10^3, 3×10^3, and 1.7×10^3 (as denoted by L, M, and S hereafter) were prepared and found to have surface areas of 5.7, 5.5, and 4.6 m^2/g, respectively.

The polymers were immersed in an aqueous solution of H_2PtCl_6 of about 8×10^{-3} Pt g/l in concentration, heated at 90 °C for 2 h and then washed thoroughly with ion-exchanged water. The catalysts were dried *in vacuo* at room temperature. The concentration of Pt dispersed on PA was determined according to the procedure described in the reference.[6] The catalysts with Pt concentration of 0.5 to 2.7 wt% were prepared. Elemental analysis showed that the amount of chlorine atoms remaining on the treated 2.7 wt% Pt–PA-M catalyst was estimated, in terms of the Cl/Pt ratio, at 1.7.

Characterization of Catalyst. In order to examine the valence states of Pt bonded to PA, a Hewlett-Packard 5950A ESCA spectrometer with a monochromatic Al $K\alpha$ X-ray was used and a flood gun was operated at 0.3 mA with 0—0.7 eV to avoid the charging of the samples. The binding energy of C 1 s of CH_2 group in PA, 284.8 eV, was taken as standard. X-Ray diffraction and electron microscopic studies were done to ascertain the presence of Pt crystallites and also their distributions on the surface.

Equilibration Reaction. The equilibration reaction be-

tween H_2 and D_2 was studied using a closed circulating apparatus which was similar to that used before.[7] Hydrogen, hydrogen deuteride, and deuterium were analyzed by a gas chromatograph connected to the system.[7] Prior to the kinetic run, a fresh catalyst was evacuated at 150 °C for 1 h and then cooled to the reaction temperature, 0—35 °C. Hydrogen (99.98% pure), and deuterium (containing less than 0.5% HD) were obtained from Takachiho Chemical Co. and used without further purification.

Results

Figure 1 shows the time course of the equilibration reaction at 0 °C using the catalyst evacuated at 150 °C. The rate of equilibration is expressed as

$$\ln (X_o - X_e)/(X_t - X_e) = k_e t \qquad (1)$$

where X_o, X_t, and X_e are, respectively, the fraction of HD at $t=0$, t, and equilibrium. In the initial stage of the first run (curve a), the experimental values were considerably off the linearity but, after three or more successive runs, they turned out to fit a linear expression. The reaction rate k_e is derived from the slope and then k_m is defined as

$$k_m = nk_e/N_{Pt} \quad \text{(molecule s}^{-1}\text{ Pt atom}^{-1}\text{)} \qquad (2)$$

where n is the number of molecules in the gas phase and N_{Pt} the number of Pt atoms. Figure 2 shows the dependence of the reaction rate upon the time of exposure of the catalyst to hydrogen of 20 Torr at 0 °C after evacuation at 150 °C. The catalytic activity increased with the contact time and no further increase was observed after 24 h. The highest activity, about 10 times as high as the original one of the first run without H_2-preadsorption, was diminished by evacuation at 150 °C for 3 h to the original level, but the treatment with hydrogen at 0 °C promoted again the activity to the highest level. This cycle

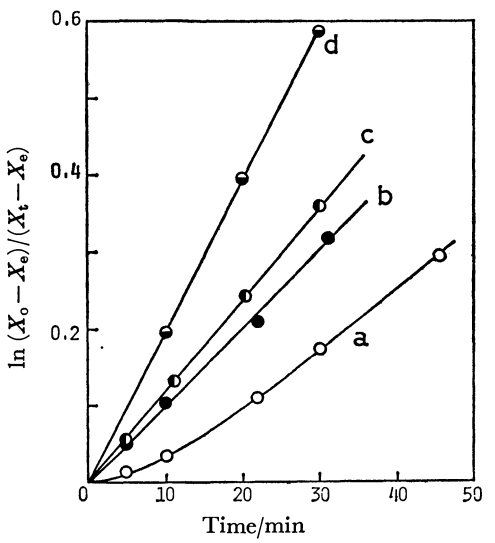

Fig. 1. H_2-D_2 exchange reaction on 0.5 wt% Pt-PA-M. ○: First run, ●: second, ◐: third, ◒: fourth. Between each run, the catalyst was evacuated at 0 °C for 10 min. The reaction conditions are as follows unless otherwise stated. Total pressure=20 Torr, $H_2/D_2=1$, reaction temperature=0 °C.

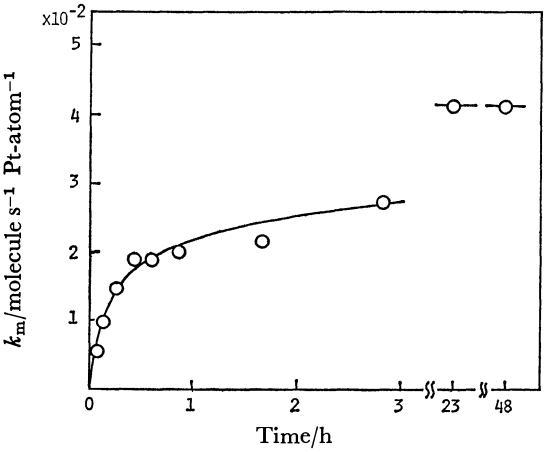

Fig. 2. Increase in k_m as a function of time exposed to hydrogen.
Catalyst: 0.5 wt% Pt-PA-M, $P_H=20$ Torr, temperature=0 °C.

of activation and deactivation was quite reversible and reproducible. Evacuation at 0 °C for less than 30 min caused no significant change in the highest activity, which was taken as the measure for comparison of catalytic activity, unless otherwise stated.

The dependence of k_m on Pt concentration for three catalysts, Pt–PA-L, -M, and -S, is shown in Fig. 3. Each catalyst has a maximum k_m value around 0.8—1.0 wt% of Pt. The activity beyond the maximum declined sharply. Figure 4 shows Arrhenius plots for the H_2–D_2 equilibration on 0.5, 0.8, 1.0, and 2.0 wt% Pt–PA-M catalysts. The evaluated activation energies were almost constant as 7.2±0.2 kcal/mol (1 kcal=4.184 kJ) irrespective of Pt content. The total pressure dependence of the exchange rate for these four catalysts using an equimolar mixture of H_2 and D_2 as reactant is shown in Fig. 5. The reciprocals of the square root of both total pressure P and k_m provided a linear relationship for each catalyst, indicating that k_m can be represented as $K_1P/(1+K_2\sqrt{P})^2$

where K_1 and K_2 are constants.

In order to see the detailed kinetic behavior of the reaction and also to ascertain whether the isotope effect is present or not, the partial pressure dependence was investigated at 0 °C. For 1.0 wt% Pt–PA-M catalyst, the reaction order with respect to hydrogen pressure, P_H, was about 0.5 in a range from 2 to 4.7 Torr at a fixed deuterium pressure, P_D, of 7 Torr, and the deuterium order was the same as that of hydrogen in a range of P_D from 0.4 to 4.5 Torr at a fixed P_H of 5 Torr. This close similarity in the partial pressure dependence between H_2 and D_2 predicts that there exists little isotope effect at the reaction temperature.

The adsorption of hydrogen at 0 °C in an activation process occurred in a slow manner analogous to the increase of activity observed in Fig. 2; thus we can obtain a correlation between the amount of the preadsorbed hydrogen and the corresponding catalytic activity. The results are shown in Fig. 6. The linear relationship between k_m and the H/Pt ratio reflects the direct contribution of hydrogen to the activation of catalysts. The saturation of the preadsorbed hydrogen took place after 24 h, and evacuation of the surface at 0 °C for 10 min caused negligible desorption of the hydrogen, since no further adsorption of hydrogen was observed after the introduction of hydrogen following the evacuation. For Pt–PA-M catalysts with Pt loading ranging from 0.5 to 2.7 wt%, the saturated amount of the adsorbed hydrogen per gram Pt increased with the content, passed through a maximum at 1.0 wt%, and decreased. This change is in a close parallel to that observed in the catalytic activity. The number of active sites can be calculated from that of the hydrogen atoms preadsorbed. The turn-over frequency, k_t, in terms of molecules s^{-1} site^{-1}, is given in Fig. 3.

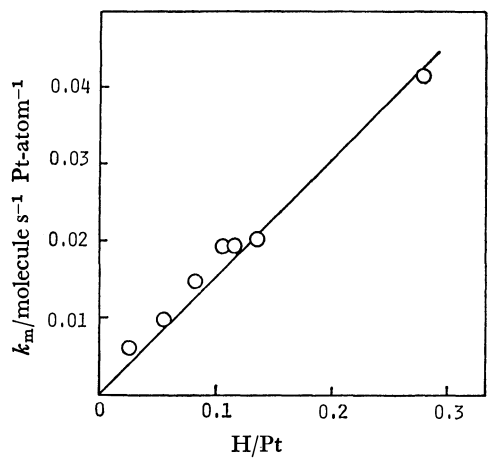

Fig. 6. Relationship between k_m and H/Pt ratio.
Catalyst: 0.5 wt% Pt-PA-M.

The effects of the preadsorbed hydrogen on the exchange reaction of catalyst hydrogen with gaseous deuterium were examined at 0 °C. Hydrogen of 3.6×10^{-6} mol was preadsorbed at 0 °C, evacuated for 10 min, and then deuterium of 2.4 Torr was introduced. The rate of HD formation is much the same in the cases of both the presence and the absence of the preadsorbed hydrogen, but smaller by a factor of about 40 compared to the ordinary rate in the steady reactions. In order to confirm whether or not the slow exchange is attributable to the reaction between the structural hydrogen in PA and gaseous deuterium, 1.0 wt% Pt–PA-M catalyst was exposed to a deuterium atmosphere at 150 °C. The number of the exchanged hydrogen atoms was found to amount to approximately 300 times that of Pt atoms, indicating that hydrogens in bulk organic groups participated in the exchange. After the exchange, the catalyst was examined by means of infrared spectroscopy, and, in addition to ordinary bands due to PA, new strong bands at 2400 and 2460 cm^{-1} and also weak bands at 2090 and 2190 cm^{-1} were observed. The former group corresponds to the bands of the characteristic region ascribable to the N–D stretching vibration. The latter

two bands are reasonably assigned to the C–D stretching vibration.

For 2.7 wt% Pt–PA-M catalyst without evacuation at high temperature after preparation, the Pt 4f region of X-ray photoelectron spectra showed three peaks, the central one of which is apparently derived from a superposition of two peaks (Fig. 7 and Table 1). From the comparison with binding energies of Pt complexes reported earlier,[8] these peaks can be associated with the 4f level of Pt(IV) and Pt(II). It was found that three peaks gradually changed to two stable peaks, $4f_{7/2}$ and $4f_{5/2}$, during the course of the photoemission measurement and that X-ray irradiation caused the reduction of Pt(IV) to Pt(II), which is analogous to the phenomena observed in XPS studies on Pt complexes.[8,9] For 2.7 wt% Pt–PA-M catalyst, which was evacuated at 150 °C, only two 4f peaks appeared at the binding energies of 72.5 and 75.7 eV, which are higher by 1.3—1.2 eV than those of Pt metal, indicating the presence of Pt(II) on PA. Further exposure of the surface to a hydrogen atmosphere at 0 °C for 24 h gave rise to no significant change in the spectra. The chlorine 2p level was monitored

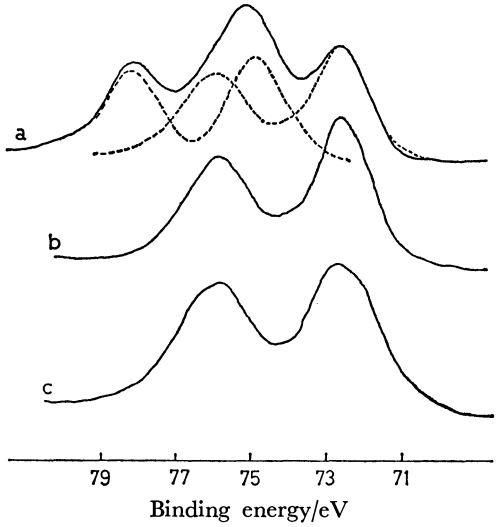

Fig. 7. Pt 4f region of XPS spectra of 2.7 wt% Pt–PA-M.
a: Evacuated at room temperature, b: evacuated at 150 °C and then exposed to 20 Torr of hydrogen at 0 °C, c: exposed to X-ray for 6.5 h after a.

but no strong peak was observed. This is probably attributed either to the low intensity of the level or to the loss of chlorine with X-ray exposure, which occurred in the case of Cl-containing Pt complexes.[8] For N ls and O ls levels, neither a significant shift of the peaks nor broadening was observed between PA and Pt–PA.

No appreciable change was observed in the infrared spectra of the organic groups characteristic in PA when the platinum complex was deposited on it. The X-ray diffraction measurement provided only a diffused peak due to PA crystallites and showed unambiguous evidence for the absence of large Pt metal particles. Electron microscopy was applied to the catalysts under a magnification of more than 90000, but failed to detect the presence of large Pt particles.

Discussion

The platinum–PA catalysts are characterized by a gradual increase in the activity for H_2–D_2 equilibration as the catalysts are exposed to a hydrogen atmosphere. One might argue that such an activity enhancement is ascribable to metal particles produced by the reduction of the Pt complexes. This is unlikely, because the activity was lost upon heat-treatment at 150 °C but again restored to the same level as before when they were exposed to a hydrogen atmosphere at 0 °C. XPS results gave no sign of a Pt 4f peak due to the metallic state, but showed the presence of bivalent platinum cation. The results obtained by electron microscopy and X-ray diffraction also support this view. The reversible change in catalytic activity mentioned above clearly shows that the preadsorbed hydrogen played an important role in the formation of catalytically active sites.

It is of interest to see that the position of peak activity shown in Fig. 3 can be correlated with the surface area of PA used as support; for both PA-L and PA-M catalysts having the surface areas of 5.7 and 5.5 m^2/g, each peak appears at a Pt content of 1 wt%, whereas for PA-S the downward shift of the position occurs by a factor of 0.2, almost the same ratio as the decrease in the surface area. This correlation indicates that the functional organic groups of PA exposed on the surface, but not those in bulk, are of importance in catalysis, and also predicts that the number of active

Table 1. Binding energy of Pt 4f, N 1s, and O 1s levels of 2.7 wt% Pt-PA-M catalyst

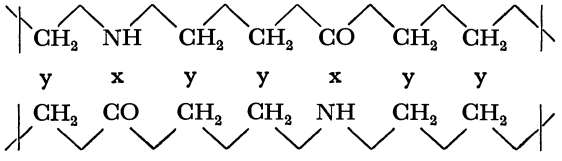
sites is proportional to that of such groups.

The (010) face of a polyamide-6 crystal consists of a unit cell with a dimension of 17.2 Å×4.78 Å and involves two NHCO groups. For 1.0 wt% Pt–PA-M catalyst, a calculation gave the ratio of Pt atoms to surface NHCO groups to be 2.3. Since even the highest value of the H/Pt ratio reaches only 0.4, not all the Pt atoms on PA can work as active sites for both the equilibration and the adsorption of hydrogen. This low ratio of H/Pt is consistent with the results obtained by Dini *et al.*;[3] their 0.6 and 3.8 wt% Pt supported on nylon-6 catalysts gave 0.08 and 0.11, respectively, at 25 °C. It should be noted that no metal crystallites as large as 100 Å, which would be anticipated in such low degrees of exposure, were detected.

The kinetic results showed that the turn-over frequency k_t for the exchange reaction is apparently independent of Pt content and that kinetic behavior such as activation energy and reaction order are almost the same over the whole range of the loading. Thus, it is suggested that there is a single kind of catalytically active site on the surface. For this view, the presence of a maximum in k_m appears somewhat puzzling, but is explained by the model on the basis of the following assumptions. The fundamental unit of polyamide-6 (α-type) is given below, where x and y represent the positions corresponding to the spacing between neighboring polymer chains.

It is likely that an NHCO group (position x) is involved in the coordination with the Pt complex, whereas a CH_2 group (position y) has a weak interaction with the complex upon its access. It is assumed that such characteristics in the structure of PA-6 lead to the formation of cluster complexes consisting of two and three Pt metal atoms, denoted as $(Pt)_2$ and $(Pt)_3$ respectively, and that only $(Pt)_3$ is catalytically active. The ratio of existing $(Pt)_3$ to $(Pt)_2$ depends on the numbers of the positions having suitable spacing



in the vicinity of NHCO group; thus it follows that the catalytic activity becomes the highest when one unit is occupied by one $(Pt)_3$ and one $(Pt)_2$. Further deposition of Pt beyond this distribution results in the decrease of the catalytic activity per gram Pt. Table 2 shows the results of calculations obtained on the basis of the distribution of $(Pt)_3$ and $(Pt)_2$ on the polyamide-6 with a periodicity of three units which contain six NHCO and fifteen $CH_2\cdots CH_2$ groups in them. The rather good agreement between the calculated and experimental values shows that the structures of the active sites are well represented by the cluster model.

Reaction Mechanism. The adsorption of hydrogen in the formation of the catalytically active sites is undoubtedly slow and irreversible at 0 °C, but induces a drastic rise in activity. The following process seems to take place.

$$(Pt)_3 + H_2 \longrightarrow (Pt^*)_3 \tag{3}$$

where $(Pt^*)_3$ represents the catalytically active sites. The H_2–D_2 equilibration on this surface is considered in terms of the Bonhoeffer-Farkas mechanism which is shown below.

$$H_2(g) \underset{k_d^H}{\overset{k_a^H}{\rightleftharpoons}} 2H(a) \tag{4}$$

$$HD(g) \underset{k_d^{HD}}{\overset{k_a^{HD}}{\rightleftharpoons}} H(a) + D(a) \tag{5}$$

$$D_2(g) \underset{k_d^D}{\overset{k_a^D}{\rightleftharpoons}} 2D(a) \tag{6}$$

The rate constants of adsorption and desorption are denoted as k_a^i and k_d^i, respectively, where i=H, HD, or D. The changes in surface concentration of hydrogen and deuterium atoms as a function of time can be represented by the following equations:

$$\frac{d\theta_H}{dt} = 2k_a^H P_H(1-\theta_H-\theta_D)^2 + k_a^{HD}P_{HD}(1-\theta_H-\theta_D)^2 - 2k_d^H\theta_H^2 - k_d^{HD}\theta_H\theta_D \tag{7}$$

$$\frac{d\theta_D}{dt} = 2k_a^D P_D(1-\theta_H-\theta_D)^2 + k_a^{HD}P_{HD}(1-\theta_H-\theta_D)^2 - 2k_d^D\theta_D^2 - k_d^{HD}\theta_H\theta_D \tag{8}$$

TABLE 2. THE H/Pt RATIO AND THE NUMBER OF Pt ATOMS ON Pt–PA CATALYSTS

Catalysts	(N_n+N_c)[a]	wt%	Obsd		Calcd[b]	
			Pt (atom/g)	H/Pt	Pt (atom/g)	H/Pt
Pt-PA-L	4.9×10^{19}	1.0	3.1×10^{19}	—	3.5×10^{19}	—
Pt-PA-M	4.7×10^{19}	1.0	3.1×10^{19}	0.40	3.3×10^{19}	0.40
		0.5	1.5×10^{19}	0.27	1.6×10^{19}	0.27
Pt-PA-S	3.9×10^{19}	0.8	2.5×10^{19}	—	2.8×10^{19}	—

a) The total number of NHCO and CH_2 surface groups per gram of catalyst. b) At the maximum activity, the surface of three units distributes fifteen Pt atoms on twenty one positions (=x+y). Numbers of Pt atoms per gram catalyst were calculated by multiplying (N_n+N_c) by 15/21. The H/Pt ratio is given by 2×(number of $(Pt)_3$)/(number of Pt atoms) under the assumption that a hydrogen molecule occupies a $(Pt)_3$. From the distribution of the cluster described in the text, the H/Pt value is calculated to be $2\times3/15=0.4$ for 1.0 wt% and $2\times1/7.5=0.27$ for 0.5 wt%. This model permits the comparison of k_m; for 1.0 wt%, k_m is given by $(3/15)k_t$, whereas for 0.5 wt% by $(1/7.5)k_t$. The ratio of k_m(1.0 wt%)/k_m(0.5 wt%), 1.5, is close to the observed one, 1.7.

where θ_H and θ_D are, respectively, the fractions of hydrogen and deuterium occupying the active sites in the complex. The neglect of the isotope effect leads to the simple relations, $k_a^H=k_a^D=k_a^{HD}=k_a$ and $2k_d^H=2k_d^D=k_d^{HD}=k_d$. The factor 2 in the desorption rate constants k_d^H and k_d^D comes from the fact that the probability of making an atom pair HD is twice as large as that of making a pair H_2 or D_2. Since the amount of hydrogen adsorbed on a catalyst surface was negligibly small compared to that in the gas phase, P_{HD} is represented by 2 $(P_H^\circ-P_H)$ or 2 $(P_D^\circ-P_D)$, where P_H° and P_D° are hydrogen and deuterium pressures at $t=0$, respectively. By introducing the steady-state approximation, $d\theta_H/dt=d\theta_D/dt=0$, and the relations described above, one can obtain the following equations:

$$(1-\theta_H-\theta_D)^2 2KP_H^\circ = \theta_H(\theta_H+\theta_D) \tag{9}$$

and

$$(1-\theta_H-\theta_D)^2 2KP_D^\circ = \theta_D(\theta_D+\theta_H) \tag{10}$$

where K denotes k_a/k_d.

Total Pressure Dependence. The rate equation which describes the time course of the reaction is given by

$$\left(\frac{N_aV}{RTN_{pt}}\right)\frac{dP_{HD}}{dt} = k_d\theta_H\theta_D - k_aP_{HD}(1-\theta_H-\theta_D)^2 \tag{11}$$

where N_a is Avogadro's number, V the volume of the reaction system, and R the gas constant. Since the equimolar mixtures of H_2 and D_2 were used as the reactants, the relations, $\theta_H=\theta_D=\theta/2$ and $P_H^\circ=P_D^\circ=P^\circ/2$, always hold in this case. Equation 9 or 10 is then transformed into

$$\theta_H + \theta_D = \theta = \frac{\sqrt{2KP^\circ}}{1+\sqrt{2KP^\circ}} \tag{12}$$

The insertion of Eq. 12 into Eq. 11 provides

$$\left(\frac{N_aV}{RTN_{Pt}}\right)\frac{dP_{HD}}{dt} = \frac{k_dKP^\circ}{(1+\sqrt{2KP^\circ})^2}\left(\frac{1}{2}-\frac{P_{HD}}{P^\circ}\right) \tag{13}$$

By introducing the fraction of HD in the gas phase, $X_{HD}=P_{HD}/P^\circ$ and that in equilibrium, $X_e=P_{HD}^e/P^\circ=1/2$, Eq. 13 can be rewritten as

$$\frac{dX_{HD}}{dt} = k_e(X_e-X_{HD}) \tag{14}$$

where

$$k_e = \frac{k_dKRTN_{Pt}}{N_aV(1+\sqrt{2KP^\circ})^2} \tag{15}$$

The integration of Eq. 14 gives the experimental relation (1), and Eq. 2 on k_m is correlated with k_e in Eq. 15 as

$$k_m = \frac{nk_e}{N_{Pt}} = \frac{k_dKP^\circ}{(1+\sqrt{2KP^\circ})^2} \tag{16}$$

This equation accords well with the observed kinetic behavior shown in Fig. 5.

Partial Pressure Dependence. By solving Eq. 9 and 10, one can obtain the following expressions for θ_H and θ_D:

$$\theta_H = \frac{\sqrt{2KP_H^\circ}}{\sqrt{(P_H^\circ+P_D^\circ)}\,[1+\sqrt{2K(P_H^\circ+P_D^\circ)}]} \tag{17}$$

$$\theta_D = \frac{\sqrt{2KP_D^\circ}}{\sqrt{(P_H^\circ+P_D^\circ)}\,[1+\sqrt{2K(P_H^\circ+P_D^\circ)}]} \tag{18}$$

The measurements on the partial pressure dependence of the rate were carried out only at the initial stage of reaction and then P_{HD} in Eq. 11 was safely omitted from the expression.

$$\left(\frac{N_aV}{RTN_{pt}}\right)\frac{dP_{HD}}{dt} = k_m' = k_d\theta_H\theta_D = \frac{2k_dKP_H^\circ P_D^\circ}{(P_H^\circ+P_D^\circ)[1+\sqrt{2K(P_H^\circ+P_D^\circ)}]^2} \tag{19}$$

where $k_m'=k_m/2$ when $P_H^\circ=P_D^\circ$. This equation can be transformed into

$$\sqrt{\frac{P_H^\circ P_D^\circ}{k_m'(P_H^\circ+P_D^\circ)}} = \sqrt{\frac{1}{2k_dK}} + \sqrt{\frac{1}{k_d}}(P_H^\circ+P_D^\circ)^{1/2} \tag{20}$$

Figure 8 shows the plot of experimental values of $\sqrt{P_H^\circ P_D^\circ/k_m'(P_H^\circ+P_D^\circ)}$ against $(P_H^\circ+P_D^\circ)^{1/2}$. Besides, the values of k_d and K were evaluated at 2.2 molecule s^{-1} Pt atom^{-1} and 3.6×10^{-3} Torr^{-1}, respectively, from the observed rate shown in Fig. 5. These values were inserted into Eq. 20 and the line thus obtained is also shown in Fig. 8. In spite of the lower accuracy in the values of initial rate, the correspondence between the results of the separate studies seems fairly good and suggests that the proposed mechanism is an acceptable one. The equation derived on the basis of the Rideal-Eley mechanism did not fit with the experimental pressure dependence.

It is of interest to compare the present kinetic results with those on metal platinum. The value of k_m is smaller by a factor of about 10^3 at 0 °C than the absolute equilibration rate (molecule s^{-1} Pt atom^{-1}) on Pt wire cleaned by outgassing around 1100 °C,[10] and the activation energy of about 7 kcal/mol in the present study makes a contrast to the negligibly small value for Pt wire at temperatures higher than −73 °C.[10] The detailed analysis of energy level of the adsorbed hydrogen is permitted by use of the thermal desorption technique and will be presented in a subsequent paper.

Structures of Active Sites and Role of Preadsorbed Hydrogen. There are several possibilities about the structures of the active sites of Pt–polyamide catalysts. The monoatomic dispersion of platinum metal with a suitable arrangement of appropriate amide group spacing was first proposed in order to explain the formation of cyclohexene in the benzene hydrogenation,[2] but confirmative support has not been so far obtained by other workers. Bernard *et al.*[11] observed the formation of Pt metal crystallites on nylon-66 upon heating, but showed that such an aggregation is due to the specific structure of nylon-66. Such formation is not the case in polyamide-6. On the other hand, the importance of platinum complexes containing chlorine atoms has been pointed out; Dini *et al.* reported the ratio of Cl/Pt to be 2 for 0.6 wt% Pt–nylon-6 catalyst.[3] From the diamagnetic properties of Pt on nylon, Rasadkina *et al.* concluded that platinum is non-metallic in character.[12] These results indicating the presence of Pt(II) are consistent with our XPS results.

The present kinetic results for the equilibration are well explained by the Bonhoeffer-Farkas mechanism. Since the mechanism involves the dissociative adsorption of both hydrogen and deuterium and needs at least four sites available in the neighborhood, it seems unlikely that a complex of single Pt atom can work as the active site. The requirement of such multiple sites and of the presence of a bivalent cation provides further support to the existence of the cluster such as $(Pt)_3$ which was proposed on the basis of the model discussed earlier. Although no experimental evidence has yet been obtained, it seems plausible that the clusters are analogous to complexes with bridging metal–halogen bonds. The process of activation of the catalysts probably involves the dissociation of hydrogen molecules into atoms. The splitting of the hydrogen molecule is likely to take place, since UV spectra on Rh–polyamide catalysts showed the formation of a hydride complex when the catalysts in an aqueous alcoholic solution were exposed to a hydrogen atmosphere.[13] However, the exchangeable hydrogen takes a different configuration and location on the surface from those of the preadsorbed hydrogen used for activation, because the exchange of the former hydrogen is very rapid. The difinite structure of the clusters and the conformation of the hydrogen on them have to await further study. The loss of the activity upon heating at 150 °C can be explained by a reverse process to reproduce the original complex by the desorption of hydrogen.

Exchange of Hydrogen in PA with Deuterium. The exchange rate of the structural hydrogen in PA support with gaseous deuterium at 0 °C was lower than that of H_2–D_2 equilibration by a factor of about 40 under ordinary conditions, and showed no enhancement even for the activated catalysts. The infrared spectra of Pt–PA-M systems in which hydrogen was replaced by deuterium to different extents showed that the exchange of hydrogen atoms in NH and NH_2 groups was preferentially invoked as a first step, followed by the exchange of hydrogen in the CH_2 group. These results together with those of the measurement of electric conductivity of polyamides by Eley and Spivey[14] suggest that the slow exchange described here takes place with proton diffusing on the surface and also in the bulk of the polyamide.

The Origin of the Polarity of a Radical in Hydrogen Abstraction Reactions

Hiroyuki SHINOHARA* and Akira IMAMURA**

Department of Radiology, Fujigaoka Hospital, Showa University, Fujigaoka, Midori-ku, Yokohama 227

(Received February 14, 1979)

The electrophilicity of the H atom in hydrogen abstraction reactions was studied by the CNDO/2 method. The origin of the electrophilicity of the H atom was well understood using the stabilization energy due to the delocalization of electrons (SEDE) between the radical and substrate; this energy was calculated along the reaction path. The electrophilic energy (SEDE from the substrate to the radical) governs the relative reactivities of substrates, $CH_4<CH_3CH_3<CH_3CH_2CH_3<(CH_3)_3CH$, which correspond to the order of the increase in the electron density. The electrophilic energy is also important in hydrogen abstraction by the H atom from aliphatic alcohols. In the case of the Cl_2^- radical, the nucleophilic energy (SEDE from the radical to the substrate) determines the relative reactivities of substrates, $CH_3OH<C_2H_5OH<i\text{-}C_3H_7OH$. The polarity of a free radical is tentatively clarified by using its ionization potential.

The polarities of free radicals in abstraction reactions (nucleophilicity or electrophilicity) have been examined experimentally by the Hammett or the Taft equation.[1-4] Although the equation does allow the determination of the polarity, its origin has not been clarified theoretically. In previous papers,[5] we attempted to explain the polarity of a free radical by the stabilization energy due to the delocalization of electrons (SEDE) between the radical and substrate; this was calculated by the CNDO/2 method.[6,7] The nucleophilic stabilization energy, defined by the SEDE from the radical to substrate (contribution of the structure **1** in the reacting system R···H···X), and the electrophilic stabilization energy, defined by the SEDE from substrate to the radical (structure **2** in Eq. 2), contribute in determining the relative reactivities of substrates (RH: hydrogen donor, X: radical).

$$RH + X \longrightarrow [R\cdots H\cdots X] \longrightarrow R + HX \quad (1)$$

$$[\overset{\delta-}{R}\cdots\overset{\delta+}{H}\cdots\overset{\delta+}{X} \longleftrightarrow \overset{\delta+}{R}\cdots\overset{\delta+}{H}\cdots\overset{\delta-}{X}] \quad (2)$$

1 **2**

The polarity of a free radical is correlated with the relative importance of these structures. Thus the radical is a nucleophile if the relative reactivities of substrates are governed by the nucleophilic energy (nucleophilic stabilization energy) and an electrophile when the reactivities are governed by the electrophilic energy (electrophilic stabilization energy). The electrophilicity of the OH and CH_3 radicals in hydrogen abstractions with methane derivatives or the nucleophilicity of the CH_3 radical in hydrogen abstraction with chlorinated methanes is well understood by using the SEDE.[5]

In the present work, we examined the polarity of the H atom in hydrogen abstractions with aliphatic hydrocarbons. The hydrocarbon–H system is useful to check our ideas on the polarity because the reaction path for CH_4–H system was deduced by the *ab initio* MO method,[8] which enabled us to calculate the SEDE in detail along the reaction path. The electrophilic energy changes remarkably from one substrate to another substrate, compared with the change in nucleophilic energy. The former thus plays a dominant role in determining the relative reactivities of substrates, $CH_4<CH_3CH_3<CH_3CH_2CH_3<(CH_3)_3CH$, which correspond to the order of the increase in the electron density. On the other hand, in hydrogen abstractions by the Cl_2^- radical from aliphatic alcohols, the nucleophilic energy changes remarkably compared with the electrophilic energy, although the absolute magnitude of these energies changes with a change of the geometry in the reacting system. The ionization potential of the radical is found to be the important factor determining the polarity, judging from the present results obtained in the reactions of the H atom and Cl_2^- radical.

Method of Calculation

The total energies for the reacting systems were calculated by the UHF method[9] in the CNDO/2 approximation.[6,7] The values of the parameters included in the method are the same as those used in the original papers.

Geometries used for calculation are as follows: for CH_4,[10] CH_3CH_3, $CH_3CH_2CH_3$, and $(CH_3)_3CH$, r(C–H)=1.09 Å and r(C–C)=1.54 Å; for CH_3OH,[11] C_2H_5OH, and $i\text{-}C_3H_7OH$, r(C–H)=1.094 Å, r(C–O)=1.425 Å, r(O–H)=0.945 Å, ∠COH=108.53°. The bond angles HCH for these compounds were assumed to be 109.47°.

Procedure of Analysis.[5] (i) The total energy of the reacting system [R···H···X] without the delocalization of electrons is calculated with the UHF method in the CNDO/2 approximation after dropping all the resonance integrals (I_{rs}) between atomic orbitals (AO's) on the fragment RH and those on the fragment X. Thus we obtain the MO's localized on the fragment RH and those on the fragment X. (ii) By using the MO's obtained in step (i), the modified resonance integrals between AO's (I'_{rs}) are calculated according to Eq. 3 in order to take the delocalization of electrons between particular MO's into account.

$$I'_{rs} = \sum_{(i_1-j_1)} C_{RHi_1,r} C_{Xj_1,s} I_{i_1j_1} \quad (3)$$

where $C_{RHi_1,r}$ is the coefficient of AO in the i-th MO of the substrate RH and $C_{Xj_1,s}$ is for the radical X. $\sum_{(i_1-j_1)}$ denotes the summation over a particular orbital

TABLE 1. THE SCHEMATIC REPRESENTATION OF THE ORBITAL INTERACTION BETWEEN SUBSTRATE RH AND RADICAL X[a)]

Interaction	α-Spin			β-Spin		
Electrostatic (Zero)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
Nucleophilic (*N*)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
Electrophilic (*E*)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac

a) The orbital interaction which includes the $I_{i_1 j_1}$ is represented by a solid line. The symbol for the interaction used in the text is given in the parentheses.

set (i_1, j_1). (iii) I'_{rs} values are employed to calculate the total energy of the reacting system with the delocalization of electrons, which corresponds to the nucleophilic or the electrophilic nature of the radical in question. (iv) When the vacant MO's of the substrate and occupied MO's of the radical are chosen for i_1 and j_1, respectively, in Eq. 3, the difference between two energies obtained in steps (i) and (iii) corresponds to the SEDE from the radical to the substrate. This energy should be the nucleophilic energy; it is represented by the symbol *N*. When the occupied MO's of the substrate and the vacant MO's of the radical are chosen for i_1 and j_1, respectively, the electrophilic energy *E* is obtained. Table 1 shows the schematic representation of intermolecular interaction between the MO's of RH and X obtained by dropping the I_{rs} (they interact electrostatically with each other, but the delocalization of electrons is prohibited).

Results and Discussion

The Electrophilicity of the H Atom. The coordinate system for a hydrogen abstraction reaction by the H atom from aliphatic hydrocarbons is shown in Fig. 1. We specify the reaction path with a notation (r_1, r_2), where r_1 is the distance (in Å) between the carbon atom C^1 and the hydrogen atom H^5 to be abstracted, while r_2 is the distance between this hydrogen atom H^5 and the incoming H atom. Calculations were carried out at six path points: A(1.2, 1.1), B(1.3, 0.95), C(1.365, 0.873), D(1.38, 0.85), E(1.5, 0.80), and F(1.7, 0.75), which are very nearly on the potential valley deduced by *ab initio* calculations.[8)] Figure 2a shows the correlation of the activation energy[12)] and the electron density on the hydrogen atom. The activation energy decreases with an increase in the electron density. The origin of the electrophilicity of the H atom can be understood by *N* and *E*, as summarized in Tables 2a—2f. *E* is about 6—10 times larger than *N* before transition state (C) and after the state, the difference becomes nearly constant as the reaction proceeds. When the substrate changes from CH_4 to CH_3CH_3, $CH_3CH_2CH_3$, or $(CH_3)_3CH$,

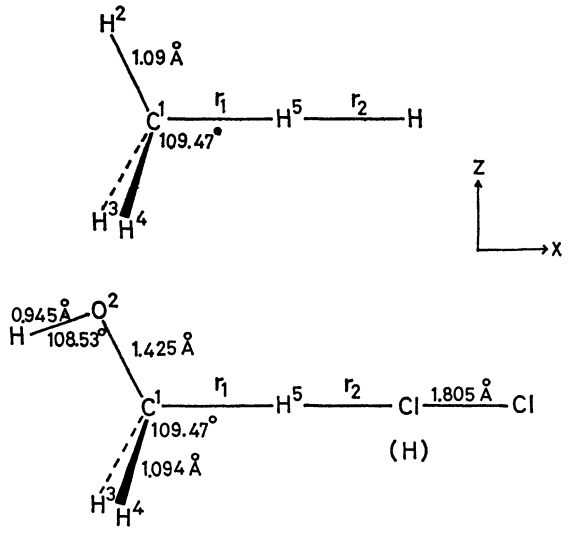

Fig. 1. The coordinate systems for hydrogen abstractions by the H atom and the Cl_2^- radical from CH_4 and CH_3OH, respectively.

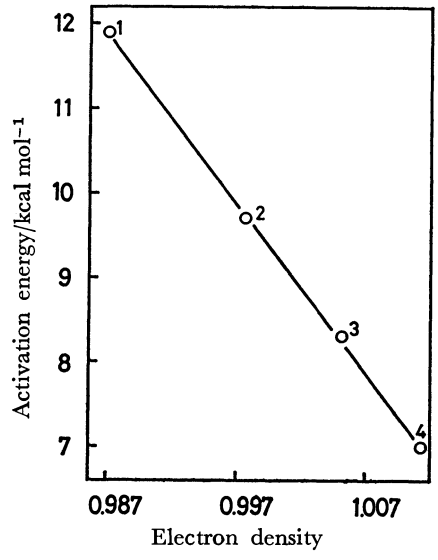

Fig. 2a. The correlation of the activation energy[12)] and the electron density in hydrogen abstraction by the H atom from aliphatic hydrocarbons. 1: CH_4, 2: CH_3CH_3, 3: $CH_3CH_2CH_3$, 4: $(CH_3)_3CH$.

E increases remarkably with the increasing number of electron donating CH_3 groups, while *N* does not change significantly in any substrate. The contribution of the structure **2** in the reacting system is an important factor in determining the relative reactivities of substrates, and thus the reactivities are explained by *E*, as is shown in Fig. 2b. The electrophilicity of the H atom suggested by the electron density is ascribable to the correlation of the electron density and *E* in Fig. 2c.

The Nucleophilicity of the Cl_2^- Radical. Radical anions $(Br_2^-$, $(CNS)_2^-$, CO_3^-, and $Cl_2^-)$ are known as the free radical probes which attack specific residues in enzymes[13,14)] and give the information on the active sites. In comparison with OH radical, the radical anions are highly selective in reactions with amino acid residues. The polarity of the radical anion is

interesting from a theoretical point of view since it has a negative charge, unlike a neutral radical. In the present work, we calculated the SEDE in hydrogen abstraction by the Cl_2^- radical from aliphatic alcohols[15] by assuming the following reaction paths: A(1.2, 1.4), B(1.3, 1.4), C(1.4, 1.3), and D (1.5, 1.27). Calculations were also carried out for hydrogen abstraction by the H atom from aliphatic alcohols[16] to study the factors which determine the polarity of a radical. The coordinate systems for these reactions are shown in Fig. 1. The optimized Cl–Cl distance of the Cl_2^- radical is 1.805 Å. It is slightly longer than that of Cl_2 molecule (1.75 Å).[17] Table 3 shows the result for the H atom. As is shown in the previous section, the electrophilic energy governs the relative reactivities of alcohols, which confirms the electrophilicity of the H atom (Fig. 3). Although the points A, B, C, and

energy, but the latter increases as the C^1–H^5 bond is elongated. Thus, at the initial stage, the SEDE from the substrate to the radical is a driving force of the reaction; but as the reaction proceeds, the SEDE from the radical to the substrate is an important force in completing the reaction. It is noteworthy that although the absolute magnitude of *N* or *E* changes along the reaction path, the nucleophilic energy governs the relative reactivities of alcohols, as is shown in Fig. 4.[5c,5] Therefore the Cl_2^- radical reacts as a nucleophile.

Both frontier electron densities of HOMO (f_{HOMO}) and LUMO (f_{LUMO}) on the α hydrogen atom of alcohol[18] increase as follows: CH_3OH (f_{HOMO}: 0.234, f_{LUMO}: 0.185); C_2H_5OH (f_{HOMO}: 0.297, f_{LUMO}: 0.347); *i*-C_3H_7OH (f_{HOMO}: 0.314, f_{LUMO}: 0.592). In the case of the Cl_2^- radical, the electrophilic or the nucleophilic energy increases with an increase in f_{HOMO} or f_{LUMO}, respectively, while the nucleophilic energy does not increase in hydrogen abstractions by the H atom. The SOMO of the Cl_2^- radical (an electron occupies the LUMO of Cl_2 molecule) is high enough so that the increase of f_{LUMO} contributes largely to the increase in the nucleophilic energy, while the SOMO of the H atom is so low that the above situation is not attainable. The result obtained here leads to the conclusion that a radical having a low ionization potential is a nucleophile and one having a high potential is an electrophile. Table 5 shows the correlation of the ρ values in hydrogen abstractions by radicals[4d] and the ionization potentials. It is expected that C_2H_5 radical will react as a weak nucleophile with substituted toluenes. Although the CH_3 radical reacts as an electrophile in this case, it reacts as a nucleophile in hydrogen abstractions with chlorinated methanes.[5d] As the ionization potential of the CH_3 radical is not

so high as that of the electrophilic OH radical or Cl atom, the nucleophilic energy will change largely from substrate to substrate in a nucleophilic reaction. Therefore a radical having a moderate ionization potential reacts as an electrophile or a nucleophile according to the nature of the substrate.

We would like to express our gratitude to the Computer Center, Tokyo University, for its generous permission to use the HITAC 8700/8800 computer.

The Reaction of Recoil ^{35}S Atoms with Organic Compounds. II. The Insertion Reaction of Recoil ^{35}S Atoms into the C–H and C–C Bonds in Ethane in the Gas Phase

Kazuhiro NIISAWA* and Ko TAKI

Faculty of Industrial Hygiene, Kitasato University, Asamizodai, Sagamihara, Kanagawa 228

(Received March 3, 1979)

The sulfur atoms produced by the nuclear transformation of $^{35}Cl(n,p)^{35}S$ were allowed to react with gaseous ethane in the presence or in the absence of radical scavengers. The products were hydrogen sulfide, methanethiol, ethanethiol, dimethyl sulfide, and other sulfur-containing compounds. The yield of the C–H insertion product (ethanethiol) increased upon the addition of a small amount of the scavenger and then decreased with an increase in the amount of the scavenger to give a constant value, but the yield of the C–C insertion product (dimethyl sulfide) did not vary. The increase in the ethanethiol yield at low concentrations of the scavenger may be ascribed to a protective effect by the scavenger. By the addition of ethanethiol before thermal-neutron irradiation, the yield of ethanethiol was increased, but that of dimethyl sulfide was not increased, therefore the primary yield of ethanethiol could be determined. The spin state of the reactive sulfur atoms in the thermal-insertion reaction was also estimated to be the ^3P state upon the addition of COS and C_2H_4.

Recently, there have been intensive investigations of the reactivities of the sulfur atoms generated by the photolysis of COS and by nuclear transformations. Kremer and Spicer have studied the reactions of recoil ^{35}S or ^{38}S atoms produced from ^{34}S or ^{40}Ar atoms with several reactants.[1,2]

Church and Rowland have also investigated the reaction of ^{35}S atoms produced from ^{35}Cl atoms with propane; they found that the atoms are predominantly inserted into the secondary C–H bond in the triplet state.[3]

The sulfur atoms generated photolytically from COS can be inserted into the C–H bond of hydrocarbons to produce the corresponding thiols. These insertion reactions have been investigated in detail by Strausz and Gunning;[4] they have established that the atoms can be inserted into the C–H bond in ethane in the singlet state.

In our previous paper,[5] it has been demonstrated that the recoil sulfur atoms produced by the nuclear transformation of $^{35}Cl(n,p)^{35}S$ in the liquid phase are capable of being inserted into the C–C bond of 2-methylbenzothiazole by the energetic process, and that the insertion into the C–H bond of benzothiazole takes place not only in the energetic process but also in other processes, such as the thermal and the dissociation processes.

In this paper, the primary yield of sulfur compounds in the reaction of the sulfur atoms produced by the nuclear transformation of $^{35}Cl(n,p)^{35}S$ process with gaseous ethane will be estimated, and the ratio of the insertion rate of the C–H bond to that of the C–C bond will be decided. Also, the spin state of the sulfur atoms in this reaction will be discussed.

Experimental

Materials. Ethane (purchased from the Takachiho Chem. Co.; purity, 99.9%) and dichlorodifluoromethane as a chlorine source (Asahi Glass Co., Ltd.; purity, 99.8%) were purified by trap-to-trap distillation.

Methanethiol, ethanethiol, and dimethyl sulfide were also purified by trap-to-trap distillation before use. Carbonyl sulfide (prepared from KSCN and sulfuric acid) and hydrogen sulfide (prepared from NaSH and hydrochloric acid) were purified by gas-chromatographic separation using a silica-gel column.

Nitrogen monoxide was purified by trap-to-trap distillation, while oxygen from the tank was purified by passing it through a NaOH trap to remove a trace amount of carbon dioxide.

Thermal-neutron Irradiation. Thermal neutron irradiation was carried out by means of a Triga Mark II nuclear reactor (Institute for Atomic Energy, Rikkyo University) at a thermal-neutron flux of about 1.5×10^{12} n cm^{-2} s^{-1} for 1 h.

A mixture of ethane and dichlorodifluoromethane was irradiated in a quartz ampoule (about 5 ml) at a total pressure of about 700 Torr.†

The ratio of the ethane pressure to the dichlorodifluoromethane pressure was 2.05 ± 0.02. Additives were also added to this system. The irradiation was carried out in the gas phase and at a reactor temperature of about 40 °C. The irradiated samples were stored below −78 °C and then at −196 °C until analysis.

The Separation and the Purification of the Reaction Products. Carriers [carbonyl sulfide, hydrogen sulfide, methanethiol, ethanethiol, dimethyl sulfide, carbon disulfide, ethyl methyl sulfide, and diethyl sulfide (about 0.2×10^{-5}—0.5×10^{-5} mol each; Tokyo Kasei Co.; purity, above 98% except for hydrogen sulfide and carbonyl sulfide)] were added to avoid the loss of trace amounts of ^{35}S-labeled compounds during separation and purification. The separation and the purification of the products were performed by means of a gas-chromatograph equipped with a thermal conductivity cell, using hydrogen as the carrier gas. The column contained 15% tritolyl phosphate, 15% *m*-bis(*m*-phenoxy phenoxy) benzene (polyphenyl ether, 5 rings), 15% squalane and 10% α-[4-(1,1,3,3-tetramethyl butyl)phenyl]-ω-hydroxy poly(oxy-1,2-ethanediyl) [Triton-X 305] on Chromosorb-T (40—60 mesh) in stainless steel tubes (3-mm diameter; 7 m, 5 m, 3 m, and 2 m long).

The Reduction of the Reaction Products to $H_2{}^{35}S$.[6] Each eluted sulfur compounds from the gas-chromatograph was passed through quartz tube containing platinized quartz wool as a catalyst and heated above 800 °C to produce hydrogen sulfide-^{35}S. The hydrogen sulfide thus produced was trapped at the temperature of liquid nitrogen. The reduction efficiency was about 60—80%.

The Radioassay of the Reaction Products. The amount and the radioactivity of hydrogen sulfide was measured by

† 1 Torr=133.3 Pa.

means of a radio-gas-chromatograph equipped with a thermal conductivity cell and with a proportional flow counter. The specific radioactivity of each product was determined by comparing the mass peak area with the radioactivity of the hydrogen sulfide.

The radiochemical yield was determined from the specific radioactivity of each product and the standard hydrogen sulfide obtained by the simultaneous irradiation of ammonium chloride in the following processes:

$$NH_4Cl \xrightarrow{\text{irradiation with thermal neutrons}} {}^{35}S \xrightarrow[\text{oxidation by } HNO_3]{Na_2SO_4\text{(carrier)}} {}^{35}SO_4^{2-} \xrightarrow{BaCl_2\ aq} Ba^{35}SO_4 \xrightarrow[Pt\text{(catalyst)}]{H_2 \text{ at } 900\,^\circ C} Ba^{35}S^{9)} \xrightarrow[H_3PO_4]{} H_2{}^{35}S^{10)}$$

The column for the quantitative determination of the hydrogen sulfide consisted of silica gel (60—80 mesh) in a stainless steel tube (2 m long, 3-mm diameter).

No isotopic exchange was found between the products and the carriers, as confirmed by the following experimental fact. The methanethiol separated gas-chromatographically from a mixture of labeled hydrogen sulfide-^{35}S, ethanethiol-^{35}S and non-radioactive methanethiol did not show any radioactivity under the same experimental conditions as those in the analysis of the reaction product. The standard deviation in the figures represents the experimental error in 2 or more runs.

Results and Discussion

The Effects of the Radical Scavenger. When recoil sulfur atoms react with an organic compound, roughly two processes (thermal and energetic) must be considered. In order to eliminate the thermal process, radical scavengers have been used in a number of recoil and radiation chemical studies. Nitrogen monoxide has been used as a radical scavenger by Hyder and Markowitz in the reactions of recoil sulfur atoms with hydrogen sulfide and other reactants.[11] Oxygen has been also used by Lee and his coworkers in the reactions of recoil sulfur atoms with CO and CO_2 to produce $CO^{35}S$, especially, it may be said that oxygen reacts fast with the triplet sulfur atoms.[13]

The effects of the scavenger on the formations of the two insertion products are shown in Fig. 1. The formation of dimethyl sulfide was not affected by the addition of NO, but the yield of ethanethiol was affected by the addition of NO.

The results of the effects of the scavenger show that both the thermal and energetic processes are obviously involved in the formation of ethanethiol, but the thermal process sensitive to NO may not be involved in the formation of dimethyl sulfide. This sulfide formation seems to be inserted directly by means of the recoil sulfur atoms with excess translational energy into the C–C bond.[14] The insertion of a diradical into the C–C bond in the thermal reaction has not been known. The fact that the C–C insertion takes place only in the energetic process may not conflict with usual chemical reactions. This finding had already been discussed in a previous paper.[5]

Figure 1 shows that the yield of ethanethiol increases slightly at the low concentration of NO, but as the concentration of NO is increased the yield decreases

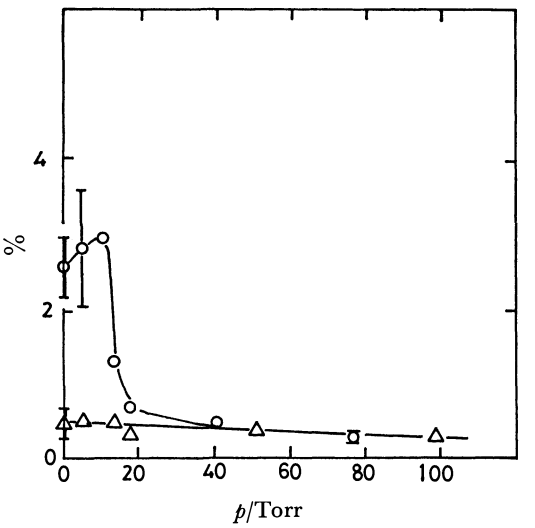

Fig. 1. Plots of the yield of ethanethiol and dimethyl sulfide as a function of NO pressure.
○: Ethanethiol, △: dimethyl sulfide.

to about 0.4%. This may be considered to show that the increase is due to a protective effect by the radical scavenger. The main characteristic of the action of NO may be the high reactivity with radicals or fragments, which reduce the thiol yield.

Thiols are easily decomposed by radicals and by some other fragments formed in an irradiated system. These types of behavior have also been seen in the reaction of recoil tritium atoms with pure ethane[16] in the presence of oxygen and in the reactions of recoil carbon atoms with methane[17] and ammonia,[18] in which the increases the yields of ethylene-t and methylamine have been ascribed to the protective effect of oxygen.[19]

The Addition of Thiols and Dimethyl Sulfide. If an additive which is identical with a product is present in the reaction system before the irradiation, the product may be protected from the attack of radicals formed by radiation, and then the primary yield may be estimated, because the number of additive molecules is much greater than that of the product molecules formed in the system. The effects of the additives on the formation of ethanethiol and dimethyl sulfide are shown in Figs. 2—4 in the presence or in the absence of *ca.* 20 Torr oxygen as a radical scavenger. By the addition of ethanethiol the yield of radioactive ethanethiol increased in both the presence and the absence of the radical scavenger.

This increase suggests that the sulfur atoms also react with added thiol by means of the collisional exchange with the sulfur in the added ethanethiol. Then the intercept of the plots of the thiol yield in the scavenged and non-scavenged systems in Fig. 2 may give the primary yield of ethanethiol in the energetic and the sum of the energetic and thermal processes.

The values are 0.4% and 3.7% respectively. The difference in the yield (dotted line) of ethanethiol between that in the presence and that in the absence of the scavenger in Fig. 2 increases slightly. This

◇: Diethyl sulfide in the presence of methanethiol and in the absence of O_2, ◆: diethyl sulfide in the presence of methanethiol and in the presence of *ca.* 20 Torr O_2, □: diethyl sulfide in the presence of ethanethiol and in the absence of O_2, ■: Diethyl sulfide in the presence of ethanethiol and in the presence of *ca.* 20 Torr O_2.

indicates that there are other thermal processes involved in the formation of ethanethiol. One of these processes may be the hydrogen exchange of $C_2H_5{}^{35}S\cdot$ species with the added thiols. The radioactive ethylthio radical may react with ethanethiol to give radioactive ethanethiol, as in (1); it also reacts with methanethiol to give the ethanethiol, as in (2), by almost the same S–H bond dissociation energy as that of ethanethiol, as is shown in Fig. 3.

$$C_2H_5{}^{35}S\cdot + C_2H_5SH \longrightarrow C_2H_5{}^{35}SH + C_2H_5S\cdot \quad (1)$$

$$C_2H_5{}^{35}S\cdot + CH_3SH \longrightarrow C_2H_5{}^{35}SH + CH_3S\cdot \quad (2)$$

However it does not react with hydrogen sulfide by means of a higher S–H bond dissociation energy than that of the thiols ($\Delta D = 17.7$ kJ mol^{-1}).[20]

Figure 4 shows the decrease in the ethanethiol yield as the hydrogen sulfide is increased. The existence of the ethylthio radical is also supported by the following experimental fact.

The yield of diethyl sulfide decreases drastically in the presence of ethanethiol and methanethiol as is shown in Fig. 5.

The formation mechanism of this sulfide may be mainly considered to be the combination of ethylthio and ethyl radicals, because the yield of the sulfide was very much affected by the radical scavenger. The addition of the thiol may reduce the yield of the sulfide by the hydrogen donation. Accordingly, the existence of the ethylthio radical in the reaction system is confirmed by the above experimental findings but it can not become the precursor of ethanethiol without the help of the thiol additives. On the other hand, the radiochemical yield of dimethyl sulfide was not affected both in the presence and in the absence of the added dimethyl sulfide carrier.

The dimethyl sulfide thus does not seem to react with the radicals and the fragments formed in the reaction system.

The Effects of Carbonyl Sulfide and the Spin State of the Sulfur Atoms. The electronic states of the sulfur atoms produced by the nuclear transformation are not known. At a high initial recoil energy, many higher electronic states and S^{n+} ions may be possible. However, the sulfur in the higher excited states and in the ionic states may be quickly deactivated to the lowest electronic states by elastic and non-elastic collisions with its surroundings, and then chemical reactions may occur. These states are $^3P_2$ (ground state (0.00 kJ mol^{-1}), $^3P_1$ (4.76 kJ mol^{-1}), $^3P_0$ (6.85 kJ mol^{-1}), $^1D_2$ (110.46 kJ mol^{-1}) and $^1S_0$ (265.22 kJ mol^{-1}).[4] Although some differences in reactivity may exist in the three triplet states, it may be difficult to discriminate among them by usual chemical means.

For convenience, the sulfur atoms will be considered simply to have a ^3P ground-state and the two excited singlet-states, which are both metastable with transitions among them.[4]

Strausz and Gunning have proposed the following reaction schemes for the sulfur atoms produced by the photolysis of COS with hydrocarbons:[4]

$$\mathrm{COS} \xrightarrow{h\nu} \mathrm{S(^1D)} + \mathrm{CO} \quad (3)$$

$$\mathrm{S(^1D)} + \mathrm{RH} \begin{cases} \longrightarrow \mathrm{RSH} & (4a) \\ \longrightarrow \mathrm{S(^3P)} + \mathrm{RH} & (4b) \end{cases}$$

$$\mathrm{S(^1D)} + \mathrm{COS} \begin{cases} \longrightarrow \mathrm{S_2} + \mathrm{CO} & (5a) \\ \longrightarrow \mathrm{S(^3P)} + \mathrm{COS^*} & (5b) \end{cases}$$

$$\mathrm{S(^3P)} + \mathrm{COS} \longrightarrow \mathrm{S_2} + \mathrm{CO} \quad (6)$$

$$\mathrm{S(^3P)} + \mathrm{S(^3P)} \longrightarrow \mathrm{S_2} \quad (7)$$

$$\mathrm{S(^3P)} + \mathrm{S(^3P)} + \mathrm{M} \longrightarrow \mathrm{S_2} + \mathrm{M} \quad (8)$$

$$n\mathrm{S_2} \longrightarrow \mathrm{S}_{2n} \quad (9)$$

The rate constants of several steps have been reported: $k_{4a}=5\times10^7$ M^{-1} s^{-1},[21] $k_{5a}\geqslant4\times10^{10}$ M^{-1} s^{-1},[22] and $k_6=1.8\times10^6$ M^{-1} s^{-1},[23] then, the disappearance of the S(^{1}D) atoms is about 1000 times greater than that of the corresponding thiol formation. In the

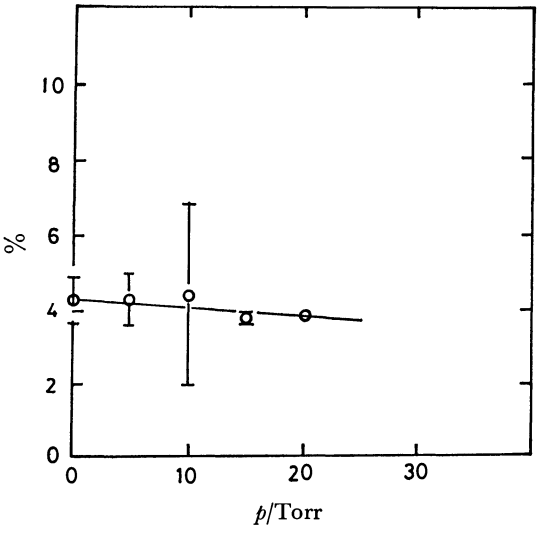

Fig. 6. Plots of the yield of ethanethiol as a function of COS pressure in the presence of 10 Torr ethanethiol.
The plots were corrected for the yield of ethanethiol-^{35}S in the collisional exchange reaction by the addition of 10 Torr ethanethiol as a protecting agent.

○: Ethanethiol, △: dimethyl sulfide.

^{35}Cl(n,p)^{35}S reaction, the sulfur atoms produced are carrier-free, so the sulfur-sulfur combination reaction is improbable. Therefore, Schemes 7, 8, and 9 can be excluded.

The radiochemical yield of ethanethiol in the reaction of sulfur atoms with ethane in the presence of COS is shown in Fig. 6. The yield of ethanethiol is 0.4% for an energetic reaction and 3.3% for a thermal reaction, as has been mentioned above. Therefore, the formation of ethanethiol proceeds mostly by means of a thermal process. The electronic states of the sulfur atoms for the formation of ethanethiol may be considered to be those of thermal sulfur atoms. The formation of ethanethiol was not affected by the addition of COS, and the yield kept constant. Such

a constancy of the yield may imply that the contribution of $S(^1D)$ atoms to the formation of ethanethiol is negligible in the thermal process.

Moreover, the formation of ethanethiol was not affected with the variation of the reaction pressure from 400 Torr to 1100 Torr, as is shown in Fig. 7. Strausz and Gunning have shown that the deactivation of the $S(^1D)$ state to the $S(^3P)$ state increases when the pressure of the reaction system is increased (300—2000 Torr).[4]

The yield of ethanethiol was reduced from about 2.6% to 1.1% by the addition of a small amount of ethylene. Davis and his coworkers have reported that ethylene reacts fast with the $S(^3P)$ atoms (rate constant, 5×10^8 M^{-1} s^{-1}).[13] Also, thermochemically, the insertion reaction of the $S(^3P)$ atoms into the C–H bond of ethane is 231.8 kJ mol^{-1} exothermic.

From the above facts and the thermochemical calculation, the insertion of $S(^3P)$ atoms into the C–H bond may be possible, although the $S(^3P)$ atoms must be accompanied by a spin conversion in the formation of the C–^{35}S–H bond.

Church and Rowland[3] have also reported that the $S(^3P)$ atoms can be inserted into the secondary C–H bond of propane in the presence of a large amount of argon as a moderator.

Furthermore, Ring and Rabinovitch[25,26] have reported that the reaction of the triplet CH_2 (a diradical) produced by the photolysis of diazomethane in a large excess of inert N_2 can be inserted into the C–H bond of propane and isobutane in the gas phase. On the other hand, Gunning and his co-workers have concluded that the $S(^3P)$ atoms do not insert into the C–H bond of hydrocarbons in the photolysis of COS; they concluded this from the marked decrease in the thiol yield in the presence of a large amount of CO_2.[4] This discrepancy can not be explained clearly, but it may presumably be expected that, in this system, a small yield of a sulfur compound is detectable, even if the reaction rate of the insertion by the $S(^3P)$ is extremely slow as compared with that of the $S(^1D)$ atoms; a small excess of the translational energy in this thermal reaction may then cause the insertion, even in the $S(^3P)$ states.

The Ratio of the C–H and C–C Insertions. The insertion yield of the C–H bond in ethane is about 0.4% as an energetic process, and about 3.3% as a thermal process and the insertion yield of the C–C bond is about 0.3% as an energetic process.

Therefore the ratio of the rate constant in the energetic reaction can be represented as the ratio of the yields per bond, *i.e.*, (0.4/6)/0.3. The insertion into the C–C bond is about 5 times faster than that of the C–H insertion in the energetic process. In a previous paper,[5] it was pointed out that the insertion rate of the 2-position of the C–H bond in benzothiazole to that of the C–C bond in 2-methylbenzothiazole was slightly larger in the C–H bond.

In general, the insertion reaction of diradical into the C–H bond always takes place more easily in a weaker bond than a strong bond. For instance, the insertion rate in the reaction of CH_2, generated from the photolysis of diazomethane, into the primary C–H bond relative to that of the secondary in the propane molecule is 1:1.22.[27] The bond dissociation energy is 410.0 kJ mol^{-1} for the primary C–H bond and 395.4 kJ mol^{-1} for the secondary C–H bond in the propane molecule.[28]

Even in the energetic reaction, a similar fact was shown by Church and Rowland,[3] they concluded that the recoil sulfur atoms are inserted predominantly into the secondary C–H bond rather than the primary C–H bond in propane.

Moreover, it has been reported that the formation of the tritiated hydrogen (abstraction reaction) is reduced as the bond dissociation energy of hydrocarbons becomes greater.[29]

The above insertion and abstraction reactions are discussed in just the C–H bond in both the thermal and energetic processes. In the energetic reaction, it may be considered that the insertion reaction occurs also in the C–C bond, and a comparison of the insertion rate into the C–H bond with that of the C–C bond seems to show that it is also affected by the bond-dissociation energy. The bond-dissociation energy of the C–C bond is smaller than that of the C–H bond by about 41.8 kJ mol^{-1} in ethane.[28]

This work was supported by the Visiting Researchers Program in the Rikkyo Reactor. The authors wish to express their appreciation to Dr. S. Harasawa and others for their kind cooperation in the thermal-neutron irradiation.

Kinetics of the Formation and Transformation of Alkoxy-derived Calcium Metasilicate

Osamu YAMAGUCHI,* Muneaki KAMATA, and Kiyoshi SHIMIZU*

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received January 10, 1979)

Wollastonite(β-$CaSiO_3$) was formed directly from the mixed powder prepared by simultaneous hydrolysis of calcium and silicon alkoxides. Crystallization isotherms were described by the Avrami equation $\ln(1-\alpha)=-kt^n$ with $n=3$ and the activation energy was determined as 284.5 kJ/mol. The kinetics of transformation of β- into α-$CaSiO_3$ was best interpreted by the contracting cube equation $1-(1-\alpha)^{1/3}=kt$. The value of the activation energy was 983.2 kJ/mol.

Calcium metasilicate($CaSiO_3$) exists in three polymorphic modifications; wollastonite(triclinic, β-$CaSiO_3$), pseudowollastonite(triclinic, α-$CaSiO_3$), and parawollastonite (monoclinic). Parawollastonite has been recognized as a mineral. Many investigations[1-7] have been made on the solid state reaction of an equimolar mixture of silica and either calcium carbonate or calcium oxide. It is shown that calcium orthosilicate (Ca_2SiO_4) is always one of the first products at any reaction temperature. For example, Jander and Hoffmann[3] reported that Ca_2SiO_4 and $Ca_3Si_2O_5$ are the first-formed products and gradually convert into $CaSiO_3$, the final product. They observed also a strong effect of grinding on the formation of $CaSiO_3$.

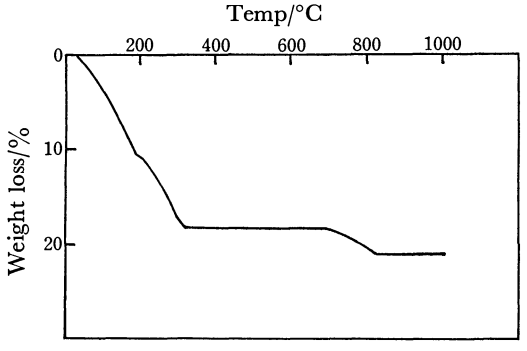

Fig. 1. TG curve of the starting powder.
Sample weight: 20 mg.

This indicates that the contact of reactants in the powder mixture plays an important role. On the other hand, though it has been reported that β-$CaSiO_3$ transforms into α-$CaSiO_3$ at 1125±10 °C,[8] 1180 °C,[5] or 1190 °C,[9] no kinetic study has been carried out.

In the present study, it was found that β-$CaSiO_3$ is formed directly from the mixed powder prepared by simultaneous hydrolysis of calcium and silicon alkoxides. On the basis of this result, kinetic studies have been made on the formation of β-$CaSiO_3$ and the transformation of β- into α-$CaSiO_3$. The kinetic data were analyzed with available solid state models.

Experimental

Materials and Procedure. Silicon ethoxide used was of guaranteed purity. Calcium methoxide was synthesized by heating calcium metal in an excessive amount of dehydrated methanol at 65 °C for 5 h. The purity of calcium metal was 99.9%. A mixture of these alkoxides with the mole ratio of $Ca^{2+}/Si^{4+}=1:1$ was prepared, and then poured into aqueous ammonia solution at 30 °C. The temperature was slowly raised up to 85 °C while being stirred. The resulting mixed powder was washed repeatedly with hot water and dried at 60 °C under reduced pressure. The mixed powder, in the description below, is termed starting powder. The average particle size of the starting powder is *ca.* 400 Å.

Measurement. Thermal analyses (TG, DTA) were carried out in air at a heating rate of 10 °C/min. Alpha-alumina was used as a standard material in DTA. On

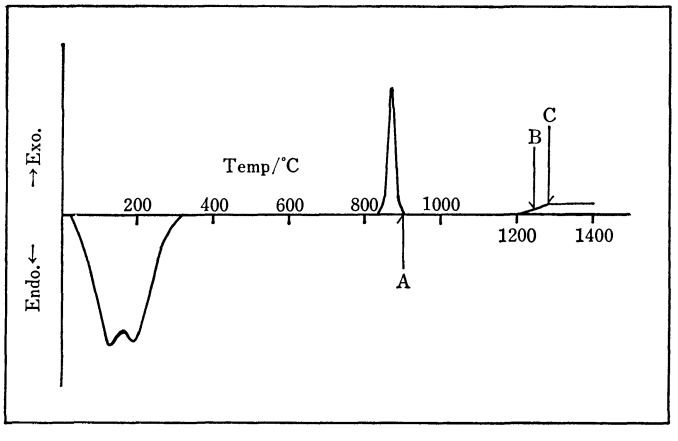

Fig. 2. DTA curve of the starting powder.
Sample weight: 20 mg.

○: 820 °C, ●: 840 °C, ◐: 870 °C.

the basis of the DTA data, the starting powder was heated in an electric furnace up to a desired temperature at a heating rate of 10 °C/min, and then cooled rapidly to room temperature. The specimens were examined by means of X-ray diffractometer using nickel filtered copper K_α. The fractional transformation was determined from the heights of the main peaks characteristics of α-(d=3.20 Å) and β-$CaSiO_3$ (d=2.97 Å), using the calibration curve prepared with known compositions.

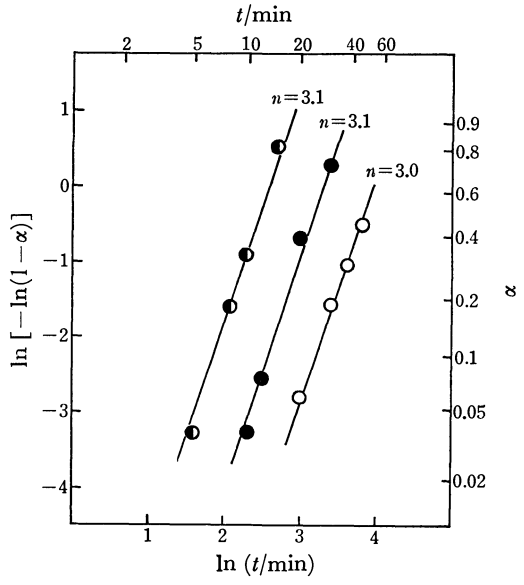

Fig. 5. Plots of ln $(1-\alpha)$ *vs.* time t of the data shown in Fig. 4.

Results and Discussion

Thermal Analysis. Figure 1 shows a TG curve of the starting powder. The weight loss of 18.2% up to 320 °C is attributed to the loss of ammonia, surface-absorbed methanol and ethanol, absorbed water, and hydrated water. Continued weight loss, 2.8%, was observed between 690 and 820 °C. The specimens heated in this temperature range were grayish. This may be due to the alcoholic hydrocarbon occluded in powders and/or free carbon produced by heating, which reacts with oxygen of bulk at the surface, resulting in the evolution of the decomposition products such as carbon monoxide, carbon dioxide, and water vapor.[10-11]

A DTA curve of the starting powder is shown in Fig. 2. Two exothermic reactions were observed at 830—900 °C and 1200—1280 °C. From the results of X-ray diffraction, the reactions were found to be the crystallization of β-$CaSiO_3$ from an amorphous phase and the transformation of β- into α-$CaSiO_3$, respectively.

X-Ray Analysis. Figure 3 shows the variation of X-ray diffraction patterns of $CaSiO_3$ with increasing temperature. The starting powder was amorphous, and no significant changes were observed up to 800 °C. The peaks corresponding to β-$CaSiO_3$ appeared after heating at 820 °C for 10 min, and the intensity increased rapidly up to 900 °C. No other peaks were identified except for the β-$CaSiO_3$ spectrum up to 1170 °C. The peaks of α-$CaSiO_3$ began to appear when heated at 1180 °C for 20 min, and the specimen heated at 1280 °C showed an X-ray diffraction pattern characteristic of α-$CaSiO_3$.

Kinetics of the Formation of β-$CaSiO_3$. Figure 4 shows the fraction of the crystallized β-$CaSiO_3$ at 820, 840, and 870 °C. The starting powder was preheated at 500 °C for 1 h. The fractional crystallization of each specimen was determined from the height

(×20000)

of d=2.97 Å which is the strongest peak of the β-$CaSiO_3$ spectrum. A well-crystallized specimen was obtained by heating the starting powder at 1150 °C for 20 min. Quartz was used as an internal standard material. Crystallization isotherms were characterized by sigmoidal shape (Fig. 4), the kinetics being best described by the Avrami equation[12] (Fig. 5),

$$\ln(1-\alpha) = -kt^n \qquad (n=3\text{—}3.1\fallingdotseq 3) \qquad (1)$$

where α, t, k, and n are the fractional crystallization, time, rate constant and a constant related to the reaction mechanism, respectively. Electron micrograph of the β-$CaSiO_3$ powder consisting of nearly spherical particles is shown in Fig. 6. In view of this fact and also the fact that the Avrami equation with n=3 was fitted over the whole range of crystallization

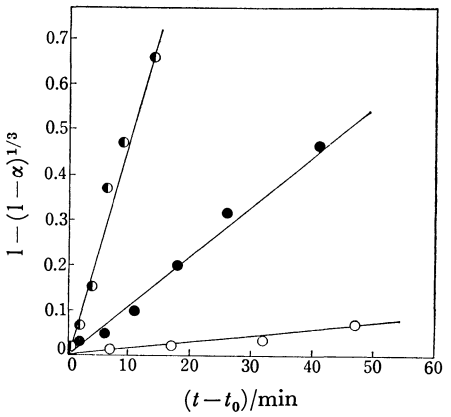

Fig. 8. Plots of $1-(1-\alpha)^{1/3}$ *vs.* time $t-t_0$ of the data shown in Fig. 7.

curves, three-dimensional growth of β-$CaSiO_3$ with site-saturation for nucleation is probably the rate-determining step. The activation energy calculated from the Arrhenius plot was 284.5 kJ/mol.

Kinetics of the Transformation of β- into α-$CaSiO_3$. Figure 7 shows the fractional transformation of β- into α-$CaSiO_3$ as a function of time at different temperatures. The specimens heated at 1150 °C for 20 min were used as a starting material. Induction periods were observed, attempts being made to fit the results to kinetic laws by considering the induction periods. As shown in Fig. 8, transformation isotherms are best described by the contracting cube equation,[13]

$$1-(1-\alpha)^{1/3} = k(t-t_0) \qquad (2)$$

where α is the fractional transformation, t time and t_0 induction period. This indicates that the transformation is controlled by the rate of advance of the reaction interface. The rate constants were determined from the slopes of the straight lines and the activation energy was determined as 983.2 kJ/mol.

Pressure Effects on the Base Hydrolysis Reaction Rates of α-, β-[Co(edda)$(NH_3)_2]^+$ and α-[Co(edda)$(NO_2)_2]^-$ in a Carbonate Buffer

Yoichi KITAMURA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received January 20, 1979)

The pressure effects on the base hydrolysis reaction rates of α-, β-[Co(edda)$(NH_3)_2]^+$ and α-[Co(edda)-$(NO_2)_2]^-$ in a carbonate buffer were measured up to 1500 kg/cm² (1 kg/cm²=98.0665 kPa). The activation volumes at normal pressure were found to be 16.6, 22.3, and 11.9 cm³/mol respectively. These values are consistent with those expected from the S_N1 CB mechanism, where the conjugate bases dissociate *via* the I_d mechanism.

The pressure dependence of a reaction rate gives the value of the activation volume (ΔV^*). In the base hydrolysis reaction of a Co(III)-complex, the magnitude of ΔV^* is comparatively large (20±10 cm³/mol) for the S_N1 CB mechanism, since the volume change in the pre-equilibrium to produce the conjugate base amounts to about 20 cm³/mol.[1] In contrast, it is smaller than 9 cm³/mol for the S_N2 mechanism.[2] Thus, the activation volume is a useful quantity for use in discriminating the mechanisms for a base hydrolysis reaction.

It has been shown by Kuroda *et al.* that, in a carbonate buffer, the base hydrolysis reactions of α-, β-[Co(edda)$(NH_3)_2]^+$ and α-[Co(edda)$(NO_2)_2]^-$,

$$\alpha\text{-}[Co(edda)(NH_3)_2]^+ + OH^- \rightarrow \alpha\text{-}[Co(edda)(NH_3)OH] + NH_3, \quad (1)$$

$$\beta\text{-}[Co(edda)(NH_3)_2]^+ + OH^- \rightarrow \beta\text{-}[Co(edda)(NH_3)OH] + NH_3, \quad (2)$$

$$\alpha\text{-}[Co(edda)(NO_2)_2]^- + OH^- \rightarrow \alpha\text{-}[Co(edda)(NO_2)OH]^- + NO_2^-, \quad (3)$$

are followed by successive carbonation steps (ethylenediamine-*N*,*N*′-diacetic acid=H_2edda).[3-5] The rates of the carbonation step are relatively high for the reactions of α-[Co(edda)$(NH_3)_2]^+$ and α-[Co(edda)-$(NO_2)_2]^-$, and relatively low for that of β-[Co(edda)-$(NH_3)_2]^+$, compared to the base hydrolysis rates. By assuming a first-order reaction for the base hydrolysis, the rate constants of Reactions 1,[3] 2,[6] and 3[5] have been calculated at a normal pressure.

In this experiment, the pressure dependences of the rate constants of Reactions 1, 2, and 3 were examined up to 1500 kg/cm². The mechanisms are discussed from the standpoint of the activation volume.

Experimental

Materials. The preparative methods and the absorption maxima of the complexes used in this study are summarized in Table 1. The buffer solutions were made from reagent-grade chemicals. The water was distilled after passing it through an ion-exchange column.

Kinetic Measurement. The procedures were the same as those in a previous work.[11]

Results

The first-order rate constant, k_1, of the base hydrolysis was determined by

$$\ln[(D_\infty - D_{t'})/(D_\infty - D_t)] = k_1(t - t'),$$

where $D_{t'}$ and D_t represent the optical densities at the moment when the high pressure is reached, and at the moment when the high pressure is released, respectively. For the reaction of α-[Co(edda)$(NH_3)_2]^+$, D_∞ represents the optical density (OD) at equilibrium. For the reactions of β-[Co(edda)$(NH_3)_2]^+$ and α-[Co(edda)-$(NO_2)_2]^-$, D_∞ represents the estimated OD values of the base hydrolysis products: β-[Co(edda)(NH_3)OH] and α-[Co(edda)(NO_2)OH]$^-$ respectively. Kuroda's D_∞/D_0 values are used, where D_0 represents the OD at the moment of the dissolution of the initial complex. The D_∞/D_0 values (λ(nm) used to follow the reaction) are 1.9 (540) for Reaction 1,[3] 0.7 (500) for Reaction 2,[6] and 4.86 (590) for Reaction 3.[5] ($t-t'$) is the reaction time. The k_1 values at each pressure are summarized in Table 2. An increase in pressure by 1000 kg/cm² reduces the k_1 values below half, from which large positive magnitudes (*ca.* 20 cm³/mol) of the activation volumes can be expected for these reactions. They were fitted to the formula, $\ln(k_1/k_{10}) = aP + bP^2$, where k_{10} is the rate constant at a normal pressure and where P is expressed in kg/cm² (Fig. 1).

At a normal pressure, the k_1 values are proportional to [OH$^-$] *i.e.*, $k_1 = k_2[OH^-]$.[3,5,6] Then, the activation volume and its pressure dependence are given by[2]

$$\Delta V^* = -RT\frac{d\ln k_2}{dP} = -RT\frac{d\ln k_1}{dP} + RT\frac{d\ln[OH^-]}{dP}$$

$$= -RT(a+2bP) + RT\frac{d\ln K_w}{dP} - RT\frac{d\ln K_2}{dP}$$

$$\frac{d\Delta V^*}{dP} = -2bRT + RT\frac{d^2\ln K_w}{dP^2} - RT\frac{d^2\ln K_2}{dP^2},$$

where K_w and K_2 represent the ionic product of water and the second dissociation constant of carbonic acid respectively. By using the known pressure dependences

of the K_w and K_2, the values of ΔV^* and $d\Delta V^*/dP$ at the normal pressure are calculated.[2] El'yanov and Hamann have proposed a formula for the pressure dependence of the volume change of an acid-base equilibrium:

$$d\Delta V/dP=(-1.80\times10^{-4}\ cm^2/kg)\Delta V,$$

where ΔV is the volume change at a normal pressure.[11] The second derivatives of K_w and K_2 are estimated following their method. The results are summarized in Table 3.

Discussion

From the proportionality of the k_1 values to $[OH^-]$, the S_N2 and S_N1 CB mechanisms are possible for these reactions. In the case of the S_N2 mechanism, ΔV^* is estimated to be smaller than 9 cm³/mol.[2] The large positive values of ΔV^* obtained for Reactions 1 and 2 can then be considered as evidence for the S_N1 CB mechanism. For Reaction 3, the obtained magnitude of ΔV^* is not large enough. However, this complex ion has a negative charge, and so the formation of a seven-coordinated intermediate or an ion pair with an OH^- ion would be improbable. Therefore, Reaction 3 should also proceed *via* the S_N1 CB mechanism.

In this mechanism, the reaction series for Reactions 1 and 2 are

$$\alpha\text{-, }\beta\text{-}[Co(edda)(NH_3)_2]^+ + OH^- = \alpha\text{-, }\beta\text{-}[Co(edda)(NH_2)(NH_3)] + H_2O$$

$$\alpha\text{-, }\beta\text{-}[Co(edda)(NH_2)(NH_3)] \rightarrow \alpha\text{-, }\beta\text{-}[Co(edda)(NH_2)] + NH_3$$

$$\alpha\text{-, }\beta\text{-}[Co(edda)(NH_2)] + H_2O \rightarrow \alpha\text{-, }\beta\text{-}[Co(edda)(NH_3)OH],$$

where the first and the third steps are rapid and where

5	β-[Co(edda)(en)]⁺	20.0	16.9	3.1	−1.4	1.6	176	195	4)

a) Reaction number. b) Ref. for E_a and ΔS^*. The units are: ΔV^*, ΔV_{pre}, $\Delta V^{*\prime}$ (cm³/mol); $\frac{d\Delta V^*}{dP}$, $\frac{d\Delta V^{*\prime}}{dP}$ (10^{-3} cm⁵ mol⁻¹ kg⁻¹); E_a (kJ/mol); and ΔS^* (J K⁻¹ mol⁻¹).

the second is the rate-determining process. Analogously, the series for Reaction 3 is

$$\alpha\text{-}[Co(edda)(NO_2)_2]^- + OH^- = \alpha\text{-}[Co(edda^*)(NO_2)_2]^{2-} + H_2O$$

$$\alpha\text{-}[Co(edda^*)(NO_2)_2]^{2-} \rightarrow \alpha\text{-}[Co(edda^*)(NO_2)]^- + NO_2^-$$

$$\alpha\text{-}[Co(edda^*)(NO_2)]^- + H_2O \rightarrow \alpha\text{-}[Co(edda)(NO_2)OH]^-,$$

where edda* represents the conjugate base of the edda ligand. Thus, the activation volume is given by $\Delta V^* = \Delta V_{pre} + \Delta V^{*\prime}$, where ΔV_{pre} is the volume change in the pre-equilibrium and $\Delta V^{*\prime}$ is the activation volume of the second step.

The isomerization reactions in a carbonate buffer,

$$\beta\text{-}[Co(edda)(tn)]^+ \rightarrow \alpha\text{-}[Co(edda)(tn)]^+, \quad (4)$$

$$\beta\text{-}[Co(edda)(en)]^+ \rightarrow \alpha\text{-}[Co(edda)(en)]^+, \quad (5)$$

also proceed *via* the S_N1 CB mechanism. In a previous report, the ΔV_{pre} value for Reactions 4 and 5 was estimated as 18.8 cm³/mol.[2] Later, for the equilibrium,

$$\alpha\text{-}[Co(edda)(H_2NCH_2CH_2OH)]^+ + OH^- = \alpha\text{-}[Co(edda)(H_2NCH_2CH_2O)]^0 + H_2O, \quad (6)$$

the volume change ($\Delta V = 16.9 \pm 0.7$ cm³/mol) was obtained at 25 °C and a low ionic strength.[1] This equilibrium is analogous to the pre-equilibria of Reactions 1, 2, 4, and 5, and the ΔV_{pre} values for these reactions may be taken approximately as 16.9 cm³/mol. In Equilibrium 6, $\Delta Z^2 = -1$, where Z is the charge of the complex ion; the contribution (ΔV_{el}) of the electrostrictive volume change of the complex ion is positive. In contrast, in the pre-equilibrium for Reaction 3 ($\Delta Z^2 = 3$), ΔV_{el} would be negative and ΔV_{pre} would be smaller than 16.9 cm³/mol. Values of $\Delta V = 19.9 \pm 1$ cm³/mol are known for the neutralization equilibria of trivalent complex ions ($\Delta Z^2 = -5$) such as $[Fe(H_2O)_6]^{3+}$, $[Co(NH_3)_5(H_2O)]^{3+}$, and $[Cr(H_2O)_6]^{3+}$.[1] Since ΔV_{el} is proportional to ΔZ^2, the ΔV_{pre} value for Reaction 3 must be approximately 13.9 cm³/mol.[1] The magnitudes of $\Delta V^{*\prime}$ thus obtained for Reactions 1, 2, and 3 are comparable to those for Reactions 4 and 5. In the activated states of Reactions 4 and 5, the $-NH_2$ group liberated from the conjugate base must remain in the vicinity of the five-coordinated intermediate, since it is linked to the intermediate through the molecular chain of tn or en. Therefore, the conjugate bases in Reactions 1, 2, and 3 may dissociate *via* the I_d mechanism; *i.e.*, in the activated state the leaving group remains in the second coordination sphere.

The aquo-exchange reaction,

$$[Co(NH_3)_5H_2O]^{3+} + H_2O^* \rightarrow [Co(NH_3)_5H_2O^*]^{3+} + H_2O, \quad (7)$$

also proceeds *via* the I_d mechanism and $\Delta V^* = 1.2$ cm³/mol is known at 25 °C.[13] In the activation step of Reaction 7, the electrostrictive volume change is not involved. In the dissociative activation steps for Reactions 1 and 2, a neutral NH_3 departs from the neutral conjugate base, and the electrostrictive volume change is also ignored. In that of Reaction 3, only a separation of charge occurs, and the electrostrictive volume change may be insignificant. Therefore, the $\Delta V^{*\prime}$ values for the I_d dissociation in Reactions 1, 2, and 3 may be expected to be comparable to the ΔV^* for Reaction 7. The experimentally obtained magnitudes of $\Delta V^{*\prime}$ are consistent with this expectation.

If the conjugate bases completely dissociate in the activated state (D mechanism), $\Delta V^{*\prime}$ can be estimated from the partial molar volumes ($\overline{V}$) by

$$\Delta V^{*\prime} = \overline{V}(\alpha\text{-},\beta\text{-}[Co(edda)(NH_2)]) - \overline{V}(\alpha\text{-},\beta\text{-}[Co(edda)(NH_2)(NH_3)]) + \overline{V}(NH_3),$$

and

$$\Delta V^{*\prime} = \overline{V}(\alpha\text{-}[Co(edda^*)(NO_2)]^-) - \overline{V}(\alpha\text{-}[Co(edda^*)(NO_2)_2]^{2-}) + \overline{V}(NO_2^-).$$

Stranks assumes that the intrinsic volume difference between the five-coordinated intermediate and its six-coordinated precursor is zero.[14] This volume difference may be estimated from the volume difference between a square pyramid or a trigonal bipyramid and an octahedron, with each center-apex length 3 Å. This leads to the intrinsic volume difference of -10.8 and -7.6 cm³/mol. $\overline{V}(NH_3)$ is *ca.* 24.9 cm³/mol.[15] Then, in the D mechanism, the $\Delta V^{*\prime}$ values for Reactions 1 and 2 would be 14.1 cm³/mol or larger. $\overline{V}(NO_2^-)$ is *ca.* 31.6 cm³/mol.[16] Taking account of the electrostrictive volume expansion (*ca.* 2.3 cm³/mol) of the complex, the $\Delta V^{*\prime}$ value for Reaction 3 would be 23.1 cm³/mol or larger in the D mechanism. Thus, the values of $\Delta V^{*\prime}$ to be expected from the D mechanism are considerably larger than those obtained from the experimental results.

The values of $d\Delta V^{*\prime}/dP$ are calculated from $d\Delta V^*/dP$ (Table 3):

$$(d\Delta V^{*\prime}/dP) = (d\Delta V^*/dP) - (d\Delta V_{pre}/dP),$$

where $d\Delta V_{pre}/dP$ is -3×10^{-3} and -2.5×10^{-3} cm⁵ mol^{-1} kg^{-1} for $\Delta V_{pre} = 16.9$ and 13.9 cm³/mol respectively (estimated after El'yanov and Hamann).[12] The values of $d\Delta V^{*\prime}/dP$ are comparatively small for Reactions 4 and 5, where the liberated $-NH_2$ group is linked to the five-coordinated intermediate. In contrast, they are comparatively large for Reactions 1, 2, and 3, where the leaving group is not linked to the intermediate. Hence, the increases in the $\Delta V^{*\prime}$ with the increase in the pressure are caused by the enhancement of the separation of the leaving group from the five-coordinated intermediate at high pressures. In other words, the mechanism of the dissociation of the conjugate base changes from the I_d mechanism at a normal pressure to the D mechanism at higher pressures. A possible factor promoting the separation at high pressures may be the increasing stability of the hydrogen bonds between the leaving group and the water molecules, which decreases the interaction between the leaving group and the intermediate.

The activation energies (E_a) obtained by Kuroda are listed in Table 3. In the S_N1 CB mechanism, $E_a \simeq \Delta H_{pre} + E_a'$, where ΔH_{pre} is the enthalpy change for the pre-equilibrium and where E_a' is the activation energy for the dissociation of the conjugate base. ΔH_{pre} would be negative, since an evolution of heat was noticed in the analogous neutralization Equilibrium 6.[1] The abnormally large magnitudes of E_a'

can be understood only by considering the Co–N bond rupture to be the activation step.[3] There can be found an qualitative correspondence relation between the magnitude of E_a and the position of the first absorption band.[9,17] This indicates that the ligand-field strength is one factor which influences the activation energy. The activation entropies calculated from the first-order rate constants are listed in Table 3. An ordinary compensation relation is found between the magnitudes of E_a and ΔS^*. This relation is often found for a series of related reactions and is interpreted as indicating that the essential reaction mechanism is the same for all of a given series.[18] Another linear correlation is found between ΔS^* and ΔV^* except for Reaction 3. Thus, the values of $\Delta V^{*\prime}$, E_a, and ΔS^* for Reactions 2 and 5 are comparatively larger than those for Reactions 1 and 4. One possible interpretation of this may be that, in the activated states for Reactions 2 and 5, the leaving group is more separated from the five-coordinated intermediate than in those for Reactions 1 and 4. Then, the smaller magnitude of $d\Delta V^{*\prime}/dP$ for Reaction 2 than that for Reaction 1 may be interpreted as showing that, for Reaction 2, the separation increases rather moderately with the pressure, since it is already considerable at the normal pressure.

The author wishes to thank Professor Kashiro Kuroda of Ehime University for permission to refer to his unpublished results and for his valuable suggestions throughout this work. The author is also indebted to Mr. Yoshifumi Noma for his co-work in the preliminary experiments on the reaction of α-$[Co(edda)(NH_3)_2]^+$.

Heteropolyanions of Methylarsonate and Dimethylarsinate: The Crystal Structures of Guanidinium Hexamolybdomethylarsonate Hexahydrate, $(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$ and Guanidinium Tetramolybdodimethylarsinate Monohydrate, $(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$

Kazuko Y. MATSUMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 1, 1979)

The crystal and molecular structures of polymolybdo complexes of methylarsonate and dimethylarsinate have been determined by the X-ray diffraction technique. The crystal of $(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$ is trigonal, with the space group R3 and the cell dimensions of $a=9.653(6)$ Å, $\alpha=87.01(15)°$, and $Z=1$. The anion is an assemblage of six MoO_6 octahedra and a tetrahedral CH_3AsO_3 group. The six MoO_6 octahedra constitute a ring with alternate edge- and corner-sharing, and the tetrahedral CH_3AsO_3 group joins the anion, with its three oxygen atoms shared with the ring. Each molybdenum atom has two terminal oxygen atoms in the *cis* position and is coordinated by one water molecule. $(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$ crystallizes in the space group $P2_1/c$ of the monoclinic system, with the cell dimensions of $a=8.530(5)$, $b=8.532(4)$, $c=30.121(15)$ Å, $\beta=95.50(16)°$, and $Z=4$. The $Mo_4O_{14}(OH)$ moiety in the $[(CH_3)_2AsMo_4O_{14}(OH)]^{2-}$ anion is formed with two face- and two edge-sharings of MoO_6 octahedra into an almost flat rectangle. The oxygen atom located at the center of the anion and bonded to all the four molybdenum atoms is protonated and is, in fact, a hydroxyl group.

It is well known that arsenic acid reacts with molybdic acid to yield various heteropoly acids. Some of them have been structurally elucidated by X-ray diffraction: $AsMo_{12}O_{40}^{3-}$ with the Keggin structure,[1,2] $H_4AsMo_{12}O_{50}^{4-}$[3] with the "reversed" Keggin structure, $AsMo_9O_{34}^{9-}$,[4] $As_2Mo_{18}O_{62}^{6-}$,[5,6] and $As_2Mo_5O_{23}^{6-}$.[7] Alkyl- or arylarsonic acids and -arsinic acids, $RAsO_3H_2$ and R_2AsO_2H, seem to be similar to phosphoric or arsenic acid in their chemical properties in the following respects: they form dimers of the pyrophosphoric-acid type and are weak acids (the pK values of $RAsO_3H_2$ are 3—4, whereas pK_1 is 2.1 for phosphoric acid and 2.3 for arsenic acid). In view of the fact that the heteropolyanions containing phosphorus or arsenic atoms are formed through dehydration between phosphoric or arsenic acid and molybdic acid, these organo-arsenic acids can be expected to react with molybdic acid to give organo-heteropolyanions.

Such anions are noteworthy from the following points of view: the organo-heteropolyanions have their heteroatoms, that is, As(V) in the present case, partly coordinated by organic groups. Therefore, the arsenic atoms can not be coordinated by four oxygen atoms, unlike those in non-alkylated arsenic acids, as long as the former keep their coordination number of 4. Otherwise, they may increase the coordination number from 4 to 6. Whichever of the two may be the case, new structural types may be expected for these anions. Recently, the present author has reported the crystal and molecular structure of $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2\cdot 4H_2O$,[8] whose anion's interconversion with $[(C_6H_5As)_2Mo_6O_{24}]^{4-}$ in an aqueous solution[9] has added valuable knowledge concerning the intermediate species involved in the formation of these anions and the pH regions where they are stable.

In this paper the author will report on the crystal and molecular structures of guanidinium polymolybdomethylarsonate and polymolybdodimethylarsinate, $(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$ and $(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$. The first synthetic description of these complexes was made by Gibbs as early as in 1883[10] and later by Rosenheim and Bilecki,[11] but their analytical results are unsatisfactory and the molecular formulae they gave seem doubtful. As for the heteropolyanions containing methylarsonic acid, the synthesis and the structure of $[(CH_3As)_2Mo_6O_{24}]^{4-}$ have recently been reported,[12] but the author has independently obtained a hexamolybdomethylarsonate anion which seems to have a different molecular formula, *i.e.*, $[CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$. Thus, the formation conditions and structural differences of these anions are of interest and would give information about the reactions occurring in an aqueous solution containing molybdic acid and methylarsonic acid. On the other hand, regarding the heteropolyanion containing dimethylarsinic acid, a short communication on the crystal structure of $(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$ recently appeared;[13] it briefly discusses the anion's structure. In this paper, the whole crystal structure, together with the anion's structure, will be discussed, and the full and detailed data on the bond distances, bond angles, and the crystal packings, including the network of hydrogen bondings, will be presented.

Experimental

$(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$. *Preparation*: 4.3 g (0.03 mol) of MoO_3 was gradually added to 75 cm³ of a boiling aqueous solution containing 1.46 g (5 mmol) of $Na_2AsCH_3O_3$, and the pH of the solution was decreased to *ca.* 2 with HCl. After the solution has been boiled for a few minutes, it was filtered to remove a small amount of unreacted MoO_3 and the filtrate was condensed on a water bath to 12.5 cm³. The addition of 1 g of CN_3H_6Cl to the solution readily gave a lolorless precipitate, which was subsequently filtered, recrystallized from hot water, and air-dried. The reaction is expressed as follows:

$$CH_3AsO_3^{2-} + 6MoO_3 + 6H_6O \longrightarrow [CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$$

Found: C, 2.69; H, 2.94; N, 6.48%. Calcd for $(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$: C, 2.73; H, 2.80; N, 6.37%.

The addition of $(CH_3)_4NBr$ or KCl instead of CN_3H_6Cl

precipitated the corresponding salts of the anion. The potassium salt was recrystallized from hot water. However, the tetramethylammonium salt is insoluble in most aqueous and organic solvents. The addition of $(n\text{-}C_4H_9)_4NBr$ to the solution gave a yellow-green precipitate, which was a mixture of several polyanions. By the fractional recrystallization of this mixture from CH_3NO_2, the $[(CH_3As)_4Mo_{12}O_{46}]^{4-}$ anion was obtained together with other polyanions, such as $[CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$ and $Mo_6O_{19}^{2-}$. The $[(CH_3As)_4Mo_{12}O_{46}]^{4-}$ [12] and $Mo_6O_{19}^{2-}$ [14] anions were identified by elemental analyses and IR spectra.

Crystal Data: Although many kinds of salts of the $[CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$ anion were prepared, as has been described above, most of them were obtained in powder or microcrystalline form. Among them, guanidinium salt seemed likely to give a single crystal of an appropriate size, though it would not do so easily. Thus, attempts were made to obtain it by a diffusion method, and a crystal with approximate dimensions of $0.1\times 0.08\times 0.08$ mm was used for X-ray measurements. Although this crystal gives slightly smeared diffraction spots, it is fairly stable in air and against X-ray irradiation, at least for the period of X-ray data collection. Such smeared spots have been observed in other isopoly- and heteropolyanions; they are probably attributed to the loose packings of large anions and the existence of easily mobile water of crystallization occupying the cavities between the large anions.[15,16] Although a crystal structure analysis with a high precision can not be expected for this crystal, X-ray measurement was undertaken, because at least the structure of the anion could be elucidated and this would be valuable information for the chemistry of heteropolyanions containing methylarsonic acid. The lattice constants were refined with twelve 2θ values measured on a diffractometer with Mo $K\alpha$ radiation ($\lambda=0.7107$ Å). The crystal data for $(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$ are: trigonal, R3, $a=9.653(6)$ Å, $\alpha=87.01(15)°$, $V=895.9$ Å^3, $M.W.=1338.0$, $Z=1$, $D_m=2.45$ g cm^{-3}, $D_x=2.48$, $\mu=13.3$ cm^{-1}.

Data Collection: All the intensities were measured on a Philips automatic four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The ω-2θ scan mode was employed with the scan rate of 1 ° min^{-1} in 2θ. The scan width was determined for each reflection according to this formula $\omega=(1.4+0.6\tan\theta)°$. Background counts of 20 s were taken at each scan end. Three standard reflections were monitored every 3 h, but no significant intensity loss was observed throughout the data collection. The data were corrected for Lorentz and polarization effects. Absorption and extinction corrections were not applied. The intensities were collected up to $2\theta=60°$, of which 1094 independent reflections with $|F_o|\geq 3\sigma(|F_o|)$ were used for the structural analysis.

Solution and Refinement of the Structure: Two independent molybdenum atoms were located from the Patterson map, and successive Fourier syntheses revealed the positions of all non-hydrogen atoms in the anion. At this stage, a problem arose concerning the space group of this crystal. Although this anion itself is, strictly speaking, dissymmetric, a close examination of the atomic coordinates (Table 1) exhibits that this anion is approximately centrosymmetrical except the part of the As–C bond. For instance, many atoms in the anion are related to each other nearly centrosymmetrically, *i.e.*, Mo(1) and Mo(2), O(3) and O(9), O(4) and O(8), and O(6) and O(7). Moreover, when the structure analysis had proceeded further, it was found that the cations and water molecules also occupy centrosymmetric positions (C(1) and C(2), N(1) and N(2), and H_2O(1) and H_2O(2)). As the R3 and R$\bar{3}$ space groups can not be distinguished from the systematic absence of reflection, two different refinements were attempted, one based on the R3 space group, and the other, on R$\bar{3}$, assuming a statistical distribution of the anions in the right-handed and left-handed orientations, with an equal weight for each. Disorder of

this kind has sometimes been observed in crystals of isopoly- and heteropoly acids and their salts,[16,17] and is considered as one of their specific properties. The R value for R3 was 0.20, whereas that for $R\bar{3}$ was 0.21. Therefore the R3 space group was assumed to be the true one. After several cycles of refinement with isotropic temperature factors by the block-diagonal least-squares method using the UNICS program,[18] anisotropic temperature factors were applied for all the atoms; further refinements reduced the R value to 0.16 ($R=\sum||F_o|-|F_c||/\sum|F_o|$). All the cations and water of crystallization were located on the basis of the difference synthesis, and the structure was finally refined to $R=0.14$. Although the final R value is not low enough, this is because of the unsatisfactory quality of the crystal, as has been mentioned, and does not basically obviate the elucidated anion's structure.

The atomic coordinates and temperature factors are listed in Tables 1 and 2. The final F_o-F_c table is available at the Office of Chemical Society of Japan as Document No. 7930A. The atomic scattering factors were taken from Ref. 19, while the corrections of the effect of the anomalous dispersion for molybdenum and arsenic atoms were based on Ref. 20. The calculation was performed on a HITAC 8700/8800 computer at the Computer Center of the University of Tokyo.

$(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$. *Preparation*: This compound was prepared according to the method described in Ref. 11. Found: C, 5.41; H, 2.51; N, 9.90; Mo, 45.52%. Calcd for $(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$: C, 5.54; H, 2.44; N, 9.68; Mo, 44.22%.

Cyrstal Data: A colorless rectangular crystal with the approximate dimensions of $0.2\times0.2\times0.1$ mm was used. The cell dimensions were obtained from twelve 2θ values measured on a diffractometer with Mo $K\alpha$ radiation. The crystal data for $(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$ are: monoclinic $P2_1/c$, $a=8.530(5)$ Å, $b=8.532(4)$, $c=30.121(15)$, $\beta=95.50(16)°$, $M.W.=867.9$, $Z=4$, $D_m=2.63$ g cm^{-3}, $D_x=2.64$, $\mu=41.0$ cm^{-1}.

Data Collection: All the intensity measurements were performed on a Rigaku four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The conditions for the data collection were basically the same as those described above. The scan rate was 2° min^{-1} in 2θ, and the scan range was determined according to this formula: $\omega=(1.4+0.6\tan\theta)°$. A background count was made for 10 s at the end of each scan. Three standard reflections, monitored every 50 measurements, remained essentially constant during the data collection. The data were corrected for Lorentz and polarization effects. Absorption and extinction cor-

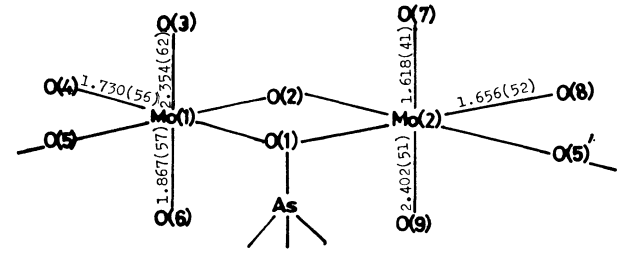
rections were not applied. 5222 independent reflections with $|F_o| \geq 3\sigma(|F_o|)$ up to $2\theta=60°$ were used for the computation.

Solution and Refinement of the Structure: The coordinates for the four independent molybdenum atoms were deduced from the Patterson map. All the remaining non-hydrogen atoms were located from the successive Fourier maps. A few cycles of refinement with individual isotropic temperature factors for all the atoms, followed by several further cycles of anisotropic refinement, resulted in a final R value of 0.091. The final coordinates and temperature factors are listed in Tables 3 and 4, while the F_o-F_c table is kept at the office of this Bulletin as Document No. 7930B.

Description of the Structure and Discussion

$(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$. The structure of the anion is illustrated in Fig. 1. The anion consists of six MoO_6 octahedra, which form a ring by alternate corner- and edge-sharing (the shared corner is O(5) and the shared edge is O(1)–O(2)), and a CH_3AsO_3 tetrahedron connected to the ring with its three oxygen atoms shared with the ring. The six molybdenum atoms are not coplanar and deviate from the best plane by about 0.4 Å, upward and downward alternately. Only Mo(1), Mo(2), As, C, and the nine oxygen atoms coordinated to these molybdenum and arsenic atoms are crystallographically independent; the remaining part of the anion is related



∠O(3)-Mo(1)-O(4)	82.5(2.3)°	∠O(8)-Mo(2)-O(9)	90.4(2.1)°
∠O(4)-Mo(1)-O(6)	107.4(2.4)°	∠O(7)-Mo(2)-O(8)	102.7(2.2)°
∠O(3)-Mo(1)-O(6)	168.5(2.2)°	∠O(7)-Mo(2)-O(9)	166.6(1.8)°

Fig. 2. The geometry of the terminal oxygen atoms around Mo(1) and Mo(2) in the $[CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$ anion.

to the independent atoms by a three-fold axis which coincides with the As–C bond axis. The bond lengths in the anion and cations are listed in Table 5. It is noteworthy that each molybdenum atom seemingly possesses three terminal oxygen atoms. However, for the reasons to be presented below, it is concluded that each molybdenum atom is surrounded not by three terminal oxygen atoms, but by two terminal ones and a water molecule. One of the reasons is concerned with the distances of the terminal Mo–O bonds. As is illustrated in Fig. 2, the Mo(1)–O(3) and Mo(2)–O(9) distances are obviously longer than the other four terminal ones (Mo(1)–O(4), Mo(1)–O(6), Mo(2)–O(7), and Mo(2)–O(8)). The distances, 2.35 Å for Mo(1)–O(3) and 2.40 Å for Mo(2)–O(9), are comparable to the Mo–OH_2 distances of 2.28 Å in $MoO_3\cdot 2H_2O$[21] and of 2.33 Å in $K_2(Mo_2O_5(C_2O_4)_2(H_2O)_2)$.[22] The second reason is concerned with the arrangement of the oxygen atoms coordinated to the molybdenum atoms and the bond angles. In the present polyanion, the three terminal oxygen atoms occupy the *mer* position, whereas the mononuclear and binuclear oxo-complexes of Mo(VI) with three terminal oxygen atoms investigated thus far possess the oxygen atoms in the *fac* position.[22,23] The angles between these three Mo–O bonds are given in Fig. 2. It is generally accepted that the repulsion between two terminal oxygen atoms always, without exception, causes fairly large O(terminal)–Mo–O(terminal) bond angles, ranging from 101° to 108°,[22,24] while the O(terminal)–Mo–H_2O angle in $K_2(Mo_2O_5(C_2O_4)_2(H_2O)_2)$ is reduced to

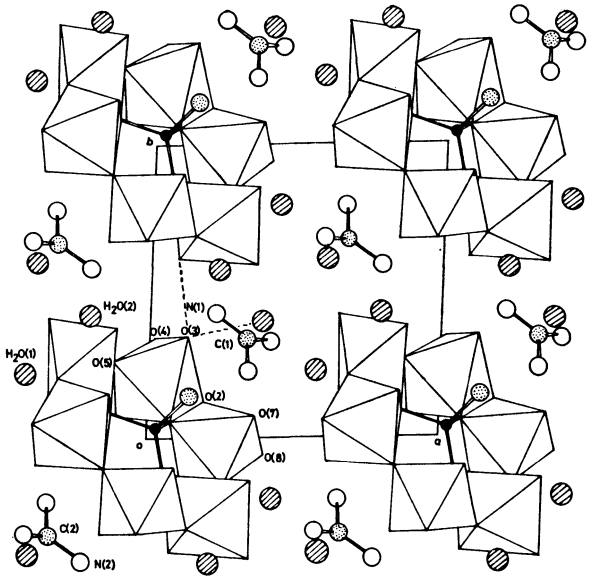


Fig. 3. The crystal structure of $(CN_3H_6)_2[CH_3AsMo_6O_{21}(H_2O)_6]\cdot 6H_2O$ viewed normal to a and b axes.

85.50°.[22] Considering the fact that the O(3)–Mo(1)–O(4) and O(8)–Mo(2)–O(9) angles in the present anion are as small as the latter, O(3) and O(9) can be identified as water molecules without any risk of serious mistake. This assignment is also supproted by the fact that each molybdenum atom is coordinated by two terminal oxygen atoms in the cis position, which is the usual geometry not only in polyacids but also in mono- and binuclear oxo-complexes of Mo(VI). Trans terminal oxygens have been found only in d^2 complexes, such as in $(MoO_2(CN)_4)^{4-}$,[25] but not in Mo(VI) complexes.

Although there have been some reports concerning the coordination of water molecules to heteroatoms in polyanions and their substitution reactions,[26,27] the present anion would seem to be one of the few examples of water molecules coordinating to addenda atoms, that is, molybdenums; another example is found in $Na_3[PMo_9O_{31}(H_2O)_3]\cdot nH_2O$.[28]

The crystal structure is shown in Fig. 3, while selected interionic distances are listed in Table 6. The anions, water molecules, and cations form a three-dimensional network of hydrogen bondings.

$(CN_3H_6)_2[(CH_3)_2AsMo_4O_{14}(OH)]\cdot H_2O$. Figure 4 illustrates the structure of the $[(CH_3)_2AsMo_4O_{14}(OH)]^{2-}$ anion, which consists of four MoO_6 octahedra joined to form a flat group of Mo_4O_{15}, with two face-sharings (the shared faces are O(4)–O(8)–O(10) and O(1)–O(4)–O(15)) and two edge-sharings (the shared edges are O(4)–O(5) and O(4)–O(12)). A $(CH_3)_2AsO_2$ tetrahedron shares two oxygen atoms (O(10) and O(15)) with the Mo_4O_{15} moiety. The bond lengths and angles in the anion are listed in Tables 7 and 8. O(4) is common to all four octahedra, and the Mo(n)–O(4) (n=1, 2, 3, and 4) bond lengths are noticeably large; the distance of Mo(3)–O(4) is 2.538 Å in the present work, one of the largest Mo–O lengths recorded, so far as the author knows. Not many examples of face-sharing of octahedra, as is seen in the present anion, are known, either; other examples are the Mo_2O_9 part of the mannitol-molybdate complex, $H_2Mo_2O_9C_6H_8(OH)_2$,[29] and the molybdocerate anion, $[CeMo_{12}O_{42}]^{8-}$.[30]

Considering the fact that the distances of As–O (terminal) are generally smaller than those of the As–O(bridging) distances in pyroarsenic acids,[31,33,34] the As–O(bridging) distances in the present anion are

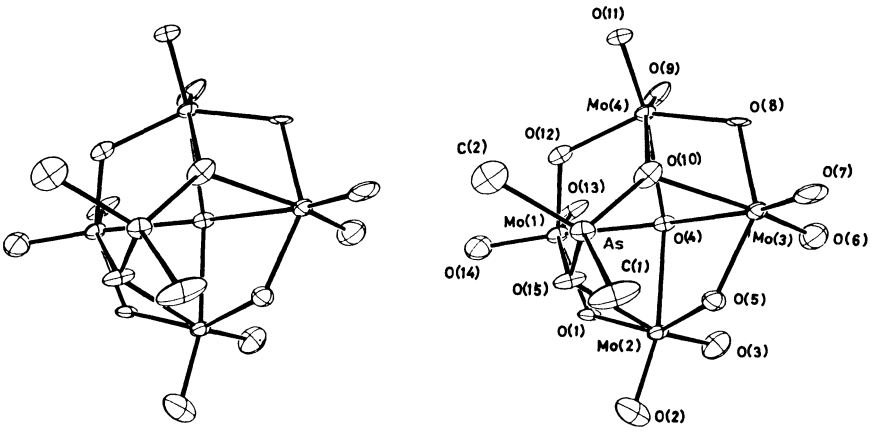

Fig. 4. The structure of the $[(CH_3)_2AsMo_4O_{14}(OH)]^{2-}$ anion.
The vibrational ellipsoids are drawn at the 50% probability level. (ORTEP Johnson, 1971)

rather short, with lengths comparable to the As–O (terminal) distances. The O–As–O angles do not deviate significantly from the usual values in AsO_4^{3-} anions.[32,34]

It is of interest to know where the unique hydrogen atom is located and what kind of role it plays in the crystal. Barkigia *et al.* reported[13] that IR absorption is observed at 3615 cm^{-1} in unhydrated tetrabutylammonium salt; this absorption can be identified as O–H stretching. They also reported that the anion

can not be neutralized by alkali; instead, it is directly decomposed. On the other hand, a close contact of 2.77(2) Å is observed between O(4) and the water molecule O(16), which suggests a hydrogen bonding. These facts all together lead to the conclusion that O(4) is, in fact, a hydroxyl group and is hydrogen-bonded to O(16).

Guanidinium cations are almost flat triangles. The close contacts between nitrogen and oxygen atoms in the polyanions water molecules suggest probable hydrogen bondings (see Fig. 5). Table 9 lists the interionic distances less than 3 Å.

The author wishes to thank Professor Yukiyoshi Sasaki of the University of Tokyo for his continual interest in the present work and for his valuable discussions. Thanks are also due to Professor Hisao Kuroya and Dr. Keiji Matsumoto of Osaka City University for the use of a Philips automatic diffractometer.

The Thermal Decomposition of Vanadium(III) Chloride Oxide and Its Reaction with Oxygen

Akimasa YAJIMA, Ryoko MATSUZAKI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 15, 1979)

The thermogravimetry and differential thermal analysis of VClO in an argon stream were carried out. The products obtained by heating VClO in an argon stream at various temperatures were examined by chemical analysis and X-ray analysis. Also, the reaction between VClO and oxygen was examined in the same manner. When VClO is heated in an argon stream, it decomposes above about 400 °C to form V_2O_3 and VCl_3, $3VClO(s) \rightarrow V_2O_3(s)+VCl_3(s)$. Subsequently, the resulting VCl_3 disproportionates to form VCl_2 and VCl_4, $2VCl_3(s) \rightarrow VCl_2(s)+VCl_4(g)$. VClO reacts with oxygen above about 120 °C to form V_2O_5 and VCl_3O, $6VClO(s)+3O_2(g) \rightarrow 2V_2O_5(s)+2VCl_3O(g)$; this reaction is accompanied by the $4VClO(s)+3O_2(g) \rightarrow 2V_2O_5(s)+2Cl_2(g)$ reaction.

As regards the thermal decomposition of vanadium(III) chloride oxide(VClO), McCarley and Roddy[1] have examined the thermal stability of VClO at a pressure of *ca.* 10^{-3} mmHg in the course of their investigation of the reduction of vanadium(V) trichloride oxide(VCl_3O) with hydrogen, and have estimated that, when VClO is heated, the $3VClO=V_2O_3+VCl_3$ and $6VClO=2V_2O_3+VCl_2+VCl_4$ reactions probably occur simultaneously above 650 °C, although at a higher temperature the latter reaction should become relatively more important since vanadium(III) chloride (VCl_3) becomes increasingly unstable with an increase in the temperature. Schäfer and Wartenpfuhl[2] have briefly reported that, when VClO is heated at a pressure of 10^{-5} mmHg, the thermal decomposition of VClO occurs above 620 °C. In addition to these reports, Oppermann[3] has reported that the thermal decomposition of VClO, $7VClO(s)=2V_2O_3(s)+2VCl_2(s)+VCl_3O(g)$, occurs above 600 °C; he has also given the equilibrium pressure of the above reaction in the temperature range of 750—850 °C, based on vapor-pressure measurements by a static method using a Bourdon-type sickle gauge. As has been mentioned above, the thermal decomposition of VClO was not clarified. Also, there has been no report on the reaction between VClO and oxygen.

In this paper, the thermal decomposition process of VClO in an argon stream and the reaction process between VClO and oxygen will be revealed.

Experimental

The VClO used was obtained by heating vanadium(IV) chloride oxide (VCl_2O) at 370 °C in an argon stream, based on the results of a previous investigation concerning the disproportionation of VCl_2O;[4] it was confirmed to be VClO[5] by X-ray analysis. The chemical analysis gave V, 49.8; Cl, 34.6% (Calcd for VClO: V, 49.75; Cl, 34.62%). VCl_3 was obtained by the thermal decomposition of VCl_4, which had been prepared by the reaction between vanadium (V, 99.8% up) and chlorine at 500 °C,[6] at 180 °C in an argon atmosphere;[7] it was confirmed to be VCl_3[8] by X-ray analysis. The chemical analysis gave V, 32.4; Cl, 67.6% (Calcd for VCl_3: V, 32.38; Cl, 67.62%). The oxygen was dried by passing it through concd sulfuric acid and over phosphorous(V) oxide.

The sensitivity of the quartz helix used for the thermogravimetry(TG) was approximately 67 mm/g. 0.15—0.20 g of the sample was heated at a rate of 2.5 °C/min. The flow-rate of argon or oxygen was maintained at 50 cm³/min. The differential thermal analysis (DTA) was performed in an argon stream at the same heating rate for TG. α-Al_2O_3 was used as a reference.

The X-ray analysis of the solid sample was performed using Ni-filtered Cu radiation. The sample chamber of the diffractometer was maintained under a dry nitrogen atmosphere to prevent the contamination of the sample with moisture in the air during the irradiation.

The products obtained by heating VClO in an argon stream at various temperatures were examined by the following procedures. The sample (1.0 g) in a quartz boat (60 mm length, 13 mm width, 7 mm depth) was placed in a straight reaction tube (16 mm i.d.) with a water-cooled condenser. Argon was introduced into the reaction tube at a flow-rate of 50 cm³/min. The sample part was then placed in the centre of an electric furnace (300 mm in heating length) maintained at a specified temperature for a specified period. The temperature of the sample part was controlled to within ±2 °C.

The products obtained by heating VClO in an oxygen stream at various temperatures were examined in the manner described above, except that oxygen was introduced into the reaction tube instead of argon at the same flow-rate as that of argon.

The liquid product (VCl_4 or VCl_3O) was collected in a trap cooled in solid carbon dioxide through the condenser. The chlorine formed was absorbed in a KI solution through the trap and was determined by iodometry. The total amount of chlorine formed during the reaction was determined by adding the above value and the amount of chlorine dissolved in the liquid product in the trap cooled in solid carbon dioxide.[9,10] The determination of the amount of chlorine dissolved in the liquid product will be described later.

The chemical analysis of solid and liquid products was performed as follows. The vanadium content in the sample was determined by chelatometric titration,[11] while the chlorine content was gravimetrically determined as AgCl after dissolving the sample in dilute nitric acid. When the sample contained vanadium chloride, the chloride oxide, and the oxide, the water-soluble chloride (VCl_2, VCl_3) was dissolved in water and filtered, and the water-insoluble residue (V_2O_3, unreacted VClO) was dissolved in dilute nitric acid. The vanadium and chlorine contents in the both solutions were determined as has been described above.

The amount of chlorine dissolved in the liquid product in the trap cooled in solid carbon dioxide was determined as

Table 1. Thermal decomposition products of VClO in an argon stream

Temp/°C	Heating time/h	Product/% In the boat			Outside the heating zone			Unreacted VClO/%
		V_2O_3	VCl_2	VCl_3	VCl_4	VCl_3	Cl_2	
420	6	5	2	<1	3	<1	<0.1	89
700	1	28	11	—	16	2	0.4	42

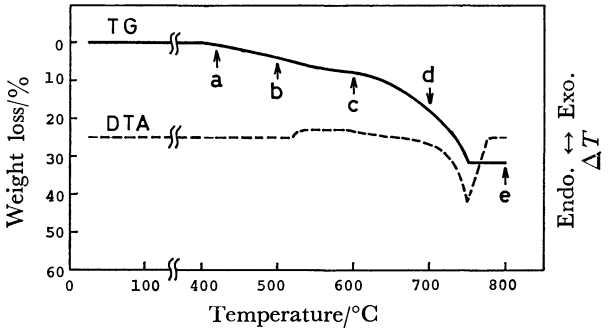

Fig. 1. TG and DTA curves of VClO in an argon stream.

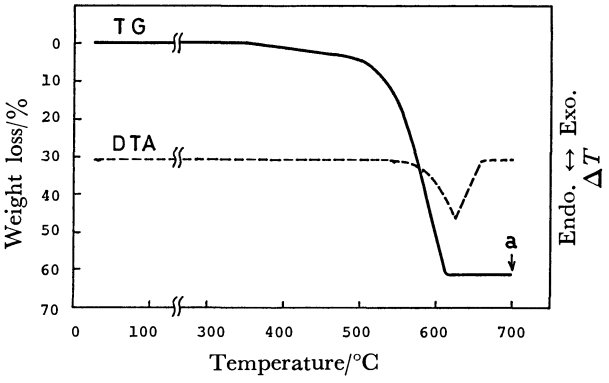

Fig. 2. TG and DTA curves of VCl_3 in an argon stream.

follows. After the reaction was over, the liquid product was allowed to warm to room temperature in an argon atmosphere in order to liberate the chlorine from the liquid product. The liberated chlorine was absorbed in a NaOH solution. A small amount of the liquid product which vaporized during the above procedure was also absorbed in the NaOH solution. The total amount of chlorine in the NaOH solution was gravimetrically determined as AgCl, while the vanadium content in the NaOH solution was also determined by chelatometric titration. From the vanadium content, the amount of the liquid product absorbed in the NaOH solution was calculated. The amount of chlorine dissolved in the liquid product was calculated by subtracting the amount of chlorine corresponding to the liquid product absorbed in the NaOH solution from the total amount of chlorine in the NaOH solution. Also, the total amount of the liquid product formed was corrected by adding the amount of the liquid product absorbed in the NaOH solution to the amount of the liquid product in the trap.

Throughout this work, the chlorides and chloride oxides of vanadium were handled in an argon atmosphere or *in vacuo* to prevent any contamination with moisture.

Results and Discussion

Thermal Decomposition Process of Vanadium(III) Chloride Oxide in an Argon Stream. The TG and DTA curves of VClO in an argon stream are shown in Fig. 1.

The TG curve showed that VClO gradually lost weight above about 400 °C. The samples heated up to Point a (420 °C), Points b (500 °C) and c (600 °C), Point d (700 °C), and Point e (800 °C) in Fig. 1 were found by X-ray analysis to be VClO, a mixture of vanadium(III) oxide(V_2O_3)[12] and unreacted VClO, a mixture of V_2O_3, VCl_2,[13] and unreacted VClO, and a mixture of V_2O_3 and VCl_2, respectively. A weak exothermic effect followed by an endothermic peak was observed in the DTA curve. The weight loss at Point e in Fig. 1 was 31.4%. This value was in good agreement with the calculated value, 31.37%, based on the assumption that the $3VClO(s) \rightarrow V_2O_3(s) + VCl_3(s)$ and $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$[14-17] reactions occur when VClO is heated. However, VCl_3 was not observed by X-ray analysis.

Then, the products formed by heating VClO at various temperatures for a specified period were examined by chemical analysis and X-ray analysis. The results are shown in Table 1. The amount of each product is shown as a weight percentage of the product to the initial weight of VClO.

The results showed that a small amount of VCl_3 was formed as a solid product, in addition to V_2O_3 and VCl_2, at 420 °C. The gaseous product formed was confirmed to be VCl_4. Also, the formation of small amounts of VCl_3 and chlorine outside the heating zone was considered to be due to the thermal decomposition of the gaseous VCl_4 formed, $2VCl_4(g) \rightarrow 2VCl_3(s) + Cl_2(g)$,[18] since the molar ratio of the amount of VCl_3 to that of chlorine was calculated to be approximately 2 : 1.

From the above-mentioned results, the solid products on heating VClO were found to be V_2O_3, VCl_2, and VCl_3. Among these products, VCl_3 is unstable on heating. It has been reported that, when VCl_3 is heated, the disproportionation, $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$, occurs above 380 °C,[14] 400 °C,[15] 425 °C,[16] or 450 °C.[17]

To confirm the disproportionation of VCl_3, the following experiments were carried out.

The TG and DTA curves of VCl_3 in an argon stream are shown in Fig. 2. The TG curve showed that VCl_3 gradually lost weight above about 350 °C. The sample heated up to Point a (700 °C) in Fig. 2 was found by X-ray analysis to be VCl_2. The weight loss at Point a was 61.3%. This value was in good agreement with the calculated value, 61.27%, based

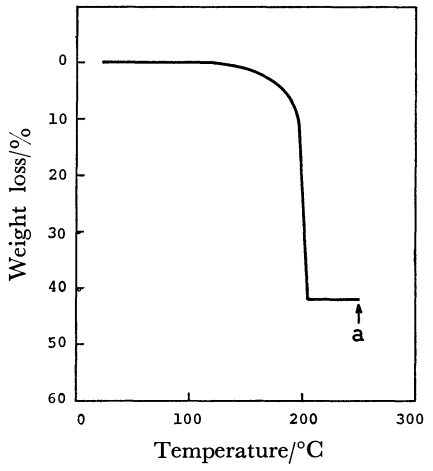

Fig. 3. TG curve of VClO in an oxygen stream.

on the disproportionation of VCl_3, $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$. Also, the gaseous product was confirmed to be VCl_4 by the chemical analysis of the product obtained outside the heating zone by heating VCl_3 (1.0 g) in an argon stream at 600 °C for 1 h.

From these results, it is clarified that VCl_3 disproportionates above about 350 °C with an endothermic effect, according to the $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$ reaction.

Considering the above-mentioned results, it is found that, when VClO is heated in an argon stream, the $3VClO(s) \rightarrow V_2O_3(s) + VCl_3(s)$ reaction occurs above about 400 °C. Subsequently, the resulting VCl_3 disproportionates according to the $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$ reaction, since the disproportionation of VCl_3 occurs as early as about 350 °C.

The exothermic effect observed in the DTA curve, shown in Fig. 1, is considered to be due to the $3VClO(s) \rightarrow V_2O_3(s) + VCl_3(s)$ reaction, since the disproportionation of VCl_3 is accompanied by an endothermic effect. It was considered that the observed exothermic effect was very weak, because the $3VClO(s) \rightarrow V_2O_3(s) + VCl_3(s)$ reaction proceeded slowly at the lower temperature and was accompanied by the disproportionation of the resulting VCl_3, with an endothermic effect.

As has been mentioned above, Oppermann[3] has reported that the thermal decomposition, $7VClO(s) \rightarrow 2V_2O_3(s) + 2VCl_2(s) + VCl_3O(g)$, occurs when VClO is heated in a sealed tube. On the other hand, the formation of VCl_3O was not observed on heating VClO in an argon stream. It may be considered that the VCl_3O was formed by the reaction between unreacted VClO and gaseous VCl_4,[2] which had itself been formed *via* the thermal decomposition of VClO, as has been revealed in this work.

Reaction Process between Vanadium(III) Chloride Oxide and Oxygen. The TG curve of VClO in an oxygen stream is shown in Fig. 3.

The results showed that VClO reacted with oxygen before decomposing and that the reaction proceeded rapidly above about 200 °C. The sample heated up to Point a (250 °C) was found by X-ray analysis to be a mixture of vanadium(V) oxide(V_2O_5)[19] and a small amount of vanadium(IV) oxide(VO_2).[20]

To obtain more detailed information on the reaction between VClO and oxygen, the products formed by heating VClO for a specified period at various temperatures in an oxygen stream were examined by X-ray analysis and chemical analysis.

At 110 °C, no reaction product was observed. The reaction products obtained at various temperatures above 120 °C and their weight percentages relative to the initial VClO were determined by chemical analysis and X-ray analysis.[5,19,20] The results are shown in Table 2.

These results indicate that the reaction between VClO and oxygen proceeds above about 120 °C. V_2O_5, VCl_3O, and a small amount of chlorine were formed below 170 °C. Above 190 °C, VO_2 was also formed in addition to these products.

The most stable oxide phase of vanadium under the conditions of this work is V_2O_5,[21] and, as is shown in Table 2, VO_2 was not formed below 170 °C. However, the formation of VO_2 in addition to V_2O_5 was observed above 190 °C. As is shown in Table 2, the reaction between VClO and oxygen proceeded markedly above 190 °C to form a large amount of gaseous VCl_3O. Consequently, the concentration of oxygen decreased temporarily in the neighborhood of the sample VClO in the boat. Under such a low concentration of oxygen, the oxidation of VClO has been thought to yield VO_2. Then, the solid products obtained by heating VClO (0.25 g) at 200 °C under various flow-rates of oxygen for 0.5 h were examined.

The results are shown in Table 3.

From the results, it was observed that VO_2 was not formed under a high flow-rate of oxygen. This confirms the above consideration of the formation of VO_2.

Based on the experimental results presented above, the reaction process between VClO and oxygen will now be discussed.

The experimental results for the reaction products between VClO and oxygen at various temperatures, shown in Table 2, showed that V_2O_5 and VCl_3O were the main products. This fact was considered to indicate that the main reaction which occurred upon heating VClO in an oxygen stream was

$$6VClO(s) + 3O_2(g) \rightarrow 2V_2O_5(s) + 2VCl_3O(g). \quad (1)$$

The reactions which possibly gave the chlorine (in Table 2) were considered to be

$$4VClO(s) + 3O_2(g) \rightarrow 2V_2O_5(s) + 2Cl_2(g) \quad (2)$$

and the reaction between gaseous VCl_3O formed by Reaction 1 and oxygen,

$$4VCl_3O(g) + 3O_2(g) \rightarrow 2V_2O_5(s) + 6Cl_2(g).^{22)} \quad (3)$$

It has previously been reported that Reaction 3 does not proceed below 400 °C.[22] The present authors also confirmed that Reaction 3 began at about 400 °C and proceeded almost completely above about 700 °C. On the basis of these results, the formation of a small amount of chlorine obtained by heating VClO in an oxygen stream was considered to be due to Reaction 2.

Based on the assumption that the formation of chlorine was due to Reaction 2, the amount of V_2O_5 formed by Reaction 2 was calculated from the amount of chlorine formed (in Table 2). The molar ratio of the amount of VCl_3O to the amount of V_2O_5 obtained by subtracting the amount of V_2O_5 formed by Reaction 2 from the total amount of V_2O_5 formed was calculated to be approximately 1 : 1. In this calculation, the amount of VO_2 formed was converted into that of V_2O_5 on the assumption that VO_2 was oxidized to V_2O_5. These results confirmed that the main reaction which occurred when VClO was heated in an oxygen stream was Reaction 1 and that this reaction was accompanied by Reaction 2.

The above-mentioned results reveal that VClO reacts with oxygen above about 120 °C according to Reaction 1 and that this reaction is accompanied by Reaction 2. As a result, V_2O_5 (under a low concentration of oxygen, VO_2 is formed in addition to V_2O_5), VCl_3O, and a small amount of chlorine are formed.

A Proton Conductive Coordination Polymer. I. [*N,N'*-Bis(2-hydroxyethyl)-dithiooxamido]copper(II)[15]

Seiichi KANDA,* Kenichi YAMASHITA,** and Kuwako OHKAWA†

Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Minamijosanjima 2-1, Tokushima 770

(Received April 4, 1979)

In a family of *catena*-μ-*N,N'*-disubstituted dithiooxamidocopper(II) complexes which have been assumed as two-dimensional coordination polymers, one complex with HOC_2H_4– substituents is an electronic conductor as well as others, and also a protonic conductor uniquely. The latter property was proved both by spectroscopic detection of the hydrogen molecules evolved from d.c. electrolysis of pressed pellets of the powder specimen and by observation of the anomalous increase (three orders of magnitude) of the electric conductivity as an effect of 10^3 Pa of H_2O or D_2O vapor on the dehydrated specimen in an evacuated conductivity cell. A novel conduction mechanism was suggested for such a solid system with both conjugated double bonds and extended hydrogen bonds.

The [*N,N'*-disubstituted dithiooxamido]copper(II) complexes, abbreviated as R_2-dtoa-Cu(earlier as R-DTOA-Cu),[1] have been regarded as two-dimensional polymers from several experimental facts[1,2] as shown in Fig. 1. Those copper containing polymers with a pair of CH_3–, $C_6H_5CH_2$–, C_6H_{11}–, $C_{12}H_{25}$– radicals as the two substituents on the two nitrogen atoms of a dithiooxamide molecule are the amorphous semiconductors in which the delocalized electrons on the two-dimensional atomic network constructed from carbon, nitrogen, sulfur, and copper atoms take part.

An anomalous time dependence of electric conductivity of $(HOC_2H_4)_2$-dtoa-Cu is observed which implies a part of the conductance at least originated from the characteristic behavior of the hydroxyl protons. The proton conduction in solid has recently attracted attention from the view point of both pure and applied sciences;[3-7] as a consequence a few comprehensive reviews have been published.[8]

In this report we try to prove the proton conduction, and propose a possibility of a novel mechanism of the charge transfer in solid which is attributed to the cooperation of electrons and protons due to the specific structure of the compound.

Experimental

Materials. Ligand, *N,N'*-bis(2-hydroxyethyl)dithiooxamide, abbreviated as $(HOC_2H_4)_2$-dtoa-H_2, was of a commercial preparation, purified by recrystallization from distilled water. Copper(II) sulfate pentahydrate of reagent grade was recrystallized from distilled water. The coordination polymer was precipitated by addition of 5% ligand ethanol solution to a lukewarm copper aqueous solution with stirring, followed by washing several times with distilled water and ethanol alternatively. The gelatinous precipitate was centrifugated and dried in an evacuated desiccator. The analytical values will be discussed in detail later.

Measurements of Conductance. The measurements were made on the pressed disk (13 mm diameter × 1.5—2.0 mm thick) prepared in a press and a die at 1.3×10^8 Pa for 30 s. Electrical leads were silver pasted on the disk from the both sides with an area of 0.7—0.8 cm^2. The measurements were carried out in a cell which could be evacuated to 10^{-2} Pa and kept the blank value of resistance more than 10^{17} Ω. In order to improve an electrical insulation, the electrical leads for the electrodes entered the cell through Teflon plugs (a). A vacuum tight of the Teflon plugs to the metal plate and to the brass bolts(d) was made with O-rings(b) and with O-stat-seals 660(c), respectively, as shown in Fig. 2. The other leads for a thermocouple and a heater were connected to hermetic seals on the plate.

After installation of the specimen in position the cell was evacuated and flushed with nitrogen several times to remove the gas molecule such as H_2O adsorbed on the specimen,

before admitting dry nitrogen of 10^4 Pa as heat conductor for temperature control. In addition to nitrogen, H_2O or D_2O vapor of 10^3 Pa was introduced for confirmation of effects of water vapor.

For electrolysis the three pellets were connected in parallel in an evacuated cell (Fig. 3) and d.c. (6.8×10^{-1} C) was passed under 300—500 V for 170 h. After the procedure mentioned above, the gas in the vessel was transported to the Geissler tube(a) in Fig. 3 through a 77 K trap(b) to remove leaked gases, H_2O and CO_2, if any. By application of an a.c. voltage (6000 V, 60 Hz) an atomic spectrum was taken on a photographic film (Fuji SSS) with a spectrograph (Shimadzu-OC-50) using a mercury lamp as a calibration source. The blank test was performed for the same processes without the application of the d.c. voltage.

DTA and TGA measurements were carried out simultaneously by a derivatograph (Rigakudenki 8002) with α-Al_2O_3 as a reference, at a rate of temperature rise of 5 °C/min.

Results and Discussion

Chemical Constitution and the Structure. Analysis of $(HOC_2H_4)_2$-dtoa-Cu, Found: C, 25.7; N, 9.77; H, 3.91; Cu, 23.0%. And a weight loss in TGA up to 150 °C; 3.3%. In the light of the coordination chemistry, the constitutional formula of $(HOC_2H_4)_2$-dtoa-Cu is proposed as $Cu((HOC_2H_4)_2\text{-dtoa})_{0.985}(OH)_{0.03}(OH_2)_{0.5}$: Calcd for the constituents: C, 25.7; N, 9.99; H, 3.97; Cu, 23.00; H_2O, 3.26%. These values are in excellent agreement with each other except those for nitrogen. The discrepancy is not serious for the proposed formula, as the nitrogen atom coordinated directly to copper ion has a tendency to result in a lower value in the analysis than expected. The other homologous complexes R_2-dtoa-Cu's are assumed to have a two-dimensional structure of sheet polymer on the basis of several experimental facts.[1,2] Assuming the same two-dimensional structure for this compound, the nonstoichiometric 0.03 mol hydroxide in the formula suggests that the molecules were terminated by coordination of two of OH instead of $(HOC_2H_4)_2$-dtoa at some parts of the edge of the sheet polymer. One half mole of OH_2 is assumed to be the coordinated water on copper(II) ions as the water is not removed even in an evacuated desiccator but is lost at the temperatures up to 150 °C as observed in the TGA analysis.

From IR study of the complex in KBr pellets the following results were obtained; 1) no peak between

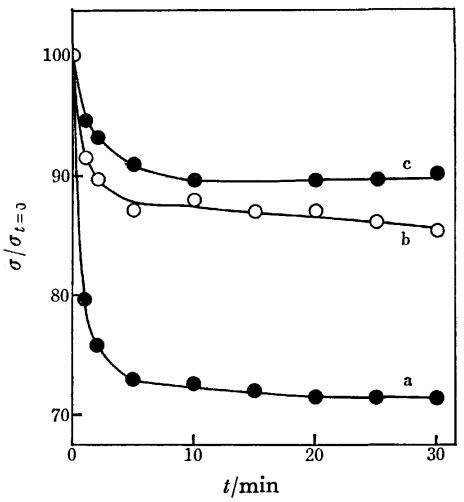

Fig. 4. Time decrease(%) of conductivity, at a) 22 °C, b) 50 °C, and c) 78 °C.

4000 and 3400 cm^{-1} and 2) a broad intense band around 3340 cm^{-1} with a half-value width of *ca.* 400 cm^{-1}. These results suggest the followings; 1) Free $HOCH_2CH_2$–, H_2O and/or –NH groups (which should indicate ν_{OH} at 3600 cm^{-1}) do not exist, 2) almost all nitrogen atoms separate protons for coordination to the copper ions, and 3) the HOC_2H_4– and H_2O form inter- and/or intramolecular hydrogen bonds to the oxygen, nitrogen, or sulfur atoms, which are proved by the peak shifted to 3340 cm^{-1} assigned to $\nu_{OH\cdots X}$. Provided that the macromolecules are the two-dimensional sheets as mentioned before,[1,2] intermolecular hydrogen bonds would connect the parallel macromolecules on their both sides of the lamellar layer.

Electric Conductivity. Figure 4 shows the typical time dependence of the electric current through the pellet of the specimen at applying d.c. voltage of 32 V/1.5—2.0 mm. As shown in Fig. 4 the current

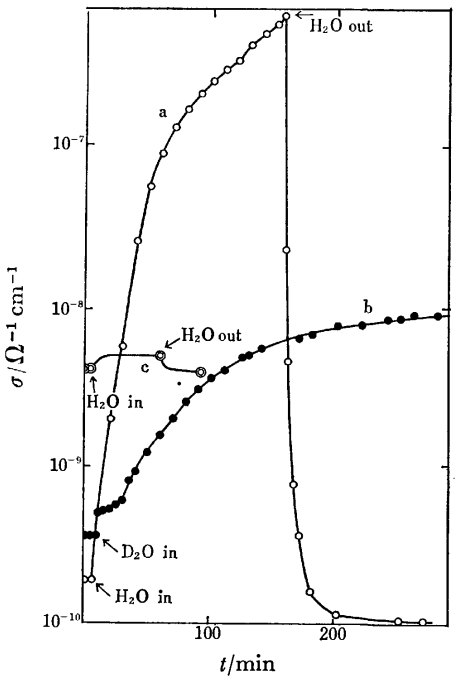

Fig. 8. Effect of water vapor on the conductivity of $(HOC_2H_4)_2$-dtoa-Cu. a) Vapor of H_2O (white circle), b) vapor of D_2O (black circle), c) contrasted with that of $(C_6H_5CH_2)_2$-dtoa-Cu.

voltage relation deviates to higher current side at a higher voltage region as shown in Table 2 together with that of $(C_6H_5CH_2)_2$-dtoa-Cu for comparison; the deviations are expressed as a percentage, 100 $(i_o-i_c)/i_o$ where i_o is the observed current and i_c is that calculated from the initial slope assuming Ohm's law.

In the case of trap-limited or ionic conduction, the current has non-Ohmic character and follows an eq. $i=A \sinh bV$ which has a non-linear character.[9] The values for $(HOC_2H_4)_2$-dtoa-Cu in Table 2 support the proton conduction mechanism.

Figure 8 illustrates the marked effects of water vapor (*ca.* 10^3 Pa) on the conductivity of the hydroxyethyl homologue and that of benzyl-substituted one for comparison. Conductivity of the former compound increases gradually by a factor of 10^3 in 2 h, whereas that of the latter increases only by 10%, levels off within 10 min and decreases to original value by re-evacuation of the water vapor. As is shown in Fig. 8, by a reevacuation the conductivity of the former rapidly decreases not to the initial but to 50% of the initial value, probably because the crack of the pellet or the partial peeling of the cathode causes a decrease of the apparent conductivity. Introduction of deuterated water in the cell results in the slower increase of the conductivity than in the case of normal water. The difference between the effects of H_2O and D_2O would be attributed to that in the diffusion coefficients of the water molecules in the pellets and in the mobilities of H^+ and D^+ in an electric field through hydrogen bonds, although these data are not sufficient for quantitative analysis. The slow effects of water vapor imply that the increment of the current originates not only from the water molecules adsorbed on the surface of the pellets but also from that absorbed into the pellets.

In order to confirm a proton conduction mechanism in $(HOC_2H_4)_2$-dtoa-Cu complex, three pellets connected in parallel were subjected to d.c. voltage (av. 400 V) for 170 h, resulting in a charge flow of *ca.* 0.7 C and a certain amount of electrolytically generated gas. From the spectrogram of the gas, H_β (486.1 nm) medium line, H_γ (434.0 nm) very strong line, and H_δ (410.1 nm) weak line of Balmer series of hydrogen atom were assigned by comparison with the line spectra of mercury as a standard for wavelength determination. This fact proves directly the generation of hydrogen gas by applying d.c. voltage on the specimen. Now it became apparent that the generated hydrogen causes the cracks of the pellets and the peeling of the cathodes observed only in case of the $(HOC_2H_4)_2$-dtoa-Cu compound.

The experimental facts on this compound can be summarized as follows: 1) H_2 is generated at a cathode, 2) the charge carrier other than electrons will be protons, and 3) the charge drift and the gas evolution seem to occur not only on surface but also in the inner part of the pellet as well. The third conclusion needs more consideration in detail. The pellet is an aggregate of the microscopic amorphous grains, and the "inner part of the pellet" mentioned above could mean both the surface and the interior of the grain. However, they are indistinguishable because the surface of the grain and that of the two-dimensional amorphous macromolecule located inside behave almost in the same manner as far as the proton conduction mechanism is concerned.

In order to elucidate the hydrogen evolution at the location remote from the cathode, an appropriate mechanism should be proposed. The conventional mechanisms of electric conduction by linked chain of hydrogen bonds are reviewed and classified as follows:[10] Type 1, through chains of hydrogen bonds π-electrons drift without evolution of hydrogen gas to give rise the steady current as was proposed by Eley and his school for protein and amino acids.[11] Type 2, a hydrogen bonded proton transfers from molecule A to molecule B sequentially followed by reorientation processes of the chain, that is, the molecular rotation of B by which further transfer of the proton takes place from B to C through a newly formed hydrogen bond between them. The arrangement of

A, B, and C is more or less parallel to the electric field. In such case that the reorientation processes are energetically difficult, the step could be substituted by the intramolecular proton migration. The transition of the mechanism from type 1 to type 2 at about 100 °C was reported in the polyamides.[12] The generation of molecular hydrogen at the locations other than cathode is hard to be explained by both the types.

The $(HOC_2H_4)_2$-dtoa-Cu specimen containing nonstoichiometric H_2O and OH^- provides the several possible paths for the electric conduction due to either electrons or protons, or both (Fig. 9). That is, the serial bondings $\{S–C–C–S–Cu\}_n$, $\{N–C–C–N–Cu\}_n$, and $\{S–C–C–N–Cu\}_n$ in the framework of the macromolecule could operate as the pure π-electronic macroscopic conduction paths independently from the hydrogen bond chain. As the figure shows, a set of the complicated hydrogen bonds could be composed between $-C_2H_4OH$, coordinated water, nitrogen and sulfur of ligand molecules; the bonds could construct a) extended chains of the hydrogen bonds solely, and b) mixed chains of the hydrogen bonds and the conjugate double bonds, both resulting the macroscopic paths. In case (a) the protons move to the cathode and are discharged there to evolve hydrogen molecules, whereas in case (b) the protons could be discharged at the contact points between the hydrogen bond chains and the conjugate double bond paths as well as at the metallic cathode. Especially the D-defect (doppel Besetzung) in the hydrogen bonds[13] presents a probable opportunity of the H_2 generation in the interior of the specimen. Many studies[14] on cooperative phenomena of H^+-jump and e^--transfer in microscopic scale have been done as a kind of redox reactions in the liquid phases. Coexistence of conjugated double bonds and extended hydrogen bonds in solid phases makes a following conduction mechanism possible in macroscopic scales (type 3); the sequence of the proposed mechanism is shown in Fig. 10 by way of a simple example (peptide bonds), which is adoptable easily for any other systems with H^+-bonds and conjugate π-bonds. In this case neither the conduction band of π-electrons in an extended hydrogen bond system (type 1) nor the molecular rotation mechanism with hydrogen evolution on the electrode (type 2) are needed. The cyclic sequence (1, 2, 3, and 4), type 3A, is that of no hydrogen evolution and of the time independence of the conductivity, whereas the other sequence (1, 2, 3, and 5), type 3B, is that of the hydrogen evolution on a positive electrode surface and/or in the interior of the solid. In type 3B the electric conduction path through hydrogen bonding chains will be bleached gradually. Consequently 3A mechanism allows the time independent part of the whole electric current. Although some residual possibility of type 2 mechanism can not be ruled out, the hydrogen evolution from the interior of the specimen suggested by its cracking induces us to conclude the functioning of the type 3B mechanism. At the present stage the type 3 mechanism is presented as a working hypothesis which should be ascertained quantum-mechanically and experimentally in future.

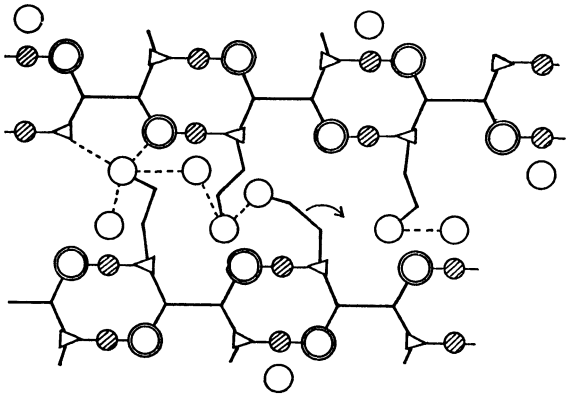

Fig. 9. The possible conduction paths by both electron and proton. Shaded circle, double circle, and triangle exhibit copper, sulfur, and nitrogen atoms respectively. White circles are OH and/or water molecule. All carbon atoms are abbreviated. Covalent bonds and coordinate bonds are represented by broad and narrow lines. Dotted lines are hydrogen bonds and the circled arrow exhibits an internal rotation of the hydroxyethyl group to transfer of hydrogen bond.

(Received April 23, 1979)

The crystal structure of ethylenediaminebis[2-(aminomethyl)pyridine]cobalt(III) hexacyanocobaltate(III) dihydrate, $[Co(H_2NCH_2CH_2NH_2)(C_5H_4NCH_2NH_2)_2][Co(CN)_6]\cdot 2H_2O$, has been determined by the X-ray diffraction method and subsequently refined by a block-diagonal least-squares method to give $R=0.050$ for 5238 non-zero reflections. The crystals are triclinic with a space group $P\bar{1}$; $a=9.034(2)$, $b=17.267(2)$, $c=8.395(2)$ Å, $\alpha=87.1(3)$, $\beta=96.2(3)$, $\gamma=104.6(3)°$, and $Z=2$. The crystal is ionic, comprising the $[Co(H_2NCH_2CH_2NH_2)(C_5H_4NCH_2NH_2)_2]^{3+}$ cation and the $[Co(CN)_6]^{3-}$ anion. The complex cation is a slightly distorted octahedron with three five-membered chelate rings in a *lel* conformation. The two pyridine nitrogen atoms occupy *trans* positions. Thus, the cation has an approximate twofold axis of rotation. The anion is also a distorted octahedron, with the coordination of CN^- through the carbon atom. The cobalt atoms of the anions occupy the special positions. Two cations in the unit cell are connected by these anions through hydrogen bonds to form a three-dimensional network typical of an ionic crystal.

The cobalt(III) complexes of bidentate 2-(aminomethyl)pyridine (2-picolylamine, abbreviated as pic) have been reported from the synthetic and spectroscopic points of view.[1-5] In a previous investigation,[4] a mixed-ligand complex, the ethylenediaminebis[2-(aminomethyl)pyridine]cobalt(III) cation, $[Co(en)(pic)_2]^{3+}$, was prepared and separated into all three possible geometrical isomers by means of a chromatographic method. The structures were assumed from the elution order and the PMR spectra. In the present investigation, a crystal-structure analysis has been carried out to confirm the previous assumption. One of the isomers has been selected in which two pyridine groups may occupy *trans* positions of the octahedron, and its hexacyanocobaltate(III) salt has been used.

Experimental

The complex was prepared and separated by the previously reported method.[4] Orange prismatic crystals were obtained by a diffusion method using aqueous solutions of the complex chloride and $K_3[Co(CN)_6]$. A crystal of $0.2\times0.2\times0.2$ mm was selected, and the X-ray diffraction intensities were measured on a Philips PW 1100 four-circle automatic single-crystal diffractometer with Mo $K\alpha$ radiation monochromated by a graphite plate. The θ-2θ scan technique was used at a scan rate of 0.0668°/s in θ with a scan width of $(0.90+0.30\tan\theta)°$. The intensities of three reference reflections monitored every 2 h remained constant during the data collection. Of 5326 observed independent reflections measured up to $\theta=30°$, 5238 with $|F_o|>3\sigma$ were used for the structure analysis. No corrections were made for absorption and extinction effects ($\mu r=0.14$). The cell dimensions were obtained from the least-squares method, based on 14 2θ values. The crystal data are listed in Table 1.

Determination and Refinement of the Structure

The coordinates of the three cobalt atoms were determined from the Patterson map; successive Fourier synthesis gave the approximate skeletal structure. The block-diagonal least-squares refinement was carried out based on 5238 non-zero reflections with the weight of 1.0 for $|F_o|>3.5$ and that of 0.5 for the others. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[6]

At the beginning stage of refinement, both atoms of each cyano group were assumed to be carbon. After several cycles of refinement with isotropic temperature factors, the R-value was 0.088. Anisotropic temperature factors were, then, introduced for all the non-hydrogen atoms. At this stage, if the coordination atom of each cyano group was assumed to be nitrogen, the R-value was 0.073. On the other hand, if it was carbon, the R-value was lowered to 0.058. It was thus concluded that the cyano groups coordinate through the carbon atoms.

The positional parameters of all the hydrogen atoms except for those of the water molecules were calculated using sp^2 and sp^3 models. They were refined with the isotropic temperature factors fixed at 4.0 Å^2. The final R-value was 0.050.

The final atomic parameters are listed in Table 2. The observed and calculated structure amplitudes are deposited with the Chemical Society of Japan (Document No. 7933).

The refinement of the structure and the drawing of the thermal ellipsoids were carried out with HBLS-IV[7] and ORTEP[8] programs respectively. The other calculations were carried out with programs written by one of the present authors (M. S.). Description of the Structure and Discussion

The crystal is ionic, comprising $[Co(en)(pic)_2]^{3+}$ and $[Co(CN)_6]^{3-}$ ions and water molecules. The arrangement of the ions in the crystal is shown in Fig. 1. The unit cell has two formula units, which are related to each other by an inversion center. The cobalt atoms of the cations occupy the general positions, while those of the anions occupy the special positions, (0, 0, 0) and (1/2, 1/2, 0), of the triclinic cell.

The structure of the cation is shown in Fig. 2, together with the anisotropic thermal ellipsoids of the non-hydrogen atoms. Each of the 2-(aminomethyl)pyridine molecules acts as a bidentate ligand through the amino nitrogen and pyridine nitrogen atoms. The two pyridine nitrogen atoms are located at *trans* positions, while the two amino nitrogen atoms are at *cis* positions of the octahedron. The remaining two coordination positions are occupied by the ethylenediamine nitrogen atoms. Thus, the cation has an approximate twofold axis of rotation through the cobalt atom and bisecting the C–C bond of ethylenediamine. This structural feature agrees with the assumption by

the previous investigation.[4,5]

Three five-membered chelate rings exhibit the *lel* conformation. The value of the dihedral angle between the N(21)C(22)C(23) and C(22)C(23)N(24) planes is 51.2°. On the other hand, those between the C(6)C(7)N(8) and N(1)C(6)C(7) planes and between the C(16)C(17)N(18) and N(11)C(16)C(17) planes give smaller values of 19.6° and 15.3° respectively. These values indicate that 2-(aminomethyl)pyridine nearly forms a plane in contrast to the usual *gauche* conformation of ethylenediamine.

The bond distances and angles are listed in Table 3. The coordination bond distances of the cation show an average value of 1.96 Å; the coordination bond angles in the chelate rings are smaller than 90° (average, 84°). These results are similar to those for $[Co(en)_3]^{3+}$.[9] All the three coordination bond angles in *trans* positions of the octahedron deviate from 180°. Especially the N(1)–Co–N(11) angle is considerably small (171.7°). Thus, the octahedron of the cation is distorted.

The octahedral coordination in the anion is also

slightly distorted. The Co–C and C–N bond distances are normal,[9] with the mean values of 1.89 and 1.15 Å respectively. The average value of the Co–C–N angles is 177°.

The complex cations and anions are connected to one another through hydrogen bonds between amino and cyano nitrogen atoms, in addition through electrostatic interactions. The water molecules are also hydrogen-bonded with these ions. These hydrogen bonds are summarized in Table 4 and are also shown in Fig. 1. No contacts shorter than 3.5 Å are observed between any cations or between any anions. Thus, a three-dimensional network typical of the ionic crystal is completed by these intermolecular interactions.

The authors are grateful to Professor Yoichi Iitaka of the University of Tokyo for the measurements of the intensities with the diffractometer.

The Crystal Structure and Absolute Configuration of $(-)_{589}$-Bis(2,4-pentanedionato)(1,3-propanediamine)chromium(III) Iodide Monohydrate

Keiji MATSUMOTO* and Shun'ichiro OOI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received May 15, 1979)

The crystal structure of $(-)_{589}$-$[Cr(acac)_2(tn)]I\cdot H_2O$ has been determined from the X-ray diffraction data collected on a diffractometer. The crystal is orthorhombic, with the space group $P2_12_12_1$ and with $a=20.834(6)$, $b=12.015(3)$, $c=7.621(2)$ Å, and $Z=4$. Block-diagonal least-squares refinement for 1426 independent reflections with $F_o^2>3\sigma(F_o^2)$ converged to $R=4.91\%$. The complex cation has the Λ absolute configuration. The 1,3-propanediamine ligand assumes a chair conformation. One of the 2,4-pentanedionato chelate rings is almost planar, while in the other the 2,4-pentanedionato plane is bent away from the plane defined by Cr and 2 O donor atoms because of the intramolecular repulsion, the interplanar angle being 9.4°. The interrelation between the absolute configuration and the circular dichroism was discussed for the $[Cr(acac)_n(tn)_{3-n}]^{(3-n)+}$-type complexes.

The optically pure $(-)_{589}$-$[Cr(acac)_3]$ (acac=2,4-pentanedionate anion) was isolated by Mason *et al.*[1] using asymmetric synthesis. The circular dichroism spectrum(CD) of the complex had previously been related to those of Λ-$(+)_{589}$-$[Cr((+)\text{-atc})_3]$[2] ((+)-atc=(+)-3-acetylcamphorate anion) and *Λ-trans*-$(-)_{589}$-$[Cr(d\text{-hmc})_3]$[3] (*d*-hmc=*d*-hydroxymethylene-camphorate anion) the structures of which had already been determined by means of X-ray analysis and stereoselectivity respectively. The Δ configuration had thus been given to $(-)_{589}$-$[Cr(acac)_3]$. Recent X-ray work has confirmed that the assignment of the Δ configuration to $(-)_{589}$-$[Cr(acac)_3]$ is correct.[4]

The $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ (tn=1,3-propanediamine) complex was prepared and resolved by Nakano and Kawaguchi.[5] The CD curve of the complex is similar in shape to that of Λ-$(+)_{589}$-$[Cr(acac)_3]$, although the former is shifted to a higher wave number. Therefore, the Λ configuration could be assigned to the $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ complex. The $(-)_{589}$-$[Cr(acac)_2(tn)]I\cdot H_2O$ crystal was subjected to X-ray structure analysis in order to confirm the absolute configuration of the complex cation.

Experimental

X-Ray Data Collection. Preliminary photographic data obtained using a Weissenberg camera indicated that the Laue symmetry was mmm and that the space group was $P2_12_12_1$. The specimen employed for the data collection was an approximate sphere, the diameter of which was 0.3 mm. The crystal was mounted on a glass fibre along the c axis.

The cell dimensions were obtained by the least-squares refinement of the θ values of 26 automatically centered reflections by means of a Philips PW1100 four-circle diffractometer.

Crystal Data: $(-)_{589}$-$[Cr(C_5H_7O_2)_2(C_3H_{10}N_2)]I\cdot H_2O$, *F.W.*=469.3, orthorhombic, $a=20.834(6)$ Å, $b=12.015(3)$ Å, $c=7.621(2)$ Å, $U=1907.7(9)$ Å^3, $Z=4$, $D_x=1.63$, $D_m=1.62$ g·cm^{-3}, space group $P2_12_12_1$, μ(Mo $K\alpha$)=22.8 cm^{-1}, λ(Mo $K\alpha$)=0.7107 Å.

The intensity data ($2\theta\leqq55°$) were collected at room temperature by the use of graphite-monochromated Mo $K\alpha$ radiation. The ω-scan mode was employed, since the reflections were rather broad. The scan range was (1.6+0.5 tan θ)°, and the scan speed, 2°/min; the background was counted for 10 s at each side of the scan range. During the data collection, the intensities of three standard reflections were monitored every 180 min in order to check the orientation and stability of the crystal. No appreciable decay was observed. A total of 1426 reflections with $F_o^2>3\sigma(F_o^2)$ were observed and used in the subsequent structure determination and refinement. The observed intensities were corrected for Lorentz-polarization and absorption effects (r=0.015 cm), and the relative structure factors were derived.[6]

Structure Determination and Refinement. The crystal structure was solved by the heavy-atom method. The parameters of all the non-hydrogen atoms were refined by

the block-diagonal least-squares method, using the anisotropic temperature factors for the I and Cr atoms. Although the difference Fourier map computed at this stage showed the positions of all the hydrogen atoms except for those of the hydrogen atoms of the CH_3 groups and the water of crystallization, the hydrogen atoms were located in geometrically calculated positions (N–H, C–H=1.03 Å, B=4.0 Å^2) and their contributions to the structure factors were taken into account. However, their parameters were not refined. The final agreement indices R and $R'=[\sum w\Delta F^2/\sum wF_o^2]^{1/2}$, were 0.0491 and 0.0640 respectively. A weighting scheme of $w=(44.4/F_o)^2$ for $F_o>44.4$, $w=1$ for $17.8\leqq F_o\leqq 44.4$, and $w=0.6$ for $17.8>F_o$ was used to make $w\Delta F_o^2$ approximately constant over the whole range of F_o values. All the parameter shifts in the final cycle refinement were less than 0.2σ. The atomic scattering factors were taken from Ref. 7. The real and imaginary parts of the anomalous dispersion correction were applied for the I and Cr atoms.[7] The final difference Fourier map was rather flat, the largest peak being 0.6 e/Å^3. The atomic coordinates and the temperature factors are listed in Table 1. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7934).

The absolute configuration of the complex cation was determined by the anomalous dispersion technique. Table 2 gives the calculated structure amplitudes of several Bijvoet pairs and the observed inequality relationships which were obtained from Weissenberg photographs taken with Cu $K\alpha$ radiation. The observed relationships indicate that the absolute configuration of the complex cation is Λ.

The computer programs used in the calculations included the local version of the UNICS.[8] All the calculations were performed on a FACOM 230-60 computer at Osaka City University.

Results and Discussion

Figure 1 shows a view of the $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ complex. The absolute configuration of the complex cation has been determined as Λ. The projections of the three chelate rings are given in Fig. 2, along with the deviations(Å) of the atoms from the planes formed by the Cr and two ligator atoms. One of the Cr-acac six-membered chelate rings is nearly planar, and the [Cr, O(1), O(2)] and [O(1), O(2), C(1), C(2), C(3), C(4), C(5)] planes make an angle of 2.6°, while the other somewhat deviates from a plane, the interplanar angle between the [Cr, O(3), O(4)] and

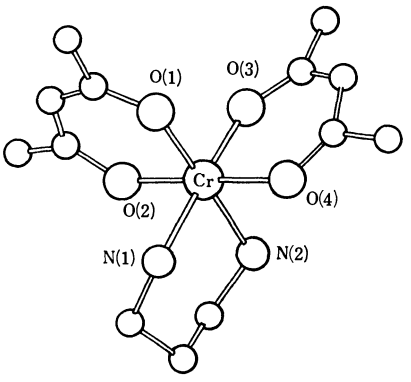

Fig. 1. A perspective view of $(-)_{589}$-$[Cr(acac)_2(tn)]^+$.

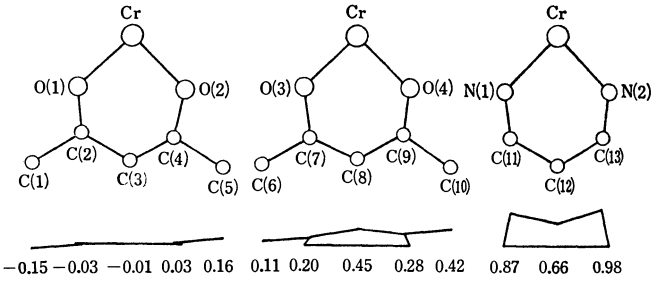

Fig. 2. Projections of the three chelate rings.

[O(3), O(4), C(6), C(7), C(8), C(9), C(10)] planes being 9.4°. The Cr-tn chelate ring is of a chair form. The average length of the Cr–O bonds is 1.96(1) Å, which is in agreement with the 1.951(7), 1.97 (1), and 1.964(5) Å found in $[Cr(acac)_3]$,[9] Λ-$(+)_{589}$-$[Cr((+)\text{-atc})_3]^{3+}$,[2] and $(-)_{589}$-$[Cr(acac)_3]$[4] respectively. The chelate bite angle (90.6(4)°) in the Cr-acac ring is slightly smaller than 91.9(6)[9] and 91.9(1)°[2] in these related complexes, but it agrees well with 90.8(2)° in $(-)_{589}$-$[Cr(acac)_3]$.[4] Both the Cr–N distance (2.06(1) Å) and the N–Cr–N angle (88.2(4)°) are normal compared with the values previously reported.[10,11] The bond distances and angles are given in Table 3.

Figure 3 gives the CD spectra of the four $[Cr(acac)_n(tn)_{3-n}]^{(3-n)+}$-type complexes in the octahedral $^4A_{2g}\rightarrow {}^4T_{2g}$ transition, whose absolute configurations are considered to be Λ. The X-ray diffraction study of $(-)_{589}$-$[Cr(acac)_3]$ indicates that this complex has the Δ absolute configuration. The Λ configuration is, therefore, given to the enantiomeric form $(+)_{589}$-$[Cr(acac)_3]$ of the complex. The present X-ray study has revealed that the configuration of $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ is Λ. In the case of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$, the structure of the corresponding Co(III) complex was determined by the X-ray method.[12] The $(+)_{589}$-$[Co(acac)(tn)_2]^{2+}$ complex, which shows a positive CD peak in the first absorption band region, has the Λ configuration. As the CD curve of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ is similar to that of the cobalt analogue, the configuration of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ is Λ. In the CD spectrum of $(-)_{589}$-$[Cr(tn)_3]^{3+}$, the positive CD peak was identified as the ^4E component from the ion-pairing effect.[13] Therefore, the configuration may be Λ.

C (4)-C (5)	1.51 (2)	C (2)-C (3)-C (4)	127.2 (13)
C (6)-C (7)	1.52 (2)	C (7)-C (8)-C (9)	122.4 (11)
C (7)-C (8)	1.42 (2)	C (11)-C (12)-C (13)	115.0 (11)
C (8)-C (9)	1.40 (2)	O (1)-C (2)-C (1)	114.7 (11)
C (9)-C (10)	1.55 (2)	O (2)-C (4)-C (5)	111.9 (12)
C (11)-C (12)	1.51 (2)	O (3)-C (7)-C (6)	116.8 (11)
C (12)-C (13)	1.50 (2)	O (4)-C (9)-C (10)	116.0 (11)
		C (1)-C (2)-C (3)	121.6 (12)
		C (5)-C (4)-C (3)	123.6 (13)
		C (6)-C (7)-C (8)	118.7 (11)
		C (10)-C (9)-C (8)	116.9 (11)

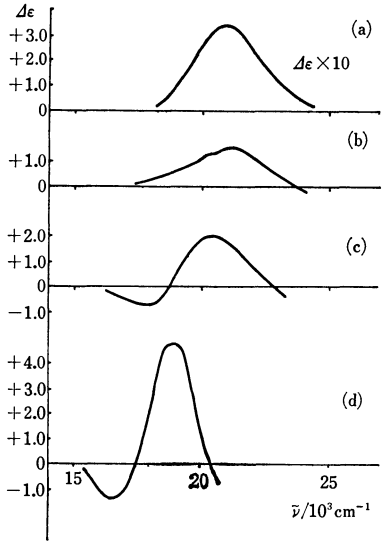

Fig. 3. CD spectra of $[Cr(acac)_n(tn)_{3-n}]^{(3-n)+}$-type complexes in the region of the octahedral $^4A_{2g}$-$^4T_{2g}$ absorption.
(a) $(-)_{589}$-$[Cr(tn)_3]^{3+}$, (b) $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$, (c) $(-)_{589}$-$[Cr(acac)_2(tn)]^+$, (d) $(+)_{589}$-$[Cr(acac)_3]$.

In the CD spectrum of $(+)_{589}$-$[Cr(acac)_3]$, the negative CD peak at the lower wave number is assigned to the $^4A_1$ component, and the positive CD peak at the higher wave number, to the ^4E component.[14] The CD spectrum of $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ is similar in shape to that of $(+)_{589}$-$[Cr(acac)_3]$, although the former is shifted to a higher wave number. Therefore, the positive CD peak of $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ is mainly due to the ^4E component of the $^4T_{2g}$ transition of $(+)_{589}$-$[Cr(acac)_3]$. The $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ complex gives two positive CD components in the region of the octahedral $^4T_{2g}$ absorption. The two components are due to the combined $^4A_1$, $^4B_2$, and $^4B_1$ components derived from the octahedral $^4T_{2g}$ transition of Cr(III)[15,16] and seem to have a sign reflecting that of the positive CD peak of $(-)_{589}$-$[Cr(acac)_2(tn)]^+$. The combined $^4A_1$, $^4B_2$, and $^4B_1$ components of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ have the same sign as the CD of $(-)_{589}$-$[Cr(tn)_3]^{3+}$, and the CD peaks of the two complexes are observed at approximately equal energies. Therefore, the positive CD peaks of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ and $(-)_{589}$-$[Cr(tn)_3]^{3+}$ are likely to have the same origin. Consequently, the absolute configuration of $(-)_{589}$-$[Cr(tn)_3]^{3+}$ is Λ, in accordance with the assignment from the ion-pairing effect.[13]

Table 4. Possible hydrogen bonds(l/Å)

I···O(H_2O)			3.58 (1)
N(1)···O(H_2O)			3.02 (2)
O(4)···O(H_2O)$(1-x,\ 1/2+y,\ 1/2-z)$			2.96 (2)
N(2)···I$(x,\ 1+y,\ z)$			3.61 (1)
N(1)-H	1.02	H···O(H_2O)	2.07
N(2)-H	1.03	H···I$(x,\ 1+y,\ z)$	2.97

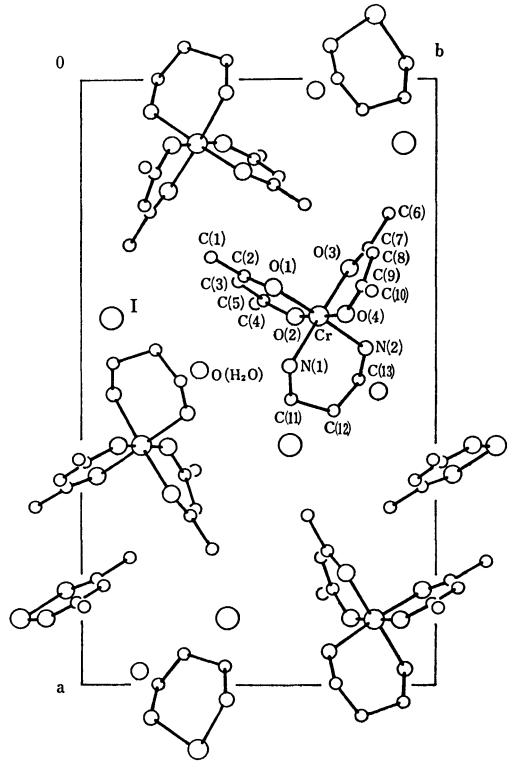

Fig. 4. A projection of the crystal structure along the c axis.

Figure 4 gives the crystal structure viewed down the c axis. Possible hydrogen bonds are summarized in Table 4. The Cr-acac six-membered chelate ring containing the O(3) and O(4) atoms is bent away

from the [Cr, O(3), O(4)] plane to C(1)($1/2-x$, $1-y$, $1/2+z$) by 9.4° (Fig. 2). As the interatomic distances between C(10) and C(1) ($1/2-x$, $1-y$, $1/2+z$) and that between C(10) and C(11) ($1-x$, $1/2+y$, $1/2-z$) are 3.92 and 4.11 Å respectively, the large deviation of the acac ring from the coordination plane (9.4°) may result from an intramolecular repulsion.

We wish to thank Professor Shinichi Kawaguchi for providing the sample and for his continuing interest in this study. This research was supported by a Grant-in-Aid from the Ministry of Education.

Quantification of Phenols in Gas from Rotten Liquid Swine Manure by Computer-controlled Gas Chromatography-Mass Spectrometry

Akio YASUHARA* and Keiichiro FUWA

Division of Chemistry and Physics, National Institute for Environmental Studies, Yatabe, Tsukuba-gun, Ibaraki 300-21

(Received April 10, 1979)

Analytical studies on phenol, *o*-cresol, *m*-cresol, *p*-cresol, and *p*-ethylphenol from liquid swine manure were performed with selected ion monitoring in computer-controlled gas chromatography-mass spectrometry. Phenol, *p*-cresol, and *p*-ethylphenol in effluent gas from liquid swine manure and in the head-space gas over liquid swine manure were determined.

Some odorous phenols have already been detected in liquid swine manure.[1] Phenols contributed greatly to malodor of liquid swine manure, because there is a relationship between the nature of the putrid odor and the quantity of phenols present.[2] Phenols are present at a relatively high concentration in liquid swine manure. It is very valuable to quantify phenols in gas from rotten liquid manure in order to estimate the role of phenols on the malodor from the piggery. The analytical methods reported for phenols are mainly gas chromatography (GC).[3-5] Selected ion monitoring (SIM) in gas chromatography-mass spectrometry however has the advantage of higher selectivity and sensitivity, when compared to GC. SIM controlled by computer has been shown to have sufficient accuracy and stability for long-time measurement in the quantification of geosmin.[6]

This paper reports an analytical method for phenols by SIM and the results of measurements on phenols in the gas from liquid swine manure.

Experimental

Gas Chromatography. A 3 m×2 mm i.d. glass column packed with KG-02[7] was used. The column temperature was 170 °C, the injection port temperature was 250 °C and the carrier gas was helium at a flow-rate of 30 ml/min (2.4 kg/cm^2).

Computer-controlled Selected Ion Monitoring. A JEOL Model JMS-D 100 mass spectrometer was connected with a JEOL Model JGC-20 K gas chromatograph and a JEOL Model JMA-2000 mass data analysis system. The mass spectrometer was operated with a resolution (10% valley) of *ca.* 1000. The magnetic field was set at *m/e* 93 and the accelerating voltage and electric field were changed at intervals of 0.3 s. Six-time repetitions of a small range sweep (1 mass unit) on each mass number setting (94, 105, 107) were carried out and the latter four values were averaged for the correction of deviations of the magnetic field. The ionizing current was 3×10^{-4} A and the ionizing energy was 75 eV.

Absorption Process and Extraction of Phenols. A fixed volume of gas was passed through a glass filter and then into sodium hydroxide solution (20 ml, 1 M) to trap phenols. After acidification of the solution with concd hydrochloric acid (5 ml), phenols were extracted with dichloromethane (10 ml) twice. The combined solution after drying over anhydrous sodium sulfate was concentrated to a few millilitres using a Kuderna-Danish concentrator under atmospheric pressure. One μg of butyl benzoate was added as an internal standard to 1 ml of the sample solution.

Isolation of Phenols from Rotten Liquid Manure by a Gas-stripping Method. Liquid swine manure (2.5 l) which had been digesting anaerobically or acrobically was transfered to a three-necked flask (3 l) and warmed to 35 °C. Nitrogen or air was passed into the flask at a rate of 220 ml/min for 3 h. The effluent gas was treated with the absorption process described above.

Isolation of Phenols from Head-space Gas over Rotten Liquid Swine Manure in the Pigsty. The head-space gas over the reservoir of liquid manure in a pigsty near Tsukuba New Town, Ibaraki, was passed into sodium hydroxide (20 ml, 1 M) at a rate of 1 l/min for 1 h. Subsequent procedures were the same as described above.

Results and Discussion

It has already been reported that the column packing material, KG-02, used here had excellent ability for the separation of several phenols.[8]

The mass numbers used for ion detection were 94 for phenol and 107 for three cresols and *p*-ethylphenol. As the dynamic range in the mass spectrometer is very narrow and injection of an exact volume with a microsyringe is not sufficiently accurate, quantitative analysis was carried out using an internal standard method. Butyl benzoate was selected as the internal standard, since the retention times of phenols and butyl benzoate in the gas chromatogram were close and a base peak at *m/e* 105 in the mass spectrum of butyl benzoate was close to the mass numbers of the selected ions for phenols.

Extended measurements by SIM with a magnet-type mass spectrometer has been considered to be difficult until a few years ago, because the magnetic field is not so stable at a resolution (10% valley) over 1000. Improvements of instruments have now enabled

Average	89	91	92	95	97

extended measurements over 10 h to become possible, since deviations of the magnetic field can now be corrected by computer. This is achieved by generating the electric field and accelerating voltage as a continuously varying triangular wave function which sweeps over a small mass range (1 mass unit). The sweep correction technique is described in the experimental section.

The calibration curve for each phenol was prepared using the ratio of the peak areas of the component and butyl benzoate. An example of the calibration curves is shown in Fig. 1. The detection limit of each compound was 50 ng/ml and an example of SIM is shown in Fig. 2. The precision of measurement was obtained by making measurements on six samples five times respectively. The coefficients of variation are shown in Table 1.

A standard gas containing a fixed amount of phenols

cannot be prepared because of the low volatility of phenols and also because of adsorption loss on the container walls. Therefore, a fixed volume of gas containing a suitable amount of phenols was passed consecutively through two bottles containing sodium hydroxide solution (20 ml, 1 M). This extraction procedure was the same as those of the samples and extracted phenols were measured by SIM. Phenols were not detected from the second trap so that subsequent experiments utilized only one bottle containing sodium hydroxide solution (20 ml, 1 M).

Next, to test whether phenols trapped in alkaline aqueous solution are oxidized by aeration, air was passed into 1 M aqueous solution (20 ml) of sodium hydroxide containing phenol (6.2 μg), *o*-cresol (4.2

13	44.1	233	28.4	ND	3.0
14	42.5	232	26.7	ND	3.7
15	42.8	245	25.9	ND	3.5
16	39.8	212	23.0	ND	9.7

a) Unit of concentration is volume ppb (10^{-9}). ND means "not detected."

μg), *m*-cresol (6.9 μg), *p*-cresol (8.3 μg), and *p*-ethylphenol (19.4 μg) under the same conditions as those of measurements. The results are shown in Table 2.

Figures 3 and 4 show the SIM for the phenols isolated from aerobically or anaerobically digested liquid manure by gas stripping. Phenol and *p*-cresol were detected under aerobic digestion, whereas five phenols were sometimes detected from anaerobically digested manure. Phenol, *p*-cresol, and *p*-ethylphenol were always detected at a higher concentration under anaerobic digestion than under aerobic digestion. The results of measurements are shown in Table 3.

Phenols in the head-space gas over the reservoir of liquid manure, in which a small amount of fresh manure was continuously poured, were measured according to this procedure. The results are shown in Table 4. The concentration of phenol was greater than that of *p*-ethylphenol in the head-space gas, compared with the gas-stripping method.

Table 4. Concentration of phenols in head-space gas over the reservoir of liquid swine manure[a)]

Run No.	Phenol	*p*-Cresol	*p*-Ethylphenol
1	13	0.83	0.86
2	11	0.35	0.38
3	9	ND	0.31
4	13	ND	ND

a) Unit of concentration is volume ppb (10^{-9}). ND means "not detected."

Quantification of carboxylic acids by SIM was unsuccessful, because the concentration of carboxylic acids in liquid manure or head-space gas was lower than that of phenols. For the analysis of carboxylic acids it is necessary to use an adsorption method with a precolumn rather than the absorption method with an alkaline aqueous solution.

The authors wish to thank Mr. Minoru Kuriyama, a hog raiser near Tsukuba New Town, Ibaraki Prefecture, for his offer of liquid swine manure and for his permission on the measurements in his pigsty.

Peri Interaction in Naphthalene Ketones

Masao KUBO and Takeo SATO*

Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received June 24, 1978)

Peri interaction in several naphthalene ketones was investigated using the carbon-13 NMR, IR, and UV spectra. The carbonyl carbon resonances for 7*H*,14*H*-cycloocta[1,2,3-*de*:5,6,7-*d'e'*]dinaphthalene-7,14-dione and its 7-oxa analog were found to be shifted upfield by 27 and 24 ppm respectively compared with those of model compounds. The anomalous shift for the former was attributed to π-orbital compression, which inhibited the polarization of carbonyl groups because of a forced parallel geometry, while the latter was attributed to field effects. The conclusion was supported by UV and IR data.

Recently we have observed the unusual chemical shifts for the sterically perturbed sp^2 carbon resonances in certain cyclophanes.[1] Unlike the conventional steric effects on the carbon chemical shifts,[2] which in general lead a resonance upfield through the charge polarization of the C–H bonds induced by the steric compression, this new type of steric effect seems to be caused by the interactions between π-orbitals along the orbital axis. In order to distinguish these two sterically induced shifts with opposite signs, we call the former (conventional) shifts "σ-orbital compression shifts" and the latter (new), "π-orbital compression shifts."

As the π-compression shifts may conveniently be used to assess the steric perturbation of π-orbitals, we have studied the proximity effects on the carbonyl carbon chemical shifts of naphthalene peri ketones, whose peri positions are only 2.4—2.5 Å apart.[3] The structural features of these ketones were also investigated in order to obtain collaborative evidence of the π-orbital compression effect.

Experimental

Spectral Measurements. The carbon-13 NMR spectra were recorded using a JEOL JNM FX-60 spectrometer equipped with a JFA-100 data system (8 K) operating at 15.00 MHz. The sample was dissolved in $CDCl_3$. The concentration was *ca.* 0.2 M except for **3**, for which a saturated solution was used. The samples were contained in 10 mm o.d. tubes. The spectra were obtained by storing the free induction decays produced by a series of 9 μs r.f. pulses (45° pulse), followed by the Fourier transformation. The sample temperature was 25 °C. Generally, 4 K data points (real 2 K points) were collected for a sweepwidth of 4 kHz, giving an effective resolution of 2 Hz (±0.13 ppm). The delay between pulses was 3—5 s, and 500—1000 transients were required to obtain a good signal-to-noise ratio. The chemical shifts are shown in a δ value downfield from the internal TMS.

The carbonyl stretching frequencies in the IR spectra were recorded using a Perkin-Elmer 225 spectrometer on samples dissolved in $CHCl_3$ (0.25 and 0.5% solutions) using a 1-mm cell. A symmetrical carbonyl band was observed in the expanded spectrum (×8) except for **4a**, which showed low-intensity bands at 1632 and 1623 cm^{-1} in addition to a strong band at 1653 cm^{-1}. The data are collected in Table 1, together with the shift and frequency differences from **1**.

The UV spectra were recorded on a Hitachi-124 spectrometer, using 95% ethanol as the solvent. The data are summarized in Table 3, while some representative curves are shown in Fig. 1.

*7-Oxa-7H,14H-cycloocta[1,2,3-de : 5,6,7-d'e']dinaphthalene-14-one (**4a**).* A mixture of 6.3 g (0.02 mol) of 8-(1-naphthyloxy)naphthalene-1-carboxylic acid (mp 128.5—130 °C), prepared by the Ullmann reaction between ethyl 8-bromonaphthalene-1-carboxylate[4] and sodium 1-naphthoate in DMF, using cupric oxide as the condensing reagent, followed by hydrolysis, and 300 g of polyphosphoric acid was warmed at 100 °C for 30 min. A usual work-up subsequently gave pale yellow needles; mp 210—212 °C; recrystallized from benzene; *m/e* 296; δ (C), 118.7, 123.4, 124.4, 124.9, 126.0, 127.0, 128.0, 128.6, 129.6, 130.4, 131.9, 133.2, 134.0, 134.5, 135.8, 136.9, and 173.2. Found: C, 84.31; H, 4.07%. Calcd for $C_{21}H_{12}O$: C, 85.12; H, 4.08%.

*7-Thia-7H,14H-cycloocta[1,2,3-de : 5,6,7-d'e']dinaphthalene-14-one (**4b**).* A mixture of 2.1 g (6.4 mmol) of 8-(1-naphthylthio)naphthalene-1-carboxylic acid (mp 202—203.5 °C), prepared by the Ullmann reaction between ethyl 8-bromonaphthalene-10-carboxylate and sodium 1-naphthalenethiolate, followed by hydrolysis, and 77 g of polyphosphoric acid was heated at 120 °C for 7.5 h after the literature method.[6] Pale yellow needles; mp 235.5—236.5 °C; recrystallized from benzene; *m/e* 312; δ (C), 123.1, 126.0, 127.3, 128.3, 129.9, 130.9, 133.2, 134.5, 137.7, 146.2, 200.5. Found: C, 80.69; H, 3.81%. Calcd for $C_{21}H_{12}S$: C, 80.74; H, 3.87%.

*12H-Benzo[f]naphtho[1,8-bc]oxepin-12-one (**5c**).* The acyl chloride obtained from 8-phenoxy-1-naphthoic acid (21.5 g, 0.082 mol) was dissolved in 100 ml of benzene, and to this we added 22 g (0.10 mol) of aluminum chloride. Column chromatography on silica gel gave pale yellow needles; mp 97.5—98.5 °C; 10% yield. Found: C, 83.33; H, 4.05%. Calcd for $C_{17}H_{10}O_2$: C, 82.91; H, 4.09%.

Results and Discussion

The naphthalene peri ketones examined in this paper, **1**—**5**, are shown in Table 1. 1-Benzoyl- (**1**)[5] and 1,8-diaroyl-naphthalenes (**2**),[6] 7*H*,14*H*-cycloocta[1,2,3-*de*:5,6,7-*d'e'*]dinaphthalene-7,14-dione (**3**),[7] 7(12*H*)-pleiadenone (**5a**),[8] and 7,12-pleiadenedione (**5b**)[8] were prepared according to the reported method. 7-Oxa-7*H*,14*H*-cycloocta[1,2,3-*de* : 5,6,7-*d'e'*]dinaphthalene-14-one (**4a**) and sulfur analog **4b**,[9] and 12*H*-benzo[*f*]naphtho[1,8-*bd*]oxepin-12-one (**5c**) were prepared from ethyl 8-bromonaphthalene-1-carboxylate (see Experimental section).

The chemical shift of the carbonyl-carbon resonances for these compounds are shown in Table 1, in which are also shown the chemical-shift differences, $\Delta\delta$'s, from that of the reference compound **1**. The carbon-

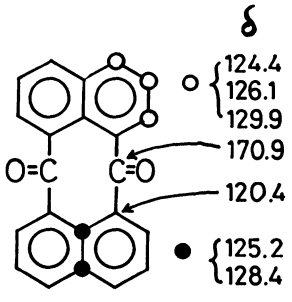
13 NMR data for selected compounds are summarised in Table 2. Quaternary carbon resonances were assigned by means of the ^1H single-frequency off-resonance decoupling (SFORD) technique. The protonated aryl carbon resonances having double intensity are designated in Table 2. The carbon-13 NMR spectra for the less symmetrical **4a**, **4b**, **5a**, and **5b** were too complex to analyze. The data for these compounds are, therefore, not included in Table 2.

Taking compound **3** as an example, the procedures of the assignment will now be illustrated. Compound **3** showed a carbonyl resonance at δ 170.9, together with six aromatic carbon resonances. The aromatic carbon peaks at δ 120.4, 125.2, and 128.4 were attributed to the protonated carbons by means of the SFORD technique. The lowest field resonance, at δ 120.4, was assigned to the carbon directly bonded to the carbonyl group, since it appeared as the double intensity peak. The resonances at δ 124.4, 126.1, and 129.9 all appeared as double-intensity peaks which were split into doublets in the SFORD spectrum.



The chemical shifts of the carbonyl carbons depend strongly upon the conjugative interactions between the adjacent unsaturated bonds. The chemical shifts of the carbonyl carbons in the conjugated systems usually appear at a higher field than those in the non-conjugated systems. For example, the carbonyl carbon for di-*t*-butyl ketone at δ 215.8 is shifted to δ 195.2 for benzophenone.[10]

Carbonyl-carbon resonances for **1**, **2a**, **2b**, and **2c** at δ 197—198 are only slightly downfield from those of the unhindered aryl ketone ($\Delta\delta$ *ca.* 3 ppm). These slight downfield shifts may result from the peri interactions, which might inhibit the conjugation between the naphthalene ring and the carbonyl group. Because of additional conjugation in the benzoyl moiety, the extent of conjugation inhibition by the peri interaction in these systems could not be correctly estimated. The situation, however, may not be as serious as in the case of 9-acetylanthracene ($\Delta\delta$ 11 ppm),[10] in which two peri interactions exist. The UV spectral data for **1** and **2** in Table 3 revealed that the conjugations between the naphthalene ring and carbonyl groups were quite similar to each other, as is shown in Fig. 1.

With the 8-membered cyclic compound **3**, the carbonyl carbon resonance appeared at δ 170.9, which is, to our best knowledge, the highest field signal thus far reported for ketones. The shift difference, $\Delta\delta$, from compound **1** was −26.7 ppm. This observation is somewhat surprising, since the compound has a rigid structure in which two carbonyl groups are parallel to each other and are nearly perpendicular to the naphthalene ring plane.[11] The UV spectrum of **3** shows that the naphthalene chromophores are in an unfavorable geometry for conjugation (Table 2, Fig. 1). Furthermore, the 8-membered ketones have been known to show the $\delta_{C=O}$ at the lowest field among the other cycloalkanones.[12] Both the electronic and ring-size considerations call for downfield shifts of carbonyl carbons, the opposite of what we have observed. It is, therefore, apparent that a possible angle strain can not be responsible for the observed anomalous chemical shift.

Instead, we attribute the primary origin of the unusual up-field shift to the increased double-bond character of the carbonyl group in **3**, possibly caused by the inhibition of the carbonyl-bond polarization. In this compound, not only do two carbonyl groups come into a parallel geometry, but also the π electrons interact directly by means of the forced paralled orientation. The latter situation can not be expected for the related *s-cis* α-diketone, in which the nordal planes of the carbonyl carbons lie nearly on a single plane.

Carbon-13 upfield shifts were observed for all the other naphthalene carbon resonances in **3**, indicating the increased electron density of the aryl carbons in **3**. Especially, the resonance due to the carbons directly bonded to the carbonyl group was shifted upfield by more than 10 ppm from the equivalent resonances for 1 and 2. This may indicate a partial inhibition of the conjugation between carbonyls and aryl rings, which in turn increases the electron density of the aryl rings in **3** relative to those in **1** and **2**.

The carbonyl-stretching frequency of **3** was shifted by 25 cm^{-1} to 1685 cm^{-1} compared to that of the model compound **1**, indicating the increased double-bond character of the carbonyl group, again caused by the conjugation inhibition. Part of this frequency shift should also be ascribed to the $\angle$C–CO–C deformation

characteristic of the medium-sized cyclic ketones, which also show $\nu_{C=O}$ at a high frequency. The IR as well as UV spectral data are consistent with our interpretation of the anomalous chemical shift of the carbonyl carbons for **3**.

In order to obtain further insight into the stereochemical features of **3**, we have examined two analogs, **4a** and **4b**, in which one of the carbonyl groups in **3** is replaced by oxygen or by sulfur respectively. The carbonyl carbon in **4a** was observed at δ 173.3, at a field higher by 24.4 than that of **2a**. Unlike **3**, however, $\delta_{C=O}$ of **4a** appeared at a frequency lower by -7 cm^{-1} than that of **1**. Nakashima and Maciel[14] observed the $\nu_{C=O}$ in 4-oxacyclooctanone shifted by 3.9 ppm compared to cyclooctanone and attributed the phenomenon to the electric-field effect. As the nitrogen analog showed an upfield shift of 13 ppm, they considered this upfield shift to be caused by the transannular effect arising from the through-space charge-neutralization proposed by Leonard *et al.*[15] The upfield shift for **4a** may also be due to the transannular effects. The **4b**, sulfur analog, gave a less anomalous chemical shift for the carbonyl carbon, perhaps because of the enlarged ring size and also the poor electron-donating ability of sulfur compared to oxygen. Because of the substantial geometrical difference, no further comparison between acyclic models and **4** was attempted.

The **4a**, oxygen analog, showed a high intensity plateau at a long wavelength, indicative of substantial conjugation. The sulfur analog **4b** also exhibited an UV absorption similar to that of **4a** but the long wave band fell off to a shorter wavelength. The conformational rigidity of an 8-membered ring in **4b** was confirmed by Johnson *et al.*[6] using a derivative of **4b**.

The pleiadene ketones, **5a**, **5b**, and **5c**, are less anomalous with respect to the carbon-13 NMR and IR data. That these have conformational mobility and undergo inversion at an appreciable rate is shown by the variable temperature NMR spectra.[16] Two carbonyl groups are not in a parallel geometry, but point outward in **5b**. Conjugation between carbonyl and aryl groups dominates these compounds, as is shown by the data in Tables 1 and 3.

A New Method for the Synthesis of 2-Substituted 2-Buten-4-olide *via* α-Substituted β-Phenylthio-γ-butyrolactone

Mikio WATANABE, Kozo SHIRAI, and Takanobu KUMAMOTO*

Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka, Kanagawa 259-12

(Received January 5, 1979)

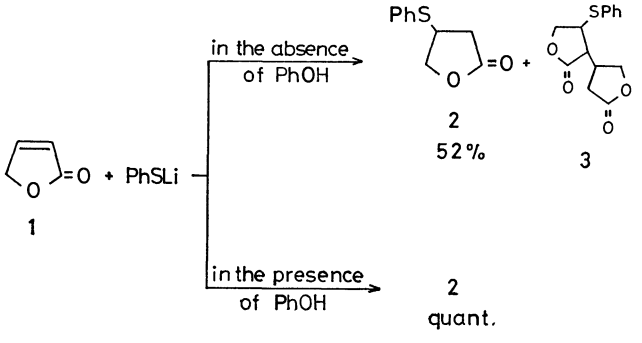
The addition reaction of lithium benzenethiolate to 2-buten-4-olide in the presence of aldehydes and ketones afforded α-substituted β-phenylthio-γ-butyrolactones (**4a—f**). The dehydrosulfenylation of **4a—d** proceeded smoothly to give 2-substituted 2-buten-4-olide by the reflux of α-substituted β-phenylsulfinyl-γ-butyrolactone, which was prepared by the oxidation of **4a—d**, in the presence of triethylamine.

A number of methods for the preparation of 2- or 3-buten-4-olides[1a-d] exist because of the interest in the synthesis of natural products. In a previous paper, a covenient method for the preparation of 3-substituted 2-buten-4-olide using α,α-bis(phenylthio)-γ-butyrolactone was reported which was readily prepared by the reaction of γ-butyrolactone with *N*-phenylthiophthalimide.[2]

In the present study, the introduction of substituent groups to the α-position of 2-buten-4-olide (**1**) was investigated by the reaction of the lithium salt of β-phenylthio-γ-butyrolactone (**2**) with aldehydes and ketones and subsequent dehydrosulfenylation.

Results and Discussion

*Synthesis of α-Substituted β-Phenylthio-γ-butyrolactones (**4a—f**).* The Michael addition reaction of lithium benzenethiolate to **1** afforded **2**. However, when lithium benzenethiolate was allowed to react with **1** in THF at −50 °C and the reaction mixture quenched with 10% hydrochloric acid, **2** was obtained in only 52% yield because of the addition reaction of the resulting lithium salt of **2** to unreacted **1** to yield the lactone derivative (**3**). Therefore, in order to avoid the undesired addition reaction, the reaction was conducted in the presence of phenol, which neutralized the resulting lithium salt of **2** to give **2** quantitatively.



The alkylation of **2** with alkyl halides (methyl iodide, benzyl bromide, butyl bromide) in the presence of lithium diisopropylamide was examined, but this attempt was unsuccessful due to the formation of alkyl phenyl sulfide. This shows that the α-anion of **2** decomposes to the benzenethiolate anion and **1**.

The synthesis of α-substituted β-phenylthio-γ-butyrolactones was established by the reaction of the α-anion of **2** with aldehydes and ketones as electrophiles. The reaction of **2** with benzaldehyde in the presence of lithium diisopropylamide in THF at −50 °C for 2 h afforded α-(1-hydroxybenzyl)-β-phenylthio-γ-butyrolactone (**4a**) in 52% yield. Furthermore, it was found that the yield of **4a** was increased to 92% when a mixture of benzaldehyde and **1** was added to a solution of lithium benzenethiolate in THF at −50 °C. This reaction involves two different addition reactions, *i.e.*, the α-anion of **2** generated by the addition of lithium benzenethiolate to **1** underwent subsequent addition to benzaldehyde to give **4a**.

Scheme 1.

In a similar manner, the reactions with other aldehydes and ketones were investigated and these results are given in Table 1. As shown in Table 1, the reaction with acetophenone or 3-pentanone gave unsatisfactory results compared with the other aldehydes.

Dehydrosulfenylation. Dehydrosulfenylation[3] of **4a—d** to **8a—d** was achieved by elimination of the sulfinyl group of the α-substituted β-phenylsulfinyl-γ-butyrolactones (**7a—d**) prepared by the oxidation of **4a—d**. Oxidation of **4a** to α-(1-hydroxybenzyl)-β-phenylsulfinyl-γ-butyrolactone (**7a**) with *m*-chloroperbenzoic acid was conducted in dichloromethane at 0 °C for 1 h. Subsequent elimination of the sulfinyl group of **7a** without further purification in refluxing THF for 3 h in the presence of one equivalent of triethylamine afforded 2-(1-hydroxybenzyl)-2-buten-4-olide (**8a**) in 75% yield. Substitution of lead acetate as the eliminating agent in refluxing methanol gave **8a** in 60% yield. The results of dehydrosulfenylation of **4a—d** to **8a—d** are summarized in Table 2. For **8b**, **8c**, and **8d**, where the reaction time was longer than 1.5 h in the

4	Octanal[b]	−50	1.5	**4d**	56
5	Acetophenone[c]	−50 −40	1 1	**4e**	17
6	3-Pentanone[c]	−40 −30	1 1	**4f**	7

a) The yields are based on **1**. b) For entry 1, 2, 3, and 4, 1.5 equiv of aldehyde was used. c) For entry 5 and 6, 2 equiv of ketone was used.

Table 2. Formation of **8a—d**

Entry	Oxidation[a] Sulfenyl lactone	Oxidation[a] Sulfinyl lactone	Thermolysis[b] Time h	Product	Yield[c] %
1	**4a**	**7a**	3	**8a**	65
2	**4b**	**7b**	1.5	**8b**	84
3	**4c**	**7c**	1.5	**8c**	58
4	**4d**	**7d**	1.5	**8d**	69

a) Oxidation was conducted in dichloromethane at 0 °C and the oxidation products were used for the subsequent thermolysis without further purification. b) Thermolysis was conducted in refluxing THF in the presence of triethelamine. c) Yields are calculated from sulfenyl lactones **4a—d**.

thermolysis step, dehydration products were obtained.

In addition, a second method of dehydrosulfenylation, which involves [2,3] sigmatropic rearrangement of allyl sulfoxide (**6a**),[4] was attempted. The conversion of **4a** to **6a** was conducted as follows. Compound **4a** was treated with one equivalent of sulfuric acid in refluxing benzene with azeotropic removal of water to give α-benzylidene-β-phenylthio-γ-butyrolactone (**5a**) (90% yield). Oxidation of **5a** with *m*-chloroperbenzoic acid in dichloromethane afforded **6a** quantitatively. Several reaction conditions for the [2,3] sigmatropic rearrangement were examined, however, but the desired **8a** could not be obtained, the starting material **6a** being recovered in almost cases. The use of trimethylphosphite as the thiophile gave the reduction product, **5a**.

Thus a convenient method for the preparation of **8a—d** was established. Several reports exist of the introduction of substituent groups on the α-position of α,β-unsaturated ketones and esters.[5] In the reaction studied here the α-anion of **2** serves as an α-anion of **1**. The advantages of this method are (1) the starting materials are inexpensive and readily available; (2) there is no need to isolate the intermediate **2** and (3) the generation of the α-anion of **2** is performed by a week base, lithium benzenethiolate.

Experimental

Preparation of β-Phenylthio-γ-butyrolactone (2). To a solution of benzenethiol (1.10 g, 0.01 mol) in THF (10 ml) was added dropwise a hexane solution of butyllithium (15%, 6.3 ml, 0.01 mol) at −50 °C under nitrogen and the mixture stirred for 15 min. A THF (8 ml) solution of 2-buten-4-olide (**1**)[6] (0.84 g, 0.01 mol) and phenol (0.94 g, 0.01 mol) was added to this mixture over 10 min, and the mixture stirred for 1 h at −50 °C. The reaction mixture was warmed to room temperature and washed with 10% sodium carbonate to remove the phenol and extracted with three 30 ml portions of ether and dried over sodium sulfate. After removal of the solvent, the residual oil was chromatographed on silica gel using benzene as an eluting agent to yield 1.90 g (98%) of **2**: mp 51—52 °C (recrystallized from 2-propanol). IR 1770 cm^{-1}. NMR ($CDCl_3$) δ 6.98—7.27 (5H, m), 3.70—4.50 (3H, m), 2.06—3.00 (2H, m). MS 194 (M^+). Found: C, 61.55; H, 5.15; S, 16.46%. Calcd for $C_{10}H_{10}O_2S$: C, 61.83; H, 5.19; S, 16.50%.

α-(1-Hydroxybenzyl)-β-phenylthio-γ-butyrolactone (4a).

To a THF (8 ml) solution of benzenethiol (550 mg, 5 mmol) was added butyllithium (in hexane, 15%, 3.2 ml, 5 mmol) at −50 °C and the mixture stirred for 15 min. To this solution was added dropwise over 15 min a mixture of **1** (420 mg, 5 mmol) and benzaldehyde (795 mg, 7.5 mmol) in THF (10 ml) and the reaction mixture stirred for 1.5 h at −50 °C. The reaction mixture was poured with stirring into cold saturated ammonium chloride solution and extracted with three 30 ml portions of ether and the extracts dried over anhydrous sodium sulfate. After removal of the solvent, the residual oil was chromatographed on silica gel using benzene as an eluting agent to give 1344 mg (92%) of **4a**. Further purification of **4a** was conducted by recrystallization from 2-propanol: mp 127—127.5 °C. IR 3420, 1758 cm^{-1}. NMR (DMSO-d_6) δ 6.83—7.20 (10H, m), 6.02 (1H, d), 4.00—4.85 (3H, m), 3.30 (1H, s), 2.45 (1H, br). MS 300 (M^+). Found: C, 67.84; H, 5.37; S, 10.65%. Calcd for $C_{17}H_{16}O_3S$: C, 67.99; H, 5.37; S, 10.67%.

In a similar manner, α-(1-hydroxybutyl)-β-phenylthio-γ-butyrolactone (**4b**), α-(1-hydroxyhexyl)-β-phenylthio-γ-butyrolactone (**4c**), α-(1-hydroxyoctyl)-β-phenylthio-γ-butyrolactone (**4d**), α-(1-hydroxy-1-phenylethyl)-β-phenylthio-γ-butyrolactone (**4e**), and α-(1-ethyl-1-hydroxypropyl)-β-phenylthio-γ-butyrolactone (**4f**) were obtained in 61%, 73%, 56%, 17%, and 7% yields respectively. The reaction temperature and time for each aldehyde or ketone are as follows: −50 °C for 1.5 h for butanal, hexanal, and octanal; −50 °C for 1 h, −40 °C for 1 h for acetophenone; −40 °C for 1 h, −30 °C for 1 h for 3-pentanone. **4b**: IR 3450, 1758 cm^{-1}. NMR ($CDCl_3$) δ 7.20—7.60 (5H, m), 3.37—4.70 (4H, m) 2.42—2.85 (2H, m), 1.30—1.80 (4H, m), 0.93 (3H, t). MS 266 (M^+). **4c**: IR 3450, 1760 cm^{-1}. NMR ($CDCl_3$) δ 7.10—7.38 (5H, m), 3.70—4.68 (4H, m), 3.15 (1H, s) 2.52 (1H, t), 1.30 (8H, br), 0.88 (3H, t). MS 294 (M^+). **4d**: IR 3450, 1770 cm^{-1}. NMR ($CDCl_3$) δ 7.10—7.38 (5H, m), 3.72—4.68 (4H, m), 3.41 (1H, s), 2.52 (1H, t), 1.25 (12H, br), 0.88 (3H, t). MS 322 (M^+). **4e**: IR 3490, 1770 cm^{-1}. NMR (DMSO-d_6) δ 6.90—7.20 (10H, m), 4.50 (1H, s), 2.93—3.75 (3H, m), 2.38 (1H, d), 1.63 (3H, s). MS 314 (M^+). **4f**: IR 3500, 1775 cm^{-1}. NMR ($CDCl_3$) δ 7.35—7.65 (5H, m), 3.92—4.40 (2H, m), 2.20—3.35 (3H, m), 1.22—1.82 (4H, m), 0.83 (6H, dt). MS 280 (M^+).

*Preparation of α-Benzyliden-β-phenylthio-γ-butyrolactone (**5a**).* A solution of **4a** (3.00 g, 0.01 mol) in benzene (50 ml) in the presence of one equivalent of *p*-toluenesulfonic acid or concd sulfuric acid was heated under reflux for 8 h using a water separator. The reaction mixture was cooled to room temperature, washed with 10% sodium carbonate solution, extracted with THF–$CHCl_3$ (1:1), and dried. Removal of the solvent under reduced pressure and recrystallization from 2-propanol gave 2.54 g (90%) of **5a**: mp 218—219 °C. IR 1760 cm^{-1}. NMR (DMSO-d_6) δ 6.20—7.20 (11H, m), 3.50—4.65 (3H, m). MS 282 (M^+). Found: C, 72.27; H, 5.00; S, 11.35%. Calcd for $C_{17}H_{14}O_2S$: C, 72.53; H, 4.94; S, 11.40%.

*Preparation of α-Benzyliden-β-phenylsulfinyl-γ-butyrolactone (**6a**).* To a solution of **5a** (564 mg, 2 mmol) in dichloromethane (20 ml) was added dropwise a dichloromethane (15 ml) solution of *m*-chloroperbenzoic acid (414 mg, 2.4 mmol) at 0 °C. The reaction mixture was stirred for 1 h. The reaction mixture was washed with 10% sodium hydrogencarbonate, extracted with dichloromethane and dried over anhydrous sodium sulfate. Evaporation of the solvent gave an oil of **6a** and treatment with ether provided crystals of **6a** (578 mg, 97%): mp 169 °C (dec). IR 1780 cm^{-1}. NMR (DMSO-d_6) δ 6.80—7.60 (11H, m), 3.60—4.65 (3H, m). MS 298 (M^+). Found: C, 68.87; H, 4.92; S, 10.77%. Calcd for $C_{17}H_{14}O_3S$: C, 68.44; H, 4.73; S, 10.75%.

*General Procedure for Oxidation of **4a—d**.* To a solution of the β-phenylthio lactone derivative in dichloromethane (15 ml, for 1 g of the lactone) was added dropwise a dichloromethane solution of *m*-chloroperbenzoic acid (1.2 equiv) at 0 °C. The reaction mixture was stirred for 1 h at 0 °C, washed with 10% aqueous sodium hydrogencarbonate and dried. Evaporation of the solvent under reduced pressure gave the β-phenylsulfinyl derivative in quantitative yield. The products thus obtained, **7a—d** were used for subsequent thermolysis without further purification.

*General Procedure for Thermolysis of β-Phenylsulfinyl-γ-butyrolactones (**7a—d**).* A solution of the β-phenylsulfinyl-γ-butyrolactone derivative in THF (20 ml for 1 g of the lactone) in the presence of one equivalent of triethylamine was heated under reflux for 1.5—3 h. After removal of the solvent under reduced pressure the residue was chromatographed on silica gel using benzene–ether (3:1) as an eluent to give the 2-substituted 2-buten-4-olide.

Analytical and spectral results are as follows:

*2-(1-Hydroxybenzyl)-2-buten-4-olide (**8a**).* 75%. IR 3425, 1740 cm^{-1}. NMR ($CDCl_3$) δ 6.95—7.25 (6H, m), 5.40 (1H, s) 4.65 (2H, t), 3.37 (1H, br). MS 190 (M^+). Found: C, 69.97; H, 5.38%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%.

*2-(1-Hydroxybutyl)-2-buten-4-olide (**8b**).* 84%. IR 3425, 1730 cm^{-1}. NMR ($CDCl_3$) δ 7.18—7.30 (1H, m), 4.76 (2H, t), 4.42 (1H, br), 4.10 (1H, s), 1.08—1.98 (4H, m), 0.90 (3H, t). MS 138 (M−18). The spectral data of the dehydration product, 2-(1-butenyl)-2-buten-4-olide, of **8b** was shown since the elemental analysis of **8b** gave unsatisfactory results. IR 1745 cm^{-1}. NMR (CCl_4) δ 5.92—7.22 (3H, m), 4.80 (2H, s) 2.15 (2H, q), 1.08 (3H, t). MS 138 (M^+).

*2-(1-Hydroxyhexyl)-2-buten-4-olide (**8c**).* 58%. IR 3425, 1735 cm^{-1}. NMR ($CDCl_3$) δ 7.31—7.35 (1H, m), 4.80 (2H, t), 4.45 (1H, br), 3.55 (1H, br), 1.33 (8H, brs), 0.90 (3H, t). MS 166 (M−18). Found: C, 64.90; H, 9.04%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

*2-(1-Hydroxyoctyl)-2-buten-4-olide (**8d**).* 69%. IR 3425, 1750 cm^{-1}. NMR ($CDCl_3$) δ 7.10—7.25 (1H, m), 4.80 (2H, t), 4.38 (1H, br), 3.10 (1H, br), 1.30 (12H, brs), 0.90 (3H, t). MS 194 (M−18). Due to the difficulty in the further purification of **8d**, elemental analysis was achieved by dehydration product, 2-(1-octenyl)-2-buten-4-olide, of **8d** as follow. Found: C, 74.04; H, 9.31%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34% [IR 1750 cm^{-1}. NMR (CCl_4) δ 5.90—7.23 (3H, m), 4.76 (2H, s), 1.35 (10H, brs), 0.90 (3H, t). MS 194 (M^+).]

The Oxidation of Toluene by Cobalt-Copper-Bromide System. A Side-chain Acetoxylation

Toshihiko OKADA* and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received January 27, 1979)

The liquid-phase oxidation of toluene catalyzed by the cobalt(II) ion and the bromide ion in the presence of the copper(II) ion has been studied. Benzyl acetate was obtained in a good yield (50—70%) with mixed catalysts of metal acetates and sodium bromide in acetic acid at 100—150 °C, accompanied by small amounts of benzaldehyde and benzoic acid. The product distribution was greatly dependent on the NaBr concentration, which can be explained in terms of the high oxidizing ability of the copper(II) ion coordinated by the bromide ion. A synergistic effect was found on the yield of benzyl acetate upon the addition of copper(II) acetate with a high NaBr concentration, the maximum yield being obtained at the Co:Cu:NaBr ratio of 1:1:5—10. A change in the oxygen partial pressure also varied the product distribution, suggesting that the competitive reaction of the copper(II) ion with the oxygen molecule for the benzyl radical was simultaneously taking place at a diffusion-controlled rate. Benzyl acetate was considered to result from the oxidation of the benzyl radical by copper(II) bromide and the subsequent solvolysis by acetic acid. The addition of acetic anhydride had a negative effect on the formation of benzyl acetate.

The transition metal ion-catalyzed autoxidation of alkylbenzenes, especially with the cobalt(II) ion and the bromide ion, in acetic acid has been widely studied.[1-6] The autoxidation of *p*-xylene catalyzed by the cobalt(II) ion and the bromide ion to terephthalic acid is important from the viewpoint of the petrochemical industry. The oxidation products, however, are mainly acids or carbonyl compounds, although in rare cases in the presence of acetic anhydride,[2,3] they also include acetoxylated compounds.

Hay[2] has reported that methylbenzenes were converted to the acetoxylated compounds in the oxidation catalyzed by the cobalt(II) ion and the bromide ion in the presence of acetic anhydride, *e.g.*, the oxidation of toluene gave benzyl acetate in a 44% yield, but not in the absence of acetic anhydride. On the other hand, copper(II) acetate is well known to act as an inhibitor[9] in the cobalt(III) ion-catalyzed autoxidation and to behave as an oxidizing reagent for alkyl radicals.[8]

We previously suggested that the deactivation of cobalt(III) acetate by copper(II) acetate in the oxidation of toluene is due to the formation of a binuclear complex.[9] Therefore, it seems difficult to obtain benzyl acetate by the oxidation of toluene, which has a relatively high ionization potential, by copper(II) acetate. Recently, Imamura reported the oxidation of 1,2,3,4-tetrahydronaphthalene catalyzed by copper(II) acetate with a high LiCl concentration; in this case, the copper(II) ion, bearing the Cl ion, was considered to be a monomer species that is capable of oxidizing 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide.[10]

We attempted to obtain benzyl acetate by means of the oxidation of toluene in the presence of cobalt–copper catalysts and found that a side-chain acetoxylation of toluene occurred and that the yield was dependent on the reaction conditions.

Experimental

Materials. The acetic acid, copper(II) acetate, cobalt(II) acetate, and other metal acetates were used without further purification. The sodium bromide were dried under a vacuum at 150 °C for 5 h. The toluene was purified by the usual method: distillation after washing with concentrated sulfuric acid, an aq alkaline solution, and water and drying over ($CaCl_2$ and sodium metal).

Procedure. The oxidation was carried out with two methods.

Method A: A 200 ml three-necked round-bottomed flask equipped with a gas inlet, a thermometer, and a condenser was used. Oxygen was blown onto the surface of the reaction mixture.

Method B: A 200 ml autoclave made of Ti was used. The reaction was carried out with a batch method; the total pressure of the mixed gas was 40 kg/cm^2.

Analysis. The reaction mixture, with an internal standard (1-chloronaphthalene), was poured into ice water and then extracted with ether. The extract was submitted to GC analysis after having been washed with water and aqueous Na_2CO_3 and then dried (Na_2SO_4). The benzoic acid was analyzed by GC directly or after esterification with a MeOH–BF_3 reagent. The products were identified by means of IR, NMR, and GC-MS. PhCHO: 9.9 ppm (1H), 7.7 ppm (5H), 2750 cm^{-1}, 1690 cm^{-1}, M$^+$ 106 (*MW* 106). $PhCH_2OCOCH_3$: 7.3 ppm (5H), 5.1 ppm (2H), 2.1 ppm (3H), 1730—1760 cm^{-1}, 1220—1260 cm^{-1}, M$^+$ 150 (*MW* 150). $PhCH_2Br$: M$^+$ 171 (*MW* 171). A gas chromatograph (Shimadzu GC-3BT) was mainly used for the analysis of the products.

Column: PEG 20 M 10% on Celite 545, 1 m, 2 m, 145 °C, 180 °C, He gas, 40 ml/min.

Results and Discussion

Effect of Bromide-ion Concentration on the Co–Cu Catalysis. The effect of the Br-ion concentration on the product distribution in the presence of cobalt(II) acetate and copper(II) acetate was investigated (Fig. 1). The ratio of the bromide ion to the cobalt(II) ion drastically affected the product distribution. At ratios lower than four, the major product was benzoic acid, while benzyl acetate was formed in only a minor amount. When the ratios were higher than five, the major products were benzyl acetate and benzyl bromide.

On the oxidation of alkyl radicals by copper(II) salts, Kochi[8] clarified that there is an equilibrium between the monomeric and dimeric copper(II) ion,

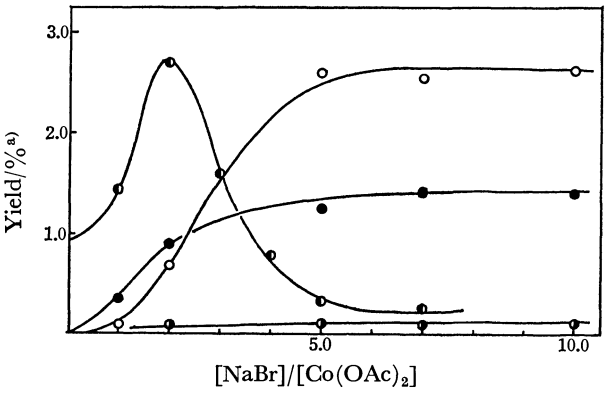

Fig. 1. Oxidation products of toluene catalyzed by Co-Cu-Br as a function of the ratio of [NaBr]/[$Co(OAc)_2$].
Reaction conditions: 100 °C, 20 h, [$Co(OAc)_2$]=[$Cu(OAc)_2$]=5.71×10^{-2} M, [toluene]=1.39 M, method A. a) Based on initial toluene.

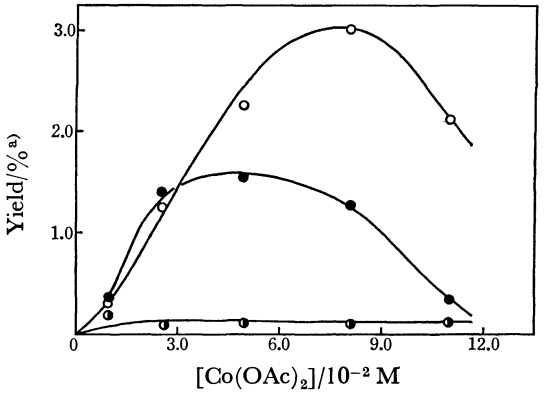

Fig. 2. Oxidation products of toluene catalyzed by Co-Cu-Br as a function of catalyst concentration.
Reaction conditions: 100 °C, 20 h, [$Co(OAc)_2$]:[$Cu(OAc)_2$]:[NaBr]=1:1:7, [toluene]=1.39 M, method A. a) Based on initial toluene.
○: $PhCH_2OAc$, ●: $PhCH_2Br$, ◑: PhCHO.

and that the active species in the oxidation is the monomeric one. Upon the addition of the acetate ion[8] or the chloride ion,[10-12] this dimer-monomer equilibrium becomes favorable to the monomer side. In our experiments, this equilibrium may be present, and the monomer with the bromide ion is predominant upon the addition of the bromide ion to the cobalt–copper system at ratios higher than five; thus, the benzyl radical was oxidized by the monomeric copper(II) ion to benzyl acetate and benzyl bromide. On the other hand, Gaevskii[13] recently discussed the active species in the oxidation of ethyl benzene catalyzed by the cobalt(II) ion and the bromide ion; he concluded that cobalt(III) monobromide is an active species, for it has a high stability constant. Accordingly, at a low ratio of the bromide ion to the cobalt(II) ion, the main reaction may be an abstraction of the α-hydrogen of toluene by cobalt(III) monobromide. Figure 1 indicates that the ratio of the amount of benzyl acetate to that of benzyl bromide retains constant, even when the bromide-ion concentration is increased by a factor of two. This fact suggests that the oxidation of the benzyl radical proceeds not through the carbonium ion but through a so-called ligand-transfer reaction.

Table 1. Effect of sodium salts on the reaction products in the oxidation of toluene by the Co-Cu system

Sodium salts	Products (mol %)a)
None	—b)
NaOAc	
NaCl	—
NaBr	$PhCH_2OAc$ (64.3)
	$PhCH_2Br$ (11.4)
	PhCHO (1.2)
	PhCOOH (23.1)
NaI	PhCOOH (100)

Reaction conditions: Method A, 100 °C, 24 h, [$Co(OAc)_2$]=[$Cu(OAc)_2$]=5.71×10^{-2} M, [NaX]=0.4 M, [toluene]=1.39 M. a) Based on the total amounts of all oxidation products. b) No reaction occurred.

Effect of Catalyst Concentration. Figure 2 shows the effect on the oxidation of the catalyst concentration at the ratio of Co : Cu : Br^- = 1 : 1 : 7. The maximum yield of benzyl acetate was obtained at the 0.08 M cobalt concentration.

According to Kochi,[8] this ligand-transfer reaction determines the rate of diffusion control. It seems that a higher catalyst concentration is required since the copper(II) ion and oxygen will be competing for the benzyl radical. However, when the concentration of the catalyst was higher than 0.08 M, low yields of benzyl bromide and benzyl acetate were observed. This phenomenon can be explained in terms of an aggregation of metal acetates[14] or a complex formation between metal acetates and hydroperoxide.[15]

As the concentration of a catalyst becomes higher, the ratio of benzyl acetate to benzyl bromide increases, suggesting that the reaction of benzyl bromide with cobalt(II) acetate is playing a part, an idea supported by Hay.[2]

Effect of Sodium Salts. The effect of sodium salts on the product distribution was also investigated. As may be seen from Table 1, it is obvious that the bromide ion is the most effective for the synthesis of benzyl acetate. According to the studies by Imamura[10-12] of the liquid-phase oxidation catalyzed by the Cu–Cl system, the main reaction is a decomposition of hydroperoxide by Cu–Cl compounds and no significant oxidation by the Co–Cu–Cl system seems to occur, since hydrogen abstraction is important in this reaction. The addition of sodium acetate did not change the oxidizing activity of the Co–Cu system and resulted in the recovery of toluene. These results may be attributed to their redox potentials being lower than that of the Co–Cu–Br systems.

When sodium iodide was added to the Co–Cu system, a small amount of benzoic acid was obtained, perhaps for the same reason as in the case of the chloride ion.

Recycling of the Bromide Ion in the Course of the Oxidation. Figure 3 shows the time dependence on the yield of products in the oxidation of toluene in acetic acid at 100 °C. In the early stage of the oxidation, benzyl bromide was primarily formed and benzyl acetate increased gradually. After 20 h, benzyl acetate turned into the major product. Many workers[1-6] have suggested that the reaction of benzyl bromide with acetic acid proceeds easily at 100 °C. In our study, however, this reaction was very slow, presumably because of the high bromide-ion concentration. The formation of benzyl bromide in the early stage suggests that the ligand transfer by the copper(II) ion is mainly bromide-ion transfer; consequently, the structure of the copper(II) ion might be $CuBr_n^{m-}$. Here, $m=0$—2 and $n=2$—4, according to Imamura.[10-12] The Br ion concentration decreases in the course of the oxidation; hence, the activity of the copper(II) ion is gradually lost. Under these conditions (method A), benzoic acid and benzaldehyde were minor products, since the oxygen concentration in the reaction media was very low. The dependence of the reaction temperature on the product distribution was also investigated (Table 2).

It was found that the selectivity changes drastically with the reaction temperature and that benzyl bromide disappears at temperatures above 140 °C. As reported by Hay,[2] the solvolysis of benzyl bromide in the oxidation catalyzed by the cobalt(II) ion and the bromide ion in acetic acid is quite difficult at temperatures lower than 100 °C. In our study, benzoic acid was formed at low reaction temperatures; that is, the oxidizing ability of the cobalt(III) ion was maintained because of the high additional bromide-ion concentration. The amount of products which can be regarded as resulting from the oxidation of the benzyl radical by the copper(II) ion was relatively small because of the deterioration of the copper(II) ion. At low temperatures, the monomeric copper(II) ion gradually turns to a dimer, becoming inactive for the oxidation of the benzyl radical in the course of the oxidation, because the bromide ion in the reaction media decreases because of the slow rate in the solvolysis of benzyl bromide. At 150 °C for 1—5 h, the yield of benzyl acetate was at its maximum. The solvolysis of benzyl bromide may proceed easily at these temperatures.

Therefore, the activity of the catalyst in the oxidation can be maintained. On the other hand, at temperatures higher than 150 °C, the oxidation of benzyl acetate and benzyl bromide can not be ignored, for it results in a lower yield of benzyl acetate.

According to the study by Howard and his coworkers[16] of the hydrogen abstraction at the α-position of toluene, benzyl bromide, and benzyl acetate by the *t*-butylperoxyl radical at 30 °C, though there is a small difference in the reactivity between the *t*-butylperoxyl radical and cobalt(III) bromide acetate, their rates are 0.012, 0.0075, and 0.006 $M^{-1}\,s^{-1}$ respectively.

Benzyl acetate is oxidized to benzaldehyde *via* benzylidene diacetate. Thus, it is obvious that the optimum reaction temperature is about 150 °C for the synthesis of benzyl acetate.

Effect of the Oxygen Partial Pressure. The dependence of the oxygen partial pressure on the product yields is shown in Table 3. As has been mentioned above, the ligand-transfer is a competitive reaction with the oxygen molecule for the benzyl radical. Therefore, when a low oxygen partial pressure was used, the yield of benzyl acetate was high. However, it should be mentioned that the oxidant in this reaction

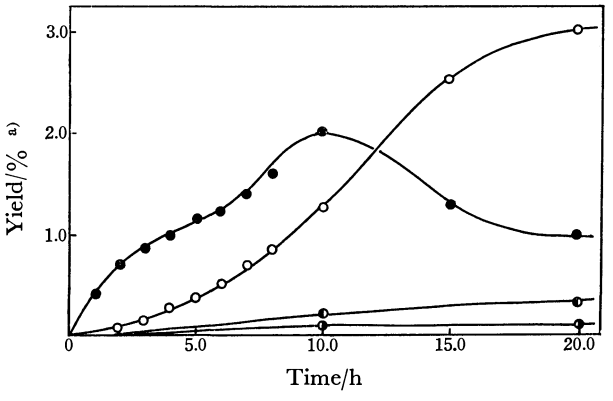

Fig. 3. Oxidation products of toluene catalyzed by Co-Cu-Br as a function of reaction time.
Reaction conditions: 100 °C, $[Co(OAc)_2]=[Cu(OAc)_2]=5.71\times10^{-2}$ M, [NaBr]=0.4 M, [toluene]=1.39 M, method A. a) Based on initial toluene.

140	64	44	—[b]	23	43
150	77	49	—	15	33
170	61	48	—	21	30

Reaction conditions: method B, 5 h, total pressure, 40 kg/cm², $(O_2/N_2=1/3)$, $[Co(OAc)_2]=[Cu(OAc)_2]=5.71\times10^{-2}$ M, [NaBr]=0.4 M, [toluene]=1.39 M. a) Based on toluene consumed. b) Not detected.

Table 3. Effect of the partial pressure of oxygen on the reaction products in the oxidation of toluene by the Co-Cu-Br system

Partial pressure of oxygen	Toluene conversion	Products (mol %)[a]		
kg/cm²	%	$PhCH_2OAc$	PhCHO	PhCOOH
20	83	29	13	56
10	77	49	15	33
5	34	60	27	12
0	0	Trace	0	0

Reaction conditions: method B, 150 °C, 5 h, $[Co(OAc)_2]=[Cu(OAc)_2]=5.71\times10^{-2}$ M, [NaBr]=0.4 M, [toluene] =1.39 M. a) Based on toluene consumed.

Table 4. Effect of the $[Cu(OAc)_2]/([Co(OAc)_2]+[Cu(OAc)_2])$ ratio on the reaction products in the oxidation of toluene by the Co-Cu-Br system

[Cu]/([Co]+[Cu])	Toluene conversion	Products (mol %)		
mol %	%	$PhCH_2OAc$	PhCHO	PhCOOH
0.00	98	6	2	88
0.25	91	25	8	66
0.50	77	49	15	33
0.75	76	45	15	37
1.00	65	38	13	48

Reaction conditions: method B, 150 °C, 5 h, $[Co(OAc)_2]+[Cu(OAc)_2]=1.14\times10^{-1}$ M, [NaBr]=0.4 M, [toluene]= 1.39 M; total pressure, 40 kg/cm² ($O_2/N_2=1/3$). a) Based on toluene consumed.

is ultimately oxygen; hence, benzyl acetate was not obtained under a nitrogen atmosphere, that is, the active species could not be generated from the reaction between cobalt(II) acetate bromide and the benzylperoxyl radical.

Effect of the Ratio of [Cu]/([Co]+[Cu]). The effect of the copper(II) acetate concentration in the constant NaBr and metal acetate concentrations on the oxidation was also studied (Table 4).

A remarkable synergistic effect was observed at the [Cu]/([Co]+[Cu]) ratio of 0.5; that is, Co : Cu=1 : 1. With an increase in the concentration of copper(II) acetate, the products changed from benzoic acid to benzyl acetate and the conversion of toluene went down little by little. In the region of [Cu]/([Co]+[Cu])=0—0.5, the benzyl radical may react with the oxygen molecule; consequently, the main product was benzoic acid.

On the other hand, the product distribution was similarly changed in the ratio of the 0.5—1.0 region. In the copper(II)-ion and bromide-ion system, although the oxidizing ability was small, as has been shown by Shigeyasu,[17] benzyl acetate was also obtained as well as a large amount of benzoic acid, and precipitates of presumably copper(II) oxide or hydroxide were formed in a manner similar to the oxidation of naphthalene catalyzed by the palladium–copper–chloride system in acetic acid.[18] The reason for the synergistic effect is not clear, but it might be due to the formation of a binuclear complex between cobalt(III) acetate and copper(II) acetate. In a study of the additive effect of metal acetates to cobalt(III) acetate, Kawai[9] suggested that the formation of the binuclear complex was caused by the lowering of the activity and the redox potential of cobalt(III) acetate.

We found that toluene can not be oxidized by cobalt–copper system without the bromide ion, although it was easily oxidized to benzyl acetate by the addition of NaBr.

Additive Effect on the Product Distribution. The additive effects of other transition-metal acetates, acetic anhydride, ethyl methyl ketone, and paraacetaldehyde, were also investigated.

No remarkable effects on the product selectivity were found upon the addition of $Ni(OAc)_2$, $Ce(OAc)_3$, $Cr(OAc)_3$, and $Mn(OAc)_2$.

The synergistic effect of Mn^{2+} in the oxidation of alkylbenzenes catalyzed by the cobalt ion and the bromide ion has previously been reported.[5]

In our study, however, no additive effect of Mn^{2+} on this system was observed, suggesting that the reaction between the peroxyl radical and the metal ion is not very important. Replacing 0.01 part of acetic acid partly with acetic anhydride reduced the yield of benzyl acetate at 150 °C for 5 h. The same effect was observed with ethyl methyl ketone and paraacetaldehyde.

A reaction between these additives and catalyst seems to occur.

Mechanistic Consideration. A plausible mechanism is shown in the Scheme except for the formation of a binuclear complex between cobalt(III) acetate and copper(II) acetate. The present reaction is considered to be substantially a ligand transfer of the benzyl radical with the copper(II) ion based on the studies by Kochi[8] in Eqs. 6 and 7. Very recently, the oxidation of methylbenzenes with cerium(IV) pyridinium salt was reported by Rol;[19] a ligand-transfer reaction similar to that in the case of the copper(II) ion occurs and arylalkyl chloride and arylalkyl methoxide were

obtained. The active species in a hydrogen abstraction has been proposed by many workers.[2-6]

One of the present authors[20] also clarified that the active species, cobalt(III) acetate bromide, produced by the reaction of cobalt(II) acetate bromide with the peroxyl radical has a reactivity similar to that of the Br radical toward various alkylbenzenes (Eqs. 1 and 3).

$$PhCH_3 + Co(III)Br \longrightarrow PhCH_2\cdot + Co(II)BrH \quad (1)$$

$$PhCH_2\cdot + O_2 \rightleftharpoons PhCH_2OO\cdot \quad (2)$$

$$PhCH_2OO\cdot + Co(II)BrH \longrightarrow PhCHO + Co(III)Br + H_2O \quad (3)$$

$$PhCHO + O_2 \longrightarrow PhCOOH + H_2O \quad (4)$$

$$[Cu(OAc)_2]_2 + y\mathrm{NaBr} \rightleftharpoons 2Cu(OAc)_xBr_y + y\mathrm{NaOAc} \quad (5)$$

$$PhCH_2\cdot + Cu(OAc)_xBr_y \longrightarrow PhCH_2OAc + Cu(I) \quad (6)$$

$$PhCH_2\cdot + Cu(OAc)_xBr_y \longrightarrow PhCH_2Br + Cu(I) \quad (7)$$

$$PhCH_2Br + AcO^- \longrightarrow PhCH_2OAc + Br^- \quad (8)$$

$$Cu(I) + O_2 + HX \longrightarrow Cu(II)(OAc)_xBr_y \quad (9)$$

(HX=HOAc, HBr. x=0,1,2,3,4. y=0,1,2,3,4.)

Scheme 1. Oxidation mechanism of toluene catalyzed by Co-Cu-Br.

The coupling reaction between the benzyl radical and the oxygen molecule proceeds at the rate of diffusion control, although it is considered that this reaction may proceed to the reverse side in Eq. 2 and the concentration of the benzyl radical in the reaction media will be high at higher temperatures.[21]

Studies of Unusual Amino Acids and Their Peptides. XI. The Resolution of β-(2-Furyl)-β-alanine and β-(2-Thienyl)-β-alanine and Their Absolute Configurations

Shigeru KUWATA, Takashi YAMADA, Tatsuya SHINOGI,** Naoki YAMAGAMI,*** Fumio KITABASHI,**** Toshifumi MIYAZAWA, and Hiroshi WATANABE*

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada, Kobe 658

(Received February 5, 1979)

(+)-β-(2-Furyl)-β-alanine and (+)-β-(2-thienyl)-β-alanine were obtained by resolving the *N*-benzyloxycarbonyl-DL-amino acids with quinine and by removing the protecting group from them. It was concluded, from the changes in their ORD curves depending on the pH, and also from the sign of the Cotton effects of their DCHA salts of the *N*-ethylthiocarbonothioyl derivatives, that both the compounds belong to the L-series. This conclusion was supported by the fact that the aspartic acid obtained by the oxidation of these amino acids belongs to the D-series.

In connection with β-(2-thiazolyl)-β-alanine,[1] present in a peptide antibiotic bottromycin as a C-terminal amino acid, we had an interest in the β-amino acids bearing a heterocycle in the β-position. Among these amino acids, we attempted to prepare β-(2-furyl)- and β-(2-thienyl)-β-alanine as analogs of the thiazolylalanine. Both the compounds are known,[2,3] but no attempt has been made to resolve them or to determine the absolute configuration of their optically active form.

These β-amino acids were prepared by the reaction of 2-furaldehyde or 2-thiophenecarbaldehyde with malonic acid in the presence of ammonium acetate according to the literature.[2a,3b] The racemates could be successfully resolved by treating the *N*-benzyloxycarbonyl derivatives with quinine in ethyl acetate or ethanol. From the crystalline quinine salts, separated out from the solution, the alkaloid base was removed; the following optically active compounds were thus obtained: *N*-benzyloxycarbonyl-(+)-β-(2-furyl)-β-alanine, mp 123—125 °C, $[\alpha]_D^{20}$ +55.9° (*c* 1, MeOH), *N*-benzyloxycarbonyl-(+)-β-(2-thienyl)-β-alanine, mp 128—129 °C, $[\alpha]_D^{20}$ +45.4° (*c* 1, MeOH). The *N*-protecting group could be removed by hydrobromic acid in acetic acid in the usual way, though the yields were unexpectedly low in both cases. The amino acids obtained were: (+)-β-(2-furyl)-β-alanine, $[\alpha]_D^{20}$ +12.9° (*c* 1, H_2O), (+)-β-(2-thienyl)-β-alanine, $[\alpha]_D^{20}$ +15.3° (*c* 1, H_2O). By hydrogenolytic deprotection, the former amino acid of $[\alpha]_D^{20}$ +13.7° (*c* 1, H_2O) was obtained in a much better yield than in the case of acidolysis.

In previous papers we proposed two empirical rules for the determination of the absolute configuration of the β-amino acid. One is that the value of the molecular rotation of L-β-amino acid[4] in water at various pH decreases in the order of neutral>acidic>alkaline media.[5] The other is that the dicyclohexylamine (DCHA) salt of the *N*-ethylthiocarbonothioyl (ETCT) derivative of the L-β-amino acid shows a negative Cotton effect.[6] In order to apply these rules to the optically active β-amino acids obtained here, their ORD spectra in water at different pH values were measured; it was found that the values decreased in both the β-amino acids in the order of neutral> acidic>alkaline media. On the other hand, the CD spectra of the DCHA salts of the *N*-ETCT-β-amino acids in some solvents showed negative Cotton effects in all the cases, as is shown in Table 1. Both the results denote that these β-amino acids belong to the L-series. It should be pointed out that solvents have a remarkable influence on the Cotton effects of the *N*-ETCT-β-aromatic β-amino acids, depending on the structure of the aromatic ring (Table 1).

Table 1. Cotton effects of *N*-ETCT-L-β-aromatic β-amino acids ($C_2H_5SSC-NH\underset{\displaystyle X}{\underset{|}{C}}HCH_2COOH$) and their DCHA salts in several solvents

X	Free acid			DCHA salt		
	MeOH	C_6H_6	$CHCl_3$	MeOH	C_6H_6	$CHCl_3$
Phenyl-[6]	−	−	−	−	−	−
2-Thiazolyl-	−	−, +	+	−	−	−
2-Thienyl	−	+	+	−	−	−
2-Furyl-	+	+	+	−	−	−

Terent'ev reported that *N*-benzoyl-DL-β-(2-furyl)-β-alanine or its amide was oxidized with alkaline permanganate to the benzoyl derivative of aspartic acid[7] or asparagine[2c] in a good yield. We also observed that β-(2-furyl)-α-alanine was easily converted into aspartic acid.[8] These facts suggest another route for determining the configuration of β-(2-furyl)- or β-(2-thienyl)-β-alanine by oxidizing it and by examining the chirality of the resulting aspartic acid. The β-amino acids belonging to the L-series should give D-aspartic acid upon the oxidation.

The oxidation of *N*-benzyloxycarbonyl-(+)-β-(2-furyl)-β-alanine with alkaline permanganate proceeded very smoothly and afforded *N*-(benzyloxycarbonyl) aspartic acid almost quantitatively; it was determined to be the D-isomer by a comparison of the optical rotation of the dimethyl ester with that of a sample derived from L-aspartic acid. On the other hand, the oxidation of *N*-benzyloxycarbonyl-(+)-β-(2-

** Present address: Star Rubber Ind. Co., Ltd., No. 2-3, 1-Chome, Nishishiriike-cho, Nagata-ku, Kobe 658.

*** Present address: The Green Cross Corporation, 2-2-11, Gokodori, Fukiai-ku, Kobe 651.

**** Present address: Amagasaki Chemical Industries Co., Ltd., 24-1-Chome, Rinkaicho, Izumiotsu-shi 595.

thienyl)-β-alanine to an aspartic acid derivative did not proceed so smoothly, and it was accompanied by many by-products. From the oxidation products obtained at 40 °C, *N*-(benzyloxycarbonyl)aspartic acid was isolated in a 12% yield after repeated purification by preparative silica gel TLC; benzoic acid was also isolated in a 51% yield. The configuration of the aspartic acid obtained here was confirmed to be the D-form, quite similar to the above case. Consequently, the original (+)-β-(2-furyl)- and (+)-β-(2-thienyl)-β-alanine could be attributed to the L-series.

The identity of the conclusions deduced both from the empirical rules and from the chemical evidences would demonstrate the usefulness of these rules.

Experimental

The melting points are uncorrected. The optical rotations were measured on a JASCO DIP-4 polarimeter. The ORD and CD curves were recorded on a JASCO ORD/UV-5 spectropolarimeter.

DL-β-(2-Furyl)-β-alanine (I). This compound was synthesized in a 28% yield by the condensation of 2-furaldehyde, malonic acid, and ammonium acetate according to the literature;[2a] mp 199—201 °C (dec), lit,[2a] mp 200—201 °C (dec).

N-Benzyloxycarbonyl-DL-β-(2-furyl)-β-alanine (II). I was acylated with benzyloxycarbonyl chloride and sodium hydroxide as usual; 79% yield; mp 143—143.5 °C (from aq EtOH).

Found: C, 62.31; H, 5.29; N, 4.71%. Calcd for $C_{15}H_{15}NO_5$: C, 62.28; H, 5.23; N, 4.84%.

Optical Resolution of DL-β-(2-Furyl)-β-alanine. *N-Benzyloxycarbonyl-(+)-β-(2-furyl)-β-alanine (III)*: II (8.7 g) and quinine (9 g) were dissolved in ethyl acetate (150 ml) and then allowed to stand for several days in a refrigerator. The crystals thus separated were collected and recrystallized from ethyl acetate: mp 109—111 °C, $[\alpha]_D^{20}$ −86.0° (*c* 1, MeOH).

By the removal of quinine from this salt with hydrochloric acid, optically active *N*-benzyloxycarbonyl-β-(2-furyl)-β-alanine was obtained; mp 123—125 °C (from aq EtOH), $[\alpha]_D^{20}$ +55.9° (*c* 1, MeOH). The overall yield from II was 70%.

(+)-β-(2-Furyl)-β-alanine (IV). Debenzyloxycarbonylation by Acidolysis: A 25% hydrogen bromide solution in acetic acid was added to III (600 mg), which dissolved immediately, forming a deep blue solution. After about ten minutes, the solution was concentrated under reduced pressure, and the resulting residue was washed with dry ether several times. After the remaining viscous, deep blue material had been dissolved in water and decolorized, the aqueous solution was passed through an Amberlite CG-120 (H^+ form) column. The amino acid was then eluted with aq ammonia, and the eluate was, after decolorization, concentrated to dryness under reduced pressure; yield, 44%. Recrystallization from water afforded large plates; mp 205—207 °C (dec), $[\alpha]_D^{20}$ +12.9° (*c* 1, H_2O).

Debenzyloxycarbonylation by Hydrogenolysis:[9] In a quantitative hydrogenation apparatus, a solution of III (723 mg; 2.5 mmol) in a mixture of 1 M NaOH (7 ml) and methanol (4 ml) was hydrogenated in the presence of 5% Pd–C (80 mg) at room temperature. Hydrogenation was stopped when 50 ml of hydrogen (*ca.* 2.2 mmol) had been absorbed. The reaction mixture was then filtered, and the catalyst was washed thoroughly with water. The filtrate and the washings were combined, acidified with hydrochloric acid, and extracted with ethyl acetate. The aqueous layer neutralized with 1 M NaOH to pH 6, was passed through the Amberlite CG-120 (H^+ form) column, which had been thoroughly washed with water. The amino acid was eluted with aq ammonia, and the eluate was concentrated to dryness under reduced pressure: 360 mg (93%). The NMR spectrum of this compound was identical with that of the (+)-β-(2-furyl)-β-alanine obtained by acidolysis and showed no peak attributable to the tetrahydrofuran ring. Recrystallization from water afforded large plates; $[\alpha]_D^{20}$ +13.7° (*c* 1, H_2O).

DL-β-(2-Thienyl)-β-alanine (V). This compound was synthesized in a 43% yield by the condensation of 2-thiophenecarbaldehyde,[10] malonic acid, and ammonium acetate according to the literature;[3b] mp 199—201 °C (dec), lit,[3b] mp 201—203 °C.

N-Benzyloxycarbonyl-DL-β-(2-thienyl)-β-alanine (VI). V was benzyloxycarbonylated as usual in an 86% yield; mp 118—118.5 °C (from aq EtOH).

Found: C, 59.02; H, 4.94; N, 4.34%. Calcd for $C_{15}H_{15}NO_4S$: C, 59.00; H, 4.95; N, 4.59%.

Optical Resolution of DL-β-(2-Thienyl)-β-alanine. The resolution was carried out in a manner similar to that used in the case of the furan derivative.

Easily crystallizable quinine salt of *N*-benzyloxycarbonyl-β-(2-thienyl)-β-alanine was obtained in a 60% yield; mp 155—156 °C (from EtOH), $[\alpha]_D^{20}$ −29.3° (*c* 1, MeOH).

N-Benzyloxycarbonyl-(+)-β-(2-thienyl)-β-alanine (VII). Yield, 95%; mp 128—129 °C (from aq EtOH), $[\alpha]_D^{20}$ +45.4° (*c* 1, MeOH).

(+)-β-(2-Thienyl)-β-alanine (VIII). VII was debenzyloxycarbonylated with hydrogen bromide in acetic acid and worked up similarly to the case of furylalanine. Yield, 54%; mp 206—208 °C (dec), $[\alpha]_D^{20}$ +15.3° (*c* 1, H_2O).

Measurement of CD Spectra of N-ETCT-amino Acids and Their DCHA Salts. Both β-amino acids, IV and VIII, and (+)-β-(2-thiazolyl)-β-alanine[1] were converted to the corresponding ethyl dithiocarbamates as well as their DCHA salts according to the literature.[11] The signs of the Cotton effects of their CD spectra in several solvents are summarized in Table 1.

Oxidation of N-Benzyloxycarbonyl-(+)-β-(2-furyl)-β-alanine. III (289 mg) was dissolved in a sodium hydroxide solution (NaOH 40 mg, H_2O 5 ml), into which an alkaline potassium permanganate solution ($KMnO_4$ 1.6 g, NaOH 0.5 g, H_2O 50 ml) was added, drop by drop, under ice-cooling until the violet color of the reaction mixture had come to persist. The residual permanganate was destroyed with aqueous sodium sulfite, the precipitated manganese dioxide was filtered off, and the filtrate was extracted with ethyl acetate after having been acidified with hydrochloric acid. The organic layer was then washed with water and dried over anhydrous sodium sulfate. The evaporation of the solvent gave white crystals (mp 110—114 °C), the IR spectrum of which agreed well with that of *N*-benzyloxycarbonyl-L-aspartic acid; the yield was 266 mg (quantitative). The optical rotation was measured after converting it to dimethyl ester with diazomethane; $[\alpha]_D^{20}$ +15.3° (*c* 1.7, MeOH), $[\alpha]_D^{20}$ −29.5° (*c* 1.3, $CHCl_3$). (*N*-Benzyloxycarbonyl-L-aspartic acid dimethyl ester:[12] $[\alpha]_D^{20}$ −20.4° (*c* 1, MeOH), $[\alpha]_D^{20}$ +27.5° (*c* 1, $CHCl_3$)).

Oxidation of N-Benzyloxycarbonyl-(+)-β-(2-thienyl)-β-alanine. VII (600 mg) was oxidized with alkaline permanganate similarly to the case of the furan derivative, except that the reaction temperature was kept at about 40 °C. The color change of the reaction mixture was very slow compared

with that of the furan derivative, so a large excess of the oxidizing reagent was added to ensure the oxidation. The separation of the crude oxidation products was carried out by preparative TLC (adsorbent: Merck silica gel GF_{254}; developing solvent, $CHCl_3$:MeOH:AcOH=95:15:3). The zone of the chromatogram containing *N*-(benzyloxycarbonyl)-aspartic acid was scraped off and extracted with methanol. The extract was then concentrated and purified again in the same manner. The methanol extract was then dissolved in ethyl acetate, and the solution was washed with water and dried over sodium sulfate. The subsequent evaporation of the solvent gave white crystals (mp 114—115 °C), the IR spectrum of which agreed well with that of *N*-benzyloxycarbonyl-L-aspartic acid; the yield was 64 mg (12%); dimethyl ester, $[\alpha]_D^{20}$ +17.7° (*c* 1.2, MeOH), $[\alpha]_D^{20}$ −20.3° (*c* 1.2, $CHCl_3$). Another component of the oxidation product, with a larger R_f value than that of the aspartic acid derivative, was also isolated in a similar manner. This compound melted at 119—121 °C after recrystallization from water and showed no depression of the melting point when admixed with benzoic acid. The yield was 122 mg (51%).

Pyrrolizidine Alkaloids. The Synthesis and Absolute Configuration of All Stereoisomers of Monocrotalic Acid

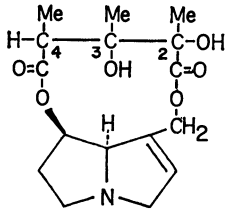
Takashi MATSUMOTO,* Makoto TAKAHASHI, and Yutaka KASHIHARA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

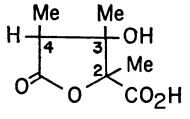
(Received March 7, 1979)

All stereoisomers (**3a, b**—**6a, b**) of monocrotalic acid have been synthesized. Methylation of (±)-*cis*-2,3,4-trimethyl-2-pentenedioic acid with diazomethane followed by *cis*-hydroxylation with potassium permanganate afforded two epimeric γ-lactone esters in a ratio of *ca.* 1:5. These esters were then hydrolyzed with dilute hydrochloric acid to the corresponding acids, (±)-**3** and racemic monocrotalic acid (**4**). Optical resolution of (±)-**3** with brucine afforded **3a** (2*R*,3*R*,4*S*) and **3b** (2*S*,3*S*,4*R*). The racemic monocrotalic acid was also resolved by means of brucine to give natural monocrotalic acid (**4a**: 2*R*,3*R*,4*R*) and its enantiomer (**4b**: 2*S*,3*S*,4*S*). Subsequently, (±)-*trans*-2,3,4-trimethyl-2-pentenedioic acid was resolved with cinchonidine to give **8a** and **8b**, whose stereochemistry was assigned respectively as *S*- and *R*-configuration by correlation to the known (*R*)-(−)-2-phenylpropanoic acid. Methylation of **8a** followed by *cis*-hydroxylation and hydrolyses afforded γ-lactone acids, **5a** (2*R*,3*S*,4*S*) and **6b** (2*S*,3*R*,4*S*). Similarly, the enantiomer **8b** was also converted into the corresponding acids, **5b** (2*S*,3*R*,4*R*) and **6a** (2*R*,3*S*,4*R*). The stereochemical course of the above hydroxylations with potassium permanganate was well explained by a modification of Cram's rule of asymmetric induction. The CD spectra of **3a,b**—**6a,b** were also discussed.

The pyrrolizidine alkaloid monocrotaline (**1**) has been isolated from *Crotalaria spectabilis* Roth.,[1,2] *C. retusa* L.,[2-4] and *C. grahamiana* Wight *et* Arn.[5] Hydrogenolysis of **1** produced a necic acid component, monocrotalic acid (**2**), which possesses three asymmetric carbons in the molecule. Therefore, eight stereoisomers (**3a,b**—**6a,b**) are possible for **2**. The structure of monocrotalic acid was established by degradation and synthesis by Adams *et al.*[6,7] On the basis of the stereospecificity of the synthetic reaction,[7] they assigned the relative configuration of methyl groups on C-2 and C-3 to be *cis* (2*R*,3*S* or 2*S*,3*R*). This means that the stereostructure of monocrotalic acid is shown as one of four diastereomers (**5a**, **5b**, **6a**, and **6b**).



1



2

Cervinka *et al.*[8,9] also studied the stereochemistry of monocrotalic acid and assigned the absolute configuration of C-2 to be *R* by the method of asymmetric transformation and by means of the optical rotatory dispersion. On the other hand, Crout *et al.*[10,11] disagreed with the result of Adams *et al.*[7] and found the chirality of three asymmetric centers in monocrotalic acid to be 2*R*,3*R*,4*R* (**4a**) by comparing the rate constant of dehydration of methyl monocrotalate with those of methyl trichodesmate,[12] 3-hydroxy-4-butyrolactone, and mevalonolactone, and by correlation of C-2 and C-4 to the known compounds, (2*R*,3*S*)-2,3-dihydroxy-2-methylbutanoic acid and (*S*)-3-hydroxy-2-methylpropanohydrazide. Although this discrepancy concerning the configuration of C-3 had been explained by Crout *et al.*,[10] it was desirable to obtain the direct confirmation of the stereochemistry of C-3 by an unambigous synthesis. The key step in the reported synthesis[7] was the stereospecific hydroxylation of (±)-*cis*-2,3,4-trimethyl-2-pentenedioic acid (**7**) with pertungstic acid, which is known to give predominantly *trans*-hydroxylation of olefinic double bonds. However, Crout *et al.*[10] have reported that the above hydroxylation actually proceeded in

a stereospecifically *cis* manner. This confusion about the stereochemical course of the synthetic reaction seemed to have occurred because of using the acidic compound (**7**) which did not react with potassium permanganate or osmium tetraoxide.[7] In previous papers,[13] we have reported that similar compounds, methyl *trans*-3-methoxycarbonyl-2-methyl-3-pentenoate and its *cis*-isomer, were easily hydroxylated with potassium permanganate in a *cis* manner. Therefore, it was of interest to study the hydroxylation of dimethyl *cis*-2,3,4-trimethyl-2-pentenedioate (**9**) and its *trans*-isomer (**10**) with potassium permanganate. We were further interested in studying the steric course of the hydroxylation to the olefinic double bonds directly bonded to asymmetric carbon atoms. This paper describes the syntheses and absolute configurations of all stereoisomers of monocrotalic acid, and the stereochemistry of the potassium permanganate hydroxylations. In addition, the relationship between the absolute configurations and the circular dichroism (CD) spectra of the synthetic γ-lactone acids was also discussed.

A mixture of racemic *cis*- (**7**) and *trans*-2,3,4-trimethyl-2-pentenedioic acid (**8**) was prepared by the procedure of Adams *et al.* and then successfully separated by column chromatography on silica gel. The NMR spectrum of (±)-**7** showed a methine proton quartet at δ 4.43 ppm and two methyl singlets at δ 1.75 and 1.90 ppm, while that of (±)-**8** showed the corresponding signals at δ 3.74 (q) ppm and at δ 1.94 (6H, s) ppm. The appearance of the methine proton signal of (±)-**7** in the field lower than that of (±)-**8** suggested that these dioic acids, (±)-**7** and (±)-**8**, have respectively *cis*- and *trans*-configuration. Methylation of the *cis*-isomer, (±)-**7**, with diazomethane afforded the dimethyl ester (**9**), which was submitted to oxidation with aqueous potassium permanganate in the presence of magnesium sulfate at −20 °C. Purification of the crude product by column chromatography on silica gel produced, as expected, two epimeric γ-lactone esters, (±)-**11** and (±)-**12**, in a ratio of *ca.* 1:5. The IR and NMR spectra of the major product, (±)-**12**, were identical with those of natural methyl monocrotalate. Since it is well known that potassium permanganate reacts with olefins to add two hydroxyl functions to the double bond in a *cis* manner, the relative configuration of the methyl groups on C-2 and C-3 in both (±)-**11** and (±)-**12** is *trans*, supporting the assignment of Crout *et al.*[10] The γ-lactone esters, (±)-**11** and (±)-**12**, were hydrolyzed with dilute hydrochloric acid to the corresponding acids, (±)-**3** and (±)-**4**, which were subsequently methylated back into (±)-**11** and (±)-**12** with diazomethane. This proved that there was no configurational change during the hydrolyses. The (±)-**4** acid was then resolved by means of brucine to give monocrotalic acid (**4a**), $[\alpha]_D$ −5.6° (EtOH), and its enantiomer (**4b**), $[\alpha]_D$ +5.3° (EtOH). Methylation of **4a** and **4b** with diazomethane, followed by dehydration of the resulting esters, **12a** and **12b**, with phosphoryl chloride in pyridine afforded respectively methyl (*R*)-(+)-anhydromonocrotalate (**15a**),[10,11] $[\alpha]_D$ +205° ($CHCl_3$), and its (*S*)-(−)-enantiomer (**15b**), $[\alpha]_D$ −195° ($CHCl_3$). From the above synthesis the absolute configuration of monocrotalic acid was conclusively assigned as being 2*R*,3*R*,4*R* (**4a**). The (±)-**3** acid was also resolved by means of brucine to give **3a**, $[\alpha]_D$ −32° (EtOH), and **3b**, $[\alpha]_D$ +22° (EtOH),[14] which, after methylation with diazomethane, were dehydrated with phosphoryl chloride in pyridine to afford **15a** and **15b** respectively. Thus, the absolute configurations of **3a** and **3b** were also assigned as being 2*R*,3*R*,4*S* and 2*S*,3*S*,4*R* respectively.

Subsequently, our attention was directed toward the syntheses of the other four diastereomers. For this purpose, (±)-**8** was resolved by means of cinchonidine to give **8a**, $[\alpha]_D$ +121° (ether), and **8b**, $[\alpha]_D$ −120° (ether), which were methylated with diazomethane to yield dimethyl esters, **10a** and **10b**. The absolute configurations of **8a** and **8b** were determined by the following correlation. Reduction of **10a**[15] with lithium aluminium hydride, followed by acetylation of the resulting diol (**16**) with acetic anhydride in

pyridine, afforded a diacetate (**17**), $[\alpha]_D$ +9.1° ($CHCl_3$). This was then submitted to ozonization to yield 4-acetoxy-3-methyl-2-butanone (**18**). The Grignard reaction of the crude **18** with methylmagnesium iodide gave a diol (**19a**) which was characterized as its monoacetate, 3-hydroxy-2,3-dimethylbutyl acetate (**20a**), $[\alpha]_D$ +16.9° ($CHCl_3$). Transformation of the known (*R*)-(−)-2-phenylpropanoic acid (**21**)[16] into **20a** or its enantiomer (**20b**) was also carried out as follows. Methylation of **21** with diazomethane afforded the corresponding methyl ester (**22**), which was converted into (*R*)-(−)-2-phenylpropyl acetate (**24**) by reduction with lithium aluminium hydride and subsequent acetylation of the resulting alcohol (**23**) with acetic anhydride in pyridine. Ozonization of **24** followed by methylation of the resulting acid (**25**) with diazomethane afforded methyl (*S*)-(+)-3-acetoxy-2-methylpropanoate (**26**), $[\alpha]_D$ +18.2° ($CHCl_3$), which was then converted into (*S*)-(−)-3-hydroxy-2,3-dimethylbutyl acetate (**20b**), $[\alpha]_D$ −27.1° ($CHCl_3$), by the Grignard reaction with methylmagnesium iodide and subsequent acetylation. The IR and NMR spectra of **20b** was identical in every respect with those of **20a**. Thus, the stereochemistry of **20a** was assigned to be *R*-configuration and **8a** and **8b** consequently have *S*- and *R*-configuration respectively.

20b R=Ac

Oxidation of **10b** with potassium permanganate afforded two γ-lactone esters, **13b** and **14a**, in a ratio of *ca.* 5:2. The NMR spectrum of **13b** showed a quartet at δ 3.04 ppm due to a methine proton at C-4, while that of **14a** showed the corresponding signal at δ 2.61 ppm. These chemical shifts suggested that the relative configuration of the methine proton and a hydroxyl group at C-3 is *cis* in **13b** and *trans* in **14a**. From the above spectral data and the consideration of the stereochemical course of the oxidation, the absolute configurations of **13b** and **14a** were assigned as 2*S*,3*R*,4*R* and 2*R*,3*S*,4*R* respectively. These assignments were further supported by the dehydration of **13b** and **14a** with phosphoryl chloride in pyridine, yielding **15b** and **15a** respectively. Hydrolyses of **13b** and **14a** with dilute hydrochloric acid yielded the corresponding acids, **5b** (2*S*,3*R*,4*R*), $[\alpha]_D$ +60° (EtOH), and **6a** (2*R*,3*S*,4*R*), $[\alpha]_D$ −5.1° (EtOH). The enantiomers, **5a** (2*R*,3*S*,4*S*) and **6b** (2*S*,3*R*,4*S*), were also synthesized from **10a** by oxidation and subsequent

hydrolyses of the resulting γ-lactone esters, **13a** and **14b**. Further, (±)-**10** prepared from (±)-**8** was also converted into (±)-**5** and (±)-**6** *via* (±)-**13** and (±)-**14**. Resolution of (±)-**5** by means of cinchonidine afforded **5a** and **5b**, whereas that of (±)-**6** was unsuccessful. Thus, the syntheses of all stereoisomers of monocrotalic acid were successfully achieved.

The stereochemical course of the potassium permanganate hydroxylation of olefinic esters having an asymmetric carbon atom adjacent to the double bond can be well explained by a modification of Cram's rule of asymmetric induction (open-chain model)[17,18] as shown in Figs. 1 and 2. For example, in the *trans* ester **10b** and its *cis*-isomer **9** which is shown only one enantiomer of the racemate, the A and C conformations should be more stable than the corresponding B and D conformations, as has been reported by Karabatsos,[18] because the effective steric size of three substituents on the asymmetric carbon atom is Me>CO_2Me>H.[19] Therefore, the double bonds in the A and B conformations are attacked by the permanganate anion from the side of the smallest hydrogen atom, as pictured, leading to the major product **13b** and the minor one **14a**. Similarly, the C and D conformations also lead to the major product **12a** and the minor one **11b** respectively.

It has been reported that the sign of the Cotton effect in the CD spectra of γ-lactones depends on the configuration of C-4,[20-22] while in the cases of γ-lactones possessing a carboxyl group at C-2 it depends on the configuration of C-2.[8,9] On the other hand, we have also reported that when γ-lactones possess a carboxyl group at C-3, the sign is influenced by the configuration of C-4.[13] In connection with these previous works, the CD spectra of our synthetic acids (**3a,b**—**6a,b**) were also measured to obtain further information on the relationship between the absolute configuration and the sign of the CD spectrum. The CD spectra of the present samples may be divided into two classes. The compounds of the first class, **3a,b** and **5a,b**, which have the opposite absolute configurations at C-2 and C-4 (2*R*,4*S* or 2*S*,4*R*), show two distinct Cotton effects at 204 and 224 nm; these respectively represent the configurations of C-2

and C-4. Those of the second class, **4a,b** and **6a,b**, which have the same absolute configurations at C-2 and C-4 (2*R*,4*R* or 2*S*,4*S*), exhibit only one effect at 204 nm. It is clear that when the absolute configuration of C-2 or C-4 is *R*, the sign is negative, and when *S*, it is positive. It is also evident that the Cotton effect due to the configuration of C-2 is superior to that of C-4, as has been reported by Cervinka *et al.*[8,9] In the cases of **4a,b** and **6a,b**, the two Cotton effects are apparently overlapped and, consequently, only the strong effect due to the configuration of C-2 is observed at 204 nm. These results in the CD study seemed to be very useful for the prediction of the absolute configurations of both C-2 and C-4 in γ-lactones carrying a carboxyl group at C-2.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as the internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, dd: double doublet, q: quartet, m: multiplet. The CD spectra were recorded on a JASCO J-40CS spectropolarimeter. Column chromatography was performed using Merck silica gel (0.063 mm).

(±)-cis-2,3,4-Trimethyl-2-pentenedioic Acid (7) and Its (±)-trans-Isomer (8). A mixture of (±)-**7** and (±)-**8** prepared by the procedure of Adams *et al.*[7] was chromatographed on silica gel[24] using acetone-benzene (3:97) as the eluent to give an anhydride of (±)-**7**; IR: 1790, 1736, 1657 cm^{-1}; NMR: 1.51 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.95 and 2.01 (each 3H and s, 2=CCH_3), 3.25 (1H, q, J=7 Hz, $CH_3C\underline{H}$–). Further elution gave (±)-**7**, which was recrystallized from ether-petroleum benzine: mp 118—120 °C; NMR (CD_3COCD_3): 1.20 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.75 and 1.90 (each 3H and bs, 2=CCH_3), 4.43 (1H, q, J=7 Hz, $CH_3C\underline{H}$–). Found: C, 55.71; H, 7.18%. Calcd for $C_8H_{12}O_4$: C, 55.80; H, 7.03%.

Further elution with acetone-benzene (1:9) afforded (±)-**8**, which was recrystallized from ether-petroleum benzine: mp 132—133 °C; NMR (CD_3COCD_3): 1.23 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.94 (6H, s, 2=CCH_3), 3.74 (1H, q, J=7 Hz, $CH_3C\underline{H}$–). Found: C, 55.97; H, 6.96%. Calcd for $C_8H_{12}O_4$: C, 55.80; H, 7.03%.

The above anhydride was hydrolyzed with aqueous sodium hydroxide at 40 °C for 2 h to give (±)-**7**.

Dimethyl (±)-cis-2,3,4-Trimethyl-2-pentenedioate (9) and Its (±)-trans-Isomer (10). *a)*: A sample of (±)-**7** in ether was methylated with diazomethane to give the corresponding dimethyl ester (**9**); NMR: 1.20 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.68 and 1.85 (each 3H and s, 2=CCH_3), 3.60 and 3.68 (each 3H and bs, 2–CO_2CH_3), 4.34 (1H, q, J=7 Hz, $CH_3C\underline{H}$–).

b): Similarly, (±)-**8** was methylated with diazomethane to afford the corresponding ester (**10**); NMR: 1.16 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.79 and 1.81 (6H, m, 2=CCH_3), 3.58 and 3.62 (each 3H and s, 2–CO_2CH_3), *ca.* 3.6 (1H, overlap, $CH_3C\underline{H}$–).

Oxidation of (±)-9 with Potassium Permanganate. A solution of potassium permanganate (182 mg) and magnesium sulfate heptahydrate (254 mg) in water (9.0 ml) was added at −20±2 °C into a solution of (±)-**9** (170 mg) in methanol (5.0 ml) with stirring. The mixture was further stirred for 3 h at this temperature, and sodium hydrogensulfite was then added. After the methanol had been evaporated under a vacuum, the mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated under a vacuum. The residue was purified by column chromatography on silica gel using ether–benzene (15:85) as the eluent to give a γ-lactone ester (**11**) (19 mg: 11.1%) as an oil; IR: 3590, 3450, 1777, 1737 cm^{-1}; NMR ($CDCl_3$): 1.16 (3H, d, J=7 Hz, C_4–CH_3), 1.23 (3H, s, C_3–CH_3), 1.59 (3H, s, C_2–CH_3), *ca.* 2.4 (1H, bs, –OH), 2.76 (1H, q, J=7 Hz, C_4–H), 3.77 (3H, s, $-CO_2CH_3$). Found: C, 53.20; H, 7.06%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

Further elution gave another γ-lactone ester (**12**) (91 mg: 53.0%) which was recrystallized from ether-petroleum benzine: mp 76—77 °C; IR: 3580, 3450, 1780, 1732 cm^{-1}; NMR ($CDCl_3$): 1.18 (3H, d, J=7 Hz, C_4–CH_3), 1.19 (3H, s, C_3–CH_3), 1.62 (3H, s, C_2–CH_3), *ca.* 2.5 (1H, bs, –OH), 2.87 (1H, q, J=7 Hz, C_4–H), 3.78 (3H, s, $-CO_2CH_3$). Found: C, 53.47; H, 6.97%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%. The IR and NMR spectra of (±)-**12** were identical with those of natural methyl monocrotalate.

Hydrolyses of (±)-11 and (±)-12. *a)*: A mixture of (±)-**11** (826 mg) and dilute hydrochloric acid (4 mol dm^{-3}: 33 ml) was refluxed for 2 h and then evaporated with benzene under a vacuum to dryness. The residue was chromatographed on silica gel[24] using acetone-benzene (1:4) as the eluent to give an acid (**3**) (587 mg: 76.4%) which was recrystallized from acetone-petroleum benzine; mp 156—158 °C; NMR (CD_3COCD_3): 1.13 (3H, d, J=7 Hz, C_4–CH_3), 1.38 (3H, s, C_3–CH_3), 1.57 (3H, s, C_2–CH_3), 2.80 (1H, q, J=7 Hz, C_4–H). Found: C, 51.16; H, 6.51%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%. Methylation of (±)-**3** with diazomethane yielded (±)-**11**.

b): A mixture of (±)-**12** (1.738 g) and dilute hydrochloric acid (4 mol dm^{-3}: 65 ml) was refluxed for 2 h and then treated as described for the preparation of (±)-**3**. The crude product was recrystallized from acetone-petroleum benzine to give the racemic monocrotalic acid (**4**) (659 mg: 40.8%); mp 187—189 °C; NMR (CD_3COCD_3): 1.14 (3H, d, J=7 Hz, C_4–CH_3), 1.27 (3H, s, C_3–CH_3), 1.62 (3H, s, C_2–CH_3), 2.84 (1H, q, J=7 Hz, C_4–H). Found: C, 51.30; H, 6.53%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%. The mother liquor of the above crystallization was evaporated under a vacuum and the residue was chromatographed on silica gel[24] using acetone-benzene (1:4) as the eluent to give some additional (±)-**4** (451 mg: 27.9%). Methylation of (±)-**4** with diazomethane afforded (±)-**12**.

Resolution of (±)-3. A mixture of (±)-**3** (551 mg) and brucine dihydrate (1.262 g) was dissolved in ethanol (100 ml) by heating. The solution was concentrated, allowed to stand at room temperature, and then filtered to give colorless crystals (870 mg), which were recrystallized three times from ethanol to give a brucine salt (464 mg); mp 218—225 °C dec; $[\alpha]_D$ −39.4°.

The salt was suspended in dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated to dryness. The residue was purified by column chromatography on silica gel[24] to give **3a** (2*R*,3*R*,4*S*) (120 mg); $[\alpha]_D$ −32° (EtOH); CD (H_2O): $[\theta]_{204}$ −15000, $[\theta]_{224}$ +2700.

The filtrate from the above salt was evaporated under a vacuum and the residue was recrystallized from ethanol to yield another brucine salt (550 mg); mp 165—168 °C;

$[\alpha]_D$ −11.1°.

This salt was also treated with dilute hydrochloric acid as described above and the crude product was purified by column chromatography on silica gel[24] to give **3b** (2*S*,3*S*,4*R*) (103 mg); $[\alpha]_D$ +22° (EtOH); CD (H_2O):[23] $[\theta]_{204}$ +9200, $[\theta]_{224}$ −1800.

Resolution of (±)-4. A mixture of (±)-**4** (1.112 g) and brucine dihydrate (2.545 g) in ethanol (150 ml) was refluxed, concentrated, and then allowed to stand at room temperature. The crystals (1.790 g, mp 207—208 °C dec) were collected by filtration and recrystallized twice from ethanol to give a brucine salt (1.165 g); mp 208—209 °C dec; $[\alpha]_D$ −11.4°.

The salt was suspended in dilute hydrochloric acid, extracted with ether, and the ether extract was washed with brine. After drying over sodium sulfate, the solution was evaporated to afford a colorless solid (210 mg), which was recrystallized from acetone–petroleum benzine, giving monocrotalic acid (**4a**) (2*R*,3*R*,4*R*); mp 185—187 °C; $[\alpha]_D$ −5.6° (EtOH) (lit, mp 181—182 °C,[2] $[\alpha]_D$ −4.65±0.5° (EtOH)[7]); CD (H_2O): $[\theta]_{204}$ −11000.

The filtrate from the above salt was evaporated and the residue was recrystallized from ethanol to give another salt (1.145 g); mp 214—216 °C dec; $[\alpha]_D$ −32°.

This salt was also treated with dilute hydrochloric acid and the product (228 mg) was recrystallized from acetone–petroleum benzine to give **4b** (2*S*,3*S*,4*S*); mp 185—187 °C; $[\alpha]_D$ +5.3° (EtOH); CD (H_2O): $[\theta]_{204}$ +11000.

Dehydration of 11a and 11b. *a)*: A sample of **3a** (59 mg) was methylated with diazomethane to yield the corresponding methyl ester (**11a**), which was dissolved in a mixture of phosphoryl chloride (246 mg) and pyridine (0.6 ml). The solution was refluxed for 30 min, cooled, diluted with a mixture of ice and dilute hydrochloric acid, and then extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel using ether–benzene (2:98) as the eluent to give methyl (*R*)-(+)-anhydromonocrotalate (**15a**) as an oil (35 mg: 60%); $[\alpha]_D$ 203°; IR: 1757, 1732, 1675 cm^{-1}; NMR ($CDCl_3$): 1.64 (3H, s, C_2–CH_3), 1.83 and 1.99 (each 3H and s, 2=CCH_3), 3.76 (3H, s, $-CO_2CH_3$). Found: C, 58.58; H, 6.67%. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%.

b): A sample of **3b** (60 mg: $[\alpha]_D$ +18° (EtOH)) was methylated with diazomethane to afford a methyl ester (**11b**), which was refluxed with a mixture of phosphoryl chloride (248 mg) and pyridine (0.5 ml) for 30 min. After the same work-up as described in a) above the crude product was purified by column chromatography on silica gel to give methyl (*S*)-(−)-anhydromonocrotalate (**15b**) (47 mg: 76%) as an oil, $[\alpha]_D$ −101°, whose IR and NMR spectra were identical with those of **15a**.

Dehydration of 12a and 12b. *a)*: A sample of monocrotalic acid (**4a**) (143 mg) was methylated with diazomethane to give methyl monocrotalate (**12a**), which was refluxed with phosphoryl chloride (560 mg) in pyridine (1.2 ml) for 30 min. After the same work-up as described above, the crude product was purified by column chromatography on silica gel to afford an oil (100 mg: 72%), $[\alpha]_D$ +205°, whose IR and NMR spectra were identical with those of methyl (*R*)-(+)-anhydromonocrotalate (**15a**).

b): Methylation of **4b** (43 mg) with diazomethane gave the corresponding methyl ester (**12b**), which was dehydrated with phosphoryl chloride (170 mg) in pyridine (0.5 ml) as described above. Purification of the crude product by column chromatography on silica gel afforded methyl (*S*)-(−)-anhydromonocrotalate (**15b**) (35 mg: 83%) as an oil, $[\alpha]_D$ −195°.

(S)-(+)-3-Acetoxy-2-methylpropanoic Acid (25). (*R*)-(−)-2-Phenylpropanoic acid (**21**)[16] (6.136 g, $[\alpha]_D$ −63.8°) was methylated with diazomethane to give a methyl ester (**22**) (6.701 g), $[\alpha]_D$ −85°.

A sample of **22** (6.137 g) was reduced with lithium aluminium hydride (852 mg) in ether (60 ml) at room temperature for 2 h. After the usual work-up, the crude alcohol (**23**) (5.038 g: $[\alpha]_D$ +4.5°) was immediately acetylated at 80 °C for 1.5 h with acetic anhydride (19 ml) in pyridine (25 ml) to give (*R*)-(−)-2-phenylpropyl acetate (**24**) (6.254 g); $[\alpha]_D$ −4.5°; NMR: 1.30 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.96 (3H, s, $-OCOCH_3$), 3.05 (1H, m, $CH_3C\underline{H}$–), 4.10 (2H, bd, J=7 Hz, $-CH_2O$–), 7.21 (5H, s, $-C_6H_5$).

A solution of **24** (5.810 g) in chloroform (30 ml) was ozonized at 0—15 °C for *ca.* 70 h. The solution was evaporated under a vacuum and the residue was chromatographed on silica gel[24] using ether–benzene (1:9) as the eluent to afford an acid (**25**) as an oil (1.813 g); $[\alpha]_D$ +16.2°; NMR: 1.25 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 2.23 (3H, s, $-OCOCH_3$), 2.78 (1H, m, $CH_3C\underline{H}$–), 4.16 (2H, d, J=7 Hz, $-CH_2O$–).

Methyl (S)-(+)-3-Acetoxy-2-methylpropanoate (26). A solution of **25** (1.508 g) in ether (10 ml) was methylated with diazomethane to give the corresponding methyl ester (**26**) (1.567 g); $[\alpha]_D$ +18.2°; NMR: 1.19 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 2.00 (3H, s, $-OCOCH_3$), 2.70 (1H, m, $CH_3C\underline{H}$–), 3.69 (3H, s, $-CO_2CH_3$), 4.13 (2H, d, J=7 Hz, $-CH_2O$–).

(S)-(−)-3-Hydroxy-2,3-dimethylbutyl Acetate (20b). The Grignard reagent, prepared from methyl iodide (5.0 ml) and magnesium (1.306 g) in dry ether (10 ml), was diluted with dry benzene (15 ml), and then the ether was distilled off. After the addition of a solution of **26** (1.323 g) in dry benzene (3.0 ml), the mixture was stirred at room temperature for 30 min and then refluxed for 1.5 h. The reaction mixture was poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The aqueous layer was further extracted continuously with ether for *ca.* 2.5 h. The ether extracts were combined, washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and then evaporated. The residual oil (925 mg) was purified by column chromatography on silica gel using ether–chloroform (1:1) as the eluent to give (*S*)-2,3-dimethyl-1,3-butanediol (**19b**) (615 mg); NMR: 0.82 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.12 and 1.19 (each 3H and s, $(CH_3)_2C$–), 3.58 (2H, d, J=7 Hz, $-C\underline{H}_2OH$).

The above diol **19b** (64.8 mg) was acetylated with acetic anhydride (0.3 ml) in pyridine (0.5 ml) at room temperature for 36 h. After the usual work-up, the crude product was purified by column chromatography on silica gel using ether–chloroform (1:9) as the eluent to give (*S*)-(−)-3-hydroxy-2,3-dimethylbutyl acetate (**20b**) (54.3 mg) as an oil: $[\alpha]_D$ −27.1°; IR: 3605, 3460, 1725 cm^{-1}; NMR: 0.94 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.12 and 1.17 (each 3H and s, $(CH_3)_2C$–), 2.00 (3H, s, $-OCOCH_3$), 3.6—4.4 (2H, m, $-CH_2O$–). Found: C, 59.69; H, 9.78%. Calcd for $C_8H_{16}O_3$: C, 59.98; H, 10.07%.

Resolution of (±)-trans-2,3,4-Trimethyl-2-pentenedioic Acid (8). A mixture of (±)-**8** (3.455 g) and cinchonidine (11.812 g) was dissolved in ethyl acetate (2.3 l) by refluxing, concentrated to about half volume, and then allowed to stand at room temperature. The colorless crystals (8.14 g) were collected by filtration and recrystallized twice from ethyl acetate to afford a cinchonidine salt (5.537 g); mp 185—187 °C; $[\alpha]_D$ −64°.

An aliquot of the above salt (500 mg) was suspended in dilute hydrochloric acid, extracted with ether, and the ether extract was washed with brine. After drying over sodium sulfate, the solution was evaporated to give (*S*)-(+)-*trans*-2,3,4-trimethyl-2-pentenedioic acid (**8a**) (121 mg), which was recrystallized from ether-petroleum benzine; mp 108—110 °C; $[\alpha]_D$ +121° (ether).

The filtrate from the above salt was evaporated under a vacuum and the residue was recrystallized several times from ethyl acetate to give another cinchonidine salt (1.787 g); mp 166—168 °C; $[\alpha]_D$ −97°.

This salt was also treated with dilute hydrochloric acid to afford (*R*)-(−)-*trans*-2,3,4-trimethyl-2-pentenedioic acid (**8b**) (375 mg); mp 108—110 °C; $[\alpha]_D$ −120° (ether).

*Methylation of **8a** and **8b**.* *a)*: Methylation of **8a** with diazomethane afforded dimethyl (*S*)-(+)-*trans*-2,3,4-trimethyl-2-pentenedioate (**10a**) as an oil, $[\alpha]_D$ +114° (ether), whose IR and NMR spectra were identical with those of (±)-**10**.

b): Methylation of **8b** with diazomethane afforded dimethyl (*R*)-(−)-*trans*-2,3,4-trimethyl-2-pentenedioate (**10b**) as an oil, $[\alpha]_D$ −111° (ether), whose IR and NMR spectra were identical with those of (±)-**10**.

*(S)-(+)-1,5-Diacetoxy-2,3,4-trimethyl-2-pentene (**17**).* A solution of **10a** (1.670 g, $[\alpha]_D$ +102° (ether)) in dry ether (15 ml) was added dropwise to a suspension of lithium aluminium hydride (950 mg) in dry ether (20 ml) with stirring. The mixture was refluxed for 2 h, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated to give a diol (**16**) (1.101 g) as an oil, $[\alpha]_D$ +7.4° (ether).

The above crude diol (**16**) (1.101 g) was immediately acetylated with acetic anhydride (4.4 ml) in pyridine (6.0 ml) at 80 °C for 2 h. After the usual work-up, the crude product was purified by column chromatography on silica gel using ether-benzene (2:98) as the eluent to give a diacetate (**17**) (665 mg) as an oil: $[\alpha]_D$ +9.1°; IR: 1725 cm^{-1}; NMR: 0.98 (3H, d, J=7 Hz, $C\underline{H}_3CH$–), 1.70 (6H, br, 2=CCH_3), 1.95 and 1.99 (each 3H and s, 2–$OCOCH_3$), 3.92 (2H, d, J=7 Hz, $-CH_2O$–), 4.51 (2H, s, =CCH_2O–). Found: C, 63.02; H, 9.13%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

*(R)-(+)-3-Hydroxy-2,3-dimethylbutyl Acetate (**20a**).* A solution of **17** (323 mg) in chloroform (10 ml) was ozonized at −10 °C for 3 h and then evaporated to give a crude ketone (**18**) (331 mg).

A solution of the above ketone (**18**) (321 mg) in dry benzene (3.0 ml) was refluxed for 1.5 h with the Grignard reagent, prepared from methyl iodide (1.1 ml) and magnesium (345 mg) in dry ether (5.0 ml) and benzene (5.0 ml). After the same work-up as described for the preparation of **19b**, the crude product was purified by column chromatography on silica gel using ether-chloroform (1:1) as the eluent to give a diol (**19a**) (83 mg) whose IR and NMR spectra were identical with those of **19b**.

The above diol **19a** (68 mg) was acetylated with acetic anhydride (0.3 ml) in pyridine (0.5 ml) at room temperature for 36 h. After the same work-up as described for the preparation of **20b**, the crude product was purified by column chromatography on silica gel to afford (*R*)-(+)-3-hydroxy-2,3-dimethylbutyl acetate (**20a**) (52 mg) as an oil, $[\alpha]_D$ +16.9°, whose IR and NMR spectra were identical with those of **20b**. Found: C, 59.73; H, 10.17%. Calcd for $C_8H_{16}O_3$: C, 59.98; H, 10.07%.

*Oxidation of **10b** with Potassium Permanganate.* A solution of **10b** (355 mg) in methanol (10 ml) was oxidized at −20±2 °C with a solution of potassium permanganate (380 mg) and magnesium sulfate heptahydrate (531 mg) in water (18 ml) as described above. The crude product was purified by column chromatography on silica gel using ether-benzene (15:85) as the eluent to give a γ-lactone ester (**13b**) (2*S*,3*R*,4*R*) (104 mg), which was recrystallized from ether-petroleum benzine; mp 93—95 °C; $[\alpha]_D$ +28.5°; IR: 3450, 1780, 1740 cm^{-1}; NMR ($CDCl_3$): 1.19 (3H, d, J=7 Hz, C_4–CH_3), 1.28 (3H, s, C_3–CH_3), 1.58 (3H, s, C_2–CH_3), 3.04 (1H, q, J=7 Hz, C_4–H), 3.82 (3H, s, $-CO_2CH_3$). Found: C, 53.62; H, 6.84%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

Further elution gave another γ-lactone ester (**14a**) (2*R*, 3*S*,4*R*) (44 mg) which was recrystallized from ether; mp 133—135 °C; $[\alpha]_D$ +5.1°; IR: 3450, 1780, 1730 cm^{-1}; NMR ($CDCl_3$): 1.22 (3H, d, J=7 Hz, C_4–CH_3), 1.53 (3H, s, C_3–CH_3), 1.58 (3H, s, C_2–CH_3), 2.61 (1H, q, J=7 Hz, C_4–H), 3.83 (3H, s, $-CO_2CH_3$). Found: C, 53.58; H, 7.18%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

*Dehydration of **13b** and **14a**.* *a)*: A sample of **13b** (86 mg) was dehydrated with phosphoryl chloride (324 mg) in pyridine (0.8 ml) as described above. The crude product was purified by column chromatography on silica gel to afford methyl (*S*)-(−)-anhydromonocrotalate (**15b**) (40 mg: 51%) as an oil, $[\alpha]_D$ −199°.

b): A sample of **14a** (39 mg) was also dehydrated with phosphoryl chloride (148 mg) in pyridine (0.5 ml) to yield methyl (*R*)-(+)-anhydromonocrotalate (**15a**) (13 mg: 35%) as an oil, $[\alpha]_D$ +170°.

*Hydrolyses of **13b** and **14a**.* *a)*: A sample of **13b** (88 mg) was refluxed with dilute hydrochloric acid (4 mol dm^{-3}:4.0 ml) for 2 h. The product (71 mg) was recrystallized from acetone-petroleum benzine to give the corresponding γ-lactone acid (**5b**) (2*S*,3*R*,4*R*); mp 185—188 °C; $[\alpha]_D$ +60° (EtOH); NMR (CD_3COCD_3): 1.11 (3H, d, J= 7 Hz, C_4–CH_3), 1.28 (3H, s, C_3–CH_3), 1.53 (3H, s, C_2–CH_3), 3.09 (1H, q, J=7 Hz, C_4–H). Found: C, 51.08; H, 6.46%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%.

Methylation of **5b** with diazomethane gave **13b**.

b): A sample of **14a** (39 mg) was hydrolyzed with dilute hydrochloric acid. The product (27 mg) was recrystallized from acetone-petroleum benzine to give the corresponding γ-lactone acid (**6a**) (2*R*,3*S*,4*R*); mp 185—187.5 °C; $[\alpha]_D$ −5.1° (EtOH); CD (H_2O): $[\theta]_{204}$ −5500; NMR (CD_3COCD_3): 1.13 (3H, d, J=7 Hz, C_4–CH_3), 1.53 (3H, s, C_3–CH_3), 1.56 (3H, s, C_2–CH_3), 2.82 (1H, q, J=7 Hz, C_4–H). Found: C, 51.10; H, 6.45%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%.

Methylation of **6a** with diazomethane gave **14a**.

*Oxidation of **10a** with Potassium Permanganate.* A solution of **10a** (1.075 g) in methanol (32 ml) was oxidized at −20±2 °C with a solution of potassium permanganate (1.150 g) and magnesium sulfate heptahydrate (1.607 g) in water (60 ml), as described for (±)-**9**. The crude product was chromatographed on silica gel using ether-benzene (15:85) as the eluent to give a γ-lactone ester (**13a**) (2*R*, 3*S*,4*S*) (432 mg), which was recrystallized from ether-petroleum benzine; mp 94—96 °C; $[\alpha]_D$ −29.6°. The IR and NMR spectra of **13a** were identical with those of **13b**.

Further elution gave another γ-lactone ester (**14b**) (2*S*, 3*R*,4*S*) (188 mg), which was recrystallized from ether: mp 133—135 °C; $[\alpha]_D$ −5.4°. The IR and NMR spectra of **14b** were identical with those of **14a**.

*Hydrolyses of **13a** and **14b**.* *a)*: A sample of **13a** was refluxed with dilute hydrochloric acid for 2 h. Purification of the product gave **5a** (2*R*,3*S*,4*S*); mp 186—189 °C; $[\alpha]_D$ −69° (EtOH). The NMR spectrum of **5a** was identical

with that of **5b**.

Methylation of **5a** with diazomethane gave **13a**.

b): A sample of **14b** was hydrolyzed with dilute hydrochloric acid to afford **6b** (2*S*,3*R*,4*S*); mp 185.5—188 °C; $[\alpha]_D$ +6.3° (EtOH); CD (H_2O): $[\theta]_{204}$ +5400. The NMR spectrum of **6b** was identical with that of **6a**.

Methylation of **6b** with diazomethane gave **14b**.

Oxidation of (±)-10 with Potassium Permanganate. A sample of (±)-**10** was oxidized with potassium permanganate as described for (±)-**9**. Chromatographic purification of the crude product yielded a γ-lactone ester, (±)-**13**, which was recrystallized from ether-petroleum benzine: mp 93—94.5 °C. Found: C, 53.73; H, 6.96%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

Further elution gave another γ-lactone ester, (±)-**14**, which was recrystallized from ether, mp 110—111.5 °C. Found: C, 53.55; H, 7.06%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

Hydrolyses of (±)-13 and (±)-14. *a)*: A sample of (±)-**13** was hydrolyzed with dilute hydrochloric acid to give (±)-**5**, mp 161—165 °C. Found: C, 50.78; H, 6.50%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%.

b): A similar hydrolysis of (±)-**14** afforded (±)-**6**, mp 199—203 °C. Found: C, 51.10; H, 6.45%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%.

Resolution of (±)-5. A mixture of (±)-**5** (1.048 g) and cinchonidine (1.639 g) was dissolved in hot ethyl acetate (600 ml) and then concentrated. The crystals were collected by filtration and recrystallized from ethyl acetate to afford a cinchonidine salt (930 mg); mp 199.5—201 °C dec; $[\alpha]_D$ −77.2°.

The salt was suspended in dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated to give **5b** (2*S*,3*R*,4*R*) (311 mg), which was recrystallized from acetone-petroleum benzine; mp 186—189 °C; $[\alpha]_D$ +70.0° (EtOH); CD (H_2O): $[\theta]_{204}$ +12000, $[\theta]_{224}$ −4200.

The filtrate from the above salt was evaporated and the residue was recrystallized from ethyl acetate to give another cinchonidine salt (788 mg); mp 187—189 °C; $[\alpha]_D$ −62.9°.

This salt was also treated with dilute hydrochloric acid to give **5a** (2*R*,3*S*,4*S*) (279 mg), which was recrystallized from acetone-petroleum benzine; mp 186—189 °C; $[\alpha]_D$ −69.4° (EtOH); CD (H_2O): $[\theta]_{204}$ −12000, $[\theta]_{224}$ +4200.

The authors wish to express their thanks to Professor D. H. G. Crout, University of Exeter, for his generous gift of monocrotalic acid. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Acyl Cyanide. VI. The Synthesis of 1-Cyano-1-alkenyl Esters by the Reaction of Acyl Cyanides with Acid Chlorides. Synthesis and Mechanism

Akira Oku* and Shingo Arita

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received March 16, 1979)

The reactions of enolizable acyl cyanides (acetyl, propionyl, isobutyryl, and diphenylacetyl cyanide) with acid chlorides (acetyl, propionyl, benzoyl, *p*-nitrobenzoyl, diphenylcarbamoyl, and dimethylcarbamoyl chloride) in the presence of tertiary amines gave the corresponding 1-cyano-1-alkenyl carboxylates or carbamates in good yields. Among several solvents and amines examined in the reaction of acetyl cyanide with propionyl chloride, benzene and pyridine seem to be most appropriate. The maximum yield (98%) of the ester was attained in benzene when both the chloride and pyridine were used in excess amounts (1.2—1.4 times the amount of the cyanide). The rate of reaction depended little on the concentration of the chloride but on both the cyanide and the amine being of first order in each reactant; it was also influenced by the basicity of tertiary amines and, in the case of weak bases, additionally by their nucleophilic power.

In the preceding paper,[1] we reported that 1-cyano-1-alkenyl esters can be easily synthesized by simply mixing acid anhydrides with primary or secondary acyl cyanides under the influence of amine catalysts. In the present study, we have extended the choice of acylating reagent from acid anhydride to acyl chloride including not only carboxylic acid chlorides but also carbamoyl chlorides, and have carried out their reactions with potentially enolizable acyl cyanides in the presence of stoichiometric amount of tertiary amines. In this report, solvent effects, base catalysis, and reaction mechanisms are discussed together with the synthesis.

Results and Discussion

The results of the reactions between four enolizable acyl cyanides and nine acid chlorides are listed in Table 1. Tertiary amines were adopted as the base, tetrahydrofuran (THF) and dichloromethane were used as solvents. The yields listed in this table are based upon the products isolated by fractional distillation and are not necessarily the best ones (as for improving product yields, see the following sections).

$$R^1R^2CH\text{-}CO\text{-}CN + R^3\text{-}CO\text{-}Cl \xrightarrow{\text{amine}} R^1R^2C{=}C(CN)\text{-}OCOR^3 + \text{amine}\cdot HCl$$

Although a stoichiometric amount of amine is required in this reaction in contrast to its catalytic amount in the reaction with acid anhydrides,[1] the product esters were obtained in relatively high yields and in pure states not contaminated by such by-products as the dimer of acyl cyanide.

Solvents. In order to increase the reaction rates and also the product yields in this synthesis, the choice of appropriate solvents is important. As a model reaction, the reaction of acetyl cyanide with propionyl chloride in the presence of pyridine was chosen and the effect of solvents (acetonitrile, dichloromethane, benzene, and THF) were examined by plotting the product yields against reaction time (see Fig. 1). With this figure it becomes evident that the solvent effect on the rate of reaction is in the following order $CH_3CN \approx CH_2Cl_2 > C_6H_6 > THF$.[2] On the other hand, the yield was the highest in benzene (80% when the reactant ratio was cyanide/chloride/amine=1/1/1) but in CH_3CN or CH_2Cl_2 the yield hit a ceiling at *ca.* 60%, possibly due to the faster consumption of the chloride[3] than of the cyanide. Therefore, benzene seems to be most useful among the four solvents examined.

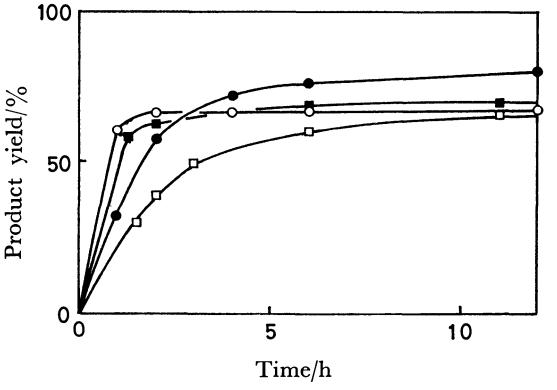

Fig. 1. The effect of solvent on the formation of 1-cyanovinyl propionate.[a]
CH_3CN (■), CH_2Cl_2 (○), C_6H_6 (●), THF (□).
a) Reactant ratio: cyanide/chloride/pyridine=1/1/1, 0.02 mol/18 ml for each reagent, at 25 °C. Product yields were determined by VPC using the method of calibration curves.

Reactant Ratios. At the last stage of average reactions where the initially charged reactant ratios were [cyanide]/[chloride]/[amine]=1/1/1 as in the cases of the reactions of Table 1, usually the chloride was completely consumed while some amount of the cyanide remained unreacted. This implied that some side reactions were taking place competingly to consume the chloride.[3] Thus we thought that the increase in the initial amount of chloride relative to that of the cyanide would improve the yield. We inspected this effect in the reaction of acetyl cyanide with propionyl chloride in the presence of pyridine, and the results are shown in Table 2. This table clearly indicates that acetyl cyanide can be converted into 1-cyanovinyl propionate almost quantitatively when an excess amount of the chloride and amine (both 1.2—1.4 times more than the cyanide) are used. Proved also is the necessity of an equivalent amount of amine to that of chloride

Table 1. Preparation of 1-cyano-1-alkenyl carboxylates by the reaction of acyl cyanides with acyl chlorides

3	1.0	1.4	1.4	96/10, 98/26
4	1.0	1.6	1.4	90/10, 97/24

a) In dry benzene at 25 °C. Standard reactant concentration for the cyanide was 0.02 mol in 16 ml of benzene. b) Determined by VPC analysis, calibrating with authentic compounds.

in this improved method.

Reaction Rate. In Table 3 are shown the effects of reactant ratios on the initial rates of reaction. Evidently, the rates seem to be dependent on the concentration of both the cyanide and the amine, being of first order in the concentration of each of these reactants, and hardly dependent on the concentration of the chloride.

Based on the above observations and subsidiarily on the fact that the chloride reacts rapidly with the amine to form a pyridinium salt **20**,[4,5] the following reaction channel is proposed.

$$C_2H_5COCl + \text{pyridine} \underset{}{\overset{K}{\rightleftharpoons}} \underset{\mathbf{20}}{[C_2H_5CO\text{-pyridine}]^+Cl^-} \quad (1)$$

$$CH_3COCN + \text{pyridine} \xrightarrow[\text{slow}]{k} \underset{\mathbf{21}}{[CH_3COCN][\text{pyridine}]} \quad (2)$$

$$[CH_3COCN][\text{pyridine}] + C_2H_5COCl \xrightarrow[\text{fast}]{} CH_2{=}C(CN)OCOC_2H_5 + \text{pyridine}\cdot HCl \quad (3)$$

Equation 1 means a rapidly established equilibrium prior to the condensation reaction. In Eq. 2 an intermediate (or a transition state) **21** consisting of the cyanide and pyridine is formed, whose structure will be discussed in the following section.

According to this mechanism, the initial rate of reaction R_0 is calculated and expressed by

$$R_0 = \frac{k}{2K}A_0[-\{1+K(E_0-P_0)\}+\sqrt{\{1+K(E_0-P_0)\}^2+4KP_0}] \quad (4)$$

where E_0, P_0, A_0 are the initial concentration of the chloride, pyridine, and cyanide respectively. By substituting the observed values of Runs 1 and 4 in Table 3 for Eq. 4, $k = 3.06\times10^{-2}$ L/mol·s and $K = 0.10$ were obtained. With these two constants we calculated the initial rates R_0(calcd) which agreed well with the observed R_0(obsd), thus the reaction channel proposed above seems to be compatible with the experimental results.

Base Catalysis. In this reaction it must be noticed that the rate of reaction depends markedly upon the choice of amine catalysts. To find a general

Table 3. Effect of the molar ratios of reactants on the initial rates of reaction R_0

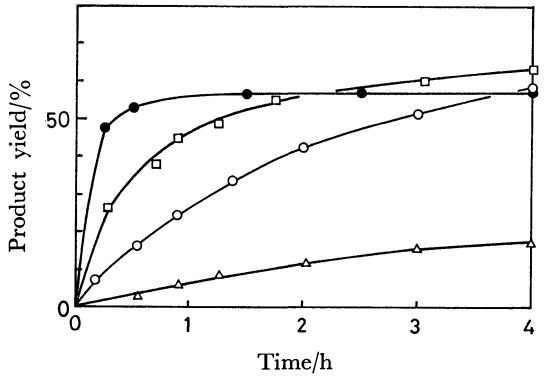

Fig. 2. The effect of tertiary amines on the rates of formation of 1-cyanovinyl propionate in benzene.[a]
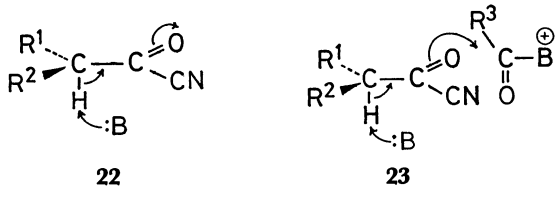
2-Picoline (△), pyridine (○), 2,6-lutidine (□), 1,4-diazabicyclo[2.2.2]octane (●).
a) Reactant ratio: cyanide/chloride/amine=1/1/1, 0.02 mol/18 mL for each reagent, at 25±0.5 °C. Product yields were determined by VPC using the method of calibration curves.

rule in this catalysis along the line of solving the reaction mechanism, the influence of five tertiary amines, *i.e.*, 1,4-diazabicyclo[2.2.2]octane (Dabco), 4-(dimethylamino)pyridine, 2,6-lutidine, 2-picoline, and pyridine, upon the reaction rate were examined by means of direct measurements by NMR and also by VPC analysis using the internal reference technique. The tendencies of the base catalysis obtained in triplicate experiments were reproducible and the same in both methods. Results are shown in Fig. 2. Amines with strong basicity (and possibly with strong nucleophilicity), *e.g.*, Dabco (pK_a 8.7) and 4-(dimethylamino)-pyridine (pK_a 9.71),[6] showed the greatest rate-enhancement whereas the product yields were relatively low, probably due to some side reactions such as polymerization of the ester. In contrast, the best yield was attained when pyridine, a weaker base than the others, was adopted.

Looking at Figure 3, one notices that the effect of methyl-substituted pyridines on the rate acceleration is in the order of 2,6-lutidine (pK_a 6.75)>pyridine (5.27)>2-picoline (5.97),[6] which is not in laccord with the order of basicity nor nucleophilic power. Therefore, the rate is not solely dependent on either character of amines but seems to be controlled by both of them.

As a rational structure of the transition state which is compatible not only with the behavior of bases but also with the rate Eq. 4, a base-catalysis model **22** is postulated where the proton-abstraction composes the rate-determining step. According to Eq. 1 the concentration of free amine must depend upon its nucleophilic power which, in the reaction of methyl-substituted pyridines toward acyl chloride, seems to be in the order of 2-picoline (steric factor is conformationally negligible with regard to its pyridinium structure) > pyridine > 2,6-lutidine. Therefore, the equilibrium constant K must be small for 2,6-lutidine, and large enough for 2-picoline to cancell out its higher basicity than pyridine's. As for strong bases above p$K_a\approx8$, the nucleophilicity may not change so much as the pK_a does that the basicity plays an important role in the transition state.



Scheme 1.

As an alternative transition state, a push-pull model **23** seems to be proposable where the ionic character of the N–CO bond in pyridinium ion plays a part of the rate acceleration. In this, 2,6-lutidine acts as a strong base and simultaneously as a weak nucleophile that enhances the ionization of the N–CO bond, whereas 2-picoline acts in the opposite way. The nucleophilicity of pyridine, though being a weaker base than picoline, may lie in between the other two amines as explained above. Although, at a glance, the rate seems to be dependent on the concentration of the chloride in this sort of general acid-base catalysis, the possibility of rate acceleration by the increase in acyl chloride must be cancelled out by the decrease in free amine concentration at the other reacting terminus. Therefore, the rate may become almost insensitive to the change in the chloride concentration.

Experimental

General. NMR chemical shifts and coupling constants are expressed by δ and Hz unit respectively. Acyl cyanides (acetyl, propionyl, isobutyryl, and diphenylacetyl cyanide) were prepared according to the reported method.[1] Other reagents were commercially available.

Reaction of Acyl Cyanide with Acyl Chloride; A General Synthetic Procedure. Under ice-cooling, tertiary amine (0.04 mol) dissolved in 10 mL of a solvent was added to a mixture of an acyl cyanide (0.04 mol) and an acyl chloride (0.04 mol)

both dissolved in 10 mL of the same solvent. Immediate formation of the pyridinium salt was observed. After stirring the mixture at ambient temperature for several hours, the solution was filtered, the filtrate was washed with water three times and dried over anhyd $MgSO_4$. Fractional distillation of the solution gave the expected 1-cyano-1-alkenyl ester. The product yields and amines used are listed in Table 1. In the following paragraphs, the spectroscopic data of some 1-cyano-1-alkenyl esters are listed. For the other esters, see the preceding report.[1]

*1-Cyanovinyl Chloroacetate (**2**)*: Bp 70—75 °C/4 Torr. IR 2240, 1780 cm^{-1}. NMR ($CDCl_3$) 5.93 (2H, a pair of d, J=3.2), 4.27 (2H, s).

*1-Cyanovinyl Ethyl Carbonate (**4**)*: Bp 46—50 °C/3 Torr. IR 2230, 1765 cm^{-1}. NMR ($CDCl_3$) 5.70 (2H, a pair of d, J=3.0), 4.25 (2H, q, J=7.3), 1.40 (3H, t, J=7.3).

*1-Cyanovinyl p-Nitrobenzoate (**6**)*: Mp 132—135 °C. IR 1760 cm^{-1}. NMR ($CDCl_3$) 8.47 (4H, m), 6.03 (2H, a pair of d, J=3.5).

*1-Cyanovinyl Benzoate (**5**)*: Mp 35.5—38 °C. Bp 88—95 °C/0.4 Torr. IR 2220, 1740 cm^{-1}. NMR ($CDCl_3$) 8.2—7.3 (5H, m), 5.87 (2H, a pair of d, J=2.5).

*1-Cyano-1-propenyl Chloroacetate (**10**)*: Bp 75—84 °C/3 Torr. IR 2220, 1780 cm^{-1}. NMR ($CDCl_3$) *Z*-isomer 6.30 (1H, q, J=7.3), 4.27 (2H, s), 1.80 (3H, d, J=7.3); *E*-isomer 6.35 (1H, q, J=7.4), 4.23 (2H, s), 2.00 (3H, d, J=7.4). Z/E=5.

*1-Cyano-1-propenyl Ethyl Carbonate (**11**)*: Bp 67—69 °C/5 Torr. NMR ($CDCl_3$) *Z*-isomer 6.20 (1H, q, J=7.1), 4.35 (2H, q, J=7.0), 1.85 (3H, d, J=7.1), 1.40 (3H, t, J=7.0); *E*-isomer 6.85 (1H, q, J=7.1), 4.32 (2H, q, J=7.0), 1.97 (3H, d, J=7.1), 1.37 (3H, t, J=7.0). Z E=7.0.

*1-Cyano-1-propenyl p-Nitrobenzoate (**12**)*: Mp 153—154 °C (*Z*-isomer). IR 2220, 1780 cm^{-1}. NMR ($CDCl_3$) *Z*-isomer 8.35 (4H, s), 6.38 (1H, q, J=7.3), 1.87 (3H, d, J=7.3); *E*-isomer 8.32 (4H, s), 6.47 (1H, q, J=7.3), 2.09 (3H, d, J=7.3). Z/E=6.7.

*1-Cyano-1-propenyl Dimethylcarbamate (**13**)*: Bp 75—78 °C/0.6 Torr. IR 2230, 1725 cm^{-1}. NMR (CCl_4) *Z*-isomer 1.77 (3H, d, J=7.1), 3.01 (6H, bs), 6.08 (1H, q, J=7.1); *E*-isomer 1.99 (3H, d, J=7.4), 2.98 (6H, bs), 6.11 (1H, q, J=7.4). Z/E=2.4. 1,1-Dicyanopropyl dimethylcarbamate was also formed (8%), NMR (CCl_4) 1.30 (3H, t, J=7.2), 2.35 (2H, q, J=7.2), 3.00 (6H, bs), MS (*m/e*) 181 (M^+).

*1-Cyano-1-propenyl Diphenylcarbamate (**14**)*: Mp 213—216 °C. IR 2220, 1720 cm^{-1}. NMR (CCl_4) *Z*-isomer 7.25 (10H, s), 5.92 (1H, q, J=7.1), 1.60 (3H, d, J=7.1); *E*-isomer 7.25 (10H, s), 6.04 (1H, q, J=7.1), 1.80 (3H, d, J=7.1). Z/E=2.8.

*1-Cyano-2-methyl-1-propenyl Dimethylcarbamate (**17**)*: IR 2220, 1720 cm^{-1}. NMR ($CDCl_3$) 1.83 (3H, s), 2.05 (3H, s), 3.01 (6H, bs).

*1-Cyano-2-methyl-1-propenyl Diphenylcarbamate (**18**)*: Mp 110—112 °C. IR 2230, 1730 cm^{-1}. NMR ($CDCl_3$) 7.27 (10H, s), 1.98 (3H, s), 1.73 (3H, s).

*1-Cyano-2,2-diphenylvinyl Diphenylacetate (**19**)*: Mp 126—126.5 °C. IR 2220, 1773 cm^{-1}. NMR ($CDCl_3$) 5.03 (1H, s), 7.1—7.4 (10H, m). Found: C, 84.03; H, 4.79; N, 3.17%. Calcd for $C_{29}H_{21}NO_2$: C, 83.83; H, 5.09; N, 3.37%.

Examination of Solvents. To a mixture of purified acetyl cyanide and propionyl chloride (0.02 mol each) in 10 mL of purified solvent (acetonitrile, THF, CH_2Cl_2, or benzene) was added the solution of pyridine (0.02 mol) dissolved in the same solvent (8 mL), and successively isobutyl isobutyrate (0.02 mol, as the internal standard for VPC analysis). The reaction mixture was kept at 25 or 0 °C and an aliquot of the mixture was sucked up by a syringe at specified time intervals and analyzed by VPC.

Kinetics. Reagents: Methyl benzoate (as the internal standard) and acetyl cyanide were dried over anhyd $CaSO_4$ and distilled. Propionyl chloride was purified according to Paul's method.[7] Pyridine was purified by the reported method.[8] Each of the reagents thus purified was divided into several 0.5 mL portions which were stored in ampule tubes. In each experimental run, reagents from new ampules were used.

Procedure: Into a NMR tube which was preliminarily flushed by dry N_2 and sealed with a septum cap, the specified amounts of benzene-d_6, methyl benzoate, acetyl cyanide, and propionyl chloride were injected and mixed. Then pyridine was added, the solution was vigorously mixed for a few seconds at 25 °C, the tube was inserted into the NMR cavity whose temperature was controlled at 35 °C. The rates of formation of 1-cyanovinyl propionate (**3**) were measured at specified time intervals by integrating the relative intensity of the methylene protons to the internal standard. The number of data collections per reaction was more than eight in all cases.

Data Analysis: Molar change of **3** *vs.* reaction time was plotted and from this curve the fractions of yield per minute ($\Delta Y/\Delta t$) for the first 6 min were measured. These fractions were extrapolated to t=0 to obtain Δ[product]/Δt=R_0, the initial rate of reaction. These R_0(obsd) values are listed in Table 3.

Derivation of R_0*(calcd)*: Based on the reaction Eqs. 1, 2, and 3, the initial rate of reaction R_0(calcd) was derived as follows. Abbreviations: E, P, A are the concentrations of propionyl chloride, pyridine, and acetyl cyanide respectively, E_0, P_0, A_0 are the corresponding initial concentrations.

$$R_0 = \frac{\mathrm{d[product]}}{\mathrm{d}t} = kAP \tag{5}$$

Since the equilibrium (Eq. 1) is established at the initial stage of the reaction and the concentrations of **21**, **3**, and pyridine·HCl are negligible, P_0, E_0, and A_0 are expressed by

$$E_0 = E + KPE,\ P_0 = P + KPE,\ A_0 = A \tag{6}$$

From Eq. 6, P is expressed by the following equation

$$P = \frac{1}{2K}[-\{1+K(E_0-P_0)\}+ \sqrt{\{1+K(E_0-P_0)\}^2+4KP_0}] \tag{7}$$

Substituting Eqs. 6 and 7 for Eq. 5, R_0 is obtained as expressed by Eq. 4.

Examination of the Effect of Amines. Reagents: Three amines (2,6-lutidine, 2-picoline, pyridine) were purified by the reported method.[8] Purified *o*-dichlorobenzene was used as the internal standard in VPC analysis. For the other reagents, see the preceding paragraph.

Procedure: In a 50 mL flask equipped with a septum cap, a 0.02 mol each of acetyl cyanide, propionyl chloride, and *o*-dichlorobenzene were mixed in 10 mL of dry benzene under dry N_2 atmosphere. The flask was held in a bath controlled at 20±0.5 °C, and then the solution of a tertiary amine (0.02 mol in 8 mL of benzene) was added to the mixture at one time. An aliquot of the solution was then periodically analyzed by VPC by means of calibration curves independently prepared from authentic compounds.

The authors are indebted to Dr. Masaaki Teramoto of Kyoto Institute of Technology for his helpful discussion on the results of kinetics.

Syntheses of Alkylphosphonic Esters by the Reactions of Aliphatic Thiones with Trialkyl Phosphites

Tokuzo KAWASE, Shigeo YONEDA, and Zen-ichi YOSHIDA*

Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received February 5, 1979)

Aliphatic thiones were found to react with trialkyl phosphites to give (alkylthio)- and/or mercapto-alkylphosphonic esters. The reaction is interpreted in terms of the carbophilic attack with trialkyl phosphites at the carbon atom of the thiocarbonyl group, and the subsequent migration mechanism *via* the betaine intermediate.

Reactions of thiocarbonyl compounds with nucleophiles are different from those of carbonyl compounds.[1] For example, though Grignard reagents normally attack at the carbon atom of a carbonyl group (carbophilic attack), they may attack at the sulfur atom of a thiocarbonyl group (thiophilic attack) rather than at the carbon atom.[2] The reactions of thiocarbonyl compounds with phosphites have been the focus of interest in the past several years, because phosphites have both "carbophilicity" and "thiophilicity"[3] toward organosulfur compounds. When trivalent phosphorus compounds such as phosphines and phosphites are employed as nucleophiles, they have generally been regarded as thiophiles, not as carbophiles, in the previously reported works.[4] However, in our preceding papers,[5] it was elucidated that cycloalkanethiones react with trialkyl phosphites at the carbon atom of the thiocarbonyl group to give phosphonic esters.

In this work, we have carried out the reactions of aliphatic thiones with trialkyl phosphites and succeeded in the syntheses of sulfur-containing phosphonic esters. This reaction is also explained by the initial carbophilic attack of phosphites at the thiocarbonyl carbon atom to form the betaine intermediate.

Results and Discussion

The syntheses of 1-(alkylthio)- and 1-mercaptocycloalkylphosphonic esters by the reactions of cycloalkanethiones with trialkyl phosphites were reported in our previous papers.[5] Similar reactions of aliphatic thioketones with trialkyl phosphites successfully yielded new sulfur containing alkylphosphonates.

In our preceding papers,[5] cycloalkanedithiols were utilized as precursors of cycloalkanethiones because of the instability of the latter. Cycloalkanethiones were easily generated from the corresponding dithiols at elevated temperatures. Similarly, the *gem*-dithiols[6] (**1**—**4**), as precursors of thioacetone, methyl ethyl thioketone, diethyl thioketone, and methyl isopropyl thioketone, were also employed in this study.

When a solution of propane-2,2-dithiol (**1**) and 4 equiv of trimethyl phosphite in toluene was heated under refluxing, hydrogen sulfide evolved vigorously and the reaction mixture became pink. The evolution of hydrogen sulfide and the pink coloration indicate the formation of thioacetone. After the complete decoloration, distillation gave a mixture of *O*,*O*-dimethyl 1-methyl-1-(methylthio)ethylphosphonate (**5a**) and *O*,*O*-dimethyl 1-mercapto-1-methylethylphosphonate (**6a**), which were separated by gas chromatography. The structures were determined by the elemental analyses and spectral data.

The reaction of **1** with triethyl phosphite also gave a mixture of *O*,*O*-diethyl 1-(ethylthio)-1-methylethylphosphonate (**5b**) and *O*,*O*-diethyl 1-mercapto-1-methylethylphosphonate (**6b**). The reaction of **1** with triisopropyl phosphite gave only *O*,*O*-diisopropyl 1-mercapto-1-methylethylphosphonate (**6c**), but no esters

a) Hexamethyltrithiane was obtained in 30—40% yields.

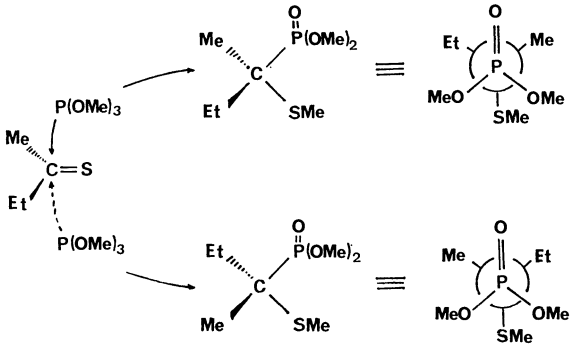

Fig. 1. Projection formulas of **7a** with respect to the C–P bond (staggered conformers).

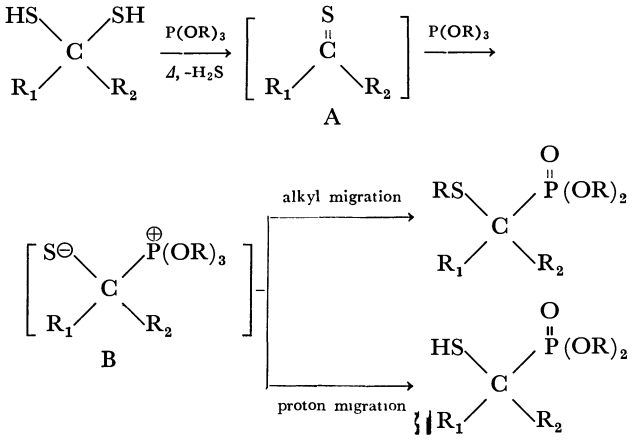
having an alkylthio group were obtained.

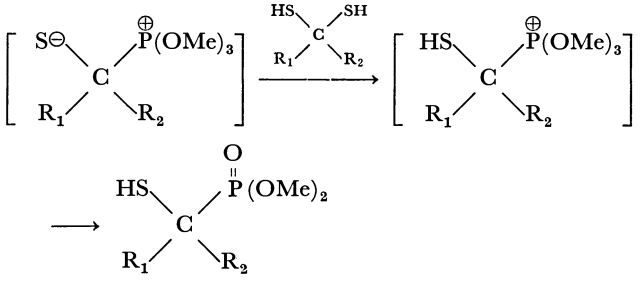
In these reactions, a side reaction (trimerization) also occurred to afford hexamethyltrithiane in 30—40% yield.

The reactions of butane-2,2-dithiol (**2**) with trialkyl phosphites were carried out under similar conditions. The reaction with trimethyl phosphite gave a mixture of *O,O*-dimethyl 1-methyl-1-(methylthio)propylphosphonate (**7a**) and *O,O*-dimethyl 1-mercapto-1-methylpropylphosphonate (**8a**). In the NMR spectrum of **7a**, the protons of the methyl group attached to the oxygen atom appeared as two doublets at δ 3.73 and 3.79 in the ratio 1 : 1 with $J_{P-H}=10.0$ Hz. As seen in Fig. 1, in the staggered conformer of the projection formulas of **7a** with respect to the C–P bond, the two methyl groups attached to the oxygen atoms are situated in different environments, which accounts for the appearance of two doublets in the NMR spectrum. In addition, the attacks of trimethyl phosphite at the thiocarbonyl group of methyl ethyl thioketone from the different sides of the molecular plane should also yield two isomers possessing different configurations (*R*- and *S*-) in the ratio 1 : 1. Such an indication could be obtained with the aid of chiral shift reagent [europium(III)-tris(3-trifluoroacetyl-1*R*-campherate)], that is, the methyl protons attached to the oxygen atom appeared as two kinds of two doublets.[7]

The reactions of pentane-3,3-dithiol (**3**) and 2-methylbutane-3,3-dithiol (**4**) with trialkyl phosphites



Scheme 2.



Scheme 3.

were carried out under similar conditions.[8] The results are summarized in Scheme 1 and Table 1.

The mechanistic interpretation of the reactions of aliphatic thioketones with trialkyl phosphites is outlined in Scheme 2. The reaction is initiated by the removal of hydrogen sulfide from *gem*-dithiols to form the corresponding thioketones (A). The resulting thioketones might immediately react with excess trialkyl phosphites. The phosphites should attack at the carbon atom of thiocarbonyl group and from the betaine intermediate (B). From the intermediate B the migration of an alkyl group or proton would afford the phosphonic esters containing a sulfur atom in alkylthio and/or mercapto groups. When the phosphites are trimethyl and/or triethyl phosphites, the negatively charged sulfur

atom would intramolecularly attack the alkyl group attached to the oxygen atom; this would result in the formation of alkylthio phosphonic esters. When triisopropyl phosphite was used, this nucleophilic attack should be hindered, and so the proton migration would occur to afford the mercapto phosphonic esters.

However, even when the trimethyl phosphite was used, the mercapto phosphonic esters were obtained in fair yields; their formation can be explained by Scheme 3.

Experimental

The infrared spectra were recorded on a Hitachi EPI-G3 grating infrared spectrophotometer; the ^1H NMR spectra were recorded on a Varian Associates AH-100 spectrometer with TMS as an internal standard. Mass spectra were taken on a Hitachi RMU-6C mass spectrometer. Gas-liquid chromatography was carried out with a Shimadzu gas chromatograph Model GC-6A, using a stainless steel column packed with 20% silicon DC-550 on Celite 545, and the preparative VPC was carried out with a Varian Aerograph Model 920 using 20% Silicon DC-550. Elemental analyses were carried out at the Elemental Analytical Center of Kyoto University.

Materials. Propane-2,2-dithiol (**1**), butane-2,2-dithiol (**2**), pentane-3,3-dithiol (**3**), and 2-methylbutane-3,3-dithiol (**4**) were prepared from the ketimines and hydrogen sulfide according to the literature procedure by Magnusson,[6] and distilled under reduced pressure at temperatures below 70 °C. Trimethyl and triethyl phosphites were commercial matrials and were used after distillation. Triisopropyl phosphite was prepared utilizing the procedure of Ford-Moore.[9]

*General Procedure for the Reactions of Alkanedithiols (**1**—**4**) with Trialkyl Phosphites.* A mixture of 0.01 mol of alkanedithiol (**1**—**4**) and 0.04 mol of trialkyl phosphite in 30 ml of toluene was heated at reflux temperature under nitrogen for 20—30 h. When the temperature of the mixture exceeded 80 °C, gas evolution and pink coloration were observed. After removal of toluene and excess phosphite, the residue was distilled under reduced pressure to give a colorless viscous liquid. In the reactions with trimethyl and triethyl phosphites, the distillates were mixtures of the (alkylthio)- and mercapto-alkylphosphonates. They were separated by gas chromatography to determine the yields.

The boiling points, IR, ^1H NMR, and mass spectral data, and the results of elemental analyses are as follows.

O,O-*Dimethyl 1-Methyl-1-(methylthio)ethylphosphonate (**5a**)*: Bp 78—80 °C (14 Torr) as a mixture of **5a** and **6a**; 23% yield; IR (Neat) 1255 (P=O), 1180, 1060, 1030, 830, and 800 cm^{-1}. NMR (CCl_4) δ=1.49 (d, 6H, J_{P-H}=15.5 Hz, CH_3), 2.28 (s, 3H, SCH_3) and 3.80 (d, 6H, J_{P-H}=10.0 Hz, $POCH_3$); MS *m/e* 198 (M^+). Found: C, 36.53; H, 7.86; P, 15.66%. Calcd for $C_6H_{15}O_3PS$: C, 36.36; H, 7.63; P, 15.63%.

O,O-*Dimethyl 1-Mercapto-1-methylethylphosphonate (**6a**)*: 23% yield; IR (Neat) 2500 (SH), 1250 (P=O), 1180, 1060, 1025, 830, and 790 cm^{-1}. NMR (CCl_4) δ=1.59 (d, 6H, J_{P-H}=15.5 Hz, CH_3), 2.16 (d, 1H, J_{P-H}=4 Hz, SH) and 3.78 (d, 6H, J_{P-H}=10.0 Hz, $POCH_3$); MS *m/e* 184 (M^+). Found: C, 32.43; H, 7.07; P, 16.85%. Calcd for $C_5H_{13}O_3PS$: C, 32.60; H, 7.11; P, 16.82%.

O,O-*Diethyl 1-(Ethylthio)-1-methylethylphosphonate (**5b**)*: Bp 82—83 °C (9 Torr) as a mixture of **5b** and **6b**; 25% yield; IR (Neat) 1250 (P=O), 1060, 1030, and 963 cm^{-1}. NMR (CCl_4) δ=1.13 (t, 3H, J=7.5 Hz, $SCH_2C\underline{H}_3$), 1.25 (t, 6H, J_{H-H}=7.0 Hz, $POCH_2C\underline{H}_3$), 1.30 (d, 6H, J_{P-H}=15 Hz, CH_3), 2.78 (q, 2H, J=7.5 Hz, $SC\underline{H}_2CH_3$), and 4.03 (dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=8.0 Hz, $POC\underline{H}_2CH_3$); MS *m/e* 240 (M^+). Found: C, 44.65; H, 9.08; P, 12.69%. Calcd for $C_9H_{21}O_3PS$: C, 44.98; H, 8.81; P, 12.89%.

O,O-*Diethyl 1-Mercapto-1-methylethylphosphonate (**6b**)*: 17% yield; IR (Neat) 2503 (SH), 1245 (P=O), 1050, 1023, and 955 cm^{-1}. NMR (CCl_4) δ=1.26 (t, 6H, J_{H-H}=7.0 Hz, $POCH_2C\underline{H}_3$), 1.40 (d, 6H, J_{P-H}=15 Hz, CH_3), 2.16 (d, 1H, J_{P-H}=4 Hz, SH), and 4.05 (dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=8.5 Hz, $POC\underline{H}_2CH_3$); MS *m/e* 212 (M^+). Found: C, 39.67; H, 8.11; P, 14.41%. Calcd for $C_7H_{17}O_3PS$: C, 39.61; H, 8.07; P, 14.59%.

O,O-*Diisopropyl 1-Mercapto-1-methylethylphosphonate (**6c**)*: Bp 92—93 °C (11 Torr); 62% yield; IR (Neat) 2500 (SH), 1250 (P=O), 1005, and 985 cm^{-1}. NMR (CCl_4) δ=1.33 [d, 12H, J_{H-H}=6.5 Hz, $POCH(C\underline{H}_3)_2$], 1.45 (d, 6H, J_{P-H}=15 Hz, CH_3), 2.24 (d, 1H, J_{P-H}=4 Hz, SH), and 4.64 [dsep, 2H, J_{H-H}=6.5 Hz, J_{P-H}=8.5 Hz, $POC\underline{H}(CH_3)_2$]; MS *m/e* 240 (M^+). Found: C, 44.65; H, 9.13; P, 12.51%. Calcd for $C_9H_{21}O_3PS$: C, 44.98; H, 8.81; P, 12.89%.

O,O-*Dimethyl 1-Methyl-1-(methylthio)propylphosphonate (**7a**)*: Bp 98—99 °C (13 Torr) as a mixture of **7a** and **8a**; 35% yield; IR (Neat) 1249 (P=O), 1185, 1060, 1031, 823, and 780 cm^{-1}. NMR (CCl_4) δ=0.97 (t, 3H, J=7.1 Hz, $CH_2C\underline{H}_3$), 1.27 (d, 3H, J_{P-H}=15.5 Hz, CH_3), 1.58—1.97 (m, 2H, $C\underline{H}_2CH_3$), 2.19 (s, 3H, SCH_3), and 3.73 and 3.79 (two d, 6H, J_{P-H}=10.0 Hz, $POCH_3$); MS *m/e* 212 (M^+). Found: C, 39.58; H, 8.14; P, 14.49%. Calcd for $C_7H_{17}O_3PS$: C, 39.61; H, 8.07; P, 14.59%.

O,O-*Dimethyl 1-Mercapto-1-methylpropylphosphonate (**8a**)*: 18% yield; IR (Neat) 2520 (SH), 1252 (P=O), 1186, 1060, 1034, 830, and 782 cm^{-1}. NMR (CCl_4) δ=1.04 (t, 3H, J=7.5 Hz, $CH_2C\underline{H}_3$), 1.40 (d, 3H, J_{P-H}=15.0 Hz, CH_3), 1.61—2.01 (m, 2H, $C\underline{H}_2CH_3$), 2.07 (d, 1H, J_{P-H}=5 Hz, SH), and 3.76 and 3.80 (two d, 6H, J_{P-H}=10.5 Hz, $POCH_3$); MS *m/e* 198 (M^+). Found: C, 36.52; H, 7.42; P, 15.28%. Calcd for $C_6H_{15}O_3PS$: C, 36.36; H, 7.63; P, 15.63%.

O,O-*Diethyl 1-(Ethylthio)-1-methylpropylphosphonate (**7b**)*: Bp 98—103 °C (5.5 Torr) as a mixture of **7b** and **8b**; 17% yield; IR (Neat) 1245 (P=O), 1058, 1030, and 960 cm^{-1}. NMR (CCl_4) δ=0.98 (t, 3H, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.20 (t, 3H, J=7.5 Hz, $SCH_2C\underline{H}_3$), 1.28 (d, 3H, J_{P-H}=15 Hz, CH_3), 1.32 and 1.33 (two t, 6H, J_{H-H}=7.0 Hz, $POCH_2C\underline{H}_3$), 1.61—1.97 (m, 2H, $C\underline{H}_2CH_3$), 2.73 and 2.83 (two q, 2H, J=7.5 Hz, $SC\underline{H}_2CH_3$), and 4.08 and 4.13 (two dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=8.0 Hz, $POC\underline{H}_2CH_3$); MS *m/e* 254 (M^+). Found: C, 47.10; H, 9.23; P, 12.25%. Calcd for $C_{10}H_{23}O_3PS$: C, 47.23; H, 9.12; P, 12.18%.

O,O-*Diethyl 1-Mercapto-1-methylpropylphosphonate (**8b**)*: 24% yield; IR (Neat) 2510 (SH), 1250 (P=O), 1055, 1030, and 963 cm^{-1}. NMR (CCl_4) δ=1.06 (t, 3H, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.34 (t, 6H, J_{H-H}=7.0 Hz, $POCH_2C\underline{H}_3$), 1.40 (d, 3H, J_{P-H}=15.5 Hz, CH_3), 1.60—1.93 (m, 2H, $C\underline{H}_2CH_3$), 2.04 (d, 1H, J_{P-H}=6 Hz, SH), 4.12 and 4.15 (two dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=8.0 Hz, $POC\underline{H}_2CH_3$); MS *m/e* 226 (M^+). Found: C, 42.62; H, 8.64; P, 13.47%. Calcd for $C_8H_{19}O_3PS$: C, 42.46; H, 8.46; P, 13.69%.

O,O-*Diisopropyl 1-Mercapto-1-methylpropylphosphonate (**8c**)*: Bp 100—101 °C (6.7 Torr); 76% yield; IR (Neat) 2505 (SH), 1246 (P=O), 1108, 1005, and 980 cm^{-1}. NMR (CCl_4) δ=1.04 (t, 3H, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.32 [d, 12H, J_{H-H}=6 Hz, $POCH(C\underline{H}_3)_2$], 1.40 (d, 3H, J_{P-H}=13.0 Hz, CH_3), 1.54—1.97 (m, 2H, $C\underline{H}_2CH_3$), 2.07 (d, 1H, J_{P-H}=6 Hz, SH), and 4.35—4.96 [m, 2H, $POCH(CH_3)_2$]; MS *m/e* 254 (M^+). Found: C, 47.31; H, 9.36; P, 11.92%. Calcd for $C_{10}H_{23}O_3PS$: C, 47.23; H, 9.12; P, 12.18%.

O,O-*Dimethyl 1-Ethyl-1-(methylthio)propylphosphonate (**9a**)*;

Bp 111—112 °C (6.5 Torr) as a mixture of **9a** and **10a**; 43% yield; IR (Neat) 1246 (P=O), 1182, 1060, 1031, 824, and 770 cm^{-1}. NMR (CCl_4) δ=0.95 (t, 6H, J=7.1 Hz, $CH_2C\underline{H}_3$), 1.54—1.97 (m, 4H, $C\underline{H}_2CH_3$), 2.18 (s, 3H, SCH_3), and 3.76 (d, 6H, J_{P-H}=10.2 Hz, $POCH_3$); MS *m/e* 226 (M^+). Found: C, 42.37; H, 8.62; P, 13.90%. Calcd for $C_8H_{19}O_3PS$: C, 42.46; H, 8.46; P, 13.69%.

O,O-*Dimethyl 1-Ethyl-1-mercaptopropylphosphonate (**10a**)*: 11% yield; IR (Neat) 2500 (SH), 1245 (P=O), 1060, 1030, 820, and 770 cm^{-1}. NMR (CCl_4) δ=1.00 (t, 6H, J=6.5 Hz, $CH_2C\underline{H}_3$), 1.73 and 1.87 (dq, 4H, J_{H-H}=6.5 Hz, J_{P-H}=13.5 Hz, $C\underline{H}_2CH_3$), 2.03 (d, 1H, J_{P-H}=6 Hz, SH), and 3.77 (d, 6H, J_{P-H}=10.1 Hz, $POCH_3$); MS *m/e* 212 (M^+). Found: C, 39.51; H, 8.00; P, 14.79%. Calcd for $C_7H_{17}O_3PS$: C, 39.61; H, 8.07; P, 14.59%.

O,O-*Diethyl 1-Ethyl-1-(ethylthio)propylphosphonate (**9b**)*: Bp 123—124 °C (6.7 Torr) as a mixture of **9b** and **10b**; 24% yield; IR (Neat) 1250 (P=O), 1060, 1032, and 960 cm^{-1}. NMR (CCl_4) δ 0.98 (t, 6H, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.21 (t, 3H, J=7.5 Hz, $SCH_2C\underline{H}_3$), 1.33 (t, 6H, J_{H-H}=7.0 Hz, $POCH_2C\underline{H}_3$), 1.73 and 1.88 (dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=14 Hz, $C\underline{H}_2CH_3$), 2.78 (q, 2H, J=7.0 Hz, $SC\underline{H}_2CH_3$), 4.05 (dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=8.1 Hz, $POC\underline{H}_2CH_3$); MS *m/e* 268 (M^+). Found: C, 46.24; H, 8.97; P, 10.71%. Calcd for $C_{11}H_{25}O_3PS$: C, 46.16; H, 8.80; P, 10.82%.

O,O-*Diethyl 1-Ethyl-1-mercaptopropylphosphonate (**10b**)*: 29% yield; IR (Neat) 2500 (SH), 1245 (P=O), 1060, 1025, and 965 cm^{-1}. NMR (CCl_4) δ=1.01 (t, 6H, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.32 (t, 6H, J_{H-H}=7.0 Hz, $POCH_2C\underline{H}_3$), 1.74 and 1.87 (dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=13.5 Hz, $C\underline{H}_2CH_3$), 2.10 (d, 1H, J_{P-H}=5.5 Hz, SH), and 4.03 (dq, 4H, J_{H-H}=7.0 Hz, J_{P-H}=8.0 Hz, $POC\underline{H}_2CH_3$); MS *m/e* 240 (M^+). Found: C, 45.11; H, 8.90; P, 12.67%. Calcd for $C_9H_{21}O_3PS$: C, 44.98; H, 8.81; P, 12.89%.

O,O-*Diisopropyl 1-Ethyl-1-mercaptopropylphosphonate (**10c**)*: Bp 120—121 °C (5.5 Torr); 80% yield; IR (Neat) 2502 (SH), 1243 (P=O), 1108, 1004, and 980 cm^{-1}. NMR (CCl_4) δ=1.00 (t, 6H, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.32 [d, 12H, J_{H-H}=6.1 Hz, $POCH(C\underline{H}_3)_2$], 1.71 and 1.84 (dq, 4H, J_{H-H}=7 Hz, J_{P-H}=13.4 Hz, $C\underline{H}_2CH_3$), 2.05 (d, 1H, J_{P-H}=6 Hz, SH), and 4.63 [dsep, 2H, J_{H-H}=6.1 Hz, J_{P-H}=7.2 Hz, $POC\underline{H}(CH_3)_2$]; MS *m/e* 268 (M^+). Replacement of Methoxyl Group on the Grignard Reaction of *N*-(*o*-Methoxybenzylidene)aniline

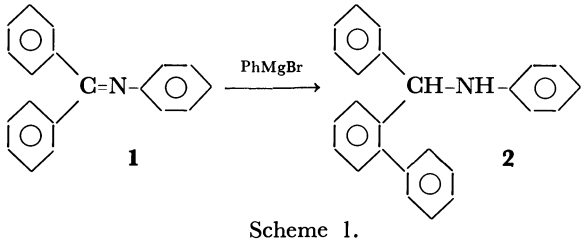
Masao Ōkubo* and Sonoko Ueda

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840

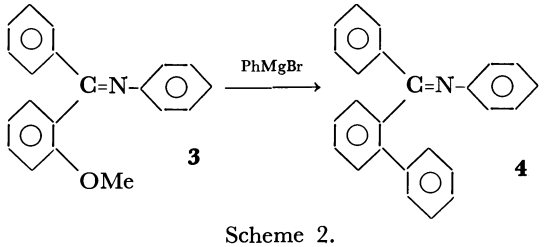
(Received March 17, 1979)

The methoxyl group of the title imine was replaced by the phenyl group on treatment with PhMgBr, the same group of *N*-benzylidene-*o*-anisidine remaining. The result was discussed on the basis of radical chain mechanism involving the initial electron-transfer.

The Grignard reaction of >C=N– compounds has not been extensively studied. Gilman and his co-workers reported that *N*-(diphenylmethylene)aniline (**1**) on the "forced" reaction with phenylmagnesium bromide (PhMgBr) affords the *o*-phenylation product (**2**) as the result of 1,4-addition (Scheme 1).[1] The characteristic deep-red coloration of the reaction mixture seems to indicate the presence of radical species. From the results of recent studies on the Grignard reaction of hindered benzophenones,[2,3] a similar, more facile *o*-phenylation is expected if the substrate has an *o*-methoxyl group. We thus attempted to realize the replacement reaction of Scheme 2.

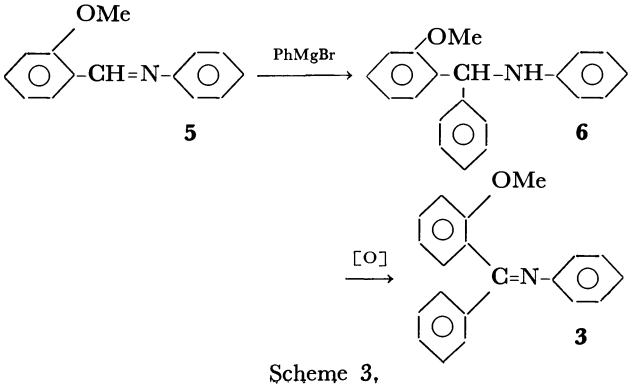


Scheme 1.



Scheme 2.

For the preparation of **3**, however, attempts to condense the benzophenone and aniline by use of some Lewis' acid catalysts ($POCl_3$,[4] $ZnCl_2$,[5] and BF_3[6]) were unsuccessful. In the course of studies on the Grignard reaction of *o*-methoxy-substituted *N*-benzylideneanilines in order to find another preparative route (Scheme 3), an interesting replacement of *o*-methoxyl group was found. The results are reported in this paper.

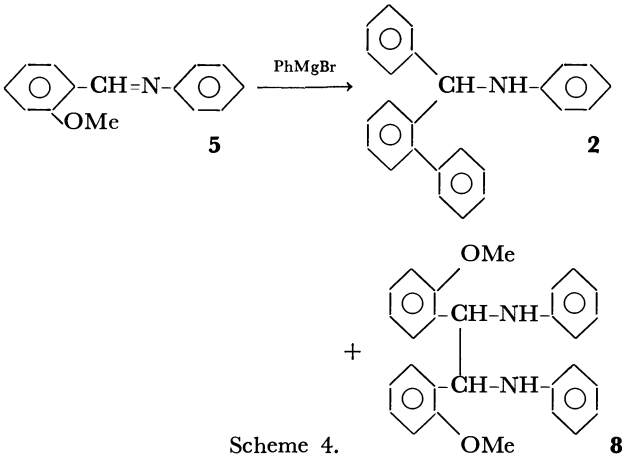


Scheme 3.

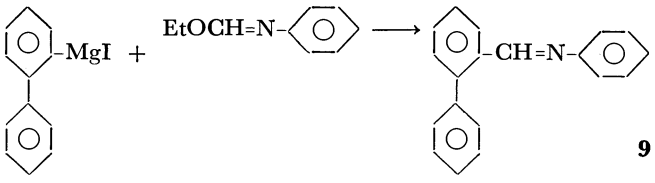
Results and Discussion

Preparation of o-*Methoxy-substituted* N-*Benzylideneanilines.* *N*-(*o*-Methoxybenzylidene)aniline (**5**) and *N*-benzylidene-*o*-anisidine (**7**) were prepared by the condensation of the corresponding benzaldehydes and anilines in methyl alcohol.[7] However, in both cases the colorless crystalline products obtained after recrystallization from the same solvent were found by NMR to be 1:1-molecular complexes, **5** with methyl alcohol and **7** with *o*-anisidine. In order to obtain purified pale-yellow imines, the alcohol combined with **5** should be removed by evacuation at 70 °C for about 1 h and **7** distilled under reduced pressure.

Grignard Reaction. The reaction was carried out in tetrahydrofuran(THF) under N_2. On reaction of **5** with five molar equivalents of PhMgBr at 50—55 °C for 5 h, the products isolated by column chromatography on silica gel (petroleum ether : diethyl ether : benzene=10 : 1 : 1) were the Gilman product **2** (58%) and the dimer **8** (0.5%) (Scheme 4). 25% of **5** recovered. Formation of **2** is obviously the result of the methoxy-replacement accompanied by 1,2-addition. Absence of the simple addition product **6** was confirmed by comparing the thin-layer chromatogram of the product mixture of this reaction with that of the independent reaction:  +  -MgBr→**6** and other products. *N*-(2-Biphenylylmethylene)aniline (**9**), prepared according to Scheme 5,[8] was not detected in the reaction mixture, nor recognized as an intermediate product. Formation of **8** suggests that the radical chain mechanism is involved.



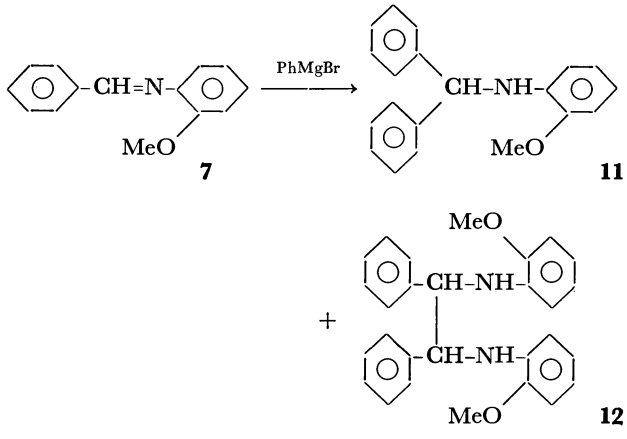
Scheme 4.



9

Scheme 5.

In contrast, the *o*-methoxyl group of **7** was not replaced at all even by treatment with five molar equivalents of PhMgBr at 50—55 °C for 5 h (Scheme 6). A fair yield of the secondary amine **11**[9] (64%) and the dimer **12** (0.8%) were isolated. 28% of **7** recovered. Two isomeric dimers giving the same TLC spot were obtained: **12a**, mp 135—138 °C, NMR ($CDCl_3$), δ=6.24—7.22 (18H, m, aromatic), 5.15 (2H, broad d, NH), 4.9 (2H, d, >CH), and 3.80 (6H, s, OCH_3); **12b**, mp 198—201 °C, NMR ($CDCl_3$), δ= 6.22—7.22 (18H, m, aromatic), 5.15 (2H, broad s, NH), 4.58 (2H, d, >CH), and 3.80 (6H, s, OCH_3). No stereochemical assignment was made. Formation of **12** suggests the intermediate formation of the radical derived from **7** *via* initial electron-transfer.

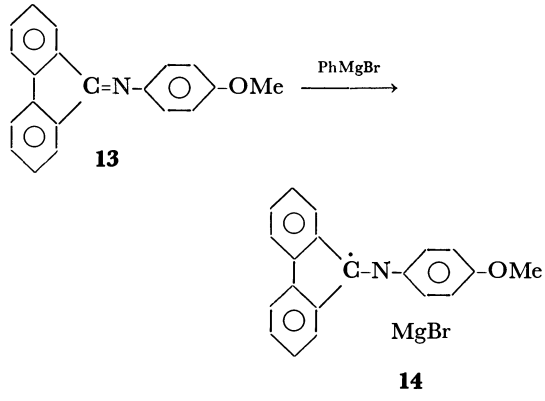


Scheme 6.

The low reactivity of *N*-benzylideneanilines and *N*-(diphenylmethylene)anilines towards PhMgBr should be noted. This is demonstrated by the fact that no heat evolution usually observed in the reaction of >C=O compounds was detectable in all the reactions of >C=N- compounds examined, and about 50% of **7** was recovered after it had been treated with 1.3 molar equivalents of PhMgBr at 50—55 °C for 30 min. Such a low reactivity of >C=N- compounds can be interpreted by their much lower electrophilic character as compared to that of >C=O compounds due to the lower electronegativity of nitrogen atom.

ESR Study. Attempts to detect radical species in the reaction of **5** and **7** were unsuccessful. No ESR signal was detected at lower temperatures (−20 °C and −40 °C) and at higher one (+40 °C) even by the use of concentrated reaction solutions.

However, in the reaction of Scheme 1, an ESR signal gradually became very strong at room temperature accompanied by deep purple coloration; no resolvable hyperfine splitting was observed probably because of the non-planarity of the diphenylmethylene moiety. In the reaction of *N*-fluorenylidene-*p*-anisidine(**13**) with PhMgBr (Scheme 7), a strong ESR signal accompanied by deep green coloration was detected, hyperfine splitting being observed when the reaction mixture was diluted. The well-resolved spectrum consists of 45 lines expected solely from the number of protons of the planar fluorenylidene moiety (**14**, $2p+2o+4m$). The same hyperfine splitting was observed in the reaction of *N*-fluorenylideneaniline.[6]



Scheme 7.

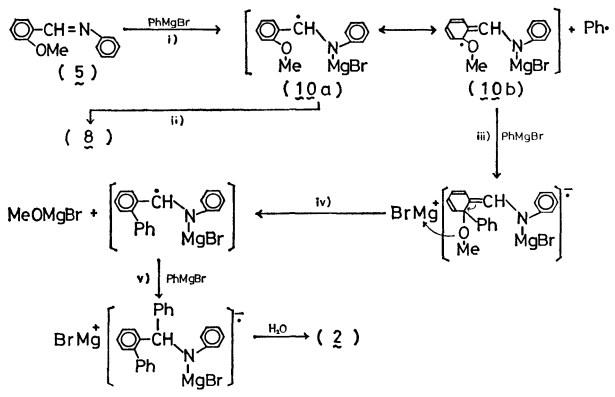
General Discussion. From the observation of strong ESR signals in the reactions of **1** and **13**, the original suggestion that Gilman's reaction of **1** (Scheme 1) proceeds *via* initial electron-transfer was verified.

On the basis of discussion on the steric hindrance effect on the amount of radicals detectable in the Grignard reaction of >C=O compounds,[2] failure to detect radical species in the reactions of **5** and **7** is attributed to their less crowded molecular structures as compared to those of **1** and **13**. The radical formed as the result of initial electron-transfer would accumulate if the subsequent reactions involving the attack of another Grignard molecule are hindered by the crowded molecular structure of substrate such as **1** and **13**. In contrast, the radicals formed from the less crowded **5** and **7** would be rapidly consumed by the subsequent reactions.

The failure to detect ESR signals in the cases of **5** and **7** is also attributable to their low electrophilicity in contrast to that of >C=O compounds. The success to detect ketyl radicals of unhindered benzophenones at lower temperatures[2] is due to their high electrophilicity and to the suppression of the subsequent reactions by the lowered temperature. In cases of much less electrophilic >C=N- compounds, it is reasonable to consider that even the application of low temperature is ineffective since the velocity of electron-transfer is retarded. The higher temperature is ineffective due to the shortened life time of radicals.

Attempts to detect CINDP signal were abandoned since a similar attempt on the reaction of hindered benzophenones failed in spite of very high radical concentrations detected by ESR. The reaction probably proceeds *via* "radical-anion" mechanism of S_{RN}-type[10,11] and not *via* "radical-pair" mechanism.

Scheme 8 could be proposed for explaining the formation of Gilman product **2** in the reaction of Scheme 4. Formation of the dimeric product **8** indi-



Scheme 8.

cates that the initial electron-transfer (step i) and the dimerization (step ii) are involved. The fate of Ph· produced by a step similar to i was discussed.[2] The step subsequent to the initial electron-transfer should be the replacement (steps iii and iv) but not the 1,2-addition. If the latter is the case, the radical chain will terminate leading to the originally expected product **6**. However, this was not the case. The release of the methoxyl anion (step iv) should be easy due to its coordination to $^{+}$MgBr species.[3] The final addition (step v) leads to the formation of the main product **2**.

The result of ESR measurement in the reaction of **13** indicates that the free spin of the radical **14** delocalizes mainly on the fluorenylidene moiety. Thus in the reaction of Scheme 1, the subsequent addition of another PhMgBr to the initially formed radical in the 1,4-manner could be facilitated by the relatively high spin-density at the *ortho*-position. Similarly, the free spin in the radical **10** and that derived from **7** are considered to delocalize mainly on the respective benzylidene moieties. This mode of spin-distribution is responsible for the effective release of the methoxyl anion from the benzylidene moiety as well as for the survival of the group on the aniline moiety.

Experimental

All melting and boiling points are uncorrected.

Materials. Commercial benzophenone, fluorenone, benzaldehyde, *o*-anisaldehyde, aniline, *o*- and *p*-anisidine (reagent grade) were used. *N*-Fluorenylidene-*p*-anisidine (**13**) was prepared by the method of Taylor and Fletcher:[6] mp 135—136 °C. *N*-(*o*-Methoxybenzylidene)aniline (**5**) was prepared by the usual method.[7] The molecular complex with methyl alcohol melted in the range 85—88 °C, and the purified imine at 42—43 °C: NMR ($CDCl_3$), δ=8.85 (1H, s, –CH=), 6.80—8.18 (9H, m, aromatic), and 3.82 (3H, s, OCH_3). *N*-Benzylidene-*o*-anisidine (**7**) was prepared by the same method. The molecular complex with *o*-anisidine melted in the range 62.5—74 °C, and the oily pure imine was obtained by distillation: bp 158—159 °C/2 mmHg; NMR ($CDCl_3$), δ=8.30 (1H, s, –CH=), 6.70—7.88 (9H, m, aromatic), and 3.78 (3H, s, OCH_3). *N*-(2-Biphenylylmethylene)aniline (**9**) was prepared by the method of Smith and Nichols.[8] The method has been established for aldehyde synthesis, but the treatment of the Grignard reaction mixture with aqueous NH_4Cl and not aqueous HCl directly afforded **9**: mp 137—138 °C; NMR ($CDCl_3$), δ=8.16 (1H, s, –CH=), and 6.86—7.36 (14H, m, aromatic). Tetrahydrofuran for the ordinary Grignard reaction was dried over sodium wire, distilled, and stored on sodium wire. The same solvent for ESR measurement was dried by sodium hydride, frozen, degassed repeatedly, and distilled into the storage vessel on a vacuum line containing sodium-potassium alloy.

Procedures. Phenylmagnesium bromide (0.05 mol) was prepared in the usual way in THF (25 ml), imine **7** (0.01 mol) dissolved in THF (20 ml) being added at room temperature. No heat evolution took place. The resulting yellow mixture was stirred at 50—55 °C for 5 h, and quenched with saturated aqueous NH_4Cl. The residue obtained after the usual work-up was chromatographed on silica gel. Appropriate fractions were combined, solvent was removed, and the residue was recrystallized from methyl alcohol: **11**, mp 90.5—92 °C; NMR ($CDCl_3$), δ=7.12—7.36 (10H, m, phenyl), 6.20—6.72 (4H, m, *o*-substd phenyl), 5.40 (1H, s, –CH), 4.65 (1H, broad s, NH), and 3.75 (3H, s, OCH_3).

The reaction of **5** and product separation were carried out in a similar way. The Gilman product **2**: mp 140 °C; NMR ($CDCl_3$), δ=6.20—7.60 (19H, m, aromatic), 5.52 (1H, s, >CH), and 4.0 (1H, s, NH). The dimeric product **8**: mp 206—209 °C; NMR ($CDCl_3$), δ=6.44—7.20 (18H, m, aromatic), 5.35 (2H, d, >CH), 4.84 (2H, broad s, NH), and 3.68 (3H, s, OCH_3).

ESR-Spectrum was recorded on JEOL ME-1X model spectrometer. The apparatus for the measurement was constructed and used as reported.[12]

Halogenated Sesquiterpene Phenols and Ethers from the Red Alga *Laurencia glandulifera* Kützing[1]

Minoru Suzuki and Etsuro Kurosawa*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 31, 1979)

Several brominated sesquiterpene phenols and the related ethers were isolated from the red alga *Laurencia glandulifera* Kützing. The structures of these compounds were determined on the basis of spectroscopic evidence and chemical correlation.

In the course of our continuing studies of the constituents of the red algae genus *Laurencia* (Rhodomelaceae), we have reported a variety of metabolites which have been isolated from *L. glandulifera* Kützing, *i.e.*, laurencin,[2] several halogenated chamigrenes,[3,4] spirolaurenone,[5] two bromocuparenes,[6] and laurene.[7] In a previous communication[8] we reported the isolation and structural elucidation of three brominated aromatic sesquiterpene ethers as minor components from this alga. The isolation of these ethers prompted us to investigate the remaining portion of the neutral oil of this alga, and three brominated phenols were isolated. We wish to report herein the isolation and structures of these minor brominated sesquiterpene phenols, (**1a**), (**2a**), and (**3a**), and the related ethers, (**8**), (**9**), and (**10**).

Freshly collected and half-dried algae were extracted with MeOH in the usual manner. The neutral MeOH extracts, which, on silica gel TLC, reveal a chromatogram similar to that of the previous extracts, were fractionated by column chromatography on neutral alumina.

Sesquiterpene Phenols: Diethyl ether fractions, which consisted of a mixture of alcohols, were rechromatographed on a silica-gel column. The earlier benzene eluates afforded a mixture of phenols which, following acetylation, was further submitted to preparative TLC on silica gel to yield three acetylated products, (**1b**), (**2b**), and (**3b**).

The major compound (**2b**) was identified as the acetate of laurenisol (**2a**), isolated from *L. nipponica* Yamada,[9] by a direct comparison of their physical properties.

One of the minor compounds, **1b**, $C_{17}H_{20}O_2Br_2$ (*m/e* 418, 416, and 414; M^+), had the following spectral characteristics: ν_{max} 1760 cm^{-1}; δ 0.73 (3H, d, J= 7 Hz), 1.14, 2.25, 2.36 (each 3H, s), 2.85 (1H, q, J=7), 6.01 (1H, br s), 6.85, and 7.27 (each 1H, s). The IR and NMR spectra of **1b** are very similar to those of laurenisol acetate (**2b**). In the NMR spectra of **1b** and **2b**, however, distinct differences were observed in the lower-field region; *e.g.*, in the spectrum of **2b**, absorptions due to three aromatic protons appeared at 6.75 (1H, br s), 6.85 (1H, br d, J=8), and 7.01 (1H, d, J=8) instead of two aromatic protons in the spectrum of **1b**. Hence, **1b** must be a bromo analog of laurenisol acetate (**2b**). Saponification of **1b** with 5% methanolic KOH gave the original phenol (**1a**). The structure of **1a** was confirmed by the following reaction: laurenisol (**2a**) was treated with bromine in acetic acid under the same conditions as the bromination of debromolaurinterol (**6a**)[10] to yield a brominated product, which was found to be identical with **1a** in all respects.

Another minor compound (**3b**), $C_{17}H_{21}O_2Br$ (*m/e* 338 and 336; M^+), $[\alpha]_D^{25}$ +45°, indicates in its IR and NMR spectra the presence of a secondary methyl group [0.66 (3H, d, J=7) and 2.70 (1H, q, J=7)], which was shifted to the higher magnetic field as same as **1b** and **2b**, a tertiary methyl group [1.12 (3H, s)], an aromatic methyl group [2.27 (3H, s)], a 2,4,5-trisubstituted phenyl acetate grouping [1763 cm^{-1}; 2.36 (3H, s), 6.84 and 7.25 (each 1H, s)], and a terminal methylene group [1655 and 885 cm^{-1}; 4.80 and 4.90 (each 1H, br s)]. These spectral data reveal that **3b** has a structure similar to that of **1b** except for a terminal methylene group instead of a bromomethylene group in **1b** and would, therefore, be represented by formula **3b**, an isomer of laurinterol acetate (**5b**) and isolaurinterol acetate (**7b**).[10] The spectral properties were identical to those reported[11] for the acetate of allollaurinterol (**3a**), isolated from *L. filiformis* as a major metabolite[11,12] and *L. subopposita* as a minor one.[13] Debromoallolaurinterol (**4a**) was also isolated from *L. subopposita*.[13]

Although the stereochemistry of a double bond between C-3 and C-6 in **2a** has remained unsettled, the assignment of the *Z*-configuration to this double bond can now be made with the aid of chemical shifts of the proton at C-2 in the NMR spectra of **1a**, **2a**, **3a**, and **4a**. In these spectra, the signals of C_2–H in **1a** (δ 3.11 q) and **2a** (δ 3.15 q) appear in a lower-field region than those in **3a** (δ 2.95 q) and **4a** (δ 2.95 q). These low-field chemical shifts in **1a** and **2a** are due to the deshielding being caused by C_6–Br, which is situated close to C_2–H.

Sesquiterpene Ethers: The hexane fraction was repeatedly chromatographed on a silica-gel column and subsequently on a PLC to yield three bromo ethers, (**8**), (**9**), and (**10**), along with laurene, isolaurene, bromocuparenes, and halo-chamigrenes.[4]

One of the three bromo ethers, **8**, $C_{15}H_{19}OBr$ (*m/e* 296 and 294; M^+), was identified as the ether isomerized from laurenisol (**2a**)[9] by comparisons of the spectral data.

The second bromo ether, **9**, mp 86—87 °C, $[\alpha]_D^{23}$ +22°, $C_{15}H_{18}OBr_2$ (*m/e* 376, 374, and 372; M^+), shows in its NMR spectrum the presence of three methyl groups at 0.74 (3H, d, J=7), 1.38 (3H, s), and 2.29 (3H, s), a $BrCH_2$-group at 3.41 and 3.55 (each 1H, AB-q, J=10), and two aromatic protons at 6.55 and 7.08 (each 1H, s). The IR and NMR spectra of **9** are very similar to those of **8**, suggesting that **9** must be a bromo analog of **8**. The structure

of **9** was confirmed by the following reactions. Treatment of **8** with bromine in acetic acid yielded a dibromo compound, which was identical with **9** in all respects. Although, on treatment with *p*-toluenesulfonic acid in acetic acid at room temp (2 h), **1a** was recovered, treatment of **1a** with TsOH in acetic acid under reflux gave **9** in a low yield.

The third bromo ether, **10**, mp 125—126 °C, $[\alpha]_D^{21}$ +79°, $C_{15}H_{18}OBr_2$ (*m/e* 376, 374, and 372; M^+), shows in its IR and NMR spectra the presence of three methyl groups [0.68 (3H, d, J=7), 1.35 (3H, s), and 2.22 (3H, s)], a Br_2CH-group [5.65 (1H, s)], and a 2,5-substituted aryl ether moiety [1622, 1577, 1505, 1245, and 815 cm^{-1}; 6.50 (1H, br s), 6.50 (1H, br d, J=8), and 6.82 (1H, d, J=8)].

The NMR spectrum of **10** displays signals comparable to those of **8** except for the absorptions due to a two-proton quartet at δ 3.40 and 3.52 (attributed to the $BrCH_2$-group in **8**) instead of a one-proton singlet at δ 5.65 (attributed to the Br_2CH-group in **10**). Thus, formula **10** can completely interpret all spectral properties. The related compounds, filiformin (**11**) and filiforminol (**12**), were also isolated from *L. filiformis*.[11,12]

Experimental

All the mps were uncorrected. The IR spectra were measured on a Nihon-Bunko IR-S spectrometer in a $CHCl_3$ soln. The NMR spectra were recorded on a JEOL JNM-PS-100 spectrometer, TMS being used as the internal reference in a CCl_4 soln. The optical rotations were measured in a $CHCl_3$ soln. Alumina (Merck, activity II—III) and silica gel (Mallinckrodt, 100 mesh) were used for the column chromatography. Silica gel (Merck, Kieselgel GF_{254} (Type 60)) was used for the preparative TLC (PLC).

Isolation. *L. glandulifera* was collected at Oshoro Bay Hokkaido, early in August, 1978. The half-dried algae (600 g) were extracted with methanol. After the separation of the acidic and basic components by shaking with 1M aqueous KOH and 1M aqueous HCl respectively, a neutral oil (7.3 g) was obtained; this oil was subsequently chromatographed on a neutral alumina column. Elution with hexane gave an oily substance, which consisted of a mixture of hydrocarbons, aromatic ethers, and fatty acid methyl esters. Elution with ether gave a mixture of alcohols, which was then rechromatographed on a silica-gel column. The earlier benzene eluates gave a mixture of phenolic compounds, which was acetylated with acetic anhydride in pyridine at room temp in the usual manner and subsequently chromatographed on a PLC plate to give **1b** (0.5% of neutral oil), **2b** (0.2%), and **3b** (0.07%). These acetates were converted to the original phenols, (**1a**), (**2a**), and (**3a**), by treatment with 5% KOH in methanol. The above oily substance eluted with hexane was rechromatographed on a silica-gel column. The later hexane eluates were further repeatedly chromatographed on a PLC plate to yield **8** (0.07%), **9** (0.05%), and **10** (0.05%). These phenols and ethers were also obtained from the previous extracts but in different ratios.

1a: Colorless oil; $[\alpha]_D^{22}$ +74° (*c* 0.58); IR, ν_{max} 3680, 3360, 1640, 1610, 1500, 1397, 1380, 1255, 1150, 1070, and 885 cm^{-1}; NMR, δ 0.73 (3H, d, J=7 Hz), 1.19 (3H, s), 2.28 (3H, s), 3.11 (1H, q, J=7 Hz), 4.60 (s: OH), 5.98 (1H, br s), 6.47 (1H, s), and 7.13 (1H, s); MS, *m/e* (rel. intensity) 376, 374, 372 (7, M^+), 361, 359, 357 (2), 295, 293 (21), 253, 251 (7), 214 (53), 199 (21), 149 (47), 115 (16), 91 (18), 77 (18), 71 (58), 57 (55), and 43 (100). Acetate **1b**: colorless oil; $[\alpha]_D^{20}$ +76° (*c* 0.95); IR, ν_{max} 1760, 1642, 1375, 1190, 1147, 1070, and 908 cm^{-1}; MS, *m/e* 418, 416, 414 (4, M^+), 403, 401, 399 (1), 376, 374, 372 (10), 337, 335 (46), 295, 293 (53), 294, 292 (51), 279, 277 (23), 265, 263 (14), 214 (100), 201 (25), 199 (28), 159 (10), 145 (11), 115 (11), 91 (13), 77 (10), and 43 (65).

2a and **3a**: **2a** and **3a** were identified as laurenisol and allolaurinterol respectively by comparisons of the spectral data of the corresponding acetates, **2b** and **3b**. Attempts to crystallize **3b** [white solid, $[\alpha]_D^{25}$ +45° (*c* 0.35)] failed; allolaurinterol acetate,[11] mp 86.6—89.1 °C (from methanol), $[\alpha]_D$ +48.2° (*c* 1.03 in $CHCl_3$).

8: The IR and NMR spectra were superimposable on those of an authentic sample (**8**).[9]

9: Mp 86—87 °C (from methanol); $[\alpha]_D^{23}$ +22° (*c* 1.16); IR, ν_{max} 1612, 1557, 1395, 1380, 1357, 1240, 1152, 1085, 1020, 935, and 880 cm^{-1}; MS, *m/e* 376, 374, 372 (8, M^+), 295, 293 (17), 239, 237 (14), 214 (29), 201 (13), 199 (15), 107 (100), 95 (43), and 91 (27).

10: Mp 125—126 °C (from methanol); $[\alpha]_D^{21}$ +79° (*c* 0.38); IR, ν_{max} 1622, 1577, 1505, 1390, 1355, 1308, 1245, 1175, 1150, 1083, 1017, 965, 872, and 815 cm^{-1}; MS, *m/e* 376, 374, 372 (46, M^+), 295, 293 (35), 214 (40), 213 (100), 201 (50), 159 (51), 135 (30), 133 (20), 121 (30), 105 (15), and 91 (20).

Conversion of ***2a*** *to* ***1a***. One molar equivalent of bromine (8 mg) in acetic acid (2 ml) was added to a soln of **2a** (15 mg) in acetic acid (1 ml). The mixture was allowed to stand at room temp for 15 min and then extracted with ether. The ether soln was successively washed with water, 5% aqueous $NaHCO_3$, and saturated brine, and dried over Na_2SO_4. A crude substance obtained after the removal of the solvent was chromatographed on a PLC plate to give **1a** (18 mg); The IR and NMR spectra were superimposable on those of natural **1a**.

*Conversion of **8** to **9**.* One molar equivalent of bromine (21 mg) in acetic acid (2 ml) was added to a soln of **8** (40 mg) in acetic acid (1 ml). The mixture was allowed to stand at room temp for 15 min and then worked up as has been described above. Crude crystalline products were chromatographed on a PLC plate to give **9** (38 mg); crystals; mp 85 °C; The IR and NMR spectra were superimposable on those of natural **9**.

*Conversion of **1a** to **9**.* A soln of **1a** (16 mg) and *p*-toluenesulfonic acid (15 mg) in acetic acid (1 ml) was refluxed for 30 min. The mixture was then poured into water and extracted with ether. The ether soln was successively washed with water, 5% aqueous $NaHCO_3$, and saturated brine, and dried over Na_2SO_4. Crude products were chromatographed on a PLC plate to give **9** (6 mg).

Halogenated and Non-halogenated Aromatic Sesquiterpenes from the Red Algae *Laurencia okamurai* Yamada[1)]

Minoru Suzuki and Etsuro Kurosawa*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 31, 1979)

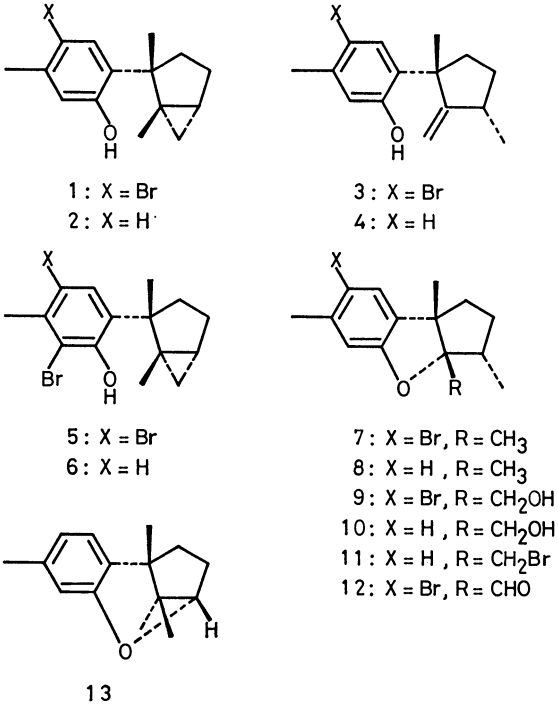
The taxonomic reexamination of the red alga '*L. intermedia* Yamada,' previously collected at Oshoro Bay, Hokkaido, showed that this alga consistd of a mixture of *L. intermedia* Yamada, *L. capituliformis* Yamada, and *L. okamurai* Yamada. Within the Japanese species of genus *Laurencia*, laurinterol and debromolaurinterol were found to be characteristic metabolites of *L. okamurai*, not of *L. intermedia*. In the course of this examination, dibromophenol and debromoaplysinol were newly isolated.

Red algae of the genus *Laurencia* (Rhodomelaceae) are a rich source of halogenated sesquiterpenes, diterpenes, and non-terpenoid C_{15} acetylenic ethers,[2-5)] and various species of *Laurencia* contain unique halogenated metabolites with some overlap ("species-specific"). Since species separation in the genus *Laurencia* is complicated by the high degree of morphological variation within the species, halogenated secondary metabolites might be useful for taxonomic purposes at the species level.[6)]

Previously we reported that laurinterol (**1**) and debromolaurinterol (**2**) were the major components of *L. okamurai* Yamada, specimens of which were collected in two different locations, Hakata-shima, the Inland Sea of Japan[7)] and Okino-shima, Kochi Prefecture,[8)] and also of '*L. intermedia* Yamada,' collected at Oshoro Bay, Hokkaido.[9)] Recently we collected *L. intermedia* Yamada at Inomisaki, Tosa Bay, and examined its neutral oil. There was no halogenated compound in this alga. The above-mentioned results conflicted with the concept of "species-specificity." Therefore, we carried out a taxonomical reexamination of the alga '*L. intermedia*,' previously collected at Oshoro Bay, to reveal that this material consisted of a mixture of *L. intermedia* Yamada, *L. capituliformis* Yamada, and *L. okamurai* Yamada. An examination of fresh algae *L. intermedia* and *L. capituliformis*, collected at Oshoro Bay, showed that these species did not contain any halogenated compound. On the other hand, the freshly collected alga *L. okamurai* was extracted with methanol, and the methanol extracts were subjected to separation by a combination of column and thin-layer chromatography to give laurinterol (**1**), debromolaurinterol (**2**), isolaurinterol (**3**), debromoisolaurinterol (**4**), aplysinol (**9**), isoaplysin (**11**), cuparene-type ether (**13**), bromocuparene (**23**), isobromocuparene (**24**), and isolaurene (**25**). Furthermore, dibromophenol (**5**) and debromoaplysinol (**10**) were newly isolated.

The structure of debromoisolaurinterol (**4**), $C_{15}H_{20}O$, $[\alpha]_D^{23}$ −104°, which has not been obtained in the pure state,[9)] was confirmed by the chemical correlation with aplysin (**7**). Treatment of **4** with bromine in acetic acid afforded a bromo compound, which was found to be identical with aplysin (**7**) by a comparison of the spectral data. The structure of debromoaplysinol (**10**), $C_{15}H_{20}O_2$, $[\alpha]_D^{23}$ −32°, was deduced by a comparison of the spectral data with those of aplysinol (**9**).[7)]

Dibromophenol (**5**), $C_{15}H_{18}OBr_2$ (*m/e* 376, 374, 372; M+), mp 50—52 °C, $[\alpha]_D^{23}$ +8°, exhibited the same intense sharp hydroxyl absorption in the IR spectrum at ν_{max} 3570 cm^{-1} as that of neolaurinterol (**6**), isolated from *L. okamurai* in Okino-shima.[8)] The NMR spectrum exhibited the signals due to a cyclopropane ring at δ 0.2—1.1 (3H, m), two tertiary methyl groups at 1.30 and 1.38 (each 3H, s), an aromatic methyl group at 2.51 (3H, s), and one aromatic proton at 7.59 (1H, s). The signal of the aromatic methyl group was shifted to a lower magnetic field region than those due to the methyl groups of **1** (δ 2.22), **6** (δ 2.33), and other bromophenols. The IR and NMR spectra suggest that dibromophenol should be represented by formula **5**. The structure of **5** was confirmed by the chemical correlation with laurinterol (**1**). Treatment of **1** with *N*-bromosuccinimide in CCl_4[8)] gave a dibromo compound, which was found to be identical with natural **5** in all respects.



The similarities of the components (Table 1) between the algae *L. okamurai* in Okino-shima[8)] and in Oshoro Bay led to a reexamination of the previous extracts of *L. okamurai* in Hakata-shima[7)] and '*L. intermedia*' in Oshoro Bay.[9)] The results of the reexamination will be described in the experimental section and

Table 1. Aromatic sesquiterpenes from *Laurencia* species

Species	Location	Compounds
L. okamurai	Oshoro Bay (Japan)	**1, 2, 3, 4, 5, 9, 10, 11, 13, 23, 24, 25**
L. okamurai	Okino-shima (Japan)	**1, 2, 3, 4, 6, 11, 13, 23, 24, 25**
L. okamurai	Hakata-shima (Japan)	**1, 2, 5, 7, 8, 9, 10, 11, 13, 23, 24, 25**
L. pacifica	La Jolla, Calif. (USA)	**1**
L. pacifica	Ensenada (Mexico)	**3**
L. nidifica	Kahala Reef, Hawaii (USA)	**1, 7**
L. desidua	Alpha Helix Baja (Mexico)	**1, 3, 7, 9**
L. nipponica	Moheji, Hokkaido (Japan)	**15, 24, 25, 26**
L. glandulifera	Oshoro Bay (Japan)	**14, 15, 16, 18, 19, 20, 23, 24, 25, 26**
L. filiformis	Port MacDonnell (Australia)	**16, 21, 22, 26**
L. subopposita	La Jolla, Calif. (USA)	**16, 17, 26**
L. species (?)	Cape Omaezaki (Japan)	**1, 3, 7, 9, 12**

summarized in Table 1. As shown in Table 1, laurinterol (**1**) and debromolaurinterol (**2**) are characteristic major metabolites of Japanese species *L. okamurai*, and several aromatic compounds are common metabolites with only slight differences. Only Hakata-shima's species contained a chamigrene-type sesquiterpene, johnstonol.[10]

26

Laurinterol (**1**) was also isolated from *L. pacifica*,[11] *L. nidifica*,[12] and *L. desidua*.[13] Isolaurinterol (**3**) was also isolated from *L. pacifica*[14] and *L. desidua*.[13] On the other hand, allolaurinterol-type phenols and the related ethers have been obtained from several *L.* species. Allolaurinterol (**16**) and the related ethers, **21** and **22**, were isolated from *L. filiformis*.[15,16] **16** was also isolated from *L. subopposita*[17] along with debromoallolaurinterol (**17**). *L. nipponica*,[18] a Japanese species of *Laurencia*, contained a bromo phenol, laurenisol (**15**), which was also isolated from *L. glandulifera*[20] together with other bromo phenols, **14** and **16**, and the related ethers, **18**, **19**, and **20**. It is interesting to note that these *Laurencia* species contained not only allolaurinterol-type metabolites but also halo-chamigrene derivatives,[19,20] other halo-sesquiterpene derivatives,[16,17] and C_{15} acetylenic ethers.[17,19,20]

Among other Japanese species of the genus *Laurencia*, *L. papillosa* and *L. undulata* did not contain any halogenated compound, and *L. majuscula* contained only halo-chamigrene derivatives.[21,22] Ohta and Takagi have reported the isolation of several aromatic sesquiterpenes, **1**, **3**, **7**, **9**, and **12**, from the red algae *Marginisporum aberrans*, *Amphiroa zonata*, and *Corallina pilulifera* (Corallinaceae), collected at Cape Omaezaki, Shizuoka Prefecture, Japan.[23] As has been described by the authors, these compounds may be derived from *Laurencia* species, for some *Laurencia* species grow in the vicinity of Cape Omaezaki.

Experimental

All the mps were uncorrected. The IR spectra were measured on a Nihon-Bunko IR-S and a A-102 spectrometer. The NMR spectra were recorded on a JEOL JNM-PS-100 spectrophotometer, TMS being used as the internal reference in a CCl_4 soln. The optical rotations were measured in a $CHCl_3$ soln. Alumina (Merck, activity II—III) and silica gel (Mallinckrodt, 100 mesh) were used for the column chromatography. Silica gel (Merck, Kieselgel GF_{254} (Type 60)) was used for the preparative TLC (PLC).

Isolation. *L. okamurai* was collected at Oshoro Bay, Hokkaido, early in August, 1978. The half-dried algae (250 g) were extracted with methanol and then worked up as has previously been described.[9] After the separation of the acidic and basic components, a neutral oil (4 g) was obtained and submitted to column chromatography on neutral alumina.

Hexane Fraction: This fraction consisted of a mixture of hydrocarbons, aromatic ethers, and fatty acid methyl esters. Repeated chromatography on a silica-gel column and a PLC plate yielded isoaplysin (**11**) (0.4% of the neutral oil), cuparene-type ether (**13**) (0.8%), bromocuparene (**23**) (2%), isobromocuparene (**24**) (0.2%), and isolaurene (**25**) (0.6%).

Hexane/Benzene (10 : 1) Fraction: This fraction was rechromatographed on a silica gel column to give dibromophenol (**5**) (0.3%) upon elution with hexane. A benzene eluate gave a mixture of fatty acid methyl esters.

Benzene Fraction: This fraction consisted of laurinterol

(**1**), debromolaurinterol (**2**), isolaurinterol (**3**), and debromoisolaurinterol (**4**). As has previously been described,[9] the isolation and purification of these compounds were carried out *via* their acetates by repeated silica-gel column chromatography and PLC; **1** (40%), **2** (15%), **3** (3.5%), and **4** (2.5%) were thus obtained.

Ether Fraction: This fraction consisted of aplysinol (**9**), debromoaplysinol (**10**), and cholesterol. Repeated chromatography on a PLC plate gave **9** (0.3%) and **10** (0.3%).

Previous Extracts: The neutral oil of '*L. intermedia*,' which was previously collected at Oshoro Bay[9] and stored in an ice box in a N_2 atmosphere, was subjected to separation as described above to give **1** (20%), **2** (10%), **3** (0.6%), **4** (0.3%), **9** (0.1%), **10** (0.2%), **11** (0.1%), **13** (0.7%), **23** (1.1%), **24** (0.3%), and **25** (1.3%). The neutral oil of *L. okamurai*, collected at Hakata-shima,[7] was subjected to separation to give **1** (30%), **2** (13%), **5** (0.1%), **7** (3%), **8** (3%), **9** (0.7%), **10** (0.2%), **11** (0.3%), **13** (0.4%), **23** (0.3%), **24** (0.1%), **25** (1.7%), and johnstonol (0.7%).

*Debromoisolaurinterol (**4**)*: Colorless oil; $[\alpha]_D^{23}$ $-104°$ (*c* 1.10); IR (film), ν_{max} 3490, 3070, 1642, 1620, 1575, 1505, 1380, 1291, 1247, 1160, 1138, 950, 901, 889, and 807 cm^{-1}; NMR, δ 1.20 (3H, d, J=7 Hz), 1.43 (3H, s), 2.23 (3H, s), 4.91 (1H, br s), 5.05 (1H, br s), 5.20 (br s: OH), 6.52 (1H, br s), 6.56 (1H, br d, J=8), and 7.08 (1H, d, J=8); MS, *m/e* (rel. intensity) 216 (34, M^+), 201 (100), 173 (15), 160 (20), 159 (60), 115 (3), 91 (45), and 77 (4).

Acetate: Colorless oil; $[\alpha]_D^{23}$ $-91°$ (*c* 1.43); IR (film) ν_{max} 3075, 1773, 1650, 1622, 1577, 1510, 1380, 1200, 1143, 1070, 1020, 955, 900, and 822 cm^{-1}; NMR, δ 1.13 (3H, d, J=7), 1.23 (3H, s), 2.19 (3H, s), 2.30 (3H, s), 4.71 (1H, br s), 4.99 (1H, br s), 6.70 (1H, br s), 6.79 (1H, br d, J=8), and 7.20 (1H, d, J=8); MS, *m/e* 258 (8, M^+), 216 (20), 201 (100), 173 (6), 160 (8), 159 (16), 115 (3), 91 (4), 77 (3), and 43 (10).

*Dibromophenol (**5**)*: Mp 50—52 °C (from MeOH–H_2O); $[\alpha]_D^{23}$ $+8°$ (*c* 1.0); IR ($CHCl_3$), ν_{max} 3570, 1593, 1395, 1380, 1315, 1290, 1187, 1160, 1130, and 890 cm^{-1}; NMR, δ 0.2—1.1 (3H, m), 1.30 (3H, s), 1.38 (3H, s), 2.51 (3H, s), 5.66 (s: OH), and 7.59 (1H, s); MS, *m/e* 376, 374, 372 (45, M^+), 361, 359, 357 (67), 319, 317, 315 (20), 308, 306, 304 (100), 280, 278 (28), 254, 252 (50), 212 (24), 199 (25), 173 (66), 158 (28), 115 (33), 109 (32), 93 (30), 91 (30), and 77 (30).

*Debromoaplysinol (**10**)*: Mp 85—87 °C (from hexane); $[\alpha]_D^{21}$ $-32°$ (*c* 0.44); IR ($CHCl_3$), ν_{max} 3590, 1620, 1595, 1501, 1280, 1267, 1159, 1100, 1081, 1035, 1000, 948, 855, and 805 cm^{-1}; NMR, δ 1.07 (3H, d, J=7), 1.24 (3H, s), 2.26 (3H, s), 3.57, 3.75 (each 1H, br AB-q, J=12), 6.44 (1H, br s), 6.52 (1H, br d, J=8), and 6.78 (1H, d, J=8); MS, *m/e* 232 (86, M^+), 201 (55), 199 (38), 173 (15), 159 (100), 115 (4), 91 (4), and 77 (3).

*Conversion of **4** to Aplysin (**7**)*. One molar equivalent of bromine (9 mg) in acetic acid (2 ml) was added to a soln of **4** (12 mg) in acetic acid (1 ml). The mixture was allowed to stand at room temp for 15 min and then extracted with ether. The ether soln was successively washed with water, 5% aqueous $NaHCO_3$, and saturated brine. After drying over Na_2SO_4, the solvent was removed to yield a colorless oil, which was purified by PLC to give aplysin (**7**) (11 mg); crystals; mp 85 °C (from MeOH). The IR and NMR spectra were superimposable on those of an authentic sample (**7**).

*Conversion of **1** to **5**.* A soln of **1** (30 mg) and *N*-bromosuccinimide (18 mg) in CCl_4 (2.5 ml) was stirred for 1 h at room temp, and then ether was added. The subsequent removal of the solvent, after filtering from an insoluble substance, gave a residual substance, which was chromatographed on a PLC plate to give dibromophenol (**5**) (33 mg); crystals; mp 50 °C (from MeOH–H_2O). The IR and NMR spectra were superimposable on those of natural **5**.

The authors are grateful to Dr. Hiroshi Yabu and Dr. Yuzuru Saito, Faculty of Fisheries, Hokkaido University, for collecting and identifying the algae *Laurencia* species.

Diels-Alder Reaction of 2-Substituted Tropones with Ethylene. HMO Level Aspect of the Regioselectivity

Tadao UYEHARA* and Yoshio KITAHARA†

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received April 6, 1979)

2-Chloro-, 2-methoxy-, 2-phenyl-, and 2-methyltropones (2,4,6-cycloheptatrien-1-ones) and benzoate of tropolone (2-hydroxy-2,4,6-cycloheptatrien-1-one) reacted with ethylene affording Diels-Alder type 1,4-addition products, bicyclo[3.2.2]nona-3,6-dien-2-ones. The regioselectivities of the cycloaddition are quite random, while they are reproduced by the calculated interaction energies based on Salem's PMO equation which includes the closed-shell repulsion term.

Recently we have reported that tropone (2,4,6-cycloheptatrien-1-one, **1**) reacts relatively easily with alternant hydrocarbons (neutral olefins), such as ethylene, styrene and acenaphthylene giving Diels-Alder type 1,4-addition products.[1] The HOMO-LUMO orbital arrangements of the reactions indicate that the interaction between $HOMO_{dienophile}$—$LUMO_{tropone}$ is dominant in each case. On the basis of Sustmann's classification,[2] those reactions are of the "inverse electron demand" type.

From a theoretical point of view, a diene synthesis utilizing ethylene as the dienophile is of interest. We can treat the Diels-Alder reaction quantitatively because of absence of complicated secondary interactions. We now like to describe the regioselectivities of the Diels-Alder reaction of 2-substituted tropones with ethylene and perturbational MO (PMO) approach to the selectivities based on Eqs. 1 and 2.

The stabilization energy through the interconjugation between a diene and a dienphile at the transition state is evaluated by Eq. 1, based on which the frontier orbital approach was derived.[3]

$$\Delta E = 2\left(\sum_{i}^{occ}\sum_{j}^{unocc} - \sum_{l}^{unocc}\sum_{j}^{occ}\right)\frac{(C_{lr}^{l}C_{2r}^{j}+C_{ls}^{l}C_{2s}^{j})^2}{E_{1l}-E_{2j}}\gamma^2 \qquad (1)$$

Equation 2, derived by Salem,[4] consists of the closed-shell repulsion term (the first term, E_{rep}) and the overlap stabilization terms (E_{stab}) which are similar to Eq. 1. Here subscripts r and r′ refer to a pair of atoms in a diene and a dienophile at which a bond is formed. q is the charge density and S denotes the overlap integral. k is the value of the ratio of interaction integral to overlap integral.

$$\left.\begin{aligned} E_{int} = {} & -k\sum_{rr'}(q_r+q_{r'})S_{rr'}^2 \\ & -2\sum_{j}^{occ}\sum_{k'}^{unocc}\Big(\sum_{rr'}C_{jr}C_{k'r'}S_{rr'}\Big)^2[k^2/(E_{k'}-E_j) \\ & \qquad + (E_{k'}-E_j)/4] \\ & -2\sum_{j'}^{occ}\sum_{k}^{unocc}\Big(\sum_{rr'}C_{kr}C_{j'r'}S_{rr'}\Big)^2[k^2/(E_k-E_{j'}) \\ & \qquad + (E_k-E_{j'})/4] \end{aligned}\right\} \qquad (2)$$

Results and Discussion

The dienophile, ethylene, is able to add to the 4- and 7-positions of 2-substituted tropones giving 3-substituted bicyclo[3.2.2]nona-3,6-dien-2-ones (A-type adducts) and to the 2- and 5-positions affording 1-substituted ones (B-type adducts). A reaction of 2-substituted tropones (**2**—**6**) with ethylene was carried out in a stainless steel autoclave. The reaction conditions and the results are listed in Table 1.

Table 1. The reaction conditions and the results of Diels-Alder reaction of 2-substituted tropones with ethylene

Tropone	Conditions (°C, day)	Product (ratio)[a]	Total yield[a]
2	135, 3.5	**2a** (40.5), **2b** (59.5)	100
3	140, 3	**3a** (12.3), **3b** (87.7)	100
4	135, 3	**4a** (100)	87.5
5	140, 3	**5a** (58), **5b**(42)	91.5
6	135, 3	**6a** (60), **6b**(40)[b]	78[b]

a) By VPC analysis using 1 m×3 mm columns containing 5% PDEGS on Diasolid H or 10% SE-30 on Diasolid H. b) After isolation.

		A-type	B-type
X=H	**1**		
X=Cl	**2**	**2a**	**2b**
X=OCH_3	**3**	**3a**	**3b**
X=Ph	**4**	**4a**	(**4b**)
X=CH_3	**5**	**5a**	**5b**
X=OCOPh	**6**	**6a**	**6b**

A reaction of 2-chlorotropone (**2**) with ethylene gave the two types of adducts (**2a** and **2b**) in a ratio of 40.5 to 59.5, which were separated by chromatography on silica gel. Struture elucidation of the products was performed easily by means of their NMR spectra. A reaction of 2-methoxytropone (**3**) with ethylene proceeded regioselectively giving **3a** (12.3%) and **3b** (87.7%). 2-Phenyltropone (**4**) afforded only the A-type adduct (**4a**), while 2-methyltropone (**5**) gave both types of adducts (**5a** and **5b**: 58 and 42% respectively). The adducts (**6a** and **6b**) were obtained from benzoate of tropolone (**6**) in 60 and 40%, respectively. Thus, regioselectivities of the Diels-Alder reactions are quite random. The cycloadditions should be kinetically controlled: compound **2b** was completely recovered under the cycloaddition conditions, and when it was heated in C_6D_6 (in a sealed tube) at 135 °C for 3 d.

† Deceased February 4, 1976.

Table 2. Caluculated interaction energies (β) based on Eq. 2[a)]

Adduct	E_{int}	E_{repul}	E_{stab}
2a	0.0125	−0.4393	0.4518
2b	0.0128	−0.4382	0.4510
3a	0.0116	−0.4395	0.4511
3b	0.0123	−0.4372	0.4495
4a	0.0101	−0.4401	0.4502
(**4b**)	0.0024	−0.4400	0.4424
5a	0.0093	−0.4400	0.4493
5b	0.0087	−0.4367	0.4454

a) The overlap integral is 0.2. The ratio of the interaction integral to the overlap integral is 2.85 β.

The frontier orbital approach[2)] to the regioselectivity of the reaction of the tropones (**2**—**5**) did not reproduce the experimental results, when we used the Hückel MO calculations based on Streitwieser's parameters.[5)] Our calculations[6)] based on Eq. 1 indicated preferred formation of the A-type adduct in every case. In reality, **2a** and **3a** are not predominant adducts. Thus the stabilization energy concept through the interconjugation is not sufficient to explain the regioselectivities.

It has been mentioned by Salem that the repulsion energy term must be included in a quantitative evaluation of interaction energies.[4)] The interaction energies calculated from Eq. 2 for the transition states of the present Diels-Alder reactions are shown in Table 2. The differences in E_{int} between the A- and B-type adduct formations are uniformly small, and yet they are qualitatively in line with the observed preponderance of one adduct isomer over the other.

The overlap energies (E_{stab}), from the second and third terms of Eq. 2, also show that the predominant adducts are A-type ones in all cases. Thus, the closed-shell repulsion is not negligible in PMO approach to the regioselectivities.

Experimental

General. Melting points were determined on a Thomas Hoover MP apparatus, and are not corrected. Infrared spectra were recorded on Hitachi EPI-3 and Model 215 spectrophotometers. Ultraviolet spectra were recorded on a Hitachi EPS-2T spectrometer. NMR spectra were obtained on Varian A-60 and HA-100 spectrometers equipped with spin decouplars, using tetramethylsilane as the internal standard. The mass spectral studies were conducted using a Hitachi RMU-6D spectrometer. VPC analyses were carried out on a Hitachi gas chromatograph K-53 equipped with a FID. Preparative GLC were done on a Varian Aerograph Model 700 gas chromatograph equipped with a TCD.

*Diels-Alder Reaction of Tropones (**2**—**6**) with Ethylene.* A solution of a tropone (1—2.5 g) in toluene (10—15 ml) was placed in a stainless steel autoclave (100 ml), and heated with excess of ethylene (*ca.* 13 MPa, at 130 °C). After removal of the solvent *in vacuo*, the adducts were isolated by respective way.

*3- and 1-Chlorobicyclo[3.2.2]nona-3,6-dien-2-ones (**2a** and **2b**, respectively).* A mixture of **2a** and **2b**, obtained from 1.65 g of 2-chlorotropone, was chromatographed on silica gel (Wako C-200, 50 g). Elution with hexane gave 245 mg of **2a** and that with benzene gave 450 mg of **2b**. **2a**: Colorless oil; UV_{max} (CH_3OH) 238 (log ε 3.69), 265 (3.44)[sh] and 330 nm (1.94); IR (CCl_4) 1689, 1630 and 1600 cm^{-1}; NMR (CCl_4) δ=7.23 (d, J=9.4 Hz, H_4), 6.54 (ddd, J=8.0, 7.2 and 1.2 Hz, H_6), 6.06 (ddd, J=8.2, 7.6, and 1.2 Hz, H_7), 3.65 (m, H_1), 3.40 (m, H_5), and 2.1—1.5 (4H, m). 2,4-DNP of **2a**: 203—205 °C (dec). Found: C, 51.70; H, 3.92; N, 15.69%. Calcd for $C_{15}H_{13}ClN_4O_4$: C, 51.51; H, 3.75; N, 15.62%. **2b**: Colorless needles; mp 55—56 °C; UV_{max} (CH_3OH) 226.5 (log ε 3.82) and 330 nm (1.97); IR (KBr) 1680 and 1615 cm^{-1}; NMR ($CDCl_3$) δ=7.12 (dd, J=11.2 and 8.9 Hz, H_4), 6.55 (dd, J=9.0 and 7.2 Hz, H_6), 6.01 (dd, J=9.0 and 0.8 Hz, H_7), 5.89 (dd, J=11.2 and 0.8 Hz, H_3), 3.43 (m, H_5), 2.4 (2H, m), and 1.9 (2H, m). Found: C, 64.08; H, 5.35%. Calcd for C_9H_9ClO: C, 64.10; H, 5.38%.

*3- and 1-Methoxybicyclo[3.2.2]nona-3,6-dien-2-ones (**3a** and **3b**, respectively).* Isolation of the adducts was performed by preparative GLC using a 10 ft × 3/8 in aluminium column containing 5% PDEGE on Diasolid H at 180 °C. **3a**: Colorless prisms (from hexane–ether); mp 48—49 °C; UV_{max} (CH_3OH) 234.5 (log ε 3.64), 276.5 (3.68) and 335 nm (2.43)[sh]; IR (CCl_4) 1686, 1635 and 1620 cm^{-1}; NMR ($CDCl_3$) δ=6.60 (ddd, J=8.3, 7.5 and 1.0 Hz, H_6), 6.06 (bd, J=9.5 Hz, H_4), 5.95 (ddd, J=8.3, 6.5 and 1.0 Hz, H_7), 3.65 (m, H_1), 3.52 (3H, s), 3.40 (m, H_5), and 2.0—1.6 (4H, m). Found: M+, 164. Calcd for $C_{10}H_{12}O_2$: M, 164. 2,4-DNP of **3a**: mp 207 °C (dec). **3b**: Colorless oil; UV_{max} (CH_3OH) 228 (log ε 3.77) and 340 nm (2.22); IR (CCl_4) 1685 and 1635 cm^{-1}; NMR ($CDCl_3$) δ=7.02 (dd, J=11.1 and 8.5 Hz, H_4), 6.54 (dd, J=9.0 and 7.1 Hz, H_6), 6.03 (dd, J=9.0 and 0.9 Hz, H_7), 5.83 (dd, J=11.4 and 0.8 Hz, H_3), 3.49 (3H, s), 3.38 (m, H_5), and 2.2—1.7 (4H, m). 2,4-DNP of **3b**: mp 217 °C (dec). Found: C, 55.71; H, 4.79; N, 16.64%. Calcd for $C_{16}H_{16}N_4O_5$: C, 55.81; H, 4.68; N, 16.77%.

*3-Phenylbicyclo[3.2.2]nona-3,6-dien-2-one (**4a**).* Recrystallization of the crude product, from 1 g of 2-phenyltropone (**4**), was performed from hexane–ether yielding 750 mg of **4a**. The mother liquor gave 270 mg of **4a** and trace of **4**, after chromatography on silica gel. **4a**: Colorless needles (from ethanol); mp 93—95 °C; UV_{max} 223.5 (log ε 4.07), 275 (3.56) and 335 nm (2.05)[sh]; IR (KBr) 1670 and 1628 cm^{-1}; NMR ($CDCl_3$) δ=7.24 (5H, m), 7.07 (d, J=9.0 Hz, H_4), 6.58 (ddd, J=8.1, 7.2 and 1.0 Hz, H_6), 6.13 (ddd, J=8.1, 8.1 and 1.1 Hz, H_7), 3.68 (m, H_1), 3.46 (m, H_5), and 2.15—1.6 (4H, m). Found: C, 85.97; H, 6.86%. Calcd for $C_{15}H_{14}O$: C, 85.69; H, 6.71%.

*3- and 1-Methylbicyclo[3.2.2]nona-3,6-dien-2-ones (**5a** and **5b**, respectively).* A mixture of **5a** and **5b**, and unreacted 2-methyltropone (**5**, 8.5%) were separated by preparative GLC (5% PDEGS). The adducts **5a** and **5b** were separated by preparative GLC using a 20 ft × 3/8 in column containing 20% SE-30, at 180 °C. **5a**: Colorless oil; UV_{max} (CH_3OH) 231.5 (log ε 3.82), 255 (3.68)[sh] and 330 nm (2.10); IR (CCl_4) 1668 and 1638 cm^{-1}; NMR ($CDCl_3$) δ=6.91 (dq, J=9.0 and 1.5 Hz, H_4), 6.53 (ddd, J=8.3, 6.3 and 1.2 Hz, H_6), 6.06 (ddd, J=8.3, 7.3 and 1.0 Hz, H_7), 3.55 (m, H_1), 3.30 (m, H_5), 2.0—1.6 (4H, m), and 1.72 (3H, d, J=1.5 Hz); MS (25 eV), *m/e* (rel intensity), 148 (69, M+), 133 (96), 131 (73), 106 (62), 105 (99), 93 (48), 92 (100), and 91 (89). 2,4-DNP of **5a**: mp 193—194.5 °C. Found: C, 58.22; H, 4.81; N, 16.94%. Calcd for $C_{16}H_{16}N_4O_4$: C, 58.53; H, 4.91; N, 17.07%. **5b**: Colorless oil; UV_{max} (CH_3OH) 227.5 (log ε 3.90) and 326 nm (2.17); IR (CCl_4) 1665 and 1633

cm^{-1}; NMR ($CDCl_3$) δ=7.01 (dd, J=11.2 and 8.6 Hz, H_4), 6.53 (dd, J=8.8 and 6.2 Hz, H_6), 5.77 (dd, J=8.8 and 1.0 Hz, H_7), 5.65 (dd, J=11.2 and 0.5 Hz, H_3), 3.30 (m, H_5), 2.0—1.6 (4H, m), and 1.29 (3H, s); MS (25 eV), *m/e* (rel intensity), 148 (69, M^+), 133 (96), 131 (73), 106 (62), 105 (99), 93 (48), 92 (100), 91 (89), 79 (64), and 55 (60).

*2-Oxobicyclo[3.2.2]nona-3,6-dien-3-yl and 7-yl Benzoates (**6a** and **6b**, Respectively).* Chromatography of a mixture of **6a** and **6b**, obtained from 1 g of benzoate of tropolone (**6**), on 50 g of silica gel (elution with benzene–ether, 10:1) gave 320 mg of **6a** and a mixture of **6a** and **6b**. The latter was chromatographed on Florisil (eluted with benzene) yielding 165 mg of **6a**, 363 mg of **6b** and 95 mg of 1 : 1 mixture of them. **6a**: Colorless needles; mp 104—105 °C (from ethanol); UV_{max} (CH_3OH) 232 (log ε 4.37) and 330 nm (2.04); IR (KBr) 1740, 1675, 1643, and 1625 cm^{-1}; NMR ($CDCl_3$) δ=8.2—7.95 (2H, m), 7.65—7.4 (3H, m), 6.87 (d, J=9.8 Hz, H_4), 6.67 (ddd, J=8.7, 7.2 and 1.0 Hz, H_6), 6.15 (ddd, J=8.7, 7.6 and 1.0 Hz, H_7), 3.72 (m, H_1), 3.45 (m, H_5), and 2.2—1.7 (4H, m). Found: C, 75.57; H, 5.57%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%. **6b**: Colorless needles (from ethanol); mp 74—75 °C; UV_{max} (CH_3OH) 230.5 (log ε 4.33) and 333 nm (1.83); IR (KBr) 1722, 1672 and 1635 cm^{-1}; NMR ($CDCl_3$) δ=8.2—8.0 (2H, m), 7.6—7.35 (3H, m), 7.00 (dd, J=11.2 and 8.5 Hz, H_4), 6.52 (dd, J=9.0 and 7.0 Hz, H_6), 6.28 (bd, J=9 Hz, H_7), 5.92 (d, J=11.2 Hz, H_3), 3.42 (m, H_5), and 2.8—1.75 (4H, m). Found: C, 75.52; H, 5.48%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%.

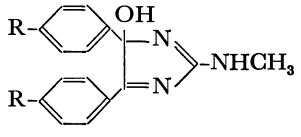
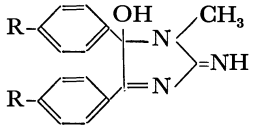
(Received April 9, 1979)

The crystal and molecular structure of (±)-2-methylamino-4,5-bis(*p*-chlorophenyl)-4-hydroxy-4*H*-imidazole has been determined by the single-crystal X-ray diffraction method. The crystals are monoclinic with space group $P2_1/c$, cell dimensions: $a=14.872(5)$, $b=9.216(7)$, $c=12.945(11)$ Å, $\beta=99.53(5)°$, and $Z=4$. The structure was determined by the symbolic addition method and refined by the least-squares method to give the final R factor of 0.072 for 1616 non-zero reflections.

In conection with the development of the new synthetic method of 2-aminoimidazoles,[1-3] 4,5-diaryl-4-hydroxy-4*H*-imidazoles (**1**) were prepared by the reaction of the corresponding benzils with methylguanidine.[4] The NMR spectra of these compounds (**1**) show a slightly broad singlet for the *N*-methyl protons indicating the structure of 4,5-diaryl-4-hydroxy-2-imino-1-methyl-5-imidazoline (**1b**).[4] On the other hand, the fact that hydrogenation of **1** produced 4,5-diaryl-2-methylaminoimidazoles suggests isomeric 4,5-diaryl-4-hydroxy-2-methylamino-4*H*-imidazoles (**1a**) as the structure of **1**.[4] Since structural interconversion between **1a** and **1b** in solution is possible,[2] it is difficult



1a



1b

to determine which isomeric structure **1a** or **1b** corresponds to compounds (**1**). Thus, an X-ray crystallographic analysis of the bis(*p*-chlorophenyl) derivative (**1**, R=Cl) was undertaken to determine the position of the methyl group and the conformation of the molecule.

Experimental

Preparation of 2-Methylamino-4,5-bis(p-chlorophenyl)-4-hydroxy-4H-imidazole (1). A mixture of 4,4′-dichlorobenzil (2.70 g) and methylguanidine (0.73 g) in 16 ml of methanol was stirred at room temperature for 30 min. The presipitate was filtered, washed with methanol, chloroform, and then ether and air-dried at room temperature. Colorless powder, mp *ca.* 295 °C dec (gradual darkening ≳125 °C), yield 3.03 g (91%). Recrystallization of **1** with methanol gave pale yellowish crystals; mp >280 °C (gradual darkning ≳126 °C); NMR (DMSO-d_6) $\delta=2.87$ (3H, s, NCH_3), 3.19 (3H, s, OCH_3), *ca.* 4.1 (2H, broad, disappeared on addition of D_2O, OH), *ca.* 7.1 (1H, broad, disappeared on addition of D_2O, NH), 7.30 (4H, s, 4-C_6H_4Cl), 7.50 (2H, d, $J=9.3$ Hz, $H_{3,5}$ of 5-C_6H_4Cl), 7.97 (2H, d, $J=9.3$ Hz, $H_{2,6}$ of 5-C_6H_4Cl). The NMR spectrum was recorded with a Hitachi R-24 (60 MHz) spectrometer. The size of crystal used for obtaining X-ray data was $0.3\times0.2\times0.4$ mm. The data are given in Table 1. The cell constants were determined by the least-squares procedure from the 2θ values of 25 reflections measured on a diffractometer using monochromated Mo $K\alpha$ radiation. The density was determined by the flotation method. The integrated intensities of the reflections were collected on a Rigaku automatic four circle diffractometer with Mo $K\alpha$ radiation monochromatized by a graphite plate. Background was counted for 10 s at both sides of each peak. Three standard reflections were measured every 50 reflections during the couse of collection. The intensities of unique reflections with 2θ values than 69° were collected, a total of 1616 reflections with $|F|>3\sigma(|F|)$ being obtained. The data were corrected for Lorentz and polarization factors, but not for absorption. The atomic scattering factors for C, O, N, and Cl were given by Cromer and Mann,[5] and that for H by Stewart *et al.*[6]

TABLE 1. CRYSTAL DATA

$C_{16}H_{13}ON_3Cl_2\cdot CH_3OH$	
Monoclinic	Space group $P2_1/c$
$a=$ 14.872 (5) Å	$D_m=1.39$ g·cm^{-3}
$b=$ 9.216 (7) Å	$D_c=1.391$ g·cm^{-3}
$c=$ 12.945 (11) Å	$Z=4$
$\beta=$ 99.53 (5)°	
$V=$ 1749.7 Å^3	

Determination of Structure

The structure was determined by the symbolic addition method.[7] The distribution and statistics of $|E|^s$ agree with the theoretical values for the centrosymmetric case. The resulting E map revealed the location of all the 24 non-hydrogen atoms including methanol molecule. Several cycles of least-squares refinement of the coordinates with isotropic temperature factors gave an R value of 0.15. Anisotropic thermal parameters were introduced for all non-hydrogen atoms, the R value being reduced to 0.11. Of seventeen hydrogen atoms, the two hydrogen atoms of the hydroxyl group of compound **1** and the methylamino group were located on the difference map, but the other hydrogen atoms could not be identified. Refinement of the coordinates with anisotropic temperature factors for non-hydrogen atoms and isotropic thermal factors for hydrogen atoms gave the final R value 0.072. At the final stage of the refinement the difference electron density map showed only featureless peaks, which were about half of those of the two hydrogen atoms H(1) and H(2). The complete F_o-F_c data are deposited as Document No. 7932 at the Chemical Society of Japan.

Results and Discussion

The molecular structure and numbering are shown in Fig. 1. The methyl group was found to be bonded with the 2-amino group. The final atomic coordinates and thermal parameters with their standard deviations are given in Table 2, and bond distances and angles with their standard deviations in Tables 3 and 4, respectively. The sum of the bond angles around the N(1) atom is 359.4°, and the bond length of N(1)–C(2) is 1.34 Å. The values suggest that the atomic configuration of N(1) is sp^2 hybridized, and that the N(1)–C(2) bond is conjugated with the imidazole ring. The crystal structure projected along the b axis is shown in Fig. 2. The crystal of compound **1** contains four methanol molecules in an unit cell. The

oxygen atom of the methanol molecule is hydrogen-bonded with the hydrogen atom of the hydroxy group of compound **1** and the methylamino group. The N(3) atom is also hydrogen-bonded with the H(1) atom. A stereoscopic view of compound **1** is shown in Fig. 3. The dihedral angles are given in Table 6. The dihedral angle between two phenyl groups is 95.5° and that between the imidazole ring and the phenyl group attached to C(3) and the phenyl group attached to C(4) is 6.88° and 96.2°, respectively. The least-squares planes and deviations of atoms from these planes are given in Table 5. The benzene ring attached to C(3) and the imidazole ring are nearly coplanar. C(1), N(1), and H(2) are almost of the imidazole ring plane, and H(2) is on the N(2) side and C(1) on the N(3) side of the imidazole ring.

Syntheses of Cationic Mononucleotide Analogs and Their Interaction with Polynucleotide and Polynucleotide Analogs

Takeo SHIMIDZU,* Akira MURAKAMI, Kazushige YAMANA, and Yoshiyuki KONISHI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received April 9, 1979)

Cationic mononucleotide analogs were synthesized through a quaternization reaction of *N*-halogenoethylated derivatives of nucleic acid bases or 5′-halogeno-5′-deoxynucleoside. When they interacted with polynucleotide and polynucleotide analogs with negative charges, base-base interactions were observed. The interactions between complementary bases were stronger than the others. It is suggested that an anionic field originating from the polynucleotide or polynucleotide analog contributes to the interaction of complementary bases.

Several polynucleotide analogs with positive charges have been synthesized.[1,2] Their interactive properties with nucleic acid bases,[3] nucleotides,[2,4] polynucleotides,[3] and nucleotide analogs with negative charges[5,6] have also been investigated. In these studies, the mode of interactions was predominantly the base-base stacking. This evidence for the contribution of stacking interaction has also been found in the interaction of nucleotides or nucleotide analogs with negative charges in the cationic polyelectrolyte.[5] The mode of the interaction was also affected by the hydrophobic polymer domain. The cross-linked cationic polynucleotide analogs have a tendency to interact with the complementary nucleotide,[4] and so template-directed syntheses of oligonucleotides were carried out.[7]

In comparison with those phenomena, it is significant to elucidate the effect of the ionic field originating from the polynucleotide. For this purpose, some nucleotide analogs with the charge opposite to that of the nucleotide were synthesized. The present paper will give the details of the syntheses of the cationic mononucleotide analogs and the interactive properties with polynucleotides and their analogs with negative charges. Some consideration regarding the contribution of the ionic field to the base-base interaction will also be paid.

Results and Discussion

The cationic mononucleotide analogs shown in Fig. 1 were synthesized in the following manner. Nucleic acid bases were first converted to the corresponding *N*-halogenoethylated derivatives by the literature method.[8] 5′-Halogeno-5′-deoxynucleoside was synthesized by the literature procedure.[9] To *N*-halogenoethylated derivatives and 5′-halogeno-5′-deoxynucleosides, pyridine and trimethylamine were added; cationic mononucleotide analogs were then obtained through a quaternization reaction. In general, it is recommended that the reactions are carried out without any solvent. In the case of trimethylammonium derivatives, though, a good result was also yielded by using ethanol as a solvent. The precipitates during the reaction were almost purely the desired substances. These derivatives were hygroscopic.

The UV characteristics, R_f values, and electropho-

	Py-C_2'-Thy	3.0
	TMA-Ado	2.1
	TMA-Urd	2.5

The total concentration of nucleic acid bases in the mixture was 5.4×10^{-5} mol dm^{-3}.
a) Potassium salts of polynucleotides were used. b) The hypochromicities were calculated at 260 nm.

retical mobilities of cationic mononucleotide analogs are shown in Table 1. Their mobilities were almost twofold in the opposite direction, based on the corresponding nucleotides. This result indicates that they have a cationic charge even in neutral aqueous media.

The interactive properties of the present cationic mononucleotide analogs have also been investigated. Evidence for interaction between cationic mononucleotide analogs and polynucleotides came from the apparent hypochromicities in mixtures of them. When solutions of polynucleotides were mixed with solutions of cationic mononucleotide analogs, apparent hypochromicities down to a low percentage were observed. The results are shown in Table 2. Generally, a UV hypochromicity is not observed in a mixture of polynucleotide and nucleotide at the present concentration

Table 3. Apparent hypochromicities in the mixing curves of cationic mononucleotide analogs and anionic polynucleotide analogs[a]

Anionic polynucleotide analog	Cationic mononucleotide analog	Hypochromicity[b] %
PAA-Ado_8 	TMA-C_2'-Ade	1.0
	TMA-C_2'-Thy	5.8
	TMA-C_2'-Cyt	2.5
	Py-C_2'-Ade	0.0
	Py-C_2'-Thy	1.5
	TMA-Ado	1.0
	TMA-Urd	2.3
PAA-Urd_{15} 	TMA-C_2'-Ade	2.5
	TMA-C_2'-Thy	1.0
	TMA-C_2'-Cyt	0.0
	Py-C_2'-Ade	1.6
	Py-C_2'-Thy	0.0
	TMA-Ado	2.4
	TMA-Urd	0.0

The total concentration of nucleic acid bases in the mixture was 5.4×10^{-5} mol dm^{-3}.
a) Anionic polynucleotide analogs were synthesized by the condensation reaction of poly(acrylic acid) with nucleoside. The content of adenine or uridine was determined by a UV measurement. b) The hypochromicities were calculated at 260 nm.

range. Such an interaction suggests a dominant contribution of Coulombic forces in the interaction between the cationic mononucleotide analog and the polynucleotide.

The observed hypochromicities of the complementary base's sets (Poly A-T derivative, Poly A-U derivative, and Poly U-A derivative) were larger than those of the incomplementary base's sets (Poly A-A derivative, Poly A-C derivative, and Poly U-C derivative, Poly U-T derivative, and Poly U-U derivative). This fact indicates that both a base stacking and a hydrogen bonding contribute to the mode of intermolecular base-base interaction.

The apparent hypochromicities in the mixing curves of the cationic mononucleotide analogs and the anionic polynucleotide analogs are shown in Table 3. A mode of interaction similar to that of polynucleotide was observed. This shows that hydrogen bonding between complementary bases takes place in the intermolecular interaction of the bases. As the contrary, previous studies of the interaction between nucleotides and cationic polynucleotide analogs showed that the stacking interaction was overwhelming.[2,4]

Now we can deduce that the anionic field originating from polynucleotides and polynucleotide analogs makes a large contribution to the base-base interaction; the anionic field contributes to the hydrogen bonding in the complementary base-base interaction.

Experimental

General Method. Paper chromatographies were carried out by the descending technique using Whatman 3 MM

paper in the following solvent systems: A, 2-propanol–concentrated ammonia–water (7:1:2, v/v); B, ethanol–1 M ammonium acetate (pH 7.5) (7:3, v/v). Paper electrophoresis was carried out on the same paper at 35 V cm^{-1} in a 0.1 M phosphate buffer (pH 7.0). The UV absorption spectra were obtained on a Hitachi EPS-3T spectrophotometer. The NMR spectra were recorded with a Varian HR-220 spectrometer.

Reagents. The pyridine was distilled by a general method. A 30% trimethylamine–ethanol solution was obtained by dissolving a dry trimethylamine gas in ice-cooled ethanol.

Materials. The 9-(2-bromoethyl)adenine, 9-(2-chloroethyl)adenine, and 1-(2-chloroethyl)thymine were synthesized by the literature procedure.[8] The 1-(2-chloroethyl)cytosine was synthesized by the modification of the literature method:[8] 15 cm^3 of thionyl chloride was added to 1 g of 1-(2-hydroxyethyl)cytosine, and the mixture was stirred for 90 min at 35 °C and then was refluxed for 30 min. After the removal of the excess thiony chloride under reduced pressure, the residue was dissolved in water and treated with 5% of a sodium carbonate solution, and the precipitate thus formed was filtered off and dried. Recrystallization from ethanol gave 1-(2-chloroethyl)cytosine as pale yellow needles (48% yield). Found: C, 41.38; H, 4.69; N, 23.81; Cl, 19.63%. Calcd for $C_6H_8N_3OCl$: C, 41.51; H, 4.65; N, 24.20; Cl, 20.42%. The 5′-bromo-5′-deoxyuridine was synthesized by the literature method.[9] The 5′-chloro-5′-deoxyadenosine was kindly given by the Tanabe Pharmacy Company, Ltd.

2-(Adenin-9-yl)ethyltrimethylammonium Chloride, TMA-C_2'-Ade: In 25 cm^3 of a 30% trimethylamine–ethanol solution, 0.6 g of 9-(2-chloroethyl)adenine was dissolved. The mixture was sealed in a thick glass tube and then heated at 80 °C for 48 h. A white precipitate was filtered, washed with ethanol, then dried (63% yield). Found: C, 44.24; H, 6.86; N, 31.43; Cl, 13.48%. Calcd for $C_{10}H_{17}N_6Cl$: C, 46.78; H, 6.62; N, 32.74; Cl, 13.84%. NMR (D_2O) δ 8.45 (1H, s, 2 position of adenine), 8.43 (1H, s, 8 position of adenine), 4.93 (2H, t, 2 position of ethylene), 4.23 (2H, t, 1 position of ethylene), 3.23 (9H, s, trimethylammonium).

2-(Thymin-1-yl)ethyltrimethylammonium Chloride, TMA-C_2'-Thy: In 10 cm^3 of a 30% trimethylamine–ethanol solution, 0.5 g of 1-(2-chloroethyl)thymine was dissolved. The mixture was sealed in a thick glass tube and then heated at 80 °C for 70 h. A white precipitate was obtained after cooling. It was washed with ethanol and then dried (26% yield). Found: C, 43.26; H, 7.44; N, 15.29; Cl, 12.70%. Calcd for $C_{10}H_{18}N_3O_2Cl$: C, 47.74; H, 7.16, N, 16.70; Cl, 14.12%. NMR (D_2O) δ 7.92 (1H, s, 6 position of thymine), 4.74 (2H, t, 2 position of ethylene), 4.12 (2H, t, 1 position of ethylene), 3.69 (9H, s, trimethylammonium).

2-(Cytosin-1-yl)ethyltrimethylammonium Chloride, TMA-C_2'-Cyt: In 15 cm^3 of a 30% trimethylamine–ethanol solution, 0.2 g of 1-(2-chloroethyl)cytosine was dissolved. The mixture was sealed in a thick glass tube and then heated at 80 °C for 72 h. Pale yellow needles were filtered out, washed with ethanol, and then dried (52% yield). Found: C, 45.45; H, 7.37; N, 23.89; Cl, 14.96%. Calcd for $C_9H_{17}N_4OCl$: C, 46.45; H, 7.31; N, 24.09; Cl, 15.27%. NMR (D_2O) δ 7.98 (1H, d, 6 position of cytosine), 6.30 (1H, d, 5 position of cytosine), 4.49 (2H, t, 2 position of ethylene), 3.86 (2H, t, 1 position of ethylene), 3.41 (9H, s, trimethylammonium).

1-[2-(Adenin-9-yl)ethyl]pyridinium Bromide, Py-C_2'-Ade: In 2 cm^3 of a freshly distilled pyridine, 0.11 g of 9-(2-bromoethyl)-adenine was dissolved. The mixture was sealed under nitrogen and then heated in boiling water for 78 h. A white precipitate was filtered out, washed with ethyl acetate, and then dried (28% yield). Found: C, 44.80; H, 3.97; N, 26.02; Br, 25.03%. Calcd for $C_{12}H_{13}N_6Br$: C, 44.87; H, 4.08; N, 26.17; Br, 24.88%. NMR (D_2O) δ 8.86 (2H, d, α proton of pyridinium), 8.80 (1H, dd, γ proton of pyridinium), 8.29 (1H, s, 8 position of adenine), 8.18 (2H, dd, β proton of pyridinium), 8.10 (1H, s, 2 position of adenine), 5.29 (2H, t, 2 position of ethylene), 5.02 (2H, t, 1 position of ethylene).

1-[2-(Thymin-1-yl)ethyl]pyridinium Chloride, Py-C_2'-Thy: In 5 cm^3 of a freshly distilled pyridine, 0.1 g of 1-(2-chloroethyl)-thymine was dissolved. The mixture was then refluxed on a steam bath for 5 h. White needle crystals were obtained after cooling. They were washed with ethanol and then dried (17% yield). Found: C, 52.33; H, 5.34; N, 15.14; Cl, 13.15%. Calcd for $C_{12}H_{14}N_3O_2Cl$: C, 53.84; H, 5.27, N, 15.70; Cl, 13.24%. NMR (D_2O) δ 9.09 (2H, d, α proton of pyridinium), 8.82 (1H, dd, γ proton of pyridinium), 8.30 (2H, dd, β proton of pyridinium), 7.57 (1H, s, 6 position of thymine), 5.09 (2H, t, 2 position of ethylene), 4.05 (2H, t, 1 position of ethylene).

(Adenosin-5′-yl)trimethylammonium Chloride, TMA-Ado: In 15 cm^3 of a 30% trimethylamine–ethanol solution, 0.2 g of 5′-chloro-5′-deoxyadenosine was dissolved. The mixture was sealed in a thick glass tube and then heated at 55 °C for 70 h. A white precipitate was filtered, washed with ethanol, and then dried (38% yield). Found: C, 45.63; H, 6.35; N, 23.96; Cl, 10.43%. Calcd for $C_{13}H_{21}N_6O_3Cl$: C, 45.28; H, 6.10; N, 24.38; Cl, 10.30%. NMR (D_2O) δ 8.16 (1H, s, 8 position of adenine), 8.14 (1H, s, 2 position of adenine), 3.18 (9H, s, trimethylammonium).

(Uridin-5′-yl)trimethylammonium Bromide, TMA-Urd: In 20 cm^3 of a 30% trimethylamine–ethanol solution, 0.7 g of 5′-bromo-5′-deoxyuridine was dissolved. The mixture was sealed in a thick glass tube and then heated at 55 °C for 70 h. A white precipitate was filtered, washed with ethanol, and then dried (12% yield). Found: C, 38.74; H, 5.65; N, 10.96; Br, 22.36%. Calcd for $C_{12}H_{20}N_3O_5Br$: C, 39.36; H, 5.74; N, 11.48; Br, 21.84%. NMR (D_2O) δ 7.50 (1H, d, 6 position of uracil), 6.82 (1H, d, 5 position of uracil), 3.19 (9H, s, trimethylammonium).

UV Measurements. The measurements were carried out in water at 15 °C. The pH of the unbuffered solutions was 5.4—5.6. Absorbances were obtained in a 10-mm quartz cell. The apparent hypochromicity was calculated according to the following equation:[10]

$$\% \text{ Hypochromicity} = \left(1 - \frac{I_{a+b}}{mI_a + nI_b}\right) \times 100$$

where m and n are the volume fractions of the solutions of Compounds a and b, and where I_a, I_b, and I_{a+b} are the absorbances of the solutions of Compound a, Compound b, and the mixture of Compounds a and b respectively.

The authors are indebted to Prof. Kenichi Fukui for his encouragement. This investigation was supported by a Grant-in-Aid of the Ministry of Education.

A Synthesis of 7α-Methoxycephalosporins through Selenenamides

Takeo KOBAYASHI and Tetsuo HIRAOKA*

Central Research Laboratories, Sankyo Co., Ltd., 1-2-58, Hiromachi, Shinagawa-ku, Tokyo 140

(Received April 16, 1979)

The *o*-nitrobenzeneselenenamides were oxidized with active manganese dioxide to give the imines, which were converted to the 7α-methoxycephalosporins **3** by the reaction with lithium methoxide. The selenenamides **3** were acylated with phenoxyacetyl chloride to afford the desired cephamycin derivatives **4** *via* tertiary amide **5**, which was not isolable. This methoxylation reaction was also carried out in penicillin series to give the desired 6α-methoxypenicillin **8** although the ring opening compound **9** was a major product. The difference between sulfenamides and selenenamides in their acylation reactions was discussed.

Much attention has been focused on 7α-methoxycephalosporins after isolation of cephamycins from cultures of *streptomyces* species[1] and subsequent modification of the original compound to those with enhanced activity.[2] Several methods have been developed for introduction of a methoxyl group at the seven position of cephalosporins starting from 7-aminocephalosporins or 7-acylaminocephalosporins.[3] However, some difficulties still remain in the synthesis of 7α-methoxycephalosporins having a complex 7β-acylamino side chain.[4] Recently, we have shown that 7β-sulfenamidocephalosporins and 7β-sulfinamidocephalosporins were converted to 7α-methoxycephalosporins *via* the intermediacy of novel 7-sulfenylimine β-lactams.[5]

As a part of program to device a new method for introduction of a methoxyl group at the seven position of cephalosporins, we were interested in a synthesis of an analog of the sulfenamide in which the sulfur atom is suitably substituted by selenium atom. We now describe a method for a synthesis of 7α-methoxycephalosporins utilizing selenenamidocephalosporins *via* selenenylimine intermediates.

The chemistry of selenenamides (amide of selenenic acid) has been little studied and only a very limited number of examples of this class are known[6-8] owing to the lack of the stabilities of those compounds. In view of the scope and limitations of selenenamides, a study of selenenamidocephalosporins is of considerable interest. A recent study of selenenamides has suggested that the Se–N bond is hydrolyzed slowly at room temperature and rapidly with acids or at an elevated temperature.[6] The method generally used for the preparation of selenenamides is the reaction of corresponding amines with selenenyl halides. Of several possible starting materials, first, we chose benzeneselenenamidocephalosporins. Treatment of *t*-butyl 7β-amino-3-methyl-3-cephem-4-carboxylate with benzeneselenenyl chloride in the presence of triethylamine gave a spot ascribable to the benzeneselenenamide **1c** on silica gel thin layer chromatography, by short time development, but this spot vanished on further development. The isolation of the benzeneselenenamide **1c** also failed by chromatography on silicic acid. Difficulty in isolation of benzeneselenenamide **1c** probably results from the known instability of Se–N bond.

It is frequently observed that benzeneselenenyl compounds without *o*-substituent exhibit properties differing from those of the corresponding *o*-substituted derivatives with higher stabilities.[9] Thus we examined *o*-nitrophenylselenenamidocephalosporin which has an electron-withdrawing group on the ortho position of the aromatic ring, expecting more stable Se–N bond. Treatment of *t*-butyl 7β-amino-3-methyl-3-cephem-4-carboxylate with *o*-nitrophenylselenenyl chloride in the presence of triethylamine afforded *o*-nitrophenylseleneamide **1a** in 79.0% yield after silica-gel chromatography. This procedure using ortho-nitrophenylselenenyl compound, also worked well in the case of benzhydryl 3-acetoxymethyl-7β-amino-3-cephem-4-carboxylate and *p*-bromophenacyl 6β-aminopenicillanate to give **1b** and **6** in 60.0% and 53.3% yields, respectively. When *p*-nitrophenylselenenyl bromide was used in place of *o*-nitrophenylselenenyl chloride in the reaction with *t*-butyl 7β-amino-3-methyl-3-cephem-4-carboxylate, a clear spot ascribable to the desired selenenamide was observed in thin layer chromatography; however, attempted isolation of selenenamide **1d** by chromatography on silica gel resulted in decomposition of the product. Thus the synthesis of selenenamides of cephalosporins and penicillin derivatives was successful only in *o*-nitrophenylselenenamide series.

Next our effort was directed to the conversion of selenenamides **1** to selenenylimines **2**. Only a few selenenylimines have been reported in the literature and they were prepared by addition of benzeneselenenyl and *p*-nitrophenylselenenyl chlorides to 1,1-di-*p*-tolylmethanimine in the presence of triethylamine.[8] These crystalline selenenylimines were observed to decompose to an oil after several weeks under nitrogen in the dark. So, we had a great concern about the stability of the selenenyliminocephalosporins. Treatment of *o*-nitrophenylselenenamidocephalosporins **1a** and **1b** with active manganese dioxide in benzene solution according to the sulfenamide oxidation[5a] gave the corresponding selenenyliminocephalosporins **2a** and **2b** in 60.0% and 41.0% yields, respectively, which were crystalline solids and stable on exposure to air at room temperature for several weeks. The structure of the imines **2a** and **2b** was unambiguous on the basis of their NMR spectra which showed a sharp singlet at 5.32 and 5.42 ppm, respectively, due to the hydrogen at the six position. In the penicillin series the reaction leading to the selenenylimine took place similarly as in the cephalosporin series. Thus, the reaction of the selenenamidopenicillin **6** with active manganese dioxide gave the selenenyliminopenicillin **7** as an amorphous solid in 49.7% yield, which was also stable under the same conditions as the selenenylimines of cephalosporins.

Treatment of the selenenylimines **2a** and **2b** with

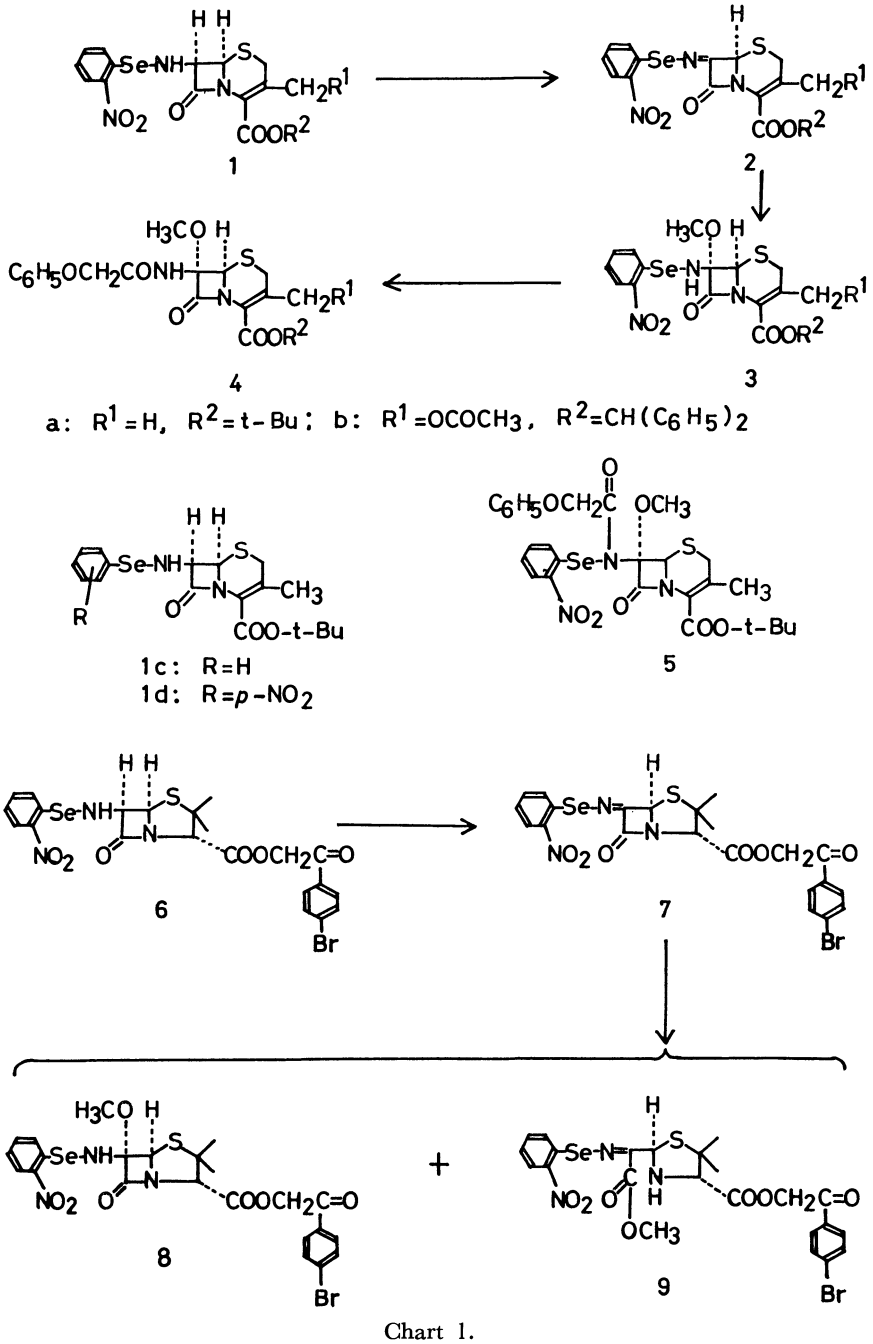

Chart 1.

excess of lithium methoxide in methanol and tetrahydrofuran at −78 °C for 3 h afforded 7α-methoxyselenenamidocephalosporins **3a** and **3b** in 87.1% and 21.6% yields, respectively. The low yield of **3b** was due to the production of 2-cephem isomer (benzhydryl 3-acetoxymethyl-7α-methoxy-7β-*o*-nitrophenylselenenylamino-2-cephem-4-carboxylate) (26.8%), whose formation was frequently observed in the compound having 3-acetoxymethyl group in a basic medium. As in the case of the sulfenyliminocephalosporins[5a] only α-methoxy isomers were obtained by attack of methoxide anion from less hindered α-face of the molecules. Methoxylation of the selenenyliminopenicillin **7** under the same reaction conditions gave the desired 6α-methoxy-6β-(selenenylamino)-penicillin **8** only in 8.8% yield together with the ring opened diester **9** (79.9%) as a major product. It should be noted that the ratio of **8**/**9** (8.8/79.9) was significantly small as compared with the case of the corresponding sulfenyliminopenicillin in which the ratio of the methoxylated product to the ring cleaved compound was 30.9/58.4. This difference might arise from the less effective overlapping of the d-orbital of the selenium of the compound **7** with the imine part and *o*-nitrobenzene ring. Thus, electrophilicity at the six position of **7** would decrease as compared with the corresponding sulfenyliminopenicillin. We should also note that the ring opened selenenylimine **9** was not attacked by methoxide any more.

Acylation of 7α-methoxyselenenamide **3a** with phenoxyacetyl chloride in dichloromethane in the absence of any base gave **5** judging from silica gel thin

a) the reaction was checked by silica gel TLC plate
b) isolated yield

layer chromatography, which showed a less polar spot ascribable to the tertiary amide **5**. Attempted purification of **5** by chromatography on silica gel resulted in decomposition. Therefore the obtained compound was used in the subsequent reaction without further purification. The crude compound **5** was treated with lithium methoxide or sodium benzenethiolate to furnish 7α-methoxy-7β-phenoxyacetamidocephalosporin **4** in 18% and 15% yields, respectively. The physical properties of **4** were identical in all respects with an authentic sample.[5]

A comparison of selenenamidocephalosporins with sulfenamidocephalosporins in the reaction with an acyl chloride is interesting in connection with the bonding character between nitrogen and sulfur or selenium. Thus we examined the reaction of sulfenamides and selenenamide with phenoxyacetyl chloride in dichloromethane. Results are summarized in Table 1. *o*-Nitrophenylselenenamide **1a** was found to be more reactive than *p*-nitrophenylsulfenamide **10b**, which was the most reactive in the sulfenamide series. Namely, ortho-substituted benzenesulfenamides **10a** and **10c** did not react with phenoxyacetyl chloride, while the *p*-nitro derivative **10b**, was easily converted into phenoxyacetamide **11**, and in the case of the selenenamide ortho-substitution gave no effect on the reaction with phenoxyacetyl chloride to afford the desired amide **11** with great ease without detection of the tertiary amide corresponding to **5**.

Although the Se–N bond in selenenamide is generally unstable and sensitive to nucleophiles, the method *via* the intermediacy of selenenyliminocephalosporins provides a versatile and useful alternative to functionalization at the 7(6) position of cephalosporins (penicillins).

Experimental

All melting points are not corrected. IR spectra were recorded on a JASCO A-2 spectrometer. NMR spectra were measured on Hitachi R-24 spectrometer using tetramethylsilane as an internal standard. The abbreviations in the NMR spectra are as follows: s, singlet; bs, broad singlet; d, doublet; dd, doublet of doublets; q, quartet; m, multiplet.

*t-Butyl 3-Methyl-7β-o-nitrophenylselenenylamino-3-cephem-4-carboxylate (**1a**).* A solution of *t*-butyl 7β-amino-3-methyl-3-cephem-4-carboxylate (6.50 g, 24 mmol) and triethylamine (3.36 ml, 24 mmol) in chloroform (150 ml) was stirred and cooled to 0—5 °C. To this solution was added *o*-nitrophenylselenenyl chloride (4.73 g, 20 mmol) dissolved in chloroform (50 ml) over a period of 10 min. The mixture was then stirred for an additional 2 h at 0—5 °C. The mixture was diluted with ethyl acetate, washed successively with saturated $NaHCO_3$ solution and water. Evaporation of the dried ($MgSO_4$) organic phase *in vacuo* provided a residue, which was chromatographed on silica gel using benzene–EtOAc (10:1) to give *o*-nitrophenylselenenamide **1a** (7.25 g, 79.0%) as yellow crystals. **1a**: mp 133—134 °C (EtOAc–diisopropyl ether); IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.55 (9H, s), 2.10 (3H, s), 3.35 and 3.60 (2H, ABq, J=18 Hz), 3.53 (1H, d, J=13.5 Hz), 4.95 (1H, dd, J=13.5 and 4.5 Hz), 5.08 (1H, d, J=4.5 Hz), 7.3—8.7 (4H, m).

*Benzhydryl 3-Acetoxymethyl-7β-o-nitrophenylselenenylamino-3-cephem-4-carboxylate (**1b**).* To a mixture of benzhydryl 7β-amino-3-acetoxymethyl-3-cephem-4-carboxylate hydrochloride (10.4 g, 22 mmol) and triethylamine (5.85 ml, 42 mmol) in dry chloroform (150 ml) under nitrogen was added *o*-nitrophenylselenenyl chloride (4.73 g, 20 mmol) in chloroform (25 ml) at 0—5 °C over a period of 10 min. The mixture was stirred for 3 h at 0—5 °C, and then EtOAc was added. The organic phase was washed with saturated $NaHCO_3$ solution and water, dried over $MgSO_4$, and evaporated *in vacuo* to give a residue. Subsequent chromatography on silica gel using benzene–EtOAc (10 : 1) provided *o*-nitrophenylselenenamide **1b** (7.61 g, 60.0%) as yellow crystals: **1b**: mp 124—125 °C ($CHCl_3$–diisopropyl ether); IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.90 (3H, s), 3.35 and 3.50 (2H, ABq, J=18 Hz), 3.50 (1H, d, J=13.5 Hz), 4.75 and 4.98 (2H, ABq, J=13.5 Hz), 4.90 (1H, dd, J=13.5 and 4.5 Hz), 4.93 (1H, d, J=4.5 Hz), 6.97 (1H, s), 7.1—8.5 (14H, m).

p-*Bromophenacyl 6β-o-Nitrophenylselenenylaminopenicillanate (6).* To a stirred solution of *p*-bromophenacyl 6β-aminopenicillanate hydrochloride (4.95 g, 11 mmol) and triethylamine (2.79 ml, 20 mmol) in $CHCl_3$ (75 ml) was added a solution of *o*-nitrophenylselenenyl chloride (2.36 g, 20 mmol) in $CHCl_3$ (25 ml) at 0 °C. After 3 h at 0 °C, EtOAc was added and organic solution was washed successively with saturated $NaHCO_3$ solution and water, and then dried ($MgSO_4$). Evaporation of the organic part and chromatography of the residue using benzene–EtOAc (5 : 1) afforded *o*-nitrophenylselenenamide **6** (3.27 g, 53.3%) as amorphous solid. **6**: IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.73 (3H, s), 1.77 (3H, s), 3.58 (1H, d, J=12 Hz), 4.63 (1H, s), 4.75 (1H, dd, J=12 and 4.5 Hz), 5.38 and 5.53 (2H, ABq, J=16.5 Hz), 5.65 (1H, d, J=4.5 Hz), 7.3—8.6 (8H, m).

t-*Butyl 3-Methyl-7-o-nitrophenylselenenylimino-3-cephem-4-carboxylate (2a).* To a solution of selenenamide **1a** (2.0 g, 4.25 mmol) in benzene (100 ml) was added active manganese dioxide (100 g) at room temperature and reaction mixture was stirred at room temperature for 60 min. The solid substance was filtered off, washed with benzene, and evaporation of the combined filtrates *in vacuo* afforded selenenylimine **2a** (1.20 g, 60.0%) which was practically pure judging by NMR and used for the next step without any purification. **2a**: mp 185—186 °C ($CHCl_3$–diisopropyl ether); IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.58 (9H, s), 2.17 (3H, s), 3.25 and 3.52 (2H, ABq, J=18 Hz), 5.32 (1H, s), 7.2—8.8 (4H, m).

Benzhydryl 3-Acetoxymethyl-7-o-nitrophenylselenenylimino-3-cephem-4-carboxylate (2b). A solution of selenenamide **1b** (2.3 g, 3.6 mmol) in benzene (100 ml) was stirred at room temperature with active manganese dioxide (115 g). After 1 h the reaction mixture was filtered and active manganese dioxide was washed with benzene. The combined filtrates were evaporated *in vacuo* to give selenenylimine **2b** (944 mg, 41.0%), which was pure judging by NMR and used in the next reaction without further purification. **2b**: mp 126—127 °C (EtOAc–diisopropyl ether); IR ($CHCl_3$) 1790 cm^{-1}; NMR ($CDCl_3$) δ=2.03 (3H, s), 3.45 and 3.61 (2H, ABq, J=18 Hz), 4.90 and 5.08 (2H, ABq, J=13.5 Hz), 5.42 (1H, s), 6.26 (1H, s), 7.3—8.9 (14H, m).

p-*Bromophenacyl 6-o-Nitrophenylselenenyliminopenicillanate (7).* A solution of selenenamide **6** (1.0 g, 1.63 mmol) in benzene (50 ml) was stirred at room temperature with active manganese dioxide (50 g) for 60 min. Active manganese dioxide was filtered off and the filtrate was evaporated *in vacuo* to give selenenylimine **7** (497 mg, 49.7%), which was found to be pure by NMR and used in the subsequent reaction without further purification. **7**: amorphous solid; IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.60 (3H, s), 1.67 (3H, s), 4.85 (1H, s), 5.50 (2H, s), 5.98 (1H, s), 7.3—8.8 (8H, m).

t-*Butyl 7α-Methoxy-3-methyl-7β-o-nitrophenylselenenylamino-3-cephem-4-carboxylate (3a).* A stirred solution of selenenylimine **2a** (939 mg, 2.0 mmol) in dry MeOH (30 ml) and dry THF (60 ml) was cooled to −78 °C, and lithium methoxide (prepared from 77 mg of lithium, 11 mmol) in dry MeOH (10 ml) was added with vigorous stirring. The mixture was stirred for 3 h at −78 °C, and then glacial AcOH was added. After dilution with EtOAc, the organic solution was washed successively with water, saturated $NaHCO_3$ solution, and water, dried ($MgSO_4$) and evaporated *in vacuo* to afford a residue. Purification by chromatography on silica gel using benzene–EtOAc (10:1) gave 7α-methoxyselenenamide **3a** (870 mg, 87.1%) as a yellow oil. **3a**: IR ($CHCl_3$) 1770 cm^{-1}; NMR ($CDCl_3$) δ=1.50 (9H, s), 2.12 (3H, s), 3.18 and 3.35 (2H, ABq, J=18 Hz), 3.58 (3H, s), 4.18 (1H, s), 4.93 (1H, s), 7.2—8.6 (4H, m).

Benzhydryl 3-Acetoxymethyl-7α-methoxy-7β-o-nitrophenylselenenylamino-3-cephem-4-carboxylate (3b). To a solution of selenenylimine **2b** (204 mg, 0.32 mmol) in dry MeOH (5 ml) and dry THF (10 ml) was added lithium methoxide in methanol (5 ml) (from 14.7 mg of lithium, 2.1 mmol) at −78 °C and the solution was vigorously stirred for 3 h. The reaction mixture was quenched with glacial AcOH and diluted with EtOAc. The organic solution was washed with water, aqueous $NaHCO_3$, and again water. Evaporation of the solvents (dried over $MgSO_4$) and chromatography of the residue gave 7α-methoxy-*o*-nitrophenylselenenamide **3b** (46.0 mg, 21.6%; R_f=0.39: benzene–EtOAc 10:1) and benzhydryl 3-acetoxymethyl-7α-methoxy-7β-*o*-nitrophenylselenenylamino-2-cephem-4-carboxylate (57.3 mg, 26.8%; R_f=0.33: benzene–EtOAc 10:1), which were eluted from the column with benzene–EtOAc (10:1). **3b**: yellow oil; IR ($CHCl_3$) 1770 cm^{-1}; NMR ($CDCl_3$) δ=2.05 (3H, s), 3.38 and 3.53 (2H, ABq, J=18 Hz), 3.63 (3H, s), 4.33 (1H, s), 4.90 and 5.03 (2H, ABq, J=13.5 Hz), 4.98 (1H, s), 7.03 (1H, s), 7.3—8.7 (14H, m). Benzhydryl 3-acetoxymethyl-7α-methoxy-7β-*o*-nitrophenylselenenylamino-2-cephem-4-carboxylate: yellow oil: IR ($CHCl_3$) 1775 cm^{-1}; NMR ($CDCl_3$) δ=1.97 (3H, s), 3.50 (3H, s), 4.22 (1H, s), 4.67 (2H, bs), 5.22 (2H, s), 6.48 (1H, bs), 6.98 (1H, s), 7.2—8.6 (14H, m).

p-*Bromophenacyl 6α-Methoxy-6β-nitrophenylselenenylaminopenicillanate (8).* To a cold solution of selenenylimine **7** (201 mg, 0.33 mmol) in dry MeOH (5 ml) and dry THF (10 ml) was added lithium methoxide (prepared from 17.4 mg of lithium, 2.5 mmol) in dry MeOH (5 ml) at −78 °C. After vigorous stirring for 3 h, glacial AcOH was added. After dilution with EtOAc the organic solution was washed successively with water, saturated $NaHCO_3$ solution, and again water. The organic phase was dried ($MgSO_4$), evaporated, and the residue was chromatographed on silica gel. 7α-Methoxy-*o*-nitrophenylselenenamide **8** (18.7 mg, 8.84%; R_f=0.47: benzene–EtOAc 5:1) and diester **9** (169 mg, 79.9%, R_f=0.56: benzene–EtOAc 5:1) were eluted with benzene–EtOAc (5:1). **8**: yellow oil; IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.58 (3H, s), 1.62 (3H, s), 3.53 (3H, s), 4.28 (1H, s), 4.67 (1H, s), 5.40 (2H, s), 5.48 (1H, s), 7.3—8.7 (8H, m). **9**: yellow oil; IR ($CHCl_3$) 1755 cm^{-1}; NMR ($CDCl_3$)[10] δ=1.49 (3H, s), 1.63 (3H, s), 3.98 (3H, s), 4.26 (1H, s), 5.59 (2H, s), 5.93 (1H, s), 7.2—8.9 (8H, m).

t-*Butyl 7α-Methoxy-3-methyl-7β-phenoxyacetamido-3-cephem-4-carboxylate (4).* To a solution of 7α-methoxyselenenamide **3a** (50.0 mg, 0.10 mmol) in CH_2Cl_2 (5 ml) was added phenoxyacetyl chloride (0.08 ml, 0.58 mmol). The mixture was stirred for 3 h at room temperature and then the solvent was evaporated. The residue was dissolved again in dry THF (5 ml), and lithium methoxide (prepared from 8 mg of lithium, 1.2 mmol) in dry MeOH (3 ml) was added. The reaction mixture was stirred vigorously at −78 °C for 2.5 h, and quenched with glacial AcOH. After dilution with EtOAc the organic solution was washed with water, aqueous $NaHCO_3$, and water, and dried over $MgSO_4$. Evaporation of the solvents *in vacuo* and chromatography (solvent: benzene–EtOAc 10:1) afforded phenoxyacetamide **4** (8.0 mg, 18.0%). **4**: IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.53 (9H, s), 2.12 (3H, s), 3.08 and 3.33 (2H, ABq, J=18 Hz), 3.55 (3H, s), 4.60 (2H, s), 5.07 (1H, s), 6.8—7.5 (6H, m).

t-*Butyl 3-Methyl-7β-phenoxyacetamido-3-cephem-4-carboxylate (11).* A stirred solution of *t*-butyl 3-methyl-7β-*o*-nitrophenylselenenylamino-3-cephem-4-carboxylate **1a** (47.8

mg, 0.10 mmol) in dry dichloromethane (5 ml) was cooled to 0 °C, and phenoxyacetyl chloride (0.06 ml, 0.35 mmol) was added under vigorous stirring. The mixture was stirred 30 min at 0 °C. Evaporation of the solvent *in vacuo* gave a residue, which was purified by preparative chromatography on silica gel to provide 7β-phenoxyacetamide **11** (38.2 mg, 92.9%) using benzene–EtOAc (5:1). **11**: oil: IR ($CHCl_3$) 1780 cm^{-1}; NMR ($CDCl_3$) δ=1.53 (9H, s), 2.10 (3H, s), 3.15 and 3.50 (2H, ABq, J=19 Hz), 4.57 (2H, s), 5.01 (1H, d, J=4.5 Hz), 5.85 (1H, dd, J=4.5 and 10 Hz), 6.8—7.8 (6H, m).

We are grateful to Dr. Y. Kishida, the director of chemical research, for his encouragement through this work.

Enantioface-differentiating Reactions Using (2*S*,2′*S*)-2-Hydroxymethyl-1-[(1-alkyl-2-pyrrolidinyl)methyl]pyrrolidines as Chiral Ligands. Addition of Lithium Derivatives of Methyl Phenyl Sulfide, Acetonitrile, *N*-Nitrosodimethylamine, and 2-Methylthiothiazoline to Aldehydes

Kenso SOAI and Teruaki MUKAIYAMA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

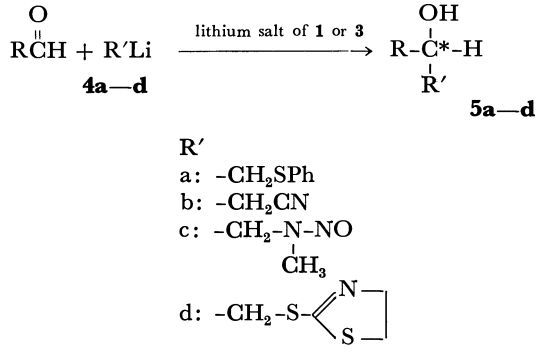
(Received May 2, 1979)

Optically active oxiranes, β-hydroxy nitrile, β-hydroxy *N*-nitrosoamine, and thiirane were obtained (up to 72% optical purity) by the enantioface-differentiating addition of lithium derivatives of methyl phenyl sulfide, acetonitrile, *N*-nitrosodimethylamine, and 2-methylthiothiazoline to aldehydes using (2*S*,2′*S*)-2-hydroxymethyl-1-[(1-alkyl-2-pyrrolidinyl)methyl]pyrrolidines (**1a**—**f**) as chiral ligands. Optical purity of the products depended greatly on the reaction medium (dimethoxymethane or dimethyl ether gave the best results) and the structure of pyrrolidine moieties of **1a**—**f**.)

One of the current interests in organic chemistry is asymmetric syntheses, and recently there have been many investigations reported on various types of asymmetric synthesis.[1] Among these, *enantioselective* reactions are one of the most difficult problems.

Concerning the enantioselective asymmetric reactions of organolithium compounds, several reports have been given on asymmetric reductions using metal hydride complexes.[2] However, on the *enantioselective* addition of organolithium compounds to aldehydes, very few investigations have been reported.[3] Recently, (+)-2,3-dimethoxy-*N*,*N*,*N*′,*N*′-tetramethyl-1,4-butanediamine (**2**) was reported as an effective chiral ligand for the enantioface-differentiating addition of butyllithium to aldehydes by Seebach *et al.*[4] In the synthesis, the highest optical yield of the alcohols obtained is 40%, probably due to the rather weak interaction of the chiral ligand **2** with the reactants.

In the preceding papers,[5] it was shown that **1** and (2*S*,2′*S*,2″*S*)-2-hydroxymethyl-1-[[1-[(1-methyl-2-pyrrolidinyl)methyl]-2-pyrrolidinyl]methyl]pyrrolidine (**3**), easily derived from (*S*)-proline, are very effective chiral ligands for the enantioface-differentiating addition of alkyl-, alkynyllithium, and dialkylmagnesium to aldehydes, and that the corresponding secondary alcohols of very high optical purity are obtained (Fig. 1). The explosive increase of the use of lithium compounds in organic synthesis[6] during the last decade prompted us to extend the above enantioface-differentiating reaction to addition of some lithium derivatives of various functionalized organic compounds such as methyl phenyl sulfide, acetonitrile, *N*-nitrosodimethylamine, and 2-methylthiothiazoline (Eq. 1).

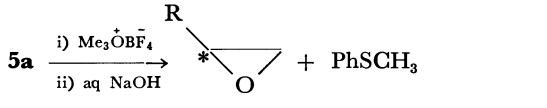


(1)

In this paper, we wish to describe the scope and limitations of the enantioface-differentiating additions of these functionalized lithium compounds to aldehydes.

Optically active **5a**—**d** are known to be converted respectively to the corresponding optically active compounds (oxirane, thiirane, *etc.*). The conventional methods are as follows.

Optically active β-hydroxy sulfides (**5a**) can be converted to optically active oxiranes with little racemization by the use of trimethyloxonium tetrafluoroborate and aq sodium hydroxide (Eq. 2).[7a]



(2)

Since optically active oxiranes play an important role in metabolic processes,[8] many attempts have been reported on the asymmetric syntheses of the oxiranes.[9] For example, epoxidation of olefins by optically active peroxy acids,[9a] or by hydrogen peroxide in the presence of an optically active phase transfer catalyst,[9b] nucleophilic alkylidene transfer by optically active oxosulfonium ylides,[9c] and optically active metal complex catalyzed epoxidation of allylic alcohols with alkyl hydroperoxide,[9d] however, optical yields of oxiranes obtained by these methods are not high in general (maximum 50% e.e.[9d]).

As to the formation of β-hydroxy nitrile (**5b**), a report was given in 1974 utilizing aldehydes and the

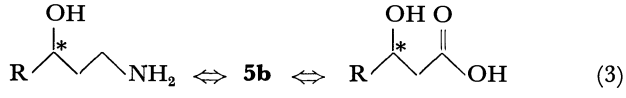
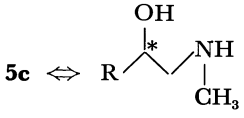
lithium salt of **1a**. It was also found that the enantiomeric excess of **8** depended on the concentrations and β-hydroxy carboxylic acid (Eq. 3), no report has appeared on the asymmetric synthesis of **5b** itself, to our knowledge.



(3)

Moreover **5c** is obtained by the reaction of aldehydes and the lithium derivative of *N*-nitrosodimethylamine, a masked nucleophilic α-(alkylamino)methylating reagent[11] (Eq. 4).



Halostahine **11**
(R=Ph)

(4)

Seebach *et al.* reported the asymmetric synthesis of **5c** (15% optical purity) by the enantioface-differentiating addition of **4c** to benzaldehyde using **2** as a chiral media.[6]

The compound **5d** is known as an intermediate for the formation of thiirane.[12] Concerning the asymmetric synthesis of thiirane, there have been two methods reported, namely, (a) the reaction of chiral 2-methylthiooxazoline (**6**)[13a] and (b) the reaction utilizing the chiral lithiocarboxylate (**7**).[13b] Reactants possessing a chiral moiety are employed in both methods (a) and (b), and as yet no method for the preparation of optically active thiiranes by enantioface-differentiating reactions utilizing chiral ligands has been reported. Therefore this report deals with the first example of enantioface-differentiating reactions using chiral ligands.

Results and Discussion

Oxiranes. As for the generation of phenylthiomethyllithium (**4a**) from methyl phenyl sulfide, Corey and Seebach reported a method using 1,4-diazabicyclo-[2.2.2]octane (DABCO).[14] However, it was found in the preliminary study, that the reaction of equimolar amounts of methyl phenyl sulfide, butyllithium, and the lithium salt of (2*S*,2′*S*)-2-hydroxymethyl-1-[(1-methyl-2-pyrrolidinyl)methyl]pyrrolidine (**1a**) in THF at 0 °C for 45 min or in dimethoxymethane at 0 °C overnight produced **4a** in 95% yield, as determined by subsequent quenching with deuterium oxide and quantitative NMR analysis.

To a mixture of **4a** and the lithium salt of **1a**, formed under the above reaction conditions, benzaldehyde in various solvents was added at low temperatures (−78—−123 °C), and the reaction mixture was stirred for 1 h. Usual work-up gave 1-phenyl-2-phenylthioethanol (**8**), of which enantiomeric excess was determined by quantitative analysis of NMR spectra of the corresponding esters of (+)-α-methoxy-α-trifluoromethylphenylacetic acid (Table 1).

As shown in Table 1, effects of solvents were remarkable. The best result was obtained when the reaction was carried out in dimethoxymethane (entry 6). Moreover it is noted that the enantiomeric excesses of the alcohols obtained became higher as the solvating ability of the reaction media increased (entry 1, 2, and 3), and this tendency was the same as that of alkyllithium, reported in the preceding papers.[5b,d] This might suggest that solvation plays an important role in the formation of the complex of **4a** and the

J. L. Coke and A. B. Richon, *J. Org. Chem.*, **41**, 3516 (1976).

lithium derivative of acetonitrile.[10)] Though **5b** is a synthetic equivalent to optically active γ-amino alcohol of the reactants (entry 6, 7, and 8), and that the most suitable concentration of benzaldehyde was found to be 5 M (entry 6). In the preceding paper[5)] it was shown that optical purity of secondary alcohols obtained by asymmetric addition of alkyllithium or dialkylmagnesium to aldehydes are greatly influenced by the structure of chiral ligands. Therefore we examined asymmetric addition of **4a** to benzaldehyde in dimethoxymethane using various kinds of chiral ligands (**1a**—**d**, **3**). (Table 2).

The highest enantiomeric excess (72% e.e.) of **8** was achieved by the use of (2*S*,2′*S*)-2-hydroxymethyl-1-[(1-neopentyl-2-pyrrolidinyl)methyl]pyrrolidine (**1c**) which has bulky neopentyl substituent at the nitrogen atom (entry 3). However, in this case, 1-phenyl-1-pentanol was also produced in 34% yield by the side reaction of butyllithium with benzaldehyde. These results suggest that steric hindrance of the neopentyl group at the nitrogen atom of **1c** decreased the rate of the formation of **4a**. After a number of unsuccessful attempts to develop a satisfactory method, we devised an excellent method; the formation of the complex of **4a** with **1c** was carried out in petroleum ether at 25—30 °C overnight, and the asymmetric addition was carried out at −100 °C after the substitution of petroleum ether for dimethoxymethane.

When benzaldehyde was employed under the above mentioned reaction conditions, optically active (+)-**8** was obtained in 83% yield $[\alpha]^{28}_D$ + 7.96° (c 8.7, CH_2Cl_2) and its enantiomeric ratio (84:16) was determined by quantitative NMR (100 MHz) analysis of the corresponding ester of (+)-α-methoxy-α-trifluoromethylphenylacetic acid. According to the procedure of Shanklin *et al.*,[7a)] the compound **8** thus obtained was converted without racemization to (*R*)-(+)-2-phenyloxirane (54%, $[\alpha]^{26}_D$ +4.5° (c 4.0, acetone), 68% optical purity).[7b)]

In a similar manner, several optically active 2-substituted oxiranes were obtained from the corresponding aldehydes and the results are summarized in Table 3.

Lithium Derivatives of Acetonitrile and N-*Nitrosodimethylamine.* It is well known that the abstraction of a proton from acetonitrile by butyllithium at −78 °C easily produces lithium derivatives (**4b**).[10)] The reaction conditions of the enantioface-differentiating addition of **4b** to benzaldehyde were studied by varying both, type of solvents and structure of chiral ligands. The results are summarized in Table 4.

The highest enantiomeric excess (40% e.e.) of β-hydroxy nitrile (**5b**) was achieved when the reaction was carried out in dimethyl ether at −123 °C using the lithium salt of **1d** as a chiral ligand (Table 4, entry 3).

As to the asymmetric addition of the lithium derivative of *N*-nitrosodimethylamine (**4c**) to benzaldehyde in dimethoxymethane at −100 °C, the corresponding 2-(*N*-nitrosomethylamino)-1-phenylethanol (**5c**)[15)] was

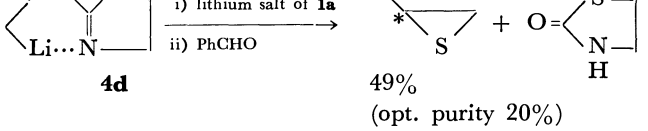
obtained in 96% yield ($[\alpha]_D^{25}$ +12.46°), and subsequent denitrosation gave 2-methylamino-1-phenylethanol (**11**) Halostahine, $[\alpha]_D^{24}$ +11.9° (*c* 1.68, EtOH), opt. purity 25%.[16]

The reason that enantiomeric excesses of the adducts **4b** and **4c** are not so high as those of the addition of alkyllithium as reported in the previous papers[5] may be explained as follows; it is clear that efficient complexes of lithium derivatives with chiral ligand should be tight and stable for achievement of higher enantioselectivity. It is also well known that ionic character of the lithium–carbon bond of lithium derivatives increases as the pK_a value of the parent compound decreases. Hence, the lithium–carbon bond of **4b** and **4c** becomes looser than that of alkyllithium. Therefore, the enantiomeric excesses of the adducts obtained may depend on the decrease in the stability of the chelated complexes of **4b** and **4c** with chiral ligand **1** as compared with that of alkyllithium.

Thiirane. Enantioface-differentiating addition of lithium compound (**4d**) to benzaldehyde was carried out in dimethoxymethane at −100 °C for 1 h in the presence of lithium salt of **1a**. The optical purity of the obtained (*R*)-(−)-2-methylthiirane was 20%[17] (Eq. 5).



4d 49% (opt. purity 20%) (5)

It is noticeable that **4d** has a rather rigid structure because of the coordination between the nitrogen atom and the lithium atom.[18]

This rigidity of **4d** may interfere in the formation of the complex between **4d** and the lithium salt of **1a**, and decreases enantioselectivity. Though optical purity of this procedure is comparable to that of the previously reported method using chiral **6**,[13a] this procedure has an advantage over previous methods in that there is no need to synthesize chiral thiazoline derivatives.

In conclusion, the chiral ligands **1** and **3**, easily prepared from (*S*)-proline, are efficient for the enantioface-differentiating addition of a wide variety of organolithium compounds to aldehydes. Optical yields of the various products thus obtained are higher than those illustrated in the previous methods. Furthermore, this method has an advantage over previous methods of asymmetric syntheses, in the simplicity of the reaction procedure, namely, there is no necessity of introducing and removing chiral moieties in the reactants at any stage.

Experimental

General. NMR spectra were taken on a Hitachi R-24B Spectrometer. Infrared spectra were taken on a Hitachi EPI-G2 spectrometer. Optical rotation was taken on a JASCO DIP-SL automatic polarimeter. THF, dimethoxyethane, dimethoxymethane, diethyl ether, and dipropyl ether were distilled from $LiAlH_4$ prior to use. Dimethyl ether was dried by passing the gas through a tube packed with calcium chloride. Reactions involving air-sensitive compounds were carried out under an atmosphere of argon. For evaporative bulb-to-bulb distillation, a Büchi Kugelrohrofen was used. According to the reported procedure,[5d] preparation of chiral ligands from (*S*)-proline and recovery of them after the asymmetric reactions were carried out.

*Asymmetric Addition of Phenylthiomethyllithium (**4a**) to Aldehydes Using **1c** as Chiral Ligand.* Methyl phenyl sulfide (0.670 g, 5.4 mmol) in 8 ml of petroleum ether (bp 37 °C) was added to a mixture of hexane (8.65 ml) solution of butyllithium (13.5 mmol) and petroleum ether (36 ml) solution of **1c** (2.057 g, 8.1 mmol) at 0 °C, and the mixture was stirred at room temperature (25—30 °C) for 17 h. Solvent was removed by evaporation with vacuum pump (1 mmHg) for 10 min at room temperature.[19] The residue was dissolved in 40 ml of dimethoxymethane, and was added a dimethoxymethane solution (4 ml) of benzaldehyde (0.212 g, 2 mmol) at −100 °C, and the stirring was continued for 1 h. The reaction was quenched with 3 M hydrochloric acid, extracted with ether and dried over Na_2SO_4. After removal of the solvent, the residue was purified by silica-gel TLC (CH_2Cl_2) and the isolated product was further purified by short-path distillation. 1-Phenyl-2-phenylthioethanol (**8**) (0.384 g, 83%, $[\alpha]_D^{28}$ +7.96° (*c* 8.7, CH_2Cl_2), optical yield

68%e.e.) was obtained as a yellow oil of which enantiomeric excess was determined according to Mosher's method.[20] In a similar manner, isobutyraldehyde and dodecanal were employed and the spectra data of the adducts were as follows; **8**; IR (neat) 3400, 3050, 2900, 1580, 1485, 1475, 1450, 1435, 1055, and 1025 cm^{-1}; NMR ($CDCl_3$) δ=2.77—3.30 (3H, m), 4.66 (1H, m) and 7.23 (10H, m). **9**; IR (neat) 3420, 3050, 2960, 2950, 2870, 1590, 1480, 1440, 1100, 1050, 1030, and 1000 cm^{-1}; NMR ($CDCl_3$) δ=0.90 (6H, d, J=6 Hz), 1.46—2.06 (1H, m), 2.30—3.65 (4H, m), and 7.16 (5H, m). **10**; Mp 52—53 °C IR (KBr) 3380, 2920, 2840, 1585, 1475, 1460, 1435, 1345, 1090, 1065, 1060, 735, 730, and 690 cm^{-1}, NMR ($CDCl_3$) δ=1.22—1.60 (23H, m), 2.44 (1H, broad), 2.75—3.35 (2H, m), and 3.70 (1H, m).

Optically Active 2-Substituted Oxiranes. According to the procedure of Shanklin *et al.*,[7a] **8a** was converted to 2-phenyloxirane (0.107 g, 54%, optical purity 68%).[7b] Optically active 2-undecyl oxirane was obtained in a similar manner. The structures of these compounds were identified by their IR and NMR spectra.

*Asymmetric Addition of Lithium Derivative of Acetonitrile to Benzaldehyde Using **1d**.* Diethyl ether (0.5 ml) solution of **1d** (0.915 g, 4.0 mmol) was added to dimethyl ether (20 ml) at −78 °C, and butyllithium (6.7 mmol) was added subsequently. After the reaction mixture was stirred for 15 min, acetonitrile (0.111 g, 2.7 mmol) in Et_2O (1 ml) was added. Stirring was continued for further 15 min, then benzaldehyde (0.106 g, 1.0 mmol) in Et_2O (1 ml) was added at −123 °C to the reaction mixture. After the mixture was stirred for 30 min, the reaction was quenched by adding 3 M hydrochloric acid, and the mixture was extracted with diethyl ether, dried over Na_2SO_4. The organic layer was concentrated under reduced pressure. The residue, subjected to preparative TLC on silica gel (CH_2Cl_2) yielded 3-hydroxy-3-phenylpropanenitrile (0.111 g, 76%), $[\alpha]_D^{18}$ +24.4° (c 4.1, CH_2Cl_2). The enantiomeric exess (40%e.e.) was determined by Mosher's method.[20] The structure was identified by IR and NMR.

*Asymmetric Addition of Lithium Derivative of N-Nitrosodimethylamine Using **1a** as Chiral Ligand.* Butyllithium (6.7 mmol) was added to dimethoxymethane (12 ml) solution of **1a** at 0 °C, and the mixture was stirred for 30 min. Then, *N*-nitrosodimethylamine[21] (0.200 g, 2.7 mmol) in dimethoxymethane (4 ml) was added to the mixture at −100 °C and the stirring was continued for 10 min. To the reaction mixture, benzaldehyde (0.106 g, 1.0 mmol) in dimethoxymethane (1.5 ml) was added at −100 °C. After the reaction mixture was stirred for 1.5 h, the reaction was quenched with water (5 ml), then the aqueous layer was adjusted to pH 5. The mixture was extracted with diethyl ether, and the extract was dried over anhydrous sodium sulfate. After the extract was concentrated under reduced pressure, the residue was purified by preparative TLC on silica gel [CH_2Cl_2–AcOEt (1 : 1)]. 2-(*N*-nitrosomethylamino)-1-phenylethanol (**5c**) (0.172 g, 96%, $[\alpha]_D^{25}$ +12.5° (c 5.8, CH_2Cl_2) was obtained which was further purified by short-path distillation. The structure of **5c** was identified by IR and NMR spectra.

*Halostahine (**11**).* According to the procedure of denitrosation[15] reported by Seebach and Enders, **5c** was converted to halostahine. $[\alpha]_D^{24}$ +11.9° (c 1.7, EtOH). Optical purity 25% [based upon the reported rotation $[\alpha]_D$ −47.03°].[16] Mp 74—75 °C [lit, 75—76 °C][16] IR (KBr) 3320, 1445, 1345, 1200, 1140, 1115, 1085, 1065, 930, 760, 750, and 700 cm^{-1}. NMR ($CDCl_3$) δ=2.40 (3H, 5), 2.72 (2H, d, J=6 Hz), 3.56 (2H, s), 4.75 (1H, t, J=6 Hz), and 7.34 (5H, s).

Asymmetric Addition of Lithium Derivative of 2-Methylthiothiazoline to Benzaldehyde. Butyllithium (6.7 mmol) was added to a dimethoxymethane (15 ml) solution of **1a** (0.803 g, 4.0 mmol) at 0 °C, and the mixture was stirred for 30 min. After the mixture was cooled to −78 °C, 2-methylthiothiazoline[22] (0.359 g, 2.7 mmol) in dimethoxymethane (2 ml) was added, and the stirring was continued for 1 h. Then, benzaldehyde (0.106 g, 1.0 mmol) in dimethoxymethane (2 ml) was added at −100 °C to the reaction mixture. The mixture was stirred for 1 h, the reaction was quenched with water (15 ml). Organic layer was extracted with ether, and the extract was dried over anhydrous sodium sulfate. After the concentration of the extract under reduced pressure, the residue was subjected to silica gel column chromatography (CH_2Cl_2) to remove chiral ligand **1a**. Further purification utilizing preparative silica-gel TLC (hexane) gave 2-phenylthiirane (0.067 g, 50%) $[\alpha]_D^{27}$ −8.8° (c 2.6, heptane). Optical purity 20% [based upon the reported value, lit $[\alpha]_D$ −43.85° (heptane)].[17] IR (neat) 2930, 1600, 1500, 1495, 1450, 1070, 1045, 760, 695, and 665 cm^{-1}, NMR ($CDCl_3$) δ= 2.43 (1H, dd, J=6 Hz, 2 Hz), 2.70 (1H, dd, J=6 Hz, 2 Hz), 3.70 (1H, t, J=6 Hz), and 7.05 (5H, s).

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

F-Propene-Dialkylamine Reaction Products as Fluorinating Agents

Akio TAKAOKA, Hiroshi IWAKIRI, and Nobuo ISHIKAWA*

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 15, 1979)

The reaction products of *F*-propene and dialkylamines, mixtures of α,α-difluoroalkylamine and α-fluoro enamine, were found to be useful fluorinating agents for alcohols and carboxylic acids. These reagents were superior to the adduct of chlorotrifluoroethene and diethylamine, the so-called Yarovenko reagent, for their readier preparation and higher stability.

2-Chloro-1,1,2-trifluorotriethylamine (**1**), the adduct of chlorotrifluoroethene and diethylamine, has been known as a useful fluorinating agent for alcohols.[1] This agent, which is sometimes called as "Yarovenko reagent,"[2] can replace a hydroxyl group with a fluorine atom under mild conditions and has been used especially for the syntheses of fluoro steroids.[1]

$$Et_2NH + CF_2{=}CFCl \longrightarrow \underset{\mathbf{1}}{Et_2NCF_2CHFCl}$$

$$ROH + \mathbf{1} \longrightarrow R\text{-}F + Et_2NC(=O)CHFCl + HF$$

However, the addition reaction of chlorotrifluoroethene with diethylamine to give (**1**) is not so easy and it requires rather long time in a sealed vessel in order to get a good yield. Further, the adduct (**1**) is not so stable at room temperature and it can not be stored more than a few days.

For the past several years, we have been studying on the nucleophilic reactions of *F*-propene and its oligomers, and it has been known that *F*-propene reacts with dialkylamines much more easily than with chlorotrifluoroethene. We now wish to report on the utility of the reaction products of the *F*-propene and dialkylamines as fluorinating agents of alcohols and carboxylic acids.

Results and Discussion

Reaction between F-*Propene and Dialkylamines.* Many years ago the nucleophilic reaction of *F*-propene with diethylamine giving addition and substitution products was reported by Knunyants *et al.*, though not in detail.[3] We carried out the reaction of *F*-propene with a number of secondary amines in diethyl ether, and determined the ratios of fluoroalkylamine (**2**) to fluoro enamine (**3**) from the signal intensities of ^{19}F NMR spectra.

$$R_2NH + CF_2{=}CFCF_3 \longrightarrow \underset{\mathbf{2}}{R_2NCF_2CHFCF_3} + \underset{\mathbf{3}}{\begin{matrix} R_2N & & F \\ & \diagdown\!\!=\!\!\diagup & \\ F & & CF_3 \end{matrix}}$$

The assignment of the NMR signals for **2** and **3** (R=Et) was done as shown in Fig. 1. Regarding the geometric isomers of **3**, only *E*-isomer was found in the product. Thus the F-F coupling constant was determined as 117 Hz (R=Et), which agrees to the expected value for *trans* F-F coupling constant, 109—131 Hz, and is quite different form that for *cis* F-F, 19—58 Hz.[4]

The formation of *E*-form rather than *Z*-form can

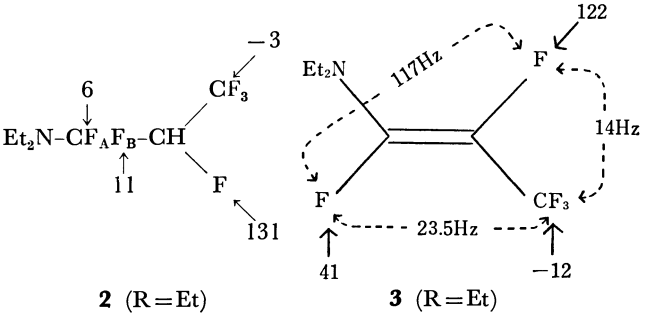

Fig. 1. The ^{19}F NMR spectra for **2** and **3** (R=Et). (Chemical shifts are given in δ ppm up field from external CF_3CO_2H).

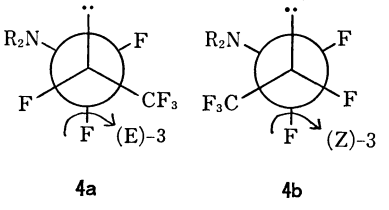
be explained by considering the conformation of the intermediate carbanion (**4**). The *E*-isomer should be formed by the *trans*-elimination of fluoride ion from **4a**, whereas the *Z*-isomer should be from **4b**. However, **4b** must be less stable than **4a** due to the electronic replusion between lone pair electrons of the nitrogen atom and those of the fluorine atom of CF_3. Thus the formation of (*E*)-**3** through **4a** would predominate over the formation of (*Z*)-**3** through **4b**. We have already observed similar phenomenon in the case of nucleophilic aryloxylation of *F*-propene.[5]

$$R_2NH + CF_2{=}CFX \longrightarrow \underset{\mathbf{4}}{R_2N\text{-}CF_2\text{-}\overline{C}FX}$$

$$\xrightarrow{+H^+} R_2N\text{-}CF_2\text{-}CHFX \quad (\mathbf{1}\ X=Cl_3;\ \mathbf{2}\ X=CF_3)$$

$$\xrightarrow{-F^-} R_2N\text{-}CF{=}CFX \quad (\mathbf{3}\ X=CF_3)$$



4a **4b**

As was shown in Table 1, the ratio **2** to **3** in the reaction products increased in the order of the bulkiness of the used amines, *i.e.*, piperazine<diethylamine< dibutylamine. Thus the bulkier the nucleophile is, the more enamine (**3**), which is more released from the steric hindrance than alkylamine (**2**), is formed.

Nucleophilic Reactivities and Reaction Products. Several methods for the preparation of **1**, the "Yarovenko reagent," were reported in the literature. A typical procedure is to have diethylamine and chlorotrifluoroethene react in a sealed vessel at room temperature for 48 h using dichloromethane as solvent[6]

Table 1. C_3F_6/R_2NH reaction products

R_2N	Product		
	Bp/°C (mmHg)	**2** : **3**[a]	Yield/%[b]
Et_2N	56—57(58)	3 : 1	72
n-Bu_2N	55—57(5)	2 : 1	78
Piperidino	49—50(7)	(2 only)	80

a) Determined by ^{19}F NMR. b) Isolated yield.

or without solvent.[7] Another procedure is to bubble chlorotrifluoroethene gas through diethylamine at atmospheric pressure.[2] However, we observed almost no reaction occurred by the latter procedure. In contrast, we found that *F*-propene reacted much more easily with diethylamine, and the perfluoroolefin was exothermally absorbed at room temperature by a solution of diethylamine in diethyl ether. As a result the reaction mixture itself could be used as a fluorinating agent without further purification by distillation.

The reaction product of *F*-propene and diethylamine was, as mentioned above, a mixture of fluoroalkylamine **2** and fluoro enamine **3** (R=Et), whereas that of chlorotrifluoroethene was almost pure fluoroalkylamine **1**. These facts can be explained by the difference between electronic effects of a Cl and a CF_3 group. Chlorine as a substituent group is known to manifest an electron-donative R-effect (or electron-repelling I_π effect by lone pairs) as well as an electron-withdrawing I_σ effect. On the other hand, a trifluoromethyl group behaves solely as an electron-withdrawing group by its strong negative I_σ effect. Therefore, the intermediate carbanion **4** (X=CF_3) formed by the reaction of *F*-propene and dialkylamine should be rather stable than that of chlorotrifluoroethene and dialkylamine, **4** (X=Cl). These effects should result in the higher reactivity of *F*-propene compared with that of chlorotrifluoroethene. Further, the negative charge of the carbanion **4** (X=Cl) is less delocalized than that of **4** (X=CF_3), and hence the former should be more strongly protophilic. Consequently, chlorotrifluoroethene gave predominantly the alkylamine **1**, while the *F*-propene gave a mixture of the alkylamine **2** and the enamine **3**.

The chlorotrifluoroethene–diethylamine adduct, **1**, is a rather unstable liquid, and it colored gradually

in several days even by storage in a refrigerator. It also fumed strongly by contact with atmospheric moisture, and it is recommended to be prepared just before the use.[1] In contrast, the *F*-propene–diethylamine reaction product (**2**+**3**) was so stable that no coloration was observed by storage at room temperature. Even after half a year, it could be used without any deterioration, and it could be handled much easier than **1**.

Fluorination of Alcohols. Fluorination of various alcohols using the *F*-propene–diethylamine reaction product (**2**+**3**) mentioned above was carried out. In these reactions, we found that the pure **3**, which was prepared in another route, has no fluorinating ability. Nevertheless, when a mixture of **2** and **3** was used, hydrogen fluoride which was formed by the reaction of **2** and an alcohol added to **3** giving **2**. As a whole, all of **3** was consumed as a fluorinating agent through **2**.

$$ROH + \underset{\mathbf{2}}{Et_2NCF_2CHFCF_3} \longrightarrow RF + Et_2NC(=O)CHFCF_3 + HF$$

6

$$Et_2NCF{=}CFCF_3 + HF \longrightarrow \mathbf{2}$$

Several other *F*-propene–dialkylamine reagents were also examined for fluorination, however, there were no differences among their abilities as a fluorinating agent. From the practical point of view, however, it was necessary to choose an appropriate amine component, otherwise the fluorinated product and the formed amide might have similar boiling points, which would make the separation of them difficult.

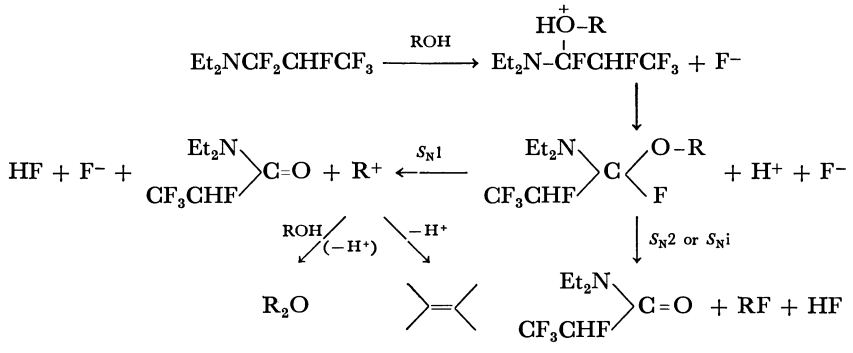
Various primary alcohols were subjected to the fluorination using *F*-propene–dialkylamine reaction products, using diethyl ether as a solvent. After 20 h's reaction at room temperature, the yields of the fluorinated products were determined based on the signal intensities of ^{19}F NMR (Table 2). Most of the primary alcohols were fluorinated in good yields. However, benzyl alcohol, which readily gives a benzyl cation, formed 25% of dibenzyl ether.

Secondary and tertiary alcohols, which also tend to form carbonium ions, gave considerable amounts of alkenes and dialkyl ethers (Table 3). For example, 2-octanol in diethyl ether gave 25% of a mixture of *trans*-2-octene, *cis*-2-octene, and 1-octene (4 : 3 : 1), besides 62% of 2-fluorooctane. When the reaction was carried out in acetonitrile, a highly polar solvent, the formation of alkene reached up to 52%.

Borneol gave a fluorinated product formed through carbonium rearrangement. α-Hydroxycarboxylic acid ester such as ethyl DL-mandelate gave α-fluoro carboxylic acid ester in a good yield. Choresterol also afforded the expected cholesteryl fluoride by fluorination in dichloromethane at low temperature. The fluorination of *t*-butyl alcohol was notable, as it afforded *t*-butyl fluoride in 78% of yield. 1-Adamantanol also gave 1-fluoroadamantane in a high yield.

The reaction mechanism of the fluorination by chlorotrifluoroethene–diethylamine reagent is suggested to involve S_N1, S_N2, or S_Ni, though no diethylamine reagent is suggested to involve S_N1, S_N2, or S_Ni, though no kinetic investigation has been done.

The fluorination of alcohols with the *F*-propene–diethylamine reagent should also undergo through the following pathway.



Fluorination of Carboxylic Acids. Carboxylic acids are known to be converted directly to their fluorides by using chlorotrifluoroethene–diethylamine reagent.[2,10] The *F*-propene–diethylamine reagent could also be used for the fluorination of aliphatic or aromatic carboxylic acids into their fluorides (Table 4).

Experimental

Reaction of F-*Propene with Diethylamine.* *a) Reaction under Pressure*: Diethylamine (11 mg, 0.15 mol) and dried

diethyl ether (30 ml) were placed in a glass pressure-vessel, and the whole was cooled to ≈ −70 °C by means of a Dry Ice–acetone bath. Liquefied *F*-propene (25 g, 0.17 mol) was introduced to the vessel and sealed. The cooling bath was removed and the mixture was brought to room temperature with magnetical stirring. After stirring over a night, the reaction mixture was filtered to remove the crystals of diethylamine hydrofluoride, and the solvent was evaporated. Resulting residue was subjected to distillation in a vacuum, and a liquid (23.7 g, 72%) bp 56—57 °C/58 mmHg, was obtained. The ^{19}F NMR spectrum revealed that this oil is a mixture of **2** and **3** in a ratio 3 : 1. When the vessel is stoppered tight, this material could be stocked at room temperature for more than half a year with only a slight discoloration.

b) Reaction at Atmospheric Pressure: A solution of diethylamine (105 g) in dried diethyl ether (200 ml) was placed in a three-necked flask which was equipped with a Dry Ice–acetone-cooled reflux condenser and a gas inlet tube. The whole was cooled to 0—5 °C with an ice-bath and *F*-propene gas (240 g) was bubbled through the mixture. Vigorous stirring was continued throughout this process and the temperature was kept below 10 °C. The whole gas was completely absorbed by 2 h's bubbling. After removing the ice-bath, the reaction mixture was allowed to stand overnight. The mixture thus obtained can be used as a fluorinating agent. However, for further purification, the solvent was evaporated and the residue was distilled in a vacuum giving an oil (273 g, 89%), bp 51—53 °C/40 mmHg. This liquid was a mixture of **2** and **3** in the ratio 1 : 1.

1-Fluorooctane. A solution of the *F*-propene–diethylamine reagent (13 g, 60 mmol) in diethyl ether (50 ml) was dropped into a solution of 1-octanol (6.5 g, 50 mmol) in diethyl ether (30 ml) at 0—5 °C. After stirring for 4 h, the reaction mixture was thrown into water and an oily layer was extracted with diethyl ether. The extract was washed with water, dried over magnesium sulfate, and evaporated to remove the solvent. The residue was distilled to give 1-fluorooctane (5.4 g, 82%), bp 145—146 °C.

Other primary alcohols were fluorinated in similar manners.

2-Fluorooctane. Fluorination of 2-octanol was carried out similarly to that of 1-octanol. The reaction product was subjected to gas chromatographic analysis using benzotrifluoride as a standard material. Following products were found in the reaction mixture: 2-fluorooctane (62%), 2-octene (22%, *trans*/*cis*=3/1), and 1-octene (3%).

Cholesteryl Fluoride. Into a solution of cholesterol (1.17 g) in dichloromethane (7 ml), a solution of *F*-propene–diethylamine reagent (0.81 g) in dichloromethane (3 ml) was dropped at 0—5 °C. Stirring was continued further several hours at that temperature, and the reaction mixture was thrown into water. An oily layer was extracted with dichloromethane, and the extract was washed with water, dried over magnesium sulfate and subjected to column chromatography on silica gel. Petroleum ether was used as the eluent, and the main elution was subjected to evaporation, affording white crystals (0.96 g, 83%) of cholesteryl fluoride, mp 92—93 °C (lit,[11] mp 93—94 °C).

Propionyl Fluoride. Into *F*-propene–diethylamine reagent (11.9 g, 56 mmol), propionic acid (3.9 g, 50 mmol) was dropped at room temperature. The mixture was stirred at 60 °C for 1 h and subjected to distillation. Propionyl fluoride (2.4 g, 62%) came out at bp 43—45 °C (lit,[1] bp 44 °C), followed by *N*,*N*-diethyl-2,3,3,3-tetrafluoropropionamide (10.5 g, 89%), bp 86—89 °C/11 mmHg.

Reactions of 1-Halo-1-nitroso- and 1-Halo-1-nitrocycloalkanes with Triphenylphosphine. A New Synthesis of Lactam[1]

Ikuo SAKAI,[††] Norio KAWABE,[†††] and Masaji OHNO*,[†]

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248

(Received May 16, 1979)

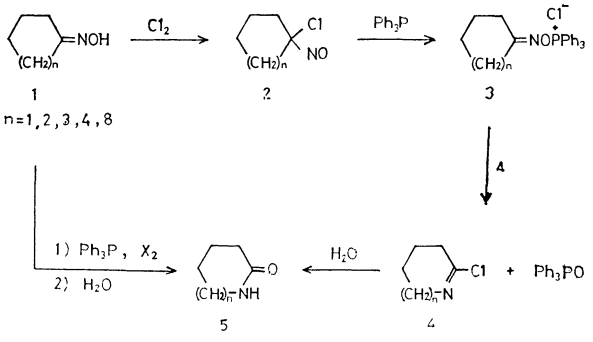
Reactions of 1-halo-1-nitroso- and 1-halo-1-nitrocycloalkanes with triphenylphosphine have been carried out. The Perkov reaction and Beckmann rearrangement occurred successively with the formation of lactams in high yields. The reaction of cycloalkanone oxime with halogen in the presence of triphenylphosphine also gave lactams in one step.

Many works have been carried out on the Perkov reaction since 1955.[2] However, little is known about the reaction of halonitroso- and halonitroalkanes with trivalent organophosphorus compounds. The reactions of 2-chloro-1-nitrosopropane with 1 mol of triethyl phosphite and 2-chloro-2-nitropropane with 2 mol of triethyl phosphite afforded diethyl isopropylideneamino phosphate, but no Beckmann rearrangement product was obtained by its pyrolysis.[3] The reaction of bromonitromethane and triphenylphosphine smoothly forms a phosphonium salt that gives triphenylphosphine oxide and fulminic acid[4] with aqueous alkali at 0 °C. Treatment of 1-bromo-1-nitroalkanes with triphenylphosphine generally gives nitriles.[5] However, no investigation has been carried out on the Perkov type reaction of 1-halo-1-nitroso- and 1-halo-1-nitrocycloalkanes with trivalent organophosphorus compounds.[2]

We wish to report the first successful Beckmann rearrangement of 1-halo-1-nitroso- and 1-halo-1-nitrocycloalkanes (**2** and **6**) with triphenylphosphine.

All 1-halo-1-nitrosocycloalkanes (**2**) were prepared by the reaction of cycloalkanone oximes (**1**) with halogens according to the method of Piloty and Stork.[6] 1-Chloro-1-nitrocyclohexane was prepared by the reaction of sodium salt of nitrocyclohexane and chlorine according to the method of Robertson.[7] 1-Chloro-1-nitrocycloalkanes of 8- and 12-membered rings were prepared by the oxidation of the corresponding compound **2** with nitric acid according to the method of Iffland *et al.*[8]

Reaction of 1-Halo-1-nitrosocycloalkanes. 1-Chloro-1-nitrosocycloalkanes (**2**) were dissolved in nonpolar solvents such as benzene, toluene, ether, or tetrahydrofuran, and treated with 1 mol equivalent of triphenylphosphine at room temperature. The reaction was exothermic, the deep blue color characteristic of the nitroso group disappearing gradually. The reaction temperature reached 40—70 °C. After 30—60 min, the reaction mixture was hydrolyzed, the corresponding lactams (**5**) being obtained in moderate to excellent yields. When the temperature was kept at 0—10 °C, a very hygroscopic precipitate (the IR spectrum shows an absorption at 1655 cm^{-1}, characteristic of C=N group) was formed, which was then heated in dry benzene at 60 °C. The reaction mixtures were worked up in the same way as described above. Lactam (**5**) and triphenylphosphine oxide were obtained in high yields. The results of reactions of compound **2** with triphenylphosphine are summarized in Table 1.



Scheme 1.

In order to simplify the reaction, compounds **1** were directly treated with halogens in the presence of equivalent amount of triphenylphosphine. The corresponding lactams **5** were obtained in good yields in the case of chlorine and bromine, and in fair yields in the case of iodine. The results are also summarized in Table 1.

Reaction of 1-Halo-1-nitrocycloalkanes. On the basis of the reaction of compound **2** with triphenylphosphine, reactions of 1-chloro-1-nitrocycloalkane (**6**) with triphenylphosphine were studied. 1-Chloro-1-nitrocyclohexane was treated with 2 mol of triphenylphosphine in benzene under reflux for 5 h. After the reaction mixture had been treated with 2 M hydrochloric acid, the benzene solution afforded triphenylphosphine oxide in 86% yield and the aqueous solution afforded ε-caprolactam in 55—60% yield. Treatment with 1 mol and 3 mol of triphenylphosphine gave ε-caprolactam in 34 and 77% yields, respectively. It seems reasonable to assume that 2 mol of triphenylphosphine are required to remove two oxygen atoms of the nitro group. The same reaction of 1-chloro-1-nitrocyclooctane and 1-chloro-1-nitrocyclododecane with 2 mol of triphenylphosphine afforded perhydroazonin-2-one in 43% yield and azacyclotridecan-2-one in 32% yield, respectively.

Mechanisms. The reactions of 1-chloro-1-nitroso- and 1-chloro-1-nitrocycloalkanes with triphenylphosphine provide a new synthetic method of lactams. The mechanisms of the new reactions are explained in Schemes 1 and 2.

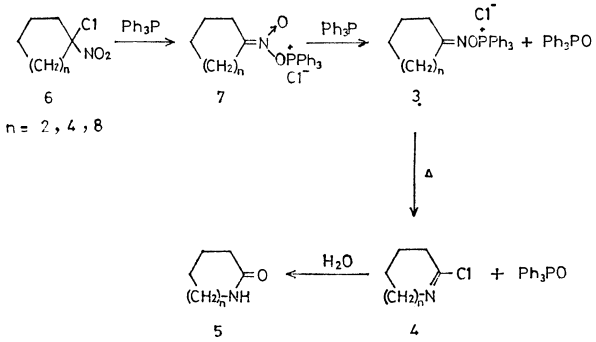
Table 1. Reactions of 1-halo-1-nitroso- and 1-halo-1-nitrocycloalkanes with triphenylphosphine

Starting material	Reagent	Product[a)]	Yield/%
1-Chloro-1-nitrosocyclopentane	$(C_6H_5)_3P$	δ-Valerolactam	57
1-Chloro-1-nitrosocyclohexane	$(C_6H_5)_3P$	ε-Caprolactam	96
1-Chloro-1-nitrosocycloheptane	$(C_6H_5)_3P$	Perhydroazonin-2-one	76
1-Chloro-1-nitrosocyclooctane	$(C_6H_5)_3P$	Perhydroazonin-2-one	83
1-Chloro-1-nitrosocyclododecane	$(C_6H_5)_3P$	Azacyclotridecan-2-one	78
Cyclopentanone oxime	$(C_6H_5)_3P,Cl_2$	δ-Valerolactam	76
Cyclohexanone oxime	$(C_6H_5)_3P,Cl_2$	ε-Caprolactam	86
Cyclohexanone oxime	$(C_6H_5)_3P,Br_2$	ε-Caprolactam	74
Cyclohexanone oxime	$(C_6H_5)_3P,I_2$	ε-Caprolactam	39
Cyclooctanone oxime	$(C_6H_5)_3P,Br_2$	Perhydroazonin-2-one	74
Cyclooctanone oxime	$(C_6H_5)_3P,I_2$	Perhydroazonin-2-one	60
Cyclododecanone oxime	$(C_6H_5)_3P,Br_2$	Azacyclotridecan-2-one	81
Cyclododecanone oxime	$(C_6H_5)_3P,I_2$	Azacyclotridecan-2-one	48
1-Chloro-1-nitrocyclohexane	$(C_6H_5)_3P$	ε-Caprolactam	77
1-Chloro-1-nitrocyclooctane	$(C_6H_5)_3P$	Perhydroazonin-2-one	42
1-Chloro-1-nitrocyclododecane	$(C_6H_5)_3P$	Azacyclotridecan-2-one	32

a) All lactams were confirmed to be identical with authentic samples prepared by the usual Beckmann rearrangement.



Scheme 2.

In the case of compound **2**, the mechanism includes initial attack of phosphorus on oxygen to give phosphonium salts (**3**) directly followed by thermal rearrangement to chloro imine (**4**) which could not be isolated, and in line with the present understanding of the reactions of α-bromo ketone with triphenylphosphine.[9)]

The reaction of compound **6** with triphenylphosphine differs a great deal from that of compound **2**. The former is endothermic, requiring drastic conditions, but the latter is exothermic and can be carried out smoothly at room temperature. The evidences combined with the fact that no blue coloration takes places during the course of reaction suggest that the reaction mechanism is not by way of compound **2**, but by the formation of Perkov type intermediate (**7**) followed by transformation into a phosphonium salt (**3**) and then the Beckmann rearrangement.

Experimental

Melting points and boiling points are uncorrected. IR spectra were taken on a Hitachi EPI-S2 spectrometer.

1-Chloro-1-nitrosocyclohexane. In a 1-litre three-necked, round-bottomed flask, equipped with a gas inlet tube and a mechanical stirrer, were placed 500 ml of cyclohexane and 56.5 g of cyclohexanone oxime. The flask was covered with a black cloth so as to prevent exposure to sun-light. Chlorine gas was passed into the solution with stirring at room temperature in the course of about 2 h. A solution of a deep blue color was obtained. The excess chlorine remaining in the flask was removed under reduced pressure. The solution was washed successively with water, 1 M sodium hydroxide, and water; dried over anhydrous sodium sulfate. Cyclohexane was removed by distillation, and the residue was distilled under reduced pressure. The yield of **2** was 63.5 g (86%) of dark blue liquid, bp 75 °C/41 mmHg. IR (liquid film): 1570 cm^{-1} (NO).

Of 1-chloro-1-nitrosocycloalkanes prepared by the same procedure, 5-, 6-, 7-, and 8-membered ring compounds are dark blue liquids. Only 1-chloro-1-nitrosocyclododecane is a blue crystalline material which melts at 53—55 °C after recrystallization from ethanol.

Their infrared spectra show an absorption at 1570—1580 cm^{-1}, characteristic of monomeric nitroso group.

Reaction of 1-Chloro-1-nitrosocyclohexane with Triphenylphosphine. In a 300 ml three-necked, round-bottomed flask fitted with a condenser, a dropping funnel, and a mechanical stirrer were placed 10 g (0.068 mol) of 1-chloro-1-nitrosocyclohexane and 100 ml of benzene. A solution of 17.8 g (0.068 mol) of triphenylphosphine in 100 ml of benzene was slowly added from the dropping funnel, with stirring for 30 min at room temperature. The deep blue color of the solution disappeared within 15 min and the temperature rose as high as 70 °C. After 30 min, the reaction mixture was treated with 100 ml of 1 M hydrochloric acid. Triphenylphosphine oxide was obtained in 95% yield (18.5 g) from the organic layer. The aqueous fraction was evaporated to dryness under reduced pressure on a water bath. The residue was neutralized with 2 M sodium hydroxide, and extracted with three 100 ml portions of dichloromethane–ether (1 : 1). The extract was dried with anhydrous sodium sulfate and evaporated to dryness under reduced pressure on a water bath. The residual solid was 7.6 g (99%) of crude ε-caprolactam and was distilled under reduced pressure. The main fraction was distilled at 165—167 °C/33 mmHg. Its infrared spectrum and mp were identical with those of an authentic sample.

Other 1-halo-1-nitrosocycloalkanes were treated with triphenylphosphine in a similar way. Lactams of 6- to 8-membered ring showed a single characteristic absorption (1650—1660 cm^{-1}). Those of 9- and 13-membered ring

showed two characteristic absorptions (1635—1655 cm^{-1} and 1535—1550 cm^{-1}).

Reaction of Cyclohexanone Oxime with Chlorine in the Presence of Triphenylphosphine. In a 300 ml three-necked, round-bottomed flask, fitted with a gas inlet tube, a mechanical stirrer, and a condenser, were placed a solution of 5.7 g (0.05 mol) of cyclohexanone oxime and 13.1 g (0.05 mol) of triphenylphosphine in 100 ml of benzene. Chlorine gas was passed into the solution with stirring at room temperature, the reaction temperature rising as high as 50—60 °C. After the temperature had fallen to room temperature, bubbling of chlorine was stopped. The reaction mixture was worked up in a similar way to that above. ε-Caprolactam was obtained in 86% yield (4.9 g) from the aqueous layer and triphenylphosphine oxide being obtained quantitatively from the benzene layer. A solution of bromine or iodine in benzene could also be used instead of chlorine gas.

1-Chloro-1-nitrocyclohexane. In a 100 ml Erlenmeyer flask provided with a magnetic stirrer was placed 10 g (0.08 mol) of nitrocyclohexane. A solution of 5 g (0.123 mol) of sodium hydroxide in 60 ml of water was added dropwise with stirring at room temperature. After being stirred for 3 h, the reaction mixture became homogeneous. Chlorine gas was then passed into the solution which had been cooled to −5—0 °C in an ice–salt bath. Pale blue oil separated out after 1.5 h. The reaction mixture was extracted three times with 60 ml portions of dichloromethane–ether (1 : 1). The extract was dried with anhydrous sodium sulfate and evaporated to dryness. The oily residue (12.3 g) was distilled under reduced pressure. The principal fraction was 10 g of 1-chloro-1-nitrocyclohexane, a colorless oil boiling at 53.5 °C/1 mmHg.

1-Chloro-1-nitrocyclododecane. In a 200 ml separatory funnel was placed a solution of 5.00 g (0.022 mol) of 1-chloro-1-nitrosocyclododecane in 50 ml of cyclohexane, and 12.5 ml of concentrated nitric acid was added. The funnel was then shaken until the blue color of the solution disappeared. The reaction mixture was washed successively with 50 ml of water, 50 ml of 5% aqueous sodium hydroxide, and 50 ml of water. After being dried over anhydrous sodium sulfate, the cyclohexane was removed under atmospheric pressure, and 5.44 g of the oily residue was distilled under reduced pressure. The product of 1-chloro-1-nitrocyclododecane was 3.62 g (68%) of colorless crystal boiling at 118—119 °C/0.2 mmHg and melting at 49.5—50.5 °C after recrystallization from acetone. IR (KBr): 1556, 1348 cm^{-1} (NO_2). 1-Chloro-1-nitrocyclooctane was also prepared in a similar way. The product was 5.52 g (44.2%) of colorless liquid boiling at 74 °C/0.6 mmHg. IR (liquid film): 1563, 1333 cm^{-1} (NO_2).

Reaction of 1-Chloro-1-nitrocyclohexane with Triphenylphosphine. In a 100 ml flask fitted with a reflux condenser was placed a solution of 4.8 g (0.0294 mol) of 1-chloro-1-nitrocyclohexane in 40 ml of benzene and a solution of 16.2 g (0.0618 mol) of triphenylphosphine in 20 ml of benzene. The mixture was refluxed for 4 h on a steam bath. The reddish reaction mixture was washed three times with 180 ml portions of 2 M hydrochloric acid. The yellow organic layer was dried with anhydrous sodium sulfate and evaporated. Triphenylphosphine oxide was obtained in 86% yield (14.0 g). The aqueous layer was evaporated. The oily residue was made basic to litmus with 2 M sodium hydroxide and was extracted with dichloromethane–ether (1 : 1). After the extract had been dried over anhydrous sodium sulfate, the dichloromethane and ether were removed by distillation. ε-Caprolactam was obtained in 58% yield (1.93 g).

Reactions of 1-chloro-1-nitrocyclooctane and 1-chloro-1-nitrocyclododecane with triphenylphosphine were also carried out in a similar way.

A Kinetic Study of the Reaction of Arylthiotrimethylsilane with Carboxylic Acid Giving Acyloxytrimethylsilane and Arenethiol

Seizi KOZUKA* and Takuro KITAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi, Osaka 558

(Received May 18, 1979)

The mechanism of the reactions of arylthiotrimethylsilanes with carboxylic acids has been studied kinetically. The reaction was found to obey a second-order kinetic equation. The substituent effects of the aryl moiety ($\rho=-2.4$) and of the silicon atom, the hydrogen-deuterium kinetic isotope effect of the acid ($k_H/k_D=3$) were observed. A mechanism involving the 5-coordination of the silicon atom prior to the rate-determining protonation of the sulfur atom has been suggested for the reaction. A remarkable base catalysis was observed. The formation of the coordinated intermediate has been suggested to be the slow step in the presence of a bese.

The kinetic behavior of silicon–sulfur bond cleavage has scarcely been studied at all. Only one kinetic study, to the best of our knowledge, has been reported dealing with the hydrolysis of the Si–S bond in aqueous dioxane.[1] On the other hand, we have ourselves

$$R_3Si\text{-}SAr + H^+ \rightleftharpoons R_3Si\text{-}S^+(H)Ar$$

$$R_3Si\text{-}S^+(H)Ar + nH_2O \xrightarrow{\text{slow}} R_3Si\text{-}OH + ArSH + H^+ + (n-1)H_2O$$

reported a kinetic aspects of the acyloxy-exchange reaction of acyloxysilane with carboxylic acid, which involves Si–O bond fission.[2] In the mean time, an analogous reaction of carboxylic acid with thiosilane

$$RCOO\text{-}SiR'_3 + R''COOH \rightleftharpoons RCOO\text{-}Si^-(R'_3)\text{-}O\overset{+OH}{\overset{\|}{C}}R'' \xrightarrow{\text{slow}} RCO\text{-}Si^-(R'_3)\text{-}OCOR'' \rightleftharpoons RCOOH + R'_3Si\text{-}OCOR''$$

has also been known to give the acyloxysilane in a Si–S bond cleavage reaction.[3] We have now extended our kinetic study to this reaction: *i.e.*, the reaction of

$$RCOOH + (Me_3Si)_2S \longrightarrow H_2S + 2RCOO\text{-}SiMe_3$$

$$RCOOH + EtS\text{-}SiMe_3 \longrightarrow EtSH + RCOO\text{-}SiMe_3$$

arylthiotrimethylsilane with carboxylic acid in order to obtain more knowledge about the mechanism of the Si–S bond fission.

Results and Discussion

The reaction of arylthiosilane with carboxylic acid in chloroform was found to proceed smoothly at room temperature to give arenethiol and acyloxytrimethylsilane in high yields. The product was isolated and characterized.

$$Me_3Si\text{-}SAr + RCOOH \longrightarrow Me_3Si\text{-}OCOR + ArSH$$

The reverse reaction, *i.e.*, that giving the thiosilane from the acyloxysilane and arenethiol, was not found to proceed at all under the conditions used. Small amounts of hexamethyldisiloxane (8—10%) and trimethylsilanol (2%) were detected in the reaction mixture by NMR analysis, as in the acyloxy exchange reaction,[2] but the amounts were found to be unchanged during the reaction. This suggests that these side products are independent of the reaction of thiosilane with acid. They may be formed by the interaction of the thiosilane with moisture, giving silanol, while the subsequent dehydration of the silanol results in the formation of the disiloxane.[4]

The rate of the reaction of thiosilane with two equivalents of carboxylic acid was measured by monitoring the decrease in the ^1H NMR trimethyl signal of the starting thiosilane (δ 0.25—0.27 ppm) and the increase in that of acyloxysilane (δ 0.32—0.40 ppm). A good second-order rate constant was obtained with satisfactory reproducibility. The rate of the reaction with acetic acid could not be obtained by this kinetic procedure because the trimethyl signal of acetoxytrimethylsilane (δ *ca.* 0.3 ppm) appeared rather close to that of the starting material, therefore, the amounts of the two components could not be measured with a high accuracy. Accordingly, chloro-, dichloro-, and trichloroacetic acids were used in the present study. The results are given in Table 1. Good Hammett correlations were found for the reactions with each carboxylic acid with apparently negative ρ value ($\rho_{(\sigma)}=-2.4$, with $CHCl_2COOH$). The value thus obtained appeared quite similar in magnitude to those of the dissociation constants of arenethiols with the opposite sign ($\rho=+2.24$).[5] This would suggest that the present reaction involves the formation of a sulfonium ion.

The effect of the acid strength of the attacking carboxylic acids was observed on the rate of the reaction. A plot of the results given in Table 1 against the σ^* constants gave a straight line with a ρ^* value of $+1.34$ ($X=OCH_3$; $\gamma=0.968$; similar ρ^* values were obtained

Table 1. Rate constants for the reactions of p-X-C_6H_4-S-$SiMe_3$ (0.60 mol/dm^3) with RCOOH (1.20 mol/dm^3) in $CHCl_3$ at 34 °C[a]

	k_2/dm^3 mol^{-1} s^{-1}		
	R in RCOOH		
X	CH_2Cl ($\times 10^4$)	$CHCl_2$ ($\times 10^3$)	CCl_3 ($\times 10^2$)
OCH_3	2.58±0.07	1.47±0.14	4.70±0.80

for each substituent, X). The ρ^* value appeared quite similar to that observed for the acyloxy exchange reaction of acyloxytrimethylsilane with various carboxylic acids.[2]

In order to obtain the activation parameters, the rate of the reaction of trimethyl(phenylthio)silane with dichloroacetic acid in chloroform was measured at various temperatures. The results are shown in Table 2. An Arrehnius plot of the data gave 8.8 kcal/mol (4.184 J) and −45.6 e.u. for the enthalpy and entropy values respectively. Here again, the values appeared to be quite similar to those observed for the acyloxy exchange reaction.[2] The large negative entropy value suggests a tight transition state for the reaction, but it does not suggest a 4-centered reaction, since a remarkably negative ρ value was observed in the present study, as has been mentioned above. The tight transition state may be explained in terms of an ionic reaction which is forced to proceed in a nonpolar solvent, as was suggested for the reaction of thiostannane with haloalkane, in which a large negative entropy value was observed when the reaction was carried out in a nonpolar solvent, while the value fell to a normal magnitude in a polar solvent.[6]

The steric and electronic effects of the silicon substituent were examined by carrying out the reaction of dichloroacetic acid with alkyl (or aryl)dimethyl(phenylthio)silanes. The results obtained can be explained in terms of the steric effect rather than the electronic effect of the substituent. The hydrogen-deuterium kinetic isotope effect was also examined,

and a positive isotope effect was observed. The results are summarized in Table 3. The positive kinetic isotope effect and the negative ρ value suggest a rate-determining protonation of the sulfur atom. In the meantime, the steric effect of the bulky substituent on the silicon atom appeared almost the same as those observed in the acyloxy exchange reactions of the corresponding acyloxysilanes, as is shown in Table 3. These results, together with the similarity of the ρ^* value, the activation parameters, and the positive kinetic isotope effect to those of the acyloxy exchange reaction,[2] strongly suggest that these two reactions are similar in their mechanisms; *i.e.*, the reaction involves the 5-coordination of the silicon atom prior to the rate-determining proton transfer. Thus, the most plausible mechanism for the reaction can be formulated as follows. The first step of the reaction

$$ArS\text{-}SiMe_3 + RCOOH \rightleftharpoons \left[ArS\text{-}Si^{-}(Me_3)\text{-}O\text{-}\overset{+OH}{\overset{\|}{C}}R\right] \xrightarrow{\text{slow}} \left[ArS^{+}(H)\text{-}Si^{-}(Me_3)\text{-}O\text{-}\overset{O}{\overset{\|}{C}}R\right] \longrightarrow ArSH + Me_3Si\text{-}O\text{-}\overset{O}{\overset{\|}{C}}R$$

would be the formation of a 5-coordinated intermediate by a reversible reaction. Thus, the bulky substituent on the silicon atom disfavors the formation of the intermediate. The second step is the rate-determining proton migration from the carbonyl oxygen to the sulfur atom. An electron-withdrawing substituent on the aryl moiety would destabilize the second intermediate of the sulfonium ion, resulting in a deceleration of the reaction and bringing forth a negative ρ value. The sulfonium intermediate would rapidly col-

lapse into the products.

According to the mechanism, one can expect the base catalysis of the reaction, since the carboxylate ion would be a better reagent than the conjugate acid for the formation of a 5-coordinated silicon atom. Furthermore, an opposite substituent effect of the aryl ring, that is, a positive ρ value, would be expected for the base-catalyzed reaction because of the lack of the protonation step. The rate of the reaction was found to be markedly accelerated by the addition of a base, as is shown in Table 4. The rates of the reactions of arylthiotrimethylsilanes with dichloroacetic acid in the presence of pyridine as the base are given in Table 5. As expected, a small but clearly positive substituent effect ($\rho = +0.74$) was observed. The reaction scheme in the presence of a base is formulated below:

$$RCOOH + :B \rightleftharpoons RCOO^- + BH^+$$

$$RCOO^- + Me_3Si\text{-}SAr \rightleftharpoons RCOO\text{-}Si^-(Me_3)\text{-}SAr$$

$$RCOO\text{-}Si^-(Me_3)\text{-}SAr \longrightarrow RCOO\text{-}SiMe_3 + ArS^-$$

The substituent on the aryl ring affects the stability of the coordinated silicon atom with a formal anionic character through the sulfur linkage. As a result, a positive ρ value would result in a moderate magnitude.

Experimental

Materials. The arylthiotrimethylsilanes were prepared from chlorotrimethylsilane and lead arenethiolates.[7] Benzyl (or phenyl)dimethyl(phenylthio)silane was prepared similarly from the corresponding chlorodimethylsilane; bp 142—146°C/1 mmHg (133.332 Pa), NMR ($CDCl_3$) δ(ppm), 0.46 s(6H), 2.36 s(2H), and 7.00—7.23 m(10H). The carboxylic acids were purified by distillation. Dichloroacetic acid-*d* was obtained by the hydrolysis of the corresponding anhydride with D_2O. The deuterium content was measured by the integration of the NMR signals (90%).

Product Analysis. Trimethyl(phenylthio)silane (48 mg, 0.26 mmol) and dichloroacetic acid (70 mg, 0.56 mmol) were dissolved in chloroform-*d* (0.37 cm^3), and then the mixture was allowed to stand for 5 h at room temperature. Trimethyl(dichloroacetoxy)silane (75%), benzenethiol(81%), haxamethyldisiloxane ($\simeq$10%), and trimethylsilanol (2%) wew detected in the reaction mixture by NMR analysis. No other compound was detected. The assignmemt of these signals was performed by comparing them to those of the authentic samples. The latter two compounds were found in almost the same amounts even at the beginning of the reaction and in the absence of the acid. Thus, these two compounds were concluded to be formed by the hydrolysis of the thiosilane during work-up. Trimethyl(dichloroacetoxy)silane was isolated by GLC separation (SE-30, 2 m, 150°C), and the structure was characterized by comparison with an authentic sample.[8]

Kinetics. Trimethyl(phenylthio)silane (48 mg, 50 mm^3, 0.26 mmol) was dissolved in chloroform (0.37 cm^3), after which the solution, in a sample tube was placed in a NMR probe. Dichloroacetic acid (70 mg, 46 mm^3, 0.56 mmol) was then added to the solution. Immediately after the addition, trimethyl signals of the starting thiosilane (δ 0.25 ppm) and the product (δ 0.36 ppm) were recorded repeatedly at short time intervals. Twenty to thirty measurements were done for each run until the completed conversion exceeded a half. After the reaction, the total volume of the solution was measured, and the concentrations of each component were calculated. The second-order rate constant, k, was obtained by means of the following equation, where a and b are the initial concentrations of the thiosilane and the acid respectively, and where x is the amount of the acetoxysilane formed at time t. A good reproducibility was obtained ($\pm$10% error established by a duplicate run). The kinetics of the base-catalyzed reactions were done by using half concentrations of the starting materials.

$$kt = \frac{l}{b-a} \ln \frac{a(b-x)}{b(a-x)}$$

1,3-Dipolar Cycloadditions to 2-Phenyl-1-azaspiro[2.2]pent-1-ene[1)]

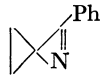
Otohiko TSUGE,* Hiroyuki WATANABE, and Yōko KIRYU

Research Institute of Industrial Science, Kyushu University 86, *Hakozaki, Higashi-ku, Fukuoka 812*

(Received May 19, 1979)

Benzonitrilium-*p*-nitrobenzylide undergoes 1,3-dipolar cycloaddition to highly strained 2-phenyl-1-azaspiro-[2.2]pent-1-ene, yielding the cycloadduct which is thermally converted to the dihydrobenzo[*f*]quinazoline and pyrimidine. In the reaction with α,*N*-diarylnitrone, the spiroazapentene gives 1-(benzylideneamino)-1-(*N*-phenylbenzamido)cyclopropane arising from the initial cycloadduct.

It seemed of interest to investigate the cycloadditions of highly strained 2-phenyl-1-azaspiro[2.2]pent-1-ene (**1**)[2)] having an 1-azirine moiety, because it is known that 1-azirines are useful reagents for the synthesis of a large number of heterocyclic systems.[3)] However, no studies on the cycloadditions to **1** have so far been

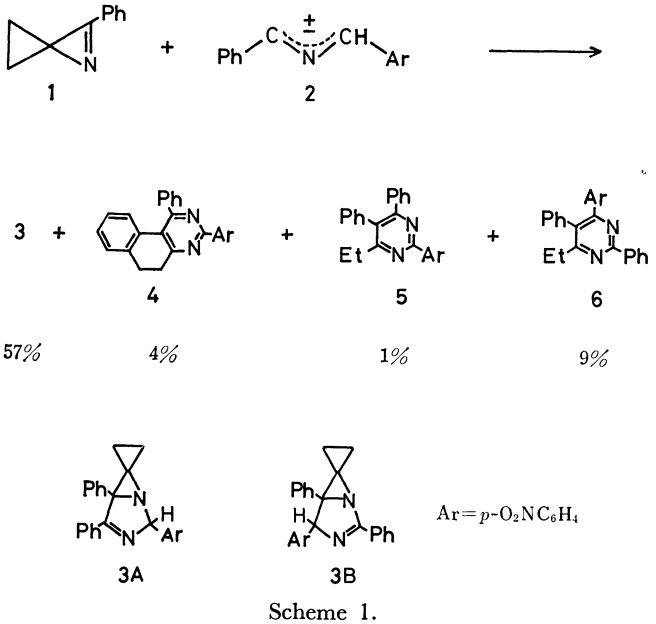


1

reported. We now wish to report on the reactions of **1** with benzonitrilium-*p*-nitrobenzylide (**2**) and α,*N*-diarylnitrones (**8**).

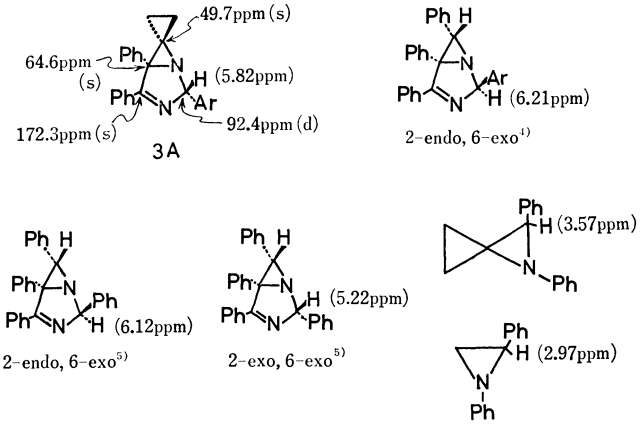
Reaction with Benzonitrilium-p-nitrobenzylide. Schmid and his co-workers[4)] reported that benzonitrilium-*p*-nitrobenzylide (**2**) undergoes 1,3-dipolar cycloaddition to 2-phenyl- and 2,3-diphenyl-1-azirines, yielding the bicyclic adducts. However, 3,3-dimethyl-2-phenyl-1-azirine does not react with **2**. Although **1** is a 3,3-disubstituted 2-phenyl-1-azirine, **1** might react with **2** due to its highly strained structure.

When **1** was allowed to react with 1 equivalent of **2** generated *in situ* from *N*-*p*-nitrobenzylbenzimidoyl chloride and triethylamine in benzene under nitrogen at room temperature, the 1:1 cycloadduct **3** was obtained as the major product, along with by-products **4**, **5**, and **6** (Scheme 1). Structural elucidation of these products, **3**—**6**, was accomplished on the basis of their spectral data and chemical correlations.



Scheme 1.

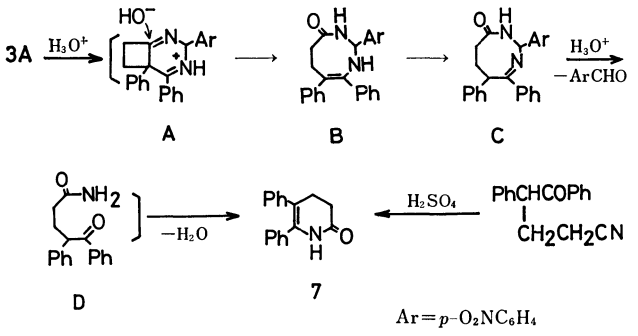
Although ^{1}H- and ^{13}C-NMR spectra of **3** (see Scheme 2 and Experimental Section) do not permit a clear assignment as to which structures, 2′-(*p*-nitrophenyl)-4′,5′-diphenylspiro[cyclopropane-1,6′-[1,3]diazabicyclo-[3.1.0]hex-3′-ene] (**3A**) or 4′-(*p*-nitrophenyl)-2′,5′-diphenylspiro[cyclopropane-1,6′-[1,3]diazabicyclo[3.1.0]-hex-2′-ene] (**3B**), would be more reasonable for **3**, **3** was assigned to be **3A** on the basis of results of chemical conversions which will be described below.



Scheme 2.

The stereochemistry of **3A** is hereinafter described. As illustrated in Scheme 2, the value of chemical shift of benzylic methine proton in **3A** is situated between those of *endo*- and *exo*-benzylic methine protons in other reported 1,3-diazabicyclo[3.1.0]hex-3-enes. On the other hand, the benzylic methine proton of 1,2-diphenyl-1-azaspiro[2.2]pentane[6)] appears at a lower field than that of 1,2-diphenylaziridine,[7)] because of anisotropy effect of cyclopropyl ring of the azaspiropentane. From a consideration of anisotropy effect of cyclopropyl ring in **3A**, it seems most reasonable to conclude that **3A** is the 2-*exo* structure.

Hydrolysis of **3** with 10% hydrochloric acid afforded 3,4-dihydro-5,6-diphenyl-2-pyridone (**7**) and *p*-nitrobenzaldehyde in 26 and 20% yields respectively. The structure of **7** was confirmed by the identification with an authentic sample prepared by a modification of the reported method.[8)] This result strongly supports that **3** is **3A** but not **3B**.[9)] The pathway for the formation of **7** from **3A** is illustrated in Scheme 3. The compound **3A** undergoes hydrolysis with concurrent ring expansions to form **C** through **A** and then **B**. This is followed by further hydrolysis of the cyclic amidine **C** to yield the benzaldehyde and amide **D**, and subsequent cyclization of **D** with dehydration leads to the formation of **7**.

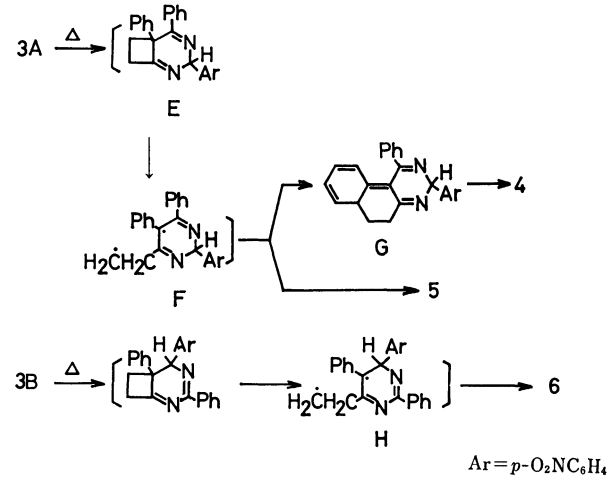


Scheme 3.

Contrary to the formation of pyridazine compound from the bicyclic adduct of **2** to 2,3-diphenyl-1-azirine,[4] thermolysis of **3A** in boiling xylene afforded 5,6-dihydro-3-*p*-nitrophenyl-1-phenylbenzo[*f*]quinazoline (**4**) and 6-ethyl-2-*p*-nitrophenyl-4,5-diphenylpyrimidine (**5**) in 64 and 8% yields respectively. It is thus evident that the products **4** and **5** of the reaction are derived from **3A**.

The product **6** which is an isomer of **5** was deduced to be 6-ethyl-4-*p*-nitrophenyl-2,5-diphenylpyrimidine.

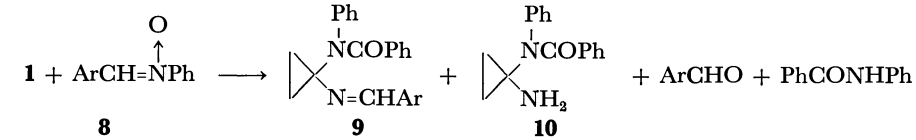
The pathways for the formation of **4**, **5**, and **6** are illustrated in Scheme 4. The initial adduct **3A** is subjected to ring expansion to form **E**. This is followed by homolytic rupture of the cyclobutane ring of **E** to yield biradical **F**, which can lead to **4** through **G** and to **5**. The formation of **6** can be also interpreted as arising from the initial reversed cycloadduct **3B** through biradical **H**. It is thought that **3B** whose structure is a cyclic amidine could not be isolated owing to its lability.



Scheme 4.

Reaction with α,N-Diarylnitrones. Although nitrones undergo 1,3-dipolar cycloaddition to C=N bonds of heterocumulenes such as isocyanates, isothiocyanates, and carbodiimides,[10] no studies on the cycloaddition of nitrones to simple C=N bonds have been reported. As mentioned above, the C=N bond of **1** exhibited high reactivity toward **2**. Thus our attention was directed to the reaction of **1** with α,*N*-diarylnitrones (**8**).

After **1** was allowed to react with 1 equivalent of α,*N*-diphenylnitrone (**8a**) in boiling benzene, the reaction mixture was chromatographed on silica gel to give 1-amino-1-(*N*-phenylbenzamido)cyclopropane (**10**), benzaldehyde, and benzanilide. A similar reaction of **1** with α-(*p*-nitrophenyl)-*N*-phenylnitrone (**8b**) afforded 1 : 1 adduct, 1-(*p*-nitrobenzylideneamino)-1-(*N*-phenylbenzamido)cyclopropane (**9b**), *p*-nitrobenzaldehyde, and benzanilide (Scheme 5). Structural elucidation of **9b** and **10** was accomplished on the basis of spectral data as well as of chemical conversions. Hydrolysis of **9b** gave **10** and *p*-nitrobenzaldehyde, while **10** reacted with the benzaldehyde to give **9b**.



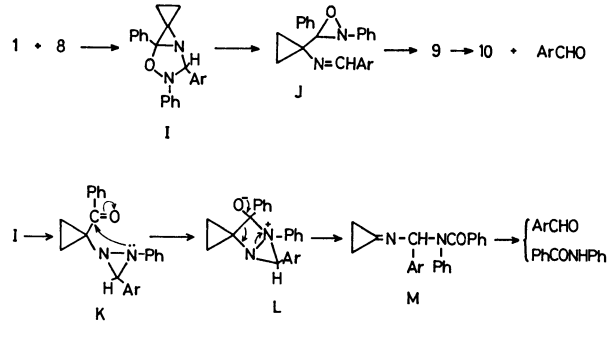
a : Ar=Ph	—	51%	14%	39%
b : Ar=*p*-$O_2NC_6H_4$	16%	—	33%	23%

9b ⇌ **10** + ArCHO

Scheme 5.

The pathways for the formation of products are assumed as depicted in Scheme 6. The nitrone **8** undergoes 1,3-dipolar cycloaddition to **1**, yielding labile cycloadduct **I**. The formation of **9** can be understood as proceeding through the oxaziridine **J** which is arising from **I**, since it is known that *C,N*-diaryloxaziridines are readily isomerized into the amides.[11]

As described above, hydrolysis of **9b** afforded **10** and the benzaldehyde, but not benzanilide. This fact suggests that benzanilide obtained from the reaction is derived from hydrolysis of a compound other than **9**. Although mechanistic considerations are still speculative, a possible pathway is also shown in Scheme 6. The rearrangement of **I** to the diaziridine **K**,



Scheme 6.

followed by a nucleophilic attack of the nitrogen atom on the carbonyl carbon atom yields the tricyclic betaine **L**. This is followed by ring cleavage to give **M**, which on hydrolysis gives the benzaldehyde and benzanilide. The process (**K**→**L**→**M**) is similar to that proposed for the formation of *N,N*-dibenzoylaniline from the photooxygenation of 1,2-diphenyl-2-(phenylimino)-1-ethanone.[12,13]

Experimental

All melting points are uncorrected. IR, NMR, and mass spectra were obtained on a JASCO IRA-1 spectrometer, Hitachi R-40, JEOL SX-100 spectrometers, and a Hitachi RMS-4 spectrometer, respectively.

Materials. Azaspiropentene **1**,[2] *N*-*p*-nitrobenzylbenzimidoyl chloride,[14] and α,*N*-diarylnitrones **8a**,[15] **8b**[16] were prepared by the reported methods respectively.

*Reaction of Azaspiropentene **1** with Benzonitrilium*-p-*nitrobenzylide (**2**).* To a vigorously stirred solution of **1** (0.44 g, 3 mmol) and *N*-*p*-nitrobenzylbenzimidoyl chloride (0.85 g, 3 mmol) in benzene (30 ml) was dropwise added a solution of NEt_3 (1.75 g, 17.3 mmol) in benzene (10 ml) at 0 °C over a period of 1 h under nitrogen. The reaction mixture was stirred at room temperature for 24 h, and then filtered to remove formed triethylammonium chloride. The filtrate was concentrated *in vacuo*, and the residue was chromatographed on silica gel (Wako gel C-300) using benzene as the eluent.

The first fraction gave crystals which were recrystallized from benzene to give 53 mg (4%) of 5,6-dihydro-3-*p*-nitrophenyl-1-phenylbenzo[*f*]quinazoline (**4**), mp 225—226 °C, as yellow needles. ^{1}H-NMR ($CDCl_3$) δ 3.09 (s, 4H), 6.8—7.8 (m, 9H), 8.28 8.73 (each d, 2H, *J*=9 Hz). ^{1}H-NMR (C_6D_6) δ 2.4—3.0 (m, 4H), 6.6—7.4 (m, 7H), 7.6—7.8 (m, 2H), 8.08, 8.67 (each d, 2H, *J*=9 Hz). ^{13}C-NMR ($CDCl_3$) δ 28.3 (t), 32.0 (t), 123.5, 125.1, 126.1, 127.9, 128.4, 128.6, 128.9, 129.5, 129.6, 130.5, 138.3, 138.9, 143.3, 149.0, 159.2, 162.1, 169.3. MS *m/e* 379 (M^+, base peak). Found: C, 76.05; H, 4.43; N, 10.92%. Calcd for $C_{24}H_{17}N_3O_2$: C, 75.97; H, 4.52; N, 11.08%.

The second fraction afforded crystals which were recrystallized from hexane to give 108 mg (9%) of 6-ethyl-4-*p*-nitrophenyl-2,5-diphenylpyrimidine (**6**), mp 134—135 °C, as colorless needles. ^{1}H-NMR ($CDCl_3$) δ 1.28 (t, 3H, *J*=7 Hz), 2.75 (q, 2H, *J*=7 Hz), 6.9—7.7 (m, 10H), 8.03 (d, 2H, *J*=9 Hz), 8.45—8.80 (m, 2H). ^{13}C-NMR ($CDCl_3$) δ 12.7, 28.9, 122.8, 128.0, 128.5, 128.8, 129.9, 130.8, 135.7, 137.5, 145.0, 147.5, 161.1, 162.8, 171.0. MS *m/e* 381 (M^+), 380 (base peak). Found: C, 75.50; H, 4.85; N, 10.89%. Calcd for $C_{24}H_{19}N_3O_2$: C, 75.57; H, 5.02; N, 11.02%.

The third fraction gave 12.3 mg (1%) of 6-ethyl-2-*p*-nitrophenyl-4,5-diphenylpyrimidine (**5**), mp 194—195 °C, as colorless needles (from EtOH). ^{1}H-NMR ($CDCl_3$) δ 1.28 (t, 3H, *J*=7.6 Hz), 2.76 (q, 2H, *J*=7.6 Hz), 6.6—7.5 (m, 10H), 8.27, 8.77 (each d, 2H, *J*=9 Hz). ^{13}C-NMR ($CDCl_3$) δ 12.7, 28.9, 123.5, 127.8, 128.5, 128.8, 129.0, 129.8, 130.0, 130.9, 136.2, 138.2, 143.9, 149.1, 160.4, 163.8, 170.8. MS *m/e* 381 (M^+), 380 (base peak). Found: C, 75.42; H, 5.05; N, 11.13%. Calcd for $C_{24}H_{19}N_3O_2$: C, 75.57; H, 5.02; N, 11.02%.

The fourth fraction gave crystals which were recrystallized from ether to give 2′-(*p*-nitrophenyl)-4′,5′-diphenylspiro-[cyclopropane-],6′-[1,3]diazabicyclo[3.1.0]hex-3′-ene] (**3A**), mp 167—169 °C, as colorless prisms. IR (KBr) 1602 (C=N), 1575, 1339 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ 0.8—1.2 (m, 2H), 1.4—2.1 (m, 2H), 5.82 (s, 1H), 7.2—7.5 (m, 8H), 7.5—7.9 (m, 4H), 8.22 (d, 2H, *J*=9 Hz). ^{13}C-NMR ($CDCl_3$) δ 0.6 (t), 9.4 (t), 49.7 (s), 64.6 (s), 92.4 (d), 123.7, 128.0, 128.4, 128.5, 129.0, 131.1, 131.9, 135.1, 147.5, 148.0, 172.3. MS *m/e* 381 (M^+). Found: C, 75.60; H, 4.98; N, 11.08%. Calcd for $C_{24}H_{19}N_3O_2$: C, 75.57; H, 5.02; N, 11.02%.

*Hydrolysis of 1 : 1 Adduct **3A**.* A suspension of **3A** (110 mg) in 10% HCl (10 ml) was stirred at room temperature for 30 h. Filtration gave crystals which were recrystallized from EtOH to give 18.2 mg (26%) of 3,4-dihydro-5,6-diphenyl-2-pyridone (**7**), mp 220—221 °C, as colorless needles. This compound was identical with an authentic sample prepared by the method described below.

The filtrate was concentrated *in vacuo*, and the residue was chromatographed on silica gel using benzene as the eluent, giving 9 mg (20%) of *p*-nitrobenzaldehyde.

*3,4-Dihydro-5,6-diphenyl-2-pyridone (**7**).* A solution of deoxybenzoin (3.0 g) in THF (50 ml) was treated with NaH (0.8 g, 50% suspension in oil) at 60—70 °C for 1 h, and then a solution of 3-chloropropionitrile (1.4 g) in THF (10 ml) was added to the resultant solution at 0 °C. The reaction mixture was stirred at room temperature for 2 h, and refluxed for 2 h, and then poured into water to give solid (1.9 g). After a solution of the solid (1.9 g) in concd H_2SO_4 (50 ml) was stirred at room temperature for 12 h, the solution was poured into water to give crystals which were recrystallized from EtOH to afford 1.95 g (51%) of **7**, mp 220—221 °C (lit,[8] mp 218—219 °C). Found: C, 81.79; H, 5.83; N, 5.72%. Calcd for $C_{17}H_{15}NO$: C, 81.90; H, 6.06; N, 5.62%.

*Thermolysis of 1 : 1 Adduct **3A**.* A solution of **3A** (100 mg) in xylene (4 ml) was refluxed for 15 h. The solvent was evaporated *in vacuo* to leave the residue which was chromatographed on silica gel using benzene as the eluent to give 64 mg (64%) of **4** and 8 mg (6%) of **5**.

*Reaction of Azaspiropentene **1** with α,*N*-Diarylnitrones (**8**).* A solution of **1** (326 mg, 2.28 mmol) and α,*N*-diphenylnitrone (**8a**) (450 mg, 2.28 mmol) in benzene (10 ml) was refluxed for 3 h under nitrogen. The reaction mixture was concentrated *in vacuo*, and the residue was chromatographed on silica gel using $CHCl_3$ as the eluent. From the first and second fractions, 40 mg (14%) of benzaldehyde and 78 mg (39%) of benzanilide were obtained respectively. The third fraction gave 215 mg (51%) of 1-amino-1-(*N*-phenylbenzamido)cyclopropane (**10**) as colorless oil. IR (neat) 3400, 3320 (NH), 1650 cm^{-1} (C=O). ^{1}H-NMR (CCl_4) δ 0.5—1.4 (m, 4H), 2.27 (broad, 2H), 6.8—7.5 (m, 10H). MS *m/e* 252 (M^+), 147 (M^+—PhCO, base peak), 105.

A similar reaction of **1** (400 mg, 2.81 mmol) and α-(*p*-nitrophenyl)-*N*-phenylnitrone (**8b**) (680 mg, 2.81 mmol) in benzene (10 ml) for 5 h afforded 140 mg (33%) of *p*-nitrobenzaldehyde, 184 mg (23%) of benzanilide, and 170 mg (16%) of 1-(*p*-nitrobenzylideneamino)-1-(*N*-phenylbenzamido)cyclopropane (**9b**), mp 185—186 °C, as colorless prisms (from EtOH). IR (KBr) 1662 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ 1.20—1.83 (m, 4H), 6.8—7.5 (m, 10H), 7.90, 8.25 (each d, 2H, *J*=9 Hz), 8.51 (s, 1H, N=C**H**). ^{13}C-NMR ($CDCl_3$) δ 21.3, 62.6, 123.7, 126.5, 127.9, 128.6, 128.8, 129.0, 130.1, 135.9, 141.5, 142.9, 151.9, 170.7. MS *m/e* 385 (M^+). Found: C, 71.72; H, 4.93; N, 10.84%. Calcd for $C_{23}H_{19}N_3O_2$: C, 71.67; H, 4.97; N, 10.90%.

The reaction of **10** with 1 equivalent of *p*-nitrobenzaldehyde in boiling EtOH for 3 h afford **9b** in 36% yield.

*Hydrolysis of 1 : 1 Adduct **9b**.* A suspension of **9b** (47 mg) in EtOH (6 ml) was stirred with concd HCl (2 drops) at room temperature. After 1 h the suspension turned to a clear solution. After the solution was concentrated *in vacuo*, water was added to the residue and then the mixture was extracted with ether. The extract was concentrated

to give 7 mg (38%) of *p*-nitrobenzaldehyde. The aqueous layer was made basic with NaOH aq solution, and then extracted with ether. The extract was evaporated *in vacuo* to leave 30 mg (100%) of **10**.

Oxygen-17 Nuclear Magnetic Resonance. III.[1] Oxygen Atoms with a Coordination Number of Two

Tadashi SUGAWARA, Yuzo KAWADA, Morimatsu KATOH, and Hiizu IWAMURA*

Division of Applied Molecular Science, Institute for Molecular Science, Myodaiji, Okazaki 444

(Received May 23, 1979)

Fourier transform ^{17}O NMR spectra have been measured for a number of alcohols, ethers, acetals, formates, acetates, and esters of inorganic acids in natural abundance at 10.8 MHz. The ^{17}O chemical shifts which cover a range as large as several hundred ppm are primarily governed by the sum of electronegativity of the first atoms or groups attached to the central oxygen. The downfield shift due to β-methyl groups in alcohols and ethers is in parallel with decrease in their ionization potentials, demonstrating the importance of the paramagnetic screening term in the ^{17}O shifts of these compounds. Diamagnetic shift due to γ-carbons and -oxygens has also been disclosed.

The first observation of ^{17}O nuclear magnetic resonance signals was reported as early as in 1951.[2] Chemical shifts of more than one hundred organic compounds of relatively small molecular weight were documented by Christ *et al.* in 1961.[3] Wider applications of the ^{17}O NMR technique have since been hampered both by a low natural abundance (0.037%) and by an appreciable electric quadrupole moment ($Q=-2.6\times10^{-26}$ cm^2) which effects line broadening of the ^{17}O isotope. Recent advances in FT-NMR instrumentation together with rf units with a frequency synthesizer and probe heads with a tunable preamplifier have made observation of ^{17}O NMR routinely available on samples with ^{17}O isotope in natural abundance.[4] In view of an important role of oxygen-containing functions in chemistry, establishment of a useful ^{17}O NMR shifts *vs.* structure correlation is indispensable. We wish to report here the ^{17}O NMR shifts of a variety of alcohols, ethers, acetals, formates, acetates, and esters of inorganic acids, and review a number of empirical rules governing the shift data of these compounds as well as the literature values[4] for some typical compounds with dicoordinated oxygen functions.

Results and Discussion

A General Trend in ^{17}O Shifts. The ^{17}O NMR shift data of dicoordinated oxygen functions are given in Table 1. Firstly we note that the ^{17}O shifts have a wide range of several hundred ppm. This is quite large in reference to 10 and 200 ppm of the ^1H and ^{13}C shift ranges, respectively, of ordinary organic compounds and will give the impression that ^{17}O NMR spectra can be most informative as a structural probe. Strictly speaking, however, we have also to take into account of the wide ^{17}O NMR line-width unprecedented in ^1H and ^{13}C NMR. The amount of information derivable from chemical shift is approximately given by the shift range (Δ) divided by the spectral line width ($\Delta_{1/2}$). When the ^1H, ^{13}C, and ^{17}O NMR are compared, Δ can be taken as 0.8, 4, and 8 kHz for example and $\Delta_{1/2}$ may be typically 1, 1, and 100 Hz, respectively. Therefore, the capacity of information derivable from chemical shift data of ^1H, ^{13}C, and ^{17}O NMR spectroscopies would be ($\Delta/\Delta_{1/2}=$) 800, 4000, and 80, respectively. The widest shift range observed for the ^{17}O NMR should not necessarily be overemphasized.

It may be noted in the second place that the water molecule has the oxygen atom which resonates at one of the highest field region,[5] and the resonance for the central oxygen atom of ozone appears at the extreme downfield. Other data on the oxygens attached to various kinds of elements are scattered in between. Changes in the oxygen-17 chemical shift appear to be due primarily to alterations in the electron density at oxygen caused by changes in the electronegativity of α-atoms attached to the central oxygen atom. As illustrated by an approximately linear correlation in Fig. 1, downfield shift is produced as more electronegative atoms are introduced. The line has a slope of about 270 ppm/electronegativity unit which is about six times as steep as those obtained by similar plots of the ^{13}C shifts *vs.* the electronegativity of the adjacent hetero atoms.[6] We point out that, whereas the diamagnetic electric current which is directly affected by the electronegativity of ligands plays a major role in controlling the chemical shifts of ^1H, the ^{13}C and ^{17}O NMR shifts are governed by the paramagnetic screening and decrease of shielding with the increasing electronegativity of the substituents may be provided by increase in the mean inverse cube of the 2p electron radius $\langle r^{-3}\rangle_{oxygen}$ and the orbital term Q_{AA} (*vide infra*).[7]

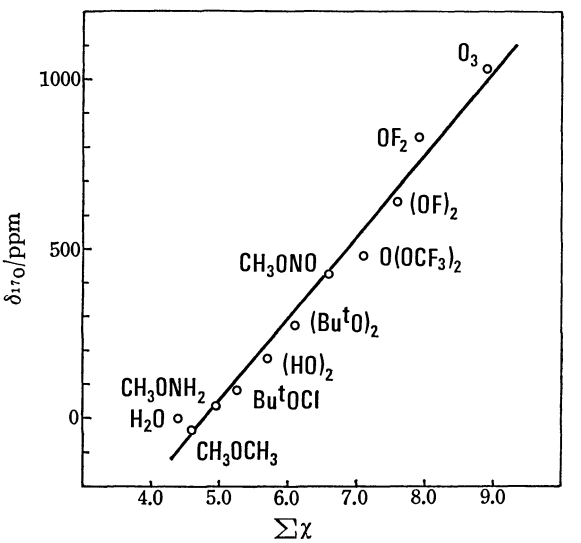

Fig. 1. Plots of ^{17}O NMR shifts *vs.* the sum of the electronegativities for dicoordinated oxygen compounds. Electronegativities (which are group values where relevant) are from Ref. 20.

a) An approximate ratio in volume. b) Shift values in parentheses are for doubly bonded oxygens. c) No window function was applied for the measurement except for alcohols where a sensitivity enhancement parameter was set at -0.02 s throughout.

Simple Alcohols and Ethers. Shifts to lower field in the ^{17}O resonance are observed as the α-carbon is substituted with alkyl groups. Primary, secondary, and tertiary alcohols, for example, have their characteristic shift ranges: -3—10 (except for -38 ppm of methanol), 30—40 and 55—70 ppm downfield relative to water, respectively. We have so far met no exception to the above rule on the ^{17}O shifts brought about by the alkyl substitution. The presence of diamagnetic γ-effect is suggested by a slightly high field shift of 1-butanol and 2,3-dimethyl-2-butanol as compared to ethanol and *t*-butyl alcohol, respectively. An example which would violate the above shift ranges could be found in sterically congested alcohols. Changes in chemical shifts are steeper in ethers than in alcohols and esters.

The findings have two facets of importance. One is as a new method for differentiating among primary, secondary, and tertiary structures of unknown alcohols, ethers and esters. The method appears quite unique and useful, but let us point out that there is a certain limitation to the practical application of this rule to the structural elucidation of complex organic molecules. Since the oxygen-17 nucleus ($I=5/2$) has electric quadrupole moment and the line width of resonance signals is directly proportional to correlation time τ_c for the overall rotation of the molecules which in turn is correlated to solution viscosity η, a fairly fluid sample solution must be employed. When isotropic molecular tumbling is rapid on the NMR time scale, the line width ($1/T_1$) determined by quadrupole relaxation is given by Eq. 1, where q and η stand for the electric field gradient and the asymmetry parameter at the nuclear site. The Stokes-Einstein-Debye equation (Eq. 2) relates τ_c to temperature T. The measurement at elevated solution temperature is thus preferred. A

$$\frac{1}{T_1} = \frac{3}{125}\left(1+\frac{\eta}{3}\right)\left(\frac{e^2Qq}{h}\right)^2\tau_c \quad (1)$$

$$\tau_c = \frac{4\pi\eta a^3}{3kT} \quad (2)$$

sample of relatively large molecular weight ($M>150$) for which a solution of considerably high concentration may be required by the sensitivity of the present instrument often tends to be hard to measure because of line-broadening. The limitation could be avoided in principle by the use of a spectrometer with higher magnetic field and/or isotopically enriched samples.

The other is on the origin of the observed ordering of chemical shifts. There are ample examples which show that electron density at the oxygen atom increases as we go from methanol *via* ethanol and 2-propanol to *t*-butyl alcohol. The polar substituent, constants σ^* for the methyl, ethyl, isopropyl, and *t*-butyl groups are 0 (by definition), −0.1, −0.19, and −0.3, respectively. The observed shifts in Table 1 show that ^{17}O screening decreases on going from methanol to *t*-butyl alcohol, and is not compatible with the electron density at oxygen dominating the ^{17}O shifts as was the case in the previous section.

According to the Pople-Karplus theory on paramagnetic screening,[7] the screening constant of atom A bound to other atom B is given by Eq. 3. The Q's are orbital terms related to charge density on atom

$$\sigma_p^A = -\frac{e^2\hbar^2\langle r^{-3}\rangle}{2m^2c^2(\Delta E)}[Q_{AA}+\sum_{B\neq A}(Q_{AB})] \quad (3)$$

A and bond order between A and B, and ΔE is a mean or effective excitation energy. If the diamagnetic screening or the $\langle r^{-3}\rangle$ and Q_{AA} terms in the paramagnetic screening were the determining factor, tertiary alcohols and ethers which have highest electron density at oxygen should have given the highest field shifts in the ^{17}O resonance. Resonance can move downfield as the lowest-energy electronic transition is shifted to longer wavelength. The $n\rightarrow\pi^*$ transition has been shown to be crucial to the shift differences in the ^{17}O NMR of carbonyl compounds.[8] In the present case of aliphatic alcohols and ethers, the excited states to be mixed with the ground state by an external magnetic field is either the $n\rightarrow\sigma^*$ or Rydberg states.[9] Since the corresponding transition appears in the vacuum ultraviolet region and is not unambiguously characterized, let us take the adiabatic ionization potentials of these compounds as a measure of ΔE. A reasonably smooth correlation is found in the ^{17}O chemical shifts *vs.* the inverse of the ionization potentials plots both for alcohols and ethers as shown in Fig. 2.

Whereas there is no strict meaning in the apparent linearity of the plots, the correlation appears to demonstrate that the energy levels of the oxygen n-electrons are more sensitive to the structural changes in the alkyl groups than the terminating orbital levels of oxygen and that ΔE gets smaller on going from the methyl through ethyl and isopropyl to *t*-butyl groups. The paramagnetic contribution to the total screening constant is concluded to be important in simple alcohols and ethers.

Simple cyclic ethers present no anomaly in that

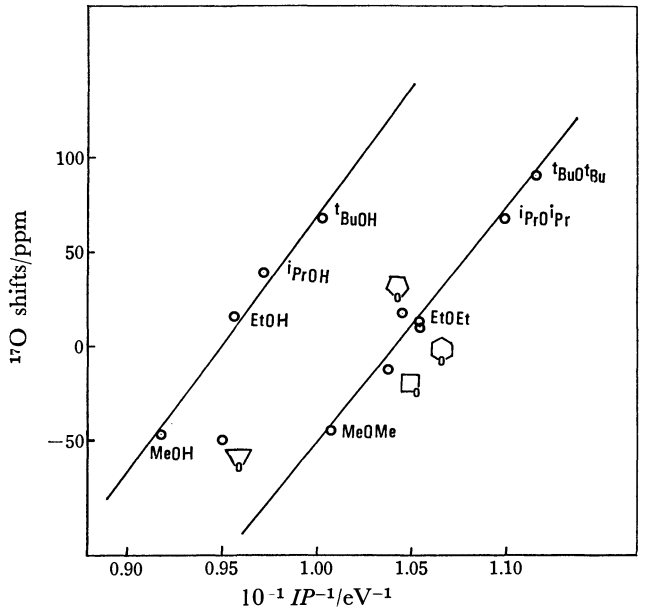

Fig. 2. Plots of ^{17}O chemical shifts *vs.* the inverse of adiabatic ionization potentials (from Ref. 11) of alcohols and ethers.

their ^{17}O shifts *vs.* $1/IP$ plots conform to a line given by acyclic ethers. Oxiranes form a conspicuous exception to this trend. Just as the well-known case of the ^1H and ^{13}C shielding of three membered rings, the ^{17}O resonance of oxiranes shows a marked shielding effect. The diamagnetic shielding is, however, not as strong as it should be expected from the ^{17}O shifts *vs.* $1/IP$ plots for other ethers. These anomalies of oxiranes will be discussed separately in the forthcoming paper in view of the importance of the epoxide functions in many fields of chemistry.

Acetals and Orthoesters. When the β-methylene group in methyl propyl ether (δ −18)[10] is replaced by oxygen to make dimethoxymethane (δ 10), downfield shift by 28 ppm is obtained. The downfield shift of a similar amount ($\Delta\delta$ 27 ppm) is observed on going from tetrahydropyran (δ 10) to 1,3-dioxane (δ 37). An approximate additivity appears to hold for this downfield shift due to introduction of the β-oxygen atoms. A shift by 56 ppm on going from dipropyl ether (δ 7)[10] to bis(methoxymethyl) ether (δ 65) is just twice as large as 28 ppm. The ^{17}O resonances for 1,3,5-trioxane and 2,8,9-trioxaadamantane appear at 54 and 56 ppm downfield of tetrahydropyran, respectively.

γ-Effects. Effects of the γ-carbon atom on the ^{17}O NMR shifts have been pointed out;[10] replacement of β-hydrogens in ethyl methyl ether with the methyl groups produces a stepwise highfield shift by 6, 1.5, and 2.5 ppm. Now, replacement of the γ-carbon atom in butyl methyl ether (δ −18)[10] by oxygen to give 1,2-dimethoxyethane accompanies 5 ppm upfield shift. Similar upfield shifts are observed also in diethylene glycol dimethyl ether (6.5 ppm from dibutyl ether (δ 3.5)) and *p*-dioxane (11 ppm from tetrahydropyran).

The observed diamagnetic shifts of 6 and 12 ppm of ethylene glycol and 2-chloroethanol, respectively,

relative to 1-propanol (δ 0) may be additional examples of γ-effect due to a hetero atom.

Esters. The effect of alkyl groups on ^{17}O shifts of the ethereal oxygen of esters is similar to that in alcohols and ethers but is less pronounced. The shift differences between two extreme alkyl groups, namely, the methyl and *t*-butyl derivatives, are 130 and 106 in ethers and alcohols, respectively, and only 93, 70, and 60 ppm in nitrites, formates, and acetates, respectively. The results may be a manifestation of resonance interaction as depiced in Eq. 4 serving as a buffer of the electronic effect of alkyl groups R. Contribution of the zwitterionic canonical structure in each resonance hybrid will be in the order: acetates>formates>nitrites.

$$\begin{array}{l} R'-\underset{\underset{O}{\|}}{C}-\dot{O}-R \leftrightarrow R'-\underset{\underset{O^-}{|}}{C}=\overset{+}{O}-R \\ \\ O=N-O-R \leftrightarrow {}^-O-N=\overset{+}{O}-R \end{array} \qquad (4)$$

We conclude that, in spite of some difficulties inherent in natural-abundance ^{17}O NMR measurements, this new technique has a number of merits worth the effort. Firstly, the technical difficulties are partly compensated by the short spin-lattice relaxation times of the quadrupolar ^{17}O which enable us to accumulate a large number of transients in a given time. Often a spectrum with good S/N ratios is obtained within a time period shorter than that necessary for measuring ^{13}C NMR signals due to quaternary carbons of relatively long T_1 and with almost no NOE effect. Secondly, we have pointed out that ^{17}O NMR spectra are highly informative as a structural probe. Shift ranges as large as 1000 ppm for dicoordinated oxygens are governed by the paramagnetic screening and can be interpreted in terms of empirical rules basically similar to the familiar ones employed in ^{13}C NMR spectroscopy.

Experimental

Spectral Measurements. The measurements were made with the ^{17}O nuclei in natural abundance (0.037 %) on a Varian FT-80A spectrometer at 10.782 MHz. For a 8000 Hz spectral width, 320 data points in the time-domain spectra were used, the Fourier number being kept at 16384. The number of transients accumulated with a 90° pulse and an acquisition time of 0.02 s was in the range 10^4—10^5 to get spectra of reasonable S/N ratios. When a longer acquisition time (AT) of 0.1 s was employed, the number of data points (DP) increased to 1600 according to equation $DP=2AT\cdot SW$ (SW is a spectral width). The measurement under these conditions was found to be worse with respect to the S/N of spectra, not only because it required the accumulation time five times as long as the previous one to get the same sum of the number of transients, but also because it sampled mostly noise signals after the free induction signals practically decayed at $5T_1$(<0.02 s). The ^{17}O shifts and half-band-widths did not differ at all from those obtained under the standard conditions. Since quadrupole relaxation of ^{17}O nuclei is rapid, the use of long delay times between the end of each rf pulse and the beginning of data collection is not in principle necessary. However, some baseline distortions in transformed frequency-domain signals often resulted due to incomplete spectrometer recovery following rf pulse, when too short delay times were employed.[12] This was more pronounced in ^{17}O NMR, as the rf frequency was lower than those of ^{1}H and ^{13}C spectroscopy. Alpha delay was usually set at 800—1000 μs.

Chemical shifts were measured as frequency shifts from the rf synthesizer frequency (8.532000 MHz) and expressed in ppm relative to the oxygen of water which resonated at 10.78321 MHz when measured in a capillary tube placed concentrically within a sample tube of 10 mm o.d. Chemical shifts are accurate to $\pm$1 ppm. The sample temperature was at 34—36 °C unless otherwise stated in Table 1. The half-band-widths of alcohols and ethers were 60—280 Hz under these conditions.

Materials. The following compounds were prepared according to the literature and their purity was confirmed by VPC and/or spectral data: di-*t*-butyl ether,[13] trimethyloxonium tetrafluoroborate,[14] bis(methoxymethyl) ether,[15] 2,8,9-trioxaadamantane,[16] and 2,8,9-trioxa-1-phosphaadamantane.[17] The samples of (2*H*-)1,3-benzodioxole and 1,4,6,9-tetraoxaspiro[4.4]-nonane were kindly supplied by Prof. Dr. S. Smoliński of Jagellonian University, Kraków, Poland. Pure samples from commercial sources were used otherwise.

(Received June 11, 1979)

The *cis*-isomers of *N,N'*-diacylindigo (*e.g.*, *cis-N,N'*-diacetyl-, distearoyl-, dibenzoyl-, and bis(3,5-dinitrobenzoyl)-indigo) were found to separate out in a crystalline form from a solution of the corresponding *trans*-isomer upon irradiation. The kinetics of the *cis*-to-*trans* isomerization of these four *cis-N,N'*-diacylindigos was studied, the relative rates being 7.9, 11.0, 1.0, and 5.1 respectively. Several amines were found to accelerate the *cis*-to-*trans* isomerization in the order of: $Et_2NH > PrNH_2 > Et_3N > i\text{-}Pr_2NH$ in the case of *cis-N,N'*-diacetylindigo and in the order of: $Et_2NH > i\text{-}Pr_2NH > PrNH_2 > Et_3N$ in the case of *cis-N,N'*-dibenzoylindigo.

Photochemical and thermal isomerizations are of interest in the field of natural products, including retinal,[1] bilirubin,[2] phytochrome,[3] and trichochrome.[4] During the course of an investigation of melanins, we have interested indigoid pigments as model compounds of trichochromes.

Indigo is a *trans* compound: attempts to convert it photochemically to the corresponding *cis*-isomer have been unsuccessful.[5] This photostability was first explained by hydrogen-bonding,[6] and the explanation was substantiated by the observation that the *N,N'*-diacetyl-[5,7] and *N,N'*-dimethylindigo[8,9] show phototropic behavior. Wyman[10] later suggested the contribution of a fast proton transfer in the excited state, and also reported the existence of a photochemical equilibrium between *cis*- and *trans*-thioindigo in an inert solvent. Recently, the preparation and spectroscopic properties of a basic chromophore of thioindigo have been reported.[11]

As far as indigo derivatives are concerned, the separation of the *cis*-isomer has been unsuccessful, while the isomerization of *cis-N,N'*-diacylindigo has not yet been examined. This paper will be concerned with the isolation of *cis*-isomers of *N,N'*-diacylindigo and with a kinetic study of the *cis*-to-*trans* isomerization in the dark as well as the effect of amines on the *cis*-to-*trans* isomerization of *N,N'*-diacylindigo.

Results and Discussion

Isolation of cis-N,N'-*Diacylindigo.* We found that *cis-N,N'*-diacetyl-, distearoyl-, dibenzoyl-, and bis(3,5-dinitrobenzoyl)indigo separated in crystalline form from a solution of the corresponding *trans*-isomer on irradiation. The yield of the *cis*-isomer was almost quantitative after repeated irradiation and concentration.

The structure of each *cis*-isomer was confirmed by elemental analyses and UV and IR spectra. The IR spectra show two carbonyl bands characteristic of the *cis*-isomer.[11] The UV spectrum of *cis-N,N'*-diacetylindigo was almost superimposable with the calculated spectrum.[12] All four *cis-N,N'*-diacylindigos changed quantitatively into the corresponding *trans*-isomers when dissolved in a solvent.

The cis-*to*-trans *Isomerization of* cis-N,N'-*Diacylindigo.* It is generally accepted that the size and the structure of substituents on the two nitrogen atoms of the indigo molecule (I) sterically affect the *cis-trans* isomerization of this compound. In order to ascertain the effects of the substituents, we prepared benzene solutions of *cis-N,N'*-diacetyl-, distearoyl-, dibenzoyl-, and bis(3,5-dinitrobenzoyl)indigo, which were then kept at a constant temperature in the dark. The change in the absorption curve with the time showed the isomerization of the *cis*-isomer to the *trans*-isomer. From the change in the *cis*-isomer percentage with the time, the reaction-rate constants were calculated: the other kinetic parameters were also calculated, as is shown in Table 1.

The relative rate shows that alkyl substituents correspond to a faster rate than do the aryl substituents. The value of the activation free energy is almost 20 kcal/mol, while the activation energy is between 19 and 23 kcal/mol. The value of the activation energy is far less than that of stilbene, 42.8 kcal/mol,[13] or methyl cinnamate, 41.6 kcal/mol.[14] Substituents on stilbene decrease the activation energy.[15] These facts reveal that *cis-N,N'*-diacylindigos are less stable than *cis*-stilbene or *cis*-cinnamate because the structure of the latter can be planar.

Effects of Amines on the cis-*to*-trans *Isomerization of* cis-N,N'-*Diacylindigo.* We found that amines accelerate the *cis*-to-*trans* (IIa to Ia) isomerization of *cis-N,N'*-diacetylindigo. In order to clarify the rela-

tion between the effectiveness and the amount of amines for the *cis*-to-*trans* isomerization, the rate was measured in the presence of an equimolar amount of triethylamine under various concentrations. The reaction was found to be pseudo-first-order for the indigo, and the amine concentration was constant during the reaction. These facts reveal that the amine acts as a catalyst.

Also, the observed reaction rate constant was proportional to the concentration of triethylamine. This suggests that equimolar amounts of the indigo and the amine make up the reaction intermediate (III).

Furthermore, the effects of several kinds of amines were compared in the case of *cis*-*N,N'*-diacetylindigo (IIa) as well as in the case of *cis*-*N,N'*-dibenzoylindigo (IIc). Their relative rates are summarized in Table 2. It can be concluded that the order of acceleration by these amines is roughly in accord with the basicity of the amines except when steric hindrance plays an important role, as in the case of diisopropylamine or triethylamine.

Experimental

trans-N,N'-*Diacetylindigo (Ia).* Ia was prepared by the modified method reported by Blanc and Ross[12] and was recrystallized from benzene: mp 256—257 °C. IR (KBr): 1690, 1680, 1595 cm^{-1}. UV (C_6H_6) max: 562 nm (ε 7000).

trans-N,N'-*Distearoylindigo (Ib).* A mixture of indigo (1.0 g) and stearoyl chloride (11.6 g) in pyridine (10 ml) was refluxed for 20 min to give Ib, which was then recrystallized from petroleum ether: 28% yield: mp 101—102 °C. IR (KBr): 1690, 1670, 1600 cm^{-1}. UV (C_6H_6) max: 567 nm (ε 7100). Found: C, 78.28; H, 9.65; N, 3.43%. Calcd for $C_{52}H_{78}N_2O_4$: C, 78.54; H, 9.88; N, 3.52%.

trans-N,N'-*Dibenzoylindigo (Ic).* Ic was prepared by the modified method reported by Posner.[12b] Mp 256—257 °C. IR (KBr): 1700, 1660, 1590 cm^{-1}. UV (C_6H_6) max: 574 nm (ε 7700).

trans-*Bis(3,5-dinitrobenzoyl)indigo (Id).* Id was prepared from indigo (1.0 g) and 3,5-dinitrobenzoyl chloride (8.89 g) and was recrystallized from hexane–chloroform. 50% yield. Mp 249—252 °C. IR (KBr): 1700, 1680, 1620, 1600, 1550, 1345 cm^{-1}. UV (C_6H_6) max: 552 nm (ε 6200). Found: C, 55.38; H, 2.14; N, 12.23%. Calcd for $C_{30}H_{14}N_6O_{12}$: C, 55.39; H, 2.16; N, 12.92%.

General Method for the Isolation of cis-N,N'-*Diacylindigo.* The *trans*-isomer was dissolved in a slightly soluble solvent, such as benzene, petroleum ether, or hexane, and was then irradiated with visible light, the wave length being more than 550 nm, the light source being a mercury lamp (100 W), and the filter solution being cobalt sulfate 60 g+potassium chromate 3.24 g+sodium carbonate 12 g/750 ml water, for an appropriate period. This afforded precipitates of the corresponding *cis*-isomer.

cis-N,N'-*Diacetylindigo (IIa).* Ia was dissolved in benzene by heating, and then an equivalent volume of hexane was added (5×10^{-4} mol/l). The solution was irradiated with visible light for 5 h. Crimson needles; mp 244—246 °C. IR (KBr): 1720, 1690, 1590 cm^{-1}. UV (C_6H_6) max: 438 nm (ε 4500). Found: C, 69.29; H, 3.95; N, 7.99%. Calcd for $C_{20}H_{14}N_2O_4$: C, 69.36; H, 4.07; N, 8.08%.

cis-N,N'-*Distearoylindigo (IIb).* Ib was dissolved in petroleum ether by heating, and an approximately saturated solution was irradiated by visible light for 30 min. Orange needles; mp 101—103 °C. IR (KBr): 1720, 1700, 1600 cm^{-1}. UV (C_6H_6) max: 435 nm (ε 3900). Found: C, 78.58; H, 9.92; N, 3.48%. Calcd for $C_{52}H_{78}N_2O_4$: C, 78.54; H, 9.88; N, 3.52%.

cis-N,N'-*Dibenzoylindigo (IIc).* Ic was dissolved in benzene by heating, and then petroleum ether was added to the mixture. After cooling, precipitates were filtered off, and the filtrate was irradiated with visible light for 10 h: mp 245—247 °C. IR (KBr): 1725, 1675, 1595 cm^{-1}. UV (C_6H_6) max: 460 nm (ε 3900). Found: C, 76.01; H, 3.71; N, 5.82%. Calcd for $C_{30}H_{18}N_2O_4$: C, 76.58; H, 3.85; N, 5.95%.

cis-N,N'-*Bis(3,5-dinitrobenzoyl)indigo (IId).* Id was dissolved in benzene by heating (4×10^{-4} mol/l), and then the solution was irradiated with visible light for 4 h to afford orange needles; mp 205—210 °C. IR (KBr): 1730, 1680, 1620, 1600, 1540, 1340 cm^{-1}. UV (C_6H_6) max: 436 nm (ε 2800). Found: C, 55.93; H, 2.18; N, 12.48%. Calcd for $C_{30}H_{14}N_6O_{12}$: C, 55.39; H, 2.16; N, 12.92%.

Kinetics for the cis-*to*-trans *Isomerization of* N,N'-*Diacylindigo.* The *cis*-isomer was dissolved in benzene, the concentration being in the order of 10^{-4} mol/l. The sample solution was sealed in several ampoules, each aliquot being 3 ml. Each ampoule was wrapped in aluminum foil and kept in a thermostat. After an appropriate time, each ampoule was pulled out from the thermostat and the *cis*-isomer percentage was measured from the change in the visible absorption curve of each ampoule solution. From the change in the *cis*-isomer percentage with the time pseudo-first-order rate constant, k, was calculated at 45.2 °C, from which the activation free energy, ΔG^{*}, was subsequently calculated. The activation enthalpy, ΔH^{*}, was derived from the activation energy, E_a, which was itself calculated from the rate constants at different temperatures, 45.2 °C and 54.6 °C.

Acceleration Effect of Amines on the cis-*to*-trans *Isomerization of* cis-N,N'-*Diacetylindigo. Concentration of Amines*: A

benzene solution (5 ml) of *cis-N,N'*-diacetylindigo (IIa) with a concentration of 6.54×10^{-4}, 7.52×10^{-4}, 8.18×10^{-4}, and 1.02×10^{-3} mol/l, and a benzene solution of triethylamine with an equivalent mol/l concentration were prepared. Each indigo solution was mixed with 5 ml of a triethylamine solution of the corresponding concentration. Then the absorbance at 562 nm was scanned by the recorder at time intervals of 15 min. For each concentration, the rate constants were found to be 3.85×10^{-5}, 4.90×10^{-5}, 5.74×10^{-5}, and $7.74\times10^{-5}/s^{-1}$.

Acceleration Effect and Structure of Amines. The relation between the acceleration effect and the structures of the amines was examined by measuring the reaction rate of the *cis*-to-*trans* isomerization of *cis-N,N'*-diacetylindigo or *cis-N,N'*-dibenzoylindigo in a benzene solution to which an equimolar amount of each amine had been added.

A Novel Carbonization of Naphthalene and Other Aromatic Compounds in a Molten Mixture of $AlCl_3$–NaCl–KCl[1)]

Etsuro OTA,* Sadao INOUE, Masahiro HORIGUCHI,† and Sugio OTANI†

College of Technology, Gunma University, Kiryu, Gunma 376

(Received December 25, 1978)

The use of molten salt as the solvent made it possible to carry out the carbonization process throughout in the liquid state. The process proceeded at a lower temperature than conventional ones, resulting in higher yields. The carbon was deposited from the reaction mixture as powder or flakes; it was similar to "raw coke" in its composition. Thus, 12.8 g of naphthalene was treated in a mixed melt (mp 95 °C) of $AlCl_3$, NaCl, and KCl (60:26:14 mol%) at 300 °C for 10 h, yielding 11.3 g of carbon. Anthracene, phenanthrene, substituted naphthalene, and biphenyl also gave carbon in yields 69—99% of the theoretical yields, while N-containing heterocycles hardly reacted at all. The X-ray parameters of the carbons, the d_{002} spacing and the crystal thickness, L_c, varied with the kind of compound used and with other factors; after heat-treatment at 2800 °C, these values were 3.37—3.52 and 20—700 Å respectively. As the mode of reaction, an acid-catalyzed ionic mechanism was proposed, and the role of hydrogen-disproportionation was discussed.

Carbonization in a homogeneous liquid system is interesting in many aspects. It would seem to favor, at least, theoretical studies facilitating the introduction of powerful analytical methods into the carbon chemistry. The coking of pitch is a typical process involving liquid carbonization, but in this case the whole system can not avoid solidifying as the reaction proceeds, since the reaction solvent is the reactant itself. Therefore, an inert solvent which is not incorporated into the resulting carbon is desirable for the carbonization in question.

Lewis and Singer[2)] presented *m*-quinquephenyl as an inert solvent for carbonization, but according to Evans and Marsh[3)] this compound polymerized and pyrolysed and did react with the reactant during carbonization. This seems to indicate that an organic material ultimately can not be an inert carbonization solvent.

On the other hand, some Lewis acids are known to be effective catalysts for the polycondensation of aromatic compounds.[4–6)] One of the present authors previously studied the effect of the aluminium chloride catalyst on the carbonization of coal-tar pitches.[7)] The catalyst acted to lower the carbonization temperature and to give graphitizable carbon. Recently Mochida and his coworkers[8)] reported similar effects of this catalyst on the carbonization of aromatic compounds.

On the basis of these facts, we attempted carbonization in an inorganic melt containing aluminium chloride as the reaction solvent. Among many reports on the use of inorganic melts for organic reactions, only a few[9)] have mentioned the formation of carbonaceous matter as an undesired by-product, and none have mentioned the use of a melt specially planned for the purpose of carbonization.

As the melt, a mixture of 60 mol% of anhydrous aluminium chloride and 40 mol% of alkali metal chlorides was used. The reasons for this choice were its relatively low melting point, its strong acidity, its low cost, and the ease of handling. According to Kikkawa *et al.*,[10)] this molten system is believed to be in an equilibrium state, as is shown in Scheme 1, and to exhibit the catalytic action of aluminium chloride only when its content is over 50 mol% because of the very large equilibrium constant. In this melt, therefore, about 20 mol% of aluminium chloride can be expected to be present as active Lewis acid.

$$0.6\,AlCl_3 + 0.4\,MCl \rightleftharpoons 0.4\,AlCl_4^- + 0.4\,M^+ + 0.2\,AlCl_3 \quad (1)$$

M: K and Na

As the raw material, naphthalene was mostly used, among other carbocyclic and heterocyclic aromatic compounds.

In consequence, carbonization was successfully carried out throughout in the liquid state; a remarkable lowering of the carbonization temperature as well as a high carbon yield also resulted. Here we wish to describe this quite new method of carbonization.

Experimental

Materials. *Phenanthrene*: Prepared from a raw product of technical grade (90% pure) by purifying[11)] it to a purity of 99% or more; mp 99 °C (ethanol).

Tetrabenzo[a,c,h,j]*phenazine*(*PZ*): Prepared according to Pschorr;[12)] mp 480 °C(nitrobenzene).

Other Aromatic Compounds and Inorganic Salts: Commercially available reagents of an extra pure and guaranteed grade were used without further purification.

Standard Procedure. A 100-cm³ three-necked flask was fitted with a stirrer, a thermometer, and an air condenser with a calcium chloride tube on the top. In the flask a mixture of 0.6 mol of anhydrous aluminium chloride, 0.26 mol of sodium chloride, and 0.14 mol of potassium chloride was placed, after which the mixture was heated to melt (mp 95 °C). With vigorous stirring 0.01 mol of a raw material was then added at once. The temperature was raised to 300 °C for 2 h at a constant rate, and held there (±5 °C) for an additional 10 h. After some cooling, but before solidification, the mass was poured into a mixture of 500 g of crushed ice and 50 cm³ of 1 mol dm^{-3}-hydrochloric acid. The resulting black precipitate was filtered with suction, washed thoroughly with 0.1 mol dm^{-3}-hydrochloric acid and distilled water successively, and dried on calcium chloride in a vacuum. The crude product thus obtained was refluxed with 100 cm³ of benzene for 1 h and filtered while still hot to separate it into benzene-soluble (BS) and benzene-insoluble (BI) portions. The BI was dried in air and then on phosphorus pentaoxide in a vacuum. Hereafter, the BI shall be called "carbon" for reasons to be

a) Calcd for the amount of the raw meterial used, based on the assumption that BS is the unchanged raw material. b) Calcd for the theoretical amount of carbon in the raw material used, based on the assumption that BI consists of pure carbon. c) The evolution of HBr was obserbed at 150 °C. d) The evolution of a brown gas was observed at 120 °C. e) Tetrabenzo(*a,c,h,j*)phenazine. f) Extracts by nitrobenzene (not by benzene), almost pure PZ. g) The evolution of HCl was observed soon after the mixing. h) A run specially designed to obtain precise quantitative data with a scale 10 times the others. i) No reaction. j) Almost no reaction.

described later.

All the runs were carried out by this procedure unless otherwise stated.

Estimation of the Reactivity of the Raw Materials. During the reaction, a series of specimens of the reaction mixture were taken out at regular intervals and poured into 0.1 mol dm^{-3}-hydrochloric acid; the mode of the resulting precipitate was observed. The first substance to be yielded was a floating brown precipitate, which consisted of tar or pitch; then a sinking black precipitate was yielded, with an increase in the reaction time. The time necessary for the first appearance of such a heavy precipitate was regarded as a measure of the reactivity of the raw materials.

Evaluation of Graphitizability of the Carbon. The carbons obtained were heated at 2800 °C in an argon stream for 15 min. The X-ray parameters for the carbons before and after the heat-treatment were calculated from the 002-diffraction profiles.

Results and Discussion

Properties of the Carbon Obtained. Outline: Most of the BI's formed black powder or flakes, and most were insoluble in usual organic solvents. Even upon hot-quinoline extraction they lost only a small percentage of their weight. At red-heat they were infusible, and they only slowly disappeared after prolonged heating. As is shown in Fig. 1 as an example, the X-ray diffraction profile of every BI exhibited a rather broad peak near the diffraction angle (2θ) of 25°, indicating that every BI has a layer structure similar to those of known carbon materials. The results of the elemental analysis of the BI's, given in Table 1, show that the values of the atomic hydrogen-to-carbon ratio (H/C) fall mostly within a range of 0.4—0.5.[13] These values correspond with those of carbonaceous mesophase isolated from various carbon materials made by simple heating in the temperature range of 390—490 °C.[14] Raw coke[15a] and so-called carboid coke[15b] have been reported to have similar H/C values, 0.49 and 0.41 respectively. All these facts support the idea of calling the BI's "carbon material" or "carbon" in a broader sense.

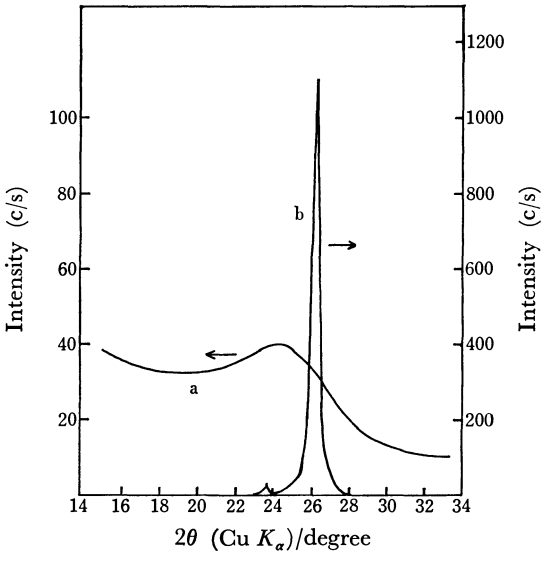

Fig. 1. 002-Diffraction profiles of a BI from naphthalene a) before and b) after heat-treatment at 2800°C.

The total value of the elemental analysis of each BI is short of 100%. The deficiency can be partly ascribed to the water and oxygen content. For example, the BI from anthracene (Run 1 in Table 1) lost 5.5% of its weight when heated in a glass tube over a small flame, yielding water drops on the cold wall of the tube. Regarding the oxygen content, no direct evidence has yet been obtained. However, as will be described below, some facts suggest that the

BI's have a tendency to take in oxygen in some way.

Graphitizability: The results of the X-ray analysis, given in Table 2, show that the graphitizability of the carbons ranged widely. As factors influencing the graphitizability, besides the kind of raw material, the atmosphere during the reaction and the after-treatment proved important. An oxidative atmosphere showed a tendency to make the carbon nongraphitizable. About this problem a detailed investigation is now in progress.

Shape and Size: As Fig. 2 shows, the carbons were of various types as to their shape and size; that is, one type formed a fine powder, and another, rough films or plates. Some of the largest of the latter were 4—5 mm in diameter. The type seems to be determined mainly by the kind of raw material. The more reactive raw materials, such as bromonaphthalene and naphthol, gave large flakes, while the moderately reactive ones, such as naphthalene and anthracene, yielded fine particles. However, this is not always the case. A compound could often give different types of carbons when the reaction conditions are modified.

These results, considered together with those of the graphitizability, indicate the possibility of controlling the properties of the carbon by a proper combination of raw material and reaction conditions.

Mode of the Reaction. The standard melt is a colorless, clear liquid of a low viscosity in the temperature range of 95—400 °C, while it is immediately colored by the addition of a raw material. Only a few miligrams of every compound were enough for the coloration. The hue varied depending on the nature of the raw material; for example, it was deep blue with anthracene and dull orange with biphenyl. At the same time, the temperature of the reaction mixture rose by several degrees. No appreciable gas evolution was observed during all the period of reaction except in the cases described in the footnote in Table 1.

The temperature rise mentioned above indicates the dissolution of the raw material with a large heat of solution due to the strong solvation, and suggests, together with the coloration, the formation of some reactive intermediate.

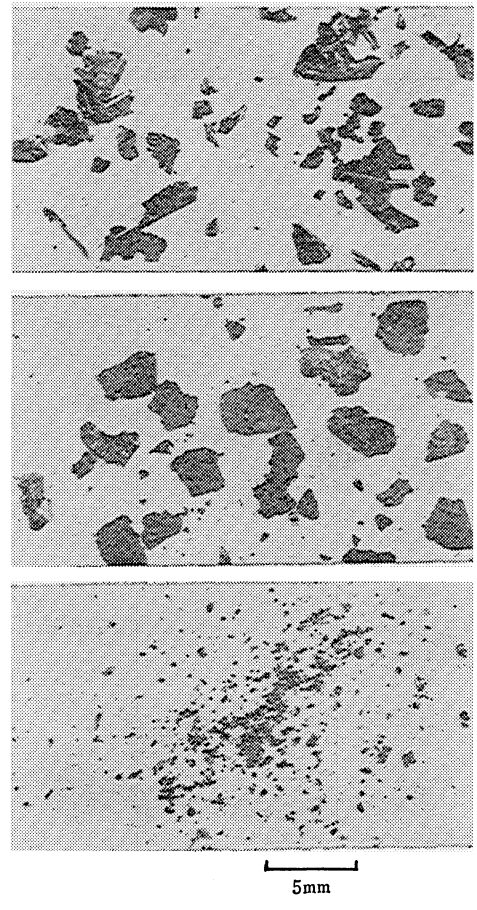

Fig. 2. Shape of BI's from a) 1-bromonaphthalene, b) 1-naphthol, and c) anthracene.

In the majority of cases, a reaction period of 4—8 h at 300 °C was almost enough for the first appearance of carbon in the reaction mixture. A longer reaction time increased the carbon yield.

In the case of naphthalene, during the first 1—2 h the reaction mixture was a homogeneous brown liquid, which yielded a tarry matter after the salts have been washed off; after 30 h, the mixture separated into

black precipitates and a clear, almost colorless medium. The BS from naphthalene, represented in Table 1, proved soluble in the melt at 100 °C, with a brown color.

From these facts, the reaction seems to proceed in solution, at least during the important stages.

Generally, in the precipitation polymerization of a linear polymer, the precipitating polymer does not grow further because the reactive chain end is deactivated by the entanglement of the chain. On the other hand, carbon is usually constructed from planar polymer, which is thought to be free from entanglement. The carbon here obtained is probably like this. Therefore, the fringe of the plate of carbon just produced should be still reactive for further polymerization, and the plate will continue to grow. Secondary aggregation among the plates may also be important for the growth to a visible size.

Regarding the mode of reaction, another possible one is as follows: the molten raw material is dispersed, not dissolved, in the melt as small oil drops, and inside of these oil drops the reaction proceeds under the catalytic action of aluminium chloride. In this case, the character of the reaction is essentially the same as that of the reactions mentioned above.[4-8] We can, however, find little support for this mode of reaction, but much counterevidence. For example, it can hardly explain why anthracene reacts far below its melting point, and yet more actively than naphthalene.

Reactivity of the Raw Materials. A rough evaluation of the reactivity of the raw materials was made from the estimation of the ease of carbonization. The carbon yields were also taken to consideration.

About this problem, an additional series of experiments were carried out with a shortened reaction time and at various reaction temperatures. The carbon (BI) yields of these runs, as is given in Table 3, clearly indicate the differences in reactivity among the compounds used.

From these results, the following sequences as to the reactivity may be drawn;

a) anthracene>naphthalene>phenanthrene>stilbene >biphenyl>PZ>benzene>quinoline

and b) 1-nitronaphthalene>1-bromonaphthalene>1-naphthol>1-methylnaphthalene>naphthalene.

The a) sequence indicates roughly that the larger conjugation system of the aromatic skeleton makes the compound more reactive. One of the reasons for the very small reactivities of PZ and quinoline is their general properties being inactive toward an electrophilic reagent. Another is probably the lack of a neutral molecule as the substrate for electrophilic attack. This lack can be caused by the almost complete formation of such a type of complex as $[-\overset{+}{N}=\cdots AlCl_3^-]$. The b) sequence is not likely to reflect simply the polar effect of substituents, but to show the reactivity of an individual compound in a complicated specific reaction involving the displacement and/or decomposition of the substituent itself. This view is based on the facts that nitronaphthalene decomposed soon after the mixing with the melt, evolving a brown gas; similarly, bromonaphthalene evolved hydrogen bromide. Moreover, bromonaphthalene gave carbon in a good yield at such a low temperature as 200 °C, as is shown in Table 3. These two compounds are generally less reactive toward the electrophilic reagent than naphthalene. These particular reactions present a tangential but interesting problem.

Table 3. Reaction temperatures and the yields of products[a]

No. of runs	Raw material	Reaction temp (°C)	Yield of products BS (%)[b]	BI (%)[b]
14	Naphthalene	350	8	92
15	Naphthalene	300	23	67
16	Phenanthrene	350	11	83

23	Anthracene	$AlCl_3$-NaCl-KCl (0.49 : 0.35 : 0.16)	19	84
24	Anthracene	$AlCl_3$-NaCl-KCl (0.4 : 0.3 : 0.3)	25	76
25	Biphenyl	$AlCl_3$-NaCl-KCl (0.4 : 0.3 : 0.3)	91	2
26	Naphthalene	$AlCl_3$-NaCl-KCl (0.4 : 0.3 : 0.3)	80	16

a) All the runs were carried out in the same way as in the standard procedure, except for the use of melts of different compositions. b) Calcd, respectively, as stated in Table 1. c) The anthracene was recovered quantitatively. d) Transferred from Table 1 for the convenience of comparison.

Effect of the Acidity of Melt. Table 4 shows the effect of the acidity of various melts on the carbon yield. In the cases with [$AlCl_3$–NaCl–KCl] systems, the decreasing content of aluminium chloride resulted in a decrease in the yield of carbon. A melt containing 60 mol% of zinc chloride, known as a weaker Lewis acid than aluminium chloride, was quite inactive. These facts indicate the critical importance of the acidity of the melt.

It is also noteworthy that, although weaker, the

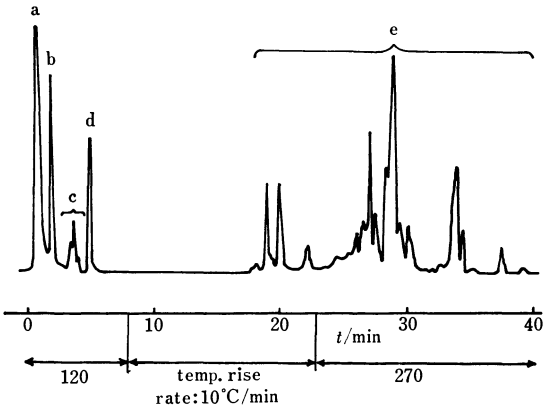

Fig. 3. Gas liquid partition chromatogram of a tar obtained from naphthalene by a reaction at 100 °C for 30 min. a: Solvent, b: *p*-dichlorobenzene as an internal standard, c: low boiler (Y: 1.02 mol%), d: naphthalene (Y: 2.78 mol%), e: high boiler (Y: 24.7 mol%).
Column: OV-17 5% on Chromosorb WAW DMCS 80—100 mesh, 3 mm×3 m; carrier gas: He, 60 cm³/min; detecter: TCD.

activity of the melt still remained when the content of aluminium chloride was lower than 50 mol%. This can be ascribed partly to the small amounts of aluminium chloride free in the equilibrium, and partly to the strong affinity of the compounds used to the Lewis acid. In the melt containing 40 mol% of aluminium chloride, anthracene, naphthalene, and biphenyl gave carbons, in yields decreasing in that order, in accordance with their decreasing basicity.

Products in the Earlier Stage of Reaction. Some runs with naphthalene were carried out with the standard procedure but at a fixed low temperature of 100 °C to yield the titled products. The tarry products were analyzed by TLC, GLPC, IR, UV, and NMR.

The results from GLPC, given in Fig. 3 as an example, show that the naphthalene reacted very fast, diminishing to a small percentage of the original amount during the first 30 min of the reaction. The products can be classified into three groups. The first (low-boiling, 1.02%) and the second (high-boiling, 24.7%) consists of substances with shorter and longer retention time than naphthalene respectively. The third (*ca.* 70%) consists of substances which did not give any peaks in the chromatogram because of their small volatility. The last two groups together form the greater part of the tar and can be accepted as consisting of polymerization products. The low-boiling group will be dicussed below.

The NMR spectrum of the tar, given in Fig. 4, shows that the tar contains aliphatic hydrogen atoms amounting to 50—60% for aromatic ones. This indicates that the polymerized naphthalene is partially hydrogenated. The IR spectrum of the tar supports this view. It shows a strong absorption band at 2920 cm^{-1} which can be assigned to the aliphatic C–H stretching vibration.

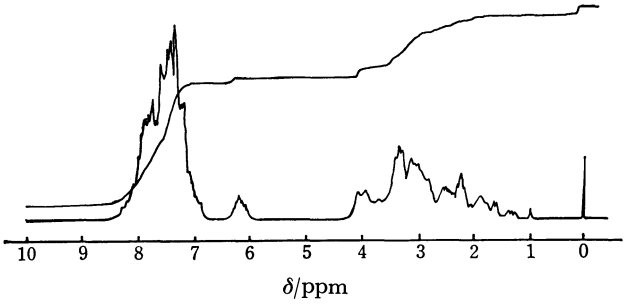

Fig. 4. ^{1}H-NMR Spectrum (60 MHz, in $CDCl_3$) of a tar obtained from naphthalene by a reaction for 30 min at 100 °C.

By TLC with the [silica gel–hexane] system, the tar was revealed to contain a number of substances which enamate a strong visible fluorescence when irradiated with ultraviolet rays. This indicates the formation of an aromatic condensed-ring structure with four or more rings. In fact, perylene was detected by a TLC-UV combined technique (R_f: 0.22, blue fluorescence; λ_{max}: 434 nm in ethanol).

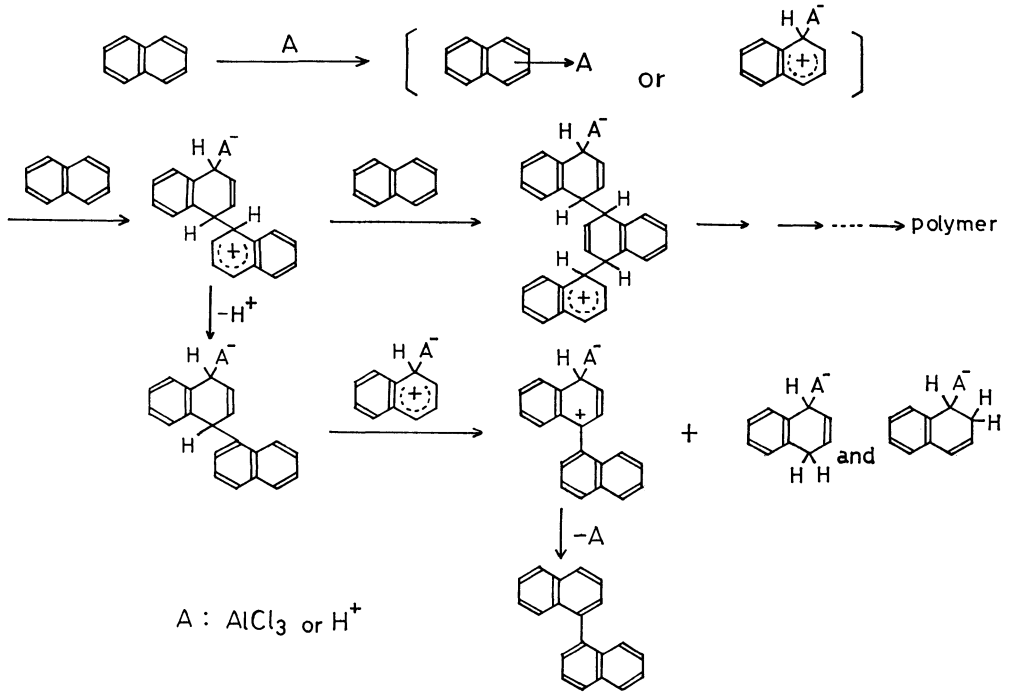
The formation of the low-boiler is noteworthy, though the amount was small. The GLPC analysis of the tar using a glass capillary column revealed that the low-boiler consists of 1,2,3,4-tetrahydronaphthalene, 1,2-dihydronaphthalene, and several other compounds.

Possible Reaction Mechanism and Pathway. Many of the facts mentioned above all indicate that the reaction proceeds through an ionic mechanism. No evidence has been obtained to support a radical mechanism, which is believed to control the carbonization by simple heating.

The first step in the polycondensation toward carbon must be a C–C bond formation between two aromatic nuclei. This reaction probably involves an electrophilic attack by a positively charged aromatic nucleus, which is produced from an aromatic molecule and Lewis acid or proton, on a remaining neutral aromatic molecule. Similar ideas have been presented[6] and supported[16] by several authors concerning the condensation of aromatic compounds in the presence of Lewis acid. In the present system the mechanism is thought to be essentially the same. The coloration of the melt seems consistent with this mechanism. This assumption regarding the coloration finds supports in Morita and Hirosawa's report[17] and in the studies[18-19] referred to therein.

In parallel with the C–C bond formation, hydrogen disproportionation must take place. The hydrogen atoms necessary for the formation of the hydronaphthalenes must be supplied from the condensation. This reaction is probably also catalyzed by acids, probably in a manner similar to that described by Wristers[20] in the hydrogenation of benzene in superacid systems. It is important to recognize that this hydrogen transfer occurs not only between monomers, but also between any organic species in the system, and that, therefore, it plays a certain role in all stages of the reaction.

From these facts, the reaction, for example, with naphthalene should proceed as is shown in Scheme 2.



Scheme 2.

The 1,1′-type of condensation product may be predominant at first, while it may rearrange to the 2,2′-type in a thermodynamically controlled reaction.[6]

The fluorescent substances mentioned above seem to be formed by the intra- and intermolecular condensation of the naphthalene polymers. This type of condensation will become more important in the middle and later stages of reaction, and the combination of all the types of reactions mentioned above should produce carbon at last.

The true character of the catalyst is not clear. Throughout this series of experiments the invasion of the reaction system by moisture could not be prevented, and as a result the evolution of hydrogen chloride occurred. Therefore, it is reasonable to postulate that the catalytic action of the melt is partly attributable to that of a superacid system of [hydrogen chloride–aluminium chloride].

Features of This Process. The present process is characterized as *a solution reaction* through *an ionic mechanism*, resulting in *a low carbonization temperature* and *a high carbon yield.*

When simply heated, most polycyclic aromatic compounds first begin to be carbonized near 500 °C;[21] therefore, the compounds boiling below that temperature can not be carbonized under an ordinary pressure. The addition of aluminium chloride lowers the carbonization temperature. For example, by the $AlCl_3$-addition process Mochida *et al.*[8] succeeded in obtaining "coke" from polycyclic aromatic compounds with 2—4 rings under an ordinary pressure at 300 and/or 380 °C. However, the carbon yield does not appear to be high.[22] In our experiment, by the $AlCl_3$-addition process with naphthalene under conditions (with 5 mol% of aluminium chloride at 300 °C for 10 h) similar to those employed by Mochida *et al.*, the yields of BI and quinoline-insoluble matter (QI) were 39 and 7% respectively for the theoretical yield of carbon, while by the present process these yields were determined to be 94 and 85% (Run 13). The observed high yield—in other words, the high reaction velocity— in the present process can be ascribed mostly to the highly ionic character of the solvent, including the strong acidity, although the details of how these properties influenced the reaction machanism are not clear. The molten salt system should, at least, be more favorable for the formation of the positively charged species, the assumed reaction intermediates, than the organic system in the $AlCl_3$-addition process. One of the reasons for the occurrence of nongraphitizable carbons in the present study may be the too fast reaction, which is believed often to prevent the growth of a layer structure.

In practice, being a solution reaction makes the inspection of a reaction easy. The low carbonization temperature made the use of an autoclave unnecessary for the carbonization of materials with low boiling points.

This process can be modified in use. When the reaction stops halfway, tar or pitch is generally obtained. For example, naphthalene gave a pitch suitable for making graphitizable carbon. Methylnaphthalenes proved to isomerize and disproportionate quickly through the migration of the methyl group in the earlier stage of reaction; as a result, tars with a fixed composition were obtained from the different isomers.[23] These may be of importance for the commercial use of this process.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education. Project Number 155315 (1977).

Crystal Structure and Related Physical Properties of [*N,N,N,N',N',N'*-Hexamethylhexamethylenediammonium]$^{2+}$-[Tetracyanoquinodimethane]$_4^{2-}$: as a Two-dimensional Magnetic System

Serge FLANDROIS,* Daniel CHASSEAU,† Pierre DELHAES, Jacques GAULTIER,† Jacques AMIELL, and Christian HAUW†

Centre de Recherche Paul Pascal, Domaine Universitaire, 33405 Talence Cedex, France

† *Laboratoire de Cristallographie, Université de Bordeaux I, 33405 Talence Cedex, France*

(Received July 24, 1978)

The crystal structure, electrical conductivity and magnetic properties of (HMHDA)(TCNQ)$_4$ are studied. It appears that this ion-radical salt consists of planar arrays of (TCNQ)$_2^-$ dimers (diads) in weak interaction. The structure may thus be considered as quasi two-dimensional, the magnetic behavior being in line with two-dimensionality.

Organic radical-ion salts and charge transfer complexes, especially those based on tetracyanoquinodimethane (TCNQ), have received considerable attention in recent years.[1] As shown by crystallographic studies these compounds are often formed in linear chains of molecules. Physical properties such as electrical conductivity exhibit a high degree of anisotropy, makes these systems considered as quasi one-dimensional electronic substances.

Some questions have arisen as to the existence of a real electronic one-dimensionality.[2] There is always some interchain coupling whatever the mechanism is, and at 0 K the system must be three-dimensional. Many experimental and theoretical works deal with the cross-over from a one-dimensional behavior to a three-dimensional one, but at the present stage the situation is far from clear.

Our purpose was to investigate the dimensionality effects by synthesizing an homologous series of compounds, in which we would be able to vary the distance between the radical-ion chains. One way to accomplish this could be the use of cations such as polymethylene-diammoniums: $R_3N^+-(CH_2)_n-N^+R_3$. According to the length of the polymethylene chain we could expect a gradual variation of distances between TCNQ stacks. Thus the larger the number of CH_2 groups, the more rigorous should be the one-dimensionality of the electronic or magnetic system.

Hadek *et al.*[3] synthesized a series of TCNQ salts with *N,N,N,N',N',N'*-hexamethylpolymethylenediammonium cations model compounds for polymeric TCNQ salts. However, only the electrical conductivity was measured on powdered samples. This study incited us to prepare TCNQ salts of cations $(CH_3)_3N^+-(CH_2)_n-N^+(CH_3)_3$ and examine their crystal structure and physical properties on single crystals.

In this paper we will report a detailed study of the salt with $n=6$:

$$[(CH_3)_3N^+-(CH_2)_6-N^+(CH_3)_3](TCNQ)_4^{2-}$$

or (HMHDA)(TCNQ)$_4$. Contrary to our expectation TCNQ molecules in this salt do not crystallize in one-dimensional stacks. Actually the structure consists of diads with two-dimensional magnetic interactions.

Table 1. Crystal data for (HMHDA)(TCNQ)$_4$

$(C_{12}H_{30}N_2)(C_{12}H_4N_4)_4$—Molecular mass=1016		
Triclinic—Space group $P\bar{1}$		
$a=14.172$ (8) Å	$\alpha=77.67$ (5)°	$V=1371.2$ Å^3
$b=13.487$ (8) Å	$\beta=99.20$ (5)°	$Z=1$

$F(000)=530$	Cu $K\alpha$($\lambda=1.5418$ Å)	$\mu=6.33$ cm^{-1}

Experimental

Preparation of (HMHDA)(TCNQ)$_4$. To a hot methanol solution (40 ml) of Li-TCNQ (420 mg) was added a hot methanol solution (20 ml) of *N,N,N,N',N',N'*-hexamethylhexamethylenediammonium diiodide (460 mg). The solution was allowed to cool slowly down to room temperature. The resulting complex (700 mg) was collected and washed with water, methanol and ether. A deep blue crystalline product of (HMHDA)(TCNQ)$_2$ was obtained.

To a hot acetonitrile solution (40 ml) of (HMHDA)-(TCNQ)$_2$ obtained as above was added a solution (40 ml) of neutral TCNQ (408 mg) in acetonitrile heated at the same temperature. After being cooled down to room temperature the crystalline precipitate (600—700 mg) was filtered and washed successively with acetonitrile and ether.

The stoichiometry of the complexes was checked by electronic absorption spectroscopy with a Cary spectrophotometer, using acetonitrile as a solvent.

Crystal Data. The space group and unit cell dimensions were obtained initially from oscillation and Weissenberg photographs by using Cu $K\alpha$ radiation. The cell constants were subsequently refined on a Siemens computer-controlled three-circle diffractometer. Intensity data of 4763 independent reflexions were collected on this diffractometer from a crystal of dimensions $0.1\times0.22\times0.35$ mm with a $\theta/2\theta$ scan, a scintillation counter and Cu $K\alpha$ radiation; 2793 reflexions are significantly above zero. The c direction is the growth

direction of the crystals; the a and b directions, which belong respectively to the large and small lateral faces of the crystal, are tilted from the plane perpendicular to the c direction (Fig. 1).

Structure Determination. The structure was solved from a three dimensional Patterson synthesis and refined by block diagonal least squares. Refinement of the positional and isotropic thermal parameters of the 39 non-hydrogen atoms gave the residual $R=0.15$.

Positional parameters of the 23 hydrogen atoms were found on the difference Fourier synthesis. Further refinement of the non-hydrogen and hydrogen atoms with the aid of anisotropic and isotropic thermal parameters respectively gave a final value of 0.07 for R. The following weighting scheme was used

$$\sqrt{\omega} = 1 \qquad \text{if } |P_0| < P_1$$

$$\sqrt{\omega} = \frac{P_1}{P_0} \qquad \text{if } |P_0| > P_1$$

where $P_1=40$.

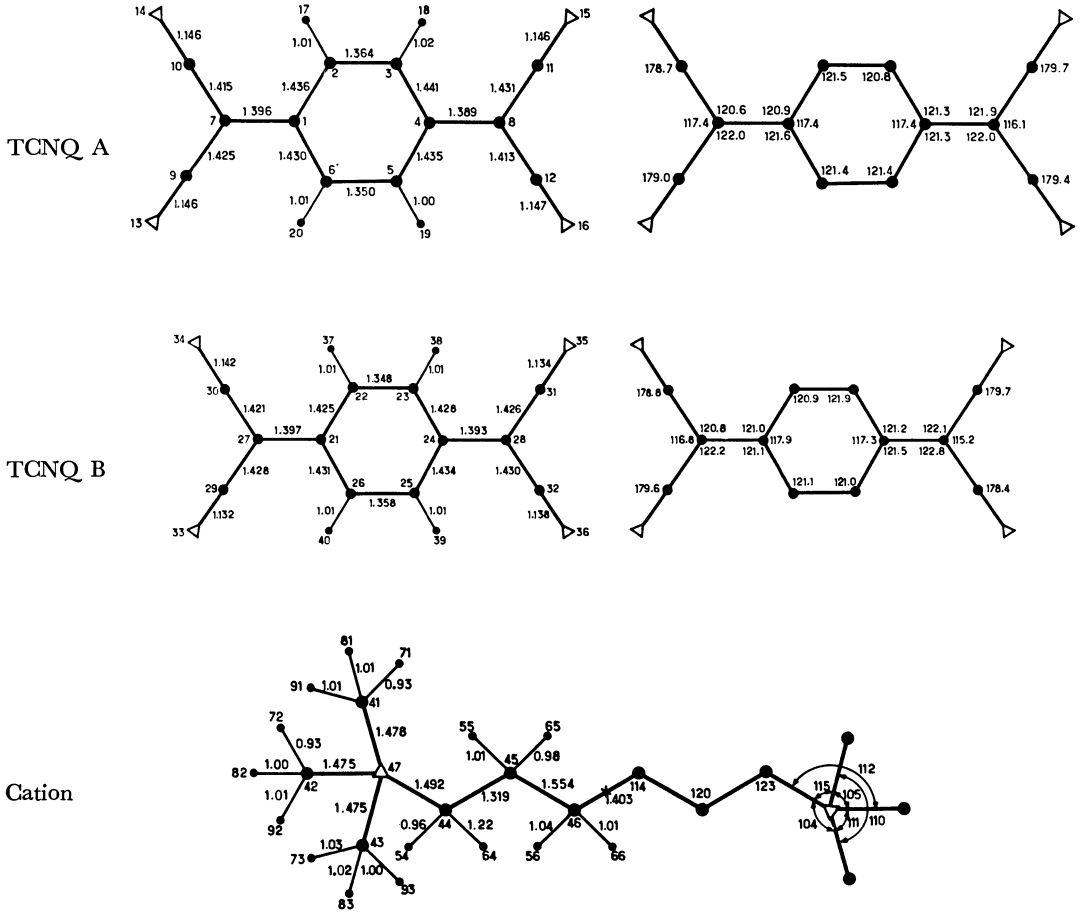

Fig. 3. Bond lengths (Å) and angles of TCNQ (A), TCNQ (B) and the cation.

The final positional and thermal parameters, together with their standard deviations, are listed in Tables 2 and 3.

Least squares planes were calculated through each quinonoid ring of the TCNQ molecules;** the distances of the atoms from these planes are shown in Fig. 2.

Electrical and Magnetic Measurements. The d.c. conductivities of single crystals (typical dimensions: $2\times0.2\times0.05$ mm) were determined by using a classical four-electrode technique. The electrical contacts were made with silver wires and silver paint.

Magnetic susceptibilities were obtained on microcrystalline samples by using Faraday's method in the temperature range 2.5—362 K. The core diamagnetism (-5.7×10^{-4} emu/mol) was calculated from Pascal's constants and from the value measured for TCNQ molecule.[4]

EPR measurements were carried out on single crystals with a Varian X-band spectrometer equipped with thermal variation accessories.

Results

Molecular and Crystal Structure. The dimensions of the two crystallographically independent types of TCNQ moiety are shown in Fig. 3. The average bond lengths of molecules A and B are nearly equal within experimental error, the differences between the averaged lengths of chemically equivalent bonds not exceeding 0.01 Å. The electronic charge of each TCNQ, calculated by the method developed by Flandrois and Chasseau,[5] is 0.46 electron and 0.50 electron for A and B, respectively. The negative charge is thus delocalized, leaving a half negative charge on each TCNQ molecule.

TCNQ A: The carbon atoms of the quinonoid ring are nearly in the same plane, the C–$(CN)_2$ groups being out of this plane and on the same side (Fig. 2). The dihedral angles between the plane of the quinonoid ring and the planes of the C(7)–$(CN)_2$ and C(8)–$(CN)_2$ groups are respectively 1.8° and 1.6°. The twist angles of the cyanomethylene groups around the C(1)–C(7) and C(4)–C(8) bonds are respectively 0.8° and 0.3°.

TCNQ B: The carbon atoms of the quinonoid ring are in the same plane : the C–$(CN)_2$ groups are clearly out of this plane, particularly the C(27)–$(CN)_2$ group, and on the same side. The dihedral angles between the plane of the quinonoid ring and the planes of the C(27)–$(CN)_2$ and C(28)–$(CN)_2$ groups are respectively 7.1° and 2.2°. The twist angles of the cyanomethylene groups around the C(21)–C(27) and C(24)–C(28) bonds are respectively 0.5° and 1.2°.

In each TCNQ, both –$C(CN)_2$ groups lie entirely on the same side of the quinonoid skeleton of the TCNQ molecule, so that the molecule has the shape of a shallow boat. In TCNQ B, the stronger deformation may be explained by a very short intermolecular distance

** XYZ are orthogonal atomic coordinates in Å where X is along a, Y in the (ab) plane orthogonal to a and Z orthogonal to the (XY) plane.

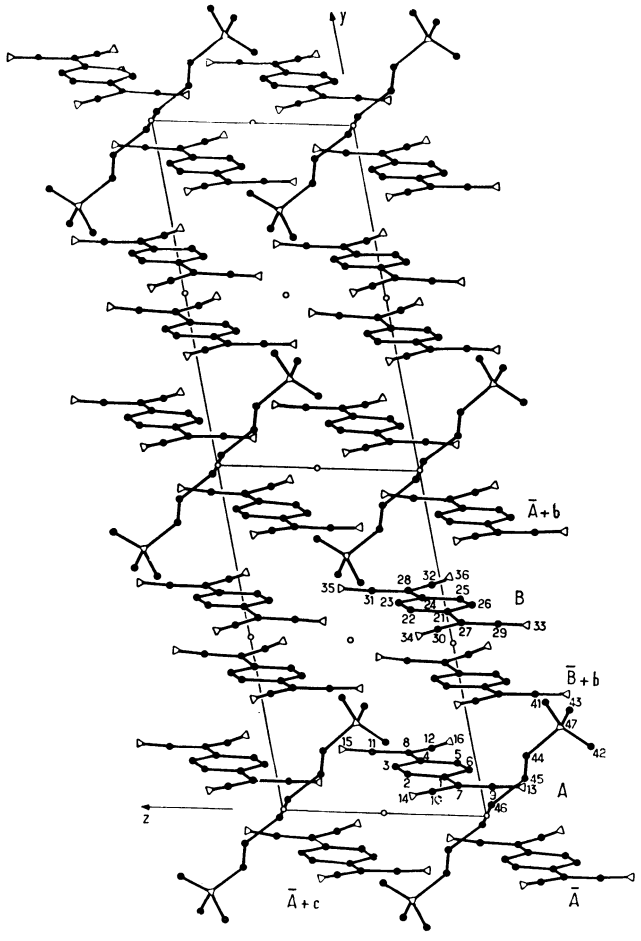

Fig. 4a. Projection of the crystal structure along the a axis.

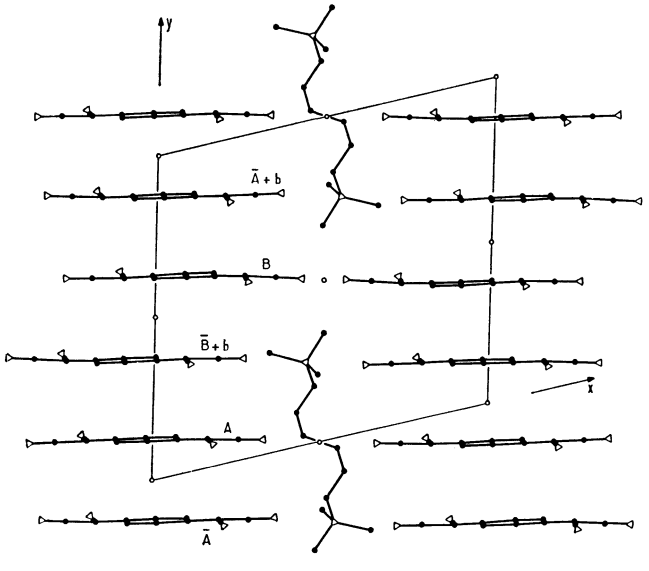

Fig. 4b. Projection of the crystal structure along the c axis.

between the N(34) atom and the C(41) atom of a cation methyl group (C–N=3.21 Å).

These results also confirm the general correlation found between the rotation of the $C(CN)_2$ groups and the length of the C–C bond adjacent to the quinonoid ring:[5] if this bond is shorter than 1.41 Å as

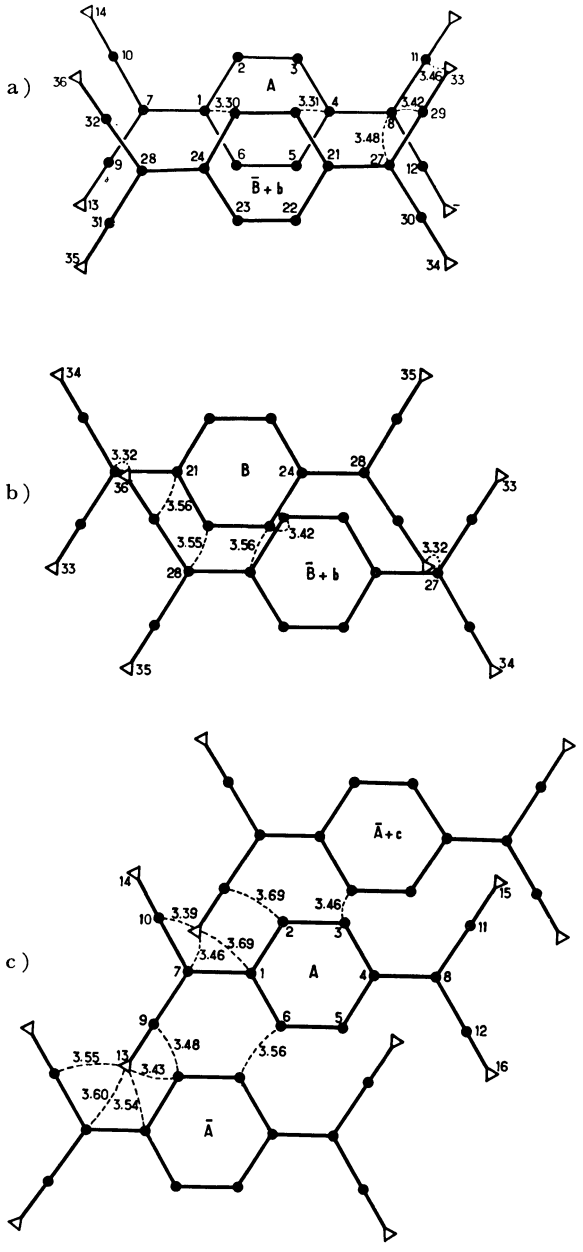

Fig. 5. Projection along the normal to the quinonoid ring of TCNQ molecules: a) $\overline{B}$+b on A; b) $\overline{B}$+b on B; c) $\overline{A}$ and $\overline{A}$+c on A. Some short distances between atoms of neighboring molecules are given.

in the present case the rotation is sligth, always less than 2°.

In the methylene chain, we found unusual and anomalous bond lengths (Fig. 3); the very short distance (1.32 Å) between the C(44) and C(45) atoms does not characterize a localized double bond; in the same way, the distance 1.40 Å of C(46)–C(46), cannot be a conjugated bond. Disorder, suggested by the high values of the temperature factors, may be a good explanation of these anomalous results. For the sake of comparison, the C–C bond lengths are 1.48, 1.56, and 1.48 Å in *N,N,N,N′,N′,N′*-hexamethylhexamethylenediammonium dibromide[6] and 1.53, 1.55, and 1.50 Å in *N,N,N,N′,N′,N′*-hexamethylhexamethylene-

diammonium dichloride dihydrate.[7]

Figures 4a and 4b show a general view of the crystal structure projected respectively along the a and c axes. The unit cell contains one cation and four roughly parallel TCNQ molecules, A, $\bar{B}$, B, $\bar{A}$,*** with two crystallographically independent molecules; the dihedral angle between the planes of the molecules A and B is 0.6°.

Cations, centered at 1/2, 0, 0 alternate in the a direction with the TCNQ groups; these groups make an angle of 56° with the best plane through the hexamethylene chain and an angle of 38° with the N(47)–$\bar{N}$(47) direction.

A good insight of the molecular arrangement is given by the projection of TCNQ moieties along the normal to the quinonoid ring (Fig. 5). This figure gives evidence for the pairing in (A, $\bar{B}$+b) diads. Within the (A, $\bar{B}$+b) dimer, the mode of overlap looks like those found, for example, in morpholinium–TCNQ salts:[8,9] the double bond of the quinonoid ring of one molecule is placed above the ring of the second one. The interplanar distance is 3.22 Å.

Between dimers there is only very weak overlap. The centrosymmetric pair of molecules B and $\bar{B}$+b has an interplanar separation of 3.38 Å. Only two short intermolecular contacts exist:

$$C_{25}(B) - C_{25}(\bar{B}+b) = 3.42\ \text{Å}$$

$$N_{36}(B) - C_{27}(\bar{B}+b) = 3.32\ \text{Å}$$

Between molecules A and $\bar{A}$, related by the symmetry operation −x, −y, −z, there is no real overlap, but the interplanar spacing is short (3.22 Å). Two short intermolecular contacts of 3.48 Å and 3.56 Å exist between C(9, A)–C(2, $\bar{A}$) and C(6, A)–C(3, $\bar{A}$) respectively. Similarly the $\bar{A}$+c molecule, related to A by the symmetry operation −x, −y, −z+1, has a short contact of 3.46 Å between the C(6, $\bar{A}$+c) and C(3, A) atoms, the interplanar spacing A−$\bar{A}$+c being 3.38 Å.

Thus the lattice appears to be constituted of diads in weak interaction in a plane parallel to the (b c) plane. Each diad D_1=(A, $\bar{B}$+b) is surrounded by five other diads in this plane: D_2=($\bar{A}$, B−b), D_3=($\bar{A}$+c, B−b+c), D_4=($\bar{A}$+b, B), D_5=(A+c, $\bar{B}$+b+c) and D_6=(A−c, $\bar{B}$+b−c),†† the distances between the centres of gravity of these diads being respectively D_1-D_2=7.44 Å, D_1-D_3=7.95 Å, D_1-D_4=7.17 Å, D_1-D_5=7.78 Å=D_1-D_6.

The planes containing these arrays of diads are separated by sheets of *N,N,N,N′,N′,N′*-hexamethylhexamethylenediammonium cations, giving rise to a quasi two-dimensional molecular lattice.

*** $\bar{A}$ and $\bar{B}$ are related to A and B respectively by the symmetry operation −x, −y, −z.

†† A, B x, y, z $\bar{B}$+b −x, −y+1, −z

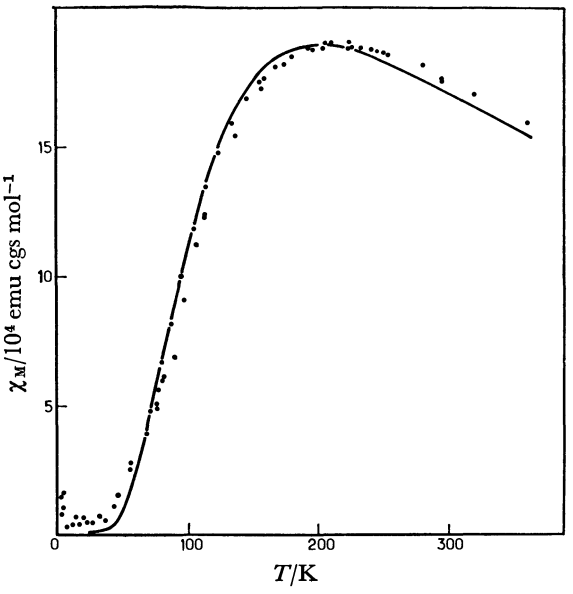

Fig. 6. Temperature dependence of paramagnetic susceptibility. The continuous line is a singlet-triplet fitting with J=0.028 eV.

In this way, (HMHDA)(TCNQ)$_4$ differs from most other radical anion salts in which the TCNQ molecules occur in continuous columns within which there is closer molecular contact than between adjacent columns. Nevertheless a structure exhibiting similar features has already been observed in some other 1:4 TCNQ salts such as *N,N′*-Diethyl-4,4′-bipyridinium–(TCNQ)$_4$.[10]

Electrical Conductivity. The conductivity at 300 K along the long crystal axis (c axis, Fig. 1) is *ca.* 4×10^{-3} $(\Omega\ \text{cm})^{-1}$. The radical-anion salt behaves as a typical semiconductor in the range 150—330 K, with an exponential dependence of conductivity on temperature obeying the equation: $\sigma=\sigma_0\ \exp(-E_a/kT)$, with a continuous dependence of E on temperature from 0.15 eV at *ca.* 150 K to 0.30 eV near room temperature.

Magnetic Properties. The temperature dependence of paramagnetic susceptibility is shown in Fig. 6 after substracting the diamagnetic part from the measured susceptibility. The curve exhibits a maximum at *ca.* 210 K. Below this temperature the susceptibility decreases to zero, although a slight increase appears at very low temperatures (T>10 K). The behavior is typical for semiconducting TCNQ salts [10] and may be interpreted in terms of an excited triplet state lying above the singlet diamagnetic ground state. The χ upright at low temperatures is probably due to impurities or lattice defects and corresponds to *ca.* 0.1% of the spins giving a slight Curie contribution.

For a compound with two electrons per mole, the susceptibility due to an excited triplet state is given by

$$\chi_M = 2Ng^2\mu_B^2/[kT(3+\exp(J/kT)] \quad (1)$$

where J is the energetic singlet-triplet separation, μ_B the Bohr magneton, g the g-factor, N the Avogadro number and k the Boltzmann constant.

The paramagnetic susceptibility of (HMHDA)-(TCNQ)$_4$ can be fitted by this expression within a

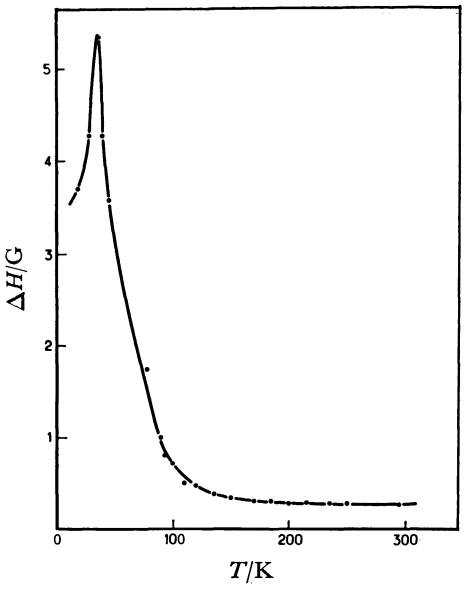

Fig. 7. Temperature dependence of EPR linewidth for the orientation of single crystal giving the largest variation with temperature.

good approximation (Fig. 6); the continuous line corresponds to a J-value of 0.028 eV.

The triplet character of the paramagnetic excitation is generally evidenced by a splitting of EPR spectra, caused by the dipole-dipole interaction of the electrons in the triplet state: [11] at high temperatures EPR spectra show an exchange-narrowed single line, but as the temperature is lowered the line broadens until finally it splits into a doublet. Actually no fine structure splitting could be detected in (HMHDA)(TCNQ)$_4$. The spectra showed a single line at all temperatures, although a rapid increase of linewidth was observed for some crystal orientations, when the temperature was lowered below 100 K (Fig. 7). The sharp maximum between 30 and 40 K reflects the disappearance of the activated part of the susceptibility and the prominence of the Curie contribution.

The linewidth exhibited a temperature dependent anisotropy. The variations shown in Fig. 8 correspond to rotations of the crystal around the c axis. When $\theta=0$ the magnetic field is along b′ axis (Fig. 1). Similar results were obtained at Q-band with a Varian spectrometer: the linewidth behavior is thus field independent. Figure 8 shows that the results can be fitted with the empirical expression:

$$\Delta H = a + b(3\cos^2\theta - 1) + c(3\cos^2\theta - 1)^2 \qquad (2)$$

where a, b, and c are temperature-dependent parameters.

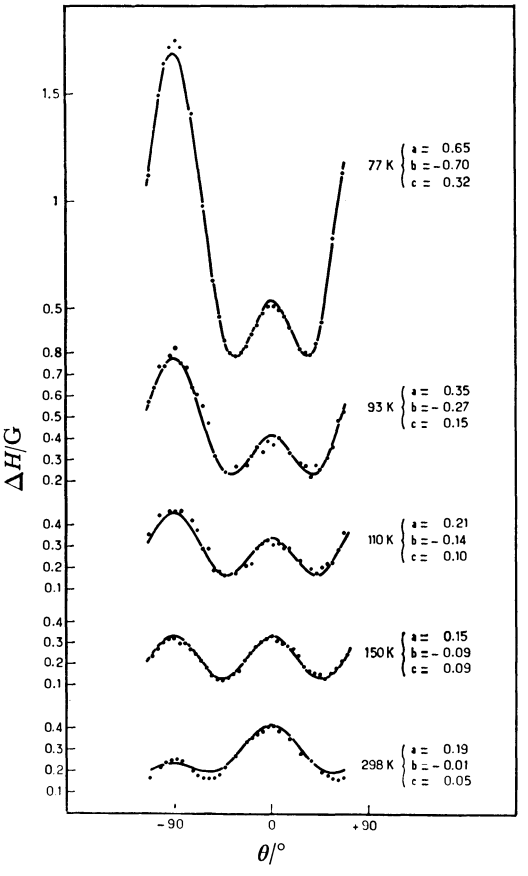

Fig. 8. Angular variation of the EPR linewidth at different temperatures for a single crystal. The rotation axis is the c axis. The parameters a, b, and c are in: $\Delta H=a+b(3\cos^2\theta-1)+c(3\cos^2\theta-1)^2$.

Discussion

Electrical Conductivity and Structure. Since the structure is two-dimensional the electrical conductivity should be isotropic in the corresponding plane. However, because of the smallness of crystals it was impossible to measure the conductivity along the b′-direction (Fig. 1).

The value of σ at room temperature along the c axis is very close to that of TCNQ salts of 1:4 stoichiometry with similar crystal structures.[10] This value is surprisingly high in comparison with other diadic compounds having a very weak overlap between the diads.

From a systematic examination of conductivities and structural data[12] it appears that the electrical conductivity depends on the plane-to-plane distances of TCNQ molecules, their types of overlap and the electronic charge distribution between TCNQ molecules (for a number of electrons smaller than the number of TCNQ molecules). A non-uniform distribution indicates that some charge localization occurs, leading to a smaller conductivity. In (HMHDA)(TCNQ)$_4$ the charge seems to be distributed uniformly, each TCNQ bearing a half electronic charge. The apparent delocalization compensates for the poor molecular overlaps and some rather large distances (3.38 Å) (Fig. 4), giving rise to a conductivity value better than expected.

Magnetic Properties and Structure. Thermal Variation of χ_p: A singlet-triplet behavior of χ_p is generally found for TCNQ salts in which each spin interacts strongly with only one adjacent spin. This occurs when TCNQ molecules form alternating stacks, composed of diads, triads or tetrads. The triplet character of the magnetic excitations is well understood[11] and clearly indicated experimentally by the dipolar splitting observed in EPR spectra at lowexcitati on concentra-

tion.

Another class of radical-anion salts and charge transfer complexes is known to crystallize in regular stacks with equal exchange interaction between neighbors along a given stack. In some of them an activated paramagnetic susceptibility $\chi_p \propto T^{-1} \exp(-\Delta E_p/kT)$ has been found. To our knowledge only charge transfer complexes with mixed stacks (···AD AD···) are concerned, such as TMPD–chloranil,[13] PD–chloranil[14] or TMPD–TCNQ.[15] No satisfactory explanation has been given concerning the origin of ΔE_p, but experimental results are interpreted by assuming a Wannier spin exciton model[16] where spin excitations are spatially uncorrelated.

At first view (HMHDA)(TCNQ)$_4$ seems to belong to none of the above classes. The lattice appears to be constituted of diads in weak interaction inside a plane. Moreover each diad bears an $S=1/2$ spin which is equally distributed on the two TCNQ molecules. So the spins appear to be delocalized on diads, the closest contacts of which are nearly van der Waals distances (3.42 Å to 3.51 Å). However, careful examination of the structure for C–C distances shows that there are more numerous close contacts between B molecules of two successive diads than between A molecules. So a slight tendency to the formation of tetrads AB BA is observed. If we calculate the zero-field parameter D for this arrangement from the approximately known spin-density distribution,[17] we get a value of several gauss. The value is small, but a splitting should be observed on the EPR spectra, which is not realized and thus seems to confirm the magnetic two-dimensionality of this system.

Angular Dependence of EPR Linewidth: The angular dependence of EPR linewidth shown in Fig. 8 is unusual. However, several similar features have been found for some TCNQ salts[18,19] and for charge transfer complexes of TMPD with TCNQ[15] and chloranil.[20] Two explanations have been proposed.

It has been shown that the angular variation, $\Delta H(\theta)$, of EPR linewidth in two-dimensional magnetic systems such as K_2MnF_4[21] or $(C_2H_{10}N_2)(MnCl_4)$[22] is approximately described by an expression of the form $\Delta H(\theta)=A+B(3\cos^2\theta-1)^2$, where θ is the angle between the applied magnetic field and the normal to the plane of the two-dimensional magnetic systems. For several TCNQ salts Takagi and Kawabe[18,19] fitted their results with the empirical relation:

$$\Delta H(\theta) = \alpha(3\cos^2\theta-1)^2 + \beta\sin^4\theta \qquad (3)$$

In spite of the lack of detailed structural information they inferred that the TCNQ salts studied are two-dimensional.

On the other hand, Soos and coworkers[20] showed that the linewidth anisotropy of TMPD–chloranil for which the one-dimensionality is firmly established was accurately reproduced by the secular part of the electron dipolar interaction. The angular dependence could be expected for spatially uncorrelated spin excitations.

Both explanations could be convenient for (HMHDA)(TCNQ)$_4$. From the crystal stucture data it looks like a nearly two-dimensional magnetic system. However, it is quite certain that the angular dependence of linewidth could be fitted by the angular dependence in the second moment of the secular part of the electron dipolar interaction, if the spin-densities distributions were accurately known, which is not the case.[20] The thermal variation of the angular dependence of linewidth could reflect either a change of spin distribution with temperature or a continuous thermal modification of the lattice, or, more probably, both together.

Contrary to the recent assertion of Takagi and Kawabe,[23] the temperature dependence of the linewidth does not seem to be related to the structural symmetry of the cation. From the study of several TCNQ salts with cyanine dyes as cations they deduced that for symmetrical cations the linewidth decreases when the temperature is lowered, while it increases for salts with unsymmetrical cations. Actually HMHDA is structurally symmetrical and the linewidth increases sharply with decreasing temperature (Fig. 7). Thus the behavior of ESR linewidths is not well understood, for both semiconducting salts as well as conducting ones.[24]

g*-*Tensor Anisotropy: Since two-dimensionality could not be evidenced by electrical measurements for experimental reasons, we thought that it could be reflected by the ***g***-tensor anisotropy. Actually the results show that the principal axis directions correspond to the molecular symmetry axes and not to the crystal axes.

The *g*-value perpendicular to the TCNQ molecular plane is found to be $g_{zz}=2.0021\pm0.0003$, the *g*-value along the in-plane molecular long axis is $g_{yy}=2.0028\pm0.0003$ and the third value $g_{xx}=2.0033\pm0.0003$. The average of this tensor: $\bar{g}\simeq 1/3\ (g_{xx}+g_{yy}+g_{zz})=2.0027\pm0.0003$ corresponds closely to the isotropic *g*-value of TCNQ anions in solution: 2.00263 ± 0.00005.[25]

Conclusion

From structural data it appears that (HMHDA)(TCNQ)$_4$ consists of planar arrays of $(TCNQ)_2^-$ dimers (diads) in weak interaction. Thus the structure may be considered as quasi two-dimensional, unlike most other TCNQ compounds for which a quasi one-dimensionality is generally assumed and sometimes established. The magnetic properties are in line with the two-dimensionality, although the linewidth behavior could be interpreted differently.

The study of this compound is interesting from another point of view. We recently obtained [26] a TCNQ salt with a parent cation: *N,N,N′,N′*-tetramethylhexamethylenediammonium (TMHDA). The salt, the stoichiometric formula of which is: (TMHDA)(TCNQ)$_2$(I)$_2$, has a metallic behavior above 120 K and contains iodine chains, although the method of preparation is the same. The reason why iodine is retained in the structure is not clear. The only difference with HMHDA is the substitution of two CH_3 groups by hydrogen atoms. A structural comparison between these compounds will be very useful. The study is in process.

We are grateful to Mrs. M. Joussot-Dubien and

M. L. Choukroun for preparing the samples.

(Received December 27, 1978)

A rapid extraction-polarographic method has been developed for the direct determination of bismuth, copper, iron(III), palladium, and uranium(VI) extracted into the organic phase. Oxinates of metals were extracted into molten naphthalene at different pH values. With lowering of temperature, naphthalene separated out as a solid containing the metal oxinates. The solid mass was dissolved in DMF and the polarograms were recorded in the presence of a suitable supporting electrolyte. The metal oxinates give well defined waves. The relation between diffusion current and concentration is linear over a wide range of concentration with an average relative error not more than 1.05%. Interferences of various ions have been studied of the anions studied, only EDTA interfered in the extraction of bismuth, copper, iron(III), and uranium(VI). Of the cations studied, palladium interfered in the determination of bismuth, copper, iron(III), and uranium(VI). However, the intereference was eliminated by carrying out extraction first at low pH. In the determination of bismuth only copper interfered but its interference can also be eliminated as in the case of palladium. In the case of copper determination, only iron(III) interfered. In the determination of iron, copper interfered but interference can be eliminated by using a suitable masking agent. The determination of palladium and uranium(VI) is free from all interferences.

Of the heterocyclic nitrogen compounds, 8-quinolinol (oxine) reacts with more than fifty elements.[1] Studies on the use of this reagent in solvent extraction revealed that even with proper control of pH, the reagent is not selective in extracting specific elements, although many masking agents have also been examined.[2] The selectivity can be achieved by polarographic determination of metals after extracting into the organic phase. All the methods involve the use of mixed solvents, *i.e.* the extract is mixed with some other solvent in order to obtain well defined waves.[3-5] There are two disadvantages: (a) the sensitivity is much decreased since the amount of organic solvent used for the extraction is large, (b) the pH of the extract has to be readjusted in order to match the conditions with the standard.

We have developed a new method in which the metal complex is extracted with molten naphthalene and separated from the aqueous phase by solidification and subsequent filteration or decantation. Since the extraction is carried out at high temperature, the equilibrium in the two phases is attained rapidly and the complexes are extracted merely by contact with molten naphthalene. The main advantage is that a very small amount of the organic phase is required for complete extraction in order to get well defined waves and better sensitivity. The method has been tested and found successful for the extraction and polarographic determination of cadmium,[6] lead,[6] molybdenum,[7] indium,[8] and nickel.[9] In the present study, bismuth, copper, iron(III), palladium, and uranium(VI) have been extracted by this technique and determined polarographically. Elements such as Be(II), Hg(II), Sn(IV), Ti(IV), V(V), Cr(III), W(VI), Ce(IV), Co(II), Ga(III), Mn(II), Zn(II), and Zr(IV) can also be extracted by this technique, but they are not reduced at the dropping mercury electrode under these conditions, *i.e.* from 0.0 to −1.1 V. Above this potential oxine itself starts giving its own current. Interferences of various ions have been studied in detail. The method can be applied to the determination of these metals in complex materials.

Experimental

Reagents. All the metal salts solutions were prepared from G. R. samples in double distilled water, metal contents being controlled by classical methods (10). 0.1 M solution of oxine was prepared in alcohol. 2 M solution of pyridine, sodium perchlorate and perchloric acid were prepared as according to indicated in Table 2. Naphthalene and *N*,*N*-dimethylformamide (DMF) were also of G.R. grade and tested polarographically before use. Ammonia and perchloric acid were used for controlling the pH of the solutions.

Equipment. Polarograms in all cases were recorded at 25±0.5 °C with a Yanagimoto polarograph P-8 with three electrode systems. An H-type cell with fine porosite sintered glass disk between the two compartments was used. A saturated calomel electrode used as a reference electrode was connected to one compartment of the polarographic cell through potassium chloride agar-bridge. Dropping mercury electrode had the following characteristics, m: 1.52 mg/s, t: 4.78 s, and H: 60 cm in DMF with open circuit. In all instances the solution was deaerated with nitrogen for five minutes before recording the polarogram. A Hitachi pH-meter with glass electrode was used.

Metal Oxinates Standard in DMF. Aliquots of metal solutions were taken and precipitated with oxine,[11] filtered, washed with cold water, dissolved in DMF, transferred to 100 ml measuring flasks and made exactly 100 ml with DMF in each case. The solutions were used for studying the polarographic behaviour of metal oxinates in DMF.

General Procedure. An aliquot of each metal solution was taken separately. To this was added 1.0 ml of the reagent (oxine), the pH being adjusted as given in Fig. 2 after being transferred to round bottomed flasks with stopper and heated in a water bath at about 60 °C, 2 g of naphthalene was added, heating in the water bath being continued till naphthalene melted and formed a separate liquid layer. This was stirred vigorously till the naphthalene separated out as a solid mass. Once again the contents were heated in the water bath to remelt the naphthalene, shaken vigorously and allowed to stand. Naphthalene was separated from the aqueous phase by filteration, dried in the folds of the filter paper and dissolved in warm DMF (*ca.* 40 °C).

Table 1. Effect of naphthalene on the polarograms of iron(III) and palladium oxinates

Amount of naphthalene added, g	Amount of Fe(III) added: 168.00 μg Perchloric acid: 0.1 M Pyridine: 0.1 M				Amount of Pd(II) added: 106.00 μg Sodium perchlorate: 0.1 M Pyridine: 0.1 M

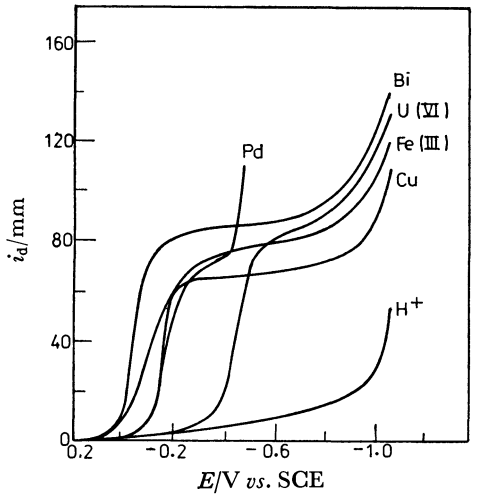

Fig. 1. Polarographic waves of metal oxinates in DMF. Bismuth: 82.80 μg, perchloric acid: 0.1 M, naphthalene: 1.0 g drope time: 4.78 s, H: 60 cm and the recorder sensitivity: 5×10^{-9} A/mm. Copper: 79.37 μg, sodium perchlorate: 0.1 M, recorder sensitivity: 10×10^{-9} A/mm, rest of the conditions are the same as for bismuth. Iron(III): 168.00 μg, pyridine: 0.1 M + 0.1 M perchloric acid, recorder sensitivity: 7×10^{-9} A/mm, rest of the conditions are the same as for bismuth. Palladium: 106.00 g, 0.1 M sodium perchlorate + 0.1 M pyridine, recorder sensitivity: 3×10^{-9} A/mm, rest of the conditions are the same as for bismuth. Uranium(VI): 95.21 μg, recorder sensitivtiy: 3×10^{-9} A/mm, rest of the conditions are the same as for iron(III).

A supporting electrolyte of appropriate type was added in each case, the volume being made exactly 20 ml with DMF in a measuring flask. 10 ml of the solution was taken separately in the polarographic cell and deaerated with pure nitrogen for 5 min. The polarogram was recorded, in each case i_d being referred to the calibration curve prepared under similar conditions.

Preliminary observations indicated that the metal oxinates give well defined waves (Fig. 1). Bismuth: 0.1 M perchloric acid (solution prepared in DMF), copper: 0.1 M $NaClO_4$ (solution of $NaClO_4$ in H_2O), iron and uranium: both in 0.1 M $HClO_4$ in DMF + 0.1 M pyridine in H_2O (waves were not diffusion controlled when both the electrolytes solutions were prepared in DMF) and palladium: 0.1 M pyridine + 0.1 M $NaClO_4$ (both electrolytes in DMF, aqueous solutions of the electrolytes gave distorted waves for palladium). In the case of palladium two waves appeared in the supporting electrolytes. Only the first wave was used for the analysis since a large maximum appeared on the second wave which was not supressed with the use of common maxima supressors.

Effect of Naphthalene on the Polarograms of Metal Oxinates. Aliquots of the metal oxinates solutions were taken individually (Bi: 82.80 μg, Cu: 79.37 μg, Fe(III): 168.00 μg, Pd: 106.00 μg, and U(VI): 95.21 μg) in the polarographic cell. The amount of naphthalene was varied from 0.0—2.1 g by adding a different volume of its 30% solution in DMF. The supporting electrolytes were added, the final volume being made 10 ml with DMF. The solution was deaerated and the polarograms were recorded. In case of bismuth, copper and uranium(VI), i_d remained constant up to 1.8 g of naphthalene added. Above this amount, i_d started decreasing slightly due to the increase in the viscosity of the medium given in Table 1. The wave for iron(III) and palladium developed only in the presence of naphthalene, *i.e.* in the absence of naphthalene a large current appeared. The large current might be due to the streaming effect eliminated in the presence of naphthalene which increases the viscosity of the medium (Table 1). In case of iron(III), i_d remained constant in the range 0.3—1.5 g of naphthalene and 0.6—1.5 g of palladium. In general, $E_{1/2}$ remained almost constant in all cases but i_d started decreasing when the amount of naphthalene exceeded a certain amount, obviously due to the further increase in the viscosity of the medium.

Effect of the Chelating Agent on the Polarograms of Metal Oxinates. Aliquots of the metal oxinates solutions were taken under conditions similar to those described above. To these were added supporting electrolytes, 1 g of naphthalene in the form of 30% solution. The amount of oxine being varied from 0.0—75.0 mg by adding different volume of its 5% solution in DMF. In all the cases except palladium, $E_{1/2}$ shifted towards negative direction. This indicates that the metals form stable oxinate complexes in the presence of excess of oxine, while palladium oxinate might be decomposed under these conditions. i_d remained constant in the range 0.0—11.5 mg for bismuth, 0.0—18.25 mg for copper, 0.0—15.0 mg for iron(III), 0.0—75.0 mg for palladium and uranium(VI). Above this concentration of the oxine added,

Table 2. Polarographic characteristics of metal oxinates in the presence of 1 g of naphthalene in DMF

Metal	Supporting electrolyte	$E_{1/2}$/V from log plot	I	Range of concentration in μg/20 ml	Value of slope from log plot in mV	Remarks	Average relative error %
Bismuth	0.1 M $HClO_4$ in DMF	−0.05	2.399	10.35—248.40	65.0	Irreversible	0.95
Copper	0.1 M $NaClO_4$ in H_2O	−0.14	3.858	3.96—198.40	38.0	Slightly irreversible	0.78
Iron(III)	0.1 M $HClO_4$ in DMF + 0.1 M Pyridine in H_2O	−0.11	1.466	11.20—324.80	87.0	Irreversible	0.97
Palladium	0.1 M Pyridine + 0.1 M $NaClO_4$ both in DMF	−0.18	1.259	10.60—212.00	76.85	Irreversible	0.05
Uranium(VI)	0.1 M $HClO_4$ in DMF + 0.1 M Pyridine in H_2O	−0.45	1.398	5.95—190.40	64.75	Reversible	0.88

Drop time: 4.78 s, m: 1.52 mg/s, H: 60 cm. Recorder sensitivity, bismuth: 5×10^{-9} A/mm, copper: 10×10^{-9} A/mm, iron(III): 7×10^{-9} A/mm, palladium: 3×10^{-9}, and uranium(VI): 3×10^{-9} A/mm.

the lower plateau in the case of bismuth and iron(III) became distorted. A prewave might start appearing in the presence of higher amount of oxine before the actual wave which was not fully developed. In the case of copper a maximum appeared in the higher amount of oxine added.

Effect of Water on the Polarograms of Metal Oxinates: Aliquots of each metal oxinate solution were taken separately in a polarographic cell. The amount of water was varied from 0.0—1.5 ml in different steps. The total volume of the solution was kept 10 ml in each case. In the case of bismuth 0.4 ml of water had no effect on i_d on the shape of the polarogram but above this amount of water, i_d started decreasing. A part of naphthalene might be separated in the colloidal state which would hinder the diffusion of the metal ions. The wave was drawn out at 1.5 ml of the water added. For this amount of water, naphthalene was separated out which increases the resistance of the medium, giving a drawn out wave for bismuth. 0.5 ml of water can be tolerated in case of copper, above this volume i_d started decreasing but $E_{1/2}$ remained constant. In the case of iron(III), 0.7 ml of water can be tolerated but above this volume a maximum appearing might be due to the streaming effect. Only 0.2 ml of water can be tolerated in the case of palladium above this amount i_d started decreasing though $E_{1/2}$ remained constant. The wave of palladium is very sensitive to water as indicated in the preliminary observations. In the case of uranium(VI), i_d started decreasing and $E_{1/2}$ started shifting towards positive potential when the amount of water exceeded 0.4 ml. The uranium complex might be decomposed under these conditions.

The linear dependence of the limiting current on the square root of the height of mercury column indicates that the rate of reduction of these metal oxinates is diffusion controlled. The plot of $\log i/i_d - i_d$ *vs.* E gives a straight line. The values of slopes and $E_{1/2}$ calculated from the plot are given in Table 2. Copper undergoes reduction slightly irreversible with two electron change while uranium(VI) undergoes reduction reversibly with one electron change, bismuth, iron(III), and palladium are reduced irreversibly. The graph plotted between the concentrations of metal oxinates and diffusion currents give straight lines over a wide range of concentration. The diffusion current constants were calculated using the Ilkovic equation, $I=i_d/Cm^{2/3}t^{1/6}$

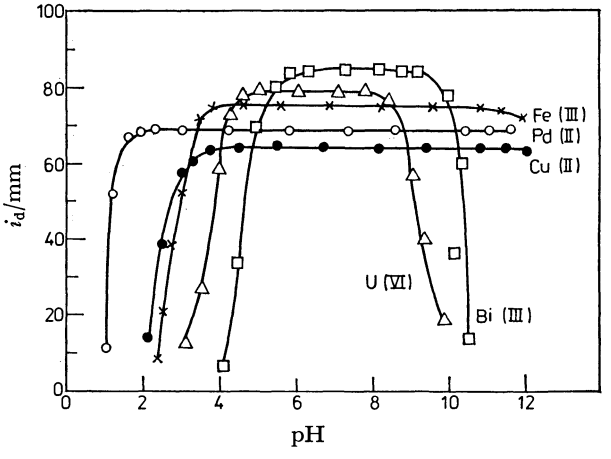

Fig. 2. Effect of pH on the extraction of bismuth, copper, iron(III), palladium, and uranium(VI). Naphthalene taken for each extraction: 2.0 g. Oxine used in each case: 1.0 ml of 1% solution in ethanol. Rest of the conditions are the same as Fig. 1.

and are also given in Table 2. They are constant, indicating that the method is as sensitive as most of the polarographic method in the aqueous media. The average relative error did not exceed 1.05%.

Effect of pH *on the Extraction of Metals.* Extraction was carried out by the general procedure but at different pH. The effect is shown in Fig. 2.

Effect of the Chelating Agent on the Extraction of Metals. Extraction was carried out at different concentration of oxine. It was found that extraction was complete; Bi: 7—20 mg, Cu: 2.5—15.0 mg, Fe(III): 4.0—20 mg, Pd: and U(VI): 6.0—18 mg of the oxine added.

Effect of Naphthalene on the Extraction of Metals. Extraction was complete in all cases when the amount of naphthalene used was higher than 0.8 g, so 2.0 g was used for safe side.

Effect of Aqueous Phase on the Extraction of Metals. The volume of the aqueous phase was varied from 20 ml to 250 ml. The extraction was more than 99% when the volume of the aqueous phase did not exceed the following amounts:

Table 3. Effect of anions on the determination of bismuth, copper, iron(III), palladium, and uranium(VI)[a]

Salt added	Amount of ion added in mg	Bismuth found in μg	Copper found in μg	Iron found in μg	Palladium found in μg	Uranium found in μg	Remarks
Sodium citrate	31.45	80.50	42.50	160.50	106.00	30.25	Extraction completed
	7.85	—	79.50	167.50	—	94.50	at low concentration

Manganese sulfate	00.27	80.50	80.25	169.75	107.50	96.00

a) Conditions the same as those given in Fig. 2. b) Interfering cation removed by extraction at low pH. c) Determination not possible.

Bi: 120 ml, Cu: 100 ml, Fe(III): 105 ml, Pd: 190 ml, and U(VI): 150 ml. Extraction was not quantitative above the volume of the aqueous phase.

Effect of Diverse Ions on the Determination of Metals. The effect is given in Tables 3 and 4. Among the anions examined the extraction of bismuth, copper, iron(III), and uranium(VI) is not possible in the presence of EDTA. In the presence of citrate, oxalate, tartrate, phosphate, and fluoride, the results are low in the case of copper, iron(III), and uranium(VI). However, they are satisfactory in the presence of a relatively low concentrations of the anions. In the determination of bismuth, copper, iron(III), and uranium(VI), palladium interfered, but its interference can be eliminated by extracting palladium first at low pH and then the other metal ions were extracted from the aqueous phase at their proper pH values (Fig. 2). In the determination of bismuth only copper interfered but its interference can be eliminated as in the case of palladium. In the determination of copper,

only iron(III) interfered while in the determination of iron(III), only copper interfered. The interference can be eliminated by using suitable masking agents.[12] There is no interference in the determination of palladium and uranium(VI).

(Received April 9, 1979)

A compound of the type $Cu(AcLeu)_2$ and its amine adducts of the type $Cu(AcLeu)_2B_n$ (AcLeu=*N*-acetyl-DL-leucinato ion; $n=2$ and B=pyridine, 3- and 4-methylpyridine, *N*-methylpiperazine, morpholine, and piperidine; $n=1$ and B=1,10-phenanthroline, 2,2′-bipyridyl, piperazine, and pyridazine) were prepared and investigated by means of electronic, infrared and EPR spectroscopy and magnetic moment measurements. The results suggest a tetragonal configuration for the $Cu(AcLeu)_2$ complex and the amine adducts with CuO_4 and CuO_2N_2 chromophores, respectively. For the green $Cu(AcLeu)_2 \cdot pid$ complex a binuclear configuration similar to that observed for the bis(acetato)copper(II) monohydrate complex is suggested. The amino acid in all the complexes is found to coordinate toward the carboxylato group. In the assignment of the way in which the carboxylato group coordinates, in addition to the difference between their antisymmetric and symmetric stretching frequencies, we also pay special attention to the position of the symmetric stretch, which is directly connected with the oxygen atom linked to the metal ion.

The amino acids containing terminal *N*-acetyl residues are of great interest not only because they are present in protein, albumin, mosaic virus, ovalbumin, cytochrome C, and other natural proteins and peptides, but also because it is possible that an acetylamino acid might be the starting unit in the biosynthesis of some peptide chains which grow the stepwise addition of acylamino residues to the acetylated N-terminal amino acid.[1]

Being interested in the donor properties of amino acids as models for metal-protein interaction, we have paid particular attention to the interaction of some transition metal ions with simple *N*-protected amino acids containing a peptide group, as the *N*-acetyl and *N*-benzoyl derivatives of the glycine, alanine and valine.[2]

In this paper we have now investigated the coordination properties of the *N*-acetyl-DL-leucine (hereafter abbreviated as AcLeuH) with the copper(II) ion and the effect of additional ligands, such as saturated and aromatic heterocyclic amines, on the amino acid coordination.

Experimental

All the reagents used were of the best chemical grade.

Preparation of the Compounds. The *Cu(AcLeu)*$_2$ complex, which was used as starting material for the adduct preparations, was obtained by adding a copper(II) perchlorate hexahydrate (2×10^{-2} mol) solution in anhydrous ethanol (10 ml) to a *N*-acetyl-DL-leucine (4×10^{-2} mol) solution (50 ml) neutralized with a stoichiometric amount of potassium hydroxide. From the cooled solution (4—5 °C) the potassium perchlorate precipitated was filtered off and the green solution was slowly concentrated (20 ml). A blue solid compound separated by cooling after 24 h. *Cu(AcLeu)*$_2$*B*$_n$ ($n=1$ and B=bpy, phen pid; $n=2$ and B=py, Mepipz, morph, pipd) complexes were prepared by adding an excess of amine to a methanolic $Cu(AcLeu)_2$ solution. Solid compounds precipitated from the concentrated solutions on adding diethyl ether and on cooling. *Cu(AcLeu)*$_2$*B*$_2$ (B=3-pic and 4-pic) complexes were prepared in ethanol as reported above. *Cu(AcLeu)*$_2$*·pipz* complex instantaneously precipitated on mixing $Cu(AcLeu)_2$ (1.5×10^{-3} mol) and piperazine (3×10^{-3} mol) in ethanol.

Physical Measurements. The IR spectra of the compounds in KBr or Nujol (4000—250 cm^{-1}) were recorded with a Perkin-Elmer 180 spectrophotometer. The room temperature spectra of the solid compounds were recorded as mull transmission spectra with a Shimadzu MPS 50L spectrophotometer. The room temperature magnetic moments were measured with the Gouy method, using $Ni(en)_3S_2O_3$ as calibrant and correcting for diamagnetism with the appropriate Pascal constant. The EPR spectra were recorded on a JEOL PE-3X spectrometer. Quartz sample tubes were employed for polycrystalline samples. Spectra were calibrated with 2,2′-diphenyl-1-picrylhydrazyl (DPPH, $g=2.0036$) as a field marker.

Analyses. Nitrogen, carbon, and hydrogen were analyzed by Mr. Giuseppe Pistoni, using a Perkin-Elmer 240 Elemental Analyser.

Results and Discussion

The analytical results are reported in Table 1. The room temperature EPR spectrum of the bis(*N*-acetyl-DL-leucinato)copper(II) complex (Table 2 and Fig. 1), which is of axial type, shows g values of a typical isolated compound having a CuO_4 chromophore.[3,4] The broad EPR line excludes the possibility of exchange interaction between copper ions.[5] Its room temperature electronic spectrum (Table 1 and Fig. 2) also strongly resembles those reported for tetragonal copper(II)–oxygen systems.[4] By correlating the g values and the electronic spectrum, which shows two d-d bands at 12990 and 16950 cm^{-1} tentatively assigned to the $d_{xy}\rightarrow d_{x^2-y^2}$ and $d_{xz,\,yz}\rightarrow d_{x^2-y^2}$ transitions,[4] respectively, values of the molecular orbital coefficients ($k_\parallel=0.58$, $k_\perp=0.61$) are obtained. Since $k_\perp>k_\parallel$, this indicates the presence of more π bonding of the d_{xy} orbitals than of the d_{xz}, d_{yz} orbital. A tetragonal distortion in our complex greater than that found for some copper(II)–oxygen systems[4] may be suggested from the comparison of their g and k values and d-d band positions.

All the amine adducts, which have "normal" magnetic moments, show EPR spectra (Table 2) of axial type, except the pipd adduct which presents a rhombic spectrum. For these adducts the observed EPR line shapes are quite similar to each other and indicate a normal elongated tetragonal structure, while for the pipd adduct they indicate a rhombically-distorted

tetragonal configuration. Their g values are lower than those found for the bis(*N*-acetyl-DL-leucinato)-copper(II) complex, suggesting a chromophore change from CuO_4 to CuO_2N_2 as a consequence of the amine coordination.[4,6] From the shape and positions of the d-d bands (Table 2) a tetragonal distortion in the aliphatic heterocyclic amine adducts greater than in the aromatic heterocyclic amine adducts may be generally proposed, in agreement with the pK_a values of the former amines greater than those of the latter.

A correlation between EPR and electronic spectra[7] gives an approximate measure (k_0^2=0.45—0.58) of the degree of covalency for the copper(II)–ligand bondings, which are strictly similar to those reported for copper(II) complexes of other amino acids with an essentially CuO_2N_2 chromophore.[7]

The narrow EPR line in the pipz adduct (Fig. 1) ($\Delta H_\parallel$=20 G; $\Delta H_\perp$=5 G) is suggestive of a fairly strong spin exchange interaction through the piperazine molecules "bridging" two copper(II) ions.[5,8]

The "anomalous" room temperature magnetic moment and the EPR spectrum (Fig. 3) of the green $Cu(AcLeu)_2 \cdot pid$ complex are indicative of a binuclear structure.[9,10] In particular the EPR spectrum shows zero field splitting of 0.39 cm^{-1} and the presence of magnetically dilute copper(II) impurities. Its room temperature electronic spectrum (Fig. 2) are also strictly similar to those of the dimeric carboxylates.[9,11,12] It also presents a band at 24390 cm^{-1}, which is considered characteristic of dimeric carboxylate and similar

Fig. 3. EPR spectrum of the $Cu(AcLeu)_2 \cdot pid$ complexes.

complexes.[9,11,12]

The electronic spectrum (14140 cm^{-1}, $\varepsilon = 188$ $l \cdot mol^{-1} \cdot cm^{-1}$) of the green methanolic solution of the $Cu(AcLeu)_2$ complex is very different to that of the solid state complex. The blue $Cu(AcLeu)_2B_2$ (B= py, 3pic, 4pic, morph, Mepipz, pipd) adducts in methanolic solution ($1 \div 3 \cdot 10^{-2}$ $mol \cdot dm^{-3}$) also give rise to green solutions, which show electronic spectra (14100—14600 cm^{-1} and $\varepsilon = 75 \div 90$ $l \cdot mol^{-1} \cdot cm^{-1}$) different to those of the solid state complexes. The color of the solutions and the position of the d-d bands suggest the presence of binuclear species due to a dissociation equilibrium involving the solvent molecules of this type:

$$2Cu(AcLeu)_2B_2 + 2Solv \rightleftharpoons [Cu(AcLeu)_2 \cdot Solv]_2 + 4B$$

This may be confirmed as an amine excess addition in the methanolic adduct solutions results in a blue shift of the d-d band (15350—15870 cm^{-1}) and generally in a decrease of the molar extinction (57—80 $l \cdot mol^{-1} \cdot cm^{-1}$). The lower d-d band positions of the blue solution complexes than those of the solid complexes (16000—17800 cm^{-1}) indicate that they are different and a lower tetragonal distortion in the former than in the latter complexes, being probably four amines entered in the coordination sphere around the metal ion.

The assignments of the more relevant infrared bands (Table 3) for emphasizing the amino acid coordination are made by comparing the amino acid, its sodium and potassium salts and their deuterated analogues. The coordination sites of the amino acid may be securely evidentiated, as the IR spectra of the complexes are very similar in shape and position to those of the sodium and potassium *N*-acetyl-DL-leucinato salts (Table 3).

This suggests that the carboxylato group is the only group of the ligand involved in the coordination of the metal ion, confirming the previous results obtained from the electronic spectra.

Trends in positions of and separation ($\Delta\nu$) between antisymmetric and symmetric carboxylate stretching bands provide a useful observation for assigning its

coordination type. In fact a large splitting of the carboxylate stretching frequencies is often an indication of a monodentate coordination, as the CO bonds become inequivalent, and a small splitting is indicative of bidentate coordination or bidentate "bridging" coordination.[10,13] In bidentate coordination $\Delta\nu$ values consistent with the above considerations may be obtained only in the absence of any strong hydrogen bonding effects.[13,14]
